To a solution of 0.9 g (2 mmol) of lythridine (**5**) in 20 mL dry tetrahydrofuran was added 0.29 g of sodium hydride (50% oil, 6 mmol) and the suspension was stirred at 0–5°C for 0.5 h. Methyl iodide (2.84 g, 20 mmol) was added to the resulting suspension and stirring continued at ice bath temperature for an additional 5 h. The reaction was diluted with water to 100 mL and was extracted with ether. The organic extract was washed with water, dried over anhydrous $MgSO_4$, and after filtration was evaporated to a glassy residue. Column chromatography of this material on Al_2O_3 with ether solvent yielded 0.3 g of the desired compound ($R_f = 0.62$), mp 138–140°C; ir (Nujol): 1724, 1123, 1052, 1030 cm^{-1}; ^1H nmr ($CDCl_3$): 7.45–6.7 (m, 5H, aromatic), 4.90 (s, 1H, C*H*OCO), 4.5 (q, X part of ABX system, 1H, $J_{AX} = 3$ Hz, $J_{BX} = 10$ Hz, C*H*OCH_3), 3.82, 3.75, 3.67, and 3.35 (s, 4 × 3H, 4 × OCH_3), 3.1–1.2 (m). *Anal.* calcd. for $C_{28}H_{35}NO_6 \cdot 1/2\ H_2O$: C 68.55, H 7.40, N 2.86; found: C 68.57, H 7.50, N 2.76.

*17-Methyl-13-*epi*-lythridine (12,13-Dihydro-17,22,23,-trimethoxy-13(*S*)-hydroxylythran-11-one, 9)*

A solution of **6** (2.0 g, 4.2 mmol) in 50 mL of aqueous (1:1) tetrahydrofuran was treated with 4.6 g (6.3 mmol) of mercuric acetate at room temperature for 96 h. The solution was cooled in an icebath while 1.0 g (30 mmol) of sodium borohydride was slowly added. The product was separated from the metallic mercury precipitate by extraction with chloroform (3 × 40 mL) and the organic extract was dried over anhydrous sodium sulfate. After filtration the chloroform solution was chromatographed on an alumina column using ethyl acetate solvent. After elution of 0.8 g of recovered starting material, 1.2 g (57%) of product **9** ($R_f = 0.2$) was isolated, crystallized from petroleum ether – chloroform, mp 187–188°C; ir (Nujol); 1680, 1250, 1123, 1030 cm^{-1}; ^1H nmr ($CDCl_3$): 7.0–6.7 (m, 5H, aromatic), 4.90 (br s, 1H, CHOCO), 4.2 (br m, 1H, C*H*OH), 3.90, 3.80, and 3.70 (s, 3 × 3H, 3 × OCH_3), 3.15–1.3 (m). *Anal.* calcd. for $C_{27}H_{33}NO_6 \cdot 1/4\ H_2O$: C 68.89, H 7.15, N 2.96; found: C 68.40, H 7.13, N 2.93.

Received February 19, 1980

This paper is dedicated to the memory of Dr. Léo Marion

MARIA D. ROZWADOWSKA, FU-LIAN HSU, ARTHUR E. JACOBSON, KENNER C. RICE, and ARNOLD BROSSI. Can. J. Chem. **58**, 1855 (1980).

(−)-4-Hydroxy-*N*-formylmorphinan-6-one (**4**) was prepared in 70% overall yield from ketone **1**, via carbamate **2**, and *N*-formylation of ketone **3**. Bromination of **4** afforded either the 6-ketomorphinan **7** or the ketone **8**, depending on the reaction conditions applied. Both bromo ketones **7** and **8** could be converted by standard reactions into 4,5-epoxy-*N*-methylmorphinan-6-one (**1**). The ketomorphinan **4** emerges from these investigations as a versatile intermediate, well suited for the synthesis of 4-hydroxymorphinans and 3-deoxyopioids.

MARIA D. ROZWADOWSKA, FU-LIAN HSU, ARTHUR E. JACOBSON, KENNER C. RICE et ARNOLD BROSSI. Can. J. Chem. **58**, 1855 (1980).

On a préparé la (−)hydroxy-4 *N*-formylmorphinanone-6 (**4**) avec un rendement global de 70% en transformant la cétone **1** en carbamate **2** suivie de la *N*-formylation de la cétone **3**. La bromation du composé **4** conduit suivant les conditions de réaction soit à la céto-6 morphinane **7** soit à la cétone **8**. Les deux bromocétones **7** et **8** peuvent être transformées en époxy-4,5 *N*-méthylmorphinanone-6 (**1**) en faisant appel à des réactions connues. Sur la base de ces études, la cétomorphinane **4** apparait comme un intermédiaire polyvalent convenant très bien à la synthèse des hydroxy-4 morphinanes et des déoxy-3 opioides.

[Traduit par le journal]

The interesting pharmacological profiles recently reported for several 3-deoxy opioids (1), prepared by chemical deoxygenation of (−)-dihydromorphine, prompted a search for a more versatile route into the 3-deoxy series. In this connection it became apparent that 3-deoxynor derivatives, or precursors which could readily be *N*-deblocked, would offer advantages. In order to study this problem, which is of interest in connection with a total synthesis, and to prepare samples needed for the ultimate comparison with synthetic material, we initiated a program on which we would like to report. All of the compounds prepared were derived from dihydromorphine and therefore possess the absolute configuration expressed in their formulas.

Treatment of 4,5-epoxy-*N*-methylmorphinan-6-one (**1**) (1) with 2,2,2-trichloroethyl chloroformate (2) readily provided carbamate **2** in 92% yield. Reduction of **2** with Zn/NH_4Cl in ethanol (3) smoothly effected the cleavage of the carbamate function with concomitant reductive opening of the oxide bridge, to afford the norketone **3** in 94% yield. On the other hand, when carbamate **2** was treated with zinc in aqueous acetic acid (2), the oxide bridge remained intact and the morphinone **5** was obtained in 87% yield. It is interesting to note that the different activity of the zinc in these media, observed previously by Schöpf and Pfeifer (4) and Beyerman and co-workers (2, 3), determines whether only cleavage of the carbamate function occurs or whether this reduction involves simultaneous opening of the oxygen bridge. *N*-formylation of **3** and **5** with refluxing ethyl formate gave the corresponding *N*-formyl derivatives **4** and **6** in 75% and 85% yield, respectively. Both **4** and **6**, as well as the other *N*-formyl derivatives prepared, showed the existence of pairs of rotamers, as observed in similar cases (5, 6). The two rotamers were visible by nmr and tlc but isolation afforded only one single compound. The measured value of the optical rotation of the *N*-formyl derivatives may depend on the proportion of the individual rotamers. Hydrolysis of **6** with dilute HCl in MeOH afforded the nor compound **5** in quantitative yield. Bromination of **4** with 1.1 mol of bromine in AcOH afforded, as in the *N*-Me series (7), the 1-bromo congener **7** in 56% yield from which **4** was smoothly regenerated by hydrogenolysis with Pd/C in MeOH. Morphines (8) and 4-hydroxymorphinans (7, 9) are believed to brominate first in the 1-position, and successful conversion of compound **7** into the morphine derivative **8** is in agreement with this assumption. The aromatic protons seen as

doublets at 7.31 and 6.63 ppm do not clearly discriminate between **7** and its 3-bromo isomer.[3] The *N*-substituent seems to have little influence as shown by the formation of **10** (**7** → **9** → **10**) from **11**. Bromination of **4** with 2.2 mol of bromine in AcOH, followed by treatment of the residue with aqueous NaOH, gave the 4,5-epoxy derivative **8** in 85% yield. Precedent for oxide ring closure of this type is found in the conversion of dihydrothebainone to dihydrocodeinone (8, 9, 10).

Reductive cleavage of the oxide bridge of amide **8** to regenerate the 1-bromo derivative **7** was accomplished in 61% yield with Zn/NH_4Cl in ethanol, as in the case of the transformation of **2** to **3**. It is

[3]Details of this ^{13}C nmr study, which was done by C. D. Hufford, School of Pharmacy, University of Mississippi, will be published elsewhere.

interesting to note that this reduction leaves the 1-bromo substituent intact, as well as the *N*-CHO group. Hydrogenolysis of the bromine in **8** with $Pd/C/H_2$ afforded **6** in 88% yield. Acid hydrolysis of the title compound **4** gave **3** in quantitative yield. Reductive alkylation of **3** with $CH_2O/H_2/Pt/C$ gave the *N*-methyl derivative **11**, isolated as the hydrobromide hemihydrate which could be transformed to bromoketone **10** by treatment with 1.1 mol of bromine in AcOH (50% yield). Regeneration of **11** from **10** by hydrogenolysis ($Pd/C/H_2$) in aqueous AcOH was readily accomplished. Bromination of **11** with 2.5 mol of bromine in AcOH, followed by treatment of the residue with aqueous NaOH and catalytic reduction of the nonphenolic fraction, afforded **1** in 84% yield based on **11**. The norketone **5**, which was obtained by acid hydrolysis of **6** and from **2** as described above, also afforded **1** on reductive alkylation with $Pd/C/CH_2O/H_2$ (78% yield). Reductive cleavage of the oxide bridge in **1** was efficiently effected with Al/Hg (95% yield) (7) or, preferably, with Zn/NH_4Cl reagent in ethanol in similar yield. Furthermore, acid hydrolysis of the 1-bromo derivative **7** afforded the nor base **9** which was reductively alkylated with $Pt/C/H_2/CH_2O$ to **10**. 4,5-Epoxy-*N*-methylmorphinan-6-one (**1**) is best accessible from ketone **4** by either of two sequences: **4** → **6** → **5** → **1** or **4** → **3** → **11** → **1**, both involving three practical operations. We prefer at this moment the former sequence, which seems to give better yields and intermediates which are easier to purify.

The *N*-formyl ketone **4** emerges from these investigations not only as a versatile intermediate for a synthesis of **1** and congeners, but can also be utilized to prepare antinociceptive 4-hydroxymorphinans,[4] and their *N*,*O*-substituted congeners.

Experimental

Melting points (uncorrected) were determined on a Fisher–Johns apparatus. Elemental analyses were performed by the Section on Microanalytical Services and Instrumentation of the laboratory. Infrared spectra were recorded on a Beckman IR 4230 instrument. Optical rotations were measured using a Perkin–Elmer Model 141 polarimeter using the solvents and concentrations specified. Nuclear magnetic resonance spectra were determined using a JOEL JNM-FX 100 spectrometer with TMS as the internal reference. Mass spectra were obtained with a Hitachi Perkin–Elmer RMU-6E spectrometer (70 eV). Thin layer chromatography (tlc) utilized silica gel GF plates from Analtech, Inc., (Newark, DE.), and $CHCl_3$–MeOH–NH_4OH (90:9:1) as the solvent system, unless otherwise stated.

*4,5-Epoxy-*N*-(2,2,2-trichloroethoxycarbonyl)-morphinan-6-one (2)*

To a well stirred mixture of 7.0 g (26 mmol) of **1**, 70 mL of chloroform and 38.0 g (0.38 mol) of anhydrous potassium bicarbonate, 21.6 g (101 mmol) of 2,2,2-trichloroethyl chloroformate was added dropwise during 10 min, under argon. The mixture was refluxed for 3 h, cooled, and 70 mL of water and 60 mL of chloroform were added. The aqueous layer was separated and extracted (2×) with 30 mL of chloroform. The combined organic layers were washed with water, 5% HCl, water, dried, and evaporated. The oily residue was treated with 40 mL of ether, which immediately deposited a crystalline solid. The solid was digested with 100 mL of ether for 15 min under reflux to give 10.3 g (92%) of **2**; mp 206–208°C; $[\alpha]_D^{20}$ −240° (*c* 0.63, $CHCl_3$); ir (KBr): 1710, 1725 (shoulder, CO) cm^{-1}; nmr ($CDCl_3$) δ: 7.12 (1H, m, ArH), 6.76 (2H, m, ArH), 4.80 (2H, m, CH_2), 4.66 (1H, s, C5–H); ms *m/e*: 429 (M^+), 431 ($M^+ + 2$), 433 ($M^+ + 4$). *Anal.* calcd. for $C_{19}H_{18}NO_4Cl_3$ (430.71): C 52.98, H 4.21, N 3.25, Cl 24.69; found: C 53.23, H 4.49, N 3.34, Cl 24.28.

4-Hydroxymorphinan-6-one (3)

(*A*) From **2**. Ammonium chloride (40.7 g, 0.76 mol) was added to a solution of 10.3 g (24 mmol) of carbamate **2** in 400 mL of ethanol, and the mixture was heated to reflux. To this heterogeneous system, zinc powder (6.1 g, 90 mg-at.) was added portionwise during 6 h. A second portion of zinc (6.1 g, 90 mg-at.) was added in one batch and the mixture was refluxed until tlc indicated that **2** had completely reacted (24 h). After cooling, the catalyst was filtered off and washed several times with 95% ethanol until a positive test with Dragendorff reagent was no longer observed.

The combined filtrates were evaporated to dryness, saturated sodium sulfate solution (70 mL) was added, and this slurry was extracted several times (total 800 mL) with chloroform–isopropanol (3:1). The organic extracts were evaporated to dryness and the residue was dissolved in 50 mL of 1% HCl. The acidic solution was washed (2×) with 70 mL of chloroform, then rendered alkaline (pH 9) with concentrated NH_4OH and extracted several times with a total volume of 400 mL of chloroform–isopropanol (3:1). After drying, solvents were removed *in vacuo* to give 6.1 g of an oil, which upon treatment with tetrahydrofuran deposited an off-white crystalline solid (5.8 g, 94%); mp 220°C (dec.); $[\alpha]_D^{20}$ −72° (*c* 0.935, MeOH); ir (KBr): 1710 (CO), 3300 (NH), 3400 (broad, OH) cm^{-1}; nmr (DMSO-d_6) δ: 6.92 (1H, m, ArH), 6.48 (2H, m, ArH); ms *m/e*: 258 ($M^+ + 1$). *Anal.* calcd. for $C_{16}H_{19}NO_2$ (257.33): C 74.68, H 7.44, N 5.44; found: C 74.98, H 7.42, N 5.44.

(*B*) From **4**. A solution of 285 mg (1 mmol) of **4** in 8 mL of methanol which contained 0.8 mL of 37% HCl was refluxed overnight. The methanol was evaporated, 3 mL of 1% HCl added, and the mixture was extracted with 15 mL of chloroform. The aqueous layer was rendered alkaline with concentrated NH_4OH (pH 9) and extracted with chloroform until a negative Dragendorff test was obtained. After drying and removal of the solvent, the remaining foam was treated with tetrahydrofuran, to give 210 mg (82%) of pure **3**.

N-*Formyl-4-hydroxymorphinan-6-one (4)*

(*A*) From **3**. Compound **3** (6.1 g, 23.7 mmol) was refluxed in 600 mL of ethyl formate for 48 h to give *N*-formyl derivative **4** as a solid which was filtered (3.8 g). The filtrate was washed with 1% HCl, water, dried, and concentrated to ca. ¼ of its volume, depositing an additional amount of **4** (1.3 g, 75% overall); mp > 310°C (dec.); $[\alpha]_D^{20}$ −237° (*c* 0.6, AcOH); ir (KBr): 1640 (CO), 1710 (CO), ca. 3100 (broad, OH) cm^{-1}; nmr (DMSO-d_6) δ: 9.42 (1H, s, OH, exchanges with D_2O), 6.90 (1H, m, ArH), 6.55 (2H, m, ArH); ms *m/e*: 285 (M^+). *Anal.* calcd. for $C_{17}H_{19}NO_3$ (285.35): C 71.56, H 6.71, N 4.91; found: C 71.61, H 6.51, N 4.75.

(*B*) From **7**. One hundred and twenty milligrams (0.33 mmol) of **7** in 12 mL of methanol was hydrogenated at 45 psi in the presence of 10% Pd/C catalyst at room temperature, overnight. The catalyst was filtered, washed with methanol, and the filtrate

[4]The antinociceptive activities of the compounds discussed and several of their derivatives will be published elsewhere.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was concentrated *in vacuo* to half its volume, to give 50 mg of pure **4** (tlc, ms, mp), followed by a second crop of crystals (35 mg, 90% total).

4,5-Epoxymorphinan-6-one (5)

(*A*) From **2**. Compound **2** (4.5 g, 17.5 mmol) was heated to solution in a mixture of 42 mL of 80% acetic acid and 52 mL of glacial acetic acid, cooled to room temperature, and stirred overnight with 2.9 g of powdered zinc (44 mg-at.). Water (4 mL) was added and the zinc filtered. The filtrate was evaporated to a syrup and treated with 20 mL of saturated sodium sulfate and 40 mL of chloroform. The aqueous layer was separated and extracted with chloroform until the Dragendorff test was negative. The combined organic layers were extracted with 2 × 10 mL of 1% HCl and discarded. The aqueous phase was rendered alkaline with concentrated NH_4OH and extracted with chloroform–isopropanol (3:1) until, again, a negative Dragendorff test was obtained. Organic extracts were combined, dried, and evaporated to give a crystalline residue. This was digested with ether, leaving 2.3 g (87%) of crystalline **5**; mp 160–161°C; $[\alpha]_D^{20}$ −273° (*c* 0.99, $CHCl_3$); ir (KBr): 1725 (CO), ca. 3350 (NH) cm^{-1}; nmr ($CDCl_3$) δ: 7.08 (1H, m, ArH), 6.72 (2H, m, ArH), 4.6 (1H, s, C5—H); ms *m/e*: 255 (M^+). *Anal.* calcd. for $C_{16}H_{17}NO_2$ (255): C 75.29, H 6.66, N 5.49; found: C 75.07, H 6.77, N 5.45. Hydrobromide salt, mp 240°C (dec.), $[\alpha]_D^{20}$ −171° (*c* 0.5, CH_3OH). *Anal.* calcd. for $C_{16}H_{17}NO_2 \cdot HBr \cdot \frac{1}{2} H_2O$ (345.24): C 55.66, H 5.55, N 4.06, Br 23.14; found: C 55.33, H 5.78, N 3.79, Br 22.79

(*B*) From **6**. One hundred and twenty-four milligrams (0.5 mmol) of **6** was refluxed with methanol (4 mL) containing 0.4 mL of 37% HCl for 6 h. The solution was concentrated to half volume and left overnight to afford, quantitatively, the hydrochloride salt of mp > 280°C. The base prepared from it in the usual way was identical with that prepared above (mixture mp, ms, tlc using $CHCl_3$–MeOH–NH_4OH (80:18:2)).

4,5-Epoxy-N-formylmorphinan-6-one (6)

(*A*) From **5**. Compound **5** (1.1 g, 4.3 mmol) and 50 mL of ethyl formate were refluxed overnight to give crystalline **6** (0.55 g). Additional amounts of **6** (0.49 g) were recovered from the filtrate, after washing with 1% HCl, drying, and concentration (total yield 85%); mp 246–247°C (after recrystallization from ethyl acetate); $[\alpha]_D^{20}$ −360° (*c* 0.89, $CHCl_3$); ir (film): 1660 (CHO), 1720 (CO) cm^{-1}; nmr ($CDCl_3$) δ: 8.20 and 8.00 (1H, 2s, CHO, signals of two rotamers), 7.12 (1H, m, ArH), 6.86 (2H, m, ArH), 4.64 (1H, s, C5—H); ms *m/e*: 283 (M^+). *Anal.* calcd. for $C_{17}H_{17}NO_3$ (283.33): C 72.07, H 6.05, N 4.94; found: C 72.18, H 6.24, N 4.87.

(*B*) From **8**. A solution of **8** (0.18 g, 0.5 mmol) in AcOH (6 mL) containing 300 mg (3.6 mmol) of sodium acetate and 40 mg of 10% Pd/C was hydrogenated at 50 psi for 18 h, at room temperature. The catalyst was filtered and washed with 20 mL of AcOH. The combined filtrates were evaporated, and the residue partitioned between 2% NaOH and chloroform. The aqueous phase was extracted (2×) with chloroform. The combined organic layers were washed with 1% HCl and brine, dried, and evaporated to give **6** as an oil (0.14 g) which crystallized from methanol (0.125 g, 88%). The material was identical (mp, tlc, ir) with that prepared above.

(*C*) From **4**. The ketone **6** could be prepared from **4** in 62% yield via **7** and **8** without isolation (see below).

1-Bromo-4-hydroxy-N-formylmorphinan-6-one (7)

(*A*) From **4**. To a well stirred solution of **4** (1.14 g, 4 mmol), 44 mL (4.4 mmol) of 0.1 *M* Br_2 in AcOH was introduced dropwise over 1.5 h at room temperature. After an additional 0.5 h, the solvent was evaporated and the residue was partitioned between 1% HCl and chloroform (50 mL). The separated aqueous layer was extracted (2×) with 20 mL of chloroform. The combined organic extracts were treated with 20 mL of 2% NaOH. After 10 min, the separated organic phase was extracted with 10 mL of 2% NaOH. The alkaline extracts were treated with 37% HCl to pH 9, and extracted with chloroform (3 × 50 mL). The combined chloroform extracts were washed with water and dried to give a foam (1.2 g). Crystallization from ethanol gave **7** (820 mg, 56%); mp 286–287°C (dec.); $[\alpha]_D^{20}$ −270° (*c* 0.53, $CHCl_3$); ir (KBr): 1645 (CHO), 1705 (CO), 3250 (broad, OH) cm^{-1}; nmr ($CDCl_3$) δ: 8.40 (1H, s, OH, disappears on treatment with D_2O), 8.22 and 8.06 (1H, 2s, CHO, pair of rotamers), 7.24 (1H, d, *J* = 9 Hz, ArH), 6.68 (1H, d, *J* = 9 Hz, ArH); ms *m/e*: 364 (*M* + 1), 366 (*M* + 3). *Anal.* calcd. for $C_{17}H_{18}BrNO_3$ (364.25): C 56.06, H 4.98, N 3.84, Br 21.94; found: C 56.19, H 5.07, N 3.63, Br 21.69.

(*B*) From **8**. To a refluxing mixture of 130 mg (0.34 mmol) of **8** and 1.7 g (31 mmol) of NH_4Cl in 17 mL of 95% ethanol, two 250 mg (3.8 mg-at.) batches of powdered zinc were added at 1 h intervals. After refluxing 3 h, the mixture was cooled and the catalyst was filtered and washed with anhydrous ethanol. The combined solvent was evaporated to dryness *in vacuo*, saturated Na_2SO_4 (2 mL) was added, and this was extracted with chloroform (25 mL). The organic layer was washed with 1% HCl and brine, dried, and evaporated to give 98 mg of a foam which, after crystallization from ethanol, gave 75 mg (61%) of pure **7** identical with a specimen prepared above (mp, tlc, ir).

1-Bromo-4,5-epoxy-N-formylmorphinan-6-one (8)

(*A*) From **4**. A solution of 0.1 *M* bromine in AcOH (22 mL, 2.2 mmol) was added dropwise during 0.5 h to a solution of **4** (285 mg, 1 mmol) in 10 mL of AcOH at room temperature. After stirring for another 0.5 h the solvent was evaporated and the residue partitioned between 2% NaOH and 20 mL chloroform, after a pH of 11 was sustained. After 5 min the organic phase was separated, the aqueous phase extracted with 10 mL chloroform (2×), the combined organic extracts washed with 1% HCl, brine, dried, and evaporated to give an oil which crystallized from methanol to afford 310 mg (85%) of compound **8**; mp 222–224°C; $[\alpha]_D^{20}$ −313° (*c* 0.53, $CHCl_3$); ir (KBr): 1645 (CHO), 1725 (CO) cm^{-1}; nmr ($CHCl_3$) δ: 8.20 and 9.04 (1H, 2s, CHO, a pair of rotamers), 7.32 (1H, d, *J* = 8 Hz, ArH), 6.72 (1H, d, *J* = 8 Hz, ArH), 4.68 (1H, s, C5—H); ms *m/e*: 362 (M^+ + 1), 364 (M^+ + 3). *Anal.* calcd. for $C_{17}H_{16}BrNO_3$ (362.23): C 56.37, H 4.45, N 3.87, Br 22.06; found: C 56.00, H 4.48, N 3.80, Br 22.34.

(*B*) From **7**. Compound **7** (0.24 g, 0.66 mmol), in 7 mL of AcOH, was brominated with 6.7 mL (0.67 mmol) of 0.1 *M* bromine in AcOH, according to the procedure used for the preparation of **7**, except that extraction was carried out at pH > 11. Recrystallization from methanol gave 0.165 g (69%) of **8**, identical with the material described above (mp, tlc, ir).

4-Hydroxy-N-methylmorphinan-6-one (11)

(*A*) From **3**. A mixture of 257 mg (1 mmol) of **3**, 0.7 mL of aqueous 37% formalin, and 70 mg of 10% Pt/C catalyst, in 15 mL of methanol, was hydrogenated at room temperature, at 40 psi, overnight. The catalyst was filtered, washed with methanol, and the solvent evaporated to dryness. The residue was partitioned between 1% HCl and chloroform and the aqueous layer was rendered alkaline with concentrated NH_4OH and extracted with chloroform–isopropanol (3:1). Drying and evaporation of solvents gave 250 mg of an oil that crystallized from methanol to give 190 mg (70%) of pure **11**, identical with material previously reported. *Anal.* calcd. for $C_{17}H_{21}NO_2$ (271.36): C 75.24, H 7.80, N 5.16; found: C 75.21, H 7.89, N 5.23.

(*B*) From **10**. A mixture of **10** (70 mg, 0.16 mmol), anhydrous NaOAc (124 mg), and 10% Pd/C catalyst (20 mg) in 2 *N* AcOH (5 mL) was hydrogenated at 50 psi at room temperature for 16 h.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The catalyst was filtered and was washed with 2 *N* AcOH. The solution was adjusted to pH 9–10 with NH_4OH and extracted with chloroform. The combined chloroform extracts were washed with H_2O, dried, and evaporated to give a crude product which was recrystallized from benzene – petroleum ether to afford **11** (40 mg, 91%), identical with material prepared above (tlc, ir, mixture mp).

*1-Bromo-4-hydroxy-*N*-methylmorphinan-6-one (**10**)*

(*A*) From **11**. To a solution of **11** (400 mg, 1.47 mmol) in 15 mL AcOH was added a solution of Br_2 in AcOH (0.1 *M*, 14.7 mL) dropwise at room temperature. The solution was stirred for 10 min and the excess bromine and AcOH evaporated to give a residue which was recrystallized from H_2O to afford **10** (0.25 g, 50%); mp 218–221°C: $[\alpha]_D^{20}$ −43.2° (*c* 0.92, MeOH); ir (KBr): 3300 (OH), 1705 (CO) cm^{-1}; nmr (CD_3OD) δ: 7.31 (1H, d, J = 9.5 Hz, ArH), 6.63 (1H, d, J = 9.5 Hz, ArH), 4.30 (1H, d, J = 14 Hz, C5—H), 2.97 (3H, s, NCH_3); ms *m/e*: 349 (M^+), 351 ($M^+ + 2$). *Anal.* calcd. for $C_{17}H_{20}BrNO_2 \cdot HBr \cdot 0.5\,H_2O$ (440.18): C 46.39, H 5.04, N 3.18, Br 36.31; found: C 46.25, H 5.33, N 2.91, Br 36.43. The free base was prepared in the usual way, mp 222–224°C (MeOH). *Anal.* calcd. for $C_{17}H_{20}BrNO_2$ (350.26): C 58.3, H 5.76, N 4.00, Br 22.81; found: C 58.58, H 5.76, N 4.14, Br 22.61.

(*B*) From **9**. A mixture of 95 mg (0.26 mmol) of **9** · HCl, 0.22 mL of 37% formalin, and 21 mg of 10% Pt/C catalyst, in 10 mL of methanol, was hydrogenated under 40 psi at room temperature overnight. The catalyst was filtered and washed with methanol. The solvent was evaporated and the residue was partitioned between 5 mL of ether and 3 mL of 1% HCl to give a white precipitate. Filtration gave 65 mg of pure **10** · HCl: mp 220°C (dec.). *Anal.* calcd. for $C_{17}H_{20}NO_2Br \cdot HCl \cdot 1.5\,H_2O$ (413.74): C 49.35, H 5.85, N 3.39; found: C 49.27, H 5.53, N 3.49.

*1-Bromo-4-hydroxymorphinan-6-one (**9**)*

A solution of 140 mg (0.38 mmol) of **7** in 4 mL of methanol containing 0.4 mL of 37% HCl was refluxed for 6 h. The solution was then concentrated to half volume and, after standing overnight, gave 110 mg (71%) of crystalline **9** · HCl; mp 280°C (dec.); $[\alpha]_D^{20}$ −19° (*c* 1.25, MeOH); ir (KBr): 1710 (CO), 2400–3600 (broad, OH, NH_2^+) cm^{-1}; nmr (DMSO-d_6) δ: 10.16 (1H, s, NH), 9.5 (2H, broad, NH, OH), 7.3 (1H, d, J = 9 Hz, ArH), 6.7 (1H, d, J = 9 Hz, ArH); ms *m/e*: 335 (M^+), 337 ($M + 2$). *Anal.* calcd. for $C_{16}H_{18}Br \cdot NO_2 \cdot HCl$ (372.70): C 51.56, H 5.14, N 3.76, Cl 9.51, Br 21.44; found: C 51.18, H 5.18, N 3.73, Cl 9.48, Br 21.15.

*4,5-Epoxy-*N*-methylmorphinan-6-one (**1**)*

(*A*) From **5** · HBr. A mixture of the hydrobromide of **5** (0.168 g, 0.5 mmol), 0.42 mL of 37% formalin, and 42 mg of 10% Pt/C, in 10 mL of methanol, was hydrogenated under 45 psi at room temperature for 7 h. The catalyst was filtered and washed with methanol. The methanolic solution was concentrated *in vacuo* and the residue was dissolved in 1% HCl (5 mL). The aqueous solution, after washing with chloroform, was rendered alkaline with concentrated NH_4OH and extracted with chloroform until a negative Dragendorff test was obtained. The combined organic extracts were dried and evaporated to give a solid which after recrystallization from ethyl acetate gave pure **1** (0.1 g, 78%) identical with a reference sample.

(*B*) From **11**. A solution of bromine in AcOH (0.1 *M*, 46 mL, 4.6 mmol) was added dropwise to a solution of **11** (0.5 g, 1.84 mmol) in AcOH (6 mL), stirred for 20 min, and the AcOH then evaporated. The crude brominated product was treated with 0.5 *N* NaOH (5 mL) and chloroform and stirred for 10 min. The $CHCl_3$ layer was separated and the aqueous layer was extracted with $CHCl_3$. The combined chloroform extracts were washed with H_2O, dried, and evaporated to give a solid (240 mg). A part of this material (160 mg) and 10% Pd/C catalyst (40 mg) were suspended in a solution of anhydrous NaOAc (350 mg) in 6 mL of 2 *N* AcOH and hydrogenated at 50 psi for 16 h. The catalyst was filtered and washed with 2 *N* AcOH. The filtrate was adjusted to pH 10 with 6 *N* NaOH and extracted with chloroform. The combined chloroform extracts were washed with H_2O, dried, and evaporated to give a solid which was recrystallized from ethyl acetate to afford **1** (102 mg, 82%), identical with the material prepared above.

Acknowledgments

We would like to thank Dr. Franz Scheidl, head of the Microanalytical Laboratory, Hoffmann–La Roche Inc., Nutley, NJ, U.S.A., for having analyzed several samples described in this paper. The interest of Dr. C. D. Hufford, School of Pharmacy, University of Mississippi, University, MS, in the ^{13}C nmr spectra of several brominated morphinans is gratefully appreciated.

Conversion of stereoisomeric 2-amino-1-carbamoylcyclohexane-5,5-dicarboxylates into 6-amino-3-azabicyclo[3.3.1]nona-2,4-dione-1-carboxylates

VINKO ŠKARIĆ, MIRJANA SEDJAK, VERA TURJAK-ZEBIĆ, AND DJURDJICA ŠKARIĆ

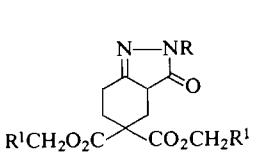
Laboratory of Stereochemistry and Natural Products, Rudjer Bošković Institute, 41001 Zagreb, Croatia, Yugoslavia

Received February 11, 1980

This paper is dedicated to the memory of Dr Léo Marion

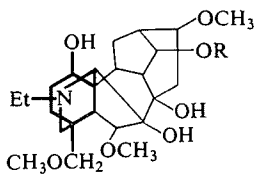
VINKO ŠKARIĆ, MIRJANA SEDJAK, VERA TURJAK-ZEBIĆ, and DJURDJICA ŠKARIĆ. Can. J. Chem. **58**, 1860 (1980).

The separation of *cis*- and *trans*-2-amino-*r*-1-carbamoylcyclohexane-5,5-dicarboxylates **2** and **3** as 2-*N*-benzyloxycarbonyl (**15**, **16**) and 2-*N*-benzoyl- (**17**, **18**) derivatives is described. A dipeptide containing suitably protected L-phenylalanine and *cis*-2-amino-1-carbamoylcyclohexane (**2**) was also prepared. Moreover, *cis*- (**17**) and *trans*- (**18**) benzamido isomers were converted into ethyl *t*-6- (**23**) and *c*-6- (**24**) benzamido-*r*-1-carboxylate-3-azabicyclo[3.3.1]nona-2,4-dione, respectively. Similarly, ethyl *c*-6-phthalimido-*r*-1-carboxylate-3-azabicyclo[3.3.1]nona-2,4-dione (**25**) was obtained from diethyl *t*-2-phthalimido-*r*-1-carbamoylcyclohexane-5,5-dicarboxylate (**22**).



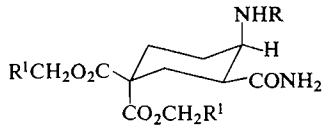
VINKO ŠKARIĆ, MIRJANA SEDJAK, VERA TURJAK-ZEBIĆ et DJURDJICA ŠKARIĆ. Can. J. Chem. **58**, 1860 (1980).

On décrit la séparation des composés amino-2 carbamoyl-1-*r* cyclohexanedicarboxylates-5,5 *cis* et *trans* **2** et **3** sous forme de dérivés *N*-benzyloxycarbonyl-2 (**15**, **16**) et *N*-benzoyl-2 (**17**, **18**). On a également préparé un dipeptide contenant la L-phénylalanine et l'amino-2 carbamoyl-1 cyclohexane *cis* (**2**) convenablement protégés. De plus, on a transformé les isomères benzamido *cis* (**17**) et *trans* (**18**) respectivement en benzamido 6-*t* (**23**) et 6-*c* (**24**) aza-3 bicyclo[3.3.1] nonadione-2,4 carboxylate 1-*r* d-éthyle. D'une façon analogue, on a obtenu le phtalimido 6-*c* aza-3 bicyclo[3.3.1] nonadione-2,4 carboxylate 1-*r* d'éthyle (**25**) à partir du phtalimido 2-*t* carbamoyl 1-*r* cyclohexanedicarboxylate-5,5 d'éthyle (**22**).



[Traduit par le journal]

Previously, we described the synthesis and properties of all possible positional isomers in the 4,5,6,7- tetrahydro- 3- oxo- 2*H*- indazolecarboxylic acid series (1) as part of our continuing interest in the stereochemical criteria of their reductive ring opening. For instance diethyl 4,5,6,7-tetrahydro-3-oxo-2*H*-indazole-5,5-dicarboxylate **1** was cleaved (2) into a mixture of diethyl *c*-2- (**2**) and *t*-2- (**3**) amino-*r*-1-carbamoylcyclohexane-5,5-dicarboxylate. With these polyfunctional alicyclic isomers on hand, the synthesis of an essential part of delcosine (**4**) and delsoline (**5**) alkaloids[1] (indicated with heavy lines) via the 3-azabicyclo[3.3.1]nonane derivatives (*vide infra*) seemed accessible. However, no precise knowledge has yet been obtained with regard to the separation of isomers **2** and **3**. The present paper deals with 2-*N*-acyl derivatives of the compounds **2** and **3**, most of which have been successfully separated and utilized in several sterically controlled intramolecular cyclizations.



We first showed that compound **1** on treatment with freshly prepared Raney nickel (6) in isopropanol underwent several concomitant reactions. However, a mixture of the desired aminocarbamoylcyclohexanes **2** and **3** was isolated as the main product, showing very close tlc mobilities at

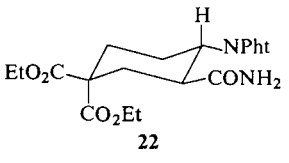
$R_f \sim 0.11$. Two isolated by-products were identified as diethyl 2-oxo-1-carbamoylcyclohexane-5,5-dicarboxylate (**6**) and diethyl *t*-2-isopropylamino-*r*-1-carbamoylcyclohexane-5,5-dicarboxylate (**7**). The formation of the cyclohexanone **6** can be explained by invoking a partial hydrolysis of an intermediary monocyclic ketimine (7). In other words the Raney nickel hydrogenolysis of compound **1** was preceded by =N–NH— bond rupture.

By simply allowing compound **6** to react with phenylhydrazine in 50% ethanol, 4,5,6,7-tetrahydro-3-oxo-2-phenylindazole-5,5-dicarboxylate (**8**) was easily prepared. The latter was identical with an authentic sample independently prepared from 2-oxo-1,5,5-tricarbethoxycyclohexane (8). It should be mentioned that the ^{1}H nmr spectrum of **6** exhibited a singlet at δ 14.03 suggesting a predominance of enol rather than keto form. A weak multiplet at δ 3.70–3.30 and a weak triplet at 1.30 were assigned to the C(1) and methyl protons of the minor keto tautomer. It is also interesting to note the highly stereoselective hydrogenation of the compound **6** by Raney nickel in isopropanol which gave diethyl *t*-2-hydroxy-*r*-1-carbamoylcyclohexane-5,5-dicarboxylate (7) (**9**) in 97% yield. The latter was characterized as *t*-2-*O*-benzoyl derivative (**10**), showing nmr spectral characteristics consistent with the conformational assignment.

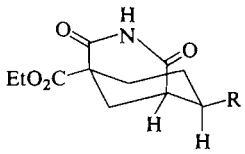
The nmr signals of the C(2) protons of compounds **2** and **3**, obscured by those of methylene protons of the ethyl groups, prompted us to undertake the synthesis of dimethyl 4,5,6,7-tetrahydro-3-oxo-2*H*-indazole-5,5-dicarboxylate (**11**) to be reductively cleaved into a mixture of dimethyl *c*-2- (**12**) and *t*-2- (**13**) amino-*r*-1-carbamoylcyclohexane-5,5-dicarboxylates. Dimethyl 2-oxo-1-carbamoylcyclohexane-5,5-dicarboxylate (**14**) was also isolated as a by-product. The ^{1}H nmr spectrum of **14** exhibited a broad singlet at δ 14.88 attributed to the OH of the preferential enol form.

To obtain pure stereoisomeric cyclohexylamines **2** and **3** the 2-*N*-benzyloxycarbonyl derivatives **15** and **16**, which were prepared and separated successfully, were subjected to deprotection reactions. To our surprise, these reactions under mild hydrogenating conditions gave back a mixture of **2** and **3**. In every case tested, spontaneous isomerization and conformational equilibration of non-derivatized isomers **2** and **3** led to mixtures, thus preventing chromatographic separation of the components. In order to elucidate the conformational properties of the separated isomers **2** and **3**, blocking the 2-amino groups as *N*-benzoyl derivatives **17** and **18** has proven effective, as we already described in the ethyl 3(4)-aminocyclohexanecarboxylate series (9). In this manner dimethyl *c*-2- (**19**) and *t*-2- (**20**) benzamido-*r*-1-carbamoylcyclohexane-5,5-dicarboxylate were also successfully separated.



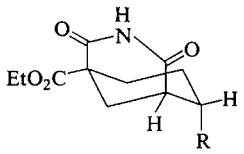
The successful separation of the *N*-acylated isomers described, in which the *trans* were favoured over the *cis* isomers, encouraged us to attempt the preparation of the corresponding aminocyclohexane carboxylic acid peptides. However, condensation of the stereoisomeric cyclohexylamines **2** and **3** with *tert*-butoxycarbonyl-L-phenylalanine *N*-hydroxysuccinimidoester (10) afforded diethyl 2-*N*-(*tert*-butoxycarbonyl-L-phenylalanyl)-*c*-2-amino-*r*-1-carbamoylcyclohexane-5,5-dicarboxylate (**21**) as the only crystalline product, in 33.4% yield. A very specific reaction resulted when a stereoisomeric mixture of compounds **2** and **3** was treated with phthalic anhydride at elevated temperature, affording diethyl *t*-2-phthalimido-*r*-1-carbamoylcyclohexane-5,5-dicarboxylate (**22**) in 68% yield. This could be explained by an epimerization which favours the *trans*-isomer **3** but as yet no precise information has been obtained experimentally to substantiate such transformations.

The nmr spectra support the geometries proposed for the *N*-acylated compounds which exhibited downfield multiplets centred at δ:4.02, ~4.69, and 4.38 for the equatorial protons at C(2) in the *cis* series (**15**, **17**, **19**), and at δ:3.59, ~3.64, ~3.69, and 3.61 for the axial protons at C(2) in the *trans* series (**16**, **18**, **20**, and **22**), respectively. All chemical shifts and pertinent characteristics of the ^{1}H nmr spectra are assembled in the Experimental.



Attention was next directed to the challenging problem of intramolecular cyclizations of the *N*-acylated, polyfunctional, and conformationally

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



correlated alicyclic compounds. The benzamido derivatives **17** and **18** proved to be the most versatile, being converted at elevated temperature under nitrogen into ethyl *t*-6-benzamido- (**23**) and *c*-6-benzamido- (**24**) *r*-1-carboxylate-3-azabicyclo[3.3.1]nona-2,4-dione, respectively. These stereoselective intramolecular cyclizations establish an axial proton at C(6) in compound **23** and an equatorial one in compound **24**, appearing in the nmr spectra as unresolved multiplets shifted downfield at δ 4.10 and 4.35, respectively.

22

23 R = NHBz

24 R = NHBz
25 R = NPht

The efficient separation of the *t*-2-phthalimido compound (**22**) allowed its cyclization into the ethyl *c*-6-phthalimido-*r*-1-carboxylate-3-azabicyclo-[3.3.1]nona-2,4-dione (**25**). Nuclear magnetic resonance data of the latter revealed the axial conformation of the C(6) proton, as shown by the multiplet at δ:4.77–4.50.

Experimental

Melting points are uncorrected and were determined on a Kofler hot-stage apparatus. The infrared spectra were performed for potassium bromide pellets on a Perkin-Elmer 137 spectrophotomer, ultraviolet spectra for solution in 95% ethanol on a Beckman DU-2-spectrophotometer, and proton magnetic resonance spectra for solutions in deuteriochloroform on a Varian A60 or JEOL JNMC-60HL spectrometer using tetramethylsilane as an internal standard. Mass spectra were determined on a Varian MAT CH7 spectrometer. Column chromatography was performed over silica gel (Merck; 0.08 mm). The silica gel (Merck HF_{254}, type 60) which was used for preparative and thin layer chromatography (20 cm plates) was activated at 110°C for 60 min. The plates were developed in methylene chloride – methanol (95:5) unless otherwise stated and located by exposure to iodine vapour, uv illumination, or ninhydrin spray.

Reductive Cleavage of Diethyl 4,5,6,7-Tetrahydro-3-oxo-2H-indazole-5,5-dicarboxylate (2) (1)

To a solution of indazoledicarboxylate (2) (**1**) (500 mg, 1.75 mmol) in isopropanol (50 mL), Raney nickel (6) (~5 g), previously washed with isopropanol, was added. The mixture was refluxed and stirred for 2.5 h. The catalyst was filtered and washed with hot isopropanol. The filtrate and washings were evaporated to an oil (340 mg) under reduced pressure, dissolved in methylene chloride, and chromatographed on a silica gel (17 g) column. Methylene chloride eluted a fraction, $R_f \sim 0.67$ (95 mg, 19%), identified as diethyl 2-oxo-1-carbamoylcyclohexane-5,5-dicarboxylate (**6**), mp 119–120°C (from methylene chloride – ether – *n*-hexane); uv λ_{max}: 256 nm (log ε 3.79); ir ν_{max}: 3423, 3350, 1749, 1724, 1672, 1638 cm^{-1}; nmr δ: 14.03 (~0.8H, s, OH of predominant enolic form, disappearing in D_2O), 5.78 br (2H, s, $CONH_2$, disappearing in D_2O), 4.22 and 4.19 (4H, 2q, J_{ET} = 7.2 Hz, $2OCH_2$ of enolic and keto form, respectively), 3.70–3.30 (~0.2H, m, H at C(1) of minor keto form), 2.73 br (2H, s, H_2 at C(6)), 1.30 and 1.25 (6H, 2t, J_{ET} = 7.2 Hz, CH_3 of keto and enolic form, respectively); ms *m/e*: 285 (M^+), 240 ($M^+ - 45$), 212 ($M^+ - CO_2Et$). *Anal.* calcd. for $C_{13}H_{19}NO_6$ (285.29): C 54.73, H 6.71, N 4.91; found: C 54.49, H 6.61, N 5.14.

Elution with methylene chloride – methanol (98:2) afforded an unidentified product (14 mg), $R_f \sim 0.54$, mp 165–170°C. Methylene chloride – methanol (95:5) then eluted diethyl *t*-2-isopropylamino-*r*-1-carbamoylcyclohexane-5,5-dicarboxylate (**7**) (33 mg, 6.6%), $R_f \sim 0.22$, mp 117–119°C (from methylene chloride – ether – *n*-hexane); ir ν_{max}: 3390, 1745, 1684, 1631 cm^{-1}; nmr δ: 5.68 br (2H, s, $CONH_2$, disappearing in D_2O), 4.22 and 4.16 (4H, 2q, J_{ET} = 7.1 Hz, $2OCH_2$), ~2.92 (1H, partly obscured m, H_a at C(2)), 1.25 and 1.21 (6H, 2t, J_{ET} = 7.1 Hz, $2CH_3$), 1.04 and 1.0 (6H, 2d, $C(CH_3)_2$); ms *m/e*: 328 (M^+), 313 ($M^+ - 15$), 296 ($M^+ - 32$), 283 ($M^+ - 45$), ($M^+ - 60$). *Anal.* calcd. for $C_{16}H_{28}N_2O_5$ (328.40): C 58.71, H 8.59, N 8.53; found: C 58.44, H 8.45, N 8.37.

Further elution with methylene chloride – methanol (95:5) afforded fractions showing $R_f \sim 0.10$ and 0.11 (180 mg, 35%) identified as a mixture of stereoisomeric diethyl 2-amino-1-carbamoylcyclohexane-5,5-dicarboxylates **2** and **3**.

Diethyl 4,5,6,7-Tetrahydro-3-oxo-2-phenylindazole-5,5-dicarboxylate (8)

A solution of cyclohexanone (**6**) (78 mg, 0.273 mmol) in 50% ethanol (1.05 mL) was treated with phenylhydrazine (30.2 mg, 0.279 mmol) and refluxed for 6 h, cooled, and refrigerated overnight. The crystalline product (74.9 mg, 73%), $R_f \sim 0.66$ (methylene chloride – methanol (9:1)), mp 65–71°C, was identical (mixture mp, and uv and ir spectra) with that obtained previously (8). Nuclear magnetic resonance δ: 10.20–9.90 (~0.9H, m, OH-enolic, disappearing in D_2O), 7.65–7.37 (2H, m, aromatic protons), 7.27–7.00 (3H, m, aromatic protons), 4.12 (4H, q, J_{Et} = 7.0 Hz, $2OCH_2$), 3.70–3.10 (~0.1H, m, H at C(3a) of minor keto form), 2.66 (2H, s, H_2 at C(4)), 1.18 (6H, t, J_{Et} = 7.0 Hz, $2CH_3$).

Stereoselective Reduction of 2-Oxo-1-carbamoylcyclohexane-5,5-dicarboxylate (6)

To a solution of cyclohexanone (**6**) (100 mg, 0.351 mmol) in isopropanol (10 mL) Raney nickel (~1 g) was added. The mixture was stirred and refluxed for 2 h and then filtered. The filtrate was evaporated under reduced pressure to an oil which crystallized from chloroform (98 mg, 97%), identified as the previously prepared diethyl *t*-2-hydroxy-*r*-1-carbamoylcyclohexane-5,5-dicarboxylate (7) (**9**), R_f ~ 0.34, mp 156–157°C. The ir spectra of the samples were superimposable. Nuclear magnetic resonance δ: (in DMSO-d_6): 7.15 br and 6.70 br (2H, 2s, $CONH_2$, disappearing in D_2O), 4.75 (1H, d, OH, disappearing in D_2O), 4.12 and 4.04 (4H, 2q, J_{Et} = 6.8 Hz, $2OCH_2$), 3.69 (1H, obscured m, H_a at C(2)), 1.20 and 1.16 (6H, 2t, J_{Et} = 6.8 Hz, $2CH_3$); ms *m/e*: 288 (M^+). *Anal.* calcd. for $C_{13}H_{21}NO_6$ (287.31): C 54.34, H 7.37, N 4.88; found: C 53.98, H 7.69, N 4.99.

Diethyl t-2-O-benzoyl-r-1-carbamoylcyclohexane-5,5-dicarboxylate (10)

To a solution of cyclohexanol (**9**) (43 mg, 0.149 mmol) in methylene chloride (0.2 mL) and pyridine (2 mL), benzoyl chloride (0.017 mL, 0.149 mmol) was added. The mixture was set aside at room temperature for 48 h and then poured into

For personal use only.

chilled water to be partitioned with methylene chloride. The organic layer was washed with 5% HCl, 5% $NaHCO_3$, and water, and then evaporated under reduced pressure to an oil (35.2 mg, 60%). Preparative tlc ($R_f \sim 0.68$) afforded the product, mp 159–160°C (from methylene chloride – ether – *n*-hexane); uv λ_{max}: 231 nm (log ε 4.13), λ_{min}: 209 nm (log ε 3.46); ir ν_{max}: 3420, 3300, 1753, 1731, 1723, 1679, 1663 cm^{-1}; nmr δ: 8.15–7.82 (2H, m, aromatic protons) 7.62–7.32 (3H, m, aromatic protons), 5.68 br (2H, s, $CONH_2$), 5.42–4.85 (1H, m, H_a at C(2)), 4.25 and 4.17 (4H, 2q, J_{ET} = 7.1 Hz, $2OCH_2$), 1.28 and 1.25 (6H, 2t, J_{Et} = 7.1 Hz, $2CH_3$).

Dimethyl 4,5,6,7-Tetrahydro-3-oxo-2H-indazole-5,5-dicarboxylate (11)

A solution of 4,5,6,7-tetrahydro-3-oxo-2*H*-indazole-5,5-dicarboxylic acid (11) (500 mg, 2.212 mmol) in 3% methanolic hydrochloric acid (50 mL) was heated under reflux for 16 h. The mixture was evaporated to dryness under reduced pressure by azeotropic distillation with anhydrous methanol and then with benzene. The residue dissolved in water was passed through a column of Amberlite IR-4B (10 mL) and evaporated to a crystalline product (375.3 mg, 67%), mp 196–197°C (from methanol–ether – *n*-hexane); uv λ_{max}: 249 nm (log ε 3.44), λ_{min}: 214 nm (log ε 3.11); ir ν_{max}: 3559, 1757, 1739 cm^{-1}; nmr δ (in DMSO-d_6): 11.00–9.00 (2H, m, NH and OH enolic), 3.65 (6H, 2s, $2OCH_3$). *Anal.* calcd. for $C_{11}H_{14}N_2O_5$: C 51.96, H 5.55, N 11.02; found: C 51.99, H 5.59, N 11.08.

Reductive Cleavage of Dimethyl 4,5,6,7-Tetrahydro-3-oxo-2H-indazole-5,5-dicarboxylate (11)

A solution of indazoledicarboxylate (**11**) (500 mg, 1.97 mmol) in isopropanol (50 mL) was treated with Raney nickel (~5 g), heated under reflux for 1.5 h, and worked up as described for compound **1**. An oil (316 mg) was obtained which, dissolved in chloroform, separated into neutral (93 mg) and basic (198 mg) fractions by partitioning with 0.5% sulphuric acid and then with basic solution by $NaHCO_3$ treatment. The preparative tlc and column chromatography of isolated fractions using methylene chloride – methanol (98:2) as eluant afforded a product, $R_f \sim$ 0.63 (32.5 mg, 6.4%), identified as dimethyl 2-oxo-1-carbamoylcyclohexane-5,5-dicarboxylate (**14**), mp 154–156°C (from methylene chloride – ether – *n*-hexane); uv λ_{max}: 254 nm (log ε 3.85); ir ν_{max}: 3484, 3390, 1736, 1718, 1692 cm^{-1}; nmr δ (in DMSO-d_6): 14.88 br (1H, s, OH enolic, disappearing in D_2O), 7.23 (2H, s, $CONH_2$, disappearing in D_2O), 3.65 (6H, s, $2OCH_3$), 3.20–2.80 (1H, m, H at C(1)), 2.64 (2H, s, H_2 at C(6)). *Anal.* calcd. for $C_{11}H_{15}NO_5$: C 51.36, H 5.88, N 5.45; found: C 51.43, H 5.74, N 5.73.

Methylene chloride – methanol (95:5) eluted from the chromatographs of the basic fraction two unidentified products showing $R_f \sim 0.49$ (28 mg) and 0.18 (21 mg). Further elution with the same solvent afforded a product (113 mg, 26%), $R_f \sim 0.10$, identified as a mixture of stereoisomeric dimethyl 2-amino-1-carbamoylcyclohexane-5,5-dicarboxylates **12** and **13**, mp 174–176°C (from methylene chloride – ether – *n*-hexane); ir ν_{max}: 3430, 3360, 1745, 1725, 1665 cm^{-1}; nmr δ: 6.71 and 5.65 br (2H, 2s, $CONH_2$, disappearing in D_2O), 3.75 and 3.68 (6H, 2s, $2OCH_3$), 1.77 (2H, s, NH_2, disappearing in D_2O). *Anal.* calcd. for $C_{11}H_{18}N_2O_5$: C 51.15, H 7.03, N 10.85; found: C 51.34, H 7.34, N 10.60.

Diethyl c-2- *(15) and* t-2- *(16) Amino*-N-*benzyloxycarbonyl*-r-1-*carbamoylcyclohexane-5,5-dicarboxylates*

To a cooled solution (0°C) of stereoisomers **2** and **3** (250 mg, 0.873 mmol) in methylene chloride (15 mL) 50% benzyloxycarbonyl chloride (0.147 mL, 0.437 mmol) solution in toluene was added. The mixture was stirred for 2 min, then treated with triethylamine (0.15 mL, 0.873 mmol). After 10 min a second portion of benzyloxycarbonyl chloride (0.147 mL) was added and stirring continued for an additional 5 min at 0°C and then at room temperature for 1.5 h. Water was added and the product separated by extraction with methylene chloride. The organic layer was dried over sodium sulphate and then evaporated to a mixture of stereoisomeric products (367 mg). Preparative tlc (three developments, acetone as eluant) separated the *cis*-benzyloxycarbonyl derivative **15**, $R_f \sim 0.68$ (59 mg, 16%), mp 122–123°C (from methylene chloride – ether – *n*-hexane); ir ν_{max}: 3405, 3330, 1728, 1690, 1655 cm^{-1}; nmr δ: 7.36 (5H, s, aromatic protons), 5.81 (2H, s, $CONH_2$, disappearing in D_2O), ~5.52 (1H, partly obscured m, NHOCO, disappearing in D_2O), 5.08 (2H, s, CH_2), 4.21 and 4.18 (4H, 2q, J_{Et} = 7.1 Hz, $2OCH_2$), ~4.02 (1H, partly obscured, m, H_e at C(2)), 1.25 and 1.24 (6H, 2t, J_{Et} = 7.1 Hz, $2CH_3$). *Anal.* calcd. for $C_{21}H_{28}N_2O_7$: C59.99, H 6.71, N 6.66; found: C 59.71, H 6.75, N 6.89.

The *trans*-isomer **16**, $R_f \sim 0.65$ (160 mg, 44%) recrystallized from methylene chloride – ether – *n*-hexane, mp 167–168°C; ir ν_{max}: 3440, 3330, 1728, 1685, 1655 cm^{-1}; nmr δ: 7.35 (5H, s, aromatic protons), 6.44 br and 5.99 br (2H, 2s, $CONH_2$, disappearing in D_2O), 6.35–5.38 (1H, m, NHOCO), 5.08 (2H, s, CH_2), 4.24 and 4.17 (4H, 2q, J_{Et} = 7.1 Hz, $2OCH_2$), 3.85–3.34 (1H, m, H_a at C(2)), 1.25 and 1.23 (6H, 2t, J_{Et} = 7.1 Hz, $2CH_3$). *Anal.* calcd. for $C_{21}H_{28}N_2O_7$: C 59.99, H 6.71, N 6.66; found: C 60.18, H 6.51, N 6.33.

Diethyl c-2- *(17) and* t-2- *(18) Benzamido*-r-1-*carbamoylcyclohexane-5,5-dicarboxylates*

To a solution of stereoisomers **2** and **3** (130 mg, 0.454 mmol) in methylene chloride (0.3 mL) and anhydrous pyridine (3.4 mL) benzoyl chloride (0.052 mL, 0.454 mmol) was added, and then stirred at room temperature for 24 h. The work up was as described for compound **10**. A mixture of the stereoisomers was obtained from the organic layer (CH_2Cl_2) in 70% yield (124.3 mg). Preparative tlc (in methylene chloride – ether (9:1), four developments, acetone as eluant) separated the *cis*-stereoisomer **17**, $R_f \sim 0.64$ (23.0 mg, 13%), mp 199–200°C (from methanol–ether – *n*-hexane); uv λ_{max}: 228.5 nm (log ε 3.80), λ_{min}: 212.5 nm (log ε 3.56); ir ν_{max}: 3323, 1735, 1695, 1656 cm^{-1}; nmr δ (in DMSO-d_6): 7.89 (1H, d, J = 6 Hz, NH—CO, disappearing in D_2O), 7.88–7.64 (3H, m, aromatic protons), 7.58–7.27 (2H, m, aromatic protons), 6.80 br (2H, s, $CONH_2$, disappearing in D_2O), ~4.69 (1H, partly obscured m, H_e at C(2)), 4.18 and 4.14 (4H, 2q, J_{Et} = 7.1 Hz, $2OCH_2$), 1.19 and 1.15 (6H, 2t, J_{Et} = 7.1 Hz, $2CH_3$); ms *m/e*: 390 (M^+), 345 ($M^+ - CONH_2$), 317 ($M^+ - CO_2Et$), 300 ($M^+ - CO_2Et - NH_2$). *Anal.* calcd. for $C_{20}H_{26}N_2O_6$ (390.42): C 61.52, H 6.71; found: C 61.40, H 6.88.

The *trans*-isomer **18**, $R_f \sim 0.60$ (51.2 mg, 28%) recrystallized from methanol–ether – *n*-hexane, mp 224–226°C; uv λ_{max}: 228 nm (log ε 4.01), λ_{min}: 212.5 nm (log ε 3.80); ir ν_{max}: 3365, 3290, 1753, 1720, br, 1673, 1640 cm^{-1}; nmr δ (in DMSO-d_6): 8.00 (1H, d, J = 8.3 Hz, NHCO, disappearing in D_2O), 7.92–7.67 (2H, m, aromatic protons), 7.60–7.30 (3H, m, aromatic protons), 6.95 and 6.85 br (2H, s, $CONH_2$, disappearing in D_2O), 4.23 and 4.14 (4H, 2q, J_{Et} = 7.1 Hz, $2OCH_2$), ~3.64 (1H, obscured m, H_a at C(2)), 1.21 and 1.18 (6H, 2t, J_{Et} = 7.1 Hz, $2CH_3$); ms *m/e*: 390 (M^+), 345 ($M^+ - CONH_2$), 317 ($M^+ - CO_2Et$), 300 ($M^+ - CO_2Et - NH_2$). *Anal.* calcd. for $C_{20}H_{26}N_2O_6$: C 61.52, H 6.71, N 7.18; found: C 61.50, H 6.99, N 7.40.

Dimethyl c-2- *(19) and* t-2- *(20) Benzamido*-r-1-*carbamoylcyclohexane-5,5-dicarboxylates*

A solution of stereoisomers **12** and **13** (96.4 mg, 0.373 mmol) in methylene chloride (0.2 mL) and pyridine (3 mL) was treated with benzoylchloride (0.043 mL, 0.373 mmol) and worked up as for compounds **17** and **18**. A crude mixture of stereoisomers was isolated in 73% yield (98 mg). Preparative tlc separated the *cis*-isomer **19**, $R_f \sim 0.53$ (13.1 mg, 13.4%), mp 206–207°C (from

For personal use only.

methylene chloride – ether – *n*-hexane); uv λ_{max}: 227.5 nm (log ε 4.06), λ_{min}: 213 nm (log ε 3.89); ir ν_{max}: 3403, 3268, 3215, 1743, 1726, 1698, 1673 cm^{-1}; nmr δ (in DMSO-d_6): 7.89 (1H, d, J = 7.8 Hz, NHCO), 7.80–7.15 (5H, m, aromatic protons), 6.82 br (2H, s, $CONH_2$), 6.49–4.07 (1H, m, H_e at C(2)), 3.68 and 3.63 (6H, 2s, $2OCH_3$); ms *m/e*: 362 (M^+), 330 ($M^+ - 32$), 303 ($M^+ - 59$), 286 ($M^+ - 76$).

The *trans*-isomer **20**, $R_f \sim 0.51$ (36 mg, 37%) was recrystallized from methylene chloride – ether – *n*-hexane, mp 250–253°C; uv λ_{max}: 228 nm (log ε 3.92), λ_{min}: 213 (log ε 3.71); ir ν_{max}: 3360, 3195, 1745, 1730, 1678, 1665 cm^{-1}; nmr δ (in DMSO-d_6): 8.02 (1H, d, J = 8.8 Hz, NHCO, disappearing in D_2O), 7.88–7.58 (2H, m, aromatic protons), 7.52–7.21 (3H, m, aromatic protons), 6.97 br and 6.85 br (2H, 2s, $CONH_2$, disappearing in D_2O), ~3.9 (1H, obscured m, H_a at C(2)), 3.72 and 3.67 (6H, 2s, $2OCH_3$); ms *m/e*: 362 (M^+), 345 ($M^+ - 17$), 331 ($M^+ - 31$), 317 ($M^+ - 45$). *Anal.* calcd. for $C_{18}H_{32}N_2O_6$ (362.37): C 59.66, H 6.12, N 7.73; found: C 59.85, H 6.17, N 7.89.

Diethyl 2-N-(tert-*butoxycarbonyl*-L-*phenylalanyl*)-c-2-*amino*-r-1-*carbamoylcyclohexane*-5,5-*dicarboxylate* (**21**)

A mixture of stereoisomers **2** and **3** (286 mg, 1 mmol) and *N*-BOC-L-Phe-ONSu (10) (362 mg, 1 mmol) were dissolved in 1,2-dimethoxyethane (5 mL) and stirred at room temperature for 4.5 h. The mixture was then partitioned between water and methylene chloride. The organic layer was dried over $MgSO_4$ and then evaporated to an oil (530 mg). The preparative tlc separated the product (178 mg, 33.4%), $R_f \sim 0.55$, mp 186–187°C (from ethylacetate–ether – *n*-hexane); ir ν_{max}: 3430, 3325, 1738 (sh), 1728, 1687 (br), 1650 (sh) cm^{-1}; nmr δ: 7.23 (5H, s, aromatic protons), 6.65–6.20 (1H, m, PhNH, disappearing in D_2O), 5.90 br and 5.40 br (2H, s, $CONH_2$, disappearing in D_2O), ~4.25 (1H, obscured m, H_e at C(2)), 4.17 and 4.12 (4H, 2q, J_{Et} = 7.0 Hz, $2OCH_2$), 1.37 and 1.35 (6 + 3H, 2s; $C(CH_3)_3$), 1.23 (6H, t, J_{Et} = 7.0 Hz, $2CH_3$). *Anal.* calcd. for $C_{27}H_{39}N_3O_8$: C 60.77, H 7.37, N 7.88; found: C 60.52, H 7.08, N 8.17.

Diethyl t-2-*Phthalimido*-r-1-*carbamoylcyclohexane*-5,5-*dicarboxylate* (**22**)

A mixture of the stereoisomers **2** and **3** (252 mg, 0.882 mmol) and phthalic anhydride (131 mg, 0.882 mmol) was ground in a mortar and then heated at 220–225°C under nitrogen. The product was partitioned between chloroform and 5% $NaHCO_3$. The organic layer was washed with 0.5 mol dm^{-3} H_2SO_4 and water, dried over sodium sulphate, and evaporated to a crude product (320 mg, 87%) which on preparative tlc afforded the product (250 mg, 68%), $R_f \sim 0.59$, mp 208–209°C (from methylene chloride – *n*-hexane); uv λ_{max}: 222 nm (log ε 4.64); ir ν_{max}: 3484, 3268, 1786 sh, 1784, 1709, 1667 cm^{-1}; nmr δ: 7.99–7.51 (4H, m, aromatic protons); 5.62 br (2H, s, $CONH_2$, disappearing in D_2O), 4.30 and 4.20 (4H, 2q, J_{Et} = 7.1 Hz, $2OCH_2$), 3.61 (1H, sx, $J_{2a,1a}$ = 12 Hz, $J_{2a,3a}$ = 12 Hz, $J_{2a,3e}$ = 3.5 Hz, H_a at C(2)), 1.35 and 1.24 (6H, 2t, J_{ET} = 7.1 Hz, $2CH_3$). *Anal.* calcd. for $C_{21}H_{24}N_2O_7$: C 60.56, H 5.81, N 6.73; found: C 60.79, H 5.80, N 6.83.

Ethyl t-6-*Benzamido*-r-1-*carboxylate*-3-*azabicyclo*-[3.3.1]*nona*-2,4-*dione* (**23**)

The *cis*-benzamido compound **17** (46 mg, 0.118 mmol) was heated at 220–230°C under nitrogen for 20 min and then dissolved in methylene chloride and filtered. Preparative tlc afforded the product (31.6 mg, 78%), $R_f \sim 0.77$, mp 191–192°C (from methylene chloride – ether); ir ν_{max}: 3395, 3250, 1738, 1720 sh, 1705, 1645 cm^{-1}; nmr δ (in DMSO-d_6): 11.18 br (1H, s, H at N(3)), 8.24 (1H, d, J = 7.6 Hz, CONH), 8.00–7.70 (2H, m, aromatic protons), 7.67–7.36 (3H, m, aromatic protons), 4.18 (2H, q, J_{Et} = 7.1 Hz, OCH_2), ~4.10 (1H, obscured m, H_a at C(6)), 1.19 (3H, t, J_{Et} = 7.1 Hz, CH_3). *Anal.* calcd. for $C_{18}H_{20}N_2O_5$: C 62.78, H 5.86, N 8.14; found: C 63.01, H 6.16, N 8.29.

Ethyl c-6-*Benzamido*-r-1-*carboxylate*-3-*azabicyclo*-[3.3.1]*nona*-2,4-*dione* (**24**)

The *trans*-benzamido compound **18** (59 mg, 0.151 mmol) was heated at 240–250°C for 20 min, worked up, and purified as described above. The product (31 mg, 60%) crystallized from methylene chloride – ether, mp 217–218°C; ir ν_{max}: 3323, 3223, 1746, 1728, 1696, 1638 cm^{-1}; nmr δ (in DMSO-d_6): 11.21 br (1H, s, H at N(3)), 8.34 (1H, d, J = 7.7 Hz, CONH), 8.09–7.76 (2H, m, aromatic protons), 7.62–7.38 (3H, m, aromatic protons), 4.42–4.28 (1H, obscured m, H_e at C(6)), 4.17 (2H, q, J_{Et} = 7.1 Hz, OCH_2), 1.20 (3H, t, J_{Et} = 7.1 Hz, CH_3). *Anal.* calcd. for $C_{18}H_{20}N_2O_5$: C 62.78, H 5.85, N 8.14; found: C 62.48, H 5.64, N 7.88.

Ethyl c-6-*Phthalimido*-r-1-*carboxylate*-3-*azabicyclo*-[3.3.1]*nona*-2,4-*dione* (**25**)

The *trans*-phthalimido compound **22** (188 mg, 0.452 mmol) was heated at 240–250°C for 20 min. The product (158 mg) was purified on tlc plates, R_f ~0.78. Yield 29.3 mg (17.5%), mp 214–215°C (from methylene chloride – ether); uv λ_{max}: 222 nm (log ε 4.59); ir ν_{max}: 3462, 3250, 1775, 1748, 1728, 1710 cm^{-1}; nmr δ: 8.53–8.20 (1H, m, H at N(3)), 8.06–7.59 (4H, m, aromatic protons), 4.77–4.50 (1H, m, H_e at C(6)), 4.28 (2H, q, J_{Et} = 7.1 Hz, OCH_2). *Anal.* calcd. for $C_{19}H_{18}N_2O_6$: C 61.61, H 4.90, N 7.56; found: C 61.40, H 5.12, N 7.39.

From preparative tlc plates an unidentified product, $R_f \sim 0.83$ (13 mg), separated, mp 165–166°C (from methylene chloride – *n*-hexane).

This paper is dedicated to the memory of Dr. Léo Marion

JOHN A. AKINNIYI, JOSEPH D. CONNOLLY, DAVID S. RYCROFT, B. LUCAS SONDENGAM, and N. PATIENCE IFEADIKE. Can. J. Chem. **58**, 1865 (1980).

Three new compounds, 3,4-secotirucalla-4(28),7,24-trien-3,21-dioic acid **1**, the corresponding 3-monomethyl ester **12**, and 2′-hydroxyrohitukin **13**, have been isolated from the bark of *Guarea cedrata* (Meliaceae). The structures of **1** and **12** were confirmed by correlation with methyl 3-oxotirucalla-8,24-dien-21-oate (methyl isoelemonate) **6**. The ^1H and ^{13}C nmr data are reported.

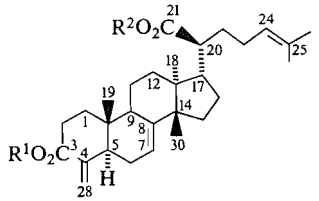
JOHN A. AKINNIYI, JOSEPH D. CONNOLLY, DAVID S. RYCROFT, B. LUCAS SONDENGAM et N. PATIENCE IFEADIKE. Can. J. Chem. **58**, 1865 (1980).

On a isolé, de l'écorce de *Guarea cedrata* (Méliaceae), trois triterpènoides nouveaux, l'acide 3,4-secotirucalla-4(28),7,24-trièn-3,21-dioique **1**, son ester méthylique **12** et 2′-hydroxyrohitukin **13**. On a confirmé les structures **1** et **12** par une corrélation avec méthyl 3-oxotirucalla-8,24-dièn-21-oate **6**. Les spectres rmn sont présentés.

In a continuation of our investigation (1, 2) of the constituents of the Meliaceae family we have examined the extract of the bark of *Guarea cedrata* and have isolated three new compounds, the ring A secotirucallane derivatives *A* **1** and *B* **12** and 2′-hydroxyrohitukin **13**, whose structures were assigned on the following evidence.

Compound *A* **1**, $C_{30}H_{46}O_4$, has spectroscopic properties consistent with the presence of two carboxyl groups (ir: 3200–2500 (br), 1709 cm^{-1}; δ_C 183.5 and 181.3), an exomethylene (δ_H 4.80 (2H, bs); δ_C 132.4 (s) and 114.1 (t)), and two trisubstituted double bonds (δ_H 5.23 (m, H-7) and 5.09 (bt, H-24); δ_C 123.5 (d, C-24), 147.5 (s, C-25), and 118.0 (d, C-7), 145.8 (s, C-8)). The molecule is therefore tricarbocyclic. In addition there are three tertiary methyls (δ_H 0.81, 0.87, and 0.95) and three vinyl methyls (δ_H 1.55, 1.65, and 1.75). Hydrogenation over palladium/charcoal of the dimethyl ester **2**, obtained by reaction of **1** with diazomethane, afforded the tetrahydroderivative **3** whose ^{13}C nmr spectrum (δ_C 118.3 (d, C-7) and 145.6 (s, C-8)) clearly showed that one of the trisubstituted double bonds was resistant to hydrogenation under normal conditions. On treatment with dry hydrogen chloride in chloroform the tetrahydrodimethyl ester **3** was converted into the isomeric compound **4** with a tetrasubstituted double bond. Under similar conditions the dimethyl ester **2** gave the chlorodiene **5** (δ_C 70.8 (s, C-25), 147.3, 137.6 (both s, C-8 and C-9), 129.8 (s, C-4), 113.8 (t, C-28)). This acid-induced isomerisation of a hindered trisubstituted to a tetrasubstituted double bond is reminiscent of the behaviour of Δ^7 tetracyclic triterpenoids, e.g. odoratol (3), and, taken in conjunction with the above spectroscopic evidence, led us to **1** as a biogenetically acceptable structure for compound *A*. This was confirmed in the following way.

Methyl 3-oxotirucalla-8,24-dien-21-oate **6**, isolated from elemi resin according to the procedure of Halsall and co-workers (4), was hydrogenated over palladium/charcoal to give the non-crystalline 24,25-dihydro-derivative **7**. Baeyer–Villiger oxidation of **7** with peracetic acid afforded a mixture of the lactone **8** and the epoxylactone **9**, separable by preparative tlc. The former was converted into the diene dimethyl ester **11**, via the hydroxy dimethyl ester **10**, by alkaline hydrolysis, methylation, and dehydration with thionyl chloride. Hydrogenation of **11** yielded dimethyl 3,4-secotirucall-8-en-3,21-dioate **4**, identical in all respects with the product of acid isomerisation of dimethyl tetrahydro-*A* **3**. This series of transformations confirmed that compound *A* is 3,4-secotirucalla-4(28),7,24-trien-3,21-dioic acid **1**.



The spectroscopic properties of compound *B* **12**, $C_{31}H_{48}O_4$, (see Experimental) suggested that it is a monomethyl ester of compound *A*. This was readily established by methylation with diazomethane

to give the dimethyl ester **2**. Comparison of the ^{13}C nmr spectra of the three compounds **1**, **2**, and **12** indicated that the free carboxyl group of *B* (δ_C 183.5) is associated with the downfield carboxymethyl group (δ_C 176.4) of the dimethyl ester **2**. It is therefore assigned as the C-21 carboxyl group on the basis of normal ^{13}C substitution rules (5). Thus compound *B* is 3,4-secotirucalla-4(28),7,24-trien-3,21-dioic acid 3-methyl ester **12**.

The third compound from the extract is a new complex tetranortriterpenoid, 2′-hydroxyrohitukin **13**, $C_{34}H_{42}O_{14}$, belonging to the small group of compounds, related to prieurianin and rohitukin **14**, (2), which give broad ^1H nmr spectra at room temperature as a result of conformational processes occurring at an intermediate rate on the nmr time scale. At 60°C the ^1H nmr spectrum of **13** is well resolved and readily revealed the structural features. Thus it has resonances for a β-substituted furan, an acetate, a formate, two hydroxyl groups (δ 5.21 and 2.45, exchangeable with D_2O), 2H-29 (δ 4.17, bs), H-17 (δ 3.98, t, J = 9 Hz), an *exo*-methylene (δ 5.90 and 5.49, both s, 2H-30), H-1 (δ 5.10, m), H-2′ (δ 3.13, d, J = 4 Hz), three tertiary (δ 0.95, 1.73, and 1.78) and two secondary methyl groups (δ 0.83 and 0.65, both d, J = 7 Hz). Decoupling experiments identified the characteristic ring C system involving H-9 (δ 3.76, d, J = 7 Hz), H-11 (δ 5.45, dd, J = 12, 7 Hz) and H-12 (δ 6.13, d, J = 12 Hz). The ^{13}C nmr spectrum (see Experimental) confirmed the presence of the ε- and δ-lactones and the ketol system in ring D. The above data suggested that **13** only differed from rohitukin **14** in the nature of the ester function attached to C-12. This was confirmed by comparison of their ^{13}C nmr spectra which are virtually identical with the exception of the resonances associated with the ester functions. It is apparent that the 3-methylbutanoate **15** (5) of rohitukin has been replaced by a 2-hydroxy-3-methylbutanoate **16** in **13**.

Experimental

Nuclear magnetic resonance spectra (^1H and ^{13}C) were run at ambient temperature (unless otherwise stated) on a Varian XL-100 spectrometer with VFT-100 accessory, for solutions in deuteriochloroform with tetramethylsilane as internal reference. The ^{13}C assignments are based on chemical shifts, multiplicities in off-resonance decoupled spectra, and comparison with similar compounds (2).

Extraction

Powdered bark (6 kg) of *G. cedrata*, collected in Okonolinga (Cameroon), was extracted with hexane in a Soxhlet. A solid (1.2 g) which separated during the extraction was shown by preparative tlc (benzene – ethyl acetate, 3:1) to be mainly one compound. Crystallization from methanol afforded *2'-hydroxyrohitukin* **13** (0.6 g), mp 231–237°C; ir (CCl_4): 3620, 3440, 1750, 1740 and 1720 cm^{-1}; ^{13}C nmr δ (at 60°C): 206.4 (C-15), 173.3 (C-7), 169.4 (C-3), 169.4 (CH_3COO), 160.3 (HCOO), 143.3 (C-23), 140.9 (C-21), 124.9 (C-20), 110.6 (C-22), 138.9 (C-8), 122.8 (C-30), 81.1 (C-4), 79.4 (C-14), 78.1 (C-29), 75.6 (C-12), 74.9 (C-11), 71.3 (C-1), 51.9 (C-9), 49.8 and 46.3 (C-10 and C-13), 42.7 (C-5), 42.0 (C-16), 37.5 (C-2), 35.4 (C-17), 32.1 (C-6), 23.3, 21.4, 13.0 (C—*Me*), and 21.2 (CH_3COO); ms *m/e*: 614 ($M - 60$). *Anal.* calcd. for $C_{34}H_{42}O_{14} \cdot H_2O$: C 58.95, H 6.35; found: C 58.9, H 6.3. A further crop of solid (0.5 g) was shown by tlc (methylene chloride – methanol, 19:1) to contain a second compound as a major component. Chromatography over silica gel and elution with hexane–ether (19:1) yielded compound *B*, *3,4-secotirucalla-4(28),7,24-trien-3,21-dioic acid 3-methyl ester* **12** (300 mg) mp 190°C (ex methanol), $[\alpha]_D + 11°$ (*c* 0.5, methanol); ir (CCl_4): 3500–2500, 1741, 1703, 1640 cm^{-1}; ^1H nmr δ: 0.78, 0.89 and 0.97 (C—*Me*), 1.75, 1.65 and 1.55 (vinyl Me), 3.62 (CO_2Me), 4.8 (2H, bs, $CH_2{=}C\lesssim$), 5.09 (1H, bt, H-24), and 5.23 (1H, m, H-7); ^{13}C nmr δ: 183.4 (C-21), 174.4 (C-3), 147.3 (C-25), 123.6 (C-24), 145.9 (C-8), 118.3 (C-7), 132.3 (C-4), 113.9 (C-28), 51.4 (CO_2Me), 51.3, 43.3 and 36.8 (s), 50.0, 49.3, 47.5, and 40.6 (d), 33.6, 32.2, 32.0, 30.2, 30.1, 28.1, 27.4, 26.1, and 18.1 (t), and 27.4, 25.7, 22.5, 21.7, 17.6, and 15.8 (q); ms *m/e*: 484. *Anal.* calcd. for $C_{31}H_{48}O_4$: C 76.8, H 10.0; found: C 76.85, H 9.70. Concentration of the hexane extract gave an oily solid which was washed with benzene and chloroform. The solid residue (8 g) was dissolved in methanol–chloroform and adsorbed on a silica gel column. Elution with benzene gave compound *A*, *3,4-secotirucalla-4(28),7,24-trien-3,21-dioic acid* **1** (5.75 g) mp 170°C (ex benzene), $[\alpha]_D + 18°$ (*c* 1.4, methanol); ^{13}C nmr δ: 51.4, 43.3, and 36.4 (s), 50.3, 50.0, 48.8, and 40.7 (d), 33.6, 32.3, 30.5, 30.1, 30.1, 27.2, 27.2, 26.0, and 18.1 (t), 27.0, 25.7, 21.7, 21.4, 17.7, and 16.2 (q); ms *m/e*: 470. *Anal.* calcd. for $C_{30}H_{46}O_4 \cdot H_2O$: C 75.3, H 10.0; found: C 75.0, H 10.3.

Dimethyl 3,4-Secotirucalla-4(28),7,24-trien-3,21-oate 2

Reaction of either compound *A* **1** or compound *B* **12** with diazomethane in methanol followed by purification by preparative tlc yielded the non-crystalline dimethyl ester **2**; ^1H nmr δ: 0.78, 0.83, and 0.94 (C—*Me*), 1.74, 1.64, and 1.53 (vinyl Me), 3.63 (2 × CO_2Me), 4.80 (2H, bs, $CH_2{=}C\lesssim$), 5.05 (1H, bt, H-24), and 5.23 (1H, m, H-7); ^{13}C nmr δ: 176.5 (C-21), 174.3 (C-3), 147.3 (C-25), 123.7 (C-24), 145.9 (C-8), 118.3 (C-7), 132.0 (C-4), 113.9 (C-28), 51.5 and 51.1 (2 × CO_2Me), 51.1, 43.1, and 36.8 (s), 49.8, 49.4, 47.6, and 40.6 (d), 33.8, 32.4, 31.8, 30.2, 30.2, 28.1, 27.4, 26.1, and 17.8 (t), and 27.1, 25.7, 22.4, 21.9, 17.6, and 15.9 (q); ms *m/e*: 498.

Dimethyl 3,4-Secotirucall-7-en-3,21-dioate 3

The dimethyl ester **2** (146 mg) in ethyl acetate solution was hydrogenated over 10% palladium/charcoal until uptake of hydrogen ceased. Normal work-up afforded the non-crystalline *tetrahydrodimethyl ester* **3** (140 mg); ^1H nmr δ: 3.64 (2 × CO_2Me) and 5.26 (1H, m, H-7); ^{13}C nmr δ: 176.6 (C-21), 174.6 (C-3), 145.6 (C-8), 118.3 (C-7), 51.5 and 51.1 (2 × CO_2Me); ms *m/e*: 502.

Dimethyl 3,4-Secotirucall-8-en-3,21-dioate 4

Dry hydrogen chloride gas was bubbled through a chloroform solution of the tetrahydrodimethyl ester **3** (100 mg) for ten minutes and the reaction left for one hour at room temperature. *Dimethyl 3,4-secotirucall-8-en-3,21-dioate* **4** (90 mg), obtained on work-up, was crystallized from ether – light petroleum and had mp 92–94°C; ^1H nmr δ: 3.64 (2 × CO_2Me), no vinyl protons; ms *m/e*: 502. *Anal.* calcd. for $C_{32}H_{54}O_4$: C 76.45, H 10.85; found: C 76.3, H 10.85.

Dimethyl 25-Chloro-3,4-secotirucalla-4(28),8-dien-3,21-dioate 5

On treatment with dry hydrogen chloride gas under the above conditions the dimethyl ester **2** (100 mg) was converted into the *chlorodiene* **5** (87 mg) mp 114–115°C (ex ether – light petroleum); ^1H nmr δ: 0.80, 0.86, 0.90 (C—*Me*), 1.52 (6H, Cl—C*Me*$_2$), 1.73 (vinyl Me), 3.68 (2 × CO_2Me), 4.68 and 4.89 (each 1H, bs, $CH_2{=}C\lesssim$); ms *m/e*: 498 (M – HCl). *Anal.* calcd. for $C_{32}H_{51}O_4Cl$: C 71.85, H 9.55, Cl 6.65; found: C 71.85, H 9.8, Cl 6.7.

Methyl 3-Oxotirucall-8-en-21-oate 7

Methyl 3-oxotirucalla-8,24-dien-21-oate **6** (150 mg) mp 110–113°C, isolated from elemi resin (4), was dissolved in ethyl acetate and hydrogenated over 10% palladium/charcoal. Normal work-up afforded the non-crystalline methyl 3-oxotirucall-8-en-21-oate **7** (130 mg); ^1H nmr δ: 3.66 (CO_2Me); ms *m/e*: 470.

Baeyer–Villiger Oxidation of 7

Acetic anhydride (20 mL) was added dropwise over a period of twenty minutes to a stirred, ice-cold solution of methylene chloride (20 mL) containing hydrogen peroxide (90%, 6 mL) and a drop of concentrated sulphuric acid. Stirring was continued for thirty minutes at room temperature. Excess of this peracetic acid was added dropwise to a stirred, ice-cold solution of the dihydroderivative **7** (130 mg) in dry methylene chloride (20 mL) in the presence of anhydrous disodium hydrogen phosphate (160 mg) and the reaction allowed to stand overnight at room temperature. Analytical tlc of the crude product showed the presence of two products which were separated by preparative tlc (13% ether–benzene). The *lactone* **8** (50 mg) was crystallized from ether – light petroleum and had mp 135–137°C; ^1H nmr δ: 3.66 (CO_2Me); ^{13}C nmr δ: 176.7 (C-21), 174.3 (C-3), 134.2 and 133.5 (C-8 and C-9), 86.0 (C-4), 51.0 (CO_2Me); ms *m/e*: 486. *Anal.* calcd. for $C_{31}H_{50}O_4$: C 76.5, H 10.35; found: C 76.5, H 10.45. The *epoxylactone* **9** (40 mg) was crystallized from ether – light petroleum and had mp 169–170°C; ^1H nmr δ: 3.63 (CO_2Me); ^{13}C nmr δ: 176.6 (C-21), 173.3 (C-3), 85.5 (C-4), 69.6 and 68.8 (C-8 and C-9), 51.5 (CO_2Me); ms *m/e*: 502. *Anal.* calcd. for $C_{31}H_{50}O_5$: C 74.05, H 10.05; found: C 74.25, H 10.0.

Dimethyl 4-Hydroxy-3,4-secotirucall-8-en-3,21-dioate 10

The lactone **8** (50 mg) was refluxed in ethanolic potassium hydroxide solution (5%) for two hours. Acidification with acetic acid, extraction with chloroform, methylation with diazomethane, and purification by preparative tlc (13% ether–benzene) yielded the *hydroxy dimethyl ester* **10** (40 mg) mp 97–98°C (ex ether – light petroleum); ir (CCl_4): 3501 and 1735 cm^{-1}; ^1H nmr δ: 3.66 (2 × CO_2Me); ^{13}C nmr δ: 176.8 (C-21), 176.0 (C-3), 138.5 and 130.8 (C-8 and C-9), 75.3 (C-4), 51.7 and 51.0 (2 × CO_2Me); ms *m/e*: 500 (M – 18). *Anal.* calcd. for $C_{32}H_{54}O_5$: C 74.1, H 10.5; found: C 74.4, H 10.6.

Dimethyl 3,4-Secotirucalla-4(28),8-dien-3,21-dioate 11

An ice-cold solution of the hydroxy dimethyl ester **10** (28 mg) in dry pyridine (3 mL) was treated with thionyl chloride (three drops) and allowed to stand for five minutes. Water was added

and the solution extracted with chloroform. The crude product was purified by preparative tlc (13% ether–benzene) to give the *diene dimethyl ester* **11** (25 mg) mp 105–106°C (ex ether – light petroleum; ^{1}H nmr δ: 4.68 and 4.89 (each 1H, bs, CH_2=C<), 3.66 (2 × CO_2Me), 1.72 (vinyl Me); ms *m/e*: 500. *Anal.* calcd. for $C_{32}H_{52}O_4 \cdot H_2O$: C 74.1, H 10.5; found: C 74.2, H 10.5.

Hydrogenation of 11

The diene dimethyl ester **11** (25 mg) was dissolved in ethyl acetate and hydrogenated over 10% palladium/charcoal as above. Preparative tlc of the crude product and crystallization from ether – light petroleum gave *dimethyl 3,4-secotirucall-8-en-3,21-dioate* **4** (21 mg) mp 92–93°C, identical in all respects (nmr, mass spectrum, mixture mp, and tlc) with the compound obtained by hydrogenation and acid isomerisation of the dimethyl ester **2** derived from compounds *A* **1** and *B* **12**. *Anal.* calcd. for $C_{32}H_{54}O_4$: C 76.45, H 10.85; found: C 76.4, H 11.0.

The synthesis of daunosaminyl ε-rhodomycinone, daunosaminyl 10-epi-ε-rhodomycinone, daunosaminyl ε-pyrromycinone, and 10-descarbomethoxy-ε-pyrromycin

JOHN M. ESSERY[1] AND TERRENCE W. DOYLE

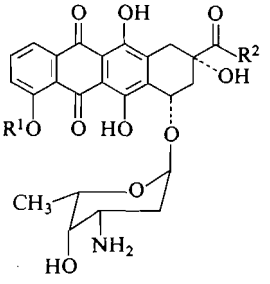
Research Division, Bristol Laboratories, Division of Bristol-Myers Company, Syracuse, NY 13201, U.S.A.

Received February 6, 1980

This paper is dedicated to the memory of Dr. Léo Marion

JOHN M. ESSERY and TERRENCE W. DOYLE. Can. J. Chem. **58**, 1869 (1980).

The epimerisation at C10 of ε-rhodomycinone by aqueous alkali treatment of its 6,7-acetonide is described. Daunosaminyl ε-rhodomycinone and daunosaminyl 10-epi-ε-rhodomycinone were prepared and compared with regard to their antibacterial properties. Daunosaminyl ε-pyrromycinone and 10-descarbomethoxy-ε-pyrromycin were synthesized and their antitumor properties were compared with some naturally occurring glycosides of ε-pyrromycinone.



JOHN M. ESSERY et TERRENCE W. DOYLE. Can. J. Chem. **58**, 1869 (1980).

On décrit l'épimérisation, au niveau du carbone en position 10 de l'ε-rhodomycinone, à partir de son acétonide-6,7 sous l'influence d'une solution aqueuse de base. On a préparé la daunosaminyl ε-rhodomycinone et la daunosaminyl épi-10 ε-rhodomycinone et on les a comparé par rapport à leurs propriétés antibactériennes. On a synthétisé la daunosaminyl-ε-pyrromycinone et la descarbométhoxy-10 pyrromycine et on a comparé leurs propriétés anti-tumorales à celles de quelques glycosides de ε-pyrromycinone naturelles.

The chemistry and biology of adriamycin (**1***a*) and the structurally related anthracyclines daunomycin (**1***b*) and carminomycin (**1***c*) have been extensively studied (1). Recently the isolation and characterization of a number of new anthracyclines which have considerable structural and biological differences from the adriamycin class of antitumor agents have been reported (2). Earlier communications from these laboratories have described a number of new agents based on the aglycone ε-

1*a* $R^1 = CH_3$, $R^2 = CH_2OH$
1*b* $R^1 = R^2 = CH_3$
1*c* $R^1 = H$, $R^2 = CH_3$

pyrromycinone (**2***a*) (2*a*–*d*). Oki and co-workers (2*e*–*g*) have reported additional members of this group as well as numerous antitumor agents based on the closely related aglycone aklavinone (**2***b*). Structurally there are a number of differences between the members of the aklavinone–pyrromycinone group and those of the adriamycin group. While the monosaccharides **1***a*–*c* are quite

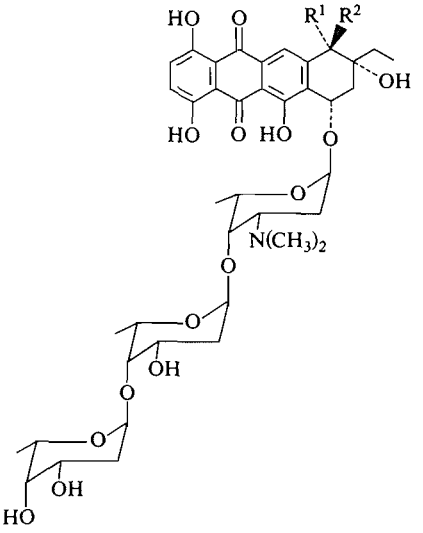
2*h*	H	OH	CO_2CH_3	H	Daun
2*i*	H	OH	H	CO_2CH_3	H
2*j*	H	OH	CO_2CH_3	H	H

potent antitumor agents, it has been shown that pyrromycin (**2***c*) and aklavin (**2***d*) possess little or no antitumor activity (2*e*, 3). *A priori* a number of reasons may be advanced to explain this lack of activity: (*1*) the substitution of rhodosamine for daunosamine in the glycosides **2***c* and **2***d*; (*2*) the presence of a 10-carbomethoxy group in compounds **2***c* and **2***d*; and (*3*) the different oxygenation pattern in the anthraquinone portion of the molecule.



We have shown previously that removal of the 10-carbomethoxy function or epimerization at C10 in marcellomycin (**3***a*) resulted in compounds **3***b* and **3***c*, respectively. These compounds were significantly less active than **3***a* (2*b*, *d*). We would now like to report the syntheses of 10-descarbomethoxy-ε-pyrromycin (**2***e*), daunosaminyl

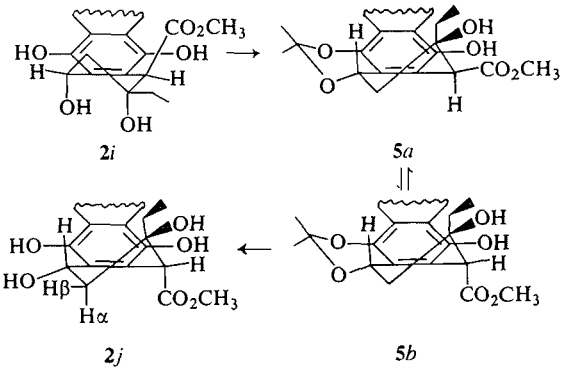
ε-pyrromycinone (**2***f*), daunosaminyl ε-rhodomycinone (**2***g*),[2] and daunosaminyl 10-epi-ε-rhodomycinone (**2***h*). We felt that a comparison of the activities of **2***c*, **2***e*, **2***f*, and **2***g* would permit an estimate of whether or not the lack of activity of pyrromycin was due to the amino sugar differences, the presence of the 10-carbomethoxy group, or the anthracycline oxygenation pattern. It has been shown that both ε-pyrromycinone (**2***a*) and ε-rhodomycinone (**2***i*) possess the absolute stereochemistry 7*S*,9*R*,10*R* (5, 6). It was suggested that the preferred conformation of ring A in **2***a* and **2***i* was that shown in partial structure **2***i* (Fig. 1), i.e. with the 10-carbomethoxy group pseudoaxial (5).

While in the pyrromycinone-based anthracyclines epimerization at C10 was readily effected by treatment with 1,5-diazabicyclo[4.3.0]-non-5-ene (DBN) (2*c*), similar attempts with ε-rhodomycinone **2***i* failed completely. In the case of **3***a* the ratio of marcellomycin (**3***a*) to mimimycin (**3***c*) at equilibrium was 77:23. Presumably in the ε-rhodomycinone series the added steric effect of an 11-hydroxyl with the 10-carbomethoxy group in the 10*S* (pseudoequatorial) configuration was sufficient to displace the equilibrium completely towards the naturally occurring 10*R* configuration. In **2***i* the conformation of the A ring holds both the 7-hydroxyl and the 10-carbomethoxy groups in a pseudoaxial position. We suspected that if the 6,7-acetonide (**5***a*) could be formed, ring A would be forced into a conformation resulting in a steric interaction between the carbomethoxy group and the *peri*-phenolic group at C11. This steric strain could be relieved by epimerization at C10 as depicted in Fig. 1. Acid-catalyzed reaction of **2***i* with 2,2-dimethoxypropane gave as expected the 7,9-acetonide (**4**) (5). In the presence of *N*,*N*-dimethylformamide, however, there was obtained a mixture of **4** and the 6,7-acetonide (**5***a*) (Scheme 1) which was readily separated by column chromatography. Epimerization at C10 occurred when a chloroform solution of **5***a* was stirred with dilute aqueous sodium hydroxide to give a roughly 60:40 mixture of **5***a* and **5***b*. The epimer **5***b* was separated by silica gel chromatography and was characterized by the ^1H nmr spectrum. An upfield shift of 0.26 ppm for the resonance due to the C10 proton relative to that of **5***a* and a downfield shift of 0.06 ppm for the carbomethoxy resonance was observed. These are similar to the shifts found for the corresponding resonances in mimimycin (**3***c*) compared to marcellomycin (**3***a*) although in the present case the shift in the carbomethoxy resonance is smaller. Hydrolysis of **5***b* provided 10-epi-ε-rhodomycinone (**2***j*) which crystallized from methanol as red needles of mp 197–198°C. The infrared spectrum of **2***j*, in both the solid state and in solution, was very similar to that of **2***i* with absorptions due to the ester carbonyl at 1725 cm^{-1} and to the hydrogen-bonded quinone carbonyls at 1600 cm^{-1}. The uv–visible spectrum of **2***j* was also similar to that of **2***i* but with an additional absorption at 577 nm. The three phenolic protons gave singlets in the nmr spectrum at 13.5, 12.9, and 11.9 ppm, indicating hydrogen bonding to the quinone carbonyl groups. The signals due to the aromatic, ethyl, and C7 protons had similar chemical shifts to those in **2***i* although the line shape of the signal for the C7 proton was very similar to that seen in **5***b*, indicating a pseudoaxial orientation for this proton. The most notable differences in the spectra of **2***j*



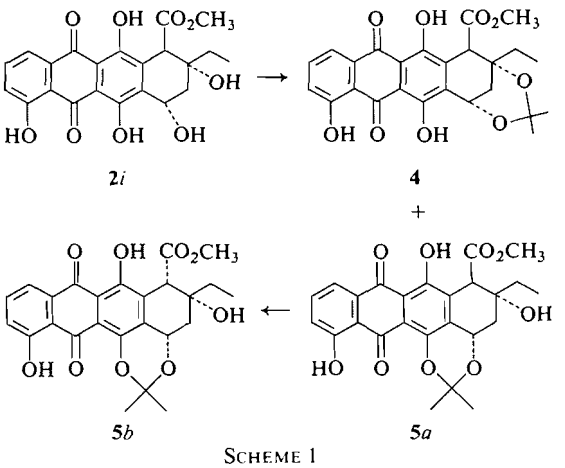


FIG. 1. Conversion of **2***i* to **2***j*.

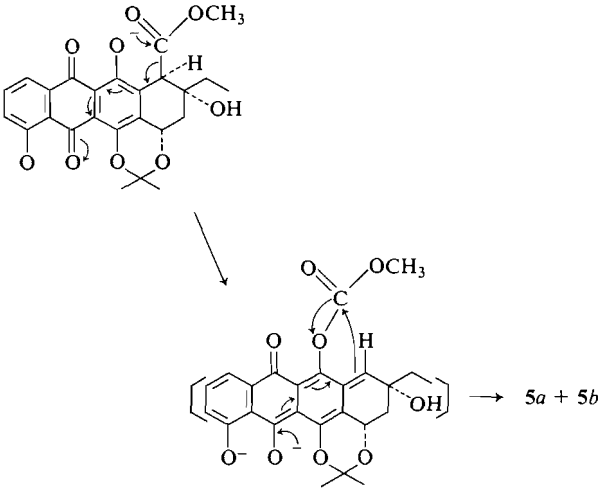

[2]While our work was in progress the synthesis of **2***g* was reported (4).

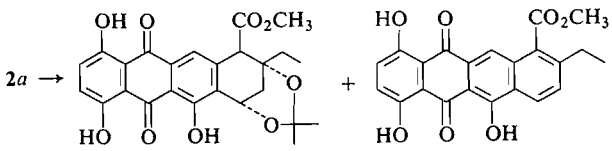
SCHEME 1

and **2***i* were the upfield shift of 0.21 ppm of the C10 proton resonance and the change in both chemical shift and coupling constants for the C8 protons, the latter reflecting a change in conformation of the saturated ring. In this case, the carbomethoxy resonance was shifted upfield by 0.04 ppm relative to that in **2***i*. The ^{13}C spectrum of **2***j* was very similar to that of **2***i* (**2***c*) there being only minor differences in most carbon resonances for the A ring. A shift of 1.7 ppm to higher field for the C9 resonance was the greatest shift observed. These properties showed **2***j* to be different from an aglycone, isolated from an unnamed *Streptomyces* species by Bowie and Johnson (7), called θ-rhodomycinone which they suggested was an isomer of ε-rhodomycinone. θ-Rhodomycinone, mp 220°C dec., had carbonyl absorptions at 1712, 1642, and 1622 cm^{-1} and it was postulated that the ester group was equatorial and hydrogen-bonded to the C11 phenolic group. The infrared and nmr spectral evidence clearly indicate that in **2***j* the C11 phenol is bonded to the C12 carbonyl and not to the ester. When the epimerization of **5***a* was carried out in a $CDCl_3$–D_2O–NaOD mixture, it was found by monitoring the course of the reaction via nmr spectra that the C10 proton did not exchange with the deuterium atoms present. This would seem to preclude proton abstraction at C10 as the mechanism for the epimerization, and leads us to postulate participation by the *peri*-phenol anion as follows:[3]

Relief of steric strain in the saturated ring is a consequence of the change in configuration of the ester group from pseudoequatorial (as in **5***a*, Fig. 1) to pseudoaxial, which lessens its interaction with the 9-ethyl and 11-hydroxyl groups. If this mechanism is operating, it would be expected that the corresponding epimerization would not occur with the 6,7-acetonide of ε-pyrromycinone which does not possess the necessary phenol function at C11. Unfortunately we were unable to prepare this compound. Reaction of **2***a* with 2,2-dimethoxypropane in the absence of DMF afforded the 7,9-acetonide **6**, and in the presence of DMF the only isolable products were the 7,9-acetonide and the known η-pyrromycinone (**7**) which resulted by elimination of water from **2***a* (Scheme 2). It was found that neither of the 7,9-acetonides **4** and **6** underwent base-catalyzed epimerization at C10.



With the appropriate aglycones in hand i.e., **2***a*, **2***i*, and **2***j*, the conversion of these into their daunosamine glycosides was carried out. Following known procedures daunosamine (**8**) was converted to the *O*,*N*-protected bromo-sugar **9** (8) which was condensed with **2***i* to yield **2***g* (after removal of the protecting groups (8)) as its α-anomer. This was shown by the position (δ 5.5) and appearance (broadened singlet of half-band width 6 Hz) of the anomeric proton in the ^1H nmr spec-

TABLE 1. ^{13}C nmr shifts for selected carbons in **2***c* and **2***e*[a]

Carbon	**2***c*	**2***e*
C10	57.4 d	42.9 t
C9	71.8 s	70.0 s

SCHEME 2

trum (9). Similarly 10-epi-ε-rhodomycinone (**2***j*) provided in low yield the α-glycoside **2***h*. For the conversion of ε-pyrromycinone (**2***a*) to its glycoside **2***f* the method of Arcamone *et al.* (10) using the *O*,*N*-bistrifluoroacetyl daunosaminyl chloride **10** was employed. This gave **2***f* in low yield following deprotection.

	R^1	R^2	R^3
8	H	H	OH
9	*p*-$NO_2C_6H_4CO$	$COCF_3$	Br
10	$COCF_3$	$COCF_3$	Cl

The synthesis of 10-descarbomethoxy-ε-pyrromycin (**2***e*) was accomplished using the method of Wiley *et al.* (11). Treatment of **2***c* with aqueous potassium hydroxide gave the crude 10-carboxylic acid which, when allowed to stand in dimethylformamide, decarboxylated to yield **2***e*. The structure of **2***e* was evident from its ^1H and ^{13}C nmr spectra. Thus the loss of signals for the C10 and carbomethoxy protons in **2***c* coupled with the appearance of an AB quartet at δ 1.99 for the C10 protons in **2***e* indicated that the desired conversion had been achieved. In the ^{13}C nmr spectrum the signal for C10 at δ 57.4 in **2***c* disappeared to be replaced by a methylene signal at δ 42.9 in **2***e*. The signals for C13 and C9 also showed significant shifts (Table 1).

Pyrromycin (**2***c*) has been shown previously to be marginally active against L-1210 leukemia (3). Both 10-descarbomethoxy-ε-pyrromycin (**2***e*) and daunosaminyl ε-pyrromycinone (**2***f*) were inactive in L-1210 leukemia and displayed lower antibacterial activity in a plate assay.[4] Previously Smith *et al.* (4) have shown that daunosaminyl ε-rhodomycinone **2***g* was 16-fold less active than **2***c*. This loss in potency parallels that observed in going from marcellomycin (**3***a*) to mimimycin (**3***c*). In the paper describing the synthesis of **2***g* (4) the synthesis and activity of 13-deoxydaunomycin was reported. This compound was less potent (~½) but had comparable activity to **1***b*.

[4]W. T. Bradner and M. Misiek, unpublished results. The plate assay is against *B. subtilis* ATCC 6633.

These results indicate that anthracyclines containing a carbomethoxy function at C10 and an ethyl group at C9 are inactive or marginally active antitumor agents when in the form of monosaccharides containing daunosamine or rhodosamine. For expression of significant activity, the substituent at C7 must be a di- or tri-saccharide, and maximum antitumor activity is associated with 10*R* stereochemistry. The lack of activity of 10-descarbomethoxy-ε-pyrromycin (**2***e*), in contrast to that of 13-deoxydaunomycin, may be a reflection of the deleterious effect of the hydroxyl group at C1.

Experimental

Melting points were determined in open capillary tubes and are uncorrected. Nuclear magnetic resonance spectra were recorded on a Varian HA-100 or XL-100 spectrometer using $CDCl_3$ as solvent (unless otherwise specified) and tetramethylsilane as internal standard. Infrared spectra were recorded as KBr disks on a Beckman IR-2420 and uv–visible spectra on a Beckman Acta III spectrophotometer.

ε-Rhodomycinone-7,9-acetonide (4) and -6,7-Actonide (5a)

A mixture containing 21.4 g of ε-rhodomycinone (**2***i*), 0.7 g of *p*-toluenesulfonic acid monohydrate, 350 mL of 2,2-dimethoxypropane, and 175 mL of dry DMF was heated under reflux with stirring for 17 h. Volatile components were removed under reduced pressure and the residue was triturated with $CHCl_3$ to provide 5.32 g of **4**. Recrystallization from $CHCl_3$ gave an orange solid, 252–253°C; nmr δ:13.47 (s, 1H, OH), 12.86 (s, 1H, OH), 12.26 (s, 1H, OH), 7.94–7.63 (m, 2H, C1—H and C2—H), 7.35 (dd, 1H, C3—H), 5.48 (m, 1H, C7—H), 4.25 (s, 1H, C10—H), 3.79 (s, 3H, CO_2CH_3), 2.42 (m, 2H, C8—H), 1.95–1.50 (m, 5H, CH_2—CH_3 and C—CH_3), 1.27–1.06 (m, 6H, CH_2—CH_3 and C—CH_3). *Anal.* calcd. for $C_{25}H_{24}O_9$: C 64.10, H 5.16; found: C 63.77, H 5.26.

The filtrate from **4** was evaporated and the residue chromatographed on 300 g of silica gel (Mallinckrodt CC-7) using chloroform as the solvent to give 0.44 g of **4** and then 17.7 g of a mixture containing **4** and **5***a*. This mixture was rechromatographed by the dry column technique on deactivated silica gel using $CHCl_3$–MeOH 95:5 as the solvent, and provided 1.70 g of **4** (total yield 7.46 g, 32%), 2.42 g (10%) of **5***a*, and 10.55 g (49%) of ε-rhodomycinone. Compound **5***a*, mp 164–165°C; ir: 1735, 1620 cm^{-1}; uv–visible (EtOH) λ_{max}:476 (ε15 000), 291 (10 800), 251 (sh 21 700), 234 (44 400); nmr δ:13.60 (s, 1H, OH), 13.01 (s, 1H, OH), 7.76–7.46 (m, 2H, C1—H, C2—H), 7.18 (dd obscured by solvent, C3—H), 5.06 (dd, J = 8 Hz, 1H, C7—H), 4.32 (s, 1H, C10—H), 3.71 (s, 3H, CO_2CH_3), 2.59 (dd, J = 8 Hz, 14 Hz, 1H, C8—H), 2.26–1.56 (m, 9H includes C8—H, CH_2CH_3, $C(CH_3)_2$), 1.08 (t, 3H, CH_2—CH_3). *Anal.* calcd. for $C_{25}H_{24}O_9 \cdot 1/4\ H_2O$: C 63.48, H 5.22; found: C 63.56, H 5.34.

10-epi-ε-Rhodomycinone-6,7-acetonide (5b)

A solution of 1.52 g of **5***a* in 75 mL of $CHCl_3$ was stirred for 16 h with 7.5 mL of 2.5% aqueous NaOH. The mixture was diluted with H_2O and acidified with HOAc. The $CHCl_3$ layer was separated, washed (H_2O), dried (Na_2SO_4), and evaporated to give 1.43 g of red foam. This was chromatographed on a dry column of 140 g of deactivated silica gel using $CHCl_3$–EtOAc 9:1 as the developing solvent to provide 228 mg of **5***a*, 450 mg of a mixture of **5***a* and **5***b*, and 600 mg of **5***b* as a red foam. A portion of this was crystallized from ether – Skellysolve B to give a red solid of mp 177–178°C. Infrared: 1740, 1615 cm^{-1}; uv–visible (EtOH) λ_{max}:475 (ε 10 400), 293 (6040), 250 (14 000), 234 (30 600); nmr δ: 7.81–7.50 (m, 2H, C1—H, C2—H), 7.25 (obscured by

solvent, C3—H), 5.26 (dd, J = 6 Hz, 11Hz, 1H, C7—H), 4.06 (s, 1H, C10—H), 3.79 (s, 3H, CO_2CH_3), 2.38 (dd, J = 6 Hz, 13 Hz, 1H, C8—H), 1.90–1.54 (m, 9H, includes C8—H, CH_2—CH_3, $C(CH_3)_2$), 1.01 (t, 3H, CH_2—CH_3). *Anal.* calcd. for $C_{25}H_{24}O_9 \cdot H_2O$: C 61.72, H 5.39; found: C 61.88, H 5.23.

10-epi-ε-Rhodomycinone (2j)

A solution of 550 mg of **5***b* in 40 mL of THF and 20 mL of 2 *N* HCl was stirred for 5 h. The solution was diluted with THF and washed with 2 × 10 mL portions of brine. The organic phase was dried (Na_2SO_4) and the solvent removed to give a red solid which was chromatographed on a dry column of deactivated silica gel using $CHCl_3$–MeOH 9:1 as the developing solvent. The major fraction consisted of **2***j* contaminated with traces of **2***i*. A 140 mg sample of pure **2***j* was obtained and recrystallization from methanol gave red needles of mp 197–198°C. Infrared ($CHCl_3$): 1725, 1600 cm^{-1}; uv–visible (EtOH) λ_{max}:577 (ε 9900), 531 (15 600), 495 (10 600), 295 (11 100), 251 (38 000), 234 (46 800); $[\alpha]_{578}^{23}$ +218° (*c* 0.05, THF); nmr δ: 13.48 (s, 1H, OH), 12.88 (s, 1H, OH), 11.87 (s, 1H, OH), 7.84–7.53 (m, 2H, C1—H, C2—H), 7.24 (dd partially obscured by solvent, C3—H), 5.20 (m, 1H, C7—H), 4.02 (s, 1H, C10—H), 3.72 (s, 3H, CO_2CH_3), 3.56 (bs, 1H, OH), 2.36 (dd, 1H, J_1 = 14, J_2 = 6 Hz, C8—Hα), 1.95 (dd, 1H, J_1 = 14, J_2 = 4 Hz, C8—Hβ), 1.68 (m, 2H, CH_2CH_3), 0.98 (t, 3H, J = 7 Hz, CH_2CH_3); ^{13}C nmr (DMSO-d_6):189.6 (C5), 185.5 (C12), 170.39 (CO_2CH_3), 161.1 (C4), 155.2, 155.9 (C6, C11), 138.6 (C12a), 137.0 (C2), 134.7 (C10a), 132.8 (C6a), 124.3 (C1), 118.8 (C3), 115.7 (C4a), 110.4, 110.5 (C11a, C5a), 69.8 (C9), 61.0 (C7), 51.5 (CO_2CH_3), 51.0 (C10), 35.8 (C8), 32.8 (C13), 7.57(C14). *Anal.* calcd. for $C_{22}H_{20}O_9$: C 61.68, H 4.71; found: C 61.32, H 4.86.

Daunosaminyl ε-Rhodomycinone (2g)

To a stirred slurry of 143 mg (0.33 mmol) of ε-rhodomycinone, 500 mg (2.3 mmol) of yellow mercuric oxide, 103 mg (0.35 mmol) of mercuric bromide, and 3 g of powdered 3A molecular sieves in 40 mL of dry THF under reflux was added 0.33 mmol of a solution of the bromo-sugar **9** (prepared according to Acton *et al.* (8)) in 4 mL of THF. After the mixture had been heated for 20 h, an additional 0.33 mmol of **9** was added and after another 7 h another 0.33 mmol of **9** was added. After an additional 16 h under reflux, the mixture was allowed to cool and was filtered and the filtrate (and THF washings) were evaporated to a red foam. This was chromatographed on a dry column of deactivated silica gel to provide 825 mg of a mixture of **2***i* and product. Column chromatography on silica gel using $CHCl_3$–Et_2O 1:1 provided the desired product as the first fraction. Removal of the protecting groups (as in ref. 7) gave 64 mg of red solid. Column chromatography on silica gel with $CHCl_3$ removed impurities and **2***g* was eluted with $CHCl_3$–MeOH 1:1 to afford 32 mg (15%). Infrared: 1730, 1600 cm^{-1}; nmr δ: 7.88–7.56 (m, C1—H, C2—H), 7.26 (dd partially obscured by solvent, C3—H), 6.30 (broad, includes exchangeable protons), 5.50 (bs, peak width at 1/2 height 6 Hz, C1′-H), 5.25 (bs, C7—H), 4.3 (s, C10—H), 4.3–4.06 (m, C5—H), 3.76 (s, CO_2CH_3), 3.54 (bs, C4′—H), 3.18 (b, C3′—H), 2.40–2.24 (m, C8—H), 2.02–1.09 (m, includes C2′—H, CH_2—CH_3, C5′—CH_3, CH_2—CH_3). *Anal.* calcd. for $C_{28}H_{31}NO_{11} \cdot 2H_2O$: C 56.65, H 5.94, N 2.36; found: C 56.51, H 5.87, N 2.46.

Daunosaminyl 10-epi-ε-Rhodomycinone (2h)

Similarly, 143 mg (0.33 mmol) of 10-epi-ε-rhodomycinone (**2***j*) was reacted with 1 mmol of bromo-sugar (**9**) to provide 23 mg (12%) of **2***h*. Infrared: 1730, 1600 cm^{-1}; nmr ($CDCl_3$ + D_2O) δ: 7.95–7.56 (m, 2H, C1—H, C2—H), 7.28 (dd partially obscured by solvent, C3—H), 5.46 (bs, 1H peak width at 1/2 height 6 Hz, C1′—H), 5.14 (bm, 1H, C7—H), 4.22 (s, 1H, C10—H), 3.98 (q, 1H, C5′—H), 3.74 (s, 3H, CO_2CH_3), 3.65–3.32 (m, 2H, C3′—H, C4′—H), 2.6–0.8 (m, includes C8—H, C2′—H, CH_2—CH_3, C5′—CH_3). *Anal.* calcd. for $C_{28}H_{31}NO_{11} \cdot 0.5\ H_2O$: C 59.36, H 5.69, N 2.47; found: C 59.35, H 5.63, N 2.25.

Daunosaminyl ε-Pyrromycinone (2f)

A slurry of 214 mg (0.5 mmol) of ε-pyrromycinone (**2***a*), 428 mg (1.98 mmol) of yellow mercuric oxide, 107 mg (0.30 mmol) of mercuric bromide, and 1.0 g of powdered molecular sieves (3A) in 45 mL of ethanol-free $CHCl_3$ was stirred for 1 h. A solution of 1.2 mmol of the chloro-sugar (**10**, prepared according to Arcamone *et al.* (10)) in 10 mL of $CHCl_3$ was added in two equal portions 22 h apart. After a reaction time of 93 h, the mixture was filtered and the filtrate was evaporated to dryness. The residue was dissolved in 100 mL MeOH and heated under reflux for 30 min. The mixture was filtered and the filtrate evaporated to dryness. The residue was chromatographed on a dry column of deactivated silica gel using $CHCl_3$–MeOH 9:1 as the solvent to provide, as the fast-moving fraction, 15 mg of η-pyrromycinone (**7**), mp 218–220°C. The major fraction was a mixture of the aglycone (**2***a*) and the *N*-protected glycoside, and the latter crystallized from a concentrated solution of this mixture in $CHCl_3$. A solution of 100 mg of this glycoside in 10 mL of THF and 10 mL of 0.1 *N* NaOH was stored at 5°C for 4.5 h. The solution was diluted and the pH adjusted to 8.5. The product was extracted into $CHCl_3$ and the washed (H_2O) and dried (Na_2SO_4) extracts were evaporated to a purple solid which crystallized from ether to give 38 mg (14%) of **2***f*, mp 154–155°C. Infrared: 1735, 1600 cm^{-1}; nmr δ: 7.63 (s, 1H, C11—H), 7.20 (s, 2H, C2—H C3—H), 6.80 (b, 5H, exchangeable protons), 5.46 (s, 1H, peak width at half-height 6 Hz, C1′—H), 5.26 (s, 1H, C7—H), 4.30–4.06 (m, 2H, includes C5′—H, C10—H), 3.76 (s, 3H, CO_2CH_3), 3.50 (m, 1H, C4′—H), 3.15 (b, 1H, C3′—H), 2.70–2.24 (m, 2H, C8—H), 2.0–1.5 (m, 4H, C2′—H, CH_2—CH_3). 1.5–1.0 (m, 6H, C5′—CH_3—CH_2CH_3). *Anal.* calcd. for $C_{28}H_{31}NO_{11} \cdot H_2O$: C 58.43, H 5.78; found: C 58.32, H 5.72.

10-Descarbomethoxypyrromycin (2e)

A solution of 1.17 g (2 mmol) of pyrromycin (**2***c*) in 10 mL of 0.53 *N* potassium hydroxide was let stand 16 h at ~23°C. The solution was diluted with 20 mL of water and the pH was adjusted to 5.9 with 2 *N* hydrochloric acid. The slurry was filtered and the resulting solid washed with water. The combined mother liquors were lyophilized. Both solids (1.113 g) were combined, dissolved in 30 mL of dimethylformamide, and let stand for 18 h. The solvent was removed at reduced pressure and the resulting gum chromatographed on 15 g of silica gel (10% by weight of water added) using chloroform as eluent. Fractions were collected visually and assayed by tlc. In addition to a number of unidentified by-products, there was obtained 83 mg of η-pyrromycinone (**7**) and 642 mg of crude **2***e*. Compound **2***e* was rechromatographed on silica gel (10% by weight of water added) using chloroform–methanol (9:1) as eluent to yield 140 mg of **2***e* mp 188–190°C; ^1H nmr ($CDCl_3$) δ: 7.56 (s, 1H, C11—H), 7.25 (s, 2H, C2—H + C3—H), 5.50 (bs, 1H, C1′—H), 5.20 (bs, 1H, C7—H), 2.5–3.2 (m, 3H, C3′, C4′, C5′H's), 1.99 (AB quartet, 2H, C10—H's), 2.27 (s, 6H, $N(CH_3)_2$), 1.5–2.0 (m, 6H, C8, C13, C2′H's), 1.43 (d, 3H, C5′—CH_3), 1.09 (t, 3H, CH_2CH_3); ^{13}C nmr ($CDCl_3$) δ:190.1 (C5), 185.6 (C12), 161.7 (C6), 158.0, 157.4 (C1, C4), 145.6 (C10a), 132.0 (C6a), 130.7 (C11a), 129.6, 129.4 (C2, C3), 120.7 (C11), 113.5 (C5a), 112.4, 112.1 (C4a, C12a), 100.7 (C1′), 70.8 (C7), 70.0 (C9), 66.5, 65.9 (C4′, C5′), 60.0 (C3′), 42.0 (C10), 41.9 (NMe_2), 37.3 (C13), 35.0 (C8), 28.4 (C2′), 17.0 (C6′), 7.4 (C14). *Anal.* calcd. for $C_{28}H_{33}NO_9 \cdot 3/2\ H_2O$: C 60.64, H 6.50, N 2.53; found: C 59.84, H 6.26, N 2.66.

^{13}C nuclear magnetic resonance spectroscopy of methylenedioxy group-containing C_{19}-diterpenoid alkaloids and their derivatives

S. WILLIAM PELLETIER, NARESH V. MODY, AND OLIVER D. DAILEY, JR.

Institute for Natural Products Research and Department of Chemistry, University of Georgia, Athens, GA 30602, U.S.A.

Received February 18, 1980

This paper is dedicated to the memory of Dr. Léo Marion

S. WILLIAM PELLETIER, NARESH V. MODY, and OLIVER D. DAILEY, JR. Can. J. Chem. **58**, 1875 (1980).

The natural abundance carbon-13 nmr spectra of some methylenedioxy group-containing C_{19}-diterpenoid alkaloids and their derivatives (dictyocarpine, 14-acetyldictyocarpine, dictyocarpinine, 14-dehydrodictyocarpine, 14-dehydrodictyocarpinine, 6-dehydrodictyocarpinine, 6,14-didehydrodictyocarpinine, deltaline (eldeline), deltamine (eldelidine), 6-dehydrodeltamine, delcorine, 6-acetyldelcorine, and 6-dehydrodelcorine) have been determined. Self-consistent assignments of nearly all the resonances in these compounds have been made with the aid of single-frequency off-resonance proton decoupling techniques, additivity relationships, and the effects induced by certain structural changes. Particular attention is directed towards features of the spectra which are most useful for structure elucidation and identification of the C_{19}-diterpenoid alkaloids.

S. WILLIAM PELLETIER, NARESH V. MODY et OLIVER D. DAILEY, JR. Can. J. Chem. **58**, 1875 (1980).

On a déterminé les spectres rmn du ^{13}C de quelques alcaloides diterpéniques en C-19 contenant des groupes méthylènedioxy et de leurs dérivés (dictyocarpine, acétyl-14 dictyocarpine, dictyocarpinine, déhydro-14 dictyocarpine, déhydro-14 dictyocarpinine, déhydro-6 dictyocarpinine, didéhydro-6,14 dictyocarpinine, deltaline (eldeline), deltamine (eldelidine), déhydro-6 deltamine, delcorine, acétyl-6 delcorine et la déhydro-6 delcorine). On a identifié d'une façon positive presque toutes les résonances de ces composés en utilisant les techniques de découplage hors champs du proton à fréquence unique, les relations d'additivité et les effets induits par certains changements de structure. On a accordé une attention spéciale aux particularités des spectres qui sont les plus utiles à la détermination de la structure et à l'identification des alcaloides diterpéniques en C-19.

Introduction

Plants of *Aconitum*, *Consolida*, and *Delphinium* species are known to elaborate a variety of alkaloids modelled on a C_{19}-skeleton (1). Some of these alkaloids are highly poisonous and exhibit marked biological activity. Recently there has been a great deal of interest in this class of alkaloids because of the wide range of biological activities exhibited by the extracts of *Aconitum* species. The structures of these alkaloids are complex and their determination in early work depended largely on chemical degradation. Because of the low yields of these alkaloids from the plant, such studies were time-consuming and difficult. Structure determination by ^1H nmr analysis is not conclusive or reliable. Although mass spectroscopy has made some contributions to the elucidation of the structures of these alkaloids, this method is not unambiguous in establishing the stereochemistry and position of various substituent groups. The application of ^{13}C nmr spectroscopy to the structure elucidation of the C_{19}-diterpenoid alkaloids was introduced for the first time in 1972 by Jones and Benn (2). Later we reported comprehensive ^{13}C nmr studies of more than sixty aconitine- and lycoctonine-type alkaloids and their derivatives (3–5). While the ^{13}C nmr spectra of these alkaloids have been examined extensively, not a single spectrum for methylenedioxy group-containing diterpenoid alkaloids has been recorded. In this paper, we report for the first time an analysis of the ^{13}C nmr spectra of some rare C_{19}-diterpenoid alkaloids which contain the methylenedioxy and C(10) hydroxy groups. The purpose of this paper is to describe approaches we have used to analyze and interpret the ^{13}C nmr spectra of these alkaloids. Because structure elucidation of these alkaloids is frequently so difficult as to require extensive chemical work or X-ray crystallography, this ^{13}C nmr analysis should be of considerable value in solving structural problems in related systems.

Results and Discussion

The general method for ^{13}C nmr data acquisition and assignment of the carbon resonances for the compounds reported here involved determination of the noise-decoupled and the single-frequency off-resonance decoupled (SFORD) spectra. The signals were assigned with the help of the single-frequency proton off-resonance decoupling technique, application of known chemical shift rules for hydroxyl substitution and acetylation shifts, steric effects, and from comparisons of spectra from compound to compound.

Assignments for Dictyocarpine (1), 14-Acetyldictyocarpine (2), and Dictyocarpinine (3)

During an investigation of the alkaloids of *Delphinium glaucescens*, a plant native to the western

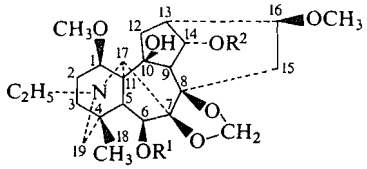
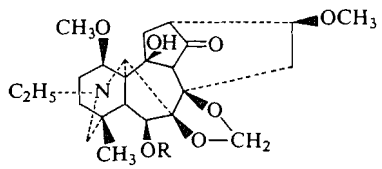
[a]Chemical shifts in ppm downfield from TMS; solvent is deuteriochloroform.
[b]Chemical shifts for the C(14) acetyl group occur at 171.7 and 21.4 ppm.
[c]These assignments may be interchanged in any vertical column.
[d]Values given for primed carbons refer to chemical shifts for methoxyls.



United States, we isolated[1] a known alkaloid, dictyocarpine. Along with dictyocarpine, we also isolated a new alkaloid, dictyocarpinine (**3**), a basic hydrolysis product of dictyocarpine. Dictyocarpine has been reported (6) to occur in *D. dictyocarpum*, a plant native to the Soviet Union. On the basis of extensive degradation work, ^{1}H nmr, and mass spectral data, structure **1** was assigned to dictyocarpine by Yunusov and co-workers (6).

The ^{13}C chemical shifts and assignments for dictyocarpine (**1**), 14-acetyldictyocarpine (**2**), and dictyocarpinine (**3**) are presented in Table 1. The chemical shift assignments for these alkaloids were made by correlation with previously published ^{13}C nmr spectra of the lycoctonine-type alkaloids (4). The presence of the methylenedioxy group in dictyocarpine was confirmed by observing a triplet at 94.0 ppm in the single-frequency off-resonance spectrum. The chemical shift of C(11) in **1** appears at 55.1 ppm, significantly downfield compared with other lycoctonine-type alkaloids such as delcorine (**11**) and lycoctonine (4). This observation suggests that the neighbouring carbon at C(10) is substituted by a hydroxyl group. The presence of the tertiary hydroxy group at C(10) was confirmed by a singlet at 79.9 ppm in the spectrum of dictyocarpine. A quartet at 25.5 ppm and a singlet at 34.0 ppm indicate the presence of the methyl group at C(4). The unusual upfield shift (~3 ppm) of the C(14) hydroxyl group in comparison with other lycoctonine-type alkaloids (e.g. browniine, delcosine) (4) results from the presence of the β-hydroxyl at C(10) in ring C of dictyocarpine. The assignments of the two quaternary carbons at C(8) and C(10) are based on the spectra of delcorine (**11**) and its derivatives. Two singlets at 82.9 and 79.9 ppm are assigned to C(8) and C(10), respectively; the singlet at 79.9 ppm is absent in the specrtrum of delcorine.



Comparison of the spectrum of dictyocarpine (**1**) with that of dictyocarpinine (**3**) reveals the absence in **3** of chemical shifts due to an acetyl group, some minor changes in the chemical shifts at C(7) and the methylenedioxy carbon, and no change in the chemical shift at C(6). The latter was expected because similar phenomena were observed in other

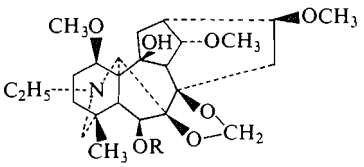
7

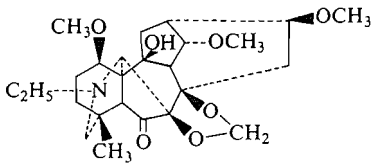
C_{19}-diterpenoid alkaloids containing the C(6) β-hydroxyl and acetate groups (7). In contrast, ^{1}H nmr studies showed a profound change in the chemical shifts of the C(6) α proton and methylenedioxy carbon-containing protons between dictyocarpine and dictyocarpinine. Acetylation of the C(14) hydroxy group of **1** shifted the C(14) resonance in **2** downfield (~2 ppm) as a result of the electron withdrawing effect of the acetoxy group relative to the hydroxy group. The ^{13}C nmr spectrum of 14-acetyldictyocarpine (**2**) reveals the presence of two extra signals at 21.4 and 171.7 ppm for an acetyl group at C(14) in comparison with dictyocarpine. All the ^{13}C chemical shifts of dictyocarpine, 14-acetyldictyocarpine, and dictyocarpinine are in agreement with their structures **1**, **2**, and **3**, respectively.

Assignments for 14-Dehydrodictyocarpine (4), 14-Dehydrodictyocarpinine (5), 6-Dehydrodictyocarpinine (6), and 6,14-Didehydrodictyocarpinine (7)



The recent discovery of several C(6) and C(14) keto group-containing lycoctonine-type alkaloids in some *Delphinium* species prompted us to examine the ^{13}C nmr spectra of this type of compound. We have prepared[1] 14-dehydrodictyocarpine (**4**), 14-dehydrodictyocarpinine (**5**), 6-dehydrodictyocarpinine (**6**), and 6,14-didehydrodictyocarpinine (**7**). A downfield singlet at 215.0 ppm in compound **4** indicates the presence of the carbonyl group at the C(14) position. The presence of the carbonyl group at C(14) in **4** moves the chemical shifts at C(8), C(9), C(13), and C(16) significantly downfield in comparison with dictyocarpine. These shifts are a result of the disappearance of the 1,3-diaxial interactions of the C(14) α-hydroxyl group with the C(16) β-methoxyl group and the C(8) oxygen. Comparison of the ^{13}C nmr spectrum of **5** with that of **4** revealed the absence of acetoxy group signals and an unusual upfield shift (1.4 ppm) of the C(14) carbonyl group.

The introduction of a keto group at C(6) in compound **6** results in a number of chemical shift changes. The resonance for C(6) is shifted to the five-membered ring ketone region (217.7 ppm) and the C(5) and C(4) resonances are moved downfield 4.6 and 1.3 ppm, respectively, as expected, relative to dictyocarpinine (**3**). The unusual upfield shifts of C(7) and C(11) in **6** relative to **3** can be explained by the presence of the strained five-membered ring ketone at C(16) (11). Two singlets at 211.2 and 215.6 ppm in compound **7** are assigned to C(14) and C(6) by comparison with compounds **5** and **6**. As a result of the β-effect of the C(6) and C(14) keto groups, the methine resonances at C(5), C(9), and C(13) in compound **7** have moved downfield as expected. The quaternary carbons at C(4), C(7), C(8), and C(11) in **7** are also shifted accordingly in comparison with dictyocarpinine.



Assignments for Deltaline (8), Deltamine (9), and 6-Dehydrodeltaline (10)

Deltaline, also known as eldeline, was isolated as one of the minor alkaloids of *D. glaucescens*.[1] Previously deltaline had been isolated from several *Delphinium* species and the structure was established (9) as **8** on the basis of chemical correlation with lycoctonine. Compounds **9** and **10** were prepared by standard procedures.[1] The chemical shift assignments for compounds **8** to **10** are made by correlation with the earlier described ^{13}C nmr spectra of dictyocarpine and its derivatives. These data indicate that compounds **8**, **9**, and **10** are similar to **1**, **3**, and **6**, respectively, except for the presence of the methoxyl group at C(14) instead of the

8 R = Ac Deltaline
9 R = H Deltamine

10

11 R = H Delcorine
12 R = Ac

13

hydroxyl group. The presence of the methoxyl group at C(14) in **8** to **10** results in the downfield shifts of C(13) and C(14) relative to compounds **1**, **3**, and **6**, respectively. The ^{13}C chemical shifts of deltaline, deltamine, and 6-dehydrodeltamine are in agreement with their respective structures **8**, **9**, and **10**.

Assignments for Delcorine (11), 6-Acetyldelcorine (12), and 6-Dehydrodelcorine (13)

Delcorine was isolated (10) from *D. corumbosum* by Yunusov and co-workers in 1973. On the basis of extensive chemical reactions and spectral studies, structure **11** was established for delcorine. Recently the isolation of 6-dehydrodelcorine from *D. iliense* was reported (8). Table 1 presents the ^{13}C chemical shifts and assignments for delcorine (**11**), 6-acetyldelcorine (**12**), and 6-dehydrodelcorine (**13**). Comparison of the ^{13}C nmr spectrum of delcorine with that of deltamine (**9**) reveals the absence of chemical shifts due to the C(10) tertiary hydroxyl group and the presence of some new chemical shifts due to the CH_2—O—CH_3 group at C(4). As expected, changes in chemical shifts of quaternary carbons C(4) and C(11), relative to deltamine, are evident. The singlets of C(4) (38.1 ppm) and C(11) (50.2 ppm) were shifted downfield and upfield, respectively, in delcorine. The chemical shifts of the ring A carbons changed also as expected because of the change in stereochemistry of the C(1) methoxyl group. The ^{13}C nmr spectrum of 6-acetyldelcorine indicated the presence of two more signals (21.6 and 170.0 ppm) of the acetoxy group than are present in delcorine. Acetylation of the secondary hydroxyl group at C(6) in **12** showed no substitution effect on the chemical shift of C(6) and very little effect on the neighbouring carbon atoms (ref. 11, pp. 149–150).

The new downfield resonance at 216.7 ppm in 6-dehydrodelcorine (**13**) is a singlet and can be assigned to C(6). The most noticeable changes are the large downfield shifts at C(4), C(5), and the methylenedioxy carbon, and the upfield shifts at C(7), C(8), C(10), and C(11) in compound **13**, relative to delcorine, caused by the presence of a five-membered ring ketone at C(6). All other assignments in the ^{13}C nmr spectra of compounds **11**, **12**, and **13** are in agreement with their structures.

This catalogue of ^{13}C chemical shifts of an important group of alkaloids should assist in the structure elucidation of newly isolated methylenedioxy and C(10) hydroxyl group-containing C_{19}-diterpenoid alkaloids.

Experimental

Carbon-13 nmr spectra were determined at 15.03 MHz in the Fourier mode using a JEOL FX-60 spectrometer in conjunction with a JEC-980 computer. The spectra were obtained at 30°C in deuteriochloroform solutions (which also provided the lock signal) with tetramethylsilane as an internal reference. Samples were contained in precision ground 5 mm od tubes. On the average a 5 μs pulse, corresponding to an approximate tilt angle of 45°, was employed. For the average spectral width of 4000 Hz, the delay between pulses was 2.5 s. Acquisition times averaged 2–24 h over 8K data points for concentrations of the order of 0.05–0.5 *M*. For off-resonance spectra this time was 8–48 h.

Details of the isolation of compounds **1**, **3**, and **8** and of the preparation of compounds **2–7**, **9**, **10**, **12**, and **13** will be reported at a later date.[1]

Photocyclization of aryl halides. Part I. 5-(2-Halogenophenyl)-1,3-diphenylpyrazoles; homolytic fission assisted by radical complexation

JAMES GRIMSHAW AND A. PRASANNA DE SILVA

Department of Chemistry, Queen's University, Belfast BT9 5AG, Northern Ireland

Received February 12, 1980

This paper is dedicated to the memory of Dr. Léo Marion

JAMES GRIMSHAW and A. PRASANNA DE SILVA. Can. J. Chem. **58**, 1880 (1980).

The photocyclization of 5-(2-halogenophenyl)-1,3-diphenyl pyrazoles proceeds efficiently with the exclusion of solvent participation hydrogen abstraction reactions. In a given solvent, the quantum yields of cyclization (ϕ) of Cl, Br, and I compounds show no correlation with carbon–halogen bond dissociation energies. In a series of solvents, ϕ varies smoothly with solvent viscosity and is independent of solvent polarity. The ϕ values are independent of triplet quenchers, air, intensity and wavelength of radiation, and reactant concentration. Photocyclization can be triplet sensitized at up to 80% of the direct reaction rate and the reactant triplet energies are about 65 kcal mol^{-1} while D_{C-Br} is 81 and D_{C-Cl} is 95 kcal mol^{-1}. A mechanism of homolytic fission assisted by radical complexation is proposed to accommodate the results. Photocyclization of the H- and MeO-substituted analogues proceeds inefficiently and with ϕ values dependent on solvent polarity. An electrocyclic mechanism is followed in these cases. The assisted homolysis model explains several anomalies in the field of aryl halide photochemistry.

JAMES GRIMSHAW et A. PRASANNA DE SILVA. Can. J. Chem. **58**, 1880 (1980).

La photocyclisation des (halogéno-2 phényl)-5 diphényl-1,3 pyrazoles se fait d'une manière efficace sans participation du solvant et sans élimination d'hydrogène. Dan un solvant donné, les rendements quantiques de cyclisation (ϕ) des composés du chlore, du brome et de l'iode n'indiquent pas de corrélation avec les énergies de dissociation de la liaison carbone–halogène. Dans une série de solvants, les valeurs de ϕ varient légèrement avec la viscosité du solvant et sont indépendantes de sa polarité. Les valeurs de ϕ sont indépendantes des inhibiteurs de triplets, de l'air, de l'intensité et de la longueur d'onde de la radiation et de la concentration des réactifs. La photocyclisation peut être sensibilisée par un triplet jusqu'à 80% de la vitesse de la réaction directe et les énergies des reactifs triplets sont d'environ 65 kcal mol^{-1} tandis que les valeurs de D_{C-Br} et D_{C-Cl} sont respectivement égales à 81 et à 95 kcal mol^{-1}. Pour expliquer ces résultats, on propose un mécanisme de scission homolytique assistée par une complexation radicalaire. La photocyclisation des analogues ayant des substituants H ou MeO n'est pas efficace et dans ces cas les valeurs de ϕ dépendent de la polarité du solvant. Dans ces cas on a un mécanisme électrocyclique. Le modèle d'homolyse assistée explique plusieurs anomalies dans le domaine de la photochimie des halogénures d'aryles.

[Traduit par le journal]

Introduction

The intermolecular photochemical reaction of aryl iodides in benzene to give diphenyls has been known since 1961 (1). The related intramolecular photochemical cyclization of appropriately substituted aryl halides has been used extensively as a synthetic route since the early work of Kupchan and Wormser (2) and of Kharasch and co-workers (3). Reviews devoted to the photochemistry of aryl halides (4) and the photocyclization reaction (5) discuss the early work and the photocyclization reaction continues to be of use in synthesis. As background to the present paper we will cite the synthesis of aporphine alkaloids by this route.

The synthesis of aporphine alkaloids by photocyclization of substrates bearing non-conjugated aromatic rings, e.g. **1** → **2**, proceeds in yields of 15–30% and photochemically induced homolytic cleavage of the carbon–halogen bond is assumed to be the first step (6). Photocyclization of substrates bearing conjugated aromatic rings, e.g. **3** → **5**, proceeds in alcoholic solvents in presence of a base and it has been speculated that these reactions proceed via an electrocyclic reaction and intermediates like **4** (7). There is no mechanistic investigation in the literature of an aryl halide cyclization to support either of these speculations. We have embarked on an examination of the photocyclization process, in view of its considerable value for synthesis, and a preliminary account of this paper has appeared (8).

The fission of a single bond is conceptually one of the simplest chemical reactions and if it occurs in a molecule which can be studied conveniently, a detailed mechanistic understanding can be expected to emerge. The photocyclizations of 5-(2-halogenophenyl)-1,3-diphenylpyrazoles, **6** → **7**, are conveniently studied and the results described here are applicable to improving the yield from other reactions. Compounds **6**, (X = H, OAc, OMe) also gave relevant mechanistic information. Much recent interest has been shown in general aryl halide photochemistry stemming from the presence of aryl chlorides as environmental contaminants and the quantitative information which is available is discussed in the final section dealing with our results and mechanistic discussion.

The pyrazoles **6**, (X = Cl, Br, I, OAc, and OMe)

show similar uv, fluorescence, and phosphorescence spectra, and data for the chloro-compound are given in the Experimental. From the fluorescence and phosphorescence spectra in ethanol we can derive the singlet energy, E_S = 84 kcal mol^{-1} and the triplet energy, E_T = 65 kcal mol^{-1}. The ring system in the parent compound **6**, (X = H) can become more planar so that its spectral characteristics are somewhat different from those of the chloro-compound. The intensities of these luminescence phenomena reveal a moderate internal heavy atom effect for the bromo- and iodo-compounds and the phosphorescence lifetime ($\tau_P \sim$ 0.11 s) for **6** (X = H) suggests that the phenomenon is associated with a $^3\pi,\pi^*$ transition rather than a $^3n,\pi^*$ transition which would have a millisecond lifetime (9).

Preparative Photochemistry

The photoreaction **6** → **7** has been described (10). It is very clean when carried out with light of 254 nm wavelength in deoxygenated methanol and hplc monitoring shows the formation of one product **7** only. Checks showed that the monitoring procedure could separate the starting material, **6** (X = H), and **7**. The conversion and isolated yields recorded in Table 1 are limited by mechanical losses during the analytical procedure and isolation respectively. The presence of air does not alter the rate of formation of **7** or the conversion but gives rise to coloured side products. Yields of cyclized product **7** from the acetoxy- and methoxy-compounds are lower due to slower reaction and incomplete conversion.

Cyclization of **6** (X = Cl, Br, or I) could also be sensitized by benzophenone in benzene solution to give fair yields of **7** reported in Table 2. Cyclohexane could also be successfully used as solvent in this sensitized reaction but slow consumption of benzophenone then occurred due to its hydrogen abstraction reaction with solvent molecules. In contrast, cyclization of **6** (X = OAc or OMe) was not sensitized significantly, even prolonged irradiation gave only traces or none of **7** (by hplc) corresponding to maximum sensitized rates of 4% and 1% respectively of the direct reaction rates. Xanthone as sensitizer in methanol also failed to effect any significant cyclization in these two cases.

A second reaction occurred on prolonged sen-

[b]Cyclohexane was used as solvent.

sitized irradiation of **6** (X = Br), particularly using xanthone as sensitizer in methanol, and a new product appeared at the expense of **7**. On the basis of its molecular formula and uv spectrum, the new product appeared to be a bromo-substitution product of **7** and indeed it was readily obtained by bromination of **7**. Simple pyrazoles are readily brominated on the 4-position of the pyrazole ring (e.g. ref. 11) so this product is assigned structure **8**. Its mass spectrum shows an abundant fragment at *m/e* 190 ($C_{14}H_8N$) which is also present in the mass spectrum of **7** and corresponds to the loss of PhCN and either Br or H from the molecular ion by breakup of the pyrazole ring. In the nmr spectrum of **7** the line due to the pyrazole ring proton lies under the aromatic proton envelope. Bromination of **7** causes one aromatic proton resonance to move 0.5 ppm downfield and appear as the X-part of an ABX system, which is consistent with structure **8** for the product, and such long range deshielding effects of a halogen atom are well documented (12).

Oxidative photocyclization of **6** (X = H) failed to yield **7** in any isolable quantity under a variety of conditions, though hplc and uv monitoring revealed the appearance of **7** at a slow but finite rate (Table 5). This rate of appearance is faster by a factor of 5 in methanol than in cyclohexane which is compatible with a dipolar electrocyclic intermediate **9** (X = H). This point will be amplified in connection with **6** (X = OMe). However the subsequent bimolecular oxidation step by O_2 and I_2 is also slow, which means that the overall reaction will be polarity dependent to only a moderate degree.

Excluding the parent heterocycle, in all of the above cyclization experiments no **6** (X = H) could be detected as a product (0.2% conversion could have been detected) at any stage of the reactions. Such side reactions brought about by hydrogen abstraction from the solvent are known to compete with some photocyclizations[1] and are believed to arise because phenyl σ-radicals are reaction intermediates.

The photochemistry of aryl halides in the presence of a dialkylaniline as light absorber has been studied (14). Reaction occurs via an exciplex between the excited dialkylaniline and the aryl halide, with electron transfer from the dialkylaniline to form the aryl halide radical-anion, which decomposes with carbon–halogen bond fission to give the aryl σ-radical and halide ion. Application of this method using diethylaniline as light absorber gave exclusive cyclization from **6** (X = Cl). However, since E_T for diethylaniline (15) is 69 kcal mol^{-1} and is greater than the pyrazole triplet energy, reaction could be due to energy transfer sensitization and electron transfer may not occur in this case.[2]

Photochemical Kinetics
Results and Mechanistic Discussion

The effect of variables on the quantum yield (ϕ) for the formation of **7** from **6** was examined.

Substrate Concentration, Irradiation Intensity

The insensitivity of ϕ (see Table 3) to a twenty-fold change in concentration of **6** (X = Cl, Br, or I) confirms the intramolecular nature of the cyclization at its rate determining stages. All quantum yields are reproducible to a maximum error of ±10% but the figures are dependent on whether apparatus A or B, whose illumination conditions are very different (see Experimental), was used. Moderate changes of irradiation intensity cause

Triphenylene[b]	4.0×10^{-3}	66.5	0.21	0.30	0.12
Phenanthrene[b]	6.0×10^{-3}	62.0	−0.02[c]	0.00[c]	0.01[d]

[a]These and other necessary sensitizer data: S. L. Murov. Handbook of photochemistry. Dekker, New York. 1973.
[b]Due to practical considerations involving the uv monitoring of 7, the sensitizer concentrations were such that definite fractions of radiation were directly absorbed by **6**. These were calculated and allowed for to yield the sensitized φ values given. Fractions of radiation absorbed by benzophenone, triphenylene, and phenanthrene were 0.63, 0.74, and 0.67 respectively. The quantum yields of intersystems crossing of the sensitizers were also taken into account.

[d]±0.01.

negligible alteration in φ values (Table 4), and the results from apparatus A or B show only 50% variation in φ even though I_{abs} varies by a factor of 2000.

Substituent X and Solvent

The results are summarized in Table 5. Contrary to expectations based on a simple homolysis mechanism, the three halogen compounds **6** (X = Cl, Br, or I) have comparable φ values in a given solvent even though the bond strengths D_{C-X} vary considerably. However, a further small increase in D_{C-X} for the compounds **6** (X = OAc and OMe) causes a precipitous drop in φ. A further observation is the smooth correlation of φ with solvent viscosity for compounds **6** (X = Cl, Br, I, or OAc) even though the solvents differ widely in polarity. This suggests a reaction involving non-polar intermediates and a step involving an increase in effective volume and/or a separation of radical species (16). In contrast, the φ values for compound **6** (X = OMe) with the highest D_{C-X} show a strong polarity (as opposed to viscosity) sensitivity. Thus a discontinuous change in the photocyclization mechanism occurs at high values of D_{C-X}.

Additives Including Energy-transfer Agents

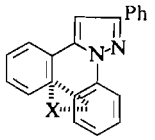

Table 6 gives data for the influence or triplet quenchers on φ. For compounds **6** (X = Cl, Br, or I), φ is unaltered by the presence of low energy triplet quenchers, oxygen or piperylene. Thus the direct reaction proceeds via unquenchable excited states which eliminates T_1 as a possible intermediate state. Evidence given below shows that the T_1 can be quenched. Reactive free radical intermediates such as phenyl σ-radicals which can be diverted from cyclization by reaction with oxygen (17) or alkenes (18) can also be excluded.

The cyclization can be efficiently triplet sensitized and forced to proceed via T_1 even though the direct unsensitized reaction avoids this state. The T_1 state is quenched reversibly by energy-transfer agents as evidenced by the dependence of the value of φ for the sensitized reaction on the sensitizer E_T (19). A further observation is the similarity of the sensitized and unsensitized φ values; the former is 80% of the latter when high energy triplet donors are used, which suggests that these two reaction routes may have some common intermediate states.

Another important point to emerge from these results is the fact that the input of 65 kcal mol^{-1} (E_T of **6**) is sufficient to cleave effectively C—Cl, C—Br, and C—I bonds of D_{C-X} 95, 81, and 64 kcal mol^{-1} respectively (20). This rules out a simple homolysis mechanism, at least in the cases of the chloro- and bromo-compounds and shows the presence of some factor which provides a much lower energy path for cyclization. This factor cannot efficiently accommodate the cleavage of C—OAc and C—OMe bonds where the bond strength (21) is approximately 98 kcal mol^{-1}.

10

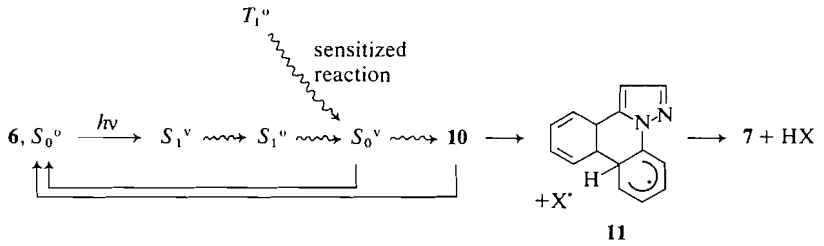
Because of the solvent effects mentioned previously, this factor is related in some way to simple homolysis. We believe this factor to be a type of anchimeric assistance whereby the l-phenyl ring can, through its π-cloud, complex the developing radical centres in the stretching C—X bond and thus lower the transition state energy for reaction. Halogen atoms are electron deficient species with high electron affinities (22) and their complexation by aromatic molecules is well known from photohalogenation (23) and flash photolysis (24) studies. Such complexation has been considered important in several photochemical problems (25), though these reactions were subsequently reinterpreted along different lines (26). Anchimeric assistance to bond homolysis by radical complexation is not a new concept, having been documented twenty years ago in thermal free radical chemistry by product analysis and activation parameters (27). These principles can be applied to the photochemistry of aryl halides, and the transition state, or intermediate, in the cyclization of **6** will therefore be represented by **10**.

The mechanism affords an explanation why, in a given solvent, the chloro-compound cyclizes faster than the iodo-compound even though $D_{C-Cl} > D_{C-I}$, since the transition state **10** is reached earlier along the reaction coordinate for X = Cl than for X = I due to the higher electron affinity of the chlorine atom (22). Even though D_{C-Cl} is high, only a small fraction of that energy is required to reach the transition state. The moderate efficiency for cyclization of **6** (X = OAc) seems to be the limit of rate enhancement by assistance since ϕ has dropped markedly from the values obtained with the halogen compounds. At a small further increase of D_{C-X} in **6** (X = OMe), the mechanism suffers a discontinuous change.

Cyclization of **6** (X = OMe) would therefore involve relatively high energy reaction intermediates. Coupling this deduction with the solvent polarity effect seen in Table 3 suggests the dipolar intermediate **9** (X = OMe) arising from an electrocyclic reaction as the reaction intermediate. The strong polarity effect is observed because formation of **9** (X = OMe) is probably the rate determining stage and subsequent elimination of methanol is rapid. Attempts to trap this 1,3-dipolar species in the case of **9** (X = H) with dimethyl acetylenedicarboxylate gave inconclusive results due to complications of light absorption by the dipolarophile and the possibilities for formation of 2π + 2π adducts with **9** (X = H) by analogy with reactions of furans (28).

Several examples (29) of photocyclization with loss of the elements of methanol are known and in each of these cases the corresponding oxidative photocyclization of the parent compound (3, 30) can be brought about. Photocyclization with loss of methanol is assumed in the literature to involve an electrocyclic intermediate as for our example but no mechanistic evidence has previously been brought forward to support this view.

Wavelength of Irradiation



The observed invariance, within experimental error, of ϕ values with irradiation wavelength (Table 7) renders unlikely the possibility of a mechanism of predissociation into a repulsive state involving σ* orbitals from the higher vibrational levels of S_1. This conclusion holds within the range of energies studied which covered the whole absorption band. It is characteristic of such a mechanism that ϕ changes when the molecule is excited to an S_1^v level close to the crossing point into the dissociative state (31).

This conclusion coupled with those reached from the sensitization studies leads to the suggestion that

TABLE 7. Wavelength dependence of ϕ for irradiation of 4×10^{-3} *M* solutions of **6** in aerated methanol to give **7** using apparatus B

	ϕ,[a] Group X =

302	0.57	0.63	0.35

[a]A quinine sulphate quantum counter was used to check equal intensity of irradiation, ref. 49.

SCHEME 1

a vibrationally excited ground state is the reactive excited state. The role of S_0^v states in general aryl halide photochemistry has been debated in the literature (32), but we believe that this state can lead to carbon–halogen bond weakening within a single vibrational period. The results from sealed tube thermolyses of **6** (X = Br and OMe) support this idea. The bromo-compound gives a 5% yield of **7** after 48 h at 370°C, whereas the methoxy-compound gives no detectable amounts of **7** after similar treatment. Because the two compounds show this different behaviour, a thermal electrocyclic mechanism is unlikely and we can conclude that assisted homolysis of **6** (X = Br) via transition state **10** is possible at 370°C. In contrast, thermal homolysis of bromobenzene derivatives requires temperatures in excess of 700°C (33).

Further Mechanistic Discussion

The deductions made thus far enable us to propose a reasonable mechanism for the transformation of **6** (X = Cl, Br, or I) to **7** as given in Scheme 1. The species **10** is given the status of a reaction intermediate where the π-donor aromatic ring complexes the halogen atom and possibly also the formed carbon σ-radical. This complexed radical may relax to **6** or proceed to **11**. An alternative view is that species **10** is a transition state which continues along the reaction path to give **11** as a caged radical pair which may either revert to **6** or form a separated radical pair and eventually give **7**.

The lack of correlation between fission rate and bond strength was noted for compounds **6** (X = Cl, Br, I) and a similar phenomenon has been reported for the photoreduction of other aryl halides (34). Comment has also been made in the literature on the homolytic fission of bonds when the excited state energy is less than the bond strength in the cases of some halogeno-biphenyls (35, 36) and naphthalenes (37, 38). This anomaly was explained by assuming intermolecular exciplex formation between an excited and a ground state molecule of the substrate with subsequent electron transfer to give a radical-ion pair and then decomposition of the radical-anion to generate aryl radicals. As a test for this mechanism, the rate of carbon–halogen bond cleavage was enhanced on addition of triethylamine which functioned as an alternative electron donor to the excited aryl halide molecule.

For our particular compounds **6** (X = Cl, Br, or I) the exciplex model is inapplicable on several grounds. First, the quantum yield for this model which involves radical-ion pair formation by complete electron transfer is dependent on the solvent polarity and greatest in polar solvents. Quantitative information on this solvent dependence is available for the photoreduction of 4-chlorobiphenyl in the presence of triethylamine (35). For our halogeno-compounds, ϕ is independent of solvent polarity. Also, ϕ is independent of concentration, so any electron transfer must be intramolecular. The phosphorescence emissions of the halogen compounds are not red shifted nor are they weak with respect to **6** (X = H) as would be expected if a triplet exciplex reaction involving the C—X bond was present under the observation conditions. Geometric restrictions do not allow the sandwich arrangement usually, though not necessarily (39), attained in π,π type exciplexes. Finally, contrary to our observations, radical-anions from iodobenzenes dissociate faster than those from bromo- and chlorobenzenes (40).

From a general viewpoint, the choice between the electron transfer and the assisted homolysis models may depend on the molecule under consideration. Those molecules with extensive delocalization such as fused aromatic hydrocarbons have redox properties favorable to the electron transfer model and bond fission can occur in spite of their low excited state energies. In contrast benzene systems show a bias towards the homolysis model and their higher excited state energy is a key factor. Proponents of the exciplex, electron transfer model have recently demonstrated that it cannot account for the photoreduction of chlorobenzene and that the compound **12**, which can be demonstrated spectroscopically to form an intramolecular exciplex, has a cleavage rate lower than that for chlorobenzene (41).

Early workers (42) noted a rate enhancement of

the photolysis of 4-bromobutyrophenone by potential quenchers, pentene and piperylene, and more recently quantitative measurements have been made for a similar rate enhancement observed with chloronaphthalenes (37, 43). These results

12

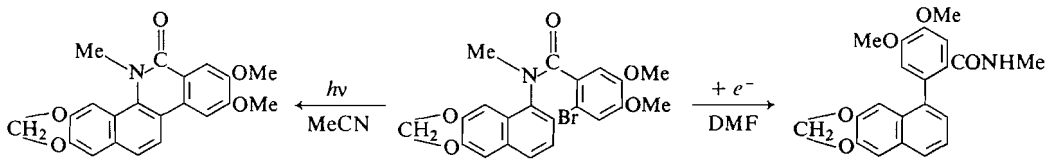
(37, 43) have been interpreted in terms of the exciplex, electron transfer model where the added quencher acts as an electron donor. Quenchers of the diene type have polarizable π-clouds and we therefore make the suggestion that rate enhancement can be the result of the assisted homolysis model with intermolecular complexation between the diene and the developing radical centres of the excited aryl halide.

A further anomaly which can be explained on the assisted homolysis model is, for example, the non-identity of the electro- and photoreduction products from **13** (44). Whereas the photogenerated primary product is a type of radical pair, one partner of which is the electron deficient bromine atom, the electro-generated primary product is a radical-anion which decomposes to a phenyl radical and a bromide ion where the electron deficiency is much less. Thus complexation effects would be important in the photochemistry but not in the electrochemistry of **13**, which would therefore lead to different products.

Finally, mention must be made of reactions which lead to halogen atom dependent product distributions, sometimes resulting in high product specificities. An extreme example, which was explained in terms of thermodynamic and kinetic control of strained intermediates, is the photolysis of **14** (45). The product distribution is understandable in terms of a transition state analogous to **10** which is reached early when X = Cl, leading to predominant cyclization, but late for the weak complex from X = I. If the strain energy associated with complexation is large as in this case, this transition state may well be nonexistent for X = I, so that simple homolysis of a weak bond determined by the excited state energy leads to free radical derived products, competing cyclization, and reaction with solvent.

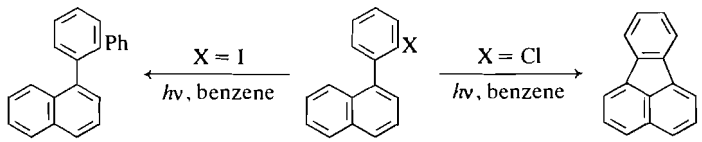
In conclusion we wish to emphasize the importance of homolysis assisted by radical complexation in the photochemistry of aryl halides and are of the opinion that this concept may be relevant to other photochemical systems. Experiments to test the scope and applicability of the assisted fission model are in progress.

Experimental



Irradiation Apparatus

It was impractical to use a single irradiation apparatus for photochemical kinetic measurements. Two basic systems were used with modifications, as required, for the study with each variable. Due to the differences between these systems, the results obtained on one cannot be strictly compared with those obtained on the other.



Apparatus A

The light source was a 72 W low pressure mercury arc lamp (PCQ-Xl from Ultra-Violet Products Inc.) consisting of four independent circular units which allowed the insertion of a quartz photolysis tube with its quartz filter jacket along the cylindrical cavity. Homogeneity of the photolyte was attained by magnetic stirring and gas bubbling. The filter (46) was a 0.6 cm path of an aqueous solution of $CoSO_4 \cdot 7H_2O$ (117 g L^{-1}) and $NiSO_4 \cdot 6H_2O$ (333 g L^{-1}) and gave 254 nm irradiation of 94% purity from the above source. After preirradiation for 1 h this filter maintained its transmittance indefinitely. The experimental arrangement was completed by surrounding the lamps with a cylinder and a cone of aluminium which acted as a reflector and helped to maintain a constant photolyte temperature of 35 ± 2°C. Light flux was determined by uranyl oxalate actinometry (47) (0.01 *M* in UO_2^{2+} and 0.05 *M* in $C_2O_4^{2-}$) before and after the kinetic runs. Apparent intensities (flux/photolyte volume) of ca. 4×10^{-4} E L^{-1} min^{-1} were obtained.

The data in Table 4 were obtained using a single lamp of the PCQ-Xl source with interposed gauze cylinders varying in

13

14

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

number and mesh size. The photolyte temperature was 25 ± 3°C and ferrioxalate actinometry (48) was necessary.

Apparatus B

The output of a 125 W medium pressure mercury arc lamp (Phillips) was focussed onto the entrance slit of a monochromator using a quartz lens. The photolyte was contained in a 1 cm square quartz cell which could be reproducibly repositioned. The intensity was monitored before and after kinetic runs by (*a*) a quantum counter (49) constructed from a 1 cm quartz cell containing quinine sulphate (4 g L^{-1}) in *N*-sulphuric acid, the output falling on a photomultiplier tube, and (*b*) ferrioxalate actinometry. The irradiation intensities at different wavelengths were equalized to about 1×10^{-7} E L^{-1} min^{-1} by adjusting the monochromator slit width. There was no facility for stirring the photolyte but reactions were slow enough (low I_{abs}) for diffusion to prevent the establishment of concentration gradients.

Quantum Yields

These were calculated from measurements on the appearance rate of the product **7** at low conversions for optically dense solutions of **6**, and actinometry. With apparatus A, the large photolyte volume (100 mL) permitted withdrawal of aliquots and the construction of concentration–time profiles from which the initial gradient, constant up to 15% conversion, was obtained. With apparatus B, the total photolyte volume was analysed after 1% conversion. Large rate reductions result at high conversions due to screening and quenching by the more conjugated product.

All data are reproducible within the limits of error, ±10% except where otherwise stated.

The ultraviolet absorption of **7** shows sharp vibronic bands at long wavelengths where **6** has negligible absorption. The longest wavelength band was used to follow the appearance of **7**. Though **7** may be first formed as the hydrohalide salt, atmospheric moisture causes hydrolysis to the free base. Solutions of **7** in methanol show no change in uv spectrum when made $10^{-3}M$ in hydrochloric acid.

Preparation of Pyrazoles (6)

These were prepared from the chalcone and phenylhydrazine and then oxidation of the pyrazoline with lead-(iv) acetate (10). The following pyrazoles are new and were crystallized from ethanol: 5-(2-methoxyphenyl)-1,3-diphenylpyrazole, mp 142–143°C; *Anal.* calcd. ($C_{22}H_{18}N_2O$): C 81.0, H 5.6, N 8.6%; found: C 81.2, H 5.6, N 8.4; 5-(2-acetoxyphenyl)-1,3-diphenylpyrazole, mp 98–100°C; *Anal.* calcd. ($C_{23}H_{18}N_2O_2$): C 78.0, H 5.3, N 7.9%; found: C 78.0, H 5.3, N 8.0; 5-(2-iodophenyl)-1,3-diphenylpyrazole, mp 116–117°C; *Anal.* calcd. ($C_{21}H_{15}IN_2$): C 59.7, H 3.6, N 6.6%; found: C 59.8, H 3.6, N 6.7.

5-(2-Chlorophenyl)-1,3-diphenylpyrazole in cyclohexane showed λ_{max}: 259 nm (ε 26 000) and in ethanol at 80 K fluorescence λ_{max}: 343 nm, phosphorescence λ_{max}: 446 nm. 1,3,5-Triphenylpyrazole in cyclohexane showed λ_{max}: 255 nm (ε 31 000) and in ethanol at 80 K fluorescence λ_{max}: 347 nm, phosphorescence λ_{max}: 463 nm.

Preparative Photochemistry

Conversion of 6 to 7

The pyrazole **6** (0.66 mmol) in methanol (100 mL) was irradiated with the PCQ-X1 lamp under nitrogen until tlc or hplc monitoring indicated absence of **6**. The photolyte was then evaporated and the residue recrystallized from ethanol to yield **7**, mp 152–154°C with a solid phase change at 140–142°C (lit. (10) mp 151–153°C); ms *m/e*: M^+ 294 (100%), 293 (20%), 190 (16, $M - H - PhCN$), 147 (10, M^{2+}). For hplc analysis (Spectraphysics SP 3500 instrument) aliquots were evaporated, dissolved in benzene, and injected on a 250 mm column of Spherisorb silica (S5 W) eluted with dichloromethane–cyclohexane (2:1, by volume), flow rate 0.8 mL min^{-1}, uv monitoring at 260 nm. Thin layer chromatography was carried out on silica plates with the same solvent system. No **6** (X = H) was detected by hplc and the system could separate this from all the starting pyrazoles.

Benzophenone Sensitized Conversions

Radiation with $\lambda > 350$ nm, not absorbed by **6**, was obtained by filtering the output from a 150 W medium pressure mercury arc (TQ-150, Hanau) through a 0.2 cm path of Pyrex glass and 0.5 cm path of $2.5 \times 10^{-3}M$ bismuth chloride in $6M$ hydrochloric acid (50). The filtered source was immersed in a solution (100 mL) of 1 to $6 \times 10^{-3}M$ pyrazole **6** and an equimolar amount of benzophenone in benzene under nitrogen. When tlc indicated complete reaction, the mixture was evaporated and crystallized from ethanol to yield **7**, mp 152–154°C.

Xanthone Sensitized Conversion of 6 (X = Br) to 7

The bromopyrazole (125 mg, 0.3 mmol) and xanthone (130 mg, 0.6 mmol) in methanol (500 mL) was irradiated as in the previous paragraph for 10 min, after which tlc showed signs of commencement of consecutive reactions. The mixture was made alkaline by addition of triethylamine (1 mL) and evaporated to yield a solid which was subjected to preparative tlc (silica, elution with dichloromethane–cyclohexane 2:1 by volume) to give, after crystallization from methanol, **7** as needles (58 mg, 58%), mp. 152–153°C.

Upon repetition of the experiment with an irradiation time of 30 min, tlc showed the disappearance of **7** with the formation of **8**. The photolyte was evaporated to dryness and chromatographed on a silica column with the above eluant to retain the xanthone. Elution and then crystallization from benzene – light petroleum (bp 40–60°C) afforded *3-bromo-2-phenylpyrazolo[1,5-f] phenanthridine* as needles (80 mg, 64%), mp 176–178°C; ms *m/e*: M^+ 374 and 372 (100%), 294 (20), 293 (35, $M^+ - Br$), 292 (28), 190 (65, $M^+ - Br - PhCN$). *Anal.* calcd. ($C_{21}H_{13}BrN_2$): C 67.6, H 3.5, N 7.5%; found: C 67.6, H 3.7, N 7.3.

Compound **7** (30 mg, 0.1 mmol) in refluxing methanol (10 mL) was treated dropwise with bromine (16 mg, 0.1 mmol) in methanol (5 mL) with instant decolorization. A colorless solid precipitated on cooling and crystallized from benzene – light petroleum to give **8** (23 mg), mp and mixture mp 176–178°C.

Photolysis of 6 (X = Cl) in Presence of Diethylaniline

A solution of the chloropyrazole (110 mg, 0.33 mmol), diethyl aniline (500 mg, 3.3 mmol), and triethylamine (330 mg, 3.3 mmol) in methanol (150 mL) was irradiated under nitrogen with radiation of $\lambda > 300$ nm obtained by filtering the TQ-150 lamp emission through 0.2 cm Pyrex glass. The hplc monitoring showed no detectable **6** (X = H) at any stage and formation of **7** was rapid. After 30 min irradiation the photolyte was evaporated, the residue dissolved in benzene, washed with hydrochloric acid and water, dried ($MgSO_4$), and evaporated to yield **7**, needles from ethanol, mp 153–154°C (55 mg, 56%).

Thermolysis of 6 (X = Br and OMe)

The bromopyrazole (250 mg) in a sealed tube was kept at 370°C for 48 h. The resulting black mass was dissolved in chloroform, filtered through a short silica column, and chromatographed on silica plates with chloroform elution to yield **7** (10 mg, 5%) as needles, mp 151–153°C. No reaction of **6** (X = Br) occurred at 180°C. An identical experiment with **6** (X = OMe) (100 mg) at 370°C gave no evidence for the formation of **7** by tlc or uv spectroscopy.

A stereospecific synthesis of napelline

SAT PAUL SETHI, KARNAIL S. ATWAL, RINALDO M. MARINI-BETTOLO, THOMAS Y. R. TSAI, AND KAREL WIESNER

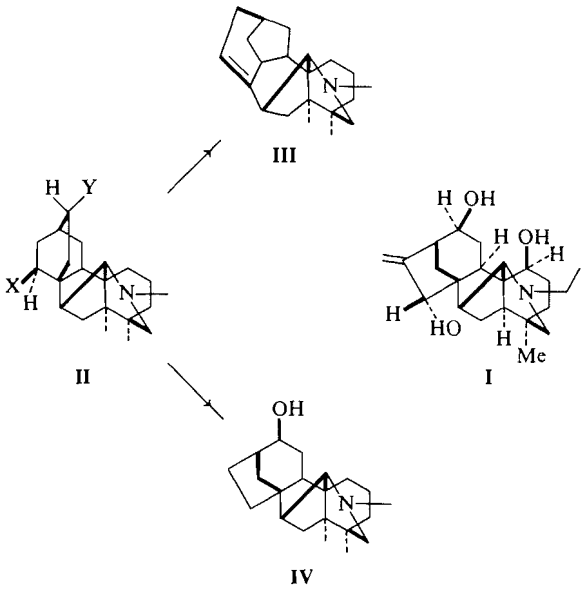
Natural Products Research Center, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received January 31, 1980

This paper is dedicated to the memory of Dr. Léo Marion

SAT PAUL SETHI, KARNAIL S. ATWAL, RINALDO M. MARINI-BETTOLO, THOMAS Y. R. TSAI, and KAREL WIESNER. Can. J. Chem. **58**, 1889 (1980).

A simple and stereospecific synthesis of the triketolactam **15** is described. This compound has been previously converted to napelline **I**. The key step of the synthesis is the rearrangement of the "denudatine" intermediate **11** to the napelline derivative **12**. The denudatine skeleton was constructed by a stereospecific diene addition between the *o*-quinone acetal **4** and benzyl vinyl ether. It is expected that this last process will be capable of general application in the synthesis of complex compounds.



SAT PAUL SETHI, KARNAIL S. ATWAL, RINALDO M. MARINI-BETTOLO, THOMAS Y. R. TSAI et KAREL WIESNER. Can. J. Chem. **58**, 1889 (1980).

On décrit une synthèse simple et stéréospécifique du tricétolactame **15**. On a transformé antérieurement ce composé en napelline **I**. L'étape clef de cette synthèse est la transposition de l'intermédiaire "dénudatine" **11** en un dérivé de la napelline **12**. On a réalisé le squelette de la dénudatine par une addition stéréospécifique, de type diènique entre l'acétal de *o*-quinone et l'éther benzylvinylique. On espère que ce dernier procédé pourra être appliqué d'une façon générale à la synthèse de composés complexes.

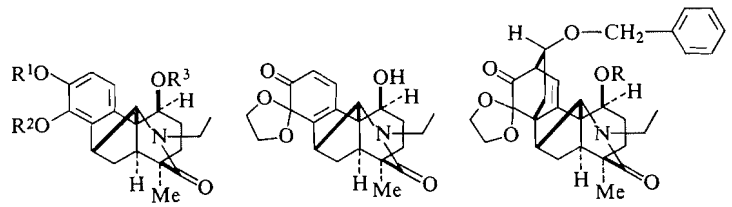
[Traduit par le journal]

Several years ago we reported a stereoselective synthesis of the hexacyclic aconite alkaloid napelline **I** (1).

We now wish to disclose a very much more efficient stereospecific and simple construction of the same compound based on our "fourth generation methods" which we have developed for the synthesis of delphinine-type alkaloids (2). Both the delphinine and the napelline system may be built by basically the same strategy which is illustrated by the formulae **II**, **III**, and **IV**.

Ejection of the leaving group X from the "denudatine" structure **II** followed by rearrangement and deprotonation yields a "pyrodelphinine"-type intermediate **III**. Alternatively, the napelline derivative **IV** may be obtained by ejection of the leaving group Y followed by rearrangement and capture of a nucleophile. An exploration of this strategy on model compounds has been published (3).

The starting material was the aromatic intermediate **1** (mp 138–140°C) (4) which was synthesized exactly as the analogous derivative used previously in the construction of 13-desoxydelphonine (2).[1]



Lithium borohydride reduction of compound **1** yielded the alcohol **2** (mp 104–105°C). This material was heated with 6 *N* HCl to 50°C for 1 h and the product **3** (mp 121.5–122.5°C) was purified by

[1]All compounds gave a molecular ion in mass spectrometry and all spectral data were compatible with the structures assigned to them. All crystalline compounds gave acceptable elemental analyses.

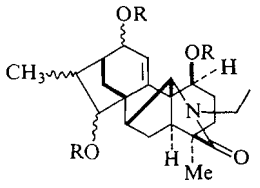
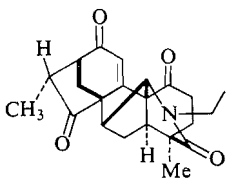
chromatography and crystallization. The yields of all these operations were practically quantitative.

A suspension of $CaCO_3$ in a solution of the phenol **3** in THF was cooled to 0°C and $Tl(NO_3)_3$ was added. The mixture was stirred for 15 min, poured into saturated aqueous bicarbonate, and extracted with $CHCl_3$. The *o*-quinone acetal **4** (mp 204–205°C) was purified by crystallization from $CHCl_3$–ether and it was obtained in a yield of 95%; uv (EtOH) λ_{max}: 245, 294 nm ($\log \varepsilon$ = 4.2, 3.5); ir ($CHCl_3$): 3670 (OH), 1685 (CO), 1635 (CON) cm^{-1}; ^1H nmr ($CDCl_3$) τ: 2.33, 4.30 (2d, J = 10 Hz, 1H each, vinylic H), 5.80 (m, 4H, $-O-CH_2-CH_2-O$). The masked quinone **4** was heated with an excess of benzyl vinyl ether in CH_2Cl_2 to 40°C for 24 h. The adduct **5** (mp 192–193°C) was purified by chromatography and crystallization and it was obtained in a yield of 94%;[2] ir ($CHCl_3$): 3650 (OH), 1740 (CO), 1635 (CON) cm^{-1}; ^1H nmr ($CDCl_3$) τ: 2.70 (s, 5H, aromatic H), 3.77 (d, J = 6 Hz, 1H, olefinic H), 5.57 (m, 2H, benzylic, 1H, C*H*OH), 5.93 (m, 4H, $-O-CH_2-CH_2-O$).

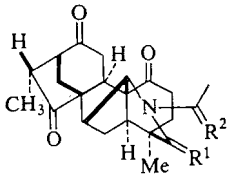


The adduct **5** was converted quantitatively to the oily tetrahydropyranyl derivative **6** by treatment with dihydropyran and pyridinium *p*-toluenesulfonate in CH_2Cl_2. Treatment of compound **6** with trimethyl silyl methyl magnesium chloride in dry THF (cf. ref. 3) at 80°C for 12 h gave the two epimeric alcohols **7** in a yield of 84%. This material was immediately without separation heated in a mixture of 70% $HClO_4$ and THF to 60°C for 2 h. The α,β-unsaturated ketone **8** (mp 170–172°C) was obtained in a yield of 85% after crystallization from ether–hexane; uv (EtOH) λ_{max}: 217 nm ($\log \varepsilon$ = 4.3); ir ($CHCl_3$): 3640 (OH), 1710 (CO), 1635 (CON, $>C=CH_2$) cm^{-1}; ^1H nmr ($CDCl_3$) τ: 2.67 (s, 5H, aromatic H), 3.43 (d, J = 6 Hz, 1H, endocyclic



9 $R^1 = -CH_2-$
$R^2 = -CO-CH_3$

10 R^1 = H
$R^2 = -CO-CH_3$



11 R^1 = Ms
$R^2 = -CO-CH_3$

12 R = $-CO-CH_3$
13 R = H

14

15 R^1 = O
$R^2 = H_2$

16 $R^1 = H_2$
R^2 = O

[2]It is remarkable that a dimethylacetal corresponding to **4**, which can be prepared from the precursor of compound **1** ($R^1 = -CH_2-O-CH_3$, $R^2 = -OCH_3$) in two steps is unreactive in the diene addition. This seems to be a striking example of steric hindrance.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

vinylic H), 4.15, 4.77 (2d, J = 2 Hz, 1H each, exocyclic vinylic H), 5.45 (d, 2H, benzylic H).

Reduction of ketone **8** with $LiBH_4$ followed by acetylation with acetic anhydride and pyridine yielded 90% of the oily homogeneous diacetate **9** in which the stereochemistry of the two new chiral centers is left unassigned.

Hydrogenolysis of the benzyl group in compound **9** with Pd–charcoal in methanol gave the oily alcohol **10** and this material was mesylated with mesyl chloride and triethylamine in CH_2Cl_2 to the oily mesylate **11**.

The stage was now set for the rearrangement of the "denudatine" system **11** to the "napelline" system **12**. The rearrangement was accomplished in a yield of 95% by refluxing the mesylate **11** in glacial acetic acid for 2.5 h. The triacetate **12** was saponified with 5% methanolic KOH to the triol **13** and this material was oxidized with the CrO_3–dipyridine complex in CH_2Cl_2 to the homogeneous oily unsaturated triketolactam **14** in an overall yield of 90%; uv (EtOH) λ_{max}: 242 nm (log ε = 4.3); ir ($CHCl_3$): 1745 (cyclopentanone), 1710 (cyclohexanone), 1675 (cyclohexenone), 1650 (lactam) cm^{-1}; ^1H nmr ($CDCl_3$) τ: 3.80 (s, 1H, olefinic H).

Hydrogenation of the triketone **14** with Pd–$CaCO_3$ in ethanol gave quantitatively the saturated triketolactam **15** which was recrystallized from $CHCl_3$–ether and melted at 172–173°C. The totally synthetic racemate **15** was identical by all spectral and chromatographic criteria with the optically active compound of the same structure (mp 193°C) prepared many years ago in our laboratory (5). The methyl group in **15** and its derivatives is assigned the *endo* configuration. This configuration has been established in the optically active derivative by a mild acid catalyzed isomerization, allylic alcohol → ketone, and we agree with all the arguments recently summarized by Pelletier *et al.* in favour of the *endo* methyl stereochemistry of such isomerization products (cf. ref. 6). Infrared ($CHCl_3$): 1740 (cyclopentanone), 1710 (cyclohexanone), 1650 (lactam) cm^{-1}; ^1H nmr ($CDCl_3$) τ: 8.73 (m, 6H, C—CH_3, —CH_2—CH_3), 8.87 (d, J = 2 Hz, 3H, CH—CH_3). Reduction of the racemate **15** with $LiAlH_4$ as described for the optically active compound **15** (5) yielded racemic dihydronapelline.[3] Since dihydronapelline has been converted to napelline (1), the synthesis of **15** constitutes a formal synthesis of napelline.

We have described previously (1) the preparation of napelline from the triketo amide **16**. The same method should be applicable to the isomer **15** and since we have 300 mg of this racemic material in our hands, we hope to accomplish also a direct synthesis of racemic napelline in the near future.

[3]The reduction of **15** with hydride is known to yield a triol with all three alcoholic groups in the "natural napelline" configuration (formula **I**).

The structure of merosinigrin

MICHAEL BENN

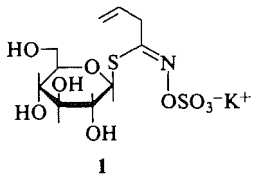
Chemistry Department, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received March 3, 1980

This paper is dedicated to the memory of Dr. Léo Marion

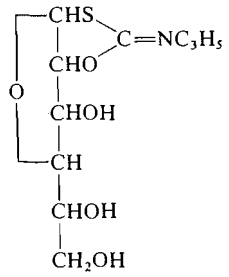
MICHAEL BENN. Can. J. Chem. **58**, 1892 (1980).

On the basis of spectroscopic evidence, a new structure is proposed for merosinigrin, a transformation product of potassium allylglucosinolate (sinigrin).



MICHAEL BENN. Can. J. Chem. **58**, 1892 (1980).

A partir des preuves spectroscopiques obtenues, on propose une nouvelle structure pour la mérosinigrine, un produit de transformation provenant de l'allylglucosinolate de potassium (sinigrine).

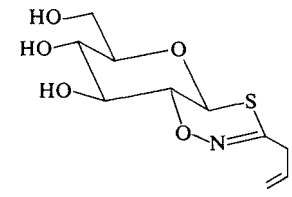


[Traduit par le journal]

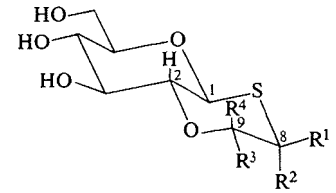
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In 1914, Schneider and Wrede (1) reported that the reaction of potassium allylglucosinolate (sinigrin, **1**) with methanolic potassium methoxide gave, besides 1-thioglucose, a small amount (at most 11%) of a crystalline compound which analysed as $C_{10}H_{15}O_5NS$ (**1** − $KHSO_4$). This substance, which they named merosinigrin, was highly dextrorotatory, formed a triacetate, did not reduce Fehling's reagent (even after prolonged boiling with dilute sulfuric acid), or yield lead sulfide when boiled with an alkaline solution of a lead salt. On the basis of this evidence, and accepting Gadamer's structure for sinigrin, Schneider and Wrede proposed that merosinigrin was the compound **2**.

1



2



Following Ettlinger and Lundeen's deduction of **1** as the correct structure for sinigrin (2), Kjaer (3) suggested that merosinigrin was **3**.

Recently we had occasion to repeat Schneider and Wrede's experiment and isolated (in about 3% yield) material with physical constants in good agreement with those previously reported. With the availability of modern spectroscopic methods we undertook a reexamination of this merosinigrin with the results which we now present.

Our merosinigrin had mp 191–192°C (uncorr.) and $[\alpha]_D^{25}$ +158(±17)° (*c* 0.18, H_2O) (lit. (1) mp 191–192°C and $[\alpha]_D^{20}$ +149° (*c* 5.4, in H_2O)). The ir

3

4a $R^1 = R^4 = H, R^2 = CN, R^3 = CH_3$
b $R^1 = R^3 = H, R^2 = CN, R^4 = CH_3$
c $R^1 = CN, R^2 = R^3 = H, R^4 = CH_3$
d $R^1 = CN, R^2 = R^4 = H, R^3 = CH_3$

spectrum contained absorptions at ν_{max} (KBr) 3480 and 3330 (br s, OH) and 2250 (wm) cm^{-1}, and there was no sign of absorptions due to C=C or C=N. A ^{13}C nmr spectrum (D_2O solution, CH_3OH internal reference (δ = 49.0 ppm)) had absorptions at δ: 19.0 (q), 35.2 (d), 60.6 (t), 70.0 (d), 73.3 (d), 74.0 (d), 75.1 (d), 81.4 (d), 83.0 (d), and 118.1 (s) ppm. The 200 MHz ^1H nmr spectrum (DMSO-d_6 solution, DMSO = δ 2.52 ppm) was also very revealing; δ: 1.29 (3H, d, J = 6.5 Hz), 3.1–3.55 (m, includes a DOH signal), 3.69 (1H, dd, J = 11 and 5.5 Hz), 3.91 (1H, dq, J = 6.5 and 2.5 Hz), 4.48 (1H, d, J = 2.5 Hz), 4.51 (1H, d, J = 8.3 Hz), 4.66 (1H, t, J = 5.5 Hz), 5.23 (1H, d, J = 5.5 Hz), and 5.35 (1H, d, J = 5.0 Hz). Mass spectra: 261 (M^+, in accord with $C_{10}H_{15}NO_5S$), with 145 amu as base-peak.

These data were clearly inconsistent with **3**, and

0008-4042/80/171892-02$01.00/0

SCHEME 1

instead suggested that merosinigrin was one of the isomers **4***a*–*c*.[1] (The fourth isomer, **4***d*, could be rejected on the basis of the small coupling constant, J = 2.5 Hz, between H-8 and H-9.) Distinction between these various possibilities followed from some nOe experiments. Irradiation of the methyl signal resulted in significant nOe enhancements (ca. 4% (difference experiment, coupled spectra)) of the signals for H-8 and H-9. Similar experiments, also at 200 MHz, in which H-9 was irradiated, were inconclusive, but at 400 MHz a ca.17% enhancement of the signal for H-2 was observed (this signal, a triplet at δ 3.23, J = 8.3 Hz, was identified by preliminary selective decoupling experiments), as well as ca.16% in H-8.

Accordingly we conclude that merosinigrin is **4***a*.

The formation of this compound from **1** can be rationalized by the reactions depicted in Scheme 1. The intermediate **5** has previously been postulated by Olesen-Larsen and co-workers to account for other products arising from the base-catalysed rearrangement of glucosinolates (5). The conformational preference of the cyano function is interesting and recalls the "anomeric effect", for although H-8 is easily exchanged for deuterium the nmr spectra showed no sign of epimerisation occurring at this centre during this process.

[1]A similar conclusion has been reached by Professor Peter Laur, Inorganic Chemistry Institute, R.W.T.H., Aachen, Bundesrepublik Deutschland (private communication).

Acknowledgements

We thank Dr. Tom Nakashima and Glen Bigam of the Chemistry Department, University of Alberta, for the nOe experiments. Thanks are also due to Professors Anders Kjaer, Martin Ettlinger, and Peder Olesen Larsen who at various moments stimulated my interest in the merosinigrin problem.

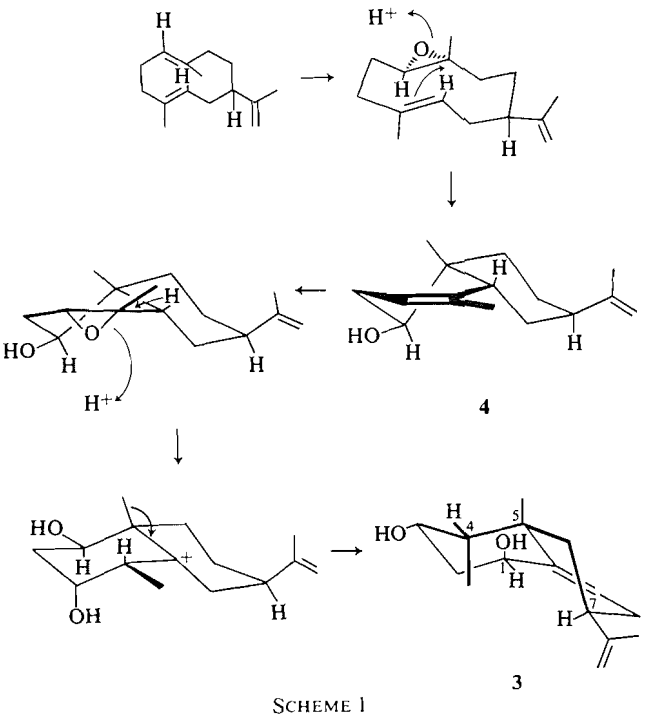
During the past decade, over twenty sesquiterpenes have been isolated from species of the *Solanaceae* under various stress conditions. Formation of most of these stress metabolites has been induced by fungal invasion of potato, aubergine, sweet pepper, jimson weed, and tobacco species (1, 2). Several, which exhibit antifungal activity, may have a role as post-infectional defensive agents (phytoalexins). The majority are bicyclic compounds, either of the eudesmane class or plausibly derived from eudesmanes by rearrangements of varying degrees of complexity. In recent years, the biosynthesis of several members of the series has been studied experimentally by several groups (3–6). For example, we recently utilized the double labelling technique with sodium acetate-1,2-$^{13}C_2$ to determine the carbon labelling patterns in ten sesquiterpenes induced by fungi in potatoes (4). It is apparent that, initially, cyclization of farnesyl pyrophosphate occurs to yield a germacrene; this is supported by the isolation of 2,3-dihydroxygermacrene (**1**) from jimson weed (7). Subsequent cyclization of these germacrene intermediates proceeds through eudesmane carbocations such as **2**. There appear to be a variety of ways in which the second cyclization may be triggered (1, 2), but, in general, the process would appear to require a hydride shift from C-5 to C-4. Direct support for this feature, however, has not been provided by the studies to date. We wish to present

1

2

3

results from deuterium incorporation experiments which establish the occurrence of such a hydride shift in the genesis of capsidiol (**3**), an antifungal stress metabolite isolable from tobacco, jimson weed, and sweet peppers (8).



Incorporation studies by Brooks and co-workers (3) using sodium acetate-1,2-$^{13}C_2$ under stress conditions with sweet peppers revealed the carbon labelling pattern for **3** and confirmed that the angular methyl group arises by migration from the 10-position of an eudesmane-type intermediate. This appears to have been the first experimental demonstration of this long-postulated methyl shift in the eudesmane–eremophilane rearrangement (9). A number of possible pathways for the biosynthesis of **3** have been proposed (1) of which two could be subsequently discounted by structural revision of congeners which had been suggested to function as possible intermediates. However, a third alternative, which had been mechanistically the most attractive from the outset, is shown in Scheme 1 and includes sequential *syn* migration of hydrogen (C-5 → C-4) and methyl (C-10 → C-5), similar to the postulated biosynthesis of occidentalol (10). An interesting in vitro analogy for the generation of

SCHEME 1

cis-decalins has been described (11) but we are unaware of in vivo demonstration of this sequence for the *cis* series. However, the corresponding hydride shift has been demonstrated for the *trans* series (12).

In the present instance, cyclization of a presumed simple germacrene induced by cleavage after epoxidation at one of the double bonds would give rise to the eudesmane analog **4**. A second epoxidation followed by acid-catalyzed cleavage sets the stage for a hydride shift (C-5 → C-4), the angular methyl shift (C-10 → C-5), and proton loss to form the 9,10-double bond in **3**. In the scheme, the skeletally bonded hydrogens shown are those originally at C-4 in the mevalonate precursors. To obtain evidence to support our proposed sequence, incorporation experiments utilizing mevalonolactone-4,4-d_2[3] were carried out following the method described previously (3). After isolation and recrystallization, **3** was acetylated to the corresponding diacetate because of its higher solubility. The ^{2}Hmr spectrum of capsidiol diacetate in Freon-11 contained three signals (see Fig. 1), one of which is significantly deshielded relative to the others. Clearly the deuterium atom from each of the three mevalonate units involved in the genesis of **3** is retained. Since the angular methyl group is bonded to a carbon originating from C-4 in mevalonate, a hydride (deuteride) shift has occurred. The low specific incorporation (0.3%) of mevalonate, as monitored by the presence of a small amount of radioactive mevalonolactone in the feeding experiments, clearly precludes other possible in-

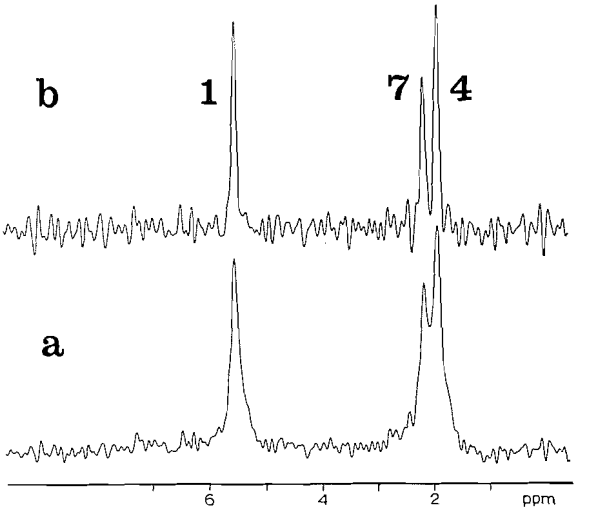

FIG. 1. 30.71 MHz ^{2}Hmr spectra of **3** in $CFCl_3$ (a) normal data processing, 4K transform, 1K spectral width (300 Hz illustrated), 11K transients, 30° flip angle, 0.40 s acquisition; (b) resolution enhanced spectrum, RE = 0.06.

[3]This compound was synthesized following the reported sequence for the 4-^{13}C labelled analog (13), using ethyl trideuterioacetate rather than ethyl [2-^{13}C]-acetate.

terpretations. The lowest field signal in the ^2H spectrum arises from deuterium on the C-1 carbinyl carbon. The chemical shift of this nucleus (5.52 ppm) is known from the proton spectrum and its separation, in ppm, from the 4-proton, coupled to the tertiary methyl protons, was determined by the required spin decoupling experiment. Irradiation at 1.95 ppm collapsed the methyl doublet (0.92 ppm) to a singlet, thus H-1 and H-4 are separated by 3.57 ppm. This is the separation between the highest and lowest field signals in the ^2H spectrum confirming the indicated assignments. The signal at intermediate field strength, 3.34 ppm upfield from the carbinyl resonance, is clearly attributable to the allylic deuterium at C-7. The relative intensity of this signal is noticeably smaller (~25%) than either of the others, presumably because of allylic exchange.

These results offer strong support for a sequence including *syn* migration of hydrogen and methyl. These data rule out an earlier suggestion that capsidiol, an 4-*epi*eremophilane, may arise from an eremophilane by a trivial epimerization (10).

Experimental

Feeding Experiments

Capsicum frutescens var. Red Sweet, harvested locally in the early ripening stage (red blush), was washed, halved, deseeded, and charged with 0.4 mL per half of a solution prepared by dissolving MVA-2-^{14}C (24.4 mg; 5.7 μCi from Amersham Corp., Oakville, Ont.) and MVA-4,4-$^2H_2$ (257.5 mg; >98% 4,4-$^2H_2$) in 96% EtOH (5 mL) and diluting to 560 mL with water. Approximately 1 h later, each half fruit was treated with 10 mL of a spore suspension of *Monilinia fructicola* prepared in the usual way (4). More MVA solution (1 mL per half fruit) was added 7 h after fungal inoculation and again after a further 16 h. The product was collected 48 h after fungal inoculation by decanting and rinsing the shells with water. The combined liquids (ca. 2 L) were extracted with 4 successive half volumes of Et_2O, which were washed with a little water. The residue obtained on evaporation of the extract was filtered in EtOAc, reevaporated (223 mg), and chromatographed over silica gel (Camag DF5, not activated, 225 g) in MeOH/$CHCl_3$ (1:9) in 25 mL fractions. Fractions 22–26 (105 mg) crystallized and were recrystallized from EtOAc and CH_2Cl_2 to constant specific radioactivity (4.96×10^5 cpm/mmol); specific activity of the MVA-2-^{14}C-4,4-$^2H_2$ under the same conditions, 5.20×10^6 cpm/mmol; hence, specific incorporation was 0.95% (~0.32% at each of 3 hypothetical sites). The purified capsidiol (61 mg, mp 150–152.5°C) was treated overnight at room temperature with pyridine (0.9 mL) and Ac_2O (0.6 mL). Evaporation furnished the pure diacetate-$^{14}C_x$-$^2H_2$ as an oil; ^{1}Hmr ($CFCl_3$) δ: 0.92 (d, *J* ~7 Hz, 3H, 4-Me), 1.37 (s, 3H, 5-Me), 1.72 (s, 3H, 11-Me), 1.98 (s, 3H), 2.01 (s, 3H), 4.67 (m, 2H, H-12), 5.52 (dd, $J = 2.3$ and 3.9 Hz, H-1), 5.59 (dt, *J*'s 12.6 and 4.8 Hz, H-3), 6.15 (dd, *J*'s 6.5 and 2.3 Hz, H-9), 1.95 (H-4, by spin decoupling), 2.14 (H-7, from the ^2H spectrum).

Nuclear Magnetic Resonance Spectra

The ^1H and ^2H spectra were recorded with a Varian XL-200 spectrometer at 200 and 30.7 MHz, respectively, using a solution of capsidiol diacetate-^2H_x in $CFCl_3$ (40 mg in 0.5 mL). The illustrated ^2H spectrum was obtained with proton noise decoupling.

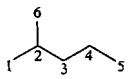
A note on the application of graph theory to the thermodynamic properties of isomeric alkanes

JOHN T. EDWARD[1]

Physicochimie des Solutions, LA CRNS 161, E.N.S.C.P., Université Pierre et Marie Curie, 11 Rue Pierre et Marie Curie, 75231 Paris, France

Received March 7, 1980

JOHN T. EDWARD. Can. J. Chem. **58**, 1897 (1980).



It has been claimed that trends in the thermodynamic properties of alkane isomers follow an ordering based on p_2 and p_3, the number of paths of length two or three, respectively (M. Randic and C. L. Wilkins. J. Phys. Chem. **83**, 1525 (1979)). A possible explanation of the approximate ordering of the partial molal volumes $\bar{V}^0$ of isomers in carbon tetrachloride at 25°C comes from the ordering, based on p_2 and p_3, of (*a*) the number N of methyl groups, and (*b*) the mole fraction Z_g of *gauche* arrangements in the different isomers. However, N and Z_g have opposite effects on $\bar{V}^0$, and specific cases of isomeric heptanes and nonanes are noted in which a reversal in trends in $\bar{V}^0$ may be expected.

JOHN T. EDWARD. Can. J. Chem. **58**, 1897 (1980).

On a prétendu que les tendances des propriétés thermodynamiques des alcanes isomères se classent en fonction de p_2 et p_3, le nombre de chemins de longueur deux ou trois respectivement (M. Randic et C. L. Wilkins, J. Phys. Chem. **83**, 1525 (1979)). Une explication possible du classement approximatif des volumes molaires partiels $\bar{V}^0$ des isomères en solution dans le tétrachlorure de carbone à 25°C vient du classement à partir de p_2 et p_3 (*a*) des nombres N de groupes méthyle et (*b*) de la fraction molaire Z_g des arrangements *gauches* des différents isomères. Cependant N et Z_g ont des effets opposés sur $\bar{V}^0$ et on a noté des cas spécifiques d'heptanes et de nonanes isomères pour lesquels on peut prévoir des tendances inverses de $\bar{V}^0$.

[Traduit par le journal]

A molecule may be regarded as a graph, with the atoms as points and the bonds as lines (1, 2). A path p_i in a molecular graph is a sequence of i adjacent bonds with no atom appearing more than once. The various paths found in the hexane isomer, 2-methyl pentane, are listed in Scheme 1 (cf. ref. 3). The numbers of paths of different length for this and for the other isomers of hexane are given in Table 1.

Path length i	Paths p_i	Numbers of path p_i
1	1–2, 2–3, 3–4, 4–5, 2–6	5
2	1–2–3, 2–3–4, 3–4–5, 1–2–6, 6–2–3	5
3	1–2–3–4, 6–2–3–4, 2–3–4–5	3
4	1–2–3–4–5, 6–2–3–4–5	2

SCHEME 1

A scrutiny of this and other tables of groups of isomers (3) shows that for any group p_1 must be identical, and the individual isomer is characterized (but not always completely (3)) by p_2, p_3, ... p_{n-1}, where n is the number of carbon atoms. Randic and Wilkins (3) found that trends in the thermodynamic properties of hydrocarbon isomers seemed to be determined chiefly (and perhaps entirely) by p_2 and p_3. To show trends, they displayed the properties of the isomers on grid graphs having p_2 and p_3 as coordinates; Figs. 1–3 are examples. In Figs. 1*a*, 2*a*, and 3*b* we display the partial molal volumes $\bar{V}^0$ in carbon tetrachloride at 25°C (4) of the isomers of hexane (Fig. 1*a*), of eight of the nine isomers of heptane (Fig. 2*a*), and of fifteen of the 35 isomers of nonane (Fig. 3*b*).

An examination of these figures shows that trends in $\bar{V}^0$ conform (with the exception of $\bar{V}^0$ of 3,3-dimethylpentane (Fig. 2*a*) and of 2,2- and 3,3-dimethylheptane (Fig. 3*b*), discussed below) to a (+, −) pattern: (+) indicating that in the direction of increasing p_2 (constant p_3), $\bar{V}^0$ increases; (−)

TABLE 1. Number of paths p_i of hexane isomers

Isomers	Symbol	Number of paths				
		p_1	p_2	p_3	p_4	p_5
n-Hexane	*n*	5	4	3	2	1
2-Methylpentane	2M	5	5	3	2	
3-Methylpentane	3M	5	5	4	1	
2,2-Dimethylbutane	$22M_2$	5	7	3		
2,3-Dimethylbutane	$23M_2$	5	6	4		

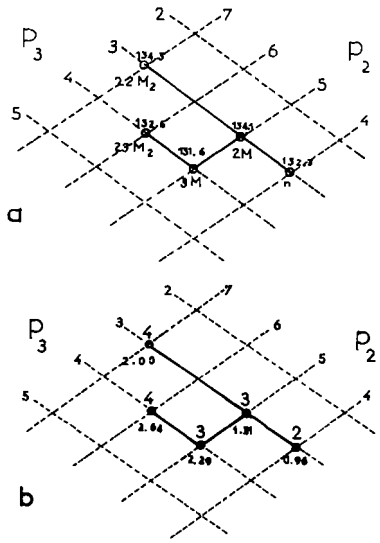

FIG. 1. Grid pattern for hexane isomers: (*a*) partial volumes $\bar{V}^0$ (in mL mol^{-1}; numbers above points); symbols of isomers (Table 1) below points; (*b*) numbers of methyl groups (above points); Z_g (below points).

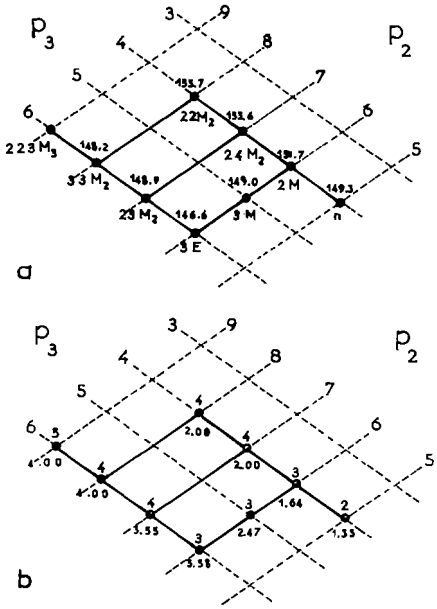

FIG. 2. Grid pattern for heptane isomers: (*a*) $\bar{V}^0$, above points; symbols below points (3E is 3-ethylpentane); (*b*) numbers of methyl groups, above points; Z_g, below points.

indicating that in the direction of increasing p_3 (constant p_2), $\bar{V}^0$ decreases. Randic and Wilkins consider that exceptions to trends may be due either to experimental error, or to the neglect of contributions from higher values of p_i; we show below that the exceptions noted above may be of more fundamental origin. However, the usefulness of the grid graphs in producing at least an approximate ordering of $\bar{V}^0$ is apparent. Randic and Wilkins found the graphs equally useful in showing trends in a large number of other properties: specific dispersions, molar volumes, heats of formation, molar refractions (trend (+,−)); surface tensions, heats of combustion, critical temperatures, volume molar factors, connectivity indices (5)(−,+); critical volumes, mean molecular radii as calculated by Altenburg (6), characteristic polynomials (7) (−,−); critical densities, critical pressures, molar magnetic susceptibilities, deviations of enthalpies of atomization from the values calculated by Somayaluju and Zwolinski (8), and Wiener's parameters ΔW and ΔP (+,+). Most of these molecular quantities are experimental, but some are theoretical (5–9). Discrepancies from the general trends were generally few and small; the occasional large discrepancy may indicate experimental error.

Randic and Wilkins point out that "there is as yet no theoretical basis for our ordering rule". A possible basis for the (+,−) trend in $\bar{V}^0$ emerges when we consider the equation recently (4) found to apply with reasonable accuracy to $\bar{V}^0$ of isomeric alkanes:

$$[1]\quad \bar{V}^0 = V_c + \sum_i n_i I_i - 2.5 Z_g$$

where V_c is a constant covolume of 11.61 mL mol^{-1}, I_i is the volume increment due to group i (—CH_3, 26.85; >CH_2, 17.36; >CH, 10.35; quaternary carbon 3.4 mL mol^{-1}); n_i is the number of groups i; and Z_g is the mole fraction of *gauche* conformations in a given isomer at 25°C. The cal-

culation of Z_g follows a procedure described by Mann (10). The mole fraction γ of each different conformation, containing z_g *gauche* arrangements, is calculated by the methods of statistical mechanics; then $Z_g = \Sigma\gamma z_g$. In these calculations it is assumed that while two adjacent *gauche* arrangements g^+g^+ or g^-g^- are possible, g^+g^- or g^-g^+ arrangements contribute negligibly because they bring the terminal carbon atoms excessively close, and hence have excessively high energies.

The alkanes of an isomeric group all have the same number of carbon and hydrogen atoms, and so have $\bar{V}^0$ values approximately equal. The small differences from $\bar{V}^0$ of the *n*-alkane that come with branching, and an increase in p_2 and p_3, are associated (according to [1]) with changes in two molecular parameters:

(*1*) The number N of methyl groups increases. In fact, as shown in Figs. 1*b*, 2*b*, and 3*c*, N follows a (+,0) trend. This should cause $\bar{V}^0$ also to follow a (+,0) trend, since (in effect) the hydrogen atoms of methyl occupy more volume than the hydrogen atoms of methylene or methine.[2]

(*2*) Z_g increases with p_2 and p_3, following a (+,+) trend, except at high values of p_3, when it follows a (0,+) trend (Figs. 1*b*, 2*b*, and 3*d*). This should lead to a (−,−) or (0,−) trend in $\bar{V}^0$. The effects of the changes in N and Z_g oppose each other, so that the net result could be either a (+,−) or a (−,−) trend in $\bar{V}^0$, depending on whether N or Z_g was more important. In fact, with increasing branching the volume increase due to the greater number N of methyl groups seems to be more important than the volume decrease due to the increase in Z_g, so that an (approximately) (+,−) trend is observed.[3]

We may now consider the exceptions to this trend noted above. The trend would require $\bar{V}^0$ of 3,3- to be greater than $\bar{V}^0$ of 2,3-dimethylpentane (Fig. 2*a*). In fact, it is smaller, although the difference is less than the experimental error. This agrees with [1], which requires it to be smaller because, although it has the same N, it has a larger Z_g (Fig. 2*b*). Similarly, the (+,−) trend would require $\bar{V}^0$ of 2,2-dimethylheptane to be greater than $\bar{V}^0$ of 2,6-dimethylheptane (Fig. 3*a*). In fact, it is smaller (Fig. 3*b*) by an amount greater than experimental error. Again, N of the two isomers (Fig. 3*c*) is the same, but Z_g is greater for 2,2-dimethylheptane (Fig. 3*d*), so that the result agrees with [1]. Similar considerations apply to $\bar{V}^0$ of 3,3-dimethylheptane which, counter to a (+,−) trend, is smaller than V^0 of 3,5-dimethylheptane (Figs. 3*a* and 3*b*).

We can conclude that, to the extent that we can have confidence in [1], the (+,−) trend in $\bar{V}^0$ shown in Figs. 1*a*, 2*a*, and 3*b* should be approximate but not exact. Since Z_g affects not only $\bar{V}^0$ but also molar refractions and heats of combustion (10, 11), it seems likely that the same conclusions apply to these properties also.

A further test of these conclusions might come from determination of $\bar{V}^0$ of some of the twenty isomers of nonane not yet examined. Thus [1] predicts that the (+,−) trend in $\bar{V}^0$ in Fig. 3*b* should be violated in the following cases: 3,3- vs. 2,3-dimethylheptane and 2-methyl-4-ethylhexane; 3-methyl-3-ethyl- vs. 3-methyl-4-ethylhexane; and 2,2,3- vs. 2,3,4-trimethylhexane and 2,4-dimethyl-3-ethylpentane. This prediction is based on the Z_g values calculated for these and for twelve other isomers for the first time, and shown in Fig. 3*d*. An additional point of interest came out in these calculations. While, wherever possible, a chain molecule avoids a g^+g^- or g^-g^+ arrangement, for several of the nonane isomers of Fig. 3*a* this is not possible. One $g^{\pm}g^{\mp}$ arrangement is necessarily present in any staggered conformation of the following compounds: 2,2,4- and 2,4,4-trimethylhexane, 2,2-, 2,3-, and 2,4-dimethyl-3-ethylpentane, and 2,2,3,4-tetramethylpentane. Two such arrangements must be present in the staggered conformation of 2,2,4,4-tetramethylpentane (**1**).

1

The presence of such highly compressed arrangements might be expected to result in a pronounced drop in $\bar{V}^0$, and a pronounced rise in molar refractions and heats of combustion.

The hospitality and interest of Professor Schaal and financial support from the National Research Council of Canada, Le Centre National de la Recherche Scientifique de France Scientific Cooperation Program are warmly appreciated.

[2]Accepting a constant increment of 3.4 mL mol^{-1} for a carbon atom, the increment (in mL mol^{-1}) of a hydrogen atom varies according to its attachment as follows: CH_4, 9.2; CH_3, 7.8; CH_2, 7.0; CH, 7.0. (This corrects an error in ref. 4.) Possible reasons for this monotonic change are discussed in ref. 4.

[3]The exceptions to the (+,−) trend come from the fact that while Z_g increases continuously, N increases in stepwise fashion, and has the same value for each isomer of the aberrant pairs.

Thermodynamics of binary mixtures of 1,2-dichloroethane with aromatic hydrocarbons

RAM K. NIGAM, PREM P. SINGH, KRISHAN C. SINGH, MOHAN SINGH, AND RUCHI MISHRA

Department of Chemistry, Maharshi Dayanand University, Rohtak (Haryana), India

Received October 31, 1979

RAM K. NIGAM, PREM P. SINGH, KRISHAN C. SINGH, MOHAN SINGH, and RUCHI MISHRA. Can. J. Chem. **58**, 1902 (1980).

Molar excess volumes, V^E at 298.15 and 308.15 K, molar excess enthalpies H^E at 308.15 K, and total vapour pressure at 298.15 and 308.15 K have been measured for binary mixtures of 1,2-dichloroethane with aromatic hydrocarbons. The V^E and H^E data for an equimolar mixture at 308.15 K only have been utilized to predict V^E, H^E, and TS^E values (using Sanchez and Lacombe theory) for these mixtures as a function of temperature and composition. The agreement between the predicted and the corresponding experimental values is good so far as V^E and H^E data are concerned but the same is not true of the TS^E values.

RAM K. NIGAM, PREM P. SINGH, KRISHAN C. SINGH, MOHAN SINGH et RUCHI MISHRA. Can. J. Chem. **58**, 1902 (1980).

On a mesuré les volumes molaires en excès V^E à 298,15 et 308,15 K, les enthalpies molaires en excès H^E à 308,15 et la pression totale de vapeur à 298,15 et 308,15 K des mélanges binaires de dichloro-1,2 éthane avec des hydrocarbures aromatiques. On a utilisé uniquement les données de V^E, H^E d'un mélange équimolaire à 308,15 K pour prédire les valeurs de V^E, de H^E et de TS^E (en utilisant la théorie de Sanchez et Lacombe) de ces mélanges en fonction de la température et de la composition. L'accord est parfait entre les valeurs théoriques et expérimentales tant que les données de V^E et de H^E sont impliquées mais ce n'est pas le cas pour les valeurs de TS^E.

[Traduit par le journal]

Introduction

Sanchez and Lacombe have recently formulated a unified molecular theory (1–3) of liquid and gaseous mixtures. The theory (1–4) has been quite successful in describing/predicting not only the liquid–liquid and liquid–vapour equilibrium but also the lower critical solution temperature and the upper critical solution temperature for binary mixtures of non-electrolytes. Further, by allowing empty lattice sites on the lattice, this theory provides, unlike the lattice theory of Flory and Huggins (5), a means to calculate excess volumes for non-electrolytic fluids. In the present work we have employed this theory to predict molar excess volumes, V^E, molar excess enthalpies, H^E and TS^E values for binary mixtures of 1,2-dichloroethane with aromatic hydrocarbons at 308.15 and 298.15 K from *the corresponding* V^E *and* H^E *data for an equimolar mixture at 308.15 K only.*

Experimental

Analytical grade benzene, toluene, *o*-xylene, *m*-xylene, *p*-xylene, and 1,2-dichloroethane were purified by standard techniques (6, 7). The purity of the final samples was checked by density determination at 298.15 ± 0.01 K which agreed to within ± 0.00005 g cm^{-3} with their corresponding literature values (8–10).

Molar excess volumes were measured at 298.15 and 308.15 K as a function of composition using the direct dilatometric method (11). The temperature of the thermostatic bath was controlled to ±0.01 K and the uncertainty in the experimental V^E values is 0.5%.

Molar excess enthalpies as a function of composition were measured at 308.15 K in an adiabatic calorimeter described elsewhere (12). The time was recorded by an electronic timer (type 701, Systronics, Ahmedabad, India) which could read to ±0.0001 s. The temperature variation of the thermostatic bath was found to be within ±0.01 K and the uncertainty in H^E values is about 1.1%.

Total vapour pressures of these mixtures were determined by a static method described earlier (13). The apparatus was placed in a water thermostat which in turn was placed in another water bath. The temperature of the outer thermostat was controlled to ±0.01 K and the temperature drift in the inner thermostat was found to be less than ±0.003 K. The mercury heights in the manometer were read by a cathetometer which could read to ±0.001 cm. All vapour pressure measurements were reproducible to better than ±0.02 Torr.

Our measured vapour pressures at 298.15 K of benzene, *o*-xylene, and *p*-xylene compare within ±0.3% with their corresponding literature values (14, 15) at 298.15 K. However, our measured vapour pressures for toluene, *m*-xylene, and 1,2-dichloroethane compared within ±0.4% with those obtained from Antoine equation using the parameters given elsewhere (16).

Results

V^E data[1] at 298.15 and 308.15 K and H^E data[1] at 308.15 K were expressed by expressions of the type

[1] $$V^E(\text{cm}^3\ \text{mol}^{-1})/x_1(1 - x_1)$$

or $$H^E(\text{J mol}^{-1})/x_1(1 - x_1)$$

$$= \sum_{i=0}^{2} V_i \quad \text{or} \quad H_i(2x_1 - 1)^i$$

where V_i or H_i are adjustable parameters and x_1 is the mole fraction of 1,2-dichloroethane. These

parameters were evaluated by fitting $V^E/x_1(1 - x_1)$ and $H^E/x_1(1 - x_1)$ to [1] by the method of least squares and are recorded together with the standard deviation of the molar excess volumes, $\sigma(V^E)$, and molar excess enthalpies, $\sigma(H^E)$, in Table 1.

The total vapour pressure data[1] for these mixtures at 298.15 and 308.15 K were used to evaluate molar excess Gibbs free energies of mixing, G^E, by Barker's method (17). The form of the function used for G^E, following Redlich and Kister (18), is

$$[2] \quad G^E/RT = x_1(1 - x_1) \sum_{i=0}^{2} G_i(2x_i - 1)^i$$

where G_i are adjustable parameters. These parameters are recorded in Table 1. The second virial coefficients for benzene were taken from literature (19) while those for toluene, *o*-xylene, *m*-xylene, and *p*-xylene and 1,2-dichloroethane were calculated from Berthelot's equation (20); the necessary critical constant data were taken from literature (21).

Discussion

V^E data for all these binary mixtures are positive and follow the sequence toluene < benzene < *o*-xylene ≈ *p*-xylene < *m*-xylene. On the other hand, while H^E values are positive over the entire 1,2-dichloroethane concentration range for 1,2-dichloroethane and benzene mixtures, they are negative for low and positive for high 1,2-dichloroethane concentration for the rest of these binary mixtures.

V^E, H^E, and TS^E data were examined for Sanchez and Lacombe's theory (1, 2), which is an improvement over the one proposed by Flory and Huggins (5). This visualizes that all fluids are lattice or Ising fluids and that some of the lattice sites are empty. Each molecule is then characterized by an energy parameter $\tilde{\varepsilon}^*$ (which is the energy required to create a lattice vacancy) and a parameter r (which is the measure of the repulsive or hard core part of the intermolecular potential). Further, each lattice site is assumed to have a coordination number Z and while mers at the chain ends have $Z - 1$ nearest non-bonded and one bonded neighbour, each interior r-mer is surrounded by $Z - 2$ nearest non-bonded neighbours. The number of configurations available to a r-mer occupying r sites and N_0 vacant sites were then obtained as suggested by Guggenheim (22–24).

In order to predict V^E, H^E, and TS^E values for the various mixtures at any temperature and composition, H^E and V^E values for an equimolar mixture at 308.15 K were used to evaluate $\tilde{\rho}_{mix}$ from [4] and $\tilde{\varepsilon}^*_{ij}$ from [3]

$$[3] \quad H^E = RTr_{mix}\{\tilde{\rho}\sum\sum\phi_i\phi_j\chi_{ij} + \sum(\tilde{\rho}_i\phi_i{}^0 - \tilde{\rho}\phi_i)/T_i\} + PV^E$$

[4] $$V^E = \left[\frac{1}{\tilde{\rho}_{mix}} - \sum \phi_i \tilde{v}_i\right] \overset{*}{v}_{mix} r_{mix}$$

where

[5] $$\phi_i^0 = (m_i/\overset{*}{\rho}_i \overset{*}{v}_i)/(\sum m_i/\overset{*}{\rho}_i \overset{*}{v}_i)$$

[6] $$\phi_i = (m_i/\overset{*}{\rho}_i)/(\sum m_i/\overset{*}{\rho}_i)$$

[7] $$m_i = x_i M_i/\sum x_i M_i$$

(M_i = molecular weight of component i in the mixture)

[8] $$\overset{*}{v}_{mix} = \sum \phi_i^0 \overset{*}{v}_i$$

[9] $$r_{mix} = \sum x_i (\overset{*}{v}_i r_i^0/\overset{*}{v}_{mix})$$

[10] $$X_{ij} = (\overset{*}{\varepsilon}_{ii} + \overset{*}{\varepsilon}_{jj} - 2\overset{*}{\varepsilon}_{ij})/RT$$

and

[11] $$\overset{*}{\varepsilon}_{mix} = \sum\sum \phi_i \phi_j \overset{*}{\varepsilon}_{ij}$$

All the parameters in eqs. [5]–[11] are known from the properties of pure compounds.

The $\overset{*}{\varepsilon}_{ij}$ and $\tilde{\rho}_{mix}$ values thus obtained were utilized to see as to how closely [12] was satisfied

[12] $$\tilde{\rho}_{mix}^2 + \frac{RT}{\overset{*}{\varepsilon}_{mix}}\left[\left(1 - \frac{1}{r_{mix}}\right)\tilde{\rho}_{mix} + \ln(1 - \tilde{\rho}_{mix})\right] + \frac{P_{mix}\overset{*}{v}_{mix}}{\overset{*}{\varepsilon}_{mix}} = 0$$

It was observed that [12] was satisfied to 0.01. In all subsequent evaluations of $\tilde{\rho}_{mix}$ for the mixture at any other temperature and composition, [12] was always solved to this accuracy by numerical techniques. The $\overset{*}{\varepsilon}_{ij}$ value thus obtained for the mixture from its V^E and H^E values for an equimolar mixture at 308.15 K was next used to calculate $\overset{*}{\varepsilon}_{mix}$ and $\tilde{\rho}_{mix}$ from [11] and [12] and hence V^E and H^E for the mixture at any other temperature and composition. These V^E and H^E values at 308.15 and 298.15 K are recorded in Table 2 and are also compared with their corresponding experimental values (the H^E data at 298.15 K were taken from the literature (25)). The corresponding TS^E values were then evaluated from

[13] $$TS^E = -RT[\sum x_i \ln x_i/\phi_i + r_{mix} \times (\tilde{v}_{mix} - 1)\ln(1 - \tilde{\rho}_{mix}) + \ln \tilde{\rho}_{mix} - \sum x_i\{r_i^0(\tilde{v}_i - 1)\ln(1 - \tilde{\rho}_i) + \ln \tilde{\rho}_i\}]$$

These TS^E values are recorded in Table 2 and are also compared with the corresponding experimental values. All the parameters in [3]–[13] have the same significance as suggested by Sanchez and Lacombe (1, 2). The parameters $\overset{*}{\varepsilon}$, $\overset{*}{v}$, r^0, $\overset{*}{T}$, and $\overset{*}{\rho}$ for benzene, toluene, *o*-xylene, *m*-xylene, and *p*-xylene were taken from the literature (1) while those for 1,2-dichloroethane were evaluated in the manner described by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Sanchez and Lacombe (1); the necessary vapour pressure data at various temperatures were taken from the literature (26) while the corresponding density data were obtained by extrapolating the available density data (10). These parameters are recorded in Table 1.

Examination of Table 2 reveals that this theory is reasonably successful in predicting V^E and H^E values for the various mixtures at 308.15 and 298.15 K. However the same is not true of the TS^E values.

The qualitative difference in the behaviour of 1,2-dichloroethane towards various hydrocarbons may be related to the difference in the pure component parameters ε^* and r. Thus relative to 1,2-dichloroethane, benzene among all the hydrocarbons has the smallest repulsive intermolecular potential. Consequently V^E for the binary mixtures 1,2-dichloroethane with aromatic hydrocarbons should vary in the order benzene < toluene < *o*-xylene ≈ *p*-xylene < *m*-xylene. This is really true of the binary mixtures of 1,2-dichloroethane with *o*-, *m*-, and *p*-xylenes. For the remaining two mixtures, the V^E data can be explained if it is assumed that these mixtures are characterized by the charge transfer interactions between the components of these mixtures also. The introduction of a CH_3 substituent in benzene as in toluene would then increase the π-electron density of the aromatic ring in toluene which would then be readily accommodated in the vacant *d* levels of Cl atoms of 1,2-dichloroethane, as compared to benzene. Since the observed V^E would be the net effect of the repulsive intermolecular potential and charge transfer interaction, V^E for toluene would be less than that for benzene in their binary mixtures with 1,2-dichloroethane.

Again the sign and magnitude of H^E depends primarily on the contribution of the terms in ref. 3. Since the contribution of first term in ref. 3 which depends on χ_{12} (value in Table 1) outweighs those due to $\sum_i(\tilde{p}_i\phi_i^0 - \tilde{p}\phi_i)/T_i$, H^E is negative. This is true for all except the binary mixtures of 1,2-dichloroethane with benzene. This may be attributed to the small negative χ_{12} value for this mixture which suggests that in this mixture the unlike interactions are energetically more favoured than the like ones. However, the close proximity of 2 Cl atoms of 1,2-dichloroethane in its interaction with the π-electrons of the benzene ring may give rise to a repulsive contribution and since the observed H^E is the cumulative sum of the contributions due to unlike and steric interactions, H^E for this mixture is positive.

Determination of $D[C_6F_5CH_2—Br]$ by the toluene carrier method

R. JOHN KOMINAR AND MICHAEL J. KRECH
Chemistry Department, Wilfrid Laurier University, Waterloo, Ont., Canada N2L 3C5
AND
STANLEY JAMES W. PRICE[1]
Chemistry Department, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received April 22, 1980

R. JOHN KOMINAR, MICHAEL J. KRECH, and STANLEY JAMES W. PRICE. Can. J. Chem. **58**, 1906 (1980).

The pyrolysis of $C_6F_5CH_2Br$ has been studied by the toluene carrier technique over the temperature range 727–800°C. Rate constants are based on analysis for residual parent compound by gas chromatography using an internal standard technique. In selected runs a material balance of 100 ± 2% was obtained for bromine based on $C_6F_5CH_2Br$ plus HBr. Within the limits of the experimental technique the process appears to be first order and homogeneous. In addition to HBr the other major products of the thermal decomposition are $C_6F_5CH_3$, $(C_6F_5CH_2)_2$, $C_6F_5CH_2CH_2C_6H_5$, and $(C_6H_5CH_2)_2$. The Arrhenius equation obtained is

$$\log k_1\,(s^{-1}) = 14.54 \pm 0.42 - (225000 \pm 6000)/19.1T$$

The log A value is very close to the value of 14.6 recommended by Benson and O'Neal for the decomposition of $C_6H_5CH_2Br$. The activation energy, 225 ± 6 kJ mol^{-1}, should be a reasonable estimate of $D[C_6F_5CH_2—Br]$.

R. JOHN KOMINAR, MICHAEL J. KRECH et STANLEY JAMES W. PRICE. Can. J. Chem. **58**, 1906 (1980).

Utilisant la technique du toluène comme vecteur, on a étudié la pyrolyse du $C_6F_5CH_2Br$ sur une échelle de température allant de 727 à 800°C. Les constantes de vitesse sont calculées à partir de l'analyse du composé initial résiduel par chromatographie en phase gazeuse en faisant appel à la technique d'une référence interne. Dans des expériences choisies, on a obtenu un bilan pondéral de 100 ± 2% pour le brome en se basant sur le $C_6F_5CH_2Br$ plus le HBr. A l'intérieur des limites de la technique expérimentale, la réaction semble être homogène et d'ordre un. En plus du HBr, les autres produits principaux de la décomposition thermique sont: $C_6F_5CH_3$, $(C_6F_5CH_2)_2$, $C_6F_5CH_2CH_2C_6H_5$ et $(C_6H_5CH_2)_2$. On obtient l'équation d'Arrhénius suivante:

$$\log k_1\,(s^{-1}) = 14{,}54 \pm 0{,}42 - (225000 \pm 6000)/19{,}1T$$

La valeur de log A est très près de celle de 14.6 recommandée par Benson et O'Neal pour la décomposition de $C_6H_5CH_2Br$. L'énergie d'activation de 225 ± 6 kJ mol^{-1} serait une évaluation raisonnable de $D[C_6F_5CH_2—Br]$.

[Traduit par le journal]

Introduction

No previous studies of the pyrolysis of bromomethylpentafluorobenzene have been reported. Szwarc, Ghosh, and Sehon have studied the decomposition of $C_6H_5CH_2Br$ in a toluene carrier system and report that the Arrhenius parameters for the rupture of the C—Br bond are $E = 211$ kJ mol^{-1} and log $A = 13.0$ (2). However, based on the rate constants from the work of Szwarc *et al.* and thermodynamic arguments, Benson and O'Neal suggest "preferred values" of $E = 237$ kJ mol^{-1} and log $A = 14.6$ (1). Studies of related compounds by X-ray photoelectron spectroscopy and evaluation by ACHARGE and CNDO/2 calculations would suggest a slightly lower electron density on the methyl carbon in $C_6F_5CH_2Br$ cf. $C_6H_5CH_2Br$ (3, 4). Thus, it might be expected that $D[C_6F_5CH_2—Br]$ would be slightly lower than $D[C_6H_5CH_2—Br]$. The A factors for the carbon–bromine bond dissociations in the two compounds should be very similar.

Experimental

Materials

(a) Bromomethylpentafluorobenzene

The $C_6F_5CH_2Br$ used was obtained from Imperial Smelting Corporation. Prior to use, $C_6F_5CH_2Br$ was vacuum distilled and the head and tail fractions were discarded. Analysis by gas chromatography (6 ft × 0.125 in. 15% Apiezon L on Chromosorb W, N_2 carrier, 30 cm^3/min, isothermal for 4 min at 100°C and temperature programmed from 100–160°C at 32°C/min) using a flame ionization detector, showed only minor impurities estimated at a maximum of 0.01% of the sample.

(b) Toluene

Toluene from sulfonic acid (Eastman Organic X325) was prepared for use by refluxing over sodium under vacuum and then degassing by bulb-to-bulb distillation.

(c) n-Undecane

n-Undecane used as the internal standard for gc analysis was obtained from BDH Chemicals Ltd. and used as received.

Apparatus and Procedure

The basic toluene carrier system has been previously described (5). The quantity of $C_6F_5CH_2Br$ required for a run was injected via a gas tight syringe through a rubber septum. This procedure was subsequently modified by adding stop-cocks to the line so that after injection of $C_6F_5CH_2Br$ it could be isolated, frozen down, and degassed to remove any traces of air dissolved in the $C_6F_5CH_2Br$ or admitted during injection. The stop-cocks

*P runs in packed reaction vessel, surface-to-volume ratio 17 times that in unpacked vessel.

could then be adjusted to allow the toluene to pick up the $C_6F_5CH_2Br$. All lines into and out of the reaction zone were wrapped with heating windings controlled by variacs, to prevent condensation. The section containing the $C_6F_5CH_2Br$ was separately wound with its own variac to control the concentration of $C_6F_5CH_2Br$ in the toluene stream. Total pressures were taken by a differential manometer, after $C_6F_5CH_2Br$ had been removed from the system, while only toluene was flowing. The reaction vessels were treated with hot fuming nitric acid prior to use. Residual acid was baked out under vacuum after a vessel was installed in the system.

Toluene, unreacted $C_6F_5CH_2Br$, HBr, and other condensibles were trapped at −80°C. In experiments where the amount of HBr produced was to be quantitatively determined, the liquid products were isolated, the cold bath removed, and 25 mL of standardized NaOH introduced into the flask. The entire contents were stirred for 10–15 min with a magnetic stirrer while under vacuum. The aqueous layer was separated and titrated with standard HCl. The organic layer was dried over $MgSO_4$, filtered, and transferred to a tared amber sample bottle with a Teflon lined top. The sample was weighed and a weighed amount of internal standard, *n*-undecane, added. In experiments where HBr analyses were not carried out, the collected liquid products were transferred directly to amber bottles, weighed, and a weighed amount of internal standard introduced. The samples were analyzed on a P.E. Model 3920 Gas Chromatograph for $C_6F_5CH_3$, $C_6F_5CH_2Br$, $(C_6H_5CH_2)_2$, $C_6F_5CH_2$—$CH_2C_6H_5$, and $(C_6F_5CH_2)_2$ (6 ft × 0.125 in. 15% Apiezon L on Chromosorb W, N_2 carrier 16 cm/min, isothermal at 125°C for 8 min then 32°/min to 180°C, 4 min hold at 180°C). The peak areas were determined using a Columbia Scientific Industries Model CSI 38 digital electronic integrator.

Results and Discussion

Selected experimental results are given in Table 1. They may be discussed in terms of the following mechanisms:

[1] $C_6F_5CH_2Br \rightarrow C_6F_5CH_2 + Br$

[2] $Br + C_6H_5CH_3 \rightarrow C_6H_5CH_2 + HBr$

[3] $C_6F_5CH_2 + C_6H_5CH_3 \rightarrow C_6F_5CH_3 + C_6H_5CH_2$

[4] $C_6F_5CH_2 + C_6H_5CH_2 \rightarrow C_6F_5CH_2CH_2C_6H_5$

[5] $2C_6H_5CH_2 \rightarrow (C_6H_5CH_2)_2$

[6] $2C_6F_5CH_2 \rightarrow (C_6F_5CH_2)_2$

In addition, trace quantities of hydrogen and methane were observed, indicating very slight decomposition of the toluene carrier (0.001–0.01%).

First order rate constants were based on analysis for undecomposed $C_6F_5CH_2Br$. In addition, in six runs the quantity of HBr produced was determined. The amount of decomposition in these runs ranged from 12% to 71%. In these runs a material balance based on HBr + $C_6F_5CH_2Br$ was obtained with an average deviation of ±2%. Values of k_1 at various concentrations are shown in Table 2. Within the limits of the experimental method these results would appear to be consistent with first order behaviour.

TABLE 3. Representative product distribution for products involving $C_6F_5CH_2$ and $C_6H_5CH_2$

	Concentration (mol × 10^5)			
T (K)	$C_6F_5CH_3$	$(C_6F_5CH_2)_2$	$(C_6H_5CH_2)_2$	$C_6F_5(CH_2)_2C_6H_5$
751	3.14	0.57	3.43	2.95
773	6.42	0.99	8.30	6.92
784	9.57	1.49	11.90	9.50
784	10.00	1.67	13.16	10.69
797	12.52	1.71	14.36	11.06
800	13.08	1.68	14.11	10.94

of reactions [3] through [6] are shown in Table 3. The amount of decomposition in the runs used in this table ranges from 20% to 90%. With the system used, quantitative recovery of the dimers formed in reactions [4]–[6] was often difficult. Based on analysis for residual $C_6F_5CH_2Br$, the recoveries of $C_6F_5CH_3$, $(C_6F_5CH_2)_2$, and $C_6F_5(CH_2)_2C_6H_5$ fell in the range of 82%–100% with an average recovery of 93%. Based on the yields of fluorinated products, the quantities of dibenzyl found are all within ± 10% of the expected values. The yields of the recombination products are in agreement with the expected and required constancy of the rate constant ratio k_5k_6/k_4^2.

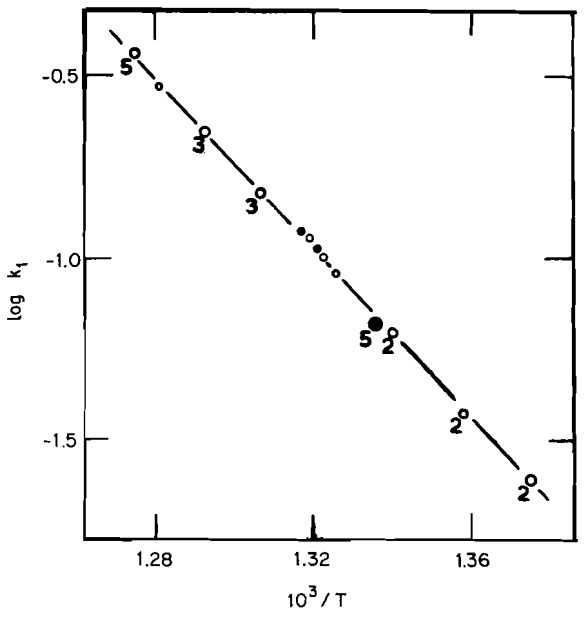

FIG. 1. Arrhenius plot for the decomposition of $C_6F_5CH_2Br$. Open circles: runs in unpacked reaction vessel. Full circles: runs in packed reaction vessel. Numbers are number of runs averaged to obtain the given point. Size of the point indicates the range of values.

The Arrhenius plot for values of k_1 is shown in Fig. 1. Approximately one-quarter of the experiments were carried out using a packed reaction vessel with a surface-to-volume ratio 17 times that of the unpacked vessel. No detectable surface effects were found. The data may be adequately represented by

$$\log k_1\,(s^{-1}) = 14.54 \pm 0.42 - (225000 \pm 6000)/19.1T$$

The error limits are based on two times the standard deviation. The activation energy, 225 ± 6 kJ mol^{-1}, should be a reasonable estimate of $D[C_6F_5CH_2—Br]$. The A factor is very close to the "preferred" value of 14.6 given by Benson and O'Neal for the pyrolysis of $C_6H_5CH_2Br$ (1) while the present activation energy is some 12 kJ mol^{-1} less than the estimated value for $C_6H_5CH_2Br$, giving a possible indication that fluorination of the aromatic ring slightly weakens the C—Br bond.

The sonolysis of uracil

TAIN-JEN YU, RONALD G. SUTHERLAND, AND RONALD E. VERRALL[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received August 28, 1979[2]

TAIN-JEN YU, RONALD G. SUTHERLAND, and RONALD E. VERRALL. Can. J. Chem. **58**, 1909 (1980).

The sonolysis of uracil (**1**) has been studied at 630 kHz in the presence of air, oxygen, nitrogen, and argon. The degradation products were identified by gc–ms analysis. Under aerated conditions the following products were found: uracil glycols (**7**), isobarbituric acid (**8**), *N*-formyl-*N'*-glyoxylurea (**6**), 5-hydroxyhydantoin (**9**), dialuric acid (**10**), alloxan monohydrate (**12**), parabanic acid (**13**), and oxaluric acid (**14**). In deaerated solutions **6**, **13**, and **14** were not observed but either 6-hydroxy-5,6-dihydrouracil (**17**) or its isomer (**18**) were detected in addition to **7**, **8**, **9**, **10**, and **12**. The observed products have been used to develop a possible mechanism for the sonolytic degradation and the results are similar to those obtained in radiolysis.

The sonolytic degradation of 5-bromouracil (**19**) is also reported; the products observed were 5-bromobarbituric acid (**20**), **12**, **13**, **14**, and **9** and these can be rationalized by a similar mechanistic scheme.

TAIN-JEN YU, RONALD G. SUTHERLAND et RONALD E. VERRALL. Can. J. Chem. **58**, 1909 (1980).

On a étudié la sonolyse de l'uracile (**1**) à 630 kHz en présence d'air, d'oxygène, d'azote et d'argon. On a identifié les produits de dégradation par spectrométrie de masse couplé à un chromatographe en phase gazeuse. En présence d'air, on obtient les composés suivants: le glycol d'uracyle (**7**), l'acide isobarbiturique (**8**), la *N*-formyl *N'*-gloxylurée (**6**), l'hydroxy-5 hydantoine (**9**), l'acide dialurique (**10**), le monohydrate l'alloxane (**12**), l'acide parabanique (**13**) et l'acide oxalurique (**14**). Dans des solutions en absence d'air, on n'observe pas les composés **6**, **13** et **14** mais on décèle les composés **7**, **8**, **9**, **10** et **12** avec en plus soit l'hydroxy-6 dihydro-5,6 uracile (**17**) soit son isomère (**18**). Sur la base des produits observés on a développé un mécanisme possible de la dégradation sonolytique et les résultats sont semblables à ceux obtenus par radiolyse.

On rapporte également la dégradation sonolytique de la bromo-5 uracile (**19**); les produits observés sont l'acide bromo-5 barbiturique (**20**), **12**, **13**, **14** et **9** et on peut les rationnaliser selon le même mécanisme.

[Traduit par le journal]

Introduction

Chemical reactions can be initiated by ultrasonic waves in liquids if the acoustic intensity is sufficient to induce cavitation (1,2). In this paper we report the sonolytic degradation of uracil (**1**) and it is part of a series (3, 4*a*) in which we examine the effect of ultrasound on biologically important molecules related to DNA and RNA. There are two other reports on the sonolysis of uracil in the literature (2, 5); however, the results of this study are much more detailed and demonstrate, for the first time, the use of the technique of gc–ms to separate and analyze the degradation products.

Since the radiolysis of uracil has been exhaustively investigated (6–14) and the primary reactions in the sonolysis of aqueous solutions (15–21) are known to be essentially similar to those produced in radiolytic reactions, the sonolysis and radiolysis results are compared and contrasted.

The sonolysis of 5-bromouracil (**19**) is also reported since the results obtained differ from those previously reported (5) where no degradation was observed.

Experimental

Ultrasonic Irradiation System and General Procedures

Irradiations were carried out with a Multisons MC 500-1 (Macrosonics Corporation, Cartaret, NJ) broad band generator coupled to a cobalt barium titanate transducer operated at 630 kHz with an average power output of 3.63×10^2 rads/s. Aliquots (50 mL) of aqueous solutions were insonated in a glass cell with a Mylar 500A plastic window (3, 22). A gas inlet was inserted into the glass cell and the solutions were saturated with the appropriate gas for at least 30 min prior to and during sonolysis when the experiment was carried out under air, O_2, N_2, or Ar atmosphere. Alternatively, a closed system was used without continuous bubbling of the gas during sonolysis in experiments when air was involved. The coupling liquid was an ethylene glycol – water mixture (60:40 by volume) whose temperature was maintained at 25°C. The aliquots were freeze-dried immediately after sonolysis and analyzed by gc–ms techniques.

A Cary 118 spectrophotometer was used to measure the change in absorbance at λ_{max} of the sample before and after sonolysis. Uracil absorbance was measured at 259.5 nm in a 1.0 cm quartz cell and that of 5-bromouracil at 276 nm. A Beckman Expandomatic SS-2 pH meter was used to measure the pH values before and after sonolysis.

General Analysis Procedures

After lyophilization the degradation products were converted to their trimethylsilyl (TMS) derivatives for gc–ms analysis (4*a*). Silylations were conducted by heating the reactants in an oil bath (150°C) for 10 min using the following proportions: one mg of the degradation products mixed with 100 μL of *N,O*-bis(trimethylsilyl)-trifluoroacetamide (BSTFA) and 100 μL of acetonitrile in a silylation vial (4*b*).

The gc–ms analyses were performed using a Finnigan Model 3300 gas chromatograph – mass spectrometer. Electron ionization (EI) spectra were obtained at an ionizing voltage of 70eV and the chemical ionization (CI) spectra were obtained using methane as the reagent gas. The chromatographic conditions were as follows: temperature program, 80–240°C at 4°C/min; injector temperature 250°C; detector temperature 280°C; air flow rate: 300 mL/min; hydrogen flow rate: 30 mL/min; and

nitrogen flow rate: 30 mL/min. In the CI mode methane was used as the carrier gas for gc separation with a flow rate ca. 20 mL/min while the source pressure was optimized at 800 μm. Spectra were recorded at a rate of 2 s per scan. Accumulation of spectra and data manipulation were performed using a Finnigan Model 2300 INCOS data system.

The sonolytic degradation products were identified using both CI and EI mass spectra. Whenever possible final confirmation was made by comparison with authentic samples.

Materials

Uracil (Aldrich Chemical Co.) and 5-bromouracil (ICN·K&K Laboratories, Inc.) were recrystallized from triply distilled water before use. Urea (McArthur Chemical Co. Ltd.), alloxan, parabanic acid (Eastman Kodak Co.), isobarbituric acid, barbituric acid (Sigma Chemical Co.), and *p*-dimethylaminobenzaldehyde (J. T. Baker Chemical Co.) were used without further purification. BSTFA, acetonitrile, Pyrex columns (approximately 1.5 × 2 mm id), silylation vials, and column packing (8% SE-30 on AW-DMCS Chromosorb W, 80–100 mesh) were purchased from Chromatographic Specialties (Brockville, Ont.). Reagent grade tertiary butanol (Fisher Scientific Co.) was used without further purification.

The water used in this study was prepared by distillation of previously deionized water from alkaline permanganate followed by acidic perchromate solutions. All glassware used in these experiments was baked at 650°C before use.

Results and Discussion

The degradation products observed when 2 m*M* uracil solutions are insonated at 630 kHz for 80 min are dependent to some extent upon the gas used to saturate the aqueous solutions. In the presence of air or oxygen, eight degradation products have been identified: *N*-formyl-*N'*-glyoxylurea (**6**), uracil glycols (**7**), isobarbituric acid (**8**), 5-hydroxyhydantoin (**9**), dialuric acid (**10**), alloxan monohydrate (**12**), parabanic acid (**13**), and oxaluric acid (**14**). In the presence of nitrogen or argon six compounds were identified: uracil glycols (**7**), isobarbituric acid (**8**), 5-hydroxyhydantoin (**9**), dialuric acid (**10**), alloxan monohydrate (**12**), and either 6-hydroxy-5,6-dihydrouracil (**17**) or 5-hydroxy-5,6-dihydrouracil (**18**). Absorbance measurements showed that uracil was 74% degraded in the presence of air in a closed system without continuous air saturation and 60% with continuous gas saturation during insonation. The extent of degradation in oxygen was 52%, argon 49%, and nitrogen 10%, respectively. A pH decrease was observed during insonation under all conditions: from 6.5 to 3.4 in air; from 6.4 to 4.0 in oyxgen; and from 6.3 to 4.4 in argon or nitrogen. The degradation of 20 m*M* uracil solutions insonated in the presence of air for 80 min in a closed system was only 14% with an accompanying decrease in pH from 6.4 to 3.6. However, the products were found to be similar to those found at concentrations of 2 m*M*.

Figure 1 is an example of a reconstituted gc spectrum of the degradation products of uracil, in this case after 80 min insonation in a closed system

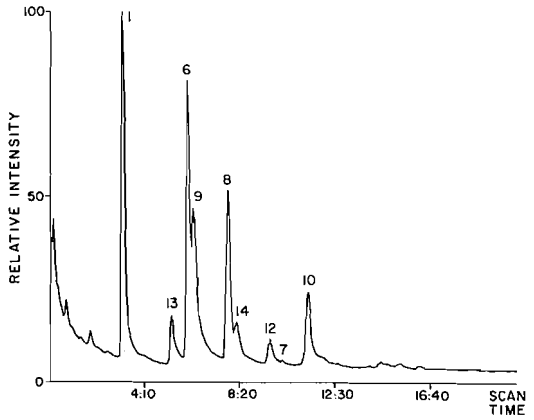

FIG. 1. A gc spectrum of 2 m*M* uracil insonated at 630 kHz for 80 min in the presence of air in a closed system. The gc conditions are given in the text. (Methane as the carrier gas.)

under air. It is very similar to that obtained when air is bubbled through continuously except that more parabanic acid and uracil glycols are present. Shorter insonation periods resulted in less degradation and a smaller pH drop, e.g. 30 min insonation in a closed system resulted in 27% degradation and a pH decrease from 6.4 to 3.8; however, the product profile is similar. Longer insonation periods resulted in almost complete conversion with 97% degradation in 120 min. The addition of tertiary butanol resulted in scavenging of the primary radicals and only 2% degradation in 80 min under argon; the pH change was unaffected by the lack of degradation. The relative product yields under a variety of conditions are given in Table 1.

The gc spectrum of the degradation products of 2 m*M* 5-bromouracil (**19**) insonated at 630 kHz for 80 min in the presence of air in a closed system is shown in Fig. 2; here the conversion is 59% and the pH dropped from 5.7 to 2.8. Six compounds were identified: 5-bromobarbituric acid (**20**), dialuric acid

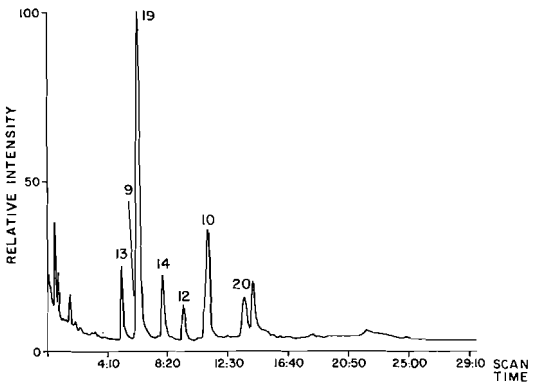

FIG. 2. A gc spectrum of 2 m*M* 5-bromouracil insonated at 630 kHz for 80 min in the presence of air in a closed system. The gc conditions are given in the text. (Methane as the carrier gas.)

Uracil glycols	3	0.5	1		7	4	15	12	
Dialuric acid	7	9	6	4	8	12	7	12	27
5-Bromobarbituric acid									10
Unidentified compounds	19	2.5	7	12	5	4	6	7	22

[a]Calculations are based on taking the peak heights of the gc spectra. Estimates obtained from gc peak height for unreacted uracil and from absorbance loss of uracil due to sonolytic degradation differ by 10–15% from previous method.
[b]These two gc peaks cannot be resolved. Mass spectra indicate major component is alloxan monohydrate.
[c]The gc peaks of these isomers and isobarbituric acid are unresolvable. Mass spectra show the latter is the major component.
[d]The gc peak of 5-hydroxyhydantoin is masked by that of 5-bromouracil.

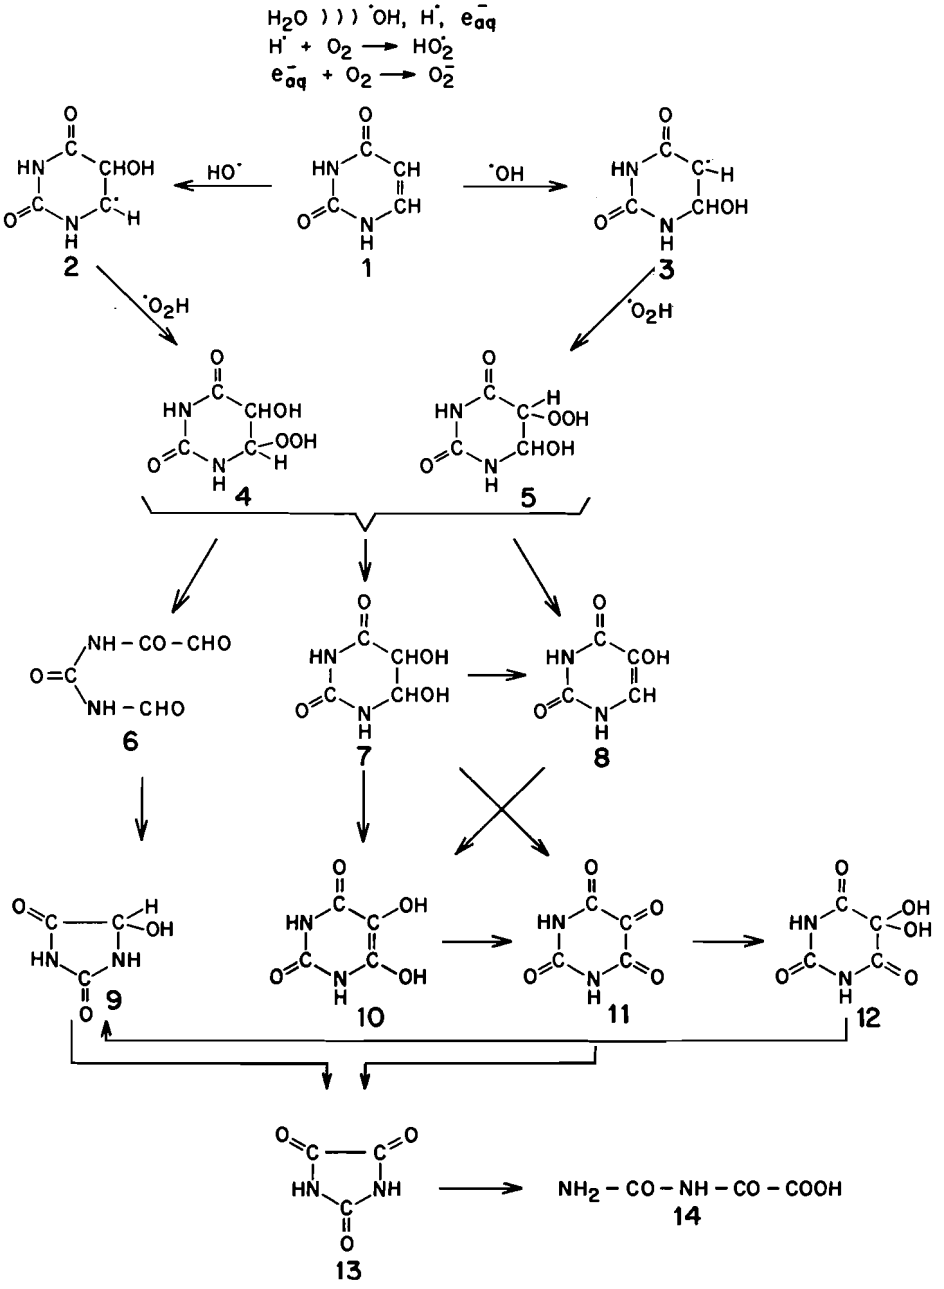

FIG. 3. Proposed sonolytic mechanism of degradation of aqueous uracil solutions in aerated state.

(**10**), alloxan monohydrate (**12**), parabanic acid (**13**), oxaluric acid (**14**), and 5-hydroxyhydantoin (**9**). The peak for **9** overlaps that of **19** but its presence was confirmed by its mass spectrum. Attempts to identify urea using *p*-dimethylaminobenzaldehyde (23) were negative.

The sonolytic degradation products of uracil under aerated conditions are quite similar to those reported (12, 14) for radiolytic degradation in air and this suggests that the mechanism of degradation may be similar. A sonolytic mechanism for uracil in the presence of air or oxygen is summarized in Fig. 3 and described as follows:

During cavitation the primary species produced are $OH^{\cdot}$, $H^{\cdot}$, and e^-_{aq} and in the presence of air (oxygen) the following two reactions occur.

[1] $e^-_{aq} + O_2 \rightarrow O_2^-$

[2] $^{\cdot}H + O_2 \rightarrow HO_2^{\cdot}$

The initial step in sonolysis under these condi-

For personal use only.

tions is the addition of an hydroxyl radical across the 5,6 double bond of uracil (**1**) to form the adducts **2** and **3**, which is followed by $HO_2^{\cdot}$ reacting with the radical adducts to form the hydroperoxides **4** and **5**. These give rise to the uracil glycols (**7**) by the loss of oxygen.[3] Isobarbituric acid (**8**) could be formed by two distinct pathways, from the hydroperoxides by the loss of hydrogen peroxide or from uracil *cis*-glycol by the loss of water. *N*-formyl-*N'*-glyoxylurea (**6**) is a major degradation product in contrast with the radiolytic results (11, 14). It probably results from ring opening of the hydroperoxides since it is not observed in the absence of oxygen, i.e., sonolysis in the presence of N_2 or Ar.

Dialuric acid (**10**) could be produced both by the dehydrogenation of uracil glycols or by the oxidation of isobarbituric acid (24). Alloxan (**11**), detected in radiolysis (12, 14) studies was not found in sonolysis, but its monohydrate (**12**) was. Compound **11** could be an oxidation product of dialuric acid (24), the yield of which is lowered by oxygen, but it could also be formed through dehydrogenation of uracil glycols.

5-Hydroxyhydantoin (**9**) may be derived from the peroxides through *N*-formyl-*N'*-glyoxylurea (10) and also from alloxan monohydrate through a rearrangement process since it was still observed in the absence of oxygen where peroxides are not formed.

Parabanic acid (**13**) may arise from oxidation of 5-hydroxyhydantoin (10) or from rearrangement of alloxan (24). Further hydrolysis of parabanic acid would lead to open chain products like oxaluric acid (**14**).

One of the major differences between the degradation products in radiolysis and sonolysis is the lower yield of uracil glycols in the latter. This may be explained by a faster transformation into isobarbituric acid under acidic conditions (8). Urea and formylurea were both detected in radiolysis (12, 14) but not in sonolysis. It has been reported (3) that the amount of urea formed decreases with increasing insonation time but neither urea nor formylurea were detected when uracil was insonated for 30 min. The acidic condition arising from sonolysis may accelerate their decomposition, but authentic samples were stable under the same pH conditions in the absence of an ultrasonic field and could be detected. This leads one to conclude that the non-detection of urea and formylurea may be due to condensation reactions from *N*-formyl-*N'*-glyoxylurea and may also explain the rather high yields of the latter.

[3]The sterochemistry of these glycols can be either *cis* or *trans* but these cannot be distinguished by the gc–ms technique.

In the absence of oxygen fewer degradation products are detected in sonolysis than in radiolysis (8, 14). A suggested mechanism is shown in Fig. 4 and the rationale is as follows. Since oxygen is absent then hydrogen atoms and hydrated electrons are present in addition to hydroxyl radicals (cf. eqs. [1] and [2]). Hydroxyl radical attack on the 5,6 double bond of uracil occurs as before producing the adducts **2** and **3**. However, since no HO_2 radicals are present to scavenge adducts, these undergo the disproportionation observed in radiolysis (14, 25, 26) to form uracil (**1**) or uracil (**1**) and its glycols (**7**). This would also account for the lower conversion of uracil. Isobarbituric acid (**8**), dialuric acid (**10**), and alloxan (**11**) or alloxan monohydrate (**12**) can arise from uracil glycols as before and 5-hydroxyhydantoin (**9**) from alloxan monohydrate. *N*-formyl-*N'*-glyoxylurea, parabanic acid, and oxaluric acid are not formed because of the lack of oxygen.

Either 6-hydroxy-5,6-dihydrouracil (**17**) or its isomer (**18**) may occur through addition of a water molecule to the hydrogen uracil adducts **15** and **16** in the presence of H_2O_2 (14). Both of these isomers can be derived by attack of either an hydrated electron or hydrogen atom on uracil (14). Both products **17** and **18** are formed in radiolytic studies (14). While the fragmentation pattern of these compounds may be different, it is difficult to establish in this case since **17** or **18**, or a mixture of both, overlaps with **8** which is a major component. However, it has been stated (27) that the 5-hydrogen uracil adduct is more stable than the 6-hydrogen uracil adduct in radiolysis. No evidence has been obtained for the formation of dimers although they have been observed in radiolysis. Some of higher molecular weight species were observed in the mass spectra but we have not yet identified them.

Six products have been identified in the sonolysis of 5-bromouracil (**19**) in the presence of air. They are dialuric acid (**10**), 5-bromo-barbituric acid (**20**), alloxan monohydrate (**12**), parabanic acid (**13**), oxaluric acid (**14**), and 5-hydroxyhydantoin (**9**). On the basis of these degradation products the mechanism proposed for the sonolysis of uracil in air has to be modified to account for the isolation of **10** and **20**. These can be derived from the bromine-containing analogue of **7**, 5-bromo-5,6-dihydroxy-dihydrouracil. Dialuric acid (**10**) would be formed by the elimination of hydrogen bromide and **20** by the loss of water from the glycol. The other products can be accounted for as in the scheme for uracil (Fig. 3). The lower sonolytic conversion is likely due to the electron withdrawing effects of bromine (5). The pH drops have previously been observed

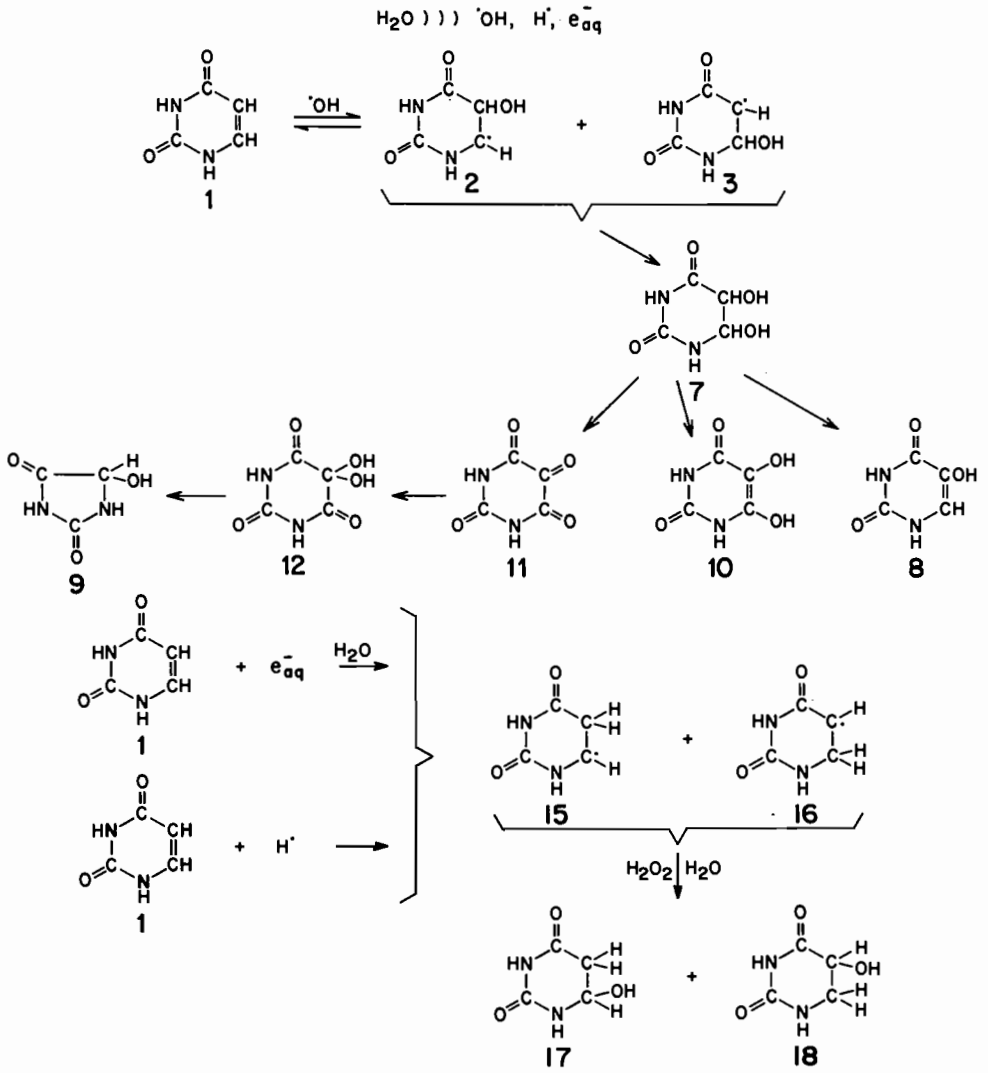

FIG. 4. Proposed sonolytic mechanism of degradation of aqueous uracil solutions in deaerated state.

in the sonolysis of water alone (28) but some of the identified products could accentuate the increase in acidity.

Finally, other work in this laboratory (4) has shown that a train of gas bubbles in a sonic field can have a detrimental effect on cavitation. For short insonation periods (<15 min), it has been found that conversion is reduced under these conditions compared with simply presaturating the solution for long periods and insonating in the absence of a continuous gas stream. However, for long insonation periods, the latter procedure does not assure a steady state concentration of dissolved gas because of degassing. This may explain the different conversions reported between closed and open systems. Furthermore, since it was very difficult to control the bubble flow of gases, the values of conversion as calculated from absorbance data may not be quite comparable under different gases. However, it is interesting to note that there is a difference in sonolytic effects of dissolved gases observed in this study (air > O_2 > Ar > N_2) and others (2,5) (Ar > O_2 > air > N_2).

An experimental evaluation of nonselective proton spin–lattice relaxation rates: analyses of data for the eight isomeric 2,3,4-tri-*O*-acetyl-1,6-anhydro-β-D-hexopyranoses[1]

KLAUS BOCK,[2,3] LAURANCE D. HALL, AND CHRISTIAN PEDERSEN[3]

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received January 4, 1980

KLAUS BOCK, LAURANCE D. HALL, and CHRISTIAN PEDERSEN. Can. J. Chem. **58**, 1916 (1980).

The nonselective spin–lattice relaxation rates (R_1-values) have been determined for all of the ring protons of the eight isomers of 2,3,4-tri-*O*-acetyl-1,6-anhydro-β-D-hexopyranose as 0.1 molar solutions in benzene-d_6. The effects on the proton R_1-values of changes in solvent, concentration, temperature, and proton impurities are documented and ^{13}C R_1-values are given to show that the first two sets of variations are due to changes in motional correlation times of the molecules. The proton relaxation data can be fitted by regressional analyses to a single set of interproton relaxation contributions, the numerical values of which accord with a $^1C_4$ conformation for the pyranose ring somewhat distorted by the 1,6-anhydro bridge.

KLAUS BOCK, LAURANCE D. HALL et CHRISTIAN PEDERSEN. Can. J. Chem. **58**, 1916 (1980).

On a déterminé les vitesses de relaxation spin–réseau non sélectives (valeur R_1) de tous les protons du cycle des 8 isomères du tri-*O*-acétyl-2,3,4 anhydro-1,6 β-D-hexopyrannose dans des solutions 0.1 molaire dans le benzène-d_6. On a étudié les effets des variations du solvant, de la concentration, de la température et des impuretés du proton sur les valeurs R_1 des protons et on donne les valeurs R_1 du ^{13}C pour montrer que les deux premiers ensembles de variation sont dus aux changements des temps de corrélation du mouvement des molécules. Les données de relaxation du proton peuvent s'adapter par analyse régressive à un ensemble simple de contributions de relaxation interproton, dont les valeurs numériques sont en accord avec une conformation $^1C_4$ du cycle pyrannose quelque peu déformée par le pont anhydro-1,6.

[Traduit par le journal]

Introduction

Previous studies (2) have demonstrated that the spin–lattice relaxation rates of the protons of complex organic molecules can be measured under conditions where the intramolecular dipole–dipole mechanism provides the dominant source of relaxation. Under these circumstances, the nonselective relaxation rate of any proton or any set of equivalent protons, $R_1^A(NS)$ can be represented by the summation

$$R_1^A(NS) = \frac{3}{2}\left(\sum_i \rho^A_{(i\rightarrow A)}\right)$$

where the terms $\rho_{i\rightarrow A}{}^A$ represent the specific relaxation contributions between A and the other protons. One of the principal purposes of this study is to show that these interproton relaxation contributions can be obtained by a regressional analysis of the nonselective relaxation rates of a series of configurationally related compounds. The eight possible isomers of the 2,3,4-tri-*O*-acetyl-1,6-anhydro-β-D-hexopyranoses were eminently suitable substrates for several reasons, but principally because they each give 100 MHz spectra, in benzene-d_6 solutions, which are sufficiently dispersed to allow the R_1-value of almost every proton to be separately determined.

It is appropriate to preface a discussion of these data with a brief summary of the various assumptions which are implicit in this approach and which have to be either confirmed or eliminated by suitable quality-control experiments. The first requirement is that it should be possible to properly define a spin–lattice relaxation rate for a scalar-coupled proton. We shall initially assume that the initial slope approximation (3) of the total magnetization intensity of the components of a multiplet resonance satisfies that requirement. The second requirement is that it is possible to intercompare data obtained from different molecules measured at different times in different solutions. This requirement has been tested by a series of independent quality-control experiments and has been fully justified. As will be seen, this aspect of our work provides the second major theme for this study; surprisingly, we can find no equivalent evidence in the literature. Several additional assumptions are also pertinent to any attempts to use these interproton ρ-values as the basis of structural assignments and although they are not of principal concern here, they will be briefly discussed towards the end of this paper.

It is also appropriate to summarize in eq. [1] a simplified formulation for the intramolecular dipole–dipole mechanism which applies equally well

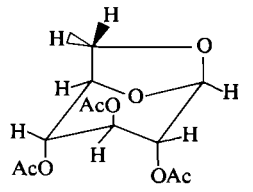
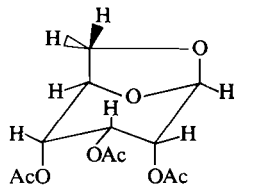
to the ^1H and ^{13}C relaxation rates to be discussed here.



$$[1]\quad \frac{1}{T_1^A} = R_1^A = C \cdot \tau_c \cdot \left(\sum_i r_{A,i}^{-6}\right)$$

Discussion and Results



The first series of experiments intended to document the variations in proton R_1-values which accompany changes in solvent, solute concentration, and temperature used 2,3,4-tri-*O*-acetyl-1,6-anhydro-β-D-mannopyranose (**1**) as solute.

The data in Table 1 illustrate the variations of R_1-values[4] as the solvent is varied from benzene-d_6, to acetone-d_6, to chloroform-d, to dimethylsulphoxide-d_6, with the concentration of **1** held constant at 0.1 *M*; only one of several possible series of comparisons is emphasised in the table. These data demonstrate the rather substantial effect of solvent changes on ^1H R_1-values; for the H-1 resonance, the value changes from 69 ms^{-1} in acetone-d_6 to 143 ms^{-1} in dimethylsulphoxide-d_6. The clear inference here is *that comparisons between different molecules can only be made for data obtained in the same solvent*,[5] and, although we provide no experimental documentation here, it is obvious that the solutions used should all be free of paramagnetic impurities, including dissolved oxygen.

Using the same solute (**1**) a series of solutions in benzene-d_6 were prepared, with concentrations 0.05, 0.1, 0.2, 0.5, and 1.0 *M*. An almost linear increase in relaxation rate with increase in concentration was observed and these data are summarized in Table 2. It follows from this experiment *that comparisons between molecules in different solutions should be conducted at a standardized concentration*, but that if the concentration has to be varied for any reason, it may be possible to make an interpolative correction.

Using a 0.1 *M* sample of **1** in benzene-d_6 the effects of variation of the temperature were also studied.

The results are presented in Table 3 and it is clearly seen *that comparisons of data between different molecules should be conducted at the same temperature*.

If the relaxation of the protons of **1** occurs exclusively via the dipole–dipole mechanism, then two sources are possible for the above variations: either the correlation time of the molecules is dependent on the solvent, concentration, and temperature, or *inter*molecular relaxation is making a substantial contribution; or possibly both effects are operating simultaneously. We shall now provide evidence which suggests that the former effect is the dominant one.

It is well known (4) that ^{13}C spin–lattice relaxation rates provide a qualitative measure of the motional correlation time of a molecule. Without going into great detail here, the relaxation rates listed in Table 4 imply two points. First, that 2,3,4-tri-*O*-acetyl-β-D-mannopyranose (**1**) tumbles isotropically in solution; thus the ring carbon atoms bearing a single proton have essentially identical R_1-values, whereas C-6, which bears two protons, relaxes approximately twice as fast. More important for the

[4]Throughout this work, (ms^{-1}) is used in abbreviation for (s^{-1}) × 10^{-3}. Thus an R_1-value of 200 ms^{-1} is equivalent to a value of 0.2 s^{-1}; the equivalent relaxation time is 5 s.

[5]A referee suggested that there will probably be better agreement between the T_1's in *some* of the solvents studied if a correction is made for their different viscosities. We concur with this statement, but draw attention to the need to specify only "some" solvents. With this reservation in mind we do not recommend the practice of using macroscopic viscosities to correct for changes in a *molecular* event.

present discussion is the fact that the ^{13}C R_1-values show quantitatively the same trend as the proton values, increasing as the solvent is changed from acetone, to benzene, to chloroform, to dimethylsulphoxide. If the changes in ^1H R_1-values had been solely due to solvation effects then only minor changes would have been anticipated in the relaxation rates of the ^{13}C nuclei, each of which is effectively shielded by its proton substituent.

Although the above evidence clearly indicates the importance of changes in molecular correlation times on the observed R_1-values, it seemed worthwhile attempting to measure any *inter*molecular relaxation for **1** in benzene-d_6 solution. It is well known that benzene preferentially solvates organic molecules which bear a carbonyl substituent and thus makes it more likely that intermolecular relaxation from the solvent may occur.

TABLE 5. Proton spin–lattice relaxation rates (ms^{-1}) for 2,4,5-tri-*O*-acetyl-1,6-anhydro-β-D-mannopyranose (**1**) showing the effects of added C_6H_6 on a solution in C_6D_6

Solvent[a]	H-1	H-2	H-3	H-4	H-5	H-6	H-6′
C_6D_6 (99.5%)	112	224	191	220	213	658	645
C_6D_6 + 5% C_6H_6	112	220	194	212	215	680	680
C_6D_6 + 50% C_6H_6[b]	136	243	214	227	234	680	680

[a]All solutions were 0.1 M.
[b]Values ±15% (see footnote [5] in text).

Accordingly the proton R_1-values were determined for **1** in three separate benzene-d_6 solutions, each 0.1 *M* in **1** and containing respectively 0.5% C_6H_6, 5% C_6H_6, and 50% C_6H_6. The latter concentration corresponds to ca. 10 *M* C_6H_6, hence these three solutions contained molar ratios of **1**/C_6H_6 of approximately 1, 10, and 100. Although the design of this experiment is not flawless (for example, it is assumed that **1** has the same correlation time in a C_6H_6 and a C_6D_6 solution), the data given in Table 5 are, nevertheless, of interest. Even a 100-fold excess of C_6H_6 only increases the relaxation rate of the ring protons of **1** by ca. 11%.[6] We infer from these results that the relaxation of **1** is largely dominated by the intramolecular mechanism even in the presence of ca. 10 *M* C_6H_6, and in 99.5% C_6D_6 this statement must be even closer to reality. Of course, this experiment tells us nothing about *inter*-molecular interactions between individual molecules of **1**; we shall return to this point at the end of this section.

Thus providing that both solvent and solute concentration, along with temperature and paramagnetic impurities, are held constant it should be possible to compare the proton relaxation data of a series of molecules whose size and overall conformational symmetry are similar. The data for the isomeric derivatives **1**–**8** summarized in Table 6 clearly support this conclusion.

These data can be used in several different ways. In the present discussion we wish to illustrate a simple, almost naive, level of intercomparisons which we hope will illustrate the very direct relationships which exist between molecular configuration and nonselective proton relaxation rates, and we have deliberately chosen to avoid more comprehensive forms of regressional analysis for the present.

According to the simplified formulation for the dipole–dipole relaxation mechanism, the relaxation efficiency between two protons of an isotropically tumbling molecule falls off as the sixth power of the interproton separation (eq. [1]). It follows then, that nearest-neighbour, proton–proton interactions will be the dominant source of relaxation contributions. In the present system, the relaxation of H-1 should be dominated by the contribution from H-2; and to a first approximation 2/3 $R_1{}^1$ will be equal to $\rho_1{}^1(2 \rightarrow 1)$. The $R_1{}^1$-values for the compounds cited in Table 6 fall between 104 and 120 ms^{-1} with a mean value of 111 ms^{-1} which implies that the nearest neighbour approximation is an adequate one. By the same token the relaxation of H-2 should now be dominated by contributions from both H-1 and H-3, thus

$$2/3\, R_1{}^2 = \rho_1{}^2(1 \rightarrow 2) + \rho_1{}^2(3 \rightarrow 2)$$

Since $\rho_1{}^1(2 \rightarrow 1) = \rho_1{}^2(1 \rightarrow 2)$ and we already have a value for the former, it is a trivial matter to calculate the value of $\rho_1{}^2(3 \rightarrow 2)$. For H-2 the situation can be somewhat more complex because it is feasible, in e.g. compounds **4** and **6**, for H-2 to receive an additional relaxation contribution from H-4; but this contribution would depend on the configurations at C-2 and at C-4 and would be detectable when the arithmetic was performed for several compounds.

It is possible with a computer program[7] to make a least-squares fit to a set of equations of this type using the relaxation contributions listed in Table 7. Without labouring individual intercomparisons further, it is interesting to see the results in Table 6 (calculated values) of this trivial form of regressional analysis. The agreement between the observed relaxation rates and the "calculated" values is very close indeed.

Only compound **3**, 2,3,4-tri-*O*-acetyl-1,6-anhydro-β-D-allopyranose, differs substantially more from the observed values than the experimental error (±5%) (Table 6). This could be explained by an extra degree of freedom in the motion of this molecule, e.g. a conformational equilibrium between different twist forms for the 6-membered

[6]This experiment can only be considered accurate within ±15%, because of dynamic range problems due to the large signal from C_6H_6.

[7]A basic program was written by Mr. H. Thøgersen for BNC-12 computers. This program will estimate the best fit (using a least-squares fit) to n unknowns in $n + x$ ($x \geq 1$) equations.

ring. This could cause the proton–proton distances to be changed, but a conformational equilibrium could also offer an alternative source of relaxation (5). This explanation is supported by an X-ray examination of 1,6-anhydro- β-D-allopyranose (6), which shows that this compound even in the crystal adopts three different conformations with the 6-membered ring flattened.

The interproton relaxation contributions obtained from the above regressional analyses are summarized in Table 7. These values include contributions from the acetate methyl protons. These latter contributions are readily detectable in a comparison of the R_1-values of **2** with those of its 2,3,4-tri-*O*-(*trideuteroacetyl*) derivative (Table 8). In concluding this paper we wish to mention three additional experiments which both support and extend the above discussions.

It is now possible to measure a *selective* R_1-value for any well resolved resonance **1**: simply, a selective 180°-pulse is applied to the resonance of interest and then the rate of recovery of the magnetization of that resonance is monitored in the usual fashion with a nonselective 90° (7). Theory states (8) that the ratio of this value, compared with the value obtained via a conventional, nonselective inversion–recovery experiment will be 1.5:1 if all of the relaxation of that proton comes from the dipole–dipole mechanism,[8] if none of its relaxation is dipolar then the ratio will be unity. The ratios found for the H-1 and H-4 resonances of **1** in 0.1 *M* deuterobenzene-d_6 solution were 1.46 and 1.50. It seems reasonable to infer from this experiment that the relaxation of all the protons of **1**, and by inference of all of the protons of the other seven isomers, are mediated by the dipole–dipole mechanism; and on the basis of the data given in Table 5 it

[8]The relationship between this experiment and the nuclear Overhauser effect is not accidental.

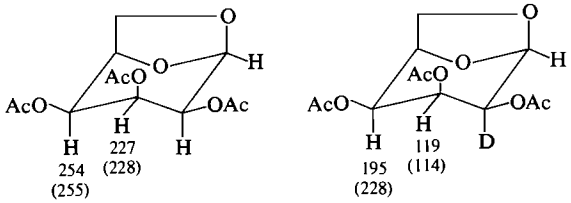

TABLE 9. Comparison of the proton spin–lattice relaxation rates (ms^{-1}) of 2,3,4-tri-*O*-acetyl-1,6-anhydro-β-D-mannopyranose (**1**) in C_6D_6 solution (0.1 *M*) measured at 100, 90, 270, and 300 MHz[a]

Observing frequency	H-1	H-2	H-3	H-4	H-5	H-6	H-6′
100 MHz 35°C	112	224	191	220	213	658	645
90 MHz 25°C	134 (1.20)	259 (1.15)	229 (1.20)	259 (1.18)	251 (1.18)	802 (1.22)	775 (1.20)
270 MHz 25°C	134 (1.20)	258 (1.15)	225 (1.18)	256 (1.16)	252 (1.18)	799 (1.21)	762 (1.18)
300 MHz 27°C	138 (1.23)	266 (1.19)	239 (1.25)	273 (1.24)	272 (1.28)	855 (1.30)	826 (1.28)

[a] Values in parentheses are the ratios to the values measured at 100 MHz.

also seems reasonable to infer that *intra*molecular dipole–dipole relaxation is dominant.

In a separate experiment, the magnitudes of several of the interproton relaxation contributions were confirmed by examination of a specifically deuterated analog, 2,3,4-tri-*O*-acetyl-2-deutero-1,6-anhydro-D-talopyranose (**4**), which was kindly provided by Professor H. Paulsen (Hamburg). The relaxation data for that compound are appended to the structural formula below.

Comparison between these data and those of the normal compound with a proton at C-2 gave a direct estimate of the interactions from H-2 to H-3 and H-4; the figures obtained by regressional analysis are listed in parentheses. The use of specific deuteration in relaxation studies of carbohydrates has been discussed in detail elsewhere (9).

Finally, the relaxation rates for **1** at 300 MHz, using a Varian SC300 spectrometer, at 270 MHz, using a Bruker HX-270 spectrometer, and at 90 MHz, using a Bruker WH-90 spectrometer are summarized in Table 9, together with their ratios to the corresponding values measured at 100 MHz. It can be seen that the ratios are essentially constant, proving that it is possible to determine and compare relaxation rates reliably even if they are obtained on different spectrometers.

Conclusions

The data reported here indicate that it is feasible to intercompare the proton spin–lattice relaxation rates of a series of organic molecules in separate solutions. It is necessary to work in a common solvent, at constant concentration and temperature, and care must be taken to exclude paramagnetic impurities, including dissolved oxygen. This finding has a number of important implications. It means that it is possible to intercompare proton R_1-values in much the same way as chemical shifts and coupling constants, ascribing observed changes to specific chemical or stereochemical differences between the compounds. It also implies that regressional analysis methods can be used to evaluate relaxation data obtained from a series of compounds; this complements methods based on either specific deuteration (8) or multiple, selective-pulse relaxation determinations (2).

Experimental

The preparation of samples, the measurements of spin–lattice relaxation rates, and the subsequent data processing all followed procedures described previously (9).

Samples of the derivatives were available from other studies.

A survey of the proton spin–lattice relaxation rates of selected furanose derivatives[1]

KLAUS BOCK,[2] LAURANCE D. HALL, AND CHRISTIAN PEDERSEN[2]

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received January 4, 1980

KLAUS BOCK, LAURANCE D. HALL, and CHRISTIAN PEDERSEN. Can. J. Chem. **58**, 1923 (1980).

The non-selective proton spin–lattice relaxation rates of 3,5-di-*O*-acetyl-2,6-dibromo-2,6-dideoxy-D-mannono (**1**), or -glucono (**2**), 1,4-lactone, methyl-α,(β)-D-ribofuranoside (**3**), methyl-α,(β)-D-arabinofuranoside (**4**), methyl-α(β)-D-xylofuranoside (**5**), 3,5-di-*O*-acetyl-1-*O*-benzoyl-2,6-dibromo-2,6-dideoxy-α and β-D-mannofuranose (**6**) and (**7**), 3,5-di-*O*-acetyl-6-bromo-2,6-dideoxy-D-*arabino*-1,4-lactone (**8**), and 2,3,5,6-tetra-*O*-acetyl-1,4-anhydro-D-mannitol (**9**) have been measured at 270 MHz. Substantial differences are found for the R_1-values of epimeric pairs of substances which can be used for structural evidence. The anomalous R_1-values in deuteriochloroform for the H-2, H-3, and H-4 resonances of **1** are discussed.

KLAUS BOCK, LAURANCE D. HALL et CHRISTIAN PEDERSEN. Can. J. Chem. **58**, 1923 (1980).

On a mesuré à 270 MHz les vitesses de relaxation spin–réseau non sélectives du proton des composés suivants: di-*O*-acétyl-3,5 dibromo-2,6 didéoxy-2,6 D-mannono (**1**) ou glucono (**2**) lactone-1,4; α(β)-D-ribofurannoside de méthyle (**3**); α(β)-D-arabinofurannoside de méthyle (**4**); α(β)-D-xylofurannoside de méthyle (**5**); di-*O*-acétyl-3,5 *O*-benzoyl-1 dibromo-2,6 didéoxy-2,6 α et (β)-D-mannofurannose (**6**) et (**7**); di-*O*-acétyl-3,5 bromo-6 didéoxy-2,6 D-arabino lactone-1,4 (**8**) et tétra-*O*-acétyl-2,3,5,6 anhydro-1,4 D-mannitol (**9**). On a trouvé des différences importantes pour les valeurs R_1 des paires de substances épimères qui peuvent être utilisées comme preuves de structure. On discute des valeurs R_1 anormales des résonances des protons en positions 2, 3 et 4 dans le deutériochloroforme.

[Traduit par le journal]

Introduction

Although many unambiguous methods are available for assigning the configurations and conformations of pyranose sugars in solution, application of those same techniques to furanose derivatives is often less satisfactory, and in many instances the results are ambiguous. For example, measurements (2) of proton (^{1}H) vicinal coupling constants and chemical shifts have met with variable success as have equivalent studies (3) based on natural abundance carbon-13 (^{13}C) nuclear magnetic resonance (nmr) spectra.

Encouraged by the substantial differentials which have been observed in the proton spin–lattice relaxation rates (R_1-values) of many families of pyranose sugars (4–6) we have undertaken a survey of the R_1-values of epimeric pairs of furanose sugars which were available from other studies. Two reports (7, 8) describing the same type of measurements on furanose derivatives have recently been published.

It will be recalled (9) that the spin–lattice relaxation[3] of most protons of diamagnetic organic molecules appears to be dominated (10) by the intramolecular dipole–dipole mechanism (11), the form of which is given in eq. [1], where R_1^A(NS) is the composite, nonselective relaxation rate of a nucleus A, separated by a distance (r_{AB}) from another nucleus B located in the same molecule. As a result, interproton relaxation contributions fall very rapidly with increase in internuclear distance

$$[1] \quad R_1^A(\mathrm{NS}) = 3/2\hbar^2\gamma_A^2\gamma_B^2\, T_c(A-B) r_{AB}^{-6}$$

and hence composite proton relaxation rates are dominated by nearer neighbour interactions. From this it follows that any structural change, such as inversion of configuration at an individual carbon atom, which causes changes in interproton distances should cause detectable changes in the R_1-values of protons which are spatially close to that centre; and as a corollary it follows that the R_1-values of protons remote from that centre should remain unchanged.

As will be seen below, several series of furanose derivatives accord with the above expectation and it seems reasonable to infer that proton R_1-values can provide valuable new structural information for such derivatives.

Results and Discussion

The primary structures of derivatives **1** and **2** have been previously assigned by unambiguous chemical interconversions (12) and also by ^{1}H and ^{13}C nmr spectroscopy, the vicinal ^{1}H—^{1}H coupling constants of both epimers (Table 1) showing the values anticipated for molecules which favour the $^3T_4$ conformation (**A**). That the R_1-values of H-5,

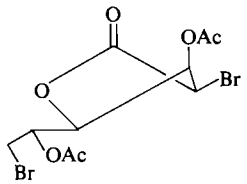
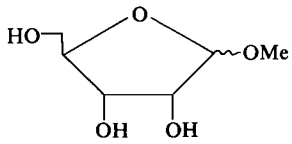
TABLE 1. Chemical shifts (δ-values), $^1H—^1H$ coupling constants (Hz), and proton spin–lattice relaxation rates (R_1-values, $s^{-1} \times 10^3$) for derivatives **1** and **2** measured at 270 MHz in deuteriobenzene solution (0.1 *M*) at 293 K

Compound	Parameter	Proton H-2	H-3	H-4	H-5	H-6	H-6′
1	δ-value	4.90	5.87	4.86	5.28	3.73	3.68
	J-value	$J_{23} = 5.0$	$J_{34} = 3.5$	$J_{45} = 9.5$	$J_{56} = 3.0$	$J_{56'} = 3.7$	$J_{66'} = 12.0$
	R_1-value	278	345	333	303	833	909
2	δ-value	4.16	5.52	5.09	5.31	3.79	3.67
	J-value	$J_{23} = 0$	$J_{34} = 3.4$	$J_{45} = 9.6$	$J_{56} = 3.0$	$J_{56'} = 4.2$	$J_{66'} = 12.0$
	R_1-value	137	250	270	263	833	833

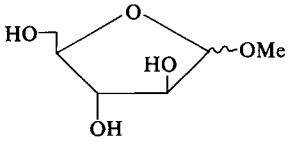


H-6, and H-6′ are closely similar for both compounds immediately suggests that they both tumble in solution with approximately the same motional correlation time (which was subsequently confirmed by the ^{13}C R_1-values, *vide infra*). On that basis the enhancement (ca. 100%) of the R_1-value of H-2 of **1**, compared with its counterpart in **2**, can be ascribed to its *cis*-relationship with H-3. The somewhat smaller rate enhancements observed for the H-3 and H-4 resonances of **1** further confirm this configurational assignment.

1

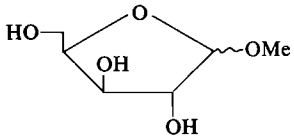


2



A

When a mixture of both anomeric forms is available, studies on the mixture can give useful structural information (4). For example, the R_1-values of the H-1 protons of anomeric mixtures of the known (13) methyl ribofuranosides (**3**), methyl arabinofuranosides (**4**), and methyl xylofuranosides (**5**) show the anticipated differentials with the *cisoid* relationship between H-1 and H-2, again resulting in an enhanced R_1-value. This dependence parallels that reported by Preston (14) for the 1,2:5,6-di-*O*-isopropylidene derivatives of α-D-gluco- and allo-furanose, and also results described in a more recent report (8).



It is interesting to note that even though R_1-values are concentration dependent (1) the ratio between the R_1-values of methyl α- and β-D-ribofuranoside is independent of the relative

3

4

5

amount of the two compounds present and of the total concentration. It furthermore appears that the ratios between the R_1-values of the anomeric pairs for arabino- and xylofuranose derivatives are almost the same as the one found for ribofuranose.

Derivatives **6** and **7** exemplify a pair of epimers for which the vicinal $^1H—^1H$ coupling constants are essentially identical (Table 3). The previous (15) assignment of the anomeric configuration was based on intercomparison of the $[\alpha]_D$-values and ^{13}C nmr chemical shifts, which implied that **6** was the α-anomer, with the interconversion of both **6** and **7** to the same glycosyl bromide being cited as evidence that the configurations at all other centers were identical.

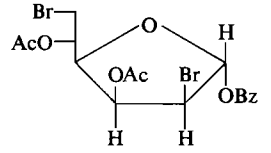
The enhanced R_1-values observed for H-1 and H-2 of **7** implied that these protons have a *cis*-relationship, in accord with the previously assigned structure.

The data for derivatives **8** and **9** demonstrate that methylene protons which, as a result of their closeness, tend to relax each other very efficiently, can pick up sufficient relaxation from other protons in the same molecule to evidence a configurational change at a vicinal carbon atom. Thus the H-2 resonances of **8**, for which an unequivocal assignment can be based on their vicinal coupling constants with H-3 (Table 3), show a 21% rate enhancement for the proton which is *cis* to H-3.

The H-1 resonances of **9** cannot be distinguished

TABLE 2. Spin–lattice relaxation rates (R_1-values, $s^{-1} \times 10^3$) for anomeric protons in derivatives **3**, **4**, and **5** measured at 270 MHz in D_2O at 300 K

Compound	Methyl D-ribofuranoside (3)		Methyl D-xylofuranoside (5)		Methyl D-arabinofuranoside (4)		Methyl[a] D-ribofuranoside (3)	
Anomer	α	β	α	β	α	β	α	β
Concentration (M)	0.3	0.3	0.3	0.3	0.4	0.2	0.3	0.5
R_1-value	318	248	308	225	252	358	385	301
Ratio $R_1 cis/R_1 trans$	1.28		1.37		1.42		1.28	



[a]Values obtained on same sample at 90 MHz at 295 K gave $R_1(\alpha) = 515$ and $R_1(\beta) = 398\ s^{-1} \times 10^3$, i.e. a ratio of 1.29.

TABLE 3. Proton chemical shifts (δ-values), ^1H—^1H coupling constants (J-values, Hz), and proton spin–lattice relaxation rates (R_1-values, $s^{-1} \times 10^3$) for derivatives **6**, **7**, **8**, and **9**, measured at 270 MHz in deuteriochloroform (0.1 M) at 293 K

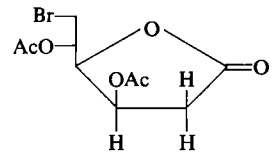
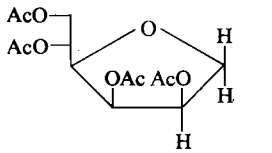
on the basis of their vicinal couplings, but it seems eminently reasonable to assign the high field resonance to H-1α merely on the basis of its enhanced R_1-value.



In all of the above experiments we have directed attention to the nonselective proton R_1-values and have ignored the various quality control experiments which can be used (9) to independently probe the validity of some of the assumptions which are implied in these simple intepretations. In the final section of this paper we shall discuss briefly two of these controls as applied to derivatives **1** and **2**.



6

7

8

9

Fundamental to any intercomparison of the proton R_1-values of an epimeric pair of substances is the assumption that both epimers tumble in solution at the same rate (actually a more rigorous condition is implied, namely that both the molecules also tumble isotropically and hence that the motional correlation times for all interproton vectors are identical; we shall ignore that extra subtlety here) (16). Previously in this discussion we used the near identity of the R_1-values of the H-5, H-6, and H-6′ protons for **1** and **2** to justify that assumption, but independent evidence from the carbon-13 R_1-values will now be cited. As we have shown elsewhere (9*c*, 17), ^{13}C R_1-values are directly proportional to the motional correlation times of the ^{13}C–^1H vectors. It follows then that the near identity of the individual ^{13}C R_1-values for **1** and **2** indicates that these substances tumble with approximately the same rates in both deuteriobenzene and deuteriochloroform (Table 4). Al-

	η-value	C_6D_6	107	107	104	111	104
	R_1-value	C_6D_6	1.92	1.69	1.67	1.67	2.86

though in this instance the R_1-values are essentially independent of the solvent, this is not invariably so. Indeed, as we have found (1) during a study of the tri-*O*-acetyl-1,6-anhydro-β-D-hexopyranoses, R_1-values in either acetone or dimethylsulphoxide solutions are very different from those in either benzene or chloroform. It follows from this that *intercomparisons between pairs of epimers must be made using a common solvent.*

A second assumption which we have not thus far questioned concerns the extent to which the protons are relaxing via the dipole–dipole mechanism. Clearly any major deviation from this assumption could irreversibly confuse interpretations of proton R_1-values. Fortunately a quantitative quality control has been developed. Briefly, the normal (18) two-pulse relaxation experiment is modified (19, 20) so that the 180°-pulse now selectively perturbs only the resonance of choice (A, say) rather than all the protons; the recovery of the magnetization of A is then monitored using the usual nonselective 90°-pulse and the resultant data processed to give the *single-selective* spin–lattice relaxation rate of A, $R_1^{A}(S)$. Theory then states (10) that if proton A is relaxing exclusively via the dipole–dipole mechanism with the other protons, the ratio of the normal nonselective R_1-value of A, $R_1^{A}(NS)$ to the single selective value, $R_1^{A}(S)$ will be 1.5. If none of the relaxation of A is mediated by the dipole–dipole mechanism then the ratio will be unity; thus the dynamic range of this ratio varies between 1 and 1.5. Our previous experience (10, 14, 19)[4] with methine and methylene protons is that 1.5 ratios are invariably obtained and it seems reasonable to assume that unless peculiar circumstances pertain, most protons in medium sized molecules can relax exclusively with other protons in the same molecule. We shall now present an apparent exception to this seemingly general rule.

As can be seen from Table 5, a change in solvent to deuteriochloroform for compounds **1** and **2** results in a drastic change of the R_1-values for H-2, H-3, and H-4 for **1** compared to the values obtained in deuteriobenzene (Table 1). In contrast to that, the R_1-values for H-5, H-6, and H-6′ for **1** and all the R_1-values for **2** are only changed as would expected *due* to a change of the solvent (1).

Selective T_1-experiments on H-2 and H-4 of **1** in deuteriochloroform gave ratios to nonselective values of 1.04. The same experiment performed on H-5 of **1** in deuteriochloroform or H-4 of **1** in deuteriobenzene gave a ratio of 1.30, whereas measurements on H-2 and H-4 of **2** in deuteriochloroform gave values of ca. 1.40. This clearly indicates that the H-2, H-3, and H-4 resonances of **1** in deuteriochloroform are availing themselves of some alternative source of relaxation or the initial slope approximation used in the evaluation of the nonselective R_1-values is seriously in error. The other protons for **1** and **2** seem, from the selective T_1-experiments, to obtain, within experimental error, most of their relaxation from protons within the same molecule. A possible source of relaxation for protons H-2 and H-4 in **1** could arise from a pseudorotation (21) of the five membered ring with a frequency component close to the resonance frequency of the nuclei, which is supported by the frequency dependence of the R_1-values (Table 5).

Conclusion

We have clearly demonstrated that epimeric pairs of furanose derivatives can be distinguished via comparison of their nonselective proton spin–lattice relaxation rates, the salient feature being the substantial enhancement of R_1-value in-

[4]L. D. Hall, K. F. Wong, and H. D. W. Hill. J. Chem. Soc. Chem. Commun. 951 (1979).

TABLE 5. Proton spin–lattice relaxation rates (R_1-values, $s^{-1} \times 10^3$) for derivatives **1** and **2** measured in deuteriochloroform solutions (0.1 *M*) at 293 K at 90 and 270 MHz. Single-selective R_1-values are indicated in parentheses, along with the calculated ratios for R_1(NS):R_1(SS)

Compound	Frequency	H-2	H-3	H-4	H-5	H-6	H-6′
1	90 MHz	769	588	667	385	1260	1240
	270 MHz	1250 (1200; 1.04)	833	1111 (1066; 1.04)	417 (325; 1.28)	1250	1250
2	90 MHz	238	370	417	417	1180	1240
	270 MHz	244 (176; 1.39)	345	370 (864; 1.40)	385	1160	1250

duced by a *cis* interaction between protons on adjacent carbons. Thus the proton relaxation method shows great promise as a powerful tool in structural studies of furanoses and further studies of other classes of these important derivatives are clearly warranted. The abnormal relaxation behaviour of some of the resonances of derivative **1** has been rationalized and although we believe that this is rather rare, it would seem prudent that any quantitative or critical structural study should incorporate, in addition to the conventional nonselective R_1-measurements, measurements of single-selective R_1-values.

Experimental

The nmr spectra were measured on Bruker HX-270 or WH-90 instruments operating in the Fourier transform mode. The ^{1}H nmr spectra at 270 MHz were obtained at 293 K using a 90° pulse of 12 μs for deuteriochloroform and deuteriobenzene samples and 17 μs for water samples (22), 16K of computer memory, and a spectral width of 3000 Hz. The ^{1}H nmr spectra at 90 MHz were obtained at 293 K using a 90° pulse of 6.5 μs, 8K of computer memory and a spectral width of 1000 Hz. The ^{13}C nmr spectra at 67.89 MHz were obtained at 305 K using a 90° pulse of 12 μs, 16K of computer memory, and a spectral width of 10 000 Hz. The ^{13}C nmr spectra at 22.63 MHz were obtained at 305 K using a 90° pulse of 16.5 μs, 8K of computer memory and a spectral width of 5000 Hz.

The T_1-experiments were performed using the inversion–recovery method (18) using the initial slope approximation ($T \leq T_1$) (10). The R_1-values were determined both from a regressional semilogarithmic fit with $T \leq T_1$ and also from an experimental fit to all the relaxation data.[5] The agreement between these two values was in general within 5%, which was also considered the experimental error.[6]

[5]Program written for BNC-12 computer in BASIC by H. Thøgersen, Lyngby, based on ref. 23.

[6]A referee queried if the 5% error estimate is reasonable; we believe that it is, at least within certain contexts (see ref. 1). Thus, the R_1-values reported here are "repeatable" within 5% when measured on the same sample, using the same spectrometer, and even with intercomparison between *different* samples on the *same* spectrometer appear to be equally reproducible. Furthermore, even if their absolute magnitudes are in substantial error, the *relative* magnitudes for the protons of any one compound are not. It is worth noting that the accuracy of R_1-values obtained with a superconducing solenoid exceeds that from an electromagnet system. Likely this reflects both the enhanced sensitivity of the superconducting spectrometer together with the increased overall stability of the B_0-field.

The solutions were made up in the appropriate solvents and degassed by bubbling nitrogen through the solution for 5 min. The selective proton relaxation rates were obtained using the decoupler as source for the selective field (20).

The ^{13}C nOe factors were determined using the gated technique (25).

Compounds 3,5-di-*O*-acetyl-2,6-dibromo-2,6-dideoxy-D-mannono (**1**) or -glucono (**2**), 1,4-lactone, 3,5-di-*O*-acetyl-1-*O*-benzoyl-2,6-dibromo-2,6-dideoxy-α and β-D-mannofuranose (**6**) and (**7**), 3,5-di-*O*-acetyl-6-bromo-2,6-dideoxy-D-*arabino*-1,4-lactone (**8**), and 2,3,5,6-tetra-*O*-acetyl-1,4-anhydro-D-mannitol (**9**) were all available from other studies (12, 15). Compounds α,β**3**, α,β**4**, and α,β**5** were synthesized as mixtures according to published methods (13). Their identities were checked by comparison of ^{13}C chemical shifts with values published (3).

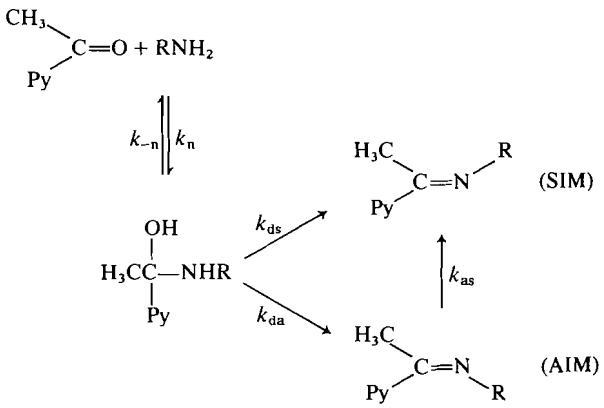
LIANG K. TAN and MICHAEL COCIVERA. Can. J. Chem. **58**, 1929 (1980).

The ^{1}H nuclear magnetic resonance spectra obtained during the addition of amines to 4-acetyl-1-methylpyridinium iodide in aqueous solution provide data for the kinetic parameters associated with: (*1*) the rapid equilibrium of the addition step to form the carbinolamine intermediate; (*2*) the rate determining dehydration step to form the *syn* and *anti* imines; and (*3*) the *anti* to *syn* isomerization. Depending on the amine used, (*1*) can result in methyl proton exchange that is either fast or slow relative to the chemical shift between the acetyl-CH_3 resonance of 4-acetyl-1-methylpyridinium iodide and the corresponding one due to carbinolamine. The line width data and the equilibrium constant K_n, which is determined by flow uv, provide values for the rate constants (k_n and k_{-n}) of the forward and reverse steps of the equilibrium. The logarithm of k_n does not correlate with log K_n or pK_a of the amines. In addition, the enthalpy change ΔH for the equilibrium step is found not to depend significantly on the nature of the amine. It remains relatively constant at about -11 kcal M^{-1}. The dehydration step is subject to general acid and base catalysis with the effect decreasing in the order hydrazine, hydroxylamine, semicarbazide, and methoxyamine. For hydrazine and hydroxylamine, the *syn*/*anti* ratios are pH dependent. For hydrazine and semicarbazide the *anti* to *syn* imine conversion depends on pH. The occurrence of *anti* to *syn* isomerism indicates that the dehydration of carbinolamine gives the *anti* imine as the product of kinetic control.

LIANG K. TAN et MICHAEL COCIVERA. Can. J. Chem. **58**, 1929 (1980).



Les spectres rmn du ^{1}H obtenus lors de la réaction d'addition des amines sur l'iodure d'acétyl-4 méthyl-1 pyridinium en solution aqueuse fournissent des données sur les paramètres cinétiques associés à: (*1*) l'équilibre rapide de l'étape d'addition qui conduit à la carbinolamine intermédiaire, (*2*) la déshydratation qui est l'étape déterminante lors de la formation des imines *syn* et *anti* et (*3*) l'isomérisation *anti* à *syn*. Selon l'amine utilisée, (*1*) peut provoquer l'échange de proton du méthyle qui peut être rapide ou lent par rapport au déplacement chimique entre la résonance du CH_3 du groupe acétyle de l'iodure d'acétyl-4 méthyl-1 pyridinium et la résonance correspondante due à la carbinolamine. Les données sur la largeur du pic et la constante d'équilibre K_n qui est déterminée par uv à écoulement fournissent les valeurs des constantes de vitesse (k_n et k_{-n}) des étapes directe et inverse de l'équilibre. Le logarithme de k_n ne correspond pas au log K_n ou au pK_a des amines. De plus, on a trouvé que la variation d'enthalpie, ΔH, de l'équilibre ne dépend pas d'une façon importante de la nature de l'amine. Elle demeure relativement constante aux environs de -11 kcal M^{-1}. L'étape de déshydratation est sujette à une catalyse générale par les acides et par les bases dont l'effet décroît dans l'ordre: hydrazine, hydroxylamine, semicarbazide et méthoxyamine. Dans le cas de l'hydrazine et de l'hydroxylamine, les rapports *syn*/*anti* dépendent du pH. Dans le cas de l'hydrazine et de la semicarbazine, l'isomérisation *anti*–*syn* dépend du pH. Cette isomérisation *anti*–*syn* indique que la déshydratation de la carbinolamine donne comme produit cinétique l'imine *anti*.

[Traduit par le journal]

Introduction

The use of ^{1}H nuclear magnetic resonance (nmr) spectroscopy has provided detailed information concerning various steps associated with the nucleophilic addition to carbonyl compounds (1). As part of a continuing study, we have undertaken the investigation of the addition of α-effect nucleophiles to 4-acetyl-1-methylpyridinium iodide (AMPI), which has a structure not unlike that of 4-formyl-1-methylpyridinium iodide, a compound used to study transamination (2). Of particular interest is information about the rate of nucleophilic addition as well as the rates of formation of the imine isomers. Hydroxylamine (HA), hydrazine (HYD), methoxyamine (MA), and semicarbazide (SM) were used as the nucleophiles because they represent a range of pK_a values.

Because of the detailed information available in the nmr spectrum, it is possible to measure directly the rate constants for the reaction steps indicated in Scheme 1 in which Py denotes methylpyridinium iodide.

SCHEME 1

Experimental

Chemicals

AMPI was prepared from 4-acetylpyridine (vacuum distilled before use) and methyl iodide in benzene. It was recrystallized from acetonitrile giving red-brown crystals with mp 177–179°C,

which agreed with the previously reported value (3). Methoxyamine hydrochloride was recrystallized from absolute alcohol; imidazole was recrystallized twice from benzene; and diazabicyclooctane (Dabco) was purified by sublimation under reduced pressure. The oxazolidine of 4-acetylpyridine was prepared from 4-acetylpyridine (vacuum distilled) and 2-amino-2-methyl propan-1-ol according to the procedure reported in the literature (4). It was purified by distillation under reduced pressure (bp 85°C/1.0 Torr), solidifying immediately into white crystals. The oxazolidine of AMPI was prepared from the oxazolidine of 4-acetylpyridine and methyl iodide in anhydrous ether and recrystallized from acetonitrile giving light brown crystals with mp 167–169°C. The oxazolidine of acetone was prepared using the same procedure (4) and was purified by distillation under reduced pressure (bp 56°C/5.9 Torr). Other chemicals were obtained from suppliers and used without purification.

Kinetics

The kinetic measurements involved either line shape analysis of ^{1}H nmr spectra or determination of the time dependence of spectra obtained using a Varian HA 100-15 operating at 100 MHz (1). In either case, the reaction mixture was made by mixing equal volumes of aqueous AMPI and nucleophile solutions at an ionic strength of 1.30 *M* (KCl) and 30 ± 0.1°C. To determine time dependent spectra when the reaction was slow, temperature equilibration was done outside the nmr probe in a bath at 30.0 ± 0.1°C. The intensity of each signal was obtained from the ratio of its measured intensity to the intensity of the internal reference signal. In this manner, changes in magnetic field homogeneity during the period of the reaction did not affect the intensities of the signals being studied. For the same purpose, the line width measurements were also obtained relative to the line width for the internal reference signal in all runs.

The equilibrium constant K_n for the addition step forming the carbinolamine was determined at several temperatures by flow uv using a Cary 118 spectrometer as described previously (1).

Results and Discussion

Spectra

Figure 1 illustrates representative 100 MHz proton resonance spectra observed at 30°C for static spinning samples under the following conditions: A, 0.100 *M* AMPI solution buffered at pH 7.0; B, reaction mixture containing 0.100 *M* AMPI and 0.150 *M* HA solution (pH 7.0) immediately after mixing: C, reaction mixture of 0.100 *M* AMPI and 0.200 *M* MA solution (pH 7.0) immediately after mixing; D, same conditions as B but 9.0 minutes after mixing; E, reaction mixture B at the end of the reaction.

The two signals in Fig. 1A are assigned to be the

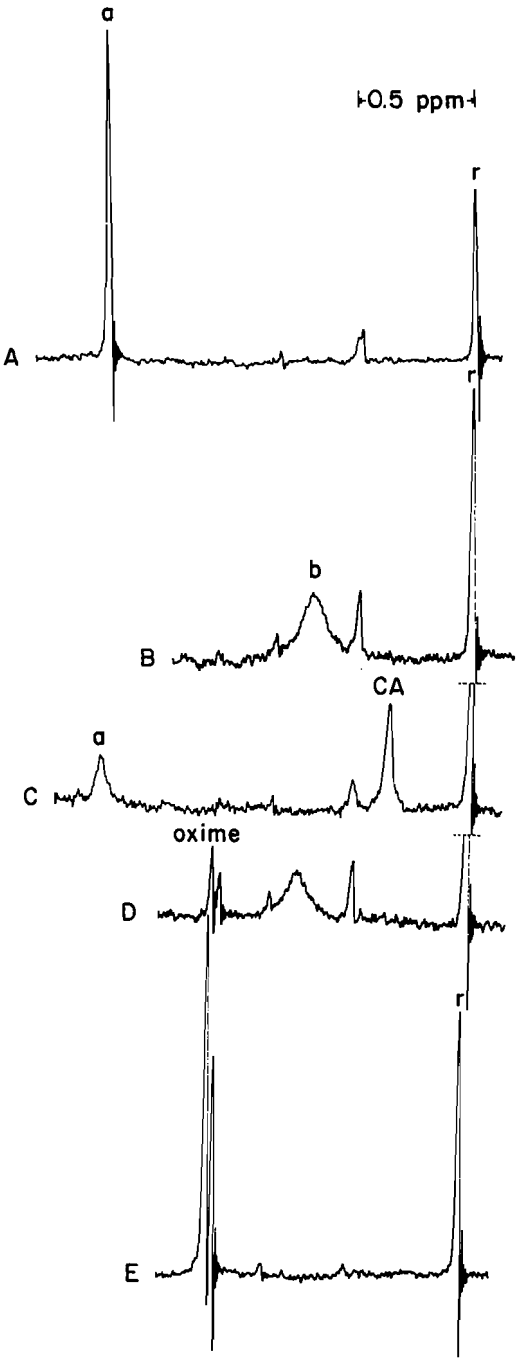

FIG. 1. Proton nmr spectra of aqueous solutions obtained at 100 MHz and 30°C. Only the portion of the spectral range upfield from water signal is illustrated. The most upfield signal (labeled r) in each spectrum is the methyl proton resonance of *tert*-butyl alcohol, which acts as intensity and line width internal reference. (A) Solution buffered at pH 7.0 with 0.350 *M* phosphate, containing 0.100 *M* AMPI. Signal labeled a is due to the acetyl CH_3-proton resonance of AMPI. The two small signals have not been identified, although the signal at higher field may be due in part to the hydrate of AMPI and to methyliodide. These signals are observed in the other spectra, although the intensity of the higher field signal has decreased at the end of the reaction (cf. (E)). (B) Reaction mixture of 0.100 *M* AMPI and 0.150 *M* HA, buffered with 0.350 *M* phosphate at pH 7.0, immediately after mixing. (C) Reaction mixture of 0.100 *M* AMPI and 0.200 *M* MA, buffered with 0.200 *M* phosphate at pH 7.0, immediately after mixing. (D) Reaction mixture as in (B), 9.0 min after mixing. (E) Reaction mixture as in (B), at the end of the reaction. For the assignment and chemical shifts of the resonances, see the text.

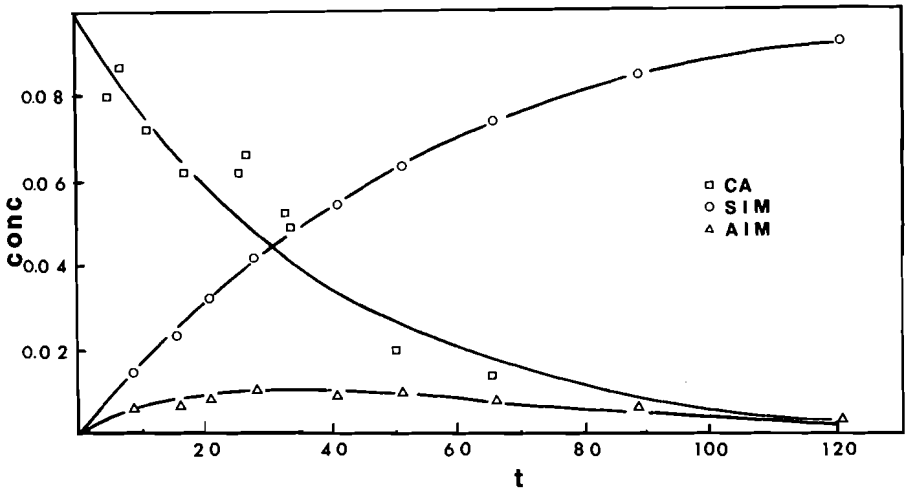

FIG. 2. Molar concentration of CA, SIM, and AIM as a function of time in minutes for an aqueous solution of 0.100 *M* AMPI and 0.405 *M* HYD buffered with 0.400 *M* Dabco (after mixing) at pH 8.2 and 30°C. The solid lines represent the simulated time dependences based on rate constants obtained by an iterative method (see text).

carbonyl CH_3-proton resonance of the AMPI (labeled a), and the CH_3-proton resonance of *tert*-butyl alcohol, which serves as the internal reference signal (labeled r). The broad signal (labeled b) in Fig. 1B, which is observed immediately after mixing with HA, is assigned to be the coalescence signal as a result of exchange between carbinolamine (CA) intermediate and AMPI (1*c*, 5) for the following reasons. The chemical shift of the broad signal is between the chemical shift of the acetyl-CH_3 resonance of AMPI and the expected CA-CH_3 resonance. This broad signal appears before the oxime signals grow (Figs. 1B, D, and E) and is a transient whose rate of decay is the same as the rate of growth for the *syn* and *anti* oximes (Fig. 2). That the broadening is a result of a fast exchange process is proved by the following observations. The line width and chemical shift of this signal are dependent upon the HA initial concentration when the initial concentration of AMPI is held constant, i.e., increasing the initial concentration of HA increases the line width of this signal and causes it to move upfield. A similar line width effect (1*c*, 5) is observed when HYD is used as the nucleophile.

On the other hand, when either MA or SM is the nucleophile, slow exchange (1*b*, *e*, 5) is observed, i.e., the acetyl-CH_3 resonance due to AMPI and the corresponding signal due to CA are not coalesced and can be observed separately (Fig. 1C for MA). In this case, the line widths but not the chemical shifts of these resonances are dependent on the concentration of nucleophile. Consequently the chemical shift between CH_3-proton resonances due to AMPI and CA can be measured directly. On the other hand, for HA and HYD, this chemical shift is obtained from the nucleophile concentration dependence of the chemical shift of the coalescence signal and the value for the equilibrium constant K_n (1, 5), which is discussed below. As expected, these chemical shift values are almost identical for all four nucleophiles (Table 1). In addition, they agree closely with the one for the structurally similar oxazolidine of AMPI (δ, 1.68).

TABLE 1. Chemical shifts[a] in H_2O at 30°C

Nucleophile	Carbinolamine[b]	Dehydration product	
		syn	*anti*
Hydroxylamine	1.57±0.02	2.32	2.29[c]
Methoxyamine	1.58±0.001	2.31	2.30
Hydrazine	1.61±0.002	2.20	2.26
Semicarbazide	1.69±0.001	2.32	2.35[d]

[a]Relative to TMS in ppm.
[b]The pH of the solutions is adjusted to 7.5 using phosphate for HA, MA, and SM. Solutions of pH 9.7 using Dabco are used for HYD.
[c]At pH 9.2 *syn* oxime has a chemical shift δ of 2.28 and the corresponding *anti* isomer is 2.30. This may be due to the deprotonation of H on =N—OH group at such high pH. Assignment of signals is based on ref. 7. See text.
[d]Resonances are well resolved with almost no overlap.

Equilibrium Constants

For evaluation of the kinetic parameters of both the rapid preequilibrium and the dehydration steps, K_n was measured using flow uv (1*e*) as described below, and the pK_a of CA for each nucleophile was estimated by starting with the pK_a value for a corresponding base and adjusting for substituent effects using σ* values (6) for —OH, —NH_2, —OCH_3, and —$NHCONH_2$ groups. Since a σ* value for the pyridyl-*N*-methyl iodide group does not appear to

be available, its effect was estimated by comparison of the pK_a values for the oxazolidine of AMPI (pK_a, 3.47) and the oxazolidine of acetone (pK_a, 7.06).[2] Using this approach, the estimated pK_a values for CA derived from HA, HYD, MA, and SM are 2.3, 4.7, 0.8, and 2.7, respectively.

The constant K_n for the equilibrium between AMPI and CA was determined for each nucleophile by measuring the decrease in absorbance at wavelength 278 nm when AMPI and nucleophile solutions are mixed. In order to simplify the mathematical analysis, the pH was sufficiently high so that protonation of the nucleophile was negligible. Solutions buffered with phosphate at pH 8.0 were used for HA, MA, and SM, and solutions buffered with Dabco at pH 10.0 were used for HYD. Under these conditions, less than two percent of the nucleophile is protonated, and the concentration of protonated carbinolamine (CAH^+) is negligible. The absorbance of CA is taken into account by assuming its molar absorptivity is the same as that for the structurally similar oxazolidine of AMPI. Based upon these considerations, K_n is determined at different temperatures using the expression

$$[1] \quad K_n = \frac{(A_3 - A_1 - A_2)\varepsilon_A}{b^0[A_1(\varepsilon_{CA} - \varepsilon_N) - (A_3 - A_2)\varepsilon_A]}$$

in which A_1, A_2, and A_3 represent the absorbance of AMPI solution, nucleophile solution, and the mixed solution, respectively. In all cases, the absorbance is measured when the liquid is flowing, b^0 is the initial concentration of nucleophile, and ε is the molar absorptivity at 278 nm.[3] Subscripts A, N, and CA denote AMPI, nucleophile, and carbinolamine, respectively. As mentioned above, ε_{CA} is assigned the molar absorptivity of the oxazolidine of AMPI (299.4 M^{-1} cm^{-1}). Values reported in Table 2 are averages of three nucleophile concentrations. For SM and MA, which exhibit slow exchange, K_n may also be calculated directly from the areas for the CH_3-proton resonances of AMPI and CA at 30°C, and the respective values of 6.8 ± 0.7 and 16 ± 2 M^{-1} agree well with the values in Table 2. Each of these nmr values is an average of about twenty experiments over the pH range 6.0 to 9.2. The enthalpy (ΔH°) of this equilibrium step, which is calculated from the relation

$$\ln K_n = -\Delta H^\circ/RT + C$$

by linear least squares, does not appear to depend significantly on the nature of the nucleophile (Table 2).

Preequilibrium Rates

Using these data, the rate constants k_n and k_{-n} (Scheme 1) were evaluated from line width data for slow and fast exchange as described previously (1). For slow exchange (1*b*, *e*, 5), the reciprocal of the exchange lifetime for AMPI and CA has the relations $1/\tau_A = \Delta_A$ and $1/\tau_{CA} = \Delta_{CA}$, in which $\Delta = \pi(\Delta\nu_e - \Delta\nu_o)$, $\Delta\nu$ is the width at half height of the appropriate signal, and the subscripts e and o denote exchange and no exchange, respectively. For CA, $\Delta\nu_o$ is obtained from a freshly prepared solution of oxazolidine of AMPI. The exchange lifetime τ is related to the rate contants by the equations: $1/\tau_{CA} = k_{-n}$ and $1/\tau_A = k_n[N]$ in which [N] is the equilibrium concentration of the nucleophile free base. The results for MA are listed in Supplementary Table 3. Each number is an average of at least three measurements.[4] Although the precision of the values appears very satisfactory, the rate constants are probably accurate to within 15% at the concentrations employed, since $\Delta\nu_o$ is about 1.7 Hz and $\Delta\nu_e$ varies from 3 to 6 Hz as the concentration of MA increases. The fact that the ratio of k_n/k_{-n} is about 16.0 M^{-1}, which differs by only 9% from the equilibrium constant K_n determined by flow uv (14.6 M^{-1}), provides substantiation of the reliability of the data in Supplementary Table 3. For SM, $(\Delta\nu_e - \Delta\nu_o)$ is small, varying from 0.2 to 0.9 Hz, depending on the concentration of SM employed, so that the data must be considered semiquantitative with k_n and k_{-n} equal to 5 and 0.9 M^{-1} s^{-1} respectively. The ratio of these two numbers gives a value of about 5.5 M^{-1} which is within 16% of K_n measured by flow uv (6.52 M^{-1}).

For HA and HYD, which cause fast exchange, the exchange lifetime (1, 5) is calculated using the equation $\Delta = P_A P_{CA} \delta^2 \tau$, in which $\Delta = \pi\{\Delta\nu_e - P_A(\Delta\nu_o)_A - P_{CA}(\Delta\nu_o)_{CA}\}$, $1/\tau - k_n[N] = k_{-n}$, and [N] is the equilibrium concentration of nucleophile free base. For these two nucleophiles, Δ makes a major contribution to the line width of the coalescence signal. Rate constants listed in Supplementary Table 3 are averages of at least three runs.

In general, data for the four nucleophiles show that k_n and k_{-n} are independent of pH and buffer

[2]These values take into account the decomposition of oxazolidines in acid media.

[3]HA and MA have negligible absorbance at the wavelength of the experiment, while HYD and SM have molar absorptivities of 2.17 and 0.221 M^{-1}cm^{-1} respectively.

[4]All of the data for HYD along with those for MA and HA are on file in Supplementary Table 3, which contains 426 values obtained for various buffers and pH values. This information can be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]The k_n data listed for AMPI are average values obtained from all the results given in Supplementary Table 3.
[b]The buffers and their concentration ranges were: sodium phosphate, 0.100–0.350 M; imidazole, 0.200–0.800 M; and Dabco, 0.200–0.800 M. The ionic strength was held constant at 1.3 M (KCl).
[c]Data for pyruvate anion are taken from ref. 1*e*.
[d]Calculated based on slow exchange since both the ketone and carbinolamine signals can be observed. Previously (1*e*) interpreted as fast exchange.

concentration, as well as independent of the concentration of the nucleophile. These results agree with the mechanism formulated previously (1*b*, *e*) for the nucleophilic addition to other carbonyl compounds (Scheme 2). Since the only steps in this sequence that are independent of acid and base catalysis are the addition step to form $CA^{\pm}$ and direct interconversion of $CA^{\pm}$ to CA, our experimental results are consistent either with this path or with a rate-determining formation of $CA^{\pm}$. A similar conclusion was reached for addition to pyruvate anion (1*e*). As with the pyruvate anion, we find that a good free energy relationship between k_n and either K_n or K_a is not obtained, although K_n appears to give a better fit than K_a for the four nucleophiles (Table 3).[5] While AMPI and the pyruvate anion show the same trend in values for k_n vs. nucleophile, the relative magnitudes differ substantially (Table 3). Understanding these differences will require a systematic study of a number of electrophiles. In contrast with AMPI, 4-formylpyridine reacts with secondary amines such as piperazine and sarcosine via both uncatalyzed and catalyzed routes. For the uncatalyzed addition by sarcosine at 25°C, the rate constant is 1.0×10^4 M^{-1} s^{-1} (2*c*).

SCHEME 2

Product Time Dependence

The time dependence of the *syn* (SIM) and *anti* (AIM) imines provides values for the rate constants (k_{ds} and k_{da}) for the dehydration step and also the rate constant (k_{as}) for the isomer conversion step on Scheme 1. Assignment of the acetyl-related CH_3 signals (Table 1) for the SIM and AIM products obtained with the four nucleophiles is based on the work of Karabatsos and co-workers (7). Figure 2 illustrates a representative time dependence for the concentration of SIM and AIM using HYD. The decay of AIM and growth of SIM indicate that dehydration of CA gives AIM as the product of kinetic control. The AIM to SIM interconversion is slower for the other three nucleophiles. In addition,

[5]Data in Table 3 are average values obtained from all the results given in Supplementary Table 3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

for HYD and SM this interconversion is pH dependent as discussed below. Isomeric interconversion has been noted before but not studied in the detail reported here (1*a*, *f*).

Analysis of the time dependence has involved two independent sets of data: (*1*) those for CA, which provide values for the total dehydration rate constant $k_d = k_{ds} + k_{da}$; and (*2*) those for AIM and SIM, which provide values for k_{ds}, k_{da}, and k_{as} as well as the dehydration rate constant k_d. First, consider the dehydration step. Because of the magnitude of K_n for each nucleophile, the equilibrium concentrations of AMPI and CA are appreciable during the dehydration reaction, which, therefore, cannot be treated as either pure first order or pure second order reaction. Consequently the value for $(k_{ds} + k_{da})$ has been calculated using the expression (1*f*): $\ln [AMPI]_t = (k_{ds} + k_{da})\beta t + C$ in which $[AMPI]_t$ is the total concentration of AMPI and β is $K_n[N]/(K_n[N] + 1)$.[6] In this expression [N], which is the concentration of nucleophile free base, is time dependent, i.e., for each value of t, [N] was calculated using the appropriate equilibrium constants taking into account the amount of AMPI and nucleophile that had been converted to product. A least-squares fit of $\ln [AMPI]_t$ vs. βt provided the value for $(k_{ds} + k_{da})$. The limitations of this approach have been discussed previously (1*f*). This approach was used for the decay data of the coalescence signal of (AMPI + CA) and the growth data for SIM plus AIM. For the latter the growth of the sum of the intensities of the two signals (AIM + SIM) was used since isomerization also occurs. The results from the growth and decay data are in close agreement. For example, at pH 7.5 and 0.200 *M* phosphate, values of 10.4×10^{-2} min^{-1} and 8.7×10^{-2} min^{-1} were obtained for the decay and growth, respectively, using 0.150 *M* HA as the nucleophile. In practice, because the signals of SIM and AIM were not exchange broadened, they were used predominantly to obtain values for the dehydration rate constants, some of which are listed for HYD in Table 4.[7]

To calculate values of k_{as}, the rate constant for conversion of AIM to SIM when HYD or SM is the nucleophile, an iterative program (Fortran IV, ref. 1*g*) was used to analyze the time dependence data of SIM and AIM in terms of the equations

$$\begin{aligned} d[CA]/dt &= -(k_{ds} + k_{da})[CA] \\ d[SIM]/dt &= k_{ds}[CA] + k_{as}[AIM] \\ d[AIM]/dt &= k_{da}[CA] - k_{as}[AIM] \end{aligned} \quad [2]$$

These equations do not include a term for SIM to AIM conversion because AIM converts completely to SIM for these two nucleophiles. The values for $(k_{ds} + k_{da})$ and k_{as} listed in Table 4[7,8] were obtained in this manner using k_{ds}/k_{da} ratios obtained from initial SIM/AIM intensity ratios that had been obtained by extrapolation. A measure of the internal consistency of the various treatments is given by the following values for $(k_{ds} + k_{da})$ obtained for the reaction between 0.100 *M* AMPI and 0.405 *M* HYD buffered with 0.400 *M* Dabco at pH 8.2: 3.4×10^{-2} min^{-1} (decay of CA, least squares), 3.8×10^{-2} min^{-1} (growth of SIM + AIM, least squares), and 3.5×10^{-2} min^{-1} (iterative treatment of AIM and SIM time dependences).

For all nucleophiles (Table 4 and Supplement), $(k_{ds} + k_{da})$ appears to be independent of nucleophile concentration but is dependent on pH and phosphate buffer concentration. In addition $(k_{ds} + k_{da})$ for HA is dependent on Dabco concentration. Consequently, the dehydration step is subject to a general acid and base catalysis. The slope and intercept (k_4^0) of the plot of $(k_{ds} + k_{da})$ vs. buffer concentration, which was calculated by least-squares fit, are listed in Table 5. Assuming a linear relationship between the slope and the fraction of buffer existing in its acid form, the general acid k_4^{GA} and general base k_4^{GB} catalytic rate constants are calculated (Table 5). With the four nucleophiles, k_4^{GA} is found always to be higher than k_4^{GB} for phosphate buffer, and the order of decreasing magnitude of k_4^{GA} or k_4^{GB} is HYD > HA > SM > MA, whereas the order for pK_a is HYD > HA > MA > SM. In the case of HA, Dabco appears to be a general base catalyst.

The values for k_4^0 are listed in Table 5 for all the buffers. For the cases in which Dabco and imidazole had a negligible catalytic effect, extrapolation provided only a minor correction. For a given nucleophile, the good agreement between k_4^0 values obtained at the same pH for different buffers indicates the reliability of the nmr technique in this type of study. The pH dependence of k_4^0 was analyzed according to the relation, $k_4^0 = k_h + k_4^+[H^+] + k_4^-[OH^-]$, where k_h is the rate constant for the dehydration of CA in the absence of H_3O^+ or OH^- catalysis. For HYD, a linear correlation between

[6] In view of the low estimated pK_a values for CA derived from each of the nucleophiles, no correction for protonation of CA (1*f*) is necessary for the pH range employed.

[7] Additional listings for HYD along with data for HA, SM, and MA are found in Supplementary Table 4. This table is also available from the Depository of Unpublished Data, see footnote 4.

[8] Isomerization may occur either via CA or the diamine formed by reversible addition of HYD or SM to the imine (or both). The present data are insufficient to allow a choice. Consequently a more complicated analysis has not been attempted.

[a]Total concentration after mixing, includes all degrees of protonation.
[b]Total initial concentration after mixing, includes all degrees of protonation. The free base nucleophile was used in calculation. The initial concentration of AMPI after mixing was 0.100 *M* in all runs.
[c]Determined by extrapolation of the ratio [SIM]/[AIM] to zero time. Each value listed is the average of three determinations.

$[H^+]$ and k_4^0 obtains over the whole pH range, 7.0 to 9.2, and k_4^+ and k_h are listed in Table 5. For HA, k_4^0 correlates with either $[H^+]$ or $[OH^-]$ depending upon the pH range (Table 5). In both cases, the intercept k_h is identical as would be expected for the proposed model. Over the pH range employed, MA and SM exhibit an identical $[H^+]$ dependence as indicated by the k_4^+ value in the table. The intercept k_h for these two sets of data indicates that k_h is probably reliable to within about a factor of two. The dependence of these parameters (k_4^+ and k_h) on pK_a has been examined. While k_4^+ increases monotonically with pK_a, the linear free energy correlation is marginal (Fig. 3). A better correlation is obtained for k_h, which may, however, be fortuitous in view of the semiquantitative nature of these data (Fig. 3).

The k_{ds}/k_{da} ratio is independent of the nature and concentration of the buffer (Table 4 and Supplement). However it depends on the pH employed when HYD and HA are the nucleophiles. In the case of HYD a plot of k_{ds}/k_{da} vs. pH (Fig. 4) could be interpreted as having a sigmoid form with an inflection point at about pH 8.2. The corresponding plot for HA does not bend over for the highest pH (9.2) employed (Fig. 4). For SM and MA, k_{ds}/k_{da} is independent of pH in the range 6.0 to 7.5.

It is interesting to speculate about the cause of

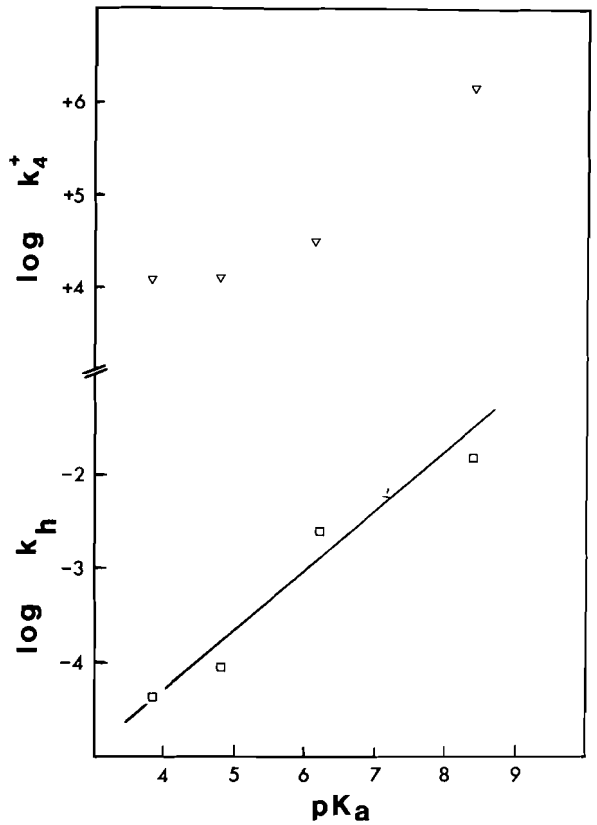

FIG. 3. The logarithm of hydronium ion catalysis (k_4^+) and the logarithm of water catalysis (k_h) for the dehydration step, plotted as a function of the pK_a of the nucleophiles. The solid line represents a least-squares fit of the data (see text).

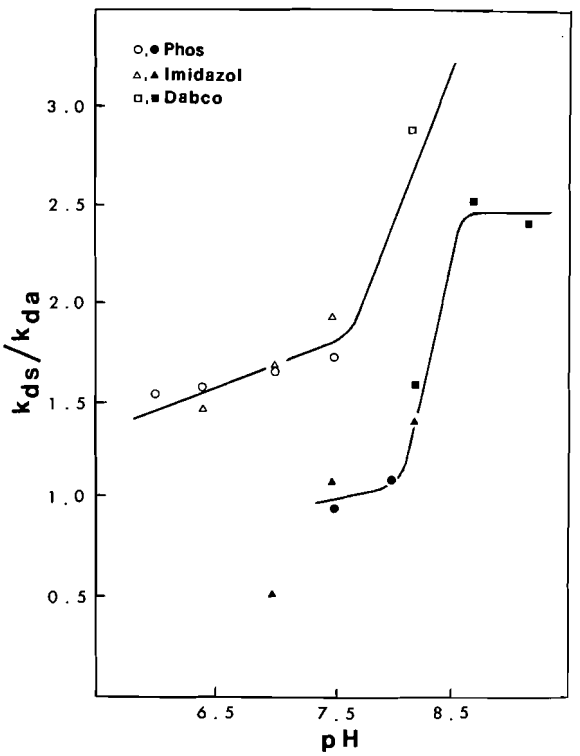

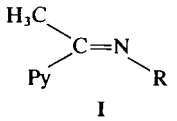

FIG. 4. The pH dependence of the ratio of k_{ds}/k_{da}. Each point represents the average value of k_{ds}/k_{da} at a given pH using several buffer concentrations. Data represented by open symbols are for nucleophile HA, and data represented by solid symbols are for nucleophile HYD. At pH 9.2, the value of k_{ds}/k_{da} is 4.3 The solid lines represent qualitative visual fits of the data.

these different responses to pH, assuming that they represent titration curves. Since there appears to be no buffer effect on the k_{ds}/k_{da} ratio, the pH effect for HYD and HA may reflect the degree of protonation of CA rather than acid or base catalysis. This protonation must occur at a position that can influence the dehydration of CA to form more *anti* isomer (structure **I**) than the unprotonated form (R

I

equals NH_2 or OH). Since there is no reason to suspect that protonation of the nitrogen atom bonded to carbon can affect the stereochemistry of the dehydration of CA, we have considered the possibility that the stereochemistry is affected by protonation at the R group and that the protonated forms are $-NH_3^+$ and —OH for CA derived from HYD and HA respectively. According to this description the orienting effect would be due to an interaction between these protonated R-groups and the π electrons of pyridine. Likewise, the absence of a pH effect for MA and SM could be explained by the fact that $-OCH_3$ and $-NHCONH_2$ are not protonated significantly in the pH range employed. The pK_a for $Py(CH_3)C(OH)NHNH_3^+$ is estimated to be 6.4 by adjusting the pK_a of hydrazine for substituent effects based on a ρ value of about -3 (8) and σ^*_{XNH} values for CH_3 and CH_2OH that have been estimated from σ^* values (6) assuming the relation $\sigma_X = 2.8\sigma_{XCH_2}$ holds when the CH_2 group is replaced by the isoelectronic NH group. The σ^* value for the Py group is estimated from the pK_a values for the oxazolidines of acetone and AMPI. Although this estimated pK_a value should be considered approximate (predicted and measured values can differ by 0.5 units (6)), the two-unit difference between this value and that obtained from Fig. 4 is probably too large.[9] Consequently, the evidence for this model is conflicting, i.e., on the one hand a pH response for HYD and HA differs from that for SM and MA in a manner expected for the model, but on the other hand there is insufficient

[9]Altering the sigmoid curve to include the point at low pH in Fig. 4 does not change the inflection point appreciably.

agreement between the predicted pK_a value for the CA of HYD and the inflection point in Fig. 4. In this regard, the pK_a for CA of HA was not estimated since the data in Fig. 2 are insufficient to give a clear indication of the inflection point. It should be noted that the *syn* and *anti* oxime CH_3-proton resonances are pH dependent (below pH 8.7 $\delta_{syn} > \delta_{anti}$, at pH 8.7 $\delta_{syn} = \delta_{anti}$, and above pH 8.7 $\delta_{syn} < \delta_{anti}$).

As indicated above, the SIM/AIM ratio is also time dependent with AIM converting completely to SIM. This conversion was not studied for HA and MA because of the long time period involved. For HYD and SM, the values for k_{as} calculated using the iterative method are listed in Table 4 and Supplement. The values for SM in the pH range 6.0 to 7.5 exhibit no dependence on SM concentration but show an increase (except for pH 7.0) as the phosphate buffer concentration is increased (unfortunately, the trends are not sufficiently large relative to the precision to allow quantitative analysis of the data). In addition k_{as} decreases monotonically by about a factor of 20 as the pH is increased from 6.0 to 7.5 (Table 4 and Supplement). For HYD, k_{as} does not appear to depend on the concentration of either Dabco or imidazole. There appears to be a slight dependence on HYD concentration, but the data are erratic and the trend barely exceeds experimental error (Table 4 and Supplement). As with SM, k_{as} depends on pH, but the effect is not as large and k_{as} appears to level off when the pH exceeds 8.2. To check the effect of pH on k_{as}, values of k^0_{as} (Table 5) were obtained by extrapolation to zero buffer concentration. While this extrapolation makes a small correction to k_{as}, the values in Table 5 should be considered semiquantitative in view of the precision indicated in Table 4. Nevertheless, the data are sufficiently quantitative to indicate a linear dependence on $[H^+]$ for SM. On the other hand k_{as} for HYD appears to go through a minimum although the accuracy decreases as the pH increases because the AIM signal becomes small.

Although not conclusive, the pH dependence of k^0_{as} indicates that isomerization may proceed in part via a mechanism in which the imine is protonated at the doubly-bonded nitrogen atom. A similar study of HA and MA was not attempted because the isomerization is slower for these nucleophiles. At any rate AIM converts completely to SIM for each of the nucleophiles. Consequently SIM appears to be the thermodynamically stable isomer, and the dehydration of CA gives the *anti* imine as the product of kinetic control.

Acylation of aromatic substrates with ketenes. II.[1] Hammett–Brown studies on substituted aromatic compounds

K. R. FOUNTAIN,[2] PAMELA HEINZE,[3] DAVE MADDEX,[4] GREG GERHARDT,[5] AND PAUL JOHN[6]

Northeast Missouri State University, Kirksville, MO 63501, U.S.A.

Received January 14, 1980

K. R. FOUNTAIN, PAMELA HEINZE, DAVE MADDEX, GREG GERHARDT, and PAUL JOHN. Can. J. Chem. **58**, 1939 (1980).

Competition reactions using dimethylketene (DMK) – aluminum chloride complexes on a variety of substituted benzene derivatives gave partial rate factors. The logs of these P_f^x values when plotted versus σ^+ values gave two line segments of $\rho = -6.59$ for less active substrates, and $\rho = -0.92$ for more active substrates. Similar results were found for diphenylketene ($\rho = -9.47$ and -1.07).

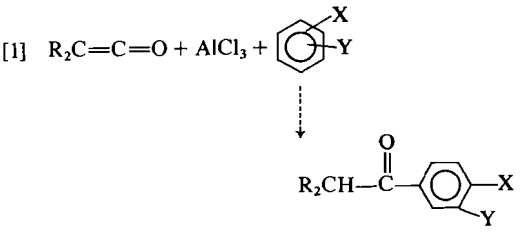
These results were rationalized by analogy to vinyl cation alkylations. A pair of π complexes (outer then inner) occur between initial approach of the reagent and final, product-determining π-complex formation. In one of these complexes the C=C bond of the ketene complex may be able to back-bond in a manner similar to that found in inorganic complexes of CO and metals.

K. R. FOUNTAIN, PAMELA HEINZE, DAVE MADDEX, GREG GERHARDT et PAUL JOHN. Can. J. Chem. **58**, 1939 (1980).

Des réactions de compétition entre le complexe de diméthylcétène (DMC) – chlorure d'aluminium et différents dérivés du benzène permettent d'obtenir des facteurs de vitesse partielle. Les courbes des logarithmes de valeurs de P_f^x en fonction des valeurs de σ^+ donnent deux segments de droite de pente $\rho = -6.59$ pour les composés moins réactifs et de pente $\rho = -0.92$ pour les composés plus réactifs. On obtient avec le diphénylcétène des résultats semblables ($\rho = -9.47$ et -1.07).

On rationalise ces résultats par analogie avec l'alkylation des cations vinyliques. Il se produit une paire de complexes π (externes aussi bien qu'internes) entre l'approche initiale du réactif et la formation finale d'un complexe π qui détermine la vitesse de la réaction. Dans l'un de ces complexes, la liaison C=C du complexe incluant le cétène peut établir une liaison inverse de façon analogue à celle trouvée dans les complexes inorganiques entre le CO et des métaux.

[Traduit par le journal]



Our previous paper (1) reported the results of studies of substrate specificity using competition studies of benzene vs. toluene for Friedel–Craft acylations of dimethyl and diphenyl ketenes (DMK and DPK). Through a combination of kinetic isotope effect studies and the relative rates of acylations of benzene and toluene we were able to conclude that the ketene – aluminum chloride complex was more selective than an ordinary acyl chloride Friedel–Crafts reagent. The dimethylketene reagent was more reactive than the acetylium ion; the diphenylketene reagent was less reactive. Compared with the stereoelectronically similar vinyl cations the ketene – aluminum chloride complexes were also more selective.

These results indicated that the unique nature of the ketene – aluminum chloride reagent would be interesting to study. This paper deals with the Hammett–Brown linear free energy study of reactions of substituted aromatic substrates in competition for limited amounts of dimethyl and diphenylketene – aluminum chloride reagents.

Results

The reaction which was studied was acylation of substituted benzenes with dimethylketene and diphenylketene (eq. [1]). R was Me or Ph and X and

Y were various substituents giving the substrates listed in Tables 1 and 2 along with the abbreviations for the substrates which are used in this paper.

The method used was a standard competition method in which a small amount of the ketene was allowed to react with a large excess of a mixture of two substrates (2).

Several points of explanation are needed for the competition studies with dimethylketenes as recorded in Table 1. First, the reaction mixtures using dimethylketene and the less activated substrates (entries 1–5 of Table 1) were difficult to analyze by gas chromatography, so extensive use was made of spiked samples for peak identification and artificial mixtures for quantitation of the areas

of the peaks of interest. Second, all the singly substituted substrates (1, 2, and 4 of Table 1) and the doubly substituted ones, XylH, OClTolH, and OBrAnH (entries 3, 5, and 6, Table 1) gave only one product (1), namely, the ketone which resulted from substitution *para* to the most activating substituent. Third, *o*-methylanisole (entry 8) gave two products (eq. [2]) which were impossible to resolve

[2]

4-isomer 5-isomer

by gc. The nmr of the ketone mixture showed the presence of the 5-isomer in that the OCH_3 signals occurred at $\delta = 3.72$ (4-isomer) and 3.64 (5-isomer) in the ratio of 29:5. The aryl CH_3 signal was likewise broadened at $\delta = 2.14$. The percentage of the 5-isomer was thus 14.7% by nmr analysis. All of the calculations concerning the reaction of OMeAnH were corrected by this amount, and the P_f^{x} calculations for attack at the 5-position of OMeAnH are based on 14.7% of the 5-isomer present in the reaction mixture. In no other case did any other isomers in the dimethylketene acylations appear except for anisole (entry number 7) in which case the *o*/*p* ratio was 4.47×10^{-3} (1).

The results for competition reactions involving diphenylketene acylations are similarly reported in Table 2. Once again the OMeAnH gave two products in a manner entirely consistent with acylations of these substrates with dimethylketenes.

Hammett–Brown plots of P_f^{x} (partial rate factors) versus σ^+ values are displayed in Fig. 1 for competitions with methylketenes and in Fig. 2 for diphenylketenes. In Fig. 1 linear regression of σ^+ vs. log P_f^{x} for the moderately activated substrates 1 through 6 and for the reaction at the 5-position of OMeAnH (entry 8*a*) gave $\rho^+ = -6.59$ (correlation coefficient = 0.9488). The limiting value for the slope of the curve in the anisole and 4-(*o*-methylanisyl) end was determined graphically, as shown in the Fig. 1, to be −0.921. The Hammett–Brown plot is seen to go smoothly from a nearly straight line segment of slope nearly −6.59 to a segment of limiting slope −0.94 indicating a smooth change in mechanism (3, 4).

Figure 2 shows a similar treatment for acylation reactions using diphenylketenes. Linear regression for entries 1 through 5 and the 5-position of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

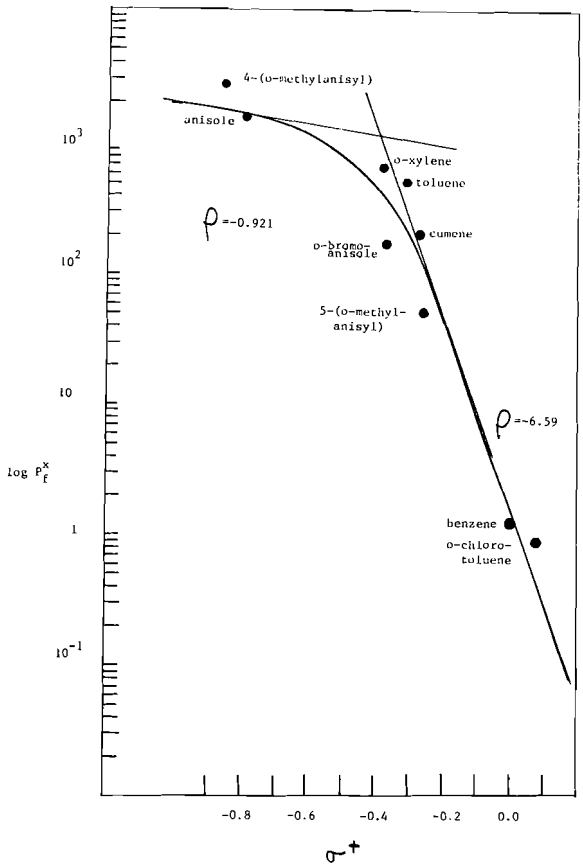

FIG. 1. Hammett–Brown plot for acylations with ketenes (DMK).

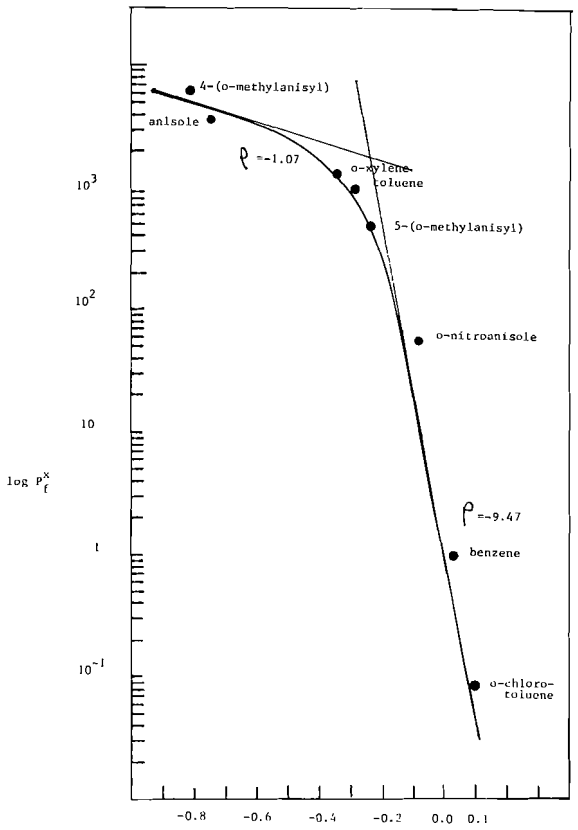

FIG. 2. Hammett–Brown plot of P_f^x for ketene acylations (DPK).

OMeAnH (Table 2, 6*a*) gave a ρ^+ value of -9.47 (correlation coefficient = -0.9667). The limiting value for ρ^+ in the upper region of the curve (large $-\sigma^+$ values) was determined graphically, as shown in Fig. 2, to be -1.07. The Hammett–Brown plot for diphenylketene acylations shows the same general pattern as the plot for dimethylketene (a line correlating moderately activated substrates, and one line correlating highly activated substrates).

It is apparent that, as the ρ^+ value shifts from near -6 to -10 to near -1.0, selectivity is decreased but not drastically so, i.e., *o*/*p* ratio of anisole is 4.47×10^{-3} and no *meta* isomer is found (1). (As little as 0.1% could have been detected.) Thus, although reactivity increases drastically (less negative ρ^+ value), selectivity (5) remains high. The line segments in the Hammett–Brown plots for reactive anisole derivatives resemble the Hammett–Brown plot for vinyl cation alkylation (6) ($\rho^+ = -2.567$), and the reactions are of similar selectivity. The plots for moderately active benzene derivatives resemble ordinary acetylation ($\rho^+ = -9.1$) but with exceptional selectivity (i.e., no *meta* isomers) (5).

Discussion

Stang and Anderson (6) have also reported unusually high positional selectivity combined with very low substrate selectivity. They explained this dilemma of how an intermolecularly nonselective species with a low ρ value (-2.567 for vinyl cations) acquires such great intramolecular selectivity by postulating the existence of two transition states prior to the formation of the usual σ complex (6).

> The first transition state determines the intermolecular selectivity (ρ) and the second transition state determines the intramolecular selectivity (isomer distribution). The low value of ρ indicates that the alkylating agent shows little differentiation between various monosubstituted aromatic rings, based on the electron-donating or withdrawing ability of the substituent. As an electrophilic species approaches an aromatic ring, electrons will flow out of the π cloud of the ring and toward the electrophilic species. The π cloud can be said to be disrupted to the extent that electrons are lost in the transition state. Since the substituent will act to stabilize the growing positive charge on the ring by electron donation, one would expect that the substituents most able to donate electrons (CH_3O, CH_3) would react much faster (sic) than substituents that are less able to donate electrons (H, Cl) to the disrupted π system. However, since all substituents

react at (sic) similar rates (low ρ value), the π system must not be significantly disrupted in the transition state. Hence the first transition state must, therefore, resemble an "inner" π complex rather than a σ complex which involves a greater disruption of the π system.

Such descriptions of inner π complexes as models for transition states of electrophilic aromatic substitutions also appear in the literature of aromatic nitration (7). They are not, however, without controversy (8, 9). Typically the formation of these π complexes is as depicted in eq. [3] (8, 10). The

[3] 

"Outer" complex π-Complex benzonium ion σ Complex

"outer" complex forms first, is transformed to an "inner" complex (the benzonium ion), and finally the product-determining σ complex is formed. These ideas can be summarized as in Fig. 3, the potential energy diagram for electrophilic substitution. In cases where formation of the benzonium ion π complex is rate limiting one would observe this transition state to be higher than for benzonium ion formation (dotted line in Fig. 3).

Applying these ideas to the reaction of aromatic substrates with ketene–$AlCl_3$ complexes we see that as long as one is acylating moderately active substrates the reaction is very much like acetylation (ρ = −9.1) (5).

With greatly activated substrates such as the anisole derivatives the reaction behaves like that for vinyl cations. π-Complexes similar to those postulated for vinyl cations must apply in the reactions of ketenes with very activated substrates.

There remains to be explained the difference in behavior between the acylations of modestly active substrates with ketenes and the alkylation of similar substrates with vinyl cations. In the latter case no change in slope was observed in the Hammett plot (ρ = −2.507) for toluene, benzene, fluorobenzene, and chlorobenzene. In the case of the ketene–$AlCl_3$ complexes resonance stabilization involving the oxygen atom undoubtedly stabilizes the complex and makes it less reactive than a vinyl cation (1). Using the k(Tol)/k(Ph—H) ratios as a measure of the kinetic stability of the ketene–$AlCl_3$ complexes and including the k(Tol)/k(Ph—H) (= 6.76) ratio for the electronically similar vinyl cations (6) one can order the series of species (of course, neglecting solvent differences) in the order of kinetic stability:

$$\underset{k(\text{Tol})/k(\text{Ph—H})\ 6.76}{Ph—\overset{+}{C}=CMe_2} < \underset{47.3}{Cl_3\bar{A}l—O—\overset{+}{C}=CMe_2}$$

$$< \underset{117\ (8,\ 10)}{Cl_3\bar{A}lO—\overset{Cl}{\overset{|}{C}}—\overset{+}{C}Me} < \underset{125\ (8,\ 10)}{O=\overset{+}{C}—Me} < \underset{173}{Cl_3\bar{A}l—O—\overset{+}{C}=CPh_2}$$

There are two surprises in these data. One is that the kinetic stability of the dimethylketene – aluminum chloride complex does not resemble more closely the kinetic stability of the vinyl cation, because the DMK–$AlCl_3$ complex resembles the vinyl cation electronically. The second is that the diphenylketene – aluminum chloride complex differs greatly in reactivity from the dimethylketene – aluminum chloride complex.

The difference between the DMK–$AlCl_3$ complex and a vinyl cation seems to involve the greater stability in the DMK-complex due to delocalization of charge as in **1**.

$$Me_2C=\overset{+}{C}—O—\bar{A}lCl_3 \longleftrightarrow Me_2C=C=\overset{+}{O}—\bar{A}lCl_3$$

1

Of course, one must also keep in mind that the DMK–$AlCl_3$ complex is a neutral compound and the vinyl cation is positively charged. The origin of the greater kinetic stability of the DPK–$AlCl_3$ complex compared to the DMK–$AlCl_3$ complex is more obscure.

In what follows below we extend the idea of rate limiting π-complex formation in terms of the unique stereoelectronic features of ketenes (and vinyl cations). If a unified mechanism connects the electronically similar vinyl cations and DMK or DPK–$AlCl_3$ complexes, the rationalization must contain the following features. It must explain why a vinyl cation behaves as though it forms a substrate-selecting π complex before a product-selecting σ complex in both greatly activated systems and in modestly activated systems. It must

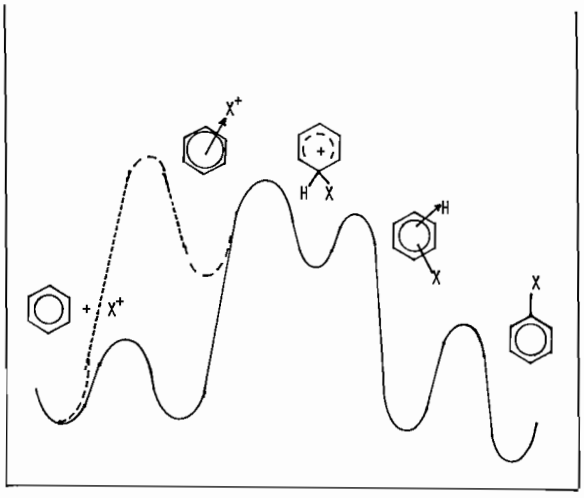

FIG. 3. Potential energy diagram for electrophilic substitution.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

also explain why the less reactive DMK–$AlCl_3$ complex behaves similarly to an ordinary acylation in attacking modestly activated rings, yet behaves like a vinyl cation for highly activated rings. Lastly, it must explain why the DPK–$AlCl_3$ complex is greatly substrate selective with modestly activated rings, but with very activated rings behaves like DMK–$AlCl_3$ or a vinyl cation.

There are basically two types of orbital interactions possible, from first principles, in π-complex formation. These are shown in Figs. 4 and 5. We will label the interaction in Fig. 4 as a parallel approach and that of Fig. 5 as a perpendicular approach. The approach of Fig. 4 is described by Olah *et al.* (10) as a "benzonium ion" π complex. The second type of orbital interaction in Fig. 5 is taken to be similar to that postulated by Woodward and Hoffman (11) for $\pi^2s + \pi^2a$ processes, especially those that involve ketenes. Because of the unique stereoelectronic properties of any ketene – aluminum chloride complex the approach of the reagent to the substrate can involve both of these types of orbital interactions as in Fig. 6. Both types of overlaps may make significant contributions to the stability of the transition states before the ultimate product controlling σ complex. Note that in this scheme it is necessary to consider the HOMO–LUMO interaction between the substrate and the electrophilic reagent *and* the LUMO–HOMO interaction between the two. This is in clear contrast to the theoretical consideration of only the interaction between LUMO of the electrophile and HOMO of the substrate (12).

When a very reactive vinyl cation approaches a moderately active ring, π-complex formation takes place readily, involving both modes of bonding. As the "benzonium" π complex is formed, charge is placed more on the ring than in the "outer complex" formation. This additional charge on the ring causes back-bonding, of the type in Fig. 5, from the π orbital of the vinyl cation to the LUMO of the ring. This occurs in even moderately activated rings because of the great reactivity of the vinyl cation. When a more stable DMK–$AlCl_3$ complex approaches a moderately activated ring, sufficient charge is not transferred to the ring to allow significant amounts of back bonds, as in Fig. 5, to occur, due to the greater kinetic stability of the complex. Thus a normal course of events is followed in which a rate-determining σ complex occurs. With the more activated anisole derivatives more stabilization of the charge in the π complex (benzonium ion) occurs which in turn allows more back-bonding from the π orbitals of the C=C bond in the DMK–$AlCl_3$ complex to occur with the ring. Thus when activated species of rings are approached by the DMK or DPK–$AlCl_3$ complex, the reaction resembles alkylation by a vinyl cation. The decrease in ρ value for the DPK–$AlCl_3$ complex is probably due to the conjugation of the C=C π bond with the phenyl rings, thus making it less available for back-bonding and correspondingly the DPK–$AlCl_3$ complex would be more sensitive to substituents on the benzene ring.

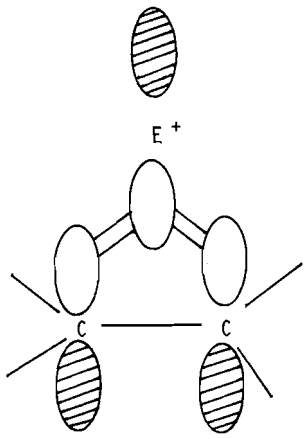

FIG. 4. Parallel approach.

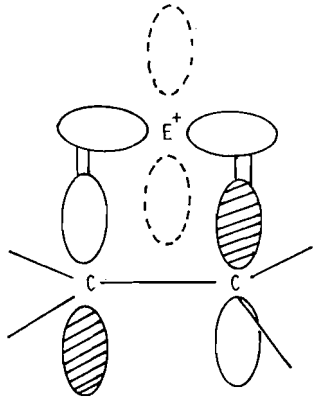

FIG. 5. Perpendicular approach.

This rationalization explains why the change in rate limiting step occurs with anisole and its derivatives for DMK– or DPK–$AlCl_3$ complexes, but not for vinyl cations. The interactions of the phenyl rings on DPK–$AlCl_3$ with the remainder of the molecule are not clear at the present time, so we cannot rationalize why the DPK–$AlCl_3$ complex is so kinetically stable; yet it behaves like a vinyl cation with active rings.

Experimental

General

Infrared spectra are neat or Nujol mulls except where noted, and are run on a Beckman IR4. The nmr spectra are run in the solvents noted with TMS or DSS as internal standard.

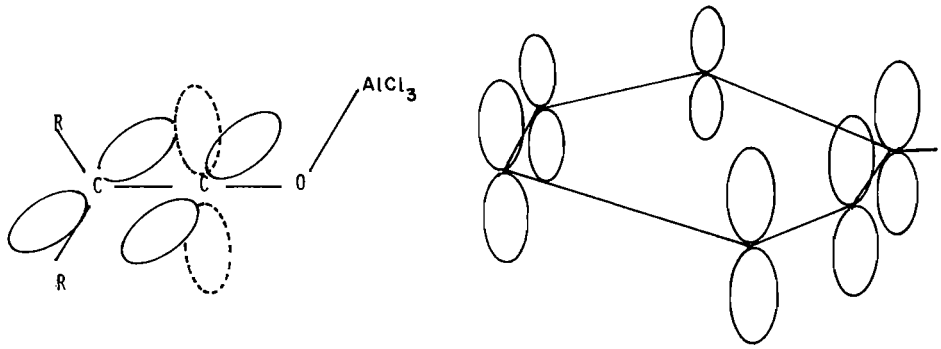

FIG. 6. Substituted ketene–$AlCl_3$ complex approaching a substituted benzene ring illustrating both parallel and perpendicular approaches in ketone acylations.

Statistical Analysis

The slopes of the two lines in Figs. 1 and 2 were calculated by means of a Texas Instruments TL-55 hand calculator using the regression routine provided.

Microanalytical work was done by Galbraith Labs, Knoxville, TN, or by Industrial Testing Laboratory, Inc., St. Louis, MO. All chemicals were reagent grade Eastman or Aldrich products.

Preparation of Ketenes

Dimethylketene was prepared by the pyrolysis of dimethylmalonic anhydride as per Staudinger *et al.* (12). The material thus obtained was distilled twice before use and opened only to a dry nitrogen atmosphere.

Diphenylketene was made by debromination of α,α-bromodiphenylacetyl bromide (13) with triphenyl phosphine in ligroin. The dibromotriphenyl phosphorane was filtered through a sintered glass funnel and hydroquinone (0.1 g) was added. The ligroin was removed by distillation under reduced pressure and the residue distilled to give yields of 60–85% of diphenylketene.

Preparation of Authentic Aryl Isopropyl Ketones

The preparations of authentic materials have been reported in ref. 1.

Competition Experiments with Dimethylketene

General Procedure

Dimethylketene generated and purified as reported above was added to a 20-fold excess of a 50 mol% mixture of each substrate. Aluminum chloride was added portionwise with mechanical stirring, and the reactions were stirred one hour after the addition was completed. Work-up was as recorded above.

Gas chromatographic analysis was done on a Perkin-Elmer 3920 instrument (TC Bridge) with a 6 ft 10% Carbowax 20 M on 80/100 Chromosorb W column at a temperature of 190°C, He flow rate of 30 mL/min.

Relative response factors were determined by mixing known concentrations, in hexane, of ketones (in g/100 mL) and determining the ratios of areas. This procedure gives a relative response factor (RRF) of (area/g of ketone I)/(area/g of ketone II). These are summarized in Table 3. All competitions were done by comparing the rates of reaction with toluene for experimental convenience. The rate constant ratios were determined by the formula

$$\frac{k_a}{k_b} = \frac{[AX]}{[BX]} \Big/ \frac{[A_0]}{[B_0]}$$

TABLE 3. Relative response factors for ketones from acylation with dimethylketene

Ketone from	Retention time (min)	RRF[a]	(Standard deviation)
1. Benzene	3.15	0.7547	(0.0492)
2. Toluene	4.20	1.0000	—
3. *o*-Xylene	6.55	1.2191	(0.0087)
4. *o*-Chlorotoluene	7.80	0.8771	(0.0214)
5. *o*-Methylanisole	15.25	1.2990	(0.0071)
6. Anisole	12.90	1.0651	(0.0115)
7. Cumene	8.15	1.1090	(0.0019)
8. *o*-Bromoanisole[b]	4.43	0.2977	(0.0009)

[a]RRF = (area of ketone/g ketone)/(area of tolyl ketone/g tolyl ketone).
[b]This compound was determined by liquid chromatography on a Waters 6000 dual pump instrument equipped with a 660 Solvent Programmer and a 440 UV-Detector. The column was a Whatman Partisil 10M9 ODS2 column 250 mm × 9.40 mm (id). Flow rate was 2.0 mL/min of 15% H_2O–methanol.

In all cases the substrate ratios to ketene were large enough to insure small errors in the rate ratios (2). In the cases involving the very active anisoles, relative rates of anisole vs. *o*-methyl anisole were used as a check on the accuracy of the relative rates vs. toluene. The former figures were used in the Hammett study. Integration was done by a Spectra Physics electronic integrator.

Authentic samples of ketones were mixed to give artificial mixtures as a check on the accuracy of the integration technique. It was found that at very high ratios the integrator consistently overestimated the amount of the smaller component. Corrections were applied where appropriate or the run was redone using a larger amount of less active substrate.

The benzene–toluene ratios were determined in this way using ratios of 1:1 benzene–toluene, 3:1, and 5:1. These results are summarized in Table 4.

The results for the 5:1 experiment were used to determine the toluene/benzene ratio as follows.

(Note: (RRF benzene/toluene)/(RRF toluene/ketone x)
= RRF benzene/ketone x)

k(Substrate)/k(Benzene)
= area ratio × 1/RRF × statistical factor
× mol. wt. isobutyrophenone/mol. wt. substituted isobutyrophenone

$= 51.86 \times 1/0.7547 \times 6 \times 148/162$

$= 376.7$

TABLE 4. Relative areas of ketones in benzene–toluene competition

Ratio of benzene–toluene	Moles of substrate:moles ketene	Ketone areas (area tolyl/area phenyl)
1:1	$(0.65 + 0.65)/1.313 \times 10^{-2} = 99$	52.34
3:1	$(1.95 + 0.65)/1.41 \times 10^{-2} = 184$	50.95
5:1	$(3.25 + 0.65)/1.52 \times 10^{-2} = 257$	51.86

TABLE 5. Rates of acylations relative to benzene

Substrate	Area ratio	Statistical factor	Mol. wt. ratio	P_f^x[a]	σ^+
1. Benzene	0.0193	1.000	1.000	1.00	0.000
2. Toluene	1.000	6	148/162	380.2	−0.306
3. *o*-Xylene	3.58	3	148/176	455.4	−0.375
4. Cumene	0.549	6	148/190	153.5	−0.276
5. *o*-Chlorotoluene	0.0033	6	148/196.45	0.718	+0.0070
6. Anisole	88.44	6	148/178	1259.7	−0.764
7. *o*-Methylanisole	649.52	6	148/192	2959.7	−0.833
8. *o*-Bromoanisole[b]	4.573	6	148/255.9	131.9	−0.373

[a] P_f^x = area ratio × 1/RRF × area tolyl ketone/area phenyl ketone × statistical factor × mol. wt. ratio (2).
[b] Determined by lc on the instrument described in footnote (*b*) of Table 3.

In a similar manner all the ketones were determined with the results in Table 5. In each case the reactions were done as competition of a given substrate with toluene. They are corrected relative to benzene by the toluene/benzene reactivity ratio. It was convenient to use toluene as the fundamental comparison reagent because benzene gave very low yields with dimethylketene, probably due to reaction of dimethylketene with itself to give dimer and then further reaction with $AlCl_3$.

Competitions with Diphenylketenes

A typical experiment involved adding a known amount of freshly prepared distilled diphenylketene to a large excess of a 50:50 mixture of hydrocarbons (mole:mole) present in a large molar excess. Thus 0.05 mol of diphenylketene was added to 2.0 mol of *o*-methylanisole and 20 mol of toluene in a flask fitted for mechanical stirring. Through a solids hopper, with the flask maintained at 25°C, 5.22 g (2.5 equivalents) of aluminum chloride was added rapidly, but not so as to cause a great temperature change. The reaction was quenched in 200 mL of dilute (6 *N*) HCl – ice water. The separated organic layer was washed with three 100 mL portions of NaOH, dried over $MgSO_4$, and the solvent removed on a rotary evaporator.

Analysis of the residues from this and all of the other reaction mixtures was done via liquid chromatography. The apparatus was a Waters hplc apparatus including a UL 6 injection loop, a pair of 6000 pumps, a 440 uv detector, and a 660 solvent programmer. The column was a Whatman Partisil 10M9 ODS2 reverse phase 250 mm × 9.40 mm. Flow rate was 2.5 mL/min of 25% H_2O – methanol.

The relative response factors at 254 mm for the ketones were determined from authentic mixtures of samples of known concentration. The RRF factors relative to toluene or benzene are recorded in Table 6 as well as the area ratios, which were determined from the integrator of a Soltec Model 250A recorder.

The partial rate factors in Table 2 are obtained from the area ratios as follows:

P_f^x = area ratio ÷ RRF × statistical factor × area toluene/area benzene.

When the area ratio was determined by competition with benzene, the last multiplier was omitted.

The benzene–toluene area ratio was obtained from an experiment in which the (moles of benzene/moles of toluene) starting material was 10 (1).

TABLE 6. Area ratios and RRF factors for diphenylketene competitions

Experiment	Substrate	Area ratio[a]	RRF[c]
1	*o*-Nitroanisole	4.3426[b]	0.3691
2	*o*-Chlorotoluene	4.529[b]	0.4185[b]
3	Benzene	4.44×10^{-2}	0.7720
4	Toluene	1	—
5	*o*-Xylene	3.03	1.1570
6	Anisole	2.128	0.5251

ALEX D. BAIN, RUSSELL A. BELL, JEREMY R. EVERETT, and DONALD W. HUGHES. Can. J. Chem. **58**, 1947 (1980).

An alternative two-dimensional nmr pulse sequence, (90°–t_1/2–90°–t_1/2–FID), correlates the chemical shifts of coupled nuclei. The application of this technique to the solution of the complicated proton nmr spectra of oligoribonucleotides is discussed.

ALEX D. BAIN, RUSSELL A. BELL, JEREMY R. EVERETT et DONALD W. HUGHES. Can. J. Chem. **58**, 1947 (1980).

Une rmn alternative à impulsion (90°–t_1/2–90°–t_1/2–FID) coordonne les déplacements chimiques des noyaux couplés. On discute de l'application de cette technique à la résolution des spectres rmn compliqués d'oligoribonucléotide.

[Traduit par le journal]

Introduction

The principles of two-dimensional (2D) Fourier Transform (FT) nmr spectroscopy are very similar to those of normal one-dimensional (1D) FT nmr spectroscopy. In the normal 1D experiment, magnetization, due to all the spins, is created in the x,y plane by a pulse of radiofrequency energy. During the free induction decay (FID) the magnetization is sampled at regularly incremented times t_2. The resulting data are Fourier transformed to give the normal spectrum in which intensity is plotted as a function of a frequency axis f_2.

A 2D FT nmr (1, 2) experiment is similar if we consider the detector to be one of the lines in the 1D nmr spectrum. Magnetizations corresponding to all the lines in 1D spectrum are created by an initial pulse. The magnetizations rotate in the x,y plane for a certain time, after which each magnetization has a characteristic phase determined by its Larmor frequency. A second pulse, called the mixing pulse, will now transfer phase information from one magnetization to other magnetizations in a selective fashion. Thus, at the end of time t_1, the phase of a given magnetization depends on both its own Larmor frequency and the Larmor frequencies of any other magnetizations that were mixed with it. This given magnetization may now be sampled and Fourier transformed in exactly the same manner as the 1D experiment, and in addition, the experiment is repeated over regularly incremented times t_1. This yields a spectrum in f_2 for each t_1 value used. The phase dependence, as a function of t_1, of a magnetization corresponding to a line in f_2 allows that magnetization to act as a selective detector of only the magnetizations to which it is connected. Usually, this connection is via scalar coupling (2) although chemical exchange (3) and dipolar coupling (4, 5) are also possible connection mechanisms. A second Fourier transformation of each data point in f_2 as a function of t_1 leads to a single 2D nmr spectrum in which signal intensity is plotted as a function of two orthogonal frequency axes, f_2, the "normal" axis of the 1D experiment, and f_1, the second frequency axis. Each line in f_2, serving as a detector, displays what it has detected along the second frequency dimension f_1.

Just what appears in the second dimension depends upon the spin system, and the nature of the pulse sequence used on it. In the case of a 90°–t_1/2–180°–t_1/2–FID sequence (2) applied to a weakly coupled spin system, a line in a multiplet in f_2 is mixed only with the symmetrically disposed line on the other side of the multiplet, giving a single line in f_1 for each line in f_2. When strong coupling is present (6) or the 180° pulse is changed to any other angle $x°$ ($x \neq n \times 180°, n = 0, 1, 2, 3 \ldots$) the situation is more complex. More lines appear in f_1 because, in general, a line in the spectrum in f_2 associated with a particular nucleus can be mixed with any other line belonging to that same nucleus or another nucleus coupled to it, provided that this other nucleus is also affected by the pulse. This means that with respect to the evolution time t_1, modulation may be detected at frequencies involving both coupling constants and chemical shift differences. Thus, by the use of this 2D chemical shift correlated nmr spectroscopy, the relative chemical shift of a nucleus may be found from the spectra of any nucleus coupled to it, as in the INDOR experiment

(7). A proton spectrum may be correlated with itself (1) or with the ^{13}C or ^{31}P (8–12) spectra of the same molecule.

In this paper we use 2D chemical shift correlated nmr spectroscopy and a $90°-t_1/2-90°-t_1/2-FID$ pulse sequence to help unravel the complicated proton nmr spectra of 5′-adenosine monophosphate (5′-AMP) and cytidyl-3′,5′-adenosine (CpA). We further show how details of the effects in the 2D spectra may be calculated for an ABX-type spin system.

Experimental

The nucleotides were lyophilised from D_2O and then dissolved in 100% D_2O which contained 0.01 *M* sodium phosphate buffer (pD 7.0) and 1.0 *M* sodium chloride. The solution concentrations of 5′-AMP and CpA were 0.41 and 0.25 *M* respectively and the sample temperatures were 71 ± 2°C.

Spin-echo FID's were accumulated at 90 MHz on a Bruker WH90 spectrometer equipped with a BNC-12 data system and a NIC-293 I/O controller. The pulse sequence used was $90°-t_1/2-90°-t_1/2-FID$ (t_2). A total acquisition time t_2 of 4 s over 2K data points gave an f_2 sweep width of ∼±250 Hz. Four pulse sequences were used to accumulate the 5′-AMP FID's, eight were used in the case of CpA. The evolution time t_1 was incremented by 0.003 s 180 times from an initial value of 0.001 s. The sweep width in f_1 was thus ±83.3 Hz. Delay times of 4 s and 6 s between pulse sequences were used in the accumulation of the data on CpA and 5′-AMP respectively. The FID data were transferred to and processed on a Nicolet 1180 computer system. Nicolet kindly provided the data transfer program.

Results

5′-Adenosine Monophosphate

Table 1 gives the predicted and observed f_1 frequencies in the 2D spectrum of the low field (f_2) H-1′ transition of 5′-AMP. Tables 2 and 3 give the

corresponding data for the lowest field H-2′ and H-3′ transitions respectively. Table 4 lists the f_2 frequencies (relative to the carrier) of all the transitions in the H-1′, H-2′, and H-3′ multiplets.

Cytidyl-3′,5′-adenosine

Table 5 lists the f_1 frequencies and their analysis for the low field AH-1′ transition in CpA. Tables 6 and 7 list corresponding data for the high field CH-5 transition and low field CH-1′ transition respectively.

Discussion

The frequencies of lines that appear in a 2D FT nmr spectrum can be worked out in terms of the mixing of magnetizations corresponding to connected f_2 transitions (13). However, since it is difficult to represent the magnetizations in a coupled spin system in three-dimensional space (14), the determination of the details of intensities and phase relationships in the spectra requires more sophisticated calculation. This can be done using standard techniques, in which the effect of pulses on spin wavefunctions is calculated (1). A more efficient and elegant technique is to calculate the effect of pulses on the magnetizations directly, using single transition operators (14, 15) or the superspin formalism (16, 17). We feel the latter method provides the simplest method of calculation and gives the clearest picture of what is going on, particularly with regard to the formation of spin echoes (18, 19). The details of the superspin analysis of the ABX system (16) and of a general 2D FT nmr experiment (17) have been published elsewhere. However, we outline the theory below.

TABLE 4. A table of frequencies in f_2 in Hz for all the transitions of the H-1′, H-2′, and H-3′ spin multiplets in 5′-AMP

Proton	f_2 Transition frequency (Hz)[a]
H-1′	−22.2
	−27.2
H-2′	−140.8
	−145.8
	−150.7
H-3′	−159.5
	−163.8
	−168.8

[a]Relative to the carrier frequency at 0 Hz.

At equilibrium the only nonzero part of the density matrix is associated with a superspin of 1, representing the total magnetization of all the spins (20, 21). This means that the first pulse creates only single quantum coherence; in other words, it excites only the transitions we normally observe in a spectrum. This is a general result for any nonselective pulse on any type of spin system. In terms of our formalism, this coherence, corresponding to a transition frequency ω_i, is made up of two counterrotating components. These are associated with superspin z components of +1 and −1 and evolve in time as $\exp(i\omega_i t)$ and $\exp(-i\omega_i t)$. Note that these are positive and negative absolute frequencies representing the two senses of precession around the static magnetic field B_0. However, associated with the radio-frequency field are two counterrotating frames of reference, so that each sense of rotation is detected in its own rotating frame and appears as a frequency relative to the carrier.

The magnetizations created by the first pulse evolve at their characteristic frequencies until a second pulse is applied. The second pulse mixes the magnetizations so that lines in the spectrum

show modulation with respect to the evolution time t_1. If we collect the spectrum immediately after the second pulse, we get a two-dimensional correlated spectrum (1). Delaying the acquisition by a time equal to the interval between the pulses (i.e. a spin echo sequence) splits the spectrum into two parts, which we have called an additive and subtractive spectrum (13).

The additive spectrum arises from coherence which is mixed by the pulse with coherence precessing in the same sense. The frequencies (with respect to the carrier) add, and the lines in the f_1 spectrum appear $(\omega_i + \omega_j)/2$ where ω_i is the f_2 frequency of the line itself and ω_j is any other f_2 frequency that can be mixed in. The subtractive spectrum results from the mixing of coherence of opposite senses of precession and the lines in f_1 appear at $(\omega_i - \omega_j)/2$. The intensities of these lines are a sensitive function of the flip angle of the second pulse. For a $90°-t_1/2-180°-t_1/2$–FID pulse sequence, the additive spectrum disappears and in weakly coupled systems, the subtractive spectrum is particularly simple, since all but one of the expected lines have zero intensity. This results in a J-resolved 2D nmr spectrum (2). In the general case for a $90°-t_1/2-x°-t_1/2$–FID pulse sequence, some of the lines in the subtractive spectrum (e.g. $(\omega_i - \omega_i)/2$) have positions that are independent of the static field B_0. This means that they are unaffected by B_0 inhomogeneity and are responsible for spin echo formation (18, 19). Other lines in the subtractive spectrum and in general all the lines in the additive spectrum will suffer a broadening in f_1 due to B_0 inhomogeneity. The extent of this broadening is determined by how strongly the f_1 frequency at the start of acquisition depends on B_0. In general

the f_1 spectrum will consist of an additive and a subtractive spectrum plus one more line, a "phantom", due to coherence created by the second pulse (22). This is illustrated in Fig. 1, which shows the f_1 spectrum of a single uncoupled line (the AH-2 proton in CpA) obtained from a $90°$–t_1/2–$90°$–t_1/2–FID experiment. The subtractive line appears at 0.2 Hz ($(\omega_i - \omega_i)/2 = 0$ Hz, ω_i = 178.5 Hz in f_2 relative to the carrier) and the additive line appears at 12.8 Hz ($(\omega_i + \omega_i)/2 = 178.5$ Hz which folds to $178.5 - 2 \times 83.3 = 11.8$ Hz). The line at −76.9 Hz is the phantom ($\omega_i/2 = 89.3$ Hz which folds to $89.3 - 166.7 = -77.4$ Hz). Digitization in both f_2 and f_1 accounts for the frequency discrepancies. The subtractive line is the narrowest, since the B_0 effects have cancelled out; the phantom has only dephased for $t_1/2$, so it is not as broad as the additive line which has been dephasing for a full t_1.

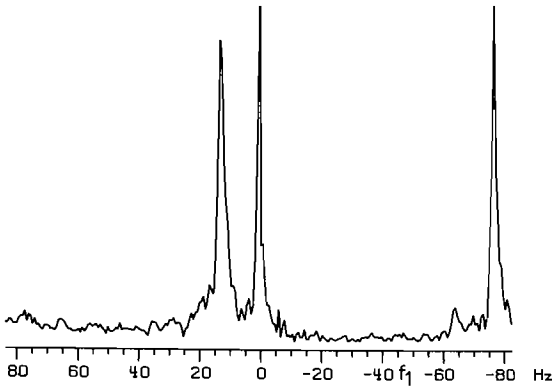

FIG. 1. The real f_1 spectrum of the AH-2 proton in CpA.

Since only single quantum coherence was present before the second pulse, no new frequencies will appear in f_1; only combinations of those observed in f_2. More pulses are needed to create multiple quantum coherence (23). The additive spectrum can be suppressed by a more complex series of pulses (24), leaving only the subtractive spectrum.

We have written a computer program which simulates the experiment based on the pulse sequence α_1–t_1/2–α_2–t_1/2–FID, where α_1 and α_2 are the flip angles of the two pulses, applied to an ABX spin system. The program was written in BASIC on

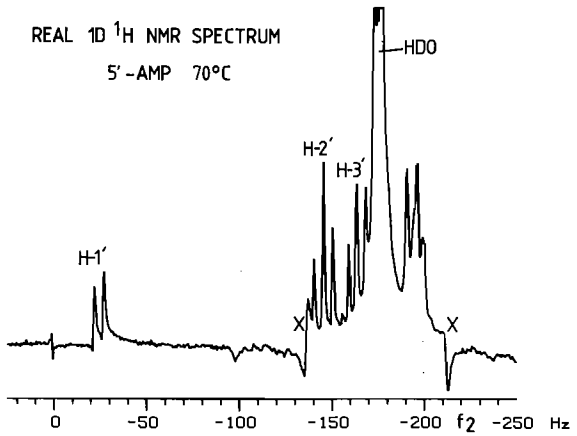

FIG. 2. The 1D ^{1}H nmr spectrum of 5′-AMP in the region of the ribose protons. X indicates a sideband of the strong, residual HDO resonance. Phase errors exist since the spectrum is the transform of an FID from the 2D experiment with the minimum evolution time t_1. The f_2 frequencies are relative to the carrier frequency at 0 Hz.

Analysis of the ^1H Chemical Shift Correlating 2D nmr Spectrum of 5′-AMP

Figure 2 shows the normal 1D ^1H nmr spectrum of 5′-AMP. This spectrum has been recorded many times (25, 26) and its analysis is well documented, but we shall use it here to illustrate our method. The H-1′, H-2′, and H-3′ multiplets are all clearly visible in the 1D spectrum and the exact f_2 frequencies of the transitions in these multiplets are given in Table 4. We shall start our analysis with the H-1′ proton and see how the f_1 spectrum of each transition in f_2 can be predicted from a knowledge of the f_2 transition frequencies of all the appropriate coupled lines.

Figure 3(A) shows the real 2D nmr spectrum in the region of the H-1′ proton. Figure 3(B) shows the simulation of this region produced by our calculation program. With the exception of a few minor intensity differences, the agreement between the real and simulated spectra is good.

Figures 4(A) and 4(B) show the real and simulated f_1 spectra of the low field transition in f_2 of the H-1′ proton. Table 1 gives the predicted and observed f_1 frequencies in this spectrum, a total of eleven lines. The table also lists the origin of all these lines. The low field H-1′ magnetization mixed with itself in both an additive and subtractive sense to give the lines at -21.8 and -0.2 Hz respectively. It also mixed with its upfield partner to give the lines at -24.6 and 2.6 Hz. Since the H-1′ proton is coupled to the H-2′ proton, the low field H-1′ transition also mixed with each of the three H-2′ magnetizations to give lines at -81.2, 82.5, and 80.2 Hz from additive mixing and lines at 59.5, 62.1, and 64.2 Hz from subtractive mixing. All these lines were predicted correctly to within the limits of digitization (0.9 Hz), by the simple addition and subtraction of the appropriate connected f_2 frequencies. This analysis accounts for ten lines; the eleventh is a phantom line and occurs at one half the f_2 frequency of the H-1′ transition, i.e. -11.1 Hz.

The spectrum of H-2′ is a doublet of doublets due to coupling to both H-1′ and H-3′. However, since the two coupling constants are similar in magnitude, the two central lines overlap to give the appearance of a triplet. One of the two overlapped lines is connected progressively to H-1′, and the other is connected regressively, in the generalized sense of these terms (1). In the f_1 spectrum of H-1′ the two lines due to the mixing of the H-1′ magnetization with these two central lines of H-2′ are 180°

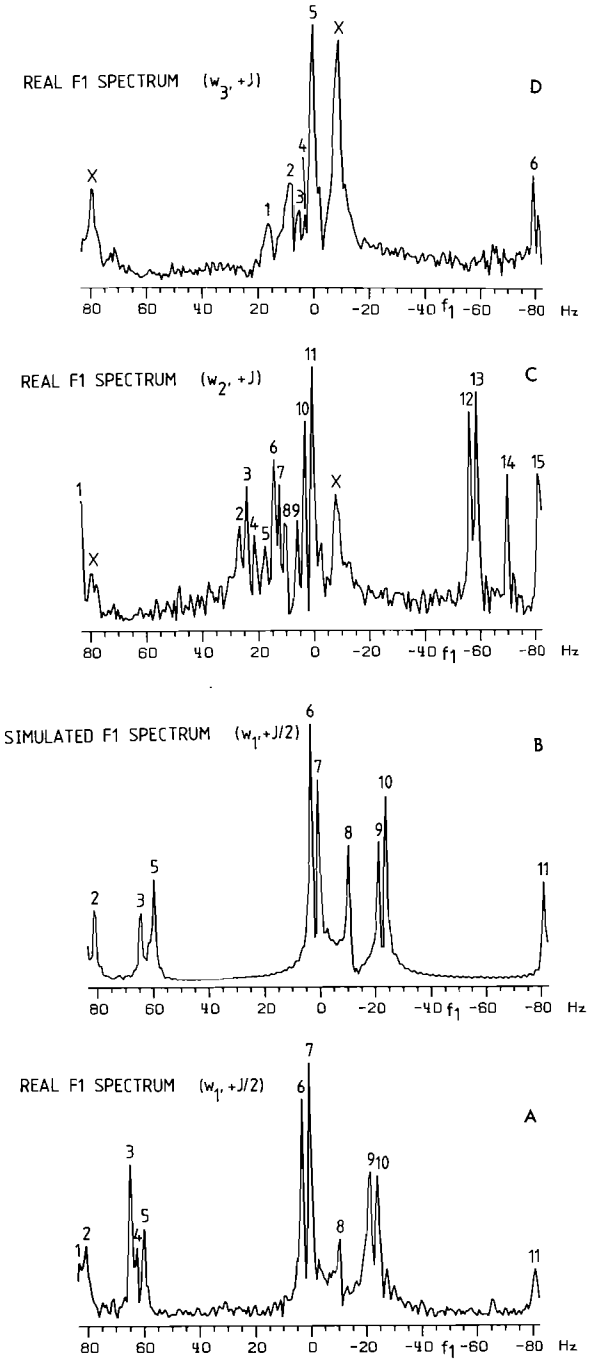

FIG. 4. (A) The real f_1 spectrum of the low field (f_2) H-1′ transition in 5′-AMP; (B) the simulated f_1 spectrum of the low field (f_2) H-1′ transition in 5′-AMP; (C) the real f_1 spectrum of the lowest field (f_2) H-2′ transition in 5′-AMP. X indicates lines due to the overlap from the f_1 spectrum of the HDO peak; (D) the real f_1 spectrum of the lowest field (f_2) H-3′ transition in 5′-AMP. X indicates lines due to the overlap from the f_1 spectrum of the HDO peak.

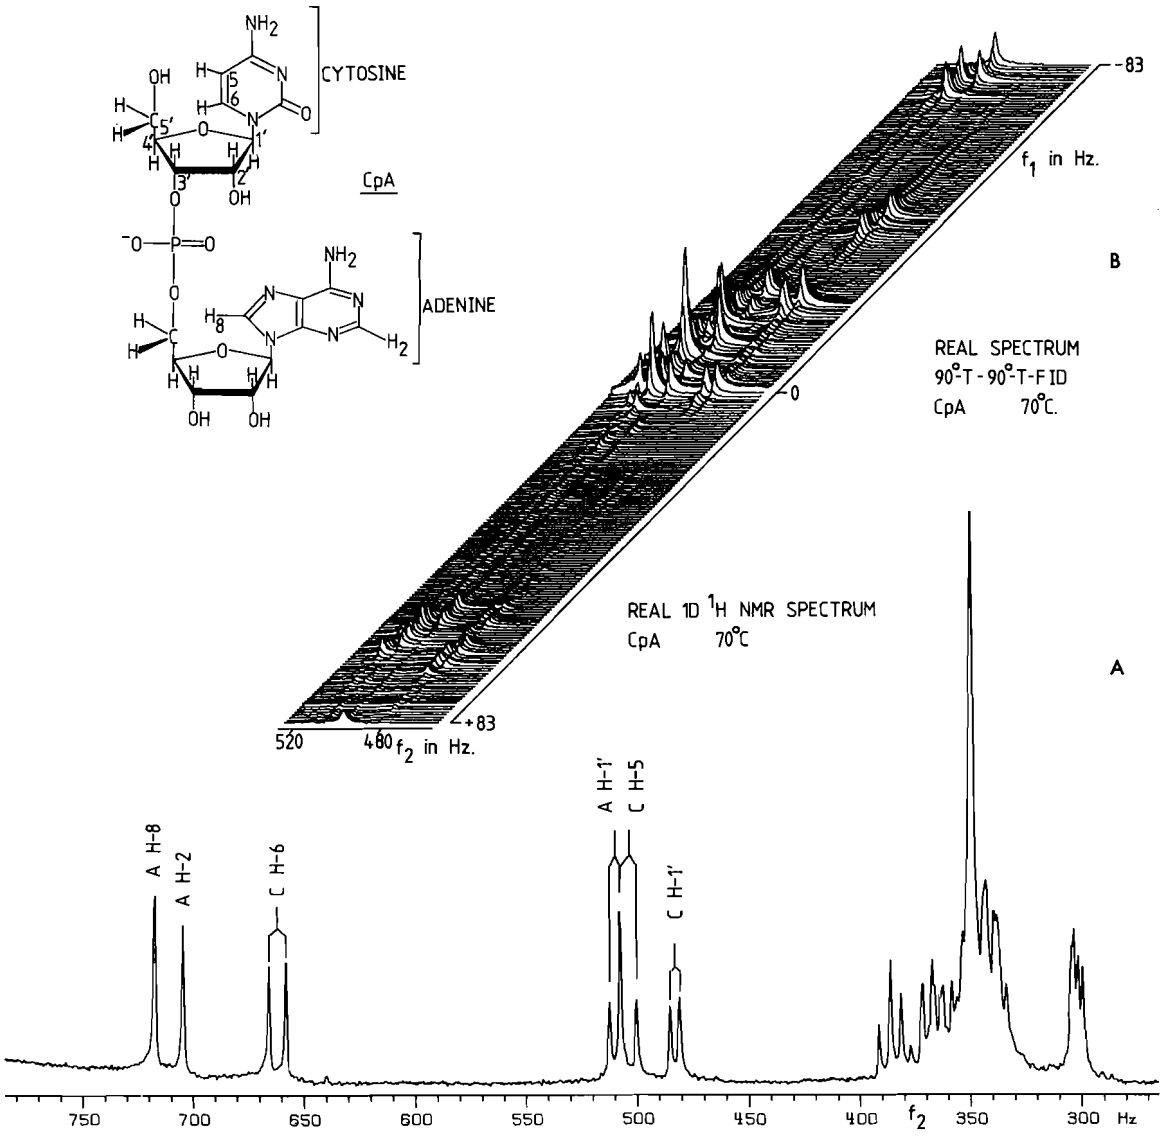

FIG. 5. (A) The 1D ^{1}H nmr spectrum of CpA. The f_2 frequencies are calibrated using internal *tert*-butanol; (B) the real 2D ^{1}H nmr spectrum of CpA in the region of the H-5 and H-1′ protons.

out of phase with one another. Since they overlap in f_1, they partially cancel each other out, leaving a very weak central line in the triplet in f_1, as can be seen in Fig. 4. This is a common feature when coherence is transferred between nuclei (2).

Figure 4 also shows the real f_1 spectra of the lowest field AH-2′ and AH-3′ transitions. Tables 2 and 3 give the predicted and observed frequencies of the lines in the f_1 spectra which were again calculated on the basis of the simple addition and subtraction of the appropriate f_2 frequencies given in Table 4. As before, agreement between predicted and observed f_1 frequencies was good. No lines in the f_1 spectrum of the H-3′ transition which indicated mixing with the H-4′ proton could be identified. However, the H-4′ proton is the C part of an ABCDX spin system, and as such it probably has an extremely complicated signal, many of the lines of which would be very weak (26).

Thus we can account for all of the lines in the 2D nmr spectrum of this relatively simple compound. We shall now turn our attention to the analysis of the more complicated spectrum of CpA.

Analysis of the Chemical Shift Correlated 2D nmr Spectrum of CpA

Figure 5 shows the normal 1D nmr spectrum of CpA. The 1D ^{1}H nmr spectrum has been recorded

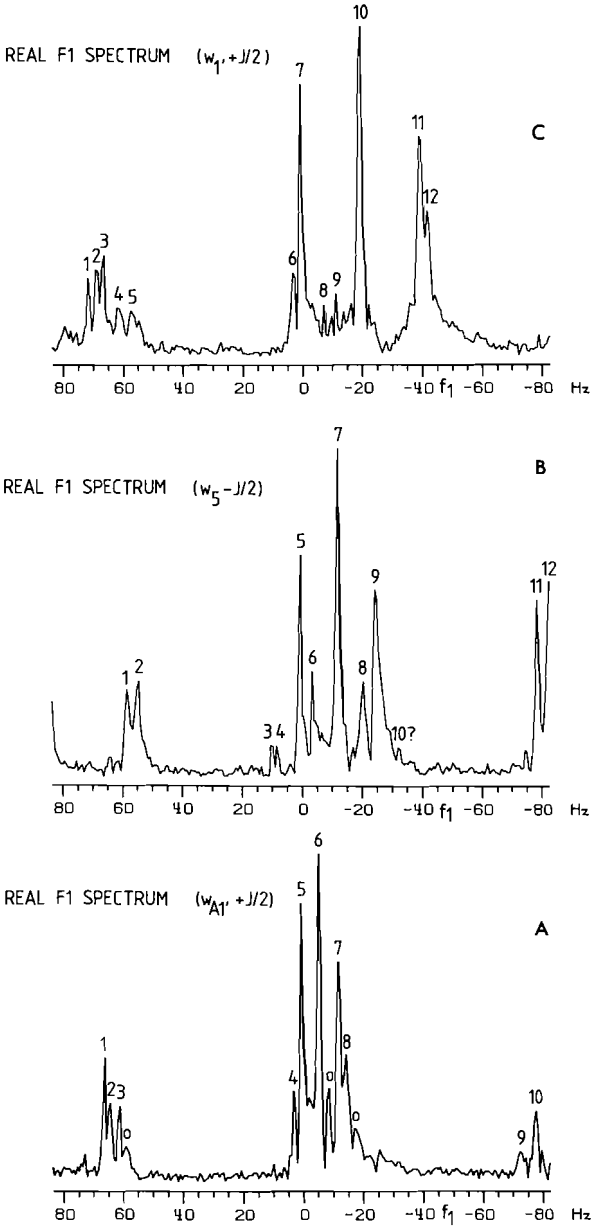

FIG. 6. (A) The real f_1 spectrum of the low field (f_2) AH-1′ transition in CpA. Overlapped lines from other f_1 spectra are indicated by O; (B) the real f_1 spectrum of the high field (f_2) CH-5 transition in CpA; (C) the real f_1 spectrum of the low field (f_2) CH-1′ transition in CpA.

at superconducting field strengths by Sarma and co-workers (27) who used simulation/iteration methods to analyse the spectrum. The results obtained here from the 2D analysis agree in general; however, differences in temperature, concentration, and solvent prevent direct comparison.

Figure 5 shows the real 2D nmr spectrum in the region of the AH-1′, CH-5, and CH-1′ resonances. Figure 6(A) shows the real f_1 spectrum of the low field AH-1′ transition. An analysis of this spectrum in terms of the mixing of the appropriate AH-1′ and AH-2′ magnetizations is given in Table 5. This analysis allowed the location of the AH-2′ resonance as a pseudo triplet at ~ -140 Hz from the carrier in f_2. This signal can be distinctly seen in the normal 1D spectrum. A similar analysis applied to the f_1 spectra of the f_2 transitions of the newly-located AH-2′ proton allowed the assignment of the AH-3′ proton as the pseudo triplet at ~ -159 Hz from the carrier in f_2.

Figure 6(B) shows the real f_1 spectrum of the high field CH-5 transition and Fig. 6(C) shows the real f_1 spectrum of the low field CH-1′ transition. Table 6 gives an analysis of the f_1 spectrum of the CH-5 transitions in f_2. An interesting feature of this spectrum is that it reveals the presence of a connection between the CH-1′ and the CH-5 protons via a five bond coupling. The two weak lines at 7.6 and 9.8 Hz are due to subtractive mixing with CH-1′. If these lines were perfectly resolved, they would form a doublet of doublets with a large splitting (observed) due to $^3J_{(H2'—H1')}$ and a smaller splitting (unresolved in the experiment) due to $^5J_{(H5—H1')}$. The lines split by this latter coupling overlap and partially cancel in the f_1 spectrum because they are of opposite phase; if the coupling constant was 0 Hz, they would cancel exactly. The digitization in this experiment was not good enough to measure this coupling, but the peaks in the f_1 spectrum were a clear indication of the presence of the $^5J_{H,H}$ coupling. Similar small $^5J_{H,H}$ couplings in similar systems have been observed in the past (25).

Table 7 gives an analysis of the f_1 spectrum of the low field CH-1′ transition in f_2. Aside from confirming the presence of the $^5J_{H,H}$ coupling this spectrum revealed the exact chemical shift of the CH-2′ "triplet" which was completely hidden in the 1D spectrum under a residual solvent signal and a mass of other resonances.

Conclusion

A new pulse sequence (13, 24) for 2D nmr spectroscopy has been described which allows chemical shift correlations between coupled nuclei to be made. The technique has been shown to be invaluable in the determination of the precise location of buried resonances and also in the discovery of small, long-range couplings not normally detected by 1D nmr spectroscopy. As such this new technique promises to be very useful to practising chemists especially, since the spectra may be accumulated and processed in a matter of a few hours on standard spectrometers.

This technique is a development of a previous one (1) in which there was no delay after the mixing

pulse. The advantage of inserting the second delay is that it allows the partial cancellation of B_0 inhomogeneity in f_1. With a more sophisticated pulse sequence (24) which suppresses the additive spectra a further advantage is accrued in that the f_1 width can be reduced to the largest chemical shift difference between two coupled nuclei rather than being equal to the f_2 width. This saves time and data storage.

The metabolism of 2-hydroxymethyl-3-methylquinoxaline-di-*N*-oxide in the chicken, rat, and dog

S. K. FIGDOR AND D. C. HOBBS

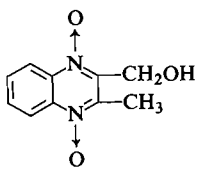
Drug Metabolism Department, Pfizer Inc., Groton, CT 06340, U.S.A.

Received September 27, 1979[1]

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

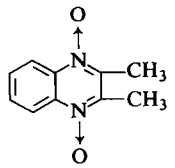
S. K. FIGDOR and D. C. HOBBS. Can. J. Chem. **58**, 1957 (1980).

2-Hydroxymethyl-3-methylquinoxaline-di-*N*-oxide (GS-7443) is rapidly metabolized in the chicken, rat, and dog to 3-carboxy-2-methylquinoxaline-1-oxide and a conjugate of 3-carboxy-2-methylquinoxaline-di-*N*-oxide. No appreciable amounts of other metabolites nor unchanged GS-7443 could be detected in the excreta from these animals. There were minor quantitative differences in the relative amounts of the two metabolites; moreover, the conjugating group employed by the chicken is different from that of the dog but the material being conjugated is the same. Although measurable tissue levels of drug-related material were noted in several organs of the chicken 6 days after drug administration, all chicken tissues examined were cleared of radioactivity within 21 days.



S. K. FIGDOR et D. C. HOBBS. Can. J. Chem. **58**, 1957 (1980).

Le di-*N*-oxyde de l'hydroxyméthyl-2 méthyl-3 quinoxaline (GS-7443) est métabolisé rapidement chez le poulet, le rat et le chien en oxyde-1 de la carboxy-3 méthyl-2 quinoxaline et en son espèce conjugée, le di-*N*-oxyde de la carboxy-3 méthyl-2 quinoxaline. On n'a pas pu déceler des quantités appréciables d'autres métabolites ou de GS-7443 de départ dans les excrétions de ces animaux. Quantitativement il y a très peu de différences entre les deux métabolites; de plus, le groupe conjugué employé par le poulet est différent de celui employé par le chien mais c'est le même produit qui devient conjugué. Bien qu'on ait pu déceler des quantités mesurables des drogues mentionnées dans les tissus de plusieurs organes du poulet six jours après que les drogues eurent été administrées, toute la radioactivité des tissus examinés disparait après 21 jours.



[Traduit par le journal]

Introduction

Quinoxaline-1,4-di-*N*-oxides were synthesized in the early 1940's and evaluated as human chemotherapeutic agents. A variety of undesirable side effects rendered these compounds unsuitable for clinical therapy. However, as a result of the effective antibacterial activity shown by this group of chemicals, a renewed interest in quinoxalines emerged for uses as antiinfective agents in food producing animals. 2-Hydroxymethyl-3-methylquinoxaline-di-*N*-oxide (GS-7443, **1**) was first described by Francis *et al.* in 1956 (1) as one of the metabolites of 2,3-dimethylquinoxaline-di-*N*-oxide (**2**) in sheep. The occurrence of further and additional metabolic transformations was not excluded since only a small percent of administered **2** was recovered unchanged.

1 GS-7443

2

GS-7443 has been shown in our laboratory to be an extremely effective gram negative chemotherapeutant for poultry with antibacterial activity extending to Terramycin resistant *E. coli*. In connection with its proposed use in food producing animals, the distribution and metabolism of GS-7443 in the chicken and appropriate experimental animal species, such as the rat and dog, was of interest.

Results

Excretion of Radioactivity

In the chicken, rat, and dog a dose of 30 mg/kg was rapidly excreted and most of the dose was recovered during the 24 h period following administration of the drug (Table 1). In the rat and dog approximately two-thirds of the administered radioactivity was recovered in urine and the remainder in the feces.

Paper chromatography indicated that the excreta of all animals contained two major metabolites of differing polarities. No GS-7443 (**1**) was observed. Thin layer chromatography also indicated the presence of trace amounts of several other radioactive materials not seen on papergrams; these were not investigated further but may have included degradation products of the polar metabolite (see below). Semi-quantitative information regarding the relative amounts of the two major metabolites was derived from the papergram scans as indicated in Table 2.

In the chicken and dog the polar metabolite predominated whereas in the rat the converse was observed.

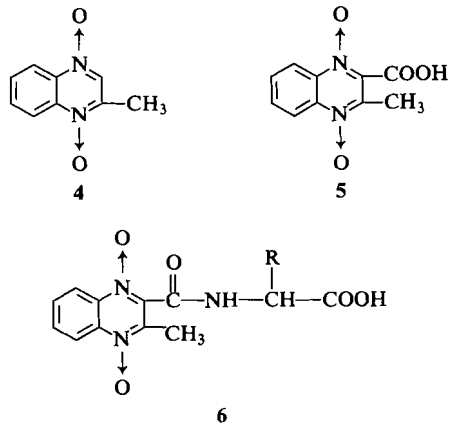
Isolation of Metabolite No. 1, the Non-polar Metabolite

Rat and dog urine and aqueous extracts of chicken excreta (suitably diluted with excreta from animals receiving non-labeled drug to provide sufficient material for isolation) were first passed through a cation exchange column (water elution) with purification and little loss of radioactivity. The lyophilized and reconstituted eluates when chromatographed on Sephadex G-10 columns gave a complete separation of the two metabolites, the polar material (metabolite No. 2) emerging first. In the case of the rat and dog, fractions containing metabolite No. 1 were lyophilized and the residue crystallized from water. This material, recrystallized from chloroform–hexane (mp 148°C), was anionic (electrophoresis) and had a uv spectrum in methanol indicative of a mono-*N*-oxide; λ_{max}: 325 (ε 8200), 243 (ε 28 200) nm (2). The nmr spectrum showed aromatic and *C*-methyl protons only. Thus the non-polar metabolite No. 1 is very likely 3-carboxy-2-methylquinoxaline-1-oxide, **3**. This was

3

confirmed by mass spectral analysis, which also excluded the isomeric 4-oxide, and by elemental analysis (*Anal.* calcd. for $C_{10}H_8N_2O_3$: C 58.82, H 3.95%; found: C 57.61, H 3.92%). Confirmation for assignment of the position of the *N*-oxide was also provided by subsequent synthesis of **3**. This compound (position of *N*-oxide unspecified) has also been isolated from urine of mice and dogs following the administration of **2** (3). The identity of metabolite No. 1 from the chicken was established by isotope dilution. To the appropriate Sephadex eluate containing the labeled nonpolar chicken metabolite was added crystalline metabolite No. 1 isolated from dogs receiving nonlabeled GS-7443. Several crystallizations from water and chloroform–hexane to constant specific activity established that the two were identical. Paper chromatography of this recrystallized material in three different systems showed that radioactivity aligned with **3**.



Isolation of Metabolite No. 2, the Polar Metabolite

Metabolite No. 2 as obtained from the Sephadex G-10 column was free of any other labeled material. It was also anionic (electrophoresis) but the uv spectrum was indicative of a di-*N*-oxide (maxima at 237, 261, 351, and 367 in water; at 235, 270, and 377 in methanol). Its early emergence from the Sephadex column and polarity suggested a conjugate. Treatment with glucuronidase and sulfatase, however, caused no change in the material.

One lot of the conjugated metabolite No. 2 from the dog, free of other labeled material, was converted on standing to an anionic nonpolar material with a uv spectrum similar to that of the conjugate and distinguishable from **3** by paper chromatography (R_f 0.6 on system D-20) and electrophoresis. This conversion could not be repeated with other lots of metabolite No. 2 and remains unexplicable, although it may have been due to residues of a peptidase introduced from tissue samples. On silica gel chromatography the purified material was converted to a neutral substance with a uv spectrum again similar to that of metabolite No. 2 conjugate. The neutral material, after purification on a small Sephadex G-10 column, was characterized as 2-methylquinoxaline-di-*N*-oxide (**4**) by comparison of its infrared and mass spectra with those of an authentic specimen. The anionic unconjugated material is very likely 2-methyl-3-carboxyquinoxaline-di-*N*-oxide (**5**) which was decarboxylated to **4** during silica gel chromatography. On silica gel chromatography **4** was also obtained in poor

For personal use only.

4 5 6

yield directly from the conjugate. The isolation of **4** from chicken excreta by this method was also possible (see below). The decarboxylation of **5** has precedence since, in attempts to synthesize **5** by oxidation of the corresponding aldehyde with *m*-chloroperbenzoic acid, **4** could be isolated in good yield. The acid **5** is probably linked to an amino acid residue since metabolite No. 2 conjugate **6** is also anionic.

Metabolite No. 2 from the chicken, although having a similar uv spectrum, could be distinguished from the dog metabolite No. 2 by Sephadex chromatography of a mixture of non-labeled dog metabolite and labeled chicken metabolite (fractions analyzed by uv and radioactivity). The chicken metabolite, however, also yielded **4** on silica gel chromatography. The difference between metabolites No. 2 of the two species appears to reside in the nature of the conjugating group.

Further comparison of dog and chicken metabolites No. 2, and the identification of 2-methylquinoxaline-1,4-di-*N*-oxide as one product obtained from the polar metabolites of dog and chicken, were carried out as follows. Crude dog metabolite No. 2 free of metabolite No. 1 was slurried overnight with silica gel in chloroform–methanol – acetic acid (80:15:5). The supernatant liquid from this slurry was then examined by paper chromatography and compared with the major radioactive fraction resulting from silica gel chromatography of the crude chicken metabolite No. 2 fraction. The paper chromatograms were very similar and revealed one minor and two major components. One of the major components aligned with the reference standard, 2-methylquinoxaline-di-*N*-oxide (**4**), in two paper and two thin-layer systems. It is estimated that this compound comprises from 40 to 50% of the mixture. The two other components, neither of which has been identified and neither of which is unaltered metabolite No. 2, may result from decomposition of the polar metabolite by alternative reactions. 2-Methylquinoxaline-di-*N*-oxide (**4**) was also isolated from the chicken silica gel chromatography reaction mixture by isotope dilution.

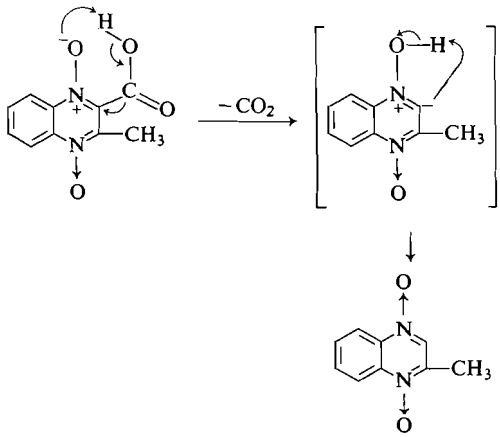
TABLE 3. Distribution of radioactivity, calculated as μg GS-7443 per g tissue, in the chicken after a single oral dose of GS-7443-^{14}C

	Days after 30 mg/kg GS-7443		
Tissue	6[a]	14	21
Kidney	0.32	0	0
Liver	3.5[b]	0.35	0
Skin	0.14	0	0
Heart	0.15	0	0
Lung	< 0.5	0	0
Stomach	0[c]	0	0
Light muscle	0	0	0
Dark muscle	0	0	0

[a]Average of three chickens.
[b]Average of five chickens.
[c]0 = < 0.1 μg GS-7443 equivalent per gram of tissue.

Distribution of Radioactivity

Since GS-7443 was proposed for use as an antibacterial agent it was important to determine whether drug related residues were present in chicken tissues after GS-7443 administration. The distribution of radioactivity in various tissues of the chicken is shown in Table 3. Animals were "stressed" for four days on chicken feed containing 250 g/ton non-labeled GS-7443, then dosed orally with 30 mg/kg labeled GS-7443, and maintained on regular chicken feed prior to sacrifice. Paper chromatograms of extracts of chicken liver revealed the same distribution of radioactivity as extracts of chicken excreta, with approximately the same relative proportions of the two metabolites. Thus liver, which retains radioactivity longer than the other tissues, is cleared by 21 days, and the residue contained in liver appears to be the same as the excreted metabolites.



Discussion

The oxidative metabolic conversion of 2,3-dimethylquinoxaline-di-*N*-oxide (**2**) to GS-7443 (**1**) earlier detected in the sheep (1) appears to be merely part of a general oxidative sequence ending with the carboxylic acid. Although no unchanged GS-7443 could be detected in the excreta of the three species of the present study, the presence of GS-7443 in sheep's urine might simply be a function of metabolism in sheep. An alternative explanation may involve the considerably larger doses administered at an earlier step in the oxidative sequence (2,3-dimethylquinoxaline, **2**) and the in-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ability of sheep to further metabolize all of the resulting oxidized transformation product (2-hydroxymethyl-3-methylquinoxaline, **1**).

In the rat, dog, and chicken the mono-*N*-oxide carboxylic acid **3** is excreted exclusively in the uncoupled form whereas the corresponding di-*N*-oxide **5** is eliminated entirely as the conjugate. Although the latter acid was not obtained from the conjugate in pure form for characterization, its identity would appear to rest on a fairly firm foundation for several reasons. (*1*). Its formation from GS-7443 is metabolically reasonable, particularly since the corresponding mono-*N*-oxide is readily formed. (*2*). The limited analytical data on the acid are consistent with its formation. (*3*). The facile decarboxylation to 2-methylquinoxaline-di-*N*-oxide has precedent in synthetic studies and is mechanistically explicable:

The adjacent *N*-oxide must participate, since in its absence (in **3**) there is no decarboxylation under identical conditions.

The proposal regarding the nature of the conjugating group is speculative but an amino acid function is reasonable in light of the electrophoretic studies which indicate that the polar conjugate is acidic. The dissimilarity of the conjugating functions in the chicken and dog is clearly evident from the chromatographic studies on Sephadex columns. The amino acids for the dog and chicken may be glycine and ornithine, respectively, since a similar relationship is well known for other aromatic acids (4).

Experimental

Materials

Synthesis of GS-7443 Uniformly Labeled with Carbon-14 in the Benzene Ring

2,3-Dimethylquinoxaline-^{14}C

To 25 mL of benzene was added 0.532 g uniformly labeled ^{14}C-*o*-phenylenediamine (specific activity 1.18 mCi per mmol, Nuclear Research Chemicals, Inc., Orlando, Florida), 4.5 g nonradioactive *o*-phenylenediamine purified by recrystallization and sublimation, and 4.4 g freshly distilled diacetyl. The reaction mixture was stirred at reflux with a Dean–Stark water take-off tube for 5.5 h. After this period an aliquot was removed and assayed by paper chromatography. At this time no *o*-phenylenediamine remained in the reaction mixture and the entire solution was concentrated to dryness *in vacuo*. Yield was 7.38 g, 5.12 mCi.

*2,3-Dimethylquinoxaline-1-*N*-oxide-*^{14}C

2,3-Dimethylquinoxaline-^{14}C (7.38 g) was dissolved in 12 mL of glacial acetic acid with gentle warming. To this solution was added with stirring 9.3 g of 40% peracetic acid. The amount of added peracetic acid represents a 4% excess over one equivalent. The solution was allowed to stir at 35°C overnight. The following morning the reaction solution was diluted with 50 mL of water, extracted with 2 × 50 mL of chloroform, the chloroform in turn washed with one additional 50 mL portion of water. The combined chloroform filtrates were dried over sodium sulfate, filtered, and concentrated *in vacuo* to a small volume. The chloroform concentrate was added to a column of 400 g of Fischer's absorption alumina (80–200 mesh) in chloroform, and 125 mL chloroform fractions were collected. Paper chromatographic assay followed by radio scanning of all fractions indicated that fractions 1–3 consisted primarily of unreacted starting material, fractions 4–12 were the pure mono-*N*-oxide, and subsequent fractions from 13–16 contained mixtures of the mono-*N*-oxide and the di-*N*-oxide. Fractions 4–12, pure mono-*N*-oxide, were combined and concentrated to dryness; yield 5.109 g.

2-Acetoxymethyl-3-methylquinoxaline-^{14}C

2,3-Dimethylquinoxaline-1-*N*-oxide-^{14}C (5.109 g) was dissolved in 11 mL of acetic anhydride and the reaction mixture stirred at reflux for 1 h. At the end of this period the solution was concentrated to an oily residue under vacuum, redissolved in approximately 10 mL of ethanol, and again concentrated to dryness *in vacuo*. The crude reaction mixture was added to a 300 g column of acid-washed Florisil in chloroform and 500 mL of chloroform fractions were eluted. Each fraction was again assayed by paper chromatography, radio scanned, and appropriate fractions combined. In this manner, 6.4 g of 2-acetoxymethyl-3-methylquinoxaline-^{14}C was obtained.

*2-Acetoxymethyl-3-methylquinoxaline-di-*N*-oxide-*^{14}C

To a solution of 6.4 g of 2-acetoxymethyl-3-methylquinoxaline-^{14}C in 100 mL of chloroform was added slowly with stirring 16 g of 85% *m*-chloroperbenzoic acid. The reaction mixture was stirred at room temperature for 20 min and then slowly brought to reflux and subsequently refluxed a total of 16 h. The reaction mixture was cooled to room temperature, the solid material removed by filtration, and the filter cake repulped with several small portions of chloroform. The chloroform filtrate and washings were combined and washed with two 100 mL portions of saturated sodium bicarbonate, two 100 mL portions of water, and the aqueous phases, in turn, passed through four 100 mL portions of chloroform. The chloroform extracts were combined, dried over sodium sulfate, and concentrated to dryness *in vacuo*. Yield was 7.35 g.

*2-Hydroxymethyl-3-methylquinoxaline-di-*N*-oxide-*^{14}C*, GS-7443 (1)*

The total crude reaction product obtained from the previous reaction (7.35 g) was dissolved in 25 mL of concentrated HCl and stirred at room temperature overnight. The reaction mixture was poured into a separatory funnel, 50 mL of chloroform was added, and 100 mL of saturated sodium bicarbonate solution was slowly added with shaking. The reaction mixture was extracted with four 100 mL chloroform portions which were, in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

turn, passed through four 50 mL aqueous washings. The combined chloroform extracts were dried over sodium sulfate, filtered, and concentrated to dryness *in vacuo*; yield, 5.22 g. The crude reaction product was purified by crystallization from a mixture of chloroform and acetonitrile with the addition of Darco and subsequently recrystallized once from chloroform and twice from acetone. The final product, 0.760 g, melting point 186–187°C, had a specific activity of 0.55 μCi/mg. No contaminating materials were visible in radio scans of the chromatographed product.

Methods

Radiometric Methods

All radioactive samples were measured in a Nuclear Chicago Model 725 liquid scintillation spectrometer. Quenching corrections were made by the internal standard procedure employing ^{14}C-toluene. Nonaqueous samples were assayed in a scintillator consisting of 0.3% 2,5-diphenyloxazole (PPO) and 0.01% *p*-bis[2-(5-phenyloxazolyl)]benzene (POPOP) in toluene. Aqueous samples (urine, water) were counted in a similar scintillator in which the solvent was 30% ethanol in toluene (30/70 scintillator). A maximum of 0.2 mL of aqueous solution was assayed in 15 mL of scintillator solution.

Feces were assayed by homogenizing in a Waring Blender with an equal weight of water and lyophilizing the resulting slurry. Samples of the dried powdered feces weighing approximately 50 mg were burned in an atmosphere of oxygen in a Schöniger combustion flask with an ethanolamine – ethyl cellosolve (1:2) mixture to trap $^{14}CO_2$. Aliquots of this solution were counted in 30/70 scintillator solution.

Chicken feces were assayed by dissolving from 2 to 25 mg of the lyophilized powder in a small volume of Hyamine (Packard Instrument Co., Downers Grove, IL), followed by the addition of 15 mL 30/70 scintillator solution.

Tissues were assayed by homogenizing 1 g of fresh wet tissue with 3 mL Hyamine in a Potter–Elvehjem tissue grinder. One mL of the resulting clear solution, equivalent to 0.25 g fresh tissue, was dissolved in 15 mL 30/70 scintillator solution and counted.

In vivo Experiments

Chickens, rats, and dogs received labeled drug as aqueous solutions by stomach tube at a level of 30–70 mg/kg and were thereafter kept in plastic or stainless steel metabolism cages. Nonlabeled drug at the same dose levels was also administered to accumulate sufficient amounts of metabolites to facilitate isolation; the rats received the nonlabeled GS-7443 in the drinking water (0.5 mg/mL). Because of the known (2) photoinstability of quinoxaline-*N*-oxides, all animals were maintained in darkened rooms (chickens and dogs) or in light-tight enclosures (rats). Experimental procedures were carried out in darkened rooms wherever possible.

Aqueous extracts of dog and rat feces were used to merely establish (paper chromatography) the similarity between fecal and urinary metabolites; lyophilized chicken feces preextracted with hexane to remove inactive oily material also provided the basis for the isolation of metabolites.

Chromatography

Paper chromatographic systems used were system D-20 (chloroform–ethanol – formic acid, 2:1:2, lower phase), system BCF (benzene–chloroform, 1:1, saturated with formamide), system 80 (methyl isobutyl ketone – formic acid – water, 2:1:1, upper layer), and benzene–acetone – formic acid – water (10:5:2:6). The BCF gave a good separation of GS-7443 from its metabolites, and the other systems resolved the two metabolites. Thin-layer chromatography was performed with chloroform–methanol – acetic acid (80:15:5), chloroform – ethyl acetate – formic acid (50:40:10), and 5% acetic acid in ethyl acetate. Electrophoresis was on Whatman #ET-1 paper in a pH 7.0, 0.05 *M* sodium acetate buffer at 300 V and 50 mA. Radioactivity was localized on the paper strips with a Vanguard Model 880 Autoscanner; thin layer plates were evaluated with the Vanguard tlc attachment or by autoradiography using Kodak type F X-ray film.

Column chromatography was performed on Sephadex G-10 in water, silica gel H in chloroform–methanol – acetic acid (80:15:5), and on a cation exchange resin (Dowex 50, H form). Aliquots of individual fractions were assayed for radioactivity by liquid scintillation counting.

Physical Measurements

The nmr spectra were obtained on a Varian A-20 instrument with tetramethylsilane calibration. The mass spectra were run on an Atlas model CH_4 instrument.

Metal complexes as antioxidants. 8. A kinetic and product study of the reaction of tertiary alkylperoxy radicals with cobalt(II) acetylacetonate[1]

J. A. HOWARD AND S. B. TONG[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received February 25, 1980

J. A. HOWARD and S. B. TONG. Can. J. Chem. **58**, 1962 (1980).

tert-Butylperoxy radicals react rapidly with $Co(acac)_2$ in non-polar solvents and rate constants measured by kinetic electron spin resonance spectroscopy obey the Arrhenius equation $\log (nk/M^{-1}\,s^{-1}) = (8.9 \pm 0.7) - (4.7 \pm 1.5)/\theta$, where $\theta = 2.303RT$ kcal mol^{-1} and n is ~ 0.1. Cumylperoxy radicals react with $Co(acac)_2$ to give mainly α-cumyl alcohol and acetophenone. There is no evidence for the formation of "long-lived" alkylperoxy radicals co-ordinated to cobalt (III) or a stable alkylperoxo cobalt(III) complex in these systems.

J. A. HOWARD et S. B. TONG. Can. J. Chem. **58**, 1962 (1980).

Les radicaux *tert*-butylperoxy réagissent rapidement avec $Co(acac)_2$ dans des solvants non polaires et la constante de vitesse mesurée par la résonance paramagnétique électronique cinétique obéit à l'équation d'Arrhénius: $\log (nk/M^{-1}\,s^{-1}) = (8{,}9 \pm 0{,}7) - (4{,}7 \pm 1{,}5)/\theta$ où $\theta = 2{,}303RT$ kcal mol^{-1} et n est $\sim 0{,}1$. Les radicaux cumylperoxy réagissent avec $Co(acac)_2$ pour donner principalement l'alcool α cumylique et l'acétophénone. Dans ces systèmes, on n'a pas pu mettre en évidence la formation de radicaux alkylperoxy de "longue vie" coordonnés au cobalt(III) ou d'un complexe stable alkylperoxocobalt(III).

[Traduit par le journal]

Introduction

Although there is an extensive literature concerned with liquid phase hydrocarbon autoxidation and hydroperoxide decomposition initiated by soluble cobalt complexes (1–7) there have been comparatively few studies of the reaction of these complexes with alkylperoxy radicals. It is, however, known that cobalt(II) complexes can undergo a chain termination reaction with alkylperoxy radicals, reaction [1] (8–10), while it has been reported that co-ordinatively unsaturated cobalt(III) complexes form a stable paramagnetic complex with $RO_2^{\bullet}$, reaction [2] (11–14).

[1] $RO_2^{\bullet} + Co(II) \rightarrow Co(III) + \text{products}$

[2] $ROOH + Co(II) \rightarrow Co(III)\cdots RO_2^{\bullet}$

The studies that have been made on the reaction of alkylperoxy radicals with cobalt(II) complexes have yielded rate constants in the range $2 \times 10^4 - 8 \times 10^5\ M^{-1}\,s^{-1}$ at temperatures of 60–74°C (8–10). These rate constants are, however, rather unreliable because they have been obtained *indirectly* relative to other rate constants for reactions of alkylperoxy radicals.

In this paper we present the results of a *direct* study of the reaction of the *tert*-butylperoxy radical with $Co(acac)_2$ using the kinetic electron spin resonance spectroscopic method that has been successful for direct studies of the reactions of $t\text{-}BuO_2^{\bullet}$ with hindered and non-hindered phenols and aromatic amines (15, 16), trivalent phosphorus compounds (17), alkyl hydroperoxides (18), and organo-tin and -lead compounds (19). In addition we report a product study of the reaction of cumylperoxy with this complex.

Experimental

Materials

$Co(acac)_2$ (Alfa, Ventron) was recrystallized from methanol and heated under vacuum at 50°C for 2 days. Standard solutions of this material were prepared immediately before use. Azocumene was prepared by the method of Nelsen and Bartlett (20) and di-α-cumyl hyponitrite by the method of Kiefer and Traylor (21). Di-*tert*-butyl ketone was obtained from Chemical Samples Co. Solvents were purified by standard procedures.

Radical Generation

tert-Butylperoxy radicals were generated by photolysis of di-*tert*-butyl ketone in oxygen- or air-saturated toluene. The concentration of this radical after the light was masked was followed by time resolved electron spin resonance spectroscopy (17). The induction period (15) and titration (16) methods were used to estimate the number of *tert*-butylperoxy radicals destroyed by each molecule of $Co(acac)_2$, i.e., the stoichiometric factor, n.

Cumylperoxy radicals were produced by thermolysis of azocumene in oxygen-saturated solvent at 323 K. In the presence of $Co(acac)_2$ rates of oxygen absorption were slightly faster than rates of production of cumyl radicals and slightly more than the theoretical concentration of oxygen was absorbed. For instance, azocumene (0.0245 M) in chlorobenzene containing $Co(acac)_2$ (0.049 M) absorbed oxygen at an initial rate of $2 \times 10^{-6}\ M\,s^{-1}$ whereas the calculated initial rate of production of cumyl radicals was $1.6 \times 10^{-6}\ M\,s^{-1}$ and 0.057 M of oxygen were absorbed.

Product Analysis

Products from reaction of cumylperoxy, cumyloxy, and cumyl hydroperoxide with $Co(acac)_2$ were analyzed, after distillation from inorganic products, either by gas chromatography or high performance liquid chromatography. The gas chromatograph was a Varian 2800 equipped with a 12% OV-101

on Chromosorb W (80/100 mesh) column (12 ft × 1/8 in.) and a flame ionization detector. The liquid chromatograph was a Spectra Physics 3500 equipped with a Brown-Lee RP-8 column and uv detector (254 nm); the eluting solvent was H_2O–CH_3CN (65:35, v/v).

Cobalt(III) yields were determined by uv-spectroscopy at 594 nm using a Hewlett-Packard 8450 A UV/VIS Spectrophotometer.

Results and Discussion

Kinetics

Photochemically generated *tert*-butylperoxy radicals decayed rapidly in the presence of excess $Co(acac)_2$ in the temperature range 183–213 K. Plots of ln [*t*-BuO_2·] against time were linear, indicating exponential radical decay, i.e.,

$$-d[t\text{-}BuO_2\cdot]/dt = k_\psi[t\text{-}BuO_2\cdot]$$

where k_ψ is the pseudo-first-order rate constant.

Values of k_ψ appeared to be linearly dependent on the concentration of $Co(acac)_2$ (Table 1) implying that this reaction obeys the rate law

$$-d[t\text{-}BuO_2\cdot]/dt = nk[t\text{-}BuO_2\cdot][Co(acac)_2]$$

where n is the stoichiometric factor and k is the bimolecular rate constant for reaction of the *tert*-butylperoxy radical with $Co(acac)_2$.

$$[1a] \quad t\text{-}BuO_2\cdot + Co(acac)_2 \xrightarrow{nk} \text{Products}$$

Unfortunately nk could only be measured over a narrow range of $Co(acac)_2$ concentrations because above $\sim 10^{-3}$ M the concentration of *t*-BuO_2· was too small to give meaningful decay kinetics while below $\sim 10^{-4}$ M the complex was consumed very rapidly by continuous photolysis.[3]

Values of nk fell in the range 2×10^3 to 1.1×10^4 M^{-1} s^{-1} from 183 to 213 K (Table 1) and a plot of log (nk/M^{-1} s^{-1}) against the reciprocal of the absolute temperature gave

$$\log (nk/M^{-1}\ s^{-1}) = (8.9 \pm 0.7) - (4.7 \pm 1.5)/\theta$$

where $\theta = 2.303\ RT$ kcal mol^{-1}.

This pre-exponential factor is similar to the *A*-factor of 2.9×10^9 M^{-1} s^{-1} reported by Shcheredin and Denisov (8) for reaction of the poly(peroxystyryl)peroxy radical with $Co(acac)_2$ obtained indirectly from a study of the influence of $Co(acac)_2$ on the autoxidation of styrene. The Russian workers, however, reported an activation energy of 7.8 kcal mol^{-1}, ~3 kcal mol^{-1} larger than our value.

Rate constants for reaction of 2-cyano-2-propylperoxy and poly(peroxystyryl)peroxy radicals with $Co(acac)_2$ have been reported to be 2.3×10^4 M^{-1} s^{-1} and 3.5×10^4 M^{-1} s^{-1}, respectively at 74°C (8). Our Arrhenius equation predicts a value significantly larger and our rate constants are in better agreement with rate constants that have been obtained by the chemiluminescence technique (9, 10).

[3] $Co(acac)_2$ at these concentrations in nonpolar solvents is monomeric (22).

TABLE 1. Kinetic data for reaction of *t*-BuO_2· with $Co(acac)_2$[a]

[a] In toluene.

Stoichiometric Factor

The simplest mechanism for destruction of alkylperoxy radicals by $Co(acac)_2$ involves the electron transfer reaction

$$RO_2\cdot + Co(II) \rightarrow RO_2^-Co(III)$$

and a stoichiometric factor of 1.

We could not estimate this parameter by the induction period method because the concentration of *tert*-butylperoxy increased in a pulsating manner during continuous photolysis and did not reach the uninhibited rate of radical production. On the other hand this technique works very well for 2,6-di-*tert*-butyl-4-methylphenol and gave a stoichiometric factor of 2 for this compound. The difference in the [*t*-BuO_2·]–time profiles for these two inhibitors is illustrated in Fig. 1.

Typical data obtained by the titration method are given in Table 2 and suggest that the stoichiometric factor is ~0.1 which is similar to the value of 0.26 reported by Shcheredin and Denisov (8).

Reaction Products

The organic product yields from reaction of cumylperoxy, cumyloxy, and cumyl hydroperoxide with $Co(acac)_2$ at 323 K are summarized in Table 3. Acetophenone (K) and α-cumyl alcohol (A) were the major organic reaction products and the total yield of these products, [A] + [K], was ~70% from cumylperoxy, ~90% from cumyloxy, and ~100% from cumyl hydroperoxide. Clearly the reaction products $PhCMe_2OOCo(acac)_2$ and $PhCMe_2OCo(acac)_2$ are not stable under our ex-

ERRATA

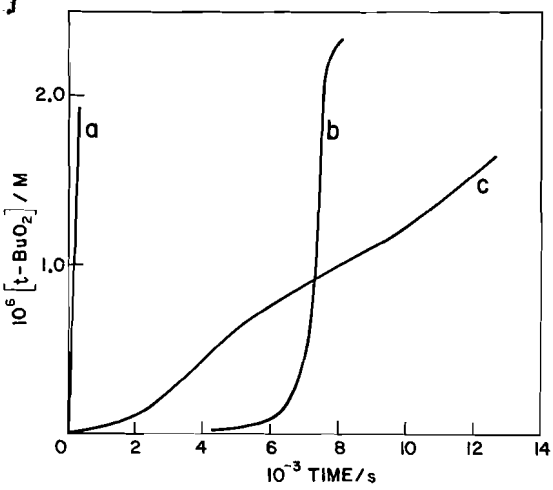

FIG. 1. The accumulation of t-$BuO_2\cdot$ with respect to time during photolysis of oxygen-saturated toluene containing di-*t*-butyl ketone at 303 K: (*a*) no additive; (*b*) 2,6-di-*tert*-butyl-4-methylphenol (2.4×10^{-5} M); (*c*) $Co(acac)_2$ (2.4×10^{-5} M).

perimental conditions. Interestingly pumping the chlorobenzene from decomposition of cumyl hyponitrite in the presence of $Co(acac)_2$ into a trap at the temperature of liquid nitrogen gave an initial yield of [A] + [K] ~ 70%. Addition of fresh chlorobenzene followed by distillation gave more A (~20%) but no K.

Cumylperoxy radicals reacted with an equivalent concentration of $Co(acac)_2$ in PhCl to give [A]/[K] = 1.3 whereas in the absence of the complex [A]/[K] was 0.6. This ratio increased to 4 when $[Co(acac)_2]_0$ was twice the initial concentration of azocumene. A higher value of [A]/[K] (2.2) was also observed when *tert*-butylbenzene was used as solvent instead of chlorobenzene.

Cumyloxy radicals in the presence of an equivalent concentration of $Co(acac)_2$ gave principally α-cumyl alcohol ([A]/[K] = 16.5) a result which is consistent with the recent finding by Niki, Kudo, and Kamiya (23) that a fraction of the *tert*-butoxy radicals from di-*tert*-butyl peroxyoxalate are reduced mainly to *tert*-butyl alcohol by $Co(acac)_2$. These workers concluded that the balance of t-$BuO\cdot$ were tied up as t-$BuOCo(acac)_2$.

Decomposition of cumyl hydroperoxide by catalytic and stoichiometric concentrations of $Co(acac)_2$ gives [A]/[K] = 2–2.5, ratios similar to ratios obtained from cumylperoxy rather than cumyloxy radicals.

We have not made a thorough investigation of the fate of $Co(acac)_2$ in its reactions with $PhCMe_2O_2\cdot$ and $PhCMe_2O\cdot$. Quantitative concentrations of $Co(acac)_3$ would, however, appear to be formed in these systems, i.e.,

$$3Co(acac)_2 \rightarrow 2Co(acac)_3$$

Complexed Peroxy Radicals

Tkáč and co-workers (12–14) have reported that reaction of an alkyl hydroperoxide with $Co(acac)_2$

gives a paramagnetic complex-bonded peroxy radical, $Co^{III}(acac)_2 \cdots RO_2^{\bullet}$, in which the radical is rendered persistent at ambient temperatures by co-ordination with cobalt(III).

Such a species should have been formed by reaction of t-$BuO_2^{\bullet}$ with $Co(acac)_2$ because co-ordinatively unsaturated Co(III) is formed which would be expected to complex with another t-$BuO_2^{\bullet}$ in the system. We could, however, find no experimental evidence for the formation of such a "complexed" radical.

In addition we have not been able to prepare $Co^{III}(acac)_2 \cdots RO_2^{\bullet}$ using *tert*-butyl hydroperoxide and $Co(acac)_2$ as described by Tkáč (13). A possible explanation for the apparent inconsistency in this work is that Tkáč isolated t-$BuOOCo(acac)_2$ which in solution could give t-BuOOH and $HOCo(acac)_2$ by reaction with adventitious water. Reaction of t-BuOOH with cobalt would then appear to give "persistent" t-$BuO_2^{\bullet}$ by the continuous generation method described by Ingold (24).

Conclusions

tert-Butylperoxy radicals react rapidly with $Co(acac)_2$ and the bimolecular rate constants obey the Arrhenius equation

$$\log (nk/M^{-1}\,s^{-1}) = (8.9 + 0.7) - (4.7 + 1.5)/\theta$$

This equation almost certainly applies to other alkylperoxy radicals since the rate of such a fast reaction should not depend on the nature of R in $RO_2^{\bullet}$.

The reaction of $RO_2^{\bullet}$ with $Co(acac)_2$ probably involves coordination of the radical with the complex followed by electron transfer to give $ROOCo(acac)_2$. Alkylperoxo cobalt(III) complexes have in fact been isolated after reaction of 4-alkyl-2,6-di-*tert*-butylphenols with molecular oxygen in the presence of bis(3-salicylideneaminopropyl) amino cobalt(II) in aprotic solvents (25, 26).

Hydrolysis of $ROOCo(acac)_2$ by adventitious water would give ROOH and $HOCo(acac)_2$ and the hydroperoxide would be rapidly reduced by $Co(acac)_2$. Such a mechanism is consistent with the similarity between the products obtained from reactions of $PhCMe_2O_2^{\bullet}$ and $PhCMe_2OOH$ with $Co(acac)_2$ and the low stoichiometric factors.

[3] $RO_2^{\bullet} + Co(acac)_2 \rightleftarrows RO_2^{\bullet} \cdots Co(acac)_2 \rightarrow RO_2Co(acac)_2$

[4] $ROOCo(acac)_2 + H_2O \rightarrow ROOH + HOCo(acac)_2$

[5] $ROOH + Co(acac)_2 \rightarrow RO^{\bullet} + HOCo(acac)_2$

[6] $RO^{\bullet} + Co(acac)_2 \rightarrow ROCo(acac)_2$

Alternatively, in the absence of water, $ROOCo(acac)_2$ could react with $Co(acac)_2$ (8) by an electron transfer process, a mechanism which is also consistent with the reaction products and stoichiometry.

[7] $ROOCo(acac)_2 + Co(acac)_2 \rightarrow [R\bar{O}OCo(acac)_2 + C\dot{o}(acac)_2] \rightarrow RO^{\bullet} + (acac)_2CoOCo(acac)_2$

We cannot, of course, rule out the possibility that the alkylperoxo cobaltic acetylacetonate undergoes O—O bond homolysis,

[8] $ROOCo(acac)_2 \rightarrow RO^{\bullet} + {}^{\bullet}OCo(acac)_2$

The marked difference between [A]/[K] for reaction of $PhCMe_2O_2^{\bullet}$ and $PhCMe_2O^{\bullet}$ with $Co(acac)_2$ would, however, appear to rule out the intermediacy of free alkoxy radicals.

Further work is in progress in our laboratory to determine the influence of the ligands attached to Co(II) on this chain terminating reaction.

Received March 24, 1980

M. ALISON ARMITAGE, GERALD A. BRYDON, PAUL J. J. CONNELLY, CHUMMER J. E. FARINA, HEATHER L. GORDON, KEITH B. OLDHAM, and TADASHI YANAGI. Can. J. Chem. **58**, 1966 (1980).

Studies of a cell consisting of a sheet of a porous medium soaked with an aqueous electrolyte solution containing the mercurous ion and sandwiched between mercury pools show that steady-state electrolysis may be attained in the absence of convection. Several different porous matrices have been studied and, in some cases, a very simple model of the pore structure predicts behaviour close to that observed experimentally.

M. ALISON ARMITAGE, GERALD A. BRYDON, PAUL J. J. CONNELLY, CHUMMER J. E. FARINA, HEATHER L. GORDON, KEITH B. OLDHAM et TADASHI YANAGI. Can. J. Chem. **58**, 1966 (1980).

L'étude d'une cellule, consistant en une lame de substance poreuse imprégnée d'une solution aqueuse d'un électrolyte contenant un ion mercureux et plaçée entre deux bains de mercure, indique que l'électrolyse dans l'état stationnaire peut être réalisée en l'absence de convection. On a étudié plusieurs matrices poreuses différentes et dans certains cas un modèle très simple de la structure des pores prédit un comportement qui se rapproche de celui observé expérimentalement.

At working electrodes to which transport occurs by planar semiinfinite diffusion, steady-state electrolysis is not theoretically possible in the absence of convection. Under such conditions at spherical electrodes, steady-state electrolysis is achieved (1) but only at times long in comparison with r^2/D where r is the radius of the spherical electrode and D is the diffusion coefficient of the electroactive species. With a finite electrolysis cell, in which parallel planar electrodes are separated by a distance L, the attainment of a convection-free steady state is again theoretically possible (provided that the anode reaction is the converse of that at the cathode), but its realization requires the passage of times large in comparison with L^2/D. Special fabrication techniques are needed to achieve values of r or L less than about 10^{-4} m, and since D in aqueous solutions is typically 10^{-9} m^2 s^{-1}, one must wait for at least 1 min to achieve such steady states. In most circumstances, however, 1 min is ample time for natural convection to develop as a result of density gradients generated by the electrolysis itself. Accordingly, almost all non-equilibrium electrochemical experiments can be classified into one of two categories: either non-steady-state (i.e. transient) techniques in which convection is absent, or steady-state techniques in which convection (natural or artificial) is present. It is disappointing that steady-state convection-free conditions are difficult to achieve, because steady-state results are easier to interpret than transient results and convection is notoriously difficult to treat quantitatively.

The forces that give rise to natural convection must operate over rather large distances to be effective. Consequently, convection in an electrolysis cell can be inhibited by compartmentalizing the electrolyte solution into small intercommunicating chambers, as occurs when the electrolyte solution is absorbed into a porous matrix. This is the principle that is exploited in the cell that is the subject of this article. It consists of a sheet of porous material soaked in electrolyte solution and then sandwiched between mercury electrodes. In its performance this cell displays no effect that can be attributed to convection. In addition to preventing convection, the porous sheet serves the function of accurately positioning the two electrodes parallel to each other with an interelectrode spacing L equal to the sheet's thickness. No third electrode is present in the cell, both mercury pools being "working" electrodes.

When the cell solution contains a concentration C of mercurous ion and any potential E in the range from zero to about 1.5 V is applied across the cell, the negative electrode functions as a cathode at which the reaction

[1] $Hg_2^{2+} + 2e \rightarrow 2Hg$

occurs, while at the other electrode the complementary anodic reaction

[2] $2Hg \rightarrow Hg_2^{2+} + 2e$

takes place. Alternatively, if the cell solution initially contains a concentration $2C/n$ of the ion M^{n+}

(such as Pb^{2+} or Tl^{+}), then no current flows through the polarized cell unless E is large enough to effect the electroreduction

[3] $M^{n+} + ne \rightarrow M(Hg)$

at the negative electrode. The anode reaction is again described by eq. [2], so that M^{n+} is continuously replaced by Hg_2^{2+}. In these circumstances, by the time that the steady state is reached, the cell functions exactly as if it had originally contained a concentration C of mercurous ions. Other electroreducible species, such as oxygen, are likewise replaced by equivalent concentrations of mercurous ion prior to the attainment of a steady state, the overall cell reaction being

[4] $O_2 + 4H^+ + 4Hg \rightarrow 2H_2O + 2Hg_2^{2+}$

in the case of dissolved oxygen.

Supporting electrolyte has been present in all our experiments. A low pH is generally necessary to inhibit the formation of insoluble mercuric species, especially at the anode. In a few of our experiments the electrolyte solution was neutral but contained a large concentration of iodide ion; the steady-state anodic and cathodic reactions were then

[5] $Hg + 4I^- \rightleftarrows HgI_4^{2-} + 2e$

because HgI_4^{2-} is the thermodynamically stable species under these conditions. These latter experiments (and others in which I^- plus I_3^- served as the redox pair) will not be reported here.

The complexity and heterogeneity of the pore geometry impedes an exact treatment of electrochemical transport in our cell. Instead, one must resort to models. A simple, but surprisingly successful, model envisages the pore structure as a bundle of non-intersecting tubules, all of length λL, which penetrate the porous matrix from one surface to the other. This so-called "uniform tortuosity model" predicts that the steady-state current is given by

[6] $$I_\infty = \frac{2nAFCD\theta}{\lambda^2 L} \tanh \frac{nFE}{2RT}$$

when supporting electrolyte is in excess (2). In this equation n equals 2, A is the area of each of the electrodes, θ is the porosity of the matrix (the fraction of its volume that is void, an independently measurable quantity), λ is its tortuosity and other symbols have either been defined earlier or are accorded their usual significances. Alternative models (2, 3) lead to different predictions but all models that treat the matrix as uniform (in the sense that there is no systematic variation in its structure on proceeding from one internal subregion of the matrix to another) lead to the conclusion that the quantity

[7] $$\frac{LI_\infty}{2nAFCD} \coth \frac{nFE}{2RT}$$

is a constant less than unity. In an experiment in which no porous matrix whatever was present (not an experimentally realizable situation, of course), expression [7] would be unity; the fractional value of this quantity thus represents the extent to which an actual matrix impedes the steady-state diffusion of mercurous ion from anode to cathode. Different models interpret this dimensionless quantity differently, but all predict its constancy. The experimental work of Topol and Oldham (4) demonstrated the constancy of expression [7], for a given matrix, and our own data have confirmed this.

In most of our studies (and all those reported in detail here) the solution soaking the porous matrix contained mercurous ion plus excess supporting electrolyte and the experiment was commenced by applying the potential step 0.0 V $\rightarrow E$ across the previously short-circuited cell. Because reactions [1] and [2] are fast and the cell resistance is very small, the initial current is immeasurably large. However, I falls rapidly and after several seconds approaches its steady-state value I_∞, as exemplified in Fig. 2. The transient phase of the experiment may be treated theoretically if one adopts the uniform tortuosity model. The prediction is that

[8a] $$\frac{\lambda I}{nAFC\theta} \coth \frac{nFE}{2RT} = \left(\frac{D}{\pi t}\right)^{1/2} \sum_{j=-\infty}^{\infty} \exp \frac{-j^2\lambda^2 L^2}{4Dt}$$

[8b] $$= \frac{2D}{\lambda L} \sum_{j=-\infty}^{\infty} \exp \frac{-4j^2\pi^2 Dt}{\lambda^2 L^2}$$

these two expressions being mathematically equivalent (2). At short times only the $j = 0$ term in [8a] is significant and reduction to

[9] $$(I\sqrt{t})_{t\rightarrow 0} = \frac{nAFC\theta}{\lambda} \sqrt{\frac{D}{\pi}} \tanh \frac{nFE}{2RT}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ensues. $I\sqrt{t}$ is predicted to be almost constant over the time range $0 < t < 2t_2$ where t_2 is the time it takes for the current I to fall to twice its ultimate I_∞ value. Over a somewhat larger time range, in fact for $0 < t < 8t_2$ approximately, the $j = 0, \pm 1$ terms in [8*a*] are important but those with $|j| > 1$ can be ignored. Under these circumstances one can show that a plot of the logarithm of $2(I\sqrt{t})_0/[I\sqrt{t} - (I\sqrt{t})_0]$ versus $1/t$ should yield a straight line passing through the origin and that the gradient of this line

$$[10] \quad \frac{d}{d(1/t)} \ln \frac{2(I\sqrt{t})_0}{I\sqrt{t} - (I\sqrt{t})_0}$$

is a constant equal to $\lambda^2 L^2/4D$. At longer times [8*b*] is a more useful expression and there exists a wide time range over which only the $j = 0, \pm 1$ terms in this equation are important. During this period (approximately $2t_2 < t < \infty$) the logarithm of $2I_\infty/[I - I_\infty]$ should give a linear plot versus t, extrapolating through the origin and having a gradient

$$[11] \quad \frac{d}{dt} \ln \frac{2I_\infty}{I - I_\infty}$$

equal to $4\pi^2 D/\lambda^2 L^2$. Of course, as $t \to \infty$, eq. [8*b*] shows that I approaches the constant I_∞ given by eq. [6].

The interpretation of the transient phase of an experiment is very model-dependent, though few models more complex than the uniform tortuosity model are capable of explicit solution. However, one conclusion, namely that the quantity

$$[12] \quad \frac{(I\sqrt{t})_{t\to 0}}{nAFC} \sqrt{\frac{\pi}{D}} \coth \frac{nFE}{2RT}$$

is a constant less than unity, is common to all models that treat the matrix as uniform. This dimensionless constant is predicted to equal the fraction of the cathode area that is exposed to the electrolyte solution (3).

In our laboratory several studies have been, or are being, conducted using the convection-free cell. The purpose of the present article is to describe the perfecting of the experimental technique, and to report on the testing of the uniform tortuosity model by the analysis of steady-state and transient results.

Experimental

A typical solution used to soak the porous matrix in these studies had the composition 5.00 m*M* $Hg_2(NO_3)_2$ + 50 m*M* HNO_3 + 2.0 *M* KNO_3 and was prepared by direct weighing of the ingredients and their dissolution in deionized water. The Hg_2^{2+} ion concentration was confirmed by titration with a standard ferric ion solution (5). Stock solutions were deaerated by the passage of argon and were stored under argon and over mercury.

All the experiments reported in this article employed one or other of the following porous media: (*i*) A felted glass fibre matrix known as "GF-81" and marketed (by W. & R. Balston Limited, London, England) for filtration and chromatographic support purposes. This material was purchased as large sheets and was trimmed to circles of about 60 mm diameter before use. (*ii*) Another porous medium sold primarily for filtration purposes is the "MF-Millipore" (Millipore Corporation, Bedford, MA) manufactured from mixed esters of cellulose. In the particular form used in this research, however, the membranes (manufacturer's code THWP102F0) are marketed for surgical use in nerve and tissue repair. This MF material was obtained as sterile 10 cm × 10 cm squares of nominal 25 μm thickness and 0.45 μm pore size. The squares were quartered for use in electrochemical and other measurements. (*iii*) "Whatman No. 5" filter paper (also manufactured by W & R Balston). Circles of 70 mm diameter (0.19 mg ash per circle) were invariably used. These three porous media, which we shall refer to as "glass", "esters", and "cellulose" matrices, were selected for study because they are manufactured with closely-controlled physical properties and because they span a range of porosities and thicknesses, as shown in Table 1. Before use, all matrices were thoroughly rinsed in deionized water and allowed to air-dry (as purchased, the filter paper was significantly contaminated by chloride ion).

Thicknesses were measured by placing the matrix, soaked with the solution to be used electrochemically, between optically flat glass plates mounted on a specially-constructed micrometer. This device is designed to exert on the matrix a pressure (usually 10.8 kPa) equal to that it would experience in the electrochemical cell. Double layers of a matrix were employed to investigate the dependence upon thickness.

Knowing the external dimensions of a matrix, the porosity was determined by comparing its dry weight with the apparent mass when the matrix is suspended in the electrolyte solution (of known density). These data also permit a determination of ρ, the density of the fibres from which the matrix is constructed. Values of ρ, which are also listed in Table 1, were calculated as a means of checking the validity of the porosity measurements.

The soaking of a matrix in electrolyte solution – whether for a thickness measurement, a porosity measurement, or an electrochemical experiment – was carried out very carefully so as to exclude the possibility of air pockets being trapped in the pores. The dry matrix was positioned above a pool of electrolyte solution in a vessel from which the air was then evacuated. After 10 min the matrix was dislodged and caused to fall into the pool. Atmospheric pressure was restored after the matrix had lain beneath the surface of the solution for several minutes. Prior to transfer to the electrochemical cell, each face of the matrix was wiped with a glass rod to dislodge excess liquid.

Figure 1 is a cross-sectional diagram of the electrochemical cell, which consists of three polymethylmethacrylate parts. The soaked matrix is firmly clamped between raised annular rings on the inward-facing faces of the left and right sections of the cell. An outer sleeve serves to locate the two cell sections opposite each other. The matrix is thus exposed to three chambers; a left

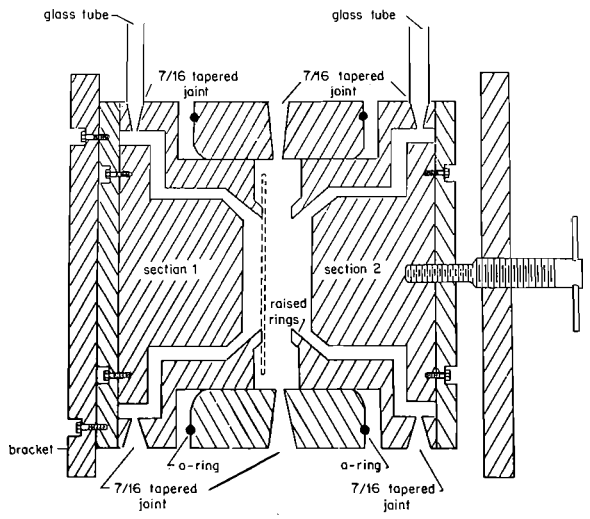

FIG. 1. A cross-sectional diagram of the cell. In operation sections 1 and 2 are firmly forced together, clamping the porous matrix (shown by dashed lines) between the raised rings. The matrix is thus exposed to three chambers.

chamber and a right chamber, each of which meets the matrix in an area

[13] $A = 1134\ \text{mm}^2$

which is accurately defined by the 38.0 mm inner diameter of the raised rings; and a peripheral chamber which surrounds all the surfaces of the matrix beyond the 46.0 mm outer diameter of the raised rings.

Two ports communicate with each chamber, one with its lowest point, the other with its highest point, so that fluids can be introduced. Glass sighting tubes fit into the three upper ports. After introducing a soaked matrix into the cell, argon is passed through the three chambers to remove the air that entered during assembly. Then the two lower ports serving the left and right chambers are commoned and carefully-purified mercury is admitted. The mercury level is allowed to rise slowly and evenly until both chambers are entirely filled and the menisci have reached predetermined levels in the sighting tubes.

In early experiments the peripheral chamber was filled with the same solution in which the matrix had been soaked. However, after results showed that this had no effect, the peripheral chamber was more often left empty. In some experiments that we discuss later, anomalous results could be attributed to the cellulose matrix being "too wet". The problem was corrected by passing dry argon through the peripheral chamber for a sufficient time; water evaporated into the argon and the excess solution was thereby wicked away from the electrochemical cell.

To perform an electrochemical experiment the interconnection between the two mercury pools is broken and a constant potential E is applied between the pools. More often than not E was in the range 100–150 mV, for which values the hyperbolic term in expresssions [7] and [12] is effectively unity. However, experiments employing potentials less than this gave results that, after correction by multiplication by the hyperbolic cotangent term, were indistinguishable from those which engendered complete concentration polarization. The electrical potential step was applied using a Model 170 Electrochemical System (Princeton Applied Research Corporation, Princeton, New Jersey), and the XY recorder which is an integral part of the instrument was used to monitor the current–time response.

The cell was not thermostatted. Experiments were conducted at an ambient temperature close to 294 K.

Results and Discussion

Figure 2 is a typical current–time trace. As predicted, the current does approach a constant steady-state value I_∞ at long times. Figure 3 is a typical plot of $I\sqrt{t}$ versus t. The $I\sqrt{t}$ product is predicted to be a constant at small times but this is not exactly what is observed. Instead we found $I\sqrt{t}$ to be almost constant over a range of short times, but with a small rise as $t \rightarrow 0$. This is precisely what would occur if the pores, on average, experience a slight flaring as they reach the cathode surface, as one might well expect to be the case. As illustrated in Fig. 3, we choose to associate $(I\sqrt{t})_0$ with the minimum value of $I\sqrt{t}$, acquired over a range of times close to t_2.

The results of numerous experiments employing a variety of L, C, and E values are assembled into Table 2 which reports, for each of the three matrices, average values of the dimensionless expressions [7] and [12] along with the corresponding standard deviations. Expression [13] for A together with the value

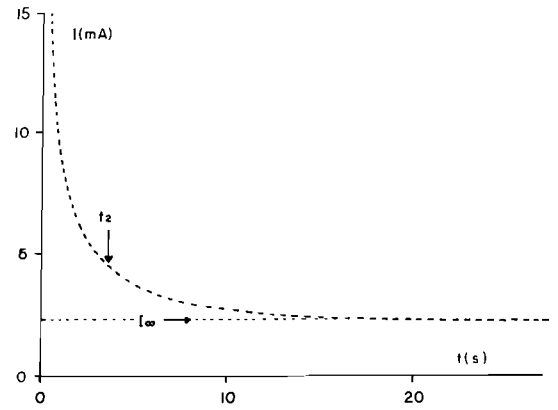

FIG. 2. A typical current versus time graph. t_2 is the time after which the current has fallen to a value twice that of the ultimate steady-state current I_∞.

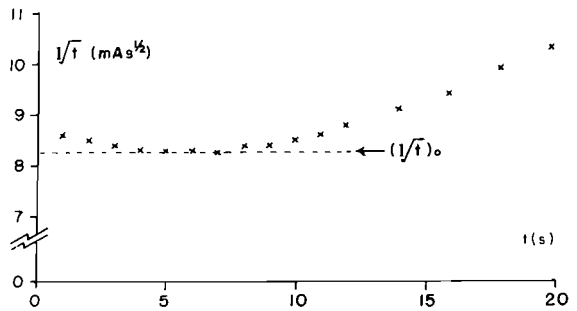

FIG. 3. A constant value of $I\sqrt{t}$ is predicted at short times. As this typical graph shows, experimental values pass through a shallow minimum.

TABLE 2. Values of dimensionless expressions that all models predict should be constant and less than unity

Matrix	Expression [7]	Expression [12]

[14] $D = 946\ \mu m^2\ s^{-1}$

(6) were used in compiling the tabulated data.

The constancy of expressions [7] and [12] is predicted by all models whereas, it will be recalled, the linearity of the graphs exemplified by Figs. 4 and 5 is predicted only by the uniform tortuosity model. These figures, which are typical, show that the plots are indeed linear over the time ranges predicted by the model. The gradients of many such graphs were measured and Table 3 is a compilation of such data. Notice that the glass and cellulose matrices generate graphs of comparable slopes, but that the slopes of the graphs produced by the esters matrix differ by two orders of magnitude, largely because this matrix is much thinner than the other two.

In some experiments with the cellulose matrix, when the applied potential was in the range 50–100 mV, erratic currents were obtained. The potential range in which these anomalies were found corresponds to that in which polarographic maxima are common and we believe the two phenomena have related causes. Large electroosmotic forces must operate in our cell, and it appears that their sign is such as to push the solution towards the cathode. Normally these forces do not result in any movement of the electrolyte solution because mercury from the anode cannot enter the pores to replace the migrating solution. However, with the cellulose matrix, it appears that the standard soaking and wiping procedure leaves sufficient solution adhering to the surface of the matrix that small pockets, sustained by electroosmosis, can develop between the mercury cathode and the matrix itself. Motion within these pockets is, we believe, responsible for the anomalous currents. As mentioned, we found that the anomalies disappear after dry argon is passed for a sufficient length of time through the peripheral chamber. If the drying is continued for too long, a precipitous fall in current ensues; a "sufficient" length of time is one that just fails to cause this condition.

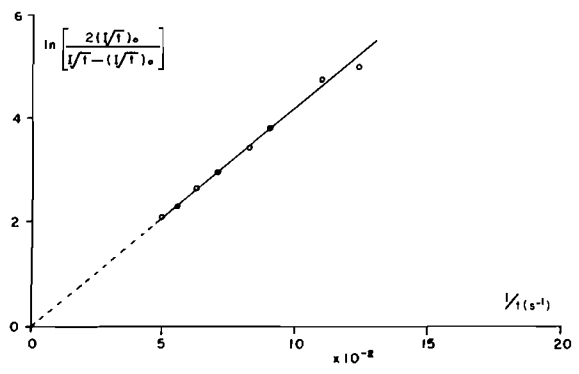

FIG. 4. The uniform tortuosity model predicts that the graph of which a typical example is shown should be linear at short times and should extrapolate through the origin.

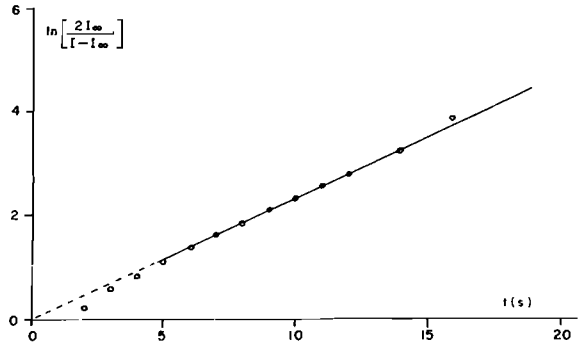

FIG. 5. According to the uniform tortuosity model the plot exemplified in this figure should be linear, except at short times, and should extrapolate through the origin.

For the three matrices that we report in this article, one sample is very like the next, but nevertheless there is more scatter in our results than one would find in a typical series of electrochemical experiments that did not employ porous media. Taking this into account, the data in Table 2 can be considered to display adequate constancy, implying that the model-independent aspects of the theory of cell operation are satisfactory. Note that the value of expression [12] is in each case about 30% larger than the value of expression [7]. In the absence of a model, no particular structural significance can be attached to the numerical values of the constants in Table 2, except that one might expect some correlation with the porosities of the matrices. This expectation is not borne out, however, because the sequence of porosities

[15] glass > cellulose > esters

does not match the sequence of magnitudes of expression [7] and [12], namely

[16] glass > esters > cellulose

One might conclude that the cellulose matrix impedes the progress of Hg_2^{2+} ions, and restricts their

access to the cathode, more than would be expected on the basis of the porosity of this matrix.

Let us now turn to the question of how well the predictions of the uniform tortuosity model are borne out by experiment. Recall that the model predicts that expressions [10] and [11] will equal $\lambda^2L^2/4D$ and $4\pi^2D/\lambda^2L^2$ respectively. The product of these expressions should therefore be π^2. Table 3 incorporates a column which lists average values of the products of expressions [10] and [11], together with standard deviations. With one exception the products are, indeed, within about one standard deviation of π^2. Even the exception lies only 1.55 standard deviations from π^2 and such a departure would be expected once in eight cases if the model were true.

Another way of testing the uniform tortuosity model is by comparing the values of λ calculated by different methods. The tortuosity λ is, in fact, calculable by four independent methods according to the model: (*i*) The uniform tortuosity model predicts that expression [7] is a constant equal to θ/λ^2. Since θ is measurable independently, λ can be calculated. (*ii*) Similarly, expression [12] equals θ/λ according to the model, whereby λ is calculable. (*iii*) Since the model predicts that expression [10] equals $\lambda^2L^2/4D$ and L and D are known, λ can be calculated. (*iv*) Likewise expression [11] equals $4\pi^2D/\lambda^2L^2$ according to the model, whereby λ is calculable. Tortuosity values calculated in this variety of ways are assembled into Table 4. The tabulation shows that the λ values calculated by method (*ii*) are discordant, and that in two cases this method produces nonsensical values of less than unity. It comes as no surprise that method (*ii*) fails to agree with the others; this method utilizes the $(I\sqrt{t})_{t\to 0}$ datum which (see Fig. 3) is ill-defined in practice. If one excludes values given by method (*ii*), excellent agreement is found between the remaining three values for the glass and cellulose matrices, with less satisfactory concordance in the case of the esters matrix.

The linearity of the graphs exemplified in Figs. 4 and 5, together with the fact that the linear sections extrapolate naturally through the origin, is further indirect evidence in support of the uniform tortuosity model. To assess the extent to which these graphs accurately diagnose the uniformity of pore tortuosities, we simulated a matrix in which the pores were non-intersecting tubules but in which all tortuosities between 1.00 and 2.00 occur with equal frequency. Synthetic current–time data were then generated and subjected to the logarithmic analyses of methods (*iii*) and (*iv*). Figures 6 and 7 show the results. The full lines in these figures span the time ranges in which the uniform tortuosity model predicts linearity. Notice that the lines are decidedly curved. Moreover, notice that if each curve were to be approximated by a "best" straight line, this would not extrapolate through the origin. Evidently heterogeneity in pore tortuosities can be detected quite easily in attempting to employ methods (*iii*) and (*iv*).

The dashed lines in Figs. 6 and 7 are forced through the origin. Analysis of the gradients of these lines according to methods (*iii*) and (*iv*) leads

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

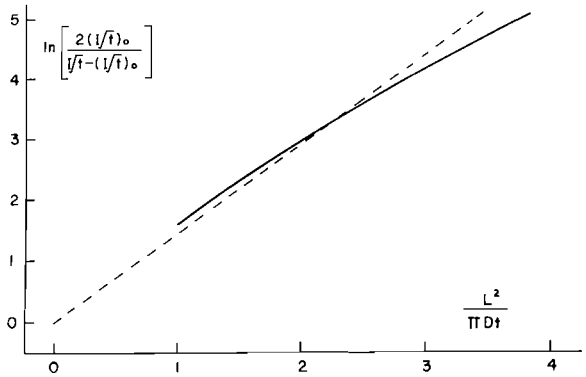

FIG. 6. The full curve is based on simulated data for a matrix in which tortuosities between 1.00 and 2.00 are equally probable. The dashed line has been forced through the origin.

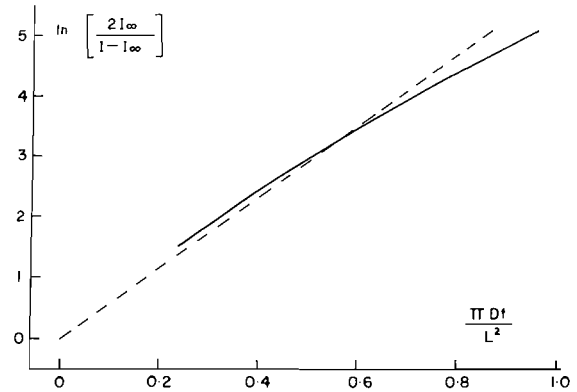

FIG. 7. The full and dashed lines have the same significance as those in Fig. 6.

to λ values of 1.38 and 1.48 respectively. From these gradients one can show that the product that the model predicts to be π^2 when tortuosities are uniform is only 8.21 when tortuosities range from 1.00 to 2.00. Evidently the π^2 test is quite discriminating.

Conclusions

The most significant result of the study reported here is the successful design and construction of an electrochemical cell in which steady-state electrolysis is established in the absence of convection. Experimental techniques have been perfected to a point at which reproducibility is better than 10% (see Table 2) between replicate experiments. The dependence of the steady-state current on thickness, concentration, and applied potential is as predicted by the model-independent theory.

The π^2 test of the uniform tortuosity model is surprisingly successful for all three matrices and has been shown to be discriminating. The intercomparison presented as Table 4 is less satisfactory but, for the glass and cellulose matrices, the agreement of three independent measurements of tortuosity is remarkably close. Moreover, the numerical tortuosity values that the model generates — 1.08 for the glass matrix and about 1.45 for the cellulose — are very reasonable values for matrices of 93% and 75% porosity respectively.

The success of the model does not, of course, imply that the pores of these media are actually non-intersecting tubules of common length. Rather it indicates that, under the imposed electrochemical conditions, the matrices facilitate the passage of a current of similar magnitude to that predicted by the simple model.

Received October 22, 1979[1]

GUY J. COLLIN and JAN A. HERMAN. Can. J. Chem. **58**, 1973 (1980).

We have studied the isomerization of butenes and methylbutenes by noble gas-sensitized radiolysis. The isomerization of isobutene to but-2-ene is more efficient in the presence of xenon than in the presence of krypton or argon. The isomerization of but-1-ene into isobutene has a low radiolytic yield and occurs only in the presence of small quantities of dimethylamine. These observations are in agreement with the isomerization of the excited parent ion.

In the methylbutene systems, whatever the sensitizing agent, isomerization occurs with a high radiolytic yield. Thus, a chain mechanism is needed to explain the results. The addition of dimethylamine has a reverse effect relative to that observed in but-1-ene. It is concluded that the mechanism invoked for the butene systems is not adequate for explaining the isomerization observed in the methylbutene systems.

GUY J. COLLIN et JAN A. HERMAN. Can. J. Chem. **58**, 1973 (1980).

Nous avons étudié, par radiolyse sensibilisée aux gaz nobles, l'isomérisation des butènes et des méthylbutènes. L'isomérisation de l'isobutène en butène-2 est surtout efficace lors de la radiolyse sensibilisée au xénon. L'isomérisation du butène-1 en isobutène est de peu d'importance et n'est révélée que par l'addition de diméthylamine. Ces observations sont en accord avec un mécanisme mettant en jeu l'isomérisation de l'ion parent excité.

L'isomérisation des méthylbutènes a lieu quelle que soit la nature de l'agent sensibilisateur et se fait avec des rendements radiolytiques impliquant un mécanisme en chaîne. L'addition de diméthylamine a un effet opposé à celui observé dans le butène-1. On en conclut que le mécanisme valide pour les butènes n'est pas approprié pour expliquer l'isomérisation observée dans les méthylbutènes.

Introduction

The isomerization of radical-cations formed by the ionization of C_4H_8 alkenes is well known. For example, P. Ausloos *et al.* have shown that direct photoionization of one of the butenes induces the formation of others in various amounts depending on the wavelength of the uv lamp, pressure, additives, ... (1). $[C_4H_8]^+$ ions formed through various radiolytical techniques have also been prepared, and each of them isomerizes (2). The same trend was observed in the photoionization of several methylbutenes. For example, the photoionization of 3-methyl but-1-ene gives rise to an extensive formation of 2-methyl but-2-ene (3), and the same was also observed in the gaseous radiolysis (4). However, in this last case, another mechanism was thought to be responsible for the observations: it was proposed that the isomerization takes place through protonated methylbutene (4). In this paper we have extended our previous studies to the γ-sensitized radiolysis of butenes and methylbutenes in order to shed more light on the isomerization processes.

Experimental

The experimental methods have already been described (3, 4). Butenes and methylbutenes are from the American Petroleum Institute and have better than 99.9% purity. Rare gas, ammonia, nitric oxide, and oxygen, are Research grade products from Matheson of Canada (≥99.9% purity). They were used without further purification following vacuum degassing (10^{-5} Torr – 1.3×10^{-3} N m^{-2}). Dimethylamine was also used as received from Matheson of Canada.

The samples were prepared in a Pyrex vacuum line (mercury free) equipped with Teflon stopcocks and Wallace and Tiernan metallic membrane manometers.

All irradiation techniques have also been described (4). Dosimetry was carried out by measuring the saturation current and the W (rare gas) values were used to calculate dose rates. The dose rates measured in each of the rare gases were 5.20×10^{13}, 1.04×10^{14}, and 1.68×10^{14} eV cm^{-3} min^{-1} in 100 Torr (13300 N m^{-2}) of argon, krypton, and xenon, respectively. Analysis of the irradiated samples (irradiation time: 120 min) was carried out by gas chromatography. It is sufficient to say that but-1-ene, the couple 1,3-butadiene + isobutene, *cis*-, and *trans*-but-2-ene were separated on a squalane column. Finally, an alumina column (temperature programmed between 50 and 120°C – 1°C/min) was used to analyse 1,3-butadiene.

Each irradiation was carried out at least twice. The reproducibility was better than ± 10% unless otherwise indicated.

Results and Discussion

The yields of the products are indicated in the tables as $G(x)$ values: the number of x molecules

formed per 100 eV energy absorbed by the sensitizing rare gas. We have only given the yields of pertinent products and the reader is encouraged to refer to a recent paper by one of us, especially for details concerning the mechanistic interpretation (5). Allene is generally thought to be formed in the fragmentation of a neutral excited or superexcited molecule (6), and its radiolytic yield is rather insensitive to the addition of oxygen, ammonia, or dimethylamine. The complex behaviour of the yields of isobutane–isobutene system (7), *n*-butane – linear butene system (8), or isopentane–methylbutene system (9) is apparent from the effect of different additives.

(a) The Case of Isobutene

The xenon-sensitized radiolysis of isobutene induces isomerization of the parent molecule: the G(but-2-ene) value being 0.23 and 0.48 in the absence and presence, respectively, of dimethylamine. These observations are in line with the following reactions:[2]

[1] $Xe^+ + \text{iso-}C_4H_8 \rightarrow [\text{iso-}C_4H_8^*]^+ + Xe$ $\quad \Delta H = -282 \text{ kJ mol}^{-1}$

[2] $[\text{iso-}C_4H_8^*]^+ \rightarrow [2\text{-}C_4H_8^*]^+$ $\quad \Delta H = 0.0 \text{ kJ mol}^{-1}$

[3] $2\text{-}C_4H_8^+ + \text{iso-}C_4H_8 \rightleftarrows \text{iso-}C_4H_8^+ + \textit{cis}\text{-}2\text{-}C_4H_8$ $\quad \Delta H = +9.9 \text{ kJ mol}^{-1}$

[4] $2\text{-}C_4H_8^+ + (CH_3)_2NH \rightarrow (CH_3)_2NH^+ + \textit{cis}\text{-}2\text{-}C_4H_8$ $\quad \Delta H = -80 \text{ kJ mol}^{-1}$

Assuming that dimethylamine intercepts the majority of the $2\text{-}C_4H_8^+$ ions (8), the G(process [4]) is at least equal to 0.48. Thus, this last value is a lower value for the radiolytic yield of process [2]. The radiolytic yield of the Xe^+ ions is equal to 100 eV divided by the average energy, W, required to produce an ion pair in xenon: W(xenon) = 21.9 eV (11) and $G(Xe^+) = 4.57$. Thus it turns out that around 11% of the initially formed Xe^+ ions give rise to the formation of but-2-ene and the $G([C_4H_8^*]^+)$ value is at least 0.48. In fact, the noble gas ion may transfer its charge to any of the additives (the ionization potential of the added noble gas is higher than that of any additive) so that the yield of isobutene radical cations is less than that of the yield of the noble gas ions. There, more than 11% of the Xe^+ ions which react with isobutene leads to its isomerization.

In the photoionization experiments, the isomerization quantum yield was observed to be very sensitive to the energy content of the parent ion. At 10.0 eV (960 kJ mol^{-1}), less than 2% of the parent ions isomerise to the but-2-ene structure. This percentage increases to 13 at 11.6–11.8 eV at a pressure of 1 Torr. Moreover, the increase of the pressure has a strong reverse effect: in the presence of 266 Torr of neon, the isomerization of the parent ion drops from 13 to less than 2% (1). In the present study, the isomerization seems more important since the 11% value (see above) was measured at 300 Torr and is relatively much less sensitive to pressure. This would indicate that the parent isobutene ion has more internal energy than in the 11.6–11.8 eV photolytic experiments. The exothermicity of process [1] must be shared among the products. The rare gas atom may only support kinetic energy (the available energy is far from sufficient to produce a metastable noble gas atom). Thus, it may be assumed that most if not all of the exothermicity of process [1] is located in the butene radical cation (12).

In this interpretation is correct, i.e. the energy content of the butene cation is higher than 11.6–11.8 eV, it would eliminate the involvement of the dimer noble gas ion. The appearance potential of Xe_2^+ ion is close to 11.3 eV. Energy transfer from this dimer ion would release less energy and the butene cations would contain less internal energy that when they are formed in the direct photo-

ionization at 11.6–11.8 eV (Fig. 1). In photoionization experiments part of the photon energy is taken by the electron. This part is, however, small and may be ignored here.

The butene cations formed in process [1] have an internal energy of about 12.1 eV — the ionization potential of xenon (12) — above the ground state of neutral butene molecules. Thus, it is likely that some of these excited cations decompose, since the appearance potentials of several ionic fragments is lower than 12.1 eV (5). For example, Fig. 2 shows the variation of G(propene) value with pressure, in the xenon-, krypton-, and argon-sensitized radiolysis of isobutene. This product is, at least partly, the result of the chemistry of $C_3H_5^+$ ions formed in the decomposition of internally excited [iso-C_4H_8*]$^+$ ions (7, 13). This assumption is in agreement with the increase of the G(propene) values with increase of ionization potential of the noble gas (Fig. 1). It is also worthwhile to note the very low G(but-2-ene) values measured in the krypton- and argon-sensitized radiolytic experiments. In these cases, the energy released in the charge transfer from the noble gas ion to isobutene is too large, and the internally excited isobutene cation decomposes preferentially.

[5] $Kr^+ + \text{iso-}C_4H_8 \rightarrow Kr + [\text{iso-}C_4H_8^*]^+$ $\Delta H = -462$ kJ mol^{-1}

[6] $Ar^+ + \text{iso-}C_4H_8 \rightarrow A + [\text{iso-}C_4H_8^*]^+$ $\Delta H = -629$ kJ mol^{-1}

But-1-ene was not observed as a product (Table 1). The isomerization process

[7] $\text{iso-}C_4H_8^+ \rightarrow \text{1-}C_4H_8^+$ $\Delta H = 54$ kJ mol^{-1}

is strongly endothermic, and, as such, is not a favoured chemical path.

(b) The Case of Linear Butene

Table 2 shows the $G(C_4H_8)$ values measured in the but-1-ene and *cis*-but-2-ene systems. But-1-ene has a higher ionization potential (IP = 9.58 eV) than any of the other butenes. If other butene radical cations are formed in the but-1-ene system, a charge acceptor should be added in order to reveal the presence of such positive ions through charge transfer process. Thus, the formation of isobutene, and the increase of the G(but-2-ene) values upon addition of dimethylamine (IP = 8.24 eV) may be ascribed to the charge transfer process similar to process [4]. The situation is reversed in the *cis*-but-2-ene system, since this compound has a low ionization potential (see Fig. 1).

[a]Typical mixtures: noble gas:2-methyl but-1-ene (145 ± 10:1.45 ± 0.10 Torr — 19000 ± 1300:190 ± 130 N m^{-2}). The G(2-methyl but-2-ene) values are ±20%.

In the but-1-ene system, the amount of dimethylamine is probably sufficient to intercept all 2-$C_4H_8^+$ ions (8) (no attempt was made to get a "plateau" value). However, the G(2-C_4H_8) value may be as high as 1.80. Taking into account the possible fragmentation of the internally excited but-1-ene ions (see, for example, the formation of propylene (5)), it can be seen that the majority of the non-decomposing but-1-ene ions isomerize to but-2-ene (1). Conversely, the yield of isobutene is very low. Taking into account the large uncertainties in its measurement, it can be said that the isomerization of but-1-ene ion to isobutene is not an efficient process (14).

In the *cis*-but-2-ene system, the formation of the *trans*-isomer may be ascribed to various mechanisms and, as such, will not be discussed here. However, it seems that the formation of the isobutene structure is slightly easier here than in the previous system (14). This result is also in agreement with the photoionization experiments (1).

(c) The Case of the Methylbutenes

A glance at Tables 3, 4, and 5 exemplifies the high radiolytic yields of isomers formed in each system. Thus, the yields of isomers are much larger than those measured in the above-mentioned butene systems. In some cases, the total G(isomer) values were larger than the expected G(noble gas ion) values: $G(Xe^+) = 4.57$, $G(Kr^+) = 4.15$, and $G(Ar^+) = 3.80$ (11). In one case, not indicated in Table 5, a G(2-methyl but-2-ene) value of 10.0 was obtained! Thus a chain mechanism seems more appropriate to explain these high figures.

Moreover, whatever the sensitizing noble gas is, the isomerization is important. The excess energy available from the charge transfer process from Kr^+ and Ar^+ ions does not seem to decrease the importance of the isomerization process by favouring the decomposition of the internally excited $[C_5H_{10}{}^*]^+$ ions. This observation is contrary to the trend observed in the isobutene system.

The effect of the addition of nitric oxide or dimethylamine is not the one expected on the grounds

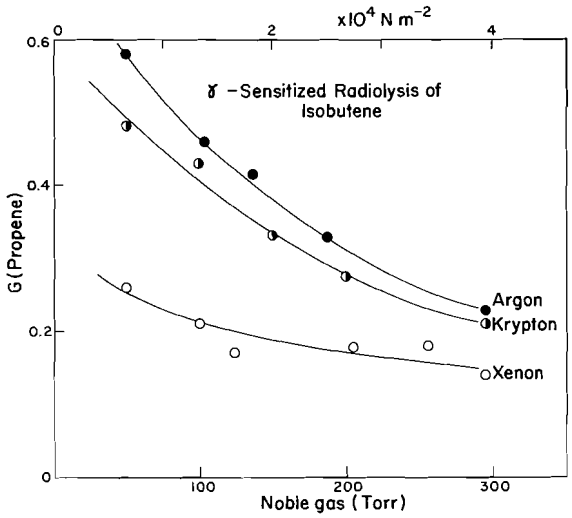

FIG. 2. The G(propene) values measured in the noble gas sensitized radiolysis of isobutene vs. the total pressure.

of the charge transfer process from any $C_5H_{10}^+$ ion. Thus, in the 3-methyl but-1-ene system, the ionization potentials of 2-methyl but-1-ene and 2-methyl but-2-ene are lower than the parent molecule (see Fig. 1). In the presence of only xenon, 3-methyl but-1-ene, and oxygen, there is no positive charge transfer from the expected 2-methyl but-1-ene and 2-methyl but-2-ene positive ions to any of the additives. The addition of nitric oxide or, much better, of dimethylamine should favour the positive charge transfer process, and an increase in the yield of isomer is expected. In fact the lower yields were measured in the presence of this additive. This observation would eliminate the parent ion as the intermediate involved in the isomerization reaction.

Finally, the addition of ammonia in the 3-methyl but-1-ene system (Table 3) has an interesting effect: it decreases the 2-methyl but-2-ene yield and it increases that of the 2-methyl but-1-ene. This effect was also observed in the radiolysis of 3-methyl but-1-ene sensitized by methane although it was much more important: the 2-methyl but-1-ene yield was larger than that of 2-methyl but-2-ene (9).

Although no definitive proof can be invoked to support this mechanism, together with the need for a chain mechanism, it is tempting to link the above-mentioned observation to the isomerization of a $C_5H_{11}^+$ ion, as was proposed in previous papers (4, 9).

[8] $RH^+ + (CH_3)_2CHCH{=}CH_2 \rightarrow R + [(CH_3)_2CHCHCH_3]^+$

[9] $[(CH_3)_2CHCHCH_3]^+ + (CH_3)_2CHCH{=}CH_2 \rightarrow (CH_3)_2C{=}CHCH_3 + [(CH_3)_2CHCHCH_3]^+$

$\Delta H = -13.6$ kJ mol^{-1}

[10] $[(CH_3)_2CHCHCH_3]^+ \rightarrow [(CH_3)_2CCH_2CH_3]^+$

$E_A = +9$ kJ mol^{-1} (4)

$\Delta H = -46$ kJ mol^{-1}

[11] $[(CH_3)_2CCH_2CH_3]^+ + (CH_3)_2CHCH{=}CH_2 \rightarrow CH_2{=}C(CH_3)CH_2CH_3 + [(CH_3)_2CHCHCH_3]^+$

$\Delta H = +39$ kJ mol^{-1}

[12] $[(CH_3)_2CCH_2CH_3]^+ + (CH_3)_2CHCH{=}CH_2 \rightarrow (CH_3)_2C{=}CHCH_2 + [(CH_3)_2CHCHCH_3]^+$

$\Delta H = +3.2$ kJ mol^{-1}

Of course, the formation of the various C_5H_{10} isomers in the presence of dimethylamine may partly be the result of the isomerization of the parent radical cations. The isomerization processes of radical cations become smaller with increasing molecular size (15, 16). Finally, it should be added that *cis*- and *trans*-pent-2-ene have been observed in the radiolysis of methylbutenes at 77 K. The formation of these products has been related to the isomerization of the parent ion through a cyclopropane structure: various dimethylcyclopropanes were also observed (17).[3]

Acknowledgments

We should like to thank the ministère de l'Éducation du Québec, programme FCAC for financial help throughout this work. The assistance of Mme Deslauriers in analytical work is also very much appreciated.

[3]NOTES ADDED IN PROOF:

Recently Lias *et al.* have studied the isomerization processes of *trans*-but-2-ene to isobutene in an ion cyclotron resonance spectrometer. The isomerization process is explained in terms of a proton transfer process through a long-lived ($M{\cdot}sec$-$C_4H_9^+$) complex capable of isomerization towards the ($M{\cdot}t$-$C_4H_9^+$) structure (18).

As suggested by one of the referees, we have performed a few xenon-photosensitized experiments ($\lambda = 147$ nm) (see footnote *b* in Table 3). Clearly the energy transfer from metastable xenon atom does not result in 2-methyl but-2-ene formation.

The reaction between 2,2-di(4-nitrophenyl)1,1,1-trifluoroethane and *tert*-butoxide ion in *tert*-butyl alcohol solvent

ARNOLD JARCZEWSKI[1] AND KENNETH T. LEFFEK

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received March 13, 1980

ARNOLD JARCZEWSKI and KENNETH T. LEFFEK. Can. J. Chem. **58**, 1979 (1980).

The reaction between 2,2-di(4-nitrophenyl)1,1,1-trifluoroethane and excess sodium *tert*-butoxide in *tert*-butyl alcohol takes place rapidly to yield first the olefin, by elimination of HF. This is followed by a slower addition of *tert*-butoxide to the olefin, which upon reaction with the solvent gives the *tert*-butyl ether as the final product. The blue anions involved in each of these reactions are observed.

Rate constants, the primary deuterium kinetic isotope effects, and the activation parameters have been measured for the appearance of the initial blue colour and also for the formation of the olefin. It is concluded that the reaction proceeds by a reversible E1cB mechanism.

ARNOLD JARCZEWSKI et KENNETH T. LEFFEK. Can. J. Chem. **58**, 1979 (1980).

La réaction entre le di(nitro-4 phényl)-2,2 trifluoro-1,1,1 éthane et un excès de *tert*-butylate de sodium dans l'alcool *tert*-butylique se produit rapidement et conduit en premier lieu à l'oléfine par élimination de HF. Cette étape est suivie d'une addition lente de *tert*-butylate sur l'oléfine qui, par réaction avec le solvant, conduit à l'éther *tert*-butylique comme produit final. On a observé les anions bleus impliqués dans chacune de ces réactions.

On a mesuré les constantes de vitesse, les effets isotopiques cinétiques primaires du deutérium et les paramètres d'activation de l'apparition de la couleur bleue initiale et également de la formation de l'oléfine. On en conclut que la réaction se fait suivant un mécanisme reversible E1cB.

[Traduit par le journal]

Introduction

In an earlier publication (1) the β-elimination reaction of 2,2′-di(*p*-nitrophenyl)-1,1,1-trifluoroethane initiated by sodium methoxide in methanol was investigated. It was concluded from the magnitude of the second-order rate constant and the lack of a primary detuerium isotope effect that the reaction proceeded via an $(E1cB)_R$ mechanism, eqs. [1] and [2], with k_{-1} [BH] very much greater than k_2.

[1] $B^- + (pNO_2C_6H_4)_2CH{-}CF_3$

k_{-1} ⇅ k_1

$(pNO_2C_6H_4)_2C^-{-}CF_3 + BH$

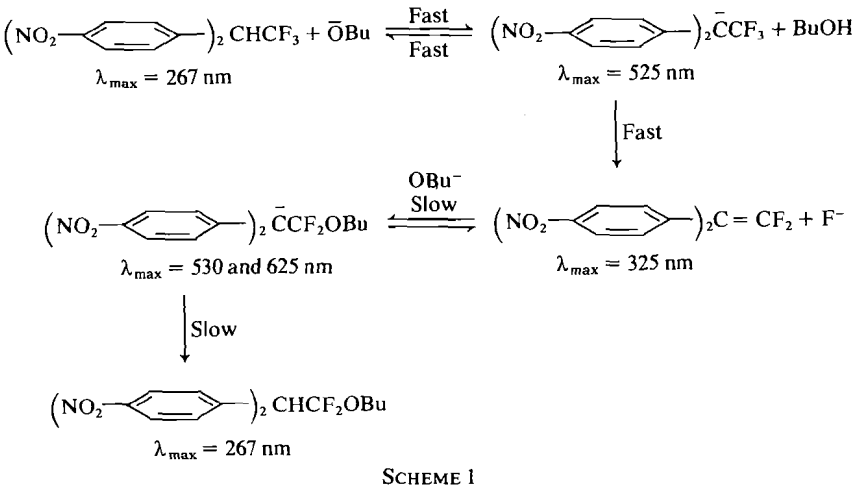
[2] $(pNO_2C_6H_4)_2C^-{-}CF_2 \xrightarrow{k_2} (pNO_2C_6H_4)_2C{=}CF_2 + X^-$

When the above substrate is mixed with sodium *tert*-butoxide in *tert*-butyl alcohol, a blue colour appears immediately. Since the *tert*-butoxide is a stronger base than methoxide, k_1 should be larger for *tert*-butoxide. *tert*-Butyl alcohol is a less polar solvent than methanol which should give a smaller k_2 for *tert*-butyl alcohol. Therefore, it would be expected that the carbanion would be more stable and exist in larger concentration in *tert*-butoxide/*tert*-butyl alcohol than in methoxide in methanol. If the blue colour observed is due to the anion of the substrate, it should be possible to observe all three rate processess k_1, k_{-1} [BH], and k_2 for this reaction.

Results and Discussion

The substrate in *tert*-butyl alcohol solvent has a uv absorption peak at 267 nm. The spectrum of a mixture of the substrate ($5 \times 10^{-5}M$) and sodium *tert*-butoxide ($5 \times 10^{-3}M$) in *tert*-butyl alcohol, taken a few minutes after mixing, shows no peak at 267 nm, but a new peak at 325 nm and a broad peak at 510–530 nm. The 325 nm peak is assigned to the product olefin (1).

This spectrum is not stable and changes markedly over a period of several hours. The change is dependent upon the conditions under which the reaction mixture was prepared, so all solutions for the experiments were made up and stored in an atmosphere of dry nitrogen. Under these conditions the product peak disappears after 3–4 hours and is replaced by a peak at 267 nm, while the absorption in the visible region shifts to about 600 nm.



It is concluded that the product 2,2-di(4-nitrophenyl)-1,1-difluoroethylene is undergoing a further reaction, the products of which have absorption spectra quite similar to the substrate and

SCHEME I

its anion. The most likely reaction is the addition of *tert*-butoxide ion to the olefin to yield an anion which by reaction with solvent can yield the ether as the final product. Such a reaction of methoxide ion with fluoro-olefins has been observed by Miller *et al.* (2).

Reaction of 2,2-Di(4-nitrophenyl)1,1-difluoroethylene with tert-*Butoxide Ion*

The olefin was prepared by reaction of the trifluoride with sodium methoxide in methanol as previously described (1). This material dissolved in *tert*-butyl alcohol showed a single broad absorption peak at 336 nm. Upon addition of sodium *tert*-butoxide, no blue colour appeared immediately, but after a few minutes the colour appeared together with a peak in the 260–270 nm region, while the olefin peak fell. The reaction was complete after about four hours, after which the colour faded while the 260–270 nm peak continued to increase.

The complete reaction sequence of the trifluoride with sodium *tert*-butoxide is set out in Scheme 1.

Kinetic Investigation of Formation of Initial Carbanion

The appearance of the initial blue colour was followed at 525 nm using a stopped-flow spectrophotometer. Pseudo first-order rate constants were measured in the presence of a large excess of base using the usual technique for organic proton transfer reactions (3). The half-life of the first-order reactions varied between three and ten seconds depending on the conditions of base concentration and temperature. The correlation coefficients for the Guggenheim plot were usually 0.998 or better. The observed first-order rate constants were plotted against the base concentration and the second-order rate constants were calculated from the slope of the graph. The measurements were carried out for both the normal and deuterated trifluoride at five different temperatures and these results are shown in Table 1. The intercepts of the plots of observed first-order constants against base concentration for the hydrogen compound have values of 0.045 to 0.06 s^{-1}, which give an average equilibrium constant for anion formation of 533 ± 15 L mol^{-1}.

Whether the base takes part in the reaction as an ion-pair or as free *tert*-butoxide is difficult to determine. There is no doubt (4–7) that a large part of the *tert*-butoxide is present, in solutions of the concentrations used in this work, as ion-pairs and larger aggregates. However, it has been shown that the dissociated *tert*-butoxide ion has a much greater chemical reactivity than the ion-pairs (5). Also, when this same assumption was made for methoxide and ethoxide, we were able to derive dissociation constants for the ion-pairs of these bases from kinetic measurements which were in agreement with those calculated from conductance data (8). The latter method has yielded a value of 0.0016 for potassium *tert*-butoxide (7) and if this value is assumed for sodium *tert*-butoxide, the observed first-order rate constants, k_H, in Table 1 may be analysed according to eq. [3]

$$[3] \quad k_H = k_{2H(ip)}\, c(1-\alpha) + k_{2H(i)}\, c\alpha$$

where $k_{2H(ip)}$ and $k_{2H(i)}$ are the second-order rate constants for the reaction with ion-pairs and free ions of base, respectively; c is the total base concentration, and α is the degree of ionization. A plot of $k_H/c\alpha v((1-\alpha)/\alpha)$ is linear with a slope of $k_{2H(ip)}$ and an intercept $k_{2H(i)}$. The difficulty with an analysis such as this is that the possible error in the derived rate constants is very large compared to the magnitude of the rate constants themselves. However, it does show that $k_{2H(ip)}$ is about 10 times smaller than $k_{2H(i)}$. Thus, about 90% of the reaction proceeds via the dissociated *tert*-butoxide ion.

The second-order rate constants yield $\Delta H^{\ddagger}_H = 3.5 \pm 0.3$ kcal mol^{-1}, $\Delta S^{\ddagger}_H = -40.6 \pm 1.0$ cal mol^{-1} deg^{-1}, $\Delta H^{\ddagger}_D = 4.4 \pm 0.3$ kcal mol^{-1}, $\Delta S^{\ddagger}_D = -38.3 \pm 0.9$ cal mol^{-1} deg^{-1}. These enthalpies of activation are quite low, but do compare reasonably with the value of 6.4 kcal mol^{-1} observed (3) for the proton transfer from di-(4-nitrophenyl)methane to *tert*-butoxide in *tert*-butyl alcohol containing 10% toluene, particularly since the addition of toluene to the solvent increases the enthalpy of activation (9). The entropies of activation are very similar for these two reactions, except that for the trifluoride ($\Delta S^{\ddagger}_D - \Delta S^{\ddagger}_H$) is positive, the usual result for primary deuterium isotope effects, whereas the methane gave a value of ($\Delta S^{\ddagger}_D - \Delta S^{\ddagger}_H$) which was −2.4 cal mol^{-1} deg^{-1}. Thus, for the methane the istope effect on the entropy of activation reinforces that on the enthalpy of activation, giving $k_H/k_D = 7.2$ at 30°C, whereas in the present case the two effects cancel each other to a large extent, giving $k_H/k_D = 1.3$ at 30°C. Such a small isotopic rate ratio is very unusual for a proton transfer reaction from a carbon acid. However, McLennan and Wong (10) have reported k_H/k_D values of 5.4 at 30°C for methoxide ion in methanol and 3.4 at 45°C for ethoxide ion in ethanol for the dehydrochlorination reaction of $DDT(pClC_6H_4)_2CHCCl_3$. For this reaction evidence was presented that the rate determining step was the formation of the carbanion (11). For the dehydrochlorination of 2,2-di(4-nitrophenyl)1,1,1-trichloroethane, the same workers reported k_H/k_D values of 4.95 and 3.82 at 30°C for methoxide in methanol and *tert*-butoxide in *tert*-butyl alcohol (11). Thus, fairly small isotopic rate ratios may be expected for the *tert*-butoxide reaction.

Rate of Olefin Formation

The rate of appearance of the olefin product was measured using the same technique as above, following the reaction at 325 nm. Both the normal and deuterated trifluorides were used and these gave identical first-order rate constants. The plots of k_{obs} versus base concentration passed through the origin and yielded the second order rate constants shown in Table 2. The second order rate constants yield $\Delta H^{\ddagger} = 2.4 \pm 0.3$ kcal mol^{-1}, $\Delta S^{\ddagger} = -45.0 \pm 1.0$ cal mol^{-1} deg^{-1}.

The second-order rate constant at 30°C (17.5 L $mol^{-1}s^{-1}$) is about 29 times faster than the corresponding constant for the methoxide reaction (1) which is comparable to the butoxide/methoxide ratio of 36 found by McLennan and Wong for 2,2′-di(4-nitrophenyl)1,1,1-trichloroethane at 30°C (12).

	10.9	24.8	

Comparing the second-order rate constant for the *tert*-butoxide elimination, the trifluoro compound is 12 to 13 times slower than the trichloro compound (12). This seems to be a reasonable ratio for the relative reactivity of the two compounds, although it is unfortunate that we have no comparison of the activation parameters.

In the kinetic treatment of this reaction, is has been implicitly assumed that there is a preequilibrium between the initial state and the carbanion ion-pair, which means that the rate constant, k, for olefin appearance (Table 2) is made up of k_1k_2/k_{-1} [BH] as defined by eqs. [1] and [2].

The values of k_1 and k_{-1} [BH] are obtained from the proton transfer step. For the normal substrate, k_1 is k_{2H} from Table 1, 25.2 L $mol^{-1}s^{-1}$ at 30°C, and k_{-1} [BH] is the intercept of the plot of k_H against base concentration, that is, 0.05 s^{-1} at 30°C. The rate constant for olefin appearance, from Table 2, is 17.5 L $mol^{-1}s^{-1}$ at 30°C. These values yield k_2 = 0.035 s^{-1}. Thus, k_2 is not significantly lower than k_{-1} [BH] so that to treat the reaction as a preequilibrium may yield observed rate constants containing some systematic error. However, the data fit the preequilibirum mechanism excellently, so that it would not be possible to find a better fit using the kinetic equation for consecutive reactions. Hammett (13) has noted the difficulty of recognizing a multistep reaction as such from the deviation from first-order behaviour because the deviation is very small when the rate constants for each step are slightly different.

It is concluded that this reaction proceeds by a reversible E1cB mechanism, since there is no kinetic isotope effect on the rate of olefin production. However, the mechanism must be fairly close to the transition point between the $(E1cB)_R$ and the irreversible E1cB mechanisms, since k_2 is not a great deal smaller than k_{-1} [BH].

Experimental

Materials

Tertiary butyl alcohol (Baker Analyzed Reagent) was dried overnight with Molecular Sieve Type 3A and then with calcium hydride. The alcohol was then fractionally distilled from dibutyl phthalate. The fraction boiling at 82.4°C was collected and stored in a vessel protected from moisture and CO_2 under dry O_2-free nitrogen.

Sodium *tert*-butoxide solutions were prepared by dissolving clean sodium metal in *tert*-butyl alcohol in flasks protected from moisture and CO_2. The concentration of the stock solution was determined by titration with standard HCl solution using methyl red as indicator.

The preparation of 2,2'-(4-nitrophenyl)1,1,1-trifluoroethane and its deuterated analogue were described in an earlier publication (1).

Kinetic Measurements

The kinetic runs were carried out with a Durrum stopped-flow spectrophotometer using the standard technique previously described (14).

An investigation of anthraquinone-catalysed alkaline pulping via component modeling and electron spin resonance experiments

M. B. HOCKING,[1] H. I. BOLKER, AND B. I. FLEMING

Department of Chemistry, Pulp & Paper Building, McGill University, 3420 University Street, Montreal, P.Q., Canada H3A 2A7

Received March 21, 1980

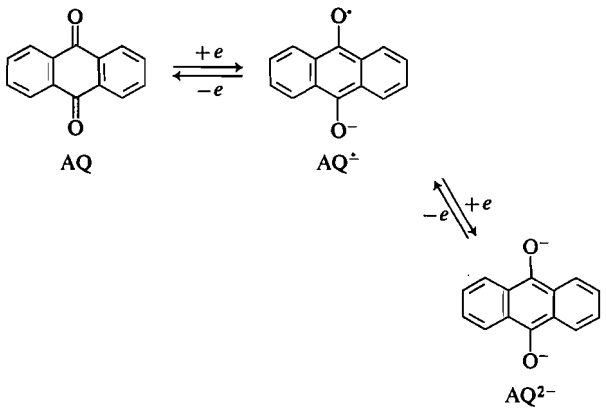
M. B. HOCKING, H. I. BOLKER, and B. I. FLEMING. Can. J. Chem. **58**, 1983 (1980).

The radical anion of anthraquinone ($AQ^{\cdot -}$) has been generated by the reduction of anthraquinone (AQ) with sugars in aqueous alkaline solution. This appears to be the first time that the radical has been observed (esr spectrometry) in an entirely aqueous medium. Alkaline methanol solutions of AQ, when irradiated with light, yielded colourless solutions also exhibiting strong esr signals characteristic of $AQ^{\cdot -}$.

The ability of various carbohydrate and lignin preparations to reduce AQ, or to oxidize the reduced forms of AQ, was also investigated, both by direct observation and by electrode potential measurements. In very concentrated alkali, AQ was reduced by glucose to a green solid thought to be a quinhydrone.

M. B. HOCKING, H. I. BOLKER et B. I. FLEMING. Can. J. Chem. **58**, 1983 (1980).

On a produit l'anion radical de l'anthraquinone ($AQ^{\cdot -}$) en réduisant l'anthraquinone (AQ) par les sucres dans une solution aqueuse basique. Il semble que c'est la première fois qu'on observe le radical (spectroscopie de rpe) dans un milieu complètement aqueux. Quand on irradie les solutions basiques de méthanol de AQ, on obtient des solutions incolores qui montrent également de forts signaux caractéristiques du $AQ^{\cdot -}$ en rpe.



En utilisant l'observation directe et les mesures de potentiel d'électrode on a également étudié la capacité qu'ont diverses préparations de sucre ou de lignine, de réduire AQ ou d'oxyder les formes réduites de AQ. En solution basique très concentrée, le glucose réduit le AQ en un solide vert que l'on pense être une quinhydrone.

[Traduit par le journal]

Introduction

Interest in the chemistry of anthraquinone (AQ) has recently been revived, because a discovery of considerable industrial importance has revealed that in small quantities it accelerates the alkaline delignification of wood (1) and increases the yield of residual carbohydrate fibres. Proposed mechanisms (2–4) consider AQ to function as a redox catalyst by transferring electrons to lignin from a predominantly carbohydrate source. However, the nature of the species formed when AQ is reduced in alkaline solutions is far from clear (3). Although the red color of alkaline reduced AQ solutions has been ascribed to the dianion, AQ^{2-} (5, 6), one might also expect the semiquinone anion radical ($AQ^{\cdot -}$) to absorb light in the visible region (7–10). The anion radicals of amino- (10) and sulphonated- (8) anthraquinones have been reported to absorb between 450 and 520 nm, and there are reports that $AQ^{\cdot -}$ itself is red (9, 11). There are also reports that it is yellow (in aqueous methanol (12)) and pale brown (in pyridine (13)).

One investigation indicated that AQ may have as many as 5 stable reduced forms (including 2 radicals) in alkaline media (12), and there is always the possibility that $AQ^{\cdot -}$, if formed, may disproportionate rapidly to a mixture of AQ and AQ^{2-} (14).

The picture is further complicated by the variety of solvents used in previous experimental work.

When formed by electrolysis, photolysis, radiolysis, or chemical oxidation–reduction, $AQ^{\cdot -}$ is very stable in organic solutions (14–23), and in aqueous organic solutions (9, 12, 17, 24–29). Consequently, the esr spectrum of the radical is very well known, and all the 25 theoretical lines (24) have been observed in aqueous methanol (10% H_2O) solution (12). We have not, however, found any reports of esr spectra of the radical anion in 100% aqueous solution, although one paper indicated that $AQ^{\cdot -}$ formed at a pH above 12 in aqueous solution when an AQ-treated graphite electrode was maintained at a suitably low potential (30). In this work, our aim has been to identify the various

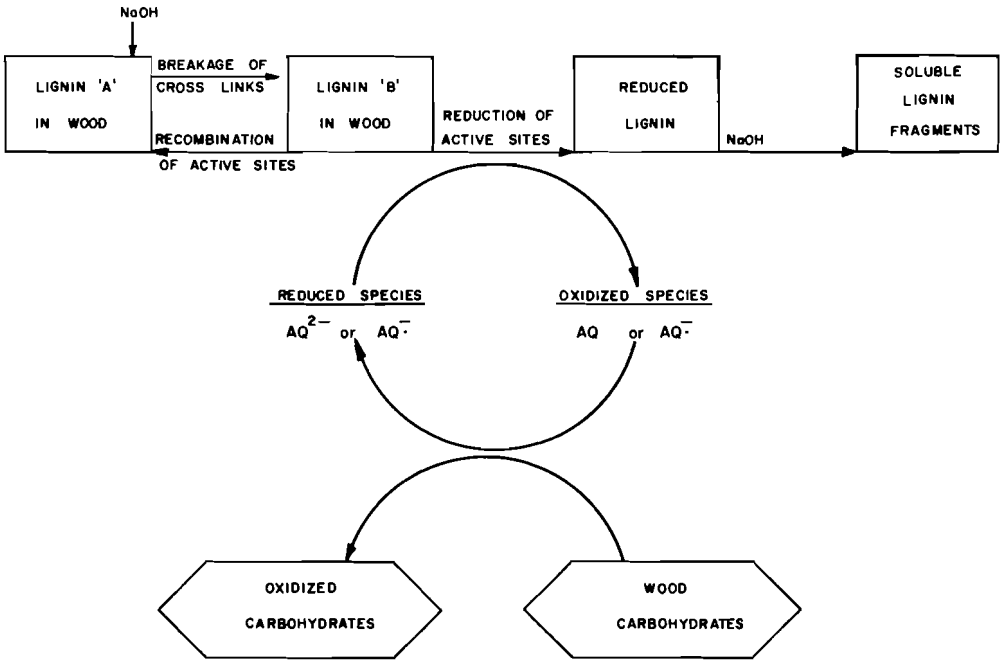

FIG. 1. Proposed mechanism for delignification rate enhancement in alkaline pulping with anthraquinone (3).

reduced states of anthraquinone in 100% aqueous solution, and to evaluate the stability of $AQ^{\cdot-}$ in aqueous alkaline media, with the objective of contributing to the detailed understanding of the catalytic role of AQ in alkaline pulping (Fig. 1).

In polarographic investigations, AQ showed only one wave in aqueous alkaline solution (3), indicating that the radical anion was not formed at a mercury electrode under reducing conditions.

We now report the preparation of the radical anion $AQ^{\cdot-}$ from anthraquinone by chemical reduction in aqueous alkaline solution. Although all the aqueous radical-containing solutions were red, alkaline methanolic solutions of AQ, after exposure to light, remained virtually colorless, yet still showed strong esr signals due to the radical anion.

As a step towards further elucidating the chemistry of the pulping process, modeling experiments were done in order to determine which wood components are capable of reducing AQ to the dianion, i.e. of acting as the source of electrons for AQ. Another part of the work describes tests conducted to determine those wood components present which were capable of accepting electrons from reduced AQ, i.e. AQ dianion.

Experimental

Anthraquinone (AQ) supplied by the Aldrich Chemical Co. was precipitated in fine particle size by adding a saturated solution in 50 mL dimethylformamide at 120°C, while hot, to 10 L of vigorously stirred cold water. The precipitated AQ was filtered off, washed with deionized water, and dried at 60°C.

Aqueous solutions of sodium and potassium hydroxides of all concentrations were freshly prepared for each series of experiments from distilled water and the appropriate base, and were sparged with high purity nitrogen (< 10 ppm O_2) for 1 h prior to use.

Solvents were commercially dried varieties which had been stored over fresh Molecular Sieve 4A for at least 24 h prior to use, and were used without any further precautions to exclude moisture. Sodium ethoxide and methoxide were freshly prepared for each experiment by the addition of the appropriate mass of clean sodium to the appropriate dry alcohol in a reflux assembly fitted with a drying tube.

Electron Paramagnetic Resonance Experiments

Electron paramagnetic resonance experiments were conducted on a Varian V4501-B spectrometer fitted with a rectangular TE_{104} dual sample cavity. Further instrumental details are given elsewhere (31).

The various reduced AQ solutions to be examined were loaded into standard epr capillaries (1.0 × 90 mm nominal) from serum capped preparation flasks via a gas tight polypropylene syringe fitted with a needle long enough to reach the bottom of the capillary. The transfer was conducted in a dry box flushed with high-purity nitrogen gas bubbled through three flasks of Fieser's deoxygenating solution (32), and thence through a tube (5 × 100 cm) packed with indicating Drierite. The liquid levels in the filled esr capillaries were dropped 2 to 3 mm by touching the surfaces with filter paper, and the tubes were sealed with Five-minute Epoxy cement (Lepage's Ltd.). At least 20 min setting time was allowed before tubes were withdrawn from the nitrogen atmosphere.

An internal standard of benzoquinone radical anion placed in the second cavity of the spectrometer was used to calibrate the line width of the AQ radical anion spectra. The radical solution

was prepared by a variation of the flow system developed by Venkatamaran (33). Hydroquinone (50.0 mg) was dissolved in 15 mL of 95% ethanol and 20 drops (0.46 mL) of 0.1 *M* aqueous sodium hydroxide added while this solution was exposed to air. Portions of the yellow solution obtained were sealed into several esr capillaries within 10 min according to the procedure outlined above, and gave the expected strong five-line esr signal of about 2.4 G line-width. The signal decreased to about 1/20 of its original intensity (1/2 h after preparation) 4 h after it was first observed. All sealed esr tubes now looked colorless to the eye. An open tube showed a thin brown line at the open end. For AQ samples having low radical concentrations, the hydroquinone charge was decreased to 5.0 mg.

To determine the absolute number of spins of AQ radical anion samples, fresh diphenylpicrylhydrazyl (DPPH, mp 135–139°C, 19.7 mg) was finely ground and thoroughly dispersed into 13.8 g of previously powdered sodium chloride (Fisher) containing less than 7×10^{-4} mg iron/g. When well packed, this powder had a bulk DPPH concentration of 5×10^{-3} *M*. Samples of exact known weight were sealed in esr capillaries with epoxy and the integrated area (by weighing) of the single line spectrum was used as a standard for determining numbers of spins. Determination of the absolute number of spins of the various AQ samples was simplified by irradiating the sample with sufficient power to saturate the sample and cause collapse of the normal 13 or 19 line spectra (31) to a single line of similar line width to that of DPPH. The absolute number of spins in a sample containing AQ radical anions was estimated by simultaneously scanning both samples and DPPH in the dual cavity probe, with a modulation amplitude high enough to cause saturation. The gain settings required to obtain the same peak area for sample and reference were then compared (34). For greater accuracy, the whole procedure was repeated with the reference DPPH and the sample positions reversed in the cavities of the spectrometer and the average of the two gain ratios was used to determine the absolute number of spins. It was then possible to relate the absolute number of spins of other AQ samples by comparing their signal strengths to that of the calibrated AQ sample, both now run under ordinary conditions.

Redox Potential Measurements

These were made in a closed cell containing a smooth platinum electrode with a saturated calomel reference electrode (Fisher No. 13-639-115 and 13-639-51 respectively). The voltage was measured with a high impedance (10^{12} ohm) voltmeter (Aardvark Instrument Co., Model PEC-VM) whose output was fed to a pen recorder.

Glucose (1.0 g), sodium dithionite (1.0 g), and cellobiose (1.0 and 2.0 g) were added to 25 mL of freshly nitrogen-purged sodium hydroxide (1.0 *M*), and the change in potential was recorded as a function of time. A parallel set of experiments was conducted in 1.0 *M* aqueous potassium hydroxide. Attempts to obtain redox potential curves for cellobiose in KOH solution failed to yield reproducible results.

Reduction of Anthraquinone by Glucose

One example (No. 22-1) is described. A suspension of 25 mg of AQ (0.120 mmol) in 25 mL 1.0 *M* aqueous sodium hydroxide (previously sparged with nitrogen, 1 h) placed in a serum-capped Erlenmeyer flask was magnetically stirred for 5 min while flushing with nitrogen via two syringe needles through the serum cap. Stirring was stopped, 21.6 mg (0.120 mmol) of glucose was added, the serum cap was replaced and wired on, and nitrogen flushing was continued for 2 min before stirring was resumed. The exit flushing needle was removed before the nitrogen entry needle to give a positive pressure of 7 kPa. In 3 h the originally white suspension had become slightly pink, and in 47 h had become a clear deep red solution. Details of other experiments with glucose as reductant are given in Table 1. Reductions in nonaqueous or aqueous-organic media (Table 2) were conducted in a manner strictly parallel to the aqueous reductions.

Reduction of Aqueous Anthraquinone by Sodium Dithionite

These experiments were conducted in a similar manner to the aqueous sugar reductions except that preparation No. 15-1 was carried out in a stoppered, magnetically stirred, completely full one liter Erlenmeyer flask in the open air, and the resulting solution was then transferred to esr capillaries in a nitrogen box. Details are given in Table 3.

Reduction of Aqueous Anthraquinone by Cellobiose

The sugar (123 mg; 0.360 mmol) was added to a previously nitrogen-purged flask containing a suspension of AQ (25 mg; 0.120 mmol) in 25 mL 1.0 *M* sodium hydroxide. A serum cap was wired on and the system was flushed with nitrogen through two needles for a further 5 min before leaving a slight positive nitrogen pressure. This suspension was then magnetically stirred for 1 h, with no change in appearance, whereupon it was placed in a water bath at 50°C. In 1 h the suspension had become red, and most of the AQ had dissolved. A trace of undissolved AQ remained after 1.5 h, but the suspension had become a clear deep red solution after 15 h stirring.

Reduction of Aqueous Anthraquinone by Cellulose and Lignin Preparations

Three suspensions of AQ (10 mg) in 10 mL of 1.0 *M* sodium hydroxide in screw-capped Reacti-Flasks[2] fitted with Teflon-lined silicone rubber septa and Teflon-covered stirring bars were prepared in a nitrogen-flushed glove-bag. Samples of Whatman No. 1 filter paper, cotton linters, and hydrocellulose (35) were finely chopped, a weighed sample (202 ± 2 mg) of each was added to a flask, and the flasks were tightly closed. Stirring 24 h at room temperature (21°C) induced no change in appearance. All the flasks were placed in a stirred oil bath which was gradually heated to 70°C over 8 h while stirring of the contents of each flask was continued. The paper experiment showed no change, while after 2 h at 65–70°C the linters and hydrocellulose mixtures had become colored. The observations, set out in Table 4, indicate that hydrocellulose in aqueous alkali reduced AQ more effectively than linters, while filter paper failed to reduce AQ.

Cuoxam lignin (200 mg) prepared as described in ref. 36 also failed to reduce AQ (10 mg) in aqueous alkali below 150°C (Table 4). A second sample was heated at 160°C without any red color being produced. Dioxane lignin (37) gave a dark solution at room temperature, and thus could not be tested. Periodate lignin (38) gave a brownish-red supernatant after 30 min at 25°C indicating reduction of AQ. A control experiment without AQ had a quite different brown color. Because of the seemingly different behaviour of cuoxam and periodate lignins towards AQ, we examined the redox potentials of 1 *M* sodium hydroxide containing these materials. As anticipated, periodate lignin gave a low potential (−0.62 V after 10 min at 25°C) while cuoxam lignin yielded a less powerfully reducing solution (−0.42 V vs. SCE).

A further experiment with 207.2 mg of finely chopped Whatman No. 1 filter paper placed in a Reacti-Flask[2] with 10 mL of 20 *M* aqueous sodium hydroxide and 10.0 mg of AQ, with the same precautions as above, was heated with stirring to 150°C during 1 h in a stirred oil bath without any visible change. After 1.7 h at 157°C the flask contents became a pale reddish brown color, and after a further 0.5 h a green upper layer appeared. The

67–2	0.36 0.12	KOH, 1 *M*	25	0.6	4	Deep red, no radicals detected

[a]The time at which the first pink coloration was detectable from the initially white suspensions.
[b]The time at which a clear (non-turbid) deep red solution was obtained.
[c]After 48 h stirring at room temperature the mixture was gradually heated to 93°C over 48 h. The color of the reaction with 0.024 mmol glucose gradually faded to white, the other showed no change.
[d]Color change sequence observed was: 5 min, yellow; 10 min, pale brown; 15 min, greenish brown; 30 min, brownish green; 45 min, green suspension; gradually during next 4.5 h becoming a very dark green suspension. Pressure filtration under nitrogen yielded a clear colorless filtrate without a detectable esr signal and a green precipitate. On exposure to air the green solid did not change in appearance during three days, but had become white in one month.
[e]Initial yellow suspension gradually became a stable yellow orange suspension after 7 h.

flask was swirled occasionally while heating for another 0.5 h without any further change, so the temperature of the bath was raised during the next 0.5 h to 169°C. At this point the flask contents became a pale purple color, again with the green upper layer present. After 1.7 h at this temperature with no further visible change the flask exploded.

Oxidation of Reduced AQ by Model Wood Components

Anthraquinone (8.2 mg, 0.04 mmol) and 1.0 *M* aqueous sodium hydroxide (10 mL) were added to each of six Reacti-Flasks under nitrogen in a glove bag and, 16 h later, glucose (14 mg, 0.08 mmol) was added, yielding, after standing overnight, a red solution of reduced AQ. Dioxane lignin, periodate lignin, cuoxam lignin, cotton linters, Whatman filter paper, and hydrocellulose in 200 ± 2 mg amounts were added to the flasks in turn. The dioxane lignin dissolved immediately to give a solution too dark for further observation. In the other mixtures, the red color was unchanged after 72 h at 25°C. Upon gradually heating to 160°C, there was little change in the flasks containing carbohydrates. The periodate lignin mixture became too dark for further observation above 100°C, but the paler cuoxam lignin mixture was seen to lose some of its color above 120°C.

This interaction of reduced AQ and lignin was observed by polarography in the following way. The AQ (6 mg), hydrocellulose (40 mg), and 1 *M* NaOH (7.5 mL) were placed in Pyrex glass tubes (1/2 in. × 6 in.) sealed at one end and fitted at the other with a Teflon valve (Omnifit 022 BAA). One of the tubes also contained cuoxam lignin (60 mg). The tubes were purged with nitrogen before the chemicals were added, otherwise no precautions were taken to exclude traces of air. The sealed tubes were heated in a glycol bath for 30 min at 140°C, and then, by inverting the tubes and opening their valves, the contents could be transferred under pressure to a nitrogen-purged polarograph cell; DC polarograms were recorded immediately on a Princeton Applied Research 174A polarograph with a model 303 dropping mercury electrode.

Results and Discussion

The Identity of the Reduced AQ Species

Solutions of reduced AQ, prepared in a variety of ways, were examined by esr spectroscopy in an attempt to discover the conditions giving radical anions. AQ reduced with an excess of sodium dithionite (Table 3) in 1 *M* NaOH (No. 15-1) gave a deep red solution which had no esr signal in the total absence of oxygen. When air was admitted to the sample tube, a fully resolved 19-line spectrum appeared (Fig. 2), and gradually increased in intensity. Alkaline dithionite thus seems to reduce AQ completely to the dianion; partial oxidation generates the radical anion.

AQ reduced with 3 mol of glucose per mol of AQ in 1 *M* NaOH (Table 1; No. 22-2) gave a deep red solution which exhibited a weak 19-line esr signal. As can be seen from the redox potential curves in

TABLE 2. Reduction of anthraquinone (AQ) by glucose (Gluc) in non-aqueous suspensions at room temperature

Experiment No.	Gluc:AQ mmoles	Base, and amount, mmol	Solvent, and vol. of solution	Time to color change	Remarks
51–3	0.0 0.10	NaOH, 10	50% Aqueous ethanol, 20 mL	No change	Remained as white suspension
55–3a	0.12 0.05	Nil	Water, 10 mL	No change	White solid suspension
55–2a	0.12 0.05	Nil	Ethanol, 100% 10 mL	No change	White solid suspension
55–2b	0.12 0.50	$NaOC_2H_5$, 15, in 3 mL	As above, base added after 23 h	1 h[a]	An initial cream-colored suspension[a]
51–2	0.12 0.10	NaOH, 10	50% Aqueous ethanol, 20 mL	5 min, yellow 80 min, green	90% of AQ dissolved; stable green color
55–1a	0.12 0.05	Nil	Dimethylformamide (DMF), 10 mL	No change	30 min to stable colorless solution
55–1b	0.12 0.05	$NaOC_2H_5$, 5, in 1 mL C_2H_5OH	DMF, 10 mL, base added after 23 h	Instant dark green when base added	Stable suspension
63–3	0.84 0.28	$NaOCH_3$, 50	Methanol, 50 mL	1 h, green 15 h, red	Near solution, radicals present
67–1	0.0 0.280	$NaOCH_3$, 50	Methanol, 50 mL	[b]	Nearly all AQ dissolved in 5 h, no radicals unless irradiated

[a]Color change sequence observed was: 1 h, pale cream; 80 min, yellow; 110 min, green; 2 h, dark green suspension and nearly all in solution; 3 h, brownish red and all dissolved; 7 h, deep red and stable color.
[b]No color change in subdued light, became yellow in daylight or under fluorescent lights.

TABLE 3. Sodium dithionite reductions of anthraquinone (AQ) in aqueous suspensions

Experiment No.	$Na_2S_2O_4$:AQ, (mmol)	Base, and amount (mmol)	Solvent (volume of solution)	Time to color change	Remarks
15–1	11.0 5.0[a]	NaOH (1000)	H_2O (1 L)	10 min, pink 4 h, deep red	Turbid suspension No radicals observed
62–1	0.42 0.14	KOH (30)	H_2O (30 mL)	10 s, pink 0.3 h, deep red	Turbid suspension Clear solution
63–2	0.42 0.14	NaOH (30)	H_2O (30 mL)	10 s, pink 0.3 h, deep red	Turbid suspension Clear solution
21–12	0.87 0.48	NaOH (400)	H_2O (20 mL)	10 min, yellow 4 h, brown	Turbid suspension After 48 h became a dark green suspension, see text

[a]Anthraquinone used was not previously reprecipitated, i.e. it had a large particle size.

Figs. 3 and 4, alkaline glucose solutions have less reducing power than dithionite solutions. Decreasing the amount of glucose to 1 mol per mol of AQ in 1 *M* NaOH (Table 1; No. 22-1) gave a deep red solution with a strong 19-line esr signal. The absolute concentration of $AQ^{\cdot -}$ was close to 1% of the total AQ present and did not diminish over a period of 3 months when the solution was in a sealed capillary, kept in subdued light at room temperature. When the amount of glucose was decreased to 0.5 or 0.25 mol per mol of AQ, the amount of AQ dissolved decreased correspondingly and pink suspensions were obtained. The reduction mechanism and equilibria appear to favour the formation of the stoichiometric equivalent of AQ^{2-} rather than $AQ^{\cdot -}$.

AQ reduced with 3 mol equivalents of glucose in 1 *M potassium* hydroxide (Table 1; No. 67-2) gave a deep red solution but *no esr signal* in absence of oxygen (less than $1 \times 10^{-7} M$ radical species present). A possible explanation for the failure of KOH solutions to produce radicals lies in the slightly

TABLE 4. Reduction of anthraquinone in 1 *M* aqueous sodium hydroxide[a] by model wood components

Temperature, °C	Time, h	Filter paper, Whatman No. 1	Cotton linters	Hydrocellulose	Cuoxam lignin	Periodate lignin
21	24	White suspension, chopped pieces, non-dispersed	Off-white suspension	White suspension	Light brown solution, brown and white solids underneath	Brownish red solution,[b] brown solid
21–70	8	No change	Pink suspension	Deep orange color	No change	No change
70–100	1	No change	Red suspension, part of AQ dissolved	Intense red color	No change	No change
100	3	No change	No change	Red, all AQ dissolved	No change	Solution too dark for further observation
100–130	1	No change	Intense red color, nearly all AQ in solution	No change	Brown solution, no evidence of AQ reduction	
130	3.5	No change	Intense red color, all AQ appears to be in solution, linters well dispersed	No change	No change	
130–150	0.5	Pale yellow mixture	No change	Intense red-brown	No change	
150	0.5	As above, fiber well dispersed	No change	Dark red-brown	No change	
150–210	2	Color faded to white	Red color retained, approx. 0.2 mL volume loss	Red color retained	Brown solution, no red color	

[a]See Experimental for full details.
[b]A control sample without AQ gave a brown solution.

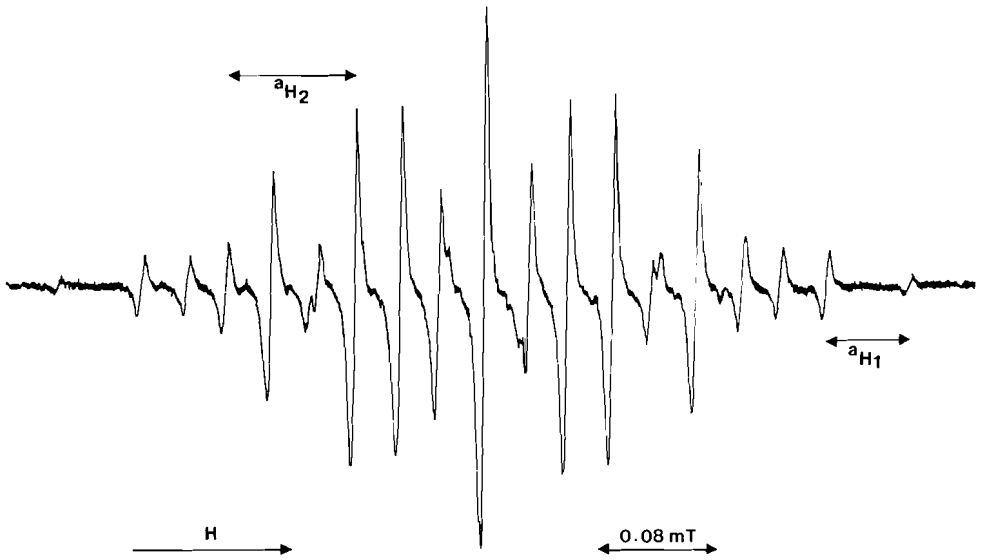

FIG. 2. Electron spin resonance spectrum of anthraquinone radical anion in aqueous 1.0 *M* sodium hydroxide at room temperature, produced by initial reduction with excess sodium dithionite followed by partial oxidation with air (No. 15-1).

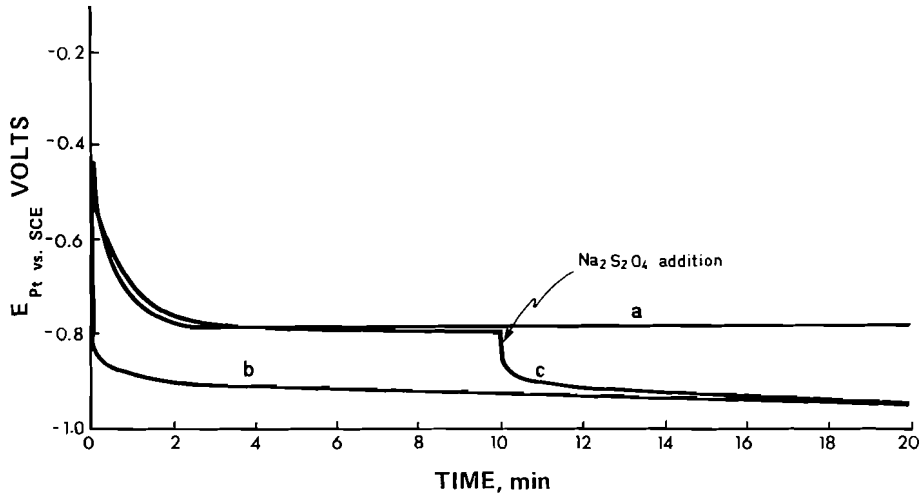

FIG. 3. Redox potential vs. time for (a) 1 g glucose (0.22 *M*), (b) dithionite (1 g), and (c) glucose followed by dithionite, when mixed with 1 *M* sodium hydroxide (25 mL) solution at 23°C.

lower redox potentials observed in KOH solutions of carbohydrates (Fig. 4, lowest curve).

In 1 *M* methanolic $NaOCH_3$, AQ was reduced by 3 equivalents of glucose to a deep red solution which gave a very intense 13-line esr spectrum (No. 63-3, Fig. 5) for $AQ^{\cdot -}$. A 13-line spectrum is commonly observed for $AQ^{\cdot -}$ in methanol solution (29), because the coupling constants of the anion radicals are solvent-dependent (18, 24). The overlapping of lines which produces a 13-line spectrum is also the main reason for the increased signal intensity.

When glucose was omitted from a methanolic AQ solution containing $NaOCH_3$, the solution remained colorless and gave no esr signal (Table 2, No. 67-1). But, when exposed to light, the solution became pale yellow and slowly faded to colorless again. Both of the latter solutions showed very strong 13-line esr spectra of $AQ^{\cdot -}$. The formation of radicals by photoreduction has been noted previously (16, 23), but *colorless* solutions giving the esr spectra of $AQ^{\cdot -}$ have not been reported. In absence of oxygen, the radical anions are stable over long periods (3 months) and do not yield any colored products.

Formation of a Green Material

When an excess of sodium ethoxide was added to

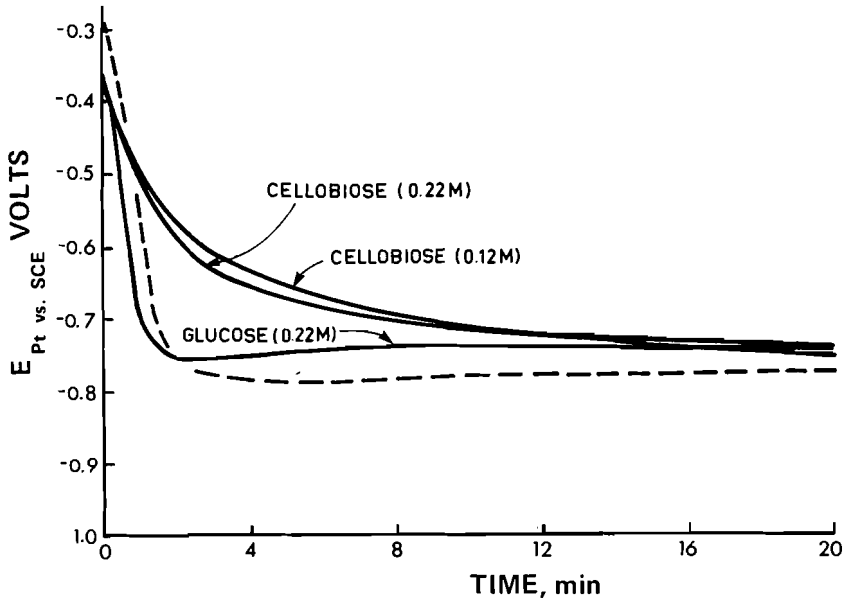

FIG. 4. Redox potential curves for glucose and cellobiose in 1 *M* sodium hydroxide at 23°C. The dotted line was produced by glucose (0.22 *M*) in 1 *M* potassium hydroxide at 23°C.

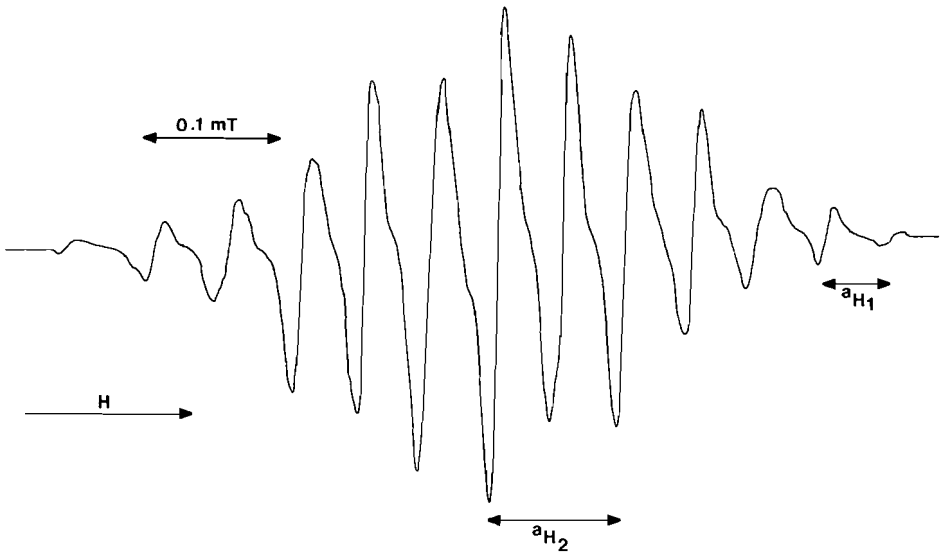

FIG. 5. Electron spin resonance spectrum of anthraquinone radical anion in methanolic 1.0 *M* sodium methoxide after exposure to light (No. 67-1).

a colorless ethanolic suspension of AQ containing glucose, it yielded a dark green suspension in 2 h, and gradually formed a stable red solution over a 7-h period (Table 2, No. 55-2b). Control mixtures of AQ and glucose in ethanol (Table 2, No. 55-2a) or water (Table 2, No. 55-3a), but with no base, and solutions with base but no glucose (No. 51-3) gave no visible reaction. Dark green solutions were obtained from AQ, glucose, and base in dimethylformamide (No. 55-1b); in the absence of base, there was no color (Table 2, No. 55-1a).

When AQ was added to a 1 *M* solution of sodium methoxide in methanol in the presence of 3 equivalents of glucose, a dark green suspension formed in 1 h, then gradually became a red solution (Table 2, No. 63-3). The green material was obtained as a stable end-product when AQ was reduced in 20 *M* aqueous sodium hydroxide with 1.7 equivalents of glucose (Table 1, No. 57-1) or sodium dithionite. When the green suspension from glucose reduction was pressure-filtered under N_2 and the filtrate examined by esr, no signal was observed. The dark

TABLE 5. DC polarographic measurement of the oxidation of reduced AQ by cuoxam lignin

	Color of suspension	Height of AQ[a] wave (I_d), μA	AQ concentration, ppm[b]		Redox potential (V) of liquor (Hg vs. SCE)
			Reduced	Oxidized	
AQ + hydrocellulose + 1 *M* NaOH	Deep red	9.0	152	2	−0.84
AQ + hydrocellulose + cuoxam lignin + 1 *M* NaOH	Orange	2.1	29	7	−0.78

[a]Measurements made at 95 ± 5°C in liquor blown out of a glass digester tube previously heated at 140°C.
[b]Calibrated with AQ standards in alkaline sodium dithionite solution at 25°C (39).

green precipitate from either source appears to be reasonably stable in air (footnote *d*, Table 1; Table 3).

Deffner and Brunner (12) have reported the formation of green solutions by partial oxidation of anthrahydroquinone solutions in methanol. They considered the color to be caused by quinhydrone formation. This concept is supported by our observation that, when the whole green suspension in 20 *M* NaOH was injected into 80 mL 1 *M* NaOH (oxygen-free conditions), a red solution and a white precipitate formed instantly, evidently by disproportionation. Filtration under nitrogen allowed separation of the white solid, which was anthraquinone (by mp, mixture mp, and ir) and comprised about one half of the initial anthraquinone. Exposure of the red filtrate to air, with stirring, rapidly generated a white suspension in a colorless solution, which on filtration yielded further anthraquinone.

Components of Wood Capable of Reducing AQ

Glucose reduced AQ rapidly at room temperature in 1 *M* aqueous sodium hydroxide, but not as rapidly as sodium dithionite. This is predicted by the redox potential curves (Fig. 3) wherein dithionite is shown to be the more powerful reductant. The asymptotic minimum potential recorded for glucose in the absence of AQ was −0.78 V (Pt vs. SCE), and is reached about 2 min after mixing in NaOH solution.

The stoichiometry of the reduction was approximately 1:1 on a molar basis, glucose to AQ (see Table 2), and was demonstrated to occur at sodium hydroxide concentrations of 0.25 *M* to 5.0 *M*, and probably also at 20 *M* but with a different final product.

Cellobiose was found to reduce AQ slowly at room temperature in 1 *M* aqueous sodium hydroxide, but rapidly at 50°C. The asymptotic minimum redox potential recorded for cellobiose in 1 *M* sodium hydroxide was about the same as that of glucose (−0.75 V, Pt vs. SCE) but is more slowly attained (Fig. 4).

Cotton linters in 1 *M* aqueous sodium hydroxide began to reduce AQ at 70°C (Table 5), with rapid reduction occurring at 130°C. Hydrocellulose produced from these linters by acid hydrolysis (35) was more active, with full reduction occurring at 100°C. Whatman No. 1 filter paper, on the other hand, did not reduce AQ even at 150°C in 1 *M* sodium hydroxide. When the experiment was repeated at 170°C in 20 *M* sodium hydroxide, a pale purple solution and green upper phase were evidence of some slight AQ reduction, but the process was apparently accompanied by decarboxylation of some of the hydrolytic products and caused gas release which, possibly accompanied by some attack of the glass, ruptured the flask.

Cuoxam lignin did not reduce AQ in aqueous alkali in contrast to periodate lignin which, in contact with aqueous NaOH, was found to give much lower redox potentials than cuoxam lignin.

Components of Wood Capable of Oxidizing Reduced AQ

Reduced AQ solutions were treated under oxygen-free conditions with wood components in excess to test their ability to oxidize the red solution, i.e. to participate in the upper half of the proposed AQ redox pulping cycle (Fig. 1). None of the materials listed in Table 4 produced any noticeable oxidation during 3 days at room temperature, or when heated slowly to 130°C. Periodate lignin, as expected, did not oxidize the red solution up to 100°C, at which point the solution became dark. Polarograph measurements showed that cuoxam lignin was able to oxidize solutions of reduced AQ at 140°C (Table 5). Hydrocellulose was the preferred reagent for the reduction of AQ in this experiment because, unlike glucose, it did not form dark-colored products during the reaction.

Conclusions

It now seems quite clear that the red form of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

reduced AQ is the dianion. The radical anion is colorless, or, at most, pale yellow. Under conditions of high base strength, a green substance, possibly a quinhydrone, may be observed.

The maximum concentration of radical anion observed in the aqueous room temperature experiments amounted only to 1% of the AQ charge, although the possibility exists of higher equilibrium radical concentrations at pulping temperature (170°C).

In aqueous alkaline solution AQ can be reduced by polysaccharide end groups, but the ease of reduction, as judged by the temperature required, seems to be a function of chain length, the order of reduction efficiency being: glucose > cellobiose > hydrocellulose > cotton linters > filter paper. This conclusion is supported, at least for glucose/cellobiose, by both the much slower development of the asymptotic minimum redox potential and the slightly less negative asymptotic minimum reached for the same molar concentrations (Fig. 4).

Two insoluble lignin preparations behaved differently towards AQ in alkaline solution. Periodate lignin was able to reduce AQ under alkaline conditions at room temperature, but cuoxam lignin did not. On the contrary, when heated to 140°C, alkaline solutions of reduced AQ were oxidized by cuoxam lignin. The difference in behavior doubtless stems from the modification of lignin during isolation. Periodate lignin is considerably demethylated and oxidized during isolation (40) and it is thus not a particularly good model for virgin lignin. Cuoxam lignin, on the other hand, has chemical and physical properties which resemble more closely those of lignin in wood (41).

Quantitative prediction of stereochemistry in the reduction of cyclohexanones by sodium borohydride

R. MURUGAN

University Service and Instrument Centre, Madurai Kamaraj University, Madurai-625 021, India

Received April 11, 1980

R. MURUGAN. Can. J. Chem. **58**, 1993 (1980).

An extremely simple method is presented for quantitatively predicting the stereochemical product ratio in the reduction of alkylcyclohexanones by sodium borohydride. Accurate predictions are made except in the cases of highly hindered ketones.

R. MURUGAN. Can. J. Chem. **58**, 1993 (1980).

On présente une méthode quantitative extrêmement simple qui permet de prévoir le rapport des produits stéréochimiques de la réduction des alkylcyclohexanones par le borohydrure de sodium. Les prévisions sont justes sauf dans le cas de cétones fortement encombrées.

Introduction

Reduction of cyclohexanones by sodium borohydride and other similar reducing agents has attracted much attention. Many ideas and theories have been advanced to account for the interesting stereochemical control exhibited in these reactions (1–10). In contrast, however, much less attention has been paid to the matter of quantitatively predicting these stereochemical product ratios, with only two approaches, those of Wigfield (11) and of Wipke and Gund (12), having been presented in the literature.

Discussion

The method presented here is an extremely simple, yet useful, empirical method that applies to the reduction of cyclohexanones by sodium borohydride. The assumptions made for the quantitative prediction are as follows.

(*1*) Changes in stereoselectivity from one ketone to another are simply the consequence of differential steric impedance between ketone and reducing agent.

(*2*) The difference in stereoselectivity between a substituted cyclohexanone and cyclohexanone is assumed to be due to the substituent present in the cyclohexanone ring. For example, the stereoselectivity of cyclohexanone and 3-methyl cyclohexanone are respectively (product ratio, axial/equatorial) A/E (cyclohexanone) = 86:14 and A/E (3-methyl cyclohexanone) = 87:13. That is, a 3e methyl group has no effect on the stereoselectivity in the reduction of cyclohexanone by sodium borohydride.

(*3*) The stereoselectivity of free cyclohexanone is taken as the base value for the calculation.

(*4*) The increments are given for calculating the percentage of equatorial alcohol formed. Positive increment values are given for substituents which hinder equatorial attack of the reagent, negative increment values are given for substituents which hinder axial attack of the reagent, and zero values for substituents which do not hinder either axial or equatorial attack of the reagent. From previous work and from models it is clear that 2e(6e) and 3a(5a) substituents hinder axial attack and so are given negative increment values; 2a(6a) and 4a substituents hinder equatorial attack and so are given positive increment values; 3e(5e) and 4e substituents do not hinder equatorial or axial attack and so are given zero values.

(*5*) The effect due to two or more substituents on the stereoselectivity is assumed to be additive.

From a detailed study of the stereoselectivity of the different cyclohexanones (16) the increment values for methyl substituents at various positions in the cyclohexanone ring are given in Table 1. For substituents other than the methyl group the increment values are also given in Table 1.

For example, the calculation of percentage of equatorial alcohol formed for 2,4,4-trimethyl cy-

24.	2,5,5-Trimethyl cyclohexanone	34	29
25.	*trans*-3,4-Dimethyl cyclohexanone	86	88
26.	3,3,5,5-Tetramethyl cyclohexanone	6	5
27.	*cis*-2-Methyl-4-*tert*-butyl cyclohexanone	76	79
28.	*trans*-1-Decalone	69	68

clohexanone (Fig. 1) is: base value = 86%; Me at 2e = −12; Me at 4a = +6; Me at 4e = 0. Calculated total = 80%; observed total = 82%.

Calculated percentage of equatorial alcohols using this method and the experimentally observed (11,12,15,16,17) values are shown in Table 2. Examination of Table 2 makes it clear that there is good agreement between the calculated and the experimental values. The method is able to predict satisfactorily for a good number of cyclohexanones including steroidal ketones. The prediction for the ketone, 3,3,5,5-tetramethyl cyclohexanone, is in excellent agreement with the observed value. For 2-substituted cyclohexanones, the difference in value is tolerable for the methyl group but is higher for the *tert*-butyl group, which may be due to the participation of the less stable conformation (13,14) in the reduction process.

FIG. 1

The major limitation of this method is the oversimplification which would lead to predictions of less than 0% or greater than 100% of the equatorial alcohol if too many critical substituents are present. 11-Keto steroids and axial *cis*-2,6-dimethyl cyclohexanones respectively would be examples of this problem. In most cases, however, the prediction is simpler to obtain and as accurate as the method of Wigfield, and far simpler and more accurate than the approach of Wipke and Gund.

The synthesis and chlorinolysis of 5-phenyl-2,4,5-trithiapentane-2,2-dioxide

TERENCE PATRICK AHERN, RICHARD FRANCIS LANGLER,[1] AND ROBERT LEONARD MCNEIL
Chemistry Department, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received March 26, 1980

TERENCE PATRICK AHERN, RICHARD FRANCIS LANGLER, and ROBERT LEONARD MCNEIL. Can. J. Chem. **58**, 1996 (1980).

Application of mercaptide anions to the dechlorination of an α-polychlorosulfonyl substrate has provided the key step in a successful synthesis of the title compound. 5-Phenyl-2,4,5-trithiapentane-2,2-dioxide undergoes chlorinolysis in an aqueous medium to yield products consistent with the view that α-sulfonyl oxodichlorosulfonium chlorides and α-sulfonyl dichlorosulfonium chlorides may undergo unusually facile Pummerer rearrangements.

TERENCE PATRICK AHERN, RICHARD FRANCIS LANGLER et ROBERT LEONARD MCNEIL. Can. J. Chem. **58**, 1996 (1980).

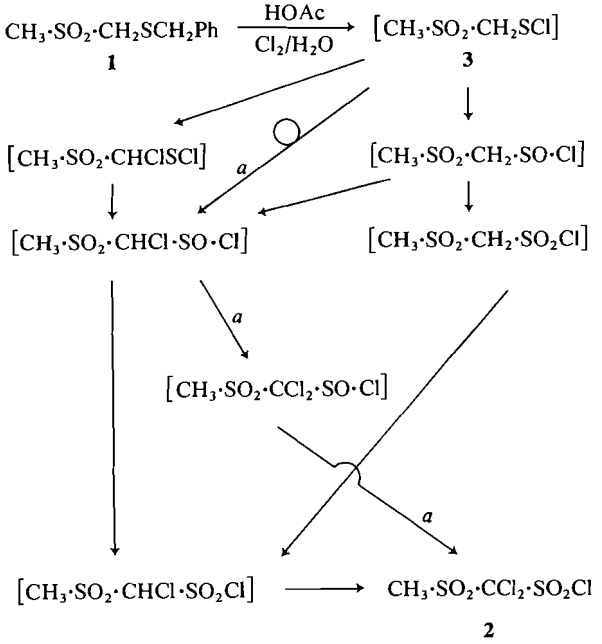
L'application des anions thiolates à la déchloration d'un substrat α-polychlorosulfonyle s'avère l'étape clé d'une synthèse satisfaisante du composé mentionné dans le titre. Le phényl-5 trithia-2,4,5 pentane dioxyde-2,2 subit une chlorolyse en milieu aqueux et conduit à des composés qui sont en accord avec le fait que les chlorures d'α-sulfonyloxodichlorosulfonium et les chlorures d'α-sulfonyldichlorosulfonium peuvent subir aisément des transpositions de Pummerer.

[Traduit par le journal]

Introduction

For some time now, we have been studying the pathways followed by sulfur compounds upon chlorinolysis in aqueous and nonaqueous media (1–6). In an earlier report (7), we have described the aqueous chlorinolysis of **1** which furnishes **2** as shown in eq. [1].

[1] $\underset{\mathbf{1}}{CH_3SO_2CH_2SCH_2Ph} \xrightarrow[HOAc]{Cl_2/H_2O} \underset{\mathbf{2}}{CH_3SO_2CCl_2SO_2Cl} + PhCH_2Cl + PhCH_2OAc$



Our conclusions about the pathway for the conversion **1** → **2** are presented as pathway *a* in Scheme 1.

We have undertaken the synthesis of $CH_3SO_2CH_2SSPh$ (**4**) with the expectation that aqueous chlorinolysis of **4** would accomplish the conversion **4** → **3** → **2** if pathway *a* is correct.

Results and Discussion

The synthesis of **4** is depicted in Scheme 2. An attempt to dechlorinate **6** with the reagent system of choice, based on a previous report (6), was complicated by an unwanted substitution reaction as shown in eq. [2].

[2] $\underset{\mathbf{6}}{CH_3SO_2CCl_2S{-}OCH_3} \xrightarrow[CH_3OH/CH_3ONa]{PhCH_2SH} \underset{\mathbf{7}}{CH_3SO_2\overset{\overset{SCH_2Ph}{|}}{CH}{-}S{-}OCH_3}$

SCHEME 1

The mass spectrum of **4** showed an interesting new rearrangement.[2] A fragmentation scheme consistent with the observed data is presented in Scheme 3.

Chlorinolysis of **4** in aqueous acetic acid gave **2** and benzenesulfonyl chloride in good yields as shown in eq. [3].

[3] $\underset{\mathbf{4}}{CH_3SO_2CH_2SSPh} \xrightarrow[HOAc]{Cl_2/H_2O} \underset{\mathbf{2}}{CH_3SO_2CCl_2SO_2Cl} + PhSO_2Cl$

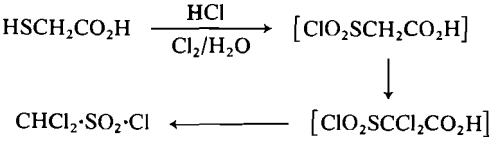
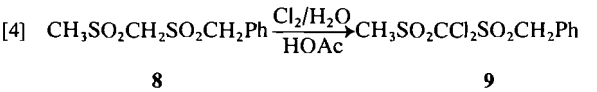


SCHEME 2

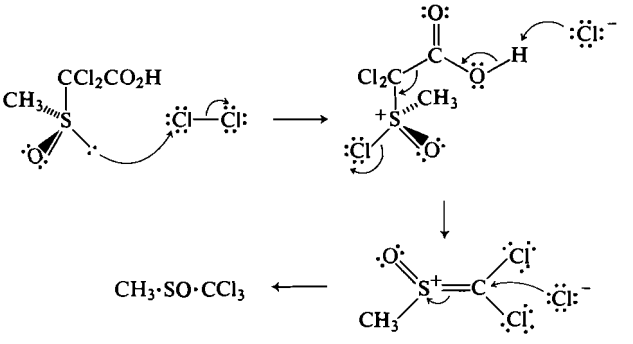
This result makes it unnecessary to invoke chlorosulfide or sulfoxide intermediates in the chlorinolysis of **1**, although it does not rigorously exclude them.

SCHEME 3



We have recently become aware of a study of the chlorinolysis of thioglycolic acid (9, 10). The proposed pathway, which avoids Pummerer rearrangements altogether, is shown in Scheme 4.

SCHEME 4



Since we have demonstrated (1) that a related substrate incorporates chlorine on carbon by Pummerer rearrangements and that decarboxylation occurs from an oxochlorosulfonium chloride salt (*vide* Scheme 5) we presumed that the rationale shown in Scheme 4 was in error. In any case, in our system, a disulfonyl methylene would not be expected to chlorinate by an acid catalyzed mechanism and would be unlikely to react (via the anion) with chlorine at a meaningful rate in aqueous acetic acid containing HCl.

To confirm our assumptions we have subjected the model disulfone **8** to aqueous chlorinolysis.

The surprising result shown in eq. [4] invalidates our assumptions and requires consideration of both $CH_3SO_2CH_2SO_2Cl$ and $CH_3SO_2CHClSO_2Cl$ as intermediates in the chlorinolysis of **1**. A preliminary kinetic study[3] of the reaction in eq. [4] indicates that it is base catalyzed but remains rapid enough under the reaction conditions to occur at a significant rate.

While the results from the chlorinolysis of **4** lend further support to Scheme 1 (pathway *a*), the results from the chlorinolysis of **8** introduce three pathways (Scheme 1) which proceed through the

SCHEME 5

sulfone sulfenyl chloride **3** and are consequently equally as reasonable as those portrayed in Scheme 1 (pathway *a*).

It is now clear that conclusive evidence concerning the facility of Pummerer rearrangements in α-sulfonyl sulfenyl and α-sulfonyl sulfinyl chlorides will only come from chlorinolyses of the appropriate substrates in an *anhydrous medium*.

In conclusion, the present results combined with our previous report (7), while not conclusive, offer tantalizing support for the possibility that α-sulfonyl sulfinyl chlorides may undergo very facile Pummerer rearrangements when treated with chorine. Since it is unlikely that such behaviour would be uniquely induced by a neighbouring sulfonyl group, there is now a reasonable probability that the chlorination of thioglycolic acid (9, 10) proceeds through an α-carboxy sulfinyl chloride which would undergo unusually facile Pummerer rearrangement.

Pending further investigation, it must remain unclear which is the preferred pathway for the

chlorinolyses of **1** and thioglycolic acid, viz. (*i*) conversion to the unchlorinated sulfonyl chloride with chlorine incorporation on carbon as the final process or (*ii*) conversion to the chlorinated sulfinyl chloride with oxidation of the sulfinyl chloride to the sulfonyl chloride as the terminal step.

Experimental

General

The ir spectra were recorded on a Perkin-Elmer 237B grating spectrophotometer. The nmr spectra were obtained on a Varian T60 instrument using TMS as the internal standard. The mass spectra were recorded on a Dupont CEC model 21-104 mass spectrometer. Samples were directly introduced using an all glass probe and the spectra run at 30 eV with a source temperature of 150°C. Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected.

Preparation of 5

Chlorine (ca. 200 mL/min) was bubbled into a solution of the sulfone-sulfide **1** (5.25 g) (7) in methylene chloride (25 mL) until the temperature of the reaction mixture fell 1–2°C below ambient temperature (ca. 1 h). The solution was concentrated and the residue rectified at reduced pressure affording the sulfone-sulfenyl chloride **5** (5.22 g) which was identical with previously described material (7).

Preparation of 6

The sulfenyl chloride **5** (3.910 g) was dissolved in methanol (100 mL) and the solution refluxed for 0.5 h. The methanol was evaporated and the residue chromatographed on silica gel (300 g) employing 1% v/v methanol in chloroform (100 mL aliquots) elution. Fractions 7–10 were combined and concentrated affording the sulfenate ester **6** (1.722 g). Upon recrystallization **6** had mp 43–44°C; ir ($CHCl_3$): 1340 and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 4.06 (3H, s) and 3.30 (3H, s); ms *m/e*: 149 (18.5%), 147 (69.0%), 145 (100%), 81 (20.6%), and 79 (61.8%). *Anal.* calcd. for $C_3H_6Cl_2O_3S_2$: C 16.00, H 2.68; found: C 15.91, H 2.73.

Reaction of 6 with $PhCH_2SH$

Crude sulfenate ester **6** was prepared as described above from the sulfenyl chloride **5** (1.279 g). Unchromatographed **6** was added to a solution of sodium methoxide (from 0.265 g sodium) and phenylmethanethiol (2.8 mL) in methanol (50 mL). The reaction mixture was stirred overnight. Methylene chloride (200 mL) was added and the resultant solution washed with water (100 mL). The organic phase was dried, concentrated, and the residue chromatographed on silica gel (300 g) employing 1% v/v methanol in chloroform (100 mL aliquots) for elution. Fractions 15–17 were combined affording clean sulfone-sulfide-sulfenate ester **7** (0.227 g, mp 72–74°C); ir ($CHCl_3$): 1310 and 1130 cm^{-1}; nmr ($CDCl_3$) δ: 7.23 (5H, s), 4.00 (3H, s), 3.97 (1H, s), 3.76 (2H, s), and 3.00 (3H, s); ms *m/e*: 278 (15.1%) and 91 (100%). *Anal.* calcd. for $C_{10}H_{14}O_3S_3$: C 43.14, H 5.06; found: C 42.98, H 5.28.

Preparation of 4

Benzenethiol (5.898 g) and chromatographed sulfenate ester **6** (3.0136 g) were added to dry pyridine (100 mL) and the reaction mixture stirred at ambient temperature for 0.5 h. Methylene chloride (200 mL) was added and the resultant solution washed with 5% HCl (100 mL aliquots) until the aqueous pH remained acidic. The organic layer was dried and concentrated and the residue chromatographed on silica gel (600 g) employing chloroform (100 mL fractions) for elution. Fractions 53–64 were combined and retained affording clean **4** (1.410 g). Upon recrystallization the sulfone disulfide had mp 64–66°C; ir: 1320 and 1130 cm^{-1}; nmr[4] ($CDCl_3$) δ: 7.23 (5H, m), 4.06 (2H, s), and 2.93 (3H, s); ms *m/e*: 234 (M^+, 8.5%), 155 (63.8%), 109 (76.5%), and 91 (100%). *Anal.* calcd. for $C_8H_{10}O_2S_3$: C 41.00, H 4.30; found: C 41.36, H 4.35.

Chlorinolysis of 4

The sulfone disulfide **4** (4.025 g) was added to a solution of glacial acetic acid (25 mL) and water (5 mL); Cl_2 (ca. 200 mL/min) was bubbled into the reaction mixture for 1 h 15 min. The solvent was distilled off at reduced pressure. The residue was rectified at 0.6 Torr affording benzenesulfonyl chloride (1.702 g) which was identical with authentic material by ir, nmr, ms, and bp. The distillation residue was the dichlorosulfone sulfonyl chloride **2** (2.858 g) which was identical to previously obtained samples (7) by ir, bp, and nmr. A sample (1.464 g) of **2** was hydrolyzed by our reported procedure (7) furnishing dichloromethyl methyl sulfone (0.583 g after recrystallization).

Chlorinolysis of 8

The disulfone **8** (0.500 g) was added to a solution of glacial acetic acid (25 mL) and water (5 mL); Cl_2 (ca. 200 mL/min) was bubbled into the reaction mixture for 45 min. Water (50 mL) was added and the resultant mixture washed with methylene chloride (100 mL). The organic layer was washed with 2.5% NaOH (two 50-mL aliquots). The organic layer was dried and concentrated affording the dichlorodisulfone (**9**) (0.639 g). Upon recrystallization the product was shown to be identical with previously obtained material (11) by nmr, ir, mp, and ms.

RAMUNAS J. MOTEKAITIS, ARTHUR E. MARTELL, DAVID HAYES, and WAYNE W. FRENIER. Can. J. Chem. **58**, 1999 (1980).

At temperatures above 100°C iron(III) oxidizes coordinated EDTA to ethylenediaminetriacetic acid in aqueous solution in the absence of molecular oxygen. The reaction proceeds with an activation energy of 28.6 kcal/mol, and its rate is directly proportional to the concentration of Fe(III) and inversely proportional to pH. At 125°C, the halflife of Fe(III) in the presence of excess EDTA is about 3 h at pH 9.3, but increases to >70 h at pH 5.4. The reaction is stoichiometric and no other reaction products or by-products were detected by nmr, gc, and gc – mass spectroscopy. In the presence of oxygen iron catalyzes quantitative oxidation of ethylenediamine-*N,N,N',N'*-tetraacetic acid (EDTA) to ethylenediaminetriacetic acid. The copper(II)–EDTA chelate undergoes a similar reaction but higher temperatures (≲170°C) are required. Iron(III) also oxidizes nitrilotriacetic acid (NTA) to iminodiacetic acid (IDA) and glycine. The hydrolyzed species Fe(OH)EDTA is shown to be the reactive intermediate, and the well-known $(Fe–EDTA)_2O^{4-}$ μ-oxo dimer is shown not to exist at elevated temperatures (above 100°C). Probable mechanisms are proposed for these reactions and comparisons are made with earlier work.

RAMUNAS J. MOTEKAITIS, ARTHUR E. MARTELL, DAVID HAYES et WAYNE W. FRENIER. Can. J. Chem. **58**, 1999 (1980).

A des températures supérieures à 100°C, en solution aqueuse et en l'absence d'oxygène moléculaire, le fer(III) oxyde le EDTA coordonné en acide éthylènediaminetriacétique. L'énergie d'activation de la réaction est de 28.6 kcal/mol et sa vitesse est directement proportionnelle à la concentration de Fe(III) et inversement proportionnelle au pH. A 125°C, la période de demi-vie du Fe(III) en présence d'un excès de EDTA est d'environ de 3 h à un pH de 9.3 mais elle augmente au delà de 70 h à un pH de 5.4. La réaction est stoechiométrique et la rmn, la chromatographie en phase gazeuse et la spectroscopie de masse couplée à la chromatographie en phase gazeuse n'ont pas permis de déceler d'autres réactions ou d'autres produits secondaires. En présence d'oxygène, le fer catalyse l'oxydation quantitative de l'acide éthylènediamine-*N,N,N',N'*-tétracétique (EDTA) en acide éthylènediaminetriacétique. Le chélate cuivre(II)–EDTA subit une réaction analogue mais à des températures plus élevées (≲170°C). Le fer(III) oxyde également l'acide nitriloacétique (NTA) en acide iminodiacétique (IDA) et en glycine. On montre que les espèces hydrolysées du type Fe(OH)EDTA sont les réactifs intermédiaires et que le dimère bien connu $(Fe–EDTA)_2O^{4-}$ et μ oxo n'existe pas à des températures élevées (au-dessus de 100°C). On propose les mécanismes probables de ces réactions et on établit des comparaisons avec un travail antérieur.

[Traduit par le journal]

Introduction

The coordination chemistry of ethylenediamine-*N,N,N',N'*-tetraacetic acid (EDTA) in aqueous solution at normal temperatures (0–100°C) and pressures is well understood in terms of its coordination reactions with metal ions, and the reactions involved are described by appropriate equilibrium constants (1). The ability of EDTA to form stable, soluble metal chelates in solution has resulted in a wide variety of chemical, analytical, and industrial applications for EDTA including water softening, scale removal, and preservative action through the suppression of catalytic effects of metal ion impurities (2). For applications involving high temperatures, there are many reactions that limit the lifetime of EDTA in solution that are not encountered in moderate temperature ranges. In addition to changes in the magnitudes of the thermodynamic parameters, the values of which vary greatly with temperature, there are also extensive changes in

For personal use only.

the hydrolytic stability of the free ligand (3). Indeed, it has been shown that at 175°C and pH 9.4 the EDTA molecule splits via hydrolysis into equimolar amounts of iminodiacetic acid (IDA) and 2-hydroxyethyliminodiacetic acid (HEIDA), at a rate having a half-life of about 4 h (4).

Another important high-temperature degradative pathway becomes available at high temperature when EDTA is bound to a metal ion which has a stable lower valence state (e.g., Fe(III), Cu(II), Co(III), etc.). In these systems the EDTA becomes oxidized by an internal electron transfer process involving the coordinated metal ion. This paper describes a study of the rates and probable mechanism of the oxidation of EDTA by coordinated Fe(III), and of catalytic processes based on this reaction involving molecular oxygen.

Experimental

Reagents

EDTA, iron(III) salts, and other compounds were reagent grade quality materials and were used as received without further purification.

Kinetics

The kinetic experiments were carried out with a Parr glass-lined 2 L stirred autoclave. Appropriate quantities of an inorganic iron(III) salt and EDTA were mixed, diluted with water, and the pH was adjusted to the desired value (usually 9.3) with ammonia or sodium hydroxide. The reaction mixture was heated quickly to the desired temperature under an inert atmosphere and aliquots were removed at predetermined time intervals for spectrophotometric measurement of Fe(III)EDTA concentration. The analysis was made at room temperature by observing the intensity of the 475 nm band which is a quantitative measure of the concentration of $[(Fe(III)EDTA)_2O]$ (5, 6). The equilibrium constant for the dimerization of Fe(III)EDTAOH^{2-} was redetermined for the conditions employed in this investigation ($10^{1.88}$ at 25°C) while the pK_a used for the equilibrium

$$Fe(III)EDTA \rightleftharpoons Fe(III)EDTAOH^{2-} + H^+ \text{ is } 7.58.$$

The analytical samples taken from the autoclave were also analyzed for residual EDTA by nmr spectrometry in D_2O/NaOD solvent systems after removal of the Fe(III) ion.

Product Analysis

The determination of reaction products was made initially through nmr chemical shift assignments, which were subsequently confirmed by glc and mass spectrometry measurements on methyl ester derivatives of the reaction products. These analytical results were compared with parallel measurements of standard compounds considered to be probable candidates for the reaction products and intermediates.

Instrumentation

Visible spectra were recorded with a Cary model 14 spectrophotometer equipped with a thermostatted cell compartment. The temperature of the 1.000 cm matched cells was controlled at 25.0°C with a Haake refrigerated constant temperature bath. The nmr spectra were measured at 36°C with a Varian T-60 spectrometer equipped with a variable temperature probe. Precision nmr tubes were employed, and samples were prepared in NaOD/D_2O solutions with internal trimethylsilylpropanesulfonic acid (TMS*) as reference. The reaction vessel was a 2-L, glass-lined all titanium stirred pressure vessel equipped with a sampling stopcock, stainless steel valve, titanium tube gas inlet and outlet, thermometer well, and a pressure gauge. Gas chromatograms were obtained with a Hewlett-Packard Model 5830A gas chromatograph equipped with both TC and FI detectors. The gc mass spectrograms were measured on esterified samples with a Hewlett-Packard Model HP-5982-59-33 at the Texas A&M Center for trace characterization. Column conditions were 150–250°C at 16°/min, 3% OV-1, 1/8 in. × 10 ft, 20 mL/min flow rate.

Synthesis of Ethylenediaminetriacetic Acid (ED3A) from EDDA

Ethylenediamine-*N,N'*-diacetic acid (EDDA) lactam (0.050 mol) was treated with 8.34 g (0.06 mol) $BrCH_2COOH$ and NaOH while maintaining the pH of the solution between 7–9 at 35°C. After 24 h, the solution was passed through a DOWEX 50WX-8 column in acid form, and the amino acid fraction was concentrated to 25 mL. Crystals of ED3A lactam formed when the solution was allowed to stand for 12 h.

Molecular weight calculated for $C_8H_{12}N_2O_5 \cdot H_2O$ 252; found by titration 254: nmr 3.93 (1), 3.47 (3), 3.30 (1), 3.13 (1), 2.87 (3) in the ratio 1:1:1:1:1.

Conversion of EDTA to ED3A

Refluxing Procedure

A solution containing 19 g (0.065 mol) of ethylenediaminetetraacetic acid disodium salt dihydrate and 24 g (0.056 mol) $Fe(SO_4)_2 \cdot NH_4 \cdot 12H_2O$ was prepared in about 75 mL H_2O by careful addition of a solution containing 7.0 g NaOH in about 10 mL H_2O adjusted to 100 mL and was refluxed under a blanket of oxygen for 168 h. The red Fe_2O_3 precipitate was filtered off and a part of the filtrate was reserved for analysis. Standard Fisher esterification with MeOH was employed to volatilize the amino carboxylic acids for the determination of conversion to reaction product by gas chromatography. The ratio of ED3A/EDTA found was 2.5:1 representing better than 50% conversion with substantial IDA and HEIDA as primary contaminants. Purification was effected by passing 10 mL of the reaction mixture through a DOWEX 50 W X-8 column in the H^+ form using 25 mL wet resin/10 mL of solution, and eluting with water. EDTA passed through unhindered in the first 250 mL of eluate, while the second 250 mL contained almost pure ED3A lactam. The only contaminant appeared to be a trace of IDA.

In the above procedure, ammonia was also used to make the initial solution basic with almost identical results but slightly lower yield.

Autoclave Procedure

A solution containing 58.4 g (0.20 mol) EDTA, 96.0 g (0.20 mol) $FeNH_4(SO_4)_2$, and made basic with 75 mL concentrated NH_3 was heated at 142–145°C for 6 h in a 2-L autoclave initially pressurized to 100 lb/in.^{2}. The resulting Fe_2O_3 was filtered off and all volatiles were removed with a rotary evaporator. Some water was replaced, the solution was acidified, and an equivalent of $FeCl_3$ solution was added. Dilution with isopropyl alcohol (2:1 v/v C_3H_7OH:H_2O) gave 20 g ferric ED3A (34%) as a tan powder. The iron was removed by raising the pH to 10, followed by centrifugation and ion exchange chromatography as described above.

Results and Discussion

Stoichiometry

It was found that when a solution containing 1.00 mol Fe(III) and 1.50 mol EDTA adjusted to pH 9.3 is heated to 175°C, a reaction occurs within minutes to produce a yellow green solution of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

1.00 mol Fe(II)EDTA containing 0.50 mol of an oxidized reaction product. Also, it has been shown in separate experiments that the Fe(II)EDTA complex is stable under these reaction conditions toward any further decomposition for at least 24 h. When a solution containing a 1:1 ratio of Fe(III) to EDTA is heated at pH 9.3 and at 175°C, the same reaction takes place, except that one third of the iron(III) precipitates as ferric oxide, Fe_2O_3. Several experiments were run with ratios of [EDTA]/[Fe(III)] greater than 1.5, with no change in the results; i.e., excess EDTA was inert under the reaction conditions employed, as would be expected from previous work on this ligand (3, 4). Figure 1 illustrates the nmr evidence for these reactions. The nmr spectra (after removal of iron) show that the initial sample taken at just above 100°C is essentially pure EDTA. At $t = 0$, the evidence presented indicates that the reaction is already more than half complete, while the spectra at $t = 0.33$ h and at 3.0 h show that no further changes occur on this time scale. Also, integration over the ethylene proton peaks indicates the ultimate formation of a product in the ratio of 1 mol decomposed product to 2 mol of unchanged EDTA.

The above observations are consistent with the proposed stoichiometry shown in eqs. [1] and [2] for the reactions involving 1.5:1 and 1:1 ligand-to-metal molar ratios, respectively.

[1] $2\text{Fe(III)EDTA} + \text{EDTA} \xrightarrow[\text{pH 9.3}]{175^\circ\text{C}} 2\text{Fe(II)EDTA} + \text{EDTA}_{\text{decomp}}$

[2] $3\text{Fe(III)EDTA} \rightarrow 2\text{Fe(II)EDTA} + (1/2)\text{Fe}_2\text{O}_3 + \text{EDTA}_{\text{decomp}}$

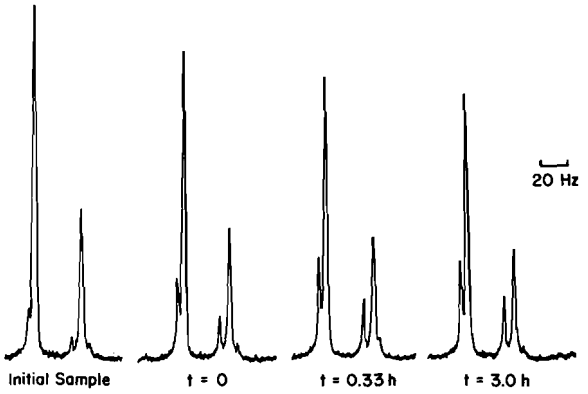

FIG. 1. Proton nmr spectra (after removal of metal ion) of samples of a 1:1 molar ratio of EDTA to Fe(III) after heating to various times at 175°C. The pH was adjusted at room temperature to 9.3 with ammonia. The initial sample is the spectrum taken when the temperature was near 100°C. At $t = 0$ the autoclave contents are at 175°C. After $t = 0.33$ h, the system ceases to react. The heating rate was such that it took 15 min for the temperature to rise from 145 to 175°C.

It is therefore concluded that two electrons are transferred to two Fe(III) ions from one ligand molecule.

Mechanistic Considerations

In order to work out the mechanism of this redox reaction, reaction rates were measured under several sets of conditions. It was found that the rate of reaction is proportional to the concentration of total Fe(III) present. A typical example of the kinetic method employed is illustrated in Fig. 2, in which the ordinate represents the natural logarithm of the total Fe(III) concentration. The Fe(III) concentration was measured spectrophotometrically from the intensity of the 475 nm band ($\varepsilon = 180\ M^{-1}\ cm^{-1}$) which actually is a measure of the room temperature concentration of the μ-oxo dimer, $Fe_2L_2O^{4-}$ in equilibrium with Fe(III)L(OH). The total Fe(III) concentration was computed using the previously measured (*vide supra*) equilibrium constants and standard mass balance equations. Similar kinetic plots were obtained for several pH values at temperatures ranging from 102–143°C. The first order rate constants for the disappearance of Fe(III) thus obtained are presented in Table 1.

It was concluded on the basis of the temperature dependence of the dimerization equilibrium of the hydrolyzed chelate that the reactive species in the

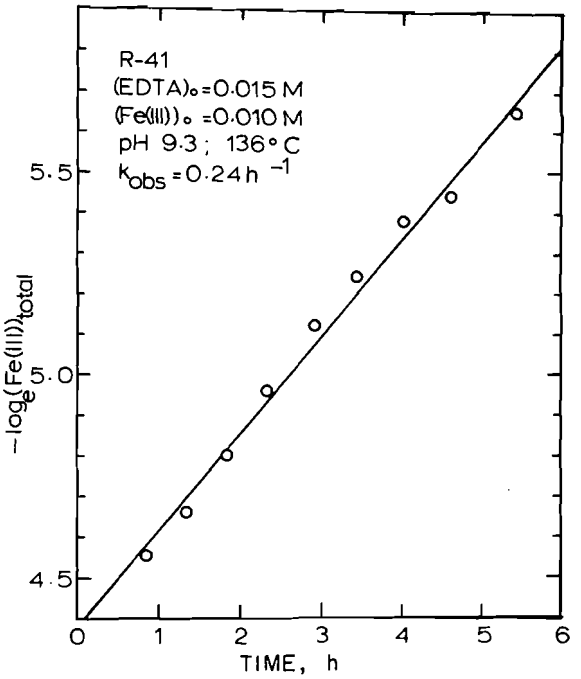

FIG. 2. A plot of the natural logarithm of total remaining Fe(III) concentration vs. time for the system: $[\text{EDTA}]_{\text{initial}} = 1.5 \times 10^{-3}\ M$, $[\text{Fe(III)}]_{\text{initial}} = 1.0 \times 10^{-2}\ M$, pH = 9.3, $t = 136$°C. Slope = $k_{\text{obs}} = 0.24\ \text{h}^{-1}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

redox reaction is $Fe(OH)EDTA^{2-}$. Figure 3 contains a plot of log K_D vs. $1/T$ where T is the temperature in degrees Kelvin and K_D is defined by eq. [3].

$$[3] \quad 2\,FeL(OH)^{2-} \rightleftharpoons (FeL)_2O^{4-}$$
$$K_D = [(FeL)_2O^{4-}]/[FeL(OH)^{2-}]^2$$

Each equilibrium point was measured spectrophotometrically in 10° intervals from 25 to 95°C. The ΔH of dimerization was determined from the slope and was found to be -11.6 kcal/mol. The actual concentrations of $Fe(OH)EDTA^{2-}$ and EDTA—Fe—O—Fe—$EDTA^{4-}$ are plotted in Fig. 4 for a 0.0100 M solution of FeEDTA. These plots clearly show that as the temperature is raised at pH 9.30, the predominant species becomes Fe(OH)EDTA.

Additional evidence for implicating mononuclear Fe(OH)EDTA as the reactive intermediate comes from a pH dependence study on the rate of reaction. Table 1 shows that as the pH is lowered, the rate of the oxidation reaction decreases. At 136°C, pH 9.3, the rate constant is 0.24 h^{-1}, at 7.4 it is 0.13 h^{-1}, while at pH 5.4 the reaction practically ceases. Since the pK_a for the hydrolysis of the Fe(III)EDTA chelate is 7.58 (5, 6) (reaction [4]), the observed trend in reaction rates with pH at con-

$$[4] \quad FeL^{-1} \rightleftharpoons FeLOH^{2-} + H^+$$

stant temperature is explained in terms of the concentration of the reactive monohydroxo form of the metal chelate, $FeLOH^{2-}$. The energy of activation for the oxidation at pH 9.30 was found to be 28.6 kcal/mol.

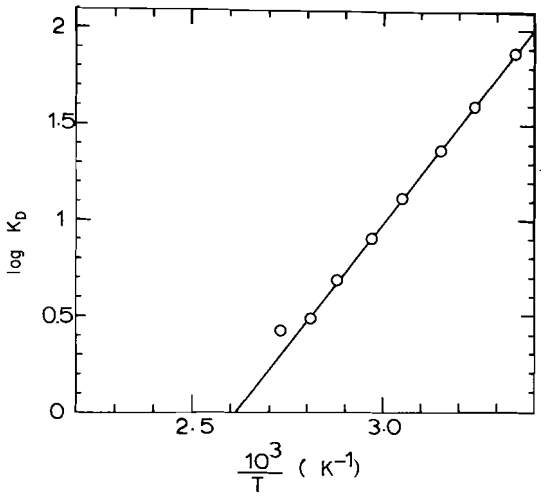

FIG. 3. Plot of log K_D vs. reciprocal of the absolute temperature; $K_D = [Fe_2EDTA_2O^{4-}]/[Fe(OH)EDTA^{2-}]^2$. From the slope, $\Delta H = -11.6$ kcal/mol.

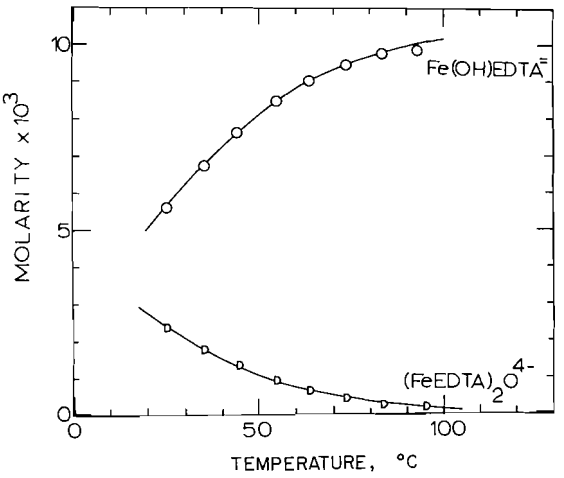

FIG. 4. For initial concentrations of $[Fe(III)]_0 = 0.010\,M$ and $[EDTA]_0 = 0.015\,M$, pH = 9.3, the calculated concentrations of monomer, $Fe(OH)EDTA^{2-}$, and dimer, $Fe_2EDTA_2O^{4-}$, are plotted as a function of temperature. By extrapolation to $t >$ 100°C, the predominant species is $Fe(OH)L^{2-}$, with less than 1% of the iron(III) in the form of the μ-oxo dimer.

TABLE 1. First order rate constants for the oxidation of EDTA by Fe(III)[a]

t (°C)	pH	k (h^{-1})
143	9.30	0.38
136	9.30	0.24
135	9.30	0.22
102	9.30	0.0092
137	7.4	0.13
135	5.4	<0.01

[a] The molar composition of all runs was 0.010 M Fe^{3+}, 0.015 M EDTA; pH was adjusted with NH_3 to 9.30; NaOH was used to adjust lower pH runs.

Identification of Products

Although nmr was very useful in following the reaction rates through the disappearance of EDTA an unambiguous determination of reaction products formed could not be made on the basis of proton nmr measurements alone. Table 2 lists the chemical shifts of several reference compounds which were required for identification of the products formed in this study. Although the chemical shifts are indeed similar, there are differences in the relative integrated intensities of the peaks. Although the spectra were all run in basic $NaOD/D_2O$ solution, in practice the chemical shifts relative to TMS* do vary somewhat as a function of pH, concentration, and the presence of even traces of paramagnetic ions, thus making absolute assignments tenuous. For example, the spectra in Fig. 1 beyond $t = 0$ are consistent with but not necessarily limited to the interpretation that the only reaction product is ethylenediaminetriacetic acid, ED3A.

TABLE 2. Proton magnetic resonance spectra (60 MHz) of reference compounds measured in 0.15 *M* D_2O solutions containing 5% NaOD; chemical shifts are reported in Hz relative to trimethylpropanesulfonate (TMS*)

Compound	Chemical shifts (relative intensities)	
	Acetate	Ethylene
Ethylenediaminetetraacetic acid	190 (4)	160 (2)
Ethylenediamine-*N,N,N'*-triacetic acid[a]	194 (1), 191 (2)	160 (2)
Ethylenediamine-*N,N'*-diacetic acid	190 (1)	160 (1)
Glycine	186	

[a] To obtain nmr spectrum of ED3A the pure lactam was heated on a steam bath with 7 *M* NaOH for 1 h. Solvent was stripped off, D_2O added, and the spectrum was run.

TABLE 3. Gas chromatographic – mass spectral parameters of methylated reference compounds used for identification of reaction products of Fe(III)-catalyzed oxidation of EDTA

Retention time (min)	Standard	Mass, form	Last four peaks				Strongest peak
1.7	IDA	161, diester	130.0	146.1	161.1	162.0	102.0
3.5	HEIDA	173, monoester lactone	171.0	173.1	174.1	175.1	114.0
4.1	S-EDDA	172, monoester lactam	173.1	174.0	186.1	187.0	85.1
5.2	U-EDDA	172, monoester lactam	157.1	163.0	172.1	173.0	113.1
6.7	ED3A	244, diester lactam	213.1	215.1	244.1	245.1	185.1
8.1	EDTA	348, tetraester	317.1	348.2	349.2	350.2	174.1

Because of these uncertainties, a more direct measurement involving gc and gc – mass spectrometry determinations was selected. A number of standards were run individually and the retention times in the order of increasing elution time are shown in Table 3. Although mass spectra generally have many peaks, it is sufficient for most analytical purposes to consider the four peaks having the highest molecular weights, plus the major, or the highest intensity peak.

The gas chromatogram of a typical sample taken from the initial reaction mixture having a 3:1 molar ratio of EDTA to Fe(III), heated at 130°C, consisted of two major peaks, which were found at 6.7 min, with the first peak smaller than the second. The mass spectrograms were identical with those previously obtained for ED3A and EDTA respectively. This result clearly supports the conclusion that in the absence of oxygen, at pH 9.30 the reaction involves the conversion of EDTA to ED3A until all Fe(III) present has been reduced.

In another experiment a sample at pH 9.3 containing a 10:1 molar ratio of EDTA to Fe(III) under a blanket of 92 psig oxygen was heated for 3 h at 135°C. When this reaction mixture was analyzed by gc – mass spectrometry, the gas chromatogram again possessed only two peaks, at 6.7 min and at 8.1 min. In this case, the ED3A peak was about twice as large as the remaining EDTA. Thus it appears that in this system EDTA becomes catalytically oxidized to ED3A according to the following scheme:

[5] $2Fe(III)EDTA + EDTA \rightarrow 2Fe(II)EDTA + ED3A$

[6] $Fe(II)EDTA \xrightarrow{O_2} Fe(III)EDTA$

This catalytic cycle would continue until either the oxygen or the reducing agent (EDTA) becomes exhausted.

The explanation now offered for the nearly stoichiometric conversion of EDTA to ED3A involves the possible combination of three favorable reaction rates: at 135°C the oxidation of Fe(II)EDTA to Fe(III)EDTA by molecular oxygen is almost instantaneous. This means that Fe(III)EDTA is regenerated as rapidly as EDTA is oxidized by Fe(III)EDTA. Secondly, at 135°C, the hydrolysis reaction of EDTA to form IDA and HEIDA is negligible (4). This means that the thermal degradation products would not form from the excess EDTA employed in the reaction. Finally, at 135°C, the reaction of interest proceeds at a convenient rate, with a half-life of about 3 h.

The stoichiometric nature of the oxidation of EDTA requires further discussion in view of the low yields reported above in the adaptation of the reaction for the synthesis of ED3A from EDTA. The magnitudes of the yields reported were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

primarily a reflection of the percent conversion of EDTA, rather than the result of the formation of by-products which were apparently produced in very small amounts. The reported yields would have been greatly increased by separation and recycling of the unreacted EDTA remaining in the reaction mixtures.

Other Systems

In order to confirm the generality of the metal aminocarboxylate redox reaction several other systems were studied. It was found that a 1:1 Cu:EDTA solution, buffered with ammonia to pH 9.30 and heated at 175°C, also undergoes a first order redox reaction in which EDTA is converted to ED3A as the major product. In 24 h under these conditions about 40% ED3A was formed with the remainder of the EDTA found unreacted. Other minor components identified were IDA and HEIDA. Copper(II) was converted to Cu(0). In the absence of oxygen the copper(II)EDTA reaction is interpreted as proceeding in the manner shown in reaction [7].

[7] $\mathrm{CuEDTA} \rightarrow \mathrm{Cu(0)} + \mathrm{ED3A}$

The rate constant for this reaction was determined to be $0.024\ \mathrm{h}^{-1}$. Thus the copper(II) reaction is much slower at comparable temperatures than is the corresponding Fe(III)EDTA redox reaction.

In order to determine the susceptibility of a similar chelating agent to oxidative attack by Fe(III), NTA was investigated under similar conditions with a large excess of ligand-to-metal ion, and in the presence of oxygen. After 24 h at 135°C, the major product identified by gas chromatography was IDA along with lesser amounts of glycine and unreacted NTA. Similarly, when a 2:1 molar ratio of NTA to Fe(III) was heated at 175°C, the following reaction appeared to take place nearly quantitatively:

[8] $2\mathrm{Fe(III)(NTA)_2} \rightarrow 2\mathrm{Fe(II)NTA} + \mathrm{IDA} + \mathrm{NTA}$

Related Studies

A number of studies have been made which indicate that EDTA is oxidized by metal ions at or near room temperature. Lambert and Jones (7) found that at 50°C in aqueous solution hexacyanoferrate(III) oxidizes EDTA according to the following ultimate stoichiometry:

[9] $\mathrm{EDTA^{4-}} + 4\mathrm{Fe(CN)_6^{3-}} + 4\mathrm{OH^-} \rightarrow$ Oxidized organic products $+ 4\mathrm{Fe(CN)_6^{4-}}$

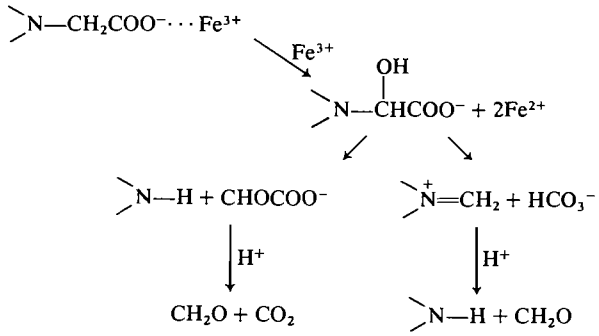
The organic products suggested are IDA and glycolic acid, but were not rigorously shown to be present. The nature of the reaction products was inferred by analogy with the oxidation of EDTA by its own *N,N'*-dioxide.

Hanna and co-workers (8–10) studied the oxidation of EDTA by Ce(IV) in sulfuric acid (8) and perchloric acid (9, 10) media. They found that 4 mol of Ce(IV) per mol of EDTA are required for the initial reaction, but that ultimately 14 mol of Ce(IV) are reduced. The mechanism suggested is represented by reaction [10].

[10] $2\mathrm{Ce(IV)} + \rangle\mathrm{N{-}CH_2CO_2H} \rightarrow \rangle\mathrm{N^+{=}CH_2} + \mathrm{CO_2} + 2\mathrm{Ce(III)} + \mathrm{CO_2} + \mathrm{H^+}$

Thus each acetate function of EDTA is indicated as undergoing a two electron oxidative decarboxylation. The products suggested are the result of a series of such steps in which acetate functions are removed, producing a mixture of the tri-, di-, and monoacetates of ethylenediamine as well as ethylenediamine itself.

Rao (11), on the other hand, observed only a single stoichiometric redox reaction involving a 9:1 molar ratio of Ce(IV) to EDTA. Conflicting results involving earlier work by others were also pointed out by Rao (11).



In an environmentally important study, Lockhart and Blakeley (12) investigated photolytic degradation of the Fe(III)EDTA chelate in the presence of oxygen over a period of several days. The products identified include ED3A, iminodiacetic acid (IDA), ethylenediaminediacetic acid (EDDA) (both isomers), ethylenediaminemonoacetic acid (EDMA), and glycine. The reaction was run at pH values of 4.5, 6.9, and 8.5. The following stoichiometry was suggested as the first step in this complex reaction:

[11] $2\mathrm{FeEDTA^-} + 2\mathrm{H_2O} + \mathrm{O_2} \xrightarrow{h\nu} 2\mathrm{CO_2} + 2\mathrm{CH_2O} + 2\mathrm{OH^-} + 2\mathrm{FeED3A}$

In contrast to the rather non-specific nature of the photochemical and redox reactions described above, the thermal Fe(III)EDTA oxidation as described in this work is a highly specific reaction. In the absence of oxygen at pH 9.3 and at temperatures above 100°C Fe(III) continues to oxidize EDTA as long as any is left in the reaction mixture. Two mol of Fe(III) are needed for each mol of triacetate formed. The ferrous ion produced is present in the reaction mixture as the Fe(II)–EDTA chelate, and in separate experiments it has been found to be stable indefinitely at the temperatures employed in this study.

On the basis of the evidence obtained in this research, and the redox reactions of similar systems described above, the mechanism now suggested for Fe(III)-catalyzed oxidation of EDTA is the following:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The alternate routes indicated for the fission of the acetate group from EDTA cannot be distinguished from each other on the basis of evidence now available. Further investigation of these systems to obtain details of the rate-determining electron-transfer step, and to determine the conditions favoring formaldehyde or glyoxylic acid as the final reaction product seems warranted.

The role of the molecular environment for the primary photoprocesses of phenol in solution

J. ZECHNER, G. KÖHLER, G. GRABNER, AND N. GETOFF[1]

Institut für Theoretische Chemie und Strahlenchemie der Universität Wien und Ludwig Boltzmann Institut für Strahlenchemie, Währingerstraße 38, A-1090 Vienna, Austria

Received April 9, 1980

J. ZECHNER, G. KÖHLER, G. GRABNER, and N. GETOFF. Can. J. Chem. **58**, 2006 (1980).

Quantum yields of fluorescence as well as of solvated electron and H atom formation have been measured for phenol in several pure solvents and mixtures of varying polarity. The influence of excitation energy has been studied by excitation of phenol in the first and second excited singlet states. The solvent dependences of fluorescence and photoejection parameters are strongly correlated. The results are interpreted in terms of specific solute–solvent interactions, in particular H-bonded structures.

J. ZECHNER, G. KÖHLER, G. GRABNER et N. GETOFF. Can. J. Chem. **58**, 2006 (1980).

On a mesuré les rendements quantiques de fluorescence ainsi que les rendements d'électrons solvatés et de formation d'atomes d'hydrogène pour le phénol dans plusieurs solvants purs et dans des mélanges de différentes polarités. On a étudié l'influence de l'énergie d'excitation en excitant le phénol dans ses premier et deuxième états singulets excités. L'influence du solvant sur la fluorescence et les paramètres de photoéjection sont fortement reliés. On interprète les résultats en fonction d'interactions spécifiques solvant–soluté en particulier en terme de structures comportant des liaisons hydrogène.

[Traduit par le journal]

Introduction

Solvent effects on photophysical properties of molecules are well known from studies of spectral energy shifts between gas phase and solution. Many of the effects observed could be explained by a general theory of electrostatic interactions (1). However, the influence of solute–solvent interactions on excited state decay processes and primary photochemical reactions is less well understood.

As various studies carried out during the last years have demonstrated, simple aromatic molecules such as phenols, anilines, indoles, and aromatic amino acids share the interesting photophysical property of having a fluorescence quantum yield (Q_F) which is not independent of the energy of excitation (2–5). It has been early recognized that this effect is strongly influenced by the solvent environment: the dependence of Q_F on excitation energy is pronounced in hydrocarbon solvents, small in polar organic solvents, but notable again in water (2, 6). A correlation between the effect on Q_F and the hydrogen bonding capability of the solvent was suggested in the case of phenol (7). Furthermore, a connection with excitation energy-dependent H atom abstraction in hydrocarbon solvents and formation of hydrated electrons in aqueous solutions was established (7–11).

A few studies carried out on indolic compounds have sought to clarify the role of the solvent by studying the dependence of the excitation energy effect on general liquid state parameters, such as the static dielectric constant (12) or Kosower's micropolarity parameter Z (6, 13). These investigations showed that there is no simple relationship between solvent and fluorescence behaviour in the case of the systems studied; the decrease of Q_F at higher excitation energies is related to the static dielectric constant in a non-linear way (12). The behaviour of Q_F in different classes of solvents (hydrocarbons, polar organic solvents, water) is reflected in a different dependence on Z within each of these classes (13).

The aim of the present study was to obtain more information about solvent effects on primary photoprocesses from S_1 and S_2 states of phenol. To this effect, the influence of excitation energy on the fluorescence quantum yield as well as on electron photoejection and H atom formation by OH bond rupture has been investigated in pure polar and apolar solvents and in solvent mixtures. Particular attention has been paid to the possible role of specific solute–solvent interactions on these processes.

Experimental Section

All chemicals used were reagent grade (E. Merck, Darmstadt). Phenol was further purified by sublimation under low pressure, diethyl ether by column distillation, methanol and propanol-2 by distillation under addition of 2,4-dinitrophenyl hydrazine and sulfuric acid, cyclohexane by column chromatography with alumina Woelm B, activity I. Four times distilled water was used for the preparation of aqueous solutions. The purity of all solvents was checked by fluorescence measurements. 2-Chloro-ethanol was kept overnight over K_2CO_3 and then distilled under reduced pressure. Oxygen-free solutions were obtained by saturation with argon. For steady-state irradiations, phenol concentration was 0.01 M. Temperature was kept constant at 30°C.

Ultraviolet absorption spectra were obtained on a Perkin-Elmer spectrophotometer (Coleman 575). Details of fluorescence measurements (2, 7) as well as of steady-state irradiations at 254 and 229 nm (11), actinometry at these wavelengths (11, 14, 15), and the design of irradiation vessels (16) have been described in detail. Absolute fluorescence quantum yields are based on $Q_F = 0.95$ for 9,10-diphenylanthracene in cyclohexane (17). Changes in refractive indices were taken into account for measurements of absolute yields in other solvents (refs. 2, 18*a*, data about refractive indices were taken from ref. 18*b*).

H atoms originating from excitation of phenol react with the organic solvents used in this work by H atom abstraction. The resulting H_2 was collected in a vacuum line in connection with a gas chromatograph and determined quantitatively (11). Corrections were made for the concurrent reaction of H atoms with phenol using the following rate constants

$$k(\mathrm{H} + \text{phenol}) = 1.8 \times 10^9\ M^{-1}\ s^{-1}\ (19)$$

$$k(\mathrm{H} + \text{methanol}) = 2.5 \times 10^6\ M^{-1}\ s^{-1}\ (20)$$

$$k(\mathrm{H} + \text{propanol-2}) = 6.7 \times 10^7\ M^{-1}\ s^{-1}\ (20)$$

$$k(\mathrm{H} + \text{cyclohexane}) = 4 \times 10^7\ M^{-1}\ s^{-1}\ (21)$$

2-Chloroethanol was used as a specific scavenger for solvated electrons in a concentration of 0.06 *M*; the Cl^- resulting from this reaction was determined by potentiometric titration with $AgNO_3$. The Cl^- yield can be taken as a quantitative measure of the amount of electron photoejection (22).

Results

The characteristic feature of the excitation energy dependence of the fluorescence of phenolic (2, 7) and indolic (3, 5, 6) compounds is a drop of Q_F in the region of overlap between the S_1 and S_2 absorption bands. Q_F is constant within each absorption band. The effect is formally described by the parameter β defined by

$$[1]\quad \beta = Q_F(\lambda_{exc})/Q_F(S_1)$$

β can be equated to the internal conversion efficiency from S_2 to S_1. Figure 1 shows the characteristic behaviour of β for phenol dissolved in cyclohexane – diethyl ether mixtures of varying composition. The lowest value of β is obtained in pure cyclohexane, whereas it is near to 1 in pure diethyl ether.

The two wavelengths at which the steady-state irradiations have been carried out, 254 and 229 nm, fall into the S_1 and S_2 states of phenol. For the processes of photoejection of electrons and H atoms, we define the parameter α in an analogous way to the definition of β:

$$\alpha_{e,H} = Q_{e,H}^{229} - \beta^{229} \times Q_{e,H}^{254}$$

Inasmuch as there is good evidence that α is also constant for excitation within S_1 or S_2 (8, 11), α and β can be related to each other (23). Table 1 shows the quantum yields of fluorescence, electron and H atom formation, as well as the values of β, α_e, and α_H for phenol in various solvents.

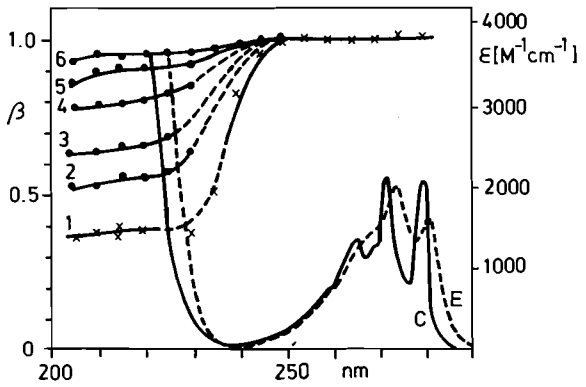

FIG. 1. Dependence of β on excitation wavelength for phenol in cyclohexane – diethyl ether mixtures. (*1*) Pure cyclohexane; (*2*) 0.027 *M*, (*3*) 0.058 *M*, (*4*) 0.15 *M*, (*5*) 0.55 *M* diethyl ether in cyclohexane; (*6*) pure diethyl ether. Curves *C* and *E*: absorption spectra of phenol in cyclohexane and diethyl ether.

β is the lowest in cyclohexane, not much below unity in alcohols, and intermediate in water. Q_e is considerably higher in water than in alcohols, and below the detection limit in cyclohexane. Very few H atoms are ejected in water and alcohols, whereas this is the main photolytical process in cyclohexane. All photolytical processes are more efficient at higher excitation energy ($\alpha > 0$). All these results can be attributed to phenol monomers; indeed, dimer formation in hydrocarbon solution, where it must be expected to be the strongest, is less than 5% for a phenol concentration of 0.01 *M*, as used in the steady-state irradiations (7).

The behaviour of the quantum yields and of the parameters α and β is shown in Figs. 2 and 3 for phenol dissolved in mixtures of H_2O and methanol, and in Fig. 4 for mixtures of cyclohexane and methanol.

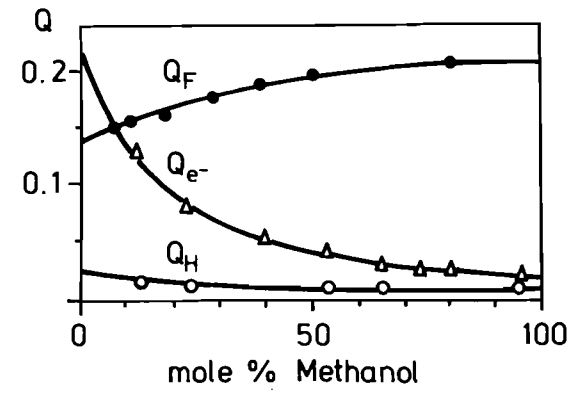

FIG. 2. Quantum yields of fluorescence (Q_F), solvated electrons (Q_e), and H atoms (Q_H) as a function of methanol content in water for solutions of phenol (excitation in S_1 at 30°C).

In figure 2 the scale is to be divided by a factor of 10 for Qe and for Q_H. ERRATA

FOR ERRATA SEE v59 #2 19...81...P...1744

In figure 3 the scale is to be divided by a factor of 10 for α_e and by a factor of 3 for $\alpha_{(e+H)}$.

TABLE 1. Quantum yields of fluorescence (Q_F), solvated electrons (Q_e), and H atoms (Q_H), and values of β, α_e, and α_H for phenol in various solvents at 30°C (see text for definition of α and β)

ERRATA

Solvent	$Q_F(S_1)$	β^{229}	Q_e^{254}	Q_e^{229}	α_e	Q_H^{254}	Q_H^{229}	α_H
Water	0.14	0.71	0.021	0.033	0.018	0.002	0.064	0.06
Cyclohexane	0.08	0.37	$< 10^{-3}$	$< 10^{-3}$	—	0.11	0.55	0.51
Methanol	0.21	0.93	1.8×10^{-3}	$(1.80 \pm 0.1) \times 10^{-3}$	—	0.001	0.003	0.002
Propanol-2	0.22	0.93	4.5×10^{-4}	1×10^{-3}	$< 10^{-3}$			
tert-Butanol	0.22	0.93	5.7×10^{-4}	1×10^{-3}	$< 10^{-3}$			

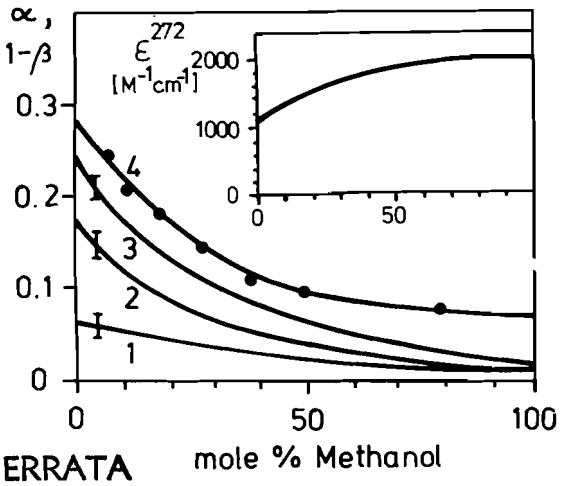

FIG. 3. α_H (*1*), α_e (*2*), $\alpha_{(e+H)}$ (*3*), and $1 - \beta$ (*4*) as a function of methanol content in water for solutions of phenol (see text for definition of α and β). Insert: extinction coefficient of phenol as a function of methanol content in water at 272 nm.

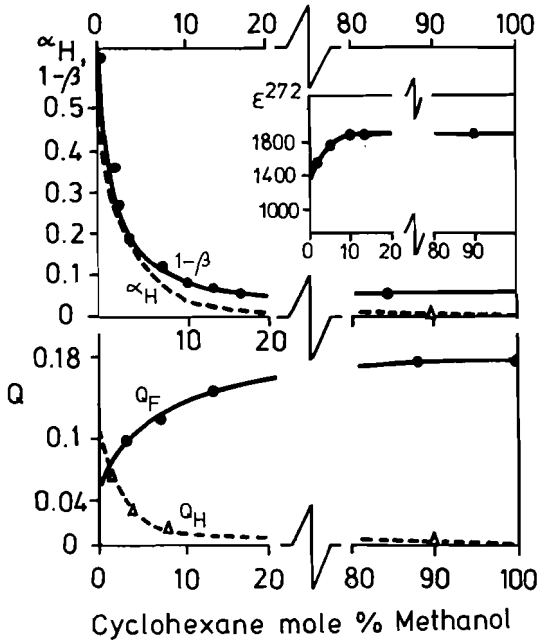

FIG. 4. Quantum yields of fluorescence (Q_F) and H atoms (Q_H) and values of α_H and $1 - \beta$ as a function of methanol content in cyclohexane for solutions of phenol (see text for definition of α and β). Insert: extinction coefficient (ε^{272}, M^{-1} cm^{-1}) of phenol as a function of methanol content in cyclohexane at 272 nm.

The effect of solvent composition on the extinction coefficient at a fixed wavelength within S_1 is also exhibited. The results show a remarkable parallelism in the sense that all parameter variations occur in the same ranges of solvent composition. In addition, the changes in the yields of fluorescence and photolytical processes show opposite trends.

Discussion

The results of the present work confirm our previous conclusion (7, 8, 11, 23) that excitation of phenol both in its S_1 and S_2 state can lead to formation of solvated electrons and/or H atoms. The quantum yields for excitation in S_2 are higher, which results in efficient competition to the very fast process of internal conversion to S_1. This state of affairs holds in all solvents as well as in all mixtures investigated in this work. It must be noted that the relation between the α's and β is not quantitative: as shown explicitly in Figs. 3 and 4, α is always smaller than $1 - \beta$. This is most probably due to geminate recombination processes which do not populate the fluorescent state.

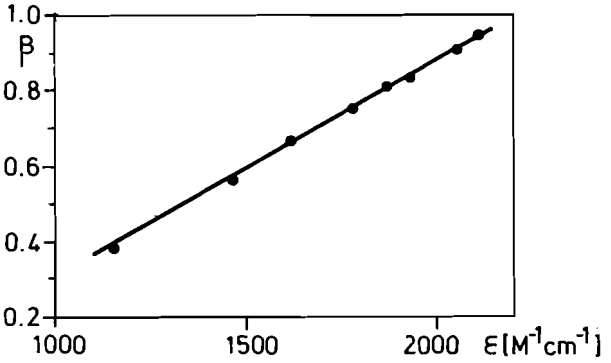

FIG. 5. Correlation plot of β (excitation at 215 nm) vs. the extinction coefficient (ε^{267}, M^{-1} cm^{-1}) at 267 nm for phenol in cyclohexane – diethyl ether mixtures.

In order to answer the question of the possible mechanisms of solvent action, we may note that solvent effects on photoprocesses, in a way analogous to spectral energy shift phenomena (1), fall into two broad categories: (*a*) solvent effects caused by physical perturbation of the relevant molecular states of the chromophore; (*b*) specific chemical solvent effects like hydrogen bond formation, proton or charge transfer, solvent-dependent aggregation and others.

Electrostatic effects on excited energy levels are theoretically well understood (24) and corroborated by emission and absorption spectroscopy with the notable exception of hydrogen bond-forming solvents (25). Accordingly, these models do not apply to shift phenomena in aqueous solutions of phenolic compounds (1, 25). This observation is in broad agreement with the inadequacy of general liquid state parameters, such as the static dielectric constant or Kosower's parameter Z, to account for the observed solvent effect on photophysical and photochemical processes of these compounds, especially in aqueous solutions and in aqueous/organic mixtures. Indeed, a correlation of the data of the present work with these parameters leads to results which are very similar to those reported in the literature for indolic compounds (6, 12, 13), and which yield little information about the mechanisms responsible for the observed effects.

It seems therefore more promising to look to specific solute–solvent interactions to explain the behaviour of phenol. Hydrocarbons, alcohols, and water may be considered as three classes of solvents which specifically alter the solute's photophysical and photochemical behaviour. Indeed, while several hydrogen-bonded structures of different stoichiometry can be envisaged for phenol in hydroxylic solvents (26), there is a characteristic difference between the probability of occurrence of the two simplest structures in alcohols and in water (26, 27):

Type I Type II

R = H or alkyl group

Type I structures, where phenol acts as the proton donor, are predominant in ethers and alcohols. They result in a red shift of absorption and emission spectra as compared to hydrocarbon solutions. The solvation structure of these systems can be expected to exhibit a single well-defined pattern, as the occurrence of several isosbestic points in the absorption spectra of phenol in cyclohexane–dioxane mixtures demonstrates (25, 28). In contrast, phenol acts as proton acceptor in *Type II structures*; this type of hydrogen bond may be responsible for the blue shift of the absorption spectra of phenol and anisole in water.

This classification of solvents according to different hydrogen-bonded structures can easily be correlated with an analogous classification according to our experimental results: (*a*) In hydrocarbon solutions (no H-bonded structures in dilute solutions), the rupture of the OH bond is the main photochemical event. The quantum yield of this process is higher at higher excitation energy, which is reflected in a corresponding decrease of Q_F (see Table 1). (*b*) In alcohols, H atom formation is almost completely suppressed. e^-_{sol} are formed with a comparably very low yield. Concurrently, β is near unity (Table 1). It appears that Type I structures have a strong stabilizing effect in the sense that OH bond rupture is efficiently reduced (29). As Figs. 2, 3, and 4 show, addition of moderate concentrations of methanol to either cyclohexane or water are sufficient to achieve this effect. (*c*) In aqueous solutions, Q_H is very small, but the formation of e^-_{sol} is of importance; both processes, along with fluorescence, are dependent on excitation energy (Table 1). The different behaviour of aqueous and alcoholic solutions is at least partly attributable to variations in electron solvation ability; however, the predominance of Type II structures in water may also play a role, as witnessed by the observation that anisole, which can only participate in Type II structures, shows almost constant Q_F with respect to excitation energy both in hydrocarbons and in alcohols, but not in water (7).

This classification according to H-bonded structures does not distinguish between possible differences between the ground state and the excited states of the solute with respect to solute–solvent interactions. Such differences should eventually show up in a comparison of the influence of solvent composition on absorption parameters (transition energies, extinction coefficients) on the one hand, and emission parameters and photochemical yields on the other. In Fig. 5, we show a correlation plot between the values of β and of the extinction coefficient at 267 nm (S_1 band) for phenol in cyclohexane – diethyl ether mixtures. This plot yields a correlation coefficient of 0.997

and thus suggests a similar dependence of both β and ε on the solvent structure.

In conclusion there is no evidence for the contribution of others than the ground state solvent configuration for photoprocesses occurring from S_2 states in the particular case of phenol.

Cyclopentadienyl platinum(IV) complexes: ^1H, ^{13}C nuclear magnetic resonance and optically active shift reagent study

GORDON HAMER[1] AND ALAN SHAVER[2]

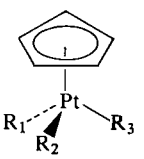
Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, P.Q., Canada H3A 2K6

Received February 4, 1980

GORDON HAMER and ALAN SHAVER. Can. J. Chem. **58**, 2011 (1980).

The ^1H and ^{13}C nmr parameters for the recently reported complexes $(\eta^5\text{-}C_5H_5)PtR_1R_2R_3$ where R_1, R_2, and R_3 are combinations of CH_3, C_2H_5, and $C(O)CH_3$ groups are reported and compared to those for known octahedral di- and trimethylplatinium (IV) complexes. The C_5H_5 group has a relatively weak nmr *trans*-influence. A chiral shift reagent study on complex **5** ($R_1 = C(O)CH_3$, $R_2 = CH_3$, and $R_3 = C_2H_5$) resolved the peaks due to the enantiomers, consistent with its structure and establishing its stereochemical stability. The four groups attached to the platinum atom in **5** differed greatly in their sensitivity to the shift reagent. The methyl groups in complex **4** ($R_1 = C(O)CH_3$, and $R_2 = R_3 = CH_3$) become diastereotopic in the presence of chiral shift reagent. The J(Pt—H) values for **5** were not affected by the shift reagent.

GORDON HAMER et ALAN SHAVER. Can. J. Chem. **58**, 2011 (1980).



On rapporte les paramètres de la rmn du ^1H et du ^{13}C pour les complexes $(\eta^5\text{-}C_5H_5)PtR_1R_2R_3$ où R_1R_2 et R_3 sont des combinaisons des groupes CH_3, C_2H_5 et $C(O)CH_3$, décrits récemment et on les compare à ceux de complexes octaédriques connus de di- et triméthylplatine(IV). Le groupement C_5H_5 a une influence *trans* relativement faible en rmn. L'utilisation d'un réactif de contact chiral sur le complexe **5** ($R_1 = C(O)CH_3$, $R_2 = CH_3$ et $R_3 = C_2H_5$) a permis de résoudre les bandes provenant des énantiomères et qui sont en accord avec leur structure tout en révélant leur stabilité stéréochimique. Les quatres groupes attachés à l'atome de platine dans le composé **5** diffèrent notamment par leur sensibilité au réactif de contact. Les groupes méthyles du complexe **4** ($R_1 = C(O)CH_3$ et $R_2 = R_3 = CH_3$) deviennent diastéréotopiques en présence du réactif de contact. Les valeurs de J(Pt—H) du composé **5** ne sont pas affectées par le réactif de contact.

[Traduit par le journal]

Introduction

There is a great deal of activity in the emerging field of chiral organometallics (1, 2) and catalysts. Most systems studied to date contain relatively easily dissociated ligands such as carbonyls, phosphines, or olefins. Previously, we reported (3) the synthesis of complexes of platinum(IV) containing the cyclopentadienyl ligand and three alkyl groups: $(\eta^5\text{-}C_5H_5)PtR_1R_2R_3$.

Complex **1** had been reported earlier (4) but complexes with other than three methyl substituents were unknown. The pseudotetrahedral or piano stool arrangement of the ligands (5) confers optical isomerism upon complex **5**. In addition, complexes **1–6** are interesting metal alkyls that bear no easily dissociated ligands. Their reactivity to electrophilic metal–carbon bond cleavage reagents is quite different from other organometallics (3). This new class of compounds has been fully characterized by ^1H and ^{13}C nmr spectroscopy. Also the dependence of the ^1H nmr spectrum of **4** and **5** upon the addition of optically active europium shift reagent was studied.

1 $R_1 = R_2 = R_3 = CH_3$
2 $R_1 = R_2 = CH_3$, $R_3 = C_2H_5$
3 $R_1 = CH_3$, $R_2 = R_3 = C_2H_5$
4 $R_1 = C(O)CH_3$, $R_2 = R_3 = CH_3$
5 $R_1 = C(O)CH_3$, $R_2 = CH_3$, $R_3 = C_2H_5$
6 $R_1 = C(O)CH_3$, $R_2 = R_3 = C_2H_5$

Experimental

The complexes were prepared as previously described (3). The ^{13}C and ^1H nmr spectra were measured in $CDCl_3$ solution at 36 ± 2°C on a Bruker WH-90 spectrometer operating in the pulsed Fourier transform mode at 22.6 MHz and 90.0 MHz, respectively. The ^{13}C spectra were determined with noise-modulated proton decoupling. Chemical shifts are reported relative to TMS as internal reference. Proton spectral analyses of compounds **2**, **5**, and **6** were carried out with the Bruker NMRSIMIT program on an Aspect 2000 computer. The shift reagent, tris[3-trifluoromethylhydroxymethylene-*d*-camphorato]europium(III) (trade name Eu-Opt) was purchased from Alfa Inorganics and used without further purification. A weighed portion of the reagent was placed in a disposable pipette which was long enough to be inserted to the bottom of the nmr tube. A small filter-plug of Kimwipe® was wedged in the neck of the pipette and one or two pieces of molecular sieve placed above the plug. By sucking the sample past the plug the reagent was dissolved. The solution was forced back into the nmr tube, the plug serving to filter any undissolved particles or impurities. Additional portions of reagent were added in the same way.

Results and Discussion

The ^1H and ^{13}C nmr parameters are given in

Tables 1 and 2. The values appear within the normal range for such compounds (6). It is interesting to compare **1–6** to complexes **7** (7) and **8** (8, 9). The coupling of the methyl and acyl groups to platinum-195 is greater in **1–6** than in **7** or **8** (with the exception of ^3J(Pt—C(O)CH_3)). Since the C_5H_5 ring is a uninegative, six electron "tridentate" ligand it is formally equivalent to the two $(CH_3)_3As$ groups and a halide ligand. Trends in platinum–ligand coupling constants in complexes such as **7** and **8** are usually discussed in terms of *trans*- and *cis*-influences (9, 10) which are related to the hybridization of the central platinum atom and steric effects respectively. In the case of **1–6** the situation is complicated by the fact that the C_5H_5 ring is both "*cis*" and "*trans*" to the remaining groups. Since the *trans*-influence is considered dominant, it is reasonable to conclude that the hybridization of the central platinum atom in **1–6** concentrates more *s*-character in the platinum–alkyl bonds than exists in **7** and **8**. This is consistent with the postulate that there is low *s*-character in the M or C orbitals used in the M—C bond (11) to the *pentahapto*cyclopentadienyl ligand.

The similarity of the chemical shifts for the acyl carbon atoms in **4**, **5**, **6**, and **7** to those in unsaturated aldehydes and ketones is noted (12). The infrared stretching frequencies for the carbonyl groups in **4**, **5**, and **6** are in the range

TABLE 3. Ranges of the ^1H and ^{13}C nmr parameters for the cyclopentadienyl ring in complexes of platinum in oxidation states II and IV

Type of complex	Range of δ (range of coupling constant)[a]	
	C_5H_5[J(Pt—H)][b]	C_5H_5[J(Pt—C)][b]
η^1-CpPt(II)	6.46–5.89(28.0–43.5)[10]	115.2–116.5(87.8–96.8)[2]
η^5-CpPt(II)	6.26–5.07(10.5–19.0)[19]	93.2–94.1(3.8–8.4)[2]
η^5-CpPt(IV)	5.633–5.857(5.50–5.86)[6]	95.85–98.87(8.8–15.6)[6]

[a]Data collected from refs. 21, 22, and this work.
[b]The superscript beside each coupling constant is the number of complexes included in the range.

1699–1662 cm^{-1} (3) expected for unsaturated ketones (13). However, the ^{13}C chemical shift for the acyl carbon atom in $(\eta^5\text{-}C_5H_5)Fe(CO)_2[C(O)CH_3]$ is 254.4 ppm (14) and the stretching frequency is 1655 cm^{-1} (15), significantly different from **4**, **5**, and **6**. Many metal-acyls have reduced stretching frequencies due to metal → acyl d_π–p_π backbonding (16). The spectroscopic data for **4**, **5**, **6**, and **7** is consistent with there being little backbonding, as expected for a metal in a high oxidation state.

It is often difficult to distinguish between *monohapto* and *pentahapto* bonding modes for the C_5H_5 ligand. For molecules that do not contain complicated ligands infrared spectroscopy can sometimes be useful (17). In the nmr spectrum, however, both bonding modes result in only a single band. Chemical shift arguments have been used for the assignment (18) but this is not reliable in our opinion. The shifts of C_5H_5 rings in either bonding mode are dependent on solvent, temperature, and the presence of other ligands (19, 20). However, the coupling between platinum-195 and the ring provides a facile diagnostic test for both the bonding mode of the ring and the oxidation state of the metal atom. In Table 3 ranges of nmr parameters are given for three different combinations of bonding mode and oxidation state. The platinum(II) data are taken from earlier work (21, 22) while those for platinum(IV) are from this work. The coupling constants form mutually exclusive sets thus the bonding mode of the ring and the oxidation state of the metal can be determined simply and unambiguously from the ^1H nmr spectrum.

The ^1H nmr spectra of the ethyl groups in **2**, **3**, **5**, and **6** were very complex. Second order effects due to the similarity of the shifts of the methylene and the methyl groups plus the presence of platinum coupling generated a multitude of peaks. The $PtCH_2CH_3$ spectrum of $CpPtMe_2Et$, **2**, was analyzed iteratively as an A_2B_3X spin system. The analysis requires that ^2J(Pt—H) and ^3J(Pt—H) have opposite signs (23*a*); ^2J(Pt—H) in methyl derivatives of platinum(II) and (IV) has previously been shown to be negative (23*b*). In $CpPtMeEt_2$, **3**, CpPtMeAcEt, **5**, and $CpPtAcEt_2$, **6**, the ethyl CH_2 protons are non-equivalent. The CH_2CH_3 spectra of **5** and **6** were analyzed iteratively as ABC_3 systems; due to its greater complexity, no attempt was made to analyze **3**. Values of ^3J(Pt—H) were obtained for **5** and **6** by simulation of the CH_3 group high field satellite spectra. Precise values of ^2J(Pt—H) could not be obtained due to poor resolution of the low field satellite lines and band overlap with the acyl resonance.

Trends in the shifts and coupling constants were observed for **1**–**6**. There are two sub-groups of complexes: (*a*) $CpPtMeR_2R_3$ and (*b*) $CpPtAcR_2R_3$ where R_2, R_3 = Me, Et. Within each group the proton chemical shifts and couplings are very little affected by increasing Et substitution. The polar acyl group deshields the C_5H_5, CH_3, and CH_2 protons. The ^{13}C shifts are more sensitive to acyl substitution which produces downfield shifts for all carbons (again with the exception of the methyl carbon of Et). The magnitude of J(Pt—C) increases with increasing substitution for all J's except for $^2J(PtC(O)CH_3)$ which decreases. It is difficult to establish more quantitative trends since the Et substituent is a rather weak perturbation of the Pt—C bonding.

Addition of Eu-Opt to a sample of **5** causes a shift of the ^1H nmr resonances to low field (24) due to complexation of the acyl-oxygen atom with the europium reagent. Figure 1 plots the change in chemical shift (Δδ) of the four ligands as a function of the shift reagent to substrate molar ratio (R). The $C(O)CH_3$ and CH_3 groups are the most sensitive, while the CH_2CH_3 and C_5H_5 groups are affected little. This is of some interest since previous studies on organometallic complexes have indicated that the C_5H_5 group was very sensitive (25–27). However, most of these complexes did not have simple alkyl groups near the complexing ligand.

Figure 2 plots the diastereotopic splitting (ΔΔδ) vs. R. The splitting is greatest for the CH_3 group, least for the C_5H_5 group, while the CH_2CH_3 and $C(O)CH_3$ ligands are intermediate. Thus while the

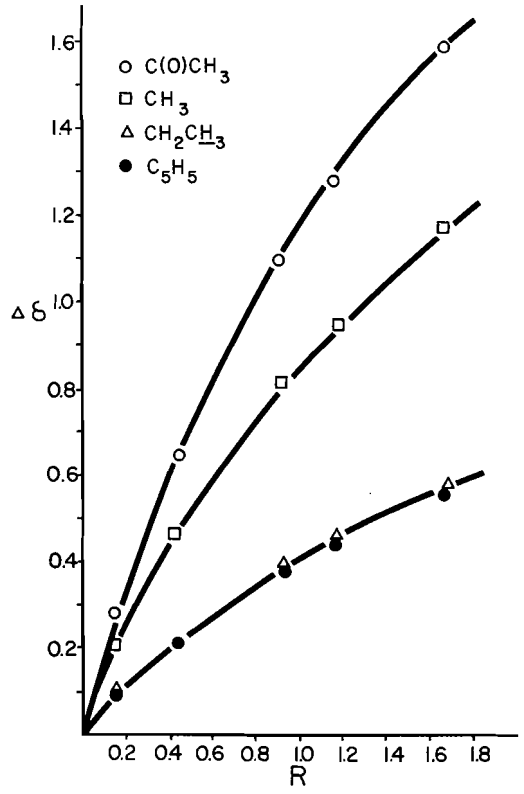

FIG. 1. Change in chemical shift (Δδ) vs. molar ratio of shift reagent/**5** (*R*).

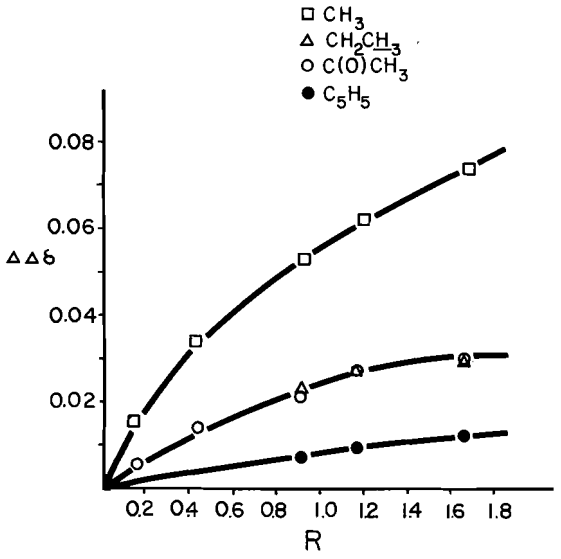

FIG. 2. The splitting of the peaks (ΔΔδ) vs. molar ratio of shift reagent/**5** (*R*).

$C(O)CH_3$ group was shifted the most its splitting was fairly weak, being comparable to CH_2CH_3 and C_5H_5 ligands. Figure 3 relates Δδ to ΔΔδ. It seems particularly significant that there is no positive correlation between a group's shift sensitivity (Δδ) and its tendency to split (ΔΔδ).

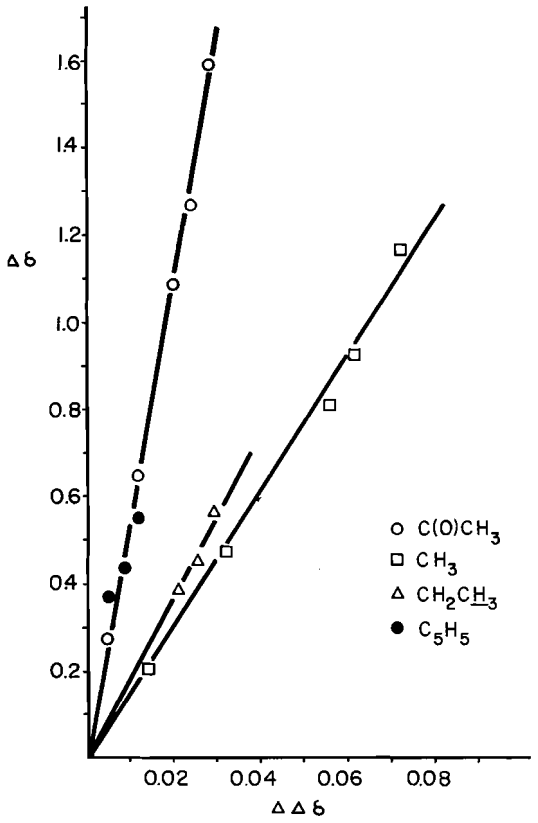

FIG. 3. Change in chemical shift (Δδ) vs. the splitting of the peaks (ΔΔδ).

The splitting of the peaks is due to the diastereotopic interaction of the two enantiomers of **5** with the chiral shift reagent (28, 29). Two reasons are generally invoked to explain this splitting: one is geometry, the other, differing equilibrium constants for the complexes formed. The geometry of the two complexes between the enantiomers of **5** and Eu-Opt are different since Eu-Opt is "resolved". A chiral pocket in Eu-Opt can be envisioned, into which one isomer fits one way, the other isomer, another. Therefore, the platinum–methyl group for example would be in two different magnetic environments and hence have different chemical shifts, giving rise to splitting. Geometry is also the reason that molecules such as DMSO and other organic (30) and inorganic molecules (31) show splitting in their spectra. Uncomplexed, these molecules have a mirror plane of symmetry; however, complexation removes this. Such an effect was observed for complex **4** which has two methyl groups related by a mirror plane that passes through the $C(O)CH_3$ group. In the

For personal use only.

presence of Eu-Opt two peaks due to the methyl groups are observed while the acyl-methyl and the cyclopentadienyl group each give only one peak. Such splitting cannot be due to a difference in equilibrium constants since only one type of complex is formed. These observations prove that geometry alone could account for the nmr resolution of chiral complexes such as **5**.

Differences in equilibrium constants have also been postulated as a reason for the splitting and resolution of the spectra of chiral molecules (28, 29). The diastereomeric complexes formed between **5** and Eu-Opt might well have different equilibrium constants and this would cause different shifts and hence splitting of peaks. We feel that the difference between the equilibrium constants is likely to be small due to the similarity of the two sides of the molecules as viewed down the Pt—$C(O)CH_3$ bond (i.e. CH_2CH_3 vs. CH_3).

The subtle nature of the phenomenon is particularly evident in the differences in the sensitivities of the different groups in **5**. Each functional group behaves differently with the most shifted group (i.e. $C(O)CH_3$) not being the most split. This sort of behaviour is also evident in the data reported by other investigators (29, 31). No facile explanation for these observations is at hand.

Previous to this study no organometallic compound having extensive metal-to-hydrogen spin–spin coupling has been subjected to a lanthanide shift reagent study. We were interested to see if the $J(^{195}Pt—H)$ values for the four groups on **5** would vary upon addition of Eu-Opt. They do not. This is consistent with studies on organic compounds where variations in coupling constants are observed only in rather specialized cases involving changes in conformation upon complexation (32).

In conclusion, the chiral shift reagent study on **5** is consistent with its expected chiral nature and indicates that it is configurationally stable on the nmr time scale. It should in principle be possible to resolve complex **5**.

An experimental evaluation of simplified procedures for determining the proton spin–lattice relaxation rates of natural products[1]

LAWRENCE D. COLEBROOK[2] AND LAURANCE D. HALL[3]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received December 27, 1979

LAWRENCE D. COLEBROOK and LAURANCE D. HALL. Can. J. Chem. **58**, 2016 (1980).

A general discussion is given of the determination of the proton spin–lattice relaxation rates of natural products, with particular emphasis on use of the null-point method which, for the systems studied here, gives identical results with those obtained via the conventional (and relatively time consuming) computational method.

LAWRENCE D. COLEBROOK et LAURANCE D. HALL. Can. J. Chem. **58**, 2016 (1980).

On présente une discussion générale sur la détermination des vitesses de relaxation spin–réseau du proton des produits naturels en mettant l'accent sur l'utilisation de la méthode du point zéro, qui, dans le cas des systèmes étudiés, donne des résultats identiques à ceux obtenus au moyen de méthodes conventionnelles de calculs qui sont relativement longues.

[Traduit par le journal]

Introduction

Although the development of pulse Fourier transform (F.t.) nuclear magnetic resonance (nmr) spectrometers has made the measurement (1) of proton spin–lattice relaxation rates (R_1 values) routine, relatively few such studies have thus far been reported for complex natural products, studies of carbohydrate (2) and nucleoside (3) derivatives providing the principal exceptions, with a lesser emphasis on other compounds (4). There are many good reasons for this neglect, not the least of which is the substantial amount of time which is required to process the experimental data using conventional methods. The main thrust of this report is to delineate some simple experimental procedures whereby proton R_1 values can be obtained rapidly and without prejudicing either the numerical accuracy, or the chemical significance, of the resultant data.

Results and Discussion

The Relaxation Mechanism

The diagnostic potential of proton R_1 values depends on the fact (5) that it is possible experimentally to ensure that the spin–lattice relaxation of the protons of a diamagnetic molecule is dominated by the intramolecular dipole–dipole (D.D.) mechanism, the complete formulation of which, for non-selective excitation, is given in eq. [1].

$$[1]\quad R_1(\mathrm{ns}) = \frac{\gamma_D^2\gamma_R^2h^2}{r^6(\mathrm{D,R})}I(I+1)\left\{\frac{\tau_c}{1+\omega_0^2\tau_c^2} + \frac{4\tau_c}{1+\omega_0^2\tau_c^2}\right\}$$

Providing that the molecule is tumbling in the extreme narrowing limit ($\omega_0^2\tau_c^2 \ll 1$), the simplified formulation, eq. [2] can be used. This makes clear

$$[2]\quad R^R(\mathrm{ns}) = K\sum\frac{\gamma_R^2\gamma_D^2}{r^6(\mathrm{D,R})}\tau_c(\mathrm{D,R})$$

the dependence of the observed relaxation rate on three experimentally manipulatable parameters; γ_D, the magnetogyric ratio of the donor nuclide, D, which contributes to the relaxation of the receptor nucleus, R; r(D,R), the internuclear distance separating each pair of donor and receptor nuclides, and τ_c(D,R), the motional correlation time of the vector between D and R.

The dependence on γ_D^2 generally results in the domination of the relaxation by the other protons in the system, these being the only nuclides with a high value of γ. Hall and Hill have previously described (6) a rigorous quality control experiment whereby the extent to which the relaxation of a proton arises via dipole–dipole interactions with the other protons of a diamagnetic system may be quantitatively ascertained; experience in this laboratory over the past seven years suggests that few protons of medium size (200–700 dalton) diamagnetic molecules will show appreciable relaxation contributions from any other mechanism. The dependence on the inverse sixth power of the inter-proton separations is illustrated graphically in Fig. 1 which indicates some of the interesting

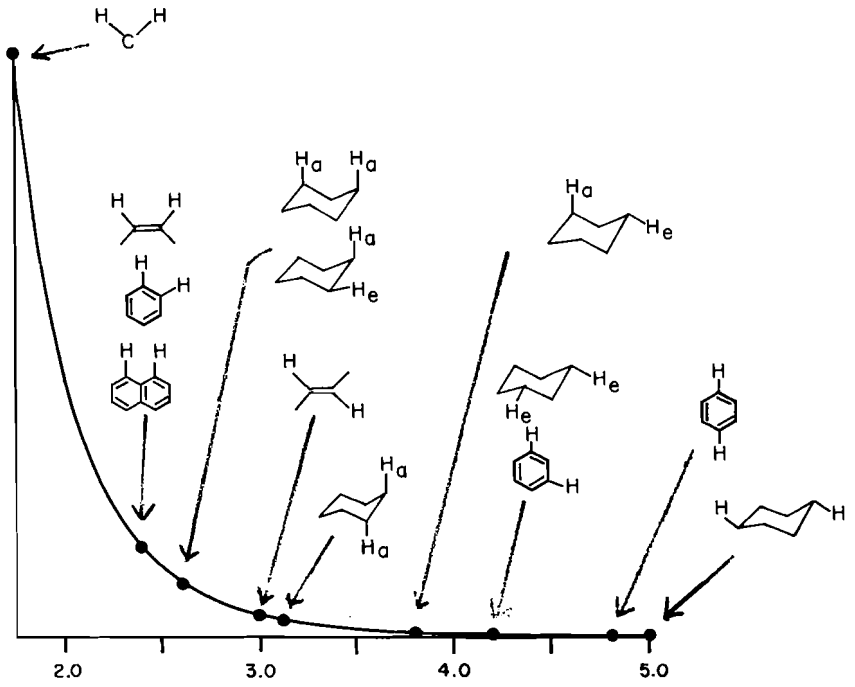

FIG. 1. Plot of the relative relaxation efficiency between two protons versus the inverse sixth power of their internuclear separation (derived from measurements of Dreiding Stereomodels).

stereochemical dependencies which can be anticipated for natural products. We shall return later to the dependence on τ_c(D,R).

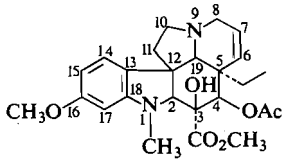
Sample Preparation

The experimental precautions required (2*a*, *b*) to ensure that the intramolecular dipole–dipole mechanism R_1^A(DD), is at least dominant (and probably exclusive), are nicely illustrated with reference to eq. [3], which summarizes the probable relaxation contributions for any proton, A. Intermolecular contributions, R_1^A(inter), between the protons of different solute molecules are minimized

$$[3] \quad R_1^A(\text{ns}) = R_1^A(\text{DD}) + R_1^A(\text{inter}) + R_1^A(\text{solvent}) + R_1^A(\text{para})$$

by working at high dilution, typically 0.1 *M* or less. Contributions from the solvent, R_1^A(solvent), will be zero if the solvent contains no strongly magnetic nuclei (for example, CS_2 or CCl_4) or can be reduced substantially if a perdeuterated solvent is used.[4] Insofar that most F.t. nmr spectrometers require a deuterium resonance for the field-frequency lock system, the latter choice of solvent is the more common, and for proton R_1 values of 0.2 s^{-1} or more this is perfectly acceptable.[5]

The principal sources[6] of paramagnetic impurities, R_1^A(para), are solid particles of decayed automobile (readily removed by filtration) and dissolved oxygen; the latter can be removed either by repeated "freeze–pump–thaw" cycles, or by sparging with a stream of nitrogen gas, followed by sealing under vacuum. However, these procedures are inconvenient and time consuming, especially if many samples are to be studied and, as it happens, are unnecessary for qualitative studies of the protons of natural products having R_1 values of 0.2 s^{-1} or more. This follows from knowledge that the relaxation contribution from dissolved oxygen is approximately 0.2 s^{-1}.



The data for vindoline (**1**) in deuterochloroform solution (Fig. 2 and Table 1) are typical, and show that dissolved oxygen has essentially no effect on the relative disposition of the proton R_1 values.

[4]From eq. [1] it can be seen that the relaxation efficiency of a donor nucleus is proportional to $\{I(I+1)\gamma^2\}$, from which it follows by simple numerical substitution that relaxation from a deuterated species will be ca. 6.3% that of the equivalent protio species.

[5]We strongly caution against using this procedure for small organic molecules having R_1 values of 0.1 s^{-1} or less.

[6]Deuterium oxide can also contain significant quantities of dissolved paramagnetic metal ions which can substantially affect protons which have very long R_1 values, especially if the solute molecule has a high affinity for metal ions.

Acquisition of Relaxation Data and Calculation of R_1 *Values*

In a conventional, non-selective[7] "two-pulse" (1) or "three-pulse" (7) sequence, the spins of interest are first "heated" by application of a 180° pulse then, after the lapse of some defined delay period (t), during which some of the excess energy leaks to the lattice, the residual magnetization is monitored using a non-selective 90°-pulse. Generally, a series of 30, or so, partially relaxed spectra[8] are obtained in this fashion, and the resultant spectra plotted in the form of a stack plot (Fig. 3). Although this is a reasonably efficient process, the subsequent calculation of the R_1 values (see Experimental section) is, unfortunately, rather time-consuming. As a result, we strongly recommend for all *qualitative* (and some quantitative) studies a simpler and more rapid procedure in which the R_1 value of each resonance is taken directly from its null point using the relationship $R_1 = 0.69/t$, where t is the delay time (in s) of the two-pulse, partially relaxed spectrum for which the magnetization of that proton has reached its null point. Given an adequate number of partially relaxed spectra and the excellent sensitivity of pulse F.t. proton spectrometers, the null point can generally be determined within 0.1 s. The R_1 values obtained for **1** in ca. 15 min from the data given in Fig. 3 are compared in Fig. 4 with the values obtained by a least-squares fit procedure which took ca. 12 hours' work; clearly the two sets of data are in excellent agreement.

The advantages of the null point approach are that it is rapid (visual inspection of the partially relaxed spectra) and that an estimate can often be obtained for overlapping resonances; this latter feature is particularly important for natural products where conventional data processing is frequently precluded. Furthermore, because the nmr spectra are plotted directly it is applicable to F.t. instruments which lack any data storage device.

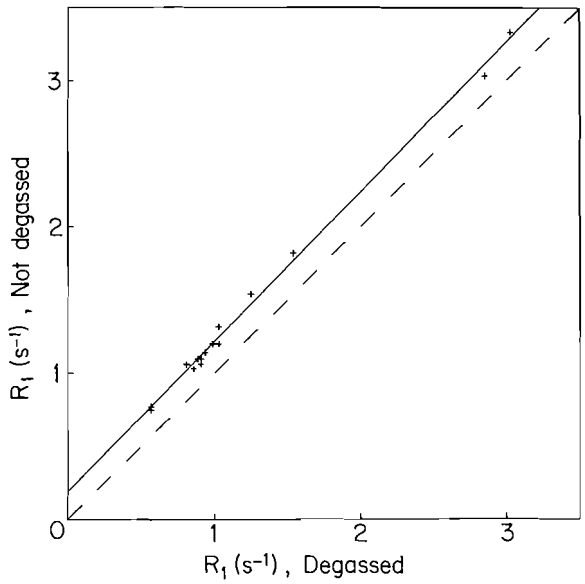

FIG. 2. Plot of the proton R_1 values for vindoline (0.1 M in $CDCl_3$ solution) determined by the null point method. Ordinate values, measured without degassing; abscissa values measured after six freeze–pump–thaw cycles followed by sealing under vacuum.

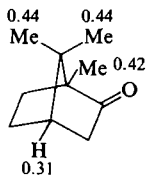
On the debit side, errors in setting the duration of the 180° pulse are more serious than in the conventional two-pulse method and for some resonances the null point method may violate the initial slope approximation (8); the experimental precautions required to minimize this danger are summarized in the Experimental section. However, based on experience with about 40 natural products and a large number of carbohydrate derivatives (9) we believe that, with care and a good spectrometer, the total accrued error of the method is unlikely to compromise the chemical significance of any R_1 values, and in most instances the numerical accuracy can compare favourably with that of the conventional, and more laborious, computational procedures.

Use of R_1 *Values for the Assignment of Proton Resonances*

Relaxation data can be used in a wide variety of ways. At the simplest level, the partially relaxed spectra themselves can be illuminating since they often enable otherwise overlapping resonances to be separately resolved. For example, the components of the overlapping signals near 2.6 δ in the spectrum of **1** have distinctly different relaxation rates (0.8–1.8 s^{-1}), enabling the chemical shift of a relatively sharp, slowly relaxing signal at 2.66 δ to be identified as that of H-19.

Because of the inverse distance dependence,

[7]An experiment in which the 180° pulse is applied simultaneously to all of the proton spins. In contrast, a single selective R_1 value is obtained (6) from an experiment in which only one proton resonance is subjected to the 180° pulse.



[8]The intensity of the resulting resonances then depends on the relative magnitudes of the chosen delay time (t) and the R_1 value of each individual resonance; for $t \gg T_1$ the nuclei will have recovered their thermal equilibrium with the lattice when the sampling pulse is applied and they will give the normal, positive-going resonance; for $t \ll T_1$ the resonance signal will be negative-going because the magnetization is still inverted.

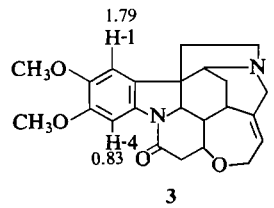
protons which are spatially isolated will relax more slowly than those which are in close proximity; this often allows for the identification of methine and hydroxyl protons. For example, the resonance of the relatively isolated bridgehead proton of camphor, **2**, is easily identified as a triplet at 2.04 δ



2

because it relaxes more slowly ($R_1 = 0.31\ s^{-1}$) than any other of the skeletal protons (0.4–0.5 s^{-1}), all of which have a *geminal* neighbour (cf. Fig. 1).

It is important to note that "spatial proximity" often involves interactions with protons on pendant substituents or on adjacent rings, and this can often facilitate the otherwise ambiguous spectral assignments. For example, one of the two aromatic protons of brucine, **3**, relaxes 2.15 times faster than the other. Consideration of the relaxation pathways of these two protons with those on other rings indicates that H-1 should relax faster than H-4, thereby providing an unambiguous assignment for those two resonances.

Effects of Molecular Motion on Proton R_1 *Values*

In addition to the pronounced distance dependence alluded to earlier, full interpretation of proton R_1 values often involves consideration of the effects of the motional correlation times (τ_c values) of the individual inter-proton vectors (10). These values reflect the tumbling rate of the molecule as a whole (which need not necessarily be isotropic (10*a*)) plus any additional degrees of motional freedom such as the internal motion of a side-chain with respect to a ring, an excellent example of which is the motion of the methyl and other side-chain protons of a steroid. An *increase* in the rate of motion is equivalent to a decrease in τ_c and hence a *decrease* in relaxation efficiency. From the practical standpoint, however, it is more important to recognize that molecular tumbling rates depend on three experimental variables, temperature, solvent, and solute concentration. As an illustrative example, Fig. 5 shows the effect of changing solvent on the R_1 values of **1**. This is why it is usual practice to keep all three of the above parameters constant if meaningful intercomparisons are to be made between the R_1 values of different substances (11). Even then difficulties arise for molecules of differing molecular mass or shape, and we suggest that a plausible procedure for such systems is to nor-

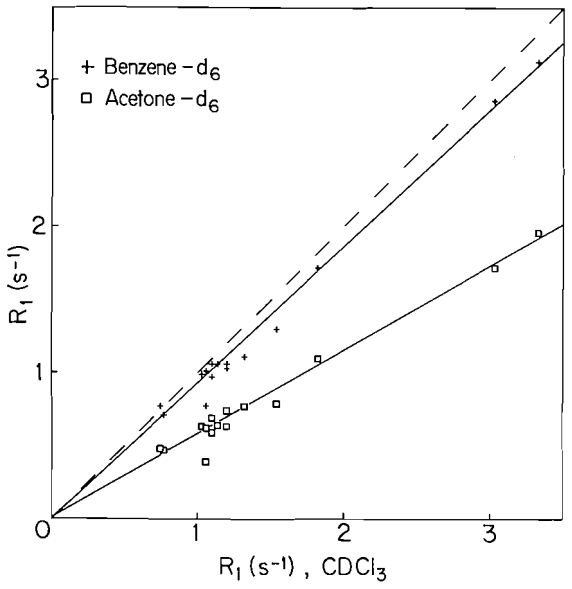

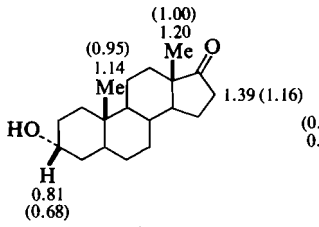

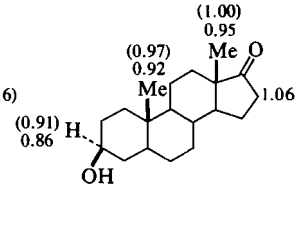

FIG. 5. Proton R_1 values for vindoline obtained by the null point method with the ordinate showing the data measured in $CDCl_3$ solution (0.1 *M*). The abscissa shows the data for 0.1 *M* solutions in benzene-d_6 (+) and in acetone-d_6 (□), measured at the same temperature.

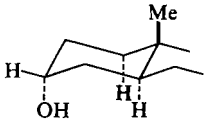
malize the observed R_1 values to that of a particular proton which has a closely similar environment in the separate molecules under study. For example, the R_1 values for the protons of androsterone, **4**, and its C-3 epimer epiandrosterone, **5**, are distinctly different at each site, even though the two molecules were studied under identical conditions. Evidently these two epimers have sufficiently different molecular interactions with the solvent that their overall tumbling motion is significantly different. However, when the R_1 values are normalized (values in parentheses) to those of the 18-methyl group, chosen for this purpose because that group is remote from the site of epimerization, the R_1 values of H-16 and H-19 show excellent agreement between the epimers. In contrast, the axial proton at C-3 in **5** relaxes 34% faster than its equatorial counterpart in **4**. This rate enhancement for an axial



4

5

proton was first observed for pyranose carbohydrates (2*b*) and simply reflects the shorter internuclear separation between H-3 axial and the axial protons at positions 1 and 5 as compared with those of H-3 equatorial. Clearly this dependence has substantial diagnostic potential yet, it would not be detectable without the normalization procedure.

Conclusions

We believe that the spin–lattice relaxation rates of the protons of natural products have substantial diagnostic potential for practicing chemists since they contain information concerning the overall steric environment and molecular motion of each proton. We suggest that access to this information can be rapidly obtained via measurements of null point R_1 values, using a normalization procedure if intercomparisons are to be made between the R_1 values of substances which have different molecular sizes or which have to be studied in different solvents. Given the substantially higher sensitivity of the proton nmr experiment compared with that of ^{13}C nmr there seems to be a strong case for using the former rather that the latter method to study molecular motion of natural products; indeed when limited quantities of material are available measurement of ^{13}C R_1 values may be impossible.

It seems appropriate to end with a comment concerning the null point method, which has previously been regarded by many workers as being so fraught with pitfalls as to be worthless. We feel that

For personal use only.

it is important to recall that those opinions were largely based on attempts to measure ^{13}C R_1 values with spectrometers which were only capable of producing rather long 180° pulses (typically 120 μs); thus the criteria (12) for a good 180° pulse over the entire spectral width (typically 5 kHz) were far more demanding than those required by the proton experiments described here and could not, in fact, be achieved. Even so, the purity of the 180° pulse is still critical, and all reports describing null point R_1 values should be accompanied either by an intercomparison between data obtained by the conventional and the null point methods or by an experimental evaluation of the performance of the spectrometer vis-à-vis the effectiveness of the 180° pulse.

It seems clear from the experiments which we have performed with our spectrometer that any additional errors associated with the null point method are rather small compared wtih those implicitly associated with the conventional two pulse determination of spin–lattice relaxation rates. Nevertheless, it would clearly be preferable if any remaining reservations held by others could be professionally resolved; in this regard the recent report by Levitt and Freeman (13) describing the use of composite pulses to minimize errors in R_1 determinations resulting from infidelities in the 180° pulse is welcome indeed. An appraisal of that procedure in the context of proton relaxation studies of complex natural products is deferred until a later date.

Experimental

Samples

All solvents were stored over molecular sieves prior to use. All solutes gave proton nmr spectra in entire accord with the assigned structures and showed no resonances from impurities.

All solutions were filtered through glass or cotton-wool directly into precleaned nmr tubes. Degassing was performed either by six consecutive freeze–pump–thaw cycles followed by sealing under vacuum, or by sparging with a slow stream of oxygen-free nitrogen followed by sealing with a rubber septum cap.

The Spectrometer

All measurements were made with a home-built 270 MHz spectrometer which was assembled at the Universtiy of British Columbia from what was originally a Nicolet TT-23 spectrometer operating at 100 MHz, and a Nicolet 1080 computer. The operating frequency was increased to 270 MHz by externally heterodyning against 170 MHz from a frequency synthesizer, and the 270 MHz signal was amplified using a home-built 50 W class C power amplifier. The single coil probe for 5 mm sample tubes and 6.5 Tesla superconducting solenoid were from Oxford Instruments. Although no field-frequency lock was used, the observed frequencies changed by less than ±0.2 Hz per hour.

Many of the data reported were obtained with the instrument based on a Nicolet 1180 computer (40 k), a Nicolet 293A pulse programmer, and a Diablo high density disk drive (model 30).

Criteria for 180° Pulse

Before each measurement, the 180° pulse duration was optimized by finding the length which produced a null in the amplitude of the free induction decay signal. Typically the duration was ca. 25 μs; this corresponds to a total pulse width of ca. 40 kHz which is far in excess of the ca. 3 kHz spectral widths of interest; and according to the calculations of Meakin and Jesson (12) under these conditions both intensity and phase errors would be negligible.[9]

Data Acquisition and Processing

Spectra were measured using the two-pulse, 180°–t–90° inversion-recovery sequence (1) with averaging of four free induction decay signals. The delay between each sequence was at least five times the estimated value of the longest T_1. Typically, data for about 30 values of t were separately averaged, filtered, Fourier transformed, phase corrected, and stored automatically on disk for later processing, the appropriate range of t values having been selected either by preliminary experiments or by experience. The longest value of t was chosen so that all peaks had relaxed through their null points.

R_1 values were determined by the "null" method, using extrapolation between data sets straddling the null point itself. The same partially relaxed spectra were used for conventional calculations of R_1 values. The intensity(ies) of the component(s) of each resonance were obtained from the computer peak printout; for multiplet resonances these were summed. The total magnetization intensity for each resonance was then processed in the usual fashion (14, 15) to give an R_1 value. In partial cognizance of the requirements of the initial slope approximation (8), the R_1 values were then recalculated using the data obtained during the first calculated T_1 period of the individual proton. R_1 values could typically be measured with a reproducibility of ±1–4% using the null point method, and with a standard (random) error of 1–4% by the conventional (regression) method. Additional systematic errors inherent in the two-pulse method may also be present.

Acknowledgments

It is a pleasure for one of us (L.D.C.) to thank the University of British Columbia for the facilities provided for his sabbatical leave during 1977–1978 when this study was performed. Funds for the components of the 270 MHz spectrometer were provided by the Chemistry Department, University of British Columbia and by the President's Emergency Research Equipment Fund of the University of British Columbia. Both authors wish to thank the National Research Council of Canada for operating grants.

C-Nucleosides and related compounds. XV. The synthesis of D,L-2′-*epi*-showdomycin and D,L-showdomycin

GEORGE JUST, T. J. LIAK, MU-ILL LIM, PIERRE POTVIN, AND YOULA S. TSANTRIZOS
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3C 3G1

Received March 26, 1980

GEORGE JUST, T. J. LIAK, MU-ILL LIM, PIERRE POTVIN, and YOULA S. TSANTRIZOS. Can. J. Chem. **58**, 2024 (1980).

The conversion of the Diels–Alder adduct of methyl β-nitroacrylate with furan to the title compounds and to D,L-2,5-anhydroglucose derivatives is described.

GEORGE JUST, T. J. LIAK, MU-ILL LIM, PIERRE POTVIN et YOULA S. TSANTRIZOS. Can. J. Chem. **58**, 2024 (1980).

On décrit la transformation du produit de la réaction Diels–Alder du méthyle β-nitroacrylate avec le furane en dérivés du D,L-2,5-anhydroglucose, en D,L-2′-*épi*-showdomycine, et en showdomycine.

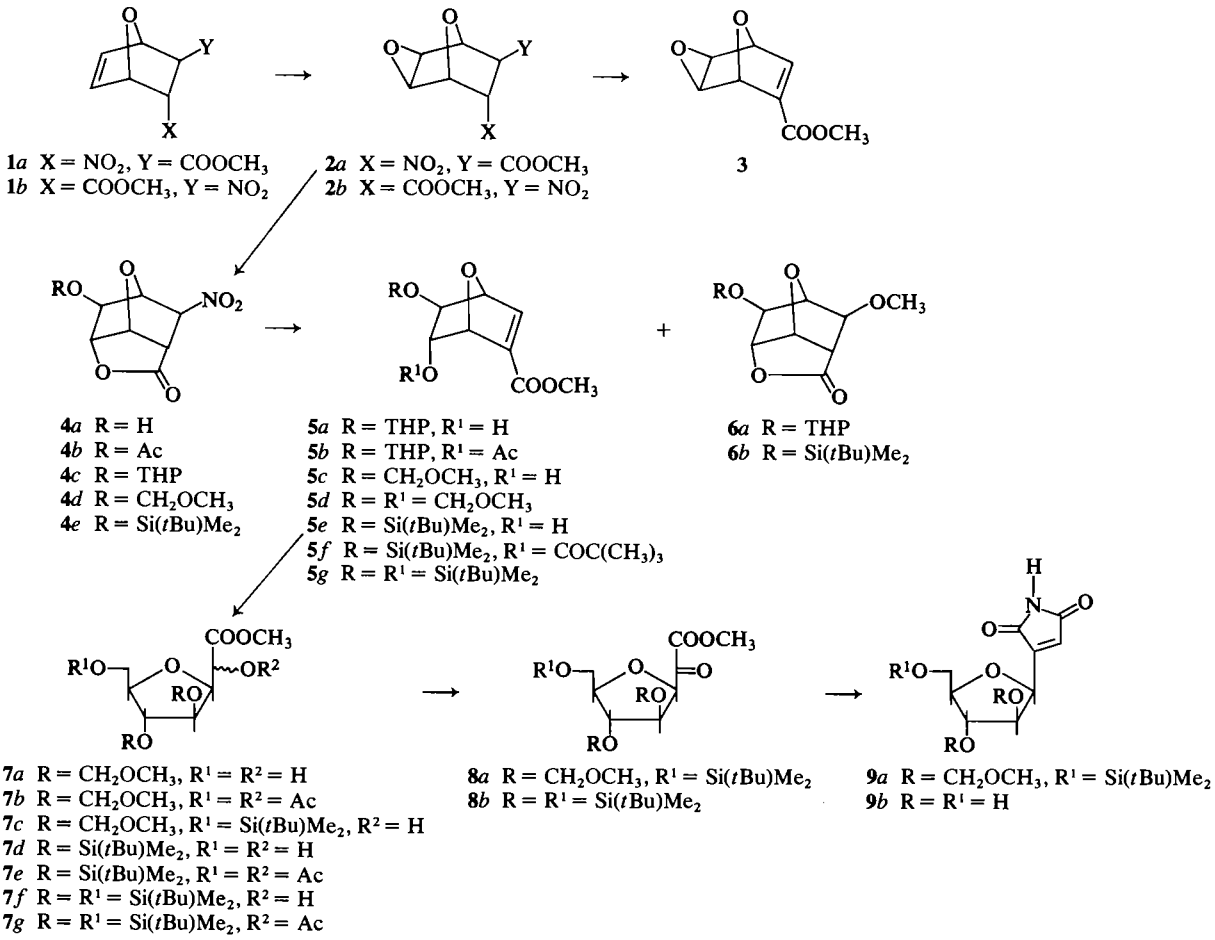
As part of a programme to synthesize *C*-nucleosides, we were interested in developing a method to prepare an arabinose derivative **8**, bearing at the anomeric center a functionalized carbon atom, which could serve as a precursor for the synthesis of compounds such as *ara*-showdomycin (**9***b*).

Reaction of furan with methyl β-nitroacrylate gave the known adducts **1***a* and **1***b* (1). Prolonged treatment with *m*-chloroperbenzoic acid gave epoxides **2***a* and **2***b*, which upon treatment with diazabicyclo[5.4.0]undec-5-ene (DBU) gave olefinic epoxide **3**. As expected (2*a*), nmr analysis of this compound revealed that the stereochemistry of the epoxide function was *exo*, since the coupling constant between the bridgehead protons and the *endo*-protons α to the epoxide was 0 Hz (dihedral angle ~ 90° (2*b*)).



Treatment of *endo*-carbomethoxy epoxide **2***b* with acetic acid and hydrochloric acid at 95°C for 2 h gave lactone **4***a* in 60% yield. There is ample precedent that lactonizations of this type proceed in the manner depicted, and it has been recently reconfirmed in an unambiguous manner for a closely related system (12).

Attempts to acylate hydroxy lactone **4***a* with acetic anhydride or pivaloyl chloride in pyridine failed, leading to decomposition products. However, acetylation using acidic conditions gave acetate **4***b* in good yield. Tetrahydropyranyl ether **4***c* could also be easily prepared.

Attempts to transform lactone **4***c* into the α,β-unsaturated ester **5***a* using one or more equivalents of sodium methoxide in methanol, the conditions which had cleanly converted the corresponding bromolactone in the bicyclo[2.2.1]heptane series to an analogous compound (3), failed because of the formation of the sodium salt of **4***c*. However, treatment of **4***c* with DBU in methanol gave ester **5***a*, accompanied by varying amounts of **6***a*. From the relative ratios of **5***a* to **6***a* as a function of reaction time, it was obvious that **5***a* was transformed to **6***a*. Compound **5***a* was characterized as its acetate **5***b*. At this point, it became apparent that the tetrahydropyranyl protecting group obscured the nmr spectrum of **5***a* and **5***b* enough to make some of the assignments doubtful. The reaction sequence was therefore repeated with the dimethyl-*tert*-butylsilyl ether lactone **4***e*, providing **5***e* and **6***b*; **5***e* was characterized as its pivalate **5***f*. Since Just and Ouellet (3) subsequently established in the analogous carbocyclic series that the pivalate group interacted with the hydroxy group generated in the subsequent ozonolysis–reduction sequence **5** → **7**, it was decided to block the hydroxy group in **5***e* as its dimethyl-*tert*-butylsilyl ether **5***g* (4). Silylation of **5***e* proceeded in an unpredictable manner, providing the disilylation product **5***g*, except for one instance, in low yield.

Ozonolysis of the olefin **5***g*, followed by treatment with dimethyl sulfide and the reduction of the resulting keto aldehyde, obtained in part as its hydrate, with 4 equivalents of lithium tri-*tert*-butoxyaluminum hydride, gave diol ester **7***d*. Selective silylation of **7***d* gave the trisilyl ether **7***f*. That the silylation had proceeded with the desired selectivity was proven by acetylation, where only one proton was shifted downfield from 2.96 to 3.63 ppm. Oxidation (5) of **7***f* provided the relatively unstable ketoester **8***b*. Because of the low silylation yield encountered at one stage in this sequence, the methoxymethyl protecting group (6) was used in the analogous sequence **4***d* → **5***d* → **7***c* → **8***a*. In this sequence, considerable difficulty was experienced when the method worked out for the transformation **4***c* → **5***a* was applied to transformation **4***d* → **5***c*, and it had to be modified. The highest reproducible yields (40–50%) of **5***c* were obtained

0008-4042/80/192024-10$01.00/0

when **4***d* was boiled for 7 hours with triethylamine in dry methanol. It was transformed to its methoxymethyl ether **5***d* in high yield. The structure and stereochemistry of **5***d* follow from its mode of formation and nmr spectrum, which indicated that H4 was split by H3 (2 Hz), whereas the coupling constant H4—H5 was close to 0 Hz, indicating an *exo*-configuration of the 5-substituent. On the other hand *J*(H1—H6) was 4 Hz as expected, indicating that the 6-substituent was *endo*. This was confirmed by the fact that *J*(H5—H6) was close to 0 Hz.

Ozonolysis of **5***d*, followed by reduction with dimethylsulphide and lithium aluminum tri-*tert*-butoxyhydride, gave diol **7***a*, characterized as its diacetate **7***b*. Selective silylation with *tert*-butyldimethylsilyl chloride gave monosilyl ether **7***c*. Silyl ether **7***c* seemed to consist of one diastereomer only. The stereochemistry at C2 was of no consequence, since the next step involved oxidation (5) to ketoester **8***a*.

Whereas the ozonolysis, reduction, and oxidation sequence should not have affected the stereochemistry at $C2^1$, $C3^1$ and $C4^1$, there was some doubt about the stereochemistry at $C1^1$ especially in ketoester **8***a*. The following spectral and chemical data support the assignment of stereochemistry made: whereas the nmr spectrum of **7***c* in deuterochloroform or benzene was uninformative, addition of Eu(fod)$_3$ to the deuterobenzene solution of **7***c* allowed an assignment of most signals. The lowest-field signal (1H, C2) appeared as a doublet (J = 8 Hz). The $C1^1$-proton appeared at somewhat higher field as a doublet of doublets ($J_{2,1'}$ = 8 Hz, $J_{1',2'}$ = 4 Hz). This latter coupling constant is indicative of a *cis* relation (8, 20) for $H1^1$—$H2^1$. The $H3^1$ proton consisted of a 4-line system (J_a, $J_b \simeq$ 2 Hz, 2.5 Hz). The $C4^1$-proton consisted of complex signal which did not permit first order interpretation. The appearance of the protons corresponding to $C1^1$, $C2^1$, $C3^1$, $C4^1$, and $C5^1$ was similar in ketoester **8***a* and in showdomycin analogs **9***a* and **9***b*, except

For personal use only.

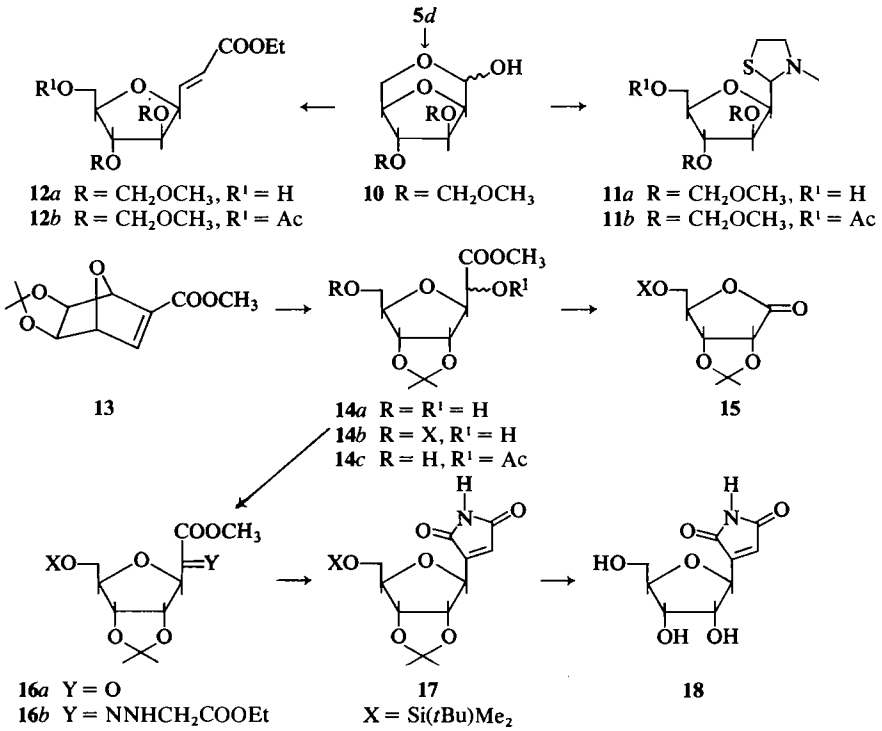
for the absence of C2—C1^1 coupling in **8***a* and for the appearance of a 2 Hz long-range coupling between the olefinic proton of the heterocycle and C1^1—H. The stereochemical assignment was confirmed by the following conversion. Compound **5***d* was ozonized at −78°C and the ozonide reduced with borohydride to the corresponding triol (**7***a*, $COOCH_3$=CH_2OH). Without purification, the triol was oxidized with periodate to give 2,5-anhydroglucose **10**, which existed predominantly in the hemiacetal form shown, as indicated by spectral and microanalytical data. The formation of a hemiacetal proves that triol **7***a* ($COOCH_3$=CH_2OH) and therefore triol derivative **7***c* had most likely the same *cis* configuration at C1^1 and C4^1.

Compound **10** was transformed to the thiazolidine acetate **11***b* and the α,β-unsaturated ester **12***b*, using the methods described for the analogous anhydroallose (1). Both types of compounds have been shown to be versatile precursors to *C*-nucleosides (10).

Compound **8***a* was obtained from nitroacrylate adduct **1***b* in an overall yield of 6.5% in 8 steps.

Following procedures used for the synthesis of showdomycin (21) and showdomycin analogues (13, 14), the ketoester **8***a* was reacted with 1 equivalent of carbamoylmethylenetriphenylphosphorane (7) in chloroform at room temperature for 2 h. The reaction gave a single major product together with considerable amounts of polar by-products. Purification of the crude product by flash chromatography (19) using petroleum ether – ethylacetate (3:1) gave the maleimide **9***a* in an overall yield of 40% from the hydroxy ester **7***c*. The nmr spectrum of this substance clearly showed the disappearance of the methyl ester group, the presence of a single NH proton at δ 8.08 and a vinyl proton at δ 6.39. The ir spectrum showed characteristic absorptions at 1790 and 1740 cm^{-1} for the carbonyl function and at 1665 cm^{-1} for the olefinic bond. In the mass spectrum, the molecular ion peak was found at *m/e* 431 and other major peaks at *m/e* 400 ($M^+ - OCH_3$) and 374 ($M^+ - C(CH_3)_3$). Furthermore, the uv spectrum revealed the typical maleimide chromophore having absorption maximum at 222 nm ($\log \varepsilon = 4.2$).

Completion of the synthesis of 2′-*epi*-showdomycin then only required removal of the protecting groups. Treatment of **9***a* with 80% aqueous trifluoroacetic acid led to the simultaneous removal of both *tert*-butyldimethylsilyl and methoxymethyl groups. Subsequent purification on silica gel plates gave crystalline D,L-2′-*epi*-showdomycin **9***b*, mp 170–171°C, in 60% yield. The uv spectrum of the product showed an absorption at 222 nm and the molar extinction coefficient ($\log \varepsilon$ 4.36) was also in accord with that of the known showdomycin (8), thus confirming the structure of the aglycon moiety of **9***b*. The ir data and elemental analysis were consistent with the structure of **9***b*. Furthermore, this compound was fully identified by its mass spectrum.



The mass spectrum of 2′-*epi*-showdomycin **9***b* was quite typical of other *C*-nucleosides (9) and showed a minor molecular ion peak at *m/e* 229 and an abundant peak at *m/e* 211 corresponding to loss of water from the molecular ion. The base peak was found at *m/e* 126 (B + 30) where B was the heterocyclic aglycon. The B + 30 peak is strongly suggestive of a formyl type residue attached to the base. Comparison of the major peaks of showdomycin with those of 2′-*epi*-showdomycin **9***b* revealed considerable similarity in the fragmentation pattern.

The nmr spectrum of **9***b* showed clearly H4 as a doublet coupled to H1^1 ($J_{1',4}$ = 2 Hz), and H1^1 as a doublet of doublets ($J_{1',4}$ = 2 Hz, $J_{1',2'}$ = 4 Hz). A coupling constant of 4 Hz indicates *cis*-related protons. Comparison of spectra (8, 20) of *C*-nucleosides and sugars having a β-configuration at the anomeric centre to related compounds having the α-configuration shows that the chief difference is that the coupling constant corresponding to $J_{1',2'}$ in the α-anomers, having otherwise identical stereochemistry, is close to 0 Hz. We are therefore quite convinced that the stereochemistry of **9***b* is as indicated.

The overall yield for the formation of 2′-*epi*-showdomycin, based on the *exo*-nitro adduct **1***b*, was 1.6%.

The synthesis of D-showdomycin **18**, first accomplished by Kalvoda *et al.* (11) and improved by Trümmlitz and Moffatt (21), was carried out in a similar manner for the racemate, and is described below.

The readily available bicyclic ester **13** (1) was ozonolysed at −78°C, and the resulting ozonide reduced with dimethyl sulphide. The resulting ketoester aldehyde, which, when freshly prepared, seems to contain 60% of the expected aldehyde (by nmr), was normally obtained as its hydrate. Its reduction with 2.5 equivalents of lithium aluminum tri-*tert*-butoxy hydride gave diol **14***a*, presumably as a mixture of diastereoisomers, in 60–78% yield, based on **13**. It was characterized as its diacetate **14** (R = R^1 = Ac). When treated with one equivalent of *tert*-butyldimethylsilyl chloride, **14***b* was obtained. Its structure followed from the fact that acetylation gave **14***c*, in which the proton α to the acetate

function had shifted downfield by 1 ppm with respect to the same proton in **14***b*. Further confirmation was derived from the fact that the di-*tert*-butyldimethylsilyl ether of **14***a* could be selectively hydrolysed to an isomeric monosilylether **14** (R = H, R^1 = Si (*t*Bu)Me_2), acetylation of which gave **14** (R = Ac, R^1 = Si (*t*Bu)Me_2) in which two protons shifted downfield by 0.8 ppm. Oxidation of alcohol **14***b* with a variety of reagents such as ruthenium tetroxide (5), *N*-bromosuccinimide (15), or Collins reagent (16) resulted in either decomposition, formation of lactone **15**, or formation of the desired ketoester **16** in an irreproducible manner. However, with acetic anhydride – dimethylsulfoxide (17), the unstable ketoester **16** could be obtained in 80% yield. The analogous oxidation of related compounds such as the carbocyclic analog of **14***b* (13, 14) had never given rise to this type of erratic behaviour.

Treatment of the crude ketoester **16** with carbamoylmethylenetriphenylphosphorane (7) gave D,L-showdomycin derivative **17**, in 35% yield. The nmr spectrum of **17** was fully consistent with the structure assigned. In particular, the isopropylidene group gave two well-spaced singlets (18) indicating that only the desired "β-anomer" was obtained. Hydrolysis gave D,L-showdomycin, mp 143–144°C. Its mass spectrum was identical to that of naturally occurring showdomycin (9*a*).

Attempts to prepare pyrazomycin by cyclization of **16***a*, which had been successful for analogous compounds in the carbocyclic (13) and other series, was unsuccessful, and no pure D,L-pyrazomycin could be obtained from **16***a*, although the uv spectrum of a purified sample indicated that it had been formed in very low yield.

Experimental

Melting points were determined on a Gallenkamp block and are uncorrected. Preparative thin layer chromatography was performed using Merck HF-254 and Brinkmann HF-254 silica gel on 20 cm × 20 cm plates. Merck silica gel 60 and Woelm neutral alumina were used for column chromatography. Woelm silica gel 32–63 μ was used for flash chromatography. Mass spectra were obtained on AE1-MS-902 or LKB-900 mass spectrometers at 70 eV using a direct-insertion probe. Nuclear magnetic resonance spectra were recorded on Varian Associates T-60, T60A, HA-100, or Bruker FT90 spectrometers. Infrared spectra were obtained on a Unicam SP1000 and Perkin–Elmer 257 and 297 ir spectrophotometers. Ultraviolet spectra were determined with a Unicam SP-800 or a Cary 17 spectrophotometer. Microanalyses were carried out by Dr. C. Daessle, Montreal.

3-Exo-*carbomethoxy*-*2*-endo-*nitro*-*5,6*-exo-*epoxido*-*7*-*oxabicyclo*[*2.2.1*]*heptane* (2a)

To a solution of **1***a* (2.02 g, 10 mmol) in methylene chloride (40 mL) was added by portions a solution of 85% *m*-chloroperbenzoic acid (2.49 g, 14 mmol) in methylene chloride (40 mL). The mixture was stirred for 2 days at room temperature. Excess peracid was then destroyed by addition of 10% sodium sulfite solution. The organic phase was washed with 5% aqueous sodium bicarbonate and water and dried ($MgSO_4$). Solvent removal left an oil which was crystallized from ethyl ether. Recrystallization from chloroform–hexane gave 1.31 g

(60%) of **2***a*, mp 100–101°C; ir (KBr) ν_{max}: 1745 (C=O), 1550 (C—NO_2) cm^{-1}; nmr (DMSO-d_6) δ: 3.52 (m, 2H), 3.69–3.76 (s + m, 4H), 4.83 (s, 1H), 4.94 (d, 1H, J = 5 Hz), 5.53 (t, 1H, J = 4 Hz); mass spectrum (70 eV) *m/e*: 215 (M^+), 184 ($M^+ - OCH_3$), 169 ($M^+ - NO_2$), 109 ($M^+ - COOCH_3 - HNO_2$). *Anal.* calcd. for $C_8H_9NO_6$: C 44.65, H 4.17, N 6.51; found: C 44.54, H 4.44, N 6.77.

2-Endo-*carbomethoxy-3*-exo-*nitro-5,6*-exo-*epoxido-7-oxabicyclo[2.2.1]heptane* (**2**b)

To a solution of **1***b* (3.03 g, 15 mmol) in methylene chloride (50 mL) was added dropwise a solution of 85% *m*-chloroperbenzoic acid (3.66 g, 17 mmol) in methylene chloride (50 mL). Stirring was continued for 2 days at room temperature. The reaction mixture was washed with 10% sodium sulfite (3 × 30 mL) and 5% sodium bicarbonate solution, water, and finally with brine. Drying over sodium sulfate and evaporation gave 2.44 g (74.4%) of **2***b* as an oil which was crystallized from methanol and recrystallized from chloroform, mp 109–110°C; ir (KBr) ν_{max}: 1745 (C=O), 1550 (C—NO_2) cm^{-1}; nmr (DMSO-d_6) δ: 3.66 (m, 2H), 3.73 (s, 3H), 3.93 (t, 1H, J = 4 Hz), 4.88 (d, 1H, J = 5 Hz), 5.10 (s, 1H), 5.25 (d, 1H, J = 4 Hz); mass spectrum (70 eV) *m/e*: 215 (M^+), 169 ($M^+ - NO_2$), 109 ($M^+ - COOCH_3 - HNO_2$). *Anal.* calcd. for $C_8H_9NO_6$: C 44.65, H 4.17, N 6.51; found: C 44.66, H 4.34, N 6.68.

5-*Carbomethoxy-2,3*-exo-*epoxido-7-oxabicyclo[2.2.1]-hept-5-ene* (**3**)

A solution of **2***a* (319 mg, 1.48 mmol) and DBU (281 mg, 1.77 mmol) in methylene chloride (10 mL) was refluxed for 40 min. The mixture was diluted with methylene chloride, washed with 0.1 *N* hydrochloric acid three times, with water, then evaporated to dryness, leaving a syrup which was purified by eluting it through a column of silicic acid using chloroform. Crystallization of the major product from carbon tetrachloride – hexane gave 152 mg (61%) of **3**, mp 76–77°C; ir (KBr) ν_{max}: 1700 (C=O), 1595 (C=C) cm^{-1}; nmr ($CDCl_3$) δ: 3.48 (d, 1H, J = 3.5 Hz), 3.62 (d, 1H, J = 3.5 Hz), 3.75 (s, 3H), 4.88 (d, 1H, J = 2 Hz), 5.00 (s, 1H), 7.26 (d, 1H, J = 2 Hz); mass spectrum (70 eV) *m/e*: 168 (M^+), 153 ($M^+ - CH_3$), 139, 136 ($M^+ - CH_3OH$). *Anal.* calcd. for $C_8H_8O_4$: C 57.14, H 4.80; found: C 57.37, H 4.85. Using the conditions described above, **2***b* was transformed to **3**, identical in all respects with **3** obtained from **2***a*.

5-Exo-*6*-endo-*dihydroxy-3*-exo-*nitro-7-oxabicyclo-[2.2.1]heptane-2*-endo-*carboxylic Acid γ-Lactone* (**4**a)

A solution of **2***b* (3.12 g, 15 mmol) in acetic acid (60 mL), hydrochloric acid (30 mL), and water (30 mL) was heated at 95–100°C for 2 h. After cooling to room temperature, the solvents were evaporated *in vacuo* to dryness and the residue was coevaporated with ethanol. The black residue was dissolved in hot acetone and treated with charcoal. The filtrate was concentrated to afford a yellow oil. Crystallization from acetone–chloroform gave 2.34 g (60%) of **4***a*, mp 170–171°C; ir (KBr) ν_{max}: 3500 (OH), 1800 (lactone), 1575 (C—NO_2) cm^{-1}; nmr ($(CD_3)_2CO$) δ: 3.36 (bs, 1H), 3.63 (d, 1H, J = 5 Hz), 4.10 (s, 1H), 4.60 (d, 1H, J = 5 Hz), 5.25 (s, 1H), 5.33 (s, 1H), 5.60 (t, 1H, J = 5 Hz); mass spectrum (70 eV) *m/e*: 201 (M^+), 155 ($M^+ - NO_2$). *Anal.* calcd. for $C_7H_7NO_6$: C 41.79, H 3.48, N 6.96; found: C 41.66, H 3.75, N 7.17.

5-Exo-*acetoxy-6*-endo-*hydroxy-3*-exo-*nitro-7-oxabicyclo-[2.2.1]heptane-2*-endo-*carboxylic Acid γ-Lactone* (**4**b)

A mixture of **4***a* (165 mg) and acetic anhydride (2 mL) containing one equivalent of *p*-toluenesulfonic acid monohydrate was stirred at room temperature for 30 min. The resulting solid was collected by filtration and washed with cold water to give 139 mg (70%) of analytically pure **4***b*, mp 198–200°C; ir (KBr) ν_{max}: 1800 (lactone), 1745 (C=O), 1560 (C—NO_2) cm^{-1}; nmr (DMSO-d_6) δ: 2.08 (s, 3H), 3.62 (d, 1H, J = 5 Hz), 4.82 (d, 1H, J = 5 Hz), 4.98 (s, 1H), 5.36 (s, 1H), 5.62 (t, 1H, J = 5 Hz), 5.83 (s, 1H); mass spectrum (70 eV) *m/e*: 243 (M^+), 196 ($M^+ - NO_2$), 155, 109. *Anal.* calcd. for $C_9H_9NO_7$: C 44.44, H 3.70, N 5.76; found: C 44.24, H 3.73, N 5.41.

6-Endo-*hydroxy-3*-exo-*nitro-5*-exo-*tetrahydropyranyl-oxy-7-oxabicyclo[2.2.1]heptane-2*-endo-*carboxylic Acid γ-Lactone* (**4**c)

To a solution of **4***a* (1.0 g, 5 mmol) and *p*-toluenesulfonic acid (10 mg) in acetone was added dihydropyran (2 mL). The mixture was stirred at room temperature for 4 h and then evaporated, leaving a solid residue. Recrystallization from acetone–hexane gave 1.21 g (85%) of **4***c*, mp 123–124°C; ir (KBr) ν_{max}: 1800 (lactone), 1560 (C—NO_2), 1040 cm^{-1}; nmr ($(CD_3)_2CO$) δ: 1.57 (m, 6H), 3.33–3.57 (m, 3H), 3.90 (s, 1H), 4.36–4.70 (m, 2H), 5.03 (bs, 2H), 5.23 (t, 1H, J = 4 Hz). *Anal.* calcd. for $C_{12}H_{15}NO_7$: C 50.53, H 5.26, N 4.91; found: C 50.43, H 5.47, N 5.12.

6-Endo-*hydroxy-3*-exo-*nitro-5*-exo-*methoxy-methyloxy-7-oxabicyclo[2.2.1]heptane-2*-endo-*carboxylic Acid γ-Lactone* (**4**d)

To a stirred solution of **4***a* (1.33 g, 6.6 mmol) and methylal (5 mL) in tetrahydrofuran (30 mL) was added phosphorus pentoxide (about 5 g). After standing for 1.5 h at room temperature the mixture was filtered and the residue was washed with tetrahydrofuran. The filtrate was evaporated to dryness. The residue was dissolved in ethyl acetate and washed with 5% sodium bicarbonate solution, water, and brine. Evaporation of the dried organic phase gave 1.53 g (93%) of **4***d* as an analytically pure solid, mp 154–155°C; ir (KBr) ν_{max}: 1800 (lactone), 1560 (C—NO_2) cm^{-1}; nmr ($(CD_3)_2CO$) δ: 3.06 (s, 3H), 3.36 (d, 1H, J = 5 Hz), 3.86 (s, 1H), 4.40 (d, 1H, J = 5 Hz), 4.43 (s, 2H), 5.23 (s, 2H), 5.50 (t, 1H, J = 5 Hz); mass spectrum (70 eV) *m/e*: 245 (M^+), 199 ($M^+ - NO_2$). *Anal.* calcd. for $C_9H_{11}NO_7$: C 44.08, H 4.52, N 5.71; found: C 44.22, H 4.75, N 5.54.

6-Endo-*hydroxy-3*-exo-*nitro-5*-exo-*tert-butyldimethylsilyloxy-7-oxabicyclo[2.2.1]-heptane-2*-endo-*carboxylic Acid γ-Lactone* (**4**e)

To a solution of **4***a* (2.01 g, 10 mmol) in tetrahydrofuran (20 mL) and dimethylformamide (20 mL) was added dimethyl-*tert*-butylsilyl chloride (2.26 g, 15 mmol) and imidazole (1.70 g, 25 mmol). The reaction mixture was stirred at room temperature for one day. After evaporation of the solvents the residue was dissolved in ethyl acetate, washed with water, dried, and evaporated. The residue was chromatographed on a column of silicic acid (40 g) using methylene chloride. Crystallization from hexane gave 2.84 g (90%) of **4***e*, mp 112–113°C; ir (Nujol) ν_{max}: 1800 (lactone), 1560 (C—NO_2) cm^{-1}; nmr ($CDCl_3$) δ: 0.16 (s, 6H), 0.95 (s, 9H), 3.76 (d, 1H, J = 5 Hz), 4.00 (s, 1H), 4.58 (d, 1H, J = 5 Hz), 4.84 (s, 1H), 5.14 (s, 1H), 5.51 (t, 1H, J = 5 Hz); mass spectrum (70 eV) *m/e*: 315 (M^+), 258 ($M^+ - C(CH_3)_3$). *Anal.* calcd. for $C_{13}H_{21}NO_6Si$: C 49.52, H 6.67, N 4.44; found: C 49.77, H 6.87, N 4.56.

5-*Carbomethoxy-3*-endo-*hydroxy-2*-exo-*tetrahydro-pyranyloxy-7-oxabicyclo[2.2.1]hept-5-ene* (**5**a) *and* 6-Endo-*hydroxy-3*-exo-*methoxy-5*-exo-*tetrahydro-pyranyloxy-7-oxabicyclo[2.2.1]heptane-2*-endo-*carboxylic Acid γ-Lactone* (**6**a)

A solution of **4***c* (336 mg, 1.18 mmol) and DBU (205 mg, 0.13 mmol) in methanol – methylene chloride (1:1) was refluxed for 45 min. The solvents were then evaporated and the residue was dissolved in chloroform, washed with 0.1 *N* hydrochloric acid (3×) and water, dried (Na_2SO_4), and evaporated. The residue was applied on silica gel plates using chloroform. Elution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of the major, more polar, band gave 220 mg (70%) of **5***a* as an oil; ir ($CHCl_3$) ν_{max}: 3480 (OH), 1720 (C=O), 1625 (C=C) cm^{-1}; nmr ($CDCl_3$) δ: 1.68 (m, 6H), 2.70 (bs, 1H), 3.65 (m, 2H), 3.76 (s, 4H), 4.25 (d, 1H, J = 4 Hz), 4.76 (m, 1H), 5.00–5.08 (m, 2H), 7.17 (d, 1H, J = 2 Hz). *Anal.* calcd. for $C_{13}H_{18}O_6$: C 57.77, H 6.71; found: C 57.65, H 6.58. Elution of the minor, less polar, band gave 45 mg (14%) of **6***a*, mp 134–136°C; ir (KBr): 1800 (lactone) cm^{-1}; nmr ($CDCl_3$) δ: 1.66 (m, 6H), 2.73 (d, 1H, J = 4 Hz), 3.40 (s, 3H), 3.50–4.00 (m, 4H), 4.56 (d, 1H, J = 4 Hz), 4.67–4.90 (m, 2H), 5.36 (t, 1H, J = 5 Hz); mass spectrum (70 eV) *m/e*: 270 (M^+), 238 ($M^+ - CH_3OH$). *Anal.* calcd. for $C_{13}H_{18}O_6$: C 57.71, H 6.71; found: C 57.82, H 6.71.

*3-*Endo-*acetoxy-5-carbomethoxy-2-*exo-*tetrahydropyranyloxy-7-oxabicyclo[2.2.1]hept-5-ene (5b)*

A solution of **5***a* (91 mg) and acetic anhydride (1 mL) in pyridine (2 mL) was stirred overnight at room temperature. The mixture was then evaporated to dryness *in vacuo*. The residue was dissolved in chloroform and washed with water. The dried organic phase was evaporated and purified by chromatography on a silica gel plate using ethyl ether, giving 70 mg (67%) of **5***b* as an oil which solidified on standing, mp 81–82°C; ir ($CHCl_3$) ν_{max}: 1740 (C=O), 1625 (C=C) cm^{-1}; nmr ($CDCl_3$) δ: 1.69 (m, 6H), 1.96 (s, 3H), 3.47 (m, 1H), 3.76 (s + m, 5H), 4.76 (bs, 1H), 5.05 (m, 2H), 5.16 (d, 1H, J = 4 Hz), 7.17 (d, 1H, J = 2 Hz); mass spectrum (70 eV) *m/e*: 312 (M^+), 281 ($M^+ - OCH_3$), 228 ($M^+ - O(CH_2)_4CH$). *Anal.* calcd. for $C_{15}H_{20}O_7$: C 57.68, H 6.46; found: C 57.47, H 6.49.

*5-Carbomethoxy-3-*endo-*hydroxy-2-*exo-*methoxymethyloxy-7-oxabicyclo[2.2.1]hept-5-ene (5c)*

A solution of **4***d* (1.2 g, 4.89 mmol) and triethylamine (510 mg, 3 mmol) in dry methanol (60 mL) was refluxed for 8 h. Then the solution was filtered to remove small amounts of precipitate and the filtrate was evaporated to dryness. The residue was dissolved in chloroform, washed twice with water, dried over sodium sulfate, and evaporated. The oil obtained was chromatographed on a column of alumina using 3:1 chloroform – ether and slowly increasing the polarity to pure ethyl ether. Compound **5***c* was obtained as a colourless oil in 40% yield (500 mg); ir ($CHCl_3$) ν_{max}: 3500 (alcohol), 1730 (ester), 1625 (olefin) cm^{-1}; nmr ($CDCl_3$) δ: 2.89 (bs, 1H, OH), 3.20 (s, 3H, CH_2OCH_3), 3.51 (d, 1H, $CHOCH_2OCH_3$, J = 1 Hz), 3.73 (s, 3H, $COOCH_3$), 4.22 (dd, 1H, $CHOH$, J = 1, 4 Hz), 4.71 (s, 2H, CH_2OCH_3), 4.92–5.04 (m, 2H, bridgeheads), 7.06 (d, 1H, J = 2 Hz, C=CH) ppm. *Anal.* calcd. for $C_{10}H_{14}O_6$: C 52.17, H 6.13; found: C 52.08, H 6.28.

*5-Carbomethoxy-2-*exo-*3-*endo-*dimethoxymethyloxy-7-oxabicyclo[2.2.1]hept-5-ene (5d)*

To a stirred solution of **5***c* (1.3 g, 5.6 mmol) in dry chloroform (50 mL) were added methylal (10 mL) and approximately 3 g of phosphorus pentoxide. After 2 h at room temperature, the mixture was poured into 5% sodium bicarbonate solution. The organic layer was washed with water, dried over sodium sulfate, and evaporated to dryness. The residue was purified on a column of silicic acid using chloroform–hexane – ethyl ether (10:6:1), giving 1.3 g (84%) of **5***d* as a homogeneous syrup; ir ($CHCl_3$) ν_{max}: 1730 (ester), 1625 (olefin) cm^{-1}; nmr ($CDCl_3$) δ: 3.36 (2s, 3H + 3H, CH_2OCH_3), 3.66 (d, 1H, CH_3OCH_2OCH, J = 0.8 Hz), 3.76 (s, 3H, $COOCH_3$), 4.20 (dd, 1H, CH_3OCH_2OCH, J = 0.8, 4 Hz), 4.66 (q, 2H, OCH_2, J = 3, 6 Hz), 4.76 (s, 2H, OCH_2), 4.99 (d, 1H, CH=CH—CH, J = 2 Hz), 5.12 (d, 1H, CH=C—CH, J = 4 Hz), 7.15 (d, 1H, C=CH, J = 2 Hz); ms (70 eV) *m/e*: 259 ($M^+ - CH_3$), 243 ($M^+ - OCH_3$), 213 ($M^+ - CH_3OCH_2O$), 148. *Anal.* calcd. for $C_{12}H_{18}O_7$: C 52.55, H 6.62; found: C 52.38, H 6.53.

*5-Carbomethoxy-3-*endo-*hydroxy-2-*exo-*tert-butyldimethylsilyloxy-7-oxabicyclo[2.2.1]hept-5-ene (5e) and 6-*Endo-*hydroxy-3-*exo-*methoxy-5-*exo-*tert-butyldimethylsilyloxy-7-oxabicyclo[2.2.1]heptane-2-*endo-*carboxylic Acid γ-Lactone (6b)*

To a stirred refluxing solution of DBU (635 mg) in methylene chloride – methanol (15:15 mL) was added dropwise a solution of **4***e* (1.22 g, 3.8 mmol) in methylene chloride (15 mL). The mixture was kept refluxing for an additional 15 min. After evaporation of the cooled solution the residue was dissolved in chloroform, washed with dilute hydrochloric acid and water, dried over sodium sulfate, and evaporated. The residue was chromatographed on a column of silicic acid using chloroform, giving 976 mg (84%) of the more polar **5***e* as a colorless syrup; ir ($CHCl_3$) ν_{max}: 3500 (OH), 1725 (C=O), 1620 (C=C) cm^{-1}; nmr ($CDCl_3$) δ: 0.13 (s, 6H), 0.97 (s, 9H), 3.37 (bs, 1H), 3.66 (s, 1H), 3.76 (s, 3H), 4.13 (d, 1H, J = 5 Hz), 4.75 (d, 1H, J = 2 Hz), 5.01 (d, 1H, J = 5 Hz), 7.08 (d, 1H, J = 2 Hz). The less polar compound **6***b* (62 mg) was also obtained; ir ($CHCl_3$): 1800 (lactone) cm^{-1}; nmr ($CDCl_3$) δ: 0.15 (s, 6H), 0.85 (s, 9H), 2.67 (d, 1H, J = 5 Hz), 3.33 (s, 3H), 3.62 (s, 1H), 3.68 (s, 1H), 4.30–4.50 (m, 2H), 5.63 (m, 1H).

*5-Carbomethoxy-3-*endo-*pivaloyloxy-2-*exo-*tert-butyldimethylsilyloxy-7-oxabicyclo[2.2.1]hept-5-ene (5f)*

A mixture of **5***e* (320 mg, 1 mmol) and pivaloyl chloride (1 mL) in dry pyridine (5 mL) was stirred overnight at room temperature and then evaporated to dryness *in vacuo*. The mixture was coevaporated with toluene as a chaser, dissolved in chloroform, and washed with 5% hydrochloric acid and water. The dried organic phase was chromatographed on a column of silicic acid (act. III) using ethyl ether – hexane (1:1), giving 300 mg (89%) of **5***f* as a syrup that solidified on standing, mp 48–49°C; ir (neat) ν_{max}: 1760, 1750 (C=O), 1630 (C=C) cm^{-1}; nmr ($CDCl_3$) δ: 0.10 (s, 6H), 0.87 (s, 9H), 1.13 (s, 9H), 3.72 (s, 3H), 3.80 (bs, 1H), 4.80 (bs, 1H), 4.88 (d, 1H, J = 5 Hz), 5.25 (d, 1H, J = 5 Hz), 7.28 (d, 1H, J = 2 Hz); mass spectrum (70 eV) *m/e*: 369 ($M^+ - CH_3$), 353 ($M^+ - OCH_3$), 327 ($M^+ - C(CH_3)_3$), 258, 201. *Anal.* calcd. for $C_{19}H_{32}O_6Si$: C 59.35, H 8.39; found: C 59.66, H 8.28.

*5-Carbomethoxy-2-*exo-*3-*endo-*di-O-*tert-*butyldimethylsilyloxy-7-oxabicyclo[2.2.1]hept-5-ene (5g)*

The mixture of **5***e* (1.14 g, 3.8 mmol), dimethyl-*tert*-butylsilyl chloride (1.44 g, 9.5 mmol) and imidazole (610 mg, 8.9 mmol) in dimethylformamide (20 mL) was stirred at room temperature for 6 h and then evaporated to dryness. The residue was dissolved in ethyl acetate, washed with water and with brine, dried over sodium sulfate, and evaporated. The resulting syrup was chromatographed on a column of silicic acid using ethyl ether – hexane (1:1), giving 600 mg (51%) of **5***g* as an oil which solidified on standing, mp 90–91°C; ir (KBr) ν_{max}: 1738 (C=O), 1630 (C=C) cm^{-1}; nmr ($CDCl_3$) δ: 0.10 (s, 12H), 0.83 (s, 9H), 0.90 (s, 9H), 3.54 (bs, 1H), 3.64 (s, 3H), 4.02 (d, 1H, J = 4 Hz), 4.62 (d, 1H, J = 1 Hz), 4.85 (d, 1H, J = 4 Hz), 7.02 (d, 1H, J = 2 Hz). *Anal.* calcd. for $C_{20}H_{38}O_5Si_2$: C 57.97, H 9.18; found: C 57.88, H 9.27.

Methyl 2-(2¹,3¹-Di-O-methoxymethyl-β-D,L-arabinofuranosyl) Glycolate (7a)

Through a solution of **5***d* (327 mg, 1.19 mmol) in dry methylene chloride at −78°C was bubbled ozone until a faintly blue color was observed. Excess ozone was flushed with dry nitrogen while the system was kept at −78°C and dimethyl sulfide (0.5 mL) was added. The mixture was allowed to rise to room temperature over a period of 5 h. The solution was then evaporated to dryness. To a precooled solution of the residue in freshly distilled tetrahydrofuran (50 mL) at 0°C was added lithium tri-*tert*-butoxyaluminum hydride (0.91 g, 3.57 mmol).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The resulting clear solution was then allowed to warm to room temperature and stirred overnight under dry nitrogen. A solution of ammonium sulfate (2 g) in water (2 mL) and Celite (1 g) were added to the reaction at 0°C. The mixture was stirred for 30 min and finally filtered over a layer of Celite. Following evaporation of the solvent the residue was dissolved in ethyl acetate, washed with water, dried ($MgSO_4$), and evaporated. The crude clear oil was crystallized from chloroform–hexane giving 222 mg (60%) of **7***a* as white crystals, mp 70–71°C; ir ($CHCl_3$) ν_{max}: 3500 (alcohol), 1745 (ester) cm^{-1}; nmr ($CDCl_3$) δ: 3.33 (s, 3H), 3.36 (s, 3H), 3.67–3.96 (m, 6H), 4.06–4.56 (m, 5H), 4.56–4.83 (m, 5H) ppm. *Anal.* calcd. for $C_{12}H_{22}O_9$: C 46.45, H 7.15; found: C 46.28, H 7.28.

Methyl 2-O-acetyl-2-(5¹-O-acetyl-2¹,3¹-di-O-methoxymethyl-β-D,L-arabinofuranosyl) Glycolate (7b)

The compound 7*a* (73 mg) was acetylated using acetic anhydride (1 mL) and pyridine (1 mL) with stirring overnight. After evaporation to dryness the residue was chromatographed on a column of silicic acid using ethyl ether – hexane (1:1) giving 84 mg (92%) of 7*b* as an oil; ir (neat) ν_{max}: 1745, 1755 (C=O) cm^{-1}; nmr ($CDCl_3$) δ: 2.00 (s, 3H), 2.03 (s, 3H), 3.21 (s, 3H), 3.24 (s, 3H), 3.26 (s, 3H), 3.90–4.13 (m, 5H), 4.13–4.30 (m, 1H), 4.32 (d, 2H, J = 1 Hz), 4.40 (s, 2H), 4.86 (s, 0.5H), 5.0 (s, 0.5H); mass spectrum (70 eV) *m/e*: 363 ($M^+ - OCH_3$), 317, 289 ($M^+ - COCH_3 - CH_3OCH_2OH$). *Anal.* calcd. for $C_{16}H_{26}O_{11}$: C 48.73, H 6.60; found: C 48.63, H 6.88.

*Methyl 2-(2¹,3¹-Di-O-methoxymethyl-5¹-O-*tert*-butyldimethylsilyl-β-D,L-arabinofuranosyl) Glycolate (7c)*

A mixture of **7***a* (169 mg, 0.54 mmol), dimethyl-*tert*-butylsilyl chloride (82 mg, 0.54 mmol), and imidazole (92 mg, 1.35 mmol) in dimethylformamide (5 mL) was stirred at room temperature for 18 h. Then the reaction mixture was added to 60 mL of ethyl ether and washed three times with water, dried, and evaporated, leaving a syrup. The latter was chromatographed on a column of silicic acid eluting with ethyl ether – hexane (2:1) giving 197 mg (85%) of **7***c* as an oil which crystallizes below room temperature; ir ($CHCl_3$) ν_{max}: 3500 (alcohol), 1745 (ester) cm^{-1}; nmr ($CDCl_3$) δ: 0.10 (s, 6H), 0.96 (s, 9H), 3.32 (s, 3H), 3.36 (s, 3H), 3.48 (m, 1H), 3.60–4.00 (m, 6H), 4.08–4.43 (m, 4H), 4.62 (bs, 4H) ppm. *Anal.* calcd. for $C_{18}H_{36}O_9Si$: C 50.94, H 8.94; found: C 50.68, H 8.37.

*Methyl 2-(2¹,3¹-Di-O-*tert*-butyldimethylsilyl-β-D,L-arabinofuranosyl) Glycolate (7d)*

After reductive ozonolysis of **5***g* (386 mg, 0.93 mmol) in methylene chloride, the solution was washed with brine twice, dried, and evaporated. To a solution of the residue in dry tetrahydrofuran (40 mL) was added lithium tri-*tert*-butoxyaluminum hydride (945 mg, 3.72 mmol) at 0°C. The resulting clear mixture was allowed to warm to room temperature and stirred overnight under nitrogen. A solution of ammonium sulfate (2 g) in water (2 mL) and Celite (1 g) were added to the reaction mixture at 0°C. The mixture was stirred for 30 min and finally filtered over a layer of Celite. The residue was washed with tetrahydrofuran. Following evaporation of the solvent the residue was dissolved in ethyl acetate, washed with water, dried, and evaporated. The residue was purified on silica gel plates using ethyl ether – hexane (2:1), giving 250 mg (59%) of 7*d* as an oil; ir ($CHCl_3$) ν_{max}: 3500 (OH), 1745 (C=O) cm^{-1}; nmr ($CDCl_3$) δ: 0.10 (m, 12H), 0.86 (s, 9H), 0.90 (s, 9H), 1.96 (bs, 1H), 2.70 (bs, 1H), 3.53–4.36 (m, 10H). *Anal.* calcd. for $C_{20}H_{42}O_7Si_2$: C 53.33, H 9.33; found: C 53.00, H 9.17.

*Methyl 2-O-acetyl-2-(5¹-O-acetyl-2¹,3¹-di-O-*tert*-butyldimethylsilyl-β-D,L-arabinofuranosyl) Glycolate (7e)*

The compound 7*d* (126 mg) was acetylated with acetic anhydride (1 mL) and pyridine (1.5 mL). After the usual work-up, the crude product was purified by column chromatography (aluminum oxide act. III) using ethyl ether – hexane (1:2) to give 136 mg (91%) of **7***e* as an oil which solidified on standing, mp 74–77°C; ir (KBr) ν_{max}: 1755 (C=O), 1240, 1080 cm^{-1}; nmr ($CDCl_3$) δ: 0.13 (m, 12H), 0.96 (s, 18H), 2.03 (s, 3H), 2.10 (s, 3H), 3.76 (s, 3H), 3.90–4.33 (m, 6H), 4.70, 4.96 (bs, 0.5H each); mass spectrum (60 eV) *m/e*: 519 ($M^+ - CH_3$), 503 ($M^+ - OCH_3$), 477 ($M^+ - C(CH_3)_3$). *Anal.* calcd. for $C_{24}H_{46}O_9Si_2$: C 53.93, H 8.61; found: C 54.12, H 8.84.

*Methyl 2-(2¹,3¹,5¹-Tri-O-*tert*-butyldimethylsilyl-β-D,L-arabinofuranosyl) Glycolate (7f)*

To a solution of 7*d* (106 mg, 0.24 mmol) in dimethylformamide (5 mL) was added dimethyl-*tert*-butylsilyl chloride (36 mg, 0.24 mmol) and imidazole (40 mg, 0.6 mmol). The mixture was stirred at room temperature for 21 h. The solvent was evaporated *in vacuo* and the residue was coevaporated several times with ethyl acetate. The residue was dissolved in chloroform, washed with water, dried, and evaporated. The resulting syrup was chromatographed on a column of alumina using ethyl ether – hexane (1:2) to give 125 mg (94%) of 7*f* as an oil; ir ($CHCl_3$) ν_{max}: 3500 (OH), 1730 (C=O) cm^{-1}; nmr ($CDCl_3$) δ: 0.10 (m, 18H), 0.92 (m, 27H), 2.96 (bs, 1H), 3.30–3.90 (m, 5H), 3.90–4.45 (m, 5H). *Anal.* calcd. for $C_{26}H_{56}O_7Si_3$: C 55.32, H 9.93; found: C 55.59, H 9.84.

*Methyl 2-O-acetyl-2-(2¹,3¹,5¹-tri-O-*tert*-butyldimethylsilyl-β-D,L-arabinofuranosyl) Glycolate (7g)*

The compound **7***f* (125 mg, 0.22 mmol) was acetylated with acetic anhydride (1.5 mL) and pyridine (1.5 mL). After the usual work-up the crude product was chromatographed on a column of alumina using ethyl ether – hexane (1:1) to give 134 mg (100%) of **7***g* as an oil which solidified on standing, mp 68–72°C; ir (KBr) ν_{max}: 1760 (C=O), 1080, 840 cm^{-1}; nmr ($CDCl_3$) δ: 0.10 (m, 18H), 0.87 (bs, 27H), 2.06 (s, 3H), 3.63 (m, 1H), 3.71 (s, 3H), 3.85–4.33 (m, 5H), 4.70, 4.85 (two bs, 1H). *Anal.* calcd. for $C_{28}H_{58}O_8Si_3$: C 55.45, H 9.55; found: C 55.16, H 9.32.

*Methyl 2-(2¹,3¹-Di-O-methoxymethyl-5¹-O-*tert*-butyldimethylsilyl-β-D,L-arabinofuranosyl) Glyoxylate (8a)*

To a solution of **7***c* (424 mg, 1 mmol) in carbon tetrachloride (40 mL) were added ruthenium dioxide dihydrate (20 mg) and a solution of sodium periodate (856 mg, 4 mmol) in water (40 mL). The pH of the reaction mixture was controlled between 6 and 7 by the addition of a 5% sodium bicarbonate solution. After 6 h, stirring at room temperature or until a yellow color persisted, the reaction was terminated by adding a few drops of isopropyl alcohol. After collection of the black precipitated solid (RuO_2) on Celite, the organic phase was washed with water and brine, dried over magnesium sulfate, and evaporated, leaving 359 mg of crude **8***a* as a low mp white solid (less than 25°C). Attempted purification by chromatography on silicic acid led to partial decomposition and accordingly the material was used directly in the next step; ir (neat) ν_{max}: 1750, 1775 (ketone, ketoester) cm^{-1}; nmr ($CDCl_3$) δ: 0.08 (s, 6H), 0.86 (s, 9H), 3.13 (s, 3H), 3.25 (s, 3H), 3.36–3.58 (m, 2H), 3.72 (s, 3H), 3.76 (m, 1H), 4.13 (bs, 1H), 4.30 (m, 1H), 4.40–4.70 (m, 4H), 5.06 (d, 1H, J = 5 Hz) ppm.

*Methyl 2-(2¹,3¹,5¹-Tri-O-*tert*-butyldimethylsilyl-β-D,L-arabinofuranosyl) Glyoxylate (8b)*

To the mixture of **7***e* (416 mg, 0.74 mmol) in carbon tetrachloride (40 mL) and ruthenium dioxide dihydrate (20 mg) was added a solution of sodium periodate (633 mg) in water (40 mL). The pH of the mixture was controlled between 6 and 7 by the addition of a 5% sodium bicarbonate solution. After vigorously stirring at room temperature until a yellow color persisted, a few drops of isopropyl alcohol were added to terminate the reaction. Ruthenium dioxide was removed on Celite and the organic

For personal use only.

phase was washed with water and brine, dried ($MgSO_4$), and evaporated, giving 353 mg of crude **8***b*; ir ($CHCl_3$) ν_{max}: 1750, 1730 (C=O) cm^{-1}; nmr ($CDCl_3$) δ: 0.13 (m, 18H), 0.86 (m, 27H), 3.76–4.00 (m, 5H), 4.13 (m, 1H), 4.33 (m, 1H), 4.53 (bs, 1H), 4.66 (d, 1H, J = 4 Hz).

*2-(2¹,3¹-Di-O-methoxymethyl-5¹-O-*tert*-butyldimethylsilyl-β-D,L-arabinofuranosyl)maleimide (9*a*)*

A solution of carbamoylmethylenetriphenylphosphorane (400 mg, 1.2 mmol) and the crude ketoester **8***a* (450 mg, 1.07 mmol) in freshly distilled chloroform (20 mL) was stirred at room temperature for 2 h. The solvent was then evaporated and the residue was purified by chromatography on a silica gel column using petroleum ether – ethyl acetate (3:1), giving 216 mg (47%) of solid **9***a*, mp 49–50°C; ir ($CHCl_3$) ν_{max}: 3460, 3250 (alcohol, amine), 1740, 1790 (maleimide), 1655 (olefin) cm^{-1}; nmr ($CDCl_3$, D_2O), 100 MHz δ: 0.10 (s, 6H, $Si(CH_3)_2$), 0.82 (s, 9H, $C(CH_3)_3$), 3.20 (s, 3H, OCH_3), 3.26 (s, 3H, OCH_3), 3.53–3.70 (m, 2H, $SiOCH_2CH$), 3.70–4.10 (m, 1H, $SiOCH_2CH$), 4.30 (d, 1H, OCH_2OCH, J = 2 Hz), 4.50 (d, 1H, OCH_2OCH, J = 4 Hz), 4.65 (q, 2H, CH_3OCH_2), 4.80 (q, 2H, CH_3OCH_2), 5.0 (q, 1H, "anomeric" proton, J_1 = 4 Hz, J_2 = 3 Hz), 6.39 (d, 1H, C=CH, J = 2 Hz); ms (70 eV) *m/e*: 431 (M^+), 400 ($M^+ - OCH_3$), 374 ($M^+ - C(CH_3)_3$), 328. *Anal.* calcd. for $C_{19}H_{33}NO_8Si$: C 52.90, H 7.66, N 1.62; found: C 52.68, H 7.76, N 1.49.

*2¹-*Epi*-showdomycin (9*b*)*

A solution of **9***a* (212 mg, 0.5 mmol) in a mixture of trifluoroacetic acid – water–tetrahydrofuran (4:1:1) (12 mL) was stirred at room temperature for 4 h. After evaporation to dryness *in vacuo* the residue was crystallized from acetone–hexane to give 68 mg (60%) of **9***b* with mp 170–171°C; ir (KBr) ν_{max}: 3470, 3110 (alcohol, amine), 1775, 1720 (maleimide), 1625 (olefin) cm^{-1}; uv (λ_{max}^{EtOH}): 222 nm (log ε 4.36); nmr (D_2O), 100 MHz δ: 3.8–3.9 (m, 2H, $HOCH_2$—CH), 4.1–4.25 (m, 1H, $HOCH_2CHO$), 4.28 (q, 1H, J_1 = 2 Hz, J_2 = 3 Hz), 4.55 (q, 1H, J_1 = 2 Hz, J_2 = 4 Hz), 5.1 (q, 1H, "anomeric" H, J_1 = 2 Hz, J_2 = 4 Hz), 6.85 (d, 1H, C=CH, J = 2 Hz); ms (70 eV) *m/e*: 229 (M^+), 211 ($M^+ - H_2O$), 180, 140 ($M^+ - HOCHCH_2B$), 127 (B + 31), 126 (B + 30), 110, 87, 85, 69, 57, 55, 45, 44, 43, 32, 31, 28 (B is maleimide). *Anal.* calcd. for $C_9H_{11}NO_6$: C 47.16, H 4.80, N 6.15; found: C 47.05, H 4.75, N 6.08.

3,4-Di-O-methoxymethyl-2,5-anhydro-D,L-glucose (10)

To a solution of **5***d* (230 mg, 0.84 mmol) in methylene chloride was bubbled ozone until a faintly blue color was observed. Excess ozone was flushed with dry nitrogen and evaporation of solvent left a white foam. The ozonide in isopropanol was treated with sodium borohydride (500 mg) at 0°C and then refluxed for 4 h. The solution was then cooled in an ice-bath and stirred with 50% aqueous acetic acid (10 mL) for 30 min and evaporated *in vacuo*. The residue was coevaporated with ethanol and dissolved in water and stirred with sodium periodate (300 mg) for 1 h at room temperature. The resulting precipitate was removed by filtration on cotton and the filtrate extracted with chloroform three times. The organic phase was dried and evaporated, giving 77 mg (37%) of **10** as a colorless syrup; ir ($CHCl_3$) ν_{max}: 3500, 3420 (OH), 2840, 2800 cm^{-1}; nmr ($CDCl_3$) δ: 3.36 (bs, 6H), 3.56 (bs, 1H), 3.90 (m, 1H), 3.93–4.27 (m, 3H), 4.36 (m, 2H), 4.72 (m, 4H), 4.98 (bs, 1H). *Anal.* calcd. for $C_{10}H_{18}O_7$: C 47.99, H 7.25; found: C 47.65, H 7.51.

N-methyl 2-(2¹,3¹-Di-O-methoxymethyl-β-D,L-arabinofuranosyl) Thiazolidine and its 5¹-Acetate (11b)

To a solution of **10** (77 mg, 0.31 mmol) in dry benzene (15 mL) was added *N*-methylthioethanolamine (31 mg, 0.34 mmol). The reaction mixture was stirred overnight at room temperature. After evaporation of the solvent the crude product (**11***a*) was directly acetylated with acetic anhydride in pyridine. The compound (**11***b*) was purified by a column of alumina using chloroform to give 86 mg (77%) of **11***b* as a colorless oil; ir ($CHCl_3$) ν_{max}: 2870, 2830 (N—CH_3), 1755 (C=O) cm^{-1}; nmr ($CDCl_3$) δ: 2.03 (s, 3H), 2.30, 2.40 (s + s, 3H), 2.60–3.26 (m, 4H), 3.30 (s, 3H), 3.40 (s, 3H), 3.90–4.23 (m, 6H), 4.37–4.53 (m, 1H), 4.57–4.76 (m, 4H); mass spectrum (70 eV) *m/e*: 365 (M^+), 333 ($M^+ - CH_3OH$), 318 ($M^+ - CH_2SH$), 102. *Anal.* calcd. for $C_{15}H_{27}NO_7S$: C 49.32, H 7.40, N 3.84, S 8.77; found: C 49.53, H 7.60, N 4.08, S 8.53.

Ethyl trans*-3-(2¹,3¹-Di-O-methoxymethyl-β-D,L-arabinofuranosyl) Acrylate (12a)*

To a solution of crude **10** (144 mg, 0.58 mmol) in methylene chloride (10 mL) was added carbethoxymethylenetriphenylphosphorane (242 mg, 0.69 mmol). After 4 h at room temperature, the solvent was evaporated and the residue was partitioned between chloroform and water. The organic phase was dried over sodium sulfate and evaporated. The residue was chromatographed on a column of alumina using chloroform, eluting 143 mg (79%) of **12***a* as a chromatographically homogeneous syrup; ir ($CHCl_3$) ν_{max}: 3500 (OH), 1730 (C=O), 1680 (C=C) cm^{-1}; nmr ($CDCl_3$) δ: 1.23 (t, 3H, J = 7 Hz), 2.23 (t, 1H, J = 6 Hz), 3.26 (s, 3H), 3.30 (s, 3H), 3.53–4.30 (m, 8H), 4.52 (d, 2H, J = 2 Hz), 4.60 (s, 2H), 5.98 (d, 1H, J = 14 Hz), 6.85 (dd, 1H, J = 14 Hz, J = 4 Hz); mass spectrum (70 eV) *m/e*: 320 (M^+), 289 ($M^+ - OCH_3$), 243, 230 ($M^+ - 2CH_3OCH_2$). *Anal.* calcd. for $C_{14}H_{24}O_8$: C 52.49, H 7.55; found: C 52.48, H 7.62.

Ethyl trans*-3-(5¹-O-acetyl-2¹,3¹-di-O-methoxymethyl-β-D,L-arabinofuranosyl) Acrylate (12b)*

The compound **12***a* (40 mg, 0.13 mmol) was acetylated using acetic anhydride (1 mL) and pyridine (2 mL). Evaporation to dryness and separation on a column of alumina, eluting with chloroform gave 40 mg (89%) of **12***b* as a colorless oil; ir ($CHCl_3$) ν_{max}: 1750, 1730 (C=O), 1680 (C=C) cm^{-1}; nmr ($CDCl_3$) δ: 3.27 (t, 3H, J = 6 Hz), 2.06 (s, 3H), 3.28 (s, 3H), 3.33 (s, 3H), 3.90–4.30 (m, 8H), 4.57 (d, 2H, J = 2 Hz), 4.62 (s, 2H), 6.02 (d, 1H, J = 14 Hz), 6.88 (dd, 1H, J = 14 Hz, J = 4 Hz); mass spectrum (70 eV) *m/e*: 362 (M^+), 331 ($M^+ - OCH_3$), 317 ($M^+ - 2CH_3O$), 272 ($M^+ - 2CH_3OCH_2$). *Anal.* calcd. for $C_{16}H_{26}O_9$: C 53.03, H 7.23; found: C 53.10, H 7.32.

Diol 14a from Olefin 13

The olefin **13** (452 mg, 2 mmol) in dry methylene chloride (50 mL) was treated with ozone at −78°C until the blue colour persisted. The excess ozone was removed by bubbling in dry nitrogen gas, and then 1 mL of dimethyl sulfide was added at −78°C. The solution was then allowed to warm up to room temperature with stirring, at which time it was evaporated.

To the resulting oily residue in dry tetrahydrofuran (THF), (50 mL) at 0°C under a nitrogen atmosphere was added lithium aluminum tri-(*tert*-butoxy) hydride (7.0 mmol, 1.78 g). After stirring at 0°C for 3 h, ammonium sulfate (2 g) in 10 mL of water was added, and the stirring continued for another 30 min. The mixture was then filtered, and the residue washed with 25 mL of THF, the combined filtrates were evaporated to dryness and the resulting residue was dissolved in ethyl acetate (50 mL), washed with brine (20 mL × 3), dried (Na_2SO_4), and evaporated to afford 315 mg (65%) of diol **14***a*; ir ($CHCl_3$) ν_{max}: 3650–3350 (OH), 1755 (C=O), 1395 cm^{-1}; nmr ($CDCl_3$) δ: 1.33 (s, 3H), 1.52 (s, 3H), 3.66 (d, 2H, J = 4.0 Hz, CH_2OH), 3.76 (s, 3H, $COOCH_3$), 3.78–4.85 (m, 7H, two deuterium exchangeable protons) ppm; ms (80°C) *m/e*: 262 (M^+), 247 ($M^+ - CH_3$), 230 ($M^+ - CH_2OH$), 203 ($M^+ - COOCH_3$), 201, 187, 185, 173 ($M^+ - CHOHCOOCH_3$), 169, 139, 85, 83. *Anal.* calcd. for $C_{11}H_{18}O_7$: C 50.38, H 6.91; found: C 50.59, H 6.76.

*Diacetate 14 (R = R¹ = Ac) from Diol 14*a

The diol **14***a* (131 mg, 0.5 mmol) was stirred overnight at room temperature in 5 mL pyridine – acetic anhydride (3:2). After the removal of the solvent, chloroform (25 mL) was added to the residue and the solution washed with dilute hydrochloric acid (10 mL × 2), water (10 mL × 2), dried (Na_2SO_4), and evaporated. The diacetate **14** (R = R¹ = Ac) was obtained in quantitative yield; ir ($CHCl_3$) ν_{max}: 1765 and 1755 (C=O), 1390 cm^{-1}; nmr ($CDCl_3$) δ: 1.35 (s, 3H), 1.52 (s, 3H), 2.08 (s, 3H, CO*CH*$_3$), 2.19 (s, 3H, COC*H*$_3$), 3.75 (s, 3H, COOC*H*$_3$), 4.12 (bs, 2H, C*H*$_2$OCOCH$_3$), 4.22–4.95 (m, 4H), 5.12 (d, *J* = 4 Hz, C*H*OCOCH$_3$) ppm; ms (150°C) *m/e*: 346 (M^+), 331 ($M^+ - CH_3$), 287 ($M^+ - COOCH_3$), 271, 245, 243, 229, 215, 211, 201, 179, 169. *Anal.* calcd. for $C_{15}H_{22}O_9$: C 52.03, H 6.35; found: C 52.33, H 6.75.

*Monosilylated Diol 14*b *from Diol 14*a

To the diol **14***a* (524 mg, 2 mmol) and imidazole (340 mg, 5 mmol) in *N,N*-dimethylformamide (5 mL) was added *tert*-butyldimethylchlorosilane (302 mg, 2 mmol). After stirring at room temperature for 18 h, the solvent was removed under high vacuum. To the residue was then added ethyl acetate (50 mL) and the solution was washed with water (20 mL × 3), dried (Na_2SO_4), and evaporated. The crude product was chromatographed on silica gel. Elution with ether–hexane (1:1) afforded 677 mg (90%) of the silyl ether **14***b*; ir ($CHCl_3$) ν_{max}: 3550 and 3400 (OH), 1770 (C=O), 1395 cm^{-1}; nmr ($CDCl_3$) δ: 0.13 (s, 6H, Si(C*H*$_3$)$_2$), 0.92 (s, 9H, Si—*t*Bu), 1.32 (s, 3H), 1.50 (s, 3H), 3.73 (bs, 5H, COOC*H*$_3$ and C*H*$_2$OSi), 3.86–4.82 (m, 6H) ppm; ms (180°C) *m/e*: 361 ($M^+ - CH_3$), 317 ($M^+ - COOCH_3$), 287 ($M^+ - CHOHCOOCH_3$), 261 ($M^+ - (CH_3)_2Si$—*t*Bu), 201. *Anal.* calcd. for $C_{17}H_{32}O_7Si$: C 54.25, H 8.51; found: C 54.55, H 8.72.

*Monoacetate 14*c *from Monosilylated Diol 14*b

The acetate **14***c* was prepared from the alcohol **14***b* by the usual acetylation procedure; ir ($CHCl_3$) ν_{max}: 1770 (C=O), 1395 cm^{-1}; nmr ($CDCl_3$) δ: 0.08 (s, 6H, (C*H*$_3$)$_2$), 0.8 (s, 9H, Si—*t*Bu), 1.32 (s, 3H), 1.50 (s, 3H), 2.11 (s, 3H, COC*H*$_3$), 3.60 (d, 2H, *J* = 5 Hz, C*H*$_2$OSi), 3.68 (s, 3H, COOC*H*$_3$), 3.83–4.78 (m, 4H), 5.08 (d, 1H, *J* = 5 Hz, C*H*OCOCH$_3$) ppm; ms (170°C) *m/e*: 403 ($M^+ - CH_3$), 387 ($M^+ - OCH_3$), 361 ($M^+ - t$Bu), 303 ($M^+ - (CH_3)_2Si$—*t*Bu), 261, 243, 201.

Silylated Diol 14 (R = R¹ = (CH$_3$*)*$_2$*Si*—t*Bu) from Diol 14*a

The disilyl ether **14** (R = R¹ = $(CH_3)_2Si$—*t*Bu) was prepared with two equivalents of *tert*-butyldimethylchlorosilane from **14***a* by the usual silylation procedure; nmr ($CDCl_3$) δ: 0.07 (s, 12H, 2 Si(C*H*$_3$)$_2$), 0.89, 0.92 (each s, 18H, 2 Si—*tBu*), 1.29 (s, 3H), 1.49 (s, 3H), 3.56 (m, 2H), 3.63 (s, 3H, COOC*H*$_3$), 3.80–4.72 (m, 5H) ppm.

Monosilylated Diol 14 (R = H, R¹ = (CH$_3$*)*$_2$*Si*—t*Bu) from Silylated Diol 14 (R = R¹ = (CH*$_3$*)*$_2$*Si*—t*Bu)*

Disilyl ether **14** (R = R¹ = $(CH_3)_2Si$ +) (490 mg, 1 mmol) was stirred in a solution of acetic acid – water–THF (3:1:1) (5 mL) at room temperature for 20 h. After evaporation of the solution, chloroform (40 mL) was added to the residue, which was washed with saturated sodium bicarbonate solution (15 mL × 2), water (15 mL), then dried (Na_2SO_4) and evaporated. The alcohol **14** (R = H, R¹ = $(CH_3)_2Si$ +) was obtained in 90% yield; ir ($CHCl_3$) ν_{max}: 3550 (OH), 1770 (C=O), 1400, 1395 cm^{-1}; nmr ($CDCl_3$) δ: 0.08, 0.11 (each s, 6H, Si(C*H*$_3$)$_2$), 0.95 (s, 9H, Si—*t*Bu), 1.33 (s, 3H), 1.54 (s, 3H), 2.77 (bs, 1H, O*H*), 3.66 (m, 2H, C*H*$_2$OH), 3.76 (s, 3H, COOC*H*$_3$), 3.96–4.82 (m, 5H) ppm.

Monoacetate 14 (R = Ac, R¹ = (CH$_3$*)*$_2$*Si*—t*Bu) from Monosilylated Diol 14 (R = H, R¹ = (CH*$_3$*)*$_2$*Si*—t*Bu)*.

Monoacetate **14** (R = Ac, R¹ = $(CH_3)_2Si$—*t*Bu) was prepared from alcohol **14** (R = H, R¹ = $(CH_3)_2Si$—*t*Bu) by the usual acetylation procedure; ir ($CHCl_3$) ν_{max}: 1760 (C=O), 1400, 1390 cm^{-1}; nmr ($CDCl_3$) δ: 0.08, 0.11 (each s, 6H, Si(C*H*$_3$)$_2$), 0.92 (s, 9H, Si—*t*Bu), 1.32 (s, 3H), 1.53 (s, 3H), 2.03 (s, 3H, COC*H*$_3$), 3.70 (s, 3H, COOC*H*$_3$), 4.12 (s, 2H, C*H*$_2$OCOCH$_3$), 4.16–4.85 (m, 5H) ppm.

*Lactone 15 from Monosilylated Diol 14*b

To alcohol **14***b* (94 mg, 0.25 mmol) in methylene chloride (5 mL) was added 15 equivalents of chromium trioxide – pyridine complex in methylene chloride (10 mL). After stirring for 30 min at room temperature, the solution was decanted from the black residue, and the residue was triturated with anhydrous ether (20 mL). The combined organic layers were washed with 5% HCl (15 mL), saturated sodium bicarbonate solution (15 mL), and brine (15 mL), followed by drying (Na_2SO_4) and evaporation. Recrystallization from petroleum ether (bp 30–60°C) afforded 59 mg (78%) lactone **15**; ir ($CHCl_3$) ν_{max}: 1800 (lactone C=O), 1395 cm^{-1}; nmr ($CDCl_3$) δ: 0.07 (s, 6H, Si(C*H*$_3$)$_2$), 0.86 (s, 9H, Si—*t*Bu), 1.36 (s, 3H), 1.44 (s, 3H), 3.73 (m, 2H, C*H*$_2$OSi), 4.29–4.79 (m, 4H) ppm; ms (270°C) *m/e*: 287 ($M^+ - 15$), 258, 217. *Anal.* calcd. for $C_{14}H_{26}O_5Si$: C 55.63, H 8.61; found: C 55.98, H 8.94.

*Keto-ester 16 from Monosilylated Diol 14*b

Alcohol **14***b* (320 mg, 1 mmol) was stirred in dimethyl sulfoxide – acetic anhydride (3:2) (3 mL) overnight at room temperature. The solution was further stirred for 15 min after the addition of chloroform (25 mL) and saturated Na_2CO_3 solution (15 mL). The organic layer was washed with water (10 mL × 2), dried (Na_2SO_4), and evaporated. The unstable keto-ester **16** was obtained in 80% yield; ir ($CHCl_3$) ν_{max}: 1755 and 1745 (C=O), 1400, 1390 cm^{-1}; nmr ($CDCl_3$) δ: 0.07 (s, 6H, Si(C*H*$_3$)$_2$), 0.86 (s, 9H, Si—*t*Bu), 1.37 (s, 3H), 1.52 (s, 3H), 3.67 (m, 2H, C*H*$_2$OSi), 3.80 (s, 3H, COOC*H*$_3$), 4.06–4.96 (m, 4H) ppm.

D,L-Showdomycin Derivative 17 from Keto-ester 16

To keto-ester **16** (374 mg, 1 mmol) in dry chloroform (10 mL) was added carbamoylmethylenetriphenylphosphorane (319 mg, 1 mmol). After stirring at room temperature for 3 h, the crude product was purified by silica plates to afford 134 mg (35%) of D,L-showdomycin derivative **17**; ir ($CHCl_3$) ν_{max}: 3480 (maleimide NH), 2985, 2895, 1795, 1745, 1395 cm^{-1}; uv (EtOH) λ_{max}: 222 nm (ε 13 400), shoulder ~ 275 nm (ε 1430); nmr ($CDCl_3$) δ: 0.07 (s, 6H, Si(*CH*$_3$)$_2$), 0.87 (s, 9H, Si—*tBu*), 1.35 (s, 3H), 1.57 (s, 3H), 3.66 (m, 2H, *CH*$_2$OSi), 4.13 (bm, 1H), 4.55–4.82 (m, 3H), 6.41 (t, 1H, *J* = 2 Hz), 7.99 (bm, 1H, N*H*) ppm; ms (150°C) *m/e*: 368 ($M^+ - CH_3$), 326 ($M^+ - t$Bu), 268 ($M^+ - (CH_3)_2Si$—*t*Bu).

D,L-Showdomycin 18 from D,L-Showdomycin Derivative 17

To showdomycin derivative **17** (383 mg, 1 mmol) was added 3 mL of trifluoroacetic acid – water 4:1. After stirring at room temperature for 10 min, the solution was evaporated to dryness. Recrystallization from benzene–acetone afforded 176 mg (77%) D,L-showdomycin **18**, mp 143–144°C; nmr (acetone-d_6) δ: 3.15–4.75 (m, 10H), 6.60 (t, 1H, *J* = 2 Hz); ms (180°C) *m/e*: 229 (M^+), 211 ($M^+ - H_2O$), 180, 156, 152, 140, 139, 127 (B + 31), 126 (B + 30), 123, 110, 85, 73.

*Hydrazone 16*a *from Keto-ester 16*

To keto-ester **16** (374 mg, 1 mmol) and pyridine (87 mg, 1.1 mmol) in methanol (10 mL) was added ethyl hydrazinoacetate hydrochloride (170 mg, 1.1 mmol). After stirring at room temperature overnight, the solution was evaporated to dryness. Chloroform (40 mL) was added to the residue, which was washed (2 × 15 mL H_2O), dried (Na_2SO_4), and evaporated. The crude product was purified by silica plates to afford 389 mg (82%) hydrazone **16***a* as *syn*- and *anti*-isomers. (*Syn*-isomer) ir ($CHCl_3$) ν_{max}: 3300 (NH), 2985, 2890, 1760 (C=O), 1700 (C=N), 1400, 1390 cm^{-1}; uv (EtOH) λ_{max}: 294 nm (ε 13 800);

nmr ($CDCl_3$) δ: 0.05 (s, 6H, $Si(CH_3)_2$), 0.89 (s, 9H, Si—*t*Bu), 1.26 (t, 3H, $J = 7$ Hz, CH_2CH_3), 1.34 (s, 3H), 1.52 (s, 3H), 3.57 (d, 2H, $J = 5$ Hz, CH_2OSi), 3.73 (s, 3H, $COOCH_3$), 3.86–5.05 (m, 8H), 10.21 (bm, 1H, N*H*); ms (140°C) *m/e*: 474 (M^+), 459 ($M^+ - CH_3$), 417 ($M^+ - t$Bu).

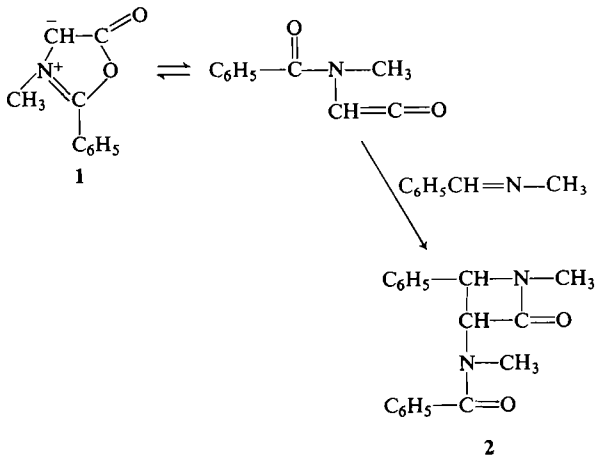
Cycloaddition reactions of *meso*-ionic oxazolone with cinnamaldehyde anils

BIR SAIN, GOPALAKRISHNA THYAGARAJAN, AND JAGIR S. SANDHU
Regional Research Laboratory, Jorhat-785006, India

Received January 16, 1980

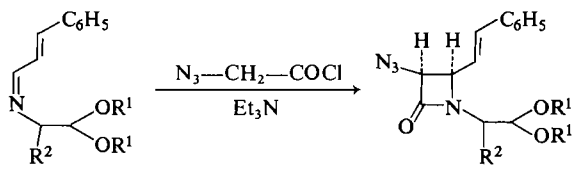
BIR SAIN, GOPALAKRISHNA THYAGARAJAN, and JAGIR S. SANDHU. Can. J. Chem. **58**, 2034 (1980).



During the reaction of the azlactone **5** with different cinnamaldehyde anils, we obtained α-pyridones with no evidence for the formation of β-lactams. The products have been characterized through elemental and spectral analyses.

BIR SAIN, GOPALAKRISHNA THYAGARAJAN et JAGIR S. SANDHU. Can. J. Chem. **58**, 2034 (1980).

La réaction de l'azalactone **5** avec différents anils de l'aldéhyde cinnamique a conduit à des α pyridones sans formation apparente de β lactames. On a caractérisé les composés par des analyses élémentaires et spectrales.

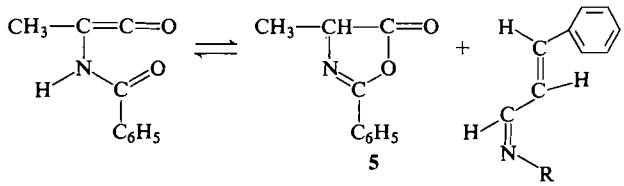


[Traduit par le journal]

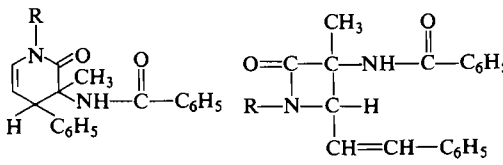
Huisgen first discovered that azlactones (Δ^2-oxazolin-5-ones) can undergo cycloaddition reactions with a variety of multiple bonds (1), with the elimination of carbon dioxide. However, benzylidene-methylamine reacted with oxazolone **1** to give a β-lactam structure **2**, the formation of which was explained via ketene intermediate (2).

1 **2**

Addition reactions of ketene on to C=N bonds have been of much interest in view of conflicting reports. In particular the products obtained from cinnamaldehyde anils had been in considerable controversy. Staudinger (3) claimed the formation of β-lactams from dimethyl ketene and diphenyl ketene, whereas Pfleger and Jager (4) claimed the formation of α-pyridones, when phenyl ketene and ketene were used. Recently Doyle *et al.* (5) have prepared β-lactam precursors **4** from **3** for the synthesis of their nuclear analogs of β-lactam antibiotics.[1]



3 **4**



a $R^1 = CH_3$, $R^2 = H$
b $R^1 = C_2H_5$, $R^2 = COOC_2H_5$

Just *et al.* (6) have also demonstrated the formation of *cis* β-lactams when the *N*-alkyl part is replaced by aromatic amines; however, in some cases β-lactams formed were found not to have *cis* geometry.

We have used azlactone **5** (which on analogy to Huisgen's findings can equilibrate to ketene) and are able to obtain α-pyridones, with no evidence for the formation of β-lactams.

5 **6**(*a–h*)

7(*a–h*) **8**(*a–h*)

a R = C_6H_5
b R = $C_6H_4OCH_3(p)$
c R = $C_6H_4Br(p)$
d R = $C_6H_4Cl(p)$
e R = $C_6H_3Cl_2(2,4)$
f R = $C_6H_4CH_3(p)$
g R = CH_3
h R = C_6H_{11}

[1]Azido-acetyl chloride and cinnamaldehyde anils reacted in the presence of triethylamine to give β-lactam analogs. T. W. Doyle, personal communication.

Equimolecular quantities of oxazolone **5** and anil **6***a* dissolved in dry benzene and allowed to stand at room temperature gave on evaporation a white crystalline solid, mp 240°C, in 85% yield. The ir(KBr) spectral analysis clearly ruled out the formation of any β-lactam of the type **8***a*, which is likely to absorb well above 1740 cm^{-1} (5). A strong band at 1699 cm^{-1}, weaker ones at 1667 cm^{-1} and 3350 cm^{-1}, corresponded to amide and NH respectively. The nmr spectrum ($CDCl_3$) δ: 8.12(s, 1H), 7.24–7.67(m, 15H), 6.43(dd, 1H), 5.23(dd, 1H), 5.00(m, 1H), 1.15(s, 3H) is consistent with structure **7***a*. The position of olefinic protons did not show significant shift even when the *N*-aryl group was replaced by an *N*-alkyl group (see **7** (*g* and *h*), Table 2). Presumably this behaviour is because of the 2-keto group present, which influences the electronic distribution significantly. The mass spectrum showed a molecular ion at *m/e* 382 (0.02%) and major fragments at 261(80%), 260(100%), 232(10%), 208(40%), 206(30%), 105(50%), and 77(30%). Plausible schemes showing these fragmentations are given below.

The reaction was generalized by employing different cinnamaldehyde anils using aromatic as well as aliphatic amines. In all the cases investigated we obtained α-pyridone analogs of **7***a* only and there was no evidence for the formation of β-lactam analogs of **8***a*. The characteristics of these pyridones thus obtained are given in Tables 1 and 2.

Duran *et al.* (7, 8) described the formation of α-chloro-2-pyridones from cinnamylidene anils and dichloro ketene and proposed two mechanistic pathways. One involved a dipolar intermediate and the other an acyl intermediate. In our case the reaction appears to proceed through dipolar intermediate **9** since the reaction rate was found to be dependent on the nucleophilicity of nitrogen.

Further investigation using differently substituted azlactones and imines is in progress.

Experimental

Melting points were taken in open capillary on a Büchi apparatus and are uncorrected. The nmr spectra were recorded on a Varian-A-60T instrument with chemical shift values recorded in δ parts per million relative to internal standard (tetramethylsilane). Mass spectra were determined on a AEI MS 30 instrument. The infrared spectra were recorded on a Perkin Elmer 237B ir spectrometer.

The anils **6** described in this study were prepared by known methods and mp/bp values agreed with those recorded in the literature.

Typical Procedure for the Formation of Oxazolone 5

A suspension of DL-α-benzoyl alanine (1.93 g, 0.01 mol) in acetic anhydride (30 mL) was warmed to 50°C. A clear solution was obtained in about 15 min. Acetic acid and excess acetic anhydride were rapidly removed *in vacuo* at 50°C (bath temperature); the residue thus obtained was dissolved in 10 mL of dry benzene. This solution of oxazolone **5** (0.01 mol) was directly used for reaction purposes.

General Procedure for the Reaction between Schiff Bases and Oxazolone

To a solution of cinnamylidene–aniline **6***a* (2.07 g, 0.01 mol) in 10 mL of dry benzene, a solution of oxazolone **5** (0.01 mol) in dry benzene (10 mL) was added at room temperature. The mixture was allowed to stand for 16 h, and the separated solid filtered to give 2.8 g of pyridone. An additional 0.447 g of the compound was obtained by evaporating the filtrate *in vacuo* and working up the residue. The product obtained was crystallized from benzene. Total yield 85%, mp 240°C.

Pyridones **7** (*b–f*) were similarly prepared. Pyridone **7***g* and **7***h* could be obtained only when the reaction was allowed to proceed at 4°C for 12 h. In all the cases benzene was used as the solvent for crystallization.

Spectral and photochromic properties of two long-chain spiropyranindoline monolayers at the air–solid interface[1]

MARCEL MORIN, ROGER M. LEBLANC, AND ILONA GRUDA

Groupe de Recherche en Biophysique, Département de Chimie–Biologie, Université du Québec à Trois-Rivières, Trois-Rivières (Qué.), Canada G9A 5H7

Received January 21, 1980

MARCEL MORIN, ROGER M. LEBLANC, and ILONA GRUDA. Can. J. Chem. **58**, 2038 (1980).

Some long-chain spiropyranindolines have been studied at the air–water and the air–solid interfaces. We have measured the surface pressure – area isotherms of these compounds and two of them are characterized by a solid film. We have also investigated the spectroscopic properties (uv–visible) of these spiropyranindolines in monolayer and in solution. The deposition of monolayers on quartz slides allowed the study of the photochromic properties of these compounds at the air–solid interface. The 3′,3′-dimethyl-1′-hexadecyl-6-nitrospiro(2H-1-benzopyran-2,2′-indoline), irradiated at 253.7 nm, showed the appearance of a new absorption band at 570 nm which varied in intensity when the number of monolayers and the time of irradiation were changed.

MARCEL MORIN, ROGER M. LEBLANC et ILONA GRUDA. Can. J. Chem. **58**, 2038 (1980).

L'étude de quelques spiropyranindolines possédant un substituant à longue chaîne a été effectuée aux interfaces air–eau et air–solide. Nous avons mesuré les isothermes de pression de surface de ces substances à l'interface air–eau. Deux d'entre elles sont caractérisées par un film solide. Les propriétés spectroscopiques (uv–visible) de ces spiropyranindolines ont été étudiées en solution et en monocouche. La déposition de monocouches sur lamelles de quartz a permis l'étude des propriétés photochromiques de ces substances à l'interface air–solide. Le 3′,3′-diméthyl-1′-hexadécyl-6-nitrospiro (2H-1-benzopyran-2,2′-indoline), irradié à 253.7 nm, a démontré l'apparition d'une nouvelle bande d'absorption à 570 nm dont l'intensité varie avec le nombre de monocouches et le temps d'irradiation.

Introduction

The photochromic process involves a reversible modification in the structure of molecules during irradiation. There has been an increasing interest in the understanding of the mechanisms of these processes, their kinetics and their fatigue phenomena in solution as well as in solid films or membranes (1).

Spiropyranindolines are well-known for their photochromic properties. The spectral, electrical, and photochromic properties of these compounds have been widely studied (1–5). In solid films, there are many studies on the photochromic properties of the spiropyrans alone (6–8) or complexed with polymers (9–12). These photochromic properties were investigated by uv–visible spectroscopy (1–5, 7–13) or by uv–laser irradiation (14, 15).

Recently, Kato *et al.* (13) have prepared photoresponsive membranes by incorporating a photochromic spiropyran with phosphatidylcholine in a cellulose acetate membrane. The membrane-bound spiropyran exhibited normal photochromism: a colorless form under visible light irradiation and a colored form under uv light irradiation. Only one study has investigated the photochromic properties of a spiropyranindoline in monomolecular state. In their paper, Polymeropoulos and Mobius (16) reported the surface pressure and surface potential properties of mixed monolayers of a long-chain spiropyran with tripalmitine as well as the photochromic properties of these mixed monolayers. They observed, from their experiments, a photochromic reaction not only in a monomolecular film at the air–water interface but also in a monolayer system at the air–solid interface.

Recently, we synthesized nine long-chain spiropyranindolines (17) and studied the monolayer properties of these compounds at air–water interface. Two of them showed a solid isotherm at relatively high surface pressure[2] (above 15 mN m^{-1}) while the others exhibited some inflections in the isotherms between 5 and 15 mN m^{-1}, probably due to some modifications in the conformation of the compounds during the compression.

We present in this paper the surface-pressure properties of some long-chain spiropyranindolines at the air–water interface. Their spectral properties in monolayers as well as in solution along with their photochromic properties at the air–solid interface are described.

Experimental

Material

The 3′,3′-dimethyl-1′-hexadecyl-6-nitrospiro-(2H-1-benzopyran-2,2′-indoline) and 1,3-dimethyl-3-hexadecyl-8′-nitro-

[1]Part III of Photochromic Studies in Monolayers.

[2]In our previous paper (17), these two spiropyranindolines were mentioned as compounds **7***c* and **8***b*. We must read **8***c* instead of **8***b*, i.e. 1,3-dimethyl-3-hexadecyl-8′-nitrospiro-(indoline-2,3′-(3H)-naphtho(2,1-*b*)-pyran).

spiro)indoline-2,3′-(3H)-naphtho(2,1-*b*)-pyran) were synthesized and purified according to the method described previously (17). Absolute ethanol (95%) and certified grade *n*-hexane (99 mol% pure) (Fisher Sci. Co., Montreal) were used, without purification, as solvents in spectroscopic experiments.

For all the monolayer experiments, "Analar" grade diethyl ether (BDH Chemicals, Montreal) was used as spreading solvent. Phosphate buffer was prepared from certified ACS grade sodium phosphate monobasic and dibasic (Fisher Sci. Co., Montreal). Arachidic acid (99+% pure) was purchased from Applied Sciences Laboratories, State College, PA. Distilled water was prepared by, first, filtering and demineralizing tap water on a Super-Q™ Millipore system (Millipore Co., Mississauga, Ontario) and, subsequently, by distilling twice on a glass system, using potassium permanganate and sodium hydroxide in the first distillation. Finally, the distilled water was filtered in Millipore (0.22 μ) to eliminate all particles and microorganisms.

Quartz cells (path length of 1, 2, and 10 mm) for spectroscopic studies in solution were obtained from Hellma Canada Ltd., Toronto. Quartz slides (5.00 cm × 2.50 cm × 0.10 cm) for spectroscopic studies in monolayers were purchased from Esco Products, NJ, U.S.A. The low pressure mercury light source (253.7 nm, 2.5 mW) was purchased from Sargent-Welch Co., Montreal.

Absorption spectra were recorded on Perkin-Elmer Coleman 124 or Unicam SP-1800 spectrophotometers.

Methods

For the determination of the surface pressure – area isotherms and the deposition of the monolayer on slide, we utilized a simple Langmuir-type film balance described elsewhere (18, 19). The calibration of the balance was achieved with arachidic acid and the sensitivity of the balance was 0.229 ± 0.005 mN m^{-1} deg^{-1}. To adjust the pH of the subphase to 7.5–8.0, we used sodium phosphate (10^{-3} mol dm^{-3}). The water temperature was maintained at 18.0 ± 0.5°C and the room temperature at 19.0 ± 1.0°C.

The monolayers were formed at the air–water interface by delivering the spreading solution (100 μL) at 5 mm above the water surface with a Hamilton microsyringe and by compressing the molecules manually at a constant speed of 2.8 $Å^2$ $molecule^{-1}$ min^{-1}. Approximately 10 min were allowed to let the solvent evaporate and the molecules equilibrate before starting compression. The isotherms were repeated at least five times each so as to obtain a good reproducibility of the results (±1–2 $Å^2$ $molecule^{-1}$ and ±0.2 mN m^{-1}).

To clean the quartz slides, we immersed them in hot sulfochromic acid or in a mixture of concentrated sulfuric acid and hydrogen peroxide 50% (1:1 v/v) for about 10 min. After that, the slides were rinsed many times, with bi-distilled water. Then the slides were dried in a stream of nitrogen.

For the deposition of the monolayer on the quartz slide, the following method was used: first, the slide was dipped into the trough to a depth of 3.2 cm with the help of an electric motor which lowered and raised the vertically clamped slide at a constant speed of 0.25 rpm. Then, the water surface was cleaned (18) and we spread 100 μL of the spiropyran solution on the water surface. We compressed the molecules to a surface pressure of 15 mN m^{-1}. At that pressure, the slide was raised and the monolayer transferred from the water surface to the slide, each side of the slide having one monolayer. We should note that, during the deposition of the monolayer, we must always apply a constant pressure of 15 mN m^{-1}, otherwise we will have some irregularities in the aggregation of the molecules in monolayer. The deposition ratio normally obtained has a value of 1.0 ± 0.1; it is defined as A_1/A_s where A_1 is the decrease of area occupied by the monolayer at the air–water interface and A_s is the area coated by the monolayer at the air–solid interface.

After the deposition of the monolayer on the slide, the absorption spectrum was recorded as described elsewhere (18). We needed five slides, each having one monolayer on each side, to get a good spectrum with a sufficient absorbance.

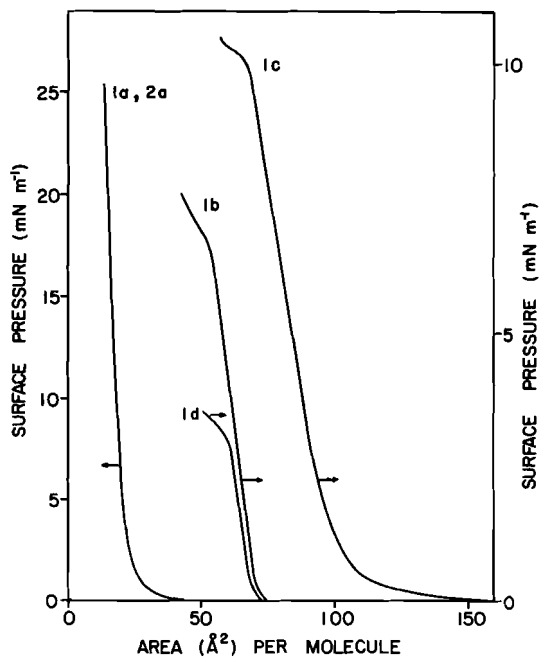
Finally, the irradiation of the monolayers was carried out by putting the five slides in front of a low pressure mercury light source (λ_{exct} = 253.7 nm; $I_o = 3.17 \times 10^{15}$ photons s^{-1}). The support with the slides was placed at about 3 cm from the source. After irradiation, the absorption spectrum was recorded the same way as before irradiation.

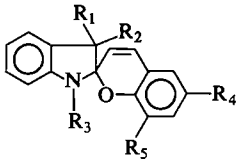
Results and Discussion

Π-A *Curves*

The surface pressure – area (Π–*A*) isotherm is normally used as the characteristic description of an insoluble monolayer at the air–water interface. It corresponds to the relationship between the surface pressure observed and the area occupied on the water surface by the molecules of the film. The surface pressure – area isotherms of the spiroindolinobenzopyran (**1***a*) and the spiroindolinonaphthopyran (**2***a*) are shown in Fig. 1. Each curve was recorded at least five times and the maximum variation between the different runs was not more than ±2 $Å^2$ $molecule^{-1}$. The shape of the curve is typical of the condensed monolayers, i.e. solid films (20).

The limiting area per molecule is situated at 20.9





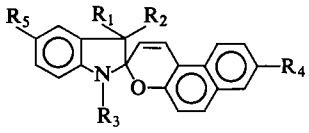


FIG. 1. Pressure-area isotherms of compounds **1***a*, **1***b*, **1***c*, **1***d*, and **2***a* on phosphate buffer (pH 7.6) at the air–water interface. *T*: 18.5 ± 0.5°C.

TABLE 1. Structure of the spiropyranindolines

Compound	R_1	R_2	R_3	R_4	R_5
					
1*a*	CH_3	CH_3	$C_{16}H_{33}$	NO_2	H
1*b*	CH_3	CH_3	$C_{16}H_{33}$	H	OCH_3
1*c*	CH_3	$C_{16}H_{33}$	CH_3	H	OCH_3
1*d*	CH_3	$C_{16}H_{33}$	CH_3	NO_2	H
					
2*a*	CH_3	$C_{16}H_{33}$	CH_3	NO_2	H
2*b*	CH_3	CH_3	$C_{16}H_{33}$	H	H
2*c*	CH_3	CH_3	$C_{16}H_{33}$	NO_2	H
2*d*	CH_3	CH_3	$C_{16}H_{33}$	H	NO_2

$Å^2$ for compound 1*a* and 19.9 $Å^2$ for compound 2*a*. These spiropyrans have a molecular area almost identical with the molecular cross-sectional areas of fatty acids like stearic and arachidic acids. The compression of the spiropyranindoline films was stopped before the collapse of the monolayers which is well beyond a surface pressure of 30 mN m^{-1}.

On the basis of these results, we can affirm that the long aliphatic chain of the spiropyranindolines (1*a*, 2*a*) is oriented perpendicularly at the air–water interface (Π greater than 15 mN m^{-1}), the rest of the molecule being more or less immersed in water. The three other spiroindolinobenzopyrans (1*b*, *c*, *d*; Table 1) form liquid films as shown in Fig. 1. However, the three other spiroindolinonaphthopyrans (2*b*, *c*, *d*; Table 1) form isotherms with a surface pressure between 0 and 2 mN m^{-1} and a molecular area between 60 and 20 $Å^2$.

Our results show that in the spiropyranindoline series there is a very narrow range of structures allowing the formation of a solid monolayer at air–water interface. It is quite evident that a strongly hydrophilic substituent is indispensable to immerse the whole aromatic part of the molecule into the subphase, which makes possible a strong interaction between the aliphatic chains. Two hydrophilic centers of a spiropyranindoline, the amino nitrogen and the oxygen of the pyran ring, have too weak polar characteristics to immerse the polycyclic part of the molecule. Adding a methoxy group does not increase enough hydrophilic interactions. The much more polar nitro group seems to be sufficiently hydrophilic hence only nitrospiropyranindolines give solid monolayers.

Another important factor is the position of the aliphatic chain. As one can see in Table 1 and Fig. 1, in the benzopyran series, the chain at 1′ gives a solid monolayer whereas in the naphthopyran series the long chain must be at 3′. This phenomenon is more difficult to justify. The examination of molecular models shows that spiropyrans may exist in two conformations determined by the C—O—C angle in the pyran ring. Probably only in one of the two conformations (Fig. 2, conformation **I**), the aliphatic chains may come close enough to allow a strong chain–chain interaction. The equilibrium ratio of the conformers depends on structural factors and is difficult to evaluate. We suppose that the formation of a solid monolayer with strong chain–chain interactions is possible only for conformation **I** and that the inflections in the isotherms may be due to the change of the conformation equilibrium during compression.

Absorption Spectroscopy

The monolayer spectra of compounds 1*a* and 2*a* were recorded at room temperature and are shown in Figs. 3 and 4. Table 2 presents the absorption maxima for the compounds 1*a* and 2*a* in solution in ethanol, *n*-hexane, and in the monomolecular state, respectively.

In ethanol solution, the spectrum shows absorption in both regions, ultraviolet and visible. In the monomolecular state, only ultraviolet region presents maxima for both compounds; in the visible, compound 1*a* does not show any absorption while compound 2*a* shows two shoulders.

If we compare, for each compound, the spectrum in monolayer with those in solution (Figs. 3, 4, and Table 2), we could note that some bands, present in solution, completely disappear in monolayer.

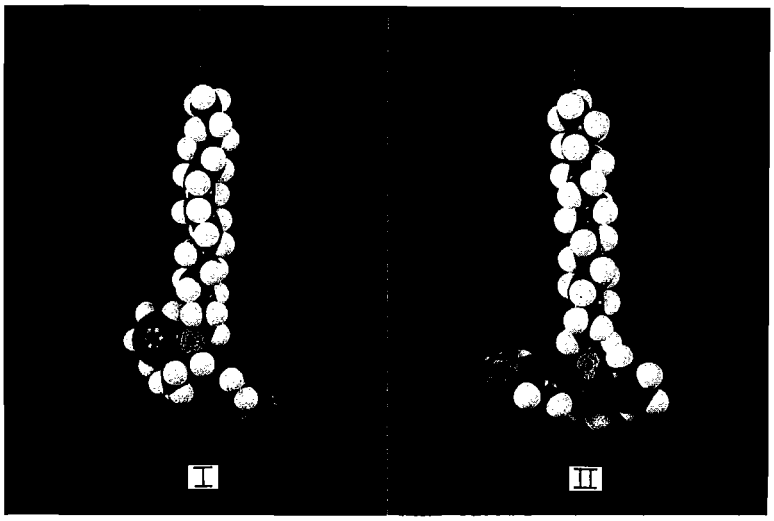

FIG. 2. Models of compound 1*a* at the air–water interface: conformation I (model A) and conformation II (model B).

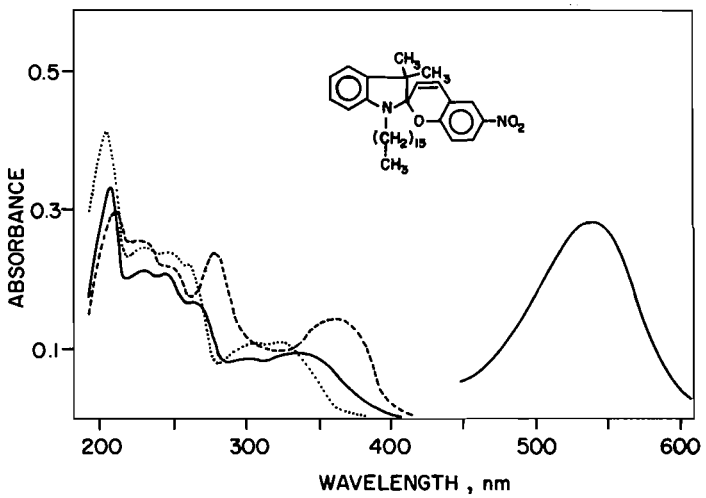

FIG. 3. Absorption spectra of compound 1*a* respectively in ethanol (—), *n*-hexane (· · ·) and monolayer at the air–solid interface (---).

Also, for both compounds, the spectra in the monolayer show a red shift compared to the solution spectra.

The spectral behavior of both compounds in monolayers may be due to the fact that the molecules are present in aggregates and are in distinct geometry compared to the solution, where the polarity of the solvent plays an important role in the shifts.

Photochromism

The photochromism of the two spiropyrans was studied as a function of time of irradiation when the compounds are irradiated with uv light at 253.7 nm.

When colorless films of compound 1*a* are irradiated with uv light at a suitable wavelength, one can observe the appearance and increase in intensity of the absorption band in the visible region and the decrease of the bands in the uv region. Figure 5 represents typical spectra obtained at different times of irradiation for compound 1*a*. The irradiation effect could be explained by the fact that a new isomer is formed with a new band in the visible region. Thus the change in the spiropyran molecule from colorless to colored form results in the change of its absorption spectrum in both uv and visible region (8).

Our experiments have shown that the maximum coloration is obtained after about 15 min of irradiation, depending on the number of monolayers; if we

†In our previous paper (17), it should read 541.5 nm instead of 590.0 nm for the spectral characteristics of compounds **7***e*.

continue the irradiation after that time, the absorption bands in the uv region still slowly decrease and those in the visible region also begin to decrease in intensity. After 15 min irradiation, an equilibrium is reached and further irradiation causes degradation of both isomers.

We have also observed the process of decoloration of these monolayers. We noted, after 5 h in darkness, a decoloration of about 75% and a complete decoloration after at least 10 h. Furthermore, it seems from Tyczkowski and Kryosewski (8) that the best photochromic properties are shown by the spiropyrans which, in position R_4, have a nitro group as a substituent. This generally agrees with the observation of photochromic properties of spiropyrans in solution and shows the important role played by the nitro group and its position in the molecule of spiropyran in the process of photocoloration (8).

The absorption spectrum of compound **2***a* was

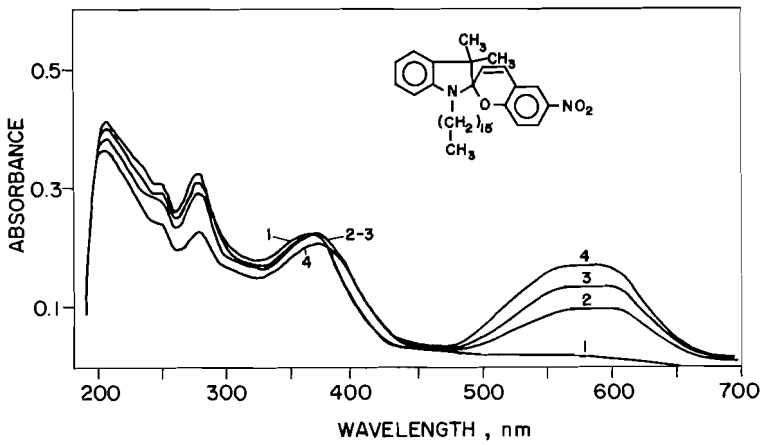

FIG. 5. Absorption spectra of compound 1*a* in monolayer before irradiation (curve *1*), after 2 min (curve *2*), 5 min (curve *3*), and 15 min (curve *4*) of irradiation.

taken after 2.5 and 15 min of irradiation under the same experimental conditions as for compound **1***a*. However, for this compound no change was observed in the spectrum after irradiation. Nevertheless, that does not mean that the compound **2***a* does not respond to irradiation. It might be possible that the reaction occurs in a very fast time, too fast to be observed by conventional spectroscopy.

Base-catalysed ring opening of *N*-(aminothioxomethyl)-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamides

MARSHALL KULKA

Uniroyal Limited, Research Laboratories, Guelph, Ont., Canada N1H 6N3

Received April 7, 1980

MARSHALL KULKA. Can. J. Chem. **58**, 2044 (1980).

The condensation of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (**1**) with ethyl 3-phenylamino-2-butenoate (**2**) has yielded a mixture of ethyl 1,4-dihydro-2-(5,6-dihydro-2-methyl-1, 4-oxathiin-3-yl)-6-methyl-1-phenyl-4-thioxo-5-pyrimidine carboxylate (**3**) and *N*-[(phenylamino)thioxomethyl]-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamide (**4**, R′ = phenyl). It has been discovered that compounds **4**, in general, rearrange to 1-substituted-2,3-dihydro-5-[(2-hydroxyethyl)thio]-6-methyl-2-thioxo-4(1*H*)-pyrimidinones (**5**) at room temperature when stirred with dilute aqueous sodium hydroxide. The products of the reaction of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (**1**) and phenylhydrazine, when treated with dilute aqueous sodium hydroxide, did not yield the rearrangement product **5** (R′ = NHC_6H_5). Instead, a mixture of the two triazole-3-thiones **9** and **10** was formed. *N*,2-Bis(5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl)hydrazinecarbothioamide (**12**) with dilute aqueous sodium hydroxide yielded one rearrangement product (out of a possible four), namely, 5-6-dihydro-2-methyl-*N*-[1,2,3,4-tetrahydro-5-[(2-hydroxyethyl)thio]-6-methyl-4-oxo-2-thioxo-1-pyrimidinyl]-1,4-oxathiin-3-carboxamide (**13**).

MARSHALL KULKA. Can. J. Chem. **58**, 2044 (1980).

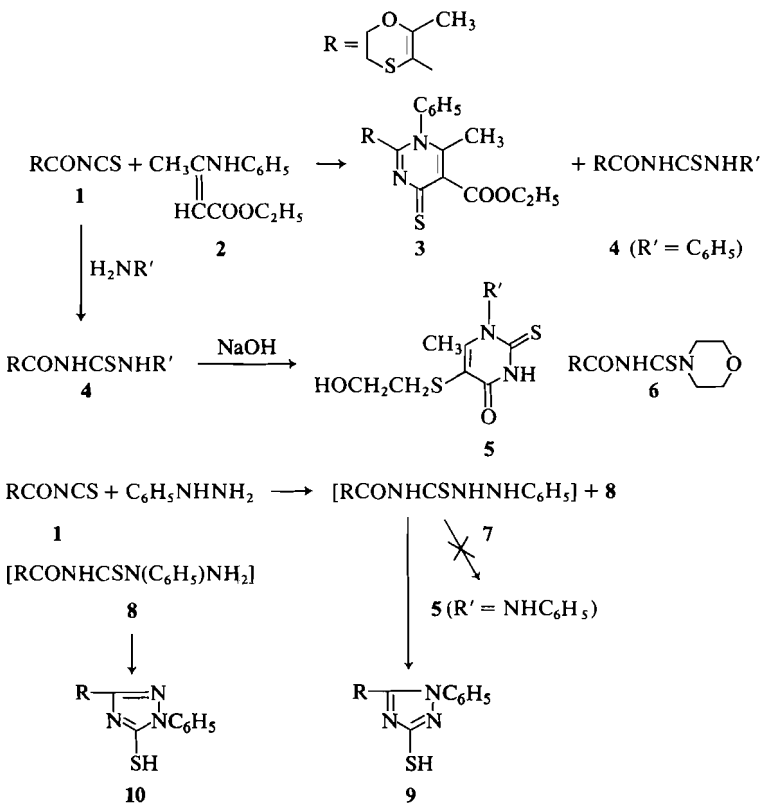
La condensation du dihydro-5,6 méthyl-2 oxathiinne-1,4 carbonylisothiocyanate-3 (**1**) sur le phénylamino-3 butène-2 oate d'éthyle (**2**) donne un mélange de dihydro-1,4 (dihydro-5,6 méthyl-2 oxathiinne-1,4 yl-3)-2 méthyl-6 phényl-1 thioxo-4 pyrimidine-5 carboxylate d'éthyle (**3**) et de *N*-[(phénylamino) thioxométhyl]dihydro-5,6 méthyl-2 oxathiinne-1,4 carboxamide-3 (**4**, R′ = phényle). On a découvert que d'une façon générale, les composés du type **4** se transposent en dihydro-2,3 [(hydroxy-2 éthyl) thio]-5 méthyl-6 thioxo-2 pyrimidinones-4 (1*H*) (**5**) substituées en position 1 quand on les agite à la température ambiante avec une solution aqueuse diluée d'hydroxyde de sodium. On n'obtient pas de composé de transposition **5** (R′ = NHC_6H_5) lorsqu'on traite les produits de la réaction du dihydro-5,6 méthyl-2 oxathiinne-1,4 carbonylisothiocyanate-3 (**1**) avec la phénylhydrazine par une solution aqueuse diluée d'hydroxyde de sodium. On obtient de préférence un mélange de deux triazolethiones-3 (**9** et **10**). Le composé *N*,-bis(dihydro-5,6 méthyl-2 oxathiinne-1,4 carbonyl-3)-2 hydrazinecarbothioamide (**12**, traité par une solution aqueuse diluée d'hydroxyde de sodium, donne un seul des quatre produits de transposition possibles soit le dihydro-5,6 méthyl-2 *N*-[tétrahydro-1,2,3,4 [(hydroxy-2 éthyl)thio]-5 méthyl-6 oxo-4 thioxo-2 pyrimidyl-1] oxathiium-1,4 carboxamide (**13**).

[Traduit par le journal]

The systemic fungicides, 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxanilide (Vitavax ®[1]) and its sulfone (Plantvax®[1]) were discovered (1) in 1966 and are now used worldwide for combatting fungal pathogens of plants and are saving food crops from destruction. This has stimulated great interest in the chemistry and biological activity of the 1,4-oxathiins. A recent paper published from this laboratory (2) records ring opening reactions of some dihydro-1,4-oxathiins. The purpose of this paper is to describe further work on the ring opening reactions of 3-carbonyl substituted-5,6-dihydro-1,4-oxathiins through base-catalysed nucleophilic attack on carbon-2.

The condensation of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (**1**) with ethyl 3-phenylamino-2-butenoate (**2**) (3) yielded a mixture of two compounds. These were separated by hand-picking into yellow crystals and into white crystals. The yellow crystals were identified by elemental analysis and nmr spectrum as ethyl 1,4-dihydro-2-(5,6-dihydro-2-methyl-1,4-oxathiin-3-yl)-6-methyl-1-phenyl-4-thioxo-5-pyrimidine-carboxylate (**3**) and the white crystals as *N*-[(phenylamino)thioxomethyl]-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamide (**4**, R′ = phenyl). These assignments are in agreement with that of Goerdeler and Gnad (4) who found similar products from the condensation of benzoyl isothiocyanate with **2**.

A better method for the separation of the mixture of **3** and **4** was sought and it became apparent that the use of aqueous sodium hydroxide should provide an easy method of separation. Dilute aqueous sodium hydroxide dissolved the white crystals, **4** (R′ = phenyl) and the yellow crystals (**3**) could be filtered off in pure form. However, acidification of the basic solution did not yield **4** (R′ = phenyl). Instead, another compound was obtained which was identified by elemental analysis and nmr spectrum as 2,3-dihydro-5-[(2-hydroxyethyl)thio]-6-methyl-1-phenyl-2-thioxo-4(1*H*)-pyrimidinone (**5**, R′ = phenyl).



This rearrangement by ring opening of the dihydro-1,4-oxathiin, **4**, through intramolecular nucleophilic attack at carbon-2 under the mild con-

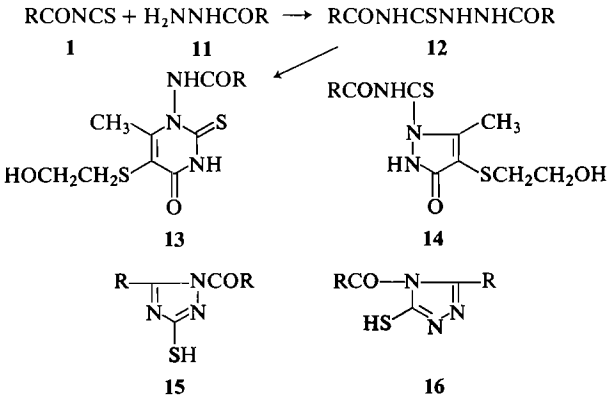
ditions of dilute aqueous sodium hydroxide at room temperature to form **5** appears to be a general reaction. Thirteen *N*-(aminothioxomethyl)-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamides (**4** where R′ = H, 1-methylethyl, *n*-butyl, *n*-hexyl, *n*-octyl, 2-phenylethyl, dimethylamino, phenyl, 4-chlorophenyl, 4-methoxyphenyl, 2-methylphenyl, 2-furanylmethyl, and 2-pyridinyl) were synthesized through the condensation of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (**1**) with the corresponding primary amines. These oxathiin-3-carboxamides (**4**) rearranged readily to the corresponding 1-substituted-2,3-dihydro-5-[(2-hydroxyethyl)thio]-6-methyl-2-thioxo-4(1*H*)-pyrimidinones (**5**) when dissolved in dilute aqueous sodium hydroxide at room temperature. This rearrangement is similar to that previously found (2) in which *N*-[(phenylamino)carbonyl]-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamide (the oxygen analog of **4**, R′ = phenyl), was converted to 5-[(2-hydroxyethyl)thio]-6-methyl-1-phenyluracil (the oxygen analog of **5**, R′ = phenyl). However, the oxygen analog of **4** (R′ = phenyl), required heating under reflux in toluene with sodium hydride instead of dilute aqueous sodium hydroxide at room temperature for the rearrangement.

The aqueous base-catalysed rearrangement is limited to those *N*-(aminothioxomethyl)-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamides (**4**) in which the amino nitrogen bears at least one hydrogen atom. Thus *N*-[(4-morpholinyl)thioxomethyl]-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamide (**6**), which was prepared through the condensation of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (**1**) with morpholine, remained unchanged when treated with dilute aqueous sodium hydroxide.



Another case where the 1,4-oxathiin ring resists opening in the presence of aqueous base was encountered. The mixture of **7** and **8** formed by the condensation of **1** with phenylhydrazine, when treated with aqueous sodium hydroxide did not yield any of the rearrangement product **5** (R′ = NHC_6H_5). Instead, another mixture was formed which was separated by fractional precipitation from sodium hydroxide into two compounds. The nmr spectra showed that these compounds contained the 1,4-oxathiin ring and they were identified as (5,6-dihydro-2-methyl-1,4-oxathiin-3-yl)-1,2,4-triazole-3-thiones **9** and **10**. Sufficient evidence is not available at the present time to distinguish between **9** and **10**. The formation of the

For personal use only.

triazole-3-thiones **9** and **10** from 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (**1**) and phenylhydrazine is in agreement with the work of Pohloudek-Fabini and Schroepl (5) who found the formation of the benzene analogs from benzoyl isothiocyanate and phenyl hydrazine.

N,2-Bis(5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl)hydrazinecarbothioamide (**12**), which was readily prepared through the condensation of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (**1**) with 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylic acid hydrazide (**11**), appears to be a versatile compound. It could theoretically rearrange in base to form four different compounds, two (**13** and **14**) resulting from nucleophilic attacks at the carbon-2 position of each of the oxathiin rings and two (**15** and **16**) resulting from the ring

R = 5,6-dihydro-2-methyl-1,4-oxathiin-3-yl

closures at each of the carbonyl groups. Actually when **12** was treated with aqueous sodium hydroxide at room temperature, one compound was obtained in good yield. The nmr spectrum of this compound showed the presence of a (2-hydroxyethyl)thio group. This indicates that the product is neither **15** nor **16** and that a nucleophilic attack on carbon-2 must have occurred to form either the structure **13** or **14**. At the present time evidence is insufficient to distinguish between the structures **13** and **14**. The structure **13** is tentatively assigned to this compound on the basis that in general pyrazolinones are more difficult to form than 2-thioxo-4(1*H*)-pyrimidinones. The 2-thioxo-4(1*H*)-pyrimidinone, structure **13** is indicated also by the comparison of its nmr spectra with that of model compounds such as 2,3-dihydro-5-[(2-hydroxyethyl)thio]-6-methyl-1-phenyl-2-thioxo-4(1*H*)-pyrimidinone (**5**, R′ = phenyl).

Experimental

The nmr spectra were recorded using an R-20 Hitachi Perkin-Elmer spectrometer and are expressed in ppm (δ values) relative to tetramethylsilane as internal standard. Infrared spectra were obtained on Perkin-Elmer 237B or 521 grating ir spectrometers. Melting points were determined on a Gallenkamp melting point apparatus and are uncorrected.

Ethyl 1,4-Dihydro-2-(5,6-dihydro-2-methyl-1,4-oxathiin-3-yl)-6-methyl-1-phenyl-4-thioxo-5-pyrimidinecarboxylate (3) and N-*[(Phenylamino)thioxomethyl]-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamide (4 R′ = Phenyl)*

To a mixture of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylic acid (20 g, 0.125 mol) and chloroform (50 mL) was added thionyl chloride (25 mL) and the reaction mixture was heated at 50–55°C for 1 h. The solvent and excess thionyl chloride were removed *in vacuo*, the last traces by alternate addition and removal of toluene. The residual acid chloride was dissolved in dry acetone (30 mL) and the solution added portionwise to a solution of ammonium thiocyanate (9.6 g) in acetone (60 mL). The reaction mixture was let stand 4 h and then treated with ethyl 3-(phenylamino)-2-butenoate (3) (25.6 g, 0.125 mol). The resulting reaction mixture was allowed to stand overnight and then poured into cold water. The precipitated oil which soon solidified was filtered, pulverized, washed with cold methanol, and then crystallized from 95% ethanol. This yielded a mixture of yellow and white crystals which were separated by picking with a pair of tweezers. The yellow crystals, *ethyl 1,4-dihydro-2-(5,6-dihydro-2-methyl-1,4-oxathiin-3-yl)-6-methyl-1-phenyl-4-thioxo-5-pyrimidinecarboxylate* (**3**) melted at 225–227°C (dec.). Infrared (KBr): 3040, 750, 700 (aromatic), 1730 (ester), 1060 (C=S) cm^{-1}. Nuclear magnetic resonance ($CHCl_3$): 7.65–7.18 (5H, m, aromatic), 4.35 (2H, q, J = 7 Hz, CH_2), 4.05 (2H, m, CH_2O), 2.50 (2H, m, CH_2S), 1.88 (3H, s, CH_3), 1.80 (3H, s, CH_3), 1.38 (3H, t, J = 7 Hz, CH_3). *Anal.* calcd. for $C_{19}H_{20}N_2O_3S_2$: C 58.76, H 5.19, N 7.21; found: C 59.04, H 5.37, N 7.38.

The white crystals melted at 112–113°C and were identical with N-*[(phenylamino)thioxomethyl]-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamide* (**4**, *R′ = phenyl*) prepared by the condensation of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (**1**) and aniline (general method described below). Infrared (KBr): 3360 (NH), 1670 (CONH), 1590, 730, 690 (aromatic) cm^{-1}. The nmr spectrum was consistent with that of the structure **4** (R′ = phenyl), (see below).

2,3-Dihydro-5-[(2-hydroxyethyl)thio]-6-methyl-1-phenyl-2-thioxo-4(1H)-pyrimidinone (5, R′ = Phenyl)

In another experiment, the mixture of **3** and **4** (R′ = phenyl) prepared from 20 g of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylic acid (see above) was stirred with 3% aqueous sodium hydroxide (50 mL) for 1 h, filtered, washed with water, and the yellow product crystallized from ethanol yielding 10.3 g of yellow crystals, mp 224–226°C (dec.), identical with ethyl 1,4-dihydro-2-(5,6-dihydro-2-methyl-1,4-oxathiin-3-yl)-6-methyl-1-phenyl-4-thioxo-5-pyrimidinecarboxylate (**3**) (see above). The aqueous alkaline filtrate was acidified, the white precipitate filtered, washed with water, dried, and crystallized from ethanol–dioxane. The white crystals (9.1 g) melted at 193–195°C and did not depress the melting point of 2,3-dihydro-5-[(2-hydroxyethyl)thio]-6-methyl-1-phenyl-2-thioxo-4(1*H*)-pyrimidinone (**5**, R′ = phenyl) prepared from **4** (R′ = phenyl) through base-catalysed rearrangement (see below).

Preparation of N-*(Aminothioxomethyl)-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamides (4)*

A reaction mixture of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylic acid (0.25 mol), chloroform (50 mL), and thionyl chloride (40 mL) was heated at 50–55°C until dissolved (1 h). Then the solvent and excess thionyl chloride were removed *in vacuo* at 50–60°C, the last traces by alternate addition and removal of toluene. The residual acid chloride which solidified was dissolved in dry acetone (40 mL) and the solution added to a

For personal use only.

cold solution of ammonium thiocyanate (20 g, 0.26 mol) in acetone (100 mL). The resulting reaction mixture was allowed to stand 4 h and then treated portionwise with the amine (0.25 mol) in acetone (25 mL), keeping the temperature at 30–35°C by cooling on a water bath. After allowing the reaction mixture to stand overnight it was poured into cold water. The precipitate was filtered, washed with water, and crystallized from methanol or toluene. N-*[(Phenylamino)thioxomethyl]-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamide* (**4**, *R′ = phenyl*), mp 112–113°C, yield, 70%; nmr ($CDCl_3$): 12.50 (1H, s, NH), 9.20 (1H, s, NH), 7.8–7.1 (5H, m, aromatic), 4.40 (2H, m, CH_2O), 2.90 (2H, m, CH_2S), 2.30 (3H, s. CH_3). *Anal.* calcd. for $C_{13}H_{14}N_2O_2S_2$: C 53.06, H 4.80, N 9.52; found: C 53.21, H 4.87, N 9.43. N-*[(2-Pyridylamino)thioxomethyl]-5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxamide* (**4**, *R′ = 2-pyridyl*), mp 143–145°C, yield, 60%; nmr ($CDCl_3$): 12.95 (1H, s, NH), 9.14 (1H, s, NH), 8.75 (1H, d, J = 8 Hz, aromatic), 8.40 (1H, m, aromatic), 7.70 (1H, m, aromatic), 7.10 (1H, m, aromatic), 4.40 (2H, m, CH_2O), 2.92 (2H, m, CH_2S), 2.30 (3H, s, CH_3). *Anal.* calcd. for $C_{12}H_{13}N_3O_2S_2$: C 48.81, H 4.44, N 14.23; found: C 49.02, H 4.48, N 14.23.

Other compounds in this series, for which yields, analyses, and nmr spectra are available from the Depository of Unpublished Data,[2] are **4**, where R′ is in turn H, mp 170–172°C; —$CH(CH_3)_2$, mp 84–86°C; *n*-C_4H_9, mp 70–72°C; *n*-C_6H_{13}, mp 51–52°C; *n*-C_8H_{17}, mp 39–40°C; —$CH_2CH_2C_6H_5$, liquid; —$N(CH_3)_2$, mp 149–150°C; 4-ClC_6H_4—, mp 136–138°C; 4-$CH_3OC_6H_4$—, mp 128–130°C; 2-$CH_3C_6H_4$—, mp 112–114°C; 2-furanylmethyl, mp 101–103°C.

N-*[(4-Morpholinyl)thioxomethyl]-5,6-dihydro-2-methyl-1,4-oxathiin-3- carboxamide* (**6**)

This was prepared from 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (**1**) and morpholine by the method described above for **4**, mp 134–135°C, yield, 67%. Nuclear magnetic resonance ($CDCl_3$): 8.30 (1H, s, NH), 4.35 (2H, m, CH_2O), 3.78 (8H, s, $4CH_2$), 2.82 (2H, m, CH_2S), 2.23 (3H, s, CH_3). *Anal.* calcd. for $C_{11}H_{16}N_2O_3S_2$: C 45.83, H 5.60, N 9.72; found: C 46.09, H 5.53, N 9.71.

This compound remained unchanged when stirred in 2% aqueous sodium hydroxide for 24 h.

1-Substituted-2,3-dihydro-5-[(2-hydroxyethyl)thio]-6-methyl-2-thioxo-4(1H)-pyrimidinones (**5**) *from* **4** *by Base-catalysed Rearrangement*

The *N*-(aminothioxomethyl)-5-6-dihydro-2-methyl-1,4-oxathiin-3-carboxamide (**4**) (0.1 mol) was added to 2% aqueous sodium hydroxide (2 L) and the reaction mixture stirred at room temperature for 20 h. The solution was filtered, the filtrate neutralized, and the precipitate filtered, washed with water, dried, and crystallized from alcohol. This gave the rearrangement products in high yields. In the case of **5**, R′ = 1-methylethyl, the rearrangement was not complete so it was heated at 50°C for an additional hour. *1-Phenyl-2,3-dihydro-5-(2-hydroxyethylthio)-6-methyl-2-thioxo-4(1H)-pyrimidinone* (**5**, *R′ = phenyl*), mp 194–195°C, yield, 80%; nmr (DMSO-d_6): 12.80 (1H, m, NH), 7.5–7.1 (5H, m, aromatic), 4.70 (1H, m, OH), 3.50 (2H, m, CH_2O), 2.82 (2H, m, CH_2S), 2.12 (3H, s, CH_3). *Anal.* calcd. for $C_{13}H_{14}N_2O_2S_2$: C 53.06, H 4.80, N 9.52; found: C 53.14, H 4.77, N 9.82. *1-(2-Pyridyl)-2,3-dihydro-5-(2-hydroxyethylthio)-6-methyl-2-thioxo-4(1H)-pyrimidinone* (**5**, *R′ = 2-pyridyl*), mp 226–227°C (dec.), yield, 87%; nmr (DMSO-d_6): 12.90 (1H, m, NH), 8.58 (1H, m, aromatic), 8.0 (1H, m, aromatic), 7.50 (2H, m, aromatic), 4.70 (1H, m, OH), 3.50 (2H, m, CH_2O), 2.83 (2H, m, CH_2S), 2.10 (3H, s, CH_3). *Anal.* calcd. for $C_{12}H_{13}N_3O_2S_2$: C 48.81, H 4.44, N 14.23; found: C 49.14, H 4.48, N 13.97.

Other compounds in this series, for which yields, analyses and nmr spectra are available from the Depository of Unpublished Data,[2] are **5**, where R′ is in turn H, mp 180–182°C (dec.), —$CH(CH_3)_2$, mp 155–157°C; *n*-C_4H_9, mp 115–117°C; *n*-C_6H_{13}, 111–112°C; *n*-C_8H_{17}, mp 102–104°C; —$CH_2CH_2C_6H_5$, mp 156–158°C —$N(CH_3)_2$, mp 143–145°C; 4-ClC_6H_4, mp 228–230°C; 4-$CH_3OC_6H_4$, mp 193–194°C; 2-$CH_3C_6H_4$, mp 202–204°C; 2-furanylmethyl, 134–135°C.

*1,2-Dihydro-5-(5,6-dihydro-2-methyl-1,4-oxathiin-3-yl)-1-phenyl-3*H*-1,2,4-triazole-3-thione* (**9**) *and 2,4-Dihydro-5-(5,6-dihydro-2-methyl-1,4-oxathiin-3-yl)-2-phenyl-3*H*-1,2,4-triazole-3-thione* (**10**)

5,6-Dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (**1**) (0.25 mol) in toluene (200 mL) was treated with a solution of phenylhydrazine (27 g) in toluene (50 mL), while the temperature was maintained at 30–35°C, and then left to stand overnight. The reaction mixture was filtered, washed with toluene, and the combined filtrate and washings were evaporated to "dryness" at reduced pressure. The liquid residue which would not solidify was stirred with 3% aqueous sodium hydroxide (1.5 L) for 20 h, filtered, and then neutralized. The semi-solid precipitate was filtered, washed, dried, and separated into two compounds by fractional precipitation from dilute aqueous sodium hydroxide followed by crystallization from ethanol. The compound which was more soluble in aqueous sodium hydroxide melted at 173–175°C and is tentatively assigned the structure **9**, yield, 6.0 g. Infrared (KBr): 1560 (—C=N—), 760, 690 (aromatic) cm^{-1}; nmr (DMSO-d_6): 7.61 (5H, s, aromatic), 4.35 (2H, m, CH_2O), 3.10 (2H, m, CH_2S), 1.58 (3H, s, CH_3), SH is too broad for reading. *Anal.* calcd. for $C_{13}H_{13}N_3OS_2$: C 53.61, H 4.52, N 14.43; found: C 53.99, H 4.84, N 14.42.

The compound which was less soluble in aqueous sodium hydroxide is tentatively assigned the structure **10**. It melted at 212–214°C, yield, 5.5 g; nmr (DMSO-d_6): 13.75 (1H, m, D_2O exchangeable, SH), 8.10 (2H, m, aromatic), 7.55 (3H, m, aromatic), 4.40 (2H, m, CH_2O), 3.15 (2H, m, CH_2S), 2.07 (3H, s, CH_3). *Anal.* calcd. for $C_{13}H_{13}N_3OS_2$: C 53.61, H 4.52, N 14.43; found: C 53.84, H 4.75, N 14.62.

N,*2-Bis(5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl)hydrazinecarbothioamide* (**12**)

5,6-Dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (**1**) (0.125 mol) in warm toluene (120 mL) was treated with a suspension of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylic acid hydrazide (22 g) (2) (**11**) in toluene (120 mL) and 5 drops of triethylamine. After stirring the reaction mixture at room temperature overnight it was cooled, filtered, washed, dried, and crystallized from toluene–methanol, mp 166–168°C, yield 34.2 g (73%); nmr ($CDCl_3$): 13.35 (1H, m, NH), 9.93 (1H, m, NH), 9.12 (1H, s, NH), 4.48 (4H, m, $2CH_2O$), 3.00 (4H, m, $2CH_2S$), 2.33 (6H, s, $2CH_3$). *Anal.* calcd. for $C_{13}H_{17}N_3O_4S_3$: C 41.60, H 4.57, N 11.20; found: C 41.54, H 4.68, N 11.32.

Rearrangement of N,*2-bis(5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl)hydrazinecarbothioamide* (**12**) *to 5,6-Dihydro-2-methyl-*N*-[1,2,3,4-tetrahydro-5-[(2-hydroxyethyl)thio]-6-methyl-4-oxo-2-thioxo-1-pyrimidinyl]-1,4-oxathiin-3-carboxamide* (**13**)

N,2-Bis(5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl)hydrazinecarbothioamide (**12**) (15 g) was added to 2% aqueous sodium hydroxide (1.2 L) and the reaction mixture stirred overnight. It was then filtered and the cold filtrate acidified. The white precipitate was filtered, washed, dried, and recrystallized from ethanol, mp 203–205°C, yield 12.5 g (83%). Infrared (KBr): 3340 (OH and NH), 1690 (CO), 1660, 1580 (amide) cm^{-1}; nmr (DMSO-d_6): 13.0 (1H, m, NH), 10.70 (1H, m, NH), 4.75 (1H, m,

Ozonolysis of olefins containing monochloro substituted double bonds[1]

HELMUT KEUL AND KARL GRIESBAUM[2]

Engler–Bunte Institut, Bereich Petrochemie, Universität Karlsruhe (T.H.), D-7500 Karlsruhe, W. Germany

Received March 27, 1980

HELMUT KEUL and KARL GRIESBAUM. Can. J. Chem. **58**, 2049 (1980).

Ozone cleavage of 12 substituted vinyl chlorides (**1**) in methanol occurred such that the chlorinated moiety of the double bond afforded the carbonyl fragment (i.e. acyl chloride) and the nonchlorinated moiety afforded the carbonyl oxide fragment. All of these fragments underwent secondary reactions: formyl chloride gave carbon monoxide and hydrogen chloride; all other acyl chlorides yielded the corresponding methyl esters. The carbonyl oxides were converted into the corresponding methoxy hydroperoxides. Under the influence of hydrochloric acid unsubstituted and monosubstituted methoxy hydroperoxides were dehydrated to form the corresponding methyl esters, whereas the disubstituted methoxy hydroperoxide of acetone produced the cyclic trimeric peroxide of acetone.

HELMUT KEUL et KARL GRIESBAUM. Can. J. Chem. **58**, 2049 (1980).

Le clivage par l'ozone dans le méthanol de 12 chlorures vinyliques substitués (**1**) se produit d'une façon telle que la partie chlorée de la double liaison conduit au fragment porteur du groupement carbonyle (i.e. chlorure d'acyle) et la partie non chlorée fournit le fragment porteur de l'oxyde de carbonyle. Tous ces fragments subissent des réactions secondaires: le chlorure de formyle donne le monoxyde de carbone et le chlorure d'hydrogène; tous les autres chlorures d'acyles conduisent aux esters méthyliques correspondants. Les oxydes de carbonyle sont transformés en méthoxy hydroperoxydes monosubstitués correspondants. Sous l'action de l'acide chlorhydrique, les méthoxyhydroperoxydes non substitués et monosubstitués donnent, par déshydratation, les esters méthyliques, alors que le méthoxyhydroperoxyde disubstitué de l'acétone produit le peroxyde cyclique trimère de l'acétone.

Introduction

The reaction of ozone with organic compounds containing chloro substituted double bonds attracts increasing attention from the standpoint of ecological chemistry. In recent years, a number of papers have appeared which were concerned with the rate of attack, with the reaction course, and with the reaction products of the ozonolysis of olefins containing 1,2-dichloro substituted double bonds (1–5). By contrast, to our knowledge, there is no systematic investigation of the course and the products of the ozone cleavage of olefins containing monochloro substituted double bonds. On the other hand, however, compounds containing such structural moieties are important chemical products. Their behavior towards ozone may, therefore, have far-reaching consequences, both from the standpoint of stability and from the standpoint of ecology if such compounds are exposed to or emitted to the environment.

In the present paper we report the ozonolysis of 12 model compounds (**1***a*–**1***l*) containing monochloro substituted double bonds. They have been selected such that the double bonds exhibit different types of substitution. From preliminary results it became evident that their ozonolysis in nonparticipating solvents affords very complicated product mixtures, including oligomeric peroxidic materials. Therefore, the ozonolyses were carried out in the participating solvent methanol.

A priori, one might anticipate two sets of primary products upon ozone cleavage of **1**, viz. either fragment pair **2** and **3** formed by route *A* or fragment pair **4** and **5** formed by route *B* in Scheme 1. Of these, the chlorinated fragments **3** and **4** would not be stable under the reaction conditions, but would be converted into the corresponding methyl esters of structure **7** (6),[3] so that they could not be expected to furnish information about the actual mode of cleavage. Fragments **2** and **5**, on the other hand, were expected to be recognizable in the form of the methoxy hydroperoxide **6** and as such, respectively. The ratio of their occurrence could thus provide evidence for the relative importance of routes *A* and *B*.

Results

Substrates **1***a*–*g* and **1***i*–*l* were ozonized in methanol solution at −78°C and they reacted spontaneously with ozone under these conditions. Due to its lower solubility, substrate **1***h* was ozonized in methanol at ambient temperatures. Its reaction with ozone was slow, and some ozone passed the reaction vessel unconsumed.

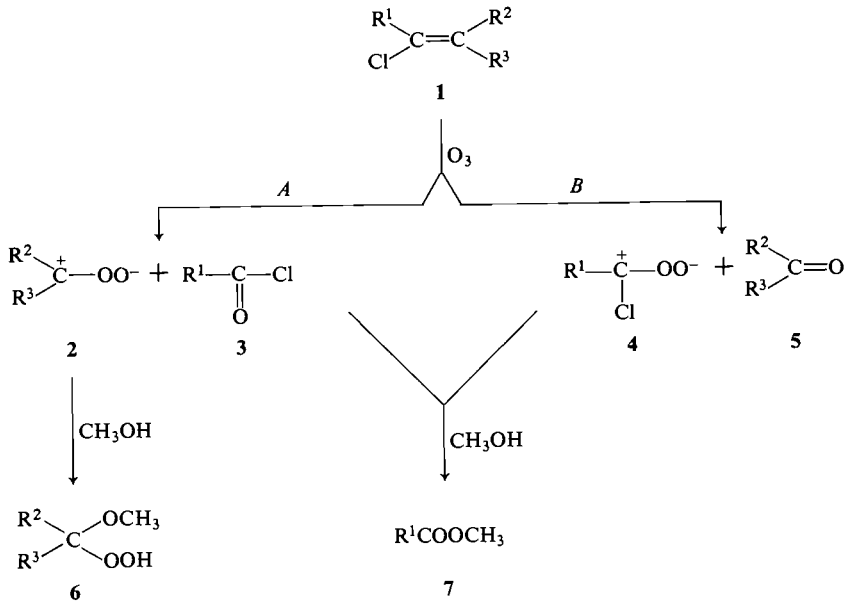
[2]Author to whom correspondence should be addressed.



[3]In previous work we have shown that the ozonolysis of olefins containing 1,2-dichloro substituted double bonds in methanol affords ester fragments from each moiety of the double bond. This means that carbonyl oxides of type **4** are converted into esters in the presence of alcohols.

SCHEME 1. Possible fragmentation patterns of olefins containing monochloro substituted double bonds.

Immediately after the ozonolysis reaction, all reaction mixtures gave positive peroxide tests. When the cold solutions were allowed to warm up, exothermic reactions occurred as the mixtures had reached approximately room temperature. The intensity of these reactions was different, depending on the structure of the substrates ozonized. The ozonized solutions of the substrates **1***e*, **1***g*, **1***i*, and **1***j* reacted so vigorously that the mixtures came to reflux. After completion of these reactions the peroxide contents of the solutions had disappeared. The ozonized solutions of the substrates **1***a–d* and of substrates **1***f* and **1***h* reacted less vigorously. Their peroxide contents had also decreased but not disappeared after the exothermic reactions had ceased. After prolonged standing at ambient temperatures or heating of the samples to 30–60°C, however, no peroxidic material was left. The ozonized solutions of the trisubstituted substrates **1***k* and **1***l* exhibited only a weak exothermic reaction, and the reaction mixtures remained strongly peroxidic even after prolonged standing at ambient temperatures.

For structural identification of the ozonolysis products, the peroxide free reaction mixtures obtained from the substrates **1***a–j* were analyzed by glc with the help of authentic samples. The quantitative determination of the reaction products was carried out by nmr spectroscopy, using 1,1,1-trichloroethane as a standard. The products from the ozonolysis of **1***d*, **1***f*, **1***h*, **1***i*, and **1***j* were also isolated. The results obtained are given in Table 1. The 2-chloroalkenes of structures **1***a–d* afforded the corresponding methyl esters **8***a–d* in yields of 80–95% and methyl formate (**9**) in yields of 65–80%. The low yields of methyl formate (**9**) may be due to losses owing to its high volatility.

1*a–d* **8***a–d* **9**

The 1-chloroalkenes of structures **1***e* and **1***f* gave the corresponding methyl esters **10***e* and **10***f* in 85% and 75% yield, respectively, but no detectable amounts of methyl formate. In the off-gases from the ozonolysis reactor, carbon monoxide and carbon dioxide were qualitatively detected by glc analysis.

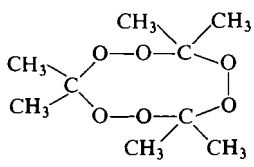
$R^2CH{=}CHCl$ R^2COOCH_3

1*e*, **1***f* **10***e*, **10***f*

The acyclic chloroalkenes **1***g* and **1***h* yielded nearly two equivalents of the corresponding methyl ester fragments **11***g* and **11***h*, respectively. The cyclic chloroalkenes **1***i* and **1***j* produced in high yields the corresponding dimethyl esters **12***i* and **12***j*, respectively.



$R(Cl)C{=}CHR$ $RCOOCH_3$ 

1*g*, **1***h* **11***g*, **11***h* **1***i*, **1***j*

$CH_3OOC{-}(CH_2)_n{-}COOCH_3$

12*i*, **12***j*

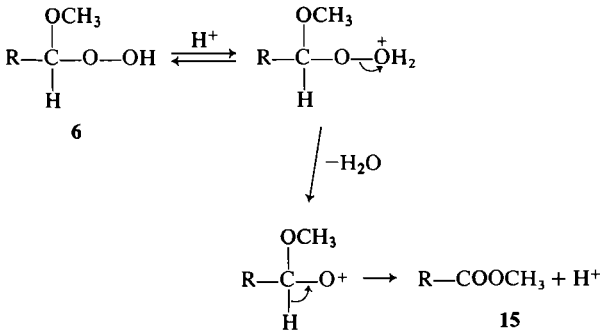
From the persistently peroxidic reaction mixtures obtained by ozonolysis of **1***k*, the trimeric peroxide of acetone (**13**) precipitated upon prolonged standing. It was isolated in 34% yield. In the mother liquors, methyl acetate (**14**) was detected in approximately 95% by nmr analysis.

$(CH_3)_2C{=}C(Cl)CH_3$  CH_3COOCH_3

1*k* **13** **14**

From the also persistently peroxidic reaction mixture obtained by ozonolysis of **1***l* no products could be identified at this stage of the analysis. The course of the reaction could, however, be elucidated by the trapping experiments discussed in the following section.

Reaction Course

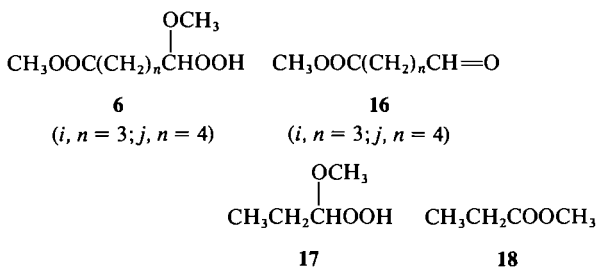


The foregoing results can be readily rationalized by the following sequence of reactions. In the first step the chlorinated double bonds in the substrates **1***a*–*l* are predominantly cleaved so as to form acyl chlorides (**3**) and nonchlorinated carbonyl oxides (**2**), i.e. cleavage occurs by route *A* in Scheme 1. This is in line with the previous experience that in the ozonolysis of unsymmetrically substituted olefins the carbonyl oxide fragment is preferentially formed at the carbon atom which is tied to the least electron deficient substituents (7). Thus, for 1-chloro-2-butene and for 3-chloropropene the ozone cleavage was reported to afford the corresponding nonchlorinated carbonyl oxides in proportions of 89% and 83%, respectively (8).

In secondary steps, substituted acyl chlorides are solvolyzed by methanol to form the corresponding methyl esters (**7**) and hydrogen chloride, formyl chloride is decomposed to carbon monoxide and hydrogen chloride, and the carbonyl oxides (**2**) are trapped by methanol to form the corresponding methoxy hydroperoxides (**6**). In the presence of hydrogen chloride, the latter apparently are not

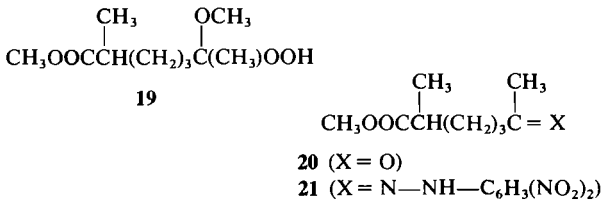
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

stable and undergo further reactions. The rates, the courses, and the results of these further reactions are different, depending on the structure, i.e. the substituents R^2 and R^3, of **6**.



Methoxy hydroperoxides bearing two (**6***a–d*) or at least one hydrogen atom at the central carbon position (**6***e–j*) are converted into the corresponding methyl esters **15**. This conversion occurs probably by acid catalyzed intramolecular dehydration:

The conversion of the unsubstituted (**6***a–d*) and of the phenyl substituted methoxy hydroperoxides (**6***f*, **6***h*) into the corresponding esters (**15**) was rather slow. Hence they could be detected in the reaction mixtures by nmr spectroscopy (δ 4.87 ppm, s, CH_2-group in **6***a–d*; δ 5.70 ppm, s, CH-group in **6***f* or **6***h*). Their gradual conversion into methyl formate and methyl benzoate, respectively, could be also followed by nmr spectroscopy.



Conversion of the monoalkyl substituted methoxy hydroperoxides (i.e. **6***e*, **6***g*, **6***i*, and **6***j*) into the corresponding esters (**15**) was very fast, as indicated by vigorous exothermic reactions. Nevertheless, the intermediacy of these hydroperoxides as precursors form the esters **15** could be ascertained in some cases and thus rendered likely for the other cases by the following experiments. When the freshly ozonized solutions of 1-chlorocyclopentene (**6***i*) and of 1-chlorocyclohexene (**6***j*) were treated with one equivalent of sodium methoxide in methanol at −78°C, the corresponding methoxy hydroperoxides **6***i* and **6***j* could be preserved. Subsequent reduction of the latter with dimethyl sulfide afforded the corresponding ester-aldehydes **16**. Treatment of **6***j* or of independently prepared **17** with a solution of hydrogen chloride in methanol, on the other hand, produced in good yields dimethyladipate (**12***j*) and methyl propionate (**18**), respectively.

Methoxy hydroperoxides bearing no hydrogen atom at the central carbon position are not converted into esters under the prevailing conditions, i.e. by hydrogen chloride at ambient temperatures. The methoxy hydroperoxide **6***k* is partly converted

into the trimeric peroxide **13**. This was confirmed by treatment of independently prepared, authentic **6***k* with a solution of hydrochloric acid in methanol. It afforded **13** along with other nonidentified products but no detectable amounts of methyl acetate.

The methoxy hydroperoxide **19**, which is formed by ozonolysis of **1***l*, also undergoes secondary reactions under the influence of hydrogen chloride, but none of the products were identified. The formation and existence of **19** itself, however, was definitely established. Treatment of the freshly ozonized mixture with sodium methoxide at −78°C preserved **19**, which was subsequently isolated at room temperature. Its reduction with triphenyl phosphine afforded the expected ketoester **20**, which was characterized as its derivative **21**.

Materials and Methods

Materials

The substrates **1***a* (9), **1***b* (10), **1***c* (11), **1***d* (12), **1***e* (13), **1***f* (14), **1***g* (15), **1***h* (16), **1***i* (17), **1***j* (18), **1***k* (19), and **1***l* (20) were prepared by known procedures. Methanol was of analytical grade and was dried by refluxing over magnesium shavings. Stock solutions of hydrochloric acid in methanol were prepared by introducing gaseous anhydrous hydrogen chloride into methanol at 0°C and titration of these solutions with aqueous sodium hydroxide using phenolphthalein as indicator. Stock solutions of sodium methoxide were prepared by adding the appropriate amount of sodium to anhydrous methanol.

Analytical Methods

Gas–liquid chromatographic analyses were carried out on a Varian model 1440 unit with flame ionization detector; stainless steel columns: 0.3 × 500 cm, 5% Nitrilesiliconoil XE 60 on Chromosorb G. Conditions: 60°C to 160°C at 4°C per min, injection block 200°C, N_2 stream 30 mL/min. Nuclear magnetic resonance spectra were recorded on a Varian model A 60 spectrometer.

General Procedure for the Ozonolysis and for the Analysis of the Reaction Products

Mixtures of the substrates **1** and of methanol in the ratios given in Table 1 were ozonized at the temperatures indicated in Table 1. Ozone treatment was terminated when the solutions

TABLE 2. Isolation of ester products

Substrate		Methanol	Reaction temperature	Ester products			
					Yield		
Type	g	mL	°C	Structure	g	(%)	Boiling point
1*d*	6.90	69	−78	$C_6H_5COOCH_3$	5.78	(85)	96–98°C/24 Torr
1*f*	6.90	69	−78	$C_6H_5COOCH_3$	5.20	(76)	96–98°C/24 Torr
1*h*	6.42	64	Room temperature	$C_6H_5COOCH_3$	5.22	(64)	98°C/24 Torr
1*i*	5.10	51	−78	$(CH_2)_3(COOCH_3)_2$	6.50	(81)	93°C/10 Torr
1*j*	5.00	50	−78	$(CH_2)_4(COOCH_3)_2$	6.20	(83)	110°C/13 Torr

assumed a blue color. Excess ozone was removed by a stream of nitrogen and a sample of the cold crude reaction mixture was tested for its peroxide content by its reaction with sodium iodide. The ozonolysis products of all substrates (**1***a–l*) gave positive peroxide tests. Then the crude reaction mixtures were allowed to warm up. When they had reached temperatures between 0°C and room temperature, exothermic reactions set in.

For the products derived from ozonolysis of **1***e*, **1***g*, **1***i*, and **1***j* these reactions were so vigorous that intermittent cooling was necessary. When the reaction had ceased, the solutions were free of peroxide. The final products were identified by glc analysis by coinjection with authentic samples. Quantitative determination of the products occurred by nmr spectroscopy; 1,1,1-trichloroethane was added to the mixture in amounts equivalent to the substrate used (Table 1) and the esters were determined on the basis of their CH_3O-signals.

The products derived from ozonolysis of **1***a–d*, **1***f*, and **1***h* reacted less vigorously and no cooling was necessary. The mixtures remained peroxidic after the exothermic reaction had terminated. Equivalent amounts of 1,1,1-trichloroethane was added (Table 1) and the mixtures were analyzed by nmr. In the ozonolysis products of **1***a–d* the singlet CH_2-signal of the corresponding methoxy hydroperoxide (**6***a*) appeared at 4.87 ppm. In the ozonolysis products of **1***f* and of **1***h* the singlet CH-signal of the corresponding methoxy hydroperoxide (**6***f*) appeared at δ 5.70 ppm. Upon standing for approximately 15 h at room temperature or after warming to 30°C for approximately 3 h, the peroxide contents of all samples and the signals at 4.87 ppm and 5.70 ppm, respectively, had disappeared. The glc and nmr analyses showed only the peaks and signals, respectively, of the corresponding ester fragments. Their yields were again determined on the basis of the CH_3O-signals of the methyl ester groups with the help of 1,1,1-trichloroethane as a standard (Table 1).

The products derived from the ozonolysis of **1***k* and of **1***l* gave only weak exothermic reactions and they remained strongly peroxidic. From the ozonolysis product of **1***k*, solid **13** had precipitated after the mixture was left at room temperature for 15 h. The solid was filtered off, washed with methanol, and dried; yield 148 mg (34%); mp 96–97°C (lit. (21) mp 96–97°C). To the mother liquor 1,1,1-trichloroethane was added in amounts equivalent to the substrate **1***k* used (Table 1), and the mixture was analyzed by nmr spectroscopy. The amount of methyl acetate was quantitatively determined on the basis of its CH_3O-signal (Table 1); other signals in the spectrum were not assigned. The reaction products obtained from the ozonolysis of **1***l* could not be identified on the basis of the nmr spectrum of the crude reaction mixture.

General Procedure for the Ozonolysis and Subsequent Isolation of Ester Products

Mixtures of the substrates **1***d*, **1***f*, **1***h*, **1***i*, or **1***j* and methanol were ozonized in the ratio and at the temperatures listed in Table 2. The end of the ozonolysis was indicated by the appearance of a blue color if the ozonolysis was carried out at −78°C; it was detected by the disappearance of the substrate by glc analysis if the ozonolysis was carried out at room temperature. The reaction mixtures were flushed with nitrogen and then allowed to warm up, whereby exothermic reactions occurred. When they had ceased, the mixtures were heated to 60°C for 3 h and then the methanol was distilled off. The residue was dissolved in ether, sequentially washed with a 10% aqueous solution of sodium hydroxide and with water, and dried over sodium sulfate. After removal of ether, the residue was submitted to a vacuum distillation. The results are summarized in Table 2. The glc and nmr analyses of the distilled products showed in each case no detectable amounts of impurities.

*Identification of Methoxy Hydroperoxides **6**i, **6**j, and **19** as Reaction Intermediates*

*Identification of **6**i*

A mixture of 1.02 g (10 mmol) **1***i* and 10 mL methanol was ozonized at −78°C until the solution turned blue. Excess ozone was removed by a stream of nitrogen and 2.3 mL of a precooled 10% solution of sodium methoxide in methanol was immediately added to the cold reaction mixture. The mixture was allowed to warm up to room temperature and the precipitated sodium chloride was removed. To the peroxidic mother liquor 1.24 g (20 mmol) of dimethyl sulfide was added and the mixture was left standing for 1 h. Then the volatile components were removed under vacuum on a rotary evaporator. The residual aldehyde-ester **16***i* was converted into its 2,4-dinitrophenylhydrazone derivative; mp (recrystallized from cyclohexane) 105–106°C (lit. (22) mp 105–106°C); yield 1.7 g (55%); ^1H nmr ($CDCl_3$, TMS) δ: 1.83–2.25 (broad signal, 2H), 2.33–2.73 (broad signal, 4H), 3.70 (s, 3H), 7.60 (t, J = 4.5 Hz, 1H), 7.91 (d, J = 9.5 Hz, 1H), 8.4 (dd, J = 9.5 Hz, J = 2.4 Hz, 1H), 9.11 (d, J = 2.4 Hz, 1H), 11.05 (broad signal, 1H).

*Identification of **6**j*

A mixture of 580 mg (5 mmol) **1***j* in 5.8 mL methanol was ozonized, subsequently treated with sodium methoxide (1.15 mL of a 10% solution in methanol) and with 0.62 g (10 mmol) dimethylsulfide, and then worked up as described above. The residual aldehyde-ester **16***j* was converted into its 2,4-dinitrophenylhydrazone derivative: mp (recrystallized from cyclohexane) 104–105°C (lit. (23) mp 104–105°C); yield 0.8 g (50%). ^1H nmr ($CDCl_3$, TMS) δ: 1.57–1.90 (broad signal, 4H), 2.27–2.67 (broad signal, 4H), 3.69 (s, 3H), 7.54 (t, J = 5.2 Hz, 1H), 7.91 (d, J = 9.5 Hz, 1H), 8.40 (dd, J = 9.5 Hz, J = 2.56 Hz, 1H), 9.11 (d, J = 2.56 Hz, 1H), 11.05 (broad signal, 1H).

*Identification of **19***

A mixture of 720 mg (5 mmol) **1***l* and 7.2 mL methanol was ozonized, subsequently treated with sodium methoxide (1.15 mL of a 10% solution in methanol), and warmed up to room temperature. After removal of the sodium chloride, methanol was removed under vacuum on a rotary evaporator. The residue was dissolved in ether, washed with water, dried over

sodium sulfate, and the ether distilled off. The residue was 1 g (91%) of essentially pure methoxy hydroperoxide **19**; ^{1}H nmr (CCl_4, TMS) δ: 1.15 (d, J = 7.0 Hz, 3H), 1.32 (s, 3H), 1.40–1.78 (broad signal, 6H), 2.45 (m, 1H), 3.32 (s, 3H), 3.68 (s, 3H).

A solution of 1 g (4.5 mmol) of **19** and 1.44 g (5.5 mmol) of triphenyl phosphine in 10 mL of hexane was refluxed for 1 h. Then the mixture was separated by preparative thin layer chromatography (silica gel, dichloromethane) to give **20**; ^{1}H nmr (CCl_4, TMS) δ: 1.08 (d, J = 7.0 Hz, 3H), 1.33–1.63 (broad signal, 4H), 2.00 (s, 3H), 2.20–2.50 (broad signal, 3H), 3.60 (s, 3H).

The keto-ester **20** was converted into its 2,4-dinitrophenylhydrazone (**21**). Melting point (recrystallized from cyclohexane) 89–90°C; ^{1}H nmr ($CDCl_3$, TMS) δ: 1.19 (d, J = 6.96 Hz, 3H), 1.47–1.83 (broad signal, 4H), 2.07 (s, 3H), 2.27–2.70 (broad signal, 3H), 3.69 (s, 3H), 7.94 (d, J = 9.5 Hz, 1H), 8.40 (dd, J = 9.5 Hz, J = 2.56 Hz, 1H), 11.04 (broad signal, 1H). *Anal.* calcd. for $C_{15}H_{20}N_4O_6$: C 51.13, H 5.72, N 15.90; found: C 51.13, H 5.71, N 15.94.

Treatment of Methoxy Hydroperoxides **6***j*, *17, and* **6***k with Hydrochloric Acid*

Treatment of **6***j*

A mixture of 580 mg (5 mmol) **1***j* in 5.8 mL methanol was ozonized at −78°C and treated with sodium methoxide (1.15 mL of a 10% solution in methanol) as described above. After warming to room temperature and removal of methanol on a rotary evaporator, the crude methoxy hydroperoxide **6***j* is obtained as residue; ^{1}H nmr ($CDCl_3$, TMS) δ: 3.50 (s, 3H), 3.68 (s, 3H), 4.72 (t, J = 5.0 Hz, 1H). To this crude **6***j* 5 mL of a 1 N solution of hydrogen chloride in methanol was added at room temperature. A vigorous exothermic reaction ensued. After it had ceased, the mixture was analyzed by glc and by nmr spectroscopy. Dimethyl adipate was the only product detected.

Treatment of **17**

To a mixture of 1.06 g (10 mmol) **17** (24) in 1 mL of methanol was added 10 mL of a 1 *N* solution of hydrogen chloride in methanol. To avoid losses during the exothermic reaction, the mixture was cooled with ice water and then left standing for 3 h at room temperature. After addition of 1.32 g (10 mmol) of 1,1,1-trichloroethane, nmr analysis showed the presence of 90% of methyl propionate (**18**).

Treatment of **6***k*

To a mixture of 1.06 g (10 mmol) **6***k* (25) in 1 mL of methanol was added 10 mL of a 1 *N* solution of hydrogen chloride in methanol. After standing overnight, crystalline **13** had precipitated and was collected by filtration; yield 260 mg (30%); mp 96–97°C; mixture mp with an authentic sample (21) showed no depression; ^{1}H nmr ($CDCl_3$, TMS) δ: 1.45 (s). Nuclear magnetic resonance analysis of the mother liquor showed as the major component additional **13**, along with signals of unidentified components; however, no methyl acetate was detected.

JEAN-PIERRE LAUSSAC and BIBUDHENDRA SARKAR. Can. J. Chem. **58**, 2055 (1980).

Recent studies have shown that Ni(II) in human blood serum is bound to albumin and the binding site is located at the NH_2-terminus of the protein. In this article, the nature of the Ni(II)-binding site of the NH_2-terminal tripeptide segment of human albumin: L-aspartyl-L-alanyl-L-histidine-*N*-methyl amide (AAHNMA) is reported as deduced by ^{13}C- and ^1H-nmr spectroscopy. The ^{13}C spectrum shows that the Ni(II) complex is in slow exchange on the nmr time scale, and resonances for Ni(II)–peptide complex and metal-free peptide are observed clearly in the pH range 6.4 to 9.1. The Asp COO^- carbon is most affected by Ni(II) binding. The imidazole ring system also shows large variation. Furthermore, the results implicate the involvement of the NH_2 group. The introduction of Ni(II) ion into the solution containing peptide causes profound changes in the ^1H-nmr spectra in the pH range 6.4 to 9.1. Most significantly, there is a complete disappearance of Ala and His N—H protons which confirm the coordination of these two peptide nitrogens. The measurement of the ^{13}C spin–lattice relaxation times (T_1) for AAHNMA and its 1/1 complex provide confirmatory evidence for the existence of a definite complex. The overall results suggest that Ni(II) forms complex with the NH_2-terminal peptide of human albumin involving the α-NH_2, N(3) imidazole, two deprotonated peptide nitrogens, and Asp COO^- group in a pentacoordinated structure.

JEAN-PIERRE LAUSSAC et BIBUDHENDRA SARKAR. Can. J. Chem. **58**, 2055 (1980).

Des études récentes ont montré que, dans le sérum humain, le Ni(II) se lie à l'albumine; cette protéine présente un site de fixation fort qui a été identifié comme étant le site NH_2-terminal. Nous avons étudié la complexation par spectroscopie de rmn des noyaux ^{13}C et ^1H, du Ni(II) avec le fragment tripeptidique NH_2-terminal de la serumalbumine: L-Asp-L-Ala-L-His-*N*-methyl amide (AAHNMA). Dans l'intervalle de pH 6,4 à 9,1, nous observons en ^{13}C que le système est en échange lent. Le carbone AspCOO^- est le plus affecté à la complexation; de la même façon, les carbones du cycle imidazole montrent un important déplacement chimique. Ces résultats sont confirmés par les spectres en résonance du proton qui, dans le même intervalle de pH, montrent de larges variations. Dans le DMSO-d_6, il est intéressant de constater la disparition des protons amides Ala et His N—H qui confirme la coordination de ces deux azotes. Les mesures du temps de relaxation spin–réseau (T_1) en résonance du ^{13}C sur le peptide libre et complexé sont également discutées et confirment les résultats obtenus en ^{13}C et ^1H (δ). L'ensemble de ces données montrent que le nickel se trouve dans un environnement pentacoordonné, les sites de complexation étant le α-NH_2, le N(3) imidazole, les deux azotes peptidiques et le groupement carboxyl AspCOO^-.

Introduction

Metal toxicity caused by environmental pollution or occupational exposure in industry is of great concern around the world. Studies have revealed an association between Ni(II) exposure and nasal carcinoma (1, 2). An investigation of workers at a nickel refinery in Norway found that the degree of epithelial keratinization was more pronounced in the Ni(II) exposed group than in the controls (3). It has been observed that there is a high level of Ni(II) in the blood of healthy individuals in a mining town in North America (4). Very little is known, however, about how this metal is handled by the body or transported.

In our continuing investigation of the biological transport of metals and their toxic effects in humans (5–8), we have recently found that Ni(II) in human blood serum is bound to albumin and to L-histidine (9). From previous reports it appears that the Ni(II)-binding site of human albumin is located at the NH_2-terminus of the protein (10) but the structure of the binding site remains unknown. The synthesis of the NH_2-terminal tripeptide segment of human albumin: L-aspartyl-L-alanyl-L-histidine-*N*-methyl amide in this laboratory (11) has made it possible to investigate the Ni(II)-binding to human albumin in detail.

Nuclear magnetic resonance (nmr) spectroscopy is a well-established method for studying the structure of metal–ligand complexes. The measurable quantities such as chemical shifts, spin–spin coupling constants, and nuclear relaxation times can provide direct information on molecular dynamics and structure. In this article we report the structure of the Ni(II)-binding site of the peptide fragment representing the NH_2-terminus sequence of human albumin as deduced by ^{13}C- and ^1H-nmr spectroscopy.

Experimental Section

The tripeptide, L-aspartyl-L-alanyl-L-histidine-*N*-methyl amide (AAHNMA) was synthesized according to the procedure described earlier (11). D_2O from Merck, Sharp and Dohme, Canada, was used as a solvent. Stock solutions of $NiCl_2$ (Fisher

complex is in slow exchange on the nmr time scale, and resonances for Ni(II)–peptide complex and metal-free peptide are observed clearly in the pH range 6.4 to 9.1.[3] Since the system is in slow exchange, it is possible to unequivocally assign the carbon resonances for the Ni(II) complex. The method used for the assignment of the proton bearing carbon resonances was specific irradiation of the directly bonded ^{1}H resonances; in the same way carboxyl and carbonyl carbons are assigned by off-resonance techniques. The individual chemical shifts ($\Delta = \delta_{1/1\ \text{complex}} - \delta_{\text{free peptide}}$) for all carbons are shown in Fig. 2. All the carbons are shifted downfield except the C(5) imidazole which is shifted upfield. The Asp Cβ shows a downfield shift at low pH but at pH 9.1 it is shifted upfield. The Asp COO^- carbon is affected most of all by Ni(II) binding ($\Delta = 8.32$ ppm at pH = 9.1), which is consistent with carboxylate–Ni(II) coordination. The imidazole ring system also shows large variation, for example, $\Delta = -2.45$ ppm for the C(5) carbon. The Ala Cβ carbon is also affected (not the His-$NHCH_3$), but here the shift must be due largely to conformational effects. Indeed, the CPK space-filling model building indicates that the Ala Cβ is near the carboxylate group. The amino titration ($pK = 7.73$) affects the Asp CO more strongly than Asp COO^- and the β carbon more strongly than the nearest α carbon. But upon complexation, the Ni(II)-binding to the NH_2-terminal and COO^-

[3]Species analysis of the Ni(II)–AAHNMA system in 0.15 *M* NaCl, 25°C shows the presence of four complex species MA ($\log \beta_{101} = 5.50$), MA_2 ($\log \beta_{102} = 11.56$), $MH_{-1}A_2$ ($\log \beta_{1-12} = 4.75$), and $MH_{-2}A$ ($\log \beta_{1-21} = -5.94$) in the pH range 5.0–10.0. At pH 9, $MH_{-2}A$ is the only complex species present in the system. The spectrum of this species is that of typical diamagnetic Ni(II) complex. Results of the magnetic moment measurements are consistent with a diamagnetic system (34).

Scientific Company) were prepared and calibrated titrimetrically. Nickel(II) was added with a Hamilton microliter syringe from a stock solution to obtain appropriate [AAHNMA]/[Ni(II)] ratios. The pH was varied by adding NaOD or DCl to the solution. All quoted pH values have meter readings which are uncorrected for D_2O solutions. It was assumed that pD and pH values of this solution were not significantly different for the interpretation of the results (12).

Carbon-13 spectra were recorded at 25.2 MHz on a Varian XL-100-15-NMR spectrometer operating in the pulse-Fourier transform mode. Probe temperature, under proton decoupled conditions, was 32 ± 3°C. All chemical shifts were reported in ppm downfield from internal DSS. The deuterium resonance of the solvent D_2O was used for the lock signal and the concentration of the solution was 0.1 *M*.

Spin–lattice relaxation time (T_1 in s) measurements were performed by the inversion recovery method (13) by the use of the $(180°-\tau-90°-T)_n$ pulse sequence method where τ is a variable delay time, T is at least five times longer than the longest T_1 to be measured. The value of the spin–lattice relaxation time is given by using semi-logarithmic plot:

$$A = A_\infty[1 - 2\exp(-\tau/T_1)]$$

where A is the observed intensity and A_∞ is the equilibrium intensity. The nmr spectra were generally obtained for 10 different τ values and T_1 was calculated from the slopes of a plot of $\ln|A_\infty - A|$ vs. τ. Samples with a volume of 1.5 mL (0.3 *M*) were prepared in 12-mm nmr tubes and were degassed five times using the freeze–pump–thaw technique. The accuracy of T_1 values was ±10%.

Nuclear Overhauser enhancement (nOe) was measured by comparing the integrated intensities of the ^{13}C resonances in proton noise-decoupled spectra and coupled spectra. The proton-bearing α, β, and imidazole carbons yielded enhancement of 2.8 ± 0.1.

The proton magnetic resonance studies were performed on a Varian HR.220 FT NMR spectrometer. Chemical shifts were reported in ppm downfield from internal DSS. Samples run in D_2O or in DMSO-d_6 were replaced in 5-mm tubes and the spectrometer locked directly on the solvent resonance.

Results and Discussion

^{13}C- and ^1H-Nuclear Magnetic Resonance Studies of Free Peptide

Carbon-13 and proton nmr results of free peptide are shown at various pH values in Tables 1 and 2. Assignments were made with homonuclear decoupling experiments, spectra of free amino acids, and analysis of pH dependent resonances. The assignments are also consistent with some of the results reported recently on the ^{13}C-nmr spectra of the peptide (14).

pH Studies

There are some important aspects of the results with ^{13}C chemical shift titration:

1. All the carbon resonances are affected except the methyl carbons, Ala Cα, and C(5) where no significant change in chemical shift is observed from pH 6.4 to 9.1.

2. The shifts are downfield with increasing pH. The phenomenon of downfield shifts with deprotonation for ^{13}C resonances has been previously noted (15, 16).

3. The amino titration affects the Asp CO more strongly than Asp COO^- and the β carbon more strongly than the nearby α carbon (pK_a = 7.73). The titration of imidazole group (pK_a = 6.55) affects the quaternary C(4) resonance far more than those of the C(2) and C(5). This has been explained by predominance of N(1)H tautomer form (17, 18). The invariability of the C(5) chemical shift suggests that the N(1)H form remains predominant, but the charge redistribution in the imidazole ring has probably been modified by an intramolecular interaction (*vide infra*) (19).

Proton nmr spectra also show changes in the chemical shifts as a result of deprotonating the imidazole ring of His and Asp—NH_2 terminal, all resonances being shifted upfield with increasing pH (20). This opposite phenomenon, compared to those of ^{13}C resonances which show only downfield shifts with deprotonation, has been explained by several authors (17, 21). In accordance with the data on histidine residues, the lower field resonance which exhibits the greater pH shift is identified with the C(2)H proton, and the upper field resonance with the C(5)H hydrogen. C(2)H is the most affected (0.62 ppm) of all protons. It is known that the proton resonances of the imidazole residue are sensitive to pH changes. The amino titration affects more strongly the Asp α (0.54 ppm) than the Asp β (0.29 ppm).

Interestingly, the changes in pH do not cause any large changes in the vicinal coupling constants, indicating that protonation or deprotonation occurs without major alterations in rotamer populations around the bonds.

Spectra in DMSO-d_6

The use of DMSO-d_6 as a solvent for ^1H-nmr studies allows direct observation of the exchangeable protons. These protons have all been assigned by homonuclear spin decoupling of the CH and CH_3 resonances. Double resonance experiments demonstrate that the two doublets at δ 8.93 ppm ($^3J_{NH-\alpha CH}$ = 5.9 Hz) and δ 8.35 ppm ($^3J_{NH-\alpha CH}$ = 8.2 Hz) originate from the NH groups of the alanine and histidine residues. Decoupling also identifies the quadruplet at δ 7.85 ppm ($^3J_{NH-\alpha CH_3}$ = 4.5 Hz) with the NH of CH_3—NH. The resonance from the imidazole N(1)H can be accounted at δ 11.95 ppm.

^{13}C- and ^1H-Nuclear Magnetic Resonance Studies of Nickel(II)–Peptide Complex

^{13}C-Nuclear Magnetic Resonance Studies

The ^{13}C spectrum (Fig. 1) shows that the Ni(II)

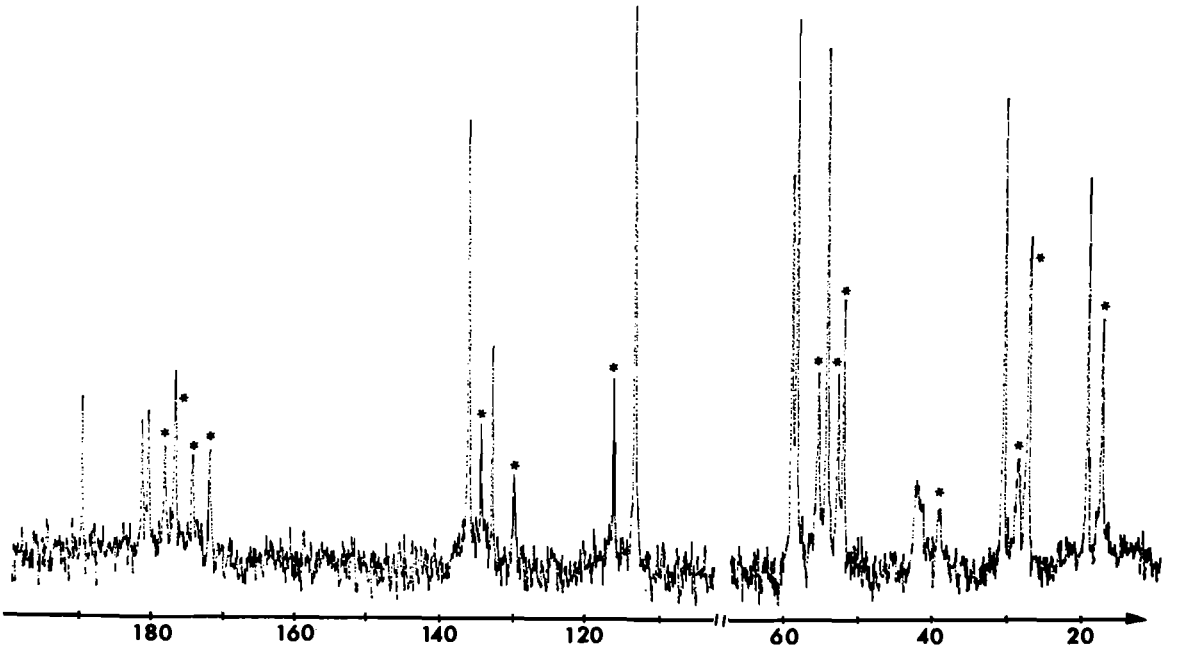

FIG. 1. ^{13}C-nmr spectrum of AAHNMA:Ni(II) (3/2) in D_2O at pH 7.0. Peak with * is free peptide; peak without *is Ni(II)–peptide complex.

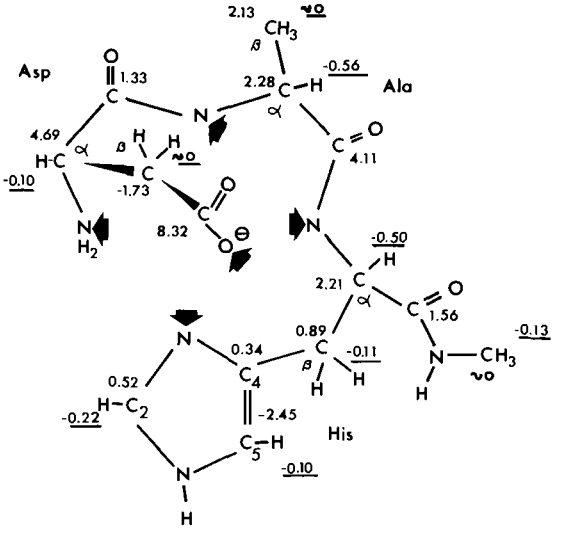

FIG. 2. Chemical shift ($\Delta = \delta_{1/1\ \text{complex}} - \delta_{\text{free peptide}}$) for the 1/1 AAHNMA–Ni(II) complex in D_2O at pH 9.1. Underlined numbers represent ^{1}H values and numbers without underline shows ^{13}C values in ppm. Arrows are directed toward the proposed site of Ni(II)-binding to the peptide.

group affects the α carbon (4.69 ppm) more strongly while in the case of β carbon, we observe a shielding effect (−1.73 ppm) at pH 9.1.

^{1}H-Nuclear Magnetic Resonance Studies

The introduction of Ni(II) ion into the solution containing peptide causes profound changes in the ^{1}H-nmr spectra in the pH range 6.4 to 9.1 in 1/1 Ni(II):AAHNMA solution. There are overall upfield chemical shifts for all protons. The same phenomenon has been observed for different Ni(II) complexes with peptides (22, 23). Many upfield chemical shifts are observed for imidazole residues C(2)H (0.22 ppm), C(5)H (0.10 ppm), and also the CHα protons (Asp α (0.10 ppm), Ala α (0.56 ppm), His α (0.50 ppm)) all at pH 9.1. For all groups which are affected by titration, the upfield chemical shifts are more pronounced in case of complexation (Asp $CH_2\beta$, Asp CHα, C(2)H, and C(5)H) than deprotonation at pH 9.1. It appears that the pronounced upfield shifts induced by diamagnetic nickel ion result from the diamagnetic metal ion and not from the ligand involved. Most significantly, in DMSO-d_6 solution containing Ni(II)—AAHNMA, there is a complete disappearance of Ala and His N—H protons, which confirms the coordination of these two peptide nitrogens. It is known that the metal ion promotes the ionization of peptide protons with subsequent binding to the negatively charged nitrogen atom (24, 25).

Studies of Spin–Lattice Relaxation Times

The ^{13}C spin–lattice relaxation times (T_1) for AAHNMA and its (1/1) Ni(II) complex have been determined at pH 7.0 and 10.0. NT_1 values, where N is the number of directly bonded hydrogen atoms, are given in Table 3. In general, ^{13}C spin–lattice relaxation times of protonated carbons of large molecules are relatively easy to relate to

TABLE 3. Spin–lattice relaxation values (NT_1's) (s) measured for AAHNMA and its 1:1 Ni(II)–complex

	Spin–lattice relaxation value

*Peak is broadened.

dynamic properties of the molecules in solution. This is because the ^{13}C relaxation of such carbons is dominated by a single relaxation mechanism, namely the ^{13}C–^1H dipolar interaction with the directly bonded hydrogen (26, 27). Indeed, in our case, the nuclear Overhauser enhancement (nOe) factor was found to be 2.8, within experimental error (pH = 10.0), and at our magnetic field (25.2 MHz), the ^{13}C–^1H dipolar relaxation satisfies the extreme narrowing conditions. Therefore, we have the relation: $NT_1 = f(1/\tau_{eff})$ where τ_{eff} is the isotropic rotational correlation time. In the present conditions, more rapid rotational motion (shorter rotational correlation time) is reflected in a longer value of NT_1. A large decrease is observed for T_1 values in Ni(II) binding. These data suggest that complexation results in a rigidification and a restriction of segmental motion (28). The present T_1 measurement shows that the 1/1 Ni(II)–AAHNMA complex moiety is more rigid than the free peptide.

There is little effect of pH change on the relative mobilities of the individual residues in AAHNMA and its complex as manifested in the NT_1 values (Table 3). Nevertheless, the values for the majority of the nuclei at neutral pH are lower than those at basic pH, except those of methyl groups which have the same mobility in both pH's. However, it should be pointed out that the observed change approaches the experimental error. In the case of the free peptide the observation is consistent with the resonance intensities and linewidths near the pK values of the imidazole (6.55) and Asp (7.73) titrating groups. It is known that certain resonances which are sensitive to titration undergo a broadening effect in the pH range near the pK of the titrating group (29). The difference for the 1/1 complex at pH 7.0 and 10.0 is more significant. The ^{13}C nmr spectra show a different behavior with pH changes. In acidic solution (pH 2.5) the signals of the Asp COO^-, Asp Cα, and Asp Cβ are broadened and they disappear with increasing pH (3.5), but again appear and sharpen when the pH rises above 5.0. In this condition and in the absence of all the available nitrogen ligands, the ionized carboxyl group of aspartic residue is involved in paramagnetic complex formation. But within the pH range 6 to 10, a diamagnetic species is observed (magnetic moment measurements show a diamagnetic complex at pH 9.0). The visible spectra support the conclusions drawn from the nmr results. These data are consistent with previously observed species distribution as a function of pH for the system AAHNMA/Cu(II) (30). However, at pH 7.0 we have a small amount of paramagnetic species; for this reason the NT_1 values obtained at neutral pH for the Ni(II)–complex (1/1) are lower than those for basic pH, which give a different correlation time (*vide infra*). Within the experimental errors for the same pH, all the three different α carbons had identical ^{13}C T_1 values; this would be strong evidence for isotropic rotation of compounds in D_2O. We find that this relaxation time corresponds to an isotropic rotational correlation time $\tau_{eff} = 1.6 \times 10^{-10}$ s (pH = 7.0) and 1.3×10^{-10} s (pH = 10) for complex. This value for AAHNMA may be compared with correlation times estimated for the peptide TRF (thyrotropin releasing factor) (1.2×10^{-10} s at pH 9.9) which have similar molecular weights (31).

The β carbons of Asp and His residues in the free peptide and complexes show greater motion than the corresponding Cα. For example at pH = 10.0, the ratio of their T_1 Asp is 1.5. The substantially lower T_1 ratio (1.2) of 1/1 complex at the same pH suggests that in this case the side chain of Asp experiences restricted mobility about the Cα—Cβ bond, which is consistent with the involvement of COO^- group. The T_1's of the protonated carbons of the histidine ring in free peptide are similar to that of the β-carbon suggesting a restricted rotation of the ring about the Cα—Cβ bond. The side chain of Asp is slightly more mobile than the His residue. For example, the Cβ/Cα His ratio is ~1.3 at pH 7.0 and 10.0 in the free peptide. The lower ratio and the

For personal use only.

invariability of the C(5) chemical shift by titration suggests a slightly higher proportion of the N(1)H tautomer that could be stabilized by an intramolecular interaction.

The largest values of NT_1 in Table 3 are observed for the methyl groups. Here, the rotational motion about their axis is expected to make a dominant contribution. Comparison of the NT_1 for methyl groups with those for the corresponding Cα (Ala) shows a ratio of 3.8 (pH 7.0) and 3.4 (pH 10.0) in free peptide and 6.5 (pH 7.0) and 4.0 (pH 10.0) upon Ni(II) binding. The ratio of the NT_1 value for the methyl group to the NT_1 value for the central residue Cα increased with increasing distance from the central Cα. The maximum ratio for a freely rotating methyl group attached directly to a rigid backbone undergoing isotropic reorientation is 9 (26).

Structure of the Nickel(II)–Peptide Complex

Assuming that the (1/1) Ni(II)–AAHNMA complex tumbles isotropically, the overall results provide confirmatory evidence for the existence of a definite complex. The above results suggest that Ni(II) forms complex with this peptide involving the α-NH_2, N(3) imidazole, two deprotonated peptide nitrogens, and the Asp COO^- group in a pentacoordinated structure as shown by the arrows in Fig. 2. Nickel(II) complexes are commonly found to be square planar or octahedral. However, Sacconi and co-workers (32) first reported a pentacoordinated Ni(II) complex and since then several such complexes have been found.

There is considerable similarity in the binding properties of Ni(II)–AAHNMA and those of Ni(II) – human albumin (10). The involvement of the histidine residue in the third position in the polypeptide chain is reinforced by the recent results[4] of Ni(II)-binding to dog albumin where the histidine is replaced by a tyrosine residue (33). Taking all these into account, it appears that the Ni(II)-binding site of human albumin is similar to that found in the Ni(II)–AAHNMA complex. Detailed studies are underway with human albumin.

Hydrolytic behavior of two β-lactams and their corresponding imidate salts. New evidence for stereoelectronic control

PIERRE DESLONGCHAMPS AND MAURICE CARON[1,2]

Laboratoire de Synthèse Organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received April 23, 1980

PIERRE DESLONGCHAMPS and MAURICE CARON. Can. J. Chem. **58**, 2061 (1980).

The basic hydrolysis and the concurrent carbonyl–oxygen exchange of ^{18}O-labelled *N*-phenyl-4-phenyl-2-azetidinone (**5***) and *N*-2,6-dimethylphenyl-2-azetidinone (**6***) have been studied. β-Lactam **5*** was easily hydrolysed and showed no carbonyl–oxygen exchange with 0.1 *N* sodium hydroxide (dioxane–water, 9:1). Under the same conditions, β-lactam **6*** gave no exchange and was found resistant to basic hydrolysis. Hydrolysis and exchange was observed when **6*** was refluxed with 0.1 *N* and 1 *N* sodium hydroxide in water.

The hydrolysis of the corresponding imidate salts **7** and **8** was also investigated. Under basic conditions, salt **7** gave an 8:2 mixture of ester amine **9** and β-lactam **5**, while under acidic conditions the hydrochloride salt of ester amine **9** was the only product. Under basic conditions, the imidate salt **8** produced only the β-lactam **6**, and under acidic conditions, a 3:7 mixture of the hydrochloride salt of **10** and β-lactam **6**. Under stronger acidic conditions (≥3 *N* HCl), **8** gave only the starting β-lactam **6**.

The results of these hydrolysis reactions are easily explained on the basis of the stereoelectronic theory for the cleavage of tetrahedral intermediates, and by taking into account that the nitrogen of tetrahedral intermediates must be either protonated under acidic conditions, or hydrogen bonded with the solvent under basic conditions in order to observe the cleavage of the C—N bond.

PIERRE DESLONGCHAMPS et MAURICE CARON. Can. J. Chem. **58**, 2061 (1980).

L'hydrolyse basique et l'échange O-18 au carbonyle de la *N*-phényl phényl-4 azétidinone-2 (**5***) et de la *N*-diméthyl-2,6 phényl azétidinone-2 (**6***) ont été étudiées. La β-lactame **5*** s'hydrolyse facilement et ne subit pas d'échange O-18 au carbonyle avec l'hydroxyde de sodium 0.1 *N* (dioxanne–eau, 9:1). Dans les mêmes conditions, la β-lactame **6*** ne subit pas d'échange et résiste à l'hydrolyse basique; ce n'est qu'à reflux avec l'hydroxyde de sodium 0.1 *N* et 1 *N* dans l'eau que la lactame **6*** s'hydrolyse et subit l'échange.

L'hydrolyse des sels imidates correspondants **7** et **8** fut aussi étudiée. En milieu basique, le sel **7** donne un mélange 8:2 d'ester-amine **9** et de β-lactame **5** et en milieu acide, il donne l'hydrochlorure de l'ester-amine **9** comme produit unique. En milieu basique l'imidate **8** donne seulement la β-lactame **6** et en milieu acide il donne un mélange (3:7) de l'hydrochlorure de **10** et de β-lactame **6**. En milieu plus acide (≥HCl 3 *N*) l'imidate **8** donne uniquement la β-lactame **6** de départ.

Les résultats de ces réactions d'hydrolyse sont expliqués facilement par la théorie stéreoélectronique sur le bris des intermédiaires tétraédriques en tenant compte que le bris du lien C—N d'un intermédiaire tétraédrique ne peut se faire que si l'azote (de l'intermédiaire tétraédrique) est soit protoné en milieu acide, soit lié par un pont hydrogène avec le solvant en milieu basique.

We have recently shown that carbonyl–oxygen exchange concurrent with the basic hydrolysis of ^{18}O-labelled amides is a powerful technique to demonstrate the importance of stereoelectronic effects in the cleavage of tetrahedral intermediates (1, 2). In the course of this work, we have also shown conclusively that the nitrogen of tetrahedral intermediates in the T^- ionic form must be hydrogen bonded with the solvent in order to observe the cleavage of the C—N bond. For instance, *N*-2,6-dimethylphenyl *N*-methylformamide **1** (Scheme 1) was found to be resistant to basic hydrolysis, and this result was explained by the fact that in the corresponding tetrahedral intermediate **2**, the presence of the two methyl groups on the phenyl ring prevents the formation of a hydrogen bond between the tertiary nitrogen and water.

We have also described that the basic hydrolysis of imidate salts **3** (3) and **4** (4) gave only the corresponding amide alcohol products. Again, these results were explained by the fact that the nitrogen in their corresponding tetrahedral intermediates cannot form a hydrogen bond with the solvent.

In order to emphasize these results, we have undertaken the study of the carbonyl–oxygen exchange in the basic hydrolysis of ^{18}O-labelled β-lactams **5*** and **6***. We have also studied the acid and basic hydrolysis of the corresponding imidate salts **7** and **8** which can either give the β-lactams **5** and **6** or the ester amines **9** and **10** respectively. We wish now to report this work.

Synthesis of β-Lactams and Imidate Salts

N-phenyl-4-phenyl-2-azetidinone (**5**) was prepared by utilizing the Reformatsky reaction (5) with ethyl bromoacetate and the imine **11** (Scheme 2) derived from benzaldehyde and aniline. Compound **5** was also produced by the zinc reduction of

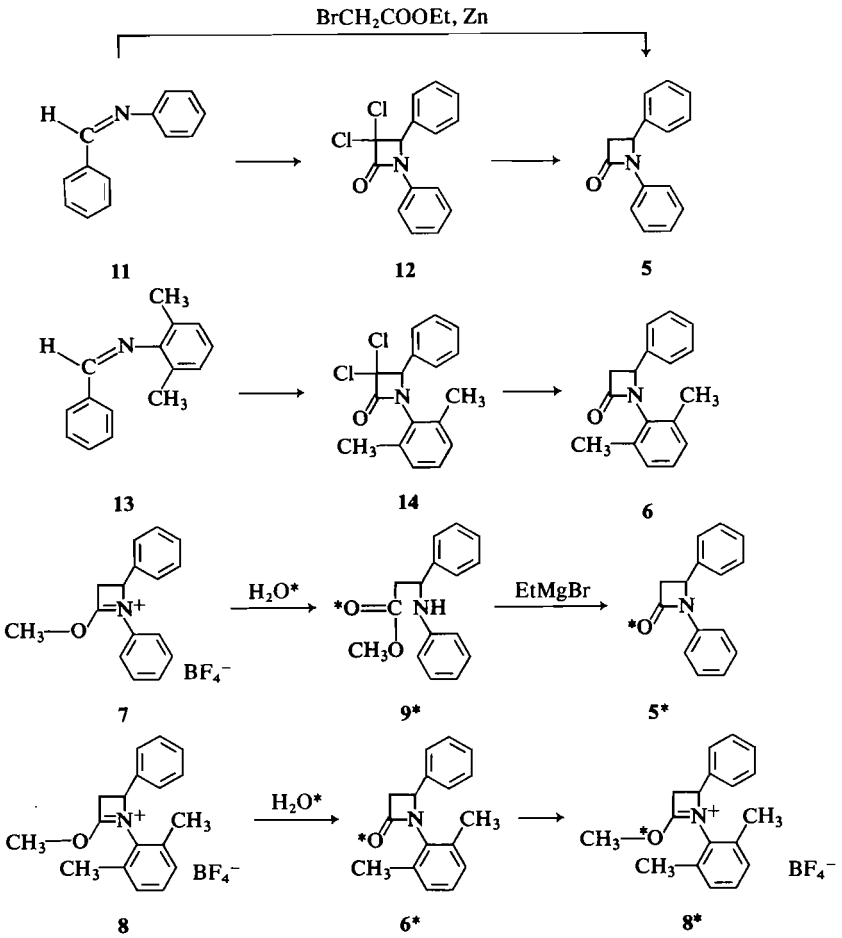
SCHEME 1 (O* = ^{18}O)

dichlorolactam **12** which was obtained by the condensation of imine **11** with dichloroketene (6). Condensation of dichloroketene with imine **13**, derived from benzaldehyde and 2,6-dimethyl aniline, gave the dichlorolactam **14**. Reduction of **14** with zinc yielded the desired *N*-2,6-dimethylphenyl-2-azetidinone (**6**).[3]

The imidate salts **7** and **8** were prepared by the reaction of trimethyloxonium tetrafluoroborate on the corresponding β-lactams **5** and **6** (8). The ^{18}O-labelled products were obtained in the following manner. Hydrolysis of imidate salt **7** with ^{18}O-labelled water gave ^{18}O-labelled ester amine **9*** which was converted into ^{18}O-labelled **5*** by the action of ethyl magnesium bromide (9). Reaction of imidate salt **8** with ^{18}O-labelled water gave directly the ^{18}O-labelled β-lactam **6***. Alkylation of β-lactam **6*** with trimethyloxonium tetrafluoroborate gave ^{18}O-labelled imidate salt **8***.

[3]A different β-lactam derived from 2,6-dimethylaniline has been synthesized recently (7).



Results and Discussion

β-Lactams **5*** and **6*** were hydrolysed at reflux temperature with 0.1 *N* and 1 *N* sodium hydroxide. The results are described in Table 1.

Concurrent carbonyl–oxygen exchange was not observed during the basic hydrolysis of β-lactam **5***. We have previously predicted and shown (1, 2) that tertiary amides do not undergo carbonyl–oxygen exchange concurrent to hydrolysis, thus compound **5*** behaves like a typical tertiary amide.[4] β-Lactam **5*** must therefore react with hydroxide ion to give, with stereoelectronic control (10), the tetrahedral intermediate **15**. The intermediate **15** has proper electron pair orientation to eject either the unlabelled OH group or the amino group, yielding either the labelled β-lactam **5*** or the hy-

[4]Formamides are essentially the only exceptions, in these compounds, the energy barrier for conformational change in the corresponding tetrahedral intermediate is lower than usual due to the presence of the hydrogen atom which is smaller than an alkyl group (2).

SCHEME 2

drolysis product **16**. Since the nitrogen of the tetrahedral intermediate **15** can easily form a hydrogen bond with the solvent, the ring opening barrier is low. Consequently, conformational change (and appropriate proton transfer) to give the intermediate **17** which would then yield the unlabelled β-lactam **5** or the hydrolysis product **16**, cannot compete with the breakdown of **15** with stereoelectronic control.[5]

The β-lactam **6*** is hydrolysed at a considerably slower rate than the β-lactam **5*** and contrary to **5***, **6*** does undergo concurrent carbonyl–oxygen exchange. These results can also be readily explained: **6*** can form first the tetrahedral intermediate **18**. However, the barrier to ring opening of the intermediate **18** is raised on account of steric hindrance to hydrogen bonding. Conformational change (**18** → **20**) can therefore compete with hydrolysis, with the result that carbonyl–oxygen exchange (**20** → **6**) is observed.

The hydrolyses of imidate salts **7** and **8** were carried out under a range of pH conditions at room temperature and the results are summarized in Table 2.

We have previously shown that the hydrolysis of *syn* and *anti* imidate salts can be understood by taking into consideration the principle of stereoelectronic control and the ionic form of the tetrahedral intermediate which depends upon the pH of the medium.[6]

[5]The absence of carbonyl–oxygen exchange in **5*** can also be explained if the cleavage **15** → **16** occurs at a faster rate than the cleavage **15** → **5**. The cleavage **15** → **16** would be unusually fast due to the release of strain caused by the opening of the four-membered ring.

[6]The tetrahedral intermediate exists in the T^- ionic form **31** (Scheme 5) under strongly basic conditions (pH > 11), in the T^0 form **30** or the kinetically equivalent $T^{\pm}$ ionic form **29** at a pH corresponding to the pK_a of the tetrahedral intermediate (pH ≃ 10), and the T^+ ionic form **28** under acidic conditions. Also, the tertiary nitrogen in the T^- ionic form **31** must be able to form a hydrogen bond with water (**32**).

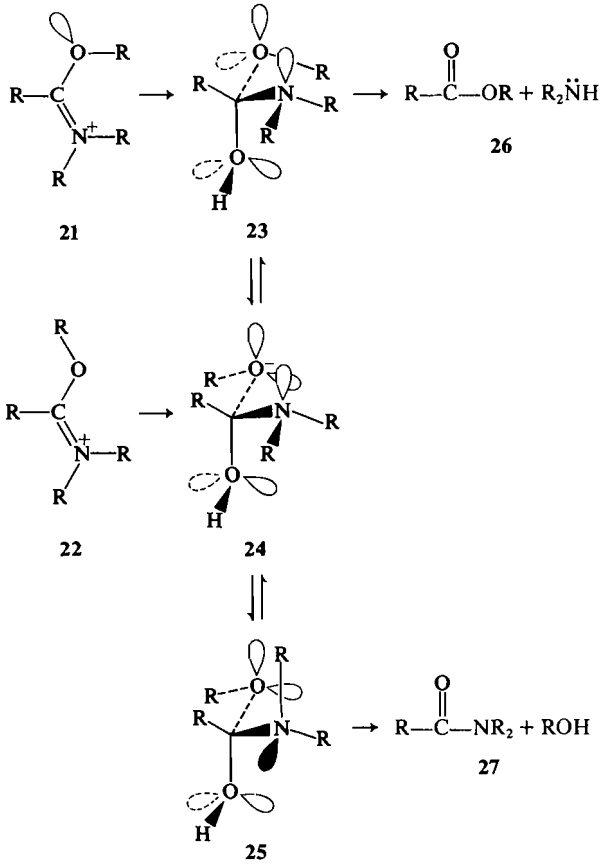
1.0 *N*	Water —	**6**	336	24	40

[a]Detected by ^{1}H nmr.



It is necessary to summarize this rationalization. The *anti* form **21** (Scheme 4) of an imidate salt gives the intermediate **23** in which the cleavage of the C—N bond to yield **26** can take place with stereoelectronic control regardless of whether **23** exists in the T^+, $T^\pm$, or T^- ionic form. The *syn* form **22** of an imidate salt gives first the intermediate **24** which cannot break down with stereoelectronic control; it therefore undergoes a conformational change to either **23** or **25**. The T^- ionic form of **25** can break down with stereoelectronic control. Assuming that both conformational changes, **24** → **23** and **24** → **25**, can take place, *syn* imidate salts will give a mixture of ester amine and amide alcohol products **26** and **27** under strongly basic conditions. The $T^\pm$ and T^+ ionic forms of intermediate **25** cannot undergo a cleavage of the C—O bond with stereoelectronic control because the nitrogen electron pair is no more available. Consequently, *syn* imidate salts will give the ester amine product **26** only, under such conditions. Thus, in résumé, *anti* imidate salts always give the ester amine product **26** over the complete range of pH values, whereas *syn* imidate salts yield the ester amine product **26** under acidic conditions, and a mixture of ester amine and amide alcohol products **26** and **27** under basic conditions. These conclusions have been previously verified experimentally (3, 4, 11).

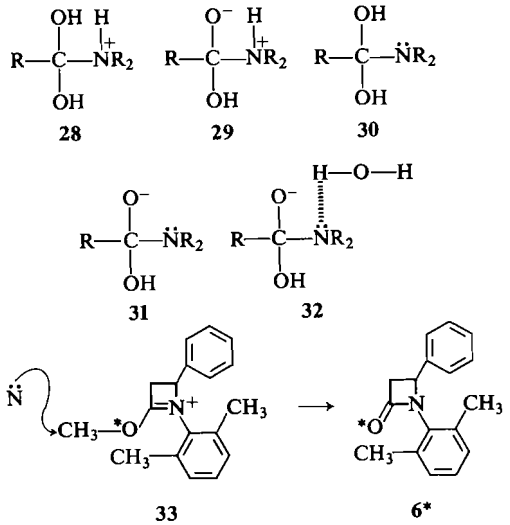
TABLE 2. Hydrolysis of imidate salts at various pH values at room temperature

Medium	Imidate salt 7		Imidate salt 8	
	β-Lactam 5 (%)	Ester-amine 9 (%)	β-Lactam 6 (%)	Ester-amine 10 (%)
1.0 *N* NaOH	20	80	100	0
pH 12.7	12	88	100	0
pH 9	0	100	100	0
pH 7	0	100	100	0
pH 4	0	100	68	32
0.1 *N* HCl	0	100	56	44
0.5 *N* HCl	0	100	65	35
1.5 *N* HCl	0	100	87	13
3.0 *N* HCl	0	100	100	0
6.0 *N* HCl	0	100	100	0

SCHEME 4

Under basic conditions (pH > 11), imidate salt **7** yields a mixture of ester amine **9** and β-lactam **5**, and from pH 9 to 6 *N* hydrochloric acid, the only product formed is the ester amine **9**. Consequently imidate salt **7**, which very likely exists as a mixture of *syn* and *anti* isomers (11), reacts normally.



If one of the parameters that we have discussed in the hydrolysis of *syn* and *anti* imidate salts is changed, for instance if there is a situation where there is considerable steric hindrance at the tetrahedral intermediate level which will prevent protonation of the tertiary nitrogen, different results should be obtained. We believe that this is indeed the case with imidate salt **8** in which the two methyl groups on the *N*-phenyl substituent render the nitrogen electron pair in the corresponding tetrahedral intermediate unavailable to approach by a molecule of water or a proton donor source.

Imidate salt **8** when hydrolysed under strongly basic conditions gave the β-lactam **6** only. This result shows that if **23** is formed, it cannot break down, **23** is therefore converted into **25** (or an equivalent) which yields the β-lactam **6** (or **27**). At pH 7–9, the β-lactam **6** is again the only hydrolysis product. Under these conditions, the tetrahedral intermediate must first exist in the T^0 form, but T^0 is no longer easily converted into the $T^{\pm}$ ionic form necessary for the breakdown because of the unusual steric hindrance to proton transfer. The absence of ester amine **10** (or **26**) is therefore readily understood in this case. As soon as the nitrogen can be protonated (≃pH 4), ester amine **10** starts to be formed (32%). It is, however, remarkable that the formation of T^+ is not complete at pH 4, indicating that even under acidic conditions it is not easy to protonate the tertiary nitrogen.

The unexpected gradual decrease of ester amine **10** under stronger acidic conditions suggests a change in the reaction mechanism. This was verified by carrying out the hydrolysis of ^{18}O-labelled imidate salt **8***: at pH 4, the β-lactam **6** produced from **8*** did not contain ^{18}O, at higher pH (0.1 *N* HCl) there was a 25% transmission of the ^{18}O label, and with 3 *N* hydrochloric acid there was a complete transmission of the ^{18}O-label from the imidate salt **8** to the β-lactam **6**.

Formation of β-lactam **6** from salt **8** can either occur via the formation of a tetrahedral intermediate or by an S_N2 type displacement reaction on

SCHEME 5

the methoxy group (**33** → **6***). If the imidate salt **8** contains an ^{18}O atom, this label should be lost if the first mechanism is operative, but it should be totally transmitted into the β-lactam (**6***) in the second mechanism (12).

The results obtained with ^{18}O-labelled imidate salt **8*** clearly indicate that the displacement reaction can compete with the other at pH lower than 4 and it becomes the only reaction under strong acid conditions. An attractive explanation for this change of mechanism is simply that under increasingly acidic conditions, water becomes a weaker nucleophile, and the tetrahedral intermediate formation can no longer compete with the displacement reaction which can take place for instance with chlorine ion. The formation of methyl chloride was indeed observed by nmr spectroscopy under strong acidic conditions.

Experimental

The ir spectra were taken on a Perkin-Elmer 257 spectrophotometer. The ultraviolet (uv) spectra were registered on a Varian Techtron 635 spectrophotometer. Proton nmr spectra were recorded on a Varian A-60 or a Bruker WP-60 instrument. The following abbreviations have been used: s: singlet; d: doublet; dd: doublet of doublet; t: triplet; m: multiplet. Chemical shifts are reported in δ values relative to tetramethylsilane as internal standard.

Mass spectral assay were obtained using a Hitachi-Perkin-Elmer RMU-6-A instrument at 70 eV. Percentages of ^{18}O were calculated using the formula:

$$\%\ ^{18}O = \frac{100\,(P+2)}{P+(P+2)}$$

where P is the height of the parent peak and $(P+2)$ is that of the parent peak plus two m/e units. The percentage exchange is thus

$$\%\ \text{exchange} = \frac{(\%\ ^{18}O \text{ before hydrolysis}) - (\%\ ^{18}O \text{ after hydrolysis})}{(\%\ ^{18}O \text{ before hydrolysis})} \times 100$$

Microanalyses were carried out by Dr C. Daessle, Organic Microanalyses, Montreal. Anhydrous sodium sulfate was used as the drying agent in working reactions. Imines **11** and **13** are known compounds and were prepared by standard procedures (13). Cycloaddition leading to dichlorolactam **12** and the Reformatsky reaction giving the β-lactam **5** were also previously reported in the literature (5, 6).

Imine 11

Melting point 52–53°C (lit. (13) 51–54°C); ir ($CHCl_3$): 1630 cm^{-1}; nmr ($CDCl_3$) δ: 8.20 (1H, s, C_6H_5—C*H*=NC_6H_5), 7.95–7.18 (5H, m, C_6H_5CH=NC_6H_5), 7.13 (5H, m, C_6H_5—CH=NC_6H_5).

Imine 13

Boiling point 110°C/0.4 Torr; ir ($CHCl_3$): 1642 cm^{-1}; nmr ($CDCl_3$) δ: 8.00 (1H, s, C_6H_5C*H*=N—), 7.70 (2H, m, C_6H_5—CH=N—), 7.28 (3H, m, C_6H_5CH=N—), 6.85 (3H, m, C_6H_5CH=N—$C_6H_3(CH_3)_2$), 2.07 (6H, s, —$NC_6H_3(CH_3)_2$).

Dichlorolactam 12

Melting point 162–163°C; ir ($CHCl_3$): 1785 cm^{-1}; nmr ($CDCl_3$) δ: 7.17 (10H, m, two phenyls), 5.37 (1H, s, C_6H_5—C*H*—N—C_6H_5); ms m/e: 292 (M^+), 294 ($M+2$), 296 ($M+4$), 256 (M^+ – HCl).

Dichlorolactam 14

Imine **13** (12.4 g, 59.5 mmol) and triethylamine (12.5 mL, 89.2 mmol) were dissolved in dry benzene (200 mL). At room temperature was added, dropwise, a solution of dichloroacetyl chloride (8.6 mL, 89.2 mmol) in benzene (40 mL). The mixture was stirred at room temperature for 1 h. Then the solution was washed with 5% hydrochloric acid, water, dried, and evaporated. The residue was filtered on silica gel with chloroform – ethyl acetate (9:1). The isolated oil crystallized when treated with methanol giving dichlorolactam **14** (14.9 g, 78%); mp 98–99°C; ir ($CHCl_3$): 1795 cm^{-1}; nmr ($CDCl_3$) δ: 7.17 (5H, s, C_6H_5), 6.92 (3H, s, N—$C_6H_3(CH_3)_2$), 5.70 (1H, s, —C*H*C_6H_5), 2.35 (6H, s, $C_6H_3(CH_3)_2$); ms m/e: 320 (M^+), 322 ($M+2$), 324 ($M+4$), 284 (M^+ – HCl). *Anal.* calcd. for $C_{17}H_{15}NOCl_2$: C 63.76, H 4.72, Cl 22.15; found: C 63.83, H 4.55, Cl 22.25.

β-*Lactam 5*

The dichlorolactam **12** (52.3 mg, 0.18 mmol) was dissolved in glacial acetic acid (2 mL) containing traces of water. Zinc dust (64 mg, 0.97 mmol) was added and the mixture was refluxed for 3 h. A second portion of zinc dust (100 mg, 1.53 mmol) and glacial acetic acid (3 mL) containing traces of water were added and the reflux was maintained for 2 h. The zinc was filtered and the solvent was evaporated to dryness using benzene. Purification of the residue by thick layer chromatography on silica gel gave pure β-lactam **5** (32 mg, 80%); mp 153–154°C (lit. (5) 153–154°C); uv (dioxane) λ_{max}: 251 nm (ε 9 143), 285 nm (ε 565); ir ($CHCl_3$): 1760 cm^{-1}; nmr ($CDCl_3$) δ: 7.23 (10H, m, two phenyls), 5.02 (1H, dd, J_1 = 5.6 Hz, J_2 = 2.7 Hz, —C*H*—N), 3.59 and 2.93 (2H, dd, J_1 = 5.6 Hz, J_2 = 2.7 Hz, J_3 = 15.2 Hz, CH_2—CH—N); ms m/e: 223 (M^+), 180 ($M^+ - CH_3C{\equiv}O^+$).

The β-lactam **5** was also synthesized using Gilman's procedure (5) and showed identical physical and spectroscopic properties.

β-*Lactam 6*

The dichlorolactam **14** (27 mg, 0.08 mmol) was dissolved in glacial acetic acid (4 mL) containing traces of water. Zinc dust (556 mg, 8.5 mmol) was added and the mixture was refluxed 4 h. The zinc was filtered and the solvent was evaporated to dryness using benzene. Purification of the residue by thick layer chromatography on silica gel gave pure β-lactam **6** (11 mg, 51%); mp 90–91°C; uv (dioxane) λ_{max}: 245 nm (ε 2 709), 287 nm (ε 287); ir ($CHCl_3$): 1750 cm^{-1}; nmr ($CDCl_3$) δ: 7.25 (5H, s, C_6H_5), 6.95

(3H, s, $C_6H_3(CH_3)_2$), 5.12 (1H, dd, J_1 = 5.1 Hz, J_2 = 2.9 Hz, —C*H*—N), 3.49 and 3.22 (2H, dd, J_3 = 15.1 Hz, J_1 = 5.1 Hz, J_2 = 2.9 Hz, CH_2—CH—N), 2.21 (6H, s, $2CH_3$); ms *m/e*: 251 (M^+), 208 ($M^+ - CH_3C{\equiv}O^+$). *Anal.* calcd. for $C_{17}H_{17}NO$: C 81.24, H 6.82; found: C 80.92, H 7.07.

Imidate Salt 7

The β-lactam **5** (261 mg, 1.17 mmol) was added to trimethyloxonium tetrafluoroborate (173 mg, 1.17 mmol) suspended in dichloromethane (10 mL). The mixture was stirred overnight at room temperature. Evaporation of the solvent and recrystallization from dichloromethane–ether mixture gave pure **7** (311 mg, 82%); mp 129°C (dec); ir (CH_2Cl_2): 1670 cm^{-1}; nmr (CD_2Cl_2) δ: 7.43 (5H, s, $C_6H_5\overset{+}{N}$—), 7.34 (5H, s, C_6H_5—CH), 5.75 (1H, dd, J_1 = 1.8 Hz, J_2 = 4.4 Hz, C_6H_5CH—$CH_2\overset{+}{N}$), 4.54 (3H, s, OCH_3), 4.34 and 3.53 (2H, dd, J_3 = 17.2 Hz, J_1 = 1.8 Hz, J_2 = 4.4 Hz, CH_2—CH—C_6H_5).

Imidate Salt 8

The β-lactam **6** (111 mg, 0.44 mmol) was added to trimethyloxonium tetrafluoroborate (65 mg, 0.44 mmol) suspended in dichloromethane (10 mL). The mixture was stirred overnight at room temperature. Evaporation of the solvent and recrystallization from dichloromethane–ether mixture gave pure **8** (114 mg, 73%); mp 148–149°C (dec); ir (CH_2Cl_2): 1675 cm^{-1}; nmr (CD_2Cl_2) δ: 7.40 (5H, m, C_6H_5—CH), 7.14 (3H, m, C_6H_3—$(CH_3)_2$—$\overset{+}{N}$), 5.88 (1H, dd, J_1 = 2.3 Hz, J_2 = 3.9 Hz, C_6H_5CH—CH_2—$\overset{+}{N}$), 4.60 (3H, s, OCH_3), 4.59 and 4.19 (2H, dd, J_3 = 17.3 Hz, J_2 = 3.9 Hz, J_1 = 2.3 Hz, CH_2—CH—C_6H_5), 2.54 (3H, s, CH_3), 1.97 (3H, s, CH_3).

Ester Amine 9

The β-lactam **5** (52 mg, 0.23 mmol) was refluxed with sodium methoxide (19.3 mg) in methanol (15 mL) for 2 h. The solvent was evaporated and the residue diluted with water (10 mL). The solution was extracted with chloroform. The chloroform extracts were dried and evaporated. Pure ester amine **9** was obtained (56 mg, 96%); mp 105.5–106°C (lit. (14) 106–107°C); uv (methanol) λ_{max}: 213 nm (ε 6 684), 248 nm (ε 8 379), 295 nm (ε 1 275); ir ($CHCl_3$): 3420, 1745 cm^{-1}; nmr ($CDCl_3$) δ: 7.34 (5H, m, C_6H_5—CH), 7.29–6.51 (5H, m, C_6H_5—N), 4.86 (1H, t, *J* = 6.6 Hz, *CH*—C_6H_5), 4.56 (1H, m, N—*H*), 3.66 (3H, s, OCH_3), 2.83 (2H, d, *J* = 6.6 Hz, CH_2COOCH_3); ms *m/e*: 255 (M^+), 182 ($M^+ - CH_2COOCH_3$). The ester amine **9** isolated from the hydrolysis of imidate salt **7** was identical to the material prepared by the action of sodium methoxide on the β-lactam **5**.

Ester Amine 10

The ester amine **10** was isolated from the hydrolysis of imidate salt **8** with hydrochloric acid 0.1 *N*; uv (methanol) λ_{max}: 218 nm (ε 10 354), 244 nm (ε 7 651); ir ($CHCl_3$): 1740 cm^{-1}; nmr ($CDCl_3$) δ: 7.27 (5H, s, C_6H_5—CH), 6.90 (3H, m, C_6H_3—$(CH_3)_2$), 4.70 (1H, t, *J* = 7.0 Hz, *CH*—C_6H_5), 3.58 (3H, s, OCH_3), 2.90 (2H, d, *J* = 7 Hz, CH_2COOCH_3), 2.18 (6H, s, $2CH_3$); ms *m/e*: 283 (M^+), 210 ($M^+ - CH_2COOCH_3$).

β-*Lactam 5**

To the imidate **7** (96 mg, 0.30 mmol) was added $H_2{}^{18}O$ (70 μL ca. 95% enriched) followed by $H_2{}^{16}O$ (50 μL). The mixture was left overnight at room temperature. Water was added (5 mL) and the solution was extracted with dichloromethane and dried. The crude product (74 mg, 0.29 mmol) was dissolved in dry ether (30 mL) and under nitrogen was treated with ethyl magnesium bromide (434 μL of 0.67 *N* solution). The solution was stirred for 30 min and 10% ammonium chloride solution (30 mL) was added. The aqueous phase was extracted with ether and dried. β-Lactam **5*** was purified by thick layer chromatography on silica gel (57 mg, 88%). The β-lactam **5*** contained 61% of ^{18}O; ir ($CHCl_3$): 1760 (C=O), 1730 (C=^{18}O) cm^{-1}; ms *m/e*: 225 (*M* + 2) (61%), 223 (M^+). The nmr was identical to the unlabelled β-lactam **5**.

β-*Lactam 6**

To the imidate **8** (218 mg, 0.62 mmol) was added $H_2{}^{18}O$ (200 μL ca. 95% enriched) followed by $H_2{}^{16}O$ (400 μL). The mixture was left overnight at room temperature. Water was added (5 mL) and the solution was extracted with dichloromethane and dried. The crude product was purified by thick layer chromatography on silica gel (118 mg, 76%). The β-lactam **6*** contained 43% of ^{18}O; ir ($CHCl_3$): 1750 (C=O), 1720 (C=^{18}O) cm^{-1}; ms *m/e*: 253 (*M* + 2) (43%), 251 (M^+). The nmr was identical to the unlabelled β-lactam **6**.

Basic Hydrolysis and Concurrent Carbonyl–Oxygen Exchange Experiments (Typical Procedure)

β-*Lactam 5**

The labelled β-lactam **5*** (57 mg, 0.25 mmol) (^{18}O = 61%) was dissolved in dioxane (30 mL) and sodium hydroxide (1.0 *N*, 4.56 mL) was added. The solution was refluxed and at convenient times 5 mL aliquots were withdrawn and poured over hydrochloric acid (1.2 *N*, 1 mL). This solution was extracted several times with dichloromethane and dried. The percentage of hydrolysis was established by nmr spectroscopy. The methine resonance (C_6H_5—C*H*N) appears at higher field in the amino acid (4.88 δ) than in the β-lactam (5.02 δ) in chloroform. Unreacted β-lactam **5*** was purified by thick layer chromatography and submitted to mass spectroscopy. For each aliquot withdrawn material recovered was greater than 84% and β-lactam **5*** isolated revealed a constant incorporation of ^{18}O (61%).

Hydrochloride salt of amino acid **16**: mp 134–136°C (lit. (14) 135–136°C); ir ($CHCl_3$): 3600–2800, 1720 cm^{-1}; nmr ($CDCl_3$) δ: 7.34 (5H, s, C_6H_5—CH), 7.08–6.48 (8H, m, C_6H_5N and $\overset{+}{N}H_2$, COOH), 4.88 (1H, t, *J* = 6.8 Hz, CHC_6H_5), 2.87 (2H, d, *J* = 6.8 Hz, CH_2COOH).

β-*Lactam 6**

The labelled β-lactam **6*** (13 mg, 0.05 mmol) (^{18}O = 43%) was dissolved in dioxane (15 mL) and sodium hydroxide (1.0 *N*, 1.70 mL) was added. The solution was refluxed under argon and after a desired time the reaction was completely stopped. The solution was extracted with dichloromethane and dried. The aqueous phase was acidified with 1.2 *N* hydrochloric acid, extracted with dichloromethane, and dried. The percentage of hydrolysis was established according to the material isolated (greater than 90%). Under this condition β-lactam **6*** did not exchange and revealed constant incorporation of ^{18}O (43%). The identical procedure was used when hydrolysis and exchange took place with sodium hydroxide (0.1 *N* and 1.0 *N*, no dioxane).

Hydrochloride salt of amino acid **19**: mp 150–165°C (sublimes slowly); ir ($CHCl_3$): 3600–2400, 1720 cm^{-1}; nmr ($CDCl_3$) δ: 7.34 (3H, s, $\overset{+}{N}H_2$ and COO*H*), 7.18 (5H, m, C_6H_5—CH), 6.85 (3H, m, $C_6H_3(CH_3)_2$), 4.60 (1H, t, *J* = 7.1 Hz, *CH*—CH_2COOH), 2.90 (2H, d, *J* = 7.1 Hz, CH—CH_2—COOH), 2.08 (6H, s, $2CH_3$).

Imidate Salt Hydrolysis

Typical Procedure

To the imidate salt **7** or **8** (=0.05 mmol) was added water (8 mL) at the desired pH. Both imidate and hydrolysis products were insoluble and the heterogeneous solution was left overnight unstirred.[7] Dichloromethane (15 mL) was added and the solution was neutralized with solid sodium carbonate when solutions were acidic. The aqueous phase was extracted with

[7]Complete hydrolysis was verified by nmr spectrum from crystals taken out from water and dissolved in deuterated dichloromethane. With imidate **7** hydrolysis was complete after 4 h.

dichloromethane and dried. The nmr spectrum was recorded and the ratio of the hydrolysis products determined. The material recovered from extractions was greater than 90%. The methine resonances of the ester amine **9** and the β-lactam **5** appear at 4.86 and 5.02 δ respectively in chloroform. The methine resonance of the ester amine **10** and the β-lactam **6** appear at 4.70 and 5.12 δ respectively. In the case of hydrolysis under acidic conditions, the solution was neutralized before extraction. The ester amine **9** was also obtained by the reaction of sodium methoxide on the β-lactam **5**.

Labelled imidate **8*** (27% O^{18}) was submitted to the same procedure. Mass spectroscopy revealed 27% of ^{18}O in β-lactam **6*** isolated from the hydrolysis with 3.0 *N* hydrochloric acid. Hydrolysis with 0.1 *N* hydrochloric acid gave 6.8% of ^{18}O incorporated in β-lactam **6*** and the unlabelled β-lactam **6** was isolated when imidate **8*** was hydrolysed at pH 4.

Formation of Methyl Chloride

Imidate salt **8** (22 mg, 0.06 mmol) was dissolved in deuterated dichloromethane (0.6 mL) and a solution of deuterated hydrochloric acid (3 *N*, 0.25 mL). The mixture was left for 1.5 h and then vigorously shaken. The nmr spectrum of the dichloromethane phase was recorded and revealed a singlet at 2.88 δ which corresponds to that of methyl chloride. Addition of a few drops of a saturated solution of methyl chloride in deuterated dichloromethane enhanced the singlet at 2.88 δ. Addition of methanol into the nmr tube gave a new singlet at 3.27 δ.

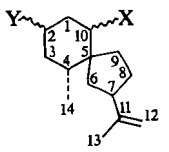
2-Epi- and 15-dihydro-2-epilubimin: new stress compounds from the potato[1,2]

A. STOESSL AND J. B. STOTHERS

Agriculture Canada Research Institute and the Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

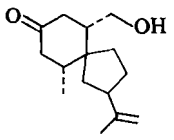
Received May 30, 1980

A. STOESSL and J. B. STOTHERS. Can. J. Chem. **58**, 2069 (1980).



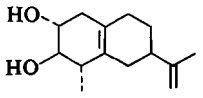
The complement of sesquiterpenoidal stress compounds produced in the interaction of potato with the pathogenic fungus, *Alternaria solani*, includes representatives of a new stereochemical series, 2-epilubimin (**1**) and its reduction product, 15-dihydro-2-epilubimin (**3**). Their structures were deduced from ^{13}C and ^{1}H magnetic resonance data.

A. STOESSL et J. B. STOTHERS. Can. J. Chem. **58**, 2069 (1980).



Le complément des composés sesquiterpéniques de stress qui proviennent de l'interaction entre la pomme de terre et le champignon pathogène *Alternaria solani* comprend des composés caractéristiques d'une nouvelle série stéréochimique, l'épilubimine-2 (**1**) et son produit de réduction la dihydro-15 épilubimine-2 (**3**). On a déduit leurs structures à partir de données de la rmn du ^{13}C et du ^{1}H.

[Traduit par le journal]



Fungal infection or treatment with certain chemicals induces the formation of complex mixtures of bicyclic sesquiterpenoids in potato tubers (1–4). Some of these stress metabolites, of which eighteen have been characterized, are considered to be phytoalexins, i.e., post-infectional defensive agents, on the basis of their fungitoxic properties. A close overall biosynthetic relationship between these compounds is abundantly clear, since all can be, at least formally, derived from eudesmane precursors (1). However, with respect to details, some of the relationships remain obscure. For instance, the predominant vetispirane subgroup of these compounds has hitherto been found to occur in two stereochemical forms, a normal series as represented by lubimin (**2**) and 15-dihydrolubimin (**4**) and a 10-epi series with 10-epilubimin (**5**) and 15-dihydro-10-epilubimin (**6**) as examples. Compound **4** accumulates in large amounts in potatoes invaded by *Glomerella cingulata* and certain other fungi as well as in pure cultures of these fungi supplemented with **2** (5); there is, therefore, no doubt that it is mainly a product of fungal reduction of **2**. In contrast, in potatoes inoculated with *Monilinia fructicola*, very small amounts of **6** have been found, accompanied by even smaller traces of **4** (6). It is not yet clear to what extent these two compounds, under these conditions, are products of potato or fungal metabolism, nor whether the dihydroepi compound is a precursor for, or a product of, **5**. It is clear, however, from these and other data that the

1 X = α-CHO; Y = β-OH
2 X = α-CHO; Y = α-OH
3 X = α-CH_2OH; Y = β-OH
4 X = α-CH_2OH; Y = α-OH
5 X = β-CHO; Y = α-OH
6 X = β-CH_2OH; Y = α-OH

7

8

invading fungus can exert a considerable effect on the spectrum of compounds produced, at least in part, as a result of its own metabolic activity but possibly also by specific effects on biosynthetic pathways of the potato tissue. We have recently extended our investigations of these phenomena to the interaction of potatoes with *Alternaria solani*. This fungus was chosen both because of our interest in its metabolism (7) and because it is an important pathogen of solanaceous crops (8). These experiments led to the discovery of yet another stereochemical series among the vetispirane family. Two new compounds have been isolated in small amounts from potatoes inoculated with mycelial suspensions of *A. solani* and their structures elucidated by spectroscopic methods. We wish to present these results to characterize the 2-epi series of these stress metabolites.

[a]In ppm from internal TMS for $CDCl_3$ solutions (5–10%, w/v).
[b]Data for 2 and 4 taken from ref. 6.

The first compound, 2-epilubimin (**1**), was isolated as an oil having the constitution $C_{15}H_{24}O_2$ by precise mass measurement. The ^1H and ^{13}Cmr spectra indicated the presence of an aldehyde, a hydroxyl group, and a terminal double bond. In addition, the ^1Hmr spectrum revealed a secondary methyl group and the fact that the double bond is part of an isopropenyl group. All spectra closely resembled those exhibited (9) by lubimin (**2**) but with some significant and informative differences, attributed to stereochemical modification. Specifically, the width of the carbinyl proton absorption for **1** was smaller (14 vs. 32 Hz) and this pattern was centred at lower field (4.14 vs. 3.69 ppm). These differences suggest an axial orientation for the hydroxyl group in **1** as opposed to its equatorial disposition in **2**. The formyl proton appearing as a doublet at 9.92 ppm, $J \sim 3$ Hz, was shown by decoupling experiments to be vicinal to a proton at 2.71 ppm; the latter multiplet, a doublet of triplets, was collapsed to a four-line X pattern by irradiation of the formyl proton. This behavior is identical to that found for **2** and the widths of the X patterns are the same for each (16 Hz), indicating that the methine proton on carbon bearing the formyl group is axial in each. Furthermore, irradiation at 1.8 ppm collapsed the carbinyl proton pattern to a triplet and that at 2.71 ppm to a doublet indicating that the hydroxyl and formyl groups are bonded to carbons separated by a common methylene group. The methine proton at 2.71 ppm is 0.45 ppm less shielded than the corresponding proton in **2**; a similar difference was found for the methine proton on carbon bearing the secondary methyl group, while the latter is similarly shielded in each, 0.90 and 0.94 ppm. The shift of 0.45 ppm for each of these protons is consistent with an axial orientation for the hydroxyl function. The signals characterizing the isopropenyl group for **1** and **2** gave rise to very similar patterns in both ^1H and ^{13}C spectra. The major differences in the ^{13}C spectra of **1** and **2** (see Table 1) were the shieldings observed for three of the methine carbons. The carbinyl carbon of **1** at 65.0 ppm is 4.3 ppm upfield from that for **2** while the methine signal at 54.2 ppm is 4.2 ppm upfield from the C-10 absorption in **2**. The latter signal was unequivocally identified in the spectrum of **2** for material obtained from incorporation experiments utilizing sodium acetate-$^{13}C_2$ (6). The highest field methine absorption for **1** at 35.2 ppm is 5.8 ppm upfield from that for C-4 in **2**. It may be noted that the fourth methine signal for **1** is essentially the same as the C-7 signal in **2** (47.2 vs. 47.4 ppm). The upfield shifts for the three methine carbons in **1** constitute strong supporting evidence for an axial 2-hydroxyl substituent. Thus, the nmr evidence led to the 2-epi assignment for **1**, the first example of this stereochemical series.

The structural characterization of the second compound as the 15-dihydro derivative **3** was straightforward since **3** was formed from **1** on treatment with sodium borohydride as evidenced by its chromatographic behavior. The close resemblance of the ^{13}C spectra of **3** and **4** mirrored that described above for **1** and **2** in that three of the methine carbons were distinctly shielded (by 3.7–5.7 ppm) for **3** vs. **4** while the remaining carbons exhibited similar shieldings in both compounds (see Table 1). These three upfield shifts signal the axial disposition of the hydroxyl group. The ^1Hmr spectrum for **3** was also closely similar to that for **4** with the important difference in the band width and position of the carbinyl methine absorption analogous to that described above for **1** and **2**. For **3**, this pattern is deshielded by 0.5 ppm and is much narrower. The patterns for the methylene protons of the hydroxymethyl group in **3** and **4** were essentially identical, appearing as the AB portion of an ABX spectrum with $\delta_{AB} = 0.67$ ppm. This shift difference may be contrasted with the 0.15 ppm difference previously recorded for the isomeric 10-epi-dihydro derivative **6** (6).

As noted above, the reduction of **2** to **4** by the fungus accounted for most, if not all, of the **4** which accumulated in the potato – *Glomerella cingulata* interaction (9). *Alternaria solani* has also been demonstrated to effect this reduction (10). Preliminary evidence (see Experimental) indicates that a similar reduction of **1** by *A. solani* is responsible for the formation of **3** in the interaction of the fungus

with potato. It is of some interest to note that we were able to detect 2-epilubimin (**1**) in only one, although **3** was isolated from each of three separate experiments. The functional and biogenetic significance of the 2-epi compounds in the complex array of stress metabolites produced by infected potatoes is unclear. With compounds **1** and **3** in hand, we were able to check the product of a potato – *Monilinia fructicola* interaction for their presence; **3** was detected but only in vanishingly small amount. The apparently differential effect of different fungi on the spectrum of stress metabolites produced will receive further attention.

Experimental

Nuclear Magnetic Resonance and Mass Spectra

The spectra were recorded with Varian XL-100-12 and XL-100-15 spectrometers using $CDCl_3$ solutions (5–10%, w/v) of the stress metabolites. Proton spectra were obtained on the first instrument using c.w. operation while Fourier transform methods were used on the second to obtain the ^{13}C spectra. For the latter, square-wave modulated proton decoupling gave completely decoupled spectra and single frequency proton irradiation gave off-resonance decoupled spectra. Shielding data (±0.05 ppm) are given relative to internal TMS. Mass spectra were obtained from a Varian MAT 311A system.

Feeding Experiments and Fungal Cultures

Potatoes, var. Kennebec, purchased locally, were stored at ca. 4°C and were 4–7 months old when used. These were inoculated as described previously (6) except that suspensions of homogenized mycelium of *A. solani* in water containing streptomycin (200 ppm) were used instead of spore suspensions.

Monilinia fructicola (Wint.) Honey was from a culture routinely maintained at the Research Institute; it was used as a spore suspension containing ca. 2×10^5 spores/mL.

Alternaria solani (Ell. & Mart.) Jones & Grout was a pigment-producing strain kindly provided by Prof. U. Matern, University of Freiburg, West Germany, and routinely maintained on V-8 juice agar. Inoculum from an agar slope was grown in 6 Erlenmeyer flasks (200 mL capacity) containing medium T (11) (25 mL/flask) for 10–12 days when the mycelia were collected, rinsed with sterile water, homogenized, and resuspended in medium T contained in Roux bottles (100 mL in each of 40–60 bottles).

Column chromatography was done on silica gel, Camag DF5, not activated, using ca. 1 g/mg substance, and MeOH/Et_2O 5:95 as solvent (25 mL fractions) unless otherwise specified. Precoated silica gel plates (0.2 mm; Macherey-Nagel Polygram Sil N-HR/UV) were used for tlc, with MeOH/Et_2O 5:95, MeOH/$CHCl_3$ 5:95, and *i*PrOH/EtOAc 5:95 as standard irrigants. Vanillin (0.5%) in phosphoric acid (50%) was used as chromogenic reagent at 110°C.

Isolation of Metabolites

Incubation of ca. 30 kg of potatoes with a mycelial suspension of *Alternaria solani*, grown in 3 Roux bottles for 12 days, furnished a diffusate from which 310 mg of ether-soluble material was extracted after 2 days as previously described (6). On column chromatography, the extract yielded the known compounds lubimin (**2**), 10-epilubimin (**5**), and isolubimin (**7**) as a mixture (fractions 50–59; 25 mg; identification by ^{13}Cmr); practically pure **2** (fractions 60–69; 53 mg); rishitin (**8**) admixed with unidentified compounds (fractions 91–95; 18.6 mg); and crystalline **4** (fractions 107–116; 32.7 mg). Fractions 41–48 (9.4 mg) consisted of essentially pure **1**. Fractions 96–106 (26 mg) were rechromatographed (40 g silica gel; 10 mL fractions) to yield crude **3** (6.9 mg). This was combined with similar material (26 mg) from two similar experiments and purified by rechromatography in *i*-PrOH/EtOAc (5:95).

2-Epilubimin (1)

This compound was isolated as an oil. *Exact mass* calcd. for $C_{15}H_{24}O_2$: 236.1776; found (high resolution ms): 236.1775; ir (liq. film): 1710 cm^{-1}; ^1Hmr ($CDCl_3$) δ: 0.90 (d, J = 7 Hz, 3H), 1.71 (bs, 3H), 2.71 (m, 1H), 4.14 (tt, 1H), 4.69 (m, 2H), 9.92 (d, $J \sim 3$ Hz, 1H).

Treatment of a small amount (< 1 mg) with $NaBH_4$ (a few grains) in MeOH at ice-temperature gave, after several hours and upon ether extraction of the acidified solution, the reduced product **3** as judged by R_f (0.26 in *i*PrOH/EtOAc 5:95, 0.17 in MeOH/$CHCl_3$ 5:95) and the characteristic red color with the vanillin reagent.

About 4.5 mg of **1** in 96% EtOH (0.9 mL) was injected under sterile conditions into the medium below a 7-day old culture of *A. solani* in a Roux bottle. After 48 h, the mycelium was filtered off and the filtrate extracted with Et_2O. The complex extract (22 mg) contained no detectable starting material but a small amount of substance indistinguishable from **3** by tlc in 3 systems.

15-Dihydro-2-epilubimin (3)

This compound occurred as a viscous oil which did not crystallize even upon sublimation (60°C). The ms showed only a very small molecular ion at *m/e* 238 (< 1%); hence the elementary composition was confirmed on the $M^+ - H_2O$ ion. *Exact mass* calcd. for $C_{15}H_{26}O_2 - H_2O$: 220.1827; found: 220.1825; ^1Hmr ($CDCl_3$) δ: 0.88 (d, J = 7 Hz, 3H), 1.79 (bs, 3H), 3.31 (dd) and 3.98 (dd) forming the AB portion of an ABX pattern, J_{AB} = 11 Hz, 4.11 (m, 1H), 4.71 (m, 2H).

The ether extract (21.2 mg) obtained from potatoes (25 kg) incubated with a spore suspension of *M. fructicola* in the usual way was chromatographed by our standard procedure. Fractions 41–46 (1–2 mg) contained a small amount (~0.4 mg) of **3** as judged by careful chromatographic comparisons. Fractions 47–62 on rechromatography yield crude hydroxylubimin (8 mg) and **6** (5.2 mg) identified by their ^1Hmr spectra (7). The yields of **2** and **8** in this experiment were 19 and 13 mg, respectively.

Reactions of singlet oxygen. Part V. Dye sensitized photooxidation of *m*-hydroxydiphenylamine[1]

NATHU RAM AND K. S. SIDHU

Department of Chemistry, Punjabi University, Patiala-147002, India

Received May 29, 1979[2]

NATHU RAM and K. S. SIDHU. Can. J. Chem. **58**, 2073 (1980).

Methylene blue sensitized photooxidation of *m*-hydroxydiphenylamine gives *N*-(3-hydroxyphenyl)-*p*-benzoquinoneimine as the primary product in acetonitrile–water medium. The experimental results are in good agreement with the theoretical plots calculated on the basis of the reaction undergoing through the participation of $O_2(^1\Sigma_g^+$ or $^1\Delta_g)$ as well as the excited dye interacting with the substrate. β-Value and rate constant of reactivity of *m*-hydroxydiphenylamine with singlet oxygen have been calculated. The effects of β-carotene, 1,4-diazabicyclo[2,2,2]octane, triethylamine, allyl thiourea, 2,5-diphenylfuran, and dielectric of different solvents show the participation of singlet oxygen at low substrate concentration and interaction of the excited dye with the substrate at its high concentrations. The data on oxygen concentration effect fit into the derived rate expressions. No complexation between methylene blue and *m*-hydroxydiphenylamine is observed.

NATHU RAM et K. S. SIDHU. Can. J. Chem. **58**, 2073 (1980).

L'oxydation photochimique de la *m*-hydroxydiphénylamine sensibilisée par le bleu de méthylène donne la *N*-(hydroxy-3 phényl) *p*-benzoquinoimine comme produit principal dans un milieu acétonitrile–eau. Les résultats expérimentaux sont en parfait accord avec les courbes théoriques calculées en se basant sur les réactions se produisant avec la participation de O_2 ($^1\Sigma_g^+$ ou $^1\Delta_g$) tant que le colorant excité interagit avec le substrat. On a calculé la valeur β et la constante de vitesse de réactivité de la *m*-hydroxydiphénylamine avec l'oxygène singulet. Les effets du β carotène, du diaza-1,4 bicyclo[2,2,2] octane, de la triéthylamine, de l'allylthiourée, du diphényl-2,5 furanne et les effets diélectriques des différents solvants mettent en évidence la participation de l'oxygène singulet à faible concentration et l'interaction du colorant excité avec le substrat à forte concentration. Les données des effets de la concentration de l'oxygène s'adaptent aux expressions dérivés de vitesse. On n'a pas observé de complexation entre le bleu de méthylène et la *m*-hydroxydiphénylamine.

[Traduit par le journal]

Introduction

Photosensitized oxidations of amines and other compounds have been studied (1–10) and it is well known that dyes act as sensitizers in a large number of these reactions (1, 5–10). In some of these systems *in situ* formation of singlet $O_2(^1\Sigma_g^+$ or $^1\Delta_g)$ is reported (1, 5, 6, 9, 10), whereas in others interaction of the excited dye with the substrate has been postulated (7, 8). Photooxidation of anthracene and 2,3-dimethylbut-2-ene sensitized by rose bengal and methylene blue leads to the formation of 9,10-endoperoxide (11) and 3-hydroperoxy-2,3-dimethylbut-1-ene (12), respectively. Kautsky proposed that these types of reactions involve the participation of singlet oxygen (13) and this has been confirmed by other workers (14, 15).

Dye sensitized photooxidation of mono-, di-, and tri-*n*-butylamines has been suggested to take place without the participation of singlet oxygen (16). The dye sensitization reaction in the flash photolysis of amines has been observed not to involve singlet oxygen ($^1O_2$) as a reactive intermediate (7) but the dye radical anions have been observed as a result of an electron transfer from amine to the excited triplet dye. The final products have been suggested to be formed by the proton transfer from amine radical ion and the following reactions of the resulting amine radical with oxygen. The uncertainty about the generation of $^1O_2$ in dye-sensitized oxidation of amines is due to the intrinsic possibility of hydrogen abstraction and exciplex formation by the dyes.

It has been a point of controversy whether the dye sensitization reactions take place through the participation of $^1O_2$ or through hydrogen abstraction or electron transfer processes. In certain cases the comparison of the photosystems with the one in which singlet oxygen is generated by chemical methods (14) or electrodeless discharge (15) is expected to help in sorting out the reaction paths. Limonene gives rise to the same product distribution and kinetic features in both sensitized photooxidation and chemically produced singlet oxygen oxidations (17). But Bartholomew and Davidson have pointed out that there is a competition between the two primary processes viz. energy transfer from the excited sensitizer to oxygen and substrate (8). The efficiency of each path depends upon the concentration of the reactants as well as the rate constants of the two processes. Davidson *et al.* have recently postulated that both the mechanisms are operative in rose bengal sensitized

photooxidation of triethylamine (18, 19). This work was undertaken to ascertain the role of singlet oxygen as the reactive intermediate and to lay down the detailed mechanism for the photosensitized oxidation reaction of *m*-hydroxydiphenylamine (HDPA). It was hoped that the study would clarify the interactions of triplet methylene blue with the constituents of the system, particularly at varying concentrations of HDPA.

Experimental

High purity BDH (AR) grade solvents were distilled before use. *m*-Hydroxydiphenylamine (K & K Lab., U.S.A.) was crystallized from benzene – petroleum ether to sharp melting point 81°C. Stock solutions were prepared in blackened standardized volumetric flasks. The other reagents were of high purity and were crystallized to sharp melting points before use.

A Pyrex cell (20 mm diameter × 130 mm) with a narrow capillary for passing gases along the side of the cell was used for photolysis purposes. The capillary was so adjusted as not to be in the light path. The cell was fitted with a condenser at the top and cold water was circulated through it in order to avoid excessive evaporation of the solvent. A white mercury lamp (Philips, India; 125 W) fed from a stabilized power supply was used as a light source. The light was filtered through an optically flat glass plate with cut off at 4700 Å. The emission of the lamp was monitored through the current flowing in the circuit and was found to be constant. Presaturated oxygen gas was passed through the solution at suitable rates. The reaction was found to be very slow in pure acetonitrile, and in order to get reasonable conversions, 4% water was added to the medium except when otherwise stated.

For kinetic runs the reaction was monitored on a precalibrated Hilger and Watt's spectrophotometer at 4900 Å where the product has maximum extinction coefficient in the visible region. Aliquots of 3 mL were withdrawn from the photolysis cell at different intervals of time and were transferred back to the cell after absorbance measurements. Absorbances were measured in Pyrex cell of 10 mm path length.

Results and Discussion

N - (3 - Hydroxyphenyl) - *p* - benzoquinoneimine (HPBQ) was the only primary product as reported earlier (1). Since amines have a lone pair of electrons on nitrogen, there exists the possibility of complexation of amines with the dye (may be charge transfer type (20, 21)) and this can influence the reaction (22, 23). The effect of concentration of methylene blue (MB) was, therefore, examined and the results are given in Table 1. The relative reaction rate increases with the increase in MB concentration and in the region of essentially complete absorption of incident radiation any further increase in MB concentration ceases to affect the rate. This rules out the possibility of any role of complexation because if the complex would have been formed the rate would have increased more at higher concentrations of the dye since the concentration of the complex is expected to be more at higher concentrations of the dye. Furthermore, no product was observed in the absence of light which negates any ground state complexation of amine with the dye.

TABLE 1. Effect of concentration of methylene blue*

[MB] × 10^5, *M*	Relative reaction rate†
0.850	1.00
2.125	1.67
4.250	2.33
6.375	2.50
10.625	2.67
14.875	2.87

*HDPA = 8.0×10^{-4} *M*; O_2 flow rate = 25 mL min^{-1}; solvent = acetonitrile:water::24:1.
†Relative reaction rates have been calculated from the linear plots of [HPBQ] vs. time of irradiation.

Charge transfer complexation was further examined by obtaining the visible spectra of 1.0×10^{-5} *M* MB in acetonitrile–water in the presence of varying amounts of HDPA (1.0×10^{-4} *M* to 8.0×10^{-2} *M*). No spectral shift was observed which supports the absence of any such complexation.

The dielectric of the medium plays an important role in the reactions where amines are involved or where the transition state has some charge separation (24). The effect of dielectric of the medium was examined by varying the proportion of water in the acetonitrile–water solvent and the results are given in Fig. 1. A linear plot of log *R* vs. $1/\varepsilon_0$ (*R* = relative reaction rate; ε_0 = dielectric constant of the medium) shows a good correlation between the solvent polarity and relative rate. A specific solvent effect because of intermolecular interaction can

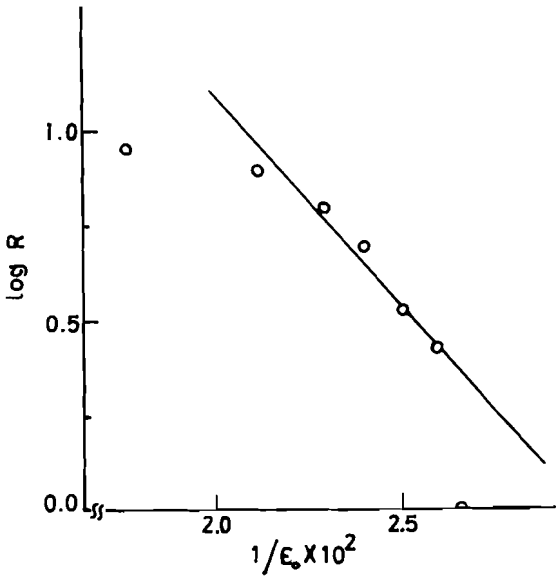

FIG. 1. Plot of log *R* vs. $1/\varepsilon_0$; HDPA = 2.0×10^{-3} *M*; MB = 9.0×10^{-5} *M*.

For personal use only.

influence either the rate of deactivation or rate of reactivity of singlet oxygen and this may be the basis for anomalous behaviour observed at very low and high concentrations of water (water varied from 0 to 40%) (25). The lifetime of singlet oxygen decreases with the increase in water concentration (τ for singlet oxygen is 2 μs and 30 μs in water and acetonitrile respectively) which shows that it is the dielectric which affects the rate and not the lifetime of singlet oxygen.

An electron transfer from the substrate to the dye has been established in some systems (7). The effect of HDPA concentration was studied to examine this possibility in the present system and Fig. 2 gives the results. The relative rate of oxygenation first increases and then decreases after reaching a maximum value. This indicates that the reaction may involve more than one path. One may consider the following scheme to explain the observed results.

[1] $D + h\nu \longrightarrow {}^1D$

[2] ${}^1D \xrightarrow{k_1} D + h\nu'$

[3] ${}^1D \xrightarrow{k_2} D$

[4] ${}^1D \xrightarrow{k_3} {}^3D$

[5] ${}^3D \xrightarrow{k_4} D$

[6] ${}^3D + {}^3O_2 \xrightarrow{k_5} D + O_2({}^1\Delta_g)$

[7] $O_2({}^1\Delta_g) \xrightarrow{k_6} {}^3O_2$

[8] $O_2({}^1\Delta_g) + A \xrightarrow{k_7} [O_2({}^1\Delta_g)\cdots A] \longrightarrow \text{Products}(AO_2)$

[9] ${}^3D + A \xrightarrow{k_8} [{}^3D\cdots A] \xrightarrow{O_2} AO_2$

[10] ${}^1D + A \xrightarrow{k_9} D + A$

D = Dye; ${}^1D$, ${}^3D$ are the first excited singlet and triplet states of the dye respectively; A = HDPA.

SCHEME 1

If the reaction solely occurs with the participation of singlet oxygen, steady state treatment of steps [1] to [8] gives

$$[11]\quad \phi_{AO_2} = \phi_{{}^1O_2}\frac{\alpha_1[A]}{[A] + \beta}$$

where $\beta = k_6/k_7$, ϕ_{AO_2} = quantum yield of product formation; α_1 = fraction of the complex $[O_2({}^1\Delta_g)\cdots A]$ giving products and $\phi_{{}^1O_2}$ = quantum yield of singlet oxygen formation

$$[12]\quad \phi_{{}^1O_2} = \frac{k_3}{k_1 + k_2 + k_3} \times \frac{k_5[{}^3O_2]}{k_4 + k_5[{}^3O_2]}$$

A theoretical plot based on eq. [11] can be made if

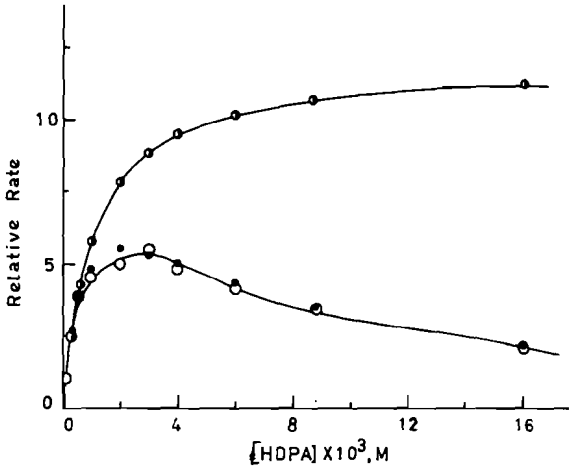

FIG. 2. Effect of concentration of HDPA; ○, experimental; ●, calculated for reaction occurring via $^1O_2$ and triplet dye; ◑, calculated for reaction occurring via $^1O_2$; MB = 9.0×10^{-5} *M*; solvent = acetonitrile:water::24:1.

β is known. Equation [11], when rewritten in the form

$$[13]\quad [AO_2]^{-1} = (\phi_{{}^1O_2}\alpha_1 I_a)^{-1}(1 + k_6/k_7[A])$$

where I_a is the number of mole quanta absorbed per litre during irradiation, can be used for the evaluation of β. A plot of $[AO_2]^{-1}$ vs. $[A]^{-1}$ gives a straight line with β equal to the ratio of the slope and intercept on the $[AO_2]^{-1}$ axis. The results are given in Fig. 3 which gives a β value of 11.04×10^{-4} *M*. With the calculated value of β and known value of rate

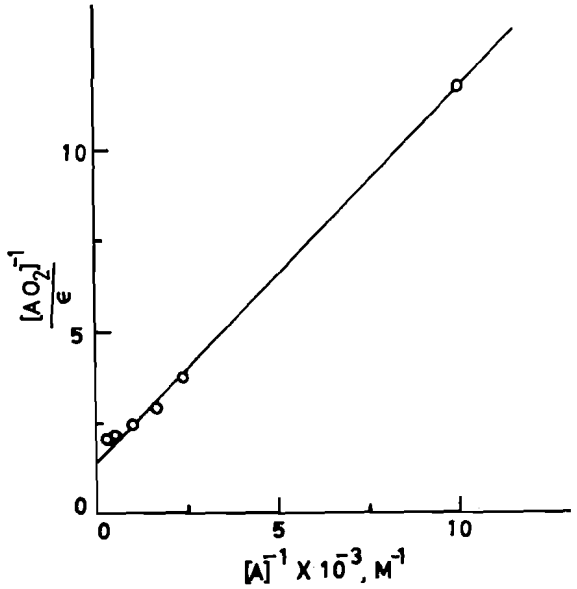

FIG. 3. Plot of $[AO_2]^{-1}$ vs. $[A]^{-1}$ (i.e. 1/product vs. 1/substrate); MB = 9.0×10^{-5} *M*; solvent = acetonitrile: water::24:1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

constant of deactivation of singlet oxygen ($k_6 = 3.33 \times 10^4\ s^{-1}$) in acetonitrile (26), the rate constant of reactivity of HDPA with singlet oxygen (k_7) comes out to be 3.02×10^7 L mol^{-1} s^{-1}.

A theoretical curve based on eq. [11] with the calculated β value agrees well with the experimental points at low HDPA concentrations (Fig. 2) but there is a complete divergence at its higher concentrations. The decrease in the rate cannot be due to triplet energy transfer to the substrate because this process is strongly endothermic and is bound to be inefficient (27). The observed decrease in the rate beyond 3.0×10^{-3} *M* HDPA concentration points to an alternate pathway since the product remains the same.

The interaction of the triplet dye with the substrate is an obvious pathway. However, deactivation of the singlet dye must also be considered as reported in the literature (18, 19). The steady-state treatment of Scheme 1 now gives

$$[14]\quad \phi_{AO_2} = \frac{k_3[A]}{(k_1 + k_2 + k_3 + k_9[A])(k_4 + k_5[^3O_2] + k_8[A])}\left(\frac{k_5 k_7 \alpha_1 [^3O_2]}{k_6 + k_7[A]} + k_8\alpha_2\right)$$

where α_2 = fraction of the complex $[^3D\cdots A]$ giving products.

The singlet–singlet energy transfer at high amine concentration is not possible because of the endothermicity of the process (MB and HDPA have first excited singlet state energies 44.3 kcal and 80 kcal, respectively). Furthermore, the interaction of amine with singlet dye is not expected because the rate constant for the decay of singlet dye is very high ($\sim 2.5 \times 10^9\ s^{-1}$). For an appreciable interaction the amine concentration should be very high as compared to the one used here.

Using literature values for some of the rate constants (19), calculated value of β, $k_9(k_1 + k_2 + k_3)^{-1} = k_9\tau \simeq 40$ (19), $\alpha_1 = 0.15$ and $\alpha_2 = 0.007$, a plot based on eq. [14] can be obtained between the theoretical values of relative reaction rate and HDPA concentration which agrees well with the experimentally observed points. The values of α_1 and α_2 have been adjusted and a good fit of the data shows that the reaction follows both the reaction paths.

Oxygen is expected to strongly influence the reaction both at low and high amine concentrations since it is one of the reactants. Its effect has been examined both at low and high HDPA concentrations and Fig. 4 gives the results. Equation [11], when rewritten in the form

$$[15]\quad [AO_2]^{-1} = \left\{\frac{k_3\alpha_1[A]I_a}{(k_1 + k_2 + k_3)([A] + \beta)}\right\}^{-1} \times \left(1 + \frac{k_4}{k_5}[^3O_2]^{-1}\right)$$

predicts a linear relationship between $[AO_2]^{-1}$ and $[^3O_2]^{-1}$ at constant amine concentration which is in agreement with the observed results (Fig. 4, curve I). This shows the participation of singlet oxygen at low amine concentration.

The curve showing the oxygen concentration effect at high HDPA concentration is linear and passes through the origin (Fig. 4, curve II). This is not explained by eq. [14] which predicts a non-zero rate at zero oxygen concentration. However, if the following processes are considered together with steps [1] to [5], the predicted rate may agree with the observed rate.

$$[16]\quad {}^3D + A \xrightarrow{k_{10}} [^3D\cdots A]$$

$$[17]\quad [^3D\cdots A] \xrightarrow{k_{11}} D + A$$

$$[18]\quad [^3D\cdots A] + {}^3O_2 \xrightarrow{k_{12}} AO_2$$

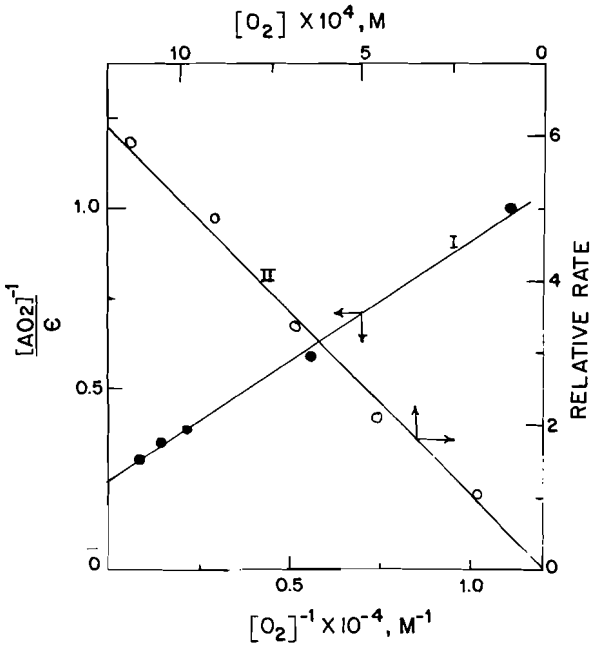

FIG. 4. Effect of oxygen concentration; curve I, HDPA = 8.0×10^{-4} *M*; curve II, HDPA = 8.8×10^{-3} *M*; MB = 9.0×10^{-5} *M*; solvent = acetonitrile:water::24:1.

This gives the quantum yield of product formation as

$$[19]\quad \phi_{AO_2} = \frac{k_3 k_{10} k_{12}[A][^3O_2]}{(k_1 + k_2 + k_3)(k_{11} + k_{12}[^3O_2])(k_4 + k_{10}[A])}$$

which is obviously for high HDPA concentration where the role of the singlet oxygen is negligible. Equation [19] predicts a direct linear relationship between rate and oxygen concentration at constant amine concentration (as observed) if $k_{12}[^3O_2]$ is neglected in comparison to k_{11}; this is reasonable because step [17] involves back electron transfer from dye to amine and is known to be an efficient process (8). It is, therefore, apparent that at high concentrations of HDPA triplet dye is interacting with the substrate and singlet oxygen is not being formed.

In order to further examine the role of singlet oxygen the effect of singlet oxygen quenchers, 1,4-diazabicyclo[2,2,2]octane (DABCO) (28) and β-carotene (29) were examined separately at low and high concentrations of HDPA and the results are given in Fig. 5. For low concentrations the data fit into the Stern-Volmer equation

$$[20]\quad \phi_0/\phi = 1 + \frac{k_q[Q]}{k_6 + k_7[A]}$$

where k_q is the quenching rate constant of singlet oxygen by the quencher Q; ϕ_0 and ϕ are the quantum yields in the absence and presence of the quencher respectively. From the slopes of the lines 1 and 2 the quenching efficiency of β-carotene has been found to be 0.39×10^3 times more than DABCO which can be compared with a reported value of 0.79×10^3 for hexamethyleneammonium hexamethylenedithiocarbamate in ethanol (30). This is in good agreement with the present results, particularly in view of the expected difference in reactivity of the substrate. However, the quenching by DABCO at high HDPA concentrations (Fig.5, curve 3) is nearly 11 times less efficient, showing that at high amine concentrations singlet oxygen does not significantly contribute to the reaction. Further increase in HDPA concentrations is certain to further decrease the contribution of singlet oxygen. The lowering in the reaction rate at high substrate concentrations can, therefore, be attributed to electron transfer exciplex formation mechanism since the product remains the same.

To further substantiate the role of singlet oxygen the effect of triethylamine (TEA), which is a good acceptor of singlet oxygen and as good a quencher as DABCO (31, 32) was studied and the results are given in Table 2. The relative reaction rate decreases with the increase in TEA concentration. Quenching of triplet methylene blue by TEA can be competitive with quenching of singlet oxygen by TEA in its effect on relative overall reaction quantum yields. This is directly related to the solvent used, the lifetime of singlet oxygen in that solvent,

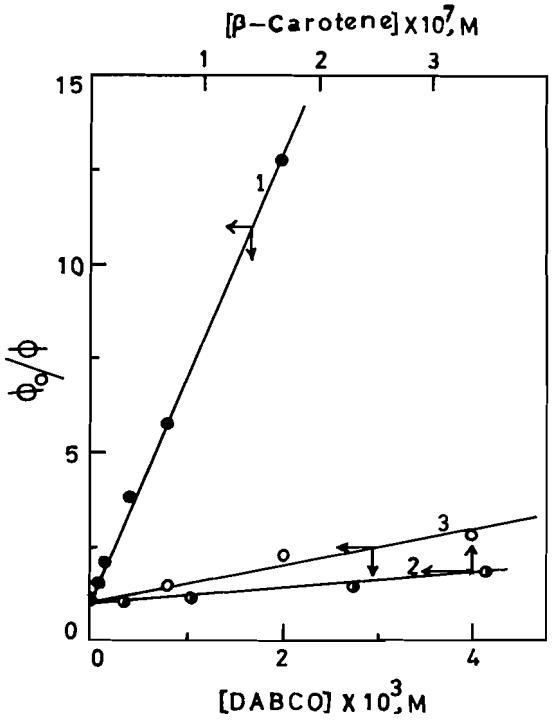

FIG. 5. Effect of DABCO and β-carotene on the rate of reaction; ϕ and ϕ_0 are the reaction rates with and without quenchers respectively. Curve 1 is for DABCO and curve 2 for β-carotene; HDPA = 8.0×10^{-4} *M*; curve 3 is for DABCO; HDPA = 8.8×10^{-3} *M*. MB = 9.0×10^{-5} *M*; solvent = acetonitrile:water::24:1.

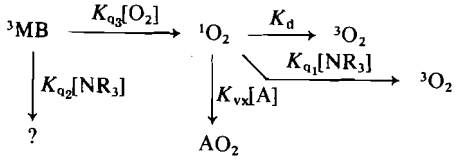
TABLE 2. Effect of adding triethylamine (TEA)*



[TEA] × 10^5, *M*	Relative reaction rate†

etc. Unfortunately, not all of the needed rate constants are available for methylene blue, TEA, and singlet oxygen in acetonitrile. However, the lifetime of singlet oxygen is known and if one assumes that the other quenching rate constants by TEA are the same in acetonitrile as they are in methanol, then the following arguments can be made.

$$K_d = \frac{1}{\tau_{1_{O_2}}} \cong \frac{1}{57 \times 10^{-6}} \cong 1.7 \times 10^4$$

$$K_{q_1}[NR_3] \cong 2.8 \times 10^8 [5.8 \times 10^{-5}] \cong 1.6 \times 10^4$$

Thus, then two values are nearly equal, and the calculated efficiency of the photo-oxidation reaction is expected to be 50%, which was found experimentally (Table 2).
Also

$$K_{q_3}[O_2] \cong 3 \times 10^9 [2 \times 10^{-3}] \cong 6.0 \times 10^6$$

$$K_{q_2}[NR_3] \cong 4.7 \times 10^7 [5.8 \times 10^{-5}] \cong 2.7 \times 10^3$$

Thus, the quenching of triplet state at the concentrations of amine used is much slower than the quenching of the triplet state of the dye by oxygen. This shows that the effect of TEA is on singlet oxygen and not on the triplet state of the dye and the observed decrease can be safely attributed to the quenching of singlet oxygen.

Singlet oxygen is known to react with 2,5-diphenylfuran (DPF) very efficiently (25) and the effect of its addition was studied at low HDPA concentrations. The extent of the reaction decreases in the initial stages of the reaction and after a time, which increases with the increase in DPF concentration, becomes equal to the rate in the absence of the quencher. This effect is due to the rapid consumption of DPF because k(DPF)/k(HDPA) = 6.3.

In order to further examine the electron transfer from the substrate to the triplet dye the effect of addition of allyl thiourea (ATU), a reducing agent, was examined and the results are given in Table 3. The efficiency of the reaction decreases with increase in ATU concentration which negates the possibility of the semiquinone form of the dye as an intermediate since in that case the reaction would have increased (30). It is thus apparent that the reaction takes place through singlet oxygen at low HDPA concentrations.

†Relative reaction rates have been calculated from the linear plots of [HPBQ] vs. time of irradiation.
‡Calculated from the initial part of the curve as it became non-linear after 20 min.

The effects of viscosity and dielectric of the medium have been reported elsewhere (1). However, in order to examine the properties other than dielectric and viscosity of the solvent which might influence the reaction, the effect of various solvents was examined at low and high HDPA concentrations and the results are given in Table 4. The relative reaction rate is maximum in ethylene glycol and minimum in acetonitrile. If we look at the viscosities of these solvents the rates increase with the increase in viscosity but not regularly. The increase in the relative reaction rate cannot be attributed to the viscosity alone because there is a simultaneous change in the dielectric of the medium. A lot of other effects like quenching of some triplet states by oxygen in a non-energy transfer process, hydrogen bonding ability, and stabilization of transition state involved can also occur and their extent is different in different solvents. Unfortunately, very little is known about the quenching of different excited states in various solvents which makes it difficult to work out the absolute values of reaction rates. The higher rate in ethylene glycol, however, can be taken to support the participation of singlet oxygen as reported previously (25). It appears that the electron transfer mechanism is also influenced

TABLE 4. Effect of various solvents*

by the hydrogen bonding ability of the hydroxylic solvents. The effect is, however, complex and defies a simple correlation. Thus we conclude that the methylene blue sensitized photooxidation of HDPA proceeds through the participation of singlet oxygen as well as electron transfer exciplex formation and the efficiency of each path is dependent upon substrate concentration.

Vibrational spectroscopic studies of molecular associations by local anesthetics

M. GUÉRIN,[1] J.-M. DUMAS,[1] AND C. SANDORFY

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Received April 22, 1980

M. GUÉRIN, J.-M. DUMAS, and C. SANDORFY. Can. J. Chem. **58**, 2080 (1980).

Infrared spectroscopic studies have been performed on H-bonding for a number of local anesthetics: benzocaine, procaine, tetracaine, lidocaine, dibucaine, and three barbiturates: phenobarbital, pentobarbital, and thiopental. All these compounds have a marked tendency for self-association. When they are put into contact with systems containing H-bonds of the N—H---O=C$\diagdown$, N—H---N, or O—H---O types, however, the degree of self-association decreases and new H-bonds are formed at the expense of the former. The possible consequences of this for the chemical mechanism of anesthesia are briefly discussed.

M. GUÉRIN, J.-M. DUMAS et C. SANDORFY. Can. J. Chem. **58**, 2080 (1980).

Les liaisons hydrogène formées par les anesthésiques locaux: benzocaïne, procaïne, tetracaïne, lidocaïne et dibucaïne ont été examinées par les méthodes de la spectroscopie infrarouge. Trois barbituriques: phenobarbital, pentobarbital et thiopental ont été également étudiés. Tous ces composés montrent une nette tendance à l'auto-association. Cependant quand ils sont mis en contact avec des systèmes qui contiennent les liaisons hydrogène du type N—H---O=C, N—H---N ou O—H---O, la proportion des molécules auto-associées diminue et de nouvelles liaisons hydrogène hétéro-associées sont formées. Les conséquences que cela peut avoir pour le mécanisme de l'anesthésie sont brièvement discutées.

Introduction

Molecular associations of *general* (inhalation) anesthetics have been the topic of previous publications from this laboratory (1–5). Particular emphasis has been laid on the dissociative effect exerted by halofluorocarbon anesthetics on hydrogen bonds. This effect was studied by measuring infrared spectra of model systems containing H-bonds of the

N—H---O=C$\diagdown$, N—H---N, and O—H---O

types and anesthetics like chloroform, halothane, methoxyflurane, ··· . Such H-bonds are needed to keep in the right conformation the macromolecules (lipids and proteins) forming the membrane of the nerve cell. Perturbing them might alter the permeability of the membrane thereby interfering with the normal functioning of the nervous system. It has been proposed, on the basis of the results obtained, that while lipid solubility and hydrophobic interactions are necessary to bring the anesthetic into the membrane, both hydrophobic and polar interactions (among these the perturbation and formation of H-bonds) have to be invoked in order to explain the anesthetic action at the molecular level. Polar interactions might not be important for weak anesthetic action but they appear to be essential when potent anesthetics are required. It is not intended to elaborate here on the theories of anesthesia, however. Instead, we are going to report on the extension of our studies to local anesthetics.

Local anesthetics generally contain two or more strongly associative groups. Since this is so, it seemed to us of interest to examine the associations of a number of local anesthetics with similar model systems. The question as to whether there are analogies between the behavior of general and local anesthetics seemed to us a particularly intriguing one.

Two categories of anesthetics have been examined. (*a*) Benzylalcohol, benzocaine, procaine, tetracaine, lidocaine, and dibucaine; while some of these can exert anesthetic action both as neutral molecules and positive ions, only the neutral molecules have been studied. (*b*) Phenobarbital, pentobarbital, and thiopental.

Contrary to general anesthetics, local anesthetics have a strong tendency to self-association. It has become clear after some preliminary measurements that the best way to investigate their associations is to study the competition between self-association and hetero-association (formation of H-bonded species in which the proton donor and the proton acceptor are different molecules) in the presence of selected perturbers. This can be done through infrared spectroscopic methods. The perturbers were *N*,*N*-dimethylacetamide (NNDA), *N*-methylacetamide (NMA), and benzylalcohol. NNDA is a proton acceptor while NMA and benzylalcohol can act both as proton donors and proton acceptors. These "perturbers" were chosen to represent associative sites in the membrane. Benzylalcohol was used both as a "perturber" and an "anesthetic". In most cases the concentration of

the perturber was kept low so that its self-association could be disregarded. The concentrations of the anesthetics were in the range of concentrations used in clinical practice or lower (see, for example, Adriani *et al.* (6)).

Experimental

The infrared spectra were measured on a Perkin-Elmer model 621 spectrometer at room temperature, using standard techniques. Those of the compounds in category (*a*) were measured in CCl_4 solutions, those in category (*b*) in CH_2Cl_2 since they did not show sufficient solubility in CCl_4.

Benzylalcohol was a Baker Analyzed Reagent, *N,N*-dimethylacetamide and *N*-methylacetamide were high purity Eastman products. They were further purified by vacuum distillation under dry nitrogen atmosphere and were kept on molecular sieves. Benzocaine was a high purity Eastman product and was used without further purification. The other compounds of category (*a*) were Astra or Winthrop products. The free bases were obtained from their hydrochlorides by adding KOH and were extracted with ether. Spectrograde CCl_4 was kept on molecular sieves in a dry box.

The barbiturates were May and Baker U.S.P. Products. Phenobarbital was used without further purification. Pentobarbital and thiopental were prepared from the aqueous solutions of their sodium salts (May and Baker) by adding 10% HCl, extracting with ether and rinsing with water. They were dried at 105°C and kept in a desiccator.

Fisher spectral analyzed CH_2Cl_2 was dried on P_2O_5, distilled, and kept on molecular sieves in a dry box.

The solutions were prepared immediately before measuring the spectra.

The infrared spectra of the self-associated molecules are presented in apparent molar extinction coefficients (ε, in L mol^{-1} cm^{-1}) against wavenumbers in cm^{-1}. The ε values are apparent since to compute them the overall concentrations were used, the proportion of the free and the various associated species being undetermined. The other spectra are plotted in absorbance against wavenumbers in cm^{-1}.

The chemical formulas of the compounds treated in this paper are given in Fig. 1 for convenience.

Results and Discussion

(I) Self-association of "Caine" Type Anesthetics

It is necessary to have at our disposal the absorption curves of the anesthetics at various concentrations so that we can assess the extent of perturbation exerted by the added perturber.

Figure 2 shows the spectrum of benzylalcohol. The free band is at 3619 cm^{-1} for a concentration of about 3×10^{-3} *M* in CCl_4. The band exhibits a shoulder at its high frequency side. This is due to rotational isomerism about the C—O bond as has been shown for a number of alcohols by Krueger, Jan, and Wieser (7). The relative intensities of the band and the shoulder appear to be independent of concentration. In the given range of concentrations the only associated species that can be seen in the spectrum is the dimer whose band, near 3500 cm^{-1}, increases in intensity with increasing concentration.

Benzocaine and procaine have nearly identical spectra and only that of benzocaine is shown (Fig. 3). The two NH stretching bands of the primary amino group are at 3500 and 3410 cm^{-1}. The shoulder at 3383 cm^{-1} disappears upon dilution and must belong to an associated species. In the spectrum of tetracaine (Fig. 4), a secondary amine, the free band is double. As in the previous case this is believed to be due to rotational isomerism. At higher concentrations the associated band is well pronounced at 3387 cm^{-1}.

As to the nature of self-association in tetracaine this is likely to involve mostly N—H---N (tertiary) association but N—H---C=O (ester) and N—H---N—H are probably also involved. While no quantitative studies are reported here it is noteworthy that the relative intensity change in the carbonyl band is less than what is observed for the NH band.

Dibucaine is a secondary amide; its spectrum is very similar to that of tetracaine. Lidocaine is also a secondary amide but with the nitrogen (not the carbonyl) linked to the benzene ring. Its spectrum is apparently simple (Fig. 5). The peak is near 3320 cm^{-1} and at low concentrations it appears to be nearly symmetrical. At higher concentrations, however, the lower frequency side increases in intensity and the band becomes asymmetrical. Thus the peak at 3320 cm^{-1} is likely to correspond to the free species while the associated band is centered near 3225 cm^{-1}.

The carbonyl bands of these anesthetics decrease in intensity upon self-association. At the low concentrations used, however, the associated carbonyl band could not be observed, being hidden under the low frequency wing of the free band.

The curves in Figs. 2 to 5 are to be compared to those presented in the next section in order to assess the changes brought about by hetero-association. As is seen the concentrations of the anesthetics were chosen so that little self-association occurs.

(II) Hetero-associations of "Caine" Type Anesthetics

In Figs. 6, 8, and 10 two curves are shown. The dashed curves are the sum of the curves of the (unmixed) anesthetic and the perturber. They were obtained by putting into the sample beam two cells in a row. The solid lines represent the spectra of the mixture of the anesthetic and the perturber at the same concentrations. Thus whatever difference is observed between the two curves is a consequence of association between the anesthetic and the perturber.

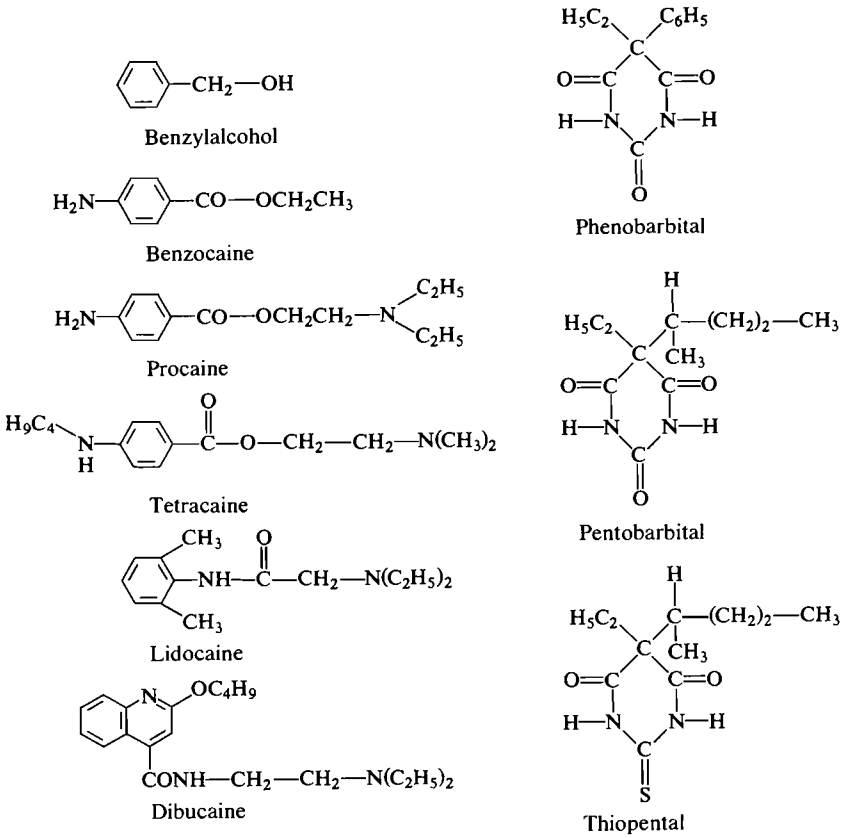

FIG. 1. Formulas of the compounds examined.

In Figs. 7 and 9 the absorption curves of the anesthetic, the perturber, and their mixture are given separately.

(a) Association with N,N-*Dimethylacetamide*

The effect of adding benzylalcohol to NNDA is shown in Figs. 6 and 7. The free band of the alcohol decreases in intensity and an intense new band appears near 3440 cm^{-1} representing the hydrogen bond formed between the "anesthetic" (benzylalcohol) and the perturber (NNDA). Since at the same time the carbonyl band of NNDA becomes asymmetrical with a shoulder appearing at its low wavenumber side we can assign the new band to O—H---O=C bonds. Some O—H---N type H-bonds might also be present.

Benzocaine and procaine again give practically identical spectra. Figures 8 and 9 show the spectra of the procaine + NNDA system. Upon mixing, new bands appear which can only belong to the N—H bonds of procaine hydrogen bonded to NNDA. The new band of lower frequency (3350 cm^{-1}) is largely free-standing while the one of higher frequency (about 3450 cm^{-1}) becomes a shoulder. The main observation from the point of view of this study is that these bands cannot belong to self-associated procaine. As has been shown above (Fig. 3) the associated band for the latter species is at 3383 cm^{-1} and it is easily distinguished from the new bands due to procaine-NNDA association.

The tetracaine + NNDA system gives similar results although the observed spectral change is less spectacular (Fig. 10). Upon mixing the intensity of the NH stretching band of tetracaine diminishes and a new band appears with maximum at about 3350 cm^{-1}, which can only correspond to tetracaine–NNDA association. The NH band for self-association is at distinctly higher frequencies, about 3387 cm^{-1}. Thus here again we observe the trend favoring mixed association.

Similar observations are made on the dibucaine + NNDA system despite the fact the proton donor NH group is engaged in an amide linkage in this molecule. The new band appears near 3300 cm^{-1} (Fig. 11). Self-associated dibucaine has its band at

3335 cm^{-1}. As in the previous case self-association seems to involve both N—H---O=C and N—H---N type H-bonds.

Unfortunately, in the case of the lidocaine + NNDA system, the bands of the self-associated and the mixed complex coincide and the new band cannot be discerned. The observed intensity in the spectral region concerned is, however, higher; indicating that such mixed complexes are formed.

The observations made on the NNDA +

anesthetic systems are not surprising and are in line with general knowledge on H-bonding. NNDA (which in this context represents an associative site in proteins) dissociates some of the H-bonds in self-associated local anesthetics replacing them by H-bonds with itself, representing an associative site in the membrane. While in our experiments NNDA was in great excess, this is in line with clinical conditions where the anesthetic is always applied at low concentrations.

(b) Associations between N*-Methylacetamide (NMA) and "-caine" Anesthetics*

Figure 12 shows the ir spectrum of a mixture of NMA and benzylalcohol (the alcohol playing the role of anesthetic). There is a broad region of absorption superimposed on the bands of the components extending from about 3550 to 3200 cm^{-1} which is readily assigned to O—H---O=C H-bonding. (The band and the shoulder at 3620 cm^{-1} are free OH while the band at 3475 cm^{-1} is the free NH band of NMA.) There is a fair amount of evidence in the literature that the carbonyl group is the more eligible proton acceptor in NMA. The contribution of O—H---N type H-bonds is probably minor. Another possibility is H-bonding between the NH group of NMA as the proton donor and the alcohol as the proton acceptor. This has been ascertained by measuring the spectrum of a mixture of NMA and the methylether of benzylalcohol, $C_6H_5CH_2OCH_3$. A slight broadening and intensification of the bonded NH absorption region was observed. Anyway, as expected, the new absorption region can only correspond to hetero-association.

Procaine with NMA (and similarly benzocaine) give the results shown in Fig. 13. The bands at 3500 and 3410 cm^{-1} (superimposed on the broad associated band) are the NH stretching bands of the primary amino group of procaine while the band at 3475 cm^{-1} belongs to the secondary amino group of NMA. The new band of the mixture appears clearly in the 3350 cm^{-1} region. Thus just as for benzylalcohol hetero-association is demonstrated at concentrations where little self-association takes place.

In tetracaine conditions are similar except that this molecule has a greater tendency to self-association than the previous ones (Fig. 14). The band at 3475 cm^{-1} belongs to the free NH stretching vibration of NMA while the band at 3430 cm^{-1} belongs to the NH group of tetracaine. The sum-curve exhibits a broad band with maximum at 3365 cm^{-1} but the increased absorption of the complex in this region indicates the trend for hetero-association. It is good to point out in this respect that both NMA and tetracaine contain a secondary NH and a C=O group so that both can enter self-association with the same type of N—H---O=C H-bond as the one responsible for hetero-association.

Dibucaine and lidocaine behave similarly.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(c) Benzylalcohol as Representative of a Membrane Site (Protein Side Chain, for example)

With procaine (and benzocaine) (Fig. 15), at concentrations where no self-association occurs in either procaine or the alcohol, new absorption regions appear in the difference spectrum near 3550, 3450, and 3300 cm^{-1}. The first two are readily assigned to OH groups associated with the proton acceptors present in procaine, namely, the ester, the amino-group, or the phenyl ring. In all likelihood the most affected of these is the ester group. Its carbonyl band (at 1710 cm^{-1}) decreases in intensity and a shoulder appears at its low frequency wing. The broad feature around 3300 cm^{-1} probably contains more highly associated species in which further alcohol molecules rally the procaine–alcohol dimer. H-bonds in which the amino group is the proton donor and the phenyl ring of the OH group of benzylalcohol the acceptor are also possible. The shoulder at 3383 cm^{-1} seems to be eligible for this assignment. This has been confirmed by using the methylether of benzylalcohol instead of the alcohol itself.

The observations that can be made for tetracaine, dibucaine, and lidocaine are similar. For dibucaine (Fig. 16) in the spectrum of the mixture a well pronounced new shoulder appears near 3480 cm^{-1} and a broad band is centered around 3350 cm^{-1}.

As in the examples above, the main observation is that hetero-association occurs at concentrations where little or no self-association is observed. The pattern of these associations is believed to be complicated involving more than one associative site in the "caines" and in benzyl alcohol. The

interaction is likely to be the most important one. As to the N—H---phenyl H-bonds these were shown to exist in the case of complexes between *N*-methylacetamide and various phenyl derivatives (9) and they might make some contribution.

III. Barbiturates

In the spectrum of a 4×10^{-3} mol L^{-1} solution of phenobarbital in CH_2Cl_2 only the free NH stretching band is seen at 3365 cm^{-1}. In the carbonyl region the three well known bands are found at 1762, 1740, and 1714 cm^{-1}. The assignment of these bands has been the subject of much discussion (10–13) (for a review see ref. 10). The band of the highest frequency (1760 cm^{-1}) is thought to belong to the carbonyl in the 2 position (between the two NH groups) mainly on the ground that the replacement of its oxygen by sulfur displaces this band

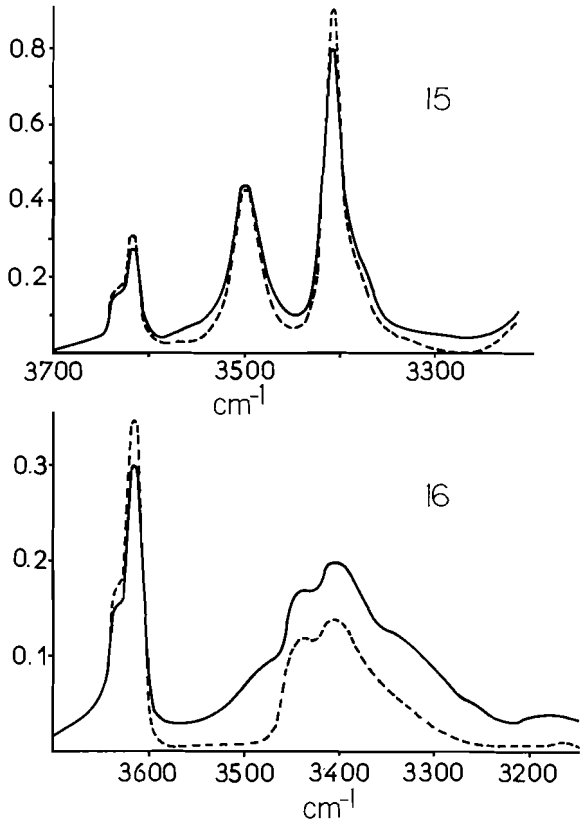

FIG. 15. ---, summation spectrum of unmixed benzylalcohol (3.002×10^{-2} mol L^{-1}) and procaine (4.663×10^{-2} mol L^{-1}); —, mixture of the two at the same concentrations.

FIG. 16. ---, summation spectrum of unmixed benzylalcohol (3.399×10^{-2} mol L^{-1}) and dibucaine (1.939×10^{-2} mol L^{-1}); —, mixture of the two at the same concentrations.

whereas the 1738 and 1712 cm^{-1} bands are unshifted.

In a 1:20 mixture of 4×10^{-3} mol L^{-1} phenobarbital and NNDA the intensity of the free NH band diminishes but the weak associated band is overlapped by solvent absorption. The amide I (carbonyl) band is at 1635 cm^{-1}. The most conspicuous change with respect to the spectrum of phenobarbital itself is a sizeable decrease in the intensity of the 1762 cm^{-1} band which becomes a shoulder. The other two carbonyl bands undergo very slight bathochromic shifts only.

There is no indication for enolization in the spectrum.

Entirely similar observations are made when pyridine is used instead of NNDA. The loss of intensity of the 1762 cm^{-1} band is even more pronounced.

At somewhat higher concentrations (3×10^{-2} mol L^{-1}) self-associated phenobarbital exhibits a weak and broad NH band at about 3225 cm^{-1}. At 3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

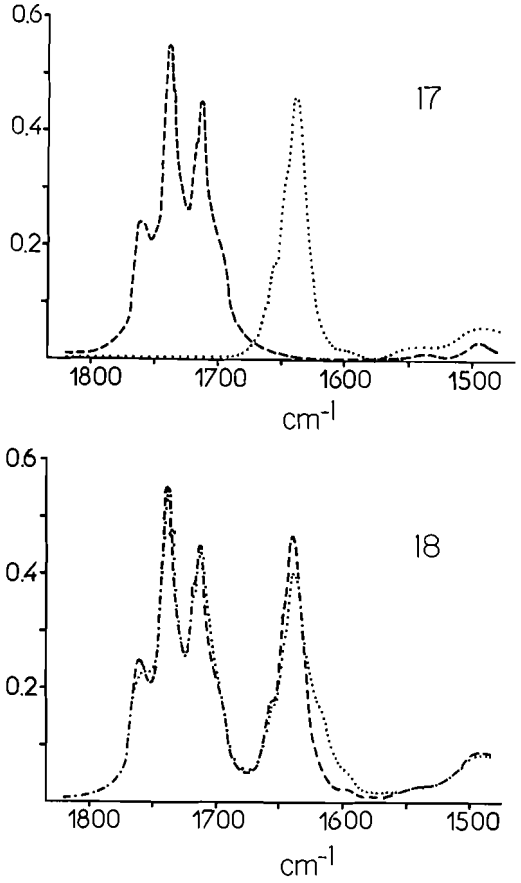

FIG. 17. The double bond stretching region of the ir spectra of phenobarbital (3.0×10^{-2} mol L^{-1}) --- and *N*,*N*-dimethylacetamide (4.8×10^{-2} mol L^{-1}) ···.

FIG. 18. The double bond stretching region of the ir spectra of phenobarbital (3.0×10^{-2} mol L^{-1}) and *N*,*N*-dimethylacetamide. ---, summation curve, ···, mixture of the two at the same concentrations.

$\times 10^{-2}$ mol L^{-1} a pronounced shoulder appears near 1610 cm^{-1}. This band, which can only belong to associated NNDA, does not appear in pure NNDA at the same concentration so it cannot belong to self-association. The 1762 cm^{-1} band decreases in intensity as before (Figs. 17 and 18).

The only explanation of these facts appears to be that a H-bond is formed in which an N-H group of phenobarbital is the proton donor and the carbonyl of NNDA is the proton acceptor. This implies that the intensity of the 1762 cm^{-1} band decreases due to the indirect effect of H-bond formation by its NH neighbors and that the associated NH stretching band is too weak to be seen. The latter assumption is not unusual. These bands are often very weak.

The observation that phenobarbital can form H-bonds with an amide (supposed to represent the peptide H-bond) even at concentrations where self-association with its own carbonyls is already significant might be important for its anesthetic action.

If instead of NNDA we use NMA (2:1 to the concentration of phenobarbital in CH_2Cl_2) we find the free NH band of the amide at 3462 cm^{-1} and the free NH band of phenobarbital at 3368 cm^{-1}. In $CHCl_3$ solution ($3 \times 10^{-2} M$ for phenobarbital), where there is less overlap by the solvent bands, the associated NH band of phenobarbital appears at about 3225 cm^{-1}. The associated NH band of the amide is not seen. The 1762 cm^{-1} carbonyl band of phenobarbital, however, diminishes in intensity just like in NNDA and the associated amide carbonyl band is clearly distinguished at 1615 cm^{-1}. Thus it must be assumed that in this case too the association consists of the formation of H-bonds in which the NH of phenobarbital is the proton donor and the amide carbonyl is the proton acceptor. Conditions might change with concentration and environment but it appears that at low anesthetic concentrations similar to those used in clinical practice, this is the pattern of association and that it is favored with respect to self-association of the anesthetic.

Pentobarbital and thiopental behave similarly. For pentobarbital the carbonyl bands are at 1759, 1736, and 1708 cm^{-1}. For thiopental they are at 1740 and 1706 cm^{-1}; a band at 1508 cm^{-1} has been assigned to the N—C=S group by different authors (10, 14). No separate discussion seems to be necessary.

Conclusions

Our spectroscopic study indicates that while local anesthetics have a tendency to self-association, they prefer hetero-association when put into contact with H-bond systems like those which occur in cell membranes. In other words, just as for general (inhalation) anesthetics, mutual perturbations between local anesthetics and H-bonds present in the membrane can be expected to alter the conformation of the macromolecules forming the membrane. This, in turn, could affect the permeability of the membrane and perturb the nervous system. Whereas general and local anesthetics exert different physiological effects, the chemical mechanism of their action — through perturbing molecular associations — might be similar.

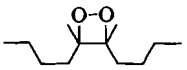
Thermolysis and photolysis of 3,3:4,4-dibutano-1,2-dioxetane[1]

KARL R. KOPECKY AND JUAN A. LOPEZ SASTRE[2]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

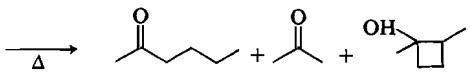
Received April 14, 1980

KARL R. KOPECKY and JUAN A. LOPEZ SASTRE. Can. J. Chem. **58**, 2089 (1980).



Thermolysis of 5×10^{-3} *M* 3,3:4,4-dibutano-1,2-dioxetane **2**, $E_a = 25.3 \pm 0.3$ kcal/mol, $\Delta S^{\ddagger} = 0 \pm 2$ eu, in degassed decane solution at 42°C produced a 300:1 ratio of cyclopentanone **3**:4-pentenal, **4**. From the quantum yield of photolysis of **3** to **4**, determined to be 0.27 using 313 nm light, it is calculated that 2.5% excited **3** is formed on thermolysis of **2**. Photolysis of (>380 nm) 5×10^{-4} *M* **2** produces a 54:1 ratio of **3**:**4** corresponding to a 13.5% yield of excited **3**. Excited state yields determined by measuring luminescence of benzene solutions of **2** containing DPA and DBA were 1×10^{-4}% singlet and 8.7% triplet. The reason for the 300% discrepancy between the two methods for determining excited state yields is not known.

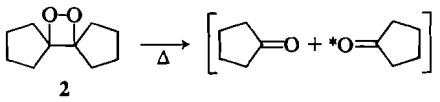
KARL R. KOPECKY et JUAN A. LOPEZ SASTRE. Can. J. Chem. **58**, 2089 (1980).



Pour la thermolyse à 42°C d'une solution 5×10^{-3} *M* de dibutano-3,3:4,4 dioxétane-1,2 (**2**) dans du décane dégazée, $E_a = 25.3 \pm 0.3$ kcal/mol, $\Delta S\ddagger = 0 \pm 2$ eu on obtient comme produits de la cyclopentanone (**3**) et du pentène-4 al (**4**) dans un rapport de 200:1. En se basant sur un rendement quantique de 0.27 pour la photolyse de **3** en **4**, valeur obtenue en utilisant de la lumière à 313 nm, on a calculé que la thermolyse de **2** conduit à 2.5% de **3** à l'état excité. La photolyse d'une solution 5×10^{-4} *M* de **2** (~380 nm) conduit à **3** et **4** dans un rapport de 54:1 correspondant à un rendement de 13.5% de **3** à l'état excité. Les rendements de l'état excité déterminés par la mesure de la luminescence des solutions de **2** dans du benzène contenant du DPA et du DBA sont de 1×10^{-4}% pour le singulet et 8.7% pour le triplet. On ne peut pas expliquer la différence de 300% qui existe entre les deux méthodes de détermination des rendements de l'état excité.

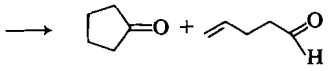
[Traduit par le journal]

Yields of carbonyl compounds formed in the excited state on thermolysis have usually been determined by measuring either the amount of photo product formed (1) or light emitted from fluorescers (2) after energy transfer to appropriate acceptors (for a review see ref. 3). Only a few dioxetanes have been prepared which could yield directly photolabile products (4). The yield of excited state formed could then be determined directly by measuring the amount of rearranged or decomposition product formed if the quantum yield for the photoreaction of the carbonyl compound has been determined independently. The only dioxetane for which the yields of excited state products formed has been determined by both methods is 3,4-di-(1-butyl)-3,4-dimethyldioxetane, **1**. However, the yields of excited 2-hexanone formed as determined from the distribution of thermolysis products [1],



[1] 

1

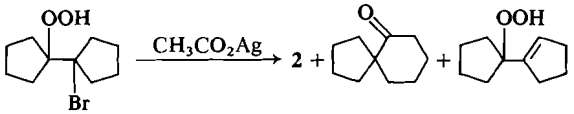


3.5% triplet and 5%, singlet (4*b*, *c*), are quite different from those determined by chemiluminescence measurements, 25% triplet and 0.08% singlet (4*f*).

The present paper reports a study of the decomposition of 3,4:3,4-dibutano-1,2-dioxetane, **2** (11,12-dioxadispiro[4.0.4.2] dodecane) which yields directly a product, cyclopentanone, **3**, which if produced in the excited state would yield 4-pentenal, **4**, [2].

[2] 

2



3 **4**

The thermolysis and photolysis of **2** were carried out and the yield of excited **3** formed on thermolysis of **1** was determined both from the ratio of **3**:**4** produced and from measurement of light emitted in the presence of 9,10-dibromoanthracene (DBA) and 9,10-diphenylanthracene (DPA) (2).

Results

Only ~4% of **2** was produced on treatment of 1-bromo-1′-hydroxycyclopentylcyclopentane, **5**, with silver acetate, [3].

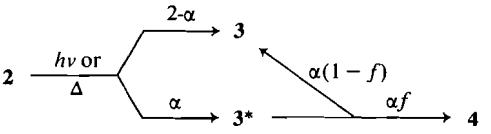
TABLE 1. Product ratios from thermolysis and photolysis of **2** in decane

Temperature (°C)	Concentration (*M*)	**3**/**4**[a]	Total yield (%)	% excited state
42	5.5×10^{-3} [b]	415 ± 25	109	1.7
42	5.5×10^{-4} [c]	300 ± 40	108	2.5
0	5×10^{-4} [d]	54 ± 5	97	13.5

[a] Average of two runs.
[b] Thermolysis, aerated.
[c] Thermolysis, degassed.
[d] Photolysis through a 380 nm cutoff filter.

The main products were spiro[4.5]decan-6-one, **6**, and 1-hydroperoxy-1- (1-cyclopentyl)cyclopentane, **7**, which were isolated in 44 and 15% yields, respectively. Most of the ketone **6** in the crude reaction mixture was converted to the semicarbazone and pure **2** could then be isolated in ~1% yield by repeated column chromatography at −30°C. The hydroperoxide **7** appeared to be the exclusive product formed on treatment of **5** with base (5) and also in the photosensitized oxygenation of cyclopentylidenecyclopentane.

Rates of thermolysis of **2** in benzene were obtained by monitoring the luminescence of solutions of **2** containing DBA (2, 3, 6). At 40.9 and 60.4°C the rates were 5.44 ± 0.05 and 58.4 ± 0.08 × 10^{-5} s^{-1}, respectively; $E_a = 25.3 \pm 0.3$ kcal/mol, $\Delta S^{\ddagger} = 0 \pm 2$ eu (40°C). The stability of **2** is quite similar to that of tetramethyldioxetane (6).



The yields of excited singlet and triplet **3** formed from thermolysis of **2** in benzene, as determined by measuring the luminescence intensities of solutions of **2** as a function of DPA and DBA concentration (2, 3, 7), were 1 × 10^{-4} and 8.7%, respectively, based on the luminol light standard (7).

The product distributions resulting from thermolysis of 5.5 × 10^{-3} *M* and photolysis of 5 × 10^{-4} *M* **2** in decane are given in Table 1. The only product detected besides **3** and **4** was a very small amount of an unidentified material that was eluted from the gc just after air. Quantum chain decomposition (8) of **2** should be negligible because of the low concentrations used and the short lifetime of triplet **3** (9). The ratio **3**/**4** is greater in aerated solutions because oxygen quenches some excited **3**, resulting in a decreased yield of **4** (10).

Decomposition of **2** according to Scheme 1 leads to an expression [4] for the yield α of excited **3**

$$[4] \quad \alpha = 2/(3/4 + 1)f$$

formed in terms of the product ratio **3**/**4** and *f*, the quantum yield for formation of **4** from **3**. This quantum yield depends on the conditions of the reaction, being 0.37 in neat **3** (10) and is somewhat lower in dilute benzene solution as indicated by two

SCHEME 1

determinations which, however, differ by a factor of two: 0.24 (9) and 0.11 (11). The quantum yield was redetermined by irradiating decane solutions of **3** with 313 nm light in a merry-go-round apparatus using as actinometer 2-hexanone, decane solutions of which were irradiated in parallel with those of **3**. A value of 0.19 (12) was used for the quantum yield of acetone formation from 2-hexanone, which is independent of temperature (13). The quantum yield for formation of **4** from **3** was found to be 0.27 at both 22 and 40°C. This is in close agreement with the higher of the previous solution values and there is little, if any, effect of temperature on this quantum yield.

The yields (Table 1) of excited **3** formed from thermolysis and photolysis of **2** were calculated using this value for the quantum yield.

Discussion

The two methods used here for determining the yield of excited **3** formed on thermolysis of **2** give results that differ by a factor of about three, with the yield as determined by product distribution being the lower. A similar discrepancy occurs with the dioxetane **1** which yields 2-hexanone on thermolysis. Attention had been focused on the anomalously high yield of excited singlet 2-hexanone formed from **1** as calculated from the product distribution (4*b*, *c*). It has been pointed out that only a small difference in product ratios would result in a much smaller calculated yield of excited singlet (4*f*). Nevertheless, the fact remains that the absolute yield of products is such that the total yield of excited states calculated this way (assuming that the yield of excited singlet is very small) is only about a fifth of that derived from measurement of luminescence intensities from solutions containing fluorescers: ~5 vs. ~25%.

The yields of excited state products formed on photolysis of **1**, ~5%, and **2**, ~14%, also appear to be lower than might be expected on the basis of results reported for photolysis of tetramethyldioxetane. Irradiation of the latter dioxetane with 360 nm light produces about 53 (14) to 65% (15) total yield of excited acetone, as determined by trapping experiments with appropriate alkenes.

The reasons for the discrepancies between the two methods for measuring the yields of excited state from **1** and **2** are not known. Although the yields of **4** from **2** and of acetone and dimethylcyclobutanols from **1** are low and subject to error, they should be in error by as much as 300 to 500%. Nor should measurement of the absolute light intensities from solutions of DBA be in error by this amount. Since the excited state yields obtained via luminescence in the presence of DBA agree well with those obtained by various chemical trapping experiments (3, 16), we conclude that the DBA results obtained here are more likely to be the correct ones. It is possible that anomalously high efficiencies could be obtained by the DBA method however, if there were a bimolecular reaction between DBA and **2**. The effect of DBA concentration on the rate of thermolysis of **2** was not determined, but no effect with DBA has been observed in several other systems (2, 3, 6), so it is not likely that there will be an effect with **2**.[3]

Further studies using a 1,2-dioxetane which can be prepared in higher yield than either **1** or **2** and which produces a ketone whose photolysis proceeds with a high quantum yield are in order.

Experimental

Melting points and boiling points are uncorrected. Nuclear magnetic resonance spectra were recorded with a Varian analytical spectrometer Model A-60. Gas chromatography was carried out on an Aerograph A-90-P3 gas chromatograph using a 10 ft × 1/4 in. stainless steel column packed with 15% dinonylphthalate on 60/80 chromosorb W operating at 145°C. Decane was purified by shaking several times with concentrated H_2SO_4 and then with water. After drying ($MgSO_4$) it was distilled at reduced pressure.

Preparation of **5** and manipulations with concentrated, crude solutions of **2** were carried out behind shields with the aid of tongs while hands were protected with heavy canvas gloves.

Cyclopentylidenecyclopentane

This material was prepared by pyrolysis of the corresponding orthoformate ester (17). A mixture of 50 g 1,1′-dihydroxycyclopentylcyclopentane (18) and 47 mL triethyl orthoformate was heated at 135°C until no more ethanol distilled, 4 h. The temperature was raised to 175°C and kept there until no more ethanol distilled, 3 h. The residue was distilled through a spinning band column to give 27.7 g (69%) of product, bp 87°C/23 Torr, n_D^{22} 1.4896 (lit. (19) bp 76°C/13 Torr, n_D^{20} 1.4934).

1-Bromo-1′-hydroperoxycyclopentylcyclopentane, 5

A dry ether solution of the crude title compound, prepared from 10 g of cyclopentylidenecyclopentane by the usual method (5), was treated with 10 g of 1,4-diaza[2.2.2]bicyclooctane and the resulting solution kept at −78°C for several hours. The white precipitate which formed was filtered on a precooled funnel, washed with ether at −78°C, and then shaken with a mixture of ether and water. The ether layer was shaken several times with water, dried, and concentrated at 0°C under reduced pressure. The semisolid residue was crystallized from 30 mL isopentane at −78°C. Three crops of crystals were obtained, 8.6 g (47%), mp 35–36°C; τ(CCl_4) 1.73 (s, 1H, 8.02 (broad, 18H)) (required ratio 1:16); 99.5% active oxygen.

This material is extremely unstable. Impure material exploded at 10°C soon after solvent was removed. Pure material invariably explodes within a minute at 50°C. It may be stored for several weeks as the 1,4-diaza[2.2.2]bicyclooctane complex at −10°C.

Product Distribution from Reaction of 1-Bromo-1′-hydroperoxycyclopentylcyclopentane with Silver Acetate

A solution of 2.5 g of **5** in 10 mL benzene was added to a suspension of 2 g silver acetate in benzene at 5°C. The mixture was stirred at 5°C for 30 min, filtered, and the filtrate concentrated at 20°C under vacuum. The residue was chromatographed on a 1.5 × 30 cm column of silica gel at −40°C. The column was eluted with Skelly B containing gradually increasing amounts of ether. The eluent was analyzed by tlc (the tlc plate was visualized by heating after spraying with sulfuric acid) and by testing for luminescence by adding a few drops of eluent to a hot solution of DBA. Four fractions were isolated: fraction *1*, 0.63 g, was luminescent and shown by tlc and gc to be < 90% **6** and < 10% **2** (as cyclopentanone by gc); fraction *2*, 0.14 g, was pure **6** identical (ir and nmr) with an authentic sample (20); fraction *3*, 0.27 g, was pure **7**; and fraction *4*, 0.06 g was an unidentified, fragrant oil.

In a separate experiment the crude product from treatment of 1.1 g **5** with silver acetate at 5°C in isopentane, after removal of solvent at 0°C, was taken up in 10 mL ether and the resulting solution added slowly to a stirred suspension of 1 g lithium aluminum hydride in 40 mL ether at −40°C. The reaction mixture was allowed to come to 20°C and, after workup, the crude product was chromatographed on 20 g silica gel. All the 1,1′-dihydroxycyclopentylcyclopentane, the product of reduction of **1** was eluted pure in one fraction, 0.03 g (4%), mp and mixed mp with authentic material 109–110°C. The yield of diol should represent the yield of **2** (6).

3,3:4,4-Dibutano-1,2-dioxetane 2

A solution of 10.4 g **5** in 50 mL Skelly B was added dropwise to a stirred suspension of 25 g silver acetate in 500 mL Skelly B at 20°C. The mixture then was stirred 5 min and filtered. The filtrate was evaporated under reduced pressure and the residual yellow oil poured into a saturated aqueous solution containing 5 g semicarbazide hydrochloride and 7.5 g sodium acetate. Methanol was added until the mixture became homogeneous. This was cooled to −10°C for 1 h and filtered. The precipitate was washed with pentane and the filtrate shaken with several portions of pentane. The combined pentane solutions were shaken with sodium bicarbonate, dried, and concentrated under vacuum. The residual yellow oil was chromatographed at −30°C on a 2 × 30 cm column of silica gel using 2% ether in 2-methylbutane as eluant. Fractions, 10 mL each, containing dioxetane (luminescence on addition to hot benzene solutions of DBA)

[3]A referee has noted that the quantum yield for photolysis of **2** appears to be concentration dependant, increasing with increasing concentration, but that if the reverse were true and an excimer were formed in thermolysis of **2**, then the DBA and chemical measures of efficiency might be reconciled.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

were combined, concentrated, and the residual yellow oil rechromatographed in this way. After a total of four chromatographs 0.049 g (1%) of yellow needles were isolated, mp 55–56°C (from 2-methylpentane), 93% active oxygen.

1-Hydroperoxy-1-(1-cyclopentenyl)cyclopentane, 7

(*A*) A stirred solution of 1.36 g cyclopentylidenecyclopentane and 30 mg methylene blue in 30 mL 1:1 methanol–benzene was irradiated at 10°C under oxygen with two 200 W incandescent lamps until 300 mL oxygen had been taken up. The reaction mixture was poured into ice water, and the resulting mixture was extracted with ether (3 × 50 mL). The combined ether layers were shaken with water, brine, dried, and concentrated under vacuum at 0°C. The residual oil was chromatographed on a 1.5 × 20 cm column of silica gel using 5% ether in pentane as eluant to give 1.30 g (80%) of **7** as a clear oil; τ (CCl_4) 2.07 (s, 1H, OOH); 4.43 (1H, vinyl H), 7.67 (broad, 4H), 8.25 (broad, 10H). No evidence for the presence of dioxetane could be detected by tlc in the crude product.

(*B*) A solution of 1.25 g **5** in 10 mL methanol was added to a solution of 1 g NaOH in 10 mL cold methanol. After 10 min the reaction mixture was worked up as above to give 0.055 g (65%) **7**. No dioxetane could be detected by tlc in the crude product.

Kinetic Studies

Rates of thermolysis were determined by the luminescence decay method using the apparatus described previously (6) at 60.4 and 40.9°C with 5×10^{-4} *M* and 1.4×10^{-3} *M* solution of **2**, respectively, in aerated benzene also containing 10^{-2} *M* DBA. Rates were followed for at least three half-lives of decomposition. Rate constants obtained were 5.92 and 5.76×10^{-4} s^{-1} and 5.39 and 5.49×10^{-5} s^{-1} at 60.2 and 40.9°C, respectively.

Excited State Yields from 2 from Luminescence Intensities

The apparatus and methods used have been described (7). Plots of the reciprocal of the light intensity vs. the reciprocal of fluorescer concentration for 2.8×10^{-3} *M* solutions of **2** in benzene were made. Experiments with DBA were conducted at 40.9°C and those with DPA at 60.4°C because emission was so weak at 40.9°C. The apparatus was calibrated with a solution of tetramethyldioxetane containing DBA (7). The yield of triplet acetone formed from tetramethyldioxetane was taken to be 31% (7) and the efficiency of energy transfer from triplet **3** to give singlet DBA was taken as 0.2 (3). The absolute light intensities of infinite fluorescer concentrations were then determined from the intercepts of the plots and the excited state yields were calculated as described (7).

Photolysis and Thermolysis of 2

Solutions of 5.5×10^{-3} *M* **2** in purified decane were heated at 42°C in sealed ampoules for 10 half lives of decomposition. Degassed solutions were prepared using 3 freeze–thaw cycles under 1×10^{-3} Torr. Degassed solutions of 5×10^{-4} *M* **2** in purified decane were irradiated at 0°C with a 200 W medium pressure Hanovia lamp through a CS-562 filter (380 nm cutoff). The resulting solutions were then analyzed by gc. The ratios of **3**:**4** were determined with the aid of calibration charts which were constructed with solutions containing known amounts of **3** and authentic (21) **4** that bracketed the experimental values.

Quantum Yield of Photolysis of 3

Degassed decane solutions 1.0 *M* in **3** in Pyrex tubes were irradiated on a merry-go-ground apparatus with a 200 W medium pressure Hanovia lamp and a potassium chromate filter to isolate the 313 nm line. As actinometers degassed decane solutions 1.0 *M* in 2-hexanone were irradiated in parallel. Irradiations were carried out to less than 3% decomposition. The amounts of **4** and acetone were determined by gc using solutions of known concentrations of these materials to make calibration charts. The quantum yield of acetone formation from 2-hexanone was taken to be 0.19 (12).

Solvolysis of specifically C-6 deuterated 7-halonorbornyl brosylates; stereoselectivity of proton loss for "E1-like" 1,3-elimination in locked bicyclo[2.2.1]heptyl systems

NICK HENRY WERSTIUK, FRANK PETER CAPPELLI, AND GEORGE TIMMINS

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

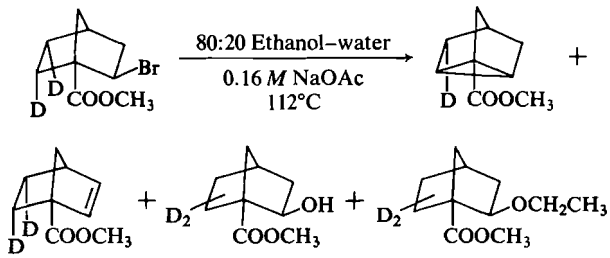
Received May 1, 1980

NICK HENRY WERSTIUK, FRANK PETER CAPPELLI, and GEORGE TIMMINS. Can. J. Chem. **58**, 2093 (1980).

We have solvolyzed the *syn*-7-chloro-*endo*-6-*d*, *anti*-7-chloro-*endo*-6-*d*, *syn*-7-chloro-*exo*,*exo*-5,6-d_2, *anti*-7-chloro-*exo*,*exo*-5,6-d_2, *syn*-7-bromo-*endo*-6-*d*, and *anti*-7-bromo-*endo*-6-*d* norbornyl brosylates **1***c*, **2***c*, **1***d*, **2***d*, **1***e*, and **2***e* in 80:20 ethanol–water buffered with NaOAc, isolated the 3-halonortricyclenes, the products of 1,3-elimination, and assayed for deuterium mass spectrometrically. Analysis of the deuterium-loss data established that there is a 10:1 to 15:1 preference for loss of an *endo*-6-proton for formation of the 7-halonortricyclenes from the 7-halonorbornyl cations. The isotope effects for "E1-like" 1,3-elimination are 1.78, 1.71, 1.53, and 1.52 for **1***c*, **2***c*, **1***e*, and **2***e*, respectively. That there is an increase in the degree of 1,3-elimination in the solvolysis of *anti*-7-chloro-*exo*-2-norbornyl brosylate-*exo*-3-*d* (**3**) relative to the non-deuterated brosylate indicates that the destabilizing effect of the β-deuterium at C-3 leads to an increase in the degree of 1,3-elimination from C-6.

NICK HENRY WERSTIUK, FRANK PETER CAPPELLI et GEORGE TIMMINS. Can. J. Chem. **58**, 2093 (1980).

Nous avons solvolysé les brosylates des chloro-7-*syn d*-6-*endo* (**1***c*), chloro-7-*anti d*-6-*endo* (**2***c*), chloro-7-*syn* d_2-5,6-*exo*-*exo* (**1***d*), chloro-7-*anti* d_2-5,6-*exo*-*exo* (**2***d*), bromo-7-*syn d*-6-*endo* (**1***e*) et bromo-7-*anti d*-6-*endo* (**2***e*) norbornyles dans une solution à 80:20 éthanol–eau tamponnée avec du AcONa, nous avons isolé les halogéno-3 nortricyclènes, produits d'une élimination 1,3 et nous avons dosé le deutérium par spectrométrie de masse. Une analyse des données relatives à la perte de deutérium établit qu'il y a une préférence allant de 10:1 à 15:1 pour la perte proton 6-*endo* lors de la formation des halogèno-7 nortricylènes à partir des cations halogèno-7 norbornyles. Les effets isotopiques pour l'élimination "pseudo E-1" sont respectivement de 1.78, 1.71, 1.53 et 1.52 pour **1***c*, **2***c*, **1***e* et **2***e*. Le fait qu'il y a une augmentation du degré d'élimination 1,3 au cours de la solvolyse du brosylate du chloro-7-*anti d*-3-*exo* norbornyle-2-*exo* (**3**) par rapport au brosylate non deutéré indique que l'effet déstabilisant du deutérium en β conduit à une augmentation du degré d'élimination à partir du carbone en position 6.



[Traduit par le journal]

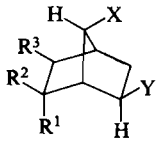
Introduction

The mechanistic details of 1,2-elimination have been probed extensively and the results are documented in many substantial reviews. However, 1,3- and 1,4-elimination reactions have not been studied as extensively although there has been a gradual increase in activity in the field over the past decade. 1,3-Elimination occurs in acyclic and cyclic systems and developments in the area have been documented in several recent publications (1, 2).

Our interest in detailing the mechanism of $H^+(D^+)$ catalyzed ring-opening of nortricyclenes (4–6) led us to study the stereochemistry of the reverse process, "E1-like" 1,3-elimination. In a previous study we established that there is at least a 15:1 preference for loss of an *endo* proton (deuteron) for formation of methyl 1-nortricyclene carboxylate from deuterated methyl *exo*-2-bromo-1-norbornanecarboxylate via 1,3-elimination (Scheme 1).

In this publication we report the results of our study. As in the case of solvolysis of the locked system methyl *exo*-2-bromo-1-norbornanecarboxylate (Scheme 1), we find that there is at least a 15:1 preference for loss of an *endo* proton for 1,3-(6,2)-elimination in the case of *syn*-7- and *anti*-7-chlorobrosylates **1***c* and **2***c*. In the case of the *syn*-7- and *anti*-7-bromobrosylates **1***e* and **2***e*, the *endo* preference appears to be reduced somewhat.

SCHEME 1



Results

Preparation of Substrates

While the non-deuterated *syn*- and *anti*-chlorohydrins, the precursors of the brosylates **1***a* and **2***a*, were prepared by the method of Roberts (3), the *syn*- and *anti*-bromohydrins were obtained via the acid-catalyzed ring-opening of 3-bromonortricyclene (4). The deuterated chloro and bromobrosylates **1***c*, **1***e*, **2***c*, and **2***e* were prepared from the corresponding deuterated chlorohydrins and bromohydrins that were obtained via acid-catalyzed ring-opening of 3-chloro- and 3-bromonortricyclene in deuterated medium (4). the deuterium in **1***c*, **1***e*, **2***c*, and **2***e* was 80–90% stereochemically pure *endo* at C-6 was established by ^{1}H nmr and ir spectroscopy (4).

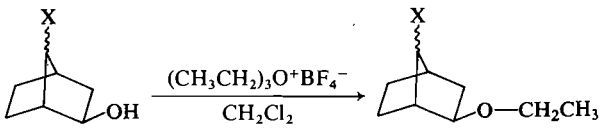
To prepare *syn*-7-chloro-*exo*-2-norbornyl brosylate-*exo*,*exo*-5,6-d_2 (**1***d*), we converted norbornene-*endo*,*endo*-5,6-d_2 into the *syn*-7-chlorohydrin via Roberts' method and brosylated the deuterated chlorohydrin. We began the synthesis of *anti*-7-chloro-*exo*-2-norbornyl brosylate-*exo*,*exo*-5,6-d_2 (**2***d*) with a $LiAlD_4$ reduction of acetoxynorbornadiene that yielded *anti*-7-norbornenol-*exo*,*exo*-5,6-d_2. The dideuterated norbornenol was converted into *anti*-7-chloronorbornene-*exo*,*exo*-5-6-d_2 (5), the chloronorbornene was hydroborated, and the deuterated chlorohydrin was brosylated. That the deuterium was at least 90% stereochemically pure *exo* was established by ^{1}H nmr spectroscopy (5). *Anti*-7-chloro-*exo*-2-norborneol-*exo*-3-*d*, the precursor of brosylate **3***a*, was prepared by deuteroboration of *anti*-7-norbornenyl chloride. To establish that the deuterium was located specifically *exo* at C-3, we recorded the ^{1}H nmr spectra of the deuterated and nondeuterated chlorohydrins in the presence of Eu(fod)$_3$ (5).

Identification of Products



A large scale solvolysis of the *syn*-chlorobrosylate **1***a* yielded a mixture of products that were separated by preparative glpc. While the major products of solvolysis of **1***a* were identified as **4***a*, **5***a*, **5***b*, **6***a*, and **6***b* by comparison of their ^{1}H nmr spectra to those of authentic samples, the major products from the *anti*-chlorobrosylate **2***a* were identified simply by analytical glpc retention times. The major products, **4***b*-*d*, **5***c*-*d*, **5***d*-*d*, **6***c*-*d*, and **6***d*-*d*, of solvolysis of the deuterated *syn*- and *anti*-bromobrosylates **1***e* and **2***e* were isolated by preparative glpc from a large scale solvolysis and identified by ^{1}H nmr spectroscopy. Authentic samples of the 7-halo-*exo*-2-norbornyl ethyl ethers **5***b*, **5***d*-*d*, and **6***d*-*d* were prepared from the corresponding halohydrins and $(CH_3CH_2)_3\overset{+}{O}BF_4^-$ (Scheme 2).

Determination of Relative Yields of Products

To determine the relative yields of the products (Table 1), we extracted solvolysis solutions obtained from γ-KIE studies (5) as described in the Experimental.

Determination of Deuterium Losses

To determine the deuterium losses we carried out large scale solvolyses of the deuterated brosylates **1***c*, **1***d*, **1***e*, **2***c*, **2***d*, and **2***e*, isolated the 3-halonortricyclenes by preparative glpc, and assayed for deuterium mass spectrometrically. The isotopic compositions of the starting brosylates and the 3-halonortricyclenes and the deuterium losses are listed in Table 2.

SCHEME 2

Discussion

It is clear from Table 2 that there is an *endo* stereoselectivity for loss of a proton (deuteron) from C-6 of the 7-halobrosylates. This result is

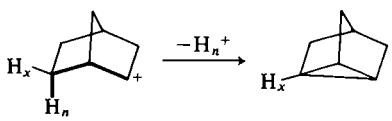


TABLE 1. Relative percent yields of solvolysis products[a]

[a]Determined by analysis of the corresponding 7-halonorbornanones.

consistent with our previous finding that loss of an *endo* proton from C-6 of a locked norbornyl system is preferred over loss of an *exo* proton by 15:1 (*vide supra*) and indicates that the semi-U path (6) is preferred. From the data listed in Table 1 it is possible to evaluate the elimination isotope effects (EIE's) using eq. [1] that was described previously

$$[1]\quad \left(\frac{k_H}{k_D}\right)^{1,3\text{-Elimination}} \simeq \left(\frac{\%\ \text{Elimination (H)}}{\%\ \text{Substitution (H)}}\right) \Big/ \left(\frac{\%\ \text{Elimination (D)}}{\%\ \text{Substitution (D)}}\right)$$

(7). The EIE's are 1.78, 1.71, 1.58, and 1.52 for **1***c*, **2***c*, **1***e*, and **2***e*, respectively. Based on an *endo*-6-*d* stereochemical purity of 90% for 7-chlorobrosylates **1***c* and **2***c*, an 80% stereochemical purity for 7-bromobrosylates **1***e* and **2***e*, and a series of *endo*:*endo* preferences, we have calculated the expected relative yields of the 3-halonortricyclenes and the isotopic compositions using eq. [2] and [3] that were developed previously (7).

$$[2]\quad \left(\frac{\%\ d_n\ \text{Species}}{100}\right)\left(\begin{array}{c}\text{Fractional}\\ \text{amount}\\ \textit{endo-d}\ \text{or}\\ \textit{exo-d}\end{array}\right)\left(\begin{array}{c}\text{Assumed}\\ \text{preference}\end{array}\right)\left(\frac{1}{\text{EIE}}\right)\left(\begin{array}{c}\text{Relative}\\ \text{yield of}\\ \Delta_H\end{array}\right) = \left(\begin{array}{c}\text{Relative yield}\\ \text{of } d_x \text{ species}\end{array}\right)$$

$$(x = n - 1)$$

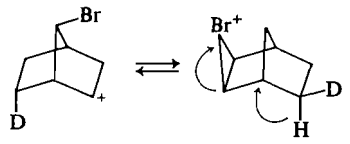

TABLE 3. Relative percent yields and isotopic composition of 3-halonortricyclenes; comparison of calculated and experimental values

Substrate	Stereochemical purity (%)	Assumed *endo*:*exo* preference[a]	Composition d_0	d_1	d_2	Relative % yield Δ

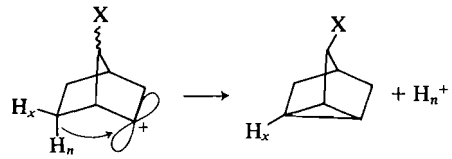
		20:1	80.9	19.1	—	6.8
			(67.9)	(30.6)	(1.4)[c]	(7)

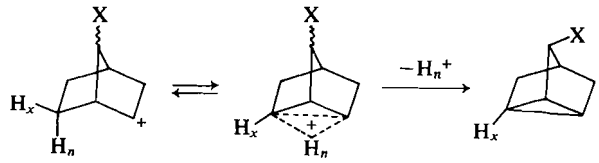
[a]The EIE's for **1***c*, **2***c*, **1***e*, and **2***e* are 1.78, 1.71, 1.58, and 1.52, respectively.
[b]The small amounts of d_2 species (Table 2) were omitted in the analysis using eq. [2].
[c]Experimentally observed values.

[3] Relative yield $\Delta_D = \Sigma$ relative yields of d_x species

The results are listed in Table 3. It is clear from the data that there is a 10:1 to 15:1 preference for loss of an *endo* proton (deuteron) for "E1-like" 1,3-elimination from **1***c*, **2***c*, and **2***e*. The reason for the reduced stereoselectivity for proton loss from **1***e* is not obvious although it is possible that the *syn*-7-bromo-2-norbornyl cation **7** rearranges to the *exo* bromonium ion **8**



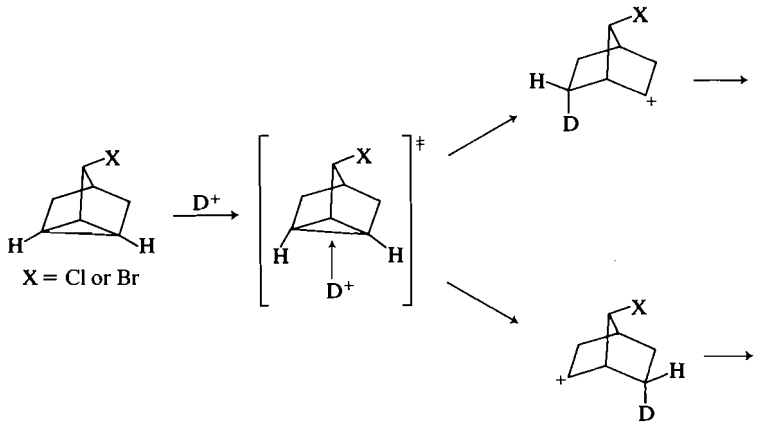
7 **8**



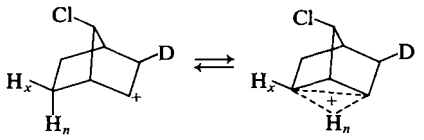
which leads to 3-bromonortricyclene via loss of an *endo* proton.

Since E1-like 1,3-elimination of a proton (deuteron) from the 7-halonorbornyl cations should be the reverse of the $H^+(D^+)$ catalyzed ring-opening of the corresponding 3-halonortricyclenes, the stereochemistry of the 1,3-elimination should be related to the stereochemistry of the ring-opening. As we have documented in preceding papers (4, 8) this is, in fact, the case because 3-chloronortricyclene and 3-bromonortricyclene are preferentially ring-opened by *edge-wise* attack on the most basic bond of the three-membered ring by D^+ to form, in our view, classical 7-halonorbornyl cations (Scheme 3).

It is of interest to speculate on the nature of the transition state of 1,3-elimination. Does proton (deuteron) loss occur from the classical species **9** or from an edge-protonated (deuteronated) nortricyclene **10** which is one of the intermediates of

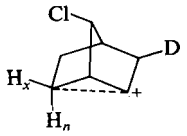


9 (X = Cl or Br)



9 (X = Cl or Br) **10**

solvolysis? That cleavage of an *exo* C—H bond (semi-W type path) is preferred for steric and perhaps stereoelectronic reasons as well (9) in the case of homoenolization of bicyclo[2.2.1]heptanones such as fenchone suggests that proton (deuteron) loss from locked 7-halonorbornyl cations occurs from an edge-protonated nortricyclene.



SCHEME 3

Interestingly, we find that there is a substantial increase (Table 1) relative to the non-deuterated brosylate **2***a*, in the degree of 1,3-elimination when *anti*-7-*exo*-3-*d* brosylate **3** is solvolyzed. If elimination does indeed occur from an edge-protonated (deuteronated) nortricyclene **10**, which along with the classical species **9** is one of the intermediates in the solvolysis reaction, then introduction of the β-deuterium at C-3 would cause an increase in the equilibrium population of this edge-protonated species and thereby result in an increase in 1,3-elimination. Another possibility is that the decrease in stability of **11** relative to the non-deuterated

11

species is compensated by homohyperconjugation to the *exo* and *endo* C—H bonds at C-6, with the result that the C—H bonds at C-6 are activated and undergo cleavage more readily.

Experimental

General

Nuclear magnetic resonance spectra were recorded on Varian T-60, A-60, and HA-100 spectrometers with tetramethylsilane (TMS) as the internal standard. Samples were dissolved in either carbon tetrachloride or carbon disulfide and chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. Infrared spectra were recorded on Perkin Elmer 337 and Beckman IR-5 infrared spectrometers and the samples were dissolved in carbon tetrachloride or carbon disulfide. Spectra were calibrated with a polystyrene thin film and peak positions are expressed in cm^{-1}. Mass spectra were recorded on a Hitachi-Perkin Elmer RMU-6A spectrometer at 80 eV and deuterium assays were performed at 10–15 eV. Analytical gas liquid partition chromatograms (glpc) were obtained on a Varian Aerograph Model 204B dual column analytical gas chromatograph equipped with dual flame ionization detectors using helium as the carrier gas. The helium flow rate was usually 20–30 mL/min. Product ratios were determined by an Aerograph Model 485 electronic digital integrator. Preparative gas liquid partition chromatography was carried out on a Varian Aerograph Model A-90-P gas chromatograph equipped with a thermal conductivity detector at a helium flow rate of 50–60 mL/min. Melting points were recorded on a Kofler hot-stage apparatus and are uncorrected. Boiling points are also uncorrected. Pentane was stirred vigorously over fuming sulfuric acid, washed with sodium bicarbonate solution, dried, and distilled. Dry ether refers to ether that was distilled from lithium aluminum hydride. Pyridine was refluxed over barium oxide for 48 h and distilled. All solutions were dried with either anhydrous sodium sulfate or magnesium sulfate.

Preparation of Brosylates

The brosylates were prepared from the appropriate halohydrins via the method described in a preceding publication (5).

Deuterium Assay of Brosylates

Since both the deuterated halohydrins and their corresponding halobrosylates gave weak parent ions when analyzed by mass spectrometry, the determination of deuterium content of these compounds by this method was not reliable. Therefore, we determined the deuterium content mass spectrometrically by analyzing the corresponding deuterated haloketones which were obtained by oxidation of the deuterated halohydrins.

Identification of Products

Syn-7-chloro-*exo*-2-norbornyl brosylate (5.5 g) and buffered 80:20 ethanol–water (75 mL) were magnetically stirred in a round-bottomed flask and heated in an oil bath at 56 ± 2°C for 36 h. All the brosylate dissolved after several hours. After the reaction mixture cooled to room temperature, it was extracted with pentane (3 × 200 mL). Water (700 mL) was added to the aqueous layer and further extractions with ether (3 × 250 mL) were carried out. The pentane and ether extracts were combined and washed with water (2 × 100 mL), saturated bicarbonate solution (2 × 100 mL), water (2 × 150 mL), and dried. After the solvent was removed under reduced pressure, a yellow residue remained which was found by analytical glpc on a 1/8 in. × 10 ft 10% Carbowax column at 170°C to contain five major products.

Each product was collected by preparative glpc on a 1/4 in. × 10 ft 15% FFAP column at 175°C. In order of increasing retention time, the products were identified as, 3-chloronortricyclene (**4***a*), *anti*-7-chloro-*exo*-2-norbornyl ethyl ether (**6***b*), *syn*-7-chloro-*exo*-2-norbornyl ethyl ether (**5***b*), *syn*-7-chloro-*exo*-2-norbornanol (**5***a*), and *anti*-7-chloro-*exo*-2-norbornanol (**6***a*). Careful analysis of the ^{1}H nmr spectrum of **4***a* revealed that chloronorbornenes, the products of 1,2-elimination, were not present. When the fourth product, *syn*-7-chloro-*exo*-2-norbornanol, was subjected to analytical glpc on a 1/8 in. × 10 ft 10% Carbowax column at 175°C, the glpc peak had an appreciable shoulder. A small portion of the sample was oxidized as previously described to the corresponding chloroketones (5). By comparison of retention times, it was shown with analytical glpc on a 1/8 in. × 10 ft 10% Carbowax column at 145°C that the contaminant was *exo*-3-chloro-2-norbornanone. The ratio of *syn*-7-chloro-2-norbornanone to *exo*-3-chloro-2-norbornanone was determined to be 9:1 and establishes that the solvolysis of *syn*-7-chloro-*exo*-2-norbornyl brosylate yields small amounts of *exo*-3-chloro-*exo*-2-norbornanol. *Anti*-7-chloro-*exo*-2-norbornyl brosylate (4.00 g) was solvolyzed in buffered 80:20 ethanol–water (100 mL) and worked up as described above. The products which had identical retention times to the products from **1***a* were isolated by preparative glpc and subjected to mass spectrometric analysis. The mass spectra of the products were identical in all respects to the mass spectra of **4***a*, **5***a*, **5***b*, **6***a*, and **6***b* isolated from solvolysis of **1***a*. Compound **4***a*: ir (CS_2); 3075, 2940, 1308, 1292, 1244, 958, 858, 825, 719; ^{1}H nmr (CS_2, 60 MHz) δ: 3.98 (sharp m, 1H, H-3), 2.18 (broad m, 2H, H-4 and *syn*-7-H), 1.8–1.3 (6H, nortricyclyl envelope); ms *m/e*: 128, 130(M^+), 93, 91, 79, 77, 66, 65, 58. Compound **6***b*: ir (CS_2); 2960, 1244, 1100, 1063; ^{1}H nmr (CS_2, 60 MHz) δ: 4.13 (sharp m, 1H, H-3), 2.48 (broad m, 2H, —O—CH_2CH_3), 2.33 (broad m, 2H, H-1 and H-4), 2.3–1.6 (norbornyl envelope), 1.22 (t, 3H, J = 7 Hz, O—CH—CH_3); ms *m/e*: 176, 174(M^+), 139, 138, 93, 91, 79, 77, 72, 67. Compound **5***b*: ir (CS_2); 2960, 1365, 1348, 1305, 1244, 1115, 1068; ^{1}H nmr (CS_2, 60 MHz) δ: 3.78 (sharp m, 1H, H-7), 3.40 (broad m, 2H, —O—CH_2—CH_3), 2.40 (m, 1H, H-1 or H-4), 2.25 (m, 1H, H-1 or H-4), 2.2–1.4 (norbornyl envelope), 1.15 (t, 3H, J = 7 Hz, —O—CH_2—CH_3); ms *m/e*: 176, 174(M^+ very weak), 138, 93, 91, 72, 67, 65. Compound **5***a*: ir (CS_2); 3580, 2960, 1245, 1088, 1050, 1018; ^{1}H nmr (CS_2, 60 MHz) δ: 4.02 (sharp m, 1H, H-7), 3.75 (broad pentuplet, 1H, H-2), 2.42 (broad m, 2H, H-1 and H-4), 2.2–1.0 (norbornyl envelope and —O—H); ms *m/e*: 131, 129(M^+ − OH), 110, 93, 91, 67, 66. Compound **6***a*: ir (CS_2); 3620, 3400, 2960, 1245, 1084, 1002; ^{1}H nmr (CS_2, 60 MHz) δ: 4.22 (sharp m, 1H, H-7), 3.83 (dd, 1H, J = 7, 1.5 Hz, H-2), 2.08 (s, 1H, —O—H), 2.4–1.0 (norbornyl envelope); ms *m/e*: 130, 128($M^+ - H_2O$), 110, 93, 91, 87, 79, 66, 67.

Determination of Deuterium Losses from Chlorobrosylates

In a typical reaction, buffered 80:20 ethanol–water (35–45 mL) was heated at 63 ± 2°C in an oil bath in a round-bottomed flask equipped with a reflux condenser and a calcium chloride drying tube. The deuterated chlorobrosylate (0.17 g of **1***c* and 0.50 g of **2***c*, 0.17 g of **1***d*, and 0.18 g of **2***d*) was added to the solution and the mixture was heated for about 50 h. Water (500 mL) was added and the mixture was extracted with ether. After the solvent was distilled off and the residue was concentrated to 0.05 mL, the total reaction mixture was subjected to preparative glpc on a 1/4 in. × 10 ft. 15% Carbowax column at 110°C in one injection and the fraction corresponding to 3-chloronortricyclene was collected in a U-shaped tube cooled in liquid nitrogen. Analysis of a mixture of 3-chloronortricyclene, *exo*-5-chloronorbornene, and *endo*-5-chloronorbornene by preparative glpc under the conditions described above revealed that the compounds were separated from each other. Compound **4***d-d* from **2***c*: ms *m/e*: M^+ 128, 129, 130, 131; 77.2% d_0, 22.8% d_1, 0.1% d_2, (0.23 excess d per molecule). Compound **4***a-d* from ms *m/e*: M^+ 128, 129, 130, 131; 78.1% d_0, 21.7% d_1, 0.2% d_2 (0.22 excess d per molecule). Compound **4***a-d* from **1***d*: ms *m/e*: M^+ 128, 129, 130, 131; 6.9% d_0, 9.1% d_1, 84.0% d_2 (1.77 excess d per molecule). Compound **4***a-d* from **2***d*: ms *m/e*: M^+ 128, 129, 130, 131; 7.2% d_0, 9.2% d_1, 88.6% d_2 (1.81 excess d per molecule).

Determination of Products and Deuterium Losses for Solvolysis of Bromobrosylates

Deuterated *syn*-bromobrosylate **1***e* (1.2 g) was dissolved in buffered (0.04 *M* NaOAc) 80:20 ethanol–water (25.6 mL) and the solution was heated at 65 ± 1°C for 24 h. Water was added (100 mL) and the mixture was extracted with purified pentane (4 × 50 mL). The combined extracts were washed with water (3 × 40 mL), dried, and the solvent was removed by distillation through a 15 in. glass helices-packed column. Analytical glpc analysis on a 1/8 in. × 12 ft 10% FAPP column at 150°C showed that **4***b*, **5***c*, **5***d*, **6***c*, and **6***d* comprised >85% of the reaction mixture. Three of the major products **4***b-d*, **5***d-d*, and **5***c-d* were isolated by preparative glpc on a 1/4 in. × 8 ft 15% Carbowax column at 150°C. Compound **4***b-d*: ^{1}H nmr (CS_2, 100 MHz) δ: 4.28 (sharp m, 1H, H-3), 2.03 (sharp m, 1H, H-4), 1.97 (d with fine structure, 1H, H-5), 1.5–1.0 (nortricyclyl envelope, < 5H); ms *m/e*: M^+ 172, 174; 61.5% d_0, 38.4% d_1, 0.1% d_2; (0.39 excess d per molecule). Compound **5***d-d*: ^{1}H nmr (CS_2, 100 MHz) δ: 3.69 (m, 1H, H-7), 3.33 (broad m, 3H, H-2 and —O—CH_3—), 2.38 (broad d, 1H, H-1), 2.25 (broad t, 1H, H-4), 2.15–1.25 (norbornyl envelope), 1.09 (t, J = 6.5 Hz, —CH_3). Compound **5***c-d*: ^{1}H nmr (CS_2, 100 MHz) δ: 3.26 (sharp m, 1H, H-7), 2.05 (broad p, 1H, H-2), 2.25 (broad m, 2H, H-1 and H-4), 2.03 (d, 1H, J = 11 Hz, —OH), 1.9–0.9 (norbornyl envelope).

Deuterated *anti*-bromobrosylate **2***c* (2.76 g) was dissolved in buffered 80:20 ethanol–water (55.2 mL) and the solution was heated at 65 ± 1°C for 24 h. Water was added (200 mL) and the mixture was extracted with purified pentane (4 × 100 mL) and after the usual workup the three major products were isolated by preparative glpc. The nmr of the nortricyclene was identical to that of **4***b-d* isolated from the solvolysis of **1***e*; ms *m/e*: M^+ 172, 174; 67.9% d_0, 30.6% d_1, 1.4% d_2 species (0.34 excess d per molecule). Compound **6***d-d*: ^{1}H nmr (CS_2, 100 MHz) δ: 4.06 (sharp m, 1H, H-7), 3.30 (broad m, 3H, H-2 and —O—CH_2—CH_3), 2.28 (broad m, 1H, H-1), 2.20 (broad t, 1H, H-4), 2.1–1.2 (norbornyl envelope), 1.10 (t, 3H, J = 6.5 Hz, —O—CH_2—CH_3). Compound **6***c-d*: ^{1}H nmr (CS_2, 100 MHz) δ: 4.13 (sharp m, 1H, H-7), 2.70 (dd, 1H, J = 8, 2.5 Hz, H-2), 3.35 (s, 1H, —OH), 2.25 (broad t, 1H, H-4), 2.13 (broad m, 1H, H-1), 2.1–1.9 (norbornyl envelope).

Syn-*7-chloro*-exo-*2-norbornyl Ethyl Ether*

Compound **5***a* (0.10 g) was dissolved in methylene chloride (3 mL) in a round-bottomed flask fitted with a nitrogen inlet and a calcium chloride drying tube. The system was flushed with nitrogen for 15 min. To this solution was added 0.12 g of triethyloxonium fluoroborate and the mixture was magnetically stirred for 24 h at 25°C. Water (10 mL) was added and the solution was extracted with methylene chloride (3 × 15 mL). The combined extracts were washed with water (2 × 10 mL) and dried. After the solution was concentrated under reduced pressure, analytical glpc analysis on a 1/8 in. × 10 ft. 15% FFAP column at 190°C showed one major product. The major product was isolated by preparative glpc on a 1/4 in. × 10 ft 15% FFAP column at 175°C as a clear liquid and identified as *syn*-7-chloro-*exo*-2-norbornyl ethyl ether. Infrared (CS_2): 1365, 1348, 1320, 1305, 1265, 1245, 1190, 1115(s), 1070: ^{1}H nmr (CS_2, 100 MHz) δ: 3.72 (s with fine structure, 1H, H-7), 3.32 (m, 3H, H-2 and —O—CH_2—), 2.33 and 2.30 (broad s, each 1H, H-1 and H-4), 2.12–1.02 (m, 6H, norbornyl envelope), 1.09 (t, 3H, J = 8 Hz, —CH_3).

Syn-*7-bromo*-exo-*2-norbornyl Ethyl Ether*

Deuterated *syn*-bromohydrin **5***c-d* (0.065 g, >95% pure) was dissolved in dry CH_2Cl_2 (2 mL) in a 5 mL two-necked flask and N_2 was slowly bubbled through the solution for 15 min. Freshly distilled thiethyloxonium tetrafluoroborate (0.15 g) was added and the flask was flushed with dry N_2 and stoppered. After 24 h water (10 mL) was added, the mixture was extracted with ether (3 × 10 mL), and the combined layers were washed with water (2 × 10 mL) and dried. Distillation of the solvent gave an oil that was composed of five major products of which the *syn*-bromoether was the major component as established by preparative glpc on a 1/4 in. × 8 ft 15% Carbowax column at 155°C. The ^1H nmr (CS_2, 100 MHz) was identical in all respects to the spectrum of the ether isolated from solvolysis of **1***e*.

Anti-*7-bromo*-exo-*2-norbornyl Ethyl Ether*

Deuterated *anti*-bromohydrin (0.059 g, 95% pure) was dissolved in dry CH_2Cl_2 (2 mL) and treated in the normal manner with triethyloxonium tetrafluoroborate. After workup the *anti*-bromoether that was the major component of the five major products of the reaction was isolated by preparative glpc on a 1/4 in. × 8 ft 15% Carbowax column at 150°C. The nmr was identical to that of the deuterated *anti*-7-bromo ether isolated from solvolysis of **2***e*.

Determination of Relative Yields of Products

The solutions from the kinetic runs (5) of the *non*-deuterated brosylates **1***a*, **1***b*, **2***a*, and **2***b* and the deuterated brosylates **1***d*, **1***e*, **2***d*, **2***e*, and **3** were combined and water (10–20 mL) was added. The mixtures were extracted with ether (2 × 80 mL, 1 × 30 mL), the combined extracts were washed with water (20 mL), saturated aqueous $NaHCO_3$ (2 × 20–35 mL), water (3 × 15–30 mL), and dried. The solvent was carefully distilled off through a 30 cm glass-helices column and the residues were analyzed by analytical glpc on a 1/8 in. × 10 ft 10% Carbowax column at 155°C. Peak areas were determined with a Varian Aerograph Model 485 electronic integration.

Photolyse du butyne-1 dans la région de 147 à 174 nm

HÉLÈNE DESLAURIERS, JOVETTE DESCHÊNES ET GUY J. COLLIN[1]

Département des Sciences Pures, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Reçu le 14 avril 1980

HÉLÈNE DESLAURIERS, JOVETTE DESCHÊNES et GUY J. COLLIN. Can. J. Chem. **58**, 2100 (1980).

La photolyse du butyne-1 a été observée à 147, 163 et 174 nm. Les principaux produits C_1 à C_5 ont été mesurés dans le monomère pur ou en présence d'additifs et à différentes pressions (0,5 à 100 Torr – 65 à 13 300 N m^{-2}). Le radical méthyle est l'espèce intermédiaire dont le rendement est le plus important. L'acétylène, l'éthylène et le vinylacétylène sont produits en présence d'intercepteur radicalaire et proviennent probablement de la fragmentation de la molécule photoexcitée. On a noté en outre une forte polymérisation même en présence d'intercepteur radicalaire, et la presque impossibilité d'intercepter les radicaux C_3H_3 par l'iodure d'hydrogène. Des réactions secondaires diverses interviennent très certainement et compliquent l'interprétation. Par exemple l'augmentation du rendement en éthylène sur addition d'oxygène est difficilement explicable sur la notion simple habituellement admise de l'interception des radicaux libres par cet additif.

HÉLÈNE DESLAURIERS, JOVETTE DESCHÊNES, and GUY J. COLLIN. Can. J. Chem. **58**, 2100 (1980).

We have studied the 147, 163, and 174 nm photolysis of 1-butyne. Several products from C_1 to C_5 were observed under various conditions such as in the presence of additives, or at different pressures between 0.5 and 100 Torr (65 to 13 300 N m^{-2}). The methyl radical is the most important radical intermediate. Acetylene, ethylene, and vinylacetylene are produced in the presence of radical scavengers and are probably the result of the fragmentation of the photoexcited molecule. Propargyl radicals are thought to be produced but appear not to be scavenged by hydrogen iodide. Polymerization was observed even in the presence of radical scavengers. Secondary processes are numerous and make the interpretation of our results difficult; for example, the ethylene quantum yield increased upon addition of 10% oxygen, the simple radical scavenging effect of this additive does not explain such an effect.

Introduction

La photolyse des oléfines entre 147 et 174 nm a montré un effet de pression fort intéressant (1, 2). Dans certains cas des informations sur la chimie des radicaux allyles ont été obtenues (3, 4). Il est intéressant d'étudier la famille des alcynes pour voir si des informations similaires peuvent être obtenues sur les radicaux propargyles et ses dérivés. Le choix du butyne-1 pour aborder cette étude est lié à différents facteurs secondaires. Il est intéressant à priori d'étudier aussi la fragmentation de la molécule excitée. En particulier, il est nécessaire de savoir si les liaisons C—C en position β de la triple liaison sont aussi importantes dans la photolyse des alcynes que dans celle des oléfines (1, 2). Le butyne-1 permet de comparer l'importance de la scission de la liaison C—C située en position β par rapport à celle située en α de la triple liaison.

Le butyne-1 a déjà fait l'objet d'une étude à 123,6, 147 et au-dessus de 220 nm (5). Mis à part la réaction de fragmentation du radical butènyle-1 aucun effet de pression n'a été mentionné, il est vrai dans un domaine de pression restreint. Nous avons repris l'étude à 147 nm en ajoutant l'effet de l'iodure d'hydrogène et en élargissant l'échelle de pression.

Méthode expérimentale

Matériaux

Le butyne-1 est un produit API de pureté moléculaire affichée 99,94 ± 0,03%. L'analyse chromatographique de ce produit montre la présence d'une impureté dont le temps de rétention correspond à celui du méthyl-3-butyne-1-ène-3: 1470 ppm ainsi que de méthyl-3-butène-1: 38 ppm. L'oxygène (99,99%), l'oxyde nitrique (99,0%) et le propane (99,99%) sont des produits de qualité recherche de la compagnie Matheson du Canada. L'iodure d'hydrogène et le sulfure d'hydrogène sont les produits perdeutériés de la compagnie Merck, Sharp et Dohme du Canada (99,9%).

Préparation et irradiation des échantillons

Les échantillons sont utilisés après avoir été dégasés sous vide (10^{-5} mm mercure) dans une rampe en Pyrex équipée de valves en Téflon, de manomètres à membrane métallique Wallace et Tierman et d'une pompe à diffusion à huile située en amont d'une pompe mécanique. Les techniques d'irradiation ont été décrites et l'actinométrie est faite en comparant les chromatogrammes obtenus avec ceux obtenus lors de la photolyse du *cis*-butène-2 (6) ou du propène (2).

Les lampes utilisées sont elles aussi connues. La lampe au xénon (147 nm – 8,4 eV) est monochromatique (7), celle au brome (≈163 nm – 7,6 eV) (9) et celle à l'azote (≈174 nm – 7,1 eV) (8) le sont beaucoup moins. Le coefficient d'absorption du butyne-1 est de 800 ± 50 et de 250 ± 30 atm^{-1} cm^{-1}, respectivement à 147 et à 163 nm (9) et celui de l'iodure d'hydrogène est de 50 ± 20 atm^{-1} cm^{-1} à 147 nm (10*a*). Sans avoir trouvé ou mesuré le coefficient d'absorption du DI à 163 et à 174 nm, l'addition de cet intercepteur (25%) au butyne-1 ne provoque pas de diminution notable d'absorption de la lumière par l'alcyne. Celui de H_2S est de 285 atm^{-1} cm^{-1} à 147 nm et il est probablement plus faible à 163 et 174 nm (10*b*).

Analyse

Les produits sont analysés par chromatographie en phase gazeuse par ionisation de flamme en utilisant une colonne de squalane (25% – 8 m) à la température de la chambre (11). Une colonne de *n*-octane/Porasil C permet en outre d'extraire le rendement en propane ainsi que celui en butène-1.

Résultats

Avant de présenter les résultats qui accompagnent le texte, il y a lieu de parler ici de la difficile reproductibilité rencontrée dans l'expérimentation. Contrairement aux précédentes études faites avec les oléfines, la fenêtre, qui sépare la lampe d'irradiation de la chambre réactionnelle, devient de plus en plus opaque au fur et à mesure que les temps de photolyse s'additionnent. La fig. 1 montre le nombre de photons émis par seconde après des temps variables de photolyse du mélange butyne-1:oxygène (100:10). La mesure est faite en photolysant le *cis*-butène-2 (6, 7). Le remplacement de l'oxygène par l'oxyde nitrique ne modifie pas substantiellement la décroissance de la transmission de la fenêtre. Evidemment, le nettoyage de la fenêtre avec un solvant habituel (acétone, tétrachlorure de carbone, ...) permet de retrouver la transmission initiale. Cette perte de transmission est encore plus sévère lors de la photolyse du monomère pur. Il s'ensuit que chaque irradiation de butyne-1 est encadrée par deux irradiations de *cis*-butène-2 pour les fins de l'actinométrie. Mais même dans ce cas, la précision de la mesure n'est au mieux connue qu'à ±10%. Les rendements quantiques ont été calculés en faisant la moyenne arithmétique de l'intensité de la lampe déterminée avant et après chaque photolyse. Aux résultats qui accompagnent le texte et qui apparaissent dans les tableaux et les figures, il faut ajouter les suivants.

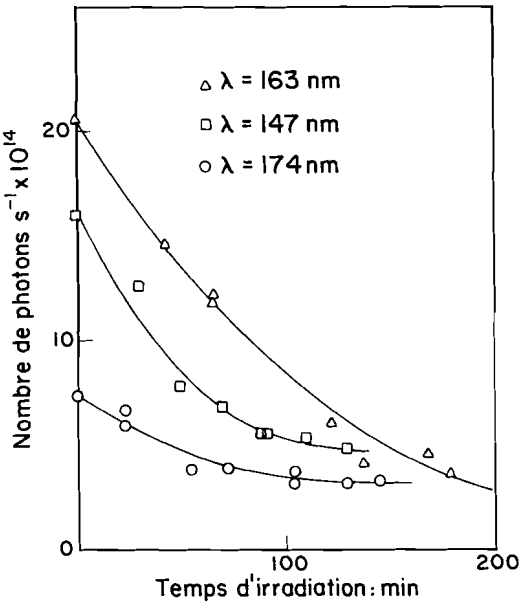

FIG. 1. Intensité du flux photonique entrant dans la chambre réactionnelle, mesurée à travers la photolyse du *cis*-butène-2. Les temps d'irradiations sont ceux des photolyses de butyne-1 qui sont effectuées entre les photolyses de butène-2; note: l'échelle pour la lampe à xénon (147 nm) doit être divisée par 10.

A 163 nm

1. La photolyse du mélange butyne-1:DI:SF_6 (50:1,25:x Torr) avec x variant entre 0 et 150 Torr, ne montre aucune variation substantielle des rendements quantiques des produits, sauf celui attribuable à l'effet de pression (voir plus loin).

2. Le pentadiène-2,3 est observé dans la photolyse du butyne-1 pur: $\Phi = 0{,}028$ à 10 Torr.

3. L'addition de l'oxyde nitrique a un effet similaire à celui de l'oxygène (tableau 1) sauf en ce qui a trait au rendement quantique en éthylène. Ce dernier diminue d'environ 50%: $\Phi(C_2H_4) = 0{,}04_5$, $0{,}05_5$ et 0,06 à 1,0, 5,0 et 10,0 Torr respectivement.

A 147 nm

Les résultats sont comparables à ceux déjà publiés par Hill et Doepker (5). On note par exemple des valeurs $\Phi_{O_2}(C_2H_4)$ environ deux fois plus importantes que celles de $\Phi_{NO}(C_2H_4)$. Nos rendements quantiques sont en général un peu plus élevés sauf ceux relatifs au vinylacétylène. Par contre nous observons un effet de pression sur la majorité des produits. Par exemple ces auteurs indiquent une valeur $\Phi_{NO}(C_4H_4)$ de 0,33 constante entre 0,5 et 20 Torr. Notre étude entre 0,5 et 90 Torr montre une variation faible certes, mais nette entre 0,5 et 90 Torr: $\Phi_{O_2}(C_4H_4)$ varie de 0,25 et 0,13.

Discussion

Photolyse à 163 nm

Le tableau 1 résume les principaux résultats obtenus dans la photolyse du butyne-1 dans différentes conditions. Les produits majeurs qui apparaissent lors de l'irradiation du produit pur sont l'éthane, l'allène et le vinylacétylène. En présence d'oxygène, le rendement en éthane disparaît, laisse inchangés ceux en allène et en vinylacétylène et augmente, double, celui en éthylène. En présence d'iodure d'hydrogène, le méthane est de loin le produit majeur avec un rendement quantique qui dépasse la valeur 1/2. Toujours en présence d'iodure d'hydrogène, les rendements en allène et en vinylacétylène ne sont pas perturbés, tandis que celui en butène-1 s'accroît de façon substantielle.

L'effet de l'addition de l'iodure d'hydrogène dans ces systèmes est relativement bien connu (11–13): il sert d'intercepteur radicalaire.

[1] $R + DI \rightarrow RD + I$

Ainsi la croissance du rendement en méthane en

[a]En Torr (1 Torr = 133 N m^{-2}).
[b]Effet de l'oxyde nitrique similaire sauf pour la valeur $\Phi_{NO}(C_2H_4)$; voir résultats.
[c]n.m.: non mesuré.
[d]Identification très incertaine; voir réf. 13.

présence de cet additif est liée à la présence de radicaux méthyles. En supposant en outre qu'en présence d'oxygène ou d'oxyde nitrique tous les radicaux méthyles libres sont interceptés par l'un ou l'autre de ces deux additifs, la relation suivante peut être utilisée pour la mesure de rendements quantiques du radical méthyle:

$$[A] \quad \Phi(CH_3) = \Phi_{DI}(CH_4) - \Phi_{O_2 \text{ ou } NO}(CH_4)$$

ou

$$[B] \quad \Phi(CH_3) = \Phi_{D_2S}(CH_4) - \Phi_{O_2 \text{ ou } NO}(CH_4)$$

L'effet est sans doute similaire à celui de l'hydrogène sulfuré (11–13). Les deux relations [A] et [B] permettent de déterminer un rendement en radicaux méthyles de l'ordre de 0,62 ± 0,06. Ce rendement en radicaux méthyles est suffisant pour expliquer la formation de l'éthane dans la photolyse du produit pur, et est conforme à la disparition de ce produit lors des photolyses réalisées en présence d'oxygène ou d'oxyde nitrique. Cette proposition, de même que les relations [A] et [B], excluent la possibilité de réactions entre les radicaux méthyles et le monomère.

Un second produit important obtenu en présence de DI est le butène-1. Sur la base de la réaction [1], la formation de ce produit est liée à la présence de radicaux C_4H_7. La voie la plus directe pour la formation de ces radicaux C_4H_7 est celle de l'addition d'atome d'hydrogène sur le monomère (5, 14).

$$[2] \quad H + CH_3CH_2C{\equiv}CH \rightarrow CH_3CH_2\dot{C}{=}CH_2^* \qquad \Delta H = -200 \text{ kJ mol}^{-1} \quad \text{(réf. 15)}^2$$

$$[3] \quad CH_3CH_2\dot{C}{=}CH_2^* + M \xrightarrow{k_s} CH_3CH_2\dot{C}{=}CH_2 + M$$

$$[4] \quad CH_3CH_2\dot{C}{=}CH_2^* \xrightarrow{k_d} CH_3 + CH_2{=}C{=}CH_2(A) \qquad \Delta H = +150 \text{ kJ mol}^{-1}$$

Un deuxième intermédiaire radicalaire est donc l'atome d'hydrogène. Le radical vinylique C_4H_7 formé dans la réaction [2] est vibrationnellement excité: il doit être stabilisé par collision, sans quoi il a toutes chances de se fragmenter en un radical méthyle et en allène. Le mécanisme réactionnel proposé ([3] et [4]) est régi par la relation bien connu de Stern–Volmer (16):

$$[C] \quad [\Phi(A)]^{-1} = [\Phi_0(A)]^{-1} + [\Phi_0(A)]^{-1}(k_s/k_d)[M]$$

où Φ et Φ_0 sont les rendements quantiques à pression quelconque et à pression nulle; A est l'allène; k_s et k_d, respectivement, les constantes d'ordre deux et d'ordre un des réactions [3] et [4]; et [M] tient lieu de pression. Cette relation linéaire de $[\Phi(A)]^{-1}$ en fonction de la pression est présentée à la fig. 2. La courbure observée n'est pas importante compte tenu de l'incertitude expérimentale, mais n'est pas non plus impossible (16). D'autre part, le rendement en atome d'hydrogène dépend lui aussi de la pression (voir plus loin): il diminue probablement légèrement lorsque la pression croît. Ce qui doit ajouter à la non-linéarité de la relation [C]. Par conséquent, il ne peut se calculer avec une relation aussi simple que les relations [A] ou [B]: il faut tenir compte de l'effet de pression et

$$[D] \quad \Phi[H] \simeq \Phi_{DI}(C_2H_5CH{=}CH_2) + \Phi_{DI}(CH_2{=}C{=}CH_2) - \Phi_{O_2 \text{ ou } NO}(C_2H_5CH{=}CH_2) - \Phi_{\text{moléculaire}}(CH_2{=}C{=}CH_2)$$

Comme le rendement en butène-1 en présence d'oxygène est nul, l'expression [D] se simplifie. Il

[2]Les valeurs thermodynamiques usuelles sont tirées de Rosenstock et coll. (15) (voir le tableau 5).

TABLEAU 2. Photolyse du mélange butyne-1:DI (5:x Torr) à 163 nm

x	$\Phi(C_4H_4)$	$CH_3C{\equiv}CH$	$CH_2{=}C{=}CH_2$	$C_2H_5CH{=}CH_2$	[D']

1,21	$0,10_5$	$0,05_2$	0,09	0,18	0,27

[a] $\Phi_{O_2}(CH_3C{\equiv}CH) = 0,00$ et $\Phi_{O_2}(C_2H_5CH{=}CH_2) = 0,00$.

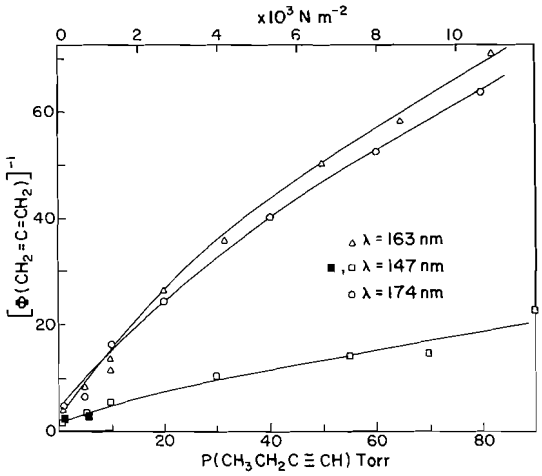

FIG. 2. Inverse du rendement quantique de l'allène en fonction de la pression de butyne-1 dans le mélange butyne-1: oxygène (100:10) ■: voir réf. 5.

reste cependant à évaluer le rendement $\Phi_{\text{moléculaire}}(CH_2{=}C{=}CH_2)$. La réaction [4] est un processus qui se fait avec une fréquence de l'ordre de grandeur de celle de collision à une pression de 1 Torr (133 N m^{-2}) ([4] est en compétition avec [3]). Donc l'oxygène et l'oxyde nitrique ajouté en faible proportion sont incapables d'intercepter les radicaux chauds $C_4H_7{}^*$. Par conséquent la réaction [4] génère l'allène même en présence de ces additifs (5). Il existe cependant au moins une autre possibilité de formation de l'allène par décomposition de la molécule photoexcitée

[5] $CH_3CH_2C{=}CH + h\nu \rightarrow CH_3CH_2C{\equiv}CH^{**}$

[6] $CH_3CH_2C{\equiv}CH^{**} \rightarrow (C_4H_6{}^{**}) \rightarrow CH_2{=}C{=}CH_2 + CH_2$

$\Delta H = +418$ kJ mol^{-1}

Cette possibilité est à éliminer. En effet, on admet généralement dans ces systèmes que la fragmentation directe des molécules photoexcitées se fait avec une fréquence beaucoup plus grande que la fréquence de collision sous pression normale ou de la réaction d'isomérisation. Dans ces conditions, la fig. 2 montre que la réaction [6] a un rendement quantique maximum inférieur à 0.02. La même conclusion a été proposée à 147 nm (5). En ignorant cette possibilité, la relation [D] se réduit à

[D'] $\Phi(H) = \Phi_{DI}(C_2H_5CH{=}CH_2) + \Phi_{DI}(CH_2{=}C{=}CH_2)$

et le rendement quantique en atome d'hydrogène est voisin de 0,29 ± 0,03. Cette valeur est probablement une valeur par défaut. En effet, l'interception des atomes d'hydrogène par le butyne-1 est en compétition avec celle par l'iodure d'hydrogène. Malgré un pourcentage élevé de DI (25%) (tableau 1) le rendement en allène ne semble pas être altéré tout au moins à l'incertitude expérimentale près. Le tableau 2, montre une étude plus systématique de l'effet de DI. La valeur de [D'] montre une variation à la baisse lorsque la concentration de DI croît. Compte tenu de l'incertitude expérimentale, on peut estimer que la variation de la concentration de DI de 5 à 25% fait diminuer la valeur de [D'] de 25%. De telle sorte que la valeur de [D'] est plutôt voisine de 0,4 ± 0,05 avec un rapport $k(H + DI)/k(H + C_2H_5C{\equiv}CH)$ voisin de 2,3 ± 0,3. La formation de méthyl-2-butène-1 en l'absence d'additifs est explicable par la combinaison des radicaux méthyles et butényles issus des réactions [2] et [3].

Un troisième radical est aussi révélé par l'addition de DI ou de D_2S: le radical éthyle. Les deux relations [A] et [B] appliquées au rendement en éthane sont contradictoires: $\Phi_{DI}(C_2H_5) = 0,45$ et $\Phi_{D_2S}(C_2H_5) = 0,15$ et l'explication de ces différents effets n'est pas aisée. Notons cependant la formation du propane attribuable à la combinaison des radicaux méthyles et éthyles, formation qui disparaît en présence d'oxygène ou d'oxyde nitrique.

Un autre produit révélé par l'usage de DI est le radical C_3H_3 via la formation du propyne. La réaction [1] appliquée à cette formation entraîne la relation suivante.

[E] $\Phi(C_3H_3) = \Phi_{DI}(CH_3C{\equiv}CH) - \Phi_{O_2 \text{ ou } NO}(CH_3C{\equiv}CH)$

et $\Phi(C_3H_3) \simeq 0,05 \pm 0,01$

Le rendement en propyne obtenu en présence de D_2S est beaucoup plus faible que celui mesuré en présence de DI. La structure du radical C_3H_3

suggérée partir de la structure de monomère est le radical propargyle $CH_2C{\equiv}CH$:

[7] $CH_3CH_2C{\equiv}CH^{**} \rightarrow \dot{C}H_3^* + \dot{C}H_2C{\equiv}CH^*$
$\Delta H = +320$ kJ mol^{-1} (réf. 17)[3]

[8] $\dot{C}H_2C{\equiv}CH^* + M \rightarrow \dot{C}H_2C{\equiv}CH + M$

[9] $\dot{C}H_2C{\equiv}CH^* \rightarrow C_3H_2 + H$
$\Delta H = +347$ kJ mol^{-1} (?)

[10] $\dot{C}H_2C{\equiv}CH^* \rightleftarrows CH_2{=}C{=}\dot{C}H^*$

[11] $CH_2{=}C{=}\dot{C}H^* + M \rightarrow CH_2{=}C{=}\dot{C}H + M$

[12] $\dot{C}H_2C{\equiv}CH \rightleftarrows CH_2{=}C{=}\dot{C}H$

où R* est un fragment primaire qui emporte une part inconnue de l'excédent de l'énergie du photon. L'interception du radical propargyle $\dot{C}H_2C{\equiv}CH$ par D_2S est une réaction endothermique, la chaleur de la liaison $H{-}CH_2C{\equiv}CH$ étant plus faible que celle de la liaison H—SH: $D(H{-}CH_2C{\equiv}CH)$ = 89,3 kcal mol^{-1} (18) et $D(H{-}SH)$ = 90,5 kcal mol^{-1} (19). Sur cette base et de façon similaire à l'interception des radicaux allyles, l'hydrogène sulfuré ne doit pas intercepter les radicaux propargyles (11). Le radical propargyle est cependant en résonance électronique avec la structure allènique. Des études théoriques (20) tout autant expérimentales (21) ont montré que le radical propargylique est probablement plus stable que le radical allènique. Expérimentalement, Kebarle et coll. ont montré que le rapport des concentrations à l'équilibre favorise le radical propargylique dans un rapport 3 à 1. Compte tenu de la valeur du rendement $\Phi_{DI}(CH_3C{\equiv}CH)$, la valeur du rendement en allène provenant de l'interception du radical allènique par DI ne devrait pas dépasser 0,02, une valeur de l'ordre de grandeur de l'incertitude expérimentale sur la mesure du rendement de l'allène. En ajoutant cette dernière valeur à celle de $\Phi_{DI}(C_3H_3)$ trouvée plus haut à partir de la formation du propyne, on observe un rendement maximum en radicaux C_3H_3 de 0,07.

L'iodure d'hydrogène n'est sans doute pas un excellent intercepteur radicalaire lorsqu'il s'agit de radicaux très insaturés comme C_2H ou C_3H_3 (13) surtout en présence d'un monomère dont on connaît peu de chose sur sa réactivité vis-à-vis les radicaux. Il faut d'ailleurs ajouter ici que le radical C_2H ne réagit pas avec l'oxyde nitrique (22) mais qu'il réagit passablement vite avec les alcanes et les oléfines: l'un des produits majeurs de telles interactions est l'acétylène (22, 23).

Il faut aussi traiter de la formation de l'éthylène et de l'acétylène. La formation de radicaux éthyles se relie simplement à la fragmentation de la molécule photoexcitée.

[13] $CH_3CH_2C{\equiv}CH^{**} \rightarrow C_2H_5^* + C_2H^*$
$\Delta H = +419$ kJ mol^{-1}

[14] $C_2H_5^* \rightarrow C_2H_4 + H$ $\Delta H = 79$ kJ mol^{-1}

[15] $C_2H_5^* + M \rightarrow C_2H_5 + M$

La relation de Stern–Volmer s'applique également au rendement en éthylène (fig. 3) et les commentaires faits précédemment pour la courbure de la droite de Stern–Volmer s'appliquent aussi ici. Il faut cependant mentionner l'effet différent de l'oxygène et de l'oxyde nitrique: $\Phi_{O_2}(C_2H_4) > \Phi_{NO}(C_2H_4)$. A basse pression, la valeur $\Phi_{O_2}(C_2H_4)$ est le double de la valeur $\Phi_{NO}(C_2H_4)$ (tableau 1). Cette différence a aussi été observée par Hill et Doepker (5). Les notions simples, ou peut-être trop simplistes, de l'interception des radicaux libres par les intercepteurs utilisés ne donnent pas un éclairage suffisant pour fins d'explication.

Une autre possibilité de formation de l'éthylène est la libération d'une molécule d'éthylène et d'acétylène à partir de la molécule photoexcitée. Cela nécessite évidemment l'isomérisation de la molécule photoexcitée

[16] $CH_3CH_2C{\equiv}CH^{**} \rightarrow (C_4H_6)^{**} \rightarrow C_2H_4^* + C_2H_2^*$
$\Delta H = +27{,}2$ kcal mol^{-1}

Les remarques faites à propos de la réaction [6] s'appliquent encore. D'autre part si l'excédent de l'énergie du photon est localisée dans l'éthylène, cette molécule a suffisamment d'énergie pour se fragmenter à nouveau en acétylène. Il faut rappeler ici que l'énergie minimum des photons est de 680 kJ einstein^{-1} à 174 nm. Dans ces conditions, la réaction [16] ne pourrait rendre compte que de la formation de l'éthylène et de l'acétylène (fig. 4) à haute

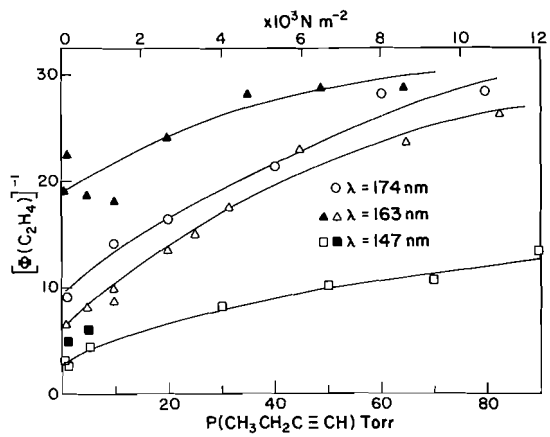

FIG. 3. Inverse du rendement quantique de l'éthylène en fonction de la pression de butyne-1. Le mélange contient 10% d'oxygène (△, ○, □) ou 5% d'oxyde nitrique ■ (réf. 5).

[3] $\Delta H_f^0(\dot{C}H_2C{\equiv}CH) \simeq 82$ kcal mol^{-1}. Voir la réf. 17.

pression. Dans ce cas $\phi([16]) \leq 0{,}04$. Inversement, il faut ajouter que des états excités à longue durée de vie ont été postulés pour l'acétylène (24). Cette possibilité n'a cependant pas été retenue pour les alcynes supérieurs (25). Notons en outre que les états excités du type Rydberg ont été observés dans cette région (9, 26).

Finalement, un dernier produit dont le rendement est plutôt insensible aux additifs est le vinylacétylène. Son rendement varie avec la pression (fig. 5). Deux possibilités sont disponibles:

[17] $CH_3CH_2C{\equiv}CH^{**} \rightarrow H_2 + CH_2{=}CHC{\equiv}CH$
$\Delta H = +120$ kJ mol^{-1}

[18] $CH_3CH_2C{\equiv}CH^{**} \rightarrow H + CH_3\dot{C}HC{\equiv}CH^{*}$
$\Delta H = +361$ kJ mol^{-1} (réf. 17*c*)[3]

[19] $CH_3\dot{C}HC{\equiv}CH^{*} \rightarrow H + CH_2{=}CHC{\equiv}CH$
$\Delta H \simeq +195$ kJ mol^{-1}

[20] $CH_3CHC{\equiv}CH^{*} + M \rightarrow CH_3CHC{\equiv}CH + M$

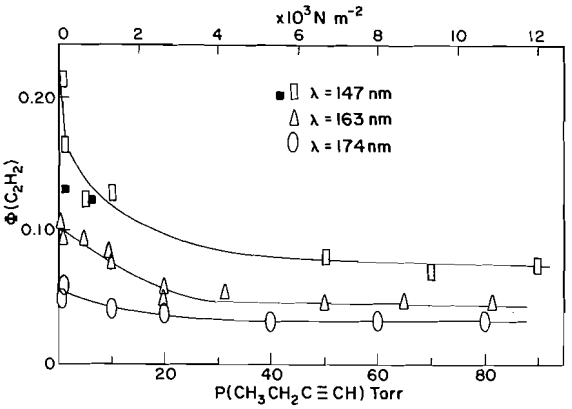

FIG. 4. Rendement quantique de l'acétylène en fonction de la pression de butyne-1 dans le mélange butyne-1:oxygène (100:10); ■ (réf. 5).

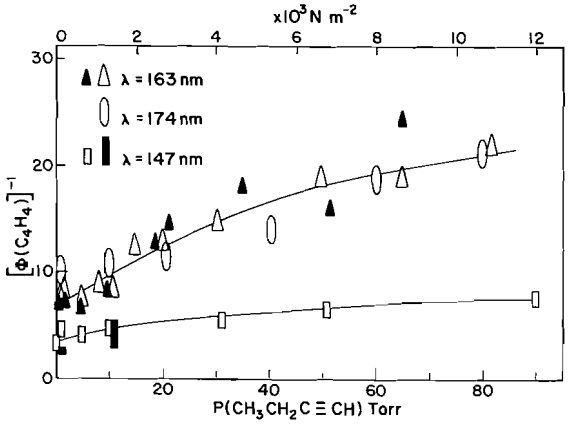

FIG. 5. Inverse du rendement quantique en vinylacétylène en fonction de la pression de butyne-1. Le mélange contient 10% d'oxygène (■, □, ○, △) ou 5% d'oxyde nitrique (▲). ■ (réf. 5).

La réaction [17] a contre elle les mêmes remarques faites à propos de la réaction [16]: l'effet de pression doit porter sur un état excité à longue vie. Les réactions [18] à [20] sont plus conformes à ce qui a été observé avec les oléfines (1, 2). La réaction [18] est la réaction majeure observée dans la photolyse sensibilisée par le mercure (21). Contrairement au radical propargylique où la forme allènique est moins stable, le radical $CH_3CHC{\equiv}CH$ semble exister plus facilement sous la forme allènique $CH_3CH{=}C{=}CH$ (21). Le produit résultant de sa combinaison avec le radical méthyl est observé dans le système pur sous forme de pentadiène-2,3.

Il est intéressant maintenant de faire les bilans. Puisque deux sources de radicaux méthyles ont été identifiées, le rendement du processus primaire [7] est au plus égal au rendement en radicaux méthyles diminué du rendement en allène: réaction [4]. Le tableau 1 permet ainsi de calculer $\phi([7]) \simeq 0{,}50 \pm 0{,}05$. Par contre, la mesure du rendement $\Phi(C_3H_3) \simeq 0{,}07$ calculée plus haut est insuffisante. Le produit C_3H_2 s'il est formé n'a pas été analysé. Le processus primaire [13] est au plus égal à la somme des rendements en radicaux éthyles et en éthylène. L'effet de DI, évalue à $0{,}11 \pm 0{,}02$ la valeur maximum de $\phi([13])$. Si la réaction [16] participe aussi à la formation de l'éthylène, alors $\phi([13]) \simeq 0{,}07$. A nouveau on ne retrouve pas le complément c'est-à-dire le radical C_2H. Finalement la mesure du rendement en vinylacétylène à pression nulle donne une valeur minimum à la somme $\phi([17]) + \phi([18]) \geq 0{,}15$. La mesure du rendement en radicaux $CH_3CHC{\equiv}CH$ ou $CH_3CH{=}C{=}CH$ est difficile de telle sorte qu'il devient impossible de faire le bilan complet du comportement de la molécule photoexcitée. Un fait cependant demeure, c'est l'abondante "polymérisation" du butyne-1 (fig. 1). La réactivité du radical C_2H (et probablement du radical C_3H_3) envers le monomère explique cette polymérisation. Ajoutons enfin, qu'un état photoexcité du monomère à temps de vie long n'est pas improbable bien que rien ici ne permet de le justifier.

A 147 nm

Les produits sont identiques à ceux mesurés à 163 nm. Cependant les rendements quantiques sont plus élevés (tableau 3). L'effet de pression est aussi beaucoup plus faible qu'à 163 nm (figs 2, 5). Ces deux arguments favorisent à la fois la plus grande décomposition et/ou la plus grande importance des fragmentations secondaires, et/ou la plus grande fréquence de fragmentation de l'isomère du monomère à long temps de vie.

L'application du modèle développé à 163 nm

conduit à des rendements à 147 nm qui sont les suivants: $\phi([7]) \simeq 0,9$, $\phi([13]) \simeq 0,13$, $\phi([16]) = 0,10$ et $\phi([17]) \geq 0,33$, soit un total de 1,46! C'est évidemment une valeur trop élevée à moins d'admettre l'amorce d'un mécanisme en chaîne. L'impossibilité à nouveau d'intercepter les radicaux C_3H_3 et C_2H par DI, et l'accumulation de polymère sur la fenêtre, l'augmentation du rendement en éthylène sur addition d'oxygène conduit à proposer un mécanisme radicalaire de polymérisation. Certaines de ces chaînes en croissance peuvent donner lieu à la libération d'une part des produits mesurés et expliquer ainsi la valeur de 1,46 calculée plus haut. Il faut aussi mentionner que les atomes d'iode libérés dans la réaction (1) peuvent ne pas être inertes.

Vers 174 nm

Les rendements mesurés sont très semblables à ceux mesurés à 163 nm (tableau 4 et figs 2–5). Une exception toutefois, le rendement en acétylène semble un peu plus faible surtout en présence d'oxygène.

TABLEAU 4. Photolyse du butyne-1 vers 174 nm. Rendements quantiques

Conclusion

Le spectre d'absorption du butyne-1 est connu (9). En-dessous de 159 nm et jusque vers 121,8 nm (le potentiel d'ionisation du butyne-1), Nakayama et Watanabe ont proposé trois séries de bandes Rydberg. Par contre au-dessus de 165 nm et jusque vers 200 nm, un large continuum avec un maximum à 177 nm a été enregistré. Sur celui-ci on croît pouvoir distinguer de faibles bandes de type Rydberg (27). Ainsi, l'absorption à 147 nm a lieu dans une zone d'absorption Rydberg sans qu'on sache très bien ce qui se passe au-dessus de 160 nm. Le présent travail n'aide pas non plus. Finalement, il est difficile de quantifier l'importance de la scission de la liaison C—C située en position β par rapport à celle située en α. Disons qu'elle semble être la plus importante. Par rapport aux oléfines cependant, elle l'est moins. Par contre la scission C—H semble être ici plus importante (1, 2, 7, 8).

Remerciements

Nous voudrions remercier vivement le Conseil de recherches en sciences naturelles et en génie du Canada qui nous a permis de faire cette étude, et l'Université du Québec à Chicoutimi qui a défrayé le salaire de l'un d'entre nous (J.D.).

[a] $\Delta H_f^0(CH_3\dot{C}HCH{=}CH_2)$ = 127,6 kJ mol^{-1} (15)[2] et $\Delta H_f^0(CH_3CH_2\text{-}\dot{C}{=}CH_2) \approx \Delta H_f^0(CH_3\dot{C}HCH{=}CH_2)$ + énergie de résonance de radical allylique.
[b] $\Delta H_f^0(CH_3C{\equiv}C\dot{C}H_2)$ = 308 kJ mol^{-1} (17*c*)[3].

Photolyse du butyne-2 dans la région de l'uv sous vide

JOVETTE DESCHÊNES, HÉLÈNE DESLAURIERS ET GUY J. COLLIN[1]

Département des Sciences Pures, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Reçu le 14 avril 1980

JOVETTE DESCHÊNES, HÉLÈNE DESLAURIERS et GUY J. COLLIN. Can. J. Chem. **58**, 2108 (1980).

La photolyse dans l'uv sous vide du butyne-2 a été étudiée à 147, 163 et 174 nm. L'usage de l'iodure d'hydrogène montre l'importance du radical méthyle dans la fragmentation de la molécule photoexcitée. On en conclut que la fragmentation principale de la molécule photoexcitée implique la rupture de la liaison C—CH_3: $\Phi_{147} \simeq 0.9$ et $\Phi_{163} \simeq 0.8$. On n'a cependant pas pu mesurer convenablement le rendement de la contrepartie, soit le radical C_3H_3. La diminution rapide de la transmission de la fenêtre suggère qu'une polymérisation radicalaire se fait même en présence d'oxygène ou d'oxyde nitrique. Finalement, on a pu suivre la variation du rendement du propyne et en vinylacétylène en fonction de la pression. Le premier produit est le résultat de la fragmentation du radical butènyle vibrationnellement excité tandis que le deuxième est probablement le résultat de la fragmentation du radical C_4H_5.

JOVETTE DESCHÊNES, HÉLÈNE DESLAURIERS, and GUY J. COLLIN. Can. J. Chem. **58**, 2108 (1980).

The vacuum uv photolysis of gaseous 2-butyne has been studied at 147, 163, and 174 nm. The use of hydrogen iodide as radical scavenger shows the importance of methyl radical formation in the fragmentation of the photoexcited molecule. It is concluded that the principal fragmentation of the photoexcited molecule involves the cleavage of a C—CH_3 bond: $\Phi_{147} \simeq 0.9$ and $\Phi_{163} \simeq 0.8$. Unfortunately, it was not possible to scavenge the corresponding C_3H_3 radicals. From the fast decrease of the transparency of the window it is concluded that an important radical polymerization takes place, even in the presence of oxygen or nitric oxide. Finally, from the pressure effect, it is shown that propyne results from the fragmentation of the vibrationally excited butenyl radical and vinylacetylene arises from the fragmentation of an excited C_4H_5 radical.

Introduction

A la suite de nos études sur le comportement photochimique sur les oléfines (1), nous avons pensé faire des études similaires sur les alcynes. La raison principale de cet intérêt réside dans le fait que la spectroscopie des deux familles de composés est assez différente. Alors que les oléfines (sauf l'éthylène) présentent peu de structure dans le spectre d'absorption et que celui-ci correspond surtout à une absorption de type $N \rightarrow V, (\pi, \pi^*)$, les alcynes ont un spectre d'absorption très structuré qui correspond à une absorption de type Rydberg vers 140–180 nm (2, 3).

Nous avons donc entrepris une étude similaire à celle faite sur les oléfines. Ce rapport présente les résultats obtenus avec le butyne-2. Avec le butène-2, la fragmentation de la molécule photoexcitée a lieu par moitié par scission de la liaison C—C située en α de la double liaison et par moitié par scission de la liaison C—H située en β par rapport à la double liaison (4). Le but premier est ici évidemment de voir si cette caractéristique est maintenue.

Méthode expérimentale

Les lampes de photolyse ont été décrites dans la publication précédente de ce journal, de même que la nature et la qualité de certains produits et les techniques d'analyse (5, 6). Le butyne-2 est un produit API de pureté 99,95 ± 0,04%. L'analyse révèle des quantités mineures de vinylacétylène (1,1 ppm) et de butyne-1 (5,0 ppm). Tous ces produits sont utilisés tel que reçus après avoir été dégasés dans un système à vide en Pyrex équipé de robinets en Téflon et de manomètres à membrane métallique Wallace et Tiernan. Dans la totalité des photolyses, le taux de conversion a été limité à moins de 0,5% (cas des monomères purs) et à moins de 0,1% dans le cas des irradiations en présence d'oxygène ou d'oxyde nitrique.

Le spectre d'absorption du butyne-2 est moins connu que celui du butyne-1. Une étude récente a montré que vers 174 nm, son coefficient d'absorption est supérieur à 1000 atm^{-1} cm^{-1} (3), de même qu'à 163 et à 147 nm (2).

Résultats

Les résultats expérimentaux sont exprimés dans les tableaux et les figures qui accompagnent le texte. Ils sont indiqués sous la forme de rendements quantiques. Ceux-ci ont été obtenus par comparaison avec ceux des produits obtenus dans la photolyse du *cis*-butène-2 (3) ou du propène (7) à la longueur d'onde d'intérêt.

A nouveau il faut mentionner la diminution de la transmission des fenêtres avec le temps d'irradiation du butyne-2 (fig. 1). Voir aussi la publication précédente de ce journal. La précision de la mesure des rendements quantiques qui en résulte a aussi été discutée précédemment.

Discussion

A 147 nm: les réactions radicalaires

Le tableau 1 montre la variété des produits obtenus lors de la photolyse du monomère pur, en présence d'iodure d'hydrogène ou d'oxyde nitrique. Les produits majeurs que sont l'éthane, les *cis*- et *trans*-butène-2 et le pentyne-2 disparaissent en présence d'oxygène ou d'oxyde nitrique. La

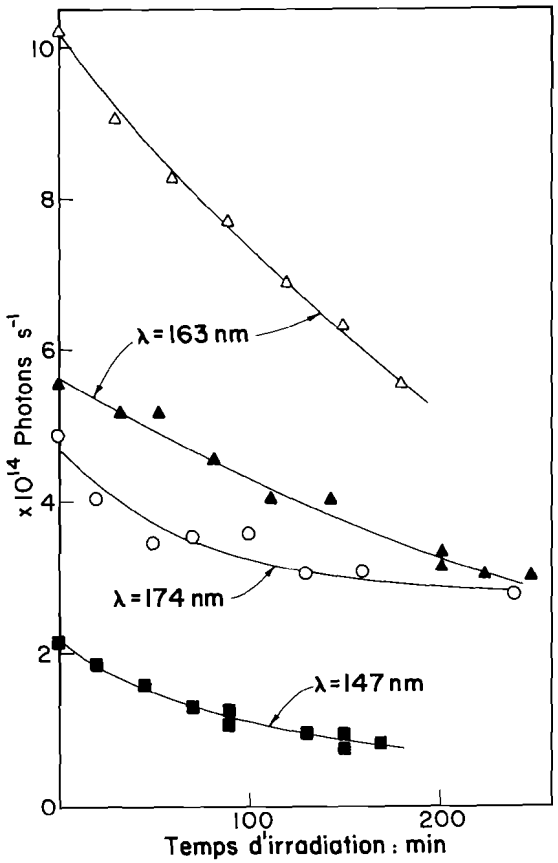

FIG. 1. Effet du temps de photolyse sur la transmission des fenêtres △, ○: mélange butyne-2:O_2 (100:10); ▲, ■: mélange butyne-2:NO (100:5). L'échelle doit être multipliée par 10 à 163 nm (△, ▲).

nature des mécanismes qui président à leur formation est donc très probablement radicalaire. Il en est de même pour certains C_4 et pour les C_5.

L'iodure d'hydrogène accroît fortement le rendement en méthane, et dans une moindre mesure ceux des butène-2 et du propyne. En admettant que l'iodure d'hydrogène intercepte les radicaux libres usuels (8–10):

[1] $R\cdot + HI \rightarrow RH + I$

la croissance du rendement en méthane, par exemple, est alors liée à la présence de radicaux méthyles. En supposant en outre qu'en présence d'oxygène ou d'oxyde nitrique, tous les radicaux libres sont interceptés, la relation suivante peut être utilisée pour la mesure des rendements quantiques des radicaux libres:

[A] $\Phi(R\cdot) = \Phi_{HI}(RH) - \Phi_{NO}(RH)$

Ainsi le produit majeur identifié est le radical méthyle: $\Phi(CH_3\cdot) \simeq 1{,}0$. De ce fait la formation de l'éthane dans le monomère pur est attribuable à la combinaison des radicaux méthyles.

La relation [A] permet aussi d'identifier les radicaux C_4H_7. La voie la plus simple pour la formation de cette espèce est l'addition d'un atome d'hydrogène sur le monomère. Un second intermédiaire est identifié: l'atome d'hydrogène. La mesure du rendement quantique est ici sujette à une sous-estimation. En effet, l'iodure d'hydrogène est en compétition avec le butyne-2 pour l'interception de ces atomes. Bien que le rapport des constantes de vitesse des réactions [2] et [3] ne soit pas disponible, la situation est probablement similaire à celle observée avec les alcènes (9), et la valeur $\Phi(C_4H_7) = \Phi_{HI}$(butène-2) donne probablement une valeur inférieure à la valeur réelle de $\Phi(H\cdot)$.

[2] $H + HI \rightarrow H_2 + I$

[3] $H + CH_3C{\equiv}CCH_3 \rightarrow CH_3CH{=}\dot{C}CH_3^*$

$\Delta H \simeq -175\ \text{kJ mol}^{-1}$

La combinaison des radicaux méthyles et butènyles explique la formation du méthyl-2-butène-2. Les radicaux butènyles formés dans le processus [3] sont vibrationnellement excités et doivent être auparavant stabilisés par collision.

[4] $CH_3CH{=}\dot{C}CH_3^* + M \xrightarrow{k_s} CH_3CH{=}\dot{C}CH_3$

[5] $CH_3CH{=}\dot{C}CH_3^* \xrightarrow{k_d} CH_3 + CH_3C{\equiv}CH(Py)$

$\Delta H = +138\ \text{kJ mol}^{-1}$

Un traitement cinétique simple conduit à la relation bien connue de Stern–Volmer (11):

[B] $[\Phi(Py)]^{-1} = [\Phi_0(Py)]^{-1} + [\Phi_0(Py)]^{-1}(k_s/k_d)[M]$

où l'indice zéro indique la mesure du rendement quantique obtenue par extrapolation à pression nulle; k_s et k_d sont les constantes d'ordre 2 et d'ordre 1 des réactions [4] et [5] respectivement; [M] est la pression dans le réacteur (fig. 2). Dans un article récent nous avons également proposé que le radical butènyle-2 excité peut aussi s'isomériser vers la forme allylique (7). La formation de butadiène-1,3, qui est formé par décomposition du radical α-méthallyle excité, peut donc aussi s'expliquer à partir du radical butènyle: $\Phi_{NO}(C_4H_6) \simeq 0{,}03$ à 147 nm (tableau 1).

Un autre radical mis en évidence par l'usage de l'iodure d'hydrogène est le radical C_3H_3. L'addition de cet additif fait croître à la fois le rendement en allène et en propyne (réaction [1]). La structure du monomère suggère le radical propynyle suivant: $CH_3C{\equiv}C^{\cdot}$. Par contre l'allène ne peut être formé

TABLEAU 1. Photolyse du butyne-2 à 147 nm

Butyne-2	1,0[a]	5,0	10,0	1,0	5,0	10,0	1,0	5,0	10,0

[d] n.m.: non mesuré.

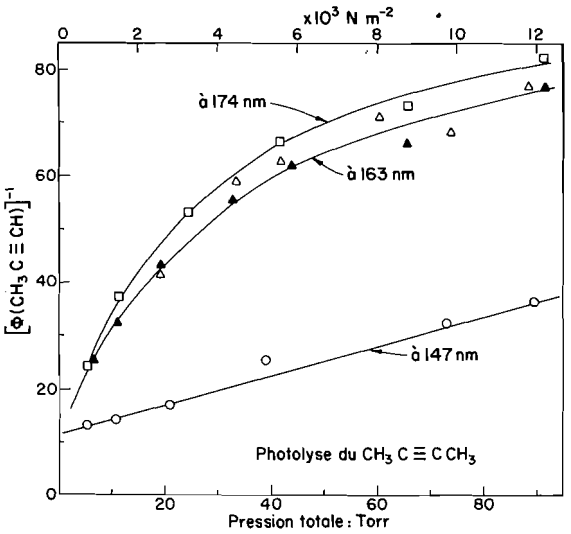

FIG. 2. Variation de l'inverse du rendement quantique du propyne en fonction de la pression à diverses longueurs d'onde. Mélange butyne-2:oxygène (100:10): □, △, ○; et butyne-2: oxyde nitrique (100:10): ▲.

qu'à partir du radical allènyle $CH_2{=}C{=}\dot{C}H$. Il y a donc lieu d'admettre un processus d'isomérisation soit de la molécule photoexcitée avant fragmentation, soit d'un fragment. Le radical allènyle est en résonance électronique avec le radical propargyle $^{\cdot}CH_2C{\equiv}CH$. Des études théoriques (12) tout autant qu'expérimentales (13) ont montré que l'équilibre favorise la structure propargyle dans un rapport de 3 à 1. On devrait donc trouver 3 fois plus de propyne que d'allène par interception des radicaux allènyles et propargyles par DI. Compte tenu de la formation de propyne par le processus [5], le rapport de 3 à 1 est à peu près conservé (tableau 1). De la même façon dans le produit pur on devrait retrouver trois fois plus de butyne-1 que de butadiène-1,2, produits issus de la réaction de combinaison des radicaux méthyles et allènyles et propargyles (13). On trouve en fait au moins autant de butadiène-1,2 que de butyne-1 dans le produit pur. Il doit donc y avoir une autre source radicalaire de butadiène-1,2. Cette interprétation suppose donc que tous les radicaux C_3H_3 n'ont pas la structure $CH_3C{\equiv}C^{\cdot}$ telle que suggérée par la structure du monomère.

Un autre radical est révélé par la présence de pentyne-2 et de méthyl-3-butadiène-1,2:

[6] $CH_3C{\equiv}C\dot{C}H_2 + \dot{C}H_3 \rightarrow CH_3C{\equiv}CCH_2CH_3$

[7] $CH_3C{\equiv}C\dot{C}H_2 \rightleftarrows CH_3\dot{C}{=}C{=}CH_2$

[8] $CH_3\dot{C}{=}C{=}CH_2 + \dot{C}H_3 \rightarrow (CH_3)_2C{=}C{=}CH_2$

En accord avec la prépondérance de la stabilité du radical propargylique sur celle du radical allènylique (13) le rendement en pentyne-2 est environ 5 fois supérieur à celui du méthyl-3-butadiène-1,2: $\Phi(C_5H_8) \simeq 0,18$ dans le produit pur.

Finalement il faut mentionner la légère augmentation du rendement en éthylène ($\simeq$0,07) et en acétylène ($\simeq$0,03) en présence d'iodure d'hydrogène ce qui, interprété sur la base de la réaction [1], est l'indice de formation des radicaux $C_2H_3\cdot$ et $C_2H\cdot$ et la relation [A] permet d'estimer les rendements $\Phi(C_2H_3\cdot) \simeq 0,05 \pm 0,02$ et $\Phi(C_2H\cdot) \simeq 0,01 \pm 0,01$. La structure du monomère oblige à admettre une isomérisation non négligeable soit de la molécule photoexcitée, soit de certains intermédiaires.

Il est dès lors tentant d'établir les bilans complets des rendements radicalaires via l'usage de l'iodure d'hydrogène. Il faut cependant faire les commentaires qui suivent. On a déjà mentionné l'interférence causée par l'addition de HI sur l'addition de l'atome d'hydrogène sur la triple liaison. Il faut aussi ajouter qu'on ne connaît finalement que peu de chose de la réactivité des radicaux sur les alcynes: la chimie des radicaux insaturés est d'autant plus méconnue que l'insaturation croît. Par exemple, le radical $C_2H\cdot$ s'il est présent, voir plus haut, à une chimie assez inhabituelle et ne semble pas intercepté par l'oxyde nitrique (14). Même en présence de quantités notables de NO, C_2H réagit avec le butène-2 et produit de l'acétylène et des pentadiènes (15). Que dire des radicaux C_3H_3 avec les alcynes?

La présence des radicaux C_4H_5, réactions [6]–[8], résulte soit de la rupture de la liaison C—H dans la molécule photoexcitée soit du transfert d'un atome d'hydrogène du monomère vers un radical

[9] $R + CH_3C{\equiv}CCH_3 \rightarrow RH + CH_3C{\equiv}C\dot{C}H_2$

Il est donc possible qu'une part de l'acétylène formé en présence d'oxygène résulte d'une telle réaction (voir plus loin).

A 147 nm: la fragmentation de la molécule photoexcitée

Le produit majeur identifié plus haut est le radical méthyle, et seulement un processus secondaire qui le produit semble bien identifié: réaction [5]. En soustrayant du rendement en méthane obtenu en présence d'iodure d'hydrogène celui du propyne obtenu en présence d'oxyde nitrique, on obtient un résidu en radicaux méthyles de l'ordre de 0,9 ± 0,05. Etant donné que d'autres processus secondaires non identifiés peuvent participer à ce rendement, cela donne une valeur maximum au processus primaire suivant: $\phi([11]) \leq 0{,}9 \pm 0{,}06$

[10] $CH_3C{\equiv}CCH_3 + h\nu \rightarrow CH_3C{\equiv}CCH_3{}^{**}$

[11] $CH_3C{\equiv}CCH_3{}^{**} \rightarrow CH_3 + CH_3C{\equiv}\dot{C}^{*}$

$\Delta H = +384\ \text{kJ mol}^{-1}$

Le rendement en radicaux C_3H_3 mesuré à travers l'effet de DI est beaucoup plus faible. D'après la discussion précédente

[C] $\Phi(C_3H_3) = \Phi_{HI}(\text{allène}) + \Phi_{HI}(\text{propyne}) - \Phi_{NO}(\text{propyne})$

Cette dernière relation donne un rendement $\Phi(C_3H_3)$ voisin de 0,20 ± 0,04. L'usage de DI n'est pas sans défaut. En particulier, son efficacité déficiente dans l'interception des radicaux C_3H_3 a déjà été mentionnée (10) et la chimie des radicaux C_3H_3 est vraiment mal connue. La valeur trouvée donne cependant une valeur minimum pour le processus [11] (voir plus bas).

L'autre radical qui a un rendement important est l'atome d'hydrogène. Le seul processus primaire évident est la rupture d'un lien C—H:

[12] $CH_3C{\equiv}CCH_3{}^{**} \rightarrow H + CH_3C{\equiv}C\dot{C}H_2{}^{*}$

$\Delta H = 374\ \text{kJ mol}^{-1}$

[13] $CH_3C{\equiv}C\dot{C}H_2{}^{*} \rightleftarrows CH_3\dot{C}{=}C{=}CH_2{}^{*}$

[14] $CH_3C{\equiv}\dot{C}CH_2{}^{*} \rightarrow CH_2{=}\dot{C}CH{=}CH_2{}^{*}$

[15] $CH_2{=}\dot{C}CH{=}CH_2{}^{*} \rightarrow H + CH{\equiv}CCH{=}CH_2$

Même en présence d'iodure d'hydrogène, il n'y a pas formation de butadiène-1,2. Par contre on observe une faible formation d'un mélange de butyne-1 et de butadiène-1,3. La formation de butadiène-1,3 est aussi possible à partir du radical butènyle (voir ci-haut). Le seul produit relié à la formation d'atome d'hydrogène est le vinylacétylène. Pour chaque molécule de ce produit, il y a libération d'un atome dans le processus primaire [12] et dans le processus secondaire [15]. Une autre possibilité serait évidemment l'élimination directe (en une étape) d'une molécule d'hydrogène:

[16] $CH_3C{\equiv}CCH_3{}^{**} \rightarrow (C_4H_6)^{**} \rightarrow H_2 + CH{\equiv}CCH{=}CH_2$

$\Delta H = 170\ \text{kJ mol}^{-1}$

L'effet de pression, sans être important, est notable (fig. 3). Un intermédiaire a donc un temps de vie suffisamment long pour être intercepté et stabilisé par collision. Cet intermédiaire peut être la molécule photoexcitée elle-même, une molécule très excitée, isomère du monomère, ou l'un des radicaux $C_4H_5{}^{*}$ (réactions [14] et [15]). Les

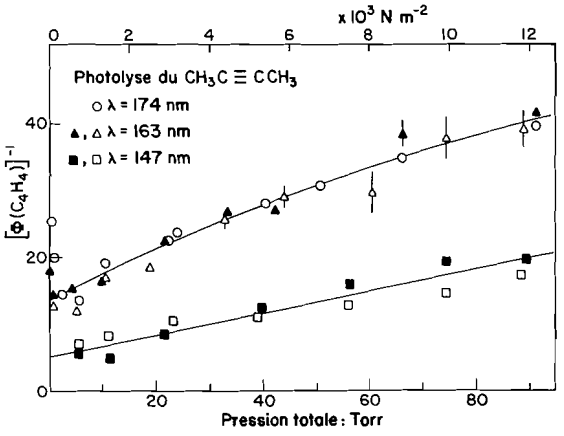

FIG. 3. Courbes de type Stern–Volmer. Variation de l'inverse du rendement quantique du vinylacétylène en fonction de la pression. Mélange butyne-2:oxygène (100:10): ○, △, □ et butyne-2:oxyde nitrique (100:10): ▲, ■.

courbes de type Stern–Volmer sont en accord avec une telle proposition.

Par contre, il est de coutume dans ce genre de travail d'admettre que les processus primaires, ceux qui impliquent la décomposition de la molécule photoexcitée, se font avec une fréquence beaucoup plus grande que la fréquence de collision. Ils ne sont donc pas sensibles à la pression. La seule exception notable est l'acétylène. Il faut se rappeler que l'absorption dans cette région met en jeu des états Rydberg, et le comportement de la molécule photoexcitée peut être particulier. Le haut rendement en hydrogène atomique favorise cependant les réactions [14] et [15]. En admettant que le mélange C_4H_6 obtenu en présence d'hydrogène consiste uniquement en butadiène-1,3, alors

$$[D] \quad \phi([12]) \geq \Phi_{NO}(C_4H_4) + \Phi_{HI}(C_4H_6) - \Phi_{NO}(C_4H_6)$$

Cette relation conduit à une valeur $\phi([12])$ de l'ordre $0{,}18 \pm 0{,}03$. Il y correspond un rendement en atome d'hydrogène de l'ordre égal à $\Phi(H) = \phi([12]) + \Phi(C_4H_4)$, soit $\Phi(H) \simeq 0{,}35$ et 0,30, à 1 et 10 Torr, respectivement. Ces valeurs sont minimum, car on ne sait rien de l'efficacité de l'interception des radicaux C_4H_5 par le HI.

Quant à la formation d'acétylène et d'éthylène (figs 4 et 5), on a déjà mentionné la réaction d'abstraction d'un atome d'hydrogène par le radical correspondant: processus [9]. On peut aussi proposer l'élimination d'une molécule d'acétylène

$$[17] \quad CH_3C{\equiv}CCH_3^{**} \rightarrow (C_4H_6^{**}) \rightarrow C_2H_2^* + C_2H_4^* \qquad \Delta H = +114 \text{ kJ mol}^{-1}$$

ou encore tout autre chemin mettant en cause les radicaux C_2H et C_2H_3. Il faudrait dans ces cas admettre une isomérisation importante de la molécule photoexcitée.

Cette proposition va à l'encontre des processus proposés dans le cas de la photolyse des oléfines. La présence d'états Rydberg dans cette région du spectre peut jouer un rôle particulier. La réaction [17] a contre elle le fait qu'il reste un excédent d'énergie de quelque 690 kJ mol^{-1} qu'il faut distribuer entre les fragments. L'éthylène aurait ainsi très probablement suffisamment d'énergie interne pour se fragmenter davantage.

A 163 nm

Les résultats sont similaires à ceux mesurés à 147 nm (tableau 2). La photolyse du monomère pur ou en présence d'oxyde nitrique conduit à des rendements qui sont en général 50% plus faibles ici comparativement à ceux discutés plus haut. Par

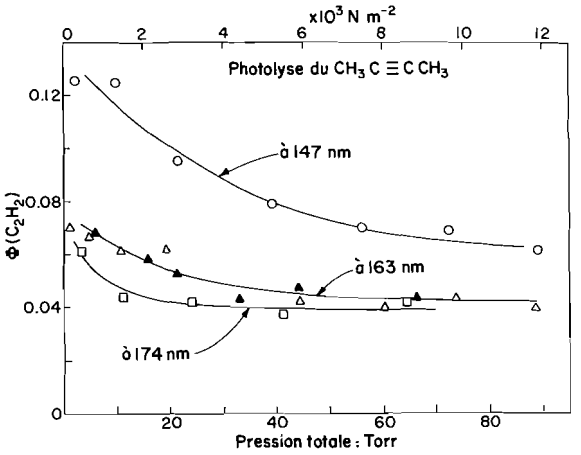

FIG. 4. Variation du rendement quantique de l'acétylène avec la pression à différentes longueurs d'onde. Mélange butyne-2:oxygène (100:10): ○, △, □ et butyne-2:oxyde nitrique (100:10): ▲.

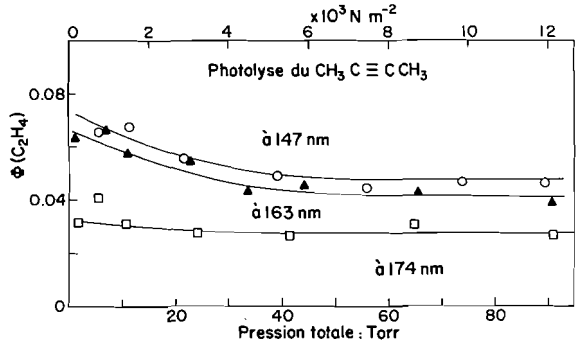

FIG. 5. Variation du rendement quantique de l'éthylène avec la pression à différentes longueurs d'onde. Mélange butyne-2:oxygène (100:10): ○, □; butyne-2:oxyde nitrique (100:10): ▲.

contre, les rendements en radicaux mesurés à travers l'effet de l'iodure d'hydrogène sont comparables. Sur la base de la relation [A], on obtient les valeurs suivantes: $\Phi(CH_3) = 0{,}87 \pm 0{,}03$; $\Phi(C_2H) \simeq 0{,}03$; $\Phi(C_2H_3) = 0{,}07$; $\Phi(C_3H_3) = 0{,}19$ (relation [C]). En outre, à 10 Torr, $\Phi(C_4H_7) = 0{,}53$. Par conséquent les rendements radicalaires ne sont pas ou peu affectés par la diminution de l'énergie photonique. Cette remarque est évidemment en faveur de la formation des radicaux par processus primaires, alors que les produits moléculaires le sont surtout par des processus secondaires. Les effets de pression (figs 2 à 5) sont aussi en accord avec une telle proposition. Sans reprendre au complet la discussion faite précédemment à 147 nm, la réaction [11] demeure la principale source de radicaux méthyles et du même coup c'est encore la

principale voie de fragmentation de la molécule photoexcitée: $\phi_{163}([11]) \leq 0,82 \pm 0,03$. Le rendement en vinylacétylène à pression nulle est voisin de 0,08: $\phi([15]) \simeq 0,08$ et $\phi([12]) \geq 0,08$. Une part des radicaux C_4H_5* formés par le processus [12] sont sans doute stabilisés par collision et il est difficile d'en évaluer la quantité. L'importance du rendement en pentyne-2 dans le système pur comparativement à ce qui est observé à pression nulle tend à montrer que le processus [12] est ici moins important qu'à 147 nm. On retrouve à nouveau une formation limitée d'éthylène et d'acétylène (figs 4 et 5) et de butadiène-1,3 + butyne-1.

L'effet de l'addition de l'hydrogène sulfuré est déroutant. Dans la photolyse du butyne-1, Doepker a observé que D_2S intercepte certains radicaux allènyles (10). Cette observation est en accord avec le fait que la liaison C—H dans l'allène est plus forte que la liaison HS—H. Une valeur de la liaison C—H dans l'allène a été calculée voisine de 108,1 kcal/mol (16), comparativement à 90,5 ± 1,1 kcal/mol dans le cas de la liaison HS—H (17). L'allène n'est pas un produit dans le présent mélange butyne-2:D_2S. Il n'y aurait donc pas ou peu de radicaux allènyles. L'isomérisation envisagée à 147 nm est donc de peu d'importance. Inversement, toujours dans le même travail, Doepker ne rapporte pas de formation de propyne dans le mélange $CH_3CH_2C{\equiv}CH$:D_2S. Le radical $^{\cdot}CH_2C{\equiv}CH$ ne serait pas intercepté par l'hydrogène sulfuré. Cette observation est en accord avec le fait que la liaison $CH{\equiv}CCH_2$—H est plus faible que la liaison HS—H: $D(CH{\equiv}CCH_2$—H) = 89,3 kcal/mol (18). Le propyne est aussi un produit de la photolyse du mélange butyne-2:D_2S. Par conséquent le radical intercepté par D_2S ne pourrait être que le radical $CH_3C{\equiv}C^{\cdot}$ en accord avec la structure du monomère d'une part, et en accord avec le fait que la chaleur de la liaison $CH_3C{\equiv}C$—H a été calculée voisine de 128 kcal/mol (16). Le rendement en radicaux propynyles est de l'ordre de 0,2, c'est-à-dire beaucoup moins que celui calculé à partir de la réaction [12]. Par conséquent les radicaux C_3H_3 disparaissent du milieu réactionnel, et HI est incapable de les titrer convenablement tout au moins sous la forme du produit propyne.

Remerciements

Nous tenons à exprimer notre gratitude au ministère de l'Education du Québec (programme FCAC) qui nous a soutenu monétairement pendant cette étude, de même que l'Université du Québec à Chicoutimi (FIR).

On the evaluation of the nuclear electric quadrupole moment of vanadium-50

MAHMOUD ADAM HABAYEB AND O. E. HILEMAN, JR.

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 3, 1980

MAHMOUD ADAM HABAYEB and O. E. HILEMAN, JR. Can. J. Chem. **58**, 2115 (1980).

^{50}V- and ^{51}V-nmr relaxation spectra were recorded for neat $VOCl_3$ at 298 K. In addition, the line width at half-height ($W_{1/2}$) of each resonance was measured. The average $Q(^{50}V)/Q(^{51}V)$ ratio was calculated to be |3.55|. A quadrupole moment, $|Q|$, of ^{50}V was estimated using these data along with the reported Q values of ^{51}V. The magnetic moments, μ, of both isotopes were also evaluated from the ratio of their Larmor frequencies.

MAHMOUD ADAM HABAYEB et O. E. HILEMAN, JR. Can. J. Chem. **58**, 2115 (1980).

Opérant à 298 K, on a enregistré les spectres des relaxation en rmn du ^{50}V et du ^{51}V du $VOCl_3$ homogène. De plus, on a mesuré la largeur des raies à mi-hauteur ($W_{1/2}$) de chaque résonance. On a calculé un rapport moyen $Q(^{50}V/^{51}V)$ de |3,55|. On a évalué le moment quadrupolaire $|Q|$ du ^{50}V en utilisant ces données de concert avec des valeurs connues de Q du ^{51}V. On a également évalué les moments magnétiques, μ, des deux isotopes à partir du rapport de leur fréquences de Larmor.

[Traduit par le journal]

Introduction

Data from ^{50}V-nmr investigations of various vanadium (V) species present in neat liquids or solutions have not appeared frequently in the literature. Howarth and Richards (1) reported the line widths of the ^{50}V and ^{51}V resonances observed in $VOCl_3$ (neat). From these data and an estimated value of the nuclear electric quadrupole moment, Q, of ^{51}V they calculated a value of Q for ^{50}V. No authors — to the best of our knowledge — have reported the results of either T_1 or T_2 measurements on this nucleus.

The purpose of this communication is to report the results of an investigation of the nmr parameters of the ^{50}V nucleus in $VOCl_3$ (neat) using FT-nmr techniques. From these data and from ^{51}V-nmr parameters we estimated a new value of $|Q|$ for ^{50}V and confirmed the reported values of the magnetic moments, μ, for ^{50}V and ^{51}V (2).

Experimental Details

Preparation of Samples

Two samples of neat $VOCl_3$ were used in this work. The first was prepared in house as reported in the literature (3). The product was thrice distilled under N_2 at 10^{-3} Torr. The purified product was transferred to an 8 mm od nmr tube connected to the vacuum line. The tube was sealed off after collection of 4 mL of sample. The second sample was prepared by transferring, within a dry-box (N_2), stock material (Canadian Scientific Co.) to an 8 mm od nmr tube fitted with a Teflon connector/stopcock. The tube was connected to a vacuum line and the sample was degassed by the freeze/thaw method at 10^{-3} Torr (N_2). The tube was sealed off below the connector/stopcock while still connected to the line. Both samples were stored in the dark and at 0°C between nmr measurements. No differences in nmr observables were detected between the two samples.

^{50}V and ^{51}V NMR Measurements

^{50}V- and ^{51}V-nmr relaxation spectra were recorded at 8.97 and 23.66 MHz respectively in a magnetic field of 2.114 T using a pulse FT-nmr technique on a Bruker WH-90 nmr spectrometer interfaced with a Bruker BNC-12 data system. To obtain nmr spectra, the 8 mm sample tube was placed inside a 10 mm nmr tube. Field/frequency stabilization was achieved by locking on the ^{2}H resonance of C_6D_6 containing in the 10 mm tube. Also, the line widths at half-height ($W_{1/2}$) of the ^{50}V and ^{51}V resonances were measured at 24.94 and 65.79 MHz, respectively, in a magnetic field of 5.9 T using a pulse FT-nmr technique on a Bruker WM-250 nmr spectrometer.

Spin–lattice relaxation times (T_1's) measurements on ^{50}V and ^{51}V were performed in a magnetic field of 2.114 T using the usual 180–τ–90° (inversion recovery method) pulse sequence as described in the literature (4). Spin–spin lattice relaxation times (T_2) were obtained from natural line widths ($W_{1/2}$) given by $W_{1/2}$, Hz $= 1/\pi T_2$, where $W_{1/2}$ is the resonance line width at half-height. For T_1 measurements, typical spectral widths of 5 kHz and 8K of data memory were used. For normal ^{50}V and ^{51}V spectra, spectral widths of 12 kHz in 8K of data memory and 90° pulses (30 μs) were applied. All measurements were performed at 298 ± 1 K. The results are shown in Table 1.

Results and Discussion

For quadrupolar nuclei such as ^{50}V and ^{51}V the line width of each resonance is determined by the nuclear quadrupole moment of each isotope and the molecular correlation time as given in eq. [1] (5):

$$[1]\quad \pi W_{1/2} = \frac{1}{T_1} = \frac{1}{T_2} = \frac{3(2\pi)^2}{40}\,\frac{(2I+3)}{I^2(2I-1)} \times (e^2Qq/h)^2(1+\eta^2/3)\tau_c$$

The various symbols used above have their usual meaning. The individual values of q, η, and τ_c are identical for the isotopic pair. Thus, eq. [1] may be

Collective model	+0.04	0.14	0.14
	−0.12	0.43	0.42

*Values of Q of ^{51}V were reported in ref. 6.
†T_1 and $W_{1/2}$ values are given in Table 1.

used to evaluate $|Q|$ of ^{50}V if Q of ^{51}V is known and $W_{1/2}$ and T_1 values of both ^{50}V and ^{51}V resonances are determined.

One of the main difficulties in calculating $|Q|$ values for ^{50}V by this method is the wide range of ^{51}V Q values reported in the literature (6). Representative values are included in Table 2. Several of these, namely, 0.28, 0.26, −0.12, and 0.007 b, have been called into question and then were ruled out as reasonable values by Saraswati (6). In addition, the short relaxation times obtained in the present work (18 ± 2 ms) along with that reported by Gillen and Noggle (23 ms) (7) for the ^{51}V nucleus in $VOCl_3$ (neat) indicate that the value of Q for ^{51}V must be larger than 0.007 b.

Using T_1 and $W_{1/2}$ values of the isotopic pair in this work, the various ^{51}V Q values reported by Saraswati (6) and eq. [1], the $Q(^{50}V)/Q(^{51}V)$ ratios were calculated to be |3.5| from $W_{1/2}$ data and |3.6| based on T_1 measurements. With these ratios, the various $|Q|$ values of ^{50}V shown in Table 2 were calculated.

Using the known viscosity of neat $VOCl_3$ (η = 0.68 cP at 30°C) (7, 8), an estimate of an average weighted molecular radius, a = 2.80 Å and the Debye equation $\tau_c = 4\pi a^3\eta/KT$ gives $\tau_c = 15 \times 10^{-12}$ s.[1] With this τ_c value, ^{51}V-T_1 value, asymmetry parameter value reported by Allerhand (10), and eq. [1] we calculated e^2Qq/h = 2.98 MHz. This value is significantly less than that reported by Allerhand (10) for solid $VOCl_3$ (5.4 MHz).

Howarth and Richards (1) reported $W_{1/2}$ values of 55 and 90 Hz for the ^{50}V and ^{51}V resonances, respectively.[2] In contrast, our values for the isotopic pair are 69 ± 2 and 20 ± 1 Hz. This discrepancy may be due to sample characteristics. A second suggestion is that the relaxation rates are frequency dependent. Values of $\omega_0\tau_c$ for both isotopes, however, are in the extreme narrowing condition ($\omega_0\tau_c \ll 1$). This proposal was confirmed by the observation that our T_1 and T_2 values for each nucleus of the isotopic pair are equal within experimental error. In addition, the observed line widths were found to be insensitive to changes in the applied magnetic field strength. In contrast, the data of ref. 1 lead to calculated values of T_2 that are not equal to the experimentally determined T_1 values for each nucleus.

Finally, to evaluate the magnetic moments of both isotopes it was necessary to measure the ratios of their Larmor frequencies. These ratios are: $\nu(^{51}V)/\nu(^1H)$ = 0.263022 (10), $\nu(^{50}V)/\nu(^1H)$ = 0.099700 (10), and $\nu(^{51}V)/\nu(^{50}V)$ = 2.638129 (10). Using the magnetic moment of the proton in H_2O (μ_p = 2.7927740 (11)) reported by Cohen and Taylor

[1]The V—O and V—Cl bond distances are 1.56 Å and 2.12 Å, respectively. The oxygen and chlorine ionic radii are 0.66 Å and 0.90 Å, respectively (9). To calculate a, the oxygen and chlorine ionic radii were added to the V—O and V—Cl distances and then the weighted average was estimated.

[2]These line widths were obtained by multiplying the values reported in ref. 1 by $\sqrt{3}$ since these values are absorption derivative line widths and must be corrected for comparison in Table 1.

(11) and a similar procedure to that reported by Kautt *et al.* (12) for the calculation of μ of ^{95}Mo and ^{97}Mo isotopes, one can calculate the μ values of ^{50}V and ^{51}V nuclei. The results are shown in Table 1. These magnetic moment values are in good agreement with those reported in the literature (2). Minor differences may be due to the fact that no diamagnetic corrections were made in the present work.

Under the same experimental conditions 4-methoxytoluene brings about homolytic benzylation of isoquinoline while 3,4-dimethoxytoluene gives a coupling reaction. Proton loss by the radical cation X—$\overset{+\cdot}{\text{Ph}}$—$CH_3$ in the former case and its electrophilic attack to the starting aromatic in the latter account for these experimental findings.

ANGELO CLERICI et OMBRETTA PORTA. Can. J. Chem. **58**, 2117 (1980).

Dans les mêmes conditions expérimentales, le méthoxy-4 toluène amène à une benzylation homolytique de l'isoquinoléine alors que le diméthoxy-3,4 toluène donne lieu à une réaction de couplage. On peut expliquer ces observations par la perte d'un proton du radical cation X—$\overset{+\cdot}{\text{Ph}}$—$CH_3$ dans le premier cas et par l'attaque électophilique du radical cation sur le cycle aromatique de départ dans le deuxième cas.

[Traduit par le journal]

Several reports on oxidation reactions of ring-substituted benzenes by peroxydisulphate are now available in the recent literature (1–7); the one-electron oxidation of the aromatic ring to a radical cation is commonly postulated in reactions involving the radical anion $SO_4^{-\cdot}$. Our previous studies (8) showed this possibility for $SO_4^{-\cdot}$, easily obtainable from thermal decomposition of peroxydisulphate, to transfer an electron from aromatics having a relatively low oxidation potential, such as compound **1** where X = H and Y = CH_2CH_2-COOH. It is also known that the Ag^{2+} species, formed in the Ag^+-catalyzed decomposition of peroxydisulphate, is considered able to oxidize the aromatic ring to the radical cation **2** in the initial step (9, 10) (Scheme 1).

An undoubted case of formation of **2** (X = $CH(CH_3)_2$ and Y = H) is given by *p*-cimene oxidation with Co(III)acetate in which an almost quantitative yield of benzyl radical was described (11).

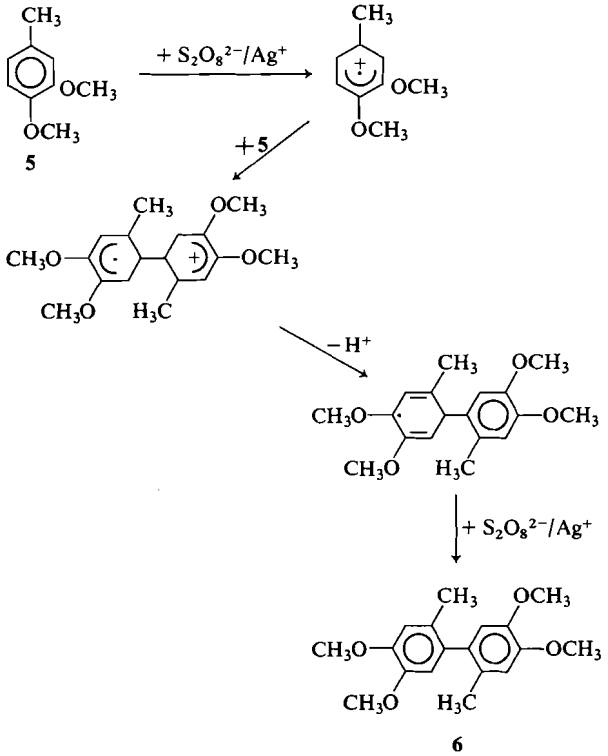
SCHEME 1

In view of this general interest in reactions leading to side-chain functionalization of alkylaromatic compounds, we happened to investigate the oxidation of 4-methoxytoluene (**3**) with the peroxidisulphate–silver(I) salt system in the presence of protonated isoquinoline. Homolytic benzylation (12) occurs at position 1 of the heteroaromatic base and 1-(4-methoxybenzyl)-isoquinoline (**4**) was the only reaction product along with traces of 4-methoxybenzaldehyde (Scheme 2).

SCHEME 2

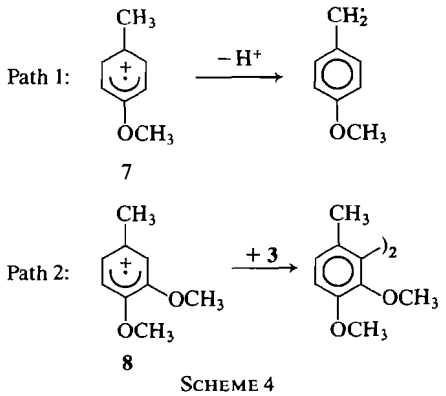
A typical run is as follows: isoquinoline (0.03 mol), concentrated H_2SO_4 (0.015 mol), compound **3** (0.1 mol), $AgNO_3$ (0.006 mol) in 30 mL of CH_3CN/H_2O (1:1) solution, were kept at 50°C for 3 h while slowly adding $(NH_4)_2S_2O_8$ (0.03 mol) in 10 mL of H_2O to the mixture. Product **4** (1.15 g) was obtained as a thick oil after work-up (12). Its purity (≥99%) was checked by glc analysis. Yield based on starting isoquinoline: 15% in moles; ^1H nmr ($CDCl_3$) δ: 3.7 (3H, CH_3O—, s); 4.6 (2H, —CH_2Ph, s); 6.7 ($2H_{ar}$, in α to —CH_2—, d); 7.2 ($2H_{ar}$, in α to —OCH_3, d); 7.4 ($4H_{ar}$, C_6H_4, m); 8.15 ($1H_{ar}$, in β to N, m); 8.5 ($1H_{ar}$, in α to N, d); ms *m/e*: 249 ($M^{+\cdot}$), 234, 217, 128, 121, 91.



On replacing isoquinoline with quinoline, under the same experimental conditions and with the same molar ratio, homolytic benzylation occurs at positions 2 and 4 giving a mixture of isomers in the ratio 1:4, revealed by glc analysis. The isomer mixture (2.40 g) was obtained as an oil after work-up. Yield based on starting quinoline: 33% in moles; ms *m/e*: 249 ($M^{+\cdot}$), 234, 217, 128, 121, 91.

The success of these first results prompted us to extend the oxidation with $S_2O_8^{2-}/Ag^+$ to 3,4-dimethoxytoluene (**5**) with the aim of exploiting the synthetic potentiality of the reaction for a one-step synthesis of a precursor of papaverine, 1-(3,4-dimethoxybenzyl)-isoquinoline.

Surprisingly, we did not obtain any product resulting from the attack of the 3,4-dimethoxybenzyl radical to the protonated isoquinoline. The only reaction product was 2,2′-dimethyl-4,5,4′,5′-tetramethoxybiphenyl (**6**) along with traces of 3,4-dimethoxybenzaldehyde. The mechanism of this coupling reaction seems, in our viewpoint, compatible with the sequence in Scheme 3, reaction of $S_2O_8^{2-}/Ag^+$ with the aromatic substrate with generation of the radical cation, followed by reaction of this electrophile with the activated starting aromatic followed by oxidative rearomatization.



A similar result is given in the oxidation of 4-bromoveratrole with thallium(III)trifluoroacetate for which an analogous mechanism was considered (13).

A typical run (in the absence of the protonated aromatic base) is as follows: **5** (0.026 mol), $AgNO_3$ (0.0065 mol) in 20 mL of CH_3CN/H_2O (1:1) solution were kept for 4 h at 50°C while slowly adding $(NH_4)_2S_2O_8$ (0.013 mol) in 10 mL of H_2O to the initial mixture. Product **6** (1.80 g) was obtained as

pale yellow needles after work-up and hexane–ether recrystallization (mp 121–122°C). Its purity (≥99%), isomer free, was checked by glc analysis. Conversion: 70%. Yield based on converted aromatic: 65%; yield based on the dipersulphate: 92%; ^1H nmr ($CDCl_3$) δ: 2.0 (6H, $2CH_3$—, s); 3.8 (6H, $2CH_3O$—, s); 3.9 (6H, $2CH_3O$—, s); 6.65 ($2H_{ar}$, s); 6.8 ($2H_{ar}$, s); ms *m/e*: 302 ($M^{+\cdot}$), 287, 259, 244, 152, 151. *Anal.* calcd. for $C_{18}H_{22}O_4$: C 71.40, H 7.40, O 21.20; found: C 71.48, H 7.35, O 21.17.

Concluding, these findings indicate that when only one electron-donating group, such as —OCH_3, is present in the aromatic ring the proton loss by the radical cation **7** to give the benzyl radical is the favoured process (path 1), while the introduction of a second —OCH_3 group, increasing the stabilization of the radical cation **8**, makes the proton loss slower than the electrophilic attack to the starting aromatic (path 2) (Scheme 4).

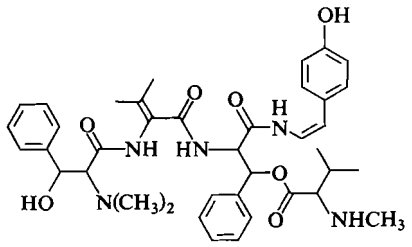
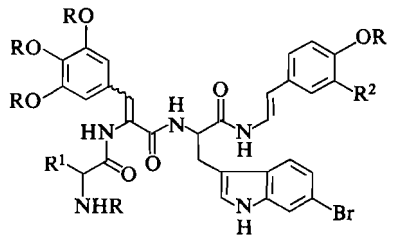
Received May 8, 1980

RICHARD J. STONARD and RAYMOND J. ANDERSEN. Can. J. Chem. **58**, 2121 (1980).



Celenamides C (**7**) and D (**8**), two novel alkaloids closely related to peptide alkaloids found in higher plants, have been isolated as their penta (**12**) and nonacetyl (**13**) derivatives, respectively, from acetylated extracts of the sponge *Cliona celata* (Grant). The structure elucidation of **7** and **8** is described.

RICHARD J. STONARD et RAYMOND J. ANDERSEN. Can. J. Chem. **58**, 2121 (1980).

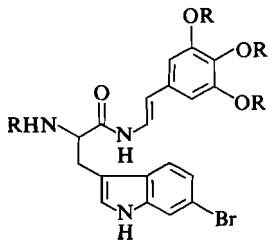


On a isolé deux nouveaux alcaloïdes les célénamides C (**7**) et D (**8**) qui s'apparentent beaucoup aux alcaloïdes peptidiques que l'on trouve dans les plantes supérieures. On les obtient sous forme de dérivés penta (**12**) et non acétylés (**13**) à partir des extraits acétylés de l'éponge *Cliona celata* (Grant). On décrit la détermination de la structure des composés **7** et **8**.

[Traduit par le journal]

We have recently reported the structural elucidation of two novel linear peptide alkaloids (**1**) which bear close resemblance to cyclopeptide alkaloids isolated from several terrestrial plant families (2) and to the linear peptide alkaloid lasoidine A (**1**) obtained from an African Rhamnaceae (3). Celenamides A (**2**) and B (**3**) were isolated as their hexacetyl derivatives **4** and **5**, respectively, from British Columbia and Californian samples of the ubiquitous burrowing sponge *Cliona celata* (Grant). Clionamide (**6**) (4) was the major metabolite present in both collections. In this paper we wish to describe the structure determination of celenamides C (**7**) and D (**8**), two minor metabolites of *C. celata* collected from Howe Sound, British Columbia (−20 m). Celenamide D (**8**) represents the first nonindolic linear peptide alkaloid isolated from *Cliona* and it is a rare example of a dehydropeptide possessing multiple aromatic dehydroamino acid residues.[1]

1



2	R = H	R^1 =	R^2 = OH
3	R = H	R^1 =	R^2 = OH
4	R = Ac	R^1 =	R^2 = OAc
5	R = Ac	R^1 =	R^2 = OAc
7	R = H	R^1 =	R^2 = H
12	R = Ac	R^1 =	R^2 = H

Acetylated celenamides were obtained from crude acetylated methanol extracts of *C. celata* by silica column chromatography employing a stepwise methylene chloride – ethyl acetate gradient. Analysis of the column eluate by high pressure liquid chromatography (hplc) and ^{1}H nmr indicated that the fraction eluting with 25% EtOAc in CH_2Cl_2 was composed of a mixture of several acetyl-

[1]For examples of aromatic dehydroamino acid containing peptides, see ref. 5.

6 R = H
9 R = Ac

celenamides (Fig. 1a). Subsequent fractions were comprised of mixtures of hexacetylcelenamide A (**4**), B (**5**), and tetracetylclionamide (**9**) (6) (e.g. Fig. 1b). Repetitive silica preparative thin layer chromatography (ptlc) of the acetylcelenamide containing fractions afforded **4** (0.03% wet weight), **5** (0.02%), and the more minor components, pentacetylcelenamide C (**12**, ~0.003%), and nonacetylcelenamide D (**13**, ~0.002%) as noncrystalline solids. The homogeneity of compounds **4**, **5**, **12**, and **13** was established by hplc, ^{1}H nmr, and electron-impact mass spectroscopy (eims).

8 R = H
13 R = Ac

^{1}H nmr analysis demonstrated that the ptlc bands corresponding to the hplc peaks observed at $R_T \sim 6$–8 min as shown in Fig. 1a were composed of a complex mixture of acetylcelenamide related compounds.

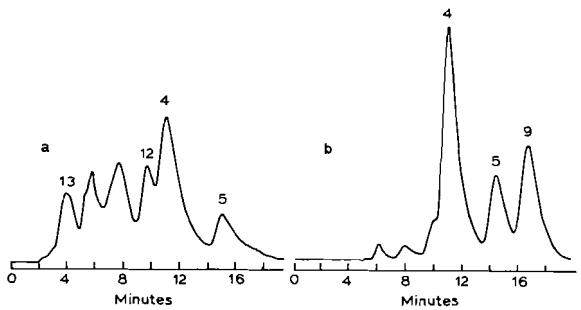

FIG. 1. High pressure liquid chromatography of acetylcelenamides eluted from silica gel G with (a) CH_2Cl_2–EtOAc (4:1); (b) CH_2Cl_2–EtOAc (2:1). Analysis conditions: LiChrosorb Si60 (10μ, 4 × 250 mm); solvent, CH_2Cl_2—CH_3CN (4:1); flow rate, 1.2 mL/min; room temperature; A 290 nm.

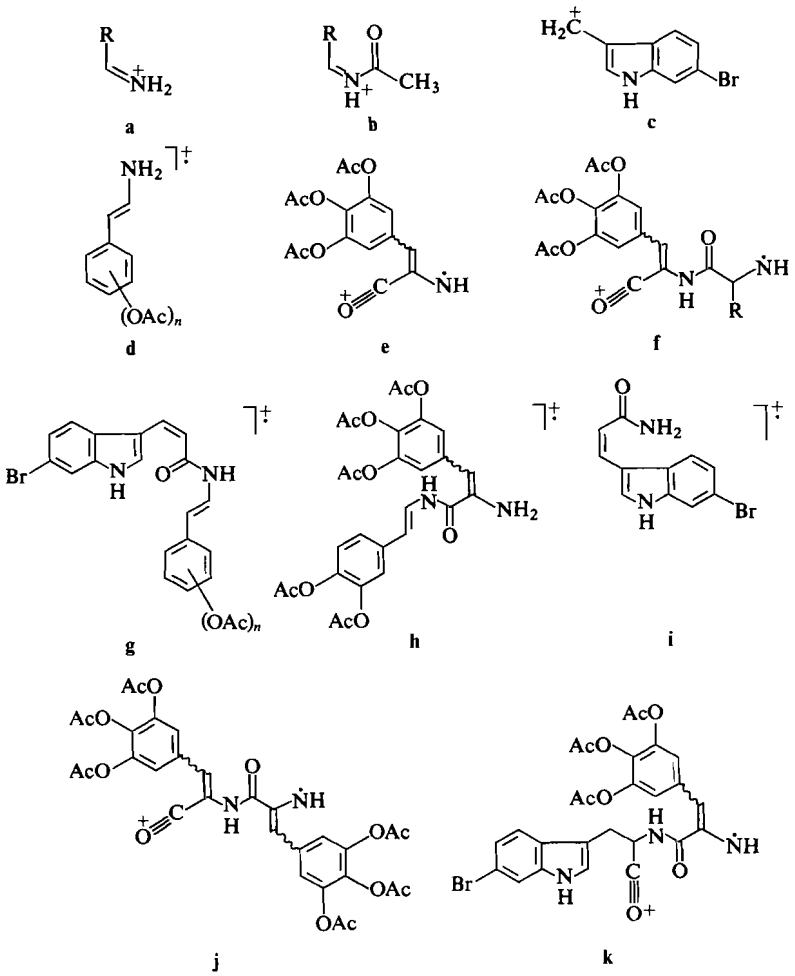
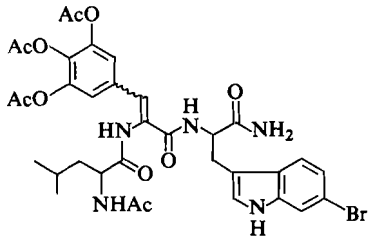
The 270 MHz ^{1}H nmr spectrum of pentacetylcelenamide C (**12**) showed remarkable similarity to the spectrum displayed by hexacetylcelenamide A (**4**, Table 1). Comparison of the two spectra indicated the presence of resonances corresponding to a 1,4-disubstituted phenyl ring in the spectrum of **12**, in contrast to the presence of signals resulting from a 1,3,4-trisubstituted phenyl ring in the spectrum of **4**.[2] The eims of **12** (Table 2) contained major fragment ions corresponding to 4-acetoxystyrylamine (ion **d**, n = 1) and 4-hydroxystyrylamine. Hence, **12** must encompass the gross structure of **4** but with a C-terminal (*E*)-4-acetoxystyrylamino residue instead of the (*E*)-3,4-diacetoxystyrylamino grouping present in **4**. It was also evident from eims that the amino acid sequence of **12** corresponded to that of **4** (Table 2).



Confirmation of the proposed structure for **12** was provided by chemical degradation. Hydrolysis with hydrochloric acid in acetonitrile at room temperature afforded a primary amide (**14**) which was identical (see Tables 1 and 2) to the primary amide obtained when **4** was treated in a similar fashion.

It was immediately apparent from ^{1}H nmr studies (Table 1) that, unlike hexacetylcelenamide A (**4**), B (**5**), and pentacetylcelenamide C (**12**), nonacetylcelenamide D (**13**) did not possess a 6-bromotryptophan residue and that leucine (αCH δ 4.48 m, NH 7.91 d, J = 5 Hz) represented the sole α-amino acid in the molecule. Ions **a** (*m/e* 86) and **b** (*m/e* 128) observed in the eims (Table 2) defined acetylleucine as the N-terminal residue. Characteristic resonances at δ 6.60 (d, J = 15 Hz), 7.59 (dd, J = 10, 15 Hz), and 9.65 (d, J = 10 Hz) in the ^{1}H nmr spectrum of **13** suggested the presence of a C-terminal styrylamine residue. Intense fragment ions at *m/e* 235 (ion **d**), 193, and 151 in the eims (Table 2) further suggested that the C-terminus was an (*E*)-3,4-diacetoxystyrylamine[2] group as in **4** and **5**. This was confirmed by hydrolysis with hydrochloric acid in acetonitrile at room temperature to give the primary amide **15**. The ^{1}H nmr (δ 6.53 and 7.30 (each 1H, s); Table 1), ir (3640, 3540 cm^{-1}), and mass spectra (Table 2) of **15** indicated that the C-terminal styrylamine present in **13** was absent in **15** and that the C-terminal residue of **15** was protected as a primary amide as a result of the *trans*-substituted enamide hydrolysis.



The remaining structural features of nonacetyl-

[2]Ozonolysis (*1*. O_3, −78°C, CH_3OH *2*. $(CH_3)_2S$) of a mixture of acetylcelenamides similar in composition to that shown in Fig. 1a afforded 3,4,5-triacetoxy-, 3,4-diacetoxy-, and 4-acetoxybenzaldehyde as the only isolable products. The substitution pattern of each of the benzaldehydic products was determined by comparison with synthetic samples.

celenamide D (**13**) were elucidated by ^{1}H nmr (Table 1). Two uncoupled olefinic signals at δ 7.06 and δ 7.59, two highly deshielded NH singlets at δ 9.18 and δ 9.89, and two 2H aromatic singlets at δ 7.43 and 7.47 clearly indicated the presence of two 3,4,5-triacetoxy-α,β-didehydrophenylalanine[2] residues. The observation of fragment ions **j** (*m/e* 638), **h** (*m/e* 554), **f** (*m/e* 432), and **e** (*m/e* 319) in the eims of **13** (Table 2) furnished conclusive evidence for this proposal. Hence, the structure of nonacetylcelenamide D (**13**) must be as shown.

14

The nature of the naturally occurring sponge metabolites was demonstrated by a small scale isolation procedure employing acetic anhydride-d_6 as acetylating agent. The ^{1}H nmr of the ptlc purified

15

deuteroacetylcelenamide mixture did not display any resonances corresponding to phenolacetate or acetamide. Hence, **12** and **13** must exist in the sponge as their nonacetylated precursors celenamide C (**7**) and celenamide D (**8**).

[g]Exact mass measurement obtained.
[h]Distinguished from ion **j** fragmentation by high-resolution ms of daughter ions.

Experimental

Low-resolution and high-resolution mass spectra were recorded on A.E.I. MS-902 and MS-50 spectrometers, respectively. Infrared spectra were recorded on a Perkin-Elmer Model 710B spectrometer. Optical rotations were measured on a Perkin-Elmer Model 241C polarimeter using a 10 cm microcell. The ^{1}H nmr spectra were recorded on a Nicolet-Oxford-270 spectrometer with tetramethylsilane ($\delta = 0$) as an internal reference. High pressure liquid chromatography (hplc) was performed on a Perkin-Elmer Series 2 instrument equipped with a Perkin-Elmer LC55 uv detector system and a Hewlett-Packard 18850A microprocessor.

Isolation of Pentacetylcelenamide C (12) and Nonacetylcelenamide D (13)

The sponge *Cliona celata* (450 g wet weight) was collected by hand using SCUBA in Howe Sound, British Columbia (−20 m). The crude sponge metabolites were extracted, acetylated, and the acetylated residue fractionated on a column of silica gel G as previously described (1). Pure pentacetylcelenamide C (**12**; 12 mg, ~0.003% wet weight) and nonacetylcelenamide D (**13**; 10 mg, ~0.002% wet weight) were obtained as noncrystalline solids following repeated silica ptlc (20 × 20 cm, 1.0 mm) using chloroform–methanol (14:1) as the developing solvent. High pressure liquid chromatographic analysis of column and ptlc purified components was performed as described in Fig. 1.

Pentacetylcelenamide C (**12**): $[\alpha]_D^{25}$ +14°(*c* 0.30, acetone); ir ($CHCl_3$): 3300 (broad), 1780, 1660 (broad); ^{1}H nmr (see Table 1); ms (see Table 2) *m/e* (ion **f**): 432 (3), 390 (3), 348 (3), 306 (1); (ion **e**): 319 (1), 277 (3), 235 (5), 193 (5); (ion **d**): 177 (10), 135 (20); base peak 43.

Nonacetylcelenamide D (**13**): $[\alpha]_D^{25}$ −25° (*c* 0.54, acetone); ir ($CHCl_3$): 3300 (broad), 1780, 1680 (broad); ^{1}H nmr (see Table 1); ms (see Table 2) *m/e* (ion **j**): 638 (1), 596 (2), 554 (5), 512 (11), 470 (11);[3] (ion **h**): (554, 512, 470),[3] 428 (9), 386 (6), 344 (2); (ion **f**): 432 (39), 390 (53), 348 (53), 306 (26); (ion **e**): 319 (11), 277 (26), 235 (60),[3] 193 (19); (ion **d**): 235,[3] 193 (61), 151 (67); base peak 43.

[3]These ions were not distinguished by high-resolution ms.

Hydrolysis of Pentacetylcelenamide C (12) with Hydrochloric Acid

Pentacetylcelenamide C (**12**, 3 mg) was dissolved in acetonitrile (15 mL) and concentrated HCl (0.1 mL in 2 mL CH_3CN) was added. After 24 h at room temperature the solvent was evaporated and the residue purified by ptlc ($CHCl_3$–CH_3OH, 5:1) to give the primary amide **14** (1 mg). Compound **14** was identical (tlc, ^{1}H nmr (Table 1), ms (Table 2)) to the hydrolysis product isolated following similar treatment of hexacetylcelenamide A (**2**).

Hydrolysis of Nonacetylcelenamide D (13) with Hydrochloric Acid

Nonacetylcelenamide D (**13**, 8 mg) was treated with HCl and the reaction mixture purified as described for **12**, to give the primary amide **15** (3 mg): ir (CH_3CN): 3640, 3540, 3350, 1780, 1680 (broad); ^{1}H nmr (see Table 1); ms (see Table 2) *m/e* (ion **j**): 638 (0.1), 596 (0.2), 554 (0.5), 512 (1), 470 (1), 428 (1), 386 (1); (ion **f**): 432 (2), 390 (3), 348 (3), 306 (2); (ion **e**): 319 (1), 277 (3), 235 (5), 193 (4); base peak 43.

Isolation with Acetic Anhydride-d_6

A small scale isolation procedure (40 g wet weight of sponge) employing acetic anhydride-d_6 (10 mL, 99 + atom %, Aldrich) as the acetylating agent yielded a mixture of deuteroacetylated celenamides following silica ptlc ($CHCl_3$–CH_3OH, 14:1). The hplc of this mixture was analogous to that shown in Fig. 1a. The ^{1}H nmr (270 MHz, acetone-d_6) indicated the absence of signals arising from naturally occurring acetamides (—NHCOCH_3) and phenolacetates (Ph—OCOCH_3).

Studies on nucleation phenomena occurring in aqueous solutions supersaturated with calcium sulfate. III. The cation:anion ratio

DOUGLAS M. KELLER, RONALD E. MASSEY, AND O. E. HILEMAN, JR.
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received March 7, 1980

DOUGLAS M. KELLER, RONALD E. MASSEY, and O. E. HILEMAN, JR. Can. J. Chem. **58**, 2127 (1980).

Nucleation rates from solutions of calcium sulfate dihydrate were measured at constant supersaturation but at varying cation:anion ratios. Induction times were also measured. The values of each were found to be dependent on the Ca:SO_4 ratio. The results of empirical modeling studies are reported. These suggest that ion pair formation has an impact on the nucleation event beyond that of ion removal.

DOUGLAS M. KELLER, RONALD E. MASSEY et O. E. HILEMAN, JR. Can. J. Chem. **58**, 2127 (1980).

On a mesuré les vitesses de nucléation ainsi que les temps d'induction à partir de solutions de sulfate de calcium dihydraté sursaturé à niveau constant mais où l'on fait varier les rapports cation/anion. On a trouvé que les valeurs de ces deux mesures dépendent du rapport Ca:SO_4. On rapporte les résultats d'études faites à l'aide de modèles empiriques. Les résultats suggèrent que la formation des paires d'ions a un impact sur la nucléation en plus de l'élimination de l'ion.

[Traduit par le journal]

Introduction

Crystal nucleation from supersaturated solution is frequently studied by mixing together solutions that separately contain each of the moieties that comprise the precipitate. One of two experimental approaches has been used in most of these experiments: mixing together a series of reagent solution pairs each of increasing stoichiometric concentration levels; or, mixing together a series of reagent solution pairs prepared so that the concentration level across the final set of solutions of one of the moieties of interest is constant while that of the other is increasing across the members of the set. With each approach the supersaturation is calculated from the original solution compositions. Either the supersaturation level at the onset of particle formation or the rate of new particle formation (rate of nucleation) at each supersaturation level is determined experimentally. Then various parameters important in nucleation theory are evaluated using eq. [1].

$$[1] \qquad J = A \exp\left[-\beta\sigma^3 v^2 (kT)^{-3} (\ln S)^{-2}\right]$$

where J is the rate of new crystal formation (nucleation) in $cm^{-3}\ s^{-1}$; β is a shape factor for the newly forming phase; σ is the surface energy in ergs cm^{-2}; v is the volume of the monomer in the newly forming phase in cm^3; A is a pre-exponential factor; and k and T have their usual definitions. For strong electrolytes nucleating from aqueous solutions the supersaturation, S, is defined by eq. [2].

$$[2] \qquad S = [(\mathrm{IP})(K_{sp})^{-1}]^{r/n}$$

where $M_mX_x(s) \rightarrow mM^{q+} + xX^{r-}$; (IP) = ion product = $\{M\}^m\{X\}^x$; $n = m + x$; $mq + x(-r) = 0$; and K_{sp} has its usual definition.

By convention, the value of S at the point where J equals 1.0 $cm^{-3}\ s^{-1}$ is called the critical supersaturation, S^*. For ease of comparison with other studies, values of S^* along with estimates of n^*, r^*, and ΔG^* are usually reported. These are calculated using eqs. [3], [4], and [5].

$$[3] \qquad n^* = 2\beta\sigma^3 v^2 (kT \ln S^*)^{-3}$$

$$[4] \qquad r^* = 2\sigma v (kT \ln S^*)^{-1}$$

$$[5] \qquad \Delta G^* = \beta\sigma^3 v^2 (kT \ln S^*)^{-2}$$

where n^*, r^*, and ΔG^* are the critical number of monomers in an embryo, the critical radius of an embryo, and the critical free energy of an embryo, respectively.

The question of the effect of a changing cation:anion ratio across a suite of experimental runs —a feature of the second experimental approach noted above—on the values of the various nucleation and critical parameters has, to our knowledge, never been discussed in the literature. Mealor and Townshend (1) reported that during their studies on $BaSO_4$ nucleation a change in crystal size and morphology was observed as the initial $[Ba^{2+}]$:$[SO_4^{2-}]$ ratio changed through a series of experimental runs. These authors also noted a dependence of the slope of plots of the log (particle concentration) vs. log (reactant concentration) on the cation:anion ratio with the largest slope occurring when the ratio has a value of one.

The authors report in this paper the results of a set of experiments designed to examine the ques-

*$[\ ]_i$ = initial analytical concentrations of species in solution directly involved in the reactions of interest; $[SO_4^{2-}]_i = 2[S_2O_8^{2-}]_i$; $S_i = 34.46$; $T = 307.5 \pm 1.0$ K; J' = the experimentally determined rate of new particle formation per unit time and volume (2); τ = the time interval between the attainment of a time independent supersaturation and a time independent rate of nucleation.

tion of the impact on the experimental observables and on the various nucleation parameters of a changing cation:anion ratio at constant analytical ion product using calcium sulfate dihydrate as a model system.

Experimental Details and Results

The nucleation from solution experiments were carried out using the droplet technique coupled with *in situ* generation of the solute of interest (DTiGS). Events within the droplet population were recorded photomicrographically using dark field illumination. The information contained on the resulting 35 mm slides was used to obtain the number of particles formed in the population as a function of droplet volume and time. From these data values of J' were calculated.

The supersaturation required to overcome the barrier to $CaSO_4 \cdot 2H_2O$ nucleation from solution was generated using the iodide–peroxydisulfate reaction. The initial ion product ($[Ca^{2+}]_i[SO_4^{2-}]_i$) was set at a value of 0.03063 in each experiment but the initial ($[Ca^{2+}]_i$:$[SO_4^{2-}]_i$) ratio varied from 0.330 to 4.00 across the set of experiments. The generation reaction was initiated by mixing a solution containing Ca^{2+}, $S_2O_8^{2-}$, K^+, and NO_3^- with a solution containing NH_4^+ and I^-. The initial solution composition for each experiment in the series is shown in Table 1. Droplets were prepared from these reaction mixtures. The results of the nucleation events within the populations were recorded photomicrographically and then the data analysis was carried out following standard procedures reported elsewhere (2). The results are recorded in Table 1.

Discussion

The various J' values recorded in Table 1 for the nucleation of $CaSO_4 \cdot 2H_2O$ from solution were determined at the same analytical supersaturation level but at differing cation:anion ratios. A statistical analysis of these data led to the data of Table 2: the confidence levels at which the individual ln J' values are significantly different from that of ln J' for experiment E21 (cation:anion ratio = 1.00). We conclude from these data that the ln J' values observed for all cation:anion ratios differ significantly from that value observed for a cation:anion ratio equal to 1.00.

TABLE 2. Levels of confidence at which values of ln J_{EN}' are significantly different from ln J_{E21}' at one degree of freedom

E26–E21	99

In addition to a changing cation:anion ratio, the composition of each solution in the series was rather different from that of the others. Thus the question of the impact of this compositional variation on the extent of ion pair formation, on ion activities, and on the ion product was considered. Data for the analytical solubility of the precipitate in the various reaction solutions were taken from ref. 3. The K_{sp} and the ion pair formation constant values used were those reported by Liu and Nancollas (4). The results of an iterative calculation that combines together equilibrium considerations and the extended Debye–Hückel theory are included in Table 3 as $[\alpha]$ (Ca^{2+} as ion pairs (mol L^{-1})), the activities of $\{Ca^{2+}\}$ and $\{SO_4^{2-}\}$, and the ionic activity product in the reaction solution just before the nucleation event.

An analysis of the $[\alpha]$ values suggests that those calculated for experiments E18 through E23 are not statistically different from each other and have a mean value of $0.514 \times 10^{-1} \pm 0.014 \times 10^{-1}$ (absolute, 95% C.I.). The ionic activity product values

*[ ]$_f$ and [ ]$_j$ = analytical concentrations of species in solution after the generation and ion pair formation reactions have reached equilibrium; [α] = mol L^{-1} Ca^{2+} reacted to form ion pairs; ion pair formation constant = 169; $f_{Ca}f_{SO_4}$ = 0.020352 ± 0.000039 = ionic activity coefficient product for Ca^{2+} and SO_4^{2-}; $K_{sp} = 2.58 \times 10^{-5}$; μ = ionic strength of the solution just before the nucleation event takes place. See Appendix for the method of calculation used to generate the data of this table.

were also subjected to statistical analysis. It was found that, within experimental and calculational uncertainties, those values noted for experiments E17 through E24 are members of the same set with a mean value of 3.02 ± 0.08 (absolute, 95% C.I.) × 10^{-4}.

Plots of ln J' as a function of the ln (cation:anion ratio) either at constant initial ion product or at constant activity product are shown in Fig. 1. The logarithmic scales are used for convenience only. Also, adjacent points, except those at the apparent maximum, have been joined together by straight lines to aid in the visualization of data trends. The apparent maximum in ln J' cannot be located with precision, but it seems to occur at a cation:anion ratio of less than 1.0. The data shown in Fig. 1 suggest that the assumption of the independence of observed nucleation rates from changing cation:anion ratios at a constant ion product level must be questioned.

The induction times, the time interval between the attainment of a time independent supersaturation value and a steady state nucleation rate, observed in this set of experiments are noted in Table 1 and are also shown in Fig. 1. It is quite clear that the measured values depend on changes in the cation:anion ratio. Also, the values seem to go through an apparent minimum at a ratio of 0.75 ± 0.1.

It is tempting to note at this point that the ratio of the diffusion coefficients for Ca^{2+}:SO_4^{2-} is about 0.8, a number close to that of the cation:anion ratio at the apparent peak and apparent minimum in the

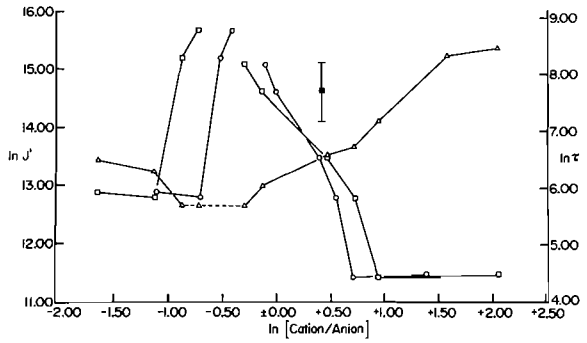

FIG. 1. A plot showing ln J' vs. ln $[[Ca]_i/[SO_4]_i]$ (○), ln J' vs. ln $[\{Ca\}/\{SO_4\}]$ (□), and ln τ vs. ln $[\{Ca\}/\{SO_4\}]$ (△). ■, 95% C.I.

ln J' and ln τ curves, respectively. This may be a coincidence or it may suggest that a diffusion mechanism is controlling the nucleation rate. With data limited to one system only, it is rather difficult to evaluate either hypothesis.

Empirical modeling studies were initiated to gain some insight into the nature of the dependence of the observed J' values on the cation:anion ratio. Two approaches were used. Firstly various alternative models for the estimation of the supersaturation were evaluated. The details of each are shown in Table 4. The resulting values of S were then substituted into eq. [1] and J' values were determined. The fit of these values to those determined experimentally is indicated by the parameter r^2 in Table 4. Secondly, various alternative models for the estimation of the rate of nucleation at constant supersaturation but at various cation:anion

*$\ln J' = aA'' + bB'' + cC'' + dD'' + \ln A - \beta\sigma^3 v^2 (kT)^{-3} (\ln S)^{-2}$; best fit values: $a = 2424$, $b = 873$, $c = 889$, $d = -142$, $r^2 = 0.7740$; $a = 2625$, $b = c = 959$, $d = -156$, $r^2 = 0.7660$.

ratios were evaluated. The details of each are shown in Table 5. Models with calculated r^2 values less than 0.5000 were not included in either Tables 4 or 5.

Generally, r^2 values calculated for models that do not include [α] are rather low (below 0.5). This observation suggests that the presence of ion pairs in the solution has an impact on the nucleation event beyond that of the removal of ionic participants. This suggestion is strengthened by the observation that the adjustable parameter for [α] in the best models is ~3 × that for the individual ions. Representatives of these best models, one from each approach, are shown as eqs. [6] and [7].

$$[6] \quad \ln J' = -\beta\sigma^3 v^2 (kT)^{-3} \{\tfrac{1}{2}[\ln (96.03[\alpha] + 34.68\{Ca\} + 35.24\{SO_4\} - 3.235 - \ln K_{sp}]\}^{-2} + \ln A$$

$$[7] \quad \ln J'_{(S)} = 2424[\alpha] + 873\{Ca^{2+}\} + 889\{SO_4^{2-}\} - \beta\sigma^3 v^2 (kT)^{-3} (\ln S)^{-2} + \ln A - 142$$

Either of the equations may be used in the calculation of nucleation parameters from data obtained during studies on solutions supersaturated with $CaSO_4 \cdot 2H_2O$ at constant supersaturation but with changing cation:anion ratios.

The adsorption and the reaction of NH_3 and NO_x on supported V_2O_5 catalysts: effect of supporting materials

MAKI TAKAGI-KAWAI, MITSUYUKI SOMA, TAKAHARU ONISHI, AND KENZI TAMARU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, Japan

Received April 8, 1980

MAKI TAKAGI-KAWAI, MITSUYUKI SOMA, TAKAHARU ONISHI, and KENZI TAMARU. Can. J. Chem. **58**, 2132 (1980).

The effects of supporting materials (Al_2O_3, SiO_2, TiO_2) on the catalytic activity and selectivity of V_2O_5 in the reduction of NO_x with ammonia are reported. The adsorbed state and the reactivity of the surface species were examined by an ir spectroscopy together with volumetric measurements, and the electronic state and the surface composition were studied by XPS.

The reactivity of an adsorbed ammonia (NH_4^+) for NO_2 over the supported catalysts was in the following increasing order, $TiO_2 > Al_2O_3 > SiO_2$. NH_4^+(ad) and NO_2(ad) were both reactive species in the reaction over V_2O_5, V_2O_5/Al_2O_3, and V_2O_5/TiO_2. Among these catalysts, the oxidized surface of V_2O_5/TiO_2 adsorbs NO as NO_2(ad), i.e. the reactive species, whereas other catalysts did not adsorb NO unless oxygen coexisted in the gas phase. In the case of V_2O_5/SiO_2, the reaction between NH_4^+(ad) and NO_2(ad) was very slow, while the surface oxygen was easily removed by the reduction with NH_3 and resupplied by the introduction of NO on the surface. This leads to the N_2O formation through so-called redox mechanism. The NH_4^+(ad) on V_2O_5/SiO_2 showed an ir absorption band at 1435 cm^{-1} which was much higher than those on other catalysts, and XPS measurement suggested that V_2O_5 on SiO_2 is electrically isolated.

MAKI TAKAGI-KAWAI, MITSUYUKI SOMA, TAKAHARU ONISHI et KENZI TAMARU. Can. J. Chem. **58**, 2132 (1980).

On présente les effets des supports (Al_2O_3, SiO_2, TiO_2) sur l'activité catalytique et la sélectivité du V_2O_5 lors de la réduction de NO_x par l'ammoniac. On a étudié l'état adsorbé et la réactivité des espèces à la surface par spectroscopie ir de concert avec des mesures volumétriques alors que l'on a étudié l'état électronique et la composition de la surface par XPS.

La réactivité de l'ammoniac adsorbé (NH_4^+) vis-à-vis le NO_2 sur les catalyseurs varie dans l'ordre croissant suivant: $TiO_2 > Al_2O_3 > SiO_2$. Le NH_4^+(ad) et le NO_2(ad) sont les deux espèces réactives dans la réaction sur le V_2O_5, V_2O_5/Al_2O_3 et V_2O_5/TiO_2. Parmi ces catalyseurs, la surface oxydée du V_2O_5/TiO_2 adsorbe le NO sous forme de NO_2(ad), i.e. l'espèce réactive, alors que les autres catalyseurs n'adsorbent pas le NO sauf si l'oxygène coexiste dans la phase gazeuse. Dans le cas du V_2O_5/SiO_2, la réaction entre le NH_4^+(ad) et le NO_2(ad) est très lente alors que l'oxygène de la surface est facilement enlevé par une réduction par le NH_3 et redéposé par l'introduction de NO sur la surface. Ceci conduit à la formation de NO_2 selon un mécanisme de pseudo redox. Le NH_4^+(ad) sur le V_2O_5/SiO_2 montre une bande d'adsorption dans l'infrarouge à 1435 cm^{-1} qui est plus haute que celle des autres catalyseurs et une mesure par XPS suggère que le V_2O_5/SiO_2 est isolé électriquement.

[Traduit par le journal]

Introduction

It has been shown previously that the reduction of NO by NH_3 proceeds over V_2O_5 in the presence of oxygen via the reaction between adsorbed NH_4^+(ad) and NO_2(ad) to form N_2 and H_2O (1), as follows.

$$NO + (1/2)O_2 \longrightarrow NO_2(ad)$$

$$NH_3 + \text{≡}OH \longrightarrow \text{≡}O^-—NH_4^+(ad)$$

$$NO_2(ad) + \text{≡}O^-—NH_4^+(ad) \longrightarrow N_2 + 2H_2O + \text{≡}O$$

SCHEME 1

In practice, various supports such as TiO_2, Al_2O_3, or SiO_2, are usually used for this reaction. It is generally accepted that the catalytic activity of V_2O_5 depends markedly on the material used for its support (2, 3). Moreover, when SiO_2 is used as the support, N_2O is formed as one of the reaction products, which is different from other cases (2). In order to elucidate the effect of the support on the catalytic activity and the selectivity for this reaction, we have studied adsorption and reactivity of surface species by means of ir and XPS methods. This paper describes the results on the adsorbed state of surface species and their reactivity studied by ir and volumetric methods. Furthermore, XPS data are also presented on the electronic state of the supported catalysts and the surface species, and the composition of the catalyst surfaces. The mechanism of the reaction is briefly discussed on the basis of these data.

Experimental

The ir measurements were carried out as described previously (4), using a Nihon Bunko IRA-2 or a JEOL JIR10 spectrometer (FT-IR). The catalyst powders (30–50 mg) were formed into disks which were 20 mm in diameter. These catalysts were heated in the ir cell under vacuum at 400°C for 2 h and then oxidized with 100 Torr of oxygen at the same temperature for 1 h before use. One to two g of catalysts were used for volumetric measurements. XPS measurements were taken using a McPherson ESCA 36. The catalysts were treated in a vacuum line and then mounted into the vacuum chamber of the spectrometer without getting into contact with air (O_2), using a dry-box purged by dry N_2 gas. The supported catalysts were prepared as described previously (1), by impregnating the supports with V_2O_5 saturated solution of oxalic acid. Commercial V_2O_5 (Nakarai Chemicals, special grade) was used. γ-Al_2O_3, SiO_2, and TiO_2

(Anatase form) were obtained from Degussa Co. Ltd. The oxidized surface was obtained by treating the catalysts with 100 Torr of O_2 at 300°C for 1 h then evacuated at room temperature. The reduced surface was obtained by reducing the oxidized surface with 30 Torr of NH_3 at 200°C for 1 h followed by the evacuation for 1 h at the same temperature. For ir measurements, 23 wt% V_2O_5 supported catalysts were used unless mentioned. The reaction products, N_2 and N_2O, were detected by gas-chromatography, using molecular sieve 13X and Porapac Q columns of 4 m long at room temperature. Chemically pure NO (Takachiho Chemical Co., Ltd) was used without further purification. NO_2 was prepared by oxidizing NO with oxygen, then purified by distillation under vacuum until colourless crystals at liquid nitrogen temperature were obtained. NH_3 was purified by distillation.

Results

I. Adsorption of NO, NO_2, and NH_3 on Supported V_2O_5 Catalysts: IR and Volumetric Measurements

Adsorption of NO and NO_2

When 50 Torr of NO was introduced onto oxidized or reduced surface of V_2O_5, V_2O_5/Al_2O_3, or V_2O_5/SiO_2 at room temperature, it gave no change in ir spectra and no decrease in the pressure of NO. By introducing mixed NO and O_2, NO_2(ad) was adsorbed on each catalyst giving ir spectra shown in Fig. 1. The adsorption of NO_2 gas gave the same spectra as that obtained for the mixed NO and O_2 gases. This means that unless oxygen was also present in the gas phase, NO was not adsorbed on the oxidized surface of V_2O_5/Al_2O_3, V_2O_5/SiO_2, nor V_2O_5 alone.

The V_2O_5 catalyst on TiO_2 support, on the other hand, exhibited a very different behaviour as will be described below. On the oxidized surface of V_2O_5/TiO_2, the adsorption of NO was detected to give a single absorption band at 1620 cm^{-1}, which was the same as that obtained when NO_2 gas itself or the mixture of NO and O_2 was introduced on the oxidized or reduced catalyst. It was assigned to the antisymmetric stretching of NO_2(ad) (1). After V_2O_5/TiO_2 was reduced by 30 Torr of ammonia, followed by a 1.5 h evacuation at 400°C, the adsorption of NO was not detected by ir nor was the decrease in the NO pressure by volumetric measurement observed. Moreover, when NO_2(ad) formed upon introduction of NO on the oxidized surface of V_2O_5/TiO_2 was desorbed by evacuating at 160°C, NO was not adsorbed any more on the surface at room temperature. These facts suggest that NO was oxidized by the surface oxygen of V_2O_5/TiO_2 to form NO_2(ad), and the amount of adsorbed NO as NO_2(ad) on the oxidized surface of V_2O_5/TiO_2 was equal to the amount of surface active oxygen.

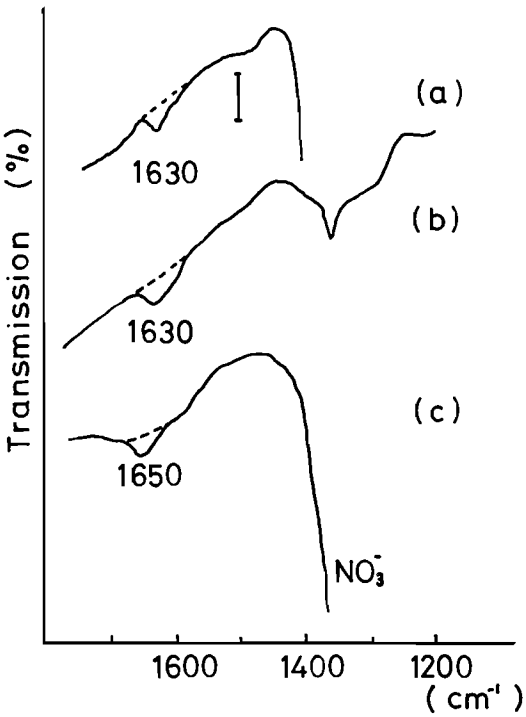

FIG. 1. Infrared spectra of adsorbed NO_2(ad) by the introduction of NO + O_2 onto the oxidized surface of (*a*) V_2O_5, (*b*) V_2O_5/Al_2O_3, and (*c*) V_2O_5/SiO_2. The bar shows the transmission of 10%. NO_3^- is formed on the NaCl window of the ir cell; 50 Torr of NO and 10 Torr of O_2 were introduced at room temperature. The spectra were taken after the gas phase was evacuated.

On the oxidized surface of TiO_2 itself, NO was also adsorbed as NO_2(ad) to give a single absorption band at 1620 cm^{-1} (Fig. 2*a*). The adsorption of NO_2 gas over oxidized or reduced TiO_2 gave a spectrum with two absorption bands at 1630 and 1200 cm^{-1} (Fig. 2*b*). These bands exhibited no changes in intensity when TiO_2 was heated to 160°C, whereas the adsorbed NO over the oxidized surface of TiO_2 in the form of NO_2(ad) could be desorbed at this temperature. Although the surface active oxygen forms NO_2(ad) from NO on the TiO_2 surface, the reactivity of NO_2(ad) on V_2O_5/TiO_2 was much higher than that on TiO_2 alone, as will be seen in the following section.

Adsorption of NH_3

The adsorption of NH_3 on the supported catalysts was examined as follows: 30 Torr of NH_3 was introduced onto the oxidized surface of each catalyst at room temperature and the ir spectra were taken after the gas was evacuated at the same temperature (Figs. 3, 4). Table 1 shows the positions and assignments of the ir absorption bands

due to the adsorbed ammonia, and N1*s* binding energies obtained by XPS. The adsorption of ammonia on V_2O_5 and V_2O_5/Al_2O_3 have been discussed previously (1). The TiO_2 supported catalyst showed absorption bands at 1424, 1605, and 1238 cm^{-1}, which were assigned to symmetric deformation of NH_4^+(ad), degenerate and symmetric deformation of NH_3(ad), respectively, as in the case of V_2O_5/Al_2O_3. The SiO_2 supported catalyst showed two bands at 1620 and 1435 cm^{-1} due to NH_3(ad) and NH_4^+(ad). Binding energies of N1*s* of the adsorbed species were 400 and 401 eV for NH_3(ad) and NH_4^+(ad), respectively, which gave a good correspondance with the ir results.

Reactivity of the Adsorbed Species

The reaction between adsorbed ammonia and gaseous NO_2 was carried out over each of the supported catalysts. Figure 5 shows the amount of N_2 production with time for a unit amount of preadsorbed ammonia. V_2O_5/TiO_2 exhibited the highest activity, V_2O_5/Al_2O_3 exhibited an activity of the same order of magnitude as that of the unsupported V_2O_5, whereas V_2O_5/SiO_2 showed an activity 1/10 that of V_2O_5/Al_2O_3.

It was found that the adsorbed ammonia on V_2O_5, V_2O_5/Al_2O_3, and on V_2O_5/SiO_2 reacted with NO_2 to form N_2, but did not react with NO. No decrease in the ir band of adsorbed ammonia and no N_2 production were observed by the introduction of NO. On the other hand, when NO was introduced over the surface of V_2O_5/TiO_2 preadsorbed with ammonia at room temperature, N_2 was formed at the initial stages (Fig. 5*d*). This suggests that the reaction takes place until the active oxygen on the surface of V_2O_5/TiO_2 is exhausted. The large enhancement of reactivity of system (*a*) over system (*d*) may be due to difference in the total amount of available NO_2(ad) on the surface of the catalysts.

The reaction between two adsorbates, NH_4^+(ad) and NO_2(ad), was examined separately by ir measurement. In order to observe these two adsorbates together, the pressure of NH_3 and NO_2 were carefully controlled. The band intensity of adsorbed ammonia (NH_4^+) on V_2O_5, V_2O_5/Al_2O_3, and V_2O_5/TiO_2 decreased gradually by the introduction of NO_2 or NO + O_2. That of NO_2(ad), on the other hand, decreased by the introduction of ammonia.

*δ_d: degenerate deformation; δ_s: symmetric deformation.

For both cases, N_2 was formed in the gas phase. The band intensity of two adsorbates on V_2O_5/SiO_2, however, did not decrease by the introduction of each gas. The reaction between the two adsorbates for the V_2O_5/Al_2O_3 and V_2O_5/SiO_2

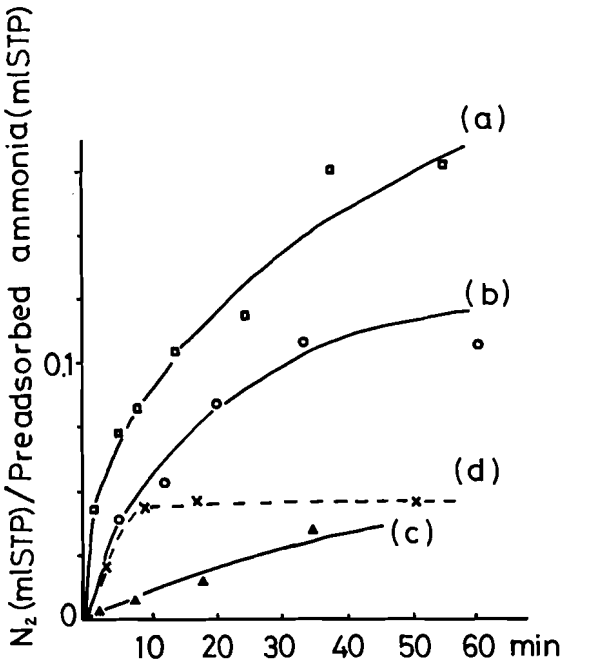

FIG. 5. Reaction between NO_2 and adsorbed ammonia at room temperature (25°C) on 23 wt% V_2O_5 supported catalysts. The amount of N_2 production divided by the amount of preadsorbed ammonia is plotted. (*a*) V_2O_5/TiO_2, (*b*) V_2O_5/Al_2O_3, (*c*) V_2O_5/SiO_2. The broken line (*d*) shows the reaction between adsorbed ammonia and NO gas over V_2O_5/TiO_2. The experimental conditions are as follows: amount of catalyst in g, adsorbed ammonia in mL STP/g, and NO_2 in Torr, V_2O_5/Al_2O_3, 1.68, 20.7, 22; V_2O_5/SiO_2, 1.30, 27.0, 19; V_2O_5/TiO_2, 1.00, 18.0, 22.

are shown in Fig. 6. The decrease of the absorption bands on V_2O_5/Al_2O_3 were observed with time and they were found to vanish in 20 min at room temperature, whereas those on V_2O_5/SiO_2 remained almost unchanged. Both adsorbates NH_4^+(ad) and NO_2(ad) on V_2O_5/SiO_2, which reacted readily on other V_2O_5 catalysts to form N_2, were comparatively inert.

The reactivity of NO_2(ad) on TiO_2 was examined by both ir and volumetric methods. The absorption band of NO_2(ad) on TiO_2 showed no change by the introduction of NH_3 at room temperature, except that extra absorption bands by adsorbed ammonia appeared in the spectrum. In the case of V_2O_5/TiO_2, adsorbed NO_2(ad) readily reacted with NH_3 at room temperature to form N_2.

II. N_2O Formation from NO and NH_3 over V_2O_5/SiO_2 Catalyst

When NO was introduced at 300°C onto V_2O_5/SiO_2, which was reduced by 100 Torr of ammonia at 200°C for 1 h, N_2O was detected in the gas phase, whereas N_2O production was not detected

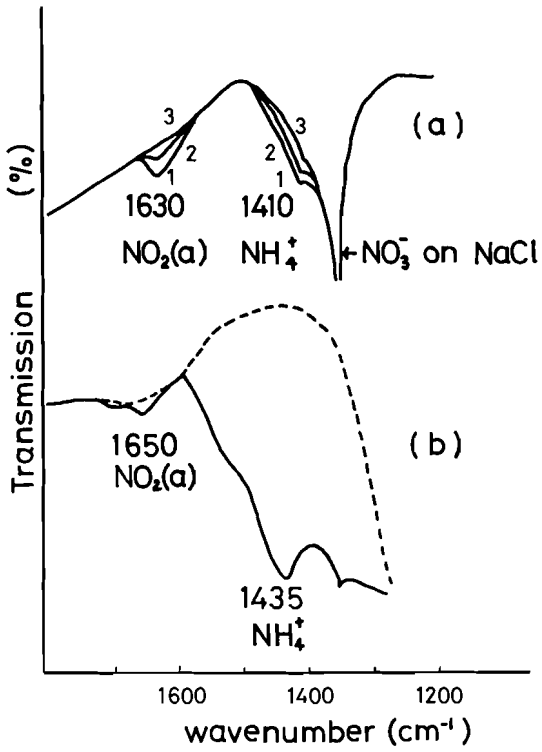

FIG. 6. Infrared spectra of the adsorbates on (*a*) V_2O_5/Al_2O_3, (*b*) V_2O_5/SiO_2. *1*, *2*, *3* in (*a*) show the decrease in the intensity of the absorption bands. The broken line shown in (*b*) is the background spectrum before the adsorption.

over V_2O_5 alone or V_2O_5/Al_2O_3. The changes in the amount of surface oxygen due to the surface treatment and the reaction were examined. It was found that the ratio of XPS emission peak area of O1*s* to that of V2*p* on V_2O_5/SiO_2 decreased by about 10% of its initial value when it was reduced by 30 Torr of NH_3 at 200°C for 1 h followed by evacuation at the same temperature. It increased to restore the original value when the reduced catalyst was exposed to 100 Torr of NO at 300°C for 1 h. In the case of V_2O_5 alone or V_2O_5/Al_2O_3, the ratio of XPS peak area of O1*s*/V2*p* stayed constant within experimental error after the surface was treated by NH_3. For SiO_2 alone, the ratio of O1*s* to Si2*p* exhibited no change due to the surface treatment.

III. XPS Measurement of V_2O_5 Catalysts

The effect of the support on the electronic state of V_2O_5 was examined by XPS. Table 2 shows the binding energies of $V2p_{3/2}$ of V_2O_5 supported over Al_2O_3, SiO_2, and TiO_2. For V_2O_5/SiO_2 the binding energy of V obtained from the $V2p_{3/2}$ shifted to a value 0.8–0.9 eV higher than that for V_2O_5 itself, whereas that for V_2O_5/Al_2O_3 gave a shift of only about 0.3 eV. These shifts in binding energy are

TABLE 2. Binding energies obtained by XPS (Au $4f_{7/2}$ = 83.7eV)*

	$V(2p_{3/2})$	O(1*s*)	Al(2*s*)	Si(2*p*)
V_2O_5	516.8	529.9		
23% V_2O_5/Al_2O_3	517.2	530.8	118.6	
23% V_2O_5/SiO_2	517.7	532.6		103.2
23% V_2O_5/TiO_2	516.9	529.9		
Al_2O_3		531.3	119.2	
SiO_2		532.6		103.2
TiO_2		529.9		

*Each catalyst was oxidized in 100 Torr of oxygen at 300°C for 1 h, and then evacuated for 30 min after cooling down to room temperature.

observed in the region where the content of V_2O_5 is less than 30 wt% for V_2O_5/SiO_2. In the case of V_2O_5/TiO_2, $V2p_{3/2}$ was observed at 516.9 eV, which was the same as that of V_2O_5 alone.

When Au was evaporated over 10% V_2O_5/SiO_2, the peak of $V2p_{3/2}$ was observed at 516.9 eV (the same value as V_2O_5 itself), whereas it was shifted to 517.8 eV without Au evaporation. The location of other emission peaks such as O1*s* or Si2*p* apparently stayed unchanged.

Discussion

(a) Surface Adsorbates of V_2O_5 Catalysts

It was demonstrated accordingly by ir and volumetric methods that NO was not adsorbed on the oxidized or reduced surface of V_2O_5, V_2O_5/Al_2O_3, or V_2O_5/SiO_2 unless oxygen was also present in the gas phase. Furthermore, we could see that NO with O_2 or NO_2 was adsorbed on these catalysts in the form of NO_2(ad). However, on the oxidized surface of V_2O_5/TiO_2, NO could be adsorbed as NO_2(ad) without gaseous oxygen. Although the same feature was observed for the TiO_2 support only, NO_2(ad) adsorbed on TiO_2 was entirely different in reactivity from that on V_2O_5/TiO_2. NO_2(ad) on V_2O_5/TiO_2 reacted to form N_2 when NH_3 was introduced to the surface at room temperature, leaving adsorbed NH_3 on the surface. On the other hand, NO_2 adsorbed on TiO_2 did not react with NH_3. The amount of NO adsorbed as NO_2(ad) on the oxidized surface of 23 wt% V_2O_5/TiO_2 was 0.2 mL STP/g, whereas that of ammonia was 19.0 mL STP/g. This means that the amount of surface active oxygen on V_2O_5/TiO_2 which adsorbs NO as NO_2(ad) is about 1/100 of adsorbed ammonia. If we assume that the V_2O_5 is uniformly supported on the surface of the support (as in the case of SiO_2 or Al_2O_3 supported catalysts), the amount of ammonia adsorbed is about 1/2 of the surface V atoms on the catalyst.

Several ir absorption peaks in the region, 1100–1600 cm^{-1} may be assigned to surface ammonia NH_3(ad) and NH_4^+(ad). These NH_4^+(ad)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and NH_3(ad) species could be well correlated with the XPS peaks which reflected the charge distribution in the molecules, and the ir peaks due to NH_3(ad) on the supports could be easily separated from the NH_4^+(ad) on V_2O_5.

NO_2(ad) and NH_4^+(ad) were both revealed to be the reactive species on V_2O_5, V_2O_5/Al_2O_3, and V_2O_5/TiO_2. Among them, NH_4^+(ad) on V_2O_5/TiO_2 reacted with NO to form N_2 until the surface active oxygen which forms NO_2(ad) from NO are exhausted. These facts suggest that the mechanism of the reduction of NO_x by NH_3 on V_2O_5/TiO_2 catalysts could also be described as that proposed for V_2O_5 only or V_2O_5/Al_2O_3 (1) (Scheme 1). It could be expected that under low NO pressure condition (in the practical system, NO is a few hundred ppm), where the rate of NO_2 formation in the gas phase should be slow, V_2O_5/TiO_2 can show high activity for the reduction of NO_x by NH_3 compared with that over the other supported catalysts, such as V_2O_5/Al_2O_3 or V_2O_5/SiO_2, because of the existence of the active oxygen on V_2O_5/TiO_2 to form reactive NO_2(ad) on the surface.

(b) Redox Mechanism over V_2O_5/SiO_2 to Form N_2O

It is well known that N_2O is formed by the reaction of NO with NH_3 over V_2O_5/SiO_2 (2). The observed changes in the amount of surface oxygen on V_2O_5/SiO_2 (section II) indicated that when V_2O_5 is supported on SiO_2, the oxygen on V_2O_5 is easily reduced by NH_3, while the reoxidation of the reduced surface by NO takes place, which offers a new route to the formation of N_2O. It was also demonstrated that the surface reaction between NH_4^+(ad) and NO_2(ad) is slow (or does not occur) on the V_2O_5/SiO_2 (Fig. 6) and this catalyst exhibited low activity in the reaction of NH_4^+(ad) with gaseous NO_2 (Fig. 5). Accordingly, on V_2O_5/SiO_2, there is a route to form N_2O via the so-called redox mechanism. It should be mentioned that the surface oxygen could be easily removed by NH_3 at 200°C, which means that even though the surface was oxidized at the initial stage, it could be easily reduced when NH_3 was present in the system.

(c) Electronic State of V_2O_5 Catalysts

The shift in the binding energy of V ($V2p_{3/2}$) when V_2O_5 is supported on SiO_2 can be attributed to two effects; the chemical effect or the relaxation effect. If the change in the observed binding energy of $V2p_{3/2}$ is due to the chemical effect, that is, the electronic state of vanadium is changed when supported on SiO_2, then the shift should be observed also after the evaporation of Au on the surface of V_2O_5/SiO_2, which was not the case in this study. The fact that V2*p* on SiO_2 is shifted toward higher binding energy without Au evaporation seems to suggest that V_2O_5 is electrically isolated when supported on SiO_2. The shifts in photoelectron peaks due to the local electric isolation and the local difference in chemical activity on a surface of a catalyst have been reported (5).

Superoxide mediated autoxidation of hydrocarbons

EDWARD LEE-RUFF AND NEIL TIMMS

Department of Chemistry, York University, 4700 Keele Street, Downsview, Ont., Canada M3J 1P3

Received September 12, 1979[1]

EDWARD LEE-RUFF and NEIL TIMMS. Can. J. Chem. **58**, 2138 (1980).

Potassium superoxide was found to initiate autoxidations of fluorene, diphenylmethane, and distyrylmethane. In each case the oxidation results in the formation of ketones as primary products. Kinetics of the fluorene and diphenylmethane oxidations showed typical sigmoidal autoxidation rate profiles. External hydroperoxides did not affect the rates of these reactions, however, these were efficiently transformed to ketones in the presence of O_2^-. A mechanism for these autoxidations is proposed.

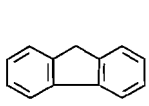
EDWARD LEE-RUFF et NEIL TIMMS. Can. J. Chem. **58**, 2138 (1980).

On a trouvé que le superoxyde de potassium initie l'autoxydation du fluorène, du diphénylméthane et du distirylméthane. Dans chaque cas, l'oxydation conduit à la formation de cétones comme produits primaires. Les cinétiques de l'oxydation du fluorène et du diphénylméthane montrent un profil de vitesse typique d'une autoxydation sigmoidale. Les hydroperoxydes extérieurs n'affectent pas les vitesses de ces réactions; cependant elles sont transformées efficacement en cétones en présence d'ions O_2^-. On propose un mécanisme pour ces réactions d'autoxydations.

[Traduit par le journal]

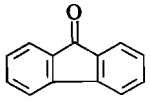
As part of a program on the study of the organic chemistry of superoxide (1), we became interested in the possible involvement of O_2^- in autoxidation reactions. The effect of metal and metal ions in the enhancement of autoxidation rates is well documented (2, 3) and has been rationalized in terms of the involvement of these in interfering with the chain initiating and propagating steps in the basic autoxidation scheme. It is conceivable that in the presence of metals and reducing metal ions superoxide may be produced and involved in the autoxidation scheme shown below.

Initiation: $M^{+n} + O_2 \rightarrow M^{+n+1} + O_2^-$



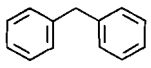
$R^- + O_2 \rightarrow R^\cdot + O_2^-$

$O_2^-(M^{+n+1}) + RH \rightarrow HO_2^- + R^\cdot$

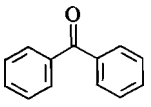


Chain propagation: $R^\cdot + O_2 \rightarrow RO_2^\cdot$

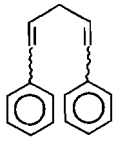
$RO_2^\cdot + RH \rightarrow R^\cdot + ROOH \rightarrow$ oxidation products



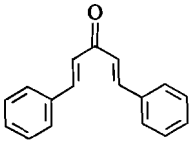
Superoxide, once formed from one electron reduction of triplet oxygen by either reducing species such as metals, metal ions, or even organic anions in base-catalyzed autoxidations, may abstract a hydrogen atom from the hydrocarbon to initiate the chain process. This step might be expected to be more efficient with O_2^- than with triplet oxygen and lead to rate enhancements. Triplet oxygen singlet substrate interactions in the ground state are spin forbidden and require appreciable activation energies. In the transformation of the primary hydroperoxides (ROOH) to more stable oxidation products, O_2^- may act as one electron reducing agent or a base (4) to produce other free radicals leading to chain branching and an acceleration of rates. On the other hand, superoxide may also participate in the chain terminating steps as a radical scavenger or as a reducing species of alkyl radicals leading to shorter chains and a deceleration of the overall rate. In order to evaluate the effect of superoxide in autoxidation reactions we studied the oxidation of hydrocarbons possessing benzylic and allylic hydrogens such as fluorene (**1**), diphenylmethane (**2**), and distyrylmethane (**3**) with oxygen in the presence of catalytic amounts of potassium superoxide. In all cases ketones **4**, **5**, and **6** were



1



4



2

5

3

6

formed as major products accompanied by trace amounts of hydrocarbon dimers. That these were not direct superoxide oxidations was seen by the stoichiometry of these transformations. Catalytic amounts of O_2^- down to 1/100 equivalent were sufficient to cause these transformations to proceed

to completion although the rates were significantly lowered with decreasing O_2^- concentrations. There were complications with the distyrylmethane oxidation in that a mixture of products consisting of ketone **6**, benzaldehyde, and cinnamic acid was obtained whose composition depended on the amount of superoxide initially present in the system. It was subsequently shown that benzaldehyde and cinnamic acid are secondary products derived from the direct oxidation by O_2^- of ketone **6** under the same conditions. Similar observations have been made by Poupko and Rosenthal (5). The rate profile (Figs. 1 and 2) shows the typical curve for an autoxidation reaction characterized by an induction period followed by an acceleration in rate and then a deceleration towards completion. The maximum rates are seen to depend on hydrocarbon concentrations with the rate increasing with RH concentration. It can also be seen from the rate profiles that the induction period is also affected by RH concentration in an inverse way. That these transformations are not base-catalyzed by O_2^- or spurious hydroxide was shown by similar experiments using potassium hydroxide in identical concentrations. Although autoxidations did occur under the latter conditions, the rates of the reactions were anywhere from 20 to 100-fold slower. The effect of varying superoxide concentration on the rate of oxygen uptake is seen to follow a similar pattern with rates and induction periods being affected by O_2^- concentration.

Table 1 summarizes the kinetic data of the fluorene oxidations. Oxygen consumption is close to but never exceeds 1 suggesting that if hydroperoxides are formed their subsequent transformation to ketones does not involve a second equivalent of oxygen but possibly a base-catalyzed

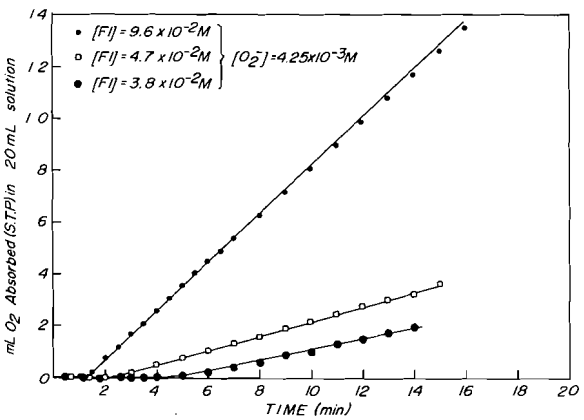

FIG. 1. Rate profile for fluorene autoxidation mediated by O_2^- (25°C), varying fluorene concentration.

degradation. Independent studies on the fluorenyl hydroperoxide reaction with potassium superoxide as well as with potassium hydroxide showed a complete conversion to fluorenone *in the absence of oxygen*. With superoxide, oxygen evolution was associated with these transformations. The autoxidation rates represent lower limits since a two phase system is used and limited by the rate of oxygen diffusion into the liquid solution. The experimental orders in hydrocarbon and superoxide concentrations and bimolecular rate constants are tabulated in Table 2. In both the fluorene and diphenylmethane oxidations the order in hydrocarbon concentration is greater than 1 and that for superoxide is less than 1. It is also seen that the rate for fluorene autoxidation is about 30 times faster than for diphenylmethane. This is consistent with the relative order for hydrogen abstraction of fluorene and diphenylmethane as reported by Russell (6). At 90°C the rate of hydrogen abstraction of fluorene by alkyl peroxy radicals is more than 3 times as fast as in diphenylmethane. Assuming positive activation energies it would be expected that these rate differences would be larger at lower temperatures. However, direct quantitative comparisons cannot be made between our results and those of Russell since the latter were obtained for constant rate of chain initiation which is not the case in the present work. Our kinetic data for fluorene oxidation are also consistent with those reported by Ohkatsu and co-workers (7), who studied these oxidations using electrogenerated O_2^- with tetraethylammonium phosphate as the supporting electrolyte in pyridine solutions. However, they report that diphenylmethane oxidation is 3.5 times faster than fluorene oxidation. It may be that

TABLE 2. Kinetic data for O_2^- autoxidations

	Order in RH	Order in O_2^-	k (L/mol − s)
Fluorene	1.6	0.66	1.02×10^{-3}
Diphenylmethane	1.4	0.54	2.88×10^{-5}

solvent effects and the nature of the gegenion may contribute to rate differences and even reversals in rate orders.

Following the basic autoxidation scheme the rate of oxidation can be expressed by the equation:

$$R = \frac{k_2[O_2]R_i^{1/2}(k_3[RH] + k_6^{1/2}R_i^{1/2})}{k_3k_4^{1/2}[RH] + k_2k_6^{1/2}[O_2] + (k_4k_6R_i)^{1/2}}$$

By making the approximation that the rate initiation R_i is rate determining the above expression can be reduced to:

$$R = \frac{k_2k_3[O_2][RH]R_i^{1/2}}{k_3k_4^{1/2}[RH] + k_2k_6^{1/2}[O_2]}$$

Basic Autoxidation Scheme

Production of R· or $RO_2^·$ radicals: initiation rate = R_i

$$R^· + O_2 \xrightarrow{k_2} RO_2^·$$

$$RO_2^· + RH \xrightarrow{k_3} RO_2H + R^·$$

$$\left.\begin{array}{ll} 2R^· & \xrightarrow{k_4} \\ R^· + RO_2^· & \xrightarrow{k_5} \\ 2RO_2^· & \xrightarrow{k_6} \end{array}\right\} \text{inert products}$$

For sufficiently high oxygen pressures the rate expression can be further simplified to one involving first order in hydrocarbon concentration and independent of oxygen concentration, i.e.

$$R = k[RH]R_i^{1/2}$$

If one proposes that in the presence of superoxide, the dominant initiation process is hydrogen abstraction from hydrocarbon RH by O_2^- the rate expression becomes:

$$R = k[RH]^{3/2}[O_2^-]^{1/2}$$

The experimental orders (Table 2) fall within the range of the predicted rate equation suggesting O_2^- is primarily involved in the rate determining initiation step of these oxidations. Studies on the rates of autoxidation in the presence of fluorenyl hydroperoxide (10^{-4} M) showed a minimal decrease in the rate attributable to the reaction of O_2^- with hydroperoxide as described above. This would suggest that hydroperoxides are not responsible for autocatalysis under these conditions. The initiation rate constant k_i can be estimated from values of k_6 and k_3 of 6×10^5 and 10 L/mol-s respectively for γ-methylcrotylbenzene (12), a related system. A value of 5.3×10^{-3} L/mol-s is calculated for fluorene hydrogen abstraction by O_2^-. This is about three orders of magnitude slower than the corresponding hydrogen abstractions by peroxy radicals in line with the expected decreased reactivity of radical anions towards hydrogen abstaction. It is noteworthy that such a slow initiation step is more compatible with a hydrogen abstraction by O_2^- rather than a proton abstraction. Work is in progress to investigate the nature of these radicals by spin-trapping experiments.

Experimental

Diphenylmethane was redistilled from a commercial sample. Distyrylmethane (mixture of isomers) was prepared by Wittig reaction of 1,3-dibromopropane with benzaldehyde (8). Fluorene was recrystallized from a commercial sample. Fluorenyl hydroperoxide was prepared according to the method of Hock *et al.* (9). *Trans* dibenzalacetone was synthesized according to a literature method (10).

Qualitative Experiments

Solutions (50 mL) of hydrocarbon (10^{-2} to 10^{-3} M) in dimethyl sulfoxide containing 10^{-4} M potassium superoxide were placed in a gas bubbler. Oxygen gas was passed through the solution for 1–2 h. The solutions were diluted with 200 mL of water and extracted with 3 × 50 mL of ether. The ether extracts were dried with anhydrous magnesium sulfate and evaporated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The residue was chromatographed on a silica gel column (hexane–benzene 1:1). The nonpolar fractions (<5%) were identified as dimeric material from their mass spectra ($2M^+ - 2$). The ketone fractions (>90%) were compared with authentic material.

The fluorenyl hydroperoxide oxidation was carried out as follows: 50 mg of hydroperoxide (9) in 5 mL of benzene was added to 2 mL of a suspension of 100 mg of finely crushed KO_2 in benzene in a closed system saturated with N_2. Evolution of a gas was observed during addition. After the addition was complete the mixture was poured into 10 mL of water – crushed ice mixture. The solution was extracted with ether and the ether layer worked up in the usual manner to give 40 mg of fluorenone. The same procedure was repeated using KOH instead of KO_2.

Oxidation of Distyrylmethane (3) and Dibenzalacetone (6) with Potassium Superoxide

A solution containing 0.5 g of distyrylmethane (**3**) (mixture of isomers) in 50 mL dimethyl sulfoxide was placed in a gas bubbler. Oxygen was passed through the solution for 2 h. The solution was added to 200 mL of water and extracted with 3 × 50 mL of ether. The combined ether extract was dried with anhydrous magnesium sulfate and evaporated. The residue was chromatographed on a silica gel column. Hexane–benzene 1:1 eluted 45 mg of benzaldehyde (dinitrophenylhydrazone mp 235–236°C (lit. (11) mp 237°C)), and 340 mg of *trans* dibenzalacetone, mp 109–110°C, identical by ir spectroscopy to *trans* dibenzalacetone prepared according to ref. 10. The aqueous solution was neutralized with concentrated HCl and extracted with 2 × 50 mL of ether. The ether extract was washed neutral with water, dried with $MgSO_4$, and evaporated to give 64 mg of *trans* cinnamic acid, mp 131°C. This was identical by ir with an authentic sample. Mixture melting point showed no depression.

The control oxidation of dibenzalacetone with potassium superoxide was carried out as follows. To a solution of 0.5 g of dibenzalacetone in 50 mL dimethyl sulfoxide was added 0.5 g of KO_2. The solution turned to an orange-brown colour after a few minutes. After stirring for 2 h the mixture was added to 200 mL water and worked up in the same way as above yielding 0.15 g of benzaldehyde and 0.24 g of cinnamic acid.

Kinetic Runs

In a closed system consisting of a gas burette and a reaction assembly with an addition flask was introduced 10 mL of a dimethyl sulfoxide solution containing potassium superoxide. A 10 mL solution containing the hydrocarbon was introduced into the addition funnel. The reaction assembly was equilibrated with oxygen for one hour. The hydrocarbon solution was rapidly added to the reaction flask and the oxygen uptake was followed by gas burette reading and corrected to STP.

MOHAMMED AHSAN, ROSS ELMORE ROBERTSON, MICHAEL JESSE BLANDAMER, and JOHN MARSHALL WILLIAM SCOTT. Can. J. Chem. **58**, 2142 (1980).

In aqueous solution, the α-deuterium isotope effects in the solvolyses of benzyl nitrates derivatives depend on the nature of the substituent in the benzene ring. In addition, the isotope effect for some derivatives depends on mole fraction of added acetonitrile while for others the isotope effect is insensitive to solvent composition. However, the kinetic solvent isotope effects for *para*-methyl and *meta*-trifluoromethyl derivatives remain unchanged when acetonitrile is added. These observations are accounted for in terms of a model which describes the solvolytic reaction as a two-stage process and contrasts the relative importance of bond-making and bond-breaking.

MOHAMMED AHSAN, ROSS ELMORE ROBERTSON, MICHAEL JESSE BLANDAMER et JOHN MARSHALL WILLIAM SCOTT. Can. J. Chem. **58**, 2142 (1980).

En solution aqueuse, les effets isotopiques des deutérium α observés lors des solvolyses de nitrates de benzyles dépendent de la nature du substituant fixé sur le cycle. De plus les effets isotopiques de quelques dérivés dépendent de la fraction molaire d'acétonitrile ajouté alors que d'autres effets isotopiques sont indépendants de la composition du solvant. Cependant les effets isotopiques cinétiques du solvant pour les dérivés *para*-méthylé et *méta*-trifluorométhylé demeurent les mêmes quand on ajoute de l'acétonitrile. On interprète ces observations en fonction d'un modèle qui décrit la réaction de solvolyse, une réaction en deux étapes où s'opposent les importances relatives de la rupture et de la formation d'une liaison.

[Traduit par le journal]

Introduction

In principle, a detailed understanding of the mechanism of solvolytic reactions involving organic substrates of the general form RX should be forthcoming from a study of the α-deuterium isotope effects as measured by the ratio k_H/k_D. A similar comment applies to the information provided by the kinetic solvent isotope effect as measured by the ratio k_{H_2O}/k_{D_2O}. However, as more information became available the interpretation of these isotope effects became less clear-cut. Thus Shiner (1) attempted to use k_H/k_D as an indicator of the extent of nucleophilic involvement in the rate determining step for displacement of chloride ion. However, Bentley and Schleyer (2) argue that the reference value of k_H/k_D is not known for systems where nucleophilic driving forces are absent. Turning to the solvent isotope effect, there was reason to anticipate that in terms of the Ingold description (3), the ratios would follow the sequence $1° > 2° > 3°$. However, these ratios for displacement of halide, nitrates, and sulphonates from a saturated carbon atom are often close to unity (4), the slight deviation from unity being partially attributed to initial state differences (5).

The work reported in this paper was prompted by the observations of Koshy and Robertson (6, 7). For a series of benzyl nitrates in water, the α-k_H/k_D ratios vary between 0.99 and 1.18 per deuterium atom. Moreover it was noted (7) that the latter ratios correlated with the heat capacities of activation, $\Delta C_p^{\ddagger}$, calculated from the dependence of rate constant for solvolysis in water on temperature. However, a reappraisal (8) of the latter dependence has indicated that the calculated $\Delta C_p^{\ddagger}$-quantity is an artefact of the mechanism which is more correctly described in terms of a two-stage process. This raises the question of whether a similar model could account for the isotope effects. The data reported in this paper for the solvolysis of a series of substituted benzyl nitrates prompt the development of such a model. Here the reaction proceeds through an intermediate which is characterized by appreciable charge separation in the C—X bond. The transition state characterizing the next stage is appreciably ionic whereas the nucleophile H_2O (D_2O) is reactant-like, whether the reacting carbon centre is primary, secondary, or tertiary. This new model shifts the emphasis away from the traditional assumption which stresses the compensation be-

tween bond-making and bond-breaking in displacement reactions.

Results

The α-deuterium isotope effects for the solvolysis of various benzyl nitrates in water are reported in Table 1. The ratios range from 1.16 for *o*-methylbenzyl nitrate to 0.986 for the *m*-trifluoromethyl derivative showing that α-deuteration can increase or decrease the rate constant.

A more interesting trend is observed when the solvent is changed by adding acetonitrile. In some cases the ratio k_H/k_D changes; in the case of *o*-methylbenzyl nitrate, the ratio shifts from 1.158 to 1.070 when the mole fraction of acetonitrile increases from 0 to 0.20. However, the ratio for some substrates is insensitive to the mole fraction of added acetonitrile, e.g. *m*-trifluorobenzyl nitrates. A similar solvent dependence of k_H/k_D is observed for the solvolyses of three benzyl chlorides (Table 2).

The effect of added acetonitrile on the kinetic

*Adjusted to 25°C.

solvent isotope effect is shown in Table 3 for two benzyl nitrates. Here we note that this isotope effect is insensitive to the solvent composition.

In summary the data show (*1*) how the α-deuterium isotope effects depend on the substituent in the benzene ring; (*2*) how the ratio of k_H/k_D may or may not depend on the solvent composition; and (*3*) how the solvent isotope effect is unchanged when acetonitrile is added. In the following section we attempt to formulate a model which accounts for these observations.

Discussion

It could be argued that the ratio k_H/k_D reflects the balance of bond-breaking and bond-making in a chemical solvolytic reaction which proceeds by a process characterized by one activation barrier/transition state. In these terms the data require that there is a larger degree of bond-breaking or charge-separation in the *p*-methyl derivative than in the *m*-CF_3 derivative, yet the latter is the less reactive by a factor of 5.7×10^3 at 25°C. With decrease in ionizing power of solvent, the same model suggests that less bond-breaking is required at the transition state for the *p*-Me derivative. In contrast the ratio k_H/k_D for the less reactive *m*-CH_3 derivative is insensitive to solvent composition. The difference between these trends for *m*-CF_3 and CH_3 derivatives must be contrasted with the insensitivity of the kinetic solvent isotope effect on addition of acetonitrile. Clearly the kinetic solvent isotope effect for reaction in the pure solvents does not stem from the inherent differences between the structural properties of the H_2O and D_2O. If this were so, we would anticipate that the solvent isotope effect would diminish when acetonitrile is added. The difficulties in the interpretation outlined above stem from the hypothesis (9) which argues that nucleophilic driving forces lower the activation energy for the displacement process by reducing the large heterolytic gas phase enthalpies to thermally available energies in solution. Thus even direct reactions of nucleophiles with triarylcarbonium ions require an activation energy although *no* bonds are broken and *no* incoming group/leaving group repulsions are present (10, 11).

The above arguments lead us to propose a different model for these reactions which is consistent with the observed α-deuterium and solvent isotope effects. The solvolytic reaction in water is treated in terms of a two-stage process along the lines visualized by Albery and Robinson (12), by Sneen (13), and by our recent calculations (8) concerning the dependence of rate constants on temperature. In these terms, the experimental rate constant is a function of parameters (8, 12) describing the formation of an intermediate and its subsequent chemical reaction with the solvent. The formation of the intermediate involves charge separation within the C—X bond; the intermediate is stabilized by solvation interactions. At this stage the charge separation is incomplete. Interaction of the intermediate with water leading to initiation of bond-making necessitates some critical level of positive charge being localized on the reacting carbon in the *subsequent* transition state. Further, the degree of bond separation at the transition state depends on the substrate. The small kinetic solvent isotope effect arises from the fact that the water nucleophile is reactant-like at the transition state. However, for different substrates, the C—X distance at the transition state is characteristic of the substrate. Subsequent reorganization leading to products occurs beyond the transition state and is not kinetically significant. The variation of the α-*d* ratios is a consequence of varying degrees of separation of the incipient anion at the transition state. Hence across a range of related substrates, this distance will change, resulting in a different k_H/k_D ratio and, more importantly, in different sensitivities to added cosolvent.

Clearly, the level of charge localized on the reacting carbon at the transition state is an important parameter in relation to the initiation of nucleophilic attack. The ability of the carbonium ion to disperse positive charge will be reflected in greater separation of the heterolysing fragments before the required level of charge at the reacting carbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

is attained. This hypothesis is consistent with Ritchie's observations (10). Triarylcarbonium ions which are efficient at delocalizing charge react the slowest. Indeed the barrier in these reactions may largely reflect the energy required to "relocalize" the charge in these highly delocalized systems. For any comparable level of bond extension the smaller charge on the reacting extracyclic carbon atom results in a greater separation of charges in, for example, *p*-methylbenzyl nitrate relative to the *m*-trifluoromethyl substrate.

Experimental

The substituted benzyl chlorides and nitrates were prepared as described by Koshy and Robertson (6, 14). As a further refinement after reduction of the corresponding acids, the alcohols were purified by a zone–freeze–melt operation. Where comparison was possible (for hydrolysis in water), agreement with the rate constants calculated from the Valentiner constants reported by Koshy was excellent.

Acetonitrile was reagent grade and solutions were made up to the indicated composition with distilled water.

The rates were determined by conductance as described by Robertson and Sugamori (15). Temperatures were determined using a platinum resistance thermometer. The isotope effects were determined in pairs of cells run simultaneously, and so the effect of temperature variation was minimized. The rate constants were calculated by a Moore-type equation (16) which uses a nonlinear least-squares procedure coupled with an iterative calculation, the latter refining an estimated rate constant for the reaction.

Rates of OH radical reactions. VII. Reactions of OH and OD radicals with n-C_4H_{10}, n-C_4D_{10}, H_2 and D_2, and of OH with *neo*-C_5H_{12} at 297 K[1]

GEORGE PARASKEVOPOULOS AND WING S. NIP[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received June 5, 1980

GEORGE PARASKEVOPOULOS and WING S. NIP. Can. J. Chem. **58**, 2146 (1980).

Absolute rate constants of hydrogen and deuterium atom abstraction by OH and OD radicals from n-C_4H_{10}, n-C_4D_{10}, H_2 and D_2, and by OH radicals from *neo*-C_5H_{12} have been measured at room temperature in the gas phase using the flash photolysis-resonance absorption technique. The rate constants in units of $cm^3\ mol^{-1}\ s^{-1}$ were found to be:

$k_{OH+n\text{-}C_4H_{10}} = 1.61 \pm 0.13 \times 10^{12}$ $\quad$ $k_{OH+neo\text{-}C_5H_{12}} = 5.48 \pm 0.59 \times 10^{11}$

$k_{OH+n\text{-}C_4D_{10}} = 4.20 \pm 0.41 \times 10^{11}$ $\quad$ $k_{OH+D_2} = 1.27 \pm 0.11 \times 10^{9}$

$k_{OD+n\text{-}C_4H_{10}} = 1.66 \pm 0.13 \times 10^{12}$ $\quad$ $k_{OD+H_2} = 3.70 \pm 0.25 \times 10^{9}$

$k_{OD+nC_4D_{10}} = 4.84 \pm 0.38 \times 10^{11}$ $\quad$ $k_{OD+D_2} = 1.33 \pm 0.13 \times 10^{9}$

The quoted errors are the 95% confidence limits. A kinetic isotope effect was observed when hydrogen was replaced by deuterium in the paraffin and H_2, whereas there was no significant effect when OH was replaced by OD.

GEORGE PARASKEVOPOULOS et WING S. NIP. Can. J. Chem. **58**, 2146 (1980).

Les constantes de vitesse absolues pour l'abstraction d'atomes d'hydrogène et de deutérium de n-C_4H_{10}, n-C_4D_{10}, H_2 et D_2 par les radicaux OH et OD, et d'atomes d'hydrogène de *néo*-C_5H_{12} par OH, ont été mesurées en phase gazeuse, à température ambiente. Les radicaux OH et OD sont produits par photolyse-éclair et détectés par spectrométrie d'absorption de résonance. Les constantes de vitesse en unités de $cm^3\ mol^{-1}\ s^{-1}$ sont:

$k_{OH+n\text{-}C_4H_{10}} = 1.61 \pm 0.13 \times 10^{12}$ $\quad$ $k_{OH+neo\text{-}C_5H_{12}} = 5.48 \pm 0.59 \times 10^{11}$

$k_{OH+n\text{-}C_4D_{10}} = 4.20 \pm 0.41 \times 10^{11}$ $\quad$ $k_{OH+D_2} = 1.27 \pm 0.11 \times 10^{9}$

$k_{OD+n\text{-}C_4H_{10}} = 1.66 \pm 0.13 \times 10^{12}$ $\quad$ $k_{OD+H_2} = 3.70 \pm 0.25 \times 10^{9}$

$k_{OD+n\text{-}C_4D_{10}} = 4.84 \pm 0.38 \times 10^{11}$ $\quad$ $k_{OD+D_2} = 1.33 \pm 0.13 \times 10^{9}$

Les écarts correspondent au niveau de confiance de 95%. On observe un effet isotopique sur les constantes de vitesse lorsque le deutérium substitue l'hydrogène dans n-C_4H_{10} et H_2 mais le remplacement de OH par OD ne produit aucune variation significative de ces constantes.

Introduction

Hydroxyl radical reactions play an important role in combustion and atmospheric chemistry and therefore there is a need for accurate values of their kinetic parameters for use in numerical modeling of these processes. Hydrogen abstraction rate data for the reactions of OH and OD with paraffins and deuterated paraffins are also of fundamental interest to chemical kinetics in that they may provide insights into the reactivity of OH radicals and may enable eventual prediction of the rate constants of such reactions.

In the present paper, which is part of a program of kinetic studies of OH radical reactions, we report absolute rate constants at 297 K for the reactions of OH and OD with n-C_4H_{10}, n-C_4D_{10}, H_2 and D_2, and of OH with *neo*-C_5H_{12}, measured in the gas phase using the flash photolysis – resonance absorption technique. Rate constants from previous studies have been reported only for the reactions of OH with n-C_4H_{10} (1), *neo*-C_5H_{12} (1), and D_2 (2–4); there have been no measurements for the other reactions studied in this work.

Experimental

The apparatus and experimental technique have been described in detail before (5, 6) and will be mentioned here briefly. The apparatus consists of a fast flash photolysis system coupled to a spectrophotometric detection system. The OH and OD concentrations were monitored by following the time-resolved attenuation of the OH or OD resonance radiation (Q_1^3 rotational line at 308.15 nm for OH and Q_1^5 rotational line at 307.60 nm for OD, of the (0,0) band of the $A^2\Sigma^+ \rightarrow X^2\Pi$ transition) produced by a microwave discharge in a flowing low pressure Ar/H_2O or Ar/D_2O mixture. The radiation was detected with a photomultiplier (EMI 9783B) mounted on the exit slit of a 1 m Czerny-Turner monochromator (Jarrell-Ash). The signal was amplified, filtered, recorded in digital form and accumulated in a signal averager from which it was transferred to an on line PDP 11/10 minicomputer for further processing (5, 6). Signal averaging improved the signal-to-noise ratio and rates in the range (0.5–6) $\times 10^4\ s^{-1}$ were measured using 16 to 48 flashes.

The OD (0,0) band has been analyzed by Clyne *et al.* (7). The

emission spectrum of the OD (0,0) band from our resonance lamp is shown in Fig. 1. Experiments, in which different low partial pressures of D_2O in He were flashed at constant flash energy (150 J), showed the expected logarithmic dependence of the maximum OD absorption (which in the absence of another reactant corresponds to the initial OD absorption (5, 6)) on the pressure of D_2O for absorptions of up to 30%, indicating that Beer's law is obeyed in this range. Our rate measurements were made at initial absorptions in the range 4 to 15%.

Two sources of OH/OD radicals were used in this work. The flash photolysis of small pressures (0.3–0.6) Torr of H_2O or D_2O at the vacuum uv ($\lambda > 165$ nm) was used with H_2, D_2, and *neo*-C_5H_{12} which are transparent at this wavelength. For these conditions the initial OH/OD concentration estimated approximately from the initial absorption of the OH/OD resonance radiation (5, 6) was (4–8) $\times 10^{-11}$ mol cm^{-3}. With the butanes, however, which absorb very weakly at 165 nm (8) and may be photodissociated, we used the flash photolysis of N_2O/H_2 or N_2O/D_2 mixtures with light of wavelength $\lambda > 200$ nm as a source of OH/OD. (A filter 8 mm deep of O_2 at 600 Torr eliminated radiation below 200 nm.) This technique, in which $O(^1D)$ atoms from the photolysis of N_2O react rapidly with H_2 or D_2 to give OH or OD radicals, has been used before in this laboratory and is described in more detail in ref. 9. The OH/OD concentration was estimated (9) to be $\sim(1–2) \times 10^{-11}$ mol cm^{-3}, i.e. about 4 to 8 times lower than that from the photolysis of H_2O/D_2O. From the relative rates of the reactions of $O(^1D)$ with H_2 (10), D_2 (11), N_2O (12), and *n*-C_4H_{10} (13), and the concentrations used (see Table 1 below), we estimated that virtually all the $O(^1D)$ atoms will react with H_2 or D_2 and not with N_2O or the butanes.

The materials used were of the highest available purity (generally 99.95–99.999%) and with the exception of H_2, D_2, and He were thoroughly degassed before use. Mass spectrometric analysis of *n*-C_4D_{10} and D_2 confirmed the stated minimum D atom content of >98% and >99.5% respectively. The N_2O, Matheson 98%, was used after degassing and bulb-to-bulb distillation *in vacuo* in which only the middle fraction was retained.

Results and Discussion

Various aspects of the experimental conditions, procedure, and treatment of the data are given in refs. 5 and 6. The concentration of the other reactant [RH] was always much greater than the initial OH concentration so that the reaction was pseudo first order. The pseudo first order rate constant, k_I, was obtained from the linear plots of ln [OH] against time as described before (5, 6).

For the experiments in which OH was formed by photolysis of H_2O or D_2O, the values of k_I obtained over a range of [RH] concentrations are related to the second order rate constant, k_{II}, by the equation $k_I = \alpha + k_{II}[RH]$ (5, 6). Representative plots of k_I against [RH] for the reactions of OD with H_2 and D_2 are shown in Fig. 2. The second order rate constants, k_{II}, were obtained from the slopes of these plots by weighted least square fits, as described before (5, 6). The measured values of k_{II} for the reactions of OH with D_2 and *neo*-C_5H_{12} and of OD with H_2 and D_2 together with the experimental conditions are given in Table 1.

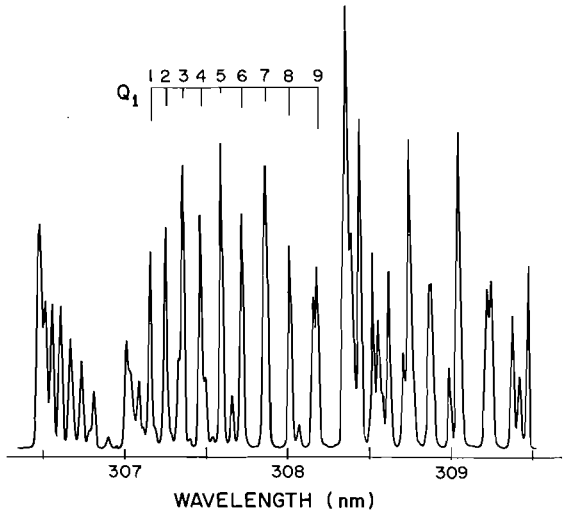

FIG. 1. Emission spectrum of OD (0,0) band of the $A^2\Sigma^+ \rightarrow X^2\Pi$ transition.

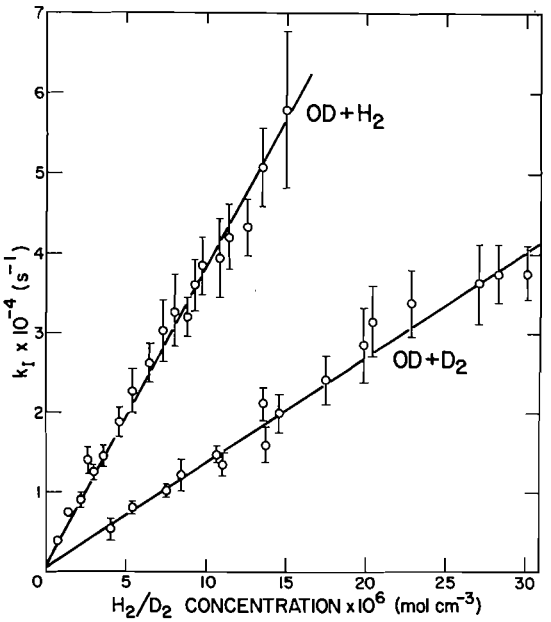

FIG. 2. Plot of the pseudo first order rate constant, k_I, against the concentration of H_2 and D_2 for the reactions of OD with H_2 and D_2.

For the experiments in which OH was produced by photolysis of N_2O/H_2, N_2O/D_2 mixtures, the values of k_I measured at constant $[H_2]$ concentration and over a range of [RH] concentrations are related to the second order rate constants k_{II} of H_2 and RH by the equation (9)

$$k_I = k_{II}^{(H_2)}[H_2] + k_{II}^{(RH)}[RH]$$

TABLE 1. Measured values of the second order rate constants, k_{II}, at 297 ± 2 K[a]

Reaction	k_{II}[b] (cm^3 mol^{-1} s^{-1})	Number of experiments
OH + *neo*-C_5H_{12}	$5.48 \pm 0.59 \times 10^{11}$	26
OH + D_2	$1.27 \pm 0.11 \times 10^9$	17
OD + H_2	$3.70 \pm 0.25 \times 10^9$	20
OD + D_2	$1.33 \pm 0.13 \times 10^9$	16
OH + *n*-C_4H_{10}	$1.61 \pm 0.13 \times 10^{12}$	14
OH + *n*-C_4D_{10}	$4.20 \pm 0.41 \times 10^{11}$	14
OD + *n*-C_4H_{10}	$1.66 \pm 0.13 \times 10^{12}$	11
OD + *n*-C_4D_{10}	$4.84 \pm 0.38 \times 10^{11}$	11

[a]The experimental conditions were as follows: flash photolysis of H_2O or D_2O; $H_2O/D_2O \approx$ (0.3–0.6) Torr, [OH] ≈ (4–8) × 10^{-11} mol cm^{-3}, (4–8) flashes of 150 J per mixture. Flash photolysis of N_2O/H_2 or N_2O/D_2; the ratios N_2O/H_2 and N_2O/D_2 were constant and equal to 0.1 (i.e., in mol cm^{-3} $[N_2O] = 2.7 \times 10^{-7}$, $[H_2] = 2.7 \times 10^{-6}$, and $[N_2O] = 5.4 \times 10^{-7}$, $D_2 = 5.4 \times 10^{-6}$) [OH] ≈ (1–2) × 10^{-11} mol cm^{-3}, 1 flash of 150 J per mixture.
[b]The indicated uncertainties are the 95% confidence limits calculated from the standard deviation and Students *t* distribution (14).

Plots of k_I against [RH] for the reactions of the butanes are shown in Fig. 3. The values of $k_{II}^{(RH)}$ (slope) and $k_{II}^{(H_2)}[H_2]$ (intercept) were obtained by weighted least square fits of the equation above to the data (9). The k_{II} values for the butanes and the experimental conditions are given in Table 1. The average values of the intercepts for the reactions of OH and OD are:

$$\text{Intercept}_{(OH)} = k_{II}^{(H_2)}[H_2] = 1.02 \pm 0.10 \times 10^4 \text{ s}^{-1}$$

$$\text{Intercept}_{(OD)} = k_{II}^{(D_2)}[D_2] = 0.756 \pm 0.080 \times 10^4 \text{ s}^{-1}$$

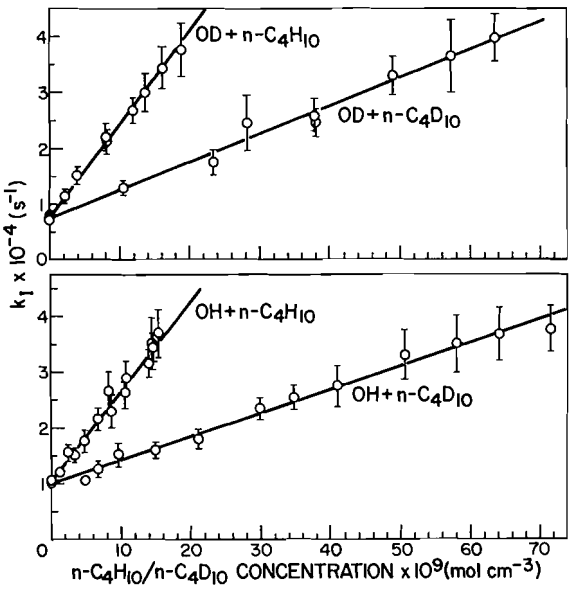

FIG. 3. Plots of the pseudo first order rate constant, k_I, against the concentration of the butanes for the reactions of OH and OD with *n*-C_4H_{10} and *n*-C_4D_{10}.

from which we calculate the second order rate constants for OH + H_2 and OH + D_2 to be in cm^3 mol^{-1} s^{-1}, $k_{II}^{(H_2)} = 3.78 \pm 0.37 \times 10^9$ and $k_{II}^{(D_2)} = 1.40 \pm 0.15 \times 10^9$ which agree well with our previous and present direct determinations of $3.5 \pm 0.16 \times 10^9$ (5) and $1.33 \pm 0.06 \times 10^9$ for OH + H_2 and OH + D_2 respectively; the uncertainties are 1 standard deviation.

In the experiments with H_2, D_2, and neopentane a variation of the OH/OD concentration by a factor of 5–10 effected by varying both the pressure of H_2O (0.2–2) Torr and the flash energy (30–350) J did not change the measured rates within the experimental error, indicating that there is no significant interference from secondary reactions of OH/OD radicals with the products of the primary reaction (5, 6). The same is true, of course, for the reactions of the butanes for which we used OH concentrations 4–8 times lower than with neopentane.

The total pressure was 50 Torr for the experiments with the butanes and 150 Torr (made up with He) with neopentane. It was demonstrated, by varying the total pressure, that the measured rate constants were independent of pressure.

Comparison of Rate Constant Values

As mentioned in the Introduction, rate constants have been reported only for the reactions of OH with *n*-C_4H_{10}, *neo*-C_5H_{12}, and D_2. All rate constants quoted below are in units of cm^3 mol^{-1} s^{-1}. For *n*-C_4H_{10} our value ($1.61 \pm 0.13 \times 10^{12}$) agrees very well with those measured by Greiner (15) ($1.55 \pm 0.10 \times 10^{12}$), Stuhl (16) ($1.42 \pm 0.21 \times 10^{12}$), and Perry *et al.* (17) ($1.64 \pm 0.16 \times 10^{12}$). It also agrees within the large error limits with the relative values determined by Gorse and Volman (18) and Campbell *et al.* (19); these, however, depend on the rate constant of the reference reaction OH + CO which has been found to be pressure dependent (20). On the other hand the value of Gordon and Mulac (21) ($2.54 \pm 0.10 \times 10^{12}$) and of Morris and Niki (22) (2.45×10^{12}) are significantly higher (~50%) than all the other determinations. In view of the good agreement among the majority of the data from very different experimental techniques and conditions, a value of $k_{n\text{-}C_4H_{10}} = 1.6 \pm 0.2 \times 10^{12}$ cm^3 mol^{-1} s^{-1} is recommended for use in photochemical air pollution models.

Our value for *neo*-C_5H_{12} ($5.48 \pm 0.59 \times 10^{11}$) lies between the absolute value of Greiner (15) ($4.97 \pm 0.28 \times 10^{11}$) and the relative value (reference reaction OH + *n*-butane) reported by Darnall *et al.* (23) ($6.26 \pm 1.02 \times 10^{11}$); it agrees well with both within the experimental uncertainty.

TABLE 2. Kinetic isotope effect; relative values k_H/k_D and k_{OH}/k_{OD} for the reactions of OH and OD with H_2, D_2, n-C_4H_{10}, and n-C_4D_{10}

Reaction	k_H/k_D
OH + H_2 (D_2)	2.75[a]
OD + H_2 (D_2)	2.78
OH + n-C_4H_{10} (n-C_4D_{10})	3.83
OD + n-C_4H_{10} (n-C_4D_{10})	3.43

Reaction	k_{OH}/k_{OD}
H_2 + OH (OD)	0.94[a]
D_2 + OH (OD)	0.95
n-C_4H_{10} + OH (OD)	0.97
n-C_4D_{10} + OH (OD)	0.87

[a]The value of $k_{OH+H_2} = 3.49 \pm 0.16 \times 10^9$ was taken from our earlier determination by the same technique (5).

Finally, there is excellent agreement among all the reported rate constants for OH + D_2, i.e., this work ($1.27 \pm 0.11 \times 10^9$), Greiner (2) ($1.27 \pm 0.16 \times 10^9$), Stuhl and Niki (3) ($1.24 \pm 0.18 \times 10^9$), and Smith and Zellner (4) ($1.32 \pm 0.24 \times 10^9$).

Kinetic Isotope Effect

Table 2 lists the ratios k_H/k_D and k_{OH}/k_{OD} at room temperature for the reactions studied. A kinetic isotope effect was observed when hydrogen was replaced by deuterium in the paraffin and H_2 whereas there was no significant effect when OH was replaced by OD. Similar isotope effects have been reported for hydrogen atom abstraction by OH and OD radicals from CH_4 and C_2H_6 (2) and by CH_3 and CD_3 radicals from H_2 and D_2 (24).

Acknowledgment

The authors wish to thank Dr. R. Overend who participated in the early measurements with neopentane.

DONALD S. GAMBLE. Can. J. Chem. **58**, 2150 (1980).

A potentiometric titration method of measuring accurate H^+ concentrations is demonstrated for aluminum orthophosphate solutions. A calibration procedure has been used which permitted the glass electrode to be used as a concentration probe instead of as a quasi-activity probe. The random error "background noise" has been reduced by the use of Fortran computing for chemical calculations, data handling and sorting, and averaging by least squares polynomial fits. The distribution of experimental errors along the sample titration curve is indicated by estimates for its various regions.

DONALD S. GAMBLE. Can. J. Chem. **58**, 2150 (1980).

On démontre une méthode de titrage potentiométrique qui permet de mesurer avec précision les concentrations en ions H^+ des solutions d'orthophosphate d'aluminium. On a utilisé un procédé d'étalonnage qui permet d'employer une électrode de verre comme sonde de concentration et non comme sonde de quasi activité. On a réduit l'erreur fortuite due au bruit de fond en utilisant la méthode Fortran pour les calculs chimiques et la manipulation des données pour trouver les moyennes par la méthode des moindres carrés. La distribution des erreurs expérimentales le long de la courbe de titration de l'échantillon est indiquée par des évaluations faites pour ses différentes sections.

Introduction

The reactions of orthophosphate with Al^{III} have been extensively investigated because of their importance to soil fertility and environmental quality (1–5). The existing literature is largely concerned with the preparation and properties of solid products, however, with very limited success having been reported for the investigations of solution species. A number of authors found evidence of solution complexes, but were unable to determine their chemical compositions or stability constants (6–12). In 1931 Bjerrum and Dahm were able to estimate the orders of magnitude for stability constants, only by postulating some solution complexes (6).

A fuller understanding of these reactions will require that solution or colloidal sol species, and solid products, be investigated together. The hydrogen ion is a key chemical reactant governing the composition of the solutions or colloidal sols, and the glass pH electrode is one of the few suitable probes available. Veith, for example, has used the inflection points in the pH titration curves of aluminum orthophosphate samples for determining the stoichiometric composition of precipitates (12). A rare and important precedent for the present Al^{III} orthophosphate investigations is the work of Childs (13). He applied glass electrode measurements of H^+ concentrations to the study of metal ion orthophosphate species in solution. Al^{III} was not included in his work, however.

It is now evident that in addition to titration equivalence points, investigations of solution species in systems such as the present one require accurate measurements of H^+ concentrations. A number of authors have pointed out or demonstrated this same requirement for various chemical problems (14–27). A concentration probe is evidently required. When used for conventional pH measurements, however, the glass electrode is instead a quasi-activity probe. This has been emphasized by the discussions of Irving *et al.* (17), McBryde (19, 28), Hedwig and Powell (23), and Bates (18). There are four fundamental reasons for this.

The first three of these are the systematic errors described in the literature. These include the activity coefficient and liquid junction potential effects, and as emphasized by Bates (18), the unknown relationship of standard buffer systems such as that of the U.S. National Bureau of Standards to Lewis and Randall standard states. Relatively high concentrations are usually used for the constant ionic strength method of minimizing or fixing the magnitudes of these systematic errors (18, 19, 23, 28, 29). Investigations of soil solutions and fresh surface waters require that a low ionic strength procedure also be developed.

The practical importance of the fourth type of error has been less widely recognized. Gamble has observed two categories of random errors in the H^+ concentration measurement of acid–base titration curves (22, 24, 25). These were the random scatter within a run, and the randomly occurring biases found in any collection of replicate runs. These errors can be appreciable, and Childs (20), for

example, has reported an error in a calibration constant for his H^+ concentration measurements of ± 0.04 log unit. This translates to an error of $\pm 9.7\%$.

Any investigation of the solution or colloidal sol chemical species will require a sequence of chemical calculations. Since such calculations tend to magnify and accumulate the original errors of measurement, the four types of errors may seriously restrict the interpretation of calculated results. The objective of this work is therefore to develop and demonstrate a potentiometric titration method of measuring H^+ concentrations in aqueous Al^{III} orthophosphate systems. It is intended that such titration curves be used for future investigations of the solution or colloidal sol species in low ionic strength systems. The chemical calculations required for this purpose make it necessary that the above four types of errors be minimized.

Experimental Work

Equipment

1, Orion model 801 digital pH meter, with a Metrohm micro combination pH electrode, model EA 147; *2*, 5.000 mL microburett in a constant temperature room at 23.0 ± 1°C; *3*, 150 mL thermostatted titration beaker, fitted with a magnetic stirrer and N_2 flow fittings; *4*, constant temperature bath, at 25.000 ± 0.005°C; *5*, Perkin Elmer 124 UV–visible spectrophotometer and 1 cm quartz cells.

The combination electrode, pH meter, and connecting cables were shielded, grounded, and free from field effects (30).

Chemicals

Water was redistilled under N_2. The 0.1 *N* NaOH was Fisher Certified Sodium Hydroxide Solution, Lot 784814. The concentration specified by Fisher is 0.1000 within the outer limits of ±0.2%. A check against U.S. National Bureau of Standards Acid Potassium Phthalate Standard Sample 185d verified the concentration to within 0.1%. All other chemicals were of reagent grade.

Standard Stock Solutions

A calibration solution containing H_3PO_4 and NaCl, and an experimental stock solution containing $AlCl_3$ and H_3PO_4 were prepared gravimetrically from NaCl crystals and from analysed stock solutions. H_3PO_4 analysis was by titration end point, while Al^{III} analysis was done by the 8-hydroxyquinoline photometric method. J. T. Baker "Dilute-it" Aluminum Standard was used for the analysis. Aliquots (100 g) of these Standard Stock Solutions were used for calibration and sample titrations.

Instrument Calibration Titrations

An instrument calibration titration was run before each experimental sample titration. Each of the calibration titrations had 70 to 80 data points, with voltage readings being taken 1 min after the additions of standard base. The experimental conditions for calibration are given in Table 1. The volume increments of standard base listed there were arranged according to the shape of the calibration curve. The purpose of this was to optimize the density and distribution of data points along the curve. This is especially important at the first orthophosphate equivalence point, where the curve drops steeply between 0.185 and 0.070 V. Without careful planning there would be serious gaps in the calibration curve. A related procedure has been found in the literature. The limited use of acetic acid titrations for H^+ concentration calibrations was reported by Rajan and Martell in 1964 (26).

Experimental Sample Titration

Sample solutions initially contained 0.722×10^{-3} *m* total orthophosphate, 0.751×10^{-3} *m* total Al^{III}, and 2.253×10^{-3} *m* Cl^-. Aliquots (10.000 g) were titrated with the 0.1 *N* standard NaOH at 25.00°C. Voltage readings were taken 1 min after additions of standard base. A typical sample run had 56 V vs. mL data points. In contrast to the calibration titrations, the sample titrations had volume increments of titrant constant at 0.05 mL.

Data Processing and Calculations

The raw data consist of potentiometric titrations of orthophosphoric acid calibration solutions, and of experimental sample solutions. A typical experiment is shown in Fig. 1, with the calibration conditions being given in Table 1. Random error "background noise" was reduced by averaging a substantial amount of data from four replicate experiments. The production of an averaged sample titration curve in H^+ molalities from four or more experiments in this way requires a considerable amount of data processing and chemical calculations. These have been programmed in Fortran IV, and are done in five stages: *1*, the calculation of H^+ molalities for the orthophosphoric acid instrument calibration titrations; *2*, the sorting of the calibration data into a series of curves having decade ranges of H^+ molalities; *3*, the matching of experimental sample data to the Decade Range calibration curves; *4*, the production of H^+ molality vs. mL data points for sample titration curves; *5*, final averaging by the method of least squares, to produce an averaged sample titration curve.

Two Fortran programs were used for the present work, the first of which executed the first four stages. The first stage of the computing requires that the first two orthophosphoric acid dissociation equilibria be known as functions of total orthophate concentration, at the experimental temperature. Experimental data from the literature (31–36) have been recalculated to give the equilibrium concentration quotients on the molal scale, K_1 and K_2, as polynomials in C_p, total orthophosphate concentration. Although a separate investigation of K_1 and K_2 is in progress, the essential features of the calculations can be outlined here. The calculations were based on the original electrochemical measurements of Bates (31), Nims (32), and Lugg (33), with hydrogen and Ag–AgCl electrodes in cells without liquid junctions. The unsurpassed quality of these data makes them uniquely valuable for instrument calibration. Bates correctly pointed out at the time of publication that the lack of suitable

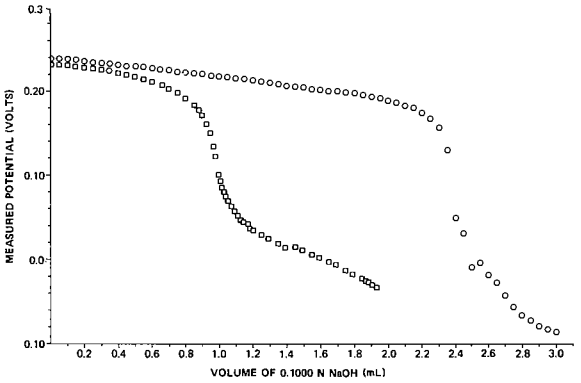

FIG. 1. The calibration and sample titration curves of a typical experiment. See Table 1 and the text for the experimental conditions. ⊡, calibration run. ⊙, experimental sample run.

activity coefficient data precluded the calculation of concentration quotients. Subsequent developments have since made such calculations feasible. First, McBryde (28) has suggested that Debye–Hückel calculations are a reasonable approximation for ionic strengths up to 0.1 *M*. Secondly, Elmore *et al.* (35) have concluded from their comparison of experimental methods that for constant ionic strengths up to almost 1 *m*, $\gamma_{\pm} = (\gamma_H\gamma_{Cl})^{1/2}$ has the same values in orthophosphate–chloride mixed solutions as in HCl solutions. It is proposed that these rather high concentration limits given by McBryde and by Elmore *et al.* are excellent justification for the use of the published HCl $\gamma_{\pm}$ values of Harned and Owen (36) in orthophosphate–chloride solutions of approximately 10^{-3} *m*. It has also been assumed that the experimental $\gamma_{\pm}$ values are preferable to the theoretical calculations. The resulting polynomials are used as input for the first Fortran program. The K_1 and K_2 polynomials have been prepared for use within the orthophosphate range $0 < C_p < 2 \times 10^{-3}$ *m*. The present work is confined to orthophosphate concentrations less than 1×10^{-3} *m*. The changes in the first and second H^+ dissociation equilibria are nonetheless significant. Over the range $0 < C_p < 1 \times 10^{-3}$ *m*, K_1 increases 6.9% with increasing C_p, while the increase for K_2 is 17.8%.

The calibration data are sorted into Decade Ranges of H^+ molality, for the purpose of optimizing the quality of the least squares fits. If too wide a range of values is fitted, then the manipulation of the normal equations results in the calculation of small differences between relatively larger numbers. This can give unreliable values for the H^+ molality vs. volts polynomial coefficients (37).

Stages 3 and 4 of the computing calculate H^+ molalities for experimental sample titrations, from experimental volts and the fitted Decade Range calibration curves. Each calibration curve is generally fitted to a set of polynomials up to the sixth degree.

The calibration polynomials having the best fits were chosen from the printout of the first Fortran IV program. Table 2 lists the computing results for the selection of Decade Range instrument calibration curves, and their use for the calculation of H^+ molalities in the sample titrations. The last column in Table 2 gives the numbers of sample titration data points used with each Decade Range calibration curve for the calculation of the sample H^+ molalities. These numbers resulted from the computerized matching of sample data to the calibration curves.

Stage 4 of the computing averages the calibration data, but leaves the experimental sample data unaveraged. This is done in the last stage, using the second Fortran IV program. The Stage 5 computing is summarized in Table 3. For this final averaging in Stage 5, the experimental sample titration curve was fitted in four sections. These sections were chosen as seen in Tables 3 and 4 according to the shape of the titration curve and the ranges of m_H values. The reason for doing this was again to achieve the best least squares fits to polynomials. These sections were made to overlap, and the fitted polynomials used were those that give the lowest standard deviations consistent with agreement of values at the overlaps. The results are listed in Tables 3 and 4. The overlap values have been averaged in Table 4.

The two Fortran programs, labelled TE17 and TE04, are available from the Depository of Unpub-

lished Data.[1] Descriptions of the programs are included. The orthophosphoric acid data required as input for TE17 are attached to it.

Results and Discussion

The Quality of the Titration Curve

The experimental objective has been achieved with the aluminum orthophosphate titration curve shown in Fig. 3. Table 4 lists it in digital form, for use in future calculations. The ionic strengths are relevant to soil solutions and fresh surface waters. The high ionic strength procedures found in the literature are not applicable to these cases, but instead are most properly used for such systems as blood and sea water.

Activity coefficient and liquid junction potential effects, which contribute systematic errors, have been minimized. Exact calculations of activity coefficient errors are not practical, because of the lack of the required data for these mixed solutions. Considering the compositions given in Table 1 and the text for calibration and sample solutions, however, it is inferred from the data of Harned and Owen (36) and Robinson and Stokes (38) that the activity coefficient errors should have an upper limit of about 1%. In comparison, Feldman has reported that H^+ concentrations estimated from conventional pH measurements may have errors of 10% to 25% (29). By using some measurements by Harned (39), Feldman has also given estimates of liquid junction potentials. From the application of his estimates to the present experimental work, it is concluded that the liquid junction potential errors

[1]Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

in the titration curve are about 0.1% to 0.2%. Somewhat more important than these systematic errors are the random errors from the glass electrode measurements. Two typical sample titration runs in Fig. 2 illustrate the titration curve biases. In addition to the random scatter within a run, a set of replicate runs shows these biases also to be random. This random error "background noise" has been averaged out by the method of least squares. The details given in Tables 2 and 3 and Fig. 2 are quite consistent with earlier work done with a humic polyelectrolyte (22, 24, 25). The final result is the averaged titration curve given in Table 4. Its shape is shown in Fig. 3. The total errors in Table 4 have been estimated from the calibration and sample data of Tables 2 and 3.

It is evident from the error estimates in Table 4 that the part of the titration curve which may be used for detailed chemical calculations includes the region from 1×10^{-5} *m* down to 1×10^{-7} *m* H^+. This region of the curve is very important to natural systems such as soil solutions. The calibrations for this region reported in the earlier work were unsatisfactory (22, 24, 25). The orthophosphoric acid calibration has made a substantial improvement, with data gaps being avoided. The range of H^+ concentrations between 1×10^{-7} *m* and 1×10^{-8} *m* is also of great practical interest. Unfortunately, the errors of measurement become large here. The uses of the fourth section of the curve in Table 4 will be limited to preliminary and semiquantitative estimates of chemical properties. The reason for this indicated by the data of Tables 2 and 3 is poor electrode response in the potential region of 0.0 to −0.06 V. Although this disturbing result remains generally unrecognized, evidence of it has persisted in the literature for more than forty years (13, 16, 19, 23, 24, 28, 40, 41). For example, earlier titrations with fulvic acid had an average error of ±30%, in the region 1×10^{-5} to 1×10^{-9} *m* H^+ (24). Hedwig and Powell (23), Childs (20), and Tanford (40) have all reported unsatisfactory glass electrode measurements in this concentration range. As long

ago as 1935, Ellis and Kiehl found the problem to be greatest in pure water of low conductivity (41). They postulated the generation and slow dissipation of electric charges.

Properties and Significance of the Titration Curve

The titration curve is intended for use in future work, for detailed chemical calculations and interpretation. This will require that the precipitation which gradually develops during the titration be characterized.

It is anticipated that some unknown number of chemical species will exist, including Al^{III}, orthophosphates, and aluminum orthophosphates. Their physical states might include true solution, colloidal sol, and the precipitate in physical suspension. Some sort of true or metastable equilibrium distribution of H^+ among these chemical species and physical states is also expected. It should be recognized that this phenomenon partly controls the solution phase concentrations of H^+, but does not interfere with its measurement by the electrode system. It is in fact seen as potentially the basis of a method for characterizing the system. Pending such future work, some important features of the titration curve may be examined immediately.

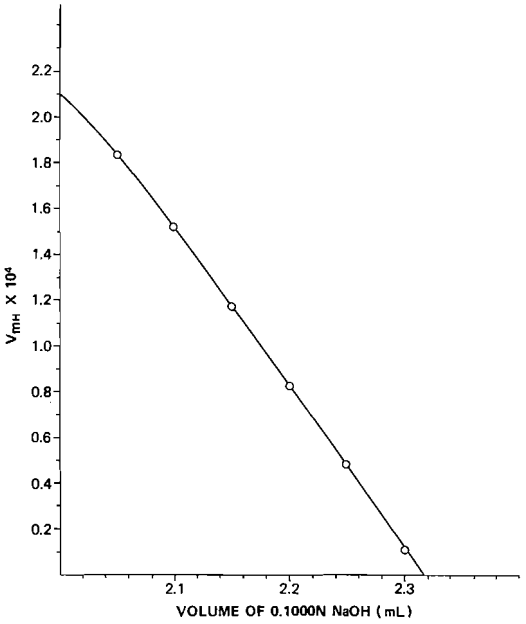

FIG. 4. Gran's plot for the averaged titration curve of Fig. 3. First equivalence point at 2.320 mL of 0.1 *N* standard NaOH.

The first feature to note is the sharp break in the curve, seen in Fig. 3 just beyond 2.3 mL. A very definitive Gran's plot was obtained for this break, indicating an equivalence point of 2.320 mL of 0.1 *N* standard base. This corresponds to 3.214 mol of H^+ per mole of total orthophosphate and 3.090 mol of H^+ per mole of total Al^{III} (= ±0.2%). Gran originally proposed his function in the form $V \times 10^{k - pH}$ (42). With the titration curve in terms of H^+ molalities, this reduces to the simpler form Vm_H. This is seen in Fig. 4.

The next feature of the curve is a low "bump" between 1.6 and 1.8 mL, in Fig. 3. Although this shape is quite subtle, two important observations concerning it may be made in Fig. 2. The first is that this curve shape is reproduced in each of the replicate runs. In addition, it does not reflect any structural feature of the calibration curves. It is therefore postulated that this effect is real. It may be

related to the onset of precipitation, since turbidity first appears in this part of the titration.

A third characteristic is noted between 2.3 and 2.5 mL. The low slope indicates relatively greater buffering, which may also be related to precipitation.

The Advantages and Limitations of the Experimental Method

Earlier versions of this potentiometric method have been used for fulvic acid, which is a purely organic polyelectrolyte. A more developed version has now been demonstrated for a totally inorganic system. This potentiometric titration procedure is therefore proposed as a quite general experimental method. It is possible that in future investigations of the acidic properties of samples, experimentalists might want to consider determining their own K_a concentration quotients for the calibrating weak acid. Two existing procedures for converting the glass electrode to a concentration probe are based on the use of known concentrations of strong acids, and could be employed in the evaluation of such reference K_a values. In one of these (22, 24, 25), computer calculations of sample K_a's are based directly on instrument calibrations with known HCl concentrations. In the other method (19, 28), standard buffers are checked against known concentrations of strong acids in a two-step calibration procedure. The alternative method presented here permits the required K_a's for the calibrating weak acid to be generated from computerized data. These data have been recalculated for this purpose from the hydrogen electrode measurements of Bates, Nims, and Lugg. Overall, this approach offers three distinct advantages, including the previously mentioned solutions to the high constant ionic strength and calibration curve gap problems. Thirdly, glass electrode measurements are unlikely to match the quality of the hydrogen electrode measurements, and thus the use of computer generated reference K_a values as described is recommended. Two important limitations in the present "state of the art" identified in this study should be emphasized. The first is the poor response region in glass electrode measurements. A reduction of this problem should be sought. The other limitation exists in the reduction of the random error "background noise". It might well be argued that four, or even six replicate experiments are insufficient for averaging out the random biases of titration curves. The practical restriction encountered in this problem is the cost of experimental time and labour. The solution to the problem must lie with the development of an improved system of instrumentation and data processing.

Appendix

Iterative Calculation Procedure for m_H

In the Fortran Program TE17, H^+ molality is estimated from the material balance relations for total phosphate and for total titratable acid in the appropriate region of the titration curve, and with K_1, K_2, and K_3 evaluated as described above. The molalities of H_3PO_4, $H_2PO_4^-$, HPO_4^{2-}, and PO_4^{3-} and final values of H^+ molality are iteratively calculated together from the material balance relation for total orthophosphate and the equations for K_1, K_2, K_3, and K_w. The concentrations of H_3PO_4 and PO_4^{3-} are of course frequently expected to become unimportant.

Pyrones. VI.[1] The total synthesis of phacidin

GERALD ARTHUR POULTON[2] AND TERRY DONALD CYR
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received April 14, 1980

GERALD ARTHUR POULTON and TERRY DONALD CYR. Can. J. Chem. **58**, 2158 (1980).

Phacidin (4-methoxy-6-nonanoyl-2*H*-pyran-2-one-3-carboxaldehyde) is synthesized from triacetic acid lactone in four steps.

GERALD ARTHUR POULTON et TERRY DONALD CYR. Can. J. Chem. **58**, 2158 (1980).

On a synthétisé la phacidine (méthoxy-4 nonanoyl-6 2*H*-pyrannone-2 carboxaldéhyde-3) en 4 étapes à partir de la lactone de l'acide triacétique.

[Traduit par le journal]

Phacidin, **1**, a metabolic product of the canker fungus *Potebniamyces balsamicola* var. *boycei* Funk, has been shown to be a methoxypyrone derivative (1) possessing potentially useful antifungal activity (2). The synthesis of phacidin was required in order to verify the assignment of structure and to provide an alternate source of the compound. Herein we report an unambiguous synthesis of phacidin from 4-hydroxy-6-methyl-2*H*-pyran-2-one (triacetic acid lactone, **2**) in an overall yield of 13%.

Experimental

Nuclear magnetic resonance data were obtained on a Perkin Elmer R12B (60 MHz) or R32 (90 MHz) instrument (proton) or Nicolet TT-14 (15.1 MHz) instrument (carbon) in $CDCl_3$ solution and are referenced to internal TMS. Mass spectra (70 eV) were obtained using the Hitachi-Perkin Elmer RMU-7E, ultraviolet spectra in 95% EtOH on the Beckman SP800, and infrared spectra on the Perkin Elmer 283 instruments. All mp are uncorrected.

*4-Hydroxy-6-nonyl-2*H*-pyran-2-one (**3**)*

To triacetic acid lactone (3), (**2**, 6 g, 47.6 mmol) dissolved in dry THF (100 mL) and HMPT (20 mL) at −78°C under a nitrogen atmosphere was added *n*-butyllithium (62 mL of 1.7 *M* solution in hexane, 105 mmol). The mixture was allowed to warm to 0°C, stirred for 2 h, and then 1-bromooctane (9.66 g, 50 mmol) was added. The solution was stirred for 14 h at −5°C, then treated with ice-water (100 mL) and the hexane layer separated. The aqueous layer was extracted with pentane (3 × 50 mL), then acidified with dilute HCl (5%) to pH 6. The resulting solution was extracted with ether (3 × 10 mL), the ether extracts washed with water followed by saturated NaCl solution, and then dried (Na_2SO_4). Chromatography of the crude material obtained from these extracts on Florisil using ethyl acetate/pentane (1:1) gave 4-hydroxy-6-nonyl-2*H*-pyran-2-one, 3.9 g (34%), mp 78–79°C (hexane); ν_{max} (KBr); 1704, 1665, 1634 cm^{-1}; λ_{max} (95% EtOH): 282 (log ε = 3.85), 238 (3.86), and 203 nm (4.32); ^1H nmr ($CDCl_3$) δ: 11.1 (bs, 1H, OH), 6.02 (bd, J = 4.5 Hz, 1H, H-5), 5.60 (d, J = 4 Hz, 1H, H-3), 2.48 (t, J = 7 Hz, 2H, $ArCH_2$), 1.8–1.0 (m, 14H, $(CH_2)_7$), and 0.88 (t, J = 7.5 Hz, 3H, nonyl-CH_3); ^{13}C nmr ($CDCl_3$) δ: 172.9 (s, C-4), 168.6 (d, J = 2.0 Hz, C-2), 167.3 (m, C-6), 101.4 (dd, J = 174.7, 2.5 Hz, C-5), 89.8 (d, J = 170.5 Hz, C-3), 33.7 (C-7), 31.9 (C-13), 29.3 and 29.0 (C-9–C-12), 26.7 (C-8), 22.7 (C-14), and 14.1 (C-15); ms *m/e* (relative intensity): 239 (6.5), 238 (21, M^+), 178 (30), 163 (25), 140 (18), 139 (98), 137 (20), 136 (39), 127 (15), 126 (31), 112 (16), 111 (87), 110 (15), 98 (46), 97 (31), 95 (21), 85 (31), 84 (69), 83 (21), 82 (38), 81 (20), 71 (25), 69 (53), 57 (31), 55 (39), 45 (30), 44 (10), 43 (100), and 41 (36). *Anal.* calcd. for $C_{14}H_{22}O_3$: C 70.55, H 9.30; found: C 70.43, H 9.25%.

*4-Methoxy-6-nonyl-2*H*-pyran-2-one (**4**)*

To 4-hydroxy-6-nonyl-2*H*-pyran-2-one (100 mg, 0.42 mmol) and anhydrous K_2CO_3 (380 mg, 2.75 mmol) in 2-butanone (20 mL) was added dimethyl sulfate (64 mg, 0.50 mmol). The mixture was heated to reflux under a dry nitrogen atmosphere for 3 h, additional dimethyl sulfate (64 mg, 0.50 mmol) added, and the heating continued for an additional 20 h. After cooling, the reaction mixture was filtered and evaporated *in vacuo*. Chromatography on silica gel with ethyl acetate/pentane (1:3) yielded 4-methoxy-6-nonyl-2*H*-pyran-2-one (**4**), 91 mg (86%), mp 58–59°C (pentane); ν_{max} (KBr): 1736, 1648, 1565 cm^{-1}; λ_{max} (95% EtOH): 279 nm (log ε = 3.99); ^1H nmr δ: 5.86 (d, J = 2.5 Hz, 1H, H-5), 5.48 (d, J = 2.5 Hz, 1H, H-3), 3.87 (s, 3H, OCH_3), 2.49 (t, J = 8 Hz, 2H, CH_2Ar), 2.0–1.1 (m, 14H, $(CH_2)_7$), and 0.90 (bt, 3H, nonyl-CH_3); ^{13}C nmr δ: 171.3 (m, J = 1.9, 2.9 Hz, C-4), 165.8 (dt, J = 5.7, 2.1 Hz, C-6), 165.0 (s, C-2), 99.6 (dt, J = 171.0, 3.8 Hz, C-5), 87.5 (dd, J = 168.8, 2.9 Hz, C-3), 55.9 (OCH_3), 33.7 (C-7), 31.9 (C-13), 29.3 and 29.0 (C-9–C-12), 26.7 (C-8), 22.7 (C-14), and 14.1 (C-15); ms *m/e* (relative intensity): 253 (5), 252 (26, M^+), 223 (3), 152 (62), 140 (74), 125 (100), 112 (16), 111 (11), 98 (32), and 69 (29). *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.39, H 9.59; found: C 71.47, H 9.52%.

*4-Methoxy-6-nonyl-2*H*-pyran-2-one-3-carboxaldehyde (**5**)*

To 4-methoxy-6-nonyl-2*H*-pyran-2-one (500 mg, 2.0 mmol) in 1,1-dichloromethyl methyl ether (5 mL) at −5°C under a dry nitrogen atmosphere was added dropwise titanium tetrachloride (2.2 mL, 20 mmol); the evolved HCl was removed by the continuous nitrogen flow, while stirring was continued for 14 h, and the temperature allowed to reach 15°C. Ice and diethyl ether were added, cautiously. The ether layer was washed with water (2 × 25 mL), saturated aqueous sodium chloride (25 mL), dried (Na_2SO_4), evaporated, and the product recrystallized from cyclohexane: 4-methoxy-6-nonyl-2*H*-pyran-2-one-3-carboxaldehyde, (**5**), 487 mg (87%), mp 66–70°C; ν_{max} (KBr): 1750, 1727, 1654, 1629 cm^{-1}; λ_{max} (95% EtOH): 322 (log ε = 3.08), 247 (2.76), and 227 nm (3.17); ^1H nmr ($CDCl_3$) δ: 10.11 (s, 1H, CHO), 6.12 (s, 1H, H-5), 4.02 (s, 3H, OCH_3), 2.56 (t, J = 6 Hz, 2H, CH_2Ar), 1.95–1.1 (m, 14H, $(CH_2)_7$), and 0.88 (bt, 3H, nonyl-CH_3); ^{13}C nmr ($CDCl_3$) δ: 186.5 (d, J = 182.4 Hz, CHO),

*4-Methoxy-6-nonanoyl-2*H*-pyran-2-one-3-carboxaldehyde (1)*

4-Methoxy-6-nonyl-2*H*-pyran-2-one-3-carboxaldehyde (30 mg, 0.12 mmol) and freshly sublimed selenium dioxide (110 mg, 1.0 mmol) in *m*-xylene (2 mL) were heated to reflux with vigorous stirring under dry nitrogen for 30 min. The mixture was then cooled, evaporated *in vacuo*, added to ether (40 mL), filtered, and the organic layer washed with water (2 × 25 mL), saturated aqueous sodium chloride (25 mL), and dried (Na_2SO_4). The reaction mixture contained unreacted starting material (18 mg) and the desired product (**1**) which was isolated by preparative tlc: 4-methoxy-6-nonanoyl-2*H*-pyran-2-one-3-carboxaldehyde, 6.5 mg (53%, based on reacted starting material), mp 111–114°C (cyclohexane) (lit. (1) mp 112–113°C); ν_{max} (KBr): 1729, 1701, 1688 and 1617 cm^{-1}; λ_{max} (95% EtOH): 342 ($\log \varepsilon$ = 3.97), 272 (3.28), and 223 nm (4.13); ^1H nmr ($CDCl_3$) δ: 10.22 (s, 1H, CHO), 7.08 (s, 1H, H-5), 4.13 (s, 3H, OCH_3), 2.94 (t, J = 7 Hz, 2H, CH_2CO), 1.9–1.1 (m, 12H, $(CH_2)_6$), and 0.88 (t, J = 6 Hz, 3H, nonanoyl-CH_3); ms *m/e* (relative intensity): 294 (3.5, M^+), 266 (3), 265 (0.5), 238 (1), 154 (12), 153 (100), 141 (6), 125 (12), 123 (4), 71 (11), 69 (15), 57 (17), 55 (16), 43 (16), and 41 (15).

Results and Discussion

Addition of two moles of *n*-butyllithium to triacetic acid lactone **2** (4) results in the rapid formation of the dilithio dianion (5, 6) as a white precipitate which dissolved almost immediately upon addition of 1-bromooctane, leading to smooth monoalkylation at the 7 position. Alkylation of the ring at C-5 which has been observed (5) as a competing process (e.g. when $NaNH_2/NH_3$ was used) does not appear to be occurring under the conditions used here. This product, 4-hydroxy-6-nonyl-2*H*-pyran-2-one (**3**), was then *O*-alkylated using conditions which have been shown (7) to produce only 4-methoxy-2*H*-pyran-2-ones. Diazomethane or other nonbasic methylation systems, which can result in the formation of mixtures containing the isomeric 2-methoxy-4*H*-pyran-4-ones, were not used in order to avoid ambiguities in the synthesis. The product of *O*-methylation of **3** with dimethyl sulfate was assigned the structure 4-methoxy-6-nonyl-2*H*-pyran-2-one (**4**) by analogy with the literature findings (7) and on the basis of a detailed spectral analysis. The carbonyl stretching frequencies found for isomeric pairs of 4-methoxy-2-pyrones and 2-methoxy-4-pyrones have been reported (5) to be diagnostic, although experience has shown that care must be taken in making an assignment of structure when both isomers are not available for direct comparison (8). The CO absorption in 2-pyrones is generally in the 1740–1720 cm^{-1} range, and between 1680 and 1650 cm^{-1} in 4-pyrones; our methylated product had an absorption band at 1736 cm^{-1}, agreeing best with the 2-pyrone assignment. Similar arguments can be presented using the uv data (4-methoxy-6-methyl-2*H*-pyran-2-one, 280 nm; 2-methoxy-6-methyl-4*H*-pyran-4-one, 240 nm (8); compound **4**, 279 nm).

The assignment of a 2-pyrone structure to **4** was further confirmed by the subsequent transformation; 2-pyrones are known (9) to undergo electrophilic substitution with ease at C-3, while 4-pyrones are inert (see for example ref. 10) to most similar processes. One-step electrophilic formylation with dichloromethyl methyl ether (11) gave an excellent yield of the aldehyde **5**; introduction of the aldehyde group at C-3 rather than C-5 follows the normal behaviour of 2-pyrones (9) and can be supported by the following nmr data. Using the known compounds 4-methoxy-6-methyl-2*H*-pyran-2-one (nmr signals at 5.44, H-3, and 5.84 ppm, H-5 (12)) and 3-acetyl-4-methoxy-6-methyl-2*H*-pyran-2-one (nmr signal at 6.11 ppm, H-5 (13)) as models, the assignment of ring proton resonances in 4-methoxy-6-nonyl-2*H*-pyran-2-one (**4**) is made as 5.48 (H-3) and 5.86 (H-5), and in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

aldehyde **5** as 6.12 (H-5). The parallel is clear, indicating the C-3 has been substituted.

Assignments of structures **4** and **5** are also supported by interpretation of the ^{13}C nmr data.

Oxidation of pyrone methyl groups is known to be practicable (14) as a result of the pseudoaromatic nature of the ring. Thus, treatment of the nonylpyrone **5** with freshly sublimed selenium dioxide in refluxing *m*-xylene gave a modest yield of the nonanoyl compound **1**. The spectral properties of this synthetic material were identical with those of the natural product, thus confirming the structure of phacidin to be 4-methoxy-6-nonanoyl-2*H*-pyran-2-one-3-carboxaldehyde.

Received November 21, 1979

JOHN E. DRAKE, BORIS M. GLAVINČEVSKI, and RAYMOND T. HEMMINGS. Can. J. Chem. **58**, 2161 (1980).

The symmetrically substituted disilyl chalcogenides $(Me_nH_{3-n}Si)_2E$ where E = O, S, Se, Te; $n = 0 \rightarrow 3$, have been prepared and characterized spectroscopically and by cleavage reactions. The synthetic routes include reactions of halogenosilanes with water, mercury(II) sulfide, lithium telluride, and complex thio- and seleno-aluminates. The spectroscopic properties of the $(MeH_2Si)_2E$ and $(Me_2HSi)_2E$ species, which have not been reported previously, are discussed in some detail.

JOHN E. DRAKE, BORIS M. GLAVINČEVSKI et RAYMOND T. HEMMINGS. Can. J. Chem. **58**, 2161 (1980).

On a préparé des chalcogénides disilylés $(Me_nH_{3-n}Si)_2E$ ou E = O, S, Se, Te; $n = 0 \rightarrow 3$ symétriquement substitués et on les a caractérisé par spectroscopie et par des réactions de clivage. Les différentes synthèses font intervenir les réactions des halogénosilanes avec l'eau, le sulfure mercurique, le tellurure de lithium et les complexes de thio et de sélénoaluminates. On discute en détail des propriétés spectroscopiques des composés $(MeH_2Si)_2E$ et $(Me_2HSi)_2E$ nouveaux.

[Traduit par le journal]

Introduction

The parent disilyl chalcogenides $(H_3Si)_2E$ (1–4) and $(Me_3Si)_2E$ (5–8) where E = O, S, Se, Te, have been known for some time. As a continuation of our investigations on silyl and germyl Group VI species (9, 10) we report herein the preparation of the disilyl chalcogenides $(Me_nH_{3-n}Si)_2E$, where E = O, S, Se, Te; $n = 0 \rightarrow 3$. Comparisons are made of reactions of halogenosilanes with water, mercury(II) sulfide, lithium telluride, and complex thio- or seleno-aluminates. The chalcogenides are characterized by their ^1H nmr, infrared, Raman, and mass spectral parameters and analysed by their cleavage reactions with anhydrous hydrogen halides, chalcogenides, and methoxytributylstannane.

Experimental

All manipulations were carried out on a conventional vacuum line equipped with greaseless stopcocks. Halogeno-silanes (11) and -germanes were either commercially obtained or prepared by literature methods. Lithium telluride, Li_2Te, was prepared from the elements in liquid NH_3(9). Complex thio- and seleno-aluminates were prepared from $LiAlH_4$ (12) and hydrogen sulfide and hydrogen selenide were obtained via the hydrolysis of the respective aluminum chalcogenides (13). Other materials were of commercial origin.

Infrared spectra were recorded on a Beckman IR12 spectrometer with expansion facilities, using a 90 mm gas cell fitted with KBr windows. The low volatile species were recorded as smears between CsI plates in an air-tight device. The Raman spectra were recorded on a Spectra Physics 700 spectrometer using the argon ion laser exciting line at 488.0 nm with the liquids held in sealed capillaries (ca. 2 mm id). Slitwidths used were 8 cm^{-1} (routine scans), 4 cm^{-1}; and 2 cm^{-1}. Strong bands were estimated to ± 1 cm^{-1} and weaker bands to ± 4 cm^{-1}. The same capillaries were used for the ^1H nmr spectra, recorded on a JEOL C60-HL instrument. Mass spectra were recorded at 70 eV on a Varian GMAT CH5 spectrometer fitted with a greaseless vacuum inlet system.

Reactions of Halogenosilanes with Water

In a typical experiment, MeH_2SiI (0.70 g, 4.07 mmol) was condensed under vacuum conditions, into a reaction vessel (ca. 40 mL) containing degassed distilled water (ca. 8 mL). The contents were allowed to react at room temperature with occasional shaking of the vessel. After ca. 20 min, the volatile material was allowed to distill through a series of U-traps held at −45, −78, and −196°C. The fraction at −78°C was passed again through traps held at −45, −78, and −196°C to give $(MeH_2Si)_2O$ (0.21 g, 1.97 mmol; 96%, identified spectroscopically) at −78°C. By a similar procedure Me_2HSiI (0.54 g, 2.9 mmol) was reacted with H_2O (ca. 6 mL) to give $(Me_2HSi)_2O$ (0.185 g, 1.38 mmol). The analogous reactions of Me_3SiBr (0.41 g, 2.68 mmol) and H_3SiBr (0.29 g, 2.61 mmol) with H_2O (ca. 6 mL) gave $(Me_3Si)_2O$ (0.21 g, 1.29 mmol, 96%) and $(H_3Si)_2O$ (0.095 g, 1.22 mmol, 93%, collected at −126°C) and the purity was confirmed by their vibrational (14), ^1H nmr (8, 15), and mass spectral $((C_5H_{15}Si_2O)^+$ *m/e* 147–149, 78.6%; $(H_nSi_2O)^+$ *m/e* 72–80, 73.6%) parameters.

Reactions of Iodosilanes with Mercuric Sulfide

Details of these reactions have appeared elsewhere (16). The overall yield of the disilthianes, based on the corresponding iodosilane consumed, was 94%. The purity was confirmed by their spectroscopic parameters (14, 16). The parent species $(H_3Si)_2S$ and $(Me_3Si)_2S$ gave ms peaks at *m/e* 88–96 $(H_nSi_2S)^+$ and *m/e* 178–181 $(C_6H_{18}Si_2S)^+$.

Reactions of Halogenosilanes with Complex Thio- and Seleno-aluminates

Typically, H_3SiI (0.38 g, 2.40 mmol) was condensed into the reaction vessel containing the seleno-aluminate and allowed to react at −45°C for ca. 2 h, with occasional shaking of the reaction vessel. Fractionation of the volatile material through U-traps held at −78 and −196°C gave $(H_3Si)_2Se$ (0.14 g, 0.99 mmol,

83%; ms peak *m/e* 130–146 $(H_nSi_2Se)^+$) at −78°C and Me_2O and traces of H_3SiSH (17) at −196°C. Similar sets of experiments using MeH_2SiI (0.52 g, 3.02 mmol), Me_2HSiI (0.68 g, 3.66 mmol), and Me_3SiBr (0.44 g, 2.89 mmol) with excess of seleno-aluminate in the absence of solvent at room temperature for ca. 3 h afforded the corresponding disilselenanes: $(MeH_2Si)_2Se$ (0.24 g, 1.42 mmol, 94%); $(Me_2HSi)_2Se$ (0.315 g, 1.60 mmol, 87%); and $(Me_3Si)_2Se$ (0.20 g, 0.89 mmol, 62%; ms peak *m/e* 220–230 $(C_6H_{18}Si_2Se)^+$). The analogous reactions with thioaluminate gave similar yields of the disilthianes.

Reactions of Halogenosilanes with Lithium Telluride

The reactions were carried out in essentially the same manner as in the synthesis of telluro-germanes (9). Typically, H_3SiI (1.05 g, 6.65 mmol), MeH_2SiI (1.37 g, 7.97 mmol), Me_2HSiCl (1.08 g, 11.42 mmol), and Me_3SiCl (1.12 g, 10.31 mmol) with excess of Li_2Te in ether gave $(H_3Si)_2Te$ (0.565 g, 2.98 mmol, 90%; ms peak *m/e* 178–194 $(H_nSi_2Te)^+$); $(MeH_2Si)_2Te$ (0.77 g, 3.54 mmol, 89%), $(Me_2HSi)_2Te$ (1.30 g, 5.29 mmol, 92%), and $(Me_3Si)_2Te$ (1.35 g, 4.93 mmol, 95%, ms peak *m/e* 268–278 $(C_6H_{18}Si_2Te)^+$).

Reactions of Disilyl Chalcogenides with H_2E where E = O, S, or Se

Typically $(Me_3Si)_2Te$ (0.27 mmol) and H_2S (1.9 mmol) were condensed into a semi-micro nmr tube which was then sealed and allowed to warm to room temperature. After ca. 10 min the ^1H nmr spectrum showed the resonances to be expected for $(Me_3Si)_2Te$ δ(Me) 0.58 ppm and H_2S δ(SH) 0.78 ppm relative to $(Me_3Si)_2O$. After ca. 2 h, tellurium was deposited on the walls of the tube and additional resonances had appeared assignable to Me_3SiSH (18). Further examination showed resonances at 0.65 and −7.9 ppm in the ratio 9:1 assignable to the new tellurol Me_3SiTeH, and H_2Te could also be detected (δ = 5.41) (17). Similarly $(Me_3Si)_2Te$ (0.22 mmol) reacted with H_2Se with formation of Me_3SiSeH (δMe 0.44, δSeH 2.26 ppm) and H_2Te. Alternatively, the silane thiols and selenols, $Me_nH_{3-n}SiEH$ (E = S, Se; $n = 0, 3$) were formed as reported elsewhere (17) from the corresponding sulfides and selenides with H_2S and H_2Se, respectively. Similar reactions with H_2O gave the corresponding disiloxanes.

Cleavage Reactions of Disilthianes and Disilselenanes with Hydrogen Halides

Typically $(Me_2HSi)_2Se$ (1.40 mmol) and HBr (3.12 mmol) were condensed into a 25 mL reaction vessel held at −196°C. The reactants were warmed to room temperature and allowed to react for ca. 30 min. Fractionation of the volatile products gave Me_2HSiBr (2.76 mmol, 99%) in a trap held at −78°C and a mixture of H_2Se and unreacted HBr in one held at −196°C. Similarly, the other species gave quantitative amounts of the corresponding halide.

Reaction of $(Me_2HSi)_2Te$ with Air

When the telluride $(Me_2HSi)_2Te$ (0.36 g, 1.46 mmol) was exposed to air, tellurium was deposited immediately. Fractionation gave H_2Te, which readily decomposed on warming to H_2 and Te, traces of $(Me_2HSi)_2$ and some $(Me_2HSi)_2O$. The ^1H nmr spectrum of the mixture showed resonances at δ(SiH) 4.71, 3.75 and δ(Me) 0.15 ppm relative to TMS. The Raman features characteristic for $(Me_2HSi)_2O$ were ν(SiH) 2128 sh,p; ν_s(SiO) 547 cm^{-1} m,p; and for $(Me_2HSi)_2$ (36) at ν(SiH) 2106 vs,p; ν(Si—Si) 408 cm^{-1} vs,p.

Reaction of $(Me_2HSi)_2O$ with n-Bu_3SnOMe

Typically $(Me_2HSi)_2O$ (0.27 g, 2.0 mmol) was distilled into a reaction vessel (ca. 25 mL) containing 6.1 mmol of degassed *n*-Bu_3SnOMe. The reactants were isolated and allowed to react at room temperature for ca. 22 h with occasional shaking. Fractionation of the volatile material gave $[Me_2(MeO)Si]_2O$ (0.36 g, 1.85 mmol, ^1H nmr (C_6H_{12}) δ(MeO) 3.41 ppm; ms peak *m/e* 179–181 (100%) $(Me_5Si_2O_3)^+$; XPS binding energies (eV) Si 2*p*, 107.1; C 1*s*, 292.15 and 289.25; O 1*s* 537.65) condensing in a trap held at −23°C, whilst an involatile material remained in the reaction vessel.

Results and Discussion

In keeping with the well known heavy-metal salt exchange series (16, 19) iodosilanes are readily converted to disilthianes when passed as gases over mercury(II) sulfide, i.e.

$$[1]\quad 2Me_nH_{3-n}SiI + HgS \xrightarrow[-HgI_2]{25°C} (Me_nH_{3-n}Si)_2S\ (n = 0 \rightarrow 3)$$

Although Li_2S and Li_2Se may be used to prepare the thio- and seleno-silanes (9) the corresponding lithium aluminate salts, $LiAl(EH)_4$ or $LiAlE_2$, may be substituted. These salts are easily prepared and with iodo- or bromo-silanes react readily to give $(Me_nH_{3-n}Si)_2E$ (E = S, Se). The methylated silane is added to the solid aluminate in absence of solvent. The yields are high for the reactions carried out at room temperature, and there is no disproportionation. This method has been well established in the synthesis of methyl-thio and -seleno silanes and germanes (20) but the thermal instability of H_2Te makes it inconvenient for the preparation of the symmetrically disubstituted silyl tellurides. However, these are efficiently prepared from Li_2Te and the corresponding halogenosilane, e.g.

$$[2]\quad 2Me_2HSiCl + Li_2Te \rightarrow (Me_2HSi)_2Te + 2LiCl$$

The yields are high even when the reaction is carried out at room temperature in ether and there is no disproportionation of the product $(Me_2HSi)_2Te$.

The disilyl chalcogenides are all clear, colorless liquids, but $(Me_3Si)_2Se$ and the telluro species soon become pale yellow to brownish at room temperature. The hydridic species $(H_3Si)_2Se$ and $(H_3Si)_2Te$ do not disproportionate at room temperature unless they are stored for several weeks. All of these compounds are sufficiently volatile that they can be easily handled under vacuum line conditions, provided contact with silicone-grease is kept to a minimum. The thio-, seleno-, and telluro-silanes react rapidly with oxygen or H_2O to give the corresponding siloxane and H_2E, i.e.

$$[3]\quad (Me_nH_{3-n}Si)_2E + H_2O \rightarrow (Me_nH_{3-n}Si)_2O + H_2E \qquad (E = S, Se, Te)$$

A similar reaction leading to $Me_nH_{3-n}SiEH$ occurs with excess of the corresponding hydrogen chalcogenide, H_2E (17). Unlike the germyl analogues (9), the disilyl chalcogenides may also be intercon-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

verted by exchange with a "lighter" hydrogen chalcogenide. For example, a tellurosilane can be converted to a selenosilane $(Me_nH_{3-n}Si)_2Se$ or $Me_nH_{3-n}SiSeH$ via cleavage with H_2Se while a thiosilane may be produced by using H_2S. These reactions also present a convenient route to the formation and identification of silanetellurols, e.g.

[4] $(Me_3Si)_2Te + H_2Se \rightarrow Me_3SiSeH + Me_3SiTeH$

When an excess of H_2Se or H_2S is used, the reactions occur with quantitative formation of Me_3SiSeH or Me_3SiSH and H_2Te. Previous methods have typically given poor yields. Elimination of tellurium may result from the thermal instability of Me_3SiTeH or H_2Te. Similarly, elimination of tellurium, resulting in the formation of disilane and disiloxane, is also observed when $(Me_2HSi)_2Te$ is exposed to air, or when tellurosilanes are sealed in cyclohexane solution. Disiloxane, in contrast with other Group VI analogues, reacts smoothly with *n*-Bu_3SnOMe to give $[Me_2(MeO)Si]_2O$. This methoxydisiloxane is identified by its parent peak in the mass spectrum and its ^1H nmr spectrum. Two C 1*s* signals are observed in XPS in the expected intensity ratio of 1:2 at 292.15 eV (typical of MeO) and 289.25 eV (typical of MeSi).

Characterization of the Disilyl Chalcogenides

(i) ^1H Nuclear Magnetic Resonance Spectra

The ^1H nmr spectra (Table 1) not only provided the initial characterization for the calcogen compounds, but also confirmed their purity (>99%) based on the absence of any other proton-containing species. All of the chalcogenides give first order spectra consistent with the free rotation about the skeletal bonds.

As methyl groups substitute for protons along a series $(H_3Si)_2E \rightarrow (MeH_2Si)_2E \rightarrow (Me_2HSi)_2E$ there is a successive down-field shift in the SiH resonance. However, the change is relatively small for E = O (4.61 → 4.69 ppm) and large for E = Te (3.71 → 4.82 ppm) with the sulfides and selenides falling in between, suggesting that the contributing factors must be quite complex. For the series $(H_3Si)_2E$ and $(MeH_2Si)_2E$, the SiH chemical shift moves to higher field in the order O → S → Se → Te as would be expected on the basis of a decreasing inductive effect. This order is maintained in related compounds such as Me_2HSiX (X = F, Cl, Br, I) (21) and in the germanes $(Me_nH_{3-n}Ge)_2E$ (E = O, S, Se, Te) (9). However, in the $(Me_2HSi)_2E$ series the order of high field shift changes to Te → Se → O → S, indicating that the factors contributing to the "methyl shifts" outweigh the inductive effect. The chemical shift of the methyl resonances in all cases decreases (shifts to higher field) with increasing methyl substitution, but increases as the chalcogen changes from O → S → Se → Te. This is the case for the methyl proton shifts in the corresponding halogenosilanes (20) and related halogeno- and chalco-germanes (9, 22, 23). This general feature appears to be more related to the size of the substituents and hence has been attributed to anisotropy and related effects (24). Satellites arising from proton coupling with the magnetic isotope of selenium (^{77}Se) and tellurium (^{125}Te) are observed, indicating that there is no rapid exchange of silyl groups under these conditions. The hydridic chalcogenols H_3SiEH (E = S, Se) give long range, first-order coupling as do the related germyl species H_3GeEH (9, 17). However, coupling involving the hydrogen of the EH entity in Me_3SiEH with the methyl protons is not observed. The sequential shifts in both SiH_3 and CH_3 proton resonances follow the trends observed for the symmetric species and the shifts of the EH proton resonances are close to the values for Et_3SiEH chalcogenols (25).

(X = F, Cl, Br, I) (26). The skeletal vibrational frequences are very close to the values reported for the parent species $(H_3Si)_2E$ (4, 27, 28) and $(Me_3Si)_2E$ (14). As the chalcogen changes in the series $(MeH_2Si)_2E$, the Si—E—Si stretching vibrations give a sequence of bands which fall at: 1085 vs and 581 vs,p (O); 461 vs,p (S); 388 m and 380 vs,p (Se); 332 s and 328 cm^{-1} vs,p (Te). Clearly, the ir counterpart for ν(SiS) remains unobserved but appears at 489 cm^{-1} in the dimethylated analogue. The small separation between the asymmetric and symmetric modes in the heavier chalcogenides relative to the large split in the oxides is as expected for an Si—E—Si angle close to 90° in all compounds except the oxide. The frequency shifts of ν(SiE) for the other series $(Me_2HSi)_2E$ appear to follow the same trend, but the result of extra methyl groups on these frequencies can be seen in the Raman spectra. As expected, ν(SiO) occurs as a single peak at lower frequency 547 cm^{-1} while the heavier Si—E—Si stretches show a new band as a shoulder on the low frequency side. The shoulder can be resolved into a distinct band as illustrated in Fig. 1. The occurrence of this splitting appearing at 472 vs,p and 459 sh,p (S); 387 vs,p, and 373 sh,p (Se); 335 vs,p and 323 cm^{-1} sh,p (Te) is thought to arise from possible conformational effects. Apparently, this doublet feature appears to be characteristic only for the $(Me_2HSi)_2S,Se,Te$ since ν(Ge—E—Ge) appears as a single band in the related germyl species (9). In the low frequency region of the Raman spectra the SiESi and CSiE deformations are clearly observed. The resulting trend of decreasing deformation frequencies for SiESi along the series confirmed that the heavy atom skeletons are bent at the central atom like the related species. The splitting between the two CSiE deformations decreases as the chalcogen becomes heavier and in the case of $(MeH_2Si)_2Se,Te$ and $(Me_2HSi)_2Te$ become coincident. The methyl stretching and deformation modes are unambiguously assigned in the expected 2979–2899 cm^{-1} and 1426–1246 cm^{-1} regions as are the SiH stretches at 2159–2125 cm^{-1}. The assignment of the remaining vibrations for the $Me_nH_{3-n}Si$-moieties are comparable to the related halogenosilanes (26).

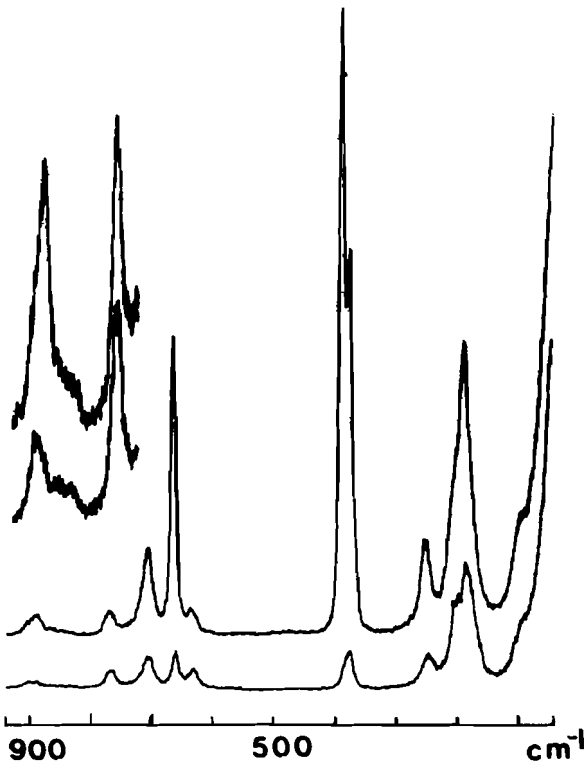

FIG. 1. Partial Raman spectrum of $(Me_2HSi)_2Se$.

(iii) Mass Spectra

In a preceding paper (29) we reported a detailed study of the mass spectra of $(Me_3Si)_2E$ series, so we describe here only the characteristic features associated with $(MeH_2Si)_2E$ and $(Me_2HSi)_2E$ where E = O, S, Se, Te. The observed cluster ions are collected in Tables 4 and 5, along with their relative abundances. Examination of the data shows that the molecular ion (M^+ or $(M - nH)^+$) is present in every case and the sequence of decreasing relative abundance on going through the series O → S → Se → Te apparently parallels the thermal stability of the species or the Si—E—Si bond strength on electron impact. Aside from the telluro species, the molecular ion is predominant for $(MeH_2Si)_2E$ while silicon–methyl bond cleavage appears in greater abundance for $(Me_2HSi)_2E$ species. The fact that the Si—O bond is stronger than the Si—S, Si—Se, or Si—Te bond is shown by the lesser fragmentation of the Si—O—Si linkage. The contribution of the $(Me_3Si)^+$ ion arises as in the dimethylated ger-

myl species (9) from a migration of a methyl group from one silicon atom to the other. However, an interesting feature is the elimination of tellurium leading to $(Me_2HSi)_2^+$ species, suggesting that Te elimination noted for reactions could be intramolecular.

Hydrolysis and carbonyl-oxygen exchange in tertiary amides. Estimation of the free energy changes for breakdown and conformational changes of tetrahedral intermediates

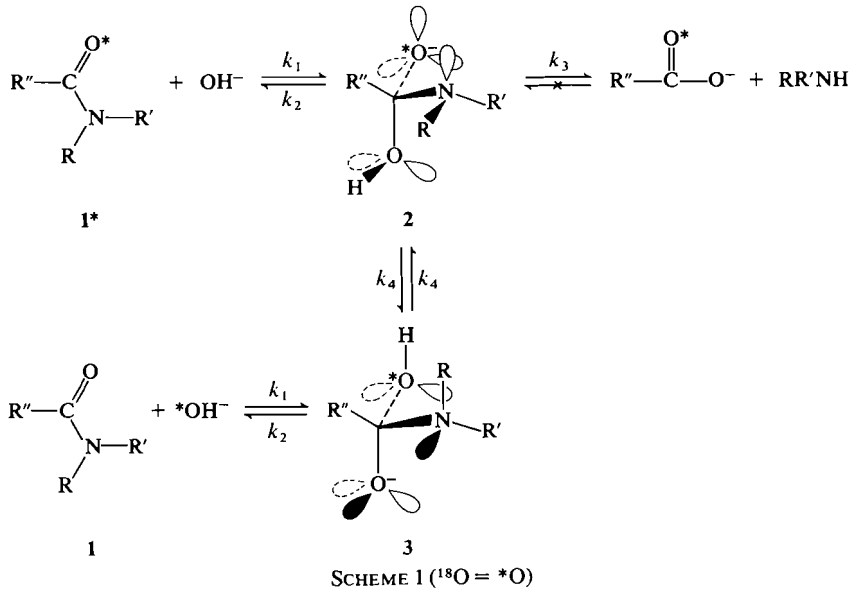
PIERRE DESLONGCHAMPS, ROGER BARLET,[1] AND ROLAND J. TAILLEFER

Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received May 1, 1980

PIERRE DESLONGCHAMPS, ROGER BARLET, and ROLAND J. TAILLEFER. Can. J. Chem. **58**, 2167 (1980).

Second order rate constants were measured at several temperatures for the basic hydrolysis and for concurrent carbonyl-oxygen exchange with solvent for *N*-benzyl-*N*-methylformamide-^{18}O, *N*-benzyl-*N*-methyltrideutéroacetamide-^{18}O, and *N*-benzyl-*N*-methyl-α,α-dideuteropropionamide-^{18}O. Carbonyl-oxygen exchange with solvent is rationalized by invoking a conformational change in the tetrahedral intermediate. Energy barriers for these conformational changes are estimated to be of the order of 5.6, 8.0, 8.2 kcal/mol respectively for the above amides.



PIERRE DESLONGCHAMPS, ROGER BARLET et ROLAND J. TAILLEFER. Can. J. Chem. **58**, 2167 (1980).

On a mesuré les constantes de vitesse de 2e ordre à plusieurs températures pour l'hydrolyse basique et l'échange concurrente d'oxygène avec le solvant pour le *N*-benzyl-*N*-méthylformamide-^{18}O, le *N*-benzyl-*N*-méthyl-trideutérioacétamide-^{18}O et le *N*-benzyl-*N*-méthly-α,α-dideutériopropionamide-^{18}O. L'échange de l'oxygène du carbonyle avec le solvant est expliqué en invoquant un changement conformationnel au niveau de l'intermédiaire tétraédrique. Les barrières pour ces changements conformationnels sont de l'ordre de 5.8, 8.0 et 8.2 kcal/mol respectivement pour ces trois amides.

Application of the theory of stereoelectronic control to the cleavage of tetrahedral intermediates (1) which are formed during the basic hydrolysis of carbonyl-^{18}O amides has led to the following predictions: primary and secondary amides, but not tertiary amides or secondary and tertiary lactams, could give rise to isotope exchange with solvent, concurrent with hydrolysis (2).

The basic postulate is that a stereoelectronically controlled nucleophilic attack by hydroxide ion on the ^{18}O-labeled amide **1*** (Scheme 1) gives specifically the tetrahedral conformer **2**, which exists in the monoanionic form (T^-) above pH 11. The second postulate is that the energy barrier for the stereoelectronically controlled breakdown of **2** is lower than that for its conformational change.

In the case of primary or secondary amide, the R group in intermediate **2** is a hydrogen atom. It is assumed that proton transfer on the two oxygens can take place prior to the breakdown of intermediate **2** (3). The same assumption is also made for proton exchange on the nitrogen (**2** ⇄ **3**) which

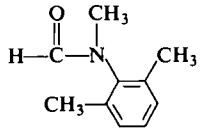
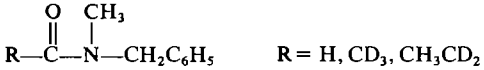
must occur via the following process which, we think, has also a low energy barrier.



The N—H as well as the O—H bond can therefore be considered equivalent to a nonbonded electron pair. Under these conditions, intermediate **2** has proper electron pair orientation to give the starting amide **1*** and the hydrolysis products or the unlabeled amide **1** via **3**. As k_2 is larger than k_3 (OH being a better leaving group than NH_2), primary and secondary amides should exhibit significant exchange, a prediction which is supported by experiments (4). Consequently, in the case of primary and secondary amides, there is no need to postulate a conformational change prior to breakdown in order to observe carbonyl-oxygen exchange.[2]

In tertiary amides, intermediate **2** can fragment in only two ways, yielding the starting labeled amide **1*** or the hydrolysis products. In order to observe carbonyl-oxygen exchange, intermediate **2** must be converted first into another conformer such as **3** which can give unlabeled amide **1** or the hydrolysis products. Oxygen exchange in tertiary amides depends therefore on the relative ease by which **2** can yield **3** or the hydrolysis products by direct fragmentation. The change of **2** into **3** can be obtained by either a 120° rotation around the C—N bond, or by an inversion of the nitrogen atom followed by a 60° rotation, with appropriate proton transfer on oxygens. For conformational change to occur at rates competitive with fragmentation, it is necessary that the energy of activation for the conformational change be less than or comparable to that for fragmentation.

We have initially obtained experimental evidence that tertiary amides and secondary and tertiary lactams do not undergo carbonyl-oxygen exchange, confirming the above postulate (2). Since then, we have observed that *N*,*N*-disubstituted formamides (5) gave significant oxygen exchange at room temperature and at 90°C during their basic hydrolysis at pH 13. These results, in contradiction with the initial predictions, can, however, be easily interpreted. The energy barrier to rotation of **2** to **3** is lowered when R″ = H compared to R″ = alkyl (5).



It was also shown (5) that in tertiary acetamides and propionamides, isotopic exchange with the solvent, which was negligible, or absent, at room temperature became significant at 90°C. Further, the exchange rate increased with temperature more rapidly than did the hydrolysis rate.

This phenomenon was explained by taking into account that the nitrogen atom of the tetrahedral intermediate must be hydrogen-bonded to the solvent in order to observe hydrolysis. This association, which favors the heterolytic cleavage but disfavors the rotation step necessary for exchange, becomes less important at higher temperature, and the exchange rate is therefore favored over that of hydrolysis by an increase of temperature. This solvent effect was clearly shown with *N*-2,6-dimethylphenyl-*N*-methylformamide (**4**), in which steric effects inhibit such hydrogen bonding. Indeed, this formamide does not hydrolyse (0.15 *N* KOH, 90°C, 70 h) but undergoes considerable carbonyl-oxygen exchange (91%) (5).

4

We now report the rates of hydrolysis and carbonyl ^{18}O exchange with solvent ($D_2{}^{16}O$) of amides **5** in order to estimate the magnitude of the energies involved in these processes. α-Deuterated amides were required because under our experimental conditions (KOD, D_2O) hydrogen–deuterium exchange occurred.

5

Experimental

Vapor-phase chromatographic (vpc) analyses and separations were carried out on a Varian Aerograph instrument model 920 with a thermal conductivity detector. The columns used were 10% Versamid 900 (5 ft × 1/4 in.) and 5% SE-30 (5 ft × 1/4 in.), both on Chromosorb W, 100–200 mesh. Infrared spectra were taken on a Perkin-Elmer spectrometer model 257. Proton nmr spectra were recorded on a Varian A-60 instrument, or a Bruker WP-60 instrument. Chemical shifts are reported in δ values relative to tetramethylsilane as the internal standard. Constant temperature baths were obtained using a Thermistemp YSI model 71 temperature controller. Temperatures were constant within ±0.25°C.

Mass spectra were obtained using a Hitachi-Perkin-Elmer RMU-6A instrument at 70 eV. Percentages of ^{18}O were obtained by measuring the peak height of the parent peak (P) and that of the parent peak plus two mass units (P + 2). These heights were corrected for background if necessary. The unlabeled amides (^{16}O) presented a small P + 2 peak due to natural abundance ^{18}O,

[2]The rapid oxygen exchange in primary and secondary amides can also be explained by the rapid interconversion of **2** and **3** via a conformational change. The energy barrier for the interconversion of **2** and **3** in intermediates derived from primary and secondary amides must be lower than that from tertiary amide because the substitutents on the nitrogen are smaller.

^2H, ^{13}C, the percentage of which was subtracted from the (P + 2) peak in the sample. After these corrections, the percentage ^{18}O was given by

$$\%^{18}O = \frac{100\,(P+2)}{P+(P+2)}$$

Each assay was an average of 25 scans.

Syntheses

Unlabeled amides were prepared by standard procedures. Their physical properties corresponded to literature values and their spectra were in accord with their structures. α-Deuteroamides were obtained by base catalysed hydrogen–deuterium exchange in CH_3O^-/CH_3OD at 80°C ($CD_3CON(CH_3)$–$(CH_2C_6H_5)$) or 50°C ($CH_3CD_2CON(CH_3)$–$(CH_2C_6H_5)$). Three to four exchange cycles were necessary to completely deuterate the amides. *N*-Methyl-*N*-benzylformamide-^{18}O (**5***, R = H) was prepared as previously reported (5). Other labeled amides were prepared as described in Scheme 2.

N-*Methyl*-N-*benzyltrideuteroacetamide*-^{18}O

Method A

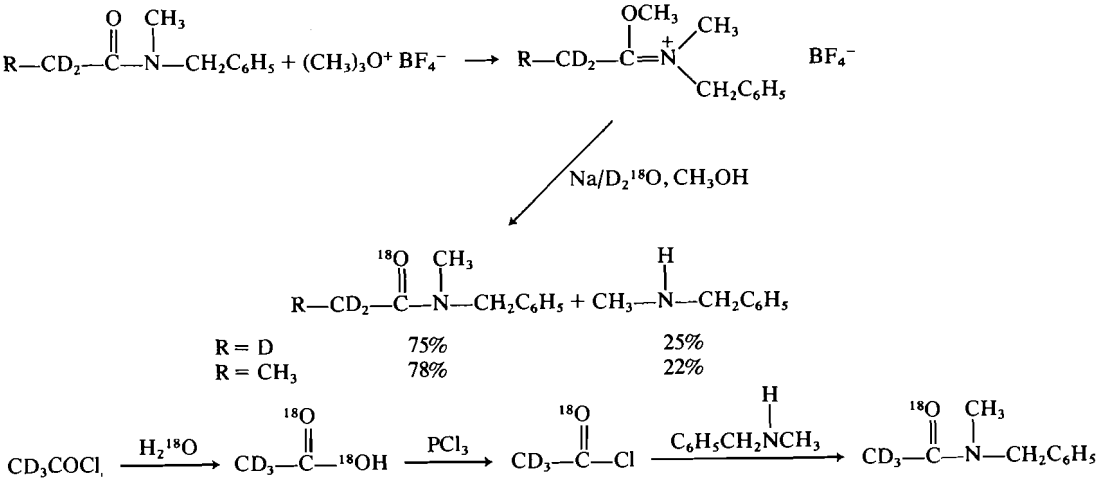
Trimethyloxonium tetrafluoroborate (225 mg, 1.51 mmol) was added to freshly distilled methylene chloride (5 mL). Trideuteroacetamide (133 mg, 0.93 mmol) dissolved in methylene chloride (10 mL) was added and the mixture was stirred at room temperature overnight. Filtration and solvent evaporation gave the acetamidate (220 mg, 90%) present in both the *E* and *Z* configurations.

Sodium metal (28 mg, 1.2 mmol) was added to methanol-*O*-*d* (200 μL). When all the sodium had reacted, $D_2{}^{18}O$ (22 μL, 50% ^{18}O, Merck, Sharp and Dohme) was then added, followed by the mixture of acetamidate salts (0.83 mmol) dissolved in methanol-*O*-*d* (100 μL). The solution was stirred for two hours. Methylene chloride was then added, and the mixture was filtered. The filtrate was evaporated to dryness. Nuclear magnetic resonance analysis of the residue showed 75% amide and 25% amine. The mixture was then dissolved in water and the solution was saturated with ammonium chloride. The solution was then extracted several times with methylene chloride. After drying, solvent evaporation gave 0.62 mmol of amide (overall yield 66%) containing 18.8% ^{18}O.

Method B

Trideuteroacetyl chloride (407 mg, 5 mmol, >99% d_3, Merck, Sharp and Dohme) was placed in a septum sealed test tube in which two needles were placed in order to circulate dry nitrogen. $H_2{}^{18}O$ (0.91 μL, 46 mmol) was added and the solution was stirred overnight. The solution was then cooled to 0°C and phosphorus trichloride (168 μL) was slowly added followed by methylene chloride (2 mL, freshly distilled from P_2O_5). The solution was left warming to room temperature for one hour to eliminate the HCl produced. The solution was then cooled again and methylbenzylamine (2 mL, 17 mmol) was slowly added. The solution was left standing for 3–4 hours. Aqueous hydrochloric acid (50% 1 *N*, 50% saturated aqueous NaCl solution) was then added and the solution was extracted with methylene chloride. The organic solution was then washed with bicarbonate, dried, and evaporated. Purification by vpc (Versamid, 180°C) gave 313 mg (total yield 38%) of labeled amide containing 54% ^{18}O.

N-*Methyl*-N-*benzyl*-α,α-*dideuteropropionamide*-^{18}O



This compound, which was prepared by utilizing method A, was isolated in 78% total yield and contained 20% ^{18}O.

Kinetics

The hydrolyses were done in deuterated buffer solutions of total ionic strength of 0.5 *M*, adjusted with KCl. Potassium hydroxide solutions (KOD) were prepared by adding potassium metal to D_2O. Concentrations were 0.25 to 0.36 *N*.

The labeled amides were dissolved in the buffer solutions at the appropriate temperature such that their final concentrations were 0.028 *M* to 0.035 *M*. At appropriate times, samples were removed, quenched with solid ammonium chloride, and assayed directly by nmr spectroscopy integration for the percentage of amide (*N*-methyl peak) and the percentage of amine (*N*-methyl peak). The sample was then extracted several times with methylene chloride. After drying and evaporation of solvent, the unreacted amide was isolated by preparative vpc, and assayed for ^{18}O by mass spectroscopy.

For the case of *N*-methyl-*N*-benzylformamide where the working temperatures were lower (27–45°C), two parallel reactions were made. One was in an nmr tube and nmr analysis was made without quenching by transferring the tube to the nmr probe kept at the same temperature as that of the run. In this case the time of the point was taken as the median time before and after the FT accumulations. The second parallel reaction was done in a reaction vessel. Samples were removed, quenched as above, and extracted rapidly for mass spectral assay.

[a]Errors in pseudo-first order constants are estimated to be less than ±5%.

Results

Table 1 lists the data obtained for hydrolysis and exchange of amides **5** (R = H, CD_3, CH_3CD_2). Pseudo-first order rate constants were found by following the disappearance of starting amide (k_h^1) or following the disappearance of the ^{18}O-label (k_{ex}^1) in the starting amide. Second order rate constants were obtained by dividing the pseudo-first order constants by the base concentration. This assumes the rate law described by eq. [1]. However, second order terms in hydroxide ion concentration (eq. [2]) have sometimes been observed (6) in amide hydrolysis. That such was not the case under our conditions is shown in Table 2. The second order rate constants are the same within experimental error for each base concentration.

$$[1] \quad \text{Rate} = k\,[\text{amide}]\,[OH^-]$$

$$[2] \quad \text{Rate} = k'\,[\text{amide}]\,[OH^-] + k''\,[\text{amide}]\,[OH^-]^2$$

The activation parameters, found by plotting ln (k/T) vs. $1/T$ where k is the second order rate constant for hydrolysis (k_h) or exchange (k_{ex}), are summarized in Table 3.

Discussion

The activation parameters for hydrolysis $\Delta H_h^{\ddagger}$, $\Delta S_h^{\ddagger}$, and $\Delta G_h^{\ddagger}$, described in Table 3 are in accord with values obtained previously on similar amides (7, 8). The large negative entropy of activation agrees with the fact that the nitrogen in the tetrahedral intermediate must form a hydrogen bond with the solvent in order to observe hydrolysis. As expected, the formamide is more reactive towards hydrolysis than the other two amides.

Comparison of the activation parameters for carbonyl-oxygen exchange and for hydrolysis show that in the case of formamide, the rate of exchange is only slightly lower than that of hydrolysis, whereas in the case of acetamide and propionamide, the exchange occurs at a significantly lower rate. These results are in accord with our previous studies (2, 4).

In order to obtain a free energy diagram for hydrolysis and carbonyl-oxygen exchange, it is necessary to analyze in more detail the mechanism of these two processes. Consider the following simple mechanism for amide hydrolysis, where A is the amide, T, the tetrahedral intermediate, and P, the products

$$A + OD^- \underset{k_2}{\overset{k_1}{\rightleftharpoons}} T \xrightarrow{k_3} P$$

Application of the steady-state approximation for this mechanism gives

$$k_h = k_1 k_3/(k_2 + k_3)$$

Under the present conditions, because there is isotope exchange with solvent, k_3 must be the rate determining step and since an OH group is a better leaving group than an R_2N group, we must have k_2

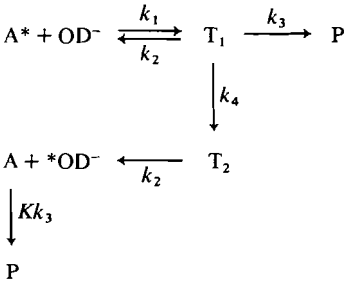
[a]Extrapolated.

$\gg k_3$ and hence

[3] $k_h = K k_3$

where $K = k_1/k_2$, the equilibrium constant for tetrahedral intermediate formation.

For the exchange mechanism, we must consider two conformations of the tetrahedral intermediate:



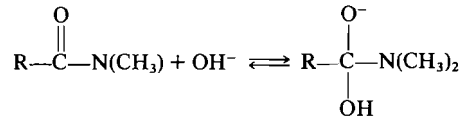
where A* is the labeled amide, A the unlabeled amide, and T_1 and T_2 are conformers **2** and **3** of Scheme 1. In this mechanism, formation of T_2 from A and $^*OD^-$ is considered negligible because the labeled deuteroxide is diluted in the D_2O pool. Further, if we consider the methyl and the benzyl substituents on nitrogen as very similar groups,[3] then T_1 and T_2 are close to mirror images so that their interconversions go at similar rates (k_4). Steady-state treatment on this mechanism gives

$$k_{ex} = k_1 k_2 k_4/(k_2 + k_3)(k_2 + k_3 + 2k_4)$$

As before, $k_2 \gg k_3$. Also, if we assume that the decomposition of T_1 into starting material is a much easier process than conformational changes, then $k_2 \gg k_4$. If $k_2 \gg k_3 + 2k_4$, then

[4] $k_{ex} = k_1 k_2 k_4/k_2^2$
$= K k_4$

If these approximations hold, the exchange mechanism is effectively reduced to



[3]The Taft's ρ* value for a benzyl group is +0.22 compared to 0.0 for methyl. Also, Taft's steric parameter is −0.33 for the benzyl group compared to 0.0 for the methly group (9).

i.e. once the first tetrahedral intermediate T_1 is formed it will go back to starting A* and OD^- most of the time. However, every so often T_1 will evolve to products via k_3 or to T_2 via k_4. Once T_2 is formed on the other hand, it decomposes rapidly to unlabeled amide and $^*OD^-$.

To estimate the constants k_3 and k_4 in eq. [3] and [4], the knowledge of the equilibrium constant K for tetrahedral intermediate formation is required. Recently, Guthrie (7) has estimated these equilibrium constants for *N*,*N*-dimethylformamide and *N*,*N*-dimethylacetamide. They are shown in Table 4, together with the value calculated for the propionamide using the ρ* value defined by the points R = H, and R = CH_3. Assuming the benzyl group is not very different from a methyl group,[3] and neglecting the solvent isotope effect and the secondary isotope effects in the acetamide and propionamide, these equilibrium constants can then be used to estimate k_3 and k_4. These are shown in Table 5 and illustrated in Fig. 1.

Table 5 shows that the free energy of activation for the tetrahedral intermediate decomposition step (k_3, $\Delta G_3^{\ddagger}$) does not vary considerably with the amide structure, while that for the conformational change at the nitrogen (k_4, $\Delta G_4^{\ddagger}$) varies appreciably from the formamide to the acetamide (or propionamide) case. It is expected that the conformational change step would be influenced appreciably by the steric interaction of the R group. These differences in $\Delta G_4^{\ddagger}$ militate against interpreting the k_4 step as a proton transfer step. The free energy for

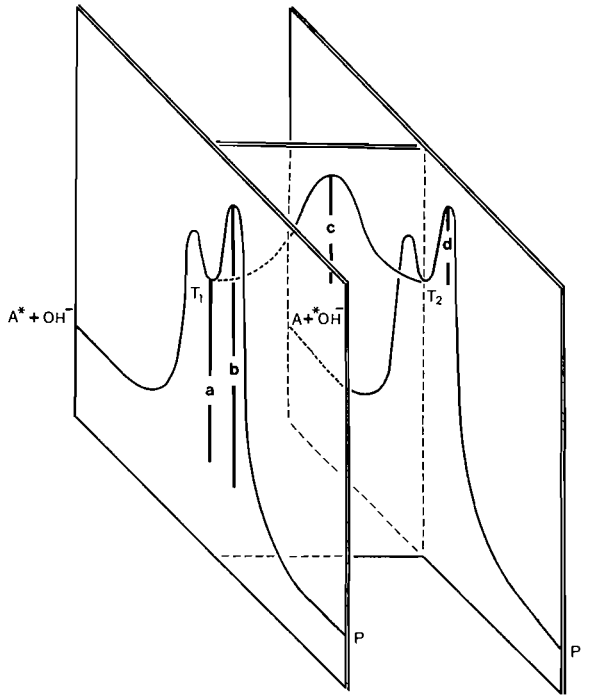
[a]25°C.
[b]From Table 4, cf. text.



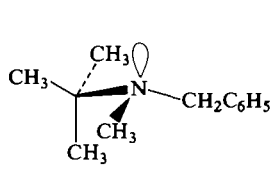


FIG. 1. Free energy diagram (kcal/mol) for hydrolysis and carbonyl oxygen exchange. (a) ΔG° for formamide is 17.7, for acetamide 18.8, and for propionamide is 19.0; (b) $\Delta G_h^{\ddagger}$ for formamide is 22.8, for acetamide 25.0, and for propionamide is 25.5; (c) $\Delta G_4^{\ddagger}$ for formamide is 5.8, for acetamide 8.0, and for propionamide is 8.2; (d) $\Delta G_3^{\ddagger}$ for formamide is 5.2, for acetamide 6.2, and for propionamide is 6.5.

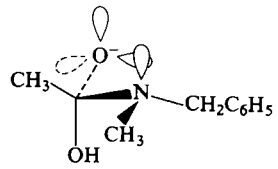

such a step would not vary much from R = H to R = CH_3CD_2.

In summary, the above interpretation of the results obtained indicates that carbonyl-oxygen exchange with solvent, concurrent to the hydrolysis of tertiary amides, arises through a rate determining step which involves a conformational change at the nitrogen in the tetrahedral intermediate. The free energy changes for these conformational changes have been estimated to be of the order of 5.8, 8.0, and 8.2 kcal/mol^{-1} for formamides, acetamides, and propionamides respectively.

It is interesting to compare *tert*-butylbenzylmethylamine (**6**) and the tetrahedral intermediate **7** derived from *N*-benzyl-*N*-methylacetamide which have a similar degree of substitution.

6

7

The rotation barrier for the $(CH_3)_3C$—N bond and the nitrogen inversion barrier in *tert*-butylbenzylmethylamine have been found identical and estimated at 6.2 kcal/mol (10). The slightly higher value of 8.0 kcal/mol for the intermediate **7** may be due to an electronic reason, related to the anomeric effect (11).

This work constitutes further evidence in favor of the principle of stereoelectronic control which governs the cleavage of tetrahedral intermediates in hydrolysis reactions.

Synthesis of ring A of ambruticin and proof of its absolute stereochemistry

GEORGE JUST AND PIERRE POTVIN[1]

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received May 26, 1980

GEORGE JUST and PIERRE POTVIN. Can. J. Chem. **58**, 2173 (1980).

Appropriately derivatized ambruticin was converted by reductive ozonolysis to tetrahydropyran **9***c* and cyclopropane **12***a*, which were synthesized from L-arabinose and (*R*)-Feist's acid in an unambiguous manner.

GEORGE JUST et PIERRE POTVIN. Can. J. Chem. **58**, 2173 (1980).

L'ambruticine, sous forme derivée, fut convertie en tétrahydropyranne **9***c* et cyclopropane **12***a*, qui furent eux-mêmes synthétisés de manière non-ambigüe à partir du L-arabinose et de l'acide de Feist résolu.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Ambruticin, a novel antifungal agent, has been assigned structure **11**, based on X-ray diffraction studies (1). We were interested in developing an efficient synthesis of this compound, starting from chiral precursors corresponding to the three ring-systems, and therefore had to know the absolute stereochemistry of **11**, since most inexpensive chiral precursors are not available in both enantiomeric forms.

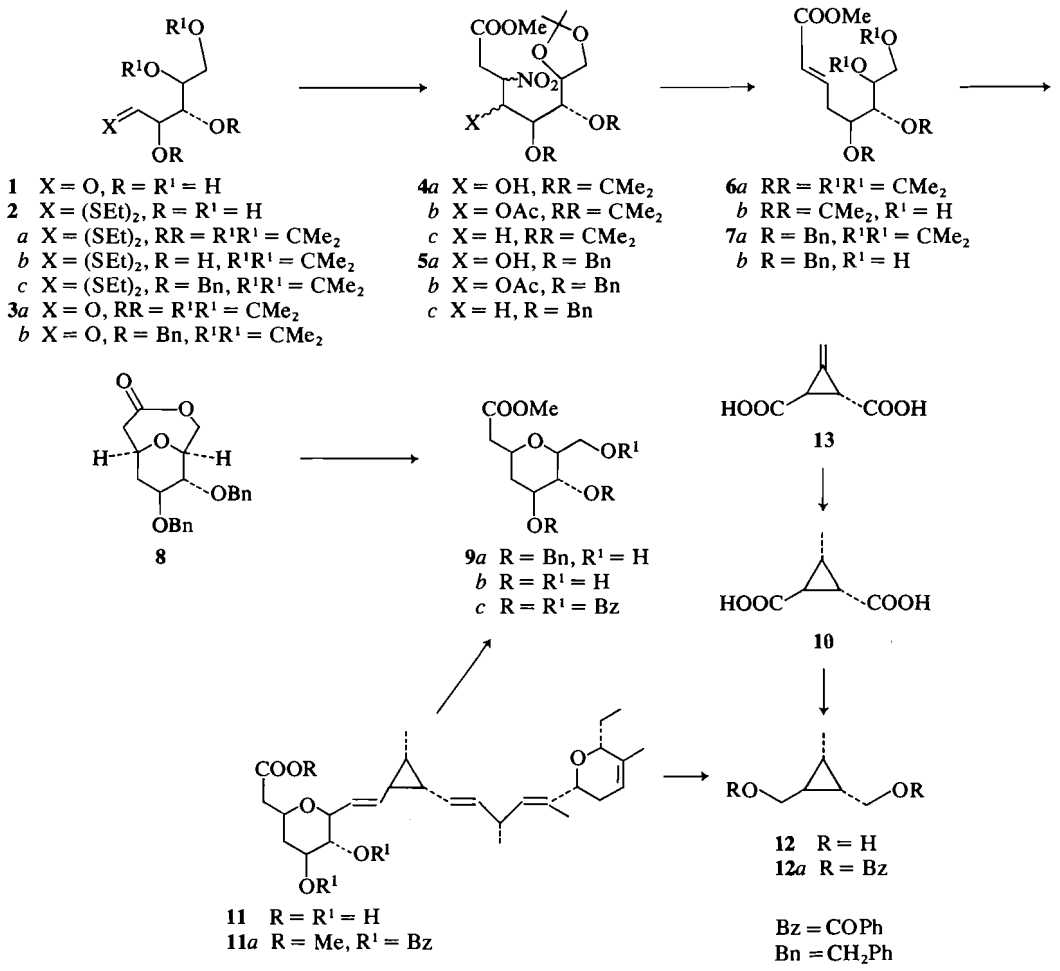
Because of the ready availability of both D- and L-arabinose, it was decided to synthesize ring A from L-arabinose (**1**), and to compare it to the appropriately modified ozonolysis fragment derived from ambruticin.

Reaction of the known aldehyde **3***a* (2) with methyl 3-nitropropionate (3) and potassium *tert*-butoxide in tetrahydrofuran gave adduct **4***a* as a mixture of isomers, which was acetylated *in situ* using acetic anhydride and 4-dimethylaminopyridine to give acetates **4***b*. Elimination of acetic acid with triethylamine and reduction with sodium borohydride (12) gave **4***c* as a mixture of diastereomers.

Treatment of **4***c* with diazabicycloundecene (DBU) in chloroform gave the α,β-unsaturated ester **6***a* in 45% yield, based on aldehyde **3***a*. Partial hydrolysis of **6***a* with acetic acid (4) gave diol **6***b*. All attempts to effect ring closure failed, and seemed to result in elimination of the vinylogously β-alkoxy group at C5 of **6***a*, followed by further reaction which we did not care to investigate. The failure to close the ring was attributed to strain generated in forming the *trans*-fused trioxahydrindanes of type **9** (RR=CMe_2).

The sequence was therefore repeated using 2,3-*O*-dibenzyl-4,5-*O*-isopropylidene-L-arabinose, **3***b*, prepared from the dithioacetal **2** by partial ketalization with acetone – pyridinium *para*-toluenesulfonate (5), followed by benzylation (6) and hydrolysis of the thioacetal using iodine in water (7) to give unstable **3***b* (**2** → **2***b* → **2***c* → **3***b*). Reaction of **3***b* with methyl 3-nitropropionate, followed by the steps outlined above for diacetonide **3***a* (**3***b* → **5***a* → **5***b* → **5***c* → **7***a* → **7***b*) using modified experimental conditions gave dibenzyloxy diol **7***b* in 25–30% yield, based on **3***b*. This time, ring-closure could be effected smoothly by boiling **7***b* in toluene in the presence of a catalytic amount of sodium methoxide, and slowly distilling off the methanol formed in the reaction. This reaction gave bicyclic lactone **8**, mp 154–156°C, $[\alpha]_D^{21}$ −6.4°, in 51% yield, and ensured the *cis*-stereochemistry of the two chains attached to the tetrahydropyran ring. Reaction of lactone **8** with sodium methoxide in methanol gave **9***a*. Considerable difficulties were encountered in removing the benzyl groups of **9***a* by catalytic hydrogenation. However, treatment of **9**a with trimethylsilyl iodide gave **9***b* which was isolated in modest yield and characterized as its tribenzoate **9***c* (mp 134–136°C, $[\alpha]_D^{21}$ +11.1°).

(*R*,*R*)-Feist's acid **13**, mp 198–199°C, $[\alpha]_{546}^{21}$ +172°, (lit. (8) mp 203–205°C, $[\alpha]_{546}^{25}$ +176°), resolved through its quinine salt (8),[2] was hydrogenated over palladium on charcoal to give (*S*,*S*)-**10**, mp 162.5–163.5°C, $[\alpha]_D^{21}$ +92.4° (lit. (9) mp 130–131°C, 147° for *rac*-**10**). Diborane reduction gave (*S*,*S*)-**12**, which was characterized as its dibenzoate (*S*,*S*)-**12***a*, $[\alpha]_D^{21}$ −12.9°.



In order to correlate ambruticin **11** with **9***c* and **12***a*, it was transformed to its methyl ester dibenzoate **11***a* by reaction with diazomethane, followed by benzoyl chloride – pyridine. Ozonolysis in methylene chloride at −78°C, followed by treatment with dimethylsulfide and zinc borohydride, gave a mixture of alcohols, from which could be isolated diol **12** and triol **9***b*. These were separately transformed to their respective perbenzoates **12***a*

[1]Holder of a N.S.E.R.C. Scholarship, 1979–1981, and a D.G.E.S. Scholarship, 1978–1980.

([α]$_D^{21}$ −9.0°) and **9***c* (mp and mixture mp 132–134°C, [α]$_D^{21}$ +8.6°). The spectra (200 MHz ^{1}Hmr, ir, mass) of **9***c* obtained from ambruticin were identical to those of **9***c* obtained from L-arabinose.

Compound **12***a* was chromatographically homogeneous (tlc, hplc, flash chromatography (10)), but minor differences in the 200 MHz ^{1}Hmr and ir spectra of **12***a* obtained from ambruticin from those of **12***a* obtained from (*R*,*R*)-Feist's acid suggest the presence of an unidentified contaminant, which explains the slightly lower optical rotation of natural-source **12***a*. In view of the report (1) that ozonolysis of the ambruticin system had failed to give identifiable products, we were satisfied that the similarities in optical rotation of the synthetic and natural-source perbenzoates **9***c* and **12***a* prove that the absolute stereochemistry of ambruticin is as depicted in formula **11**.

Experimental

Thin-layer chromatography was performed on Merck Silica Gel 60 aluminum-backed plates. Flash chromatography was done using Woelm Silica (32–63 μ) using predistilled solvents. Petroleum ether used was the fraction boiling in the 30–60°C range. The nmr spectra (all in $CDCl_3$) were recorded on Varian T-60A or XL-200 instruments; infrared spectra were measured on a Perkin-Elmer 297 spectrometer. Optical rotations were measured in a 1 dm cell on a Perkin-Elmer 141 polarimeter. Melting points were measured on a Gallenkamp block and are uncorrected. Elemental analyses were performed by Midwest Microlab Ltd., Indianapolis. High pressure liquid chromatography was performed on an Altex 300 instrument, equipped with an ultraviolet detector, using an analytical column of silica gel (10 μ spherical).

Diisopropylidene α,β-Unsaturated Ester **6**a

Methyl 3-nitropropionate (3) (0.26 g, 2 mmol) in 3 mL of dry THF was added dropwise to a stirred suspension of potassium *tert*-butoxide (0.22 g, 2 mmol) in 6 mL of dry THF, at 0°C under a dry N_2 atmosphere. After stirring the yellow solution for 15 min, a solution of 2,3;4,5-di-*O*-isopropylidene-L-arabinose **3***a* (2) (0.46 g, 2 mmol) in 3 mL of dry THF was added dropwise. After stirring a further 30 min at room temperature, tlc (3:2 ether – petroleum ether) indicated complete adduct formation. After neutralization (using 0.53 mL of a 20% THF solution of acetic acid), acetic anhydride (0.20 mL, 2.2 mmol) and a catalytic amount of 4-dimethylaminopyridine were added to the intermediate nitro-alcohols **4***a*. After stirring for 2 h at room temperature, the reaction mixture consisted of acetates **4***b* and some

elimination product. Triethylamine (0.26 mL, 2 mmol) was added, and the mixture was filtered and evaporated to dryness. The residue was dissolved in acetonitrile (4 mL) and treated with excess sodium borohydride while stirring at room temperature for 1 h. The reaction mixture was diluted with ether (20 mL), filtered, and evaporated, and the residue, mainly **4***c*, was dissolved in $CHCl_3$ (20 mL) and brought to reflux. To this solution was added DBU (0.30 mL, 2 mmol), dropwise. After 30 min, at which time the elimination was complete (tlc), the solution was washed twice with KH_2PO_4 buffer (pH 4.4) and once with brine, while reextracting the aqueous layers with $CHCl_3$ (3 times). The combined organic layers were dried ($MgSO_4$) and evaporated to dryness to give 750 mg of crude product, which was purified by flash chromatography using 10% ethyl acetate – petroleum ether to give 0.24 g of pure **6** (45%), as a slightly yellow oil which gave hexane-soluble crystals on standing, mp 38.5–41.5°C; $[\alpha]_D^{21}$ −19.3° (*c* 2.56, $CHCl_3$); ir (neat): 1725 ($COOCH_3$), 1660 (CH=CH) cm^{-1}; 60 MHz nmr δ: 1.38 and 1.41 (2 bs, 12H, isopropylidene), 2.11–2.84 (m, 2H, CH=CH—C*H*$_2$—CH), 3.31–4.21 (m, 5H), 3.70 (s, 3H, OCH_3), 5.86 (2t, 1H, *J* = 1.5, 15 Hz, CH_3OOCCH=CH), 6.96 (2t, 1H, *J* = 7, 15.5 Hz, CH_3OOCCH=C*H*); mass spectrum (70 eV) *m/e* (rel. %): 315 (1.2) ($M^+ + CH_3$), 300 (0.9) (M^+), 299 (2.9) ($M^+ - H$), 287 (2.5), 286 (12.7), 285 (77.7) ($M^+ - CH_3$), 143 (100), 101 (96.5). *Anal.* calcd. for $C_{15}H_{24}O_6$: C 59.98%, H 8.05%; found: C 60.08%, H 7.92%.

Monoisopropylidene α,β-*Unsaturated Ester* 6b

A solution of di-isopropylidene ester **6***a* (0.24 g, 0.8 mmol) in 2.4 mL of 80% aqueous acetic acid was stirred for 3 h at 55°C. The reaction mixture was evaporated to near dryness, then diluted with ethyl acetate and washed twice with saturated $NaHCO_3$ solution (2×) and water (1×). The washings were reextracted with ethyl acetate (2×). The combined organic layers were dried ($MgSO_4$) and evaporated to give crude diol **6***b* containing some tetraol. This was purified by flash chromatography, using ethyl acetate as eluent to give 0.15 g of pure **6***b* (72%) as a slightly yellowish oil; $[\alpha]_D^{21}$ −27.9° (*c* 2.73, $CHCl_3$); ir (neat): 3420 (b, OH), 1710 (b, $COOCH_3$), 1655 (CH=CH) cm^{-1}; 60 MHz nmr δ: 1.40 (bs, 6H, isopropylidene), 2.40–2.73 (m, 2H, CH=CH—C*H*$_2$—), 2.93 (bs, 2H, O*H*), 3.47–4.27 (m, 5H), 3.70 (s, 3H, OC*H*$_3$), 5.94 (2t, 1H, *J* = 1.5, 15 Hz, CH_3OOC-C*H*=CH), 7.05 (2t, 1H, *J* = 7, 15 Hz, CH_3OOCCH=C*H*); mass spectrum (70 eV) *m/e* (rel. %): 256 (0.5), 247 (0.6), 246 (2.1), 245 (16.7), 242 (0.2) ($M^+ - H_2O$), 241 (0.1), 59 (100). *Anal.* calcd. for $C_{12}H_{20}O_6$: C 55.37%, H 7.75%; found: C 55.21%, H 7.90%.

*4,5-*O*-Isopropylidene-*L*-arabinose Diethyldithioacetal* 2b

A suspension of 22 g of L-arabinose diethyldithioacetal **2** (11) (0.090 mol) in 900 mL of acetone (freshly distilled over $KMnO_4$) and 22 mL of 2,2-dimethoxypropane (0.18 mol) was treated with 1.12 g of pyridinium *p*-toluenesulfonate (5) (4.5 mmol), and allowed to stir for 90 min. The reaction mixture was evaporated, dissolved in $CHCl_3$, and washed twice with water. The $CHCl_3$ solution was then dried ($MgSO_4$) and evaporated. The crude crystalline product was recrystallized from hot toluene to give 38.3 g of pure monoacetonide **2***b* (74%), mp 75–76°C, $[\alpha]_D^{22}$ +76.5° (*c* 0.83, $CHCl_3$) (lit. (4) mp 70–72°C, $[\alpha]_D^{20}$ −68.9° (*c* 2.19, $CHCl_3$) for the D-arabinose derivative). We report here, for the first time, spectral data for **2***b*: 60 MHz nmr ($CDCl_3$ + D_2O) δ: 1.27 (t, 6H, *J* = 7.5 Hz, SCH_2CH_3), 1.33 and 1.40 (2s, 6H, isopropylidene), 2.66 and 2.68 (2q, 4H, *J* = 7.5 Hz, SCH_2CH_3), 3.60–4.14 (m, 6H); mass spectrum (70 eV) *m/e* (rel. %): 296 (3.7) (M^+, *S*-cluster), 283 (0.5), 282 (0.6), 281 (3.8) ($M^+ - CH_3$), 263 (0.5), 256 (0.3), 236 (0.5), 235 (3.5) (M^+ − SEt), 135 (100).

*2,3-Di-*O*-benzyl-4,5-*O*-isopropylidene-*L*-arabinose Diethyldithioacetal* 2c

A 50% oil suspension of sodium hydride (5.81 g, 121 mmol) was washed by successively stirring and decanting with *n*-hexane (3×) and dry THF (1×), under an inert atmosphere (N_2). After cooling to 0°C, dry THF (100 mL) was added, 14.83 g of monoacetonide **2***b* was stirred in (50 mmol), and a crystal of imidazole added to accelerate anion formation. The evolution of H_2 was complete when the reaction mixture became homogeneous, at which time 14.4 mL of benzyl bromide (121 mmol) was added, followed by 0.92 g of tetra-*n*-butyl ammonium iodide (2.5 mmol). The reaction mixture was allowed to warm up to room temperature and stir for 3 h or when tlc (15% ethyl acetate in petroleum ether) showed the complete disappearance of **2***b*. Florisil (3.5 g, 100–200 mesh, Fisher) was added and the whole was transferred to a 500 mL round-bottomed flask, where it was evaporated to near-dryness under reduced pressure. The crude mixture was then repeatedly triturated with portions of petroleum ether to extract the product. After evaporation of the petroleum ether solution, one obtained 26.18 g of crude yellow dibenzyl compound **2***c* (quantitative yield) contaminated with some residual benzyl bromide. Although this crude product tended to darken at room temperature, the darkening is considerably slowed at −20°C, and it can be used directly for the next transformation. An analytically pure sample could be obtained through flash chromatography, using 7% ethyl acetate – petroleum ether as eluent, to give a stable, colorless oil; $[\alpha]_D^{21}$ −29.6° (*c* 3.15, $CHCl_3$); ir (neat): no assignable absorptions, 1500, 1455, 1380, 1370, 1070, 700 cm^{-1}; 60 MHz nmr δ: 1.23 and 1.24 (2t, 6H, *J* = 7.5 Hz, SCH_2CH_3), 1.34 and 1.42 (2s, 6H, isopropylidene), 2.66 and 2.69 (2q, 4H, *J* = 7 Hz, SCH_2CH_3), 3.64–4.44 (m, 6H), 4.78 and 4.83 (s and ABq, 4H, *J* = 11 Hz, C*H*$_2$φ), 7.31 (bs, 10H, φ); mass spectrum (70 eV) *m/e* (rel.%): 476 (0.6) (M^+, S-cluster), 461 (0.6) ($M^+ - CH_3$), 410 (0.7) (M^+ − SEt), 358 (0.5), 357 (1.7), 91 (100). *Anal.* calcd. for $C_{26}H_{36}O_4S_2$: C 65.50%, H 7.61%, S 13.45%; found: C 65.76%, H 7.50%, S 11.90%.

*2,3-*O*-Dibenzyl-4,5-*O*-isopropylidene-*L*-arabinose* 3b

The dithioacetal **2***c* (10.4 g, 22 mmol) in 150 mL of acetone and 25 mL of water was treated with 4 g of sodium bicarbonate (48 mmol) and, with slow portionwise addition at 0°C with good stirring, 6.1 g of iodine (24 mmol). After the addition, the mixture was allowed to warm up to room temperature and to stir overnight. Further portions of 6.1 g of iodine and 4 g of sodium bicarbonate were added in the morning at 0°C, and stirring was continued at room temperature for a further 8–10 h, at which time the excess iodine was destroyed by adding saturated sodium thiosulfate solution. After partial evaporation of the acetone, the product was extracted into ethyl acetate (3 × 50 mL) and the combined extracts washed with water (3 × 15 mL). After drying ($MgSO_4$) and evaporation of solvent, the crude product was purified by flash chromatography, using 15% ethyl acetate in petroleum ether. In one run 1.39 g of starting dithioacetal (13%) and 3.85 g of the unstable aldehyde **3***b* (yield 55%, based on converted starting material) were obtained. Other runs furnished **3***b* in 42–92% yield. Aldehyde **3***b* must be used immediately.

Compound **3***b* $[\alpha]_D^{22}$ +6.0° (*c* 1.46, $CHCl_3$); ir (neat): 1730 (CHO), 1612, 1495, 1455 cm^{-1}; 60 MHz nmr δ: 1.23 and 1.31 (2s, 6H, isopropylidene), 3.50–4.02 (m, 5H), 4.25 and 4.38 (s and ABq, 4H, *J* = 10.5 Hz, C*H*$_2$φ), 6.80 and 6.85 (2s, 10H, φ), 9.09 (d, 1H, *J* = 1 Hz, CHO).

*Dibenzylisopropylidenyl-*α,β-*unsaturated Ester* 7a

To a solution of methyl 3-nitropropionate (0.56 g, 4.2 mmol) and diisopropyl amine (0.46 mL, 3.3 mmol) in dry DMF (6 mL) was added 1.11 g of aldehyde **3***b* (3 mmol) in 1 mL of dry DMF. After stirring for 6 h at room temperature, 60 mL of water was added, and the product mixture was extracted into ether (3 × 30 mL). The ether layers were washed with water (5 × 15 mL), and the combined ether layers were dried ($MgSO_4$) and evapo-

For personal use only.

rated to give an oily mixture of nitro-alcohols **5***a* and excess methyl 3-nitropropionate. This was dissolved in 6 mL of anhydrous ether, and 0.56 mL of acetic anhydride (6 mmol) and a catalytic amount of 4-dimethylaminopyridine were added. The solution was allowed to stir for 2 h at room temperature, after which time 0.84 mL of triethylamine (6 mmol) was added, and the mixture was stirred a further 2 h. The solution was washed with KH_2PO_4 buffer (pH 4.4) and water, and the aqueous solutions reextracted once with ether. The combined ether layers were dried ($MgSO_4$) and evaporated to give crude nitro-olefin, as an oil. This was treated as before, for **6**, to give 1.10 g of crude **7***a*, which was purified by flash chromatography using 15% ethyl acetate in petroleum ether, to yield 0.34 g of pure **7***a* (25%) as an oil, $[\alpha]_D^{22}$ +4.3° (*c* 1.62, $CHCl_3$); ir (neat): 1725 ($COOCH_3$), 1660 (CH=CH) cm^{-1}; 60 MHz nmr δ: 1.28 and 1.37 (2s, 6H, isopropylidene), 2.22–3.07 (m, 2H, CH=CH—C*H*$_2$), 3.35–4.26 (m, 5H), 3.58 (s, 3H, OC*H*$_3$), 4.38 and 4.53 (s and ABq, 4H, *J* = 10.5 Hz, C*H*$_2$φ), 5.58 (2t, 1H, *J* = 1.5, 15 Hz, CH_3OOC-C*H*=CH), 6.63 (2t, 1H, *J* = 7, 15 Hz, CH_3OOCCH=C*H*), 7.03 and 7.06 (2s, 10H, φ); mass spectrum (70 eV) *m/e* (rel. %): 291 (0.6), 274 (0.2), 259 (0.9), 243 (0.6), 241 (0.1), 91 (100). *Anal.* calcd. for $C_{26}H_{32}O_6$: C 70.89%, H 7.32%; found: C 70.85%, H 7.41%.

Dibenzyldihydroxy-α,β-unsaturated Ester **7**b

Isopropylidene compound **7***a* (0.36 g, 0.8 mmol) was stirred for 3 h at 55°C in 4 mL of 80% aqueous acetic acid. The reaction mixture was worked up as before, for **6***a*, to give 0.29 g of diol **7***b* (88%) as a colorless oil which can be used as is for the next transformation. An analytical sample was obtained by flash chromatography, using 60% ethyl acetate in petroleum ether as eluent; $[\alpha]_D^{21}$ −0.92° (*c* 2.18, $CHCl_3$); ir (neat): 3460 (OH), 1715 ($COOCH_3$), 1650 (CH=CH) cm^{-1}; 60 MHz nmr δ: 2.30 (b, 2H, O*H*), 2.37–3.13 (m, 2H, —CH=CH—C*H*$_2$), 3.30–4.20 (m, 5H), 3.67 (s, 3H, OC*H*$_3$), 4.48 and 4.52 (2s, 4H, C*H*$_2$φ), 5.76 (2t, 1H, *J* = 1, 15 Hz, CH_3OOC—C*H*=CH), 6.81 (2t, 1H, *J* = 7, 15 Hz, CH_3OOCCH=C*H*), 7.20 (s, 10H, φ).

Dibenzyl Lactone **8**

The acyclic diol **7***b* (0.57 g, 1.4 mmol) in 14 mL of toluene was treated with 0.28 mL of a 0.5 *N* methanolic solution of sodium methoxide (0.14 mmol) at room temperature. A yellowish color was immediately discharged, and tlc indicated complete conversion to an intermediate C3-epimeric mixture of cyclic alcohols **9***a*. The solution was heated for 6 h at 20–80°C in an open flask while allowing a slow distillation of solvent, and replacing it with more toluene from time to time. While still warm, the solution was neutralized with methanol- and toluene-washed Dowex 50W-X8 resin (H^+), and allowed to cool. The resin was filtered off, washed with toluene, and the combined filtrate and washings were evaporated to give a quantitative yield of crude crystalline product. This was purified by flash chromatography, using 30% ethyl acetate in petroleum ether, followed by recrystallization from hot toluene to give 0.27 g of pure lactone **8** (51%), mp 154–156°C; $[\alpha]_D^{21}$ −6.4° (*c* 2.25, $CHCl_3$); ir ($CHCl_3$): 1715 (lactone), 1490, 1445, 1112, 1070 cm^{-1}; 60 MHz nmr δ: 1.23–2.51 (2m, 4H, ROOC—C*H*$_2$— and C*H*$_2$—CH(OBn)—), 2.91–4.31 (m, 6H), 4.53 and 4.81 (s and ABq, 4H, *J* = 11 Hz, C*H*$_2$φ), 7.13 (bs, 10H, φ); mass spectrum (70 eV, C.I.) *m/e* (rel. %): 355 (19.3), 313 (14.8), 286 (19.3), 285 (26.1), 284 (42.0), 283 (20.5), 267 (83), 256 (100); *Anal.* calcd. for $C_{22}H_{24}O_5$: C 71.72%, H 6.57%; found: C 71.50%, H 6.45%.

Dibenzyloxyhydroxymethyl Tetrahydropyran **9**a

Lactone **8** (0.11 g, 0.3 mmol) in 12 mL of methanol was treated with 0.6 mL of a 0.5 *N* methanolic sodium methoxide solution (0.3 mmol) at room temperature, and conversion to **9***a* seems to be immediate by tlc. After neutralization with methanol-washed Dowex-50W-X8 resin (H^+) and filtration, the solvent was evaporated to give a quantitative yield of oily **9***a* (0.115 g), which was used as is for the next step; $[\alpha]_D^{21}$ −6.9° (*c* 1.81, $CHCl_3$); ir (neat): 3440 (b, OH), 1730 ($COOCH_3$) cm^{-1}; 60 MHz nmr δ: 1.40–2.63 (m, 5H, CH_3OOC—C*H*$_2$—, —C*H*$_2$—CH(OBn)—, and O*H*), 3.13–4.23 (m, 6H), 3.69 (s, 3H, OCH_3), 4.68 and 4.82 (s and ABq, 4H, *J* = 11 Hz, C*H*$_2$φ), 7.37 (bs, 10H, φ); mass spectrum (70 eV) *m/e* (rel. %): 310 (1.3) ($M^+ - CH_2\phi + H$), 309 (8.2) (M^+—$CH_2\phi$), 203 (3.9), 187 (0.5), 186 (1.0), 185 (12.3), 91 (100).

Synthetic Tribenzoate **9**c

A solution of 90 mg of cyclic alcohol **9***a* (0.225 mmol) in 9 mL of dry methylene chloride was treated with 0.13 mL of trimethylsilyl iodide (0.91 mmol), at room temperature, under an atmosphere of N_2. Thin-layer chromatography indicated almost complete and immediate conversion to a very polar compound or complex. After stirring for 2 h, the reaction was quenched with methanol, the solvent evaporated, and the residue taken up in 1 mL of dry pyridine, to which was added 0.12 mL of benzoyl chloride (1.01 mmol), and a trace of 4-dimethylaminopyridine. After stirring overnight and stirring with H_2O for 1 h, the solution was diluted with chloroform (20 mL), washed with 0.5 *N* HCl (2 × 10 mL), saturated $NaHCO_3$ (2 × 10 mL), and water (1 × 10 mL). The aqueous layers were reextracted once each with chloroform (10 mL) and the combined organic layers were dried ($MgSO_4$), evaporated, and coevaporated with toluene (to rid the product of the last traces of pyridine) to give crude tribenzoate **9***c* along with some benzoyl chloride and an unidentified less polar compound present in significant amounts. Flash chromatography, using 25% ethyl acetate in petroleum ether gave 19 mg of pure crystalline tribenzoate **9***c* along with less pure fractions. Recrystallization from ether – petroleum ether gave material with mp 134–136°C; $[\alpha]_D^{21}$ +11.1° (*c* 0.95, $CHCl_3$); ir (film from solution): 1725 (b, $COOCH_3$, φCOO), 1600, 1582 cm^{-1}; 200 MHz nmr δ: 1.79 (q, 1H, *J* = 11 Hz), 2.12 (m and ABq of d, 3H, *J* = 6, 7, 15 Hz), 3.64 (s, 3H, OCH_3), 4.02 (m, 1H), 4.19 (m, 1H), 4.48 (ABq of d, *J* = 3, 5.5, 12 Hz), 5.44 (t of d, 1H, *J* = 4.5, 10 Hz), 5.54 (t, 1H, *J* = 10 Hz), 7.33–7.60 and 7.93–8.06 (m, 15H, φCOO—); mass spectrum (70 eV), *m/e* (rel.%): 289 (0.5), 288 (3.3), 275 (0.3), 263 (0.3), 105 (100), 77 (20.9). *Anal.* calcd. for $C_{30}H_{28}O_9$: C 67.66%, H 5.30%; found: C 67.37%, H 5.31%.

Diacid **10**

Partially resolved (*R*,*R*)-Feist's acid (88 mg, $[\alpha]_{546}^{22}$ +172° (*c* 0.6 EtOH), (lit. (8) $[\alpha]_{546}^{25}$ +176° (*c* 0.7, EtOH)) was hydrogenated in a Parr apparatus at 40 psi, using dry H_2 gas in 10 mL ethyl acetate over 10 mg of 5% Pd on charcoal. After 1 h, the catalyst was filtered off and washed several times with ethyl acetate, and the combined filtrate and washings were evaporated to give 90 mg of crude diacid **10**, mp 162.5–163.5°C, $[\alpha]_{546}^{21}$ +110°, $[\alpha]_D^{21}$ +92° (*c* 0.8, EtOH). When recrystallized from ether – petroleum ether, the diacid gave mp 163–164°C. No evidence for the formation of 2-ethylsuccinic acid could be found, as had been reported (9). We report here, for the first time, spectral data for **10**: 60 MHz nmr δ: 1.31 (d, 3H, *J* = 5.5 Hz, CH_3), 1.61–2.51 (m, 3H), 11.70 (bs, 2H, COOH); mass spectrum (70 eV) *m/e* (rel. %): 127 (1.9), 126 (5.1) ($M^+ - H_2O$), 100 (12.9) ($M^+ - CO_2$), 99 (100) ($M^+ - COOH$). *Anal.* calcd. for $C_6H_8O_4$: C 50.00%, H 5.60%; found: C 49.75%, H 5.75%.

Synthetic Dibenzoate **12**a

A solution of 21 mg of diacid **10** (0.15 mmol) in 1.5 mL of dry THF was treated with 0.38 mL of a 1 *M* THF solution of BH_3 (0.38 mmol) by dropwise addition at room temperature, under a dry N_2 atmosphere. A precipitate was immediately formed, accompanied by the evolution of gas. After stirring for 1 h,

For personal use only.

methanol was added, and the whole evaporated to dryness. Methanol was again added and evaporated three times to complete the distillation of trimethyl borate. The residue after the final evaporation was dissolved in 2 mL of pyridine, and treated with 0.05 mL of benzoylchloride (0.45 mmol), and a trace of 4-dimethylaminopyridine. After work-up as with **9***c*, the crude dibenzoate was purified by flash chromatography, using 5% ethyl acetate in petroleum ether to give 31 mg of pure dibenzoate **12***a* (66%) as an oil, $[\alpha]_D^{22} -12.9°$ (*c* 1.53, $CHCl_3$); ir (neat): 1710–1730 (4 pks, ϕCOO), 1602, 1585 cm^{-1}; 200 MHz F.T. nmr δ: 1.03–1.44 (m, 3H ring H), 1.17 (s, 3H, CH_3), 4.06 and 4.26–4.49 (d of d + m, 4H, CH_2OBz), 7.34–7.58 and 8.02 (m + d, 10H, ϕCOO); mass spectrum (70 eV) *m/e* (rel. %): 324 (0.2) (M^+), 219 (0.1) ($M^+ - \phi CO$), 205 (0.4), 204 (4.2), 203 (30.5), 105 (100). *Anal.* calcd. for $C_{18}H_{20}O_4$: C 74.05%, H 6.22%; found: C 73.79%, H 6.34%.

*Methyl 5,6-Dibenzoyloxypolyangioate (Ambruticin Methyl Ester Dibenzoate) 11*a

Methyl 5,6-dihydroxypolyangioate **11** (R = Me) (1), obtained from the sodium salt of ambruticin by acidification (Dowex 50W-X8 resin in ethanol) and methylation (CH_2N_2 in ether), was benzoylated in the usual manner for 2 days, and, after normal work-up, was purified by flash chromatography, using 20% ethyl acetate in petroleum ether to give dibenzoate **11***a* as a yellowish oil, ir (neat): 1725 (b, COOR), 1665 (w), 1600, 1580 cm^{-1}; 200 MHz nmr δ: 0.59–1.00 (m, 10H), 1.15–1.91 (m, 6H), 1.58 and 1.60 (2s, 6H, CH_3), 1.99–2.09 (m, 1H), 2.38–2.77 (m + ABq of d, 3H, J = 6,7,16 Hz), 3.00 (q, 1H), 3.70 (s, 3H, OCH_3), 3.82 (d of d, 1H, J = 3, 10 Hz), 3.94 (d of d, 1H, J = 6.5, 10 Hz), 4.03–4.19 (m, 2H), 4.95 (d of d, 1H, J = 9, 16 Hz), 5.17–5.58 (m, 7H), 7.39–7.65 and 7.83–8.13 (m, 10H, ϕ); mass spectrum (70 eV C.I.) *m/e* (rel. %): 697 (19.1) ($M^+ + 1$), 681 (3.8) ($M^+ - 15$), 680 (9.9), 573 (1.5), 559 (1.2), 531 (4.8), 479 (6.3), 467 (2.2), 456 (2.2), 454 (15.6), 435 (23.9), 357 (11.6), 331 (27.1), 263 (10.6), 209 (43.5), 193 (29.4), 123 (100), 105 (13.5).

*Ozonolytic Cleavage of 11*a*: Natural-source Tribenzoate 9*a *and Dibenzoate 12*a

Dibenzoate **11***a* (50 mg, 0.07 mmol) in 75 mL of dry methylene chloride was ozonolysed at −78°C until the blue color persisted. After flushing the excess ozone with a stream of nitrogen, 1 mL of dimethylsulfide was added at −78°C and the mixture was allowed to warm up to room temperature with stirring. To this was added 4.3 mL of a 0.14 *M* solution of zinc borohydride in ether (large excess), and the mixture was stirred a further 90 min while a precipitate formed. Enough saturated ammonium chloride solution was then added slowly to dissolve the precipitate and destroy excess borohydride. After separating the organic layer, the aqueous layer was extracted with ethyl acetate (6 × 40 mL), evaporated to near-dryness and reextracted with ethyl acetate (2 × 20 mL). The combined organic layers were dried ($MgSO_4$) and evaporated to give a crude mixture of alcohols. Flash chromatography of the mixture, eluting with 1:1 ethyl acetate – acetone (distilled over $KMnO_4$), furnished 3.7 mg of diol **12**, which when benzoylated as with synthetic **12**, gave 3.1 mg of dibenzoate **12***a* (13% from **11***a*), $[\alpha]_D^{21} -9.0°$ (*c* 0.15, $CHCl_3$), after hplc, using a mixture of ethyl acetate (2%), and methanol (0.3%) in petroleum ether. The remaining fractions after flash chromatography were combined, evaporated, and the residue was resubmitted to flash chromatography, eluting this time with 1:1 ethyl acetate – petroleum ether to give 22 mg of alcohol **9***c* (R^1 = H), which was immediately benzoylated as with synthetic **9***b* to afford 8.1 mg of pure crystalline tribenzoate **9***c* (21%, based on **11***a*), $[\alpha]_D^{21} +8.6°$ (*c* 0.4, $CHCl_3$), mp and mixture mp with synthetic **9***c* 132–134°C after recrystallization from ether – petroleum ether.

Dibenzoate **12***a* so prepared ran as one spot together with synthetic **12***a* on tlc, and was also homogeneous on flash chromatography and hplc analytical columns. Its spectra (200 MHz ^{1}Hmr, ir, and mass) were nearly superimposable with those of synthetic **12***a*, indicating the presence of a contaminant. Tribenzoate **9***c* so prepared had spectra (200 MHz nmr, ir, E.I. mass) superimposable with those of synthetic **9***c*. Mass spectrum (70 eV C.I.): *m/e* (rel. %): 533 (8.1) ($M^+ + 1$), 425 (3.8), 413 (3.1), 412 (11.6), 411 (50.8) ($M^+ - \phi COO$), 123 (100) ($\phi COOH_2^+$), 105 (33.8).

Received May 22, 1980

ALBERT R. NORRIS. Can. J. Chem. **58**, 2178 (1980).

The reactions of 2,4,6-trinitrotoluene (TNT) and TNT-d_3 (deuterated methyl group) with tetra-*n*-butylammonium *tert*-butoxide and with potassium *tert*-butoxide (KOBu^t), in the absence and presence of the crown ethers 18-crown-6, and dicyclohexyl-18-crown-6, have been studied kinetically in *tert*-butanol at 30.0°C. Evidence is presented to support the suggestion that, at ratios of crown ether to base > 1, the reactive base species is free *tert*-butoxide ion and that this rapidly reacts with TNT or TNT-d_3 to form, in each case, a mixture of σ-complex and purple anion. Specific rate constants for the reactions of free *tert*-butoxide ion and ion-paired KOBu^t with TNT and TNT-d_3 to form both σ-complex and purple anion are compared.

ALBERT R. NORRIS. Can. J. Chem. **58**, 2178 (1980).

On a étudié la cinétique des réactions du trinitro-2,4,6 toluène (TNT) et du TNT-d_3 (groupe méthyle deutéré) avec le *tert*-butylate de tétra-*n*-butylammonium et avec le *tert*-butylate de potassium (*t*BuOK) en l'absence et en présence des éthers 18-couronne-6 et dicyclohexyl-18 couronne-6 dans le *tert*-butanol à 30°C. On apporte des données pour appuyer la suggestion qu-à des rapports d'éther couronne/base > 1 l'espèce basique réactive est l'ion *tert*-butylate libre et cet ion réagit rapidement avec le TNT ou le TNT-d_3 pour former dans chaque cas un mélange d'un complexe σ et d'un anion pourpre. On compare la constante de vitesse spécifique des réactions de l'ion *tert*-butylate libre et de la paire d'ion *t*BuOK avec le TNT et le TNT-d_3 pour former le complexe σ et l'anion pourpre.

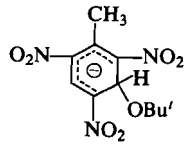
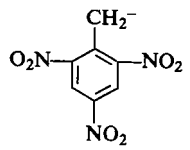
Introduction



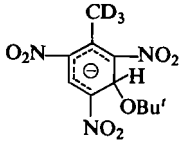
The reactions of nitroaromatic compounds with alkoxide ions in alcohols or dipolar aprotic solvents can lead to a variety of reaction products including σ- and π-complexes, radical anions, and anions derived via loss of a proton from the nitroaromatic (1).

We have previously reported on the σ-complex formation reactions of 1,3,5-trinitrobenzene (TNB) and 1,3,5-trideutero-2,4,6-trinitrobenzene (TNB-d_3) (2) and the σ-complex formation and proton abstraction reactions of 2,4,6-trinitrotoluene (TNT) and 2,4,6-trinitrotoluene fully deuterated at the methyl position (TNT-d_3) with alkoxide ions (RO^-) in the corresponding alcohols (ROH) (3–5).



The results of kinetic and spectrophotometric studies of the reactions of *tert*-butoxide ion ($^-$OBu^t) with TNT and TNT-d_3 in *tert*-butanol were interpreted in terms of a simultaneous formation of σ-complex and "purple anion", **1** and **2**, and **3** and **4**, respectively, in each system (5).

These products were considered to result from the interactions of substrate with ion-paired KOBu^t, although the reaction of substrate with free *tert*-butoxide ion could not be ruled out with absolute certainty. In both systems, the purple colored anion, TNT^- (**2**) or TNT-d_2^- (**4**), predominated over σ-complex at equilibrium. The equilibrium constant (K) for the formation of **2** at 30.0°C was determined to lie between 5×10^4 and 10^6 M^{-1}.



In an attempt to gain more detailed information concerning the role of ion-pairing in determining both the reactivity of the *tert*-butoxide ion and the relative stabilities of both σ-complex and purple anion in these systems, we have studied the reactions of TNT and TNT-d_3 with tetra-*n*-butylammonium *tert*-butoxide ((*n*-BU)$_4$NOBu^t) and with potassium *tert*-butoxide in the absence

trations ([KOBu^t]$_0$) $1.15 \times 10^{-3} M$ to $1.80 \times 10^{-2} M$, in the absence of added crown ether, at each base concentration employed and at each wavelength at which absorbances (A) were measured (420, 520, and 650 nm), plots of log ($A_\infty - A_t$) versus time were linear to at least 80% completion of reaction. For a given concentration of base, the slopes of the log ($A_\infty - A_t$) versus time plots ($\equiv k_{obs}/2.303$) were, within experimental error, independent of the initial concentration of TNT (1.0×10^{-5} to $5.0 \times 10^{-5} M$) and of the wavelength at which values of A were measured. The plot of k_{obs} versus [KOBu^t]$_0$ was linear, passed through the origin, and possessed a slope of $7{,}600 \pm 400\ M^{-1}\ s^{-1}$. A slope of $7{,}000 \pm 400\ M^{-1}\ s^{-1}$ for the k_{obs} versus [KOBu^t]$_0$ plot was reported earlier (5).

The measured A_∞ values at 420, 520, and 650 nm point to the exclusive formation of only purple anion **2** in the reaction process described above. This result is completely in accord with the observations made in previous studies (5).

At any given [KOBu^t]$_0$ over the range $1.15 \times 10^{-3} M$ to $1.15 \times 10^{-2} M$, the addition of crown ether resulted in a marked enhancement in the rate of change in absorbance at 420, 520, or 650 nm. For each of the three wavelengths at which absorbances (A) were measured, plots of log ($A_\infty - A_t$) versus time were linear to at least 80% completion of reaction. The magnitudes of k_{obs} were experimentally reproducible to ±5% and were, within experimental error, independent of the wavelength at which values of A were measured and independent of [TNT]$_0$ ($1.0 \times 10^{-5} M$ to $5.0 \times 10^{-5} M$). At any fixed initial concentration of base in the range [KOBu^t]$_0$ $1.50 \times 10^{-4} M$ to $10.0 \times 10^{-4} M$, k_{obs} values increased linearly with increasing ratio of [crown ether]$_0$/[KOBu^t]$_0$ and reached a maximum value, k_{obs} (max), at a ratio of [crown ether]$_0$/[KOBu^t]$_0 \geq 1$. Within experimental error, k_{obs} (max) at a given [KOBu^t]$_0$ was the same for both polyethers employed in these studies.

Values of k_{obs} (max) at 30.0°C plotted versus the [KOBu^t]$_0$ are shown in Fig. 1. The slope of the resulting straight line, which passes through the origin, is $6.5 \pm 0.5 \times 10^5\ M^{-1}\ s^{-1}$ and is, within experimental error, the same for both 18-crown-6 and DCH-18-crown-6.

At the same stoichiometric concentration of *tert*-butoxide ion, the reaction of TNT with (n-butyl)$_4$NOBu^t was found to be very much more rapid than the reaction of TNT with KOBu^t. In the reactions of TNT with (n-butyl)$_4$NOBu^t, absorbances recorded at 420 and 520 nm yielded log ($A_\infty - A_t$) versus time plots linear to approximately

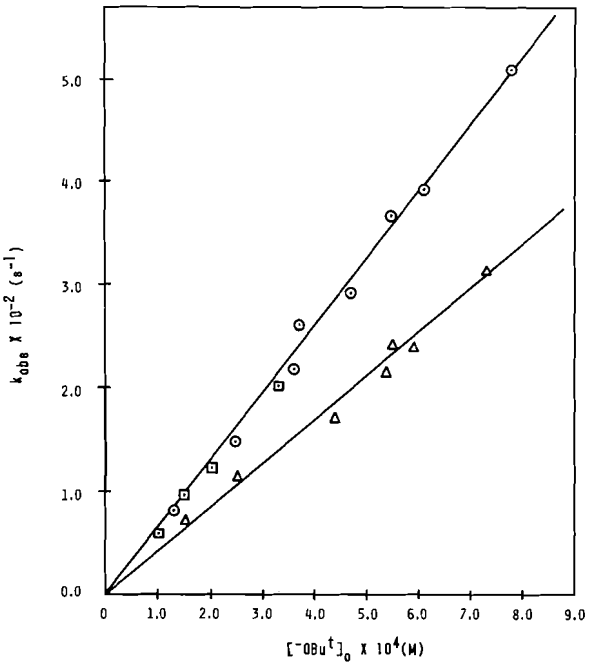

FIG. 1. k_{obs} versus [$^-$OBu^t]$_0$ for the following reactions at 30.0°C in *tert*-butanol: ⊙ 2,4,6-trinitrotoluene–KOBu^t–18-crown-6 at ratios of 18-crown-6 to KOBu$^t \geq$ 2:1; ⊡ 2,4,6-trinitrotoluene–(C_4H_9)$_4$NOBu^t; △ 2,4,6-trinitrotoluene-d_3–KOBu^t–18-crown-6 at ratios of 18-crown-6 to KOBu$^t \geq$ 2:1.

80% completion of the reaction. At a given [(n-butyl)$_4$NOBu^t]$_0$ in the range 1.0×10^{-4} to $5.0 \times 10^{-4} M$, k_{obs} values were independent of the [TNT]$_0$ (1.0×10^{-5} to $5.0 \times 10^{-5} M$) and the wavelengths at which values of A were recorded. The k_{obs} values could, however, only be obtained with a reproducibility of from ±10 to ±15% in this system as compared to a reproducibility of ±5% in the TNT–KOBu^t and TNT–KOBu^t–crown ether reaction systems. The plot of k_{obs} versus [(n-butyl)$_4$NOBu^t]$_0$ was linear, passed through the origin and possessed a slope of $6 \pm 1 \times 10^5\ M^{-1}\ s^{-1}$ (see Fig. 1).

In these fast reactions of TNT with (n-butyl)$_4$NOBu^t and KOBu^t–crown ether, at ratios of [crown ether]$_0$/[KOBu^t]$_0$ of from 2:1 to 16:1, the recorded A_∞ values at 420, 520, and 650 nm were consistent with the formation of a reaction mixture consisting of 60 ± 5% σ-complex **1** and 40 ± 5% purple anion **2**. This ratio was essentially constant over the entire range of [KOBu^t]$_0$ and ratios of [crown ether]$_0$/[KOBu^t]$_0$ (when ≥ 1) utilized in these studies.

Following the rapid formation of this mixture of products was a comparatively slow reaction leading to the formation of **1** as the exclusive nitro-

For personal use only.

aromatic species in solution. Values of k_{obs} for this slow reaction were, within experimental error, independent of the wavelength at which values of A were measured, independent of $[TNT]_0$, independent of $[KOBu^t]_0$, and at any given $[KOBu^t]_0$, independent of $[crown\ ether]_0/[KOBu^t]_0$ ratio at ratios ≥ 1. The mean value of k_{obs} for the slow reaction was $0.10 \pm 0.02\ s^{-1}$ at 30.0°C.

Kinetic Studies Employing TNT-d_3 as Substrate (30.0°C)

In the absence of crown ether, over the range of $[KOBu^t]_0$ 1.15×10^{-3} to $1.15 \times 10^{-2}\ M$, absorbances recorded at 430 nm yielded log $(A_\infty - A_t)$ versus time plots linear to approximately 60 to 70% completion of reaction. The slopes of these lines were, at a constant $[KOBu^t]_0$, independent of $[TNT\text{-}d_3]_0$. A plot of k_{obs} versus $[KOBu^t]_0$ was linear, passed through the origin, and yielded a slope of $1{,}800 \pm 100\ M^{-1}\ s^{-1}$.

At any fixed concentration of $KOBu^t$ over the range $[KOBu^t]_0$ 1.15×10^{-3} to $1.15 \times 10^{-2}\ M$, addition of crown ether resulted in a marked increase in the rate of increase in absorbance at 430 nm. Plots of log $(A_\infty - A_t)$ versus time were linear to at least 80% completion of the reaction. The slopes of these plots were experimentally reproducible to ±5% and were, within experimental error, independent of $[TNT\text{-}d_3]_0$ (1.0×10^{-5} to $6.0 \times 10^{-5}\ M$). At any fixed, initial concentration of base in the range $[KOBu^t]_0$ 1.50×10^{-4} to $1.50 \times 10^{-3}\ M$, k_{obs} increased linearly with increasing ratio of $[crown\ ether]_0/[KOBu^t]_0$ and reached a maximum value, k_{obs} (max), at ratios of $[crown\ ether]_0/[KOBu^t]_0 \geq 1$. Within experimental error, k_{obs} (max) for the reaction of TNT-d_3 with $[KOBu^t]_0$ was the same for both polyethers used in the studies. For a fixed $[KOBu^t]_0$ over a wide range of initial base concentrations and with $[crown\ ether]_0/[KOBu^t]_0$ ratios of from 1:1 to 16:1, the average ratio of k_{obs} (max) for TNT/k_{obs} (max) for TNT-d_3 at 30.0°C, was found to be 1.58 ± 0.02 (mean of 21 runs).

Values of k_{max} (TNT-d_3) at 30.0°C plotted as a function of $[KOBu^t]_0$ are shown in Fig. 1. The slope of the resulting straight line, which passes through the origin, is $4.2 \pm 0.4 \times 10^5\ M^{-1}\ s^{-1}$.

In the reactions of TNT-d_3 with $KOBu^t$–crown ether at ratios of $[crown\ ether]_0/[KOBu^t]_0$ of from 2:1 to 16:1 the A_∞ values at 430, 520, and 600 nm are consistent with the formation of σ-complex **3** and the purple anion **4**, in the ratio of 90 ± 5:10 ± 5.

A further slow reaction following the rapid formation of the above reaction mixture followed the same pattern as observed in the slow reaction in the TNT–$KOBu^t$–crown ether system. The k_{obs} in this case was $0.030 \pm 0.005\ s^{-1}$ at 30.0°C, independent of $[TNT\text{-}d_3]_0$, $[KOBu^t]_0$, and at a fixed $[KOBu^t]_0$, independent of $[crown\ ether]_0/[KOBu^t]_0$ ratio.

At any given stoichiometric concentration of *tert*-butoxide ion over the range $1.0 \times 10^{-4}\ M$ to $1.5 \times 10^{-3}\ M$, the rates of reaction of both TNT and TNT-d_3 are much greater when either $KOBu^t$, in the presence of crown ether, or $(n\text{-butyl})_4NOBu^t$ is used as a source of the *tert*-butoxide ion than when $KOBu^t$ is used as a source of the *tert*-butoxide ion. For any given $[^-OBu^t]_0$, the maximum k_{obs} in the $KOBu^t$–crown ether systems is achieved at $[crown\ ether]_0/[KOBu^t]_0 \geq 1$. Also, for any given $[^-OBu^t]_0$, both crown ether–$KOBu^t$ combinations at ratios of $[crown\ ether]_0/[KOBu^t]_0 > 1$ and $(n\text{-butyl})_4NOBu^t$ lead, within experimental error, to the same k_{obs} (Fig. 1). It seems reasonable therefore to associate the reactions of TNT and TNT-d_3 with $(n\text{-butyl})_4NOBu^t$ and with $KOBu^t$–crown ether combinations, at ratios $[crown\ ether]_0/[KOBu^t]_0 > 1$, as reactions of substrate with free *tert*-butoxide ion (7, 8).

If, as suggested previously, the reactive form of base when $KOBu^t$ is present in *tert*-butanol at 30.0°C is the ion-paired $KOBu^t$ species then, at any given stoichiometric concentration of *tert*-butoxide ion, the ratio of k_{obs} for the reaction of TNT with free *tert*-butoxide ion to k_{obs} for the reaction of TNT with ion-paired $KOBu^t$ species is of the order of 86. For the case of TNT-d_3 as substrate, the corresponding ratio of k_{obs} values at any given stoichiometric concentration of *tert*-butoxide ion is approximately 228. The ratio is not the same for the two substrates because k_{obs} is a pseudo-first order rate constant relating to the disappearance of substrate (TNT or TNT-d_3) along two competing pathways and the proportion of reaction along each pathway is not the same for the two substrates.

More meaningful comparisons of rate constants may be achieved as follows. If we consider that TNT and TNT-d_3 undergo essentially irreversible reaction with free *tert*-butoxide ion via parallel first order reaction paths then

[1] $k_{obs}\,(max) = (k_1 + k_2)[^-OBu^t]_0$

for the TNT system and

[2] $k_{obs}\,(max) = (k_3 + k_4)[^-OBu^t]_0$

for the TNT-d_3 system. In each case, k_n is the specific rate constant associated with the formation of species n according to the rate law

[3] $-d[substrate]/dt = k_n[substrate][^-OBu^t]_0$

Also, for the proposed reaction scheme

[4] $k_1/k_2 = [\mathbf{1}]/[\mathbf{2}]$

and

[5] $k_3/k_4 = [3]/[4]$

at any time t during the initial fast reaction (9).

Hence, from the slopes of the plots of k_{obs} (max) versus $[^-OBu^t]_0$ in Fig. 1 we have that

[6] $k_1 + k_2 = 6.5 \times 10^5\ M^{-1}\ s^{-1}$

and

[7] $k_3 + k_4 = 4.2 \times 10^5\ M^{-1}\ s^{-1}$

Since in the reaction of TNT-d_3 with free $^-OBu^t$ the initial fast reaction is associated with the formation of **3** and **4** in a 90 to 10 ratio, the values of k_3 and k_4 are calculated to be $\geq 3.8 \times 10^5\ M^{-1}\ s^{-1}$ (maximum value $4.2 \times 10^5\ M^{-1}\ s^{-1}$) and $4.2 \times 10^4\ M^{-1}\ s^{-1}$, respectively at 30.0°C.

Assuming that there is no kinetic isotope effect associated with the formation of the σ-complexes **1** and **3**, we obtain a value of k_1 of $\geq 3.8 \times 10^5\ M^{-1}\ s^{-1}$ at 30.0°C. Since

$$k_1 + k_2 = 6.5 \times 10^5\ M^{-1}\ s^{-1}$$

we find a maximum value of k_2 of $2.7 \times 10^5\ M^{-1}\ s^{-1}$ (minimum value $2.3 \times 10^5\ M^{-1}\ s^{-1}$). A summary of the values of the specific rate constants k_1, k_2, k_3, and k_4 is presented in Table 1.

The values of the specific rate constants k_2 and k_4 suggest that a kinetic isotope effect of 6.4 is associated with the formation of **2** and **4** via reaction of substrate with free *tert*-butoxide ion. This may be compared to a kinetic isotope effect of 8 ± 1 reported earlier (5) for the formation of **2** and **4** via the reaction of substrate and ion-paired KOBu^t. Kinetic isotope effects of 8.4 ± 1.4 and 7.0 ± 0.5 have been reported for the formation of **2** and **4** by reaction of substrate with free isopropoxide ion in isopropanol and free ethoxide ion in ethanol, respectively (3, 4).

The k_1 and k_2 values, obtained as outlined above, predict a 58.5 to 41.5 ratio of **1** to **2** at the completion of the initial fast reaction. This is in very good agreement with the 60 ± 5 to 40 ± 5 ratio observed experimentally.

The values of the specific rate constants listed in Table 1 clearly indicate that, in the reactions of TNT and TNT-d_3 to form both σ-complex (**1** or **3**) and purple anion (**2** or **4**), free *tert*-butoxide ion is a far more reactive species than is ion-paired KOBu^t. Higher reactivities of free ions as compared to ion pairs have been observed previously in both nucleophilic displacement (7, 8, 10) and electron transfer processes (11, 12). One way in which the results may be rationalized is in terms of a concept involving ion-pairing equilibria in the transition state complex (13). To the extent that charge is dispersed in the transition state relative to the reactants, ion pairing is expected to be less important in the transition state and the reaction is therefore faster for the freer species. Our higher ratio of k(free $^-OBu^t$)/k(KOBu^t) for formation of the extensively charge delocalized σ-complex (~270) as compared to the less extensively charge delocalized purple anion (~ 46) seems to be in accord with this proposal.

TABLE 1. Specific rate constants for the reactions of TNT and TNT-d_3 with free and ion-paired *tert*-butoxide ion in *tert*-butanol at 30.0°C

Species formed	k^a for ion paired KOBu^t ($M^{-1}\ s^{-1}$)	k^b for free $^-OBu^t$ ion^b ($M^{-1}\ s^{-1}$)	$\frac{k_n\text{ (free }^-OBu^t)}{k_n\text{ (KOBu}^t)}$
1	1.4×10^3	3.8×10^5	2.7×10^2
2	7.0×10^3	2.7×10^5	0.39×10^2
3	1.4×10^3	3.8×10^5	2.7×10^2
4	8.0×10^2	4.2×10^4	0.53×10^2

[a]Obtained as described in ref. 5.
[b]Obtained as described in the text.

Based on studies of the reactions of sodium isopropoxide with TNT and TNT-d_3 in isopropanol, it was concluded that free isopropoxide ion was more reactive than sodium isopropoxide in the proton transfer reaction but possessed comparable reactivity to the ion-pair in the σ-complex formation reaction (4). Different orders of reactivity in the sodium isopropoxide and potassium *tert*-butoxide systems might well arise because of differences in steric properties and solvation requirements in the two base systems. Further speculation on this point must await a direct study, following procedures described in this paper, of the reactivity of free isopropoxide ion with TNT and TNT-d_3.

Experimental

Materials

The preparation and purification of TNT and TNT-d_3 were as previously described (3, 4). Reagent grade *tert*-butanol was refluxed over Linde 4 Å Molecular Sieve for several hours, then distilled under nitrogen. Only the middle fraction of the distillate was retained. Solutions of potassium *tert*-butoxide were prepared and standardized as previously described (5). The crown ethers, 18-crown-6 and dicyclohexyl-18-crown-6, obtained from PCR Research Chemicals Inc., were dried to constant weight *in vacuo* before use and weighed and handled under an atmosphere of dry nitrogen. Eastman tetra-*n*-butylammonium hydroxide titrant in methanol (1 *M*) was used as received. Solutions containing tetra-*n*-butylammonium *tert*-butoxide were prepared following the procedure outlined by Guthrie *et al.* (14) and standardized in the same manner as the solutions of potassium *tert*-butoxide. Different batches of tetra-*n*-butylammonium *tert*-butoxide yielded reproducible kinetic results only when the evaporation and pumping down procedure used to remove methanol was repeated at least 4 times. Stock solutions (~ 10^{-1} *M*) were a pale yellow color but the solutions used in the kinetic runs (~ 10^{-4}–10^{-3} *M*) were colorless.

Procedure

The equipment and procedures used in carrying out kinetic measurements and in obtaining spectral data for the σ-complex and the purple anion have been described previously (3–5).

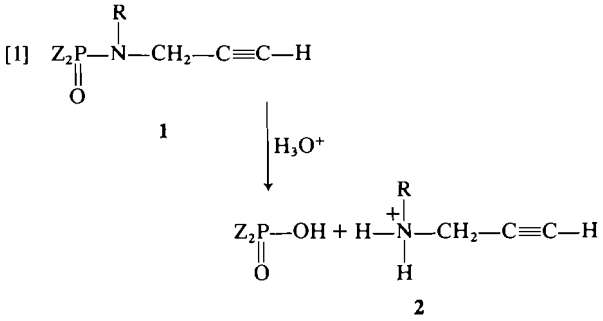
Aminomethylation of *N*-propargylphosphoramides. Synthesis of unsymmetrical acetylenic diamines

BERNARD CORBEL,[1] JEAN-PAUL PAUGAM, AND GEORGES STURTZ

Laboratoire de Chimie Hétéro-organique, ERA CNRS No. 612, Faculté des Sciences, Université de Bretagne Occidentale, F-29283 Brest, France

Received April 14, 1980

BERNARD CORBEL, JEAN-PAUL PAUGAM, and GEORGES STURTZ. Can. J. Chem. **58**, 2183 (1980).

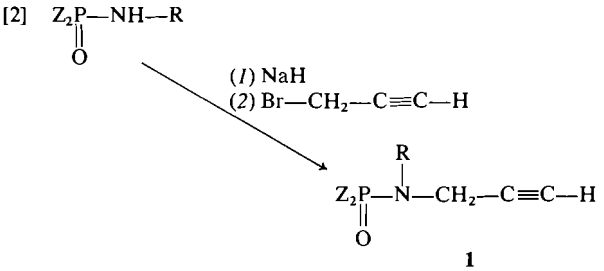


The preparation of *N*-alkyl-*N*-(4-dialkylamino-2-butynyl)phosphoramides **3** using the Mannich reaction is described. The acidic hydrolysis of those phosphoramides leads to unsymmetrical acetylenic diamines **4**.

BERNARD CORBEL, JEAN-PAUL PAUGAM et GEORGES STURTZ. Can. J. Chem. **58**, 2183 (1980).

On décrit la préparation des phosphoramides de *N*-alkyle et de *N*-(dialkylamino-4 butyne-2)yle **3** à l'aide de la réaction de Mannich. L'hydrolyse acide de ces phosphoramides conduit aux diamines acétyléniques dissymétriques **4**.

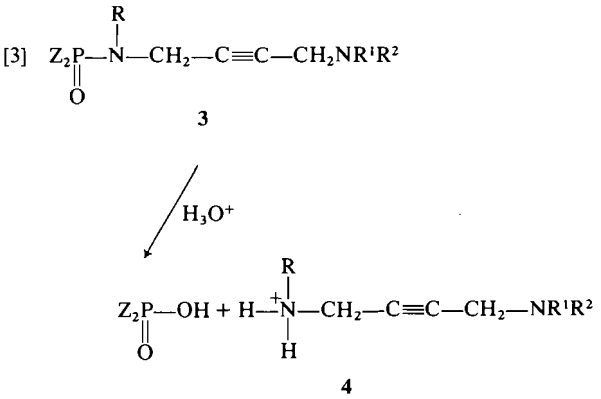
Introduction



The propargylic ammonium salts **2** have been shown to act as specific irreversible inhibiting substrates for certain flavin-linked oxidases (1). We have recently shown that such compounds are readily prepared by the acid-catalysed hydrolysis of phosphoramides of the type **1** (eq. [1])

[1] $Z_2P(=O)-N(R)-CH_2-C\equiv C-H \xrightarrow{H_3O^+} Z_2P(=O)-OH + H-\overset{+}{N}(R)-CH_2-C\equiv C-H$

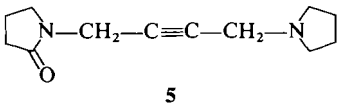
1 → **2**



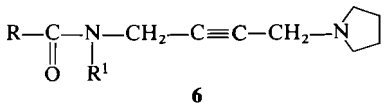
The phosphoramides in turn are obtained by the simple route shown in eq. [2] (2).

[2] $Z_2P(=O)-NH-R \xrightarrow[(2)\ Br-CH_2-C\equiv C-H]{(1)\ NaH} Z_2P(=O)-N(R)-CH_2-C\equiv C-H$

1



We now wish to report that aminomethylation of **1** leads to the unsymmetrical acetylenic derivatives **3** which are readily hydrolysed to unsymmetrical acetylenic diamines **4** (eq. [3])



[3] $Z_2P(=O)-N(R)-CH_2-C\equiv C-CH_2NR^1R^2 \xrightarrow{H_3O^+} Z_2P(=O)-OH + H-\overset{+}{N}(R)-CH_2-C\equiv C-CH_2-NR^1R^2$

3 → **4**

The amides **3** themselves are also of considerable pharmacological interest due to their structural relationship to the potent muscarinic agent oxotremorine **5** (3)[2] and the recently described carboxamides **6** (4).

5

6

Results and Discussion

The *N*-propargylphosphoramides **1**, prepared according to eq. [2], were aminomethylated by first heating **1** with paraformaldehyde in dioxane containing Cu_2Cl_2 and then adding a secondary amine (eq. [4]).

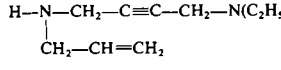
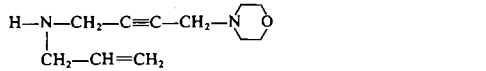
Aminomethylation of propargylic derivatives carrying a variety of other functional groups such as hydroxyl, carbonyl, or nitrile, had previously been described (5). The experimental procedure used by us was adapted from Mornet and Gouin (6).

The aminomethylation of **1** was followed by gas chromatography and found to be complete within 5 min irrespective of the nature of the secondary amine employed. The aminomethylated products **3** were obtained as colorless oils after purification by vacuum distillation. They are indefinitely stable when stored in a refrigerator but deteriorate and turn brown upon standing at room temperature. The yields of the isolated products **3** produced according to eq. [4], together with some physical properties and spectroscopic data (^{1}H and ^{13}C nmr), are given in Table 1.

The deviation of the yields from the quantitative conversions of **1** → **3** indicated by the vpc analysis is due to some mechanical loss but primarily to decomposition if the distillation temperatures were excessively high (entries *d*, *e*). Neither changes in the nature of Z ($(CH_3)_2N$— to EtO—) nor use of different secondary amines had significant effect on the rate of aminomethylation of **1** and the product yield.





The phosphoramides **3** were cleaved to the diamines **4** upon refluxing in 3 *N* hydrochloric acid for 12 h. During the reflux period the solutions turned light yellow and dark brown respectively when purified samples of **3** or crude products were used. Workup of the reaction mixture followed by vacuum distillation gave the diamines **4** in good to excellent yields (Table 2). The spectroscopic and analytical data were in full agreement with the proposed structures. The compounds decompose unless stored at cold temperatures.

The use of the diamine **4***a* in the Mannich reaction followed by hydrolysis afforded the triamine **4***h* in 60% overall yield. The sequence suggests the possibility of preparing polyamines of the type **7**.

[a]Yields are quoted for distilled or recrystallized (CH_2Cl_2 – petroleum ether) compounds.

The pharmacological properties of the new acetylenic compounds **3** and **4** as possible specific inhibiting substrates similar to **2**, **5**, and **6** are being investigated.

Experimental

General Comments

Infrared spectra were recorded as thin films on a Perkin Elmer 257 spectrometer. The main stretching frequencies were, for compounds **3***a–g* ν(P=O) = 1215 cm^{-1}, ν((P)—N—C) = 985 cm^{-1}, ν(P—N—(C)) = 745 cm^{-1}; for compounds **3***g–j* ν(P=O) = 1250 cm^{-1}; for amines **4**, ν(N—H) = 3260 cm^{-1}.

The ^1H nmr spectra were taken on a JEOL C60HL spectrometer at 60 MHz, in $CDCl_3$ with TMS as internal standard (δ = 0); ^{31}P nmr were taken on the same spectrometer at 24.3 MHz using a ^{31}P probe, the chemical shifts being taken from 85% H_3PO_4 used as external reference. For compounds **3***a–g* ^{31}P nmr δ: 22.2 ± 0.3 ppm (neat), **3***h–j* ^{31}P nmr δ: 9.3 ± 0.3 ppm (10% $CDCl_3$). The ^{13}C nmr spectra were determined on a JEOL FX60 FT nmr spectrometer interfaced to a Texas Instruments JEOL JEC 980 B computer (24K), with TMS as internal standard. Pulse widths were in the range 4–8 μs, pulse repetition 2.5 s, frequency bandwidth 2500 Hz, impulsion number 800–8000; the resolution was between 0.6 to 0.9 Hz.

The decoupling techniques, including proton noise decoupling, coherent off-resonance decoupling, gated noise decoupling (for undecoupled spectra), or low noise decoupling (51 dB) were used for the assignment of signals. The ^1H and ^{13}C chemical shifts of the diethoxy and bis-dimethylamido phosphoryl are omitted in Table 2; (CH_3—N—P) ^1H nmr δ: 2.69 ± 0.01 ppm, doublet, J_{P-H} = 9.6 ± 0.1 Hz; ^{13}C nmr δ: 36.5 ± 0.3 ppm, doublet, J_{CNP} = 3.7 Hz; (CH_3—CH_2—O—P) ^1H nmr δ: 1.35 ± 0.04 ppm, triplet; δ: 4 ± 0.01 ppm, pentuplet, $J_{H-H} = J_{P-H}$ = 7 Hz; ^{13}C nmr δ: 16.1 ± 0.1 ppm, doublet, J_{CCOP} = 7 Hz; δ: 62.2 ± 0.1 ppm, doublet, J_{COP} = 4.9 Hz. The signs of coupling constants have not been established and absolute values only are tabulated.

Mass spectroscopic data were obtained on a Varian MAT-311 spectrograph from Université de Rennes. Found M^+ are in agreement with the calculated values. The microanalyses showed the following maximum deviations from the calculated values: C, ±0.25; H, ±0.2.

Gas chromatographic analyses were carried out on a Girdel 3000 model with flame ionization detector, fitted with steel tube (150 cm × 0.125 cm) packed with 10% (w/w) SE-30 on 80–100 mesh Chromosorb W-AW DMCS, N_2 being the carrier gas (25–30 mL/min). Boiling points and melting points (Köfler) are not corrected.

N-*Alkyl*-N-*(2-propynyl)phosphoramides 1*

These compounds have been obtained from *N*-alkylphosphoramides and propargylbromide (1) (eq. [2]).

N-*Alkylphosphoramides*

The compounds have been prepared either through the slightly modified procedure of Arceneaux *et al.* (7) or Sauders *et al.* (8) (procedure (*a*)), or using the two-phase transfer process which has also been reported by Zwierzack (9) (procedure (*b*)).

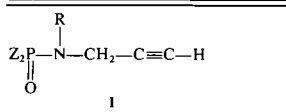
Procedure (a)

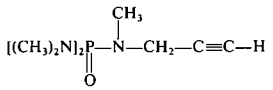
To a cold solution (−10 to +10°C) of 3 mol of primary amine[3] in dried ether (400 mL) was added dropwise an ethereal solution of chlorophosphate (1 mol in 150 mL ether). After awhile, a white solid appeared. After the addition was complete, the reaction mixture was then allowed to warm to room temperature and stirred for about 2–3 h. The hydrochloride salt was filtered off, the filtrate washed with water, and then dried over $MgSO_4$. Evaporation of the solvent, followed by vacuum distillation, gave the title compounds.

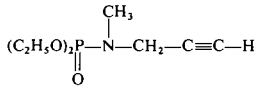
Procedure (b)

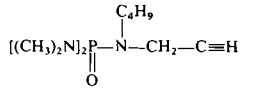
To a cold mixture (0–5°C) of 0.22 mol of amine, 20% sodium hydroxide (80 mL), and benzyltriethylammonium chloride (2 g) in methylene chloride (80 mL) was added dropwise, under stirring, a solution of bis-dimethylamidochlorophosphate (0.2 mol) in methylene chloride (50 mL). After the addition was complete, the reaction mixture was kept at 0°C for 1 h and then allowed to warm to room temperature. The phosphoramide was extracted once with methylene chloride (80 mL) and twice with chloroform (2 × 80 mL). The organic phase was dried over $MgSO_4$. After evaporation of the solvents, the vacuum distillation or crystallization gave the title compounds. Infrared spectra: ν(NH) = 3195 ± 5 cm^{-1}; ν(P=O) = 1195 ± 5 cm^{-1}.

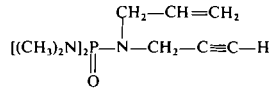
The products obtained by these procedures are collected in Table 3.

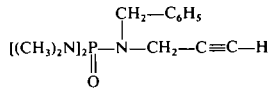












N-*Alkyl*-N-*(2-propynyl)phosphoramides 1*

To a stirred suspension of 1 mol NaH (previously washed twice with dried ether and once with THF) in 250 mL anhydrous THF was added dropwise 1 mol of *N*-alkylphosphoramide at

[3]Triethylamine was used as an acid acceptor when the amine was expensive. The yields were in the same range as when 2 equivalents of amine were employed.

TABLE 4. Physical characteristics of the *N*-alkyl-*N*-propargylphosphoramides **1** (eq. [2])

 1	Molecular formula	Boiling point, °C (Torr)	n_D^t	% yields[a]
	$C_8H_{18}N_3OP$ (203.1)	$109_{(0.05)}$; Melting point 62°C.	—	92
	$C_8H_{16}NO_3P$ (205.1)	$68_{(0.01)}$	1.4420^{18}	89
	$C_{11}H_{24}N_3OP$ (245.2)	$124_{(0.05)}$	1.4740^{21}	79
	$C_{10}H_{20}N_3OP$ (229.1)	Melting point 68°C	—	84
	$C_{14}H_{22}N_3OP$ (279.2)	Melting point 120°C	—	77

[a]Yields are quoted for distilled or recrystallized (CH_2Cl_2 – petroleum ether) compounds.

such a rate as to maintain a gentle reflux. The reaction was completed by heating (~1 h reflux) until the H_2 evolution had ceased. The reaction mixture was cooled between −10°C and −20°C and propargyl bromide (1.1 mol in 100 mL THF) was added slowly during which time sodium bromide precipitated.

After the addition was complete, the reaction mixture was stirred and allowed to warm to room temperature over 1 h. It was cautiously (it might contain excess NaH) hydrolysed and extracted once with ether (200 mL) and three times with chloroform (3 × 200 mL). The organic phase was dried over $MgSO_4$. After evaporation of the solvents, the crude products were purified by recrystallization (CH_2Cl_2 – petroleum ether) or distillation under vacuum (Table 4). Infrared spectra: ν(C—H_{free}) = 3200 cm^{-1}, ν(C—H_{ass}) = 3170 cm^{-1}, ν(C≡C) = 2100 cm^{-1}, ν(P=O) = 1195 cm^{-1}; (—CH_2—C≡C—H) ^{1}H nmr δ: 3.75 (2d, 2H, J_{P-H} = 9.7 Hz, J_{H-H} = 2.4 Hz); δ ~ 2.3 (t, 1H) sensitive to concentration; ^{13}C nmr $\delta_{(C-1)}$: 38.7 (d, J_{CNP} = 6 Hz), $\delta_{(C-2)}$: 80 ± 0.4 (d, J_{CCNP} = 3 Hz) $\delta_{(C-3)}$: 72.2 ± 0.1.

All attempt to prepare compounds **1** using the phase transfer process failed.

An excess of NaH can lead to a propargylic rearrangement. To avoid this undesired reaction the excess NaH can be removed by decanting after the amide formation is complete if the sodium salt of the amide is soluble (R = C_4H_9—, $PhCH_2$—, CH_2=CH—CH_2—). Alternatively, the reaction mixture is kept below 0°C during and after the propargyl bromide addition. In the latter case hydrolysis is done at 0°C.

N-*Alkyl*-N-*(4-dialkylamino-2-butynyl)phosphoramides 3*

A mixture of 0.1 mol of propargylic phosphoramide **1**, 0.2 mol of paraformaldehyde, and 0.2 g of Cu_2Cl_2 in dioxane (150 mL) became yellowish when heated to 60–70°C. A solution of the secondary amine (0.11 mol in 20 mL of dioxane or in water for dimethylamine) was quickly added (2 min). The reaction was complete within 5 min as shown by vpc. The dioxane was evaporated and the mixture was washed with water (100 mL) and extracted with chloroform (3 × 80 mL). The organic phase was dried over $MgSO_4$ and the solvent evaporated. Distillation of the crude products under vacuum gave the title compounds (see Table 1).

N-*Alkyl*-N-*(4-dialkylamino-2-butynyl)amines 4*

N-Alkyl-*N*-(4-dialkylamino-2-butynyl) phosphoramide (0.05 mL) was hydrolysed by refluxing with 300 mL of 3 *N* hydrochloric acid for about 10 to 12 h. After cooling, the reaction mixture was made alkaline to pH 12 by addition of commercial sodium hydroxide (40% w/w). Extraction with chloroform (3 × 80 mL), drying over $MgSO_4$, and evaporation of the solvent gave the desired amines which were purified by distillation (see Table 2).

Mass spectrometry of diamantane and some adamantane derivatives

ROBERT J. WALTMAN AND A. CAMPBELL LING[1]

Department of Chemistry, San Jose State University, San Jose, CA 95192, U.S.A.

Received December 21, 1979[2]

ROBERT J. WALTMAN and A. CAMPBELL LING. Can. J. Chem. **58**, 2189 (1980).

The mass spectrometric fragmentation of adamantane, adamantane-d_{16}, diamantane, 1- and 2-adamantanol, and 3,5,7-trimethyl-1-adamantanol has been re-examined, and new data for diamantane and 3,5,7-trimethyl-1-adamantanol are presented in more detail. Metastable peak data have been used to support potential fragmentation pathways. Simple statistical considerations applied to peak intensity data seem to indicate that ionization occurs at the primary bridgehead in both adamantane and diamantane, and that loss of a primary hydrogen is favored over loss of a secondary hydrogen atom.

ROBERT J. WALTMAN et A. CAMPBELL LING. Can. J. Chem. **58**, 2189 (1980).

On a examiné de nouveau la fragmentation en spectrométrie de masse de l'adamantane, de l'adamantane-d_{16}, du diamantane, des adamantanols 1 et 2 et du triméthyl-3,5,7 adamantanol-1 et on présente avec plus de détails les données relatives au diamantane et au triméthyl-3,5,7 adamantol-1. On a utilisé le pic métastable pour appuyer les voies potentielles de fragmentation. De simples considérations statistiques faites sur les données d'intensité du pic semblent indiquer que l'ionisation se produit au niveau de la tête de pont primaire de l'adamantane et du diamantane et que la perte d'un hydrogène primaire est favorisée par rapport à la perte d'un atome d'hydrogène secondaire.

[Traduit par le journal]

Introduction

The polycyclic compound adamantane (tricyclo[3.3.1.$1^{3,7}$]decane) has proven to be of great interest to physical chemists and radiation chemists. In particular, adamantane provides a relatively inert isolation matrix for a variety of purposes, including those involving electron spin resonance (esr) studies of organic radical species formed via molecular fragmentation induced by radiolytic or photolytic processes. Compared to inert gas matrices or SF_6, or glassy organic matrices such as 2-methylpentane and 2-methyltetrahydrofuran, adamantane matrices doped with suitable solutes provide narrow-line (often less than 1 G) well resolved isotropic esr spectra for radicals derived from the solute up to a molecular size equivalent to approximately C_{10}. Further, these solute esr spectra are obtained via a solid isolation matrix with a usable temperature range from approximately 150°C down to accessible cryogenic temperatures, and exhibiting radical half-lives that are often in excess of several days, even at temperatures up to 100°C (1).

Diamantane (pentacycl[7.3.1.$1^{4,12}$.$0^{2,7}$.$0^{6,11}$]tetradecane mp 244–245°C, also known as "congressane") can also be used for the same purpose, although it offers no advantages over adamantane as an isolation matrix (2).

The mechanism of radical formation in adamantane (or diamantane) itself, undoped with any solute, has produced a major controversy concerning the nature of the initial step produced by ionizing radiation; apparently conflicting data exist concerning the identity of the initial radical obtained from a variety of investigative techniques, including: ENDOR studies (3), X-band and Q-band esr (4), spin trapping and scavenger studies (5), product analyses, and semi-empirical calculations (6). These data are summarized in ref. 2. The major point of contention is whether the 1-hydrogen (bridgehead) or a 2-hydrogen atom (secondary position) is lost to form the adamantyl radical on radiolysis of the pure solid, or whether a stabilized radical formed by C—C bond cleavage could occur (7). In order to provide further data that might aid in clarifying this controversy, we have examined some adamantane derivatives subjected to radiolysis via the electron beam source of a conventional mass spectrometer.

Experimental Section

All compounds used (adamantane, adamantane-d_{16}, diamantane, 1- and 2-adamantanol, and 3,5,7-trimethyl-1-adamantanol) were obtained from commercial sources. Mass spectra were taken via a Hitachi Perkin-Elmer RMU-9 mass spectrometer at an ionization energy of 80 eV, or from a Varian EM-600 mass spectrometer at 70 eV.

Results and Discussion

Diamantane

The mass spectrum of diamantane, like adamantane (8), is highly unusual in that the molecular ion peak (*m/e* 188) is also the base peak (Fig. 1*b*). The great stability of the molecular ion for diamantane is attributed to the nearly strain free interlocking system of rings and the structure's

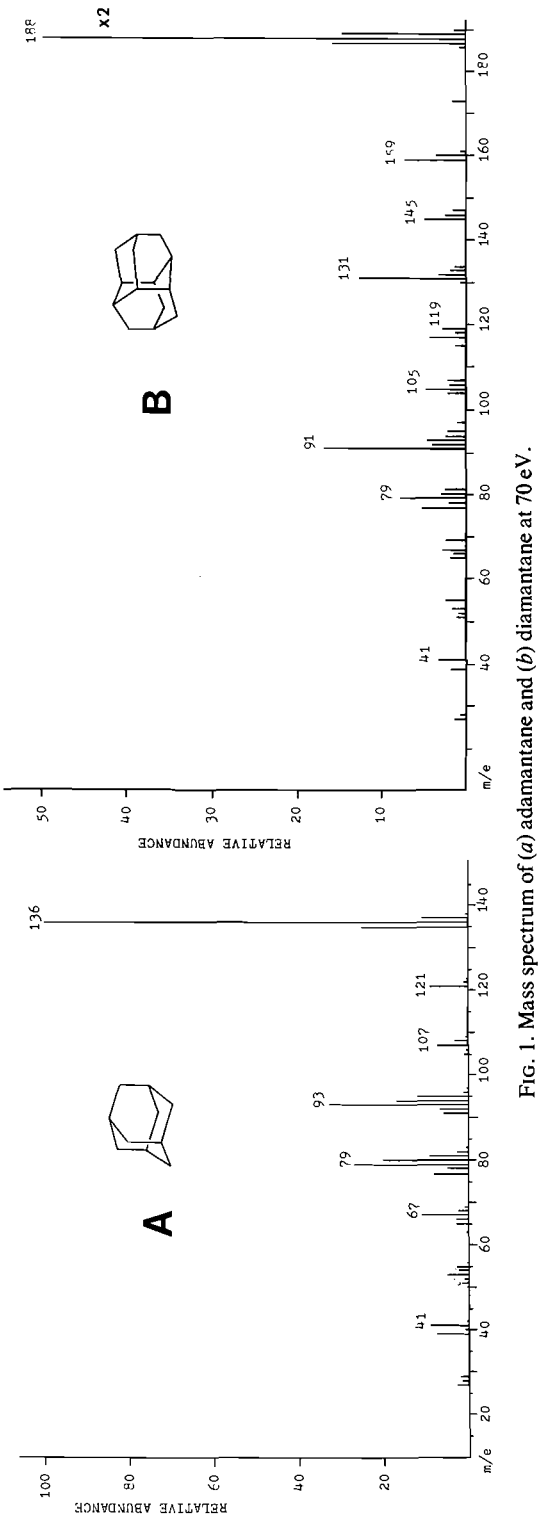

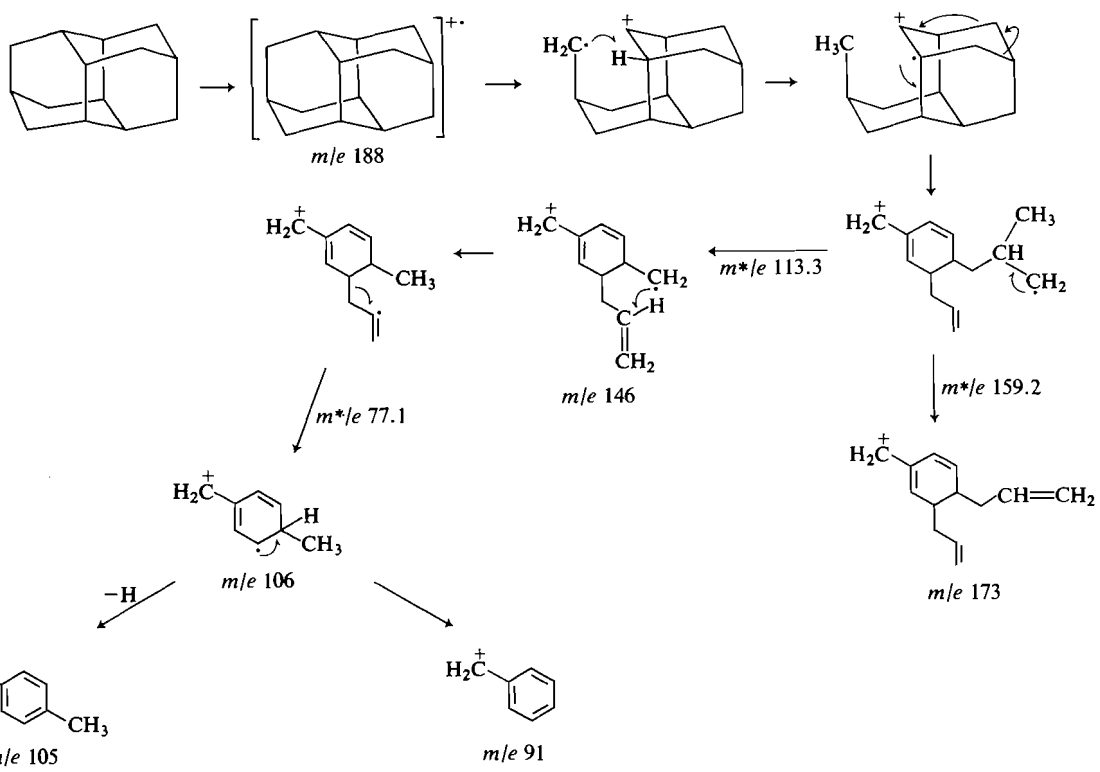

FIG. 1. Mass spectrum of (*a*) adamantane and (*b*) diamantane at 70 eV.

ability to easily accommodate the loss of an electron. The molecular ion base peak is seen to be ca. five times greater in intensity than the next most abundant fragment ion at *m/e* 91, an unusual feature. Cupas *et al.* (9) suggested this ion at *m/e* 91 results from a symmetrical splitting of the diamantane molecular ion into two equal fragments, followed by rearrangement and loss of three hydrogen atoms from one of the fragments to yield the tropylium ion $C_7H_7^+$ (10). However, Cupas *et al.* did not report metastable peaks or any other evidence to support such a fragmentation pathway, nor have we been able to observe any metastable peaks to support this particular hypothesis. Further, Fig. 1*b* shows a relative intensity of only ca. 3% for the half-mass peak at *m/e* 94. In contrast to diamantane, many polycyclic compounds which undergo symmetrical splitting into two equal fragments, e.g. pentacyclodecanes (11), usually show a large half-mass peak intensity (they are often the base peak) reflecting the relatively low energy pathway available for such a fragmentation. We therefore suggest an alternate pathway for the formation of the *m/e* 91 ion observed, and which we tentatively assign to the benzyl $C_7H_7^+$ fragment at this time. This is a multistep process involving fragmentation to produce phenylalkyl ions and various C_1–C_4 fragments, as shown in Scheme 1. Metastable peak data, on which we base our scheme, are shown in Table 1.

Further evidence to support Scheme 1 is provided by pyrolysis studies of adamantane (12) and 1-nitroadamantane (13) in which decomposition of both compounds resulted primarily in the formation of a mixture of benzene and mono- and dialkylbenzenes. Also, mass spectrometric studies of some substituted adamantanes by Dolejsek *et al.* (8) has shown that various phenylalkyl ions could be formed on fragmentation of some adamantane derivatives. We suggest that the same type of fragment ions are produced from the adamantane homolog, diamantane, as shown in Scheme 1. The great abundance of the *m/e* 91 peak in the mass spectrum of diamantane (Fig. 1) suggests intrinsic stability, such as is conferred by a delocalized system, and thus we suggest that a reasonable assignment for this fragment could well be the benzyl ion (**1**).

3,5,7-Trimethyl-1-adamantanol

For many singly substituted adamantane derivatives, the mass spectral fragmentation patterns observed are substantially similar regardless of whether the substituent is at the 1- or 2-position.

I

SCHEME 1

However, for other substituents, there are significant differences in fragmentation pathways, and it is pertinent to our discussion of the new data for this substituted adamantane to compare and contrast these aspects using 1- and 2-adamantanol as illustrative examples (8, 14). Although both charge site initiation and radical site initiation stemming from a saturated oxygen atom can cause reaction, it appears that 1-adamantanol favors a radical site initiation process while 2-adamantanol favors charge site initiation. These contrasting behavioral patterns are well illustrated in Fig. 2, where mass spectra for 1- and 2-adamantanol are shown. In 2-adamantanol, the major fragmentation pathway results in loss of the hydroxyl group as H_2O after an initial hydrogen atom transfer (which offsets the radical site's tendency to initiate a reaction) to yield the *m/e* 134 base peak. The mass spectrometry of 2-adamantanol has been discussed briefly by Greidanus (14).

For 1-adamantanol, in which elimination of the hydroxyl group is not the key fragmentation mech-

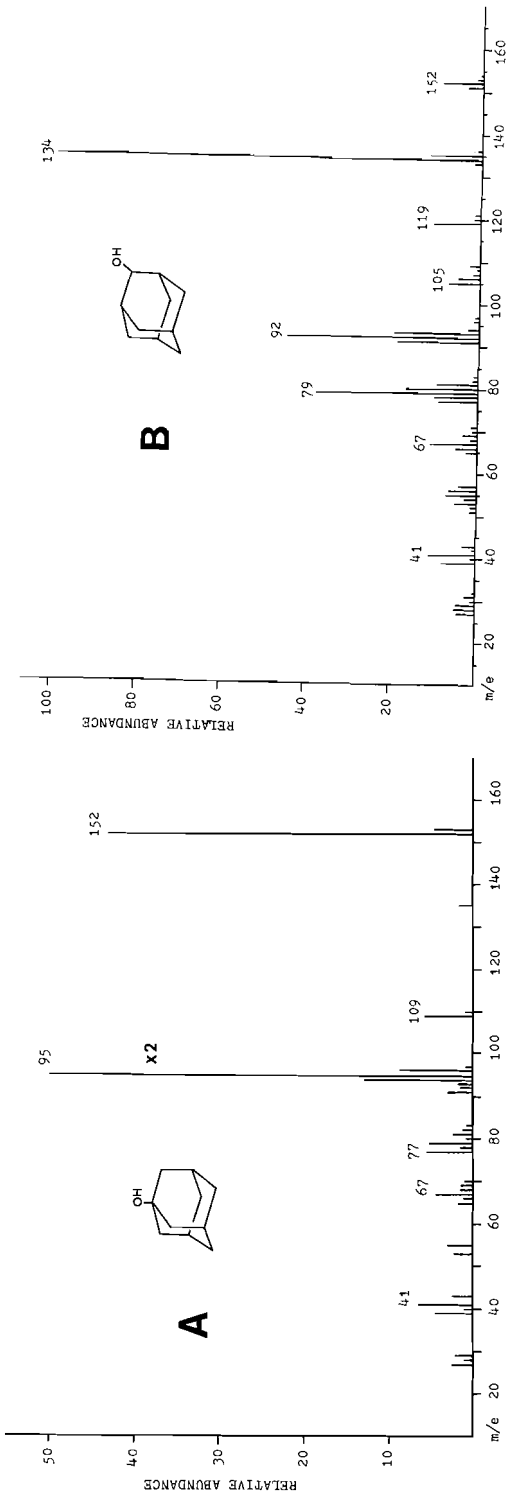

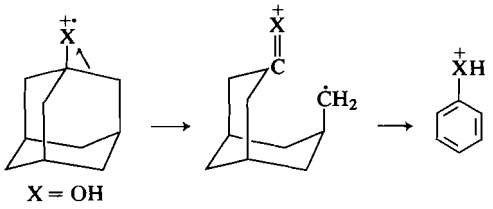

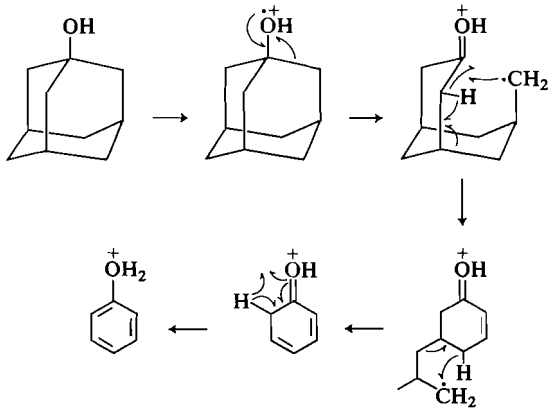

FIG. 2. Mass spectra of (*a*) 1-adamantanol and (*b*) 2-adamantanol at 70 eV.

SCHEME 2

anism, Dolejsek *et al.* (8) proposed the formation of a protonated phenol structure for the *m/e* 95 base peak involving the transfer of two hydrogen atoms and splitting-off of a $C_4H_9^{\cdot}$ neutral radical. This is shown in Scheme 2.

Utilizing this general approach proposed by Dolejsek and co-workers, we can postulate a more specific fragmentation pathway for 1-adamantanol, shown in Scheme 3, which accounts satisfactorily for the mass spectrum displayed in Fig. 2*a*.

SCHEME 3

More importantly, these data are pertinent to the fragmentation pattern we have observed for TMA, shown in Fig. 3.[3] In this previously unstudied compound, three of the four bridgehead positions are substituted with methyl groups. The most apparent changes in the mass spectrum of TMA occurred in the relative intensities of the molecular ion peaks (43% for 1-adamantanol and 26% for TMA), and in the appearance of a $(M - CH_3)^+$ peak (molecular ion minus a methyl group) in TMA, although the corresponding $(M - H)^+$ fragment (molecular ion minus a hydrogen atom) was absent in the spectrum of 1-adamantanol. This is not unusual, however, since the possibility for fragmentation usually increases with the size of the alkyl substituent.

The base peak of TMA occurs at *m/e* 123. In conjunction with this, we observed the presence of

[3]For simplicity, 3,5,7-trimethyl-1-adamantanol is referred to as TMA.

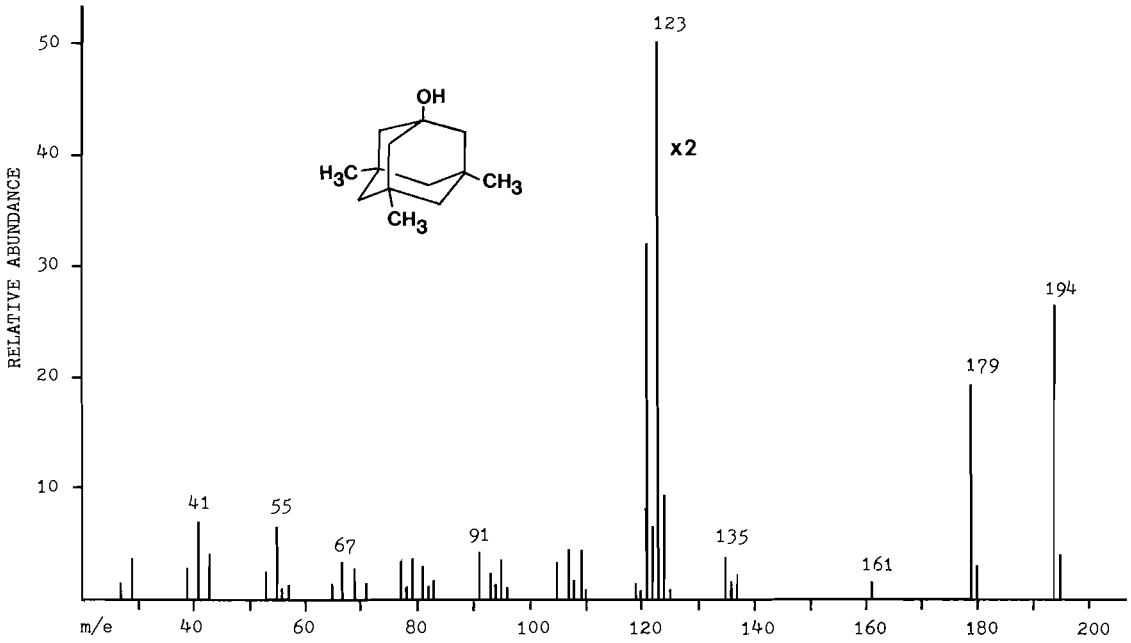

FIG. 3. Mass spectrum of 3,5,7-trimethyl-1-adamantanol at 70 eV.

TABLE 2. Metastable ion peaks m^*/e in 3,5,7-trimethyl-1-adamantanol for transformations of the type $A^+ \rightarrow B^+ + C$

a metastable peak at m^*/e 78.0 (calcd. 78.0) and postulate that transformation 2 of Table 2 could well be the key fragmentation pathway for TMA. This pathway is similar to that given in Scheme 3 for 1-adamantanol, with formation of a corresponding protonated phenol structure as originally proposed by Dolejsek *et al.* (8). To account for the major peaks in the mass spectrum from this totally bridgehead-substituted adamantane, particularly the *m/e* 121, 123, and 179 peaks, we made a careful search for metastable peaks in the range *m/e* 75 through 194, inclusively. These data are recorded in Table 2. A possible fragmentation pathway based on these data is shown in Scheme 4. From the intermediate **2**, since the preferred fragmentation pathway results from loss of the larger alkyl group, the relative abundance of the *m/e* 123 peak (path A) is much greater than the *m/e* 179 peak (path B). It is interesting to note that when TMA undergoes the same postulated fragmentation pathway as 1-adamantanol in Scheme 3, the three major peaks at *m/e* 121, 123, and 179, as well as the *m/e* 105 and 161 peaks, can be accounted for from the common ancestor **2** in Scheme 4.

Summary

Metastable peak data were collected for diamantane and 3,5,7-trimethyl-1-adamantanol, and possible fragmentation pathways were presented based on these and other data (8, 12, 13). All data appear to indicate that fragmentation of these polycyclic compounds via electron beam bombardment or via pyrolysis results primarily in the formation of alkyl-substituted benzenes.

Athough the effects on molecules of different radiation sources can differ, the results are often found to be the same; for example, the work of Filby *et al.* (15) has shown that identical results are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

SCHEME 4

obtained from both electron beam and γ-radiolysis of adamantane in the pure phase solid state. Electron beam bombardment via mass spectrometry (ca. 70 eV) of adamantane and diamantane yielded $(M - H)^+$ peaks of relative intensity 25% to 16%, respectively, while loss of the hydrogen atom from both adamantane and diamantane is thought to be the primary reaction seen via esr following γ-radiolysis of the pure solids. It appears then that gas phase isolated molecular ionization events differ substantially to the events occurring in condensed phase solid state processes (a prima facie result of the hindered energy transfer capabilities inherent to gas phase species). Further, since the origin of the hydrogen atom that is lost on ionization is yet unknown, these data from mass spectral analysis have not allowed us to identify the initial radical and/or ionic species formed on radiolysis. Deuterium labeling studies at either the bridgehead or secondary position may be helpful but will not necessarily be definitive due to isotope effects and possibly random H-atom rearrangements which are so prominent in the mass spectrometry of many saturated alicyclic and polycyclic hydrocarbons.

Substitution of the four bridgehead positions with deuterium atoms might provide more helpful data concerning initial H-atom loss in these three dimensional cage-like molecules, but synthesis does not appear to be practical at this time. Also, despite the availability of the perdeuterated adamantane-d_{16}, the mass spectrum is essentially the same as that of adamantane when the mass of the heavier isotope of hydrogen is considered, and thus no new data are obtained. However, although simple statistical considerations can be misleading, it is interesting to consider further the relative ratios of $(M - H)^+$ peaks for the two compounds. The ratios observed, 25% and 16% for adamantane and diamantane, respectively, suggest a greater participation by the bridgehead hydrogens in H-atom loss processes as compared with the secondary positions. In support of this hypothesis, we note that although diamantane has eight bridgehead hydrogen atoms, compared to only four in adamantane (see Fig. 1), they form two distinct populations, and only two of these eight bridgehead H-atoms (called "primary bridgehead H-atoms") are comparable to the four in adamantane. The ratio of the number of primary bridgehead H-atoms in adamantane to those in diamantane is thus 2 to 1, respectively, and this is approximately reflected in the experimental ratio of relative intensities of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$(M - H)^+$ peaks for adamantane and diamantane (25 to 16, respectively). Further, the number of secondary H-atoms in adamantane and diamantane are the same, so we might have predicted equal peak intensities if these were the major participants. Coupled with data reported by others, in particular the work of Filby and Gunther (15), this suggests to us that on irradiation, the bridgehead H-atoms of adamantane and diamantane may play a greater role in H-atom loss processes than the H-atoms at the secondary sites.

Photocycloaddition of 2-methyl-1,4-naphthoquinone to enol esters. A photochemical approach to benzofuran derivatives

HSING-JANG LIU AND WING HONG CHAN

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 26, 1980

HSING-JANG LIU and WING HONG CHAN. Can. J. Chem. **58**, 2196 (1980).

Naphthoquinone **1** undergoes facile photocycloaddition with vinyl acetate and isopropenyl acetate to give cyclobutane derivatives in excellent yields. The photocycloaddition reactions were found to be completely regioselective; in the case of vinyl acetate, a mixture of epimeric acetates **2** and **3** was obtained and in the case of isopropenyl acetate, a single adduct **7** was formed. Treatment of the photoadducts with dilute sulfuric acid resulted in skeletal rearrangement giving naphthofurans **4** and **8**.

HSING-JANG LIU et WING HONG CHAN. Can. J. Chem. **58**, 2196 (1980).

La cycloaddition photochimique de la naphtaquinone **1** sur les acétates de vinyle et d'isoprényle se fait facilement et conduit avec d'excellents rendements aux dérivés du cyclobutane. On a trouvé que les réactions de photocycloaddition sont complètement régiosélectives. Dans le cas de l'acétate de vinyle, on obtient un mélange des acétates épimères **2** et **3** et seul l'adduit **7** se forme dans le cas de l'acétate d'isoprényle. Lorsqu'on traite les adduits photochimiques par de l'acide sulfurique dilué, il en résulte une transposition du squelette qui conduit aux naphtofurannes **4** et **8**.

[Traduit par le journal]

It has been well established that conjugated enones undergo photocycloaddition reactions with olefinic and acetylenic compounds resulting in cyclobutane ring formation, a process which has found extensive use in organic synthesis.[1] In contrast, 2-ene-1,4-diones usually react photochemically with compounds containing carbon–carbon multiple bond by a different route giving rise to oxetanes or products derived from oxetanes and only limited number of examples are known to produce cyclobutane rings.[2] We wish to report the photocycloaddition of 2-methyl-1,4-naphthoquinone (**1**) to vinyl acetates, which proceeds regiospecifically to give cyclobutane derivatives in excellent yield. As well, we wish to illustrate the application of this method to the construction of benzofuran systems which are of considerable interest in natural product chemistry.[3]

Naphthoquinone **1** and vinyl acetate reacted cleanly and rapidly when a benzene solution was irradiated with a 450 W Hanovia high-pressure quartz mercury-vapor lamp through a Pyrex filter. The reaction was complete within 1 h and a mixture of two epimeric adducts **2** and **3** (4:1 by nmr integration) was isolated in virtually quantitative yield. The two epimers, which were inseparable by thin-layer or column chromatography, could be partially separated by crystallization using dichloromethane–cyclohexane which gave the pure crystalline minor isomer **3**, mp 115–116°C. The regiochemistry of the products was suggested by the nmr spectra[4] showing in each case a doublet of doublets (δ 5.07 for the major product and δ 5.20 for the minor) for the methine proton adjacent to the acetoxy group. The *cis* stereochemistry of the ring junction was indicated for each compound since these compounds[5] were recovered intact after prolonged treatment with *p*-toluenesulfonic acid in benzene (16). Furthermore, in the nmr spectrum of the minor product the acetoxy group appeared at δ 2.04 as a singlet while the major product gave a singlet at δ 1.94. The appearance of the acetoxy group at rather high field in the latter case suggested that it is in close proximity to the aromatic ring and is shielded by it. Structure **2** was assigned accordingly.

The photocycloaddition reaction was found to be completely regioselective; no isomers other than **2** and **3** were detected. Although the reasons for the profound selectivity remain unclear, the observed regiochemistry is expected in view of the previous observation (16, 17) that the photocycloaddition of 2-alkyl-2-cyclohexenones to olefins proceeds with difficulty whereas 3-alkyl-2-cyclohexenones undergo facile photocycloaddition reactions with vinyl acetate to give head-to-tail adducts as the major products.

[1]For reviews see ref. 1.

[2]See ref. 2 for an extensive review of the work in this area prior to 1973. Additional examples are to be found in refs. 3–14.

[3]For examples of existing methods for the preparation of benzofuran systems and natural products containing them see ref. 15.

[4]Since the major product **2** could not be obtained in pure form, its analysis was based on the nmr spectrum of the 4:1 mixture of **2** and **3** which showed a minor set of signals identical with those of pure **3**.

[5]The 4:1 mixture was used.

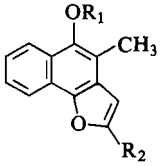
Treatment of the mixture of **2** and **3** with aqueous 5% sulfuric acid in refluxing tetrahydrofuran for 16 h gave, in 92% yield, naphthofuran **4**, mp 120–121°C, resulting apparently from an array of reactions including hydrolysis, retro-aldol, aromatization, hemiacetal formation, and dehydration. When the pure minor isomer **3** was subjected to the same acid treatment, a comparable yield of naphthofuran **4** was obtained. In addition to spectroscopic evidence, the structure of **4** was further confirmed by acetylation with acetic anhydride in pyridine to give the corresponding acetate **5**, mp 70–71°C.

By suitable choice of the two counterparts involved in the photocycloaddition, the above two-step sequence could, in principle, be extended to the preparation of naphthofurans possessing general formula **6**. A further example is illustrated below.



Irradiation of quinone **1** and isopropenyl acetate in benzene for 1 h gave, in quantitative yield, a single adduct **7** the nmr spectrum of which showed a doublet of doublets at δ 2.63 for the methine proton and a singlet for the acetoxy group at an abnormally high field of δ 1.63 in agreement only with the assigned structure. When exposed to dilute sulfuric acid in refluxing tetrahydrofuran for 30 h, the adduct **7** underwent skeletal rearrangement giving naphthofuran **8** in 75% yield.

Experimental

General

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Elemental analyses were performed by the microanalytical laboratory of this department. Infrared spectra were recorded on a Perkin-Elmer model 457 spectrometer and were obtained on solutions in chloroform. Nuclear magnetic resonance spectra were recorded on a 90 MHz Perkin-Elmer 32 spectrometer and, except where otherwise stated, were obtained on solutions in chloroform-*d* with tetramethyl silane as an internal reference. Mass spectra were recorded using A.E.I. model MS 50 mass spectrometer.

Photocycloaddition of 2-Methyl-1,4-naphthoquinone (1)

(A) With Vinyl Acetate

A solution of 2-methyl-1,4-naphthoquinone (**1**) (8.5 g, 0.049 mol) and vinyl acetate (86 g, 1 mol) in benzene (90 mL) was irradiated at room temperature for 1 h using a 450 W Hanovia high-pressure quartz mercury-vapor lamp through a Pyrex filter. Concentration of the reaction mixture gave an oil which was chromatographed on silica gel. Elution with benzene gave a mixture of epimeric acetates **2** and **3** (12.5 g, 98% yield). The ir and mass spectra of the mixture were similar to those of the minor isomer (see below). The nmr spectrum of the mixture displayed two partly superimposed sets of signals in an integral ratio of 4:1. The major set contained the following signals: δ 1.54 (s, 3H, CH_3), 1.94 (s, 3H, CH_3COO), 5.07 (dd, 1H, $J = J' =$ 8 Hz, OCH), 7.64–7.89 (complex, 2H, aromatic), and 7.91–8.22 (complex, 2H, aromatic) and the signals of the minor set were found to coincide with those of the pure minor isomer (see below). The minor isomer **3** was obtained in pure form by crystallization and showed the following physical data: mp 115–116°C (dichloromethane–cyclohexane); ir 1740 (ester), 1685, 1675 (ketones), and 1590 cm^{-1} (benzene); nmr δ 1.47 (s, 3H, CH_3), 2.04 (s, 3H, CH_3COO), 2.42–3.18 (complex, 3H, CH_2 and CH), 5.20 (dd, 1H, $J = J' = 8$ Hz, COOCH), 7.69–7.88 (complex, 2H, aromatic), and 7.97–8.21 (complex, 2H, aromatic); mass spectrum M^+ 258.0922 (calcd. for $C_{15}H_{14}O_4$: 258.0892). *Anal.* calcd. for $C_{15}H_{14}O_4$: C 69.76, H 5.46; found: C 69.50, H 5.41.

(B) With Isopropenyl Acetate

Under similar conditions, a solution of naphthoquinone **1** (5 g, 0.029 mol) and isopropenyl acetate (58 g, 0.58 mol) in benzene (60 mL) was irradiated for 1 h. Concentration followed by column chromatography on silica gel eluting with benzene gave acetate **7** (7.87 g; 100% yield): ir 1735 (acetate), 1680 (ketones), and 1590 cm^{-1} (benzene); nmr δ 1.47 (s, 3H, CH_3), 1.58 (s, 3H, CH_3), 1.63 (s, 3H, CH_3COO), 2.63 (dd, 1H, $J = 8$, $J' = 4$ Hz, CH), 2.82–3.13 (complex, 2H, CH_2), 7.64–7.80 (complex, 2H, aromatic), and 7.89–8.13 (complex, 2H, aromatic); mass spectrum *m/e* (M − 42) 230.0940 (calcd. for $C_{14}H_{14}O_3$: 230.0943). *Anal.* calcd. for $C_{16}H_{16}O_4$: C 70.58, H 5.92; found: C 70.28, H 5.91.

Conversion of Acetates 2 and 3 to Naphthofuran 4

The mixture of epimeric acetates **2** and **3** (4:1 ratio, 410 mg, 1.59 mmol) was dissolved in tetrahydrofuran (10 mL) and 5% aqueous sulfuric acid (10 mL) was added. The resulting solution was refluxed under a nitrogen atmosphere for 16 h, cooled to room temperature, and extracted with methylene chloride. Drying ($MgSO_4$), filtration, and concentration gave an oil which was chromatographed on silica gel. Elution with a solution of 5% ether in benzene gave naphthofuran **4** (290 mg, 92% yield): mp 120–121°C (benzene–cyclohexane); ir 3600 (OH), 1595 and 1580 cm^{-1} (aromatic); nmr (C_6D_6) δ 2.01 (s, 3H, CH_3), 4.27 (s, 1H, OH), 6.48, 7.32 (both d, 1H each, $J = 2$ Hz, OCH=CH), 7.13–7.47 (complex, 2H, aromatic), and 8.09–8.47 (complex, 2H, aromatic); mass spectrum M^+ 198.0680 (calcd. for $C_{13}H_{10}O_2$: 198.0681). *Anal.* calcd. for $C_{13}H_{10}O_2$: C 78.77, H 5.09; found: C 78.94, H 5.05.

When 258 mg of the pure crystalline acetate **3** was treated with sulfuric acid under the same conditions, 180 mg (91% yield) of naphthofuran **4** was obtained.

Acetylation of Naphthofuran 4

A solution of **4** (85 mg, 0.43 mmol) and acetic anhydride (0.5 mL) in pyridine (1 mL) was stirred at room temperature. After 24 h, the reaction mixture was poured into ice-cold water and extracted with methylene chloride. The extracts were washed with 1 *N* hydrochloric acid, saturated aqueous sodium carbonate solution, and water. The usual work-up of the organic solution followed by chromatography of the crude product on silica gel with benzene elution gave acetate **5** (98 mg, 95% yield): mp 70–71°C (benzene); ir 1755 (ester), 1595 and 1575 cm^{-1} (aromatic); nmr δ 2.41, 2.46 (both s, 3H each, 2 × CH_3), 6.88, 7.72 (both d, 1H each, J = 2 Hz, OCH=CH), and 7.21–8.38 (complex, 4H, aromatic); mass spectrum M^+ 240.0785 (calcd. for $C_{15}H_{12}O_3$: 240.0786).

Conversion of Acetate 7 to Naphthofuran 8

To a solution of acetate **7** (520 mg, 1.91 mmol) in tetrahydrofuran (12 mL) was added 5% aqueous sulfuric acid (12 mL). After refluxing for 30 h, the reaction mixture was cooled to room temperature and extracted with methylene chloride. The usual work-up of the extracts followed by column chromatography of the crude product on silica gel with ether–benzene (1:20) elution gave naphthofuran **8** (304 mg, 75% yield): mp 117–118°C (chloroform – petroleum ether); ir 3620 (OH) and 1590 cm^{-1} (aromatic); nmr δ 2.33 (s, 3H, CH_3), 2.47 (d, J = 1 Hz, CH_3), 4.78 (br s, 1H, OH), 6.38 (q, 1H, J = 1 Hz, OC=CH), 7.31–7.59 (complex, 2H, aromatic), and 8.07–8.22 (complex, 2H, aromatic); mass spectrum M^+ 212.0829 (calcd. for $C_{14}H_{12}O_2$: 212.0833).

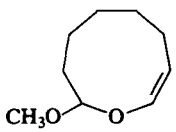
Vinyl ether hydrolysis. XIV. 2-Methoxy-2,3-dihydropyran: concurrent reaction of vinyl ether and acetal functional groups[1]

R. A. BURT, Y. CHIANG, AND A. J. KRESGE[2]

Department of Chemistry, University of Toronto, Scarborough College, West Hill, Ont., Canada M1C 1A4

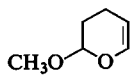
Received May 1, 1980

R. A. BURT, Y. CHIANG, and A. J. KRESGE. Can. J. Chem. **58**, 2199 (1980).



The hydrolysis of 2-methoxy-2,3-dihydropyran shows a normal isotope effect ($k_H/k_D > 1$) under catalysis by the hydrogen ion and gives an accurately linear dependence of reaction rate upon undissociated acid concentration in cyanoacetic acid and formic acid buffer solutions. This substrate, therefore, unlike its higher homolog, 9-methoxyoxacyclonon-2-ene, provides no evidence in support of an anything but a normal mechanism for vinyl ether hydrolysis. Analysis of the hydrogen isotope effect suggests that a minor amount (8%) of this hydrolysis occurs via reaction of the acetal functional group.

R. A. BURT, Y. CHIANG et A. J. KRESGE. Can. J. Chem. **58**, 2199 (1980).



L'hydrolyse du méthoxy-2 dihydro-2,3 pyranne catalysée par l'ion hydrogène, montre un effet isotopique normal ($k_H/k_D > 1$) et sa vitesse de réaction dépend d'une façon précise et linéaire de la concentration en acide non dissocié dans des solutions tampons d'acides cyanoacétique et formique. Dans le cas de ce substrat, contrairement à son homologue supérieur, le méthoxy-9 oxacyclononène-2, toutes les données indiquent que la réaction se produit par un mécanisme d'hydrolyse normal pour les éthers vinyliques. L'analyse de l'effet isotopique de l'hydrogène suggère qu'une partie infime (8%) de cette hydrolyse se produit par l'intermédiaire de la réaction du groupe fonctionnel acétal.

[Traduit par le journal]

In order to gain information which might be of use in understanding the unusual hydrolytic behavior of 9-methoxyoxacyclonon-2-ene,[3] **1** (1), we have investigated the acid-catalyzed hydrolysis of the related substance, 2-methoxy-2,3-dihydropyran, **2**. The hydrolysis of a homolog of **2**, 2-ethoxy-2,3-dihydropyran, had been examined before (2), but that study was limited to HCl solutions. In dilute aqueous HCl, **1** behaves normally in a manner characteristic of the hydrolysis of its vinyl ether functional group. In carboxylic acid buffer solutions, however, its behavior deviates from that of all other vinyl ethers examined so far, and we were particularly interested, therefore, in studying a similarly substituted vinyl ether in these media.

Experimental

Materials

2-Methoxy-2,3-dihydropyran was purchased from the Aldrich Chemical Company. Its proton nmr spectrum was consistent with its structure and showed no sign of impurities, but kinetic data for the hydrolysis of the commercial material nevertheless sometimes produced curved first-order plots. Samples freshly purified by gas chromatography, on the other hand, were well behaved, and kinetic measurements were therefore carried out on material purified in this way.

Acids were best available commercial grades and were used without further treatment. Solutions were made using either deionized H_2O purified further by distillation from alkaline permanganate or D_2O as received (Merck); buffer solutions were prepared by adding requisite amounts of aqueous sodium hydroxide to acid solutions.

Kinetics

Rates of reaction were measured spectroscopically by following the decrease in the intense absorption of the vinyl ether chromophore of the substrate in the region 210–220 nm. A Cary

118C spectrometer was used with thermostatted cell compartment operating at 25.0 ± 0.02°C. Acid or buffer solutions were first allowed to come to thermal equilibrium with the cell compartment. A few microliters of substrate, dissolved in either water or methanol, were then added. The mixture was shaken, and a continuous recording of absorbance as a function of time was begun. Substrate concentrations were chosen to give convenient initial absorbance values; when methanol stock solutions were used, the final methanol concentration in the reaction mixture was never greater than 0.2%.

For the faster runs, absorbance recording was continued for 10–12 half-lives and first-order rate constants were obtained as slopes of plots of $\ln (A - A_\infty)$ vs. time. When freshly purified substrate was used, these data adhered to the first-order rate law accurately. Infinite-time readings were not made for the slower runs, and these data were analyzed by the Guggenheim (3) or Swinbourne methods (4).

Results

First-order rate constants for the hydrolysis of 2-methoxy-2,3-dihydropyran were determined in dilute hydrochloric acid solutions using H_2O and D_2O as the solvents. The data are summarized in Table 1. In each case, rates of reaction were found to be accurately proportional to hydrochloric acid concentrations, and second-order hydrogen ion catalytic coefficients were therefore obtained by linear least-squares analysis of the relationship between first-order rate constants and acid concentration. Intercepts proved to be zero within the experimental uncertainty indicating no uncatalyzed reaction. The results provide the isotope effect $k_{H^+}/k_{D^+} = 1.56 \pm 0.06$.

Rate measurements were also made in formic acid and cyanoacetic acid buffer solutions; these data are summarized in Table 2. In each case, rate constants were determined in series of buffer solutions of constant stoichiometric buffer ratio but varying buffer concentration. Because the buffer acids were moderately strong and the buffer concentrations were low, the hydrogen ion concentrations of these series of solutions were not quite constant. Small adjustments were therefore made to the observed rate constants to correct for this "buffer failure"; these corrections were made as before (5) using activity coefficients recommended by Bates (6) and the hydrogen ion catalytic coefficient determined in HCl solutions. First-order rate constants adjusted in this way were linear functions of undissociated acid concentration, indicating adherence to the expected rate law, eq. [1]. The data were therefore fitted to this expression by least-squares analysis and values of k_{H^+} were calculated using hydrogen ion concentrations estimated for the buffer failure corrections. This treatment gave values, $k_{H^+} = (1.66 \pm 0.02) \times 10^{-2}\ M^{-1}\ s^{-1}$ and $(1.64 \pm 0.04) \times 10^{-2}\ M^{-1}\ s^{-1}$ for the cyanoacetic and formic acid solutions respectively, in excellent agreement with the result obtained in HCl solutions, $k_{H^+} = (1.67 \pm 0.02) \times 10^{-2}\ M^{-1}\ s^{-1}$.

$$[1] \quad k_1 = k_{H^+}[H^+] + k_{HA}[HA]$$

Discussion

Reaction Mechanism

With the sole exception of 9-methoxyoxacyclonon-2-ene, **1**, all vinyl ethers examined so far hydrolyze through rate-determining proton transfer from the catalyzing acid to the β-carbon atom of the vinyl ether functional group, eq. [2]. Hydration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the thus formed cation (eq. [3]) and decomposition of the ensuing hemiacetal intermediate (eq. [4]) then proceed in subsequent rapid reaction steps.

This mechanism is characterized by solvent isotope effects of appreciable magnitude in the normal direction, $k_{H^+}/k_{D^+} = 2$–4 (7), and significant general acid catalysis with a linear dependence of reaction rate upon general acid concentration, eq. [1] (5). The hydrolysis of 9-methoxyoxacyclonon-2-ene, **1**, follows this pattern in dilute mineral acid solutions, giving $k_{H^+}/k_{D^+} = 4.2 \pm 0.2$ (1). In carboxylic acid buffers, however, this reaction shows a curved dependence of rate upon general acid concentration and a saturation of buffer catalysis at moderate undissociated acid concentrations.[4] The nonlinear nature of the relationship between specific first-order rates of disappearance of substrate and undissociated acid concentration is reinforced by the fact that hydrogen ion catalytic coefficients calculated by forcing a linear dependence, i.e. by fitting the data to eq. [1], are far in excess of values determined directly in mineral acid solutions.

These buffer solution data can be fitted to a hydrolysis reaction scheme in which the initial proton transfer step, eq. [2] is reversible and some subsequent step is rate-determining. The data adhere to such a mechanism well, and they give reasonable values of the parameters which may be obtained from the analysis (1). It was originally suggested that the subsequent slow step might be hydration of the cation formed by proton transfer, eq. [3]. However, recent measurements of the rate of reaction of alkoxy-substituted carbonium ions with water (8) suggest that this reaction, in the case of the cation formed from 9-methoxyoxacyclonon-2-ene, is likely to be a diffusion-controlled process. It therefore cannot be slower than reversion of the proton transfer step, but decomposition of the hemiacetal intermediate, eq. [4], appears still to be a viable possibility for the slow step.

The homolog of 9-methoxyoxacyclonon-2-ene examined in the present study, 2-methoxy-2,3-dihydropyran (**2**) shows no such unusual behavior. In dilute mineral acid solutions its hydrolysis gives a normal solvent isotope effect, $k_{H^+}/k_{D^+} = 1.6$. (This value may be somewhat low for a substrate of this reactivity, but that can be understood in terms of an expected competing hydrolysis of the acetal functional group in this molecule; *vide infra*.) The reaction follows the normal pattern in buffer solutions as well, giving an accurately linear dependence of rate upon undissociated acid concentration. The data obtained in solutions of the weaker of the two buffer acids investigated here, for which unusual behavior is the more likely, are displayed in Fig. 1. It may be seen that there is no indication of curvature and that the intercept (= $k_{H^+}[H^+]$, cf. eq. [1]), obtained by least-squares analysis agrees very well with the value expected on the basis of the known hydrogen ion concentration and the hydrogen ion catalytic coefficient determined directly in mineral acid solutions. The data obtained in buffer solutions of the other carboxylic acid used in this study show similar conformity with normal behavior.

Thus, though structurally similar to 9-methoxyoxacyclonon-2-ene, 2-methoxy-2,3-dihydropyran does not behave in a manner which suggests that the initial protonation step in its vinyl ether hydrolysis reaction is a reversible process. It is unlike its higher homolog in this respect. It is interesting that this dissimilarity extends to a difference in reactivity: the value of k_{H^+} for 2-methoxy-2,3-dihydropyran is 0.0167 M^{-1} s^{-1} while that for 9-methoxyoxacyclonon-2-ene is 8.1 M^{-1} s^{-1}, some 500 times greater.

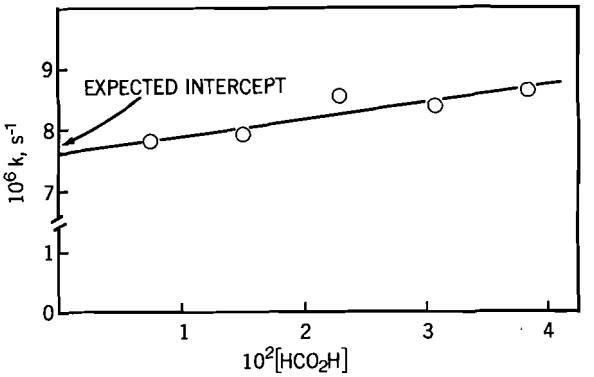

FIG. 1. Relationship between the rate of hydrolysis of 2-methoxy-2,3-dihydropyran in formic acid buffer solutions and buffer acid concentrations.

[4]In acetic acid buffers, saturation appears at [HOAc] = 0.01 M (1); a curved dependence of rate upon undissociated acid concentration has also been observed in methoxyacetic acid buffers (personal communication from Professor V. P. Vitullo).

Concurrent Acetal Hydrolysis

The 2-methoxy-2,3-dihydropyran molecule contains an acetal function in addition to its vinyl ether group. Since the reactivity of acetals in acid-catalyzed hydrolysis is generally similar to that of vinyl ethers, reaction by way of this second functional group might be expected to occur. The two hydrolysis reactions will give the same products, glutaraldehyde and methanol, and they cannot be distinguished on that basis. They will, however, show different solvent isotope effects, and this difference has in fact been used to estimate the amount of reaction occurring by each route in the case of the closely related substance, 2-ethoxy-2,3-dihydropyran (2).

The method makes use of dihydropyran, **3**, and 2-methoxytetrahydropyran, **4**, as monofunctional

3

4

models for the vinyl ether and acetal functions of the difunctional substrate. If solvent isotope effects on the hydrogen ion-catalyzed hydrolysis of these model compounds are assumed to be the same as the isotope effects on the hydrolysis of the corresponding functional groups in the difunctional substrate, then eqs. [5] and [6] may be written. Here

$$[5] \quad k_{H^+} = k_{VE} + k_A$$

$$[6] \quad k_{D^+} = ak_{VE} + bk_A$$

k_{H^+} and k_{D^+} are rate constants for the overall hydrolysis of the difunctional substrate in H_2O and in D_2O respectively, k_{VE} and k_A are the rate constants for the vinyl ether and acetal hydrolysis components of the overall rate in H_2O, and a and b are isotope effects (k_{D^+}/k_{H^+}) on the vinyl ether and acetal reactions respectively, as determined by measurements on the model compounds. With $a = (2.21)^{-1}$ and $b = (0.340)^{-1}$ (2), this analysis gives 67% reaction by the vinyl ether pathway and 33% by the acetal pathway for 2-ethoxy-2,3-dihydropyran (2), and 92% reaction by the vinyl ether pathway and 8% by the acetal pathway for the substrate studied here, 2-methoxy-2,3-dihydropyran.

It is significant that the relative amounts of reaction by the two pathways for these two substrates do not differ very much, for the substitution of an ethoxy group for a methoxy group is but a minor structural change. What difference there is is produced principally by a change in the rate constant for reaction of the acetal group (Table 3), in keeping with the fact that the structural change occurs in this function and that it should therefore have more effect here than on the reactivity of the more remote vinyl ether group. It is significant as well that changing methoxy to ethoxy raises the rate of acetal hydrolysis, for this is the direction of the change in the hydrolysis rates of the monofunctional model substrates, 2-methoxytetrahydropyran and 2-ethoxytetrahydropyran (9). The effect in the models, however, amounts to only a factor of 1.2, which is considerably less than the 6-fold difference found here. This suggests that the assumption of transferability of isotope effects may not be entirely justified.

TABLE 3. Estimated rate constants for concurrent vinyl ether and acetal hydrolysis in 2-alkoxy-2,3-dihydropyrans

Substrate	$10^2 k_{H^+}$ (M^{-1} s^{-1}) Vinyl ether pathway	Acetal pathway
2-Methoxy-2,3-dihydropyran	1.55	0.13
2-Ethoxy-2,3-dihydropyran	1.73	0.82

The highly congested molecule, methyl β,β-di-*tert*-butylvinyl ether, undergoes reaction in dilute aqueous mineral acid solutions by a normal vinyl ether hydrolysis mechanism and gives an unrearranged aldehyde product. The *tert*-butyl groups retard the rate of hydrolysis, but the effect of *cis* and *trans* substituents is not cumulative; this is attributed to a repulsive nonbonded interaction, relieved in the course of reaction, between the ether oxygen atom and the *cis*-*tert*-butyl group buttressed by the *trans*-*tert*-butyl group.

Y. CHIANG, A. J. KRESGE, T. T. TIDWELL et P. A. WALSH. Can. J. Chem. **58**, 2203 (1980).

L'éther méthyl β,β di-*tert*-butylvinyle, une molécule fortement encombrée, réagit dans des solutions aqueuses diluées d'acide minéral selon un mécanisme normal d'hydrolyse d'éther vinylique et conduit à l'aldéhyde non transposé. Le groupe *tert*-butyle retarde la vitesse d'hydrolyse, mais l'effet des substituants en position *cis* et *trans* n'est pas cumulatif. Ceci est attribué à l'interaction répulsive non liée notée au cours de la réaction entre l'atome d'oxygène de l'éther et le groupe *tert*-butyle en position *cis* comprimé par le groupe *tert*-butyle en position *trans*.

[Traduit par le journal]

Substitution of small alkyl groups such as methyl at the β-carbon atom of vinyl ethers is known to depress the rate of acid-catalyzed hydrolysis of these substances (1). The effect is thought to operate through lowering of the energy of the initial state of this reaction, via the well-known ability of alkyl groups to stabilize carbon–carbon double bonds (2). Two groups are more effective than one and, though there are differences which can be attributed to different steric requirements of *cis* and *trans* isomers, the effects are cumulative, i.e. two groups exert an influence roughly equal to the product of the effects of the two groups taken separately.

The bulky *tert*-butyl group conforms to this pattern of reactivity in part; introduction of a single *tert*-butyl group in either the *cis* or the *trans* position at the β-carbon atom of ethyl vinyl ether lowers the rate of hydrolysis of this substance (3). We have found, however, that disubstitution is surprisingly ineffective in producing a further lowering of reactivity, and that methyl β,β-di-*tert*-butylvinyl ether is in fact an order of magnitude more reactive than it would be were the effects of the individual *tert*-butyl groups cumulative.

This behavior is remarkable in view of the fact that interference between the geminal *tert*-butyl groups of the substrate should increase as the trigonal carbon atom to which they are attached becomes tetrahedral during the course of the hydrolysis reaction, eq. [1] (4). The combined bulk

$$[1]\quad (t\text{-Bu})_2C{=}CHOMe \xrightarrow[H_2O]{H^+} (t\text{-Bu})_2CHCHO + MeOH$$

of two *tert*-butyl groups at the reaction site might also impede approach of the electrophilic reagent (H^+); tri-*tert*-butylethylene is known to add bromine only slowly because of steric hindrance (5). These effects would serve to produce a rate retardation *greater* than the product of the retardations shown by the *cis* and *trans* monosubstituted substrates separately, rather than the *less* than cumulative retardation actually observed.

Experimental

Materials

Methyl β,β-di-*tert*-butylvinyl ether was prepared from the corresponding acetal which was made by heating β,β-di-*tert*-butylacetaldehyde (6) with trimethyl orthoformate and a catalytic amount of *p*-toluenesulfonic acid. The acetal was not purified; upon introduction onto a gas chromatography column (Carbowax 20M, 210°C) it eliminated methanol and formed the vinyl ether. The latter was characterized by proton nmr; δ: 5.77 (s, 1H), 3.55 (s, 3H), 1.25 (2, 9H), 1.17 (s, 9H); and by elemental analysis. *Anal.* calcd. for $C_{11}H_{22}O$: C 77.58%, H 13.02%; found: C 77.46%, H 13.30%. Samples for kinetic measurements were purified by gas chromatography.

Acids were best available commercial grades and were used without further treatment. Solutions were made using either deionized H_2O purified further by distillation from alkaline permanganate or D_2O (Merck) as received.

Product Analysis

A reaction mixture was prepared by combining 10 μL of methyl β,β-di-*tert*-butylvinyl ether and 0.5 mL of 1 *M* aqueous HCl. This two-phase system was agitated in an ultrasonic cleaning bath for 15 min to disperse the organic component, and it was then allowed to stand at room temperature for 3 h. After this time the mixture was extracted with 0.2 mL of CCl_4 and a proton nmr spectrum of the extract was taken. This showed a mixture of the starting vinyl ether and the expected hydrolysis product, di-*tert*-butylacetaldehyde (δ: 9.70 (d, 1H), 1.72 (d, 1H),

1.23 (s, 18H)) in a 2:1 ratio; no other substances could be detected, even when the spectrum was measured at the highest possible sensitivity.

Kinetics

Rates of reaction were determined spectroscopically by monitoring the decrease in the intense absorption of methyl β,β-di-*tert*-butylvinyl ether at 205–215 nm. Measurements were made using a Cary 118C spectrometer with cell compartment thermostatted at 25.0 ± 0.02°C. Acid solutions were allowed to come to temperature equilibrium with the cell compartment and reactions were then initiated by adding a few μL of substrate, dissolved in ethanol, to the equilibrated solutions and shaking the resultant mixtures. Since methyl β,β-di-*tert*-butylvinyl ether is only very sparingly soluble in water, care had to be taken to insure that shaking did produce homogeneous solutions. Ethanol concentrations in the final reaction mixtures were never greater than 0.2%.

For the faster runs, continuous records of absorbance as a function of time were made out to 10–12 half-lives and first-order rate constants were evaluated as slopes of plots of ln $(A - A_\infty)$ vs. time. With the slower runs, absorbance readings were recorded at preset time intervals out to 2–3 half-lives and rate constants were determined by the Guggenheim (7) or Swinbourne (8) methods.

Results

First-order rate constants for the hydrolysis of methyl β,β-di-*tert*-butylvinyl ether were determined in solutions of $HClO_4$ and HCl in H_2O and in solutions of DCl in D_2O. The data are summarized in Table 1.

In each kind of solution first-order specific rates proved to be accurately proportional to acid concentration, and second-order rate constants were therefore calculated by dividing the first-order rate constants by acid molarity. The results obtained from $HClO_4$ and HCl solutions are in good agreement with one another, $k_{H^+} = 0.352 \pm 0.013$ and $0.337 \pm 0.012\ M^{-1}\ s^{-1}$; combination of these two values by taking a simple average gives $k_{H^+} = 0.344 \pm 0.009\ M^{-1}\ s^{-1}$ as the best estimate of this catalytic coefficient. That, together with the result from DCl solutions, gives the isotope effect $k_{H^+}/k_{D^+} = 2.82 \pm 0.18$.

Discussion

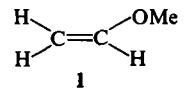
Reaction Mechanism

The mechanism by which virtually all vinyl ethers hydrolyze consists of rate-determining proton transfer from a catalyzing acid to the substrate, eq. [2],

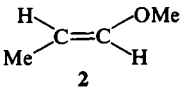
$$[2]\quad R_2C{=}CHOR \xrightarrow[\text{slow}]{HA} R_2CHCHOR^+$$

followed by rapid hydration of the ensuing cation, eq. [3], and decomposition of the hemiacetal intermediate, eq. [4].

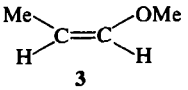
$$[3]\quad R_2CHCHOR^+ \xrightarrow[\text{fast}]{H_2O,\ -H^+} R_2CHCH(OH)OR$$



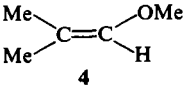
$$[4]\quad R_2CHCH(OH)OR \xrightarrow[\text{fast}]{} R_2CHCHO + HOR$$



A reaction scheme such as this is characterized by kinetic isotope effects of appreciable magnitude in the normal direction ($k_H/k_D > 1$). The fact that the isotope effect observed here is as great as it is, $k_{H^+}/k_{D^+} = 2.8 \pm 0.2$ indicates that this mechanism operates in the case of the present reaction as well. This conclusion is reinforced by the excellent agreement between this isotope effect and the value predicted for a vinyl ether of the present substrate's reactivity, $k_{H^+}/k_{D^+} = 2.7$, from a correlation of isotope effects on the hydrolysis of a large group of vinyl ethers known to react by the mechanism of eqs. [2]–[4] (9).



Reactivity



Methyl *trans*-propenyl ether, **2**, is only 0.095 times as reactive to hydrogen ion-catalyzed hydrolysis as methyl vinyl ether, **1** (9). The *cis* isomer, **3**, also shows reduced reactivity, but the factor by which it differs from the unsubsituted parent, **1**, is somewhat weaker, 0.34 (9); this difference is probably due to steric acceleration produced by relief of crowding between the vicinal methyl and methoxyl groups situated on the same side of the double bond

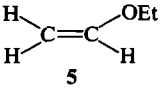
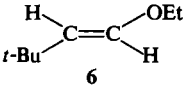
1.00

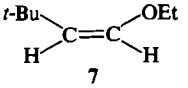
2
0.095



3
0.34



4
0.033



in the *cis* isomer. Methyl isobutenyl ether, **4**, is still less reactive than either of the propenyl derivatives, and it is interesting that the factor by which its rate constant is lower than that of the parent ether (**1**), 0.033 (9), is very nearly equal to the product of the reductions in reactivity shown individually by the two propenyl ethers: $0.095 \times 0.34 = 0.032$.

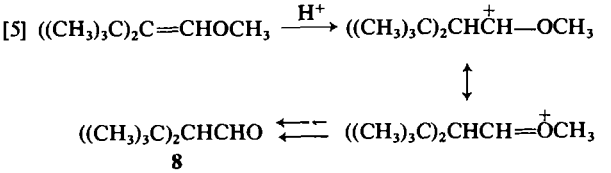
These comparisons are for hydrolysis reactions conducted in wholly aqueous solution. A similar pattern is shown by the hydrolysis of ethyl analogs in 80% aqueous dioxane (3): CH_2=CHOEt, 1.00; *trans*-MeCH=CHOEt, 0.12; *cis*-MeCH=CHOEt, 0.39; Me_2C=CHOEt, 0.029. Here again the reactivity of the isobutenyl derivative is consistent with the product of the reductions shown by the propenyl ethers, though in this case the quantitative agreement is less exact: $0.12 \times 0.39 = 0.047$.

Data are also available for the hydrolysis in 80% aqueous dioxane of the two mono-*tert*-butyl substituted vinyl ethers, **6** and **7**. Once again β-alkyl

5

6

7



substitution produces a reduction in reaction rate, and as before the *trans* isomer gives the stronger effect, 0.066 (*trans*) vs. 0.47 (*cis*). The product of these two factors would put the relative reactivity of methyl β,β-di-*tert*-butylvinyl ether at ca. 0.03, if the retardations due to the *cis* and *trans tert*-butyl groups were cumulative. The actual rate reduction seen by comparing the rate constant determined here with $k_{H^+} = 0.76\ M^{-1}\ s^{-1}$ for methyl vinyl ether (9) is only 0.45. This makes β,β-di-*tert*-butyl substitution 14 times less effective at retarding vinyl ether hydrolysis than is β,β-dimethyl substitution: k_{H^+} (*t*-Bu_2C=CHOMe)/k_{H^+} (Me_2C=CHOMe) = 14.

It seems likely that this difference in behaviour between the *tert*-butyl and methyl systems originates in buttressing steric effects present in the di-*tert*-butyl substrate. A simple geometrical calculation shows that the distance separating the oxygen atom of a *cis*-β-*tert*-butylvinyl ether from the central carbon atom of the *tert*-butyl group would be only 2.8 Å if all bond lengths and bond angles had their normal values. This is much shorter than the sum of the van der Waals radius of oxygen, 1.40 Å (10), and even the minimum radius of a *tert*-butyl group, 2.44 Å (11). The molecule will therefore distort to relieve the nonbonded repulsion implied by this short distance, and it will probably do this by opening up the C=C—C and C=C—O bond angles; in *cis*-2-butene similar strain is relieved through opening of the C=C—C angle to 127°, and calculations suggest that in *cis*-1,2-di-*tert*-butylethylene there is a further opening to 135° (12). A similar accommodation to relieve nonbonded repulsion between oxygen and the *cis*-*tert*-butyl group in β,β-di-*tert*-butylvinyl ethers can occur only at the expense of increasing repulsion between the two *tert*-butyl groups themselves, which is already quite severe; the strain energy of 1,1-di-*tert*-butylethylene has been estimated to be 12 kcal mol^{-1} (13). The second *tert*-butyl group of the β,β-di-*tert*-butylvinyl ether will therefore buttress the first, augmenting nonbonded repulsion between the oxygen atom and the *tert*-butyl group *cis* to it. Some of this increased strain will be relieved when the requirement for coplanarity of substituents on the carbon–carbon double bond is removed as the hydrolysis reaction takes place, and an increased rate of reaction will result.

It is typical that only a small portion of the strain resulting from the *cis* arrangement of two bulky groups is translated into an enhanced reactivity. Even for 1,2-di-*tert*-butylethylene the *cis*/*trans* rate ratio for protonation is only 3.8 (14).

Reaction Products

Highly congested systems such as that investigated here are prone to rearrangement; this is especially likely if their reactions produce cations which can be transformed to more stable species (4, 5, 15). The ion produced by straightforward protonation of the β-carbon of the present substrate is an alkoxy substituted cation stabilized by resonance (eq. [5]); its rearrangement is therefore apt to be an

[5] $((CH_3)_3C)_2C$=$CHOCH_3$ $\xrightarrow{H^+}$ $((CH_3)_3C)_2\overset{+}{C}HCH$—$OCH_3$ ↕ $((CH_3)_3C)_2CHCHO$ ⇄ $((CH_3)_3C)_2CHCH$=$\overset{+}{O}CH_3$

8

unfavorable process. This is supported by the fact that the only product of this reaction which we were able to detect was the expected, unrearranged aldehyde, β,β-di-*tert*-butylacetaldehyde, **8**.

The mechanism of the reaction of the Nash and the Sawicki aldehyde reagent

BRUCE JON COMPTON AND WILLIAM C. PURDY

Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, P.Q., Canada H3A 2K6

Received March 7, 1980

BRUCE JON COMPTON and WILLIAM C. PURDY. Can. J. Chem. **58**, 2207 (1980).

Synthetic and chromatographic studies are presented on the Nash and Sawicki colorimetric methods for quantitating formaldehyde. It is shown that the actual color-forming agent in the Nash method is an isolable iminodione formed *in situ* by reaction of the two components. Explanation is given for differences between these two methods.

BRUCE JON COMPTON et WILLIAM C. PURDY. Can. J. Chem. **58**, 2207 (1980).

On présente des études chromatographiques de synthèse en rapport avec les méthodes colorimétriques de Nash et de Sawicki relatives à la détermination quantitative de la formaldéhyde. On montre que l'agent qui est de fait responsable de la formation de la couleur, dans la méthode de Nash, est une iminodione que l'on peut isoler et qui se forme *in situ* par la réaction de deux réactifs. On donne une explication des différences qui apparaissent entre ces deux méthodes.

[Traduit par le journal]

Introduction

Both the colorimetric methods of Nash (1) and of Sawicki and Carnes (2, 3) involve a condensation reaction between formaldehyde and a reagent consisting of a β-diketone and ammonium acetate. In the Nash method, based on the Hantzsch pyridine synthesis (4, 5), formaldehyde reacts with a reagent consisting of 2,4-pentanedione and concentrated (~ 2 *M*) ammonium acetate (reaction 10). The chromophore, 3,5-diacetyl-2,6-dihydrolutidine (**4**), exhibits fluorescence (6). The method of Sawicki and Carnes (2) uses dimedone (5,5-dimethyl-1,3-cyclohexanedione) as the β-diketone. The reaction of formaldehyde, dimedone, and ammonium acetate (reaction 11) was first described by Vorländer and co-workers (7–9). The product, **9**, exhibits approximately 100 times greater fluorescence than the product (**4**) from 2,4-pentanedione (2).

Reactions 1–4 (Fig. 1) are possible pathways by which the Nash method can proceed. Similarly, reactions 5–9 (Fig. 2) are possible pathways for the Sawicki reagent. Reactions 1, 3, and 5–9 have been described in various places in the literature (see Experimental). Reaction 2 has not previously been reported. None of these reactions have been discussed with reference to either of the two reagents studied here.

While it was our intention to study these two methods from the standpoint of achieving greater sensitivity for formaldehyde in a continuous-flow analyzer, we discovered a general lack of understanding of the basic chemistry underlying these two methods.

Our experimental approach was to demonstrate that reactions 1–9 can occur under the conditions used for the two methods. Compounds **1–9** were then synthesized and used as standards to investigate the mechanism of the Nash and Sawicki methods. This study bridges the gap between organic and analytical work and has resulted in a superior aldehyde reagent (10).

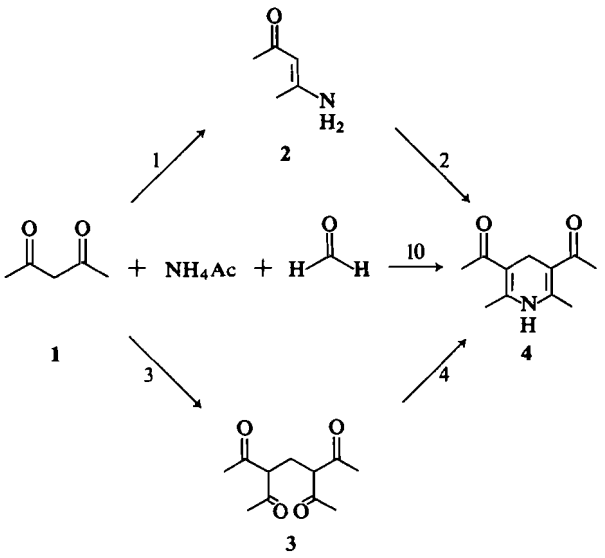

FIG. 1. The reactions and intermediates found with the Nash method.

Experimental

Two methods, a synthetic and an analytical assay procedure, were used to determine the mechanistic aspects of the reactions of interest (reactions 10 and 11). First the reaction pathways illustrated in Figs. 1 and 2 were carried out using preparative synthetic procedures. Once standards were obtained for each of the compounds shown in these two figures, assays utilizing high-performance liquid chromatography (hplc) were developed and used to monitor the actual reactions of Nash and Sawicki. Efforts were made to run all synthetic reactions under conditions similar to those found in the analytical assay systems for formaldehyde (1, 2) as well as by an alternative method from the literature. Yields were unoptimized.

Synthetic Procedures

Compound 2, 4-Amino-3-penten-2-one (Fluoral-P)

Twenty mL of 2,4-pentanedione in 50 mL of 4 *M* ammonium acetate, pH 5.5, was heated to 80°C for 3 h, extracted into chloroform, and vacuum distilled (bulb-to-bulb, 5 Torr, 64°C) to give a clear viscous liquid which solidified upon cooling (yield 32%, 5.66 g; mp 45°C; recrystallized from ethyl acetate – petroleum ether). Structural assignment was based on chemical (conversion of **2** to **4** with formaldehyde) and spectral data (ir, chloroform: 3500 (s), 3120–3440 (b), 3200 (s), 1624 (s), 1597 (s); ^{1}H nmr, 200 MHz, D-chloroform, δ: 2.75 (3), 2.87 (3), 5.87 (2), 8.10 (1), all singlets; ms (C_5H_9NO): 99.0674, and microanalysis C 61.03 (60.61), H 9.30 (9.09), N 14.38 (14.31), theoretical in parentheses. This compound was also synthesized by an alternative route (10) modified from the literature (11).

Compound 3, 3,3'-Methylene-bis-(2,4-pentanedione)

To one mL of 2,4-pentanedione in 20 mL of 99% methanol – 1% acetic acid was added 4 mL of 37% aqueous formaldehyde. After 10 min of stirring and evaporation, a white crystalline mass was isolated; this was recrystallized from ethyl acetate, yield 89%, 0.923 g; mp 140–142°C; ir 3200–3600 (b), 1695 (s); nmr δ: 1.3(3), 2.2(3), 2.6(1), 3.6(2), all singlets; ms: 212, 150, 112, 109, 43 (base). The melting point data indicate that the di-intramolecular hydrogen-bonded species was isolated since the free and mono-intramolecular hydrogen-bonded species have already been assigned different melting points (12).

Compound 4, 3,5-Diacetyl-1,4-dihydro-2,6-lutidine

The method of Erikson and Biggs (13) was used. Also, **2** was employed by reaction with formaldehyde in pH 2.25 phosphate buffer or **3** with molar ammonium acetate, pH 6.0, after 30 min of stirring. Compound **4** was recrystallized from methanol, mp 204–205°C (lit. (1) mp 200°C; (13) mp 201–205°C), with yields greater than 90%.

Compound 6, 5,5-Dimethyl-3-aminocyclohex-2-en-1-one

The method of Greenhill (14) was used (yield 81%) as well as a method similar to that described for **2** (yield 27%, mp 166.5–167°C (lit. (14) mp 164–165°C)).

Compound 7, 2,2'-Methylene-bis-(5,5-dimethyl-3-aminocyclohex-2-en-1-one)

The method of Greenhill (14) was used. In addition, this compound was isolated whenever attempts were made to convert **6** to **9** by the rapid addition of formaldehyde (mp 241–242°C (lit. (14) mp 242°C)).

Compound 8, Bis-(4,4-dimethyl-2,6-dioxocyclohexyl) Methane

The method of Horning and Horning (15) was used (yield 95%). Also this product was isolated when following the synthetic method of Sawicki and Carnes (2) for **9** if formaldehyde is added at a rate faster than dropwise (mp 191–191.5°C (lit. (16) mp 189–190°C; (15) mp 191–191.5°C)).

Compound 9, 3,3,6,6-Tetramethyl-1,2,3,4,5,6,7,8,9,10-decahydro-1,8-acridinedione

The method of Sawicki and Carnes (2) was used and the product was recrystallized from acetone (yield 10%; mp 298–301°C (lit. (17) mp 296–297°C)). Also **9** was synthesized by heating **8** in 2 *M* ammonium acetate (pH 5.5) for 3 h at 80°C or directly from **6** or **7** by modifying the alternate method for **7** to include overnight heating at 80°C.

Equipment and Chemicals

The hplc studies were conducted using a system previously described (18) except that the normal phase mode was employed with a μ-Porasil column (Waters Associates, Milford, CT). Spectral studies were made with a Cary Model 17 Spectrophotometer (Varian Associates, Palo Alto, CA) and an Aminco SPF-125 Spectrofluorometer (American Instrument Co., Silver Spring, MD).

All organic reagents were purchased from Aldrich Chemical Co. (Milwaukee, WI) and all inorganic reagents such as ammonium acetate from Anachemia Chemicals Ltd. (Montreal, P. Q.). All solvents were from American Chemicals Ltd. (Montreal, P.Q.) and were either reagent or "spectrograde" quality. Formaldehyde (37% reagent grade) was purchased from American Chemicals.

Assay Conditions

The chromatographic conditions and retention data (k') are summarized in Table 1. Reactions 10 and 11 as well as those involving the conversion of **6** to **9** (reactions 6 and 7) were investigated under the following conditions. To a preincubated (either 5 or 30 min) mixture of 0.1 *M* 2,4-pentanedione (1 mL in methanol) and molar ammonium acetate (2 mL at pH 5.5) at 22°C was added 1 mL of 1.26×10^{-2} *M* formaldehyde. Samples were

*k' has the usual meaning of (retention volume − void volume)/void volume.

introduced directly from the reaction mixture into the chromatographic system at the times indicated in Fig. 3.

The analysis of the dimedone system was similar to that of the pentanedione except that the concentrations were changed slightly, 1 mL of $1.0 \times 10^{-1} M$ formaldehyde, 1 mL of $2.0 M$ ammonium acetate, pH 5.5, and 1 mL of $0.1 M$ dimedone in methanol. Preincubation was carried out for 5 min and a white precipitate, compound **8**, formed but dissolved during the course of the analysis.

For the study of the conversion of **6** to **9**, 25 μL of $1.0 \times 10^{-3} M$ **6** in methanol was added to 1 mL of $1.24 \times 10^{-1} M$ formaldehyde and 1 mL of a $0.5 M$ phosphate buffer, pH 2.25. The mixture was incubated at 22°C and assayed after one hour.

Results and Discussion

The original objective of this study was to compare the dimedone and 2,4-pentanedione reactions for the determination of formaldehyde. Although the relative fluorescence intensity of **9** was found to be 70 times greater than **4** (cf. 100 times (2)), this was of little use when considered in the context of a mechanized reaction system for detecting formaldehyde. The production of **9** was very slow in comparison to **4** and the reaction involving 2,4-pentanedione produced at room temperature a steady-state fluorescence in approximately 1 hour while the dimedone reaction required at least 3 hours to reach steady-state fluorescence. This is not surprising when one compares the conditions recommended by Nash (1) and Sawicki and Carnes (2) for their respective methods.

Another problem involved the preparation and usage of the Nash and Sawicki reagents. Many different accounts have been given for the storage and use of the Nash reagent. For instance the reagent was reported to be usable after preparation but had to be discarded after two days (19). In another instance the Nash reagent was to be used within one hour of preparation and discarded after that time (20).

In his original communication Nash (1) describes the shift of the "first ultraviolet absorption band" which stabilizes in 24 h at a position approximately 18 nm higher in wavelength. This corresponds to the formation of compound **2** in solution (λ_{max} 271.7 nm, $\log \varepsilon = 3.43$). Nash also showed that the reaction rate for the condensation reaction (assumed first order), when measured with one-day-old reagent, gave two distinct rate constants during the course of the reaction. The initial rate was fast but then it slowed as the reaction progressed to about 50% completion. The inflection between the two rates was approximately the same with regard to the degree of completion of the reaction at two different temperatures (5° and 37°C). Up to the present this was the only attempt at a detailed study of the Nash reagent.

The reagent of Sawicki and Carnes (2) has been prepared by several methods. When cyclohexanedione was used as the β-diketone, they recommended allowing the reagent to stand overnight before usage. However, when the reagent was prepared with dimedone, it was used immediately and discarded after 6 h. Cyclohexanedione and dimedone were investigated throughout this present study but only the results

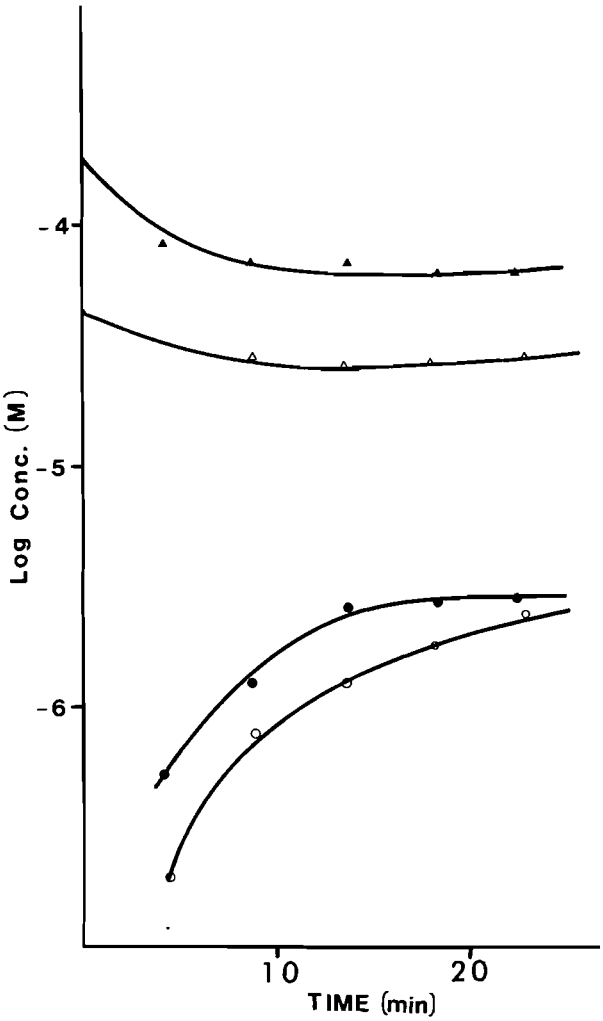

FIG. 3. Effect of preincubation and formaldehyde addition on the concentration of Fluoral-P (**2**) and the formation of **4** (○ = **4**, 5-min incubation; ● = **4**, 30-min incubation; △ = **2**, 5-min incubation; ▲ = **2**, 30-min incubation).

for dimedone are reported. The intermediates found with cyclohexanedione are very similar to those isolated for dimedone. Cyclohexanedione is quite heat sensitive (supplied with 3% NaCl stabilizer added) while dimedone is not. It reacts with ammonia (gas or as ammonium acetate solution) about twice as fast as dimedone. When preparing the respective iminodiones, dimedone containing reaction mixtures can be heated to 80°C while cyclohexanedione reactions were run at 22°C. The explanation for these differences centers around the steric effects of the 5-methyl groups which affect the coplanarity of the iminodione system (21). However, we could find no reason to treat these two reagents differently except that the dimedone-based reagent was less reactive.

This study aids our understanding of the two reagents. The hplc assay system indicated that in the Nash method the formation of **2** occurred *in situ*. Thus, as can be seen from Fig. 3, compound **2** is already present at $t = 0$ due to the 5-min preincubation of 2,4-pentanedione with ammonium acetate. Upon addition of formaldehyde there is a decrease in the concentration of **2** and the appearance and increase of **4** to a steady state.

Figure 3 also shows a duplicate experiment in which the 2,4-pentanedione is preincubated with ammonium acetate for 30 min. Greater concentrations of **2** and a faster rate of formation of **4** are noted. The reaction conditions which were used in this assay system correspond to those normally described in the literature for the Nash method.

The reaction sequence found to occur in the method of Sawicki and Carnes (2) has been partially described with regard to the identity of the intermediates (18, 22) and the general reaction sequence (14, 23, 24), but not in the context of the original reaction by Vorländer (7–9) nor from an analytical point of view (i.e., with Sawicki's assay system in mind). The results of the study of reaction 10 indicate that compound **8** is formed immediately followed by the final product, **9**. No other reaction intermediates were detected in the system. When compound **6** was assayed under conditions which had been determined would give the optimum rate of hydroacridine production, the bis-iminodione (**7**) was first detected and then the final product, **9**.

Thus it appears that reactions 1 and 2 are the ones which normally occur in the reagent mixture of Nash and the iminodione exists *in situ*. In the Nash method addition of formaldehyde yields the hydrolutidine (**4**) product directly from compound **2**, Fluoral-P.

The active agent in the Nash reagent, 4-amino-3-penten-2-one, has been studied in some detail and is a very useful aldehyde reagent (10). At pH 2.2 this compound reacts almost instantaneously with formaldehyde to form **4**. Reaction with other aldehydes is slower but selective for this class of compounds. Further studies are being carried out to characterize this reagent.

The reaction sequence which occurs with the Sawicki reagent depends greatly on how the reagent is prepared and used. In the case of dimedone, if the advice of Sawicki and Carnes (2) is followed, the events which occur follow the pathways of reactions 8 and 9. However, for the cyclohexanedione reagent, reactions 6 and 7 would be

followed because overnight storage of a reagent consisting of cyclohexanedione and ammonium acetate would produce the iminodione. This same sequence of events would occur for dimedone if the reagent were stored overnight. Compound **6** also has potential as an aldehyde reagent. However, no reproducible standard curve could be generated for the reaction of **6** with formaldehyde. An explanation for this follows.

The main difference between the Nash and Sawicki reagents is the relative reaction rates for conversion of **2** to **4** vs. **6** to **9**. In the reaction sequence of the Nash method there is no detectable intermediate between compounds **2** and **4**. The Sawicki reaction sequence, on the other hand, will go through an intermediate (**7**) which is isolable and stable. In the Sawicki method the final ring-closure step (reaction 7) to the chromophore product is acid catalyzed (12). While both **2** and **6** are susceptible to hydrolysis to their respective diones, the condensation reaction of **2** to yield **4** (2) is fast enough to be competitive with the hydrolysis reaction. As an aldehyde reagent, **2** is stored in acetonitrile. Since its reaction with formaldehyde is most rapid at pH 2.25 (10), it is used in conjunction with a buffer of low pH. No similar reagent system could be developed for compound **6**. Thus, the hydrolysis of **6** to **5** becomes the dominant reaction.

Some data exist on the acid hydrolysis of the iminodione (25) and they support our observations. A significant decrease in the hydrolysis rate occurs if the reagents are used in the pH range of the Nash and Sawicki methods (pH 5.0–7.0). However, these higher pH values do not favor rapid reactions between the reagents and formaldehyde.

While **2** has been useful to us as an aldehyde reagent, it would be desirable to develop further this family of compounds (the iminodiones). This would provide a wide choice of sensitivities and reactivities for aldehydes. Other iminodiones will represent a greater challenge with respect to optimizing reaction conditions. However, mechanized continuous-flow methods which give more reproducible reaction conditions should be of great utility in meeting this challenge.

Reçu le 22 février 1980

BRUNO BLAIVE, CHRISTIAN ROUSSEL, JACQUES METZGER et JAN SANDSTRÖM. Can. J. Chem. **58**, 2212 (1980).

L'effet d'engrenage a été découvert et étudié la première fois sur des molécules où les groupements en interaction sont des substituants alkyles. Pour se rapprocher de modèles biochimiques, cet effet est étudié ici lorsqu'un des groupements en interaction est asymétrique et fonctionnel. Dix-huit composés nouveaux, dérivés de l'alanine, ont été préparés dans ce but, et étudiés par rmn et rmn dynamique. L'effet d'engrenage est bien observé, et il apparait comme un moyen de moduler l'interaction de deux fonctions actives.

BRUNO BLAIVE, CHRISTIAN ROUSSEL, JACQUES METZGER, and JAN SANDSTRÖM. Can. J. Chem. **58**, 2212 (1980).

The gear effect has been discovered and studied for the first time on molecules where the interacting groups were alkyl substituents. In order to be closer to biochemical models, this effect has now been studied where one interacting group is asymmetric and functional. For this purpose eighteen new compounds derived from alanine have been prepared and studied by nmr and dynamic nmr. The gear effect is operating, and it appears to be a suitable means to modulate the interaction of two active functions.

Introduction

Rappelons que la notion nouvelle d'effet d'engrenage (1–5) traduit la possibilité de transmettre, à longue distance, une information conformationnelle, par l'intermédiaire de groupements alkyles convenablement placés. Ces groupements alkyles se comportent comme les roues dentées d'un engrenage, même si les rotations ne sont pas toujours concertées (3).

Les molécules sur lesquelles cet effet a été mis en évidence la première fois sont les hétérocycles Δ_4-thiazolinethione-2 portant en position 3, 4 et 5 du cycle des groupements alkyles sans carbone asymétrique.

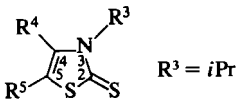

FIG. 1

Il était important, pour se rapprocher de modèles biochimiques (6, 7), d'étudier l'effet d'engrenage lorsque les groupements en interaction sont asymétriques et fonctionnels. Dans une molécule où les groupements en interaction portent des fonctions actives, l'effet d'engrenage peut être un moyen d'écarter ou de rapprocher l'une de l'autre deux fonctions (8, 9).[2]

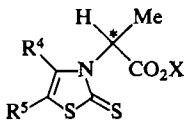
Pour faire une telle étude, le cycle des Δ_4-thiazolinethione-2 a été conservé, et comme fonction active, un groupement carboxy a été introduit dans le substituant R^3, à proximité du groupement thiocarbonyle très réactif. La famille des acides **2–9** a donc été choisie pour cette étude. Afin d'éliminer les éventuelles liaisons hydrogène, les esters méthyliques correspondant **2′–9′** ont été préparés également.

Les effets observés dans ces deux familles de composés (R^3 = $CH(Me)CO_2H$ ou R^3 = $CH(Me)CO_2Me$) seront fréquemment comparés à ceux observés antérieurement (1) pour des groupements non fonctionnels (R^3 = *i*Pr).

Nous allons d'abord décrire les conformères observés, puis étudier leurs pourcentages, enfin donner la valeur des barrières de rotation autour de la liaison C—N.

Les conformères

L'étude par rmn du proton, à différentes températures, des composés **2–9** et **2′–9′** en solu-



[1]Ce travail résume partiellement la Thèse de Spécialité de B. Blaive, Université d'Aix-Marseille III, 1976.

[2]Ces auteurs ont utilisé le composé R^5 = H, R^4 = H, R^3 = $CH(Me)CO_2H$ pour complexer l'argent entre le groupement carboxy et le soufre; on peut penser qu'une modulation de la distance entre ces deux groupements peut conduire à une modulation de la constante de complexation.

tion dans CD_3COCD_3, montre l'existence de plusieurs conformères.

Composés 2–5

Dans les spectres de rmn à température ambiante (tableau 1), la présence de signaux mal résolus ne s'explique que si les molécules sont en équilibre entre plusieurs conformations, ayant des durées de vie de 1 à 10^{-3} seconde. Il ne peut s'agir d'énantiomères se convertissant par une inversion à l'azote, puisque les trois liaisons de l'azote sont dans un même plan, comme les rayons X le montrent (10). Les conformères se différencient donc par la rotation des substituants R^3, R^4, R^5.

Par ailleurs, la variation du déplacement chimique à température ambiante du groupement méthyle de R^3, lorsque R^4 varie:

R^4	Me	Et	*i*Pr	*t*Bu
δ_{ppm}	1,66	1,68	1,74	1,88

est trop importante pour s'expliquer seulement par la variation de l'anisotropie due à R^4. Elle montre que les molécules se répartissent entre plusieurs conformères avec des populations qui dépendent fortement du substituant R^4.

A basse température, le méthyle du groupement

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

R^3 des composés **2–4** apparait sous la forme de deux doublets, au lieu d'un seul à température ambiante. De même, le signal de l'hydrogène méthinique de R^3, se dédouble en deux quadruplets bien résolus: la rotation du groupement R^3 autour de la liaison C—N devient lente à basse température, et deux positions privilégiées de R^3 apparaissent.

On peut identifier les conformères d'une part en attribuant à un même conformère des signaux d'un même spectre dont les intensités sont dans un rapport simple, d'autre part en remarquant la similitude des déplacements chimiques à −50°C des doublets suivants

R^4	Me	Et	*i*Pr	*t*Bu
δ_{ppm}	1,78	1,80	1,80	1,82

et de même la similitude des déplacements chimiques des doublets

R^4	Me	Et	*i*Pr
δ_{ppm}	1,62	1,59	1,62

de plus, **5** ne présente qu'un seul conformère, dont les signaux sont ainsi facilement repérables.

Nous appellerons I le conformère correspondant aux valeurs de δ proches de 1,80 ppm, II celui qui correspond aux valeurs proches de 1,60 ppm.

Pour déterminer la position du groupement R^3 dans les conformères I et II, on peut admettre qu'un hydrogène du groupement R^3 est déblindé lorsqu'il est à proximité du soufre exocyclique (1); alors dans les conformères I le groupement méthyle est proche du soufre, tandis que l'hydrogène méthinique en est éloigné; dans les conformères II, c'est l'inverse.

A un observateur placé dans le plan du cycle et sur le prolongement de la liaison C—N (vision de Newman, réf. 31), le groupement R^3 apparaitrait donc dans deux positions proches de celles-ci:

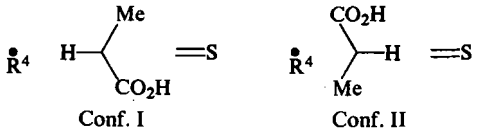

FIG. 3

Deux conformères semblables ont été mis en évidence (1) dans les composés analogues avec R^3 = *i*Pr. Pour un conformère donné (I ou II), on constate un bon accord entre les déplacements chimiques des acides (R^3 = $CH(Me)CO_2H$) et ceux des composés analogues avec R^3 = *i*Pr. Cependant le remplacement d'un méthyle de R^3 = *i*Pr par le groupement CO_2H entraîne une inversion du déplacement chimique du méthyle en position 4; elle montre que l'effet anisotrope du CO_2H prend le pas sur l'effet stérique (11).

Composés 6–9

De façon très similaire, on voit en rmn l'existence des conformères I et II (tableau 1).

Dans le cas du composé **9**, à −32°C les conformères I et II sont bien visibles, et le signal du méthyle de R^3 dans le conformère I est un doublet parfaitement résolu. Lorsqu'on abaisse la température, ses pics s'élargissent puis se dédoublent, et à −73°C on observe très nettement deux doublets au lieu d'un. Au contraire le doublet représentant le méthyle de R^3 dans le conformère II reste bien résolu entre −32 et −73°C. Il y a donc à −73°C trois conformères I_A, I_B et II, ce qui avait déja été observé pour des composés voisins (3, 4, 12).

Composés 2′–9′

Comme les acides **2–9**, les esters **2′–9′** admettent deux conformères I et II que l'on peut mettre en évidence et identifier par rmn (tableau 2).

La substitution de CO_2Me à CO_2H dans R^3 laisse presque inchangés les déplacements chimiques des protons, dans un conformère comme dans l'autre (comparaison des tableaux 1 et 2). On retrouve même, dans le composé **2′**, le fait étonnant que le méthyle en position 4 soit moins blindé dans le conformère I que dans le II. Le déplacement chimique du méthyle de l'ester est assez constant dans un conformère donné; contrairement à l'hydrogène méthinique ou au méthyle de R^3, l'ester est moins déblindé dans le conformère où il est le plus proche du soufre.

On remarque que dans le substituant R^3 la constante de couplage est toujours plus élevée pour le conformère II que pour le I.

Pourcentages des conformères

A basse température, les pourcentages p_I et $p_{II} = 1 - p_I$ des conformères I et II ont été obtenus en mesurant la surface des pics de rmn. De la température où l'échange commence jusqu'à la température T_c de coalescence, p_I a été obtenu par optimisation lors de l'étude complète de forme de courbe (13). Aux températures supérieures à T_c, il est difficile d'avoir une valeur juste de p_I.

Valeurs des pourcentages

Les figures 5(a) et 5(b) montrent l'évolution de p_I quand la taille du substituant R^4 varie. Dans les séries **2–5** et **2′–5′** (R^5 = H), la croissance de p_I quand la "grosseur" de R^4 augmente parait normale (14). Par contre, dans les séries **6–9** et **6′–9′**

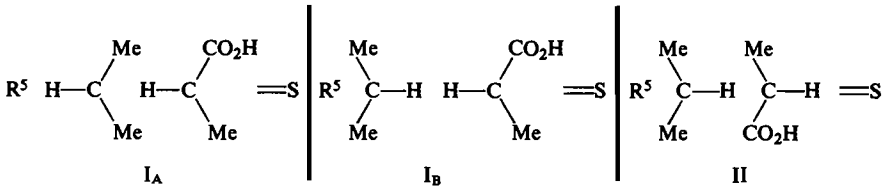

FIG. 4

(R^5 = Me), les points bas correspondant aux composés **9** et **9'** sont surprenants.

Ces courbes donnant p_I en fonction de R^4 sont très semblables à celles qui avaient été obtenues[1] pour les séries analogues avec R^3 = *i*Pr. Les valeurs très faibles de p_I correspondant aux composés R^5 = Me, R^4 = *i*Pr montrent que l'on ne peut expliquer les interactions stériques en assimilant le substituant R^4 à un volume simple, comme une sphère ou un cône (15). De plus, la différence d'allure des courbes R^5 = H et R^5 = Me montre que la nature du substituant en position 5 a un effet important sur la conformation de R^3. On peut donc parler de transmission conformationnelle par le groupement R^4. Comparons globalement les pourcentages des conformères dans les séries R^3 = *i*Pr, R^3 = $CH(Me)CO_2H$ et R^3 = $CH(Me)CO_2Me$; le remplacement d'un méthyle du groupement R^3 = *i*Pr par un groupement CO_2H ou CO_2Me favorise le conformère I (sauf dans le cas de **9**). On peut envisager *a priori* trois causes possibles de la stabilisation de la conformation I dans les acides et les esters: (*1*) soit une interaction intramoléculaire stabilisante entre le groupement acide ou ester et le thiocarbonyle dans la conformation I; une éventuelle liaison hydrogène dans la conformation II entre l'hydrogène méthinique de R^3 et le soufre exocyclique n'est pas une explication possible, car elle stabiliserait davantage la conformation II des acides et des esters que celle des composés alkyles; (*2*) soit un phénomène d'autoassociation se produisant préférentiellement dans la conformation I (une telle explication n'est envisageable que dans le cas des acides); (*3*) soit un accroissement, dans les acides et les esters, de la différence d'énergie de solvatation entre les deux conformations.

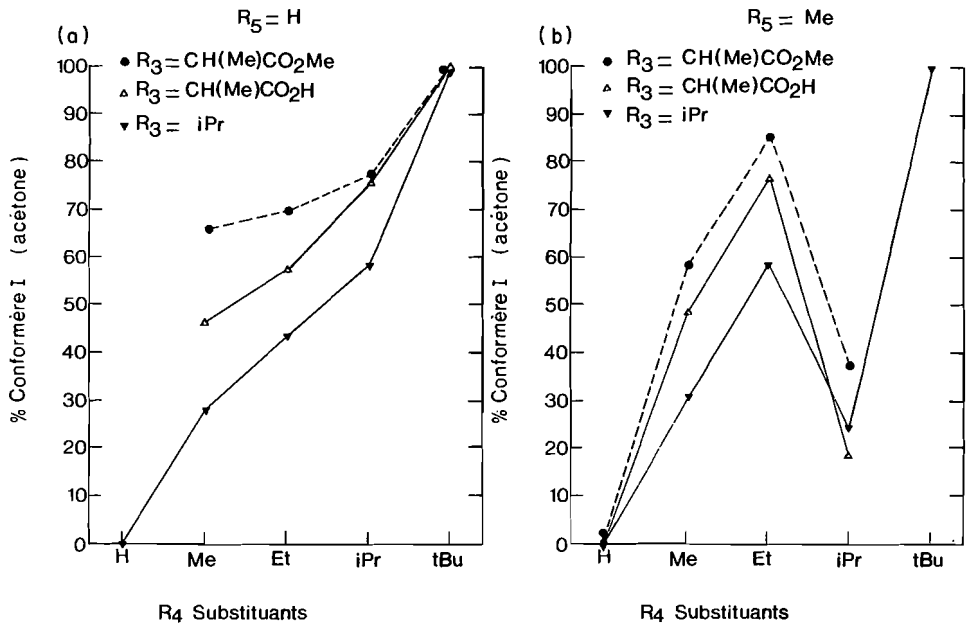

FIG. 5. Pourcentage de conformère I des acides **2–9** (R^3 = $CH(Me)CO_2H$) et des esters **2'–9'** (R^3 = $CH(Me)CO_2Me$); le pourcentage de conformère I des composés à substituant alkyle $R^3 = i$Pr est redonné pour comparaison. (a). Composés correspondant à R^5 = H. (b). Composés correspondant à R^5 = Me. Dans le cas de **9**, à −74°C les doublets correspondant aux conformères I_A et I_B ne sont pas assez séparés pour qu'on puisse mesurer avec précision les pourcentages p_{I_A} et p_{I_B}; cependant, p_{I_A} et p_{I_B} paraissent voisins l'un de l'autre. (no., p_I (%), T (°C); **2**, 46, −56; **3**, 57, −51; **4**, 75, −61; **5**, 100, −30; **6**, 0, amb.; **7**, 48, −53; **8**, 76, −46; **9**, 18, −32.)

Etude des liaisons hydrogène par infrarouge

L'absorption infrarouge des acides **2** et **5** a été mesurée; elle a été rendue difficile par la faible solubilité des composés dans tous les solvants utilisables en ir. Le spectre d'absorption de **5** dissous dans CCl_4 à la concentration de $2{,}6 \times 10^{-3}$ mol/L a l'allure suivante.

Ce spectre varie avec la dilution: à la concentration de $1{,}7 \times 10^{-4}$ mol/L, les intensités relatives des bandes sont différentes, le massif vers 3000 cm^{-1} est moins large, 3200 à 2800 cm^{-1}; I_B/I_A a décru faiblement, et l'intensité relative I_D/I_C a diminué énormément.

La forte variation, avec la concentration, du pourcentage de molécules où existe une liaison hydrogène montre que les liaisons hydrogène sont intermoléculaires. Une partie importante des molécules est sous forme de dimères (liaisons acide–acide). Par contre l'existence d'une liaison hydrogène intramoléculaire est très improbable. Une liaison hydrogène intramoléculaire engageant le soufre exocyclique aurait formé un cycle à 7 chaînons, analogue à ceux qui stabilisent probablement l'isomère *trans* de peptides (16–18); toutefois, de tels cycles sont moins fréquents dans la littérature que ceux à 6 ou 5 chaînons.

TABLEAU 3. Spectre d'absorption de **5** en ir

Bande 3532 cm^{-1} (intensité I_A)	ν_{OH} sans liaison hydrogène
Massif 3300 à 2800 cm^{-1} (I_B)	ν_{OH} avec liaison hydrogène
Bande 1767 cm^{-1} (I_C)	$\nu_{C=O}$ sans liaison hydrogène
Bande 1721 cm^{-1} (I_D)	$\nu_{C=O}$ avec liaison hydrogène

L'intensité de la bande à 1721 cm^{-1} étant légèrement supérieure à celle de la bande à 1767 cm^{-1}

On peut faire des conclusions identiques pour le composé **2**. Les constantes d'association en dimères cycliques sont du même ordre pour les composés **2** et **5**, environ 100 $L \cdot mol^{-1}$ dans $CHCl_3$.

Il résulte de cette étude que ce ne sont pas des liaisons hydrogène qui sont responsables de l'accroissement du pourcentage de la conformation I lorsqu'on substitue $R^3 = CH(Me)CO_2H$ à $R^3 = i$Pr. En effet, d'une part il n'y a pas de liaison hydrogène intramoléculaire, d'autre part les autoassociations par liaisons hydrogène ne peuvent stabiliser préférentiellement la conformation I, car on observerait alors une constante d'autoassociation plus forte pour le composé **5**, qui est totalement sous la forme I, que pour le composé **2**, ce qui n'est pas le cas.

Variation des pourcentages des conformères avec la température

La figure 6 représente, pour six composés, la variation du pourcentage de I avec la température. On remarque que cette variation est importante

T (°C)	(−1,0)	(−2,6)	(0,3)	(−2,3)	(0,0)	(−0,7)

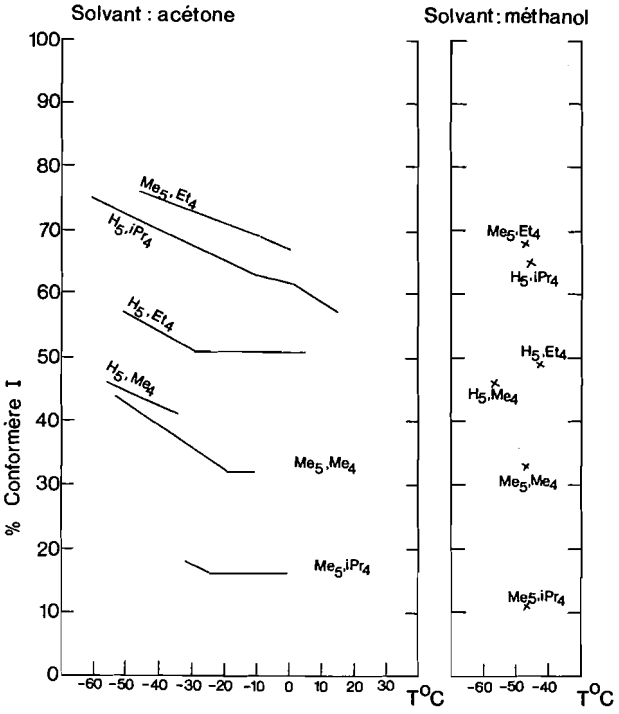

FIG. 6. Variation avec la température du pourcentage de conformère I des acides (R^3 = CH(Me)CO_2H) **2–4** et **7–9**. La méthode d'obtention de p_I aux températures où l'échange I ⇌ II est rapide étant peu précise, la partie droite de chaque courbe est approximative.

(elle peut atteindre 20%), et que le conformère I est toujours défavorisé quand la température croît.

Au contraire, dans la série analogue avec R^3 = *i*Pr, le pourcentage de I reste constant quand T varie (3). Pour expliquer cette variation avec la température, il faut imaginer qu'un phénomène sensible à la température est susceptible de stabiliser un conformère plus que l'autre. On pourrait trouver une explication plausible de la variation du pourcentage de I avec la température si les associations en dimères se faisaient préférentiellement dans certaines conformations; mais nous avons vu qu'aux erreurs expérimentales près, les associations en dimères ne semblent pas préférentielles. Toutefois l'étude par ir a été faite dans CCl_4 et à température ambiante, tandis que l'étude par rmn a été faite dans CD_3COCD_3 et à basse température.

Barrières de rotation autour de la liaison C—N (sp^3 − sp^2)

Les paramètres d'activation $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$ relatifs au passage du conformère I au conformère II ont été mesurés par la méthode de la rmn dynamique (13, 19, 20) pour les acides **2–4** et **7–9** (tableau 5). Pour cela, la constante de vitesse d'échange a été mesurée pour chaque composé à une quinzaine de températures différentes, l'analyse complète de forme de courbe portant sur le signal du méthyle de R^3. On constate (tableau 4) que la température de coalescence T_c croît avec la taille du substituant R^4, c'est-à-dire avec l'empêchement à la rotation autour de la liaison C—N; T_c croît également avec la taille de R^5. La différence des déplacements chimiques étant peu variable suivant les composés, la variation de T_c indique la variation de la barrière.

Les valeurs de $\Delta G^{\ddagger}$ et $\Delta H^{\ddagger}$ sont comprises entre 13 et 15 kcal mol^{-1}, donc nettement inférieures aux 23 kcal nécessaires pour que les conformères soient séparables à température ambiante.

On remarque que $\Delta G^{\ddagger}$ augmente régulièrement avec la "grosseur" du substituant R^4. L'évolution de $\Delta H^{\ddagger}$ est moins régulière. Les valeurs de $\Delta S^{\ddagger}$ sont assez dispersées; en particulier la valeur correspondant au composé **4** est élevée, mais cette valeur est peu précise, à cause de la démesure de p_I par rapport à p_{II}, qui rend malaisée l'étude par rmn dynamique. Cependant la valeur moyenne (∼ − 7 cal) des $\Delta S^{\ddagger}$ trouvés est voisine des valeurs correspondant à la rotation de substituants dans divers composés (21, 22). Le tableau 5 redonne également les valeurs de $\Delta G^{\ddagger}$ trouvées antérieurement pour la série analogue R^3 = *i*Pr, étudiée (1) dans $CDCl_3$.

La figure 7 représente, en fonction du substituant R^4, la différence

$$\Delta G^{\ddagger}_{(I \rightarrow II)} - \tfrac{1}{2}\Delta G_{(I \rightarrow II)} \text{ à } 298 \text{ K}$$

où la différence d'enthalpie libre ΔG a été calculée à partir des pourcentages des conformères; cette

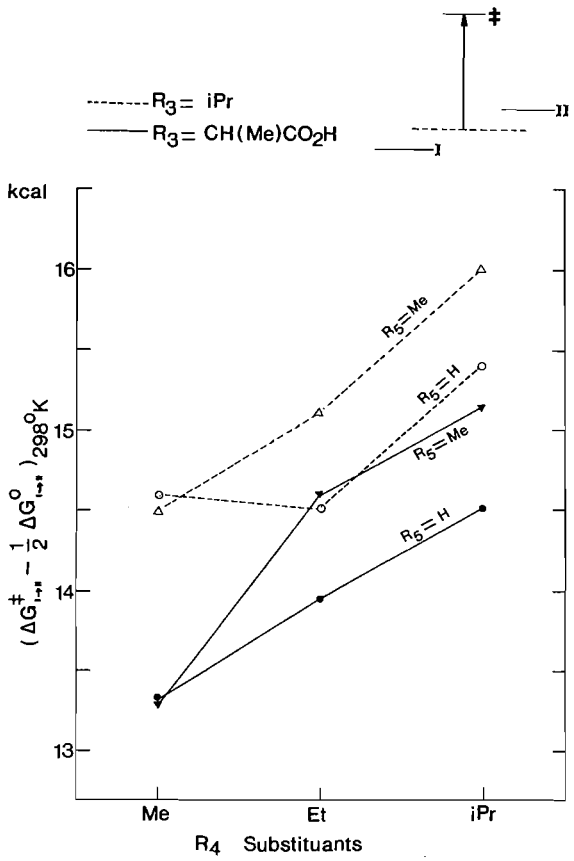

FIG. 7. Variation, en fonction du substituant R^4, de la barrière de rotation $\frac{1}{2}(\Delta G^{\neq}_{I\rightarrow II} + \Delta G^{\neq}_{II\rightarrow I}) = \Delta G^{\neq}_{I\rightarrow II} - \frac{1}{2}\Delta G^{0}_{I\rightarrow II}$ des acides **2–4** et **7–9** (R^3 = $CH(Me)CO_2H$) et des composés alkyles correspondant ($R^3 = i$Pr).

différence représente la moyenne entre $\Delta G^{\neq}_{(I\rightarrow II)}$ et $\Delta G^{\neq}_{(II\rightarrow I)}$. On remarque une diminution générale de $\Delta G^{\neq} - \frac{1}{2}\Delta G$ quand on passe de $R^3 = i$Pr à R^3 = $CH(Me)CO_2H$, et nous n'en voyons pas l'explication; ce résultat rappelle un phénomène analogue observé à propos de l'équilibre conformationnel de cyclohexanes substitués (23).[3] Par ailleurs, on remarque pour les composés ayant un substituant R^4 petit (R^4 = Me) que $\Delta G^{\neq}$ n'est pas changé lorsqu'on passe de R^5 = H à R^5 = Me.

Les valeurs de $\Delta G^{\neq}$ sont assez précises pour mériter une interprétation quantitative, hors de notre portée pour le moment.

Conclusion

Il résulte de cette étude qu'il est possible de moduler la proximité de deux fonctions actives, telles qu'une fonction thiocarbonyle et une fonction acide carboxylique par exemple, à l'aide de l'effet d'engrenage.

L'influence de la nature du groupement "transmetteur" R^4 est analogue à celle trouvée pour des composés ayant des substituants alkyles uniquement. Mais la sensibilité des pourcentages des conformères à la température est propre aux groupements fonctionnels.

Les valeurs des pourcentages des conformères et des barrières de rotation, mesurées avec précision, se joignent à un lot de valeurs semblables mesurées antérieurement dans une famille de composés très homogène. Nous voyons comme intérêt de ces données de fournir à terme des tests aux modèles théoriques ou semi-empiriques représentant les interactions d'atomes non liés, pour lesquelles les

[3]Les enthalpies libres relatives à l'équilibre conformationnel des cyclohexanes substitués par des groupements CH_3, CO_2H, CO_2CH_3 sont respectivement ΔG = 1,70; 1,35; 1,27 de sorte que dans ce cas tout se passe en apparence comme si les tailles des substituants étaient dans l'ordre $CH_3 > CO_2H > CO_2CH_3$. On peut penser à rapprocher cet ordre également de la valeur relative des pourcentages des conformères des composés $R^3 = i$Pr, $R^3 = CH_2(Me)CO_2H$, $R^3 = CH_2(Me)CO_2Me$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

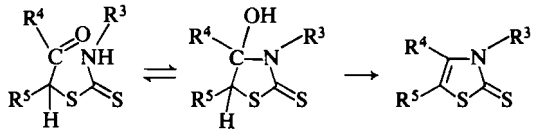
données concernant des interactions de groupements polaires sont en nombre limité.

La mise en place d'un substituant R^3 chiral est une première étape de l'introduction de deux asymétries (dans R^3 et R^4), qui conduira à des diastéréoisomères.

Partie expérimentale

Préparation des composés 2–9 et 2′–9′



Les acides **2–9** ont été préparés en faisant réagir (5) une cétone α-bromée R^4-CO—CH(Br)-R^5 ou α-chlorée, avec un dithiocarbamate R^3-NH—CS_2^-.

Bromation des cétones

La chloracétone est commerciale; le propanal est brômé en bromo-2 propanal par le bromure de dioxanne (24). Les autres cétones sont brômées par le brôme, en présence d'acide bromhydrique, dans le méthanol, à température ambiante (25, 26).

Préparation du dithiocarbamate

Le sulfure de carbone et l'alanine réagissent en milieu basique pour donner le dithiocarbamate (27) HO_2C—CH(Me)—NH—CS_2^-, Na^+ (ou K^+); dans le méthanol (8) la réaction ne dure qu'une heure et a un excellent rendement.

(A) (B) (C)

La réaction entre la cétone bromée et le dithiocarbamate qui conduit au composé (A) puis à la Δ_4-thiazolinethione-2 (C), est un cas particulier de la réaction de Hantzsch (8, 28).

On passe finalement à la forme fermée déshydratée (C) en acidifiant à pH 2 avec HCl, puis en chauffant le mélange en contrôlant par uv l'avancement de la réaction (A) ⇄ (B) → (C); (A) absorbe en uv dans l'eau aux alentours de 250 nm, (B) de 275 nm et (C) de 319 nm.

Nous n'avons pu obtenir l'acide correspondant à R^5 = Me et R^4 = *t*Bu. L'intermédiaire non cyclisé (A) a été obtenu sans difficultés. Nous pensons avoir mis en évidence par uv le composé (C) correspondant, mais nous n'avons pu l'isoler; il est probable qu'il s'hydrate pour redonner (A).

Les esters ont été préparés par action du diazométhane sur les acides (29, 30). Le rendement est de 100%. Ces valeurs ont été obtenus: no., rendement, pf (isomère L, racémique DL), spectre de masse (70 eV); **2**, 85, (159, 170), 203(100) 158(30) 131(74) 86(28) 72(29) 45(35); **3**, 85, (128, 104), 217(100) 172(31) 145(67) 144(35) 45(47) 41(35); **4**, 55, (—, 116), 231(100) 186(24) 159(36) 158(63) 144(36) 45(45) 41(41); **5**, 80, (224, 223), 245(100) 200(34) 158(51) 45(34) 41(54); **6**, 70, (126, —), 203(100) 158(50) 131(68) 72(23) 59(22); **7**, 68, (154, 148), 217(100) 172(24) 145(52) 85(16) 59(18); **8**, 30, (171, 171), 231(100) 186(34) 159(60) 158(34) 59(51) 41(25); **9**, 49, (137, —), 245(100) 200(29) 173(29) 172(58) 158(31) 59(74) 41(35); **2′**, (76, —); **3′**, huile; **4′**, (—, 110); **5′**, (194, —); **6′**, huile; **7′**, huile; **8′** (110, —); **9′**, (80, —).

Les spectres de masse et rmn sont en accord avec les structures attendues.

Mesures de résonance magnétique nucléaire

Les spectres de rmn du proton ont été enregistrés à 100 MHz sur un spectromètre JEOL JNM-MH-100 muni d'un contrôleur de température VT 3-C. Les composés ont été étudiés en solution dans l'acétone à la concentration de 0,4 mol L^{-1} environ.

Les constantes de vitesse d'échange ont été choisies de façon que le signal théorique (13) du méthyle de R^3 coïncide au mieux avec le signal expérimental. Le signal théorique est tracé pour diverses valeurs des paramètres, à l'aide d'un ordinateur Hewlett-Packard 9820 A équipé d'une table traçante 9862 A, et comparé visuellement au signal expérimental. Le temps de relaxation T_2 est déduit de la largeur à mi-hauteur du signal du ou des protons du substituant R^5 (19, 20).

Les paramètres d'activation sont calculés à partir des droites ($-\log\tau(T)$, $1/T$), et les erreurs sont évaluées statistiquement, en utilisant un seuil de confiance de 90%.

Remerciements

Nous remercions M. R. Gallo de l'I.P.S.O.I., qui a étudié par rmn dynamique les composés **2** et **8**, ainsi que M. B. Mille du Laboratoire du Professeur J. Chouteau à Marseille, Mlle. E. Gentric et M. J. Lauransan de la Faculté de Brest, qui ont étudié par ir les composés **2** et **5** et mesuré leurs constantes d'autoassociation.

Pyrochlores. XI. High-pressure studies of the antimonates $A_2Sb_2O_7$ (A = Ca, Sr, Cd) and preparation of the weberite $Sr_2Bi_2O_7$[1]

OSVALD KNOP
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3
AND
GERARD DEMAZEAU AND PAUL HAGENMULLER
Laboratoire de Chimie du Solide du CNRS, Université de Bordeaux I, 33405 Talence, France
Received April 11, 1980

OSVALD KNOP, GERARD DEMAZEAU, and PAUL HAGENMULLER. Can. J. Chem. **58**, 2221 (1980).

Reactive hot-pressing experiments at 60–70 kbar and 700–900°C indicate that the relative stability of the pyrochlore and weberite phases of the $A_2Sb_2O_7$ (A = Ca, Sr, Cd) antimonates depends primarily on the effective size of A^{2+} and the covalency of the A—O bond working in conjunction. The analogous bismuthate(V) $Sr_2Bi_2O_7$, obtained by hot pressing of $SrBiO_{3-x}$ with an excess of $KClO_3$, has been shown to have the weberite-type structure.

OSVALD KNOP, GERARD DEMAZEAU et PAUL HAGENMULLER. Can. J. Chem. **58**, 2221 (1980).

L'étude sous hautes pressions (60–70 kbar) des oxydes $A_2Sb_2O_7$ (A = Ca, Sr, Cd), dans un domaine de température compris entre 700 et 900°C, a montré que la stabilité relative des phases pyrochlore et wébérite dépendait de la taille de l'ion A^{2+} ainsi que de la covalence de la liaison A—O. L'oxyde de bismuth(V), $Sr_2Bi_2O_7$, obtenu par action sous haute pression de $KClO_3$ sur $SrBiO_{3-x}$, présente la structure wébérite.

Introduction

The antimonates $Ca_2Sb_2O_7$ and $Cd_2Sb_2O_7$ crystallize with structures of both the pyrochlore (*P*) and the weberite (*W*) type, but $Sr_2Sb_2O_7$ is only known as a weberite (2). The following is an account of an investigation undertaken to examine the possibility of the $W \rightarrow P$ conversion under pressure suggested in ref. 2, and to explore the possibility of existence of the corresponding $A_2Bi_2O_7$ phases containing Bi(V).

Experimental

The $A_2Sb_2O_7$ antimonates (Table 1) were prepared by firing dry-mixed reactants of high purity in air (cf. ref. 2).[2] The products were ground and refired as necessary. The maximum firing temperature was chosen so as to keep possible weight loss by volatilization to a minimum, consistent with the formation of a well-defined product of the intended crystal structure. The antimonic acid used was prepared by hydrolyzing purified $SbCl_5$ in ice and H_2O_2. The composition of the air-dried acid was $Sb_2O_5 \cdot 3.67\ H_2O$ (as determined by the method outlined in ref. 4).

A sample of the $Cd_2Sb_2O_7(W)$ described in ref. 5 was kindly supplied by Dr. B. Raveau.

The high-pressure experiments were carried out in a belt-type apparatus, with the samples contained in sealed Au or Pt capsules. $KClO_3$ in excess was used an an oxidant in the reactive hot-pressing runs. The perovskite $SrBiO_{3-x}$ used in the synthesis of $Sr_2Bi_2O_7$ has been prepared by heating SrO + Bi_2O_3 in oxygen under pressure.

X-ray powder diffraction patterns were obtained either in 114.6 mm diameter cameras with Straumanis-type film mounting, or with a Guinier camera, or with a Philips powder diffractometer. Owing to a certain diffuseness of the high-angle lines in the powder photographs, the unit-cell dimensions listed in Table 2 were evaluated by least-squares from low- and medium-angle peaks of the diffractograms, using high-purity Mo or KCl powders as internal standards. The small discrepancies in the unit-cell dimensions between the present work and ref. 2 are attributable in part to the difference in the evaluation procedure and in part to genuine slight differences between samples of the same nominal composition but prepared on different occasions.

Results

Phase-transformation Experiments

The available evidence indicates that the mean linear unit-cell dimension $\bar{a} = (V/Z)^{1/3}$ of a particular *W* phase at room temperature is larger than that of the corresponding *P* phase (cf. Fig. 3 of ref. 2 and Table 2). This points to the possibility of a $W \rightarrow P$ transformation under pressure. The actual values of the difference $\Delta\bar{a} = \bar{a}(W) - \bar{a}(P)$ are difficult to establish with any accuracy, as is evident from an examination of the $\bar{a}$ values of Table 2: the observed $\Delta\bar{a}(Cd_2Sb_2O_7)$ is so small as to be indeterminate, $\Delta\bar{a}(Ca_2Sb_2O_7)$ is of the order of 0.2% of $\bar{a}$, and $\Delta\bar{a}$ estimated for $Sr_2Sb_2O_7$ (the *P* phase has never been reported) is about 1% of $\bar{a}$. The Sr weberite would therefore be expected to transform more readily than the Ca and Cd weberites. However, heating $Ca_2Sb_2O_7(W)$ and $Sr_2Sb_2O_7(W)$ at 800–900°C at 78 kbar for 20 min resulted merely in an improved crystallinity of the two weberites, as evidenced by the sharpening of the lines in the X-ray powder patterns of the pressed compounds.

[1]For Part X, see ref. 1.

[2]The products described in Tables 1 and 2 are the same as those used by Ferguson (3) in his Mössbauer ^{121}Sb study of these antimonates.

*Converted from kX.
†78 kbar/800–900°C/20 min.

Reactive hot-pressing was therefore tried. A mixture of CdO + Sb_2O_3 + $KClO_3$(excess) was heated at 800°C and 60 kbar for 30 min. The sample was then quenched by cutting furnace power while maintaining the pressure. After quenching the pressure was gradually reduced to atmospheric over several hours. The product was a mixture of a poorly crystallized *P* phase and KCl. Using CaO instead of CdO under the same conditions yielded what appeared to be a mixture of the *P* and *W* phases and KCl. The similarity of the main features of the diffraction patterns of the two phases and the rather poor crystallinity did not permit an unambigous conclusion, but the *P* phase seemed to dominate. With SrO, only $Sr_2Sb_2O_7$(*W*) formed. The results of these and additional experiments at 800°C and 60 kbar can be summarized as follows:

Intended composition	Phase obtained
$Cd_2Sb_2O_7$	*P*
$CaCdSb_2O_7$	*P*
$Ca_2Sb_2O_7$	*P*+*W*
$CaSrSb_2O_7$	*W*
$Sr_2Sb_2O_7$	*W*

Later in the investigation a sample of $Cd_2Sb_2O_7$(*W*) (5) became available. Powder patterns (diffractometer and Guinier) of a product obtained by heating this material at ~700°C and 65 kbar for 20 min showed that the weberite had transformed completely into a well-defined *P* phase. On the other hand, a DTA run up to 1200°C (Pt capsule, Al_2O_3 reference) in stagnant air gave no indication of a transformation.

Strontium Bismuthate(V)

The brownish-orange product obtained by heating an intimate mixture of $SrBiO_{3-x}$ and $KClO_3$ for 15 min at 730°C and 60 kbar was a mixture of KCl and a relatively well-crystallized phase whose X-ray diffraction pattern could be indexed on an orthorhombic unit cell with $a = 7.70$ Å, $b = 7.91$ Å, and $c = 10.58$ Å. There is little doubt that this phase was the weberite $Sr_2Bi_2O_7$. Its $\bar{a}$ value, 5.44 Å, is about 2.6% larger than that of $Sr_2Sb_2O_7(W)$. The product was not analyzed chemically, partly because the quantity involved was quite small and partly because of the high accuracy that would have been required to establish with any confidence departures from oxygen stoichiometry of the weberite: the loss of as much as one oxygen per $Sr_2Bi_2O_7$ (corresponding to $Sr_2Bi^{III}Bi^{V}O_6$) would amount to a weight loss of only 2.3%. In the circumstances such an accuracy could not be hoped for.

Similar experiments designed to prepare the corresponding Ca bismuthate gave products with complex, poorly defined powder patterns, difficult to identify with confidence and most likely mixtures.

Discussion

The results obtained in the high-pressure experiments can be explained if we assume that at 60–65 kbar and 700–800°C the volume relationships are as represented schematically in Fig. 1. On this reasonable assumption it is clear that $Cd_2Sb_2O_7(P)$ and $Sr_2Sb_2O_7(W)$ will not transform under pressure but $Cd_2Sb_2O_7(W)$ will. For $Ca_2Sb_2O_7$ the difference between $\bar{a}(P)$ and $\bar{a}(W)$ must be very small. Which phase is obtained will depend on how the experimental conditions affect the delicate balance of the different factors (including kinetic) that determine the relative stability of the P and W phases, as shown by the formation of a $P + W$ mixture in the reactive hot pressing on one hand and the failure of the well-defined W phase to transform on the other.

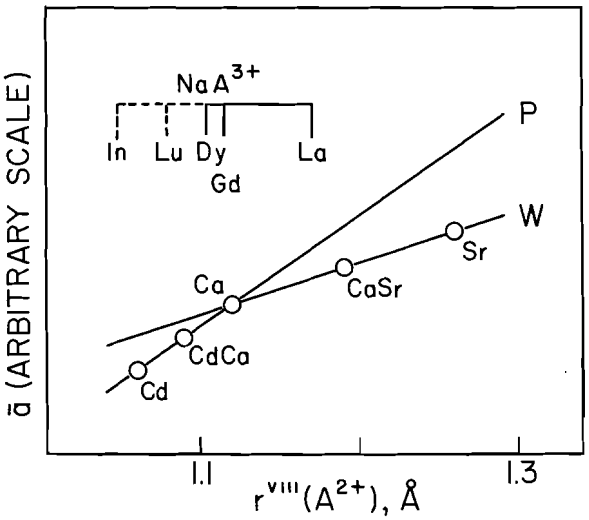

FIG. 1. Schematic representation of the pyrochlore–weberite volume relationships, at 60–65 kbar and 700–800°C, of the $A_2Sb_2O_7$ and $AA'Sb_2O_7$ antimonates.

The unexplained failure of some experiments designed to prepare $Cd_2Sb_2O_7(W)$ at atmospheric pressure (2, 6, 7) and the success of others, under seemingly identical conditions (5, 8), is undoubtedly also related to the small, pressure-dependent $\Delta\bar{a}$ of this antimonate. In the absence of compressibility data it cannot be decided whether the P–W phase relationship of Fig. 3 of ref. 2 holds at 1 atm and the P and W lines become inverted as the pressure increases, or whether the limited accuracy of the $\bar{a}$ values and the smallness of $\Delta\bar{a}$ are sufficient to introduce ambiguity into the relative positions of the P and W lines in the 1 atm plot.

The occurrence of the $NaLnSb_2O_7$ (Ln = La, Pr, Nd, Sm, Eu, Gd, Dy) antimonates as weberites (6, 9) is consistent with the volume relationships of Fig. 1. It is interesting to note that while Desgardin *et al.* (9) prepared $NaDySb_2O_7$ as a weberite, Burchard and Rüdorff (6) reported that they were unable to obtain a W phase of this composition; their experiments designed to yield $NaLnSb_2O_7$ (Ln = Dy, Er, Lu, Y) and $NaInSb_2O_7$ weberites resulted in mixtures of the unreacted sesquioxide and a P phase of unknown composition. It thus appears that Dy may be at the limit of the $NaLnSb_2O_7(W)$ field and occupies a position analogous to that of Ca in the $A_2^{2+}Sb_2O_7(W)$ series.

A further observation of interest concerns the effective ionic radius of Cd^{2+} in the W antimonates. A linear regression of $\bar{a}(W)$ on $r^{viii}(A^{2+})$ (or on the mean r^{viii} for the mixed weberites) shows clearly (Fig. 2) that Shannon's (10) $r^{viii}(Cd^{2+})$ value of 1.10 Å is too high relative to his values for Ca^{2+} (1.12 Å) and Sr^{2+} (1.26 Å). The regression equation, $\bar{a}(W) = 4.228 + 0.84r^{viii}(A^{2+})$ (14 $\bar{a}$ values, $r^2 = 0.994$, $\sigma = 0.003$ Å), requires 1.063 Å for Cd^{2+}. It also shows that the $\bar{a}$ value of 5.201 Å calculated from the unit-cell dimensions of $CdSrSb_2O_7$ (11) is lower than would be expected for $r^{viii}(Cd^{2+}) = 1.063$ Å. This is consistent with the Cd,Sr ordering reported to exist in this weberite (11).

Examination of the combined observations on $A_2Sb_2O_7$ antimonates appears to indicate that the two primary structure-determining factors are the effective size of A^{2+} and the covalency of the A—O

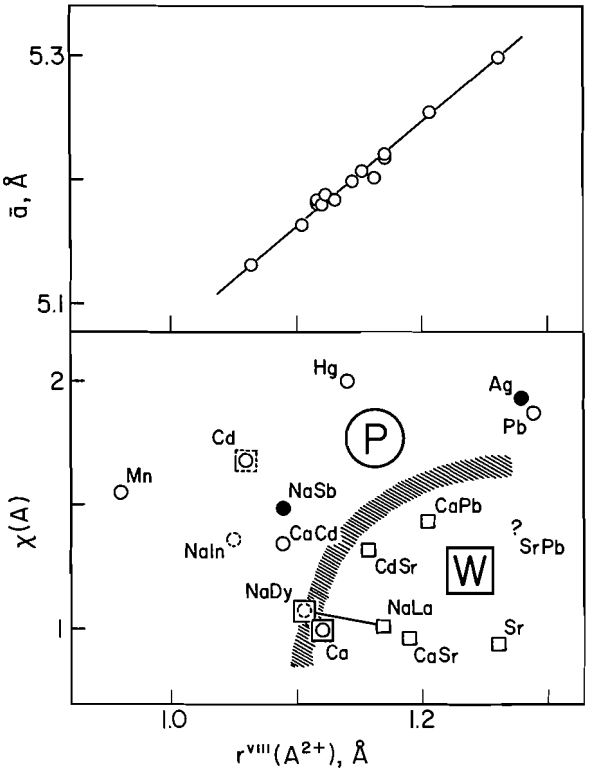

FIG. 2. (*Top*) Linear regression of $\bar{a}$ on $r^{VIII}(A^{2+})$ for $A_2Sb_2O_7(W)$. Shannon's (10) effective ionic radii are used throughout except for Cd^{2+} (see text). (*Bottom*) Pyrochlore–weberite stability relationship in dependence on the effective ionic radius $r^{VIII}(A^{2+})$ and electronegativity $\chi(A)$. Open circles, $A_2Sb_2O_7$ and $AA'Sb_2O_7$ pyrochlores. Full circles, defect antimonate pyrochlores. Squares, $A_2Sb_2O_7$ and $AA'Sb_2O_7$ weberites.

bond, and that these two factors work in conjunction. The relative *P–W* stability (within the ionic-size tolerance limits of these phases) is shown, in dependence on $r^{VIII}(A^{2+})$ and Allred's (12) electronegativity $\chi(A)$, in Fig. 2.[3] It is seen that large cations of low electronegativity favour the weberite structure. This crude separation of the *P* and *W* fields leaves out additional factors, e.g. the details of the *p–T* behaviour of the individual compounds and kinetic factors which may override the thermodynamic stability relationships and lead to formation of metastable phases. It contains no provision to account for the existence of the trigonal distortion observed in $Pb_2Sb_2O_7(P)$ (which is probably due to the lone pair on Pb^{2+}), for the effect of nonstoichiometry on the symmetry of the crystal structure, or for ordering in solid solutions $A_{2-x}A'_xSb_2O_7$, such as described in ref. 11. However, the *general* features of Fig. 2 appear to be valid.

The $Sr_2Bi_2O_7$ weberite appears to be one of the few genuine stoichiometric oxygen compounds of Bi(V). It is noted that neither of the two recently investigated mixed-valence compounds related to $Sr_2Bi_2O_7$, the golden $Ba_2Bi^{III}Bi^VO_6$ (13), and the brownish-black $(K_{1.14}Bi^{III}_{0.37})(Bi^{III}_{0.27}Bi^V_{1.73})[O_{4.9}(OH)_{1.1}](OH)_{0.8}$ (14), is a weberite. The former is an ordered perovskite with temperature-induced transitions, whilst the latter is a highly disordered pyrochlore, $\bar{a} = 5.483$ Å. If $r^{VI}(Sb^{5+})$ is taken to be 0.59 Å, the corresponding value of $r^{VI}(Bi^{5+})$, as estimated from the known Bi—O distances in the intensely yellow Na_3BiO_4 (isostructural with Na_3SbO_4) (15) and taking $r^{VI}(O^{2-}) = 1.40$ Å, is 0.64 Å. The straight line obtained by plotting $\bar{a}(Sr_2Sb_2O_7)$ and $\bar{a}(Sr_2Bi_2O_7)$ against these radii is parallel to that for Na_3SbO_4 and Na_3BiO_4. This may be taken as further evidence in support of our contention that our preparation was in fact $Sr_2Bi_2O_7$.

[3]Of the antimonates included in Fig. 2 the following have been described previously: Mn, Pb (2); Ag (4); NaSb (4, 6); Hg (18); CdSr (11); CaPb (6); NaLn (Ln = La to Dy) (6, 9). An attempt to prepare $SrPbSb_2O_7(W)$ failed (6).

Acknowledgments

We wish to thank Dr. B. Raveau for supplying a generous sample of $Cd_2Sb_2O_7(W)$. Financial support received by one of us (O.K.) under the CNRS/NRCC agreement on cooperative research during his stay at the Laboratoire de Chimie du Solide du CNRS is gratefully acknowledged.

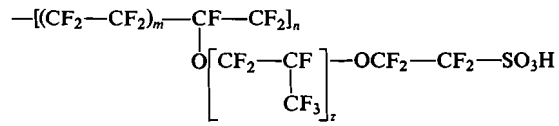
SO_2 diffusion through acetonitrile-saturated perfluorosulfonic acid membranes

FRANK M. KIMMERLE AND RAYMOND BREAULT

Department of Chemistry, Université de Sherbrooke, Sherbrooke, P.Q., Canada J1K 2R1

Received April 1, 1980



FRANK M. KIMMERLE and RAYMOND BREAULT. Can. J. Chem. **58**, 2225 (1980).

The diffusion coefficient of SO_2 and acetonitrile in Nafion perfluorinated ion exchange membranes have been determined from chromatographic measurements of SO_2 concentration and the isotopic ratios in acetonitrile solutions. The diffusion coefficients vary with residual water content and attain values about one fifth those reported for water-saturated membranes falling in the range $1-2 \times 10^{-7}$ cm^2 s^{-1}. Values obtained for Teflon reinforced material indicates diffusion takes place over an effective surface more than twice the optically open area.

FRANK M. KIMMERLE et RAYMOND BREAULT. Can. J. Chem. **58**, 2225 (1980).

Les coefficients de diffusion D_{SO_2} et D_{CH_3CN} dans les membranes d'échangeur d'ion perfluorinés ont été déterminés à partir des mesures chromatographiques et isotopiques en milieu acétonitrile. Les coefficients dépendent de la concentration résiduelle en eau et atteingent finalement des valeurs un cinquième à celles observées dans les membranes saturés en eau, soit de $1 à 2 \times 10^{-7}$ cm^{-2} s^{-1}. Des valeurs mesurées pour un matériel renforci par un tissu de Teflon indiquent que la diffusion a lieu sur une surface plus que deux fois importante que la surface apparente à l'examen microscopique.

Cation exchange membranes in general and perfluorosulfonic acid membranes in particular have attracted a lot of attention in the electrochemical industry. Dupont's Nafion® materials are described (1) as copolymers of tetrafluoroethylene and monomers such as perfluoro-3,6-dioxa-4 methyl-7-octensulfonic acid, typified by the chemical formula

where m = 5 to 13.5, n = ca. 1000, and z = 1, 2, 3 ...

The sulfonic acid groups may be assumed (2) to line the walls of a conductive network of a series of pores and cavities that permeate the otherwise hydrophobic fluoropolymer. The transport properties are largely governed by the equivalent weight (ew) of the polymer, the amount of water retained by the hydrophilic R—SO_3H groups, and the extent of cation exchange that has taken place. Ion exchange membranes are available in various forms including Nafion membrane 110: a homogeneous film 10 mils thick ew = 1100, Nafion membrane 125: a homogeneous film 5 mils thick ew = 1200, and Nafion membrane 427: a 7 mils thick film of ew = 1200 perfluorosulfonic acid resin laminated with a Basket Weave Teflon® supporting cloth.[1]

The membranes have been widely used as separators in water electrolysis (4) and chlor-alkaline cells (3, 5), and have been investigated as membranes in the production of alkali metal carbonates (6) and suggested for use in metal recovery as well as in battery, fuel cell, and dialysis applications (7). No specific mention of these solid polymer membranes in connection with aprotic electrolytes appears in the literature. We now have reason to believe that small polar molecules including acetonitrile, methylformate and methylacetate are readily retained within the cavities of the membrane. Data will be presented here showing that acetonitrile and SO_2 possess mobilities of the same order of magnitude as the water molecule in aqueous electrolytes. Work currently in progress indicates that cation transport remains high and anion transport remains negligibly small in membranes equilibrated with respect to aprotic electrolytes.

Will (8) recently investigated the diffusion of bromine in bromide solution through Nafion perfluorinated membranes, showing that D_{Br_2} depends on the chemical nature of the diffusing species as well as the counter cation. In order to minimize the number of experimental parameters, this exploratory work avoids the use of a supporting electrolyte and other solutes. Moreover, extrapolation of our results to real systems, including the commercially available Li/SO_2 batteries would be premature since only SO_2/CH_3CN ratios below 0.01 were investigated.

Experimental

Chromatographic Measurements

The effect of membrane equivalent weight, its pretreatment, and temperature were studied by following the SO_2 concentration in the two compartment cell shown in the schematic drawing of Fig. 1. The two halves, having a volume of 3.1 and 150 mL respectively, were separated by the semipermeable membrane held between two stainless steel flanges exposing an area A 2.5 cm in diameter.

The larger of the two compartments was filled with an

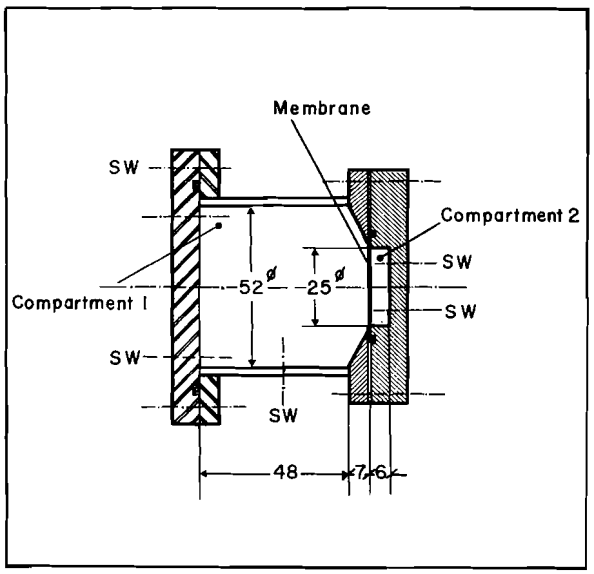

FIG. 1. Sectional view of diffusion cell. Dimensions in mm, material SS-316, Teflon seal, SW: Swagelok® male connectors 1/8 in.

~0.2 *M* SO_2/acetonitrile solution, the smaller with pure acetonitrile. Samples (5.0 μL) were withdrawn through septums held in 1/8 in. Swagelock® ports and analysed by measuring the ratio of the chromatographic peak areas SO_2/CH_3CN in both compartments. The separation of SO_2 and acetonitrile using a Carbowax 200 column at 100°C in a Gow-Mac chromatograph proved very reliable and allowed sufficient time to change the attenuation factor. As verified by iodometric titrations the peak ratio remained proportional to the SO_2 concentrations up to 0.5 *M*. Relative concentrations could be measured to within 0.5% and the concentration of the SO_2 in the larger compartment remained constant to within 1% throughout any one run.

Mass Spectrometric Measurements

The smaller of the two compartments was filled with deuterated acetonitrile and the larger with CH_3CN. Samples (5 μL) from both compartments were analysed by mass spectrometry over a period of several hours and the diffusion rate of acetonitrile was calculated from the variation of the peak ratio at $m/e = 44$ and $m/e = 41$. The spectra for ten repetitive scans were averaged to yield relative results for the m/e ratio 41/44 accurate to within 2% for the smaller compartment. The m/e ratio 44/41 for the larger compartment proved less reliable since the mass ratio remained below 2% even when diffusion equilibrium had been reached.

Acetonitrile Solutions and Membrane Pretreatment

Acetonitrile was purified following the method outlined by O'Donnel *et al.* (9). Water was removed by distillation from molecular sieves or calcium hydride and typical Karl Fisher analysis indicated less than 400 ppm H_2O. A SO_2 stock solution was prepared by bubbling SO_2 gas through dried and purified acetonitrile at room temperature. Test solutions (0.2 *M*) were prepared by volumetric dilution and their SO_2 content determined exactly by iodiometric titration (10) using dead stop end point detection. The Nafion membranes were boiled in dried acetonitrile for periods up to 100 h and immediately mounted in the cell.

Mathematical Treatment

The mathematical analysis of the results assumes steady state diffusion inside the membrane and a uniform concentration throughout the two compartments. For the diffusion of SO_2 from the large compartment [1] through a membrane of thickness l to the smaller compartment [2] it follows (11) that

$$[1]\quad \log_e \left\{\frac{{}^1_0[SO_2] - {}^2_0[SO_2]}{{}^1[SO_2] - {}^2[SO_2]}\right\} = \frac{AD_{SO_2}}{l}\left\{\frac{1}{V_1} + \frac{1}{V_2}\right\}\Delta t$$

Furthermore, since ${}^1[SO_2] = {}^1_0[SO_2]$, to within 1% throughout the run, and the initial concentration in the smaller compartment, ${}^2_0[SO_2] = 0$, the diffusion coefficient could be obtained from a logarithmic plot:

$$[2]\quad \log_e \left\{\frac{{}^1[SO_2] - {}^2[SO_2]}{{}^1[SO_2]}\right\} = \frac{AD_{SO_2}}{l}\left\{\frac{1}{V_1} + \frac{1}{V_2}\right\}t$$

For the diffusion of acetonitrile, equal diffusion coefficients were assumed for the two isotopes. Equal amounts of CH_3CN should diffuse from the larger to the smaller compartment as amounts of CD_3CN would diffuse in the opposite direction. Using expressions analogous to eq. [1] and the simplifying assumption that ${}^1[Cd_3CN] \simeq {}^1_0[CD_3CN] \simeq 0$ to within 1%, and ${}^1[CH_3CN] = {}^1_0[CH_3CN] \simeq 1.0$, the isotopic ratio in the smaller compartment was expected to vary as:

$$[3]\quad \log_e \left\{\frac{{}^2[CH_3CN]}{{}^2[CD_3CN]} + 1\right\} = \frac{AD_{CH_3CN}}{l}\left\{\frac{1}{V_1} + \frac{1}{V_2}\right\}t$$

Results and Discussion

The perfluorosulfonic acid products were not attacked by boiling acetonitrile and their appearance remained unchanged. After drying the membranes in air a net weight loss of the order of 1% was observed with respect to the original material at 35% humidity. Subsequent ir spectra of the membrane with respect to Nafion products evacuated at 0.1 Torr were almost identical to those of an acetonitrile film and the original OH band of water-boiled Nafion membranes could no longer be detected. DTA analysis revealed a weight loss peak some 20°C below that found for the original material and, as verified by Karl Fisher analysis, less than 0.05% H_2O could subsequently be extracted. When only one surface of the membranes was exposed to acetonitrile or its vapours, temporary puckering and distortion of the flat surface occurred which could be removed by plunging the entire film into the solvent. With some practice smooth films could be mounted in the diffusion cell and the two compartments filled with solvent and solution without undue exposure to the ambient air.

The increase in SO_2 concentration in the 3 mL compartment with time is shown in Fig. 2 for various Nafion membranes in acetonitrile containing 0.2 *M* SO_2. As expected from Will's work on Br_2 diffusion (8), SO_2 diffuses more rapidly in the lower equivalent weight product and across the thinner membranes. The diffusion across the membrane #427, consisting

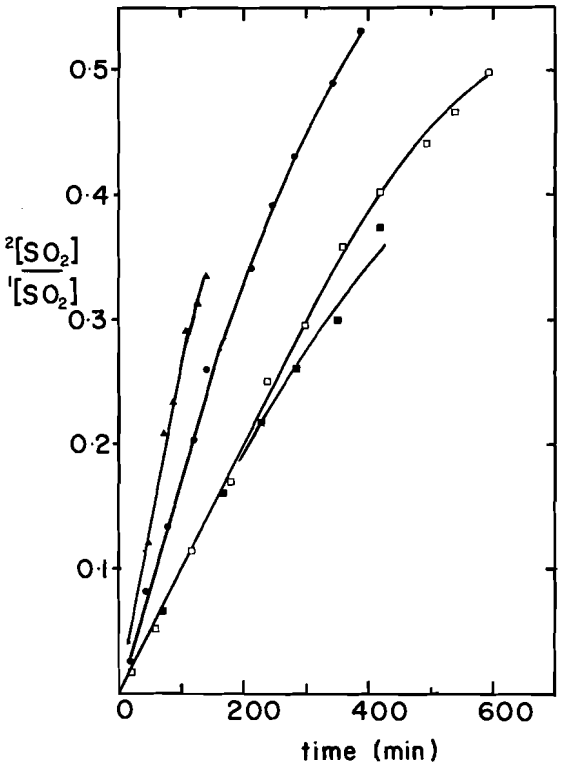

FIG. 2. SO_2 concentration ratio as a function of time. Membrane acetonitrile boiled for 20 h; ▲, membrane #110; ●, membrane #125; ■, membrane #120; □, membrane #427.

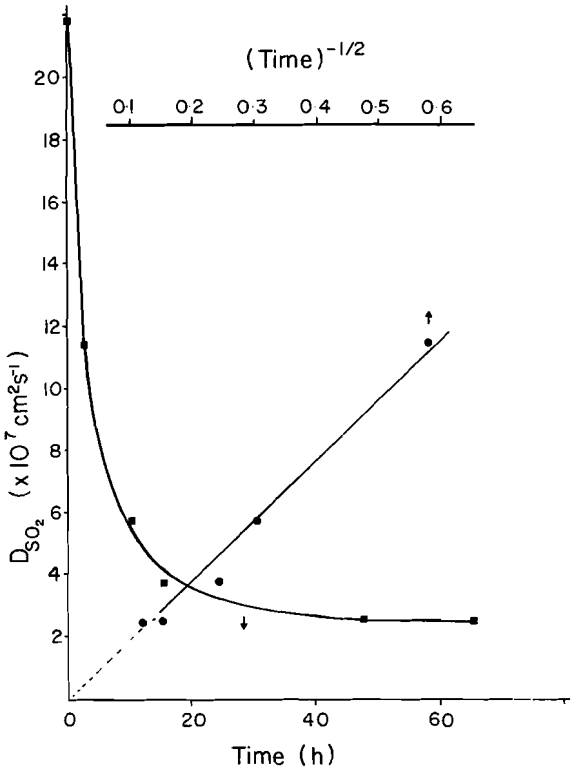

FIG. 3. Variation of diffusion coefficient D_{SO_2} with the extent of acetonitrile leaching for Nafion 110. Lower scale: τ, hours of contact with boiling CH_3CN; upper scale: $\tau^{-1/2}$.

of 0.007 in. sheet of 1200 equivalent weight perfluoronated membrane laminated to a woven Teflon fabric, is marginally greater than across a 0.010 in. thickness of the same composition.

Diffusion coefficients for membranes acetonitrile-boiled for 1 h were up to twice as great as those observed for membranes boiled overnight. Similarly, acetonitrile containing 0.5% H_2O yielded D_{SO_2} values about twice those observed in dried CH_3CN solution. Clearly the acetonitrile can replace the water molecule within the membrane given sufficient time and subsequent diffusion within the pores is slowed down appreciably. Figure 3 illustrates this effect for the Nafion 110 membrane. The diffusion coefficient diminishes as $\tau^{-1/2}$ where τ represents the numbers of hours the membrane was contacted with boiling acetonitrile. Water seems to be leached slowly from the membrane and if perfectly anhydrous conditions could be maintained, D_{SO_2} might drop to zero. In actual practice no further decrease in D was observed after 75 h even for the thicker or higher molecular weight membranes and these residual values are discussed further below.

The increase in the isotopic ratio CH_3CN/CD_3CN follows the same general behaviour as the SO_2 concentration in the smaller compartment. Diffusion coefficients were calculated from data such as presented in Table 1 using a least squares fit to eqs. [2] and [3], respectively. Most runs were abandoned after 7 h but linear plots were obtained for periods up to 30 h, SO_2 ratios up to 90%, and CH_3CN/CD_3CN ratios up to 3. The diffusion coefficients listed in Table 2 represent average values of duplicate or triplicate runs calculated using the membrane thickness measured for acetonitrile-boiled products listed in column 3. Unlike SO_2 diffusion coefficient, D_{CH_3CN} varied little with the membrane leaching time. After the initial 1 h boiling time essentially constant values were obtained indicating that the transport mechanism is fundamentally different from that of the strong Lewis acid SO_2.

Plots of log D versus $1/K$ over the temperature interval 20 to 60°C indicate an activation energy for diffusion of SO_2 of 23 kJ/mol for the 1100 equivalent weight product, only somewhat higher than that observed for concentrated aqueous NaOH solution (2). Since the diffusion processes do not seem drastically different from diffusion in aqueous solution it may be instructive to compare the D_{SO_2} values with those predicted by Gierke's cluster model (2).

*Prediction from data of ref. 2 (Gierke).

Thus, the diffusion coefficient D_{SO_2} in the membrane can be estimated from the free diffusion in acetonitrile, $D_{SO_2}^0$, the pore diameter, D_p, the Bragg spacing of the clusters, d, and an effective diameter of the SO_2 molecule σ_{SO_2}:

$$[4] \quad \frac{D_{SO_2}}{D_{SO_2}^0} = \frac{\pi}{4d^2}(D_p - \sigma_{SO_2})^2$$

From the polarographic reduction of SO_2 in acetonitrile we obtain $D_{SO_2}^0 = 2.15 \times 10^{-5}$ cm² s^{-1}, from van der Waals radii we estimate $\sigma_{SO_2} = 4.6$ Å and the other parameters are taken from Gierke's work. The experimental results are almost four times lower than the results predicted by this model. Although acetonitrile can obviously diffuse across the Nafion membranes, it does not simply replace water molecules as the transport media within the cavities of the membranes. Given the same ratios of the diffusion coefficients in the 1100 and 1200 ew films (1.85 in both acetonitrile and water-saturated products) and the similar value of the diffusional activation energy (20–25 kJ/mol) it seems likely that the transport takes place through fewer cavities but in essentially the same manner in both water- and acetonitrile-saturated membranes. The diffusion process might therefore involve only cavities containing a certain minimum number of water molecules.

For the laminated product Nafion 427 Grot (7) claimed that the open area of the T-12 weave is about 25% according to optical measurements, a value confirmed by our microscopic examination. Since the separator material is identical to that used in the homogeneous Nafion 120 and Nafion 125 products, an effective diffusion coefficient D_{SO_2} of about 3×10^{-8} cm² s^{-1} might be expected if only 25% of the material were available for diffusion. This is clearly not the case.

The experimental value 1.71 ± 0.04 × 10^{-7} cm² s^{-1} is even greater than that found in the uniform 1200 ew materials 120 and 125. We have no satisfactory explanation for this observation. Possibly the laminated material is attacked by the prolonged leaching or the Teflon cloth contributes to the transport of SO_2. D values calculated after a pretreatment of 20 h differed little from those obtained after 100 h leaching with boiling acetonitrile in contrast to all other materials examined.

Isotopic measurements indicated $D_{CH_3CN} = 0.38 \times 10^{-6}$ cm² s^{-1} for the Nafion 120 membrane and $D_{CH_3CN} = 0.24 \times 10^{-6}$ cm² s^{-1} for the diffusion across the perfluorosulfonic acid layer of the Nafion 427 membrane. If we can attribute the difference to a partial blocking of the surface by the Teflon cloth, we would estimate an open area of 0.24/0.38 = 67%. Since only one surface is reinforced and the diffusional process does not take place entirely in one straight direction, part of the membrane blocked by the Teflon cloth undoubtedly contributes to the diffusion. For acetonitrile solutions, which wet

Teflon, the effective blockage (33%) may be less than in aqueous solutions and represents less than half of the effect simple optical measurements predict (78%).

En solution aqueuse, l'*o*-phényl-phénol présente une double fluorescence qui traduit un équilibre de déprotonation dans l'état excité singulet. Cette propriété permet d'interpréter l'influence de l'oxygène sur la production photochimique primaire des radicaux phénoxy. On montre que, seul l'état excité singulet de la forme phénolate donne lieu à la photo-éjection d'électrons. L'oxygène inhibe la recombinaison des électrons éjectés avec les radicaux phénoxy. D'autres capteurs d'électrons comme les Cd^{2+} ou NO_3^- sont également susceptibles d'accroître le rendement quantique de disparition de l'*o*-phényl-phénol en solution dégazée. L'effet de l'oxygène au niveau du processus primaire permet d'interpréter les résultats acquis en photo-oxydation de dérivés phénoliques donnant naissance à des radicaux phénoxy inoxydables.

LOUISE-MARIE COULANGEON, GILLES PERBET, PIERRE BOULE, and JACQUES LEMAIRE. Can. J. Chem. **58**, 2230 (1980).

The dual fluorescence observed in aqueous solution of *o*-phenyl-phenol is attributed to a deprotonation equilibrium in the excited singlet state. The effect of oxygen on the primary photochemical process of formation of phenoxy radicals can be explained in a parallel study of the variations of fluorescence and photo-oxidation quantum yields of this phenolic compound at different pH. It is shown that photoionisation occurs only from the excited singlet state of the phenolate form. Oxygen inhibits recombination of the solvated electron and phenoxy radical. Increase of quantum yield for the disappearance of irradiated *o*-phenyl-phenol in degased solution also is observed in the presence of electron scavengers like Cd^{2+} or NO_3^- ions. Even when the phenoxy radicals are not able to react with oxygen, quantum yield for the disappearance of the phenolic compounds is higher in an aerated than in a degassed solution; the oxygen effect on the primary photochemical step may explain this difference.

Introduction

Le comportement photochimique de composés phénoliques en solution aqueuse diluée, aérée ou désoxygénée a été souvent étudié par des techniques de photolyse par éclairs ou de photolyse laser. Ces techniques permettent de déterminer la concentration des espèces radicalaires formées et leur cinétique de disparition (1–4). Les processus primaires de photodéélectronation sont également appréhendés par des techniques pulsées, comme celles récemment rapportées par Mialocq et ses collaborateurs (5).

La photolyse et la photo-oxydation des dérivés phénoliques en solution aqueuse impliquent en fait une formation primaire de radicaux phénoxy et d'électrons et une succession de processus secondaires mettant en jeu ces espèces réactives. Les résultats acquis en photolyse par éclairs ne permettent pas à eux seuls de comprendre le comportement de ces composés sous irradiation continue et à des intensités incidentes très inférieures à celles utilisées en techniques rapides. Depuis 1972, notre laboratoire s'est engagé dans une étude détaillée de l'évolution des phénols les plus simples, en solution diluée, sous excitation monochromatique et continue à 253,7 nm (6–8). Les objectifs de ces études étaient: de mesurer les rendements quantiques de disparition de dérivés phénoliques et d'étudier leurs variations avec les paramètres macroscopiques habituels (température, O_2 dissous, pH, concentration initiale, longueur d'onde d'excitation, ...); d'établir un bilan matière (au moins à faible taux de conversion); de proposer un mécanisme de photo-oxydation.

Nous avons, en particulier, remarqué que les radicaux phénoxy issus des différents phénols peuvent participer à trois processus prépondérants, soit une oxydation soit une dimérisation, soit une disproportionnation (ou dismutation). Dans des conditions expérimentales analogues (O_2 dissous, température, pH), l'importance relative de ces trois processus dépend essentiellement du phénol examiné. Le tableau 1 regroupe les principaux résultats acquis sur la photo-oxydation (irradiation en solution aérée) et sur la photolyse (irradiation en solution dégazée) de sept dérivés phénoliques simples.

On remarque que même dans les cas où les radicaux phénoxy sont inoxydables, le rendement quantique de photo-oxydation reste très supérieur au rendement de photolyse; nous avons donc été amenés à reconnaître la nécessité d'une étape primaire de production des radicaux phénoxy "assistée" par l'oxygène (l'exemple le plus significatif étant constitué par l'hydroquinone ou les radicaux phénoxy sont inoxydables). Or, les mesures de fluorescence montrent que l'oxygène dissous n'est pas susceptible de réagir avec le niveau excité singulet de courte durée de vie ($\tau = 7 \times 10^{-9}$ s pour le phénol). Et, la seule interaction rapportée entre

l'état excité triplet du phénol et l'oxygène consisterait en une complexation du niveau triplet de la forme neutre; ce complexe est alors capable, sous forte intensité lumineuse, de donner naissance par processus biphotonique à un radical phénoxy (2); sous faible intensité lumineuse, on ne connaît pas la réactivité de ce complexe.

L'étude de l'intervention de l'oxygène sur les processus photochimiques primaires, difficile pour la plupart des phénols simples, s'est avérée possible dans le cas de l'*o*-phényl-phénol. Comme nous allons le voir, cette molécule présente une double fluorescence qui traduit l'existence d'un équilibre de déprotonation dans l'état excité singulet. Cette propriété intéressante peut alors permettre d'élucider le mécanisme d'intervention de l'oxygène.

Techniques expérimentales

Les solutions aqueuses d'*o*-phényl-phénol ont été préparées à partir d'un produit Aldrich (99%). Les mélanges tampons ont été réalisés selon (10) à l'aide des substances suivantes: acide sulfurique Prolabo R. P. Normapur de pH = 0, à pH = 1; acide citrique Merck "pro analysi" de pH = 1,17 à pH = 6,69; phosphates monopotassique et disodique R.A.L. de pH = 5,29 à pH = 8,04; acide borique Merck "pro analysi" de pH = 7,61 à pH = 12,38; hydroxyde de sodium Prolabo R.P. Normapur pour pH > 12.

Les forces ioniques des solutions d'*o*-phényl-phénol tamponnées varient de 0,006 à 0,033 *M*.

Le nitrate de potassium utilisé est un produit Prolabo R.P. pour analyses, le sulfate de cadmium $3CdSO_4,8H_2O$, un produit Merck pour analyses.

Les spectres d'absorption ont été mesurés sur un spectrophotomètre Cary 118C à double faisceau; les mesures d'émission de fluorescence ont été réalisées sur un spectrofluorimètre Perkin-Elmer MPF-3L, équipé d'une lampe au Xénon Osram XBO de 150 W. Les solutions d'*o*-phényl-phénol dans l'eau ont été irradiées à 296 nm ou à 313 nm à l'aide d'un monochromateur Bausch et Lomb "haute intensité", équipé d'une lampe à vapeur de mercure "haute pression" Osram HBO 200 W. Le flux du faisceau d'irradiation est mesuré avec un phototube R.C.A. 935 et un galvanomètre A.O.I.P G.223. Ce dispositif est préalablement étalonné par une actinométrie basée sur la photoréduction du ferrioxalate de potassium (11). Les rendements quantiques de disparition initiale ont été mesurés par spectrofluorimétrie aussi bien en milieu aéré qu'en milieu dégazé. La désoxygénation des solutions a été réalisée par des cycles de congélation et de pompage sous vide dans l'azote liquide.

Résultats expérimentaux

Dans toute cette étude, nous nous sommes intéressés uniquement au comportement photochimique de l'*o*-phényl-phénol excité dans son premier état singulet.

Propriétés absorbantes et émissives de l'o-phényl-phénol

Nous avons examiné l'influence du pH sur les spectres d'absorption et de fluorescence de l'*o*-phényl-phénol dans l'eau. Le tableau 2 mentionne les propriétés absorbantes et émissives de la molécule, en solution aqueuse diluée. Les fluorescences observées ne dépendent pas de l'oxygène dissous, quel que soit le pH de la solution et elles sont invariantes après désoxygénation complète de la solution.

L'évolution comparée des spectres d'absorption et d'émission avec le pH et l'existence d'une double émission ($1 < pH < 10$) traduisent un équilibre acide–base dans l'état excité singulet, comme cela a déjà été mis en évidence pour différents composés phénoliques (12, 13) et tout particulièrement pour le naphtol-2 (13–15). La relation déduite du cycle de Förster (16):

$$pK = pK^* + 2{,}1 \times 10^{-3}\Delta\nu \quad (cm^{-1})$$

conduit à $pK^* = 0$ ou à $pK^* = 3$ selon que $\Delta\nu$ représente respectivement la différence de fréquences des maximums d'émission ou d'absorption. La courbe *a* de la fig. 1 représente les variations du rapport entre l'intensité d'émission à $\lambda_{max} = 413$ nm à différents pH à l'intensité d'émission à pH = 14. Cette courbe indique que le pK^* (S_1) est effectivement compris entre 1 et 1,5.

Etude cinétique de la photolyse et de la photo-oxydation de l'o-phényl-phénol

En milieu dégazé, le rendement quantique de disparition (ϕ_0) est indépendant de la concentration initiale et du pH de la solution; il est égal à 0,002 en milieu de pH variable entre 5 et 14 ($\lambda_{exc} = 296$ ou 313 nm).

Dans l'eau et en solution aérée, le rendement quantique de disparition ($\phi_0{}^{O_2}$) de l'*o*-phényl-phénol à 296 nm est indépendant de la concentration initiale (tableau 3). On note que comme dans le cas du phénol, des diphénols et triphénols le rendement quantique de disparition est beaucoup plus faible en photolyse qu'en photo-oxydation. Le rendement quantique initial de photo-oxydation ($\phi_0{}^{O_2}$) varie avec le pH de la solution; sur la fig. 1, la courbe *b* représente les variations du rapport des valeurs des rendements quantiques de photo-oxydation mesurées à différents pH à celle mesurée

TABLEAU 2. Propriétés absorbantes et émissives de l'*o*-phényl-phénol en solution aqueuse

pH	Absorption transition $S_0 \rightarrow S_1$	Emission transition $S_1 \rightarrow S_0$
0–1	$\lambda_{max} = 282$ nm ($\varepsilon_{max} = 4000\ M^{-1}\ cm^{-1}$)	$\lambda_{max} = 345$ nm
1–10	$\lambda_{max} = 282$ nm	$\lambda_{max} = 345$ et 413 nm
10–14	$\lambda_{max} = 310$ nm ($\varepsilon_{max} = 5750\ M^{-1}\ cm^{-1}$)	$\lambda_{max} = 413$ nm
$pK(S_0) \simeq 10$		$1 < pK^*(S_1) < 1{,}5$

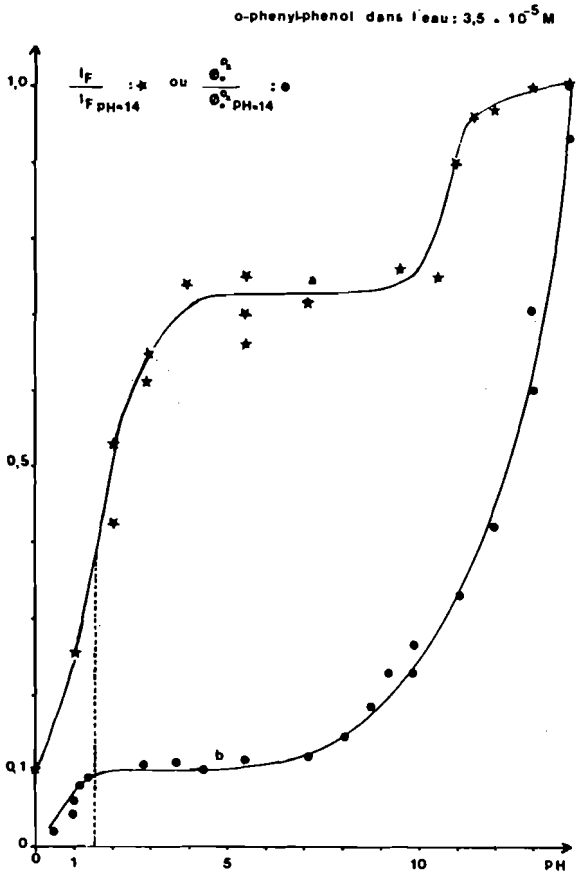

FIG. 1. (*a*) Variations du rapport I_F à $\neq$ pH/I_F à pH = 14 de l'intensité de fluorescence à 413 nm mesurée à différents pH à l'intensité de cette même fluorescence à pH = 14 pour une solution aqueuse d'*o*-phényl-phénol ($3,5 \times 10^{-5}$ *M*). (*b*) Variations du rapport $\phi_0^{O_2}$ à $\neq$ pH/$\phi_0^{O_2}$ à pH = 14 des valeurs des rendements quantiques $\phi_0^{O_2}$ de photo-oxydation mesurés à différents pH à celle mesurée à pH = 14, pour une solution d'*o*-phényl-phénol ($3,5 \times 10^{-5}$ *M*).

à pH = 14 ($\phi_{0\ ^2} = 0,15$). La confrontation des courbes *a* et *b* nous permettra par la suite de proposer un mécanisme primaire pour la formation des radicaux phénoxy issus de l'*o*-phényl-phénol.

La photo-oxydation de l'*o*-phényl-phénol à 296 nm conduit à la formation d'un produit absorbant à 250 nm et non émissif, et un produit émetteur en milieu neutre à 355 nm et absorbant à 320 nm. Le produit absorbant à 250 nm est identifié à la phényl-*p*-benzoquinone. Le produit émetteur à 355 nm n'a pas pu être isolé dans ces solutions où la solubilité de l'*o*-phényl-phénol est limitée à 3×10^{-4} *M*.

Dans le cas analogue de la photo-oxydation du phénol, les produits émetteurs à 340 nm en milieu neutre ou acide et à 390 nm en milieu basique ont été identifiés à différents trihydroxydiphényles représentant 50% du phénol transformé. Nous admettrons donc que le produit émetteur à 355 nm est un trihydroxytétraphényle.

TABLEAU 3. Rendements quantiques initiaux de photo-oxydation de l'*o*-phényl-phénol ($\lambda_{exc} = 296$ nm, pH = 5,5, oxygène dissous 3×10^{-4} *M*)

o-Phényl-phénol (*M*)	($\phi_0^{O_2}$)
$1,45 \times 10^{-4}$	$0,01_9 \pm 0,002$
$3,50 \times 10^{-4}$	$0,01_9 \pm 0,002$ $0,02_0 \pm 0,002$ $0,01_4 \pm 0,002$ $0,02_1 \pm 0,002$
$1,45 \times 10^{-5}$	$0,02_0 \pm 0,002$
$3,50 \times 10^{-6}$	$0,01_5 \pm 0,002$

*Influence des capteurs d'électrons sur la photolyse et la photo-oxydation de l'*o*-phényl-phénol*

La production de radicaux phénoxy à partir de la forme phénolate excitée dans son plus bas niveau singulet s'accompagne de photo-éjection d'électrons. Ce processus a été particulièrement étudié dans le cas du phénol (17, 18) et du β-naphtol (19). Comme nous allons le voir, nous proposons une recombinaison partielle des radicaux phénoxy avec les électrons solvatés pour interpréter les cinétiques différentes de disparition des phénols en photolyse et en photo-oxydation. La vitesse de conversion de l'*o*-phényl-phénol en radicaux phénoxy, ne se recombinant pas avec les électrons éjectés, dépend de la présence d'un capteur d'électrons. Nous rapportons l'influence de Cd^{2+} et NO_3^- sur le rendement quantique de disparition de l'*o*-phényl-phénol en solution aqueuse dégazée (ϕ_0).

Jusqu'à présent, et particulièrement dans le cas du phénol et du β-naphtol, c'est le protoxyde d'azote N_2O qui a été choisi comme capteur d'électrons. L'emploi des ions Cd^{2+} en milieu acide et de NO_3^- en milieu basique est préférable car le contrôle de la concentration des capteurs et des effets parasites est plus facile.

L'ion Cd^{2+} est susceptible de réagir avec les électrons hydratés avec des constantes de vitesse proches de 5×10^{10} M^{-1} s^{-1}; ces constantes de vitesse varient peu avec la concentration du capteur quand celle-ci est comprise entre 0,1 et 0,5 *M* (5, 20, 21). La constante de vitesse de capture des électrons hydratés par NO_3^- est voisine de 2×10^{10} M^{-1} s^{-1} quand la concentration d'ions NO_3^- est comprise entre 0,01 et 0,75 *M* (5, 22, 23).

Le tableau 4 rassemble les rendements quantiques initiaux de disparition en milieu dégazé (ϕ_0) en présence de sulfate de cadmium ou de nitrate de potassium, de même que les conditions expérimentales.

TABLEAU 4. Rendement quantique initial de disparition de l'*o*-phényl-phénol irradié à 296 nm en solution dégazée (concentration initiale $2{,}40 \times 10^{-5}$ *M*)

Concentration (*M*) du sulfate ou du nitrate			ϕ_0
$3CdSO_4,8H_2O$	$\lambda_{exc} = 296$ nm	pH = 5–6	
	10^{-5}		$0{,}008 \pm 0{,}002$
	5×10^{-5}		$0{,}01_8 \pm 0{,}004$
	10^{-4}		$0{,}02_0 \pm 0{,}004$
	$1{,}60 \times 10^{-3}$		$0{,}02_3 \pm 0{,}004$
	$1{,}60 \times 10^{-3}$		$0{,}02_4 \pm 0{,}004$
	$9{,}10 \times 10^{-3}$		$0{,}02_3 \pm 0{,}004$
KNO_3	$\lambda_{exc} = 313$ nm	pH = 14	
	2×10^{-3}		$0{,}06_0 \pm 0{,}006$
	5×10^{-3}		$0{,}08_0 \pm 0{,}008$
	7×10^{-3}		$0{,}10_7 \pm 0{,}01$
	10^{-2}		$0{,}16_9 \pm 0{,}02$
	5×10^{-2}		$0{,}17_0 \pm 0{,}02$

Aux concentrations utilisées, le sulfate de cadmium a l'avantage de ne pas absorber à 296 nm. Mais il ne peut être évidemment utilisé en milieu basique. Dans les solutions de pH égal à 14, nous avons dû employer du nitrate de potassium. L'ion nitrate absorbe avec un maximum à 300 nm; il est photostable sous excitation à 313 nm en solution dégazée.

Les rendements quantiques apparaissant dans le tableau 4 sont calculés en tenant compte de l'absorption parasite de NO_3^-. Les ions nitrate à fortes concentrations sont susceptibles de désactiver la fluorescence de l'*o*-phényl-phénolate (fig. 2); mais aux concentrations inférieures à 10^{-2} *M*, cette désactivation reste de faible importance.

Le tableau 4 montre que l'addition de capteur provoque l'augmentation du rendement de photolyse jusqu'à une valeur limite indépendante de la concentration de capteur. Cette valeur limite est généralement supérieure au rendement quantique de disparition du phénol irradié en présence d'oxygène.

Discussion

Aux erreurs expérimentales près, les courbes *a* et *b* de la fig. 1 présentent des points d'inflexion dans le même domaine de pH. On peut donc en conclure que la formation des radicaux phénoxy met en jeu l'état excité singulet de la forme phénolate. C'est d'ailleurs le même mécanisme qui a été proposé par Grabner *et al.* (18) pour le phénol et par Ottolenghi (19) pour le β-naphtol. Ainsi les courbes *a* et *b* permettent d'atteindre le p*K* de l'état excité singulet ($1 < pK^* < 1{,}5$) et celui de l'état fondamental ($pK \simeq 10$).

Si on voulait interpréter la formation des radicaux phénoxy par la déélectronation du niveau triplet de la forme phénolate ou phénol, il faut admettre, compte tenu de l'invariance des rendements quantiques de photo-oxydation ($\phi_0{}^{O_2}$) entre pH = 2 jusqu'à pH = 7, que la durée de vie de l'état triplet de la forme phénolate soit inférieure à 10^{-8} s, soit supérieure à 10^{-2} s. Si la déélectronation était issue du niveau triplet de la forme phénolate, il faudrait admettre que le processus de déélectronation contrôle la durée de vie, et que ce processus est toujours plus rapide que la protonation entre pH = 2 et pH = 7, soit: k_e (constante de déélectronation) $> \overleftarrow{k}[H^+]$, où $\overleftarrow{k}$ est la constante d'un processus contrôlé par la diffusion, et où:

$$[H^+] = \tau = 1/k_e < 10^{-8} \text{ s}$$

Si la déélectronation était issue du niveau triplet de la forme phénol, il faudrait admettre que la population de ce niveau soit indépendante du pH, et donc que la durée de vie du niveau triplet de la forme phénolate soit plus grande que la vitesse initiale de protonation, soit:

$$\tau > \overleftarrow{k}[H^+] \quad \text{où } [H^+] = 10^{-8}$$

$$\tau > 10^{-2} \text{ s}$$

La durée de vie d'un niveau triplet de la forme phénolate ne peut vérifier l'une ou l'autre de ces deux inégalités.

On constate que l'excitation directe de la forme phénolate est beaucoup plus efficace pour la production des radicaux phénoxy que l'excitation de la forme phénol dans le domaine de pH où se produit la déprotonation du niveau excité singulet. On peut interpréter ce résultat en admettant que la déélectronation se produit sur les niveaux vibrationnels excités (photo-ionisation) alors que l'équilibre de déprotonation se produit sur les niveaux vibrationnels les plus bas. La même hypothèse a été avancée pour le β-naphtol par Goldschmidt et Stein (24).

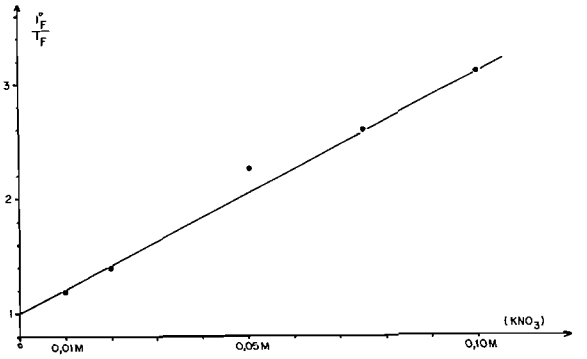

FIG. 2. Etude de l'extinction de fluorescence de l'*o*-phényl-phénolate par le nitrate de potassium. Variations du rapport I_F^0/I_F en fonction de la concentration de nitrate de potassium (KNO_3). (I_F^0 est l'intensité à 413 nm de fluorescence de l'*o*-phényl-phénolate et I_F l'intensité de fluorescence en présence de nitrate de potassium.)

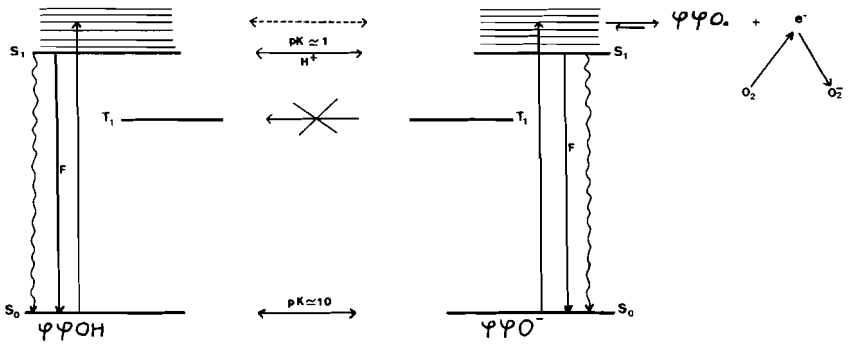

FIG. 3. Diagramme énergétique illustrant le mécanisme de production des radicaux phénoxy.

La fig. 3 résume le mécanisme de formation des radicaux phénoxy assisté par l'oxygène. Les radicaux apparaissent à la suite de déprotonation et de déélectronation successive dans les états excités. L'oxygène qui ne peut intervenir sur les états excités singulets pourrait alors augmenter le rendement quantique de disparition de l'*o*-phényl-phénol en solution aérée, en inhibant la recombinaison de l'électron solvaté et des radicaux phénoxy. Cette hypothèse est confirmée par l'influence des capteurs d'électrons utilisés.

L'introduction d'ions Cd^{2+} et NO_3^- entraîne effectivement l'augmentation de la vitesse de disparition de l'*o*-phényl-phénol en inhibant la recombinaison radical–électron. A une concentration de Cd^{2+} supérieure à 10^{-4} *M*, et à une concentration de NO_3^- supérieure à 10^{-2} *M*, le rendement quantique de photolyse devient indépendant de la concentration de capteur. Dans ces conditions, tous les électrons éjectés sont piégés par les capteurs Cd^{2+}, NO_3^- et le rendement de formation des radicaux phénoxy, égal d'ailleurs au rendement de photo-éjection, peut alors être atteint. Aux concentrations d'oxygène dissous dans l'eau, $[O_2] = 3 \times 10^{-4}$ *M* (25), la capture des électrons est pratiquement totale. La disparition du phénol irradié en solution aérée peut être simplement justifiée par le processus photochimique primaire. Il n'est donc pas nécessaire de supposer que le phénol disparaisse par une réaction thermique secondaire mettant en jeu soit O_2^-, soit des radicaux phénoxy.

En conclusion, l'excitation de la forme neutre de l'*o*-phényl-phénol dans son premier état excité singulet donne lieu successivement à une déprotonation, puis à une déélectronation. La présence d'oxygène augmente la vitesse de production de radicaux phénoxy disponibles; l'oxygène, comme les ions Cd^{2+} ou NO_3^- inhibe la recombinaison des électrons éjectés avec les radicaux phénoxy. Nous examinons actuellement la généralisation de ce mécanisme aux autres dérivés phénoliques.

The kinetics of internal energy randomisation in thermal unimolecular reactions

HUW OWEN PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received March 20, 1980

HUW OWEN PRITCHARD. Can. J. Chem. **58**, 2236 (1980).

The aim of this paper is to present a minimal theory of thermal unimolecular reactions, including explicitly the kinetics of intramolecular randomisation processes. A quasi-diatomic model is formulated and, within the framework of the model, both first- and second-order randomisation processes among reactant and product states are examined.

It is concluded that a vital mechanism for the intramolecular energy randomisation in thermal unimolecular reactions is a collisional one. On this assumption, a straightforward derivation of the Polanyi–Wigner specific rate function, as we have reinterpreted it, becomes possible.

At the same time, anomalies in the fall-off curves for the thermal isomerisations of methyl isocyanide and ethyl isocyanide can be accounted for very simply: in the former case, values for both the first- and second-order randomisation rate constants can be derived, but in the latter case it is only possible to establish a lower limit for the second-order randomisation rate constant.

HUW OWEN PRITCHARD. Can. J. Chem. **58**, 2236 (1980).

Cet article a pour but de présenter une théorie minimale des réactions unimoléculaires thermiques incluant explicitement la cinétique du mode de distribution au hasard intramoléculaire. On formule un modèle quasi-diatomique et on examine à l'intérieur du squelette de ce modèle le mode de distribution au hasard d'ordre 1 et d'ordre 2 entre les réactifs et les produits.

On conclut que le méchanisme essentiel de l'énergie intramoléculaire de la distribution au hasard dans des réactions thermiques unimoléculaires est un mécanisme de collision. Sur cette base, il devient possible de dériver directement la fonction de vitesse spécifique de Polanyi–Wigner telle que nous l'avons réinterprété.

En même temps, on peut simplement tenir compte des anomalies dans l'abaissement des courbes des isomérisations thermiques des isocyanures de méthyle et d'éthyle: dans le premier cas, les valeurs des constantes de vitesse d'ordre un et d'ordre deux de la distribution au hasard peuvent être dérivées mais dans le second cas on peut seulement établir une limite inférieure pour la constante de vitesse d'ordre deux de la distribution au hasard.

[Traduit par le journal]

I. Introduction

We have recently reformulated the original concept of Polanyi and Wigner (1) in discrete rather than in classical terms, and have found that it is possible to make very simple calculations of the specific rate constants for thermal unimolecular reactions (2). This reformulation presupposes a knowledge of the vibrational and rotational properties of the reactant molecule and the energy barrier for the reaction, and just simply by classifying states as reactive or unreactive, calculations of specific rate constants superior to any hitherto obtained are possible. It appears, therefore, that despite all the emerging complexities in the descriptions of highly vibrationally excited molecules resulting from contemporary laser studies, it is nevertheless possible to present a very simple description of thermal unimolecular reactions. In the following pages, I will present a very simple model for a thermal unimolecular reaction, including *explicit* consideration of the intramolecular randomisation processes; moreover, I hope that the extreme simplicity of the model will lend itself to a ready identification of the implicit assumptions, so that they can be thoroughly examined as and when necessary in the future.

II. List of Symbols

Table 1 is a list of symbols used in this presentation: where numerical values of the represented quantities are used in this paper, units are given if necessary.

III. A Quasi-diatomic Model for Thermal Unimolecular Reactions

Imagine a polyatomic molecule isolated in space, in an infinitely large box whose walls have a temperature of absolute zero: i.e. the molecule is in a perfectly field-free space. The molecule is vibrationally and/or rotationally excited to some energy which is *below* the lowest threshold for any reaction; the molecule's translational energy is, of course, immaterial. In this energy range, the molecule has available to it a series of non-adiabatic states; each of these states has a *nodeless* vibrational wave function (3, 4), regardless of the degree of vibrational excitation. For CO_2, there will be about 3×10^5 states per wavenumber just below the reaction threshold, and comparable figures for methyl isocyanide or cyclobutane are about 1×10^8 or 2×10^{15} states per wavenumber respectively (these state densities are estimated for adiabatic states, but

the density of non-adiabatic states will be very similar). At this point, we assume these non-adiabatic states are strictly orthogonal (whatever that may mean) to each other, they are infinitely narrow, they are all distinct, and therefore they cannot change into each other without external influence. We then have to consider the influences which can broaden these states, cause them to overlap, and thus change into each other. Given our premise of quasi-diatomic non-adiabatic and non-interacting states, there are only two kinds of external influence we can consider; radiation broadening, i.e. first-order processes, and collisional broadening, i.e. second-order process.

Since the inception of the theory of unimolecular reactions more than 50 years ago, it has been axiomatic that internal energy randomisation was a property of the reacting molecule *itself* — hence the term intramolecular — although there have been a few tentative suggestions in recent years (5–8) that such randomisation could be a collisional process. It is not the purpose of this paper to try to make theoretical predictions of the respective time scales for such processes; rather, it is to recognise that both first- and second-order randomisation processes *may* play a part, and to examine the consequences in respect of the observed overall kinetics. Thus, for the time being, I will make only very brief allusion to the intrinsic nature of these two classes of randomisation processes:

First-order Processes

Even in the rigorous absence of an imposed electromagnetic field, there is a broadening of the levels due to spontaneous emission. In principle therefore, the conversion of one state into an adjacent state can be described by spontaneous emission followed by reabsorption of the same quantum (9); likewise, in the normal presence of ambient black body radiation, stimulated radiative interconversions of a similar type will not be negligible. Whether or not there are, in addition, any "spontaneous" mechanisms within the framework of this model will remain to be seen as the ideas of Czub and Wolniewicz (3) are extended to polyatomic molecules. Nevertheless, it seems fairly well established that in the energy range of interest (i.e. just above reaction threshold),[1] we should expect to find first-order randomisation processes taking place with rate constants $\mu_1 \approx 10^{12}\ s^{-1}$ (8).

Second-order Processes

If we examine the Lennard–Jones interactions between a pair of typical organic molecules (10), we find that they exceed the spacing between the molecular energy levels, even at very considerable distances. For example, typical values of the interaction potential $V(\bar{r})$ at the mean intermolecular separation $\bar{r}$ are

p (Torr)	$\bar{r}$ (Å)	$V(\bar{r})$ (cm^{-1})
1000	30	2.5×10^{-1}
1	300	2.5×10^{-7}
10^{-3}	3000	2.5×10^{-13}

In theory, at least, it is possible to calculate the changes in the energy levels of a molecule due to the interaction $V(\bar{r})$, but at the present time, we have no basis for correlating the magnitudes of these shifts with the magnitude of $V(\bar{r})$, since such calculations are totally intractable. A cautious view would be that if $V(\bar{r}) > [\rho(E)]^{-1}$, then collisional scrambling is a possibility. Figure 1 shows a plot indicating the pressures at which $V(\bar{r})$ equals $[\rho(E)]^{-1}$ for various molecules — in other words, the threshold for the scrambling of energy levels within the molecule by pressure broadening; the points shown on this graph correspond to the mean spacings between states at the thermal threshold, and are therefore a guide for consideration in thermal reactions — other values of the spacings would have to be used at other energies, i.e. for chemical activation experiments, or for molecular states below threshold. I regard it as axiomatic that $\rho(E)$ in this context is the total density of rotational and vibrational states, since the randomising collisions, by definition, have large impact parameters and there seems to be no reason

[1]Of course, for the consideration of thermal reactions, it does not matter *at all* whether randomisation takes place *below* the thermal threshold. Above threshold, it is normal to ascribe a width to each state having a finite lifetime with respect to predissociation. These widths are very large indeed in the present model — for example, the bending mode of methyl isocyanide ($\nu = 263\ cm^{-1}$) has an equivalent width above threshold of $\Gamma = 263/\pi \approx 85\ cm^{-1}$. Such broad states would overlap with many, many millions of passive molecular states, and this could be regarded as a built-in mechanism for randomisation. I suspect that this is not so, and that these widths may only have meaning within the context of a collision experiment: in other words, if we fire the two molecular fragments towards each other and observe a phase shift; alternatively, if the rupture has taken place and we try to make observations on the trajectories of the two fragments in an attempt to deduce the initial energy. Whether or not these overlaps actually constitute a mechanism for randomisation within the framework of the quasi-diatomic model is not obvious; it would seem however, that unlike collisional randomisation, all first-order randomisation processes will be restricted by optical selection rules and/or conservation of angular momentum to either zero or small change in rotational quantum number.

TABLE 1. List of symbols and their definition

Symbol	Definition
a_{ij}	Relaxation matrix (as defined in eq. [1] or [2]). Units: s^{-1}
c	Velocity of light
d, d_k	Rate constant for decay to products from a single state k. Units: s^{-1} (only two values allowed, either $d_k = 0$ or $d_k = d = 2cv\ s^{-1}$)
δ	Mean lifetime of an "active" state ($=d^{-1}$). Units: s
δ_{ij}	Kronecker delta
E	Energy (usually in the continuous representation). Units: cm^{-1}
E_∞	Activation energy at infinite pressure. Units: cm^{-1}
ε_k	Energy of kth microscopic level. Units: cm^{-1}
g_k	Degeneracy of kth microscopic level
k	Boltzmann's constant
$k(E)$	Specific rate constant for decay to products at energy E (continuous representation). Units: s^{-1}
k_i	Effective rate constant for decay to products from ith energy grain. Units: s^{-1}
k_{uni}	Overall unimolecular rate constant. Units: s^{-1}
m_k	Fraction of the reactant molecules *within one grain* in the kth energy level. Units: normalised such that $\sum m_k = 1$
$\tilde{m}_k$	Equlibrium value of m_k
[M]	Concentration of inert gas molecules
μ	Conventional collisional relaxation rate constant. Units: when this symbol appears in an equation, the units are always s^{-1}; however, in the text, it always represents the second-order rate constant for relaxation, in $Torr^{-1}\ s^{-1}$
μ_1	First-order rate constant for randomisation *within a specified grain*. Units: s^{-1}
μ_2	Second-order rate constant for randomisation *within a specified grain* via long-range interaction. Units: see μ
μ_r	Randomisation rate constant, $r = 1$ or 2 as appropriate
n_i	Fraction of the reactant molecules in the ith energy grain. Units: normalised such that $\sum n_i = 1$
$\tilde{n}_i$	Equilibrium value of n_i
ν	Frequency of critical vibration. Units: cm^{-1}
P	Pressure. Units: Torr
p_{ij}	Probability, per collision, of a transition *from* state i *to* state j in the reactant molecule
$Q(T)$	Partition function (rotation–vibration)
$\bar{r}$	Mean intermolecular separation at pressure P
$\rho(E)$	Density of states (continuous representation)
Σ'	Summation over only those states having non-zero decay rate constants
t	Time
T	Temperature
$V(r)$	Long-range intermolecular interaction potential
Z	Gas-kinetic collision number
Z'	Collision number for bimolecular randomisation processes

why significant redistribution of angular momentum should not take place, even though the total energy interchange is minute. In the light of Fig. 1, the conclusion reached below that the second-order randomisation rate constant, μ_2, appears to increase with increasing state density is not surprising. I might add also that theories of pressure broadening

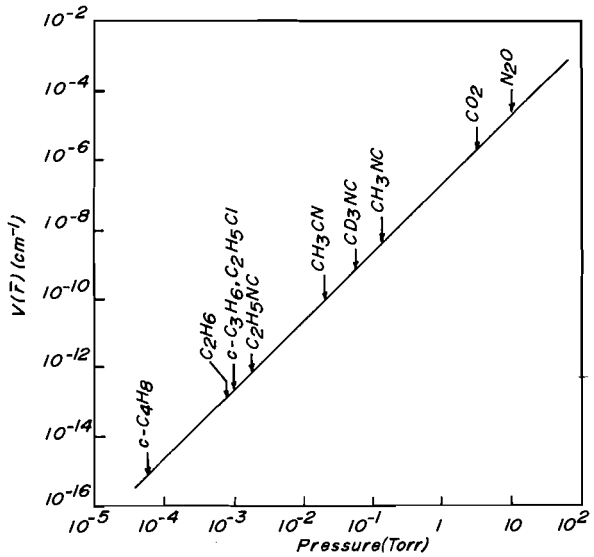

FIG. 1. Thresholds for internal energy randomisation. The arrows mark the pressures above which the estimated intermolecular potential exceeds the mean spacing between the molecular energy levels.

are reasonably well advanced, and that it may well be possible to make better empirical estimates of these thresholds than those depicted here.

IV. Summary of Existing Formulation

The following is a brief summary of our recent master-equation formulation of thermal unimolecular reactions (11), presented simply to introduce the required notation. The reactant molecule X was considered to possess a denumerable set of rotation–vibration states whose populations at thermal equilibrium are denoted by $\tilde{n}_i$, with normalisation such that $\sum \tilde{n}_i = 1$. Transitions among the various states are induced by collisions with inert molecules M: the collision number between X and M is Z and p_{ij} represents the probability per collision of a transfer *from* state i *to* state j. This relaxation process may be characterised by solving for the eigenvalues and eigenvectors of the relaxation matrix

$$[1]\quad a_{ij} = Z[\mathrm{M}]\left\{(1-\delta_{ij})p_{ji} - \delta_{ik}\sum_k (1-\delta_{ik})p_{ik}\right\}$$

The reaction is regarded as a perturbation of this relaxation process: above the thermal threshold, spontaneous decay to products may occur from various states with rate constants k_i, and the overall rate constant k_{uni} is given by the shift in the absolute magnitude of the zero eigenvalue of [1]. In the special case where the p_{ij} are taken to be the strong- or scaled strong-collision probabilities (12, 13) viz.

$$[2]\quad a_{ij} = \mu\{(1-\delta_{ij})\tilde{n}_i - \delta_{ij}(1-\tilde{n}_i)\}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

it is possible to write the expression for k_{uni} in a very simple form (14), i.e.

$$[3] \quad k_{uni} = \frac{\mu\sum\tilde{n}_i k_i(\mu + k_i)^{-1}}{1 - \sum\tilde{n}_i k_i(\mu + k_i)^{-1}}$$

where μ is the rate constant for the internal relaxation (equivalent to $\lambda Z[M]$ in conventional treatments, λ being the "collision efficiency"). Equation [3] (since it is identical with the more cumbersome expressions we gave earlier) reproduces the fall-off curves for many thermal unimolecular reactions with high precision (11).

V. Derivation of the Quantised Form for the Specific Rate Function

We showed recently that reformulation in quantum terms of the original idea of Polanyi and Wigner (1) leads to remarkably good predictions for the specific rate functions $k(E)$ for simple unimolecular reactions (2). The formulae we proposed were evolved by intuitive reasoning, and no attempt was made at a theoretical justification: however, within the framework of the quasi-diatomic model, it is a simple matter to derive the basic formula used. The essence of the reformulation was that if more energy than the critical energy is to be found in a certain assumed critical vibration, the molecule will react within that vibrational period, but if the molecule possesses the same amount of energy distributed in any other fashion, it is unreactive: the specific rate constant is then simply the time constant for the vibrational disruption multiplied by the ratio of the "active" to the "passive" states.

Within the framework of the quasi-diatomic model, we can make a simple distinction between these active and passive states: an active state is one for which the vibrational motion will carry the system irrevocably into nuclear configurations which can be classed as products; a passive state on the other hand is one in which the motion is confined by the generalised internuclear potential at all extremes to nuclear configurations which can only be classed as reactant. We need not specify at this stage the mechanisms by which the intramolecular relaxation takes place, so that passive states are converted into active states, and vice-versa; we will assume, however, on the basis of the arguments given above, that there is a collisional component which will dominate at sufficiently high pressure.

We write the master equation for the *overall* reaction as

$$[4] \quad \frac{dn_i}{dt} = [M]Z\sum_j [p_{ji}n_j - p_{ij}n_i] - k_i n_i$$

where n_i now denotes the population in group of adjacent energy levels which form a "grain" within the calculation. This grain (above threshold) comprises two kinds of states, those whose motions are bounded at all extremities, and have infinite lifetime, and those which will transform the molecule into products within the period of the vibration: all these latter states have the same lifetime of $(2c\nu)^{-1}$ s, where ν is the frequency of the vibration in wavenumber units.

We now examine the relaxation in competition with the decay processes *within* the grain. We may write another master equation for the grain itself as

$$[5] \quad \frac{dm_k}{dt} = [M]Z'\sum_l [p_{lk}m_l - p_{kl}m_k] - d_k m_k$$

where Z' is the collision number appropriate to the long-range encounters which cause randomisation (estimated for example from arguments such as depicted in Fig. 1), and d_k is the rate constant for decay of the specific state, which is either zero for a passive state, or $d = 2c\nu\ s^{-1}$ for an active state. We may also accept intuitively that the transition probabilities p_{lk} etc. are strong collision probabilities, as would be defined by an expression analogous to eq. [2], but with a relaxation rate constant μ_2. The rate constant for decay from the grain therefore becomes the same (provided that $\sum\tilde{m}_k$ is renormalised to unity) as the strong collision expression for the unimolecular rate constant, eq. [3], viz.,

$$[6] \quad k_i = \frac{\mu_2\sum\tilde{m}_k d_k(\mu_2 + d_k)^{-1}}{1 - \sum\tilde{m}_k d_k(\mu_2 + d_k)^{-1}}$$

which simplifies[2] enormously when all the d_k are either zero or d to a simple Lindemann form (15)

$$[7] \quad k_i = \frac{\mu_2 d\sum'\tilde{m}_k}{\mu_2 + d - d\sum'\tilde{m}_k}$$

where $\sum'$ denotes the summation over only those states k for which $d_k \neq 0$. Assuming we are at the high-pressure limit *with respect to the randomisation process*, then k_i for the grain becomes simply $d\sum'\tilde{m}_k$, i.e. d times the fraction of states within the grain which decay with time constant d. Hence, for each grain i, we are justified in identifying its decay rate constant k_i with the quantity $d\sum'\tilde{m}_k$ at the energy of the ith grain.

Now, since the energy difference across the grain

[2]One may have to be careful about the use of this formula, which is only valid when γ (the eigenvalue) $\ll \mu$ (the relaxation rate), which is *usually* the case. The exact solution for γ is (16)

$$\gamma[(\gamma - \mu) - d(1 - \sum'\tilde{m})] = (\gamma - \mu)d\sum'\tilde{m}$$

which easily reduces to [7] when $\gamma \ll \mu$; otherwise, the correct solution is

$$\gamma = \tfrac{1}{2}[(\mu + d) - \{(\mu + d)^2 - 4\mu d\sum'\tilde{m}\}^{1/2}]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

is infinitesimal, all states in the grain have the same Boltzmann factor $\exp(-\varepsilon_k/kT)$, whence $\tilde{m}_k = g_k/\sum g_k$, i.e. $d\sum' \tilde{m}_k = d\sum' g_k/\sum g_k$. Thus, k_i becomes $d\sum' g_k/\sum g_k$, or in continuous terms $d\rho_{n-1}'(E - E_\infty)/\rho(E)$ which is the simplest form used in ref. 2, i.e. eqs. [6*a*] and [7*a*] of that paper.

VI. Randomisation Kinetics

Equations [4]–[7] provide a direct method for incorporating the kinetics of randomisation into the calculation of the specific rate constant k_i: if the randomisation rate constant μ_2 is very large, then k_i is simply $d\sum' g_k/\sum g_k$ as we have suggested before (2), but if μ_2 becomes rate-limiting, then a lower effective value of k_i from eq. [7] ensues. Moreover, although we have written eq. [7] on the assumption of second-order randomisation processes only, with μ_2 proportional to pressure, we can also use [7] to introduce first-order randomisation processes simply by keeping the relaxation rate constant μ_1 = constant, independent of pressure.

At the moment, the formulation of k_i we have given above and in ref. 2 is very primitive, and the precise rules for its proper implementation have yet to be worked out. Consequently, for the practical calculations reported below, it is preferable to use the most accurate specific rate functions attainable, i.e. the Slater–Forst specific rate function (2, 11), slightly reinterpreted in the light of this new formulation. Thus, I will identify the term $d\sum' \tilde{m}_k$ in [7] with the Slater–Forst specific rate function $k(E)$, whence the rate constant for decay from a grain becomes

$$[8] \quad k_i = \mu_r k(E)/(\mu_r + 2c\nu - k(E))$$

where μ_r is the randomisation rate, either first- or second-order as appropriate (cf. Section II above for explanation concerning the units of μ_r); I will also assume for the time being that μ_r remains the same from grain to grain, although I will conclude below that μ_2 is probably a function of state density — a problem for examination at a later date.

Figure 2 shows the results of assuming only first-order randomisation processes to be operative, using the methyl isocyanide isomerisation reaction as an example. The top curve is the standard fall-off curve, which corresponds to an essentially infinite rate of randomisation, and the other four curves, in descending order, correspond to fixed values for the randomisation rate constants of 10^{13}, 10^{12}, 10^{11}, and 10^{10} s^{-1} respectively. All the curves merge at infinitely low pressure: this is because, from [8], $k_i = \mu_1 \times \alpha_i$, whence substitution into [3] gives the usual expression for the low-pressure limiting overall rate, but a different high-pressure rate for each value of μ_r.

Figure 3 shows the results of a similar calculation,

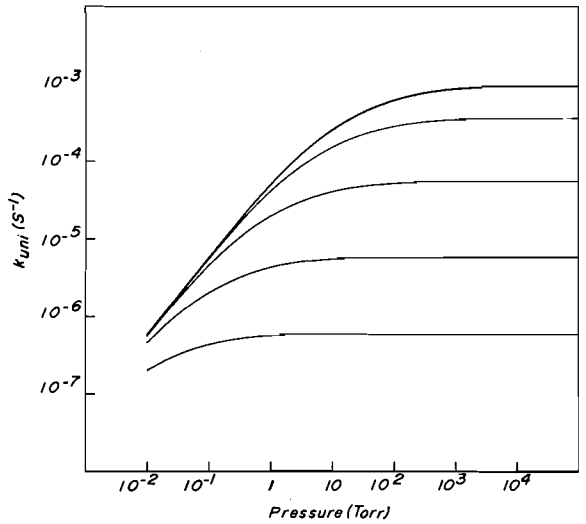

FIG. 2. Fall-off curves for the thermal isomerisation of methyl isocyanide at 230.4°C considering only first-order randomisation processes. In descending order, the curves correspond to values of $\mu_1 = \infty$, 10^{13}, 10^{12}, 10^{11}, and 10^{10} s^{-1} respectively.

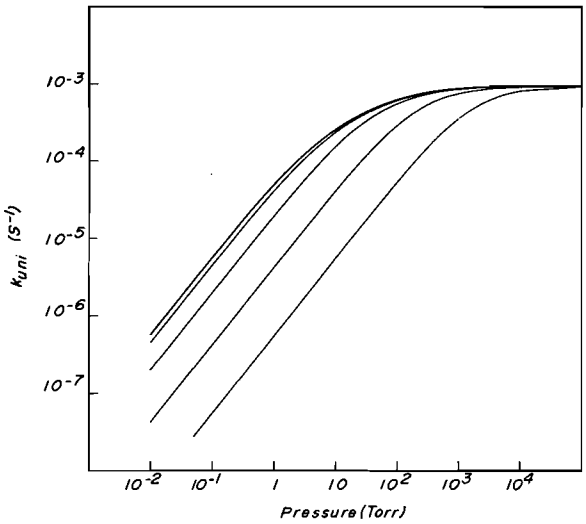

FIG. 3. Fall-off curves for the thermal isomerisation of methyl isocyanide at 230.4°C considering only second-order randomisation processes. In descending order, the curves correspond to values of $\mu_2 = \infty$, 10^{13}, 10^{12}, 10^{11}, and 10^{10} $Torr^{-1}$ s^{-1} respectively.

but this time assuming that only second-order randomisation processes are operative, with rate constants (again independent of total energy), in descending order, of 10^{13}, 10^{12}, 10^{11}, and 10^{10} $Torr^{-1}$ s^{-1} respectively; again, the topmost curve is the standard fall-off curve corresponding to an essentially infinite randomisation rate constant. Again, inspection of [8] shows how this behaviour arises: μ_r is now identified as μ_2 which is proportional to pressure,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

whence at high pressure, $k_i = k(E)$ and the normal high-pressure limiting rate ensues from [3]. The low-pressure limiting rate for k_i from [8] is however βP, and substitution of this into [3] gives a different low-pressure limit for the overall rate for each value of β, i.e. for each value of μ_2.

Notice that neither first-order nor second-order randomisation gives rise to false high-pressure limits (i.e. plateaux in the overall rate constant at intermediate pressures), such as have been postulated on several occasions (8, 17–19) on the basis of less rigorous arguments.

VII. An Assumption

Unimolecular reaction theories in the past have always accepted that the rate constant at the high-pressure limit was given by the sum $\sum \tilde{n}_i k_i$, or its continuous equivalent $[Q(T)]^{-1}\int \rho(E)k(E)\,dE$: it is also implicit that k_i or $k(E)$ are "natural" rate constants, i.e. not rate-limited by "hidden" processes such as randomisation. The results of the preceding section show that if only first-order randomisation is allowed, we can never realise this high-pressure limit unless the first-order randomisation rate constant is infinite, which is untenable: thus, second-order randomisation is a necessity in order to achieve the conventional high-pressure limiting rate constant.

In addition, in deference to the universally held belief that first-order randomisation processes are a reality (8), I will accept that there is also a first-order component, guaranteeing that we also approach the conventional magnitude of $\mu\sum'\tilde{n}/(1 - \sum'\tilde{n})$ for the limiting value of the low-pressure rate constant: second-order randomisation alone would not allow this.

Thus, in fact, we have a twin postulate, that *both* first- and second-order randomisation processes must be invoked in any rigorous treatment of thermal unimolecular reactions.

VIII. Randomisation among Product States

The arguments I have presented so far consider only randomisation amongst the reactant states but, of course, randomisation amongst product states will also occur and, in fact, in isomerisation reactions such randomisation is vital in the quasi-diatomic model for the reaction to occur.

If we consider the isomerisation of methyl isocyanide again, we may represent a quasi-diatomic potential for this process in some such generalised form as shown in Fig. 4. The shaded portion on the left side represents all those passive states whose motions are confined entirely within the reactant configuration space, and on the right side, we have all those passive states lying within the product configuration space. Since this reaction is strongly

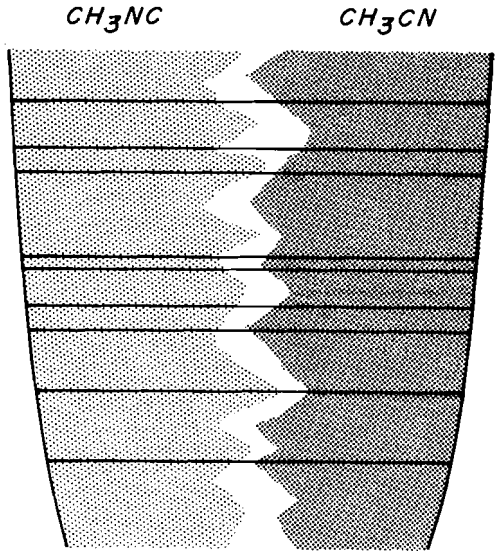

FIG. 4. Schematic pseudo-potential for the isomerisation of methyl isocyanide to methyl cyanide. The lightly shaded portion on the left represents passive states which lie entirely within the *reactant* configuration space: there are roughly 1.9×10^8 such states per wavenumber just above threshold. The more heavily shaded portion on the right represents passive states which lie entirely within the *product* configuration space: there are roughly 1.1×10^{10} such states per wavenumber in this energy range. The solid lines represent the active states, or connecting states, i.e. those states for which the molecule makes excursions through both reactant and product configurations within one vibrational period: these are fewer than 100 such states per wavenumber just above threshold, but the density of such states increases rapidly with increasing energy.

exothermic, there are many more product states than reactant states at any particular value of the total energy: nevertheless, all states are *bound* in the sense that none of them is connected with a translational continuum. The solid lines on this diagram represent those states which are common to reactant and product: according to our previous arguments (2), these are states with more than about 50 quanta in the C—N—C bending mode of the reactant, or because of microscopic reversibility, they also correspond exactly to a series of C—C—N bending states of the product. Consequently, a methyl isocyanide molecule is not transformed into a methyl cyanide molecule simply by the accumulation of more than 50 quanta in this certain vibration, since although it will have all the spatial attributes of a cyanide molecule half a vibrational period later, it will have reverted to an isocyanide molecule after another half-period. Thus, unless "fixed" as cyanide by randomisation processes, "reaction" does not take place.

Let us suppose for the moment that randomisation rate constants are equal in both the reactant and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

product configuration, and that only second-order randomisation is important. Figure 5 depicts the decay from an assembly of states, initially normalised to unity, and with the origin of the horizontal axis coincident with the transition from the left-hand to the right-hand side of Fig. 4. For the first half-vibration, i.e. $\delta = (2cv)^{-1}$ s, systems are "killed" to product states with the randomisation rate constant μ_r: then for the next period of δ seconds, the vibrational excursion is through *reactant* configurations and during this time the molecule will be randomised to reactant states, and so on. Thus, the total chance of ending up as product is the ratio of the sum of the unshaded strips to the total area, viz.

$$[9] \quad \text{Fraction} = \frac{\sum_{n=0}^{\infty} \int_{2n\delta}^{(2n+1)\delta} \exp(-\mu_r t)\, dt}{\int_0^{\infty} \exp(-\mu_r t)\, dt}$$

If $\mu_r \gg 2cv$, this ratio is 1, and if $\mu_r \ll 2cv$, it is 0.5. Figure 6 shows the form of the overall reaction rate for values of the randomisation rate constant of, in descending order, 10^{13}, 10^{12}, 10^{11}, and 10^{10} $\text{Torr}^{-1}\,\text{s}^{-1}$, respectively. In this case, both limiting rates are the usual ones: the high-pressure rate because $k_i = d\sum' g_k$ as usual, and the low-pressure rate because, although $k_i = 0.5d\sum' g_k$, the overall rate, by eq. [3], is independent of k_i in the limit.

If, on the other hand, we had chosen to perform the calculation for first-order randomisation only, a series of curves like those shown in Fig. 2 would have been obtained, except that the lowest one of the

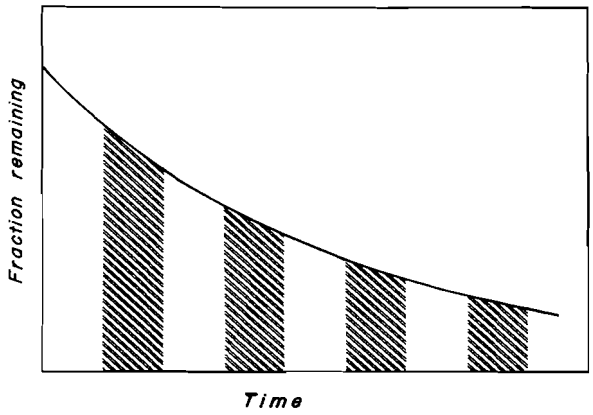

FIG. 5. Representation of the rate of stabilisation of interesting molecules by randomisation when the randomisation rate constant is the same in both reactant and product manifolds. The unshaded portions represent the vibrational half-periods when the nuclear excursions are through product configurations, and the shaded portions represent the vibrational half-periods when the nuclear configurations have the characteristics of the reactant molecule.

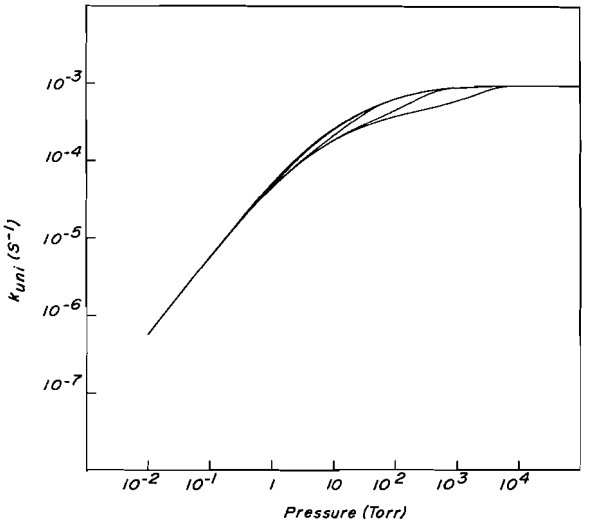

FIG. 6. Fall-off curves for the thermal isomerisation of methyl isocyanide at 230.4°C considering only second-order randomisation in both reactant and product manifolds. In descending order, the curves correspond to $\mu_2 = \infty$, 10^{13}, 10^{12}, 10^{11}, and 10^{10} $\text{Torr}^{-1}\,\text{s}^{-1}$ respectively.

set (i.e. for $\mu = 10^{10}\,\text{s}^{-1}$) would have a high pressure limiting rate just a little more than half the normal high-pressure rate.

As we will show below, the randomisation rate constant — at least the second-order one — appears to be a function of the density of state in the vicinity of the level being considered. Consequently, it is only for thermoneutral or endothermic isomerisation reactions that such manifestations of *product* non-randomisation might be observed — assuming, since we have yet to establish it below, that the effect of non-randomisation can be observed at all in thermal reactions.

When we turn to fragmentation reactions, the situation is rather different. In these cases, the right-hand wall of the pseudo-potential in Fig. 4 is absent, and hence, once the system emerges into the right-hand side representing product configurations, fragmentation is irrevocable. The particles are now moving with momenta such that, in the absence of external influences, they will inevitably recede to infinity: our picture of a randomising event is that it is something rather weak — in other words, it may change the energy of the system very slightly, but it can never *reverse* the total relative momentum (or momenta if we include rotation) of the two massive fragments; this could only be done by a *collision* in the normal sense, and this constitutes the back-reaction. Thus, product randomisation, although it will take place, will have no effect upon the *rate* of unimolecular fragmentation reactions.

IX. A Summary of the Experimental Data for Methyl Isocyanide

The landmark experimental results of Schneider and Rabinovitch (20, 21) on the thermal isomerisation of methyl isocyanide have been compared with theory on a number of occasions (11, 20–24) and the conclusion has always been that the theory does not exactly match the experimental results to the same degree that it does for (say) the isomerisation of cyclopropane (11). The discrepancies are similar (20) at each of the three temperatures studied by Schneider and Rabinovitch, and since the data for the temperature of 230.4°C are the most extensive, I will confine my attention to this set of data. The situation was confused recently by the emergence of another set of data from this laboratory (25): these experiments were not undertaken for the purposes of testing unimolecular reaction theory, and were confined to a very limited pressure range (2–100 Torr); their comparison with unimolecular reaction theory was only suggested later (11) in order to try to throw some more light on the nature of these generally agreed discrepancies. It turns out that over their limited pressure range, not only do the data of Collister and myself (25) agree very well with those of Schneider and Rabinovitch, but they also fit superbly to standard unimolecular fall-off curves corresponding to a somewhat lower high-pressure limit than that of Schneider and Rabinovitch (cf. Fig. 14 of ref. 11). Since then, we have undertaken a new series of experiments to determine which high-pressure limiting rate constant is correct, and we confirm that the value of Schneider and Rabinovitch is the correct one.[3]

X. Treatment of Alkyl Isocyanide Isomerisations including Randomisation Processes

Methyl Isocyanide

Previous theoretical treatments of this reaction have always chosen the pressure shift in such a way as to achieve the best compromise fit between theory and experiment over the whole pressure range (11, 20–24). Knowing now that first-order randomisation will ensure that the low-pressure limit coincides with the standard low-pressure limit, and that second-order randomisation will do likewise at the high-pressure limit (cf. Figs. 2 and 3), I have re-plotted the data slightly differently in Fig. 7. The dashed line is the standard unimolecular calculation (11, 15) using a collisional relaxation rate constant $\mu = 1.20 \times 10^6$ Torr^{-1} s^{-1} and the solid line shows the effect of including both first- and second-order randomisation, with rate constants $\mu_1 = 4.0 \times 10^{12}$ s^{-1} and $\mu_2 = 1.25 \times 10^{12}$ Torr^{-1} s^{-1} respectively. The agreement with the data of Schneider and Rabinovitch is virtually exact.

Perdeuteriomethyl Isocyanide

One example does not prove a theory: it is necessary to examine other similar reactions to see whether they behave equally well without making any further unjustifiable assumptions. To this end, Fig. 8 shows the fall-off data of Schneider and Rabinovitch (20, 27) for CD_3NC compared with three theoretical models: the dashed curve is again the standard unimolecular calculation (11, 15) and the dotted curve is the calculation using *the same* collisional relaxation and randomisation rate parameters as were used for CH_3NC in Fig. 7; quite unambiguously, this curve does not fit the data. The solid curve shows the plot obtained using the constants $\mu = 1.30 \times 10^6$ Torr^{-1} s^{-1}, $\mu_1 = 5.0 \times 10^{12}$ s^{-1}, and $\mu_2 = 3.0 \times 10^{12}$ Torr^{-1} s^{-1} respectively. The only *significant* difference in the parameters required to achieve this exact fit is that the second-order

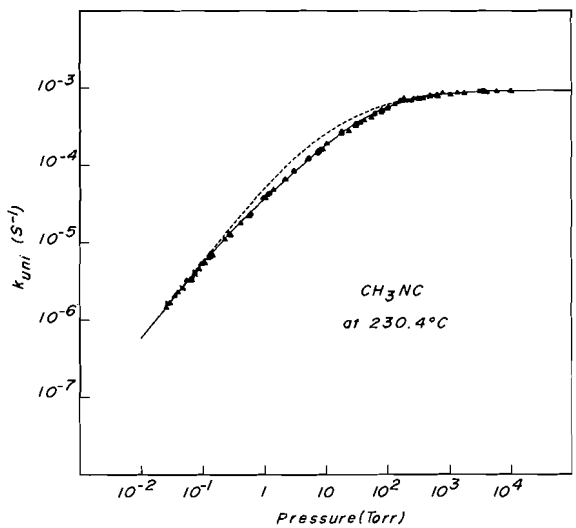

FIG. 7. Fall-off curves for the thermal isomerisation of methyl isocyanide at 230.4°C. The points represent the results of Schneider and Rabinovitch (20, 21) with the experiments in packed vessels marked by tags. The dashed line is the standard fall-off calculation without considering randomisation. The solid line includes both first-order and second-order randomisation effects, with $\mu = 1.20 \times 10^6$ Torr^{-1} s^{-1}, $\mu_1 = 4.0 \times 10^{12}$ s^{-1}, $\mu_2 = 1.25 \times 10^{12}$ Torr^{-1} s^{-1}.

[3]We (26) carried out experiments using about 50 Torr of CH_3NC pressurised with helium in a 10 mL steel vessel at 200°C; at this temperature, the Collister and Pritchard limit is 5.1×10^{-5} s^{-1} whereas the Schneider and Rabinovitch limit is 7.3×10^{-5} s^{-1}. We observed rate constants as high as 6.4×10^{-5} s^{-1} and extrapolated our results between 7 and 8×10^{-5} s^{-1} at infinite pressure: this proves conclusively (cf. also footnote 23 of ref. 8) that, despite superficial appearances, the infinite-pressure limit extrapolated from our own experiments (25) is not the correct one.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

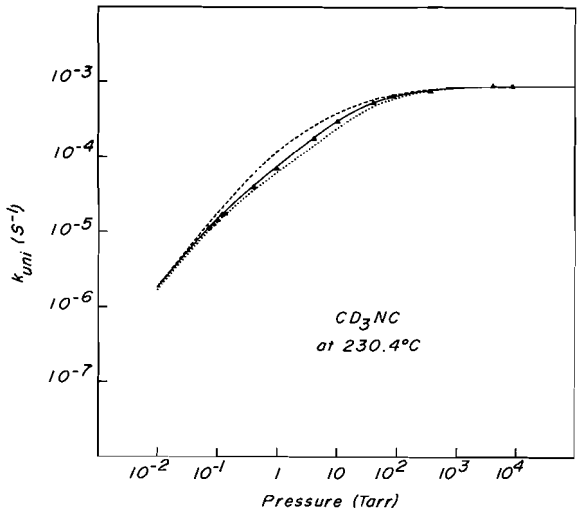

FIG. 8. Fall-off curves for the thermal isomerisation of perdeuteriomethyl isocyanide at 230.4°C. The points represent the results of Schneider (20). The dashed line is the standard fall-off calculation without considering randomisation. The dotted line includes both first-order and second-order randomisation, but with constants appropriate to methyl isocyanide as in Fig. 7. The solid line uses $\mu = 1.30 \times 10^6$ Torr^{-1} s^{-1}, $\mu_1 = 5.0 \times 10^{12}$ s^{-1}, $\mu_2 = 3.0 \times 10^{12}$ Torr^{-1} s^{-1}.

randomisation rate constant is about $2\frac{1}{2}$ times as large, which I think is quite reasonable in view of the fact that CD_3NC has 6 or 7 times the density of states of CH_3NC. The only questionable point is that μ for CD_3NC appears to be very slightly greater than that for CH_3NC, contrary to the general trend found at lower temperatures in ultrasonic relaxation experiments (28).

Schneider and Rabinovitch (27) also conducted another extensive set of experiments in which they measured the relative rate ratios for isomerisation of CH_3NC and CD_3NC, and although the general trends are well represented by standard unimolecular calculations (11, 27), there are some inexplicable discrepancies. Figure 9 shows these experimental ratios compared with the results of standard theory (dashed line) and with those calculated using the relaxation and randomisation rate parameters chosen separately in Figs. 7 and 8. Whilst this method of presentation is not entirely independent of the preceding arguments because of the remarkable internal consistency of Schneider's earlier (19) and later (27) results, it does suggest quite strongly that the unexplained "bump" in the ratios just below 1 Torr arises from the differences in randomisation rates between the two isotopic variants of the reactant molecule. Notice that in this plot, the rate constant ratio itself is plotted, rather than its logarithm as in previous presentations (11, 27).

Ethyl Isocyanide

Rabinovitch and co-workers (29, 30) have published equally remarkable sets of experimental data for the thermal isomerisations of both C_2H_5NC and C_2D_5NC. Again, as we have noted previously (11), there appears to be a slight anomaly in the observed fall-off behaviour for C_2H_5NC between 10^{-2} and 1 Torr, rather like that found for CH_3NC between 1 and 100 Torr, and which can probably be accounted for in the same fashion. Unfortunately, because of the onset of the wall activation mechanism at the lowest pressures, it is not possible to make a definitive choice for the primary energy relaxation rate constant μ. In consequence, it is not possible to derive accurate values for the two randomisation rate constants μ_1 and μ_2 in ethyl isocyanide. However, it is clear that the value of μ_2 used for methyl isocyanide is hopelessly wrong for ethyl isocyanide, and the value for the ethyl compound has to be 1×10^{14} Torr^{-1} s^{-1} *at the very least*; it is not possible to make such a categorical statement about

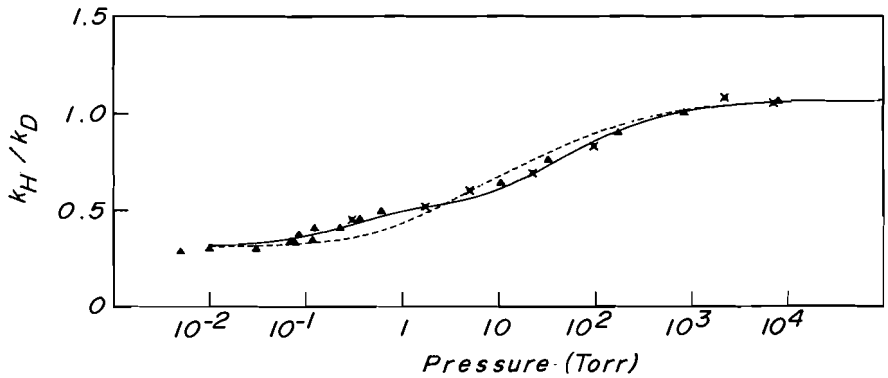

FIG. 9. Kinetic isotope effect k_H/k_D for CH_3NC and CD_3NC isomerisation as a function of pressure at 230.4°C. The points represent the two sets of ratio measurements made by Schneider and Rabinovitch (27). The dashed line uses standard fall-off calculations for each molecule, whereas the solid line allows for reactant-state randomisation with the respective rate constants as used in Figs. 7 and 8.

μ_1, but it seems that a value rather similar to those used for the two methyl isocyanides would not be inappropriate. An experimental determination of the gas-phase second-order limit for ethyl isocyanide would be extremely valuable indeed, as it would provide definitive information on the general behaviour of these first- and second-order randomisation rate constants as a function of molecular complexity.

XI. Summary

I have presented a model for the explicit inclusion of the kinetics of internal energy randomisation within the usual unimolecular fall-off calculations, and shown how the method can be applied to the thermal isomerisations of methyl and ethyl isocyanide.

I have concluded that it is sensible to admit the existence of both first-order and second-order randomisation mechanisms, with rate constants μ_1 and μ_2 respectively. The principal consideration here is the general success of earlier unimolecular reaction theories in reproducing fall-off characteristics: these earlier calculations are equivalent to the present treatment with either $\mu_1 \rightarrow \infty$ or $\mu_2 \rightarrow \infty$ or both; however, once both μ_1 and μ_2 take on rate-limiting values, it is necessary to postulate the *significant* involvement of both randomisation mechanisms in order to maintain the traditional forms for the high- and low-pressure limits.

Numerical application of this formulation to the two symmetrical isotopic forms of methyl isocyanide and (as best I can) to ethyl isocyanide suggests very strongly that the second-order randomisation rate increases markedly with increasing density of states, an observation which can easily be rationalised with arguments suggested by Fig. 1. On the other hand, until a true low-pressure limiting rate can be determined for ethyl isocyanide, there is no strong evidence to suggest that the first-order randomisation rate constant differs very much from $5 \times 10^{12}\ s^{-1}$.

The quasi-diatomic model used in these calculations provides a simple vehicle for treating randomisation processes, and leads directly to a very simple formulation of the specific rate constant for unimolecular decay. It is not necessary to understand the exact details of the processes causing randomisation in order to model practical reaction processes. However, the second-order process is clearly a collisional one, and the elucidation of the precise nature of the first-order randomisation process (or processes) may well be facilitated considerably through this approach, once the full implications of the nodeless quality of *all* vibrational wave functions (3, 4) are worked out.

Spin–lattice relaxation in MBBA and MBBA – carbon tetrachloride mixtures

MARGARET A. HELDMAN AND D. F. R. GILSON[1]

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received May 28, 1980

MARGARET A. HELDMAN and D. F. R. GILSON. Can. J. Chem. **58**, 2246 (1980).

The spin–lattice relaxation time has been measured at 33 MHz as a function of temperature for the liquid crystal MBBA and mixtures with carbon tetrachloride. The behaviour of T_1 close to the nematic–isotropic transition can be explained if the correct order fluctuation dependence is included. Diffusion constants calculated from fits to the self-diffusion contribution to relaxation are in agreement with existing results.

MARGARET A. HELDMAN et D. F. R. GILSON. Can. J. Chem. **58**, 2246 (1980).

On a mesuré le temps de relaxation–spin réseau à 33 MHz en fonction de la température du cristal liquide MBBA et de ses mélanges avec le tétrachlorure de carbone. On peut expliquer le comportement du T_1 près de la transition nématique–isotrope si l'on inclut l'ordre correct de l'influence de la fluctuation. Les constantes de diffusion ainsi calculées cadrent avec la contribution d'auto-diffusion à la relaxation et sont en accord avec les résultats existants.

[Traduit par le journal]

Introduction

The mechanism of proton spin–lattice relaxation in nematic liquid crystals has been a subject of controversy. The two principal theories are the order director fluctuation mechanism of Pincus (1), which requires a dependence on the inverse square root of the Larmor frequency, and the self-diffusion theory due to Blinc (2) which involves a simple square root dependence. At first sight, an easy distinction between the two mechanisms should be obtainable by measuring the dispersion of T_1 as a function of the frequency of measurement but the experimental results have been inconclusive in that they do not provide an unambiguous interpretation even when extended over a very wide range of frequencies. Each approach has been modified in efforts to solve the conflict. The Pincus theory was changed to incorporate a squared dependence on the order parameter (3) and by the inclusion of a cut-off frequency above which the order fluctuation mechanism does not operate (4). The self-diffusion model was extended by using a step-width parameter and a frequency independent term in the relaxation rate (5). In both cases these changes appeared to give agreement with the experimental results, but by incorporating both order fluctuations and diffusive motion together with a cross correlation term, Ukleja, Pirs, and Doane (6) proposed an improved overall theory capable of explaining the available experimental results for both PAA (*p*-azoxyanisole) and MBBA (*p*-methoxybenzylidene-*n*-*p*-butylaniline). However, this theory was later criticized on the grounds that it could not adequately explain the deuterium spin–lattice relaxation times in MBBA (7). Subsequently, measurements of T_1 for MBBA were extended into the kilohertz range by Graf, Noack, and Stohrer (8) who explained their results by dropping the cross-correlation term in favour of a molecular rotational correlation time for motion about the short molecular axis. The theory which now emerges for spin–lattice relaxation in MBBA is that order fluctuations provide the dominant mechanism at low Larmor frequencies while self-diffusion is responsible at high frequencies and at lower temperatures. Near the nematic to isotropic transition the rotational process becomes of comparable importance. Each relaxation process is weighted by the number of contributing spins.

In nearly all studies of MBBA the emphasis has been on the frequency dispersion and not on the temperature dependence of T_1. Graf *et al.* (8), for instance, covered the frequency range from 2 kHz to 270 MHz but only at four temperatures, 18, 27, 35, and 45°C. In earlier work (9, 10), we have obtained the order parameter (S) dependence upon temperature for pure MBBA and for MBBA doped with various solutes and shown that the order parameter is a universal function of reduced temperature in all cases. It seemed worthwhile to explore the temperature dependence of T_1 in MBBA (pure and doped) in greater detail, specifically in terms of the reduced temperature. Carbon tetrachloride was chosen as a non-proton containing solute molecule.

Experimental

MBBA was prepared by the condensation reaction between freshly distilled *p*-anisaldehyde and *n*-butylaniline and vacuum distilled three times. The nematic to isotropic transition temperature was 44°C. Since reduced temperature scales are used in the present study no attempts were made to obtain extremely pure material. Solutions with carbon tetrachloride were prepared

with 9.1 and 18.4 mol% solute and carefully degassed by freeze–pump–thaw cycling.

Spin–lattice relaxation times were measured on a Spin-Lock CPS-2 pulse spectrometer at 33 MHz using a $\pi-\tau-\pi/2$ sequence with delay times up to $1.3T_1$ used in the analysis. Free induction decays were captured with a Biomation model 805 transient recorder and subsequently plotted on a strip chart recorder. The sample temperature was controlled by a heated or cooled flow of nitrogen gas and measured with a copper–constantan thermocouple placed next to the sample.

Results and Discussion

The T_1 versus temperature plots are shown in Fig. 1. The relaxation time increases with increasing temperature but shows some levelling-off as the nematic–isotropic transition is approached. This effect has been observed previously (11) in a variety of liquid crystals but has been given little attention. The presence of CCl_4 as a solute decreases T_1 and also reduces the nematic temperature range and the ability to supercool the solution below the nematic–solid transition. Thus the results for the 18 mol% solution show greater scatter and are less satisfactory.

In previous applications of the order fluctuation theory various simplifications and approximations have been applied. The order fluctuation rate is given by

$$[1]\quad (T_{1OF})^{-1} = A\omega^{-1/2} + B = \frac{9}{4\sqrt{2\pi}}\frac{\gamma^4 h^2}{r^6}\frac{S^2 kT\eta^{1/2}\omega^{-1/2}}{K^{3/2}}$$

where S is the order parameter; η, the average viscosity; K, the average elastic constant; r, the internuclear separation (2.44 Å); and γ, the magnetogyric ratio, and other symbols have their usual significance. The elastic constant and viscosity are anisotropic properties and, because these are not necessarily known in sufficient detail, are replaced by average quantities. The expressions S^2/K and $T\eta^{1/2}/K^{1/2}$ are commonly assumed to vary little with temperature and therefore this contribution to the relaxation rate is taken to be temperature independent. The term B can be neglected. Graf *et al.* (8) included the viscosity as an Arrhenius-type dependence, $\eta(T) = \eta_0 \exp(-E_\eta/RT)$, in the Pincus–Doane factor, A, and a similar function for the self-diffusion term, $D(T) = D_0 \exp(-E_D/RT)$ with $D = d^2/(6\tau_{SD})$ from the Torrey formalism for self-diffusion spin–lattice relaxation (12, 13), where d is the distance of closest approach of neighbouring molecules and is equated with the mean squared flight distance. For the rotational contribution a weighting factor, ε, reflecting the anisotropy of the ellipsoids of rotation about the long and short molecular axes, and a correlation time, τ_S, again in a thermally activated mode, were included. Graf *et al.* made a computer fit to the T_1 frequency dispersion at each temperature optimizing the six parameters A, D, d, ε, τ_{SD}, and H_z (the local dipolar field) and thus to E_η, E_D, and E_S and the appropriate pre-exponential factors, the local field term can, however, be neglected for high frequency studies. This procedure led to acceptable values for the activation energy terms and good agreement with the frequency dispersion curves.

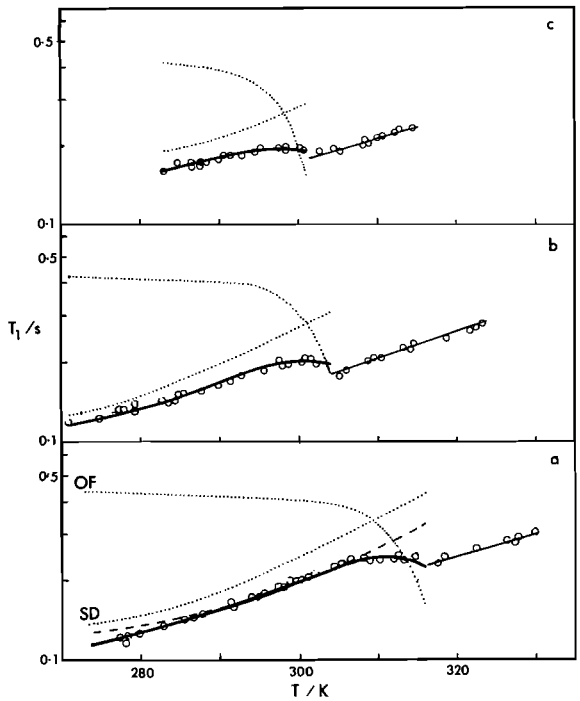

FIG. 1. Experimental spin–lattice relaxation times vs. temperature plots for (*a*) MBBA, (*b*) mole fraction CCl_4 0.091, (*c*) mole fraction CCl_4 0.183. The solid lines are the calculated dependences, the dotted line in (*a*) is calculated using the Graf–Noack–Stohrer approach.

However, when this method was applied to the temperature dependence of T_1 of MBBA at 33 MHz the dotted line of Fig. 1(*a*) was obtained. The behaviour of the spin–lattice relaxation time in the temperature region close to the nematic–isotropic transition is not explained by this theory. Experimental observations of properties such as the elastic constants, viscosity, and order parameter show that they vary quite rapidly in the vicinity of the transition. The viscosity of MBBA, in fact, shows an increase with increasing temperature. We have taken advantage of the fact that these properties

follow a reduced temperature behaviour and can be described by functions of T^*, where $T^* = T/T_N$. In Fig. 2 the Pincus–Doane factor, A, for MBBA is plotted as a function of T^*. The single constant approximations were used with values for K_{ii} and η taken from the literature (14–17), plus the S values of Lee (10). Obviously, approximations about the temperature constancy of A do not hold above $T^* \sim 0.98$ which may be responsible for the failure of the Graf–Noack–Stohrer theory to explain the observed temperature dependence.

The order fluctuation contribution to the total relaxation, $(T_{1\,OF})^{-1}$, can thus be calculated using only observed experimental data and subtracted, using the weighting factor 8/12 suggested by Graf *et al.*, from the experimental spin–lattice relaxation rate to give the contribution due to self-diffusion. The relaxation arising from rotational motion was calculated and found to be too small both at 33 MHz and close to the transition to be important. This procedure is applicable to the carbon tetrachloride solutions as well as to MBBA itself since the reduced temperature behaviour is followed.

In applying the Torrey formalism (12, 13) to the calculation of the self-diffusion relaxation the following parameters are involved; the diffusion constant, D, via $D = \langle r^2\rangle/6\tau_{SD}$, where $\langle r^2\rangle$ is the mean squared flight distance and τ_{SD} the mean time between flights, d the distance of closest approach of spins of neighbouring molecules, and the spin-density or number of protons per unit volume. In principle all these terms are temperature and concentration dependent. The ratio of flight distance to distance of closest approach can be used as an optimization parameter (7), or assumed to be unity. Graf *et al.* (8) neglected the temperature variation of the spin density and allowed d to be a temperature dependent variable. In the present treatment we have chosen to limit the number of temperature dependent variables and thus have optimized the T_{1SD} variation to τ_{SD} and d at each concentration. The value of d obtained in this way thus be subject to these assumptions.

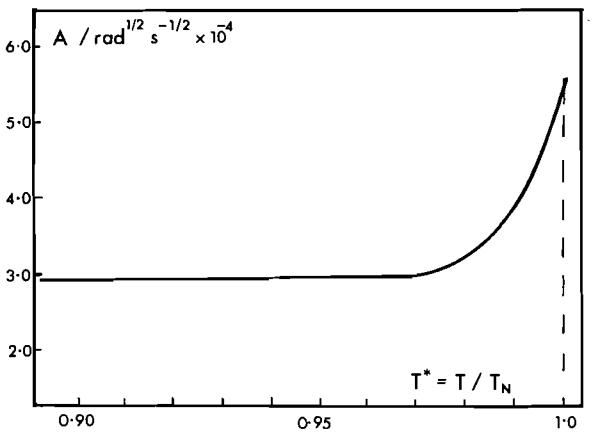

FIG. 2. Dependence of the Pincus–Doane factor A on reduced temperature.

For MBBA the optimization was extended to include the frequency dependence data at fixed temperatures (values taken from the various literature sources) together with the present results. For the carbon tetrachloride solutions the spin densities were calculated using the data given by Gierke and Flygare (18). The results are given in Table 1. The following trends are apparent, the activation energies and the distance of closest approach increase with increasing CCl_4 concentration. The latter term, however, is to be considered in the context of the approximations and assumptions mentioned above. If the expressions for τ_{SD} are converted to diffusion constants using these distances then values of D of 1.04×10^{-7}, 5.47×10^{-8}, and 2.58×10^{-8} $cm^2\ s^{-1}$ for MBBA and the 9 and 18 mol% solutions respectively at $T^* = 0.915$. At the nematic to isotropic transition these values are 3.23×10^{-7}, 2.01×10^{-7}, and 1.38×10^{-7} $cm^2\ s^{-1}$. These diffusion constants for MBBA are in good agreement with those reported by other authors (19, 20) (in the range 1×10^{-7} to 4×10^{-7} $cm^2\ s^{-1}$) although most studies have been limited to a single temperature and very few measurements exist of the activation energies for self-diffusion. There is certainly a need, as Wade has said, for much more work on the role of diffusion as a re-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

laxation mechanism in liquid crystals (21). The decrease in diffusion constant for increasing concentration of CCl_4 parallels the observations of Gierke and Flygare (18) who showed that the viscosities of MBBA – carbon tetrachloride mixtures increased with concentration. Presumably this is due to charge transfer complex formation (22) affecting the effective size and shape of the diffusing species.

Conclusions

The experimental temperature dependence of the spin–lattice relaxation time in MBBA at 33 MHz can be explained by a model which includes only order director fluctuations and self-diffusion mechanisms. The order fluctuation term is not temperature independent but can be expressed as a function of reduced temperature. A fit of the remaining contribution to a self-diffusion mechanism gives reasonable parameters even though the number of variables was limited.

On the ion exchange sorption of some complex cations and their nature of interaction with chromium ferrocyanide gel

ISHWARI P. SARASWAT, SURESH K. SRIVASTAVA, SURENDRA K. VERMA, AND ASHOK K. SHARMA

Department of Chemistry, University of Roorkee, Roorkee-247 672, India

Received October 24, 1979[1]

ISHWARI P. SARASWAT, SURESH K. SRIVASTAVA, SURENDRA K. VERMA, and ASHOK K. SHARMA. Can. J. Chem. **58**, 2250 (1980).

The sorption of ammine complex cations of Co(III), viz. $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$, on the H^+ form of chromium ferrocyanide gel has been studied under static conditions. It is observed that the majority of these complex cations (90%) are sorbed by ion-exchange process. The extent of desorption of these complex ions with some uni- and bivalent cations is in the order $K^+ > NH_4^+ > Ba^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+}$.

Infrared, Mössbauer, and magnetic susceptibility studies on the air-dried and powdered gel in H^+ form and loaded with $[Co(NH_3)_6]^{3+}$, $[Co(en)_3]^{3+}$, Fe^{3+}, and La^{3+} ions show that prussiate compounds are not formed during the gel formation and the sorbed cations are held by the electrostatic attraction forces in the matrix, which is strained by the sorption of the big cations.

ISHWARI P. SARASWAT, SURESH K. SRIVASTAVA, SURENDRA K. VERMA et ASHOK K. SHARMA. Can. J. Chem. **58**, 2250 (1980).

On a étudié, dans des conditions statiques, l'adsorption des cations complexes aminés du Co(III) du type $[Co(NH_3)_6^{3+}$ et $[Co(en)_3]^{3+}$ sous la forme protonée du gel de ferrocyanure de chrome. On a observé que la plus grande partie des cations complexes (90%) sont adsorbés par un procédé d'échange d'ions. Le taux de désorption de ces ions complexes avec quelques cations mono et bivalents a varié selon l'ordre suivant: $K^+ > NH_4^+ > Ba^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+}$.

Des études infrarouges et de susceptibilité de Mossbauer et magnétique sur le gel sous forme H^+ séché à l'air, pulvérisé et chargé en ions $[Co(NH_3)_6]^{3+}$, $[Co(en)_3]^{3+}$, Fe^{3+} et La^{3+} montrent que les composés du type pruissiate ne se forment pas pendant la formation du gel et que les cations adsorbés sont retenus par des forces électrostatiques sur la matrice qui est tendue par l'adsorption de gros cations.

[Traduit par le journal]

Introduction

Recently, we have reported the kinetics and thermodynamics of exchange of some complex cations (1), viz. $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$, on chromium ferrocyanide gel (CFC). However, some aspects such as the nature of binding between the exchanger and the sorbed species, etc., could not be well understood on the basis of kinetic and thermodynamic data alone. Therefore, it looks essential to carry out further investigations on the sorption behaviour of CFC towards these complex cations. As the exchanger has been found to be amorphous on X-ray analysis (2) and is opaque to most spectroscopic investigations, the experimental informations at the molecular level are limited. However, infrared (ir), Mössbauer effect (Me), and magnetic susceptibility (ms) studies could provide useful informations. In the present article, the sorption and desorption of these complex cations under static conditions have been reported and the results have been supplemented by ir, Me, and ms data to explain the mechanism of uptake and the nature of interaction between the gel and the sorbed cations.

Experimental

Chromium ferrocyanide gel, $K_6Cr_2[Fe(CN)_6]_3 \cdot 16H_2O$, was synthesized under optimum experimental conditions (exchange capacity 3.65 mequiv./g) and analyzed as reported earlier (2). The chromium–iron ratio of the product was 0.66. The thermogravimetric analysis of CFC showed a sharp inflexion point at 174°C, thus indicating the complete loss of water. The water content in the gel had been calculated by heating the exchanger to a constant weight at 180°C.

The complexes of cobalt, viz. hexammine cobalt(III) chloride and trisethylenediamine cobalt(III) chloride, were prepared using standard methods (3). Infrared spectra of the compounds were examined (4(*a*), (*c*)) and their purity was ascertained by the gravimetric estimations (5) of cobalt(III).

The gel was converted into H^+ form by the treatment with 1 *M* HCl. It was then saturated with different cations of interest by immersing in their salt-solutions (0.01 *M*) for long enough time (48 h). The samples were then repeatedly washed with deionized water to remove the adherent ions and dried at room temperature.

pH-measurements were made with a pH-meter, model pH 821, E.C.I., India, and the solutions of complexes were determined spectrophotometrically with a Unicam-500.

Sorption and Desorption Studies

The sorption of complex cations on the H^+ form of CFC, (100–170) B.S.S. mesh size of mean radius $(6.80 \pm 0.40) \times 10^{-3}$ cm, was studied as a function of initial solution concentration (pH 2 ± 0.02) using 0.1 g and 0.05 g of exchanger for $[Co(en)_3]^{3+}$ and $[Co(NH_3)_6]^{3+}$, respectively. The final volume of solution was 10 mL in each case. The solutions were shaken intermittently and, after equilibrium was attained (48 h), were filtered and spectrophotometrically estimated for the complex cations. The distribution coefficients of the complex cations were also determined as a function of the initial pH of the solution. The influence of HNO_3 and NH_4NO_3 concentrations on the distribution coefficients was also investigated at 0.005 *M*

initial solution concentration of the complex cations. The calculations of K_d values (mL/g) were made as:

K_d = (Milliequivalents of complex cations sorbed at equilibrium per Milliequivalents of complex cations in solution at equilibrium) (V/m)

where V is the volume of solution and m is the mass of the exchanger sample.

For desorption studies, the weighed samples of CFC in H^+ form were first equilibrated with the solutions of $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$ of known concentrations (0.01 M) and volumes sufficiently high to saturate the samples and sorption per gram of the exchanger was calculated for each complex species. Equal amounts of these saturated samples (0.1 g) were then placed in contact with solutions of different concentrations of the desorbing salts and after the equilibrium was attained (48 h), the complex cations released were estimated. The desorbing salts used were NH_4Cl, KCl, $MgCl_2$, $CaCl_2$, $SrCl_2$, and $BaCl_2$ and at equilibrium the percentage of desorption was calculated as:

$$\% \text{ Desorption} = 100 \times \frac{\text{Milliequivalents of complex cations released at equilibrium for 1 g of CFC}}{\text{per milliequivalents of complex cations required to saturate 1 g of CFC in } H^+ \text{ form}}$$

All measurements were carried out under static conditions at 25 ± 0.2°C.

Recording of Infrared Spectra

The infrared spectra of dried and powdered samples of CFC in H^+ form and those loaded with Fe^{3+}, La^{3+}, and complex cations, $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$, were recorded at room temperature (25°C) in KBr pallets on Beckmann IR-20 spectrophotometer.

Mössbauer Resonance Spectra

Mössbauer measurements were made on air-dried samples at room temperature. The studies with samples dried in vacuum and with wet samples were not carried out because of the likelihood of structural changes (6). Spectra were recorded on a Mössbauer spectrometer employing a 256 channel analyzer and Elscint type constant acceleration velocity drive. ^{57}Co in Pd matrix of intensity 2 m Ci was used as the source. Sodium nitroprusside (SNP), which gives a well resolved quadrupole split doublet of 1.7048 ± 0.0025 mm s^{-1} (7), was used for calibrating the instrument and the reported value of chemical shift is with respect to this standard. In order to minimize the error, the spectra were recorded for sufficiently long time, and at least 2×10^4 counts per channel were recorded.

Magnetic Measurements

Magnetic susceptibility measurements were carried out on a Gouy balance at room temperature. The powdered samples were well packed into a cylindrical glass tube and suspended by a fine fibre in a homogeneous magnetic field of intensity 8.5×10^3 G, generated by an electro-current stabilizer (UNICO). A semi-micro Mettler balance was employed for suspending and weighing the samples.

The ir, Me, and ms studies were performed with CFC in H^+ form and loaded with the complex cations, $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$. In order to compare the results similar investigations were made with CFC loaded with Fe^{3+} and La^{3+} ions.

Results and Discussion

Sorption and Desorption of Complex Cations

Figure 1 presents the influence of HNO_3 and NH_4NO_3 concentrations on the distribution coefficients (K_d) of the complex cations at initial solution concentration 0.005 M. It is clear from the figure that the K_d values for the two complex cations show little change at lower acid as well as ammonium ion concentrations. Further, in separate experiments carried out at the same initial concentration of the complex cations (0.005 M), the distribution coefficients for $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$, 570 ± 15 and 117 ± 8, respectively, do not show appreciable change with the variation of initial pH of the solutions (adjusted by HNO_3 or NH_4OH) in the range 2–7, suggesting that the influence of H^+ and NH_4^+ ions on K_d values at such low concentrations is negligible. The observed levelling of the plots (Fig. 1) in lower concentration range of H^+ and NH_4^+ (particularly in case of $[Co(en)_3]^{3+}$) may be due to the saturation of CFC by complex cations. Above the concentration of 0.5 M, the influence of H^+ or NH_4^+ ions becomes dominant, resulting in the abrupt fall in K_d values (Fig. 1). The break in the curves (Fig. 1) at concentration 0.5 M is probably due to a change in the sorption behaviour of CFC caused either by the high concentrations of H^+ and NH_4^+ or by the oxidizing medium. The inhomogeneity of the exchanger may also be responsible for this effect. Since the exchanger is fairly stable (2) in the solutions of salts and mineral acids at the concentrations under study and no oxidative effect of HNO_3 is observed (8), the abrupt change in the straight

For personal use only.

line plots (Fig. 1) may be attributed to the increasing sorption competence of H^+ and NH_4^+ ions and also to the inhomogeneity of the exchanger material. This behaviour is analogous to that observed for the sorption of Cs^+ on CFC (8). Similar results have also been observed by Krtil in the case of vanadium ferrocyanide (9) and tungsten ferrocyanide (10), and by Ganzerli-Valentini *et al.* in the case of zinc ferrocyanide (11).

As none of the straight line plots in Fig. 1 has a slope equal to the valence of the complex cations (+3), the sorption of $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$ may not be solely ascribed to an ion-exchange mechanism. However, in separate experiments performed at 0.01 *M* initial solution concentration of complex cations and without adding any NH_4^+ or H^+ cations from outside, it is observed by measuring the pH of the solutions initially and after the equilibrium has been attained that, within the limits of experimental error, the major part of the uptake (90%) for both complex cations is followed by an equivalent release of H^+ ions and hence by the ion-exchange mechanism. The rest of the uptake (10%) may be due to some non-exchangeable processes like physical adsorption and co-ion inclusion.

The dependence of the extent of sorption on the initial solution concentration of complex cations has been depicted in Fig. 2, in terms of sorption isotherms. The values of saturation capacity for $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$ are 3.55 mequiv./g and 0.86 mequiv./g, respectively. The saturation capacity for $[Co(NH_3)_6]^{3+}$, within 4%, is equal to the values of saturation capacity for Cs^+ (3.70 mequiv./g) and Tl^+ (3.50 mequiv./g) determined radiometrically using ^{134}Cs and ^{204}Tl (12) and to the apparent exchange capacity of CFC (3.65 mequiv./g) determined by K–H exchange (2). This suggests that almost all the pores inside the exchanger are sufficiently large to accommodate $[Co(NH_3)_6]^{3+}$ ions and thus making all the exchanging sites accessible to it. The low saturation capacity of $[Co(en)_3]^{3+}$ is due to its larger size which does not permit its passage through the pores of narrower mesh-regions. Moreover, the $[Co(en)_3]^{3+}$ ions which have undergone exchange at the easily available exchanging sites during the initial stages of equilibration may also block the pores in CFC, thus preventing the further entry of $[Co(en)_3]^{3+}$ ions and limiting the extent of exchange to such a low value.

The desorption of complex cations by some univalent and bivalent cations has been shown in Figs. 3 and 4, respectively. It is clear from the figures that the desorption is higher for the cations of smaller hydrated sizes (13). This is in accordance to the

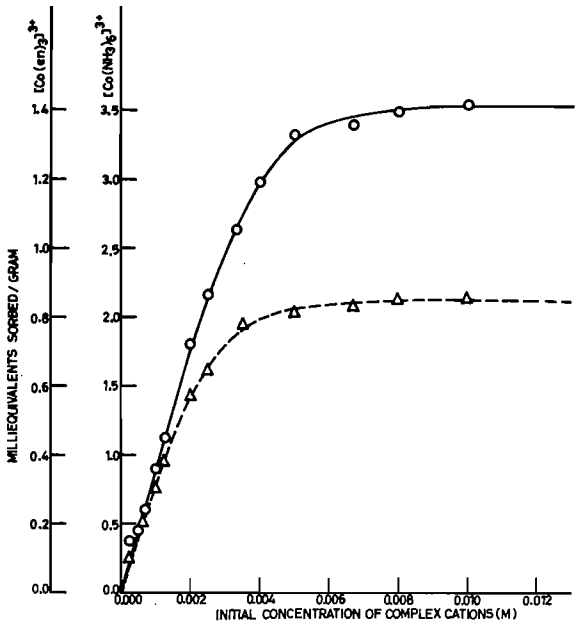

FIG. 2. Sorption isotherms of complex cations at 25°C; (○) for $[Co(NH_3)_6]^{3+}$ and (△) for $[Co(en)_3]^{3+}$.

common selectivity sequence of ion-exchangers:

$$K^+ > NH_4^+ > Ba^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+}$$

The total desorption of complex cations is not possible and much of them (35% to 55% in case of K^+

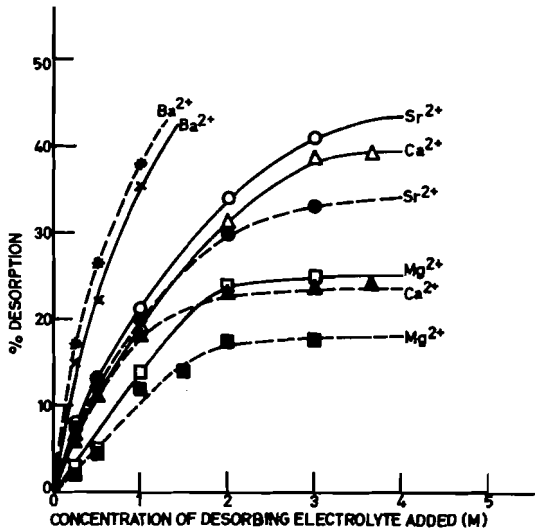

FIG. 4. Desorption of complex cations by bivalent metal ions at 25°C. Broken curves for $[Co(en)_3]^{3+}$ and solid curves for $[Co(NH_3)_6]^{3+}$.

and NH_4^+) remains in the exchanger material. Such hysteresis as well as a slow desorption are quite common with inorganic ion-exchangers (14). Further, it is quite interesting to note that among these two, the extent of desorption of $[Co(en)_3]^{3+}$ is higher for K^+, NH_4^+, and Ba^{2+} ions; however, it is less for Sr^{2+}, Ca^{2+}, and Mg^{2+} as compared to that of $[Co(NH_3)_6]^{3+}$. It can be argued here that the sorbed $[Co(en)_3]^{3+}$ cations, which block the pores in CFC, alter the pore dimensions in such a manner that the ions of hydrated sizes (13) bigger than Ba^{2+}, viz. Sr^{2+}, Ca^{2+}, and Mg^{2+}, have to encounter with the greater steric hindrance and to a certain degree their passage through the pores of inadequate mesh-regions may also be prevented, resulting in the relatively smaller extent of desorption of $[Co(en)_3]^{3+}$ as compared to that of $[Co(NH_3)_6]^{3+}$ ions.

Nature of Interaction between CFC and the Sorbed Cations

Infrared Studies

The infrared spectrum of chromium ferrocyanide in H^+ form shows absorption bands at 3400–3000, 2080, 1610, 580, 530, and 400 cm^{-1}. The broad band in the region 3400–3000 cm^{-1} is characteristic of interstitial water molecules and OH groups (15), while the band at 1610 cm^{-1} is due to HOH bending mode (15). The sharp band at 2080 cm^{-1} and another at 580 cm^{-1} are characteristic of cyanide (*4b*), and Fe—C stretching frequencies (*4b*). A strong band at 530 cm^{-1} may be assigned to bonding between chromium and oxygen which is in accordance with a similar band reported in the case of chromium(III) hydroxide gel (17). The Cr—N stretching mode, reported by Nakamoto *et al.* (18) at 444 cm^{-1}, shifts to lower frequency region, 400 cm^{-1} in the present case, thereby suggesting a weak bond formation.

In the infrared spectra of CFC loaded with $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$ cations, i.e. of CFC/$Co(NH_3)_6^{3+}$ and CFC/$Co(en)_3^{3+}$ systems, respectively, the intensity of the band at 400 cm^{-1} is significantly reduced. It may be argued that as a result of sorption of these large size complex cations, the strength of the Cr—N bond is weakened. Besides this, some new features emerged in the spectra recorded for these products. In case of CFC/$Co(NH_3)_6^{3+}$, the new peaks appeared at 1320 and 800 cm^{-1} are the high intensity peaks observed in the ir spectrum of pure $[Co(NH_3)_6]Cl_3$ complex (*4a*). Similarly, in the case of CFC/$Co(en)_3^{3+}$, the appearance of additional peaks at 1460, 1150, and 1050 cm^{-1} are due to the sorbed $[Co(en)_3]^{3+}$ ions (*4c*).

The spectra recorded for CFC loaded with Fe^{3+} and La^{3+} are identical to that observed for H^+ form. This indicates that the sorbed cations do not react chemically with CFC but are held by the electrostatic attraction forces in the matrix of the exchanger.

Mössbauer Studies

Mössbauer spectrum of the H^+ form of CFC shows only a single unsplit resonance line indicating octahedral symmetry and zero electric field gradient. This shows that the prussiate compounds (*19a*) are not formed during gel formation. In prussiate ion, e.g. in sodium nitrosyl prussiate, $Na_2[Fe^{II}(en)_5NO]$, etc., one of the cyano group is replaced by another ligand which gives rise to the quadrupole split doublet. Further, an isomeric shift of 0.16 ± 0.02 mm s^{-1} with respect to sodium nitroprusside observed in the Mössbauer spectrum of CFC indicates the existence of ferrocyanide group in the exchanger. However, the observed line-width is 0.46 mm s^{-1}, which is more than 0.23 mm s^{-1} reported for ferrous complexes (19). This is ascribed to some sort of distortion (*19b*) of the octahedral cyanide cage around Fe(II) in CFC.

Sorption of the complex cations, viz. $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$, does not affect the observed isomeric shift and the general character of the spectrum. Further, the sorption of Fe^{3+} (1.35 mequiv./g) and La^{3+} (2.90 mequiv./g) does not give rise to any new absorption peak in the Mössbauer spectrum. This also indicates that the interaction between sorbed cations and CFC is very weak.

The observed line-widths for Fe^{3+}, $[Co(NH_3)_6]^{3+}$, and $[Co(en)_3]^{3+}$ sorbed CFC are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

0.50, 0.51, and 0.57 mm s^{-1}, respectively. From this, it is concluded that the sorption of relatively larger cations causes strain in the gel structure, thereby providing some inhomogeneity at iron(II) site in the ferrocyanide ion. This argument is further supported by the thermodynamic data for the exchange of the complex cations where the observed increase in the entropies of activations (ΔS^*) have been associated with the deformations in the exchanger matrix (1).

Magnetic Susceptibility Studies

The magnetic moment (μ_{eff}) of CFC in H^+ form is 8.00 ± 0.25 BM, which may be attributed to the presence of the two ionic chromium (20) in the molecule of the exchanger, $K_6Cr_2[Fe(CN)_6]_3 \cdot 16H_2O$. Although the experimentally observed value is higher than the reported value, 3.87 BM for one Cr^{3+} ion (20), within the limits of experimental error the two are in close agreement.

The magnetic moment of CFC loaded with complex cations, viz. $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$, is the same as observed in H^+ form. Since these complex ions have zero moment (16), the same value of μ_{eff} indicates that complex cations do not undergo exchange with Cr^{3+} ions. The sorption of Fe^{3+} and La^{3+} also does not cause any change in the magnetic moment of CFC. However, in case of Fe^{3+}, which possesses five unpaired electrons, an increase in μ_{eff} value is expected. It appears that Fe^{3+} ions are sorbed on CFC as hydrocomplex, i.e. $[Fe(H_2O)_6]^{3+}$, and thus do not cause any appreciable change in μ_{eff} of the exchanger.

^{51}V FT-nmr investigations of metavanadate ions in aqueous solutions

MAHMOUD ADAM HABAYEB AND O. E. HILEMAN, JR.
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 20, 1980

MAHMOUD ADAM HABAYEB AND O. E. HILEMAN, JR. Can. J. Chem. **58**, 2255 (1980).

^{51}V-nmr chemical shifts, line widths, and area ratios obtained for various vanadium(V) species in aqueous solutions as a function of counter ion, pH, and analytical vanadium concentration changes are reported. From these data the eight vanadium(V) species shown to be present in significant amounts are identified. In the pH range 8.5 to 7.0, ^{51}V-nmr resonances were observed at 574 ppm and 582 ppm. The 574 ppm resonance is assigned to both $V_3O_9^{3-}$ and $V_4O_{12}^{4-}$ while the 582 ppm resonance has been assigned to the $V_6O_{17}^{4-}$ species. The suggestion that tetra alkyl ammonium cations stabilize $V_4O_{12}^{4-}$ species in solution is confirmed.

MAHMOUD ADAM HABAYEB et O. E. HILEMAN, JR. Can. J. Chem. **58**, 2255 (1980).

On rapporte les déplacements chimiques en rmn du ^{51}V, les largeurs des pics et les rapports de surfaces obtenus pour différentes espèces de vanadium(V) en solutions aqueuses en fonction de l'ion opposé, du pH et des changements de concentration du vanadium. A partir de ces données, on a identifié les 8 espèces de vanadium(V) présentes en quantités appréciables. On a observé, dans l'intervalle de pH allant de 8,5 à 7,0, les résonances du ^{51}V à 574 et 582 ppm. La résonance à 574 ppm est attribuée aux ions $V_3O_9^{3-}$ et $V_4O_{12}^{4-}$ tandis que la résonance à 582 ppm est attribuée à l'espèce $V_6O_{17}^{4-}$. On confirme le fait que les cations tétraalkylammonium stabilisent l'ion $V_4O_{12}^{4-}$.

[Traduit par le journal]

Introduction

Vanadium(V) speciation in aqueous solutions has been studied in detail (1–19). A variety of techniques — ranging from salt cryoscopy (1, 3) and diffusion coefficient measurements (4, 5) to potentiometric (6, 7), light scattering (9–10), ^{51}V-nmr (11–14), Raman spectroscopy (15–17), and spectrochemical measurements (20–24), have been utilized. The results of these investigations have been summarized in Fig. 1 of ref. 21 and suggest that vanadium(V) speciation is both pH and solute concentration sensitive.

There is a point of controversy, however, in the isopolyanion series $(VO_3)_n^{n-}$. Several potentiometric (6, 7) and spectrophotometric measurements (20–24) that were conducted at low solute concentration have led to the conclusion that the metavanadate ion is present in solution as the trimer "$V_3O_9^{3-}$" in the pH range of 9.0 to 7.0, while cryoscopic (1) and diffusion coefficient calculations (4) support the existence of the tetramer, "$V_4O_{12}^{4-}$". Recent Raman data (15–17) suggested the presence of a cyclic polymer, but failed to show whether this polymer is a trimer or a tetramer. Also, recent depolarized light scattering results (10) can be best explained if based on the presence of a tetramer. Finally, ^{51}V-nmr spectra (11–14) reported in the literature show two partially resolved resonances corresponding to two or more closely related species in the pH range 9.0 to 7.0. These resonances have been assigned to acyclic and cyclic $(VO_3)_n^{n-}$ type species, but to the best of our knowledge, no specific assignment of each of the two resonances has been attempted. Recently, the authors were encouraged by the report of the successful synthesis of hydrogen tetravanadate "$HV_4O_{12}^{3-}$" and hydrogen decavanadate "$H_nV_{10}O_{28}^{(6-n)-}$" anions as discrete polyanions (25). This suggests the possibility of a definitive assignment of these observed resonances.

The purpose of this work is the study of the speciation of metavanadate ions in solution as a function of pH, counter ion, and V(V) concentration using ^{51}V FT-nmr. In addition, particular attention is given to the assignment of the two resonances previously attributed to the isopolyanion series $(VO_3)_n^{n-}$.

Experimental Details

Preparation of Samples

(*a*) Aqueous sodium metavanadate solutions: isopolyvanadate stock solutions (0.25 *M*, 0.5 *M*, and 1.1 *M*) were prepared by dissolving the appropriate amounts of $NaVO_3$ as supplied (Fisher Scientific Co.) in boiling distilled water under nitrogen. The stock solutions were allowed to cool to room temperature and then were diluted to volume. Each was divided into several samples. The pH of each sample was adjusted using concentrated HCl or 4.5 *N* NaOH. The pH measurements were obtained at 298 ∓ 2 K using a Corning pH meter-130 equipped with a Fisher 13-639-51 glass electrode and Beckman 41263 reference electrode. The standard deviation in the pH values was ∓0.05. The samples were stored under N_2 at room temperature for 3–4 days before ^{51}V-nmr spectra were recorded. Check ^{51}V-nmr spectra were obtained two months later.

(*b*) $NaVO_3$–$[(CH_3)(CH_2)_3]_4NBr$ solutions: tetra-*n*-butyl ammonium bromide (16.0 g) (abbreviated as TBA-Br) (Eastman Organic Chemicals) were dissolved in 500 mL of a solution (0.0989 *M*) that contained 2.04 g of $NaVO_3$ (0.0334 *M*). This stock solution was stirred under N_2 overnight before being

For personal use only.

divided into 50-mL samples. The pH of each was adjusted by addition of concentrated HCl or 2.0 *N* NaOH.

(*c*) Preparation of $[N(C_4H_9)_4]_{6-n}H_nV_{10}O_{28}$: this compound was prepared as reported in the literature (25, 26) by dissolving either 1.1 g of V_2O_5 (J. T. Baker Chemical Co.) in 250 mL of 0.1 *N* $[(CH_3)_4NOH{\cdot}5H_2O]$ (Eastman Organic Chemicals) solution or by dissolving 1.20 g of $NaVO_3$ (Canadian Scientific Products Ltd.) in 150 mL of solution containing 6.14 g of tetra-*n* butyl ammonium chloride (Eastman Organic Chemicals) and 4.0 g of NaOH (Fisher Scientific Co.). Any residue was filtered out. The solution was stirred under N_2 for 3 days. The pH was maintained at 6.5. Acetone was added in 25 mL aliquots (a total of 200 mL) over a 2 h period. Within 24 h a yellow precipitate was observed. The supernatant liquid was decanted off. The precipitate was dissolved in distilled water and the pH was adjusted to the appropriate value using concentrated HCl or 2.0 *N* NaOH.

(*d*) Preparation of $[N(C_4H_9)_4]_3HV_4O_{12}$: $HV_4O_{12}^{3-}$ isopolyanion was prepared according to the procedure outlined in part (*c*) except that 0.56 g of $NaVO_3$ were dissolved in 100 mL of 10% tetra-*n*-butyl ammonium hydroxide (BDH) and the pH of the solution was maintained at 8.3 ± 0.2.

^{51}V-nmr Measurements

^{51}V-nmr spectra were recorded at 23.66 MHz in a magnetic field of 2.1 T using a pulse FT-nmr technique on a Bruker WH-90 spectrometer interfaced with Bruker BNC-12 data system. The ^2H-resonance of a C_6D_6 capillary (2 mm) contained in a normal 10 mm nmr sample tube provided field-frequency stabilization. Typical spectral widths of 12 kHz in 8K of data memory using a 90° pluse (30 μs) were used. Spectra were recorded using rotating, cylindrical 10 mm od samples that were referenced, externally, to neat liquid $VOCl_3$ at 298 ± 2 K. Chemical shift data were calculated in ppm with negative values in the low frequency direction relative to $VOCl_3$. The resolution of overlapping peaks and peak areas were calculated using the Nicolet-1180 Curve Analysis Program (CAP). The error associated with each chemical shift value is estimated at ±0.2 ppm in the high pH region and ±1 ppm in the low pH region. All reported line widths at half-height values ($W_{1/2}$) have an uncertainty of about ±5 Hz.

Results

A series of ^{51}V FT-nmr spectra of $NaVO_3$ solutions were recorded at various pH and V(V) concentration levels. Typical spectra for a solution containing 0.5 mol L^{-1} total V(V) as $NaVO_3$ at various pH levels are shown in Fig. 1. Figures 2 and 3 show the data obtained from aqueous metavanadate solutions containing TBA as counter ions at two pH levels, respectively.

Discussion

This section is comprised of two parts. The first is focussed on the variation in ^{51}V FT-nmr parameters — chemical shifts, resonance line widths and relative peak areas — at various V(V) molar concentrations in the pH ranges 14.0 to 10.0 and 5.0 to 1.0. The second deals with the nature and characterization of metavanadate ions in the intermediate pH range 10.0 to 5.0 using data obtained from ^{51}V FT-nmr and other related techniques. Assignment of the 574 ppm and 582 ppm resonances is also suggested in this section.

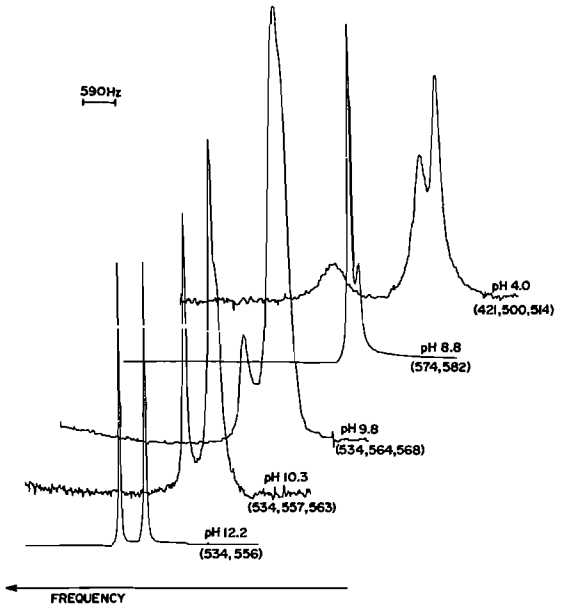

FIG. 1. Natural abundance ^{51}V-nmr spectra of 0.50 *M* metavanadate aqueous solutions at various pH levels (25°C and $I = 0.50$).

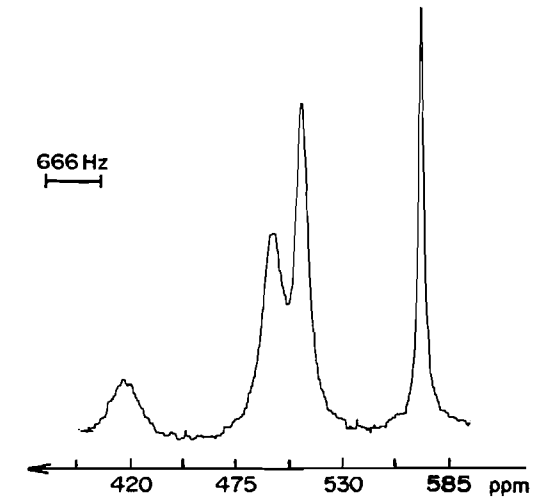

FIG. 2. ^{51}V-nmr spectrum of $V_{10}O_{28}^{6-}$ isopolyanion at pH 6.5. Resonances at 421, 496, and 512 ppm have been assigned to $V_{10}O_{29}^{6-}$ anion and the 574 ppm resonance is assigned to $V_4O_{12}^{4-}$ species. (TBA as counter ions.) $[NaVO_3] = 0.066$ *M*.

Variations of ^{51}V FT-nmr parameters with V(V) concentration change ($1.1 - 2.5 \times 10^{-1}$ *M*) and with pH change (14.0 to 10.0 and 5.0 to 1.0) observed in the present work are in general agreement with the continuous wave data reported by Howarth and Richards (11) and O'Donnell and Pope (14). Minor discrepancies are attributed to small pH variations, to the nature of the counter ions present in solution, and to the temperature at which the spectra were

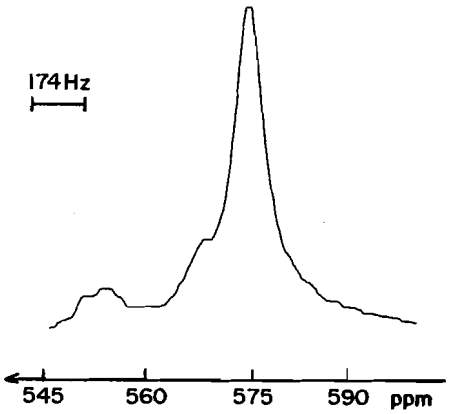

FIG. 3. ^{51}V-nmr spectrum of a metavanadate solution containing $V_4O_{12}^{4-}$ anion in the presence of TBA ions at pH = 8.3. $[NaVO_3] = 0.046\ M$.

recorded. Additionally, we are in general agreement with their arguments concerning changes in the line width and chemical shift values of the various resonances with changing pH and also with their assignments of the observed chemical shifts to the various vanadium(V) species present in solution.

We found our observed chemical shift values to be insensitive to ionic strength changes (0.25 to 0.45 (NaCl)) and to vanadium(V) concentration changes. No new resonances were observed when Na^+ was replaced with TBA as the counter ion in solution. The pH range of stability of the 574 ppm resonance, however, was extended to 10.0 from 9.7. At pH levels of 5.5 and below, only the resonances at 420, 495, and 510 ppm were observed and it was found that each chemical shift was pH sensitive. For example, the resonances shifted in the low frequency direction to 423, 507, and 527 ppm, respectively, as the pH decreased to 1.0. This sensitivity to pH changes is probably due to protonation reactions.

Our data suggest that the line widths are sensitive to pH and to vanadium(V) concentration changes. Generally, all resonances broadened significantly as the pH decreased and as the vanadium concentration increased.

The percentage total area of each ^{51}V FT-nmr resonance was dependent on the nature of the counter ion and strongly dependent on the pH at each vanadium concentration. At pH 14.0 only the 536 ppm resonance was observed. In the pH range 13.0 to 9.0, the percentage total area of the observed resonance at 534 ppm decreased from 93% to nearly zero, while the percentage total area of the resonance observed at 556 ppm increased to a maximum value of 25% at pH 10.0 and then decreased as the pH decreased to 9.0. Below pH 5.0, the intensity ratios of the three resonances observed have been reported to be 1:3:1 (11), 1:1:2 (12), and 1:2:2 (14, 27). Only the 1:2:2 ratio is in agreement with the crystalline structure of $V_{10}O_{28}^{6-}$ isopolyanion (28). The structure consists of ten VO_6 octahedra sharing edges, with two oxygen atoms in the interior of the molecule surrounded by six vanadium atoms in an octahedral geometry. This structure gives the ratio of the number of vanadium atoms occupying equivalent environments to be 2:4:4. The area ratios measured in the present work were close to 1:2:2 and were found to be independent of pH and total V(V) concentration. The ratios were sensitive to the time interval between the end of the pulse and accumulation of data points and approached 1:2:2 as the time delay decreased from 80 μs to 20 μs.

A summary of the variations of ^{51}V FT-nmr parameters with pH changes in the presence of Na^+ as a counter ion is given in Fig. 4 and in the presence of TBA is given in Fig. 5.

Variations of ^{51}V FT-nmr parameters with vanadium(V) concentration change (1.1 *M* to 0.033 *M*) and with pH change (intermediate range) observed in this work are shown in Table 1. For comparison, data from the literature (11, 12, 14) are also included in this table.

Howarth and Richards (11) observed only one resonance at 562 ppm which they assigned to $HV_2O_7^{3-}$, whereas Schneider and co-workers (12) observed resonances at 569 and 534 ppm which they assigned erroneously to the VO_3^- and $V_2O_7^{4-}$ species respectively.[1] Recently, O'Donnell and Pope (14) observed resonances at 535 ppm, 562 ppm, and 574 ppm and reported the coalescence of the latter two into a single resonance at 574 ppm as the pH decreased to 7.5. They attributed this behavior to a fast exchange between $HV_2O_7^{3-}$ and $(VO_3)_n^{n-}$ species. In our work, at pH 9.8, resonances at 534 ppm, 562 ppm, and 574 ppm were observed. As the solution was further acidified, a fourth appeared at 582 ppm — a resonance that has not been reported previously (11–14) in this pH range. The observation of partially resolved resonances at 562, 574, and 582 ppm indicates that the exchange rate between $HV_2O_7^{3-}$ and the species giving rise to the 574 and 582 ppm resonances is fairly fast.

In ref. 11, resonances were reported in the pH range 8.5 to 7.0 at 573 and 577 ppm that were as-

[1] ^{51}V-nmr chemical shifts from ref. 12 were obtained by subtracting the chemical shifts reported therein from 574 ppm. The authors of ref. 12 used the resonance of an aqueous NH_4VO_3 at pH 7.0 as a reference, while in effect, such solutions give rise to two resonances at 574 and 582 ppm relative to $VOCl_3$.

signed to $(VO_3 \cdot H_2O^-)$ and $V_3O_9^{3-}$ or $V_4O_{12}^{4-}$, respectively. In refs. 12 and 14, however, only one resonance was reported at 574 ppm and this was assigned to VO_3^- in ref. 12 and to $(VO_3)_n^{n-}$ type species in ref. 14. In the present work resonances were observed at 574 and 582 ppm. The partial resolution of these implies a fairly fast rate of interconversion between the corresponding species giving rise to the resonances.

In the pH range 6.5 to 5.5, resonances were observed at 420, 495, 510, 574, and 582 ppm. Howarth and Richards (11) observed only the first three resonances and they assigned these to the $V_{10}O_{28}^{6-}$ anion. Schneider and co-workers (12) observed the first four resonances and incorrectly assigned them to $V_3O_{10}^{5-}$ and VO_3^- species. O'Donnell and Pope (14) observed resonances corresponding to $V_{10}O_{28}^{6-}$, $(VO_3)_n^{n-}$, and a resonance at 582 ppm which they assigned to an acyclic tetramer $H_2V_4O_{13}^{3-}$. For this assignment two ^{51}V-resonances should be observed. Our observation of five resonances indicates that $H_nV_{10}O_{28}^{(6-n)-}$ species are in equilibrium with the species giving rise to the 574 ppm and 582 ppm resonances. The large separation between the sub-set of three at higher frequency and the sub-set of two at lower frequency is indicative of a slow rate of exchange between the species giving rise to each sub-set. This slow rate of exchange could be rationalized if the vanadium coordination number of the species giving rise to the 574 ppm and 582 ppm resonances is four. In contrast, metavanadate solutions containing TBA as the counter ion exhibited resonances at 420, 495, 510, 556, and 574 ppm as shown in Fig. 2. This suggests that $H_nV_{10}O_{28}^{(6-n)-}$ anion disproportionates to $V_2O_7^{4-}$ and the species corresponding to 574 ppm.

As shown in Figs. 4 and 5, the line width of the 574 ppm resonance was always less than that of the 582 ppm resonance. This points out that the species giving rise to the 574 ppm resonance is either more symmetrical or has a smaller correlation time (τ_c) or both. Also, the insensitivity of the line widths and chemical shifts of both resonances to pH variations indicates no protonation occurred as the pH decreased from 8.5 to 7.0. As seen in Figs. 6 and 7, the percentage total area of the 574 ppm resonance was always larger than that of the 582 ppm resonance and the area ratios of the 574/582 resonances were found to be sensitive to changes in pH and V(V) concentration. As depicted in Fig. 7, this ratio decreased with increasing V(V) concentration.

Based on the observations noted in the intermediate pH range, we have assigned the 574 ppm resonance to both $V_3O_9^{3-}$ and $V_4O_{12}^{4-}$ species and the 582 ppm resonance to $V_6O_{17}^{4-}$ species.

It is generally recognized that metavanadate ions are present as $V_3O_9^{3-}$ in dilute solutions ($< 0.02\ M$) (1, 24, 29) and as $V_4O_{12}^{4-}$ in more concentrated solutions (2–5, 9, 10, 30, 31). Our observation that the area of the 574 ppm resonance was the largest in both dilute solutions ($[VO_3^-] = 1.9 \times 10^{-3}\ M$) and more concentrated solutions ($[VO_3^-] = 0.25\ M$) as tabulated in Table 2 suggests that this resonance corresponds to an equilibrium between $V_3O_9^{3-}$ and $V_4O_{12}^{4-}$ species. The observation of one resonance at 574 ppm suggests that the rate of interconversion between these species is fast and this

value represents a weighted average of both resonances corresponding to $V_3O_9^{3-}$ and $V_4O_{12}^{4-}$ species.

A plot of ^{51}V-nmr chemical shifts vs. average change per vanadium atom (Z) based on the above assignments is shown in Fig. 8. This plot reveals — as pointed out elsewhere (11) — that the data fall into two distinct regions; one for vanadium species with a coordination number of four — VO_4^{3-}, $V_2O_7^{4-}$ and $H_nV_2O_7^{(4-n)-}$ — and a second for distorted octahedral species such as $V_{10}O_{28}^{6-}$ and $VO_2(H_2O)_4^+$. A discontinuity gap between these two regions is noted. The four coordinate series defines a straight line with the chemical shifts moving in the low frequency direction as Z de-

creases. The 582 ppm resonance falls on this line if it is assigned to a four coordinated $V_6O_{17}^{4-}$ species. The data of Brito (32) support the presence of such a species in solution in the intermediate pH range.

A structure that is consistent with the requirements of one vanadium environment with four coordination sites and $Z = -0.67$ that gives rise to the 582 ppm resonance is shown below.

It consists of six VO_4 tetrahedra sharing two corner oxygen atoms to form three puckered eight-membered rings. The suggestion that the structure of $V_6O_{17}^{4-}$ anion in solution is composed of two cyclic trimers joined together through an oxygen atom may be ruled out by recognizing that such a structure gives rise to two vanadium atom environments.

Our proposed structure suggests that the formation of $V_6O_{17}^{4-}$ may occur by the reaction between $V_4O_{12}^{4-}$ and $V_2O_7^{4-}$ as shown by reaction [1].

[1] $$V_4O_{12}^{4-} + V_2O_7^{4-} + 4H^+ \rightleftarrows V_6O_{17}^{4-} + 2H_2O$$

Support for this hypothesis is based on our observation that the areas of the 554 ppm and 568 ppm resonances decreased while the areas of the 574 and 582 ppm resonances increased as the total vanadium concentration increased. It should be pointed out that in metavanadate solutions (0.033 *M*) containing TBA ions — in the pH range 7.7 to 6.5 — only a resonance at 574 ppm was observed. The resonance was fairly narrow ($W_{1/2}$ = 70 ± 5 Hz) which is indicative of a symmetrical environment about the vanadium atoms. The absence of the 582 ppm resonance suggests that TBA ions preferentially stabilize the $V_3O_9^{3-}$ and/or $V_4O_{12}^{4-}$ species through ion pair formation. Fuchs *et al.* (25, 26) determined the structure of a crystalline salt prepared from similar solutions. They reported the structure to be cyclic, consisting of four VO_4 tetrahedra sharing two oxygen corners to form a puckered eight-membered ring.

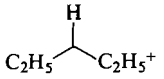
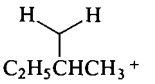
Ion molecule reactions in ethane. Thermochemistry and structures of the intermediate complexes: $C_4H_{11}^+$ and $C_4H_{10}^+$ formed in the reactions of $C_2H_5^+$ and $C_2H_4^+$ with C_2H_6



K. HIRAOKA[1] AND P. KEBARLE

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

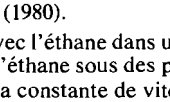


Received March 28, 1980

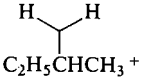
K. HIRAOKA and P. KEBARLE. Can. J. Chem. **58**, 2262 (1980).

The reactions of $C_2H_5^+$ and $C_2H_4^+$ with ethane were studied in a pulsed electron beam high ion source pressure mass spectrometer. Ethane at variable pressures in the 10–100 mTorr range in ~5 Torr hydrogen was used in experiments covering the temperature range −145 to 400°C. Reaction [7]: $C_2H_5^+ + C_2H_6 = sec\text{-}C_4H_9^+ + H_2$ was found to have a rate constant whose magnitude decreased with temperature: $k_7 = 10^{-5.12}\,T^{-2}$ (molecule^{-1} cm^3 s^{-1}). The reaction proceeds via a $C_4H_{11}^+(b)$ intermediate, which at low temperature can be stabilized and becomes the major product. The rate constant for thermal decomposition of $C_4H_{11}(b)$ by reaction [6t]: $C_4H_{11}^+(b) = sec\text{-}C_4H_9^+ + H_2$ could be measured. The activation energy was found to be $E_{6t} = 9.6$ kcal/mol. From consideration of the above data and the known ΔH_7, it was concluded that $C_4H_{11}^+(b)$ has the structure

Before dissociation to $sec\text{-}C_4H_9^+ + H_2$, this ion rearranges to



The barrier for this rearrangement is ~9.6 kcal/mol.



$C_2H_4^+$ reacts with C_2H_6 to give $C_4H_{10}^+(d)$ at low temperatures. At high temperatures $C_4H_{10}^+(d)$ becomes an intermediate in the dissociation to $sec\text{-}C_3H_7^+ + H_2$. The formation of $C_4H_{10}^+$ at low temperature has a rate constant whose magnitude decreases with temperature. The temperature dependence of the equilibrium constant K_{10} for the reaction [10]: $C_2H_4^+ + C_2H_6 = C_4H_{10}^+(d)$ could be determined. This led to $\Delta H_{10} = -15.3$ kcal/mol. The rate constant for the high temperature reaction [11]: $C_2H_4^+ + C_2H_6 = sec\text{-}C_3H_7^+ + H_2$ was $k_{11} = 8.4 \times 10^{-10} \exp(-3.9/RT$ kcal/mol) (molecule^{-1} cm^3 s^{-1}). A potential energy diagram for the reaction system is proposed. $C_4H_{10}^+(d)$ is probably a complex between $C_2H_4^+$ and C_2H_6 held largely by ion induced dipole process. Reaction [11] probably proceeds via $C_4H_{10}^+(d) \rightarrow n\text{-}C_4H_{10}^+ \rightarrow sec\text{-}C_3H_7^+ + H_2$. The barrier between $C_7H_{10}^+(d)$ and $n\text{-}C_4H_{10}^+$ is ~20 kcal/mol.

K. HIRAOKA et P. KEBARLE. Can. J. Chem. **58**, 2262 (1980).

On a étudié les réactions des ions $C_2H_5^+$ et $C_2H_4^+$ avec l'éthane dans un spectromètre de masse ayant une source d'ions à haute pression et un faisceau pulsé d'électrons. On a utilisé l'éthane sous des pressions allant de 10 à 100 mTorr et dans un intervalle de température allant de −145 à 400°C. On a trouvé que la constante de vitesse de la réaction [7]: $C_2H_5^+ + C_2H_6 = sec\text{-}C_4H_9^+ + H_2$ diminue avec la température $K_7 = 10^{-5,12}\,T^{-2}$ (molécule^{-1} cm^3 s^{-1}). La réaction se fait via un intermédiaire $C_4H_{11}^+(b)$ qui peut se stabiliser à basse température et devenir le produit majoritaire. On peut mesurer la constante de vitesse de la décomposition thermique du $C_4H_{11}^+(b)$ selon la réaction [6t]: $C_4H_{11}^+(b) = sec\text{-}C_4H_9^+ + H_2$. On a trouvé une énergie d'activation E_{6t} = 9,6 kcal/mol. En considérant les données précédentes et connaisant le ΔH_7, on en conclu que l'ion $C_4H_{11}^+(b)$ a la structure suivante

Cet ion se transpose en

avant sa dissociation en $sec\text{-}C_4H_9^+$ et H_2. La barrière d'énergie de cette transposition est d'environ 9,6 kcal/mol.

L'ion $C_2H_4^+$ réagit avec C_2H_6 pour donner $C_4H_{10}^+(d)$ à de basses températures. A des températures plus élevées, l'ion $C_4H_{10}^+$ devient un intermédiaire lors de la dissociation en $sec\text{-}C_3H_7^+ + H_2$. La constante de vitesse de la formation de $C_4H_{10}^+$ diminue avec la température. On peut déterminer l'effet de la température sur la constante d'équilibre K_{10} de la réaction [10]: $C_2H_4^+ + C_2H_6 = C_4H_{10}^+(d)$. Ceci conduit à une valeur de $\Delta H_{10} = -15,3$ kcal/mol. La constante de vitesse de la réaction [11] se produisant à haute température: $C_2H_4^+ + C_2H_6 = sec\text{-}C_3H_7^+ + H_2$ est de $k_{11} = 8,4 \times 10^{-10} \exp(-3,9/RT$ kcal/mol) (molécule^{-1} cm^3 s^{-1}). On propose un diagramme d'énergie potentielle de la réaction. L'ion $C_4H_{10}^+(d)$ est probablement un complexe entre $C_2H_4^+$ et C_2H_6 maintenu essentiellement par des forces dipolaires induites par l'ion. La réaction [11] se fait probablement par l'intermédiaire de: $C_4H_{10}^+(d) \rightarrow n\text{-}C_4H_{10}^+ \rightarrow sec\text{-}C_3H_7^+ + H_2$. La barrière entre $C_7H_{10}^+(d)$ et $n\text{-}C_4H_{10}^+$ est d'environ de 20 kcal/mol.

Introduction

Considerable information is available in the literature concerning the ion molecule reactions in ethane (see ref. 1 and references therein).

The present work concentrates on the temperature dependence of the reactions of two ions, $C_2H_5^+$ and $C_2H_4^+$, with ethane. $C_2H_6^+$, $C_2H_5^+$, and $C_2H_4^+$ are the three major ions produced by electron impact on ethane. The present work provided also information on the reactions of $C_2H_6^+$, but these did not have novel character and are therefore not discussed.

By covering a wide temperature range (−145 to 400°C) and working at a relatively high pressure of a third gas (~5 Torr H_2) information could be obtained not only on the temperature dependence of the reactions but also on some of the properties and energetics of the complexes and reaction intermediates $C_2H_5^+ \cdot C_2H_6$ and $C_2H_4^+ \cdot C_2H_6$. In this regard, the present work represents an extension of earlier results from this laboratory (2, 3) which dealt with the thermochemistry and the possible structures of $C_2H_7^+$, $C_3H_9^+$, and $C_4H_{11}^+$ formed by reactions of alkyl cations with hydrogen or suitable paraffins.

Experimental

The measurements were made with the pulsed electron beam high-pressure ion source mass spectrometer which has been described previously (4). A small amount of ethane (Phillips Research Grade) was introducted into hydrogen carrier gas (Linde U.H.P.) through a stainless steel capillary (0.3 mm × 1 m). Impurity (mainly water) was largely suppressed by passing the hydrogen through a liquid N_2 cooled molecular sieve 5 Å trap. The scatter of values of measured rate constants and equilibrium constants was within 20% when the ethane pressure was changed by a factor of more than 10.

Results and Discussion

(a) Production of Ions from Ethane

Results from four typical runs at four different temperatures are shown in Figs. 1–4. The primary ethane ions are most clearly displayed in Fig. 2 obtained at 12°C. The principal ion is $C_2H_5^+$ (~80% of total ionization). The next most abundant ion is $C_2H_4^+$ (~10%). These two major ions are probably produced by processes: [1]–[5].

[1] $e + H_2 = H_2^+ + 2e$ ~95%
$H^+ + H + 2e$ ~5%

[2] $e + C_2H_6 = C_2H_4^+$ (50%), $C_2H_3^+$ (15%), $C_2H_6^+$ (13%), C_2H_5 (10%)

[3] $H_2^+ + H_2 = H_3^+ + H$

[4] $H_2^+ + C_2H_6 = C_2H_4^+ + 2H_2$ 70%
$C_2H_6^+ + H_2$ 22%

[5] $H_3^+ + C_2H_6 = C_2H_5^+ + 2H_2$

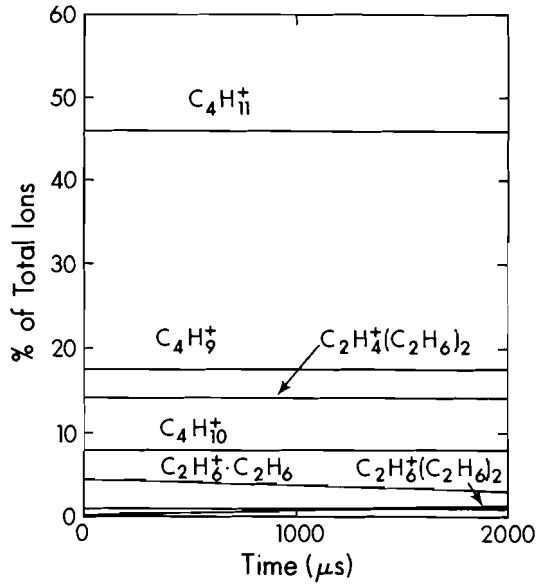

FIG. 1. Ions observed in 4 Torr H_2 containing 47 mTorr C_2H_6 at −145°C. The primary ethane ions produce "clusters" with ethane: $C_2H_6^+$ leads to $C_2H_6^+(C_2H_6)_n$, $C_2H_5^+$ leads to $C_4H_{11}^+$, some of which decomposes to $C_4H_9^+$, $C_2H_4^+$ leads to $C_4H_{10}^+$ and higher "cluster" $C_2H_4^+(C_2H_6)_2$. Reactions are very fast and therefore complete in a few microseconds.

The observed abundances of $C_2H_5^+$ and $C_2H_4^+$ in Fig. 2 can be approximately accounted as follows. Considering the preponderance of H_2 over C_2H_6, the principal ion is $C_2H_5^+$ produced by [1] → [3] → [5]. Some $C_2H_4^+$ is produced by the direct ionization of C_2H_6, process [2]. The electron impact ionization cross section of ethane is about 8 times larger than that of hydrogen and 50% of the ethane ionization leads to $C_2H_4^+$ (7). Some additional $C_2H_4^+$ is produced by [4]. This may be expected since $k_4/k_3 \approx 2.3$ (see Kim and Huntress (5) and Bowers and Elleman (6)) and 70% of the yield of [4] leads (5) to $C_2H_4^+$.

(b) Reactions $C_2H_5^+ \rightarrow C_4H_{11}^+ \rightarrow C_4H_9^+ + H_2$

The fate of the principal ion, $C_2H_5^+$, at different temperatures, can be deduced from Figs. 1–4. At the lowest temperature, −145°C Fig. 1, very fast reactions convert $C_2H_5^+$ to $C_4H_{11}^+$ and $C_4H_9^+$. The major product is $C_4H_{11}^+$. Near room temperature, 12°C Fig. 2, $C_2H_5^+$ is observed to decrease more slowly. The major product is $C_4H_9^+$, although some $C_4H_{11}^+$ is also formed. At longer reaction times ($t >$ 100 μs), the $C_4H_{11}^+$ is seen to decompose slowly to $C_4H_9^+$. The higher temperature run, 77°C Fig. 3, shows that the disappearance of $C_2H_5^+$ is much slower again, there is even less $C_4H_{11}^+$, and the $C_4H_{11}^+$ decomposes faster to $C_4H_9^+$. At the highest

For personal use only.

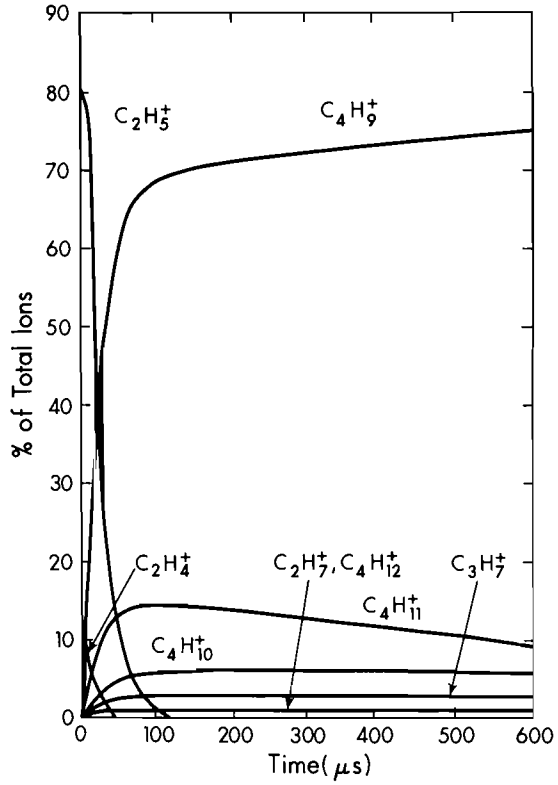

FIG. 2. Ions observed in 4 Torr H_2 containing 15 mTorr C_2H_6 at 12°C. At this temperature, the major ion $C_2H_5^+$ reacts more slowly than at −145°C. It yields mostly $C_4H_9^+$ and some $C_4H_{11}^+$. The $C_4H_{11}^+$ decomposes thermally to $C_4H_9^+$ at longer reaction times. $C_2H_4^+$ leads to $C_4H_{10}^+$ and $C_3H_7^+$.

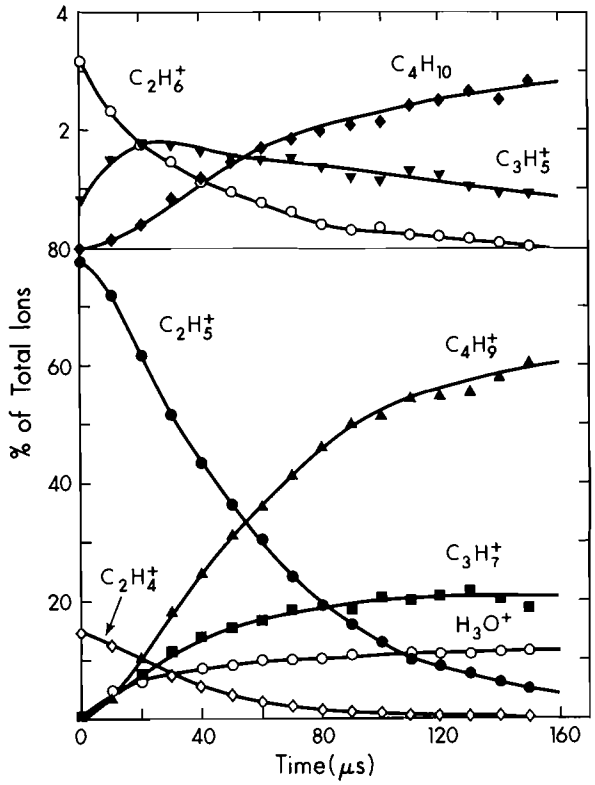

FIG. 3. Ions observed in 4 Torr H_2 containing 22 mTorr C_2H_6 at 77°C. $C_2H_5^+$ reacts more slowly at 77°C than at 12°C, major product is $C_4H_9^+$. Products of $C_2H_4^+$ are $C_4H_{10}^+$ and $C_3H_7^+$.

temperature, 352°C Fig. 4, disappearance of $C_2H_5^+$ is the slowest, $C_4H_9^+$ is the only observed product, since, presumably, the intermediate $C_4H_{11}^+$ is present at such low concentrations that it is not detected.

The observation that the rate of $C_2H_5^+$ disappearance decreases with temperature indicates that the formation of the observed $C_4H_{11}^+$ and $C_4H_9^+$ occurs via some intermediate reaction complex whose back decomposition to the initial reactants increases with temperature. A suitable reaction scheme is provided by reaction [6].

$$[6]\quad C_2H_5^+ + C_2H_6 \underset{r}{\overset{f}{\rightleftarrows}} (C_4H_{11}^+)^*$$

$$(C_4H_{11}^+)^* \xrightarrow{d} C_4H_9^+ + H_2$$

$$(C_4H_{11}^+)^* + M \xrightarrow{s} C_4H_{11}^+(b) + M$$

$$C_4H_{11}^+(b) \xrightarrow{t} C_4H_{11}^+(a) \rightarrow C_4H_9^+ + H_2$$

The $(C_4H_{11}^+)^*$ formed by [6f] is excited since its formation from $C_2H_5^+$ and C_2H_6 is exothermic. Some of the $(C_4H_{11}^+)^*$ undergoes reverse dissociation by [6r], this reverse dissociation increases with temperature. The reverse dissociation may be accompanied by hydride transfer. The hydride transfer may be made visible by using deuterium labelled compounds like C_2H_6 and C_2D_6 (see Ausloos *et al.* (8)). The $(C_4H_{11}^+)^*$ may decompose directly to $C_4H_9^+ + H_2$. This occurs to some extent even at the lowest temperature (see Fig. 1). Some of the $(C_4H_{11}^+)^*$ is stabilized by third body collisions, [6s]. At low temperatures, the stabilized $C_4H_{11}^+(b)$ does not decompose (Fig. 1). At higher temperatures, the $C_4H_{11}^+(b)$ undergoes thermal decomposition [6t], see Figs. 2, 3. The significance of the notation $C_4H_{11}^+(b)$ and $C_4H_{11}^+(a)$ will be explained later.

Plots of log $[C_2H_5^+]$ versus time were made for a series of runs in which the H_2 pressure was approximately constant but for which the temperature and ethane concentration was varied. It was found that the rate of disappearance of $C_2H_5^+$ was first order in the C_2H_6 concentration. In the higher temperature range 70–350°C, the observed $C_4H_{11}^+$ concentration was extremely low. For these condi-

For personal use only.

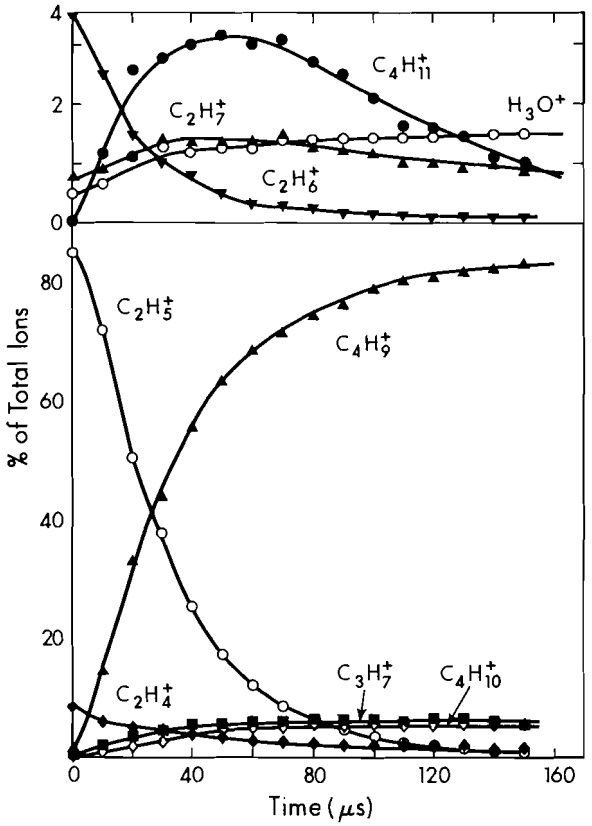

FIG. 4. Ions observed in 4 Torr H_2 containing 52 mTorr of C_2H_6 at 352°C. $C_2H_5^+$ reacts slowly to yield $C_4H_9^+$, concentration of $C_4H_{11}^+$ intermediate too low to detect. $C_2H_4^+$ leads to $C_3H_7^+$ and some small concentration of stable $C_4H_{10}^+$.

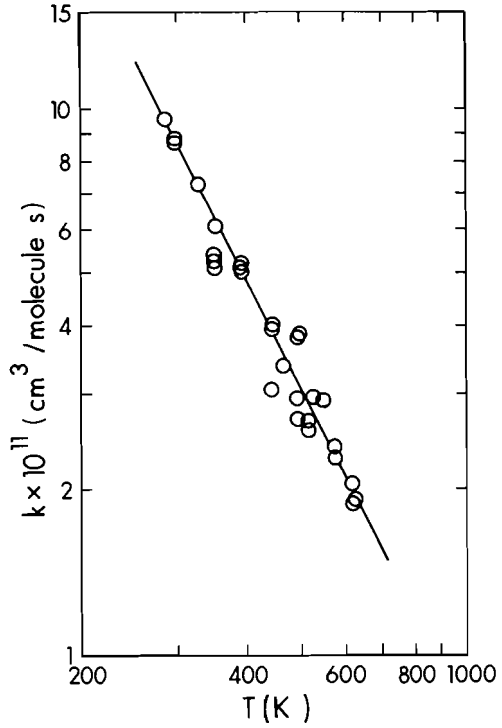

FIG. 5. Plot of rate constant k_7 for reaction [7]: $C_2H_5^+ + C_2H_6 = C_4H_9^+ + H_2$. From rate of disappearance of $C_2H_5^+$ in temperature region where concentration of $C_4H_{11}^+$ intermediate is very low. Reaction shows negative temperature dependence which can be expressed as $k_7 = 10^{-5.12}\,T^{-2}$ (cm^3 molecule^{-1} s^{-1}).

tions the disappearance of $C_2H_5^+$ can be represented by reaction [7].

[7] $C_2H_5^+ + C_2H_6 = C_4H_9^+ + H_2$

Rate constants k_7, obtained from log $[C_2H_5^+]$ versus time plots in this temperature range, are shown in Fig. 5 which is a plot of log k_7 versus log T. A straight line is obtained which defines eq. [8].

[8] $k_7 = 10^{-5.12}\,T^{-2}$ (cm^3 molecule^{-1} s^{-1})

Bennett *et al.* (1) have determined previously k_7 at two different temperatures, $k_7 = 2.5 \times 10^{-10}$ at 189 K and $k_7 = 5 \times 10^{-11}$ at 410 K. Equation [8] predicts, in good agreement, $k_7 = 2.2 \times 10^{-10}$ and $k_7 = 4.5 \times 10^{-11}$ (all values in molecule^{-1} cm^3 s^{-1}) for the same two temperatures.

The negative temperature dependence of [7] is typical for a reaction which proceeds via an excited intermediate, i.e. $(C_4H_{11}^+)^*$, whose reverse reaction to $C_2H_5^+ + C_2H_6$ [6r] increases faster with temperature than the forward decomposition; [6d] and [6s] followed by [6t].

The rate of the thermal decomposition of $C_4H_{11}^+(b)$, i.e. reaction [6t] could be determined in the temperature range 12°C to 70°C. At these temperatures $C_4H_{11}^+$ is formed and decomposes (see Figs. 2 and 3). A series of runs in this temperature range provided the data for the determination of the rate constants k_{6t}. An Arrhenius plot of k_{6t} is shown in Fig. 6. Actually two plots are given in Fig. 6 because of a certain ambiguity in the evaluation of k_{6t}. In one treatment of the data, k_{6t} was obtained by plotting log $[C_4H_{11}^+]$ versus t at long reaction times. This treatment is fully justified for conditions like those in Fig. 2 where the production of $C_4H_{11}^+$, from $C_2H_5^+$, is finished in a short time. However, at higher temperatures (see Fig. 3) the production of $C_4H_{11}^+$ is slower, while the decomposition is faster. This means that practically over all the observed time, $C_4H_{11}^+$ is produced, by [6f, s], and decomposes by [6t], so that one must treat $C_4H_{11}^+$ as an intermediate in the consecutive sequence $C_2H_5^+ \rightarrow C_4H_{11}^+ \rightarrow C_4H_9^+$. The steeper Arrhenius line in Fig. 6 was obtained by treating the high temperature concentrations as a consecutive reaction. The true temperature dependence of k_{6t} probably lies somewhere between the two plots.

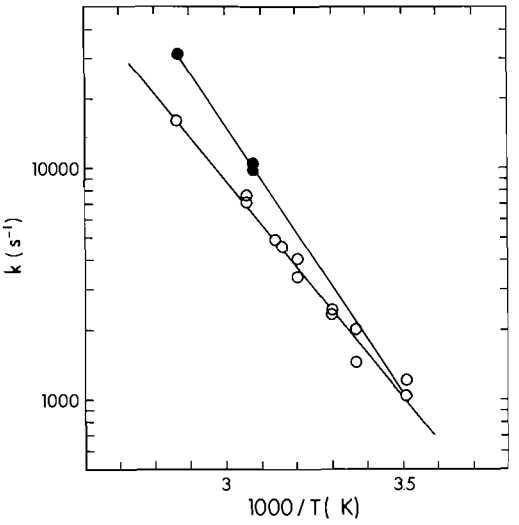

FIG. 6. Arrhenius plot of rate constant k_{6t} for thermal decomposition: $C_4H_{11}^+ \rightarrow C_4H_9^+ + H_2$. Depending on treatment of data (see text), two activation energies can be obtained, the lesser slope leads to 8.6 kcal/mol, the steeper slope to 10.6 kcal/mol.

Therefore the activation energy E_{6t} should be between the two slopes of the plots, i.e. $8.6 < E_{6t} < 10.6$ kcal/mol (see Fig. 6).

A potential energy diagram for the reaction system [6] is shown in Fig. 7. The diagram takes into account that the overall reaction to $C_4H_9^+$ has no activation energy and has a negative temperature dependence. The potential energy barrier 9.6 kcal/mol is based on the average activation energy E_{6t} from Fig. 6. The exothermicity of reaction [7] shown in the potential energy diagram as 20.8 kcal/mol was calculated using the following literature data: $\Delta H_f(C_2H_5^+) = 219$ kcal/mol (9), $\Delta H_f(sec\text{-}C_4H_9^+) = 178$ kcal/mol. This last value is based on the results of Lossing and Maccoll (10), but the enthalpy was reduced by 5 kcal/mol.[2] We have assumed that the $C_4H_9^+$ formed in reactions [6], [7] is $sec\text{-}C_4H_9^+$, following Ausloos *et al.* (8) who on the basis of neutral product analysis and deuterium labelling deduced this structure for the ion formed from $C_2H_5^+$ and C_2H_6. The well depth of 13 ± 3 kcal/mol for the $C_4H_{11}^+(b)$ compound is a somewhat arbitrary number. In earlier work (3), it was found that $\Delta H = -6.6$ kcal/mol for the reaction $C_2H_5^+ + CH_4 = C_3H_9^+$ (see Fig. 7, *II*). One can expect that the reaction $C_2H_5^+ + C_2H_6 = C_4H_{11}^+$ should be considerably more exothermic since the Lewis basicity of ethane should be much larger than that of methane. This is suggested by the Brönsted acidities, i.e. proton affinities which are: $PA(CH_4) = 127$ kcal/mol, $PA(C_2H_6) = 140$ kcal/mol (11). Furthermore, since reaction [7] was found to have no activation energy, the well depth in Fig. 7, *I* must be deeper than the 9.6 kcal/mol potential energy barrier. On the basis of these considerations we chose 13 ± 3 kcal/mol for the well depth.

The potential energy diagram of a related system studied earlier (3) is shown in Fig. 7, *II*. This is reaction [9].

[9] $C_2H_5^+ + CH_4 \rightleftarrows C_3H_9^+ \rightarrow C_3H_7^+ + H_2$

The rate for the reaction $C_2H_5^+ + CH_4 = C_3H_7^+ + H_2$ was found to increase with temperature. This increase corresponded to an activation energy of 2.5 kcal/mol. The equilibrium $C_2H_5^+ + CH_4 = C_3H_9^+(b)$ proved measurable. The temperature dependence of the equilibrium constant gave $\Delta H = -6.6$ kcal/mol. This is the well depth shown in Fig. 7, *II*. The potential energy barrier of 9.1 kcal/mol was obtained by adding the activation energy of 2.5 kcal/mol to the well depth 6.6 kcal/mol. For the present system, experimental conditions could not be found for which the equilibrium $C_2H_5^+ + C_2H_6 = C_4H_{11}^+$ could be observed. This is in line with the potential energy diagram in Fig. 7, *I* which shows a smaller internal potential barrier for the dissociation to $C_4H_9^+ + H_2$ that the well depth which corresponds to the barrier for back dissociation $C_4H_{11}^+ \rightarrow C_2H_5^+ + C_2H_6$. It is interesting to note that the internal barriers for the two systems in Fig. 7 are quite similar, i.e. both around 9 kcal/mol. In earlier work (2), it was found that $C_2H_5^+$, $sec\text{-}C_3H_7^+$, and $t\text{-}C_4H_9^+$ form only very weakly bonded complexes with H_2. These complexes were assigned the structures **A** (see Fig. 7). The structures in which the bonding comes about from the alkyl cation interacting with the electrons of a C—H bond (see Fig. 7) were called structures **B**. In analogy with that earlier work (2), we assign the $C_4H_{11}^+(b)$ ion of reaction [6] a **B** type structure. The weakly bonded $C_4H_{11}^+(a)$, precursor in the dissociation to $sec\text{-}C_4H_9^+ + H_2$ in the potential energy diagram Fig. 7, *I*, is assumed to have structure **A**. With these assignments, the barriers of ~9 kcal/mol in Fig. 7, *I* and *II* turn out to represent the barriers for rearrangement from structures **B** to structures **A**. We associate structures **B** as the precursors for dissociation to an alkyl cation and an alkane and as intermediates in hydride transfer reactions like $C_2H_5^+ + C_2H_6 = C_2H_6 + C_2H_5^+$. On the other hand, structures **A** are precursors to the dissociation to an alkyl cation and H_2.

[2]Houle and Beauchamp (9) found an I_p for $sec\text{-}C_3H_7$ radical that was 5 kcal/mol lower than that measured by Lossing and Maccoll (10). We have assumed that a similar difference exists also between the Lossing and Maccoll value for $sec\text{-}C_4H_9^+$ and the true value.

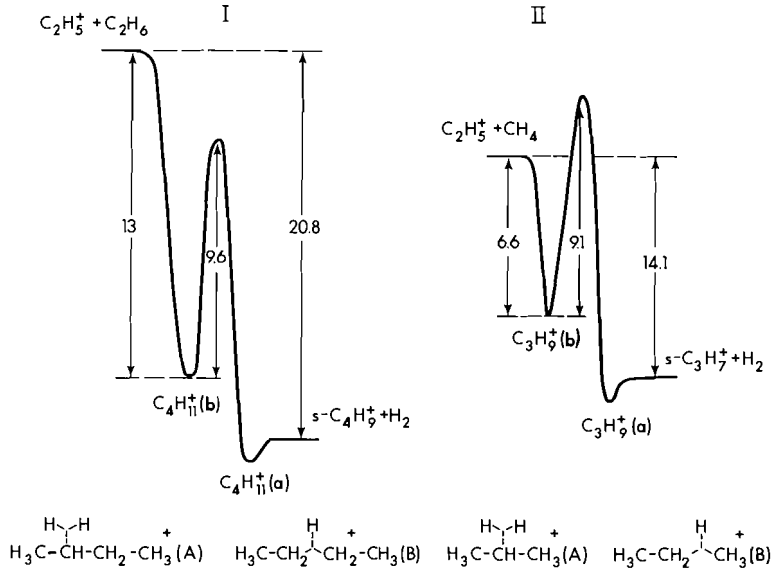

FIG. 7. Potential energy diagrams. Values given are in kcal/mol. *I*. Diagram for reaction system [6]. For origin of numbers see text. $C_4H_{11}^+(b)$ is suggested to have structure **B** and $C_4H_{11}^+(a)$ structure **A**. The barrier of 9.6 kcal/mol then corresponds to energy required for rearrangement **A** → **B**. *II*. Diagram for reaction $C_2H_5^+ + CH_4 \rightarrow C_3H_9^+(b) \rightarrow C_3H_9^+(a) \rightarrow sec\text{-}C_3H_7^+ + H_2$. From earlier work (3). Suggested structures for $C_3H_9^+(a)$ and (b) given above. The **A** structures are loose complexes of the alkyl cation and H_2. These species are of lower energies than the **B** species, however, they dissociate very easily to the alkyl cation and H_2, thus they are considered as the immediate precursors in the dissociation of a protonated alkane, to H_2 + alkyl$^+$. The **B** species behave as complexes of an alkyl cation and an alkane, i.e. ($C_2H_5{\cdot}CH_4^+$ and $C_2H_5^+{\cdot}C_2H_6$). They may be considered also as intermediates in hydride transfer reactions.

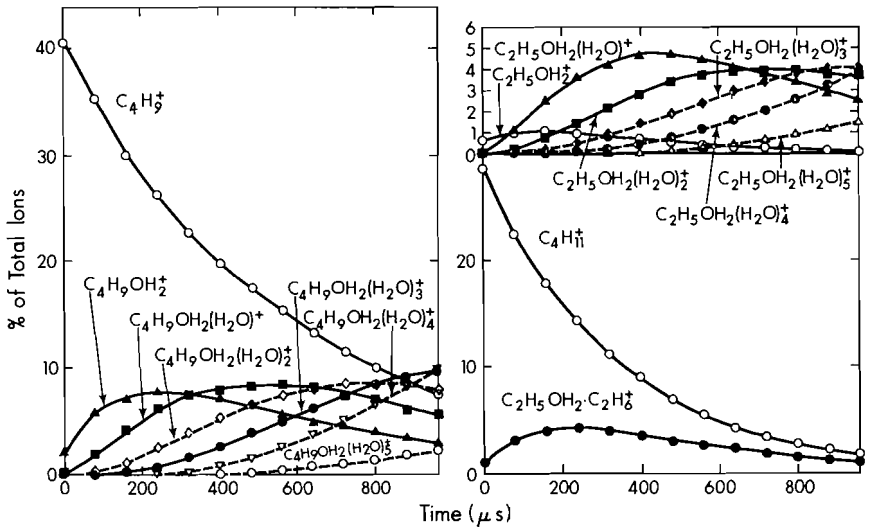

FIG. 8. Behavior of $C_4H_9^+$ and $C_4H_{11}^+$ on addition of traces of water, temperature −80°C, 4 Torr H_2, 55 mTorr C_2H_6.

Some experiments were made in which traces of water were added to the gas mixture. Typical results are shown in Fig. 8, *I* and *II*. Part *I* shows the disappearance of $C_4H_9^+$ and the resulting hydrates. Earlier work (12) from this laboratory showed that the monohydration of alkyl cations R^+ leads to the corresponding protonated alcohols ROH_2^+. Therefore the hydrates of *sec*-$C_4H_9^+$ are expected to correspond to hydrates of *sec*-butyl alcohol, $s\text{-}C_4H_9OH_2^+(H_2O)_n$. In all hydration experiments, it was found that the decrease of $C_4H_9^+$ was almost completely accounted for by the increase of $C_4H_9OH_2^+(H_2O)_n$. For example after 960 μs the decrease of $C_4H_9^+$ is 34% while the increase of corresponding hydrates is 35% (see Fig. 8).

The hydration reaction of $C_4H_{11}^+$ leads mostly to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the formation of $C_2H_5OH_2^+(H_2O)_n$. $C_4H_{11}\cdot H_2O^+$ is formed early but decreases with time. Only about two thirds of the decrease of $C_4H_{11}^+$ are accounted for by $C_4H_{11}H_2O^+$ and $C_2H_5OH_2(H_2O)_n^+$. The "missing" one third could be accounted for by the observed appearance of proton hydrates $H^+(H_2O)_n$. Similar results were observed in hydration experiments undertaken at different temperatures (−47, −65, −75°C).

It was suggested above that the $C_4H_{11}^+(b)$ has structure **B** (Fig. 7). This corresponds to an *n*-C_4H_{10} protonated on the central C—C bond. The proton affinities of the C—C protonated ethane and propane determined earlier (2) were: ~145 kcal/mol and ~152.8 kcal/mol.[3] From these values one can estimate a proton affinity for the central bond of *n*-butane of about 155 kcal/mol. This value is considerably lower than the $PA(H_2O)$ = 175 kcal/mol.[3] Proton transfer from $C_4H_{11}^+(b)$ to water is therefore an exothermic and likely reaction channel leading to the observed $H^+(H_2O)_n$. Ausloos and co-workers (8), in their study of the neutral products of the radiolysis of ethane, found *n*-butane as a product and suggested that it was formed by proton transfer from $C_4H_{11}^+$. The present results are consistent with the above finding. Thus we see that the $C_4H_{11}^+(b)$ is sufficiently butane-like to undergo proton loss and yield butane. On the other hand, the representation as a complex of $C_2H_5^+$ and C_2H_6 is also a valid partial description, since the reaction of water with $C_4H_{11}^+(b)$ leads largely to formation of $C_2H_5OH_2^+(H_2O)_n$, i.e. water, displaces ethane in the $C_4H_{11}^+(b)$ complex.

(c) Reactions $C_2H_4^+ + C_2H_6 = C_4H_{10}^+ \rightarrow C_3H_7^+ + CH_3$

At the lowest temperatures (−145°C, Fig. 1), $C_2H_4^+$ reacts with C_2H_6 to form aggregates $C_2H_4^+(C_2H_6)_n$. The ion with $n = 1$, $C_4H_{10}^+$ becomes the major product as temperature is increased to about 70°C (see Figs. 2 and 3). Around this temperature, the conversion of part of the $C_2H_4^+$ to $C_3H_7^+$ becomes noticeable. Unfortunately the exact amount of $C_3H_7^+$ originating from $C_2H_4^+$ cannot be established, since a small amount of $C_3H_7^+$ may be produced also from the reaction of $C_2H_5^+$ with C_2H_6. At 70°C the yields of $C_3H_7^+$ and $C_4H_{10}^+$ from $C_2H_4^+$ are of similar magnitude. At higher temperatures, the yield of $C_3H_7^+$ increases rapidly relative to that of $C_4H_{10}^+$. From 170°C to 352°C, the disappearance of $C_2H_4^+$ could be almost completely accounted for by the formation of $C_3H_7^+$, although a small amount of $C_4H_{10}^+$, ca. 15% of the initial $C_2H_4^+$, was formed even at the highest temperature (see Fig. 4).

The intensity ratio $C_2H_4^+/C_4H_{10}^+$ was observed to become constant at longer reaction times in the temperature range 45–80°C. It was assumed that this was due to establishment of the equilibrium [10].

[10] $C_2H_4^+ + C_2H_6 + M = C_4H_{10}^+(d) + M$

A number of runs were made in that range and the equilibrium constant K_{10} determined. A van't Hoff plot of the data is shown in Fig. 9. The plot leads to $\Delta H_{10} = -15.3 \pm 3$ kcal/mol and $\Delta S_{10}^0 = -21 \pm 4$ cal/deg.

The rate of $C_2H_4^+$ disappearance at higher temperatures, where the dominant reaction product was $C_3H_7^+$, was used to evaluate the rate constant for reaction [11].

[11] $C_2H_4^+ + C_2H_6 = C_3H_7^+ + CH_3$

k_{11} was found to increase with temperature. An Arrhenius plot of k_{11} is shown in Fig. 10. The straight line leads to a pre-exponential factor $A_{11} = 8.4 \times 10^{-10}$ molecule^{-1} cm^3 s^{-1} and an activation energy $E_{11} = 3.9$ kcal/mol.

The formation of $C_4H_{10}^+$ from $C_2H_4^+ + C_2H_6$,

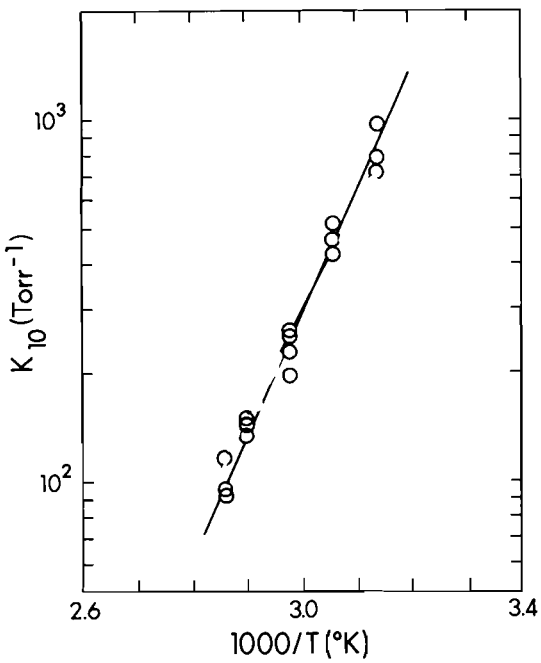

FIG. 9. van't Hoff plot of equilibrium constant K_{10} for reaction [10]: $C_2H_4^+ + C_2H_6 = C_4H_{10}^+(d)$ leads to $\Delta H_{10} = -15.3$ kcal/mol $\Delta S^0_{10} = -21$ cal/deg mol. $C_4H_{10}^+(d)$ is believed to be a complex between $C_2H_4^+$ and C_2H_6 which is held largely by ion-induced dipole forces.

[3] From ref. 2 and ref. 10 but corrected upwards by 5 kcal/mol, see Houle and Beauchamp (9).

For personal use only.

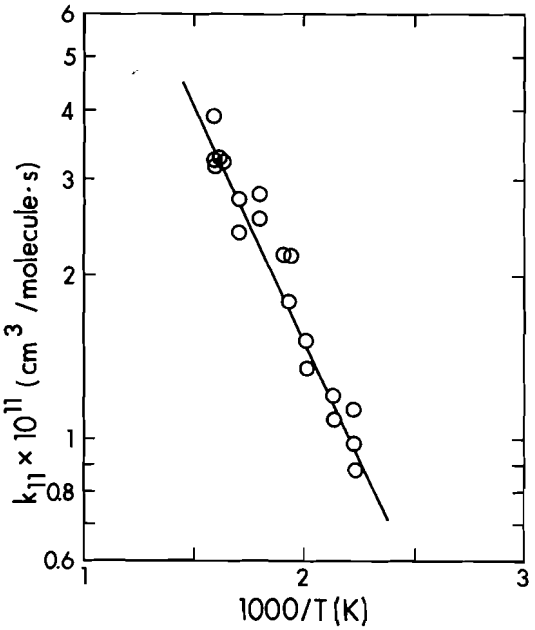

FIG. 10. Arrhenius plot of rate constant for reaction [11], $C_2H_4^+ + C_2H_6 = sec\text{-}C_3H_7^+ + CH_3$. Straight line obtained gives: $k_{11} = A \exp(-E_{11}/RT)$ with $A = 8.4 \times 10^{-10}$ molecule^{-1} cm^3 s^{-1} and $E_{11} = 3.9$ kcal/mol.

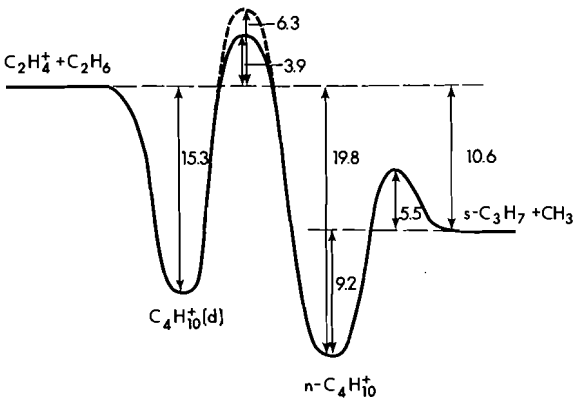
i.e., reaction [10], was first observed by Bennett *et al.* (1). These authors also reported on reaction [11], which had been observed earlier. Bennett *et al.* determined the rate constant for the overall disappearance of $C_2H_4^+$ at two temperatures 189 and 410 K. Expressed as second order rate constants their results were $K(189\ K) \approx 2 \times 10^{-10}$, $K(410\ K) \approx 0.1 \times 10^{-10}$ (molecule^{-1} cm^3 s^{-1}). According to our observations the temperature range 189 to 410 K covers two different regions. The low temperature region up to ~320 K where reaction [10] dominates. This reaction has a negative temperature dependence as found by Bennett *et al.* but is *third* order. An upper temperature region exists above 350 K where the second order reaction [11] dominates. This reaction rate *increases* with temperature. Thus no direct comparison with the rate constants quoted by Bennett *et al.* (1) can be made. In fact the results of Bennett *et al.* (Fig. 2, ref. 1) seem to indicate that in the experiments of Bennett *et al.* there was also a decrease of $C_2H_4^+$ rate of disappearance between 327 and 410 K. However the authors did not quote a rate constant for the run obtained at 327 K.

The potential energy diagram shown in Fig. 11 represents a rationalization of the experimental observations of the present work. The well of −15.3 kcal/mol for the formation of $C_4H_{10}(d)$ corresponds to ΔH_{10} obtained from the equilibrium measurements of reaction [10]. The barrier of 3.9 kcal/mol is the measured activation energy for the formation of $C_3H_7^+$ by reaction [11]. The rest of the data are based on information from the literature: $\Delta H_f(s\text{-}C_3H_7^+) = 187.3$ kcal/mol and $\Delta H_f(CH_3) = 34.9$ kcal/mol were taken from Houle and Beauchamp (9). $\Delta H_f(C_2H_4^+) = 253$ kcal/mol and $\Delta H_f(n\text{-butane}^+) = 213$ kcal/mol are from the NBS compilation (13). These data allow the calculation of the well of 19.8 kcal/mol for the formation of n-butane$^+$ from $C_2H_4^+$ and C_2H_6 and the exothermicity of 10.6 kcal/mol for the reaction $C_2H_4^+ + C_2H_6 = s\text{-}C_3H_7^+ + CH_3$. The potential energy barrier of 5.5 kcal/mol (see Fig. 11) was obtained from the difference of the appearance potential $AP(C_3H_7^+, n\text{-}C_4H_{10}) = 11.18$ eV (Chupka and Berkovitz, ref. 14) and the calculated energy for the dissociation $n\text{-}C_4H_{10} = s\text{-}C_3H_7^+ + CH_3 + e$, $\Delta H = 10.94$ eV obtained from the quoted data of Houle and Beauchamp (9). The barrier of 6.3 kcal/mol (see Fig. 11) was obtained from the difference of the appearance potential $AP(C_2H_4^+, n\text{-}C_4H_{10}) = 11.65$ (Chupka and Berkovitz, ref. 14) and $\Delta H = 11.38$ eV for the process $n\text{-}C_4H_{10}^+ = C_2H_4^+ + C_2H_6 + e$ calculated from $\Delta H_f(C_2H_4^+) = 253$ kcal/mol quoted above.

The species $C_4H_{10}^+(d)$ involved in equilibrium [10] is assumed not to be identical to $n\text{-}C_4H_{10}^+$ on the basis of the following considerations. Had $C_4H_{10}^+(d)$ been equal to $n\text{-}C_4H_{10}^+$, equilibrium [10] would not have been observed since $n\text{-}C_4H_{10}^+$ excited by some 15–20 kcal/mol dissociates predominantly to $C_3H_7^+ + CH_3$. This is evident from the breakdown graph for $n\text{-}C_4H_{10}^+$ obtained by Chupka and Berkovitz and others (14–16). Also, equilibrium [10] predicts a well for $C_4H_{10}^+(d)$ which is ~15 kcal/mol while the well of $n\text{-}C_4H_{10}^+$ is ~20



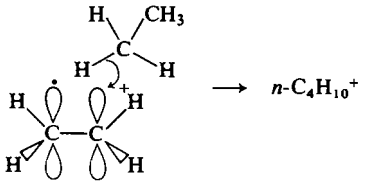


FIG. 11. Potential energy diagram showing intermediates in reactions of $C_2H_4^+ + C_2H_6$. Numbers give energies in kcal/mol. Data provide also a partial potential energy diagram for the decomposition of excited $n\text{-}C_4H_{10}^+$.

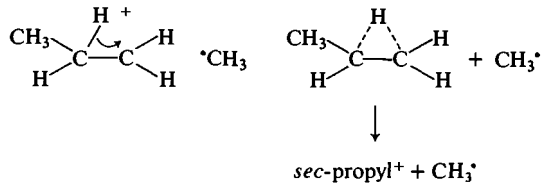
kcal/mol. The well of n-$C_4H_{10}^+$ may actually be even deeper than 20 kcal/mol. The onset of ionization of n-$C_4H_{10}^+$ from n-C_4H_{10} is very gradual (14), therefore the true adiabatic ionization potential might be a few kcal/mol lower than the value (13, 14) used for the evaluation of $\Delta H_f(n\text{-}C_4H_{10}^+)$. This expectation is also in line with the earlier mentioned observation that a small amount of relatively stable $C_4H_{10}^+$ was observed in our experiments at higher temperatures where most of the reaction of $C_2H_4^+$ with C_2H_6 leads to $C_3H_7^+ + CH_3$. This relatively stable $C_4H_{10}^+$ may be n-$C_4H_{10}^+$ formed by collisional stabilization of reaction product passing from left to right over the 3.9–6.3 kcal/mol activation barrier in Fig. 11. The formation of stabilized n-$C_4H_{10}^+$ may be expected to occur also at lower temperatures where $C_4H_{10}^+(d)$ is also formed. No distinction between the two species can be obtained by mass analysis; however, experiments in which traces of water were added, i.e. experiments like those shown in Fig. 8, showed that although most of the $C_4H_{10}^+$ was converted to $C_2H_9^+(H_2O)_n$, some small part stayed as $C_4H_{10}^+(H_2O)_n$. It is likely that the precursor of $C_2H_4^+(H_2O)_n$was $C_4H_{10}^+(d)$ while that of $C_4H_{10}^+(H_2O)_n$ was n-$C_4H_{10}^+$.



The structure and type of bonding in $C_4H_{10}^+(d)$ is unknown. One may consider a "physical" type of $C_2H_4^+ \cdot C_2H_6$ complex held together by ion induced dipole forces. This is in line with the easy conversion of $C_4H_{10}^+(d)$ to $C_2H_4^+(H_2O)$, but the binding energy $-\Delta H_{10} = 15.3$ kcal/mol appears rather large for such a complex.

The barrier 3.9–6.3 kcal/mol (Fig. 11) must be associated with the insertion of $C_2H_4^+$ into a C—H bond of C_2H_6 to produce n-$C_4H_{10}^+$. One may visualize such an insertion to occur by the electrophilic attack of an sp^2 hybridized $\dot{C}H_2$—CH_2^+ on the C—H bond of ethane as shown below:

Evidently the preparation of $\dot{C}H_2$—$\overset{+}{C}H_2$ as well as the formation of the intermediate will require energy so that the presence of an energy barrier of 3.9–6.3 kcal/mol for the reaction is not surprising.

The dissociation of n-$C_4H_{10}^+$ to sec-$C_3H_7^+ + CH_3$ occurs also in the electron impact fragmentation of n-C_4H_{10}. Wolkoff and Holmes (17), on the basis of the mass spectra of isotopically substituted n-butanes, have established that the methyl group comes mostly from terminal carbon of the n-butane$^+$. Therefore one may assume that the dissociation occurs via the intermediate shown below:

Prior to the appearance of the thermochemical data of Houle and Beauchamp (9), the dissocation of n-$C_4H_{10}^+$ to s-$C_3H_7^+ + CH_3$ was assumed to proceed without an activation energy barrier (see for example ref. 17). This assumption is not really plausible considering the requirement of a 1–2 hydrogen shift as indicated in process [13] above. The 5.5 kcal/mol barrier (Fig. 11) predicted by the modern thermochemical data (9) is a more believable result.

Crown ether catalysis of decarboxylation and decarbalkoxylation of β-keto acids and malonates: a synthetic application

DUNCAN H. HUNTER,[1] VIJAY PATEL, AND RICHARD A. PERRY
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received May 20, 1980

DUNCAN H. HUNTER, VIJAY PATEL, and RICHARD A. PERRY. Can. J. Chem. **58**, 2271 (1980).

The effect of 18-crown-6 ether on the decarboxylation rates of the sodium and potassium salts of 3-camphor carboxylic acid **1** and of 1-carbomethoxy-1-carboxycyclohexane **2** was studied. For **2** the K-18C6 salt reacted ca. 10^4 times faster than the parent acid. This remarkable difference in reactivity was used in developing a one-pot, two-step procedure for decarbalkoxylation of malonic esters. This procedure was then applied to a range of malonates, β-keto esters, and an α-cyano ester. The effect of 15C5, other cations, and good nucleophiles was also studied.

DUNCAN H. HUNTER, VIJAY PATEL et RICHARD A. PERRY. Can. J. Chem. **58**, 2271 (1980).

On a étudié l'effet de l'éther 18-couronne-6 sur la vitesse de décarboxylation des sels de sodium et de potassium de l'acide carboxylique-3 camphre **1** et du carbométhoxy-1 carboxy-1 cyclohexane **2**. Dans le cas du composé **2**, le sel K-18C6 réagit environ 10^4 fois plus vite que celui de l'acide apparenté. On a utilisé cette grande différence de réactivité pour développer une méthode en deux étapes et dans le même récipient permettant de décarboxyler des esters maloniques. On a appliqué cette méthode sur un certain nombre de malonates de β-céto esters et d'α-cyanoesters. On a également étudié l'effet du 15C5, d'autres cations et de bons nucléophiles.

[Traduit par le journal]

A prior study of the catalytic effect of crown ethers upon the rate of decarboxylation of carboxylate salts (1) revealed the importance of a number of governing factors among which was the stability of the resultant carbanion (R^-). It was found that if the corresponding hydrocarbon (RH) had a pK_a of ca. 30 or less, decarboxylation occurred under fairly mild conditions ($\leq 100°C$). Of the various acidifying groups which can provide a pK_a of less than 30, the carbonyl group occurs in a large number of compounds. This led us to look at the effect of crown ethers on the decarboxylation of both β-ketoacids and malonic acids with a view to synthetic applications.

Decarboxylation

Two carboxylic acids with β-carbonyl groups were chosen for the study of the effect of counterion on the rate of decarboxylation. Of these two the camphor-carboxylic acid **1** purchased was a mixture of *exo* and *endo*-isomers with the *endo*-CO_2H predominating. It was used as such without noticeably affecting our rate measurements. The 1-carbomethoxy-1-carboxycyclohexane **2** was prepared as described in the Experimental. The salts of both were prepared by titration and by lyophilization.

The rates of decarboxylation were measured for **1** and **2** and for their sodium and potassium salts in refluxing dioxane both in the absence and presence of 18-crown-6 ether (18C6). Benzene and tetrahydrofuran were used also to determine the sensitivity of rate to solvent. These rate data, expressed in terms of half-lives from a first order analysis are presented in Table 1. While these data show trends similar to those obtained earlier with triphenylacetates, the most dramatic comparison is of the acid forms of **2** and its potassium-crown ether complex salt form. The rate of decarboxylation changed by about 10^4 (250 000 min for **2**-H and 16 min for **2**-K,CE). This should be contrasted with the decarboxylation of **1** where the corresponding rate ratio is 20. Thus although the acid form of the malonate, **2**-H, decarboxylates much more slowly than the β-ketoacid, **1**-H, the K,CE salts react at almost the same rate. It is this dramatic rate enhancement that encouraged us to develop a crown ether assisted route for decarboxyalkylations applied, in particular, to the malonic ester synthesis as described in the following section.

The mechanism of decarboxylation of β-keto acids has received much attention and is thought to proceed through a cyclic state (for a recent critique see ref. 2). The reduced reactivity of **2** versus **1** is attributable in part to the reduced basicity of an ester carbonyl relative to a ketonic carbonyl (3) and to the relative stability of the two enolic intermediates.[2] It is tempting to attribute the similar rates of decarboxylation of the K^+,CE salts to similar stabilities of the resultant enolates; however, it is difficult to substantiate this suggestion. While the pK_a values of numerous ketones are available, esters have not proven amenable to measurement. What little data

there are suggest that acetone should be more acidic than ethyl acetate (5). But of the ketones, camphor is one of the less acidic ($pK_a^{DMSO} = 30.40$; cf. phenylcyclohexyl ketone = 26.7).[3] Thus it may be that camphor and methyl cyclohexylcarboxylate do have similar acidities.

Interpretation of the effect of added 18C6 is complicated by the fact that the reactions run in the absence of crown ether were heterogeneous. But certainly one role of the crown ether is to dissolve the salts and in the case of **1** this has led to a rate enhancement of 7 for the sodium salt and of 130 for the potassium salt. The potassium salt of **2** showed a similar rate enhancement. The replacement of dioxane by benzene in this case led to an eight-fold decrease in rate but of course the reaction temperature has been reduced by about 20° (100 to 80°C). In the case of the sodium salt of **1** the change from dioxane to THF led to only a 3-fold drop in rate in spite of a temperature drop of 35°. This seems consistent with the earlier observations (1) of the effect of solvent on decarboxylation rates.

Decarbalkoxylation

The greatly enhanced rate of decarboxylation of the potassium-crown ether salt of **2** relative to the acid form of the malonic half ester made us turn our attention to malonic esters. As part of a traditional malonic ester synthesis, the diester **3** is first hydrolyzed to the diacid **4**, which is then heated to effect decarboxylation and the acid **5** is then often reesterified for further conversions (Scheme 1). As an alternative to this procedure we decided to explore the route via the salt of the half-ester **6** which in the presence of crown ether should decarboxylate under conditions much milder than those required for the diacid **4**. We were further encouraged in this regard by the realization that crown ethers also greatly accelerate the saponification of esters (6). If a selective saponification could be realized then both steps could be telescoped into a one-pot conversion of malonate **3** to acetate **7**.

SCHEME 1

Diethyl Butylmalonate

In this regard we studied the conversion of diethyl butylmalonate **8** under a variety of conditions to optimize yields and then looked at a number of other malonates. Initial attempts were directed at preparing and utilizing a 1:1 complex of KOH–18C6 in an aprotic solvent; protic solvents reduce the rate of decarboxylation. Attempts using solid KOH and equimolar 18C6 resulted in a largely insoluble reagent in a wide range of aprotic solvents (isooctane, benzene, dioxane, THF, pyridine, aceto-

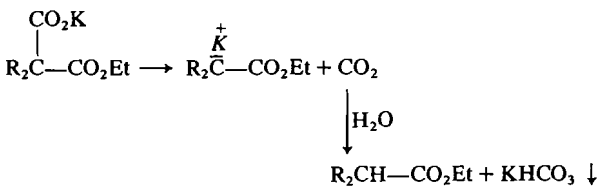
For personal use only.

nitrile). Nonetheless these reaction mixtures were stirred for 0.5 h at 25°C and then refluxed for 20–24 h and gave quite similar product distribution; ~40% recovered **8**, ~40% ethyl caproate **9**, and ~20% of other products amongst which both butylmalonic acid and caproic acid were identified. The insoluble reagent seemed to favour complete saponification of the malonate rather than selective hydrolysis to the half-ester which is needed for a successful malonate to acetate conversion.

Attempts were made to enhance the solubility of the potassium hydroxide in benzene by preforming the crown ether complex initially in water followed by lyophilization and also directly in benzene by removing the water as an azeotrope. These attempts led to no improvement in the product distribution and again a largely insoluble reagent resulted.

A homogeneous reaction mixture was obtained in ethanol with KOH–18C6 and while this led to quite selective monohydrolysis there was incomplete decarboxylation after 24 h at reflux (10% recovered **8**, 40% **9**, 45% ethyl hydrogen butylmalonate $CH_3CH_2CH_2CH_2CH(CO_2H)CO_2Et$). In an attempt to maintain homogeneity but to enhance the rate of decarboxylation, a benzene–ethanol mixture (5 vol.% ethanol) was employed for the ambient temperature hydrolysis. For the decarboxylation step, the ethanol was removed by distillation from the refluxing reaction mixture with the concurrent addition of benzene to keep the volume approximately constant. This led to 97% conversion (vpc) after 24 h and yields (after distillation) of **9** of 72% at 5 h, 81% at 16 h, and 84% at 24 h.

At this stage the use of benzene was somewhat arbitrary but did present some practical advantages. Its boiling point was high enough to effect efficient decarboxylation and removal of the ethanol. The 18C6 could be removed and subsequently recovered by washing with KCl solution (7).

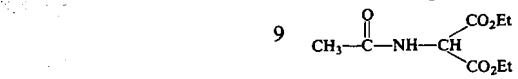


Comparison of Malonates

The near optimum yield of ethyl valerate from diethyl butylmalonate led us to apply this same two step one-pot procedure to other malonates (Table 2). These reactions, run on a 3 mmol scale, gave high yields (76–87%) of crude product sufficiently pure for further use. In some cases (runs 2, 4, 7, 9, 11) the reaction was run also on a 30 mmol scale and the product was distilled (>99% pure). As is evident in runs 2 and 4, the yields are affected by the volatility of the liquid products and a glc analysis of the crude reaction mixture showed better than 90% yields. Both monoalkyl and dialkylmalonates (runs 1–8) reacted under similar conditions to give comparable yields.

For most cases the hydrolysis step was complete in 1–3 h but the acidifying influence of a phenyl or nitro group led to competitive deprotonation of the malonic diester with consequent reduction in the rate of ester hydrolysis. The phenylmalonate (runs 10 and 11) proved to be borderline and an extended hydrolysis period sufficed to complete the reaction. However, in the case of the nitro-malonate the conversion to enolate was so complete that only starting material was recovered upon acidification. Thus, the presence of strong acidifying groups represents a limitation to this method of decarboxylation.

For most of the malonates in Table 2, a reflux period, after ethanol removal, of about 12–20 h was appropriate to complete decarboxylation. However there were two exceptions worth noting. The phenylmalonate (runs 10 and 11) proved very reactive once the ester hydrolysis was complete. In contrast, the decarboxylation of the cyclobutyl compound (run 6) was quite slow even in the higher boiling dioxane. Estimated half-lives for decarboxylation were ≥60 h in refluxing benzene and 12 h in refluxing dioxane compared with the cyclohexyl compound (run 7) with $t_{\frac{1}{2}}$ ~2 h (benzene). This reduced reactivity does not seem to reflect the stability of the derived anion (cyclobutylphenylketone pK_a^{DMSO} = 26.1; cyclohexylphenylketone pK_a^{DMSO} = 26.7[3]) and the source of this reduced reactivity remains a puzzle.



In one other case (run 9), dioxane was substituted for benzene but this was to enhance the solubility of the hydrolysis product to facilitate decarboxylation. It was also in this run that the usual precipitate of $KHCO_3$ was characterized and isolated in yields comparable to the product. Thus the CO_2 acts to trap the hydroxide generated during the final protonation producing an insoluble and unreactive precipitate.

This one-pot, two-step procedure for the decarbalkoxylation of malonate diesters to acetate esters gives good yields at moderate temperatures (80 or 100°C) under mildly basic conditions and acts to complement the other procedures for decarbalkoxylation. Thus the traditional three-step procedure (hydrolysis to the diacid, thermal decarboxylation, and re-esterification) gives comparable yields (73% ethyl caproate versus 75% of caproic acid (8); 59% ethyl valerate versus 60% (9); and 45% 2-heptanone versus 52–61% (10)). However, the present procedure employs basic rather than acidic conditions; the de-

[a]The reagent solution was added to the substrate in benzene at ~10°C over 0.5 h and then warmed to 25°C for 1 h. The ethanol was removed by distillation during the first part of the reflux period.
[b]15C5 = 15-crown-5 ether; DB18C6 = dibenzo-18-crown-6 ether.
[c]Ethyl hydrogen butylmalonate.

carboxylation step is run at a lower temperature; and fewer steps are required.

Decarboxylation has also been effected with refluxing dimethylsulfoxide (11) containing water, sometimes with added salts, with yields comparable to the present study (76% $CH_3CONHCH_2CO_2Et$ in this study versus 70%; 78% ethyl phenylacetate in this study versus 90%; and 76% $(CH_2)_3CHCO_2Et$ in this study versus 80–90%). However, the present procedure employs a significantly lower temperature, 80–100°C versus 160°C; and uses slightly basic rather than neutral conditions.

There are some limitations to the present procedure: particularly acidic substrates can deprotonate rather than hydrolyze (e.g. diethyl nitromalonate); substrates containing base sensitive groups may not be satisfactory; and large amounts of 18C6 may be needed since equimolar quantities give optimum results. The importance of this latter factor is reduced since 18C6 is recoverable by the simple expedient of a KCl wash (7). There are a number of other procedures (12) for decarbalkoxylation but most have been developed for β-ketoesters.

α-*Cyano and* β-*Keto Esters*

Although the potassium-crown ether salt of camphor-3-carboxylic acid decarboxylated only 20 times faster than the acid (Table 1), the present procedure would allow a mildly basic alternative to the usual route. Consequently three β-ketoesters were investigated (Table 3; runs 13, 14, and 15) as well as an α-cyanoester (run 16).

The reactions of 3-carbethoxy-2-heptanone (run 13) and camphor-3-methylcarboxylate (run 14) proceeded in good yield, although in both these cases it was found the hydrolysis step proceeded more rapidly without 18C6, which was added after the initial step. The 2-carbethoxy cyclopentanone (run 15) gave the usual (13) ring opening reaction even in the presence of 18C6 and only traces of the desired product were observed. The ethyl α-cyanocaproate hydrolyzed readily (before adding the crown ether) but the decarboxylation was quite slow even in refluxing dioxane. Thus even after 48 h at reflux (run 16), there was isolated 21% of α-cyanocaproic acid. This reduced reactivity presumably reflects the reduced acidifying effect of a nitrile grouping (pK_a^{DMSO}: CH_3CN 31.3; CH_3COCH_3 26.5)[3] relative to a carbonyl.

Other Cations and Crown Ethers

A series of experiments was run using diethyl butylmalonate **8** under the standard conditions for decarbalkoxylation (1–2 h at ≤25°, 20–50 h at reflux) except that the reagent was altered by varying both the cation and the crown ether. Although no attempt was made beyond this to optimize either yields or conditions, some effects are apparent. The replacement of 18C6 (run 2) with 15C5 (run 17) led to reduced amounts of both hydrolysis and decarboxylation. The replacement of potassium by sodium led to reduced yields although in this case 15C5 (run 17) was better than 18C6 (run 18). These changes are consistent with the cation selectivity shown by crown ethers (14) and with the effect of cation on the rate of decarboxylation (Table 1).

Barium (run 20) was also chosen for its compatibility with 18C6 and gave moderate yields although long reflux periods were needed. Long reflux periods were needed when less than equimolar 18C6 was used (run 21). With less than equimolar 18C6, the reaction mixture remained gelatinous but nonetheless yields were quite good. However since the 18C6 can be recovered by KCl extraction, use of equimolar crown ether seems advisable. Dibenzo-18C6 (run 22) also gave reasonable yields but pre-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

sented practical problems due to its reduced solubility. Of the cations and crown ethers surveyed, equimolar 18C6 and potassium hydroxide gave optimum yields in minimum time.

The effectiveness of quaternary ammonium cations was also explored albeit in a brief manner (runs 23, 24, and 25). While tetrapropylammonium bromide was effective, the longer chain tetrabutylammonium bromide, in equimolar amounts, behaved very similarly to K-18C6. A reduction in the amount of tetrabutylammonium bromide led to a reduction in yield both at the hydrolysis stage and at the decarboxylation stage. Although no attempt was made to optimize conditions it is fairly clear that tetrabutyl, or perhaps longer chain (15), quarternary ammonium salts can be very effective particularly on the large scale. This point deserves further study.

An S_N2 Route to Decarbalkoxylation

The feasibility of using 18C6 in combination with the salts of good nucleophiles to effect decarbalkoxylation was studied. The study with diethyl butylmalonate was limited to potassium iodide and

potassium cyanide with equimolar 18C6 in a number of solvents at reflux. The following combinations were attempted with no detectable reaction of the malonate: KI in benzene, 5% ethanol–benzene, dioxane, 5% ethanol–dioxane, acetonitrile, dimethylsulfoxide ($\leq$120°C); KCN in dioxane. The reluctance of diethyl butylmalonate to undergo even the first step made us look at the reactions of methyl oleate. Again there was no reaction with KI in tetrahydrofuran and in dioxane, and with KF in dioxane. There was reaction with potassium 2-propanethiolate in both tetrahydrofuran and dioxane but water may have been responsible for this result and the matter was not explored further.

It has been clearly demonstrated that both water and salts (KCN, NaCl, or LiCl) in refluxing dimethylsulfoxide (160°C) provide good yields in decarbalkoxylation without the use of crown ethers (11). If there is a catalytic effect of 18C6, it is not of sufficient magnitude to lower the reaction temperature to that of the solvents employed here ($\leq$100°C).

Experimental

The *d,l-3-camphorcarboxylic acid*, *diethyl* n-*butylmalonate*, *diethyl acetamidomalonate*, and *diethyl phenylmalonate* were purchased. *Diethyl propylmalonate*, *diethyl allylmalonate*, and *diethyl nitromalonate* were provided by F. H. Pattison and *2-carbethoxycyclopentanone* was provided by P. de Mayo. A sample of *3-carbethoxy 2-heptanone* was prepared in 70% yield by the procedure of Marvel and Hager (16). The *d,l-methyl-3-camphorcarboxylate* was prepared from commercial, d,l-3-camphorcarboxylic acid using the esterification procedure of Clinton and Laskowski (17). The ester was obtained as a mixture of 80% *endo*-CO_2CH_3 and 20% *exo*-CO_2CH_3 and was used as such. The *1-carbomethoxy cyclohexanecarboxylic acid* was prepared in 50% yield by the procedure of Reiffers, Wynberg, and Strating (18).

Diethyl-1,1-cyclobutanedicarboxylate was prepared by alkylation of diethylmalonate with 1,3-dibromopropane. The cyclobutyl compound was obtained in about 50% yield but contaminated with about 25% diethyl allylmalonate. The allylmalonate was removed by treatment with $KMnO_4$ and the net overall yield of purified cyclobutyl compound was 40%. The procedure follows.

A mixture of 1,3-dibromopropane (27.5 g, 0.136 mol) and diethyl malonate (21.5 g, 0.134 mol) in dry EtOH (125 mL) was added dropwise from one addition funnel into refluxing EtOH (100 mL) while simultaneously adding 150 mL of 1.7 *M* from another addition funnel, over a period of 2.5 h. After an additional half hour reflux, the solution was filtered, evaporated, and the residue extracted with CH_2Cl_2. The CH_2Cl_2 extracts were evaporated to give a liquid mixture (26.3 g) which was dissolved in glacial acetic acid (60 mL) and cooled to < 10°C. Solid $KMnO_4$ (15.0 g) was added in portions over 10 min and the exothermic reaction was maintained at < 50°C by external cooling for 3/4 hour. Dilute NaOH (100 mL) was added, and the mixture extracted with ether. The dried ether extracts were evaporated to yield a liquid which was distilled. After a forerun, the diethyl cyclobutanedicarboxylate was collected (10.83 g, bp 108–110°C (18 Torr)).

Diethyl 1,1-cyclohexanedicarboxylate was prepared by the reaction of diethyl malonate and 1,5-dibromopentane by the following procedure.

To 150 mL of 1.9 *M* sodium ethoxide in ethanol was added a solution of diethyl malonate (23.0 g, 0.144 mol) and 1,5-dibromopentane (34.5 g, 0.15 mol) in ethanol (150 mL) at reflux over 2.5 h. After an additional hour reflux the solution was cooled, pentane (100 mL) was added, and the solution filtered. The residue after evaporation of the filtrate was distilled and after a forerun of dibromopentane, the diethyl ester was collected (17.08 g, 52%, bp 83–92°C at 0.2–0.3 Torr; lit. (19) bp 100°C at 2 Torr).

Ethyl α-cyanocaproate was prepared by alkylation of ethyl cyanoacetate with butylbromide according to the following procedure. To 150 mL of 2.8 *M* sodium ethoxide in ethanol was added ethyl cyanoacetate (49.0 g, 0.43 mol) in EtOH (876 mL) followed by butyl bromide (60.5 g, 0.44 mol) in EtOH (75 mL). The solution was refluxed 8.5 h, cooled, filtered, and evaporated. The residue was extracted with pentane (200 mL), evaporated, and the resulting liquid distilled to give a forerun (25.1 g) followed by ethyl α-cyanohexanoate (30.53 g, 43%, bp. 140–144°C (134 Torr)).

The sodium and potassium salts of d,l-3-camphorcarboxylic acid and 1-carbomethoxy cyclohexanecarboxylic acid were prepared by lyophilization of an aqueous solution from titration of the corresponding acids (to the equivalence point). The 18C6 was prepared by the usual procedure (20).

Procedure for Decarboxylation

The decarboxylation reactions were run on doubly degassed solutions under an argon atmosphere. Typically 25 mL of solvent were used and sufficient substrate, 18C6, and glc

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

standard (mesitylene) to provide concentrations in the range of 0.02 *M* to 0.08 *M* were used. Aliquots of these solutions were removed to determine the progress of the reaction and for the heterogeneous reactions an attempt was made to remove representative samples. The aliquot was treated by extraction with water–pentane to remove the unreacted salt. After three water extractions and drying with sodium sulfate, the pentane layer was concentrated and analyzed by glc (5 ft × ¼ in. column of 5% SE-30 on 45–60 Chromosorb P).

Procedure for Decarbalkoxylations

The procedures described here for removal of a CO_2R group involve two distinct steps; first, low temperature hydrolysis of one of the ester groupings with an equimolar amount of potassium hydroxide in ethanol, and second, heating to reflux in benzene or dioxane to induce decarboxylation of the potassium carboxylate. The decarboxylation is facilitated by removal of the ethanol by distillation as the temperature is raised to reflux. In most reactions benzene was used as the solvent (Procedure A) while in some cases dioxane was used (Procedure B). In two cases KOH in water (Procedure C) replaced KOH in ethanol.

(*A*) *Benzene and Ethanol*

A mixture of benzene (20 mL) and potassium hydroxide in ethanol (2.8 mL (3.1 mmol) of 1.1 *M*) was added dropwise over about 25 min to a stirred solution of substrate (3.0 mmol) and 18C6 (3.0 mmol) in 30 mL of benzene at 5–10°C. After stirring several hours at room temperature to effect hydrolysis of the esters, the solution was heated to reflux. To facilitate the decarboxylation reaction about 10–15 mL of distillate was collected, resulting in removal of most of the ethanol. After the reflux period was over the reaction mixture was cooled and then acidified with 3 *M* hydrochloric acid. The benzene layer was washed three times with ca. 15 mL of saturated potassium chloride solution to remove the crown ether and then dried with sodium sulfate. The benzene was removed by distillation and the residual oil analyzed by glc and nmr.

For those reactions run on a 30 mmol scale, the residual oil was distilled and checked for purity by glc.

(*B*) *Dioxane and Ethanol*

Following procedure A, the dioxane–ethanol–hydroxide solution was added at < 15°C and the ethanol was removed by distillation until the temperature rose to 100°C. After the reflux period, the reaction mixture was cooled and 50 mL of pentane was added. (See below for acetamidoester isolation procedure.) Then 3 *N* hydrochloric acid and saturated potassium chloride solution were added and the above washing procedure followed. After evaporation of the solvent, if the crude material was contaminated with crown ether (20–50 mg), this was removed by filtration of a pentane solution through neutral alumina (1–2 g) and reevaporation. Since the acetamidoester was sparingly soluble in pentane and soluble in water, after the reaction was completed, the solution was filtered and evaporated. The residue was taken up in dichloromethane (50 mL), washed four times with saturated potassium chloride solution, dried, and evaporated to yield 54% ester and 10% diester. The combined washes were continuously extracted with ether, which was dried and evaporated to yield 24% ester product.

(*C*) *Benzene and Water*

To the compound (3.0 mmol) in benzene (50 mL) at 25°C was added 5 *N* aqueous potassium hydroxide solution (3.5 mmol, 0.7 mL). (If crown was also present then 6 mmol of potassium hydroxide were added.) After 3.5 h reflux, 18C6 (3.0 mmol) was added, the water distilled off as an azeotrope, and the solution refluxed for an additional 7.5 h. The isolation procedure of A was then followed.

Trihapto cycloheptatrienyl molybdenum and tungsten dicarbonyl compounds incorporating tridentate chelating dimethyl(1-pyrazolyl)(ethanolamine)gallate ligands

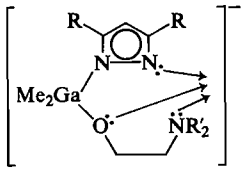
KENNETH S. CHONG AND ALAN STORR

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1W5

Received May 20, 1980

KENNETH S. CHONG and ALAN STORR. Can. J. Chem. **58**, 2278 (1980).

The synthesis and physical properties of a series of cycloheptatrienyl molybdenum and tungsten dicarbonyl compounds incorporating dimethyl(1-pyrazolyl)(ethanolamine)gallate ligands have been investigated. The monomeric, pseudo octahedral, complexes have the organogallate ligand occupying a set of facial positions with the cycloheptatrienyl ring situated opposite to the amino nitrogen atom. Proton nmr studies have shown the η^3-C_7H_7 ligand of the complexes to be fluxional in solution at room temperature. In the low temperature limiting ^1H nmr spectra of the complexes in solution, however, it is possible to distinguish all seven protons of the *static* η^3-C_7H_7 ring owing to the asymmetric nature of the octahedral molecules.



KENNETH S. CHONG et ALAN STORR. Can. J. Chem. **58**, 2278 (1980).

On a étudié la synthèse et les propriétés physiques des composés dicarboxylés du cycloheptatriénylmolybdène et du cycloheptatriényltungstène, incorporant les ligands gallate de diméthyl(pyrazolyl-1)(éthanolamine). Les complexes monomères pseudo-octaédriques ont le ligand organogallate dans un ensemble de positions faciales avec le cycle cycloheptatriényle situé à l'opposé de l'atome d'azote du groupe amine. Les études de la rmn du proton ont montré que le ligand η^3-C_7H_7 des complexes subit de fréquents changements en solution à la température de la pièce. Cependant à la basse température limite des spectres rmn du ^1H des complexes en solution, il est possible de distinguer chacun des sept protons du cycle η^3-C_7H_7 figé en raison de la nature asymétrique des molécules octaédriques.

[Traduit par le journal]

Introduction

Our continuing investigations into the coordinating properties of organogallate ligands of the type **1** has resulted in a series of dicarbonyl com-

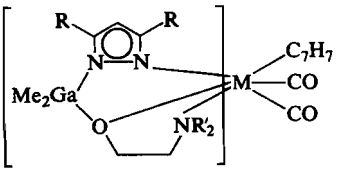
1
R = H or Me
R′ = H or Me

plexes of molybdenum and tungsten containing both the ligand **1** and the cycloheptatrienyl ligand, η^3-C_7H_7. Previous investigations using these organogallate ligands **1** had resulted in a wealth of molybdenum and tungsten dicarbonyl derivatives of the general formula $LM(CO)_2X$ (where L = **1**; M = Mo or W; X = η^3-C_3H_5, η^3-C_4H_7 (1, 2), NO (1), and η^2-CH_2SMe (3)), and a series of nickel (4), iron (5), and manganese (5) nitrosyl derivatives. In addition a variety of complexes involving the first row transition elements (Mn → Zn) and the ligands **1** have been described (6–8). Cycloheptatrienyl complexes were of interest because of the ability of the C_7H_7 ligand to coordinate in a mono-, tri-, penta-, or hepta-hapto fashion to metal atoms, and also because of the unique fluxional properties displayed by this group in solutions of such complexes. In the present series of cycloheptatrienyl compounds the C_7H_7 group occupies one coordination site in the octahedral complexes in a trihapto fashion with the ligands **1** in a *fac* conformation. The nature of the ligands **1** imparts an asymmetry to the complexes and this is reflected in the detection of seven proton signals for the C_7H_7 group, in solution, in a low temperature ^1H nmr study.

Experimental

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen, in a nitrogen-blanketed apparatus, or on a high-vacuum line. Tetrahydrofuran (THF) was dried by refluxing over Na/benzophenone and was used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation. The ligands **1** were prepared as sodium salts in THF solution as described previously (1, 2, 7). $(C_7H_7)Mo(CO)_2I$ (9), $(C_7H_7)W(CO)_2I$ (10), and $(C_7H_7)^+BF_4^-$ (11) were prepared as described previously.

*Preparation of the Complexes $LM(CO)_2(C_7H_7)$ (L = **1**; M = Mo or W)*



The preparations of the complexes $LM(CO)_2(C_7H_7)$ were all very similar and may be summarized by the following procedures. Analytical, ^1H nmr, and ir data for these complexes are given in Tables 1 and 2.

In a typical preparation, $(C_7H_7)Mo(CO)_2I$ (0.740 g, 2.0 mmol) was suspended in ~50 mL of benzene and 2.0 mmol of ligand **1** in THF added. The mixture was stirred for 1–2 days. Gradually the colour of the mixture changed from green to red–brown and a white precipitate formed. After filtration of the mixture, the solvent was removed from the filtrate under vacuo and the red–brown solid obtained recrystallized from benzene. The tungsten analogues were prepared similarly by

reaction of $(C_7H_7)W(CO)_2I$ with the organogallate ligands **1**. The yield of the desired product in these reactions was in the range of 50–70%. The complexes prepared were all air-stable in the solid state but in solution decomposed on prolonged exposure to air.

An alternative preparative route to these complexes involved reacting the $Na^+LM(CO)_3^-$ salts (1) with $(C_7H_7)^+BF_4^-$ in THF, followed by recrystallization of the crude product from benzene. However, the yields in these reactions were substantially lower, being in the range of 10–15%.

Preparation of the Complex
$[MeGa(N_2C_3H_3)_3]Mo(CO)_2(C_7H_7)$

This complex was prepared by reacting the ligand salt $Na^+MeGa(N_2C_3H_3)_3^-$ (12) (0.495 g, 1.60 mmol) with $(C_7H_7)Mo(CO)_2I$ (0.593 g, 1.60 mmol) in THF solution. The colour of the reaction mixture changed from green to a yellowish-brown colour, and a red–brown solid was obtained after removal of solvent under vacuum. This was extracted with and recrystallized from a benzene/heptane mixed solvent. The pure product was obtained as air stable orange–brown crystals. *Anal.* calcd. for $C_{19}H_{19}N_6O_2GaMo$: C 43.1, H 3.6, N 15.9; found: C 43.7, H 3.8, N 15.3. Preparation of the Complex

[MeGa($N_2C_5H_7$)$_2$(OH)]Mo(CO)$_2$(C_7H_7)

This complex was prepared by the reaction of the ligand salt $Na^+MeGa(N_2C_5H_7)_3^-$ (13) with $(C_7H_7)Mo(CO)_2I$ in THF solution. The origin of the hydroxy ligand in this type of reaction has been speculated upon previously (13). The crude product isolated from the reaction mixture was recrystallized from benzene to yield reddish brown crystals. *Anal.* calcd. for $C_{20}H_{25}N_4O_3GaMo$: C 44.9, H 4.7, N 10.5; found: C 45.1, H 4.4, N 10.1. Spectra

Mass spectra were recorded on a Varian MAT CH4 mass spectrometer at 70 eV with a source temperature of 120–200°C. Infrared spectra were recorded on a Perkin-Elmer 457 spectrophotometer and ^1H nmr spectra on a Varian XL-100 spectrometer using FT techniques.

Results and Discussion

Analysis of mass spectral, ir, ^1H nmr, and preliminary X-ray structural data for the complexes listed in Tables 1 and 2 points to a monomeric pseudo octahedral structure for the compounds $LM(CO)_2(C_7H_7)$ (where L = **1**; M = Mo or W), with the cycloheptatrienyl ligand bonded in a trihapto fashion in one of the octahedral positions. The $LM(CO)_2(C_7H_7)$ compounds can be prepared by treating the carbonyl anions, $LM(CO)_3^-$, with tropenium salts, e.g. $(C_7H_7)^+BF_4^-$, but a more productive route to the same compounds was via the reaction of the $(C_7H_7)M(CO)_2I$ compounds with the ligand salts, Na^+L^-.

Infrared Spectra

With the exception of one complex the ν_{CO} region of the ir spectra of the $LM(CO)_2(C_7H_7)$ compounds (Table 1) in solution showed two sharp strong bands of approximately equal intensity, indicating a *cis* arrangement of the two CO ligands in the pseudo octahedral complexes (14). This does not distinguish between a *fac* or *mer* arrangement for the organogallate ligand, L, about the central molybdenum atom (7). However, a *fac* arrangement for this ligand is predicted on the following counts: (*i*) previous X-ray structural studies have demonstrated this arrangement in the similar complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$ (2); (*ii*) the C_7H_7 compounds can be prepared from the anions, $LM(CO)_3^-$, which are known to have a *fac* arrangement for the ligand L (1); (*iii*) ^1H nmr studies are consistent with a *fac* arrangement for the organogallate ligand; and (*iv*) preliminary data from the crystal structure determination of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2(C_7H_7)$ has shown the organogallate ligand to be *fac* and the cycloheptatrienyl ligand to be trihapto (15).

Two pairs of ν_{CO} bands were found in the ir spectrum of the complex $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NH_2)]Mo(CO)_2(C_7H_7)$ in cyclohexane solution in approximately a 6:1 intensity ratio. Taken together with the ^1H nmr data for this complex and for the analogous tungsten compound, these results indicate the presence of two positional isomers for these derivatives which both incorporate the least sterically demanding ligand **1** with R = R′ = H. The most likely positions of substitution for the C_7H_7 groups in these positional isomers, as indicated by molecular model studies, are opposite either the pyrazolyl or the amino nitrogen atoms. As observed previously for similar complexes (1, 12, 16, 17) the ν_{CO} bands for the tungsten compounds are approximately 10–15 cm^{-1} lower than those for the corresponding molybdenum compounds.

The two compounds, $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(C_7H_7)$ and $[MeGa(N_2C_5H_7)_2(OH)]Mo(CO)_2(C_7H_7)$, both displayed two strong ν_{CO} bands in their ir spectra, consistent with a *cis* dicarbonyl grouping. In these two complexes a *cis* arrangement for the two CO groups is mandatory since the inflexibility of the tridentate chelating organogallate ligands dictates that they must adopt a facial configuration about the molybdenum atom in the pseudo octahedral complexes.

^1H Nuclear Magnetic Resonance Spectra

^1H nmr data for the complexes, $LM(CO)_2(C_7H_7)$, recorded in C_6D_6 solution, are listed in Table 2. In the majority of cases the presence of only one isomer is indicated in the solutions. Figure 1 shows the room temperature spectrum of the complex $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(C_7H_7)$. However, for the two complexes $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NH_2)]M(CO)_2(C_7H_7)$ (M = Mo or W), two sets of signals in an approximate 6:1 ratio were observed. In addition the ir spectrum of the compound where M = Mo, in cyclohexane solution (the compound where M = W was insoluble in cyclohexane), showed two pairs of ν_{CO} bands in approximately this same ratio of 6:1. These results may be explained by the presence of two positional isomers for these two complexes, as discussed above.

The observation that in solutions of all the complexes the ^1H nmr signal due to the C_7H_7 group was observed as one sharp singlet at room temperature, indicates that this group is involved in a rapid fluxional process. This premise was confirmed by a variable temperature ^1H nmr study of the complex $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]W$-

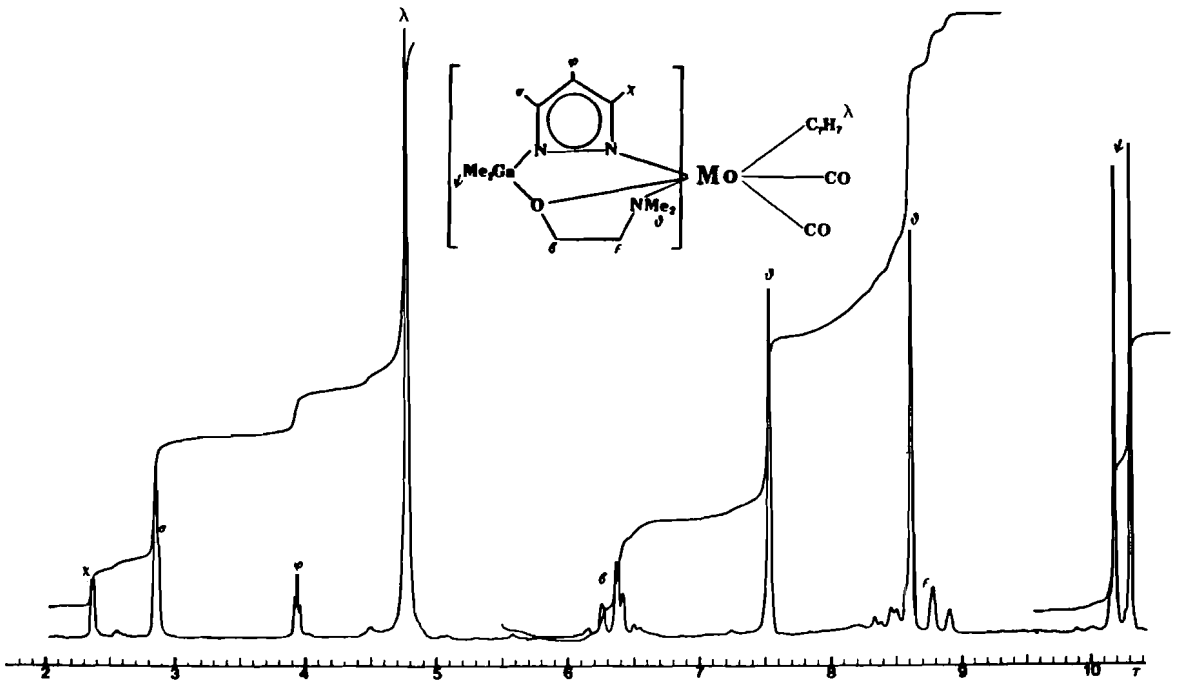

FIG. 1. Room temperature 100 MHz ^{1}H nmr spectrum of $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(C_7H_7)$ in C_6D_6 solution.

$(CO)_2(C_7H_7)$ in d_6-acetone solution (Fig. 2). As the sample solution was cooled the signal due to the C_7H_7 moiety successively broadened, disappeared, and finally reappeared as "five" distinct multiplets. The low temperature limiting spectrum was reached at -75°C and the C_7H_7 region of this spectrum is shown in Fig. 3 together with a computer simulated spectrum of the C_7H_7 protons. The assignments of the C_7H_7 protons are listed in Table 3 and are based on double resonance experiments. In Fig. 3 the three carbon atoms interacting with the tungsten atom in a trihapto "allylic" fashion are those bearing the protons *g*, *a*, and *b* with the central carbon atom bearing the proton *a*. Irradiation of the signal due to proton *a* caused the signal due to proton *g* to collapse to a doublet (the effect of this irradiation on the signal due to proton *b* could not be clearly seen because of coincident signals due to $-CH_2-$ protons). Conversely irradiation of the signals due to the protons *b* or *g* caused the signal due to proton *a* to collapse to a doublet as well as affecting the signals due to protons *c* and *f*. In addition it was noticed that irradiation of the proton *b* signal affected only the lowfield half of the *c*, *f* proton multiplet and irradiation of the proton *g* signal affected only the upfield half of the *c*, *f* proton multiplet. Irradiation of the lowfield half of the *c*, *f* proton multiplet reduced the upfield half of the *e*, *d* proton multiplet to a doublet and irradiation of the upfield half of the *c*, *f* proton multiplet reduced the lowfield half of the *e*, *d* proton multiplet to a doublet as well as reducing the *g* proton signal to a doublet. Finally irradiation of the lowfield half of the *e*, *d* proton multiplet reduced the upfield half of the *c*, *f* proton multiplet to a doublet while irradiation of the upfield half of the *e*, *d* proton multiplet reduced the lowfield half of the *c*, *f* proton multiplet to a doublet. These experiments fix the relative positions of the respective protons and since the highfield proton *a* is coupled to both the protons *b* and *g* (the other "1" proton multiplets) it must be the one associated with the central "allylic" carbon atom of the η^3-C_7H_7 group. The near identical computer simulated spectrum (based on the parameters given in Table 3) shown in Fig. 3 confirms unequivocally these assignments. The asymmetric nature of the complex, $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]W(CO)_2(C_7H_7)$, makes possible the observation of seven different proton signals due to the η^3-C_7H_7 group at low temperature in solution. This phenomenon eliminates any possibility of a monohapto cycloheptatrienyl group if it is assumed that such a ligand would freely rotate at -75°C. It is interesting to compare the low temperature limiting spectrum reported here with the spectra of other more symmetrical η^3-C_7H_7 complexes. Thus the low temperature solution ^{1}H nmr spectra of the

FIG. 2. Temperature dependent 100 MHz ^{1}H nmr spectrum of $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]W(CO)_2(C_7H_7)$ in d_6-acetone solution.

compounds $(\eta^3\text{-}C_7H_7)Co(CO)_3$ (18), $(\eta^5\text{-}C_5H_5)$-$Fe(CO)(\eta^3\text{-}C_7H_7)$ (19), and $(\eta^5\text{-}C_5H_5)Mo(CO)_2$-$(\eta^3\text{-}C_7H_7)$ (18, 20) each displayed four proton signals due to the $\eta^3\text{-}C_7H_7$ ring in the predicted intensity ratio of 1:2:2:2 with the central "allylic" proton again being to high field. Surprisingly, the low temperature solution ^{1}H nmr spectrum (21) of the pyrazolyl borate complex $[H_2B(N_2C_5H_7)_2]Mo$-$(CO)_2(C_7H_7)$ (22), which contains a B—H—Mo 2 electron-3 centre bond and a $\eta^3\text{-}C_7H_7$ ring (23), also shows only four signals due to the $\eta^3\text{-}C_7H_7$ ring protons. This is surprising since the cycloheptatrienyl group is asymmetrically positioned with respect to the pyrazolyl borate ligand, at least in the solid state, in the pseudo octahedral complex (23). In the present study the complex $[MeGa(N_2C_5H_7)_2(OH)]Mo$-

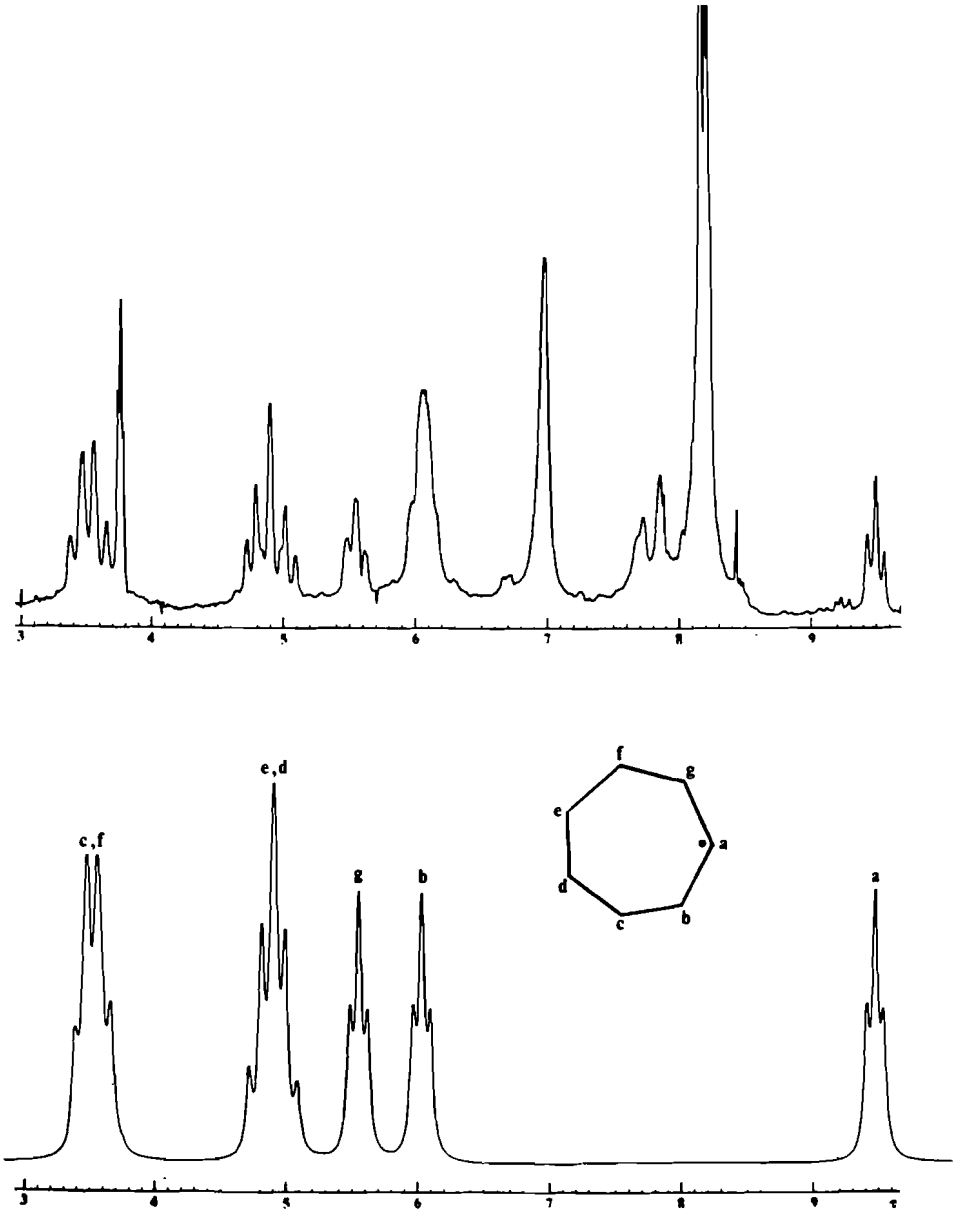

FIG. 3. Low temperature limiting ^1H nmr spectrum of C_7H_7 proton region of $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe)]W(CO)_2(C_7H_7)$ in d_6-acetone solution: experimental (top); computer simulated C_7H_7 proton spectrum (bottom).

$(CO)_2(C_7H_7)$ was synthesized to enable a comparison to be made of its low temperature ^1H nmr spectrum with those discussed above. The room temperature ^1H nmr of this complex in d_6-acetone solution was essentially identical with that of the C_6D_6 solution spectrum reported in the experimental section. Thus two equally intense pyrazolyl-H_4 proton signals, four equally intense pyrazolyl-Me signals, in addition to singlet resonances for the C_7H_7, OH, and GaMe protons, were observed. This spectrum indicates that the fluxional C_7H_7 group must be positioned opposite to one of the pyrazolyl nitrogens, rather than opposite to the OH group, in the pseudo octahedral complex. This arrangement would be expected on steric grounds (13), and should lead to an asymmetric environment for a "static" C_7H_7 group at low temperature in solution. Consequently, a similar low temperature ^1H nmr spectrum, for the C_7H_7 group, to that shown in Fig. 3 might be anticipated. Indeed, at $-82°C$, this

type of pattern was observed with the central "allylic" proton again to highfield. A slight difference from the spectrum shown in Fig. 3 was that the two midfield triplets due to protons *g* and *b* were closer together causing an overlap of the two central lines to give an approximate 1:2:2:2:1 five line pattern. The low temperature ^1H nmr spectrum of the complex $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(C_7H_7)$ at −82°C in d_6-acetone solution was not clearly resolved and unfortunately instrument limitations did not allow lower temperature spectra to be obtained. For this complex a low temperature limiting ^1H nmr spectrum of four signals for the C_7H_7 group might be expected since the tridentate chelating gallate ligand is now symmetrical and the complex is akin to those mentioned above (18–20). A tridentate chelating gallate ligand in this complex is consistent with its room temperature solution ^1H nmr spectrum (see Experimental) which shows the three pyrazolyl groups in two different environments in a 2:1 ratio. The unique pyrazolyl group would be positioned opposite to the C_7H_7 group in the pseudo octahedral complex. This arrangement is similar to that found for the pyrazolyl borate ligand in the related complex, $[PhB(N_2C_3H_3)_3]Mo(CO)_2(C_7H_7)$, for which the crystal structure has been determined (24). An earlier structural model suggested by Trofimenko for the compound of $[B(N_2C_3H_3)_4]Mo(CO)_2(C_7H_7)$ consisted of a bidentate chelating pyrazolyl borate ligand and a η^5-C_7H_7 ring (16). This model is also consistent with the ^1H nmr data, and was put forward on the basis of steric considerations and also on the grounds that the complex $[B(N_2C_3H_3)_4]Mo(CO)_2(C_5H_5)$ displays a bidentate pyrazolyl borate ligand and a η^5-C_5H_5 group, rather than a tridentate pyrazolyl borate ligand and a η^3-C_5H_5 group (25). It would appear, however, that in this type of complex the main driving force is the preference of the C_7H_7 ligand for η^3- rather than η^5-coordination, whereas for the C_5H_5 ligand this preference is reversed.

In order to provide a chemical proof of the trihapto nature of the C_7H_7 ring in the complexes $LM(CO)_2(C_7H_7)$ (where L = **1**; M = Mo or W), the preparation of "$Fe(CO)_3$" adducts was attempted. Thus if the $Fe(CO)_3$ moiety can be bound to the "butadiene" part of a coordinated η^3-C_7H_7 ring this has been taken as evidence for a trihapto as opposed to a penta- or hepta-hapto cycloheptatrienyl ring (26). Indeed, when an ethereal solution of $LMo(CO)_2(C_7H_7)$ (L = **1** where R = R′ = Me) and $Fe(CO)_5$ was subjected to uv radiation the complex $LMo(CO)_2(C_7H_7)\cdot Fe(CO)_3$ was formed. Unfortunately, however, the desired $Fe(CO)_3$ adduct could not be separated from the starting molybdenum complex using either column chromatography or fractional crystallization techniques. Nevertheless, the ir spectrum of the mixture of the $Fe(CO)_3$ adduct and the starting molybdenum complex in cyclohexane solution showed five ν_{CO} bands attributable to the $Fe(CO)_3$ adduct (in addition to the two ν_{CO} bands at 1928 and 1849 cm^{-1} due to the molybdenum starting material). These five bands occurred at 1924, 1837 (assigned to the $Mo(CO)_2$ moiety of the adduct) and 2045, 1979, and 1968 cm^{-1} (assigned to the $Fe(CO)_3$ grouping of the adduct). This pattern of five ν_{CO} bands is reminiscent of the patterns observed for a series of related compounds, $L'Mo(CO)_2(C_7H_7)\cdot Fe(CO)_3$ (where L′ = $[H_2B(N_2C_5H_7)_2]$ (21), $[HB(N_2C_3H_3)_3]$ (26), $[B(N_2C_3H_3)_4]$ (26), $[HB(N_2C_5H_7)_3]$ (26), and (η^5-C_5H_5) (27)), and strongly suggests a trihapto cyclohaptatrienyl ligand in the gallate complex.

Mass Spectra

All of the cycloheptatrienyl complexes described in this study were sufficiently volatile and stable to give readily observable parent ion signals in their mass spectra, which corresponded to the monomer species in the vapour phase. For the complexes $LM(CO)_2(C_7H_7)$ (where L = **1**; M = Mo or W) and the complex $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(C_7H_7)$ the strongest signal in the spectra was due to the parent ion minus two CO groups, whereas for the compound $[MeGa(N_2C_5H_7)_2(OH)]Mo(CO)_2(C_7H_7)$ the strongest signal corresponded to the parent ion minus two CO groups and a dimethylpyrazole molecule. The appearance of signals due to other ions in all the spectra were accountable on predictable fragmentation patterns for the complexes. The intensity ratios of the individual peaks in all multi-line signals agreed closely with theoretical predictions based on the percentage isotope compositions of the contributing metal atoms.

Preliminary data (15) on the crystal structure determination of the complex, $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]\ Mo(CO)_2(C_7H_7)$, has confirmed

the predicted "allylic" trihapto nature of the cycloheptatrienyl ligand, and the overall monomeric pseudo octahedral structure, for this complex. However, the position of substitution was found to be *trans* to the amino nitrogen rather than *trans* to the pyrazolyl nitrogen as found, or predicted, in related allyl or nitrosyl compounds (1, 2). On close inspection of molecular models this was not surprising since it became evident that the flattish *and* elongated shape of the η^3-C_7H_7 ring is best accommodated when it is aligned parallel to the pyrazolyl ring and to the two CO groups in the complex, i.e. opposite the amino nitrogen. In the position opposite the pyrazolyl nitrogen steric interactions involving the C_7H_7 group, particularly with the amino alcohol part of the gallate ligand, become more severe.

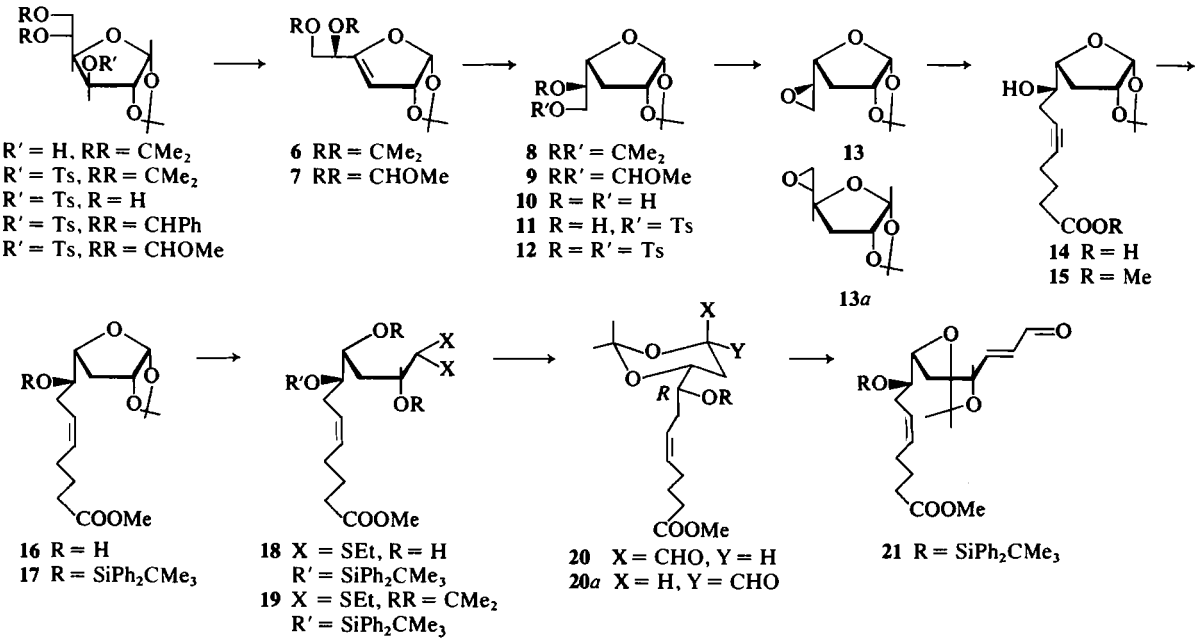
In the second paper of this series (1), we described the synthesis of methyl 8*R*,9*S*,11*R*-trihydroxy-5*Z*, 12*E*,14*Z*-eicosatrienoate (**24***f*) from epoxide **13***a*, and gave the rationale for its preparation and that of the corresponding 8*S*,9*S*,11*R* (**25***d*), 8*R*,9*R*,11*R* (**22***f*), and 8*S*,9*R*,11*R* (**23***d*) isomers. In this communication, we would like to describe the synthesis of the latter three isomers, which follows the general scheme outlined for **24***f*.

The three chiral centers in **24** are directly related to those found in **13***a*. Similarly, those found in **22** correspond to the three chiral centers in epoxide **13** (3) (see **13** → **22**). Triol **23** has the stereochemistry of **22** except for an inversion at C(8), and a similar relation holds for **25** and **24**. The first task at hand was therefore to prepare **13** (3) in a simple and reproducible manner, and then to follow the synthetic scheme used for the preparation of **24**.

Although the stereochemistry at C(8) in **23** and **25** could have been built in at the epoxide stage using a C(5) epimer of either **13** or **13***a*, it was decided to introduce it at the latest possible stage in order to avoid unnecessary labor. Model studies on compounds of type **16** indicated that elimination reactions competed very strongly with displacement reactions at C(8). Use was therefore made of participation of a neighbouring acetate to invert the stereochemistry of the alcohol function at C(8). This is detailed in the second section of the paper.

The preparation of 1,2;5,6-di-*O*-isopropylidene-3-deoxy-α-D-xylohexofuranose (**8**) has been described (2) and consists in transforming diacetone glucose **1** to its tosylate **2**, pyrolyzing **2** at 210–220°C over soda-lime to give olefin **6**, and reducing **6** catalytically to **8**.

A clean partial hydrolysis (3) of the 5,6-*O*-isopropylidene group of **8** failed in our hands, so that a different 5,6-protecting group had to be used. Diacetone glucose tosylate **2** (2) was hydrolysed to the corresponding 5,6-diol **3**, which was then transformed to the corresponding 5,6-benzylidene derivate **4** and orthoester **5** by reaction with benzaldehyde/*p*-toluenesulfonic acid in benzene and trimethyl orthoformate respectively. Both compounds were obtained as a mixture of diastereomers, and were used as such. Treatment of the 5,6-benzylidene derivate **4** with soda-lime at 220°C/5 Torr did not yield any distillate, and raising the temperature only gave tars.



However, reaction of the orthoester **5** under the same conditions gave the extremely acid-sensitive **7**, which was immediately hydrogenated with Pd/C in acid-free ethyl acetate to give deoxy-diol **10** after brief acid treatment. Tosylation of crude **10** with one equivalent of *p*-toluenesulfonyl chloride/pyridine in chloroform gave monotosylate **11**, contaminated with 10–15% each of ditosylate **12** and diol **10**. Treatment of the crude tosylation mixture with 1 equivalent of aqueous methanolic potassium hydroxide, followed by distillation of the crude reaction mixture gave epoxide **13** in overall ~ 25% yield, based on glucose monotosylate **2**.

The sequence **13** → **22***a* followed the sequence **13***a* → **24***g* described (1), and the only differences noted were the acid sensitivity of aldehyde **20** with respect to its 9-isomer, and lower yields in the two consecutive Wittig reactions **20** → **21** → **22**. The proton α- to the aldehyde in **20** appeared as a triplet (dd, $J_{10,11} \cong 6.5$ Hz) and indicated an axial conformation of the aldehyde, in contrast to the corresponding aldehyde in the series leading to **24**, where the same proton appeared as a four line system (dd, $J_{10,11} \cong 5$ Hz, ~ 10 Hz) typical of an axial hydrogen. No isomerization had therefore taken

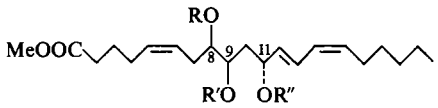
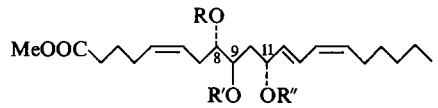
place during the transformation **19** → **20**. This was confirmed by the following experiment. Aldehyde **20** was dissolved in dry methanol saturated with potassium carbonate and was kept at room temperature for 6 hours. After this time, the isomerization of the axial aldehyde group of **20** to the diequatorial isomer **20***a* was complete. The coupling constant and chemical shift of the proton to the aldehyde was typical of an axial hydrogen (dd, $J_{10,11} \sim 5$ Hz, 10 Hz) and virtually identical to that of the corresponding aldehyde obtained in the 8*R*,9*S*,11*R* series (**24**), as were the chemical shifts of the aldehydic hydrogens in the two compounds. The isopropylidene methyls of **20***a* appeared at somewhat higher field than in the aldehyde of the 8*R*,9*S*,11*R* series (**24**), because of shielding due to the benzene rings of the *tert*-butyldiphenylsilyl group, as clearly demonstrated by inspection of models.



No isomerization occurred either during the Wittig reactions **20** → **21** → **22**, since (8*R*,9*R*,11*R*)-triacetate **22***g* was different by hplc from (8*S*,9*S*,11*R*)-triacetate **25***c* prepared below. Had isomerization taken place at C(11), the resulting triacetate would have had the 8*R*,9*R*,11*S*-configuration, and would therefore have had the same hplc behaviour as its (8*S*, 9*S*, 11*R*)-enantiomer **25***c*.

8*R*-*tert*-Butyldiphenylsilyloxy-9*R*,11*R*-di-*O*-isopropylidene ester **22***a* was obtained as a 9:1 mixture of 14*Z* and 14*E* isomers, as established by hplc, and was separated most efficiently at the triacetate stage **22***g*. Desilylation of **22***a* to alcohol **22***b* was effected by tetra-*n*-butylammonium fluoride in dry boiling THF. The acid removal of the isopropylidene group in **22***b* caused some difficulty, in contrast to its removal in **24***a*, in which the two substituents of the 1,3-dioxane ring are equatorial. This difficulty was caused by acid-catalysed trans-ketalization of **22***b* to the dioxolane **22***c*, which is considerably more stable to acid. This problem was resolved by acetylating **22***b*, and hydrolysing the resulting acetate **22***d* with aqueous methanolic hydrochloric acid. Work-up with basic resin gave a mixture of two acetates due to base-catalysed acetate migration. Base hydrolysis of the acetate mixture "(**22***e*)" gave triol **22***f*, which could not be separated into its geometric isomers. However, triacetate **22***g* (14*Z*/14*E* = 9:1) could be cleanly resolved.



The conversions of appropriately derivatized triol ester **22** to its 8*S*-isomer **23**, and **24** to its 8*S*-isomer **25** were carried out in exactly the same manner, and no major differences were noted except for the considerably greater lability of mesylate **22***i* as compared to **24***b*. The sequence will therefore only be described for **24**. Alcohol **24***a* was mesylated, and the mesylate **24***b* subjected to acid hydrolysis. The reaction conditions for the hydrolysis were very critical, since the resulting alcohol **24***c* solvolyzed to furan **26***a*, identified by mass spectrometry and nmr only.

At room temperature, furan **26***a* started being detected by tlc after 40 min, in a reaction which was independent of acid concentration. The hydrolysis

reaction was therefore carried out with relatively strong acid (~0.1 *N*) and the product immediately worked up and acetylated with acetic anhydride/4-dimethylaminopyridine in ether. Flash-chromatography gave mesylate diacetate **24***d* in 60% yield, based on **24***a*. Solvolysis of the diacetoxymesylate **24***d* in methanol containing 1.1 equiv. of potassium acetate produced a less polar spot, presumably orthoester **25***a* which slowly hydrolyzed to a mixture of trihydroxydiacetates **25***b*. The orthoester was only identified by its acid-catalyzed conversion to **25***b*. The solvolysis mixture was then treated with some acetic acid to convert orthoester **25***a* to **25***b*, which was then reacetylated. The resulting triacetate **25***c* could be cleanly separated by hplc from triacetate **24***e*, obtained by acetylation of triol **24***f*. The structure of triacetate **25***c* was confirmed by the usual spectroscopic data. Treatment with methanolic sodium methoxide gave triol ester **25***e*.

When alcohol **22***b* was submitted to an analogous reaction sequence, triacetate **23***c* was obtained.

Triols **24***f* and **22***f*, which were obtained in relatively large quantities, proved to be rather unstable and decomposed even when kept under argon at −20°C. Their ^{1}Hmr spectra and optical rotations did not allow a clear differentiation, especially when only small samples were available. However, the corresponding triacetates **24***e* and **22***g* as well as **23***c* and **25***c* were quite stable and gave very characteristic ^{1}Hmr spectra, allowing a clear distinction (see Fig. 1). No single hplc system could be found in which all four isomers could be separated. Thus, on a reverse phase system (Microbondapak C_{18} ("Waters")), **24***e* and **25***c* had identical retention times, followed by **22***g* and **23***c*. $PGF_{2\alpha}$ methyl ester triacetate had a comparatively much shorter retention time on this system. When straight-phase conditions were employed (Lichrosorb Si-100 (Brownlee Labs.)), the

For personal use only.

elution sequence was quite different, $PGF_{2\alpha}$ methyl ester triacetate having the same retention time as **24***e* and **23***c*, which were then followed by **22***g* and **25***c*.

The high-resolution mass spectra of the four acetates proved conclusively their structural identity. Their isomeric purity was ascertained by their 200 MHz ^{1}Hmr spectra, and the ^{13}Cmr of triacetates **22***g* and **25***c* and triol **24***f* (1).

Experimental

General

Mass spectra (ms) were obtained on a HP 5984 mass spectrometer or on a LKB-9000 mass spectrometer at 70 eV. Infrared (ir) spectra were obtained on a Perkin Elmer 297 spectrophotometer. Proton and carbon-13 magnetic resonance spectra were recorded on Varian T-60, T-60A, XL-200, and on Brucker FT 90 spectrometers. The hplc separations were performed on an Altex 300 instrument, using "Spherisorb $S_{10}W$" silica gel (Technical Marketing) and on a Waters 660, using Microbondapak C_{18} (reverse phase) and Lichrosorb Si-100 (straight phase) columns. Microanalyses were carried out by Mid-West Laboratories, Indianapolis, IN.

3-p-Toluenesulphonate of 1,2-O-Isopropylidene-α-D-glucofuranose (3)

A solution of tosylate **2** (2) (108 g, 0.26 mol) in MeOH (2 L) and 2.5 *M* aqueous H_2SO_4 (175 mL) was stirred at room temperature for 11 h. The solution was then neutralized with concentrated aqueous NaOH and the solvent was removed *in vacuo*; the residue was dissolved in CH_2Cl_2, dried over $MgSO_4$, and evaporated to give diol **3** as a hygroscopic solid in quantitative yield. Nuclear magnetic resonance ($CDCl_3$) δ: 1.26 (s, 3H, CH_3), 1.45 (s, 3H, CH_3), 2.42 (s, 3H, Ph—CH_3), 2.9–4.0 (m, 5H, C(5)H, C(6)H, 2OH (exchangeable with D_2O)), 4.14 (bdd, 1H, $J_{3,4} \sim 2.5$ Hz, $J_{4,5} \sim 2.5$ Hz, C(4)H), 4.56 (d, 1H, $J_{1,2} = 4$ Hz, C(2)H), 4.95 (d, 1H, $J_{3,4} = 2.5$ Hz, C(3)H), 5.79 (d, 1H, $J_{1,2} = 4$ Hz, C(1)H), 7.52 (4H, ABq, $\delta_{AB} = 0.48$, $J = 8$ Hz).

p-Toluenesulfonate of 1,2-O-Isopropylidene-5,6-O-methoxymethylidene-α-D-glucofuranose (5)

Diol tosylate **3** (79 g, 0.21 mol), *p*-toluenesulfonic acid (0.63 g), and trimethylorthoformate (100 mL) were refluxed for 0.5 h; saturated aqueous $NaHCO_3$ (100 mL) was then added, the excess trimethylorthoformate removed *in vacuo*, and the residue extracted with ether (3 × 600 mL). The ether extracts were washed with H_2O (3 × 100 mL), dried over $MgSO_4$, and evaporated *in vacuo* to give the oily orthoformate as a 2:1 mixture of diastereomers in quantitative yield. Nuclear magnetic resonance ($CDCl_3$) δ: 1.30 (s, 3H, CH_3), 1.47 (s, 3H, CH_3), 2.45 (s, 3H, Ph—CH_3), 3.17 (s, ~1H, OCH_3), 3.23 (s, ~2H, OCH_3), 3.90–4.43 (m, 4H, C(4)H, C(5)H, C(6)H), 4.80 (d, 1H, $J_{1,2} = 4$ Hz, C(2)H), 4.92 (d, 1H, $J_{3,4} = 2.5$ Hz, C(3)H), 5.52 (s, ~0.33 H, *H*—C—OCH_3), 5.65 (s, ~0.66 H, *H*—C—OCH_3), 7.62 (4H, ABq, $\delta_{AB} = 0.49$, $J = 8$ Hz).

1,2-O-Isopropylidene-5,6-O-methoxymethylidene-3-deoxy-D-erythro-3,4-hexofuranoside (7)

The pyrolysis reaction was carried out following an adaptation of the procedure described by Zinner *et al.* (2). Tosylate **5** (15 g, 36 mmol) was dissolved in benzene (50 mL) and powdered soda lime (60 g) was added; the solvent was then removed *in vacuo*, yielding an intimate mixture of substrate and base. (Note: Do not homogenize the granular mixture; this is important to prevent the soda lime from blowing over during the pyrolysis.) Vacuum (~5 Torr) was applied and the 250 mL flask was then immersed in a silicon oil bath at 225–235°C. After 10 min the product began to distill over and the vacuum was increased to ~0.5 Torr. The extremely acid labile vinyl ether **7** (2:1 mixture of diastereomers) was obtained as a colorless oil in 55–65% yield, and was at times contaminated with some starting material. Nuclear magnetic resonance ($CDCl_3$) δ: 1.41 (s, 6H, CMe_2), 3.30 (s, 3H, OCH_3), 3.73–4.30 (m, 2H, C(6)H), 4.40–4.90 (m, 1H, C(5)H), 5.15–5.36 (m, 2H, C(2)H, *H*—C—OMe), 5.76 (d, 1H, $J_{1,2} = 4$ Hz, C(1)H), 5.90–6.10 (m, 1H, C(3)H).

1,2-O-Isopropylidene-5,6-O-methoxymethylidene-3-deoxy-α-D-xylohexofuranose (9)

Olefin **7** (5 g, 20 mmol) in ethyl acetate (200 mL, freshly distilled from P_2O_5 after carbonate wash) was hydrogenated (40 lb H_2) using 5% Pd/C as catalyst (1.6 g). After 10 min the reaction mixture was filtered through Celite and the solvent removed *in vacuo* to give the desired deoxy-galacto-furanose **9** in ~90% yield. In spite of all precautions taken, **9** was always contaminated with its partial hydrolysis product **10**. Nuclear magnetic resonance ($CDCl_3$) δ: 1.22 (s, 3H, CH_3), 1.45 (s, 3H, CH_3), 1.53–2.16 (m, 2H, C(3)H), 3.15 (s, 1.5H, OCH_3), 3.19 (s, 1.5H, OCH_3), 3.19–4.76 (m, 5H, C(2)H, C(4)H, C(5)H, C(6)H), 5.50–5.66 (m, 2H, C(1)H, *H*—C—OMe).

1,2-O-Isopropylidene-3-deoxy-α-D-xylohexofuranose (10) (3)

Crude **9** (15.3 g, 62 mmol) was stirred at room temperature for 0.5 h in 200 mL concentrated HCl/H_2O/MeOH (0.01:1:100); solid $NaHCO_3$ (10 g) was then added to effect total hydrolysis of the formates formed. The MeOH was removed *in vacuo*, the residue dissolved in CH_2Cl_2, dried over $MgSO_4$, filtered, and the CH_2Cl_2 removed *in vacuo* to give diol **10** as a solid in quantitative yield. A sample, recrystallized from acetone:hexane, melted at 95.5–96°C (lit. (3) mp 97°C); nmr ($CDCl_3$) δ: 1.33 (s, 3H, CH_3), 1.57 (s, 3H, CH_3), 2.03–2.32 (m, 2H, C(3)H), 3.27 (bs, 2H, OH, exchangeable with D_2O), 3.33–4.43 (m, 4H, C(4)H, C(5)H, C(6)H), 4.68–4.93 (m, 1H, C(2)H), 5.83 (d, 1H, $J_{1,2} = 4$ Hz, C(1)H).

5,6-Anhydro-3-deoxy-1,2-isopropylidene-α-D-xylohexofuranose (13) (3)

To the crude diol **10** (12.7 g, 62 mmol) and *p*-toluenesulfonyl chloride (11.8 g, 62 mmol) under N_2 at 0°C, in CH_2Cl_2 (75 mL, distilled from P_2O_5) was added dropwise pyridine (11 mL) in 10 mL CH_2Cl_2. The reaction mixture was maintained at 0°C for 3 h and was stirred at room temperature for 20 h. The product was extracted with CH_2Cl_2 (2 × 700 mL); the extracts were washed with cold 1% HCl till the washings were acidic, and H_2O (4 × 100 mL). Evaporation gave mono-tosylate **11** in ~70% yield, contaminated with ~15% di-tosylate **12**. This crude residue was dissolved in MeOH/H_2O (300 mL/50 mL), cooled at 0°C, and 1 *N* KOH was added dropwise till the solution remained basic. The solution was neutralized with acidic resin (AM-120 H^+) and the solvents were removed *in vacuo*; the residue was redissolved in CH_2Cl_2, dried over $MgSO_4$, and the solvent removed *in vacuo*. Distillation (100°C/1 Torr) gave the epoxide **13** as an oil (crystallizes at 0°C, lit. (3) mp 27°C), in ~90% yield; nmr ($CDCl_3$) δ: 1.32 (s, 3H, CH_3), 1.54 (s, 3H, CH_3), 2.04–2.37 (m, 2H, C(3)H), 2.40–2.89 (m, 2H, C(6)H), 3.14–3.44 (m, 1H, C(5)H), 3.59–3.94 (m, 1H, C(4)H), 4.64–4.85 (m, 1H, C(2)H), 5.77 (d, 1H, $J_{1,2} = 4$ Hz, C(1)H).

Acid 14 and Methyl Ester 15

To 5-hexynoic acid (4) (2.2 g, 20 mmol) in 25 mL dry HMPA in an argon atmosphere at 5°C was added dropwise

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

n-BuLi in hexane (25 mL, 40 mmol). The colorless solution became bright orange. The epoxide **13** (1.9 g, 10 mmol) in 10 mL HMPA was added dropwise, the ice bath removed (precipitation of the dianion may otherwise occur), and the reaction mixture was stirred at room temperature for 20 h. Acetic acid (1.2 mL, 20 mmol) was then added and the solvents were removed by Kugelrohr distillation (110°C/0.1 Torr). The residue was stirred and shaken in cold 1 *N* aqueous HCl/ether, and was then extracted with ether (3 × 400 mL); the ether extracts were washed with saturated salt solution (4 × 100 mL), dried over $MgSO_4$, and evaporated to yield oily **14** which was methylated with ethereal diazomethane; excess methyl hexynoate was removed at 60°C/0.1 Torr, and the residual oil was purified by flash chromatography (5) (petroleum ether (30–50°C)/ethyl acetate 4.6:4.0) to yield 1.3 g (42% yield) of **15** as an oil. Infrared (neat): 1735 (C=O), 3490 (OH) cm^{-1}; nmr ($CDCl_3$) δ (glucose numbering): 1.33 (s, 3H, CH_3), 1.57 (s, 3H, CH_3), 1.60–2.63 (m, 10H, C(3)H, C(6)H, $CH_2CH_2CH_2$), 3.06 (d, 1H, $J_{5,OH}$ = 3.5 Hz, OH, exchangeable with D_2O), 3.65–4.43 (m, 2H, C(4)H, C(5)H), 3.68 (s, 3H, CO_2CH_3), 4.67–4.93 (m, 1H, C(2)H), 5.82 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H); ms (70 eV) *m/e*: 297 (M − CH_3), 173 (M − (CH_2—C≡C − $(CH_2)_3CO_2Me$)), 169 (CHOH—CH_2—C≡C$(CH_2)_3CO_2Me$)) 143 (*M* − 169); $[\alpha]_D^{20}$ −20.4° (*c* 4.90, $CHCl_3$). *Anal.* calcd. for $C_{16}H_{24}O_6$: C 61.54, H 7.69; found: C 61.79, H 7.40.

Z-Olefin 16 (6)

To nickel acetate (2.2 g, 8.8 mmol) in a three-neck flask equipped with a septum, was added 5 mL of 95% ethanol. The flask was connected to the hydrogenation apparatus and was flushed with hydrogen. The catalyst was produced by injecting 12.9 mL of a 0.5 *M* solution of sodium borohydride in 95% ethanol to the rapidly stirred solution of nickel acetate. The reaction vessel was reflushed with hydrogen and ethylene diamine (0.5 mL) was added. Hydrogenation was then initiated by introducing the acetylenic alcohol **15** (3.12 g, 10.0 mmol), in 10 mL ethanol, via the septum. Hydrogen uptake was quantitative within an hour and then virtually ceased. The reaction mixture was filtered through Celite, the ethanol was removed under reduced pressure, and the residue was extracted with ether (3 × 350 mL). The combined ether extracts were washed with H_2O (3 × 40 mL), dried over $MgSO_4$, and evaporated *in vacuo* to give the olefinic alcohol **16** in quantitative yield. Infrared (neat): 1735 (C=O), 3500 (OH) cm^{-1}; nmr ($CDCl_3$) δ (glucose numbering): 1.32 (s, 3H, CH_3), 1.54 (s, 3H, CH_3), 1.61–2.61 (m, 10H, C(3)H, C(6)H, $CH_2CH_2CH_2$), 2.89 (d, 1H, *J* ~ 3 Hz, OH, exchangeable with D_2O), 3.58–4.38 (m, 2H, C(4)H, C(5)H), 3.67 (s, 3H, CO_2CH_3), 4.68–4.93 (m, 1H, C(2)H), 5.41–5.68 (m, 2H, *Z*-CH=CH), 5.81 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H); Cmr ($CDCl_3$) δ: 173.67 (CO_2Me), 130.52 (C=C), 125.98 (C=C), 112.17, 105.92, 83.64, 80.56, 72.31, 51.11, 33.36, 33.14, 31.04, 26.78, 26.40, 25.75, 24.46, 23.81; *m/e* (trimethylsilylated sample): 313 (M − $SiMe_3$), 245 (M − CH_2HC=CH$(CH_2)_3COOMe$), 243 (Me_3SiOCH—CH_2CH=CH$(CH_2)_3CO_2Me$).

tert-*Butyldiphenylsilyl Ether 17*

To the alcohol **16** (2.53 g, 8.06 mmol) in dry dimethylformamide (15 mL) under N_2 was added *tert*-butylchlorodiphenylsilane (2.44 g, 8.86 mmol) and imidazole (1.21 g, 17.8 mmol); the reaction mixture was then stirred at 78°C for 17 h to effect complete silylation. Water (100 mL) was added and the product was extracted with ether (3 × 350 mL); the combined ether extracts were washed with H_2O (3 × 40 mL), dried over $MgSO_4$, and evaporated to afford the silylated alcohol, **17**, as a pale yellow oil, in quantitative yield. Nuclear magnetic resonance (glucose numbering) ($CDCl_3$) δ: 0.68–2.55 (m, 10H, C(3)H, C(6)H, $CH_2CH_2CH_2$), 1.05 (s, 9H, $SiCMe_3$), 1.28 (s, 3H, CH_3). 1.38 (s, 3H, CH_3), 3.54 (s, 3H, CO_2CH_3), 3.67–4.20 (m, 2H, C(4)H, C(5)H), 4.43–4.70 (q-like m, 1H, C(2)H), 5.08–5.38 (m, 2H, *Z*-HC=CH), 5.47 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H), 7.05–7.75 (m, 10H, $SiPh_2$); *m/e*: 537 (*M* − 15); $[\alpha]_D^{21}$ −41.44° (*c* 4.85, $CHCl_3$). *Anal.* calcd. for $C_{32}H_{44}O_6Si$: C 69.57, H 7.97; found: C 69.76, H 7.98.

*Methyl 8*R-tert-*Butyldiphenylsilyloxy-9*R,*11*R-*dihydroxy-9,11*-O-*isopropylidene-12,12-di(ethylthio)dodeca-5Z-enoate (19) from 17*

To the silylated alcohol **17** (1.5 g, 2.7 mmol) in ethanethiol (4 mL) at −10°C was added anhydrous zinc chloride (1.9 g, 14.0 mmol). After one hour at −10°C, the excess ethanethiol was removed at −10°C, *in vacuo*. The foamy residue was dissolved in ethyl acetate (50 mL) and aqueous $NaHCO_3$ (10 mL) was added; the precipitate which formed was filtered off and the filtrate was extracted with ethyl acetate (3 × 400 mL); the ethyl acetate extracts were washed with saturated salt solution (3 × 50 mL), dried over $MgSO_4$, and evaporated to give the thioacetal **18** in ~85% yield. Its nmr spectrum was consistent with the structure proposed.

To an aliquot of the crude product **18** (1.1 g, 1.8 mmol) in 50 mL acetone was added dimethoxypropane (5 mL) and *p*-toluenesulfonic acid (catalytic). After 15 min at room temperature the acetone was removed at reduced pressure and the residue extracted with ethyl acetate (3 × 400 mL); the ethyl acetate extracts were washed with aqueous $NaHCO_3$ (3 × 30 mL), saturated salt solution (3 × 30 mL), dried over $MgSO_4$, and evaporated to give the isopropylidene thioacetal **19** as a pale yellow oil in quantitative yield. Nuclear magnetic resonance ($CDCl_3$) δ: 1.05 (s, 9H, $SiCMe_3$), 1.17–2.93 (m, 16H, $5CH_2$, $2CH_3$), 1.22 (s, 6H, CMe_2), 2.65 (q, $J \simeq 7$ Hz, 4H, $2SCH_2CH_3$), 3.60 (s, 3H, CO_2CH_3), 3.60–4.17 (m, 4H, H—C—S, H—C—O), 5.13–5.57 (m, 2H, *Z*-HC=CH), 7.17–7.87 (m, 10H, $SiPh_2$); *m/e* (70 eV): 584 ($M^+ - CH_2C$-(OMe)OH), 135 ($CH(SEt)_2$, 100%); $[\alpha]_D^{22}$ 5.71° (*c* 2.75, $CHCl_3$). *Anal.* calcd. for $C_{36}H_{54}O_5S_2Si$: C 65.65, H 8.21, S 9.73; found: C 65.84, H 8.57, S 9.83.

*Methyl 8*R-tert-*Butyldiphenylsilyloxy-9*R,*11*R-*dihydroxy-9,11*-O-*isopropylidene-12-oxo-dodeca-5Z-enoate (20)*

To the dithioacetal **19** (0.49 g, 0.75 mmol) in acetone: water (26 mL: 2.6 mL) was added mercuric oxide (1.3 g, 6.1 mmol), and mercuric chloride (0.55 g, 2.0 mmol); the heterogeneous reaction mixture was stirred at room temperature for 6 h, and was then filtered into aqueous $NaHCO_3$ (100 mL); the filtrate was refiltered, the acetone removed *in vacuo*, and the residue extracted with CH_2Cl_2 (2 × 300 mL); the extracts were washed with aqueous KI (2 × 50 mL), saturated salt solution (3 × 50 mL), dried over $MgSO_4$, and evaporated to give (after flash chromatography, petroleum ether/ethyl acetate 7:2) the oily, somewhat unstable aldehyde **20**, in part as a hydrate, in 75% yield. Infrared (neat): 1737 (COOMe), 3450 (OH-hydrated aldehyde) cm^{-1}; nmr ($CDCl_3$) δ: 1.08 (s, 9H, $SiCMe_3$), ~1.1–2.5 (m, 10H, $5CH_2$), 1.23 (s, 3H, CH_3), 1.32 (s, 3H, CH_3), 3.48–3.95 (m, 2H, C(8)H, C(9)H), 3.61 (s, 3H, CO_2CH_3), 4.15 (dd, 1H, $J_{10e,11}$ = $J_{10a,11}$ ~ 6.5 Hz, C(11)H), 5.16–5.58 (m, 2H, *Z*-HC=CH), 7.18–7.88 (m, 10H, $SiPh_2$), 9.72 (s, 0.8H, CHO); $[\alpha]_D^{20}$ 4.4° (*c* 1.80, $CHCl_3$).

*Methyl 8*R-tert-*Butyldiphenylsilyloxy-9*R,*11*S-*dihydroxy-9,11*-O-*isopropylidene-12-oxo-dodeca-5Z-enoate (20*a*) from 20*

Aldehyde **20** (30 mg, 0.052 mmol) was dissolved in dry

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

methanol saturated with potassium carbonate and was kept at room temperature for 6 h to effect complete isomerization of the axial aldehyde to its equatorial epimer. The solution was then neutralized with weak acidic resin (IRC-50). Removal of the resin, followed by evaporation of the methanol gave the oily, somewhat unstable, aldehyde **20***a* in part as a hydrate, in ~90% yield; nmr ($CDCl_3$) δ: 0.73–2.37 (m, 10H, $5CH_2$), 1.04 (s, 9H, $SiCMe_3$), 1.25 (s, 3H, CH_3), 1.32 (s, 3H, CH_3), ~3.6–3.9 (m, 2H, C(8)H, C(9)H), 3.66 (s, 3H, CO_2Me), 4.13 (dd, 1H, $J_{10,11}$ ~ 3 Hz, 12 Hz, C(11)H), 5.3–5.6 (m, 2H, *Z*-HC=CH), 7.31–7.85 (m, 10H, $SiPh_2$), 9.58 (s, 0.4H, hydrated CHO); $[\alpha]_D^{22}$ −21° (*c* 0.95, $CHCl_3$).

*Methyl 8*R-tert-*Butyldiphenylsilyloxy-9*R,*11*R-*dihydroxy-9,11*-O-*isopropylidene-14-oxo-tetradeca-5Z,12*E-*dienoate (21)*

To aldehyde **20** (1.25 g, 2.26 mmol) in 15 mL dry dimethylformamide under N_2, was added formylmethylenetriphenylphosphorane (7) (0.76 g, 2.5 mmol). After 20 h stirring at room temperature, water (200 mL) was added to the reaction mixture which was then extracted with ether (3 × 300 mL); the ether extracts were then washed with H_2O (3 × 50 mL), dried over $MgSO_4$, and evaporated to give the α,β unsaturated aldehyde **21** in ~70% yield, after flash chromatography (petroleum ether/ethyl acetate 11:2). Infrared (neat): 1692 (CHO), 1738 (CO_2Me) cm^{-1}; nmr ($CDCl_3$) δ: 1.06 (s, 9H, $SiCMe_3$), ~1.2–2.4 (m, 10H, $5CH_2$), 1.26 (s, 3H, CH_3), 1.35 (s, 3H, CH_3), 3.65 (s, 3H, CO_2CH_3), 3.71–3.91 (m, 2H, C(8)H, C(9)H), 4.48–4.63 (m, 1H, C(11)H), 5.27–5.55 (m, 2H, *Z*-CH=CH), 6.51 (ABq, 2H, $J_{12,13}$ = 16 Hz, $J_{13,14}$ ~8 Hz, $J_{11,13}$ ~ 1.5 Hz, $J_{11,12}$ = 4 Hz, OCH(11)—C*H*(12)—CH(14)O), 7.33–7.87 (m, 10H, $SiPh_2$), 9.57 (d, 1H, $J_{13,14}$ = 8 Hz, CHO); $[\alpha]_D^{22}$ 12.1° (*c* 4.25, $CHCl_3$).

*Methyl 8*R-tert-*Butyldiphenylsilyloxy-9*R,*11*R-*dihydroxy-9,11*-O-*isopropylidene-eicosa-5Z,12*E,*14Z-trienoate (22*a*)*

To *n*-hexyltriphenylphosphonium bromide (1.36 g, 3.19 mmol) in dry THF (10 mL) under argon at room temperature was rapidly added *n*-BuLi (2.55 mmol). The reaction mixture turned red immediately; it was stirred for 10 min, cooled to −78°C, and then aldehyde **21** (0.88 g, 1.52 mmol, in 5 mL THF) was added slowly via syringe. The reaction was over immediately and was warmed up rapidly by immersion into a room temperature water bath. The reaction mixture was quenched with H_2O, the THF removed *in vacuo*, and the residue extracted with hexane (3 × 150 mL); the extracts were washed with H_2O (3 × 20 mL), dried over $MgSO_4$, and evaporated. Flash chromatography (petroleum ether/ethyl acetate 10:0.7) gave the desired 14-*Z* olefin **22***a*, contaminated with a small amount of its 14-*E* isomer, as an oil, in ~70% yield. A separation of the minor 14-*E* impurity could not be achieved at this stage of the synthesis. Nuclear magnetic resonance ($CDCl_3$) δ: 0.73–2.53 (m, 21H, $9CH_2$, $1CH_3$), 1.08 (s, 9H, $SiCMe_3$), 1.27 (s, 3H, CH_3), 1.35 (s, 3H, CH_3), 3.64 (s, 3H, CO_2CH_3), 3.67–3.70 (m, 2H, C(8)H, C(9)H), 4.13–4.57 (m, 1H, C(11)H), 5.10–6.75 (m, 6H, olefinic H's), 7.23–7.93 (m, 10H, $SiPh_2$); $[\alpha]_D^{21}$ 29.53° (*c* 3.20, $CHCl_3$).

*Methyl 8*R,*9*R,*11*R-*Trihydroxy-9,11*-O-*isopropylidene-eicosa-5Z,12*E,*14Z-trienoate (22*b*)*

A mixture of **22***a* (0.65 g, 1.0 mmol) and tetra-*n*-butyl ammonium fluoride (2.0 mmol) was stirred in dry tetrahydrofuran (10 mL) at 60°C under a nitrogen atmosphere for 2 h; the tetrahydrofuran was removed *in vacuo* and the residue was extracted with ether (3 × 150 mL), washed with H_2O (3 × 30 mL), dried over $MgSO_4$, and purified by flash chromatography (petroleum ether/ethyl acetate 4:1) to give an 80% yield of **22***b*, contaminated with traces of its 14-*E* isomer. Nuclear magnetic resonance ($CDCl_3$) δ: 0.67–2.57 (m, 21H, $9CH_2$, $1CH_3$), 1.42 (s, 6H, $C(Me)_2$), ~2.6 (bs, 1H, OH (exchangeable with D_2O)), 3.33–4.00 (m, 2H, C(8)H, C(9)H), 3.68 (s, 3H, CO_2CH_3), 4.17–4.62 (m, 1H, C(11)H), 5.23–6.78 (m, 6H, olefinic H's); $[\alpha]_D^{21}$ +52.64° (*c* 3.75, $CHCl_3$).

*Methyl 8*R-*Acetoxy-9*R,*11*R-*dihydroxy-9,11*-O-*isopropylidene-eicosa-5Z,12*E,*14Z-trienoate (22*d*) from 22*b

A solution of alcohol **22***b* (0.055 g, 0.14 mmol, 14*Z*/14*E* 9:1) in anhydrous ether (10 mL) containing dry acetic anhydride (1 mL) and 4-dimethylaminopyridine (catalytic) was stirred at room temperature for 0.5 h. The ether was then evaporated *in vacuo*, and excess reagents were removed by azeotroping with toluene. The residue was extracted with ether (3 × 150 mL), washed with cold 1 *N* aqueous HCl (2 × 20 mL), aqueous $NaHCO_3$ (2 × 20 mL), H_2O (2 × 20 mL), and dried over $MgSO_4$. Removal of the solvent yielded acetate **22***d* quantitatively; nmr ($CDCl_3$) δ: 0.59–2.56 (m, 21H, $9CH_2$, $1CH_3$), 1.37 (s, 6H, CMe_2), 2.09 (s, 3H, $COCH_3$), 3.67 (s, 3H, CO_2CH_3), 3.72–4.14 (m, 1H, C(9)H), 4.19–4.62 (m, 1H, C(11)H), 4.74–5.11 (m, 1H, C(8)H), 5.14–6.76 (m, 6H, olefinic H's).

*Methyl 8*R-*Acetoxy-9*R,*11*R-*dihydroxyeicosa-5Z,12*E,*14Z-trienoate (22*e*) from 22*d

Acetate **22***d* (14*Z*/*E* ≅ 9:1, 60 mg, 0.13 mmol) in 10 mL methanol and 2.5 mL 0.035 *N* aqueous HCl was stirred at room temperature for 2 h to effect complete hydrolysis. The solution was neutralized with basic resin (IR-45 OH) and the solvents removed *in vacuo*; the residue was redissolved in ether and dried over $MgSO_4$. Evaporation of the solvent gave diol **22***e*, as a 9:1 mixture of 14*Z* and *E* isomers, in quantitative yield; the minor 14*E* impurity was not separated at this stage of the synthesis. The nmr data showed the presence of two acetate peaks, in an approximate 2:3 ratio, indicative of acetate migration during the basic conditions of work-up. However, this was of no consequence since the acetate group would be removed in the next synthetic step; nmr ($CDCl_3$) δ: 0.64–2.61 (21H, $9CH_2$, $1CH_3$), 2.09 (s, ~1.8H, $COCH_3$), 2.13 (s, ~1.2H, $COCH_3$), 3.02 (bs, 2H, OH, exchangeable with D_2O), 3.69 (s, 3H, CO_2CH_3), ~3.7–~5.0 (m, 3H, three —O—C—*H*), 5.24–6.88 (m, 6H, olefinic H's).

*Methyl 8*R,*9*R,*11*R-*Trihydroxy-5Z,12*E,*14Z-eicosatrienoate (22*f*) from 22*e

Acetate diol **22***e* (55 mg, 0.13 mmol, 14*Z*/*E* ~ 9:1), in 10 mL dry MeOH containing a catalytic amount of sodium methoxide, was stirred for 0.5 h, and was then neutralized with weak acidic resin (IRC-50). Removal of the resin, followed by evaporation of the methanol, gave triol **22***f* in quantitative yield. Flash chromatography as well as hplc proved to be ineffective for separation of the 14*E* and *Z* isomers. Nuclear magnetic resonance ($CDCl_3$) δ: ~0.6–2.5 (m, 21H, $9CH_2$, $1CH_3$), ~2.5–3.2 (bs, 3H, OH, exchangeable with D_2O), 3.33–4.03 (m, 2H, C(8)H, C(9)H), 3.68 (s, 3H, CO_2CH_3), 4.33–4.77 (m, 1H, C(11)H), 5.23–6.85 (m, 6H, olefinic H's).

*Methyl 8*R,*9*R,*11*R-*Triacetoxy-5Z,12*E,*14Z-eicosatrienoate (22*g*) from 22*f

Triacetate **22***g* was synthesized in a manner analogous to that of triacetate **24***e* herein described. The 14*E* and *Z* isomers were separated by hplc (petroleum ether/ethyl acetate/MeOH 900:100:3). Nuclear magnetic resonance ($CDCl_3$) δ: 0.89 (t, 3H, $J_{19,20}$ ~ 6.5 Hz, CH_3), 1.20–2.44 (m, 18H, $9CH_2$), 2.04 (s, 3H, $COCH_3$), 2.08 (s, 6H, $2COCH_3$), 3.67 (s, 3H, CO_2CH_3), 4.93–5.06 (m, 2H, *H*C(8)OAc, *H*C(9)OAc), 5.15–5.64 (m, 5H, *H*C(11)OAc, 4 olefinic H's), 5.94 ("dd",

For personal use only.

1H, $J_{13,14} = J_{14,15} \sim 11$ Hz, C(14)H), 6.55 ("dd", 1H, $J_{13,14} \sim 11$ Hz, $J_{12,13} \sim 15$ Hz, C(13)H); Cmr ($CDCl_3$) δ: 173.86 (*C*OOCH$_3$), 170.33 (O*C*OCH$_3$), 170.22 (O*C*OCH$_3$), 170.16 (OCOCH$_3$), 134.68 (C=C), 132.02 (C=C), 129.74 (C=C), 128.63 (C=C), 127.12 (C=C), 124.34 (C=C), 73.76, 70.46, 69.42, 51.46, 35.70, 33.35, 31.42, 29.19, 28.68, 27.79, 26.58, 24.60, 22.52, 21.16, 20.88, 20.80, 14.01; *m/e*: found 494.2881 (M^+), calcd.: 494.2877 (M^+); 435 (M^+ − OCOCH$_3$), 374 (M^+ − 2AcOH), 333 (M^+ − $(CH_2)_3CO_2Me$ − AcOH), 233 (M^+ − $CH_2CH{=}CH(CH_2)_3CI_2Me$ − 2AcOH); $[\alpha]_D^{22}$ 1.68° (*c* 3.10, $CHCl_3$).

*Methyl 8*R*-Mesyloxy-9*R*,11*R*-dihydroxy-9,11*-O*-isopropylidene-eicosa-5Z,12*E*,14Z-trienoate (22*i*) from 22*b*

To a mixture of alcohol **22***b* (20 mg, 0.05 mmol, 14*Z*/14*E* 9:1) and triethylamine (20 mg, 0.2 mmol) in dry methylene chloride (5 mL), under a nitrogen atmosphere, at 5°C, was added methanesulfonyl chloride (15 mg, 0.13 mmol). After 0.5 h the reaction mixture was extracted with ether (3 × 100 mL); the extracts were washed with cold aqueous 0.3% HCl (3 × 15 mL), H_2O (3 × 15 mL), dried over $MgSO_4$, and evaporated to give highly unstable mesylate **22***i* as an oil, in quantitative yield. It was reacted immediately to avoid decomposition; nmr ($CDCl_3$) δ: 0.7–2.6 (m, 21H, $9CH_2$, $1CH_3$), 1.38 (s, 6H, $2CH_3$), 3.03 (s, 3H, SO_2CH_3), 3.63 (s, 3H, CO_2CH_3), 3.75–4.75 (m, 3H, C(8)H, C(9)H, C(11)H), 5.20–6.73 (m, 6H, olefinic H's).

*Methyl 8*R*-Mesyloxy-9*R*,11*R*-diacetoxyeicosa-5Z,12*E*,14Z-trienoate (22*k*)*

Mesylate **22***i* (24 mg, 0.05 mmol, 14*Z*/*E* = 9:1) in 4 mL MeOH and 1 mL 1 *N* aqueous HCl was stirred at room temperature for 20 min to effect complete hydrolysis. Reaction time was kept at a minimum to avoid competitive furan (**26***b*) formation. The solution was neutralized with basic resin (IR-45 OH) and the solvents removed *in vacuo*; the diol mesylate **22***j* thus obtained was redissolved in ether, dried over $MgSO_4$, filtered, and acetic anhydride (0.5 mL, excess) and a catalytic amount of 4-dimethylaminopyridine were added. After 0.5 h the ether was evaporated *in vacuo* and excess reagents were removed by azeotroping with toluene. The residue was extracted with ether (3 × 100 mL); the extracts were then washed with cold 0.3% HCl (3 × 10 mL), H_2O (3 × 10 mL), and dried over $MgSO_4$. Removal of the solvent yielded the mesylate diacetate **22***k*, as an oil, in 90% yield; nmr ($CDCl_3$) δ: ~0.7–2.6 (m, 21H, $9CH_2$, $1CH_3$), 2.05 (s, 3H, $COCH_3$), 2.09 (s, 3H, $COCH_3$), 3.04 (s, 3H, SO_2CH_3), 3.66 (s, 3H, CO_2CH_3), ~4.5–6.7 (m, 9H, C(8)H, C(9)H, C(11)H, three HC=CH).

*Methyl 8*S*,9*R*,11*R*-Triacetoxy-5Z,12*E*,14Z-eicosatrienoate (23*c*)*

Mesylate diacetate **22***k* (20 mg, 0.038 mmol, 14*Z*/*E* = 9:1) and anhydrous potassium acetate (4 mg, 0.041 mmol) in 10 mL dry methanol were refluxed for 48 h under a nitrogen atmosphere. The reaction mixture was then cooled and a catalytic amount of aqueous acetic acid added; the methanol was removed *in vacuo*, and the remaining solvents azeotroped with toluene, to yield crude acetates **23***b*; these were then dissolved in 10 mL anhydrous ether, and 0.2 mL acetic anhydride and a catalytic amount of 4-dimethylaminopyridine were added; after 15 min the excess acetic anhydride and acetic acid were azeotroped off with toluene. The residue was extracted with ether (3 × 75 mL); the extracts were washed with cold aqueous 1% HCl (2 × 10 mL), H_2O (3 × 10 mL), and dried over $MgSO_4$; evaporation of the solvent, followed by purification of the crude triacetate by flash chromatography (petroleum ether/ethyl acetate 7.5:2) yielded **23***c* (14*Z*/*E* 9:1) in 75% yield. The minor 14*E* isomer was separated by hplc (petroleum ether/ethyl acetate/MeOH 850:100:3). Nuclear magnetic resonance ($CDCl_3$) δ: 0.90 (t, 3H, $J_{19,20} \sim 6$ Hz, CH_3), 1.22–2.48 (m, 18H, $9CH_2$), 2.05 (s, 6H, $2COCH_3$), 2.06 (s, 3H, $COCH_3$), 3.68 (s, 3H, CO_2CH_3), 5.01–5.20 (m, 2H, *H*C(8)OAc, *H*C(9)OAc), 5.29–5.66 (m, 5H, *H*C(11)OAc, 4 olefinic H's), 5.96 ("dd", 1H, $J_{13,14} = J_{14,15} \sim 11$ Hz, C(14)H), 6.57 ("dd", 1H, $J_{13,14} \sim 11$ Hz, $J_{12,13} \sim 15$ Hz, C(13)H).

*Methyl 8*R*-Mesyloxy-9*S*,11*R*-dihydroxy-9,11*-O*-isopropylidene-eicosa-5Z,12*E*,14Z-trienoate (24*b*)*

To a mixture of alcohol **24***a* (1) (0.10 g, 0.25 mmol) and methanesulfonyl chloride (0.043 g, 0.38 mmol) in dry methylene chloride (4 mL), under nitrogen, at 5°C, was added triethylamine (0.05 g, 0.50 mmol). After 0.5 h the reaction mixture was extracted with ether (3 × 150 mL); the extracts were washed with cold aqueous 1% HCl (3 × 20 mL) H_2O (3 × 20 mL), dried over $MgSO_4$, and evaporated to give mesylate **24**b as an oil in quantitative yield; nmr ($CDCl_3$) δ: ~0.6–2.7 (m, 21H, $9CH_2$, $1CH_3$), 1.42 (s, 3H, CH_3), 1.48 (s, 3H, CH_3), 3.07 (s, 3H, SO_2CH_3), 3.67 (s, 3H, CO_2CH_3), 3.87–4.93 (m, 3H, C(8)H, C(9)H, C(11)H), 5.20–6.82 (m, 6H, three HC=CH); $[\alpha]_D^{20}$ 5.87 (*c* 3.95, $CHCl_3$).

*Methyl 8*R*-Mesyloxy-9*S*,11*R*-diacetoxyeicosa-5Z,12*E*,14Z-trienoate (24*d*)*

Mesylate **24***b* (0.085 g, 0.175 mmol) in 8 mL methanol and 2 mL 0.5 *N* aqueous HCl was stirred at room temperature for 1 h to effect complete hydrolysis. Reaction time was kept at a minimum to reduce competitive furan (**26***a*) formation. The solution was neutralized with basic resin (IR-45 OH) and the solvents removed *in vacuo*; the diol mesylate **24***c*, thus obtained, was redissolved in ether, dried over $MgSO_4$, filtered, and acetic anhydride (2 mL, excess) and a catalytic amount of 4-dimethylaminopyridine (8) were added. After 0.5 h the ether was evaporated *in vacuo* and excess reagents were removed by azeotroping with toluene. The residue was extracted with ether (3 × 150 mL); the extracts were then washed with cold 1% HCl (3 × 20 mL), H_2O (3 × 20 mL), and dried over $MgSO_4$. Removal of the solvent yielded the mesylate diacetate **24***d* contaminated with furan byproduct **26***a*. Purification of the above mixture by flash chromatography (petroleum ether/ethyl acetate 7:3) gave mesylate **24***d* as an oil in 60% yield; nmr ($CDCl_3$) δ: ~0.66–2.86 (m, 21H, $9CH_2$, $1CH_3$), 2.06 (s, 3H, $COCH_3$), 2.10 (s, 3H, $COCH_3$), 3.04 (s, 3H, SO_2CH_3), 3.68 (s, 3H, CO_2CH_3), 4.69–6.78 (m, 9H, C(8)H, C(9)H, C(11)H, three HC=CH); $[\alpha]_D^{22}$ −4.0° (*c* 2.75, $CHCl_3$). Tetrahydrofuran **26***c*: nmr ($CDCl_3$) δ: 0.89 (t, 3H, $J_{19,20} \sim 6$ Hz, CH_3), ~0.94–2.54 (m, 18H, $9CH_2$), 2.12 (s, 3H, $COCH_3$), 3.68 (s, 3H, CO_2CH_3), 3.97–4.12 (m, 1H, C(8)H), 4.61–4.78 (m, 1H, C(11)H), ~5.3–5.7 (m, 5H, HC(9)OAc, 4 olefinic H's), 6.00 ("dd", 1H, $J_{13,14} = J_{14,15} \sim 11$ Hz, C(14)H), 6.55 ("dd", 1H, $J_{13,14} \sim 11$ Hz, $J_{12,13} \sim 15$ Hz, C(13)H); *m/e* (70 eV): 392 (M^+), 332 (M^+ − AcOH), 191 (M^+ − AcOH − $CH_2CH{=}CH(CH_2)_3CO_2Me$).

*Methyl 8*S*,9*S*,11*R*-Triacetoxyeicosa-5Z,12*E*,14Z-trienoate (25*c*)*

Mesylate diacetate **24***d* (50 mg, 0.094 mmol) and anhydrous potassium acetate (10.6 mg, 0.108 mmol) in 10 mL dry methanol was refluxed for ~48 h under a nitrogen atmosphere. The reaction mixture was then cooled and a catalytic amount of aqueous acetic acid added; the methanol was removed *in vacuo* and the remaining solvents azeotroped with toluene to yield crude acetates **25***b*; these were then dissolved in 10 mL anhydrous ether, and 0.5 mL acetic anhydride and a catalytic amount of 4-dimethylaminopyridine were added;

after 15 min the excess acetic anhydride and acetic acid were azeotroped off with toluene. The residue was extracted with ether (3 × 150 mL); the extracts were washed with cold 1% aqueous HCl (2 × 15 mL), H_2O (3 × 15 mL), and dried over $MgSO_4$; evaporation of the solvent, followed by purification of the crude triacetate by flash chromatography (petroleum ether/ethyl acetate 7.5:2), yielded **25***c* in 75% yield. Nuclear magnetic resonance ($CDCl_3$) δ: 0.89 (t, 3H, $J_{19,20} \sim$ 6.5 Hz, CH_3), 1.18–2.44 (m, 18H, $9CH_2$), 2.05 (s, 3H, $COCH_3$), 2.07 (s, 3H, $COCH_3$), 2.10 (s, 3H, $COCH_3$), 3.67 (s, 3H, CO_2CH_3), 4.98–5.16 (m, 2H, *H*C(8)OAc, *H*C(9)OAc), 5.26–5.64 (m, 5H, *H*C(11)OAc, 4 olefinic H's), 5.95 ("dd", 1H, $J_{13,14} = J_{14,15} \sim$ 11 Hz, C(14)H), 6.53 ("dd", 1H, $J_{13,14} \sim$ 11 Hz, $J_{12,13} \sim$ 15.5 Hz, C(13)H); Cmr ($CDCl_3$) δ: 173.88 (CO_2Me), 170.28 ($OCOCH_3$), 170.02 ($OCOCH_3$), 169.96 ($OCOCH_3$), 134.62 (C=C), 131.98 (C=C), 129.16 (C=C), 128.83 (C=C), 127.11 (C=C), 124.32 (C=C), 73.41, 71.58, 70.12, 51.46, 35.91, 33.34, 31.39, 29.16, 28.53, 27.76, 26.55, 24.59, 22.50, 21.24, 20.95, 20.88, 14.02; *m/e*: found: 494.2884 (M^+); calcd.: 494.2877 (M^+); 435 ($M^+ - OCOCH_3$), 374 (M^+ − 2AcOH), 333 ($M^+ - (CH_2)_3CO_2Me$ − AcOH), 233 ($M^+ - CH_2CH{=}CH(CH_2)_3CO_2Me$ − 2AcOH), $[\alpha]_D^{22}$ 1.60° (*c* 1.60, $CHCl_3$).

*Methyl 8*R,*9*S,*11*R-*Triacetoxy-5*Z,*12*E,*14*Z-*eicosatrienoate (24e) from 24*f

A solution of triol **24***f* (60 mg, 0.16 mmol) in 10 mL anhydrous ether containing dry acetic anhydride (1 mL) and 4-dimethylaminopyridine (catalytic) was stirred at room temperature for 0.5 h. The ether was then evaporated *in vacuo* and excess reagents were removed by azeotroping with toluene. The residue was extracted with ether (3 × 150 mL), washed with cold aqueous 1 *N* HCl (2 × 20 mL), aqueous $NaHCO_3$ (2 × 20 mL), H_2O (2 × 20 mL), and dried over $MgSO_4$. Removal of the solvent yielded triacetate **24***e* quantitatively; nmr ($CDCl_3$) δ: 0.90 (t, 3H, $J_{19,20} \sim$ 6.5 Hz, CH_3), 1.20–2.46 (m, 18H, $9CH_2$), 2.04 (s, 3H, $COCH_3$), 2.05 (s, 3H, $COCH_3$), 2.06 (s, 3H, $COCH_3$), 3.68 (s, 3H, CO_2CH_3), 4.98–5.14 (m, 2H, *H*C(8)OAc, *H*C(9)OAc), 5.28–5.64 (m, 5H, *H*C(11)OAc, 4 olefinic H's), 5.95 ("dd", 1H, $J_{13,14} = J_{14,15} \sim$ 11 Hz, C(14)H), 6.52 ("dd", 1H, $J_{13,14} \sim$ 11 Hz, $J_{12,13} \sim$ 15 Hz, C(13)H); *m/e*: found: 494.2884 (M^+), calcd.: 494.2877 (M^+); 435 ($M^+ - OCOCH_3$), 374 (M^+ − 2AcOH), 333 ($M^+ - (CH_2)_3CO_2Me$ − AcOH), 233 ($M^+ - CH_2CH{=}CH(CH_2)_3CO_2Me$ − 2AcOH); $[\alpha]_D^{22}$ − 1.20° (*c* 3.75, $CHCl_3$).

The two isomers of 3-aminotropane-3-carboxylic acid have been prepared by hydrolysis of the two α- and β-tropane-3-spiro-5′-hydantoins whose configurations were determined by X-ray crystallography and ^{13}C nmr. The pK'_a values of these amino acids and the hydrolysis rates of their *N*-formyl derivatives have been determined to study the influence of the amino group in an axial or equatorial position. The biological transport – inhibitory action of the two tropane amino acids has also been compared.

GREGORIO G. TRIGO, CARMEN AVENDAÑO, EMILIA SANTOS, HALVOR N. CHRISTENSEN et MARY E. HANDLOGTEN. Can. J. Chem. **58**, 2295 (1980).

On a préparé les deux isomères de l'acide amino-3-tropane-carboxylique-3 par hydrolyse des deux α- et β-tropane-3-spiro-5′-hydantoïne dont les configurations ont été déterminées par rayons X et rmn ^{13}C. Les valeurs des pK'_a de ces aminoacides et les vitesses d'hydrolyse de leurs dérivés *N*-formylés ont été déterminées afin d'étudier l'influence du groupement amino en position axiale or équatoriale. On a comparé également l'action biologique d'inhibition du transport de ces deux aminoacides tropaniques.

Introduction

We have succeeded in preparing the epimeric tropane amino acids (**1**, **2**) and we hoped that with both epimers in hand we could contribute to the accumulated information relating to the configurational studies of aminocyclohexane- and aminocyclopentane carboxylic acids (1–4).

From the biological point of view, several diamino acids have been used to investigate transport properties of lysine analogs. Interest in them extends also to transport of neutral amino acids. 1-Methylpiperidine-4-amino-4-carboxylic acid, for instance, is effective in inhibiting uptake of the amino-*endo* isomer of the norbornane amino acid, BCH (2-aminobicyclo[2.2.1]heptane-2-carboxylic acid), that serves as a model substrate for system L, the system for neutral amino acids with bulky, apolar sidechains (5). The transport behavior of the two isomeric tropane amino acids (ATC) has been studied to see if the 2-carbon bridge might give some information about the space available around the receptor site for system L, where the amino acid is bound for transport.

Experimental

Infrared spectral data were obtained from a Perkin-Elmer 577 spectrophotometer. All compounds were compressed into KBr pellets. Nuclear magnetic resonance spectra were obtained from a Perkin-Elmer R-24 A (60 MHz) spectrometer. Elemental analyses were performed on a Carlo Erba 1104 analyzer. All melting points were uncorrected. Paper chromatography (*n*-BuOH/AcOH/H_2O 3 :1 :6) was used in the R_f determinations.

Synthesis

3α-Amino-1αH,5αH-tropane-3β-carboxylic Acid (1)

α-Tropane-3-spiro-5′-hydantoin (10 g), obtained by the Bucherer synthesis from tropinone (6), was heated with 60% sulphuric acid (85 mL), the solution was neutralized with barium carbonate, and filtered. The pure amino acid was isolated by passage over 54 mL of ion exchange resin (cationic Lewatit S100) using 0.25 *N* aqueous ammonia as eluent and removing the solvent in vacuum giving **1** (8 g, 89%); mp >300°C; R_f 0.19 (19°C); ir(KBr) ν_{max}: 3500–3250 (s), 2600–1900 (s), and 1600–1500 (s, b) cm^{-1}; ^{1}Hmr (D_2O) δ: 2.79 (s, 3H, N—CH_3). *Anal.* calcd. for $C_9H_{16}N_2O_2 \cdot 1H_2O$: C 53.44, H 8.97, N 13.85; found: C 53.30, H 9.09, N 13.95.

In order to remove the water, it was necessary to heat the compound at 100°C/0.05 Torr over P_2O_5 for 24 h. *Anal.* calcd. for $C_9H_{16}N_2O_2$: C 58.66, H 8.75, N 15.20; found: C 58.32, H 8.63, N 15.10.

N-*Formyl-3α-amino-1αH,5αH-tropane-3β-carboxylic Acid*

The formylamino acid can be prepared in 90% yield following essentially the procedure of du Vigneaud *et al.* for the formylation of DL-cystine (7). Acetic anhydride (13.5 mL) was added dropwise to a mixture of the amino acid (3 g) and 85% formic acid (42 mL) at a rate to maintain the temperature of the reaction mixture between 50–60°C. After the addition was complete, the mixture was stirred at room temperature for 1 h at the end of which time 13 mL of ice-water was added and the mixture concentrated at reduced pressure. The crude product was recrystallized from absolute ethanol; mp 294°C (dec.); ir(KBr) ν_{max}: 1685 (s) and 1500–1600 (b) cm^{-1}; ^{1}Hmr (D_2O) δ: 2.75 (s, 3H, N—CH_3), 7.95 (s, 1H, CHO). *Anal.* calcd. for $C_{10}H_{16}N_2O_3 \cdot 1H_2O$: C 52.15, H 7.87, N 12.16; found: C 52.40, H 8.06, N 11.82.

3β-Amino-1αH,5αH-tropane-3α-carboxylic Acid (2)

From the β-Hydantoin

Tropane-3-spiro-5′-hydantoin (7 g) obtained by the Read synthesis from tropinone (6), was heated with 60% sulphuric acid (35 mL) at 150°C for 24 h and the solution was treated as

in **1** to give **2** (48 g, 80%); mp >300°C; R_f 0.25; ir(KBr) ν_{max}: 3130–2050 (s, b) and 1610–1515 (s, b) cm^{-1}; ^{1}Hmr (D_2O) δ: 2.8 (s, 3H, N—CH_3).

From the Aminonitrile

3-Aminotropane-3-carboxynitrile (16.1 g) obtained from tropinone by the Strecker synthesis (8) was treated at 0°C with fuming hydrochloric acid (120 mL) and set aside overnight. The solution was then diluted with water (68 mL) and boiled under reflux for 24 h. The pure β-amino acid was isolated by passage over an ion exchange resin (cationic Lewatit S100) (108 mL) using 1 *N* aqueous ammonia as eluent and removing the solvent in vacuum, giving **2** (4 g, 22%). *Anal.* calcd. for $C_9H_{16}N_2O_2 \cdot 1/2\,H_2O$: C 55.93, H 8.86, N 14.49; found: C 55.60, H 8.67, N 14.16.

On heating at 100°C/0.05 Torr over P_2O_5 for 24 h the water was removed. *Anal.* calcd. for $C_9H_{16}N_2O_2$: C 58.66, H 8.75, N 15.20; found: C 58.82, H 8.52, N 15.46.

N-*Formyl-3β-aminotropane-3-carboxylic Acid*

The formylamino acid was prepared following the procedure of Huffman (9). The acetic formic anhydride was prepared (but not isolated) by heating acetic anhydride (4.4 mL) and 98% formic acid (1.9 mL) for 2 h at 50–60°C in a flask equipped with a stirrer and drying tube. The solution was cooled to 27°C. A gradual addition of the amino acid **2** (1 g) was made over a 15-min period using a water bath to maintain a temperature below 39°C. The reaction mixture was stirred about 29 h at room temperature after which water (30 mL) was added. The solvent was removed *in vacuo* to furnish the crude product (1.1 g, 96%) which was crystallized from water–dimethoxyethane; mp 301–305°C (dec.); ir(KBr) ν_{max}: 1685 (s) and 1590 cm^{-1}; ^{1}Hmr (D_2O) δ: 2.85 (s, 3H, N—CH_3), 8.15 (d, 1H, CHO). *Anal.* calcd. for $C_{10}H_{16}N_2O_3$: C 56.58, H 7.59, N 13.20; found: C 56.37, H 7.71, N 12.90.

3α-Amino-3β-hydroxymethyl-1αH,5αH-tropane (3)

Lithium aluminum hydride (3.27 g) in tetrahydrofuran previously distilled from $LiAlH_4$ (182 mL) was heated under reflux for 10 min after which dry, finely powdered **1** (5.5 g) was added in small portions with efficient stirring. After the addition was completed, the solution was heated under reflux for a further 4 h. With external cooling the reaction mixture was worked up after the method of Mićović and Mihailović (10) and the inorganic solid was filtered off and extracted with tetrahydrofuran (2 × 30 mL). The tetrahydrofuran filtrate and the extracts were combined and the solvent removed at 20 Torr. The residue crystallized from benzene – light petroleum (bp 60–80°C) to give **3** (3 g, 60%); mp 61.5–63.5°C: ir(KBr) ν_{max}: 3415 and 3380 (b), 3160 (b), and 1595 (m) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.1 (s, 2H, O—CH_2), 2.25 (s, 3H, N—CH_3). *Anal.* calcd. for $C_9H_{18}N_2O$: C 63.48, H 10.65, N 16.45; found: C 63.58, H 10.93, N 16.33.

Spiro[tropane-3,4′α-N-oxazolidine] (4)

3-Amino-3-hydroxymethyltropane (1.5 g) in dry benzene (16 mL) was heated under reflux for 9 h with 37% formalin solution (3 mL) and then a Dean–Stark water trap was adapted. The reflux was continued for 1 h after the formation of water ceased. The solvent was removed in vacuum and the residue was crystallized from ethyl acetate to give **4** as needles (1.3 g, 89.6%); mp 116–117°C; ir(KBr) ν_{max}: 3320 (s); ^{1}Hmr ($CDCl_3$) δ: 4.5 (s, 2H, N—CH_2—O), 3.25 (s, 2H, O—CH_2), 2.3 (s, 3H, N—CH_3). *Anal.* calcd. for $C_{10}H_{18}N_2O$: C 65.84, H 9.95, N 15.37; found: C 66.15, H 10.05, N 15.57.

Spiro[tropane-3,4′-N-oxazolidine-2′-one] (5)

3-Amino-3-hydroxymethyltropane (1.7 g) was heated with ethyl carbonate (1.18 g) and sodium methoxide (50 mg) and the ethanol formed eliminated by distillation. The solid residue was crystallized from ethanol–dimethoxyethane giving **5** (400 mg, 20.5%); mp 85–86°C; ir(KBr) ν_{max}: 3250 (b) and 1615 (s) cm^{-1}; ^{1}Hmr (D_2O) δ: 3.4 (s, 2H, O—CH_2), 2.95 (s, 3H, N—CH_3); *Anal.* calcd. for $C_{10}H_{16}N_2O_2 \cdot 3H_2O$: C 47.98, H 8.85, N 11.19; found: C 48.00, H 8.85, N 11.11.

pH Titration

The pK_a' values for the amino groups (—NH_2 and N—CH_3) and the carboxylic group of both α- and β-tropane amino acids were determined at 25°C by continuous titration of 0.1 *M* amino acid dissolved in 0.1 *M* NaCl solution with 1 *N* HCl and 1 *N* NaOH. Standard buffers, phosphate pH 7.00, and phthalate pH 4.01 (Curtin Matheson Scientific, Inc.), were used. The results were corrected for dilution. The pK_a' was calculated for each point using standard equations. Corrections for HCl serving to establish pH values of 3 and lower were made by the following standard method. We take the first equivalent of HCl added (measured here as $[Cl^-]$) to convert the amino acid R from $R^{+,-}$ to $R^{2+,-}$. Further HCl acts to form R^{2+} and free H^+ (or H_3O^+). Then by the law of electroneutrality, neglecting species at very low concentrations, we have

$$[Cl^-] = A_{H^+}/\gamma_{H^+} + [R^{2+,-}] + 2[R^{2+}]$$

where pH is taken to be $\log A_{H^+}$, and A_{H^+}/γ_{H^+} at the calculated ionic strength is taken to be $[H^+]$. Thus we apportioned the total amount of the amino acid present between the univalent cation $R^{2+,-}$ and the divalent cation R^{2+}, to obtain the ratio desired in $pH = pK_a' + \log([R^{2+,-}]/[R^{2+}])$.

Rate Constants for Hydrolysis of N-*Formyl Amino Acids*

Solutions (10 m*M*) of the *N*-formyl α- and β-amino acids were prepared in 1 *N* HCl at room temperature. Aliquots of 0.5 mL were added to individual test tubes and the tubes incubated at 50°C. The reaction was stopped after selected time intervals by adding 1 *N* NaOH and the tubes were placed on ice. The extent of hydrolysis was measured by the Rosen ninhydrin method (11) for the liberated free amino acid. The low chromogenicity of the β-amino isomer was compensated by increasing the time for colour development at 100°C from 15 min to one hour. All values were corrected for a zero-time blank. Total hydrolysis was obtained by autoclaving 2 or 3 h in a small volume of 6 *N* HCl in sealed tubes. The tubes were opened and the HCl removed by holding the samples overnight in an evacuated desiccator over NaOH pellets at room temperature.

Biological Transport Determinations

Ehrlich cells were propagated as usual in Swiss white mice, and separated and washed as usual in the Na^+-free media (12). The uptake during 30 s at 37°C was measured in about 5% suspensions in Na^+-free, choline-containing Krebs–Ringer bicarbonate medium in a 5% CO_2–O_2 atmosphere. Uptake was terminated by cold dilution and brief centrifugation. Adhering medium was blotted away from the cell pellet before weighing (13). The separated suspending medium and a sulfosalicylic acid extract of the cells were then counted for ^{14}C-BCH as usual (13, 14). Extracellular water was measured by the sucrose contained in the medium, which was retained in the cell pellet. The uptake of ^{14}C-BCH is recorded in mmol · Kg^{-1} cell water · $30\,s^{-1}$ in Fig. 1. The external concentration of BCH was nearly constant at $10^{-4}M$.

Results and Discussion

Configuration of α- *and* β-*Amino-isomers*

The acid hydrolysis of α- and β-tropane-3-spiro-

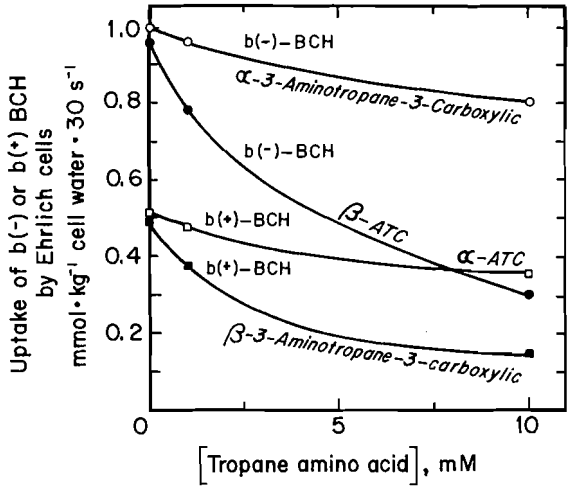

FIG. 1.

5′-hydantoins, whose configurations were determined by X-ray crystallography (15) and ^{13}C nmr data (16) gave the two α- and β-amino isomers of 3-aminotropane-3-carboxylic acids **1** and **2**. The amino acid obtained by hydrolysis of the 3-aminotropane-3-carboxynitrile was identical to the β-isomer **2** obtained from the β-hydantoin.

Lithium aluminum hydride reduction of **1** gave the corresponding aminoalcohol **3**, which was condensed with formaldehyde to give the spiro-4′-oxazolidine **4**. Condensation of **3** with ethyl carbonate gave the spiro-4′-oxazolidin-2-one **5** (Scheme 1).

*p*K′$_a$ *Determinations*

Compounds **1** and **2**, by potentiometric titration, gave the results shown in Table 1. Both tropane amino acids in water solution will be dipolar ions (α- or γ-zwitterions) (Fig. 2). By analogy with the results found in the above mentioned 1-methylpiperidine amino acid (5), the pK_3' value for the tropane amino acids is associated to a larger extent with the piperidine *N* than with the α-amino group. Furthermore, the ^1H nmr spectra in D_2O solution of both amino acids clearly show δ N—CH_3 values corresponding to a protonated piperidine nitrogen atom (pH of the solution 8.87 and 9.1 for the α-amino and β-amino isomers respectively).

Lowered values for pK_1' are characteristic for diamino acids in general (17), although the values of 1.2 and 1.5 are unexpectedly low. The lower value for compound **1** corresponds logically to the greater acidity of the equatorial carboxyl groups (18) together with the inductive effect of the closer approach of the carboxyl group to the piperidine *N*.

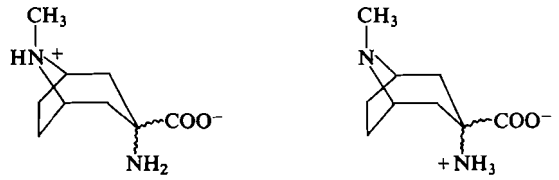
The small difference between the pK_3' values points to a less efficient solvation of the ammonium group in the γ-zwitterion for the α-amino isomer **1** than for the β-amino isomer **2**, probably due to the *cis*-relation with the carboxylate group in the first case.

Regarding the pK_2' values which are mainly attributed to the ionization of the —$\overset{+}{N}H_3$ group, the found differences show a weaker basicity for the β-amino isomer, with the NH_2 group in equatorial position. These results are in agreement with literature data for α-cyclohexaneamino acids (1, 3) but contradictory to the general consideration about the basic strength of axial and equatorial amino groups (19). Some authors (20) have explained the effect of a negative carboxylate group in weakening the acidity of the ammonium group only at great distances (up to $n = 3$ in $H_2N(CH_2)_nCOOH$ amino acids) as if the ionization of the ammonium group at short distances (α-amino acids) was accompanied by a net binding of water molecules, which, in our case and in the α-cyclohexaneamino acids may be more efficient when the α-amino group is in an equatorial position. In the tropane amino acid **2** obtained by the Strecker route, however, the nearness of the ammonium group and the tertiary nitrogen atom can also be implied.

Rate Constants for Hydrolysis of N-*Formyl Amino Acids*

Direct formylation with formic acid (7) was used to formylate **1** with 90% yield but did not give the formyl derivative of **2** in the same experimental conditions. This last derivative was obtained by reaction with acetic formic anhydride (9) with 96% yield.

We found that the 3β-formamidotropane-3α-carboxylic acid is hydrolyzed about 5 times as fast as the other isomer. The values of log $a/(a - X)$ versus



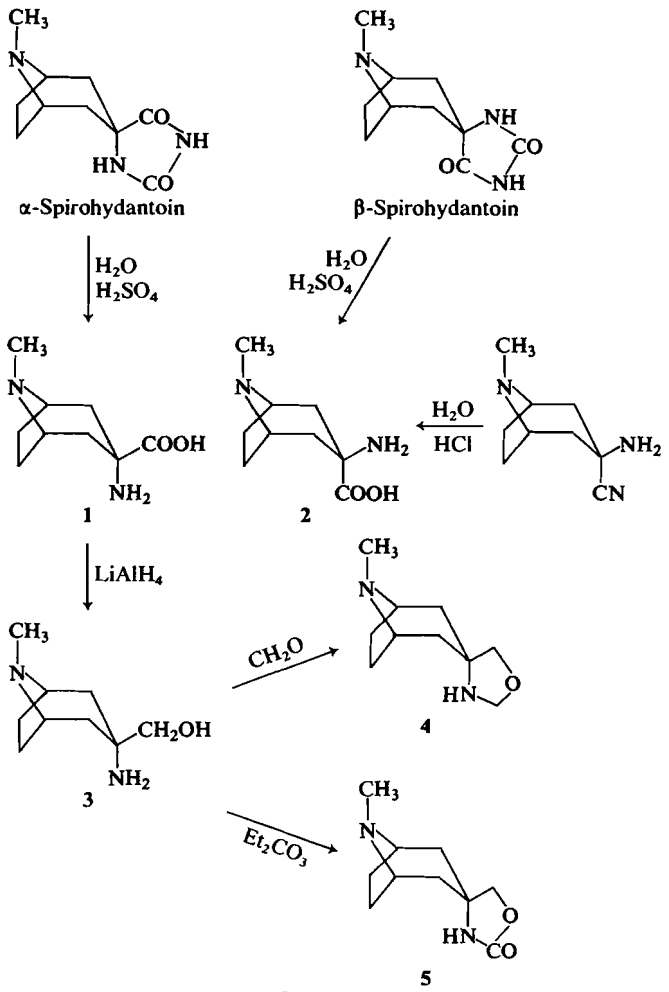


FIG. 2

TABLE 1. pK_a' values of the two isomers of 3-aminotropane-3-carboxylic acid[a]

Compounds	pK_1'	pK_2'	pK_3'
1	1.2	7.08	10.65
2	1.5	6.94	10.70

[a]Duplicate titrations were made consecutively for the two isomers, so the differences, probably even that in pK_3', are regarded as significant.

SCHEME 1

time appear to be about 0.82 and 0.16 min^{-1}, respectively, the quantity log $a/(a - X)$ being essentially linear with time. The lability of the *N*-formyl derivative of **2** to 1 *N* HCl was severe enough to allow a few percent of hydrolysis of the zero-time control sample held momentarily at room temperature and 3.5 h in ice-water while the experimental samples were held at 50°C.

The striking difference in the reactivity of the 3α- and 3β-*N*-formyltropane amino acids towards the acid hydrolysis is apparently due to the steric blockade of the axial 3-tropane derivatives by the C(6)—C(7) dimethylenic chain. Similar differences have been found in the hydrolysis and esterification of 3α- and 3β-tropane carboxynitriles (21). Furthermore the resistance to hydrolysis of 4-isopropyl- and 4-*tert*-butyl-1-amino-1-carboxynitrile hydrochlorides (α- and β-isomers) has been used as a clue to determine the configuration of the corresponding amino acids (22).

Biological Transport

The 3β-amino isomer **2** (β-ATC) is a good inhibitor of the uptake by the Ehrlich ascites tumor cell of the b(−)-BCH. The b(−) isomer of BCH has been shown to be the amino *endo* form (4). In *E. coli* it is the only one of the four BCH isomers taken up (23). The use of BCH as a system-specific model substrate is discussed elsewhere (24, 25). K_i for β-ATC is crudely estimated as 4 to 5 m*M* (Fig. 1).

The 3α-amino isomer (α-ATC) is only about one-seventh as effective (K_i roughly 25 to 42 m*M*). A rather smaller difference is seen for the two isomeric amino acids acting on the slow uptake of the less interesting (+) isomer of BCH.

By comparison with 1-methylpiperidine-4-amino-4-carboxylic acid (K_i = 1 m*M*) (5) we may suppose that the two-carbon bridge is unfavorable to affinity and that it is more unfavorable in **1** than in **2**. To evaluate the effect of the $CH_3—N<$ structure of the

Enthalpies of interaction of polar and nonpolar solutes with a perfluoro solvent

RICHARD FUCHS, L. ALAN PEACOCK, AND KAMALENDU DAS
Department of Chemistry, University of Houston, Central Campus, Houston, TX 77004, U.S.A.

Received February 27, 1980

RICHARD FUCHS, L. ALAN PEACOCK, and KAMALENDU DAS. Can. J. Chem. **58**, 2301 (1980).

Enthalpies of solution of 51 polar and nonpolar organic solutes have been determined in the solvent perfluoro-1,3-dimethylcyclohexane. The values have been combined with solute enthalpies of vaporization to give the enthalpies of transfer from vapor to solvent. These solvation enthalpies are for most solutes substantially less exothermic than those measured in other solvents. Polar interactions appear to be stronger than with hydrocarbon solvents; but this may result, in part, from incomplete dissociation of strongly associated solutes in the perfluoro solvent.

RICHARD FUCHS, L. ALAN PEACOCK et KAMALENDU DAS. Can. J. Chem. **58**, 2301 (1980).

On a déterminé les enthalpies de solution de 51 solutés organiques polaires et non polaires dans le perfluorodiméthyl-1,3 cyclohexane. On a combiné les valeurs obtenues avec les enthalpies de vaporisation des solutés pour obtenir les enthalpies de transfert de la vapeur au solvant. Dans la plupart des solutés, ces enthalpies de solvatation sont substantiellement moins exothermiques que celles mesurées dans d'autres solvants. Les interactions polaires semblent être plus fortes que celle intervenant dans les solvants hydrocarbonés, mais ceci peut provenir en partie d'une dissociation incomplète des solutés fortement associés dans le solvant perfluoré.

[Traduit par le journal]

The unusual solvent properties of completely fluorinated alkane derivatives (perfluoroalkanes) were first recognized more than three decades ago (1). These compounds show limited miscibility with nonpolar alkanes, and even less miscibility with polar liquids. On the other hand, the solubility of nitrogen (2) and of oxygen are greater than that in other solvents, and there has been wide interest in perfluorocarbons and perfluorocarbon derivatives as components of blood extenders.

The boiling points of perfluorocarbons are generally lower than those of the analogous hydrocarbons, as are the heats of vaporization (ΔH_v) in the few cases where comparison data are available (3). The fluorocarbon polarizability is slightly greater, and at equal separation the dispersion forces should be larger (4). The molar volume and mean radius are much larger, however, and at the greater distance the effective dispersion forces are smaller than in hydrocarbons.

We have recently measured the heats of solution (ΔH_s) of some polar molecules (5, 6) and nonpolar hydrocarbons (7) in the solvents cyclohexane, benzene, methanol, and dimethylformamide, and some additional hydrocarbon values (8) in acetic acid and in hexane. Values of ΔH_s have been combined with experimental (5) or literature (3) heats of vaporization (ΔH_v) to give enthalpies of transfer from vapor to solvent [$\Delta H(v \rightarrow S)$] (the solvation enthalpy). Comparison of $\Delta H(v \rightarrow S)$ for polar compounds and nonpolar model compounds has provided an estimate of the polar solute–solvent interactions (5–7). It is our eventual objective to evaluate the contributions of various types of intermolecular forces (dipole–dipole, dipole – induced dipole, dispersion, charge transfer, and hydrogen bonding) to overall solvent–solute interactions, using, in addition to model compounds, a series of diagnostic solvents.

One premise of this diagnosis has been used previously (7) to effect a rough separation of the dispersion and solvent cavity formation energy contributions to $\Delta H(v \rightarrow S)$, and will be used in the present study. When a straight chain alkane is dissolved in a nonpolar or slightly polar solvent, the observed $\Delta H(v \rightarrow S)$ results from exothermic dispersion interactions and an endothermic solvent cavity formation

energy. When an isomeric branched alkane with one or more quaternary carbon atoms is dissolved in the same solvent, the cavity energy is essentially unchanged, for branching has little effect on solute molar volume, and the shape or surface area of the cavity should have little influence, except with highly structured solvents such as water. However, dispersion interactions with the "buried" quaternary carbon atom are small or nil, and the $\Delta H(v\rightarrow S)$ difference between the straight chain and branched alkanes provides a measure of strength of dispersion interactions of which various solvents are capable.

The objective of the present study is to examine a perfluorocarbon solvent with respect to the capabilities for dispersion and polar interactions, and to compare these properties with those of a comparable hydrocarbon solvent. The perfluorocarbon chosen on the basis of availability, reasonably low vapour pressure, and relatively high purity is perfluoro-1,3-dimethylcyclohexane (PFDC).

Experimental

The solutes were commercial samples obtained from the Aldrich, Chemical Samples, and Fluka Companies (7, 8). All were stated to be of 99–99.9% purity, and are liquids at room temperature. Methyl *tert*-butyl ether (99.8%) was furnished by Professor N. L. Allinger. Cyclohexane (99+%) was obtained from Aldrich, and stored over 4A molecular sieve. Perfluoro-1,3-dimethylcyclohexane was furnished by PCR Research Chemicals Inc. After calorimetric use this solvent was recovered using three extractions with dichloromethane, followed by distillation through a short column. The material boiling at 100–102°C was collected for reuse.

The calorimetric procedure and apparatus have been described previously (7, 8). The calorimeters were immersed in water baths maintained at 25.00°C with regulation to ±0.002°C or better. Samples were introduced into the calorimeters from 10-, 20-, or 50-μL syringes. Heats of solution were corrected (0.02 kcal/mol less endothermic) to allow for the cooling due

to the sample temperature (22–23°C). This correction is based on the experimental heat of solution of 50 μL samples of perfluoro-1,3-dimethylcyclohexane at room temperature in perfluoro-1,3-dimethylcyclohexane (70 mL), and cyclohexane in cyclohexane.

A typical heat of solution involved a change of 0.2–0.4 cal, and a temperature change of 0.005 to 0.01°C. Sample concentrations were in the range of 1.5×10^{-3} to 10×10^{-3} *M*.

Results and Discussion

Experimental heats of solution in perfluoro-1,3-dimethylcyclohexane, and enthalpies of transfer from the vapor state to this solvent are presented in Table 1. The corresponding values of ΔH(v→S) for cyclohexane solvent (5–7) are also given for comparison, but heats of solution in cyclohexane appear (as a footnote) only if previously unreported.

Methylene Increment

The methylene increment in ΔH(v→S) represents the enthalpy difference between an endothermic solvent cavity formation term and exothermic contribution from the solvent–solute interactions. In the case of a nonpolar methylene group and nonpolar solvents the interactions are entirely dispersion forces. The mean increment (pentane–dodecane) in PFDC is -0.85 ± 0.04 kcal/mol, and for cyclohexane the value (7) (C_5–C_{16}) is -1.12 ± 0.02 kcal/mol. The methylene increment for six other solvents we have examined range from −0.91 kcal/mol in *N*,*N*-dimethylformamide to −1.17 kcal/mol in heptane. The values do not agree very well with those calculated (9) on the basis of the methanol–ethanol difference in the solvents cyclohexane (found −1.12, calcd. (9) −0.9), carbon tetrachloride (−1.12 vs. −0.8), and DMF (−0.91 vs. −0.6).

The methylene increment in PFDC is less exothermic than in any of the other solvents we have examined. The rather small increment in DMF can reasonably be attributed to a highly endothermic cavity formation term in this strongly associated solvent (7, 9). This is clearly not the case in a per-

fluorocarbon with particularly small values of ΔH_v (estimated to be 8.5–9.0 kcal/mol (4)) and cohesive energy density. The small methylene increment in PFDC must therefore result from particularly weak dispersion interactions with dissolved solute molecules.

Quarternary Carbon Atom Effect

Four of the hydrocarbons in Table 1 having quaternary carbon atoms (2,2-dimethylbutane, 2,2-dimethylpentane, 2,2,4,4-tetramethylpentane, and 2,2,5,5-tetramethylhexane) have molar volumes similar to those of the isomeric *n*-alkanes (mean difference 2.0 ± 1.2 mL; the molar volume contribution of CH_2 is 16 mL). Branching decreases heats of vaporization by a mean value of 0.98 ± 0.07 kcal/mol per quaternary carbon atom. The methylene increment in ΔH_v in *n*-alkanes and several other classes of straight chain compounds (10) is approximately 1.18 kcal/mol. Thus about 83% of the dispersion interactions of the "buried" carbon atom is lost by the difficulty of close approach by neighboring molecules. A similar situation occurs in solutions of the isomeric hydrocarbons. $\Delta H(v \rightarrow S)$ becomes less exothermic by 0.80 kcal/mol (methanol) to 0.98 kcal/mol (CCl_4) per quaternary carbon atom. In cyclohexane solutions the mean loss is 0.82 ± 0.06 kcal/mol, and in PFDC, 0.56 ± 0.08 kcal/mol per quaternary carbon atom. If we make the crude assumption that the equivalent of about 83% of the dispersion interactions of a methylene group is lost for each "buried" quaternary carbon atom present in a molecule, one concludes that the dispersion interactions of PCDC with a methylene group is less than 0.7 kcal/mol, compared with values of about 1.0–1.2 kcal/mol for other solvents.

Solvation of Polar Compounds

Almost all of the compounds in Table 1 having functional groups are more strongly solvated ($\Delta H(v \rightarrow S)$ more exothermic) in cyclohexane than in PFDC. The exceptions are 1-butanol and aniline, two strongly hydrogen bonded compounds. However, the polar contributions to solvent–solute interactions, taken as $\Delta H(v \rightarrow S)$ (polar compound) $- \Delta H(v \rightarrow S)$ (nonpolar model), is generally larger in PFDC. The nonpolar model is the hydrocarbon having the same number of carbon atoms as the ketone, ether, or alcohol. This provides comparisons of compounds with similar molar volumes, because of the very small contribution of an oxygen atom.

We have strong reservations about accepting the view that PFDC is capable of substantially stronger polar interactions than are hydrocarbon solvents. This is especially the case with hydrogen bonded solutes. 1-Butanol has such slight solubility in PFDC that studies of the concentration effect on ΔH_s were impossible. While typical calorimetric samples dissolve rapidly, and the system is thermally equilibrated in less than 2 min, the thermal effect with 1-butanol, and, hence, the solution process, required more than 30 min. We believe it quite likely that 1-butanol and aniline do not dissolve to give monomeric solute species, but retain appreciable hydrogen bonded association. The resulting values of ΔH_s are therefore less endothermic, and $\Delta H(v \rightarrow S)$ values are more exothermic, than would be the case if complete dissociation to monomer occurred. The association of *tert*-amyl alcohol (2-methyl-2-butanol) is probably considerably weaker, and a more realistic value of $\Delta H(v \rightarrow S)$ is obtained.

For the other polar solutes there appears to be a trend toward somewhat larger polar interactions with PFDC than with cyclohexane for the most polar solutes (ketones), but smaller differences for the less polar or sterically hindered compounds (ethers, 2,2,4,4-tetramethyl-3-pentanone). Whether this reflects greater association of the more polar compounds in PFDC solution, or a true ability of PFDC to undergo stronger polar interactions than can cyclohexane, cannot at present be stated with certainty. The uncertainties in ΔH_s(PFDC) are of the order of 0.10 kcal/mol. Four heats of solution are involved in a comparison of the polar interactions in PFDC vs. cyclohexane, with an overall uncertainty of ca. 0.20 kcal/mol. We therefore warn against overinterpretation of the data, when differences of only a few tenths of a kilocalorie per mole are observed.

Heat capacities of liquid ketones and aldehydes at 298 K[1]

RICHARD FUCHS

Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received May 23, 1980

RICHARD FUCHS. Can. J. Chem. **58**, 2305 (1980).

The heat capacities of 25 liquid aliphatic, alicyclic, and aromatic ketones and aldehydes at 298.2 K and atmospheric pressure have been measured calorimetrically with a typical uncertainty of 0.5%. Additive parameters are proposed for estimating C_p(l) of ketones and aldehydes.

RICHARD FUCHS. Can. J. Chem. **58**, 2305 (1980).

Opérant à 298,2 K et sous la pression atmosphérique, on a mesuré, par calorimétrie avec une erreur type de 0,5%, les capacités calorifiques de 25 aldéhydes et cétones aliphatiques, alicycliques et aromatiques liquides. On propose des paramètres additifs pour évaluer le C_p(l) des cétones et des aldéhydes.

Measurements of the heat capacities of many hydrocarbons and organic sulfur compounds in the liquid state have been reported, and useful schemes have been devised for the estimation of C_p(l) of additional compounds of these classes using additive group parameters (1, 2). Relatively few such data are available for many other common classes of compounds, and group parameters must be based on one or a few compounds, or may be totally unavailable. These classes include the esters, which have recently been examined (3), and the ketones and aldehydes, which are the subject of this study. A few values for some open chain aliphatic ketones have been reported previously (4, 5). This paper reports the heat capacities of 25 aliphatic, alicyclic, and aromatic ketones and aldehydes in the liquid state at 298.2 K and atmospheric pressure.

Experimental

Ketone and aldehyde samples were obtained from Fluka, Aldrich, and Chemical Samples Companies. All were stated by the suppliers to be of 99 mass% or greater purity by gas chromatographic analysis, and were used as received. Drying and redistillation of samples of propionaldehyde, cyclohexanone, acetophenone, and propiophenone through a short column did not significantly affect the measured heat capacities, although this procedure would remove adventitious water, condensation products, and oxidation products.

Calorimetry

Heat capacities of the liquids were measured in a 10 cm^3 or a 45 cm^3 vacuum jacketed glass isoperibol calorimeter fitted with a Teflon stopper through which pass thermistor, heating, and cooling probes. The thermistor ($2 \times 10^3\ \Omega$) is an arm of a Wheatstone bridge, the output of which is amplified by a Keithley Model 177 digital multimeter (which also serves as a null meter), and recorded on a potentiometric recorder. Full scale deflection results from a temperature change of 0.1 K. Measurements were made over 0.06 K increments within the range of 298.1–298.3 K, at ambient atmospheric pressure. The calorimeters were magnetically stirred continuously before, during, and following the heating period, using five revolutions s^{-1} synchronous motors. The stirring unit and calorimeter were immersed in a water bath at 298.15 ± 0.002 K. The heat capacity of each calorimeter (10 cm^3: 12.74 J K^{-1}; 45 cm^3: 33.47 J K^{-1}) was determined (for example, for the 10 cm^3 calorimeter) from the heating times required to produce equal recorder deflections for the systems calorimeter + 10 cm^3 water, and calorimeter + 10 cm^3 heptane. (C_p(l) = 75.25 J mol^{-1} K^{-1} for water (6); 225.0 J mol^{-1} K^{-1} for heptane, at 298.15 K (2).)

The heaters are metal film electronic resistors sealed in Teflon (temperature coefficient of resistance 50×10^{-6} K^{-1}), with resistances of 90.8 Ω and 561 Ω, for the smaller and larger calorimeter, respectively. Heater currents of 19.30×10^{-3} A were furnished by timed constant current sources, and monitored by a digital milliammeter in the heater circuit.

Each 10 cm^3 or 45 cm^3 sample was weighed in the sealed calorimeter. Values of C_p(l) were calculated from the mean of four to ten heating curves relative to water. Duplicate C_p(l) values determined from separate samples agreed to 1.1 J mol^{-1} K^{-1} or better (<0.5%). Appropriate heating periods (30–65 s) were used to produce recorder deflections of approximately 15 cm.

Sample heat capacities C_p(S) were calculated from the equation

$$C_p(\mathrm{S}) = [C_p(\mathrm{W}) + C_p(\mathrm{Cal})]\frac{\mathrm{defl(W)}}{\mathrm{defl(S)}} - C_p(\mathrm{Cal}) \times \frac{\text{molar mass(S)}}{\text{sample mass}}$$

where C_p(W) and C_p(Cal) are the heat capacities of the reference water sample and the calorimeter, respectively, and defl(W) and defl(S) are the recorder deflections produced by equal heat inputs into the water and ketone samples.

Results and Discussion

Of the heat capacities of liquid ketones and aldehydes in Table 1, 17 have not been previously reported. Eight others have been remeasured, giving values within 3.5 J mol^{-1} K (1.5%) of the literature values (1, 4, 5). (The mean difference is 1.6 J mol^{-1}

[a]Each new value is listed together with the standard deviation of four to ten heating curves. When two or more new values are reported the measurements involve separately weighed samples.
[b]Values calculated using group parameters in Discussion section.
[c]From group parameters of Shaw (1).
[d]Measured in 45 cm^3 calorimeter.
[e]Reference 1.
[f]Reference 4.
[g]Reference 5.
[h]Value assigned to—CHO group is 62.9 J mol^{-1} K.

K^{-1} (0.79%).) Predictions of C_p(l) for the 10 straight chain ketones on the basis of Shaw's group values (1) show a mean difference from the experimental values of 2.0 J mol^{-1} K^{-1} (maximum, 3.8 J mol^{-1} K^{-1}). No distinction is made in this scheme between 2-ketones and symmetrical ketones.

The values proposed below provide C_p(l) values for the same ten compounds which differ from the experimental by an average of 0.8 J mol^{-1} K^{-1} (maximum, 2.9 J mol^{-1} K^{-1}). The new parameters (J mol^{-1} K^{-1}) are:

$$-\overset{\overset{O}{\|}}{C}- \text{ (51.9), (CO)}-CH_2- \text{ (31.4), (CO)}-\overset{|}{C}H- \text{ (18.4),}$$

$$\text{and } H-\overset{\overset{O}{\|}}{C}- \text{ (64.9)}$$

Shaw's values (1) for $-CH_3$ (36.8) and $-\overset{|}{C}H-$ (20.9) have been retained, as have our previous values (3) of $-C_6H_5$ (114.2), (CO)$-\overset{|}{C}-$ (10.0), and $-CH_2-$ (28.9 in straight chains of up to seven atoms; 30.5 for each additional CH_2 group). For ring CH_2 (25.9) the value of Chueh and Swanson (7) has been adopted; this avoids the use of ring corrections.

No value for the aldehyde group was estimated by Shaw (1). Using his parameters for other groups, an aldehyde value of 62.9 J mol^{-1} K^{-1} provides the best fit, although no single value is completely satisfactory. Neither set of parameters is consistently reliable in predicting the experimental values for aromatic ketones.

The gas phase acidities of fluorinated acetones. An ion cyclotron resonance investigation of the role of fluorine substituents in the stabilization of planar carbanions

R. FAIRD AND T. B. MCMAHON

Department of Chemistry, University of New Brunswick, P.O. Box 4400, Fredericton, N.B., Canada E3B 5A3

Received May 22, 1980

R. FAIRD and T. B. MCMAHON. Can. J. Chem. **58**, 2307 (1980).

The gas phase acidities of a series of fluorinated acetones and acetylfluoride have been determined. The results obtained are interpreted in terms of a model for fluorine substituents in planar carbanions in which fluorine exerts an overall stabilizing influence on enolate ions, but also has a component in the interaction which is destabilizing via a repulsive interaction between fluorine lone pair electrons and the carbanion centre. Comparisons with solution phase acidities are made and the validity of the model for fluorine substituents discussed.

R. FAIRD et T. B. MCMAHON. Can. J. Chem. **58**, 2307 (1980).

On a déterminé les acidités en phase gazeuse d'une série d'acétones fluorées et du fluorure d'acétyle. On a interprété les résultats obtenus en fonction d'un modèle pour les substituants fluorés dans les carbanions plans où le fluor exerce une influence stabilisatrice globale sur les ions énolates mais participe également à l'interaction déstabilatrice par l'intermédiaire d'une interaction répulsive entre la paire d'électrons libres du fluor et le centre du carbanion. On a établi des comparaisons avec les acidités en phase liquide et on discute de la validité du modèle pour les substituants contenant du fluor.

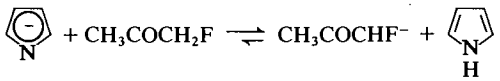
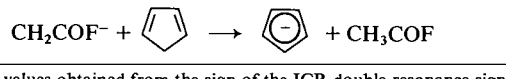
Introduction

The effects of fluorine substituents on the stability and reactivity of ionic species have been of interest to physical organic chemists for several decades (1, 2). The relatively small size of the fluorine atom relative to hydrogen generally precludes any appreciable steric effects and thus any modification of chemical properties may be attributed to a combination of inductive, resonance, and hydrogen bonding interactions (2).

On positive charge centres, fluorine substituents have been shown on the basis of gas phase fluoride affinities to exert an ambiguous effect, being capable of both destabilizing cations by inductive electron withdrawal and stabilizing them by resonance delocalization of fluorine $2p$ electrons to the empy p lobe of an adjacent carbonium ion centre (3, 4). A similar ambiguity has been suggested for effects of fluorine substituents on carbanions, based on the relative solution acidities of some fluorinated carbon acids (5, 6). In the case of planar carbanions, it is suggested that fluorine substituents stabilize negative charge centres by inductive withdrawal but at the same time, destabilize them via electrostatic repulsion between the non-bonding fluorine $2p$ electrons and the adjacent carbanion electron pair (7, 8). This inference, however, is made on the basis of solution acidity data, and it is well known that solution phase acidities do not always reveal intrinsic relative anionic stabilities due to complications associated with solvation effects (9, 10).

The concept of fluorine as a carbanion destabilizing agent is supported, however, by a number of *ab initio* molecular orbital calculations. Brundle *et al.* (11) find that in planar systems, such as ethylene, substitution of fluorine for hydrogen gives rise to a strong C—F antibonding overlap resulting from mixing of the π group orbital with the fluorine σ atomic orbitals. This prediction is supported by the vibrational fine structure of the lowest energy band of the photoelectron spectrum of C_2F_4, corresponding to removal of an electron from a π molecular orbital exhibiting C—F antibonding character. Further evidence of a dual nature of fluorine substituents in carbanions is provided by the *ab initio* calculations of Burdon and co-workers (12) for four isomeric fluorocyclohexadienyl anions. These calculations show that the most stable fluorocyclohexadienyl anion is one in which fluorine is substituted in an *ipso* position where negative charge cannot be localized on the carbon bonded to fluorine in any of the conventional valence bond structures.





To date, the only comprehensive data obtained for gas phase carbanions containing fluorine substituents are those of Sullivan and Beauchamp for fluoroethyl carbanions (13). They find that the gas phase acidities of fluoroethanes are virtually independent of the number or position of fluorine substituents. This rather bizarre result indicates that fluorine substituents must participate in a very complex interaction with the charge center even in these sp^3 hybridized, nonplanar anions.

In order to clarify the effect of fluorine substituents on planar carbanions we have therefore undertaken the present study of the gas phase

[9] $CH_3COCHF^- + CH_3COF \rightarrow CH_2COF^- + CH_3COCH_2F$	<0	+2.1	<+0.6	<358.4
[10] 	<0	−0.4	<−0.1	>355.6

[a] ΔG values obtained from the sign of the ICR double resonance signal. A negative double resonance response indicates an exothermic reaction. In cases where ΔG is indicated as $\lesssim 0$ the double resonance response was found to be negative for reaction in the forward direction *and* positive for reaction in the reverse direction.

[b] S^0_{298} values for neutrals were either experimentally known data or calculated from group equivalent methods (21). S^0_{298} values for anions were estimated from known entropy data for isoelectronic neutrals or calculated from group equivalent and methods for isoelectronic neutrals making appropriate mass corrections for translational entropy.

[c] ΔH^0_{298} calculated from $\Delta G = \Delta H - T\Delta S$ at 298 K.

[d] ΔH^0_{298}(AH) is the enthalpy change for the reaction $AH \rightarrow A^- + H^+$, based on the acidity scale of Cumming and Kebarle (19). $\Delta H^0_{298}(AH) = D(A—H) - EA(A) + IP(H)$ where $D(A—H)$ is the homolytic bond dissociation energy, EA(A) is the radical electron affinity, and IP(H) the hydrogen atom ionization potential.

acidities of a series of fluorinated acetones. Upon deprotonation these species will yield enolate anions which have fluorine substituted in sp^2 hybridized carbon in a planar system. From observation of trends in gas phase acidities with increasing fluorine substitution, it should thus be possible to provide a clear assessment of the intrinsic role of fluorine substitution on stabilities of planar carbanions.

Experimental

All experiments were carried out on a Varian Instruments, V-5900 ICR spectrometer, extensively modified to permit routine operation in both conventional drift and trapped-ion modes as described by McMahon and Beauchamp (14). All other techniques and instrumentation associated with ion cyclotron resonance experiments have been described in detail previously (15).

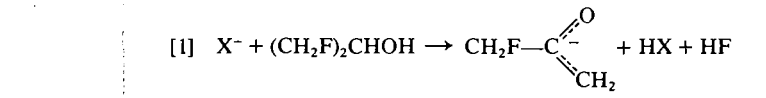
All fluoroenolate ions were generated by proton transfer from the corresponding fluoroacetone to F^-, which was generated by dissociative electron attachment to NF_3 at 3.0 eV (16).

Fluoroacetone, 1,3-difluoroacetone, 1,1,1-trifluoroacetone, and 1,1,3,3-tetrafluoroacetone were obtained from I.C.N. Pharmaceuticals Inc. Pentafluoroacetone was purchased from Columbia Organic Chemicals, NF_3 was obtained from Air Products and Chemicals Ltd., and both acetylfluoride and 1,3-difluoroisopropyl alcohol were obtained from P.C.R. Inc. All other compounds used as reference acids were readily available reagent grade chemicals.

Results

Proton transfer reactions of the fluoroenolate ions were in general found to be very slow, a phenomenon commonly observed for charge delocalized ions (17). As a result, bimolecular proton transfer equilibria could not easily be attained under the typical operating conditions of the trapped-ion ICR experiment for most of the fluoroacetones studied. Therefore, all gas phase acidities were determined using the bracketing technique of observation of the exothermic direction of proton transfer to appropriate reference acids with the aid of ICR double resonance experiments (18). With the large number of appropriate reference acids available (9, 10, 19, 20) this method can, in general, yield gas phase acidity values accurate to within ± 1 kcal/mol.

As previously demonstrated (19, 20), deprotonation of species which yield charge delocalized anions may involve significant entropy changes, largely associated with restriction of internal rotations. Thus, in order to convert the approximate free energy changes obtained in the bracketing experiment to enthalpy changes some estimate of the entropy changes must be made. Cumming and Kebarle (19) have recently outlined a procedure for estimating entropy changes largely based on Benson's group additivity tables (21). We have used similar procedures to obtain estimates of entropy changes for proton transfer reactions of the fluoroacetones investigated here. In addition, in many cases, it was also possible to estimate absolute entropies of species using isoelectronic analogues also according to methods outlined by Benson (21).



Shown in Table 1 are the proton transfer reactions used to ultimately bracket the gas phase acidity of each fluoroacetone, the free energy change inferred on the basis of the observed direction of proton transfer and double resonance experiments,

the estimated entropy change for each reaction and the resulting limits for the enthalpy change for each reaction at 25°C. The gas phase acidity of each fluorinated acetone, expressed as the difference in homolytic bond dissociation energy and the electron affinity of the corresponding free radical (D(R—H) – EA(R)), is shown in Table 2. Also shown are the electron affinities of each fluoroacetone enolate radical based on an assumed C—H bond dissociation energy of 98 kcal/mol. This latter quantity is based on observations that fluorine substitution has a minimal effect on the strength of adjacent C—H bonds in fluoromethanes (22) and the known C—H bond dissociation energy of acetone (23).

In a previous study of the gas phase negative ion chemistry of fluorinated alcohols (24), it was shown that a monofluoroacetone enolate ion could be produced by reaction of anions with 1,3-difluoroisopropylalcohol, reaction [1]

It was further shown that the enolate ion produced was more basic than that generated by simple proton abstraction from monofluoroacetone since the former ion was able to abstract a proton from 1,3-difluoroisopropylalcohol, reaction [2], while the latter was not.

This, and further proton transfer experiments involving the ion generated in reaction [1], establish that this species is a fluoroenolate in which fluorine is substituted remote from the carbanion centre and that the value of D(R—H) – EA(R) for the more weakly acidic site of fluoroacetone is 49 ± 2 kcal/mol (24).

In addition to the fluorinated acetones the gas phase acidity of acetylfluoride was also determined. The enolate derived from this compound will have fluorine substituted at an sp^2 hybridized carbon which does not have any appreciable negative charge localized on it in any resonance structures. Acidity data for this compound are also included in Tables 1 and 2.

TABLE 2. Gas phase acidities of fluorinated acetones and acetylfluoride and electron affinities of the corresponding free radicals

Compound	D(AH) – EA(A)[a] (kcal/mol)	EA(A)[b] (kcal/mol)
CH_3COCH_3	54.9	43.1
CH_3*$COCH_2F$	49±2	49
CH_3COCH_2*F	43.5±0.5	54.5
$(CH_2F)_2CO$	36.0±0.5	62.0
CH_3COCF_3	35.2±0.1	62.8 (59.5±2.9[c])
$(CHF_2)_2CO$	26±3	72
CF_3COCHF_2	17.5±1	80.5
CH_3COF	42±1	56 (51.2±2.1[c])

[a]Calculated from the ΔH^0_{298}(AH) data of Table 1. Using a value of $\Delta H^0_{f298}(H^+)$ of 367.186 kcal/mol (29).
[b]Calculated from D(AH) – EA(A) values assuming a constant value of D(A—H) of 98 ± 2 kcal/mol, ref. 23.
[c]Determined from photodetachment thresholds for the enolate ions (30).

Discussion

The basis for the proposal that fluorine substituents may destabilize planar carbanions lies in observations of reduced kinetic and equilibrium acidities of a number of fluorinated carbon acids relative to their non-fluorinated analogues. For example, in solution both fluoronitromethane and difluoronitromethane have lower equilibrium acidity values than nitromethane itself (25). Similarly, 9-fluorofluorene is found to have a lower kinetic acidity than does fluorene (5). Unfortunately, all such arguments regarding the effect of fluorine substituents on carbanions are based on solution acidity measurements and it has been definitively shown recently that solution phase acidities do not always reflect true intrinsic relative anionic stabilities (9, 10). Gas phase acidity values, however, do provide an accurate measure of intrinsic anionic stabilities and should therefore be used to determine whether fluorine indeed does exert a destabilizing effect on planar carbanion centres. For example, one case used to support arguments of the destabilizing effect of fluorine substituents is the lower acidity in solution of *p*-fluorophenol relative to phenol (26, 27). In the gas phase, however, *p*-fluorophenol is appreciably more acidic than phenol although it is found to be less acidic than *m*-fluorophenol (10). The former result would thus indicate that in gas phase phenolate ions, fluorine substituents do not exert a *net* destabilizing effect. However, the greater acidity of *m*-fluorophenol relative to the *para* isomer suggests that the *p*-fluorophenolate ion may be destabilized somewhat due to the repulsive interaction between fluorine 2*p* electrons and negative charge localized onto the *para* ring position. Unfortunately, even this latter explanation is not completely unambiguous since an alternative argument involving preferential stabilization of the *neutral p*-fluorophenol resulting from charge separated resonance structures such as **I** is also possible.

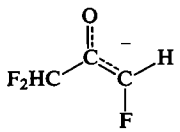
Almost no data are available for the solution acidities of fluorinated carbonyl compounds. One qualitative observation which has been made is the relative ease of formation of carbanions in mixtures of fluorinated acetate esters which are reacted in the presence of sodium hydride to effect a Claisen condensation (28). In all such cases, the fluorinated acetoacetic ester produced in greatest amount must have resulted from reaction of the carbanion containing the least number of fluorines. This result may be interpreted to indicate that the kinetic acidity of fluorinated acetate esters in solution decreases with increasing fluorine substitution.

The data presented in Tables 1 and 2 also show that a straightforward explanation of fluorine substituent effects in gas phase enolate ions is not possible. On the basis of arguments advanced from solution acidity data, it might have been anticipated that the fluorinated acetones with a fluorine α to the carbanion site would show a lower gas phase acidity than their analogues with no α fluorines. That this is not the case is most dramatically demonstrated by the 12 kcal/mol *increase* in the gas phase acidity of fluoroacetone relative to acetone. In this case, enolate **II**, the fluorine is substituted α to the carbanion site. However, even when the fluorine is remote from the carbanion centre as in the less stable form, **III**, of the fluoroacetone enolate, an increase of 6 ± 1 kcal/mol in acidity is still observed relative to acetone.

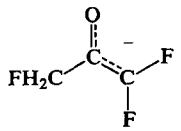
II

III



This order of acidity increase is paralleled in a comparison of data for 1,3-difluoroacetone and fluoroacetone. Addition of a remote fluorine to an enolate already bearing an α fluorine gives rise to a further increase of 7 ± 1 kcal/mol in acidity. Similarly, comparing difluoroacetone to the more weakly acidic site of fluoroacetone reveals a further 13 ± 2 kcal/mol increase in acidity by addition of an α fluorine to an enolate already having a remote fluorine substituent.

The gas phase acidity of 1,1,1-trifluoroacetone was found to be 19.7 kcal/mol greater than that of acetone. In this case of an enolate with three remote fluorines, the acidity difference from acetone is roughly equal to three times the acidity difference between the more weakly acidic site of fluoroacetone and acetone. This result would thus suggest a monotonic increase in acidity of acetones of approximately 6.5 kcal/mol for each remote fluorine substituent added. In addition, from the data for acetone, fluoroacetone, and difluoroacetone, it would appear that addition of a first α fluorine substituent to an enolate should give rise to an increase in acidity of the parent acetone of about 12 kcal/mol.



If the above postulates are correct, then it must be the case that addition of a second fluorine α to the carbanion centre cannot lead to an additive increase in acidity by an amount comparable to the first α fluorine. For example, for the gas phase acidity of pentafluoroacetone it would be calculated that addition of the second α fluorine leads to a further increase in acidity of only 6 ± 1 kcal/mol. Using this value for the increase in acidity resulting from a second α fluorine, it is possible to predict a difference in acidity between 1,1,3,3-tetrafluoroacetone and acetone of 31 kcal/mol. This agrees extremely well with the experimentally obtained value of 29 ± 3 kcal/mol.

Thus, for the fluorinated acetones studied here, all gas phase acidities may be interpreted on the basis of an increase in acidity of 6.5 kcal/mol relative to acetone for each remote fluorine substituent, 12 kcal/mol increase for the first α fluorine substituent, and a further 6 ± 1 kcal/mol increase for the second α fluorine substituent.
