We tried similar plots for our values of $\gamma_2{}^{\infty}$ listed in Tables 3 and 4, with the values for ${}^{d}\delta$, ${}^{p}\delta$, and $V$ being taken from ref. 1. Our plots of $L$ vs. $V_2{}^{p}\delta_2{}^2$ for the polar solutes in the nonpolar solvents $n$-heptane and benzene are in Fig. 4, and of $L$ vs. $V_2{}^{p}\delta_1{}^2$ for carbon tetrachloride in the polar solvents are in Fig. 5. Clearly, the broken lines through the origin are poor fits to our data, particularly in view of the relatively high precision of our $\gamma_2{}^{\infty}$ values as exemplified by their low standard deviations. In fact, better fits — but still not acceptable ones — were obtained by lines not passing through the origin. However, for comparative purposes values for $k$ were calculated for these broken lines through the origin in Figs. 4 and 5. They are entered in Table 5.

The binary systems in Fig. 5 belong to the same category as those of Weimer and Prausnitz (1), namely, a given nonpolar solute infinitely dilute in polar solvents. The binary systems in Fig. 4, on the contrary, consist of polar solutes infinitely dilute in a given nonpolar solvent, as did systems studied by Harris and Prausnitz (21). Weimer and Prausnitz clearly demonstrated a correlation between $\psi_{12}$ and ${}^{p}\delta_1$ for their systems, where subscript 1 denotes polar solvent. To conform with their method of treating the data, we necessarily tested our systems in Fig. 4 for correlation between $\psi_{12}$ and ${}^{p}\delta_2$, where subscript 2 denotes polar solute; Harris and Prausnitz did the same with their systems.

Much less scatter for our data was obtained when the values of $\psi_{12}$ were calculated by using the data in Tables 3 and 4 with [4], and then plotted against ${}^{p}\delta_2\delta_1$ for Table 3, and ${}^{p}\delta_1\delta_2$ for Table 4 (subscript 1 denotes the solvent). These plots are in Fig. 6.

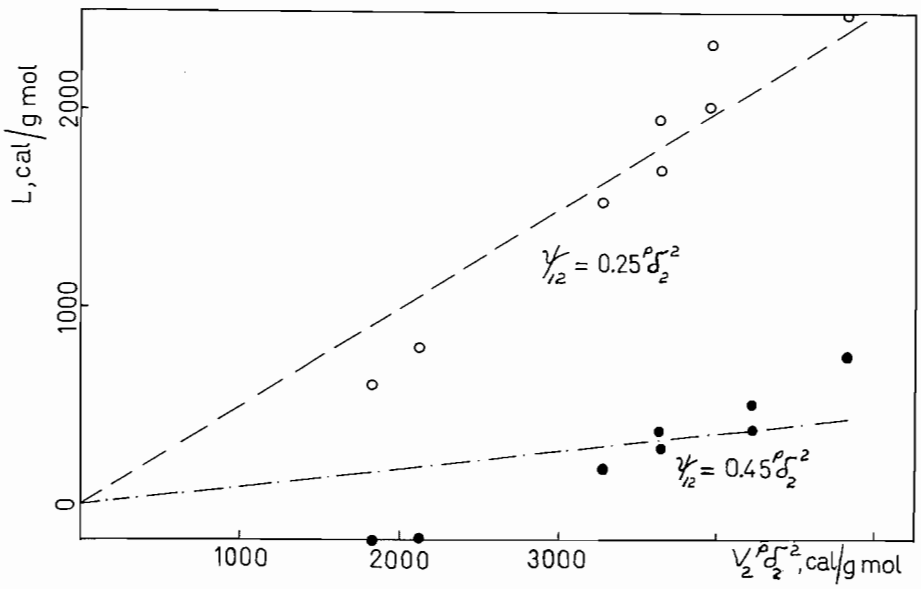

FIG. 4. Plots of $L$ ($= V_2{}^p\delta_2{}^2 - 2V_2\psi_{12}$) versus $V_2{}^p\delta_2{}^2$ for eight polar solutes (2) in *n*-heptane (○) and in benzene (●).

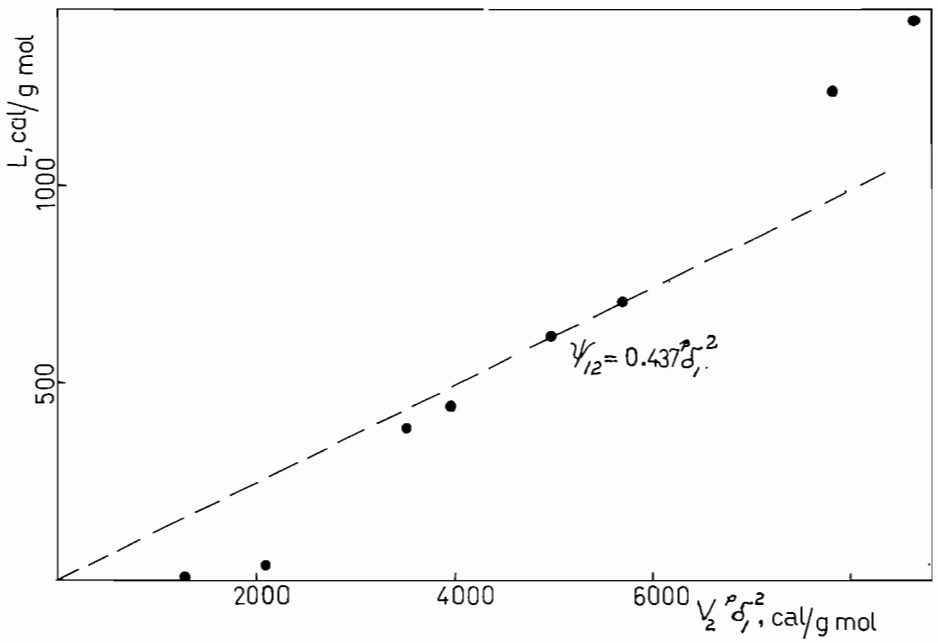

FIG. 5. Plots of $L$ ($= V_2{}^p\delta_1{}^2 - 2V_2\psi_{12}$) versus $V_2{}^p\delta_1{}^2$ for carbon tetrachloride (2) in eight polar solvents (1).

Blanks and Prausnitz (2) had proposed this $\psi_{12}$ vs. $\delta_1{}^p\delta_2$ relationship for their data on polymers.

It is clear from [4] that reliable values for $\psi_{12}$ require reliable values of ${}^d\delta_1$ and ${}^d\delta_2$. This matter was considered in the present work.

Kirchnerová and Cave (22) showed empirically that plots of $\delta$ vs. refractivity ($R$) for several homologous series of hydrocarbons gave straight lines over the range of compounds chosen, one line for each homologous series. These plots have been used (9) for estimating the polar (${}^p\delta$) and nonpolar (${}^d\delta$) contributions to the solubility parameters of polar liquids. Keller *et al.* (23) have also advocated the use of the correlation between ${}^d\delta$ and the Lorenz–Lorenz refractive-index function.

In the present work, plots of $\delta$ vs. $R$ were made

TABLE 6. Dispersion contributions to the solubility parameters of polar liquids at 25°C as calculated by three methods

| Liquid | $\delta_{total}$ (cal$^{1/2}$ cm$^{-3/2}$) | $^{d}\delta$ (cal$^{1/2}$ cm$^{-3/2}$) | | |
|---|---|---|---|---|
| | | London | Slater–Kirkwood | Homomorph plots* |

| Nitroethane | 11.41 | 7.48 | 7.92 | 8.04 |
| 1-Nitropropane | 10.46 | 7.62 | 7.98 | 8.06 |
| 2-Nitropropane | 10.12 | 7.35 | 7.88 | 7.95 |
| Acetonitrile | 11.79 | 6.84 | 7.00 | 8.03 |
| Propionitrile | 10.65 | 7.14 | 7.28 | 7.97 |
| Ethyl acetate | 8.90 | 7.08 | 7.43 | 7.58 |
| *n*-Butyl acetate | 8.61 | 7.37 | 7.76 | 7.74 |

*All homomorph-plot values except those of the esters are reported in ref. 1; those of the esters were calculated by the present writers, using the method in ref. 1.

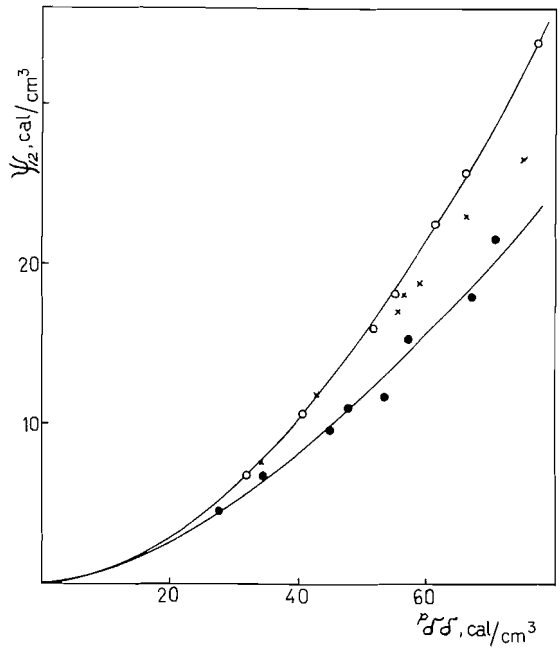

FIG. 6. Plots of the induction energy-density parameter $\psi_{12}$ versus $^{p}\delta\delta$, namely $^{p}\delta_2\delta_1$ for polar solutes ($^{p}\delta_2$) in *n*-heptane (●) and in benzene (×), and $^{p}\delta_1\delta_2$ for carbon tetrachloride ($\delta_2$) in the polar solvents (○).

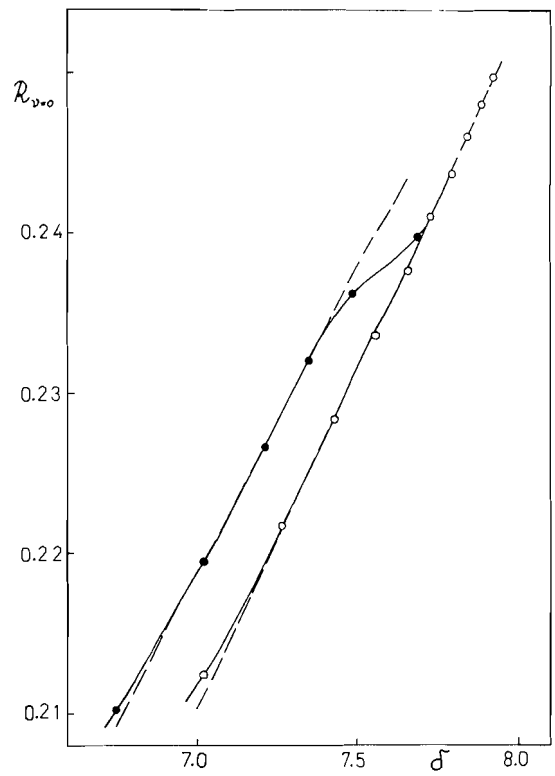

FIG. 7. Solubility parameter (δ) vs. refractivity (*R*) at zero frequency, for *n*-alkanes $C_4H_{10}$ to $C_{14}H_{30}$ (○), and 2-methyl alkanes $C_4H_{10}$ to $C_{10}H_{22}$ (●).

for *n*-alkanes and 2-methyl alkanes, over a wider range for each series than Kirchnerová and Cave had used, namely from $C_4H_{10}$ to $C_{14}H_{30}$ for the *n*-alkanes, and $C_4H_{10}$ to $C_{10}H_{22}$ for the 2-methyl alkanes. The data necessary for δ were from standard sources (24), and the values of *R* were calculated for zero frequency from bond polarizabilities (25). These plots are shown in Fig. 7. Both plots show curvature at the lower ends, and while the *n*-alkane curve then continues as a straight line, the 2-methyl alkane curve shows a limited linear region followed by a previously unreported sigmoid shape which then appears to merge with the *n*-alkane curve.

The solubility parameter may be expressed as a function of the energy of pair-interactions. The London equation for the potential energy of a pair of nonpolar molecules *in vacuo* leads to δ as a function of refractivity, *R*. Alternatively, the Slater–Kirkwood equation (26) leads to δ as a

| | | | | | | | | Mean = 1.34 |
| | | | | | | | | $s_x$ = 0.061 |
| Solvent | | | | | | | | |
| *n*-Heptane | 7.49 | | 146.55 | | | | | |
| Benzene | 9.23 | | 88.87 | | | | | |

function of $R^{3/4}n^{1/4}/V^{1/4}$, where $n$ is the number of valence electrons in the molecule. Plots of $\delta$ vs. $R^{3/4}n^{1/4}/V^{1/4}$ for the same set of *n*-alkanes and the same set of 2-methyl alkanes as were used for Fig. 7 showed shapes that were similar to those in Fig. 7, with the 2-methyl alkane curve finally merging at $C_{11}H_{24}$ with that of the *n*-alkane curve which, as in Fig. 7, was linear except at the lower end.

The values of $^{d}\delta$ for the polar solutes studied in the present work were read both from the $R$ vs. $\delta$ calibration curve, and the $R^{3/4}n^{1/4}/V^{1/4}$ vs. $\delta$ curve, and are entered in columns 3 and 4 respectively of Table 6. The values of $R$ were required at zero frequency, and were calculated from bond polarizabilities (25) except in the case of the nitro compounds. For each of them, the value of $R$ at zero frequency was calculated (27) from the refractive indices at three different frequencies. Column 5 of Table 6 gives for comparison the values of $^{d}\delta$ calculated from homomorph plots.

In the present work, when values of $^{d}\delta$ were needed they were taken from plots of $R^{3/4}n^{1/4}/V^{1/4}$ vs. $\delta$, except where otherwise noted.

By using the values of $\gamma_2^{\infty}$ in Table 3, the corresponding values of $c_{12}$ were found from [2], and those of $\psi_{12}$ from [4]. The results are in Table 7. For these calculations, values of $\delta$ at 20°C were used, and are in Table 7. They were calculated from enthalpies of vaporization at 25°C (10) and the molar heat contents of liquid and of ideal vapor. Values for $^{d}\delta$ at 20°C are also entered in Table 7. They were estimated by the method described above for the $^{d}\delta$ values in column 4 of Table 6, except that the calibration curves were for 20°C.

Of particular interest is the ratio for each polar solute of its value of $\psi_{12}$ in *n*-heptane to its value in benzene. These ratios are in column 9 of Table 7. The standard deviation is only 0.061 for the eight solutes.

The near-constancy of this ratio shows some promise of being a way to estimate from limited data the limiting activity coefficients of polar solutes in nonpolar solvents. Thus, if the limiting activity coefficient of a polar solute is known in one nonpolar solvent, it may be practical to estimate with acceptable accuracy its value in another nonpolar solvent, provided the ratio of the $\psi_{12}$ values has already been found for the two solvents. To establish the degree of generality of this empirical rule for the ratios, more solvents are currently being studied in this laboratory.

The decreases in the value of $\psi_{12}$ for a given homologous series illustrated to a very limited degree in Table 7 appear to be systematic, and suggest a generality; but the decrements per $CH_2$ group are too irregular in the table to warrant quantification at present.

## Acknowledgments

We are grateful to Mr. A. Kluck of McGill University for the fabrication of the sampling valve, to Dr. S. Afrashtehfar for assistance in some of the computations for Table 3, and to the National Research Council of Canada for financial assistance.

# Méthode générale d'obtention des α-céto esters β-fluorés

ALI OURARI, ROGER CONDOM ET ROGER GUEDJ

*Laboratoire de Chimie Structurale Organique, Université de Nice, Parc Valrose, 06034 Nice Cédex, France*

Reçu le 24 mars 1982

ALI OURARI, ROGER CONDOM et ROGER GUEDJ. Can. J. Chem. **60**, 2707 (1982).

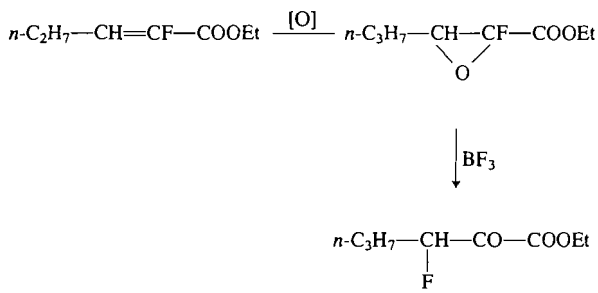
Une méthode générale de préparation des alkyl-3 (ou aryl) fluoro-3 oxo-2 esters est décrite. Les esters glycidiques sont ouverts par le mélange HF–pyridine (70% poids/poids) puis oxydés par le réactif de Jones; les dérivés correspondants des esters fluoropyruviques sont obtenus avec de bons rendements.

ALI OURARI, ROGER CONDOM, and ROGER GUEDJ. Can. J. Chem. **60**, 2707 (1982).

A general method of synthesis of 3-alkyl (or aryl) 3-fluoro 2-oxo esters is described. The opening of glycidic esters with HF–pyridine (70% w/w), followed by oxidation with Jones reagent, give the corresponding derivatives of fluoropyruvic esters in good yields.

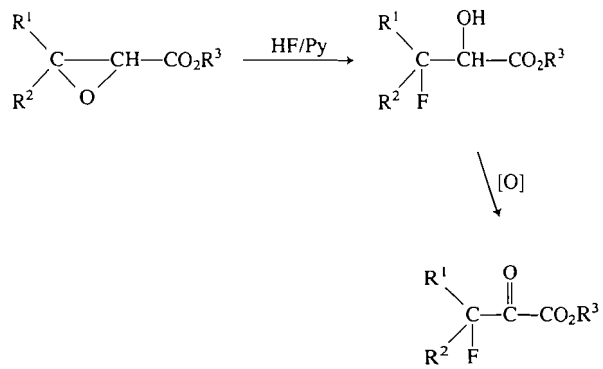
La synthèse des fluoropyruvates a été très peu étudiée, les travaux réalisés dans ce domaine concernent l'obtention de l'acide fluoropyruvique (1) et l'α-oxo-β-fluorohexanoate d'éthyle (2). Récemment, Tsushima et coll. (3, 14) ont signalé que l'action du fluor élémentaire sur les α-céto esters donne les fluoropyruvates correspondants.

Les méthodes décrites ci-dessus ne peuvent être appliquées que pour des cas particuliers; par exemple, l'acide fluoropyruvique est obtenu à partir de l'oxalo fluoroacétate et l'α-oxo β-fluoro-hexanoate d'éthyle à partir de l'ester α-fluoro glycidique correspondant:



Cette méthode n'a pas pu être étendue aux dérivés aromatiques par le fait que l'ester acrylique α-fluoré ne s'époxyde pas.

C'est la raison pour laquelle, compte tenu de l'intérêt présenté par les propriétés biologiques des pyruvates notamment dans le domaine des antibiotiques (13), nous avons mis au point une méthode de synthèse simple et générale permettant l'accès à des α-céto esters β-fluorés diversement substitués. Le schéma réactionnel est le suivant:



où $R^1$ = H, alkyle, aryle; $R^2$ = alkyle, aryle; $R^3$ = $C_2H_5$ ou $CH(CH_3)_2$.

## Partie expérimentale

Les époxydes sont obtenus par condensation du composé carbonylé sur le chloroacétate d'éthyle au moyen du *tert*-butylate de potassium (4) en quantités stoechiométriques (5). L'ester glycidique (**10***a*) a été synthétisé en utilisant l'isopropylate de potassium. L'ester glycidique ainsi obtenu (0,04 mol) est dissous dans 10 mL de $CH_2Cl_2$, puis 20 mL d'acide fluorhydrique en solution dans la pyridine (70% w/w) sont ajoutés à 5°C environ. Après distillation, le fluoroalcool (0,02 mol) est dissous dans 200 mL d'acétone. La solution est agitée magnétiquement et 210 mL du réactif de Jones sont ajoutés goutte à goutte, la température étant maintenue vers 5°C. Le mélange est abandonné pendant une nuit, puis traité. Le céto ester obtenu est distillé sous pression réduite.

## Résultats

A. Les esters glycidiques **1***a* (6), **2***a* (7), **3***a* (8), **4***a*, **5***a*, **6***a*, **11***a*, **12***a* (9), **8***a* (10), **9***a* (6) de départ sont conformes à ceux décrits dans la littérature. Composé **10***a*: rendement 25%, p.Eb: 86°C/28 Torr; rmn $^1H$ δ: 3,16 (Hα et Hβ, 2H, m); 0,98

C. Les caractéristiques des fluoropyruvates ont été rassemblées dans les tableaux 1 et 2. Remarques: Les spectres ir correspondent aux produits attendus (bande CO large 1718–1730 $cm^{-1}$). Le pourcentage en produit ènolisable est très faible (non décelé en rmn $^1H$) et en accord avec les résultats obtenus par Bergmann (12).

Les spectres rmn du proton ont été enregistrés dans $CDCl_3$ (TMS réf. interne), ceux du fluor ont été effectués dans le même solvant, la référence interne étant $CFCl_3$. Ces spectres ont été réalisés sur Brucker Spectrospin 100 MHz, les déplacements chimiques sont exprimés en ppm et les constantes de couplage en Hz.

En ce qui concerne la spectrométrie de masse: les fragments donnés dans les tableaux sont respectivement l'ion moléculaire et le pic de base. Le pic M + 1 est observé dans tous les cas et la perte de HF s'effectue à partir de l'ion moléculaire et du pic de base.

# Oxidation of 1,1-disubstituted hydrazines with benzeneseleninic acid and selenium dioxide. Facile preparation of tetrazenes

THOMAS G. BACK[1] AND RUSSELL G. KERR

*Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4*

Received March 15, 1982

THOMAS G. BACK and RUSSELL G. KERR. Can. J. Chem. **60**, 2711 (1982).

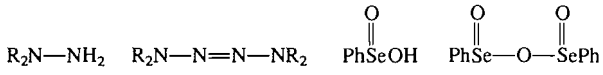
Various 1,1-disubstituted hydrazines were oxidized with benzeneseleninic acid in methanol, generally producing the corresponding tetrazenes in high yield. Studies of the by-products of the reaction, of the effects of protic vs. aprotic solvents, and trapping experiments suggest that *N*-aminonitrenes are unlikely intermediates in this oxidation. An alternative mechanism involving a Pummerer-like reaction of seleninamides derived from the hydrazines is proposed. Tetrazene formation fails when the hydrazine precursor contains an aryl or *p*-toluenesulfonyl substituent, or when it is highly hindered. Selenium dioxide may be employed as the oxidant instead of the seleninic acid, but is generally less efficacious in achieving high tetrazene yields.

THOMAS G. BACK et RUSSELL G. KERR. Can. J. Chem. **60**, 2711 (1982).

Une variété de hydrazines 1,1-disubstituées a été oxydée par l'acide benzèneséléninique et, en général, de bons rendements des tétrazènes correspondants ont été obtenus. Les études des sous-produits de ces réactions, les effets des solvants protiques et aprotiques, ainsi que le résultat d'une expérience de trappage suggèrent que les *N*-aminonitrénes sont des intermédiaires improbables dans cette oxydation. Un méchanisme alternatif est proposé, dans lequel un séléninamide dérivé de l'hydrazine de départ subit une réaction de Pummerer. La formation des tétrazènes ne réussit pas quand l'hydrazine contient un substituant aryle ou *p*-toluènesulfonyle et également quand l'hydrazine est très encombrée. Le dioxyde de sélénium peut être employé comme agent d'oxydation au lieu de l'acide séléninique, mais la formation des tétrazènes correspondants est généralement moins efficace.

A number of reagents have been employed in the oxidations of 1,1-disubstituted hydrazines **1** to tetrazenes (diaminodiazenes) **2**. Examples include oxides of lead (1, 2), mercury (3–5) and manganese (6), halogens (3, 4), potassium bromate (4), iodate (4) and permanganate (7), lead tetraacetate (8), quinone (2, 9), and *tert*-butyl hypochlorite (10).

Recent studies have shown that benzeneseleninic acid (3) and anhydride (**4**) are efficient oxidants of various hydrazines and hydrazo derivatives (11–13). As an extension of this work, we were prompted to examine the similar oxidation of 1,1-disubstituted hydrazines with **3**. Preliminary results indicated that the transformation of compounds **1** to their corresponding tetrazenes **2** could be smoothly achieved in this manner (14). It is the intent of the present article to further delineate the scope and limitations of this method and to comment on its mechanism. We also describe for the first time several experiments in which selenium dioxide was employed as the oxidant.



**1** **2** **3** **4**

## Results and discussion

The oxidation of hydrazines **1***a*–**1***g* with benzeneseleninic acid **3** in methanol provides tetrazenes **2***a*–**2***g* as the principal products, generally in high yield (see Table 1, entries 1, 6, 10–12, 14, and 16). In most cases the reactions are vigorous and enhanced tetrazene yields were obtained by performing the oxidations at −10°C and by the prompt work-up of the products. The separation of the tetrazenes from diphenyl diselenide and other by-products was readily achieved by preparative tlc. In the case of the relatively insoluble tetrazenes **2***e*–**2***g*, the products crystallized directly from the reaction mixture. This procedure therefore provides a convenient method for the conversion of a variety of 1,1-disubstituted hydrazines to tetrazenes.

Further experiments revealed that a high concentration of both reactants is necessary for optimum results. Entries 2 and 3 in the table reveal that considerable reductions in product yields occurred when either the hydrazine or the seleninic acid was introduced by slow addition. The use of water as solvent instead of methanol in the preparation of **2***a* resulted in only a small reduction in yield (entry 4) while aprotic solvents such as chloroform or diglyme afforded significantly lower yields of **2***b* (entries 7 and 8). Hydrazines **1***f* and **1***g* were oxidized as their sulfates (entries 14–16); an attempt to react the free base of **1***g* with seleninic acid **3** resulted in the recovery of starting material. The low reactivity of the latter compound is in part attributed to its poor solubility in methanol, and may to a large extent be circumvented by employment of the sulfate salt.

TABLE 1. Preparation of tetrazenes

| Entry | Hydrazine **1**, $R_2N$ | Oxidant | Yield of **2** (%)[a] | Conditions[b] |
|---|---|---|---|---|
| 1 | **1***a*  | **3** | 74 | Standard |
| 2 | **1***a* | **3** | 39 | Slow addition of **3** |
| 3 | **1***a* | **3** | 7 | Slow addition of **1***a* |
| 4 | **1***a* | **3** | 60 | $H_2O$ solvent, RT |
| 5 | **1***a* | $SeO_2$ | 73 | Standard |
| 6 | **1***b*  | **3** | 78 | Standard |
| 7 | **1***b* | **3** | 40 | $CHCl_3$ solvent |
| 8 | **1***b* | **3** | 43 | Diglyme solvent, RT |
| 9 | **1***b* | $SeO_2$ | 32 | Standard |
| 10 | **1***c*  | **3** | 75 | Standard |
| 11 | **1***d* $Me_2N$ | **3** | 28[c] | Standard |
| 12 | **1***e* $(PhCH_2)_2N$ | **3** | 75 | Standard |
| 13 | **1***e* | $SeO_2$ | 39[d] | RT |
| 14 | **1***f*[e]  | **3** | 96 | Standard |
| 15 | **1***f*[e] | $SeO_2$ | Trace | RT |
| 16 | **1***g*[e]  | **3** | 86 | RT |

[a]Isolated yield unless otherwise noted.
[b]Standard conditions are described in the experimental section. Any deviations with respect to the mode of addition, solvent, or temperature are indicated in the table. RT = room temperature.
[c]Determined by uv.
[d]Isolated as a mixture with hydrazone **8**; yield determined by integration of the nmr spectrum.
[e]Employed as the sulfate salt.

The use of selenium dioxide in lieu of seleninic acid **3** (entries 5, 9, 13, and 15) was found to give capricious results. For example, *N*-aminopiperidine (**1***a*) gave comparable yields of **2***a* with the two oxidants, while the similar morpholine derivative **1***b* afforded a much lower yield of **2***b* with selenium dioxide. Furthermore, the latter oxidant provided a poor yield of tetrazene **2***e* from **1***e* and failed to react significantly with hydrazine **1***f* even after a longer than normal reaction time at room temperature instead of at −10°C. The use of selenium dioxide also results in the formation of finely divided red selenium as a by-product, which poses additional difficulties during work-up. Consequently, the use of the dioxide in place of seleninic acid **3** is generally not recommended.

Compelling evidence exists for the formation of intermediate *N*-aminonitrenes (1,1-diazenes) **5** in the oxidations of 1,1-disubstituted hydrazines with certain other reagents such as lead tetraacetate (15). Trapping experiments employing olefins (16, 17) or sulfoxides (16, 18) have resulted in the formation of high yields of *N*-aminoaziridines and sulfoximines, respectively. In the case of the highly hindered and persistent *N*-(2,2,6,6-tetramethylpiperidyl)nitrene (**6**), direct characterization by spectroscopic methods was achieved at low temperatures (19–21). Tetrazene formation may result from the further reaction of the aminonitrenes with their precursor hydrazines to produce tetrazanes **7**, which in turn are further oxidized to the final products. In several instances, the tetrazanes have been successfully isolated (22). The direct dimerization of aminonitrenes appears

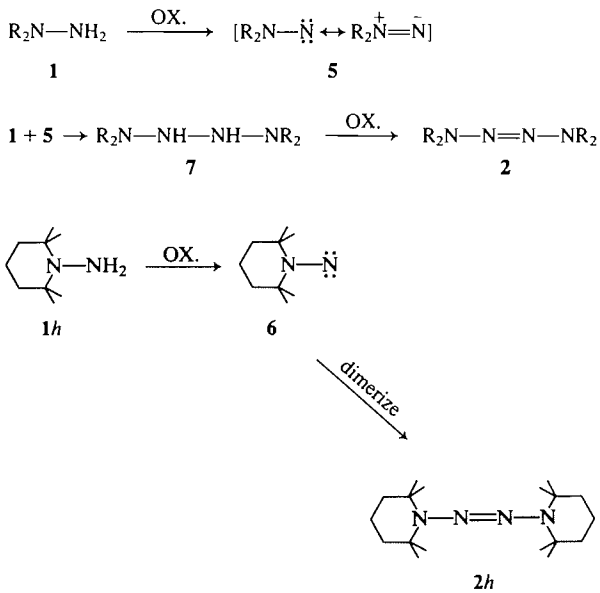
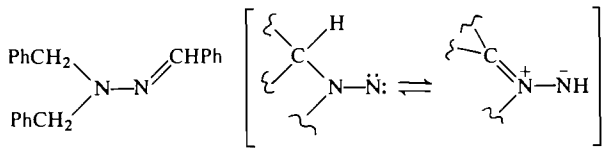
to be a less common source of tetrazenes, but evidence for such a process has been provided for the dimerization of **6** to tetrazene **2***h* (20). These processes are illustrated in Scheme 1.

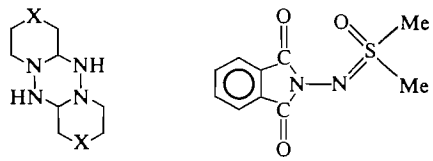
Several of our results indicate that a different mechanism is involved in the present oxidations of hydrazines **1** with **3**. First, the fragmentation of *N*-(dibenzylamino)nitrene to bibenzyl and nitrogen is known to compete favourably with tetrazene formation, frequently providing the major product (6, 9, 10, 23, 24). In contrast, the oxidation of **1***e* with **3** affords no significant amount of bibenzyl, producing instead the tetrazene **2***e* (75%) and hydrazone **8** (22%) as the principal products. Furthermore, aminonitrenes bearing α-hydrogens are capable of tautomerization to the dipolar species **9** (24, 25), a process which is favoured in protic solvents (24). Under such conditions, *N*-piperidino and *N*-morpholinonitrenes are reported to produce cyclic dimers **10**, to the nearly complete exclusion of the corresponding tetrazenes (24). Again, these results contrast with the present system wherein higher yields of tetrazenes **2***a* and **2***b* were produced in protic solvents such as methanol or water than in aprotic solvents such as chloroform or diglyme (see Table 1, entries 1, 4, and 6–8). The trapping of *N*-phthalimidonitrene with dimethyl sulfoxide during the oxidation of **1***g* with **3** was also studied. The sulfoximine **11** had previously been obtained in 74% yield when hydrazine **1***g* was treated with lead tetraacetate in dimethyl sulfoxide (18). However, the present



SCHEME 1



8 9



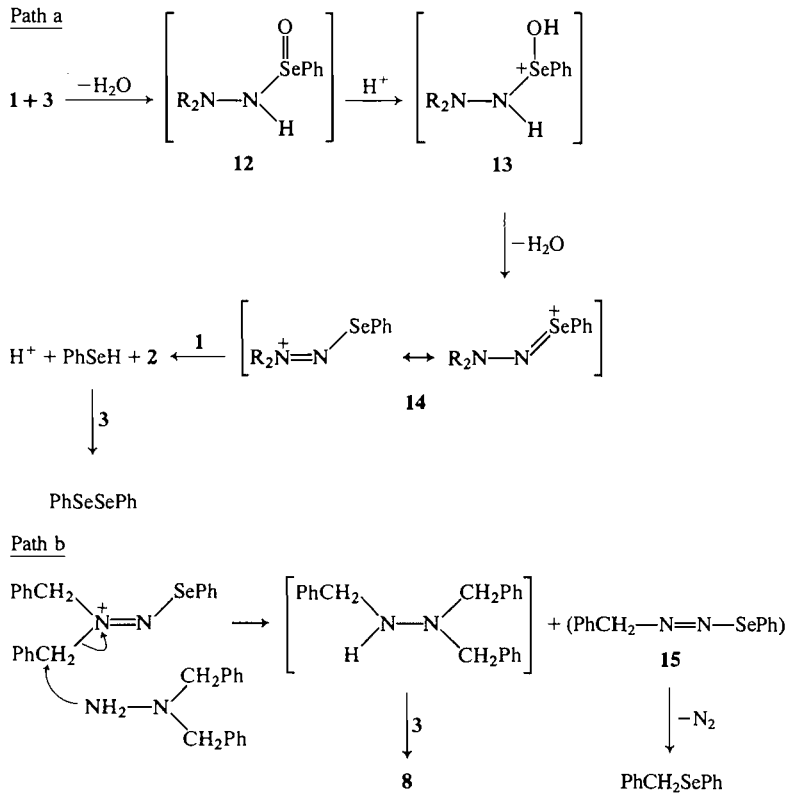
10 X = $CH_2$ or O 11

reaction with **3** afforded the far lower yield of 18% of adduct **11**. These experiments suggest that pathways other than those displayed in Scheme 1 occur in the present oxidations, and that aminonitrene intermediates do not account for a substantial portion of the products obtained.[2]

An attempt was also made to detect the formation of aminonitrene **6** in the oxidation of hydrazine **1***h* with **3**. Since intermediate **6** is known to be stable at −78°C and to possess a deep purple colour (21), its direct observation should be possible if it is produced in the present oxidation at similar temperatures. Unfortunately, the highly hindered parent hydrazine **1***h* failed to react with the seleninic acid below −5°C. At higher temperatures, nitrogen evolution occurred, accompanied by decomposition to a complex mixture of unidentified products. Conclusions regarding the intermediacy of aminonitrene **6** in the present oxidation of **1***h* are therefore precluded.

A plausible mechanism for tetrazene formation which circumvents the need for aminonitrene intermediates is shown in path a of Scheme 2. Seleninylation of **1** with **3** produces seleninamide **12**, resulting in a Pummerer-type reaction catalyzed by the seleninic acid. The Pummerer intermediate **14**

[2]A referee has commented that the evidence for aminonitrene intermediates is not compelling for all reported cases where 1,1-disubstituted hydrazines are oxidized to tetrazenes. We agree that the mechanisms of such oxidations may not be identical in all situations. However, solid evidence for the formation of aminonitrenes has been demonstrated in many of the oxidations cited above, and such species are widely accepted as being common intermediates in these processes. We therefore feel that it is not unreasonable to attribute the observed differences between our results and those in the literature to the fact that the latter reactions involve aminonitrenes as their authors suggest, whereas ours do not.



SCHEME 2

is thus generated via species **13**.[3] The further reaction of **14** with hydrazine **1** then affords the product tetrazene with concomitant formation of benzeneselenol, which is readily oxidized to diphenyl diselenide by the seleninic acid. Related Pummerer reactions of selenoxides have been previously reported (26–32) and seleninic acid **3** is known to be an effective catalyst in these processes (26, 27). The use of polar solvents such as methanol or water may facilitate these transformations by solvation of the ionic intermediates shown in the above scheme. The formation of hydrazone **8** in the oxidation of *N*,*N*-dibenzylhydrazine **1***e* is also consistent with the Pummerer reaction in Scheme 2. The Pummerer intermediate **14** may undergo attack by hydrazine **1***e* at one of the benzylic positions instead of at the *N'*-nitrogen atom (path b), resulting in the formation of tribenzylhydrazine and diazene **15**. Further oxidation of the hydrazine by **3** leads to the observed product **8**, while nitrogen extrusion from **15** provides benzyl phenyl selenide, a small amount of which was also isolated from the reaction mixture. Additional support for these steps derives from literature precedents. The formation of **8** from tribenzylhydrazine closely resembles the oxidation of certain amines with the related oxidants benzeneseleninyl chloride (33) and anhydride **4** (34) to produce imine intermediates. Also, nitrogen extrusions from aryl or acyl analogues of **15** have previously been postulated to account for the observed formation of aryl phenyl selenides and selenoesters in the oxidations of arylhydrazines or hydrazides with **3** (11). The transformations depicted in Scheme 2 are therefore entirely consistent with both the present and previous observations.

[3]The conversion of **12** to **14** could also be achieved by seleninylation rather than protonation of the seleninamide oxygen atom by **3**, resulting in the formation of intermediate **i** in lieu of **13**. Similarly, oxidations performed with methanolic selenium dioxide (dimethyl selenite) could proceed via intermediates **ii** or **iii**.

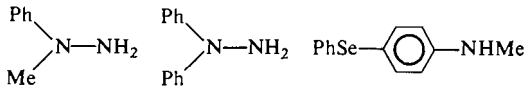
We also report that certain 1,1-disubstituted hydrazines undergo anomalous oxidations with seleninic acid **3**. Thus, *N*-methyl-*N*-phenylhydrazine (**1***i*) afforded a complex mixture which provided *N*-methyl-*p*-(phenylseleno)aniline (**16**) as the only recognizable component. Similarly, the oxidation of *N*,*N*-diphenylhydrazine (**1***j*) produced a mixture containing at least ten components, whose identification was not attempted. It therefore appears that this method is unsuitable for the preparation of tetrazenes bearing aryl substituents.



**1***i* **1***j* **16**

The oxidation of *N*-benzyl-*N*-*p*-toluenesulfonylhydrazine (**1***k*) with **3** also proved to be anomalous. When the reaction was performed in chloroform, the principal products were the sulfone **17**, the sulfinate ester **18**, and the selenosulfonate **19**, isolated in yields of 38%, 25%, and 30% respectively, along with diphenyl diselenide. These results suggest that the ambident *p*-toluenesulfinate anion is formed as an intermediate and undergoes either *S*- or *O*-benzylation, or selenenylation to afford the respective products **17**–**19**. Scheme 3 illustrates a possible mechanism in which the elimination of *p*-toluenesulfinic acid from the initially formed intermediate **20** (analogous to **12** in Scheme 2) simultaneously generates the putative benzylating species **21**. The alkylation of the sulfinate anion with the latter (or with benzyldiazonium ion derived from its decomposition) affords the observed products **17** and **18** as well as benzeneselenenic acid (**22**). Any sulfinic acid which escapes benzylation can react with the selenenic acid to furnish the selenosulfonate **19**. A similar reaction has been previously employed by Gancarz and Kice (35) to prepare this selenosulfonate from its corresponding sulfinic acid. The known disproportionation (36, 37) of unreacted selenenic acid accounts for the formation of diphenyl diselenide. A small amount of benzyl phenyl selenide was also produced. Finally, additional evidence for the presence of an electrophilic benzylating agent such as **21** (or the related diazonium species) derives from an analogous experiment performed in methanol. In this case, the nucleophilic solvent effectively competes with the sulfinic acid to produce benzyl methyl ether in 70% yield. The previous benzylation of the sulfinic acid is thus suppressed and it is free to react instead with selenenic acid **22**. Consequently, an enhanced

For personal use only.

yield of 71% of selenosulfonate **19** is obtained under these conditions.[4]

It is evident that the oxidation of 1,1-disubstituted hydrazines with benzeneseleninic acid, and less reliably with selenium dioxide, provides facile access to a variety of tetrazenes. Anomalous results are expected in those cases where the hydrazine contains aryl substituents, leaving groups such as the sulfonyl moiety, or where it is highly hindered.

## Experimental

*General*

Melting points were determined on an A. H. Thomas hot stage apparatus. Ultraviolet and ir spectra were recorded on a Varian–Cary 219 and a Perkin–Elmer 467 spectrometer, respectively. The nmr spectra were obtained on a Hitachi Perkin–Elmer R24B instrument at 60 MHz or on a Varian XL-200 spectrometer at 200 MHz. All nmr spectra were taken in $CDCl_3$ solution and are reported in ppm (δ) downfield from TMS as the internal standard. Mass spectra were recorded on a Varian MAT CH5 instrument. Elemental analyses were obtained by Mr. L. Malek. Preparative tlc was performed on Analtech 20 × 20 cm glass plates coated with 1 mm of silica gel GF. The gc analyses were carried out on a Varian 3700 instrument equipped with a flame ionization detector and a Varian CDS-111 electronic integrator. Stainless steel columns (1.8 m × 0.3 cm) packed with 10% OV-101 on Chromosorb WHP were used. Benzeneseleninic acid was either purchased from the Aldrich Chemical Co. or prepared from the nitric acid oxidation of diphenyl diselenide according to the method of Barton *et al.* (38). In the latter case, the initially formed nitrate salt was neutralized *in situ* with aqueous NaOH and reprecipitated with concentrated HCl. Literature methods were employed in the preparation of hydrazines **1***e* (39), **1***h* (3), and **1***k* (40). All other reagents were obtained from commercial sources. Diphenyl diselenide was produced in all of the hydrazine oxidations involving **3**, but was only isolated in a few representative examples.

*Preparation of Tetrazenes (see Table 1)*

N,N′-*Bis(piperidino)diazene* (**2**a)

*Under standard conditions*

A solution of *N*-aminopiperidine (**1***a*) (100 mg, 1.00 mmol) in 3 mL of MeOH was cooled to −10°C. Seleninic acid **3** (189 mg, 1.00 mmol) was added in a single portion and the solution rapidly turned yellow from the formation of diphenyl diselenide. After 5–10 min, the reaction mixture was allowed to warm to room temperature and the solvent was promptly removed *in vacuo*. The residue was separated by preparative tlc (20% EtOAc–hexane) to afford 72 mg (74%) of **2***a*; mp 42–43°C (lit. (6) mp 44°C) from EtOH–$H_2O$; identified by its ir and uv spectra (6); mass spectrum, *m/e* 196 ($M^+$).

*By slow addition*

When the seleninic acid in 5 mL of MeOH was added over 40 min (by a mechanically driven syringe pump) to the hydrazine in 3 mL of MeOH at −10°C and worked up as above, the yield of **2***a* was 38 mg (39%). Similarly, slow addition of **1***a* to **3** afforded 7 mg (7%) of **2***a*.

*In $H_2O$*

The reactants were stirred 2 h in 5 mL of $H_2O$ at room temperature. The solution was then extracted with 3 × 5 mL of $CHCl_3$, the combined organic layers were dried ($MgSO_4$) and chromatographed in the usual manner to provide 59 mg (60%) of **2***a*. Gas chromatographic analysis prior to work-up revealed no detectable *N*-nitrosopiperidine.

*With $SeO_2$ as oxidant*

A solution of $SeO_2$ (111 mg, 1.00 mmol) in 1 mL of MeOH was added in one portion to hydrazine **1***a* in 2 mL of MeOH at −10°C. A red precipitate (selenium) rapidly formed. After 5–10 min, the reaction mixture was evaporated to dryness *in vacuo*, triturated with $CHCl_3$, filtered through Celite, and chromatographed in the usual manner. The yield of **2***a* was 72 mg (73%).

N,N′-*Bis(morpholino)diazene* (**2**b)

*Under standard conditions*

*N*-Aminomorpholine (**1***b*) (102 mg, 1.00 mmol) was oxidized with **3** (189 mg, 1.00 mmol) as in the case of **1***a*. Preparative tlc (40% EtOAc – hexane) afforded 78 mg (78%) of **2***b*; mp 153–155°C (lit. (6) mp 157°C) from MeOH; identified by its ir and uv spectra (6); mass spectrum, *m/e* 200 ($M^+$). A more mobile component provided 88 mg of diphenyl diselenide, identified by comparison with an authentic sample (mp, tlc). Attempts to crystallize **2***b* directly from the reaction mixture resulted in contamination with diphenyl diselenide.

*In aprotic solvents*

When the above reaction was repeated in chloroform at −10°C or in diglyme at room temperature, the yield of **2***b* was 40% and 43% respectively.

*With $SeO_2$ as oxidant*

Hydrazine **1***b* (102 mg, 1.00 mmol) was oxidized with $SeO_2$ (111 mg, 1.00 mmol) as described for **1***a*. The yield of **2***b* was 32 mg (32%).

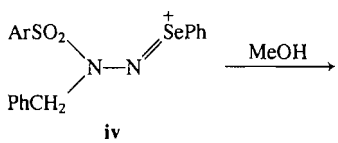
N,N′-*Bis(2,6-dimethylpiperidino)diazene* (**2**c)

*N*-Amino-2,6-dimethylpiperidine (**1***c*) (128 mg, 1.00 mmol) was oxidized with **3** (189 mg, 1.00 mmol) under the standard conditions described for **1***a*. Preparative tlc (25% EtOAc – hexane) afforded 95 mg (75%) of **2***c*, which solidified upon cooling; mp 36–40°C (lit. (5) mp 44–45°C); uv (MeCN), $\lambda_{max}$: 249 nm (ε 9800), 284 nm (sh, ε 2500); ir (film): 1455, 1370, 1320, 1282, 1212, 1110, 1054 $cm^{-1}$; Raman spectrum, 1445 $cm^{-1}$ (N=N); nmr (200 MHz) δ: 3.52 (m, 4H, CH), 1.85–1.4 (complex, 12H, $CH_2$), 1.05 (d, $J$ = 6.6 Hz, 12H, $CH_3$); mass spectrum, *m/e* 252 ($M^+$).

N,N′-*Bis(dimethylamino)diazene* (**2**d)

*N*,*N*-Dimethylhydrazine (**1***d*) (60 mg, 1.00 mmol) was oxidized with **3** (95 mg, 0.50 mmol) under the standard conditions described for **1***a*. Volatile material was distilled, first at 20 Torr then at 0.05 Torr pressure, into a cold trap maintained at −78°C. Ultraviolet analysis of the distillate (lit. (25) uv (MeOH) $\lambda_{max}$: 277 nm, log ε 3.92) indicated the presence of 16 mg

[4]The formation of **19** in methanol solution could also arise from the diazene **v**, in turn derived from the methanolysis of **iv**. However, the formation of **17** and **18** in chloroform solution would be difficult to rationalize from species **iv**. A free radical mechanism for the oxidation of **1***k* cannot be entirely ruled out, but again would not readily explain the formation of benzyl methyl ether in methanol solution.



**iv**

**v**

For personal use only.

(28%) of **2***d*. A slightly lower yield was obtained when an equimolar amount of **3** was employed.

N,N′-*Bis(dibenzylamino)diazene (2*e)

*Under standard conditions*

*N,N*-Dibenzylhydrazine (**1***e*) (212 mg, 1.00 mmol) was oxidized with **3** (189 mg, 1.00 mmol) as in the case of **1***a*. A white, crystalline precipitate formed within several seconds and was filtered after 10 min to afford 158 mg (75%) of **2***e*; mp 95–98°C (lit. (9) mp 95–96°C); uv (MeOH) $\lambda_{max}$: 287 nm (ε 12 000); ir ($CHCl_3$): 1607, 1497, 1457, 1352, 957, 700 $cm^{-1}$; nmr (60 MHz) δ: 7.12 s, 20H, Ph), 4.30 (s, 8H, $CH_2$); mass spectrum, *m/e* 420 ($M^+$). The filtrate was concentrated and separated by preparative tlc (50% $C_6H_6$ – hexane) to give 33 mg (22%) of hydrazone **8**, mp 81–82°C (from MeOH), identical (mp, ir, nmr) to an authentic sample prepared from **1***e* and benzaldehyde. A more mobile band was rechromatographed (20% $CCl_4$ – hexane) to afford 100 mg of diphenyl diselenide and 6 mg of benzyl phenyl selenide, identified by its nmr and mass spectra.

*With $SeO_2$ as oxidant*

Hydrazine **1***e* (106 mg, 0.50 mmol) and $SeO_2$ (56 mg, 0.50 mmol) were stirred in 3 mL of MeOH at room temperature. A red precipitate (selenium) gradually appeared. After 10 min, the solution was worked up as in the case of **1***a*. Preparative tlc (50% $C_6H_6$ – hexane) afforded 77 mg of an unseparated mixture of **2***e* and **8**, whose respective yields of 39% and 47% were determined from the integrated intensities of their nmr signals.

trans-*3,3′-Bis(2-oxazolidinonyl)diazene (2*f)

*Under standard conditions*

3-Amino-2-oxazolidinone sulfate (**1***f*) (100 mg, 0.50 mmol) was oxidized with **3** (95 mg, 0.50 mmol) as in the case of **1***a*. The reaction mixture was allowed to warm to room temperature and an insoluble white solid was filtered to afford 48 mg (96%) of **2***f*; mp 295–300°C dec. (lit. (4) mp 298–299°C); identified by its uv and ir spectra (4).

*With $SeO_2$ as oxidant*

When $SeO_2$ was employed instead of **3** in the above procedure, the filtered solid consisted of starting material **1***f* contaminated by a trace of tetrazene **2***f* (detected by tlc) even after a reaction time of 43 h at room temperature.

trans-N,N′-*Bis(phthalimido)diazene (2*g)

*N*-Aminophthalimide (**1***g*) (162 mg, 1.00 mmol), seleninic acid **3** (189 mg, 1.00 mmol), and sulfuric acid (98 mg, 1.00 mmol) were stirred 45 min in 3 mL of MeOH at room temperature. An insoluble white solid was then filtered to afford 137 mg (86%) of **2***g*; mp 295°C dec. (lit. (8) mp 294–299°C dec.); identified by its ir and mass spectra (8). When the experiment was performed without sulfuric acid, only unreacted **1***g* was recovered.

*Trapping of* N-*phthalimidonitrene from 1*g *and 3 with DMSO*

Hydrazine **1***g* (81 mg, 0.50 mmol) and seleninic acid **3** (95 mg, 0.50 mmol) were stirred in 1 mL of dry DMSO at room temperature. After 10 min, DMSO was removed from the yellow solution *in vacuo* and the residue was separated by preparative tlc (10% MeOH – $CHCl_3$) to provide, in decreasing order of mobility, 74 mg of diphenyl diselenide, 11 mg (15%) of phthalimide, identical to an authentic sample (mp, tlc, ir), and 21 mg (18%) of *S,S*-dimethyl-*N*-phthalimidosulfoximine (**11**); mp 208–210°C (lit. (18) mp 208–210°C); nmr (60 MHz) δ: 7.75 (m, 4H, aromatic), 3.28 (s, 6H, $CH_3$), with ir and mass spectra as reported in the literature (18). More polar components were poorly separated and were not further investigated.

*Oxidation of* N-*amino-2,2,6,6-tetramethylpiperidine (1*h) *with 3*

Hydrazine **1***h* (70 mg, 0.45 mmol) and seleninic acid **3** (85 mg, 0.45 mmol) were added to 5 mL of MeOH at −70°C. No reaction was evident and the mixture was slowly permitted to warm to room temperature. At ca. −5°C, a yellow colour appeared and gas evolution commenced, becoming increasingly vigorous as warming continued. No significant amount of tetrazene **2***h* could be isolated from the mixture. When the reaction was repeated in $CDCl_3$ solution at room temperature, copious gas evolution occurred and the nmr spectrum of the remaining solution revealed a complex mixture of products.

*Oxidation of* N-*methyl*-N-*phenylhydrazine (1*i) *and* N,N-*diphenylhydrazine (1*j) *with 3*

Hydrazine **1***i* (122 mg, 1.00 mmol) was oxidized with **3** (189 mg, 1.00 mmol) under the standard conditions described for **1***a*. Separation by preparative tlc (20% EtOAc – hexane) afforded 75 mg (29%) of *N*-methyl-*p*-phenylselenoaniline (**16**) as an oil, identical to an authentic sample (*vide infra*) in all respects, as well as a large number of unidentified products. The similar oxidation of **1***j* produced an extremely complex mixture containing at least ten components (tlc), which was not further investigated.

N-*Methyl*-p-*phenylselenoaniline (16)*

Freshly redistilled *N*-methylaniline (107 mg, 1.00 mmol) and benzeneselenenyl chloride (191.5 mg, 1.00 mmol) were stirred 3 min in 3 mL of MeOH at room temperature. The reaction mixture was evaporated *in vacuo* and separated as in the preceding procedure to provide 73 mg (28%) of **16**; ir (film): 3425, 1595, 1577, 1500, 1475, 1435, 1318, 1290, 1260, 1180, 1019, 810, 730, 685 $cm^{-1}$; nmr (200 MHz) δ: 7.44 (d, $J$ = 8.5 Hz, 2H, $C_6H_4$), 7.35–7.10 (m, 5H, Ph), 6.55 (d, $J$ = 8.5 Hz, 2H, $C_6H_4$), 3.86 (br s, exchanged, 1H, NH), 2.84 (s, 3H, $CH_3$); mass spectrum, *m/e* 263 ($M^+$, $^{80}Se$), 261 ($M^+$, $^{78}Se$). *Anal.* calcd. for $C_{13}H_{13}NSe$: C 59.54, H 5.01, N 5.34; found: C 59.51, H 5.02, N 5.36.

*Oxidation of* N-*benzyl*-N-p-*toluenesulfonylhydrazine (1*k) *with 3*

*In $CHCl_3$*

Hydrazine **1***k* (138 mg, 0.50 mmol) and seleninic acid **3** (95 mg, 0.50 mmol) were stirred 10 min in 5 mL of $CHCl_3$ at room temperature. A vigorous reaction with gas evolution was observed. The reaction mixture was concentrated *in vacuo* and separated by preparative tlc (20% EtOAc – hexane) to afford three main components. The top band provided 30 mg of a yellow oil consisting of diphenyl diselenide and benzyl phenyl selenide in a molar ratio of 57:43 (yield of selenide: 9%), as determined by integration of the nmr spectrum of the mixture. The identities of these two products was confirmed by gc – mass spectral analysis. The second band was further separated by preparative tlc ($CH_2Cl_2$) to give 46 mg (30%) of selenosulfonate **19**, identical to an authentic sample (12) (mp, ir, nmr), and 31 mg (25%) of benzyl *p*-toluenesulfinate (**18**) obtained as an oil (lit. (41) mp 22–24°C); ir (film): 1596, 1499, 1455, 1132 $cm^{-1}$; nmr spectrum as reported in the literature (42). The bottom component afforded 47 mg (38%) of sulfone **17**, mp 140–144°C (lit. (43) mp 144–145°C), identified by its ir and nmr spectra (44).

*In MeOH*

The above reaction was repeated in 5 mL of MeOH. The solution slowly turned clear and yellow. An internal standard (*p*-xylene) was added after 45 min at room temperature and gc analysis revealed the presence of 43 mg (70%) of benzyl methyl ether, further identified by gc – mass spectrometry. The mixture was then separated by preparative tlc ($CH_2Cl_2$) to afford 16 mg of diphenyl diselenide containing a trace of benzyl phenyl selenide, 111 mg (71%) of selenosulfonate **19**, and 25 mg (20%) of sulfinate ester **18**.

# Le photocatalyseur $MoO_3/SiO_2$: activité et structure

ARNAUD MAHAY ET SERGE KALIAGUINE
*Département de génie chimique. Université Laval, Québec (Qué.), Canada G1K 7P4*
ET
PIERRE C. ROBERGE
*Département de chimie, Université Laval, Québec (Qué.), Canada G1K 7P4*

Reçu le 15 avril 1982

ARNAUD MAHAY, SERGE KALIAGUINE et PIERRE C. ROBERGE. Can. J. Chem. **60**, 2719 (1982).

On a étudié l'activité d'un photocatalyseur $MoO_3/SiO_2$, constitué par un dépôt de molybdène sur de la silice, dans la réaction d'oxydation photocatalytique du cyclohexane par l'oxygène. Les résultats comparés à ceux du catalyseur $V_2O_5/SiO_2$ étudié précédemment, mettent en évidence un comportement du même type, notamment une recristallisation importante des espèces isolées photocatalytiquement actives, à la surface du catalyseur pendant la réaction. Ceci est confirmé par une analyse par spectroscopie de réflectance diffuse de la surface des catalyseurs avant et après réaction. L'ensemble de ces deux types de résultats fait apparaître deux types d'espèces superficielles: des cations $Mo^{+6}$ en coordination tétraédrique, actifs, isolés et fixes au cours de la réaction, et des cations $Mo^{+6}$ en coordination octaédrique liés sous forme d'espèces polymériques de surface, pouvant migrer dans les conditions de la réaction. Cette migration mène à une fixation et une agglomération de ces espèces octaédriques et à la possibilité de créer des ponts Mo—O—Mo entre une espèce tétraédrique et une octaédrique. Du fait de cette incorporation, la majorité des espèces tétraédriques conserve sa coordination mais perd son activité photocatalytique.

ARNAUD MAHAY, SERGE KALIAGUINE, and PIERRE C. ROBERGE. Can. J. Chem. **60**, 2719 (1982).

The activity of molybdenum oxide supported on silica gel ($MoO_3/SiO_2$) for the photocatalytic oxidation of cyclohexane has been investigated. A comparison of results with those obtained in a previous investigation with $V_2O_5/SiO_2$ indicates a similar behaviour, namely recrystallization involving photocatalytically active isolated species on the surface during the reaction. This has been confirmed by diffuse reflectance spectroscopic analysis of the catalysts before and after the reaction. From the two series of experimental results it can be concluded that two kinds of surface species exist: (1) $Mo^{+6}$ cations in tetrahedral coordination, isolated and fixed on the surface, are active in photocatalysis; (2) $Mo^{+6}$ cations in octahedral coordination, under the form of polymeric surface species, able to migrate in the conditions of the photocatalytic reaction. This migration leads to the fixation and agglomeration of these octahedral species and to the possible creation of Mo—O—Mo bridges between a tetrahedral and an octahedral species. In that case, the majority of the tetrahedral species does not change its coordination but loses its photocatalytic activity.

## Introduction

La photocatalyse hétérogène des réactions d'oxydation par l'oxygène en phase gazeuse a fait l'objet, au cours des dix dernières années, d'une importante activité de recherche. Certains ont mis à profit les conditions particulièrement douces de ces réactions (température et pression ambiantes) pour contrôler la sélectivité des oxydations partielles de différents hydrocarbures (1, 2). D'autres ont vu dans ces phénomènes une des étapes des cycles d'oxydoréduction impliquant le rayonnement et donc susceptibles d'être mis à profit pour le stockage chimique de l'énergie lumineuse (3–5). D'autres enfin étudient ces phénomènes pour les informations qu'ils fournissent sur la nature de la surface des solides photocatalyseurs (6, 7). Ces informations sont d'intérêt non seulement pour l'utilisation de ces catalyseurs en photocatalyse, mais également pour la compréhension de leur action en catalyse thermique classique.

Les objectifs du travail présenté ici, appartiennent à cette troisième catégorie. Nous nous sommes en effet intéressés aux dépôts d'oxydes de métaux de transition sur des supports isolants inertes tels que la silice. Ces catalyseurs ont le double avantage de présenter d'une part une grande surface exposée à la lumière, et d'autre part de permettre une grande dispersion de l'oxyde déposé ce qui permet des concentrations importantes de sites cationiques isolés les uns des autres à la surface du support.

Selon Kazansky et coll. (8), l'absorption du rayonnement ultraviolet et d'une partie du rayonnement visible par ce type de site mène à la formation d'un état de transfert de charge:

$$[1] \quad M^{n+} - O^{2-} + h\nu \rightleftarrows [M^{(n-1)+} \ldots O^-]^*$$

L'espèce activée $O^-$ s'est révélée très réactive, même à basse température.

Dans les travaux antérieurs de notre laboratoire, l'attention s'est portée sur des catalyseurs de ce type, susceptibles d'absorber dans la partie visible du spectre, à savoir le pentoxyde de vanadium déposé sur gel de silice ($V_2O_5/SiO_2$) (9) et le pentoxyde de tantale déposé sur gel de silice ($Ta_2O_5/SiO_2$) (10). Dans ce qui suit, nous présen-

tons une étude sur les propriétés photocatalytiques du trioxyde de molybdène déposé sur gel de silice ($MoO_3/SiO_2$). Parallèlement nous avons effectué une étude des catalyseurs utilisés, par spectroscopie de réflectance diffuse uv–visible, qui dans le cas des dépôts d'oxyde de molybdène, fournit des informations relativement précises (11) sur l'état de coordination des cations molybdène à la surface du dépôt.

## Procédures expérimentales

*Préparation des catalyseurs*

Les catalyseurs ont été préparés par imprégnation d'un gel de silice par une solution aqueuse de paramolybdate d'ammonium (pH de 5 à 6), suivi d'un séchage à 120°C et d'une calcination dans l'air pendant une nuit à 500°C. L'imprégnation a été faite par la méthode dite de remplissage du volume total des pores pour laquelle le volume de la solution ne doit pas excéder celui des pores.

Le paramolybdate d'ammonium $[(NH_4)_6(Mo_7O_{24})4H_2O]$ est un produit de pureté garantie (Anachemia AC 630) dont les principales impuretés cationiques sont le plomb (0,001%) et le magnésium (0,02%). Le support est une silice commerciale (Fisher S662) garantie pure à 99,9%, de granulométrie 60 à 200 mesh et de surface spécifique voisine de 450 $m^2/g$.

La concentration du molybdène dans les différents catalyseurs, exprimée en pourcentage pondéral de molybdène a varié de 0,1 à 2%.

*Mesure de l'activité photocatalytique*

L'étude de l'activité photocatalytique a porté sur l'oxydation en phase gazeuse, du cyclohexane par l'oxygène. Le montage expérimental utilisé à cette fin a déjà été décrit dans une publication antérieure (12, 13). Il comporte un tube réacteur vertical en quartz, à la paroi intérieure duquel le catalyseur est disposé sous forme d'une couche de 2 mm d'épaisseur. Ce réacteur contient environ 50 g de catalyseur et la surface éclairée de cette couche est d'environ 350 $cm^2$. Il est entouré double enveloppe de quartz dans laquelle circule de l'eau distillée à température contrôlée. L'ensemble est placé au foyer d'un réflecteur elliptique en aluminium poli, l'autre foyer étant occupé par une lampe tubulaire au mercure à moyenne pression (Hanovia SS78 A16) d'une puissance nominale de 2 kW et émettant effectivement 700 W dans l'ultraviolet.

Les réactifs gazeux sont alimentés par le haut et un dispositif comportant un tube de céramique poreuse permet d'effectuer un soutirage continu sur toute la hauteur de la colonne. La sortie du réacteur est reliée à un chromatographe en phase gazeuse (F et M modèle 720) par une ligne en acier inoxydable et une vanne d'échantillonnage chauffées.

L'alimentation gazeuse est obtenue en faisant circuler un débit d'oxygène dans un saturateur à température contrôlée, contenant le cyclohexane. Le cyclohexane (Fisher C-552 ou Anachemia AC-2717-5) était d'une pureté minimale 99%. L'oxygène (Linde high purity) de pureté garantie 99,6% était débarrassé de traces d'eau et de dioxyde de carbone par passage sur une colonne de Driérite et une colonne d'Ascarite.

Tous les essais rapportés ici ont été obtenus dans des conditions dites standards, déjà utilisées dans les études antérieures (7, 9, 10). Ces conditions sont: un débit d'oxygène pur mesuré avant la saturation de 35 $cm^3/min$ ramené à TPN, une température de saturation de 35°C, ce qui assure une pression partielle de cyclohexane dans l'alimentation de 20,2 kPa, une température du réacteur de 60°C.

*Essais de réflectance diffuse*

Ces essais ont été effectués à l'aide d'un spectrophotomètre Bausch et Lomb Spectronic 505 muni d'une sphère intégrante et permettant des mesures dans le domaine spectral allant de 220 à 600 nm. Les échantillons étaient constitués de mélanges très homogènes de poudre de MgO (Fisher M 51) et de catalyseur en proportion pondérale de 50%, comprimés sous une force de 90 000 N, en pastilles de 38 mm de diamètre. La référence était une pastille de MgO et de gel de silice préparée dans les mêmes conditions.

De tels essais ont été effectués avec des catalyseurs fraîchement préparés ainsi qu'avec des catalyseurs ayant été utilisés plusieurs jours dans le réacteur. Dans ce dernier cas les échantillons ont été recalcinés dans l'air à 500°C pendant plusieurs heures avant la préparation de la pastille.

## Résultats expérimentaux et discussion

*Activité photocatalytique*

Dans les conditions standards décrites ci-dessus les produits observés de l'oxydation de cyclohexane sont le $CO_2$ et l'eau. Certains produits de l'oxydation partielle tels la cyclohexanone, l'éthanal et le propanal ne sont obtenus qu'à l'état de traces. En conséquence, nous avons choisi de repérer l'activité photocatalytique par la mesure du pourcentage molaire de $CO_2$ dans les gaz quittant le réacteur. Selon la teneur en molybdène du catalyseur, deux comportements ont été observés pour les variations de l'activité photocatalytique en fonction du temps de réaction. Pour les catalyseurs comportant un pourcentage de molybdène supérieur ou égal à 0,5%, on a obtenu un comportement dit de *type A* représenté à la figure 1. Après une période initiale où le pourcentage de $CO_2$ augmente très rapidement, un maximum est atteint et l'activité photocatalytique rediminue lentement pendant une période de plusieurs jours avant d'atteindre une valeur stationnaire. Dans ce cas le catalyseur prend rapidement une couleur verte. Pour les plus faibles valeurs de la teneur en molybdène on obtient le comportement dit de *type B*, représenté à la figure 2. L'activité photocatalytique augmente continuellement avec le temps jusqu'à atteindre une valeur stationnaire. Dans ce cas le catalyseur ne se colore que très légèrement, en raison de la faible concentration superficielle des espèces hydratées. La figure 3 donne les variations du pourcentage de $CO_2$ correspondant à l'activité stationnaire, en fonction de la teneur en molybdène du catalyseur. On voit que cette activité limite passe par un maximum pour une valeur du pourcentage en molybdène voisine de 0,75%.

Le passage d'un comportement de type B à un comportement de type A pour une valeur faible de la teneur en cations, ainsi que le changement du sens de la variation de l'activité stationnaire avec la concentration superficielle des cations, ont été

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

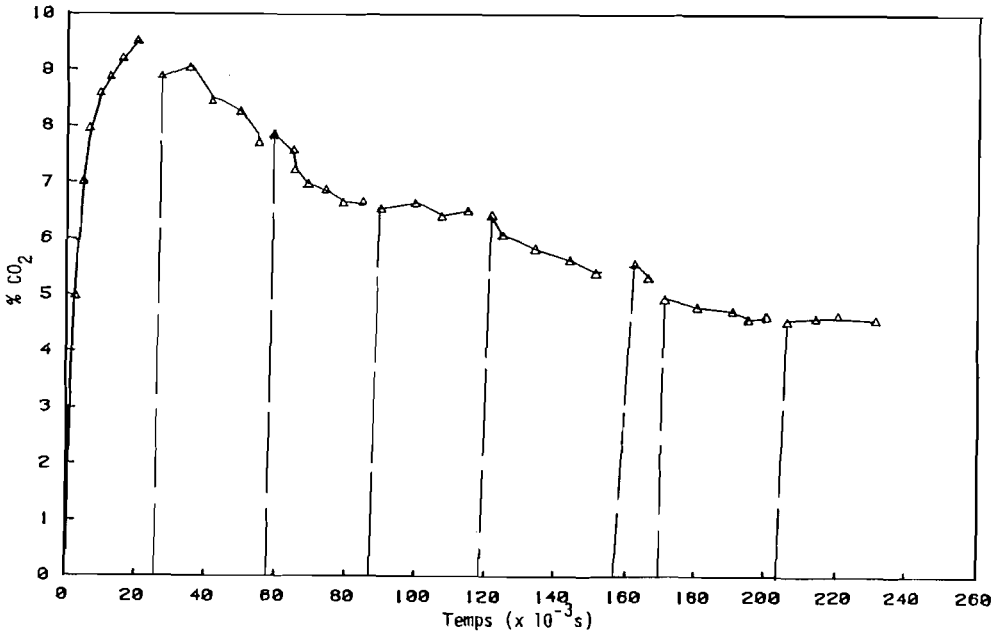

FIG. 1. Evolution de l'activité avec le temps pour le catalyseur de teneur 1% en molybdène (comportement de type A).

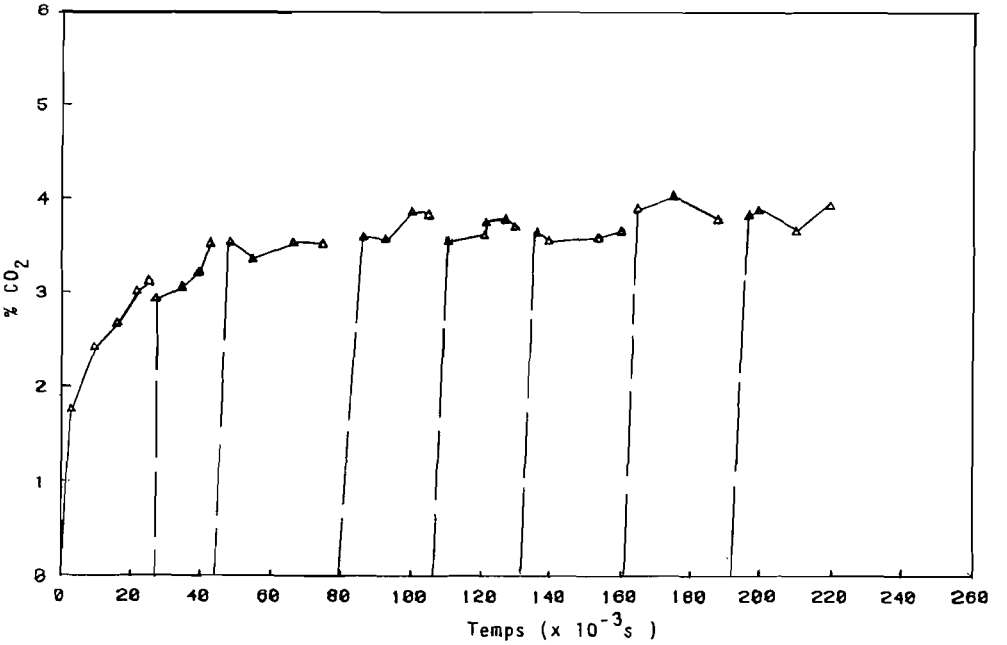

FIG. 2. Evolution de l'activité avec le temps pour le catalyseur de teneur 0,1% en molybdène (comportement de type B).

également observés avec le système $V_2O_5/SiO_2$ (9, 7). On peut donc interpréter les évolutions observées aux figures 1, 2 et 3 de la même façon que dans le cas de $V_2O_5/SiO_2$.

Les augmentations initiales d'activités aux figures 1 et 2 (mise à part la première demi-heure qui correspond à la mise en régime thermique de la lampe) sont associées à l'hydratation progressive des sites actifs. Comme l'ont montré Gristkov *et al.* (8), dans le cas de $V_2O_5/SiO_2$, l'hydratation du site

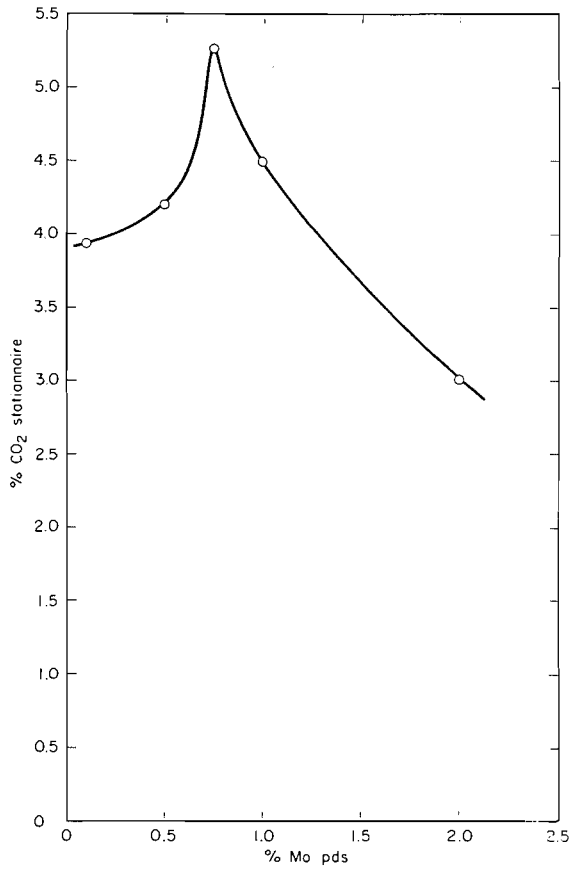

FIG. 3. Variation de l'activité stationnaire avec la teneur en molybdène.

déplace le seuil d'absorption de l'espèce active vers le rouge. L'augmentation d'activité serait alors liée à celle du nombre des photons absorbés par le site cationique, la source lumineuse utilisée étant polychromatique.

La diminution d'activité observée ensuite à la figure 1, est associée à une certaine mobilité des cations superficiels $Mo^{+6}$ dans les conditions de la réaction photocatalytique. Cette mobilité a pour effet une diminution de la dispersion des cations, qui forment des espèces oxymolybdiques polymériques bidimensionnelles et éventuellement des microcristaux superficiels de $MoO_3$. Si on admet que le site actif est un cation $Mo^{+6}$ isolé:

[2] 

cette recristallisation provoque une diminution du nombre des sites actifs sur la surface. Plus la concentration totale en molybdène est élevée, plus cette diminution devrait être importante, ce qui correspond bien aux résultats de la figure 3. Par ailleurs, nous avons vérifié que la diminution d'activité était bien irréversible: un catalyseur d'une teneur de 1% en molybdène ayant été utilisé pendant plusieurs jours et ayant donc atteint son activité stationnaire a été calciné à 500°C pendant quelques heures et réintroduit dans le réacteur. On n'observe alors pas le comportement de type A, mais bien celui de type B. En d'autres mots, le comportement de type B correspondrait à un système où les espèces molybdiques superficielles n'auraient pas de mobilité. Il est donc logique dans ce cas de trouver un tel comportement pour les très faibles teneurs en molybdène (figure 2). En effet, lors de l'imprégnation les ions métalliques ont tendance à s'adsorber préférentiellement sur les sites du support donnant lieu à l'interaction la plus forte. Les espèces produites sur ces sites pendant la calcination seraient donc également les moins mobiles.

Le phénomène de recristallisation invoqué ici serait à rapprocher de celui décrit par Callahan *et al.* (14) dans le cas du traitement hydrothermique de $MoO_3$ déposé sur un gel de silice. La croissance des cristaux superficiels de $MoO_3$ lors de ce traitement est expliquée par l'existence d'un complexe de surface mobile du type acide silicomolybdique.

*Spectres de réflectance diffuse*

Les spectres de réflectance diffuse obtenus avec nos catalyseurs comportent deux pics d'absorption respectivement aux longueurs d'onde voisines de 265 et 330 nm. Selon la littérature (11) ces pics correspondent à des espèces Mo(VI) respectivement en coordination d'oxygène tétraédrique pour le pic à 265 nm, et octaédrique pour celui à 330 nm. Ces assertions ont été vérifiées en déterminant les spectres du molybdate de sodium $Na_2MoO_4$ (Mo(VI) en coordination tétraédrique) et du paramolybdate d'ammonium et de l'oxyde pur $MoO_3$ (Mo(VI) principalement en coordination octaédrique). Ces spectres sont présentés à la figure 4.

La figure 5 donne les spectres obtenus, avec les catalyseurs fraîchement préparés. Le pic des espèces tétraèdriques déjà important pour une teneur en molybdène de 0,1% croît jusqu'à 0,75% et demeure stable aux teneurs supérieures. Par contre, le pic des espèces octaédriques quasi nul pour la teneur 0,1% croît de façon continue pour toutes les autres valeurs de la teneur en molybdène.

Si l'on rapproche ces résultats de ceux de la figure 3, on constate que l'activité catalytique est corrélée avec la hauteur du pic des espèces tétraédriques pour les trois teneurs les plus faibles. Au

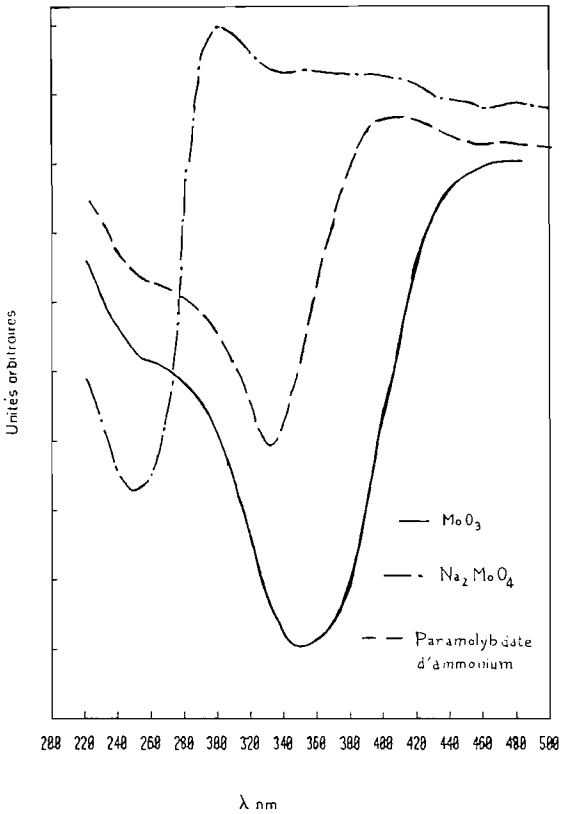

FIG. 4. Spectres de réflectance diffuse des composés purs de référence.

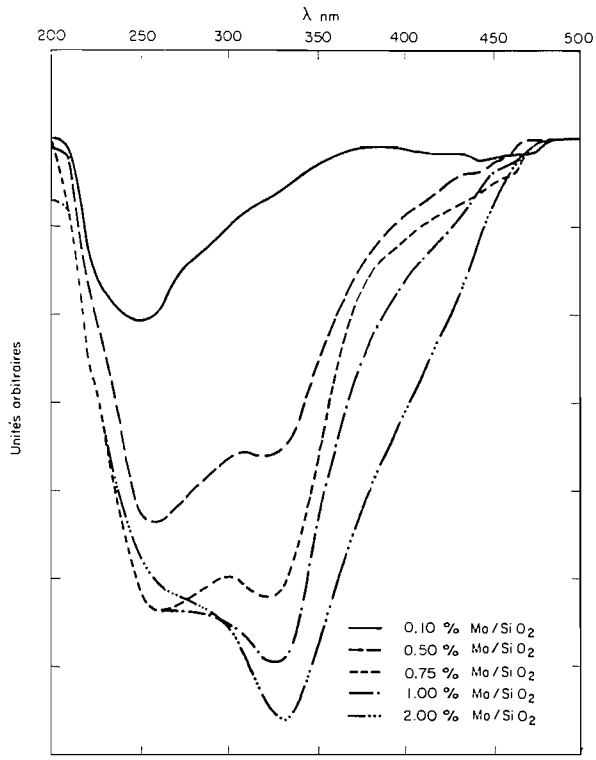

FIG. 5. Spectres de réflectance diffuse des catalyseurs avant réaction.

delà de 0,75% de molybdène, l'activité décroît alors que le pic des espèces octaédriques augmente. Il semble donc que les espèces octaédriques ne contribuent pas à l'activité photocatalytique. Ceci est en accord avec la vision selon laquelle seules les espèces isolées sont actives (8), puisque les espèces octaédriques sont des espèces oxymolybdiques polymériques, qui ne peuvent exister isolées.

Cependant, il est clair d'après la figure 5, que l'activité photocatalytique n'est plus corrélée avec la hauteur du pic tétraédrique pour les teneurs en molybdène supérieures à 0,75%. En effet, l'intensité du pic ne varie plus alors que l'activité diminue. Nous pensons que ces résultats signifient qu'il faut distinguer deux sortes d'espèces oxymolybdiques en coordination tétraédrique: une première espèce du type [2] est isolée sur la surface et active en photocatalyse, alors que la seconde est liée par au moins un pont Mo—O—Mo à d'autres espèces oxymolybdiques et perd de ce fait son activité photocatalytique.

On peut expliquer cette perte d'activité de la façon suivante: lorsque l'espèce $M^{n+}$ de l'équation [1] est liée à d'autres cations de même nature par des ponts M—O—M, les charges produites par l'absorption du rayonnement sont délocalisées sur l'ensemble polymérique. Par conséquent, l'état de transfert de charge produit par la réaction [1] a une durée de vie beaucoup plus courte, qui ne serait alors plus suffisante pour que le $O^-$ formé ait le temps de réagir avec le cyclohexane.

Nous avons également déterminé les spectres de réflectance diffuse de catalyseur ayant été utilisés dans les conditions standards pendant un temps suffisamment long pour que l'activité stationnaire soit atteinte. Après une nouvelle calcination nous avons obtenu les spectres présentés à la figure 6. La comparaison entre les résultats des figures 5 et 6 est présentée au tableau 1, qui donne les valeurs mesurées des rapports des hauteurs des pics des espèces tétraédrique et octaédrique $H_T/H_O$. Ce tableau montre que la valeur du rapport $H_T/H_O$ diminue au cours de l'utilisation du catalyseur. Pour la teneur de 0,1% en molybdène, ce rapport ne peut être déterminé avec suffisamment de précision en raison de la très petite valeur de $H_O$ dans ce cas. Ces résultats pourraient impliquer que la recristallisation produite dans les conditions de la réaction photocatalytique, s'accompagne d'un changement

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

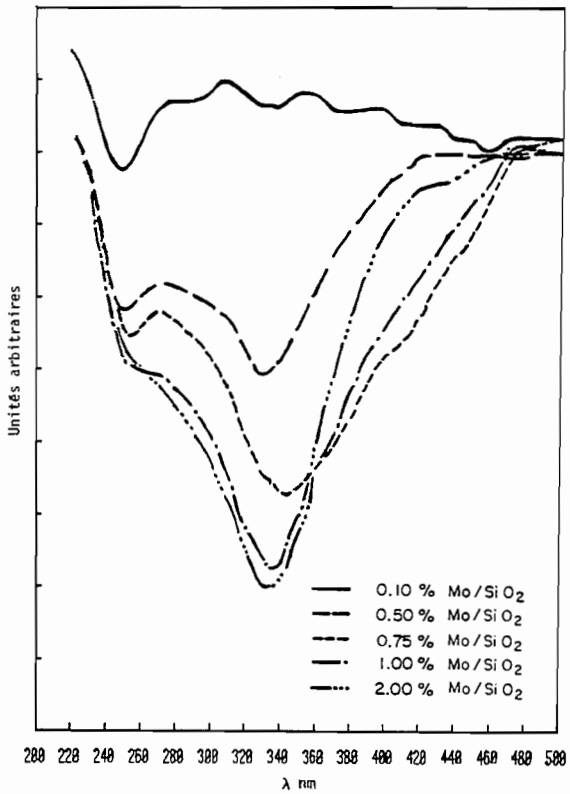

FIG. 6. Spectres de réflectance diffuse des catalyseurs après réaction.

TABLEAU 1. Valeurs des rapports $H_T/H_0$ avant et après réaction

| % pds Mo | $H_T/H_0$ catalyseur fraîchement préparé | $H_T/H_0$ catalyseur utilisé |
|---|---|---|
| 0,5 | 1,2 | 0,94 |
| 0,75 | 1,0 | 0,71 |
| 1,0 | 0,9 | 0,70 |
| 2,0 | 0,8 | 0,63 |

de coordination pour un certain nombre d'espèces tétraédriques. On ne peut toutefois exclure que la réorganisation de surface des espèces octaédriques n'entraîne une augmentation de leur absorptivité en raison d'une délocalisation électronique accrue.

## Conclusion

On peut donner une interprétation unique et cohérente des variations avec le temps de réaction et avec la teneur en molybdène, de l'activité photocatalytique d'une part, et des spectres de réflectance diffuse des dépôts $MoO_3/SiO_2$ d'autre part. Selon cette interprétation, la méthode de préparation et de prétraitement du catalyseur produit sur la surface des espèces oxymolybdiques où le molybdène peut être en coordination tétraédrique ou octaédrique. Les espèces ainsi produites sont de deux types: (1) des espèces en forte interaction avec la silice, seules formées aux plus faibles teneurs en molybdène et où le cation $Mo^{+6}$ en coordination tétraédrique est isolé et actif en photocatalyse; (2) des espèces polymériques plus faiblement liées au réseau de la silice où les cations $Mo^{+6}$ sont essentiellement en coordination octaédrique. Ces espèces ne sont pas actives en photocatalyse, mais elles possèdent une certaine mobilité dans les conditions de la réaction photocatalytique. Dans ces conditions elles peuvent alors se fixer aux espèces isolées qui perdent alors leur activité, certaines d'entre elles pouvant également changer de coordination.

# Solvent effects on the nitrogen and β-hydrogen hyperfine splitting constants of aminoxyl radicals obtained in spin trapping experiments

EDWARD G. JANZEN, GREGORY A. COULTER, UWE M. OEHLER, AND JOHN P. BERGSMA

*Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1*

Received April 12, 1982

EDWARD G. JANZEN, GREGORY A. COULTER, UWE M. OEHLER, and JOHN P. BERGSMA. Can. J. Chem. **60**, 2725 (1982).

The nitrogen and β-hydrogen hyperfine splitting constants (hfsc) for phenyl, 4-nitrophenyl, 4-pyridyl, benzoyl, and trichloromethyl spin adducts of α-phenyl *tert*-butyl nitrone (PBN) as well as for the *tert*-butoxyl adduct of 5,5-dimethylpyrroline-*N*-oxide (DMPO) have been obtained as a function of solvent (30 solvents). A useful linear relationship between the β-H hfsc and the N-hfsc of each aminoxyl is found except for the benzoyl adduct of PBN. Some speculations regarding the structural significance of these correlations is presented.

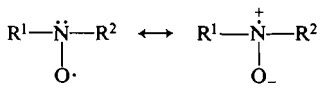
EDWARD G. JANZEN, GREGORY A. COULTER, UWE M. OEHLER et JOHN P. BERGSMA. Can. J. Chem. **60**, 2725 (1982).

On a déterminé, en fonction de solvant (30 solvants), les constantes de couplage hyperfin (cch) de l'azote et de l'hydrogène en β des adduits de spin des phényle, nitro-4 phényle, pyridyle-4, benzoyle et trichlorométhyle de l'α-phényl *tert*-butylnitrone (PBN) ainsi que l'adduit du *tert*-butylate de la *N*-oxyde de la diméthyl-5,5 pyrroline (ODMP). On a trouvé une relation linéaire utile entre les cch du H en β et la cch du N qui s'applique à chaque aminoxyle à l'exception de l'adduit du benzoyle de BPN. On présente quelques hypothèses relatives à la signification structurale de ces corrélations.

[Traduit par le journal]

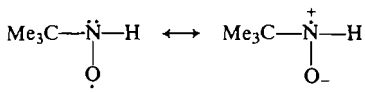
## Introduction

It is well known that nigrogen hyperfine splitting constants ($a_N$ or N-hfsc's) for dialkyl and alicyclic aminoxyl radicals increase with increase in solvent polarity (1–5)[1]. This solvent effect is attributed to the increased importance of resonance structure **2** with increase in solvent polarity:



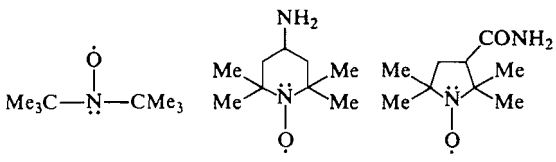
**1** **2**

That the spin density on the nitrogen atom does indeed increase with increase in solvent polarity is shown by the fact that *both* the hydrogen and the nitrogen hfsc's increase with increase in solvent polarity in the case of *tert*-butyl aminoxyl (5):



**3** **4**

Knauer and Napier (7) searched for the best correlation between $a_N$ and common solvent polarity parameters using the stable aminoxyls **5**, **6**, and **7**:

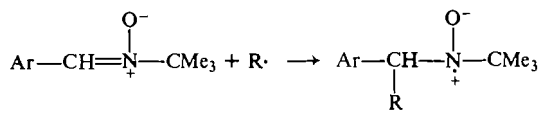


**5** **6** **7**

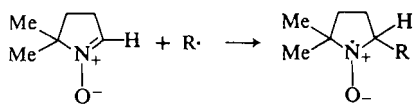
[1]It should be noted that this trend does not hold for *tert*-butoxy *tert*-butyl aminoxyl radical (6).

The best fit was obtained when the following parameters were used: Dimroth and Reichardt's $E_{t(30)}$ values (8), Kosower's *Z*-values (9), or Berson's Ω values (10). Since $E_{t(30)}$ values are available for more solvents (Knauer and Napier used 31 solvents), this parameter is most convenient for the purpose of this study. It should be noted that plots of $a_N$ for one aminoyxl vs. $a_N$ for another in the same solvents gave excellent correlations.

It is of interest and of some importance to investigate the nature of the solvent effect on both the nitrogen and β-hydrogen hfsc in aminoxyl radicals formed in spin trapping reactions:



**8**



DMPO **9**

This is because assignment of the spin adduct spectrum is usually based on producing the same aminoxyl by an alternate route. Often this alternate route involves use of a different solvent and recognition of the influence of solvent on both the N- and β-H hfsc is of utmost importance. It would be most useful if a correlation between the β-H and N-hfsc was available for each spin adduct so that the values in any solvent could be predicted given that information about these parameters in some

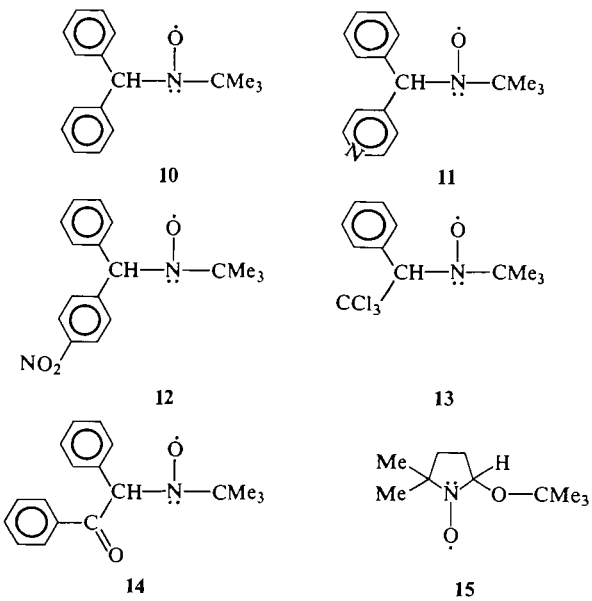
other solvent was at hand. To collect all this data seems like an impossible task. It would be better to investigate a few adducts in detail and search for some rules to use as a guide in predicting the hfsc's of some other spin adduct as a function of solvent.

In a review of spectra assigned to the hydroxy and hydroperoxy adducts of phenyl *tert*-butyl nitrone (PBN) it was found that the points on a plot of $a_\beta^H$ vs. $a_N$ appeared to fall on two lines (11): $a_\beta^H = 0.604a_N - 6.53$ and $a_\beta^H = 1.26a_N - 15.7$. These were assigned to the hydroxy and hydroperoxy adducts respectively.[2] The good agreement was taken as supporting evidence for the assignment of the spectra obtained in different solvents. In this paper the question is turned around: if spectra of known spin adducts are obtained in different solvents, will the β-H hfsc bear a linear relationship with the N-hfsc of each adduct and will the slope of this plot have any relation to the nature of the radical trapped?

Since the kinetic stability of spin adducts varies considerably, only very persistent examples can be studied. Also, since many solvents are themselves good hydrogen atom donors, the *in situ* method of producing spin adducts can not be used for all solvents. At this time results for only five spin adducts have been obtained: the phenyl adduct of PBN (**10**), the phenyl adduct of α-(4-pyridyl)-*tert*-butyl nitrone (4-PyBN) (**11**), the 4-nitrophenyl adduct of PBN (**12**), the trichloromethyl adduct of PBN (**13**), the benzoyl adduct of PBN (**14**), and the *tert*-butoxyl adduct of 5,5-dimethylpyrroline-*N*-oxide (DMPO) (**15**):



Three of these radicals (**10–12**) have groups with the same steric requirements but with slightly different polarity while two others differ in both steric requirements and polarity of one group (**13** and **14**). Most of the 31 solvents selected by Knauer and Napier (7) have been used in this study.

## Experimental

Solutions of the spin trap and radical source were either warmed for about 10 min at 45°C or photolyzed at room temperature for up to 30 min (only for **13**). The resulting solution was evaporated at room temperature to yield a solid residue. This residue was taken up in enough solvent to produce a 0.05 *M* solution (based on initial trap concentration). The solution was transferred to a degassing chamber connected to an esr flat cell (17). After outgassing with a nitrogen stream for 15 mins the solution was introduced into a flat cell without exposing the contents to the atmosphere. The specific methods used were: **10** from PBN plus phenyl radical (from commercially available phenylazotriphenylmethane (PAT)); **11** from 4-PyBN (18) plus phenyl radical from PAT; **12** from PBN plus 4-nitrophenyl from 4-nitrophenylazotriphenylmethane;[3] **13** from PBN plus trichloromethyl radical from photolysis of either $CCl_4$ or $CBrCl_3$ in the appropriate halocarbon (19); **14** from PBN and benzoyl radical (from benzaldehyde plus *tert*-butoxyl radical from thermal decomposition of di-*tert*-butyl peroxyoxalate); and **15** from DMPO plus *tert*-butoxyl radicals, also from di-*tert*-butylperoxyoxalate decomposition in benzene.

The spectra were obtained with a Varian E-104 epr spectrometer. The recorder was calibrated using Fremy's salt in aqueous alkaline solution ($a_N$ = 13.09 G) (20). The separation of the peaks of the spectrum was measured as many times as

[2]Data from three new references and one previously omitted are given below:

$C_6H_5CH(OH)N(O^\cdot)CMe_3$

Since in the original publication (11) the average error cited for these correlations was ±0.05 for the hydroxy adduct (7 examples – largest deviation ±0.09) and ±0.13 for the hydroperoxy adduct (8 examples – largest deviation +0.20), the large differences in values calculated for the assigned spectra in refs. 14 and 15 (hydroxy adduct) and 15 (hydroperoxy adduct) places some doubt on these measurements and/or assignments.

[3]We are grateful to Prof. W. A. Pryor for providing us with a sample of 4-nitrophenylazotriphenylmethane.

FIG. 1. The esr spectrum of the phenyl radical adduct to 4-PyBN (**11**) in (A) benzene, (B) water.

possible ($a_N$ eight times, $a_\beta^H$ six times, using both maxima and minima of the first derivative presentation) and an average value recorded. Solubility difficulties prevented values from being obtained for **11** in hexane and **12**, **13**, and **14** in water.

## Results and discussion

### *PBN spin adducts: nitrogen hyperfine splitting constants*

The esr spectra obtained from **11** and **15** in benzene and in water are shown in Figs. 1 and 2. The effect of increasing solvent polarity is clearly seen in the increase in both the triplet and doublet spacings. The β-H and N-hfsc's obtained in 30 solvents for **10–13** are listed in Table 1.

The plot of $a_N$ vs. $E_{t(30)}$ for **10** is shown in Fig. 3. Although there is some scatter, a good straight line correlation with solvent polarity is found ($r^2$ = 0.958, slope = 0.047). In order to test whether the hydrogen-bonding solvents are the major source of the scatter, the plot was calculated without these solvents. No substantial improvement is found in the case of **10** ($r^2$ = 0.950, slope 0.034). The slope is slightly smaller due to the value for water which lies substantially above the line of best fit for the plot including all solvents. Knauer and Napier (7) made similar observations (i.e. the slope decreased when the H-bonding solvents were omitted for 2 out of 3 examples).

Not shown in a figure is the fact that $a_N$ for **10** varies with solvent polarity in just the same way as does $a_N$ for **5**, i.e. a plot of $a_N$ for **10** vs. $a_N$ for **5** is linear and a good correlation is found: $a_N(\mathbf{5}) = 1.068\, a_N(\mathbf{10}) + 0.030$; $r^2 = 0.985$.

The plots of $a_N$ vs. $E_{t(30)}$ for **11–13** are similar to Fig. 3. The slopes and correlation coefficients are given in Table 2. It is clear that the correlations are reasonable in most cases. The slope decreases in the order **10** > **11** > **12** > **13** and is smaller if the H-bonding solvents are omitted (except for **13** (Fig. 4) where the slope is equal).[4]

The plot of $a_N$ for the benzoyl adduct, **14**, vs. $E_{t(30)}$ is shown in Fig. 5 ($r^2$ = 0.928). Not as many solvents could be utilized (17 solvents). The slope is quite small (0.025) and is similar to that found for the trichloromethyl adduct.

In summary it appears that for most $C_6H_5$-CHRN(O·)$CMe_3$ aminoxyls the N-hfsc's obtained

[4]It is interesting to note that the value for chloroform (spectro Grade) for **10**, **11**, and **12**, but not for **13**, is also too high for the straight-line correlation; Prof. J. J. Lindberg has suggested H-bonding as the reason for this deviation.

FIG. 2. The esr spectrum of the *tert*-butoxyl radical adduct to DMPO (**15**) in (A) benzene, (B) water.

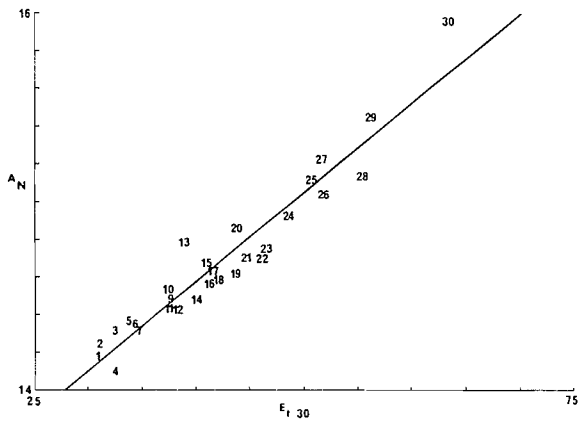

FIG. 3. Plot of $a_N$ vs. $E_{t(30)}$ for phenyl radical spin adduct to PBN (**10**).

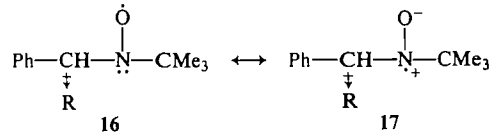
are quite well correlated with a solvent parameter such as $E_{t(30)}$. Furthermore as the electronegativity of R increases, $a_N$ *and* the slope of $a_N$ vs. $E_{t(30)}$ decreases. The former means that the contribution of **2** decreases as the R groups become more electronegative. Since the slopes also decrease with increase in electronegativity of R, the polarization of the β-bond attached to the electronegative group must also increase and cause further destabilization of **17** as the polarity of the solvent increases:



**16** **17**

On the basis of the slopes of $a_N$ vs. $E_{t(30)}$ the electronegativity of R follows the sequence: phenyl < 4-pyridyl ≃ 4-nitrophenyl < benzoyl ≃ trichloromethyl. This order is quite reasonable if based on the expected electronegativities of these groups.

### β-*Hydrogen hyperfine splitting constants*

A plot of the β-H hfsc's vs. $E_{t(30)}$ for **10** is shown in Fig. 6. The correlation is quite reasonable ($r^2$ = 0.953). Again the point for water falls considerably above the line of best fit.

Since $a_N$ has been shown to correlate with $E_{t(30)}$ for all PBN spin adducts studied (**10–14**) it should be possible to eliminate this polarity parameter and use the N-hfsc's directly since, for a given aminoxyl radical, $a_N$ can be considered a polarity parameter itself. The plot of the β-H hfsc's vs. $a_N$ for **10** in 30 solvents is shown in Fig. 7. The fit to a linear correlation is quite good: $r^2$ = 0.978.

TABLE 2. Slope and correlation coefficient data of plots $a_N$ vs. $E_{t(30)}$ for PBN spin adducts in all solvents, and with hydrogen bonding solvents removed

| Spin adduct | Slope | $r^2$, Correlation coefficient | Solvents |
|---|---|---|---|
| **10** | 0.047 | 0.958 | 30 solvents |
| **10** | 0.034 | 0.950 | No H-bonding solvents[a] |
| **11** | 0.036 | 0.921 | 29 solvents |
| **11** | 0.032 | 0.976 | No H-bonding solvents[a] |
| **12** | 0.034 | 0.988 | 29 solvents |
| **12** | 0.031 | 0.991 | No H-bonding solvents[a] |
| **13** | 0.022 | 0.869 | 28 solvents |
| **13** | 0.022 | 0.966 | No H-bonding solvents[a] |
| **14** | 0.025 | 0.928 | 17 solvents |

[a]The values for *tert*-butyl alcohol, isopropyl alcohol, benzyl alcohol, acetic acid, ethyl alcohol, methyl alcohol, ethylene glycol, and water were omitted.

The plots of the β-H hfsc's vs. $a_N$ for **11** and **12** are similar to Fig. 7. The plot of $a_\beta^H$ vs. $a_N$ for **13** is shown in Fig. 8 because of the continuing interest in the biomedical field in detecting, by spin trapping, trichloromethyl radicals from the metabolism of perhalocarbons (e.g. carbon tetrachloride (21). The correlation coefficients for the plots for **11–13** are given in Table 3.

For the benzoyl adduct, **14**, the plot of the β-H hfsc's vs. $a_N$ is severely scattered as shown in Fig. 9. Since the plot of $a_N$ vs. $E_{t(30)}$ gives a satisfactory correlation with all solvents (Fig. 5), the problem must rest with the solvent effect on the β-H hfsc. When the H-bonding solvents are removed, a fair correlation is obtained ($r^2 = 0.844$). The slope is smaller than for the trichloromethyl adduct (slope = 0.655) but has less meaning with the fewer usable solvents (17 solvents).

In summary it appears that plots of the β-H hfsc vs. $a_N$ from spin adduct spectra of aminoxyl radicals are linear for nonpolar groups or with polar groups substituted at positions far away from the nitrogen–oxygen function. If the polar group is near to this function, e.g. in the β-position, the nature of the substituent is important. Thus trichloromethyl is well-behaved while benzoyl is not. In the latter case the β-H hfsc never realizes its full potential of about 5 gauss as predicted from the

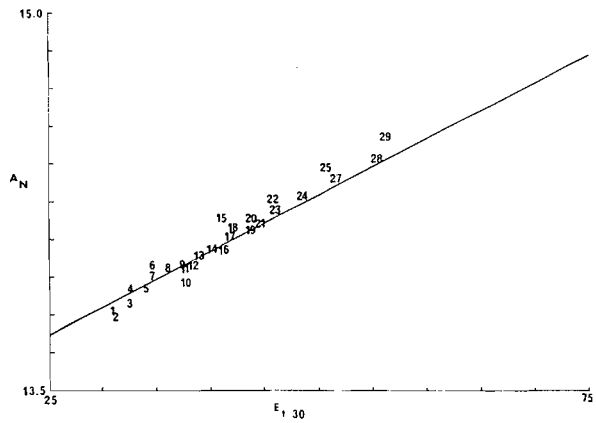

FIG. 4. Plot of $a_N$ vs. $E_{t(30)}$ for the trichloromethyl radical spin adduct to PBN (**13**).

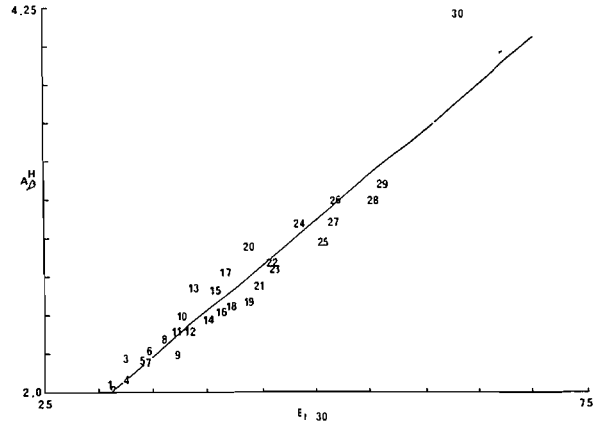

FIG. 6. Plot of $a_\beta^H$ vs. $E_{t(30)}$ for the phenyl radical spin adduct to PBN (**10**).

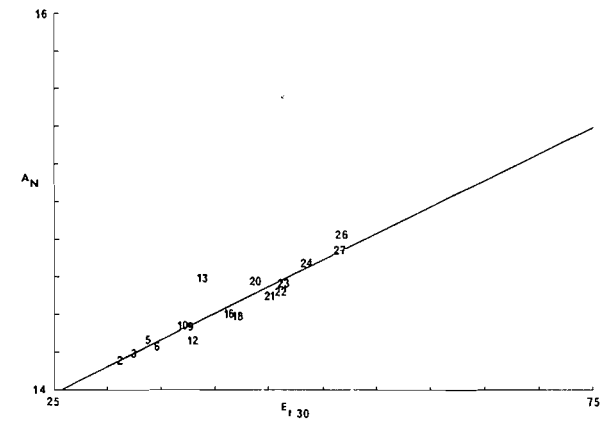

FIG. 5. Plot of $a_N$ vs. $E_{t(30)}$ for the benzoyl radical spin adduct to PBN (**14**).

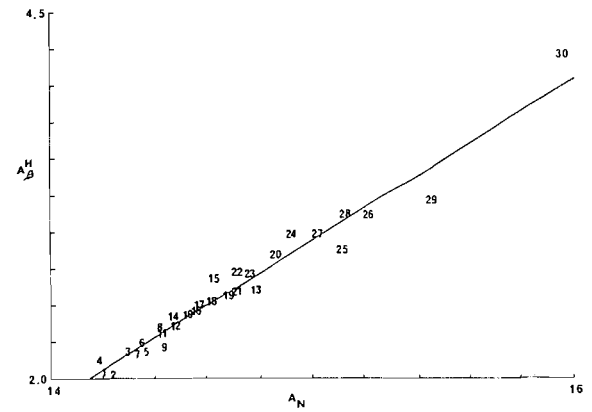

FIG. 7. Plot of $a_\beta^H$ vs. $a_N$ for the phenyl radical spin adduct to PBN (**10**).

influence of solvent polarity on $a_N$. One can speculate and attribute this to a change in the dihedral angle of the C—H bond caused by a change in conformation as a result of hydrogen-bonding. The degree to which the values for the β-H hfsc's fall off the line correlating the values in the non-hydrogen-bonding solvents is inversely proportional to the bulk of the organic group: *tert*-butyl alcohol < isopropyl alcohol < ethanol. The nature of the H-bonding solvent effect on the benzoyl adduct is not known. Perhaps H-bonding to the carbonyl of the benzoyl group and to the aminoxyl function occurs in a special way (intramolecular?), such that the dihedral angle is increased, thereby off-setting the effect of an increase in spin density on the nitrogen atom of the aminoxyl function.

The equations for the linear correlations between $a_\beta^H$ and $a_N$ for PBN spin adducts are as follows:

for **10** $a_\beta^H = 1.11\ a_N - 13.69$

**11** $a_\beta^H = 1.06\ a_N - 13.08$

**12** $a_\beta^H = 1.08\ a_N - 13.24$

**13** $a_\beta^H = 0.796\ a_N - 9.40$

**14** $a_\beta^H = 0.655\ a_N - 4.79$

(no H-bonding solvents)

*DMPO spin adducts*

It was of interest to see what the solvent effect would be on a DMPO spin adduct. However, since spin adducts of cyclic traps are less persistent than those of PBN, only the *tert*-butoxyl adduct of DMPO (**15**) has been studied at this time.

Solvent polarity has a dramatic effect on the spectrum of **15** (Fig. 2). This is almost entirely due to the large increase in β-H hfsc with increase in solvent polarity since the slope of the plot of $a_N$ vs. $E_{t(30)}$ is not unusual (slope = 0.054, $r^2 = 0.945$, Fig.

10). Another interesting feature is the change in γ-H hfsc with polarity of solvent (Table 4). While the β-H hfsc's increase with increase in solvent polarity the γ-H hfsc's decrease as the solvent polarity increases (Fig. 11). The linear correlations are as follows: $r^2 = 0.916$, slope = 3.96 for $a_\beta^H$ vs. $a_N$; $r^2 = 0.767$, slope = −0.484 for $a_\gamma^H$ vs. $a_N$.

It seems remarkable that while the slope of the β-H hfsc vs. $a_N$ is positive, the slope of the γ-H hfsc vs. $a_N$ is negative. This result can be explained in

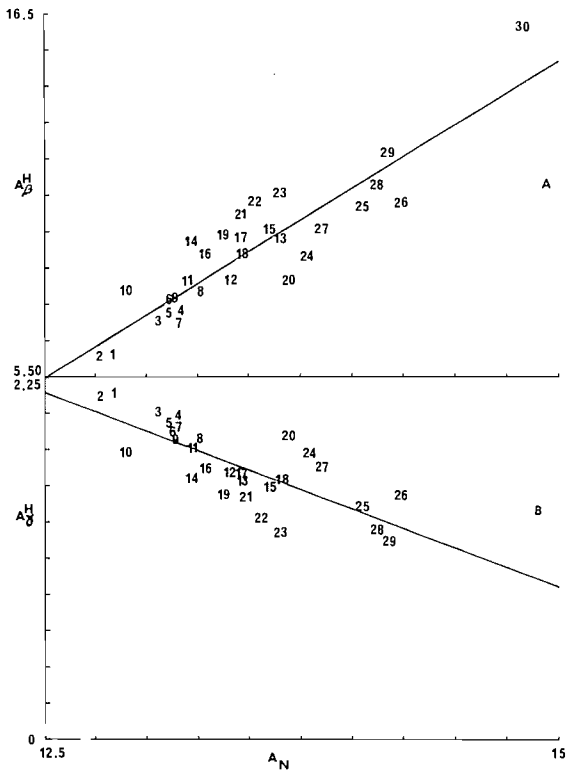

FIG. 11. Plot of (A) $a_\beta^H$ vs. $a_N$, (B) $a_\gamma^H$ vs. $a_N$ for the *tert*-butoxyl radical spin adduct to DMPO (**15**).

terms of a solvent dependent change in the dihedral angle of the β-hydrogen caused by twisting of the α-carbon so that the W-plan to the γ-hydrogen attached to the β-carbon is altered. The reason for this could be the attempt by the 5-membered ring to twist so that the N—O and C—O dipoles in **15** are opposed to the greatest possible extent. In polar solvents the aminoxyl dipole is solvated and the dipole–dipole interaction between the two functions is diminished. The ring relaxes to a more planar configuration where the dihedral angle to the β-H is smaller. Since spin transmission to the γ-hydrogen is best for twisted ring structures (22), the γ-H hfsc would be expected to be largest in nonpolar solvents and decrease as the ring becomes more planar in more polar solvents.

The equations for the best lines of fit in Fig. 11 are as follows:

$$a_\beta^H = 3.96\, a_N - 44.2$$
$$a_\gamma^H = 0.484\, a_N - 8.21$$

*Equations for the plots of the* β*-H hfsc's vs.* $a_N$

The observation that the β-hydrogen hyperfine splitting constants depend on $a_N$ for a number of aminoxyl radicals seems to point to the Heller–McConnell equation (23):

$$a_\beta^H = (B_0 + B\cos^2\theta)\rho_N$$

where $B_0 = a_\beta^H$ when $\theta = 90°$, $B$ = the hyperconjugative proportionality constant, $\theta$ = the dihedral angle between the C—H bond and the $p$-orbital on nitrogen, and $\rho_N$ = spin density on nitrogen. If $a_N$ is proportional to $\rho_N$, and $B_0$, B, and $\theta$ are all constant, as a function of solvent, a linear equation would result:

$$a_\beta^H = Ca_N$$

However, a plot of this equation should go through zero. The observed plots do not. Instead the lines take on the form:

$$a_\beta = Ca_N + C'$$

In practice $C'$ is large and negative indicating a large negative β-H hfsc remains when $a_N$ is zero. This might perhaps make sense if the aminoxyl function is nonplanar and slight changes in *both* the spin density and the configuration about nitrogen occur with change in polarity of the solvent. This point will be addressed in a future paper. In any event the Heller–McConnell equation was not meant to take nonplanarity factors at the radical center into account.

## Conclusions

Linear relationships between the two parameters ($a_\beta^H$, $a_N$) for PBN and DMPO spin adducts provide a useful tool in coupling constant prediction. By obtaining spin adduct coupling constants in only a few solvents, the hfsc's ($a_\beta^H$ and $a_N$) may be found in any other solvent from the calculated slope. Further work in this area is underway.

# The effect of an external electric field on the photochemistry of *x*-phthalocyanine particles in heptane

JOHN R. HARBOUR AND SANDRA L. ISSLER

*Xerox Research Centre of Canada, 2480 Dunwin Drive, Mississauga, Ont., Canada L5L 1J9*

Received December 14, 1981[1]

JOHN R. HARBOUR and SANDRA L. ISSLER. Can. J. Chem. **60**, 2734 (1982).

A system is described which allows for the determination of the photo-efficiency of pigment particles in low dielectric solvents as a function of electric field. The charge carriers in this system are both molecular and particulate and the photo-induced current is a function of dissolved oxygen concentration. The maximum quantum efficiency was determined to be 23% at high electric field ($2 \times 10^5$ V/cm) and low light intensity for *x*-phthalocyanine particles in heptane. Initial efforts at spin trapping in this system reveal the synergistic generation of a nitroxone and alkylperoxy spin adduct of α-phenyl *N*-*t*-butyl nitrone. Both of these adducts are, however, neutral and it is demonstrated that this system is not well suited for the detection of trapped ionic radicals.

JOHN R. HARBOUR et SANDRA L. ISSLER. Can. J. Chem. **60**, 2734 (1982).

On décrit un système qui permet de déterminer la photo-efficacité de particules de pigment dans des solvants de faible constantes diélectriques en fonction du champ électrique. Les porteurs de charge dans ce système sont à la fois moléculaires et particulaires et le courant photo-induit est fonction de la concentration en oxygène dissous. On a déterminé que l'efficacité quantique maximum est égale à 23% à champ électrique fort ($2 \times 10^5$ V/cm) et à faible intensité de lumière pour des particules de *x*-phtalocyanine dans l'heptane. Nos efforts initiaux dans le but de capter des spin dans ce système révèlent qu'il y a formation synergistique d'un adduit de spin nitronone et alkylperoxy de l'α-phényl *N*-*t*-butylnitrone. Ces deux adduits sont, cependant, neutres et on démontre que ce système ne convient pas très bien à la détection des radicaux ioniques piégés.

## Introduction

The photochemistry of pigment dispersions has been rather extensively investigated, particularly in regard to solar energy utilization (SEU) (1–4). Pigment dispersions also form the basis of a novel imaging technique referred to as photoactive pigment electrography (PAPE) (5). In both of these systems it is essential that the inherent quantum efficiency for hole/electron generation, as well as the efficiency of the subsequent interfacial charge transfer, be relatively high. The overall efficiency ($\Phi_{overall}$) can be considerably enhanced if the process is carried out in an electric field, *E*. This can be accomplished by application of an external *E* or creation of an internal *E* through formation of e.g., a Schottky barrier. Hence, in both SEU and PAPE systems it is of importance to know the *E* dependence of the overall efficiency as well as the molecular events which give rise to this dependence.

Hartmann and Schmidlin (6) and Hartmann and Noolandi (7) have reported results of photo-induced charge transfer as a function of *E* at phthalocyanine ($H_2Pc$) liquid interfaces using vacuum-sublimed thin films. Similar experiments have been reported by Tang *et al.* (8) with chlorophyll a (Chl a) films. In their study, which is closest experimentally to ours, microcrystals of Chl a were electro-deposited from non-polar solvents onto a transparent electrode which was biased negatively (implying that the microcrystals were positively charged). However, molecular Chl a was present in the solution during their experiments. The identity of the pigment particles has also been maintained in studies by Popovic (9) in which the particles were dispersed in a non-conducting polymer matrix sandwiched between two electrodes, one of which was transparent. The efficiency of charge separation as a function of *E* was determined for $H_2Pc$ pigments using this technique.

Loutfy and Sharp (10, 11) also used particle dispersions ($H_2Pc$ in polymer) overcoated with a partially transparent metal electrode which creates a Schottky barrier to determine $\Phi_{overall}$ for $H_2Pc$ pigments. This photovoltaic solar cell measures efficiency of pigment particles as a function of internal *E* (12).

It is of importance in the characterization of pigments to measure $\Phi_{overall}$ without significantly altering the properties of the particles. Only one of the above-mentioned studies measures the photo-efficiency of the pigment particles in a liquid phase (8). Since the PAPE process occurs in an insulating solvent, it is important to measure the efficiency as a function of *E* (5), under conditions as close as possible to the actual system. This paper reports on our initial efforts at creating an experimental set-up which allows one to monitor the photo-efficiency of pigments initially in dispersion as a function of *E*. In order to gain a better understanding of the

molecular events, we have applied the technique of spin trapping (13, 14) to these systems.

## Experimental

The sample cell used for this study was designed by Novotny (15). Briefly, it was comprised of two indium oxide coated glass plates (NESATRON) separated by a flat ring of Teflon. Spacers of 250 and 500 μ were used and the interior diameter of the Teflon ring was 3.8 cm. The top electrode had two ground glass ports through which the dispersion could be added or emptied and closed to the atmosphere. This electrode-spacer system was placed between two flat metal rings and the system was sealed by tightening screws with a torque wrench to a reproducible pressure.

The sample cell was placed in series with a $10^5$ Ω resistor and a 0 to 3000 V Fluke 415B High Voltage Power Supply. The current was monitored by measuring the voltage generated across the $10^5$ Ω resistor with a Philips model PM3234 storage scope.

The light source consisted of a 300 W Quartzline projection lamp controlled by a variable transformer. The lamp was located 4 cm above the cell and air cooled. A broad band interference filter (710 nm) was generally employed for the determination of photo-induced currents (PIC's) and light-generated esr signals. However, equivalent results were obtained for the PIC's with a narrow band, 620 nm interference filter. For the determination of quantum efficiency, a narrow band (± 10 nm) interference filter (620 nm) was used and the light intensity was measured using an Alphametrics Model dc 1010 radiometer with a Model P1100S Silicon light probe.

Electron spin resonance spectra were recorded on a Varian E-12 ESR spectrometer. A 0.4% by wt. $x$-$H_2Pc$ in heptane mixture was dispersed by ultrasonic irradiation and placed immediately in the electroded cell. An $E$ was applied to plate out the pigment particles and then the solvent was removed and replaced with a 0.3 $M$ PBN solution ($\lambda_{max}$ = 285 nm) in heptane. This technique does not alter the magnitude of the PIC and prevents ultrasonic irradiation of the spin trap solution which can result in spin adduct formation (16). The voltage (3000 V over 250 nm) was first switched on to determine the dark current and then the light (60 V) was turned on for 10 s before both voltage and light were switched off. The solution was immediately removed, nitrogen purged, and transferred to an aqueous esr tube for measurement. The entire process, including the recording of the spectrum, took between 2 and 3 min.

$x$-Phthalocyanine ($x$-$H_2Pc$) was prepared by the method of Byrne and Kury (17). Heptane (Burdick and Jackson, distilled in glass), 5,5-dimethyl-1-pyrroline-1-oxide, DMPO (Aldrich), and α-phenyl N-$t$-butyl nitrone, PBN (spin trap producers) were used as received. The soluble tetra-*tert*-butyl phthalocyanine ($t$-b-$H_2Pc$) was a gift from James Duff, Xerox Research Centre of Canada.

## Results and discussion

### *I. Photoconductivity measurements*

A typical current/time plot as a function of illumination for $x$-$H_2Pc$ particles dispersed in heptane is shown in Fig. 1. The magnitude of the increase reflects the efficiency of the overall charge generation and transfer. This efficiency is essentially independent of pigment loading over the range shown in Table 1. Hence the wt% of pigment loading was selected to fall in this non-critical

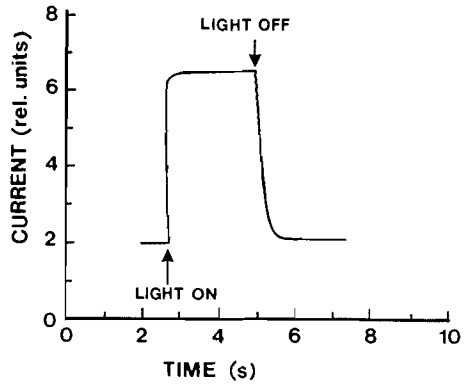

FIG. 1. Typical result for the PIC as a function of time for an $x$-$H_2Pc$ dispersion in heptane.

region (0.1 → 0.4%) where one need not worry about a PIC dependence on pigment concentration. There was no difference in PIC for either a negative or positive polarity of the top electrode. The implications of this result are discussed below.

Figure 2 shows the efficiency (PIC) as a function of $E$. This superlinear dependence is similar qualitatively to the work of Hartmann and Noolandi (7) but different from Tang *et al.* (8), who show a saturation with $E$. Changing the thickness from 250 nm to 500 nm gave the same PIC for an equivalent $E$. This demonstrates that the efficiency of the overall process is not limited by charge transfer from one electrode to the other. $\Phi_{overall}$ (at $3 \times 10^4$ V/cm) decreased with increasing light intensity as shown in Fig. 3. $\Phi_{overall}$ continued to decrease at higher light intensities. At $5 \times 10^{16}$ photons/s, $\Phi_{overall}$ dropped to 0.027 and at the highest intensity ($1.3 \times 10^{17}$ photons/s) $\Phi_{overall}$ was equal to 0.017.

The application of an $E$ in the dark brought about the electrophoretic migration of these particles to both electrodes. This implies that the dispersion originally had particles with both positive and negative surface charge. Removal of the liquid after this deposition gave a colourless solvent, indicating that essentially all of the particles plated out (phthalocyanine is totally insoluble in heptane). Hence the photoconductivity occurs from particles which are adsorbed onto the $In_2O_3$ surface.

The PIC must have some of its origin from the migration of particles between electrodes. Support for this comes from an experiment in which the cell, after application of an $E$ in the dark, is disassembled and then reassembled after one of the electrodes had been cleaned. This PIC for this new cell was very low initially but with time increased significantly. Concurrent with this increase was the

TABLE 1. PIC results for the study of concentration dependence

| | PIC (A) | | | |
|---|---|---|---|---|
| Applied $E$ (V/cm) | 0.1 wt% | 0.2 wt% | 0.4 wt% | 2.0 wt% |
| $1 \times 10^4$ | $2.1 \times 10^{-7}$ | $2.1 \times 10^{-7}$ | $2.0 \times 10^{-7}$ | — |
| $2 \times 10^4$ | $2.3 \times 10^{-6}$ | $2.2 \times 10^{-6}$ | $2.0 \times 10^{-6}$ | — |
| $3 \times 10^4$ | $7.2 \times 10^{-6}$ | $7.3 \times 10^{-6}$ | $7.2 \times 10^{-6}$ | $5.2 \times 10^{-6}$ |
| $4 \times 10^4$ | $1.7 \times 10^{-5}$ | $1.7 \times 10^{-5}$ | $1.7 \times 10^{-5}$ | $1.5 \times 10^{-5}$ |

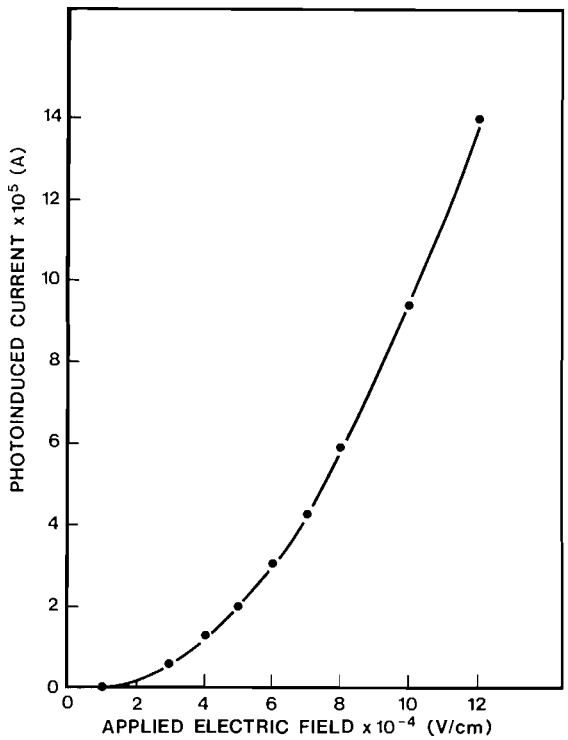

FIG. 2. PIC dependence on $E$ for an $x$-$H_2Pc$ dispersion in heptane (4 mg/mL) using a 250 μ spacer.

observation that the "cleaned" electrode was now covered with $x$-$H_2Pc$ particles. This not only demonstrates that the charged $x$-$H_2Pc$ particles do migrate across the cell, it also shows that maximum PIC's are only observed when both electrodes are coated. These results can be described by the following mechanism for particle migration assuming that the top electrode is positive.

$$[1]\quad (x\text{-}H_2Pc)^0_{anode} \xrightarrow{nh\nu} ne^- + (x\text{-}H_2Pc)^{n+}_{anode}$$

$$[2]\quad (x\text{-}H_2Pc)^{n+}_{anode} \rightarrow (x\text{-}H_2Pc)^{n+}_{cathode}$$

$$[3]\quad ne^- + (x\text{-}H_2Pc)^{n+}_{cathode} \rightarrow (x\text{-}H_2Pc)^0_{cathode}$$

Light absorbed by the $x$-$H_2Pc$ particles creates electron/hole pairs which is followed by charge injection into the $In_2O_3$ (reaction [1]). The holes ($nh^+$) remaining on the $x$-$H_2Pc$ particles cause the particle to become positively charged and it is then electrophoretically driven to the cathode (reaction [2]). The injected electrons essentially reduce the positively charged particles as shown in reaction [3]. Those particles which are adsorbed on the cathode can also absorb light and subsequently inject holes (rather than electrons) and produce current in a manner analogous to that expressed by reactions [1]–[3]. This mechanism is consistent with the fact that equivalent PIC's are observed regardless of the polarity of the top electrode and with the fact that a migration of particles within the cell is observed.

The PIC also has a contribution from ionic carriers. This would certainly be expected from the results of prior work (6–8) in which all the current was associated with ionic, soluble carriers. In our system this was confirmed by several different experiments. Purging the dispersion with $N_2$ prior to filling the cell had a significant effect on the PIC (Fig. 4) compared to both the air-saturated and $O_2$-saturated systems. In fact, the PIC showed an ~50% increase in going from $N_2$- to $O_2$-purged systems. Detection of $O_2^-$ during the photolysis of $x$-$H_2Pc$ dispersions (18, 19) suggests that $O_2^-$ may be a possible ionic carrier in this system, consistent with the oxygen effect on PIC. Finally, soluble $t$-b-$H_2Pc$, when dissolved and placed within the cell also exhibited PIC's but to a much lesser extent. Nevertheless, in this system, the only possible charge carriers are soluble ions and therefore the observation of a PIC is consistent with an ionic component to the PIC.

The $\Phi_{overall}$ for this process (Fig. 3) is shown to be 0.011 at low light intensity and an $E$ of $3 \times 10^4$ V/cm. Figure 2 shows that at the highest $E$ used ($2 \times 10^5$ V/cm), $\Phi$ is increased by a factor of ~21. This factor of 21 is surprisingly not a function of the light intensity. For light intensities of $5 \times 10^{13}$, $6 \times 10^{15}$, and $4 \times 10^{16}$ photons/cm$^2$ s, a constant value for the ratio of $\Phi_{overall}$ at $3 \times 10^4$ V/cm and $1.2 \times 10^5$ V/cm was obtained. Therefore an extrapolated value of $\Phi_{overall} = 0.23$ is achieved for maximum efficiency. (This does not take into account the increase that would be expected if the sample were $O_2$ purged). This can be contrasted to a $\Phi_{overall} \simeq 0.01$ for chlorophyll (8); $5 \times 10^{-4}$ for $H_2Pc$ films at 2

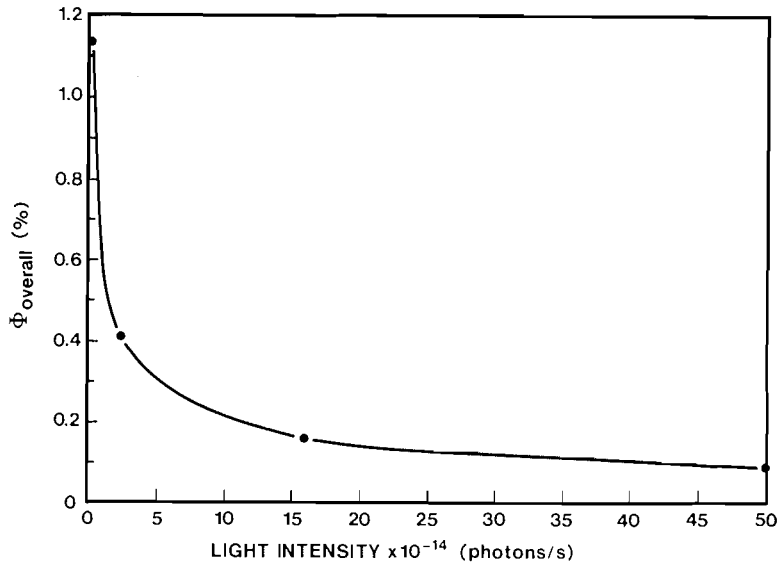

FIG. 3. The dependence of $\Phi_{overall}$ on light intensity for an $x$-$H_2Pc$ dispersion in heptane (2 mg/mL).

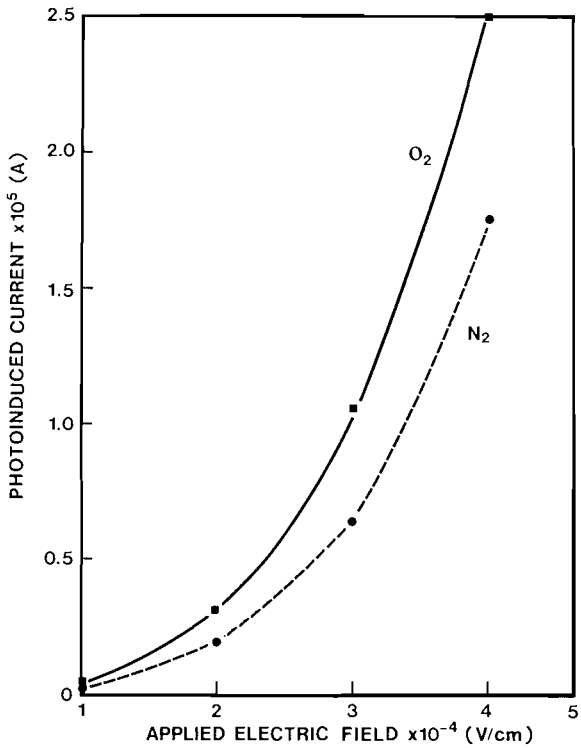

FIG. 4. The PIC as a function of $E$ for a $N_2$-purged dispersion (○) and an $O_2$-purged (□) $x$-$H_2Pc$ in heptane dispersion (2 mg/mL).

$\times$ $10^5$ V/cm (6) and $7 \times 10^{-3}$ for $H_2Pc$ films at $6 \times 10^5$ V/cm (7). This result implies that the particles of $x$-$H_2Pc$ are far more photoactive than films of $H_2Pc$ and/or that this system, which allows for particle migration, increases the efficiency by inclusion of particle charge carriers to the overall PIC's. This experimental set-up, in any event, provides for a determination of the $\Phi_{overall}$ for pigment particles which have potential for use in PAPE systems. The allowance for particle migration mimics the real PAPE system and therefore provides a more realistic determination of pigment performance under reproducible conditions in a closed cell.

*II. Spin trapping*

It is of interest to determine the nature of the molecular intermediates involved during these electric-field-enhanced photochemical reactions. Previously, spin trapping has been employed in the study of pigment dispersions in the absence of an external $E$ (14, 18, 20). These studies were successful in the detection of radical intermediates including $O_2^-$, $\cdot OH$, and $\cdot CO_2^-$ upon photolysis of pigment dispersions. We, therefore, introduced spin traps within this system in an effort to detect short-lived radical intermediates. The application of spin traps for a study of electrode reactions has been previously demonstrated (21, 22).

With PBN ($\sim 10^{-2}$ $M$) present in the $x$-$H_2Pc$ dispersion, PIC's were obtained which were only slightly less than the PIC's measured without PBN. This result suggests that PBN is acting essentially as an inert component of the system. Electron spin resonance observation of this solution after a 10 s application of an $E$ revealed that very little spin adduct formation occurred (Fig. 5*a*). Similar results were obtained upon photolysis of this dispersion in the absence of an $E$ (Fig. 5*b*). However,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

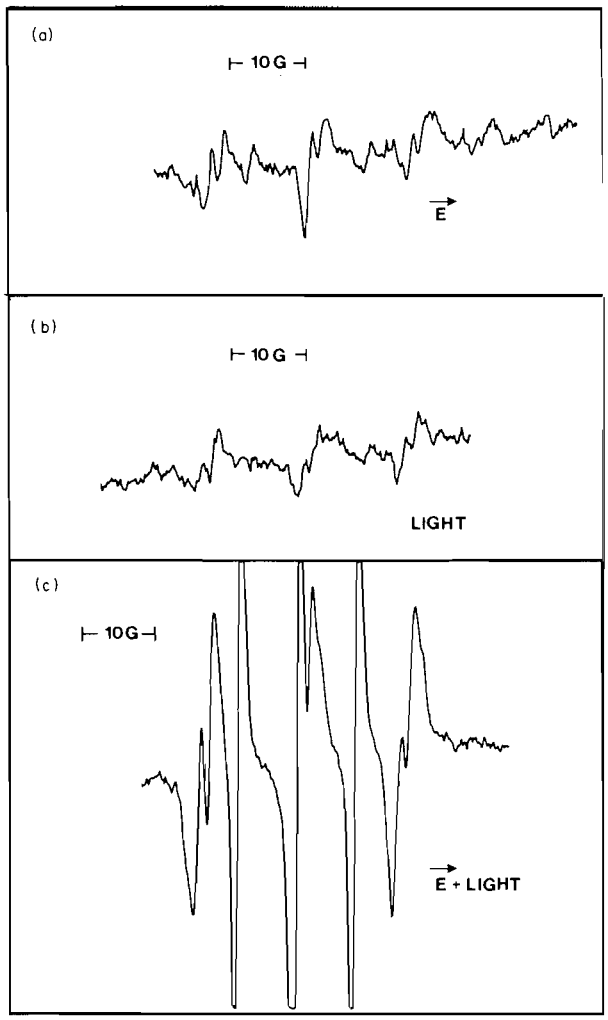

FIG. 5. The esr spectra obtained from a saturated PBN solution of heptane added to the cell after plating out of the $x$-$H_2Pc$ particles. (*a*) $E$ only ($1.2 \times 10^5$ V/cm), (*b*) light only, and (*c*) $E$ ($1.2 \times 10^5$ V/cm) and light. Spectrometer settings were equivalent for these three cases: 1.6 G, modulation amplitude; 15 mW, microwave power; 0.3 s, time constant; $1.25 \times 10^4$, receiver gain; 2 min, scan time. The solutions were $N_2$ purged before transfer to the esr cell to enhance sensitivity.

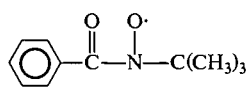
with both $E$ and illumination for a 10 s period, the esr signal shown in Fig. 5*c* resulted. This spectrum is a superposition of at least three separate nitroxide spectra. The 3 line spectrum with $a^N = 7.9$ most likely arises from a nitroxone (22).



The second major component with $a^N = 13.4$ G and $a^H = 1.5$ is typical of alkylperoxy adducts (23, 24). Apparent as shoulders on this spectrum is a third component of unknown splittings. Nevertheless, one can deduce that both $a^N$ and $a^H$ are larger than those of the alkyl peroxy adducts. Under some circumstances, temporary shorting of the electrodes at these high electric fields was observed as a spike in the oscilloscope trace. In these cases significant quantities of the alkylperoxy radical adducts were generated (Fig. 6). This was reproducible and points out the necessity of monitoring the PIC's of samples being analyzed by esr.

The cooperative effect of both light and $E$ in producing radicals is clear evidence of a synergistic process. Nevertheless, the origin of the adducts is not obvious. PBN could be oxidized to the nitroxone in this process to yield the neutral spin adduct. The alkylperoxy adduct may result from the reaction of $O_2$ with an alkyl radical generated during the electrical breakdown of the cell. In the case of no apparent shorting, the light induces a high current which could create a partial shorting resulting in the generation of the same radical adduct. The third radical adduct is unknown. The important thing to note is that both major radical adducts are neutral. This would, in fact, be the expected result since charged spin adducts would be driven by the electric field (usually with electrophoretic mobilities of $\sim 1 \times 10^{-4}$ cm$^2$/V s) to the electrode surface. It is known that radical adducts readily undergo redox reactions and would therefore react at the electrode to yield either a diamagnetic product or another nitroxide. Since the cell thickness is 250 $\mu$, a charged radical adduct would exist at an $E = 2 \times 10^5$ V/cm for $\tau \simeq 1$ ms. This millisecond lifetime severely limits the steady-state concentration of radical adducts generated from the trapping of charged radicals. On the other hand, the neutral radicals will tend to accumulate over the 10 s illumination period. Hence photogenerated $O_2^-$ radicals which might be expected as at least one of the ionic carriers (19) were not observed in the trapping experiments.

Several experiments were attempted with DMPO in spite of the fact that problems were encountered when DMPO was present. The PIC's were significantly reduced and an agglomeration of pigment particles on the Nesatron surface was observed. When the esr experiments were attempted, an adduct was generated with $a^N = 13.2$ G and $a^H = 9.9$ G (a three-line nitroxide ($a^N = 13.5$ G) was present in the dark). This unknown adduct (which could result from a peroxy radical) was generated with either light and/or $E$.

## Conclusions

A system has been presented which permits the determination of the electric field dependence of

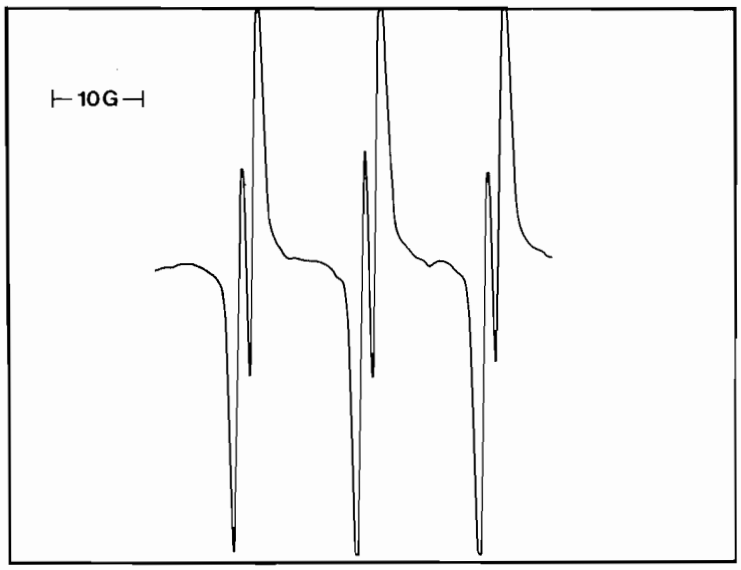


FIG. 6. Electron spin resonance signal obtained when shorting of the cell occurred. Same settings as in Fig. 5 except receiver gain was reduced to $1.25 \times 10^3$.

photochemical charge exchange of pigment particles. This is especially important for the evaluation of particles in which their identity can be maintained. An example of an application is determination of the change in photochemistry as a result of surface modification for SEU. The technique is particularly adapted for screening potential pigments in PAPE imaging systems and for noting the effect of added compounds. Both molecular and particulate charge carriers contribute to the PIC and $O_2$ is shown to enhance the effect. Spin trapping experiments reveal a synergism of *E* and light in the production of neutral spin adducts. Both an alkylperoxyl and a nitroxone were identified. "Shorting" of the cell generates the alkylperoxyl radical. It is shown that ionic radicals trapped by PBN which create charged spin adducts can not be effectively detected with this system.

# A theoretical study on the *cis/trans*-isomerization of azodioxymethane

TSUTOMU MINATO, SHINICHI YAMABE,[1] AND HISAKAZU ODA

*Department of Chemistry, Nara University of Education, Takabatake-cho, Nara 630, Japan*

Received May 5, 1982

TSUTOMU MINATO, SHINICHI YAMABE, and HISAKAZU ODA. Can. J. Chem. **60**, 2740 (1982).

The state correlation diagram for the *cis/trans*-isomerization of azodioxymethane is presented. The direct interconversion through N—N twisting is found to be symmetry-forbidden in a thermal reaction, whereas it is symmetry-allowed photochemically. In the thermal reaction, the fragmentation of the *cis* form into two nitrosomethanes and their recombination to the *trans* form take place via the symmetry-allowed "from step to step" mechanism. The potential energy is calculated by the *ab initio* MO method of a 4-31G basis set and a solvent effect is found to be indispensable in reproducing the energetics of these reactions.

TSUTOMU MINATO, SHINICHI YAMABE et HISAKAZU ODA. Can. J. Chem. **60**, 2740 (1982).

On présente le diagramme de corrélation d'état de l'isomérisation *cis/trans* de l'azodioxyméthane. On a trouvé que l'interconversion directe par l'intermédiaire d'une torsion de la liaison —N—N est interdite par raison de symétrie dans une réaction thermique, tandis qu'elle est permise photochimiquement. Dans une réaction thermique, la fragmentation de la forme *cis* en deux nitrosométhanes ainsi que leur combinaison en forme *trans* se fait par un mécanisme "étape par étape" qui est symétriquement permis. On a calculé l'énergie potentielle par la méthode *ab initio* des OM d'un ensemble de base 4-31G et on a trouvé un effet de solvant indispensable pour la reproduction des effets énergétiques de ces réactions.

[Traduit par le journal]

## I. Introduction

Aliphatic nitroso compounds, R—N=O, where R is a primary or secondary alkyl group, are known to stay almost exclusively in dimeric form in solution. From experimental studies, thermodynamical and kinetic parameters for the dimerization of nitrosoalkanes have been obtained (1). Cross-over and trapping experiments have shown that the *cis/trans*-isomerization of the dimer does not proceed by rotation around the N—N bond but via free monomers (2). So far, few theoretical studies have been made on the mechanism of isomerization. Hoffmann, with use of the extended Hueckel MO method (3), pointed out that HNO (parent molecule of nitrosomethane) dimerizes to a *trans* product in the "bent-out-of-plane path", one of the non-least-motion paths. Heiberg examined the least-motion path with the rigorous CI (4). However, it is not yet known why the direct isomerization by route (I) shown in Fig. 1 is unfavorable. It is also of interest to examine how the reaction proceeds via monomers ((II)-1 → (II)-2 in the figure).

In the present work, these reaction paths are systematically investigated with the aid of the state correlation diagram (5). This is useful in minimizing the effort in searching for the potential surface. Based on the outline of the reaction coordinate given by the diagram, we trace the minimum-energy path of the "symmetry-allowed" process with the *ab initio* MO method. In view of the potential energy and the electronic structure of the dimer and monomer, their stability and reactivity are discussed.

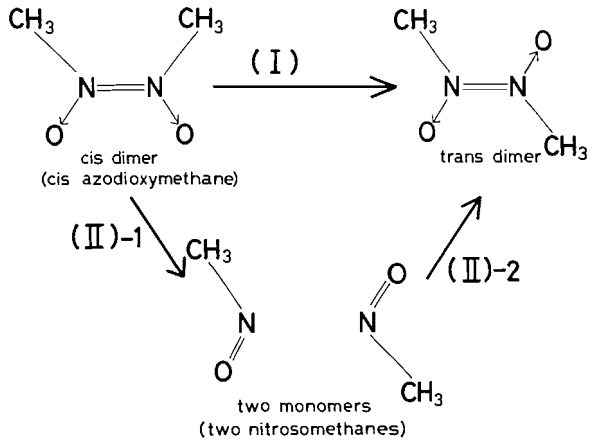

FIG. 1. Two routes (I) and (II) for the *cis/trans* interconversion of azodioxymethane.

## II. Procedure

The electron distribution is computed with RHF MO of a 4-31G valence-double-ζ basis set internal to the GAUSSIAN 70 program (6). The equilibrium geometry of the monomer and two dimers is optimized. In Fig. 2, the obtained geometries are displayed together with the Mulliken atom population and the dipole moment. The crystal structures give a 0.09 Å difference in the N—N bond length between *cis* and *trans* forms (7). The present calculation reproduces this trend, although it is somewhat smaller (0.03 Å). The N—O bonds in dimers are longer than that of the monomer. This

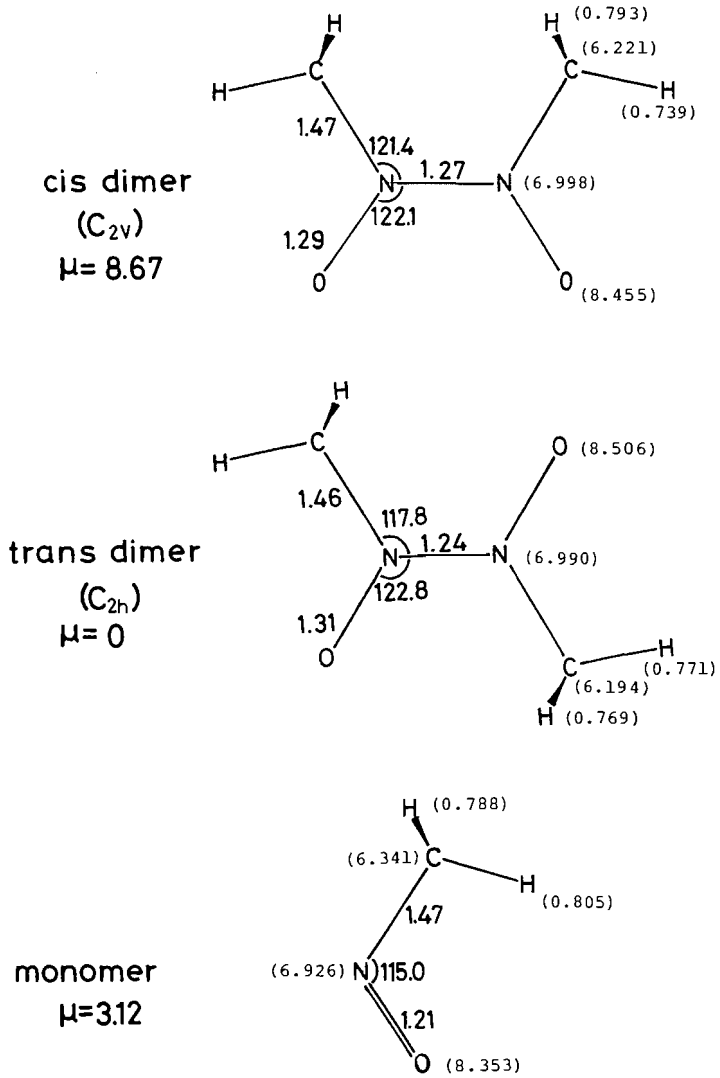

FIG. 2. The structures of *cis* and *trans* dimers and the monomer optimized with the 4-31G basis set. The bond distance and the angle are in Å and in degree, respectively. The numbers in parentheses are Mulliken atom populations. μ is the dipole moment in debye unit.

means that those bonds lose their double-bond character in dimers. It is noticed that the *cis* dimer has a remarkably larger dipole moment than the *trans* dimer and the monomer.

MO's obtained for the optimized geometries are assigned to symmetry orbitals according to the point group ($C_{2v}$ or $C_{2h}$) for the least-motion (i.e, the highest-symmetry) path. In view of the MO levels, the correlation diagram for the low-lying excited states as well as for the ground state may be drawn. When the least-motion path is found to be symmetry-forbidden in any state of interest, a non-least-motion path should be introduced. This corresponds to the relaxation of the symmetry imposed on the reacting system. For the relaxed (lowered) symmetry, it is judged whether the forbiddeness remains or not. Once the diagram gives the allowed path (i.e., the restriction by the orbital symmetry is removed), the minimum-energy path along the symmetry-allowed direction may be traced.

### III. Qualitative description of reaction paths

In Table 1, we show a schedule of examining individual correlation diagrams for the three routes in Fig. 1. In Fig. 3, route (I) of the direct *cis* → *trans*

TABLE 1. List of various state correlation diagrams for point groups imposed on the path of the isomerization in the ground state

| Route No. | Reaction | Highest symmetry | Relaxed symmetry | Figure | Judgement |
|---|---|---|---|---|---|
| (I) | *cis* dimer → *trans* dimer | $C_2$ | | Fig. 4 | Forbidden |
| (II)-1 | *cis* dimer → two monomers | $C_{2v}$ | | Fig. 5 | Forbidden |
| | | | $C_s$ | Fig. 6(*a*) | Forbidden |
| | | | $C_s'$ | Fig. 6(*b*) | Forbidden |
| | | | $C_2$ | Fig. 6(*c*) | Allowed |

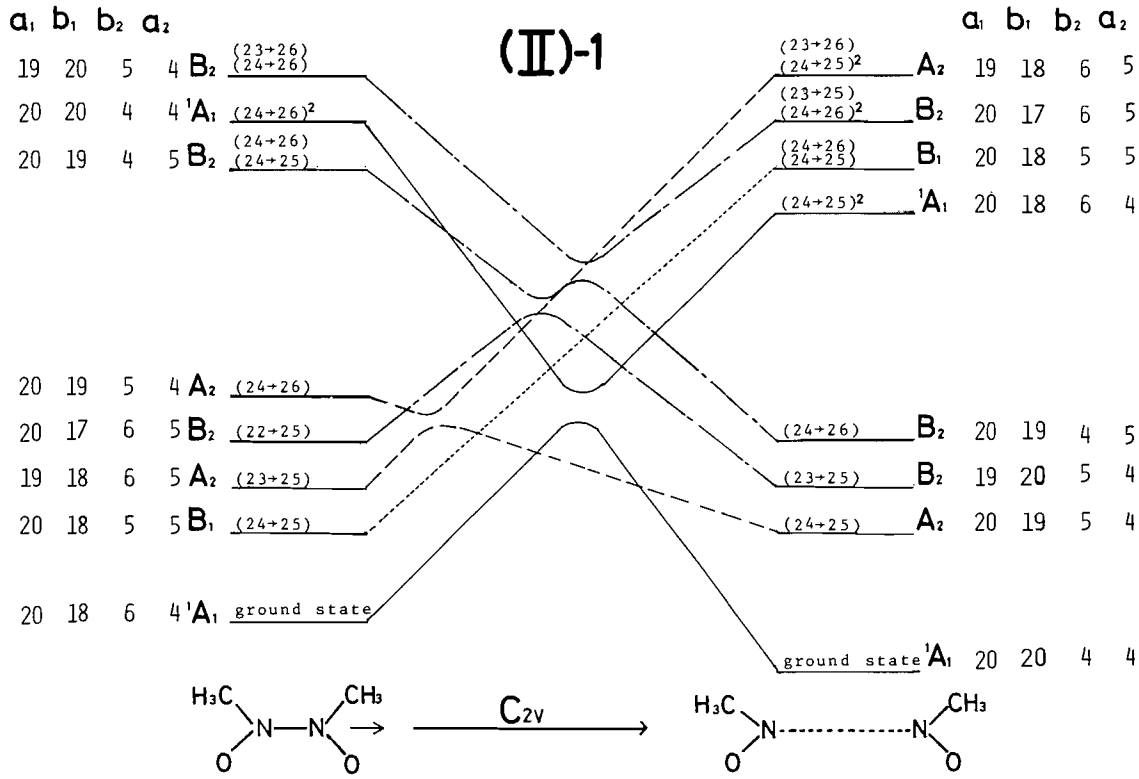

FIG. 5. The state correlation diagram of the fragmentation of the *cis* dimer to two monomers along the $C_{2v}$ path.

interconversion is exhibited. The $C_2$ axis rotating with one nitroso group is maintained. In Fig. 4, the state correlation diagram for this route is shown. It immediately demonstrates that the $C_2$ path is symmetry-forbidden with the energy barrier of the avoided crossing in the ground state. Therefore, the thermal *cis*/*trans* interconversion is evidently unfavorable. In view of this result, we move on to route (II). For the fragmentation of the *cis* dimer, (II)-1, the least-motion path retains the $C_{2v}$ symmetry. In Fig. 5, the correlation diagram is shown, which again indicates symmetry-forbiddeness for the thermal dissociation. In Fig. 6, three diagrams for the relaxation of the $C_{2v}$ symmetry are given. Among the three, only the $C_2$ path in Fig. 6(*c*) becomes symmetry-allowed. This switch is represented by the removal of the energy barrier of the avoided crossing of two curves. The bold line for state A with $a = 24$ and $b = 24$ electrons indicates the symmetry-allowed process. Another ($C_{2v} \rightarrow C_2$) distortion made by the twisting elimination (shown later in Fig. 9) is also found to bring about the symmetry-allowed path. Thus the decomposition of the *cis* dimer takes place along the $C_2$ pathway.

For the recombination of two monomers to form the *trans* dimer, (II)-2, the least-motion path keeps the $C_{2h}$ symmetry. In Fig. 7, the correlation diagram is drawn, and thermal association is symmetry-forbidden. To seek the symmetry-allowed path, three ways of distortion are introduced in Fig. 8. Among them, a course retaining the inversion operation i becomes symmetry-allowed for the ground state in Fig. 8(*c*).

Reviewing the analysis of route (II) in terms of a state correlation diagram, we may summarize the ground-state mechanism qualitatively by Fig. 9. For both (II)-1 and (II)-2, the "from step to step of stairs" dissociation ($C_2$) and recombination (i) are symmetrically favorable. However, for (II)-1, it should be energetically judged which $C_2$ path is better (expressed by "?").

The state correlation diagrams give information on not only the thermal reaction but also the photochemical reaction. Figure 4 shows that the direct isomerization which is symmetry-forbidden in the ground state is symmetry-allowed in the lowest excited state (B). That is, the direct interconversion is predicted to take place photochemically. As for route (II) in the photochemical reaction, the $C_s'$ fragmentation in Fig. 6(*b*) and the $C_2$ recombination in Fig. 8(*b*) are likely.

## IV. Results and discussion

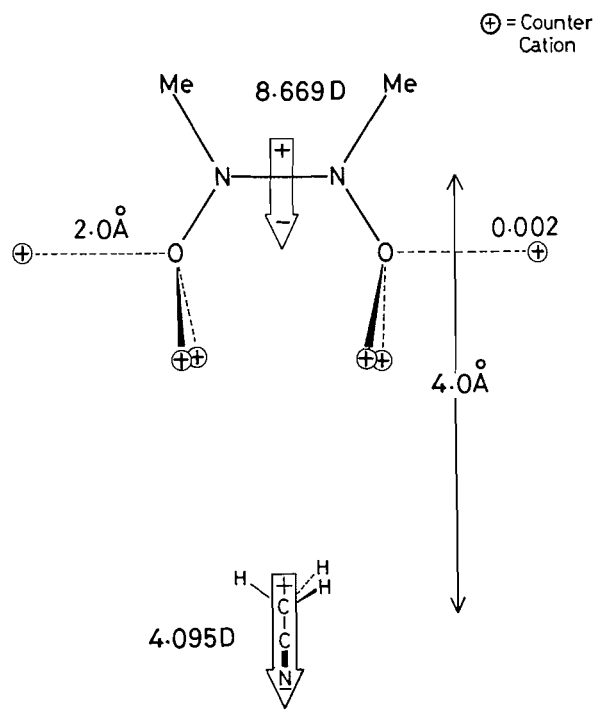
For (II)-1, the changes of $E_T$'s along two different paths (? in Fig. 9) are compared. The calculated result shows that the "from step to step" separation is more preferable than the twisting scission. In Fig. 10, a snapshot of the two routes (II)-1 and (II)-2 is exhibited. According to Heiberg's result (4), the energy ascent of the symmetry forbiddeness is sharp at $R \cong 1.7$ Å, which is avoided in our figure by the drastic bent-out-of-plane motion. At $R \leqq 1.4$ Å, the planar structures ($C_{2v}$ for (II)-1 and $C_{2h}$ for (II)-2) are retained.

In Fig. 11, two energy profiles for the path of Fig. 10 are exhibited. One is "without solvation" which is obtained by the standard SCF calculation. The other is "with solvation" and consists of an energy correction through two types of solvent effect. Such a correction is necessary in view of the experimental data. For the "without solvation" case, the structural stability is in the order of

*trans* dimer > two monomers > *cis* dimer

which is in contrast to the experimental order (2)

*trans* dimer > *cis* dimer > two monomers



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

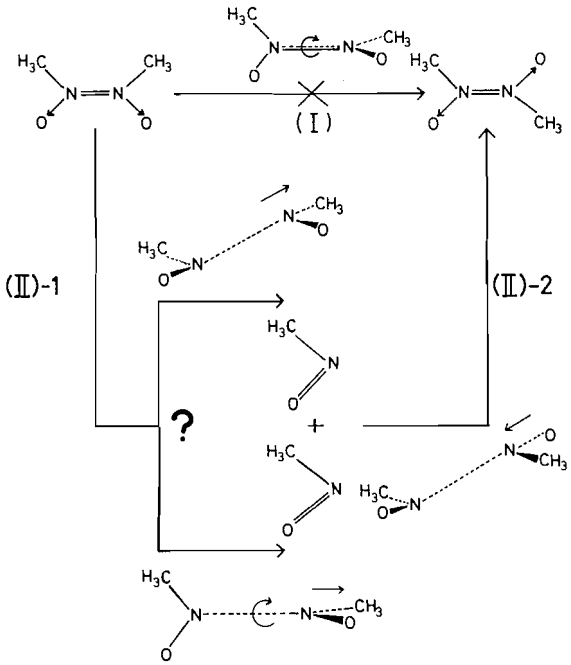

FIG. 9. Summary of the consideration on the reaction paths in the ground state based on the state correlation diagrams.

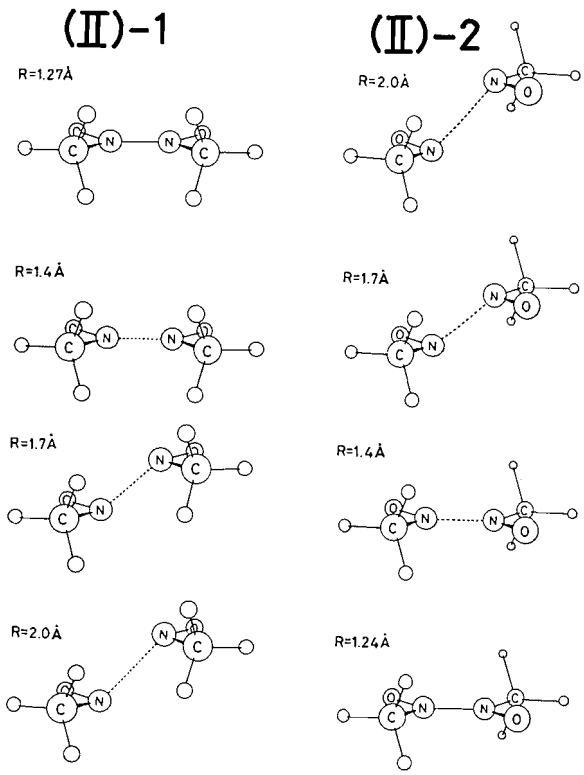

FIG. 10. The snapshots of the fragmentation of the *cis* dimer ($C_2$) and the recombination of two monomers (i). $R$ is the distance between two N atoms. Empty circles are hydrogen atoms.

This apparent discrepancy is easily solved by considering the solvent (acetonitrile) effect. This polar solvent molecule should interact with the electron-rich oxygen atom of the dimer. In general, a molecule with an electron-rich atom is stabilized significantly by the Coulombic field presented by the surrounding cationic site (methyl group) of acetonitrile. Indeed, a tentative calculation, including counter cations with their effective charge = +0.002 for two dimers and the monomer, has switched the order of stability to[2]

*trans* dimer > *cis* dimer > two monomers

Another disagreement is found in the comparison of the activation energies ($E_a$'s) of (II)-2 and the reverse route of (II)-1, route (II)-1′. Experimental analysis has suggested that $E_a$[(II)-2] is larger than $E_a$[(II)-1′] (2), whereas "without solvation" gives the opposite result. This indicates that another solvent effect should be considered. The structural difference of the two dimers is reflected in the values of the dipole moment ($\mu$) shown in Fig. 2. $\mu_{\text{acetonitrile}}$ is calculated to be 4.10 D (exptl. = 3.92 D). Since $\mu_{cis\ \text{dimer}}$ (= 8.67 D) is very large, the permanent dipole–dipole interaction as well as the Coulombic effect may not be neglected.

Acetonitrile molecules distant from the *cis* dimer (~ 4 Å) operate as an origin of the dipolar field to result in the stabilization ($E_\mu$) through this interaction. A test calculation which makes use of the model in the figure above gives $E_\mu = -15$ kcal/mol.[3] This is a serious correction to the potential energy of (II)-1, whereas that of (II)-2 is not affected at all by this interaction since $\mu_{trans\ \text{dimer}} = 0$. The potential energies of "with solvation" shown in Fig. 11 include the Coulombic and the dipole–dipole interactions and they reproduce well the experimentally suggested energy changes (2). The energy profiles with solvation and without solva-

[2]The positive point charges are located in the direction of an $sp^3$ hybrid orbital on the oxygen atoms of the dimers and the monomer. This location apparently overestimates the Coulombic stabilization of the *cis* dimer, because each oxygen is attracted not only by the positive charges close to it but also by those of the nearby oxygen. However, $E_T$'s without and with the charges are −337.1047 → −337.2045 au for the *cis* dimer and −337.1359 → −337.2375 au for the *trans* dimer, which indicates that the net stabilization of the former dimer is estimated to be almost the same as that of the latter. Alternative locations of the point charges were also tested, and were found to give a similar equality. Thus, the present way of placing the point charges toward each oxygen atom does not bias the result in favor of the *cis* form.

[3]$E_\mu$ is estimated by the following equation.

$$E_\mu = -2(\mu_{\text{acetonitrile}})^2 \cdot (\mu_{cis\ \text{dimer}})^2/(3L^6 \cdot kT) \quad (T = 298\ \text{K})$$

$k$ is Boltzmann's constant, $L$ is the distance between two dipole moments and is taken here to be 4.0 Å.

For personal use only.

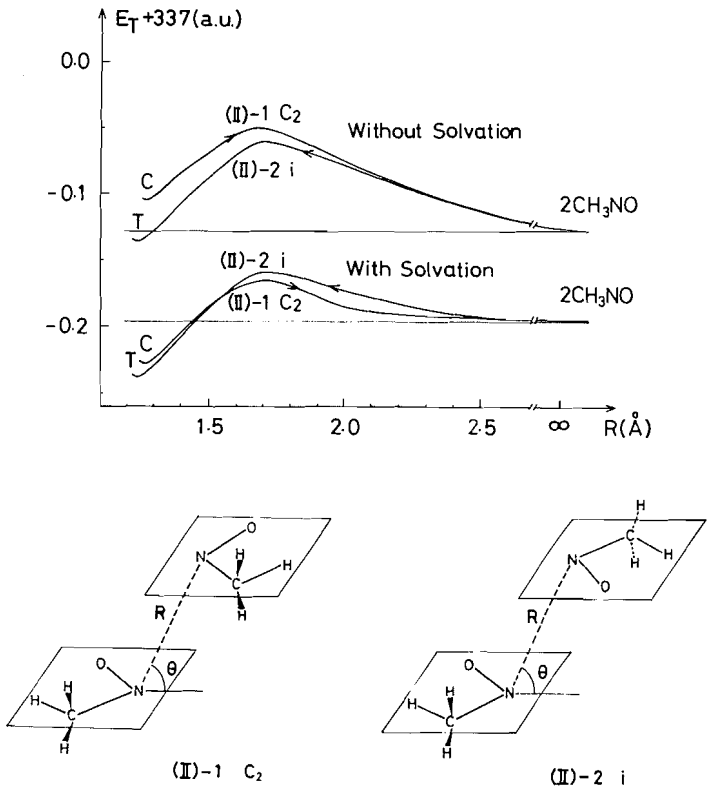

FIG. 11. The energy profile of *cis/trans* isomerization of the dimer in the ground state. C and T denote *cis* and *trans* dimers, respectively.

tion show that the fragmentation and recombination have maxima in $E_T$ at $R = 1.7$ Å. In other words, the transition states of both reactions are located there. Heiberg's result gives a sharp energy ascent at $R \simeq 1.7$ Å by the symmetry-forbiddeness (4). This ascent is removed by the bent-out-of-plane motion. The interaction between two monomers is small at $R > 2.0$ Å, as the flat energy profiles show.

## V. Concluding remarks

In this work, the *cis/trans* isomerization of azodioxymethane has been discussed in terms of the state correlation diagrams and *ab initio* calculations have been made to follow the paths. The diagrams show that direct *cis/trans* isomerization is thermally unfavorable, whereas it is a symmetry-allowed photochemical route. The thermal isomerization takes place via the fragmentation of the *cis* dimer into monomers and their recombination to the *trans* dimer. Their reaction paths are represented by the "from step to step" mechanism. Thus, the diagram may be used as a guide to seek the reaction path.

The energies in the gas phase, "without solvation", are calculated to be entirely different from the experimental ones. The consideration of a solvent effect gives a good correlation between theoretical and experimental data. The importance of this effect in the reaction is due to the large polarity of the *cis* dimer and the solvent molecule.

# Kinetics of the oxidation of ethane and 1-butene over manganese oxide supported on carbon fibres

CRAIG FAIRBRIDGE[1] AND JAMES R. MACCALLUM

*Department of Chemistry, The University of St. Andrews, St. Andrews, Fife, Scotland, KY16 9ST*

AND

ROBERT A. ROSS

*Alcan International Limited, Kingston Laboratories, Box 8400, Kingston, Ont., Canada K7L 4Z4*

Received May 3, 1982

CRAIG FAIRBRIDGE, JAMES R. MACCALLUM, and ROBERT A. ROSS. Can. J. Chem. **60**, 2749 (1982).

The oxygen/ethane and oxygen/1-butene reactions have been investigated in a continuous flow system at atmospheric pressure over a manganese oxide/carbon fibre catalyst. The products of reaction were carbon dioxide and water. Apparent activation energies were $108 \pm 4$ kJ mol$^{-1}$ for the former reaction from 673 to 573 K, and $81 \pm 4$ kJ mol$^{-1}$ for the latter from 573 to 473 K. Kinetic data for both reactions were best described by the rate equation:

$$r = \frac{kap_{O_2}^{0.5}\, bp_{HC}^{0.5}(p_{O_2}\, p_{HC})}{(1 + ap_{O_2}^{0.5} + bp_{HC}^{0.5})^2}$$

The surface mechanism may be complex and it is proposed that reactants interact as adsorbed species each of which is adsorbed on two surface sites. Both oxygen and the hydrocarbon gas appear to be directly involved in further steps. Scanning electron microscopy, X-ray photoelectron spectroscopy, and low temperature krypton adsorption were used to assess the catalyst structure.

CRAIG FAIRBRIDGE, JAMES R. MACCALLUM et ROBERT A. ROSS. Can. J. Chem. **60**, 2749 (1982).

Les réactions oxygène/éthane et oxygène/1-butene sont étudiées à pression atmosphérique dans un systeme à débit continu sur un catalyseur oxyde de manganèse/fibre de carbone. Les produits de la réaction sont le dioxyde de carbone et l'eau. Les énergies d'activation apparentes sont $108 \pm 4$ kJ mol$^{-1}$ pour la premiere réaction (673 à 573 K) et $81 \pm 4$ kJ mol$^{-1}$ pour la deuxieme réaction (573 à 473 K). Les données cinétiques pour les deux réactions sont bien décrites par l'équation suivante:

$$r = \frac{kap_{O_2}^{0.5}\, bp_{HC}^{0.5}(p_{O_2}\, p_{HC})}{(1 + ap_{O_2}^{0.5} + bp_{HC}^{0.5})^2}$$

Les mécanismes des réactions de surface peuvent être assez complexes; il est proposé une accumulation des réactifs dans une couche adsorbée. Chaque réactif est probablement adsorbé en deux sites différents sur la surface. L'oxygene et l'hydrocarbure semblent être directement impliqués dans des réactions ultérieures. La microscopie à balayage électronique, la spectroscopie photoélectronique à rayons-X, et l'adsorption de krypton à faible température sont utilisées pour déterminer la structure du catalyseur.

## Introduction

A number of key heterogeneous catalytic reactions have been examined over manganese oxides in recent years (1–4); including directly related work on the oxidation of ethane on manganese(III) oxide by nitric oxide (5), and by oxygen (6). These oxides were finely-divided, pure materials with no support or carrier, in contrast to the present investigation where high purity carbon fibres have been adapted for use as support media for manganese oxide in a study of the catalytic oxidation reactions of both ethane and 1-butene.

Catalysts consisting of metals on activated carbon supports have been used in many reactions including $NO_x$ reduction (7, 8) and hydrocarbon oxidation (9) but the application of carbon fibres as catalyst supports has received relatively little attention. Carbon filaments alloyed with transition metals such as nickel, cobalt, chromium, and manganese have been used as catalysts for the dehydration of secondary alcohols (10), while a platinum/carbon fibre catalyst was described in connection with hydrocarbon conversion reactions (11). Because of their mechanical strength, thermal stability, flame and chemical resistance, carbon fibres could prove to be applicable as supports with long service life (12), particularly in the hydrocarbon conversion field (11).

## Experimental

*Apparatus and procedure*

Helium was used as the carrier gas in the quartz reactor flow system (13) and in the Hewlett-Packard Research Chromatograph, Model 5754B. A thermal conductivity bridge and stainless steel analytical columns, 305 × 0.32 cm od packed with Poropak Q, were used to analyze for oxygen, carbon dioxide, ethane, 1-butene, and water. The column oven was temperature programmed with a 3 min post-injection interval at 333 K, followed by a 60 K min$^{-1}$ increase to 408 K, whereupon the temperature was maintained for 8 min prior to recycling.

Reaction rate measurements were conducted at a total flow rate of 350 mL $min^{-1}$ (NTP) on 1 g catalyst samples, conditions which indicated that gas phase diffusion as well as heat and mass transfer effects were minimal (14). The experimental reaction rate, equated to the rate of carbon dioxide production, was recorded after steady catalyst activity had been achieved at <8% hydrocarbon conversion. The only products observed by gas chromatography were those expected from complete hydrocarbon oxidation, namely, carbon dioxide and water.

Catalyst surface areas measured by low temperature krypton adsorption (BET; 77 K; $\sigma$ = 19.5 Å$^2$) were reproducible to $\pm$0.2 $m^2$ $g^{-1}$. Surface structures were examined by a scanning electron microscope, Cambridge Stereoscan 600, and by an X-ray photoelectron spectroscope, Vacuum Generator ESCA-3.

*Materials*

"Modmor" high modulus reinforcing carbon fibre, Type III S, was supplied by Morganite Modmor Limited. Fibres, in 10 cm lengths, were sprayed with a 50% w/w aqueous solution of manganese(II) nitrate (BDH Chemicals Limited) and dried with a hot air gun at temperatures up to 573 K. The fibres were sprayed and dried in 10 cycles and chemical analysis (15) indicated 9.5% w/w manganese on the carbon after treatment in nitrogen at 773 K for 2 h. The fibre surface area increased from 1.8 to 3.8 $m^2$ $g^{-1}$ as a result.

Ethane (99.0%), 1-butene (99.0%), and oxygen (99.99%) were supplied by Matheson of Canada Limited. Carbon dioxide (99.5%) and helium (99.995%) were obtained from Canadian Liquid Air Limited. Water used in the gas saturators was distilled, de-ionized, and degassed prior to use.

## Results

*Reaction rate order measurements*

Rate orders were determined at 623 and 523 K, respectively, for the oxygen/ethane and the oxygen/1-butene catalytic reactions.

*Oxygen/ethane*

When the catalyst was exposed to 2.63 kPa oxygen and 2.62 kPa ethane at 673 K, the initial rate of carbon dioxide formation was very high, possibly due to partial oxidation of the carbon fibres. The rate of product formation decreased quickly to a steady level in 3 h and remained constant thereafter for at least 48 h. The surface area of catalysts treated in this way was 6.9 $m^2$ $g^{-1}$.

A reaction rate order of 0.3 with respect to oxygen partial pressure was determined at 623 K, Fig. 1, by altering the partial pressure from 0.31 to 14.15 kPa. The partial pressure of ethane was maintained at 2.57 kPa for these experiments.

With the partial pressure of oxygen held constant at 2.47 kPa, the partial pressure of ethane was adjusted from 0.69 to 10.05 kPa. The rate order with respect to ethane concentration was 0.4 as determined from the linear plot of ln (rate) versus ln (partial pressure), Fig. 1.

Variations in the carbon dioxide partial pressure from 0.67 to 6.44 kPa had no effect on the rate of reaction with oxygen and ethane partial pressures maintained at 2.68 and 2.74 kPa, respectively.

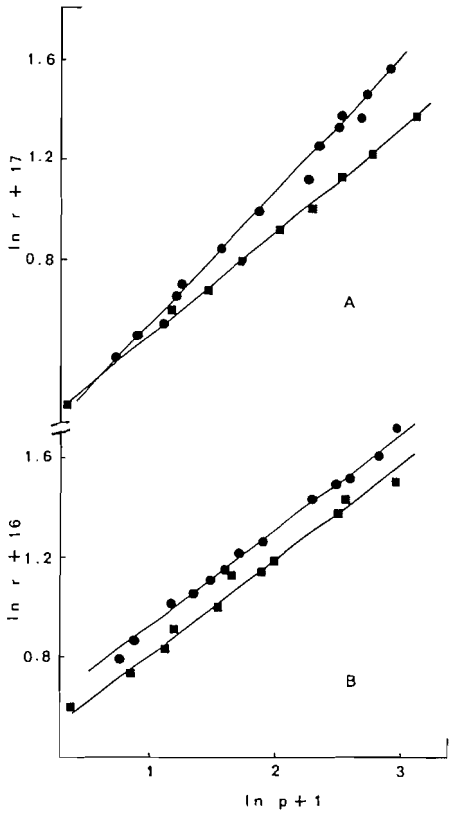

FIG. 1. The effects of component partial pressures (oxygen, ■; hydrocarbon, ●) on the reaction rate of the oxygen/ethane (*A*) and the oxygen/1-butene (*B*) reactions over manganese oxide/carbon fibre catalysts.

Therefore, the rate order was zero with respect to carbon dioxide.

Oxygen and ethane partial pressures were held at 2.63 and 2.71 kPa, respectively, while the partial pressure of water vapour was altered from 0.06 to 2.11 kPa. A zero rate order with respect to water vapour partial pressure was determined.

The experimental rate of the oxygen/ethane reaction at 623 K over the manganese oxide/carbon fibre catalyst was therefore expressed by:

$$[1] \quad r = k p_{O_2}^{0.3} p_{C_2H_6}^{0.4}$$

*Oxygen/1-butene*

Upon exposure of the catalyst to the reaction mixture, 2.69 kPa oxygen and 3.04 kPa 1-butene, a significant amount of carbon dioxide was initially liberated at 573 K. This was related to a measure of oxidation of the carbon fibres. The rate of production decreased over 24 h to a value which remained constant for at least 24 h. The catalyst surface area after this treatment was 11.1 $m^2$ $g^{-1}$.

The partial pressure of 1-butene was altered from

TABLE 1. The effect of temperature on reaction rate constants

| Oxygen/ethane | | Oxygen/1-butene | |
|---|---|---|---|
| Temperature (K) | $k \times 10^{-5}$ ($mol^{0.3}\ L^{-0.3}\ m^{-2}\ s^{-1}$) | Temperature (K) | $k \times 10^{-5}$ $mol^{0.2}\ L^{-0.2}\ m^{-2}\ s^{-1}$ |
| 673 | 26.0 | 573 | 95.3 |
| 663 | 20.5 | 563 | 66.2 |
| 653 | 13.4 | 553 | 48.8 |
| 643 | 9.55 | 543 | 36.1 |
| 633 | 7.07 | 533 | 27.3 |
| 623 | 5.16 | 523 | 18.7 |
| 613 | 3.61 | 513 | 13.4 |
| 603 | 2.48 | 503 | 9.34 |
| 593 | 1.91 | 493 | 5.71 |
| 583 | 1.31 | 483 | 4.08 |
| 573 | 0.922 | 473 | 2.46 |

0.82 to 7.15 kPa and a rate order of 0.4 was obtained while the oxygen partial pressure was held at 2.46 kPa, Fig. 1.

With 1-butene partial pressure maintained at 2.68 kPa, the oxygen pressure was adjusted from 0.32 to 7.36 kPa. The rate order derived from these results was 0.4 with respect to the partial pressure of oxygen.

The partial pressures of oxygen and 1-butene were maintained at 2.61 and 2.69 kPa, respectively, and the effects of a variation from 0.50 to 9.31 kPa in carbon dioxide partial pressure were observed. The results gave a rate order of zero with respect to carbon dioxide partial pressure.

Experiments were also carried out in which the partial pressure of water vapour was adjusted from 0.09 to 2.50 kPa in the reaction mixture of 2.57 kPa oxygen and 2.81 kPa 1-butene and a zero rate order dependence on water vapour partial pressure was determined.

The experimental rate of reaction was therefore given by:

$$[2] \quad r = k p_{O_2}^{0.4} p_{C_4H_8}^{0.4}$$

*Temperature effects*

*Oxygen/ethane*

After catalyst pretreatment with 2.63 kPa oxygen and 2.76 kPa ethane at 673 K for 4 h, rate constants were calculated from the integrated form of eq. [1] at 10 K intervals from 673 K to 573 K, Table 1. The data, when plotted in the Arrhenius fashion, Fig. 2, produced an apparent activation energy of $108 \pm 4$ kJ $mol^{-1}$ and a pre-exponential factor of $5.42 \times 10^4$ $mol^{0.3}\ L^{-0.3}\ m^{-2}\ s^{-1}$.

*Oxygen/1-butene*

The catalyst was treated at 573 K with 2.47 kPa oxygen and 2.71 kPa 1-butene for 24 h prior to kinetic studies. Rate constants, Table 1, were calculated from eq. [2] from 573 to 473 K. An apparent activation energy of $81 \pm 4$ kJ $mol^{-1}$ and a pre-exponential factor of $2.16 \times 10^4$ $mol^{0.2}\ L^{-0.2}\ m^{-2}\ s^{-1}$ resulted from the Arrhenius plot, Fig. 2.

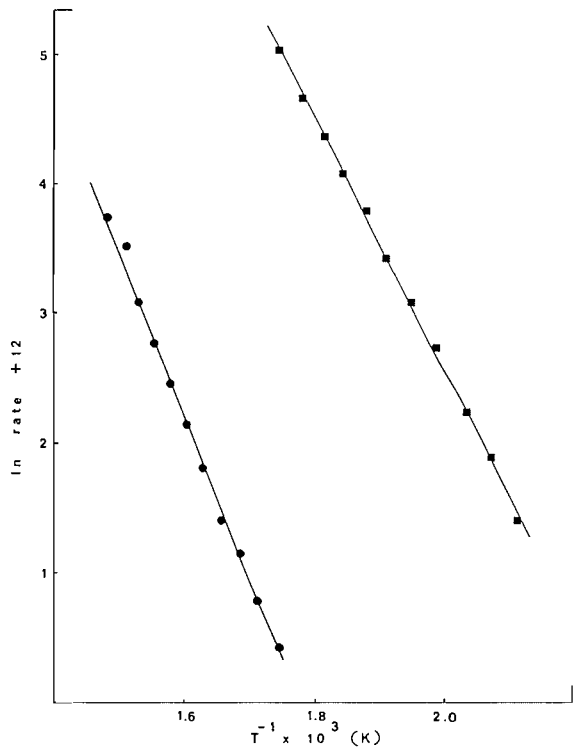

FIG. 2. Arrhenius plots for the oxygen/ethane (●) and oxygen/1-butene (■) reactions over manganese oxide/carbon fibre catalysts.

*Scanning electron microscopy*

The scanning electron micrographs, Fig. 3, show the effects of the oxygen/1-butene reaction at 573 K on the "Modmor" fibre supported catalyst. It

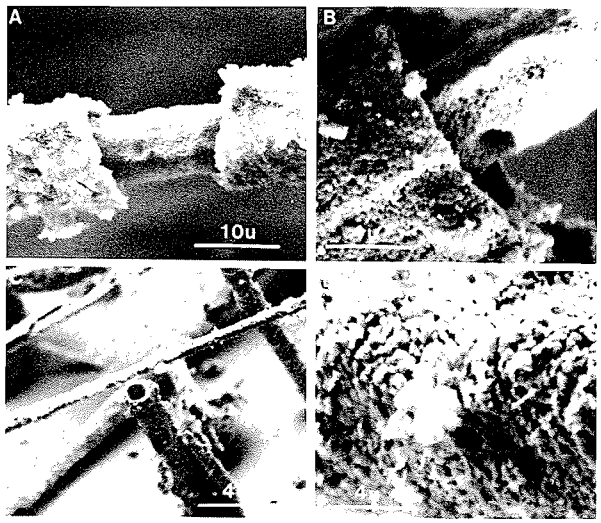

FIG. 3. Scanning electron micrographs of manganese oxide/carbon fibre catalyst after the oxygen/1-butene reaction at 573 K.

appears that the outer sheath and central core of the carbon fibre remain intact, while the radial continuum (16) has been oxidized, Fig. 3*A* and *B*. In many cases, the ends of the fibres seem hollow, Fig. 3*C*, and the fibre surface rough and pitted, Fig. 3*D*. The outer sheath of some fibres may have peeled away.

The manganese oxide particles appeared to be well dispersed on the fibre surface. Their texture resembled that observed for manganese(III) oxide catalysts in similar studies (5). The structure of the manganese oxide/carbon fibre catalyst after the oxygen/ethane reaction at 623 K was very similar to that shown in Fig. 3.

*X-ray photoelectron spectroscopy*

X-ray photoelectron spectra were obtained using Al $K_\alpha$ radiation and a 50 eV electron analyzer pass energy. Spectra were corrected for charging by reference to the C(1*s*) line at 285.0 eV. CHN analysis of pure "Modmor" gave weight percentages of 92.7 carbon, 1.5 hydrogen, 5.8 nitrogen, and 1.5 oxygen (by difference), while XPS indicated surface atomic percentages of 78 carbon, 3 nitrogen, 14 oxygen, 1 sodium, 3 sulphur, and 1 calcium. The presence of the surface impurities sodium, sulphur, and calcium indicated by XPS are difficult to rationalize and it should be noted that neither sulphur nor calcium was detected on the manganese oxide/carbon fibre catalyst after reaction.

Atomic percentages determined after the oxygen/ethane reaction at 623 K were 53 carbon, 33 oxygen, 10 manganese, and 4 sodium. After catalysis of the oxygen/1-butene reaction at 523 K, the catalyst surface contained 48% carbon, 36% oxygen, 11% manganese, and 5% sodium. The O(1*s*) spectra gave a binding energy of 529.0 eV on all samples; the Mn($2p_{3/2}$), a binding energy of 641.0 eV; the Na(1*s*), 1071 eV; and the N(1*s*) spectra on pure "Modmor" gave 400.5 eV.

The oxygen binding energy is close to that expected in metal oxides and significantly less than that usually characteristic of molecular oxygen. Although it is difficult to distinguish between manganese(II) and manganese(III) oxide by XPS alone, the spectra resemble those obtained with manganese(III) oxide catalysts (6) when both XRD and chemical analysis confirmed that the oxide was present as manganese(III) oxide in all bulk samples. If it is assumed that all manganese is associated as $Mn_2O_3$ then this accounts for approximately 15% oxygen and leaves remaining the amount of oxygen found on the original fibre surface. In terms of weight percentages, there is 30% manganese on the surface of the fibres, compared with 9.5% based on chemical analysis. This implies that the manganese is concentrated near the surface as was observed by scanning electron microscopy.

## Discussion

The interpretation of kinetic data by the application of the extended Langmuir–Hinshelwood theory to describe possible surface mechanisms has been discussed (17–19) and the limitations inherent in methods of deriving mechanistic schemes from the correlation of statistical relationships with surface reaction models have been well analyzed (20–23). The approach is applied to the present results as a useful guide to the possible nature of the surface interactions especially when considered in conjunction with the surface analysis data.

Computer analysis of the oxygen and hydrocarbon rate order results gave only one kinetic expression of a Langmuir–Hinshelwood type which could accommodate the data. It was the same for both oxygen/ethane and oxygen/1-butene reactions:

$$[3] \quad r = \frac{kap_{O_2}^{0.5} bp_{HC}^{0.5} (p_{O_2} p_{HC})}{(1 + ap_{O_2}^{0.5} + bp_{HC}^{0.5})^2}$$

where $p_{HC}$ represents appropriately the partial pressure of ethane or 1-butene, while $a$ and $b$ are adsorption coefficients. Plots of $p^{0.5}$ against $(p^{1.5}/r)^{0.5}$ were linear, Fig. 4.

The form of eq. [3] suggests that oxygen and hydrocarbon interact initially as two adsorbed species, each adsorbed possibly on two surface sites as indicated by the square root relationships of partial pressure (24). The $(p_{O_2} p_{HC})$ term indicates

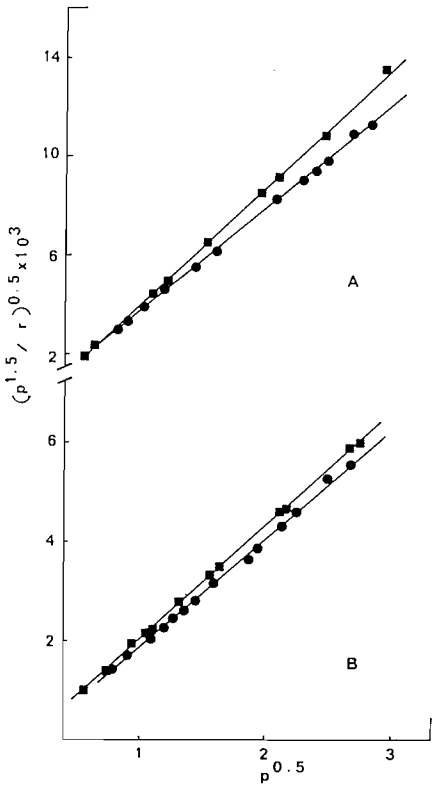

FIG. 4. Reduced plots corresponding to the Langmuir–Hinshelwood expression [3] for oxygen, ■, and hydrocarbon, ●, rate orders in the oxygen/ethane (*A*) and oxygen/1-butene (*B*) reactions over manganese oxide/carbon fibre catalysts.

that both oxygen and hydrocarbon interact in further steps within the complex overall reaction.

Evidence presented by Thomas (25) concerning ethane oxidation over nickel(II) oxide suggests that ethane was adsorbed prior to surface reaction with preadsorbed oxygen. Chemisorption of ethane was thought to involve C—H bond rupture. Yu Yao and Kummer (26) described the rate-determining step in the oxidation of ethane on nickel(II) oxide as involving the formation of a $C_2H_{5(ads)}$ species. This was believed to arise through the adsorption of ethane as $C_2H_5$ or by the interaction of adsorbed oxygen with gas phase or adsorbed ethane with attack at the C—H bond. In the absence of specific evidence regarding the adsorbed intermediates and based upon a Langmuir–Hinshelwood kinetic interpretation, a plausible surface reaction scheme for the oxygen/ethane reaction may be formulated:

[4] $C_2H_6 + 2S = C_2H_{6(ads)}$

[5] $O_2 + [\ ] + C_2H_{6(ads)} \rightarrow C_2H_{5(ads)} + [OOH]$

[6] $C_2H_6 + S + [OOH] \rightarrow C_2H_{5(ads)} + [O] + H_2O$

with additional reactions summarized by:

[7] $2C_2H_{5(ads)} + [O] + 6O_2 \rightarrow 4CO_2 + 5H_2O + [\ ] + 4S$

where S represents a surface site and [ ], a surface anion vacancy.

The square root relationships with respect to ethane and oxygen are rationalized in steps [4] and [5] respectively. Reaction [5] represents the adsorption of oxygen and interaction with adsorbed ethane to produce a surface $C_2H_5$ species. An additional reaction involving ethane is described by step [6] which represents dissociative adsorption. The additional and complex reactions involving oxygen are summarized in [7].

Rate constants derived for the oxygen/ethane reaction over unsupported manganese(III) oxide (6) were approximately sixteen times greater than those found in the present study under similar conditions from 573 to 593 K. The apparent activation energy determined in the earlier work, 130 kJ $mol^{-1}$, was somewhat higher than that here, 108 kJ $mol^{-1}$. Similarly, the pre-exponential factor for the reaction over unsupported manganese(III) oxide was higher, $9.72 \times 10^7$, than that obtained with the supported oxide, $5.42 \times 10^4$. Reaction rate orders with respect to oxygen and ethane were 0.5 and 0.6, respectively, for the oxygen/ethane reaction over manganese(III) oxide at 573 K, and 0.3 and 0.4 for the reaction over the present supported catalyst at 623 K. Comparison of the values for apparent activation energies and pre-exponential factors obtained for ethane oxidation over the two preparations of manganese oxide catalysts shows an isokinetic effect similar in extent to that analyzed for a number of hydrocarbon oxidation reactions over metallic oxides (27). A simple explanation of this would be that the catalytic rate of the oxygen/ethane reaction over unsupported manganese(III) oxide is higher because there are more active sites per unit area for catalysis. It appears also that the adsorption of each reactant may require two surface sites on the supported catalyst, and one only on the unsupported manganese(III) oxide (6).

A similar reaction scheme may be applicable to the oxygen/1-butene reaction:

[8] $C_4H_8 + 2S = C_4H_{8(ads)}$

[9] $O_2 + [\ ] + C_4H_{8(ads)} \rightarrow C_4H_{7(ads)} + [OOH]$

[10] $C_4H_8 + S + [OOH] \rightarrow C_4H_{7(ads)} + [O] + H_2O$

[11] $2C_4H_{7(ads)} + 11O_2 + [O] \rightarrow 8CO_2 + 7H_2O + [\ ] + 4S$

The square root relationships in eq. [3] with respect to 1-butene and oxygen are rationalized in steps [8] and [9], while the influence of the $(p_{O_2}p_{C_4H_8})$ term is apparent from [11] which represents the total

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

stoichiometry of a number of reactions that have not been identified separately. The overall stoichiometry for both the oxygen/ethane and oxygen/1-butene reactions corresponds to that expected for complete hydrocarbon oxidation.

The value obtained for the apparent activation energy in the oxygen/1-butene reaction in the present study was only slightly lower than that determined over unsupported manganese(III) oxide (28), 81 as opposed to 88 kJ $mol^{-1}$. The pre-exponential factor was $2.16 \times 10^4$ for catalysis on the supported oxide and $2.94 \times 10^5$ for unsupported manganese(III) oxide. The activation energy corresponds closely to that found for the complete oxidation of ethane on both palladium (29) and nickel(II) oxide (26), and to that for the oxidation of propane over manganese(IV) oxide (30). Other comparable results may be noted elsewhere including ethylene or benzene oxidation over supported manganese(III) oxide which gave activation energies of 57 kJ $mol^{-1}$ (31) while ethylene oxidation on copper(II) oxide yielded values from 84 to 113 kJ $mol^{-1}$ (32).

The rate-determining step in these reactions may involve C—H bond rupture as has been postulated previously for the oxygen/ethane reaction over various catalysts (6, 25, 26). The present investigation has indicated that carbon fibres may be used as catalyst supports in deep oxidation reactions. Further studies of various impregnation techniques should be carried out with the aim of producing a higher surface area fibre support which is able to maintain mechanical strength and physical properties.

# Osmotic and activity coefficients of triorganophosphates in *n*-octane[1]

NORMAN H. SAGERT AND DANNY W. P. LAU

*Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0*

Received April 19, 1982

NORMAN H. SAGERT and DANNY W. P. LAU. Can. J. Chem. **60**, 2755 (1982).

Vapor pressure osmometry was used to measure osmotic coefficients for tributylphosphate (TBP), tricresylphosphate (TCP), and triethylhexylphosphate (TEHP) in *n*-octane at 30, 40, 50, and 60°C and at molalities up to 0.3 mol/kg. Activity coefficients and excess thermodynamic properties (unsymmetrical definition) were calculated from these osmotic coefficients. At 30°C, the excess Gibbs free energies for 0.1 mol of solute in 1.0 kg *n*-octane were −42 J, −66 J, and −20 J for TBP, TCP, and TEHP, respectively. The more ideal behavior of the TEHP–octane system is attributed to the increasing importance of hydrocarbon–hydrocarbon interactions as the chain length is increased. The excess enthalpies for 0.1 mol of solute in 1.0 kg of solvent were −100 J, −300 J, and −150 J for TBP, TCP, and TEHP, respectively. Thus, association of these solutes arises primarily from entropic effects.

Our data could generally be accommodated adequately by postulating association of monomers into dimers. The exception was TCP at lower temperatures, where more complex models were required.

NORMAN H. SAGERT et DANNY W. P. LAU. Can. J. Chem. **60**, 2755 (1982).

On a utilisé l'osmométrie de la pression de vapeur pour mesurer les coefficients d'osmose des phosphates de tributyle (TBP), de tricrésyle (TCP) et de triéthylhexyle (TEHP) dans le *n*-octane à 30, 40, 50 et 60°C et à des molalités allant jusqu'à 0,3 mol/kg. A partir de ces coefficients d'osmose, on a calculé les coefficients d'activité et les propriétés thermodynamiques en excès (définition non symétrique). A 30°C, les énergies libres de Gibbs en excès pour 0,1 mol de soluté dans 1,0 kg de *n*-octane sont de −42 J, −66 J et −20 J respectivement pour le TBP, le TCP et le TEHP. On attribue le comportement plus idéal du système TEHP–octane à l'importance croissante des interactions hydrocarbure–hydrocarbure avec l'allongement de la chaîne. Les enthalpies en excès pour 0,1 mol de soluté dans 1,0 kg de solvant sont de −100 J, −300 J et −150 J respectivement pour le TBP, le TCP et le TEHP. Ainsi l'association de ces solutés provient principalement des effets d'entropie.

Nos données peuvent généralement s'accomoder de façon adéquate en postulant une association de monomères dans les dimères. Le TCP fait exception à de basses températures où des modèles plus complexes sont nécessaires.

[Traduit par le journal]

## Introduction

The neutral organic phosphates, particularly tributylphosphate (TBP), are used in many solvent extraction processes. In the nuclear industry, such processes are widely used for the reprocessing of irradiated nuclear fuel (1). We have begun a program to study interfacial properties relevant to these solvent extraction systems (2, 3), and thus, we need to know activity coefficients for organic phosphates in various hydrocarbon and aqueous media. The purpose of this work is to measure activity coefficients of three triorganophosphates, TBP, tricresylphosphate (TCP), and triethylhexylphosphate (TEHP), in *n*-octane. Osmotic coefficients of triorganophosphates have been measured previously (4–7), usually at high solute molality. However, data at lower solute molalities were needed for our surface studies. Also, data at lower molalities are useful in determining activities at higher molalities, since the osmotic coefficients must be integrated from zero to the given molality in order to obtain the activity coefficient at that molality.

## Experimental

Osmotic coefficients were measured at 30, 40, 50, and 60°C using a Corona/Wescan Model 232A vapor pressure osmometer. In this apparatus, the steady-state temperature difference is measured between a drop of pure solvent (*n*-octane) and a drop of solution, both drops being maintained in a chamber saturated with pure solvent vapor (8, 9). Thermistors are used as temperature sensors, and the difference in the voltage developed across the two thermistors, $\Delta V$, is measured at a constant bridge current. The operation of this particular instrument is described in detail by Burge (10). To extend the range of the technique to higher solute molalities, solutions whose osmotic coefficients were known were used as both reference solution and vapor-saturating solution. The $\Delta V$'s were obtained relative to these reference solutions (11).

At each of the four temperatures employed, the instrument was calibrated using solutions of *n*-hexadecane in *n*-octane as standards (11). The voltage difference, $\Delta V$, was divided by the *n*-hexadecane molality, $m$, and $\Delta V/m$ was plotted as a function of $m$. Since these solutions are close to ideal (12), straight lines were obtained with small slopes. The value of $\Delta V/m$, extrapolated to zero molality, was taken as the reference value $(\Delta V/m)_r$.

In addition to the measurements in *n*-octane, some measurements of osmotic coefficients were made for TBP in *n*-hexane at 25°C to allow comparison with literature values (4). The calibration procedures were similar to those described above.

The source and purification of TBP have been described (2). TCP was obtained from Applied Sciences Laboratories, TEHP from Chem Service, and *n*-hexadecane was Matheson, Coleman and Bell spectrograde. These solutes were used as received.

*n*-Octane was obtained from Humphries Chemical Co. (99+%) and was distilled in glass. It was dried over molecular sieves before use. *n*-Hexane was from Caledon Chemical Co. It was also distilled in glass and dried. Solutions were made up by volume, and molalities were calculated from measured densities.

## Results and discussion

Osmotic coefficients, $\phi$, for the solutions of triorganophosphates were calculated from eq. [1] (8, 9):

$$[1] \quad \phi = \left(\frac{\Delta V}{m}\right) \Big/ \left(\frac{\Delta V}{m}\right)_r$$

This equation assumes that the practical molal osmotic coefficient, $\phi$, for the reference condition, *n*-hexadecane in *n*-octane extrapolated to infinite dilution, is 1.000. Some typical results[2] for TBP, TEHP, and TCP at 30°C are shown in Fig. 1. Although osmotic coefficients are given to four significant figures to avoid compounding calculation errors, they are accurate only to 0.5% at best. Attempts were made to fit polynomials to the data but, because of the scatter, the fits had inflexions and thus were not satisfactory. Hence the practical molal osmotic coefficients were fitted using a simple rational function, eq. [2].

$$[2] \quad \phi = \frac{1 + A_1 m}{1 + A_2 m}$$

Table 1 lists the constants obtained from such fits using a non-linear least-squares fitting routine based on the algorithm of Brown and Dennis (13) (Chalk River Nuclear Laboratories Program MLSQQ). The errors reported in Table 1 are the standard deviations of the parameters. The solid lines in Fig. 1 were obtained from the constants listed in Table 1. From eq. [2], it is apparent that this equation predicts that practical molal osmotic coefficients will vary linearly with molality for very dilute solutions, i.e., $d\phi/dm \rightarrow A_1 - A_2$ as $m \rightarrow 0$. Thus, this rational function predicts the same limiting behavior as the more conventional polynomial fit (8, 9).

The molal activity coefficients of the solute, $\gamma_2$, were calculated using Bjerrum's relation (14), eq. [3], where $\gamma_2$ is that activity coefficient which approaches 1.0 at zero solute molality.

$$[3] \quad d[(1 - \phi)m] + m \, d \ln \gamma_2 = 0$$

When the Bjerrum expression is combined with eq. [2], an expression for the activity coefficient, eq. [4], is obtained.

[2]All the measured osmotic coefficients are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

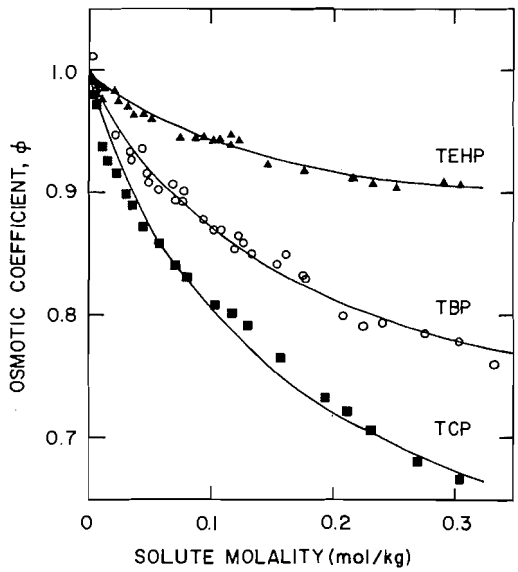

FIG. 1. Osmotic coefficients for TBP (○), TEHP (▲), and TCP (■) at 30°C plotted against solute molality. The lines are fitted using eq. [2] and the constants of Table 2.

$$[4] \quad \ln \gamma_2 = \frac{A_1 - A_2}{A_2}\left[\left\{\ln (1 + A_2 m)\right\} + \left\{\frac{A_2 m}{1 + A_2 m}\right\}\right]$$

If desired, solvent activity can be calculated using eq. [5] (8).

$$[5] \quad \ln X_1 f_1 = -\frac{m M_1 \phi}{1000}$$

where $X_1$ is the mole fraction, $f_1$ the mole fraction activity coefficient, and $M_1$ is the molecular weight of the solvent.

One framework for discussing activity coefficients is in terms of the total excess thermodynamic functions: the total excess Gibbs free energy, $G^{ex}$, the total excess enthalpy, $H^{ex}$, and the total excess entropy, $S^{ex}$, per kg of solvent (15). Expressions for these quantities, applicable for the dilute solutions used here, are given by eqs. [6], [7], and [8] (15).

$$[6] \quad G^{ex} = mRT(1 - \phi + \ln \gamma_2)$$

$$[7] \quad H^{ex} = \partial(G^{ex}/T)/\partial(1/T)$$

$$[8] \quad TS^{ex} = H^{ex} - G^{ex}$$

Total excess Gibbs free energies, $G^{ex}$, calculated from the fitted lines shown in Fig. 1, are given in Fig. 2. The TEHP–*n*-octane system is the most ideal of the three, giving the least negative values of $G^{ex}$; the TBP–*n*-octane system is intermediate, and the TCP–*n*-octane system is the least ideal, with the most negative values of $G^{ex}$. The standard states used here are such that deviations from

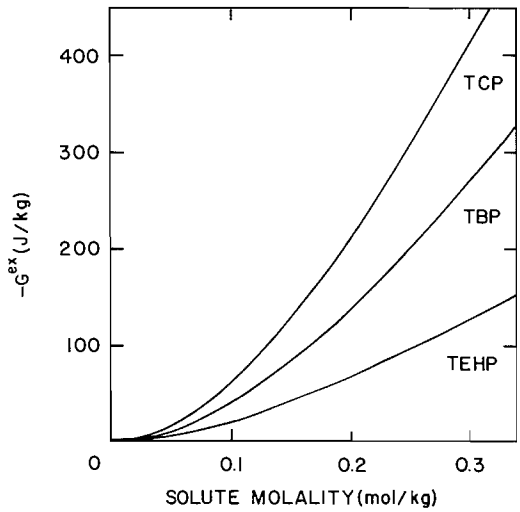

FIG. 2. Total excess Gibbs free energies for TCP, TBP, and TEHP at 30°C calculated from the fitted lines in Fig. 1.

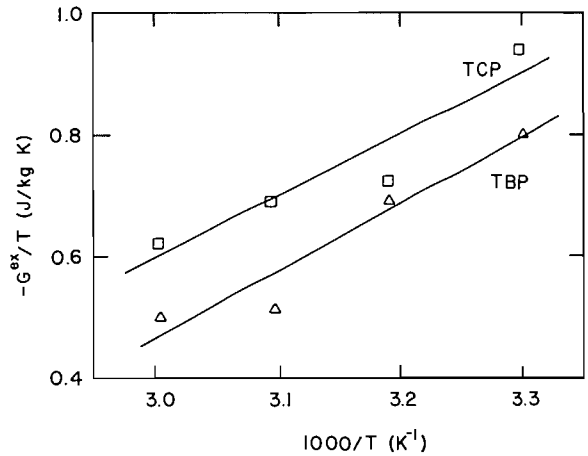

FIG. 3. Determination of total excess enthalpies using a plot suggested by eq. [7]. The results shown are for TCP (□) and TBP (△), both at 0.25 mol/kg.

ideality are essentially a measure of solute–solute interactions. Thus solute–solute interactions in *n*-octane are in the order TEHP < TBP < TCP. Apelblat (7) has also found that TEHP forms more ideal solutions in hydrocarbons than does TBP. He feels that self-association of the phosphate groups is balanced by thermal–athermal effects resulting from steric hindrance caused by the side chains of the hydrocarbon group, and that hydrocarbon–hydrocarbon interactions will become more important as the hydrocarbon chain length increases. Apparently, with TCP, solute–solute interactions are greater than with TBP. These interactions probably arise from interactions of the phosphate group with the π-bonding system of the cresyl groups. Such interactions have been postulated previously between TBP and benzene (16, 17). Direct dipole–dipole interactions are probably no larger than for TBP since the dipole moment for tritolylphosphate is smaller than that for TBP, at least in carbon tetrachloride (18).

Figure 3 shows the total excess Gibbs free energies for TBP and TCP, measured at different temperatures, plotted in the form suggested by eq. [7] so as to obtain the total excess enthalpy. These enthalpies were not determined very accurately because the temperature variation of $\phi$ was not large compared to the experimental error. Our estimates of the total excess Gibbs free energies, enthalpies, and entropies at 30°C are shown in Table 2. In all cases, the total excess enthalpies are much more negative than the total excess Gibbs free energies. Thus, a balance between entropic processes and enthalpic processes appears to control the deviations from ideality in these systems.

TABLE 2. Total excess thermodynamic functions for triorganophosphates in *n*-octane at 30°C

| Solute | Molality (mol/kg) | $G^{ex}$ (J/kg) | $H^{ex}$ (J/kg) | $S^{ex}$ (J/(K kg)) |
|---|---|---|---|---|
| TBP | 0.10 | −42.2 | −100 | −0.2 |
| | 0.25 | −243 | −1100 | −2.8 |
| TEHP | 0.10 | −20.3 | −150 | −0.4 |
| | 0.25 | −93.9 | −650 | −1.8 |
| TCP | 0.10 | −66.0 | −300 | −0.8 |
| | 0.25 | −287 | −1000 | −2.4 |

The use of Bjerrum's relationship implies that the standard states used are those of unit activity coefficient for an infinitely dilute solution of the solute in *n*-octane. This is the standard state commonly used for electrolyte solutions, as distinct from the standard state of unit activity for the pure component usually used for non-electrolyte solutions (19). Thus, our activity coefficients measure deviations from the proportionality of activity to mole fraction (or molality for dilute solutions) of solute, i.e., from Henry's law. However, they do not give any information about the Henry's law constants themselves. It is necessary to know the Henry's law constants to convert from the activity coefficients measured here to those normally reported for non-electrolyte solutions (19). Generally these constants are not available for the systems considered here. However, Rozen *et al.* (4) have measured activity coefficients for TBP in *n*-hexane at 25°C by the solvent vapor-pressure method. They were not able to consider solutions more dilute than 0.05 mole fraction (0.58 molal), but were able to deduce an activity of 4.36 for TBP when infinitely dilute in *n*-hexane, based on a standard state of unit activity for pure liquid TBP. Using this value, our activity coefficients for TBP in *n*-hexane can be compared with those of Rozen *et al.* (4), and such a comparison is shown in Fig. 4. Our results help to close the gap between zero molality and the values of Rozen *et al.*, and show reasonable agreement with them.

An entirely different way of treating the observed non-idealities is to assume that they are entirely accounted for by agglomeration of solute molecules and that the individual species behave in a totally ideal way. A number of different treatments are possible. One such treatment is to assume that agglomeration stops with the formation of dimers (20). For the systems studied here, this assumption is not unreasonable, as the chief solute–solute interaction is expected to be dipole–dipole attraction (4, 21, 22). Agglomeration into dimers leads to eq. [9] (19).

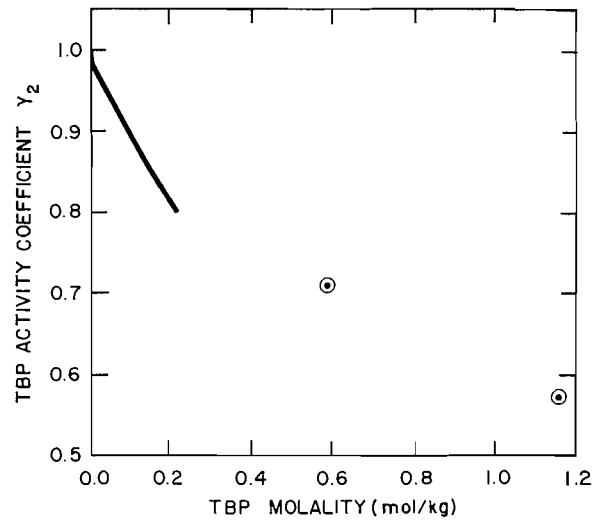

FIG. 4. Activity coefficients for TBP in *n*-hexane at 25°C. The solid line represents our fitted data and the circles (⊙) are calculated from the data of Rozen *et al.* (4).

$$[9] \quad \frac{1}{\phi} = 1 + K_2 \frac{(2\phi - 1)^2 m}{\phi}$$

where $K_2$ is the equilibrium constant for dimerization. Good fits of the experimented data for TBP and TEHP were obtained, and the dimerization constants are shown in Fig. 5 as a function of reciprocal temperature. These dimerization constants and the association constants given below are probably good to ±10%. The values for TBP dimerization constants compare well with the value of 2.9 in hexane (23) and 2.6 and 2.5 in dodecane and cyclohexane (24), all at 22°C, as measured by Petkoviç. The slopes of the lines in Fig. 5 correspond to standard enthalpies of dimerization of −27.5 and −28.4 kJ/mol for TBP and TEHP, respectively. For TCP, the monomer–dimer model did not fit the data at the lower temperatures, although it did give reasonable fits at 50 and 60°C ($r$ = 0.93 and 0.97, respectively). The two valid dimerization constants are shown in Fig. 5.

Another frequently used model (8) is that of a monomer forming a multimer by some scheme. One of these schemes is step-wise addition with equal equilibrium constants for the addition of each monomer unit. For this, eq. [10] holds (8, 19),

$$[10] \quad \frac{1}{\phi} = 1 + K_n \phi m$$

where $K_n$ is the equilibrium constant for the addition of each monomer unit. The fits of data are acceptable, although, for TBP in particular, intercepts were larger than with eq. [9]. The values of

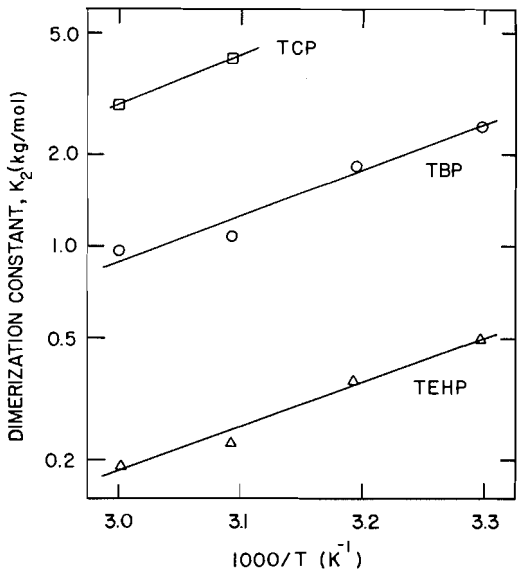

FIG. 5. Dimerization constants calculated from fits to eq. [9] for TCP (□), TBP (○), and TEHP (△), plotted against the reciprocal of the absolute temperature.

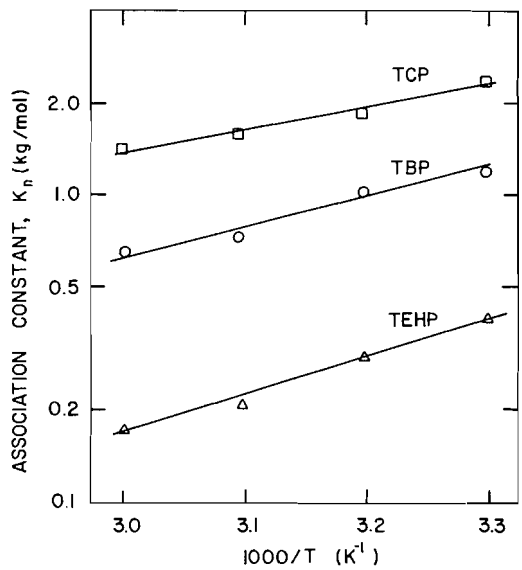

FIG. 6. Step-wise association constants calculated from fits to eq. [10] for TCP (□), TBP (○), and TEHP (△) plotted against the reciprocal of the absolute temperature.

$K_n$ are plotted in Fig. 6 as a function of reciprocal temperature. The standard enthalpies for addition of monomer segments are −13.9, −17.5, and −24.0 kJ/mol for TCP, TBP, and TEHP, respectively.

More complex treatments of association data are available (25), but they are probably not warranted for our data. Our data fit best a monomer–dimer association model for TBP and TEHP, and for TCP at higher temperatures. Thus, they give support to such a model. This is gratifying since there is evidence in the literature that neutral organic phosphates do not form aggregates higher than dimers (4, 21, 22). However, our data clearly do not support a monomer–dimer model for TCP at lower temperatures, and some form of extended aggregation is postulated.

# Synthesis and Diels–Alder reactions of (*E*)-6,6-dimethoxy-3-hexen-2-one

PETER YATES AND STEPHEN PAUL DOUGLAS
*Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1*

Received February 2, 1982

PETER YATES and STEPHEN PAUL DOUGLAS. Can. J. Chem. **60**, 2760 (1982).

Treatment of 3,3-dimethoxypropanal (**2**) with (acetylmethylene)triphenylphosphorane (**4**) gives (*E*)-6,6-dimethoxy-3-hexen-2-one (**5**). Reaction of **5** with cyclopentadiene, 1,3-cyclohexadiene, anthracene, and 1,3-diphenylisobenzofuran gives Diels–Alder adducts, which on hydrolysis are converted to the corresponding keto aldehydes. Attempts to effect intramolecular aldol condensation of the latter were unsuccessful. Hydrolysis of the *exo*-acetyl adduct from 1,3-diphenylisobenzofuran with aqueous formic acid gives 4-acetyl-2,3,3a,4,5,9b-hexahydro-5,9b-diphenylnaphtho[1,2-*b*]furan-2,5-diol, via aldehyde formation and hydrolytic cleavage of the ether bridge. The adducts from cyclopentadiene under anhydrous acid conditions give 3-acetyl-9-methoxytetracyclo[4.3.0.0$^{2,4}$.0$^{3,7}$]nonane (**27**).

PETER YATES et STEPHEN PAUL DOUGLAS. Can. J. Chem. **60**, 2760 (1982).

Le diméthoxy-3,3 propanal (**2**) réagit avec l'(acétylméthylène) triphénylphosphorane (**4**) en donnant la (*E*)-diméthoxy-6,6 hexène-3 one-2 (**5**). Le composé **5** réagit avec le cyclopentadiène, le cyclohexadiène-1,3, l'anthracène et le diphényl-1,3 isobenzofuranne en donnant des adduits de Diels Alder qui, par hydrolyse, donnent les céto aldéhydes correspondants. On a essayé vainement de réaliser une condensation aldolique intramoléculaire avec ces cétoaldéhydes. L'hydrolyse de l'adduit *exo*-acétyl provenant du diphényl-1,3 isobenzofuranne, avec l'acide formique aqueux, donne l'acétyl-4 hexahydro-2,3,3a,4,5,9b diphényl-5,9b naptho[1,2-*b*]furannediol-2,5 par l'intermédiaire de la formation de l'aldéhyde et du clivage, par hydrolyse, du pont éther. Les adduits provenant du cyclopentadiène dans un milieu acide anhydre donnent l'acétyl-3 méthoxy-9 tétracyclo[4.3.0.0$^{2,4}$.0$^{3,7}$]nonane (**27**).

[Traduit par le journal]

Shakespeare said of Cleopatra "Age cannot wither her, nor custom stale Her infinite variety." The same could be said of the Diels–Alder reaction. In recent years the scope of this reaction has been greatly expanded by the utilization of a large variety of dienes and dienophiles. We report here on the synthesis and Diels–Alder reactions of the dienophile 6,6-dimethoxy-3-hexen-2-one. We have shown that this can serve, via hydrolysis of its Diels–Alder adducts, as an equivalent of the dienophile 3-hexene-2,6-dione, but we have not been successful in effecting the intramolecular aldol condensation of the keto aldehydes resulting from such hydrolyses, which would have permitted its use as an equivalent of the dienophile 2,5-cyclohexadienone.

Base-catalyzed addition of two equivalents of methanol to propiolaldehyde (**1**) (1) gave β,β-dimethoxypropionaldehyde (**2**) (2), containing 10% of β-methoxyacrolein (**3**) as shown by $^1$H nmr spectroscopy. This mixture was treated with (acetylmethylene)triphenylphosphorane (**4**) to give 6,6-dimethoxy-3-hexen-2-one (**5**) (Scheme 1). No effort was devoted to removal of **3** from the original mixture since it was anticipated that it would be unreactive in a Wittig reaction with **4** because of electron donation to the aldehyde group by the methoxyl group. This was indeed found to be the case in that only the enone **5** was formed in the reaction of the mixture of compounds **2** and **3** with the Wittig reagent **4** and that **3** (2) alone failed to react with **4**.

The ir spectrum of **5** showed a strong band at 5.95 μm and a medium band at 6.12 μm in accord with the presence of an α,β-unsaturated ketonic system; a strong band at 10.25 μm suggested that the product has the *trans* (*E*) configuration as in **5** (3). In its $^1$H nmr spectrum the olefinic proton signals appear as a doublet at δ 6.02 ($J$ = 15 Hz) and a doublet of triplets at δ 6.63 ppm ($J$ = 15 and 7.5 Hz); the magnitude of the larger coupling constant established that the product has the *trans* (*E*) configuration. The uv spectrum of **5** ($\lambda_{max}$ (pentane) 216 nm (ε 9500), 321 nm (ε 35)) is in accord with the presence of a monosubstituted α,β-unsaturated ketonic function. In its $^{13}$C nmr spectrum the α and β ethylenic carbon signals occur at δ 133.6 and 142.3 ppm, respectively (cf. the corresponding signals in 3-buten-2-one at δ 138.5 and 129.3 ppm).

Reaction of **5** with a large excess of cyclopentadiene at 100–110°C in the absence of solvent for three days gave a 55:45 mixture of the stereoisomeric Diels–Alder adducts **6** and **7** (Scheme 2) in almost quantitative yield. Individual assignments of structure to the *endo* and *exo* isomers[1] were made from their $^1$H nmr spectra on the basis of decoupling experiments and the following earlier

[1]The designations *endo* and *exo* are made with reference to the acetyl group.

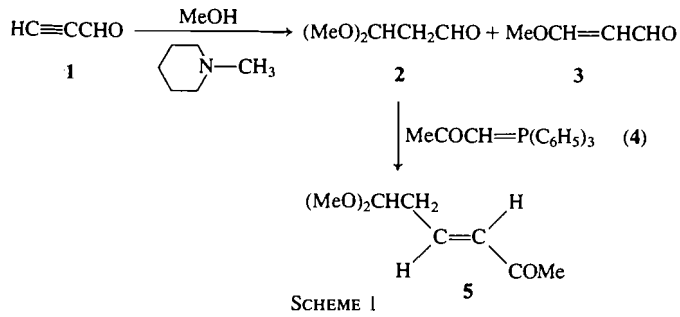

SCHEME 1

observations regarding the spectra of bicyclo-[2.2.1]heptenes: (*i*) signals of *exo* protons and the protons of *exo* substituents appear downfield relative to those of the corresponding *endo* protons (4) and (*ii*) electron-withdrawing *endo* substituents deshield the bridgehead (5) and often shield the olefinic protons nearest to them (6). Thus under the reaction conditions used there is a slight preference for formation of the *endo* adduct. It is probable that under these conditions the reaction is under kinetic control (7) and the modest stereoselectivity is analogous to that observed in the cases of other simple α,β-unsaturated carbonyl compounds under such circumstances (7, 8). Hydrolysis of **6** with 1.2 *N* hydrochloric acid in tetrahydrofuran gave the keto aldehyde **8** (Scheme 2) whose ir spectrum showed strong bands at 5.81 and 5.85 μm.

Reaction of **5** with 1,3-cyclohexadiene at 100–120°C yielded the adducts **9** and **10** (Scheme 2). The individual stereochemical assignments are again based on their $^1$H nmr spectra, since bicyclo[2.2.2]-octenes have been observed to exhibit the same downfield shift of the signals of *exo* relative to *endo* protons as in the case of bicyclo[2.2.1]heptenes (4, 6). Again the *endo* isomer was formed in slight preponderance. Hydrolysis of this isomer gave the keto aldehyde **11**, whose ir spectrum showed strong bands at 5.80 and 5.85 μm.

Cycloaddition of **5** to anthracene was best effected with an excess of the dienophile at 150°C (reaction did not occur at 120°C). Adduct **12** (Scheme 3) was thus obtained in 77% yield (based on anthracene). This product was hydrolyzed to the keto aldehyde **13**.

The Diels–Alder reaction of **5** with 1,3-diphenylisobenzofuran was carried out in boiling benzene. After 3 days, reaction was complete to give a mixture of the *exo* (**14**) and *endo* (**15**) adducts in a 4:1 ratio (Scheme 4). Individual assignments of stereochemistry were made on the basis of a comparison of the $^1$H nmr spectra of the adducts, since it has previously been shown that in systems of this type *endo* protons again are shielded relative to *exo* protons (9, 10). The carbonyl-stretching

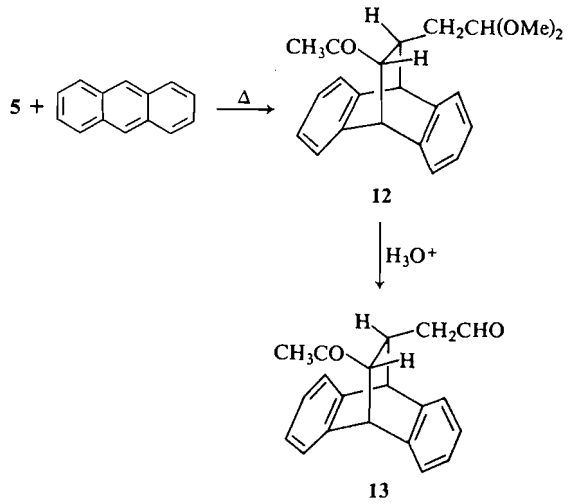
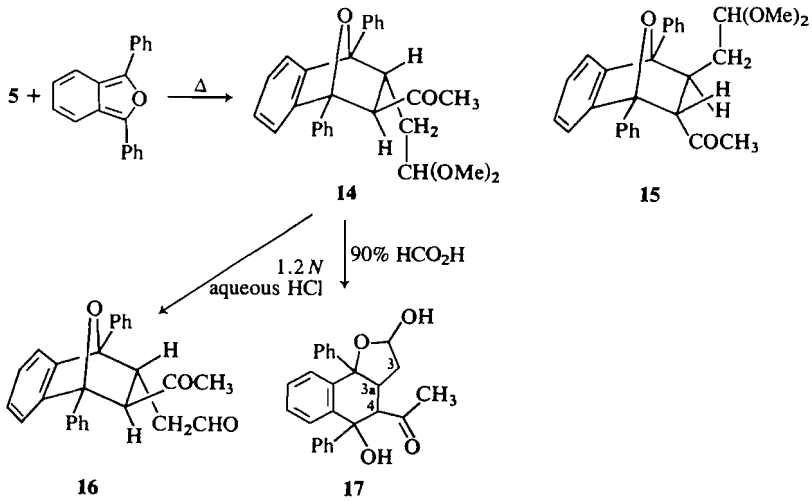


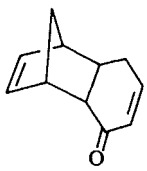
SCHEME 3

bands in the ir spectra of **14** and **15** occur at unusually long wavelength (5.92 μm); this may be the result of interaction of the carbonyl group with a methoxyl group or the phenyl substituent at the adjacent bridgehead position. Hydrolysis of **14** with 1.2 *N* hydrochloric acid in tetrahydrofuran gave the expected keto aldehyde **16**, but the reaction was capricious; in some runs the product underwent further reaction and in others hydrolysis was incomplete. Treatment with aqueous 90% formic acid (11) led to hydrolysis of both the acetal and ether bridge functions, giving hemiacetal **17** in high yield. In the $^1$H spectrum of **17** the large coupling constant ($J$ = 12 Hz) between H-4 and H-3a is attributable to a *trans* diaxial relationship between these protons, and the further coupling of H-3a with only one of the H-3 protons can be interpreted in terms of the preferred conformation of the hemiacetal ring. As in the case of **15** the carbonyl-stretching band in the ir spectrum of **17** occurs at an unusually long wavelength (5.95 μm): here the major contributing factor is probably hydrogen-bonding of the carbonyl group with the adjacent hydroxyl group. Such hydrogen bonding is also evidenced by the relatively low field position (δ 4.63) of the signal of the tertiary hydroxyl proton in the $^1$H nmr spectrum of **17**.

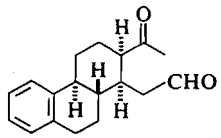
It was hoped that the keto aldehydes of type **8** could be induced to undergo intramolecular aldol condensation to give cyclohexenones of type **18**, products that are formally derived from Diels–Alder reactions of 2,5-cyclohexadienone. An analogous condensation was observed by Johns (12) on treatment of the keto aldehyde **19** with alcoholic potassium hydroxide. It was recognized that compounds of type **8** differ from **19** in having a *trans* rather than a *cis* relationship between the acetyl and acetaldehyde groups, and although Valenta and co-workers (13) have observed the aldol condensation in basic medium of the *trans* isomer **20** to give a cycloheptenone, there appears to have been no report of the closure of a six-membered ring in the *trans* series. It was considered that under the basic (or acidic) conditions of the aldol reaction equilibration of the *trans* compounds of type **8** would occur with their *cis* isomers via epimerization at the carbon atom bearing the acetyl group and that these isomers would then undergo the aldol reaction. However, no simple aldol condensation products could be detected when compounds of type **8** were subjected to a variety of basic conditions analogous to those used in the cases of **19** and **20** (12, 13) and related cases (14); only starting



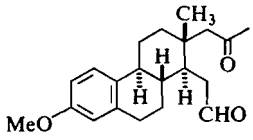
SCHEME 4



18



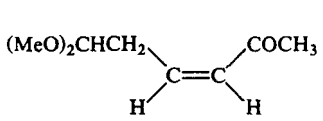
19



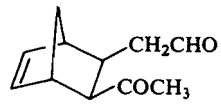
20

material or polymeric products were isolated in each case. Attempts at acid-catalyzed cyclization (15) were also of no avail.

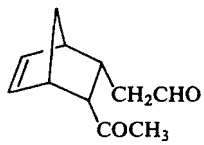
In case these results were due to the failure of the keto aldehydes of type **8** to undergo equilibration with their *cis* isomers, a preliminary investigation was made of the direct synthesis of such an isomer. Ultraviolet irradiation of **5** in benzene gave a ~ 1:1 mixture of **5** and its *cis* isomer, **21**, as shown by its $^1$H nmr spectrum. Reaction of this mixture with cyclopentadiene followed by hydrolysis gave a mixture whose $^1$H nmr spectrum indicated that it consisted of the *cis* isomers **22** and **23** together with



21



22

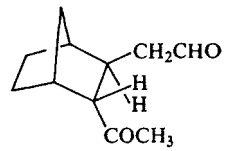


23

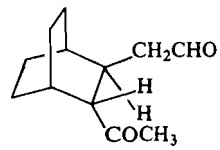
**8** and the other *trans* keto aldehyde. However, treatment of this mixture under several of the aldol conditions referred to above resulted only in the epimerization of the *cis* to the *trans* keto aldehydes.

In case the failure of the cyclization reactions was associated with the presence of the ethylenic double bond in compounds of type **8**, compounds **6** and **9** were hydrogenated and hydrolyzed to give **24** and **25**, respectively. But again aldol condensation could not be effected.

An attempt was also made to effect cyclization of a mixture of the keto acetals **6** and **7** under acidic conditions to give a product of type **26**. However, treatment of the mixture with *p*-toluenesulfonic acid in benzene gave compound **27** and a product that is tentatively assigned structure **28**, together with polymeric products (Scheme 5). The $^1$H nmr spectra of **27** and **28** showed that each retained a single methoxyl group. The ir spectrum of **27** showed a carbonyl-stretching band at 5.90 μm, indicating conjugation of the acetyl group with an ethylenic double bond or cyclopropyl group. That the latter is the case was established by the $^{13}$C nmr spectrum of **27**, which showed no olefinic carbon signals. Compounds **27** and **28** are considered to



24



25

arise from the *exo* keto acetal **7** by the routes shown in Scheme 5.

## Experimental

Melting points were determined with a Thomas–Hoover capillary melting point apparatus, and are uncorrected. Infrared spectra were taken in $CHCl_3$ solution; band intensities are strong, unless designated as medium (m) or weak (w). Proton and carbon-13 nuclear magnetic resonance ($^1$H and $^{13}$C nmr) spectra were taken in $CDCl_3$ solution. Unless otherwise stated, solutions in organic solvents were dried over anhydrous $MgSO_4$ and concentrated by means of a Buchi "Rotovapor ⟨R⟩" rotary evaporator.

*(E)-6,6-Dimethoxy-3-hexen-2-one (5)*

Propargyl alcohol was oxidized to propiolaldehyde (**1**) with chromic acid (1) in 45% yield; bp 58–60°C (lit. (1) bp 59–61°C); ir $\lambda_{max}$: 3.53 (w), 4.78 (w), 5.96 μm; $^1$H nmr δ: 9.17 (s, 1H), 3.58 (s, 1H). Base-catalyzed addition of two molar equivalents of methanol to the aldehyde (2) gave β,β-dimethoxypropionaldehyde (**2**) in 80% yield; ir $\lambda_{max}$: 3.59 (w), 5.82 μm; $^1$H nmr δ: 2.70 (m, 2H), 3.40 (s, 6H), 4.83 (t, $J$ = 5 Hz, 1H), 9.73 (t, $J$ = 2 Hz, 1H). The crude product, which contained 10% of β-methoxyacrolein (**3**) (2) as shown by $^1$H nmr spectroscopy, was used without further purification.

A solution of aldehyde **2** (23.76 g, 201 mmol) and (acetylmethylene)triphenylphosphorane (**4**) (16) (64.1 g, 201 mmol) in anhydrous tetrahydrofuran (250 mL) was boiled under reflux for 5 days under a constant positive pressure of nitrogen. The solution was concentrated and the precipitated triphenylphosphine oxide was separated by suction filtration and washed with cold benzene. The combined filtrate and washings were concentrated, the concentrate was cooled to −78°C, and a second crop of triphenylphosphine oxide was removed. Concentration of the filtrate followed by flash distillation (100°C, 0.05 Torr) of the residue gave **5** as a colorless liquid (26.44 g, 83%), bp 51–53°C (0.05 Torr); ir $\lambda_{max}$: 5.93, 6.12 (m), 7.35 (w) μm; uv $\lambda_{max}$ (ε) (pentane): 216 (9 500), 321 (35) nm; $^1$H nmr δ: 2.22 (s, 3H), 2.53 (m, 2H), 3.37 (s, 6H), 4.43 (t, $J$ = 6 Hz, 1H), 6.02 (d, $J$ = 15 Hz, 1H), 6.68 (dt, $J$ = 7.5 Hz, 15 Hz, 1H); $^{13}$C nmr δ: 26.8 (q), 36.2 (t), 53.2 (q), 103.1 (d), 133.6 (d), 142.3 (d), 198.05 (s). *Anal.* calcd. for $C_8H_{14}O_3$: C 60.74, H 8.92; found: C 60.49, H 8.87.

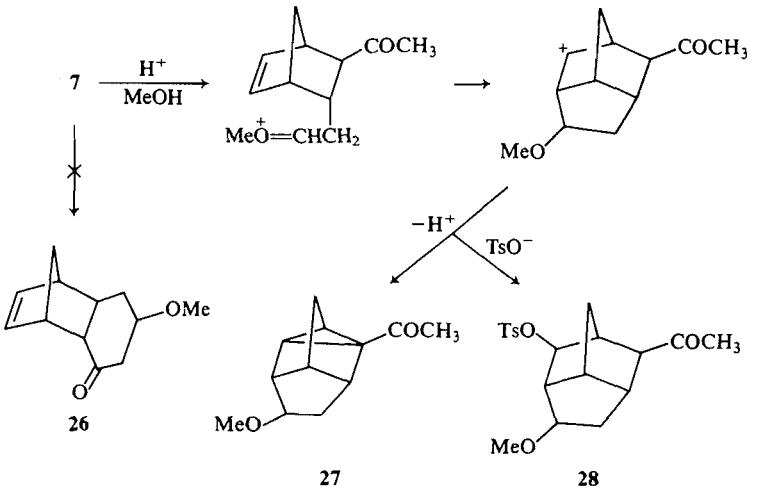

SCHEME 5

*Diels–Alder reaction of 5 with cyclopentadiene. Formation of* endo-*5-acetyl*-exo-*6-(2,2-dimethoxyethyl)bicyclo[2.2.1]-hept-2-ene (6) and* exo-*5-acetyl*-endo-*6-(2,2-dimethoxy-ethyl)bicyclo[2.2.1]hept-2-ene (7)*

Compound **5** (1.00 g, 6.32 mmol) and 1,3-cyclopentadiene (6.6 g, 100 mmol) were placed in a Carius tube (15 × 20 × 250 mm) and the tube was cooled (−196°C), sealed, and heated for 3 days at 110–120°C. The tube was cooled and opened and the contents were subjected to high vacuum pumping (0.01 Torr) at room temperature to remove most of the dimerized diene. Chromatography (silica gel, 7:3 hexane and ethyl acetate) afforded adducts **6** and **7** (total 1.37 g, 97%); the *endo*-acetyl isomer **6** had the longer retention time and comprised 57% of the mixture. Compound **7**: ir $\lambda_{max}$: 5.86 μm; $^1$H nmr δ: 1.50 (m, 2H), 1.85 (m, 2H), 2.05 (m, 1H), 2.10 (s, 3H), 2.60 (m, 2H), 3.16 (m, 1H), 3.27 (s, 3H), 3.30 (s, 3H), 4.35 (t, $J$ = 5 Hz, 1H), 5.83 (m, 1H), 6.20 (m, 1H). Compound **6**: ir $\lambda_{max}$: 5.86 μm; $^1$H nmr δ: 1.42 (m, 2H), 1.55 (m, 2H), 2.02 (m, 1H), 2.23 (s, 3H), 2.50 (m, 1H), 2.88 (m, 2H), 3.30 (s, 6H), 4.31 (t, $J$ = 5 Hz, 1H), 6.18 (m, 2H); $^{13}$C nmr δ: 28.4 (q), 36.6 (d), 38.2 (t), 45.9 (d), 46.4 (t), 47.2 (d), 52.3 (q), 59.3 (d), 103.9 (d), 131.6 (d), 137.9 (d), 207.5 (s). *Anal.* calcd. for $C_{13}H_{20}O_3$: C 69.61, H 8.98; found: C 69.25, H 8.89.

*Diels–Alder reaction of 5 with 1,3-cyclohexadiene. Formation of* endo-*5-acetyl*-exo-*6-(2,2-dimethoxyethyl)bicyclo-[2.2.2]oct-2-ene (9) and* exo-*5-acetyl*-endo-*6-(2,2-dimethoxyethyl)bicyclo[2.2.2]oct-2-ene (10)*

Compound **5** (1.00 g, 6.32 mmol) and 1,3-cyclohexadiene (6.6 g, 100 mmol) were heated in a Carius tube as described above. High vacuum pumping (0.01 Torr) at 35–40°C removed most of the dimerized diene and chromatography (silica gel, 6:4 cyclohexane and ethyl acetate) of the residue afforded the *endo* and *exo* stereoisomers **9** and **10** (1.02 g, 68%); the *endo* acetyl adduct (60% of the mixture) had the longer retention time. Compound **10**: ir $\lambda_{max}$: 5.85 μm; $^1$H nmr δ: 1.05–1.09 (m, 7H), 1.9–2.5 (m, 3H), 2.19 (s, 3H), 3.22 (s, 6H), 4.25 (t, $J$ = 5 Hz, 1H), 6.00 (m, 2H). Compound **9**: ir $\lambda_{max}$: 5.85 μm; $^1$H nmr δ: 1.05–1.09 (m, 7H), 1.9–2.5 (m, 2H), 2.12 (s, 3H), 2.78 (m, 1H), 3.23 (s, 3H), 3.28 (s, 3H), 4.29 (t, $J$ = 5 Hz, 1H), 6.14 (m, 2H); $^{13}$C nmr δ: 18.4 (t), 26.4 (t), 28.3 (q), 33.2 (d), 34.5 (d), 37.7 (t), 52.6 (q), 53.1 (q), 58.8 (d), 104.4 (d), 129.9 (d), 136.6 (d), 209.3 (s). *Anal.* calcd. for $C_{14}H_{22}O_3$: C 70.56, H 9.30; found: C 70.76, H 9.21.

*Diels–Alder reaction of 5 with anthracene. Formation of* trans-*7-acetyl-8-(2,2-dimethoxyethyl)dibenzobicyclo-[2.2.2]octadiene (12)*

Compound **5** (1.35 g, 8.54 mmol) and anthracene (1.01 g, 5.68 mmol) were heated in a Carius tube at 150°C for 5 days. High vacuum pumping (0.01 Torr) at 50°C followed by elution through a silica gel column (30 × 2 cm) with 70% hexane in ethyl acetate afforded the adduct **12** (1.48 g, 77% based on consumed anthracene) as a viscous oil; ir $\lambda_{max}$: 5.83 μm; $^1$H nmr δ: 1.50 (m, 3H), 2.07 (s, 3H), 2.42 (m, 1H), 3.19 (s, 3H), 3.25 (s, 3H), 4.12 (m, 1H), 4.35 (m, 1H), 4.44 (m, 1H), 7.10 (m, 8H); $^{13}$C nmr δ: 28.5 (q), 37.1 (d), 38.7 (t), 47.4 (d), 49.4 (d), 52.5 (q), 53.1 (q), 60.2 (d), 103.8 (d), 126.3–123.1 (7 signals), 139.2 (s), 141.05 (s), 142.5 (s), 143.8 (s), 207.1 (s). *Anal.* calcd. for $C_{22}H_{24}O_3$: C 78.54, H 7.19; found: C 78.56, H 7.44.

*Diels–Alder reaction of 5 with 1,3-diphenylisobenzofuran. Formation of* exo-*2-acetyl-1,2,3,4-tetrahydro*-endo-*3-(2,2-dimethoxyethyl)-1,4-epoxynaphthalene (14) and* endo-*2-acetyl-1,2,3,4-tetrahydro*-exo-*3-(2,2-dimethoxyethyl)-1,4-epoxynaphthalene (15)*

Compound **5** (1.00 g, 6.32 mmol) and 1,3-diphenylisobenzofuran (1.70 g, 6.30 mmol) were heated in boiling benzene (20 mL) for 72 h. The solvent was removed and the oily residue was crystallized from hexane – ethyl acetate to give the *exo*-acetyl isomer **14** (2.01 g, 74%), mp 103–105°C. The mother liquor contained the *endo*-acetyl isomer **15** together with a small amount of **14**. Compound **15**: ir $\lambda_{max}$: 5.92, 6.23 (w) μm; $^1$H nmr δ: 1.70 (s, 3H), 1.45–2.2 (m, 2H), 2.80 (m, 1H), 3.17 (s, 6H), 3.70 (m, 1H), 4.25 (m, 1H), 7.40 (m, 14H). room temperature for ca. 10 h. Addition of water (10 mL) followed by extraction with dichloromethane (3 × 5 mL), washing of the extract with aqueous 5% sodium bicarbonate, drying, and removal of the solvent gave the keto aldehydes in quantitative yield.

endo-*6-Acetyl*-exo-*5-(2-oxoethyl)bicyclo[2.2.1]hept-2-ene (8)*: ir $\lambda_{max}$: 3.63 (w), 5.81, 8.85 μm; $^1$H nmr δ: 1.5–7.5 (m, 3H), 2.15 (s, 3H), 2.5–2.8 (m, 4H), 3.21 (m, 1H), 5.85 (dd, $J$ = 3, 6 Hz, 1H), 6.22 (dd, $J$ = 3, 6 Hz, 1H), 9.74 (t, $J$ = 2 Hz, 1H). *Anal.* calcd. for $C_{11}H_{14}O_2$: C 73.13, H 7.92; found: C 73.92, H 8.00.

endo-*6-Acetyl*-exo-*5-(2-oxoethyl)bicyclo[2.2.2]oct-2-ene (11)*: ir $\lambda_{max}$: 3.64 (w), 5.80, 5.85 μm; $^1$H nmr δ: 1.1–1.9 (m, 5H), 2.15 (s, 3H), 2.3–2.6 (m, 4H), 2.85 (m, 1H), 5.9–6.6 (m, 2H), 9.75 (t, $J$ = 2 Hz, 1H). *Anal.* calcd. for $C_{12}H_{16}O_2$: C 74.97, H 8.39; found: C 74.48, H 8.33.

trans-*7-Acetyl-8-(2-oxoethyl)dibenzobicyclo[2.2.2]octadiene (13)*: ir $\lambda_{max}$: 3.64 (w), 5.81, 5.83 (sh) μm; $^1$H nmr δ: 1.23 (m, 1H), 2.15 (s, 3H), 2.20 (m, 3H), 4.16 (d, $J$ = 2 Hz, 1H), 4.44 (d, $J$ = 2 Hz, 1H), 7.12 (m, 8H), 9.64 (t, $J$ = 1 Hz, 1H).

*Treatment of 14 with 90% formic acid. Formation of 4-acetyl-2,3-3a,4,5,9b-hexahydro-5,9b-diphenylnaptho[1,2-b]-furan-2,5-diol (17)*

A solution of **14** (0.250 g, 0.853 mmol) in aqueous 90% formic acid (15 mL) was allowed to stand under nitrogen at room temperature for 2 h. The mixture was diluted with water (20 mL) and extracted with dichloromethane (3 × 5 mL). Crystallization of the oily residue from hexane – ethyl acetate yielded the tricyclic hemiacetal **17** as colorless prisms (0.201 g, 86%), mp 191–192°C; ir $\lambda_{max}$: 2.80 (w), 2.95 (m), 5.95, 6.26 (w) μm; $^1$H nmr δ: 1.4–2.3 (m, 2H), 1.90 (s, 3H), 3.31 (dd, $J$ = 6, 12 Hz, 1H), 3.98 (m, 1H; absent after $D_2O$ treatment), 4.38 (d, $J$ = 12 Hz, 1H), 4.63 (s, 1H; absent after $D_2O$ treatment), 5.75 (dd, $J$ = 3, 5 Hz, 1H; d, $J$ = 5 Hz, after $D_2O$ treatment), 6.6–7.8 (m, 14H); $^{13}$C nmr δ: 34.4 (q), 35.6 (t), 44.3 (d), 58.0 (d), 76.4 (s), 88.4 (s), 98.8 (d), 125.8–147.4 (13 signals), 216.8 (s). *Anal.* calcd. for $C_{26}H_{24}O_4$: C 77.98, H 6.04; found: C 77.72, H 6.05.

*Attempted intramolecular aldol condensation of keto aldehydes 8, 11, and 13*

The conditions tried included treatment with the following reagents under the conditions indicated: aqueous 10% potassium hydroxide in methanol (12) with stirring at room temperature, 40°C, and at reflux; potassium hydroxide in boiling aqueous tetrahydrofuran (13, 14*a*); increasingly concentrated aqueous potassium hydroxide (5, 10, 15, and 20%) in equal volumes of methanol; a catalytic amount of piperidinium acetate in benzene (14*b*) at room temperature; methanolic tetramethylammonium hydroxide at 60°C; an excess of aluminum *tert*-butoxide in boiling benzene (14*c*); a catalytic amount of potassium *tert*-butoxide in boiling *tert*-butyl alcohol; potassium carbonate in boiling methanol (14*d*); a catalytic amount of anhydrous *para*-toluenesulfonic acid in boiling benzene (15*a*); hydrochloric acid, water, and tetrahydrofuran (15*b*) with stirring at room temperature and at reflux.

*Irradiation of (E)-6,6-dimethoxy-3-hexen-2-one (5). Formation of (Z)-6,6-dimethoxy-3-hexen-2-one (21)*

A solution of **5** (0.160 g, 0.010 mol) in benzene (100 mL) was degassed by bubbling nitrogen from a fine capillary tube through the length of a 40 × 5 cm quartz tube for 1 h. The tube was sealed and irradiated in a Rayonet photochemical reactor (330 nm) for 6 h. Benzene was removed and the resulting oil was molecularly distilled to give a ~ 50:50 mixture of **21** and **5** (92%); ir $\lambda_{max}$: 5.93, 6.12 (m), 7.35 (w) μm; $^1$H nmr δ (**21** only): 2.10 (s, 3H), 2.95 (m, 2H), 3.33 (s, 6H), 4.45 (t, $J$ = 6 Hz, 1H), 6.20 (m, 2H).

*Treatment of 6 and 7 with p-toluenesulfonic acid. Formation of 3-acetyl-9-methoxytetracyclo[4.3.0.0$^{2,4}$.0$^{3,7}$]nonane (27)*

A solution of **6** and **7** (0.508 g, 2.26 mmol) and anhydrous *p*-toluenesulfonic acid (0.60 g, 0.31 mmol) in dry benzene (25 mL) was boiled under reflux for 1 h. The solution was diluted with water (10 mL) and extracted with ether (4 × 5 mL) and the organic phase was concentrated, yielding a black oil. This was triturated with a small amount of hexane – ethyl acetate (7:3) which separated insoluble, polymerized material. The solution was concentrated and chromatographed (silica gel, 7:3 hexane and ethyl acetate) and yielded tosylate **28** as an oil (0.1421 g, 18%) and the tetracyclic ketone **27** (0.0925 g, 21%) as a colorless oil which was molecularly distilled at 44.5°C (0.065 Torr). Compound **28**: ir $\lambda_{max}$: 5.86, 6.23 (w) μm; $^1$H nmr δ: 1.2–2.5 (m, 9H), 2.07 (s, 3H), 2.44 (s, 3H), 3.14 (s, 3H), 3.60 (m, 1H), 4.14 (m, 1H), 7.32 (d, $J$ = 8 Hz, 2H), 7.26 (d, $J$ = 8 Hz, 2H); $^{13}$C nmr δ: 21.7, 28.8, 33.5, 40.4, 40.7, 44.0, 45.0, 54.3, 56.8, 59.1, 85.9, 88.1, 127.6, 129.8, 134.2, 144.7, 206.2. Compound **27**: ir $\lambda_{max}$: 5.90, 9.90 (w) μm; $^1$H nmr δ: 1.38 (m, 1H), 1.67 (m, 3H), 1.97 (s, 3H), 2.10 (m, 2H), 2.29 (m, 3H), 3.24 (s, 3H), 3.61 (m, 1H); $^{13}$C nmr δ: 27.0 (q), 27.6 (d), 29.4 (d), 31.1 (t), 35.8 (t), 40.8 (d), 42.0 (d), 48.8 (d), 56.1 (q), 81.7 (d), 206.5 (s). *Anal.* calcd. for $C_{12}H_{16}O_2$: C 74.97, H 8.39; found: C 74.77, H 8.46.

The ion chemistry is discussed for fuel-rich, nearly sooting, methane–oxygen flames at atmospheric pressure with added acetylene. Different types of ion–molecule reactions, both positive and negative, which can contribute through chemical ionization (CI) processes are summarized including their dependence on temperature, pressure, and equivalence ratio $\phi$. Extensive data were presented previously involving ion concentration profiles measured with a mass spectrometer as a function of distance along the axis of conical flames. An understanding of the dominant CI processes provides insight into the early chemical stage of soot formation associated with the flame reaction zone. The negative ion profiles show moderately unsaturated hydrocarbon ions upstream formed by proton transfer followed by progressive dehydrogenation; the highly unsaturated, carbonaceous ions observed downstream appear to arise by two- and three-body electron attachment, charge transfer, and H-atom stripping. The negative hydrocarbon ions can all be explained in terms of polyacetylene derivatives. The same build-up of carbonaceous species downstream is evident from the positive ion profiles. A major role is ascribed to proton transfer reactions with lesser contributions from charge transfer and ion–molecule condensation; three-body association is probably insignificant. Experiments with added acetylene indicate extensive fuel pyrolysis early in the reaction zone. There is no evidence that an ionic mechanism is dominant in forming soot precursors compared with neutral condensation reactions. Because of complexities in the positive ion chemistry, the negative ions appear to provide the more straightforward probe of the underlying neutral chemistry.

JOHN M. GOODINGS, SCOTT D. TANNER et DIETHARD K. BOHME. Can. J. Chem. **60**, 2766 (1982).

On discute de la chimie ionique dans les flammes du méthane–oxygène riches en combustible et sur le point de former de la suie, auxquelles on a ajouté de l'acétylène et à la pression atmosphérique. On classifie les différents types de réactions ion–molécule, tant positives que négatives qui peuvent contribuer via des processus d'ionisation chimique (IC) et on inclut également l'effet de la température, de la pression et du rapport d'équivalence $\phi$ sur ces réactions. On a présenté antérieurement de nombreuses données impliquant les profils de concentration des ions mesurés à l'aide d'un spectromètre de masse en fonction de la distance le long de flammes coniques. Une compréhension des processus IC dominant fournit un renseignement au sujet de la première étape de formation de la suie associée à la zone de réaction de flamme. Les profils de l'ion négatif montrent que, près de la flamme, on retrouve des ions d'hydrocarbonés modérement insaturés qui se forment par un transfert de proton suivi d'une déshydrogénation progressive. Les ions carbonés hautement insaturés observés plus loin semblent provenir de liaisons électroniques à deux et trois composantes saturées, de transferts de charge et de l'élimination d'atomes d'hydrogène. On peut expliquer les ions carbonés négatifs en termes de dérivés polyacétyléniques. La même accumulation d'espèces carbonés loin de la flamme peut être mise en évidence à partir des profils des ions positifs. On attribue un rôle prépondérant aux réactions de transfert de proton accompagné de contributions moindres de transferts de charge et de condensations ion–molécule: une association à trois composantes n'est probablement pas importante. Les expériences conduites avec de l'acétylène ajouté indiquent une abondante pyrolyse du carburant se produisant très tôt dans la zone de réaction. Il n'y a pas de preuve d'un mécanisme ionique dominant lors de la formation des précurseurs de suie par comparaison avec les réactions neutres de condensation. A cause de la complexité de la chimie de l'ion positif, les ions négatifs apparaissent comme les meilleures guides pour étudier la chimie neutre sous jacente.

## Introduction

In a recent article (1), here designated as paper I, we reported experimental data on the axial distribution of both positive and negative ions monitored directly through the reaction zones of fuel-rich $CH_4$–$C_2H_2$–$O_2$ flames at atmospheric pressure. The natural hydrocarbon ions $C_nH_x^{\pm}$ were studied as a probe of the early chemical stages of soot formation. In that paper, the phenomenological changes in the ion distribution which accompanied changes in the equivalence ratio $\phi$ and temperature were noted. In this report we interpret the previous data from the point of view of the ion–molecule reaction chemistry. It is hoped that an understanding of the kinetics and energetics of the ion–molecule reactions responsible for the observed flame-ion distribution will lead to further insights into the initial chemistry leading to soot.

The types of reactions commonly thought to dominate the ion chemistry of flames have been conveniently classified. Those processes which result in the ionization of neutral flame intermediates include chemi-ionization, thermal ionization, electron attachment, charge transfer, and proton-transfer. The latter four reaction types share the characteristic that the neutral reactant of molecular weight $M$ is converted in most cases to an ion of $m/e = M^{\pm}$, $(M + 1)^+$, or $(M - 1)^-$. As a result, the identification of the neutral precursors from the ion

spectrum is relatively simple for systems in which these reaction types predominate. More difficult to deconvolute is the spectrum resulting from "ionic polymerization" reactions such as condensation and three-body association.

### Types of ion–molecule reactions relevant to hydrocarbon flame chemistry

A considerable data base on the kinetics of relevant hydrocarbon ion–molecule reactions exists. However, most of the kinetic measurements have been performed at or near room temperature and at low pressure. This section presents an overview of our current understanding of the kinetics of ion–neutral reactions involving hydrocarbon molecules and radicals. To facilitate the application of the data base to flames burning at atmospheric pressure, the dependence of the kinetics of the major reaction types on temperature ($T$) and pressure ($P$) is reviewed.

*1. Chemi-ionization*

Neutral reactions leading to the formation of ions are usually endothermic. Exceptions may arise when the reactants are radicals and electronically-excited molecules, the concentrations of which will show a strong positive $T$-dependence. It is now generally agreed that the major source of natural flame ions is the chemi-ionization reaction (2, 3)

[1] $CH + O \rightarrow CHO^+ + e^-$

Of those chemi-ionization reactions which yield directly a hydrocarbon ion, the most frequently cited are

[2] $CH^* + C_2H_2 \rightarrow C_3H_3^+ + e^-$

[3] $CH^* + C_2H_4 \rightarrow C_3H_5^+ + e^-$

However, these latter sources have been discounted as anything but minor contributors to the total ion density (4). No $P$-dependence is expected for chemi-ionization reactions, except for the possible quenching of excited reactants.

*2. Thermal ionization*

The spontaneous ionization of energetic molecules may be regarded as a quasi-unimolecular Lindemann process

[4$a$] $C_nH_x + M \rightarrow (C_nH_x)^* + M$

[4$b$] $(C_nH_x)^* \rightarrow C_nH_x^+ + e^-$

In the high pressure limit, appropriate for thermal ionization in atmospheric pressure flames, the classical RRK treatment (5) yields an Arrhenius-type unimolecular rate constant

$$k = \nu \exp(-E_a/RT)$$

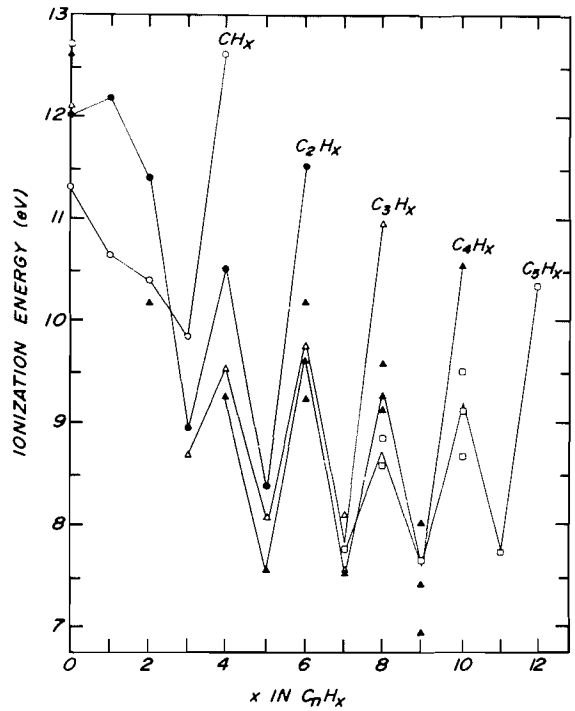

FIG. 1. Ionization energies of aliphatic hydrocarbon radicals and molecules. In cases where data for several isomers are shown, the line is drawn through the arithmetic mean of the ionization energies.

where $\nu$ is typically $10^{13}$ to $10^{15}$ $s^{-1}$ and the activation energy $E_a$ is approximately the ionization energy IE of $C_nH_x$. The IE's of aliphatic $C_nH_x$ radicals and molecules show remarkable trends with the parity of $x$ and magnitude of $n$, as given in Fig. 1. The obvious feature is the alternation of IE with $x$; IE's of odd-$x$ species are roughly 1.5 eV lower than those of similar species with even-$x$. Also, the IE tends to decrease with increasing $n$ (except for $x = 0$). It is assumed that the thermal ionization process is pressure-saturated for an atmospheric pressure flame.

*3. Proton transfer*

These reactions are frequently observed to be simple and fast. Examples include

[5] $HCO^+ + C_2H_2 \rightarrow C_2H_3^+ + CO$

[6] $OH^- + CH_3C_2H \rightarrow C_3H_3^- + H_2O$

for which these were the only reaction channels observed (6, 7), and the rate constants were large, $(1.4 \pm 0.4) \times 10^{-9}$ and $(1.7 \pm 0.3) \times 10^{-9}$ $cm^3$ $molecule^{-1}$ $s^{-1}$, respectively. In fact, the rate constants for proton transfer reactions are generally found to be well-approximated by the AADO

TABLE 1. Proton affinities, $PA^0_{298}$ in kJ mol$^{-1}$, for some hydrocarbon flame species in order of decreasing PA[a]

| Ion | Molecule | PA | Ref. | Ion | Molecule | PA | Ref. |

[a]The PA's of some important flame ions containing oxygen are included as benchmarks.

ion–molecule collision theory of Su, Su, and Bowers (8). This theory predicts reactions involving non-polar species to be temperature-independent, while reactions involving very polar species can be expected to approach a $T^{-1/2}$-dependence. It is commonly the case that proton transfer will take place if it is exothermic. The data base of proton affinities for aliphatic hydrocarbons is rather scant; some relevent values that have been reported are listed in Table 1. Occasionally, an exothermic proton transfer process is observed to compete (with varying success) with other reaction channels. Such is the case for the reaction

$$[7]\quad O^- + C_2H_2 \xrightarrow{0.6} e^- + C_2H_2O$$
$$\xrightarrow{0.3} C_2H^- + OH$$
$$\xrightarrow{0.05} HC_2O^- + H$$
$$\xrightarrow{0.05} C_2^- + H_2O$$

which, nonetheless, has the large overall rate constant $(2.0 \pm 0.3) \times 10^{-9}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ (17). Finally, dissociative proton transfer, in which the product ion breaks up in a unimolecular process, is frequently observed in reactions for which the simple proton transfer is sufficiently exothermic, for example (18),

$$[8]\quad CH_5^+ + C_2H_6 \rightarrow C_2H_7^+ + CH_4$$
$$\rightarrow C_2H_5^+ + CH_4 + H_2$$

Since it is expected that the proton affinities of $C_nH_x$ species increase with $n$, more pronounced dissociation of the proton transfer product ion may occur for the larger hydrocarbons. The overall rate constant is not expected to be $P$-dependent. However, the branching ratio may show $P$-dependence depending on the lifetime of the ionic collision complex.

*4. Charge transfer*

The rate constants for many charge transfer reactions involving simple species are also often found to be in good agreement with the predictions of the AADO collision theory. However, in such cases two conditions are usually met: (*a*) the reactants are polyatomics (since the requirement for energy resonance is more easily fulfilled when there is a high density of states); and (*b*) other reaction channels, such as proton transfer and condensation, are not competitive. The latter requirement appears to be more difficult to satisfy for charge transfer reactions involving hydrocarbons; we are not aware of any example in the published literature. Examples of charge transfer to a hydrocarbon proceeding in isolation but involving dissociation are known, however. The thermochemistry which governs these reactions involves the ionization energies of the reactants, and so the data of Fig. 1 apply here as well. The rates of charge transfer reactions, when efficient, are expected to show only a weak $T^{-1/2}$-dependence and no $P$-dependence.

*5. Condensation*

Reactions in which new bonds between heavy atoms (e.g. C, O) are formed are termed condensation reactions. Examples which have been reported may be separated into two classes which are defined by the observed kinetics. The rate constants for condensation reactions which are rapid at room temperature are usually well-approximated by the AADO collision theory. Some of these reactions are slow at room temperature and may be

expected to show a $T$-dependence which is positive. Many examples are provided in the summaries given in Tables 2 and 3 for reactions of hydrocarbon ions with $CH_4$ and $C_2H_2$, respectively. Reactions of these ions with $H_2$, a major product in fuel-rich flames, are summarized in Table 4. One representative of the first type of condensation reactions is (23)

[9] $CH_3^+ + C_2H_2 \rightarrow C_3H_3^+ + H_2$

which is rapid ($1.2 \times 10^{-9}$ $cm^3$ $molecule^{-1}$ $s^{-1}$) and no other products were observed. By the same token, the reaction (19, 21)

[10] $C_2H_3^+ + CH_4 \rightarrow C_3H_5^+ + H_2$

is slow ($0.17 \times 10^{-9}$ $cm^3$ $molecule^{-1}$ $s^{-1}$) which probably places it in the category of reactions

having an activation energy. Condensation reactions are not necessarily limited to positive ions; the somewhat special case of associative detachment may be thought of as negative ion condensation. An example which competes successfully with proton transfer has already been presented in [7] involving the reaction of $O^-$ with acetylene where the condensation product is uncharged (17). Also, room-temperature studies of reactions of $C_2^-$ and $C_2H^-$ with $CH_4$ and $C_2H_2$ (27) failed to reveal any condensation products ($k$'s < $10^{-13}$ cm³ molecule$^{-1}$ s$^{-1}$).

*6. Three-body association*

Ion–molecule clustering reactions are commonly viewed as proceeding via a simple energy transfer mechanism

[11a] $C_2H_3^+ + C_2H_2 \rightarrow (C_2H_3^+ \cdot C_2H_2)^*$

[11b] $(C_2H_3^+ \cdot C_2H_2)^* + M \rightarrow C_2H_3^+ \cdot C_2H_2 + M$

A strongly negative $T^{(1-s)}$-dependence (where $s$ is the number of internal degrees of freedom involved in "sinking" the excess energy) is observed at low pressures (28), changing to a weak $T^{-1/2}$-(AADO)-dependence at pressure saturation (8). A linear $P$-dependence is observed for the unsaturated process. The saturation pressure is decreased for stronger cluster bonds, for more complex intermediates (larger values of $s$), and for lower temperature. Three "types" of cluster ions may be distinguished on the basis of the strength of the association bond. the weakest type is the simple electrostatic bond, such as that for $O_2^+ \cdot N_2$. These bond dissociation energies are typically $\lesssim$ 80 kJ mol$^{-1}$. On the other end of the scale are the strong chemical bonds, such as that observed for $C_2H_3^+ \cdot H_2$ which is indistinguishable from $C_2H_5^+$ derived from the protonation of ethylene (29). Bridging these extremes are the proton-bound intermediates such as $C_2H_3^+ \cdot C_2H_2$ which is a symmetric example.

*7. Electron attachment*

Little experimental work has been done on the $T$-dependence of polyatomic electron attachment reactions. The process is generally believed to take place via a modified Bloch–Bradbury mechanism:

[12a] $C_nH_x + e^- \rightarrow (C_nH_x^-)^*$

[12b] $(C_nH_x^-)^* + M \rightarrow C_nH_x^- + M$

Of the two systems which have been studied in detail, attachment to $O_2$ appears to be well-described by this mechanism, while that to NO is not. This has been explained (30) in terms of the great difference in the lifetimes of the resonant states, $(X^-)^*$; that for $(O_2^-)^*$ is sufficiently long to allow the reaction to be viewed as taking place through two distinct stages, while that for $(NO^-)^*$ is so short that a one-step mechanism must be invoked. However, it may be expected that the energy-transfer (2-step) mechanism is appropriate for the polyatomic $C_nH_x$ hydrocarbons because of the greater number of internal degrees of freedom available to stabilize the intermediate. The kinetics should then be described by the same equations invoked earlier for three-body association reactions. For large molecules having many degrees of freedom, the lifetimes of the intermediates may be long enough to allow the reaction to be characterized as bimolecular (31). Electron affinity (EA) values are known for the $CH_x$ ($x$ = 0–3) species. For higher $C_nH_x$ ($n \geq 2$) species, EA values for the most part are either unknown or uncertain. The stable hydrocarbons have, in general, negative EA's and so electron attachment is an important process only for radical species. It has often been suggested (32) that hydrocarbon anions in flames may result from dissociative attachment reactions. Chief among these is the source proposed for $C_2H^-$

[13] $e^- + C_2H_2 \rightarrow C_2H^- + H$

However, for the thermal electrons of the flames discussed here this reaction is sufficiently endothermic (260 kJ mol$^{-1}$) so as to ensure that its contribution to the observed $C_2H^-$ concentration is minimal. The same conclusion is likely to apply to all stable hydrocarbons. Not enough is known about the energetics of $C_nH_x$ radicals to predict the importance of their dissociative attachment reactions to the negative ionization observed in flames.

*8. Associative detachment*

Competing with the thermal detachment of elec-

trons from anions in flames are associative detachment reactions. The relatively large H-atom concentration in hydrocarbon flames facilitates reactions of the type

[14] $C_nH_x^- + H \rightarrow C_nH_{x+1} + e^-$

Most commonly, the product of this reaction is a stable (i.e. non-radical) hydrocarbon molecule. Associative detachment reactions are also expected to be rapid with OH and possibly O. The kinetics may be obtained by applying the principle of detailed balance to dissociative attachment. Since the equilibrium constant may be expected to shift in favor of the reactants ($X^- + H$) as the temperature increases, and the rate constant for dissociative attachment decreases with $T$ (33), the rate constant for associative detachment reactions may be expected to show a slightly negative $T$-dependence. Phelps (33) has argued that for reactions involving a complex which has a short lifetime ($< 10^{-14}$ s) against auto-detaching (such as $O^- + H_2$), the rate constant will be essentially independent of temperature; those having longer auto-detaching lifetimes (such as $O^- + NO$) will demonstrate a weak, approximately $T^{-1/2}$-dependence. Despite the decrease of the rate constant with temperature, the rate of associative detachment reactions in flames may be expected to increase rapidly with temperature in response to the overriding increase in the rate of formation of radicals.

## Discussion

The companion paper I (1) concluded with a summary of the major observations involving positive and negative ion profiles in fuel-rich $CH_4$–$O_2$ flames with, and without, added $C_2H_2$. Much more can be learned about the early chemical stage of soot formation by a detailed consideration of these results in terms of the kinds of ionic reactions given in the previous section which dominate in different regions of these flames: upstream; in the reaction zone proper; and downstream in the burnt gas. This discussion will be presented in accordance with the summary in I; total ionization profiles will be considered first, followed by the behaviour of individual negative ion species, and then positive ion species. Finally, the trends evident in the flame chemistry are discussed as the equivalence ratio $\phi$ is increased at constant temperature towards the sooting point by the addition of acetylene.

### *A. Total ionization profiles*

*Positive ions*

The total positive curves in all flames studied show the usual rapid rise through the reaction zone, peaking just downstream, before tailing away through the burnt gas via electron–ion recombination. At constant $\phi$, the peak magnitude shows a positive temperature dependence $T^\beta$ with $\beta \simeq 2.5$ (Fig. 1(*b*) of I). This strong positive $T$-dependence is reasonable for both kinds of source reactions mentioned in the previous section, namely, chemi-ionization and thermal ionization. If the pair of curves with $T_{ad} = 2401$ and 2488 K for $\phi = 2.22 \pm 0.01$ are normalized at the peak, the rising portions through the reaction zone are the same, and there is no shift in peak position. Accordingly, there is no reason to invoke any source reaction other than the usual chemi-ionization process (2, 3)

[1] $CH + O \rightarrow HCO^+ + e^-$

upstream and through the reaction zone. On the other hand, the rate of recombination in the hotter flame is reduced downstream through the burnt gas. Most of the positive charge in this region is present as $H_3O^+$ ions, whose rate of electron–ion recombination

[15] $H_3O^+ + e^- \rightarrow H + H + OH$

has been variously found to have zero $T$-dependence (34) or a $T^{-1.6}$-dependence (35). The downstream behaviour might be accounted for by the negative $T$-dependence. Alternatively, it may possibly indicate the involvement of an additional source term, namely, thermal ionization of carbonaceous radicals of low ionization energy whose presence is expected downstream in these very fuel-rich flames.

*Negative ions*

The total negative ion profile in all flames studied is double-peaked. It rises upstream in approximate coincidence with the total positive profile and then breaks away to form a primary maximum midway through the reaction zone. The profile shows a valley near the end of the reaction zone, followed by a secondary maximum just downstream. The magnitude of the upstream peak decreases with increasing $\phi$ (negative $\phi$-dependence) and has little $T$-dependence. This upstream maximum arises because of the relative rates for formation and loss of negative ions, the rates being equal at the peak. The formation process is mainly three-body electron attachment, primarily to $O_2$, while the loss processes include thermal detachment and ion–radical associative detachment reactions, primarily with H atoms in these fuel-rich flames (36). The negative $\phi$-dependence at constant temperature is a consequence of the decrease in the concentration of $O_2$ and increase in H atoms. The apparent lack of $T$-dependence was observed for a pair of flames at constant $\phi$ (Fig. 1(*b*) in I); in the hotter flame, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

positive ions increase while the negative ions remain about the same. This relative decrease in negative ion concentration is in keeping with an enhanced rate for both kinds of loss processes; note that the concentration of H increases at higher temperature. However, little of this upstream behaviour provides much insight into the chemical initiation of soot formation.

In contrast, the secondary maximum downstream shows both a strongly positive $\phi$- and $T$-dependence. Also, the negative ion profile in the richer flame tails out considerably further downstream. As discussed below, this behaviour is consistent with an increase in the rate of production of $C_nH_x^-$ ions from hydrocarbon neutrals, for example polyacetylenes or their radicals, whose concentrations increase rapidly with both $\phi$ and $T$. These species must be intimately involved in the initiation of soot.

*B. Negative ion profiles*

The individual negative ion profile peaks appear in three distinct regions. In the first of these, oxygenated anions are found upstream (e.g. $O^-$, $OH^-$, $O_2^-$, $CH_3O^-$, $O^-\cdot H_2O$, $OH^-\cdot H_2O$, impurity traces of $^{35}Cl^-$ and $^{37}Cl^-$, $C_2HO^-$, $C_2H_3O^-$, $CHO_2^-$, $O_3^-$, etc., in order of increasing mass, and including $^{13}C$, $^{18}O$, and D isotopically substituted species). These ions are formed by charge transfer from primary $O_2^-$ ions and by proton transfer from parent neutrals by strong bases such as $OH^-$ and $O^-$; every profile peaks close to the $OH^-$, $O^-$, and $O_2^-$ peak positions. In fact, all of the anions with $m/e < 80$ amu can be interpreted as oxygenated species (Fig. 5 of I) with the exception of $C_2H^-$ and possibly a trace of $C_2^-$.

In the second region, a number of moderately unsaturated hydrocarbon anions are observed to peak in the valley region of the total negative ion profile (Figs. 1 and 5 of I). All of these can be interpreted as arising by proton transfer from a stable neutral hydrocarbon, viz. $C_2H^-(C_2H_2)$, $C_3H_3^-(C_3H_4)$, $C_3H_5^-(C_3H_6)$, $C_4H^-(C_4H_2)$, $C_4H_3^-(C_4H_4)$, $C_4H_5^-(C_4H_6)$, and $C_5H_5^-(C_5H_6)$

[16] $OH^- + C_nH_x \rightarrow C_nH_{x-1}^- + H_2O$

In each case, a decreasing concentration of the reagent anion $OH^-$ combined with a rising concentration of the reagent neutral might be expected to yield a maximum product ion concentration in the valley region. It is just possible that the prominent signals at 41, 53, and 65 amu represent a series based on deprotonated ketenes $HC(=C)_m=O^-$ with $m = 1$, 2, and 3, respectively. The important point is that at least some of these peaks in the valley region provide clear evidence for the growth of unsaturated hydrocarbon species as the combustion process proceeds.

In the third region, very highly unsaturated $C_nH_x^-$ ions are observed to peak just beyond the reaction zone, completing a picture of progressive dehydrogenation as the flame chemistry develops. The resultant hydrogen made available appears downstream as $H_2O$ and $H_2$. An important point in the negative ion chemistry is the degree to which it is likely to be free from condensation reactions which complicate the positive ion chemistry. Attention has been drawn to this hypothesis earlier in connection with pure $CH_4$–$O_2$ flames (36). It is important because, if valid, the wide variety of negative ions observed argues in favour of a neutral rather than an ionic mechanism for the buildup of carbonaceous species leading to soot formation.

The whole series of highly unsaturated $C_nH_x^-$ ions in the third region arises near the maximum concentration of free electrons at $z = 0.04 \pm 0.02$ mm. The concentrations of the observed ions alternate with the parity of $n$, the even-$n$ species being larger in agreement with the early observations of Green (37). For $n$ even, the most abundant species are the acetylenic anions $C_2H^-$, $C_4H^-$, $C_6H^-$ ..... with $x = 1$. For $n$ odd, the most abundant ions tend to be those with $x = 0$ and 5 such as $C_3^-$, $C_3H_5^-$, $C_5^-$, and $C_5H_5^-$.

The obvious question concerns the identity of the primary negative ions downstream. The $OH^-$ profile has a secondary maximum at this point in the flame (Fig. 7 of I) which could arise in coincidence with the free electron maximum by dissociative or three-body electron attachment

[17] $e^- + H_2O \rightarrow OH^- + H$

[18] $e^- + OH + M \rightarrow OH^- + M$

The relatively high concentrations of $H_2O$ and OH in this region would favour the rates of reactions [17] and [18]. A strong base such as $OH^-$ would promote chemical ionization of carbonaceous neutrals by proton transfer as in reaction [16]. Secondary ions (e.g. $C_n^-$) can be produced by stripping reactions

[19] $C_nH_x^- + H \rightarrow C_nH_{x-1}^- + H_2$

As an alternative to the proton transfer/stripping mechanism, it is probable that some of the $C_nH_x$ neutrals have positive electron affinities such that three-body and even two-body electron attachment processes may be competitive (31, 36). In general, however, the proton transfer-based mechanism is preferred.

In the $C_4H_x^-$ series, small signals corresponding to $x = 3$, 4, and 5 were also observed (Fig. 2(*b*) of I) which could arise by proton abstraction from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

dimethylacetylene followed by H atom stripping. This mechanism is thought to be more likely than hydrogenation of the highly unsaturated species, for example, by the reverse of reaction [19], although the thermochemistry is not known.

Methylpolyacetylenes $C_nH_4$ or the isomeric polyallenes can lead to ionic species with $n$ odd, but impose a limit on $x \leq 4$. In the lower series with $n = 3$ and 5, the ionic concentrations increase with decreasing $x$, and the ions with $x = 4$ are not observed. Presumably the same combination of proton transfer followed by H atom stripping reactions is involved as with $n$ even. However, these parent molecules do not explain the origin of the relatively large signals observed for $n$ odd with $x = 5$. The $C_nH_5^-$ ions are thought to arise by proton abstraction from $C_nH_6$ species derived, for example, by $H_2$ elimination reactions of polyacetylenes with propylene, or methylpolyacetylenes with ethylene.

Note that these schemes provide a probable explanation for the observed intensity alternation with the parity of $n$ (Fig. 2(*a*) in I). Both the $C_nH_4$ and $C_nH_6$ parent neutrals invoked for the ions with $n$ odd are secondary reaction products of the basic polyacetylenes responsible for the larger ion signals observed with $n$ even. For a given $n$, the concentrations of the secondary derivatives would be expected to be less than the concentration of the corresponding primary reagent. The main reason for exploring this negative ion chemistry in some depth is to show that all of it can be based on acetylene. The early chemical stage leading to soot formation appears overwhelmingly to involve neutral condensation (polymerization) reactions of acetylene, the negative ions serving as a probe. Implicit in this discussion has been the notion that a negative chemical ionization process applied to a neutral flame intermediate preserves the identity of that neutral by producing an ion of the same, or nearly the same, mass.

### *C. Positive ion profiles*

The positive hydrocarbon ions $C_nH_x^+$ form a number of series through the flame reaction zone defined by the value of $n$ with $0 \leq x \leq 10$ (Fig. 2(*c*) of I). In each series, the profile peak positions evolve downstream with decreasing values of $x$ amounting to progressive dehydrogenation (Figs. 3 and 4 of I). Also within each series, the peak magnitudes (*a*) tend to be larger for small values of $x$, (*b*) maximize for $x = 3$, and (*c*) show a measure of alternation with the parity of $x$, odd $x$ being larger. Overall, the series are remarkably similar such that the positive ion chemistry appears to be essentially independent of $n$.

To what degree are these positive ions formed by simple CI processes (e.g. proton transfer, charge transfer, etc.) involving large hydrocarbon neutrals? Or, do they merely result from fast, ion–molecule condensation reactions which reveal little about the buildup of carbonaceous precursors to soot formation? Or possibly the ion–molecule condensation reactions are themselves competitive, with implications for an ionic mechanism of soot formation? These are the questions this discussion attempts to answer by considering the kinds of positive ion–molecule reactions likely to be involved, by making use of published data available for individual ion–molecule reactions given in Tables 2–4, and by seeking a correlation with the negative ion data.

#### *Thermal ionization*

This process can be discounted as a significant ion source in ordinary hydrocarbon flames (38). There is no known constituent of sufficient concentration and low enough ionization energy (IE) to yield a reasonable ion density even at equilibrium, and the kinetics are too slow for equilibrium to be approached in the flame reaction zone. Nevertheless, it is worth noting for aliphatic $C_nH_x$ radicals and molecules the trends in IE with $n$ and $x$ given in Fig. 1. The obvious feature is the alternation of IE with $x$; IE's of odd-$x$ species are roughly 1.5 eV lower than those of similar species with even-$x$. This, of course, describes quite well the alternation observed in the positive ion mass spectrum. Also, the IE tends to decrease with increasing $n$ (except for $x = 0$). We have estimated the concentration of $C_4H_5^+$ from thermal ionization of $C_4H_5$ radicals present with a mole fraction of $10^{-5}$ at the adiabatic flame temperature $T_{ad} = 2455$ K for a flame with $\phi = 2.15$. The calculated density of $1 \times 10^8$ ions cm$^{-3}$ agrees very well with the maximum concentration measured for $C_4H_5^+$, based on an estimate of $4 \times 10^{10}$ ions cm$^{-3}$ for the peak of the total positive ionization curve (39). This model can be discounted upstream in the reaction zone where the temperature $< T_{ad}$ because of the strong positive $T$-dependence for thermal ionization. Nevertheless, it may possibly represent a competitive process for hydrocarbonaceous ion formation downstream in the burnt gas. This is the source process mentioned in Section A on total ionization profiles to explain the apparent decrease in the rate of electron–ion recombination observed with increasing $\phi$ and $T$.

#### *Three-body association*

The bond-dissociation energies of electrostatically-bound ion–molecule clusters are expected to increase with increasing dipole moment of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

neutral. The relatively low dipole moments of the hydrocarbon intermediates, the difficulty in explaining the observed intensity alternation with $x$, and the failure to account for the dehydrogenation series for a given $n$ all argue against any major contribution from three-body association. Certainly in the hot part of the flame, the strong negative $T$-dependence of these reactions renders them unlikely. A somewhat greater contribution might be expected in the cooler domain far upstream except that oxygenated hydrocarbons would be preferred as clustering agents in this region for reasons of higher dipole moment and concentration. Similar considerations apply to three-body association reactions leading to the formation of hydrogen-bonded or chemically-bonded adducts even though their rates may be higher.

*Condensation*

Many of the smaller hydrocarbon ions have been observed to undergo condensation reactions having high rate constants at room temperature with both elements of the fuel, $CH_4$ and $C_2H_2$, as is evident from Tables 2 and 3. A condensation-dominated ion chemistry might explain the positive ion $n$-series to some extent. Complications arise because a number of the hydrocarbon ions can participate in rapid, exothermic, *hydrogenation* reactions even at room temperature as given in Table 4. Molecular hydrogen is available as a reagent since it becomes a major combustion product downstream in these fuel-rich flames. Ion–molecule condensation reactions will be occurring throughout the flame with simultaneous dehydrogenation, e.g. reaction types (*a*), (*b*), (*c*), (*g*), (*h*), and (*j*) given in Tables 2 and 3, although the extrapolation of this data base to flame temperatures and higher-$n$ ions is uncertain. However, the limited room temperature data are of little help in explaining the intensity alternation with $x$. On the other hand, the similarity of the various $n$-series is consistent with ubiquitous condensation reactions involving the same neutral reagents, namely, $CH_4$ and $C_2H_2$.

*Charge transfer*

Charge transfer reactions cannot explain the rapid buildup of hydrocarbon ions of high molecular weight. If charge transfer plays a major role, it presupposes the neutral polymerization of the fuel early in the flame. From Fig. 1, the lower IE's of the $C_nH_x$ neutrals having odd $x$ mean that charge transfer is the best mechanism available to account for the measure of intensity alternation (Fig. 2(*c*) of I) observed within each $n$-series. It is significant that, typically, IE($C_nH_x$, $x$ odd) < IE(HCO) $\simeq$ 8.7 eV < IE($C_nH_x$, $x$ even), such that charge transfer reactions of primary $HCO^+$ ions are exothermic with many odd-$x$ species formed by fuel pyrolysis. These reactions may be fast enough to deplete the $HCO^+$ as rapidly as it is formed, in keeping with the failure to observe significant amounts of $HCO^+$ far upstream where $C_nH_x^+$ ions are prominent. If a charge transfer mechanism is truly dominant, the initial neutral pyrolysis products must undergo sequential dehydrogenation via the *neutral* flame chemistry; the $C_nH_x^+$ series would then evolve by progressive charge transfer to the dehydrogenation intermediates.

*Proton transfer*

The data base of known PA's for $C_nH_x$ species given in Table 1 is insufficient to identify any clear-cut trends with $n$ and $x$, although the PA appears to increase with the degree of unsaturation (increasing C/H ratio). However, a proton transfer mechanism is consistent with the observed intensity alternation with $x$ within each $n$-series. Even-$x$ hydrocarbon neutrals (except for $x = 0$) almost always correspond to stable molecules which will tend to be present in higher steady-state concentrations in the flame, unlike odd-$x$ species which are always free radicals. Obviously, even-$x$ neutrals protonate to form odd-$x$ ions.

If the positive ion chemistry is dominated by proton transfer, it presupposes that the neutral chemistry involves an initial pyrolysis stage with condensation followed by progressive dehydrogenation. The latter is expected to proceed mainly via H atom abstraction in such a fuel-rich flame. The terminal stable member of each $n$-series of neutrals from a point of view of dehydrogenation is a polyacetylene which must await oxidative cleavage or neutral condensation. This may explain the maximum for $x = 3$ obtained in each $n$-series of ions. Also, this chemical scheme (neutral pyrolysis with condensation, ionic proton transfer) provides a consistent basis for the observed similarity of the various $n$-series of ions.

### *D. The influence of $C_2H_2$ added to the $CH_4$ fuel*

The results discussed in Sections B and C pertain to a $CH_4$–$C_2H_2$–$O_2$ flame (17.7% $C_2H_2$) with $\phi$ = 2.47 in which traces of yellow soot luminescence could be seen around the cooler perimeter. However, similar profile data were also measured for a leaner $CH_4$–$O_2$ flame without added $C_2H_2$ having $\phi$ = 2.15 burning at the *same temperature*. When the data from the richer flame are compared with those from the leaner, most of the differences are entirely consistent with decreased C/O and increased C/H ratios (point 6 in the summary of I): unsaturated $C_nH_x^{\pm}$ ion signals increase at the expense of oxygenated ions upstream; the ion profile peaks

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

become broader (it was suspected that the reaction zone thickness had increased) and more skewed in the downstream directions (e.g., $C_3H_3^+$ in Fig. 8 of I); positive ions having high $n$ and low $x$ values are enhanced.

In a relatively few isolated cases, profile peak magnitudes in the reaction zone showed a considerable decrease with added $C_2H_2$ (at +15, +49, +61, −17, and −60 amu from Figs. 6 and 7 of I). Some of these are readily understandable in terms of known fast reactions with $C_2H_2$ which have been measured at room temperature; for example

[20] $CH_3^+ + C_2H_2 \rightarrow C_3H_3^+ + H_2$ (23)

[21] $OH^- + C_2H_2 \rightarrow C_2H^- + H_2O$ (6)

Somewhat surprisingly, however, the two sets of profiles obtained for the two flames were remarkably similar as to relative peak heights, positions, and shapes. Evidently the identities of the fuel molecules are essentially lost early in the reaction zone through pyrolysis and decomposition processes. Even the upstream peaks of the $C_2H^-$ and $C_2H_3^+$ profiles (Figs. 7 and 8 of I) which are closely related to acetylene did not respond greatly to the addition of 17.7% of $C_2H_2$. In fact, the significant change at −25 amu was the appearance of an additional shoulder in a position *intermediate* between the upstream and downstream peaks. This shoulder is indicative of $C_2H_2$ synthesis in the reaction zone subsequent to the disappearance of the original $C_2H_2$ fuel. Thus, these results with varying $\phi$ at constant temperature provide additional evidence that the fuel undergoes pyrolysis very early in the flame.

## Conclusions

The total ionization profiles, both positive and negative, in these fuel-rich flames were examined with regard to their $T$-dependence, $\phi$-dependence, profile shape, peak position, and possible source and sink reactions. The positive profiles are consistent with a major chemi-ionization source reaction upstream persisting through the reaction zone, and possibly a minor source term downstream arising from thermal ionization of hydrocarbon radicals of low ionization energy. This latter source term may well become dominant as the flame is made increasingly fuel-rich (40). The behaviour of the negative profiles is consistent with electron attachment to oxygen upstream, and hydrocarbon ion production downstream in the burnt gas based on the presence of carbonaceous neutral species.

Individual negative ion profiles correspond to oxygenated anions upstream. Further downstream in the reaction zone, in a region corresponding to a valley in the total negative ion profile, several profiles show peaks representative of moderately unsaturated hydrocarbon anions. They appear to be formed by proton transfer from stable hydrocarbon neutrals, and are resistant to destruction by associative detachment with H atoms. They are important because they illustrate the growth of unsaturated hydrocarbon species originating in the reaction zone. The progressive dehydrogenation continues downstream in the burnt gas giving rise to highly unsaturated carbonaceous anions which appear to be formed by proton abstraction from corresponding neutrals by $OH^-$ and H atom stripping. An important point is the degree to which negative ions participate in ion–molecule condensation reactions; if minimal, the observations argue for neutral condensation as the mechanism responsible for the buildup of large carbonaceous species leading to soot formation. Note that all of the negative hydrocarbon ions can be explained in terms of polyacetylene derivatives; we favour the idea that methylpolyacetylenes and not allenic derivatives are responsible for the intensity alternation observed for $C_nH_x^-$ ions (lower for $n$ odd).

Individual positive profiles for $C_nH_x^+$ ions have been considered in the light of several kinds of ion–molecule reactions. The relative contributions of the different kinds can be judged to some extent from observations on progressive dehydrogenation downstream, intensity maxima for $x = 3$, $x$ intensity alternation, the great similarity of different $n$ series, and considerations involving magnitudes of measured rate constants, $T$-, $\phi$-, and $P$-dependence, and the dependence of IE on $n$ and $x$ (see Fig. 1). On these bases, we conclude that proton transfer reactions play a major role throughout the flame in the chemical ionization of neutral species and, to a lesser extent, charge transfer. These mechanisms presuppose extensive fuel pyrolysis early in the reaction zone, and a backbone of neutral polymerization chemistry resulting in the formation of large carbonaceous species, the precursors of soot. Ion–molecule condensation reactions must also be occurring but appear to be of lesser importance; perhaps such reactions involving methane are responsible for masking the intensity alternation with $n$ which is a major feature of the negative ion spectrum (see Fig. 2 of I). Thermal ionization will not be competitive in these flames except perhaps for a minor contribution downstream in the burnt gas. Finally, the role of three-body association reactions is probably insignificant in view of the observations and considerations outlined above.

Many of these notions are reinforced by the experiments in which acetylene was added to the methane fuel. In general, the fact that nearly all of

the ion profiles, both positive and negative, are remarkably unaffected by acetylene provides additional evidence for early fuel pyrolysis. As a general conclusion based on these studies of the early chemical stages leading to soot formation, the ion–molecule chemistry might conceivably make some contribution but is not thought to be dominant compared with neutral mechanisms involving polymerization of the fuel. Because of complexities associated with the positive ion chemistry, we believe that the negative ion profiles give the better picture of the chemical growth towards soot formation, the negative ions merely serving as a probe of the underlying neutral chemistry.

# Étude, par spectroscopie de vibration, de deux solvants de la cellulose: La *N*-méthyl morpholine *N*-oxyde et son monohydrate

PHAM THI MAÏ, MARIE-HÉLÈNE HERZOG-CANCE, ANTOINE POTIER ET JACQUELINE POTIER[1]

*Laboratoire des Acides Minéraux, L.A. 79 associé au C.N.R.S., Université des Sciences et Techniques de Languedoc, Place Eugène Bataillon, 34060 Montpellier Cédex, France*

Reçu le 1 avril 1982

PHAM THI MAÏ, MARIE-HÉLÈNE HERZOG-CANCE, ANTOINE POTIER et JACQUELINE POTIER. Can. J. Chem. **60**, 2777 (1982).

Les spectres infrarouge et Raman de la *N*-méthyl morpholine *N*-oxyde et de son monohydrate ont été étudiés entre 4000 et 50 $cm^{-1}$. Pour ces deux composés, classés parmi les meilleurs solvants de la cellulose, il existe seulement le conformère où les groupes NO et $CH_3$ sont respectivement en positions axiale et équatoriale. Sur les spectres Raman de la *N*-méthyl morpholine *N*-oxyde anhydre, l'interaction dipôle–dipôle est caractérisée par une raie intense à 75 $cm^{-1}$.

Les molécules peuvent être divisées en deux parties: une partie hydrophobe ($O(CH_2)_2$) qui ne joue aucun rôle dans la dissolution de la cellulose, et une partie hydrophile qui est capable de stabiliser une chaine de molécules d'eau et révèle l'importance de l'environnement pyramidal des molécules d'eau dans le monohydrate.

PHAM THI MAÏ, MARIE-HÉLÈNE HERZOG-CANCE, ANTOINE POTIER, and JACQUELINE POTIER. Can. J. Chem. **60**, 2777 (1982).

The ir and Raman spectra of *N*-methyl morpholine *N*-oxide and its monohydrate have been investigated in the frequency range 4000–50 $cm^{-1}$. For these two compounds, classified among the best cellulose solvents, there exists only the conformer where NO and $CH_3$ groups are respectively in axial and equatorial positions. For anhydrous *N*-methyl morpholine *N*-oxide, the dipole–dipole interaction is characterized by a strong line at 75 $cm^{-1}$ in the Raman spectra.

The molecules can be divided into two parts: a hydrophobic part ($O(CH_2)_2$) not active in the cellulose dissolution, and a hydrophilic part, which is able to stabilize a chain of water molecules and reveals the importance of the pyramidal environment of water molecules in the monohydrate.

## Introduction

La *N*-méthyl morpholine *N*-oxyde est connue pour son pouvoir solvant vis à vis de la cellulose (1). Une bonne connaissance des interactions entre l'eau et cette base est une première approche de l'étude de ce phénomène complexe. On peut penser que le comportement de la *N*-méthyl morpholine *N*-oxyde (NMMNO) vis à vis des associations par liaisons hydrogène qui existent dans la glace est une image de ce qui se passera dans le milieu complexe cellulose–NMMNO.

L'analyse des spectres de NMMNO et de son monohydrate a été menée en les comparant à ceux de la morpholine et de la *N*-méthyl morpholine (NMM) dans l'état cristallisé. Pour la première, on dispose cependant de l'étude détaillée de Vedal *et al.* (2) qui est une base de départ appréciable, en particulier, au niveau de la détermination des vibrations du cycle; tandis que le passage de la morpholine à NMM permet de préciser les vibrations du groupe $CH_3$. Grâce à la deutération sélective des atomes d'hydrogène du cycle ou de la molécule d'eau pour $NMMNO \cdot H_2O$ il est possible d'attribuer les bandes dues à la molécule d'eau.

Cette analyse spectroscopique est divisée en quatre parties consacrées respectivement aux vibrations du squelette $NC_4O$, à celles des groupes $CH_2$ et $CH_3$,[2] du groupe NO et enfin à celles de la molécule d'eau et des liaisons hydrogène.

## I. Les vibrations du squelette $NC_4O$

Les attributions sont basées non seulement sur le travail de Vedal *et al.* (2) sur la morpholine et la pipéridine mais aussi sur les données des composés hétérocycliques: l'oxyde de pentaméthylène (3), le tellurure d'oxane (4) et le séléniure de pentaméthylène (5).

### *Les vibrations de valence* ν*(CO)*

On remarque que les fréquences relevées dans ce travail sont comparables à celles de Vedal *et al.* (2) de plus, comme ces auteurs, on observe pour $\nu_s(CO)$ deux composantes à 830 et 850 $cm^{-1}$ pour la morpholine liquide; ces deux composantes traduisent l'existence des deux conformères de la morpholine (atome d'hydrogène en position axiale ou équatoriale). Pour le cristal, la présence de quatre raies sur le spectre Raman (Fig. 1) signifie qu'à côté des deux conformères existe aussi un effet de corrélation. Bien que la structure ne soit pas connue, il semble que l'existence des deux types de

conformères dans le cristal soit compatible avec une structure en chaîne où les molécules de morpholine seraient reliées par des liaisons hydrogène N—H...N.

On observe aussi la présence de deux conformères pour NMM, de plus la substitution de l'atome d'hydrogène par le groupe $CH_3$ conduit à des glissements de fréquences plus ou moins importants selon le conformère.

Le comportement de NMMNO et de son monohydrate (Fig. 1) est différent; on ne relève dans l'état cristallisé qu'une seule vibration $\nu_s(CO)$ à 812 $cm^{-1}$, il n'y a donc qu'un seul conformère ce qui est en accord avec les données structurales de Perez et coll. (6) et conformément aux travaux de Cook *et al.* (7), c'est le conformère où le groupe NO est en position axiale et le groupe $CH_3$ équatorial.

On doit remarquer qu'en Raman, le déplacement des fréquences $\nu_s(CO)$ entre NMM et NMMNO est moins important ($\Delta\nu$ = 24 $cm^{-1}$) que celui noté entre la morpholine et NMM ($\Delta\nu$ = 44 $cm^{-1}$), il est pratiquement nul lorsqu'on passe de NMMNO à NMMNO·$H_2O$. Ce fait met en évidence les perturbations provenant de l'introduction du groupe $CH_3$ sur le cycle et *exclut la participation de l'atome d'oxygène endocyclique dans la formation de la liaison hydrogène*. Le déplacement vers les hautes fréquences quand on passe de NMM à NMMNO est surprenant, on s'attendrait plutôt à un effet inverse puisque les électrons de l'atome d'azote sont engagés dans la coordination avec l'atome d'oxygène.

*Les vibrations de valence* $\nu(NC)$

*Pour les vibrations de valence* $\nu(N(CH_2)_2)$, on note la présence de deux vibrations qui correspondent aux deux conformères de la morpholine et de NMM tandis que pour NMMNO et NMMNO·$H_2O$ on ne retrouve bien évidemment que la vibration correspondant au conformère où le groupe $CH_3$ est équatorial (Fig. 2).

Entre la morpholine et NMM, on remarque un abaissement de fréquence pour $\nu(N(CH_2)_2)$ dû au fait que le groupement $CH_3$ se fixe à la place de l'atome d'hydrogène et provoque un alourdissement de l'atome d'azote; lorsqu'on passe à NMMNO et NMMNO·$H_2O$, l'augmentation de fréquence qui apparaît peut s'expliquer si l'on tient compte de la contrainte apportée aux liaisons N—$CH_2$ lors de la fixation de l'atome d'oxygène et aussi de l'interaction dipôle–dipôle très forte qui assure la cohésion de la maille cristalline dans NMMNO tandis que dans le monohydrate, où cette interaction disparaît, comme on le verra lors de l'étude du groupe NO, on remarque alors un abaissement de fréquence.

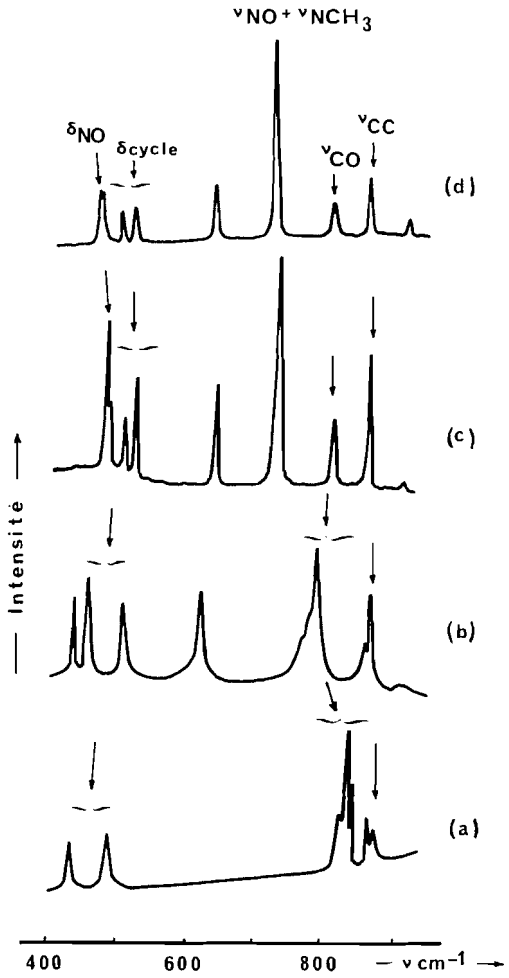

FIG. 1. Spectres Raman de (a) la morpholine, (b) NMM, (c) NMMNO et (d) NMMNO·$H_2O$ entre 400 et 800 $cm^{-1}$.

On doit noter en plus, une variation d'intensité assez remarquable, en effet, sur les spectres Raman de NMMNO la raie à 1070 $cm^{-1}$ est relativement moins intense que celle à 1093 $cm^{-1}$ (Fig. 2) tandis que pour le monohydrate elles sont toutes deux d'intensité moyenne. Il semble que l'on puisse interpréter cette augmentation d'intensité par un effet de cristal: le couplage intermoléculaire entre les deux molécules de l'unité asymérique du monohydrate exaltant l'intensité de $\nu$(CN) à 1070 $cm^{-1}$.

*La vibration de valence* $\nu(N—CH_3)$ apparaît en Raman à 1021, 1109 et 1108 $cm^{-1}$ respectivement pour NMM, NMMNO et NMMNO·$H_2O$ (Fig. 2). Comme pour les vibrations $\nu(N(CH_2)_2)$ la forma-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

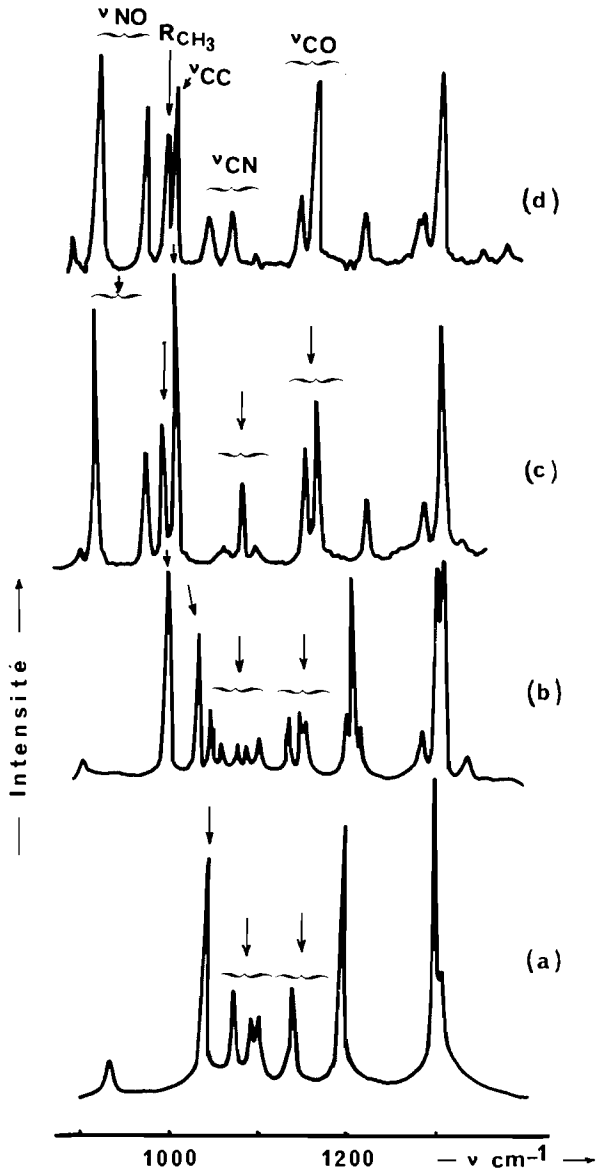

FIG. 2. Spectres Raman de (a) la morpholine, (b) NMM, (c) NMMNO et (d) NMMNO·$H_2O$ entre 900 et 1300 $cm^{-1}$.

tion de la liaison hydrogène tend à diminuer l'influence de l'interaction azote ↔ oxygène.

La figure 3 reproduit les spectres ir des composés étudiés, on y retrouve les fréquences des bandes correspondant aux vibrations ν(CN).

*Domaine entre 300 et 500 $cm^{-1}$*

Comme Vedal *et al.* (2), on observe pour la morpholine les *déformations du cycle* entre 400 et 500 $cm^{-1}$ et à des fréquences voisines pour NMM, NMMNO et NMMNO·$H_2O$.

On attend en outre plusieurs fréquences correspondant *aux déformations δ(N—$CH_3$) et δ(NO)*. Dans la triméthylamine *N*-oxyde (TMANO) où l'édifice moléculaire possède une symétrie $C_{3v}$, Giguere et Chin (8) et Kida (9) ont identifié $\delta_{deg}$ ($N(CH_3)_3$) en infrarouge autour de 380 $cm^{-1}$. On relève pour NMM des vibrations à 350 et 360 $cm^{-1}$ en ir (349, 358 et 366 $cm^{-1}$ en Raman) tout à fait compatibles avec δ(N—$CH_3$). La multiplicité des raies ou bandes est encore attribuable à l'existence de deux conformères. Pour NMMNO et NMMNO·$H_2O$ on retrouve δ(N—$CH_3$) respectivement à 328 et 330–347 $cm^{-1}$ en Raman (330 et 340–350 $cm^{-1}$ en ir).

Le glissement de fréquence entre les spectres de NMM, NMMNO et NMMNO·$H_2O$ traduit l'influence plus ou moins grande de l'atome d'oxygène sur l'atome d'azote.

## II. Les vibrations du groupe NO engagé

*Les vibrations de valence ν(NO)*

A priori on attend une seule vibration de valence pour le groupe NO, cependant, il faut noter que, par suite des couplages entre les différents vibrateurs autour de l'azote, la vibration ν(NO) n'est pas pure et doit contribuer aux vibrations ν(N—$CH_2$), ν(N—$CH_3$) et aux mouvements du cycle.

La comparaison entre les spectres ir et Raman des différents composés (Figs. 2 et 3) révèle l'existence d'un doublet à 927–988 $cm^{-1}$ en ir (932–990 $cm^{-1}$ en Raman) sur les spectres de NMMNO anhydre et 940–990 $cm^{-1}$ en ir (936–990 $cm^{-1}$ en Raman) pour le monohydrate. Lors de la deutériation du cycle, les deux raies se déplacent à 928 et 980 $cm^{-1}$ (avec un rapport isotopique $\rho \simeq 1{,}01$).

L'apparition de ce doublet, comme le triplet signalé par Devinsky *et al.* (16) est surprenante car on attend, a priori, qu'une seule vibration ν(NO). Gallais et coll. (17) lors d'une étude sur les oxydes d'amines tertiaires, a aussi remarqué un doublet à 950–970 $cm^{-1}$ pour ν(NO) des oxydes de triéthanolamine et de diméthylaniline et n'a pas su l'interpréter. En 1963, Kida (9) en étudiant des complexes avec la triméthylamine *N*-oxyde a effectivement observé un doublet pour le chlorhydrate dans l'état solide et une seule bande en solution, il attribue alors le doublet à un effet de couplage.

On pourrait penser que l'interaction dipôle–dipôle permettrait d'expliquer la présence du doublet (à 932 et 990 $cm^{-1}$) pour ν(NO) mais il n'est rien puisque ce doublet est toujours présent dans le monohydrate (à 936 et 990 $cm^{-1}$).

Notons que l'on observe aussi une variation de

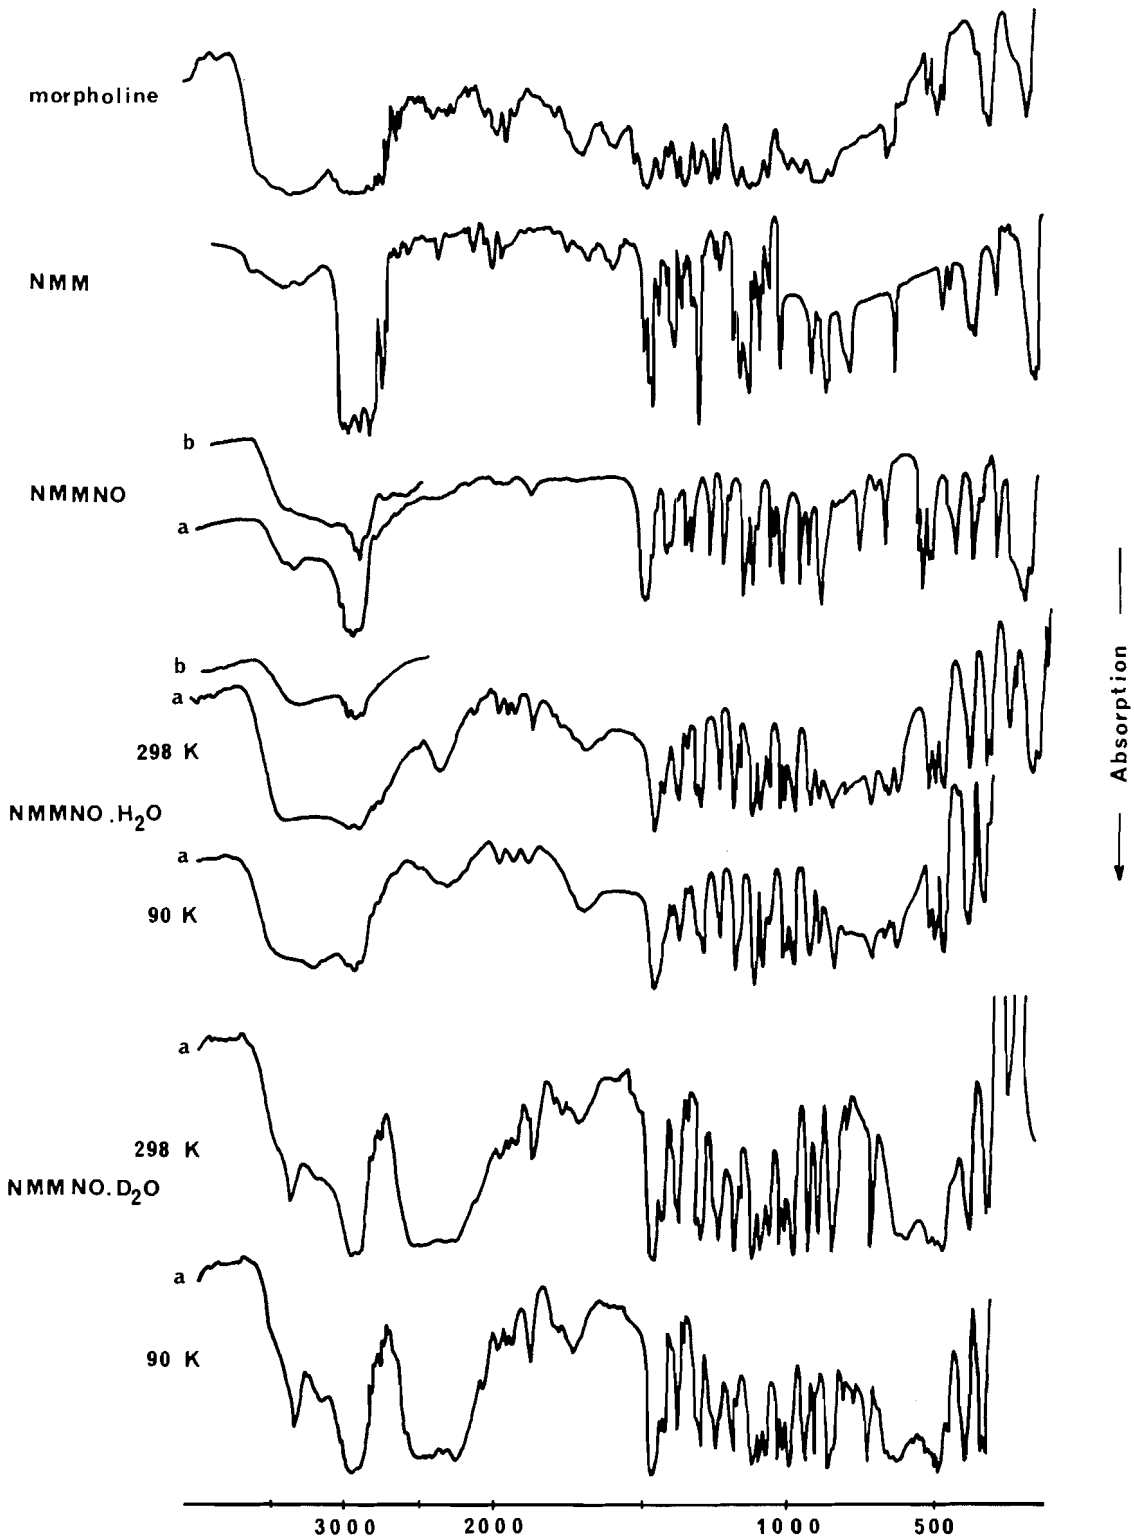

FIG. 3. Spectres ir des différents composés (en suspension (a) dans le Nujol, (b) dans le Fluorolube).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

l'intensité relative des deux raies du doublet lorsque le groupe NO est solvaté par la molécule d'eau. (Ce phénomène a déjà été observé par Devinsky pour les alkyl morpholine *N*-oxyde (16) et par Gallais et coll. pour les oxydes d'amines tertiaires (17). Ceci est compatible avec le changement de symétrie moléculaire, la symétrie $C_s$ dans NMMNO devenant $C_1$ dans le monohydrate.

Il faut souligner un autre fait surprenant: *le raccourcissement de la liaison N—O* lorsqu'on passe de NMMNO à son monohydrate. Ce renforcement de la liaison N—O est inattendu car on s'attendrait plutôt à un allongement de cette liaison lors de la formation de la liaison hydrogène et en même temps à un déplacement de ν(NO) vers les basses fréquences.

Cette évolution peut cependant être expliquée très facilement. Dans NMMNO anhydre, Perez et coll. (6) ont montré que les groupes NO sont orientés de façon antiparallèle et que l'interaction électrostatique assure la cohésion de l'édifice cristallin. C'est la polarité de la liaison NO (18) qui est responsable de cette interaction dipôle–dipôle. Cette interaction, importante, se matérialise par la présence d'une raie intense à 75 $cm^{-1}$ sur le spectre de NMMNO anhydre (raie absente sur le spectre du monohydrate) (Fig. 4). Cette fréquence s'intègre très bien parmi celles relevées par Ghersetti *et al.* (19) pour la pyridine *N*-oxyde et par Jakobsen et Brash (20) pour une série de composés organiques (entre 80 et 50 $cm^{-1}$).

On peut donc penser que la création de liaisons hydrogène dans le monohydrate amène une interaction de force comparable (ou plus faible) que celle due à l'interaction dipôle–dipôle, ce qui permet d'expliquer les évolutions des fréquences des différentes vibrations déjà signalées quand on passe de NMMNO à son monohydrate.

Par ailleurs, les fréquences relevées pour la vibration ν(NO) se classent correctement dans le diagramme $\nu(NO) = f(d(NO))$ présenté sur la figure 5 en fonction des distances $d(NO)$ = 1,391 Å et 1,383 Å trouvées respectivement pour NMMNO anhydre et monohydratée par Perez et coll. (6) lors de l'édude structurale. Ces distances sont proches de celles observées pour la triméthylamine *N*-oxyde (TMANO) (1,41 Å) (18).

Avant de clore ce paragraphe consacré aux vibrations de valence ν(NO), on doit signaler l'apparition d'une nouvelle raie ou bande vers 720 $cm^{-1}$, sur les spectres de NMMNO et NMMNO·$H_2O$. Cette composante n'est pas sans évoquer celles observés par Gambi et Ghersetti (23) pour la pyridine *N*-oxyde et Kida (9) pour la triméthylamine *N*-oxyde. Ces auteurs l'attribuent à la vibration ν(NO) couplée avec les mouvements du cycle et plus particulièrement N—$(CH_2)_2$. Il semble qu'une attribution similaire puisse être fait ici, et ceci d'autant plus que cette composante est sensible à la deutériation du cycle.

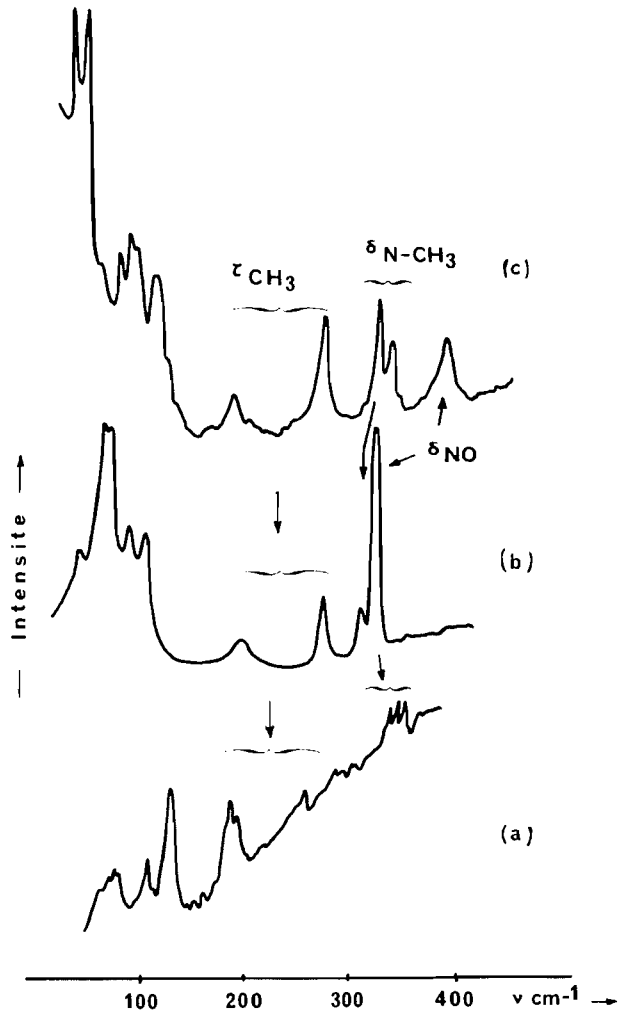

FIG. 4. Spectres Raman entre 100 et 400 $cm^{-1}$: (a) NMM, (b) NMMNO et (c) NMMNO·$H_2O$.

*Les déformations δ(NO)*

On attend deux déformations: une dans le plan, l'autre hors du plan. Ghersetti et coll. les ont observées respectivement pour la pyridine *N*-oxyde (PNO) à 468 et 226 $cm^{-1}$ (23) tandis que pour la quinoline ces auteurs retrouvent la déformation hors du plan à 340 $cm^{-1}$ (25).

La comparaison des spectres de NMMNO et NMMNO·$H_2O$ conduit à proposer pour ces deux mouvements les deux composantes à 478 et 343

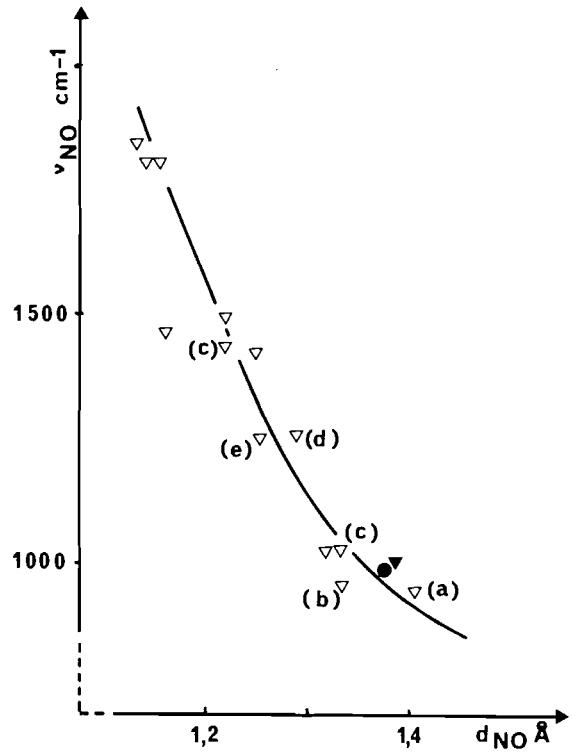

FIG. 5. Variation des fréquences ν(NO) en fonction des longueurs $d$(NO) (●) NMMNO, (▼) NMMNO·$H_2O$ (ce travail et réf. 6); (a) TMANO (18); (b) $[NO_3 \cdot 2HNO_3]^-$ (21); (c) $[NO_3 \cdot HNO_3]^-$ (22); (d) PNO (23) et (e) $H_3O^+NO_3^-$ (24).

cm$^{-1}$ en Raman (480 et 340 en ir) pour NMMNO et pour le monohydrate: 476 et 395 cm$^{-1}$ en Raman (480 et 400 cm$^{-1}$ en ir). Pour ce dernier on observe un léger déplacement de fréquence quand on passe à NMMNO·$H_2O$ (478 et 391 cm$^{-1}$ en Raman et 480 et 390 cm$^{-1}$ en ir) très certainement comme on peut le constater sur la figure 1, il y a couplage entre δ(NO) (487 cm$^{-1}$) et les déformations du cycle qui interviennent dans le même domaine de fréquence.

### III. Les vibrations de la molécule d'eau

Le spectre ir de NMMNO·$H_2O$ (Fig. 3) est complexe. La présence des liaisons hydrogène (6) contribue à la complexité du spectre en provoquant les bandes larges A, B et C (26). Elles sont localisées autour de 3200, 1500 et 800 cm$^{-1}$. On peut être étonné de la faible fréquence de la dernière. Un tel abaissement de fréquence a déjà été observé par Hadzi (26) qui attribue cet effet à l'interaction de la bande C avec une autre bande D existant vers le bas domaine pour les liaisons hydrogène faibles. Nous reviendrons sur la bande C un peu plus loin.

*Les vibrations de valence*

En Raman, on observe une raie large centrée à 3315 cm$^{-1}$ avec un épaulement à 3200 cm$^{-1}$ et en ir un massif large entre 3000 et 3500 cm$^{-1}$ (Fig. 3) (spectres enregistrés à 298 et 90 K en suspension dans le Nujol). Sur un échantillon de faible épaisseur en suspension dans le Fluorolube, on relève une seule bande large à 3350 cm$^{-1}$ tout-à-fait comparable à la raie Raman.

Dans ce domaine de fréquence, il est toujours difficile de faire une attribution sans ambiguité du fait de l'interférence de l'harmonique de $\delta_{OH}$ et des résonances de Fermi. Malheureusement, les difficultés d'obtention de grandes quantité de NMMNO anhydre ont empêché une étude complète à taux de $D_2O$ variable. On a pu, cependant, utiliser le domaine des fréquences $\nu_{OH}$ d'un complexe incomplètement deutérié.

On note que sur le spectre apparait pour $\nu_{OH}$-(OHD) une bande intense à 3340 cm$^{-1}$ avec un épaulement à 3440 cm$^{-1}$ et une bande à 3140 cm$^{-1}$. On pourrait être tenté d'attribuer ces deux bandes aux vibrateurs OH(OHD) impliqués dans les deux liaisons hydrogène (2,72 et 2,82 Å) (6). Cependant ces fréquences correspondent d'aprés la courbe de Novak (27) à des distances O...O de 2,67 et 2,75 Å; un tel écart est difficilement concevable car, il serait un des plus importants parmi les écarts expérimentaux observés.

Il parait plus logique d'attribuer l'épaulement à 3440 cm$^{-1}$ et la bande à 3340 cm$^{-1}$ aux deux vibrateurs OH(OHD) attendus ($d_{O...O}$ = 2,82 et 2,75 Å d'aprés Novak). La bande à 3140 cm$^{-1}$ serait due à la présence d'une combinaison ($\nu_{OH} + \nu_R$) comme Bertie et Whalley (28) l'ont trouvé pour la glace II. Il faut noter que ces fréquences: 3340 et 3440 cm$^{-1}$ pour NMMNO·$H_2O$ sont compatibles avec celles observées par Bertie et Whalley pour les glaces II et V (28). Pour les films de glace, Haas et Hornig (29) et Ford et Falk (30) notent des fréquences plus basses; de même que Bertie et Whalley pour les glaces I et III (31).

*Les vibrations de déformation*

On doit remarquer qu'en ir, la bande large à 1680 cm$^{-1}$ ne peut être attribuée à la base puisque sur le spectre de NMMNO anhydre on n'observe aucune bande entre 1800 et 1600 cm$^{-1}$.

Sur le spectre du produit deutérié apparaît un épaulement à 1250 cm$^{-1}$ absent sur le spectre du complexe hydrogéné; le rapport isotopique de 1,34 est tout-à-fait correct. Un fait similaire est observé en Raman où, entre 1600 et 1800 cm$^{-1}$ apparait un massif large dont le maximum est difficile à locali-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

ser pour le complexe hydrogéné tandis qu'à 1250 $cm^{-1}$ on relève sur le spectre de l'homologue deutérié un épaulement à la raie à 1237 $cm^{-1}$ attribuable à $\delta(D_2O)$.

Les bandes relevées entre 1800 et 1700 $cm^{-1}$ sur le spectre ir de NMMNO·$D_2O$ semblent attribuables à des combinaisons faisant intervenir $\delta(D_2O)$ et des modes de libration.

*Les librations*

Il reste à localiser les deux librations attendues en ir pour la molécule $H_2O$. Pour la première, sur le spectre ir de l'homologue deutérié on observe à 450 $cm^{-1}$ une bande absente sur le spectre de l'homologue hydrogéné; avec un rapport isotopique de 1,35 on peut penser qu'elle correspond à l'élargissement qui apparaît autour de 610 $cm^{-1}$ sur le spectre du composé hydrogéné.

Ceci permet de rendre compte de la bande à 2300 $cm^{-1}$ qui serait la combinaison classiquement observée: $\delta_{OH_1} + \nu_R$ (1680 + 610 = 2290 $cm^{-1}$); dans le composé deutérié elle glisse à 1700 $cm^{-1}$ (1250 + 450).

L'autre libration est plus délicate à détecter; avec des liaisons hydrogène comparables, Bertie et Whalley (28) obtiennent un spectre ir de la glace II (ou V) qui présente de nombreuses analogies avec celui de NMMNO·$H_2O$. $\nu_{OH(OHD)}$ = 3350 et $\delta_{OH}$ = 1690 $cm^{-1}$ pour la glace, 3340 et 1680 $cm^{-1}$ pour NMMNO·$H_2O$. On note en plus sur leur spectre une bande large centrée vers 800 $cm^{-1}$ que ces auteurs attribuent à une libration. Cette bande est tout-à-fait similaire à celle observée dans ce travail et qui glisse par deutériation, cependant la largeur du massif et la présence des bandes de la base rendent difficile la localisation du maximum avec précision. Bien que 800 $cm^{-1}$ soit une fréquence un peu élevée pour une libration de la molécule $H_2O$ coordinée, il est tentant de proposer cette attribution en se souvenant que l'on a déjà observé une fréquence particulièrement élevée pour $\delta(H_2O)$; ceci doit être relié à l'environnement pyramidal de l'atome d'oxygène.

On a vu que les fréquences observées pour les vibrations de la molécule d'eau sont identiques à celles notées par Bertie et Whalley pour la glace II. D'autre part la structure cristalline du monohydrate de NMMNO a révélé la présence de chaines de molécules d'eau reliées entre elles par des liaisons hydrogène et dans lesquelles l'atome d'oxygène est tricoordiné. Les molécules de NMMNO bloquent la formation de l'environnement tétraédrique de l'atome d'oxygène tel qu'il est rencontré dans la glace et plus particulièrement la glace II (32, 33).

## Conclusion

Dans ce travail, on a pu montrer, par spectroscopie de vibration, que si pour la morpholine et la *N*-méthyl morpholine il existe deux conformères dans la *N*-méthyl morpholine *N*-oxyde et son monohydrate seul subsiste le conformère où les groupes N—O et $CH_3$ sont respectivement en position axiale et équatoriale.

Il a été possible de mettre en évidence, pour NMMNO, l'interaction dipôle–dipôle caractérisée par la raie intense à 75 $cm^{-1}$ sur le spectre Raman. Cette interaction est de force comparable à celle de la pyridine *N*-oxyde et nettement plus important que celle observée par Jakobsen et Brash (20) pour une série de composés organiques.

L'évolution des fréquences ν(OH), δ(OH) et des librations (notamment celle observée à 800 $cm^{-1}$) souligne le rôle de l'environnement pyramidal de la molécule d'eau dans le monohydrate et révèle que NMMNO est apte à stabiliser une chaine de molécules d'eau aussi rigide que le cycle de la glace II. Ceci justifie le choix du monohydrate de NMMNO comme modèle de l'interaction cellulose–NMMNO.

Par ailleurs, la non variation des fréquences de ν(CO) révèle que le groupement $O(CH_2)_2$ est hydrophobe et ne jouera aucun rôle dans la dissolution de la cellulose.

## Annexe expérimentale

*Echantillons*

Les échantillons de *N*-méthyl morpholine *N*-oxyde et son monohydrate nous ont été fournis par l'équipe de Monsieur Chanzy, Maître de Recherches, au Centre de Recherche sur les Macromolécules Végétales (Grenoble, France). Les processus de synthèse sont décrits par Maia *et al.* (6).

NMMNO·$D_2O$ a été préparé au Laboratoire à partir de NMMNO anhydre.

*Appareillage*

Les spectres ir ont été enregistrés sur un spectromètre Perkin–Elmer 180. La cellule à température variable est de type conventionnel (VLT2). Les échantillons sont dispersés dans le Nujol ou le Fluorolube. Les faces utilisées sont en chlorure d'argent ou en iodure de césium.

Les spectres Raman sont enregistrés sur un spectromètre Raman Dilor couplé à un analyseur modulaire multicanaux Tracor (Northern Instrument). Le Laser à Argon ionisé Spectra Physics a une puissance maximale de 1 W sur la raie à 5145 Å. Les échantillons sont dans des tubes de verre Pyrex de 5 mm de diamètre scellés sous vide. Leur refroidissement est assuré par un ensemble cryostat et régulation de température Coderg.

## Remerciements

Nous remercions Monsieur Chanzy, Maître de Recherches au CERMAV (Grenoble, France), son équipe et particulièrement Messieurs Perez et Peguy qui nous ont fournis les échantillons de NMMNO, NMMNO-$d_8$ et NMMNO·$H_2O$ et avec

lesquels nous avons eu des discussions fructueuses.

# Régiosélectivité de l'hydrogénation catalytique de quelques pyrido[2,3-*b*]pyrazines

JEAN-MARIE COSMAO, NOËL COLLIGNON ET GUY QUEGUINER

*Laboratoire de Chimie Organique, Institut National Supérieur de Chimie Industrielle de Rouen, B.P. 8, 76130 Mont Saint-Aignan, France*

Reçu le 24 février 1982

JEAN-MARIE COSMAO, NOËL COLLIGNON et GUY QUEGUINER. Can. J. Chem. **60**, 2785 (1982).

L'hydrogénation catalytique sur charbon palladié de quelques pyrido[2,3-*b*]pyrazines dans l'éthanol conduit à des mélanges de dérivés tétrahydrogénés-1,2,3,4 ou 5,6,7,8 sauf dans deux cas où elle est régiosélective: pour l'hétérocycle non substitué la réduction a lieu sur le cycle pyrazine; pour le dérivé diphénylé en -2,3 elle concerne le cycle pyridinique. Dans l'acide acétique pur, la réduction fournit uniquement les tétrahydro-1,2,3,4 pyrido[2,3-*b*]pyrazines. L'étude particulière de la réduction de la diphényl-2,3 pyrido[2,3-*b*]pyrazine en fonction de l'acidité du solvant et celle de quelques uns de ses dérivés di- et tétrahydrogénés suggère que cette sélectivité peut résulter de l'isomérisation d'espèces intermédiaires partiellement hydrogénées.

JEAN-MARIE COSMAO, NOËL COLLIGNON, and GUY QUEGUINER. Can. J. Chem. **60**, 2785 (1982).

Catalytic hydrogenation on palladium–carbon in ethanol of several pyrido[2,3-*b*]pyrazines leads to mixtures of the 1,2,3,4- and 5,6,7,8-tetrahydro derivatives except in two cases: the reduction of the nonsubstituted heterocycle takes place on the pyrazine ring and, in the case of the 2,3-diphenyl derivative, the pyridine ring is reduced. In pure acetic acid this reduction provides only 1,2,3,4-tetrahydropyrido[2,3-*b*]pyrazines. A study of the reduction of 2,3-diphenylpyrido[2,3-*b*]pyrazine and several di- and tetrahydro derivatives as a function of solvent acidity suggests that the observed selectivity could result from the isomerization of partially hydrogenated intermediates.

[Journal translation]

Poursuivant notre travail sur la réduction de composés hétéroaromatiques polyazotés (1, 2), nous avons plus particulièrement étudié l'hydrogénation catalytique de la pyrido[2,3-*b*]pyrazine **1** et de quatre de ses dérivés substitués sur le noyau pyrazine **2–5**.

Dans les années antérieures et parallèlement à nos travaux, de nombreuses recherches ont été consacrées à la réduction de cet hétérocycle (3). Les réductions par les hydrures complexes d'aluminium (4–6) ou de bore (1, 7, 8), par le chlorure de titane (9) lui ont été appliquées avec succès de même que la réduction électrochimique (10–13) et l'action des organométalliques (5, 14).

Les produits obtenus sont généralement les dérivés tétrahydrogénés-1,2,3,4, sauf dans deux cas (7, 13) où la réduction du noyau pyridine est observée; d'ailleurs, dans ce dernier cas les auteurs obtiennent un mélange de composés réduits sur l'un ou l'autre cycle et montrent que la réduction du cycle pyridine résulte en réalité de l'isomérisation du dérivé dihydrogéné-1,4 en dérivé dihydrogéné-5,8.

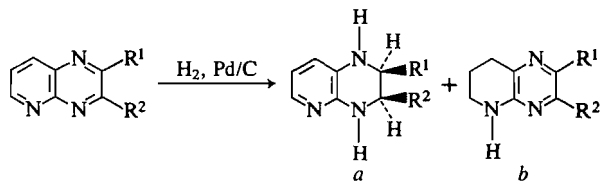
Au cours de ces travaux, l'hydrogénation catalytique n'est utilisée que de façon très ponctuelle (6, 13) et n'a fait l'objet d'aucune étude systématique. Nous avons choisi d'utiliser cette méthode pour la réduction des pyrido[2,3-*b*]pyrazines et nous nous sommes particulièrement intéressés à la régiosélectivité de la réaction, dont nous avons montré qu'elle était sous l'étroite dépendance de deux facteurs principaux: la présence de substituants sur le cycle pyrazine d'une part et l'acidité du solvant réactionnel d'autre part.

## Résultats et discussion

Dans ce travail, nous nous sommes limités à l'emploi du catalyseur commercial: charbon palladié à 10%, l'hydrogénation étant conduite à pression atmosphérique et température ambiante, jusqu'à volume d'hydrogène absorbé constant.

### I. *Réduction comparée de quelques pyrido[2,3-*b*]-pyrazines dans l'éthanol ou l'acide acétique*

Dans les conditions opératoires définies ci-dessus, l'hydrogénation catalytique de la pyrido-[2,3-*b*]pyrazine **1** et de ses dérivés: méthyl-3 **2**, diméthyl-2,3 **3**, phényl-3 **4** et diphényl-2,3 **5** conduit exclusivement aux dérivés tétrahydrogénés correspondants *a* ou *b* ou au mélange des deux (schéma 1). Le rendement chimique global est



**1**, **1***a* $R^1 = H, R^2 = H$
**2**, **2***a*, **2***b* $R^1 = H, R^2 = CH_3$
**3**, **3***a*, **3***b* $R^1 = CH_3, R^2 = CH_3$
**4**, **4***a*, **4***b* $R^1 = H, R^2 = C_6H_5$
**5**, **5***a*, **5***b* $R^1 = C_6H_5, R^2 = C_6H_5$

quantitatif. Lorsqu'ils sont en mélange, les dérivés *a* et *b* sont facilement séparables par chromatographie liquide sur alumine (l'éluant est le chloroforme).

Nous reportons sur le Tableau 1, la composition exprimée en % et déterminée par rmn $^1H$, des mélanges bruts de réduction lorsque le solvant réactionnel est l'éthanol ou l'acide acétique.

1. En milieu éthanolique l'hétérocycle **1** est réduit sélectivement du coté pyrazinique, comme avec les autres systèmes réducteurs.

Pour les dérivés substitués, la présence de groupements volumineux (alkyles ou aryles) sur le cycle pyrazine favorise la réduction du cycle pyridine. Ainsi dans le cas de **5**, obtient-on uniquement la diphényl-2,3 tétrahydro-5,6,7,8 pyrido[2,3-*b*]pyrazine.

Ces résultats sont à comparer à ceux de Braun et coll. (15–18) pour la série de la quinoléine, à ceux de Weitkamp (19) pour le naphtalène et à ceux de Fu *et al.* (20) pour les hydrocarbures aromatiques polycycliques. Dans le cas de la quinoléine, Braun et coll. montrent que la présence de substituants sur le cycle pyridine conduit à des mélanges de produits réduits, les uns sur le cycle pyridine, les autres sur le cycle benzène.

Lors de l'hydrogénation d'alkylnaphtalènes en alkyltétrahydronaphtalènes, Weitkamp obtient aussi un mélange dans lequel le composé majoritaire est réduit sur le cycle non substitué.

Nos résultats en série pyrido[2,3-*b*]pyrazine concordent bien avec ces observations et nous proposons d'expliquer ce comportement par l'existence de deux réactions compétitives conduisant à l'un ou l'autre des dérivés tétrahydrogénés *a* ou *b*. Les vitesses respectives de ces deux réactions dépendraient non seulement de l'encombrement stérique des substituants, mais également de leur effet électronique, ainsi que de la nature du solvant.

2. En milieu acide acétique, par contre, nous obtenons toujours la réduction sélective du noyau pyrazine quels que soient la taille et le nombre des substituants. Un effet analogue a déjà été mis en évidence lors de l'hydrogénation de la quinoléine et de l'isoquinoléine sur oxyde de platine (21–23): en milieu alcoolique la réduction concerne le cycle pyridine de la molécule, alors que dans les milieux très acides ($CF_3COOH$, HCl–MeOH, $H_2SO_4$–$CH_3COOH$) la réduction du cycle benzénique est prépondérante.

Ces résultats nous ont incités à étudier l'influence de l'acidité du solvant dans le cas de la diphényl-2,3 pyrido[2,3-*b*]pyrazine avec laquelle nous observons un effet maximum sur l'orientation de la réduction en passant de l'éthanol à l'acide acétique.

TABLEAU 1. Hydrogénation des pyrido-[2,3-*b*]-pyrazines

| | Solvant | | | |
|---|---|---|---|---|
| | EtOH | | AcOH | |
| Substrat | *a*% | *b*% | *a*% | *b*% |
| **1** | 100 | 0 | —* | — |
| **2** | 40 | 60 | 100 | 0 |
| **3** | 20 | 80 | 100 | 0 |
| **4** | 40† | 60 | 100 | 0 |
| **5** | 0 | 100 | 100 | 0 |

*Dans ce cas les produits de réduction n'ont pu être isolés.
†Litterature (13): **4***a*/**4***b* = 20:80.

## II. *Influence de l'acidité du solvant sur la réduction de la diphényl-2,3 pyrido[2,3-b]pyrazine* **5**

### II-1. *Résultats*

Pour couvrir un large domaine d'acidité, nous avons choisi la série des acides carboxyliques suivants: trifluoroacétique, formique, acétique et propionique. Ces acides sont utilisés à l'état pur comme solvant de réduction. Dans le cas de l'acide acétique nous avons testé également l'effet d'un cosolvant: le benzène. Les résultats sont rassemblés dans le Tableau 2, où nous avons rappelé, à titre de comparaison, le résultat obtenu avec l'éthanol.

Avec les acides trifluoroacétique, formique et acétique, la réaction s'effectue sélectivement sur le cycle pyrazine. Le cas de l'acide propionique est intéressant puisqu'il constitue l'exemple-charnière où les deux réactions de réductions sont compétitives. Enfin l'adjonction (volume à volume) d'un cosolvant neutre comme le benzène à l'acide acétique inverse complétement l'orientation de la réduction par rapport à l'acide pur: ce comportement doit pouvoir être expliqué par la dimérisation bien connue des acides carboxyliques dans le benzène qui diminue fortement leur acidité apparente (24*a*).

En vue d'approfondir le rôle fondamental de l'acidité du solvant sur l'orientation de la réduction de **5**, il nous a paru important d'essayer de préciser d'abord le site de protonation de cet hétérocycle et

TABLEAU 2. Hydrogénation de la diphényl-2,3 pyrido[2,3-*b*]-pyrazine

| Acide | p$K_a$ ($H_2O$) | % **5***a** | % **5***b** |

*Les dosages sont effectués sur les spectres rmn $^1H$ des produits bruts de réaction. Les rendements bruts globaux sont quantitatifs.

TABLEAU 3. Différences de déplacement chimique des carbones des pyrido[2,3-*b*]pyrazines **1** et **5** et de la quinoléïne entre les solvants acides et neutres

| Hétérocycle | Solvant | C2 | C3 | C4 | C6 | C7 | C8 |
|---|---|---|---|---|---|---|---|
|  **5** | HCOOH | 4,3 | 4,4 | — | −6,9 | 1 | 10,2 |
| | $CF_3COOH$ | * | * | — | −7,9 | 1 | 10,3 |
| | $CH_3COOH$/benzène | 0 | 0 | — | −1 | 0 | 0,5 |
|  **1** | $CH_3COOD$ | 0,8 | 0,9 | — | 0 | 1 | 0,7 |
| | HCOOH | 2,4 | 2,6 | — | −3,2 | 1,4 | 5,6 |
| | $CF_3COOH$ | 6,6 | 5,4 | — | −5,6 | 2,1 | 11,8 |
|  | $CH_3COOD$† | −1,8 | 1,1 | 5,8 | 2,5 | 3,5 | −4,5 |
| | $CF_3COOH$ | −5,8 | 1,2 | 13,1 | 5 | 7,4 | −8,5 |
| | $H_2O$/HCl‡ | −5,5 | 1,6 | 11 | 3,7 | 5,5 | −7,6 |

*Non déterminé.
†$CDCl_3$ (25).
‡Dans ce cas le solvant de référence n'est pas $CDCl_3$, mais le mélange $H_2O$/acétone (26).

de comparer sa basicité à celle de la quinoléine et des pyrido[2,3-*b*]pyrazines. Pour ce travail, nous avons fait appel à deux méthodes complémentaires: la résonance magnétique nucléaire du carbone-13 et la neutralisation par l'acide perchlorique.

II-2. *Analyse des spectres de rmn $^{13}C$*

Pour des raisons de solubilité nous avons limité notre étude rmn $^{13}C$ de l'hétérocycle **5** aux milieux suivants: acide trifluoroacétique, acide formique et mélange acide acétique/benzène. À titre de comparaison nous avons également étudié les spectres de l'hétérocycle **1** et de la quinoléine.

Nous reportons nos résultats (Tableau 3) en donnant, pour chaque carbone analysé, la différence de déplacement chimique $\Delta\delta$ entre la valeur mesurée dans le solvant acide et celle mesurée dans le deutériochloroforme: $\Delta\delta = \delta_{RCOOH} - \delta_{CDCl_3}$ (en ppm).

La quinoléine ($pK_a = 4{,}45$ (27)) étant totalement protonée dans l'acide trifluoroacétique (28), l'analyse des mesures de rmn $^{13}C$ permet de conclure qu'elle l'est incomplétement dans l'acide acétique.

Pour la pyrido[2,3-*b*]pyrazine **1**, les faibles valeurs des $\Delta\delta_i$ dans l'acide acétique conduisent à admettre que cet hétérocycle n'est pratiquement pas protoné dans ce solvant. Par contre, dans l'acide trifluoroacétique les $\Delta\delta_i$ des carbones C6, C7 et C8 de **1** sont très voisins des $\Delta\delta_i$ des carbones C2, C3 et C4 de la quinoléine dans le même solvant: nous en déduisons que **1** est sans doute monoprotoné sur l'azote N5 dans ce solvant. La possibilité d'une seconde protonation (sur N1 ou N4) nous semble à écarter car les $\Delta\delta_i$ des carbones C2 et C3 sont voisins et positifs; de plus, le faible $pK_a$ de **1** = 1,2 (29) n'est pas favorable à une diprotonation.

Les $\Delta\delta_i$ de **1** dans l'acide formique sont intermédiaires entre ceux de l'acide acétique et ceux de l'acide trifluoroacétique: nous postulons, dans ce cas, l'existence d'un équilibre entre la base libre et sa forme monoprotonée sur N5.

En utilisant des arguments analogues pour la diphényl-2,3 pyrido[2,3-*b*]pyrazine **5**, nos conclusions sont les suivantes: dans le mélange acide acétique/benzène (1:1), **5** n'est pas protoné; dans l'acide trifluoroacétique et dans l'acide formique, l'espèce prépondérante est la forme monoprotonée sur N5. Ce résultat tend à prouver que **5** est une base plus forte que **1**. Les mesures dans l'acide acétique pur n'ont pu être faites, mais il est probable, d'après les résultats précédents, que **5** est incomplètement protoné dans ce solvant.

II-3. *Étude de la salification des pyrido[2,3-b]-pyrazines par l'acide perchlorique dans l'acide acétique*

Nous avons tracé les courbes de titrage potentiométrique (24*b*) (différence de potentiel entre l'électrode de verre et l'électrode de référence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

TABLEAU 4. Potentiels de demi-neutralisation

| | Basicité décroissante | | | | | |
|---|---|---|---|---|---|---|
| Hétérocycle | >  ⋙  >  >  >  | | | | | |
| | | | **3** | **5** | **4** | **1** |
| $\Delta V_i$ (mV) | −198 | −178 | −118 | −106 | −94 | −60 |

$Hg|Hg_2(CH_3CO_2)_2|LiCH_3CO_2$ saturé$|LiClO_4$ 0,1 *M* dans $CH_3COOH$ anhydre) par l'acide perchlorique, des hétérocycles **1**, **3**, **4**, **5**, de la pyridine et de la quinoléïne. L'allure générale des courbes et la mesure des potentiels de demi-neutralisation nous a permis de classer les molécules étudiées par ordre de basicité décroissante (Tableau 4).

En conclusion, la pyridine et la quinoléïne sont des bases fortes dans l'acide acétique, alors que les pyrido[2,3-*b*]pyrazines **1**, **3**, **4** et **5** sont des bases faibles, donc peu protonées dans ce solvant.

II-4. *Interprétation partielle des résultats*

Les mesures précédentes montrent qu'en solution dans l'acide acétique, la diphényl-2,3 pyrido-[2,3-*b*]pyrazine **5** n'est que partiellement protonée et que la protonation a lieu sur l'azote pyridinique. Les résultats concernant la réduction de **5** dans l'éthanol (ou le mélange acide acétique/benzène) et dans l'acide acétique pur pourraient s'interpréter par le schéma 2.

Dans le premier cas (milieu non protonant) la base libre est hydrogénée sur le cycle le plus riche en électrons (voie A), dans le second cas la concentration en espèces protonées est faible mais si on admet $V_B \gg V_A$, la voie B est prépondérante et le cycle réduit est également le plus riche en électrons. L'hypothèse d'une réduction plus rapide en milieu acide résulte d'un comportement général des hétérocycles azotés (30), mais l'acidité du solvant peut également accélérer l'étape ultérieure de désorption des espèces réduites.

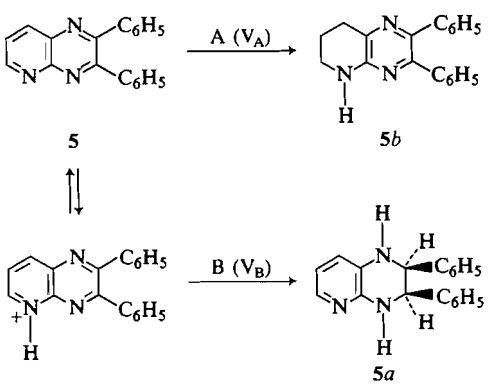

SCHÉMA 2

Cependant, lors de l'hydrogénation sur oxyde de platine du cycle benzénique de la quinoléïne en milieu très acide, Vierhapper et coll. (21, 23, 31) notent que la présence d'une charge positive sur l'azote pyridinique n'est pas le facteur déterminant puisque l'hydrogénation de sels de quinolinium *N*-méthylés conduit aux dérivés tétrahydrogénés-1,2,3,4 dans l'éthanol et aux dérivés réduits sur le cycle benzénique, dans l'acide trifluoroacétique.

Vierhapper (31) suggère alors que l'activation du cycle benzénique pourrait résulter de la formation de complexes π ou σ avec le solvant.

Enfin, le mécanisme peut aussi faire intervenir des espèces intermédiaires partiellement réduites comme dans le cas de la réduction électrochimique (13). À ce propos, dans le cadre particulier de l'hydrogénation de la diphényl-2,3 pyrido[2,3-*b*]-pyrazine, nous nous sommes proposés d'étudier la réduction de quelques formes dihydrogénées de cet hétérocycle dont nous disposions au laboratoire et susceptibles d'être des intermédiaires réactionnels. Nous avons également envisagé les possibilités d'isomérisations des composés tétrahydrogénés-1,2,3,4 et -5,6,7,8.

III. *Hydrogénation des formes partiellement réduites de la diphényl-2,3 pyrido[2,3-*b*]-pyrazine 5*

Le composé **5***b* étant le produit de réduction de **5** dans l'éthanol, il était intéressant de le soumettre aux conditions d'hydrogénation dans l'acide acétique. Au bout de 24 heures (temps suffisant pour observer la réduction complète de **5** en **5***a* dans l'acide acétique), l'analyse du mélange réactionnel montre la présence de **5***a* et de **5***b* dans des proportions équivalentes.

Cet essai montre que la transformation de **5***b* en **5***a* est effective mais lente dans ces conditions. Il est donc peu probable que **5***b* soit un intermédiaire de la réaction **5** → **5***a* puisqu'il n'est pas détecté en fin de réaction (soit environ après 24 h d'hydrogénation).

Inversement, si nous soumettons **5***a* aux conditions de l'hydrogénation dans l'éthanol, nous n'observons aucune isomérisation ni absorption d'hydrogène après 24 h de réaction. Le dérivé **5***b*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

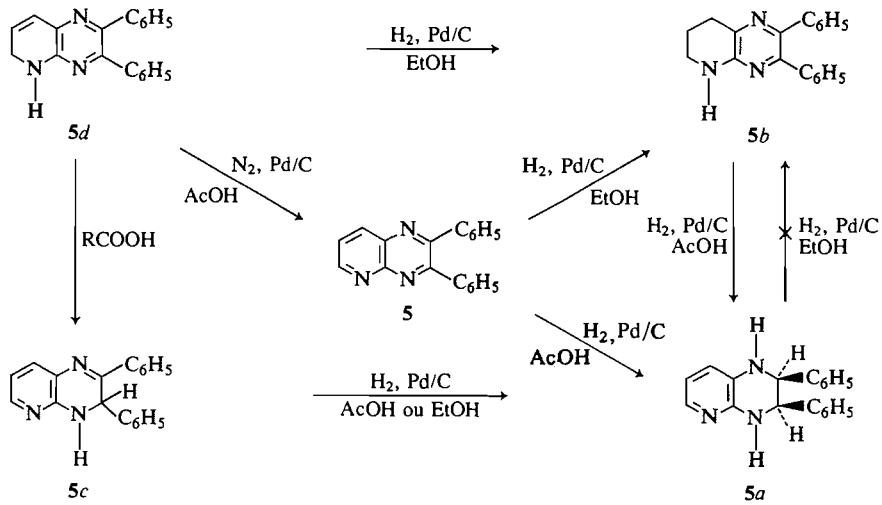

SCHÉMA 3

semble donc plus stable thermodynamiquement que le dérivé **5***a*.

L'hydrogénation de la dihydro-3,4 diphényl-2,3 pyrido[2,3-*b*]pyrazine **5***c* dans l'acide acétique (et aussi dans l'éthanol) conduit à la saturation spécifique du cycle pyrazine.

Le composé **5***c* pourrait donc être intermédiaire dans l'hydrogénation de **5** en milieu acétique. Le résultat obtenu dans l'éthanol montre par contre que **5***c* ne peut être un intermédiaire dans ce cas.

Dans l'acide acétique, l'hydrogénation de la dihydro-5,6 diphényl-2,3 pyrido[2,3-*b*]pyrazine **5***d* conduit à un mélange de **5***a* et **5***b* dans un rapport **5***a*/**5***b* variable avec le temps de purge de l'installation.

Ce résultat curieux, nous a amenés à mettre en évidence les deux phénomènes suivants. (1) À 20°C dans l'acide acétique, en présence du catalyseur, mais en l'absence d'hydrogène, **5***d* s'aromatise très rapidement en **5** en libérant de l'hydrogène. (2) À 20°C dans l'acide acétique, en l'absence de catalyseur et d'hydrogène, **5***d* se transpose en **5***c*. La réaction est complète en 1 heure; à 30°C elle est complète en 5 minutes. Dans l'acide trifluoroacétique, la réaction est pratiquement instantanée.

Ces différentes observations peuvent expliquer le résultat de l'hydrogénation de **5***d* dans l'acide acétique: la transformation **5***d* → **5***b* qui semble normale doit résulter d'une réduction directe sans intermédiaire. Par contre la transformation surprenante à priori **5***d* → **5***a* peut s'interpréter par l'existence des intermédiaires **5***c* et(ou) **5** et la formation de ces intermédiaires peut intervenir pendant la phase préparatoire de l'opération (mise en solution, purge du réacteur), ce qui explique les variations des proportions en produits finaux.

En résumé, pour l'hydrogénation de la diphényl-2,3 pyrido[2,3-*b*]pyrazine **5** dans un acide carboxylique, nous pouvons faire intervenir les chemins réactionnels compétitifs suivants (schéma 3).

Dans l'hypothèse de l'existence des intermédiaires **5***c* et **5***d* ce schéma rend bien compte des résultats reportés sur le tableau 2: dans les acides purs, lorsque l'isomérisation **5***d* → **5***c* est rapide (R = $CF_3$, H et $CH_3$), **5***a* se forme exclusivement, lorsqu'elle est plus lente (R = Et), la transformation **5***d* → **5***b* devient compétitive. Dans l'éthanol et le mélange acide acétique/benzène, cette dernière réaction est prépondérante et **5***b* est le seul produit de réduction isolé.

## Partie expérimentale

Les spectres rmn $^1H$ sont enregistrés à 60 MHz sur le spectromètre Varian T60 du service commun de mesures de physiques de l'I.N.S.C.I.R.; le solvant est le deutériochloroforme ($CDCl_3$) et la référence interne le tétraméthylsilane ($Me_4Si$); les abréviations suivantes sont utilisées: s = singulet, d = doublet, t = triplet, q = quadruplet, sex = sextuplet, mu = multiplet, m = massif. Les spectres rmn $^{13}C$ sont enregistrés à 20,11 MHz sur le spectromètre Brucker WH 90 du centre de mesures physiques de l'Université de Rouen; les échantillons sont en solution dans le deutériochloroforme ($CDCl_3$) ou dans les acides carboxyliques deutériés ou non. Ces solvants servent eux-mêmes de référence interne. Les spectres ir sont tracés sur Beckman Acculab TM (pastille KBr). Les points de fusion sont déterminés sur banc Kofler et ne sont pas corrigés. Les analyses élémentaires (C, H, N Technicon) sont en accord avec les formules brutes à ± 0,3% près.

*Synthèse des pyrido[2,3-b]pyrazines*

Parmi les modes opératoires existants pour la préparation de ce dérivé, nous avons utilisé ceux de Boutte (32) **1**, **2**, Chekir (13) **3**, et Vinot (6, 33) **4** et **5**.

Pour le dérivé méthyl-3 pyrido[2,3-*b*]pyrazine **2**, la position du substituant méthyle est établie sans ambiguité par comparaison des différences des déplacements chimiques rmn $^{13}C$ des

carbones des dérivés **1** et **2** (tableau 5) et de ceux de la quinoléine et de la méthyl-2 quinoléine (25) l'effet d'un substituant méthyle sur le déplacement chimique du carbone porteur est de +9 ppm par rapport au carbone de la molécule non substituée.

*Hydrogénations des pyrido[2,3-*b*]pyrazines*

Les hydrogénations sont effectuées dans un appareillage simple de laboratoire à pression et température ambiantes.

*Hydrogénation en milieu alcoolique*

Nous introduisons successivement dans le réacteur d'hydrogénation de 250 mL, une suspension de 300 mg de charbon palladié à 10% dans 25 mL d'éthanol puis $10^{-2}$ mol d'hétérocycle et enfin 25 mL d'éthanol. Le réacteur est purgé par 3 L d'azote puis 3 L d'hydrogène. L'hydrogénation effectuée sous agitation magnétique est poursuivie jusqu'à volume d'hydrogène absorbé constant.

Après 24 h de réaction, le catalyseur est éliminé par filtration sur un lit de Célite 545 de 3 cm d'épaisseur. Le solvant est ensuite évaporé sous pression réduite. Le dosage du produit brut est effectué sur le spectre rmn $^1$H.

*Hydrogénation en milieu acide carboxylique*

Le processus utilisé est le même que pour l'hydrogénation en milieu alcoolique sauf en ce qui concerne le traitement final: le filtrat est refroidi dans la glace puis neutralisé par une solution de soude concentrée. La solution aqueuse obtenue est extraite par trois fois 50 mL de chloroforme et la phase organique est lavée par 10 mL d'une solution de chlorure de sodium saturée, puis séchée sur sulfate de magnésium anhydre et évaporée sous pression réduite.

*Pyrido[2,3-*b*]pyrazine* **1**

L'hydrogénation de **1** en milieu alcoolique conduit avec un rendement quantitatif à un solide jaune pâle la tétrahydro-1,2,3,4 pyrido[2,3-*b*]pyrazine **1***a* (5, 8) pur en rmn. Ce dérivé recristallise de l'éther (Rdt = 75%). Fusion: 128°C; ir ($cm^{-1}$) $CHCl_3$, $\nu_{NH}$: 3430, 2940; rmn $^1$H (ppm): 7,42 (q, H6, $J_{67}$ = 4,5 Hz, $J_{68}$ = 2 Hz), 6,58 (q, H8, $J_{78}$ = 7,5 Hz, $J_{68}$ = 2 Hz), 6,38 (q, H7, $J_{67}$ = 4,5 Hz, $J_{78}$ = 7,5 Hz), 6,0 (m, NH), 4,05 (m, NH); 3,40 (m, 2H2 + 2H3).

*Méthyl-3 pyrido[2,3-*b*]pyrazine* **2**

En milieu alcoolique nous obtenons un mélange (40:60) des dérivés tétrahydrogénés **2***a* et **2***b*. Nous avons séparé 500 mg de ce mélange sur une colonne d'alumine de 30 cm de longueur en éluant au chloroforme, nous avons obtenu 200 mg de chacun de ces composés à l'état pur.

L'hydrogénation en milieu acide acétique conduit uniquement au dérivé **2***a*.

*Méthyl-3 tétrahydro-1,2,3,4 pyrido[2,3-*b*]pyrazine* **2**a

Fusion: 123°C (benzène–héxane); ir ($cm^{-1}$) $\nu_{NH}$: 3370, 3220; rmn $^1$H (ppm): 7,21 (q, H6, $J_{67}$ = 4,5 Hz, $J_{68}$ = 2 Hz), 6,60 (q, H8, $J_{68}$ = 2 Hz, $J_{78}$ = 7,5 Hz), 6,35 (q, H7, $J_{67}$ = 4,5 Hz, $J_{78}$ = 7,5 Hz), 5,4 (m, NH), 2,75–3,85 (m, 2H2 + H3), 1,18 (d, $CH_3$, $J$ = 6 Hz).

*Méthyl-3 tétrahydro-5,6,7,8 pyrido[2,3-*b*]pyrazine* **2**b

Fusion: 99–100°C (héxane); ir ($cm^{-1}$) $\nu_{NH}$: 3250; rmn $^1$H (ppm): 7,57 (s, H2), 5,1 (m, NH), 3,43 (sex, 2 H6, $J$ = 6 Hz, $J_{H6\text{-}NH}$ = 2 Hz), 2,90 (t, 2H8, $J$ = 6 Hz), 2,3 (s, $CH_3$), 2,03 (mu, 2 H7).

*Diméthyl-2,3 pyrido[2,3-*b*]pyrazine* **3**

En milieu alcoolique nous obtenons un mélange (20:80) des dérivés tétrahydrogénés **3***a* et **3***b* que nous avons séparés par chromatographie sur colonne d'alumine (éluant: chloroforme/benzène; Rdt **3***b* = 55%).

En milieu acide acétique nous obtenons sélectivement le dérivé **3***a* (Rdt = 75%).

cis-*Diméthyl-2,3 tétrahydro-1,2,3,4 pyrido[2,3-*b*]pyrazine* **3**a (4, 34, 35)

Fusion: 111,5°C; ir ($cm^{-1}$) $\nu_{NH}$: 3230, 3380; rmn $^1$H (ppm): 7,50 (q, H6, $J_{68}$ = 2 Hz, $J_{67}$ = 4,5 Hz), 6,73 (q, H8, $J_{68}$ = 2 Hz, $J_{78}$ = 8 Hz), 6,43 (q, H7, $J_{67}$ = 4,5 Hz, $J_{78}$ = 8 Hz), 4,9 (m, NH), 3,55 (m, NH + H2 + H3), 1,14 (d, $CH_3$, $J$ = 6 Hz), 1,10 (d, $CH_3$, $J$ = 6 Hz).

*Diméthyl-2,3 tétrahydro-5,6,7,8 pyrido[2,3-*b*]pyrazine* **3**b

Fusion: 114°C; ir ($cm^{-1}$) $\nu_{NH}$: 3260; rmn $^1$H (ppm): 4,9 (m, NH), 3,37 (sex, 2H6, $J$ = 6 Hz, $J_{H6\text{-}NH}$ = 2 Hz), 2,87 (t, 2H8), 2,33 (s, $CH_3$), 2,30 (s, $CH_3$), 2,03 (mu, 2 H7).

*Phényl-3 pyrido[2,3-*b*]pyrazine* **4**

En milieu alcoolique nous obtenons un mélange (35–40:60–65) des dérivés tétrahydrogénés **4***a* et **4***b* dont nous pouvons séparer une proportion importante de **4***a* par recristallisation dans le chloroforme puis par chromatographie sur alumine avec le chloroforme comme éluant, nous obtenons **4***b* (Rdt **4***a* = 25%, Rdt **4***b* = 45%).

Le dérivé **4***a* est obtenu sélectivement par hydrogénation dans l'acide acétique (Rdt = 80%).

*Phényl-3 tétrahydro-1,2,3,4 pyrido[2,3-*b*]pyrazine* **4**a (13)

Fusion: 181°C; ir ($cm^{-1}$) $\nu_{NH}$: 3200, 3360; rmn $^1$H (ppm): 7,33 (m, H6 + $C_6H_5$), 6,70 (q, H8, $J_{68}$ = 2 Hz, $J_{78}$ = 7 Hz), 5,3 (m, NH), 4,65 (q, H3, $J$ = 3,5 Hz, $J$ = 7 Hz), 3,4 (m, NH), 3,35 (m, 2H2).

*Phényl-3 tétrahydro-5,6,7,8 pyrido[2,3-*b*]pyrazine* **4**b (6)

Fusion: 166°C; ir ($cm^{-1}$) $\nu_{NH}$ = 3210; rmn $^1$H (ppm): 8,10 (s, H2), 7,83 (m, 2H($C_6H_5$)), 7,37 (m, 3H($C_6H_5$)), 5,4 (m, NH), 3,33 (sex, 2H6, $J$ = 6 Hz, $J_{H6\text{-}NH}$ = 2 Hz), 2,90 (t, 2H7, $J$ = 6 Hz, 2,03 (mu, 2H8).

*Diphényl-2,3 pyrido[2,3-*b*]pyrazine* **5**

L'hydrogénation catalytique de **5** en solution alcoolique nous permet d'obtenir quantitativement la diphényl-2,3 tétrahydro-5,6,7,8 pyrido[2,3-*b*]pyrazine **5***b* (6) que nous purifions par recristallisation dans l'alcool ou le cyclohexane (Rdt = 80%). Fusion:[1] 185°C; ir ($cm^{-1}$) $\nu_{NH}$: 3250; rmn $^1$H (ppm):[2] 7,25 (m, 10H, $2C_6H_5$), 5,6 (m, NH), 3,27 (sex, 2H6, $J$ = 5,5 Hz, $J_{H6\text{-}NH}$ = 3 Hz), 3,0 (t, 2H8, $J$ = 6 Hz), 2,05 (mu, 2H7).

L'hydrogénation catalytique de **5** dans l'acide acétique conduit à la *cis*-diphényl-2,3 tétrahydro-1,2,3,4 pyrido[2,3-*b*]pyrazine **5***a* (6) que nous pouvons recristalliser dans le mélange alcool–eau (2:3) (Rdt = 75%). Fusion = 206°C; ir ($cm^{-1}$) $\nu_{NH}$: 3240, 3415; rmn $^1$H (ppm): 7,53 (q, H6, $J_{67}$ = 5 Hz, $J_{68}$ = 2 Hz), 6,93 (H8 + $2C_6H_5$), 6,5 (q, H7, $J_{67}$ = 5 Hz, $J_{78}$ = 7,5 Hz), 5,37 (m, NH), 4,77 (m, H2 + H3), 4,03 (m, NH).

*Synthèse des dihydro diphenyl-2,3 pyrido[2,3-*b*]pyrazines* **5**c *et* **5**d[3]

*Diphényl-2,3 dihydro-3,4 pyrido[2,3-*b*]pyrazine* **5**c (15)

À une suspension de **5** (2,7 g, 0,01 mol) dans l'acide acétique glacial (50 mL) refroidi au bain de glace, nous ajoutons en 1 heure, le tétrahydruroborate de potassium (1,62 g, 0,03 mol) par petites portions en maintenant la température entre 0 et 15°C.

[1]L'analyse thermique différentielle de ce produit, montre qu'il y a absorption d'énergie vers 144°C mais que la fusion s'effectue à 185°C.

[2]Nous avons observé une variation importante du déplacement chimique des protons H6 de 3 ppm en solution saturée (70 mg dans 400 mg de solvant) à 3,3 ppm en solution diluée (10 mg dans 400 mg). L'effet sur les protons H8 est pratiquement nul et très faible pour les protons H7 (inférieur à 0,1 ppm).

Ces deux remarques[1,2] nous incitent à penser qu'il doit exister des liaisons hydrogène préférentielles entre ces molécules en solution, ce qui provoque une cristallisation dans un système métastable.

[3]La synthèse de ces dérivés fait partie d'un travail sur la réduction des pyrido[2,3-*b*]pyrazines par les hydrures métalliques qui est actuellement en cours.

TABLEAU 5. Résonance magnétique nucléaire $^{13}C$ ($CDCl_3$)

| | C2 | C3 | C6 | C7 | C8 | C9 | C10 |
|---|---|---|---|---|---|---|---|
| δ | 146,6 | 157,0 | 153,2 | 123,7 | 137,5 | 135,4 | 150,2 |
| $\Delta(\delta_2 - \delta_1)$ | +0,3 | +9 | −1,3 | −2 | −1,3 | −3,2 | −1,4 |
| | C3 | C2 | C8 | C7 | C6 | C10 | C9 |
| $\Delta(\delta_{MeQ} - \delta_Q)$* | +1 | +8,6 | −0,8 | −0,0 | −0,9 | −0,4 | −1,8 |

*Q = quinoléine; MeQ: méthyl-2 quinoléine (25).

Nous laissons 3 heures à température ambiante. Nous hydrolysons par la glace pilée (20 g), puis alcalinisons par une solution de soude concentrée. Le mélange est extrait au chloroforme (3 fois 100 mL). Les phases organiques réunies sont lavées par une solution aqueuse (2 fois 10 mL) saturée de chlorure de sodium puis séchées sur sulfate de magnésium et évaporées sous pression réduite. Le produit obtenu est solubilisé dans le minimum de chloroforme et reprécipité par 10 mL d'éther éthylique. On obtient ainsi 1,8 g (Rdt = 66%) de **5***c* que l'on peut recristalliser dans le méthanol ou un mélange benzène–hexane. Fusion: 205°C; ir ($cm^{-1}$) $\nu_{NH}$: 3210; rmn $^1H$ (ppm): 7,20–8,10 (m, H6 + H8 + $2C_6H_5$), 6,70 (q, H7, $J_{67}$ = 5 Hz, $J_{78}$ = 7,5 Hz), 5,92 (s, H3), 5,75 (m, NH).

*Diphényl-2,3 dihydro-5,6 pyrido[2,3-*b*]pyrazine* **5**d

À une solution de **5** (5,66 g, 0,02 mol) d'acide acétique (5,4 g, 0,09 mol) dans du benzène sec (100 mL), nous ajoutons en maintenant la température inférieure à 10°C, le tétrahydruroborate de potassium (1,62 g, 0,03 mol) par petites portions sous bonne agitation. Nous laissons 2 heures à température ambiante puis portons à 35°C pendant 30 min. Après un traitement analogue au précédent nous isolons 4,2 g (Rdt = 76%) de **5***d* que l'on peut recristalliser dans l'alcool. Fusion: 209°C; ir ($cm^{-1}$) $\nu_{NH}$: 3230; rmn $^1H$ (ppm): 7,23 (m, $2C_6H_5$), 6,47 (sex, H8, $J_{68}$ = 2 Hz, $J_{78}$ = 10 Hz), 6,17 (m, NH), 5,78 (mu, H7, $J_{78}$ = 10 Hz, $J_{67}$ = 4 Hz, $J_{H7\text{-}NH}$ = 2 Hz), 4,0 (mu, 2H6, $J_{67}$ = 4 Hz,[4] $J_{68}$ = 2 Hz[4]).

## Remerciements

Nous tenons à remercier Monsieur le Professeur P. Granger et le Docteur S. Chapelle pour les spectres rmn $^{13}C$ et leur précieux conseils dans ce domaine ainsi que M. et J. P. Salaun pour leur collaboration à l'étude de la protonation des pyrido[2,3-*b*]pyrazines.

# Solid states structures of 1,4-diacetyl-1,4-dihydroquinoxaline and 1,2-diacetyl-1,2-dihydrobenzo[*c*]cinnoline; two potential antiaromatic heterocyclic compounds

JOSEPH ARMAND

*Laboratoire de Physicochimie des Solutions, Université Pierre et Marie Curie, Bâtiment F, 8 Rue Cuvier, 75230 Paris Cedex 05, France*

AND

MICHÈLE PHILOCHE-LEVISALLES

*Laboratoire de Chimie Systématique, Université Pierre et Marie Curie, Bâtiment F, 8 Rue Cuvier, 75230 Paris Cedex 05, France*

Received January 20, 1982

JOSEPH ARMAND and MICHÈLE PHILOCHE-LEVISALLES. Can. J. Chem. **60**, 2792 (1982).

A crystallographic investigation shows that the 1,4-diacetyl-1,4-dihydroquinoxaline **2** possesses a plane of symmetry perpendicular to the N(1)—N(4) axis and that the 1,4-dihydropyrazine ring exists under a well developed boat conformation. This allows one to reject an azahomoaromatic structure with six delocalized π electrons and a pair of electrons localized on a nitrogen atom. The C(2)=C(3) double bond is localized. **2** shows a *ZZ* conformation and the molecule indicates an angular shape analogous to that of 1,5-dihydroalloxazines.

In the solid state 1,2-diacetyl-1,2-dihydrobenzo[*c*]cinnoline is not planar. The dihedral angle between the two benzenic rings is 19.5°. The N-acetyl groups present an *E,E*-conformation and their stereochemical arrangement prevents the nitrogen pairs from being delocalized toward the neighbouring benzenic groups. This shows that **3** is not an antiaromatic molecule.

JOSEPH ARMAND et MICHÈLE PHILOCHE-LEVISALLES. Can. J. Chem. **60**, 2792 (1982).

On montre par cristallographie que la 1,4-diacetyl-1,4-dihydroquinoxaline **2** présente un plan de symétrie perpendiculaire à l'axe $N_1N_4$ et que le noyau 1,4-dihydropyrazine adopte une forme bateau suffisamment prononcée pour exclure une structure de type azahomoaromatique comprenant un ensemble de 6 électrons π délocalisés et une paire d'électrons localisée sur un atome d'azote. La double liaison C(2)=C(3) est localisée. **2** adopte une conformation *ZZ* et l'ensemble de la molécule a une forme angulaire analogue à celle des 1,5-dihydroalloxazines.

A l'état solide, la 1,2-diacetyl-1,2-dihydrobenzo[*c*]cinnoline n'est pas plane. Les deux noyaux benzéniques présentent entre eux un angle dièdre de 19,5°. Les groupements N-acétylés ont une conformation *E,E*, leur disposition dans l'espace montre que les paires d'électrons libres des atomes d'azote ne sont pas délocalisées vers les noyaux benzéniques voisins. Ces résultats montrent que **3** n'est pas une molécule antiaromatique.

## Introduction

There has been considerable recent interest in the study of potential antiaromatic heterocyclic compounds (1). In the case of N-heterocyclic derivatives, the replacement of two diametrically opposed ethylenic groups in cyclooctatetraene by two >N—R groups leads to 1,4-dihydropyrazine derivatives, while the replacement of two vicinal ethylenic groups leads to 1,2-dihydropyridazine derivatives. These derivatives are potential 8π-electron systems (1) and the examination of their solid state structure allows a precise determination the extent of delocalization of the eight electrons. In a preceding paper we have investigated (2) the structure of 1,4-diacetyl-1,4-dihydro-2,3-diphenylpyrazine **1**. In order to define the influence of benzannelation on the the structure of 1,4-dihydropyrazine ring we have undertaken the structural examination of **2**. Further, to the best of our knowledge, the detailed structure of compounds with a 1,2-dihydropyridazine ring has never been determined; **3** appears as an example of such compounds and its stability is high enough to permit a stereochemical determination.

structure factor amplitudes and of temperature factors were put in the Depository of Unpublished Data.[1]

The molecule presents a plane of symmetry perpendicular to the N(1)—N(4) axis, thus the carbon atoms of the 1,4-dihydropyrazine ring are coplanar. The phenyl ring is planar and atoms N(1) and N(4) belong to this plane. The conformation of the 1,4-dihydropyrazine ring corresponds to a boat form displaying a mirror symmetry. If A is the middle of the C(2)—C(9) segment and B the middle of the C(3)—C(10) segment (Fig. 3), it is possible to define the following angles, as in the case of **1** (2): α = 180° − (N(1)AB), β = 180° − (N(4)BA), γ = (AN(1)C(11)), and δ = (BN(4)C(41)). In the case of **2** one finds α = β = 27.9°, γ = δ = 173.4°. As could be expected the atoms N(1), C(11), C(12), O(13) on one side and N(4), C(14), C(42), O(43) on the other side are coplanar. The angles between these planes and the mediating plane of the 1,4-dihydropyrazine ring (N(1)ABN(4) plane) is 80.2°. As shown in Fig. 1 both amide groups present a *Z* conformation. The large values of the angles around N(1) and N(4) imply a substantial $sp^2$ character for the nitrogen atoms. The dihedral angle between the N(1)C(2)C(3)N(4) and N(1)C(9)C(10)N(4) planes is equal to 33.3°.

[1]A complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

### *2. 1,2-Diacetyl-1,2-dihydrobenzo[c]cinnoline* **3**

Positional parameters and isotropic thermal parameters are given in Table 4. Table 5 lists bond lengths and Table 6 some selected bond angles. Figure 4 is an ORTEP drawing of the structure of **3**. Tables of observed and calculated structure factor amplitudes and of temperature factors were lodged with the Depository of Unpublished Data.[1]

The phenyl rings $\phi_1$ and $\phi_2$ are planar. Atoms N(1) and C(13) are in the plane of $\phi_1$ and atoms N(2) and C(12) in the plane of $\phi_2$. The dihedral angle between these two planes is equal to 19.5°; the values of the distances between N(1) and the plane of $\phi_2$ on one hand and between N(2) and the plane of $\phi_1$ on the other hand are respectively 0.8 Å and 0.77 Å. Thus the heterocyclic ring is not planar. The atoms are located in the planes of a dihedra: N(1), C(11), C(12), C(13) in one plane and N(2), C(14), C(13), C(12) in the other plane, the axis C(12)C(13) being at the intersection of the two planes. The atoms N(1), C(15), C(16), O(1) on one side and N(2), C(17), C(18), O(2) on the other side are coplanar. As shown in Fig. 4, both amide groups present an *E* conformation.

## Discussion

In the case of **2** the 1,4-dihydropyrazine ring presents a pronounced boat shape as $\alpha = \beta = 27.9°$. If one considers the axis of the orbital of the nonbonding N(1) pair as being perpendicular to the C(2)C(9)C(11) plane, it is found that this axis makes an angle of 57.9° with the plane C(2)C(3)C(9)C(10). The value of this angle — identical to that existing

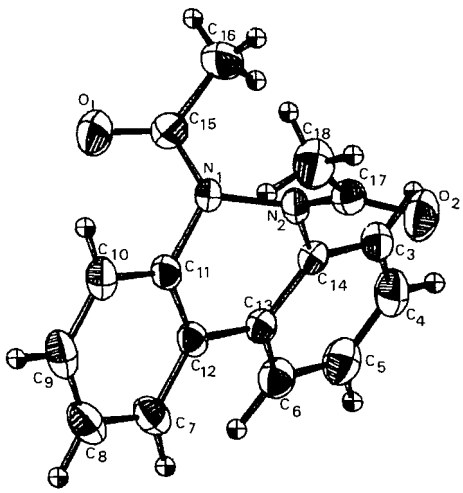

FIG. 4. ORTEP drawing of the crystal structure of **3**.

between the axis of the N(4) lone pair and the plane C(2)C(3)C(9)C(10), as the molecule is symmetrical — does not support the hypothesis of a delocalization of the nonbonding pairs of N(1) and N(4) towards the 1,4-dihydropyrazine ring. This is confirmed by the length of the C(2)C(3) double bond (1.316 Å) which corresponds to a localized double bond. These results show that the molecule is not antiaromatic and rule out the hypothesis of the separation of the eight π electrons into six electrons delocalized on the ring and two electrons on one nitrogen atom. Now, if one compares the structures of **1** and **2** it is observed that **2** presents, in contrast to **1**, a symmetry plane perpendicular to the N(1)N(4) axis (in the case of **1** (2) the values of the angles were $\alpha = 30.9°$, $\beta = 34.5°$, $\gamma = 168.1°$, $\delta = 173.5°$); the bond lengths are quite similar for **1** and **2**. In particular, the length of the C(2)C(3) bond of **2** (1.316 Å) is near that of the C(5)C(6) bond of **1** (1.320 Å). The dihedral angle between the mean N(1)C(2)C(3)N(4) and N(1)C(9)C(10)N(4) planes is 33.3° in the case of **2**; it is smaller than in the case of **1** (38.2°) but it is similar to the value found for some 1,5-dihydroalloxazines (3, 4).

In order for **3** to display an antiaromatic character the two nitrogen lone pairs should be conjugated with the benzenic ring and these two benzenic rings should be conjugated together. The angle of 19.5° measured between these rings shows that the last condition is not fulfilled. Further, as in the case of **2**, the axis of the orbital of the nitrogen lone pair of N(1) must be perpendicular to the N(2)C(11)C(15) plane; this axis makes an angle of 35° with the plane of the benzenic ring $\phi_1$ thus preventing any delocalization of the nonbonding electrons of N(1) towards $\phi_1$. In the case of N(2) the axis of the lone pair makes an angle of 39° with $\phi_2$ which also rules out any delocalization of the nonbonding electrons of N(2) towards $\phi_2$.

All these results show that **3** is not antiaromatic: π conjugation of the cyclic 8π system, and hence electron delocalization, is thwarted by the angular skeleton of the 1,2-dihydropyridazine ring and by the positions of the lone pairs of electrons on nitrogen atoms.

It should be remarked that the two acetyl groups take the *E*,*E*-conformation where the two methyl groups are neighbours. However, there is no steric hindrance as the two acetyl groups are not coplanar, the value of the dihedral angle C(15)N(1)-N(2)C(17) is 61°.

## Experimental

The 1,4-diacetyl-1,4-dihydroquinoxaline and the 1,2-diacetyl-1,2-dihydrobenzo[*c*]cinnoline have been prepared according to ref. 5. The single crystals used in the crystallographic study were obtained by slow evaporation of solutions of **2** and **3** in dimethylformamide.

Crystal data of **2** are as follows:

$C_{12}H_{22}N_2O_2$ fw = 216

Orthorhombic, $a = 10.438(2)$, $b = 15.363(3)$, $c = 6.638(2)$ Å, $V = 1064.5$ Å$^3$, $Z = 4$, $\rho_c = 1.33$ g cm$^{-3}$, $\rho_o = 1.32(2)$ g cm$^{-3}$ (20°C, Mo $K_\alpha$ $\lambda = 0.707$ Å, $\mu = 0.96$ cm$^{-1}$).

Preliminary X-ray photographs showed the following systematic absences: $0kl$, $k + l = 2n + 1$, $hk0$, $h = 2n$; a statistical analysis of the intensity data indicated the centrosymmetric space group *Pnma*. A crystal (0.45 × 0.30 × 0.25 mm) was mounted with the *a* axis parallel to the φ axis of a Philips automated diffractometer equipped with a graphite monochromator. The intensities of all reflections having 2θ less than 50° were measured using the variable ω–2θ scan technique. During the course of the data collection three standard reflections were measured every 54 reflections. A total of 1433 reflections were measured, 909 of which had $I > 4\sigma(I)$. The data were reduced to $|F_o|$ by the routine procedure. Lorentz and polarization but no absorption or extinction corrections were

applied. The scattering factors for neutral atoms were taken from ref. 6. The structure was determined by direct methods (MULTAN) (7) and refined by large block least-squares $\Sigma\omega(F_o - |F_c|)^2 = \min$ with $\omega = 1/\sigma^2$. The refinement with anisotropic thermal parameters on the non-hydrogen atoms converged to $R = 0.092$. At this stage, a difference Fourier map revealing the positions of all the hydrogen atoms was calculated; refinement of their positional parameters was carried out, using the thermal parameters of the corresponding heavy atoms at the end of isotropic refinement. The refinement converged with $R = 0.047$ and $R_w = 0.055$.

Crystal data of **3** are as follows:

$C_{16}H_{14}N_2O_2$ fw = 266

Orthorhombic, $a = 19.350(4)$, $b = 9.797(2)$, $c = 14.110(3)$ Å, $V = 2674.9$ Å$^3$, $Z = 8$, $\rho_c = 1.32$ g cm$^{-3}$, $\rho_o = 1.30(2)$ g cm$^{-3}$ (20°C, Mo $K_\alpha$ $\lambda = 0.707$ Å, $\mu = 0.85$ cm$^{-1}$).

Preliminary X-ray photographs showed the following systematic absences: $0kl$, $k = 2n + 1$; $h0l$, $l = 2n + 1$; $hk0$, $h + k = 2n + 1$; a statistical analysis of the intensity data indicated the centrosymmetric space group *Pbcn*. A crystal (0.50 × 0.20 × 0.35 mm) was mounted with the *a* axis parallel to the $\phi$ axis of a Philips automated diffractometer equipped with a graphite monochromator. The intensities of all reflections having $2\theta$ less than 50° were measured using the variable $\omega$–$2\theta$ scan technique. During the course of the data collection three standard reflections were measured every 54 reflections. A total of 2737 reflections were measured, 1714 of which had $I > 4\sigma(I)$. The data were reduced to $|F_o|$ by the routine procedure. Lorentz and polarization but no absorption or extinction corrections were applied. The scattering factors for neutral atoms were taken from ref. 6. The structure was determined by direct methods (MULTAN) (7) and refined by large block least-squares $\Sigma\omega(F_o - |F_c|)^2 = \min$ with $\omega = 1/\sigma^2$. The refinement with anisotropic thermal parameters on the non-hydrogen atoms converged to $R = 0.087$. At this stage, a difference Fourier map revealing the positions of all the hydrogen atoms was calculated; refinement of their positional parameters was carried out, using the thermal parameters of their corresponding heavy atoms at the end of isotropic refinement. The refinement converged with $R = 0.051$ and $R_w = 0.056$.

In this paper when it is stated that atoms are coplanar, it means that they were found in the same plane within experimental accuracy.

Received May 7, 1982

JOSEPH ARMAND, LINE BOULARES, CHRISTIAN BELLEC, and JEAN PINSON. Can. J. Chem. **60**, 2797 (1982).

The electrochemical reduction of quinoxalino[2,3-*b*]quinoxaline gives fluoflavine (**2**) the structure of which is discussed. The electrochemical reduction of fluoflavine in acidic medium leads to a hexahydroquinoxalino[2,3-*b*]quinoxaline. A reduction mechanism is proposed based on cyclic voltammetry results and preparative electrolysis. The results obtained in the case of quinoxalino[2,3-*b*]quinoxaline are used to rationalize the results obtained in the case of pyrazino[2,3-*b*]pyrazines and pyrazino[2,3-*b*]quinoxalines.

JOSEPH ARMAND, LINE BOULARES, CHRISTIAN BELLEC et JEAN PINSON. Can. J. Chem. **60**, 2797 (1982).

La réduction électrochimique de la quinoxalino[2,3-*b*]quinoxaline fournit la fluoflavine (**2**) dont la structure est discutée. La réduction électrochimique de la fluoflavine en milieu acide fournit une hexahydroquinoxalino[2,3-*b*] quinoxaline. Un mécanisme de réduction utilisant les résultats de la voltammétrie cyclique et des électrolyses préparatives est proposé. La présente étude permet également de rationaliser certains résultats obtenus dans des études antérieures relatives aux pyrazino[2,3-*b*] pyrazines et pyrazino[2,3-*b*] quinoxalines.

For personal use only.

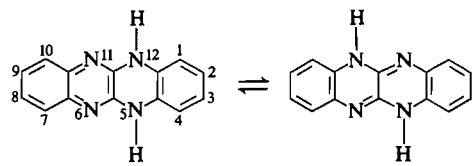
We have been interested for some time in the electrochemical reduction of heterocyclic compounds with two 1,4-nitrogen atoms in a six-membered ring. We now report the electrochemical reduction in protic and aprotic medium of the quinoxalino[2,3-*b*]quinoxaline, **1**. This compound possesses two conjugated

systems and it seemed interesting to investigate how the conjugation of two such systems would influence their electrochemical behaviour. A single electrochemical study of **1** has been published (1); however, its conclusions are erroneous.

As we shall see later on, the electrochemical reduction of the quinoxalino[2,3-*b*]quinoxaline **1** leads to fluoflavine which is a dihydro quinoxalino-[2,3-*b*]quinoxaline. It can also be prepared by condensation of 2,3-dichloroquinoxaline with *o*-phenylene diamine (2). The structure of fluoflavine has remained controversial as some authors assigned a 5,12-dihydro structure **2** (3), while others assigned a 5,11-dihydro structure **2***a* (2). Therefore, we shall first discuss the structure of fluoflavine.

### The structure of fluoflavine

Some of the problems arising in the investigation of the structure of this compound stem from its very low solubility in usual solvents (methanol, acetonitrile, dimethylsulphoxide, dimethylformamide). It can be dissolved in hot acetic acid or in cold trifluoroacetic acid. Our first attempts aimed at obtaining an unambiguous determination of the structure by X-ray crystallography, but we were unable to obtain suitable crystals from $CH_3COOH$ or $CF_3COOH$ solutions. An nmr spectrum recorded in $CF_3COOH$ shows a single AA'BB' pattern for the eight aromatic protons, which gives no indication on the structure of fluoflavine the protons of the benzenic rings being equivalent because of the protonation of the nitrogen atoms and the fast exchange of these protons.

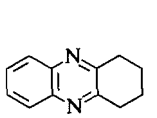


**2** **2***a*

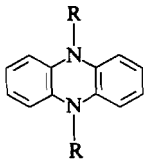
An nmr spectrum of fluoflavine in $Me_2SO$-$d_6$ obtained on a 250 MHz spectrometer after 3000 accumulations shows two aromatic multiplets located respectively at 6.45–6.75 ppm (4H) and 6.90–7.13 ppm (4H) and a broad signal at 9.92 ppm corresponding to the two NH protons. This spectrum rules out the existence of a fast equilibrium

0008-4042/82/222797-07$01.00/0
©1982 National Research Council of Canada/Conseil national de recherches du Canada

between the tautomers **2** and **2***a* because the aromatic protons of the two benzenic rings would be equivalent and the spectrum would consist of a single AA'BB' pattern, the width of which can be estimated to about 0.15 ppm (the aromatic protons of 5,10-dihydro-2,3-dimethyl-pyrazino[2,3-*b*]quinoxaline appear as an AA'BB' pattern with a width of 0.12 ppm). Thus, fluoflavine has either structure **2** or structure **2***a*. Structure **2** should give rise to two separated AA'BB' patterns. The aromatic protons of 1,2,3,4-tetrahydrophenazine **3** appear as a multiplet between 7.50 and 8.10 ppm (4) while that of 5,10-bis-*n*-propyl-5,10-dihydrophenazine **4** appear



**3**



**4** R = *n*-propyl

between 6.06 and 6.70 ppm (5). Thus, the observed spectrum is in agreement with structure **2**, but its poor resolution does not permit the measurement of the characteristics of the two possible AA'BB' patterns. This is why it is not possible to rule out structure **2***a* which could also evidence two multiplets of equal intensity. By heating fluoflavine in acetic anhydride a single diacetyl derivative **25** is obtained. Its 250 MHz nmr spectrum shows two aromatic AA'BB' patterns which proves that **25** is a 5,12-diacetylated derivative. The structure of **25** is confirmed by its electrochemical reduction (vide infra) which gives *N*,*N*'-diacetyl *o*-phenylene diamine. Obtaining a single diacetyl derivative in the 5,12-positions is in agreement with structure **2** but does not allow the exclusion of structure **2***a*; indeed, it is possible that at high temperature the **2***a* → **2** interconversion be faster than the acetylation of **2**.

We have shown previously (8) that the electrochemical reduction of the pyrazino[2,3-*b*]quinoxaline **18** leads to the only 5,10-dihydro derivative **20**, **18** and **20** forming a redox couple (see Scheme 4). As we shall see further the electrochemical reduction of **1** only gives fluoflavine and **1** and fluoflavine also form a redox couple. As **1** and **18** have very similar structures this result favours structure **2** for fluoflavine.

It should also be remarked that the condensation of 2,3-dichloroquinoxaline with 1,2-diamino-4,5-dimethylbenzene gives a solid which by heating in acetic anhydride leads to a mixture of the 5,12-diacetyl-5,12-dihydro derivative **7** and of the 6,11-diacetyl-6,11-dihydro derivative **8**. This result points to the formation of a mixture of the 5,12-dihydro derivative **5** and of a 6,11-dihydro derivative **6** upon condensation. As the influence of the methyl groups on the structure of a dihydroquinoxalino[2,3-*b*]quinoxaline is most likely very small, the structures of **5** and **6** support structure **2** for fluoflavine.

Thus, although there is no formal proof that fluoflavine has structure **2**, the above results show structure **2** as the most likely; thus it will be used in this paper.

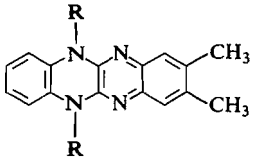
**7**, R = $COCH_3$



**6**, R = H
**8**, R = $COCH_3$

*Electrochemical reduction of quinoxalino[2,3-b]-quinoxaline*

In aprotic medium ($CH_3CN$) a voltammogram of **1** presents two reversible peaks at $E_1^0 = -0.37$ V and $E_2^0 = -1.05$ V which correspond to the formation of a radical anion and a dianion.

In hydroorganic medium (50/50 v/v water–dimethylformamide) **1** presents a 2F wave which is pH dependent between pH 4 and 12: $E_{1/2}$ (V) = 0.44 − 0.058pH; **1** is unstable in more acidic or more basic media. Between pH 4 and 6, this first wave is followed by a pH-dependent 4F wave: $E_{1/2}$ (V) = −0.75 − 0.068pH; above pH 6 the height of the second wave decreases and disappears at pH > 8.

A preparative electrolysis of **1** on the first plateau gives **2**. The second 4F wave is that of **2**. The electrochemical reduction of **2** in acidic medium where it is slightly more soluble leads to 5,5a,6,11,-11a,12-hexahydroquinoxalino[2,3-*b*]quinoxaline, **9**. When **9** is heated in acetic anhydride, it furnishes a triacetyl derivative **10**. The large value of the $^3J_{5a-11a}$ coupling constant (18 Hz) of **10** points to a *trans* configuration for the hydrogens 5a and 11a. The results are summarized in Scheme 1.

The results of a previous polarographic study of **1** (1) are erroneous as the authors do not mention the first wave of **1** and assign the second wave to **1** instead of **2**. Besides, no preparative electrolysis is described.

Concerning the reduction mechanism, the formation of **2** from **1** is in agreement with what could be expected from the known reduction of compounds with a pyrazine ring. Pyrazines (9), quinoxalines (10), and pyrido[2,3-*b*]pyrazines (11) are first reduced to compounds with a

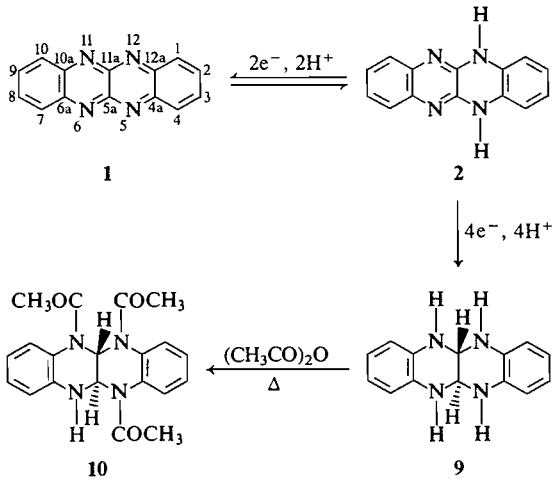
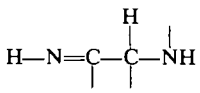
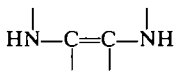


SCHEME 1

structure. The same reaction is observed for the reduction of **1** into **2**. But unlike previous compounds which rearrange to



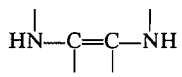
structures the



structure of **2** is stable. This is obviously related to the increased number of conjugated cycles.

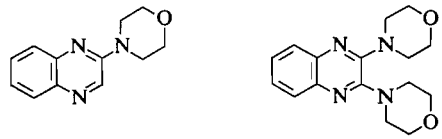
In the case of **2**, one could expect for the same reasons as above the primary formation of a 5,6,11,12-tetrahydrogenated compound **11** which would rearrange to a 5,5a,6,12-tetrahydrogenated compound **12**, the reduction of which would lead to a hexahydrogenated compound such as **9** (Scheme 3).

Compounds such as **11** with a

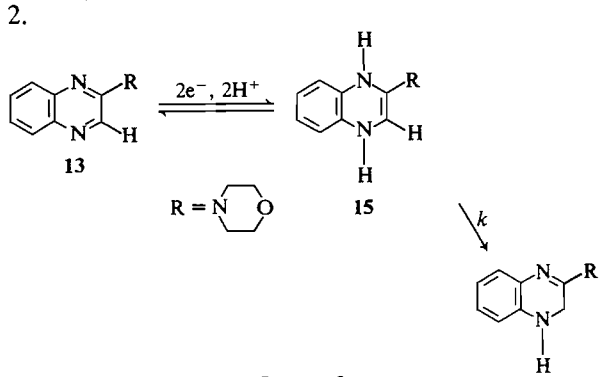


structure are usually characterized by an anodic peak on their voltammogram. The potential of this anodic peak is generally near or identical to that of the cathodic peak of the parent heterocycle (see, e.g., 2-phenylquinoxaline (10), 2,3-diphenylpyrazine (9), diphenylpyrido[3,4-*b*]pyrazine (11)). No anodic peak which could correspond to **11** can be observed on mercury, but on a glassy carbon electrode, an anodic peak $II_a$ appears at $E_{pa}$ = +0.65 V if the cathodic peak of fluoflavine $II_c$ ($E_{pc}$ = −0.93 V) has been scanned before (Fig. 1, $v$ = 0.2 V $s^{-1}$, pH 1, 50% DMF), the reversible couple which appears at $E^0$ = +0.45 V, $I_c/I_a$ being that of fluoflavine itself.

In order to find out the origin of the large positive shift of the anodic peak we investigated the behaviour of 2-morpholinoquinoxaline **13** where the pyrazine ring also bears a nitrogen substituent.

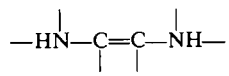


In hydroorganic medium (50/50 v/v methanol–water) **13** presents a 2F cathodic wave (1 < pH < 4.5: $E_{1/2}$ = −0.15 − 0.11 pH and 4.5 < pH < 13: $E_{1/2}$ = −0.39 − 0.061 pH). Its electrolysis in basic medium furnishes the 3,4-dihydro-2-morpholinoquinoxaline and its cyclic voltammetry in basic medium (25% DMF, 0.1 *N* NaOH, $v$ = 20 V $s^{-1}$) shows a cathodic peak at $E_{pc}$ = −1.50 V and an anodic peak at $E_{pa}$ = −0.88 V. Thus in basic media 2-morpholinoquinoxaline presents a voltammetric behaviour similar to the other quinoxalines already investigated. Its reduction is summarized in Scheme 2.

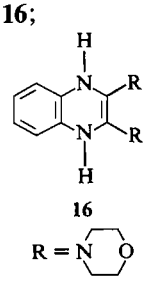


SCHEME 2

In acidic medium under the same conditions as fluoflavine ($v$ = 0.2 V $s^{-1}$, pH = 1, 50% DMF) the cathodic peak of **13** is observed at $E_{pc}$ = −0.50 V and the anodic peak corresponding to the



structure **15** appears at $E_{pa}$ = +0.73 V. In the same way 2,3-dimorpholinoquinoxaline **14** gives under the same conditions a cathodic peak at $E_{pc}$ = −0.93 V and an anodic peak at $E_{pa}$ = +0.78 V corresponding to **16**;



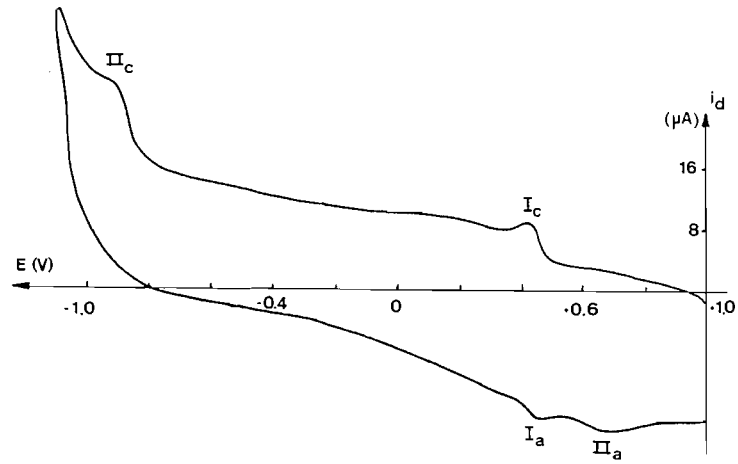


FIG. 1. Voltammogram of fluoflavin **2** at pH 1; 50% DMF; $v = 0.2\,V\,s^{-1}$.

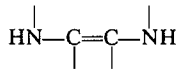
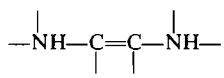
Thus, it appears that in the case of

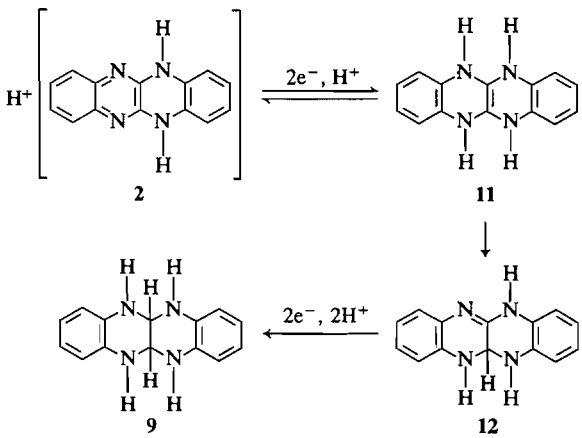


structures substituted by amino groups on the two central atoms their anodic peak is shifted to positive potentials in acidic medium. This can be related to the protonation of the amino substituents. The protonated amino groups are strongly electron-withdrawing making the reoxidation of the



system more difficult. This can also be confirmed with the diacetyl derivative of fluoflavine **25** (Scheme 5) which gives a 2F cathodic peak at $E_{pc} = -0.51\,V$ and an anodic peak at $E_{pa} = -0.31\,V$ ($v = 0.2\,V\,s^{-1}$, pH 1, 50% DMF). Indeed in the case of **25** the two substituted amino groups remain unprotonated.

Scheme 3 can be proposed for the reduction of

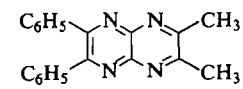


SCHEME 3

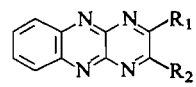
fluoflavine. It is not possible to accurately measure the rate of rearrangement of **11** to **12** as the cathodic wave of fluoflavine merges in the background discharge upon increasing the sweep rate, but its order of magnitude can be estimated to about 0.2 $s^{-1}$ from the peaks height.

*Electrochemical reduction of pyrazino[2,3-b]-pyrazines and pyrazino[2,3-b]quinoxalines*

Let us now turn back to the reduction of less conjugated systems such as pyrazino[2,3-*b*]pyrazines **17** and pyrazino[2,3-*b*]quinoxalines **18**. In the



**17**



**18**

case of **17** one observes a 2F wave corresponding to the formation of a 1,4- (or 5,8-) dihydroderivative **19**, followed by a 4F wave in acidic medium. In the same way **18** presents a 2F wave corresponding to the formation of a 5,10-dihydroderivative **20** (8) followed by a 4F wave in acidic medium (7). In both cases preparative electrolysis at the level of the second plateau lead to gummy products from which no defined product could be characterized. A cyclic voltammogram of **17** ($v = 0.2\,V\,s^{-1}$, glassy carbon electrode, pH = 4.3, 50% DMF) presents a cathodic peak at $E_{pc} = -0.50\,V$ and an anodic peak at $E_{pa} = -0.26\,V$ corresponding to the **17/19** couple. A second cathodic peak is observed at $-1.16\,V$. If one scans at potentials more negative than this second peak at $v = 50\,V\,s^{-1}$ an anodic peak appears at $+0.59\,V$ which can be assigned to **21** by comparison with the voltammograms of **2**, **13**, and **14**. The same kind of voltammogram is observed in the case of **18** where an anodic peak appears at $+0.63\,V$ ($v = 0.2\,V\,s^{-1}$) if the second cathodic peak has been

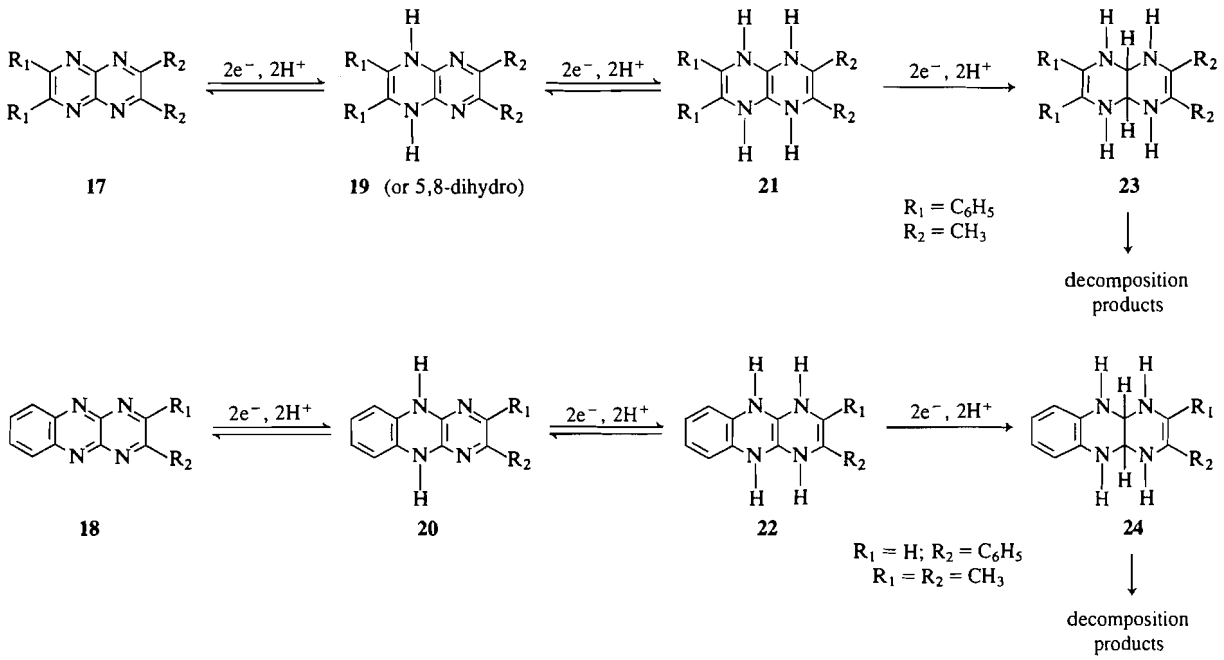


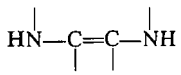
SCHEME 4

scanned beforehand. Scheme 4 can be proposed for the reduction of **17** and **18**. The instability of **23** and **24** is most likely related to their enediamine structure, while **9** which possesses a structure similar to that of *o*-phenylene diamine is stable.

*Electrochemical reduction of 5,12-diacetyl-5,12-dihydroquinoxalino[2,3-*b*]quinoxaline 25*

When heated in acetic anhydride, **2** furnishes **25** which is more soluble than **2** in the usual solvents. In $CH_3CN$, the voltammogram of **25** presents a first monoelectronic cathodic peak at $E_{pc1} = -1.5$ V followed by a bielectronic peak at $E_{pc2} = -2.35$ V (at 0.2 V $s^{-1}$). The first peak corresponds to the formation of the radical anion, while an electrolysis at the level of the second peak mainly gives fluoflavine.

An electrolysis of **25** in $CH_3CN$ in the presence of acetic anhydride gives the 5,6,11,12-tetraacetylated-5,6,11,12-tetrahydro derivative **26***a* (Scheme 5). In the presence of methylchloroformate the 5,6-diacetyl-11,12-dicarbomethoxy-5,6,11,12-tetrahydro derivative **26***b* is obtained. In hydroorganic medium ($CH_3CN$–$H_2O$; 50/50 v/v), **25** shows a 2F polarographic wave which is pH dependent, $E_{1/2}$ (V) = −0.37 − 0.08 pH. An electrolysis of a $10^{-3}$ *M* solution gives an oxidizable compound with a 2F anodic wave at a potential near that of the cathodic wave of **25**. At pH 1.5 this reduction compound gives a product more easily reduced than **25** so that 4F/mol are consumed during the electrolysis. A preparative electrolysis gives a mixture of *N*,*N*′-diacetyl orthophenylenediamine **27** and 1,2,3,4-tetrahydroquinoxaline-2-one **28**. It has been shown previously (12, 13) that the 2,3-dihydroxyquinoxaline **29** leads to **28** by electrochemical reduction, thus the formation of **27** and **28** from **25** should follow the reaction path described in Scheme 5. The primary reduction product responsible for the anodic wave on the voltammogram of **25** would be 5,6-diacetyl-5,6,11,12-tetrahydroquinoxalino[2,3-*b*]quinoxaline **30**, in agreement with a



structure described above. The formation of **30** is also supported by the formation of **26** when the reduction is carried out in the presence of acetic anhydride. **30** would be hydrolyzed in acidic medium into **27** and **29**, the latter compound leading to **28**.

## Experimental section

Melting points are uncorrected. $^1$H-nmr spectra were recorded on a Bruker WH 80, a Varian A 60, and a Bruker 250 MHz spectrometer, using tetramethylsilane (TMS) as internal standard. The apparatus and techniques used for the electrochemical studies and pH measurements have been described previously (11). All the potentials are referred to the saturated calomel electrode (sce); the temperature of the solutions was 20°C. The microanalyses were performed by the "Service de Microanalyse-Université Pierre et Marie Curie". The following abbreviations are used in reporting nmr results: s = singlet, d = doublet, t = triplet, q = quadruplet, m = multiplet.

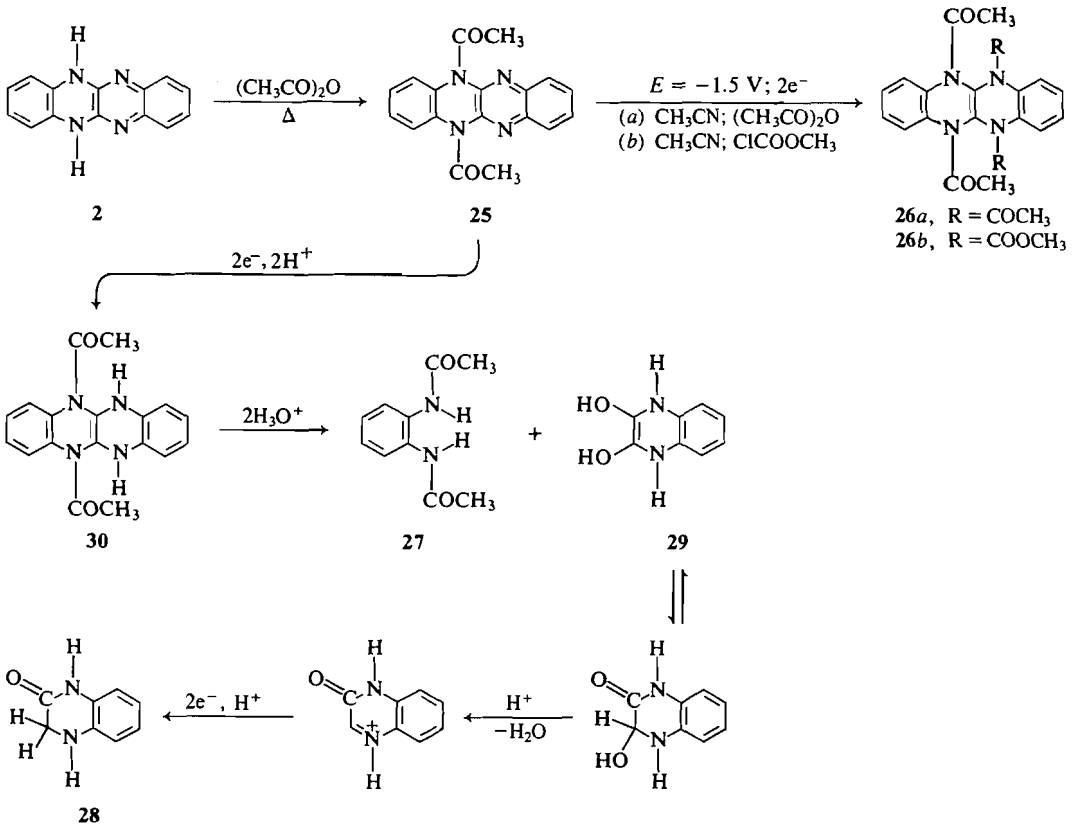

SCHEME 5

*Preparation of 1 and 2*

Quinoxalino[2,3-*b*]quinoxaline **1** was prepared from 5,12-dihydroquinoxalino[2,3-*b*]quinoxaline **2** (fluoflavine) according to ref. 14. Compound **2** was obtained (2) by condensation of *o*-phenylenediamine with 2,3-dichloroquinoxaline.

*5,12-Diacetyl-5,12-dihydroquinoxalino[2,3-*b*]quinoxaline, 25*

A suspension of 500 mg of **2** in 25 mL of acetic anhydride was refluxed for 24 h. Acetic anhydride was evaporated and the residue was crystallized from ethylacetate; 400 mg; mp 202–203°C. $^1$H-nmr ($CDCl_3$, 250 MHz): 5-$CH_3CO$ and 12-$CH_3CO$, s, 2.59 ppm (6H); 1-H, 2-H, 3-H, 4-H, AA'BB' pattern at 7.34 ppm, m (2H) and 7.94 ppm, m (2H); 7-H, 8-H, 9-H, 10-H, AA'BB' pattern at 7.82 ppm, m (2H) and 8.27 ppm, m (2H). *Anal.* calcd. for $C_{18}H_{14}N_4O_2$: C 67.91, H 4.43, N 17.60; found: C 67.85, H 4.51, N 17.56.

*Preparation of 5,12-diacetyl-5,12-dihydro-2,3-dimethylquinoxalino[2,3-*b*]quinoxaline, 7, and 6,11-diacetyl-6,11-dihydro-2,3-dimethylquinoxalino[2,3-*b*]quinoxaline, 8*

A mixture of 5 g of 2,3-dichloroquinoxaline and 6.8 g of 2,3-diamino-5,6-dimethylbenzene in 50 mL of ethyleneglycol was refluxed for 45 min. The cooled reaction mixture was filtered, washed with dimethylformamide and ethanol to give 5.2 g of a yellow–orange solid. This solid (500 mg) was then refluxed in 25 mL of acetic anhydride for 2 h. Acetic anhydride was evaporated and the residue was filtered, washed with water, and dried to give 590 mg of a mixture of **7** and **8** as shown by nmr. Compound **7** is less soluble in ethylacetate than **8**, the two products have been obtained pure after several crystallizations. **7**: mp 210°C, $^1$H-nmr ($CDCl_3$): 2-$CH_3$, 3-$CH_3$, 5-$COCH_3$, 12-$COCH_3$, 2.27 and 2.53 ppm, two s (2 × 3H); 1-H, 4-H, 7.50 ppm, s (2H); 7-H, 8-H, 9-H, 10-H, AA'BB' pattern, 7.60–8.15 ppm, m (4H). *Anal.* calcd. for $C_{20}H_{18}N_4O_2$: C 69.35, H 5.24, N 16.18; found: C 69.29, H 5.28, N 16.22. **8**: mp 215°C; $^1$H-nmr ($CDCl_3$): 2-$CH_3$, 3-$CH_3$, 6-$COCH_3$, 11-$COCH_3$, 2.50 ppm and 2.55 ppm, two s (2 × 3H); 1-H, 4-H, 7.72 ppm, s (2H); 7-H, 8-H, 9-H, 10-H, AA'BB' pattern at 7.23 ppm, m (2H) and 7.84 ppm, m (2H). *Anal.* calcd. for $C_{20}H_{18}N_4O_2$: C 69.35, H 5.24, N 16.18; found: C 69.48, H 5.19, N 16.09.

*Electrolysis of 1 in hydroorganic medium: preparation of 2*

An electrolysis was carried out at pH 6.75 and $E = -0.5$ V (sce). The cathodic compartment contained 100 mg of **1** in 200 mL of solution (dimethylformamide 50%). At the end of the electrolysis (2F per mol) the precipitate in the cell was filtered, washed with water and ethanol, then dried to give 95 mg of 5,12-dihydroquinoxalino[2,3-*b*]quinoxaline **2**.

*Electrolysis of 2 in hydroorganic medium: preparation of 9*

An electrolysis was carried out using 800 mg of **2** partially dissolved in 200 mL of solution (50% $CH_3CN$; 1 *N* $H_2SO_4$) at $E = -0.9$ V. At the end of the electrolysis (4.2 F per mol), acetonitrile was evaporated and the solution was neutralized with 2 *N* NaOH. The solid precipitated was filtered, washed with water, and dried to give 570 mg of 5,5a,6,11,11a,12-hexahydroquinoxalino[2,3-*b*]quinoxaline **9**, mp 270–275°C dec.[1]

[1]The solid state structure and the solution conformations of **9** are presently under investigation. This compound has a structure analogous to 1,4,5,8-tetraazadecalin (TAD) systems which have been the subject of recent sustained interest, see e.g., ref. 6.

$^1$H-nmr (DMSO-$d_6$): 5-H, 6-H, 11-H, 12-H, 4.45 ppm, m (2H) and 5.22 ppm, m (2H) exchanged with $D_2O$; 5a-H, 11a-H, 4.57 ppm, s (2H); 1-H, 2-H, 3-H, 4-H, 7-H, 8-H, 9-H, 10-H, 6.5 ppm, m (4H) and AA'BB' pattern centered at 7.32 ppm (4H). *Anal.* calcd. for $C_{14}H_{14}N_4$: C 70.56, H 5.92, N 23.51; found: C 70.64, H 6.01, N 23.35.

*Acetylation of 9: preparation of 10*

A solution of 650 mg of **9** in 5 mL of acetic anhydride was refluxed for 15 h, cooled at 0°C. The solid precipitated was filtered, washed with water, and dried to give 360 mg of 5,6,11-triacetyl-5,5a,6,11,11a,12-hexahydroquinoxalino[2,3-*b*]quinoxaline **10**, mp 222–223°C. $^1$H-nmr ($CDCl_3$): 5-$COCH_3$, 6-$COCH_3$, 11-$COCH_3$, three singlets at 1.90, 2.45, and 2.80 ppm (3 × 3H); 5a-H, 11a-H, two d at 4.56 ppm and 5.98 ppm, $J_{5a-11a}$ = 18 Hz; 1-H, 2-H, 3-H, 4-H, 7-H, 8-H, 9-H, 10-H, m, 7.1–8.4 ppm (8H); 12-H, broad s, 9.87 ppm (1H) exchanged with $D_2O$. *Anal.* calcd. for $C_{20}H_{20}N_4O_3$: C 65.92, H 5.53, N 15.38; found: C 66.07, H 5.56, N 15.30.

*Electrolysis of 25 in acetonitrile*

The cathodic solution contained 60 mL of solvent, 580 mg of **25**, and 6 g of tetrabutylammonium iodide; $E = -2.4$ V. At the end of the electrolysis (2.1F per mol) the solution was poured into 200 mL of water and the solid precipitated was filtered, washed with water, and dried to give 200 mg of **2**.

*Electrolysis of 25 in acetonitrile in the presence of acetic anhydride: preparation of 26*a

The cathodic solution contained 60 mL of solvent, 800 mg of **25**, 8 mL of acetic anhydride, and 6 g of tetrabutylammonium iodide; $E = -1.5$ V. A solid precipitated during the electrolysis. At the end, the precipitate was filtered, washed with water and acetonitrile, and dried to give 200 mg of 5,6,11,12-tetraacetyl-5,6,11,12-tetrahydroquinoxalino[2,3-*b*]quinoxaline ***26a***, mp > 300°C. $^1$H-nmr (TFA): 5-$COCH_3$, 6-$COCH_3$, 11-$COCH_3$, 12-$COCH_3$, s, 2.50 ppm (12H); 1-H, 2-H, 3-H, 4-H, 7-H, 8-H, 9-H, 10-H, m, 7.4–8.0 ppm (8H). *Anal.* calcd. for $C_{22}H_{20}N_4O_4$: C 65.33, H 4.99, N 13.86; found: C 65.26, H 5.04, N 13.97.

*Electrolysis of 25 in acetonitrile in the presence of methylchloroformate: preparation of 26*b

The cathodic solution contained 60 mL of solvent, 800 mg of **25**, and 6 ml of methylchloroformate and 6 g of tetrabutylammonium iodide; $E = -1.5$ V. At the end of the electrolysis ($i < 3$ mA) the catholyte was poured into 250 mL of water. The solid precipitated was filtered, washed with water, and dried to give 690 mg of 5,12-diacetyl-6,11-dicarbomethoxy-5,6,11,12-tetrahydroquinoxalino[2,3-*b*]quinoxaline, ***26b***, mp 294°C. $^1$H-nmr (TFA): 5-$COCH_3$, 12-$COCH_3$, s, 2.50 ppm (6H); 6-$COOCH_3$, 11-$COOCH_3$, s, 4.0 ppm (6H); 1-H, 2-H, 3-H, 4-H, 7-H, 8-H, 9-H, 10-H, m, 7.3–8.0 ppm (8H). *Anal.* calcd. for $C_{22}H_{20}N_4O_6$: C 60.54, H 4.62, N 12.84; found: C 60.61, H 4.64, N 12.93.

*Electrolysis of 25 in hydroorganic medium*

Electrolysis was carried out with 800 mg of **25** in 200 mL of solution (50% $CH_3CN$; 0.1 *N* $H_2SO_4$); $E = -0.7$ V. At the end of the electrolysis (4F per mol) acetonitrile was evaporated. The solution was neutralized with solid $NaHCO_3$ and extracted three times with 60 mL of chloroform. The organic layer was dried with $Na_2SO_4$ and evaporated to give 300 mg of a solid which was shown by nmr to be a mixture of *N*,*N'*-diacetylorthophenylenediamine **27** and 1,2,3,4-tetrahydroquinoxaline-2-one **28**. Compound **27** is soluble in ethyl acetate, contrary to **28**. This allows the separation of products which were both identified with authentic samples: **27** (15) and **28** (16).

*Preparation of 2-morpholinoquinoxaline 13 and 2,3-dimorpholinoquinoxaline 14*

Compound **13** was prepared according to ref. 17. 2,3-Dimorpholinoquinoxaline **14** was obtained by heating 2,3-dichloroquinoxaline (5 g) and morpholine (15 mL) in a stainless steel vessel for 24 h at 140°C. The solid obtained was poured into 200 mL of water, filtered, and crystallized in $CHCl_3/CH_3OH$; 80/20, v/v; 3.6 g, mp 223°C. $^1$H-nmr (TFA): 5-H, 6-H, 7-H, 8-H, AA'BB' pattern at 7.6–8.1 ppm (4H); $CH_2$ of morpholine ring, m at 3.8–4.5 ppm (16H). *Anal.* calcd. for $C_{16}H_{20}N_4O_2$: C 63.98, H 6.71, N 18.65; found: C 64.07, H 6.66, N 18.87.

*Electrolysis of 2-morpholinoquinoxaline 13 in hydroorganic medium*

**13** (560 mg) was dissolved in 100 mL of solution (50% $CH_3OH$, NaOH 0.1 *N*) and electrolyzed at −1.4 V. After consumption of about 2F per mol the methanol was evaporated and the solution was extracted with ether. The ethereal extracts were evaporated. The residual oil was dried over $P_2O_5$ to give 320 mg of an hygroscopic solid: 3,4-dihydro-2-morpholinoquinoxaline, mp = 90°C dec. $^1$H-nmr ($CDCl_3$ + $D_2O$): $CH_2$ of morpholine ring, m, 3.3–3.8 ppm (8H); 3-$CH_2$, s, 3.92 ppm (2H); 5-H, 6-H, 7-H, 8-H, m, 6.4–7.2 ppm (4H). *Anal.* calcd. for $C_{16}H_{22}N_4O_2$: C 63.55, H 7.30, N 18.53; found: C 63.47, H 7.38, N 18.52.

# The synthesis of some 11-substituted tetrahydrocannabinol metabolites[1,2]

JOHN W. APSIMON,[3] T. LEE COLLIER, AND MICHAEL D. GUIVER

*The Ottawa-Carleton Institute for Research and Graduate Studies in Chemistry, Carleton Campus, Ottawa, Ont., Canada K1S 5B6*

Received April 14, 1982

JOHN W. APSIMON, T. LEE COLLIER, and MICHAEL D. GUIVER. Can. J. Chem. **60**, 2804 (1982).

9-Bromo-11-oxo-hexahydrocannabinol (**5**) was prepared from the ketocannabinoid **3***b* via the epoxysulfone **4**. The dehydrobromination of the bromoaldehyde **5** could be controlled to give either the thermodynamically more stable $\Delta^8$-aldehyde **2***c*, or the $\Delta^9$-aldehyde **1***c* by an intramolecularly assisted elimination. Reduction of the unsaturated aldehydes gave the allylic alcohol metabolites **2***a* and **1***a*, respectively.

JOHN W. APSIMON, T. LEE COLLIER et MICHAEL D. GUIVER. Can. J. Chem. **60**, 2804 (1982).

On a séparé le bromo-9 oxo-11 hexahydrocannabinol (**5**) à partir du cétocannabinoïde **3***b* via l'époxysulfone **4**. On peut controler la déhydrobromation du bromaldéhyde **5** pour obtenir soit le $\Delta^8$-aldéhyde (**2***c*) thermodynamiquement le plus stable, soit le $\Delta^9$-aldéhyde (**1***c*) par une élimination intramoléculaire assistée. La réduction des aldéhydes insaturés a conduit à l'alcool allylique des métabolites **2***a* et **1***a* respectivement.

[Traduit par le journal]

## Introduction

The potential importance of tetrahydrocannabinol (THC) metabolites in biological investigations has resulted in considerable effort directed towards their synthesis (1). In this paper, we report two synthetic routes to both 11-hydroxy-$\Delta^9$-THC (**1***a*)[4] and 11-hydroxy-$\Delta^8$-THC (**2***a*), the major psychotomimetically active metabolites of $\Delta^9$-THC (**1***b*) and $\Delta^8$-THC (**2***b*), respectively.

Most of the previous syntheses of **1***a* have involved transformations of $\Delta^9$-THC (**1***b*) or $\Delta^{9(11)}$-THC (**3***a*), or condensations of olivetol (**9**) with suitable terpenoid synthons. One attempted synthesis of particular interest relating to our strategy and starting from benzylated 11-nor-9-keto-HHC[5] (**3***b*) failed to provide **1***a* by phenoxide-assisted intramolecular elimination of chloride ion in **3***c*, but instead led to the thermodynamically more stable $\Delta^8$-isomer **2***a* (2). Despite many efforts, a simple efficient synthesis of the metabolite **1***a* has not been accomplished; the highest yielding synthesis at present is 20% of the metabolite from **1***b* reported by Pitt *et al.* (3). Many of the syntheses have so far produced low overall yields, lack of regioselectivity in the introduction of the $\Delta^9$-unsaturation and the oxygen function, and often involve difficult separations. In addition, reactions involving olivetol condensations frequently give rise to abnormal THC by-products (incorrect orientation of the pentyl sidechain).

The problems stem in part from the lability of the $\Delta^9$-unsaturation, traditionally attributed to the steric interactions between H-10 and the phenolic oxygen, and H-10a and the 6α-methyl group. Under acid-catalysis the double bond at $\Delta^9$ rapidly equilibrates to the $\Delta^8$ position, relieving the steric strain of these non-bonded interactions (4). More

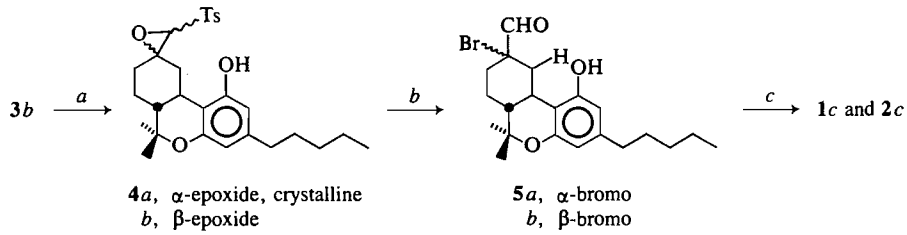

FIG. 1. Synthesis of **1***c* and **2***c*. Reagents: (*a*), $TsCH_2Cl$, phase transfer; (*b*), $MgBr_2$ in $Et_2O$ or THF; (*c*) intramolecular elimination, collidine; thermodynamic elimination, $Li_2CO_3$, LiBr, DMF.

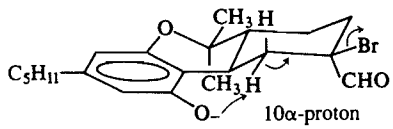
recently, an alternative explanation has been put forward by Dalzell *et al.* based on torsional strain in the THC ring system (5).

In contrast to the above, the synthesis of **2***a* has been beset by fewer problems, since this is the thermodynamically preferred isomer. Two high yield syntheses have been reported up to the present time, both from the same laboratory (6, 7). In the first synthesis, however, a difficult separation is involved.

Our synthetic strategy, outlined in Fig. 1, is based on the dehydrobromination of **5**, obtained from ketone **3***b* via an intermediate epoxysulfone **4**.[6] Under normal dehydrobrominating conditions, the thermodynamically more stable $\Delta^8$ isomer **2***c* is formed. However, under carefully controlled conditions and the judicious choice of base, the $\Delta^9$-unsaturation may be generated by H-10α proton abstraction initiated by the phenoxide anion, giving rise to isomer **1***c* as outlined in structure **6**. Phen-



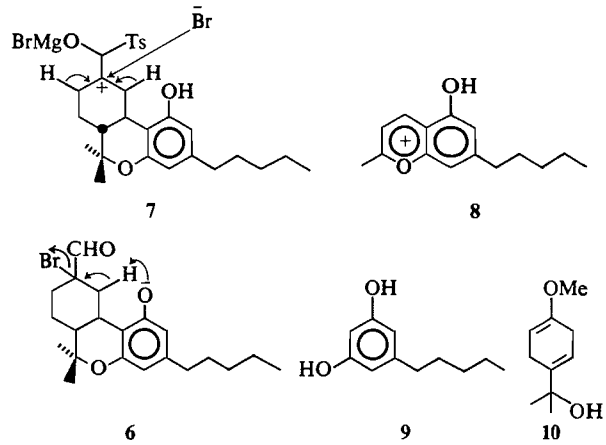
**6**

oxide-assisted intramolecular eliminations of a similar nature have already been successfully demonstrated in the contrathermodynamic conversion of $\Delta^8$-THC (**2***b*) to $\Delta^9$-THC (**1***b*) (8). However, Pitt and co-workers were unable to synthesise the metabolite **1***a* by a similar strategy (2).

## Results and discussion

The starting material, 11-*nor*-9-keto-6a,10a-*trans*-HHC (**3***b*) was prepared using a method developed by Archer and co-workers by condensing olivetol (**9**) with 2-(4-methoxy-1,4-cyclohexadienyl)-2-propanol (**10**) in the presence of stannic

[6]All compounds whose syntheses are described in this work are racemic mixtures; the naturally occurring THC ring junction (−)-(6aR,10aR) is shown only for convenience.



chloride and one molar equivalent of water to give 11-*nor*-9-keto-6a,10a-*cis*-HHC (**3***d*) in 24% yield (9). The acid-catalyzed isomerisation of the *cis*-ketone to the required starting material **3***b* with the *trans*-ring junction was accomplished in 58% yield using $AlCl_3$.

The synthesis of the bromoaldehydes **5** is based on the novel one-carbon homologation developed by Durst and co-workers in which a ketone is converted to an epoxysulfone and then cleaved with $MgBr_2$ in ether or THF to give an α-bromoaldehyde (10). Epoxysulfones may be prepared directly from ketones in high yields by using the phase transfer conditions of Makosza, obviating the isolation of an intermediate chlorohydrin (11). The overall transformation involves nucleophilic attack of the base-generated α-chloro-α-sulfonyl carbanion on the carbonyl group followed by intramolecular displacement of the chloride, to give a Darzens type condensation. Working with simple epoxysulfones, Durst and co-workers obtained bromoaldehydes cleanly and in high yield, demonstrating the value of this mild homologation method.

In this work an isomeric mixture of the unstable epoxides **4** was prepared in high yield under

phase-transfer conditions from the ketone **3***b*, chloromethyl-*p*-tolyl sulfone (prepared by a method based on ref. 12)[7] and 50% aqueous NaOH solution using benzyltriethylammonium chloride as the catalyst. The high sensitivity of these epoxides to acid-catalyzed decomposition necessitated using water adjusted to slightly basic pH during the work-up of the reaction.

Analysis of the crude products by thin layer chromatography indicated two major components with similar characteristics. The more polar of the two compounds could be isolated by crystallization and its nmr spectrum was compared with that of the mixture. Only two signals were significantly different between the two isomers in these spectra; the epoxide protons at δ 3.95 (**4***b*) and δ 3.90 (**4***a*) and the aromatic H-2 protons at δ 6.13 (**4***a*) and δ 6.06 (**4***b*). The ratio of the two isomers as determined by the relative integration of the H-2 protons was 43 (**4***a*):57 (**4***b*). The stereochemistry of the epoxides was assumed to be α and β, respectively, based on the ratio and stereochemical inversion about C-9 of the bromoaldehydes **5***a* and *b* formed in the next step of the synthetic sequence.

The Lewis acid cleavage of the epoxysulfones **4** with $MgBr_2$ in ether or THF gave a good yield of bromoaldehydes. The nature of the products formed was determined by the solvent used. In the case of THF, only isomeric bromoaldehydes **5***a* and **5***b* were obtained. In ether, where the reaction occurred more rapidly, one epimer **5***b* as well as unsaturated aldehydes **1***c* and **2***c* were formed. The stereochemistry of the bromoaldehydes was determined by comparison of the nmr spectra of the isomeric mixture **5***a* and **5***b* and the single isomer **5***b*; the latter displays a large difference in the upfield chemical shift of the 6α-methyl group (13).[8] Molecular models demonstrate that in epimer **5***b*, the 6α-methyl group is within the shielding region of the carbonyl group, whereas H-10a lies within the deshielding region. Thus, H-10a is shifted 29 Hz downfield (δ 3.97, broadened doublet, $J_{vic}$ = 13 Hz) and the 6α-methyl group is shifted 18 Hz upfield (δ 0.99) with respect to **5***a*. The ratio of the bromoaldehyde epimers arising from the epoxide cleavage in THF was also 43 (**5***b*):57 (**5***a*) as determined by integration of the aldehyde signals in the proton spectrum. The overall data suggests an $S_N2$ type reaction on epoxide cleavage by bromide ion where inversion about C-9 occurs (i.e. **4***a* → **5***b*, **4***b* → **5***a*).

As mentioned above only the β-bromoaldehyde isomer **5***b* was isolated where ether was used. We originally assumed that the α-bromo isomer, **5***a*, in which there is a 1,2-diaxial arrangement of hydrogen and bromine, spontaneously dehydrobrominates in ether, forming **1***c* and **2***c* while leaving the less-reactive **5***b* unchanged. This does not appear to be the case, however, since epoxide cleavage in THF, followed by replacement of solvent by ether, showed no evidence for unsaturated aldehydes **1***c* and **2***c* after hydrolysis of the complexes. It is therefore suggested that the dehydrobromination process observed during epoxide cleavage in ether proceeds by means of an intermediate such as **7** in which the three fates indicated lead to the observed products. Neutralisation of this carbocationic species from the least hindered β face leads to **5***b*. On the other hand, in the reaction using THF as a solvent, $S_N2$ cleavage of epoxides **4***a* and **4***b* by bromide ion would lead directly to the products observed.

The unstable $\Delta^9$-aldehyde **1***c* (5%) and the $\Delta^8$-aldehyde **2***c* (18%) were separated by careful column chromatography and crystallized. The olefinic proton of **1***c* (δ 7.88) displays an unusually large downfield chemical shift with respect to the olefinic proton of **2***c* (δ 6.88) in the nmr spectrum (3)[9] due to the highly deshielded region in which it resides. In the mass spectrum of **2***c*, which has been studied by Inayama and co-workers (14), the enhanced abundance of the common cannabinoid fragment ion *m/e* 231, **8**, is diagnostic for the $\Delta^8$-unsaturation and arises from a retro-Diels–Ader (RDA) reaction in the isoprenoid ring of the molecule. In contrast, the $\Delta^9$-aldehyde **1***c* displays a very low abundance of this ion. The $\Delta^9$-aldehyde **1***c* has been identified as a metabolite from the incubation products of **1***b* with rat liver microsomes (15). In this case, however, the investigators observed an abundant fragment ion at *m/e* 231 of the derivatised product.

Attempts to synthesise **1***c* by intramolecular displacement of bromide in **5***b* (see **6**) using potassium *t*-amylate or sodium hydride under various conditions led to indefinite results despite their successful use in the synthesis of $\Delta^9$-THC (**1***b*) (8). No evidence of either **1***c* or **2***c* in the reaction products was observed. It is clear from projection **6** that no ideal geometry for elimination exists for **5***a* or **5***b* by an intramolecular pathway. However, use of pyridine as a weak base to remove only the most

[7]The use of the bromo-analogue was found to be unsuitable, when methyl-*p*-tolylsulfone was formed as a by-product.

[8]In 6a,10a-*trans* THC's, the 6α-methyl group appears upfield with respect to the 6β-methyl substituent. See ref. 13 for a detailed nmr study.

[9]Nuclear magnetic resonance and ir spectra of the authentic materials were kindly supplied by Dr. Colin G. Pitt of the Research Triangle Institute, North Carolina, and Dr. Raj K. Razdan of the Sisa Institute for Research, Inc., Massachusetts.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

acidic phenolic proton provided evidence for this process when aldehydes **1***c* and **2***c* were cleanly obtained in the ratio of 15:85 (based on integrating the olefinic proton signals in the nmr spectrum of the mixture). By using the more hindered base, collidine, this ratio was increased to 52:48 and the unsaturated aldehydes were easily separated by column chromatography. Other bases such as 2,6-di-*t*-butyl pyridine and quinoline gave respectively no reaction and predominantly **2***c*.

Heating **5***b* with $Li_2CO_3$ and LiBr in DMF (16) (conditions which presumably exclude phenoxide participation), the 1,2-elimination of HBr proceeded smoothly to provide the $\Delta^8$-aldehyde **2***c* in 90% isolated yield together with a 3% yield of the $\Delta^9$-aldehyde **1***c*.

The aldehydes **1***c* and **2***c* were reduced to the metabolites **1***a* and **2***a* with $LiAlH_4$ in THF. In a preliminary communication from another laboratory, the reduction of **1***c* with $LiAlH_4$ was reported to proceed smoothly, but no conditions were specified (17). In our laboratories, however, various amounts of aromatic impurities in **1***a* were observed in the samples that were reduced under our conditions.

This route represents a facile synthesis of 11-hydroxy-$\Delta^8$-THC (**2***a*) from 11-*nor*-9-keto-HHC (**3***b*) via **5***b* with an overall yield of 64%. This compares favourably in terms of yield to the method reported by Pitt *et al.* (33%) (2) for the preparation of **2***a* from benzylated **3***b*. The overall yield of 11-oxo-$\Delta^9$-THC (**1***a*) via **5***b* was 36.5% based on recovered starting material. This synthetic route has the advantage that THC metabolite aldehydes and acids can also be made available if required. Our continuing work in this area is directed to the efficient regioselective formation of the thermodynamically less stable $\Delta^9$ isomers of various THC metabolites.

## Experimental

Melting points were determined on a Fisher-Johns melting point block and are uncorrected, and the infrared spectra were determined on a Perkin-Elmer 237B grating spectrophotometer. Nuclear magnetic resonance spectra were obtained on Varian Associates Model HA-100 instruments with deuteriochloroform as the solvent and tetramethylsilane as internal standard. Chemical shifts are expressed in the δ scale and the following abbreviations are used in describing the nmr signals: singlet (s), doublet (d), triplet (t), multiplet (m), and broadened (br). Combustion analyses were performed by Spang Microanalytical Laboratories, Eagle Harbour, Michigan and Guelph Chemical Laboratories Ltd., Guelph, Ontario. The mass spectra were determined with an H.P. 5985 G.C.-M.S. Quadrupole instrument at the Health and Welfare Canada operated at an ionising potential of 70 eV.

Pre-coated plates from E. Merck Reagents (silica gel F-254, 0.25 mm layer thickness) were used for thick layer; bands were observed by viewing under a uv source or by heating the plate sprayed with a 1% solution of ceric ammonium nitrate in 50% aqueous sulphuric acid.

Tetrahydrofuran was distilled from $LiAlH_4$ and benzene was distilled from, and stored over, sodium metal. Mallikrodt anhydrous ether was used in the preparation of $MgBr_2$. All other solvents were glass distilled prior to use. The term "work-up" refers to: extraction of the reaction mixture with solvent (× 3), washing the combined extracts with water (× 3) and saturated aqueous sodium chloride, drying of the organic phase with magnesium sulphate, and removal of solvent under reduced pressure. Water used in the work-up of reactions was adjusted to pH 7.2 by the addition of aqueous sodium bicarbonate and monitoring the change with a pH meter.

*11*-nor-*9-Keto-6a,10a*-cis-*HHC* (*3*d)

The *cis*-ketocannabinoid **3***d* was prepared following mainly the procedure of Archer *et al.* (9). To a stirred solution of olivetol **9** (18.025 g, 100 mmol) and **10** (20.188 g, 120 mmol) in dichloromethane (400 mL) and under nitrogen at −15°C was added water (1.8 mL, 100 mmol), followed by the dropwise addition of $SnCl_4$ (26 mL, 222 mmol) over a 2 h period. The mixture was stirred at 0°C for 7 h after which time it was poured into water (500 mL) and extracted several times with ether. The ethereal extracts were washed three times with aqueous NaOH (1 *M*), three times with water, and then dried over $MgSO_4$. After filtering off the solids and removing the solvent, the material was crystallized from hexanes to yield the *cis*-ketocannabinoid **3***d* (7.58 g, 24%) as the major product (ref. 9 reports a 12% yield). Traces of the less polar *trans* **3***b* isomer were observed by tlc analysis (20% EtOAc in benzene). Analytically pure *cis*-ketocannabinoid **3***d* was obtained by H.P.L.C. (Waters Prep System – 500, 40% EtOAc in hexanes) and had the following characteristics: mp 149.5–150.5°C (lit. 149.5–150.5°C (8*a*)); ir (KBr pellet), 3255 $cm^{-1}$ (OH), 1690 $cm^{-1}$ (C=O); nmr δ 0.87 (3H, t, $J$ = 6 Hz, C-5′ $CH_3$), 1.34 (3H, s, C-6α $CH_3$), 1.40 (3H, s, C-6β $CH_3$), 2.42 (2H, m, Ar—$CH_2$), 6.22 (2H, s, H-2 and H-4), 7.38 (1H, s, Ar—OH $D_2O$ exchangeable).

*11*-nor-*9-Keto-6a,10a*-trans-*HHC* (*3*b)

The *trans*-ketocannabinoid **3***b* was prepared mainly by the procedure of Archer *et al.* (9). Aluminum chloride (13.5 g, 100 mmol) was added to a solution of *cis*-ketocannabinoid (9.00 g, 28.4 mmol) in dichloromethane (450 mL). The mixture was stirred for 3 h at room temperature under nitrogen and then additional $AlCl_3$ (7.5 g, 562 mmol) was added and the stirring continued for a further 2 h. After work-up with dichlormethane, the solid was crystallized ($CH_2Cl_2$/hexanes) to give **3***b* as the major product by tlc analysis (20% EtOAc in benzene), with only a trace of the *cis*-isomer (**3***d*) remaining. Selective recrystallization (methanol/water) afforded pure **3***b* (5.22 g, 58%) obtained as the higher melting polymorph: mp 160–163°C (lit. 163–165°C (8*a*)); ir (KBr pellet), 3285 $cm^{-1}$ (OH), 1695 $cm^{-1}$ (C=O); nmr, δ 0.89 (3H, br t, $J$ = 6 Hz, C-5′ $CH_3$), 1.13 (3H, s, C-6α $CH_3$), 1.48 (3H, s, C-6β $CH_3$), 2.46 (2H, br t, $J$ = 8 Hz, Ar—$CH_2$), 4.19 (1H, br d, $J$ = 15 Hz, H-10a), 6.23 (1H, d, $J$ = 2 Hz, H-2), 6.31 (1H, d, $J$ = 2 Hz, H-4), 7.93 (1H, s, Ar—OH $D_2O$ exchangeable).

*9, 11-Epoxy-11-tosyl-6a,10a*-trans-*HHC* (*4*a,b)

Employing the phase transfer conditions of Makosza *et al.* (11), ketocannabinoid **3***b* (316.4 mg, 1.0 mmol), chloromethyl-*p*-tolylsulfone (204.6 mg, 1.0 mmol), and benzyltriethylammonium chloride (50 mg, 0.22 mmol) were dissolved in 8 mL of acetonitrile. 20 mL of aqueous sodium hydroxide (50%) was added and the mixture stirred vigourously under nitrogen in a stoppered flask. After 2 h, the yellow slurry was poured into water (200 mL) and worked up with ether to yield **4** (464.5 mg,

For personal use only.

96%), sufficiently pure (tlc 10% EtOAc in benzene) to use for the next step. The more polar isomer **4***a* was crystallized from ether or hexane and had the following characteristics: mp 124.5–128°C (dec); ir (KBr pellet), 2950 $cm^{-1}$ (OH), 820 $cm^{-1}$ (epoxide); nmr δ 0.88 (3H, br t, $J$ = 6 Hz, C-5′ $CH_3$), 1.09 (3H, s, C-6α $CH_3$), 1.39 (3H, s, C-6β $CH_3$), 2.45 (3H, s, Ts—$CH_3$), 3.90 (1H, s, epoxide-H), 4.09 (1H, br d, $J$ = 14 Hz, H-10a), 5.44 (1H, br s, Ar—OH $D_2O$ exchangeable), 6.13 (1H, br s H-2), 6.22 (1H, br s H-4), 7.36 (2H, d, $J_{AB}$ = 8 Hz, Ts), 7.87 (2H, d, $J_{AB}$ = 8 Hz, Ts); ms, *m/e* (rel. intensity) 484 (2), 329 (29), 328 (37), 286 (12), 285 (12), 272 (38), 231 (34), 193 (55), 91 (100). *Anal.* calcd. for $C_{28}H_{36}O_5S$: S 6.62; found: S 6.44

*9-Bromo-11-oxo-6a,10a*-trans-*HHC* (**5**a,b)

Magnesium bromide was prepared by stirring together magnesium (243 mg, 10 mmol) and 1,2-dibromoethane (0.86 mL, 10 mmol) in dry THF (20 mL) under nitrogen until the reaction was completed. A solution of **4***a*, *b* (370 mg, 0.76 mmol) in THF (20 mL) was added via syringe, and the mixture was stirred for 2 days at room temperature. The mixture was poured into water and worked up with ether. The material was purified by eluting from a thin column of Florisil (15 g, 100–200 mesh, 7% ether in light petroleum ether) to yield **5***a*, *b* (228.5 mg, 73%): ir ($CCl_4$), 3600 $cm^{-1}$ (sharp, free OH), 3475 $cm^{-1}$ (broad, H-bonded OH), 1727 $cm^{-1}$ (C=O); nmr, δ 0.88 (3H, t, $J$ = 6 Hz, C-5′ $CH_3$), 0.99 and 1.17 (3H, s, C-6α $CH_3$), 1.36 and 1.41 (3H, s, C-6β $CH_3$), 2.43 (2H, br t, $J$ = 6 Hz, Ar—$CH_2$), 3.68 and 3.97 (1H, br d, $J$ = 14 Hz and $J$ = 13 Hz, H-10a), 4.85 and 4.98 (1H, br s, Ar—OH $D_2O$ exchangeable), 6.07 and 6.10 (1H, s, H-2), 6.24 (1H, br s, H-4), 9.37 and 9.47 (1H, s, CHO); ms, *m/e* (rel. intensity), 410 (28), 408 (28), 354 (30), 352 (33), 330 (21), 329 (76), 328 (11), 311 (14), 285 (12), 245 (15), 231 (15), 193 (100).

*Reaction of 9,11-epoxy-11-tosyl-6a,10a*-trans-*HHC* (**4**a,b) *with $MgBr_2$ in ether*

Magnesium bromide was prepared by stirring together magnesium (243 mg, 10 mmol) and 1,2-dibromoethane (0.86 mL, 10 mmol) in anhydrous ether (40 mL) under nitrogen until the reaction was completed. A solution of **4***a*, *b* (484 mg, 1.0 mmol) in anhydrous ether (40 mL) was added dropwise to the cooled reagent (0°C) and the stirring was continued for 2 h, after which time the reaction mixture was poured into chilled water (200 mL). After work-up with ether, tlc analysis (10% EtOAc in benzene) indicated three major products: **5***b*, **1***c*, and **2***c*. The less polar compound **5***b* was easily isolated (65%) by elution from a thin column of Florisil (15 g, 100–200 mesh, 7% ether in light petroleum ether). Compounds **1***c* and **2***c* were separated by further careful elution from the column (12% ether in light petroleum ether) in 5% and 18% yields respectively (**1***c* isomerises to **2***c* when left on the column for a period of 12 h or more). Analytical samples of **1***c* and **2***c* were obtained by crystallization (ether/*n*-heptane and hexane respectively).

*9β-Bromo-11-oxo-6a,10a*-trans-*HHC* (**5**b): ir ($CCl_4$), 3600 $cm^{-1}$ (sharp, free OH), 3475 $cm^{-1}$ (broad, bonded OH), 1725 $cm^{-1}$ (C=O); nmr, δ 0.88 (3H, br t, $J$ = 6 Hz, C-5′ $CH_3$), 0.99 (3H, s, C-6α $CH_3$), 1.36 (3H, s, C-6β $CH_3$), 2.43 (2H, br t, $J$ = 7 Hz, Ar—$CH_2$), 3.97 (1H, br d, $J$ = 13 Hz, H-10a), 5.10 (1H, br s, Ar—OH $D_2O$ exchangeable), 6.10 (1H, br s, H-2), 6.24 (1H, br s, H-4), 9.37 (1H, s, CHO); ms, *m/e* (rel. intensity), 410 (13), 408 (13), 354 (17), 352 (16), 330 (28), 329 (91), 328 (12), 311 (21), 285 (13), 245 (22), 231 (17), 193 (100). *Anal.* calcd. for $C_{21}H_{29}O_3Br$: C 61.62, H 7.14, Br 19.52; found: C 61.87, H 7.34, Br 19.34.

*11-Oxo-6a,10a*-trans-Δ⁹-*THC* (**1***c*): mp 77–79.5°C; ir ($CCl_4$), 3600 $cm^{-1}$ (sharp, free OH), 3350 $cm^{-1}$ (broad, bonded OH), 1690 $cm^{-1}$ (C=O); nmr δ 0.88 (3H, br t, $J$ = 6 Hz, C-5′ $CH_3$), 1.15 (3H, s, C-6α $CH_3$), 1.45 (3H, s, C-6β $CH_3$), 2.48 (2H, m, Ar—$CH_2$), 3.51 (1H, br d, $J$ = 15 Hz, H-10a), 5.24 (1H, br s, Ar—OH $D_2O$ exchangeable), 6.16 (1H, br s, H-2), 6.30 (1H, br s, H-4), 7.88 (1H, br s, H-10), 9.45 (1H, s, CHO); ms, *m/e* (rel. intensity), 328 (100), 313 (8), 299 (34), 285 (18), 243 (10), 231 (6), 217 (8), 193 (12). *Anal.* calcd. for $C_{21}H_{28}O_3$: C 76.79, H 8.59; found: C 76.66, H 8.95.

*11-Oxo-6a,10a*-trans-Δ⁸-*THC* (*2c*): mp 119–120.5°C; ir ($CCl_4$), 3610 $cm^{-1}$ (sharp, free OH), 3425 (broad, bonded OH), 1680 $cm^{-1}$ (C=O); nmr δ 0.87 (3H, br t, $J$ = 6 Hz, C-5′ $CH_3$), 1.13 (3H, s, C-6α $CH_3$), 1.41 (3H, s, C-6β $CH_3$), 2.42 (2H, br t, $J$ = 7 Hz, Ar—$CH_2$), 3.92 (1H, br d, $J$ = 18 Hz, H-10α), 6.16 (1H, br s, H-2), 6.22 (1H, br s, H-4), 6.51 (1H, s, Ar—OH $D_2O$ exchangeable), 6.88 (1H, m, H-8), 9.46 (1H, s, CHO); ms (14), *m/e* (rel. intensity), 328 (82), 286 (28), 285 (19), 273 (20), 272 (100), 245 (8), 231 (74), 193 (100). *Anal.* calcd. for $C_{21}H_{28}O_3$: C 76.79, H 8.59; found: C 76.56, H 8.52.

*11-Oxo-6a,10a*-trans-Δ⁸-*THC* (*2c*)

To a solution of the bromoaldehyde **5***b* (204.5 mg, 0.50 mmol) in dimethylformamide (50 mL) was added lithium carbonate (74 mg, 1.0 mmol) and lithium bromide (16) (44 mg, 0.50 mmol). The reaction was heated at 100°C under nitrogen for 6 h, then cooled and poured into 100 mL of water. After work-up with ether and careful chromatography (Florisil 12% ether in light petroleum ether) two products were isolated: Δ⁹-aldehyde **1***c* (5.0 mg 3%) and Δ⁸-aldehyde **2***c* (148.7 mg, 90%). An analytical sample of **2***c* obtained by recrystallization from hexanes had identical spectral characteristics compared with the previously isolated compound: *Anal.* calcd. for $C_{21}H_{28}O_3$: C 76.79, H 8.59; found: C 76.53, H 8.94.

*11-Oxo-*Δ⁹-*THC* (**1***c*) *(impure sample)*: ms, *m/e* (rel. intensity), *346* (28), 328 (100), 313 (10), *311* (27), *309* (24), 299 (59), *290* (19), 285 (27), *257* (22), 243 (18), 231 (13), 217 (18), 193 (36).

*Synthesis of 11-oxo-6a,10a*-trans-Δ⁹-*THC* (**1**c) *from 9β bromo-11-oxo-6a,10a*-trans *HHC* (**5**b)

Collidine[10] (10 mL) was added to a stirred solution of bromoaldehyde (**5***b*) (79.0 mg, 0.19 mmol) in refluxing benzene (25 mL) under argon, in the presence of 4A molecular sieves. The mixture was refluxed for 72 h. Chromatography on Florisil after work-up (elution with 7% ether in light petroleum) provided **5***b* (38.4 mg, 48.6%), **2***c* (15.4 mg, 24.3%), and **1***c* (16.7 mg, 26.3%).

*11-Hydroxy-6a,10a*-trans-Δ⁹-*THC* (*1a*)

Lithium aluminum hydride (3 mg, 0.08 mmol) was added to a solution of the Δ⁹-aldehyde **1***c* (36 mg, 0.11 mmol) in THF (10 mL), and the mixture was stirred under nitrogen at room temperature for 4 h. Saturated ammonium chloride solution was added to the reaction until no more aluminum salts precipitated out, and the supernatant layer was poured off. Repeated washings of the precipitate with ether followed by work-up of the combined organics furnished the impure allylic alcohol **1***a* (36 mg, 99%); the material was partially purified by precipitation from carbon tetrachloride which was difficult to remove entirely: ir ($CCl_4$), 3600 $cm^{-1}$ (sharp, free OH), 3340 $cm^{-1}$ (broad, bonded OH); nmr δ 0.89 (3H, br t, $J$ = 6 Hz, C-5′ $CH_3$), 1.10 (3H, s, C-6α $CH_3$), 1.43 (3H, s, C-6β $CH_3$), 2.43 (2H, br t, $J$ = 7 Hz, Ar—$CH_2$), 3.26 (1H, br d, $J$ = 11 Hz, H-10a), 4.03 (2H, br s, H-11), 6.13 (1H, br s, H-2), 6.25 (1H, br s, H-4), 6.72 (1H, br s, H-10); ms (14); *m/e* (rel. intensity), 330 (19), 312 (8), 300 (22), 299 (100), 297 (18), 269 (7), 231 (13), 217 (11), 193 (13). The spectroscopic data were identical to those of the authentic material.[9]

*11-Hydroxy-6a,10a*-trans-Δ⁸-*THC* (*2a*)

To a solution containing the Δ⁸-aldehyde **2***c* (220 mg, 0.67 mmol) in 30 mL of THF was added lithium aluminum hydride

[10]Collidine was distilled from and stored over NaOH. Benzene was degassed prior to use.

(13 mg, 0.34 mmol). The mixture was stirred under nitrogen for 3 h at room temperature until no more starting material remained. Saturated ammonium chloride was added dropwise until the solution lost its yellow colour and no more aluminum hydrates precipitated out. After the organic layer was poured off, the precipitate was washed repeatedly with ether and the combined extracts were worked-up. Precipitation from carbon tetrachloride (7 mL) afforded the metabolite **2***a* (196 mg, 88%) as a white amorphous solid: ir ($CCl_4$), 3600 $cm^{-1}$ (sharp, free OH), 3340 $cm^{-1}$ (broad, bonded OH); nmr $\delta$ = 0.87 (3H, br t, $J$ = 6 Hz, C-5′ $CH_3$), 1.05 (3H, s, C-6$\alpha$ $CH_3$), 1.35 (3H, s, C-6$\beta$ $CH_3$), 2.41 (2H, br t, $J$ = 7 Hz, Ar—$CH_2$), 3.48 (1H, br d, $J$ = 17 Hz, H-10$\alpha$), 4.04 (2H, br s, H-11), 5.69 (1H, m, H-8), 6.10 (1H, d, $J$ = 1.5 Hz, H-2), 6.23 (1H, d, $J$ = 1.5 Hz, H-4); ms (14), *m/e* (rel. intensity), 330 (55), 312 (13), 297 (15), 274 (26), 270 (13), 269 (29), 257 (18), 256 (18), 246 (11), 245 (11), 231 (100), 214 (18), 193 (59), 174 (30), 173 (12). *Anal.* calcd. for $C_{21}H_{30}O_3$: C 76.32, H 9.15; found: C 76.19, H 9.43 (recrystallization from 10% ether in light petroleum ether is preferable since carbon tetrachloride is difficult to remove completely from purified samples of **2***a*).

# The stereochemistry of the enzymic decarboxylation of L-arginine and of L-ornithine[1]

JAMES C. RICHARDS AND IAN D. SPENSER[2]

*Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1*

Received May 25, 1982

JAMES C. RICHARDS and IAN D. SPENSER. Can. J. Chem. **60**, 2810 (1982).

The decarboxylation of L-ornithine to yield putrescine, catalyzed by the L-ornithine decarboxylase (EC 4.1.1.17) of *E. coli*, and the decarboxylation of L-arginine to yield agmatine, catalyzed by the L-arginine decarboxylase (EC 4.1.1.19) of *E. coli*, take place with retention of configuration.

JAMES C. RICHARDS et IAN D. SPENSER. Can. J. Chem. **60**, 2810 (1982).

La décarboxylation de la L-ornithine qui est catalysée par la décarboxylase de la L-ornithine (EC.4.1.1.17) de *E. coli* et qui conduit à la putrescine et la décarboxylation de la L-arginine, catalysée par la décarboxylase de la L-arginine (EC.4.1.1.19) de *E. coli* et qui conduit à la agmatine, se font avec rétention de configuration.

[Traduit par le journal]

## Introduction

Enzymes that catalyze the decarboxylation of L-α-amino acids are found in microorganisms, in mammalian tissues, and in plants. These enzymes show high substrate specificity for individual amino acids. The reaction that is catalyzed involves the conversion of a chiral centre within the L-α-amino acid, R—$CH(NH_2)CO_2H$, into a prochiral centre within the corresponding amine R—$CH_2$—$NH_2$. It was demonstrated (1) almost 30 years ago that the reaction mediated by three of these enzymes (EC 4.1.1.25 L-tyrosine decarboxylase, from *Streptococcus faecalis*; EC 4.1.1.18 L-lysine decarboxylase, from *Bacillus cadaveris*; EC 4.1.1.15 L-glutamate decarboxylase, from *Clostridium welchii* and from *Escherichia coli*) takes a stereochemically defined course, but it was not established at that time whether reaction takes place with net retention or with net inversion of configuration. Later, the actual stereochemical course of these reactions was determined.

The conversions of L-tyrosine into tyramine (2), of L-lysine into cadaverine (3), and of L-glutamate into γ-aminobutyric acid (4), each catalyzed by the appropriate enzyme, all take place with net retention of configuration, as shown by means of isotopic labelling with deuterium or tritium. Thus, decarboxylation of L-(i.e., *S*-)-tyrosine in $^2H_2O$ yields *R*-(1-$^2$H)tyramine (2), and of L-glutamate in $^2H_2O$ yields *R*-4-amino(4-$^2$H)butyric acid (4). Similarly, decarboxylation of L-[2-$^3$H]lysine in water generates *S*-[1-$^3$H]cadaverine, whereas L-lysine in tritiated water yields *R*-[1-$^3$H]cadaverine (3). The chirality of the products was determined by kinetic (2), enzymic (3), or chemical (4) correlation with compounds of known stereochemistry.

Net retention in the decarboxylation of L-tyrosine (5), of L-lysine (6, 7), and of L-glutamate (8–10), catalyzed by bacterial enzymes, was later confirmed by independent methods and was found also in reactions catalyzed by enzymes from mammalian sources (5, 8) and by plant systems (5, 6). Net retention has been demonstrated also in the decarboxylation of histidine, catalyzed by bacterial enzymes (EC 4.1.1.22 histidine decarboxylase, from *Lactobacillus* and from *Clostridium welchii*) (11, 12), and of tryptophan, catalyzed by a mammalian enzyme (EC 4.1.1.28 aromatic L-amino acid decarboxylase, from hog kidney) (13).

Very recently a D-amino acid decarboxylase (EC 4.1.1.20 *meso*-α,ε-diaminopimelate decarboxylase, from *Bacillus sphaericus*) has been shown to catalyze an analogous decarboxylation with inversion of configuration (14).

We now add two more L-α-amino acid decarboxylases of bacterial origin to the list of the enzymes that catalyze the decarboxylation of their substrates with net retention of configuration. The two enzymes are L-ornithine decarboxylase (EC 4.1.1.17) which catalyzes the decarboxylation of L-ornithine into putrescine, and L-arginine decarboxylase (EC 4.1.1.19), which mediates the conversion of L-arginine into agmatine (Scheme 4).

## Methods and results

DL-(2-$^2$H)Ornithine (**4**) and L-(2-$^2$H)arginine (**9**) were prepared by the reaction sequences shown in Schemes 1 and 2.

Decarboxylation of the L-component of DL-ornithine in deuterium oxide, and of the L-component of DL-(2-$^2$H)ornithine in water, catalyzed by L-ornithine decarboxylase (L-ornithine carboxylyase, EC 4.1.1.17) (ex *Escherichia coli*, Sigma

[1]A preliminary account of part of this work was presented at the 62nd Canadian Chemical Conference of the Chemical Institute of Canada, Vancouver, B.C., June 1979.

SCHEME 1. Synthesis of (±)-(2-$^2$H)ornithine.

Chemical Co.) gave the enantiomers of (1-$^2$H)-putrescine. L-Ornithine (**14**) in deuterium oxide gave (−)-(1-$^2$H)putrescine dihydrochloride (**15**), L-(2-$^2$H)ornithine in water gave (+)-(1-$^2$H)putrescine dihydrochloride. The ORD curves of the two samples are shown in Fig. 1.

The enantiomers of (1-$^2$H)agmatine were obtained similarly from L-arginine, catalyzed by L-arginine decarboxylase (L-argininine carboxylyase, EC 4.1.1.19) (ex *E. coli*, Sigma Chemical Co.). L-Arginine (**16**) in deuterium oxide gave (−)-(1-$^2$H)agmatine sulfate (**10**), L-(2-$^2$H)arginine in water gave (+)-(1-$^2$H)agmatine sulfate. The ORD curves of the enantiomeric (1-$^2$H)agmatine samples are shown in Fig. 2.

Alkaline hydrolysis with sodium hydroxide in ethanol led to quantitative conversion of agmatine into putrescine. (−)-(1-$^2$H)Agmatine sulfate (**10**) yielded (−)-(1-$^2$H)putrescine dihydrochloride (**15**), (+)-(1-$^2$H)agmatine sulfate yielded (+)-(1-$^2$H)-putrescine dihydrochloride. Within experimental error, the ORD curves of the (1-$^2$H)putrescine samples, so obtained, were coincident with those of the samples obtained by decarboxylation (Fig. 1).

The samples of (1-$^2$H)agmatine were converted in 2 steps (Scheme 3) into 4-phthalimidobutyric acid which was converted into the corresponding methyl ester.

The sample of (−)-(1-$^2$H)agmatine sulfate (**10**) gave (−)-4-phthalimido(4-$^2$H)butyric acid (**12**) which, in turn, gave (−)-methyl 4-phthalimido-(4-$^2$H)butyrate (**13**). Conversely, (+)-(1-$^2$H)agmatine sulfate gave (+)-4-phthalimido(4-$^2$H)butyric acid. The ORD curves of the enantiomeric 4-phthalimido(4-$^2$H)butyric acids are shown in Fig. 3.

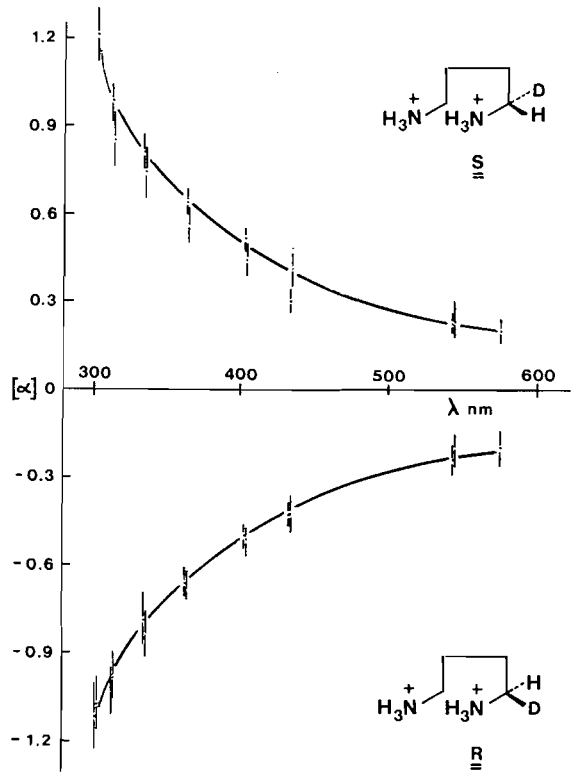

FIG. 1. Optical rotary dispersion (ORD) curves of (+)- and (−)-(1-$^2$H)putrescine dihydrochloride. The samples were prepared by decarboxylation of ornithine (value plotted on the left, for each wave length) and by hydrolysis of agmatine (value on the right).

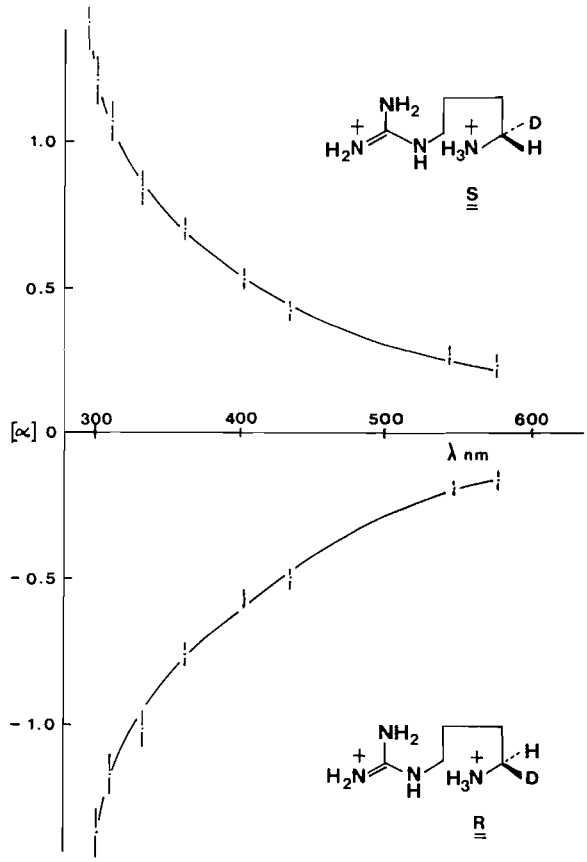

FIG. 2. ORD curves of (+)- and (−)-(1-$^2$H)agmatine sulfate.

An authentic specimen of (−)-methyl *R*-4-phthalimido(4-$^2$H)butyrate was obtained from M. H. O'Leary, University of Wisconsin. This sample had been prepared by methylation of (−)-4-phthalimido(4-$^2$H)butyric acid which had been obtained by decarboxylation in $^2H_2O$ of L-glutamic acid, catalyzed by L-glutamate decarboxylase (L-glutamate carboxylyase, EC 4.1.1.15, *ex E. coli*), and had been shown to have *R*-chirality by direct correlation with an authentic specimen, prepared from chiral (2-$^2$H)glycine by a series of reactions which did not affect the stereochemistry at the chiral centre (4).

The sample of (−)-methyl 4-phthalimido(4-$^2$H)-butyrate (**13**) derived from (−)-(1-$^2$H)agmatine sulfate (**10**) and the sample of (−)-methyl *R*-4-phthalimido(4-$^2$H)butyrate supplied by M. H. O'Leary showed similar, but not coincident, plane negative ORD curves (Fig. 4), and identical mass spectra (Fig. 5).

## Discussion

The stereochemistry of the replacement of the carboxyl group of an α-amino acid by a solvent proton, in the course of the reaction catalyzed by an L-α-amino acid decarboxylase (1, 15), can be determined if the prochiral centre that is generated in the course of the decarboxylation is rendered chiral by isotopic substitution. If the decarboxylation of the amino acid is carried out in the presence of isotopically labelled water ($^3$HOH or $^2H_2O$), one of the enantiomers of the amine will be generated. The other enantiomer arises when a 2-labelled sample ([2-$^3$H]- or (2-$^2$H)-) of the L-α-amino acid undergoes decarboxylation in aqueous solution (3, 5–7, 13, 16, 17).

When tritium is employed as the tracer (3, 5–8, 10, 11, 13, 16) a very small fraction only of the molecules that comprise the labelled starting material ([2-$^3$H]amino acid or $^3$HOH) will carry $^3$H. It follows that only very few of the molecules comprising the product will be labelled, i.e., will be chiral and, in principle, optically active. The optical activity of the resulting product will thus be immeasurably small. Stereochemical analysis of the product is possible by means of enzymes of known stereospecificity.

When deuterium is employed as the marker (4, 9,

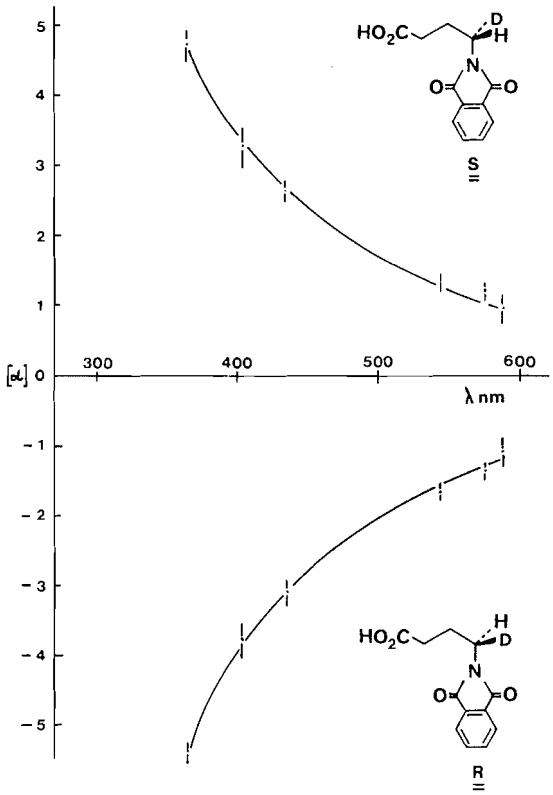

FIG. 3. ORD curves of (+)- and (−)-4-phthalimido(4-$^2$H)butyric acid.

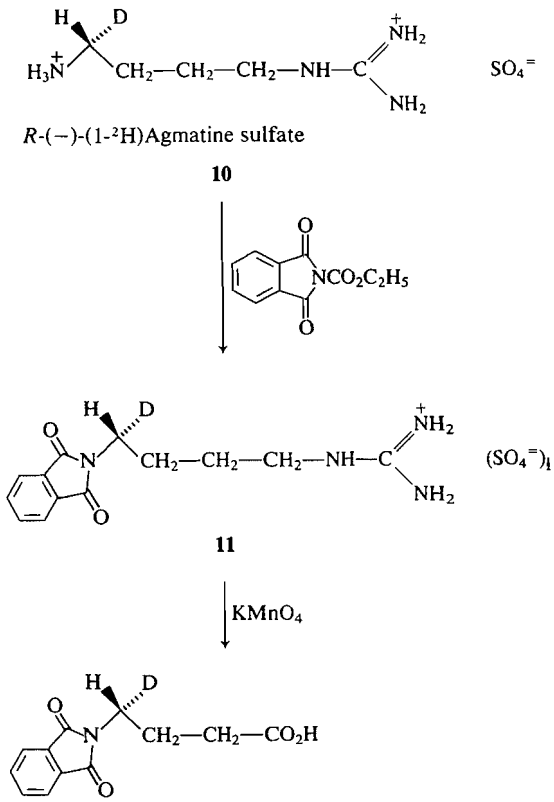
12, 14, 17) starting material can, in principle, be fully deuterated ($^2H_2O$), or fully deuterated at the appropriate position ((2-$^2$H)amino acid). The product will then consist entirely of molecules that are correspondingly deuterated, and is therefore not only chiral but its optical activity will, in all likelihood, be measurable (subject to the sensitivity of the detection instruments). The chirality of the product can then be determined by the classical method of measuring optical activity followed by assignment of configuration by comparison of this activity with that of standards of known configuration (4, 12, 14). Alternatively, nmr methods can be applied (9, 17) in the configurational assignment.

We have determined the stereochemistry of the enzymic decarboxylations of ornithine and arginine by deuterium labelling, followed by adaptation of the classical approach to configurational assignment, measurement of optical activity, and comparison with standards of known stereochemistry.

Samples of the two enantiomeric (1-$^2$H)putrescines were isolated as dihydrochlorides. They were obtained, respectively, by the action of L-ornithine decarboxylase (from *E. coli*) on L-ornithine (**14**) in the presence of $^2H_2O$ (ca. 98 at.% $^2$H), and on the L-component of DL-(2-$^2$H)ornithine. The DL-(2-



SCHEME 3. Conversion of (1-$^2$H)agmatine into methyl 4-phthalimido(4-$^2$H)butyrate.

$^2$H)ornithine (**4**) was prepared by adaptation of a conventional synthetic route (18) (Scheme 1). The ORD curves of the enantiomeric (1-$^2$H)putrescines are shown in Fig. 1. The sample derived from L-(2-$^2$H)ornithine was (+)-(1-$^2$H)putrescine dihydrochloride, that derived from L-ornithine (**14**) in $^2H_2O$ (Scheme 4) was (−)-(1-$^2$H)putrescine dihydrochloride (**15**).

Similarly, samples of the two enantiomeric (1-$^2$H)agmatines, isolated as sulfates, were obtained by action of L-arginine decarboxylase (from *E. coli*) on L-arginine in the presence of $^2H_2O$, and on L-(2-$^2$H)arginine, respectively. The L-(2-$^2$H)arginine (**9**) was prepared from α-*N*-acetyl-L-arginine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

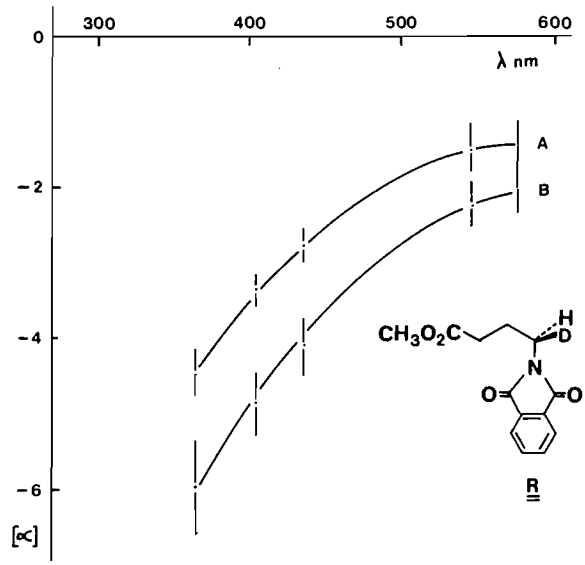


FIG. 4. ORD curves of (−)-methyl 4-phthalimido(4-$^2$H)-butyrate (**13**). Curve A: Sample supplied by M. H. O'Leary. Curve B: Sample obtained from (−)-(1-$^2$H)agmatine sulfate (**10**) (Scheme 3).

(**5**) by exchange (via the oxazolone (**6**)) and stereospecific hydrolysis employing acylase I (19) (Scheme 2). The sample of agmatine sulfate derived from L-(2-$^2$H)arginine was (+)-(1-$^2$H)agmatine sulfate, that derived from L-arginine (**16**) in $^2H_2O$ (Scheme 4) was (−)-(1-$^2$H)agmatine sulfate (**10**).

It was a simple matter to establish the relative configuration of the samples of (1-$^2$H)putrescine and (1-$^2$H)agmatine. Hydrolysis of (−)-(1-$^2$H)-agmatine sulfate (**10**) with ethanolic sodium hydroxide (10% w/v),[3] which maintained the chiral integrity at C-1 but cleaved the guanidino group, gave (−)-(1-$^2$H)putrescine dihydrochloride (**15**) (Scheme 4). Similarly, (+)-(1-$^2$H)agmatine sulfate gave (+)-(1-$^2$H)putrescine dihydrochloride.

It follows that the levorotary samples of (1-$^2$H)-putrescine dihydrochloride and of (1-$^2$H)agmatine sulfate have the same configuration at C-1. Since these two samples were derived from L-ornithine, and from L-arginine, respectively, by decarboxylation in $^2H_2O$, it follows further that the steric course of the decarboxylation of L-ornithine, catalyzed by L-ornithine decarboxylase, is identical with that of the decarboxylation of L-arginine, catalyzed by L-arginine decarboxylase.

[3]Hydrolysis with barium hydroxide solution (20, 21) or with aqueous sodium hydroxide (22), conditions which have been employed to convert L-arginine into L-ornithine (20, 21) and DL-ornithine (22), respectively, did not lead to quantitative conversion of chiral deuterio-agmatine into chiral deuterio-putrescine.

Congruently, the dextrorotary samples of (1-$^2$H)-putrescine dihydrochloride and of (1-$^2$H)agmatine sulfate correspond in configuration at C-1. Each was derived from the corresponding L-(2-$^2$H)amino acid. Thus, the decarboxylations catalyzed by L-ornithine decarboxylase and by L-arginine decarboxylase take the same stereochemical course. Either both reactions proceed with net retention of configuration or they both proceed with net inversion.

This question was settled by a chemical conversion of (−)-(1-$^2$H)agmatine into a product of known chirality by a reaction sequence which did not affect the chiral centre at C-1 (Scheme 3).

(1-$^2$H)Agmatine rather than (1-$^2$H)putrescine was chosen for chemical correlation with a known standard in order to avoid possible complications due to the $C_{2v}$ symmetry of putrescine.

(1-$^2$H)Agmatine was converted into the 1-*N*-phthaloyl derivative (**11**). The primary amino group was thus afforded protection from oxidative attack. The guanidino group was then removed by oxidation with potassium permanganate, yielding 4-phthalimido(4-$^2$H)butyric acid (**12**) whose stereochemical integrity had been maintained. By this reaction sequence (−)-(1-$^2$H)agmatine sulphate (**10**) yielded (−)-4-phthalimido(4-$^2$H)butyric acid (**12**), and (+)-(1-$^2$H)agmatine sulfate gave (+)-4-phthalimido(4-$^2$H)butyric acid.

A sample of (−)-4-phthalimido(4-$^2$H)butyric acid (**12**) was converted into the corresponding methyl ester, (−)-methyl 4-phthalimido(4-$^2$H)butyrate (**13**) (isotopic enrichment (ms) 98.2 ± 0.3 at.% $^2H_1$). This derivative was compared directly with an authentic specimen of (−)-methyl 4-phthalimido-*R*-(4-$^2$H)butyrate (isotopic enrichment 92.5 ± 0.4 at.% $^2H_1$, 4.7 ± 0.4% $^2H_2$), which had been prepared in the laboratory of M. H. O'Leary, University of Wisconsin (4). The absolute configuration of this sample ultimately rests on chemical correlation with that of *R*-(2-$^2$H)glycine (**17**) (4).

The two samples of (−)-methyl 4-phthalimido-(4-$^2$H)butyrate (**13**), that from (−)-(1-$^2$H)agmatine sulfate (**10**) and that supplied by O'Leary, both showed plane negative ORD curves (Fig. 4). They gave identical mass spectra (Fig. 5).

Since (−)-methyl 4-phthalimido(4-$^2$H)butyrate has the *R*-configuration, the (−)-(1-$^2$H)agmatine sulfate from which it was obtained, by a reaction sequence which did not affect the chiral centre, also has the *R*-configuration (see Scheme 3, no change in ligand priorities around the chiral centre).

Since this *R*-(−)-(1-$^2$H)agmatine sulfate had been obtained from L-arginine by decarboxylation in $^2H_2O$, catalyzed by L-arginine decarboxylase

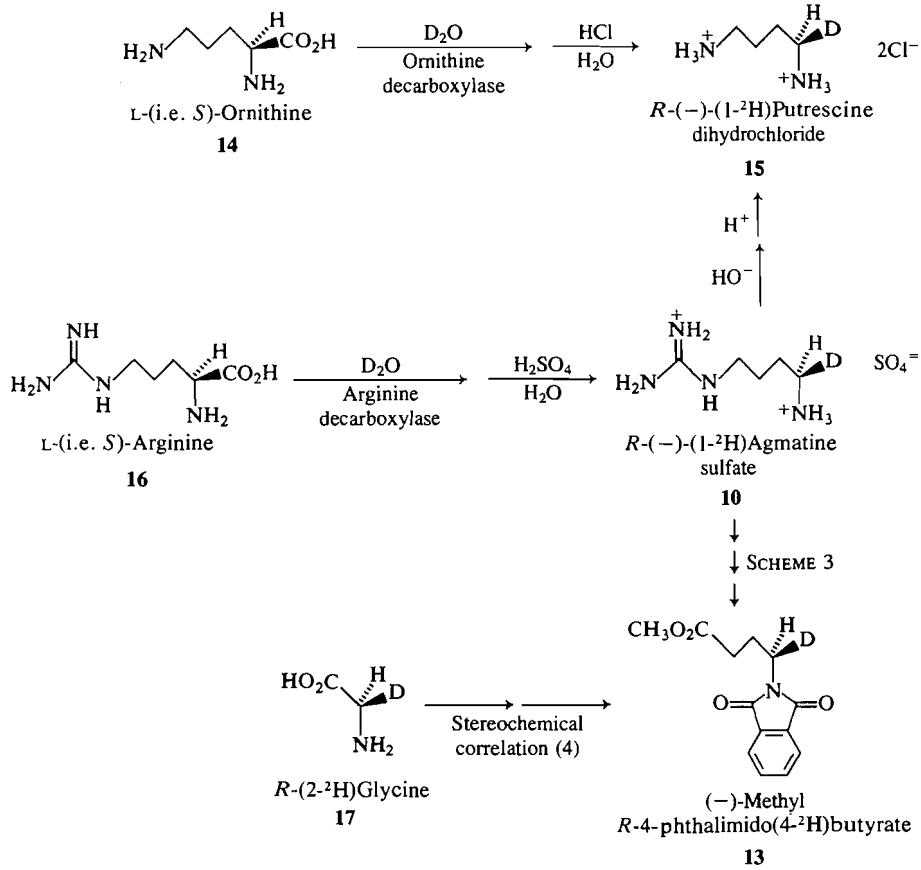

SCHEME 4. Stereochemical interrelationship of L-ornithine, L-arginine, and their conversion and degradation products.

(EC 4.1.1.19, from *E. coli*) (Scheme 4), the reaction catalyzed by this enzyme proceeds with net retention of configuration.

Since *R*-(−)-(1-$^2$H)agmatine sulfate yielded (−)-(1-$^2$H)putrescine dihydrochloride in a reaction which does not affect the chiral centre, this compound is *R*-(−)-(1-$^2$H)putrescine dihydrochloride.

Since the *R*-(−)-(1-$^2$H)putrescine dihydrochloride had been obtained from L-ornithine by decarboxylation in $^2H_2O$, catalyzed by L-ornithine decarboxylase (EC 4.1.1.17, from *E. coli*), the reaction catalyzed by this enzyme proceeds with net retention of configuration.

These configurational relationships are summarized in Scheme 4.

## Experimental

A. *(2-$^2$H)Amino acids*

1. DL-*(2-$^2$H)Ornithine (18)*

*Diethyl 2-acetamido-2-(3-phthalimidopropyl)malonate (3) (23)*

Diethyl acetamidomalonate (**2**) (Aldrich Chemical Co.) (2.16 g) was dissolved in hot dry ethanol[4] in a two-necked round bottom flask, fitted with a reflux condenser, calcium sulfate drying tube, and a pressure equalizing dropping funnel. A solution of sodium ethoxide (250 mg of sodium in 14 mL ethanol) was added and the resulting solution was heated at reflux while *N*-(3-bromopropyl)phthalimide (**1**) (Aldrich Chemical Co.) (2.69 g) in hot ethanol (14 mL) was added dropwise over 10 min. The reaction mixture was refluxed 20 h, and was then cooled to 0°C. Water (35 mL) was added to give the substitution product. Yield 2.85 g, 71%; mp 116–116.5°C (from 95% ethanol) (lit. (23) mp 115–116°C; (25) 111–112°C); $^1$H nmr ($^2HCCl_3$), δ: 1.20 (6H, t, *J* 7.2 Hz), 1.53 (2H, m), 2.00 (3H, s), 2.40 (2H, m), 3.67 (2H, t, *J* 7.2 Hz), 4.23 (4H, q, *J* 7.2 Hz), 6.80 (1H, s), 7.77 (4H, m).

DL-*(2-$^2$H)Ornithine monohydrochloride (4)*

Diethyl 2-acetamido-2-(3-phthalimidopropyl)malonate (**3**) (784 mg) was suspended in a solution of deuterium oxide containing deuterium chloride (38%, w/w in $^2H_2O$, 10 mL) (Merck, Sharp, and Dohme, 99.7 at.% $^2$H) in a small flask fitted with a reflux condenser and calcium sulfate drying tube. The mixture was heated at reflux for 18 h, cooled to 0°C, and diluted with water (10 mL). Phthalic acid, which precipitated, was filtered off and washed with water (2 × 1 mL). The combined filtrate and washings were concentrated to dryness *in vacuo*, and the residue was repeatedly dissolved in water and evaporated to dryness to remove exchangeable deuterium. The residue, crude ornithine dihydrochloride, was dissolved in hot 95% ethanol (8 mL), the solution was cooled to room temperature, filtered, and pyridine (ca. 600 mg) was added. DL-(2-$^2$H)-Ornithine monohydrochloride (398 mg) which precipitated was recrystallized from aqueous ethanol, mp 235–237°C (dec.) (lit. (nondeuteriated) (22) mp 232°C (dec.); (25) 222–224°C (dec.);

[4]Absolute ethanol purified by the Lund–Bjerrum method (24) was used throughout.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

(18) 215–216°C (dec.)). The $^1$H nmr spectrum ($^2H_2O$) was similar to that of authentic unlabelled material and indicated that this sample was ca. 98% deuterium labelled at C-2; δ: 1.90 (4H, m, H-3, 4), 3.05 (2H, t, *J* 6.8 Hz, H-5), 3.80 (ca. 0.02 H, H-2). The $^2$H nmr spectrum ($H_2O$, 107 *mM*, 200 transients) showed one signal at 3.7 ppm (relative to $^1H^2HO$ at 4.7 ppm).

In another experiment, hydrolysis of **3** (900 mg) gave a sample of DL-(2-$^2$H)ornithine monohydrochloride (**4**) (330 mg) which was ca. 92% $^2$H-labelled in the 2-position as determined by $^1$H nmr.

2. *L-(2-$^2$H)Arginine*

α-N-*Acetyl*-L-*arginine dihydrate (5)*

L-Arginine monohydrochloride (4.24 g) was acetylated with acetic anhydride in aqueous sodium bicarbonate by a published procedure (26), yielding α-acetyl-L-arginine dihydrate (4.10 g, 81%); mp 267–268°C (from water) (lit. (27) (DL) mp 256°C); $^1$H nmr ($^2H_2O$), δ: 1.73 (4H, m, H-3, 4), 2.05 (3H, s, $COCH_3$), 3.23 (2H, t, *J* 6.8 Hz, H-5), 4.20 (1H, d of d, $J_1 \sim 7.8$ Hz, $J_2 \sim 4.8$ Hz, H-2); ORD, $[\alpha]_{289}$ −10.1 ± 0.3°, $[\alpha]_{296}$ −12.3 ± 0.3°, $[\alpha]_{302}$ −14.1 ± 0.3°, $[\alpha]_{312}$ −15.8 ± 0.3°, $[\alpha]_{334}$ −16.6 ± 0.3°, $[\alpha]_{365}$ −16.0 ± 0.3°, $[\alpha]_{405}$ −13.6 ± 0.3°, $[\alpha]_{436}$ −11.9 ± 0.3°, $[\alpha]_{546}$ −7.6 ± 0.2°, $[\alpha]_{577}$ −6.7 ± 0.1°, $[\alpha]_{589}$ −6.3 ± 0.2 (*c* 2% in 1 *N* HCl, 25°C) (lit. (26) $[\alpha]_{589}$ −7.0° (*c* 2% in 1 *N* HCl)).

α-N-*Acetyl*-DL-*(2-$^2$H)arginine dihydrate (7) (cf. ref. 28)*

α-*N*-Acetyl-L-arginine dihydrate (3.9 g) was dissolved in deuterium oxide (5 mL) and the solvent was evaporated *in vacuo*. This process was repeated three times to effect replacement of the exchangeable protons by deuterium. The residue was then recrystallized from deuterium oxide (3 mL) and deuterium oxide of crystallization was removed by drying over phosphorus pentoxide at 75°C for 24 h. The product so obtained, α-acetylarginine, in which all exchangeable protons had been replaced by $^2$H, mp 253–255°C (lit. (nondeuteriated) (28) mp 250°C), was dissolved in deuterioacetic acid (25 mL) which had been prepared in the following way (cf. ref. 29).

A mixture of freshly distilled acetic anhydride (Fisher) (bp 137–138°C, 40 mL) and deuterium oxide (Merck, Sharp and Dohme, 99.7 at.% $^2$H) (8 g) was stirred at room temperature under a stream of dry nitrogen until the solution was homogeneous (ca. 3 h). Distillation under anhydrous conditions gave deuterioacetic acid, $CH_3CO_2{}^2H$, bp 112–114°C. The $^1$H nmr spectrum of a sample of the product indicated that it was ≥ 98% deuterium labelled and contained a trace of acetic anhydride (ca. 1%).

Acetic anhydride (bp 137–138°C, 1.7 mL) was added to the solution of α-*N*-acetylarginine in deuterioacetic acid, and the mixture was heated at reflux under dry nitrogen. After 2 h deuterium oxide (0.4 mL) was added and heating at reflux was continued for 30 min. The solution was cooled to room temperature, acetic acid removed *in vacuo*, and the residue, a yellow oil, was dissolved in water (5 mL). The solution was evaporated, the residue redissolved in water, and the solution again evaporated. The oil was then redissolved in water (5 mL), the pH of the solution was adjusted to pH 8 with concentrated ammonium hydroxide, acetone (1 mL) was added, and the mixture cooled to 0°C. The crystals which formed were filtered off, washed with cold water, and dried *in vacuo* over phosphorus pentoxide. The sample of α-*N*-acetyl-DL-(2-$^2$H)arginine (**7**) dihydrate (3.4 g) so obtained (optically inactive, mp 268–270°C (from water)), was 85–90% deuterium labelled at C-2 ($^1$H nmr). Deuterium was also present in the acetyl group.

*L-(2-$^2$H)Arginine (9) monohydrochloride and α-acetyl-D-(2-$^2$H)arginine (8) dihydrate (cf. refs. 19, 26)*

The pH of a solution of α-*N*-acetyl-DL-(2-$^2$H)arginine dihydrate (3.2 g) in water (140 mL) was adjusted to pH 6.8 with hydrochloric acid (10% w/v). Hog kidney acylase I (Sigma, 6300 U/mg,[5] 8.6 mg) in water (20 mL) was added. The resulting solution was incubated at 36°C in a constant temperature water bath for 23 h. The pH of the enzymic reaction mixture was then adjusted to pH 4.8 with glacial acetic acid, Norite was added, and the mixture filtered through Celite. The clear filtrate was concentrated *in vacuo* (7 mL), and after cooling in a refrigerator for several days, α-*N*-acetyl-D-(2-$^2$H)arginine (**8**) dihydrate, which crystallized, was filtered off and washed with water. Yield 1.4 g, 89%; mp 268–269°C (from water); ORD, $[\alpha]_{289}$ +14.0 ± 0.3°, $[\alpha]_{296}$ +16.9 ± 0.4°, $[\alpha]_{302}$ +18.0 ± 0.4°, $[\alpha]_{312}$ +19.4 ± 0.4°, $[\alpha]_{334}$ +19.6 ± 0.4°, $[\alpha]_{365}$ +17.9 ± 0.4°, $[\alpha]_{405}$ +15.3 ± 0.3°, $[\alpha]_{436}$ +13.2 ± 0.3°, $[\alpha]_{546}$ +8.3 ± 0.2°, $[\alpha]_{577}$ +7.2 ± 0.2°, $[\alpha]_{589}$ +6.8 ± 0.2° (*c* 2.06% in 1 *N* HCl, 25°C) (lit. (26) (nondeuteriated) $[\alpha]_{589}$ +7.0° (*c* 2% in 1 *N* HCl)).

The combined filtrate and washings containing L-(2-$^2$H)arginine (**9**) (10 mL) were diluted with water (25 mL), sodium hydroxide solution (5% w/v) was added to pH 11, and the solution was cooled in an ice bath. Benzaldehyde (1.3 mL) was added and the mixture stirred at 0°C for 2 h. The benzylidine derivative which separated was filtered off and was washed with ethanol and ether. Yield, 1.54 g, 93%; mp 198–199°C (dec.) (lit. (31) mp 206–207°C (dec.)).

The solution of the benzylidine derivative (1.53 g) in aqueous hydrochloric acid (2 *N*, 12 mL) was heated (95°C) 20 min with stirring. After cooling to room temperature, the mixture was extracted with ether (2 × 5 mL) and the ether layers were discarded. The aqueous phase, containing the dihydrochloride of L-(2-$^2$H)arginine, was evaporated *in vacuo*. The residue was dissolved in hot 95% ethanol (5 mL), the solution cooled to room temperature, and filtered. L-(2-$^2$H)Arginine monohydrochloride was precipitated from the filtrate by addition of pyridine (1.2 mL), and was recrystallized from aqueous ethanol. Yield 1.1 g, 91% from the benzylidine derivative; mp 222–223°C (lit. (nondeuteriated) (31) mp 220°C); $^1$H nmr ($^2H_2O$), δ: 1.74 (4H, m, H-3, 4), 3.17 (2H, t, *J* 6.8 Hz, H-5), 3.72 (ca. 0.15 H, H-2, i.e., ca. 85% of $^2$H); ORD, $[\alpha]_{296}$ +94.5 ± 1.9°, $[\alpha]_{302}$ +87.7 ± 1.9°, $[\alpha]_{312}$ +75.6 ± 1.5°, $[\alpha]_{334}$ +58.6 ± 1.2°, $[\alpha]_{365}$ +43.3 ± 0.9°, $[\alpha]_{405}$ +31.4 ± 0.6°, $[\alpha]_{436}$ +25.3 ± 0.5°, $[\alpha]_{546}$ +14.1 ± 0.3°, $[\alpha]_{577}$ +12.4 ± 0.3°, $[\alpha]_{589}$ +11.7 ± 0.2° (*c*, 2.06% in water, 25°C). An authentic sample of unlabelled L-arginine monohydrochloride showed a plane positive ORD spectrum: $[\alpha]_{296}$ +94.0 ± 1.9°, $[\alpha]_{302}$ +87.2 ± 1.7°, $[\alpha]_{312}$ +75.4 ± 1.5°, $[\alpha]_{334}$ +58.6 ± 1.2°, $[\alpha]_{365}$ +43.3 ± 0.9°, $[\alpha]_{405}$ +31.5 ±0.6°, $[\alpha]_{436}$ +25.4 ± 0.5°, $[\alpha]_{546}$ +14.0 ± 0.3°, $[\alpha]_{577}$ +12.4 ± 0.3°, $[\alpha]_{589}$ +11.7 ± 0.2° (*c* 2.07% in water, 25°C) (lit. (28) $[\alpha]_{589}$ +11.30° (*c*, 5.0% in water, 25°C), (31) $[\alpha]_{589}$ +12.2°, +12.3° (*c*, 5.0% in water, 25°C)).

A sample of L-(2-$^2$H)arginine monohydrochloride (67 mg) which was ≥ 92% $^2$H-labelled (by $^1$H nmr) was obtained from α-*N*-acetyl-L-arginine under a similar set of reaction conditions (see above) except that the $^2$H for $^1$H exchange reaction was optimized by following the course of the reaction in perdeuterioacetic acid – acetic anhydride solution by $^1$H nmr.

B. *Decarboxylation of (2-$^2$H)amino acids to (1-$^2$H)amines*

1. *Ornithine*

*Decarboxylation of ornithine, catalysed by L-ornithine decarboxylase (E.C. 4.1.1.17) from* E. coli

(i) *(−)-(1-$^2$H)Putrescine dihydrochloride (15) by decarboxylation of the L-component of unlabelled DL-ornithine in deuterium oxide solution*

Anhydrous sodium carbonate (Analar) (111 mg) was added to a stirred solution of perdeuterioacetic acid (Merck, Sharp, and Dohme, 99.7 at.% $^2$H) in deuterium oxide (Stohler Isotopes, 99.8 at.% $^2$H) (0.2 *M*, 15 mL) under an atmosphere of dry

[5] 1 U will hydrolyse 1 μmol of *N*-acetyl-L-methionine/h at pH 7.0 at 25°C. Hydrolysis of α-*N*-acetyl-L-arginine is ca. 60 times slower (30).

nitrogen. After stirring for 1 h, DL-ornithine monohydrochloride (Aldrich) (98 mg), which had been stripped of exchangeable protons by repeated solution in $^2H_2O$ and evaporation to dryness (3 times), and L-ornithine decarboxylase (Sigma, 0.06 U/mg)[6] (45 mg) were dissolved in the buffered solution (ca. p$^2$H 5). The enzymic reaction mixture, in a flask fitted with a calcium sulfate drying tube, was agitated at 36°C for 40 h. The enzymic reaction mixture was then acidified with 4 *N* hydrochloric acid, heated on a steam bath for 30 min, and cooled to room temperature. The precipitated enzyme was removed by centrifugation, followed by filtration of the supernatant solution through Celite. The filtrate was lyophilyzed, the residue dissolved in 10% sodium hydroxide (3 mL), and the alkaline solution saturated with sodium chloride. The product was extracted into 1-butanol (4 × 5 mL), the butanol extract was acidified by addition of a solution of hydrogen chloride in butanol, and the solution was then concentrated *in vacuo* (5 mL). (−)-(1-$^2$H)Putrescine dihydrochloride (46 mg) was recrystallized from 95% ethanol; $^1$H nmr ($^2H_2O$), δ: 1.77 (4H, m, H-2,3), 3.06 (ca. 3H, m, H-1,4); CI ms 90 (M + H, 5%), 74 (5), 73 (M − $NH_3$, 100), 72 (2), (CI ms of authentic unlabelled material, 89 (M + H, 5%), 73 (5), 72 (M − $NH_3$, 100), 71 (2)); 99.7 ± 0.3% $^2H_1$ determined by CI ms. The sample showed a plane negative ORD curve. Another sample of (−)-(1-$^2$H)putrescine dihydrochloride obtained as above from L-ornithine monohydrochloride (rather than from DL-) was 98.7 ± 1.2% mono-$^2$H labelled at C-1, determined by CI ms, and gave ORD, $[\alpha]_{302}$ −1.12 ± 0.11°, $[\alpha]_{313}$ −1.03 ± 0.08°, $[\alpha]_{334}$ −0.78 ± 0.09°, $[\alpha]_{365}$ −0.66 ± 0.05°, $[\alpha]_{405}$ −0.50 ± 0.04°, $[\alpha]_{436}$ −0.43 ± 0.04°, $[\alpha]_{546}$ −0.24 ± 0.05°, $[\alpha]_{577}$ −0.20 ± 0.06° (*c* 2.26% in 0.1 *N* HCl, 26°C, uncorrected for incomplete deuteration).

(ii) *(+)-(1-$^2$H)Putrescine dihydrochloride by decarboxylation of the* L-*component of* DL-*(2-$^2$H)ornithine*

A solution of DL-(2-$^2$H)ornithine monohydrochloride (~ 98% $^2$H) (100 mg) and L-ornithine decarboxylase (40 mg) in acetate buffer (0.2 *M*, pH 5.0, 15 mL) was incubated at 36°C for 20 h. After work-up, (+)-(1-$^2$H)putrescine dihydrochloride was obtained and recrystallized from 95% ethanol (yield 45 mg). The $^1$H nmr spectrum ($^2H_2O$) was identical with that of (−)-(1-$^2$H)-putrescine and the sample showed a plane positive ORD curve; CI ms, 90 (M + H, 3%), 74 (5), 73 (M − $NH_3$, 100), 72 (5); 97.2 ± 0.3% $^2H_1$ determined by CI ms.

Another sample of (+)-(1-$^2$H)putrescine dihydrochloride obtained by enzymic decarboxylation of DL-(2-$^2$H)ornithine (ca. 92% $^2$H) was 93.1 ± 0.9% mono-$^2$H labelled at C-1 (determined by CI ms); ORD, $[\alpha]_{302}$ +1.21 ± 0.09°, $[\alpha]_{313}$ +0.98 ± 0.06°, $[\alpha]_{334}$ +0.81 ± 0.06°, $[\alpha]_{365}$ +0.64 ± 0.04°, $[\alpha]_{405}$ +0.51 ± 0.04°, $[\alpha]_{436}$ +0.30 ± 0.03°, $[\alpha]_{546}$ +0.23 ± 0.03°, $[\alpha]_{577}$ +0.20 ± 0.04° (*c* 2.86% in 0.1 *N* HCl, 26°C, uncorrected for incomplete deuteration).

Unreacted D-(2-$^2$H)ornithine was reisolated from the incubation mixture. The alkaline solution remaining after extraction of the (1-$^2$H)putrescine into butanol was neutralized with concentrated hydrochloric acid, and was then applied to a column (25 × 1 cm) of Dowex 50-X8 ($H^+$ form). The column was washed with water (25 mL), hydrochloric acid (2 *N*, 25 mL), and water (25 mL). D-(2-$^2$H)ornithine was eluted with ammonia (1 *M*, 25 mL), and was isolated as the monohydrochloride, as described earlier.

The $^1$H and $^2$H nmr spectra of the sample of D-(2-$^2$H)ornithine monohydrochloride (ca. 92% $^2$H) were identical with those of the DL-(2-$^2$H)ornithine from which it was derived. ORD, $[\alpha]_{265}$ −157.8 ± 7.9°, $[\alpha]_{280}$ −114.8 ± 5.7°, $[\alpha]_{289}$ −98.0 ± 4.9°, $[\alpha]_{296}$ −87.3 ± 4.4°, $[\alpha]_{302}$ −80.7 ± 4.0°, $[\alpha]_{313}$ −69.2 ± 3.5°, $[\alpha]_{334}$ −52.8 ± 2.6°, $[\alpha]_{365}$ −39.3 ± 2.0°, $[\alpha]_{405}$ −29.0 ± 1.5°, $[\alpha]_{436}$ −23.4 ± 1.2°, $[\alpha]_{546}$ −14.4 ± 0.8°, $[\alpha]_{577}$ −12.9 ± 0.7°, $[\alpha]_{589}$ −12.1 ± 0.8°, (*c*. 0.63% in water, 25°C).

An authentic sample of unlabelled L-ornithine (**10**) monohydrochloride gave the following ORD: $[\alpha]_{265}$ + 166.3 ± 3.3°, $[\alpha]_{280}$ +124.9 ± 2.5°, $[\alpha]_{289}$ +107.6 ± 2.2°, $[\alpha]_{296}$ +96.1 ± 1.9°, $[\alpha]_{302}$ +88.9 ± 1.8°, $[\alpha]_{313}$ +78.1 ± 1.6°, $[\alpha]_{334}$ +61.7 ± 1.2°, $[\alpha]_{365}$ +45.1 ± 0.9°, $[\alpha]_{405}$ +32.3 ± 0.7°, $[\alpha]_{436}$ +26.1 ± 0.5°, $[\alpha]_{546}$ +13.6 ± 0.4°, $[\alpha]_{577}$ +11.5 ± 0.3°, $[\alpha]_{589}$ +11.8 ± 0.5°, (*c*, 0.49% in water, 25°C); (lit. (32) $[\alpha]_{589}$ +11.0° (*c*, 5.5% in water, 23°C)).

2. *Arginine*

*Decarboxylation of arginine catalysed by* L-*arginine decarboxylase (E.C. 4.1.1.19) from* E. coli

(i) *(−)-(1-$^2$H)Agmatine sulfate (**10**) by decarboxylation of* L-*arginine (**16**) in deuterium oxide solution*

L-Arginine monohydrochloride (Eastman) (90 mg) was twice dissolved in deuterium oxide and evaporated to dryness to effect replacement of exchangeable protons with deuterium. The amino acid was then dissolved in perdeuterioacetate–$^2H_2O$ buffer (ca. p$^2$H 5.2, 20 mL) to yield a 0.02 *M* solution. The buffer had been prepared from perdeuterioacetic acid (0.2 *M* in $^2H_2O$) and anhydrous sodium carbonate (8.36 mg/mL) (see under Decarboxylation of ornithine). L-Arginine decarboxylase (Sigma; 0.7 U/mg)[7] (43 mg) was added and the resulting solution incubated at 36°C in a flask equipped with a calcium sulfate drying tube. After 30–40 h the incubation mixture was acidified (ca. pH 2) with concentrated hydrochloric acid, treated with Norite, heated on a steam bath for 30 min, and filtered through Celite. The filtrate was evaporated, the residue dried *in vacuo* over sodium hydroxide and then dissolved in 5% sodium hydroxide solution (1–2 mL). The alkaline solution was saturated with sodium chloride and extracted with 1-butanol (4 × 3 mL). Evaporation of the butanol gave an oil which was redissolved in aqueous sulfuric acid (0.1 *M*, ca. 1 mL). After addition of methanol and cooling at 0°C overnight the crystalline sulfate of (−)-(1-$^2$H)agmatine separated and was recrystallized from water–methanol. Yield 72 mg; mp 238–240°C (lit. (nondeuteriated) (33) mp 236–239°C); $^1$H nmr ($^2H_2O$, relative to $^1H^2HO$ at 4.63 ppm), δ: 1.66 (4H, m, H-2,3), 2.95 (ca. 1H, t (br), $J \sim 6.8$ Hz, H-1), 3.18 (2H, m, H-4); ORD, $[\alpha]_{302}$ −1.37 ± 0.08°, $[\alpha]_{313}$ −1.17 ± 0.07°, $[\alpha]_{334}$ −1.01 ± 0.06°, $[\alpha]_{365}$ −0.76 ± 0.04°, $[\alpha]_{405}$ −0.57 ± 0.03°, $[\alpha]_{436}$ −0.50 ± 0.03°, $[\alpha]_{546}$ −0.19 ± 0.02°, $[\alpha]_{579}$ −0.16 ± 0.03° (*c*, 6.52% in water, 25°C, uncorrected for incomplete deuteration); $^2$H nmr ($H_2O$, 180 *mM*, 100 transients) showed one signal at 3.0 ppm apart from that due to natural abundance $^2$H in water (4.7 ppm).

(ii) *(+)-(1-$^2$H)Agmatine sulfate by decarboxylation of* L-*(2-$^2$H)arginine*

A solution of L-(2-$^2$H)arginine monohydrochloride (ca. 92% $^2$H) (0.02 *M*) and L-arginine decarboxylase (0.7 U/mg)[7] (75 mg) in acetate buffer (0.2 *M*, pH 5.2, 35 mL) was incubated at 36°C for 40 h. The reaction mixture was worked up, as described under (i), to give (+)-(1-$^2$H)agmatine sulfate (100 mg). The mp and nmr spectra ($^1$H and $^2$H) were similar to those obtained for (−)-(1-$^2$H)agmatine sulfate. The sample showed a plane positive ORD curve; $[\alpha]_{297}$ +1.42 ± 0.11°, $[\alpha]_{302}$ +1.21 ± 0.08°, $[\alpha]_{313}$ +1.07 ± 0.07°, $[\alpha]_{334}$ +0.84 ± 0.06°, $[\alpha]_{365}$ +0.70 ± 0.04°, $[\alpha]_{405}$ +0.53 ± 0.03°, $[\alpha]_{436}$ +0.42 ± 0.03°, $[\alpha]_{546}$ +0.27 ± 0.03°, $[\alpha]_{577}$ +0.23 ± 0.04° (*c*, 4.18% in water, 25°C, uncorrected for incomplete deuteration).

C. *Conversion of agmatine into putrescine*

1. *Hydrolysis of agmatine to putrescine*

A solution of agmatine sulfate (55 mg) in ethanol–water

[6] 1 U will release 1.0 μmol carbon dioxide from L-ornithine per min at pH 5.0 at 37°C.

[7] 1 U will release 1.0 μmol carbon dioxide from L-arginine per min at pH 5.2 at 37°C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

(70:30, v/v, 3 mL) containing sodium hydroxide (10%, w/v) was heated at reflux under a nitrogen atmosphere. When the reaction was complete (ca. 20 h) as revealed by paper chromatography (Whatman 3 MM, 1-butanol – acetic acid – pyridine – water 4:1:1:2; visualized with ninhydrin (0.3% w/v, in 1-butanol – acetic acid, 97:3, v/v); agmatine, $R_f$ 0.36; putrescine, $R_f$ 0.27), the reaction mixture was cooled to room temperature and acidified to pH 4 with 10% hydrochloric acid. After evaporation of the solvent the residue was dissolved in sodium hydroxide solution (10% w/v, 3 mL), the solution saturated with sodium chloride and extracted with 1-butanol (3 × 3 mL). The butanol extract was acidified with HCl–butanol and concentrated *in vacuo* (~ 4 mL). Putrescine dihydrochloride which separated was collected and recrystallized from aqueous ethanol. Yield, 33 mg, 87%. The $^1$H nmr spectrum was identical with that of authentic material.

(i) *Conversion of (−)-(1-$^2$H)agmatine sulfate (**10**) into (−)-(1-$^2$H)putrescine dihydrochloride (**15**)*

Hydrolysis of (−)-(1-$^2$H)agmatine sulfate (65 mg), as described for unlabelled material, gave (−)-(1-$^2$H)putrescine dihydrochloride (41 mg) which was twice recrystallized from aqueous ethanol: CI ms, 90 (M + H, 3%), 74 (5), 73 (M − $NH_3$, 100), 72 (2); 99.4 ± 0.4% $^2$H, determined by CI ms; ORD, $[\alpha]_{302}$ −1.07 ± 0.09°, $[\alpha]_{313}$ −0.98 ± 0.08°, $[\alpha]_{334}$ −0.84 ± 0.08°, $[\alpha]_{365}$ −0.67 ± 0.05°, $[\alpha]_{405}$ −0.52 ± 0.05°, $[\alpha]_{436}$ −0.43 ± 0.06°, $[\alpha]_{546}$ −0.21 ± 0.06° (*c*, 1.84% in 0.1 *N* HCl, 26°C, uncorrected for incomplete deuteration).

(ii) *Conversion of (+)-(1-$^2$H)agmatine sulfate into (+)-(1-$^2$H)putrescine dihydrochloride*

Hydrolysis of (+)-(1-$^2$H)agmatine sulfate (40 mg) gave (+)-(1-$^2$H)putrescine dihydrochloride (22 mg) which was twice recrystallized from water: CI ms, 90 (M + H, 5%), 74 (5), 73 (M − $NH_3$, 100) 72 (10); 91.7 ± 0.8% $^2$H, determined by CI ms; ORD, $[\alpha]_{313}$ +0.85 ± 0.09°, $[\alpha]_{334}$ +0.75 ± 0.09°, $[\alpha]_{365}$ +0.56 ± 0.06°, $[\alpha]_{405}$ +0.44 ± 0.05°, $[\alpha]_{436}$ +0.41 ± 0.06°, $[\alpha]_{546}$ +0.24 ± 0.06° (*c*, 1.61% in 0.1 *N* HCl, 26°C, uncorrected for incomplete deuteration).

Paper chromatography (see above) of the samples of (−)- and (+)-(1-$^2$H)putrescine dihydrochloride obtained from Experiments (i) and (ii), above, showed single ninhydrin positive and Sakaguchi (34) negative spots at $R_f$ 0.27. The $^1$H nmr spectra ($^2H_2O$) of both samples were identical with those of (1-$^2$H)-putrescine dihydrochloride obtained from ornithine.

D. *Conversion of agmatine into phthalimidobutyric acid*

1. *4-Phthalimidobutylguanidine sulfate* (cf. **11**)

To a stirred solution containing agmatine sulfate (228 mg, 1 mmol) and sodium bicarbonate (168 mg, 2 mmol) in water (3 mL) was added *N*-carbethoxyphthalimide (Aldrich) (232 mg, 1 mmol) in small portions over 15 min at room temperature. After stirring for 1 h, the reaction mixture was cooled to 0°C and the product, which precipitated, was recrystallized from methanol. Yield 225 mg; mp 213–214°C; $^1$H nmr ($C^2H_3CO_2{}^2H$), δ: 1.70 (4H, m (br), H-2,3), 3.30 (2H, t (br), H-1), 3.84 (2H, t (br), H-4), 7.85 (4H, m, ArH). *Anal.* calcd. for $(C_{13}H_{17}N_4O_2)_2SO_4 2H_2O$: C 47.69, H 5.85, N 17.12, $SO_4^=$ 14.67; found: C 47.65, H 5.98, N 17.09, $SO_4^=$ 14.49%.

2. *4-Phthalimidobutyric acid* (cf. **12**)

A solution of potassium permanganate (0.4 *M*) in 1 *N* sulfuric acid was added in small portions (ca. 0.1 mL) to a stirred suspension of 4-phthalimidobutylguanidine (27 mg) in 1 *N* sulfuric acid (1 mL) at room temperature. Additions of the oxidant were made until the colour of permanganate in the reaction mixture was no longer discharged (ca. 0.5 mL over 1 h). Stirring was continued for 1 h and the reaction mixture was then decolourized with sodium bisulfite. After cooling at 0°C, the product, which precipitated, was extracted into chloroform (3 × 2 mL). The combined extracts were dried over anhydrous sodium sulfate and filtered. Evaporation gave 4-phthalimidobutyric acid (13 mg) as a white solid which was recrystallized three times from water; mp 115–116°C (lit. (35) mp 115–118°C); $^1$H nmr ($^2HCCl_3$), δ: 2.01 (2H, quin., *J* 6.8 Hz, H-3), 2.32 (2H, t, *J* 6.8 Hz, H-2), 3.76 (2H, t, *J* 6.8 Hz, H-4), 7.75 (4H, m, ArH), 10.2 (1H, s (br), $CO_2H$); ms, *m/e*: 233 (M, 4%), 215 (M − $H_2O$, 19), 187 (15), 174 (70), 173 (42), 160 (100), 104 (19), 76 (24). The mp and spectral properties were the same as those of an authentic sample prepared from γ-aminobutyric acid and *N*-carbethoxyphthalimide (4).

3. *Conversion of (1-$^2$H)agmatine into 4-phthalimido(4-$^2$H)-butyric acid*

(i) *N*-Carbethoxyphthalimide (82 mg) was added to a stirred solution of (−)-(1-$^2$H)agmatine sulfate (**10**) (70 mg) in 0.5 *M* sodium bicarbonate (1.5 mL). The resulting mixture was stirred at room temperature for 20 min and then cooled to 0°C. After standing at 0°C for 30 min, the product was collected by filtration, washed with cold water (1 mL), cold ethanol (1 mL), and chloroform (1 mL), and dried *in vacuo* over sodium hydroxide. 4-Phthalimido(4-$^2$H)butylguanidine (**11**) (66 mg), so obtained, was recrystallized from methanol – acetic acid (20:1); mp 210–212°C. The $^1$H nmr spectrum ($C^2H_3CO_2{}^2H$) of the deuteriated sample was similar to that of unlabelled material (see above) except that the signal at 3.84 ppm (H-4) corresponded to ca. 1.05 hydrogen atoms only.

Permanganate oxidation of a sample of the ($^2$H)guanidine derivative (49 mg) in aqueous sulfuric acid (1 *N*), as described for unlabelled material, gave (−)-4-phthalimido(4-$^2$H)butyric acid (**12**) (23 mg) which was recrystallized three times from water; mp 112–114°C; $^1$H nmr ($C^2HCl_3$), δ: 2.05 (2H, q, *J* 6.8 Hz), 2.39 (2H, t, *J* 6.8 Hz), 3.75 (ca. 1H, t, *J* 6.8 Hz), 7.80 (4H, m), 10.2 (1H, s (br)); $^2$H nmr ($CHCl_3$, 30 *mM*, 2172 transients) showed a single signal at 3.74 ppm apart from that due to natural abundance $^2$H in $CHCl_3$ (7.27 ppm); ms, *m/e*: 234 (M, 3%), 216 (M − $H_2O$, 7), 215 (M − $H^2HO$, 9), 188 (8), 187 (6), 175 (41), 174 (30), 173 (17), 161 (100), 160 (5), 104 (16), 76 (22); 97.2 ± 0.2% $^2H_1$, determined by ms; ORD, $[\alpha]_{365}$ −5.39 ± 0.14°, $[\alpha]_{405}$ −3.79 ± 0.22°, $[\alpha]_{436}$ −3.07 ± 0.18°, $[\alpha]_{546}$ −1.64 ± 0.13°, $[\alpha]_{577}$ −1.37 ± 0.14°, $[\alpha]_{589}$ −1.08 ± 0.22° (*c*, 0.91% in methanol, 25°C, uncorrected for incomplete deuteration) (lit. (4) $[\alpha]_{589}$ −1.69°).

A sample of (−)-4-phthalimido(4-$^2$H)butyric acid (**12**) (5 mg) was dissolved in ether (1 ml), a solution of diazomethane in ether (1 mL) (36) was added, and the mixture was allowed to stand overnight. The product, (−)-methyl 4-phthalimido(4-$^2$H)butyrate (**13**) was recrystallized from methanol, mp 87–88°C (lit. (nondeuteriated) (35) mp 89–90°C); ms, *m/e*: 248 (M, 9%), 217 (M − $OCH_3$, 18), 216 (8), 189 (10), 188 (10), 175 (100), 174 (20), 161 (95), 130 (15), 104 (17), 77 (15), 76 (12); 98.2 ± 0.3% $^2H_1$, determined by ms; ORD, $[\alpha]_{365}$ −5.97 ± 0.60°, $[\alpha]_{405}$ −4.84 ± 0.40°, $[\alpha]_{436}$ −4.06 ± 0.30°, $[\alpha]_{546}$ −2.21 ± 0.30°, $[\alpha]_{577}$ −2.02 ± 0.30° (*c*, 0.34% in methanol, 25°C, uncorrected for incomplete deuteration).

An unlabelled sample of methyl 4-phthalimidobutyrate was prepared analogously; mp 87–88°C (from methanol); ms, *m/e*: 247 (M, 13%), 216 (M − $OCH_3$, 19), 215 (17), 188 (9), 187 (11), 174 (100), 173 (23), 160 (79), 130 (11), 104 (14), 77 (12), 76 (6).

An authentic sample of (−)-methyl 4-phthalimido(4-$^2$H)-butyrate (**13**) was supplied by Dr. M. H. O'Leary, University of Wisconsin. This sample had been prepared (4) by methylation of (−)-4-phthalimido(4-$^2$H)butyric acid which had been obtained by decarboxylation in $^2H_2O$ of L-glutamic acid, catalyzed by L-glutamic decarboxylase; mp 88–89°C (from methanol); ms, *m/e*: 248 (M, 13%), 217 (M − $OCH_3$, 21), 216 (10), 189 (10), 188 (8), 175 (100), 174 (15), 161 (80), 130 (15), 104 (15), 77 (10), 76 (12); 92.5 ± 0.4% $^2H_1$, 4.7 ± 0.4% $^2H_2$, determined by ms; ORD,

$[\alpha]_{365}$ −4.45 ± 0.30°, $[\alpha]_{405}$ −3.35 ± 0.20°, $[\alpha]_{436}$ −2.76 ± 0.20°, $[\alpha]_{546}$ −1.48 ± 0.30°, $[\alpha]_{577}$ −1.43 ± 0.30° (*c*, 0.39% in methanol, 25°C, uncorrected for incomplete deuteration).

(ii) A sample of 4-phthalimido(4-$^2$H)butylguanidine (80 mg) obtained by the method described above from (+)-(1-$^2$H)-agmatine sulfate (72 mg) showed mp 213–214°C (from methanol – acetic acid (20:1)) and a $^1$H nmr spectrum in which the signal at 3.84 ppm corresponded to ca. 1.15 hydrogen atoms. Oxidation of part of this sample (60 mg), as described above, gave (+)-4-phthalimido(4-$^2$H)butyric acid (28 mg), mp 112–114°C (3 times from water). The $^1$H ($^2HCCl_3$) and $^2$H ($CHCl_3$, 30 *mM*, 1584 transients) nmr spectra of this material were similar to those obtained for the (−)-(4-$^2$H)phthalimide; ms, *m/e*: 234 (M, 3%), 216 (M − $H_2O$, 8), 215 (M − $H^2HO$, 10), 188 (9), 187 (7), 175 (44), 174 (39), 173 (19), 161 (100), 160 (16), 104 (17), 76 (25); 84.7 ± 0.3% $^2H_1$ determined by ms; ORD, $[\alpha]_{365}$ +4.77 ± 0.27°, $[\alpha]_{405}$ +3.26 ± 0.29°, $[\alpha]_{436}$ +2.62 ± 0.17°, $[\alpha]_{546}$ +1.32 ± 0.11°, $[\alpha]_{577}$ +1.20 ± 0.13°, $[\alpha]_{589}$ +0.96 ± 0.22° (*c*, 0.97% in methanol, 25°C, uncorrected for incomplete deuteration).

E. *Instrumental methods*

*Measurement of optical activity*

Optical rotation was measured by means of a Perkin–Elmer 241 MC polarimeter equipped with a mercury emission lamp, using a 1 dm polarimeter tube. At least 10 readings were taken at each mercury emission line. Mean values and 95% confidence limits are reported.

*The $^1H$ nmr spectra* at 90 MHz were recorded on a Varian EM 390 spectrometer at ambient temperature. Chemical shifts are reported as ppm downfield from DSS or TMS as internal standards, respectively, for samples in $^2H_2O$ or $^2HCCl_3$ solution.

*The $^2H$ nmr spectra* were recorded on a Bruker WH 90 pulsed Fourier transform spectrometer operating at 13.82 MHz at ambient temperature, with broad band proton noise decoupling. Spectra were obtained of samples in aqueous or chloroform solution in 10 mm (od) sample tubes, using $^2H_2O$ as external lock. The signal due to natural abundance $^2$H in $^2$HOH or $^2HCCl_3$ served as internal standard. Chemical shifts are downfield from perdeuteriotetramethylsilane.

*Mass spectra* were determined on a Micromass 7070F double focussing mass spectrometer, operating with electron impact (EI) or chemical ionization (CI), by direct injection of the samples. Methane at $5 \times 10^{-5}$ mm Torr was the reagent gas for CI. The isotopic content in deuterium enriched samples was calculated as described by Biemann (37).

# Pyrones. IX.[1] Synthetic approaches to the fungal metabolite phacidin and its derivatives

GERALD ARTHUR POULTON AND TERRY DONALD CYR

*Department of Chemistry, University of Victoria, P.O. Box 1700, Victoria, B.C., Canada V8W 2Y2*

Received April 1, 1982

G. A. POULTON and T. D. CYR. Can. J. Chem. **60**, 2821 (1982).

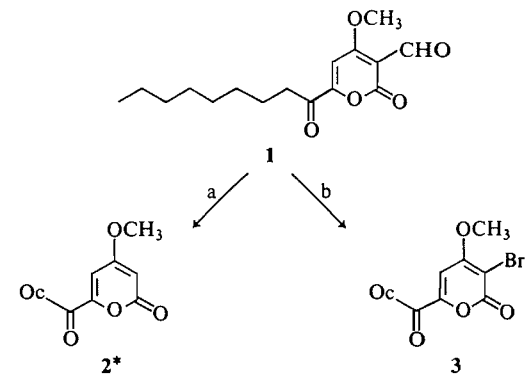
The synthesis of the antibiotic fungal metabolite phacidin **1** (4-methoxy-6-nonanoyl-2*H*-pyran-2-one-3-carboxaldehyde) and two related compounds is reported. Phacidin has been prepared in four steps from the readily available triacetic acid lactone (4-hydroxy-6-methyl-2*H*-pyran-2-one), while the decarbonylated derivative **2** and the bromo compound **3** have been synthesized utilizing a route based upon the condensation of the dianion of ethyl acetoacetate with a substituted 1,3-dithiane-2-carboxaldehyde.

G. A. POULTON et T. D. CYR. Can. J. Chem. **60**, 2821 (1982).

On rapporte la synthèse d'un métabolite fongique aux propriétés antibiotiques: la phacidine **1** (méthoxy-4 nonanoyl-6 (2*H*)pyranone-2 carboxaldehyde-3) ainsi que deux composés apparentés. La phacidine a été préparée en quatre étapes à partir de la lactone de l'acide triacétique (hydroxy-4 méthyl-2 (2*H*)pyranone-2) facilement accessible, tandis que le dérivé décarbonylé **2** et le composé bromé **3** ont été synthétisés en utilisant une voie basée sur la condensation du dianion de l'acétoacétate d'éthyle avec un dithiane-1,3 carboxaldéhyde-2 substitué.

[Traduit par le journal]

Phacidin **1**, a metabolic product of the canker fungus *Potebniamyces balsamicola* Smerlis var. *boycei* Funk, has been shown to possess potentially useful antifungal activity (1). Elucidation of the structure of this mycotoxin involved an examination of its chemical transformations and the spectra of phacidin and several derivatives, most particularly the decarbonylated compound **2** and the bromo derivative **3** (Scheme 1). Such elucidation was rendered more difficult by the great similarities in spectra between 4-alkoxy-2-pyrones and 2-alkoxy-4-pyrones (2), and final confirmation of structure was only obtained with the completion of the synthesis of phacidin (3). Herewith we report the synthetic routes which were investigated, and the experiments which led to the successful synthesis of **1**, **2**, and **3**.



*In this and all subsequent schemes and tables, Oc = *n*-octyl; reagents: a $(Ph_3P)_3RhCl$, $C_6H_6$; b $Br_2$, $H_2O$

SCHEME 1. Preparation of derivatives of phacidin.

Complex pyrones have been synthesized via three different routes: (i) by synthesis of the ring from suitably substituted acyclic precursors, (ii) from carbohydrate derivatives, and (iii) by modification of naturally occurring pyrones. Synthesis of pyrones from carbohydrate derivatives has not normally been a productive route, mainly due to low yields, and has not been used for the preparation of 4-oxy-2-pyrones. A wide variety of routes has been devised leading to these compounds which are based upon the formation of a particular carbon–carbon bond of the pyrone ring. Commonly used routes include the carboxylation of β-diketones (formation of the 2,3-bond) followed by cyclization of the 3,5-diketoacids (4), base catalyzed condensation of two β-ketoesters (forming the 3,4-bond (5)), condensations of ketenes or ketene acetals (3,4-bond (6)), or the condensation of mono- or di-anions of β-ketoesters with acid derivatives or aldehydes (formation of 4,5-bond (7) or 5,6-bond (8), respectively). Elaboration of naturally occurring pyrones into more complex, larger molecules has been achieved through functionalization of ring methyl groups by radical bromination (9), oxidation (10), or anion formation (11), although recent results (12) indicate that deprotonation at C-3 can compete with anion formation at the methyl position.

Our successful synthesis of phacidin was based upon the choice of triacetic acid lactone (4-hydroxy-6-methyl-2*H*-pyran-2-one) **4** as starting material. The key step in the proposed synthesis (see Scheme 2) was the introduction of the formyl group at C-3; accordingly, model studies were carried out with this substrate and its methyl ether (see Table

1). After fruitlessly trying a variety of reagents and conditions (13–17), we achieved success using a process which involved treatment of the methoxypyrone with excess dichloromethyl methyl ether, followed by excess anhydrous titanium tetrachloride under a nitrogen atmosphere. The intermediate product was readily hydrolyzed by water at 0°C to produce the aldehyde, 4-methoxy-6-methyl-2*H*-pyran-2-one-3-carboxaldehyde **5** (37%).

With a suitable formylation procedure in hand, triacetic acid lactone **4** was treated with two equivalents of butyllithium, and the dianion thus formed successfully alkylated at carbon with 1-bromooctane, producing 4-hydroxy-6-nonyl-2-pyrone **6** in low yield. That alkylation had proceeded as desired at the methyl group and not at C-3 or the 4-oxygen was evident from the retained signals in the $^1$Hmr spectrum at δ 11.1 (broad, OH) and at δ 6.02 and 5.60 (both doublets, $J = 4.5$ Hz, indicating unsubstituted 3,5-positions) and from the replacement of the 6-methyl signal by a two proton triplet at δ 2.48. An attempt to oxidize the benzylic position of the nonyl side chain via oxygenation of the dianion (19) was unsuccessful; only traces of the desired 4-hydroxy-6-(1′-hydroxynonyl)-2-pyrone **7** were obtained.

In order to improve selectivity and solubility, the methyl ether **8** was prepared by a normal base-promoted methylation (20). Formylation was then effected using the conditions established earlier and the desired 4-methoxy-6-nonyl-2-pyrone-3-carboxaldehyde **9** isolated in high yield. Substitution was confirmed by the disappearance of the C-3 proton resonance at δ 5.48, the collapse of the C-5 resonance to a singlet at δ 6.05, and the presence of the aldehyde resonance at δ 10.14.

Since the aldehyde itself was unlikely to survive an anion oxygenation procedure, attempts were made to protect it by derivatization. Treatment of the aldehyde **9** with ethylene glycol under acid catalysis produced, as the only isolable pyrone product, the deformylated 4-methoxy-6-nonyl-2-pyrone **8** (45%); similar results were obtained when trimethyl or triethyl orthoformate was used. The *N*,*N*-dimethylhydrazone was successfully prepared in high yield, but oxygenation of the anion of **10** gave mainly recovered starting material and decomposition products. Reduction of the formyl group (to the alcohol **12**) followed by oxygenation also gave no reaction or led mainly to decomposition products, indicating that such an oxidative route was unlikely to prove useful. Similar attempts using oxodiperoxymolybdenum (pyridine) (hexamethyl phosphoric triamide) (21) also failed.

Suzuki *et al.* (10) had demonstrated that the 6-methyl group could be successfully oxidized to a carbonyl compound by means of selenium dioxide oxidation. Again using 4-methoxy-6-nonyl-2-py-

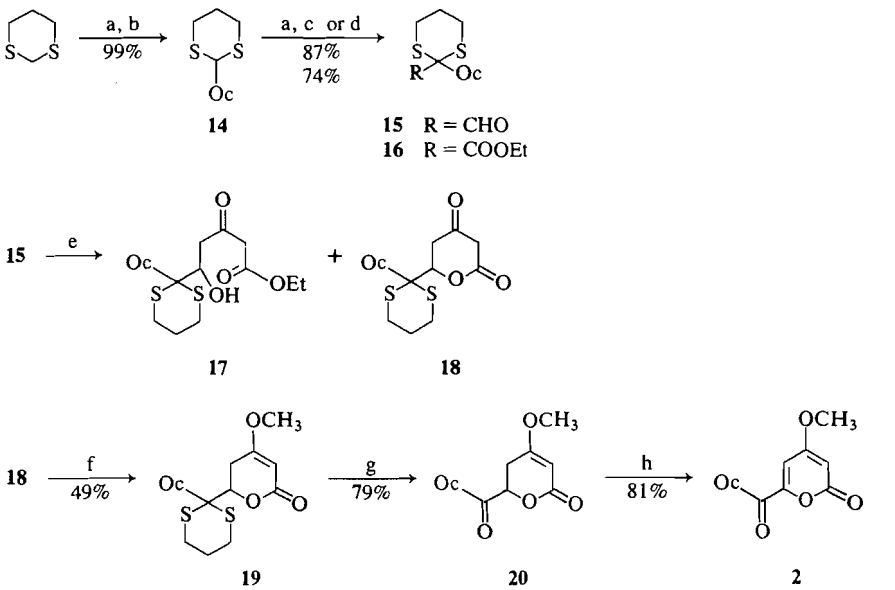
rone **8** as a model compound, conditions were developed which maximized the yield of the desired ketone **2** (see Table 2); freshly sublimed selenium dioxide was found to be essential for the reaction to succeed, as only decomposition ensued when reagent $SeO_2$ was used. Application of similar conditions to the oxidation of the aldehyde **9** (freshly sublimed $SeO_2$ in refluxing *m*-xylene, 30 min) produced a mixture of starting material **9** and phacidin **1** in a ratio of 3:1 (82% recovery). Phacidin was isolated by preparative thin layer chromatography, and the sample thus obtained had identical mp and spectral properties to the natural product.

Use of an alternate route based upon dithiane alkylation (8, 22) allowed us to prepare the derivatives **2** and **3** (see Schemes 3 and 4). 1,3-Dithiane was alkylated under standard conditions yielding 2-octyl-1,3-dithiane (**14**) in 99% yield. Subsequent treatment of **14** with n-butyllithium provided a monoanion which was reacted with dimethylformamide to produce the aldehyde **15** (87%) or with ethyl chloroformate yielding the ester **16** (74%). It was our intention to react the ester with the dianion of ethyl acetoacetate and produce the 4-hydroxy-2-pyrone directly, thus obviating the extra step involved in oxidation of the dihydropyrone; unfortunately, the desired product was not forthcoming



Reagents: a BuLi, THF; b OcBr; c DMF; d EtOOCCl; e $LiCH_2COCHCOOEt\ Na^+$; f NaH, $(CH_3)_2SO_4$; g $HgCl_2$, HgO, EtOH; h NBS, $h\nu$

SCHEME 3. Synthesis of decarbonyl phacidin **2**.

from this reaction. The aldehyde **15** smoothly condensed with the dianion of ethyl acetoacetate producing the desired 5,6-dihydropyrone **18** in 99% yield. When the reaction was carried out on a larger scale, the yield of the cyclized product dropped to 38%, and a second product, the nonlactonized ethyl 5-hydroxy-3-oxo-5-(2-octyl-1,3-dithian-2-yl)-pentanoate **17**, was also isolated. Surprisingly, this hydroxyester could not be subsequently induced to cyclize, either under acid or base conditions. The structure of the desired 5,6-dihydro-4-hydroxy-6-(2-octyl-1,3-dithian-2-yl)-2-pyrone **18** was evident from its molecular ion (*m/z* 344) and fragmentation pattern, the carbonyl stretching peaks at 1760 and 1726 $cm^{-1}$, and the $^1$Hmr spectrum.

The alcohol functionality of **18** was then methylated to produce the 4-methoxy compound **19**, showing $M^+$ at *m/z* 358 (chemical ionization) and $\nu_{CO}$ at 1720 $cm^{-1}$. Since unsaturation in the side chain has previously been shown to aid oxidation of dihydropyrones to pyrones (23), hydrolysis of the dithiane was investigated. Low and variable yields were encountered using the procedure of Seebach and Meyer (8), and therefore the hydrolysis was carried out by adding **19** dropwise to a rapidly stirred, refluxing ethanol slurry of mercuric chloride and mercuric oxide. The ketone **20** (*m/z* 268, $\nu_{CO}$ 1719 $cm^{-1}$) was obtained in 79% yield.

The dehydrogenation of **20** to a pyrone was accomplished by first brominating C-5 under free radical conditions (NBS, $h\nu$), with the subsequent spontaneous dehydrobromination yielding **2**; dehydrobromination was forced to completion simply by removing the HBr formed by bubbling a slow stream of nitrogen through the reaction mixture. The spectral data for the 4-methoxy-6-nonanoyl-2*H*-pyran-2-one **2** thus obtained were in complete accord with those of the decarbonylated compound obtained from the natural product (2).

Phacidin could not be synthesized directly from this product; formylation of **2** under the conditions used previously did not result in ring substitution, but in preparation of the *gem*-dihalide **21**, a not-unexpected transformation (18). Subsequent substitution of the ring in **21** did not ensue, presumably due to the deactivating nature of the dihaloalkyl substituent. A similar formylation attempt on the ethylenedithio derivative **22** also failed, yielding only traces of the desired aldehyde **23** and the deprotected starting material **2**. Reduction of the ketone gave the alcohol **24** which, under the same conditions, produced a complex mixture of products which decomposed extensively during chromatography. Among the products, as identified from their spectra, were the chloro-compound **25**, the chloro-aldehyde **26**, and the dehydrochlorinated aldehyde **27**.

Bromination of 2-pyrones at the 3-position has been demonstrated (24), and we therefore proceeded to the synthesis of bromophacidin **3**. Model experiments with 4-methoxy-6-methyl-2*H*-pyran-2-one **4** confirmed that modest yields of brominated

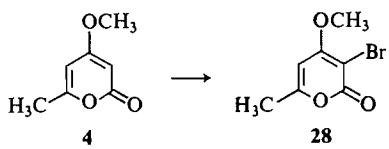
Reagents: a $Cl_2CHOCH_3$, $TiCl_4$; b $HSCH_2CH_2SH$, $BF_3{\cdot}Et_2O$; c $NaBH_4$; d NBS, $I_2$; e $MnO_2$

SCHEME 4. Transformations of 4-methoxy-6-nonanoyl-2-pyrone.

product could be obtained. Thus, bromination of 4-methoxy-6-nonanoyl-2*H*-pyran-2-one, **2**, was attempted using NBS with traces of iodine under conditions similar to those used successfully in the model, but only starting material was isolated, once



again indicating the deactivated nature of this pyrone ring.

Bromination of the hydroxyalkyl pyrone **24** proceeded smoothly under the same conditions to produce the 3-bromo compound **29** which showed molecular ions at *m/z* 348/346 and $\nu_{CO}$ at 1731 $cm^{-1}$. Bromophacidin **3** was successfully synthesized from this alcohol by a standard manganese dioxide oxidation (83%); the properties of this sample were identical in all respects with those of the material obtained from treatment of the natural product with bromine (2), thus confirming its structure and confirming the unusual bromo-deformylation which took place. Direct replacement of formyl by halogen, although not common, has been reported previously. Markovac and MacDonald (25) have used bromine in acetic acid to transform a 2-formylpyrrole to the bromide, while Canonica *et al.* (26) have used chlorine to effect deformylation in the steroid series.

## Experimental

Nuclear magnetic resonance data were obtained on a Perkin–Elmer R12B (60 MHz) or R32 (90 MHz) instrument (proton) or Nicolet TT-14 (15.1 MHz) instrument (carbon) in $CDCl_3$ solution and are referenced to internal TMS. Electron impact mass spectra (70 eV) were obtained using the Hitachi–Perkin–Elmer RMU-7E, methane chemical ionization mass spectra on the Finnigan 3300, ultraviolet spectra in 95% EtOH on the Beckman SP800, and infrared spectra on the Perkin–Elmer 283 instruments. Thin layer chromatography was performed on Polygram Sil G/UV254 precoated plates (Brinkmann Instrument Inc.), column chromatography on 60–200 mesh silica gel (Davison

Instrument Inc.), and preparative thin layer chromatography on MN-Kieselgel G/UV254 (Macherey, Nagel & Co.). Organic solvents were distilled prior to use, and organic solutions dried over anhydrous sodium sulfate. All mp are uncorrected. Bath temperature is reported for low temperature reactions.

*4-Methoxy-6-methyl-2-pyrone-3-carboxaldehyde, 5*

To 4-methoxy-6-methyl-2-pyrone, **4** (0.96g, 0.69 mmol), in dry chloroform (5 mL) was added dichloromethyl methyl ether (0.63 mL, 7.0 mmol), then $TiCl_4$ (0.66 mL, 6.0 mmol) with stirring under nitrogen at 10°C. A red oil formed at the bottom of the flask, and HCl bubbled off the reaction mixture. The reaction was worked up, after stirring 19 h at 20°C, by carefully adding ice water, then extracting the mixture with chloroform. The chloroform extracts were washed ($H_2O$, saturated aqueous NaCl), dried, evaporated, then chromatographed (50% ethyl acetate/pentane) to give 4-methoxy-6-methyl-2-pyrone-3-carboxaldehyde, **5**, 43 mg, 37%; ir (KBr): 3089, 2854, 2761, 1739, 1670, 1637, 1618, 1512, 1472, 1453, 1439, 1418, 1402, 1391, 1372, 1356, 1330, 1231, 1010, 832, 767, 700, 522 $cm^{-1}$; $^1$Hmr δ: 10.15 (1H, s), 6.29 (1H, s), 4.06 (3H, s), 2.36 (3H, s); ms *m/e* (relative intensity): 168 ($M^+$, 30), 153 (5), 140 (66), 139 (22), 125 (19), 111 (36), 110 (100), 95 (46), 93 (13), 69 (41), 53 (27), 43 (91), and 39 (21).

*4-Hydroxy-6-nonyl-2-pyrone, 6*

To triacetic acid lactone, **4** (6.0 g, 47.6 mmol) in THF (100 mL), under dry nitrogen at −78°C, was added n-BuLi (105 mmol). After warming the slurry to 0°C, then stirring for 2 h, n-octyl bromide (8.68 mL, 50 mmol) was added. The clear red solution was stirred at 20°C for 14 h, then ice water (100 mL) was added, and the hexane layer removed. The aqueous layer was extracted with pentane (3 × 50 mL), then acidified to pH 6 with concentrated HCl and extracted with ether (3 × 100 mL). The combined ether extracts were washed ($H_2O$, saturated aqueous NaCl), dried, evaporated, then chromatographed and recrystallized (hexane) to give 4-hydroxy-6-nonyl-2-pyrone **6**, 3.88 g, 34%, mp 78–79°C; ir (NaCl): 2980, 2930, 2860, 1704, 1665, 1634, 1587, 1504, 1479, 1324, 1303, 1267, 1248, 1150, 847 $cm^{-1}$; uv $\lambda_{max}$: 203 (log ε 4.32), 238 (3.86), 282 nm (3.85); $^1$Hmr δ: 11.1 (1H, br s), 6.02 (1H, br d, $J$ = 4.5 Hz), 5.60 (1H, d, $J$ = 4.5 Hz), 2.48 (2H, t, $J$ = 7.0 Hz), 1.8–1.0 (14H, m), 0.88 (3H, t, $J$ = 7.5 Hz); ms *m/e* (relative intensity): 239 (6), 238 ($M^+$, 21), 223 (7), 179 (15), 178 (30), 163 (25), 140 (18), 139 (98), 137 (20), 136 (39), 135 (13), 127 (15), 126 (36), 112 (16), 111 (87), 110 (15), 98 (46), 97 (31), 95 (21), 85 (31), 84 (69), 83 (21), 82 (38), 81 (20), 71 (25), 69 (53), 67 (16), 57 (31), 55 (39), 45 (30), 44 (10), 43 (100), and 41 (36). *Anal.* calcd. for $C_{14}H_{22}O_3$: C 70.55, H 9.30; found: C 70.43, H 9.25.

*Attempted oxygenation of 4-hydroxy-6-nonyl-2-pyrone, 6*

To 4-hydroxy-6-nonyl-2-pyrone, **6** (100 mg, 0.42 mmol), in THF (6 mL) and diisopropylamine (0.10 mL, 0.77 mmol) at −78°C under a nitrogen atmosphere was added n-BuLi (0.48 mL, 0.77 mmol). The solution was warmed to 0°C over 1 h, stirred 1 h, and oxygen admitted via a syringe. After 1 h, the oxygen was flushed out with nitrogen, triethyl phosphite (0.2 mL, 1.24 mmol) added, and the solution stirred 1.5 h. Iced HCl (5%, 10 mL) and ether (10 mL) were added, the aqueous layer extracted with dichloromethane (3 × 15 mL), and the combined organic phases dried and evaporated. Chromatography of the resulting liquid (5% iPrOH/$CH_2Cl_2$) gave a small amount of 4-hydroxy-6-(1′-hydroxynonyl)-2-pyrone **7**; $^1$Hmr δ: 6.26 (1H, br s), 5.55 (1H, br s), 4.90 (1H, m), 2.0–1.15 (12H, m), 0.90 (3H, t, $J$ = 7.5 Hz); ms *m/e* (relative intensity): 254 ($M^+$, 4.5), 178 (3), 155 (9), 135 (11), 111 (25), 83 (37), 65 (33), 58 (26), 45 (100), 44 (37), 43 (54), and 41 (32).

*4-Methoxy-6-nonyl-2-pyrone, 8*

To 4-hydroxy-6-nonyl-2-pyrone, **6** (0.97 g, 4.08 mmol), and anhydrous $K_2CO_3$ (4.15 g, 30 mmol) in 2-butanone (100 mL) was added dimethyl sulphate (0.42 mL, 4.5 mmol). The mixture was refluxed under nitrogen with stirring for 23 h, then cooled, filtered, and evaporated. Chromatography (25% ethyl acetate/pentane), then recrystallization (pentane), gave 4-methoxy-6-nonyl-2-pyrone **8**, 0.91 g, 86%, mp 58–59°C; ir (NaCl): 3076, 2958, 2925, 1853, 1736, 1648, 1565, 1468, 1459, 1447, 1411, 1262, 1240, 1134, 1026, 933, 872, 848, 827, 801, 718 $cm^{-1}$; uv $\lambda_{max}$: 297 nm (log ε 3.99); $^1$Hmr δ: 5.86 (1H, d, $J$ = 2.5 Hz), 5.48 (1H, d, $J$ = 2.5 Hz), 3.87 (3H, s), 2.49 (2H, t, $J$ = 8.1 Hz), 2.0–1.1 (14H, m), 0.90 (3H, br t); ms *m/e* (relative intensity): 253 (5), 252 ($M^+$, 26), 237 (2), 223 (3), 209 (6), 195 (5), 152 (62), 140 (74), 125 (100), 112 (16), 111 (11), 98 (32), 69 (29), 59 (15), and 55 (15). *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.39, H 9.59; found: C 71.47, H 9.52.

*4-Methoxy-6-nonyl-2-pyrone-3-carboxaldehyde, 9*

To 4-methoxy-6-nonyl-2-pyrone, **8** (0.5 g, 2 mmol), in $Cl_2CHOCH_3$ (5 mL, 55 mmol) at −5°C under nitrogen was added titanium tetrachloride (2.2 mL, 20 mmol). A continuous nitrogen flow was maintained to remove the HCl evolved, and the temperature was allowed to rise from −5° to 15°C over 15 h. Ice was carefully added to the orange product, followed by ether, until the oil had dissolved completely. The ether solution (100 mL) was then washed ($H_2O$, saturated aqueous NaCl), dried, and evaporated to give 4-methoxy-6-nonyl-2-pyrone-3-carboxaldehyde **9**. Recrystallization from cyclohexane gave 0.49 g, 87% of product, mp 66–70°C; ir (NaCl): 3100, 2952, 2920, 2848, 1750, 1727, 1645, 1629, 1525, 1470, 1448, 1434, 1410, 1378, 1340, 1263, 1244, 1220, 1114, 1015, 975, 829, 760 $cm^{-1}$; uv $\lambda_{max}$: 227 (log ε 3.17), 247 (2.76), 322 nm (3.08); $^1$Hmr δ: 10.14 (1H, s), 6.05 (1H, s), 4.01 (3H, s), 2.56 (2H, t, $J$ = 6.0 Hz), 1.9–1.1 (14H, m), 0.88 (3H, br t); ms *m/e* (relative intensity): 281 (26), 280 ($M^+$, 47), 253 (18), 252 (100), 251 (78), 224 (18), 223 (100), 181 (28), 177 (35), 167 (44), 163 (20), 154 (20), 153 (92), 140 (48), 125 (23), 123 (54), 110 (27), 95 (20), 69 (29), 57 (19), 56 (27), and 55 (31). *Anal.* calcd. for $C_{16}H_{24}O_4$: C 68.55, H 8.69; found: C 68.62, H 8.71.

*3-Hydroxymethyl-4-methoxy-6-nonyl-2-pyrone, 12*

To 4-methoxy-6-nonyl-2-pyrone-3-carboxaldehyde, **9** (50 mg, 0.18 mmol), in methanol (3 mL) was added sodium borohydride (20 mg, 0.54 mmol) with stirring at 0°C. After 1 h, a further 20 mg of sodium borohydride was added, and stirring was continued for 1 h. Water was then added, and the resulting solution was extracted with ether (2 × 25 mL). The ether solution was washed (saturated aqueous NaCl), dried, evaporated, and the product recrystallized from pentane/ether to give 3-hydroxymethyl-4-methoxy-6-nonyl-2-pyrone **12**, 47 mg, 93%, mp 63–66°C; ir (NaCl): 3500–3180 (br), 2960, 2925, 2855, 1710, 1685, 1641, 1564, 1483, 1473, 1459, 1423, 1403, 1385, 1358, 1290, 1272, 1263, 1234, 1183, 1082, 1008, 998, 901 $cm^{-1}$; $^1$Hmr δ: 6.05 (1H, s), 4.53 (2H, s), 3.88 (3H, s), 2.49 (2H, t, $J$ = 7.0 Hz), 1.9–1.1 (14H, m), 0.88 (3H, br t); ms *m/e* (relative intensity): 283 (15), 282 ($M^+$, 69), 281 (32), 267 (76), 264 (33), 253 (95), 237 (39), 165 (55), 155 (100), 153 (45), 152 (70), 127 (72), 125 (53), 95 (29), 83 (31), 81 (29), 71 (35), 69 (49), 57 (55), 55 (58), 43 (58), and 41 (53).

*Selenium dioxide oxidation of 4-methoxy-6-nonyl-2-pyrone, 8*

4-Methoxy-6-nonyl-2-pyrone **8** (100 mg, 0.4 mmol) and freshly sublimed selenium dioxide (200 mg, 1.8 mmol) were refluxed in dry bis(2-methoxyethyl) ether (diglyme, 3.5 mL) for 0.5 h under nitrogen with rapid stirring. The solution was then cooled, evaporated, and extracted with ether (20 mL). The ether extract was washed (saturated aqueous $NaHCO_3$, saturated aqueous NaCl), dried, and evaporated. The product was a mixture (90 mg) containing 4-methoxy-6-nonanoyl-2-pyrone, **2**, and 4-

For personal use only.

methoxy-6-nonyl-2-pyrone, **8**, in a ratio of 4:1. The yield of compound **2** was 65%. Spectral data were identical to those reported below.

*4-Methoxy-6-nonanoyl-2-pyrone-3-carboxaldehyde, **1***

4-Methoxy-6-nonyl-2-pyrone-3-carboxaldehyde **9** (30 mg, 0.12 mmol) and freshly sublimed $SeO_2$ (110 mg, 1.0 mmol) in dry *m*-xylene (2 mL) were refluxed for 0.5 h with rapid stirring under nitrogen. The products were isolated from the reaction mixture, as above, to give a mixture of compounds **9** and **1** in a ratio of 3:1, by $^1$Hmr. Preparative thin layer chromatography (50% ethyl acetate/pentane) gave compound **9** (18.3 mg, 61% recovery) and the desired product, compound **1** (6.5 mg, 21%). Compound **1** was recrystallized twice from cyclohexane, yield 53% (based on unrecovered starting material), mp 111–114°C (lit. (2) mp 112–113°C); ir (KBr): 2958, 2930, 1725, 1700, 1689, 1617, 1527, 1519, 1478, 1234 cm$^{-1}$; uv $\lambda_{max}$: 223 (log ε 4.13), 272 (3.28), 342 nm (3.97); $^1$Hmr δ: 10.11 (1H, s), 7.08 (1H, s), 4.13 (3H, s), 2.93 (2H, t, $J$ = 6.8 Hz), 1.9–1.1 (12H, m), 0.90 (3H, br t); ms *m/e* (relative intensity): 294 (M$^+$, 4), 266 (3), 265 (0.5), 238 (1), 154 (12), 153 (100), 141 (6), 125 (12), 123 (4), 71 (11), 69 (15), 57 (17), 55 (16), 43 (16), and 41 (15).

*2-Octyl-1,3-dithiane, **14***

To a dry THF solution (250 mL) of 1,3-dithiane (10 g, 83.4 mmol) at −10 to −15°C under dry nitrogen was added n-BuLi (84 mmol). The temperature was maintained at −15°C for 2 h, then reduced to −78°C and n-octyl bromide (16.1 g, 83.4 mmol) was added. The reaction mixture was maintained at −78°C for 2 h, −20°C for 1 h, 0°C for 1 h, then warmed to 20°C over 15 h. The THF was removed by evaporation, then water (50 mL) added, and the solution extracted with ether (2 × 100 mL). The ether extracts were washed ($H_2O$), dried ($K_2CO_3$), evaporated, then chromatographed (10% dichloromethane/pentane) to give 2-octyl-1,3-dithiane (**14**), 19.07 g, 98.5%; ir (film): 2954, 2855, 1466, 1442, 1415, 1276, 1243, 1181, 909, 867, 778, 720, 681, 660 cm$^{-1}$; $^1$Hmr δ: 4.12 (1H, t, $J$ = 6.5 Hz), 3.0–2.8 (6H, m), 2.3–1.1 (14H, m), 0.90 (3H, t, $J$ = 6 Hz); ms *m/e* (relative intensity): 232 (M$^+$, 33), 157 (17), 132 (4), 119 (100), 106 (6), 73 (7), 55 (11), 45 (15), 43 (39), 41 (44), and 39 (17). *Anal.* calcd. for $C_{12}H_{24}S_2$: C 62.01, H 10.41; found: C 62.04, H 10.62.

*2-Octyl-1,3-dithiane-2-carboxaldehyde, **15***

To 2-octyl-1,3-dithiane **14** (5 g, 21.6 mmol), in dry THF (25 mL) under nitrogen at −15°C, was added n-BuLi (24 mmol). After stirring for 3 h at −15°C, the solution was cooled to −60°C and freshly distilled dimethylformamide (3.47 mL, 45 mmol) was added dropwise. After stirring the solution a further 30 min, water (45 mL) was added and the solution acidified with concentrated HCl. The aqueous phase was extracted with ether (3 × 25 mL) and then the combined organic extracts dried, evaporated, and chromatographed (dichloromethane) to give 2-octyl-1,3-dithiane-2-carboxaldehyde **15**, 4.89 g, 87%; ir (film): 2950, 2930, 2858, 2695, 1720, 1468, 1424, 1279, 908 cm$^{-1}$; $^1$Hmr δ: 9.05 (1H, s), 3.3–1.1 (20H, m), 0.90 (3H, t, $J$ = 6 Hz); ms *m/e* (relative intensity): 260 (M$^+$, 1.5), 233 (9), 232 (16), 231 (100), 145 (2), 119 (2), 107 (3), 81 (2), 75 (2), 73 (2.5), and 55 (3). *Exact Mass* calcd. for $C_{13}H_{24}O_1S_2$: 260.131; found: 260.130.

*2-Ethoxycarbonyl-2-octyl-1,3-dithiane, **16***

To 1,3-dithiane (1 g, 8.34 mmol), in dry THF (25 mL) under nitrogen at −20°C, was added n-BuLi (8.6 mmol). The solution was stirred at −15°C for 2 h, then cooled to −78°C. n-Octyl bromide (1.45 mL, 8.34 mmol) was then added, and the temperature was allowed to rise to −30°C over 2 h, then to 20°C over 1 h. The solution was then cooled to −78°C, n-BuLi added, then warmed to 0°C over 4.5 h. The 2-octyl-2-lithio-1,3-dithiane solution was then added to ethyl chloroformate (0.2 mol) at −78°C over 15 min. The reaction mixture was stirred at −78°C for 12 h, then at 0°C for 1 h. Evaporation followed by chromatography (dichloromethane/pentane) gave 2-ethoxycarbonyl-2-octyl-1,3-dithiane (**16**), 1.72 g, 73%; ir (film): 2982, 2960, 2855, 1725, 1422, 1418, 1315, 1280, 1246, 1224, 1174, 1130, 1094, 1025, 906 cm$^{-1}$; $^1$Hmr δ: 4.35 (2H, q, $J$ = 7.5 Hz), 3.6–1.1 (20H, m), 1.36 (3H, t, $J$ = 7.5 Hz), 0.91 (3H, t, $J$ = 7 Hz); ms *m/e* (relative intensity): 304 (M$^+$, 9), 232 (18), 231 (100), 143 (17), 119 (16), 97 (19), 95 (16.5), 83 (20), 81 (20), 71 (22), 69 (27), 57 (36), 55 (42), 43 (32), and 41 (33). *Exact Mass* calcd. for $C_{15}H_{28}O_2S_2$: 304.158; found: 304.151.

*5,6-Dihydro-4-hydroxy-6-(2-octyl-1,3-dithian-2-yl)-2-pyrone, **18***

(A) To sodium hydride (54% in mineral oil, 1.2 g, 27 mmol), in dry THF (40 mL) under nitrogen at 0°C, was added ethyl acetoacetate (3.16 mL, 25 mmol). After 10 min, n-BuLi (26 mmol) was added, the temperature was maintained for 10 min, then the solution cooled to −78°C. 2-Octyl-1,3-dithiane-2-carboxaldehyde, **15** (385 mg, 14.8 mmol) was then added. After the solution was warmed to 0°C, then stirred for 0.5 h, water (125 mL) was added, and the solution stirred at 20°C for 22 h. The aqueous solution was then extracted with ether (2 × 20 mL), cooled to 0°C, acidified with concentrated HCl, and extracted with dichloromethane. The dichloromethane extracts were dried, then evaporated to give 5,6-dihydro-4-hydroxy-6-(2-octyl-1,3-dithian-2-yl)-2-pyrone, **18**, 5.05 g, 99%, which was filtered through silica gel (10% 2-propanol/dichloromethane), mp 87–90°C; ir (NaCl): 3100, 2955, 2920, 2852, 1760, 1726, 1670, 1610, 1465, 1415, 1360, 1275, 1228, 1190, 1030, 885, 826 cm$^{-1}$; $^1$Hmr δ: 4.96 (1H, dd, $J$ = 10, 5 Hz), 3.6–1.1 (24H, m), 0.87 (3H, br t); ms *m/e* (relative intensity): 344 (M$^+$, 2), 300 (11), 231 (85), 195 (15), 194 (98), 187 (20), 106 (86), 96 (28), 95 (100), 85 (39), 44 (30), and 43 (34). *Anal.* calcd. for $C_{17}H_{28}O_3S_2$: C 59.27, H 8.19; found: C 59.05, H 8.24.

(B) When the above reaction was carried out on a larger scale (120 mmol of the aldehyde **15**) the yield of compound **18** was reduced to 38%, and a second compound was isolated, ethyl 5-hydroxy-3-oxo-5-(2-octyl-1,3-dithian-2-yl)pentanoate, **17**, in 34% yield; ir (film): 3490, 2958, 2929, 2855, 1744, 1715, 1469, 1423, 1410, 1390, 1368, 1220, 1177, 1155, 1095, 1070, 1030, 909 cm$^{-1}$; $^1$Hmr δ: 4.71 (1H, dt, $J$ = 9.0, 2.5 Hz), 4.26 (2H, q, $J$ = 8.5 Hz), 3.58 (2H, s), 3.3–2.4 (7H, m), 2.2–1.2 (19H, m), 0.90 (3H, br t); ms *m/e* (relative intensity): 390 (M$^+$, 0.1), 253 (10), 252 (15), 251 (100), 119 (2), 107 (4), 106 (3), 73 (3), 69 (3), 57 (3), 55 (4), and 43 (5).

*5,6-Dihydro-4-methoxy-6-(2-octyl-1,3-dithian-2-yl)-2-pyrone, **19***

To the 4-hydroxy-2-pyrone **18** (8 g, 23.3 mmol), in dry THF (50 mL) under nitrogen, was added sodium hydride (54% in mineral oil, 1.24 g, 27.9 mmol). After stirring for 0.5 h at −10°C, the solution was cooled to −30°C and dimethyl sulphate (3.8 g, 30 mmol) added. The solution was stirred for 60 h at 20°C, then evaporated. Water was added, and the product extracted with dichloromethane (3 × 50 mL). The organic solution was dried, evaporated, then chromatographed (2-propanol/dichloromethane) to yield the 4-methoxy-2-pyrone **19**, 4.1 g, 49%; ir (film): 2928, 2855, 1720, 1628, 1460, 1444, 1383, 1340, 1280, 1249, 1225, 1195, 1176, 1095, 1080, 1040, 1000, 821 cm$^{-1}$; $^1$Hmr δ: 5.12 (1H, d, $J$ = 2.5 Hz), 4.71 (1H, dd, $J$ = 13, 4.5 Hz), 3.72 (3H, s), 3.5–1.1 (22H, m), 0.88 (3H, br t); ms *m/e* (relative intensity): CI 359 (M + 1, 16), 327 (12), 303 (15), 269 (61), and 231 (100); EI 233 (11), 232 (16), 231 (100), 145 (3), 119 (3), 107 (3), 81 (4), 73 (7), 57 (6), 55 (14), 43 (9), and 41 (20). *Exact Mass* calcd. for $C_{18}H_{30}O_3S_2$: 358.181; found: 358.178.

*5,6-Dihydro-4-methoxy-6-nonanoyl-2-pyrone, **20***

5,6-Dihydro-4-methoxy-6-(2-octyl-1,3-dithian-2-yl)-2-pyrone, **19** (1.6 g, 4.47 mmol), in 95% ethanol (20 mL) was added dropwise to a rapidly stirring slurry of mercuric chloride (1.46 g, 5.36 mmol) and mercuric oxide (1.16 g, 5.36 mmol) in 95% ethanol at 78°C. After refluxing for 1 h, the solution was cooled, filtered, then HCl (0.05 *M*, 40 mL) was added. The solution was stirred 12 h, then extracted with dichloromethane, dried, evaporated, and chromatographed (7% i-PrOH/$CH_2Cl_2$) to give 5,6-dihydro-4-methoxy-6-nonanoyl-2-pyrone, **20**, 0.95 g, 79%, mp 77–79°C (cyclohexane); ir (NaCl): 2919, 2889, 2848, 1719, 1627, 1471, 1444, 1401, 1291, 1252, 1237, 1128, 1113, 1000, 860 $cm^{-1}$; uv $\lambda_{max}$: 233.4 nm (log ε 3.95); $^1$Hmr δ: 5.27 (1H, s), 4.84 (1H, t, $J$ = 7 Hz), 3.83 (3H, s), 2.79 (2H, t, $J$ = 7 Hz), 2.75 (2H, t, $J$ = 7 Hz), 2.0–1.1 (12H, m), 0.89 (3H, br t); ms *m/e* (relative intensity): 268 ($M^+$, 3), 195 (2), 170 (1), 141 (8), 128 (34), 127 (100), 99 (5), 71 (7), 67 (7), 57 (7.5), 55 (5), 43 (13), and 41 (9). *Exact Mass* calcd. for $C_{15}H_{24}O_4$: 268.172; found: 268.173. *Anal.* calcd.: C 67.14, H 9.01; found: C 66.59, H 9.23.

*4-Methoxy-6-nonanoyl-2-pyrone, **2***

5,6-Dihydro-4-methoxy-6-nonanoyl-2-pyrone **20** (536 mg, 2 mmol) and *N*-bromosuccinimide (NBS, 392 mg, 2.2 mmol) in carbon tetrachloride (50 mL) were refluxed for 1.5 h under nitrogen, while being irradiated with a tungsten lamp (100 W). Additional NBS (39 mg, 0.22 mmol) was then added, and refluxing/irradiation was continued for 1 h. The solution was allowed to stand under nitrogen for 24 h, then nitrogen was bubbled slowly through the solution for 24 h. The $CCl_4$ solution was then washed ($H_2O$, saturated aqueous NaCl), dried, evaporated, and the product recrystallized (95% ethanol) to give 4-methoxy-6-nonanoyl-2-pyrone **2**, 430 mg, 81%, mp 123–124°C (lit. (2) mp 120–121°C); ir (NaCl): 3080, 2942, 2914, 2874, 2850, 1726, 1708, 1637, 1518, 1470, 1464, 1450, 1413, 1400, 1374, 1343, 1272, 1261, 1255, 1170, 1016, 998, 980, 879, 865, 851 $cm^{-1}$; uv $\lambda_{max}$: 220 (log ε 4.11), 254 (3.18), 306 nm (3.60); $^1$Hmr δ: 6.72 (1H, d, $J$ = 2.5 Hz), 5.68 (1H, d, $J$ = 2.5 Hz), 3.83 (3H, s), 2.85 (2H, t, $J$ = 7.5 Hz), 1.9–1.1 (12H, m), 0.87 (3H, br t, $J$ = 7 Hz); ms *m/e* (relative intensity): 266 ($M^+$ 4.5), 238 (3), 168 (3), 128 (2), 127 (6), 126 (7), 125 (100), 69 (4), 59 (5), and 43 (5). *Anal.* calcd. for $C_{15}H_{22}O_4$: C 67.69, H 8.33; found: C 67.61, H 8.37.

*4-Methoxy-6-(1′-hydroxynonyl)-2-pyrone, **24***

To 4-methoxy-6-nonanoyl-2-pyrone **2** (108 mg, 0.406 mmol), in methanol (5 mL) at −5°C, was added sodium borohydride (3.8 mg, 0.4 mmol) in three portions at intervals of 0.5 h. After a total of 2.5 h, water (15 mL) and chloroform (20 mL) were added to the reaction mixture. The chloroform solution was washed (saturated aqueous NaCl), dried, then evaporated and recrystallized (methanol/water) to yield 4-methoxy-6-(1′-hydroxynonyl)-2-pyrone **24**, 101 mg, 99%, mp 40–41°C (aqueous MeOH); ir(NaCl): 3410, 2950, 2928, 2855, 1701, 1647, 1568, 1455, 1411, 1345, 1124, 1031, 810 $cm^{-1}$; $^1$Hmr δ: 6.04 (1H, d, $J$ = 2.4 Hz), 5.36 (1H, d, $J$ = 2.4 Hz), 4.32 (1H, m), 3.76 (3H, s), 3.38 (1H, d, $J$ = 6 Hz, exch. with $D_2O$), 2.3–1.1 (14H, m), 0.88 (3H, t, $J$ = 6 Hz); ms *m/e* (relative intensity): 269 (3), 268 (16), 267 (1), 237 (2), 179 (2), 169 (5), 156 (4), 125 (100), and 69 (42). *Anal.* calcd. for $C_{15}H_{24}O_4$: C 67.14, H 9.02; found: C 66.94, H 8.97.

*3-Bromo-4-methoxy-6-methyl-2-pyrone, **28***

To 4-methoxy-6-methyl-2-pyrone **4** (280 mg, 2.0 mmol), in $CCl_4$ (20 mL), was added NBS (450 mg, 2.5 mmol) and iodine (10 mg). The solution was refluxed for 2 h in the dark, then evaporated, dissolved in dichloromethane (30 mL), washed ($H_2O$, saturated aqueous NaCl), dried, and evaporated to yield 3-bromo-4-methoxy-6-methyl-2-pyrone **28**, 200 mg, 46%, mp 157–157.5°C (lit. (19) mp 155–156°C); $^1$Hmr δ: 6.15 (1H, s), 4.01 (3H, s), 2.29 (3H, s); ms *m/e* (relative intensity): 220 ($M^+$, 82), 218 ($M^+$, 82), 192 (67), 190 (71), 178 (17), 177 (13), 176 (17), 175 (13), 149 (100), 147 (100), 139 (27), 97 (23), 95 (24), 85 (25), 83 (35), 81 (29), 71 (38), 69 (41), and 67 (21). *Anal.* calcd. for $C_7H_7Br_1O_3$: C 38.39, H 3.22; found: C 38.40, H 3.00.

*Attempted bromination of 4-methoxy-6-nonanoyl-2-pyrone, **2***

To compound **2** (54 mg, 0.2 mmol) in $CCl_4$ (7 mL) under nitrogen was added NBS (48 mg, 0.27 mmol) and iodine (2 mg). The reaction mixture was refluxed in the dark for 24 h, then diluted with dichloromethane (15 mL), washed ($H_2O$, saturated aqueous NaCl), dried, then evaporated to yield only starting material by $^1$Hmr and tlc.

*3-Bromo-4-methoxy-6-(1′-hydroxynonyl)-2-pyrone, **29***

4-Methoxy-6-(1′-hydroxynonyl)-2-pyrone **24** (42 mg, 0.16 mmol), NBS (35.6 mg, 0.2 mmol), and iodine (trace) in carbon tetrachloride (20 mL) were refluxed under nitrogen in the dark for 1 h. Dichloromethane (20 mL) was then added and the solution was washed ($H_2O$, saturated aqueous NaCl), dried, evaporated, and chromatographed (50% ethyl acetate/pentane) to yield 3-bromo-4-methoxy-6-(1′-hydroxynonyl)-2-pyrone **29**, 34 mg, 61%, which was recrystallized from pentane, mp 93–94°C; ir (NaCl): 3440, 2960, 2924, 2858, 1731, 1680, 1636, 1523, 1469, 1390, 1324, 1229, 1060 $cm^{-1}$; $^1$Hmr δ: 6.44 (1H, s), 4.6–4.25 (1H, m), 3.98 (3H, s), 3.0–2.7 (1H, m), 2.2–1.0 (14H, m), 0.88 (3H, t, $J$ = 6 Hz); ms *m/e* (relative intensity): 348 ($M^+$, 8.5), 346 ($M^+$, 10), 267 (2), 266 (4), 249 (5), 248 (4), 247 (5), 207 (10), 206 (5), 205 (32), 204 (4), 203 (24), 149 (6), 147 (6), 126 (8), 125 (100), and 41 (36). *Anal.* calcd. for $C_{15}H_{23}Br_1O_4$: C 51.88, H 6.68; found: C 51.96, H 6.61.

*3-Bromo-4-methoxy-6-nonanoyl-2-pyrone, **3***

3-Bromo-4-methoxy-6-(1′-hydroxynonyl)-2-pyrone **29** (20 mg, 0.056 mmol) in benzene (5 mL) was stirred rapidly under nitrogen with activated manganese dioxide (50 mg), for 3 h. Additional manganese dioxide (30 mg) was then added, and the stirring was continued for 18 h. The product was filtered through silica gel (50% ethyl acetate/pentane) to yield 3-bromo-4-methoxy-6-nonanoyl-2-pyrone, **3**, 16 mg, 83%, which was recrystallized from 95% ethanol, mp 78–80°C (lit. (2) mp 79–80°C); ir (KBr): 2949, 2920, 2846, 1733, 1699, 1620, 1510, 1459, 1380, 1305, 1230, 1078, 982, 939, 738 $cm^{-1}$; $^1$Hmr δ: 7.03 (1H, s), 4.07 (3H, s), 2.93 (2H, t, $J$ = 6.5 Hz), 2.0–1.1 (12H, m), 0.88 (3H, br t); ms *m/e* (relative intensity): 346 ($M^+$, 8.5), 344 ($M^+$, 9), 318 (2), 316 (2), 265 (5), 249 (5), 248 (15), 247 (6), 246 (15), 237 (13), 206 (10), 205 (99), 204 (10), 203 (100), 149 (17), 125 (40), 124 (11), 69 (7), 57 (7), 55 (7), 43 (8), and 41 (6).

# Réactivité des *N*-vinylaziridines fonctionnalisées. Synthèse de dérivés des α,β-déhydro α-amino acides

YVONNE GELAS-MIALHE, EVELYNE TOURAUD ET ROGER VESSIERE[1]

*École Nationale Supérieure de Chimie, Université de Clermont-Ferrand, B.P. 45, 63170 Aubiere, France*

Reçu le 31 mars 1982

YVONNE GELAS-MIALHE, EVELYNE TOURAUD et ROGER VESSIERE. Can. J. Chem. **60**, 2830 (1982).

Les cyano-2 et éthoxycarbonyl-2 *N*-vinylaziridines sont préparées par action de cyano-2 et éthoxycarbonyl-2 aziridines *N*-non substituées sur des composés activés, acétyléniques ou éthyléniques β-chlorés. Leur isomérisation sous l'influence d'un agent nucléophile conduit dans la plupart des cas à des α,β-déhydro α-amino esters et nitriles provenant de l'attaque du nucléophile en C-3. Leur thermolyse provoque préférentiellement la rupture de la liaison carbone–carbone du cycle, avec formation des α-vinylamino esters et nitriles.

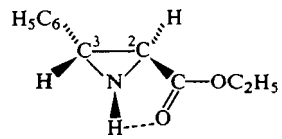
YVONNE GELAS-MIALHE, EVELYNE TOURAUD, and ROGER VESSIERE. Can. J. Chem. **60**, 2830 (1982).

Secondary 2-cyano- and 2-ethoxycarbonylaziridines react with acetylenic compounds and activated vinylic chlorides to give 2-cyano and 2-ethoxycarbonyl *N*-vinylaziridines. The nucleophile-catalysed isomerization of these compounds generally gives α,β-dehydro α-amino acid derivatives involving nucleophilic attack at C-3. Thermal isomerization, involving predominantly cleavage of the carbon–carbon bond of the ring, forms α-vinylamino esters and nitriles.

Les dérivés aziridiniques constituent les intermédiaires de synthèse d'une très grande variété de systèmes hétérocycliques (1). Ainsi les alkyl-2 ou aryl-2 oxazolines peuvent être obtenues par isomérisation thermique ou nucléophile de *N*-acylaziridines (2–8). Très peu de travaux ont été consacrés aux *N*-vinylaziridines bien que plusieurs méthodes de synthèse de ces composés soient décrites (9–30). Toutefois, plusieurs auteurs (15, 19, 23, 25, 26) ont examiné le comportement vis à vis d'agents nucléophiles de quelques *N*-vinylaziridines non fonctionnalisées sur le cycle; leurs résultats montrent que la réaction peut évoluer soit vers la formation d'un hétérocycle à cinq maillons (15, 19, 23, 25, 26) soit, plus rarement, vers l'obtention de produits d'ouverture du cycle aziridine (19*b*, 23).

Nous avons entrepris une étude plus générale de ces réactions d'isomérisation nucléophile en examinant en particulier le comportement des *N*-vinylaziridines fonctionnalisées, l'introduction d'une fonction activante étant en effet susceptible de modifier considérablement l'évolution des réactions. Nous avons également étudié l'isomérisation thermique de plusieurs composés dont nous avions examiné le réarrangement initié par un nucléophile.

Les *N*-vinylaziridines utilisées pour cette étude ont été préparées par action, sur des dérivés acétyléniques ou éthyléniques β-chlorés, de diverses aziridines secondaires fonctionnalisées (Tableau 1). Ces dernières ont été obtenues par action de l'ammoniac sur des esters, nitriles ou cétones α,β dibromés (Réaction de Cromwell (31), Schéma 1); plusieurs d'entre elles étaient connues et leur configuration,[2] notamment au niveau de l'atome d'azote, déterminée par rmn $^1$H (32, 33). Nous avons déduit la configuration relative des atomes de carbone C-2 et C-3 du cycle de la valeur de la constante de couplage $^3J_{H\text{-}2\text{—}H\text{-}3}$; la position de l'atome d'hydrogène lié à l'atome d'azote a été déterminée à partir de la valeur des couplages $^3J_{H\text{—}N\text{—}C\text{—}H\text{-}2}$ et $^3J_{H\text{—}N\text{—}C\text{—}H\text{-}3}$. Dans le cas du composé **6***S*R**, la mise en évidence du couplage $^3J_{H\text{—}C\text{—}N\text{—}H}$ (cf. partie expérimentale) montre que dans l'intervalle de température 20–60°C, la molécule possède la configuration pour laquelle l'hydrogène lié à l'atome d'azote et la fonction éthoxycarbonyle sont en position *cis*. Nous justifions la stabilité de cet invertomère, comme celle des dérivés **1** et **8** (32, 33), par l'existence d'une liaison hydrogène intramoléculaire:



**6***S*R**

Les spectres de rmn du composé **7***R*R** (cf. partie expérimentale) montrent que, entre 20 et 60°C, seul existe l'invertomère pour lequel les trois atomes d'hydrogène sont situés du même côté du plan du

[1]Auteur à qui toute correspondance doit être adressée.

[2]Les termes *S*R** et *R*R** définissent la configuration relative des atomes de carbone C-2 et C-3 du cycle aziridine; comme le montre le schéma, les atomes d'hydrogène liés aux atomes C-2 et C-3 du cycle sont en *trans* par rapport au plan du cycle dans le composé *S*R**; ils sont en *cis* dans le composé *R*R**. Les termes *E* et *Z* précisent la configuration de la double liaison.

SCHÉMA 1

cycle ce qui correspond à un encombrement minimum de la molécule.

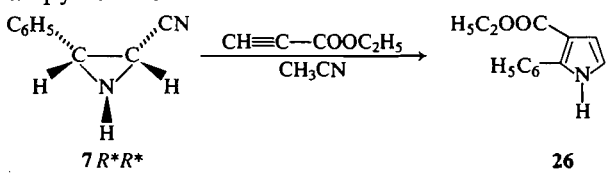
### Synthèse des *N*-vinylaziridines

Les *N*-vinylaziridines **9** à **25** ont été obtenues soit par addition nucléophile soit par substitution nucléophile des aziridines fonctionnalisées **1** à **8** sur des dérivés acétyléniques ou éthyléniques β-chlorés activés par un groupement électroattracteur Y′ (Schéma 1 et Tableau 1).

La stéréochimie[2] de tous ces composés a été établie d'après l'étude de leurs spectres de rmn $^1H$ (cf. partie expérimentale; Tableau 4). En particulier la position relative des substituants fixés sur les atomes de carbone C-2 et C-3 du cycle a été déduite du couplage vicinal $^3J_{H\text{-}2—H\text{-}3}$. Par ailleurs, lorsque R′ = H, la valeur de la constante de couplage $J_{H_{\alpha'}—H_{\beta'}}$ permet de déterminer la configuration de la double liaison. Lorsque R′ représente un groupement méthoxycarbonyle ou phényle, le déplacement chimique de l'atome d'hydrogène $H_{\alpha'}$ permet de préciser la stéréochimie de cette même double liaison.

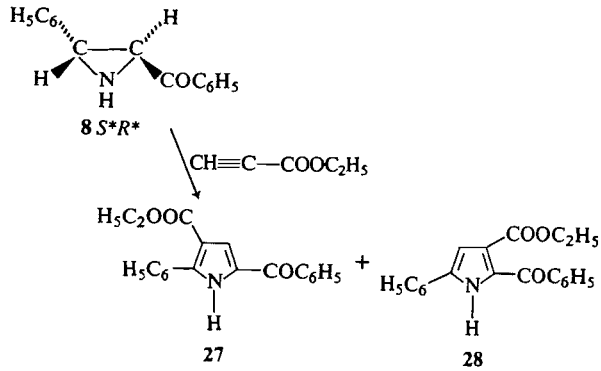
Les réactions d'addition ont été effectuées soit dans un solvant protique, l'éthanol, elles conduisent alors à un mélange des isomères *E* et *Z*, soit dans un solvant aprotique, elles sont alors très fortement stéréosélectives et correspondent à une *cis* addition de l'amine sur la triple liaison activée. Ces résultats sont en accord avec ceux de la littérature (10, 12, 14, 16).

La réaction de la phényl-3 cyano-2 aziridine **7** avec le propiolate d'éthyle ne conduit pas à une *N*-vinylaziridine; le seul produit isolé a été identifié au pyrrole **26**:



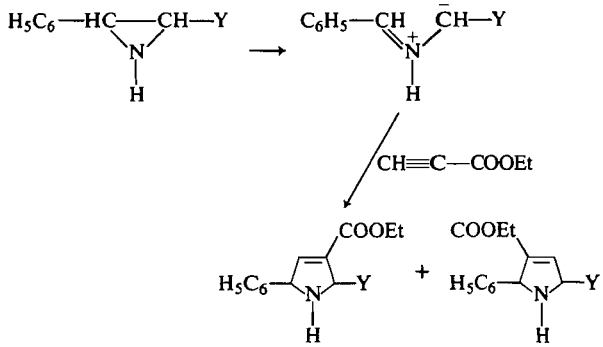
7 *R*R** 26

Il en est de même dans la réaction de la cétone **8** avec le propiolate d'éthyle (expérience No 39). Deux produits ont été isolés et identifiés aux pyrroles **27** et **28**:



27 28

Ces réactions dont un exemple est décrit dans la littérature (11) font intervenir la cycloaddition dipolaire d'un ylure d'azométhine sur l'acétylénique activé:



Les pyrrolines-3 ainsi formées conduisent aux pyrroles par déshydrogénation ou élimination de cyanure d'hydrogène.

### Isomérisation nucléophile des *N*-vinylaziridines

Les conditions dans lesquelles les réactions d'isomérisation ont été réalisées et la nature des

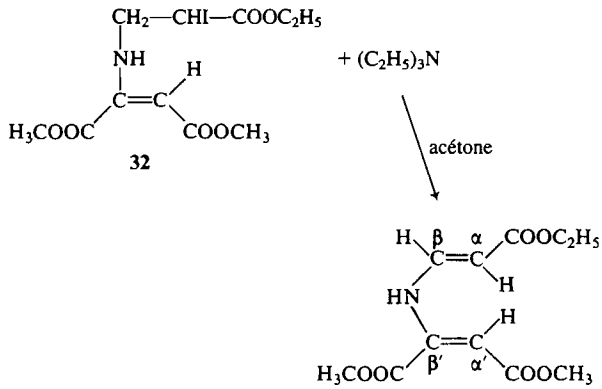
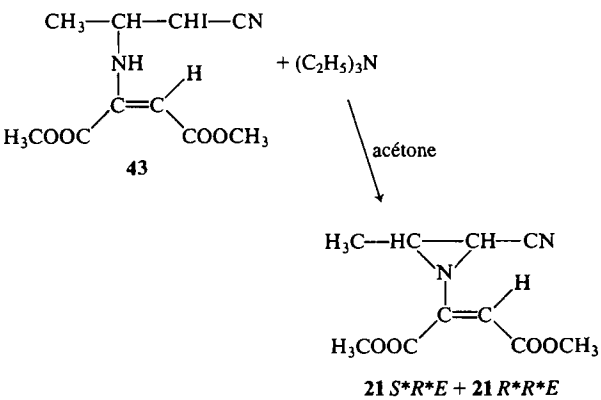
produits obtenus sont précisées dans le Tableau 2. Les composés ont été identifiés principalement par leurs spectres de rmn (cf. partie expérimentale). La structure du dérivé iodé **32** est confirmée par l'analyse élémentaire et par l'obtention, en présence de triéthylamine de l'ester α,β-insaturé β-aminé **44**:

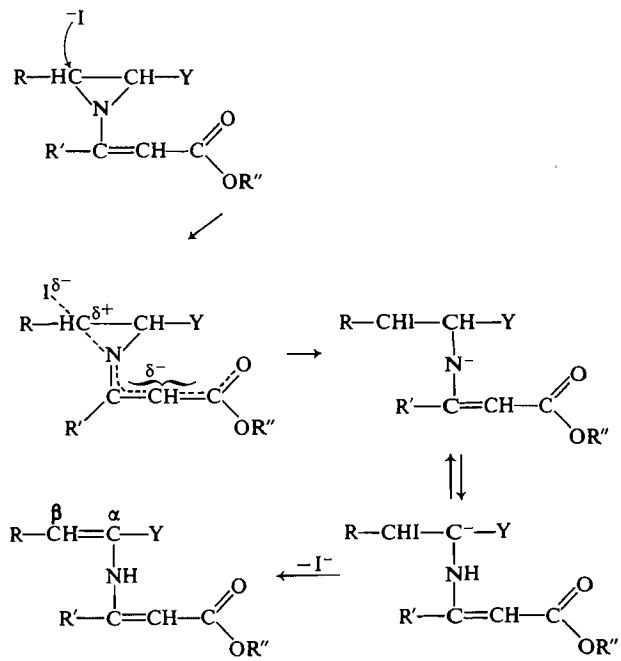


Le composé **43** traité par la triéthylamine en solution dans l'acétone conduit à l'aziridine **21** mélange des isomères *S*R** et *R*R** avec prépondérance de ce dernier:



Les résultats observés (Tableau 2) montrent que les vinylaziridines étudiées se réarrangent toujours en formant par ouverture de l'hétérocycle des produits dont la structure s'apparente à celle des divinylamines. La réactivité des aziridines non substituées en position 3 est supérieure à celle des méthyl-3 aziridines; la diméthyl-3,3 aziridine (expérience no 56) n'est pas isomérisée par l'iodure de sodium.

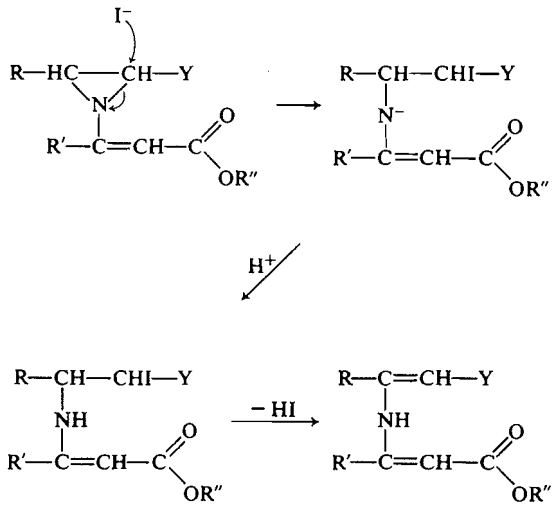
La réaction d'ouverture est généralement régiospécifique, l'attaque de l'ion iodure ayant lieu exclusivement sur l'atome de carbone C-3 (expériences no 40, 41, 46 à 54, 59). Cependant, pour trois aziridines, l'approche du nucléophile sur l'atome de carbone C-3 est compétitive avec une attaque sur l'atome de carbone C-2 porteur de la fonction activante (expériences no 42 à 45, 60). Enfin, dans le cas de la cyano-2 aziridine **14** (expériences no 57 et 58) la réaction est régiospécifique et correspond à une attaque du nucléophile sur l'atome de carbone substitué par la fonction nitrile. En l'absence de résultats cinétiques, il ne nous est pas possible de préciser si l'attaque du nucléophile en position 3 est un processus concerté (mécanisme $S_N2$) ou non concerté (mécanisme $S_N1$). Cette dernière éventualité nous semble cependant peu probable en raison du manque de réactivité de la diméthyl-3,3 aziridine **19** et de la plus faible réactivité des méthyl-3 aziridines par rapport aux composés non substitués en position 3. Un mécanisme "pseudo $S_N2$" faisant intervenir un état de transition à caractère de carbocation peut rendre compte de l'ensemble de nos résultats:



L'intermédiaire β-iodé perd facilement l'anion $I^-$ pour conduire aux dérivés α,β insaturés.

La formation des composés α-iodés β-aminés **32**, **34**, **40** et **43** implique une attaque de l'ion iodure sur l'atome de carbone porteur de la fonction activante. L'attaque ayant lieu sur l'atome de carbone dont le caractère électrophile est le plus marqué, cette réaction doit présenter un caractère $S_N2$ plus accentué que la précédente. L'intermédiaire formé lors de cette réaction étant peu apte à éliminer un ion iodure, sa protonation conduit alors aux composés α-iodés β-aminés:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.



L'élimination à partir du dérivé **40** d'une molécule d'iodure d'hydrogène conduit au β-énaminonitrile **39**.

Par ailleurs, l'examen des résultats du Tableau 2 (expériences no 43, 52, 53, 55, 56, 60) montre que parallèlement à l'ouverture nucléophile du cycle aziridine a lieu une réaction d'isomérisation de la double liaison de l'aziridine. À partir des aziridines **10***E*, **16***E*, **21***E* et **23***E* cette réaction conduit aux aziridines de configuration *Z* (expériences no 43, 52, 53, 55, et 60).

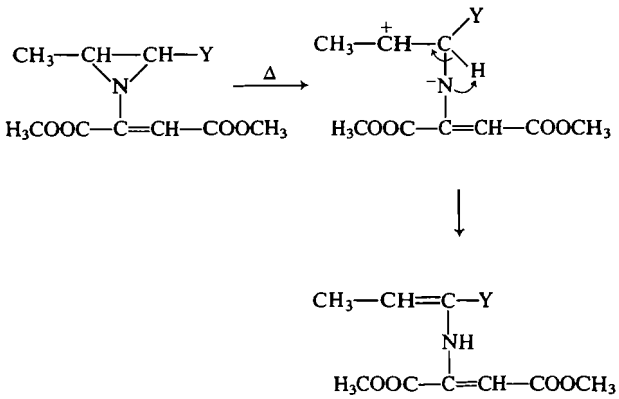
Chez les énamines obtenues, l'isomérisation des deux doubles liaisons intervient également, postérieurement à la formation de ces composés; en effet la double liaison $C_{\alpha'}=C_{\beta'}$ de l'énamine, lorsqu'elle est substituée par une seule fonction ester, adopte toujours la configuration *Z* (expériences no 41, 50, 51, 54, 59), elle prend par contre la configuration *E* lorsqu'elle est substituée par deux groupements méthoxycarbonyle (expériences no 42, 43, 44, 52, 53, 57, 58, 60) et cela, quelle que soit la configuration de la double liaison de l'aziridine. L'isomérisation de la double liaison $C_\alpha=C_\beta$ est mise en évidence par comparaison des expériences no 46 et 47; la quantité d'isomère **35***Z* augmente en effet avec le temps de réaction. L'étude de la configuration de la liaison $C_\alpha=C_\beta$ des énamines ne peut donc être utilisée pour préciser le mécanisme d'ouverture du cycle aziridine.

La plupart des réactions que nous avons étudiées ont été initiées par l'iodure de sodium. Nous avons constaté que la quantité de nucléophile utilisée ne modifie pas l'issue de la réaction, et ceci contrairement à certains résultats (7). Notre étude montre également que le remplacement de l'iodure de sodium par un iodure d'ammonium quaternaire ou par le thiocyanate de potassium ne provoque aucun changement dans l'évolution de la réaction (expériences no 47, 48, 49).

### Isomérisation thermique des *N*-vinylaziridines

Nous avons rassemblé dans le Tableau 3 les conditions expérimentales dans lesquelles ont été réalisées les isomérisations thermiques. Nous y précisons également la nature des produits identifiés.

La formation, à partir des aziridines **16** et **21** des ester et nitrile α,β-insaturés α-aminés **37** et **42** (expériences no 61 et 62) est comparable à l'obtention d'α-benzamido benzalacétophénones à partir de diaroyl-1,2 aziridines (2*e*). Cette réaction implique la rupture de la liaison C-3—N du cycle aziridine; l'hétérolyse de cette liaison est facilitée par la présence sur l'atome d'azote du groupement vinyle activé. L'intermédiaire dipolaire évolue ensuite par migration de proton:

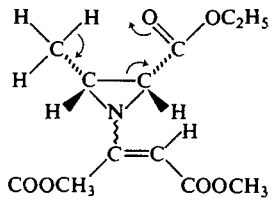


Y = $COOC_2H_5$, CN

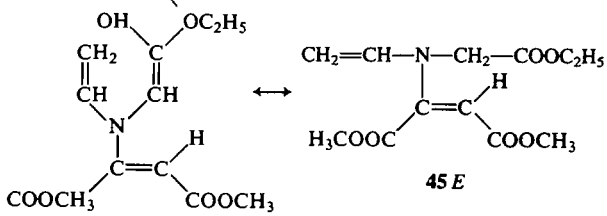
La formation, à côté des dérivés α-aminés α,β-insaturés **37** et **42** des composés α-aminés **45** et **46** montre que la rupture de la liaison C-3—N du cycle est en compétition avec celle de la liaison C-2—C-3, cette dernière étant d'ailleurs largement prépondérante. Deux mécanismes peuvent expliquer la formation de ces composés.

(a) *Mécanisme concerté – migration sigmatropique 1,5*

Ce mécanisme est analogue à celui proposé pour l'isomérisation thermique d'acyl-1 alkyl-2 cyclopropanes (34). Nous l'avons également proposé pour rendre compte de l'isomérisation en pyrroles de (*N*-méthylidenealkylamino)-2 aziridines (35). Il fait intervenir un transfert 1,5 d'hydrogène accompagnant la rupture de la liaison C-2—C-3 du cycle aziridine:



16 *R*R*E*

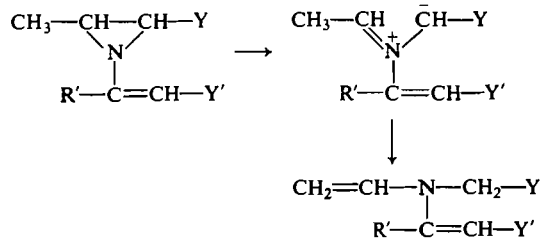


45 *E*

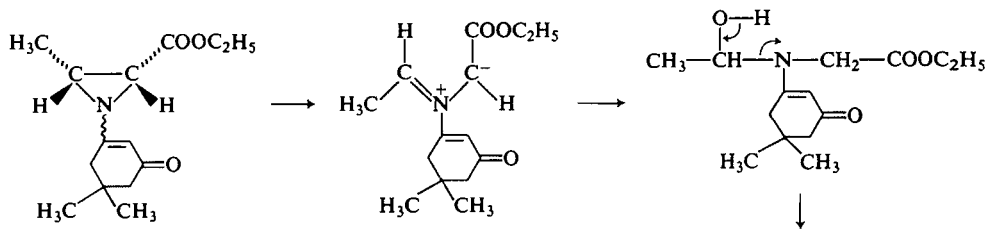
Ce mécanisme permet notamment de justifier le manque de réactivité du composé **21***S*R*Z* (expérience no 63).

(b) *Mécanisme ionique*

Un mécanisme de ce type a été proposé pour interpréter l'isomérisation des méthyl-3 benzoyl-2 alkyl-1 aziridines en pyrroles (36). Il met en jeu une ouverture conrotatoire de l'aziridine en ylure d'azométhine suivie d'une migration intramoléculaire de proton:



Dans la thermolyse de l'aziridine **18***R*R**, on note la formation, à côté du dérivé **47**, de l'aminoester **48** (expérience no 64). On peut penser, en accord avec d'autres auteurs (37–41) que l'ylure d'azométhine intermédiaire est hydrolysé en aminoalcool; ce dernier se décompose en acétaldéhyde et aminoester:



18 *R*R**

48

## Conclusion

Contrairement à ce que l'on pouvait attendre les *N*-vinylaziridines fonctionnalisées ne se réarrangent pas en hétérocycles à cinq atomes.

Leur isomérisation, sous l'influence de réactifs nucléophiles, en dérivés d'acides α-aminés α,β-insaturés constitue une très bonne méthode de préparation de ces composés auxquels il est souvent difficile d'accéder par d'autres voies (42–48). Ces dérivés font pourtant l'objet depuis quelques années d'un regain d'intérêt en raison notamment de la présence de tels enchaînements dans plusieurs antibiotiques polypeptidiques isolés du milieu de culture de microorganismes (42).

Par ailleurs, la plupart des produits d'isomérisation des *N*-vinylaziridines fonctionnalisées constituent des systèmes à 6 électrons π dont le réarrangement thermique ou photochimique que nous étudions actuellement doit conduire à des hétérocyclisations dignes d'intérêt.

## Partie expérimentale

Les spectres de résonance magnétique nucléaire ont été enregistrés à l'aide des appareils Perkin–Elmer R 24 et Varian T 60 pour $^1H$ et JEOL FX 60 pour $^{13}C$, en utilisant le tétraméthylsilane comme référence interne. Les déplacements chimiques sont exprimés en ppm et les constantes de couplage en Hz. Les spectres infrarouge ont été effectués sur un spectrophotomètre Perkin–Elmer 157. Les chromatographies sur colonne ont été

*Méthyl-3 éthoxycarbonyl-2 aziridine **3***

Obtenue sous forme d'un mélange des isomères *R*R**(70%) et *S*R**(30%): Rdt 54%; $Eb_{0,1}$ = 32–40°C (litt. (52) $Eb_{12}$ = 70–75°C); ir ($cm^{-1}$): 3335, 3225, 1745, 1730. Les deux isomères sont séparés par distillation sur colonne à bande tournante.

Isomère ***3R*R****: $Eb_{10}$ = 63°C; rmn $^1H$ ($CDCl_3$): 1,30 (t, $COOCH_2CH_3$, $J$ = 7,2), 4,25 (q, $COOCH_2$), 1,05 à 1,45 (m, N—H), 1,25 (d, $CH_3$, $J$ = 5,6), 2,30 (qd, H-3, $J$ = 5,6, $J$ = 5,8 (*cis*)), 2,61 (d, H-2, $J$ = 5,8); rmn $^{13}C$ ($CDCl_3$): 13,1 ($CH_3$), 33,6 (C-3), 34,9 (C-2).

Isomère ***3S*R****: $Eb_{10}$ = 53°C; rmn $^1H$ ($CDCl_3$): 1,35 (t, $COOCH_2CH_3$, $J$ = 7,2) 4,15 (q, $COOCH_2$), 1,25 (d, $CH_3$, $J$ = 5,2), 1,20 à 1,55 (m, N—H), 2,10 à 2,40 (m, 2H, H-2, H-3); rmn $^{13}C$ ($CDCl_3$): 18,1 ($CH_3$), 34,8 (C-2), 36,2 (C-3).

*Méthyl-3 cyano-2 aziridine **5***

Obtenue sous forme d'un mélange des isomères *S*R* (50%) et R*R* (50%) Rdt 52%; $Eb_{0,3}$* = 48–50°C; ir ($cm^{-1}$): 3250, 2210; rmn $^1H$ ($CDCl_3$): 1,25 (d, 1,5H, $J$ = 5,2), 1,35 (d, 1,5H, $J$ = 5,0), 1,58 (s large, N—H), 2,15 à 2,65 (m, H-2, H-3); rmn $^{13}C$ ($CDCl_3$): 17,9 ($CH_3$), 18,0 ($CH_3$), 21,2 (C-2), 21,5 (C-2), 31,3 (C-3), 34,6 (C-3), 118,9 (CN), 119,7 (CN).

*Aziridines **4**, **6** et **7***

À 100 mL de DMSO sec saturé d'ammoniac, on ajoute 0,02 mol de dérivé dibromé. Le mélange réactionnel est laissé sous agitation et sous pression pendant 60 h, puis versé dans de l'eau glacée. On extrait à l'éther; les phases étherées sont lavées à l'eau, séchées sur sulfate de magnésium et concentrées. Les produits obtenus sont alors purifiés par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 70:30).

*Diméthyl-3,3 éthoxycarbonyl-2 aziridine **4***

Préparée par Expert (53); rmn $^1H$ ($CDCl_3$): 1,30 (s, $(CH_3)_2$), 1,80 (s large, N—H), 2,50 (s, H-2); rmn $^{13}C$ ($CDCl_3$): 14,3–61,2–170,9 ($COOCH_2CH_3$), 18,9 ($CH_3$), 26,0 ($CH_3$), 39,7 (C-3), 42,2 (C-2).

*Phényl-3 éthoxycarbonyl-2 aziridine **6***

Le produit brut est un mélange des isomères *R*R** (50%) et *S*R** (50%) qui sont séparés par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 50:50).

Isomère ***6R*R****: Rdt 30%; $F$ = 63°C; ir ($cm^{-1}$): 3600, 1735; rmn $^1H$ ($CDCl_3$): 0,90 (t, $COOCH_2CH_3$, $J$ = 7,0), 3,86 (q, $COOCH_2$), 1,85 (s large, N—H), 2,82 (d, H-2, $J$ = 6,6 (*cis*)), 3,30 (d, H-3, $J$ = 6,6), 7,22 (s, $C_6H_5$); rmn $^{13}C$ ($CDCl_3$): 13,9–61,1–169,1 ($COOC_2H_5$), 37,2 (C-2), 39,9 (C-3), 127,5–128,1–128,4–130,0 ($C_6H_5$).

Isomère ***6S*R****: Rdt 40%; ir ($cm^{-1}$): 3225, 1730; rmn $^1H$ ($CDCl_3$): 1,90 (t large, N—H, $J$ = 7,8 (*trans*) et $J$ = 9,2 (*cis*)), 2,57 (dd, H-2, $J$ = 2,5 (*trans*) et $J$ = 7,8 (*trans*)), 3,25 (dd, H-3, $J$ = 2,5 (*trans*) et $J$ = 9,2 (*cis*)), 7,28 (s, $C_6H_5$), 1,27 (t, $COOCH_2CH_3$, $J$ = 7,0), 4,25 (q, $COOCH_2$); rmn $^{13}C$ ($CDCl_3$): 14,2–61,7–171,6 ($COOC_2H_5$), 39,5 (C-2), 40,3 (C-3), 126,2–127,7–128,4–137,9 ($C_6H_5$).

*Phényl-3 cyano-2 aziridine **7***

Obtenue sous forme d'un mélange des isomères *S*R** (50%) et *R*R** (50%) qui sont séparés par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 70:30).

Isomère ***7R*R****: Rdt 30%; $F$ = 102°C; ir ($cm^{-1}$): 3300, 2250; rmn $^1H$ ($CDCl_3$): 1,60 (t large, N—H, $J$ = 9,2 (*cis*) et $J$ = 9,4 (*cis*)), 2,80 (dd, H-2, $J$ = 6,0 (*cis*) et $J$ = 9,4 (*cis*)), 3,40 (dd, H-3, $J$ = 6,0 (*cis*) et $J$ = 9,2 (*cis*)); rmn $^{13}C$ ($CDCl_3$): 25,1 (C-2), 37,9 (C-3), 117,3 (CN), 126,9–127,9–128,5–134,0 ($C_6H_5$).

Isomère ***7S*R****: Rdt 30%; ir ($cm^{-1}$): 3280, 2230; rmn $^1H$ ($CDCl_3$): 1,82 (s large, N—H), 2,36 (s large, H-2), 3,51 (s large, H-3), 7,22 (s, $C_6H_5$); rmn $^{13}C$ ($CDCl_3$): 24,3 (C-2), 39,9 (C-3), 118,8 (CN), 125,9–128,5–129,8–135,7 ($C_6H_5$).

*Phényl-3 benzoyl-2 aziridine **8***

Préparée selon Weber et Bandlow (54). Rdt 79%; $F$ = 97–98°C (litt. (55) $F$ = 100–102°C); rmn $^1H$ ($CDCl_3$): 2,70 (t large, N—H), 3,20 (dd, H-2, $J$ = 2,4 (*trans*), $J$ = 8,8 (*cis*)), 3,50 (dd, H-3, $J$ = 2,4 (*trans*), $J$ = 6,8 (*trans*)), 7,20 à 7,80 (m, $C_6H_5$); rmn $^{13}C$ ($CDCl_3$): 43,5 (C-2), 44,1 (C-3), 126,4–128,1–128,5–128,7, 129,0–134,0–136,1–138,5 ($C_6H_5$), 196,0 (C=O).

*Synthèse des* N*-vinylaziridines*

*Préparation des dérivés **9**, **10**, **11**, **13** à **17**, **19** à **25***

À une solution de 0,02 mol d'aziridine dans 20 mL de solvant, agitée magnétiquement, on ajoute un équivalent de composé acétylénique. Le mélange réactionnel est chauffé à 40°C (DMSO) ou 60°C (éthanol ou acétonitrile), l'évolution de la réaction étant suivie par chromatographie sur couche mince. En fin de réaction, on évapore le solvant (éthanol ou acétonitrile) ou verse le mélange réactionnel dans une solution aqueuse saturée de NaCl, extrait à l'éther, lave à l'eau, sèche puis concentre (DMSO). Le produit brut est purifié par chromatographie sur colonne (éther de pétrole, acétate d'éthyle). Le pourcentage des isomères formés ainsi que les rendements de toutes les réactions sont précisés dans le Tableau 1. Les spectres de rmn $^1H$ et $^{13}C$ sont donnés dans les Tableaux 4 et 5.

*Préparation des dérivés* ***12*** *et* ***18***

À une solution de 0,02 mol d'aziridine dans 20 mL de solvant on ajoute 0,02 mol de diméthyl-5,5 chloro-3 cyclohexène-2 one et un équivalent de triéthylamine. Le mélange réactionnel maintenu sous agitation magnétique est chauffé à 50°C (DMSO) ou à reflux (éthanol) durant 48 h. Il est traité par une solution aqueuse de chlorure de sodium et extrait trois fois à l'éther. La phase organique est séchée sur sulfate de magnésium puis concentrée.

*Dérivé* ***12***: purifié par chromatographie sur colonne (acétate d'éthyle); ir ($cm^{-1}$): 1730, 1590; *Anal.* calc. pour $C_{13}H_{19}NO_3$: C 65,74, H 8,01, N 5,90, O 20,25; trouvé: C 65,58, H 8,06, N 5,90, O 20,84; rmn $^1H$ ($CDCl_3$): Tableau 4; rmn $^1H$ ($CDCl_3$): Tableau 5.

*Dérivé* ***18R*R****: purifié par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 50:50); ir ($cm^{-1}$): 1755, 1665, 1615; *Anal.* calc. pour $C_{14}H_{21}NO_3$: C 66,91, H 8,42, N 5,57, O 19,10; trouvé: C 66,98, H 8,41, N 5,62, O 18,90; rmn $^1H$ ($CDCl_3$): Tableau 4; rmn $^{13}C$ ($CDCl_3$): Tableau 5.

*Préparation du dérivé* ***26***

À 1,00 g (7 mmol) de phényl-3 cyano-2 aziridine en solution dans 10 mL d'acétonitrile sec, on ajoute 0,68 g (7 mmol) de propiolate d'éthyle. Le mélange réactionnel est porté à reflux durant trois jours. On évapore le solvant puis purifie par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 70:30). On isole le pyrrole **26**: ir ($cm^{-1}$): 3350, 1740, 1710; rmn $^1H$ ($CDCl_3$): 1,20 (t, $COOCH_2CH_3$, $J$ = 7,0), 4,12 (q, $COOCH_2$), 6,65 (spectre AB, 2H, $J$ = 3,2), 7,10 à 7,70 (m, $C_6H_5$), 9,0 (s large, N—H); rmn $^{13}C$ ($CDCl_3$): 14,2q–59,6t–165,2s ($COOC_2H_5$), 112,1d–117,8d (CH=), 128,0–128,4–128,6–129,0 (m, $C_6H_5$), 132,3s–137,0s (=C<).

*Obtention des dérivés* ***27*** *et* ***28***

À 0,01 mol de phényl-3 benzoyl-2 aziridine en solution dans 10 mL de DMSO, on ajoute 0,01 mol de propiolate d'éthyle. Le mélange réactionnel est chauffé à 30°C durant 36 h. On ajoute de l'eau et extrait au benzène. La phase organique est lavée à l'eau, séchée sur sulfate de magnésium et concentrée. On purifie par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 85:15). Deux produits sont isolés et identifiés aux pyrroles **27** et **28**.

Pyrrole **27**: $F$ = 166–167°C; rmn $^1H$ ($CDCl_3$): 1,15 (t, $COOCH_2CH_3$, $J$ = 7,0), 4,15 (q, $COOCH_2$), 7,00 à 8,00 (m, 11H); rmn $^{13}C$ ($CDCl_3$): 14,2q–60,1t–164,1s ($COOCH_2CH_3$), 114,7 (s, C=), 122,7 (d, CH=), 128,1–128,5–129,0–129,2–129,6–130,0–130,6–132,3 (m, $C_6H_5$), 137,5 (s, C=), 143,0 (s, C=), 185,1 (s, C=O).

Pyrrole **28**: rmn $^1H$ ($CDCl_3$): 1,21 (t, $COOCH_2CH_3$, $J$ = 7,0), 4,20 (q, $COOCH_2$), 7,20 à 7,80 (m, 11H); rmn $^{13}C$ ($CDCl_3$): 14,1–59,9–163,9 ($COOCH_2CH_3$), 188,1 (C=O), 117,0, 127,0, 127,4, 128,5, 128,9, 129,2, 129,7, 130,1, 131,2, 131,3, 133,5, 137,2.

*Isomérisation nucléophile des* N*-vinylaziridines*

À 1,00 g de *N*-vinylaziridine en solution dans 50 mL de diméthoxyéthane sec et fraichement distillé, on ajoute un équivalent d'iodure de sodium. Le mélange réactionnel, maintenu sous courant d'azote, est chauffé pendant un temps indiqué dans le Tableau 2. Aprés évaporation du solvant, le résidu est repris par 50 mL de chlorure de méthylène puis lavé à l'eau. Les extraits organiques sont séchés sur sulfate de magnésium puis concentrés. Le produit brut est analysé par rmn $^1H$; sa composition est donnée dans le Tableau 2.

*Isomérisation de l'aziridine* ***12***

Le dérivé **29** est purifié par chromatographie sur colonne (acétate d'éthyle): Rdt 43%; rmn $^1H$ ($CDCl_3$): Tableau 6.

*Isomérisation de l'aziridine* ***9***

Le dérivé **30***Z* est purifié par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 70:30): Rdt 30%; ir ($cm^{-1}$): 3190, 1745, 1650; rmn $^1H$ ($CDCl_3$): Tableau 6.

*Isomérisation de l'aziridine* ***10***

Les composés **10***Z*, **31***E* et **32***E* sont séparés par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 70:30).

**31***E*: Rdt 25%; ir ($cm^{-1}$): 3120, 1750, 1690, 1630; rmn $^1H$ ($CDCl_3$): Tableau 6; rmn $^{13}C$ ($CDCl_3$): Tableau 7.

**32***E*: Rdt 10%; ir ($cm^{-1}$): 3250, 1730, 1610: rmn $^1H$ ($CDCl_3$): 1,25 (t, $COOCH_2CH_3$, $J$ = 7,0), 4,20 (q, $COOCH_2$), 3,70 (m, $CH_2$—N), 3,65 (s, $COOCH_3$), 3,80 (s, $COOCH_3$), 4,50 (dd, CHI, $J$ = 6,0 et $J$ = 7,0), 5,25 (s, =CH), 8,60 (t, N—H, $J$ = 7,0); rmn $^{13}C$ ($CDCl_3$): 13,7q–62,1t ($OCH_2CH_3$), 50,9q ($OCH_3$), 52,8q ($OCH_3$), 163,7–170,0–170,2 (C=O), 19,3 (d, CHI), 49,0 (t, $CH_2$—N), 90,2 (d, =CH), 149,4 (s, N—C=); *Anal.* calc. pour $C_{11}H_{16}NO_6I$: I 32,99; trouvé: I 32,78.

*Synthèse du dérivé* ***44***

À 1 mmol de **32***E* en solution dans 5 mL d'acétone, on ajoute 3 équivalents de triéthylamine. Le mélange réactionnel est laissé à température ambiante durant 16 h. On évapore le solvant et on reprend au chlorure de méthylène. La phase organique est lavée à l'eau, séchée sur sulfate de magnésium puis concentrée. On purifie par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 70:30) et isole le dérivé **44**: Rdt 20%; rmn $^1H$ ($CDCl_3$): 1,25 (t, $COOCH_2CH_3$, $J$ = 7,0), 4,15 (q, $COOCH_2$), 3,75s–3,87s ($COOCH_3$), 5,35 (d, =CH—$COOC_2H_5$, $J$ = 13,0), 5,62 (s, =CH—$COOCH_3$), 8,02 (t, N—CH=, $J$ = 13,0), 10,06 (d, N—H, $J$ = 13,0); rmn $^{13}C$ ($CDCl_3$): 14,4–60,0 ($OC_2H_5$), 51,7–53,3 ($OCH_3$), 162,4–167,6–169,4 (C=O), 96,7 (=CH—$COOC_2H_5$), 99,9 (=CH—$COOCH_3$), 141,5 (N—CH=), 144,1 (N—C=).

*Isomérisation de l'aziridine* ***11***

Les dérivés **33** et **34** sont séparés par chromatographie sur plaques préparatives (éther de pétrole/acétate d'éthyle 85:15). **33**: Rdt 30%; rmn $^1H$ ($CDCl_3$): Tableau 6; rmn $^{13}C$ ($CDCl_3$): Tableau 7. **34**: rmn $^1H$ ($CDCl_3$): 1,30 (t, $COOCH_2CH_3$, $J$ = 7,0), 4,20 (q, $COOCH_2$), 3,65 (s, $COOCH_3$), 4,00 à 4,40 (m, 3H), 4,68 (s, =CH), 7,30 (s, $C_6H_5$), 8,65 (s large, N—H); rmn $^{13}C$ ($CDCl_3$): 13,7–62,1 ($OC_2H_5$), 50,4 ($OCH_3$), 169,9–170,1 (C=O), 19,0 (CHI), 48,5 ($CH_2$—N), 87,9 (=CH—$COOCH_3$), 163,2 (N—CH=).

*Isomérisation de l'aziridine* ***18***R*R*

Le dérivé **35**(*E*+*Z*) est purifié par chromatographie sur plaques préparatives (éther de pétrole/acétate d'éthyle 50:50): Rdt 30%; ir ($cm^{-1}$): 3220, 1725, 1590; rmn $^1H$ ($CDCl_3$): Tableau

6; rmn $^{13}C$ ($CDCl_3$): Tableau 7. Manipulation avec $[CH_3-(CH_2)_3]_4\overset{+}{N}, I^-$: on isole **35**: Rdt 40%. Manipulation avec KSCN: on isole **35***Z*: Rdt 15%.

*Isomérisation de l'aziridine **15***E

Le dérivé **36**(*EZ*+*ZZ*) est purifié par chromatographie sur colonne (hexane/éther 1:1+10% méthanol anhydre +10% acétate d'éthyle): Rdt 40%; rmn $^1H$ ($CDCl_3$): Tableau 6; rmn $^{13}C$ ($CDCl_3$): Tableau 7.

*Isomérisation de l'aziridine **16***

Les produits **16***R*R*Z*, **16***S*R*Z* et **37** sont séparés par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 85:15). **37**(*ZE*+*EE*): Rdt 40%; rmn $^1H$ ($CDCl_3$): Tableau 6; rmn $^{13}C$ ($CDCl_3$): Tableau 7.

*Isomérisation de l'aziridine **22***R*R*Z

Le dérivé **38***ZZ* est purifié par chromatographie sur plaques préparatives (éther de pétrole/acétate d'éthyle 85:15): Rdt 25%; rmn $^1H$ ($CDCl_3$): Tableau 6.

*Isomérisation de l'aziridine **23***S*R*E

Un mélange des isomères *S*R*E* et *S*R*Z* de l'aziridine **23** est isolé par chromatographie sur plaques préparatives (éther de pétrole/acétate d'éthyle 85:15): Rdt 53%.

*Isomérisation de l'aziridine **19***

Un mélange des isomères *E* et *Z* de l'aziridine **19** est isolé par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 70:30): Rdt 30%.

*Isomérisation de l'aziridine **14***E

Les composés **39** et **40** sont séparés par chromatographie sur plaques préparatives (éther de pétrole/acétate d'éthyle 70:30). **39**(*ZE*+*EE*): Rdt 15%; *F* = 84–85°C; ir ($cm^{-1}$): 3220, 3130, 2240, 1750, 1695, 1650; rmn $^1H$ ($CDCl_3$): 3,77s–3,80s–3,90s (6H, $COOCH_3$), 4,47 (d, 0,65H, *J* = 8,0), 4,81 (d, 0,35H, *J* = 13,0), 5,74s–5,79s (1H, =CH), 7,90 (d, 1H, *J* = 8,0), 7,98 (d, 1H, *J* = 13,0), 10,1 (s large, N—H); rmn $^{13}C$ ($CDCl_3$): 51,9–52,1–53,0–53,3–162,2–162,5–168,9–169,4 ($COOCH_3$), 73,4–76,7 (=CH—CN), 98,5–99,0 (=CH—$COOCH_3$), 141,8–142,5 (N—CH=), 144,5–145,5 (N—C=). **40**: rmn $^1H$ ($CDCl_3$): 3,76 (s, $COOCH_3$), 3,85 (s, $COOCH_3$), 3,80 (m, $CH_2$—N), 4,55 (dd, CHI, *J* = 6,5 et *J* = 7,6), 5,45 (s, =CH), 8,60 (t, N—H, *J* = 7,0).

*Isomérisation de l'aziridine **20***E

Le dérivé **41**(*ZZ*+*EZ*) est purifié par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 85:15): Rdt 34%. On isole: **41***ZZ*: *F* = 63°C; rmn $^1H$ ($CDCl_3$): Tableau 6; rmn $^{13}C$ ($CDCl_3$): Tableau 7. **41**(*ZZ*+*EZ*): *F* = 55–60°C; ir ($cm^{-1}$): 3160, 2210, 1670, 1625; rmn $^1H$ ($CDCl_3$): Tableau 6; rmn $^{13}C$ ($CDCl_3$): Tableau 7.

*Isomérisation de l'aziridine **21***E

L'aziridine **21***R*R*Z*, le dérivé **42** et le produit iodé **43** sont séparés par chromatographie sur plaques préparatives (éther de pétrole/acétate d'éthyle 70:30). **21***R*R*Z*: *F* = 82°C; rmn $^1H$ ($CDCl_3$): Tableau 4; rmn $^{13}C$ ($CDCl_3$): Tableau 5. **42**: rmn $^1H$ ($CDCl_3$): Tableau 6. **43**: Rdt 20%; ir ($cm^{-1}$): 3820, 2250, 1750,

1650, 1630; rmn $^1$H ($CDCl_3$): 1,45d–1,55d ($CH_3$), 3,72s–3,90s ($COOCH_3$), 3,80 (m, 1H), 4,70 (d, 1H, $J$ = 4,0), 8,20 (dd, N—H); *Anal.* calc. pour $C_{10}H_{13}N_2O_4I$: I 36,08; trouvé: I 35,98.

*Action de la triéthylamine sur le dérivé iodé* ***43***

Une solution de 1 mmol de **43** et de 3 mmol de triéthylamine dans 5 mL d'acétone est agitée pendant 24 h à température ambiante. Aprés évaporation du solvant sous vide, le résidu est purifié par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 85:15). On isole un mélange des isomères *S*R** et *R*R** de l'aziridine **21***E* identifiés par rmn $^1$H.

*Isomérisation thermique des* N*-vinylaziridines*

Un échantillon de 0,2 g de *N*-vinylaziridine pure est chauffé en tube scellé à une température et durant un temps indiqués dans le Tableau 3. Le produit brut est analysé par rmn $^1$H; sa composition est donnée dans le Tableau 3.

*Isomérisation de l'aziridine* ***16***R*R*E

Les composés **45***E*, **16***R*R*E* et **37***ZE* sont séparés par chromatographie sur colonne (benzène/acétate d'éthyle 85:15). **45***E*: Rdt 40%; rmn $^1$H ($CDCl_3$): 1,30 (t, $COOCH_2CH_3$, $J$ = 7,0), 4,23 (q, $COOCH_2$), 3,65s–3,92s ($COOCH_3$), 4,12 (s, N—$CH_2$), [4,40 (2H) et 6,45 (1H) spectre ABX, $CH_2$=CH)] 5,00 (s, =CH—$COOCH_3$); rmn $^{13}$C ($CDCl_3$): 14,1q–61,7t ($OC_2H_5$), 51,2q–53,1q ($OCH_3$), 167,2s–164,9s–166,8s (C=O), 48,4 (t, $CH_2$—N), 92,3 (d, =CH—$COOCH_3$), 94,3 (t, $CH_2$=), 134,5 (d, =CH—N), 150,8 (s, N—C=).

*Isomérisation de l'aziridine* ***21***

Le dérivé **46**, les isomères *S*R** et *R*R** de l'aziridine **21** et le dérivé **42** sont séparés par chromatographie sur colonne (éther de pétrole/acétate d'éthyle 85:15). **46***E*: Rdt 20%; $F$ = 105°C; rmn $^1$H ($CDCl_3$): 3,75s–3,98s ($COOCH_3$), 4,30 (s, N—$CH_2$), [4,50 (1H)–4,70 (1H)–6,38 (1H) (spectre ABX, $CH_2$=CH)], 5,18 (s, =CH—$COOCH_3$), rmn $^{13}$C ($CDCl_3$): 34,8 (t, $CH_2$—N), 51,6q–53,5q–164,2s–166,2s ($COOCH_3$), 95,4 (d, =CH—$COOCH_3$), 95,9 (t, $CH_2$=), 133,3 (d, =CH—N), 149,1 (s, N—C=). **42**: Rdt 10%.

*Isomérisation de l'aziridine* ***18***R*R*

Les dérivés **47** et **48** sont séparés par chromatographie sur colonne (acétate d'éthyle). **47**: Rdt 40%; ir ($cm^{-1}$): 1750, 1630, 1590; rmn $^1$H ($CDCl_3$): 1,12 (s, $(CH_3)_2$), 1,28 (t, $COOCH_2CH_3$, $J$ = 7,0), 4,25 (q, $COOCH_2$), 2,20 (s, 2H), 2,43 (s, 2H), 4,26 (s, N—$CH_2$), [4,30(1H)–4,50(1H)–6,80(1H) spectre ABX, $CH_2$=CH)], 5,30 (s, =CH); rmn $^{13}$C ($CDCl_3$): 14,2q–61,7t–167,7s ($COOC_2H_5$), 28,6 (q, $(CH_3)_2$), 33,2 (s, >C<), 40,8 (t, $CH_2$), 49,8 (t, $CH_2$), 47,9 (t, N—$CH_2$), 94,1 (t, $CH_2$=), 103,1 (d, =CH—CO), 134,2 (d, =CH—N), 159,2 (s, N—C=), 197,8 (s, C=O). **48**: Rdt 40%. $F$ = 85°C; ir ($cm^{-1}$): 3280, 1760, 1660, 1610; rmn $^1$H ($CDCl_3$): 1,10 (s, $(CH_3)_2$), 1,30 (t, $COOCH_2CH_3$, $J$ = 7,0), 4,25 (q, $COOCH_2$), 2,15 (s, $CH_2$), 2,30 (s, $CH_2$), 3,85 (d, N—$CH_2$, spectre AB), 6,10 (t large, N—H); rmn $^{13}$C ($CDCl_3$): 14,1–61,8–169,2 ($COOCH_2CH_3$), 28,3 ($(CH_3)_2$), 32,8 (>C<), 43,1 ($CH_2$), 44,3 (N—$CH_2$), 50,3 ($CH_2$), 96,5 (=CH), 162,4 (N—C=), 197,1 (C=O).

Received May 6, 1982

MIROSLAW CYGLER, MARIA PRZYBYLSKA, and RICHARD MACLEOD ELOFSON. Can. J. Chem. **60**, 2852 (1982).

Benzenediazonium tetrafluoroborate, $C_6H_5N_2^+ \cdot BF_4^-$, crystallizes in space group $P2_1/a$ with unit cell dimensions $a = 17.347(2)$, $b = 8.396(1)$, $c = 5.685(1)$ Å, $\beta = 92.14(1)°$, $Z = 4$. The structure was solved by direct phasing methods using the program SHELX 76. The parameters were refined by full-matrix least-squares to a final $R = 0.063$ for 1346 observed reflections. The bond lengths and angles agree very well with those of Rømming for benzenediazonium chloride. The C—N and N≡N bond lengths are 1.415(3) and 1.083(3) Å, respectively, and the bonds of the benzene ring do not show any significant differences as they vary from 1.371(5) to 1.383(4) Å. There are three N···F close contacts of ≤ 2.84 Å and the positive charge appears to be shared between the nitrogen atoms.

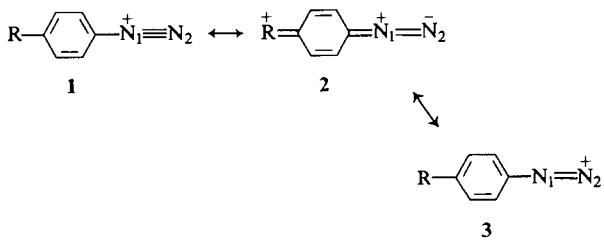
MIROSLAW CYGLER, MARIA PRZYBYLSKA et RICHARD MACLEOD ELOFSON. Can. J. Chem. **60**, 2852 (1982).

Le tétrafluoroborate de benzènediazonium $C_6H_5N_2^+ \cdot BF_4^-$ cristallise dans le groupe d'espace $P2_1/a$ avec des dimensions de maille de $a = 17,347(2)$, $b = 8,396(1)$, $c = 5,685(1)$ Å, $\beta = 92,14(1)°$, $Z = 4$. On a résolu la structure par la méthode de phase directe utilisant le programme SHELX 76. On a ajusté les paramètres par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de $R = 0,063$ pour 1346 réflexions observées. Les longueurs de liaison et les angles s'accordent bien avec ceux de Rømming relatifs au chlorure de benzènediazonium. Les longueurs de liaison C—N et N≡N sont respectivement de 1,415(3) et 1,083(3) Å et les liaisons du cycle benzène ne présentent aucune différence significative puisqu'elles varient de 1,371(5) à 1,383(4) Å. Il y a trois liaisons N···F très rapprochées ≤ 2,84 Å et la charge positive semble être partagée entre les atomes d'azote.

[Traduit par le journal]

## Introduction

The representation of aryl diazonium salts by resonance forms has concerned organic chemists for over one hundred years (1). Discussion has centred on the relative contributions of canonical structures **1**, **2**, and **3**.



**1** **2** **3**

The dominance of structure **1** for the ground state of benzenediazonium chloride was established by Rømming in 1963 (2, 3). His and subsequent X-ray investigations showed that the C(1)—N(1) bond length corresponds to that of a C—N single bond and N(1)—N(2) to a triple bond. Similar results were obtained for a number of substituted diazonium salts with complex anions. In *p*-benzenebisdiazonium tetrachlorozincate (4) in addition to N≡N and N—C bonds of 1.09(1) and 1.42(1) Å, respectively, there is an appreciable deviation from hexagonal symmetry of the benzene ring showing the "antiquinoid" geometry. There is therefore no evidence in these structures for the contribution of **2**.

Nevertheless Hammett correlations of certain other parameters such as infrared stretching frequencies (5) and redox properties (6) have continued to use $\sigma^+$ constants rather than $\sigma^p$ constants to obtain good results. These procedures suggested that contributions from the form **2** were important to describe the properties of these compounds.

In the original study of Rømming the interaction of the chlorine ion with hydrogen of the aromatic ring was indicated by the short H(2)...Cl distance of only 2.5 Å, one half of an Ångstrom unit less than the sum of the van der Waals radii of these atoms. Also in our laboratory the polarographic half-wave reduction potential of the aryl diazonium chlorides has been found to be up to 500 mV more negative than that of the tetrafluoroborate, which we interpret as evidence of complex formation (7). Since such an interaction could conceivably have altered some structural parameters it was decided to carry out X-ray analyses of some aryl diazonium tetrafluoroborate salts including *p*-diethylamino benzenediazonium tetrafluoroborate as the low accur-

acy study of a related compound (8) gave longer N—N and N—C bond lengths than expected.

## Experimental

Crystal data are as follows:

$C_6H_5N_2^+ \cdot BF_4^-$ fw = 191.9

Monoclinic, $P2_1/a$, $a$ = 17.347(2), $b$ = 8.396(1), $c$ = 5.685(1) Å, $\beta$ = 92.14°(1), $V$ = 827.4 Å$^3$, $Z$ = 4, $D_x$ = 1.54, $D_m$ = 1.53 g cm$^{-3}$ (by flotation in toluene and $CCl_4$ mixture). $F(000)$ = 384, $\mu$ (Cu K$\bar{\alpha}$) = 14.6 cm$^{-1}$.

The data were collected at room temperature with the Nonius CAD-4 procedures. Three prisms, crystallised from acetonitrile, had to be used as they deteriorated on exposure to light and X-rays. Two of them were almost spherical with diameters varying from 0.32 to 0.37 mm and the third one was 0.24 × 0.27 × 0.34 mm. Reflections in the range $1° < \theta \leq 75°$ were measured using the $\omega$–2$\theta$ technique for $\Delta\omega = (1.20 + 0.15 \tan\theta)°$, with a maximum scan time of 150 s. Two reflections were used as intensity monitors every 100 min of exposure time. Their intensities changed slowly during the first 20 to 30 h of exposure to X-rays and much more rapidly on further irradiation of the crystal. Only data collected in that first period were accepted. A decrease in intensity tolerated with each crystal did not exceed 4%.

The three sets of data were merged to produce 1757 unique reflections out of which 1346 (77%) were observed above threshold of $2\sigma(I_{net})$. The net intensities, after scaling, were corrected for Lorentz and polarization effects but not for absorption.

The atomic coordinates were found by direct methods and refined by full-matrix minimization of $\Sigma w(|F_o| - |F_c|)^2$ using the program system SHELX 76 (9).

The weighting function applied was

$$w = 16.64/(\sigma^2|F_o| + 0.00015\,|F_o|^2)$$

where $\sigma(|F_o|)$ is derived from counting statistics.

The H atoms were located on a difference map, carried out when $R$ was 0.09. The atomic scattering factors for C, N, B, and F were taken from International tables for X-ray crystallography (10) and those for H from Stewart, Davidson, and Simpson (11). Refinement with anisotropic thermal parameters for non-hydrogen atoms and isotropic for H atoms reduced $R$ to a final value of 0.063 ($R_w$ = 0.075) for the 1346 observed reflections. The final difference map showed distribution in the range −0.32 to 0.45 e Å$^{-3}$.

Some calculations were carried out with the NRC crystallographic computer programs by Ahmed, Hall, Pippy, and Huber (12).

Final positional and thermal parameters are presented in Table 1.[2]

## Discussion

The bond lengths and angles of both ions are shown in Fig. 1. The angle C(1)—N(1)—N(2) in the present structure is 179.5(3)° and the C—H bond lengths are in the range 0.89 to 1.01(4) Å.

The benzenediazonium ion has an approximate plane of symmetry passing through the N(2), N(1), C(1), and C(4) atoms as is indicated by the similarity of appropriate bonds and angles (see Fig. 1). Table 2 shows the comparison of the averaged geometry of the benzene ring in the present compound and in benzenediazonium chloride (3, 13), where the molecule was situated on a two-fold axis. The bond lengths and angles of the fluoroborate salt agree better with those from the more accurate analysis of benzenediazonium chloride, carried out at −160°C, with the exception of the three averaged bonds of the ring. However, the small differences shown by the bonds of the benzene ring in the tetrafluoroborate salt are not statistically signifi-

| C(6)—C(1)—C(2) | 126.0(2) | 124.8(6) | 126.1(2) |

*The averaged values for the symmetry related pairs.
†*a*, ref. 3, data collected at room temperature; *b*, ref. 13, investigation at −160°C.

cant and since they do not appear in the low temperature study of the chloride salt, they may not be real. In both compounds the C(1)···C(4) distance is shorter than in benzene.

The bond lengths and angles reported for benzenediazonium tribromide (14) are also very similar. However, they are not included in Table 2 as, having been derived by two-dimensional methods, they are less accurate.

The endocyclic torsion angles of the benzene ring vary from 0 to 2.1(0.5)° and the ring deviates significantly from planarity ($\chi^2 = 26.6$). The C(2) and C(6) atoms are at 0.010(3) and 0.008(3) Å, respectively, from the plane calculated for the six atoms of the ring, and C(1) with C(4) are on the opposite side with distances of −0.006(2) and −0.005(4) Å. The N(1) and N(2) atoms were found at −0.016(2) and −0.023(3) Å from the plane.

The packing of $BF_4^-$ ions surrounding the benzenediazonium cation is shown in the stereoscopic drawing by ORTEP (15) in Fig. 2. Each nitrogen atom makes four short contacts <3.1 Å with F of each of the four anions. These distances are listed in order of increasing values:

| Atoms | Distance (Å) | Atoms | Distance (Å) |
|---|---|---|---|
| N(1)···F(2) | 2.829(3)* | N(2)···F(1) | 2.841* |
| N(1)···F(3) | 2.837(4)* | N(2)···F(1) | 2.941(4)* |
| N(1)···F(1) | 2.912(3) | N(2)···F(3) | 3.005(4) |
| N(1)···F(1) | 2.996(3) | N(2)···F(2) | 3.056(3) |

The two shortest contacts of each group, marked by asterisks, are depicted in Fig. 2 by broken lines. They include the three contacts which are slightly shorter than the sum of van der Waals radii (2.85 Å).

The close approaches of F to both N atoms indicate that the electron density of the N(1)—N(2) triple bond may be displaced towards the N(1) atom resulting in sharing of the positive charge between the two nitrogen atoms. Similar observations were made concerning the structures of benzenediazonium chloride and benzenediazonium tribromide. It seems therefore that in addition to the main resonance form **1**, shown in "Introduction", the form **3** makes some contribution to the structure of the cation. There is no evidence of **2**.

In benzenediazonium chloride and tribromide derivatives the shortest of the halogen to nitrogen distances are those to the outer nitrogen N(2). In the present structure those to N(1) are the shortest. Since the small differences between N(1)···F and N(2)···F closest contacts depend not only on the charge distribution but also on the geometrical arrangement, it is not possible to derive on their basis which nitrogen is likely to have a greater

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

positive charge. It is interesting, however, that the N(1)···F closest approaches agree with the results of the CNDO/2 calculations carried out by Rømming (16) for the diazonium ion and for benzenediazonium surrounded by four negative fluorine ions, as the positive charges on N(1) turned out to be slightly higher (+0.31 and +0.33) than on N(2) (+0.18 and +0.25).

The N···F distances can be correlated with the differences in the B—F bond lengths. Since F(2) makes the closest approach to N of 2.829 Å and F(1) has four close contacts, B—F(2) and B—F(1) are expected to be the longest. They are 1.381(4) and 1.377(4) Å respectively, vs. 1.352(4) Å for B—F(3). F(4)···N(2) is appreciably longer (3.384(4) Å) and accordingly B—F(4) is the shortest of the four bonds (1.341(4) Å).

The closest F···H approaches are F(2)···H(2) = 2.38(3) Å and F(2)···H(3) = 2.42(3) Å. They are slightly shorter than the sum of van der Waals radii of 2.55 Å and they indicate that very weak C—H···F hydrogen bonds may be present. C(2)—H(2) and C(3)—H(3) are 1.01(3) and 1.00(4) Å, respectively, C(2)—H(2)···F(2) = 174.1(2.7)° and C(3)—H(3)···F(2) = 133.6(2.6)°. Since the redox potential of benzenediazonium tetrafluoroborate is normal and virtually identical to that of the perchlorate salt, it must be assumed that the bond lengths of the benzene ring are unaffected by the weak H···F interactions. Even the much stronger H(2)···Cl interactions in benzenediazonium chloride do not seem to have any such effect.

JIN-GOU XU and GERALD B. PORTER. Can. J. Chem. **60**, 2856 (1982).

$Ru(bpy)_3^{2+}$ is photodecomposed in 0.3 *M* NaOH with $\phi = 3.3 \times 10^{-4}$. With methyl viologen also present, electron transfer quenching of the luminescence is accompanied by formation of the one electron reduction product of methyl viologen, $MV^+$. The $Ru(bpy)_3^{3+}$ formed in the corresponding oxidation is rapidly reduced by either $OH^-$ or $MV^+$ to Ru(II).

JIN-GOU XU et GERALD B. PORTER. Can. J. Chem. **60**, 2856 (1982).

Le $Ru(bpy)_3^{2+}$ se décompose photochimiquement dans une solution à 0,3 *M* de NaOH avec $\phi = 3{,}3 \times 10^{-4}$. En présence de viologène de méthyle, l'arrêt de la luminescence par transfert d'électron s'accompagne de la formation d'un produit de réduction à un électron du viologène de méthyle, $MV^+$. Le $Ru(bpy)_3^{3+}$ qui se forme lors de l'oxydation correspondante est rapidement réduit soit par $OH^-$ ou $MV^+$ en Ru(II).

[Traduit par le journal]

There are a number of reports (1–7) on the photodecomposition of solutions containing the complex ion tris(bipyridyl)ruthenium(II), $Ru(bpy)_3^{2+}$, especially in non-aqueous solvents (2, 3, 6, 7). It is stable to light in acetonitrile (8) and at room temperature in 0.1 *M* HCl (1, 2). Decomposition yields are generally small except that, in chlorinated non-polar solvents, Gleria, Minto, Beggiato, and Bortolus (3) found a value of ca. 0.2. The product of photodecomposition is generally a disubstituted derivative, with one bipyridine ligand replaced by two acido ligands, two solvent molecules, or one of each. Watts, Harrington, and Van Houten (5) give evidence for a one-ended bipyridine; however, Durham *et al.* (8) state that it is only an unstable intermediate which reacts in minutes to produce the stable bis complex. In aqueous solution, $Ru(bpy)_3^{2+}$ photodecomposes, with small quantum yield only at pH ≃ 0 at room temperature or in less acid solutions at 60°C.

Okura, Kim-Thuan, and Takeuchi (9) recently described the sensitized photoreduction of methyl viologen (1,1′-dimethyl-4,4′-bipyridinium dichloride) or $MV^{2+}(Cl^-)_2$ by $Ru(bpy)_3^{2+}$ in an anaerobic 0.3 *M* NaOH solution. They established that back reaction of the reduced form of $MV^{2+}$ with the oxidized Ru(III) complex competes with reduction of Ru(III) by hydroxide. Thus, the concentration of the reduced form, $MV^+$, builds up in solution, as evidenced by the blue colour. Okura *et al.* (9) reported that $Ru(bpy)_3^{2+}$ is not used up and that $MV^{2+}$ is slowly regenerated in the dark.

We report here several further aspects of this interesting reaction.

## Experimental

$Ru(bpy)_3Cl_2 \cdot 6H_2O$ was purified by recrystallization from distilled water. Other chemicals were reagent grade and were used without further purification. Lifetimes and quantum yields were measured by techniques we have previously described (10), using a nitrogen laser/detector combination and ferrioxalate actinometry, respectively. Solutions were deoxygenated prior to irradiation by bubbling argon through for 20 min in a Zwickel flask (10). For some experiments, to ensure that air was not leaking into the cuvette, it was placed in a box through which nitrogen was flowed.

The concentrations of $Ru(bpy)_3^{2+}$ and $MV^+$ were monitored at 453 and 620 nm, respectively, in a Cary 11 Spectrophotometer, with intermittent irradiation at 436 nm from a 100 W PEK mercury lamp. The incident intensity was ca. $5 \times 10^{15}$ quanta $s^{-1}$. In experiments using nitrogen flushing around the cuvette, the concentration of $MV^+$ was measured continuously by absorption at 620 nm in situ, with a quartz halogen lamp, a double monochromator, and a photomultiplier. The resulting signal of % transmission was recorded as a function of time.

## Results

The lifetime of the emitting state of $Ru(bpy)_3^{2+}$ was found to be independent of pH in deoxygenated solution: 640 ns in 0.3 *M* NaOH solution versus 650 ns in neutral aqueous solution. Continuous irradiation in deoxygenated 0.3 *M* NaOH results in a small decrease in the maximum absorbance of $Ru(bpy)_3^{2+}$ at 453 nm. The quantum yield for disappearance of the substrate is $3.3 \times 10^{-4}$. Although we have not characterized the product of this reaction, we do not find a spectrum of $Ru(bpy)_2(OH)_2$, of $Ru(bpy)_2(H_2O)_2^{2+}$, or of $Ru(bpy)_2(OH)H_2O^+$ after irradiation (11).

$MV^{2+}$ quenches the emitting state of $Ru(bpy)_3^{2+}$ in a near diffusion-controlled process. We find a linear Stern–Volmer relation between ln τ and $[MV^{2+}]$, with $k_q = 8.8 \times 10^8\ M^{-1}\ s^{-1}$, at $[Ru(bpy)_3^{2+}] = 5.0 \times 10^{-5}\ M$. In 0.3 *M* NaOH solution,

the quenching constant is $1.2 \times 10^9 M^{-1} s^{-1}$. Other data with neutral salts added to the solution show that this is just an ionic strength effect on the quenching constant for like-charged donor and acceptor.

On irradiation of a solution containing $1.3 \times 10^{-3} M$ $MV^{2+}$, which is sufficient to half-quench the emitting state of $Ru(bpy)_3^{2+}$, the reduced form of methyl viologen, $MV^+$, is formed with an initial quantum yield of 0.029. The quantum yield decreases gradually with extent of reaction as noted by Okura *et al.* (9). On extended exposure, the concentration of $MV^+$ reaches a constant value.

After irradiation in the dark, $[MV^+]$ decreases rapidly at first and then remains constant when the cell is flushed outside with nitrogen gas. The Zwickel flask technique for deoxygenation with argon leaves the cell with a ground glass joint, which is lightly greased, and two Teflon plug stopcocks. In this cell in air, $MV^+$ decays slowly in the dark, as found by Okura *et al.* (9). When the cell is protected from air leaking in, the initial decay amounts to about 5% of the $MV^+$ present in the solution after irradiation. Subsequent to this, $[MV^+]$ remains constant for more than a day. However, the concentration of $MV^+$ remaining does vary from one run to another, and is in the range of $1–2 \times 10^{-5} M$.

$Ru(bpy)_3^{2+}$ is photodecomposed in solution containing $MV^{2+}$ with approximately the same quantum yield as that in the absence of $MV^{2+}$.

Addition of air after irradiation bleaches the blue colour of $MV^+$ instantly. However, some residual absorption remains from other decomposition products, one of which is tentatively identified as the monomethyl derivative of $MV^{2+}$: 1-methyl-4-(pyridyl)pyridinium chloride (12).

When, in addition to $MV^{2+}$, EDTA is added to the solution ($10^{-3} M$ EDTA, $0.3 M$ NaOH, $5 \times 10^{-5} M$ $Ru(bpy)_3^{2+}$, and $1.3 \times 10^{-3} M$ $MV^{2+}$), the blue colour of $MV^+$ is developed much more rapidly. In the initial stages of the reaction, the quantum yield for formation of $MV^+$ is $0.42 \pm 0.10$. After irradiation is stopped, $[MV^+]$ remains constant unless air is admitted.

## Discussion

The lifetime data show that there is no major interaction of hydroxide to quench the MLCT emitting state of $Ru(bpy)_3^{2+}$. Nevertheless, there is a reaction that leads to a small amount of substrate decomposition. It occurs whether or not $MV^{2+}$ is present, but the quantum yield measurement in the presence of $MV^{2+}$ is subject to too large an uncertainty because of overlapping spectra to decide if the quantum yield decreases in proportion to the quenching of the emitting state.

The formation of $MV^+$ on irradiation of $Ru(bpy)_3^{2+}$ in the presence of $MV^{2+}$ at high pH can be interpreted by reactions [1] to [5]:

[1] $Ru(bpy)_3^{2+} + h\nu \rightarrow {}^*Ru(bpy)_3^{2+}(MLCT)$

[2] ${}^*Ru(bpy)_3^{2+} \rightarrow Ru(bpy)_3^{2+} (+ h\nu)$

[3] ${}^*Ru(bpy)_3^{2+} + MV^{2+} \rightarrow Ru(bpy)_3^{3+} + MV^+$

[4] $Ru(bpy)_3^{3+} + MV^+ \rightarrow Ru(bpy)_3^{2+} + MV^{2+}$

[5] $Ru(bpy)_3^{3+} + OH^- \rightarrow Ru(bpy)_3^{2+} + \ldots.$

Reactions [2] and [3] are well known (13) and account for the quenching of the phosphorescence by $MV^{2+}$. In acid solution, reaction [3] occurs so rapidly that no net reaction can be observed except for the transient absorption in flash photolysis experiments (13) due to $MV^+$ as well as the concomitant bleaching of the absorption of $Ru(bpy)_3^{2+}$ itself. The electron transfer process of reaction [3] seems to be the only bimolecular quenching mode of the emitting MLCT state; energy transfer to $MV^{2+}$ cannot occur as it has no low-lying electronic states available.

At high pH, reaction [4] competes favourably with reaction [3], at least in the initial stages of the irradiation before $MV^+$ builds up. Reaction [4] has been studied by Creutz and Sutin (14) using stopped-flow spectrophotometry. The Ru(II) complex is formed in a first order reaction with, in the pH range near 13:

$$k_{obs} = 148[OH^-] + 138[OH^-]^2 \ s^{-1}$$

at 25°C and $\mu = 1 M$

The reaction products are complex: aside from $Ru(bpy)_3^{2+}$, five other eluents are found in the reacted solution by ion exchange chromatography (14). Molecular oxygen is an important product at pH 10, but amounts to only 2% of the oxidized material at pH 13.6.

Analysis of this mechanism using steady-state concentrations for ${}^*Ru(bpy)_3^{2+}$ and $Ru(bpy)_3^{3+}$ gives:

$$[6] \quad \phi_{MV^+} = \left\{\frac{\alpha k_3[MV^{2+}]}{k_2 + k_3[MV^{2+}]}\right\} \times \left\{\frac{k_5[OH^-]}{k_4[MV^+] + k_5[OH^-]}\right\}$$

in which the second order term in $[OH^-]$ has been absorbed in $k_5$ for simplicity. The factor $\alpha$ is included to recognize the fact that the electron

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

transfer may have less than unit efficiency because of "primary recombination" (15), that is, back electron transfer before the donor and acceptor can diffuse apart more than ca. one molecular diameter. According to eq. [6], the quantum yield for $MV^+$ formation decreases as the amount of $MV^+$ increases in accord with the experimental data. With $[MV^+] \simeq 10^{-5}\ M$, and assuming that $k_4 = 1.2 \times 10^9\ M^{-1}\ s^{-1}$, equal to $k_2$, eq. [6] requires that the quantum yield be reduced to less than 1% of its initial value, again consistent with the data found. The initial value of $\phi_{MV^+}$ is 0.029; however, it is likely that the initial buildup of $[MV^+]$ is too fast for our slow response apparatus to follow. Indeed, if the initial quantum yield were appreciably higher than 0.029, inadvertent exposure to stray light would reduce the apparent initial yield.

In order to investigate this point, experiments with added EDTA were carried out. The reaction

[7] $Ru(bpy)_3^{3+} + EDTA \rightarrow Ru(bpy)_3^{2+} + ....$

must be added to the mechanism. Equation [6] becomes

$$[8]\quad \phi_{MV^+} = \left\{\frac{\alpha k_3[MV^{2+}]}{k_2 + k_3[MV^{2+}]}\right\} \times \left\{\frac{k_5[OH^-] + k_7[EDTA]}{k_4[MV^+] + k_5[OH^-] + k_7[EDTA]}\right\}$$

The initial quantum yield is 0.42. Assuming that $k_7$ is also diffusion controlled, eq. [8] indicates that $\phi_{MV^+}$ does not depend on $[MV^+]$, in agreement with experiment. The concentration of $MV^{2+}$ is such as to provide exactly 50% quenching of the emitting state, thus the first term in eq. [8] is $0.5\alpha$. It follows from this value and the experimental quantum yield that $\alpha$ is one, within experimental error, and that the quenching of the luminescence is entirely a result of the electron transfer of reaction [3], without back transfer.

In the experiment without added EDTA, the small apparent initial quantum yield for $MV^+$ formation of 0.029, if caused by a trace of $MV^+$, represents $[MV^+] = 6 \times 10^{-7}\ M$. This is near the lower limit of our detection.

In the post irradiation period, $[MV^+]$ decreases rapidly at first. We suggest that either dioxygen or some other oxidant formed in the reaction of $Ru(bpy)_3^{3+}$ with $OH^-$ in minor amount reacts with $MV^+$. Once this small amount of oxidizing material is consumed, $MV^+$ is stable. With EDTA present, Ru(III) is reduced only by EDTA, other oxidizing materials are not formed, and there is no initial decay of $MV^+$.

# Determination of low specific surface areas of minerals and oxides by gas–solid chromatography[1]

PETER R. TREMAINE,[2] ALFRED G. WIKJORD, AND JACQUES C. LEBLANC

*Atomic Energy of Canada Ltd., Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0*

Received January 15, 1982

PETER R. TREMAINE, ALFRED G. WIKJORD, and JACQUES C. LEBLANC. Can. J. Chem. **60**, 2859 (1982).

Gas–solid chromatography is shown to provide a method for measuring the specific surface area of non-porous particulate mineral or oxide samples in the range 0.005 to 0.5 $m^2 g^{-1}$ with precision as high as ±10%. Mesitylene is a convenient sorbate and was found to occupy an area of 71 ± 5 $Å^2$ per molecule on silicate surfaces, by calibration with glass particles having well defined surface geometries. The rather low values obtained for the *C* parameter, when fitting retention volume data to the BET equation, suggest that the area occupied by mesitylene may be affected by the surface on which it is adsorbed. Hydrocarbon contaminants are a major interference. No specialized instrumentation is required.

PETER R. TREMAINE, ALFRED G. WIKJORD et JACQUES C. LEBLANC. Can. J. Chem. **60**, 2859 (1982).

On montre que la chromatographie solide fournit une méthode de mesurer la surface spécifique de particules non poreuses d'échantillons de minéraux ou d'oxydes de l'ordre de 0,005 à 0,5 $m^2 g^{-1}$ avec une précision pouvant atteindre ±10%. Le mésitylène est un excellent produit de sorption et on a trouvé qu'il occupe une surface de 71 ± 5 $Å^2$ par molécule sur des surfaces de silice en utilisant comme référence les particules de verre ayant des surfaces géométriques bien définies. Les valeurs plutôt faibles obtenues pour le paramètre *C*, lorsqu'on insère les données du volume de rétention dans l'équation BET, suggèrent que l'aire occupée par le mésitylène peut être affectée par la surface sur laquelle il est absorbé. Les contaminants hydrocarbonés constituent la principale interférence. Aucun instrument spécial n'est requis.

[Traduit par le journal]

## Introduction

While instrumentation for determining powder surface areas in excess of 1 $m^2 g^{-1}$ is well developed, there remains a need for simple reliable techniques capable of measuring much lower specific areas. This need is particularly acute for experimentalists studying mineral dissolution kinetics (see, for example, ref. 1) and the sorption of radionuclides by rocks such as granite (2, 3) since particle diameters in excess of 10 μm, i.e. surface areas lower than 0.5 $m^2 g^{-1}$, are often required. Very low surface areas can be measured by static techniques using xenon adsorption (4) and by commercial flow systems using nitrogen or other rare gas adsorption with special cells (5, 6). These methods require dedicated, rather specialized equipment.

The use of inverse gas–solid chromatography (GSC) to measure sorption isotherms on non-porous materials is well established (7–9). The method is appealing because it is fast and uses conventional gas chromatographs, which are readily available. Briefly, the material to be studied is packed into a chromatographic column where it acts as the stationary phase. An organic "probe" molecule is then injected into the inert carrier gas stream. Under the correct conditions (10), the volume of carrier gas required to elute the injection from the column is related to the thermodynamic partition of the probe between the mobile and stationary phases. As a result, the adsorption isotherm can be calculated from the retention volumes and elution peak heights corresponding to injections of different sizes.

Inverse chromatography has been used to measure the surface areas of inorganic salts (11) and polymer fibers (8, 9, 12–14) using large probe molecules near room temperature. Thibault and co-workers (15) measured low specific surface areas of metals using methane as a probe molecule at liquid nitrogen temperatures. The purpose of our study was to investigate the practical lower limit of usefulness of the method when used for determining the surface areas of minerals and oxides, by measuring the sorption of the large organic molecules that are convenient to use near room temperature.

## Experimental methods

A Hewlett Packard 7620 A gas chromatograph equipped with flame ionization detectors and a sub-ambient temperature controller was used. The columns containing the mineral samples were prepared by simply pouring the sample into 0.6 or 1.2 cm id copper tubing, contained at one end by a Swagelok connection fitted with stainless steel mesh. Prior to use the tubing was washed with trichloroethylene and dried under vacuum. The coiled columns were mounted vertically in the chromatograph to minimize the risk of channelling. Temperature was controlled by the air bath of the chromatograph and monitored using calibrated chromel–alumel thermocouples

fixed to the column. Variations along the length of the column were less than 0.3°C. In order to minimize back pressure, the flowrate of the nitrogen carrier gas was maintained near the lower limit of the detector, about 32 $cm^3$ $min^{-1}$ at room temperature, and was determined by a bubble flow meter. Column backpressure was monitored using a mercury manometer.

Sorption isotherms were obtained by making a series of sorbate injections ranging in volume from 10 μL to less than 1 nL and correcting the volume for the pressure drop (8, 10). The carrier gas hold up time in the column was determined by injecting a small amount of methane with the sorbate. Corrected net retention volumes, $V_N$, and sorbate partial pressures, $p$, corresponding to the maxima of elution peaks of different sizes were plotted so that $q$, the surface concentration of adsorbate (mol $g^{-1}$) would be obtained as a function of $p$ by integrating the plot in the usual way (8–10, 12–14).

Glass spheres (Chromatographic Specialities) and glass fibers (Corning) were used to test the method because of their well defined geometries. Their geometric areas were estimated by averaging the diameters of at least 25 spheres or fibers, as measured from electron micrographs, and their surface roughness, defined as the ratio of the area accessible to the sorbate molecule to the geometric area, was assumed to be unity (4). Screened samples of sintered magnetite (1), 60/80 mesh, and fractured labradorite, 40/60 mesh, were used to test the method on more realistic mineral samples. Mesitylene (Polyscience Corp.) and *n*-decane (Aldrich Gold Label) were used as the sorbates without purification.

For comparison with the GSC results using mesitylene and decane, surface areas were also measured by nitrogen physisorption at −195°C using a Quantasorb surface area analyzer (Quantachrome Corp., Syosset, NY). The data were obtained by Particle Data Laboratories Ltd. (in Elmhurst, IL) and the surface areas were calculated from a 5 point BET plot. Immediately prior to measurement, samples were degassed at 110°C for 4 h in a $H_2$ stream of 20 $cm^3$ $min^{-1}$ which flowed through the Quantasorb cell. The reproducibility of the method was adversely affected by small desorption peaks and baseline disturbances due to thermal diffusion in the sample vessel (6).

## Results

Adsorption isotherms obtained from the chromatograph were plotted in the form $p/p_0$ vs. $(p/p_0)/[q(1 - p/p_0)]$, in order to fit the result to the Brunauer–Emmett–Teller expression (16)

$$[1] \quad \frac{p/p_0}{q(1 - p/p_0)} = \frac{1}{q_m C} + \left(\frac{C - 1}{q_m C}\right)\frac{p}{p_0}$$

Here $p_0$ is the vapour pressure of the decane or mesitylene sorbate, taken from the API tables (17), $q_m$ is the monolayer capacity which we wish to obtain, and $C$ is an adjustable parameter. Typical plots are shown in Fig. 1. Values of $q_m$ and $C$ were obtained by least-squares fits of data in the range $0.05 < p/p_0 < 0.35$ to straight lines, as shown in the figure. No evidence of non-linearity was observed in this range. The $C$ values for sorption on magnetite, labradorite, and a few of the glass samples ranged from 4 to 6, typical of hydrocarbon sorption on dry oxygen-rich organic surfaces (12–14) and slightly lower than those obtained for higher surface area minerals by sorption/desorption methods (18). Many of the glass samples yielded the low results ($C$ = 2 to 3) which are expected when organic molecules are adsorbed onto hydrated surfaces (19).

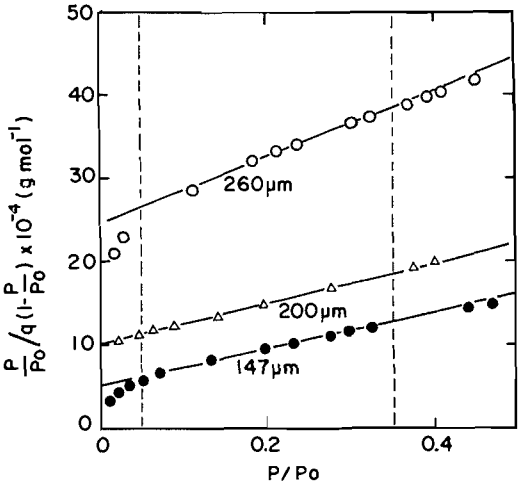

FIG. 1. Typical BET plots obtained from the adsorption of organic sorbates on 260 μm, 200 μm, and 147 μm diameter glass beads at 34.9, 25.2, and 64.7°C, respectively: △, mesitylene; ○, decane. Dashed lines show the limit of linearity assumed for the fit.

Since GSC is a dynamic method, it is important to ensure that the criteria for obtaining an equilibrium sorption isotherm from the peak maxima method are met (10). Sorption effects on the flow rate are minimal for these small injection volumes. The peak maxima throughout any set of injection volumes lay on a common envelope, although some peak rounding occurred, due to the very small retention volumes. Lowering the linear flow rate by increasing the column diameter from 0.6 to 1.2 cm did not affect the values obtained for the specific monolayer coverage within the precision of the data. Likewise, changing the temperature by ±20°C within the range −5 to 80°C and increasing the length of the column from 70 to 180 cm had no measurable effect. The area of the empty column, ≈ 0.03 $m^2$ for a column 70 cm long and 0.6 cm id, was routinely determined by the exact procedures outlined above for columns containing sample. The empty column area was subtracted from that obtained when the sample was present.

During the course of this work, two or three samples were inadvertently contaminated with traces of hydrocarbon from a compressed air line. These yielded anomalously high values of $q_m$ by comparison with duplicate, uncontaminated samples. The contaminants could be apparently removed by heating the column to 200°C, since this

TABLE 1. Comparison of specific surface areas by $N_2$ and mesitylene adsorption

| Sample | Specific surface area/$m^2\ g^{-1}$ | | |
|---|---|---|---|
| | $N_2$ (Quantasorb) | Mesitylene (GSC) | $N_2$ area / GSC area |
| Glass beads (200 μm) | 0.08† | 0.013±0.002 | 6 |
| Sintered magnetite | 0.17±0.10* | 0.033±0.004 | 5 ±2 |
| Labradorite fragments | 0.13±0.06* | 0.08 ±0.01 | 1.6±0.7 |

*Error limits are the spread between duplicate samples. The value reported is the mean.
†One sample only.

invariably produced a large irregular detector response, and subsequent measurements using the same column gave results in agreement with the uncontaminated samples.

The specific surface area of a sample can be calculated from $q_m$ if the area occupied by each mole of sorbate can be determined. We determined this by assuming that the glass bead and fiber samples had no roughness on the scale of the sorbate molecules so that the monolayer capacity could be considered to occupy an area equal to the geometric area of the surface (4). The calibration was done using sorption isotherms from the fiber samples since these had the largest specific surface areas, low back pressure and, hence, yielded the most precise monolayer capacities. The resulting area occupied per mesitylene molecule was 71 ± 5 Å². A comparison of several mesitylene and decane monolayer capacities from the same samples yielded the value 87 ± 5 Å² for decane. The correlation between geometric area and the areas measured using these values is shown in Fig. 2 for several samples of glass beads whose specific areas are much lower than the fiber samples. In all cases, GSC and geometric areas agree to within the statistical scatter.

Dorris and Gray (14) have pointed out that mesitylene is ideal for surface area measurements since it is a disk-like molecule with very limited conformational freedom. Indeed, our value of 71 Å²/molecule is very close to the value of 67 Å²/molecule which is obtained if the mesitylene monolayer can be described by close packed disks of radius 4.5 Å², consistent with the molecular dimensions of mesitylene lying flat. We believe this value is typical of the untreated silica surfaces studied here, but note that it may not be appropriate for other material since the cross sectional area occupied by organic molecules can be strongly affected by the surface on which they are adsorbed (18). For example, our value of 71 Å² is substantially larger than Dorris and Gray's result for mesitylene sorbed on cellulose, 51 Å²/molecule. Recent work by Lowell *et al.* (18) suggests that

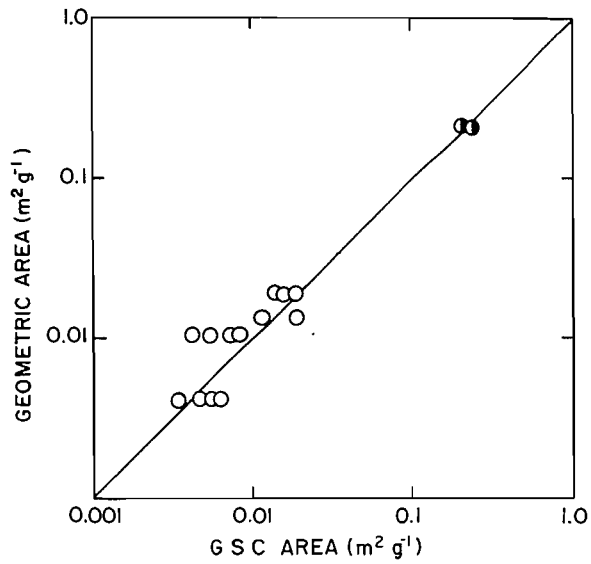

FIG. 2. Correlation between the measured geometric area and the GSC area calculated assuming 71 Å² for the area occupied by mesitylene. ○, glass beads; ◑, glass fibers.

changes in the cross sectional area of molecules on a given material, due to hydration, oxidation or some other change in the surface chemistry, would be accompanied by a marked change in the value of the *C* parameter.

As illustrated by Fig. 2, the precision of the method was about ±10% for specific surface areas above 0.01 $m^2\ g^{-1}$ and ±25% for lower specific areas, probably because the correction for the surface area of the column walls becomes substantial. The effective lower limit appears to be about 0.005 $m^2\ g^{-1}$, while the upper limit is imposed by the increasing column backpressures which accompany decreasing particle size; probably 0.5 $m^2\ g^{-1}$ is a reasonable upper limit for all but fiber samples.

Specific areas obtained by mesitylene adsorption near room temperature and $N_2$ adsorption at −195°C are compared in Table 1. The statistical scatter in the $N_2$ areas is much greater than the precision that can usually be obtained (6), possibly because of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

small desorption signals and thermal diffusion effects. Nevertheless, the values for all three samples are substantially larger than those from the GSC method using mesitylene as the sorbate. Some of the difference is undoubtedly due to the fact that nitrogen adsorption measures surface roughness on a scale (16 Å$^2$) much smaller than that for mesitylene (71 Å$^2$). Variations in the cross sectional area of the mesitylene between the different materials may also be a factor.

We conclude that gas–solid chromatography with mesitylene as a sorbate provides an accurate method for measuring the monolayer capacities of non-porous minerals whose specific areas lie in the range 0.005 to 0.5 $m^2 g^{-1}$, to a precision as high as $\pm 10\%$. These monolayer capacities provide an accurate measure of relative differences in the specific areas of samples of a given mineral on a scale of about 71 Å$^2$/molecule, providing the $C$ values lie within a narrow range. Absolute specific surface areas are less well defined because of uncertainties in the area occupied by the sorbate molecule. Trace hydrocarbons are the major interference. Because the method requires no specialized equipment and provides the necessary sensitivity, it is attractive as a research tool for characterizing batches of low surface area material to be used in subsequent experiments and for monitoring sample alterations caused by changes in parameters such as temperature or humidity, which can be made without removing the sample from the column. The technique is more time consuming (two or three samples per day) than commercial systems and requires reasonably large samples. These difficulties, coupled with the need to characterize the sorbate area for each mineral, limit its usefulness for more routine work.

# Synthèse stéréospecifique de nucléosides pyrimidiques par la méthode de Hilbert–Johnson[1]

CHRISTIAN H. GAGNIEU, ANNIE V. GROUILLER ET HENRI PACHECO

*Service de Chimie Biologique, Bât. 406, INSA, 20, av. Albert Einstein, 69621 Villeurbanne, France*

Reçu le 4 mars 1982

CHRISTIAN H. GAGNIEU, ANNIE V. GROUILLER et HENRI PACHECO. Can. J. Chem. **60**, 2863 (1982).

La condensation de la diméthoxy-2,4-pyrimidine avec les bromoglycosides dérivés des méthyl désoxy-4-pentopyranosides **2–7** et du méthyl tri-*O*-benzoyl-3,5,6-glucofuranose **20** conduit de façon stéréospécifique aux nucléosides **8–13** et **22** de configuration *trans* 1′,2′. La stéréochimie de cette réaction n'est pas influencée par la structure du sucre de départ mais est liée à la présence de l'hydroxyle en C-2. La synthèse de l'époxyde **18**, obtenue par action de NaH sur les bromhydrines **17** dérivées de **7** tend à confirmer l'hypothèse d'une réaction assistée par un intermédiaire de type époxydium à partir de la bromhydrine *trans*. Quant à la bromhydrine *cis*, elle serait soumise à la substitution directe de l'halogène anomérique par la base; l'hypothèse de la formation intermédiaire d'un ion carbonium a pu être écartée puisque les réactions de glycosylation de type $S_N1$ du composé **19** par MeOH ou t-BuOH conduisent de façon préférentielle à des composés de configuration *cis*.

CHRISTIAN H. GAGNIEU, ANNIE V. GROUILLER, and HENRI PACHECO. Can. J. Chem. **60**, 2863 (1982).

Condensation of 2,4-dimethoxy pyrimidine with bromoglucosides derived from methyl 4-deoxypentopyranosides **2–7** and from 3,5,6-tri-*O*-benzoyl glucofuranose, **20**, leads in a stereospecific manner to the nucleosides **8–13** and **22** with the *trans* 1′,2′ configuration. The stereochemistry of this reaction is not influenced by the structure of the starting sugar but rather is directed by the presence of the C-2 hydroxyl group. The synthesis of epoxide **18**, obtained by the action of NaH on the bromohydrine **17**, derived from **7**, supports the intervention of a reaction assisted by an epoxide-like intermediate derived from the *trans*-bromohydrine. On the other hand, the *cis*-bromohydrine undergoes direct substitution of anomeric halogen by base. The possibility of the formation of a carbocation-like intermediate is discounted since $S_N1$ type glycosylation reactions of **19** by MeOH or *t*-BuOH lead preferentially to products with the *cis*-configuration.

## Introduction

La synthèse de nucléosides pyrimidiques par la méthode de Hilbert–Johnson (1) utilisant les dialkoxy-2,4-pyrimidines peut être réalisée dans de bonnes conditions à partir d'halogénosucres possédant un hydroxyle libre; en effet, nous avons montré dans un précédent travail qu'une telle réaction pouvait être appliquée à des bromures de désoxy-4-pentopyranosides non protégés en C-3 et substitués en C-2 par des groupements *O*-alkyle ou *O*-acyle (2). Les résultats classiques obtenus au niveau de la stéréospécificité de cette réaction, qui se traduisent par la formation de nucléosides *trans* lorsqu' un groupement participant est présent en C-2 (3) et par l'obtention majoritaire de nucléosides *cis* lorsque ce groupement est non participant (4), nous ont permis de conclure que la stéréochimie de la réaction de glycosylation n'est que peu influencée par la fonction hydroxyle lorsque celle-ci est placée en β de l'halogène anomérique. Il est concevable qu'une telle fonction puisse jouer un rôle plus important dans la synthèse si elle est placée en α de l'halogène, en raison des possibilités de participation directe à la réaction de glycosylation. Quelques rares synthèses de nucléosides à partir d'halogénosucres présentant un hydroxyle libre en C-2 ont été rapportées (5, 6). Ces réactions qui concernaient des bases non naturelles telles que le diméthyl-5,6-benzimidazole ou des alkylpyridines conduisaient de façon prépondérante à des nucléosides *trans* 1′,2′. Il semblait intéressant de rechercher si une telle stéréospécificité pouvait être obtenue avec les méthodes classiques de synthèse des nucléosides (7), appliquées à des bromhydrines anomériques. La méthode de Hilbert–Johnson, avec laquelle l'obtention directe de nucléosides pyrimidiques non totalement protégés est aisée, a été choisie pour réaliser cette étude.

Dans le présent article nous rapportons les résultats obtenus lors de la condensation de la diméthoxy-2,4-pyrimidine (DMP) avec les bromhydrines dérivées des méthylglycosides **2–7**, ainsi que les travaux réalisés pour déterminer la nature de l'influence de l'hydroxyle libre sur la stéréochimie de la réaction.

## Résultats et discussion

Les substituants au niveau du C-3 des méthylglycosides **2–7** (Fig. 1) ont été choisis en fonction de leur nature chimique et de leur encombrement stérique de façon à évaluer, le cas échéant, leur influence sur la réaction de condensation. Les

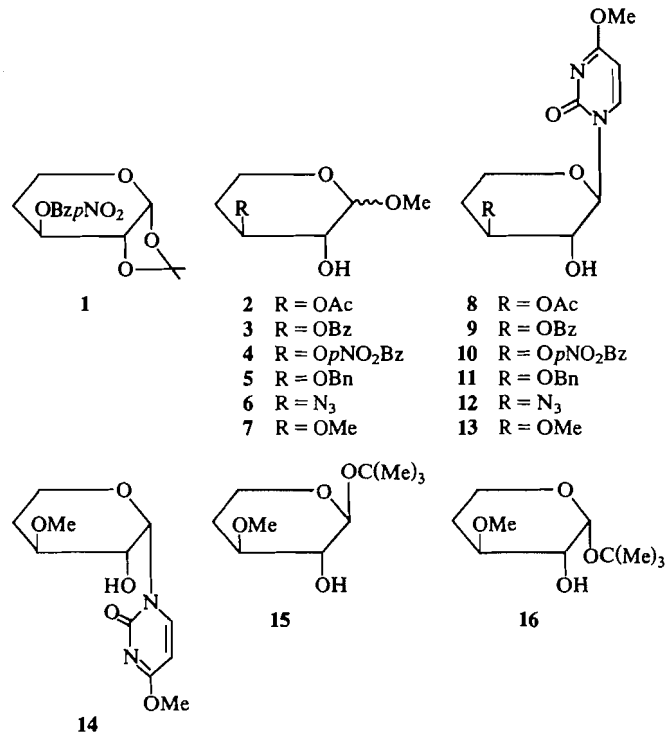

FIG. 1

dérivés acétylé, benzoylé et benzylé **2**, **3** et **5** ont été décrits dans un précédent article (2); le composé **6** présentant un groupement azide en C-3 est également connu (8).

La préparation du méthyl désoxy-4-*O*-*p*-nitrobenzoyl-3-α et β-DL-*thréo*-pentopyranoside **4**[2] a été réalisée par la méthanolyse en milieu acide du désoxy-4-*O*-isopropylidène-1,2-*O*-*p*-nitrobenzoyl-3-β-DL-*thréo*-pentopyranose **1** obtenu par action du chlorure de *p*-nitrobenzoyle en présence de pyridine sur le désoxy-4-*O*-isopropylidène-1,2-β-DL-*thréo*-pentopyranose (9). Le composé **4** a été obtenu sous forme d'un mélange des isomères α et β dans le rapport 4:1. Les méthyl désoxy-4-*O*-méthyl-3-α et β-DL-*thréo*-pentopyranosides **7** ont été obtenus séparément par action d'un excès de méthylate de sodium en solution méthanolique sur les méthyl anhydro-2,3-désoxy-4-α ou β-DL-*érythro*-pentopyranoses (10). L'ouverture de l'époxyde β est régiosélective et conduit exclusivement au composé 7α tandis que l'ouverture de l'époxyde α conduit à un mélange du composé 7β et d'un produit méthylé en C-2 et hydroxylé en C-3, dans le rapport 10:1.

La synthèse des bromoglycosides à partir des composés **2**–**7** s'est révélée aussi délicate que pour les sucres hydroxylés en C-3; le même procédé de bromuration a été utilisé mais pour les produits **5** et **6** la réaction a dû être réalisée à plus basse température (−15°C) pour limiter la débenzylation dans le cas du composé **5** et la dégradation du groupement azide pour le composé **6**. Les réactions de condensation de la DMP avec les bromhydrines obtenues ont été réalisées dans les conditions décrites pour la synthèse des nucléosides hydroxylés en C-3 (2). Les nucléosides sont obtenus très rapidement avec de bons rendements (69–85%).

À partir des méthylglycosides **2**–**6**, seuls les nucléosides de configuration *trans* 1′,2′ **8**–**12** ont été obtenus; la stéréospécificité de la réaction est ici absolue, mais dans le cas du composé méthylé **7**, des traces du nucléoside **14** de configuration *cis* 1′,2′ ont pu être détectées et isolées à côté de l'isomère *trans* **13**. La quantité de nucléoside **14** est très faible et ne représente que 4,5% de la masse totale de nucléoside méthylé obtenue. Ces résultats montrent que la nature et l'encombrement stérique des substituants en C-3 n'ont que peu d'influence sur la stéréochimie de la réaction.

Les différents mécanismes réactionnels susceptibles de conduire à des nucléosides à partir d'halohydrines ont été proposés par Freyne *et al.* (6) et sont similaires à ceux rapportés dans la figure 2.

[2]Les composés **1**–**19** sont racémiques, mais un seul énantiomère (L) est représenté dans les figures.

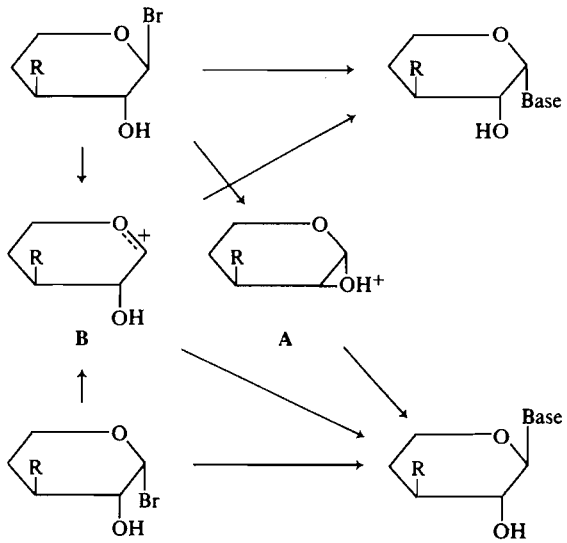

FIG. 2

La stéréospécificité observée dans les réactions de condensation, réalisées à partir de mélanges anomériques de bromures, pourrait être expliquée d'une part par la substitution de type $S_N2$ de l'halogène par la base au niveau de la bromhydrine *cis* 1,2 et d'autre part par l'ouverture en C-1 d'un intermédiaire de type époxydium (**A**) dérivé de la bromhydrine *trans* et provenant de l'attaque nucléophile de l'halogène anomérique par l'hydroxyle en C-2, en présence de la base. Le passage par un ion carbonium intermédiaire de type **B** est également envisageable mais il est vraisemblable que son intervention conduirait à la formation de composés *cis* 1',2' en liaison avec l'encombrement stérique existant au niveau du C-3.

Il était intéressant d'une part de vérifier la possibilité de formation d'un époxyde, et donc d'un ion époxydium, à partir des bromhydrines utilisées, et d'autre part d'évaluer la participation de chacun des mécanismes évoqués, dans le processus réactionnel global.

Les tentatives de synthèse d'époxydes ont été réalisées à partir du méthyl glycoside **7** dont la préparation est aisée et dont le groupement en C-3 est, dans une large mesure, chimiquement inerte. En chimie des sucres, la formation d'un cycle oxirane en C1—C2 peut être réalisée selon la méthode de Yamaguchi et Schuerch (11) par action de *t*-BuOK sur une halohydrine en solution benzénique. Cette méthode appliquée aux bromures dérivés de **7** n'a pas donné l'époxyde **18** attendu mais a conduit à la synthèse du composé **15** de configuration *trans* 1,2 présentant un groupement *tert*-butyloxy en C-1 et à des traces de son isomère **16** de configuration *cis*. La formation de l'époxyde **18** a pu être obtenue par traitement des bromures **17** avec du NaH en suspension dans $CH_2Cl_2$ à −30°C (Fig. 3) mais son isolement n'a pas pu être réalisé en

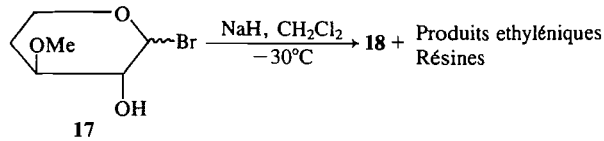

FIG. 3

raison notamment de la très grande complexité du milieu réactionnel qui contient des composés de structure éthylénique et des produits résineux. Il a pu être visualisé en ccm sur des plaques de gel de silice anhydres par révélation avec un réactif spécifique des époxydes[3] (12); sa mobilité dans AcOEt était voisine de celle des bromures.

L'analyse en rmn de ce composé ne pouvait être effectuée directement dans le milieu réactionnel brut, il fallait au préalable, éliminer $CH_2Cl_2$, ce qui a été réalisé par coévaporation avec du benzène-$d_6$. Le spectre obtenu dans ce solvant présentait en particulier 2 doublets étroits ($J \sim 2{,}5$ Hz) à 4,70 et 2,75 ppm pouvant correspondre aux protons H-1 et H-2 d'un composé de type époxyde. Les réactions reportées dans la figure 4, effectuées sur le mélange réactionnel et suivies en rmn, tendent à confirmer cette structure.

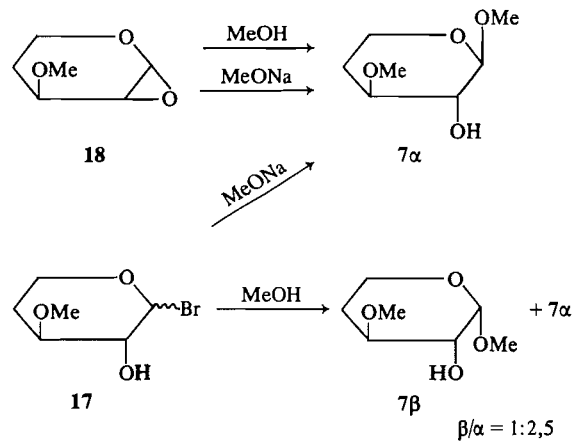

FIG. 4

L'addition de MeONa ou MeOH conduit de façon instantanée à la synthèse exclusive du méthylglycoside 7α dont le spectre rmn est très caractéristique, et à la disparition simultanée des 2 doublets. La stéréospécificité observée dans ces réactions, qui est indépendante de la nucléophilicité des réactifs, est caractéristique de l'ouverture

[3]Pulvérisation d'une solution de rouge de méthyle et de NaI dans du n-butanol suivie d'un chauffage à 140°C.

d'un époxyde. De plus, l'action de MeONa sur les bromhydrines, réalisées dans les mêmes conditions, conduit également au seul composé 7α alors que la réaction avec MeOH qui ne peut pas donner lieu à la formation d'un époxyde intermédiaire, aboutit à un mélange des composés 7α et 7β dans le rapport 2,5:1.

La formation d'un composé de type époxyde dans la réaction des bromhydrines avec une base est donc très probable, mais dans le cas de la condensation avec la DMP il ne peut s'agir que d'une entité activée, de type époxidium, puisque l'intervention d'un proton est nécessaire dans le mécanisme d'ouverture du cycle oxirane par cette base. Il est vraisemblable que la molécule réagissante soit constituée par un complexe entre l'époxyde et la base protonée.

Dans le processus réactionnel global de la condensation de la DMP avec les bromhydrines, l'importance du rôle joué par la formation de l'ion époxydium d'une part et par la substitution directe de l'halogène anomérique d'autre part dépend essentiellement de la proportion des bromhydrines *cis* et *trans* au moment de l'addition de la base. Quant à la participation d'un ion carbonium nous avons pu déduire des réactions reportées dans la figure 5 qu'elle est peu importante.

En effet, dans les réactions de glycosylation du composé **19** (13), réalisées avec MeOH ou *t*-BuOH en présence de résine Dowex $50H^+$, les groupements méthoxyle et *tert*-butoxyle sont introduits préférentiellement en position *cis* par rapport à l'hydroxyle en C-2. Ces réactions qui sont de type $S_N1$ donnent des résultats similaires avec des substrats dont l'encombrement stérique en C-3 est plus important tels que des composés benzoylé ou benzylé.

La synthèse des nucléosides à partir des désoxy-4-pentopyranoses pouvant constituer un cas particulier sur le plan stéréochimique du fait de l'absence de substituant en C-4 et C-5, il était nécessaire de réaliser le même type de réaction à partir de sucres naturels classiques dans lesquels tous les carbones sont substitués. Ainsi nous avons réalisé la condensation de la DMP sur les bromures **21** obtenus par action prolongée de HBr à $-10°C$ dans $CH_2Cl_2$ sur le méthyl tri-*O*-benzoyl-3,5-6-glucofuranose **20** (14). Cette condensation, réalisée selon la technique habituelle, a conduit de façon exclusive au nucléoside **22** de configuration *trans* 1',2' (Fig. 6). Le rendement moyen obtenu (62%) ne dépend pas de la réactivité des bromures mais de la synthèse de ces derniers qui s'accompagne d'une dégradation partielle du sucre de départ.

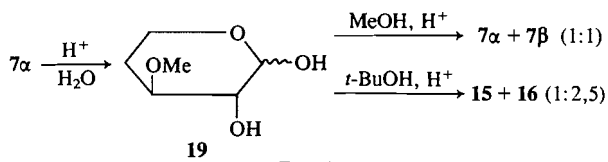

FIG. 5

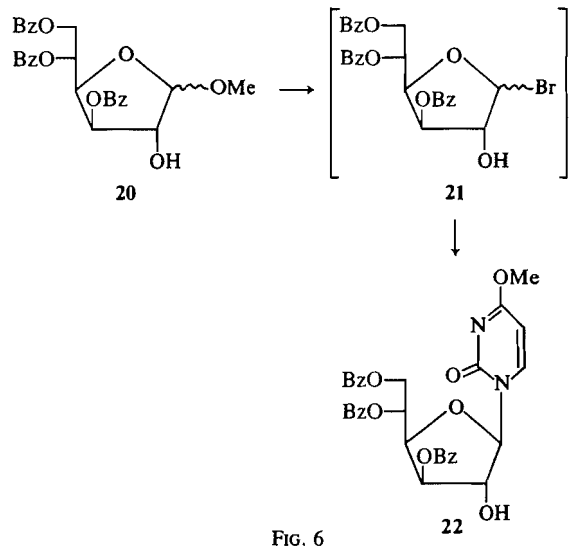

FIG. 6

## Conclusion

La stéréospécificité observée dans les réactions de condensation d'une bromhydrine en C-1, C-2 avec la DMP et qui se traduit par la formation exclusive de nucléoside *trans* 1',2' ne dépendrait pas de la structure du sucre de départ mais essentiellement des possibilités de formation d'un intermédiaire réactionnel de type époxyde liées à la présence du groupement hydroxyle en C-2.

## Partie expérimentale

*Méthodes générales*

Le déroulement des réactions a été suivi en ccm sur gel de silice (Kieselgel 60 $F_{254}$, Merck 5535) et la révélation des chromatogrammes a été réalisée par pulvérisation de réactif phosphomolybdique suivie d'un chauffage à 100°C. Les ccm de l'époxyde **18** ont été réalisées sur plaques de gel de silice préalablement déshydratées à 100°C pendant 2 h, les chromatogrammes ont été révélés par pulvérisation d'une solution contenant 100 mg de rouge de méthyle et 200 mg de NaI dans 20 mL de n-butanol suivie d'un chauffage à 140°C pendant 5 minutes; les époxydes sont révélés en jaune sur fond rouge. La purification des produits a été réalisée par chromatographie liquide sous basse pression, sur gel de silice (Kieselgel 60 $F_{254}$ et 60, Merck 10757 et 9385). Les points de fusion, mesurés sur banc Kofler ne sont pas corrigés. Les indices de réfraction ont été mesurés sur un réfractomètre OPL et les spectres ir ont été enregistrés sur le spectrophotomètre Beckman Acculab-4. Les spectres rmn ont été enregistrés à 60, 80 ou 350 MHz sur les spectromètres Perkin Elmer R 24 B, Brüker WP 80 et Caméca 350. Les déplacements chimiques sont exprimés en ppm, le tetraméthylsilane étant pris comme référence zéro. Lorsque les

spectres ont été enregistrés dans $D_2O$ comme solvant, le *tert*-butanol a été utilisé comme référence pour les déplacements chimiques. Les microanalyses ont été effectuées par le service central de microanalyse du C.N.R.S., division de Lyon.

*Désoxy-4-*O*-isopropylidène-1,2-*O*-*p*-nitrobenzoyl-3-*β-DL-*thréo-pentopyranose (1)*

À une solution de désoxy-4-*O*-isopropylidène-1,2-β-DL-*thréo*-pentopyranose (9) (1 g, 5,75 mmol) dans $CH_2Cl_2$ (20 mL) contenant de la pyridine (3 mL) sont ajoutés à 0°C et sous forte agitation, des cristaux de chlorure de *p*-nitrobenzoyle (1,1 g, 5,93 mmol). Le mélange est agité 1 h à 0°C puis 2 h à température ambiante. On ajoute alors de l'eau (20 mL) et de l'éthanol (1 mL) et on extrait la phase aqueuse obtenue par $CH_2Cl_2$ (2 × 25 mL); la phase organique est lavée par une solution saturée de $NaHCO_3$ (30 mL) puis par de l'eau (30 mL); l'extrait organique est séché sur $Na_2SO_4$ et le solvent est évaporé sous pression réduite pour donner un résidu cristallin qui, par trituration dans de l'ether éthylique (15 mL) fournit 1,4 g (75,5%) de **1** sous forme de cristaux jaunâtres. Les eaux mère de cristallisation sont évaporées et le résidu pâteux obtenu est recristallisé dans le mélange AcOEt–hexane 1:5 pour donner 330 mg supplémentaires de **1**; rendement global: 93%: pf 140°C; $R_f$ 0,75 (AcOEt–hexane, 1:1); $\nu_{max}$ (KBr): 3120, 3090, 3060, 1600 et 720 ($C_6H_4$), 1720 (ester), 1370 et 1380 (isopropylidène) $cm^{-1}$; rmn ($CDCl_3$) δ: 5,50 (m, 1H, $J_{2,3}$ = 3,6 Hz, $J_{3,4'}$ = $J_{3,4}$ = 4,3 Hz, H-3), 5,38 (d, 1H, $J_{1,2}$ = 3,3 Hz, H-1), 4,01 (t, 1H, H-2), 3,90–3,70 (m, 2H, H-5, H-5'), 2,20 (m, 1H, $J_{4,4'}$ = −14,5 Hz, $J_{4',5'}$ = 8,1 Hz, $J_{4',5}$ = 6,3 Hz, H-4'), 1,75 (m, 1H, H-4), 8,24 et 8,16 (2d, 4H, $C_6H_4$), 1,52 et 1,33 (2s, 6H, 2-$CH_3$) *Anal.* calc. pour $C_{15}H_{17}NO_7$: C 55,73, H 5,26, N 4,33; trouvée: C 55,65, H 5,45, N 4,32.

*Méthyl désoxy-4-*O*-p-nitrobenzoyl-3-désoxy-4-α et* β-DL-thréo-*pentopyranoside (4)*

Une solution de **1** (1,15 g, 3,56 mmol) dans MeOH (35 mL) contenant de la résine Dowex 50H$^+$ anhydre (1 g), fraîchement activée par HCl, est chauffée 2 h à 60°C; la résine est alors filtrée et rincée par MeOH bouillant (20 mL). Le filtrat est évaporé et le produit liquide obtenu est purifié sur colonne de gel de silice dans le solvant acétone–hexane 1:2 pour donner une poudre blanche (840 mg, 80%) constituée par un mélange des composés **4α** et **4β** dans le rapport 4:1. Ces 2 composés n'ont pas été séparés: pf 140–144°C; $\nu_{max}$ (KBr): 3520 et 3420 (OH), 3130, 1605 et 710 ($C_6H_4$), 1710 et 1280 (ester) $cm^{-1}$; rmn (DMSO-$d_6$): *composé* **4α**, δ: 4,93 (m, 1H, $J_{2,3}$ = 8,4 Hz, $J_{3,4}$ = 5,1 Hz, $J_{3,4'}$ = 10 Hz, H-3), 4,64 (d, 1H, $J_{1,2}$ = 6,7 Hz, H-1), 5,45 (d, 1H, OH), 3,37 (s, 3H, $OCH_3$), 8,25 et 8,10 (2d, 4H, $C_6H_4$); *Composé* **4β**, δ: 5,00 (m, 1H, H-3), 4,63 (d, 1H, $J_{1,2}$ = 3,4 Hz, H-1), 5,10 (d, 1H, OH), 3,25 (s, 3H, $OCH_3$), 8,25 et 8,10 (2d, 4H, $C_6H_4$). *Anal.* calc. pour $C_{13}H_{15}NO_7$: C 52,53, H 5,05, N 4,71; trouvée: C 52,41, H 5,23, N 4,64.

*Méthyl désoxy-4-*O*-méthyl-3-α ou* β-DL-thréo-*pentopyranosides (7)*

A une solution de MeONa obtenue par dissolution à chaud de sodium (2 g) dans MeOH (40 mL) est ajouté à température ambiante de l'anhydro-2,3-désoxy-4-α ou β-DL-pentopyranose (9) (5,4 g, 41,5 mmol). La solution obtenue est agitée une nuit à 35°C puis neutralisée par HCl 6 *N*. De l'acétate d'éthyle est alors ajouté (40 mL) et les sels sont filtrés puis lavés par AcOEt (10 mL). Le filtrat est évaporé et le résidu aqueux obtenu est extrait par AcOEt (2 × 30 mL). La phase organique est séchée sur $Na_2SO_4$ et évaporée sous pression réduite pour donner un liquide jaunâtre. le composé **7α**, obtenu à partir de l'anhydrosucre β, est purifié par distillation au four à boules à 115–120°C sous 3 Torr, c'est une huile incolore (5,775 g, 86%): $n_D^{20}$ 1,4580; $R_f$ 0,17 (AcOEt–hexane, 2:1); $\nu_{max}$ (film): 3460 (OH), 2850 (OMe) $cm^{-1}$; rmn ($D_2O$) δ: 2,96 (d, 1H, $J_{1,2}$ = 7,2 Hz, H-1), 2,73 (m, 1H, $J_{5,5'}$ = −12 Hz, $J_{5,4'}$ = 5,2 Hz, $J_{5,4}$ = 2,3 Hz, H-5), 2,18 (m, 1H, H-5'), 2,17 (m, 1H, H-3), 1,96 (dd, 1H, $J_{2,3}$ = 10 Hz, H-2), 0,93 (m, 1H, $J_{4,4'}$ = −13 Hz, $J_{4,3}$ = 5 Hz, $J_{4,5'}$ = 2,3 Hz, H-4), 0,27 (m, 1H, $J_{4',5'}$ = 11,5 Hz, $J_{4',3}$ = 10 Hz, H-4'), 2,25 et 2,17 (2 s, 6H, 2-$OCH_3$). *Anal.* calc. pour $C_7H_{14}O_4$: C 51,85, H 8,64; trouvé: C 51,72, H 8,80. Le composé **7β** obtenu à partir de l'anhydrosucre α est purifié par chromatographie sur gel de silice dans le solvant AcOEt–hexane 3:1 pour donner une huile incolore (91%): $n_D^{20}$ 1,4560; $R_f$ 0,37 (AcOEt–hexane, 3:1); $\nu_{max}$ (film): caractéristiques identiques à celles du composé **7α**; rmn ($D_2O$) δ: 3,53 (d, 1H, $J_{1,2}$ = 2,4 Hz, H-1), 2,53 (t, 1H, $J_{2,3}$ = 1,5 Hz, $J_{3,4'}$ = 2 Hz, $J_{3,4}$ = 1,5 Hz, H-3), 2,41 (d, 1H, H-5), 2,31 (m, 1H, H-5'), 2,30–2,18 (1H, H-2), 0,93 (m, 1H, $J_{4,4'}$ = −13,5 Hz, H-4), 0,30 (m, 1H, H-4'), 2,19 et 2,15 (2s, 6H, 2-$OCH_3$). *Anal.* calc. pour $C_7H_{14}O_4$: C 51,85, H 8,64; trouvé: C 51,81, H 8,78.

*Méthode générale de synthèse des nucléosides 8–14*

À une solution de méthylglycoside (10 mmol) dans $CH_2Cl_2$ (60 mL) à 0 ou −15°C est ajoutée une solution de HBr à demi saturation dans $CH_2Cl_2$ à raison de 5 équivalents d'acide par équivalent de sucre. Lorsque les produits de départ ont disparu, la solution est dégazée par un courant d'azote anhydre, hors du bain réfrigérant et jusqu'à réapparition des méthylglycosides (environ 10 min); on ajoute alors en une seule fois du tamis moléculaire 10 Å et on agite jusqu'à disparition totale des vapeurs d'HBr dans le vase à réaction. On procède alors à l'addition de la DMP (2 equiv./equiv. de sucre) et le mélange obtenu est porté à reflux pendant 5 min. le solvant est évaporé et le résidu pâteux est trituré dans MeOH chaud. Les sels sont éliminés par filtration et rinçés par MeOH bouillant (2 × 30 mL). Le filtrat est évaporé à sec et l'huile jaunâtre obtenue est diluée dans le mélange acétone–méthanol 10:1 (10 mL/g de résidu). Le précipité est éliminé par filtration et rincé avec de l'acétone. Le filtrat est évaporé et le concentré réactionnel huileux obtenu est purifié pour donner les nucléosides attendus.

*(O-acétyl-3-désoxy-4-α-*DL-*thréo-pentopyranosyl)-1-méthoxy-4-pyrimidinone-2 (8)*

Synthèse à partir de **2**; la dilution du concentré réactionnel par le mélange acétone–hexane 1,5:1 conduit à la précipitation d'une partie du nucléoside **8** (73%); le reste du nucléoside est obtenu par chromatographie sur gel de silice de la solution de cristallisation, dans le même solvant; rendement global 84%. Les caractéristiques physiques du nucléoside obtenu sont identiques à celles qui ont été précédemment décrites (1).

*(O-benzoyl-3-désoxy-4-α-*DL-*thréo-pentopyranosyl)-1-méthoxy-4-pyrimidinone-2 (9)*

Synthèse à partir du composé **3**; la dilution de l'extrait réactionnel par AcOEt (6 mL/g d'extrait) provoque la précipitation d'une grande partie du nucléoside **9** qui est obtenu pur sous forme d'une poudre blanche. Le reste du nucléoside, dissous dans la solution de cristallisation est isolé par chromatographie sur gel de silice dans AcOEt pur; rendement global 83%: pf 160–170°C; $R_f$ 0,45 (AcOEt); $\nu_{max}$ (KBr): 3370 (OH), 3100, 1600, 705 et 680 ($C_6H_5$), 1715 et 1270 (ester), 1670, 1630, 1545 et 1480 (base) $cm^{-1}$; rmn (DMSO-$d_6$) δ: 5,59 (d, 1H, $J_{1,2}$ = 9,3 Hz, H-1'), 5,10 (m, 1H, $J_{3',2'}$ = 9,3 Hz, $J_{3',4'}$ = 5,8 Hz, $J_{3',4''}$ = 11 Hz, H-3'), 4,08–3,68 (m, 3H, H-2, H-5', H-5''), 2,15 et 1,83 (2m, 2H, H-4' et H-4''), 5,57 (d, 1H, OH), 8,05 et 6,02 (2d, 2H, $J_{5,6}$ = 7,7 Hz, H-6 et H-5), 7,95 et 7,53 (2m, 5H, $C_6H_5$), 3,81 (s, 3H, OMe); *Anal.* calc. pour $C_{17}H_{18}N_2O_6$: C 58,96, H 5,20, N 8,09; trouvée: C 59,01, H 5,21, N 7,95.

*(Désoxy-4-*O*-p-nitrobenzoyl-3-α-*DL-*thréo-pentopyranosyl)-1-méthoxy-4-pyrimidinone-2 (10)*

Synthèse à partir du composé **4**. Le nucléoside est cristallisé à partir des extraits réactionnels par dilution avec le mélange

ether éthylique – éthanol 10:1 (10 mL/g d'extrait). La faible quantité de nucléoside restant dissoute dans la solution de cristallisation est récupérée par chromatographie dans AcOEt; rendement global 79%: pf 263–265°C (déc.); $R_f$ 0,36 (AcOEt); $\nu_{max}$ (KBr): 3410 (OH), 3125, 3090, 1605 et 720 ($C_6H_4$), 1720 et 1295 (ester), 1660, 1635, 1530 et 1490 (base) $cm^{-1}$; rmn (DMSO-$d_6$) δ: 5,60 (d, 1H, $J_{1,2}$ = 9,6 Hz, H-1'), 5,15 (m, 1H, $J_{3',2'}$ = 9 Hz, $J_{3',4'}$ = 5,3 Hz, $J_{3',4''}$ = 10,8 Hz, H-3'), 4,00 (dd, 1H, H-2'), 4,10–3,65 (m, 2H, H-5', H-5''), 2,18 (m, 1H, H-5'), 1,85 (m, 1H, H-5''), 8,33 et 8,15 (2d, 4H, $C_6H_4$), 8,05 et 6,00 (2d, 2H, $J_{5,6}$ = 7,5 Hz, H-6 et H-5), 5,64 (d, 1H, OH), 3,83 (s, 3H, OMe); *Anal.* calc. pour $C_{17}H_{17}N_3O_8$: C 52,17, H 4,35, N 10,74; trouvée: C 52,21, H 4,42, N 10,93.

*(O-benzyl-3-désoxy-4-α-*DL*-thréo-pentopyranosyl)-1-méthoxy-4-pyrimidinone-2 (**11**)*

Synthèse à partir du composé **5**; la dilution de l'extrait réactionnel par le solvant: acétone–hexane 1,5:1 (7 mL/g d'extrait) provoque la précipitation d'une grande partie du nucléoside **11** qui est récoltée par filtration et lavée par le mélange acétone–hexane 2:1. Le reste de nucléoside, contenu dans la solution de cristallisation est récupéré par chromatographie sur colonne de gel de silice dans le solvant acétone–hexane 1,5:1; rendement global: 85%; pf 128°C; $R_f$ 0,32 (acétone–hexane 1,5:1); $\nu_{max}$ (KBr): 3200 (OH), 3050, 3020 et 700 ($C_6H_5$), 1640, 1545 et 1480 (base) $cm^{-1}$; rmn (DMSO-$d_6$) δ: 5,46 (d, 1H, $J_{1',2'}$ = 8,8 Hz, H-1), 4,00–3,30 (m, 4H, H-2', H-3', H-5', H-5''), 2,09 (m, 1H, $J_{4',3'}$ = 9,5 Hz, $J_{4',4''}$ = −12,5 Hz, H-4'), 1,63 (m, 1H, $J_{4'',5'}$ = 5,5 Hz, $J_{4'',5''}$ = 11 Hz, H-4''), 8,00 et 6,00 (2d, 2H, $J_{5,6}$ = 7,3 Hz, H-6 et H-5), 7,30 et 4,66 (2s, 5H et 2H, $C_6H_5$—$CH_2$), 5,40 (d, 1H, OH), 3,83 (s, 3H, OMe); *Anal.* calc. pour $C_{17}H_{20}N_2O_5$: C 61,45, H 6,02, N 8,43; trouvée: C 61,39, H 6,00, N 8,57.

*(Azido-3-didésoxy-3,4-α-*DL*-thréo-pentopyranosyl)-1-méthoxy-4-pyrimidinone-2 (**12**)*

Synthèse à partir du composé **6**; le nucléoside est obtenu pur sous forme d'une laque par chromatographie de l'extrait réactionnel sur colonne de gel de silice dans le solvant acétone–hexane 1,5:1; la trituration de cette laque avec de l'éther éthylique provoque la cristallisation du nucléoside qui est obtenu sous forme d'une poudre blanche; rendement: 69%; pf 208–210°C (déc.); $R_f$ 0,35 (acétone–hexane, 1,5:1); $\nu_{max}$ (KBr): 3200 (OH), 2120 ($N_3$), 1650, 1550 et 1490 (base) $cm^{-1}$; rmn (DMSO-$d_6$) δ: 5,52 (d, 1H, $J_{1',2'}$ = 8,2 Hz, H-1'), 4,00–3,50 (m, 4H, H-2', H-3', H-5', H-5''), 2,00 (m, 1H, $J_{4',4''}$ = −12,5 Hz, H-4'), 1,66 (m, 1H, H-4''), 8,00 et 6,05 (2d, 2H, $J_{5,6}$ = 7,2 Hz, H-6 et H-5), 5,78 (d, 1H, OH), 3,86 (s, 3H, OMe); *Anal.* calc. pour $C_{10}H_{13}N_5O_4$: C 44,94, H 4,87, N 26,22; trouvée: C 45,00, H 4,95, N 26,08.

*(Désoxy-4-O-méthyl-3-α et β-*DL*-thréo-pentopyranosyl)-1-méthoxy-4-pyrimidinone-2 (**13** et **14**)*

Synthèse à partir du composé **7**; l'extrait réactionnel est chromatographié sur colonne de gel de silice dans le solvant acétone–hexane 7:1 pour donner les nucléosides **13** et **14** sous forme de laque. Le composé **13** cristallise par trituration dans l'éther éthylique; rendement global 72% (95,5% de **13** et 4,5% de **14**).

*Composé **13***: pf 162–164°C; $R_f$ 0,44 (acétone–hexane, 7:1); $\nu_{max}$ (KBr): 3260 (OH), 2880 et 2860 (OMe), 1650, 1540 et 1485 (base) $cm^{-1}$; rmn (DMSO-$d_6$) δ: 5,37 (d, 1H, $J_{1',2'}$ = 8,5 Hz, H-1'), 3,50 (m, 1H, H-2'), 4,00–3,30 (m, 3H, H-3', H-5', H-5''), 2,05 (m, 1H, $J_{4',4''}$ = −13 Hz, H-4'), 1,45 (m, 1H, H-4''), 7,95 et 5,95 (2d, 2H, $J_{5,6}$ = 7,4 Hz, H-6 et H-5), 5,25 (d, 1H, OH), 3,81 (s, 3H, OMe base), 3,35 (s, 3H, OMe sucre); *Anal.* calc. pour $C_{11}H_{16}N_2O_5$: C 51,56, H 6,25, N 10,94; trouvée: C 51,42, H 6,21, N 11,11.

*Composé **14***: $R_f$ 0,63 (acétone–hexane, 7:1); $\nu_{max}$ (KBr): caractéristiques identiques à celles du composé **13**; rmn (DMSO-$d_6$) δ: 5,68 (s, 1H, $J_{1',2'} \sim 1$ Hz, H-1), 3,90–3,20 (m, 4H, H-2', H-3', H-5', H-5''), 2.00 (m, 1H, $J_{4',4''}$ = −13 Hz, H-4'), 1,50 (m, 1H, H-4''), 7,83 et 5,97 (2d, 2H, $J_{5,6}$ = 7,3 Hz, H-6 et H-5), 5,33 (d, 1H, OH), 3,85 (s, 3H, OMe base), 3,35 (s, 3H, OMe sucre); *Anal.* calc. pour $C_{11}H_{16}N_2O_5$: C 51,56, H 6,25, N 10,94; trouvée: C 51,83, H 6,39, N 10,77.

*Action de NaH sur les bromhydrines dérivées de **7***

Les solutions neutres de bromhydrines, obtenues comme décrit précédemment, sont filtrées pour éliminer le tamis moléculaire. Le filtrat est refroidi à −30°C puis du NaH est ajouté (4 equiv./equiv. de sucre); la suspension obtenue est agitée à la même température jusqu'à l'arrêt du dégagement gazeux (environ 6 h) puis filtré pour éliminer le NaH en excès et les sels qui ont précipité. La ccm dans AcOEt de la solution obtenue révèle la présence de nombreux produits dont quelques uns sont révélés par une solution aqueuse neutre de $KMnO_4$ et dont un, à $R_f$ 0,15, est révélé par un réactif des époxydes. Ce composé qui disparaît instantanément lors de l'addition de MeOH ou MeONa pour donner le produit 7α serait l'époxyde **18**; rmn ($C_6D_6$) δ: 4,70 (d, 1H, $J_{1,2} \sim 2,5$ Hz, H-1), 2,75 (d, 1H, H-2).

*Réaction de glycosylation du désoxy-4-O-méthyl-3-α et β-*DL*-thréo-pentopyranose (**19**)*

Le composé **19** est obtenu par hydrolyse de **7** dans une solution d'HCl 6 *N* (15 mL/g de sucre) à 80°C pendant 1 heure. La solution est neutralisée par $Na_2CO_3$ et évaporée à sec à 50°C sous pression réduite. Le résidu pâteux obtenu est dilué par MeOH et les sels sont éliminés par filtration. Le filtrat est évaporé pour donner le composé **19** (94%) sous forme d'une huile contenant les 2 isomères α et β dans le rapport 2:1; $R_f$ 0,25–0,15 (AcOEt); $\nu_{max}$ (film): 3400 (OH), 2840 (OMe) $cm^{-1}$; rmn ($D_2O$) δ: 3,93 (d, 1/3H, $J_{1,2}$ = 2,5 Hz, H-1 β), 3,27 (d, 2/3 H, $J_{1,2}$ = 7,4 Hz, H-1 α), 2,23 (s, 3H, OMe α + β), 1,00 (m, 1H, H-4 α + β), 0,40 (m, 1H, H-4' α + β); *Anal.* calc. pour $C_6H_{12}O_4$: C 48,65, H 8,11; trouvée: C 48,60, H 8,35.

Les réactions de glycosylation sont réalisées par chauffage à 80°C pendant 1–2 h du composé **19** (10 mmol) dissous dans MeOH ou t-BuOH (30 mL) en présence de résine Dowex $50H^+$ (1 g). La réaction avec MeOH conduit de façon quantitative aux composés 7α et 7β dans le rapport 1:1. La réaction avec *t*-BuOH, plus lente et incomplète conduit à un mélange des composés **15** et **16** dans le rapport 1:2,5. Ces produits ont été séparés par chromatographie sur colonne de gel de silice dans l'acétate d'éthyle pur.

*tert-Butyl désoxy-4-O-méthyl-3-α et β-*DL*-thréo-pentopyranoside (**15** et **16**)*

Le composé **15** est cristallisé: pf 64–65°C; $R_f$ 0,60 (AcOEt); $\nu_{max}$ (KBr): 3420 (OH), 2880 (OMe) $cm^{-1}$; rmn ($CDCl_3$) δ: 4,33 (d, 1H, $J_{1,2}$ = 7,4 Hz, H-1), 4,00 (m, 1H, $J_{5,5'}$ = −12 Hz, $J_{5,4}$ = 2 Hz, $J_{5,4'}$ = 5,4 Hz, H-5), 3,60–3,15 (m, 3H, H-2, H-3, H-5'), 3,50 (s, 3H, OMe), 2,50 (s, 1H, OH), 2,07 (m, 1H, $J_{4,4'}$ = −12 Hz, H-4), 1,73 (m, 1H, H-4'), 1,33 (s, 9H, 3 $CH_3$); *Anal.* calc. pour $C_{10}H_{20}O_4$: C 58,82, H 9,80; trouvée: C 58,77, H 9,89. le composé **16** est une huile: $R_f$ 0,68 (AcOEt); $\nu_{max}$ (film): caractéristiques identiques à celles du composé **15**: rmn ($CDCl_3$) δ: 5,10 (d, 1H, $J_{1,2}$ = 2,8 Hz, H-1), 3,50 (dd, 1H, $J_{2,3}$ = 3,2 Hz, H-2), 4,00–3,30 (m, 3H, H-3, H-5, H-5'), 3,45 (s, 3H, OMe), 2,10 (m, 1H, $J_{4,4'}$ = −12 Hz, H-4), 1,77 (m, 1H, H-4'), 1,33 (s, 9H, $3CH_3$); *Anal.* calc. pour $C_{10}H_{20}O_4$: C 58,82, H 9,80; trouvée: C 59,05, H 9,74.

*Synthèse du (tri-O-benzoyl-3,5,6-β-*D*-glucofuranosyl)-1-méthoxy-4-pyrimidinone-2 (**22**)*

Une solution de méthyl tri-*O*-benzoyl-3,5-6-α et β-D-gluco-

furanose **20** (5 mmol) dans $CH_2Cl_2$ (25 mL) est saturée à −10°C par du HBr gazeux anhydre. La solution est agitée 5 h à cette température puis est laissée une nuit à 0°C. La réaction n'est pas complète et l'on note, en ccm, la présence de produits de dégradation et d'un spot à $R_f$ 0,28 (AcOEt–hexane, 1:1) correspondant aux bromures **21**. La solution est dégazée à température ambiante par un courant d'azote anhydre jusqu'à disparition des vapeurs d'HBr dans le vase à réaction; du tamis moléculaire 10 Å (5 g) est alors ajouté et la suspension obtenue est agitée pendant 5 min. De la DMP est ajoutée (15 mmol) et le mélange est chauffé 5 min à reflux. La suspension est alors traitée selon la technique habituelle et l'extrait réactionnel est chromatographié sur colonne de gel de silice dans le solvant AcOEt–hexane 3:1 pour donner le nucléoside **22** sous forme d'une poudre blanche: $[\alpha]_D^{23}$ +42° (*c* 0,046, éthanol); pf 134–140°C; $R_f$ 0,40 (AcOEt–hexane, 3:1); $\nu_{max}$ (KBr): 3420 (OH), 3060, 1600, 1590, 700 et 675 ($C_6H_5$), 1720 et 1270–1240 (ester), 1660–1620, 1550 et 1480 (base) $cm^{-1}$; rmn ($CD_3COCD_3$) δ: 6,13 (m, 1H, H-5'), 6,00 (s, 1H, $J_{1',2'} \sim 1$ Hz, H-1'), 5,84 (d, 1H, $J_{OH,2'} = 4$ Hz, OH), 5,66 (d, 1H, $J_{3',4'} = 3$ Hz, H-3'), 5,25–4,75 (m, 3H, H-4', H-6'6"), 4,63 (d, devient singulet par addition de $D_2O$, 1H, $J_{2,3'} \sim 1$ Hz, H-2), 8,45 et 6,03 (2d, 2H, $J_{5,6} = 7,5$ Hz, H-6 et H-5), 7,90 et 7,50 (2m, 15H, $3C_6H_4$), 3,84 (s, 3H, OMe). *Anal.* calc. pour $C_{32}H_{28}N_2O_{10}$: C 64,0, H 4,67, N 4,67; trouvée: C 64,13, H 4,63, N 4,58.

# Molecular rearrangements. III. Thermal decomposition of some selected thioesters

ABOEL-MAGD A. ABDEL-WAHAB,[1] AHMED M. EL-KHAWAGA, AND MOHAMED T. ISMAIL
*Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt*

Received February 5, 1982

ABOEL-MAGD A. ABDEL-WAHAB, AHMED M. EL-KHAWAGA, and MOHAMED T. ISMAIL. Can. J. Chem. **60**, 2870 (1982).

Four selected thioesters (**1–4**) were prepared and pyrolyzed in the absence of promoters either alone or in isoquinoline solvent. These esters include benzyl thiobenzoate (**1**), phenyl phenylthioacetate (**2**), benzyl phenylthioacetate (**3**), and phenyl thiobenzoate (**4**). Pyrolysis of **1** gave mainly 2,3,4,5-tetraphenylthiophene in addition to benzene, biphenyl, benzyl thiol, and benzoic acid. Thermal decomposition of **1** under nitrogen gave benzaldehyde, benzil, and only a trace of benzoic acid in addition to the former products. Compound **2** afforded essentially toluene and dibenzyl in addition to benzene, biphenyl, phenyl sulphide, thiophenol, and phenyl acetic acid. Thermolysis of **3** gave toluene and stilbene beside small quantities of benzyl thiol and phenylacetic acid. Finally, thermal decomposition of **4** in isoquinoline gave benzene, biphenyl, phenyl sulphide, thianthrene, thiophenol, benzoic acid, and 1-phenylisoquinoline. $H_2S$ and CO are also produced in all cases. In these rearrangements, the C—S bonds undergo homolytic fission either simultaneously or selectively. No isomer redistribution precedes the coupling reactions. Plausible mechanisms for the above facts are proposed.

ABOEL-MAGD A. ABDEL-WAHAB, AHMED M. EL-KHAWAGA et MOHAMED T. ISMAIL. Can. J. Chem. **60**, 2870 (1982).

On a préparé quatre thioesters (**1–4**) et on les a pyrolysés en l'absence de promoteurs soit à l'état pur ou dans l'isoquinoléine comme solvant. Ces esters comprennent: le thiobenzoate de benzyle (**1**), le phénylthioacétate de phényle (**2**), le phénylthioacétate de benzyle (**3**) et le thiobenzoate de phényle (**4**). La pyrolyse du composé **1** donne principalement le tétraphényl-2,3,4,5 thiophène en plus du benzène, du biphényle, du benzylthiol et de l'acide benzoique. La décomposition thermique du composé **1** sous azote conduit au benzaldéhyde, au benzyle et seulement à une trace d'acide benzoique en plus des premiers produits. Le composé **2** conduit essentiellement au toluène et au bibenzyle en plus du benzène, du biphényle, du sulfure de phényle, du thiophénol et de l'acide phénylacétique. La thermolyse du composé **3** donne le toluène et le stilbène à côté de faibles quantités de benzylthiol et d'acide phénylacétique. Finalement, la décomposition thermique du composé **4** dans l'isoquinoléine donne le benzène, le biphényle, le sulfure de phényle, le thianthrène, le thiophénol, l'acide benzoique et la phényl-1 isoquinoléine. Dans tous les cas, on obtient également du $H_2S$ et du CO. Dans ces transpositions, les liaisons C—S subissent une fission homolytique soit simultanément soit sélectivement. Aucune redistribution d'isomères ne précède les réactions de couplage. On propose un mécanisme plausible qui permet de comprendre les faits mentionnés ci-dessus.

[Traduit par le journal]

## Introduction

The action of Raney nickel on the decomposition of some thioesters was studied elsewhere (1). In the present work, we extended our studies on the thermolysis of sulphur compounds in the absence of promoters (2, 3) to thioesters, and the utility of such esters for the generation of free radicals and the possible fate of these radicals was also examined.

## Results and discussion

The investigated thioesters, benzyl thiobenzoate (**1**), phenyl phenylthioacetate (**2**), benzyl phenylthioacetate (**3**), and phenyl thiobenzoate (**4**), were prepared and pyrolyzed in the absence of promoters. It has been known for over a century that common esters decompose only above 300°C (4). The decomposition of **1** and **3** was found to start only above 220°C and that of **2** and **4** was started above 230°C. However, heating of benzyl thiobenzoate (**1**) at 240°C for 20 h (Expt. 1) gave mainly tetraphenylthiophene (97% yield) in addition to benzene (15%), biphenyl (10%), benzyl thiol (5%), and benzoic acid (30%). Unexpectedly, we could not isolate any trace of tetraphenylthiophene from the pyrolysate of phenyl phenylthioacetate (**2**, Expt. 5) or benzyl phenylthioacetate (**3**, Expt. 7). However, thermolysis of **2** gave mainly toluene (35%) and dibenzyl (45%) in addition to minor amounts of phenyl sulphide (20%), biphenyl (5%), thiophenol (14%), and phenylacetic acid (2%), while toluene (25%) and stilbene (35%) were the major products of the pyrolysis of **4** beside a small amount of benzyl thiol (3%) and phenylacetic acid (2%). Also, thermal decomposition of phenyl thiobenzoate (**4**) in isoquinoline gave benzene (5%), biphenyl (8%), phenyl sulphide, (40%), thianthrene (5%), thiophenol (10%), and benzoic acid (20%) in addition to 1-phenylisoquinoline (3%). Thermolysis of **4** in the absence of isoquinoline (neat) gave complicated products, together with an amount of tarry matter.

A plausible mechanism for the above facts is proposed in Schemes 1–4. According to this mechanism, the rearrangement products seem to be formed through an intermolecular process involving a homolytic fission of C—S linkages (5, 6). The fission may take place either simultaneously (7)

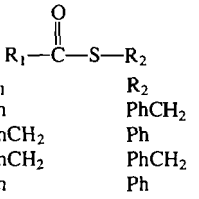
with the formation of $R_1^{\cdot}$, CO, S, and $R_2^{\cdot}$ or selectively (8) with the formation of $R-\overset{O}{\overset{\|}{C}}-S^{\cdot}$ and $R_2^{\cdot}$ or $R_1\overset{O}{\overset{\|}{C}}^{\cdot}$ and $R_2S^{\cdot}$ radicals. This, of course, is dependant on the type of $R_1$ and $R_2$.

When **1** is pyrolyzed, the fragmentation may



| | $R_1$ | $R_2$ |
|---|---|---|

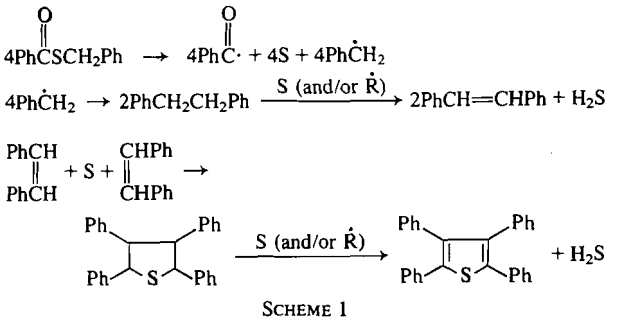
| **2** | $PhCH_2$ | Ph |
| **3** | $PhCH_2$ | $PhCH_2$ |
| **4** | Ph | Ph |

result in the formation of benzyl and thiobenzoate radicals or, most probably, benzyl and benzoyl radicals in addition to sulphur atoms. The thiobenzoate radical tends to lose sulphur, forming benzoyl radical which is amenable to splitting off carbon monoxide (9, 10). However, the formation of tetraphenylthiophene (TPT) in almost quantitative yield substantiates the second probability. The only pathway for the formation of TPT is through dehydrogenation of tetrahydrotetraphenylthiophene formed by interaction of stilbene with sulphur, readily available in the reaction medium. The dehydrogenation of dibenzyl, formed by dimerization of benzyl radicals, gives stilbene (2, 3). The production of hydrogen sulphide gas during pyrolysis indicates that sulphur acts as dehydrogenating agent during the course of the reaction.

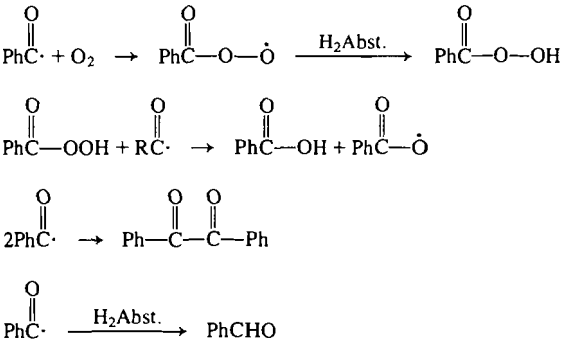
It is worthwhile to mention that the formation of one molecule of TPT requires four molecules of **1** and at least two (or three) atoms of sulphur. It is clear from Scheme 1 that the decomposition of four molecules of **1** is accompanied by the generation of four sulphur atoms, which means that the necessary sulphur is available in the reaction medium.

The isolation of benzoic acid in only 30% yield (Expt. 1) shows that most of the benzoyl radicals



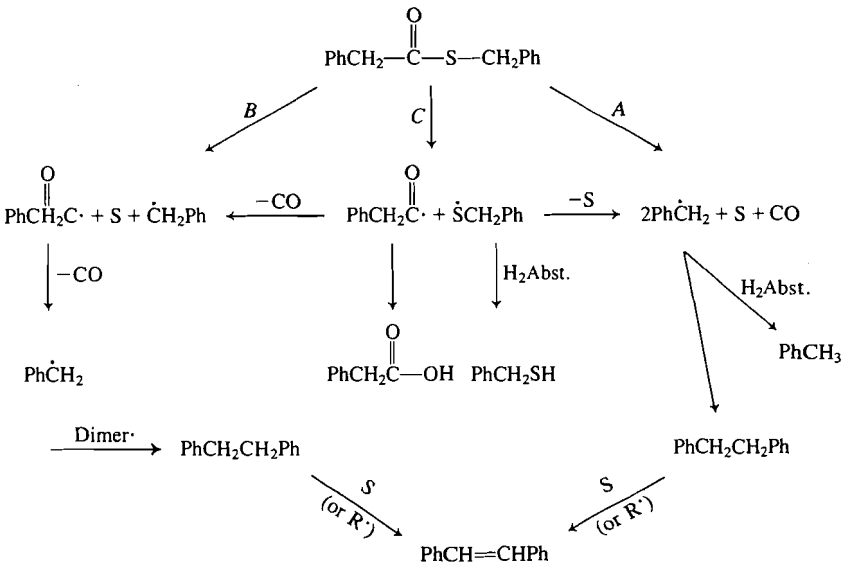
SCHEME 1

split off carbonyl groups as carbon monoxide, and phenyl radicals would be produced during the reaction. Carbon monoxide produced in this manner readily reduced palladium chloride to metallic palladium (1). The phenyl radicals were either dimerized to diphenyl or abstract hydrogen ($H_2$ Abst.) to form benzene. These findings are the same even when pyrolysis was conducted for only 8 h (Expt. 2). It is noteworthy that pyrolysis of **1** under a nitrogen atmosphere (Expt. 3) gave only a trace amount of benzoic acid. This means that the molecular oxygen is responsible for the formation of benzoic acid (11) as shown in Scheme 2. The formation of a trace amount of the acid is not unexpected during the extraction process of the pyrolysates. Furthermore, benzaldehyde and benzil were isolated in addition to the other products isolated in Expt. 1. Interestingly, pyrolysis of **1** in isoquinoline (Expt. 4) gave, in addition to the former products, the intermediates dibenzyl and stilbene, which confirms our suggested mechanism (Scheme 1). The basic extract of Expt. 4 gave 1-phenylisoquinoline and a trace of 1-benzylisoquinoline, confirming the free radical nature of these rearrangements. Furthermore, we believe that the chemisorption of the thioester, or sulphur produced from its decomposition, on the surface of the metallic catalysts or the formation of metal sulphide (10, 12) eliminates sulphur from the reaction medium and gives us a reasonable explanation for the lack of formation of TPT in the experiments of Hauptmann (1).

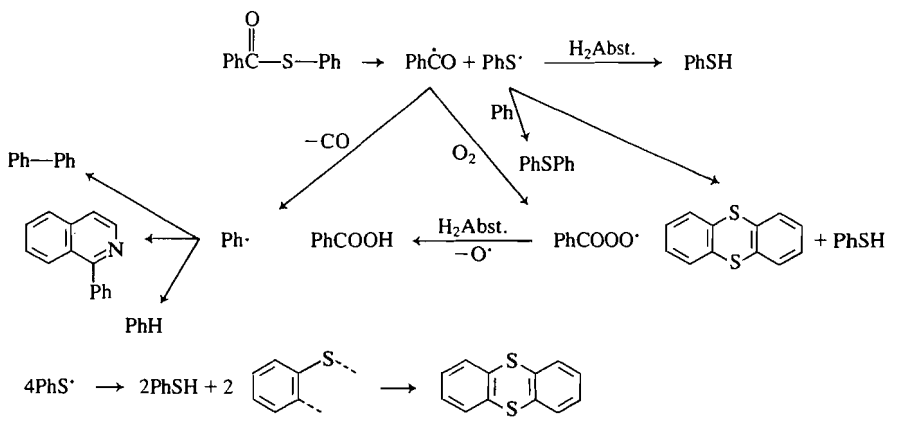


SCHEME 2

On the other hand, the lack of formation of TPT during the pyrolysis of **2** (Expt. 5) may be ascribed to the unavailability of sulphur, as the fission of the Ph—S bond is rather more difficult than that of $PhCH_2-S$ or $C-S$ bonds (8), which indicates a selective C—S bond fission during the thermal decomposition of **2**. Therefore, the benzyl radicals



SCHEME 3



SCHEME 4

formed either directly or from decarbonation of the phenylacetyl radical tend to dimerize to dibenzyl or to abstract hydrogen, forming toluene. The formation of sizeable amounts of dibenzyl indicates a free radical reation (13). The thiophenoxy radical (PhṠ) may abstract hydrogen to thiophenol or undergoes further fragmentation to phenyl radical and sulphur leading to the formation of biphenyl, phenyl sulphide, and benzene. Also, the formation of benzyl phenyl sulphide is not unexpected. However, it undergoes further fragmentation under these conditions (2). As a further confirmation of the role of sulphur in defining the type of products, when benzyl phenylthioacetate (3) was pyrolyzed under the same conditions as previously (Expt. 7), we could not isolate TPT even in trace amounts. Instead, toluene and stilbene were the major products. Of course, all sulphur was consumed in the dehydrogenation of dibenzyl to stilbene. Also, phenylacetic acid was obtained in only 2% yield, which indicates that the decarbonation of the phenylacetyl radical is easier than that of the benzoyl radical (Expts. 1 and 7) and that the benzyl radical may be formed directly. This could be ascribed to the strength of the Ph—C(=O) bond as compared to the PhCH$_2$C(=O) bond and also to the stability of the benzyl radical. Also, the low yield of

[c]Determined by glc analysis of the crude pyrolysate.

benzyl thiol (3%) indicates that route *C* (Scheme 3) is not predominant. Furthermore, a cross experiment (Expt. 8) was conducted with a mixture of **3** and sulphur under the same conditions. As expected, TPT was isolated in 90% yield, in addition to very small amounts of toluene, benzyl thiol, and phenylacetic acid.

Finally, thermolysis of phenyl thiobenzoate (**4**) at 240°C gave a complicated, black, product mixture, together with an amount of tarry matter. However, thermolysis of **4** in isoquinoline made the decomposition controlled and benzene, biphenyl, thiophenol, phenyl sulphide, thianthrene, thiophenol, benzoic acid, and 1-phenylisoquinoline were isolated.

Most probably, rearrangement of **4** takes place after selective fission of the C—S bonds. The formation of thianthrene is expected on the basis of the disproportionation of thiophenoxy radicals (14). Trapping of phenyl radicals (Expts. 4 and 10) and benzyl radicals (Expts. 2 and 9) by means of isoquinoline offers further evidence for the free radical fission of thioesters. Furthermore, it was noticed that no isomer redistribution precedes the

coupling reactions under the reaction conditions used (15).

## Experimental

Melting points were determined on a Kofler melting point apparatus and were uncorrected. Column chromatographic separations were carried out using 100 × 1 cm glass columns packed with neutral alumina using successively petroleum ether (40–60°C), petroleum ether (40–60°C) – petroleum ether (60–80°C) mixtures, petroleum ether (60–80°C), petroleum ether (60–80°C) – benzene mixtures, benzene, benzene–ether mixtures, ether, ether–methanol mixtures, and finally methanol. Thin-layer chromatography was performed using 10 × 3 cm glass plates coated with silica gel. The glc analyses were carried out on a Pye–Unicam apparatus, series 105, using a 5 ft × ¼ in. column packed with SE30 over Chromosorb.

Identification of the products was confirmed using authentic samples, elemental analysis, tlc and/or glc techniques. All molecular rearrangements were carried out in duplicate. Results are given in Table 1.

*Starting materials*

Benzyl thiobenzoate, phenyl phenyl phenylthioacetate, benzyl phenylthioacetate, and phenyl thiobenzoate were prepared as described before (16–18).

It is worthwhile to mention that a number of preliminary experiments were carried out to determine the proper temperature for pyrolysis. However, results showed that the decomposition of **1** and **3** starts only above 220°C and above 230°C for **2** and **4**. Also, it was found that 240°C is the lowest temperature at which the conversion of the thioesters (**1–4**) was complete at the end of pyrolysis.

*General procedure*

The thioester (15 g) was placed in a 50 mL round flask fitted with an efficient reflux condenser (1.5 m length) and heated either alone (Expts. 1, 2, 3, 5, and 7) or in 15 mL isoquinoline solvent (Expts. 4, 6, 9, and 10) using a temperature controlled heating mantle adjusted to the desired temperature. The temperature was measured using a thermometer immersed in the reaction flask. The exit gases were trapped in lead acetate for $H_2S$ and passed over palladium chloride for CO. After decomposition was complete, the pyrolysate was subjected to normal distillation up to 140°C (except in Expt. 3 where the oil bath temperature was raised to 200°C), using a microdistillation system, for separation of low boiling point products such as benzene and/or toluene. Benzene was collected at 75–80°C and its glc analysis showed a single peak at 0.7 min at 90°C, as for an authentic sample, and toluene was collected at 105–110°C and revealed a peak at 1 min at 90°C, comparable with an authentic sample. Benzaldehyde was collected at 175–180°C and showed a peak at 2.8 min at 90°C, as did an authentic sample; mp of 2,4-dinitrophenylhydrazine derivative and mmp 236°C (lit. (19) mp 236°C).

The nondistillable residue was dissolved in ether and the ether solution was extracted with two 10 mL portions of 10% $NaHCO_3$ solution for separation of acids and twice with 10 mL of 5% NaOH solution for separation of thiols. The alkaline extracts were separately neutralized with 2 *N* HCl and the products, acids and thiols, were separated and identified. The acid-free ether solution was resolved either directly by glc and/or column chromatography (Expts. 1, 2, 3, 5, 7, and 9) or separated into neutral and basic products (Expts. 4, 6, 9, and 10) using HCl solution. In Expts. 1, 2, and 3 most of the TPT was separated by filtration as an ether insoluble product and recrystallized from amyl alcohol, mp and mmp 189°C (lit. (20) mp 185°C). The neutral products were eluted from the chromatogram column using the former sequence of eluents. Biphenyl was eluted with petroleum ether (40–60°C), and showed a glc peak at 3.0 min at 140°C, mp and mmp 70°C (lit. (21) mp 71–79°C). Dibenzyl was eluted with petroleum ether (40–60°C) – petroleum ether (60–80°C) mixture (1:2), and showed a single peak at 3.3 min at 140°C, mp and mmp 52°C (lit. (22) mp 52–53°C). Stilbene was eluted with petroleum ether (60–80°C), mp as well as mmp 125°C (lit. (23) mp 124°C). Phenyl sulphide was eluted with petroleum ether (60–80°C) and identified as phenyl sulphone obtained from its oxidation using a $H_2O$ – acetic acid mixture (24), mp and mmp 128°C (lit. (25) mp 128–129°C). Thianthrene was eluted with petroleum ether (60–80°C) – benzene mixture (5:1), mp and mmp 158°C (lit. (26) mp 158–159°C). 2,3,4,5-Tetraphenylthiophene was eluted with petroleum ether (60–80°C) – benzene mixture (1:1), mp and mmp 188°C (lit. (20) mp 185°C). Benzil was eluted with petroleum ether (60–80°C) – benzene mixture (1:2), mp and mmp 96°C (lit. (19) mp 196°C).

The acidic extract was neutralized and the amine fraction was extracted with ether. Ether was evaporated and isoquinoline was distilled at 240°C. The residue was analysed using column chromatography. 1-Phenylisoquinoline (Expts. 4 and 10) was eluted with petroleum ether (60–80°C) – benzene (2:3) mixture, mp and mmp 95°C (petroleum ether (60–80°C), lit. (27) mp 95–96°C); mp of picrates 164°C (ethanol) (lit. (27) mp 165–166°C). 1-Benzylisoquinoline (Expts. 6 and 9) was eluted with petroleum ether (60–80°C) – benzene mixture (1:1), mp and mmp 55°C (lit. (28) mp 56°C); mp of picrates 180°C (lit. (27) mp 182°C). In Expt. 4, the mixture of 1-benzylisoquinoline and 1-phenylisoquinoline was analysed using preparative thin-layer chromatography, $R_f = 0.4$ and 0.6, respectively, and the solvent used was petroleum ether (60–80°C) – benzene mixture (1:1).

*Thermolysis of benzyl phenylthioacetate in the presence of sulphur*

A mixture of benzyl phenylthioacetate (15 g) and sulphur (2 g) was heated for 8 h. The reaction mixture was processed as described before in the general procedure (Expt. 8).

K. HIRAOKA, K. AOYAMA, T. NAKAMURA, S. MOCHIZUKI, K. MITSUMORI, and K. MATSUNAGA. Can. J. Chem. **60**, 2876 (1982).

A study was made on the decomposition of PCB's in a radio-frequency glow discharge plasma. PCB's were completely decomposed in plasmas of a few Torr of oxygen, hydrogen, and water vapor. Gaseous products from PCB's in an oxygen plasma were carbon monoxide, carbon dioxide, water, hydrogen chloride, chlorine, and chlorine dioxide. Hazardous compounds such as phosgene and vinyl chloride were not detected by gc–ms analysis. The total quantity of oxygen flowed past the sample was only about three times the stoichiometric oxygen required for the perfect oxidation of PCB's. In a hydrogen plasma, PCB's gave ethane and isobutane as major gaseous products and several higher hydrocarbons as minor products. Almost all of the chlorine in PCB's was converted to hydrogen chloride. Major products from PCB's in a water vapor plasma were carbon dioxide, carbon monoxide, and hydrogen chloride. No other products were detected. The mechanisms for reactions occurring in plasmas are discussed. The importance of the wall effect for the formation of solid products is discussed.

K. HIRAOKA, K. AOYAMA, T. NAKAMURA, S. MOCHIZUKI, K. MITSUMORI et K. MATSUNAGA. Can. J. Chem. **60**, 2876 (1982).

On a étudié la décomposition du PCB dans un plasma dont l'effluve se situe dans le domaine des fréquences radio. Le PCB se décompose complètement dans des plasmas d'oxygène, d'hydrogène ou de vapeur d'eau sous pression réduite (quelques Torr). Les produits gazeux obtenus dans un plasma d'oxygène sont le monoxyde de carbone, le bioxyde de carbone, l'eau, le chlorure d'hydrogène, le chlore et le bioxyde de chlore. L'analyse par cg–sm n'a pas permis de déceler la présence de produits dangeureux tels le phosgène, et le chlorure de vinyle. La quantité totale d'oxygène qui traverse l'échantillon représente seulement environ le triple de la quantité stochiométrique requise pour réaliser l'oxydation du PCB. Dans un plasma d'hydrogène, le PCB conduit à l'éthane, et à l'isobutane comme produits gazeux principaux et à plusieurs hydrocarbures supérieurs comme produits secondaires. Presque tout le chlore des PCB se transforme en chlorure d'hydrogène. Les produits majoritaires obtenus à partir du PCB dans un plasma d'eau sont le bioxyde de carbone, le monoxyde de carbone et le chlorure d'hydrogène. On n'a pas décelé d'autres produits. On discute des mécanismes des réactions qui se produisent dans les plasmas. On conclut à l'importance de l'effet de paroi lors de la formation de produits solides.

For the decomposition of PCB's, methods using molten salt (1), pyrolysis (2, 3), radiolysis (4–7), photolysis (8), and dechlorination by alkali metal – naphthalene (9) have been reported.

In this study, we attempted to find out whether PCB's could be decomposed in low-temperature glow discharge plasmas. It was found that PCB's were decomposed completely in plasmas of a few Torr pressure of oxygen, hydrogen, and water vapor. In this paper, the results of detailed analyses of decomposition products are given and mechanisms for the decomposition of PCB's in glow discharge plasmas are discussed.

## Experimental

*Samples*

Samples of PCB's were Kanechlor-200 (KC-200) and Kanechlor-500 (KC-500). Their empirical formulae determined by elemental analysis (Perkin-Elmer 240) were $C_{12}H_{7.99}Cl_{2.01}$ and $C_{12}H_{4.81}Cl_{5.19}$, respectively.

The purity of $O_2$ and $H_2$ gases purchased from Nippon Sanso LTD were 99.5% and 99.99999%, respectively.

*Procedure*

A few tenths of a gram of PCB's in a ceramic boat were put in a Pyrex discharge tube with an inner diameter of 10 mm. The pressure of the gas introduced to the vacuum line was controlled by adjusting a needle valve (Nupro 4BM metering valve). The PCB's were decomposed in a glow discharge plasma which was generated by a radio-frequency generator with a maximum power of 50 W. The temperature of the discharge tube in operation was about 200°C. The discharge gas flowed continuously through the discharge tube and then passed through two traps cooled to dry ice – acetone and liquid $N_2$ temperatures and was then pumped away by an oil-rotary pump with a capacity of 150 L/min.

*Product analysis*

The gaseous products in the dry ice – acetone and liquid $N_2$ traps were analysed with a Shimadzu 6APTF gas chromatograph with a thermal conductivity detector. A confirmation of products was performed using an Hitachi 063 gas chromatograph – mass spectrometer. For these analyses, 2 m stainless steel columns packed with Porapak Q (80–100 mesh) and 2,4-dimethylsulfolane (25% supported on Shimalite 60–80 mesh) were used.

The analysis for hydrogen chloride, chlorine, and chlorine oxides was done separately. In alkaline solution, chlorine and chlorides are converted to anions as follows:

$$Cl_2 \rightarrow Cl^- + ClO^-$$

$$HCl \rightarrow Cl^-$$

$$Cl_2O \rightarrow ClO^-$$

$$ClO_2 \rightarrow ClO_2^- + ClO_3^-$$

$$Cl_2O_6 \rightarrow ClO_3^- + ClO_4^-$$

[1]To whom all correspondence should be addressed.

and

$$Cl_2O_7 \rightarrow ClO_4^-$$

Thus quantitative analyses of chlorine, hydrogen chloride, and chlorine oxides could be done by means of the Mohr method and redox titration methods (10, 11) after the gaseous products were dissolved in sodium hydroxide solution or potassium iodide and sodium hydrogencarbonate solutions. The analysis of $ClO_4^-$ was done by means of the Methylene Blue method (12).

*Emission spectra*

The emission spectra of plasmas were measured using a monochromator (Optech GM-N-250) equipped with a light chopper, photomultiplier (Hamamatsu TV, R-446), and lock-in amplifier (NF Circuit Design Block, LI-573). For the measurement of the emission spectra, the plasma was generated by a microwave generator (Ewig Shokai, MR-IIIS, 2450 MHz) with a cavity resonator. The radio-frequency generator could not be used because the noise from the generator was too high for compatibility with the lock-in ac detection.

## Results

*Oxygen plasma*

When 1/10 g of PCB's was subjected to an $O_2$ plasma operating at a pressure of 1.8 Torr (the flow rate is $3.15 \times 10^{-5}$ mol/s), they quickly decomposed into gaseous products in only 5 min. Temporary brownish liquid and solid products formed on the wall of the discharge tube also decomposed easily within 10 min. There was no time difference between KC-200 and KC-500 for their complete decomposition. The only product found in the dry ice – acetone cooled trap was water. The products in the liquid-$N_2$-cooled trap were analysed by gc and gc–ms. The products detected were carbon dioxide and hydrogen chloride. No carbonaceous compounds other than carbon dioxide were detected. On the average, 40% of the carbon content in PCB's was converted to carbon dioxide. The rest (60%) should be converted to carbon monoxide which can not be trapped by a liquid-$N_2$-cooled trap. A small amount of ozone, detected as an oxygen peak in a gas chromatogram, was also a gaseous product from the glow discharge in oxygen.

Chlorine and chlorine dioxide, which were not detected by the gas chromatograph owing to their high reactivities, were confirmed as reaction products by separate experiments as described in the previous section. The yields (mol%) of hydrogen chloride, chlorine, and chlorine dioxide for KC-200 and KC-500 decomposed in a 1.8 Torr $O_2$ plasma were 90, 9, 1 and 78, 21, 1, respectively. The total content of chlorine in these products corresponds almost exactly to that of the PCB sample. No $ClO_4^-$ ion was detected in an alkaline solution of decomposition products; i.e., the amounts of $Cl_2O_6$ and $Cl_2O_7$ were negligible as reaction products.

*Hydrogen plasma*

Contrary to the decomposition of PCB's in an $O_2$ glow discharge plasma, persistent brownish solid products were produced on the wall of the discharge tube when PCB's were subjected to a $H_2$ plasma. The solid products were found to decompose only very gradually but completely within a few hours under continuous stimulation by the $H_2$ plasma.

Figure 1 shows the gas chromatogram of the gaseous products from the decomposition of KC-200 in a plasma at a pressure of 1 Torr of hydrogen, obtained using an Hitachi 063 gc–ms. The gas chromatogram of the gaseous products from KC-500 was very similar to the one shown in Fig. 1. The most probable identification of peaks in Fig. 1 is given in its caption. In parentheses are shown the relative amounts (mol%) of each component. It is worth noting that no chlorinated compounds were detected in the chromatogram; i.e., the conversion of chlorine in PCB's to hydrogen chloride was very efficient (see below). In these experiments, hydrogen chloride, which does not appear in Fig. 1, was removed from the gaseous products by putting solid sodium hydroxide in the liquid-$N_2$-cooled trap in order to protect the apparatus from corrosion.

Figure 2 shows the $H_2$ pressure dependence of the yield of $Cl^-$ ion. The total content of chlorine in the PCB sample is designated to be 100%. In all runs shown in Fig. 2, no $ClO_n^-$ ($n = 1$) ions were detected; i.e., the yield of $Cl^-$ ion corresponds to that of hydrogen chloride. The yields of $Cl^-$ show maxima at about 1 Torr of $H_2$ pressure for both KC-200 and KC-500. The decrease of the yields at lower and higher pressure can be understood as follows. The solid products on the wall of the discharge tube below 1 Torr appeared as a firm deposit, and the lower the pressure, the harder it became to achieve complete decomposition of the solid products. At higher pressures, it was easier to decompose the solid products into gaseous products; however, the flow rate of the hydrogen gas inevitably became faster and some of the solid products were carried away downstream from the plasma region before suffering decomposition into gaseous products. The higher yield of $Cl^-$ for KC-500 than for KC-200 may be due to the slower rate of vaporization of the KC-500 sample. Although complete decomposition of solid products was difficult to attain and the stoichiometry of the conversion of chlorine in PCB's into products was far from adequate in this experiment, the conversion of chlorine in PCB's to hydrogen chloride could be considered very efficient because gaseous

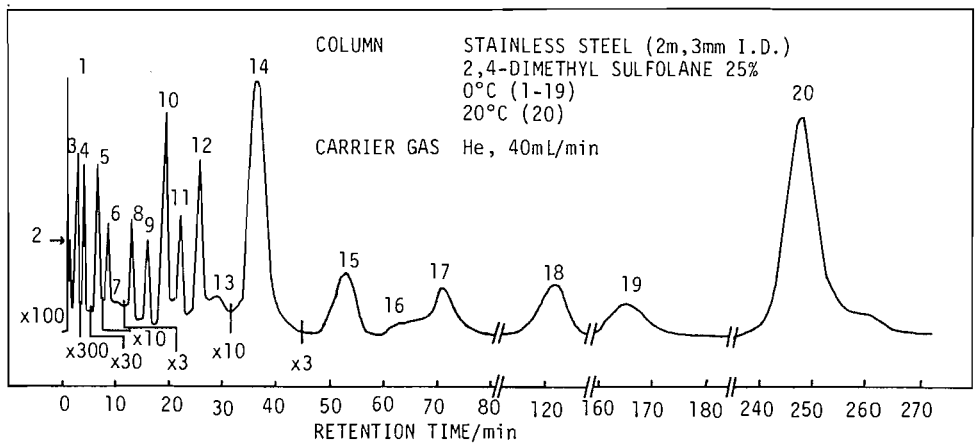

FIG. 1. Gas chromatogram of gaseous products from the decomposition of KC-200 in a plasma of 1 Torr hydrogen. The most probable identification of peaks is given below with the relative amount (mol%) of each component in parentheses: (*1*) ethane (18.0), (*2*) propane (3.6), (*3*) isobutane (7.6), (*4*) butane (43.0), (*5*) 1-pentene (5.8), (*6*) 2-methyl-1-butene (1.1), (*7*) 2-methyl-2-butene (0.1), (*8*) 4-methyl-1-pentene (0.5), (*9*) 1-butyne (0.6), (*10*) cyclopentene (1.2), (*11*) methylcyclopentane (0.6), (*12*) 3-methyl-2-pentene (1.3), (*13*) isopropenylcyclopropane (1.2), (*14*) 4,4-dimethyl-1-pentene (5.2), (*15*) 3-hexene (1.1), (*16*) cycloheptane (0.1), (*17*) 4-methyl-2-hexene (0.5), (*18*) not identified, (*19*) 1,3-butadiyne (2.4), (*20*) benzene (4.6).

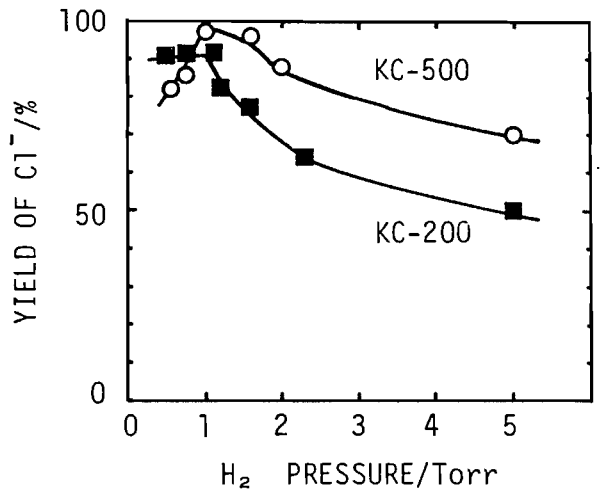

FIG. 2. The hydrogen pressure dependence on the yield of $Cl^-$ ion.

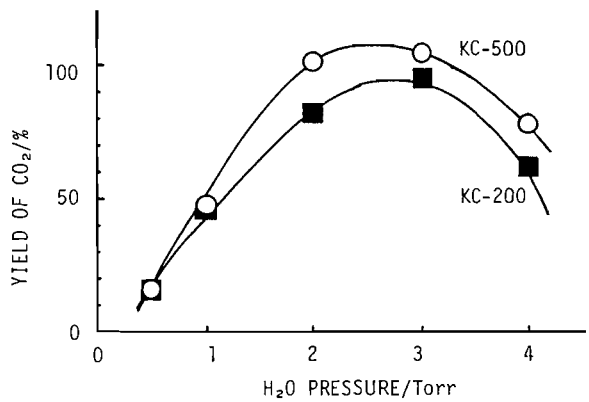

FIG. 3. The $H_2O$ pressure dependence on the yield of $CO_2$ produced from PCB's decomposed in a $H_2O$ plasma. ■: KC-200, ○: KC-500.

products detected by gc–ms did not contain chlorine atoms.

*Water vapor*

Brownish solid products were formed when ~100 mg of PCB's were decomposed in a $H_2O$ plasma as in the case of the $H_2$ plasma. However, it was much easier to decompose the solid products in a $H_2O$ plasma than in a $H_2$ plasma. The solid products could decompose completely within 60 min.

By gc and gc–ms analyses, the only products detected were $CO_2$ and HCl. The pressure dependence of the yield of $CO_2$ is shown in Fig. 3. The total carbon content in the PCB sample is designated to be 100%. Because no carbonaceous compounds other than $CO_2$ were detected by gc and gc–ms, all of the carbon in the PCB's must be converted to carbon monoxide and carbon dioxide.

In Fig. 4 is shown the $H_2O$ pressure dependence of the yield of $Cl^-$ ion. The total content of chlorine in the PCB sample is designated to be 100%. Because the conversion of the chlorine in PCB's to $Cl^-$ was found to be 100 + 2% for all pressures measured and no $ClO_n^-$ ($n \geqq 1$) was detected, almost all of the chlorine in the PCB's was converted to hydrogen chloride.

*Emission spectra*

*$H_2O$ plasma*: CH(4330m).

## Discussion

*Oxygen plasma*

As was mentioned previously, PCB's decomposed completely into gaseous products with a very high efficiency in an $O_2$ glow discharge plasma. The total quantity of oxygen flowed past the sample was only about three times the stoichiometric oxygen required for the perfect oxidation of PCB's. If a high-power radio-frequency generator were used and PCB's were fed continuously into a plasma, we think the present method could be technically applicable to the decomposition of PCB's. This high efficiency suggests that the direct decomposition of PCB's by high-energy electrons in a plasma was one of the major decomposition mechanisms of PCB's as well as the reaction of oxygen atoms with PCB's. In addition, ion/molecule reactions, whose rate constants are generally several orders of magnitude larger than those of neutral/neutral reactions, may play some roles for the dechlorination of PCB's. PCB's have positive electron affinities and thus electron capture by PCB molecules in a plasma would give a considerable concentration of negative molecular ions of PCB's in a plasma. Ion/molecule exchange reactions [1] and [2] involving $O_2$ and $O_2^-$,

[1] $MCl^- + O_2 = MO^- + ClO$

[2] $MCl + O_2^- = MO^- + ClO$

were found important in the negative ion/molecule reactions of chlorinated aromatic compounds and PCB's (13–15). The ClO radical, which can be also formed by the termolecular reaction [3],

[3] $Cl + O + M = ClO + M$

may be the precursor for the formation of $ClO_2$ (16):

[4] $ClO + ClO = ClO_2 + Cl$

Although rate constants have been measured for a number of oxygen atom reactions with aromatic molecules, the products of the elementary reactions are not well defined. Recently, Sloane identified the reaction products of $O(^3P)$ + benzene, toluene, and 1,3,5-trimethylbenzene collisions in molecular beams (17). He observed two product paths for O + benzene: (*1*) the O atom – benzene adduct, which is most likely phenol, and (*2*) carbon monoxide and a $C_5H_6$ hydrocarbon which is probably 3-penten-1-yne. The reactions of oxygen atoms with alkenes have been studied extensively, and CO has always been observed as one of the major products. The major product CO in this experiment must be formed by the reaction of oxygen atoms with various olefinic decomposition products which are formed by the primary reaction of O with PCB's and the dissociation of PCB's by electron impact in a plasma. The oxidation of CO to $CO_2$ must be ascribed mainly to the termolecular reaction [5],

[5] $CO + O + M = CO_2 + M$

where M represents the third-body or the wall.

In this experiment, it was found that the amount of solid products was relatively less than those formed in $H_2$ and $H_2O$ plasmas. As the solid products are formed mainly by the reactions of free radicals, the present experimental results suggest that the relative amount of reactive free radicals is less in an $O_2$ plasma than in $H_2$ and $H_2O$ plasmas. The ground state of an oxygen molecule is a triplet ($^3\Sigma_g^-$) and an $O_2$ molecule can act as a radical scavenger. Thus free radicals in an $O_2$ plasma could be scavenged by oxygen molecules (i.e. the formation of peroxides) and the formation of polymers by radical chain reactions or radical–radical recombination reactions must be more or less inhibited. This might explain why the $O_2$ plasma formed relatively less solid products than $H_2$ and $H_2O$ plasmas.

*Hydrogen plasma*

The efficiency of the decomposition of PCB's in a $H_2$ plasma was much lower than in $O_2$ and $H_2O$ plasmas. However, a gc–ms analysis showed that gaseous products from the decomposition of PCB's in a $H_2$ plasma did not contain chlorine atoms.

Almost all of the chlorine atoms in PCB's were converted to hydrogen chloride. This high yield of hydrogen chloride strongly suggests the very efficient dissociative electron attachment reactions of chlorinated compounds in the plasma.

[6] $MCl + e = M + Cl^-$

The produced $Cl^-$ ion would be rapidly converted to HCl in a hydrogen plasma by reaction [7],

[7] $Cl^- + H = HCl + e$

whose rate constant is very large ($0.96 \times 10^{-9}$ $cm^3$/molecule s) (18). We would like to suggest that the electron attachment reaction plays an important role for the dechlorination of PCB's in all of $O_2$, $H_2$, and $H_2O$ plasmas.

The optical radiation emitted by the $H_2$ plasma at a pressure of a few Torr contained an intense continuous spectrum in the ultraviolet region. The uv radiation may make some contribution to the decomposition of PCB's in a $H_2$ plasma. In addition, the uv radiation is strongly absorbed by solid products on the wall of the discharge tube where the polymer free radicals must be formed. The polymer free radicals are further cross-linked to form a three-dimensionally rigid solid. This may be the reason why the solid products formed in a $H_2$ plasma are quite stable against the continuous stimulation by a plasma.

*Water vapor plasma*

It was found that the decomposition of PCB's in a $H_2O$ plasma was quite efficient. The primary reactive radicals formed in a $H_2O$ plasma are OH and H. The recombination reaction [8] of two OH radicals produces an O atom.

[8] $OH + OH = H_2O + O$

Thus the major active species in a $H_2O$ plasma are considered to be H, OH, and O radicals. The decomposition of PCB's in a $H_2$ plasma was much slower than that in a $H_2O$ plasma. Thus the OH and O radicals must play important roles for the decomposition of PCB's in a $H_2O$ plasma. For the reactions with arenes, the rate constants of OH are one to two orders of magnitude larger than those of O. Perry *et al.* (19) suggested that the addition of the OH radical to the aromatic ring was a dominant path at low temperatures, and that hydrogen atom abstraction was more important at higher temperatures.

When PCB's were decomposed in plasmas of $H_2$ and $H_2O$, $Cl_2$ was not detected as a decomposition product. The $Cl_2$ molecule will be formed mainly by reaction [9].

[9] $Cl + Cl + M = Cl_2 + M$

One of the reactions which is a source of Cl radicals is the reaction of H with HCl; i.e., it consumes HCl.

[10] $H + HCl = H_2 + Cl$ (slow)

However, $Cl_2$ molecules when produced are quickly decomposed by the fast reaction [11].

[11] $H + Cl_2 = HCl + Cl$

As $Cl_2$ was one of the major products from PCB's decomposed in an oxygen plasma, the absence of $Cl_2$ for the case of $H_2$ and $H_2O$ plasmas must be due to the existence of hydrogen atoms in $H_2$ and $H_2O$ plasmas.

The strong $H_2O$ pressure dependence of the yield of $CO_2$ (Fig. 3) was not well understood. Because CO can be oxidized in a $H_2O$ plasma by reaction [12],

[12] $CO + OH = CO_2 + H$

the observed pressure dependence may be correlated with the relative concentration of OH radicals in the plasma.

The degradation of PCB's in water by ionizing radiation has been undertaken at several institutes (20). It was suggested that OH radicals in water play an important role for the decomposition of PCB's. The addition of a OH radical to the aromatic ring must be much more favorable than a hydrogen abstraction reaction in the liquid phase because the internal energy of adducts is efficiently absorbed by the medium. Thus low concentrations of PCB's in water can be made water soluble (i.e. less lipid-soluble) by the introduction of hydrophilic hydroxyl groups into PCB's — and consequently are unlikely to bioaccumulate — by bombardment with high-energy electrons.

*Wall effect*

The properties of polymeric films produced in various types of plasmas such as chemical inertness, good adhesion to the substrate, and ease and versatility of preparation could lead to important practical applications. However, the formation of nonvolatile polymeric solid films during the decomposition of PCB's in $O_2$, $H_2$, and $H_2O$ plasmas was apparently an undesirable result because the decomposition of solid films was the rate-controlling step for the complete decomposition of PCB's into gaseous products. In view of the large number of elementary reactions taking place in an electric discharge, the formulation of a mechanism for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

polymer formation and the verification of this mechanism are very difficult tasks to accomplish. It is worth noting that the polymeric solid films were produced only on the part of the discharge tube *which was in contact with the plasma flame*. If the polymeric solids were formed in the gas phase, they should also deposit downstream from the plasma region because the flow rate of gas in the discharge tube was quite high (5–10 m $s^{-1}$). Therefore the wall itself must play a very important role for the formation of polymeric solid films on the wall of the discharge tube. Because the electron temperature is very much higher than the gas and ion temperatures in a low-temperature glow discharge plasma,[2] the wall which is in contact with the plasma becomes negatively charged under steady state conditions. The potential difference between the wall and the plasma (namely the ion sheath potential) keeps the net current (due to electrons and positive ions) to the wall zero. When the positive ions pass through the ion sheath,[3] they are accelerated and gain maximum kinetic energy corresponding to the sheath potential, which may be roughly estimated as 10 eV or even more (21) under the present experimental conditions. Some of this energy is dissipated through chemical effects such as the production of free radicals on the surface of the film. This leads to the continuous growth of polymers by the reactions of radicals with radicals and molecules. In brief, we think that the major process for the formation of polymeric solids is the bombardment of the solid surface by high-energy ions as well as electrons.

The rate of decomposition of solid products formed in an $O_2$ plasma was much faster than that in $H_2$ and $H_2O$ plasmas. This suggests the existence of chemical effects for the decomposition of solid products. If physical effects involving high-energy ions and electrons such as the ablation of solid products were important for the decomposition of solid products, the rate for the decomposition of solid products should not be very different amongst $O_2$, $H_2$, and $H_2O$ plasmas. When the temperature of the discharge tube was kept at room temperature by circulating water outside the discharge tube,[4] it took hours to decompose the solid products even in an $O_2$ plasma. This result clearly indicates that there is an activation energy for the decomposition reaction of solid products. This means that oxygen atoms play an important role for the decomposition of solid products in an $O_2$ plasma, because reactions of high-energy ions with solid products or an action of electrons should not show such a marked temperature dependence. From these results, we would like to conclude that for the formation of solid products, the high-energy ions and electrons play important roles, but for the decomposition of solid products, chemically reactive radicals play important roles.

According to the positive column theory (22), the electron temperature $T_e$ in a plasma is determined by the product of the radius of the discharge tube $r$ (or more appropriately the diffusion length $\Lambda$) and the gas pressure $p$; i.e., $T_e$ is a function of $pr$. The electron temperature will decrease with an increase in the value of $pr$; i.e., the plasma condition becomes milder with an increase in $pr$. Thus in order to suppress the formation of three-dimensionally cross-linked rigid products which are hard to decompose, a discharge tube with a larger radius and a higher gas pressure should be used because the ion sheath potential $V_s$ is a function of the electron temperature $T_e$,

$$[13] \quad V_s = \frac{kT_e}{2e} \ln \frac{T_e M}{T_p m}$$

where $k$ is the Boltzmann constant, $M$ the mass of an ion, $T_p$ the ion temperature, $m$ the electron mass, and $e$ the electron charge. With a decrease of the electric power of the generator, the electron and ion densities will decrease, but $T_e$ and $V_s$ stay almost constant because $T_e$ is only dependent on the value of $pr$.

[2]Under the present experimental conditions, the electron temperature may be around 4 eV. The ion temperature in a plasma is very close to the gas temperature (i.e. the temperature of the discharge tube). See ref. 21.

[3]The thickness of an ion sheath can be approximated as the same order of the Debye length under the present experimental conditions, which is of the order of $10^{-3}$ to $10^{-2}$ cm.

[4]For this experiment, a coaxial cylindrical discharge tube was used.

# Temperature and concentration dependence of viscosity of $Mg(NO_3)_2$–$H_2O$ systems

S. MAHIUDDIN AND K. ISMAIL[1]

*Department of Chemistry, North-Eastern Hill University, Bijni Complex, Laitumkhrah, Shillong-793003, India*

Received January 7, 1982

S. MAHIUDDIN and K. ISMAIL. Can. J. Chem. **60**, 2883 (1982).

Densities and viscosities of aqueous magnesium nitrate solutions are measured as functions of temperature and composition. The temperature dependence of viscosity is described by the Vogel–Tammann–Fulcher (VTF) equation. By accounting quantitatively for the concentration dependences of all three parameters involved in the VTF equation an improved isothermal equation is obtained, it describes satisfactorily the concentration dependence of viscosity.

S. MAHIUDDIN et K. ISMAIL. Can. J. Chem. **60**, 2883 (1982).

On a mesuré, en fonction de la température et de la composition, les densités et les viscosités de solutions aqueuses de nitrate de magnésium. On décrit l'effet de la température sur la viscosité à l'aide de l'équation de Vogel–Tammann–Fulcher (VTF). En tenant compte quantitativement de l'effet de la concentration sur chacun des trois paramètres impliqués dans l'équation de VTF, on obtient une équation isotherme appropriée qui décrit d'une façon satisfaisante l'effet de la concentration sur la viscosité.

## Introduction

It is known that in electrolyte solutions all empirical expressions (1–3) fail to explain the concentration dependence of viscosity at higher concentrations. At these concentrations, the viscosity data satisfactorily fit only Vand's (4) and similarly derived equations (5–8) but it is not clear why they work as well as they do.

One of the approaches being used to obtain an isothermal equation for explaining the concentration dependence of transport properties in glass-forming molten mixtures (9–11) is by substituting the empirical concentration dependences of the three parameters, $A$, $B$, and $T_0$, in the VTF equation (12)

$$[1] \quad \eta = AT^{1/2} \exp B/(T - T_0)$$

where $\eta$ is the viscosity and $T$ is the absolute temperature.

Angell and Bressel (13) extended this approach used in glass-forming molten mixtures to the $Ca(NO_3)_2$–$H_2O$ system and interestingly found that a Vand's type equation could be derived from eq. [1]. However, in getting the isothermal equation from [1] the concentration dependence of $A$ was completely ignored and that of $B$ was partly considered. Therefore, it is possible to improve the isothermal equation obtainable from eq. [1] by accounting appropriately for the concentration dependences of the $A$ and $B$ parameters of electrolyte solutions.

In an earlier paper (14) we derived eq. [1] from the Adam–Gibbs equation (15) after proper substitution for the temperature dependence of configurational heat capacity. Such a study has provided expressions for $A$ and $B$ according to which

$$[2] \quad A = A_0 \exp(-B_1/C_1T_0)$$

and

$$[3] \quad B = (B_1/C_1)(1 - C_2T_0/C_1)$$

$A_0$, $B_1$, $C_1$, and $C_2$ are all constant parameters for a particular system. $C_1$ is the difference in the heat capacities of glass and liquid at $T_0$. $C_2$ is the difference in the slopes of the plots of heat capacity versus $T$ for the glassy and liquid states. From eqs. [2] and [3] it is apparent that a quantitative description for the concentration dependences of $A$ and $B$ is possible.

In this paper we have studied the viscosities of aqueous magnesium nitrate solutions with concentration ranging from dilute to saturation point with a view to obtain an improved isothermal equation by incorporating, in light of eqs. [2] and [3], the concentration dependences of $A$ and $B$ also.

## Experimental

BDH(analar) grade magnesium nitrate hexahydrate was used in preparing all solutions. The water used was doubly distilled in a quartz distilling unit. The exact concentrations were volumetrically determined at 25°C by the EDTA titration method. Solutions having concentrations ranging between $0.0917m$ ($m$ = molality) and $6.3682m$ (nearly the saturation point at 50°C) were studied.

The viscosity measurements were made using a Hoppler BH-2 falling ball viscometer with an accuracy of 0.5%. In this viscometer, since the solution was sealed, the loss of water at high temperatures was prevented. The densities, $\rho$, of the solutions required for calculating their viscosities were measured accurate to 0.01% using a calibrated pycnometer.

All measurements were made in a thermostated water bath of stability ±0.02° (Ultra Thermostat type NBE) and at temperatures ranging from 17 to 89°C.

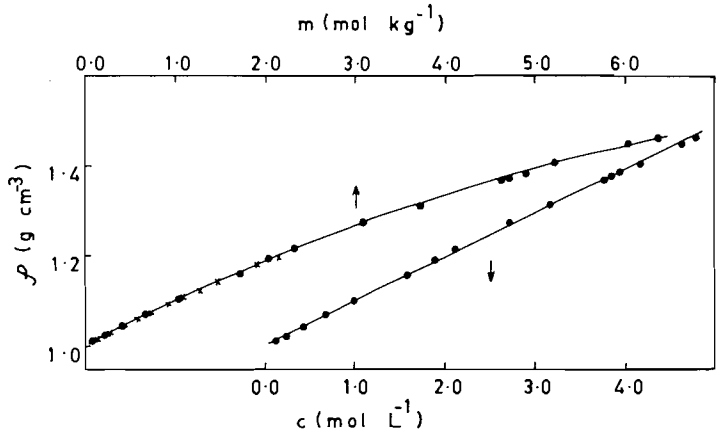

FIG. 1. Plots of densities of $Mg(NO_3)_2$–$H_2O$ systems at 20°C versus molality and molarity of $Mg(NO_3)_2$ (●, observed; ×, reported).

## Results and discussion

The measured densities of the magnesium nitrate solutions are found to be linear functions of temperature (Table 1) whereas their dependence on molality does not exhibit a linear relationship. Surprisingly, for the dependence of density on molarity, $c$ is found to be linear in the concentration range studied. Such dependences of ρ on concentration are illustrated in Fig. 1 by plotting ρ versus $m$ and ρ versus $c$ isotherms at 20°C. From Fig. 1 it may also be noted that the reported values (16) of densities of a few magnesium nitrate solutions at 20°C are in good agreement to within ±0.3% of the present values.

The measured viscosities of aqueous magnesium nitrate solutions are presented as Arrhenius plots in Fig. 2. The non-Arrhenius temperature dependences of η are therefore least-squares fitted to eq. [1]. The values of the parameters $A$, $B$, and $T_0$ so obtained are listed in Table 2.

It is clear from several studies (2, 8) that the viscosity of an electrolytic solution is governed by two types of interactions occurring in the solution, viz., ion–ion and ion–solvent. The contribution to viscosity from ion–ion interaction is described by a $c^{1/2}$ term and that due to ion–solvent or solute–solvent interaction shows an exponential dependence on concentration. It has been observed empirically that the contribution of the $c^{1/2}$ term is significant only at very low concentrations whereas at higher concentrations the exponential term due to the solute–solvent interaction dominates. Therefore, the variations occurring in the values of $A$, $B$, and $T_0$ as a function of concentration are considered to be governed predominantly by the solute–solvent interactions. Accordingly, an attempt has been made here to correlate first the variations produced in $T_0$ with the hydration phenomenon.

Hydration of the solute particles will cause the system to lose some of its configurational degrees of freedom, thereby resulting in a decrease of the configurational entropy, $S_c$, of the system. As the concentration increases $S_c$ will therefore keep on decreasing. Since $T_0$ is the temperature at which $S_c$ becomes zero, $T_0$ must increase with increase in concentration. Accordingly, $T_0$ can be related to the probability, $p$, of finding a solvent particle in the hydration shells of the solute particles which, of course, increases by increasing concentration because $p = nm/55.51$ where $n$ is the total hydration number of the solute. Consequently, the values of $T_0$ are drawn against $m$ and a linear plot is obtained (Fig. 3$a$), reflecting the dependence of $T_0$ on the hydration phenomenon of the solute. The observed

| 5.2393 | 35.0–89.0 (5.16–2.06) | 7.9671 | 508.96 | 167.0 | $4.80 \times 10^{-4}$ |
| 6.0371 | 50.0–81.5 (4.73–2.81) | 8.1115 | 530.15 | 171.5 | $9.24 \times 10^{-4}$ |
| 6.3682 | 50.0–89.4 (5.32–2.74) | 7.9414 | 542.63 | 174.0 | $1.26 \times 10^{-3}$ |

concentration dependence of $T_0$ can therefore be written as

$$[4] \quad T_0 = T_0(0) + Q_1 m$$

where $T_0(0)$ refers to the $T_0$ value of the pure solvent and $Q_1$ is the slope. The least-squares fitted (standard deviation in $T_0$ = 0.64) values of $T_0(0)$ and $Q_1$ are found to be 133.48 K and 6.4441 K mol$^{-1}$ kg, respectively. It may be noted that the value 133.48 K for $T_0$ of water is in agreement with the glass transition temperature, $T_g$ (139 K) reported for amorphous solid water (17). Moreover, the reported (9) $T_0$ values of a few concentrated $Mg(NO_3)_2$–$H_2O$ systems based on their equivalent conductance data are in agreement to within ±5 K of the values of $T_0$ obtained by extrapolating the plot of $T_0$ versus $m$ (Fig. 3*a*) to the corresponding concentrations.

After accounting quantitatively for the concentration dependence of $T_0$, that of $A$ can easily be described in light of eq. [2]. A plot of ln $A$ versus $1/T_0$ is made (Fig. 3*b*) and it is found to be linear. The linearity of such a plot envisages the applicability of eq. [2] for describing the concentration dependence of $A$ and also reveals that the $B_1/C_1$ value is fairly constant in the concentration range studied. The least-squares fitted (standard deviation in ln $A$ = 0.09) values of ln $A_0$ and $B_1/C_1$ are found to be 2.3022 and 1208.2, respectively.

On the other hand, the $B$ parameter, without showing a monotonous variation, decreases initially with increase in concentration up to 4.63$m$ and

| | 0.0917–5.2393 (0.7366–5.1554) | 0.7225 | 0.2967 | 14.3718 | $1.24 \times 10^{-2}$ |
| 323.0 | 0.0917–4.6299 (0.5692–2.7998) | 0.5581 | 0.2911 | 12.4280 | $1.03 \times 10^{-2}$ |
| | 0.0917–6.3682 (0.5692–5.3209) | 0.5476 | 0.3218 | 6.5556 | $2.71 \times 10^{-2}$ |

then increases (Table 2). The plot of $B$ versus $T_0$ is shown in Fig. 3*c*. According to eq. [3] the decrease in value of $B$ is attributable to the increase in value of $T_0$ as concentration increases. The linearity of the plot (Fig. 3*c*) implies that $C_2/C_1$ is almost constant up to $4.63m$. Both $C_1$ and $C_2$ have been found by Angell and Tucker (18) to decrease with increasing concentration for electrolyte solutions. Therefore, the constancy of $C_2/C_1$ must be due to the same rates of decrease of $C_1$ and $C_2$ up to $4.63m$, whereas the observed increase in $B$ beyond $4.63m$ appears to be attributable to the fact that, at these concentrations, the value of $C_2$ becomes very low. It may be governing the value of $C_2T_0/C_1$, causing a decrease in the value of this ratio with increase in concentration. These trends of $C_2/C_1$, viz., constancy up to $4.63m$ and then decrease, are also verified by calculating its values with the knowledge of $B$, $T_0$, and $B_1/C_1$ from the slope of Fig. 3*b*. This kind of behaviour of $B$ appears to imply a structural change around $4.63m$ which may be a transition to quasi-crystalline structure.

With the concentration dependences of $A$, $B$, and $T_0$ having been discussed, it is now possible to describe quantitatively the overall concentration dependence of η by the expression

$$[5] \quad \eta = A_0T^{1/2} \exp\left\{\frac{B_0[1 - Q_2(T_0(0) + Q_1m)]}{T - (T_0(0) + Q_1m)} - \frac{B_0}{T_0(0) + Q_1m}\right\}$$

where $B_0 = B_1/C_1$ and $Q_2 = C_2/C_1$. The values of $B_0$ and $Q_2$ are, of course, different below and above $4.63m$. By approximating $1/[T - T_0(0) - Q_1m]$ to $[1 + Q_1m/(T - T_0(0))]/(T - T_0(0))$ and $1/(T_0(0) + Q_1m)$ to $[1 - Q_1m/T_0(0)]/T_0(0)$, eq. [5] can be reduced to a simple isothermal expression of the form

$$[6] \quad \eta = A_0' \exp(b'm + c'm^2)$$

where $A_0'$, $b'$, and $c'$ are constants at a particular temperature. In fact, $A_0'$, $b'$, and $c'$ will have different values below and above $4.63m$. However, an attempt has been made to fit the viscosity data to eq. [6] in both concentration ranges $0.0917m$ to $4.6299m$ and $0.0917m$ to saturation point. It is apparent from Table 3 that in both concentration ranges the least-squares fittings are equally satisfactory. Moreover, the linearity of the plot of log η versus $b'm + c'm^2$ (Fig. 4) also reinforces the applicability of eq. [6] in explaining the concentration dependence of viscosity in the entire concentration range studied.

Finally, it is interesting to find that by neglecting the contribution of the $c'm^2$ term eq. [6] can be brought to the form of Vand's (4) as well as Angell

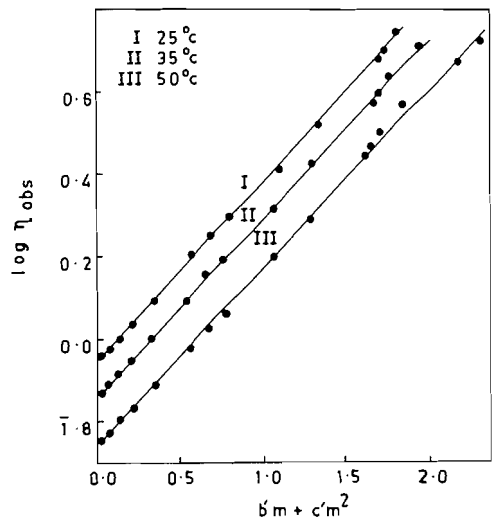

FIG. 4. Plots of log η versus $b'm + c'm^2$ for $Mg(NO_3)_2$–$H_2O$ systems (I: $b' = 0.3166$, $c' = 11.6670 \times 10^{-3}$; II: $b' = 0.2967$, $c' = 14.3718 \times 10^{-3}$; III: $b' = 0.3218$, $c' = 6.5556 \times 10^{-3}$).

and Bressels' (13) equations using the relations of $m$ with molarity and mol%. It may, therefore, be concluded that eq. [6] is an improved isothermal equation for describing the composition dependence of viscosity in aqueous solutions.

# Attraction and repulsion of floating particles

M. A. FORTES

*Departamento de Metalurgia, Instituto Superior Técnico; Centro de Mecânica e Materiais da Universidade Técnica de Lisboa, Av. Rovisco Pais, 1096 Lisboa Codex, Portugal*

Received March 17, 1982

M. A. FORTES. Can. J. Chem. **60**, 2889 (1982).

The horizontal force that has to be applied to floating cylinders to equilibrate the capillary force is calculated for a general geometry with cylindrical symmetry and for any wetting characteristics of the cylinders. The force on a cylinder can be related to a single parameter of each of the two menisci that contact the cylinder. It is found that the force between parallel vertical plates or parallelipipeds can be repulsive if one of the contact angles is acute and the other obtuse. The force on cylinders between fixed walls is also calculated and the results suggest that it may be possible to separate floating particles with different wetting properties by placing them between two walls with different contact angles.

M. A. FORTES. Can. J. Chem. **60**, 2889 (1982).

On a calculé la force horizontale que doit être appliquée à des cylindres flottants pour équilibrer les forces capillaires, pour une géométrie générale avec une symétrie cylindrique et pour n'importe quelle caractéristique de mouillage des cylindres. On peut relier la force sur un cylindre à un paramètre unique pour chacun des deux ménisques qui sont en contact avec le cylindre. On a trouvé que les forces entre les plaques verticales parallèles ou parallèlépipèdes peuvent être répulsives si un des angles de contact est aigu et l'autre obtu. On a également calculé la force qui s'exerce sur le cylindre entre deux parois fixes; les résultats suggèrent qu'il est possible de séparer des particules flottantes ayant des propriétés différentes de mouillage en les plaçant entre deux parois avec des angles de contact différents.

[Traduit par le journal]

## 1. Introduction

It is frequently observed that particles floating at the surface of a liquid at rest are submitted to forces which in most cases tend to produce clusters of particles. These may be either attracted to a wall or find an equilibrium position near the centre of the surface. These effects are due to the horizontal component of the capillary forces associated with the curved liquid surface. The calculation of such forces requires the determination of the equilibrium shape of the liquid surface (more generally of a fluid interface) by solving the Laplace differential equation submitted to the appropriate boundary conditions, for example, a constant contact angle of the liquid with the solid particles. When gravity is included, the only geometry for which the shape of the fluid interface can be determined in closed form is one with cylindrical symmetry. Gifford and Scriven (1) have analysed this situation for two "parallel" identical circular cylinders in free flotation and were able to determine the horizontal force as a function of separation by taking into account the vertical displacement experienced by the cylinders as their separation changes. They have assumed, however, that the arc wetted on each cylinder remained constant, instead of considering a constant contact angle; therefore they were not able to draw conclusions on the effect of wetting characteristics on the horizontal force. Under those conditions the (attractive) force was found to fall off nearly exponentially with separation. More recently, Chan *et al.* (2) found a similar variation for the case of two free floating spheres. They used approximate solutions for the Laplace equation, applicable to small Bond numbers (small particles). Again no special attention was given to the effect of the wetting properties of the floating bodies on the horizontal force.

The purpose of this paper is to analyse, for a cylindrical geometry, the effect of the wetting characteristics on the horizontal force between two or more floating bodies. The vertical component of the capillary forces will not be included in the analysis, that is, the positions of the floating bodies relative to some reference level are imposed by externally applied vertical forces. To simplify the treatment we shall assume frequently that the bodies are plates or prisms such that the wetted surfaces are planar and vertical. However, application to other geometries is straightforward. The analysis is a static one, as in previous treatments (1, 2), in that equilibrium of the bodies is always assumed; what is calculated is in fact the horizontal force that must be applied to the bodies to maintain equilibrium.

In section 2 we obtain the relevant equations for the fluid interface profile and in section 3 we derive general expressions for the horizontal force. It turns out that this force can be simply related to a single parameter of each of the two menisci contact-

ing a floating cylinder. Examples of calculation of such forces between two cylinders or between a cylinder and the walls of a container are given in section 4, which show the effect of wetting properties. These calculations further suggest that in favourable cases it may be possible to separate floating particles of two different materials by placing them between two parallel walls with properly chosen contact angles.

## 2. Shape of the fluid interface

We use cartesian coordinates $x$, $z$, as in Fig. 1, with the origin at the point of contact of the fluid interface with the solid; $x$ is horizontal and $z$ vertical directed in such a way that the profile is in the region $x > 0$, $z > 0$ near the origin; therefore

$$\dot{z} = dz/dx > 0$$

in this region. There are four possibilities, indicated in Fig. 1, as regards the sign of $\ddot{z}$ near the origin and the direction of $z$ relative to that of $\boldsymbol{g}$ (the gravity acceleration). Let $\rho_0$ be the radius of curvature at the origin, with the sign of $\ddot{z}$ at or near the origin; $\gamma$ is the fluid interface tension and $\Delta\rho(> 0)$ is the difference between the densities of the two fluids. By noting the way the pressure difference across the interface varies with $z$, it is easy to conclude that the Laplace equation can be written as

$$[1] \quad \pm\gamma\frac{\ddot{z}}{(1+\dot{z}^2)^{3/2}} = \frac{\gamma}{\rho_0} + g\cdot\Delta\rho\cdot z$$

where the + sign applies to the profile region between the origin and the point (if it occurs) with $\dot{x} = dx/dz = 0$, and the − sign "after" this point. To integrate eq. [1] we first note that

$$[2] \quad \frac{\ddot{z}}{(1+\dot{z}^2)^{3/2}} = \mp\frac{\ddot{x}}{(1+\dot{x}^2)^{3/2}} = \mp\frac{d}{dz}\left[\frac{\dot{x}}{(1+\dot{x}^2)^{1/2}}\right]$$

where the − sign applies if $\dot{x} > 0$. Introducing the capillary constant, $a$, defined by

$$[3] \quad a^2 = \frac{\gamma}{g\cdot\Delta\rho}$$

and the adimensional quantities $X$, $Z$ (reduced cartesian coordinates) and $R$ (reduced radius of curvature of meniscus)

$$[4] \quad X = \frac{x}{a}; \quad Z = \frac{z}{a}; \quad R_0 = \frac{\rho_0}{a}$$

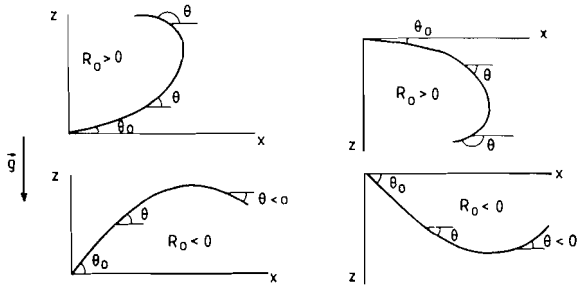

FIG. 1. Orientation of the coordinate system $x$, $z$ and definition of the angle $\theta$; $g$ is the gravity acceleration.

we may put [1] in the form

$$[5] \quad -\frac{d}{dZ}\left[\frac{\dot{X}}{(1+\dot{X}^2)^{1/2}}\right] = \frac{1}{R_0} + Z$$

applicable in the region with $\dot{X} > 0$. In other regions the − sign may have to be replaced by +. But

$$[6] \quad \frac{\dot{X}}{(1+\dot{X}^2)^{1/2}} = \cos\theta$$

where $\theta$ ($-\pi \le \theta \le \pi$) is the angle defined in Fig. 1 between the profile and the $X$-axis. If $\theta_0$ ($0 \le \theta_0 \le \pi/2$) is the value of this angle at the origin we obtain upon integration of [5]:

$$[7] \quad \cos\theta_0 - \cos\theta = \frac{Z}{R_0} + \frac{Z^2}{2}$$

It is easy to see that, with the definition of $\theta$ given above, this equation applies to the entire profile.

Equation [7] can be integrated to obtain $X(Z)$. Writing

$$[8] \quad \cos\theta = \cos\theta_0 - \frac{Z}{R_0} - \frac{Z^2}{2} = f(Z)$$

we obtain

$$[9] \quad X = \int_0^Z \frac{f(Z)}{(1-f^2(Z))^{1/2}}\,dZ$$

The integral may have to be decomposed if $\dot{X}$ changes sign. Introducing a new variable $\phi$ defined by

$$[10] \quad \phi = \frac{\pi}{2} - \frac{\theta}{2}$$

the integral [9] can be put in the form

$$[11] \quad \pm X = 2\int_{\phi_0}^{\phi}\sqrt{1-k^2\sin^2\phi}\,d\phi - (2-k^2)\int_{\phi_0}^{\phi}\frac{d\phi}{\sqrt{1-k^2\sin^2\phi}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

with the meniscus constant $k$ defined as

$$[12] \quad k = \left(\frac{2}{1 + \cos\theta_0 + 1/2R_0^2}\right)^{1/2} = \left(\frac{2}{2 + I}\right)^{1/2}$$

The + sign applies if $R_0 > 0$ ($\phi < \phi_0$ in the initial region) and the − sign if $R_0 < 0$ ($\phi > \phi_0$). Equation [11] is applicable in all cases. Introducing elliptic integrals of the first ($F$) and second ($E$) kind we obtain (3)

$$[13] \quad I > 0 \quad \pm kX = (2 - k^2)[F(\phi_0, k) - F(\phi, k)] - 2[E(\phi_0, k) - E(\phi, k)]$$

$$[14] \quad I < 0 \quad \pm X = F(\alpha_0, 1/k) - F(\alpha, 1/k) - 2[E(\alpha_0, 1/k) - E(\alpha, 1/k)]$$

where

$$[15] \quad \alpha = \arcsin(k \sin\phi)$$

For $I = 0$ ($k = 1$) the solution for $\theta > 0$ is

$$[16] \quad \pm X = G(\phi_0) - G(\phi)$$

where

$$[17] \quad G(\phi) = 2\sin\phi - \ln \operatorname{tg}\left(\frac{\phi}{2} + \frac{\pi}{4}\right)$$

For $\theta < 0$, $X$ is obtained as the sum of $X(\theta = 0)$ with $X(|\theta|)$.

Equation [12] incidentally shows that the quantity $\cos\theta + 1/(2R^2)$, where $\theta$, $R$ are the values at any point of a profile, is constant for each profile. This property is a direct consequence of eq. [2]. We may then introduce the quantity $I$ (cf. eq. [12]), the invariant of a meniscus, defined as

$$[18] \quad I = -1 + \cos\theta + \frac{1}{2R^2} = \text{constant}$$

and state that the various solutions form a one-parameter, $I$, family of curves. Since at the origin $\cos\theta_0 \geq 0$, the parameter $I$ may vary in the interval $[-1, +\infty]$. (As discussed below, for every $I$ there are in fact two solutions which are the mirror image of each other on a vertical or horizontal plane, according to the cases.)

We will now show that the solutions can be grouped into two types, which we term $a$-solutions (or $a$-menisci) and $i$-solutions (or $i$-menisci). The $a$-solutions have an apex (or $a$-point) $\dot{Z} = 0$, $\theta = 0$. (Note that all solutions have a point with $\dot{Z} = 0$, $\theta = \pi$ at the end of the region with $\dot{Z} < 0$.) The condition for an $a$-solution can be obtained from eq. [7], by making $\theta = 0$ and requiring that there is a solution for $Z$, with the result

$$[19] \quad I = \frac{1}{2R_0^2} + \cos\theta_0 - 1 \geq 0 \qquad (\dot{Z} = 0, \theta = 0)$$

The $i$-solutions have an inflection point ($i$-point), $\ddot{Z} = 0$. At this point $Z = -1/R_0$ (eq. [1]) and necessarily $0 < \cos\theta \leq 1$; eq. [7] then gives the following condition for an $i$-solution:

$$[20] \quad I = \frac{1}{2R_0^2} + \cos\theta_0 - 1 \leq 0 \qquad (\ddot{Z} = 0)$$

Both the $a$-point or the $i$-point may not be in the region with $Z > 0$. This will occur only for $R_0 < 0$.

The two types of solutions are schematically indicated in Fig. 2 up to the points with $\dot{Z} = 0$, $\theta = \pi$. Each $a$-solution can be characterized by the value, $R_a$, of the reduced radius of curvature at the apex; and each $i$-solution by the value of $\theta_i$ ($0 \leq \theta_i \leq \pi/2$), the slope at the $i$-point. Using the property [18] we have

$$[21] \quad I = -1 + \cos\theta_0 + \frac{1}{2R_0^2} = \frac{1}{2R_a^2} \quad (a\text{-solution})$$

$$[22] \quad I = -1 + \cos\theta_0 + \frac{1}{2R_0^2} = \cos\theta_i - 1 \quad (i\text{-solution})$$

For the purposes of computation it is convenient to place the origin at the $a$-point or $i$-point, as in Fig. 2, and obtain the curve $X(Z)$ from eqs. [7],

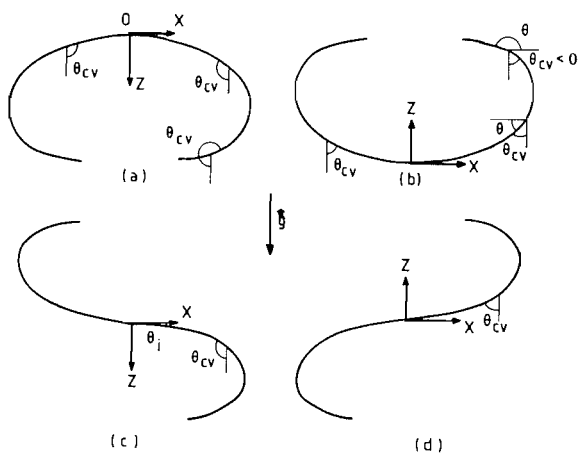

FIG. 2. Examples of $a$-solutions ($a$, $b$) and $i$-solutions ($c$, $d$). The coordinate system indicated is appropriate to the r.h.s. of the curves; the origin is at the $a$-point or $i$-point. The angle $\theta$ and the vertical contact angle $\theta_{cv}$ at various points are also indicated; $a$-solutions are even and $i$-solutions are odd.

[13], and [14], with θ in the interval 0, π. We note that $\phi_0 = \pi/2$ at an apex and $\alpha_0 = \pi/2$ at an *i*-point. For $I = 0$ the profile has a horizontal inflection point and is determined from eq. [16]. The two *a*-solutions in Fig. 2 are identical if they have the same $R_a$ (>0); and the two *i*-solutions in Fig. 2 are identical if they have the same $\theta_i$ (≥0).

### 3. Horizontal force

Consider a cylindrical body placed at a fluid interface with menisci on both sides 1, 2 of the body characterized by the values $\theta_{01}$, $R_{01}$ and $\theta_{02}$, $R_{02}$ at the lines of contact 1 and 2, respectively (Fig. 3). The horizontal force $F_{12}$ per unit length of the body, directed from side 1 to side 2, is the resultant of the horizontal components of the surface tension forces, γ, acting on the lines 1 and 2, and of the pressure difference forces, due to the curvature of the menisci, acting on the plane defined by the lines 1 and 2 (4). To keep equilibrium a force, $-F_{12}$, must be applied to the body.

Let *h* be the difference in the levels of the two contact lines ($h > 0$ if line 2 is above line 1). The pressure difference at the line of contact 1 is $\gamma/R_{01}$ and at line 2 it is $\gamma/R_{02}$. Equilibrium of pressure requires that

$$[23] \quad H = \frac{h}{a} = \frac{1}{R_{02}} - \frac{1}{R_{01}}$$

The horizontal resultant of the pressure difference forces on plane 12 is easily found to be

$$[24] \quad F_p = H\left(\frac{1}{R_{01}} + \frac{H}{2}\right) = H\left(\frac{1}{R_{02}} - \frac{H}{2}\right)$$

The horizontal force due to surface tension is

$$[25] \quad F_\gamma = \cos\theta_{02} - \cos\theta_{01}$$

Both these forces are expressed in γ units and refer to unit length of the cylinder. The total force is $F_p + F_\gamma$ which can be written, from eq. [23]

$$[26] \quad \frac{F_{12}}{\gamma} = \left(\cos\theta_{02} + \frac{1}{2R_{02}^2} - 1\right) - \left(\cos\theta_{01} + \frac{1}{2R_{01}^2} - 1\right)$$

or, using eq. [18],

$$[27] \quad F_{12}/\gamma = I_2 - I_1$$

This equation has a simple interpretation. Each meniscus exerts a horizontal force, directed to the side of the meniscus, with a value, in γ units and per unit length, equal to the invariant *I* of the meniscus profile. The net force is the resultant of the forces exerted by the two menisci. With this decomposition of $F_{12}$ in forces associated with each meniscus we may assign to an *a*-meniscus a force

$$[28] \quad F/\gamma = 1/2R_a^2$$

and to an *i*-meniscus a force

$$[29] \quad F/\gamma = \cos\theta_i - 1$$

The first is positive and vanishes for $R_a = \infty$. The other is negative and vanishes for $\theta_i = 0$. The special menisci for which $F = 0$ are of course free menisci connecting two distant cylinders or walls.

For two floating cylinders isolated at a liquid surface, the force between them is attractive if they are connected by an *a*-meniscus (Fig. 4*a*, *b*, *d*) and repulsive for an *i*-meniscus (Fig. 4*c*). This is true even if the *a*-point or *i*-point are not in the meniscus region. In the first case, if the free meniscus (side 1)

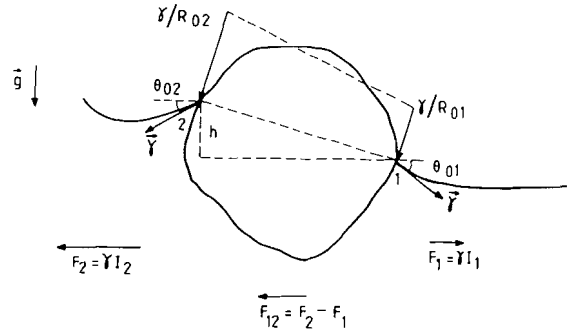

FIG. 3. Floating cylinder with menisci on both sides 1, 2. The horizontal force $F_{12}$ is the resultant of surface tension forces γ and pressure difference forces acting on the inclined plane 12 and varying from $\gamma/R_{01}$ to $\gamma/R_{02}$.

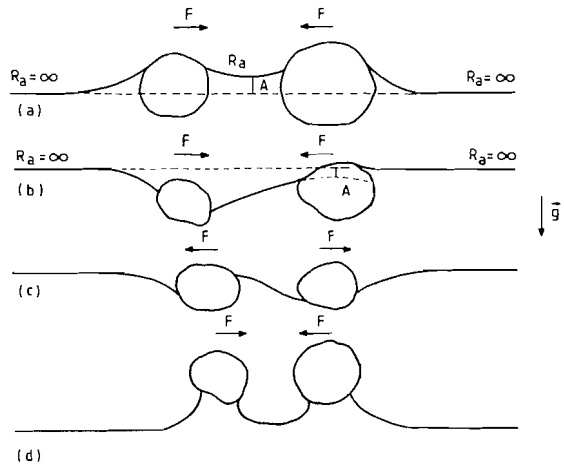

FIG. 4. Examples of menisci between two isolated floating cylinders. If the connecting meniscus is of the *a*-type (*a*, *b*, *d*) the force is attractive; if it is of the *i*-type (*c*) the force is repulsive.

is itself of the $a$-type (as in Fig. 4$a$, $b$), the radius of curvature at the apex of the connecting meniscus (side 2) must be equal to the height difference $A$ (in $a$ units) between the two apexes, so that

[30] $F_{12} = 1/2A^2$

The force is directed to side 2.

### 4. Force versus distance

In this section examples are given of the variation of the force $F$ with the width $X$ of a meniscus for fixed values of $\theta$ at the two ends of the meniscus. The results apply to any geometry of the solids, but in general the relation between the actual contact angle and the angle $\theta$ involves the slope angle of the solid surface at the line of contact. It is convenient to introduce what we term the vertical contact angle (v.c.a.) at the solid surface. This is the angle $\theta_{cv}$ defined in Fig. 2, between the fluid interface and a vertical half-plane below the line of contact, measured through the liquid phase (denser fluid). $\theta_{cv}$ can vary between $-\pi/2$ and $3\pi/2$. The relation between $\theta_{cv}$ and $\theta$ (as defined in Fig. 2) is

[31] $\theta_{cv} = \pi/2 \pm \theta$

where the + sign applies when the $z$-axis is parallel to $\boldsymbol{g}$.

Each meniscus can therefore be characterized by the values $\theta_{cv}$, $\theta_{cv}'$ of the v.c.a. at its ends and by the value of $X$, the horizontal reduced distance between the end points. The force due to the meniscus is, for the same $X$, equal to that due to a meniscus with v.c.a. $(\pi - \theta_{cv})$, $(\pi - \theta_{cv}')$ because of the identity of the menisci with the same $I$, as discussed above in relation to Fig. 2.

When two cylindrical bodies are connected by a meniscus such that the v.c.a.'s at each cylinder, respectively $\theta_{cv}$ and $\theta_{cv}'$, are both acute ($0 \leq \theta_{cv}$, $\theta_{cv}' < \pi/2$) or both obtuse, the meniscus is necessarily of the $a$-type and the force due to it is attractive. In all other cases, and in particular if one of the v.c.a. is acute and the other obtuse, the force may be repulsive or attractive depending on the type of meniscus, and therefore of distance.

In the following examples which illustrate these conclusions we shall consider only the interval 0, $\pi$ for the v.c.a. Note that the v.c.a. coincides with the actual contact angle if the solid surface is vertical at the region of contact. The examples then give directly the force on vertical plates or parallelipipeds placed at the fluid interface, with contact angles equal to the v.c.a.

Figures 5 and 6 show the horizontal capillary force, $F$, between two floating cylinders far from any other bodies, as a function of the horizontal

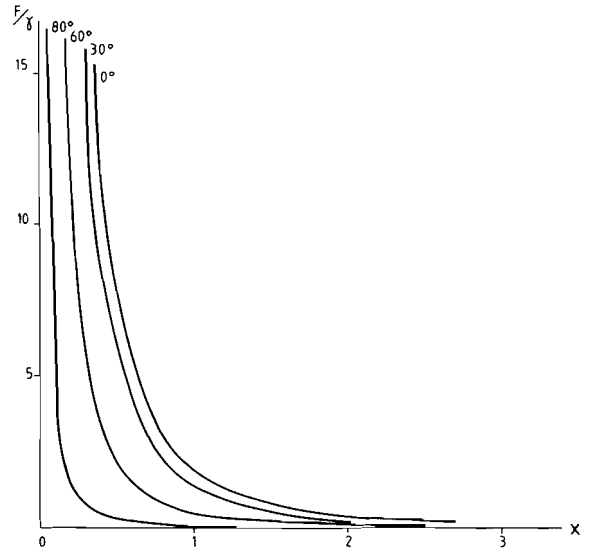

FIG. 5. Force versus separation for two floating cylinders with the same vertical contact angle $\theta_{cv}$. Each curve also applies to $\pi - \theta_{cv}$. Different curves do not intersect. All curves are asymptotic to the coordinate axes.

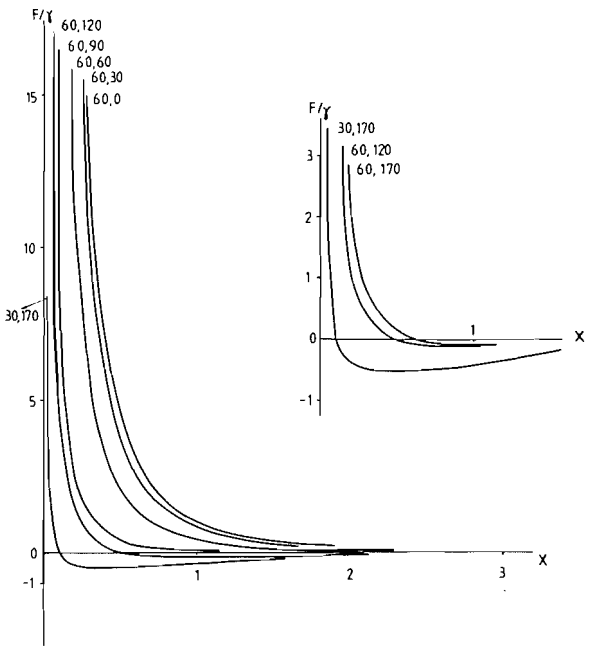

FIG. 6. Force versus separation for two floating cylinders with different vertical contact angles $\theta_{cv}$ and $\theta_{cv}'$ indicated in degrees. Each curve also applies to $(\pi - \theta_{cv})$, $(\pi - \theta_{cv}')$. The insert shows curves in a smaller scale; the continuation of the two top curves as $X \to \infty$, $F \to 0$, intersect each other. All curves are asymptotic to the coordinate axes.

distance $X$ between the lines of contact, for various combinations of $\theta_{cv}$, $\theta_{cv}'$. Each curve also applies to the complementary v.c.a.

In Fig. 5, the v.c.a.'s are the same at the two cylinders. The force is attractive at all separations ($F > 0$). The function $F(X)$ cannot be represented approximately by an exponential law, even at large distances. However, a power law, with $F$ proportional to $X^{-2}$, is a good approximation at small separations (see below).

Figure 6 applies to different angles. The curves for pairs acute–obtuse show the expected equilibrium position ($F = 0$) and a minimum (repulsive) force. At the equilibrium separation $I = 0$, and the corresponding value of $X$ can be obtained from eq. [16]. Figure 7 is a plot of the function $G(\phi)$ defined by eq. [17], from which the equilibrium position can be determined from the absolute value of the difference $G(\theta_{cv}) - G(\theta_{cv}')$. For example, for $\theta_{cv} = 0°$, $\theta_{cv}' = 120°$, the equilibrium

$$X = 0.533 - (-0.096) = 0.629$$

The equilibrium is unstable since the force is repulsive for separations larger than equilibrium separation and vice-versa. The value of the maximum repulsive force is $1 - |\sin\theta_{cv}|$, where $\theta_{cv}$ is the v.c.a. with smaller value of $|\sin\theta_{cv}|$. The repulsive force is at most equal to $\gamma$, per unit length.

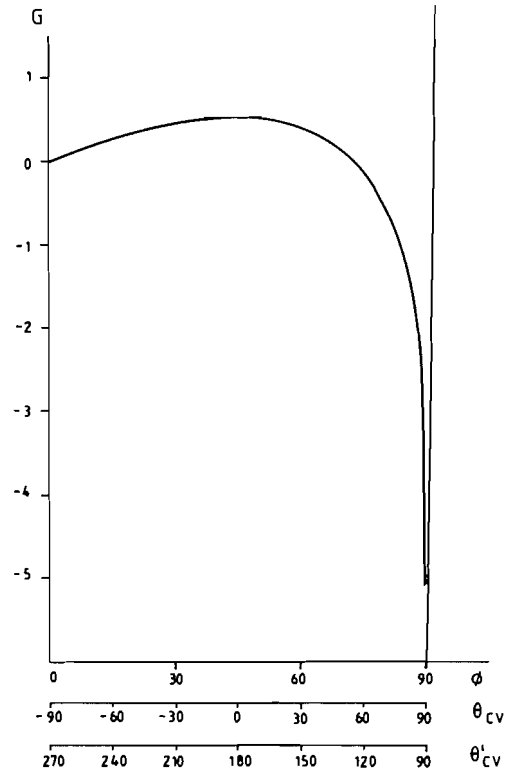

FIG. 7. The function $G(\phi)$ defined by eq. [17]. The equilibrium separation between two floating cylinders with vertical contact angles $\theta_{cv}$ and $\theta_{cv}'$ is the absolute value of $G(\theta_{cv}) - G(\theta_{cv}')$.

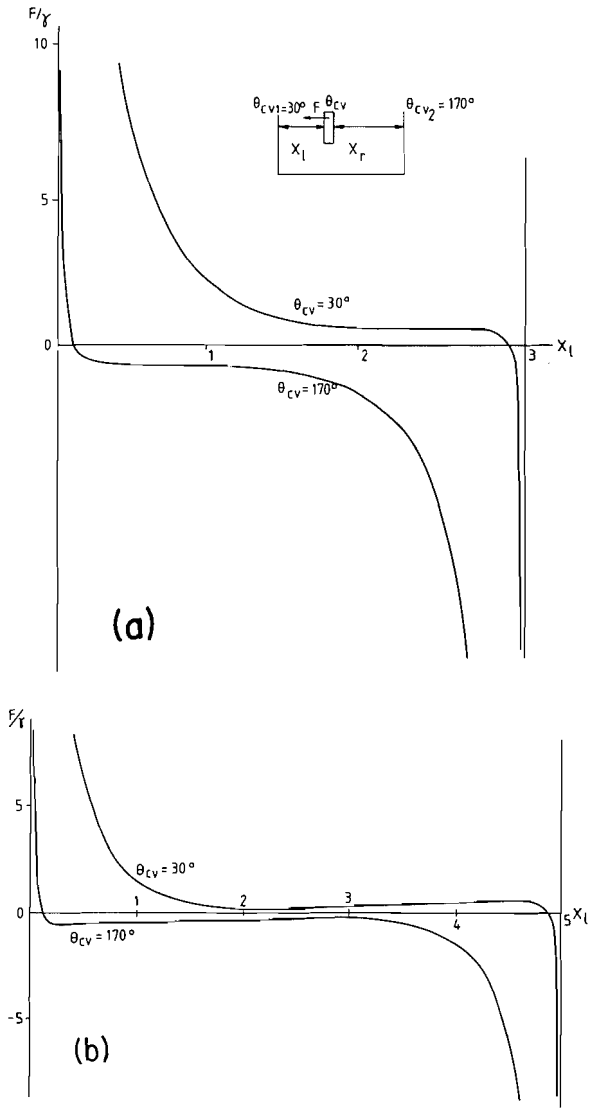

FIG. 8. The horizontal capillary force (in the direction of the left wall) on a floating prismatic particle placed between two walls as a function of the position. Wetting characteristics are indicated in the insert; (*a*) wall separation $X_l + X_r = 3a$; (*b*) wall separation $5a$.

The limiting behavior of $F(X)$ as $X \to 0$, $F \to \infty$ is easily found from eq. [11] by expanding the integrands in a power series of $k$. The result is

$$[32] \quad \frac{F}{\gamma} = \frac{2(\cos\theta_{cv} + \cos\theta_{cv}')^2}{X^2} \quad (X \to 0)$$

As $X \to \infty$, $F \to 0$, and the leading term in $X$ is

$F(\phi, k)$ for $\phi = \pi/2$, $k = 1$, which cannot be approximated by any simple function. The meniscus in this case contains an apex (with $R_a \to \infty$) or an inflection point (with $\theta_i \to 0$) between the two cylinders.

A different situation is that of a single cylindrical body between two walls at a given distance (Fig. 8, insert). The force on the cylinder as a function of its position between the walls can be obtained by combination of the curves, such as those in Figs. 5 and 6, for the appropriate v.c.a.'s at the walls ($\theta_{cv_1}$, $\theta_{cv_2}$) and at the cylinder ($\theta_{cv}$, assuming equal v.c.a. on both sides). Figures 8*a*, 8*b* apply to vertical parallelipipedic particles with contact angles 30° and 170°, respectively, for the left and right wall. In Fig. 8*a* the distance between the walls is $3a$ and in Fig. 8*b* it is $5a$. $F > 0$ indicates that the particle is attracted to the left wall. Note that the equilibrium position is stable.

## 5. Discussion

All the calculations were made on the assumption that the necessary forces are applied to keep the floating bodies at equilibrium. In addition to the horizontal force $-F_{12}$ that was calculated, a vertical force must also be applied if the bodies are to stay at equilibrium. This force must be varied as the relative position of the bodies changes, if their vertical positions relative to some reference level are to stay unchanged. Even in this case, the vertical contact angles may change as the bodies change their places, except for vertical solid surfaces. The situation is more complicated in free flotation (zero vertical applied force). When two free floating cylinders approach each other they may either tend to sink or to emerge depending on the geometry of their cross-sections. An analysis of this situation was undertaken by Gifford and Scriven (1) for free floating circular cylinders. The variation of the vertical contact angles implies that the function $F_{12}(X)$ will depend also on the geometry and densities, so that no general limiting laws are expected to hold.

The analysis of the horizontal force on a parallelipipedic particle between fixed vertical walls shows that there is a stable equilibrium position which depends on the wetting characteristics of the particle and walls. As the examples of Fig. 8 show it is in principle possible to separate particles with different wetting characteristics by placing the mixture between parallel walls of different contact angles. In the case of Fig. 8*a*, if the particles are placed at a distance $2.5a$ from the left wall ($\theta_{cv_1} = 30°$) the wettable particles ($\theta_{cv} = 30°$) will experience a small attractive force to the left wall, while the liquid repellent particles ($\theta_{cv} = 170°$) will be submitted to a larger force (approximately 12 times larger) in the opposite direction. The equilibrium positions of the two types of particles are approximately $2.8a$ apart.

Although the results of this paper apply exclusively to a cylindrical geometry, simple experiments show that the same type of effect of contact angles appears with particles of arbitrary noncylindrical shapes; in particular, the horizontal force between two such particles may be repulsive if their wetting characteristics are considerably different.

# Mise en évidence de la formation d'hydrogène par la réaction de recombinaison bimoléculaire des radicaux $HO_2$. Réaction hétérogène de basse température des radicaux $HO_2$

KRIKOR A. SAHETCHIAN, ADOLPHE HEISS ET RENÉE RIGNY

*Laboratoire de Chimie Générale, Equipe de Recherche Associée au C.N.R.S. No 457, Université Pierre et Marie Curie, Tour 55, 4ème Etage, 4, Place Jussieu, 75230-Paris Cedex-05, France*

Reçu le 19 mars 1982

KRIKOR A. SAHETCHIAN, ADOLPHE HEISS et RENÉE RIGNY. Can. J. Chem. **60**, 2896 (1982).

On montre que les radicaux $HO_2$ ne réagissent pratiquement pas avec les parois de silice ou de verre Pyrex, traitées ou non à l'acide borique, aux températures supérieures à l'ambiante alors qu'aux températures inférieures à celle-ci ces radicaux disparaissent. Leur vitesse de disparition augmente avec la diminution de la température, contrairement à ce qui se passe à haute température ($t > 150$°C). Le coefficient apparent de recombinaison hétérogène peut être exprimé sous la forme $\gamma_a = 1{,}9 \times 10^{-11} \exp(11\,000/RT)$. L'utilisation, comme nouvelle source thermique de radicaux $HO_2$, du système $O_2$ + 10 ppm de $C_7H_{15}O—OC_7H_{15}$ (t 220–240°C, réacteur en silice recouvert de $B_2O_3$ puis traité par la réaction lente $H_2/O_2$, radicaux $HO_2$ formés par la réaction $C_7H_{15}O + O_2 \rightarrow HO_2$ + produit) a permis d'étudier la réaction de recombinaison bimoléculaire des radicaux $HO_2$. La formation d'hydrogène moléculaire ayant été mise en évidence dans ce système, nous en déduisons que cette réaction engendre $H_2O_2$ et $H_2$ suivant les deux voies parallèles suivantes:

$$HO_2 + HO_2 \begin{cases} \nearrow H_2O_2 + O_2 \\ \searrow H_2 + 2O_2 \end{cases}$$

KRIKOR A. SAHETCHIAN, ADOLPHE HEISS, and RENÉE RIGNY. Can. J. Chem. **60**, 2896 (1982).

It is shown that there is practically no reaction of $HO_2$ radicals on walls of quartz or Pyrex glass, coated or not with boric acid, at temperatures higher than the ambient one, whereas at lower temperatures these radicals disappear. The rate of disappearance increases with decreasing temperature, contrary to what occurs at high temperature ($t > 150$°C). The apparent coefficient of heterogeneous recombination may be expressed by $\gamma_a = 1.9 \times 10^{-11} \exp(11\,000/RT)$. By using, as a new thermal source of $HO_2$ radicals, the system $O_2$ + 10 ppm of $C_7H_{15}O—OC_7H_{15}$ (t 220–240°C, quartz vessel coated with $B_2O_3$ and treated by the slow reaction $H_2/O_2$, $HO_2$ radicals formed through the reaction $C_7H_{15}O + O_2 \rightarrow HO_2$ + product), it was possible to study the bimolecular recombination reaction of $HO_2$ radicals. The formation of molecular hydrogen was shown; we deduce from this that the recombination reaction produces $H_2O_2$ and $H_2$ by two competitive paths:

$$HO_2 + HO_2 \begin{cases} \nearrow H_2O_2 + O_2 \\ \searrow H_2 + 2O_2 \end{cases}$$

## Introduction

La réaction de recombinaison bimoléculaire en phase gazeuse des radicaux $HO_2$ joue un rôle important tant dans le domaine de la combustion que dans celui de la pollution atmosphérique. De nombreux travaux ont été consacrés à la détermination de ses caractéristiques cinétiques, mais les résultats sont incomplets et manquent d'une certaine cohérence.

En effet, cette réaction qui paraissait simple avec formation de peroxyde d'hydrogène (1)

[3*a*] $HO_2 + HO_2 \rightarrow H_2O_2 + O_2$

s'est révélée être beaucoup plus complexe (2–7).

Récemment, l'observation a été faite (4, 8) que les rendements en peroxyde d'hydrogène étaient inférieurs à ceux prévus par la réaction classique [3*a*].

La complexité des résultats obtenus peut être due *d'une part* à la complexité des mécanismes chimiques des méthodes utilisées, et *d'autre part* au processus hétérogène.

Lors des études de combustion, la réaction hétérogène des radicaux $HO_2$ est toujours envisagée. Elle peut être rendue négligeable en comparaison des réactions homogènes grâce à un recouvrement des parois, en particulier à l'acide borique, suivi d'un traitement par la réaction lente de l'hydrogène (9, 10).

Au cours de certaines déterminations de constantes de vitesse de réactions de radicaux $HO_2$, effectuées à des températures voisines de l'ambiante, différents recouvrements ont été utilisés (4, 7, 11, 12); il nous est apparu nécessaire d'étudier la réaction hétérogène des radicaux $HO_2$ parce qu'elle peut conduire à des complexités insoupçonnées.

Partant des considérations précédentes nous avons entrepris l'étude des réactions de recombi-

naison, hétérogène et homogène, des radicaux $HO_2$.

Notre étude précédente (13) de la réaction hétérogène des radicaux, réalisée entre 300 et ~700 K, nous a incités à élargir le domaine vers les températures inférieures à l'ambiante. En fonction des résultats obtenus, nous avons choisi une plage de température où les réactions hétérogènes, de basse et de haute température, sont négligeables, pour étudier la recombinaison homogène des radicaux $HO_2$.

Comme nous l'avons montré ci-dessus, le grand nombre d'études, ne concordant pas toujours entre elles, réalisées à propos de la réaction [3*a*] nous a amenés à envisager la possibilité d'une nouvelle réaction [3*b*] en phase gazeuse, d'où le deuxième objet de cette étude:

[3*b*] $HO_2 + HO_2 \rightarrow H_2 + 2O_2$

Nous avons choisi les conditions expérimentales telles que les réactions hétérogènes soient rendues négligeables, et un mélange réactionnel où les radicaux $HO_2$ sont formés par une voie thermique (14) et où le mécanisme chimique est relativement simple.

## I. Réaction hétérogène des radicaux $HO_2$ de 230 à 300 K

Le dispositif expérimental est celui déjà décrit dans des études sur la décomposition de peroxydes (15).

Les radicaux $HO_2$ sont formés, en système dynamique (9), par la réaction lente de combustion de l'hydrogène à 510°C et sous une pression de 180 Torr, avec un mélange $2H_2 + 1O_2 + 0{,}03CO_2$, dans un réacteur préalablement traité à l'acide borique puis par cette même réaction lente (9, 10, 15). Une faible partie du flux réactionnel ($H_2$, $O_2$, $CO_2$ auxquels s'ajoutent les espèces $HO_2$, $H_2O_2$ et $H_2O$ formées dans la réaction) est extraite par la microfuite d'une sonde située dans l'axe du réacteur, en une position déterminée et pour un temps de séjour de 17 s. Ce flux extrait circule dans un tube de pyrex en U, sous une pression voisine de 0,2 Torr, puis les espèces condensables sont gelées sur le doigt, refroidi à l'azote liquide, d'un Dewar placé dans la cavité résonnante de l'appareil RPE (fig. 1) La fonction de $CO_2$ est de servir de matrice pour piéger les radicaux $HO_2$. La concentration des radicaux $HO_2$, dans le tube en U, avoisine $10^{10}$ particules/cm$^3$ et le temps de séjour est de l'ordre de quelques millisecondes. Pour rendre négligeable toute destruction aux parois des radicaux $HO_2$, les canalisations en Pyrex entre la sortie du réacteur et

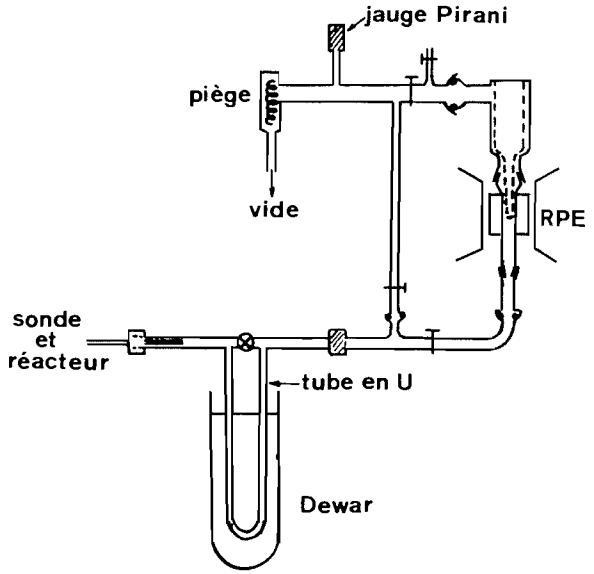

FIG. 1. Partie du montage expérimental.

le doigt froid ont également été traitées à l'acide borique. Le temps d'accumulation des radicaux sur le doigt froid est de 5 min, après quoi l'enregistrement RPE est effectué.

Les tubes de Pyrex en U ($\phi_{intérieur}$ = 5 mm, longueur ~ 21 cm), sont nettoyés avec un mélange sulfochromique, puis rincés à l'eau distillée. Ils sont: (*i*) soit plongés, à différentes profondeurs, dans un Dewar rempli d'éthanol et refroidi par de la Carboglace à une température $T$; en faisant varier la profondeur on suit l'évolution de la concentration des radicaux $HO_2$ en fonction du temps de séjour $t$ à cette température; (*ii*) soit plongés dans ce même Dewar à une profondeur déterminée, et en effectuant les expériences à des températures différentes; l'évolution de $[HO_2]$ est ainsi étudiée en fonction de la température, à temps de séjour constant; (*iii*) soit placés dans un four thermorégulé dont la température peut varier de l'ambiante à 600 K, mais le temps de séjour est fixé.

À tout moment existe la possibilité de vérifier que la concentration des radicaux $HO_2$, en fonction de la température $T$, provient bien de la réaction hétérogène sur les parois et non d'une modification des conditions de la combustion lente de l'hydrogène. Par conséquent, à l'entrée du tube en U, la concentration des radicaux $HO_2$ reste toujours constante et nous la considérerons comme la concentration initiale $[HO_2]_0$.

*Résultats*

Lorsque le flux gazeux circule par le tube en U,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

nous constatons que, pour une immersion donnée de celui-ci et des conditions identiques (température, débit, longueur du tube), la concentration des radicaux diminue en fonction de la durée d'un essai, pour finir par se stabiliser à un état stationnaire. Chaque expérience a ensuite été réalisée une fois que cet état stationnaire est atteint et le temps nécessaire à son établissement est appelé temps de mise en équilibre $\tau$. Nous avons remarqué que ce temps $\tau$ est d'autant plus court que la température du tube est plus basse.

Nous avons suivi l'évolution de la concentration des radicaux $HO_2$, $[HO_2]_T$, en fonction de leur temps de séjour $t$ dans le tube en U, celui-ci étant à basse température (de 300 à 230 K). La figure 2*a* représente cette évolution à une température de $T$ = 263 K alors que la fig. 2*b*, représentant $\ln [HO_2]_T = f(t)$, montre que la cinétique de disparition des radicaux $HO_2$ est du premier ordre (le coefficient de corrélation de la droite des moindres carrés est $r^2$ = 0,98). Ces courbes sont valables pour des conditions de pression et de parois bien définies. En effet la disparition des radicaux $HO_2$ dépend non seulement du temps de séjour, mais aussi sans doute des produits formés au cours de la réaction de combustion de l'hydrogène, par exemple $H_2O$, $H_2O_2$. En particulier, l'eau formée et adsorbée sur les parois peut influencer le phénomène (4). A partir de la droite de la fig. 2*b*, une détermination de la constante de vitesse apparente de réaction hétérogène de basse température des radicaux $HO_2$ a été effectuée. La valeur trouvée, $k_a$ = 460 $s^{-1}$ à 263 K, constitue une estimation de cette constante de vitesse apparente.

A temps de séjour $t$ constant, l'évolution de la concentration des radicaux $HO_2$, $[HO_2]_t/[HO_2]_0$, en fonction de la température $T$ du tube a également été étudiée (fig. 3). Quand cette température change, le temps de séjour, à profondeur d'immersion constante, change lui aussi très légèrement, mais cette variation est négligeable en première approximation.

Pour des températures comprises entre 300 et 400 K, nous avons un palier (13), puis la concentration des radicaux $HO_2$ diminue quand $T$ continue à augmenter. Aux températures inférieures à 300 K, cette concentration diminue très fortement pour s'annuler vers 240 K. Pour des températures < 300 K et un tube traité à l'acide borique, la forme de la courbe est identique avec un très faible décalage de température. Cette rapide décroissance de concentration est à rapprocher de celle observée avec des parois traitées avec KCl, KBr, $BaBr_2$ quand la température augmente de 300 à 400 K (13).

Nous avons pu voir, dans nos expériences, que:

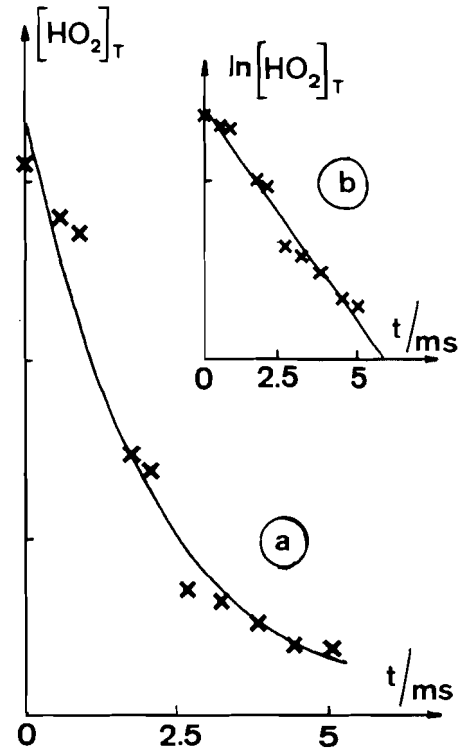

FIG. 2. (*a*) Evolution de $[HO_2]_T$ en fonction du temps de séjour $t$, à la température $T$ = 263 K, $[HO_2]_T$ en unités arbitraires. (*b*) Variation de ln $[HO_2]_T$ en fonction de $t$, à 263 K.

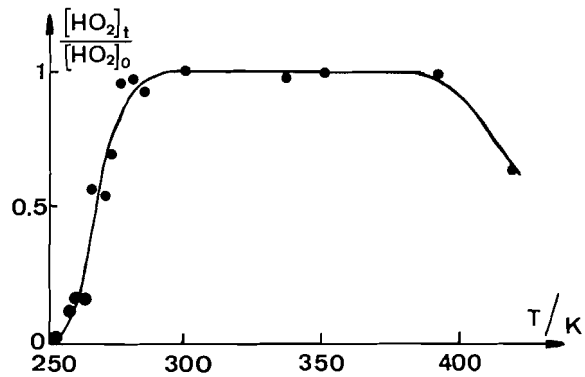

FIG. 3. Evolution de $[HO_2]_t/[HO_2]_0$ en fonction de la température absolue, pour un temps de séjour $t$ de 5 ms.

(*i*) la réaction de disparition des radicaux $HO_2$ obéit à une cinétique du premier ordre; (*ii*) la concentration de ces radicaux change très peu dans le domaine 298–400 K; (*iii*) la variation de concentration de ceux-ci à temps de séjour constant, peut être étudiée en fonction de $1/T$.

En supposant que le phénomène puisse être représenté par une équation de type Arrhénius, on obtiendra l'expression suivante, aux températures

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

$T < 298$ K:

$$\ln\left(\ln \frac{[HO_2]_0}{[HO_2]_{T,t}}\right) = -\frac{E_a}{RT} + \ln (A \times t)$$

où $E_a$ est l'incrément thermique de la réaction hétérogène de disparition des radicaux $HO_2$ et $A$ son facteur préexponentiel, $t$ représente le temps de séjour fixé. A partir du diagramme d'Arrhénius (fig. 4), la méthode des moindres carrés permet de déterminer $E_a$:

$$E_a = -11 \pm 3 \text{ kcal mol}^{-1} \text{ (erreur} = \pm 1 \text{ écart-type)}$$

Cette valeur de 11 kcal $mol^{-1}$ et l'observation expérimentale qu'il soit nécessaire de chauffer les parois pour revenir aux conditions initiales d'équilibre, permettraient de mettre en évidence une analogie entre ce phénomène et celui de la désorption de l'eau.

Bien que ce phénomène hétérogène soit différent de celui de haute température, nous estimons pouvoir lui appliquer la théorie des réactions hétérogènes de Semenov. Pour le domaine cinétique la valeur du coefficient apparent de recombinaison hétérogène $\gamma_a$ à 263 K est $\gamma_a = 2{,}3 \times 10^{-2}$. Pour nos conditions expérimentales, en tenant compte de l'énergie d'activation apparente déterminée ci-dessus, $\gamma_a$ peut être présenté sous la forme suivante:

$$\gamma_a = 1{,}9 \times 10^{-11} \exp \frac{11\,000}{RT}$$

Notons aussi que, en accord avec la référence 4, l'augmentation de la concentration en eau ou de celle d'autres produits présents dans le milieu, se traduirait par un accroissement de $\gamma_a$.

## II. Mise en évidence de la réaction $HO_2 + HO_2 \rightarrow H_2 + 2O_2$ [3*b*]

Les conditions expérimentales ayant été choisies pour rendre négligeable la réaction hétérogène des radicaux $HO_2$, nous avons entrepris une première étude de la recombinaison homogène de ces radicaux. Comme source propre thermique de radicaux $HO_2$, nous avons choisi le système oxygène + peroxyde de di-n heptyle $C_7H_{15}O—OC_7H_{15}$ (~ 10 ppm) précédemment étudié (14). La réaction en phase gazeuse, à une température comprise entre 150 et 240°C, de radicaux n-heptoxy (issus de la décomposition du peroxyde double ROOR précédent) et d'oxygène moléculaire engendre des radicaux $HO_2$. Le dispositif expérimental a déjà été décrit, mais quelques modifications lui ont été apportées.

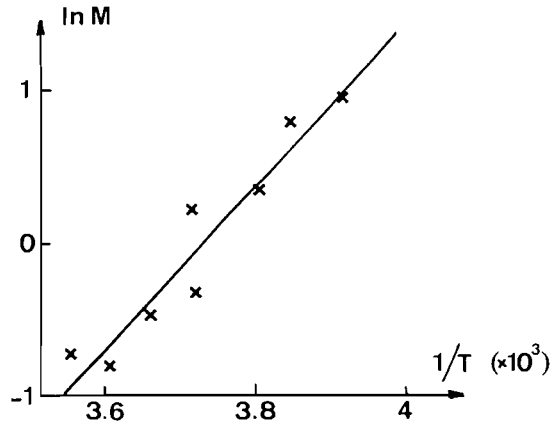

FIG. 4. Diagramme d'Arrhénius; ln $M = f(1/T)$ avec $M = \ln([HO_2]_0/[HO_2]_{T,5\text{ ms}})$ pour un temps de séjour de 5 ms.

Le peroxyde liquide ROOR est contenu dans une fiole à la température ambiante. Le flux d'oxygène passe par cette fiole et barbote dans le peroxyde liquide avant de traverser un réacteur en silice, à la pression atmosphérique. La possibilité existe d'envoyer directement le courant d'oxygène dans le réacteur sans passer par cette fiole. Le réacteur conicocylindrique (longueur 25 cm, diamètre de 1 à 4 cm) est traité à l'acide borique, puis par la réaction lente $H_2/O_2$ (10, 13, 15). Ce traitement a pour effet de rendre inertes, vis-à-vis des radicaux $HO_2$, les parois du réacteur. Celui-ci est placé dans un four à température uniforme et thermorégulée à $\pm$ 0,5°C. La sortie du réacteur est reliée à la boucle d'introduction (volume 3 $cm^3$) d'un chromatographe en phase gazeuse expérimental, conçu pour la détection de traces. Ce chromatographe a été élaboré, mis à notre disposition et manipulé par J. P. Nogier. La séparation est réalisée par une colonne garnie de tamis moléculaire 5 Å, longue de 6 m, avec l'argon N 60 (99,99990%) comme gaz porteur; la détection très sensible est réalisée dans un tube à décharge d'argon.

Le flux gazeux, à la sortie du réacteur, traverse en continu la boucle d'introduction du chromatographe pour être envoyé dans celui-ci au moment d'effectuer une analyse.

*Résultats*

Trois séries d'expériences ont été faites: (1) de l'oxygène pur (N 48 c'est-à-dire à 99,998% contenant moins de 0,1 ppm d'hydrogène, ou N 45 (99,995 avec $H_2 < 0{,}2$ ppm) est introduit dans le chromatographe, sans qu'aucun pic ne soit détecté (fig. 5*a*); (2) des mélanges d'oxygène N 45 ou d'azote N 48 contenant de faibles concentrations en hydrogène (40, 12,5 et 0,5 ppm) sont introduits

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

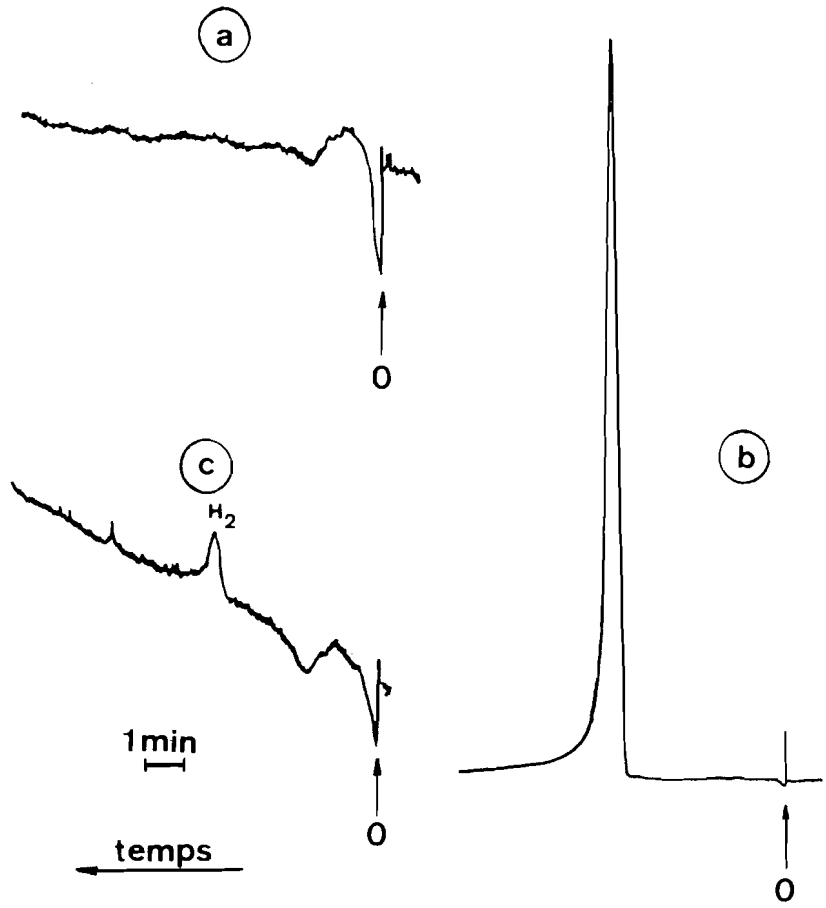

FIG. 5. Chromatogrammes en phase gazeuse. O: perturbation d'introduction. (*a*) oxygène N 45 seul; (*b*) pic obtenu avec 40 ppm. d'hydrogène dans l'oxygène N 45, sensibilité 10 fois plus faible qu'en (*a*) et (*c*); (*c*) pic d'hydrogène obtenu avec le mélange 10 ppm de ROOR dans l'oxygène N 45.

dans le chromatographe. Les chromatogrammes permettent de localiser $H_2$ (pic à 4 min) et de tester la sensibilité du détecteur vis-à-vis de ce gaz. Le pic obtenu pour une concentration de 40 ppm est représenté sur la fig. 5*b*; (3) des mélanges d'oxygène N 48 ou N 45 et de peroxyde ROOR (~ 10 ppm) avec des débits de 28 et 40 L $h^{-1}$, après passage par le réacteur à des températures de 238 ou 220°C, sont chromatographiés. Un des chromatogrammes est représenté sur la fig. 5*c*, où le pic correspond bien à celui de l'hydrogène moléculaire.

La bonne reproductibilité de ces expériences mérite d'être signalée. Plusieurs séries d'expériences complémentaires sont effectuées pour vérifier l'influence de divers facteurs.

(*i*) Après son passage dans le réacteur à 100°C, nous avons chromatographié le mélange $O_2$ + ROOR sans observer de formation d'hydrogène.

(*ii*) En opérant de même avec le mélange $O_2$ + $H_2O_2$ circulant dans le réacteur à 240°C, là aussi aucune formation de $H_2$ n'est détectée.

(*iii*) Pour des conditions identiques de température, pression, concentrations, des essais sont réalisés dans un réacteur en silice identique à celui décrit, mais avec la différence qu'il n'est pas traité à l'acide borique. Nous constatons que:

la décomposition de ROOR est pratiquement la même que dans le cas du réacteur traité; cela signifie que la décomposition se produit en phase gazeuse;

dans ces conditions, ni $H_2O_2$ (par chromatographie sur couches minces) ni $H_2$ (par chromatographie en phase gazeuse) ne sont mis en évidence.

## Discussion

Il est intéressant tout d'abord de remarquer que la formation d'hydrogène observée expérimentalement ne peut s'expliquer ni par des réactions hétérogènes, dont le rôle est négligeable aux températures auxquelles nous opérons grâce au traitement des parois effectué, ni par des réactions entre radicaux et peroxyde (ou des réactions telles que

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

décomposition, isomérisation etc ...) rendues négligeables par rapport à celle de RO avec $O_2$, grâce à la faible concentration en peroxyde ROOR et à la température des expériences relativement faible.

Les réactions principales se produisant dans le système $O_2$ + ROOR, avec nos conditions expérimentales, sont les suivantes (14).

[1] $\mathrm{ROOR} \xrightarrow{k_1} 2\mathrm{RO}$

[2] $\mathrm{RO} + \mathrm{O_2} \xrightarrow{k_2} \mathrm{HO_2} + \text{produit}$

[3] $\mathrm{HO_2} + \mathrm{HO_2} \xrightarrow{k_3} \mathrm{H_2O_2} + \mathrm{O_2}$

La réaction [2] peut aussi avoir lieu après isomérisation du radical RO. Dans les études des réactions concernant ces deux radicaux, la formation d'hydrogène atomique ou moléculaire n'est jamais mise en évidence. Pour le radical méthoxy $CH_3O$, la formation d'hydrogène atomique a été envisagée (16) alors que celle d'hydrogène moléculaire apparaît comme pratiquement très peu probable, d'après des calculs théoriques qui concluent à une barrière d'énergie très élevée pour la réaction $CH_3O \rightarrow CHO + H_2$ (17). Toutefois, même si de l'hydrogène atomique était susceptible de se produire, la vitesse de formation de $H_2$ par une réaction de H avec le peroxyde ou un produit de décomposition serait négligeable, en comparaison de la réaction $H + O_2 + M \rightarrow HO_2 + M$.

A partir des résultats expérimentaux, on observe que la présence d'hydrogène moléculaire est liée à celle des radicaux $HO_2$ et du peroxyde $H_2O_2$ dans le milieu en réaction. La formation d'hydrogène ne pouvant pas s'expliquer par les réactions [1] à [3] (et cherchant vainement dans la littérature une possible voie de formation de $H_2$ pendant la décomposition des radicaux RO), au vu des considérations précédentes, on en déduit que la réaction entre deux radicaux $HO_2$ engendre à la fois $H_2O_2$ et $H_2$. Ceci signifierait que la réaction [3] est en réalité complexe, ce qui expliquerait certaines incohérences entre la vitesse de formation de $H_2O_2$ et la disparition des radicaux $HO_2$ (4, 8). Il en résulte que la réaction de recombinaison se produirait suivant deux voies parallèles:

[3a] $\mathrm{HO_2} + \mathrm{HO_2} \rightarrow \mathrm{H_2O_2} + \mathrm{O_2}$

[3b] $\mathrm{HO_2} + \mathrm{HO_2} \rightarrow \mathrm{H_2} + 2\mathrm{O_2}$

La voie [3b] a été suggérée antérieurement (3, 5, 8).

Au cours de certaines expériences nous avons analysé le peroxyde d'hydrogène produit. A partir des chromatogrammes, une première estimation montre que le rapport $[H_2]/[H_2O_2]$ est de l'ordre de 10%. Bien que la probabilité du chemin réactionnel [3b] soit nettement plus faible que celle du chemin [3a] dans nos conditions, il peut jouer un rôle important, tant dans la chimie de la combustion que dans celle de l'atmosphère.

En effet, les radicaux $HO_2$ disparaissent par recombinaison bimoléculaire par les réactions [3a] et [3b]. Dans le domaine de la combustion, la voie [3b] constitue une rupture de chaîne alors que ce n'est pas toujours le cas pour la voie [3a], parce que le peroxyde d'hydrogène formé peut engendrer de nouvelles chaînes par suite de sa décomposition homogène ou hétérogène en radicaux. Il est bien connu que, dans la réaction d'oxydation des hydrocarbures, il se forme de l'hydrogène moléculaire; cette formation pourrait être expliquée par la réaction [3b].

En ce qui concerne la chimie de l'atmosphère, cette réaction de formation d'hydrogène n'a jamais été prise en considération. Pourtant elle pourrait jouer un rôle important dans les domaines où la concentration en radicaux $HO_2$ est relativement élevée, tels que la stratosphère ou la mésosphère. Son influence peut aussi être grande sur la teneur en eau de la stratosphère (elle serait peut-être une raison de la sécheresse inexpliquée de celle-ci), parce qu'elle diminue la formation de $H_2O_2$. Ajoutons, d'après Nicolet (18), qu'au voisinage de la mésopause, l'hydrogène atomique et l'hydrogène moléculaire doivent intervenir simultanément pour déterminer le comportement de l'hydrogène atomique dans l'exosphère.

## Conclusion

Cet article est constitué de deux parties décrivant chacune un phénomène nouveau lié aux radicaux perhydroxyles. La première se rapporte à la disparition hétérogène des radicaux $HO_2$ entre 230 et 300 K, alors que la seconde concerne une étude du mécanisme de la réaction de recombinaison bimoléculaire de ces radicaux.

La réaction hétérogène des radicaux $HO_2$ aux basses températures semble relever d'une adsorption physique de ceux-ci et cette réaction doit toujours être envisagée aux températures inférieures à l'ambiante. Elle ne dépendrait pas seulement de l'adsorption des radicaux $HO_2$, mais subirait aussi l'influence des produits formés en cours de réaction.

En ce qui concerne la réaction de recombinaison des radicaux $HO_2$ en phase gazeuse, elle s'effectuerait par les deux voies [3a] et [3b], la voie [3b] pouvant jouer un rôle non négligeable dans la chimie de la combustion, ainsi que dans celle de l'atmosphère. C'est pourquoi il est important de poursuivre l'étude de cette réaction.

## Remerciements

Les auteurs remercient vivement D. Delafosse et

M. Che pour leur discussion concernant la réaction hétérogène ainsi que J. P. Nogier pour avoir mis à notre disposition et manipulé un chromatographe en phase gazeuse conçu pour la détection de traces.

# Synthesis of *trans*(±)6-phenoxyacetamido-1-methylene-3,3-dicarboxymethyl-1-carbapenam

PIET HERDEWIJN, PAUL J. CLAES, AND HUBERT VANDERHAEGHE[1]

*Rega Institute and Pharmaceutical Institute, University of Leuven, 10 Minderbroedersstraat, B-3000 Leuven, Belgium*

Received April 16, 1982

PIET HERDEWIJN, PAUL J. CLAES, and HUBERT VANDERHAEGHE. Can. J. Chem. **60**, 2903 (1982).

Methyl 4-benzylidene-2-pyrroline-2-carboxylate and dimethyl-4-methylene-5-pyrroline-2,2-dicarboxylate were prepared by *N*-chlorination – dehydrochlorination starting from the corresponding 4-alkylidene- or 4-arylidene-pyrrolidine. Structure of the pyrroline compound was determined by spectrometry and by reaction with α-azidoacetyl chloride. The 2-carbomethoxy-4-benzylidene-$\Delta^2$-pyrroline compound gave, on reaction with α-azidoacetyl chloride, 2-benzylidene-5-carbomethoxy-6-azido-1-carbapenam. In the case of the 2,2-dicarbomethoxy-4-methylene-$\Delta^5$-pyrroline, *trans*-1-methylene-3,3-dicarbomethoxy-6-azido-1-carbapenam was formed. When *N*-chlorination – dehydrochlorination was carried out on 2-carbomethoxy-4-methylenepyrrolidine, double bond isomerization occurred with formation of 2-carbomethoxy-4-methylpyrrole.

PIET HERDEWIJN, PAUL J. CLAES et HUBERT VANDERHAEGHE. Can. J. Chem. **60**, 2903 (1982).

On a préparé le carboxylate-2 benzylidène-4 pyrroline-2 de méthyle et le dicarboxylate-2,2 méthylène-4 pyrroline-5 de méthyle au moyen d'une *N*-chloration – déhydrochloration en partant des alkylidène-4 ou arylidène-4 pyrrolidines correspondantes. On a déterminé la structure du composé pyrroline par spectrométrie et par la réaction avec le chlorure de l'α-azidoacétyle. Le composé carbométhoxy-2 benzylidène-4 $\Delta^2$-pyrroline réagit avec le chlorure d'α-azidoacétyle en donnant le benzylidène-2 carbométhoxy-5 azido-6 carbapénam-1. Dans le cas du dicarbométhoxy-2,2 méthylène-4 $\Delta^5$-pyrroline, on obtient le méthylène-1 dicarbométhoxy-3,3 azido-6 carbapénam-1 *trans*. Quand on effectue la *N*-chloration – déhydrochloration de la carbométhoxy-2 méthylène-4 pyrrolidine, il se produit une isomérisation de la double liaison avec la formation de carbométhoxy-2 méthyl-4 pyrrole.

[Traduit par le journal]

A number of penam and cefem analogs in which the sulfur atom has been replaced by other atoms have been described (1). Some of these compounds such as the 1-oxapenam, clavulanic acid (2) and the 1-carbapenem, thienamycin (3) are of therapeutic interest. The study of 1-alkylidene-1-carbapenams seemed to be of interest in this context. Certain 1-arylidene-5-alkylthio-1-carbapenams and 1-arylidene-6-alkylthio-1-carbacephams have been synthesized by Bose *et al.* (4). It should be noted that an acylamido side chain and a carboxyl group respectively in the 3- or 4-position are not present in these arylidene-β-lactams.

In the present work we investigated the preparation of methyl 4-alkylidene-5-pyrroline-2-carboxylates (**1***a–c*) and their conversion into bicyclic β-lactams by cycloaddition with azidoacetyl chloride according to Bose *et al.* (5). The synthetic approach examined for the preparation of the 4-alkylidene-5-pyrrolines (**1***a–c*) consists in *N*-chlorination of the corresponding methyl 4-alkylidene-pyrrolidine-2-carboxylates (**2***a–c*), followed by base-catalysed elimination of hydrochloric acid. A similar procedure is described by Schmidt and Poisel (6) for the preparation of racemic proline. The pyrrolidine **2***a* was obtained in five steps from 4-hydroxy-L-proline **3***a*.[2] In order to obtain a 1-methylene-1-carbapenam with the same configuration at C2 as in penicillins, 4-hydroxy-D-proline should be used as a starting material. However, in these experiments the more readily available *L*-enantiomer was used. Oxidation of *N-tert*-Boc-4-hydroxy-L-proline **3***b* with $CrO_3$/pyridine in $CH_2Cl_2$ gave the ketone **3***c* (60%), which was converted into the *N*-protected 4-methylenepyrrolidine **3***d* by condensation with methylenetriphenylphosphorane (4 equiv.) in THF (80% yield). When the Wittig reaction was carried out on the methyl ester instead of the acid **3***c*, only 5% of **3***e* was obtained. After esterification of the carboxyl group ($CH_2N_2$) and removal of the *N*-protecting group, the free base **2***a* was obtained as an unstable oil (85% yield based on **3***d*), which can be converted into a stable crystalline hydrochloride salt. When oxidation of **3***b* was attempted with DMSO–$Ac_2O$

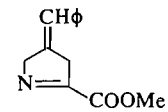
(7) the hydroxy group was converted into a methylthiomethyl ether. Oxidation of **3***b* with DMSO–DCCI–pyridine–$CF_3COOH$ gave the methylthiomethyl ester of **3***c* in a 93% yield. Removal of the methylthiomethyl ester with base or $HgCl_2/H_2S$ afforded the ketone **3***c* in low yield, due to degradation in the given reaction conditions.

The conversion of **2***a* into 5-pyrroline **1***a* was attempted by *N*-chlorination with *tert*-butylhypochlorite, followed by dehydrochlorination with $KO_2$/18-crown-6 polyether in $Et_2O$ (8). Since **1***a* contains a conjugated aldimine, one might expect that the pyrroline should be formed to some extent. However, the only compound isolated from the reaction mixture was the 2-carbomethoxy-4-methylpyrrole, which resulted from a migration of the exocyclic double bond into an *endo*-position, upon introduction of the aldimine function. Other dehydrohalogenating agents such as MeONa, pyridine, and $CH_3COOK$ gave similar results. Reaction mixtures, however, were more complex.

To avoid aromatization during the introduction of the aldimine function the *N*-chlorination – dehydrochlorination was repeated for methyl 4-benzylidene-pyrrolidine-2-carboxylate **2***b*. One might expect that the presence of the phenyl group would stabilize the exocyclic double bond and avoid to a certain extent its isomerization into an *endo*-position. Thus **3***c* was reacted with four equivalents of benzylidenetriphenylphosphorane in DMSO. The *N*-protected pyrrolidine **3***f* was isolated in a 82% yield as a 1:1 mixture of the *E*- and *Z*-isomers. Treatment of this mixture with $CH_2N_2$, followed by *N*-deprotection, afforded *E*- and *Z*-**2***b*, which were separated by fractional crystallization from ethanol–ether for further characterization. *N*-chlorination – dehydrochlorination conducted on the *E*,*Z*-mixture of **2***b* afforded 10% of the 2-carbomethoxy-4-benzylpyrrole and about 85% of an unstable pyrroline **4**, which was not isolated in a pure state. The structure **4** was based on the absence of an absorption band between 1560 and 1580 $cm^{-1}$, due to a C=N stretching vibration conjugated with an exocyclic carbon–carbon double bond (9), which excluded a 5-pyrroline structure. Absorptions at 1620 and 1630 $cm^{-1}$ (attributed to a C=C or a C=N bond conjugated with a phenyl or carbonyl group) are consistent with a methyl 2-pyrroline-2-carboxylate structure **4**. The formation of the latter results from proton abstraction in the 2-position during dehydrohalogenation. A further proof for the proposed structure was obtained by cycloaddition of azidoacetyl chloride to **4** (mixture of *E*- and *Z*-isomers) in benzene–cyclohexane containing $Et_3N$. The reaction product was found



4

to be a bicyclic β-lactam, which was isolated by column chromatography in a 50% yield (based on **2***b*). Spectral data were consistent with the structure **5***a*. The ir spectrum showed the presence of a β-lactam carbonyl group (1780 $cm^{-1}$). The $^1$Hmr spectra showed two singlets at δ 4.56 and 4.59 ppm (due to the C6-protons), broad signals at δ 6.4 and 7.2 ppm for $C_6H_5CH{=}C<$, and the absence of a C5-proton. The interpretation of the $^1$Hmr spectrum of **5***a* was somewhat obscured by the fact that it was recorded on a mixture of *E*- and *Z*-isomers. To establish the relative configuration at C5 and C6 it is necessary to simplify spectral data by converting the *E*,*Z*-mixture into a single compound by ozonolysis of the exocyclic double bond. This was performed on **5***c*, which was obtained by reduction of the azide function ($H_2S/Et_3N$) followed by *N*-phenoxyacetylation. The *trans*-stereochemistry of the side-chain and the COOMe function in **5***d* was ascertained by comparison of its $^1$Hmr spectra

obtained in $CDCl_3$ and in $CDCl_3$ – DMSO-$d_6$. A solvent shift of 1.00 ppm was observed for the amide proton (from 7.82 ppm in $CDCl_3$ to 8.82 ppm in $CDCl_3$–DMSO), which is due to the formation of

a hydrogen bond between the amide proton and DMSO. This shift should not be expected for a *cis*-β-lactam in which both functions are presumed to form an intramolecular hydrogen bond. Further indication for the absence of an intramolecular hydrogen bond can be found in the sharp NH absorption (3420 $cm^{-1}$) in the ir spectrum and in the absence of an absorption between 3100 and 3375 $cm^{-1}$.

The experiments suggest that the conversion of pyrrolidine-2-carboxylates into the corresponding 5-pyrrolines by *N*-chlorination – dehydrochlorination is only feasible if the pyrroline has no hydrogen atom in the 2-position. To verify this hypothesis the pyrroline formation was studied for dimethyl 4-methylene-pyrrolidine-2,2-dicarboxylate (**2***c*). The latter was prepared (in a 25% yield) by reaction of dimethyl aminomalonate hydrochloride with 1 equivalent of 3-chloro-2-chloromethyl-1-propene in the presence of NaOMe (10). Introduction of the aldimine function by the *N*-chlorination – dehydrochlorination procedure gave an unstable reaction product, which was found to be the desired 5-pyrroline **1***c*. The structure was proven by cycloaddition with azidoacetyl chloride. This afforded the *trans*-6-azido-1-methylene-3,3-dicarboxymethyl-1-carbapenam **6***a* (15% yield based on **2***c*). Spectral data obtained for **6***a* were in agreement with the proposed structure. The ir spectrum showed the presence of a β-lactam carbonyl group at 1790 $cm^{-1}$. In the $^1$Hmr spectrum the C6 proton appears as a doublet ($J$ = 2.7 Hz) at 4.42 ppm, the 1-methylene- and C5-protons as multiplets, respectively, at 5.28 and 4.25 ppm. The coupling constant of 2.7 Hz for the C5- and the C6-protons suggested a *trans*-β-lactam (11). Reduction of the azide function of **6***a* and *N*-phenoxyacetylation gave the crystalline β-lactam **6***b*. 100 MHz $^1$Hmr and $^{13}$Cmr spectra confirmed the proposed structure and stereochemistry.

Epimerization of carbapenams at C-6 has not been reported hereto. Procedures worked out for epimerization of penicillins (12–14) are only successful to a certain extent in the parent cephalosporin series (15). Therefore it is not likely that these methods can be applied for the isomerization of 1-methylene-1-carbapenam nucleus. Thus conversion of **6***b* into a *cis*-β-lactam was not further investigated.

## Experimental

Melting points were determined with a Büchi–Tottoli apparatus and are uncorrected. Precoated Merck silica gel F 254 plates were used for tlc. Column chromatography was performed on silica gel (Merck, 0.040–0.063 mm). Infrared (ir) spectra were recorded on a Perkin Elmer 257 spectrometer. The $^1$Hmr spectra were recorded on a Hitachi–Perkin–Elmer R-24 60 MHz instrument in $CDCl_3$ with tetramethylsilane as internal standard unless stated otherwise. Mass spectra were determined with an AEI MS-12 apparatus. Elemental analyses were performed by Janssen Pharmaceutica, B-2340 Beerse, Belgium.

N-tert-*Boc-4-oxo-*L*-proline* **3***c*

$CrO_3$ (16.8 g, 168 mmol) was added to a stirred solution of pyridine (27 mL, 336 mmol) in anhydrous $CH_2Cl_2$ (350 mL) at 0°C. The reaction mixture was stirred for 5 min at 0°C and allowed to warm up to room temperature. A solution of *N-tert*-Boc-4-hydroxy-L-proline (16) (6.5 g, 28 mmol) in anhydrous $CH_2Cl_2$ (20 mL) containing pyridine (2.5 mL, 30 mmol) was added at once to the stirred suspension. After vigorous stirring for 4 h at room temperature, the solution was decanted and the black remaining solid was washed with acetone (3 × 100 mL). The combined organic solution was filtered and evaporated. The residue was taken up in a saturated NaCl solution (200 mL), acidified to pH 2.5 with 5*N* HCl, and extracted with EtOAc (5 × 100 mL). The EtOAc solution was dried over $MgSO_4$, Celite (150 g) was added, and the solvent was removed under reduced pressure. The adsorbed *N-tert*-Boc-4-oxo-L-proline was extracted with $Et_2O$ in a Soxhlet apparatus for 5 h. Evaporation afforded **3***c* (3.9 g, 60% yield) as an amorphous solid which can be used in the next step without further purification. Crystallization from $Et_2O$ gave analytically pure **3***c*, mp 148–150°C (dec.); ir ($CH_2Cl_2$): 1750 (ketone), 1650 (COOH) $cm^{-1}$. Compound **3***c* was converted into its benzyl ester (benzyl bromide/DMF/$Et_3N$) which was used for further spectrometric identification; ir ($CH_2Cl_2$): 1770 (ester), 1750 (ketone), 1703 (carbamate) $cm^{-1}$; $^1$Hmr δ: 1.4 (s, 9H, *t*-butyl), 2.70 (AB part of ABX pattern, 2H, $J_{ax}$ = 9 Hz, $J_{bx}$ = 4 Hz, $J_{ab}$ = 19 Hz, $CH_2CH$), 3.85 (s, 2H, $CH_2N$), 4.76 (X-part, 1H, CHN), 5.15 (s, 2H, $CH_2\phi$), 7.3 (s, 5H, phenyl) ppm. Oxidation of **3***b* in DMSO–benzene (1:1) containing pyridine (2 equiv.), $CF_3CO$-OH (1 equiv.), and dicyclohexylcarbodiimide (6 equiv.) afforded 93% of the crystalline methylthiomethylester of **3***c*, $^1$Hmr δ: 1.5 (s, 9H, *t*-butyl), 2.25 (s, 3H, SMe), 2.75 (AB part of ABX pattern, 2H, $J_{ax}$ = 9 Hz, $J_{bx}$ = 4 Hz, $J_{ab}$ = 19 Hz, $CH_2CH$), 3.87 (s, 2H, $CH_2N$), 4.77 (X-part, 1H, $CH_2N$), 5.2 (s, 2H, $CH_2S$) ppm.

N-tert-*Boc-methylene-*L*-proline* **3***d*

Methyltriphenylphosphonium bromide (17) (35.7 g, 100 mmol) was added to a stirred suspension of NaH (2.4 g, 100 mmol) in anhydrous THF (250 mL). The mixture was heated at 50°C for 4 h and a solution of *N-tert*-Boc-L-proline (5.7 g, 25 mmol) in anhydrous THF (50 mL) was added over a period of 30 min. After stirring overnight at 50°C, the suspension was cooled, poured into 500 mL 5% $NaHCO_3$, and washed twice with $Et_2O$. The aqueous solution was acidified to pH 3 with 2*N* HCl and extracted three times with EtOAc. The extract was dried over $Na_2SO_4$ and evaporated. The residual oil was chromatographed on a silica gel column using $C_6H_6$–$Me_2CO$–$CH_3COOH$ (87:12:1) as eluent to yield **3***d* (4.54 g, 80%) as an oil; $^1$Hmr δ: 1.42 (s, 9H, *t*-butyl), 2.83 (m, 2H, $CH_2CH$), 4.05 (m, 2H, $CH_2N$), 4.45 (m, 1H, CHN), 4.97 (m, 2H, $CH_2$=C), 10.4 (s, 1H, COOH) ppm.

*Methyl* N-tert-*Boc-4-methylene-*L*-proline* **3***e*

To a solution of **3***d* (3.4 g, 15 mmol) in anhydrous $CHCl_3$ (50 mL) was added an excess of $CH_2N_2$ (until the yellow color persisted). After removal of the solvent, the ester was obtained in a quantitative yield as an oil; ir ($CH_2Cl_2$): 1755 (ester), 1705 (carbamate), 1405, 1127, 900 (C=$CH_2$) $cm^{-1}$; $^1$Hmr δ: 1.42 (s, 9H, *t*-butyl), 2.75 (m, 2H, $CH_2CH$), 3.72 (s, 3H, $COOCH_3$), 4.07 (m, 2H, $CH_2N$), 4.44 (m, 1H, CHN), 4.98 (m, 2H, C=$CH_2$) ppm; ms *m/e*: 241 ($M^+$).

For personal use only.

*Methyl 4-methylene-*L*-proline* **2**a

A solution of **3***e* (2.41 g, 10 mmol) in 98% HCOOH (50 mL) was kept at room temperature for 2.5 h and evaporated to dryness at a temperature below 30°C. The oily residue was partitioned between $Et_2O$ (100 mL) and 0.1 *N* HCl (100 mL). The aqueous layer was separated, made basic with 5% $NaHCO_3$, saturated with NaCl, and extracted with $CH_2Cl_2$ (3 × 100 mL). The $CH_2Cl_2$ extract was dried over $Na_2SO_4$ and evaporated to give **2***a* (1.2 g, 85%) as a light yellow oil. Analysis of the oil on tlc (10% MeOH/$CHCl_3$) showed a single spot. The compound was not stable as its free base and was converted into its hydrochloride for further characterization.

*Methyl 4-methylene-*L*-proline hydrochloride* **2**a·*HCl*

A solution of 1 *N* HCl in EtOH (5.5 mL) was added dropwise to a solution of **2***a* (705 mg, 5 mmol) in EtOH (20 mL). Addition of anhydrous $Et_2O$ afforded 820 mg of the title compound (92%) as colorless needles, mp 159–160°C (dec.) after recrystallization from EtOH/$Et_2O$; $[\alpha]_D^{25}$ −15.25° (*c* 1, $H_2O$); ir (KBr): 1750 (ester), 1677 ($CH_2$=CH) $cm^{-1}$; $^1$Hmr (360 MHz, DMSO-$d_6$) δ: 2.73 (m, 1H, $^2J_{3,3'}$ = 16.2 Hz, $^3J_{3,2}$ = 8 Hz, $^4J$ = 2 × 2.3 Hz, $^4J_{3,5}$ = 2.0 Hz, $^4J_{3,5'}$ = 0.6 Hz, H-3), 2.96 (m, 1H, $^2J_{3',3}$ = 16.2 Hz, $^3J_{3',2}$ = 8.4 Hz, $^4J$ = 2 × 2.1 Hz, $^4J_{3',5}$ = 0.95 Hz, $^4J_{3',5'}$ = 1.6 Hz, H-3'), 3.77 (s, 3H, COOMe), 3.81 (m, 1H, $^2J_{5,5'}$ = 15.2 Hz, $^4J$ = 2 × 2.2 Hz, $^4J_{5,3}$ = 2.0 Hz, $^4J_{5,3'}$ = 0.95 Hz, H-5), 3.88 (m, 1H, $^2J_{5',5}$ = 15.2 Hz, $^4J$ = 2 × 2 Hz, $^4J_{5',3}$ = 0.6 Hz, $^4J_{5',3'}$ = 1.6 Hz, H-5'), 4.56 (dd, 1H, $^3J_{2,3}$ = 8 Hz, $^3J_{2,3'}$ = 8.4 Hz, H-2), 5.15 (m, 2H, $^4J$ = 2 × 2.3 and 2 × 2.1 Hz, $^4J$ = 2 × 2.2 and 2 × 2 Hz, $CH_2$=C) ppm. *Anal.* calcd. for $C_7H_{11}O_2N$·HCl: C 47.31, H 6.82, N 7.88; found: C 47.20, H 6.71, N 7.70.

*Methyl 4-benzylidene-*N*-tert-Boc-*L*-proline* **3**g

Benzyltriphenylphosphonium bromide (21.65 g, 50 mmol) was gradually added to a solution of NaH (1.2 g, 50 mmol) in anhydrous DMSO (120 mL). The suspension was warmed up to 80°C and stirred for 1 h. The red color indicated the ylide formation. A solution of **3***c* (2.86 g, 12.5 mmol) in anhydrous DMSO (30 mL) was added dropwise over a period of 30 min to the stirred ylide solution. The reaction mixture was stirred for 6 h at 80°C, cooled to room temperature, poured into 500 mL 0.2 *N* HCl, and extracted with EtOAc (3 × 100 mL), which was then washed with water (3 × 100 mL). The organic solution was dried and the EtOAc removed. Purification of the residual oil by chromatography on a silica gel column using $C_6H_6$–$Me_2CO$–$CH_3COOH$ (89:10:1) yielded the acid **3***f*, which was converted into the methyl ester by reaction with $CH_2N_2$, as described in a previous section, yielding 3.25 g (82%) of the title compound as an oil. The $^1$Hmr spectrum showed that **3***g* was a mixture of two isomers: $^1$Hmr δ: 1.43 (s, 9H, *t*-butyl), 2.96 (m, 2H, $CH_2$CH), 3.65 and 3.67 (2 × s, 3H, $COOCH_3$), 4.15–4.65 (m, 3H, $CH_2N$ and CHN), 6.36 (m, 1H, CH=C), 7.23 (m, 5H, phenyl); ms *m/e*: 317 ($M^+$).

*Methyl 4-benzylidene-*L*-proline hydrochloride (***2***b·HCl)*

*N*-deprotection of **3***g* (3.17 g, 10 mmol) according to the procedure described for **3***e* gave **2***b* (1.93 g, 89%) as an oil, which was converted into the stable crystalline hydrochloride salt and isomers were separated by fractional crystallization from ethanol–water; ir (KBr): 1740 (ester), 1520, 1425, 1060, 910, 750, 700 (ϕ—CH=C) $cm^{-1}$. *E*-isomer, mp 164–167°C (dec.); $^1$Hmr (360 MHz, DMSO-$d_6$) δ: 2.95 (4 × d, 1H, $^2J_{3',3}$ = 17.2 Hz, $^3J_{3,2}$ = 7.4 Hz, $^4J$ = 2.6 Hz, H-3), 3.21 (4 × d, 1H, $^2J_{3',3}$ = 17.2 Hz, $^3J_{3',2}$ = 8.6 Hz, $^4J$ = 2.5 Hz, H-3'), 3.76 (s, 3H, COOMe), 3.95 (dd, 1H, $^2J_{5,5'}$ = 14 Hz, $^4J$ = 2.1 Hz, H-5), 4.05 (dd, 1H, $^2J_{5',5}$ = 14 Hz, $^4J$ = 1.7 Hz, H-5'), 4.57 (dd, 1H, $^3J_{2,3}$ = 7.4 Hz, $^3J_{2,3'}$ = 8.6 Hz, H-2), 6.57 (m, 1H, $^4J$ = 2.6 and 2.5 Hz, $^4J$ = 2.1 and 1.7 Hz, CH=C) ppm. *Anal.* calcd. for $C_{13}H_{15}O_2N$·HCl: C 61.52, H 6.37, N 5.52; found: C 61.22, H 6.36, N 5.39.

The Z-isomer has a mp of 157.5–159°C (dec.).

*2-Benzylidene-5-carbomethoxy-6-azido-1-carbapenam* **5**a

A mixture of the two geometric isomers of **2***b* was used in this reaction. To 10 mL of dry $Et_2O$ at 0°C were added separately **2***b* (2.17 g, 10 mmol) in dry $Et_2O$ (10 mL) and *tert*-butylhypochlorite (1.2 mL, 10 mmol) in dry $Et_2O$ (10 mL) over a period of 10 min. After stirring at 0°C for another 10 min, additional $Et_2O$ (50 mL) was added and the solution was washed with 0.1 *N* HCl (20 mL), with water (2 × 20 mL), dried ($Na_2SO_4$), and filtered. After cooling to −15°C, 18-crown-6 polyether (30 mg) and $KO_2$ (1.2 g) were added and the stirred reaction mixture was warmed up to room temperature over a period of 30 min. The precipitate was filtered off and the $Et_2O$ evaporated to give a pale yellow oil. Analysis of the oil by tlc ($CH_2Cl_2$–MeOH, 99:1) showed the presence of two compounds with $R_f$ 0.5 and 0.6. Partial decomposition during tlc of the more polar compound was observed. The residual oil was taken up in anhydrous benzene (100 mL) and cyclohexane (100 mL) containing $Et_3N$ (1.6 mL, 12 mmol). A solution of azidoacetyl chloride (18) (0.98 mL, 11 mmol) in cyclohexane (60 mL) was added over 1 h at room temperature. The mixture was stirred for another hour, diluted with benzene (400 mL), and washed successively with 0.5 *M* phosphate buffer pH 3 (100 mL), water (100 mL), and a saturated NaCl solution (100 mL). The organic layer was dried ($Na_2SO_4$) and concentrated to yield an oily residue, which afforded after chromatography on silica gel, using $C_6H_6$–$Me_2CO$ (99:1) as eluent, 1.5 g of **5***a* (50% yield); ir ($CH_2Cl_2$): 2130 (azide), 1780 (β-lactam), 1755 (ester) $cm^{-1}$; ms *m/e*: 298 ($M^+$). The $^1$Hmr spectrum showed two singlet signals at δ 3.72 and 3.75 ($COOCH_3$), two signals at δ 4.56 and 4.59 ($CHN_3$), and broad peaks at δ 6.4 and 7.2 ($C_6H_5CH$=C) due to the presence of two geometric isomers.

*2-Benzylidene-5-carbomethoxy-6-phenoxyacetamido-1-carbapenam* **5**c

A stream of dry $H_2S$ gas was bubbled through a solution of **5***a* (1.5 g, 5 mmol) and $Et_3N$ (0.91 mL, 6.55 mmol) in anhydrous $CH_2Cl_2$ (50 mL) at 0°C for a period of 30 min. The solution was evaporated and the crude amine **5***b* was taken up in anhydrous $CH_2Cl_2$ (50 mL). After cooling to 0°C in an ice bath, $Et_3N$ (0.71 mL, 5.05 mmol) in anhydrous $CH_2Cl_2$ (30 mL) and phenoxyacetyl chloride (920 mg, 5.4 mmol) in anhydrous $CH_2Cl_2$ (30 mL) were added simultaneously. The solution was stirred for 2 h at room temperature, washed with water (4×), dried ($Na_2SO_4$), and evaporated to yield an oil which was purified by chromatography on a silica gel column ($CH_2Cl_2$–$Me_2CO$, 98:2) to yield **5***c* (1.5 g, 75%); ir ($CH_2Cl_2$): 3415 (NH), 1775 (β-lactam), 1745 (ester), 1697 (amide) $cm^{-1}$; $^1$Hmr δ: 3.55 and 3.58 (2 × s, 3H, $COOCH_3$), 4.45 (s, 2H, $CH_2CO$), 5.38 (d, 1H, *J* = 9 Hz, H-6), 6.4 (m, 1H, CH=C), 7.75 (d, 1H, *J* = 9 Hz, NH) ppm.

*2-Oxo-5-carbomethoxy-6-phenoxyacetamido-1-carbapenam* **5**d

Ozonized oxygen containing 2.5 mmol of $O_3$ was bubbled through a solution of **5***c* (812 mg, 2 mmol) in EtOAc (50 mL) at −50°C over a period of 1 h. Excess $O_3$ was removed in a stream of $N_2$ and the reaction mixture was hydrogenated at room temperature under a pressure of 0.5 kg/$cm^2$ in the presence of 100 mg 5% Pd/$CaCO_3$ for a period of 20 min. The reaction mixture was filtered and evaporated. Chromatography on silica gel (eluent $CH_2Cl_2$–$Me_2CO$, 95:5) afforded **5***d* (478 mg, 72%) as an oil; ir ($CH_2Cl_2$): 1775 (β-lactam), 1755 and 1745 (ester and ketone), 1704 (amide) $cm^{-1}$; $^1$Hmr δ: 2.97 (m, 2H, H-1 and H-1'), 3.29 and 4.08 (AB pattern, 2H, *J* = 18 Hz, H-3 and H-3'), 3.64 (s, 3H, $COOCH_3$), 4.49 (s, 2H, $CH_2O$), 5.56 (d, 1H, *J* = 9 Hz, H-6), 6.78–7.5 (m, phenyl), 7.82 (d, 1H, *J* = 9 Hz, NH) ppm; ms *m/e*: 332 ($M^+$).

*2,2-Dicarbomethoxy-4-methylene-pyrrolidine* **2**c

3-Chloro-2-chloromethyl-1-propene (10 g, 80 mmol) was added dropwise to a stirred suspension of dimethyl aminomalonate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

hydrochloride (14.68 g, 80 mmol) in anhydrous MeOH (200 mL) containing NaOMe (240 mmol). The mixture was refluxed for 6 h and the organic solvent was evaporated, leaving an orange slurry which was taken up in 1 *N* HCl (200 mL). The aqueous solution was washed with $Et_2O$ (2 × 100 mL), made alkaline with 2 *N* NaOH (pH 10), and extracted with $Et_2O$ (3 × 100 mL). The organic phase was dried ($Na_2SO_4$) and evaporated. Chromatography of the residual oil on a silica gel column, using $CH_2Cl_2$–EtOAc (98:2) as eluent, provided 3.34 g (25%) of **2***c*; $^1$Hmr δ: 2.77 (br s, 1H, NH), 3.03 (m, 2H, $CH_2$—C), 3.70 (m, 2H, $CH_2N$), 3.77 (s, 6H, $COOCH_3$), 4.95 (m, 2H, C=$CH_2$) ppm.

*1-Methylene-3,3-dicarbomethoxy-6-azido-1-carbapenam* **6**a

To 10 mL of dry $Et_2O$ at 0°C were added simultaneously **2***c* (2.09 g, 12.5 mmol) in dry $Et_2O$ (20 mL) and *tert*-butylhypochlorite (1.5 mL, 13.7 mmol) in dry $Et_2O$ (20 mL) over a period of 20 min. After stirring for 5 min the solution was washed with 0.1 *N* HCl (30 mL), with water (2 × 30 mL), dried ($Na_2SO_4$), and filtered. After cooling to 0°C, 18-crown-6 polyether (40 mg) and $KO_2$ (1.75 g) were added and the reaction mixture was stirred at 0°C for 15 min. The precipitate was filtered off and the $Et_2O$ evaporated to give an oily residue, which was taken up in anhydrous benzene (100 mL) and cyclohexane (100 mL) containing $Et_3N$ (2.07 mL, 15 mmol). A solution of azidoacetyl chloride (1.25 mL, 13.7 mmol) in cyclohexane (60 mL) was added over 40 min at room temperature and the mixture was stirred mechanically for another 40 min. The reaction mixture was worked up according to the procedure used for the synthesis of **5***a*, yielding 0.525 g of **6***a* (15%); ir ($CH_2Cl_2$): 2120 (azide), 1790 (β-lactam), 1755 (ester) cm$^{-1}$; $^1$Hmr δ: 3.28 (m, 2H, H-2), 3.78 and 3.81 (2 × s, 6H, $COOCH_3$), 4.25 (m, 1H, H-5), 4.42 (d, $J$ = 2.7 Hz, 1H, H-6), 5.28 (m, 2H, C=C$H_2$) ppm; ms *m/e*: 280 ($M^+$).

*1-Methylene-3,3-dicarbomethoxy-6-phenoxyacetamido-1-carbapenam* **6**b

Compound **6***b* was prepared as above by reduction with $H_2S$/$Et_3N$ and, subsequently, reaction with phenoxyacetyl chloride ($Et_3N$ at 0°C). After chromatography on a silica gel column (using $C_6H_6$–$Me_2CO$; 98:2 as eluent), there was obtained 270 mg (25%) of **6***b* (starting from 2 mmol of **6***a*) which was crystallized from $Et_2O$/hexane, mp 143–145°C (dec.); ir ($CH_2Cl_2$): 3425 (NH), 1790 (β-lactam), 1755 (ester), 1700 (amide), 1610, 1440, 910 (C=$CH_2$) cm$^{-1}$; $^1$Hmr (90 MHz, $CDCl_3$) δ: 3.31 (m, 2H, H-2), 3.78 and 3.80 (2 × s, 6H, $COOCH_3$), 4.30 (m, 1H, H-5), 4.53 (s, 2H, $CH_2O$), 5.07 (q, 1H, $J$ = 8.0 Hz, $J$ = 2.7 Hz, H-6), 5.36 (m, 2H, $CH_2$=C), 6.83–7.47 (m, 5H, phenyl), 7.6 (d, 1H, $J$ = 8 Hz, NH) ppm; $^{13}$Cmr ($CDCl_3$) δ: 44.3 (C2), 53.5 and 53.6 ($OCH_3$), 63.3 (C6), 65.2 (C5), 67.2 ($CH_2O$), 72.4 (C3), 112.2 (=$CH_2$), 114.9, 122.4 and 130 (phenyl), 142.5 (C1), 157.2 (*C*—$OCH_2$), 166.2, 168.6 and 171 (C=O) ppm; ms *m/e*: 388 ($M^+$). *Anal.* calcd. for $C_{19}H_{20}O_7N_2$: C 58.75, H 5.19, N 7.21; found: C 58.52, H 5.26, N 7.09.

# Low temperature carbon-13 magnetic resonance detection of axial conformers in vinyl- and formylcyclohexane: a deshielding γ–*gauche* effect

G. W. BUCHANAN

*Ottawa–Carleton Institute for Research and Graduate Studies in Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6*

Received May 10, 1982

G. W. BUCHANAN. Can. J. Chem. **60**, 2908 (1982).

Using 50.3 MHz $^{13}C$ nmr at 173 K, distinct resonances for axial conformers of vinyl- and formylcyclohexane have been obtained. Substituent effects for axial and equatorial substitution of these groups have been derived. A deshielding γ–*gauche* effect was found for the axial substituent carbon of formylcyclohexane, a result attributed to the high preference for rotamers in which the formyl proton does not sterically interfere with *syn*-axial protons at C-3 and C-5 of the ring. Conformational free energies for the vinyl and formyl groups have been estimated to be 1.49 and 0.84 kcal/mol respectively.

G. W. BUCHANAN. Can. J. Chem. **60**, 2908 (1982).

En utilisant l'rmn de $^{13}C$ à 50.3 MHz et 173 K, on a trouvé des résonances pour la conformation axiale du vinyle- et formylecyclohexane. On a étudié les effets de la substitution axiale et equatoriale des deux groupements. Un déblindage γ–*gauche* a été trouvé pour le carbone axial du formylecyclohexane, un résultat attribué à la grande préférence pour les rotamères dans lesquels le proton formyle n'est pas dans une position près des protons *syn*-axiaux du cycle cyclohexanique. On a estimé les énergies conformationaux pour les groupements formyle et vinyle. Les valeurs sont 0.84 et 1.49 kcal/mol respectivement.

## Introduction

Low temperature $^{13}C$ nmr at high field is a powerful technique for measurement of low barrier conformational processes and detection of minor stereoisomers. Among the early applications in the latter area was the work of Anet *et al.* (1) in which the lowly populated axial conformer of methylcyclohexane was directly observed at 63.1 MHz.

Recently there has been renewed interest in determining the conformational preference of the vinyl group in substituted cyclohexanes (2). From low temperature $^{13}C$ nmr studies of *cis*-4-methyl-1-vinylcyclohexane, the conformational free energy of the vinyl group, $(-\Delta G^{0}_{CH=CH_2})$, has been determined to be $1.68 \pm 0.06$ kcal/mol, only slightly smaller than the currently accepted value of $1.75 \pm 0.06$ kcal/mol for the $CH_3$ group (3).

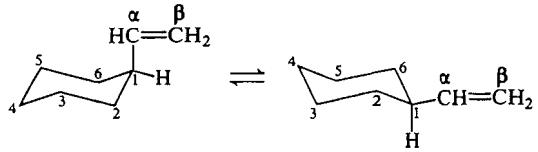
The use of 1,4-disubstituted derivatives, however, may suffer from the assumption of additivity of conformational free energies for the two substituents. Ideally one would prefer to have a direct measure of the conformational preference for a given functionality in the monosubstituted cyclohexane. In the recent report (2) it is stated that the conformational equilibrium in vinylcyclohexane is too one-sided to be measured directly. Considering the early success of high field $^{13}C$ nmr in studying methylcyclohexane (1), however, we deemed it worthwhile to search for the axial conformer of vinylcyclohexane using the same technique.

As a comparative system, we have chosen a conformationally less biased, but structurally related molecule, formylcyclohexane, for which the conformational free energy has already been directly determined via low temperature $^{1}H$ nmr (4).

## Results and discussion

### *Vinylcyclohexane*

$^{13}C$ chemical shifts for vinylcyclohexane (**1**) at room temperature in two solvent media and for individual conformers **1***A* and **1***E* at 173 K are presented in Table 1. Results for **1** in $CD_2Cl_2$–$CS_2$ are essentially identical to those reported by Eliel and Manoharan (2), for **1** in $CD_2Cl_2$.



**1***A* **1***E*

At 173 K, five new resonances appeared for **1** which were not present at room temperature or at 203 K. Figure 1 shows a typical spectrum for the α-carbon of a 3.0 *M* solution of **1** in 1:1 $CD_2Cl_2$–$CS_2$ solution at 173 K. A new resonance has appeared at 141.54 ppm with an intensity ca. 1.5% of that for the peak at $\delta_c = 144.68$. New lines of this approximate intensity were observed near all resonances except that of C-4, where peak overlap presumably precludes identification of a resonance associated with C-4 of the axial conformer.

In order to provide satisfactory signal-to-noise ratios for resonances of the axial conformer, 2000 accumulations on the 3.0 *M* solutions of **1** were required. No substantial broadening of the equato-

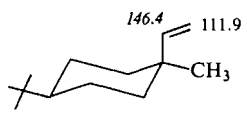
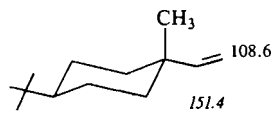
rial resonances was noted as the bands for the axial form merged with them due to the high value of the equilibrium constant.

(a) *Chemical shifts*

Examination of data in Table 1 indicates that there is only a minor effect of solvent on shift values of individual conformers, with the maximum difference being 0.29 ppm (at C-1 and C-3,5 of the axial forms). There is however a general trend to slight upfield shifts in $C_7D_8$.

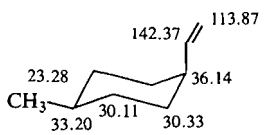
It is of particular interest to examine the steric effects on the chemical shifts of individual conformers. For the olefinic methine carbon (C-α), the axial carbon is *shielded* by an average of 3.15 ppm relative to its equatorial counterpart. This difference is somewhat smaller than that seen in stereochemically "rigid" molecules as shown below (5), but the trend is the same.

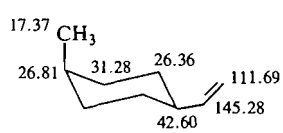




The average carbon chemical shift difference between axial and equatorial olefinic methylene groups of **1*A*** and **1*E*** is 2.23 ppm, with the equatorial methylene carbon being more shielded than its axial counterpart.

Data for the two conformers of *cis*-4-methyl-1-vinylcyclohexane (2) are also useful for comparison with **1*A*** and **1*E***, and these are presented below. The olefinic carbon shift differences between these conformers are within 0.3 ppm of those found in the present work.





Data in Table 1 also indicate a substantial shift difference between C-1 resonances for **1*A*** and **1*E***, the axial conformer being shielded by an average of 5.21 ppm relative to its equatorial counterpart.

For C-3,5 of **1*A***, involved in a γ–*gauche* interaction with the vinyl methine carbon, the upfield shift is an average of 4.70 ppm relative to C-3,5 of **1*E***. In the case of C-2,6, the upfield shifts for **1*A*** relative to **1*E*** are somewhat smaller, ca. 2.00 ppm for results averaged over the two solvent media.

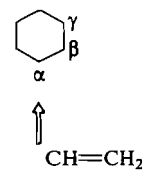
In general, the upfield shifts for the olefinic methine carbon, C-1, C-2,6, and C-3,5 of **1*A*** relative to **1*E*** are consistent with results for other pairs of monosubstituted cyclohexane conformers (1, 3, 6).

With these data in hand, combined with the cyclohexane chemical shift of 27.27 ppm at 173 K in $CD_2Cl_2$–$CS_2$, one can formulate a series of α, β, and γ substituent parameters for addition of axial and equatorial vinyl groups.

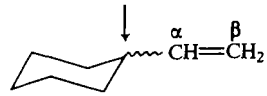
The values are as follows: $\alpha_{ax} = +10.01$, $\alpha_{eq} = +15.07$; $\beta_{ax} = +3.04$, $\beta_{eq} = +5.27$; $\gamma_{ax} = -5.84$ and $\gamma_{eq} = -0.97$. Of course these parameters will vary somewhat with solvent and solute concentration.

It is interesting to compare the above substituent effects with those for a methyl group (7), where $\alpha_{ax} = +1.1_0$, $\beta_{ax} = +5.15$, $\gamma_{ax} = -5.40$, $\alpha_{eq} = +5.6_5$, $\beta_{eq} = +8.9_0$, and $\gamma_{eq} = 0.00$.

The larger deshielding α effects of the vinyl



group (9–10 ppm more than $CH_3$) are clearly due to the β effect of the olefinic methylene group at C-1, below, an effect which is known to be deshielding (8).



As noted previously (2), the deshielding effects for both axial and equatorial vinylcyclohexanes at C-2,6 are noticeably smaller than for the methyl-

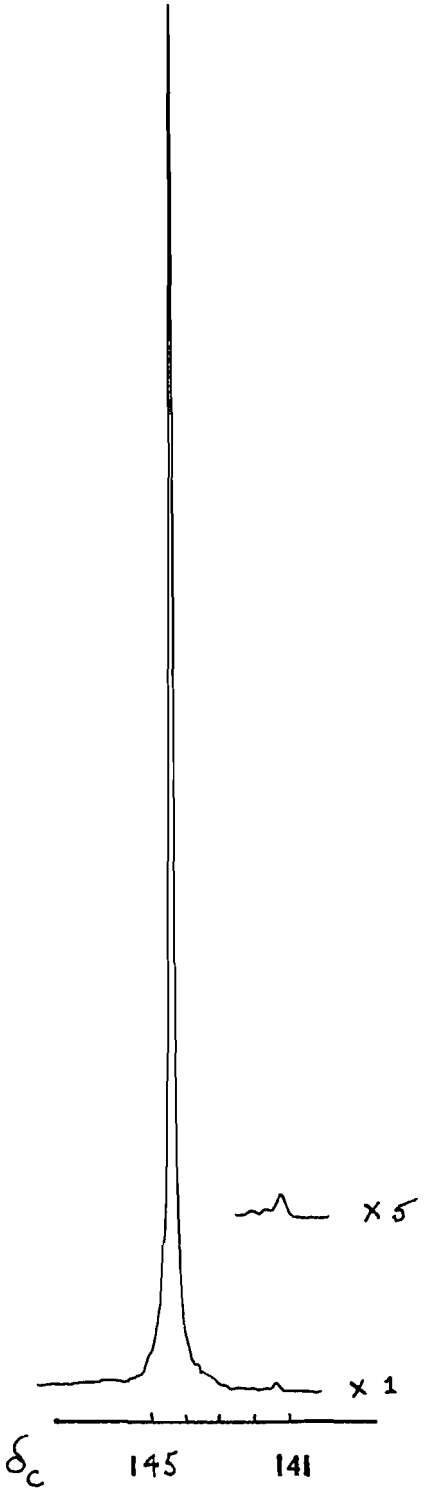

FIG. 1. C-α resonances for 1*A* and 1*E* at 173 K in 1:1 $CD_2Cl_2$–$CS_2$ (2000 accumulations on a 3.0 *M* solution).

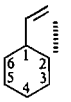
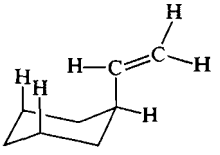
cyclohexanes, which may be due to a contribution from a steric shielding effect of the terminal methylene group (below).



This result implies at least a minor population of the conformations of the vinyl group in which the double bond is eclipsed, or nearly so, with the C(1)—C(2) or C(1)—C(6) bond, rather than with the C(1)—H bond. A recent $^1H$ nmr study of couplings in vinylcyclohexane (9) supports this suggestion.

A further point of interest here is the upfield shift for the olefinic methylene carbon of 1*E* relative to 1*A*. The origin of this shielding may lie in an increased amount of double bond eclipsing with C(1)—C(2) or C(1)—C(6) in 1*E* compared to 1*A*.

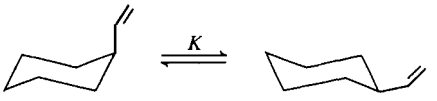
Finally the $\gamma_{ax}$ shift for vinylcyclohexane is within 0.5 ppm of that found for methylcyclohexane (1, 7), which probably indicates a substantial preference for the bisecting conformation shown below. In view of the above evidence, we therefore suggest that this bisecting conformer dominates for 1*A*, with a minor contribution from conformers in which the double bond is nearly eclipsed with the C(1)—C(2) or C(1)—C(6) bond. For 1*E*, the degree of this type of eclipsing appears to exceed that present in 1*A*.



1*A*

(b) *Conformational free energy of the vinyl group*

For determination of *K*, the relative areas of the five distinguishable resonances for 1*A* (i.e. all except C-4) were measured relative to 1*E*, using graphical methods.



The average value of *K* (in $CD_2Cl_2$–$CS_2$) was 77.0, with values ranging from 95.0 to 50.1. Substitution into the equation $-\Delta G^0 = RT\ln K$ yields an average value of 1.49 kcal/mol as the conformational free energy of the vinyl group. Our limiting

TABLE 2. $^{13}C$ chemical shifts of formylcyclohexane conformers ($\delta_c \pm 0.01$)

| Compound | Solvent | C-1 | C-2,6 | C-3,5 | C-4 | C=O \| H |
|---|---|---|---|---|---|---|

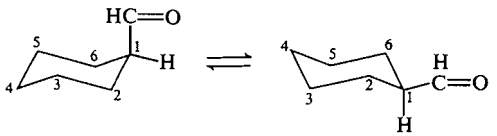
*At 173.0 ± 2.0 K.
†Abbreviation: n.o. ≡ not observable due to peak overlap.

values are 1.56 kcal/mol (for $K = 95.0$) and 1.34 kcal/mol (for $K = 50.1$) respectively.

Based on results for *cis*-4-methyl-1-vinylcyclohexane, Eliel and Manoharan (2) have determined $-\Delta G^0_{CH=CH_2}$ to be 1.68 ± 0.06 kcal/mol. Due to the obvious difficulties in the present work of measuring $K$ precisely, our uncertainty is at least a factor of two higher than that quoted in the recent work (2). Nevertheless, it appears that direct determination of $-\Delta G^0_{CH=CH_2}$ leads to a smaller value than that obtained from a 1,4-disubstituted derivative. The present value of 1.49 kcal/mol is, however, larger than that of 1.39 kcal/mol obtained using 1-vinylcyclohexanol (10). We find no effect of solvent on $K$ within the limits of uncertainty.

*Formylcyclohexane*

$^{13}C$ chemical shifts for formylcyclohexane (**2**) at room temperature in two solvent media and for individual conformers **2A** and **2E** at 173 K are presented in Table 2.

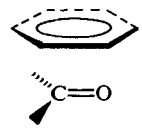


**2A** **2E**

The C-3,5 carbon resonance was distinguished from that for C-2,6 based on the totally coupled spectral appearance. At 173 K four new resonances appeared for **1** which were not present at 293 K or 203 K. Figure 2 shows a typical spectrum for the aldehyde carbon of a 1.5 *M* solution of **2** in 1:1 $CD_2Cl_2$–$CS_2$ solution at 173 K. A new resonance at $\delta_c = 206.49$ has appeared with an intensity ca. 10% of that at $\delta_c = 205.45$. Similarly, new lines were seen near all resonances except that of C-4, which was presumably obscured due to peak overlap.

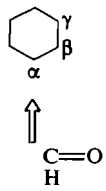
(a) *Chemical shifts*

Data in Table 2 indicate that only the formyl carbon is substantially affected by a change in solvent, its resonance being shifted upfield by ca. 2 ppm in toluene-$d_8$ relative to the $CD_2Cl_2$–$CS_2$ solvent system. This upfield shift can be rationalized in terms of a solute–solvent collision complex as depicted below in which the electron deficient carbonyl carbon lies in the inner "shielding" region of the aromatic π cloud (11).



With regard to the steric effects on shifts of individual conformers, the most remarkable finding is that the *axial* aldehyde carbon is *deshielded* relative to its equatorial counterpart by ca. 1.1 ppm. To our knowledge, this is the first example of a case in which a carbon engaged in a γ-*gauche* interaction (i.e. with C-3,5 in **2A**) is deshielded relative to its equatorial counterpart **2E** which lacks this steric interaction.

Despite the fact that the aldehyde carbon is deshielded in the axial conformer, the resonances for C-1, C-2,6, and C-3,5 are all appreciably *shielded* in **2A** relative to **2E**. Using our shift of 27.27 ppm for cyclohexane in $CD_2Cl_2$–$CS_2$ at 173 K, one can obtain α, β, and γ shift parameters for the axial and equatorial formyl group substitution in the same way as was done for the vinyl function.



The results are as follows; $\alpha_{ax} = +19.60$, $\alpha_{eq} = +23.18$; $\beta_{ax} = -2.30$, $\beta_{eq} = -1.29$; $\gamma_{ax} = -4.28$, and $\gamma_{eq} = -1.65$.

It is interesting to compare these substituent induced shifts with those for butanol, below (12).

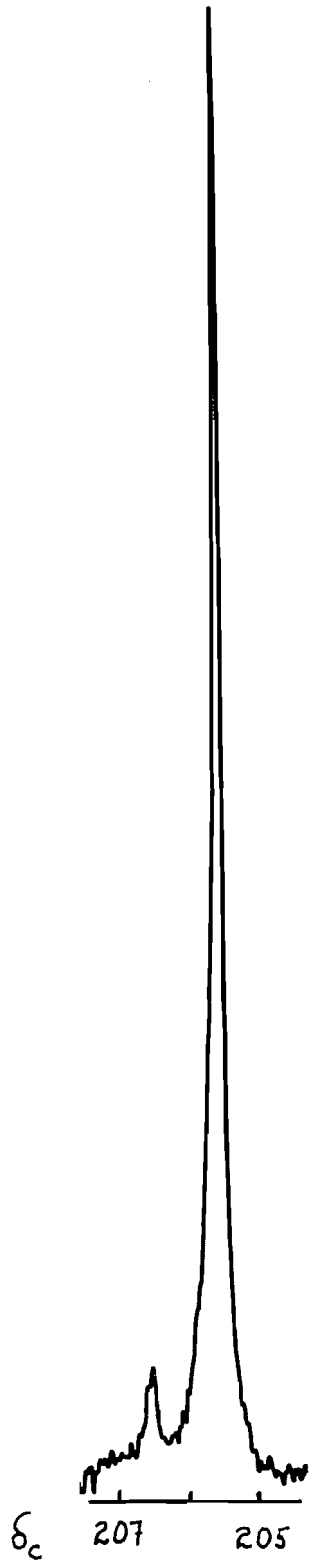

FIG. 2. Formyl carbon resonances for **2A** and **2E** at 173 K in 1:1 $CD_2Cl_2$–$CS_2$ (800 accumulations on a 1.5 *M* solution).

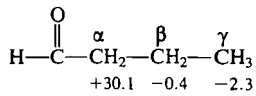
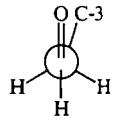
The attenuated deshielding α effect in the branched cyclohexanecarboxaldehyde relative to butanal is a normal result of chain branching and has ample precedent (8).

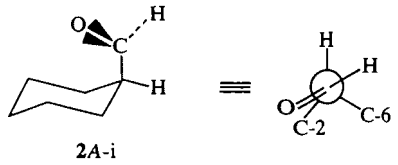


The *upfield* β shifts for butanal, **2A**, and **2E** are very likely a consequence of the presence of substantial amounts of rotamers in which the carbonyl oxygen is eclipsed with neighbouring C—C bonds. Thus, a shielding γ effect from the carbonyl oxygen becomes superimposed on a normally deshielding β effect. For butanal, it has been determined from $^1H$ nmr coupling constant analysis (13) that the eclipsed conformation (below) is present to an extent of ca. 60% at 20°C.

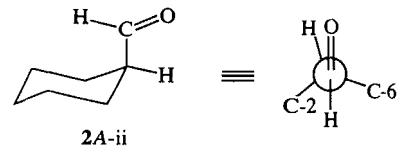


In the case of **2A** and **2E**, one can examine the relative upfield β shifts in terms of the conformer populations estimated from $^1H$ nmr (13, 14) for *cis*- and *trans*-4-*tert*-butylcyclohexanecarboxaldehydes. For **2A**, the probable conformers are shown below.

Conformer **2A**-i, or its mirror image, is deemed to be prevalent (93%) compared to a 7% population for **2A**-ii (14).

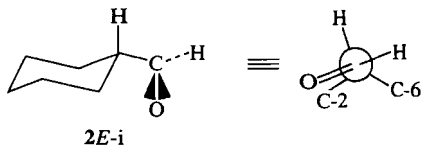


**2A**-i

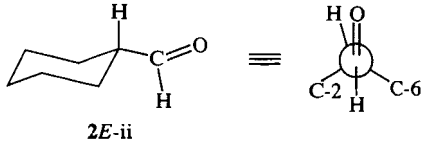


**2A**-ii

For **2E**, the probable conformers are depicted below.



**2E**-i

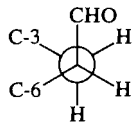


**2E**-ii

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

It was found (14) that **2***E*-i and its mirror image are favoured to the extent of 84% to 16% for **2***E*-ii. In the $^{13}C$ spectra, the β effect for **2***E* is −1.29 ppm, compared to −2.30 ppm for **2***A*. This seems consistent with the lower degree of preference for conformers having the C=O bond eclipsed with C-2 or C-6 in **2***E* than in **2***A*.

The γ effects involving $sp^3$ hybridized carbons are all shielding effects, even for **2***E*, where C-3,5 are *trans* to the formyl group. The $\gamma_{eq}$ value is only −1.65 ppm, however, compared to −4.28 ppm for $\gamma_{ax}$. One can rationalize the larger upfield γ effect at C-3,5 of **2***A* in terms of γ-*gauche* interactions between these carbons and the axial formyl carbon (below).



For the more freely rotating butanal, the magnitude of the γ shift is between those for **2***A* and **2***E*, but, as expected, considerably closer to that for **2***E*.

Finally, some comment on the *deshielded* formyl carbon in **2***A* relative to **2***E* is necessary. This appears to be the first example of an axial carbon, directly attached to a cyclohexane ring, being deshielded relative to its equatorial counterpart. The unique key feature of **2***A* is its highly preferred (93%) conformation **2***A*-i in which the formyl *proton* does not interfere spatially with the *syn*-axial protons at C-3 and C-5. One must infer, therefore, that when such an interaction is lacking, there is no reason to expect, a priori, an upfield shift for the attached axial carbon.

This phenomenon remains to be investigated for related systems, and work along these lines is in progress.

(b) *Conformational free energy of the formyl group*

From relative peak area measurements at 173 K, the average $-\Delta G^0_{CHO}$ was determined to be 0.84 ± 0.08 kcal/mol, in good accord with that determined previously (4) by $^1H$ nmr peak areas at the low temperature. No solvent dependence was evident.

## Experimental

(a) *Materials*

Vinylcyclohexane was obtained from Aldrich Chemical Corp. and distilled before use. Formylcyclohexane was purchased from Frinton Laboratories, South Vineland, New Jersey and used without further purification.

(b) *Spectra*

The $^{13}C$ nmr spectra were obtained at 50.3 MHz using a Varian XL-200 spectrometer. Sample concentrations were 3.0 *M* for **1** and 1.5 *M* for **2**, in 10 mm od tubes. Typically, spectra were obtained with complete $^1H$ noise decoupling. Normal conditions were as follows: sweep width = 10 000 Hz, number of data points = 32 000, pulse width = 7.0 μs (45°), acquisition time = 1.6 seconds, and repetition rate = 1.0 seconds. The number of accumulations for the low temperature spectra were typically 2000 for **1** and 800 for **2**.

# Thermolysis of 2-methoxy-2,5,5-trimethyl-$\Delta^3$-1,3,4-oxadiazoline

A. P. HITCHCOCK, S. ZWEEP, T. STEEL, M. BÉKHAZI, AND J. WARKENTIN
*Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1*

Received February 11, 1982

A. P. HITCHCOCK, S. ZWEEP, T. STEEL, M. BÉKHAZI, and J. WARKENTIN. Can. J. Chem. **60**, 2914 (1982).

The principal product of gas phase thermal decomposition of 2-methoxy-2,5,5-trimethyl-$\Delta^3$-1,3,4-oxadiazoline (methoxyoxadiazoline) was found to be 1-methoxy-1-[(1-methylethenyl)oxy]-ethane (vinyl ether). This arises from a selective 1,4-hydrogen shift in the carbonyl ylide intermediate. Fragmentation of the carbonyl ylide is the dominant process in the solution thermolysis of methoxyoxadiazoline. The phase and temperature dependence of this thermolysis is discussed in terms of the probable structure of the carbonyl ylide intermediate.

A. P. HITCHCOCK, S. ZWEEP, T. STEEL, M. BÉKHAZI et J. WARKENTIN. Can. J. Chem. **60**, 2914 (1982).

On a trouvé que le méthoxy-1 [(méthyléthenyl-1)oxy]-1 éthane (éther vinylique) est le produit principal de la décomposition thermique en phase gazeuse du méthoxy-2 triméthyl-2,5,5 $\Delta^3$ oxadiazoline-1,3,4 (méthoxyoxadiazoline). Ce produit provient d'un glissement sélectif 1,4 d'hydrogène dans l'intermédiaire ylure de carbonyle. La fragmentation de l'ylure de carbonyle est le processus dominant lors de la thermolyse de la méthoxyoxadiazoline en solution. On discute de l'influence de la température sur cette thermolyse en fonction de la structure probable de l'ylure de carbonyle intermédiaire.

## Introduction

$\Delta^3$-1,3,4-Oxadiazolines (e.g. 2-methoxy-2,5,5-trimethyl-$\Delta^3$-1,3,4-oxadiazoline, **1**) undergo both thermal and photochemical decomposition to give a wide variety of products the nature of which depends on both the decomposition conditions and the nature of the substituents (1). In all cases the decomposition appears to involve the ejection of molecular nitrogen and the formation of a transient carbonyl ylide species, **2** (Fig. 1). The carbonyl ylide can then undergo a variety of intramolecular reactions (1) as outlined for **1** in Fig. 1. Thermolysis of **1** at 80°C in a variety of solvents (e.g. $C_6H_6$, $CCl_4$) yields primarily the fragmentation products (**4–7**) with little, if any, of the vinyl ether **8** (1-methoxy-1-[(1-methylethenyl)oxy]-ethane) or the epoxide **3**. Solution thermolysis of other substituted oxadiazolines (e.g. 2-aryl-2-methoxy analogs of **1**[1]) does yield the appropriate analogues of **8** and **3** in addition to the related fragmentation products. All of the product distribution evidence to date, from both thermolysis and photolysis of oxadiazolines, supports the hypothesis of the carbonyl ylide intermediate (1).

We have studied the gas phase thermolysis of **1** by photoelectron spectroscopy with the goal of obtaining direct spectroscopic evidence for the carbonyl ylide intermediate **3**.[2] Although bands attributable to the carbonyl ylide have not yet been detected in the photoelectron studies (probably due to lifetime limitations), it was discovered that **1** undergoes a qualitatively different thermal decomposition when isolated in the gas phase, with the principle final product resulting from a 1,4-hydrogen shift rather than fragmentation of the carbonyl ylide. The evidence for this alternative reaction pathway is presented.

Recently Houk *et al.* (2) have reported *ab initio* calculations of the geometric and electronic structure of substituted carbonyl ylides and have discussed their influence on the subsequent decomposition. These results provide a groundwork for our discussion of the phase dependence of the thermolysis of **1**.

## Experimental

Methoxyoxadiazoline (**1**) was prepared as described earlier (*1b*). In order to investigate the phase and temperature dependence, the gas phase thermolysis of **1** was carried out both at moderate (80°C) and elevated (300–450°C) temperatures. The higher temperature thermolyses were performed in the inlet to a lab-built HeI photoelectron spectrometer which has been described previously (3). It is based on the design of Frost *et al.* (4). The sample was passed at reduced pressure (ca. $10^{-2}$ Torr) through a 30 cm long quartz tube, the temperature of which was monitored by a thermocouple to within ± 10°C. For the trapping of products a Pyrex trap cooled with liquid nitrogen was installed at the outlet of the quartz tube. For the 80°C thermolysis a small amount of **1** was sealed in a flask sufficiently large for complete volatilization. The sample was then thermostatted at 80°C for one week. During this period essentially all of the starting material decomposed. The product distributions from the thermolysis reactions were determined by $^1$H nmr.

Compound **8** was isolated by preparative glpc from the material trapped following high temperature thermolysis: $^1$H nmr ($CDCl_3/Me_4Si$) δ: 1.35 (d, 3H, $CH_3CH$), 1.84 (s, 3H, $CH_3C{=}$), 3.33 (s, 3H, $OCH_3$), 3.95 (s, 2H, $=CH_2$), 5.10 (q, 1H, HC(O)O).

Products **4** and **6** were identified from their glpc retention times and from their $^1$H nmr spectra.

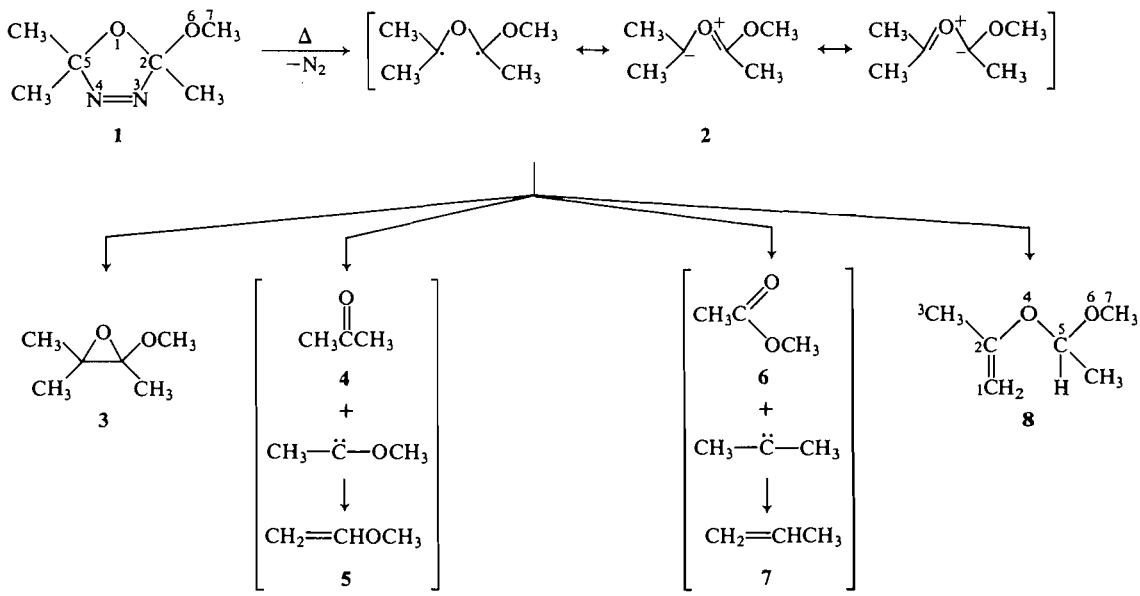

FIG. 1. Reaction pathways of methoxyoxadiazoline, **1**, following thermolysis.

## Results and discussion

Heating **1** as it entered the photoelectron spectrometer produced no detectable change in the spectrum until the furnace reached a temperature of 275°C. At this temperature the spectrum changed dramatically with the appearance of the sharp bands of molecular nitrogen. The transformation from reactant spectrum to thermolysis product spectrum occurred over a surprisingly small temperature range (ca. 25°C). This new spectrum of the thermal decomposition products remained essentially constant with increasing temperature up to 450°C, the highest temperature employed. Thus, the products of thermolysis of **1** are stable to 450°C during their residence time in the tube and essentially all of the starting material is destroyed at a temperature ≥ 300°C.

Following liquid nitrogen trapping the solidified 380°C thermolysis product mixture was warmed to room temperature (thereby losing volatile products) and analysed by gas chromatography and $^1$H nmr. Three decomposition products were positively identified: vinyl ether, **8** (ca. 70 mol% of the identified products), methyl acetate, **6** (ca. 20 mol%), and acetone, **4** (ca. 10 mol%). In addition, unidentified products gave rise to ca. 7% of the total nmr signal. The formation of methyl acetate and acetone imply the concomitant formation of propene and methyl vinyl ether **5** in equal amounts (1*a*, 1*b*) (Fig. 1). The $^1$H nmr yields listed above thus represent branching ratios in the thermal decomposition of **1** at 380°C. Signals due to **5** and **7** were not observed in the $^1$H nmr spectrum of the product mixture. Both are volatile and could have been partially lost by evaporation when the product mixture was warmed to room temperature. Vinyl ethers, such as **5** and **8**, are polymerizable and polymeric products may be responsible for some of the weak, unidentified lines in the nmr spectrum. We note that the vinyl ether **8** decomposed at room temperature in chloroform solution (open to the atmosphere) within hours after formation by thermolysis.

The possibility that catalysis by acidic sites on the walls of the quartz furnace tube is involved in the fragmentation processes was investigated by applying a passivation procedure to the quartz tube prior to one thermolysis run. The procedure consisted of washing the quartz tube with 0.1 *N* NaOH, coating with a 5% $(CH_3)_3SiCl$–toluene solution and rinsing with MeOH. Wall passivation had a negligible influence on the progress of the thermolysis as judged by the pe spectrum during decomposition and by the nmr spectrum of the trapped products. This suggests that wall reactions play a negligible role in the fragmentation.

The product distributions from gas phase thermolysis at high (380°C) and moderate (80°C) temperatures are compared in Table 1 to the product distributions from 80°C thermolysis of **1** in $CCl_4$ solution (1*a*). In contrast with solution thermolysis, where fragmentation dominates (1*a*, 1*b*), the

TABLE 1. Product yields (branching ratios) from gas phase and solution thermolysis of methoxyoxadiazoline, **1**

| | Yield (mol%) | | |
|---|---|---|---|
| | Gas phase | | Solution in $CCl_4$[a] |
| Species | $T$ = 380°C[b] | $T$ = 80°C | $T$ = 80°C |
| Vinyl ether, **8** | 69 (3)[c] | 50 (2)[c] | ≈0[d] |
| Acetone, **4** | 8 (2) | 28 (3) | 43 |
| Methyl acetate, **6** | 23 (3) | 22 (3) | 54 |
| Epoxide, **3** | 0 | 0 | 0 |

[a]The coproducts for acetone formation and for methyl acetate formation are $CH_3COCH_3$ and $CH_3CCH_3$. For the fate of these in $CCl_4$, see refs. 1*a*, 1*b*.
[b]This is the temperature of the quartz furnace. Due to the short residence time of the molecules ($10^{-2}$–$10^{-1}$ s) and limited numbers of collisions, the molecular temperature may be somewhat lower. However, the great difference in kinetics from the gas phase thermolysis (i.e. time constants of milliseconds instead of hours) is definitive evidence of a significantly higher molecular temperature.
[c]Average of three separate thermolyses. The numbers in brackets are the standard deviation in the last figure.
[d]Although **8** cannot be detected among the products, it is formed in low yield from thermolysis of **1** in other nonpolar solvents. We cannot rule out the possibility that **8** is a minor product in $CCl_4$ and that it does not survive the conditions.

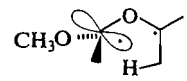
1,4-H shift is the predominant route in the gas phase, even at 80°C. The relative yields of the 80°C and 380°C gas phase thermolyses are surprisingly similar, although the rates of decomposition are many orders of magnitude different, as expected.

There are several potential explanations of the dependence of the product ratio on the phase. As Table 1 shows, the yield of **8** is large in the gas phase and near zero in $CCl_4$, at 80°C. Mechanisms which account for this must either invoke a larger rate constant for H-transfer in the gas phase than in solution or lower rate constants for fragmentations in the gas phase than in solution, or both.

The 1,4-hydrogen shift is an allowed sigmatropic rearrangement which ought to be most facile if there is good conjugation, as is the case for the 0°,0° conformation of **2**.[3] That conformation, which is also the one with maximum diradical character and minimum polarity (2), is expected to be favoured in the gas phase. Since transition states for sigmatropic processes involving neutral species do not involve much charge separation, the system would appear to be set up for a facile 1,4-shift, probably requiring relatively little twisting to reach the transition state in the gas phase. Thermal fragmentations of carbonyl ylides, on the other hand, are not allowed from the 0°,0° conformation but are allowed from 0°,90° or 90°,0° conformations (2). The latter are thought to be much more zwitterionic than the 0°,0° conformation (2) and should therefore be relatively inaccessible in the gas phase as compared to a condensed phase. Thus, the 1,4-shift model appears to be adequate to explain the phase dependence.

In an alternative model,[4] the H-transfer which converts **2** to **8** is viewed as an intramolecular radical abstraction comparable to the H-transfer which occurs in the "ene" reaction, eq. [1].

[1] 
Harding and Goddard (5) have proposed that the "ene" reaction involves an intermediate which is predominantly a diradical in the gas phase and that the H-transfer from C to O (eq. [1]) is an intramolecular disproportionation. Some details of the "ene" reaction could be explained by assuming that the intermediate adopts more zwitterionic character (eq. [1]) in solution than in the gas phase (5). Although this model is an attractive alternative at first sight, there is an important difference between the transition states that are being compared. That for the "ene" reaction is six-membered while that for the process **2** → **8** is five-membered. Examination of a model suggests that the H-abstraction transition state (**9**) can involve reasonable distances and orbital alignments only if the



**9**

geometry is one approaching a 0°,90° conformation. Twisting away from the 0°,0° conformation permits the COC bond angle to decrease, because of reduced steric interactions, and brings the reacting sites closer together. At the same time, the "abstracting orbital" becomes better aligned with the reacting C—H bond. However, an increase in zwitterionic character would have to accompany the twisting (2). H-transfer should therefore be disfavoured in the gas phase, in contradiction of the experimental results.

Another alternative explanation would attribute the phase dependence to reactions of a "hot" intermediate. A vibrationally excited carbonyl ylide is a possibility because loss of nitrogen from the oxadiazoline is exothermic.[5] In the gas phase, at low pressure, such a nonequilibrated species might react before it could be deactivated to the ground

[3]In this labelling of the conformations of the ylide, each angle refers to the orientation of an X—C—X substituent plane with respect to the central C—O—C plane (2). For **2**, the first angle refers to the $CH_3$—C—$CH_3$ end while the second refers to the $CH_3O$—C—$CH_3$ end (arbitrary assignment).

[4]We thank a referee for suggesting this model.

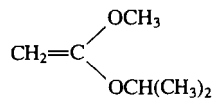
[5]Using the following approximate bond energies (6), we estimate $\Delta H$ for $N_2$ loss to be at least −32 kcal mol$^{-1}$, neglecting the resonance energy of the ylide. Bond energies (kcal mol$^{-1}$): C—$N_{azo}$ (47), N=N (100), N≡N (226).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

state through collisions. Although there are examples from the area of carbene chemistry of the dependence of final product composition on the rate of collisional deactivation (7), it is not clear in the present case that vibrational excitation should favour H-transfer over fragmentation. Although we cannot rule out this last alternative, we favour the first explanation for the phase dependence.

The temperature dependence of the product distribution in the gas phase is puzzling. There is no obvious explanation for it which is based on the intermediacy of oxirane **3**. That oxirane would have to open preferentially to ylide at high temperature and to carbenes and carbonyl compounds at low temperature. Since the fragmentations are expected to have entropies of activation at least as large as that of ring opening, such an explanation is unlikely to be correct. What is more, the known chemistry of similar oxiranes (8, 9) suggests that **3** would actually rearrange to a methoxy ketone, $CH_3COC(CH_3)_2OCH_3$. We are not aware of any precedent for conversion of **3** to **8** directly, without the intermediacy of **2**. If such a direct path is not available, then postulating equilibrium between **2** and **3** also cannot lead to a satisfactory explanation of the temperature dependence. Further studies, with other substituents, should help to establish whether or not the temperature dependence observed here is a general phenomenon in the chemistry of carbonyl ylides, whose fates are apparently very substituent dependent, as mentioned in the Introduction.

High temperature vapour phase thermolysis of **1** is a potentially useful synthetic procedure. Acetals in which one alkoxy function is enolic are rare and their synthesis by the usual avenues for acetals and ketals has not been reported. In the present thermolysis reaction the H-transfer process is quite selective in the sense that the hydrogen atom comes from the *gem*-dimethyl group and not from the other methyl group. The alternative product,



would have a vinyl signal near δ 3.0 in the $^1$H nmr spectrum, for $CH_2{=}C(OEt)_2$ absorbs at δ 3.01 (10). Since the $^1$H nmr spectra of our product mixtures have no appreciable absorption in that region, it is clear that little, if any, H-transfer occurs in the alternative sense.

# The preparation of (*S*)-3,4-dehydroproline from (2*S*,4*R*)-4-hydroxyproline

HEINRICH RÜEGER AND M. H. BENN[1]

*Chemistry Department, The University, Calgary, Alta., Canada T2N 1N4*

Received June 1, 1982

HEINRICH RÜEGER and M. H. BENN. Can. J. Chem. **60**, 2918 (1982).

(2*S*,4*R*)-*N*-Benzyloxycarbonyl-4-tosyloxyproline methyl ester, readily prepared from commercially available (2*S*,4*R*)-*N*-benzyloxycarbonyl-4-hydroxyproline, was converted to (*S*)-3,4-dehydroproline of high enantiomeric purity by a process which involved a highly regioselective phenylselenoxide elimination to introduce the olefinic function.

HEINRICH RÜEGER et M. H. BENN. Can. J. Chem. **60**, 2918 (1982).

On a transformé l'ester méthylique de la *N*-benzyloxycarbonyltosyloxy-4 proline (2*S*,4*R*), provenant de la *N*-benzyloxycarbonylhydroxy-4 proline disponible commercialement, en déhydro-3,4 proline (*S*) d'une grande pureté énantiométrique. On a introduit la fonction oléfinique en utilisant une méthode qui fait intervenir une élimination très régiosélective par le sélénate de phényle.

[Traduit par le journal]

Seventy years ago Fischer and Gerlach (1) reported that the reduction of pyrrole-2-carboxamide with phosphonium iodide and fuming hydriodic acid yielded a product which they thought to be (±)-3,4-dehydroproline. Fifty years then passed until Robertson and Witkop (2) proved that, under carefully controlled conditions, this imino acid is indeed a product of the reaction.

Robertson and Witkop (2) obtained (*S*)-3,4-dehydroproline (**1**) of good optical purity by the action of hog acylase on (±)-3,4-dehydroproline amide, and provided the first report of its biological properties: saying *inter alia* that colleagues had found **1** to be a potent antimetabolite for some microorganisms, apparently as a consequence of its ability to act as an antagonist for (*S*)-proline. Subsequently, it has been shown (3) that **1** inhibits collagen synthesis in some mammalian cells, and that its introduction into peptides in lieu of (*S*)-proline can result (4) in modified biological properties, though not necessarily so (5).

Interest in the biological properties of **1** seems to have stimulated efforts to improve its availability. Various improvements in the Fischer–Witkop approach have been reported (5*b*, 6), culminating in those of Scott *et al.* (7).

As an alternative to these approaches, which require the resolution of racemic products, we were interested in preparing **1** from (2*S*,4*R*)-4-hydroxyproline (**2**). Although Robertson and Witkop (2) had noted that extensive efforts to convert 4-hydroxyproline to 3,4-dehydroproline had met with little success, it appeared to us that recent developments in synthetic methodology were encouraging: we were particularly impressed by the reported high-yield conversion of (2*S*,4*R*)-*N*-*tert*-butoxycarbonyl-4-hydroxyproline methyl ester via a Chugaev elimination (8), and thought that a selenoxide elimination might be even more regioselective in introducing the required 3-ene, i.e. we hoped that the sequence of reactions shown in Scheme 1 would provide a convenient route to (*S*)-3,4-dehydroproline.

We were guided in this plan by reports that selenoxide eliminations which could yield an olefin with or without oxygen (9) or sulphur (10) as a heteroatom substituent strongly favoured formation of the unsubstituted olefin. After we had completed our work, a publication describing the similar directive effects of amido groups appeared (11). We selected trimethylsilyl iodide for the final N-deblocking and ester cleavage reactions since it was known to effect these reactions under mild conditions (12), which an alkene survived (13).

As detailed in the Experimental section, these hopes were fulfilled: crystalline (*S*)-dehydroproline was obtained from the commercially available **3**, in 50% yield, with an optical rotation in accord with that reported for the enantiomerically pure amino acid.

## Experimental

Melting points were determined on a Leitz microscope hotstage melting point apparatus, and are uncorrected. The nmr data were collected on a Varian XL 200 instrument and chemical shifts are reported in parts per million relative to tetramethylsilane. In the case of the $^{13}C$ nmr spectrum of **1** the shifts are reported using 1,4-dioxane as an internal standard ($\delta$ = 66.6 ppm from TMS). Infrared spectra were recorded on a Perkin–Elmer 467 grating infrared spectrophotometer. Mass spectra were measured on a Varian MAT CH-5 spectrometer (*m*/*z* (relative intensity)) at 70 eV. The cd spectra were recorded with a Jasco J-500A instrument, $[\alpha]_D$ values with a Durrum–Jasco SS-20 machine. Combustion analyses were performed on a Perkin–

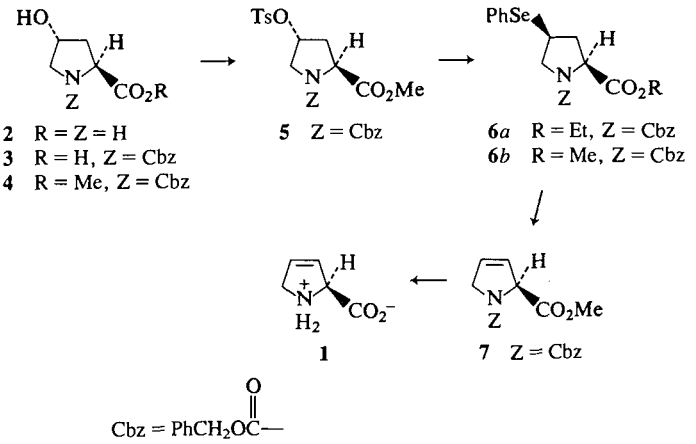

SCHEME 1

Elmer 240 elemental analyzer. All thin layer chromatography was performed using precoated Merck tlc plates: silica gel 60 F-254.

*(2S,4R)-N-Benzyloxycarbonyl-4-hydroxyproline methyl ester (4)*

To a stirred solution of (2*S*,4*R*)-*N*-carbobenzyloxy-4-hydroxyproline (Sigma) (99% pure by $[\alpha]_D$, homogeneous by tlc) (25 g, 94 mmol) in absolute EtOH (100 mL) was slowly added a cold solution of diazomethane (100 mmol) in $Et_2O$ (200 mL), the temperature being kept below 5°C. After 15 min the slight excess of diazomethane was decomposed with glacial acetic acid. The colorless solution was dried ($MgSO_4$), filtered, and concentrated to provide 25.0 g (99%) of **4** as a colorless oil (lit. oil (14), mp 82°C (15)), which was homogeneous on tlc, $R_f$ 0.57 (AcOEt/hexane 1:1); ir (film): 3450, 2960, 1745, 1700, 1495, 1425, 1360, 1210, 1170, 1125, 1090 $cm^{-1}$; nmr ($CDCl_3$) δ: 7.29 (5H, m), 5.10 (2H, m), 4.47 (2H, m), 3.74 + 3.54 (3H, s, two rotamers), 3.63 (2H, m), 2.62 (1H, br s), 2.28 (1H, m), 2.17 (1H, m); mass spectrum, *m/z*: 279 ($M^+$, 1.5), 220 (13), 176 (20), 92 (11), 91 (100), 65 (11), 44 (13).

*(2S,4R)-N-Benzyloxycarbonyl-4-tosyloxyproline methyl ester (5)*

To a solution of **4** (25.1 g, 90 mmol) in anhydrous pyridine (250 mL) was added *p*-toluenesulfonylchloride (18.9 g, 99 mmol) at 0–5°C, and the resulting mixture was refrigerated at that temperature for 1 week. The pyridine was removed under reduced pressure at 10–20°C, the residue dissolved in $Et_2O$ (400 mL), and this solution was then extracted with cold aqueous 5% HCl (3 × 30 mL) and $H_2O$ (5 × 30 mL). Evaporation of the dried $Et_2O$ layer gave an oil (40.2 g), which crystallized from $Et_2O$/pentane to give **5** (35.4 g, 91%): mp 74–75°C (lit. (14) mp 74–77°C); $[\alpha]_D^{27}$ −34.0° (*c* 5.0, $CHCl_3$); tlc, $R_f$ 0.51 (AcOEt/hexane 1:1); ir (KBr): 3060, 2990, 2950, 2870, 1735, 1690, 1425, 1355, 1275, 1180, 775, 765, 745, 710 695 $cm^{-1}$; nmr ($CDCl_3$) δ: 7.1–7.9 (9H, m), 5.10 (3H, m), 4.45 (1H, m), 3.73 + 3.51 (3H, s), 3.5–3.8 (2H, m), 2.45 + 2.43 (3H, s), 2.0–2.7 (2H, m); mass spectrum, *m/z*: 433 ($M^+$, 0.3), 158 (27), 91 (100), 65 (11). *Anal.* calcd. for $C_{21}H_{23}NO_7S$: C 58.18, H 5.35, N 3.23; found: C 58.41, H 5.39, N 3.30.

*(2S,4S)-N-Benzyloxycarbonyl-4-phenylselenoproline methyl ester (6)*

Diphenyldiselenide (8.58 g, 27.5 mmol) was dissolved in absolute EtOH (250 mL). $NaBH_4$ (2.08 g, 55 mmol) was then added in batches, while the reaction mixture was stirred under a $N_2$ atmosphere until the bright yellow solution turned colorless (9, 16). After addition of the tosylate **5** (19.1 g, 44 mmol) the reaction mixture was refluxed for 2.5 h. The solvent was removed *in vacuo*, the residue was diluted with $Et_2O$ (300 mL) and the resulting solution was washed with $H_2O$ (3 × 200 mL), then dried ($MgSO_4$), filtered, and concentrated to give a yellow oil (18.1 g). Thin-layer chromatography (AcOEt/hexane 1:2) revealed a single major product accompanied by two minor impurities. The mixture was purified by flash chromatography (17) on silica gel (300 g, 230–400 mesh, 30 × 5 cm). Petroleum ether/ethyl acetate 4:1 (500 mL), 3:1 (500 mL), and 2:1 (700 mL) eluted diphenyldiselenide (1.2 g), the ethyl ester[2] **6***a* (1.47 g, 8%), and the methyl ester **6***b* (14.97 g, 81%); **6***a* and **6***b* were homogeneous on tlc, $R_f$ 0.40, 0.34 (hexane/AcOEt 2:1) respectively, and crystallized on storage at 0°C. Recrystallization from $Et_2O$/pentane gave **6***a*, mp 46–47°C, and **6***b*, mp 53°C. The physical properties of **6***b* were as follows: $[\alpha]_D^{27}$ −25.7° (*c* 2.5, $CHCl_3$); ir (KBr): 3060, 2950, 2870, 1730, 1690, 1425, 1350, 1295, 1275, 1180, 1120, 1030, 775, 765, 745, 705, 665 $cm^{-1}$; nmr ($CDCl_3$) δ: 7.2–7.6 (10H, m), 5.12 (2H, m), 4.34 (1H, m), 4.0 (1H, m), 3.4–3.8 (2H, m), 3.71 + 3.54 (3H, s), 2.5–2.8 (1H, m), 1.95–2.2 (1H, m): mass spectrum, *m/z*: 419 ($M^+$, 1.6), 316 (9), 158 (8), 81 (100), 68 (15), 65 (19). *Anal.* calcd. for $C_{20}H_{21}NO_7Se$: C 58.33, H 5.36, N 3.24; found: C 58.45, H 5.35, N 3.22.

*(S)-N-Benzyloxycarbonyl-3,4-dehydroproline methyl ester (7)*

To a stirred solution of selenide **6***b* (8.36 g, 20 mmol) and pyridine (2.37 g, 30 mmol) in $CH_2Cl_2$ (100 mL) was gradually added 30% $H_2O_2$ (5.6 g, 50 mmol), while the reaction vessel was cooled in an ice bath (18). The reaction mixture was stirred vigorously at 25°C for an additional 1.5 h, then diluted with $CH_2Cl_2$ (100 mL) and extracted successively with aqueous 5% HCl (2 × 50 mL), saturated aqueous $Na_2CO_3$ solution (50 mL), and $H_2O$ (3 × 50 mL). The organic layer was dried ($MgSO_4$), the solvent removed under reduced pressure, and the residue purified by flash chromatography on silica gel (200 g, 230–400 mesh, 30 cm × 5 cm, AcOEt/petroleum ether 1:2), giving **7** as an oil (4.49 g, 87%); tlc, $R_f$ 0.64 (AcOEt/hexane 1:1); ir (film): 3085, 3060, 3030, 2950, 2900, 2865, 1750, 1710, 1620, 1498, 1415, 1355, 1310, 1260, 1205, 1180, 1125, 1105, 1000, 780, 770, 760, 700 $cm^{-1}$; nmr ($CDCl_3$) δ: 7.30 (5H, m), 5.97 (1H, m), 5.74 (1H, m), 5.0–5.3 (3H, m), 4.31 (2H, m), 3.74 + 3.50 (3H, s); mass spectrum, *m/z*:

[2]Formation of the ethyl ester could presumably be prevented by running the reaction in MeOH–THF.

261 ($M^+$, 0.3), 202 (25), 158 (36), 92 (19), 91 (100), 65 (21). We found no trace of the corresponding 4,5-dehydroproline, by tlc or $^1H$ nmr analysis of the crude reaction product, i.e. the selenoxide elimination must be very regioselective.

*(S)-Dehydroproline (1)*

To a solution of **7** (0.8 g, 3 mmol) in anhydrous $CH_3CN$ was added, via a syringe, trimethylsilyl iodide (1.3 mL, 9 mmol) under a nitrogen atmosphere (12, 13). The reaction mixture was then refluxed for 20 h. The mixture was then cooled to ca. 0°C and a mixture of EtOH/AcOH 1:1 (5 mL) was added quickly. After a further 20 min of stirring, the reaction mixture was further diluted with $H_2O$ (20 mL) and then extracted with $CH_2Cl_2$ (5 × 15 mL). The $H_2O$ layer was then poured onto a column of Dowex 50W-X8 (10 cm × 1.5 cm) cation exchange resin (100–200 mesh) (7). After washing the column with $H_2O$ (150 mL) until the eluates were neutral, the product was eluted with 0.5 *M* aqueous pyridine acetate solution (200 mL). The ninhydrin positive fractions were combined, and concentrated at <25°C. To remove traces of pyridine, the white residue was dissolved in $H_2O$ (20 mL) and reevaporated under the same conditions. This process was repeated once more. The wet solid residue (0.33 g) was dissolved in $H_2O$ (0.3 mL) and EtOH (3 mL), seeded, AcOEt (10 mL) added, and the solution refrigerated at −5°C overnight. The crystals which separated were filtered, washed with cold EtOH, $Et_2O$, and dried at 20°C/0.1 Torr, thus affording (*S*)-3,4-dehydroproline (**1**) (0.275 g, 80%): tlc, $R_f$ 0.22 (n-BuOH/AcOH/$H_2O$ 3:1:1); mp 242–243°C (dec.), $[\alpha]_D^{27}$ −404.6° (*c* 1.1, $H_2O$); e.e. 99.8%, (lit. (7) mp 244°C (dec.), $[\alpha]_D^{27}$ −403.1° (*c* 1.0, $H_2O$)); cd ($H_2O$): $\Delta\varepsilon_{202} = -25.4°$; ir (KBr): 3280, 3080, 2100–3300, 1620, 1600, 1360, 1330, 1280, 1270, 1230, 1195, 1065, 1005, 930, 830, 775, 740, 695; $^1H$ nmr ($CD_3COOD$) δ: 6.05 (1H, dddd, $J$ = 6.5, 2, 2, 2 Hz), 5.92 (1H, dddd, 6.5, 2.5, 2, 2 Hz), 5.15 (1H, m), 4.29 (2H, m) cf. lit. (19); $^{13}C$ nmr ($D_2O$, dioxane) δ: 172.2, 125.7, 125.4, 68.5, 52.4; mass spectrum, *m/z*: 111 ($M$ − 2, 12), 95 (12), 94 (12), 93 (12), 69 (17), 68 (70), 67 (100), 66 (16), 44 (59), 41 (100), 40 (34), 39 (59). *Anal.* calcd. for $C_5H_7NO_2$: C 53.06, H 6.24, N 12.39; found: C 53.11, H 6.36, N 12.44.

# The phosphorus-31 and metal nuclear magnetic resonance spectra of complexes of tin(II) and lead(II) with tricyclohexylphosphine oxide, sulfide, and selenide

PHILIP A. W. DEAN

*Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7*

Received June 10, 1982

PHILIP A. W. DEAN. Can. J. Chem. **60**, 2921 (1982).

The new stannous and plumbous complexes $M(OP(C_6H_{11})_3)_n^{2+}$ ($n$ = 2 or 3, M = Sn or Pb) and $[M(SP(C_6H_{11})_3)_x(SeP(C_6H_{11})_3)_{3-x}]^{2+}$ (M = Sn or Pb) have been prepared in $SO_2$ solution and characterized by their reduced temperature slow-exchange $^{31}P$ and metal ($^{119}Sn$ or $^{207}Pb$) nmr spectra. No evidence could be found for complexes in which both $OP(C_6H_{11})_3$ and $EP(C_6H_{11})_3$ (E = S or Se) are coordinated to tin(II) or lead(II). The same pattern of chemical shifts is found in the $^{119}Sn$ and $^{207}Pb$ nmr spectra: $\delta_M(M(OP(C_6H_{11})_3)_2^{2+}) < \delta_M(M(OP(C_6H_{11})_3)_3^{2+} < \delta_M(M(SP(C_6H_{11})_3)_3^{2+}) < \delta_M(M(SeP(C_6H_{11})_3)_3^{2+})$ and a monotonic but non-linear variation of $\delta_M$ with $x$ for $[M(SP(C_6H_{11})_3)_x(SeP(C_6H_{11})_3)_{3-x}]^{2+}$. From $M(AsF_6)_2$ in $SO_2$ as reference, the range of the metal chemical shifts is 999–2079 ppm and 2407–7707 ppm in the $^{119}Sn$ and $^{207}Pb$ nmr spectra respectively. In the $^{31}P$ nmr spectra, all of the appropriate two-bond M—P couplings are observed, but the fine structure expected from coupling to $^{31}P$ could not always be observed in those metal nmr spectra which were measured at high field; it is suggested that these metal nmr spectra are "smeared out" by a combination of large temperature sensitivity of the metal chemical shifts and the small temperature variation allowed by the nmr spectrometer temperature controller and/or diffusion along any temperature gradients present along the length of the nmr sample.

PHILIP A. W. DEAN. Can. J. Chem. **60**, 2921 (1982).

On a préparé les nouveaux complexes stanneux et plombeux $M(OP(C_6H_{11})_3)_n^{2+}$ ($n$ = 2 ou 3, M = Sn ou Pb et $[(SP(C_6H_{11})_3)_x(SeP(C_6H_{11})_3)_{3-x}]^{2+}$ (M = Sn ou Pb) en solution dans le $SO_2$ et on les a caractérisés par leur spectre de rmn (du $^{119}Sn$ ou $^{207}Pb$) d'échange lent entre le $^{31}P$ et le métal à basse température. On ne peut prouver l'existence de complexes dans lesquels les deux groupes $OP(C_6H_{11})_3$ et $EP(C_6H_{11})_3$ (E = S ou Se) sont coordonnés à l'étain(II) ou au plomb(II). On trouve les mêmes types de déplacements chimiques dans les spectres de rmn du $^{119}Sn$ ou du $^{207}Pb$: $\delta_M(M(OP(C_6H_{11})_3)_2^{2+}) < \delta_M(M(OP(C_6H_{11})_3)_3^{2+} < \delta_M(M(SP(C_6H_{11})_3)_3^{2+}) < \delta_M(M(SeP(C_6H_{11})_3)_3^{2+})$ et une variation monotone mais non linéaire de $\delta_M$ avec $x$ pour le complexe $[M(SP(C_6H_{11})_3)_x(SeP(C_6H_{11})_3)_{3-x}]^{2+}$. A partir du $M(AsF_6)_2$ dans le $SO_2$ comme référence, l'ordre de grandeur des déplacements chimiques du métal se situe entre 999–2079 ppm et entre 2407–7707 ppm respectivement dans les spectres de rmn $^{119}Sn$ et du $^{207}Pb$. Dans les spectres du $^{31}P$, on observe tous les couplages appropriés M—P à travers deux liaisons mais on n'a pas toujours observé la structure fine attendue d'un couplage avec le $^{31}P$ dans les spectres de rmn du métal que l'on a mesurés à haut champ. On suggère que ces spectres de rmn de métal "sont étalés" par suite d'une combinaison de la grande sensibilité des déplacements chimiques à la température et de la faible variation de température que permet le contrôle de température du spectromètre et/ou la diffusion pour tout gradient de température présent dans l'échantillon de rmn.

[Traduit par le journal]

## Introduction

In a recent paper (1) we described, among other things, the slow exchange $^{31}P$ nmr spectra of complexes of divalent tin and lead with $Ph_3PO$ and some related polydentate phosphine oxides. Here we report an extension of this earlier work to stannous and plumbous complexes of $(C_6H_{11})_3PE$ (E = O, S, or Se) and mixtures of $(C_6H_{11})_3PS$ and $(C_6H_{11})_3PSe$,[1] the tricyclohexyl derivatives being chosen to give enhanced solubility. A variety of new tin(II) and lead(II) complexes have been characterized by their slow exchange $^{31}P$ and metal nmr spectra. This combination of nmr spectral measurements has let us obtain metal chemical shifts for a range of closely related complexes of tin(II) and lead(II) containing well-defined numbers and types of Group VIA donor atoms. Such metal nmr data are particularly helpful for heavy elements like tin and lead which have large chemical shift ranges; in these cases a knowledge of at least the approximate metal chemical shift to be expected in a particular situation can shorten appreciably the time taken to find the metal resonance. The approach used here, characterization of the complexes by $^{31}P$ nmr prior to measuring the metal nmr spectra, has been used earlier for a $^{113}Cd$ nmr study of cadmium complexes with a variety of phosphine oxides and chalcogenides (2–4).

Both $^{119}Sn$ and $^{207}Pb$ nuclei have been widely exploited in nmr studies (5). Probably reflecting the relative efforts which have been applied to the coordination chemistry of the metals in the +II and +IV oxidation states, most of the nmr studies have involved species in the +IV oxidation state. There does, however, seem to be an increasing interest in $^{119}Sn$ nmr spectroscopy of tin(II) complexes (e.g. refs. 6–8).

## Experimental

*Materials*

Isotopically-enriched yellow PbO (92.4 atom% $^{207}Pb$), ob-

[1]Hereafter, $C_6H_{11}$ will be abbreviated chx.

tained from Oak Ridge National Laboratory, was dried under vacuum before use, as was isotopically natural yellow PbO (Fisher Scientific Co.). Stannous fluoride (Alfa, Ultrapure Grade), arsenic pentafluoride (Ozark-Mahoning, Inc.), and phosphorus pentafluoride (Matheson) were used as received. Antimony pentafluoride (PCR, Inc.) was purified by double distillation in a dry nitrogen atmosphere. The literature routes to $Sn(SbF_6)_2$ (9), and $Pb(SbF_6)_2$ and $Pb(AsF_6)_2.xSO_2$ (1) were used to prepare metal salts without isotopic enrichment. Tricyclohexylphosphine oxide, sulfide, and selenide were prepared during earlier work (3, 4, 10).

Sulfur dioxide (Canadian Liquid Air Ltd., Anhydrous Grade) was stored in the gas phase over Linde 3A Molecular Sieves for at least 12 h before use.

*General manipulative procedure*

Glove box and vacuum line manipulations, and preparations of sealed nmr samples were carried out as described in earlier publications from these laboratories (eg. refs. 2 and 10), except that for the nmr samples 8 mm od homemade sample tubes were used.

*Preparation of $Pb(AsF_6)_2$ from PbO*

The original preparation of $Pb(AsF_6)_2$ required anhydrous $PbF_2$ as a starting material (1). However, isotopically-enriched $PbF_2$ was not available, so $PF_5/AsF_5$ treatment of $^{107}$Pb-enriched PbO was used to prepare the $^{107}$Pb-enriched hexafluoroarsenate, following the procedure described recently for synthesis of $Cd(AsF_6)_2$ from CdO (4). *Anal.* (for an unenriched sample) calcd. for $As_2F_{12}Pb$: F 38.97, Pb 35.42; found: F 38.58, Pb 34.62. The hexafluoroarsenates prepared from PbO and $PbF_2$ show identical chemical behaviour.

*Nuclear magnetic resonance spectra*

Broad band proton decoupled 40.45 MHz $^{31}$P nmr spectra were measured using an XL-100-12 spectrometer system and referenced to external $OP(OMe)_3$ in $(CD_3)_2CO$ as reported earlier (10); the 8 mm sample tubes were held coaxially in 12 mm precision nmr tubes using a Teflon spacer. All $^{119}$Sn spectra were measured with a Bruker WH-400 spectrometer system operating at 148.93 without $^1$H decoupling. Typically, satisfactory spectra of ca. 0.075 *m* solutions in stationary 8 mm od tubes (held in a 10 mm precision nmr tube with a Teflon spacer) were obtained with several hundred 90° (35 μs) pulses at 30 $min^{-1}$ using a spectral window of 5 kHz, a 1.6 s acquisition time, and no lock. Spectra were referenced by sample interchange with a 0.075 *m* solution of $Sn(AsF_6)_2$ in $SO_2$ (prepared *in situ* from $SnF_2$:$AsF_5$ = 1:4; $Sn(AsF_6)_2$ is unstable to loss of $AsF_5$ (9)). An approximate conversion to $SnMe_4$ as reference is $\delta_{Sn(AsF_6)_2(SO_2,\ 213\ K)} = \delta_{SnMe_4(neat,\ 295\ K)} + 1898$ ppm.

Initial $^{207}$Pb nmr were obtained using a Varian XL-100 spectrometer system working at 20.89 MHz with no $^1$H decoupling. Several thousand transients were required using 90° (80 μs) pulses applied at 14 $min^{-1}$ with a 1 s acquisition time, a 12.5 kHz spectral window, and an annular $(CD_3)_2CO$ sample as a lock substance to obtain acceptable spectra from solutions containing ca. 0.075 *m* $^{207}$Pb in spinning 8 mm od tubes. The spectra of the same and additional samples were measured using the WH-400 spectrometer operating at 83.37 MHz. Typically, several hundred 90° (38 μs) pulses applied at 37 $min^{-1}$ with a 5 kHz spectral window, a 1.6 s acquisition time, and no lock were required to obtain a spectrum from stationary unlocked samples. The $^{207}$Pb nmr spectra were referenced to 0.075 *m* $^{207}$Pb-enriched $Pb(AsF_6)_2$ in $SO_2$ by sample interchange. An approximate conversion to 1.0 *M* $Pb(NO_3)_2$(aq) is $\delta_{Pb(AsF_6)_2(SO_2,\ 203\ K)} = \delta_{1\ M\ Pb(NO_3)_2(aq,\ 295\ K)} + 1105$ ppm. (Also $\delta_{1\ M\ Pb(NO_3)_2(aq)} \approx \delta_{PbMe_4(toluene)} + 2961$ ppm (5).)

*Elemental microanalysis*

Analyses were performed by Analytische Laboratorien, Elbach, W. Germany.

## Results and discussion

The salts $Sn(SbF_6)_2$ and $Pb(SbF_6)_2$ are insoluble in $SO_2$. However, addition of $(chx)_3PO$ causes their dissolution when L/M $\gtrsim$ 1.5, as has been observed for L = $Ph_3PO$ earlier (1). Similarly, addition of $(chx)_3PS$ or $(chx)_3PSe$, or mixtures of these two, causes dissolution when (total L)/M $\gtrsim$ 3. When L/M $\lesssim$ 3, the yellow colours characteristic of $(chx)_3PS$ and $(chx)_3PSe$ in $SO_2$ are blanched.

*$^{31}$P nmr spectra*

Slow exchange $^{31}$P nmr spectra of $(chx)_3PO$–$M(SbF_6)_2$ (M = Sn or Pb) mixtures in $SO_2$ can be obtained at reduced temperature when L/M $\lesssim$ 3, and for lead identical results can be obtained using $SO_2$-soluble $Pb(AsF_6)_2$. Excess ligand causes exchange-averaging (c.f. ref. 1). By observing the slow-exchange spectra as a function of L/M, the species $M(OP(chx)_3)_2^{2+}$ and $M(OP(chx)_3)_3^{2+}$ can be identified for both tin and lead, detection of the appropriate $^{117/119}$Sn and $^{207}$Pb satellites ($^{117}$Sn 7.76%, $^{119}$Sn 8.68%, $^{207}$Pb 21.11% natural abundance; all spin $I$ = 1/2) confirming the absence of intermolecular ligand exchange. The location of the $^{207}$Pb satellites was verified incidentally during $^{31}$P nmr measurements made on $^{207}$Pb-enriched samples prior to $^{207}$Pb nmr studies (see below). Details of the $^{31}$P nmr spectra of the $(chx)_3PO$ complexes of tin and lead are given in Tables 1 and 2, respectively. Particularly noteworthy in these spectra are the large complexation shifts which are typical of phosphine oxides (e.g. refs. 1, 2, 11, 12).

Slow exchange $^{31}$P nmr spectra of $SO_2$ solutions prepared from $M(SbF_6)_2$ (M = Sn or Pb) (or, for lead, $Pb(AsF_6)_2$) and $(chx)_3PS$ or $(chx)_3PSe$ or mixtures of the phosphine sulfide and selenide can be obtained provided (total L)/M $\gtrsim$ 3. When (total L)/M exceeds 3 fast exchange averages of the $M(EP(chx)_3)_3^{2+}$ and $EP(chx)_3$ spectra are observed at all temperatures; as with the phosphine oxide complexes (ref. 1 and see above) these results show that intermolecular exchange occurs associatively.

The species $M(EP(chx)_3)_3^{2+}$ (E = S or Se; M = Sn or Pb) give the anticipated slow exchange spectra consisting of a central singlet, flanked by metal satellites of the appropriate intensity and, for the $(chx)_3PSe$ complexes, $^{77}$Se satellites complete with their metal satellites ($^{77}$Se 7.58% natural abundance, spin $I$ = 1/2). In the spectra of the tin complexes separate $^{117}$Sn and $^{119}$Sn satellites were not resolved as they were in the spectra of the

[d]Relative to external $Pb(AsF_6)_2$ in $SO_2$ at 203 K, for solutions in which the total lead concentration ≈ 0.075 *m*; estimated error ±2 ppm; shifts to increasing frequency are taken as positive; $\delta_{Pb(AsF_6)_2(SO_2\ 203\ K)} \approx \delta_{1\ M\ Pb(NO_3)_2(aq,\ 295\ K)} + 1105$ ppm ($\delta_{1\ M\ Pb(NO_3)_2(aq)} \approx \delta_{PbMe_4(toluene)} + 2961$ ppm (5)); $\nu_{1/2}(Pb(AsF_6)_2) \approx 450$ Hz.
[e]The approximate linewidths in the table are those measured in the 83.4 MHz spectra; at this frequency the spectra showed no resolvable fine structure, except where noted (see text).
[f]See footnote *e* of Table 1.
[g]$\nu_{1/2} \approx 120$ Hz in the 20.9 MHz nmr spectrum.
[h]Quartet fine structure poorly resolved at 203 K, but quite clear at 223 K ($\nu_{1/2} \sim 40$ Hz; $\delta_{Pb} = 2914$ ppm); quartet fine structure ($\nu_{1/2} \approx 24$ Hz) observed in the 20.9 MHz nmr spectrum at 203 K.
[i]Quartet fine strueture ($\nu_{1/2} \approx 30$ Hz) observed in the 20.9 MHz nmr spectrum at 203 K.
[j]This resonance could not be observed in the 20.9 MHz spectrum because it fell in a region where interference was severe.

$OP(chx)_3$ complexes, for $^2J(^{117/119}Sn—E—^{31}P)$ is considerably smaller in magnitude for E = S or Se than for E = O. Again when $^{207}Pb$-enriched $Pb(AsF_6)_2$ was used as starting material the $^{207}Pb$ satellites in the spectra of the lead complexes showed the expected increase in intensity. The triligated species were the only ones present in measurable quantity even though the starting mixtures were metal-rich; no evidence was found for $M(EP(chx)_3)_2^{2+}$ when E = S or Se.

Nuclear magnetic resonance spectral details for $M(EP(chx)_3)_3^{2+}$ (E = S or Se) are included in Tables 1 and 2. The $^{31}P$ nmr complexation shifts of the $(chx)_3PS$ and $(chx)_3PSe$ complexes are small, as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

has been found previously for the cadmium complexes of these ligands also (3). However, $^1J$(P—Se) is smaller in the phosphine selenide complex than in the free ligand, an effect characteristic of coordination through selenium (2, 3, 10, 13–17).

When mixtures of $(chx)_3PS$ and $(chx)_3PSe$ are used, and (total L)/M $\gtrsim$ 3, reduced temperature $^{31}P$ nmr indicates that a total of four species are formed in solution as the $(chx)_3PS/(chx)_3PSe$ ratio is varied. Evidently all four complexes of the series $[M(SP(chx)_3)_x(SeP(chx)_3)_{3-x}]^{2+}$ exist for both tin and lead, confirming that a maximum of three sulfur/selenium atoms can be bound. The $^{31}P$ nmr spectral parameters of the mixed complexes are included in Tables 1 and 2 for tin and lead respectively. As has been noted for similar mixed ligand complexes of cadmium (3), the various chemical shifts and coupling constants in the $^{31}P$ nmr spectra are not very sensitive to replacement of $(chx)_3PSe$ by $(chx)_3PS$ or vice-versa.

Attempts to obtain evidence for complexes with $(chx)_3PO$–$(chx)_3PS$ or $(chx)_3PO$–$(chx)_3PSe$ mixtures in their coordination shell were fruitless for both tin and lead as acceptors, as they had been earlier for cadmium as an acceptor (3). Samples with $((chx)_3PO + (chx)_3PE)/M \lesssim 3$ (E = S or Se) gave $^{31}P$ nmr spectra containing resonances from $M(EP(chx)_3)_3^{2+}$ and $M(OP(chx)_3)_3^{2+}$ and/or $M(OP(chx)_3)_2^{2+}$ (depending on the (total L)/M and $(chx)_3PO/(chx)_3PE$ ratios). Indeed, the mixed O—S or O—Se kernels do not seem to form readily even in intermediates (or transition states) in ligand exchange processes. In solutions in which $((chx)_3PO + (chx)_3PE)/M > 3$ but $(chx)_3PO/M < 3$, a slow exchange spectrum is observed for $M(OP(chx)_3)_3^{2+}$ while an exchange-averaged spectrum of $M(EP(chx)_3)_3^{2+}$ and $EP(chx)_3$ is seen, i.e. excess $EP(chx)_3$ causes ligand exchange of $M(EP(chx)_3)_3^{2+}$, suggesting that the $ME_4$ kernel forms transiently, but causes little or no ligand exchange of $M(OP(chx)_3)_3^{2+}$, suggesting that the $MO_3E$ kernel does not form. A recent interpretation (18) of this "antisymbiotic" (19) or "cooperative" (18) behaviour of ligands with "hard" and "soft" (20) ("class a" and "class b" (21)) donor atoms is that the true coordination numbers of the species which do not redistribute ($M(OP(chx)_3)_3^{2+}$ and $M(EP(chx)_3)_3^{2+}$ (E = S or Se; M = Sn or Pb) in the present case) differ. If this is so, perhaps the coordination sphere of "$M(OP(chx)_3)_3^{2+}$" includes $SO_2$, or fluorine(s) from the counter-ion, though the latter, if present, must be labile, for no coupling to $^{19}F$ is seen in the metal nmr spectra (see below).

*Metal nmr spectra*

Samples for $^{207}Pb$ nmr were prepared using $^{207}Pb$-enriched $Pb(AsF_6)_2$ (see Experimental Section) as starting material, so that spectra could readily be obtained at both 20.9 and 83.4 MHz. For $^{119}Sn$ nmr, natural $Sn(SbF_6)_2$ was the starting material, and spectra were measured at 148.9 MHz. Prior to measurement of the metal nmr spectra, the contents of the solutions at the appropriate reduced temperature were checked by $^{31}P$ nmr. Details of the $^{119}Sn$ and $^{207}Pb$ nmr spectra are given in Tables 1 and 2 respectively.

Complexation of $Pb(AsF_6)_2$ in $SO_2$ at 203 K induces shifts to lower shielding ranging from 2407 ppm for $Pb(OP(chx)_3)_2^{2+}$ to 7077 ppm for $Pb(SeP(chx)_3)_3^{2+}$. For the two $OP(chx)_3$ complexes the shifts are in the order $\delta_{3:1} > \delta_{2:1}$, while for the 3:1 complexes with different donor atoms the chemical shift sequence is $\delta_{Se} > \delta_S > \delta_O$ (analogous to the "inverse halogen dependence" (22)). The chemical shift sequence $\delta_{Se} > \delta_S$ was observed for solid PbE (23). Both the solid lead chalcogenides have smaller $^{207}Pb$ chemical shifts than the corresponding $Pb(EP(chx)_3)_3^{2+}$ complexes: relative to 1.0 *M* $Pb(NO_3)_2$(aq) shifts of PbE and $Pb(EP(chx)_3)_3^{2+}$ are approximately 3900 and 5410 and 5300 and 5970 ppm for E = S and Se, respectively (refs. 23 and 24, and Table 2). However, both the lead(II) calcogenides have the NaCl structure with six-coordinate lead ions (25*a*), in contrast to $Pb(EP(chx)_3)_3^{2+}$ in which trigonal pyramidal coordination about lead, with a stereochemically active lone pair, is anticipated. The increased coordination symmetry in the solid chalcogenides should result in a decreased paramagnetic contribution to the shielding and hence a smaller chemical shift (26).

Lead-207 data have also been reported for, *inter alia*, solid $PbZrO_3$ and red and yellow PbO (24). In $PbZrO_3$, the lead has flattened trigonal pyramidal coordination by oxygens (27), similar to the coordination geometry expected to occur in $Pb(OP(chx)_3)_3^{2+}$, and the lead chemical shifts of these two species are similar: approximately 1400 and 1820 ppm from 1.0 *M* $Pb(NO_3)_2$(aq) for $PbZrO_3$ and $Pb(OP(chx)_3)_3^{2+}$, respectively (ref. 24 and Table 2). The chemical shift of $Pb(OP(chx)_3)_2^{2+}$, ca. 1300 ppm for 1.0 *M* $Pb(NO_3)_2$(aq) (Table 2), also falls close to that of $PbZrO_3$, suggesting that its coordination geometry is close to trigonal pyramidal, perhaps with a coordinated $SO_2$ or anion occupying a coordination site. The similar magnitudes of $^2J(^{207}Pb—^{31}P)$ in $Pb(OP(chx)_3)_{2\text{ or }3}^{2+}$ (Table 2) also militate against a radical change in lead environment between the two $(chx)_3PO$ complexes. The coordination geometry about lead is square pyramidal and distorted 2 + 2 in red and yellow lead respectively (25*b*), and these two oxides have significantly larger chemical shifts than Pb(OP-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

$(chx)_{3}{}_{2\text{ or }3}{}^{2+}$: approximately 2800 and 6600 ppm from $Pb(NO_3)_2$(aq) for red and yellow lead, respectively (24).

At 203 K, slow exchange $^{207}Pb$ nmr spectra were observed for equilibrium mixtures containing several members of the series $[Pb(SP(chx)_3)_x(SeP(chx)_3)_{3-x}]^{2+}$. For these complexes the $^{207}Pb$ chemical shifts increase monotonically but not linearly as $x$ decreases (Table 2). The chemical shifts can reasonably be accommodated using the concept of pairwise additivity (28) if each S–Se interaction produces a deshielding of 130 ppm from the chemical shift of $Pb(SP(chx)_3)_3{}^{2+}$ and each Se–Se interaction a deshielding of 185 ppm; these complexes presumably are trigonal pyramidal with a stereochemically active lone pair, but the sulfur – lone pair and selenium – lone pair interaction constants appear to be equal.

The chemical shifts measured in the 20.9 and 83.4 MHz $^{207}Pb$ nmr spectra did not differ significantly. However, there were noticeable differences in the extent to which the expected fine structure from two-bond $^{207}Pb$–$^{31}P$ scalar coupling was resolved (see Table 2). In the 203 K 20.9 MHz spectra, the resonances of $Pb(OP(chx)_3)_3{}^{2+}$ and $Pb(SP(chx)_3)_3{}^{2+}$ showed the expected quartet structure; there was no evidence for coupling of $^{207}Pb$ to the fluorine of any coordinated anion (see above). In contrast, and for reasons which are unclear, $Pb(OP(chx)_3)_2{}^{2+}$, though it gave a well-resolved 40.5 MHz $^{31}P$ nmr spectrum, showed a broad $^{207}Pb$ resonance with no observable fine structure. Unfortunately, instrumental limitations precluded measurement of the $^{207}Pb$ nmr spectrum of $Pb(SeP(chx)_3)_3{}^{2+}$ at 20.9 MHz. In the 203 K 83.4 MHz $^{207}Pb$ nmr spectrum of $Pb(OP(chx)_3)_3{}^{2+}$ the fine structure from $^2J(^{207}Pb—^{31}P)$ could barely be resolved, though it was better resolved at somewhat higher temperatures. At the higher field and 203 K, the signal from $Pb(OP(chx)_3)_2{}^{2+}$ was broader than at 20.9 MHz, and no fine structure could be resolved in the 83.4 MHz spectra of $Pb(EP(chx)_3)_3{}^{2+}$ (E = S or Se) at 203 K or higher temperatures. Relaxation via chemical shift anisotropy can be very important at high magnetic fields (see, for example, refs. 29 and 30) and may contribute to the broadness of the $^{207}Pb$ nmr lines observed at 83.4 MHz. However, a more mundane source of much of the linewidth is likely, for we found the $^{207}Pb$ chemical shifts of $Pb(OP(chx)_3)_3{}^{2+}$, $Pb(SP(chx)_3)_3{}^{2+}$, and $Pb(SeP(chx)_3)_3{}^{2+}$ (the only complexes for which this measurement was made) to have sizeable temperature coefficients (a decrease of ca. 10, and increases of ca. 3 and ca. 16 ppm, respectively, on changing the temperature from 203 to 223 K), and this significant temperature sensitivity (a phenomenon remarked on earlier for $^{207}Pb$ (31)), combined with the small temperature fluctuation allowed by the temperature controller (±0.3 K at the sample in the specifications for the WH-400) and/or diffusion along any temperature gradients present along the length of the sample,[2] must result in a "smearing out" of the spectrum which is more significant at the higher magnetic field, *ceteris paribus*.

The $^{119}Sn$ nmr data measured from the slow exchange 148.9 MHz spectra of the various tin(II) complexes studied at 213 K are given in Table 1. The pattern of $^{119}Sn$ chemical shifts observed is identical to that found for the analogous lead(II) complexes, leaving no doubt that tin(II), and not tin(IV) complexes, are being studied. There is a smooth but non-linear correlation between the $^{119}Sn$ and $^{207}Pb$ chemical shifts of analogous complexes. The overall range of the lead chemical shifts is 3.4 times that of the tin chemical shifts, though within the series of complexes $[M(SP(chx)_3)_x(SeP(chx)_3)_{3-x}]^{2+}$ the ratio is 6.4. A ratio of 3.0 has been noted previously for $\delta_{Pb}/\delta_{Sn}$ for a variety of organo-lead(IV) and -tin(IV) compounds (32).

The expected fine structure from $^2J(^{119}Sn—O—^{31}P)$ is observed in the $^{119}Sn$ nmr spectra of $Sn(OP(chx)_3)_n{}^{2+}$ ($n$ = 2 or 3). (There is no evidence for coupling to fluorine(s) of the anion.) However, in the spectrum of $Sn(SeP(chx)_3)_3{}^{2+}$ the quartet fine structure is barely resolved, and no fine structure would be seen in the spectrum of $Sn(SP(chx)_3)_3{}^{2+}$ for which the smallest value of the two-bond coupling to phosphorus is found by $^{31}P$ nmr (Table 1). The qualitative observation that the resolution of these spectra deteriorates with increasing spectral accumulation time at constant temperature suggests that, as for $^{207}Pb$ (see above), a combination of temperature sensitivity of $\delta_M$ and any small temperature variations within the samples smears the spectra out.

In the $^{119}Sn$ spectrum of $Sn(SeP(chx)_3)_3{}^{2+}$ the $^{77}Se$ satellites were clearly visible with intensity approximately that expected on statistical grounds for the Sn $^{77}SeSe_2$ kernel, i.e. 19.4% of the total intensity. The magnitude of the $^1J(^{119}Sn—^{77}Se)$, 570 ± 10 Hz, is smaller than that found in the tin(IV) compounds $Me_{4-n}Sn(SeR)_n$ (R = Me or Ph) (33) (e.g. 1520 ± 10 Hz for $Sn(SeMe)_4$) and somewhat smaller than the values of $^1J(^{199}Hg—^{77}Se)$ found in various complexes of $Bu^n{}_3PSe$ with mercuric halides and pseudohalides (17) (e.g. −751 ± 10 Hz for $Cl_2Hg(SePBu^n{}_3)_2$). Poorly resolved

[2]Thanks are due to a referee for suggesting the possible importance of lengthwise temperature gradients.

$^{77}$Se satellites (expected statistical intensity 14.0%) were observed for $[Sn(SP(chx)_3)(SeP(chx)_3)_2]^{2+}$; the value of $^1J(^{119}Sn—^{77}Se)$ was ca. 650 Hz. Unfortunately the $^{77}$Se satellites in the $^{119}$Sn spectrum of $[Sn(SP(chx)_3)_2(SeP(chx)_3)]^{2+}$ (expected intensity 7.58%) could not be observed, so it is not clear whether $^1J(^{119}Sn—^{77}Se)$ continues to increase with increasing substitution of $SP(chx)_3$ for $SeP(chx)_3$.

As for the analogous lead complexes (see above), monotonic but not linear changes in metal chemical shift with $x$ are found in the series $[Sn(SP(chx)_3)_x(SeP(chx)_3)_{3-x}]^{2+}$ (Table 1). The data can be accommodated by the approximate incremental pairwise additivity parameters $\Delta\delta_{S—Se} = 19$, $\Delta\delta_{Se—Se} = 29$ ppm.

HESHEL TEITELBAUM. Can. J. Chem. **60**, 2927 (1982).

A semi-empirical analysis based on a rate law for vibrational relaxation of dissociating simple harmonic oscillators allows for a detailed study of measurements of vibrational relaxation times $\tau$ and of steady dissociation rate coefficients $k_0$. It is shown that non-equilibrium populations of vibrational energy levels prevent attainment of the thermodynamically expected equilibrium energy. Even under near-isothermal and mild conditions, $\tau \ll 1/k_0$, serious experimental errors result when the Bethe–Teller relaxation rate law is used. Closed form expressions are given which permit evaluation of these errors. Measurements should be analyzed using the rate law

$$-d\varepsilon/dt = (\varepsilon - \varepsilon_T)/\tau + k_d(\varepsilon_* + h\nu - \varepsilon)$$

where $\varepsilon$ is the vibrational energy per molecule, $\tau$ the relaxation time, $k_d$ the non-equilibrium rate coefficient, $\varepsilon_T$ the thermodynamically expected vibrational energy at temperature $T$, and $(\varepsilon_* + h\nu)$ the energy just above the dissociation limit. It is also shown that if

$$e^{-t_{inc}/\tau} \lesssim k_0\tau(4D'/5kT - 3)(5/2 + x_0)/e$$

a local minimum and maximum are predicted for measured density gradients in shock tube dissociations of diatomic molecules, where $t_{inc}$ is the incubation time, $D'$ the effective dissociation energy, and $x_0$ the mole fraction of dissociating molecules in an inert diluent. Expressions are given for extracting incubation times and rate constants from such studies when $x_0 \lesssim 0.3$. Analysis of experimental data actually showing such phenomena (J. Chem Phys. **55**, 4017 (1971)) is carried out. There are indications that any analysis which does not explicitly account for transient effects could result in errors in measured $k_0$'s of factors of 2 or more.

---

HESHEL TEITELBAUM. Can. J. Chem. **60**, 2927 (1982).

Une analyse semi-empirique basée sur la loi de vitesse de relaxation vibrationnelle des oscillateurs harmoniques simples de dissociation permet d'étudier en détail les mesures des temps de relaxation vibrationnelle $\tau$ et les coefficients $k_0$ de vitesse de dissociation stationnaire. On montre que le non-équilibre des populations des niveaux d'énergie vibrationnelle empêche d'atteindre l'énergie d'équilibre thermodynamiquement attendue. Même dans des conditions douces et presqu'isothermiques $\tau \ll 1/k_0$ il en résulte des erreurs expérimentales importantes quand on utilise la loi de vitesse de relaxation de Bethe–Teller. On donne des formes d'expressions rapprochées qui permettent d'évaluer ces erreurs. Les mesures doivent être analysées en utilisant la loi:

$$-d\varepsilon/dt = (\varepsilon - \varepsilon_T)/\tau + k_d(\varepsilon_* + h\nu - \varepsilon)$$

où $\varepsilon$ est l'énergie vibrationnelle par molécule, $\tau$ le temps de relaxation, $k_d$ le coefficient de vitesse de non-équilibre, $\varepsilon_T$ l'énergie vibrationnelle attendue thermodynamiquement à la température $T$ et $(\varepsilon_* + h\nu)$ l'énergie juste au-dessus de la limite de dissociation. On montre également que si

$$e^{-t_{inc}/\tau} \lesssim k_0\tau(4D'/5kT - 3)(5/2 + x_0)/e$$

on peut prévoir un minimum et un maximum locaux pour les gradients de densité mesurés lors des dissociations des molécules diatomiques dans des tubes blindés, où $t_{inc}$ est le temps d'incubation, $D'$ l'énergie effective de dissociation et $x_0$ la fraction molaire des molécules se dissociant dans un solvant inerte. On donne les expressions qui permettent de déduire les temps d'incubation et les constantes de vitesse à partir de telles études lorsque $x_0 \lesssim 0.3$. On effectue une analyse des données expérimentales qui montrent actuellement un tel phénomène (J. Chem. Phys. **55**, 4017 (1971)). Il y a des indications à l'effet que toute analyse qui ne tient pas explicitement compte des effets transitoires peut conduire à des facteurs d'erreurs de 2 ou plus sur les mesures de $k_0$.

[Traduit par le journal]

## Introduction

Recent theoretical studies of unimolecular reactions at the low pressure limit have shown that the dissociation process creates a non-equilibrium distribution of vibrational energy level populations (1–4), and that this is a major reason why measured rate coefficients are smaller than the rate constants predicted by theories assuming strong collisions, e.g., RRKM. In principle this non-equilibrium distribution can influence the vibrational relaxation process itself even for diatomic molecules. Expressions for the steady-state rate coefficient, transient rate coefficient, and incubation time have been obtained for cases where the density of vibrational energy levels were high (1, 2, 4), and numerical calculations done for diatomics (3, 5). Here we focus on obtaining an analytical expression for the vibrational relaxation time under conditions of non-equilibrium dissociation, particularly for diatomic molecules.

**Rate law for vibrational energy**

We extend the Bethe–Teller model (6) which leads to the familiar rate law, valid only for non-dissociating molecules.

$$[1] \qquad -d\varepsilon/dt = (\varepsilon - \varepsilon_T)/\tau$$

Here $\varepsilon$ is the vibrational energy per molecule, and $\varepsilon_T$ is its value at thermal equilibrium at translational temperature $T$. We use the same model because of its success in predicting the observed rate law (7, 8) for the relaxation of vibrational energy when dissociation is not important. This model allows for single quantum transitions between vibrational levels of a harmonic oscillator effected by T–V energy transfer processes. The relaxing molecule may collide with itself or with an inert diluent. We ignore V–V energy transfer processes because they are resonant and will not affect the vibrational energy of harmonic oscillators. In order to represent the dissociation process somewhat realistically we truncate the harmonic oscillator potential at vibrational level $v_*$ just below the dissociation limit. If $N_v$ is the number of molecules in level $v$, the master equation is

$$[2] \qquad \frac{-dN_v}{dt} = k_{v,v+1}N_v + k_{v,v-1}N_v - k_{v-1,v}N_{v-1} - k_{v+1,v}N_{v+1}$$

where $k_{v,v'}$ is the rate coefficient for the transition $v \rightarrow v'$. For single quantum transitions dissociation occurs by transitions from $v_*$ to the continuum with a rate coefficient $k_{v_*,\infty}$. When recombination is ignored, only 3 terms including $N_{v_*}k_{v_*,\infty}$ appear in the expression for $-dN_{v_*}/dt$. For $v = 0$

$$-dN_0/dt = k_{0,1}N_0 - k_{1,0}N_1$$

According to the standard procedure eq. [2] is multiplied by $v$, and a summation over all $v$ is carried out:

$$[3] \qquad -\frac{d}{dt}\sum_0^{v_*} vN_v = -\sum_0^{v_*-1} k_{v,v+1}N_v + \sum_1^{v_*} k_{v,v-1}N_v + v_*k_{v_*,\infty}N_{v_*}$$

Use of the Landau–Teller scaling law

$$[4] \qquad \begin{aligned} k_{v+1,v} &= (v+1)k_{1,0} \\ k_{v,v+1} &= (v+1)k_{0,1} \end{aligned}$$

and detailed balancing, with $\theta = h\nu/k$

$$[5] \qquad k_{0,1} = k_{1,0}\, e^{-\theta/T}$$

and the constraints

$$\sum_0^{v_*} N_v = N$$

$$\sum_0^{v_*} (v + 1/2)h\nu N_v = E$$

lead to

$$[6] \qquad \frac{-d}{dt}\left(\frac{E}{h\nu} - \frac{N}{2}\right) = (k_{10} - k_{01})\left(\frac{E}{h\nu} - \frac{N}{2}\right) - k_{0,1}(N - N_{v_*} - v_*N_{v_*}) + v_*N_{v_*}k_{v_*,\infty}$$

Here $\nu$ is the fundamental frequency, and $E$ is the total vibrational energy of the $N$ molecules. The vibrational energy $E_T$ of the original $N^0$ undissociated molecules is given by

$$[7] \qquad E_T = N^0h\nu\left(\frac{1}{2} + \frac{e^{-\theta/T}}{1 - e^{-\theta/T}}\right)$$

A direct summation of eq. [2] gives

$$\sum_0^{v_*} \frac{dN_v}{dt} = -k_{v_*,\infty}N_{v_*} = \frac{dN}{dt}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

But the phenomenological rate coefficient $k_d$ is defined as

$$k_d = \frac{-dN/dt}{N}$$

Thus

[8] $$k_{v_*,\infty} N_{v_*} = k_d N$$

and eq. [6] becomes

[9] $$\frac{-dE}{dt} = k_{1,0}(1 - e^{-\theta/T}) \frac{(E - NE_T)}{N^0} + k_{0,1} N_{v_*}(v_* + 1)h\nu + (v_* + 1/2)Nk_d h\nu$$

The combination $k_{1,0}(1 - e^{-\theta/T})$ is symbolized $\tau^{-1}$, and it is this value which one normally tries to extract from experiments. The second term on the right hand side is a truncation effect. The third term accounts for the decreasing number of molecules due to dissociation. More appropriate to this study is an expression for the rate of change of the vibrational energy per undissociated molecule, $\varepsilon(= E/N)$.

$$d\varepsilon/dt = N^{-2}(N dE/dt - E dN/dt)$$

Thus, if $\varepsilon_T = E_T/N^0$ and $\varepsilon_* = (v_* + 1/2)h\nu$, and $\varepsilon_0 = (1/2)h\nu$, then

[10] $$-d\varepsilon/dt = \tau^{-1}(\varepsilon - \varepsilon_T) + h\nu(N_{v_*}/N)(v_* + 1)k_{0,1} + k_d(\varepsilon_* - \varepsilon)$$

This is the correct rate law for a dissociating harmonic oscillator. The second term on the right hand side is a truncation effect; the third term appears because of non-equilibrium depletion of the vibrational energy levels. It prevents $\varepsilon$ from reaching its thermodynamic value $\varepsilon_T$. However, the second and third terms on the right hand side are generally small during the relaxation process, and eq. [10] is usually not distinguishable from eq. [1]. Nevertheless, it is clear that when $d\varepsilon/dt = 0$ during steady-state dissociation $\varepsilon = \varepsilon^\infty \neq \varepsilon_T$, and that even during vibrational relaxation the effective or phenomenological relaxation time $\tau' \neq \tau$, where

[11] $$\tau' \equiv -(\varepsilon - \varepsilon_T)/(d\varepsilon/dt)$$

In order to evaluate $\tau'$ we must first integrate eq. [10]. Noting eq. [8] and extrapolating eqs. [4] to include the continuum so that $k_{v_*,\infty} = (v_* + 1)k_{0,1}$,

[12] $$-d\varepsilon/dt = \tau^{-1}(\varepsilon - \varepsilon_T) + k_d(\varepsilon_* + h\nu - \varepsilon)$$

$\varepsilon^\infty$ is given by setting $d\varepsilon/dt = 0$. Thus

[13] $$\varepsilon^\infty = (\varepsilon_T/\tau - k_0[\varepsilon_* + h\nu])/(1/\tau - k_0)$$

Noting that $k_0$ (the steady-state rate constant) $\ll 1/\tau$,

$$\varepsilon^\infty \simeq \varepsilon_T - h\nu(v_* + 3/2)k_0\tau$$

During the steady-state dissociation when $k_d = k_0$, the solution to eq. [12] is:

$$\varepsilon = \varepsilon^\infty + (\varepsilon^0 - \varepsilon^\infty) \exp(-t[1/\tau - k_0])$$

where $\varepsilon^0$ is the initial vibrational energy per molecule at $t = 0$. If $\tau'$ were defined as the slope of a log-plot of $(\varepsilon^\infty - \varepsilon)$ vs. $t$, then $\tau' \approx \tau(1 + k_0\tau)$. However, $\varepsilon^\infty$ is usually not measurable, and so the phenomenological definition [11] is used. Since $\varepsilon^\infty \neq \varepsilon_T$ and $d\varepsilon/dt \to 0$, $\tau'$ defined by eq. [11] actually approaches infinity as time increases into the dissociation regime. Usually relaxation times are not measured under such conditions. Nevertheless because of current interest (9) in measuring incubation times $t_{inc}$, we must account for this, since such measurements rely on the interplay between relaxation and dissociation phenomena. Furthermore, it is not uncommon to measure late-stage relaxation times at temperatures where both processes become evident during a single experiment (9, 10). The error can be quite serious under such conditions (Fig. 1). Then it is crucial to use the correct rate law [12].

In integrating eq. [12] we note one further complication: during the incubation period, $k_d$ is a strong function of time. Forst (4) has derived an expression for the time variation valid for times $> (t_{inc} - \tau)$:

$$1 - k_d/k_0 = \exp[-(t - t_{inc} + \tau)/\tau]$$

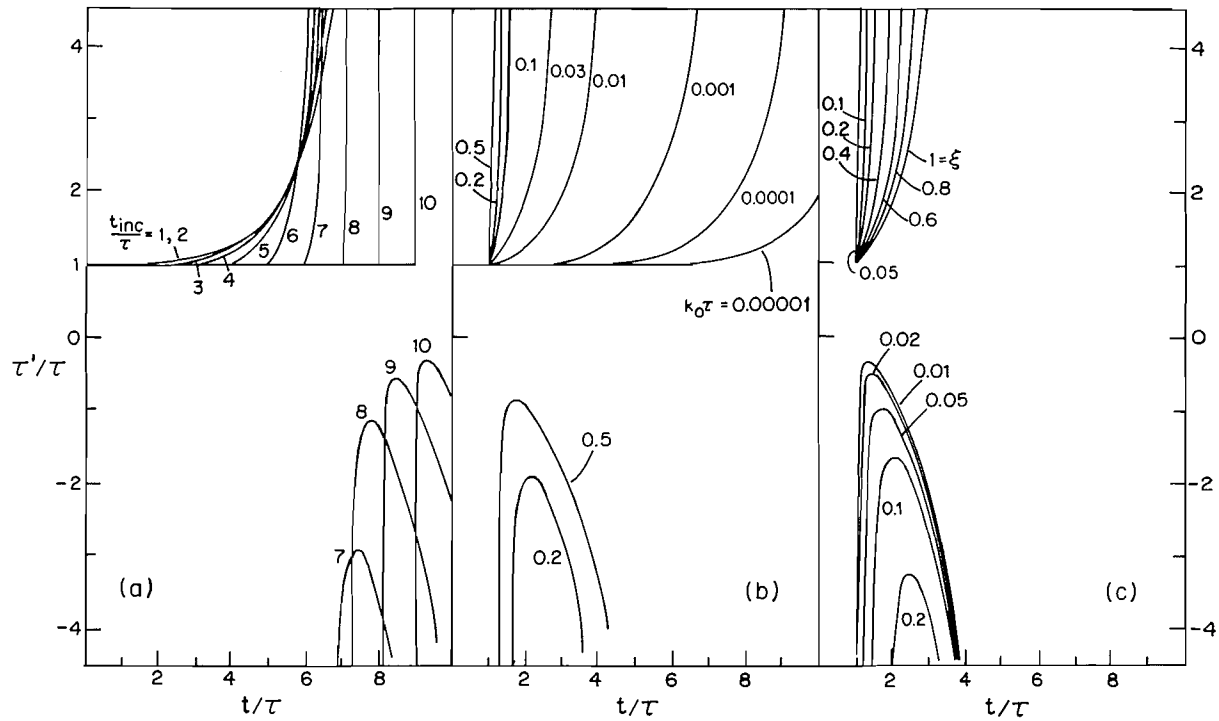

FIG. 1. Phenomenological isothermal relaxation times normalized by the simple harmonic oscillator time $k_{1,0}^{-1}(1-e^{-\theta/T})^{-1}$, as a function of reduced time, assuming no dissociation at $t \leq t_{inc} - \tau$; (*a*) dependence on incubation time; $k_0\tau = 0.001$; $\xi = 0.25$; (*b*) dependence on $k_0\tau$; $t_{inc}/\tau = 2$; $\xi = 0.25$; (*c*) dependence on $\xi = (\varepsilon_T - \varepsilon^0)/(\varepsilon_* + h\nu - \varepsilon_T)$; $t_{inc}/\tau = 2$; $k_0\tau = 0.1$. Note that if relaxation has proceeded sufficiently by $t = t_0$, then the vibrational energy overshoots its final value before equilibrating, during which time $\tau' < 0$.

where $t_{inc}$ is the incubation time necessary for the steady-state population of upper levels to evolve. At this point in time $k_d$ has reached within $e^{-1}$ of the steady dissociation constant, $k_0$. It is evident that $t_{inc}$ is larger than $\tau$, since $\tau$ is a measure of the time needed to redistribute energy among low vibrational levels only. (Figure 7 of ref. 11 shows a rare example of experiments where $\tau$, $t_{inc}$, and $k_0$ have all been measured. At low temperatures $\tau < t_{inc} \ll k_0^{-1}$.) At times earlier than $(t_{inc} - \tau)$ we set $k_d \simeq 0$. This approximation is not significant, since at early times $\tau' \approx \tau$ anyway, and at the times of interest eq. [14] is appropriate. Note that the transient behaviour of $k_d$ is determined by $t_{inc}/\tau$. At low temperatures $t_{inc} \gg \tau$, and the observed relaxation will be essentially complete before the incubation zone; however, at high temperatures when $t_{inc} \rightarrow 2$ to 4 times $\tau$, the incubation zone is one wherein a measurable portion of the relaxation takes place. Under near isothermal conditions the solution to eq. [12] is

$$[14] \qquad \frac{\varepsilon}{\varepsilon_T} = \frac{(\beta-1)k_0\tau(1-g\,e^{k_0\tau}) - (\beta k_0\tau - 1)f\,e^{k_0\tau} - \delta\,e^{-t_0/\tau}(1-k_0\tau)}{(1-k_0\tau)f e^{k_0\tau}}$$

where

$$\beta = (\varepsilon_* + h\nu)/\varepsilon_T$$

$$\delta = (\varepsilon_T - \varepsilon^0)/\varepsilon_T$$

$$t_0 = t_{inc} - \tau$$

$$f = u^{(k_0\tau - 1)}\,e^{-k_0\tau u}$$

$$u = e^{-(t-t_0)/\tau}$$

$$g = -(k_0\tau)^{-k_0\tau}[\gamma(k_0\tau, k_0\tau u) - \gamma(k_0\tau, k_0\tau)]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

and $\gamma$ is the incomplete gamma function. With the use of eq. [12], the phenomenological relaxation time as defined by eq. [11] is given (for $\beta \neq 1$) by:

[15] $\tau'/\tau = \{1 - k_0\tau(1-u)(\varepsilon/\varepsilon_T - \beta)/(\varepsilon/\varepsilon_T - 1)\}^{-1}$

Figure 1 shows this relaxation time as a function of time. If measurements are made at times $\geq (t_{inc} - \tau)$, which are feasible especially when $t_{inc} \sim 2\tau$, then large errors can result. Note that the distortion to $\tau$ depends only on the parameters $k_0\tau$, $t_{inc}/\tau$, and $\xi = \delta/(\beta - 1) = (\varepsilon_T - \varepsilon^0)/(\varepsilon_* + h\nu - \varepsilon_T)$. The last parameter is the ratio of the maximum change in vibrational energy during the relaxation process to the excess energy of an average dissociating molecule. In principle these parameters are all determined by molecular properties and by temperature; however, since the theory of transient phenomena for diatomic molecules is not sufficiently developed to provide closed form expressions for $t_{inc}$ and $k_0\tau$, we treat the three parameters as independent. Distortion to $\tau'$ is largest at the highest temperatures when $k_0\tau \rightarrow 1$ and $t_{inc}/\tau \rightarrow 1$. In Fig. 1 we have evaluated $\tau'$ at times up to $10\tau$ or to the half-life for reaction ($k_0^{-1}$) whichever is smaller. Note that if relaxation has proceeded to such an extent at $t = t_0$ that $\varepsilon$ is already in excess of its final value $\varepsilon^\infty$, then the vibrational energy overshoots and the rate of relaxation becomes negative! This occurs when $1 - \delta\, e^{-t_0/\tau} > (1 - \beta k_0\tau)/(1 - k_0\tau)$. One further feature particularly noteworthy is the special case $\beta = 1$, for which $\varepsilon^\infty = \varepsilon_T$. Then $\tau'/\tau \rightarrow (1 - k_0\tau)^{-1}$.

## Incubation time measurements

Equally appropriate to such studies is an expression for the observable quantity in an experiment. The most sensitive technique to date for measuring vibrational relaxation times at high temperatures is shock tube densitometry. Here we obtain an expression for the rate of change of the gas temperature. In shock tube studies of relaxation–dissociation processes the temperature $T$ decreases monotonically, and this loss in thermal energy is taken up by the vibrational degree of freedom and by bond-breaking. The process occurs at constant pressure approximately, and the density is affected almost entirely by variations in the temperature and in the average molecular weight. The latter changes by the factor $(1 + \alpha x_0)$ where $x_0$ is the initial mole fraction of the dissociating molecule, and $\alpha$ is the degree of dissociation defined by $N = N^0(1 - \alpha)$. Thus we look for variation in the function $F = T(1 + \alpha x_0)$. In order to obtain $T$ we must solve an energy flux conservation equation involving the gas enthalpy $H$ and bulk flow kinetic energy. To a good approximation the shock process can be considered isenthalpic, so the temperature is determined by:

[16] $H = N_A(\bar{H}_A + \Delta_A) + N_B(\bar{H}_B + \Delta_B) + N_{AB}(\bar{H}_{AB} + \Delta_{AB}) + N_M\bar{H}_M = \text{constant}$

where $N_i$, $\bar{H}_i$, $\Delta_i$ are the number of moles, the molar heat content, and the molar heat of formation of species i respectively. M is an inert diluent (usually monatomic). In order to illustrate the phenomenon we have chosen the simple diatomic dissociation AB $\rightarrow$ A + B. It should be emphasized that for actual experiments the full solutions are routinely carried out (9, 10), but that we have made these reasonable approximations in order to eliminate flow variables yet retain the physics of the dissociation problem. The full solution does not significantly alter the result. Equation [16] becomes

$$[17]\quad x_0\alpha(\bar{H}_A + \bar{H}_B + D) + (1 - x_0)\bar{H}_M + (1 - \alpha)x_0\left[\int_0^T (\bar{C} - \bar{C}_v)_{AB}\,dT + \varepsilon\right] = (1 - x_0)\bar{H}_M(T_1) + x_0\left[\int_0^{T_1} (\bar{C} - \bar{C}_v)_{AB}\,dT + \varepsilon^0\right] = A$$

where $x_0 \equiv N_{AB}^0/(N_{AB}^0 + N_M)$, $D$ is the heat of reaction

[18] $D \approx \varepsilon_* + h\nu$

$T_1$ is the initial post-shock temperature, $T_0$ is the initial temperature, $\bar{C}_i$ is the molar heat capacity of species i, $\bar{C}$ is the total initial heat capacity, and $\bar{C}_v$ is the vibrational contribution to $\bar{C}$. Only AB vibrates and hence relaxes. Differentiation of eq. [17] with respect to gas-particle time and subsequent substitution of eqs. [12] and [18] lead to an expression for $dT/dt$ in terms of $d\alpha/dt$, $\bar{H}_i$, $\bar{C}_i$, and $\varepsilon$. The vibrational energy can be obtained from eq. [17] in terms of $\bar{H}_i$, $\bar{C}_i$, and $\alpha$. Thus

For personal use only.

$$[19]\quad \frac{dT}{dt}\{\alpha x_0(\bar{C}_A + \bar{C}_B) + (1-x_0)\bar{C}_M + x_0(1-\alpha)(\bar{C} - \bar{C}_v)_{AB}\}$$
$$= \frac{d\alpha}{dt}\left\{\frac{1}{(1-\alpha)}\ [A - x_0\alpha(\bar{H}_A + \bar{H}_B + D) - (1-x_0)\bar{H}_M] - x_0(\bar{H}_A + \bar{H}_B + D)\right\}$$
$$- \frac{1}{\tau}\left[\alpha x_0(\bar{H}_A + \bar{H}_B - \bar{H}_{AB} + D) - \int_T^{T_1} \bar{C}\, dT - x_0\int_{T_1}^{T_0} \bar{C}_v\, dT\right]$$
$$+ k_d[Dx_0(1-\alpha) - A + x_0\alpha(\bar{H}_A + \bar{H}_B + D) + (1-x_0)\bar{H}_M]$$

The first term includes the effective heat capacity $\bar{C}$; the last term is the principal dissociation term which is constant at early times; the second term is a secondary dissociation term accounting for the disappearance of AB; the third term is the relaxation term which depends on $(T_1 - T)$ approximately. If the relaxation zone and dissociation zone are well separated, i.e. if $d[(1-\alpha)\varepsilon]/dt \approx (1-\alpha)d\varepsilon/dt$, then eq. [19] reduces approximately to the usual form

$$dT/dt \propto -x_0(\bar{H}_A + \bar{H}_B - \bar{H}_{AB} + D)d\alpha/dt - \bar{C}(T - T_e)/\tau$$

where $T_e$ is the temperature corresponding to thermal equilibrium prior to dissociation, were such a situation to occur: $\bar{C}(T_1 - T_e) = \bar{C}_v(T_1 - T_0)$. However, in the more general situation eq. [19] must be used. We can simplify it by noting the phenomenological definition of $k_d$, and of $\alpha$

$$[20]\quad d\alpha/dt = k_d(1-\alpha)$$

We treat $\bar{C}$ and $\bar{C}_v$ as essentially independent of temperature during reaction.

$$[21]\quad \bar{C}\, dT/dt \approx -k_d x_0(\bar{H}_A + \bar{H}_B)(1-\alpha) - \frac{1}{\tau}\{\bar{C}(T - T_1) + x_0\bar{C}_v(T_1 - T_0) + \alpha x_0(\bar{H}_A + \bar{H}_B - \bar{H}_{AB} + D)\}$$

where $\bar{H}_{AB}$ includes the true thermodynamic contribution of the vibrational energy at temperature $T$. The equation can be integrated numerically to obtain $T$ as a function of time, if one substitutes the Forst function for $k_d$ and the solution of eq. [20] for $\alpha$:

$$1 - \alpha = \exp[-k_0\tau(u - \ln u - 1)]$$

In this procedure we treat $k_0$, $\tau$, and $t_{inc}$ as being unaffected by the temperature changes. Note that $\xi$ depends on $\varepsilon_T$, $\varepsilon^0$, and $D$, i.e. on $T_1$, $T_0$, $D$, and $h\nu/kT$, basically. Thus aside from $k_0\tau$, $x_0$, $t_{inc}/\tau$, and $\xi$, a new parameter appears, $\theta/T = h\nu/kT$, which represents how classical the oscillator behaves. The observable

$$dF/dt = (1 + \alpha x_0)\, dT/dt + x_0 T\, d\alpha/dt$$

is shown in Fig. 2. Most notable is the pronounced minimum and subsequent maximum. This is to be expected, since $dT/dt$ depends on the rate of relaxation and the rate of dissociation. The former decreases as $\varepsilon^\infty$ is approached but the latter increases, after a delay time $t_0$, due to the dramatic increase in $k_d$. As the molecules begin to disappear all rates decrease. The position of the minimum and maximum can be found by setting $d^2F/dt^2$ to zero. We note that $(\bar{H}_A + \bar{H}_B - \bar{H}_{AB} + D) \equiv D' \approx D + kT/2 \simeq$ constant, at least with respect to the strongly varying $\alpha$. Thus

$$[22]\quad \bar{C}\, dT/dt = -Tf_1(t) - f_2(t)$$

where

$$f_1(t) = 5kx_0k_d(1-\alpha) + \bar{C}/\tau$$
$$f_2(t) = [x_0\bar{C}_v(T_1 - T_0) - \bar{C}T_1 + \alpha x_0(\bar{H}_A + \bar{H}_B - \bar{H}_{AB} + D)]/\tau$$

and $k$ is Boltzmann's constant. The temperature is a monotonically decreasing function of time with an initial decay constant $f_1/\bar{C}$. However, the observable depends on the rate of change of temperature, and the latter exhibits a minimum which is determined by the competition between decreasing $T$ and increasing $f_2$.

Under the most extreme conditions likely to be encountered in the laboratory $k_0\tau < 0.1$ (usually

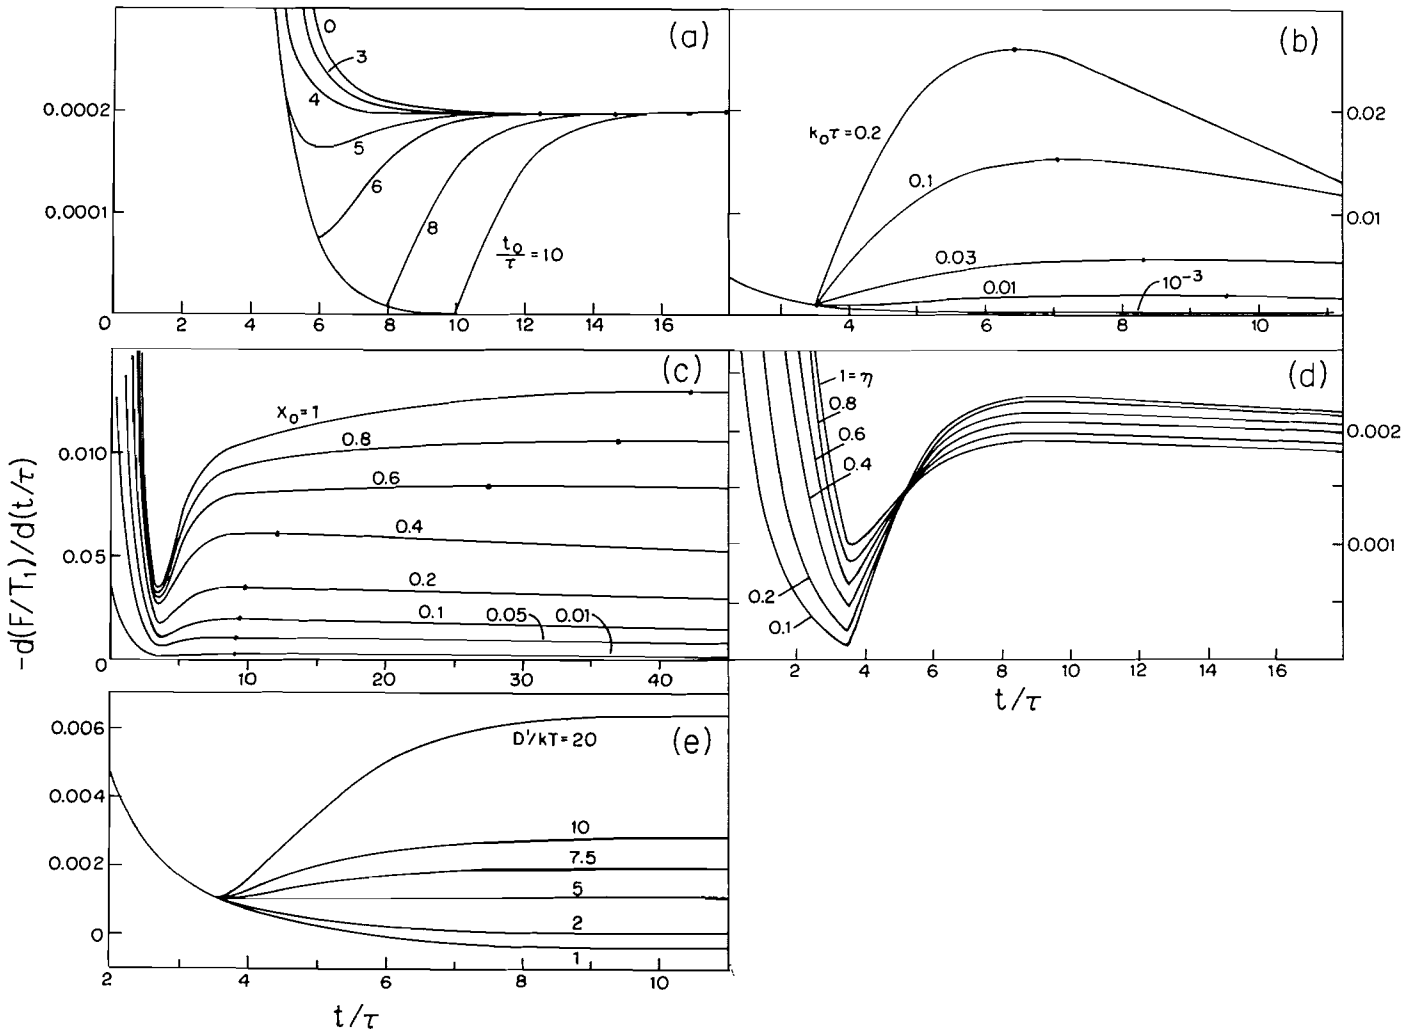

FIG. 2. Observed relaxation–dissociation rates (density gradient) as a function of reduced time. $d(F/T_1)/d(t/\tau) = (1 + \alpha x_0)d(T/T_1)/d(t/\tau) + x_0(T/T_1)d\alpha/d(t/\tau)$. Model assumes no dissociation prior to $t = t_0$. Products are each half as efficient as AB in dissociating AB. Figure shows influence of (*a*) dead time $t_0/\tau$; $k_0\tau = 0.001$; $x_0 = 0.1$; $\eta = 1.0$; $(1 - T_0/T_1) = 1.0$; $D/kT_1 = 7.5$. The extrema occur for $t_0/\tau \geq 3.9$; but the maxima are not very evident since dissociation proceeds on a time scale 1000 times longer than that for relaxation. They occur in the range $12.4 \rightarrow 18.8$ for $t_0/\tau = 4 \rightarrow 10$; (*b*) relative rates of dissociation and relaxation, $k_0\tau$. Here $t_0/\tau = 3.5$; $x_0 = 0.1$; $\eta = 1.0$; $(1 - T_0/T_1) = 1.0$; $D/kT_1 = 7.5$. The positions of the extrema are indicated by dots; (*c*) the mole fraction of dissociating gas, $x_0$. $k_0\tau = 0.01$; $t_0/\tau = 3.5$; $\eta = 1.0$; $(1 - T_0/T_1) = 1.0$; $D/kT_1 = 7.5$; (*d*) influence of closeness to classical oscillation, η; here $t_0/\tau = 3.5$; $x_0 = 0.1$; $k_0\tau = 0.01$; $(1 - T_0/T_1) = 1.0$; $D/kT_1 = 7.5$; (*e*) influence of bond strength $D/kT$. Here $t_0/\tau = 3.5$; $x_0 = 0.1$; $k_0\tau = 0.01$; $\eta = 1$; $(1 - T_0/T_1) = 1.0$. Note the change in sign at very high temperatures when molecular weight effects are more important than thermal effects.

$k_0\tau \ll 1$), and even if $t_{inc} \rightarrow \tau$ ($t_0 = t_{inc} - \tau \rightarrow 0$) under these circumstances, after one relaxation time beyond the dead-time ($t_0$), $\alpha$ is only 0.037. In order to obtain a simple expression for the position of the minimum, we set $\alpha \simeq k_0\tau(u - \ln u - 1)$ which is valid for $k_0\tau$ even as high as 0.3, and for $t < t_0 + 1.5\tau$. We can now integrate eq. [22] exactly:

$$[23] \quad \frac{dT}{dt} = -\frac{x_0\bar{C}_v}{\bar{\mathbb{C}}\tau}(T_1 - T_0)\,e^{-t/\tau_*} - \frac{x_0k_0}{(\bar{C} - \bar{\mathbb{C}})}[(5kT - D')\,e^{-v} - (5kT - D'\bar{\mathbb{C}}/\bar{C})\,e^{-\bar{C}_v/\bar{\mathbb{C}}}] - \frac{x_0k_0D'}{\bar{C}}$$

where $\tau_* = \tau(\bar{C} - \bar{C}_v)/\bar{C} \simeq \tau\bar{\mathbb{C}}/\bar{C}$ and $v = (t - t_0)/\tau$. The only further approximation made is that $k_0$, $\tau$, and $\bar{C}$ are not strongly time-dependent in the limited temperature range of a single dissociation experiment. We may now use eq. [23] to find the position of the minimum, given by $d(dF/dt)/dt = 0$, and $\alpha \simeq 0$:

$$[24] \quad \frac{d^2T}{dt^2} + 2x_0k_d\frac{dT}{dt} + x_0T\frac{dk_d}{dt} - x_0Tk_d^2 = 0$$

However, it is instructive to simplify eq. [23] for the special case $\bar{C} \simeq \bar{\mathbb{C}}$, i.e. for a dilute gas. Then

$$\frac{dT}{dt} = \begin{cases} -\dfrac{x_0\bar{C}_v}{\bar{\mathbb{C}}\tau}(T_1 - T_0)\,e^{-t/\tau} - \dfrac{x_0k_0D'(1 - e^{-v})}{\bar{\mathbb{C}}} & t \geq t_0 \\ -\dfrac{x_0\bar{C}_v}{\bar{\mathbb{C}}\tau}(T_1 - T_0)\,e^{-t/\tau} & t \leq t_0 \end{cases}$$

and we note that (*a*) $dT/dt \rightarrow -x_0k_0D'/\bar{\mathbb{C}}$ as expected for $t \gg \tau$, (*b*) the minimum occurs at exactly $t = t_0$, if (*c*) the relaxation has proceeded sufficiently by $t = t_0$ that

$$\bar{C}_v(T_1 - T_0)\,e^{-t_0/\tau_*} < k_0\tau_*D'$$

Were it not for the delay time, $dT/dt$ would vary monotonically with time, and not display a minimum.

For non-dilute gases the complete eq. [23] must be used. Since the time constant for decay of vibrational energy is slightly smaller than that for the growth of $k_d$, the true minimum will be at a time slightly beyond $t_0$, and the above criterion ought to be correspondingly modified. As written it is a conservative criterion. Equation [24] can be simplified with the use of eq. [23] and its derivative, to obtain an expression for $v = (t_{min} - t_0)/\tau$ at the minimum.

$$[25] \quad \frac{\bar{C}_v\bar{C}}{\bar{\mathbb{C}}^2\tau^2}(T_1 - T_0)\,e^{-t_0/\tau_*}\,e^{-\bar{C}_v/\bar{\mathbb{C}}} + \frac{k_0}{\tau}e^{-v}\left[\frac{5kT - D'}{\bar{C} - \bar{\mathbb{C}}} + T\right] - \frac{k_0}{\tau}e^{-\bar{C}_v/\bar{\mathbb{C}}}\frac{(5kT\bar{C}/\bar{\mathbb{C}} - D')}{(\bar{C} - \bar{\mathbb{C}})}$$
$$- (1 - e^{-v})^2k_0^2\left[\frac{T - 2x_0(5kT - D')}{\bar{C} - \bar{\mathbb{C}}}\right] - (1 - e^{-v})(1 - e^{-\bar{C}_v/\bar{\mathbb{C}}})2x_0k_0^2\frac{(5kT - D'\bar{\mathbb{C}}/\bar{C})}{(\bar{C} - \bar{\mathbb{C}})} = 0$$

An experimentalist would have to measure $k_0$, $\tau$, and $t_{min}$ (i.e. $v_{min}$), and then use eq. [25] to deduce $t_0$. However, since $k_0\tau \ll 1$, we may ignore terms in $(k_0\tau)^2$, and we obtain

$$[26] \quad \frac{t_{min}}{\tau} = \frac{t_0}{\tau} + \left(\frac{\bar{\mathbb{C}}}{\bar{C} - \bar{\mathbb{C}}}\right)\ln\left\{\frac{\bar{C}_v\bar{C}(T_1 - T_0)\,e^{-t_0/\tau_*}/\bar{\mathbb{C}}^2 - k_0\tau(5kT\bar{C}/\bar{\mathbb{C}} - D')/(\bar{C} - \bar{\mathbb{C}})}{-k_0\tau[(5kT - D')/(\bar{C} - \bar{\mathbb{C}}) + T]}\right\}$$

or $t_{min}/\tau = t_0/\tau$, whichever is greater. The latter is greater when

$$[5/2 + x_0(1 + \eta)]\eta(T_1 - T_0)\,e^{-t_0/\tau} < k_0\tau(25/4 - x_0^2)T$$

An accurate criterion for the existence of a minimum in $|dF/dt|$ is given by $d^2|dF/dt|/dt^2 > 0$. Thus, as long as

$$(5kT - D')/(\bar{C} - \bar{\mathbb{C}}) + T < 0$$

and

$$k_0\tau(5kT\bar{C}/\bar{\mathbb{C}} - D')\bar{\mathbb{C}}^2/(\bar{C} - \bar{\mathbb{C}}) < \bar{C}_v\bar{C}(T_1 - T_0)\,e^{-t_0/\tau_*}$$

then there will be a minimum; i.e. $kT$ must be less than $D'/(5 + x_0\eta)$ or $D'(\bar{\mathbb{C}}/5\bar{C})[1 - x_0\eta\bar{C}_v(1 - T_0/T_1)/(5\bar{\mathbb{C}}k_0\tau)e^{-t_0/\tau_*}]^{-1}$ whichever is more restrictive. Otherwise at high enough temperatures the effect of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

changing mole number overcomes all thermal effects, and, as can be seen in Fig. 2*e*, the observable changes sign and simply decreases monotonically. Here we have used $\theta = h\nu/kT$, and $\eta = \bar{C}_v/k = (\theta/T)^2 \times e^{-\theta/T}(1 - e^{-\theta/T})^{-2}$ which is a measure of how classical an oscillator the molecule is. In obtaining these results we have set $\alpha \approx 0$, and therefore eq. [23] contains no information about the maximum, which occurs when the molecules begin to dissociate substantially. If this occurs so early that the observable has yet to decay to its expected minimum value, then no minimum (and subsequent maximum) will be observed. The condition for observing extrema is thus $t_{min} < t_{max}$. This will be discussed below.

The position of the maximum is determined primarily by the competition between an increasing $k_d$ and a decreasing $(1 - \alpha)$. The function $(1 - u)\exp[-k_0\tau(u - 1 - \ln u)]$ maximizes at a time $t_{max}$ given by

$$(t - t_0)/\tau = 2\ln(\{\sqrt{4 + 1/k_0\tau} + 1/\sqrt{k_0\tau}\}/2)$$

When $k_0\tau < 0.1$

$$(t - t_0)/\tau \approx -\ln k_0\tau > 2.3$$

At $t_{max}$

$$k_d \approx k_0(1 - k_0\tau) \approx k_0$$

and the corresponding $\alpha$ is only 0.131 or less. Thus in order to obtain a simple expression for $T(t)$ for use in eq. [24] we set

$$5kx_0k_d(1 - \alpha) \simeq 5kx_0k_0$$

and

$$\alpha \simeq 1 - \exp[-k_0(t - t_{inc})]$$

i.e.

$$u - 1 - \ln u \approx -1 - \ln u$$

and we solve eq. [22]. The temperature in the region of the maximum is given by:

$$[27]\quad T = T_1(\bar{C}/\bar{C}') - x_0(\bar{C}_v/\bar{C}')(T_1 - T_0)[1 - (\bar{C}'/\bar{C})\,e^{-(t-t_{inc})/\tau_{\neq}}\,e^{-t_{inc}/\tau_*}] + (1 - \bar{C}/\bar{C}')T_e\,e^{-(t-t_{inc})/\tau_{\neq}} - \frac{D'x_0}{\bar{C}'}\left[1 - \frac{e^{-k_0(t-t_{inc})}}{1 - k_0\tau_{\neq}} + \frac{k_0\tau_{\neq}}{1 - k_0\tau_{\neq}}\,e^{-(t-t_{inc})/\tau_*}\right] - x_0(k_0\tau/\bar{C})[(5kT_2 - D'\bar{\mathcal{C}}/\bar{C})(1 - 1/e) + D'/e]\,e^{-(t-t_{inc})/\tau_*}$$

where $\tau_{\neq} = \tau\bar{\mathcal{C}}/(\bar{C} + 5kx_0k_0\tau) \equiv \tau\bar{\mathcal{C}}/\bar{C}'$, and where we have used the boundary condition that at $t = t_{inc}$ (where $\alpha$ is still $\approx 0$) the temperature $T_2$ is given by the integral of eq. [23]. It was assumed that $T$ does not vary by more than 10%, so that factors involving $5kT$ could be considered constant. The maximum is found by setting $d^2F/dt^2 = 0$. This leads to the transcendental equation in $y$:

$$[28]\quad \frac{D'}{\bar{C}'T}\left(\frac{1}{1 - k_0\tau\bar{\mathcal{C}}/\bar{C}'}\right)\left\{k_0\tau - \frac{\bar{C}'}{\bar{\mathcal{C}}}e^{-\bar{C}'y/\bar{\mathcal{C}} + k_0\tau y} - 2x_0k_0\tau[1 - e^{-(y+1)}](e^{-k_0\tau y} - e^{-\bar{C}'y/\bar{\mathcal{C}}})\right\} + \frac{5k}{\bar{\mathcal{C}}}e^{-\bar{C}'y/\bar{\mathcal{C}}}\left\{\frac{\bar{C}'}{\bar{\mathcal{C}}}e^{k_0\tau y} - 2x_0k_0\tau[1 - e^{-(y+1)}]\right\} + e^{-(y+1)} - k_0\tau[1 - e^{-(y+1)}]^2 + e^{-\bar{C}'y/\bar{\mathcal{C}}}\,e^{k_0\tau y}\frac{\bar{C}}{\bar{\mathcal{C}}}\left\{\frac{\bar{C}_v\bar{C}'^2}{\bar{\mathcal{C}}\bar{C}^2}\left(1 - \frac{T_0}{T_1}\right)e^{-t_{inc}/\tau_*}\frac{1}{k_0\tau} - \frac{1}{e}\left[\left(\frac{5k}{\bar{\mathcal{C}}} - \frac{D'}{\bar{C}T}\right)(e - 1) + \frac{D'}{\bar{\mathcal{C}}T}\right]\right\} = 0$$

where $y = (t_{max} - t_{inc})/\tau$, and where we have made the approximations

$$(1 + \alpha x_0) \simeq 1; \quad T_1 \approx T_2 \approx T_e \approx T; \quad (1 - \alpha) \simeq e^{-k_0\tau y}$$

as before; and

$$x_0k_0\tau[1 - e^{-(1+y)}]\,e^{-k_0\tau y} \ll 1$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

which is true since $k_0\tau \ll 1$. The above equation can be simplified by setting $k_0\tau \ll 1$, i.e. $\bar{C}' \simeq \bar{C}$. We also note that $k_0\tau y$ can never be more than $\sim e^{-2}$. A glance at Fig. 2 confirms that $y > 1.3$, so that

$$e^{-(y+1)} \ll e^{-k_0\tau y}$$

Further simplification depends on how large $y$ is. If

$$2x_0k_0\tau\, e^{-k_0\tau y} \ll e^{-y}$$

i.e. if $y$ is at its lower limit $\sim 0$.

$$[29] \quad k_0\tau\, e^{\bar{C}y/\bar{\mathbb{C}}} \approx \frac{\dfrac{\bar{C}}{\bar{\mathbb{C}}}\left\{\dfrac{D'}{T}\left(\dfrac{1}{\bar{C}}+\dfrac{1}{\bar{\mathbb{C}}}\right)-\left(\dfrac{5k}{\bar{\mathbb{C}}}+1\right)-\dfrac{\bar{C}_v}{\bar{\mathbb{C}}}\dfrac{(1-T_0/T_1)}{k_0\tau}\,e^{-t_0/\tau_*}\right\}}{e[(1-2x_0)D'/\bar{C}T-1]}$$

The value of $y$ obtained from this expression is indeed small enough when

$$x_0 < \frac{(2D'/5kT-1)}{\left[\dfrac{2D'}{5kT}\left(\dfrac{2}{e}+1\right)-\dfrac{3}{e}\right]2}$$

In the allowed range of $D'/kT$, this particular value of $x_0$ ranges between 0.212 and 0.288. In obtaining this estimate we assumed that vibrational relaxation contributes little to the position of the maximum. The results of Fig. 2*c* are well predicted by eq. [29] in the mole fraction range < 0.3. Most experiments would in fact be carried out under such conditions. Nevertheless at higher mole fractions where

$$2x_0k_0\tau\, e^{-k_0\tau y} \gg e^{-y} \approx 0$$

eq. [28] reduces to

$$[30] \quad e^{k_0\tau y} \approx 2x_0D'/(D'-\bar{C}T)$$

Under the usual laboratory conditions of $k_0\tau < 0.1$, the dissociation rate constant is roughly within one tenth of its maximum value ($T = \infty$). Thus $D'/kT \gtrsim 2.3$. Actually, a maximum exists only if $D' \gtrsim 5kT$. Furthermore, if $\bar{C}T \ll D'$ then $k_0\tau \ll 1$ and eq. [30] approaches our rough estimate of $y \simeq -\ln k_0\tau$ very closely. Equation [30] overestimates the actual position of the maximum in Fig. 2*c* by factors ranging up to 4. Under these extreme conditions our approximation that the temperature is roughly constant and $T_0 \simeq T_2 \simeq T_1 \simeq T$ breaks down seriously. For such cases numerical simulation of the experiment is necessary.

We are now in a position to evaluate the second criterion for the existence of extrema, namely $t_{min} < t_{max}$, particularly for $x_0 \lesssim 0.3$. Use of eqs. [26] and [29] lead to

$$\frac{t_{min}}{\tau} = \begin{cases} \dfrac{t_0}{\tau}, & \text{if } \dfrac{\eta(1-T_0/T_1)\,e^{-t_0/\tau}}{k_0\tau} < \dfrac{(25/4-x_0^2)}{5/2+x_0(1+\eta)} \quad [31a] \\ \left(\dfrac{\bar{\mathbb{C}}}{\bar{C}-\bar{\mathbb{C}}}\right)\ln\left\{\dfrac{\dfrac{\bar{C}_v\bar{C}}{\bar{\mathbb{C}}^2}(T_1-T_0)\,e^{-t_0/\tau}-k_0\tau\left(\dfrac{5kT\bar{C}/\bar{\mathbb{C}}-D'}{\bar{C}-\bar{\mathbb{C}}}\right)}{-k_0\tau\left(\dfrac{5kT-D'}{\bar{C}-\bar{\mathbb{C}}}+T\right)}\right\}+\dfrac{t_0}{\tau}, \\ \quad \text{if } \dfrac{(25/4-x_0^2)}{5/2+x_0(1+\eta)} < \dfrac{\eta(1-T_0/T_1)\,e^{-t_0/\tau}}{k_0\tau} < \left(\dfrac{4D'}{5kT}-3\right)(5/2+x_0) \quad [31b] \end{cases}$$

There are no extrema if

$$\eta\frac{(1-T_0/T_1)\,e^{-t_0/\tau}}{k_0\tau} > \left(\frac{4D'}{5kT}-3\right)(5/2+x_0)$$

The value of $(\eta/k_0\tau)(1-T_0/T_1)e^{-t_0/\tau}$ is indicative of the extent to which vibrational relaxation has proceeded by the time dissociation has effectively begun.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

In interpreting the extrema for a particular experiment it is worth noting that the position of the minimum is very sensitive to the value of $t_0/\tau$. $t_0/\tau$ also affects the position of the maximum; but the maximum is relatively broad and harder to locate. Thus the following procedure is suggested: Identify $t_0$ with $t_{min}$ and check the condition in eq. [31*a*]. If satisfied, then $t_0 = t_{min}$; if not, then $t_0$ is determined from eq. [31*b*] using precise measurements of $t_{min}$, $\tau$, and $k_0$ from the same experiment. Alternatively, if the maximum is well defined and if $x_0 < 0.3$, then $t_0/\tau$ can be determined by solving eq. [29] noting that $y = (t_{max}/\tau - t_0/\tau - 1)$. Furthermore, when conditions permit $t_{min} = t_0$, then $y = (t_{max} - t_{min})/\tau - 1$, and a measure of $(t_{max} - t_{min})$ will give $y$ directly, from which $t_0/\tau$ can be extracted using eq. [29]. This is sometimes preferable to using the simple expression $t_{inc} = t_{min} + \tau$ in cases where an *absolute* measure of $t_{min}$ is less accurate than that of $(t_{max} - t_{min})$ (i.e. when technical difficulties of the shock tube method near the time origin prevail). Nevertheless, as will be discussed below, interpretation of the maximum presents some problems, and use of $t_{inc} = t_{min} + \tau$ may yet lead to the most reliable measurements of incubation times.

## Discussion

The phenomena described above have actually been observed in shock tube dissociations of $H_2$ and $O_2$, although they have been attributed to other effects. Breshears *et al.* (BBK) have observed a curious "dip" in their densitometric studies (10) and gave the plausible explanation that catalytic dissociation by atoms was responsible for the sudden increase in $dF/dt$. The conditions of those experiments were exactly those necessary to observe incubation phenomena (12), and the form of the dip is exactly as predicted by Fig. 2. Nevertheless BBK assumed that at the minimum

$$k_0 = x_0(1 - \alpha)k_{AB-AB} + (1 - x_0)k_{M-AB}$$

and that at the maximum

$$k_0 = x_0(1 - \alpha)k_{AB-AB} + (1 - x_0)k_{M-AB} + x_0\alpha k_{A-AB} + x_0\alpha k_{B-AB}$$

where $k_{i-AB}$ is the quasi-first order rate coefficient for dissociation of AB by i, and where M is the inert-collider. Furthermore, it was supposed that at the minimum, relaxation was essentially complete ($k_0 \ll 1/\tau$) and that $k_d = k_0$. Under such conditions, our analysis, starting with eq. [17], could be repeated setting $\varepsilon = \varepsilon_T$; or alternatively eq. [27] with $\tau \to 0$, $t_0 \to 0$ could be used directly, and one would obtain

$$[32] \qquad \frac{dF}{dt} = -\frac{k_0 x_0 D'}{\bar{C}}(1 - \alpha)\left[1 - \frac{\bar{C}T}{D'(1 + \alpha x_0)}\right]$$

which is essentially the expression used by BBK with $\alpha = 0$ at the minimum. The maximum is supposed to occur because $k_0$ might increase faster than $(1 - \alpha)$ decreases. To simplify the discussion we make A = B, or at least $k_{A-AB} = k_{B-AB}$, i.e. the efficiencies of the two atoms in dissociating AB are similar. The maximum $\alpha_m$ is found by setting the derivative of $k_0(1 - \alpha)$ to zero. The result is

$$[33] \qquad 2\alpha_m x_0 = \frac{(1 - x_0)\phi_M + 2x_0(1 - \phi)}{1 - 2\phi}$$

where $\phi_M = k_{M-AB}/k_{AB-AB}$ is the relative efficiency of M:AB, and $\phi = k_{A-AB}/k_{AB-AB}$ is that of A:AB. A realistic solution ($0 < \alpha_m < 1$) occurs only if $\phi > 1 + (1 - x_0)\phi_M/2x_0$. BBK found $\phi_M \approx 0.1$ and $\phi \approx 6$; thus a maximum is indeed possible. However, the value of $\alpha_m$ lies in the range 0.37 to 0.45 for the mole fraction range 0.05 to 1.0, i.e. the reaction is almost half over by the time $t = t_{max}$: in other words the maximum caused by the incubation phenomenon has long passed before atom catalysis becomes important. Had $\alpha_m$ been less than that predicted by the incubation phenomenon's analysis: ($\alpha \ll 0.13$) one could say for certain that atom catalysis data could be extracted, although a modified procedure (see below) would have to be followed. However, in the present situation one is left with some doubt: either the maximum is due to an increase in $k_0$ because of $\phi$, $\phi_M$ or else it is due to transient phenomena in the dissociation of AB. In the former case the transient phenomenon occurs as well, but the possibility exists that it is unobserved and hidden in the shock front. However, our analysis showed that unless

$$\eta(1 - T_0/T_1)\, e^{-t_0/\tau} > (4D'/5kT - 3)(5/2 + x_0)k_0\tau$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

For personal use only.

and $D'/kT \lesssim (5 + x_0\eta)$, the transient phenomena *will* manifest themselves as local minima if both the relaxation zone and the dissociation zone are evident in the same experiment. The actual position of the minimum[1] determined by BBK was $t_{min}/\tau = 3.22$ (for a 10% $O_2$ mixture in argon at 5811 K) and 3.20 (for a 10% $O_2$ mixture in Kr at 4942 K) (10*a*). The corresponding reported values of $k_0\tau$ were 0.021 and 0.012 respectively. Thus, under BBK's conditions $D'/kT_e$ were 10.72 and 12.51 respectively, while $t_0/\tau$ were 3.22 and 2.98 respectively. The necessary criteria are satisfied, and we therefore believe that at least some of BBK's experiments are excellent for determining incubation times, but not necessarily $k_0$.

In order to evaluate the BBK data it is convenient to first obtain an expression for $dF/dt$ at the extrema, i.e. for $(1 + \alpha x_0)dT/dt + x_0 T k_d(1 - \alpha)$.

At $t = t_{min}$, $\alpha \simeq 0$. Substituting $t_{min} = t_0$ (eq. [31*a*]) into

$$k_d = k_0[1 - \exp(-[t_{min} - t_0]/\tau)]$$

we obtain

$$[34a] \quad \left|\frac{dF}{dt}\right|_{min} = \frac{-x_0\bar{C}_v(T_1 - T_0)\, e^{-t_0/\tau_*}}{\bar{\mathcal{C}}\tau} \quad \text{for case } (a)$$

For the other possibility in eq. [31*b*] we note that the argument of the logarithm is $\sim 1$. Thus to a very good approximation

$$\frac{t_{min}}{\tau} \simeq \frac{t_0}{\tau} + \frac{\bar{C}/\bar{\mathcal{C}}}{D'/kT - (5 + x_0\eta)}\left[\frac{\eta(1 - T_0/T_1)\, e^{-t_0/\tau}}{k_0\tau} - \frac{(25/4 - x_0^2)}{5/2 + x_0(1 + \eta)}\right]$$

Using eq. [23] for $dT/dt$ and eq. [31*b*] to simplify:

$$\left|\frac{dF}{dt}\right|_{min} = x_0 k_0 T\left\{\left(\frac{D'}{\bar{C}T} - 1\right) - \left(\frac{D'/kT - [5 + x_0\eta]}{5/2 + x_0[1 + \eta]}\right) e^{-(t_{min} - t_0)/\tau}\right\}$$

where the above approximate expression for $(t_{min} - t_0)$ can be used. Evidently the further $(t_{min} - t_0)/\tau$ is from 0, the closer $dF/dt$ approaches a pure equilibrium dissociation value $x_0 k_0 T(D'/\bar{C}T - 1)$, and the less of an error is involved by assuming $|dF/dt|_{min}$ is a measure of $k_0$, but the less distinct the minimum becomes until the situation is reached when no extrema occur. However, if $t_{min}$ is not too different from $t_0$, then the exponential can be expanded to two terms, and thus

$$[34b] \quad \left|\frac{dF}{dt}\right|_{min} \simeq \frac{x_0\eta T}{(5/2 + x_0)\tau}\left\{(1 - T_0/T_1)\, e^{-t_0/\tau_*} - \frac{x_0 k_0\tau(5/2 - x_0)}{5/2 + x_0[1 + \eta]}\right\}$$

Secondly

$$k_d = k_0\,(1 - e^{-[t_{min} - t_0]/\tau}) \simeq k_0(t_{min} - t_0)/\tau$$

Therefore at the minimum, the effective rate coefficient is

$$k_d \approx \frac{\bar{C}/\bar{\mathcal{C}}}{D'/kT - (5 + x_0\eta)}\left[\frac{\eta(1 - T_0/T_1)\, e^{-t_0/\tau_*}}{\tau} - \frac{k_0(25/4 - x_0^2)}{5/2 + x_0(1 + \eta)}\right] \quad \text{for case } (b)$$

Setting $\alpha = 0$ in eq. [32] it is easy to see that if one did not suspect transient phenomena to be involved, one would deduce the measured rate coefficient by dividing the observable at the minimum by $[x_0 D'/\bar{C}] \times [1 - \bar{C}T/D']$. Therefore BBK measured $(\bar{C}/\bar{\mathcal{C}})\,(\eta/\tau)\,[kT/(D' - \bar{C}T)]\, e^{-t_0/\tau}$ in case (*a*) or approximately so in case (*b*) when $x_0 < 0.3$, i.e. BBK measured a value ranging somewhere between $k_d$ and $\sim\tau^{-1}\, e^{-t_0/\tau}$, but not $k_0$ as supposed! The question remains why those studies were apparently so successful in measuring not only rate coefficients, but also their temperature dependence and mole fraction dependence.

We note that case (*a*) ($t_{min} = t_0$) applies to most of the BBK experiments. For those few experiments to which case (*b*) applies the value of the observable at the minimum is not very far from the value at the maximum; i.e. the "dip" is not very distinct. Later it will be shown that the maximum is a good measure of $k_0$; thus Fig. 2*a* confirms that errors are <20% in such cases. Thus we restrict our discussion in the following to case (*a*) which is the more problematical situation.

It is clear that since a linear mixture rule was found to be obeyed, it is actually $\tau^{-1}\, e^{-t_0/\tau_*}$ that obeys

[1]There is some uncertainty in location of the absolute time origin of shock wave arrival, and the reported $t_{min}$ should be considered a lower limit.

this rule, and the observed relative efficiency $\phi_M$ is for relaxation and not for dissociation! Furthermore an estimate of $t_0/\tau$ can be made from theoretical studies of Dove and Troe (11), and of Forst and Penner (4). They both find (albeit strictly for polyatomic molecules at the low pressure limit) that $Z[M]t_{iyj} = -D/\langle\Delta\varepsilon\rangle$ roughly, where $\langle\Delta\varepsilon\rangle$ is the average energy transferred per collision, $Z$ is the collision frequency, and [M] is the gas concentration. If we use this expression to get an estimate of $t_{inc}$ for diatomic molecules, and use the fact that $\langle\Delta\varepsilon\rangle$ for the harmonic oscillator model is just $-h\nu p_{10}$ (13), where $Z[M]p_{10} = k_{10}$ for the transition $v = 1 \rightarrow 0$, then $k_{10}t_{inc} \approx D/h\nu$. Also $(k_{10} - k_{01}) = 1/\tau$. Thus $t_{inc}/\tau \approx (D/h\nu)(1 - e^{-h\nu/kT})$. At the temperatures of interest here $h\nu \ll kT$; thus $t_{inc}/\tau \simeq D/kT$; and it is therefore not surprising that the BBK measurement $\simeq (ekT/D'\tau)\, e^{-t_{inc}/\tau}$ would give roughly the correct temperature dependence! Using the values of $k_0\tau$, $t_0/\tau$, $D'/kT$ cited above, the measured $(\bar{C}/\bar{\mathbb{C}})(\eta/\tau)[kT/(D' - \bar{C}T)]\, e^{-t_0/\tau}$ is $0.24k_0$ at 5811 K, and $0.44k_0$ at 4942 K. The differences between the BBK results and the $k_0$'s reported by other workers, at least for $O_2$/Ar, are explicable in terms of these factors. We therefore believe that at least some of the BBK results are fortuitous. Similar considerations may apply to $H_2$ (10*b*).

The position of the BBK maximum ($t_{max}/\tau = 6.0$ at 5811 K and 5.7 at 4942 K) using the corrected BBK values for $k_0\tau$ are very well predicted from our eq. [29]. Since $(t_{max} - t_{inc})/\tau = -\ln(k_0\tau/a)$, $k_d = k_0(1 - k_0\tau/ae)$ at the maximum, where $a$ is given by the right hand side of eq. [29], and is of the order of unity. Also

$$\alpha = 1 - \exp[-k_0\tau_*(-\ln\{k_0\tau/a\} + k_0\tau/ae)] \simeq 1 - (k_0\tau/a)^{k_0\tau\bar{\mathbb{C}}/\bar{C}}$$

Thus

$$[35] \qquad \left|\frac{dF}{dt}\right|_{max} = \frac{k_0x_0D'}{\bar{C}}\left(\frac{k_0\tau}{a}\right)^{k_0\tau\bar{\mathbb{C}}/\bar{C}}\left\{1 - \frac{\bar{C}T}{D'(1+\alpha x_0)}\left[1 - \frac{1}{e}\left(\frac{k_0\tau}{a}\right)^{\bar{\mathbb{C}}/\bar{C}}\right] + \psi\right\}$$

where

$$\psi \approx k_0\tau\left[\frac{\bar{\mathbb{C}}}{\bar{C}} - \frac{\bar{C}}{\bar{\mathbb{C}}ae} - \frac{1}{ae}\left(1 - \frac{5kT}{D'}\frac{\bar{C}}{\bar{\mathbb{C}}}\right) + \frac{\bar{C}_v}{\bar{\mathbb{C}}}\left(\frac{\bar{C}T}{D'}\right)\frac{(1 - T_0/T_1)\, e^{-t_{inc}/\tau_*}}{a}\right] \ll 1$$

i.e.

$$\left|\frac{dF}{dt}\right|_{max} \simeq -\frac{k_0x_0D'}{\bar{C}}\left(\frac{k_0\tau}{a}\right)^{k_0\tau\bar{\mathbb{C}}/\bar{C}}\left\{1 - \frac{\bar{C}T}{D'(1+\alpha x_0)}\right\}$$

which is the same as eq. [32] with $\alpha$ evaluated at $t_{max}$. Since the rate coefficient is very close to $k_0$ at the maximum, we can consider $t_{max}$ to be the origin for dissociation with the value of the measured rate coefficient equal to an adjusted $k_0$, i.e., $k_0(k_0\tau/a)^{k_0\tau_*} \approx k_0$. Thereafter, one may analyze the measurements according to eq. [32]. Alternatively, one may consider the measured rate coefficient to be exactly $k_0$ only if one interprets the maximum as corresponding to a time slightly beyond the time origin for dissociation. This delay time $\Delta t$ is given by $1 - \alpha = (k_0\tau/a)^{k_0\tau_*}$, i.e., $e^{-k_0\Delta\tau} = (k_0\tau/a)^{k_0\tau_*}$, or $\Delta t/\tau_* = \ln(a/k_0\tau)$. Since $k_0\tau < 0.1$, very little error is induced by assuming an equilibrium dissociation process starting with time zero at the maximum. Unfortunately BBK did not use the maximum as a measure of the uncatalyzed $k_0$. They assumed that it is efficient atoms which are responsible for the relatively large observable at the maximum. With this assumption

$$k_0 = k_{AB-AB}[x_0(1 - \alpha) + (1 - x_0)\phi_M + 2x_0\alpha\phi]$$

where $\alpha$ (at $t_{max}$) is supposedly given by eq. [33]. Then at $t_{max}$

$$k_{max} = k_{AB-AB}[x_0\phi + (1 - x_0)\phi_M/2]$$

and the corresponding observable is $(k_{AB-AB}x_0D'/\bar{C})\,[x_0\phi + (1 - x_0)\phi_M/2]^2/(1 - 2\phi)x_0$. For small inert species' efficiencies ($\phi_M \ll 1$, as observed), the expression becomes $(k_{AB-AB}x_0^2D'/\bar{C})\phi^2/(1 - 2\phi)$, as long as $x_0$ is not too small. Evidently the quantity $\phi^2/(1 - 2\phi)$ can be estimated by dividing the maximum observable by $k_{AB-AB}x_0^2D'/\bar{C}$ which is determined from the minimum. The minimum is supposedly $\approx (k_{AB-AB}x_0D'/\bar{C})\,[x_0 + (1 - x_0)\phi_M]$, but in actual fact this expression closely approximates the true value at the maximum, whereas $(dF/dt)_{min}$ is given in reality by eq. [34]. Thus BBK measured

$$\left(\frac{\bar{\mathbb{C}}}{\bar{C}}\right)(k_0\tau/\eta)\frac{(D' - \bar{C}T)}{kT}e^{t_0/\tau}[x_0 + (1 - x_0)\phi_M]/x_0$$

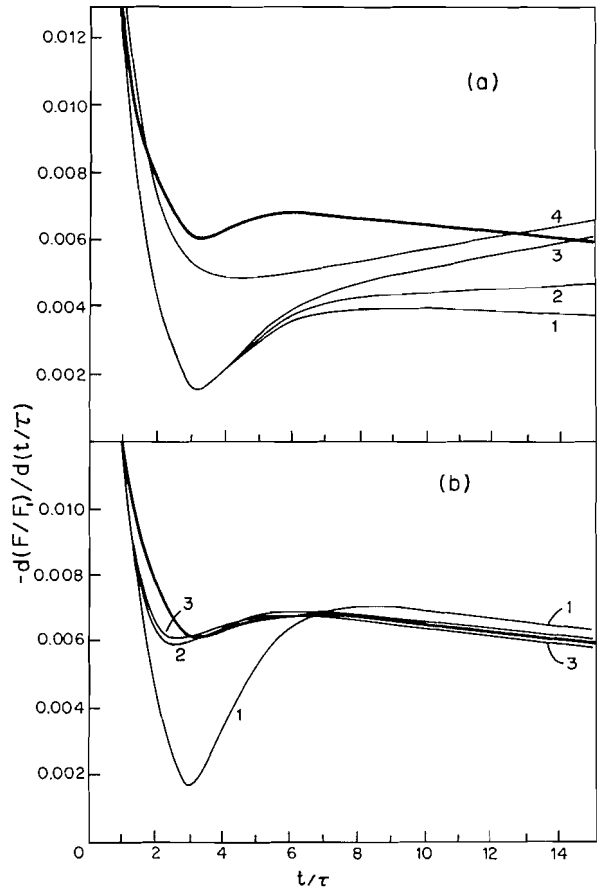

FIG. 3. Normalized density gradient as a function of reduced time for 10% $O_2$ in $K_r$ at 4942 K (= $T_e$). Thick lines are experimental results from Fig. 4 of ref. 10*a*, which has been converted from $d(\rho/\rho_0)/d(P\tau)$ to $-d(F/F_1)/d(t/\tau) = -d(F/T_1)/d(t/\tau)$ by multiplying by $P\tau/(\rho_1/\rho_0)$ under the approximation that $d\rho/\rho \simeq -dF/F$ (good to within 5% here). The gradient components due to vibrational relaxation match perfectly in scale, indicating a common time origin. $D/kT_1 = 11.6$. (*a*) Calculations with $k_0\tau = 0.012$ (as determined in ref. 10*a*) do not reproduce the dissociation portion of the gradient for any value of $t_0/\tau$ or $\phi$. Curve *1*: $t_0/\tau = 2.98$, $\phi = 0.5$ reproduces $t_{min}$, but the magnitude of the gradient and its subsequent decay rate are too small. Curves *1*, *2*, *3* show the effect of $\phi$. Curve *1*: $\phi = 0.5$; curve *2*: $\phi = 2.5$; curve *3*: $\phi = 5.0$. The maximum gradient is reproduced for $\phi = 4.5$, but $t_{max}$ is too large (28.0). Decreasing $t_0/\tau$ to 0 (curve *4*) does not decrease $t_{max}$ significantly. (*b*) Fit to experimental data using $k_0\tau \simeq 0.022$. Curve *1*: $\phi = 0.5$, $t_0/\tau = 2.98$, $k_0\tau = 0.022$. The maximum gradient and subsequent decay are reproduced exactly. Curve *2*: $\phi = 0.5$, $k_0\tau = 0.0213$, $t_0/\tau = 1.30$ additionally reproduces $t_{max}$ and the minimum gradient. Best fit (curve *3*) occurs for $t_0/\tau = 1.25$, $k_0\tau = 0.0217$, and $\phi$ in the range 0.05 to 0.55. Shown is $\phi = 0.05$. Thus the incubation time = 2.25 $\tau$.

For the conditions of ref. 10*a* (Figs. 3 and 4), this is 9.8 at 5811 K and 6.4 at 4942 K; and one inevitably extracts a large value for the relative atom efficiency regardless of what it really may be. (In Fig. 3 we estimate $\phi$ to be $0.30 \pm 0.25$ for one example.)

In summary, we have shown that the BBK experiments should not be interpreted in terms of atom catalysis, but rather in terms of non-equilibrium dissociation effects. It appears nevertheless that all the BBK results are fortuitously correct within a factor of 4. In view of the statement (10*b*) that had the maximum been used instead of the minimum in order to determine $k_{AB-AB}$ little change would have resulted, our conclusion is confirmed. Yet, it is not clear what the temperature and mole fraction dependence would be under those circumstances, nor at all clear what the atom efficiencies really are as a function of temperature.

In general when atom efficiencies play a role, the observed density gradient consists of a local minimum followed by an increase on a time scale $\sim\tau$ due to non-equilibrium effects. On a much longer time scale, the gradient would rise due to atom catalysis and then fall as the parent molecule disappears. Under rare circumstances with $k_0\tau \rightarrow 1$, atom catalysis might play a role in determining an early maximum.

This would necessitate reanalyzing the problem by replacing $k_0$ with $k_0\{1 + x_0\alpha(2\phi - 1)/[x_0 + (1 - x_0)\phi_M]\}$ which is a weak function of $\alpha$. Figure 3 shows $dF/dt$ obtained by solving eq. [21] with these changes for one example. Under the usual circumstances ($k_0\tau < 0.1$) $\phi$ has the effect of pushing the maximum out to times rather late in the dissociation. Although $\phi$ as large as 4.5 can predict the maximum gradient (using $k_0$ determined from the minimum gradient) $t_{max}$ is unsatisfactory (Fig. 3*a*). On the other hand, excellent agreement with experiment is obtained when the rate of dissociation is increased by almost doubling the uncatalyzed $k_0$, as suggested above, rather than introducing an unnecessarily large $\phi$. Even better agreement would result if the Forst function could be improved. Note, however, that a full analysis of such experiments is best done when the flow variables are included in the modelling.

Generally, if $\phi$ is smaller than the critical value, $[1 + (1 - x_0)\phi_M/2x_0]$, as it may be in the BBK studies, then a single early maximum appears which is interpreted entirely by non-equilibrium effects. Interpretation in terms of atom catalysis can lead to errors depending on the experimental conditions. Dissociation at the full equilibrium rate may be thought of as starting at a point in time just prior to the maximum. The value of the density gradient at the maximum leads to a very good estimate of initial dissociation rates. The location of the minimum and maximum are excellent measures of the incubation time for dissociation. The minimum in particular is valuable for this purpose because $t_{min} \simeq t_0$ even when atom catalysis is important, since it locates the point in time when the first molecules dissociate regardless of what species cause them to dissociate.

## Conclusion

We have used the truncated harmonic oscillator model to derive a rate law for the vibrational energy of a set of dissociating molecules. It shows that great care is needed when using the Bethe–Teller law as an approximation especially at high temperatures. Non-equilibrium effects such as the depletion of vibrational level populations cause overshoots of the vibrational energy, which does not reach its thermodynamically prescribed value. The resulting incubation time leads to measurable transient phenomena.

We have made a variety of approximations in order to show the relationship between observed local extrema and incubation times in dissociation experiments. The cumulative effect of all the approximations can be determined by comparing our analytical expressions [29] and [31] with the values of $t_{min}$ and $t_{max}$ in Fig. 2. In general the agreement is better than 5% for $x_0 < 0.3$. One can extend the range by solving the more exact transcendental equations [25] and [28] and by allowing the temperature to vary by more than a modest 10%. Further improvements to our analytical expressions require the inclusion of atom efficiencies and temperature-dependent $k_0$, $\tau$, $\eta$, $\bar{C}$, and $t_{inc}$. The use of the Forst function, valid only for $t > t_0$, introduced a discontinuity into our analysis. An improved function would smooth out Figs. 2 and 3 in the region of the minimum.

Although our analysis presents all possible values of the six parameters some are actually redundant: a given temperature automatically fixes $\eta$, $k_0$, $\tau$, $D/kT$, and $t_{inc}$ for a given molecule. Further advances in the theory of non-equilibrium dissociation of diatomic molecules should link the rate parameters and permit us *a priori* to evaluate the magnitude of the critical parameter $(\eta/k_0\tau)\, e^{-t_0/\tau}$ which determines whether a local minimum will appear in a given experiment or not. Work in this direction is now in progress. Whereas the present study indicates that the BBK experiments should be interpreted in terms of non-equilibrium kinetics, a definitive statement may have to await such theoretical advances. It is because of uncertainty concerning the participation of atoms in the dissociation that in the absence of theoretical advances one should use the local minimum (rather than the maximum) as a measure of incubation times, and the post-maximum rate of gradient decrease as a measure of the dissociation rate constant.

One major assumption explicitly made was that the molecular vibration in question could be treated as a harmonic oscillation. Clearly, molecules which dissociate cannot be well-described as harmonic oscillators. However, it must be emphasized that the present model is not used to calculate $k_0$, $\tau$, or $t_{inc}$ which are considered here to be experimentally determined. It is used to obtain an appropriate rate law for the relaxation of vibrational energy (eq. [12]) which *can* be well described in terms of harmonic oscillators. Modest corrections to the Bethe–Teller law account in a reasonable way for non-equilibrium effects. It may be argued that it is exactly these deviations which account for the whole experimental phenomena, and that it is therefore important that these deviations be treated accurately. Yet it is clear that no improvement in the relaxation model will change the conclusion that a local minimum occurs

roughly when dissociation precipitously begins, nor the conclusion that it is unwise to measure relaxation times even under relatively mild conditions such as $k_0\tau = 10^{-5}$ without accounting for the distortion to the equilibrium vibrational energy. Further work, now in progress, will determine the effect of anharmonicity.

Finally, the analysis presented here can be extended to include polyatomic molecules using the appropriate heat capacities and provided that the relaxation mechanism is known.

Utilisant plusieurs conditions différentes de culture en solution basique, on a étudié la transformation de deux dihydrofusarubines diastéréoisomères 4a,10a, produites par la *Fusarium solani* en fusarubine, en nojavanicine et en un nouveau composé la (*E*) dihydro-6,7 dihydroxy-5,8 méthoxy-2 méthylène-6 (oxo-2 propylidène)-7 naphtalènedione-1,4) isofusarubine. On a déterminé les activités antibiotique et phototoxique de ces composés et on a établi les structures des mono et diacétates de l'isofusarubine et de l'anhydroisofusarubine en faisant appel à la rmn du $^1H$ et du $^{13}C$.

[Traduit par le journal]

## Introduction

We have recently reported (1) that fusarubin **2** (2–8) is formed by nonenzymic oxidation of the diastereoisomeric 4a,10a-dihydrofusarubins **1***a* and **1***b* in alkaline cultures of *Fusarium solani*. Fusarubin has been dehydrated to anhydrofusarubin **3** by heating in glacial acetic acid (9); hydration of **3** under acidic conditions (4), or on standing in contact with the atmosphere (9), yielded **2**. The related metabolites javanicin **4** (2, 3), norjavanicin **5** (9), and bostrycoidin **6** (10) have also been obtained from *Fusarium* species. In this communication we report the isolation and structure of a new antibiotic and phototoxic compound **7** which was obtained from **1** by alkaline oxidation and to which we have given the trivial name isofusarubin. We provide evidence that **5** is also formed by nonenzymic oxidation of **1** in alkaline solutions and cultures.

## Materials and methods

*Organisms*

*Fusarium solani* strain 199 was obtained from Professor P. E. Nelson, Department of Plant Physiology, Pennsylvania State University, University Park, PA 16802, U.S.A.

*Culture medium*

One litre of medium had the following composition: maltose, 20–60 g; ammonium tartrate, 4.6–9.2 g; $KH_2PO_4$, 1 g; $MgSO_4 \cdot 7H_2O$, 0.5 g; NaCl, 0.1 g; $CaCl_2$, 0.1 g; $FeSO_4 \cdot 7H_2O$, 0.01 g; $ZnSO_4 \cdot 7H_2O$, 8.8 mg; $CuSO_4 \cdot 5H_2O$, 0.4 mg; $MnSO_4$, 0.06 mg; $H_3BO_3$, 0.06 mg; $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, 0.04 mg.

*Cultivation*

Spores from cultures grown on potato-dextrose agar for 2 weeks at 25°C were suspended in sterile distilled water and filtered through a cotton plug. The optical density of the filtrate at 640 nm was adjusted to 0.25. Each 50 mL aliquot of culture medium in a 250 mL Erlenmeyer flask was inoculated with 2.5 mL of the spore suspension and then incubated at 25°C on a rotary shaker (3.8 cm eccentricity, 220 rpm) for 2 to 6 days.

*Isolation of metabolites*

The mycelium was removed by filtration and washed with water until free of pigment. The filtrate, adjusted to about pH 3 with 1 *N* HCl, was extracted with an equal volume of ethyl acetate. The extract was washed with water, concentrated *in vacuo*, and chromatographed on a column of silicic acid using benzene – ethyl acetate mixtures for elution. Compound **3** was eluted with a 12:1, **4**, **5**, and **6** with a 6:1, **1***a* and **2** with a 3:1, and **1***b* with a 2:1 mixture. The physical constants as well as the ir, uv, and $^1H$ nmr spectral data of these compounds were indistinguishable from those reported in the literature (1, 9, 10, 11).

*Alkaline oxidation of* **1**a *and* **1**b

In preliminary experiments solutions of **1***a* and **1***b* in 0.1 *N* NaOH were sampled periodically and the formation of products was monitored by tlc. This established the following optimum conditions for producing **7**. Samples of **1***a* (708 mg) and **1***b*

7 $R_1 = R_2 = H$; $R_3 = H_1, CH_2OH$
8 $R_1 = COCH_3$; $R_2 = H$; $R_3 = CH_2$
9 $R_1 = R_2 = COCH_3$; $R_3 = CH_2$

(168 mg) dissolved in 100 and 25 mL, respectively, of 0.1 *N* NaOH were aerated by stirring for 5 minutes at room temperature. After acidification with 0.2 *N* HCl the solutions were extracted with ethyl acetate. The extracts were washed with water, concentrated *in vacuo*, and chromatographed on columns of silicic acid. Reaction products **2** and **5** were eluted with the benzene – ethyl acetate mixtures already described above, whereas a 3:2 mixture gave isofusarubin **7**, mp 157–158°C (dark red prisms from ethanol); $[\alpha]_D^{20}$ +224 (*c* 0.051, acetone); $\lambda_{max}$ (95% ethanol): 224, 296, 475, 500, and 536 nm (log ε: 4.41, 3.93, 3.83, 3.85, and 3.64); $\nu_{max}$ (KBr): 3485, 3400, 1708, and 1595 $cm^{-1}$; $M^+$ at *m/e* 306.0752 (calcd. for $C_{15}H_{14}O_7$ 306.07396).

Acetylation of **7** with acetic anhydride in pyridine for 3 h at room temperature, and evaporation under reduced pressure, gave a brown gummy residue. Preparative tlc of this material on 2 mm thick Merck silica gel F254 precoated plates using ethyl acetate as developer gave a major band which on extraction with $CHCl_3$ gave anhydroisofusarubin monoacetate **8** in 47% yield, mp 168–172°C (bright yellow rosettes from ethyl acetate – petroleum ether or ethanol); $\nu_{max}$ (KBr): 3450, 1770, 1685, 1644, and 1613 $cm^{-1}$; $M^+$ at *m/e* 330.0725 (calcd. for $C_{17}H_{14}O_7$: 330.07396). In contrast, direct extraction of the gummy residue with $CHCl_3$ gave anhydroisofusarubin diacetate **9** in 80% yield, mp 133–134°C (yellow needles from 3:1 $CHCl_3$–hexane); $\lambda_{max}$ (95% ethanol): 220 and 226 nm (log ε: 4.37 and 4.36); $\nu_{max}$ (KBr): 1760 and 1618 $cm^{-1}$; $M^+$ at *m/e* 372.

*Nuclear magnetic resonance spectra*

Spectra were recorded in $CDCl_3$ solution (5 mm tubes) with TMS as internal reference. The $^1H$ nmr spectra of **7** and **9** at 100 MHz were obtained on a Varian HA-100D continuous-wave spectrometer, using the TMS signal for internal lock. The $^{13}C$ nmr spectra of **7** and **9** were recorded at 25.16 MHz with a Varian XL-100/15 Fourier transform spectrometer under the following conditions: sweep width (SW) 6016 Hz, acquisition time (AT) 1.6 s (data accuracy ±0.3 Hz), flip angle (FA) 35°, internal $^2H$ lock to solvent, temperature 29°C, $^1H$ irradiation at 100 MHz, (a) $\gamma H_2/2\pi \sim 3800$ Hz, broadband by 0 to 180° phase modulation at 150 Hz, or (b), as for (a), but irradiating only for 1.6 s between data acquisition periods to provide high resolution (HR) spectra with retained nOe.

The $^1H$ (80 MHz) and $^{13}C$ (20 MHz) nmr spectra of **7** and **8** were recorded on a Varian FT-80A spectrometer with internal $^2H$ lock to the solvent and a temperature of 35°C. Conditions for the $^1H$ spectra were SW 1000 Hz, AT 4.1 s (data accuracy ±0.1 Hz), FA 90°. The solution of **8** was degassed prior to nOe measurements. The $^{13}C$ spectra were acquired with SW 4132 Hz (**8**), 4505 Hz (**7**), AT 0.99, 0.91 or 1.98, 1.82 (data accuracy ±0.5 or ±0.3 Hz), FA 23° or 45°, $^1H$ irradiation at 80 Hz, (a) $\gamma H_2/2\pi \sim$ 4000 Hz, modulation bandwidth 2000 Hz (broadband decoupling), (b) as for (a) but irradiating for 2.0 s between data acquisitions only to retain nOe (HR spectra), and (c) as for (b) but with additional constant $^1H$ irradiation $\gamma H_2/2\pi$ 196 Hz at frequencies of individual $^1H$ resonances (single frequency decoupling with nOe retained at all resonances).

*Biological activity*

The method of Daniels (12) was used for the general assays with bacteria and yeasts, as described previously (13, 14). Duplicate cultures were incubated overnight after the discs containing 20 μg of compound were placed on them.

## Results

### *Production of 2, 5, and 7 from 1a and 1b*

Monitoring the reactions by tlc indicated that conversion of **1***a* and **1***b* to **2**, **5**, and **7** in 0.1 *N* NaOH at room temperature began immediately and

TABLE 1. Yields of **2**, **5**, and **7** produced from dihydrofusarubin in alkaline solution*

| | **1***a* | | **1***b* | |
|---|---|---|---|---|
| Compound | mg | % | mg | % |
| **2** | 331 | 46.8 | 89 | 53.0 |
| **5** | 70 | 9.8 | 47 | 28.6 |
| **7** | 274 | 38.7 | 21 | 12.5 |
| Total | 675 | 95.3 | 158 | 94.0 |

*Samples of **1***a* (708 mg) and **1***b* (168 mg) were dissolved in 0.1 *N* NaOH and the stirred solutions kept at room temperature for 5 min. Products were isolated as described in Materials and methods and crystallized once. Yields were calculated as a percentage by weight of the starting material. Value for **2** has been corrected for small amount of **3** produced during purification process.

*Spectra were recorded (Varian HA-100-D (**7**, **9**) and FT-80A (**8**) spectrometers) in $C^2HCl_3$ with TMS as internal standard.
†H-12(t), H-12(g), and H-6 formed an ABC system in **7** (t = trans, g = gauche). Analysis of the system, with the Varian spin simulation program on a 620L computer, gave $J_{AB}$ 11.0, $J_{AC}$ 7.0, $J_{BC}$ 4.5 Hz. Signals for 5, 8, and 12-OH disappeared on addition of $^2H_2O$.
‡Signal for 8-OH in **8** disappeared on addition of $^2H_2O$ and that for H-9 (d, $^5J \sim 0.4$ Hz) became a singlet. The following nuclear Overhauser enhancements were observed (irradiated proton in parentheses): H-12, δ6.03 (H-12, δ6.32) 16%; H-3, H-9 (H-12, δ6.32) 0%; H-12's, H-3 (H-9) 0%.

was complete after 5 minutes. Yields at this time are given in Table 1. Over a 30 minute period **7** changed into many unidentified compounds and finally disappeared, whereas **5** was gradually degraded over 24 hours. On the other hand, **2** was relatively stable, with only a small amount being dehydrated to **3** over a 24 hour period.

*Production of* 1a, *1*b, *2, 4, 5, and 6 in cultures of* F. solani

Only **1***a*, **1***b*, and **4** were produced when the culture medium was rich in maltose (40 $gL^{-1}$ or above), irrespective of the ammonium tartrate concentration used (4.6–9.2 $gL^{-1}$). When maltose and ammonium tartrate were both low (20 and 4.6 $gL^{-1}$, respectively), **1***a*, **1***b*, and **4** could be isolated from a 2 day harvest and **2**, **4**, and **5** after 6 days. The production of metabolites was strongly inhibited when the medium was low in maltose (20 $gL^{-1}$) and high in ammonium tartrate (6.9–9.2 $gL^{-1}$), although some **2**, **4**, and **6** could be isolated after a 2 day interval.

*Antibiotic and phototoxic activities*

The results for **1***a* and **1***b*, their alkaline oxidation products, and related compounds isolated from *F. solani* are reported in Table 2. Compounds with phototoxic activity inhibit growth on exposure to uv irradiation only, whereas antibiotic activity is indicated if growth is inhibited in the dark also. The bioassay for **6** is incomplete because of lack of material.

## Discussion

*Structures of 7, 8, and 9*

The molecular formula $C_{15}H_{14}O_7$ obtained for **7** by accurate mass measurement is the same as that of **2** and the mass fragmentation patterns for the two compounds were similar. Thus **7** is formed, like **2** (1), by an autoxidation process involving the removal of a pair of hydrogens from **1***a* and **1***b*, the molecular skeleton probably remaining intact. Mass spectral measurements also indicated molecular formulae of $C_{17}H_{14}O_7$ for **8** and $C_{19}H_{16}O_8$ for **9**.

The characteristic singlet resonances obtained for methoxyl and quinone hydrogens in the $^1$H nmr spectra of **2**, **3** (9), and **4** (11) are also observed in the $^1$H nmr spectra of **7**, **8**, and **9** (see Table 3), suggesting that these three compounds contain the same substituted quinone ring system. Signals were present in the spectrum of **7** for an alcoholic and two phenolic hydroxyl hydrogens (chemical shifts temperature dependent and hydrogens exchangeable with deuterium), methyl hydrogens, an olefinic or aromatic hydrogen (δ 7.19), and hydroxymethyl hydrogens which are vicinally coupled to an aliphatic methine hydrogen. It was noteworthy

that the resonances for the aliphatic methine hydrogens of **1***a* and **1***b* were absent from the spectrum of **7**.

Conversion of **7** to **8** and **9** resulted in one (**8**) or both (**9**) of the phenolic hydroxyl resonances in the $^1$H nmr spectrum being replaced by signals for acetoxyl methyl groups. Furthermore, the hydroxymethyl and aliphatic methine signals were absent from the spectra of **8** and **9**, singlet resonances for two olefinic hydrogens being observed instead. Nuclear Overhauser measurements (see footnote to Table 3) combined with the absence of an observable coupling (15) indicated that these olefinic hydrogens were geminal. Thus elimination of a molecule of water at C-6 and C-12 and acetylation of the phenolic hydroxyl groups appeared to be the only structural changes that had occurred during the formation of **8** and **9** from **7**. The phenolic hydrogen of **8** was long-range coupled to the unsaturated methine hydrogen designated H-9 and the coupling was removed when the hydroxyl hydrogen was exchanged for deuterium. This evidence suggests that the phenolic hydroxyl and unsaturated methine groups are on adjacent carbons.

Structures for **7**, **8**, and **9** were finally confirmed by $^{13}$C nmr studies including single $^1$H frequency decoupling experiments to correlate the $^1$H and $^{13}$C resonances.

The $^{13}$C chemical shifts for **7**, **8**, and **9** (Table 4) were, in some respects, reminiscent of our previously reported (16) and rigorously assigned data for anhydrofusarubin and its diacetate derivative, which possess 5,8-dihydroxy-2-methoxy-1,4-naphthalenedione ring systems. The close agreement between chemical shifts of corresponding carbons in these compounds is strong evidence for the presence of a structural fragment containing the quinone ring system plus C-5 and C-8 depicted in structures **7**, **8**, and **9**. Deuterium isotope chemical shifts in the spectrum of **7**-$d_3$ and one, two, and three bond $^{13}$C—H coupling data for **7**, **8**, and **9** provide further evidence for this fragment. The signs and magnitudes of the isotope chemical shifts for C-1 ($\Delta\delta_{2H}$ +0.09), C-4 ($\Delta\delta_{2H}$ +0.14), C-5 ($\Delta\delta_{2H}$ −0.40), and C-8 ($\Delta\delta_{2H}$ −0.40) indicated that the carbonyl and phenolic carbinol carbons were geminal[4] in **7** and therefore in **8** and **9**. Also H-3 was coupled to C-1, C-2, and C-3 in all three compounds and also to C-4 and C-4a of **8** and **9**, 5-OH was coupled to C-5 of **7**, and 8-OH to C-8 and C-8a of **7** and **8**. Thus the combined evidence for the common structural unit in **7**, **8**, and **9** is overwhelming and at the same time places the acetoxyl group in **8** at C-5.

Chemical shift considerations and multiplicities due to characteristic one bond $^{13}$C—H couplings indicated that the remaining resonances in the spectrum of **7** arose from the methyl (C-11) and carbonyl (C-10) carbons of an acetyl group, quaternary olefinic (C-7) and olefinic methine (C-9) carbons (which have to be adjacent from structural considerations), and the carbons of hydroxymethyl (C-12) and aliphatic methine (C-5) groups which also have to be adjacent on the basis of the $^1$H nmr evidence and the two bond coupling of H-6 to C-12. In addition, H-9 was two bond coupled to C-10 and three bond coupled to C-8, H-11 was two bond coupled to C-10, H-6 was three bond coupled to both C-9 and C-8, and H-12 was three bond coupled to C-5 (17). These observations established the molecular relationships depicted in structure **7**, except for the geometry of the C-7,C-9 double bond. Isotope chemical shifts in the spectrum of **7**-$d_3$ provided information on the latter. The sign of the isotope chemical shift for C-10 ($\Delta\delta_{2H}$ +0.17) indicates that this carbonyl group is hydrogen bonded to a hydroxyl group,[4] which must be 12-OH because the two phenolic hydroxyl groups are already known to be similarly bonded to the quinone carbonyl groups. This indicates that the C-7,C-9 double bond has an *E*-configuration. Molecular model studies also suggest that a *Z*-configuration would be difficult to attain because of severe steric interactions, whereas the *E*-configuration provides ample opportunity for the formation of a hydrogen bond between the C-10 carbonyl group and 12-OH. The isotope chemical shifts of $\Delta\delta_{2H}$ −0.20 observed for C-7 and C-9 are also consistent with the presence of a hydroxyl group at C-8 and hydrogen bonding of the C-10 carbonyl group to 12-OH although no attempt was made to determine their relative contributions.

From $^{13}$C chemical shift and $^{13}$C—H coupling considerations it was apparent that **8** and **9** had retained the $CH_3COCH{=}C\langle$ fragment present in **7** but that the hydroxymethyl and aliphatic methine groups had been replaced by a $\rangle C{=}CH_2$ group. Once again H-9 was three bond coupled to C-8. In addition it was three bond coupled to C-6 and, surprisingly, five bond coupled to C-4a. Moreover, both olefinic hydrogens bonded to C-12 were three bond coupled to C-7 and one of them, probably the one *trans* to C-5, was five bond coupled to C-4 (17). These observations place the C-12 exocyclic meth-

[4]Unpublished results on secalonic acids.

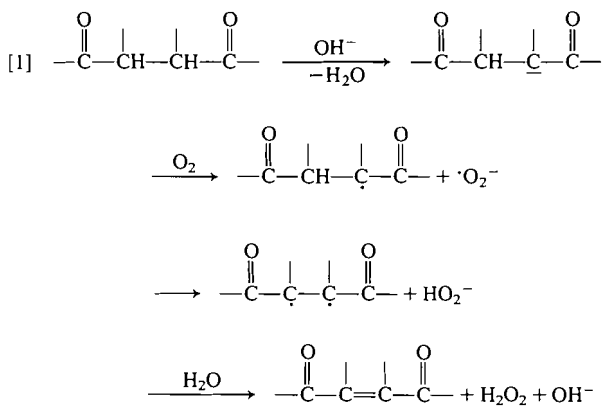
For personal use only.

ylene group vicinal to the $CH_3COCH=$ and C-5 acetoxyl groups in both derivatives. The similarity of the $^{13}C$ chemical shifts for the $CH_3COCH=C$ carbons of **7**, **8**, and **9** strongly suggests that the double bond in all three compounds has the same *E*-configuration. This was also indicated by a careful nuclear Overhauser enhancement study which gave no enhancement of the H-12 resonances for **8** when H-9 was irradiated although a similar experiment involving the H-12 hydrogens had established that they were geminal (see footnote to Table 3). Retention of configuration at the C-7,C-9 double bond of **7** during acetylation in pyridine is not unexpected. Thus the combined evidence unequivocally established that isofusarubin and its acetate derivatives have the structures **7**, **8**, and **9**.

*Nonenzymic formations of 2, 5, and 7*

Although the mechanism of autoxidation in aqueous alkaline solution is not fully understood, it is probable that hydrogen loss from **1***a* and **1***b* involves the reaction of carbanions with molecular oxygen to furnish radicals and $\cdot O_2^-$ (18). Carbanion formation followed by electron abstraction at C-4a and C-10a would lead directly to **2** (Table 1) as illustrated in eq. [1]. Proton removal by base to



produce carbanions would obviously be promoted by the adjacent carbonyl groups. However, prior opening of the tetrahydropyran ring is required before **7** could be formed by removal of hydrogens from C-4 and C-4a. Moreover, production of **5** would also require prior opening of the tetrahydropyran rings of **1***a* and **1***b* and necessarily involves loss of formaldehyde via a retroaldol reaction at the resulting hydroxymethyl group to form 6,7-dihydronorjavanicin before autoxidation occurs. Differences in the rates of the retroaldol and autoxidation reactions probably account for the relative yields of **5** and **7** (Table 1). Formation of **2**, **5**, and **7** and their subsequent degradation in aqueous alkaline solution contrasts with the autoxidation of **1***a* and **1***b* which leads exclusively to **2** (1).

It is also noteworthy that **7** derived from both **1***a* and **1***b* had the same optical activity and therefore configuration at C-6. This can be explained if the dihydrofusarubins possess the same configuration at C-4a and **1***b* is converted through enolization to the more thermodynamically stable **1***a* (1) before conversion to **7**. The integrity of the chiral centers of **1***a* would be maintained because successive enolizations involving these sites would leave the molecule unchanged. Epimerization at C-6 of **7** would also be restricted because of the keto–enol tautomerism accompanying conversion of **1***a* to **7** and the steric interactions between the substituents at C-6 and C-7 which would hamper proton transfer from C-6 to C-4.

Cultures of *F. solani* produce only **1***a*, **1***b*, and **4** if maintained at ph $\approx$ 3 by providing a medium rich in maltose or by addition of acetic acid. When maltose and ammonium tartrate concentrations are low, **1***a*, **1***b*, and **4** are formed during the first two days when the pH is still low, but the amount of **1***a* and **1***b* decreases rapidly after 3 days. This loss is accompanied by a rapid increase in the pH of the medium (pH 8.2 after 6 days) and an increasing proportion of **2**, and to a lesser extent **5**, in the product. Addition of NaOH solution to cultures (pH $\approx$ 3) harvested after 2 days converts **1***a* and **1***b* to **2** and **5**. Thus the latter are produced nonenzymically in cultures of *F. solani* and by the same process as in 0.1 *N* NaOH. Loss of stability on prolonged exposure to basic conditions explains the low yield of **5** (5% of **2**) and the absence of **7** in the cultures.

**Acknowledgements**

The authors wish to thank Margaret Flack and John van Ingen for technical assistance, Professor P. E. Nelson for the culture of *Fusarium solani*, and Professor G. H. N. Towers for the bioassays.

# Enzymes in organic synthesis. 28.[1] Reinvestigation of the horse liver alcohol dehydrogenase-catalyzed reductions of 2-alkylcyclohexanones. Identification of *cis*-alkylcyclohexanols as minor products

J. BRYAN JONES AND TETSUO TAKEMURA[2]

*Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1*

Received June 21, 1982

J. BRYAN JONES and TETSUO TAKEMURA. Can. J. Chem. **60**, 2950 (1982).

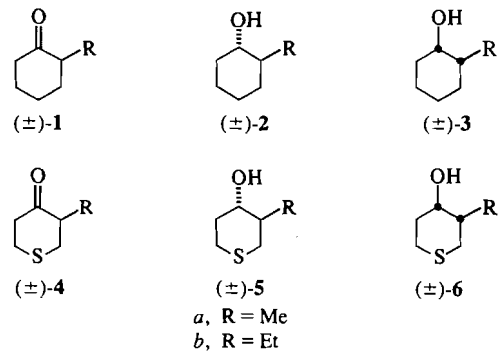
The formation of *cis*-2-alkylcyclohexanol products from horse liver alcohol dehydrogenase-catalyzed reductions of 2-alkylcyclohexanones has been detected for the first time. The *cis*-alcohols are minor (< 4%) products, with the isomeric *trans*-products being heavily predominant under all conditions. *cis*-Alcohol production can be suppressed by suitable manipulation of the reaction conditions. Exclusive formation of the *trans*-alcohols is favoured by operating in an appropriate buffer such as Tris-HCl at the lowest [E]/[S] and pH conditions possible, and by minimizing the reaction time. The results parallel the *cis*-alcohol formation observed previously with the analogous 3-alkyltetrahydrothiopyran-4-one substrates.

J. BRYAN JONES et TETSUO TAKEMURA. Can. J. Chem. **60**, 2950 (1982).

On a décelé pour la première fois la formation d'alkyl-2 cyclohexanols-*cis* lors des réductions d'alkyl-2 cyclohexanones catalysées par la déshydrogénase de l'alcool du foie de cheval. Les alcools *cis* sont des produits secondaires (<4%) tandis que les produits *trans* sont fortement majoritaires dans toutes les conditions. On peut éviter la formation d'alcool *cis* en jouant convenablement avec les conditions de réaction. On favorise la formation exclusive d'alcools *trans* en travaillant avec un tampon convenable tel le Tris-HCl aux plus faibles conditions possibles de [E]/[S] et de pH et en minimisant le temps de réaction. Les résultats sont identiques à ceux obtenus antérieurement lors de la formation d'alcools *cis* à partir des substrats analogues du type alkyl-3 tétrahydrothiopyranones-4.

[Traduit par le journal]

Horse liver alcohol dehydrogenase (HLADH)[3] is a commercially available NAD/H-dependent oxidoreductase that catalyzes highly stereoselective C=O ⇌ CH(OH) transformations for a broad structural range of aldehyde, ketone, and alcohol substrates (1, 2–9). As a result it is currently one of the most versatile and useful enzymes from the asymmetric synthetic point of view and many illustrations of its potential for the preparation of useful chiral synthons have been documented (2–9). Reductions of 2-alkylcyclohexanones were among the first of the preparative-scale HLADH-catalyzed reactions to be studied. Reductions of 2-methyl- and 2-ethylcyclohexanones ((±)-**1***a*,*b*) were reported to be stereospecific, with the (2*S*)-ketones being converted to the corresponding *trans*-alcohols (1*S*,2*S*)-**2***a*,*b* of 100% e.e., and the unreactive ketone enantiomers (2*R*)-**1***a*,*b* being recovered virtually optically pure (2–6). Subsequent work confirmed these results (5, 6). However, it was noted that in the reduction of 2-fluorocyclohexanone, a small (4%) amount of *cis*-2-fluorocyclohexanol of unrecorded chirality was formed in addition to the usual, predominant (96%), *trans*-product (6). Very recently, HLADH-catalyzed reductions of the related 3-alkyltetrahydrothiopyranone substrates (±)-**4***a*,*b* to the *trans*-alcohols **5***a*,*b* were also found to produce minor (2–3%) amounts of *cis*-alcohols **6***a*,*b*.



The formation, to whatever degree, of *cis*-alcohols during HLADH-mediated reductions of ketones such as **1** and **4** is of considerable interest with respect to delineating the possible active site orientations of such substrates (9*c*). Accordingly, we decided to reinvestigate the reductions of (±)-**1***a*,*b* since trace proportions of *cis*-alcohol products could well have escaped detection during the earlier studies. The results reported in this

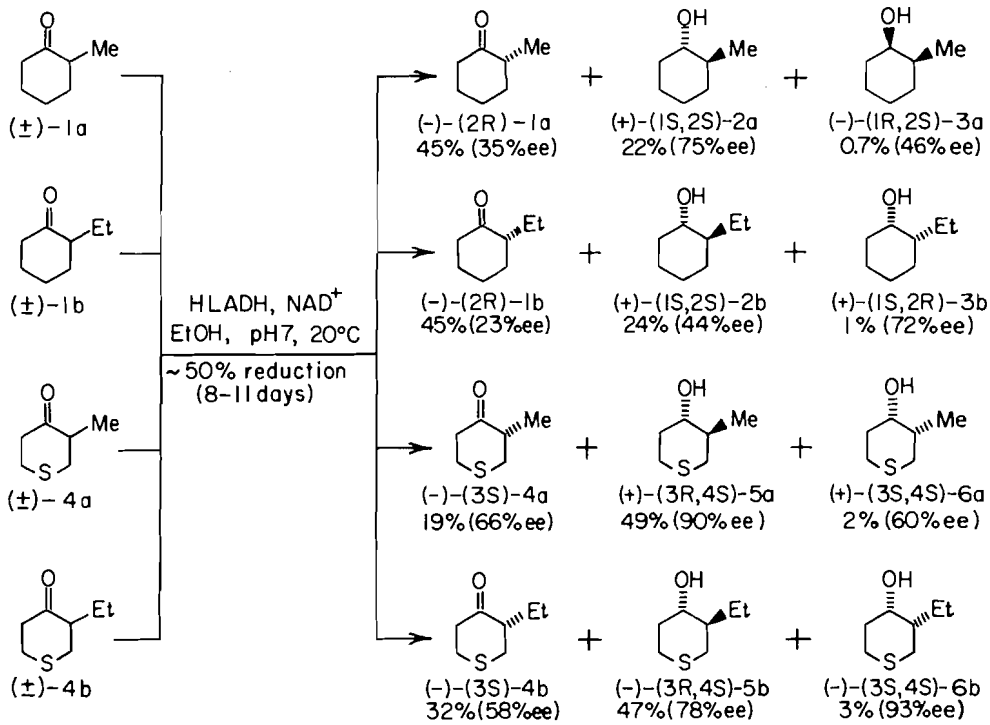

SCHEME 1

paper confirm that *cis*-alcohols can be produced in minor amounts during the reductions of all 2-substituted cyclohexanone and related substrates studied to date. Furthermore, the extent to which the *cis* compounds are formed is found to reflect the nature of the reaction conditions used. With the appropriate controls the formation of the *cis* by-products can be completely suppressed.

## Results

The racemic substrates and potential products **1**–**3***a*,*b* were all known compounds and were either purchased or prepared according to published procedures. Preparative-scale HLADH-catalyzed reductions of the alkylcyclohexanones (±)-**1***a*,*b* were carried out in phosphate buffer pH 7 on a 4-g scale. The results obtained are recorded in Scheme 1 together with the data obtained previously (1) on the 3-alkyltetrahydrothiopyranones (±)-**4***a*,*b*.

The unreacted ketones **1***a*,*b* and the product alcohols **2**,**3***a*,*b* were separated by mplc and their identities confirmed by comparison with their racemic counterparts. The e.e.'s of the ketones (−)-**1***a*,*b* were determined by their quantitative conversion to the corresponding ketals **7***a*,*b* with (−)-(2*R*,3*R*)-2,3-butanediol followed by $^{13}C$ nmr examinations of the diastereomeric ketal mixtures obtained (10). The corresponding ketals from the racemic ketones were used as reference standards. The $\Delta\delta$ values observed for the individual diastereotopic carbon atoms are recorded in Table 1. The e.e. values shown for (−)-**1***a*,*b* in Scheme 1 represent the averages of measurements on $^{13}C$ resonances of at least four different carbon atoms of **7***a*,*b*. The optical purities of the *trans*- and *cis*-alcohols **2**- and **3***a*,*b* of Scheme 1 were evaluated by $^1H$ nmr examination in the presence of Eu(fod)$_3$ of the methoxyl proton resonances of their MTPA-esters, **8***a*,*b* and **9***a*,*b* respectively (11). The $\Delta\Delta\delta$ values of the methoxyl peaks of the corresponding esters of the racemic alcohols used for comparison purposes are recorded in Table 2.

The absolute configurations of (−)-**1***a*, (+)-**2***a*, and (−)-**3***a* were assigned from the literature data (5, 12–14) and that of (−)-**1***b* by octant rule analysis (12, 15) of the Cotton effect of its cd spectrum. The absolute configurations of the *cis*- and *trans*-alcohols (+)-**3***b* and (+)-**2***b* were then established by their oxidation with pyridinium chlorochromate under neutral conditions (16) to (−)-(2*R*)-**1***b* and (+)-(2*S*)-**1***b* respectively.

The degree to which *cis*-alcohols are produced was found to be influenced by the reaction conditions and was studied in detail using (±)-**1***b* as the

representative substrate. As shown in Table 3, the proportions of *cis*-alcohol **3***b* formed during HLADH-catalyzed reduction of 2-ethylcyclohexanone ((±)-**1***b*) can be minimized by working at lower pH's, and by appropriate choice of the buffer. Tris-HCl is a more suitable buffer in this regard than phosphate. The rate of the reaction is also an important parameter (Table 4). The amount of *cis*-alcohol formed increases steadily as the reaction period is extended and selection of a suitably short reaction time ensures that the *trans*-alcohol is the exclusive product. Formation of the *cis*-alcohol can also be suppressed by using a low [E]/[S] ratio. The yields of *cis*-alcohol isolated rise monotonically as the proportions of enzyme in the reaction mixture are increased, as illustrated by Table 5.

## Discussion

The preparative-scale HLADH-catalyzed reductions summarized in Scheme 1 proceeded smoothly. Ethanol was used as the coupled substrate to recycle the catalytic quantity of the expensive $NAD^+$ coenzyme employed (17). The reductions of (±)-**1***a*,*b* were performed on a 4-g scale in order to ensure that sufficient quantities to permit complete and unequivocal characterization

of the minor *cis*-alcohol products **3***a*,*b* were isolable from each reaction.

The direct $^1$H- and $^{13}$C-nmr based measurements of the e.e.'s of the alcohol products and recovered ketones isolated from the enzymic reactions presented no problems and the values cited in Scheme 1 are considered accurate to within ±3%. The peak assignments (Experimental section) and Δδ values recorded for the $^{13}$C resonances of the ketals **7***a*,*b* (Table 1) are in excellent agreement with those published recently by Meyers *et al.* (18), with the exception of the C-3 and C-4 assignments which are reversed. Our assignments are based on the substituent-induced shifts observed between the 2-methyl- and 2-ethyl-derivatives, and their analogy with the corresponding shifts in methyl and ethylcyclohexane (19). The low e.e.'s of the recovered ketones **1***a*,*b* are largely attributable to nonenzymic epimerization at C-2 during the lengthy reaction period.[4]

The absolute configuration determinations of the Scheme 1 cyclohexane derivatives were also straightforward, with the configurations of **1***a*, **2***a*, and **3***a* having been established previously (5, 9–11). The octant rule analysis (15) of the cd spectrum of (−)-**1***b* used to assign its C-2 chirality followed the well documented approach developed on the 2-methyl analogue (12). The configurations of (+)-**2***b* and (+)-**3***b* were then confirmed by their oxidation to (+)- and (−)-**1***b* respectively.

In the earlier studies on HLADH-catalyzed reductions of 2-alkylcyclohexanones, *trans*-alcohol products were obtained exclusively (5, 6). The absence of *cis*-alcohols in these previous reactions is in marked contrast to the present results. However, the Zürich (2, 3, 5) and Antwerp (6) groups effected their transformations under reaction conditions somewhat different from those employed in the Scheme 1 reactions. Recognition of this prompted an evaluation of the influence of various experimental parameters on *cis*-alcohol formation. As the data recorded in Tables 3–5 show, the reaction conditions employed are of prime importance in controlling the degree of *cis*-alcohol content.

If suppression of *cis*-alcohol production is desired, operating in Tris-HCl (6) rather than phosphate buffer and at pH's no higher than 7 is recommended (Table 3). While the use of phosphate buffer alone at pH > 7 does permit *cis*-alcohol formation, substitution of a glycine–arsenate-modified phosphate buffer of pH 8 once again appears to preclude the production of these minor by-products (5, 9*a*). Exclusive reduction to the *trans*-alcohol products can also be ensured by keeping the reaction time short (Table 4) and by operating with the [E]/[S] ratio at a minimum (Table 5). In the HLADH-mediated reductions of 2-alkylcyclohexanones performed by the Zürich and Antwerp groups, in which no *cis*-alcohols were produced, the [E]/[S] ratios employed were even lower, by factors of ~5 (5) and ~10 (6) respectively, than the lowest level of Table 5.

Both the diamond lattice (2, 4) and the cubic-section (9*c*) active-site models developed for predicting the stereochemistry of HLADH-catalyzed oxidoreductions are valid for kinetically controlled reactions only. Under such conditions, virtually exclusive *trans*-alcohol formation is predicted (2, 4, 9*a*, *c*). The Table 4 and 5 data support this view, with short reaction times and very high excesses of [S] over [E] favouring *trans*-, and minimizing *cis*-, alcohol accumulation.

For good substrates, HLADH-catalyzed reductions are rapid and no special precautions are needed to ensure that only the kinetically favoured products are formed (2, 4, 9). However, poor substrates are reduced slowly. As a result lengthy reaction periods are often required, thereby permitting products of pathways other than that of the initial, kinetically determined, direction to build up. The 2-alkylcyclohexanone **1***a*,*b* and 3-alkyl-

[4]The variations in the optical purities of the *trans*-alcohols **3***a*,*b* and **6***a*,*b* contrast the 100% e.e. levels cited previously for such HLADH-derived products (5, 6). These e.e. variations have now been found to be markedly influenced by the reaction conditions. A systematic study of the factors controlling product e.e.'s has been undertaken and will be reported shortly.

thiopyranone **4***a*,*b* reductions are in this latter category. In these cases, the *trans*-alcohol products of kinetic control are also thermodynamically favoured, having both substituents equatorial in the preferred chair conformations. However, in the presence of HLADH, the *trans*-alcohols **2***a*,*b* and **5***a*,*b* are also oxidized back to the parent ketones much more rapidly than the slowly accumulating *cis*-alcohols **3***a*,*b* and **6***a*,*b* (1). The reverse oxidation reaction can occur because, owing to the limitations of the NADH–coenzyme recycling procedure, there is always a small proportion of $NAD^+$ available to participate in an alcohol oxidation step. Accordingly, because the *trans*-alcohols are present in much higher concentrations, and are oxidized much faster than their *cis*-isomers, any *cis*-alcohols that do form accumulate.

The cubic-section model of the active-site region (9*c*) is in accord with the more rapid oxidation of the *trans*- than the *cis*-alcohols of a given series. Furthermore, it predicts that the *cis*-alcohols formed preferentially in the reduction mode will predominate in the enantiomers possessing the (1*S*) (or (4*S*) for the thioketones) absolute configurations. This is seen to be correct for (+)-**3***b*, (+)-**6***a*, and (+)-**6***b*. Disappointingly, favouring of the opposite (1*R*,2*S*) configuration is manifest in (−)-**3***a*.[5] However, since the model was formulated only for predicting the stereochemical outcome of kinetically controlled, preferred, oxidoreductions, this is not a significant discrepancy. Furthermore, use of the enzyme is clearly not preparatively viable for the preparation of *cis*-alcohols. In contrast, HLADH-catalyzed reduction of 2-alkylcyclohexanones and related substrates remains an excellent route to the corresponding optically active *trans*-alcohols, with pure products to be expected if phosphate buffer is avoided and the minimum amount of enzyme is used in solutions of the lowest practicable pH.

[5]The preferred stereochemistry of reduction of 2-alkylcyclohexanones has been analyzed in detail in cubic-section terms (9*c*). Only the (2*S*)-enantiomer of **1***a*,*b* (or (3*R*)-**4***a*,*b*) can form an allowed ES complex to lead to *trans*-(1*S*,2*S*)-**2***a*,*b* (or (3*R*,4*S*)-**5***a*,*b*). The allowed oxidation reactions follow the microscopic reverse paths. On the other hand, neither enantiomer of any *cis*-alcohol of Scheme 1 can bind to form an ES complex without the alkyl substituent violating either cube **E1** (e.g. 1*R*,2*S*-**3***b*) or cube **B1** (e.g. 1*S*,2*R*-**3***b*). All of **E1**, and half of **B1** are forbidden regions, and will not accommodate a substrate group. Formation of the *cis*-products is thus strongly disfavoured. However, the remaining half of cube **B1** will accept a small group and is thus less intolerant than **E1**. The configurations reflecting positioning of the alkyl substituents of the (2*R*)-**1** and (3*S*)-**4** ketones adjacent to, and in, the **B1** region should thus dominate any *cis*-alcohols that are formed. This agrees with the experimental data for (1*S*,2*R*)-**3***b* and (3*S*,4*S*)-**6***s*,*b*, but not for (1*R*,2*S*)-**3***a*. The formation of the latter stereoisomer cannot be explained at the current level of sophistication of the model. Interestingly, reduction of (±)-2-fluorocyclohexanone gives the highest proportion (4%) of *cis*-alcohol (of unspecified configuration) yet reported (6). This would be expected in terms of the above analysis since fluorine is a very small substituent and should, on steric grounds, be more easily accommodated in the open half of cube **B1** than any alkyl group.

## Experimental

The instrumentation and general purification and analytical procedures used were as described previously (9*d*). HLADH (EC 1.1.1.1) was 1× crystallized material purchased from Sigma. The activity of each batch of enzyme was determined (20) prior to use; amounts of HLADH quoted refer to milligrams of active enzyme. $NAD^+$ was obtained from Kyowa Hakko Kogyo, New York. The mplc separations were performed on silica (ICN 0.032–0.63 mm) with ethyl acetate – hexane (1:6) elution. Unless indicated otherwise, ir spectra were determined in $CCl_4$ and nmr spectra in $C^2HCl_3$. The Scheme 1 data on the tetrahydrothiopyrans **4***a*,*b*, **5***a*,*b*, and **6***a*,*b* are from ref. 1.

*Preparations of racemic ketone substrates and alcohol products*

*2-Methylcyclohexanone ((±)-1a)* was purchased from Aldrich and purified by Kugelrohr distillation, bp 162–163°C (lit. (21) bp 165–166°C); ir: 1714 $cm^{-1}$; $^1H$ nmr δ: 1.02 (3H, d, $J$ = 6 Hz) and 1.15–2.8 (9H, m) ppm.

cis- *and* trans-*2-Methylcyclohexanol* were prepared by $LiAlH_4$ reduction of 2-methylcyclohexanone. Separation of the mixture by mplc gave *cis*-2-methylcyclohexanol ((±)-**3***a*, 25% yield) bp 70°C (20 Torr) (lit. (13) bp 77–78°C (20 Torr)); ir (film): 3400 $cm^{-1}$; $^1H$ nmr δ: 0.97 (3H, d, $J$ = 6 Hz), 1.1–2.3 (9H, m), 1.86 (OH, s), and 3.80 (1H, m, $W_{\frac{1}{2}}$ = 8 Hz) ppm and *trans*-2-methylcyclohexanol ((±)-**2***a*, 44% yield) bp 74°C (27 Torr) (lit. (13) bp 78–79°C (20 Torr)); ir: 3640, 3380 $cm^{-1}$; $^1H$ nmr δ: 0.7–2.2 (12H, m), 2.70 (OH, s), and 3.10 (1H, m, $W_{\frac{1}{2}}$ = 20 Hz) ppm.

*2-Ethylcyclohexanone ((±)-1b)* was obtained in 90% yield by Jones oxidation of 2-ethylcyclohexanol (*cis*/*trans* mixture, purchased from Aldrich) bp 70°C (10 Torr) (lit. (22) bp 110°C (36 Torr)); ir: 1720 $cm^{-1}$; $^1H$ nmr δ: 0.9 (3H, t, $J$ = 7 Hz) and 1.1–2.5 (11H, m) ppm.

cis- *and* trans-*2-Ethylcyclohexanol*

The mplc separation of the commercial mixture (Aldrich) gave *cis*-2-ethylcyclohexanol ((±)-**3***b*, 29% yield) bp 82°C (10 Torr) (lit. (23) bp 180–182°C); ir: 3625, 3480 $cm^{-1}$; $^1H$ nmr δ: 0.92 (3H, t, $J$ = 6 Hz), 0.9–2.1 (11H, m), 1.77 (OH, s), and 3.92 (1H, m, $W_{\frac{1}{2}}$ = 8 Hz) ppm and *trans*-2-ethylcyclohexanol ((±)-**2***b*, 36% yield) bp 82°C (10 Torr) (lit. (24) bp 87–91°C (25 Torr)); ir: 3640, 3440 $cm^{-1}$; $^1H$ nmr δ: 0.87 (3H, t, $J$ = 6 Hz), 0.9–2.25 (11H, m), 2.10 (OH, s), and 3.15 (1H, m, $W_{\frac{1}{2}}$ = 20 Hz) ppm.

*HLADH-catalyzed reductions of (±)-1a,b*

The general procedure described previously (1, 9*e*) was used to reduce the ketone (4.0 g, ~35 mmol) with HLADH (300 mg), $NAD^+$ (6.0 g, 9.1 mmol), EtOH (11 mL) in 0.1 *M* potassium phosphate buffer pH 7 (1 L) at 20°C. The reactions were monitored by glc and terminated at the ~50% reduction point. The unchanged ketones and product alcohols were separated by mplc. The spectral properties of each compound were identical with those of the corresponding racemates characterized above. The individual reactions gave the following results after Kugelrohr distillation of each chromatographically purified product.

*Reduction of (±)-1a* (44% conversion) yielded (−)-2-methylcyclohexanone ((2*R*)-**1***a*, 1.8 g, 45% yield, 35% e.e.) bp 59°C (22

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

Torr) (lit. (12) bp 59–60°C (20 Torr)), $[\alpha]_D^{25}$ −3.39° (*c* 2.2, EtOH) (lit. (5) (2*S*)-**1***a* $[\alpha]_D^{25}$ +14.4° (*c* 1.03, EtOH)); (+)-*trans*-2-methylcyclohexanol ((1*S*,2*S*)-**2***a*, 881 mg, 22% yield, 75% e.e.), bp 70°C (15 Torr) (lit. (13) bp 78°C (20 Torr)), $[\alpha]_D^{25}$ +31.0° (*c* 2.2, EtOH) (lit. (5) $[\alpha]_D^{25}$ +40.8° (*c* 0.7, EtOH); and (−)-*cis*-2-methylcyclohexanol ((1*R*,2*S*)-**3***a*, 30 mg, 0.7% yield, 46% e.e.), bp 72°C (21 Torr) (lit. (13) bp 78–79°C (29 Torr)), $[\alpha]_D^{25}$ −10.2° (*c* 0.3, EtOH) (lit. (5) (1*S*,2*R*)-**3***a* $[\alpha]_D^{25}$ +15.7° (*c* 3.4, EtOH).

*Reduction of* (±)-*1*b (44% conversion gave (−)-2-ethylcyclohexanone ((2*R*)-**1***b*, 1.81 g, 45% yield, 23% e.e.), bp 82–85°C (22 Torr), $[\alpha]_D^{25}$ −4.75° (*c* 2.2, EtOH) (lit. (5) 18° (*c* 1.8, EtOH)); (+)-*trans*-2-ethylcyclohexanol ((1*S*,2*S*)-**2***b*, 960 mg, 24% yield, 44% e.e.), bp 80°C (18 Torr), $[\alpha]_D^{25}$ +26.6° (*c* 2.1, EtOH) (lit. (5) $[\alpha]_D$ 59.2° (*c* 1.45, EtOH); and (+)-*cis*-2-ethylcyclohexanol ((1*S*,2*R*)-**3***b*, 47 mg, 1.2% yield, 72% e.e.), bp 80°C (21 Torr), $[\alpha]_D^{25}$ +15.5° (*c* 0.54, EtOH).

*Enantiomeric excess determinations*

1. *Of ketones* **1**a,b

Each racemic (for reference) and optically active ketone **1***a*,*b* (1 mmol) was converted in quantitative yield to its ketal **7***a*,*b* with (−)-(2*R*,3*R*)-2,3-butanediol (1.3 mmol) as described previously (1). The e.e. values of the ketals from the optically active ketones of Scheme 1 were determined from the $^1$H-decoupled $^{13}$C nmr spectra of **7***a*,*b* by the method of Hiemstra and Wynberg (10). The Δδ values used are recorded in Table 1. The bp's (Kugelrohr) and nmr resonances of the ketals from the racemic ketones are recorded below.

*2-Methylcyclohexanone ketal* **7**a, bp 75°C (1 Torr), $^1$H nmr δ: 0.85 and 0.9 (3H, d of d, $J$ = 6 Hz), 1.25 (6H, d of d, $J$ = 6 Hz), 1.4–2.4 (9H, m), and 3.65 (2H, m, $W_{\frac{1}{2}}$ = 12 Hz) ppm; $^{13}$C nmr δ: 14.40 and 14.48 (C-2 $CH_3$), 16.16 and 16.30 (C-9), 17.82 (C-10), 23.84 and 24.26 (C-5), 25.00 (C-4), 32.17 and 32.26 (C-3), 36.59 and 37.28 (C-6), 39.73 and 40.51 (C-2), 77.48 and 77.78 (C-7), 79.14 and 79.83 (C-8), and 110.07 and 110.34 (C-1) ppm.

*2-Ethylcyclohexanone ketal* **7**b, bp 80°C (1.2 Torr), $^1$H nmr δ: 0.9 (3H, t, $J$ = 6 Hz), 1.2 (6H, d of d, $J$ = 4 Hz), 0.6–2.4 (11H, m), and 3.60 (2H, m, $W_{\frac{1}{2}}$ = 12 Hz) ppm; $^{13}$C nmr δ: 12.00 ($CH_2CH_3$), 16.28 (C-9), 17.89 (C-10), 20.85 and 20.94 ($CH_2CH_3$), 24.16 and 23.67 (C-5), 24.84 (C-4), 28.19–28.26 (C-3), 36.62 and 37.29 (C-6), 46.79 and 47.46 (C-2), 77.51 and 77.64 (C-7), 79.15 and 79.48 (C-8), and 110.07 and 110.34 (C-1) ppm.

2. *Alcohols* **2**a,b *and* **3**a,b

The racemic (for reference) and optically active alcohols **2**,**3***a*,*b* (20–30 mg) were each converted to their MTPA esters **8**,**9***a*,*b* in quantitative yields by the literature (1, 8) procedure using freshly prepared (+)-(2*R*)-2-methoxy-2-trifluoromethylphenylacetyl chloride (100 mg, ~2 equiv.), $[\alpha]_D^{25}$ 131.9°C (*c* 1, $CCl_4$) (lit. (8) $[\alpha]_D^{25}$ 129.0 ± 0.2° (*c* 5.17, $CCl_4$). The e.e.'s of the MTPA esters of the Scheme 1 alcohols were then determined from the 60 MHz $^1$H nmr methyl resonances in the presence of Eu(fod)$_3$. The bp's (Kugelrohr) and spectral data of the MTPA esters of the racemic alcohols **2**,**3***a*,*b* used to establish the ΔΔδ values summarized in Table 2 are as follows.

trans-*2-Methylcyclohexanol MTPA ester* **8**a, bp 90°C (0.2 Torr), ir: 1757 cm$^{-1}$; $^1$H nmr ($CCl_4$) δ: 0.73 and 0.96 (3H, d of d, $J$ = 6 Hz), 1.0–2.5 (9H, m), 3.53 (3H, s), 4.60 (1H, m, $W_{\frac{1}{2}}$ = 20 Hz), and 7.2–7.8 (5H, m) ppm.

cis-*2-Methylcyclohexanol MTPA ester* **9**a, bp 95°C (0.25 Torr), ir: 1762 cm$^{-1}$; $^1$H nmr ($CCl_4$) δ: 0.75 and 0.95 (3H, d of d, $J$ = 6 Hz), 1.05–2.40 (9H, m), 3.56 (3H, s), 5.12 (1H, m, $W_{\frac{1}{2}}$ = 8 Hz), and 7.15–7.75 (5H, m) ppm.

trans-*2-Ethylcyclohexanol MTPA ester* **8**b, bp 90°C (0.2 Torr), ir: 1757 cm$^{-1}$; $^1$H nmr ($CCl_4$) δ: 0.50–2.33 (14H, m), 3.56 (3H, s), 4.74 (1H, m, $W_{\frac{1}{2}}$ = 20 Hz), and 7.2–7.8 (5H, m) ppm.

cis-*2-Ethylcyclohexanol MTPA ester* **9**b, bp 95°C (0.25 Torr), ir: 1765 cm$^{-1}$; $^1$H nmr ($CCl_4$) δ: 0.90 (3H, t, $J$ = 5.5 Hz), 1.05–2.35 (11H, m), 3.50 (3H, s), 5.25 (1H, m, $W_{\frac{1}{2}}$ = 8 Hz), and 7.15–7.75 (5H, m) ppm.

*Absolute configuration determinations*

1. *Of the enzyme-derived ketones* **1**a,b

The (2*R*)-configuration of (−)-**1***a* was assigned from the literature data (5, 12–14). The configuration of (−)-**1***b* was established from octant rule analysis (12, 15) of its cd spectrum: cd (*c* 0.0149, EtOH, 20°C): $[\theta]_{329}$ 0°; $[\theta]_{292}$ −1350°; $[\theta]_{240}$ 0°, and comparison with that of the known (12) (−)-(2*R*)-**1***a*.

2. *Of the HLADH-derived alcohols* **2**,**3**a,b

The configurations of (+)-(1*S*,2*S*)-**2***a* and (−)-(1*R*,2*S*)-**3***a* were assigned from the literature data (5, 12–14). For the ethylcyclohexanols **2**,**3***b*, the relative configurations at C-1 and C-2 were established by their identification as *cis*- or *trans*-isomers from their $^1$H nmr spectra. The chiralities of the C-2 centres were then determined by oxidation of (+)-**2***b* and (+)-**3***b* to (+)-(2*S*)-**1***b* and (−)-(2*R*)-**1***b* respectively, and by comparison of the Cotton effect of the cd spectra of (+)-(2*R*)-**1***b* with that of (+)-(2*S*)-**1***a* established previously (12).

*Oxidation of* trans-*alcohol* (+)-**2**b *to* (+)-(2R)-*1*b

(+)-*trans*-2-Ethylcyclohexanol (**2***b*, 90 mg, 0.7 mmol, $[\alpha]_D^{25}$ +55.4° (*c* 0.9, EtOH)), pyridinium chlorochromate (335 mg, 1.55 mmol), and sodium acetate (17 mg, 0.21 mmol) in $CH_2Cl_2$ (5 mL) was stirred at 20°C for 1 day (16). Base-free work-up and purification gave 2-ethylcyclohexanone ((2*R*)-**1***b*, 70 mg, 79% yield) bp 80°C (7 Torr), $[\alpha]_D^{25}$ +21.3° (*c* 0.6, EtOH); cd (*c* 0.0123, EtOH, 20°C): $[\theta]_{330}$ 0°; $[\theta]_{293}$ +1870°; $[\theta]_{240}$ 0°.

*Oxidation of* cis-*alcohol* (+)-**3**b *to* (−)-(2S)-*1*b

Oxidation of (+)-*cis*-2-ethylcyclohexanol (**3***b*, 98 mg, 0.76 mmol, $[\alpha]_D^{25}$ +1.60° (*c* 1.2, EtOH)) with pyridinium chlorochromate (360 mg, 1.67 mmol) and sodium acetate (19 mg, 0.23 mmol) in $CH_2Cl_2$ (5 mL) for 12 h at 20°C, followed by base-free work-up, gave 2-ethylcyclohexanone ((2*S*)-**1***b*, 72 mg, 74% yield) bp 40°C (3 Torr), $[\alpha]_D^{25}$ −2.2° (*c* 1, EtOH).

*Influence of reaction conditions on* cis-*alcohol formation during HLADH-catalyzed reduction of* (±)-*1*b

The effects of buffer and pH were surveyed by following (by glc) the course of reduction of (±)-**1***b* (51 mg) with enzyme (10 mg), $NAD^+$ (79 mg), and EtOH (0.1 mL) in 0.4 *M* potassium phosphate, or Tris-HCl, buffer (10 mL) of pH 6 and 8, or 7, 8, and 9 respectively, at 20°C. The [E]/[S] ratio was 3.1 × 10$^{-4}$ for these studies. The results are summarized in Table 3. The dependence of *cis*-alcohol formation on reaction time was monitored in the same way under the same conditions in 0.4 *M* potassium phosphate buffer pH 8. The results are recorded in Table 4.

The influence of changes in the [E]/[S] ratio within the range 0.44–5.0 × 10$^{-4}$ was evaluated under the above conditions in 0.4 *M* Tris-HCl pH 8 (100 mL) using (±)-**1***b* (500 mg, 4 mmol), HLADH (14–159 mg, 0.175–2.00 μmol), $NAD^+$ (700 mg, 1.06 mmol), and EtOH (1 mL). The yields of *trans*- and *cis*-alcohols **2**,**3***b* observed are recorded in Table 5.

## Acknowledgements

We are grateful to the Natural Sciences and Engineering Research Council of Canada for their support of this work and to Hoffmann-La Roche, Nutley, New Jersey for additional financial aid. We are also indebted to Professor Keith Dorrington for the use of his cd machine, and to Dr. Lung-chi Yuan for her assistance in determining the absolute configuration of (+)-(1*S*,2*R*)**3***b*.

# Structural studies of organoboron compounds. XII.[1] Crystal and molecular structures of (acetylacetonato)diphenylboron and (tropolonato)diphenylboron

STEVEN J. RETTIG AND JAMES TROTTER

*Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6*

Received June 11, 1982

STEVEN J. RETTIG and JAMES TROTTER. Can. J. Chem. **60**, 2957 (1982).

There are two crystalline modifications of (acetylacetonato)diphenylboron: triclinic, $a = 8.3557(8)$, $b = 9.3519(8)$, $c = 9.6103(9)$ Å, $\alpha = 96.094(5)$, $\beta = 94.904(6)$, $\gamma = 93.489(6)°$, $Z = 2$, space group $P\bar{1}$, and monoclinic, $a = 11.6329(11)$, $b = 17.1628(8)$, $c = 7.6542(6)$ Å, $\beta = 97.669(4)°$, $Z = 4$, space group $P2_1/c$. Crystals of (tropolonato)diphenylboron are monoclinic, $a = 12.1596(5)$, $b = 10.2614(4)$, $c = 12.4883(6)$ Å, $\beta = 100.965(2)°$, $Z = 4$, space group $P2_1/c$. All three structures were solved by direct methods and were refined by full-matrix least-squares procedures to $R$ values of 0.046, 0.041, and 0.035 for 2465, 2124, and 1722 reflections with $I \geq 3\sigma(I)$ respectively. Each structure consists of discrete molecules containing tetrahedrally coordinated boron atoms, both the acetylacetonato and tropolonato moieties being delocalized and symmetric. The chelate rings in both forms of (acetylacetonato)-diphenylboron have distorted B-envelope conformations while the chelate ring in (tropolonato)diphenylboron is essentially planar. The mean B—O and B—C distances (corrected for libration) are: 1.543(4) and 1.605(4) Å in triclinic, 1.533(3) and 1.607(4) Å in monoclinic (acetylacetonato)diphenylboron, and 1.555(11) and 1.605(6) Å in (tropolonato)diphenylboron.

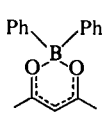
STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **60**, 2957 (1982).

L'(acétylacétonato)diphénylbore se présente sous deux formes cristallines: (*a*) une forme triclinique appartenant au groupe d'espace $P\bar{1}$ avec $a = 8{,}3557(8)$, $b = 9{,}3519(8)$, $c = 9{,}6103(9)$ Å, $\alpha = 96{,}094(5)$, $\beta = 94{,}904(6)$, $\gamma = 93{,}489(6)°$, $Z = 2$ et (*b*) une forme monoclinique appartenant au groupe d'espace $P2_1/c$ avec $a = 11{,}6329(11)$, $b = 17{,}1628(8)$, $c = 7{,}6542(6)$ Å, $\beta = 97{,}669(4)°$, $Z = 4$. Les cristaux du (tropolonato)diphénylbore sont monocliniques avec $a = 12{,}1596(5)$, $b = 10{,}2614(4)$, $c = 12{,}4883(6)$ Å, $\beta = 100{,}965(2)°$, $Z = 4$, groupe d'espace $P2_1/c$. On a résolu toutes les structures par des méthodes directes et on les a affinées par la methode des moindres carrés (matrice complète) jusqu'à des valeurs de $R$ de 0,046, 0,041 et 0,035 pour respectivement 2465, 2124 et 1722 réflexions avec $I \geq 3\sigma(I)$. Chaque structure comprend des molécules discrètes contenant des atomes de bore coordonnés de façon tétraédrique, les deux unités acétylacétonato et tropolonato étant symétriques et délocalisées. Les cycles du chélate dans les deux formes d'(acétylacétonato) diphénylbore ont des conformations du type enveloppe B déformées tandis que le cycle du chélate dans le (tropolonato) diphénylbore est essentiellement plan. Les distances moyennes B—O et B—C (corrigées pour la libration) sont de 1,543(4) et de 1,605(4) Å dans la forme triclinique et de 1,533 et 1,607(4) Å dans la forme monoclinique de l'(acétylacétonato) diphénylbore. Ces distances sont de 1,555(11) et de 1,605(6) Å dans le cas du tropolonato) diphénylbore.

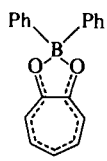
[Traduit par le journal]

## Introduction

As part of a continuing study of the molecular structures of organoboron compounds (1–11) we now report the crystal and molecular structures of the acetylacetone and tropolone esters of diphenylborinic acid. Both (acetylacetonato)diphenylboron, **1**, and (tropolonato)diphenylboron, **2**, are stabilized by both intramolecular O → B interactions and by electron delocalization in the chelate rings. The chemical and physical properties of these compounds are well documented (12–17 and references therein).



**1**



**2**

[1]References 1–11 list previous papers in this series.

## Experimental

The compounds were prepared by reacting (2-aminoethanolato)diphenylboron with the appropriate chelating agent in ethanol/acetone (1:1). With the exception of the solvent used, the procedure is identical to that previously reported for both **1** (12) and **2** (16). Two crystalline modifications of **1** were obtained. Colorless crystals of the triclinic form were isolated directly from the reaction mixture and recrystallization from acetone afforded colorless crystals of the monoclinic form. High-quality pale yellow crystals of **2** were isolated directly from the reaction mixture.

*Crystallographic studies*

*Triclinic (acetylacetonato)diphenylboron*

A crystal ca. 0.26 × 0.33 × 0.55 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo $K\alpha_1$ radiation ($\lambda = 0.70930$ Å). Crystal data at 22°C are:

$C_{17}H_{17}BO_2$ fw = 264.14

Triclinic, $a = 8.3557(8)$, $b = 9.3519(8)$, $c = 9.6103(9)$ Å, $\alpha = 96.094(5)$, $\beta = 94.904(6)$, $\gamma = 93.489(6)°$, $V = 742.1(1)$ Å$^3$, $Z = 2$, $\rho_c = 1.182$ g cm$^{-3}$, $F(000) = 280$, $\mu$(Mo Kα) = 0.70 cm$^{-1}$. Absent reflections: none, space group $P\bar{1}$ ($C_i^1$, No. 2, reduced cell) from structure analysis.

Intensities were measured with graphite-monochromated Mo

Kα radiation (λ = 0.71073 Å) on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 0.96–10.06° min$^{-1}$ over a range of (0.65 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 60°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 3%.

After data reduction, no absorption correction was made in view of the low value of μ. Of the 4297 independent reflections measured, 2465 (57.4%) had intensities greater than 3σ($I$) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with $S$ = scan count and $B$ = background count.

The centrosymmetric space group $P\bar{1}$ was indicated by the $E$-statistics. The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an $E$-map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R$ = 0.086, a difference map gave positions for all 17 hydrogen atoms which were refined with isotropic thermal parameters in subsequent least-squares cycles. The scattering factors of ref. 18 were used for non-hydrogen atoms and those of ref. 19 for hydrogen atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of refinement. Convergence was reached at $R$ = 0.046 and $R_w$ = 0.061 for 2465 reflections with $I \geq 3\sigma(I)$. For all 4297 reflections $R$ = 0.087. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.10 and 0.74σ respectively. The mean error in an observation of unit weight was 2.071. A final difference map showed no unusual features. The final positional and thermal parameters appear in Tables 1 and 2[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

*Monoclinic (acetylacetonato)diphenylboron*

Experimental details are as above except where noted. Crystal dimensions were ca. 0.33 × 0.24 × 0.45 mm. Crystal data are:

$C_{17}H_{17}BO_2$ fw = 264.14

Monoclinic, $a$ = 11.6329(11), $b$ = 17.1628(8), $c$ = 7.6542(6) Å, β = 97.669(4)°, $V$ = 1514.5(2) Å$^3$, $Z$ = 4, $\rho_c$ = 1.158 g cm$^{-3}$, $F(000)$ = 560, μ(Mo Kα) = 0.68 cm$^{-1}$. Absent reflections: $h0l$, $l \neq 2n$ and $0k0$, $k \neq 2n$ uniquely indicate the space group $P2_1/c$ ($C_{2h}^5$, No. 14).

An ω–2θ scan at 0.96–10.06° min$^{-1}$ over a range of (0.70 + 0.35 tan θ)° in ω was employed. Of 3456 independent reflections measured (to 2θ = 55°), 2124 (61.5%) had intensities greater than 3σ($I$) above background.

The structure was solved by direct methods. After refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R$ = 0.092, all H coordinates were determined from a difference map. In the final stages of refinement an isotropic Type I extinction correction (Thornley-Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (20–22). The final value of $g$ was 8.1(10) × 10$^4$. Convergence was reached at 0.041 and $R_w$ = 0.049 for 2124 reflections with $I \geq 3\sigma(I)$, for all 3456 reflections $R$ = 0.076. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.07 and 0.36σ respectively and the mean error in an observation of unit weight was 1.076. A final difference map showed no unusual features.

*(Tropolonato)diphenylboron*

Crystal dimensions were ca. 0.15 × 0.28 × 0.48 mm. Crystal data are:

$C_{19}H_{15}BO_2$ fw = 286.14

Monoclinic, $a$ = 12.1596(5), $b$ = 10.2614(4), $c$ = 12.4883(6) Å, β = 100.965(2)°, $V$ = 1529.8(1) Å$^3$, $Z$ = 4, $\rho_c$ = 1.242 g cm$^{-3}$, $F(000)$ = 600, μ(Mo Kα) = 0.43 cm$^{-1}$. Absent reflections: $h0l$, $l \neq 2n$ and $0k0$, $k \neq 2n$ uniquely indicate the space group $P2_1/c$.

An ω–2θ scan at 0.96–10.06° min$^{-1}$ over a range of (0.70 + 0.35 tan θ)° was employed. Of 3497 independent reflections measured (to 2θ = 55°), 1722 (49.2%) had $I \geq 3\sigma(I)$. The structure was solved by direct methods. After refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R$ = 0.080, the hydrogen atoms were located from a difference map. Convergence was reached at $R$ = 0.035 and $R_w$ = 0.040 for 1722 reflections with $I \geq 3\sigma(I)$, for all 3497 reflections $R$ = 0.100. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.03 and 0.18σ respectively and the mean error in an observation of unit weight was 1.803.

*Analysis of thermal motion*

The thermal motion in each of the three molecules (shown in Figs. 1 and 2) has been analysed in terms of the rigid-body modes of translation, libration, and screw-motion (23). The rms errors in the $U_{ij}$ (derived from the least-squares analyses) are 0.0009, 0.0014, and 0.0010 Å$^2$ for triclinic **1**, monoclinic **1**, and **2** respectively. Analysis of the entire molecules in each case indicated significant independent motion of the phenyl groups and gave rms $\Delta U_{ij}$ values of 0.0062, 0.0068, and 0.0047 Å$^2$ for the three structures. The $C_6H_5B$ groups were separately analysed (rms $\Delta U_{ij}$ = 0.0015–0.0023 Å$^2$). For both forms of **1** the corrections to bonds in the chelate rings were based on the analyses of the whole molecule since the (acetylacetonato) $BC_2$ fragment of the monoclinic form gave a non-positive-definite libration tensor. For **2** the tropolonato-$BC_2$ moiety was separately analysed (rms $\Delta U_{ij}$ = 0.0023 Å$^2$). All rigid-body analyses employed gave physically reasonable results. The appropriate bond distances have been corrected for libration (23, 24), using shape parameters $q^2$ of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of chelate rings are listed in Table 5. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 6–8) are included as supplementary material.

## Results and discussion

Each of the three structures consists of discrete molecules separated by normal van der Waals distances, although in monoclinic **1** there is one unusually short H···H contact (H(5)···H(5)($-x$, $-y$, $-z$) = 2.13(5) Å). In each case $Ph_2B$ may be considered as a pseudo-metal (14) coordinated to fully delocalized acetylacetonato or tropolonato ligands resulting in distorted tetrahedral coordination about the boron atoms.

The most obvious difference between the molecules of **1** in the two different crystalline forms is the orientation of the pseudo-equatorial phenyl

[2]The structure factor table, Table 2 (anisotropic thermal parameters) and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

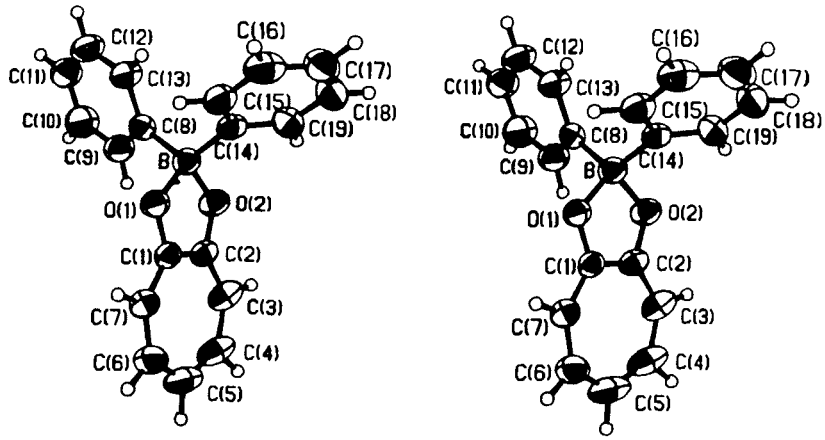

FIG. 1. Stereoscopic views of the triclinic (top) and monoclinic (bottom) forms of (acetylacetonato)diphenylboron. 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. The monoclinic form shown is the mirror image of the molecule described by the coordinates in Table 1 for comparison with the triclinic form.

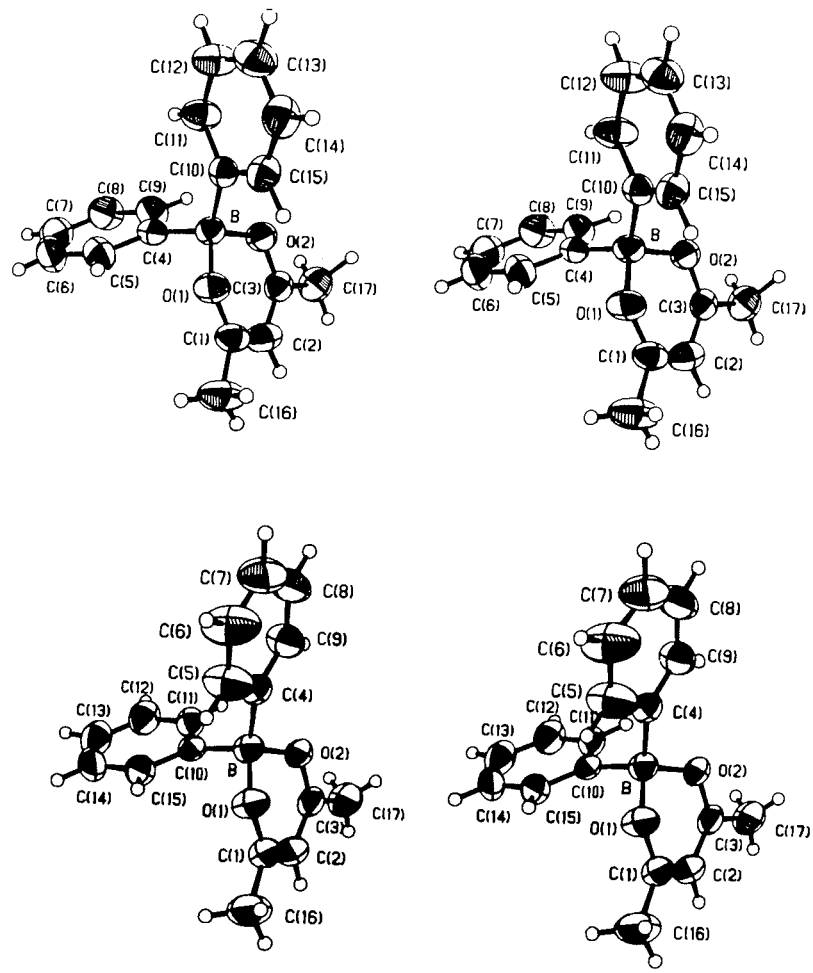

FIG. 2. Stereoscopic view of the (tropolonato)diphenylboron molecule. 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

group (which contains C(10) in the triclinic form and C(4) in the monoclinic form). The asymmetric disposition of the phenyl rings in triclinic **1** (and in **2**) is that usually observed in $Ar_2B$ chelates (1–3, 6, 9) while the symmetric disposition observed in monoclinic **1** is less common (5, 11). Bond angles at B and O atoms, bond distances involving O, and chelate ring conformations differ significantly between the two modifications of **1** (see Tables 3–5). These differences presumably arise from steric effects and induced hybridization effects.

The acetylacetonato moiety in both forms of **1** is fully delocalized and symmetric, but unlike the planar chelate ring found for (benzoylacetonato)-difluoroboron, **3** (25), the six-membered chelate rings in **1** have distorted B-envelope conformations very similar to that observed in (salicylaldehydato)diphenylboron, **4** (5). The dihedral angles between the C(1)C(2)C(3) and the OBO planes are 31.9 and 41.1° for triclinic and monoclinic **1** respectively.

The mean[3] B—O distances in triclinic and monoclinic **1** are 1.543(4) and 1.533(3) Å (overall mean 1.538(7) Å). The B—O distance in **3** of 1.488(3) Å is shorter by 0.05 Å than those in **1**, this difference being the same as that between the B—O distances in *N*-methylacethydroxamato chelates of $F_2B$ (8) and $Ph_2B$ (11). The average B—O distance in **4** of 1.537 Å compares well with the mean for the two forms of **1**, although the individual values for **4** differ considerably (1.500(4) and 1.574(4) Å). The

[3]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

mean C—O distances, 1.288(1) and 1.301(4) Å for triclinic and monoclinic **1**, lie between the values of 1.304(2) Å for **3** and the mean of 1.274 Å for a number of metal complexes of acetylacetone (26). The mean chelate ring C—C distance of 1.381(2) Å is shorter than the values of 1.389(1) Å in **3** and 1.390 Å in the metal complexes. In the structure of **3** (determined at −180°C) the C—$CH_3$ bond was unusually short at 1.485(3) Å, this also being observed for **1**, the mean C—$CH_3$ distance being

TABLE 5. Intra-annular torsion angles (deg) standard deviations in parentheses

| Atoms | Value (deg) |
|---|---|
| Triclinic **1** | |
| B —O(1)—C(1)—C(2) | 13.3(2) |
| O(1)—C(1)—C(2)—C(3) | 7.6(2) |
| C(1)—C(2)—C(3)—O(2) | −7.0(2) |
| B —O(2)—C(3)—C(2) | −14.4(2) |
| C(3)—O(2)—B —O(1) | 30.5(2) |
| C(1)—O(1)—B —O(2) | −30.0(2) |
| Monoclinic **1** | |
| B —O(1)—C(1)—C(2) | −17.9(3) |
| O(1)—C(1)—C(2)—C(3) | −8.7(3) |
| C(1)—C(2)—C(3)—O(2) | 9.5(3) |
| B —O(2)—C(3)—C(2) | 16.4(3) |
| C(3)—O(2)—B —O(1) | −38.2(2) |
| C(1)—O(1)—B —O(2) | 38.8(2) |
| **2** | |
| B —O(1)—C(1)—C(2) | 0.1(2) |
| O(1)—C(1)—C(2)—O(2) | −1.2(2) |
| B —O(2)—C(2)—C(1) | 1.8(2) |
| C(2)—O(2)—B —O(1) | −1.56(15) |
| C(1)—O(1)—B —O(2) | 0.80(15) |

1.489(6) Å (libration corrected) compared to the average of 1.524 Å observed in the metal complexes (26).

The fused five- and seven-membered ring system in **2** is planar to within 0.06 Å, each of the rings being slightly but significantly non-planar (maximum deviations from the mean planes[4] being 0.006 and 0.012 Å for the 7- and 5-membered rings respectively). The tropolonato moiety is symmetric and fully delocalized; the unique C(1)—C(2) distance is 1.446(2) Å, mean C—O = 1.313(2) Å, and the remaining six C—C bonds are essentially equal (mean C—C = 1.385(5) Å). The two B—O distances in **2** are significantly different (1.565(2) and 1.544(2) Å), the average value of 1.555 Å being similar to the corresponding value of 1.550(2) Å observed in the structure of (*N*-methylacethydroxamato)diphenylboron (11) which also contains a planar five-membered chelate ring with two oxygen atoms bonded to boron. In 4,4-dimethyl-2,2-diphenyl-1,3-dioxa-4-azonia-2-boranatacyclopentane, **5** (3), which has a non-planar chelate ring, the B—O distances are 1.506(7) and 1.556(8) Å. The B—O distances in **1** and **2** are longer than the true single bonds in the tetrahedrally coordinated ethanolamine esters of diarylborinic acids which have a mean bond length of 1.477(5) Å (1, 2, 6) and in the related ethanolamine chelate spiro(9*H*-borepino-[2,3-*b*:7,6-*b*']dithiophene-9,2'-[1,3,2]oxazaborolidine) (27), in which B—O = 1.488(2) Å at 87 K.

In all three structures, the two B—C distances are somewhat different, this difference being significant only in the case of **2**. In both forms of **1** the pseudo-equatorial B—C distances are 0.007 Å shorter than the others, the overall mean being 1.606(4) Å compared with a mean of 1.605(6) Å in **2**. These values are both near the short end of the range 1.603(4) Å in **4** to 1.639(8) Å in **5** observed for $Ar_2B$ chelates (1–3, 5, 6, 9, 11). Differences between chemically equivalent B—C distances have been observed earlier (3, 5, 6, 28). The geometry of the B-substituted phenyl rings is as expected (28). With the exception of the C(10) ring in monoclinic **1** ($\chi^2 = 1.3$), all phenyl rings in **1** and **2** are significantly non-planar ($\chi^2 = 20.8$–$88.1$) although deviations from the mean planes are less than 0.012 Å in all cases (esd's of the deviations from the mean planes are 0.001–0.003 Å).

[4]Weighted least-squares mean planes via Hamilton method.

# Five-membered ring annulation via thermal rearrangement of β-cyclopropyl α,β-unsaturated ketones. A formal total synthesis of the sesquiterpenoid (±)-zizaene

EDWARD PIERS, JACQUES BANVILLE, CHEUK KUN LAU, AND ISAO NAGAKURA

*Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6*

Received June 14, 1982

EDWARD PIERS, JACQUES BANVILLE, CHEUK KUN LAU, and ISAO NAGAKURA. Can. J. Chem. **60**, 2965 (1982).

Treatment of the β-iodo enones **7–10** with lithium (phenylthio)(cyclopropyl)cuprate provided excellent yields of the corresponding β-cyclopropyl α,β-unsaturated ketones **11–14**, respectively. When 3-isopropenyl-2-cyclohexen-1-one (**16**) was allowed to react with dimethyloxosulfonium methylide in dimethyl sulfoxide – tetrahydrofuran, 3-(1-methylcyclopropyl)-2-cyclohexen-1-one (**17**) was produced in 59% yield. Although thermal rearrangement (~425–450°C) of compounds **11** and **17** produced high yields of the annulation products **19** and **22**, respectively, similar reactions involving the β-cyclopropyl enones **12** and **13** were not efficient in terms of production of the corresponding bicyclic systems (**23**, **26**, and/or **27**, respectively). In these cases, predominant (**24** + **25** from **12**) or significant (**28** + **29** from **13**) amounts of monocyclic dienones were formed. The annulation product **22** served as a convenient starting material for a new formal total synthesis of the sesquiterpenoid (±)-zizaene (**30**). Conjugate addition of lithium divinylcuprate to **22** afforded the ketone **36** which was converted by standard methods (via **38** and **39**) into the enone **40**. Treatment of the latter substance with thiophenol in the presence of tetra-*n*-butylammonium fluoride gave **41**, which was transformed via ketalization (**41** → **42**), hydroboration (**42** → **43**), tosylation (**43** → **44**), and oxidation (**44** → **45**) into the sulfone **45**. When the latter compound was treated with potassium *tert*-butoxide in hexamethylphosphoramide, the tricyclic ketal sulfone **46** was produced in 85% yield. Reduction of **46** with sodium amalgam afforded the ketal **47**, which upon hydrolysis under mild conditions gave the ketone **32**. Treatment of the latter substance with sodium methoxide in methanol provided a 1:2 mixture of the epimeric ketones **31** and **32**, which had been converted previously by Coates and Sowerby into (±)-zizaene (**30**).

EDWARD PIERS, JACQUES BANVILLE, CHEUK KUN LAU et ISAO NAGAKURA. Can. J. Chem. **60**, 2965 (1982).

Les β-iodo énones **7–10** réagissent avec le (phénylthiocyclopropyl) cuprate de lithium en conduisant respectivement avec d'excellents rendements aux cétones α,β-insaturées, β-cyclopropyles correspondantes **11–14**. Si on laisse réagir l'isopropényl-3 cyclohexène-2 one-1 (**16**) avec le méthylure de diméthyloxosulfonium dans le diméthylsulfoxyde – tétrahydrofuranne, on obtient le (méthyl-1 cyclopropyl)-3 cyclohexèn-2 one-1 (**17**) avec un rendement de 59%. Bien que la transposition thermique (~425–450°C) des composés **11** et **17** donne avec de bons rendements respectivement les produits d'annellation **19** et **22**, les réactions analogues impliquant les β-cyclopropylenones **12** et **13** ne sont pas efficaces du point du vue de la formation des systèmes bicycliques correspondants (respectivement **23**, **26** et/ou **27**). Dans ces cas, il se forme des quantités majoritaires de diénones monocycliques (**24** + **25** à partir de **12**) ou des quantités significatives de ces mêmes composés (**28** + **29** à partir de **13**). Le produit d'annellation **22** sert de point de départ pour une nouvelle synthèse formelle et totale du sesquiterpène (±) zizaène (**30**). L'addition conjugué du divinylcuprate de lithium sur le composé **22** conduit à la cétone **36** que l'on transforme par des méthodes normales (via les composés **38** et **39**) en l'énone **40**. Cette dernière réagit avec le thiophénol en présence du fluorure de tétra-*n*-butylammonium pour donner le composé **41** que l'on transforme en sulfone **45** d'après la suite de réactions: la cétalisation (**41** → **42**), l'hydroboration (**42**→**43**), la tosylation (**43** → **44**) et l'oxydation en sulfone **45** à partir du composé **44**. Le sulfone en présence de *tert*-butylate de potassium dans l'hexaméthylphosphoramide conduit au sulfone cétal tricyclique **46** avec un rendement de 85%. La réduction du composé **46** par l'amalgame de sodium conduit au cétal **47** qui par hydrolyse dans des conditions douces fournit la cétone **32**. Cette dernière réagit avec le méthylate de sodium dans le méthanol en donnant un mélange 1:2 de cétones épimères **31** et **32** que Coates et Sowerby ont déjà transformé en (±) zizaène (**30**).

## Introduction

The first examples of the thermal vinylcyclopropane to cyclopentene rearrangement, indicated in general terms by eq. [1], were reported more than

[1] 

20 years ago (1, 2). Since that time, this interesting reaction has been studied quite extensively from a mechanistic point of view.[1] More recently, however, the synthetic utility of this type of transformation has received considerable attention, both in connection with methodology and natural product synthesis (10–24). In general, it has been found that, although successful execution of the rearrangement reaction often requires relatively high temperatures (typically in the range 400–600°C),[2] the products are, in many instances, formed cleanly and efficiently.

A recent report (25) from this laboratory de-

[1]For reviews, see refs. 3 and 4. For more recent studies, see refs. 5–9 and citations therein.

[2]An exception to this general statement can be found in the very interesting work of Danheiser and co-workers (20) who found that lithium salts of 2-vinylcyclopropanols rearrange to cyclopentenols at 25°C. For earlier work relating to the effect of substituents on the rate of the vinylcyclopropane to cyclopentene rearrangement, see ref. 21.

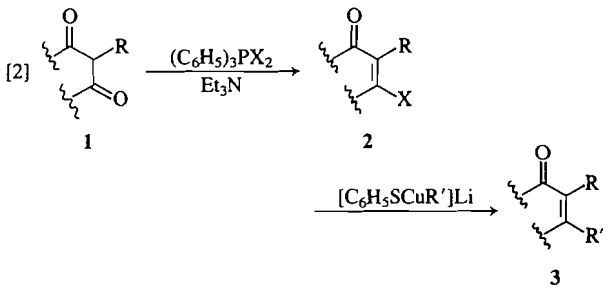
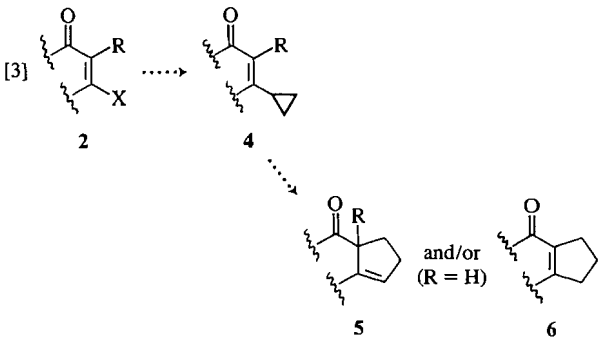
scribed an efficient conversion of cyclic 1,3-diketones **1** into the corresponding β-halo α,β-unsaturated ketones **2** (X = Cl, Br, I). Work reported in a subsequent paper (26) revealed that the latter substances, particularly the bromo and iodo derivatives, react smoothly with a number of lithium (phenylthio)(alkyl)cuprate reagents to provide excellent yields of 3-alkyl- or 2,3-dialkyl-2-cycloalken-1-ones **3** (eq. [2]). Although these transfor-



1 2 3

mations constitute a useful method for the overall conversion of **1** into **3**, we wished to extend this work to include the preparation of compounds **3** in which the R′ group would impart synthetically useful reactivity to these substances. For example, one possibility which we considered to be potentially interesting and useful is outlined in eq. [3].



2 4 5 6

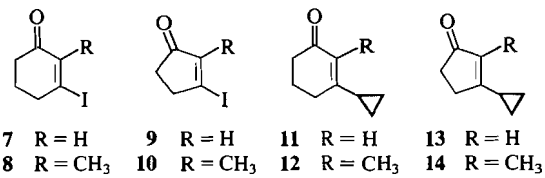
Thus, successful reaction of the β-halo enones **2** with a suitable (cyclopropyl)cuprate reagent would produce the β-cyclopropyl α,β-unsaturated ketones **4**. It is clear that the latter substances incorporate into their structures a vinylcyclopropane moiety and, if these materials were to be successfully subjected to thermal rearrangement, products **5** and/or **6** (if R = H) would be produced. In an overall sense, a new five-membered ring annulation sequence (**1** → **5** and/or **6**) would have been developed.

We report herein (a) the preparation of the β-cyclopropyl enones **11–14** and **17**, (b) the thermal rearrangement of four of these materials (**11–13, 17**), and (c) the use of one of the resultant annulated products (**22**) as a starting material for a new, formal total synthesis of the racemic modification of the tricyclic sesquiterpenoid (+)-zizaene (**30**).[3]

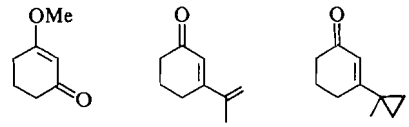
## Results and discussion

(a) *Preparation of the β-cyclopropyl α,β-unsaturated ketones 11–14 and 17 (see Chart 1)*

The β-cyclopropyl α,β-unsaturated ketones **11–14** were prepared conveniently by reaction of the corresponding β-iodo enones **7–10** (25) with lithium



**7** R = H **8** R = $CH_3$ **9** R = H **10** R = $CH_3$ **11** R = H **12** R = $CH_3$ **13** R = H **14** R = $CH_3$



**15** **16** **17**

CHART 1

(phenylthio)(cyclopropyl)cuprate in ether–tetrahydrofuran (THF). A clear, light-brown solution of the latter reagent was produced by adding freshly prepared ethereal cyclopropyllithium (29)[4] (1 equivalent) to a slurry of phenylthiocopper (31, 32) in cold (−78°C) THF, and allowing the resultant mixture to stir at −20°C for 20 min.[5] Although the conversions **7** into **11** and **9** into **13** could be carried out efficiently (yields 82 and 97%, respectively) at −78°C (2.5 h) using 1.5 equivalents of the cuprate reagent, the transformations involving substrates containing an α methyl group (**8**, **10**) were, not unexpectedly, considerably more sluggish. In these cases, a higher reaction temperature (0°C) and more cuprate reagent (2 equivalents) were required to effect complete conversion of the starting material within the same length of time (2.5 h). However, these transformations were also clean and efficient (the yields of **12** and **14** were 88 and 84%, respectively) and, thus, the reaction of β-iodo enones with lithium (phenylthio)(cyclopropyl)-

[3]For preliminary reports regarding some of the work reported in this paper, see refs. 27 and 28.

[4]The cyclopropyllithium solution was standardized by the method of Gilman and Cartledge (30).

[5]To our knowledge, the first example of the use of a (cyclopropyl)copper reagent for the conjugate addition of a cyclopropyl group to an enone was reported by Hahn and Jones (33). For subsequent reports involving the use of these synthetically versatile reagents, see refs. 34–40.

cuprate appears to be an excellent method for the preparation of β-cyclopropyl enones.

With respect to the preparation of 3-(1-methylcyclopropyl)-2-cyclohexen-1-one (**17**) it is pertinent to point out that this compound was envisaged as being the starting material for a projected synthesis of (±)-zizaene (**30**) (*vide infra*). Therefore, we required fairly large quantities of this material and since we did not have a convenient source of 1-methylcyclopropyllithium, an alternative route to compound **17** was employed. Thus, treatment of 3-methoxy-2-cyclohexen-1-one (**15**) (41) with isopropenylmagnesium bromide, followed by acid hydrolysis of the resultant 1,2-addition product, provided 3-isopropenyl-2-cyclohexen-1-one (**16**) in 84% yield. The latter substance, when allowed to react with dimethyloxosulfonium methylide (42) in a mixture of dimethyl sulfoxide and THF, was converted into the desired β-(1-methylcyclopropyl) enone **17** (59% yield).

(b) *Thermal rearrangement of the β-cyclopropyl α,β-unsaturated ketones **11–13** and **17** (see Chart 2)*

A vertically held Pyrex tube (1.2 × 32 cm), filled with glass helices and surrounded by a vertical, tubular furnace, was washed thoroughly with saturated aqueous sodium bicarbonate, water, acetone, and *n*-hexane. The tube was then heated to 450°C for 3 h, during which time it was thoroughly purged with a stream of nitrogen. While a solution of 3-cyclopropyl-2-cyclohexen-1-one (**11**) in *n*-hexane was added dropwise to the top of the heated column, a slow stream of nitrogen (~3–5 mL/min) was passed through the tube and the thermolysate

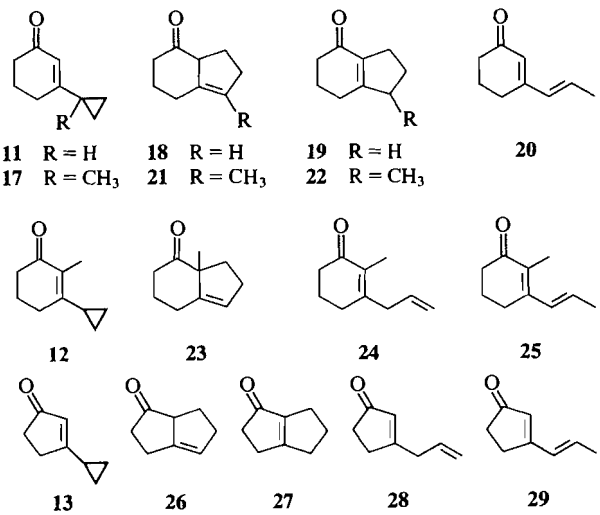

CHART 2

was collected in a two-necked flask equipped with a drying tube and immersed in a cold (−78°C) bath. Gas–liquid chromatographic analysis of the product, a colorless oil obtained in 78% yield, revealed that it consisted of three compounds, **18** (~3%), **19** (43) (~84%), and **20** (44) (~11%), along with a number of very minor unidentified components (~2%). A small sample of each of compounds **18**, **19**, and **20** was obtained by preparative glc and, in each case, the pure material exhibited spectral data in accord with the structural assignment. Furthermore, when a solution of **18** was passed through a short column of basic alumina, it was isomerized cleanly and efficiently to the conjugated enone **19**.

A brief study of the effect of thermolysis temperature on the rearrangement of compound **11** was carried out. For these experiments a longer thermolysis tube (100 cm), wrapped with a heating tape, was employed. The overall procedure used was very similar to that summarized above, although argon was employed as the "carrier gas" instead of nitrogen. The cyclopropyl enone **11** was subjected to thermolysis at 320, 400, 425, and 450°C. It was found that no rearrangement took place at 320°C, since starting material was recovered in essentially quantitative yield. At 400°C, the enone **11** was partially converted into a mixture of **18** and **19** (ratio ~2:1), but a considerable amount (~40%) of the starting material remained. The best result was obtained by carrying out the thermolysis at 425°C, under which conditions **11** was converted in high yield (98%) into an approximately 1:2 mixture of **18** and **19**, respectively, accompanied by < 5% of minor impurities. When a solution of this mixture was eluted through a column of basic alumina, the conjugated enone **19** could be obtained in 88% yield. Thermolysis of **11** at 450°C produced, in a yield (71%) significantly lower than that of the 425°C reaction, a mixture of compounds **18** (~5%), **19** (~90%), and minor impurities (~5%). This result was comparable to that obtained by rearrangement of **11** at ~450°C using the shorter thermolysis tube (*vide supra*), although the amount of the dienone **20** formed was diminished.

Thermolysis of 3-(1-methylcyclopropyl)-2-cyclohexen-1-one (**17**) at 450°C under conditions similar to those employed for compound **11** gave a mixture of two products, the ratio of which varied somewhat from one experiment to another. The spectral data derived from this mixture indicated that the two components were the positionally isomeric enones **21** and **22** and, therefore, these substances were not separated. Instead, a solution of this mixture in methanol containing sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

methoxide was stirred at 0°C for 1 h. Under these conditions, compound **21** was completely converted into the conjugated enone **22**[6] and the latter substance was isolated in 87% yield. It should be noted that, in general, the thermal rearrangement of **17** was cleaner and less "temperamental" than that of the demethyl analog **11**. Furthermore, thermolysis of **17** could readily be carried out on preparative scale, thus providing a very convenient synthesis of appreciable quantities of the enone **22**.

An investigation of the thermal rearrangement of the cyclopropyl enones **12** and **13** showed that, with respect to the formation of annulated products, these reactions are not as synthetically useful as those employing compounds **11** and **17** as substrates. Not unexpectedly (3, 4), the presence of an α methyl substituent *cis* to the cyclopropyl group (substrate **12**) and the requirement of having to form a fairly strained bicyclo[3.3.0]octenone ring system **26** (rearrangement of **13**), have deleterious effects on the efficiency of ring formation. Thus, thermolysis of 3-cyclopropyl-2-methyl-2-cyclohexen-1-one (**12**) at 450°C (conditions similar to those employed for **11** and **17**) gave a mixture of products (73% yield) containing only a minor amount (~10%) of the desired annulation product **23**. The remainder of the mixture consisted of the dienones **24** (~20%) and **25** (~50%) along with a number of minor unidentified components (gas–liquid chromatographic analysis). Pure samples of compounds **23–25** were collected by preparative glc and, in each case, the substance exhibited spectral data in accord with the structural assignment.

Analysis (glc) of the product obtained (80% yield) from thermal rearrangement of the β-cyclopropyl cyclopentenone **13** showed that it consisted of four major components, **26** (~46%), **27** (~14%), **28** (~20%), and **29** (~18%), along with minor impurities (~2%). Again, a small sample of each of the major products, obtained by preparative glc, exhibited the expected spectral properties. Furthermore, the enone **26** and the dienone **28** were readily isomerized (basic alumina) into the corresponding conjugated isomers **27** and **29**, respectively.

Although the investigation summarized above was not extensive, it is clear that from a synthetic point of view, the results are mixed. Although thermolyses of the β-cyclopropyl enones **11** and **17** provide excellent methods for preparing the bicyclic enones **19** and **22**, similar reactions involving compounds **12** and **13** are, with respect to formation of annulation products, much less efficient. Finally, it is perhaps pertinent to point out that recent work, particularly that of Hudlicky and co-workers (16–19), has shown that product distribution in the vinylcyclopropane → cyclopentene rearrangement can vary considerably with reaction conditions and that this type of transformation can be carried out successfully on structurally quite complex substrates.

(c) *A formal total synthesis of (±)-zizaene (30)*

The structurally interesting sesquiterpenoid (+)-zizaene (**30**),[7] the parent hydrocarbon of a small number of zizaane-type natural products isolated from vetiver oil, contains the tricyclo[6.2.1.$0^{1,5}$]undecane carbon skeleton.[8] One possible route which might be employed for the total synthesis of (±)-zizaene is revealed by the retrosynthetic analysis outlined in Scheme 1. Thus, removal of the two methyl groups from C-7 of **30** and replacement of the exocyclic olefinic double bond at C-6 with a carbonyl group provides the tricyclic ketone **31**. In fact, at the time that we were planning our work, the latter substance (or an equilibrium mixture of **31** and the epimer **32**) had already been employed by Coates and Sowerby (49) as an intermediate in their total synthesis of racemic zizaene. Therefore, in our work, the ketones **31** and/or **32** became the synthetic targets.[9]

Heterolytic disconnection of the C-8—C-9 bond in **31** or **32** so as to leave C-8 as a donor atom and C-9 as an acceptor site gives the bicyclic synthon **33**. A synthetic equivalent to the latter species would have to contain functional groups at C-8 and C-9 which would render these positions nucleophilic and electrophilic, respectively. Since C-8 is β to the carbonyl group in **33**, it would, in terms of normal reactivity patterns, be considered as a potential electrophilic site and, therefore, reactivity umpolung[10] would have to be employed in effecting the synthetic conversion of **33** into **31** and/or **32**. Further disconnection involving the C-1—C-10 bond in **33** would provide the synthons **34** and **35**. It is clear that a potential synthetic equivalent to the synthon **34** would be the bicyclic enone **22**. Furthermore, on the basis of steric

[6]For an alternative preparation of this compound, see ref. 45.

[7]Other names for this natural product which can be found in the literature are tricyclovetivene, khusinene, and khusene.

[8]For previous synthetic work on zizaane-type sesquiterpenoids and for literature citations regarding the isolation and structural elucidation of members of this family of natural products, see refs. 46–52, inclusive.

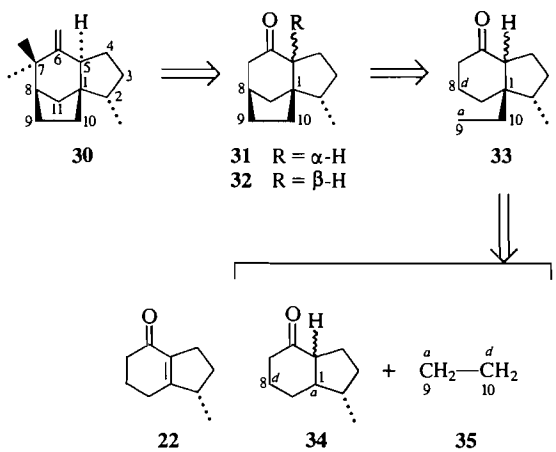
[9]Very recently, an alternative preparation of (±)-**31** has been reported by Barker and Pattenden (53).

[10]For an excellent, stimulating article on methods of reactivity umpolung, see ref. 54.

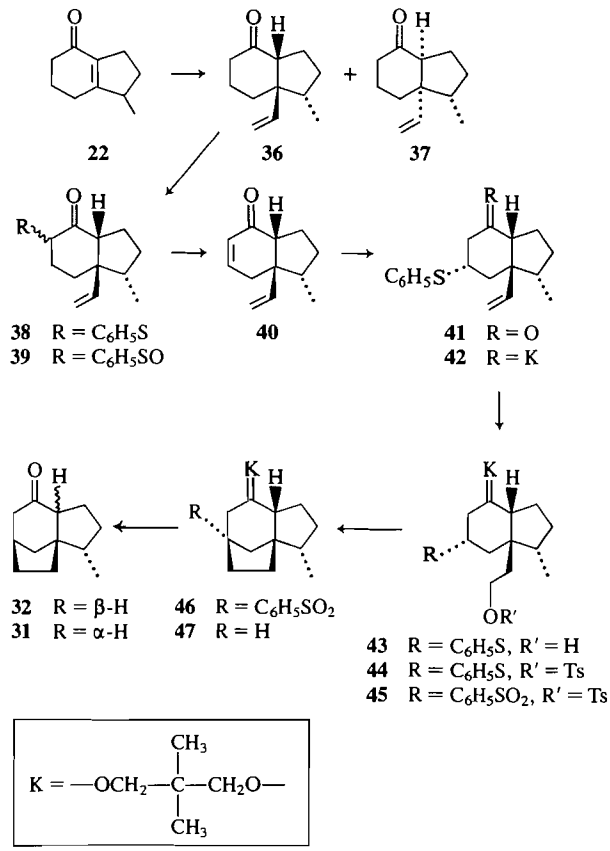
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

considerations, conjugate addition of a suitable two-carbon species to the enone system in **22** would be expected to take place stereoselectively from the side opposite the adjacent secondary methyl group, thus producing a product which would be synthetically equivalent to **33**. Therefore, since a very convenient synthesis of the enone **22** was available (*vide supra*), we wished to investigate the possibility of employing this substance as the starting material in a projected synthesis of (±)-zizaene (**30**) via the general plan summarized in Scheme 1.

The reagent which served as a convenient source of the required two-carbon unit (cf. synthon **35**) was lithium divinylcuprate, readily prepared by addition of two equivalents of ethereal vinyllithium (55) to a solution of cuprous bromide – dimethylsulfide complex (56, 57) in a mixture of ether and dimethyl sulfide. Reaction of the enone **22** with 1.1 equivalents of the cuprate reagent afforded, after suitable work-up, a product which contained a number of minor, unidentified components with relatively short retention times (gas–liquid chromatographic analysis), along with two ketones in a ratio of ~98:2. Purification of this material by column chromatography on silica gel provided a small sample of the minor ketone and allowed for the isolation of the major product in 72% yield. As mentioned previously, the conjugate addition reaction was expected to be stereoselective in the desired sense, with transfer of the vinyl group occurring preferentially to the side of the enone opposite to the secondary methyl group. Therefore, with respect to the relative orientation of the vinyl and methyl groups, the major and minor ketonic products were assigned structures **36** and **37**, respectively (see Scheme 2). Furthermore,



SCHEME 1



SCHEME 2

examination of molecular models, along with the knowledge that *cis*-hydrindan-4-one is more stable than the corresponding *trans* isomer (58), led to the conclusion that each of these compounds possesses a *cis*-fused ring system.[11] Although these latter assignments were not crucial in terms of the overall synthesis, the conclusion regarding the stereochemistry of the required isomer **36** was later shown to be correct.

When the keto olefin **36** was treated with three equivalents of lithium diisopropylamide in THF–hexamethylphosphoramide (HMPA) and the resultant enolate anion was trapped with diphenyl disulfide (59), the α-sulfenylated ketone **38** was obtained in 91% yield. The latter material, a mixture of epimers, was oxidized (sodium periodate in aqueous methanol) to the corresponding sulfoxide **39** which, upon heating (120°C/0.3 Torr) with direct distillation of the product, gave the enone **40** in 64% yield.

[11]Treatment of **36** and **37** with sodium methoxide in methanol showed that both were stable to epimerization conditions and that they were not interconvertible.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Bearing in mind the synthetic plan (Scheme 1), it was necessary at this stage of the synthesis to add an appropriate functional group to the β carbon atom of the α,β-unsaturated ketone system in **40**. The nature of this group had to be such that it would be capable of imparting nucleophilic character to the β carbon atom (cf. C-8 in synthon **33**), presumably by enhancing the acidity of the proton attached to this center. Furthermore, after having served its purpose, the group would have to be amenable to ready removal by a suitable chemical transformation. It appeared that a sulfur-containing moiety would adequately fulfil these requirements.

Treatment of the enone **40** with thiophenol in acetone containing tetra-*n*-butylammonium fluoride (60) afforded a single crystalline conjugate addition product in 95% yield. On the basis of an examination of molecular models of **40**, it seemed highly likely that the nucleophile would approach the β carbon of the enone system from the side opposite the angular vinyl group. Therefore, although conclusive evidence regarding this point was not sought, the conjugate addition product was assigned the stereochemistry shown in **41**. After ketalization of the latter substance, the vinyl group of the resultant product **42** was functionalized by hydroboration with borane – dimethyl sulfide (61). The crude product thus obtained consisted of a mixture of the starting material **42** and the desired ketal alcohol **43**. However, since the latter compound was quite unstable (interaction of the hydroxyl group and the ketal function?), this mixture was treated immediately with *p*-toluenesulfonyl chloride in pyridine. Separation of the resultant mixture by column chromatography on silica gel gave the desired tosylate **44** in 86% yield, based on unrecovered **42**.

Oxidation (*m*-chloroperbenzoic acid, dichloromethane, 0°C) of the sulfide linkage in **44** afforded a quantitative yield of the crystalline sulfone **45** and the stage was now set for effecting the closure of the five-membered ring to provide the required tricyclo[6.2.1.$0^{1,5}$]undecane ring system. Thus, when freshly prepared, dry potassium *tert*-butoxide was added to a solution of the sulfone tosylate **45** in HMPA, and the resultant solution was stirred at room temperature for 1.5 h, the crystalline tricyclic product **46** was produced in 85% yield. The phenyl sulfone moiety, having effectively served its required function, was removed cleanly and efficiently by reduction of **46** with sodium amalgam in methanol–benzene containing disodium hydrogen phosphate (62). The desired tricyclic ketal **47** was obtained in 90% yield. Treatment of compound **47** with oxalic acid in THF–methanol–water at room temperature gave the tricyclic ketone **32** (93% yield), containing none of the epimeric substance **31**. However, when a solution of **32** in methanol containing sodium methoxide was stirred at room temperature for 24 h, a 2:1 mixture of the epimers **32** and **31** was obtained. This mixture was spectrally identical[12] with a 2:1 mixture of the same two compounds which had been prepared previously by Coates and Sowerby (49) and which had been converted by these workers into (±)-zizaene (**30**). Therefore, the acquisition of this material completed, in a formal sense, a new total synthesis of the racemic sesquiterpenoid.

## Experimental

*General*

Melting points, which were taken on a Fisher–Johns melting point apparatus, and boiling points (or distillation temperatures) are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer, while infrared (ir) spectra were taken on Perkin–Elmer models 710 or 710 B spectrophotometers. Proton magnetic resonance ($^1$H nmr) spectra (deuterochloroform solution unless otherwise noted) were measured using Varian Associates spectrometers, models T-60 and/or HA-100 or XL-100. Tetramethylsilane was employed as the internal standard. High resolution mass spectrometric measurements were recorded on a Kratos MS-50 mass spectrometer. Gas–liquid chromatography (glc) was carried out with a Hewlett–Packard model 5832 A gas chromatograph (analytical) or with a Varian Aerograph model 90-P instrument (preparative). Microanalysis were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver, B.C.

*3-Cyclopropyl-2-cyclohexen-1-one (11)*

To a cold (−78°C), stirred slurry of phenylthiocopper (32) (779 mg, 4.5 mmol) in dry THF (30 mL), under an atmosphere of argon, was added a solution of freshly prepared cyclopropyllithium (29, 30) (4.5 mmol) in ether. The mixture was warmed to −20°C and stirred at this temperature for 20 min. The resulting clear, light-brown solution was cooled to −78°C and a solution of 3-iodo-2-cyclohexen-1-one (7) (25) (666 mg, 3 mmol) in 6 mL of dry THF was added. After the reaction mixture had been stirred at −78°C for 2.5 h, methanol (2 mL) and ether (20 mL) were added, the mixture was allowed to warm to room temperature, and then was filtered through a short column of Florisil (30 g, 80–100 mesh). The column was eluted with a further 300 mL of ether. Removal of the solvent from the combined eluate, followed by distillation (air bath temperature 62–75°C/0.3 Torr) of the crude oil afforded 335 mg (82%) of the desired β-cyclopropyl enone **11** (33) as a colorless oil; uv (methanol) $\lambda_{max}$: 254 nm (ε 17100); ir (film): 1660, 1625, 1610 cm$^{-1}$; $^1$H nmr δ: 0.66–2.50 (m, 11H), 5.81 (s, 1H).

*3-Cyclopropyl-2-cyclopenten-1-one (13)*

The conversion of 3-iodo-2-cyclopenten-1-one (**9**) (25) into the corresponding β-cyclopropyl enone **13** was carried out via a procedure identical with that described above. From 624 mg (3 mmol) of **9** there was obtained 355 mg (97%) of crystalline product **13**; distillation temperature ~65°C (air bath)/0.2 Torr;

[12]We are very grateful to Professor R. M. Coates for his assistance in making this comparison.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

mp 31–33°C; uv (methanol) $\lambda_{max}$: 244 nm (ε 16270); ir ($CHCl_3$): 1700, 1670, 1600 $cm^{-1}$; $^1H$ nmr δ: 0.74–1.22 (m, 4H), 2.00–2.68 (m, 1H), 3.26–3.60 (m, 4H), 5.88 (t, 1H, $J$ = 1.8 Hz). *Exact Mass* calcd. for $C_8H_{10}O$: 122.0731; found: 122.0733.

*3-Cyclopropyl-2-methyl-2-cyclohexen-1-one (12)*

The procedure used for the preparation of compound **12** was identical with that employed for the conversion of **7** into **11**, except that 2 equiv. (6 mmol) of lithium (phenylthio)(cyclopropyl)cuprate were used, and the reaction was carried out for 2.5 h at 0°C instead of at −78°C. From 708 mg (3 mmol) of 3-iodo-2-methyl-2-cyclohexen-1-one (**8**) (25) there was obtained 396 mg (88%) of an oil (distillation temperature 65–85°C (air bath)/0.35 Torr) which crystallized in a refrigerator. Recrystallization of a small sample of this material from ether–hexanes provided pure **12** (63); mp 36–37°C; uv (methanol) $\lambda_{max}$: 262 nm (ε 14950); ir ($CHCl_3$): 1660, 1610 $cm^{-1}$; $^1H$ nmr δ: 0.70–1.00 (m, 4H), 1.70–2.60 (m, 7H), 1.90 (s, 3H). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1032.

*3-Cyclopropyl-2-methyl-2-cyclopenten-1-one (14)*

This compound was obtained via a procedure identical with that described for the preparation of the β-cyclopropyl enone **12** (see above). From 666 mg (3 mmol) of the iodo enone **10** (25) there was obtained a crude oil which upon distillation (air bath temperature ~50°C/0.1 Torr) gave 343 mg (84%) of the cyclopentenone **14** (63) as a colorless oil; uv (methanol) $\lambda_{max}$: 254 nm (ε 18580); ir (film): 1698, 1637 $cm^{-1}$; $^1H$ nmr δ: 0.80–1.15 (m, 4H), 1.77 (t, 3H, $J$ = 1.2 Hz), 1.90–2.40 (m, 5H). *Exact Mass* calcd. for $C_9H_{12}O$: 136.0887; found: 136.0888.

*3-Isopropenyl-2-cyclohexen-1-one (16)*

A stirred, cold (0°C) solution of isopropenylmagnesium bromide (29.04 g, 0.20 mol) in 50 mL of dry THF, under an atmosphere of nitrogen, was diluted with 75 mL of dry ether. A solution of 3-methoxy-2-cyclohexen-1-one (**15**) (41) (12.61 g, 0.10 mol) in 20 mL of dry ether was added dropwise and the resultant mixture was stirred at room temperature for 4 h. After the solution had been cooled to 0°C, 100 mL of 5% aqueous sulfuric acid was added slowly and the mixture was stirred for a few minutes. The organic phase was separated, washed successively with dilute aqueous sodium carbonate and water, and dried over anhydrous sodium sulfate. Removal of the solvent, followed by distillation of the residual oil gave 11.46 g (84%) of 3-isopropenyl-2-cyclohexen-1-one (**16**) as a clear colorless liquid; bp 60–63°C/0.3 Torr; uv (methanol) $\lambda_{max}$: 267 nm (ε 22000); ir (film): 2980, 1666, 1626, 1586, 1256, 878 $cm^{-1}$; $^1H$ nmr ($CCl_4$) δ: 1.77–2.60 (m, 6H), 1.97 (s, 3H), 5.17 (broad s, 1H), 5.33 (s, 1H), 5.83 (s, 1H). *Anal.* calcd. for $C_9H_{12}O$: C 79.39, H 8.88; found: C 79.53, H 9.04.

*3-(1-Methylcyclopropyl)-2-cyclohexen-1-one (17)*

A solution of dimethyloxosulfonium methylide (42) (0.082 mol) in 90 mL of dry dimethyl sulfoxide, kept under an atmosphere of nitrogen, was diluted with 40 mL of dry THF and cooled to 0°C. A solution of 3-isopropenyl-2-cyclohexen-1-one (11.0 g, 0.081 mol) in 10 mL of dry THF was added dropwise and the resultant reddish reaction mixture was stirred overnight at room temperature. The solution was poured into 500 mL of cold water and the resultant mixture was extracted with six 75 mL portions of ether. The combined extract was washed with water and brine and dried over anhydrous sodium sulfate. Removal of the solvent, followed by distillation of the residual oil, yielded 7.2 g (59%) of 3-(1-cyclopropyl)-2-cyclohexen-1-one (**17**) as a colorless oil which exhibited one peak by gas–liquid chromatographic analysis; bp 72–76°C/0.3 Torr; uv (methanol) $\lambda_{max}$: 253 nm (ε 16600); ir (film): 1665, 1610 $cm^{-1}$; $^1H$ nmr ($CCl_4$) δ: 0.4–1.08 (m, 4H), 1.15 (s, 3H), 1.67–2.35 (m, 6H), 5.70 (broad s, 1H). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1039.

*Thermal rearrangement of 3-cyclopropyl-2-cyclohexen-1-one (11)*

(a) *Procedure A*

A vertically held Pyrex tube (1.2 × 32 cm), filled with glass helices and placed inside a vertical, tubular furnace, was washed successively with saturated aqueous sodium bicarbonate, water, acetone, and *n*-hexane. The tube was heated to 450°C and kept at this temperature for 3 h. During this time, the column was thoroughly purged with a stream of nitrogen. A solution of 3-cyclopropyl-2-cyclohexen-1-one (**11**) (200 mg) in *n*-hexane (20 mL) was added dropwise, over a period of 1.5 h, to the top of the heated tube. During this time, a slow flow of nitrogen (~3–5 mL/min) was passed through the column. The thermolysate was passed through a water condensor into a cold (−78°C) two-necked flask equipped with a drying tube. After the solution of **11** had been added, the hot tube was treated with an additional 30 mL of *n*-hexane. Removal of the solvent from the combined thermolysate, followed by distillation (air bath temperature ~110°C/16 Torr) of the residual material gave 156 mg (78%) of a colorless oil. Gas–liquid chromatographic analysis of this material showed that it consisted of a mixture of the ketones **18** (~3%), **19** (~84%), and **20** (~11%), along with a number of very minor unidentified components (~2%). A pure sample of each of compounds **18**, **19**, and **20** was obtained by preparative glc.

*Ketone* **18**: ir (film): 1718, 1665 $cm^{-1}$; $^1H$ nmr δ: 1.7–2.7 (diffuse m, 10H), 3.37 (m, 1H), 5.43 (m, 1H). When an ethereal solution of **18** was passed through a short column of basic alumina, compound **18** was isomerized cleanly into the conjugated isomer **19** (identification by glc, ir, and $^1H$ nmr).

*Ketone* **19**: ir (film): 1660, 1630 $cm^{-1}$; $^1H$ nmr δ: 1.7–2.8 (diffuse m). The 2,4-dinitrophenylhydrazone derivative exhibited mp 252°C (dec.) (lit. (43) mp 251.5°C (dec.)).

*Ketone* **20** (44): ir (film): 1670, 1642, 1590 $cm^{-1}$; $^1H$ nmr δ: 1.86 (d, 3H, $J$ = 5 Hz), 1.8–2.6 (diffuse m, 6H), 5.84 (s, 1H), 6.18 (m, 2H).

(b) *Procedure B*

This procedure was identical with that described above, except that the thermolysis tube was longer (100 cm), the tube was heated by means of a heating tape rather than a furnace, the "carrier gas" was argon instead of nitrogen, and the thermolysis temperature was 425°C rather than 450°C. From 200 mg of the β-cyclopropyl enone **11** there was obtained 196 mg (98%) of a distilled oil which, on the basis of analysis by glc, consisted very largely of the ketones **18** (~31%) and **19** (~67%). An ether solution of this mixture was passed through a short column of basic alumina, and the column was eluted with further volumes of ether. Removal of the solvent from the combined eluate, followed by bulb-to-bulb distillation of the residual oil, gave 176 mg (88%) of the enone **19**.

*Thermal rearrangement of 3-(1-methylcyclopropyl)-2-cyclohexen-1-one (17)*

Thermolysis of compound **17** was accomplished via a procedure very similar to that described under Procedure A, above, except that the thermolysis tube was 40 cm in length and the reaction was done on a much larger scale. Thus, from 12.3 g of **17** (added to the heated column as a solution in 30 mL of *n*-hexane) there was obtained a distilled oil which was shown by analysis (glc, ir, $^1H$ nmr) to consist of a mixture of the two ketones **21** and **22**, in a ratio of approximately 7:3, respectively.[13] This mixture was dissolved in 100 mL of methanol containing a small amount of sodium methoxide and the resultant solution was stirred at 0°C for 1 h. The methanol was removed under reduced pressure and the residue was taken up

[13]The ratio of the two products varied somewhat from one thermolysis experiment to another.

For personal use only.

in ether. The ether solution was washed with brine and dried over anhydrous magnesium sulfate. Removal of the ether, followed by distillation of the residual material gave 10.7 g (87%) of the conjugated enone **22** as a clear oil which exhibited one peak by gas–liquid chromatographic analysis; bp 55–58°C/0.3 Torr; uv (methanol) $\lambda_{max}$: 247 nm (ε 12 100); ir (film): 1670, 1638 $cm^{-1}$; $^1H$ nmr δ: 1.08 (d, 3H, $J$ = 6.5 Hz), 1.1–1.7 (m, 2H), 1.7–3.0 (diffuse m, 9H). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1032.

*Thermal rearrangement of 3-cyclopropyl-2-methyl-2-cyclohexen-1-one (12)*

Thermolysis of **12** was carried out via a procedure very similar to Procedure A, above. From 175 mg of **12** (added to the hot tube as a solution in 17.5 mL of *n*-hexane) there was obtained a crude thermolysate which upon distillation (air bath temperature ~110°C/12 Torr) gave 128 mg (73%) of a clear oil. Analysis of this material by glc showed that it consisted of a mixture of the ketones **23** (~10%), **24** (~20%), and **25** (~50%), along with a number of minor, unidentified components. A small sample of each of the major products was obtained by preparative glc.

*Ketone* **23**: ir (film): 1715, 1660 $cm^{-1}$; $^1H$ nmr δ: 1.23 (s, 3H), 1.4–2.8 (diffuse m, 10H), 5.30 (m, 1H). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1039.

*Ketone* **24**: uv (methanol) $\lambda_{max}$: 243 nm (ε 9400); ir (film): 1665, 1635 $cm^{-1}$; $^1H$ nmr δ: 1.54–2.58 (diffuse m, 6H), 1.75 (t, 3H, $J \approx$ 1 Hz), 2.95 (d, 2H, $J$ = 6.5 Hz), 4.9–5.04 (m, 1H), 5.06–5.16 (m, 1H), 5.54–6.0 (m, 1H). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1041.

*Ketone* **25**: uv (methanol) $\lambda_{max}$: 281 nm (ε 19 050); ir (film): 1660, 1630, 1585 $cm^{-1}$; $^1H$ nmr δ: ~1.8–2.08 (m, 2H), 1.86 (s, 3H), 1.91 (d, 3H, $J$ = 6 Hz), 2.32–2.58 (m, 4H), 5.96–6.36 (d of q, 1H, $J$ = 15, 6 Hz), 6.60 (broad d, 1H, J = 15 Hz). *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found: 150.1038.

*Thermal rearrangement of 3-cyclopropyl-2-cyclopenten-1-one (13)*

From 200 mg of compound **13**, thermolyzed as described under Procedure A, above, there was obtained a crude mixture of products which, upon distillation (air bath temperature 100–110°C/16 Torr), gave 160 mg (80%) of a clear oil. Analysis of this material by glc showed that it consisted very largely of four components: **26** (~46%), **27** (~14%), **28** (~20%), and **29** (~18%). A pure sample of each of these compounds was obtained by preparative glc.

*Ketone* **26**: ir (film): 1740, 1660 $cm^{-1}$; $^1H$ nmr δ: 1.57–2.84 (diffuse m, 8H), 3.12–3.43 (m, 1H), 5.42–5.60 (m, 1H). *Exact Mass* calcd. for $C_8H_{10}O$: 122.0731; found: 122.0730. When an ethereal solution of **26** was eluted through a short column of basic alumina, it was isomerized to the α,β-unsaturated ketone **27**.

*Ketone* **27**: uv (methanol) $\lambda_{max}$: 237 nm (ε 11 370); ir (film): 1690, 1630 $cm^{-1}$; $^1H$ nmr δ: 2.20–2.90 (diffuse m). *Exact Mass* calcd. for $C_8H_{10}O$: 122.0731; found: 122.0734.

*Ketone* **28**: uv (methanol) $\lambda_{max}$: 226 nm (ε 14 090); ir (film): 1705, 1610 $cm^{-1}$; $^1H$ nmr δ: 2.2–2.8 (diffuse m, 4H), 3.12 (d, 3H, $J$ = 6.5 Hz), 5.00–5.12 (m, 1H), 5.14–5.26 (m, 1H), 5.64–6.08 (m, 1H), 5.93 (t, 1H, $J$ = 1.5 Hz). *Exact Mass* calcd. for $C_8H_{10}O$: 122.0731; found: 122.0728. When an ethereal solution of **28** was eluted through a short column of basic alumina, it was isomerized to the conjugated dienone **29**.

*Ketone* **29**: uv (methanol) $\lambda_{max}$: 268 nm (ε 18 630); ir (film): 1640, 1570 $cm^{-1}$; $^1H$ nmr δ: 1.89 (d, 3H, $J$ = 6 Hz), 2.2–2.8 (diffuse m, 4H), 5.91 (broad s, 1H), ~6.30 (d of q, 1H, $J$ = 16, 6 Hz), 6.56 (d, 1H, $J$ = 16 Hz). *Exact Mass* calcd. for $C_8H_{10}O$: 122.0731; found: 122.0732.

*Reaction of the enone 22 with lithium divinylcuprate*

A stirred solution of cuprous bromide – dimethyl sulfide complex (56, 57) (10.99 g, 53.4 mmol) in a mixture of dimethyl sulfide (53 mL) and ether (72 mL) was cooled to −60°C under an atmosphere of nitrogen. During this cooling, some of the complex crystallized from the solution. A solution of vinyllithium (55) in ether (121 mL, 0.92 *M*, 115 mmol) was added dropwise while the temperature of the reaction mixture was maintained at −50°C to −60°C. To the resulting dark-brown solution was added dropwise a solution of the bicyclic enone **22** (7.9 g, 49.3 mmol) in 30 mL of anhydrous ether. After the reaction mixture had been stirred at −50°C for 20 min and at room temperature for 1 h, it was diluted with ether (200 mL) and then treated with saturated aqueous ammonium chloride. The resulting mixture was filtered and the collected solid material was washed thoroughly with ether. The combined filtrate was washed successively with aqueous ammonium chloride and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air bath temperature 60–70°C/0.3 Torr) of the residual oil, gave a clear liquid. Analysis of this material by glc showed that it contained, in addition to a number of minor unidentified components with very short retention times, two products in a ratio of about 98:2.

The distilled material was subjected to column chromatography on silica gel (400 g). Elution of the column with benzene gave a mixture of unidentified compounds which exhibited no carbonyl absorption in the ir spectrum. Further elution with benzene – ethyl acetate (9:1) gave the minor ketonic product **37**, contaminated with a small amount of the major product **36**. A small sample of **37** was obtained by preparative glc; ir (film): 3100, 1710, 1630, 900 $cm^{-1}$; $^1H$ nmr ($CCl_4$) δ: 0.77 (d, 3H, $J$ = 6.0 Hz), 2.56 (d of d, 1H, $J$ = 8, 5 Hz), 4.94 (d of d, 1H, $J$ = 18, 1.5 Hz), 5.07 (d of d, 1H, $J$ = 11, 1.5 Hz), 5.72 (d of d, 1H, $J$ = 18, 11 Hz). *Exact Mass* calcd. for $C_{12}H_{18}O$: 178.1358; found: 178.1369.

Further elution of the above chromatography column with benzene – ethyl acetate (9:1) gave the pure bicyclic ketone **36** (6.28 g, 72%) as a colorless oil which exhibited bp 65°C/0.1 Torr; ir (film): 3100, 1705, 1630, 910 $cm^{-1}$; $^1H$ nmr ($CCl_4$) δ: 0.90 (d, 3H, $J$ = 6.0 Hz), 4.89 (d of d, 1H, $J$ = 18, 1.5 Hz), 5.01 (d of d, 1H, $J$ = 11, 1.5 Hz), 5.67 (d of d, 1H, $J$ = 18, 11 Hz). *Anal.* calcd. for $C_{12}H_{18}O$: C 80.85, H 10.18; found: C 80.77, H. 10.20. *Exact Mass* calcd.: 178.1358; found: 178.1354.

Treatment of either of the two ketones **36** and **37** with sodium methoxide in methanol clearly showed that the two compounds were not interconvertible. In each case, only starting material was recovered.

*Preparation of the bicyclic α,β-unsaturated ketone 40*

To a cold (−25°C) solution of diisopropylamine (3.06 g, 30.2 mmol) in dry THF (40 mL) under an atmosphere of nitrogen was added a solution of *n*-butyllithium in hexane (11.6 mL, 2.6 *M*, 30.16 mmol) and the resulting solution was stirred for 30 min. A solution of the bicyclic ketone **36** (1.80 g, 10.1 mmol) in a mixture of dry THF (20 mL) and dry HMPA (20 mL) was added dropwise over a period of 10 min. After the reaction mixture had been stirred for 30 min at −25°C, for 1 h at 0°C, and for 15 min at room temperature, a solution of diphenyl disulfide (6.59 g, 30.18 mmol) in 20 mL of dry THF was added rapidly and the solution was stirred at room temperature for 2 h. Hydrochloric acid (10%) was added and the resultant mixture was extracted thoroughly with ether. The combined ether extract was washed successively with saturated aqueous sodium bicarbonate and brine and dried over anhydrous magnesium sulfate. Removal of the solvent afforded an oil which was subjected to column chromatography on silica gel (300 g). Elution of the column with benzene gave 2.634 g (91%) of the α-phenylthio ketone **38**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

Analysis of this material by tlc and $^1$H nmr showed that it was a mixture of two diastereomers. *Exact Mass* calcd. for $C_{18}H_{22}OS$: 286.1391; found: 286.1392.

To a cold (0°C) solution of the crude α-phenylthio ketone **38** (3.386 g, 11.8 mmol) in 50 mL of methanol was added dropwise a solution of sodium periodate (2.72 g, 12.7 mmol) in water (20 mL). After the resultant cloudy reaction mixture had been stirred at room temperature for 16 h, it was filtered and the solid collected material was washed with methanol. The combined filtrate was concentrated under reduced pressure and the residue was diluted with ether. The resultant solution was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave the crude sulfoxide **39** as a yellow oil, to which was added ~20 mg of solid calcium carbonate. The resultant mixture was heated (air bath temperature 120°C) under reduced pressure (0.3 Torr) and the collected distillate was subjected to column chromatography on silica gel (100 g). Elution of the column with benzene–ether (95:5) afforded an oil which upon distillation (air bath temperature 80°C/0.3 Torr) gave 1.34 g (64%) of the pure bicyclic enone **40**; uv (methanol) $\lambda_{max}$: 228 nm (ε 7900); ir (film): 3100, 1670, 900 cm$^{-1}$; $^1$H nmr ($CCl_4$) δ: 0.89 (d, 3H, $J$ = 6.0 Hz), 1.12–2.64 (diffuse m, 8H), 4.91 (d of d, 1H, $J$ = 18, 1 Hz), 5.03 (d of d, 1H, $J$ = 11, 1 Hz), 5.69 (d of d, 1H, $J$ = 18, 11 Hz), 5.84 (broad d, 1H, $J$ = 10 Hz), 6.73 (d of d of d, 1H, $J$ = 10, 5, 3 Hz). *Anal.* calcd. for $C_{12}H_{16}O$: C 81.77, H 9.15; found: C 81.45, H 9.40. *Exact Mass* calcd.: 176.1202; found: 176.1207.

*Preparation of the phenylthio ketone **41***

To a stirred solution of the bicyclic enone **40** (0.17 g, 0.96 mmol) and tetra-*n*-butylammonium fluoride (0.013 g) in 1.5 mL of dry acetone under an atmosphere of nitrogen was added, dropwise, 0.117 g (1.06 mmol) of thiophenol. After the reaction mixture had been stirred for 3 h at room temperature, it was diluted with ether (100 mL) and the resultant solution was washed successively with saturated aqueous sodium bicarbonate and brine and then dried over anhydrous magnesium sulfate. Removal of the solvent gave 0.263 g (95%) of a crystalline material which was homogeneous by tlc. An analytical sample of the phenylthio ketone **41**, obtained by recrystallization of this material from pentane, exhibited mp 76–77°C; ir ($CHCl_3$): 3100, 1700, 1635, 1580, 915 cm$^{-1}$; $^1$H nmr δ: 0.86 (d, 3H, $J$ = 5.5 Hz), 1.4–2.2 (diffuse m, 7H), 2.45 (d, 2H, $J$ = 8 Hz), ~2.62 (m, 1H), 3.18–3.56 (m, 1H), 4.86 (d, 1H, $J$ = 17 Hz), 5.03 (d, 1H, $J \approx$ 11 Hz), 5.66 (d of d, 1H, $J$ = 17, 11 Hz), 7.30 (m, 5H). *Anal.* calcd. for $C_{18}H_{22}OS$: C 75.48, H 7.68; found: C 75.42, H 7.76. *Exact Mass* calcd.: 286.1391; found: 286.1368.

*Preparation of the ketal **42***

A solution of the phenylthio ketone **41** (0.247, 0.86 mmol) and 2,2-dimethyl-1,3-propanediol (0.269 g, 2.6 mmol) in 12 mL of benzene containing 0.01 g of *p*-toluenesulfonic acid was refluxed under a Dean–Stark water separator for 3 h. After a small amount of solid sodium bicarbonate had been added to the cooled solution, the latter was diluted with 100 mL of benzene and the resultant solution was washed successively with saturated aqueous sodium bicarbonate and brine and then dried over anhydrous magnesium sulfate. Removal of the solvent gave 0.317 g (99%) of the ketal **42** as a clear oil which was homogeneous by tlc; ir ($CHCl_3$): 3100, 1635, 1590, 1100, 910 cm$^{-1}$; $^1$H nmr δ: 0.69 (d, 3H, $J$ = 6.0 Hz), 0.80, 0.96 (s, s, 3H each), 1.06–1.96 (diffuse m, 8H), 2.19 (m, 1H), 2.57 (broad t, 1H), 3.2–3.6 (diffuse m, 5H), 4.74 (d of d, 1H, $J$ = 17, 1 Hz), 4.95 (d of d, 1H, $J$ = 11, 1 Hz), 5.58 (d of d, 1H, $J$ = 17, 11 Hz), 7.14–7.50 (m, 5H). *Exact Mass* calcd. for $C_{23}H_{32}O_2S$: 372.2123; found: 372.2149.

*Preparation of the ketal tosylate **44***

To a cold (0°C), stirred solution of the olefinic ketal **42** (0.96 g, 2.57 mmol) in 3 mL of dry THF was added 0.30 mL (3.0 mmol) of borane – dimethyl sulfide complex. The reaction mixture was stirred at 0°C for 2 h, slowly warmed to room temperature over a period of 1 h, and then stirred at this temperature for 1 h. After the mixture had been cooled to 0°C, it was treated successively with methanol (0.6 mL) 3 *N* sodium hydroxide (0.6 mL), and 30% hydrogen peroxide (0.6 mL). The resultant mixture was warmed to 45–50°C, maintained at this temperature for 1 h, diluted with 20 mL of aqueous sodium bicarbonate, and then extracted thoroughly with dichloromethane. The combined extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent afforded a viscous oil which was dissolved immediately in dry pyridine (4 mL). The solution was treated with *p*-toluenesulfonyl chloride (0.54 g, 2.8 mmol), allowed to stand at room temperature overnight, and then poured into ice-cold water. The resultant mixture was extracted with dichloromethane. The combined extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave a viscous oil which was subjected to column chromatography on silica gel (60 g). Elution of the column with benzene – ethyl acetate (97.5:2.5) gave 0.325 g (34%) of the starting material (olefinic ketal **42**) and 0.80 g (86%, based on unrecovered starting material) of the ketal tosylate **44**. The latter substance was obtained as a clear oil which was homogeneous by tlc and exhibited ir ($CHCl_3$): 1600, 1590, 1195, 1100, 955 cm$^{-1}$; $^1$H nmr δ: 0.70 (d, 3H, $J$ = 5.5 Hz), 0.79, 0.85, (s, s, 3H each), 1.1–2.5 (diffuse m, 12H), 2.38 (s, 3H), 3.04–3.46 (diffuse m, 5H), 3.86–4.30 (m, 2H), 7.12–7.44 (m, 7H), 7.74 (d, 2H, $J$ = 8 Hz). *Exact Mass* calcd. for $C_{30}H_{40}O_5S_2$: 544.2317; found: 544.2312.

*Preparation of the sulfone tosylate **45***

To a cold (0°C), stirred solution of the sulfide tosylate **44** (0.25 g, 0.46 mmol) in 3 mL of dry dichloromethane was added, over a period of about 2 min, 0.204 g of 85% *m*-chloroperbenzoic acid and the resultant solution was stirred at 0°C for 2 h. The solution was diluted with 50 mL of saturated aqueous sodium bicarbonate and the resultant mixture was extracted thoroughly with dichloromethane. The combined extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent afforded a semicrystalline material which was subjected to column chromatography on silica gel (20 g). Elution of the column with benzene – ethyl acetate (9:1) gave 0.264 g (100%) of a crystalline compound which was homogeneous by tlc. An analytical sample of compound **45**, obtained by recrystallization of a small amount of this material from ether–hexane, exhibited mp 145–146°C; ir ($CHCl_3$): 1600, 1365, 1305, 1175, 1150, 1087, 960 cm$^{-1}$; $^1$H nmr δ: 0.75 (d, 3H, $J$ = 6 Hz), 0.82, 0.90 (s, s, 3H each), 1.10–2.56 (diffuse m, 12H), 2.44 (s, 3H), 2.94–3.54 (diffuse m, 5H), 3.94–4.32 (m, 2H), 7.30–8.00 (diffuse m, 9H). *Anal.* calcd. for $C_{30}H_{40}O_7S_2$: C 62.47, H 6.99, S 11.12; found: C 62.47, H 7.09, S 11.01.

*Preparation of the tricyclic ketal sulfone **46***

To a solution of the sulfone tosylate **45** (0.235 g, 0.41 mmol) in 3 mL of dry HMPA under an atmosphere of nitrogen was added, over a period of 2 min, freshly prepared dry potassium *tert*-butoxide (2.0 mmol) and the resultant solution was stirred at room temperature for 1.5 h. The reaction mixture was diluted with benzene (150 mL), washed 5 times with brine, and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by column chromatography (10 g silica gel, elution of the column with 9:1 benzene – ethyl acetate) of the residue gave 0.139 g (85%) of the crystalline tricyclic sulfone **46**. An analytical

sample, obtained by recrystallization of a small amount of this material from ether, exhibited mp 168–169°C; ir ($CHCl_3$): 1305, 1150, 1110 $cm^{-1}$; $^1H$ nmr δ: 0.88 (d, 3H, $J$ = 6 Hz), 0.86, 0.88 (s, s, 3H each), 1.1–2.5 (diffuse m, 14H), 3.20–3.56 (diffuse m, 4H), 7.40–7.96 (diffuse m, 5H). *Anal.* calcd. for $C_{23}H_{32}O_4S$: C 68.28, H 7.97, S 7.92; found: C 68.06, H 8.09, S 7.80. *Exact Mass* calcd.: 404.2021; found: 404.2015.

*Preparation of the tricyclic ketal* **47**

To a stirred solution of the ketal sulfone **46** (0.130 g, 0.32 mmol) in a mixture of dry methanol (2.5 mL) and benzene (1.0 mL)[14] was added 0.91 g (6.4 mmol) of anhydrous disodium hydrogen phosphate and 2.4 g of pulverized 6% sodium amalgam and the resultant mixture was stirred at room temperature for 1.5 h. The reaction mixture was diluted with benzene and decanted. The residual solid material was washed with several portions of benzene. The combined organic phase was washed successively with aqueous sodium bicarbonate and brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave an oil which was filtered through a short column of silica gel (2 g). Elution of the column with benzene – ethyl acetate (9:1) gave 0.076 g (90%) of the tricyclic ketal **47** which was homogeneous by tlc and glc. This material exhibited ir (film): 1470, 1100 $cm^{-1}$; $^1H$ nmr δ: 0.84 (d, 3H, $J$ = 6 Hz), 0.90, 0.97 (s, s, 3H each), 1.10–2.34 (diffuse m, 15H), 3.40, 3.52 (s, s, 2H each). *Anal.* calcd. for $C_{17}H_{28}O_2$: C 77.22, H 10.67; found: C 77.02, H 10.65.

*Preparation of the tricyclic ketone* **32**

To a solution of the ketal **47** (75 mg, 0.28 mmol) in a 5:3:2 mixture of THF, methanol, and water (2 mL) was added 76 mg (85 mmol) of oxalic acid and the resultant solution was stirred at room temperature for 45 min. The reaction mixture was diluted with 50 mL of benzene and then was washed successively with saturated aqueous sodium bicarbonate and brine. The organic phase was dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air bath temperature 85°C/0.3 Torr) of the residual oil, afforded 47 mg (93%) of the ketone **32** as a clear colorless oil which was homogeneous by tlc and glc; ir (film): 1705 $cm^{-1}$; $^1H$ nmr δ: 0.89 (d, 3H, $J$ = 6 Hz), 1.16–2.58 (diffuse m, 15H). *Exact Mass* calcd. for $C_{12}H_{18}O$: 178.1357; found: 178.1366.

*Equilibration of the tricyclic ketone* **32**

A solution of the ketone **32** (12 mg) in methanol (1 mL) containing 20 mg of sodium methoxide was stirred at room temperature for 24 h. Ammonium chloride was added, the methanol was removed under reduced pressure, and the residual material was taken up in a mixture of ether and water. The aqueous layer was washed with additional volumes of ether and the combined extract was dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air bath temperature 85–90°C/0.4 Torr) of the residual material, gave 10 mg of a clear colorless oil. Analysis of this oil by glc showed that it was a mixture of two compounds, ketones **31** and **32**, in a ratio of 1:2, respectively. The ir and $^1H$ nmr spectra of this mixture were identical with those of an equilibrated mixture of the same two compounds previously prepared by Coates and Sowerby (49).[12]

C. F. G. C. GERALDES, H. SANTOS, and A. V. XAVIER. Can. J. Chem. **60**, 2976 (1982).

A method is described by which conformationally averaged interproton distances in mononucleotides are obtained from measured proton spin-lattice relaxation times and published crystal coordinates of selected mononucleotides. The glycosil conformations of adenosine in $D_2O$ and DMSO-$d_6$ and of 5'-AMP, 5'-GMP, 3'-AMP, and 2'-AMP in $D_2O$ are examined by quantitative analysis of the conformationally averaged interproton distances in terms of population distributions obtained from potential energy calculations. 5'-AMP strongly prefers a single glycosyl conformation in the *anti* range. Besides the *anti* conformation, 5'-GMP has a secondary minimum in the *syn* region. 3'-AMP, 2'-AMP, and adenosine have more latitude in their glycosyl torsion angle values, with both the *syn* and *anti* regions highly populated.

C. F. G. C. GERALDES, H. SANTOS et A. V. XAVIER. Can. J. Chem. **60**, 2976 (1982).

On décrit une méthode qui permet d'obtenir les distances conformationnelles moyennes interprotons des nucléotides, à partir de la mesure des temps de relaxation spin-réseau et des coordonnées des cristaux de mononucléotides choisis que l'on trouve dans la littérature. On a étudié les conformations du glycosyle de l'adénosine dans du $D_2O$, et du DMSO-$d_6$ et celles des composés suivants: AMP-5', GMP-5', AMP-3' et AMP-2' dans du $D_2O$, en faisant appel à l'analyse quantitative des distances conformationnelles moyennes interprotons en fonction de la distribution de population obtenue à partir des calculs d'énergie potentielle. Le composé AMP-5' adopte une conformation unique du glycosyle dans la région *anti*. En plus de la conformation *anti*, le composé GMP-5' a un minimum secondaire du côté *syn*. Dans le cas des composés AMP-3' et AMP-2' et de l'adénosine les valeurs de l'angle de torsion du glycosyle sont plus flexibles quand les régions *syn* et *anti* ont une forte population.

[Traduit par le journal]

## Introduction

The interpretation at molecular level of a wide range of biological phenomena involving nucleic acids or coenzymes containing nucleotidyl units relies on the conformation of their monomeric units in solution (1). One example of this situation is the different allosteric activator properties of 5'-AMP and of its chemical analogs for the catalytic action of phosphorylase b in the degradation of glycogen (2, 3). In order to define the mode of interaction of a small ligand (e.g. a nucleotide) with a macromolecule the knowledge of the conformation of the free ligand may be very important (4).

Most of the studies of nucleotide flexibility in aqueous solution, their preferred conformation and modes of internal motion using nuclear magnetic resonance (nmr) spectroscopy (5), have used methods like coupling constants analysis (6, 7), chemical shifts studies (6, 7), the lanthanide probe method (8–11), and the nuclear Overhauser effect (nOe) (12–15). Although this last method has proved to be very convenient in the study of the preferred orientation of the base around the glycosyl bond of mononucleotides, similar structural information has become available from $^{13}C$ and $^1H$ spin-lattice relaxation time ($T_1$) measurements (16–20) using pulsed Fourier transform (FT) nmr techniques (21). In this work we extend a previous conformational study of 5'-mononucleotides in aqueous solution using $^1H$ $T_1$ measurements (20) and more general conformational search methods than previously undertaken. The study is also extended to some 3'- and 2'-mononucleotides and to different conditions of concentration, temperature, and pH. The conclusions thus obtained are compared with conclusions from independent nmr methods (6–15) and theoretical potential energy calculations on these molecules (22–24, 31).

## Experimental

The mononucleotides, purchased from Sigma Chemical Comp., were lyophilized from $D_2O$ (from Norsk Hydro), redissolved in $D_2O$ (5–30 m*M* concentrations) and their pH adjusted with DCl or NaOD. Residual paramagnetic impurities were removed by addition of 1 m*M* EDTA and residual oxygen was removed by several freeze–pump–thaw cycles on a high vacuum line.

The proton nmr spectra were run on a 100 MHz JEOL JMN 100 PFT spectrometer, equipped with a JEOL 980A computer for Fourier transformation. The proton $T_1$ measurements were carried out by the inversion–recovery method (nonselective 180°–τ–90° pulse sequence).

Calculation of the $r_{ij}$ interproton distances was carried out using the Burlesk (8) program modified to give the various molecular conformations obtained by variation of the $\psi$ and $\chi$ angles with increments of 30° and 20° respectively. Two starting conformations were used, differing in the ribose ring conformation: one was $C_3'$ *endo* (*N*), the other $C_2'$ *endo* (*S*) (33). The crystal coordinates used were obtained from the literature (10, 24).

## Results and discussion

*Determination of the calculation parameters*

The use of spin-lattice relaxation times ($T_1$) in conformational studies relies on the following basic assumptions.

(1) Spin-lattice relaxation occurs dominantly through intramolecular dipolar interactions; this assumption is met for nonquadrupolar nuclei, like $^1H$ and $^{13}C$, in dilute nucleotide $^2H_2O$ solutions (where intermolecular stacking is absent) free of paramagnetic species (21, 25, 26), except for $H_2$ of adenine nucleotides, where intermolecular dipolar interactions are dominant (18).

(2) The molecule under study is rigid and its rotational motion can be considered to be isotropic, so that the motion of any proton–proton vector can be characterized by a single rotational correlation time $\tau_R$, which corresponds to the rotation of the whole molecule. This assumption does not hold in most flexible macromolecules, but in low molecular weight molecules, such as mononucleotides, it is supported by various observations: $\tau_R$ values obtained from $^{13}C$ $T_1$ values of nucleotide C—H groups agree with each other within experimental error, $\tau_R \sim 2 \times 10^{-10}$ s at 25°C (17–20); in 5'-AMP, $T_1$ minima of all protons occur at the same temperature, giving $\tau_R$ values in agreement with those obtained from $^{13}C$ $T_1$ values (18). Therefore it is concluded that the internal motions of mononucleotides (pseudorotation of the furanose ring, rotation about the $C_{4'}$—$C_{5'}$ bond, and base rotation about the glycosidic bond, $N_9$—$C_{1'}$) are much slower than the overall isotropic molecular motion (the rate constants for all internal motions $K \ll \tau_R^{-1} \sim 10^9$ s$^{-1}$). This means that these flexible molecules are rigid in the practical sense of relaxation effects.

(3) Differences in relaxation rate between lines split by spin–spin coupling are negligible, which is valid only for first-order spectra. As the theory of relaxation of spin–spin split lines is impractical at the moment (27), we take the average of the intensity over these lines as the proton magnetization.

Under these conditions, the longitudinal magnetization $\langle I_i(t)\rangle$ of proton $i$, at time $t$ after a nonselective 180° pulse at $t = 0$, in a multispin system subject to intramolecular dipolar relaxation, can be seen not to decay experimentally to the equilibrium value $I_0$, but to be a linear combination of $n$ exponential functions of time (25). This is basically due to the existence of cross-relaxation effects. However, considering an interval from $t = 0$ to $t = \Delta t$ ($\Delta t \ll T_1$, see ref. 19), it can be seen that the initial recovery of magnetization for any proton $i$ obeys a single exponential function of time, whose time constant $T_{1i}$, is the spin-lattice relaxation time of proton $i$, and is given by eq. [1] when the extreme narrowing condition ($\omega^2_H \tau^2_R \ll 1$) holds (at 100 MHz):

$$[1] \quad T_{1i}^{-1} \equiv R_i = \frac{3}{2}\gamma_H^4 \left(\frac{h}{2\pi}\right)^2 \tau_R \sum_{j \neq i} \langle r_{ij}^{-6}\rangle = 85.35 \times 10^{-6}\, \tau_R \rho_i$$

where the relaxation rate $R_i$ is given in s$^{-1}$, $\tau_R$ in $10^{-10}$ s, and

$$\rho_i = \sum_{j \neq i} \langle r_{ij}^{-6}\rangle = \sum_{j \neq i} \rho_{ij} \text{ is in nm}^{-6};$$

$\langle r_{ij}\rangle$ is the interproton distance averaged over all possible molecular conformers. This averaging procedure is valid because the relaxation rates are much smaller than the rate constants of the internal motions, $T_{1i}^{-1} \ll K$ (25) (see Table 1).

As the relaxation rates deviate from the initial rate progressively with time, the $T_1$ values were deduced by a least-squares approximation of the observed values of $\langle I_i(t)\rangle$ to $I_0[1 - 2\exp(-t/T_1)]$ up to 50% recovery of magnetization. The $T_1$ values obtained for the mononucleotides studied in this work and values from the literature are listed in Table 1, together with the ribose conformer *N* populations, obtained by analysis of vicinal coupling constants.

*Conformationally averaged $\overline{r_{8i}}$ distances.*

*Illustration of the method for 5'-AMP*

The experimental relaxation rates $R_i$ can be analysed in the following way in order to give conformationally averaged $\rho_i \equiv \langle r_{8i}^{-6}\rangle$ values. Calculated values of $\rho_i$ for the nucleotide protons as a function of the glycosidic $\chi$ angle for the *N* and *S* furanose ring conformations (Fig. 1) were obtained from the relevant computer measured $r_{ij}$ distances derived from the crystal coordinates for selected purine nucleotides available in the literature (19, 24). In these calculations we used an average conformation of the exocyclic group, given by the populations $P_{gg} = 0.7$, $P_{gt} = 0.2$, and $P_{tg} = 0.1$, obtained from coupling constants analysis. It was verified that the calculated $\rho_i$ values of most

[c]% *N* values from refs. 7 and 32.

protons are quite insensitive to these rotamer populations.

The value of the correlation time $\tau_R$ can be calculated from $\rho_{4'}$, which is the same for *N* and *S* puckers and independent of the glycosidic angle $\chi$ (Fig. 1). Insertion of the experimental $R_{4'}$ value and the calculated $\rho_{4'}$ in eq. [1] gives $\tau_R = 1.1 \times 10^{-10}$ s for 5'-AMP. This value is in good agreement with values determined by other methods (18, 20, 28). Insertion of the experimental $R_i$ values of Table 2 and of the calculated $\tau_R$ in eq. [1] gives the $\rho_i$ values also shown in Table 2.

Within the approximations of the pseudorotational model (33) and in the intermediate exchange region of internal motions ($K \ll \tau_R^{-1}$) (25) we can write

$$[2] \quad \rho_{ij} = |N|\,\rho_{ij}^N + |S|\,\rho_{ij}^S$$

where $|N|$ and $|S|$ are the *N* and *S* conformer populations (Table 1). Therefore

$$[3] \quad \rho_i = \rho_{8i} + \{|N| \sum_{n\neq i,8} \rho_{ni}^N + |S| \sum_{n\neq i,8} \rho_{ni}^8\} \qquad (i = 1', 2', 3', 4', 5', 5'')$$

Insertion in eq. [3] of the calculated $\rho_i$, $|N|$, $|S|$, $\rho_{ni}^N$, and $\rho_{ni}^S$ values allows the $\rho_{8i}$ values to be obtained, which give the average distance of $H_8$ to the ribose protons (Table 2), in reasonable agreement with DESERT distance data.

Once that

$$[4] \quad \rho_{8i} = |N|\,\rho_{8i}^N + |S|\,\rho_{8i}^S$$

and $\rho_{8i}^N$ and $\rho_{8i}^S$ depend on the $\Omega$ distributions of the glycosidic angles $\chi_N$ and $\chi_S$, such that

$$[5] \quad \rho_{8i}^{N,S} = \int_0^{360} \Omega(\chi_{N,S})\,\rho_{8i}\,(\chi_{N,S})\,d\chi_{N,S}$$

the problem of the conformational analysis of the nucleotide base is to obtain, from the calculated curves $\rho_{8i}$ ($\chi$) (Fig. 2), $\Omega$ distributions which give a good agreement between the calculated $\rho_{8i}$ values from eqs. [4] and [5] and those obtained from the relaxation rates (Table 2).

Two types of distributions were considered. The first consisted of discrete sets of $\chi$ values ($\chi_N$ and $\chi_S$) associated with *N* and *S* ribose puckers, and is based on the assumption that the base is confined to a narrow range of the *syn* or *anti* region. The $\chi$ values which give the best agreement between calculated and experimental $\rho_{8i}$ values are ($\chi_N$, $\chi_S$) = (20°, 150°) (Table 2), a *syn–anti* equilibrium showing an interesting correlation of ribose and base conformations (*N*, *anti* and *S*, *syn*) which has already been assumed in previous studies (29). This result is also in disagreement with a previous study on this system (20), the only one in the literature to claim that 5'-AMP has the base in a *syn* conformation. We believe that the conclusions of that work are a consequence of the method of analysis used, which restricts $\chi$ distributions to a single value $\chi = \chi_N = \chi_S$.

As far as continuous distributions of $\chi$ values are concerned, as it is clear that a number of angular distributions may lead to similar experimental results, we only tested the angular distribution derived from Boltzmann's statistics of potential energy curves computed by Sarma *et al.* (31) (Fig. 3). The values thus calculated (Table 2) show that this distribution is compatible with the experimental results. Therefore, while this method by itself does not allow us to define unequivocally the average base conformation of 5'-AMP, we can test potential energy calculations. However, its use together with independent methods (e.g. para-

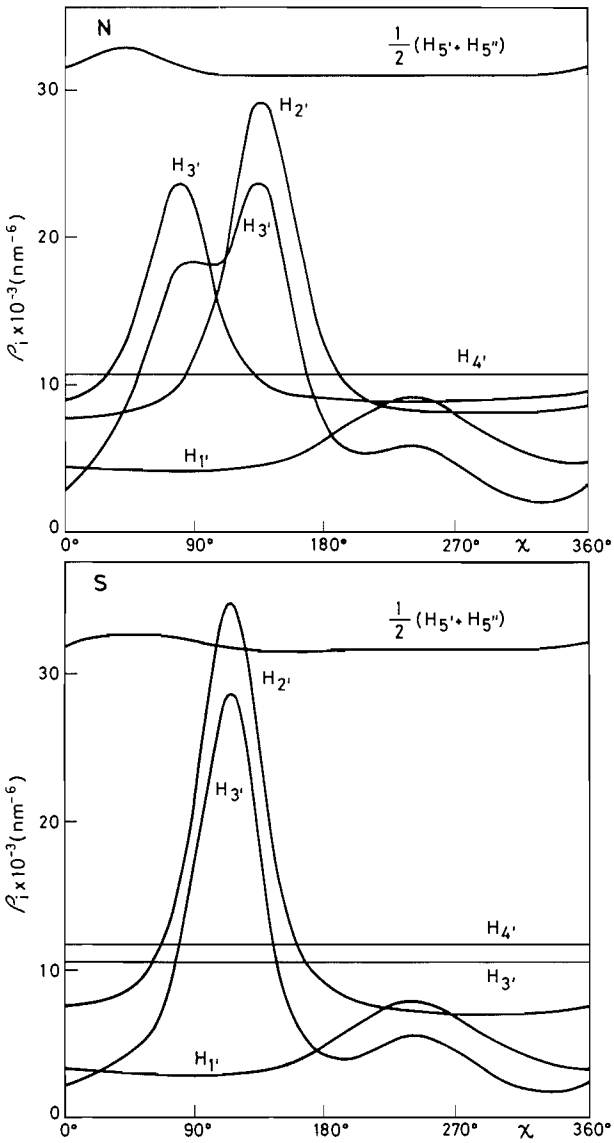

FIG. 1. $\rho_i$ as a function of $\chi$ for purine nucleotides with pure *N* and *S* puckers (see also ref. 29).

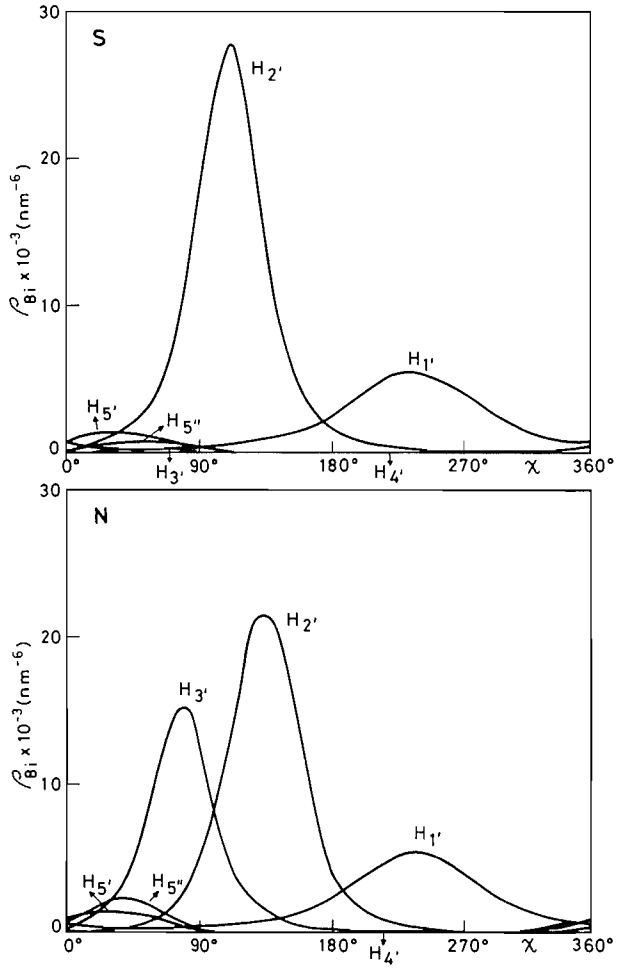

FIG. 2. $\rho_{8i}$ as a function of $\chi$ for pure *N* and *S* puckers.

magnetic probes (10)) allows us to conclude that the second distribution is in good agreement with all the experimental data.

Examination of $\rho_{8i}$ values for 5'-AMP (Table 3) in various experimental conditions shows that its base conformation is not significantly affected by pH or concentration. However a decrease of temperature to 5° C causes a decrease of $\rho_{81'}$ from 0.8 to 0.4. This is an indication of a more rigid *anti* conformation (see Fig. 2), possibly due to intermolecular base stacking, as was pointed out before (20).

### *Conformationally averaged $\overline{r_{8i}}$ distances for 5'-GMP, 3'-AMP, 2'-AMP, and adenosine*

Tables 1 and 3 present the measured proton spin-lattice relaxation times, and calculated conformationally averaged intermolecular distances for the above compounds. From the tabulated values of $\overline{r_{81'}}$ in Table 3, it is apparent that significant amounts of both *syn* and *anti* conformations exist about the glycosidic linkage in those molecules. The percentage of *syn* conformations increases in the order: 5'-AMP < 5'-GMP < 3'-AMP, 2'-AMP < adenosine.

A more quantitative interpretation of the $\overline{r_{8i}}$ values in terms of molecular conformation must include a statistical treatment over possible conformers. Angular distributions of $\chi$ values derived from several published potential energy curves were tested (22–24). In the case of 5'-GMP two possibilities were tested, corresponding respective-

ly to situations where (*i*) formation of a hydrogen bond between the O—H group of the phosphate and the $N_3$ atom of the base is possible, leading to a predominance of the *syn* base conformation, and (*ii*) a situation in which such a bond is impossible, leading to a predominance of the *anti* base conformation.

A good agreement between the calculated $\rho_{8i}$ values (Table 4) and the experimental values (Table 3) is obtained when a 1:1 equilibrium of *syn* and *anti* forms is considered (distribution 7), but this agreement no longer exists in the extreme *syn* and *anti* situations (distributions 5 and 6). Therefore the intermolecular bond POH...$N_3$ in 5'-GMP is not permanent. However, as the calculated $\rho_{82'}$ value is too small, the experimental $\chi$ angle distribution in the *anti* region goes to higher values (80°) than the calculated distribution implies (23).

In the case of 2'-AMP, various distributions were tested (distributions 16 to 19) based on potential energy calculations for 2'-GMP (23). The best agreement between experimental and calculated $\rho_{8i}$ values is obtained from distribution 16, which considers the existence of intramolecular bonds between POH and $N_3$ and between $O_5$·H and $N_3$. This distribution gives a predominantly *syn* ($\chi \sim 180°$ for $C_{3'}$ *endo* and $\chi \sim 220°$–$300°$ for $C_{2'}$ *endo* sugar conformations) over *anti* ($\chi \sim 40°$–$120°$ for $C_{2'}$ *endo* sugar conformation) base conformation.

In the case of 3'-AMP, as a phosphate group in the 3' position cannot have any direct effect on the glycosidic and exocyclic torsion angles, distributions based on potential energy calculations for adenosine (22) were used. These distributions were of course also used for the conformational analysis of adenosine in $D_2O$ and in DMSO-$d_6$. The best distributions for 3'-AMP and adenosine are, respectively, distributions 25 and 24, obtained by mixture of distributions 22 and 23 in different proportions. These assume no POH...$N_3$ intramolecular bond and the possibility of a $O_5$·H...$N_3$ intramolecular bond giving a *syn* base conforma-

## Conclusion

Conformationally averaged interproton distances in purine mononucleotides can be obtained by a new method based on measured proton spin-lattice relaxation times and published crystal coordinates of various mononucleotides. These distances compare reasonably well with values obtained from deuterium substitution effects on relaxation times (DESERT). Several published potential energy curves were tested and verified to be compatible with the experimental values. The variability of the glycosyl conformation of the purine mononucleotides increases in the order: 5'-AMP < 5'-GMP < 3'-AMP, 2'-AMP < adenosine.

# Polymer supported enantioselective reactions. III. Protonation of lithioenamine derivatives of racemic 2-methylcyclohexanone

COLIN R. MCARTHUR,[1] JI-LONG JIANG, AND CLIFFORD C. LEZNOFF[1]

*Department of Chemistry, York University, Toronto, Ont., Canada M3J 1P3*

Received July 22, 1982

COLIN R. MCARTHUR, JI-LONG JIANG, and CLIFFORD C. LEZNOFF. Can. J. Chem. **60**, 2984 (1982).

Asymmetric protonations, with enantioselectivities ranging to 90%, were observed in reactions of lithioenamines derived from imines of racemic 2-methylcyclohexanone and insoluble cross-linked copolymers of polystyrene and divinylbenzene substituted with (*S*)-2-aminoalkoxymethyl groups.

COLIN R. MCARTHUR, JI-LONG JIANG et CLIFFORD C. LEZNOFF. Can. J. Chem. **60**, 2984 (1982).

On a observé des protonations asymétriques, avec des sélectivités énantiométriques allant jusqu'à 90%, lors de réactions de lithioénamines provenant des imines de la méthyl-2 cyclohexanone racémique avec un copolymère réticulé et insoluble de polystyrène et de divinylbenzène portant des groupes aminoalkoxyméthyle-2(*S*).

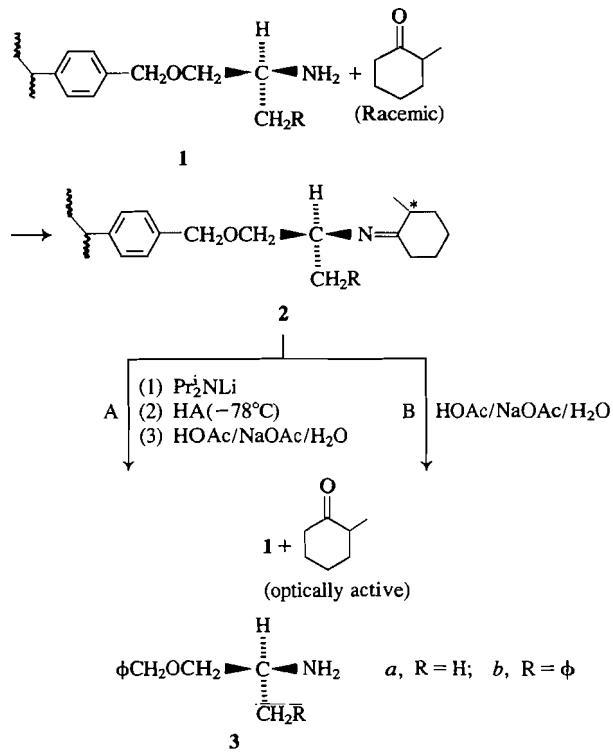
[Traduit par le journal]

Recently we reported the use of insoluble cross-linked copolymers of styrene and divinylbenzene with covalently bonded (*S*)-2-aminoalkoxy groups (**1**) in the asymmetric methylation of the lithioenamines derived from cyclohexanone and **1**. The polymeric system afforded higher enantioselectivities than were observed through the use of analogous systems, under comparable conditions, in solution (1).

We now report preliminary results in our study of asymmetric *protonations* of the lithioenamines derived from the polymer-bound ketimines **2** formed from reaction of **1** with racemic 2-methylcyclohexanone (pathway A).

Two examples of nonbiological systems involving asymmetric protonations, conducted in the solution phase, have been reported recently. Thus, amino-acids may be "deracemized" to 70% e.e. (2), and a bicyclobutane bridged enolate anion has been enantioselectively protonated to 48% e.e. (3).

In our studies, to distinguish between asymmetric protonation of the lithioenamines from **2** and a bias in the reaction of enantiomers during imine formation from racemic 2-methylcyclohexanone, imines **2** were subjected to direct hydrolysis (pathway B). The degree of resolution depends on the structure of **1**. Thus, 2-aminopropoxymethylated polystyrene (**1***a*) led to no apparent resolution, while the 3-phenyl derivative (**1***b*) afforded the 2-methylcyclohexanones with 50% excess of the (*S*)-enantiomer (Table 1). While **2***b*, then, must have (*S*)-2-methylcyclohexylidene moieties in 50% e.e., this chiral centre would be expected to be lost on deprotonation at the 2-position if a planar lithioenamine is assumed (see below).



The enantioselectivity of pathway A was found to be highly dependent on both the structure of the asymmetric inducing moiety on the polymer, and on the structure of the protonating species (Table 1). Bias is moderately towards formation of excess

[a]Isolated as previously described (1); > 98% pure as determined by gc; yields 0.1–0.2 mmol per g of polymer.
[b]Based on optical rotation of pure (*R*)-2-methylcyclohexanone at −16.4°C (8).

(*R*)-2-methylcyclohexanone using **1***a*, but more strongly towards (*S*)-2-methylcyclohexanone using **1***b* (of the same chirality). It is noteworthy that, in the case of **1***b*, bond formation to the proton must have occurred on the side of the 2-position opposite to that in bond formation to carbon in the methylation reactions described earlier (1) in order for both to lead to (*S*)-2-methylcyclohexanone.

Most significant are two extremum results. (*S*)-2-Methylcyclohexanone was obtained in 90% e.e. when the lithioenamine from **2***b* was protonated using ethanol, but only racemic product was obtained using *tert*-butyl alcohol, after the resulting polymers were hydrolyzed under the same conditions. These observations are consistent with regioselective deprotonation of **2***b* at the 2-position to form a planar lithioenamine followed by highly diastereoselective *C*-protonation when ethanol is used, or nondiastereoselective selective protonation with *tert*-butyl alcohol. Predominant deprotonation at the more highly alkylated α-position has been observed in other ketimines (4, 5) including those of cyclohexanone imines (4) using alkylithium reagents. In view of the studies of Knorr and Löw (6) the *C*-protonation may be a result of a tautomerization[2] following an initial kinetically controlled *N*-protonation to form an enamine.

Another possibility may be deprotonation at the 6-position of the 2-methylcyclohexanone imine system, as observed by Meyers *et al.* (7) in reactions of lithium diisopropylamide on imines in solution, followed by a complex equilibration prior to hydrolysis.[2]

In any event, diastereoselective *C*-protonation at the 2-position ultimately must have occurred prior to hydrolysis by a mechanism that is highly influenced by the structure of the protonating species.

An analogous system in solution was investigated. The imine from racemic 2-methylcyclohexanone and (*S*)-2-aminopropyl benzyl ether (**3***a*) (1) was treated under the same conditions as those in pathway A for the polymeric system. The product exhibited no optical activity. We plan to examine the analogous system derived from (*S*)-2-amino-3-phenylpropyl benzyl ether (**3***b*).

Our result of 90% e.e. would appear to be unprecedented in enantioselective protonation reactions in nonbiological systems. These results are consistent with earlier observations (1) of enhancement of enantioselectivities through the use of polymer supported asymmetric inducing agents relative to analogous systems in solution. While mechanisms have been proposed to explain the predominant enantioselectivities in related reactions (9, 10) additional studies are required to rationalize the results that we report here. Studies in this area are continuing.

[2]We appreciate these alternative explanations suggested by one referee.

# A carbon-13 nuclear magnetic resonance study of a series of 5-substituted benzimidazoles

BARRY J. BLACKBURN,[1] DOUGLAS W. ANKROM, AND HAROLD M. HUTTON[1]

*Chemistry Department, University of Winnipeg, Winnipeg, Man., Canada R3B 2E9*

Received December 21, 1981[2]

BARRY J. BLACKBURN, DOUGLAS W. ANKROM, and HAROLD M. HUTTON. Can. J. Chem. **60**, 2987 (1982).

Carbon-13 nmr chemical shift assignments are reported for a series of 5-substituted benzimidazoles, 2-methylbenzimidazole, and 5,6-dimethylbenzimidazole. By employing the three-parameter equation of Smith and Proulx, the chemical shifts of all the ring carbons of the 5-substituted compounds are correlated with $F$ and $R$ of Swain and Lupton and $Q$ of Schaefer; only the *ipso* carbon, C-5, has chemical shifts with a correlation coefficient less than 0.953. These correlations are compared with those obtained from the Swain–Lupton and Taft relationships; in general those from the latter two approaches are found to be less satisfactory. Correlations of the same chemical shifts with excess charge density values, calculated at the INDO level of approximation, are also presented.

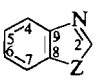
BARRY J. BLACKBURN, DOUGLAS W. ANKROM et HAROLD M. HUTTON. Can. J. Chem. **60**, 2987 (1982).

On rapporte l'identification des déplacements chimiques en rmn du $^{13}C$ d'une série de benzimidazoles substituées en position 5, de la méthyl-2 benzimidazole et de la diméthyl-5,6 benzimidazole. En utilisant l'équation à trois paramètres de Smith et Proulx, on a pu établir une corrélation entre les déplacements chimiques de tous les carbones du cycle des composés substitués en position 5 avec les $F$ et $R$ de Swain et Lupton et le $Q$ de Schaefer; seul le carbone *ipso* C-5 a des dépacements chimiques avec un coefficient de corrélation inférieur à 0,953. On a comparé ces corrélation avec celles obtenues à partir des données de Swain–Lupton et Taft. Les corrélations de Swain–Lupton et Taft sont en général moins satisfaisantes. On présente également les corrélation des mêmes déplacements chimiques avec les valeurs de densité de charge en excès, au niveau d'approximation INDO.

[Traduit par le journal]

## Introduction

The carbon-13 nmr spectrum and carbon charge densities for benzimidazole, **1**, have been reported by Pugmire and Grant (1). The carbon-13 chemical shifts for some 5-substituted benzimidazoles have been published (2, 3); correlations were observed (2) for C-2 and C-8 using $\sigma_p$ and $\sigma_6$ substituent constants. For some other benzazoles, namely derivatives of benzimidazole (4), benzothiazole, **2** (5), and benzoxazole, **3** (6), with substitution only on C-2, reasonable correlations were reported for all ring carbon atoms using the $F$, $R$, and $Q$ substituent constants (7, 8) in the three-parameter equation of Smith and Proulx (9, 10).



**1** Z = NH
**2** Z = S
**3** Z = O

Here we report the assignment of the carbon-13 resonances and the calculated carbon charge densities for a series of 5-substituted benzimidazoles with substituents ranging from strongly electron-releasing to strongly electron-withdrawing. We find benzene substituent-induced chemical shifts (SCS) do not always yield the correct assignment in benzimidazoles; thus the information presented regarding the coupled spectra should prove valuable in the assignment of other 5-substituted benzimidazoles and perhaps other benzazoles. The spectra of 2-methylbenzimidazole and 5,6-dimethylbenzimidazole were also examined as an aid to the assignments of the 5-substituted benzimidazoles. We present correlations for the chemical shifts of all the ring carbons of the 5-substituted compounds with both substituent constants and charge density values.

The results for 5-benzoylbenzimidazole are of particular interest due to the relationship of this compound to the well-known anthelmintic drug Vermox (11); Vermox differs by having a "methyl carbamate group" (carbomethoxyamino group, MeOOCNH—) in the 2 position. Work is in progress on the synthesis and carbon-13 nmr analysis of a series of these methyl (5-substituted-2-benzimidazolyl)carbamates.

## Experimental

Benzimidazole, 5-nitrobenzimidazole, and 5,6-dimethylbenzimidazole were purchased from Aldrich and used without further purification. No impurities were observed in the carbon-13 nmr spectra. The remainder of the compounds were prepared and purified by standard methods (12–15).

The carbon-13 nmr spectra were recorded on a Varian CFT-20 spectrometer at a temperature of 30°C. These compounds were run in dimethyl sulfoxide (DMSO) and, in some cases, methanol. For the protonation studies, weighed amounts of concentrated hydrochloric acid were added to the DMSO solutions. A coaxial tube containing $D_2O$ provided an external lock. Chemical shifts were referenced to TMS by setting the DMSO resonance at 40.5 ppm (16) and the methanol resonance at 49.9 (17).

Molecular orbital calculations at the INDO level of approxi-

†Approaching the limit of solubility.

mation (18, 19) were performed on an AMDAHL 470 Computer at the University of Manitoba. For the benzimidazole structure, a regular hexagon was added to the known geometry of imidazole (20). For the benzene ring portion a C—C distance of 1.378 Å and a C—H distance of 1.08 Å were used. Standard bond angles and bond lengths (18) were used for the substituents and, where rotation is possible, calculations were performed for all reasonable conformations and the results were averaged. In the amino compound the HNH angle and the angle between the $NH_2$ plane and the plane of the ring were taken to be 113° and 37.5°, respectively (21). The charge densities reported assume equal populations of the tautomeric forms.

## Results and discussion

The compounds studied are the following: the parent benzimidazole, **1**, the 5-substituted benzimidazoles, **4–9**, 5,6-dimethylbenzimidazole, **10**, and 2-methylbenzimidazole, **11**; their structures are indicated in Table 1 with their carbon-13 chemical shifts for the solvents and concentrations employed. The results indicate that there is little change in chemical shifts in going from 2 *M* to 0.5 *M* solutions in DMSO for the compounds studied; however, there are significant differences in going from DMSO to methanol solutions. For purposes of the correlations, the chemical shifts used were those obtained for 2 *M* solutions in DMSO. The carbon-13 nmr spectra for some of these compounds have been obtained previously (2, 3), but were redetermined in order to have constant experimental conditions and to be certain of the assignments (some discrepancies with the assignments in ref. 2 were found as discussed below).

### *Spectral assignment of the 5-substituted benzimidazoles*

For a preliminary assignment we applied benzene SCS values (22) to the shifts of the parent compound (1), but in examining the coupled spectra it was found that this was not always reliable in distinguishing $^{13}C$ resonances which are close together. With the exception of C-4 and C-6, all peak assignments were made on the basis of the coupled spectra. As expected, C-2 gives a doublet with a coupling of 205–210 Hz (23) due to the directly bonded proton, with no observable fine structure at the resolution obtained in these solutions (approximately 1 Hz). This large coupling serves to distinguish C-2 from the benzene ring carbon resonances which are split by 160–170 Hz. The nonprotonated carbons C-5, C-8, and C-9 can be identified by the $^3J_{(C,H)}$ values which are larger than $^2J_{(C,H)}$ values (24–27). As shown in Fig. 1 for 5-aminobenzimidazole, the *ipso* carbon, C-5, has one observable coupling, $^3J_{(C\text{-}5,H\text{-}7)}$, for the electron releasing substituents and hydrogen. For the electron-withdrawing substituents (5-nitro, 5-chloro, and 5-benzoyl) the *ipso* carbon exhibits, in addition, the two $^2J_{(C,H)}$ couplings. This increase in the two bond couplings is expected (28, 29) with electron-withdrawing substituents on the *ipso* carbon. For C-8, $^3J_{(C,H)}$ couplings are observed to H-2, H-4, and H-6; as shown in Fig. 1, the pattern is a doublet of triplets. For C-9, there is $^3J_{(C,H)}$ coupling to H-2 and H-7, giving a triplet or a doublet o

doublets depending on the relative magnitudes of these coupling constants. The origin of these patterns for C-8 and C-9 was confirmed by comparison to the coupled spectra for benzimidazole, 2-methylbenzimidazole, and 5,6-dimethylbenzimidazole. The resonance for C-7 is easily assigned as it has only a one bond C,H coupling, approximately 160–170 Hz. For C-4 and C-6, in addition to the directly bonded coupling, each has only a $^3J_{(C,H)}$; thus these resonances cannot be distinguished using only the coupled spectra. However, their large chemical shift difference permits easy assignment on the basis of the *ortho* SCS values, with C-6 always downfield of C-4 as in the parent compound. For 5-nitro- and 5-chlorobenzimidazole, we were able to confirm this on the basis of the work of Mathias and Overberger (2) who used compounds with 90% carbon-13 enrichment in the 2 position. Their assignment in methanol solution is certain for C-4 and C-6 because of the observed carbon–carbon couplings. A series of mixed solvents was used to ascertain that the order of the resonances does not change on going from methanol to DMSO. However, we do find serious discrepancies between our work and that of the above authors for 5-chloro- and 5-nitrobenzimidazole in methanol solution. Labelling of C-2 only provides an advantage in selecting the C-2, C-4, and C-7 resonances, and even at that does not distinguish between the latter two.

Pugmire and Grant (1) have shown that all the carbon resonances of the parent benzimidazole move upfield on protonation, with the exception of C-5 and C-6 which move downfield. In agreement with this, Mathias and Overberger (2) noted that, for the partial protonation of 5-chloro- and 5-nitrobenzimidazole in acetic acid, C-8 and C-9 move upfield and C-5 and C-6 move downfield. We have found that the observations for the parent benzimidazole apply to the carbon chemical shifts of 5-substituted benzimidazoles in general, except for C-7 in compounds which contain electron-withdrawing groups. For 5-nitro-, C-7 moved downfield with protonation while for 5-chloro- and 5-benzoylbenzimidazole there was little change in shift with protonation. Thus protonation studies are useful as an aid for chemical shift assignment in benzimidazoles. In this present study our assignments of C-4 and C-6 are further substantiated by protonation studies in DMSO solutions.

*Correlation of the chemical shifts with substituent parameters*

Methods (30) for the correlation of chemical shifts with substituent constants other than that of Smith and Proulx (9, 10) do not give good correlations for even the majority of carbon atoms in aromatic systems; therefore we have used the latter approach, which utilizes eq. [1], as our initial method of correlating the chemical shifts of the 2 *M*

$$[1] \quad \delta = aF + bR + cQ + d$$

DMSO solutions of the 5-substituted benzimidazoles. In [1], $F$ and $R$ are the Swain and Lupton substituent constants and $Q$ is a semi-empirical parameter defined by Schaefer and co-workers (8). To determine if the inclusion of $Q$ resulted in a significant improvement for all carbon atoms, correlations were also attempted with eq. [2] which

$$[2] \quad \delta = aF + bR + d$$

uses the Swain and Lupton constants only. As the Taft equation, [3], using $\sigma_I$ and $\sigma_R^0$ (31) for the polar

$$[3] \quad \delta = \rho_I\sigma_I + \rho_R\sigma_R^0 + d$$

and resonance substituent constants, sometimes gives better results than eq. [2], correlations with these parameters were also tried. The numerical values of the substituent constants were taken from the original articles (7, 10, 31). The coefficients obtained by multiple linear regression analysis are presented in Table 2. (The chemical shifts of the benzoyl compound were not used in these numerical analyses as all the required substituent constants are not available.) As well, in Table 2, the correlation coefficient $r$ and the $F$ test of the variance are given.

The values of the correlation coefficients for eq. [1] indicate that these results compare favorably with those obtained for other benzazole systems (4, 5, 6, 10). For the *ipso* carbon, C-5, the correlation is not quite as good; this is consistent with the results observed for the 2-substituted benzimidazoles (4). Thus chemical shifts of 5-substituted benzimidazoles can be satisfactorily predicted for compounds having substituent groups for which $F$, $R$, and $Q$ values are available. In principle, the results from Table 2 could be used to generate the $F$, $R$, and $Q$ values for the benzoyl substituent; however, we believe that the data from several systems should be used to obtain these parameters.

It can be seen from the calculations with eq. [2] that the absence of $Q$ decreases the quality of the correlation, as measured by the correlation coefficient, for all chemical shifts. Surprisingly, for the chemical shifts of the *ortho* carbon C-4, $Q$ does not seem to be statistically significant; for the *ipso* carbon, C-5, $Q$ appears to be of marginal significance. (The correlation coefficient $r$ almost inevitably gets better as more variables are added to a

*Correlation coefficient.
†$F$ test of the variance.

correlation, whereas the $F$ test only improves if the additional variable results in a statistically significant improvement, e.g. see ref. 32.) Even for C-2, where the correlation coefficients are similar, the $F$ test of the variance increases on including $Q$, indicating that its inclusion is statistically significant. Only for C-8 is there a good single parameter correlation with $R$ of Swain and Lupton ($r = 0.966$, $F$ test = 55); this is not unexpected at the *para* position.

The correlations of the chemical shifts with the Taft parameters $\sigma_I$ and $\sigma_R^0$ (eq. [3]) are not as good as those with either eq. [1] or eq. [2], except for that of C-8. The single parameter correlation of the chemical shift of C-8 with $\sigma_R^0$ ($r = 0.9782$, $F = 89$) is less satisfactory than the dual parameter correlation; the enormous decrease in the $F$ test of the variance indicates that $\sigma_I$ does make a significant contribution. (A single parameter correlation of the chemical shift of C-8 with $\sigma_I$ was very poor.) It is noteworthy that use of eq. [3] indicates that, while resonance is the most important contribution, the field effect is also significant, whereas use of eq. [2] suggests that the field effect is not statistically significant. This discrepancy is not surprising if criticism (33) that the Swain–Lupton approach does not satisfactorily separate field and resonance effects is well founded.

### *Correlation of the chemical shifts with charge densities*

The excess charge density with respect to the neutral atom, calculated at the INDO level of approximation, is given in Table 3 for each carbon atom. It is possible to test the correlation between the experimental chemical shifts and the total excess charge density (see Fig. 2) on the carbon atoms by making use of eq. [4] (34). Using all ring

$$[4] \quad \delta = Aq_{\sigma+\pi} + B$$

carbons of benzimidazole and the five 5-substituted benzimidazoles, we found that $A = -133 \pm 24$ ppm/electron and $B = 119 \pm 3$ ppm with a correlation coefficient $r = 0.870$ and $\psi = 0.51$ (where $\psi^2 = 2(1 - r)$). The standard deviation of charge density values is 0.091 and that of the chemical shifts is 13.9 ppm. Jaffe (35) has stated that $r$ must be over 0.96 and Exner (36) that $\psi$ must be less than 0.20 for a good correlation. If the correlation analysis is restricted to the 36 phenyl carbons there is a slightly better correlation, with $A = -183 \pm 30$ ppm/electron and $B = 118 \pm 2$ ppm ($r = 0.903$, $\psi = 0.44$); standard deviations of charge densities and chemical shifts

are 0.067 ppm/electron and 13.6 ppm, respectively. These results show that there is only fair agreement for these correlations. In Table 3 the correlation coefficient for chemical shift versus excess charge density is given for each carbon atom. As can be seen, the correlations for the individual carbon atoms are not satisfactory overall; a poor correlation is not unexpected (22, 37) for carbons other than the *para*. However the correlation for the *para* carbon is not too good; this could be due to

unequal tautomer populations for these benzimidazoles. This will be tested by a similar study on a series of 5-substituted benzoxazoles where tautomerism involving two positions on the 5-membered ring is not possible.

# Arylallyl cations and their stereospecific cyclization to bicyclic trienylic cations

D. M. DYTNERSKI, K. RANGANAYAKULU, B. P. SINGH, AND T. S. SORENSEN
*The Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4*

Received June 3, 1982

D. M. DYTNERSKI, K. RANGANAYAKULU, B. P. SINGH, and T. S. SORENSEN. Can. J. Chem. **60**, 2993 (1982).

A series of arylallyl alcohols, where aryl = 2,6-dimethylphenyl, mesityl, duryl, or pentamethylphenyl, was prepared. On addition to strong acid, these generate arylallyl cations. In some cases these allyl cations are observable and were characterized as *in situ* solution species by nmr spectroscopy. In other cases, an immediate cyclization takes place, leading stereospecifically to a series of bicyclic trienyl cations, which were also thoroughly characterized. The stereochemistry of this cyclization reaction, which was initially expected to follow the "rules" for electrocyclic ring closures, was probed in some detail. It is tentatively concluded that the stereochemistry in the products is not that expected from a conrotatory ring closure. Two diarylmethyl cations were also prepared. However, these did not cyclize.

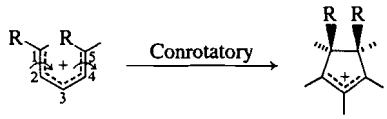
D. M. DYTNERSKI, K. RANGANAYAKULU, B. P. SINGH et T. S. SORENSEN. Can. J. Chem. **60**, 2993 (1982).

On a préparé une série d'alcools arylallyliques où le groupe aryl = diméthyl-2,6 phényle, mésityle, duryle ou pentaméthylphényle. Ces alcools en présence d'acides forts produisent des cations arylallyles. Dans certains cas on observe ces cations allyles et on les caractérise *in situ* en solution par la spectroscopie de rmn. Dans d'autres cas il se produit immédiatement une cyclisation, qui conduit de façon stéréospécifique à des séries de cations triényles bicycliques que l'on a entièrement caractérisés. On a établi de façon détaillée la stéréochimie de cette réaction de cyclisation, qui pensait-on devait suivre les règles de fermeture électrocyclique de cycles. On conclut que la stéréochimie des produits n'est pas celle attendue d'une fermeture conrotatoire de cycle. On a également préparé deux cations diarylméthyles. Toutefois ces cations ne se cyclisent pas.

[Traduit par le journal]

## Introduction

The pentadienyl → cyclopentenyl (I → II) cation ring closure was first observed nearly 20 years ago (1), subsequently classified as an "electrocyclic" closure by Woodward and Hoffmann (2) and then, using methyl-substituted derivatives of I of fixed geometry, shown (3) to follow the predicted conrotatory mode.



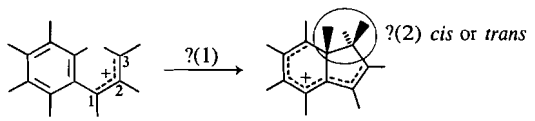
I II

This closure is irreversible, i.e. II is much more stable than I. The net bond energy changes involved in this can be very simply summarized:

[1] Pentadienyl resonance energy (R.E.) + π-bond → allyl R.E. + σ-bond

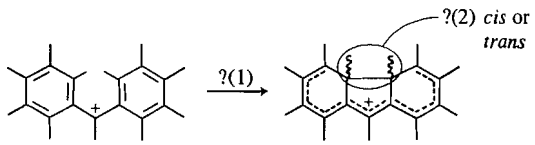
Thus, the main driving force is the favorable formation of a σ-bond from a π-bond (about 15–25 kcal/mol), the difference in the two R.E.'s expected to be small in comparison.

The present study involves extensions of the basic I framework, incorporating one and then two aromatic rings in place of the 1,2 and 4,5 "double bonds" of the pentadienyl unit. The possibility of a ring closure, analogous to I → II, can again be considered from two separate viewpoints, viz. is the open or closed cation the more stable and, secondly, in the event that ring closure does occur, what is the stereochemical outcome? The possible reactions are summarized below, the numbers in brackets referring to the above questions:



III IV

[2] Aryl R.E. + allyl R.E. + π-bond $\xrightarrow{?}$ trienyl R.E. + σ-bond



VI VII

[3] 2 × Aryl R.E. + π-bond $\xrightarrow{?}$ pentaenylic R.E. + σ-bond

Examples of diarylmethyl cations VI are numerous (4), but only a few arylallyl cations III have been studied (5–8). No previous stereochemical work on these cyclizations has been reported.

## Results and discussion

### *The arylallyl cation III case*

Our approach to studying a possible III → IV cyclization had to deal first with preventing the facile rearomatization of IV, a cation species previously unknown because of this. As it turned

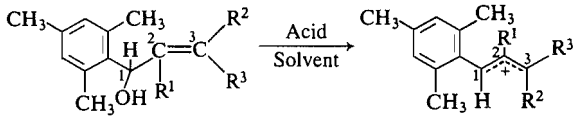
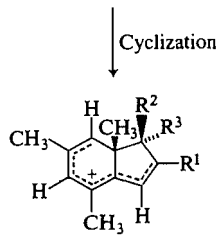
out, this was easily done by using aryl rings with both *ortho*-positions methyl-substituted. As implied, the cyclization of III to IV does occur in most of these cases, i.e. IV is thermodynamically more stable than III, in spite of the loss of aryl R.E. (see eq. [2]).

The first systems looked at were based on a mesitylene ring with the incipient allyl cation portion having either one or two methyl substituents, the one on C-3 being necessary to create the potential stereochemistry in IV. The starting alcohols **1**–**4** were prepared from mesitaldehyde and the corresponding vinyl lithium or from mesityl lithium and the α,β-unsaturated aldehyde.



**1** $R^1 = R^2 = H$, $R^3 = CH_3$
**2** $R^1 = R^3 = H$, $R^2 = CH_3$
**3** $R^1 = R^2 = CH_3$, $R^3 = H$
**4** $R^1 = R^3 = CH_3$, $R^2 = H$

III-1 $R^1 = R^2 = H$, $R^3 = CH_3$
III-2 $R^1 = R^3 = H$, $R^2 = CH_3$
Not directly observed
Not directly observed



IV-1 Not directly observed
IV-2 Not directly observed
IV-3 } $R^1 = R^2 = CH_3$, $R^3 = H$
or
IV-4 } $R^1 = R^3 = CH_3$, $R^2 = H$

Alcohols **1** and **2**, on addition to $FSO_3H$–$SO_2ClF$ (1:4) at −120°C, yield the corresponding allylic cations III-1 and III-2, although III-2 was never obtained pure. At about −100°C, III-2 rearranges to the more stable III-1 geometry and this facile process no doubt occurs to some extent in the preparation of III-2. At much higher temperatures (35°C), cation III-1 cyclizes, but a rearranged indanyl cation V-1 was the first observed species (5) (destroying any stereochemistry inherent in IV).

There are indications from previous literature examples (6) that substituting a methyl group at C-2 in III would increase the cyclization rate. This indeed was the case here and, on addition of alcohols **3** or **4** to the acid, only the cyclized ion (IV-3 or IV-4) was observed, even at temperatures as low as −120°C. The cyclized ion, by $^{13}C$ and $^1H$ nmr, appears to be a *single* stereoisomer and it is significant and disquieting that both alcohols should give the same cyclized ion.

Ideally, one would like to directly observe both cation structures III and IV *in the same system*. One possibility for the nonobservation of IV-1 might be that this ion is actually less stable than III-1. The corresponding durene-substituted alcohols **5** and **6** (analogous to **1** and **4**) were therefore prepared. Note that IV-5 and IV-6, compared to IV-4 (or a possible IV-1), have two extra methyl groups in stabilizing positions on the trienylic cation framework (denoted above in IV by ●). In any event, ionization of **5** leads cleanly to III-5 and this in turn cyclizes very cleanly to IV-5 at −70°C. Alcohol **6** (like **4**) yields only the cyclized ion IV-6, on ionization at −120°C. Both IV-5 and IV-6 appear to be *single* stereoisomers.

All of the observable III and IV ions were characterized as *in situ* solution species by $^1H$ and $^{13}C$ nmr spectroscopy and the data are given in Tables 1 and 2. Data for the further rearranged indanyl cations have been presented elsewhere (13).

*Thermodynamic aspects (question 1 in the Introduction)*

Obviously IV-4, IV-5, IV-6 (and a pentamethyl species IV-8 to be discussed subsequently) are all more stable than the open arylallyl cations III. The situation with III-1 is less clear since the cyclization here proceeds directly to a rearomatized indanyl cation V-1. However, the observation that III-5 cyclizes to IV-5 at −70°C, whereas III-1 forms the indanyl cation V-1 only at +35°C, is a strong indication that III-1 is more stable than the unseen IV-1, since there is little kinetic reason why these very similar ions should not have cyclized (III →

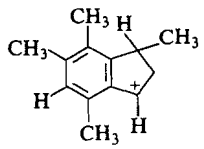
[q] d, $J$ = 7.3.
[r] q, $J$ = 7.3, also coupled to H-1 and H-2.

IV) at rather similar rates. This possible situation is presented diagrammatically in Fig. 1. Note that III-1 contains an extra *p*-Me stabilizing group, compared to III-5, while IV-5 has two extra stabilizing methyl substituents compared to the unseen IV-1.



V-1

In an attempt to find a possible case where III and IV might be in observable equilibrium (and thereby obtain proof for the Fig. 1 conjecture), the *m*-xylene system was prepared, starting with alcohol **7**. Cation III-7 should be similar in stability to III-5, but IV-7 should be less stable than IV-5 because the additional methyl groups in IV-5 are stabilizing (see IV-5 structure). However, addition of **7** to the acid solvent gave III-7, but this only yields an indanyl cation mixture on cyclization (+20°C). In spite of this negative result, we still believe that ions III and IV are similar in energy. This point is significant in our rationalization of the stereochemistry involved in the cyclization.

Cation IV is a benzenonium ion, normally considered a high energy intermediate in Friedel–Crafts alkylations. However, intermediates like IV always have a vanishly small concentration in normal alkylations *for kinetic reasons*, and one should not conclude anything about the actual thermodynamics of the benzenonium ion without some other kind of evidence.

[a] δ ppm, relative to internal $CFCl_3$ = δ 117.9. All multiplicities have been confirmed by off-resonance decoupling but a definitive assignment of closely spaced peaks of similar multiplicity is impossible. The tentative assignments are indicated by *.
[b] Line-broadening, described in the text, occurs at higher temperatures.
[c] A low field methyl carbon is present in all cases and is probably the methyl at C-8.

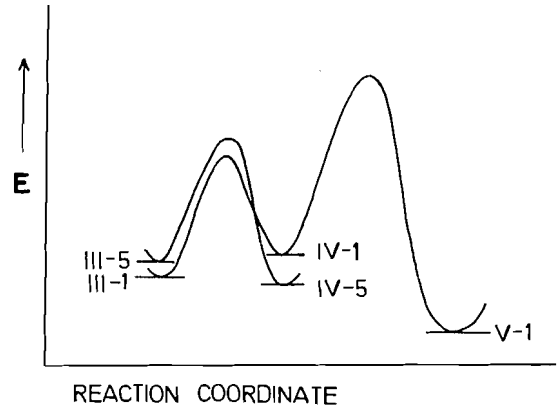

FIG. 1. This diagram is based on the assumption that the kinetics for III-1 → [IV-1] → V-1 would be similar to those observed for III-5 → IV-5 and that thermodynamic factors are responsible for the nonobservation of IV-1. III-1 is placed lower than III-5 because of the favorable *p*-Me group of the former. IV-5 is placed lower than IV-1 because of the two extra favorable methyl substituents.

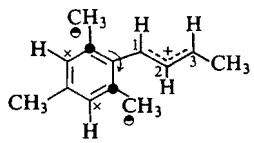
*Structure of the arylallyl cations*

In cations III-1, III-5, and III-7, all three vicinal protons on the allyl unit have a 13.6 Hz coupling constant characteristic of a mutual *trans*-orientation. This leaves the aryl ring in the expected *anti*-orientation, as shown below:



⊖, ●, and × become equivalent by 180° rotation of the aryl ring

III-1

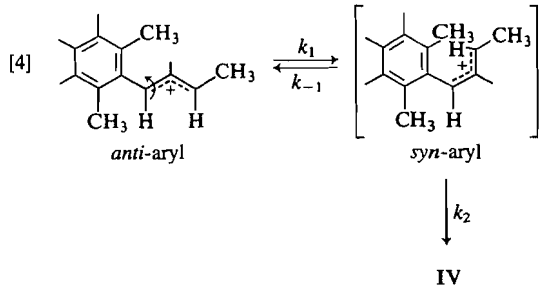
Cation III-2 likewise has a *trans*-orientation about C-1,C-2. The *cis*-orientation for H-2,H-3 in this ion follows because of the stereochemistry present in alcohol **2**, but the actual peaks for H-2 and H-3 are overlapped with others from ion III-1 and no $J_{2,3}$ constant could be obtained. The rearrangement of III-2 to III-1 is expected on stability grounds (9).

The bulky mesityl and duryl rings in III may not be entirely coplanar with the allyl part, but there is nevertheless a sizeable barrier for rotation about the C-1–aryl bond. This barrier can be determined for III-1, based on the line-broadening observed for the *ortho* and *meta* carbons ($^{13}C$ nmr) or the *ortho*-methyl groups ($^{13}C$ nmr). A barrier of 14 kcal/mol was estimated from the coalescence temperature of the aryl *meta* carbon peaks.

*The cyclization of III to IV*

Before discussing the cyclization of the arylallyl cations, one should comment briefly on the conformational requirements.

As in the pentadienyl cation case, the ring closure presumably proceeds via a geometric isomer of the arylallyl cation in which 180° rotation has occurred around the C-1,C-2 "bond" of the ground-state conformation (eq. [4]).



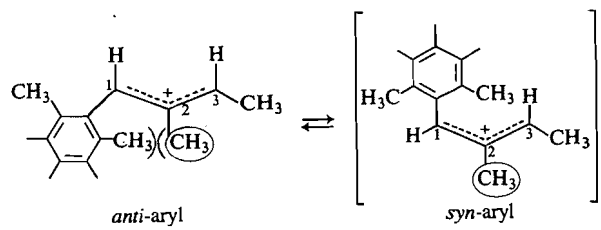
[4]

*anti*-aryl *syn*-aryl

IV

This high energy *syn*-arylallyl cation cannot be planar, but this need not affect the chances for an electrocyclic ring closure, i.e. one governed by electronic rather than steric factors, since the previously-studied pentamethylpentadienyl cation cyclizations (which are nearly stereospecific) have very similar steric interactions in their "U" (reactive) conformations (3).

The arylallyl cations involving a 2-methyl substituent, e.g. from alcohols **3**, **4**, **6**, and **8**, could not be observed because of the enormous rapidity of the cyclization rate. For example, one can estimate that this substitution in the case of alcohols **5** and **6** is responsible for a minimum $10^3$ increase in cyclization rate. The major source of this rate gain must involve a destabilization of the *anti*-arylallyl cation because it is now impossible to have a planar conjugated system, as illustrated below:



*anti*-aryl *syn*-aryl

The corresponding *syn*-arylallyl conformation is much less affected by this methyl group substitution and the overall effect is to reduce the energy difference between these ions. In this connection it should be noted that the present experiments do not tell one whether $k_1$ or $k_2$ in eq. [4] is rate-determining.

Alcohol **5**, where one can "see" both the arylallyl cation III-5 and the cyclized product IV-5, is the only case where the cyclization rate could be directly measured. The rate is first order and was experimentally measured by monitoring the loss of

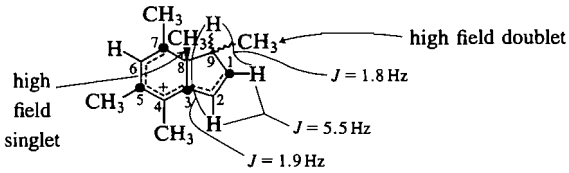
$^1$H nmr peaks due to III-5 and the formation of IV-5 peaks, giving $k_{overall} = 5 \times 10^{-4}\,s^{-1}$ in $FSO_3H$ at $-70°C$, $\Delta G^{\neq} = 15.6$ kcal/mol.

Although there is no direct evidence in these cyclizations that the *syn*-isomers exist as discrete species, we do have direct evidence for these from a *ring-opening* reaction to be discussed later in this paper.

*Structural evidence for cations IV*

In the $^1$H nmr, the cyclized cations IV all show one high field (saturated) quaternary methyl and a high field methyl doublet. In IV-5, the two low field protons are coupled, $J = 5.5$ Hz, indicating a *cis*-orientation. The $^{13}$C spectra are also very diagnostic, showing seven low field carbons. The four carbons formally sharing the positive charge



IV-5

(● in the structure above) form one group and the other three a higher field group. In the specific case of IV-5, three of the lower field group are quaternary and one is CH, while the upper field group has one quaternary and two CH carbons (see Tables 1 and 2).

The visible spectrum of IV-8 has $\lambda_{max} = 483$ nm, $\varepsilon_{max} = 9400$, as the longest wavelength absorption, in good agreement with 473 nm for an acyclic trienylic cation (10).

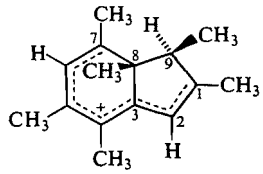
*Stereochemistry of cyclized ions IV (question 2 – Introduction)*

As previously noted, the $^{13}$C nmr spectra of IV-4, IV-5, IV-6, and IV-8 are consistent with the initial formation of a *single* stereoisomer. To try to determine this stereochemistry, the following methods were tried.

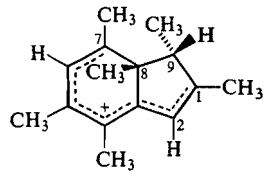
1. Assuming the product was one of kinetic control, we tried to equilibrate the ion at C-9 to at least produce *both* stereoisomers. This kind of equilibration works for the simple cyclopentenyl cations (11), e.g. 1,2,3,4,5-pentamethylcyclopentenyl cation eventually forms a *trans*/*cis* ratio of 3.9, starting from either relatively pure isomer. The usual equilibration mechanism would involve deprotonation–reprotonation at C-9 and the rate for such reactions becomes faster the weaker the acid solvent (stronger bases present) (12).

However, cation IV-6 resolutely refused to do anything, even when acids as weak as aqueous trifluoroacetic acid were used. That an acid–base equilibration reaction *was not* occurring was clear, because when $CF_3COOD$–$D_2O$ mixtures were used, no D appeared at C-9 in the ion. Eventually, if one weakens the acid solvent too much, degradation occurs but with no sign of any second equilibration partner.

2. Nuclear Overhauser enhancement nmr experiments were attempted on ion IV-6; the two possible geometries are shown below:

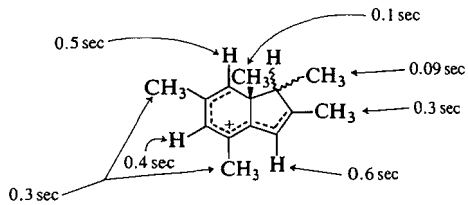


IV-6A



IV-6B

In IV-6B, the C-7 and C-9 methyl groups are quite close in space. However, using degassed samples of IV-6 in $D_2SO_4$ solvent (or IV-4 in $DSO_3F$ solvent), no measurable nOe effects were found for these methyls. A subsequent $T_1$ measurement on several of the ions revealed that the methyl groups in question have very short relaxation times (shown below for IV-4).



IV-4 $T_1$ relaxation times (−55°C, $DFSO_3$)

The usual nOe effects could be obtained on protonated DMF in $D_2SO_4$ or $DSO_3F$ and these protons also have much longer $T_1$'s, for example 1.3, 1.2 s for the high and low field methyls and 0.8 s for the methine proton in $D_2SO_4$ at 22°C. At the same temperature in $DSO_3F$, $T_1$ values are 3.1, 2.8, and 5.0 s. The short $T_1$ problem in IV-4 likely stems from the large size of the ion, resulting in correlation times very suitable for $T_1$ relaxation. It is significant in this regard that the quaternary methyl has a very short relaxation time and this protrudes from the top of the nearly planar surface formed by the remaining atoms.

3. Attempts to obtain crystalline salts of IV-8, suitable for X-ray work, were unsuccessful. The ion solutions are highly colored, making visual observation of crystal formation difficult. The usual material obtained was amorphous.

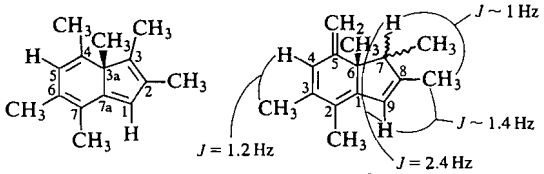
*Cation IV quenching studies*

Quenching sulfuric acid solutions of IV-6 in

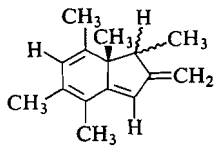
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

$H_2O$–$(CH_2OH)_2$–NaOH at ca. −20°C results in a near quantitative yield of proton-elimination products, obtained as an oil. This material (from $^1H$ and $^{13}C$ nmr) is mainly a mixture of two compounds. The major isomer is a 3aH-indene **9**, involving proton loss at C-9 in the ion. This unfortunately destroys the stereochemistry inherent in the system and is thus of no use to us. The spectral and chemical properties of **9**, as well as synthetic possibilities, are discussed elsewhere (13).

The minor component is the more interesting since it shows both the high field quaternary methyl *and* the high field doublet methyl which were present in the ion. In principle, one can eliminate a proton from the termini of IV-6 in two ways, viz. conjugated tetraenes **10** or **11**, respectively. However, a detailed analysis of the $^1H$ spectrum, particularly the coupling constants, favours **10**. This is discussed more fully in the "pentamethylbenzene" analog (ion IV-8).

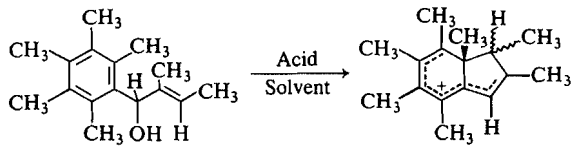


**9** **10**



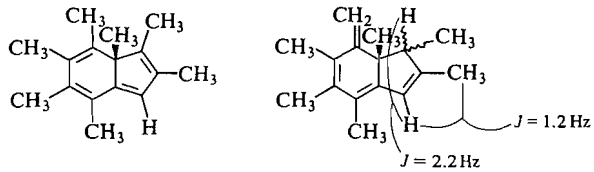
**11**

Attempts to separate **9** and **10** were unsuccessful because both compounds are very sensitive. Some chemical degradation studies were attempted on the mixture but no useful results were obtained. One can convert **9** into a ring-opened ketone (13), while leaving **10** at least partly untouched. This helps in assigning the nmr spectrum of **10**, but the isolation of pure **10** still proved impossible in our hands. We also sought quenching procedures designed to get better yields of **10**, but to no avail. However, it was discovered that the pentamethylbenzene analog, cation IV-8, could be quenched to give mainly the exocyclic tetraene component. Cation IV-8 is produced very cleanly from alcohol **8**.

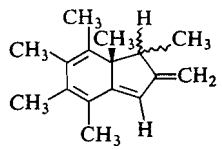


**8** IV-8

Quenching IV-8 leads to a mixture which is mainly an exocyclic tetraene, together with a smaller amount of the 3aH-indene **12** (13). The exocyclic tetraene was assigned the structure **13** rather than **14** on the basis of the $^1H$ nmr coupling constants observed (also applied to the assignment of **10** vs. **11**).

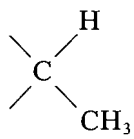


**12** **13**



**14**

Compounds **12** and **13** were obtained as an oil and attempts to separate these sensitive substances by chromatography or low temperature crystallization were unsuccessful. The apparently ready conversion of **13** to **12** makes chemical degradation studies difficult. The primary attempt in these degradation studies was to first convert the $=CH_2$ in **13** to $=O$, which could perhaps be obtained crystalline itself or as an adduct (then X-ray analysis). Numerous ozonolysis and periodic acid – $OsO_4$ reactions always led to crude mixtures in which the saturated

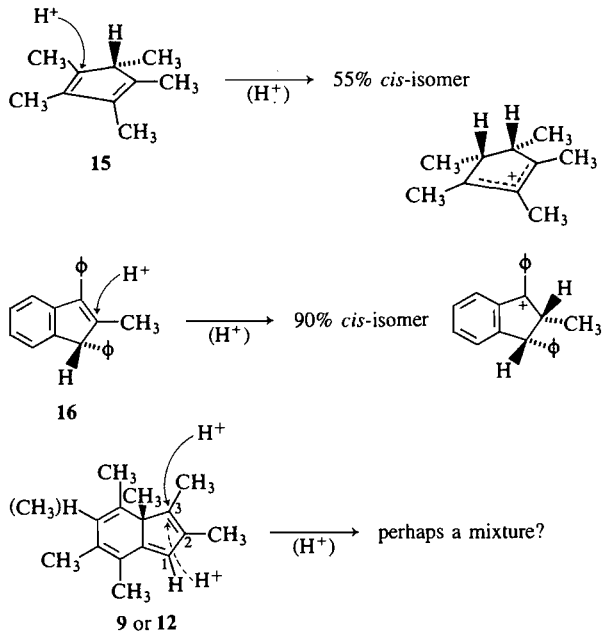


functionality was very weak or missing in the $^1H$ nmr spectra of the crude products. In attempts to convert $=CH_2$ to $-CH_2OH$, 9-BBN proved unreactive. The major problem is probably that the $=CH_2$ group is well-shielded by the other methyl substituents and reactions at other sites or **13** → **12** rearrangements intervene.

*Attempts to determine the stereochemistry in IV by kinetically-controlled protonation of 3aH-indenes 9 or 12*

With pentamethylcyclopentadiene **15** (11) or 1,3-diphenyl-2-methylindene **16** (6), protonation occurs under kinetic control and results predominantly in that cation isomer in which the proton approaches from the least hindered side, giving in these cases the less-stable *cis*-isomer. In the case of **9**, it is not immediately obvious which side is the more hindered, but the protonation in $H_2SO_4$ should defi-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

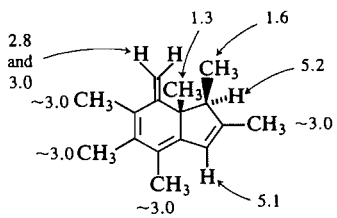


15 16 9 or 12

nitely be kinetically controlled (earlier in this paper it was remarked that no H–D exchange occurs in any of the acid solvents). However, protonation in $H_2SO_4$ results in only one cation being formed, the *same* one as produced in the original cyclization reaction. Protonation does occur at C-3 because, in $CF_3COOD$, the high field methyl doublet of IV-6 is at least partially collapsed.

*Possible stereochemical differentiation by nOe and $T_1$ studies on the tetraene* ***13***

$T_1$ values (in seconds) for degassed samples of **13**

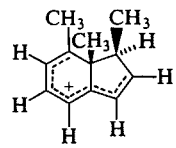


**13**

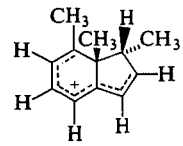
in $CDCl_3$ are given below. Both aliphatic methyl groups are seen to have rather short $T_1$'s. The nOe experiments were tried at both 200 and 400 MHz $^1H$ fields. At 400 MHz, there is virtually no enhancement of the quaternary methyl on irradiation of the methyl doublet and vice versa. Conversely, there is no nOe effect (200 MHz) between the methyl doublet and either of the $=CH_2$ protons.

*Molecular orbital calculations*

Further to our attempts to assign the stereochemistry to these ions, semiempirical MINDO/3 calculations were performed on the model cations IV-9A and IV-9B (corresponding to IV-5 with removal of C-4 and C-5 methyl groups). The geometries were fully optimized except for hydrogen dihedral angles in methyl groups. In addition, all methyl C—H bonds were made equal and, separately, all $C_{sp^2}$—H bonds were kept equal. These calculations are relevant if one assumes that the observed IV-cations might be products of thermodynamic rather than kinetic control (see Discussion). The total energies (in kcal/mol) for IV-9A and IV-9B are given next to the structure.



IV-9A 217.87 kcal/mol



IV-9B 217.91 kcal/mol

Structure IV-9A is shown in Fig. 2. These calculations suggest the two ions to be essentially of equal energy and are of no use, in a total energy sense, in helping one assign the unknown stereochemistry. However, the optimized geometries do offer some help in interpreting the H-9,H-1 coupling constant in ion IV-5.

*The H-9,H-1 vicinal coupling constant in ion IV-5*

The H-1,H-2 coupling in ion IV-5 is 5.5 Hz, typical of *cis* double bond coupling in five-membered rings, and this value can be used to calibrate the Karplus curve. The observed H-9,H-1 coupling of 1.8 Hz corresponds to a dihedral angle of about 52°. The calculated dihedral angles in IV-9A and IV-9B are 79 and 47°, respectively. Clearly, ion IV-9B is favored on this basis.

The Karplus relationship generally cannot be used to any degree of "exactness" but the two dihedral angles calculated in this case are sufficiently

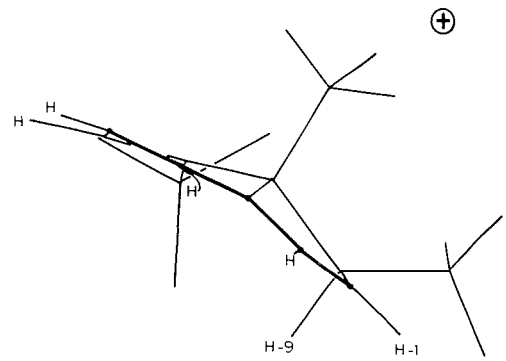


FIG. 2. Computed structure (MINDO/3) for the model cation IV-9A. Note that the H-9,H-1 dihedral angle of 79° is not consistent with the experimental nmr data, and thus the IV-9B structure is favored.

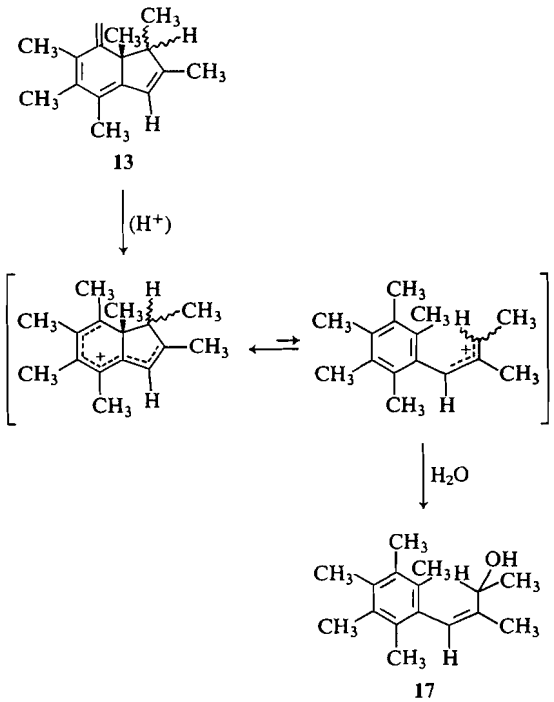
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

different that one has some confidence in the assignment.

*Ring-opening reaction of tetraene 13*

This reaction is not relevant to the stereochemistry problem, but is very relevant to the cyclization mechanism shown in eq. [4]. The tetraene mixture from the quench of ion IV-8 (mainly **12** and **13**), on standing in dilute aqueous acid (ca. pH = 1), is fairly rapidly converted to the alcohol **17**, whose structure has been proven (13).

[5]



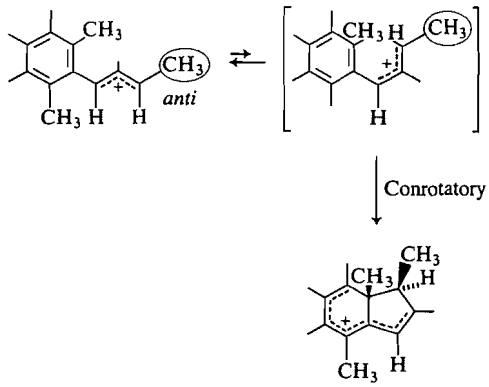
Two points are significant here: (1) the *syn*-arylallyl cation is the obvious precursor of **17**, and thus the existence of this intermediate is confirmed, and (2) the energy separation between the closed and open ions is likely small, a conclusion also reached on other grounds.

*Discussion of the arylallyl cation results*

Simple HMO theory predicts a conrotatory closure for the aryallyl cations. With a ground-state *anti*-methyl substituent as a marker, this leads to a predicted *cis*-dimethyl geometry (eq. [6]) in the cyclized ions.

Experimentally, one finds only one isomer being produced. We assume that this single isomer probably has the same stereochemistry in all of the IV-ions, although there is no complete proof that this is so. In addition, the evidence for a single ion is based on the premise that the $^{13}C$ and $^{1}H$ nmr

[6]



spectra would not be absolutely identical for the two stereoisomers.

The argument against a conrotatory ring closure in our examples is that both alcohols **3** and **4**, which have *syn*- and *anti*-methyl substituents, respectively, give the same single cyclic ion IV product. It is possible of course that III-3 and III-4 are rapidly interconverted before cyclization, since neither ion is directly observed. However, the stable isomer of the two is III-4 and this should produce the *cis*-dimethyl geometry. In the case of ions III-1 and III-2, the corresponding *syn* → *anti* rate is measurable and is indeed relatively fast.

All in all, it seems most probable that, in spite of the MO calculations, one stereoisomer, probably the *trans*-dimethyl isomer, is significantly more stable than the other and that the stereochemistry of our cyclization reaction is governed by this thermodynamic factor.

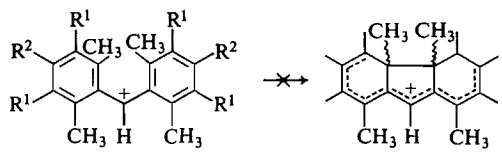
Even allowing for the above, there are excellent precedents for expecting a kinetically controlled protonation of the isoindenes **9** and **12**, which should have given a IV mixture containing both stereoisomers. Any possible isomerization of one stereoisomer to the other has already been shown not to involve a deprotonation–reprotonation mechanism, but the mechanism shown in eq. [7] could conceivably allow a rapid equilibration to the more stable IV-isomer and is illustrated for the case where the *trans*-dimethyl isomer is assumed to be the more stable. The key feature is that the "open" and "closed" ions be similar in energy, a conclusion already reached from several pieces of evidence.

*The diarylmethyl cations*

The diduryl- and dimesitylmethyl cations VI-1 and VI-2 were produced from the known alcohols (14, 15) and chemical shift data ($^{1}H$ and $^{13}C$) are given in Tables 3 and 4. In $CF_3COOH$, the cations have $\lambda_{max}$ = 510 and 526 nm, $\varepsilon_{max}$ = 23 300 and 35 700, respectively. These ions show no indication

[7] 

of cyclizing, even after prolonged storage at 20°C. In view of the previous conclusions regarding arylallyl cations, one would confidently predict that the cyclized ions VII would be of high energy relative to VI.



VI-1 $R^1 = CH_3$, $R^2 = H$
VI-2 $R^1 = H$, $R^2 = CH_3$

VII

*Discussion of the diarylmethyl cation results*

Only when rearomatization of VII can readily occur would it be possible to carry out a cyclization of VI (via VII as a high-energy intermediate). An example of this is the well-known conversion of triphenylmethanol into 9-phenylfluorene (16), carried out in strong acid. Photochemical cyclizations of triarylmethyl cations are also known (17). A mass-spectral study (18) of diphenylmethyl bromide has been interpreted in terms of a diphenylmethyl cation cyclization, to give an analog of VII, which subsequently loses $H_2$. On this basis, the cyclization stereochemistry was postulated to be the *cis* di-H analog of VII (a disrotatory cyclization), since the concerted loss of $H_2$ from the *trans* isomer was considered unlikely. However, these results are very indirect and interpretation in terms of specific structures is conjectural.

## Conclusions

With respect to the questions asked in the Introduction: (1) the cyclization of arylallyl cations is generally favorable, but there is evidence that the *energy differences are small*; (2) the cyclization product consists of only *one stereoisomer*, most probably the *trans*-dimethyl structure IV-B. However, there are still a number of unanswered mechanistic questions in this connection and (3) diarylmethyl cations VI do not cyclize to cation VII and are undoubtedly thermodynamically more stable than VII.

[a]Chemical shifts in δ ppm relative to external TMS in TMS-$d_{12}$.

## Experimental

The nmr spectra were obtained on Varian models HA-100 and XL-200 and Bruker model WH-90 spectrometers. Electronic spectra were obtained in 96% $H_2SO_4$ solution on a Cary 219 spectrophotometer. Constant temperature runs (and kinetic measurements) were obtained on the Bruker instrument using a previously described calibration procedure (19). The nmr spectra of all neutral compounds were measured in $CDCl_3$ or $CFCl_3$ solutions and are quoted relative to internal TMS (δ = 0.00).

All lithium reactions were carried out under a nitrogen or argon atmosphere. Boiling points and melting points are uncorrected.

*Ion preparations* ($FSO_3H$–$SO_2ClF$, $FSO_3H$, 96% $H_2SO_4$, $CF_3COOH$)

For $^1H$ nmr work, the alcohol (50 mg) in a small amount of $CFCl_3$ was added by pipette to 0.5 mL of 1:4 v/v $FSO_3H$–$SO_2ClF$ solutions contained in a 5 mm nmr tube and cooled to ca. −125°C using a pentane–$N_2$ slush bath. The solution was stirred with a Pt wire during the alcohol addition. All of the ions in this work are very highly colored. For $^{13}C$ nmr spectra, about 200 mg of alcohol was used (10 mm tubes) in ca. 2 mL of the acid solution. About 6000 accumulations were needed for good signal-to-noise spectra, usually employing a sweep width of 9000 Hz on the Bruker WH-90. Off-resonance spectra were also obtained to aid in the assignments. For pure $FSO_3H$ solvent, the alcohol, in a very small amount of $CDCl_3$, was added with stirring to the $FSO_3H$, the latter in an nmr tube and cooled at ca. −80°C in a Dry Ice bath. Sulfuric acid solutions were prepared by adding the acid and an equal volume upper pentane layer to a 5 mL flask. To the stirred mixture at −10 to 0°C was added dropwise the alcohol dissolved in a small amount of pentane. After a few minutes, the lower layer ion solution was removed by pipette and transferred to nmr tubes. For $CF_3COOH$ solutions, the solid alcohol was added directly in small portions to the stirred acid at 0°C.

For $FSO_3H$–$SO_2ClF$ solutions, the $^{19}F$ signal of $SO_2ClF$ was used as a lock. For $FSO_3H$ solutions, a 2 mm ($^1H$) or 5 mm ($^{13}C$) insert of TMS-$d_{12}$ was used as lock. For sulfuric acid solutions, either the TMS-$d_{12}$ or a dimethylether-$d_6$ insert was used for locking, while $CF_3COOH$ solutions were locked to the $^{19}F$ of the acid. In $FSO_3H$–$SO_2ClF$ solutions, $CFCl_3$ serves as an internal $^{13}C$ reference (δ 117.9), while in the $^1H$ spectra, a small amount of TMS in the TMS-$d_{12}$ served as a reference. The dimethyl ether-$d_6$ insert also contained a small amount of TMS. The δ positions of the various references, relative to TMS in $CDCl_3$ or $SO_2ClF$, have been determined for both iron magnet and supercon field configurations.

[a]In ppm relative to external TMS = δ 0.0, * indicates tentative assignments.

For the acid–base exchange attempts, deuterated acids $CF_3COOD$ and $CF_3COOD$–$D_2O$ solvents were used ($^1H$ nmr spectra), employing the same experimental techniques.

For the reprotonation studies on the **9**, **10** or **12**, **13** mixtures (attempted kinetic protonation), $FSO_3H$ or $H_2SO_4$ solvents were used, the former using a $CDCl_3$ solution, the latter using the pentane extraction method. The deuterated acid used in these studies was $CF_3COOD$.

The arylallyl alcohols were prepared by adding known aldehydes to known aryl or vinyl lithium compounds (prepared *in situ*). The crude alcohols were purified by vacuum distillation or recrystallization, or both. The $^1H$ nmr characterization does not include the OH proton.

E-*1-Mesityl-2-buten-1-ol* ***1***

From mesityl lithium and crotonaldehyde, the crude product directly recrystallized from pentane, 96% yield, mp 57–58°C; $^1H$ nmr: 1.66 (d, $J$ = 7, C-3 methyl), 2.19 (*p*-$CH_3$), 2.32 (*o*-$CH_3$), 5.3–5.9 (complex, protons on C-1, 2, and 3), 6.76 (*m*-H); $^{13}C$ nmr: 17.7 (C-3 methyl), 20.6 (*o*-$CH_3$), 20.7 (*p*-$CH_3$), 71.6 (C-1), 126.5 (C-3), 130.0 (*meta*), 131.7 (C-2), 135.7 (*ipso*), 136.3 (*ortho*), 136.7 (*para*). *Anal.* calcd. for $C_{13}H_{18}O$: C 82.1, H 9.5; found: C 81.9, H 9.3.

Z-*1-Mesityl-2-buten-1-ol* ***2***

Mesitaldehyde was added to the lithium reagent from *Z*-1-bromo-1-propene. The crude solid product could not be further purified since all attempts to recrystallize the alcohol from pentane resulted in an allylic rearrangement. However, the $^1H$ and $^{13}C$ nmr spectra of the crude alcohol indicated that it was nearly pure. Yield 88%, mp 45–46°C; $^1H$ nmr: 1.62 (d, $J$ = 7, C-3 methyl), 2.18 (*p*-$CH_3$), 2.35 (*o*-$CH_3$), 5.51 (complex, H-3), 5.82 (complex H-1 and H-2), 6.74 (*m*-H); $^{13}C$ nmr: 13.2 (C-3 methyl), 20.7 (*o*- and *p*-$CH_3$'s), 67.1 (C-1), 126.1 (C-3), 130.1 (*meta*), 132.1 (C-2), 136.1 (*ipso*), 136.2 (*ortho*), 136.7 (*para*). *Anal.* calcd. for $C_{13}H_{18}O$: C 82.1, H 9.5; found: C 82.2, H 9.5.

Z-*1-Mesityl-2-methyl-2-buten-1-ol* ***3***

Mesitaldehyde was added to the lithium reagent from *Z*-2-bromo-2-butene, 75% yield, bp 95–98°C/0.05 Torr. The nmr spectrum (see below) indicates that ca. 10% of the *E*-isomer is present, $^1H$ nmr: 1.54 (d, $J$ is hidden, C-3 methyl), 1.56 (C-2 methyl), 2.18 (*p*-$CH_3$), 2.28 (*o*-$CH_3$), 5.33 (quart., $J$ = 7, H-3), 5.70 (H-1), 6.71 (*m*-H); $^{13}C$ nmr: 14.2 (C-3 methyl), 21.5 (*o*-, *p*-, and C-2 methyls), 71.9 (C-1), 123.1 (C-3), 130.7 (*meta*), 136.6, 137.1, 137.3 (*ortho*, *para*, *ipso*, C-2). *Anal.* calcd. for $C_{14}H_{20}O$: C 82.3, H 9.9; found: C 82.0, H 9.8.

E-*1-Mesityl-2-methyl-2-buten-1-ol* ***4***

Tiglaldehyde was added to mesityl lithium, the crude product directly recrystallized, from pentane, 94% yield, mp 63–64°C; $^1H$ nmr: 1.56 (d, $J$ = 7, C-3 methyl), 1.48 (C-2 methyl), 2.16 (*p*-$CH_3$), 2.22 (*o*-$CH_3$), 5.32 (H-1), 5.37 (quart., $J$ = 7, H-3), 6.68 (*m*-H). Considerable long range coupling is present in the C-1, 2, and 3 methyls and protons; $^{13}C$ nmr: 13.0 and 13.6 (C-2 and C-3 methyls), 20.5 (*o*-$CH_3$), 20.7 (*p*-$CH_3$), 74.0 (C-1), 118.4 (C-3), 129.9 (*meta*), 135.3 (C-2), 135.4 (*para*), 136.7 (*ipso*), 137.1 (*ortho*). *Anal.* calcd. for $C_{14}H_{20}O$: C 82.3, H 9.9; found: C 82.3, H 9.9.

E-*1-Duryl-2-buten-1-ol* ***5***

Crotonaldehyde was added to duryl lithium and the residue purified by vacuum distillation, bp 120–122°C/0.05 Torr, mp 79–80°C, yield 83%; $^1H$ nmr: 1.60 (d, $J$ = 7, methyl on C-3), 2.15 (*m*-$CH_3$), 2.20 (*o*-$CH_3$), 5.26–5.94 (multiplet, H-1, 2, 3), 6.80 (*p*-H); $^{13}C$ nmr: 16.2 (*m*-$CH_3$), 17.7 (C-3 methyl), 20.5 (*o*-$CH_3$), 71.8 (C-1), 126.6 (C-3), 131.2 (*para*-H), 132.2 (C-2), 132.4 (*ortho*), 134.5 (*meta*), 138.8 (*ipso*). *Anal.* calcd. for $C_{14}H_{20}O$: C 82.3, H 9.9; found: C 81.9, H 9.8.

E-*1-Duryl-2-methyl-2-buten-1-ol* ***6***

Tigaldehyde was added to duryl lithium and the residue purified by vacuum distillation, bp 128–131°C/0.15 Torr, mp 45–46°C, yield 85%; $^1H$ nmr: 1.54 (d, $J$ = 7, C-3 methyl), 1.55 (C-2 methyl), 2.13 (*o*- and *m*-$CH_3$'s), 5.32 (quart., $J$ = 7, H-3), 5.52 (H-1), 6.83 (*p*-H). Considerable long range coupling is present in the C-1, 2, and 3 methyls and protons; $^{13}C$ nmr: 13.1 and 13.7 (C-2 and C-3 methyls), 16.1 (*m*-$CH_3$), 20.5 (*o*-$CH_3$), 74.5 (C-1), 118.6 (C-3), 131.0 (*p*-H), 133.1 (C-2), 134.3 (*meta*), 136.0 (*ortho*), 138.6 (*ipso*). *Anal.* calcd. for $C_{15}H_{22}O$: C 82.5, H 10.2; found: C 82.0, H 10.0.

E-*1-[1-(2,6-Dimethylphenyl)]-2-buten-1-ol* ***7***

Crotonaldehyde was added to the lithium reagent from 2-bromo-*m*-xylene. The crude solid was recrystallized from pentane, mp 49–50°C, yield 88%; $^1H$ nmr: 1.65 (d, $J$ = 7, C-3 methyl), 2.35 (*o*-$CH_3$), 5.30–5.90 (mult., H-1, 2, 3), 6.82–7.00 (mult., *m*-H, and *p*-H); $^{13}C$ nmr: 17.7 (C-3 methyl), 20.8 (*o*-$CH_3$), 71.6 (C-1), 125.9 and 127.4 (C-3 and *para* C), 129.5 (*meta*), 132.4 (C-2), 136.6 (*ortho*), 139.1 (*ipso*). *Anal.* calcd. for $C_{12}H_{16}O$: C 81.8, H 9.2; found: C 81.9, H 9.3.

E-*1(1-Pentamethylphenyl)-2-buten-1-ol* ***8***

Tiglaldehyde was added to the lithium reagent from pentamethylbromobenzene. The latter required 24 h reflux (diethyl ether solvent) to form. Distillation of the crude residue, bp 148–149°C/0.05 Torr and recrystallization from pentane gave 52% yield of the pure alcohol, mp 82–83°C; $^1H$ nmr: 1.55 (d, $J$ = 7, C-3 methyl), 1.61 (C-2 methyl), 2.20 (*o*-, *m*-, and *p*-methyl), 5.1–5.75 (H-1 and H-3); $^{13}C$ nmr: 13.1, 13.6 (C-2 and C-3 methyls), 16.6 and 17.1 (*o*- and *m*-$CH_3$), 16.9 (*p*-$CH_3$), 74.7 (C-1), 118.3 (C-3), 132.8, 133.0 (*meta* and C-2), 133.7 (*para*), 136.9, 137.0 (*ortho* and *ipso*). *Anal.* calcd. for $C_{16}H_{24}O$: C 82.75, H 10.3; found: C 82.7, H 10.6.

*2,3,6,7,8-Pentamethyl-5-methylenebicyclo[4.3.0]nona-1,3,8-triene* ***10***

This compound, in a mixture together with isoindene **9** (ca. 1:2–3 of **10**/**9**), was obtained as an oil. It was characterized by $^1H$ nmr spectroscopy: 6.09 (1H, mult., H-9), 5.82 (1H, mult., H-4), 4.69 and 4.80 (each 1H), singlets, $=CH_2$), 2.56 (1H, broad quart., $J$ = 7, H-7), 1.74 (3H) and 1.80 (6H), ($CH_3$'s at C-2, 3, and 8), 1.05 (3H, doublet, $J$ = 7, $CH_3$ at C-7), 0.89 (3H, singlet, $CH_3$ at C-6). The nmr assignments are aided by being able to convert **9** into a ketone while leaving **10** intact (13). Long range coupling

constants were obtained by decoupling studies and are shown on structure **10**.

*2,3,4,6,7,8-Hexamethyl-5-methylenebicyclo[4.3.0]nona-1,3,9-triene* ***13***

This compound, in a mixture with isoindene **12** (ca. 2–3:1 of **13**/**12**), was obtained as an oil and characterized by $^1$H nmr spectroscopy: 6.07 (1H, mult., H-9), 4.94 and 4.89 (each 1H, singlets, $=CH_2$), 2.6 (1H, broad quart., $J$ = 7, H-7), 1.82 and 1.81 (9H, $CH_3$'s at C-2, 3, 4), 1.74 (3H, $CH_3$ at C-8), 1.09 (3H, doublet, $J$ = 7.2, $CH_3$ at C-7), 0.85 (3H, singlet, $CH_3$ at C-6). Long range coupling constants were obtained by decoupling studies and are shown on structure **13**.

*Quenching experiments*

Several experiments in which $CF_3COOH$, 96% $H_2SO_4$, and $FSO_3H$ were employed as acid solvents for preparing the ions showed that 96% $H_2SO_4$ is the most convenient of these for quenching in base to give neutral products. Cations IV-6 and IV-8 were employed in these quenching studies. The only drawback to using 96% $H_2SO_4$ is the relatively high melting point. Cation IV-4, for example, is stable only up to about −30°C and therefore cannot be prepared in 96% $H_2SO_4$. The best quenching procedure was to add the sulfuric acid solution (typically 1 g of ion/10 mL of acid solvent) dropwise at 0°C to a vigorously stirred mixture of 60 g of sodium carbonate in 200 mL of water, 200 mL of ethylene glycol, and 200 mL pentane, cooled to −20°C. After warming to 20°C, the pentane layer was separated, a further pentane extraction made, and the combined layers washed with sodium carbonate solution and then water, and dried over anhydrous $K_2CO_3$. Removal of the solvent gave >90% recovery of organic material. In some cases, the main product is an alcohol (by nmr) but this alcohol is very unstable and readily dehydrates to the alkene material which is more often the direct first observed product. Other quenching procedures using $NH_2^-/NH_3$, a $CH_2Cl_2/Na_2CO_3$ suspension, or aqueous pyridine as bases were unsatisfactory.

*Molecular orbital calculations*

The standard MINDO/3 procedure of Dewar and co-workers was used (20). A PLUTO plotting routine (21) was used to construct the diagram in Fig. 2.

*Nuclear Overhauser effect experiments*

The 400 MHz measurements were performed at the University of Alberta on a Bruker WH-400 spectrometer using a subtraction routine to plot only difference spectra. The 200 MHz experiments were carried out on a Varian XL-200 using the subtraction routine No. 28 from the Varian library of pulse sequences for this instrument.

$T_1$ *experiments*

The inversion–recovery method was used, with automatic data processing by the XL-200 nmr spectrometer. Standard deviations were usually less than ±10%. Samples were deoxygenated by nitrogen purging for several hours.

*Crystalline salt attempts*

The alcohol **8** was treated for several hours at 0°C with an excess of $PCl_5$. The solid was filtered off and to the resulting solution was added a suspension of $AlCl_3$ in $CH_2Cl_2$ (1:1 molar ratio of presumed organic chloride/$AlCl_3$). An immediate reddish-black color developed and the solution was filtered under nitrogen. Partial evaporation of the $CH_2Cl_2$ usually gave a dark amorphous solid.

## Acknowledgements

We thank the Natural Sciences and Engineering Research Council of Canada for generous financial support. The University of Alberta is thanked for the 400 MHz nmr spectra. Miss B. Odell and Dr. K. Rajeswari are thanked for some preliminary experiments.

KELVIN K. OGILVIE, UKKEN O. CHERIYAN, BRUNO K. RADATUS, KENDALL O. SMITH, KAREN S. GALLOWAY, and WIEBKE L. KENNELL. Can. J. Chem. **60**, 3005 (1982).

The chemical synthesis of 9-[[2-hydroxy-1-(hydroxymethyl)ethoxy]methyl]guanine is described. This compound, known as BIOLF-62, is active against herpesviruses. This compound is a member of a novel class of nucleoside analogues which lack a rigid carbohydrate ring, but which possess all of the functional groups of naturally occurring deoxynucleosides.

KELVIN K. OGILVIE, UKKEN O. CHERIYAN, BRUNO K. RADATUS, KENDALL O. SMITH, KAREN S. GALLOWAY et WIEBKE L. KENNELL. Can. J. Chem. **60**, 3005 (1982).

L'auteur décrit la synthèse chimique du 9-[[2-hydroxy-1 (hydroxyméthyle)éthoxy]méthyl]guanine. Ce composé, connu comme le BIOLF-62, est actif contre les virus de l'herpès. Ce composé fait partie d'une nouvelle classe d'analogues nucléosides à qui il manque un anneau rigide d'hydrates de carbone, mais qui possèdent tous les groupes fonctionnels des déoxynucléosides formés naturellement.

The search for biologically active molecules has focused a great deal of attention on modified nucleosides (1–3). For several years we have been developing a nucleoside analogue structure intended to interfere with viral and bacterial systems. The structure was designed to lack the rigid conformational feature (*syn–anti*) of natural nucleosides but at the same time retain the essential chemical features of natural nucleosides (e.g., purine or pyrimidine ring, $O^{3'}$, $O^{4'}$, and $O^{5'}$ oxygen functionalities). In a preliminary report (4) we described the synthesis of the adenine analogue 9[[2-hydroxy-1-(hydroxymethyl)ethoxy]methyl]adenine. This compound was neither a substrate nor an inhibitor for adenosine deaminase, a key enzyme in animal systems that inactivates in vivo most adenine derivatives that show promising biological activity in vitro. In this report we wish to describe the synthesis of another member of this series, the potent antiviral compound 9[[2-hydroxy-1-(hydroxymethyl)ethoxy]methyl]guanine (**5**) which is known as BIOLF-62.

## Results and discussion

The first route fully explored for the synthesis of BIOLF-62 involved the condensation of 6-chloroguanine[2] (**2**) with 1,3-dibenzyloxy-2-chloromethoxypropane (**1**, ref. 4). The procedure was based on the mercuric cyanide – silylated base procedure (5). Thus, 6-chloroguanine was silylated with HMDS and coupled with **1** in refluxing benzene using $Hg(CN)_2$ and ammonium sulfate as catalysts. The condensation was generally complete within 3 h. Yields were in the 80% range for both small and large scale reactions.

Tetrabutylammonium iodide has been proposed (6) as a mild catalyst in coupling reactions of this type. Thus when **1** and **2** were condensed in acetonitrile using a catalytic amount of $(n\text{Bu})_4\text{NI}$ a fairly rapid reaction occurred. The desired product **3** was isolated in 38% yield. Finally, the Hilbert–Johnson coupling method (as elaborated by Niedballa and Vorbuggen (7)) using stannic chloride gave very low yields of desired product.

The 6-chloroguanine derivative **3** was converted into the desired guanine derivative **4** by a standard procedure (5). These conditions employ sodium methoxide, mercaptoethanol, and a trace of water in methanol at reflux for 2 to 3 h. After work-up the product **4** was obtained in 70% yield.

The removal of the benzyl groups was easily accomplished by either of two routes. In the first

case, catalytic transfer reduction (8) using palladium black and cyclohexene in refluxing ethanol gave an 84% yield of **5** after 18 h. The alternate procedure used was a Birch reduction which produced **5** in similar yields. The Birch reduction has the advantage of being a faster procedure (~ 15 min).

The synthesis of **5** from 6-chloroguanine proved to be straightforward and easy to carry out. However, it suffers from the fact that 6-chloroguanine is very expensive and sometimes difficult to obtain. Alternate routes to **5** were sought and these included the condensation of *N*-acetylguanine with **1**. Several standard condensation procedures were investigated including the use of TBAI, molecular sieves, stannic chloride, and mercuric cyanide as condensation catalysts. The TBAI reaction gave the best results with 28% yields each for the N-9 isomer **7** and the N-7 isomer **8***a*.

In another experiment, guanine was condensed

| **5** | 153.96 | 151.43 | 116.52 | 157.04 | 137.89 | 71.64 | 80.16 | 60.96 | |

*$^{13}C$ Spectra were recorded in DMSO-$d_6$ on a Bruker WP90 spectrometer.

directly to **1** using TBAI as catalyst. The slow step in this route was the silylation of guanine which required 4 days. The condensation proceeded smoothly giving a high yield in the initial condensation. However, the product was largely a 7:3 mixture of **4** and **8***b* which had similar chromatographic properties in all solvents investigated. Fortunately it was found that a mixture containing only **4** and **8***b* could be separated by fractional crystallization from ethanol. The N-7 isomer **8***b* precipitates fairly rapidly and can be separated. The N-9 isomer **4** begins to crystallize after the N-7 isomer has been removed. In this way a 41% overall yield of **4** was obtained.

The N-9 isomers were fairly easy to characterize by direct (5) comparison of their properties to known N-9 alkylated guanines including the natural nucleoside guanosine. The assignment of the N-7 isomers is also based on the spectroscopic properties. The physical properties of all compounds are collected in Tables 1 to 4.

*Sensitivity of various viruses to BIOLF-62*

Eight different herpesviruses from six animal species were tested for their susceptibility to BIOLF-62. Four of these viruses, equine herpesviruses 1 and 3 and human herpesviruses 1 and 2, were extremely sensitive to the drug, all being inhibited by 50% (effective dose, 50%) at concentrations between 0.03 and 0.3 μg/mL. Swine and bovine herpesviruses (pseudorabies and infectious bovine rhinotracheitis virus) were slightly sensitive, being 50% inhibited at 5–6 μg/mL. Feline and canine herpesviruses were insensitive, requiring 32 or more μg/mL for inhibition. Several other viruses were tested and were found resistant (human cytomegaloviruses, herpes zoster virus, vaccinia virus, and human adenovirus (9).

TABLE 3. Proton magnetic resonance data for guanine derivatives* (δ ppm)

| Compound | H-8 | $NH_2$ | H-1′ | H-3′ | H-4′ | $—CH_2\phi$ | Aromatic |
|---|---|---|---|---|---|---|---|
| **3** | 8.24 | | 5.54 | 4.04 | 3.38 | 4.34 | 7.20 |
| **4** | 7.80 | 6.50 | 5.46 | 4.02 | 3.38 | 4.20 | 7.24 |
| **5** | 7.80 | 6.50 | 5.44 | 3.40 (m, 5H) | | | |
| **7** | 8.10 | | 5.56 | 4.00 | 3.38 | 4.40 | 7.20 |
| **8***a* | 8.36 | | 5.74 | 4.10 | 3.34 | 4.36 | 7.24 |
| **8***b* | 8.10 | 6.20 | 5.68 | 4.10 | 3.34 | 4.40 | 7.24 |
| **9** | 8.13 | 6.20 | 5.72 | 3.37 | | | |

*Spectra were recorded in DMSO-$d_6$ (TMS as internal standard) on a Varian XL-200 spectrometer. Chemical shifts are reported in ppm downfield from TMS. The $NH_2$ protons were exchangeable with $D_2O$. For compounds **5** and **7** the OH protons appeared at δ = 4.60. For compound **7** the acetyl protons appeared at δ = 2.14. The numbering system is as described in Table 2.

## Experimental

*Preparation of 9-[[2-benzyloxy-1-(benzyloxymethyl)ethoxy]-methyl]-6-chloroguanine (**3**)*

*Method A*

6-Chloroguanine (15 g, 0.088 mol) was suspended in 1,1,1,3,-3,3-hexamethyldisilizane(HMDS, 200 mL). Ammonium sulfate (1.5 g) was added and the mixture was heated at reflux with exclusion of moisture for 2 h. The, by now clear, solution was concentrated at reduced pressure to leave a pale yellow solid. Mercuric cyanide (24 g, 0.095 mol) and benzene (250 mL) were added and the system was heated to reflux. To the refluxing solution was added compound **1** (29.93 g, 0.093 mol) dissolved in benzene (250 mL). The system was heated at reflux under a nitrogen atmosphere for a period of 3 h. The benzene was removed at reduced pressure and the residue was stirred with 1.5 L of dichloromethane. The solution was collected by filtration and washed twice with a 30% aqueous solution of potassium iodide (300 mL), twice with 10% aqueous potassium carbonate solution (300 mL), twice with water (300 mL), and finally with saturated sodium chloride solution (300 mL). The solution was then dried over sodium sulfate and evaporated at reduced pressure to leave 55 g of crude product.

The crude product was dissolved in a minimum volume of dichloromethane and applied to a silica gel column (8.5 × 30 cm) prepared in EtOAc–hexane (2:3). The column was eluted first with 2L of EtOAc–hexane (2:3) followed by 3 L of EtOAc–hexane (75:25). The desired product was eluted by the more polar solvent. A total of 32 g (80%) of compound **3** was obtained in this manner. Physical properties are collected in Tables 1–4.

*Conversion of **3** into 9-[[2-benzyloxy-1-(benzyloxymethyl)-ethoxy]methyl]guanine (**4**)*

Compound **3** (24 g, 0.05 mol) was dissolved in dry methanol (500 mL) and an additional 200 mL of methanol containing 4.6 g of sodium were added, followed by mercaptoethanol (16 mL) and water (1 mL). The resulting solution was refluxed under nitrogen for 1.5 h. At this point an additional 3 g of sodium in 50 mL of methanol was added and refluxing was continued for 1 h. The solution was concentrated at reduced pressure to approximately 70 mL and poured into water (400 mL). The pH of the solution was adjusted to pH 6 with glacial acetic acid. A yellow precipitate, which was collected by filtration and washed thoroughly with water and then ether, formed immediately. The solid was dried under vacuum (22 g). The nmr spectrum of the crude product indicated the presence of a major and minor (~ 20%) component. The solid was therefore stirred with warm ethyl acetate, collected by filtration, and crystallized from absolute ethanol to give 16 g (70%) of pure compound **4**. Physical properties are collected in Tables 1 to 4.

*Method B*

6-Chloroguanine (1.8 g, 10.6 mmol) was heated at reflux in HMDS (40 mL) containing ammonium sulfate (200 mg) until it became clear (2 h). The solvents were removed at reduced pressure and the residue was dissolved in dry acetonitrile (60 mL). To this solution was added tetra-*n*-butyl ammonium iodide (TBAI, 40 mg) followed by compound **1** (11 mmol) dissolved in acetonitrile (40 mL). The resulting solution was heated at reflux under a nitrogen atmosphere for 2 h. The solvents were then removed at reduced pressure and the residue was dissolved in methanol (100 mL) and the solution was stirred for 2 h. Again solvents were removed and the residue was dissolved in dichloromethane (300 mL) and the solution was filtered through Celite. After removal of solvents, 5.5 g of a viscous liquid was obtained. Pure **3** was isolated from the above liquid by flash chromatography on silica gel (Merck silica gel 60, 5 × 15 cm). The residue was dissolved in the minimum amount of dichloromethane and applied to the column which was eluted with hexane – ethyl acetate (1:3, 1 liter). Fractions of 50 mL were collected and fractions #13–19 contained the desired compound **3** (1.83 g, 38%).

*Condensation of* N*-acetylguanine (**6**a) and **1***

*Method A*

*N*-Acetylguanine (1.08 g, 5.65 mmol) was heated at reflux for 16 h in HMDS (50 mL) containing ammonium sulfate (50 mg). Solvents were removed at reduced pressure and the residue was dissolved in acetonitrile (75 mL) along with compound **1** (6 mmol) and TBAI (50 mg) and the solution was heated at reflux overnight. A mixture of methanol (40 mL) and water (10 mL)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

was added and the solution was stirred for 1 h. Solvents were removed at reduced pressure and the products were isolated by silica gel column chromatography (20 × 5.5 cm) using methanol – ethyl acetate (7:93) as eluant. Fractions of 20 mL were collected every 20 min. Fractions 10 to 30 were combined and gave 1 g of a mixture of compounds that were further separated on silica thick-layer plates developed in 5% methanol in dichloromethane. Three bands were obtained containing 490 mg, 204 mg, and 250 mg, respectively. The latter material was the 7-alkylated isomer (**8***a*) and the others were unidentified. Fractions 30 to 50 were combined to give 500 mg of the 7-alkylated derivative (**8***a*) for a total yield of 750 mg (28%, Tables 1 and 3). The $^{13}C$ spectra showed important peaks at δ 173.23 (C=O), 23.53 ($CH_3$), 74.78 (C-1'), 76.45 (C-3'), 69.60 (C-4'), and 72.08 (—$\overset{*}{C}H_2\phi$)). Fractions 52 to 85 were combined to give 750 mg of the desired N-9 product **7** (28%, Tables 1 and 3). The $^{13}C$ spectra showed important peaks at δ 173.34 (C=O), 23.69 ($CH_3$), 72.19 (C-1'), 76.83 (C-3'), 69.65 (C-4'), and 72.19 (—$\overset{*}{C}H_2\phi$).

*Method B*

This procedure was similar to method A, except that the condensation between **1** and **6***a* was carried out in dichloroethane (75 mL) at reflux for 4 h over molecular sieves (4 Å). On work-up the product distribution was found to be virtually the same as that for method A.

*Method C*

This procedure was similar to method B, except that freshly distilled stannic chloride (1 mL) was used as catalyst and the reaction (in dichloroethane) was allowed to stand overnight at room temperature. The solution was poured into aqueous sodium bicarbonate solution and the products were extracted into chloroform. On work-up the product distribution was found to be 0.15 g (3%) of the 7-isomer (**8***a*), and 0.43 g (9%) of the 9-isomer (**7**).

*Method D*

This procedure was similar to method C, except that the solvent was benzene (90 mL) and the catalyst was mercuric cyanide. After refluxing for 1½ h the products were isolated as before to give 1.03 g of the 7-isomer (**8***a*, 22%), and 0.68 g (14%) of the 9-isomer (**7**).

*Conversion of* **7** *into* **4**

Compound **7** (1.3 g, 2.7 mmol) was dissolved in pyridine (1.5 mL) and concentrated ammonium hydroxide (6 mL) was added. The solution was heated at 55°C in a tightly stoppered flask for 15 h. The product **4** crystallized from solution as it was produced and 1.18 g (99%) was collected in this manner.

*Conversion of* **8**a *into* **8**b

This procedure was identical to that described above for **7** and the product **8***b* was obtained in 95% yield.

*Conversion of* **4** *into 9[[2-hydroxy-1-(hydroxymethyl)ethoxy]-methyl]guanine* **5**

*Method A. Catalytic transfer hydrogenation*

Compound **4** (15.6 g, 36 mmol) was dissolved in refluxing ethanol (800 mL). Cyclohexene (400 mL) and palladium black (15 g) were added and refluxing was continued for 18 h. The solution was collected by filtration and the palladium catalyst was extracted five times with hot DMF (200 mL, 100°C). The filtrate and washings were combined and evaporated to leave a residue which was dissolved in hot ethanol–water (200 mL each) and filtered through Celite containing 0.5 g of activated charcoal. The solvent was removed at reduced pressure and the residue crystallized from ethanol–water (4:1). A total of 7.72 g (84%) of **5** was recovered.

*Method B. Birch reduction*

A two-liter three-necked flask fitted with a Dry Ice condenser was cooled in an acetone – Dry Ice bath under a stream of nitrogen. About one liter of liquid ammonia was collected in the flask by condensing dry ammonia gas. A slurry of the compound **4** (20 g, 45.7 mmol) in dry THF (100 mL) was added with stirring. The temperature of the bath was then allowed to rise to −45° to −40°C. Sodium was then added in small quantities until a permanent blue colour was obtained. The stirring was continued for 15 min. The blue colour was then discharged by the addition of ammonium chloride in small quantities. (Note: All the above operations were carried out under nitrogen.) The ammonia and THF were then evaporated off under a stream of nitrogen. The white residue obtained was agitated with benzene (300 mL) and filtered. The solid left behind was dissolved in water (500 mL) and extracted with benzene (3 × 200 mL). The aqueous layer was acidified with acetic acid (pH 5–6) and left overnight. The white precipitate obtained was collected by filtration. It was dissolved in boiling water (700 mL). Norite (neutral) was then added and filtered. The filtrate on standing gave 7.6 g of white crystals. The mother liquors on concentration yielded another crop of crystals (1.4 g) for a total yield of **5**, 9.0 g (77%).

*Conversion of* **8**b *into* **9**

Compound **8***b* was converted by catalytic transfer hydrogenation into **9** by a procedure identical to that described under method A for the conversion of **4** into **5**. Compound **9** was crystallized from ethanol and obtained in an 89% yield.

*Condensation of guanine* **6**b *with* **1** *to give* **4**

Guanine (3.1 g, 20.5 mmol) and ammonium sulfate (250 mg) were weighed into a 500 mL round-bottom flask. 1,1,1,3,3,3-Hexamethyldisilazane (150 mL) was added and the mixture was heated under reflux with the exclusion of moisture. After 2 days an additional 150 mg of ammonium sulfate was added and reflux was continued. After two days (total 4 days) the solution was clear.

The solvent was removed at reduced pressure and the residue was dissolved in 120 mL of freshly distilled acetonitrile. Tetra-*n*-butylammonium iodide (80 mg) was added, followed by 21.2 mmol of the chloromethylether (compound **1**) in acetonitrile (50 mL). The resulting solution was heated at reflux under nitrogen for 15 h. A thin-layer chromatogram in ethyl acetate – methanol (4:1, v/v) showed a major band at $R_f$ 0.30 and a minor band at the origin. The band at 0.30 contains the desired product and the N-7 isomer in a ratio of 7:3 (nmr determination).

The solvents were removed at reduced pressure and the residue was dissolved in 800 mL of dichloromethane. This solution was washed successively with potassium carbonate solution (10% in water, 200 mL) and water (200 mL). The dichloromethane solution was then evaporated to a small volume. Methanol (50 mL) was added and the solvents were removed at reduced pressure. The residue (10 g) was dissolved in dichloromethane (200 mL) and applied directly to a silica gel column (8.5 × 17 cm, 500 g). Elution was carried out using ethyl acetate – methanol (4:1, v/v). Fractions of 20 mL were collected every 15 min. The desired product was contained in fractions 21 to 130. The material contained in these fractions was washed with hot ethyl acetate and then crystallized from ethanol. The N-7 isomer (**8***b*) selectively crystallizes first, followed by a slower crystallization of **4**. In this way 3.64 g of **4** (41%) was obtained. The yield of the N-7 isomer was 1 g (11%).

# Thermochemical parameters for organic radicals and radical ions. Part 2.[1] The protonation of hydrocarbon radicals in the gas phase

A. MARTIN DE P. NICHOLAS, RUSSELL J. BOYD, AND DONALD R. ARNOLD[2]

*Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3*

Received June 3, 1982

A. MARTIN DE P. NICHOLAS, RUSSELL J. BOYD, and DONALD R. ARNOLD. Can. J. Chem. **60**, 3011 (1982).

A thermochemical cycle is used to estimate the gas phase acidity of several hydrocarbon radical cations: hydrocarbon radical cation ($pK_a$), methane ($\geq 86.5 \pm 1$), ethane ($101 \pm 1$, $102 \pm 1$), ethylene ($\geq 125 \pm 2$), acetylene ($118 \pm 3$, $122 \pm 1$), propene ($124 \pm 1$, $122 \pm 1$), cyclopropane ($\geq 134$, $\geq 131$), benzene ($147 \pm 1$), and toluene ($139 \pm 1$, 140). Similarly, proton affinities of the conjugate base, the hydrocarbon radical, are estimated.

An estimate of the proton affinity is obtained using *ab initio* MO calculations. A Hartree–Fock proton affinity, $PA_{HF(R^{\bullet})g}$ is defined as the difference in the computed energies of a radical cation and its conjugate base at the Hartree–Fock level. Calculations at the SCF level are carried out using both the minimal (STO-3G) and extended basis sets, without (3-21G, 4-31G, and 6-31G) and with (4-31G* and 6-31G*) polarization functions on carbon.

The agreement between the thermochemical and *ab initio* estimates of the proton affinity is satisfactory.

A. MARTIN DE P. NICHOLAS, RUSSELL J. BOYD et DONALD R. ARNOLD. Can. J. Chem. **60**, 3011 (1982).

On a utilisé un cycle thermochimique pour évaluer l'acidité en phase gazeuse de plusieurs cations radicalaires hydrocarbonés; cation radicalaire hydrocarboné ($\geq 86{,}5 \pm 1$), éthane ($101 \pm 1$, $102 \pm 1$), éthylène ($\geq 125 \pm 2$), acétylène ($118 \pm 3$, $122 \pm 1$), propène ($124 \pm 1$, $122 \pm 1$), cyclopropane ($\geq 134$, $\geq 131$), benzène ($147 \pm 1$) et toluène ($139 \pm 1$, 140). On a évalué de la même façon les affinités des différentes bases conjuguées pour le proton, ainsi que le radical hydrocarboné.

On a obtenu une évaluation de l'affinité pour le proton en utilisant les calculs de MO "*ab initio*". On définit une affinité pour le proton de type Hartree–Fock, $PA_{HF(R^{\bullet})g}$ comme étant la différence des énergies calculées du cation radicalaire et de sa base conjuguée au niveau Hartree–Fock. On a fait des calculs au niveau SCF en utilisant les deux ensembles de base (STO-3G) sous la forme la plus simple et la plus complete sans les ensembles (3-21G, 4-31G et 6-31G) et avec les fonctions de polarisation sur le carbone (4-31G* et 6-31G*). L'accord est satisfaisant entre les évaluations de l'affinité du proton faites thermochimiquement et celles faites d'après le calcul *ab initio*.

[Traduit par le journal]

## Introduction

Radical cations are formed by the protonation of radicals in the gas phase (reaction [1]). This is

[1] $\quad R^{\bullet}_{(g)} + H^{+}_{(g)} \rightarrow RH^{+\bullet}_{(g)}$

usually a facile process and in the absence of solvent all protonation reactions are highly exergonic. This results from the relative instability of the unsolvated proton, which attaches to any radical with which it collides. The basicity of hydrocarbon radicals in solution is a subject of considerable interest. These radicals show little or no tendency to protonate even in strongly acidic solutions and, therefore, direct determination of radical basicity is difficult (1, 2).

The energy change involved in the gas phase protonation reaction (reaction [1]) provides a direct measure of the intrinsic basicity of a radical. Recently experimental determinations of the proton affinity of hydrocarbon radicals have been reported (3, 4). The occurrence of a proton transfer reaction, reaction [2], has been used to bracket the proton affinity of a radical relative to standard bases. The limitation on the accuracy of this technique does not permit direct measurements of absolute proton affinities.

[2] $\quad RH^{+\bullet}_{(g)} + B_{(g)} \rightarrow R^{\bullet}_{(g)} + BH^{+}_{(g)}$

Thermochemical cycles recently have been used to establish an absolute scale of proton affinities for radicals (3), and to estimate the $pK_a$'s of radical cations in the gas phase and in solution (5). The relationship between the acidities of radical cations in the gas phase and in solution involves the solvation of $RH^{+\bullet}$, $R^{\bullet}$, and $H^{+}$. In our previous paper we have shown that the determination of the gas phase acidity of a radical cation provides a method of estimating its $pK_a$ in solution (5). The deprotonation of radical cations, an important reactive pathway in the oxidation of hydrocarbons (6, 7), has been shown to occur even in strongly acidic solutions (2, 8). Thus, establishing an absolute scale of gas phase acidities for radical cations will be useful in understanding the behaviour of these reactive species in solution.

The prediction of equilibrium geometries and relative energies of small neutral molecules, radicals, and radical ions is one of the promising areas for the application of molecular orbital (MO) theory (9). *Ab initio*, single determinant, self-consistent

field (SCF) theory can be used to estimate the energy change of eq. [1], $\Delta E_1$, at 0 K. $R^{\bullet}$ and $RH^{+\bullet}$ have the same number of electrons and multiplicity, which minimizes the difference in their correlation energies. If this difference is neglected $\Delta E_1$ can be obtained directly using Hartree–Fock (SCF) wave functions (*vide infra*).

In the present work, the $pK_a$ of hydrocarbon radical cations ($RH^{+\bullet}$) and the proton affinity of the corresponding radicals ($R^{\bullet}$) are estimated using a thermochemical cycle described previously (5). The thermochemical proton affinities are then compared with the Hartree–Fock proton affinities obtained from *ab initio* MO calculations using three types of basis functions.

This study was undertaken as part of our continuing interest in the properties of radicals and radical ions (5). The purpose of this work was to study the thermodynamics of the protonation of hydrocarbon radicals and to ascertain the feasibility of using *ab initio*, single determinant, MO calculations to determine the proton affinities of these radicals. Radicals can be classified according to the type of orbital the unpaired electron occupies and in this paper the protonation of representative p, σ and π (aliphatic), and σ and π (aromatic) radicals is described.

## Method

*Thermochemical calculations*

The gas phase acidity of a radical cation ($RH^{+\bullet}$) can be expressed in terms of the free energy change, $\Delta G_3$, for its deprotonation in the gas phase, eq. [4].

[3] $$RH^{+\bullet}{}_{(g)} \rightarrow R^{\bullet}{}_{(g)} + H^{+}{}_{(g)}$$

[4] $$pK_{a(RH^{+\bullet})g} = \Delta G_3/2.303RT$$

We have shown that the quantity $\Delta G_3$ can be calculated for many radical cations using existing thermochemical data (eq. [5]).

[5] $$\Delta G_3 = -F(\mathrm{IP(adiabatic)}_{RH}) + \Delta G^0{}_{BDE(RH)g} + \Delta G^0{}_{f(H^+)g} - \Delta G^0{}_{f(H)g}$$

where $\mathrm{IP(adiabatic)}_{RH}$ is the adiabatic ionization potential in electron volts. The changes in entropy and heat capacity on ionization of RH to the radical cation $RH^{+\bullet}$ have been shown to be small and are neglected in this work (10); $F$ is the Faraday constant and $\Delta G^0{}_{BDE(RH)g}$ is the standard free energy change associated with the homolytic cleavage of the R—H bond in the gas phase.

The proton affinity of a radical $R^{\bullet}$ in the gas phase ($PA_{(R^{\bullet})g}$) is equal to the enthalpy change for eq. [3], $\Delta H_3$, and is given by eq. [6].

[6] $$PA_{(R^{\bullet})g} = \Delta H_3 = -F(\mathrm{IP(adiabatic)}_{RH}) + \Delta H^0{}_{BDE(RH)g} + \Delta H^0{}_{f(H^+)g} - \Delta H^0{}_{f(H)g}$$

$\Delta H^0{}_{BDE(RH)g}$ is the standard enthalpy change associated with the homolytic cleavage of the R—H bond in the gas phase. $\Delta H^0{}_{f(H^+)g} - \Delta H^0{}_{f(H)g}$ is usually assumed to be equal to the ionization potential of H. This simplifies eq. [6] to eq. [7].

[7] $$PA_{(R^{\bullet})g} = -F(\mathrm{IP(adiabatic)}_{RH} - \mathrm{IP}_H) + \Delta H^0{}_{BDE(RH)g}$$

Ab initio *MO calculations*

The energy difference between $R^{\bullet}{}_{(g)}$ and $RH^{+\bullet}{}_{(g)}$, ($\Delta E_3$), at 0 K has been related to the gas phase proton affinity of $R^{\bullet}$, $PA_{(R^{\bullet})g}$, by eq. [8] (11).

[8] $$PA_{(R^{\bullet})g} = \Delta E_3 - \Delta\mathrm{ZPE} + (5/2)RT$$

The term ΔZPE is the difference in the zero point energies of $R^{\bullet}{}_{(g)}$ and $RH^{+\bullet}{}_{(g)}$, and $(5/2)RT$ is a thermodynamic temperature correction term. The term $\Delta E_3$ includes both the dominant Hartree–Fock energy difference and any correlation energy corrections. We define the Hartree–Fock energy contribution to the proton affinity of a radical as the Hartree–Fock proton affinity and denote it by $PA_{HF(R^{\bullet})}$.

[9] $$PA_{HF(R^{\bullet})} = E_{HF(R^{\bullet})} - E_{HF(RH^{+\bullet})} + (5/2)RT$$

where $PA_{HF(R^{\bullet})g}$ can be expressed under standard conditions at any temperature, $T$, eq. [9]. Due to the large computational (CPU) time required in using near Hartree–Fock basis sets, basis sets of limited size have been used in this work. However, a fair estimate of the energy difference between two species, at the Hartree–Fock level, can be obtained using basis sets of limited size. Thus, eq. [10] has been assumed, where the Hartree–Fock energy ($E_{HF}$) in eq. [9] is replaced by $E_{SCF}$, the energy

[10] $$PA_{HF(R^{\bullet})} = E_{SCF(R^{\bullet})} - E_{SCF(RH^{+\bullet})} + (5/2)RT$$

computed using an *ab initio*, single determinant, self-consistent field procedure.

Standard single determinant MO theory was used. The *ab initio* MO calculations described were obtained by the use of the GAUSSIAN 76 program (12). The open-shell, spin-unrestricted (UHF) procedure was employed (13) to compute the energies of all the radicals and radical cations. The six basis sets used have been previously described in the literature (14–18). The minimal STO-3G (14), and extended basis sets of two types (15–18) were used. These were the split-valence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

basis sets, without (3-21G (15), 4-31G (16), and 6-31G (17)) and with (4-31G* and 6-31G* (18)) polarization functions on carbon. The variation of $PA_{HF(R^{\cdot})}$ (eq. [10]), with basis sets, was studied while constraining the radical cations and their conjugate bases to their STO-3G optimized geometries. The 3-21G $PA_{HF(R^{\cdot})}$ values for the methyl, ethyl, vinyl, and ethynyl radicals were also computed using 3-21G optimized geometries.

*Geometries*

Geometry optimizations, subject only to the imposed symmetry constraints, were carried out at the STO-3G level. Complete optimizations at the STO-3G level were performed for the radical cations of propene ($C_s$ symmetry) and benzene ($D_{6h}$ symmetry). Complete optimizations were carried out at the 3-21G level, for the radical cations of ethane, acetylene, and ethylene. The STO-3G geometry of the cyclopropane radical cation was computed in our laboratory as part of another program.[3] All other optimized geometries at the STO-3G and 3-21G levels used in this work were obtained from the work of Pople and co-workers (9, 19). Due to the large CPU time requirements only partial optimization of the phenyl and benzyl radicals, and the toluene radical cation, were performed.

*Propene radical cation*

Rotation around the C—C single bond indicated that the lowest energy with $C_s$ symmetry was obtained when the molecule was oriented as shown in Fig. 1.

*Benzene radical cation*

$C_6H_6^{+\cdot}$ is obtained by the removal of a π electron from a $(1a_{2u})^2(1e_{1g})^4$ electronic configuration. The Jahn–Teller theorem states that in such a situation the molecule distorts from a $D_{6h}$ symmetry such that the degeneracy of the $e_{1g}$ orbitals is removed. However, a $D_{6h}$ symmetry was assumed in this work. Optimization at the STO-3G level lead to the following structure $D_{6h}$, $r_{CC}$ = 1.417 Å and $r_{CH}$ = 1.089 Å.

*Phenyl radical*

A $C_{2v}$ symmetry was assumed, together with the further constraint that the carbon skeleton $C_2$—$C_3$—$C_4$ and the hydrogens $H_2$, $H_3$, and $H_4$ were fixed in the same positions as in the optimized STO-3G structure of benzene (19). Optimization of the remaining parameters, assuming $r(C_1H_1)$ = 1.083 Å, $r(C_5H_5)$ = 1.083 Å, and $\angle H_1C_1C_2$ = 120°, and $\angle H_5C_5C_4$ = 120°, lead to the structure given in Fig. 2*a*.

*Benzyl radical*

The geometrical parameters of the $CH_2^{\cdot}$ group attached to a standard phenyl ring[4] were optimized (Fig. 2*b*).

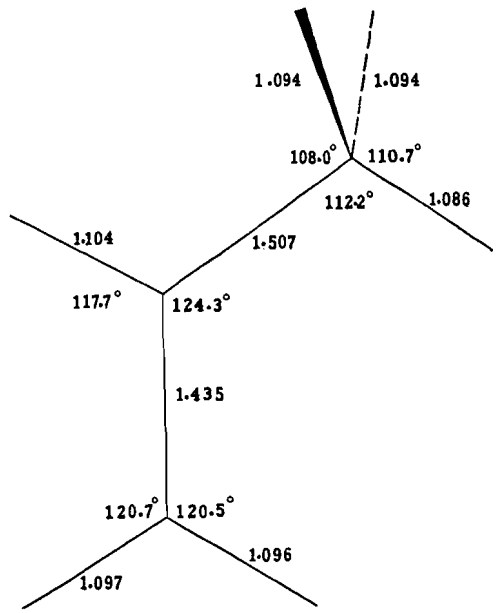

FIG. 1. Completely optimized STO-3G structure of the propene radical cation ($C_s$).

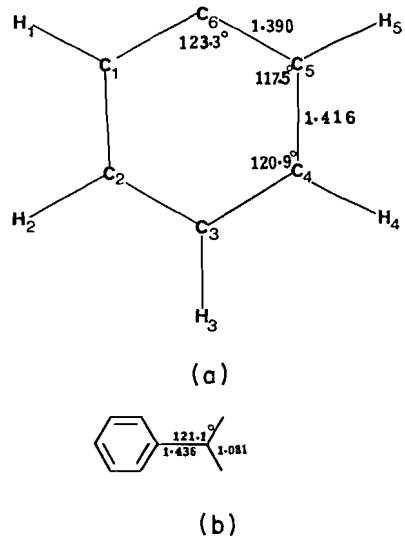

FIG. 2. Partially optimized STO-3G structures of (*a*), the phenyl radical ($C_{2v}$), (*b*), the benzyl radical ($C_{2v}$).

[d]Error limits not defined.
[e]Data calculated for the ($c$-$C_3H_6^{+\cdot}$/allyl radical) acid–base system. However, note that for the deprotonation of $c$-$C_3H_6^{+\cdot}$ the kinetically controlled product is the cyclopropyl radical (ref. 4).

*Toluene radical cation*

A hydrogen of the STO-3G optimized structure of $C_6H_6^{+\cdot}$ ($D_{6h}$) was replaced by a model $CH_3$ group ($r_{CH}$ = 1.09 Å and ∠HCH = 109.5°) at an optimized C—C bond distance ($C_s$ symmetry, $r_{CC}$ = 1.525 Å).

## Applications

Tables 1 and 2 show that the p$K_a$ of a radical cation ($RH^{+\cdot}$) is not directly correlated to either the ionization potential or the bond dissociation free energy of RH. Similarly, the variation of $PA_{(R^{\cdot})g}$ for the series of radicals studied in this work must be discussed in terms of both $IP_{RH}$ and $\Delta H_{BDE}$ of RH. From Table 2, it is seen that the radical cation of methane is the strongest acid (p$K_a$ = 86.5) and the benzene radical cation the weakest acid (p$K_a$ = 147) of the radical cations studied.

Compared to benzene, saturated hydrocarbons have higher IP values and lower $\Delta H_{BDE}$ and $\Delta G_{BDE}$ values which make their radical cations stronger acids than the benzene radical cation. Molecules

containing π-electrons and/or heteroatoms with unshared electron pairs usually have IP values lower than those of saturated compounds. Among these molecules the aromatics usually have lower IP values relative to the aliphatics. In general, aliphatic hydrocarbon radical cations are stronger acids than are aromatic hydrocarbon radical cations. However, the acidity of the radical cations of such electron-rich molecules will also depend on the nature of the conjugate base. For example, the IP values of propene and toluene are lower than those of ethylene and benzene respectively; but, the radical cations of propene and toluene are stronger acids than the radical cations of ethylene and benzene respectively. This is because the radical cations of propene and toluene are π-acids and on deprotonation yield resonance stabilized radicals, while the radical cations of ethylene and benzene are σ-acids.

*Ab initio* calculations show that the STO-3G results yield higher values for $PA_{HF(R^{\bullet})}$ compared to the extended basis sets. The difference between the Hartree–Fock and thermochemical proton affinities of radicals will not be expected to be greater than 10 kcal mol$^{-1}$ (20). Of the basis sets used in this work, the 3-21G basis set, at the STO-3G geometry, yields $PA_{HF(R^{\bullet})}$ closest to the corresponding thermochemical values. The energies of $RH^{+\bullet}$ and $R^{\bullet}$ are lowered to a greater extent by increasing the number of primitives that describe the core rather than by adding polarization functions on carbon (Table 3). The addition of polarization functions on carbon to the 4-31G and 6-31G split-valence basis sets had a greater effect on the energy of $RH^{+\bullet}$; while, increasing the number of Gaussian functions describing the core in the 4-31G and 4-31G* basis sets lowered the energy of $R^{\bullet}$ by a greater amount. Consequently, the $PA_{HF(R^{\bullet})}$ value was increased by the addition of polarization functions, and decreased by increasing the number of primitives describing the core. Complete optimization at the 3-21G level did not significantly change the $PA_{HF(R^{\bullet})}$ values (Table 4). Thus, single point calculations using larger basis sets at the STO-3G geometry can yield useful information about the effects of basis set size on $PA_{HF(R^{\bullet})}$.

In the next section the thermochemical and Hartree–Fock proton affinities of $R^{\bullet}$ in each of the acid–base pairs ($RH^{+\bullet}/R^{\bullet}$) are compared. The uncertainty of the results obtained is also discussed. Comparison with experimental determinations of $PA_{(R^{\bullet})g}$ is made in the few cases where data is available.

*Methyl ($CH_3^{\bullet}/CH_4^{+\bullet}$)*

For closed-shell species ΔZPE in eq. [8] is expected to be positive and the correlation energy usually small (20). Thus, $PA_{HF(R^{\bullet})g}$ is expected to be larger than the thermochemical value. However, the $PA_{HF(CH_3^{\bullet})g}$ values obtained for all the extended basis sets are lower than the thermochemical value.[5] This may be due to the weakening of the C—H bonds in methane on ionization to an extent such that the zero-point energy of $CH_4^{+\bullet}$ is smaller

[5]UHF calculations using a Van Duijnevelt CGTO (C⟨4*s*, 3*p*⟩ and H⟨3*s*⟩ basis set (26) also yielded $PA_{HF(R^{\bullet})g}$ values lower than the thermochemical value. $PA_{HF(CH_3^{\bullet})CGTO//STO\text{-}3G}$ = 120.0 kcal mol$^{-1}$.

than that of $CH_3^\bullet$. We intend to consider this point in detail in our future work. The thermochemical method gives only a lower limit of $PA_{(R^\bullet)g}$ because the IP(adiabatic) has been reported as an upper limit of the true value (21). The $\Delta H_{BDE}$ used in this work is based on recent experimental results and a critical review of earlier data and is the currently recommended value (22).

*Ethyl* ($C_2H_5^\bullet/C_2H_6^{+\bullet}$)

As expected, all computed $PA_{HF(R^\bullet)g}$ values are larger than the thermochemical $PA_{(R^\bullet)g}$ value. The error in the thermochemical proton affinity largely depends on the uncertainty in $\Delta H_{BDE}$ because the error in IP(adiabatic) is small (21). The proton affinity of the ethyl radical is ~20 kcal mol$^{-1}$ greater than that of the methyl radical. This indicates that replacing a H in $CH_3^\bullet$ by a methyl group results in a greater stabilization of $RH^{+\bullet}$ relative to $R^\bullet$.

*Vinyl* ($C_2H_3^\bullet/C_2H_4^{+\bullet}$)

The thermochemical method gives only a lower limit of the $PA_{(R^\bullet)g}$ value, because $\Delta H_{BDE}$ has been reported as a lower limit of the true value (23). There is a fair agreement between the experimental (4) and thermochemical proton affinities. The difference between the thermochemical and the computed Hartree–Fock proton affinities is larger than that usually expected from ΔZPE and correlation energy contributions. The proton affinity of the vinyl radical is ~30 kcal mol$^{-1}$ greater than that of ethyl radical. This results from the ease of ionization and the greater $\Delta H_{BDE}$ value of ethylene relative to ethane.

*Ethynyl* ($C_2H^\bullet/C_2H_2^{+\bullet}$)

There is a large variation between the $\Delta H_{BDE}$ values of acetylene that have been used in this work to estimate the thermochemical proton affinity (Table 1). No experimental determination is available to assess the accuracy of the thermochemical values. There is a large difference between the computed Hartree–Fock and thermochemical proton affinities; the uncertainty in the $\Delta H_{BDE}$ values precludes a discussion of the reasons for this difference. The estimated proton affinity of the ethynyl radical is lower than that of the vinyl radical, because the difference in IP(adiabatic) values ($\Delta IP \sim 20$ kcal mol$^{-1}$) more than offsets the difference in the bond dissociation enthalpies ($\Delta(\Delta H_{BDE}) \sim 15$ kcal mol$^{-1}$).

*Allyl* ($C_3H_5^\bullet/C_3H_6^{+\bullet}$)

The allyl radical can, in principle, be formed by the deprotonation of the radical cations of both propene and cyclopropane. We have estimated the proton affinity of the allyl radical in forming both of its conjugate acids. The thermochemical proton affinity for the formation of the propene radical cation is lower than the experimental value. The error in the thermochemical value is largely dependent on the accuracy of the $\Delta H_{BDE}$ value. The accuracy of the experimental determination is also limited to ±2 kcal mol$^{-1}$ by the bracketing technique used (3, 4). As expected, the $PA_{HF(R^\bullet)g}$ values are greater than the thermochemical proton affinity.

*Cyclopropyl* (c-$C_3H_5^\bullet$/c-$C_3H_6^{+\bullet}$)

There is a large variation between $\Delta H_{BDE}$ values of cyclopropane reported in the literature (4, 22*c*, 23). We have used two of these values to estimate $PA_{(R^\bullet)g}$. The thermochemical method gives a lower limit to $PA_{(R^\bullet)g}$ (Table 2). One of the estimated thermochemical proton affinities agrees well with the experimental value (Table 5). The difference between $PA_{HF(R^\bullet)g}$ and the thermochemical values is larger than in the propene system. As in the ethynyl system this difference cannot be explained by the absence of a reliable thermochemical proton affinity. The cyclopropyl radical has a proton affinity larger

than that of the vinyl and allyl radicals. This is largely due to the relatively low IP(adiabatic) of cyclopropane.

*Phenyl ($C_6H_5^{\cdot}/C_6H_6^{+\cdot}$)*

Attempts to experimentally determine $PA_{(R^{\cdot})g}$ have thus far failed (4). One of the reasons has been the absence of a suitable reference base with a proton affinity greater than 210 kcal $mol^{-1}$. The thermochemical approach provides a method of obtaining the $PA_{(R^{\cdot})g}$ value. The IP(adiabatic) of benzene has been determined with a negligible error (21). Consequently, the uncertainty in the $PA_{(R^{\cdot})g}$ estimated in this work depends on the accuracy of the $\Delta H_{BDE}$ value. Only a partial optimization was carried out to obtain the STO-3G equilibrium geometries for $C_6H_5^{\cdot}$ and $C_6H_6^{+\cdot}$. Thus, the slight difference between the Hartree–Fock and thermochemical proton affinities obtained in this work may be due to a fortuitous cancellation of errors.

*Benzyl ($C_6H_5CH_2^{\cdot}/C_6H_5CH_3^{+\cdot}$)*

The thermochemical $PA_{(R^{\cdot})}$ values agree well with the experimental determinations. In fact, one of the reported experimental values is a thermochemical value, because it was established by the use of a thermochemical cycle (3). The error in the IP(adiabatic) value and $\Delta H_{BDE}$ is small; it has been suggested that the thermochemical proton affinity of the benzyl radical is suitable to be used to establish an absolute scale of proton affinities (3).

## Conclusion

It has been demonstrated that a thermochemical approach can be used to obtain reliable proton affinities of free radicals, and to establish an absolute scale of $PA_{(R^{\cdot})g}$ values. Except for the ethynyl radical, the trend in the *ab initio* and thermochemical proton affinities agree. Thus, the *ab initio* self-consistent field MO method can be used to obtain relative values of proton affinities in the absence of accurate thermochemical data.

Studies were carried out on the kinetics of solvolysis of triphenylvinyl bromide (**1**-Br) or trianisylvinyl bromide (**2**-Br) in 70% HOAc – 30% $H_2O$ in the presence of added $Et_4NBr$, NaOAc, or $LiClO_4$ and on the degree of incorporation of $^{82}Br$-labeled bromide into **1**-Br or **2**-Br during the solvolysis. Common ion rate depression and $^{82}Br$ exchange were observed for both substrates, indicating the involvement of the dissociated triphenylvinyl and trianisylvinyl cations. For both substrates, a normal salt effect was found for NaOAc and $LiClO_4$. With NaOAc, there was also a steeper rise in rate at low concentrations of added salt, but this initial rate enhancement was only 11 and 13%, respectively, for **1**-Br and **2**-Br, and the fact that $LiClO_4$ showed only a normal salt effect suggested that probably there was no special salt effect for NaOAc. These results, considered in conjunction with previous scrambling data, led to the suggestion that the previously observed insensitivity of the extent of isotopic scrambling in the solvolysis of **1**-Br-2-$^{14}C$ may be due to a low selectivity for the less stable triphenylvinyl cation.

---

CHOI CHUCK LEE, CRAIG A. OBAFEMI et ZVI RAPPOPORT. Can. J. Chem. **60**, 3019 (1982).

On a étudié les cinétiques de la solvolyse du bromure de triphénylvinyle (Br-**1**) ou du bromure de trianisylvinyle (Br-**2**) dans un mélange de AcOH–$H_2O$ à 70:30 en présence de $Et_4NBr$, NaOAc ou $LiClO_4$, et le degré d'incorporation du bromure marqué $^{82}Br$ dans le Br-**1** ou le Br-**2** au cours de la solvolyse. On a observé une diminution de la vitesse de l'ion commun et un échange de $^{82}Br$ pour les deux substrats. Ceci indique une participation des cations dissociés de triphénylvinyle et de trianisylvinyle. On a trouvé, pour les deux substrats, un effet de sel normal dans le cas du NaOAc et du $LiClO_4$. Dans le cas du NaOAc il y a également une augmentation plus rapide de la vitesse à de faibles concentrations de sel ajouté; mais cette l'augmentation de la vitesse initiale est respectivement de 11 et de 13% seulement pour le Br-**1** et le Br-**2** et l'effet normal de sel du $LiClO_4$ suggère que probablement le NaOAc n'a pas d'effet de sel spécial. Ces résultats joints aux données antérieures de mélange, suggèrent que la constance du taux de mélange isotopique observée antérieurement au cours de la solvolyse de Br-**1** $^{14}C$-2, peut être due à une faible sélectivité envers le cation triphénylvinyle moins stable.

[Traduit par le journal]

In an early study on vinyl cations, Jones and Miller (1) reported that the decomposition in HOAc of 1-phenyl-2,2-di-*p*-tolylvinylphenyltriazene gave 80% of the unrearranged 1-phenyl-2,2-di-*p*-tolylvinyl acetate and 20% of the rearranged 2-phenyl-1,2-di-*p*-tolylvinyl acetate, the latter being derived from the rearrangement of the 1-phenyl-2,2-di-*p*-tolylvinyl cation to the more stable 2-phenyl-1,2-di-*p*-tolylvinyl cation. In the presence of 10 molar equivalents of added KOAc, however, the formation of the rearranged product was completely suppressed. Similarly, Lee and Ko (2) have found that the trianisylvinyl cation generated from the decomposition in HOAc of trianisyl[2-$^{14}C$]vinylphenyltriazene showed about 38% scrambling of the $^{14}C$-label from C-2 to C-1 arising from 1,2-anisyl shifts. When the reaction was carried out in the presence of 1.7 molar equivalents of NaOAc, the extent of scrambling was decreased to about 17%. These findings were considered to be consistent with the formation of the dissociated "free" triarylvinyl cation, the 1,2-aryl shifts in which would be decreased by the presence of the more nucleophilic acetate ion (1, 2).

In the solvolysis of triphenyl[2-$^{14}C$]vinyl triflate (**1**-OTf-2-$^{14}C$) in HOAc, HCOOH, or $CF_3COOH$, it was found that the extent of isotopic scrambling arising from 1,2-phenyl shifts was not significantly affected by the presence of 1.1 molar equivalents of the conjugate base of the solvent (3). Moreover, in the solvolysis of triphenyl[2-$^{14}C$]vinyl bromide (**1**-Br-2-$^{14}C$) in 70% HOAc – 30% $H_2O$ (by volume) (to be designated 70% HOAc), the presence of about 3 molar equivalents of NaOAc or NaBr also did not materially change the extent of scrambling (4). It was, therefore, suggested (3, 4) that in the triphenylvinyl cationic system, the degenerate rearrangement arising from 1,2-phenyl shifts likely took place in the ion pair, and at this stage of ionization, the process could be insensitive to the presence of externally added nucleophiles.

With 1–3 molar equivalents of added nucleophile, the molar ratio of solvent to nucleophile was still quite high. Hence there was the possibility that

with the triphenylvinyl cationic system, rather than involving ion pairs, the insensitivity of the extent of scrambling to the presence of added nucleophiles could be due to a predominant product formation from capture of the free ion by the excess solvent. In an attempt to resolve such conflicting possibilities, a recent study was made on the effects of relatively large amounts of added NaOAc or $Et_4NBr$ on the extent of scrambling in the solvolysis of triphenyl[2-$^{14}$C]vinyl bromide (**1**-Br-2-$^{14}$C) or trianisyl[2-$^{14}$C]vinyl bromide (**2**-Br-2-$^{14}$C) in 70% HOAc (5). It was found that in the solvolysis of **1**-Br-2-$^{14}$C in 70% HOAc, there was no significant variation in the extent of scrambling when the reaction was carried out in the presence of 25 molar equivalents of added $Et_4NBr$ or up to 30 molar equivalents of added NaOAc. The conditions of the latter experiment, 25 m*M* **1**-Br-2-$^{14}$C and 750 m*M* NaOAc, were of such high concentrations that some of the reactant, **1**-Br-2-$^{14}$C, was salted out of solution, and yet the extent of scrambling in the reaction product was not significantly affected. On the other hand, in the solvolysis of **2**-Br-2-$^{14}$C in 70% HOAc, the scrambling of the label from C-2 to C-1 observed in the reaction product was found to decrease with increasing amounts of added NaOAc (5). These findings thus appeared to be consistent with the earlier proposal that in the solvolysis of **1**-Br-2-$^{14}$C, the 1,2-phenyl shifts occurred in the ion pair stage, while in the solvolysis of **2**-Br-2-$^{14}$C, the 1,2-anisyl shifts took place in the dissociated "free" trianisylvinyl cation.

Some anomalies were noted, however, in the solvolysis of **1**-Br-2-$^{14}$C or **2**-Br-2-$^{14}$C in 70% HOAc in the presence of added NaOAc and/or $Et_4NBr$ (5). While no accurate rate constants were measured in these studies, estimates of the % reaction for individual experiments suggested that the reaction rates were decreased by the presence of added $Et_4NBr$. Such a common ion rate depression has usually been attributed to external ion returns from dissociated ions to covalent reactant (6). Moreover, in both the solvolyses of **1**-Br-2-$^{14}$C and **2**-Br-2-$^{14}$C in 70% HOAc, selected experiments showed very low extents of scrambling in the recovered unconsumed reactant, except in the reaction of **2**-Br-2-$^{14}$C in the presence of very large amounts of $Et_4NBr$. The occurrence of returns from dissociated ions to give a common ion rate depression would be consistent with an absence of scrambling in the recovered reactant only if the capture of the free ion is faster than its internal rearrangement through 1,2-shifts. In order to obtain more information to clarify such possibilities, we have carried out more detailed kinetic studies on the solvolysis of **1**-Br or **2**-Br in 70% HOAc and we have also investigated the degree of incorporation through isotopic exchange of added [$^{82}$Br]-bromide ion into the organic substrate, **1**-Br or **2**-Br, under some of the conditions previously employed in the scrambling studies (5).

## Results and discussion

In the isotopic scrambling studies with **1**-Br-2-$^{14}$C or **2**-Br-2-$^{14}$C in 70% HOAc (5), experiments were carried out with 15 or 25 m*M* **1**-Br-2-$^{14}$C in the presence of added acetate or bromide ions at 150 ± 2°C, while such experiments with **2**-Br-2-$^{14}$C mostly involved a substrate concentration of 6.0 m*M* and a reaction temperature of 120 ± 1°C. Similar, but not identical, conditions were employed in the present kinetic studies involving the presence of added NaOAc, $Et_4NBr$, or $LiClO_4$. The results are given in Tables 1 and 2 and the effects of added NaOAc or $LiClO_4$ on the specific rate constants are shown in Figs. 1 and 2.

In the exchange studies, experiments were carried out in the presence of added $^{82}$Br-labeled bromide ions, usually as $Et_4NBr$, again under conditions similar to those used in some of the scrambling studies (5). These experiments were carried to roughly 50% completion and the incorporations of $^{82}$Br-activity into the recovered **1**-Br or **2**-Br were determined. The extents of exchange in the recovered substrate were then calculated, an illustration of the calculation being given in the

Experimental section. The pertinent data are summarized in Table 3. It is of interest to point out that 100% exchange in the recovered substrate involved a complete mixing of the bromine atoms in both the added bromide and the organic bromide. Thus with a higher concentration of added labeled bromide and the same relatively low concentration of the substrate, the acutal % incorporation of $^{82}Br$ activity into the recovered substrate may become lower even though there may be a greater extent of exchange. In Expts. 2 and 3 (Table 3), for example, the concentrations of the added [$^{82}Br$]$Et_4NBr$ were 45 and 375 m*M*, respectively, while the concentration of **1**-Br was 15 m*M* in both cases. Although the % incorporation in Expt. 3 of the 375 m*M* [$^{82}Br$]-$Et_4NBr$ was lower than the % incorporation in Expt. 2 of the 45 m*M* labeled bromide, the actual amount of $^{82}Br$ incorporated into the recovered substrate, and hence the extent of $^{82}Br$ exchange, was higher in Expt. 3 than in Expt. 2. Similar trends were noted in Expts. 5 and 6 and in Expts. 7 and 8.

In discussing the present results in conjunction with the previously observed scrambling data (5), one may consider the solvolytic scheme of Winstein *et al.* (6, 7) involving progressively more dissociated ionic intermediates from covalent substrate I to intimate ion pair II to solvent-separated ion pair III to dissociated ions IV (reaction [1]). In a

[1] $\underset{\text{I}}{RX} \rightleftarrows \underset{\text{II}}{R^+X^-} \rightleftarrows \underset{\text{III}}{R^+||X^-} \rightleftarrows \underset{\text{IV}}{R^+ + X^-}$

comprehensive review on ions and ion pairs in solvolysis reactions by Raber, Harris, and Schleyer (6), it was pointed out that whenever a common ion rate depression has been observed, it has invariably also been possible to demonstrate exchange. The present results are in agreement with this conclusion. The data from Expt. TP-1 to TP-4 and TA-1 to TA-4 in Tables 1 and 2 show that there is a common ion rate depression for both **1**-Br and **2**-Br, confirming the previous indication of such rate depressions from rough estimates based on single point determinations of % reaction (5). Moreover, Table 3 shows that there is also exchange between the added labeled bromide ion and **1**-Br or **2**-Br. The observation of both the mass-law effect and $^{82}Br$ exchange thus strongly suggests the involvement of dissociated ions IV in the solvolysis in 70% HOAc of both **1**-Br and **2**-Br.

From Figs. 1 and 2 showing the effects of added NaOAc or $LiClO_4$, it is seen that the shapes of the lines for the changes in specific rate constants for the solvolysis of **1**-Br or **2**-Br with increasing amounts of NaOAc resemble those customarily observed for a "special salt effect" (6–8), i.e., a steep increase at low salt concentrations followed by a moderate increase at higher salt concentrations. A formal interpretation of such a special salt effect would indicate the intermediacy of the solvent-separated ion pair III in the present reactions with **1**-Br and **2**-Br. However, such an interpretation seems to be unlikely for two reasons. Firstly, the rate enhancement in the steep region as measured by $k_{ext}^0/k_t^0$, where $k_t^0$ is the titrimetric rate constant in the absence of added salt and $k_{ext}^0$ is the extrapolated value to zero salt concentration for that portion of the graph which shows the normal salt effect at higher salt concentrations, is only 4.79/4.30 or 1.52/1.35, equalling 1.11 or 1.13, respectively, for **1**-Br or **2**-Br. These values are much smaller than such rate enhancements in other systems showing the special salt effect which usually gave $k_{ext}^0/k_t^0$ in the order of about 2–3 (6). Secondly, a similar plot for $LiClO_4$ shows only a normal salt effect (Figs. 1 and 2) and since $LiClO_4$ is a much more efficient special salt than other salts including NaOAc, it is unlikely that in the present cases with **1**-Br and **2**-Br, $LiClO_4$ would act only as a normal salt while NaOAc would act as a special salt. While it is probable that NaOAc did not cause a special salt effect, at present we do not have an explanation for the initial 11–13% rise in the rate constants at low concentrations of added NaOAc. More experimentation will be required in order to probe the generality of this behavior.

The normal salt effect for $LiClO_4$ and for NaOAc

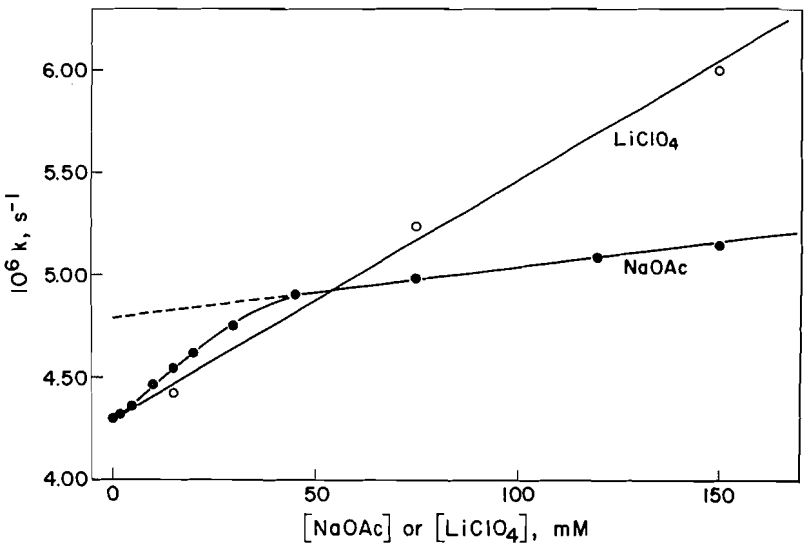

FIG. 1. Effects of added NaOAc or $LiClO_4$ on the specific rate constant in the solvolysis of triphenylvinyl bromide (1-Br) in 70% HOAc – 30% $H_2O$.

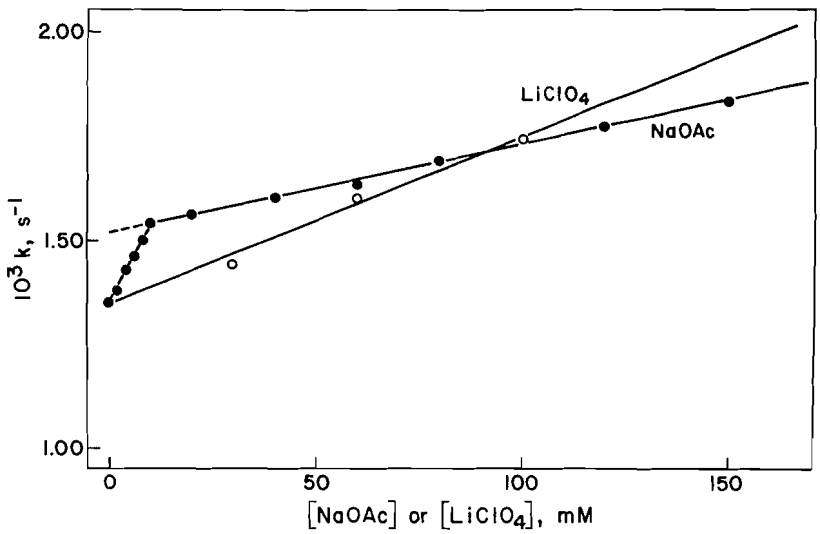

FIG. 2. Effects of added NaOAc or $LiClO_4$ on the specific rate constant in the solvolysis of trianisylvinyl bromide (2-Br) in 70% HOAc – 30% $H_2O$.

in the present reactions can be treated in terms of eqs. [2] and [3], respectively (6).

$$[2] \quad k_t = k_t^0(1 + b[\text{salt}])$$

$$[3] \quad k_t = k_{ext}^0(1 + b[\text{salt}])$$

Using eqs. [2] and [3] and data from Figs. 1 and 2, the $b$ values for the solvolysis in 70% HOAc of **1**-Br and **2**-Br, respectively, were found to be 2.5 and 3.0 for $LiClO_4$, and 0.51 and 1.4 for NaOAc. Since there is a normal salt effect, the actual rate depression due to the added common ion should be larger than the simple difference between the observed rate constant with no added salt ($k_t^0$) and the rate constant with added $Et_4NBr$ ($k_{dep}$) as given in Tables 1 and 2. The normal salt effect due to the added $Et_4NBr$ should be taken into account and this was done by calculating corrected $k_t^0$ values, $k_{corr}^0$, using eq. [2]. Since no $b$ value was obtained for $Et_4NBr$, the $b$ values for both NaOAc and $LiClO_4$ were utilized to approximate the normal salt effect of $Et_4NBr$. The results are summarized in Table 4. Since common ion rate depression arose from external ion returns from free ion IV to

covalent substrate, $1-(k_{dep}/k_{corr}^{0})$ would be a measure of the fraction of free ions that had undergone the return process. In theory, if still higher concentrations of $Br^-$ were present in the reaction mixture, further decrease in rate could result. However, from the experiments that were actually carried out to give the data in Table 4, it may be concluded that the minimum fraction of the reaction involving free ion IV (9) would be 38% and 86%, respectively, for 1-Br and 2-Br, if the $b$ value for $Et_4NBr$ were similar to that of $LiClO_4$.

In the isotopic scrambling studies with 1-Br-2-$^{14}$C (4, 5), it was found that for solvolysis in 70% HOAc in the absence of added salt or in the presence of 3 equivalents of added NaOAc or NaBr, the recovered unconsumed reactant showed what was believed to be a negligible amount of scrambling of 0.5% or less. Similarly, in the solvol-

ysis of 2-Br-2-$^{14}$C (5) in 70% HOAc in the presence of up to 30 equivalents of NaOAc and 30 equivalents of $Et_4NBr$, the recovered substrate showed isotopic scramblings of only 1% or less. In the presence of very large amounts of added $Et_4NBr$, however, significant extents of scrambling in the recovered unconsumed reactant were observed in the reactions with 2-Br-2-$^{14}$C (5) and these results are reproduced in Table 5. In order to obtain data for comparison from the triphenylvinyl system under conditions of high concentrations of added bromide ions, 1-Br-2-$^{14}$C was solvolyzed in 70% HOAc under such conditions to give the results recorded in Table 5, showing that in the presence of large amounts of $Et_4NBr$, the scramblings in the recovered reactant are indeed more than the previously reported 0.5% or less. Thus all the results discussed so far suggest a considerable degree of similarity in the behaviors of 1-Br and 2-Br during solvolysis in 70% HOAc. The previously observed scramblings of about 0.5% or 1% in the recovered reactant, although small, were probably real. The small extent of scrambling in the recovered reactant apparently is due to a high rate of the return process compared to a relatively low rate of the 1,2-shift process.

One significant difference that was observed in the solvolysis of 1-Br-2-$^{14}$C and 2-Br-2-$^{14}$C in 70% HOAc was the effect of added NaOAc on the extents of isotopic scrambling (5). In the solvolysis of 15 or 25 m*M* 1-Br-2-$^{14}$C in the presence of up to 30 equivalent of added NaOAc, the scramblings observed in the reaction product were $14.7 \pm 0.7\%$. Since the precision in measuring $^{14}$C scramblings of this type could show variation as large as $\pm 1\%$, the only conclusion that could be drawn was that added NaOAc had little effect on the extent of scrambling in the solvolysis of 1-Br-2-$^{14}$C. On the other hand, in the solvolysis of 2-Br-2-$^{14}$C in 70% HOAc, the extent of scrambling in the product was decreased by the presence of added NaOAc (5). Since exchange does not occur in the intimate ion pair II (6), II may be the least sensitive to externally added nucleophiles. Thus it was suggested (3, 4) that in the solvolysis of 1-Br, if the rearrangement from internal 1,2-shifts occurred in an ion pair stage, the presence of added NaOAc may show little effect on the extent of scrambling.

The results from the present work, however, have shown that, similar to 2-Br, the solvolysis of 1-Br in 70% HOAc also proceeds to the dissociated ion IV. If the $14.7 \pm 0.7\%$ scrambling that was observed in the solvolysis of 1-Br-2-$^{14}$C were due to 1,2-shifts in the intimate ion pair II, upon further ionization of II to IV, IV would also have already been scrambled to the extent of about 14.7% and external ion returns from such a scrambled IV should give a recovered reactant showing a much greater extent of scrambling than the approximately 0.5% that was observed. The previously suggested role for ion pairs in accounting for the insensitivity of the extent of scrambling for 1-Br-2-$^{14}$C to added NaOAc must, therefore, be reconsidered. Probably, the triphenylvinyl cation, being less stable than the trianisylvinyl cation, would react rapidly once it is formed and would show a low selectivity or low ability to discriminate between different nucleophiles (10). Thus the presence of even 30 molar equivalents of NaOAc did not significantly affect the extent of scrambling in the solvolysis of 1-Br-2-$^{14}$C in 70% HOAc (5). The finding from the present work that the degree of $^{82}$Br exchange (Table 3) and the extent of common ion rate depression (Table 4) are lower for 1-Br than 2-Br would also be consistent with a less selective cation from 1-Br.

## Experimental

*Kinetic studies*

Individual samples of 15 m*M* 1-Br or 6.0 m*M* 2-Br in 70% HOAc – 30% $H_2O$ (by volume) containing various amounts of $Et_4NBr$, NaOAc, or $LiClO_4$ as given in Tables 1 and 2 were placed in sealed tubes. The reaction mixtures were heated for various lengths of time at $150 \pm 0.2$°C or $116 \pm 0.2$°C, respectively, for 1-Br or 2-Br. At least 6 points were obtained for each experiment listed in Tables 1 and 2, the reaction being followed to at least 80% completion. The liberated $Br^-$ ions were determined by potentiometric titration with $AgNO_3$. The specific rate constants and their standard errors were then obtained from a computer program designed for the treatment of the experimental data by the method of least squares.

*$^{82}$Br exchange studies*

Individual solvolysis experiments with 1-Br or 2-Br in the presence of added $^{82}$Br-labeled bromide ions were carried out in sealed tubes under the conditions given in Table 3. After the desired length of reaction time, each tube was cooled in an ice bath before it was opened and an appropriate amount of 1-Br or 2-Br was added as carrier. The mixture was then extracted with $CHCl_3$ and from the extract, 1-Br or 2-Br was recovered and purified by passage through an alumina column. The $^{82}$Br activity incorporated into the recovered 1-Br or 2-Br was then measured using a γ-ray counter in the laboratory of the radiation safety officer, University of Saskatchewan. The added [$^{82}$Br]-$Et_4NBr$ and the recovered 1-Br and 2-Br were counted as solutions in 70% HOAc. A sample containing a known amount of $^{82}$Br was used as a reference standard and the standard was counted immediately before and after the counting of a sample to provide the correction for the decay of $^{82}$Br.

As an illustration of the treatment of the experimental data, the details for Expt. 4, Table 3 (the first entry for 2-Br) are described. In this experiment, a solution of 25.5 mg (0.060 mmol) of 2-Br and 126 mg (0.600 mmol) of [$^{82}$Br]$Et_4NBr$ in 10 mL of 70% HOAc was heated in a sealed tube at $120 \pm 0.2$°C for 12 min. Upon work up of the reaction mixture after the addition of 100.7 mg of 2-Br as carrier, 85.6 mg of 2-Br was recovered. From a parallel experiment under the same conditions except

that ordinary $Et_4NBr$ without the label was utilized, titration of the liberated bromide ion showed that the extent of the reaction was 50%.

Thus after the reaction, the original substrate remaining was $0.50 \times 25.5 = 12.8$ mg. Together with the 100.7 mg of carrier, the total 2-Br present was $12.8 + 100.7 = 113.5$ mg.

The total $^{82}Br$ activity introduced as $Et_4NBr$ was $1.84 \times 10^7$ dpm.

The $^{82}Br$ activity in the 85.6 mg of recovered 2-Br was $3.16 \times 10^5$ dpm.

Hence the $^{82}Br$ activity in the unconsumed 2-Br was $(113.5/85.6) \times 3.16 \times 10^5 = 4.19 \times 10^5$ dpm.

Therefore, the incorporation of $^{82}Br$ into the recovered unconsumed reactant was $[(4.19 \times 10^5)/(1.84 \times 10^7)] \times 100 = 2.3\%$.

For 100% exchange, there would be a complete mixing of 100% of the $^{82}Br$ in the 0.060 mmol of substrate and the 0.600 mmol of added bromide, and the $^{82}Br$ incorporation in the recovered reactant would be $100/0.660 = 152\%$ $^{82}Br$/mmol 2-Br.

The observed incorporation in the recovered reactant was 2.3% of the $^{82}Br$ in $(0.50 \times 0.060)$ mmol of 2-Br or $2.3/0.030 = 77\%$ $^{82}Br$/mmol 2-Br.

Therefore, the extent of exchange in the recovered reactant was $(77/152) \times 100 = 51\%$.

## Acknowledgments

# A $^1H$ and $^{13}C$ nuclear magnetic resonance study of nucleosides with methylated pyrimidine bases

FRANK E. HRUSKA AND WAYNE J. P. BLONSKI

*Chemistry Department, University of Manitoba, Winnipeg, Man., Canada R3T 2N2*

Received July 9, 1982

FRANK E. HRUSKA and WAYNE J. P. BLONSKI. Can. J. Chem. **60**, 3026 (1982).

Alkylated pyrimidine bases are of interest from the viewpoint of mutagenesis and carcinogenesis. $^1H$ nuclear magnetic resonance data are presented for a series of ribosides and arabinosides alkylated at the O2, O4, N3, and C5 positions of the pyrimidine base. The data provide information about the stereochemical effects of base methylation. The $J(5—6)$ proton coupling constants show that O-alkylation leads to a decrease in the $\pi$-bond order of the C5—C6 bond. The $^{13}C$ chemical shifts are related to the tautomeric changes effected by O-alkylation.

FRANK E. HRUSKA et WAYNE J. P. BLONSKI. Can. J. Chem. **60**, 3026 (1982).

Les bases alkylées du type pyrimidine présentent un intérêt du point de vue de la mutagénèse et de la carcinogénèse. On présente les données de la rmn du $^1H$ relatives à une série de ribosides et d'arabinosides alkylées en positions O2, O4, N3 et C5 de la pyrimidine. Les données fournissent des informations sur les effets stéréochimiques de la méthylation de la base. Les constantes de couplage du proton $J(5–6)$ révèlent que l'O-alkylation conduit à une diminution dans l'ordre de la liaison $\pi$ de la liaison C5—C6. On a relié les déplacements chimiques du $^{13}C$ aux changements tautomériques occasionnés par la O-alkylation.

[Traduit par le journal]

## Introduction

The alkylation of nucleic acid bases is of considerable interest from the viewpoint of mutagenesis and carcinogenesis (1–8). Following the early interest in N-7 alkylation of guanine (9, 10), much attention was shifted to O-alkylation when Loveless (11) identified $O^6$-methylguanine as a minor alkylation product and proposed that the resulting tautomeric shift could lead to mispairing of bases. An extensive array of O- and N-alkylated purine and pyrimidine bases has now been detected in nucleic acids treated with alkylating agents (12).

To continue our studies on modified nucleosides (13), we have carried out complete analyses of the $^1H$ nmr spectra of a series of uracil ribonucleosides methylated at the C5, N3, O2, and O4 positions of the base (Fig. 1). We have also obtained the $^1H$ nmr spectra of $O^4$-methylarabinouridine, an analogue of arabinocytidine. The data provide information about the stereochemical and electronic effects of base alkylation. To further characterize these molecules we report their $^{13}C$ chemical shift data obtained in aqueous solution.

## Experimental

*Materials*

The $m^2U$ was prepared according to Kimura *et al.* (14), the $m^4U$ according to Robins and Naik (15), and $m^3U$ according to Miles (16). The $m^4aU$ was prepared according to the procedure described for $m^4U$ (15). The products were purified by recrystallization or by chromatography (Whatman 3MM paper; solvent system n-butanol – ethanol–water = 80:10:25 volume ratio). U, C, $m^5U$, aU, and aC were purchased from the Sigma Chemical Co.

*$^1H$ nuclear magnetic resonance experiments*

The $^1H$ nmr spectra were obtained on either a Nicolet NT360 (Purdue University) or a Bruker WP-400 (University of Alberta, Edmonton). All samples were examined in 5 mm (od) tubes at concentrations of 2–5 mg/mL in $D_2O$ containing 0.1 mg/mL of sodium 3'-trimethylsilylpropionate-2,2,3,3-$d_4$ (TSP) as internal reference. Treatment with dithizone according to Cozzone and Jardetzky (17) removed paramagnetic metal ions. The pH was 7.0 ± 0.3 in each case (uncorrected for the deuterium isotope effect). The temperature was maintained at 298 K (400 MHz

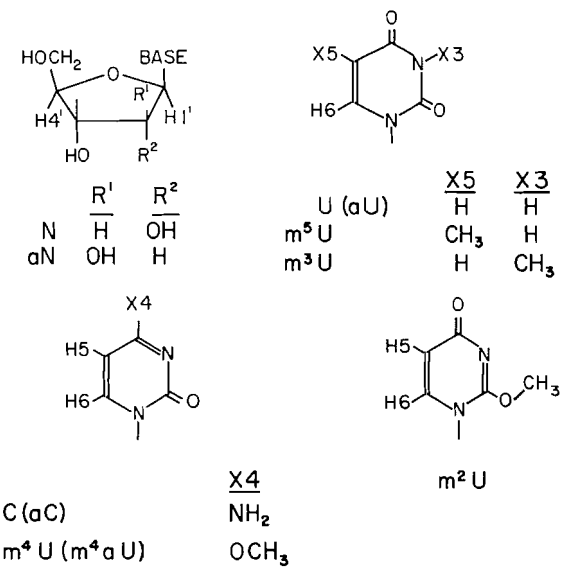

FIG. 1. (a) Structure of ribonucleosides (N): uridine (U), cytidine (C), 5-methyluridine or thymidine ($m^5U$ or T), $N^3$-methyluridine ($m^3U$), $O^4$-methyluridine ($m^4U$), and $O^2$-methyluridine ($m^2U$). (b) Structure of arabinonucleosides (aN): arabinocytidine (aC), arabinouridine (aU), $O^4$-methylarabinouridine ($m^4aU$). As oriented the bases would be in the *anti* conformer range; a 180° rotation about the N1—C1' bond would make them *syn*.

[a]Carbon data (297 K) at 22.63 MHz relative to TMS; measured relative to internal dioxane at 67.86 ppm.
[b]Symbols in Fig. 1.

data) or at 293 K (360 MHz data). Spectral analysis was carried out using LAME (18) and computer-simulated spectra were generated as a final test of the chemical shifts (δ) and coupling constants ($J$) (Table 1). The uncertainties in δ and $J$ are estimated to be about ± 0.001 ppm and ± 0.1 Hz, respectively. For comparison, literature data for U (19), Um (20), and aU (21) are included. Um is 2′-O-methyluridine, i.e. the 2′-OH of the sugar has been methylated.

### *$^{13}$C nuclear magnetic resonance experiments*

Proton-decoupled $^{13}$C nmr spectra were obtained on a Bruker WH-90DS spectrometer (22.63 MHz), according to described procedures (22). The nucleoside samples were contained in 10 mm (od) tubes at concentrations of 25–50 mg/mL in $D_2O$, containing 1% dioxane as internal reference. Following a suggestion by Dr. D. W. McBride of our department, we removed paramagnetic ions by shaking the sample with an acetylacetone–toluene mixture (equal volumes) and separating the phases. The pH was adjusted to 7.0 ± 0.2 (uncorrected for the deuterium isotope effect). The probe temperature was regulated at 297 K. The $^{13}$C chemical data (Table 2) are reported in ppm downfield from external TMS by setting internal dioxane equal to 67.86 ppm.

## Results and discussion

### *Assignment of the spectra*

The $^1$H spectral assignments were initiated with literature data for U (19), C (20), and aU (21). Also useful were data for C-, N-, and O-methylated pyrimidine bases (23) and the partial analysis of the 5′-monophosphate of m$^3$U (24). The H5′, H5″ assignment followed from the literature (25, 26). The $^{13}$C nmr assignments were made by comparison with literature data for pyrimidine bases and nucleosides (24, 27, 28). For the arabinosides, the relative chemical shifts of C2′ and C3′ are 0.6 ppm or less; the assignments here are arbitrary.

### *Conformation about the* N*-glycosyl bond*

Crystallographic studies have revealed the *anti*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

conformation (Fig. 1) for U (29), C (30), m$^5$U (31), and aC (32) in the solid state. For pyrimidine ribosides and 2′-deoxyribosides in solution a test for the *anti* and *syn* conformers (Fig. 1) is based on chemical shift comparisons, particularly for H2′ which experiences a large deshielding (0.5–0.6 ppm) in the *syn* form due to the magnetic anisotropy of the 2-keto oxygen (33). Table 1 shows that methylation at the O2, N3, O4, and C5 positions of the uracil ring has little influence on the ribose chemical shifts and hence on the *anti*, *syn* blend. In particular, δ(H2′) lies in the narrow range (4.33–4.38 ppm) expected for a preferred *anti* conformation (33). (An exception is Um (δ(H2′) = 4.09 ppm). This upfield shift can be attributed to a direct effect of the O2′-alkylation (34) rather than changes in the *anti*, *syn* blend.) In the case of m$^2$U, methylation has converted the 2-keto to a methoxyl group whose shielding effects in a *syn* pyrimidine nucleoside have not been evaluated. (This could be accomplished with, say, the 6-methyl derivative of m$^2$U.) However, the overall trends in the ribose chemical shifts and steric considerations suggest the *anti* form for m$^2$U.

Solid state (32) as well as solution data (35) point to a preference for the *anti* forms of aU and aC. The remarkable similarity in the ribose chemical shift data of aU, aC, and m$^4$aU indicates that O4-methylation of a pyrimidine arabinoside does not influence the *anti–syn* distribution and hence m$^4$aU prefers the *anti* conformation in solution as well.

Further support for the *anti* conformation in the ribosides and arabinosides is provided as follows.

(a) The presence of a 0.3–0.5 Hz five-bond coupling between H5 and H1′ is consistent with the "zig-zag" coupling path between the two protons (33, 36). (A four-bond coupling (0.2–0.3 Hz) between H6 and H1′ was also apparent in the spectra of, in particular, the O2- and O4-methylated molecules.)

(b) Methylation does not lead to the destabilization of the g$^+$(ψ) conformer expected for a *syn* pyrimidine nucleoside (13, 33). (See below.)

*Conformation of the sugar ring*

For the ribose derivatives the *cis* $J$(2′—3′) couplings (Table 1) fall in the narrow range 5.0–5.4 Hz, consistent with uniform pseudorotational parameters ($P$, $\tau_m$) (37) and typical of "normal" ribose rings (33). The *trans* couplings, $J$(1′—2′) and $J$(3′—4′), show a greater variation and the generally observed inverse correlation (33, 38). In terms of the *N* (3′-*endo*), *S* (2′-*endo*) blend, a near balance is indicated for U (53% *N*) and m$^5$U (51% *N*), while increases in *N* are evident for C (60%), Um (60%), m$^3$U (59%), m$^2$U (65%), and m$^4$U (67%) (Table 3). Theoretical treatments have linked electronic changes due to C5 substitution to changes in sugar pucker (39). Ultimately the electronic effects of O2-, O4-, and N3-methylation are responsible for the changes in pucker of the modified nucleosides, but these effects have not yet been considered with theoretical calculations.

TABLE 3. Calculated population (%) of the g$^+$(ψ), t(ψ) and g$^-$(ψ) rotamers about the C(4′)—C(5′) bond and the contribution (%) of 3′*endo* (*N*) to the $N \rightleftharpoons S$ blend

[a] $\%N = 100\% J_{3'4'}/(J_{1'2'} + J_{3'4'})$ for ribosides; for arabinosides: following ref. 21.
[b] $\%g^+(\psi)$, etc., from $J_{4'5'}$ and $J_{4'5''}$ following Haasnoot *et al.* (40).

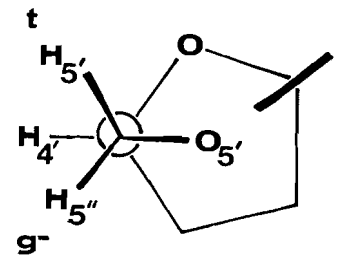

FIG. 2. Newman projection viewed along the C5′—C4′ (ψ) bond. The g$^+$ conformer is shown. t and g$^-$ give the location of Θ5′ in the t and g$^-$ conformers, respectively.

For the three arabinosides, the small variation (< 0.7 Hz) in the $J$(1′—2′), $J$(2′—3′), and $J$(3′—4′) coupling constants indicates that the sugar pucker is little affected by the modifications to the base (estimated[1] $\%N \approx 54\%$).

*Conformation about the C4′—C5′ bond*

Table 3 contains the g$^+$(ψ), t(ψ), and g$^-$(ψ) populations (Fig. 2) calculated from the $J$(4′—5′) and $J$(4′—5″) data using the parameterization of Haasnoot *et al.* (40). For the ribosides, the %g$^+$(ψ) lies in the range 61–69% while t(ψ) lies in the range 30–34%. Minimal contribution (<6%) is made by g$^-$(ψ), the conformer least often seen in crystalline ribosides (41). The m$^4$U shows both the largest

[1] According to ref. 21.

For personal use only.

%$g^+(\psi)$ and the largest %$N$, in line with a correlation already seen in pyrimidine ribosides (33, 38, 42).

Relative to the ribosides, a sizeable shift in the arabinosides occurs from the $g^+(\psi)$ to the $t(\psi)$ conformer which are now equally populated. No drastic change occurs upon O4-methylation of the uracil base of arabinouridine. The shift to the $t(\psi)$ conformer provides further evidence that the 2′,5′-hydrogen bonds noted in some crystalline arabinosides (32, 43) and predicted by theory (44) are unimportant in aqueous solution.

*J(5—6) and base tautomerism*

Methylation of a uracil base at the O4 position causes a tautomeric shift from the diketo to the 4-lactim form which resembles the cytosine base (Fig. 1). Methylation at the O2 position leads to a quininoidal structure while methylation at C5, C6, and N3 leaves the uracil in the diketo form. These differences in hybridization of the ring are reflected in the magnitude of the vicinal $J(5—6)$ coupling constants (Table 1) which fall into two narrow ranges: 8.0–8.1 Hz for the diketo molecules (U, aU, $m^3U$, Um) and 7.5–7.6 Hz for the cytosine-like (C, aC, $m^4U$, $m^4aU$) and quininoidal ($m^2U$) molecules. In line with these trends is the $J(5—6)$ coupling (7.4 Hz) in 2,2′-anhydro-(1-β-D-arabinofuranosyl)-uracil in which the quininoidal uracil structure is formed by the anhydro link between the C2 position of the base and the C2′ position of the sugar (45). Also relevant is that, upon formation of the anionic form of U and dU by ionization of the N3-H at pH 9.5, $J(5—6)$ decreases to 7.6–7.7 Hz (36). This decrease in $J(5—6)$ relative to the unionized base seems reasonable since the anion (Fig. 3a) can be represented by a combination of the cytosine and quininoid resonance structures (Figs. 3b and 3c, respectively (46)). Based on work by Veillard (47) we conclude that the π-bond orders of the C5—C6 bond of the cytosine-type and quininoidal molecules, and the anionic uracils, are similar, and smaller than the π-bond orders of the C5—C6 bonds of the diketo molecules. This view is in line with calculations (48) on cytosine, uracil, and its 4-enol-2-keto tautomer (which is isoelectronic with $m^4U$).

*Trends in the base $^1H$ chemical shifts*

Using Table 1 we have constructed Fig. 4 which shows more clearly how the proton shifts, δ(H6) and δ(H5), are affected by base alkylation. In addition to the riboside and arabinoside data, we included data for the corresponding 2′-deoxyribosides whose study is in progress ($m^2dU$, $m^4dU$,

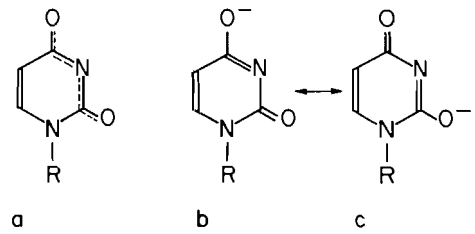

FIG. 3. (a) Standard representation of the uracil anion formed by dissociation of the N3 proton. Cytosine-like (b) and quininoidal (c) representations of the anion.

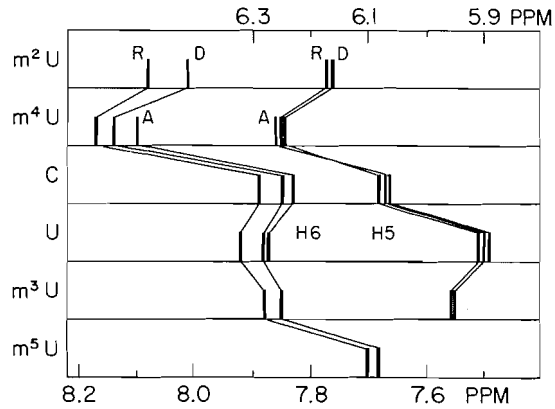

FIG. 4. Chemical shifts (ppm relative to internal TSP) of the H6 (bottom scale) and H5 protons (top scale) for a series of base-methylated ribosides, arabinosides (Table 1), and 2′-deoxyribosides (work in progress). The symbols for the *ribo*-nucleosides (U etc.) are on the vertical axis. Data for the corresponding arabinosides (aU, etc.) and 2′-deoxyribonucleosides (dU, etc.) are on the same levels. The connected δ(H6) and δ(H5) data for the riboses, arabinoses, and deoxyriboses are labelled R, A, D, respectively.

dC, dU, $m^3dU$, $m^5dU$(dT)). The following are some trends which should be useful for purposes of identification.

1. The H6 and the H5 chemical shifts show parallel behaviour for the three series of molecules, indicating that the nature of the sugar moiety does not significantly modulate the effect of the base modification.

2. For a particular base the dependence on the nature of the sugar is greater for δ(H6) than for δ(H5), in line with the relative separation of these protons from the sugar. (Compare, for example, U, aU, dU.) The largest variation for δ(H6) is 0.07 ppm ($m^2$ base), but only 0.02 ppm for δ(H5).

3. N3-methylation which does not alter the tautomeric form of the base has a small effect on δ(H5) and δ(H6) (≤ 0.05 ppm).

4. Methylation at C5 increases the shielding of H6 by 0.15–0.18 ppm, in line with the observed shielding increments for olefinic protons effected

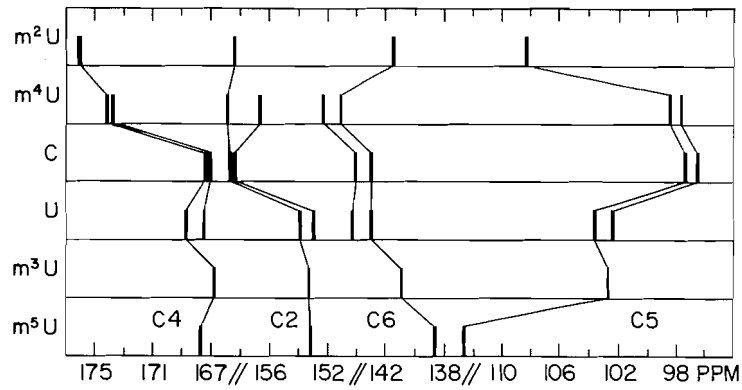

FIG. 5. Correlation diagram showing the effect of methylation on the pyrimidine ring carbon chemical shifts (in ppm) relative to TMS (Table 2). The symbols for the ribonucleosides (U, etc.) are given on the vertical axis (see Fig. 1 for definitions). The arabinoside data is given on the same level as the corresponding riboside (U-aU, C-aC, $m^4U$-$m^4aU$).

by *cis* alkylation (49). (Compare U with $m^5U$ and dU with $m^5dU$.)

5. Upon O4-methylation, H6 and H5 are deshielded by 0.25 ppm and 0.35 ppm, respectively; upon O2-methylation, H6 and H5 are deshielded by ~0.16 ppm and 0.26 ppm, respectively. This suggests that O-methylation is reflected in the electronic properties of the C5—C6 bond. In the cytosine (C) base H5 is also deshielded relative to the U base, but to a lesser extent (~0.17 ppm) than in the isoelectronic $m^4U$ base. However, relative to U, the H6 proton of C is *shielded* slightly (0.03 ppm), in contrast with the large deshielding of H6 in the $m^4U$ base.

6. The methyl proton shifts lie in the range 1.9–4.1 ppm (Table 1) with the order of increasing shielding (O2-Me < O4-Me < O2′-Me < N3′-Me < C5-Me).

### $^{13}C$ *chemical shifts*

Using the data in Table 2 we have constructed the correlation diagram (Fig. 5) which illustrates how base alkylation influences the $^{13}C$ chemical shifts of the pyrimidine base carbon atoms. In this section we discuss qualitatively some of the shielding trends, bearing in mind the attempts which have been made to relate $^{13}C$ chemical shifts to electronic properties of the bases (27, 28, 50, 51).

1. C5-methylation has a large deshielding effect on C5 (9 ppm) and a large shielding effect on C6 (4 ppm). Similar trends have been seen for U and $m^5U$ (and the parent bases) in DMSO solution (27, 28, 50, 51). In their $^{13}C$ nmr study, Ellis *et al.* (51) have found that, insofar as the $^{13}C$ shieldings of C5 and C6 are concerned, the 5-substituted uracils may be considered as either a set of trisubstituted ethylenes or of monosubstituted benzenes.

2. Since replacement of the N3 hydrogen by an alkyl group is not expected to significantly perturb the electronic structure of the base, it is not surprising that N3-methylation has the smallest effect overall on the $^{13}C$ chemical shifts. (Compare U and $m^3U$.) The largest effects are seen at C4 (+2.0 ppm) and at C6 (+2.1 ppm). It is interesting that the carbon most distant from the substituent (C6) is the most strongly affected. Comparable trends have been seen by Still *et al.* in the study of methylated pyrimidines in DMSO solution (27).

3. The largest effects are due to O2- and O4-methylation, consistent with the tautomeric changes which accompany these modifications. Methylation of either O2 or O4 leads to a large deshielding of *both* of the carbonyl carbons, C2 and C4 (3.9 to 7.4 ppm relative to U or to aU). It is interesting that C4 is more strongly affected than C2 by both O2- and O4-methylation. These observations provide further evidence for the strong conjugation of the O2—C2—N3—C4—O4 fragment. On the other hand, C5 is shielded by O4-methylation but deshielded to a comparable extent by O2-methylation (5—6 ppm). In contrast, C6 is deshielded by O4-methylation (≃2 ppm) but shielded by O2-methylation (≃3 ppm). We are not able to provide a simple rationale for all of these changes. However, they do suggest that O-methylation causes a polarization throughout the pyrimidine ring.

It is also interesting to compare the $^{13}C$ shifts of the O-methyl derivatives ($m^4U$ or $m^4aU$) with those of the corresponding cytosine derivatives (C or aC). Their C2, C5, and C6 shifts are identical to within about 2 ppm, in line with the isoelectronic nature of the $m^4U$ and C bases, and suggesting similar electronic effects of the methoxy and amino groups on these carbons. However, the C4 resonances of the $m^4U$ bases are shifted significantly downfield from the C base (≃7 ppm). This difference may simply reflect that an O-atom has greater electronegativity than a N-atom.

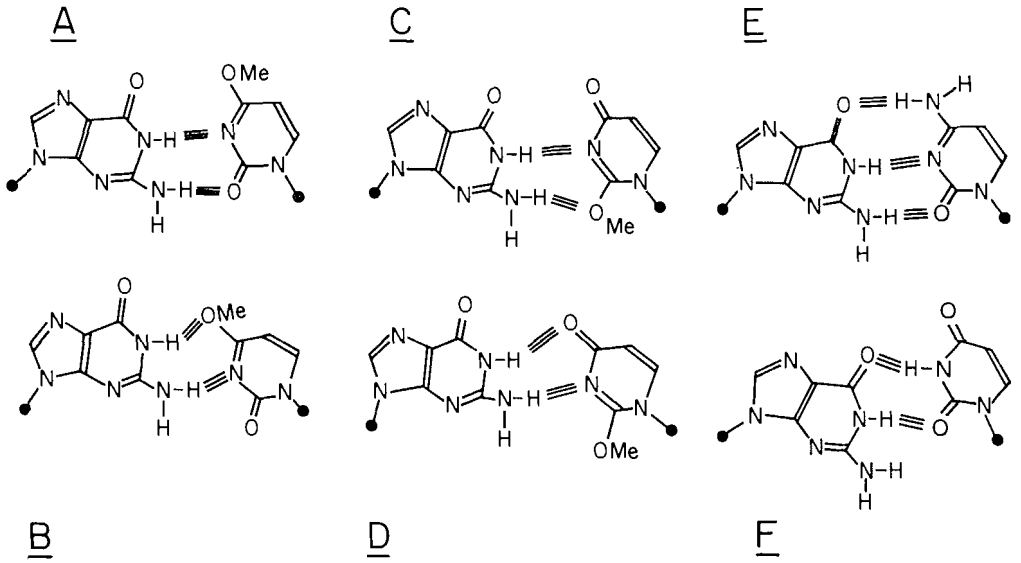

FIG. 6. Hydrogen bonded base pairs. A and B: G–m$^4$U; C and D: G–m$^2$U; E: Watson–Crick G–C; F: G–U (wobble). In A to D the methoxy group is rotated to a conformer which allows the approach of interacting groups.

4. The methyl carbon shifts are in the range 13–57 ppm. The order of increasing shielding (O2-Me < O4-Me < N3-Me < C5-Me) parallels that of the methyl proton shifts. The shifts of the sugar carbon atoms are relatively invariant to the base. The largest effect (+1.6 ppm at C1′) is due to O2- and O4-methylation and suggests some polarization of the N1—C1′ bond.

*Base pairing*

Mispairing of purine and pyrimidine bases has been invoked in attempts to rationalize the changes in the information encoded in nucleic acids which are elicited by alkylation (2, 8), but no direct experimental evidence has so far been provided for these mispairs. Both m$^2$U (or m$^2$T) and m$^4$U (or m$^4$T) can form at most one hydrogen bond with A (adenine), the normal base complement of U (or T) (2). The G–m$^4$T complex with two hydrogen bonds (Fig. 6A) was the first postulated mispair for an O-alkylated thymine base (6). Its geometry would resemble that of the Watson–Crick G–C base pair (Fig. 6E), except for the noninvolvement of the 4-methoxy and the 6-keto groups. This structure, however, overlooks any steric effects of the 4-methyl group in *syn*, planar conformation which places the methyl hydrogens near to the N3 atom. (Calculations by Psoda *et al.* on O$^6$-methylguanine (52) lead us to think that the *syn*, planar conformer is favoured in m$^4$U(m$^4$T) as well as in m$^2$U(m$^2$T), but our nmr data provide no direct information about this matter.) If we continue to overlook steric effects, we can visualize a second G–m$^4$T complex with two hydrogen bonds (Fig. 6B) which requires a "wobble" of the pyrimidine base. Similarly we can conceive of two G–m$^2$T complexes, each with a pair of hydrogen bonds. The first (Fig. 6C) would have an overall geometry resembling the G–C and G–m$^4$T base pairs while the second (Fig. 6D) requires a wobble of the pyrimidine to align the hydrogen donating and accepting groups. The wobble of the pyrimidine base (Fig. 6B, D) is opposite in direction to the G–T(U) wobble base pair (Fig. 6F) which exists in tRNA acceptor stems (53).

The base pairs (Fig. 6A–D) raise the important question whether the 2- and 4-methoxy oxygens are capable of acting as hydrogen acceptors and whether the out-of-plane conformations of the methoxyl groups which would permit hydrogen bonding are energetically not too unfavorable. We have constructed space-filling models of right-handed and left-handed (Z-DNA) double helices, and found that the four base pairs (Fig. 6A–D) can be accommodated with only small adjustments in the conformation of the ribose phosphate backbone. We are hoping to extend our present work to synthetic oligonucleotides containing O-methylated pyrimidines in order to assess their ability to enter into ordered structures.

## Summary and conclusion

The $^1$H and $^{13}$C nmr data are presented for a series of ribosides and arabinosides with O-methylated pyrimidine bases. The $^1$H nmr data demonstrate that large changes in sugar conformation do not accompany methylation at the O2, N3, O4, or C5 positions of the base. The aberrant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

biological behaviour of the O- and N-methylated molecules must be linked most closely to their altered hydrogen bonding (and perhaps base stacking) properties. The $J(5—6)$ proton couplings suggest a decreased $\pi$-bond order in the C5—C6 bonds of the O-methylated uracil bases. The $^{13}C$ chemical shifts indicate a general polarization of the base due to O-methylation.

## Acknowledgements

This work was funded by the Natural Sciences and Engineering Research Council of Canada. We acknowledge discussions with Drs. Hunter, McKinnon, McBride, Sadana, and Schaefer. We are grateful to Dr. J. L. Markley, The Biochemical Magnetic Resonance Laboratory, Purdue University (NIH Grant RR-01077) for 360 MHz spectra and Dr. D. L. Rabinstein, University of Alberta, Edmonton, for the 400 MHz spectrum of $m^4aU$. We thank L. Davies for some of the initial synthesis. We are especially grateful to Mr. K. Marat for his help in acquiring the $^{13}C$ nmr data and to Dr. W. P. Niemczura for acquiring the 360 MHz data.

Received June 8, 1982

ERWIN BUNCEL, ALBERT R. NORRIS, SPENCER E. TAYLOR, and WILLIAM J. RACZ. Can. J. Chem. **60**, 3033 (1982).

Two 1:1 methylmercury(II)-1-methylimidazoline-2-thione (methimazole, MeImSH) complexes, [MeHg(MeImSH)]$NO_3$ and [MeHg(MeImS)], have been isolated from aqueous solution under acidic and basic conditions, respectively. $^1H$ nmr and ir spectroscopy, as well as analytical data, were used to characterize the complexes. The nmr data, in particular, lead to the conclusion that the principal binding mode under both sets of conditions involves the sulfur atom at $C_2$. However, under conditions of 2:1 ($MeHg^{II}$:MeImSH) stoichiometry, binding to $N_3$ is also found to occur. These interpretations have necessitated a reexamination of the $^1H$ nmr spectrum of the free ligand, in particular with respect to assignment of NH and SH resonances corresponding to the two possible tautomeric forms. It has been found in this work that 1-methylimidazoline-2-thione shows a high affinity for $MeHg^{II}$ binding, which may be pertinent with respect to a previous report concerning the protective nature of this compound in organomercurial intoxication.

ERWIN BUNCEL, ALBERT R. NORRIS, SPENCER E. TAYLOR et WILLIAM J. RACZ. Can. J. Chem. **60**, 3033 (1982).

On a isolé deux complexes de type 1:1 de méthylmercure(II) mercapto-2 méthyl-1 imidazole (méthimazole, MeImSH) [MeHg(MeImSH]$NO_3$ et [MeHg(MeImS)] à partir de solutions aqueuses dans des conditions acides et basiques respectivement. On a fait appel à la rmn du $^1H$ à la spectroscopie ir aussi bien qu'aux données analytiques pour caractériser ces complexes. Les données de la rmn en particulier font penser que le mode principal de liaison dans les deux conditions implique l'atome de soufre au niveau du carbone en position 2. Cependant, dans les conditions stochioemétrique 2:1 de ($MeHg^{II}$:MeImSH) la liaison impliquant l'azote en position 3 s'établit également. Ces interprétations font ressentir la nécessité d'examiner de nouveau le spectre de rmn du $^1H$ du ligand libre, en particulier en ce qui à trait à l'attribution des résonances du NH et du SH correspondant aux deux formes tautomères possibles. On a trouvé, dans ce travail, que le méthimazole montre une grande affinité pour la liaison $MeHg^{II}$, laquelle peut être intéressante compte tenu des données antérieures relatives à la nature protectrice de ce composé dans les cas d'intoxication par les organomercures.

[Traduit par le journal]

## Introduction

In previous papers in this series, we have investigated the binding of methylmercury(II) towards a number of nucleoside and imidazole systems, and found the involvement of both nitrogen and carbon centers in complex formation (1–3). The present paper is concerned with the $MeHg^{II}$ binding characteristics of the 1-methylimidazole system modified by the introduction of a sulfur function at $C_2$, viz. 1-methylimidazoline-2-thione, hereafter referred to by its trivial name, methimazole, and abbreviated as MeImSH. (Formally, the $C_2$—H in 1-methylimidazole is replaced by SH; see, however, the discussion on thione–thiol tautomerism.)

Methimazole is known to have several chemotherapeutic applications, particularly in the treatment of thyroid disorders (4). Our interest in this particular imidazole derivative was initiated by the report (5) that the use of methimazole (and other sulfur-containing thyroid hormone inhibitors) afforded a significant degree of protection against the effects of dimethylmercury and diphenylmercury intoxication in laboratory animals.

The interaction of heavy metal ions with methimazole has to date received little attention. Dehand and Jordanov (6), in synthesizing $Pt^{II}$ and $Pd^{II}$ complexes for antitumor screening purposes (7), deduced on the basis of ir spectroscopy that $N_3$ was the preferred binding site under acidic conditions, while the sulfur atom was implicated under basic conditions. $^1H$ nmr spectroscopy was used to confirm the previous ir assignments (6). Unexpectedly, during the course of the present study, we were unable to reproduce the spectrum of methimazole as previously reported in $(CD_3)_2SO$ solution (6). Since many of the deductions regarding binding sites in the present study relied heavily on $^1H$ nmr analyses, a reexamination of the spectral

characteristics of methimazole is included in the present paper.

## Experimental

Methimazole was purchased from the Sigma Chemical Co. and recrystallized from ethanol before use, mp 144–146°C, lit. (8) 142°C. *Anal.* calcd. for $C_4H_6N_2S$: C 42.11, H 5.26, N 24.56; found: C 42.17, H 5.39, N 25.07.

$^1$H nmr spectra were recorded at 60 MHz on a Varian EM 360 or Bruker HX-60 instrument and referenced with respect to internal $(CH_3)_4Si$. Infrared spectra were recorded as 1% KBr discs on Perkin-Elmer 180 or 598 spectrophotometers.

Microanalyses were performed by the Guelph Chemical Laboratory. Melting points were taken on a Mel-temp melting point apparatus and are uncorrected.

*Methimazole–MeHg$^{II}$ complex formation*

An equimolar mixture of methimazole (0.183 g) and methylmercuric nitrate (0.445 g) in distilled water (7 mL) resulted in the formation of a white, gelatinous precipitate. Upon heating the precipitate dissolved, affording a neutral solution, which was set aside to crystallize. After one day, white crystals of a substance **A** appeared; these were removed by filtration, washed quickly with water, and dried *in vacuo*, mp 142–143°C (decomp.). Yield = 0.454 g. *Anal.* calcd. for [MeHg(MeImSH)]$NO_3$: C 15.32, H 2.30, N 10.73, S 8.17; found: C 15.38, H 2.34, N 10.84, S 8.26.

Under more basic conditions, but still retaining 1:1 stoichiometry, a solution (10 mL) containing methimazole (0.183 g) and sodium hydroxide (1.60 mL of a 1 *M* stock solution) was added slowly with stirring to a methylmercuric nitrate solution (0.444 g in 5 mL distilled water). During the addition a faint cloudiness was apparent which, on complete addition, yielded a white precipitate. After continuing to stir for 1–2 min, the precipitate transformed into a yellow oil. The volume of the resultant mixture was then doubled by the addition of an equal volume (15 mL) of absolute ethanol, and it was stirred vigorously for ca. 15 min, after which time the mixture still retained its two-phase nature. However, on standing, the yellow oil solidified to give a pale yellow solid ($\mathbf{B}_1$) and, almost simultaneously, small white needles ($\mathbf{B}_2$) appeared in the bulk of the solution. The apparent pH of the resultant solution was ca. 8. The total product was removed by filtration and washed with water. Separation of $\mathbf{B}_1$ and $\mathbf{B}_2$ was easily effected by the ready removal of the solid mass of the former. Yield of $\mathbf{B}_1$ = 0.133 g (mp 83–84°C). *Anal.* $\mathbf{B}_1$. calcd. for [MeHg(MeImS)]: C 18.26, H 2.43, N 8.52, S 9.74; found: C 18.15, H 2.51, N 8.71, S 9.94. Yield of $\mathbf{B}_2$ = 0.251 g (mp 76–77°C). *Anal.* $\mathbf{B}_2$. calcd. for [MeHg(MeImS)]: (as above); found: C 18.15, H 2.50, N 8.77, S 9.89.

The ir as well as the nmr spectra of $\mathbf{B}_1$ and $\mathbf{B}_2$ were identical, within experimental error. In view of this fact, and the identity within experimental error of the analytical data for $\mathbf{B}_1$ and $\mathbf{B}_2$, it is concluded that these represent the same compound, having the molecular formula [MeHg(MeImS)]. In the ensuing discussion (vide infra) this compound will be denoted by **B**.

Under conditions of 2:1 MeHg$^{II}$–methimazole stoichiometry, binding to both $N_3$ and sulfur was envisaged. To this end, an aqueous solution (5 mL) of methimazole (0.065 g, 0.57 mmol) and sodium hydroxide (0.57 mL of a 1 *M* solution, 0.57 mmol) was added to a stirred solution of methylmercuric nitrate (0.314 g, 1.13 mmol) in distilled water (5 mL). During the addition, a light-brown oil, **C**, collected at the bottom of the vessel; unlike the case of the 1:1 reaction (above), on subsequent treatment with ethanol this did not solidify. On solvent evaporation, a small quantity of a crystalline material formed and was removed. This is believed to be $NaNO_3$ by virtue of the lack of detectable protons in the $^1$H nmr spectrum and the presence of $NO_3^-$ in the ir. The $^1$H nmr spectrum of **C** showed 2:1 MeHg$^{II}$:methimazole stoichiometry, as expected, and as such **C** was formulated as being [$(MeHg)_2$(MeImS)]$NO_3$.

## Results and discussion

*Possible binding sites and tautomerism in methimazole*

At the outset of this study it was envisaged that the sulfur atom at $C_2$ would modify the MeHg$^{II}$ binding characteristics of the 1-methylimidazole system, studied previously (3). In the "parent" substrate, both $N_3$ and $C_2$ have been identified as binding sites (3). In methimazole, the sulfur bound to $C_2$ clearly prevents the possibility of direct MeHg$^{II}$ binding to $C_2$, although $N_3$ is still available. The preference of MeHg$^{II}$ for soft donor atoms such as sulfur, however, would be expected to result in this being a more likely binding site than $N_3$. In their study of binding of metal ions to methimazole, Dehand and Jordanov (6) made inferences concerning the sites of binding of Pd$^{II}$ and Pt$^{II}$, on the basis of ir and $^1$H nmr evidence. However, we were unable to reproduce the published spectrum (6) of methimazole, for which correct assignment of NH and SH resonances is crucial in assigning metal ion binding sites.

Mercaptoazole derivatives such as methimazole are capable of existing in two tautomeric forms, **1**

[1] 

**1** **2**

and **2** (reaction [1]) (9). In $(CD_3)_2SO$ solution, we find the $^1$H nmr spectrum of methimazole to consist of four resonances (Fig. 1). The signals due to the

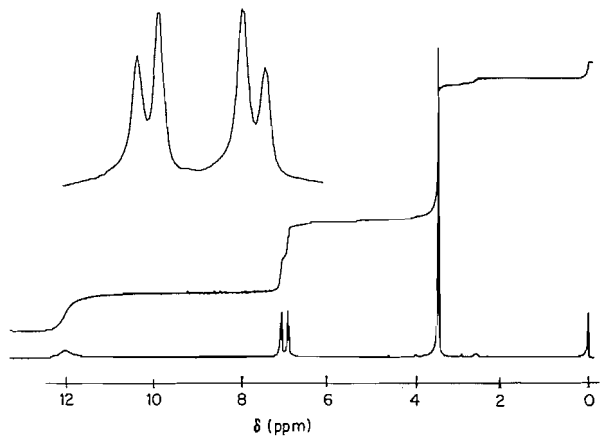

FIG. 1. Proton magnetic resonance spectrum of methimazole in $(CD_3)_2SO$. (Inset $H_4$, $H_5$ quartet on expanded scale.)

TABLE 1. $^1$H nmr spectra at 60 MHz of methimazole in various solvents at 22 ± 1°C

| Solvent | Chemical shift[a,b] | | | |

[a]Where indicated, the quoted uncertainties take into account a concentration range from 0.3–1.0 *M*.
[b]δ(ppm) from internal $(CH_3)_4Si$; s = singlet, d = doublet ($J$ = 2.5 Hz), br = broad.
[c]For a saturated solution.
[d]The relative integral height of this signal corresponds to < 1 proton (see text).

methyl group, $H_4$ and $H_5$ (δ 3.45, 6.87 (d), and 7.05 (d)), are as quoted by Dehand and Jordanov (6), but we observe an additional (broad) resonance at low field (~δ 12) which we ascribe to NH, by analogy with other azole NH functions (e.g. imidazole, δ(NH) 11.6 (3)). This is in marked contrast with the previous report (6) of a resonance at δ 5.40, assigned to the NH proton of **1** and a signal at δ 3.80 assigned to the SH proton of **2** in the same solvent. These signals, at δ 5.40 and 3.80 were not found in our system. In the published spectrum (6) it is also evident that the total integral due to "NH" and "SH" signal is >1 proton.

We find that the position of the NH resonance appears to be concentration- and solvent-dependent, varying between δ 10.7 and 12.1, and integrates to <1 proton, the difference presumably being accounted for by the **2** (SH) tautomer (10). Solvent dependences of the $^1$H nmr spectral parameters at 60 MHz, shown in Table 1, have been averaged over the concentration range 0.3–1 *M*. In none of the solvents examined was a signal at δ 3.8, previously assigned to SH, apparent. This contrasts with the case of thiomorpholin-3-thione in which both NH and SH signals appear in $CDCl_3$, at δ 8.36 and 1.88 respectively (10), such that $K_T$ (reaction [1]) ≈ 0.25 at 28°C. In the case of methimazole, as in the case of thiamorpholin-3-thione (10), the NH signal is observed to shift to higher field on decreasing the substrate concentration. Such spectral features are a consequence of self-association and solvation of the substrate (9). In methimazole, the higher concentration serves to stabilize the thioketo structure, through a dimerization equilibrium (reaction [2]) (9). The dimeric structure **1**-D is presumably the structure reflected in the solid-state ir spectrum of methimazole, as well as in the $^1$H nmr spectra of concentrated solutions of methimazole in weakly-coordinating solvents.

[2] 2(**1**) ⇌ 
**1**-D

*Sites of metal ion binding in methimazole: N- versus S-methylmercuration*

In light of the above discussion concerning tautomerism in the methimazole system, we can view the deprotonation of **1** and **2** as giving rise to the delocalized anion **3**, according to reaction [3].

[3] **1** ⇌  ⇌ **2**

**3**

One can then envisage **3** as having the potentiality of an ambidentate ligand with respect to metal ion coordination (i.e. $N_3$ versus S binding). This may serve as the basis for the structural assignment of the complexes **A**, **B**, and **C**, which have been obtained under different conditions of pH and stoichiometry (see Experimental).

The tendency for heavy metal ions such as $Hg^{II}$ to favour sulfur over nitrogen donor atoms would seem to suggest S as the most probable $MeHg^{II}$ binding site in the product **B** prepared under conditions in which deprotonation of methimazole would occur, i.e. at high initial pH ($pK_a$ for deprotonation of methimazole is 11.6 (11)). The complex **B** is found by microanalysis to correspond to the formula [MeHg(MeImS)] and this formulation is supported by the $^1$H nmr spectrum. Thus the structure of this complex can be represented by either **4** or **5**. Evidence in favour of structure **4** derives from the low value (Table 2) of $^2J(^{199}Hg$—

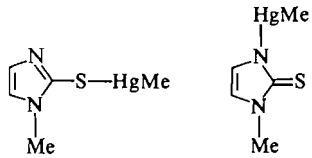
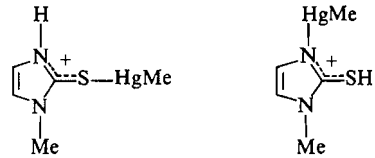
$^1H$), 184.6 Hz in $(CD_3)_2SO$, which is characteristic of *S*-bonded $MeHg^{II}$ (14).



**4** **5**

Assignment of *S* bonding in methimazole complexes has generally been based on ir spectral considerations (6, 13). Thus $Pd^{II}$, $Pt^{II}$ (6), $Co^{II}$, and $Zn^{II}$ (13) binding to S have been identified by noting changes in intensities and positions of certain assigned bands, as compared with the free ligand. However, this type of analysis, in the case of methimazole, may lead to uncertain inferences since the ir spectrum of the free ligand corresponds to the hydrogen-bonded dimer **1**-D (9), whereas metal ion complexation removes the ability for hydrogen bonding. In addition, an examination of the literature reveals that there is little agreement in the band assignments of methimazole. The various assignments given to the major bands within the range 1600–300 $cm^{-1}$ are listed in Table 3. This overall disagreement, coupled with the fact that the ir spectrum of methimazole does not correspond to that of "free" methimazole, suggests that ir spectroscopy is not a reliable method of assigning metal ion binding sites in such systems. Indeed, if the criteria used in the past (6, 13) for identifying *S* bonding were applied to the present system (i.e. a decrease in frequency of band *1* and decreases in frequency and intensity of bands *2*, *8*, and *18* (6), or a decrease in frequency (by 20–25 $cm^{-1}$) of band *16* (13)), this would lead to the conclusion that (apart from the behaviour of bands *1* and *2*) this complex is *not* *S*-bonded. However, the $^1H$ nmr and other evidence cited above provide strong support for an S-bonded structure for **B**, i.e. structure **4**.

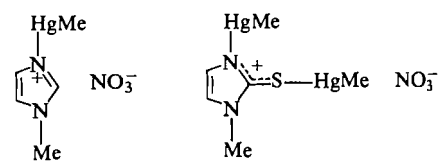
Complex **A**, formed under acidic conditions, corresponds to the formula [MeHg(MeImSH)]-$NO_3$, and can be considered as derived from a similar ambidentate system (i.e. N vs. S, as in **6** and **7**). In solution, the $^1H$ nmr spectrum of **A** reveals a broad resonance, centered at δ 13.77 (Table 2),



**6** **7**

integrating to ca. 1 proton, and ascribable to NH. Of the two possible structures for **A**, that is **6** and **7**, it appears that **6**, containing *S*-bound $MeHg^{II}$, is the more likely possibility in solution. The ir spectrum of **A** is also in accord with the formulation in **6**. The presence of nitrate is indicated (band *4*), and the positions of the ν(Hg—C) and ν(Hg—ligand) bands (*19* and *21*, respectively) are very similar to their positions in **B** where *S*-bonding (**4**) was assigned above. The positions of the latter band in **A** and **B** (~336 $cm^{-1}$) compares very well with the ν(Hg—S) stretching frequencies in $MeHg^{II}$ complexes with a number of thiols (15), whilst the ν(Hg—C) vibration (~550 $cm^{-1}$) is more typical of *S*-bonding than *N*-bonding (16).

A notable feature in the $^1H$ nmr spectrum of **A** is that the coupling constant $^2J(^{199}Hg—^1H)$ of 204.2 Hz (Table 2) is higher than the value (184.6 Hz) found for *S*-bonding in **B** (**4**). This probably reflects the fact that protonation of $N_3$ has taken place in **A** (**6**), thereby decreasing the basicity of the sulfur donor atom. It is also pertinent that $N_3$ coordination by $MeHg^{II}$ in 1-methylimidazole, which gives rise to **8**, leads to a coupling constant of 222.1 Hz (3), significantly higher than that observed for **A** (6). In addition, the ir spectrum of **8** shows no bands in



**8** **9**

the region 500–300 $cm^{-1}$, suggesting that the band observed at 336 $cm^{-1}$ for **A** is *not* due to *N*-coordination. Thus the sum of the evidence is in accord with the assignment of structure **6** to compound **A**.[4]

Under conditions of 2:1 $MeHg^{II}$:methimazole stoichiometry, a further replacement of the $N_3$ proton in **6** occurs, giving rise to complex **C**, to which structure **9** is assigned. Not surprisingly in this case, the coupling constant in **9**, 207.8 Hz, is found to be approximately intermediate between the value obtained previously (3) for **8** (222.1 Hz) and the value (184.6 Hz) for **4**, indicating rapid exchange of $MeHg^{II}$ between the two environments.

## Concluding remarks

We have found in the present study that 1:1 $MeHg^{II}$–methimazole complexes involve binding via the sulfur atom (i.e. **4** and **6**), which contrasts with the report by Dehand and Jordanov (6) that binding of $Pd^{II}$ and $Pt^{II}$ to methimazole occurs via $N_3$ at low pH, and via $N_3$ and S at high pH. In our system, under acidic conditions, S was found to be the $MeHg^{II}$ binding site, with $N_3$ protonated. Under basic conditions, S remained the donor atom, with deprotonation of $N_3$ taking place, and giving rise to the neutral complex **4**. The resulting increase in strength of the Hg—S bond is reflected in the magnitude of the $^2J(^{199}Hg—^1H)$ coupling constants. Thus methimazole shows different coordination behaviour to its parent, 1-methylimidazole (3), with $N_3$ no longer being the primary donor atom. This is in accord with the preference of $Hg^{II}$ for soft (class *b*) donor atoms such as sulfur (17).

Extrapolating to biological systems, the significance of these results is that any purine carrying a thiol (or thioketo) substituent would presumably bind $Hg^{II}$ primarily through the sulfur atom; such characteristics have previously been demonstrated by Lippard and co-workers (18) using $^{13}C$ nmr spectroscopy with sulfur-containing nucleosides. Only when the sulfur atom is blocked by alkylation or prior coordination, do other (nitrogen) sites become important.

Although the effectiveness of methimazole in protecting against organomercurial intoxication is believed to be by virtue of its action on the thyroid

[4]An X-ray crystal structure determination of **6** has been performed (A. L. Beauchamp) and will be reported in due course.

gland (5), it can be envisaged that methimazole would also be effective in competing with sulfur-containing bio-ligands for $Hg^{II}$.

# Kinetics of the reaction $C_2H_5 + H_2 \rightarrow C_2H_6 + H$ from 1111–1200 K

J.-R. CAO AND M. H. BACK

*Chemistry Department, University of Ottawa, Ottawa, Ont., Canada K1N 9B4*

Received June 16, 1982

J.-R. CAO and M. H. BACK. Can. J. Chem. **60**, 3039 (1982).

A system for the measurement of the rate constant for the elementary reaction

$$C_2H_5 + H_2 \rightarrow C_2H_6 + H$$

in the temperature range 1111–1200 K is described and is based on the thermal production of an equilibrium concentration of hydrogen atoms. In a mixture of hydrogen with about 10 ppm ethylene this reaction is the rate-controlling step in the hydrogenation of ethylene. The product ethane undergoes rapid secondary dissociation and the final product is methane. The values obtained in the present work, which are represented by the following expression,

$$\log k \text{ (L mol}^{-1} \text{ s}^{-1}) = 10.6 - 23000/2.3RT$$

($R$ = 1.987 cal mol$^{-1}$ deg$^{-1}$) are compared to those obtained at lower temperature (820–350 K) and to those calculated from measurements of the reverse reaction.

J.-R. CAO et M. H. BACK. Can. J. Chem. **60**, 3039 (1982).

On décrit un système de mesure de la constante de vitesse de la réaction élémentaire

$$C_2H_5 + H_2 \rightarrow C_2H_6 + H$$

dans l'intervalle de température allant de 1111 à 1200 K. Ce système se base sur la formation thermique d'une concentration à l'équilibre des atomes d'hydrogène. Dans un mélange d'hydrogène avec environ 10 ppm d'éthylène, cette réaction constitue l'étape déterminante de la réaction d'hydrogénation de l'éthylène. L'éthane obtenu subit une dissociation secondaire rapide et conduit au méthane comme produit final. On a comparé les valeurs obtenues que l'on représente par l'expression suivante

$$\log k \text{ (L mol}^{-1} \text{ s}^{-1}) = 10{,}6 - 23000/2{,}3RT$$

($R$ = 1,987 cal mol$^{-1}$ deg$^{-1}$), avec celles obtenues à plus basse température (820–350 K) et avec celles calculées à partir des mesures de la réaction inverse.

## Introduction

There has been much interest in recent years in extending measurements of rate constants for elementary reactions of hydrocarbon radicals into a high-temperature region. Few rate constants for these radicals have been measured at temperatures above 1000 K, yet many thermal reaction systems involving these radicals have been studied at these temperatures and higher. In order to understand the mechanisms of these reactions it is essential to have reliable measurements of the rate constants for the elementary reactions involved, many of which are obtained by extrapolation from measurements made at much lower temperatures. Serious errors may be introduced in this procedure by the non-Arrhenius behavior observed for the reactions of hydrogen atoms and small radicals (1). This behavior, which is not unexpected over a wide temperature range, is of theoretical as well as practical importance in the understanding of reaction mechanisms and the details of reaction pathways (2).

A new system for the measurement of rate constants for radical reactions at temperatures above 1000 K has been explored in this laboratory. The method is based on the premise that at these temperatures and moderate pressures of hydrogen an equilibrium concentration of hydrogen atoms can be maintained in the system. A small quantity of reactant, in our studies, ethylene, in concentrations of a few ppm, is added to the hydrogen and the rate of consumption of ethylene and appearance of the products is measured. The assumption is made, and tested by the kinetics, that the equilibrium between hydrogen molecules and atoms is not significantly perturbed by the addition of the reagent. In the present study, it is shown that as well as the equilibrium concentration of hydrogen atoms, an equilibrium concentration of ethyl radicals is attained by addition of hydrogen atoms to ethylene and the rate-controlling step is the abstraction reaction of ethyl radicals with hydrogen.

$$C_2H_5 + H_2 \rightarrow C_2H_6 + H$$

Measurements of the rate of disappearance of ethylene thus lead to values for the rate constant for this reaction over the temperature range 1111–1200 K. Only four measurements of this rate constant have been reported (3–6), all of which are below

0008-4042/82/243039-10$01.00/0

©1982 National Research Council of Canada/Conseil national de recherches du Canada

820 K. New measurements should therefore be valuable in establishing this rate constant in the high temperature region. Many measurements of the rate constant for the reverse reaction have been reported (7) and it is of interest to compare these values with those of the forward reaction through the equilibrium constant. It will be shown that agreement between the forward and reverse rate constants can be achieved only if the heat of formation of the ethyl radical is somewhat larger than has previously been accepted (8).

## Experimental

The reaction was studied in a static system with provision for storage, mixing, introduction, and sampling of the reactants and products. The reaction vessel was a quartz cylinder with diameter 4.4 cm and volume 182 $cm^3$, and was placed in the center of a Lindberg three-zone tubular furnace. A second vessel of similar dimensions and packed with quartz tubes to give a S/V ratio of 7.5 $cm^{-1}$ was used to test for the importance of surface reactions. Mixtures were prepared in a 2-L spherical flask with minimum dead space by introducing first the small pressure of ethylene and then filling with hydrogen. After a mixing period of 12 h the composition of the mixture was homogeneous and invariant. Ethylene was Research Grade (99.98%) obtained from Matheson of Canada, Whitby, Ont. Hydrogen was purified by passage through a Molecular Sieve 5A column at liquid nitrogen temperature with a residence time of 1–2 s. Such treatment is usually sufficient to reduce the oxygen impurity to less than 1 ppm (9), although the present analysis system, using gas chromatography with a thermal conductivity detector, could not detect less than 6 ppm.

The products were analyzed by expansion into a Toepler pump from which duplicate samples were taken for analysis. Analyses were made on a Hewlett-Packard model 5750 with FID detector, using a 1.2 m column of Durapak (phenylisocyanate on Porasil) maintained at 30°C. The reactant ethylene and the products methane and ethane were measured for reaction times from 1–40 min.

## Results

The rate of hydrogenation of ethylene in the unpacked vessel was measured at 1111 K for five concentrations of ethylene in hydrogen ranging from 9–36 ppm. At each concentration the rate was measured at four or five total pressures ranging from 100–300 Torr. These data allowed the determination of the order with respect to each reactant. The rate was also measured at five temperatures over the range 1111–1192 K. In addition, at 1192 K, the total order of the rate with respect to both reactants was measured.

The primary product of the hydrogenation was ethane, but at the temperature of the reaction, secondary decomposition was rapid and the final product was methane. The yields as a function of time at 1111 K are shown in Figs. 1, 2, and 3. It is clear that ethane is an intermediate product and even at the lowest temperature its yield is small. It gradually became undetectable as the temperature

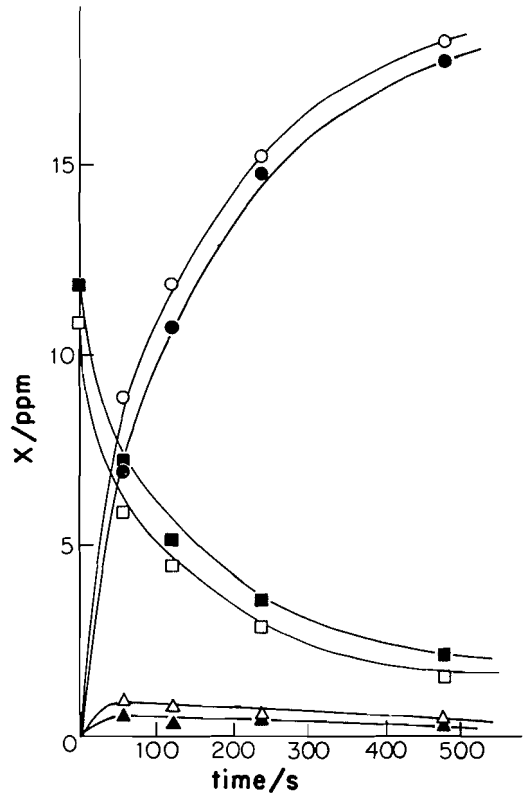

FIG. 1. Variation in mole fraction of reactant and products at 1111 K and total pressure of 182 Torr. □, $C_2H_4$; ○, $CH_4$; △, $C_2H_6$. Open symbols refer to unpacked vessel (S/V ~ 1 $cm^{-1}$) and filled symbols refer to packed vessel (S/V ~ 7 $cm^{-1}$).

was increased. It should be noted that equilibrium in this system corresponds to almost complete conversion of ethylene to methane. The reaction was therefore followed by the disappearance of ethylene and the appearance of methane.

The measurement of the initial rates from the data involved a search for an equation giving the best linear extrapolation. Integrated equations for orders of 0.5, 1, 1.5, and 2 were tested and the best extrapolation was obtained with the function $1/x$ against time. A summary of the measurements is given in Table 1. In fact, these initial rates were within about 25% of those estimated directly from the yield–time plots or from the function log $x$ against time. It should be emphasized that the function used to estimate the initial rates is not particularly significant in terms of the mechanism of the reaction during the initial stages.

The dependence of the rate on the initial concentration of the reactant is the characteristic of most importance to the mechanism. The rate of disappearance of ethylene may be written as

$$-R_{C_2H_4} = k[H_2]^m[C_2H_4]^n$$

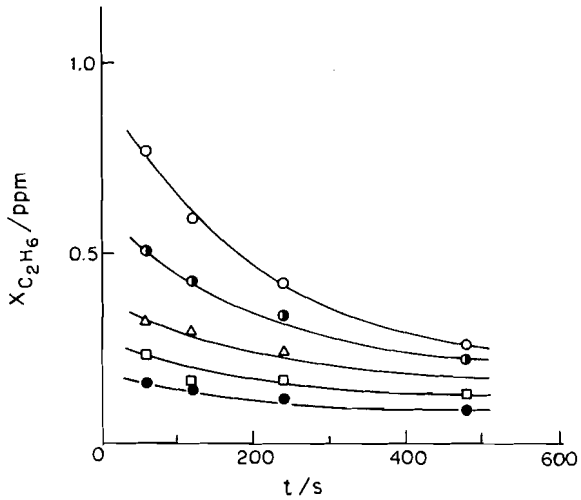

FIG. 2. Mole fraction of ethane as a function of time at various temperatures. Initial concentration of ethane: 9.33 ppm; total pressure: 182 Torr. ○, 1111 K; ◑, 1131 K; □, 1171 K; ●, 1192 K; △, 1151 K. Open symbols refer to unpacked vessel (S/V ~ 1 $cm^{-1}$) and filled symbols refer to packed vessel (S/V ~ 7 $cm^{-1}$).

where $k$ represents an over-all rate constant and $m$ and $n$ represent the order of the rate with respect to hydrogen and ethylene, respectively. Designating the mole fraction of each reactant by $X$ and making the approximation that $X_{H_2} = 1$,

$$-R_{C_2H_4} = kP^{m+n}X_{C_2H_4}{}^n$$

where $P$ is the total pressure.

A log–log plot of the initial rate as a function of $X_{C_2H_4}$ is shown in Fig. 4 for four total pressures. Since the concentration of hydrogen is essentially constant for each total pressure, the slope of these plots gives a value for $n$ of $1.0 \pm 0.1$. The initial rate as a function of the total pressure for each of the concentrations of ethylene is given in Fig. 5. The slope of these plots, all equal to $2.4 \pm 0.1$, gives the total order, $m + n$. A similar plot using the data obtained at 1192 K (Table 1) gives a value for $m + n = 2.5$. The value of $m$ is therefore $1.5 \pm 0.1$. An Arrhenius plot of the initial rate gives an activation energy of 33 kcal/mol.

In the packed vessel, rates were measured at total pressures of 116, 182, 274, and 325 Torr for each of three mixtures, 12, 18.5, and 28 ppm ethylene at 1111 K. The results are given as the corresponding filled symbols in Figs. 1, 2, and 4. The results show that heterogeneous processes are not important in the rate-determining steps of the reaction except to a slight extent at the highest pressures.

These results suggest that the hydrogenation of ethylene may occur through a simple set of reactions where the H-atom concentration in the

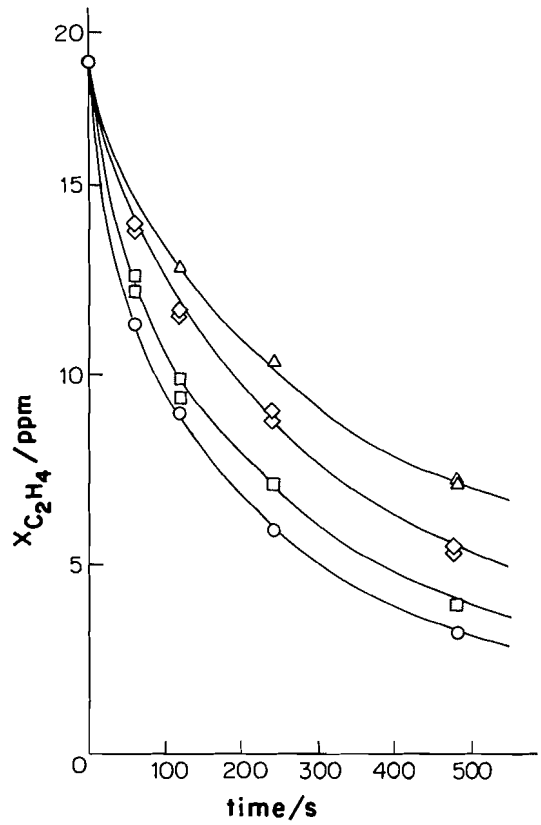

FIG. 3. Mole fraction of ethylene as a function of time at 1111 K with initial concentration of ethylene of 19.2 ppm. Total pressure: △, 85.5 Torr; ◇, 117 Torr; □, 149 Torr; ○, 182 Torr.

system is determined by the equilibrium between molecules and atoms.

[1] $H_2 \rightleftarrows 2H$

of ethyl radicals is controlled by the equilibrium reaction [2],

[8] $$-R_{C_2H_4} = k_3K_2K_1^{1/2}[H_2]^{3/2}[C_2H_4]$$

*Case 2*: If $k_{-2}[M]^x \ll k_3[H_2]$

[9] $$-R_{C_2H_4} = k_2[M]^xK_1^{1/2}[H_2]^{1/2}[C_2H_4]$$

The order of the rate is consistent with either case if $x$ is close to 1. The activation energy of the rate, 33 kcal/mol, is, however, consistent only with the first case where an equilibrium concentration of ethyl radicals is maintained. Taking $\Delta H_2 = -41.0$ kcal/mol (see Appendix) and $\Delta H_1 = 104.2$ kcal/mol, case 1 gives $E_3 = 22$ kcal/mol. It will be shown later that this is a reasonable value at temperatures in the region of 1100 K. On the other hand, from eq. [9] describing case 2, and using a value of $E_2$ of about 4 kcal/mol (7), the activation energy of the rate wil be about 56 kcal/mol, far outside the measured value. A calculation of the relative magnitude o $k_{-2}$ and $k_3[H_2]$ is not conclusive (although ar estimate gives $k_{-2}$ about five times greater thar $k_3[H_2]$) because rather long extrapolations are required in both cases and for $k_{-2}$ both the value o the rate constant and its pressure-dependence mus be obtained. It may be concluded that the mecha nism is best described by the conditions imposed by case 1 and that eq. [8] adequately expresses the rate of disappearance of ethylene in the system.

The order with respect to hydrogen and the activation energy of the rate strongly suggest tha hydrogen atoms are maintained at an equilibrium

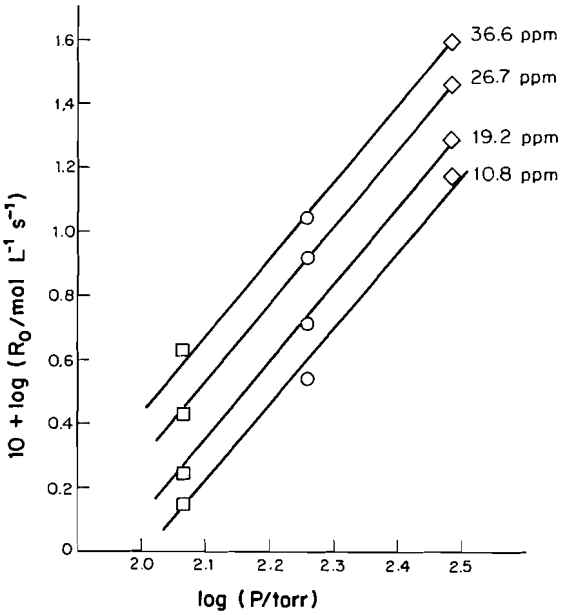

FIG. 5. Logarithm of the initial rate of reaction of ethylene as a function of the logarithm of the total pressure at 1111 K for various initial concentrations of ethylene.

concentration. It may be questioned, however, that the homogeneous rate of dissociation of hydrogen is sufficiently fast to produce the equilibrium concentration in the short times of these reactions. Calculations based on the value of the rate constant for combination of hydrogen atoms measured at room temperature (10) (an upper limit) and the equilibrium constant at the temperature of the reaction, show that homogeneous dissociation is indeed too slow by at least a factor of $10^2$. It must be concluded that dissociation is catalyzed by the quartz surface. The fact that the rate was not affected by an increase in S/V ratio of the reaction vessel further suggests that an equilibrium concentration of hydrogen atoms is rapidly attained in both vessels.

Some comments concerning the importance of other reactions which might affect the concentration of radicals in the system may clarify the mechanism. The occurrence of reaction [6] could reduce the concentration of hydrogen atoms below equilibrium. At 1111 K and a pressure of hydrogen of 182 Torr, the equilibrium concentration of hydrogen atoms is $1.7 \times 10^{-10}$ mol $L^{-1}$. Under the same conditions, with 10 ppm $C_2H_4$, the equilibrium ratio of $C_2H_5/H$ equals $1 \times 10^{-3}$. Taking again the value of $k_{-1}$ measured at room temperature (10) and a value of $1 \times 10^{10}$ L $mol^{-1}$ $s^{-1}$ for $k_6$, the homogeneous rates of reaction [−1] and [6] are comparable. We have, nevertheless, argued that the dissociation of hydrogen and the combination of hydrogen atoms must occur on the surface much more rapidly than in the gas phase. The measurements by Sepehrad, Marshall, and Purnell (19) of the rate of combination of hydrogen atoms on the surface show that this is the case. In their system hydrogen atoms disappeared at the wall in a first-order process,

[W] $H \rightarrow \frac{1}{2}H_2$

and a value of $k_w$ of $20 \pm 15$ $s^{-1}$ was obtained at temperatures in the region of 800 K. In the present system wall recombination is probably slower since the steady-state concentration of hydrogen atoms is less than in the flow system of Sepehrad *et al.* Nevertheless use of their value for $k_w$ provides an upper limit to the rate of removal of hydrogen atoms. The ratio of the rates of reactions [W] and [6] may be expressed as follows:

$$R_w/R_6 = k_w/k_6K_2[H][C_2H_4]$$

and with the conditions described above ($K_2$ at 1111 K = $1.7 \times 10^4$ L $mol^{-1}$),

$$R_w/R_6 = 2.6 \times 10^4$$

Therefore termination by reaction [6] is probably not sufficiently important to reduce the concentration of hydrogen atoms significantly below equilibrium. Furthermore, this reaction probably requires collisional stabilization, without which the ethane molecule will dissociate into two methyl radicals which will rapidly convert to methane, returning hydrogen atoms to the system.

A possible initiation process is the reaction of ethylene with hydrogen to give an ethyl radical and a hydrogen atom,

[10] $C_2H_4 + H_2 \rightarrow C_2H_5 + H$

If termination occurs by reaction [6], then, under steady-state conditions,

$$[C_2H_5] = k_{10}[C_2H_4][H_2]/k_6[H]$$

The rate constant for reaction [10] may be estimated from values of $\Delta H$ and $\Delta S$ and may be expressed as

$$\log k_{10}\ (\text{L mol}^{-1}\ \text{s}^{-1}) = 9.8 - 65300/2.3RT$$

At 1111 K, $k_{10} = 9.6 \times 10^{-4}$ L mol$^{-1}$ s$^{-1}$. Taking again the conditions of 182 Torr hydrogen and 10 ppm $C_2H_4$ and assuming $k_6 \sim 1 \times 10^{10}$ L mol$^{-1}$ s$^{-1}$ (an upper limit),

$$[C_2H_5] \sim 3 \times 10^{-14}\ \text{mol L}^{-1}$$

This value, although only approximate, is lower than the equilibrium concentration of ethyl radicals of $\sim 2 \times 10^{-13}$ estimated under the same conditions. Reaction [10] may therefore be neglected as a significant source of ethyl radicals. Furthermore, a contribution by ethylene to the initiation process would increase the order of the rate with respect to the concentration of ethylene.

It can also be shown that reaction [10] cannot itself account for the disappearance of ethylene. According to reaction [10] the rate of disappearance of ethylene may be written as

$$-R_{C_2H_4} = k_{10}[C_2H_4][H_2]$$

Taking the same conditions as an example, the rate of disappearance of ethylene may be estimated as $6 \times 10^{-14}$ mol L$^{-1}$ s$^{-1}$, while the observed rate is $3 \times 10^{-10}$ mol L$^{-1}$ s$^{-1}$ (Table 1). One further possibility for consumption of ethylene is the unimolecular dissociation,

[11] $C_2H_4 \rightarrow C_2H_3 + H$

This reaction has been observed and measured in the shock-tube pyrolysis of ethylene (11, 12) as a second-order process. A reasonable value for the unimolecular dissociation is

$$\log k_{11}\ (\text{s}^{-1}) = 16 - 104000/2.3RT$$

and at 1111 K, $k_{11} = 3.5 \times 10^{-5}$ s$^{-1}$. Taking the same conditions as above,

$$-R_{C_2H_4} = k_{11}[C_2H_4] = 8.8 \times 10^{-13}\ \text{mol L}^{-1}\ \text{s}^{-1}$$

This must be an upper limit since the dissociation will undoubtedly be partly pressure-dependent at the temperature of these experiments. Therefore neither reaction [11] nor reaction [10] are sufficiently fast to account for the rate of disappearance of ethylene.

The rates of reactions [10] and [11] may also be compared to the rate of dissociation of hydrogen, in order to compare the rate of production of hydrogen atoms in the system. A value for the rate of dissociation of hydrogen on the surface may be obtained from the equilibrium represented by reaction [W], and again represents an upper limit.

$$K_w = k_{-w}/k_w = (K_{H_2})^{1/2}$$

Using the value for $k_w$ as already discussed,

$$k_{-w} = 7.0 \times 10^{-8}\ (\text{mol/L})^{1/2}\ \text{s}^{-1}$$

The ratio of rates may be expressed as follows:

$$\frac{R_{-w}}{R_{10}} = \frac{k_{-w}[H_2]^{1/2}}{k_{10}[C_2H_4][H_2]} = 5.8 \times 10^4$$

$$\frac{R_{-w}}{R_{11}} = \frac{k_{-w}[H_2]^{1/2}}{k_{11}[C_2H_4]} = 4.2 \times 10^3$$

Even though this represents an upper limit to the rate of formation of hydrogen atoms from hydrogen, it is unlikely that reactions [10] or [11] are important in the present system.

*Rate of formation of methane*

The rate of formation of methane may be equated to the rate of disappearance of ethane if all methyl radicals react by reaction [5].

$$R_{CH_4} = 2k_4[C_2H_6]$$

The maximum concentration of ethane is given as follows,

$$[C_2H_6]_m = \frac{k_3[C_2H_5][H_2]}{k_{-3}[H] + k_4}$$

If the concentration of both the ethyl radical and the hydrogen atom are given by the relevant equilibrium constant the maximum rate of formation of methane is

[12] $$R_{CH_4} = \frac{2k_4k_3K_2K_1^{1/2}[H_2]^{3/2}[C_2H_4]}{k_{-3}K_1^{1/2}[H_2]^{1/2} + k_4}$$

since $k_{-3} = k_3/K_3$ the rate constant $k_3$ may be expressed as

TABLE 2. Initial rate of formation of methane and values for $k_3$, total pressure: 182 Torr; $X_{C_2H_4}$: 9.33 ppm

| $T$/K | $\frac{d}{dt}[CH_4]$/ mol $L^{-1}$ $s^{-1}$ × $10^{-10}$ | $K_3/10^{-3}$ | $k_4/s^{-1}$ | $k_3$/L $mol^{-1}$ $s^{-1}$ × $10^6$ |
|---|---|---|---|---|
| 1111 | 2.50 | 3.87 | 0.0676 | 1.10 |
| 1131 | 3.96 | 4.06 | 0.151 | 1.46 |
| 1151 | 4.92 | 4.21 | 0.282 | 1.76 |
| 1171 | 6.42 | 4.37 | 0.525 | 2.27 |
| 1192 | 8.62 | 4.54 | 1.00 | 2.29 |

$$[13]\quad k_3 = \frac{R_{CH_4}k_4}{K_1^{1/2}[H_2]^{1/2}\left[2k_4K_2[H_2][C_2H_4] - \frac{R_{CH_4}}{K_3}\right]}$$

Since the product ethane achieves its maximum concentration at a very short time of reaction, the maximum rate of formation of methane may be obtained by an extrapolation procedure similar to that used to obtain the initial rate of disappearance of ethylene. In other words, a maximum rate will be indistinguishable from an initial rate on the time scale of the present experiments. These rates of formation of methane are shown in Table 2.

The relative importance of the terms in the denominator of eq. [12] may be deduced from the measured activation energy of the rate of formation of methane, which was 38 kcal/mol. If $k_4 \gg k_{-3}K_1^{1/2}[H_2]^{1/2}$ and ethane is removed primarily by dissociation, the rate of formation of methane becomes

$$[14]\quad R_{CH_4} = 2k_3K_2K_1^{1/2}[H_2]^{3/2}[C_2H_4]$$

which is exactly twice the rate of disappearance of ethylene. Since the activation energies for the rate of disappearance of ethylene and the rate of formation of methane were similar, it may be concluded that the simplified expression, eq. [14], closely describes the mechanism for formation of methane. The other situation, in which $k_4$ may be neglected in the denominator, would predict a much higher activation energy, about 63 kcal/mol. Nevertheless, the initial rate of formation of methane was not exactly twice the initial rate of disappearance of ethylene, indicating that some ethane may be lost by the reverse of reaction [3]. The complete eq. [13] was therefore used to calculate $k_3$.

*Calculation of* $k_3$

Using eqs. [8] and [13] values of $k_3$ were calculated from the rate of disappearance of ethylene and from the rate of formation of methane. The results together with the values of $k_4$, $K_2$, and $K_3$ used in the calculations, are included in Tables 1 and 2. The fall-off in $k_4$ was estimated by extrapolation of the results of Lin and Back (13). Other data are given in the Appendix. An Arrhenius plot of $k_3$ is given in Fig. 6. The activation energy measured for $k_3$ is 23 ± 2 kcal/mol. These results are shown together with the four other sets of measurements previously reported at lower temperatures as the filled points in Fig. 7. Also on this graph are values of $k_3$ calculated from the measurements of $k_{-3}$, and the equilibrium constant $K_3$. The points given represent the limits of the temperature range for each set of data and the lines represent the values reported for $A$ and $E$. The thermodynamic quantities used in the calculation are given in the Appendix.

The measurements of $k_3$ derived from $k_{-3}$ are somewhat lower than the direct measurements of $k_3$, but may be considered in reasonable agreement. Two points concerning the calculations should be noted. The four measurements of $k_3$ were

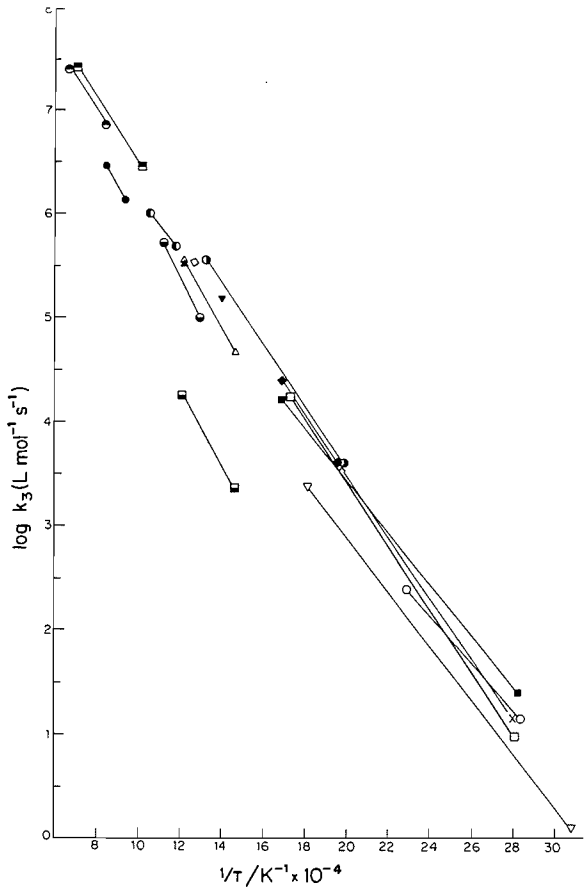

FIG. 7. Arrhenius plot for $k_3$. Filled symbols represent direct measurements of $k_3$. Other symbols represent measurements of $k_{-3}$ converted to $k_3$ using the calculated values of $K_3$. ■, ref. 3; ◆, ref. 4; ●, present work; ▲, ref. 5; ▼, ref. 6; □, ref. 27; ◑, ref. 32; ×, ref. 29; ○, ref. 21; ▽, ref. 26; △, ref. 24; ◇, ref. 30 and 31; ◒, ref. 22; ◒, ref. 23; ◐, ref. 28; ◓, ref. 25; ◓, ref. 33.

all made relative to the rate constant for the combination of ethyl radicals, $k_c$, which in each case was taken as $2.2 \times 10^{10}$ L mol$^{-1}$ s$^{-1}$. More recent work indicates that $k_c \sim 1 \times 10^{10}$ L mol$^{-1}$ s$^{-1}$ (14, 15) and these values were therefore lowered by $\sqrt{2.2}$. The equilibrium constant, $K_3$, was calculated using a value of 28 kcal/mol for $\Delta H_f(C_2H_5)$. Although this value is given in most references (8, 16) as 26 kcal/mol, $k_3$ calculated with this value is considerably lower than the direct measurements of $k_3$. Recent measurements of the heat of formation of the ethyl radical relative to that of the methyl radical using a radical buffer system in an isooctane solution (17) have given a value of 28 kcal/mol, using $\Delta H_f(CH_3) = 34.4$ kcal/mol. The fact that the independent measurements of $k_3$ and $k_{-3}$ are in reasonable agreement using the value of $\Delta H_f(C_2H_5) = 28$ kcal/mol suggests that the higher value may be preferable. The difference of 2 kcal/mol increases the calculated values of $k_3$ by a factor of two. A similar comparison between forward and reverse rate constants for the reaction of methyl radicals with hydrogen led to the acceptance of a higher value (at that time) for the heat of formation of the methyl radical (18). In a recent discussion of this system, the authors concluded that the independent measurements of the forward and reverse rate constants were in agreement within a factor of 2 or 3 (19, 20). A similar agreement is indicated in the present comparison of the system involving ethyl radicals.

The present measurements are in good agreement with the values of $k_3$ calculated from measurements of $k_{-3}$. They appear somewhat below an extrapolation of the values measured below 820 K but are within the limits of error encompassed by both sets of measurements. Most of the measured rate constants are within a factor of two of an average value. On the other hand, values for the Arrhenius parameters are often very different, as can be observed from the variation in slopes of the lines in Fig. 7.

The activation energy of $k_3$ obtained in the present results appears at first unusually high, although there are no other data for $k_3$ above about 820 K. It has been observed that the activation energy of similar abstraction reactions rises gradually but substantially above 900 K. For example, in their discussion of non-Arrhenius behaviour in some simple abstraction reactions Clark and Dove (2) showed that the literature data on reaction [−3] can be fitted by a smooth curve giving a continuously increasing activation energy with increasing temperature. From this curve, $E_{-3}$ was about 14 kcal/mol in the temperature range 1100–1200 K. Since $\Delta H_3$ at this temperature is 4.5 kcal/mol (see Appendix), $E_3$ should be 18.5 kcal/mol, in reasonable agreement with the present results. Closer examination of the combined sets of measurements may, however, throw some doubt on the magnitude of the change in activation energy over the whole temperature range. The results could, in fact, be fitted reasonably well by a linear relation. This was the conclusion reached by Sepehrad, Marshall, and Purnell (19) in a comparison of measurements reported for $k_{-5}$. Nevertheless, the best fit probably indicates a change in activation energy from 12 kcal/mol in the range 350–550 K to about 17 kcal/mol from 800–1200 K, which is a smaller increase than previously supposed. The comparison of these two sets of data shows the magnitude of error which can be expected in values for rate constants for radical abstraction reactions. It also illustrates

For personal use only.

the danger in the use of extrapolated values and the need to acquire a consistent set of data.

*Evaluation of the method*

A possible source of error in the present measurements which would lead to an underestimate of $k_3$ is an overestimate of either the hydrogen atom concentration or the ethyl radical concentration. It seems unlikely that the hydrogen atom concentration is much below equilibrium since the large increase in surface area had no effect on the rate. It is known that hydrogen atoms are strongly adsorbed on quartz surfaces, leading to heterogeneous reactions, but the absence of a perturbing effect of the surface is easily explained if atoms and molecules are in equilibrium. The concentration of ethyl radicals, on the other hand, may be reduced below the equilibrium value under conditions where $k_3[H_2]$ may become comparable in rate to the dissociation reaction, [−2]. Estimates of the relative magnitude of these two rates suggests they may be comparable, but the over-all activation energy of the rate was incompatible with the exclusion of reaction [−2] as the rate-controlling removal of ethyl radicals. This factor could cause an underestimate of $k_3$ by perhaps a factor of two. The estimate of the initial rate also involves some uncertainty, but it seems unlikely that this could be more than 30 or 40%. The system is kinetically simple and offers a well-controlled concentration of atoms. Further studies on other systems should prove useful in providing data on the region above 1000 K.

# Halogenation of 1,6-diazaphenalene. Theoretical and experimental results

ROBERT W. WEBER, SHIEU-JEING LEE, SAMUEL MILOSEVICH, WALTER B. ENGLAND,[1] AND JAMES M. COOK[1]

*Department of Chemistry and Laboratory for Surface Studies, University of Wisconsin–Milwaukee, Milwaukee, WI 53201, U.S.A.*

Received April 14, 1982

ROBERT W. WEBER, SHIEU-JEING LEE, SAMUEL MILOSEVICH, WALTER B. ENGLAND, and JAMES M. COOK. Can. J. Chem. **60**, 3049 (1982).

Bromination of 1,6-diazaphenalene **1** yields a mixture of mono-, di-, and tri-bromo derivatives, while bromination of the conjugate acid **2** provides the 7-bromo isomer **7** in 81% yield. Charge densities and localization energies have been calculated, and are found to be in agreement with the orientation pattern observed during electrophilic substitution. These observations have been employed to develop several routes to 7-substituted 1,6-diazaphenalenes.

ROBERT W. WEBER, SHIEU-JEING LEE, SAMUEL MILOSEVICH, WALTER B. ENGLAND et JAMES M. COOK. Can. J. Chem. **60**, 3049 (1982).

La bromation du diaza-1,6 phénalène **1** donne un mélange de dérivés mono-, di- et tri-bromés tandis que la bromation de l'acide conjugué **2** conduit à l'isomère bromé en position 7, **7** avec un rendement de 81%. On a calculé les densités de charge et les énergies de localisation. Les valeurs obtenues sont en accord avec le mode d'orientation observé lors d'une substitution électrophile. On a utilisé ces observations pour développer plusieurs voies d'accès aux diaza-1,6 phénalènes substitués en position 7.

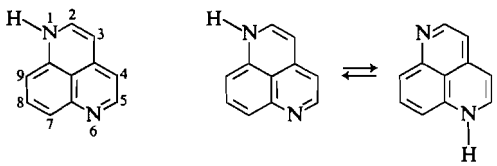
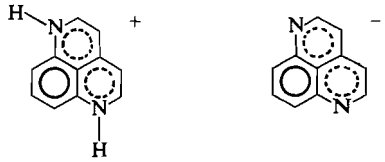
The heterocyclic base 1,6-diazaphenalene **1** was first reported in 1978 (1). This compound is of interest from both a chemical and electronic point of view for proton transfer from **1***a* to **1***b* would generate a species **1***b* identical in structure with **1***a*.



**1** **1***a* **1***b*

This process is more rapid than the nmr time scale and results in a simplified nmr spectrum analogous to the case of imidazole (2), and it has been suggested that many of the properties of **1** are imidazole-like (1). In this vein, the reaction of **1** with various electrophiles has been studied under conditions reported to provide substituted imidazoles (3, 4). These studies have dealt primarily with halogenation and nitration reactions under neutral and acidic conditions. Moreover, experiments have generally been carried out with one mole (or less) of the electrophile to more accurately determine the most reactive site for electrophilic substitution.

In order to compare the experimental results with the reactivity predicted by molecular orbital theory, INDO calculations (5) were carried out on the base **1**, conjugate acid **2**, and the anion **3**. The geometries required for the calculations were obtained using standard bond lengths (6). The neutral species **1** was considered as an enamine fused to a quinoline system. A symmetrical structure was chosen for the protonated form **2** based on nmr data (7). Similarly, removal of two hydrogen atoms from the nitrogens of **2** yielded the geometry used for the anion **3**.



**2** **3**

The total charge densities obtained for these compounds are given in Table 1. The HOMO and LUMO electron densities are given in Table 2, and

TABLE 1. Total electron densities for 1,6-diazaphenalene **1**, conjugate acid **2**, anion **3**, 3-chloro-1,6-diazaphenalene **10**, and 2,3-dichloro-1,6-diazaphenalene **11**

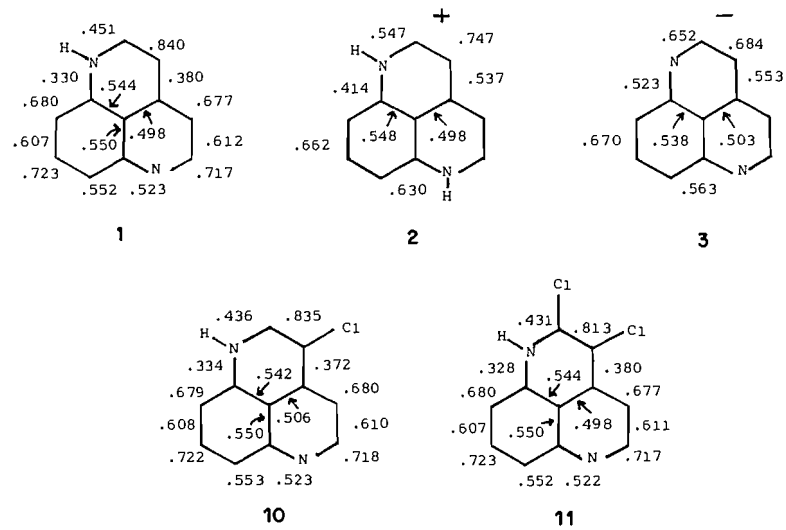

FIG. 1. Calculated bond orders ($\pi$) for 1,6-diazaphenalene **1**, the cation **2**, and anion **3**, 3-chloro-1,6-diazaphenalene **10**, and 2,3-dichloro-1,6-diazaphenalene **11**.

the calculated bond orders are listed in Fig. 1. The total charge densities in the neutral molecule **1** predict a reactivity to electrophilic substitution in the order of positions 3 > 4 > 9 > 7. In the symmetrical ions 2 and 3 the same trend (3(4) > 7(9)) is apparent. According to the frontier orbital theory of Fukui *et al.* (8), reactivity with electrophiles is governed by the electron densities of the highest occupied molecular orbital (HOMO), while the lowest unoccupied molecular orbital (LUMO) determines orientation in reactions with nucleophiles. From the HOMO densities a reactivity pattern of 7 > 3 > 4 > 9 is predicted for **1**, and this trend (7 > 3) continues for the charged species **2** and **3**. The virtual LUMO densities for all three species indicate that nucleophilic attack should occur at positions 2 and 5.

For comparison with experimental results the neutral molecule **1** will be considered first. The products obtained from the bromination of **1** under analogous conditions to those reported for the bromination of imidazole are given in Scheme 1 (9). The reactions were carried out in acetic acid – sodium acetate solution with one equivalent or less of bromine (4). Since significant amounts of di- and tri-substituted diazaphenalenes were formed in this process, yields were low due to recovery of unreacted **1**, as well as difficulties encountered during separation; however, the relative amounts of the isomers present are quite representative. When a large excess of sodium acetate was employed (40:1 ratio) the major product was the 3,4,7-tribromo derivative **4**, followed by the 2,3,4-tribromodiazaphenalene **5** and the 2,3-dibromo compound **6** (4). Upon reducing the amount of sodium acetate to 24 equivalents, the 2,3,4-tribromo derivative **5** now became the major product, followed by the 2,3-dibromodiazaphenalene **6**. At this point the 7-bromo-

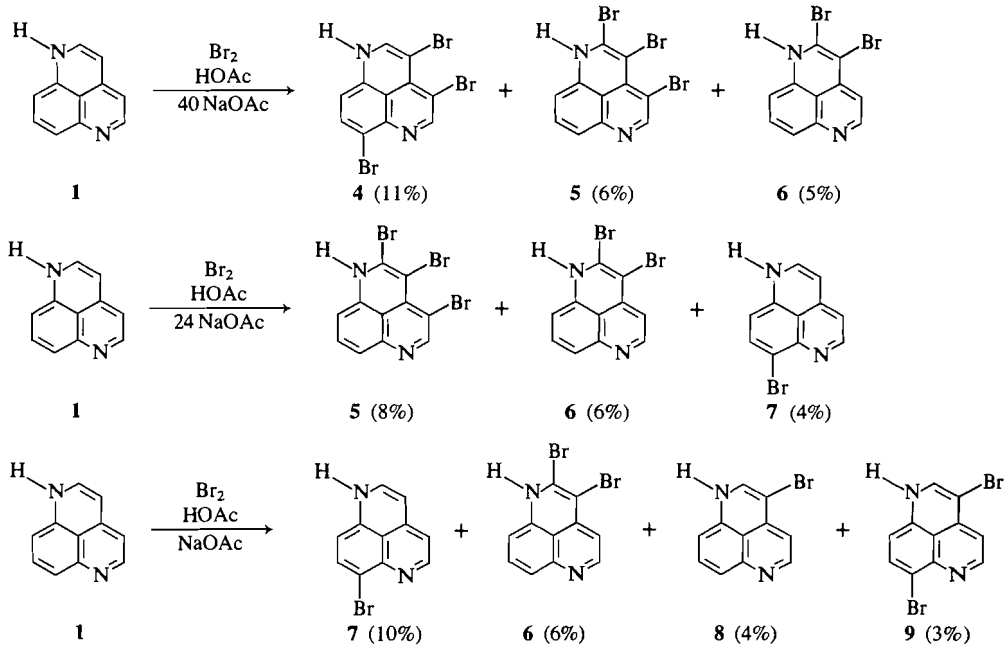
For personal use only.



SCHEME 1

diazaphenalene **7** was also obtained. Upon further reduction of the amount of sodium acetate to one equivalent, the 7-bromo derivative **7** now became the major product, followed by the 2,3-dibromo compound **6**, the 3-bromodiazaphenalene **8**, and the 3,7-dibromodiazaphenalene **9**. At this point a trend appeared clear. The more acidic reaction medium (less sodium acetate) favored formation of the 7-bromo-1,6-diazaphenalene **7** in preference to the other isomers and the amount of 2,3-dibromo-1,6-diazaphenalene **6** remained relatively constant. Similarly the pH dependence of the relative rates of bromination of imidazole has been reported (10).

While it is difficult to ascertain the order of addition in the polyhalogenated compounds, the positions substituted correspond to those of high electron density with the exception of the products having bromine in the 2 position. This is unusual for the 2 position would be the expected site of nucleophilic substitution, based on the calculated electron densities. To examine this further, INDO calculations were carried out on 3-chloro-1,6-diazaphenalene **10** and 2,3-dichloro-1,6-diazaphenalene **11** using the third row reparameterizations of Gordon *et al.* (11); we assume here that chlorine and bromine affect the molecule similarly. The total charge densities obtained are listed in Table 1, the HOMO and LUMO densities in Table 2, and the calculated bond orders are illustrated in Fig. 1. Placing the chlorine atom at position 3 alters the order of decreasing electron density from 3 > 4 > 9 > 7 to 9 > 4 > 7; however, in the 2,3-dichloro compound **11** this sequence returns to 4 > 9 > 7. The HOMO densities in the 3-chloro derivative **10** again favor substitution in the 7 position. In the dichloro derivative **11**, however, attack at the 4 position is now favored for the first time in the series.

Two pathways for the formation of the 2,3-dibromo isomer **6** are shown in Scheme 2. The path **1**

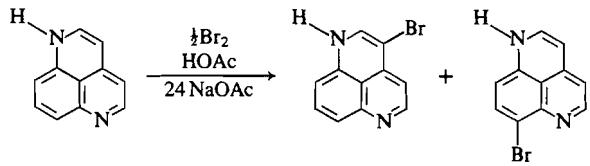
→ **8** → **13** → **6** first involves substitution of bromine at position 3, followed by addition of $Br_2$ across the 2–3 double bond. Elimination of HBr would then generate **6**. At this point an additional experiment needs to be discussed. When the base **1** was treated with half an equivalent of bromine, the major product was 3-bromo-1,6-diazaphenalene **8**, which was not isolated in substantial quantities when one equivalent of bromine was used. The other major product was the 7-bromo isomer **7**, as shown below. Since bromine is an oxidizing agent, the lesser concentration of this reagent may have impeded conversion of **12** to **6**; however, at no time was a dihydro intermediate related to **12** or **13** isolated from the reaction.

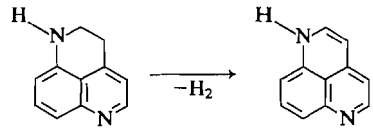


**1** **8** (11%) **7** (8%)

The INDO calculations indicate that the 2–3 bond contains the most double bond character in the molecule ($\pi$ bond order of 0.840, see Fig. 1) and substitution of a chlorine atom at the 3 position only decreases this slightly ($\pi$ bond order of 0.835). The highest degree of polarization in the molecule, considering both total electron densities and HOMO densities, is between the carbon atoms in the 2 and 3 positions. These factors should favor the addition of $Br_2$ across the 2–3 double bond. A 2,3,3-tribromo diazaphenalene such as **13** has never been observed; however, the lack of stability for such a species would be expected to prevent isolation.

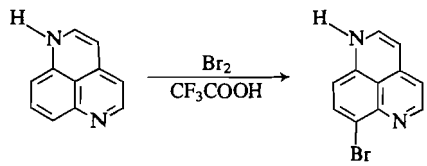
The alternate pathway, **1** → **12** → **6** involves addition of $Br_2$ across the 2–3 double bond, followed by loss of $H_2$. While the 2,3-dihydro-1,6-diazaphenalene **14** slowly (3) reverts to **1** upon standing for several weeks as shown below, one might expect loss of HBr to be a more favorable process in the case of the dibromide **12** (3). If indeed this were the case, one would expect to isolate both the 2-bromo and 3-bromo isomers generated from the loss of HBr from **12**. It is important to note here that the 2-bromo-1,6-diazaphenalene has never been observed in work carried out to date, and the only compounds obtained that bear a bromine atom in the 2 position were also substituted with bromine at the 3 position. Since both pathways appear feasible, however, the exact nature of the formation of **6** must remain, for the moment, a matter for further experiments.

In terms of synthetic utility, it is desirable to



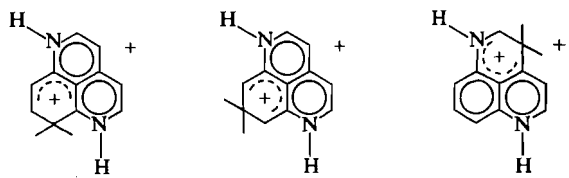
**14** **1**

obtain one product in preference to all other possible isomers. Because 7-substituted 1,6-diazaphenalenes are important intermediates for the synthesis of potential antimalarial agents (1, 7), conditions were sought under which the 7-substituted derivatives would be the major or exclusive product. From the results previously discussed it was known that increased acidity favored the formation of the 7-substituted product. It had also been shown that 1,6-diazaphenalene was protonated to yield the cation **2** in trifluoroacetic acid (4); therefore, reactions were attempted in this medium and the result with bromine is presented below.



**1** **7** (81%)

Without exception brominations carried out in this medium resulted in the almost exclusive formation of the 7-substituted product. However, in the case of the protonated diazaphenalene **2** the comparable electron densities of the 3 and 7 positions argue against exclusive substitution. We therefore utilized the Wheland model of the transition state (12) to calculate $\pi$ localization energies ($\pi$ bonding between the atom undergoing substitution and the rest of the molecule is cut off). Since the conjugate acid **2** of 1,6-diazaphenalene was symmetrical, calculations were only carried out for substitution at the 2, 3, 7, and 8 positions. The resulting localization energies indicate that the lowest energy $\sigma$ complex is reached for substitution at the 2 position, followed by substitution at positions 7(9), 8, and 3(5) in that order. Since electrophilic attack at the 2 position is electrostatically unlikely, the result that substitution at position 7(9) is favored over the other possibilities is in complete agreement with the experimental observations. The localization energies relative to substitution at position 7 are given below.



0 kcal/mol 7 kcal/mol 21 kcal/mol

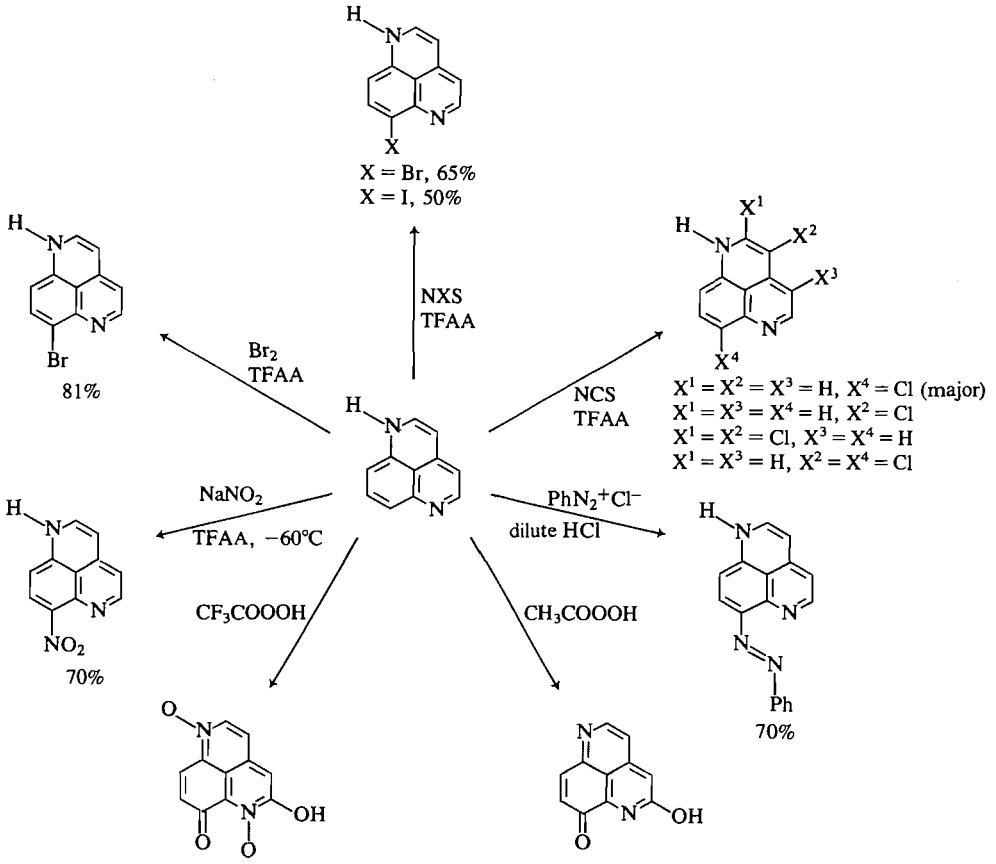

SCHEME 3

The ability to predict that protonated species **2** will react with electrophiles preferentially at the 7 position has been recently employed to design and execute a number of experiments. Outlined in Scheme 3[2] are a series of reactions in which the protonated diazaphenalene **2** has been treated with a variety of electrophiles such as chloronium, iodonium, diazonium, and nitronium ions, as well as peroxy acids. In all cases in which electrophilic substitution has been performed in acidic media, reaction occurred predominantly at the 7 position. These results correlate well with theoretical predictions; advantage will be taken of this phenomenon to prepare potential antimalarial agents.

## Experimental

Microanalyses were performed on a F and M Scientific Corp. Model 185 carbon, hydrogen, and nitrogen analyzer. Some analyses were carried out at the National Institutes of Health, Bethesda, Maryland. Melting points were taken on a Thomas–Hoover melting point apparatus and are not corrected. Nuclear magnetic resonance spectra were recorded on Varian T-60 and JEOL FX-90 spectrometers. Infrared spectra were taken on a Beckman Acculab-1 instrument, and mass spectra were recorded on a Hewlett–Packard 5855 GC/MS. High performance liquid chromatography (hplc) was carried out on a Waters Preparative LC-500 system. The preparation of **1** has been described elsewhere (see ref. 1*b*).

*General procedure for bromination of 1 in acetic acid*

The 1,6-diazaphenalene **1** (1.68g, 0.01 mol) was dissolved in glacial acetic acid (180 mL) and the appropriate amount of sodium acetate added. To the stirred mixture, bromine (0.51 mL, 0.01 mol) dissolved in acetic acid (3.3 mL) was added dropwise. After stirring for 2 hours, the solvent was removed under reduced pressure. The residue was washed with water and dried overnight. The resulting mixture was separated by hplc ($SiO_2$, 10% ethyl acetate in benzene).

*3,4,7-Tribromo-1,6-diazaphenalene 4*

Melting point >300°C; ir (KBr): 3250 (s), 1584 (s), 1340 (s), 1262 (s), 1236 (s), 1178 (s), 1080 (m), 790 (m), and 684 (m) $cm^{-1}$; nmr (DMSO-$d_6$) δ: 6.20 (1H, d, $J$ = 8 Hz), 7.42 (1H, d, $J$ = 8 Hz), 7.88 (1H, s), 8.26 (1H, s); mass spectrum (CI, $CH_4$): 406 (P + 1, 100%), 326 (34). *Anal.* calcd. for $C_{11}H_5N_2Br_3$: C 32.63, H 1.24, N 6.92; found: C 32.49, H 1.46, N 7.01.

*2,3,4-Tribromo-1,6-diazaphenalene 5*

Melting point >300°C; ir (KBr): 3325 (b), 1585 (s), 1340 (s), 1265 (s), 1235 (s), 790 (s), 765 (s), and 685 (s) $cm^{-1}$, nmr (DMSO-$d_6$) δ: 6.22 (1H, d, $J$ = 8 Hz), 7.40 (1H, t, $J$ = 8 Hz), 7.58 (1H, d, $J$ = 8 Hz), 8.02 (1H, s); mass spectrum (CI, $CH_4$): 406 (P + 1, 32%). *Anal.* calcd. for $C_{11}H_5N_2Br_2$: C 32.63, H 1.24, N 6.92; found: C 32.98, H 1.12, N 7.03.

Melting point >300°C; ir (KBr): 2860 (b), 1605 (s), 1550 (s), 1450 (s), 1283 (s), 1190 (s), 790 (s), and 760 (s) $cm^{-1}$; nmr (DMSO-$d_6$) δ: 5.83 (1H, d, $J$ = 7 Hz), 6.72 (1H, d, $J$ = 8 Hz), 7.00 (1H, d, $J$ = 8 Hz), 7.36 (1H, d, $J$ = 7 Hz), 7.41 (1H, t, $J$ = 7 Hz), and 8.15 (1H, s); mass spectrum (CI, $CH_4$): 248 (P + 1, 100%). *Anal.* calcd. for $C_{11}H_7N_2Br$: C 53.47, H 2.86, N 11.34; found: C 52.86, H 2.71, N 11.20.

*3,7-Dibromo-1,6-diazaphenalene* **9**

Melting point >300°C; ir (KBr): 3050 (b), 1580 (s), 1320 (s), 1230 (s), 1162 (m), 1068 (m), and 750 (m) $cm^{-1}$; nmr (DMSO-$d_6$) δ: 6.42 (1H, d, $J$ = 7 Hz), 7.21 (1H, d, $J$ = 8 Hz), 7.55 (1H, d, $J$ = 8 Hz), 8.04 (1H, d, $J$ = 7 Hz), and 8.61 (1H, s); mass spectrum (CI, $CH_4$): 327 (P + 1, 100%). *Anal.* calcd. for $C_{11}H_6N_2Br_2$: C 40.53, H 1.86; found: C 40.82, H 1.85.

*Bromination of* **1** *in trifluoroacetic acid*

The 1,6-diazaphenalene **1** (1.68 g, 0.01 mol) was suspended in dry methylene chloride (100 mL) and trifluoroacetic acid (24.5 mL) was added. After cooling the solution to −60°C (chloroform/Dry Ice), bromine (0.51 mL, 0.01 mol) in methylene chloride (50 mL) was added dropwise. The mixture was kept at −60°C for 1 hour followed by stirring at room temperature for 30 min. After removal of the solvent under reduced pressure, the residue was neutralized (aqueous KOH) and the resulting orange precipitate was filtered, washed with water, and dried overnight. Column chromatography ($Al_2O_3$, tetrahydrofuran – ethyl acetate gradient) yielded **7**, 2.0 g, 81% (see above).

# Synthesis of (−)- and (+)-2-hydroxy-6-keto-*N*-methylmorphinans, their *O*-methyl ethers, and 2-deoxy congeners

HELMUT SCHMIDHAMMER AND ARNOLD BROSSI[1]

*Section on Medicinal Chemistry, Laboratory of Chemistry, Institute of Arthritis, Diabetes, and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD 20205, U.S.A.*

Received June 7, 1982

HELMUT SCHMIDHAMMER and ARNOLD BROSSI. Can. J. Chem. **60**, 3055 (1982).

Bischler–Napieralski cyclization of the known phenylacetamide **1**, followed by selective ether cleavage of the 3,4-dihydroisoquinoline **2** and sodium borohydride reduction, afforded the tetrahydroisoquinoline **4**. Optical resolution of **4** with tartaric acid gave the optical isomers **4***a*, *b*, which were converted into the 6-ketomorphinans **9***a*, *b* and their *O*-methyl ethers **10***a*, *b* by the following reaction sequence: Birch reduction, *N*-formylation of the dihydro bases, Grewe cyclization, removal of the *N*-formyl protecting groups, reductive *N*-methylation, and *O*-methylation. The 2-deoxy congeners **12***a*, *b* were obtained from **9***a*, *b* by phenyltetrazolylation, and catalytic removal of the heterocyclic ether function. The (−)-enantiomer **12***a* obtained by this synthesis was identical with material prepared from natural morphine, and exhibited the high antinociceptive potency already reported.

HELMUT SCHMIDHAMMER et ARNOLD BROSSI. Can. J. Chem. **60**, 3055 (1982).

La réaction de cyclisation de Bischler–Napieralski de la phénylacétamide **1** suivie du clivage sélectif de l'éther de la dihydro-3,4 isoquinoléine **2** et de la réduction par le borohydrure de sodium, conduit à la tétrahydroisoquinoléine **4**. La résolution optique du composé **4** avec l'acide tartrique permet d'obtenir les isomères optiques **4***a*,*b* que l'on transforme en céto-6 morphinans **9***a*,*b* et en leurs éthers *O*-méthyliques **10***a*,*b* selon les réactions suivantes: la réduction de Birch, la *N*-formylation des bases dihydro, la cyclisation de Grewe, le clivage des groupes protecteurs *N*-formyle, la *N*-méthylation réductive et l'*O*-méthylation. On obtient les congénères déoxy-2 **12***a*,*b* à partir d'une phényltétrazolylation de **9***a*,*b* et de l'élimination catalysée de la fonction éther hétérocyclique. L'énantiomère (−) **12***a* obtenue de cette façon est identique au produit préparé à partir de la morphine naturelle et exhibe le même pouvoir antinociceptif déjà rapporté.

[Traduit par le journal]

The aromatic unsubstituted 6-keto-*N*-methylmorphinan **12***a*, first prepared from natural morphine, showed high antinociceptive potency in the hot-plate assay in mice (1). This result was astonishing, since it was assumed that the presence of a phenolic hydroxy group at C-3 (2) or a methyl ether group at C-4 (3) were essential to manifest good analgetic activity in this group of compounds. The little known pharmacological profiles of the (+)-enantiomers of 6-keto-morphinans suggested that a total synthesis of **12***a* be conceived, which would allow at the same time the preparation of its optical isomer **12***b*. The Grewe cyclization of appropriately substituted octahydroisoquinolines, chosen as the key reaction in the synthesis of **12***a*, *b*, is greatly facilitated by the presence of an electron withdrawing group on the amine nitrogen (4), and a hydroxy group *para*-positioned at the point of ring closure (5). It seemed therefore advisable to first attempt the synthesis of 2-hydroxy substituted 6-ketomorphinans, also needed for our SAR studies, and to eliminate the phenolic 2-hydroxy group afterwards. Elimination of phenolic hydroxy groups has been carried out in several alkaloidal systems and was not expected to give rise to any difficulties (6). This plan has now been accomplished and afforded, as expected, an easy entry into the groups of optically active 2-hydroxy-6-keto-*N*-methylmorphinans and their 2-deoxy congeners.

The synthesis of **9***a*, *b* by the route suggested had precedent in Beyerman's synthesis of 3-hydroxy-6-keto-*N*-methylmorphinan (7), and proceeded as follows. Bischler–Napieralski cyclization of the known amide **1** (8, 9), readily available from *m*-methoxybenzaldehyde, afforded the 3,4-dihydroisoquinoline (DIQ) **2**. The DIQ **2** underwent smooth *O*-demethylation at C-3′ with 48% HBr to afford the phenolic DIQ **3** (10). Reduction of **3** was carried out with $NaBH_4$ and afforded the tetrahydroisoquinoline (TIQ) **4**. Optical resolution of **4** with *d*- and *l*-tartaric acid afforded the optical isomers **4***a*, *b*. Their optical purity was determined by $^1H$ nmr analysis of the methylbenzyl urea derivatives, obtained from both isomers and optically active 1-methylbenzyl isocyanate (11). The individual diastereomers obtained showed little diastereomeric contamination and proved that **4***a*, *b* were optically > 99% pure.

The synthesis of **9***a*, *b* was carried through with the optical isomers **4***a*, *b*, employing identical reaction conditions. Since **12***a* prepared from **4***a* via **9***a* proved to be identical with material prepared from natural morphine (1), only the *a*-series will be discussed in detail. The physical data of the com-

The compounds of the a-series shown above belong to the natural series of 6-ketomorphinans.

SCHEME 1

pounds belonging to the *b*-series and the data for **4**, **5**, **6**, **7**, **8**, and **9** of the racemic series will be listed in the experimental part.

Birch reduction of **4***a* afforded the dihydro base **5***a*, which was *N*-formylated with ethyl formate prior to cyclization. The Grewe cyclization proceeded best in 80% sulfuric acid at 25°C and afforded the *N*-formyl-2-hydroxy-6-ketomorphinan (**7***a*) in 82% yield. The isomeric 4-hydroxy-6-ketomorphinans could only be detected as trace impurities by tlc analysis. This material proved to be a mixture of rotamers, already encountered in other series of *N*-formylated TIQ (12) and morphinans (13). Acid hydrolysis of **7***a* afforded **8***a*, which was converted into **9***a* by a reductive *N*-methylation, and into the *O*-methyl ether **10***a* with phenyltrimethylammonium chloride in DMF. Wolff–Kishner reduction of **8***b*, the optical anti-

pode of **8***a*, afforded (+)-2-hydroxy-*N*-methylmorphinan identical by mp and optical rotation with material prepared by a different procedure (4). Phenyltetrazolylation of **9***a* afforded the ether **11***a*, which after catalytic hydrogenation over Pd/C in acetic acid gave the aromatic unsubstituted ketomorphinan **12***a*, identical in every respect with material prepared from morphine (1). This characterizes the TIQ **4***a* as the *R*-isomer and **9***a* and **12***a* as the isomers belonging to the series of (−)-morphinans originating from natural morphine (1, 14). The enantiomers **9***b* and **12***b*, prepared similarly from **4***b*, showed the expected opposite optical behaviour and belong to the series of (+)-morphinans similarly related to (+)-morphine. The analgesic activity of the ketomorphinans prepared here was measured in mice after sc injection by the hot-plate assay. The 2-OH ketone **9***a* ($ED_{50}$ 20.7 mg/kg) was found to be about 20 times and the *O*-methyl ether **10***a* ($ED_{50}$ 8.6 mg/kg) about 10 times less potent than morphine ($ED_{50}$ 0.87 mg/kg). The aromatic unsubstituted ketone **12***a* ($ED_{50}$ 0.33 mg/kg), however, was found to be about 3 times more potent than morphine. It is thus clearly demonstrated that the position of the aromatic oxygenation in oxygenated 6-ketomorphinans is critical for antinociception. Details concerning the biological properties of 6-ketomorphinans are reported elsewhere (15).

## Experimental

Melting points (corrected) were determined with a Fisher–Johns apparatus. Elemental analyses were performed by the Section on Microanalytical Services and Instrumentation of this laboratory. Infrared spectra were recorded on a Beckman IR 4230 spectrometer. Optical rotations were measured by using a Perkin–Elmer Model 241 MC polarimeter with the solvents and concentrations specified. Nuclear magnetic resonance spectra were determined by using a Varian HR-220 spectrometer or a JEOL JNM-FX 100 spectrometer with TMS as internal reference (s = singlet, d = doublet, dd = doublet of doublets, m = multiplet). Chemical ionization mass spectra (ci ms) were obtained by using a Finnigan 1015 D spectrometer with a Model 6000 data collection system. Electron ionization mass spectra (ei ms) were obtained with a Hitachi Perkin–Elmer RMU-6E spectrometer (70 eV).

*1-(3-Methoxybenzyl)-6-methoxy-3,4-dihydroisoquinoline hydrogen bromide (**2**·HBr)*

To a solution of 97.6 g (328 mmol) of **1** in 400 mL acetonitrile were added 50 mL (0.53 mol) of $POCl_3$. At room temperature argon was passed through this mixture during 30 min. Then the mixture was refluxed for 1.0 h under argon, evaporated, cooled to 0–5°C and basified with concentrated NaOH. Extraction with $CH_2Cl_2$, followed by washings with $H_2O$ and brine, drying, and evaporation gave 91.4 g of an oily residue, which was dissolved in 60 mL MeOH. To this solution sufficient 48% HBr (55 mL) was added to give a pH of 1. Addition of $Et_2O$ and cooling to 4°C overnight yielded 91.8 g of **2**·HBr (77%). An analytical sample of **2**·HBr was provided by recrystallization from MeOH/$Et_2O$; mp 221–223°C; nmr ($CDCl_3$) δ: 3.77, 3.88 (2s, 6H, $2OCH_3$), 4.58 (s, 2H, exchanges with $D_2O$, benzylic H), 6.70–7.16 (m, 6H, ArH), 7.84 (d, 1H, ArH, $J$ = 8 Hz); ei ms *m/e*: 281 ($M^+$). *Anal.* calcd. for $C_{18}H_{19}NO_2$·HBr: C 59.67, H 5.57, N 3.82, Br 22.06; found: C 59.82, H 5.56, N 4.03, Br 22.34.

*1-(3-Hydroxybenzyl)-6-methoxy-3,4-dihydroisoquinoline (**3**)*

A solution of 85 g (235 mmol) of **2**·HBr in 200 mL of 48% HBr was refluxed for 50 min, evaporated, and the residue dissolved in 50 mL MeOH. After addition of $Et_2O$ the resulting mixture was kept at 4°C overnight to yield 67.1 g (82%) of **3**·HBr, mp 106–108°C. A portion of this material was converted to the free base **3**; mp 132–134°C (EtOH); ir ($CHCl_3$): 3600 (OH) $cm^{-1}$; nmr ($CDCl_3$) δ: 2.68, 3.62 (2t, 4H, $2CH_2$, $J$ = 8Hz), 3.82 (s, 3H, $OCH_3$), 4.01 (s, 2H, exchanges with $D_2O$, benzylic H), 6.66–7.50 (m, 7H, ArH); ei ms *m/e*: 267 ($M^+$). *Anal.* calcd. for $C_{17}H_{17}NO_2$: C 76.38, H 6.41, N 5.24; found: C 76.11, H 6.48, N 5.15.

*(±)-1-(3-Hydroxybenzyl)-6-methoxy-1,2,3,4-tetrahydroisoquinoline (**4**)*

A stirred solution of 52 g (149 mmol) of **3**·HBr in 400 mL EtOH was treated with 8 g (211 mmol) $NaBH_4$ in small portions during 20 min while maintaining the temperature at 20–30°C with an ice bath. After the addition of $NaBH_4$ was complete, the mixture was stirred for 15 min at room temperature, then cooled to 0–5°C and the excess $NaBH_4$ was destroyed with 30% AcOH to give a final pH of 5. After evaporation, the residue was dissolved in $H_2O$, rendered alkaline with concentrated aqueous $NH_3$, and extracted with $CHCl_3$/2-propanol (2:1). The organic layer was washed with brine, dried, and evaporated to yield 39.4 g (98%) crystalline product. This crude **4** was used for optical resolution. A sample was recrystallized from MeOH to give pure **4**; mp 155–156°C; ir ($CHCl_3$): 3600 (OH) $cm^{-1}$; nmr (DMSO-$d_6$) δ: 3.66 (s, 3H, $OCH_3$), 6.48–6.76 (m, 5H, ArH), 6.96–7.14 (m, 2H, ArH), 9.20 (s, broad, 1H, OH); ci ms *m/e*: 270 ($M^+$ + 1), 162 ($M^+$ − 3-hydroxybenzyl). *Anal.* calcd. for $C_{17}H_{19}NO_2$: C 75.81, H 7.11, N 5.20; found: C 75.93, H 6.98, N 5.47.

*Optical resolution of (±)-1-(3-hydroxybenzyl)-6-methoxy-1,2,3,4-tetrahydroisoquinoline (**4**)*

A mixture of 38.0 g (141 mmol) of **4** and 22.2 g (148 mmol) of *d*-tartaric acid was dissolved in 90 mL MeOH at the boiling point. This mixture was kept at 4°C for 15 h. Then the formed crystals were collected to give 17.8 g nearly pure **4***b*·*d*-tartrate. This material was recrystallized from 40 mL MeOH to yield 12.5 g of pure **4***b*·*d*-tartrate. From combined mother liquors another 14.3 g of pure **4***b*·*d*-tartrate were obtained. Together 26.8 g (91%) of optically > 99% pure **4***b*·*d*-tartrate were obtained;[2] mp 183–185°C; $[\alpha]_D^{26}$ −10.4° (*c* 0.92, $H_2O$). *Anal.* calcd. for $C_{21}H_{25}NO_8$: C 60.13, H 6.01, N 3.34; found: C 59.77, H 5.86, N 3.25.

Compound **4***b*·*d*-tartrate was converted to the free base in the usual way (described below). After recrystallization from MeOH, 16.1 g of *(−)-1-(3-hydroxybenzyl)-6-methoxy-1,2,3,4-tetrahydroisoquinoline* (**4***b*) were obtained; mp 179–180°C; $[\alpha]_D^{26}$ −35.6° (*c* 0.84, 95% EtOH).

The mother liquor of the first crystallization of **4***b*·*d*-tartrate was evaporated, dissolved in $H_2O$, rendered alkaline with concentrated aqueous $NH_3$, and extracted with $CHCl_3$/2-propanol (2:1). The organic layer was washed with brine, dried, and evaporated to give 29.1 g of a solid. Following this, 17.0 g (113 mmol) l-tartaric acid and 60 mL MeOH were added. This

[2]The optical purity was determined by reaction of the bases **4***a*, *b* with (*R*)-(+)-α-methylbenzyl isocyanate in deuteriochloroform followed by 220 MHz nmr analysis of the resulting diastereomeric urea derivatives (11).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

mixture was stirred at the boiling point until a clear solution was obtained. After 18 h at 4°C, 21.9 g of nearly pure **4***a*·l-tartrate could be collected. This material was recrystallized from 50 mL MeOH to give 16.7 g pure **4***a*·l-tartrate. From combined mother liquors another 11.2 g of pure **4***a*·l-tartrate were obtained. Together 27.9 g (94%) of optically > 99% pure **4***a*·l-tartrate·$H_2O$ were obtained;[2] mp 174–176°C; $[\alpha]_D^{24}$ +10.3° (*c* 0.86, $H_2O$). *Anal.* calcd. for $C_{21}H_{25}NO_8 \cdot H_2O$: C 57.66, H 6.22, N 3.20; found: C 57.84, H 6.13, N 3.13.

Compound **4***a*·l-tartrate was converted to the free base in the usual way. Recrystallization from MeOH yielded 15.8 g of *(+)-1-(3-hydroxybenzyl)-6-methoxy-1,2,3,4-tetrahydroisoquinoline* (**4***a*); mp 179–180°C; $[\alpha]_D^{26}$ +35.4° (*c* 0.98, 95% EtOH).

*(±)-1-(3-Hydroxybenzyl)-6-methoxy-1,2,3,4,5,8-hexahydroisoquinoline (5)*

To 500 mL distilled $NH_3$ were added 5.5 g (0.79 mol) Li metal and 250 mL of a 1:1 mixture of dry *t*-BuOH/dry $Et_2O$ at −70°C. Into this well stirred mixture a solution of 13.5 g (50 mmol) of **3** in 400 mL dry *t*-BuOH/dry $Et_2O$ (1:1) was dropped during 30 min. This mixture was stirred at −70°C for 1 h, then 100 mL MeOH were added dropwise. The mixture was allowed to warm up slowly and was then kept at room temperature overnight. After evaporation the resulting solid was dissolved in $H_2O$ and an aqueous solution of 45 g (0.84 mol) $NH_4Cl$ was added. The precipitate was collected and washed with MeOH and n-hexane to yield 12.3 g (90%) of **5**. An analytical sample of **5** was obtained by recrystallization from MeOH; mp 183–185°C; ir (KBr): 3400 and 3300 (OH, NH), 1700 and 1670 (C=C) $cm^{-1}$; nmr ($CDCl_3$) δ: 3.58 (s, 3H, $OCH_3$), 4.66 (s, 1H, C7—H), 6.64 (m, 3H, ArH), 7.12 (dd, 1H, ArH, *J* = 8, 8 Hz); ci ms *m/e*: 272 ($M^+$ + 1). *Anal.* calcd. for $C_{17}H_{21}NO_2$: C 75.24, H 7.80, N 5.16; found: C 74.92, H 7.90, N 5.11.

*(+)-1-(3-Hydroxybenzyl)-6-methoxy-1,2,3,4,5,8-hexahydroisoquinoline (5a)*

To 400 mL distilled $NH_3$ were added 7.0 g (1.0 mol) Li metal and 400 mL of a 1:1 mixture of dry *t*-BuOH/dry $Et_2O$ at −70°C. To this well stirred mixture 15.0 g (56 mmol) of powdered **4***a* were added at once. This mixture was stirred at −70°C for 1 h, then 100 mL MeOH were added dropwise. The mixture was allowed to warm up slowly and was then kept at room temperature overnight. After evaporation the resulting solid was dissolved in $H_2O$ and an aqueous solution of 60 g (1.12 mol) $NH_4Cl$ was added. The precipitate was collected, washed subsequently with $H_2O$, MeOH, and petroleum ether to yield 14.5 g (96%) of **5***a*, mp 190–193°C. Recrystallization of a portion of this material from MeOH afforded an analytical sample of **5***a*; mp 195–196°C; $[\alpha]_D^{25}$ +101.9° (*c* 0.95, 95% EtOH). *Anal.* calcd. for $C_{17}H_{21}NO_2$: C 75.24, H 7.80, N 5.16; found: C 75.11, H 7.56, N 5.07.

*(−)-1-(3-Hydroxybenzyl)-6-methoxy-1,2,3,4,5,8-hexahydroisoquinoline (5b)*

Preparation of this compound from **4***b* on the same scale and essentially as described above for the enantiomer afforded 14.6 g (97%) of **5***b*, mp 192–194°C. Recrystallization from MeOH afforded the analytical sample; mp 195–196°C; $[\alpha]_D^{26}$ −102.0° (*c* 1.10, 95% EtOH). *Anal.* calcd. for $C_{17}H_{21}NO_2$: C 75.24, H 7.80, N 5.16; found: C 75.23, H 7.71, N 5.06.

*(+)-N-Formyl-1-(3-hydroxybenzyl)-6-methoxy-1,2,3,4,5,8-hexahydroisoquinoline (6a)*

To a solution of 14.0 g (51.6 mmol) of **5***a* in 120 mL dry DMF were added 180 mL dry ethyl formate at 90°C (bath temperature) during 30 min. The resulting solution was refluxed for 60 h under argon. Evaporation yielded a crystalline solid, which was treated with 50 mL MeOH to give 14.6 g (95%) of **6***a*, mp 225–228°C. An analytical sample was prepared by recrystallization of a portion of this material with 2-propanol; mp 226–229°C; $[\alpha]_D^{24}$ +3.5° (*c* 1.03, DMSO); ir (KBr): 3180 (OH), 1705 and 1675 (C=C), 1640 (NCHO) $cm^{-1}$; nmr (DMSO-$d_6$) δ: 3.47 (s, 3H, $OCH_3$), 4.70 (s, 1H, C7—H), 6.56 (m, 3H, ArH), 7.00 (dd, 1H, ArH, *J* = 8, 8 Hz), 7.35 (s, 1H, CHO), 9.24 (s, 1H, OH); ci ms *m/e*: 300 ($M^+$ + 1). *Anal.* calcd. for $C_{18}H_{21}NO_3$: C 72.21, H 7.07, N 4.68; found: C 72.12, H 6.89, N 4.41.

*(−)-N-Formyl-1-(3-hydroxybenzyl)-6-methoxy-1,2,3,4,5,8-hexahydroisoquinoline (6b)*

Preparation of this compound from **5***b* on the same scale and exactly as described above for the enantiomer afforded 14.8 g (96%) **6***b*, mp 223–227°C. Recrystallization from 2-propanol gave an analytical sample; mp 227–229°C; $[\alpha]_D^{25}$ −0.6° (*c* 0.93, DMSO). *Anal.* calcd. for $C_{18}H_{21}NO_3$: C 72.21, H 7.07, N 4.68; found: C 72.08, H 7.11, N 4.57.

*(±)-N-Formyl-1-(3-hydroxybenzyl)-6-methoxy-1,2,3,4,5,8-hexahydroisoquinoline (6)*

This compound was prepared from 5.5 g of **5** essentially as described above to afford 5.5 g (91%) of **6**, mp 201–204°C. An analytical sample was obtained by recrystallization from 2-propanol; mp 204–206°C. *Anal.* calcd. for $C_{18}H_{21}NO_3$: C 72.21, H 7.07, N 4.68; found: C 72.01, H 6.96, N 4.44.

*(−)-N-Formyl-2-hydroxymorphinan-6-one (7a)*

To a well stirred mixture of 14.0 g (46.8 mmol) **6***a* and 500 mL $Et_2O$ were added dropwise 300 mL 80% $H_2SO_4$ at 0°C under an argon atmosphere during 3.5 h. The resulting solution was then kept at room temperature for 20 h, poured on 1.0 L ice water, and the organic solvent was evaporated. The aqueous solution was extracted with 6 × 200 mL $CHCl_3$/2-propanol (3:1). The organic layer was washed with water, dried, and evaporated to give 10.9 g (82%) **7***a* as a foam, which was used for the next step without further purification. An analytical sample was prepared by crystallization with MeOH; mp 259–261°C; $[\alpha]_D^{24}$ −219.1° (*c* 0.82, DMSO); ir (KBr): 3260 (OH), 1705 (CO), 1650 and 1620 (NCHO); nmr (DMSO-$d_6$) δ: 4.58 (m, 1H, C9—H), 6.52 (m, 2H, ArH), 7.04 (d, 1H, ArH, *J* = 8 Hz), 7.95 (s, 1H, CHO), 9.20 (s, 1H, OH); ei ms *m/e*: 285 ($M^+$). *Anal.* calcd. for $C_{17}H_{19}NO_3$: C 71.56, H 6.71, N 4.91; found: C 71.49, H 6.47, N 4.79.

*(+)-N-Formyl-2-hydroxymorphinan-6-one (7b)*

Preparation of this compound from **6***b* on the same scale and essentially as described above for the enantiomer afforded 11.2 g (84%) **7***b* as a foam, which was used for the next step without further purification. Crystallization with MeOH gave an analytical sample; mp 260–262°C; $[\alpha]_D^{24}$ +222.5° (*c* 0.87, DMSO). *Anal.* calcd. for $C_{17}H_{19}NO_3$: C 71.56, H 6.71, N 4.91; found: C 71.34, H 6.64, N 4.68.

*(±)-N-Formyl-2-hydroxymorphinan-6-one (7)*

This compound was prepared in a similar manner as described for both enantiomers, from 4.3 g **6** to give 3.5 g (85%) **7** as a foam, which was used for the next step without further purification. Crystallization with MeOH afforded an analytical sample; mp 244–247°C; *Anal.* calcd. for $C_{17}H_{19}NO_3 \cdot 0.5H_2O$: C 69.37, H 6.85, N 4.76; found: C 69.70, H 6.74, N 4.66.

*(−)-2-Hydroxymorphinan-6-one (8a)*

A solution of 8.0 g (28.0 mmol) **7***a* in 81 mL MeOH and 9 mL concentrated HCl was refluxed for 16 h and then evaporated. The oily residue was dissolved in $H_2O$, basified with concentrated aqueous $NH_3$, and extracted with a total amount of 250 mL $CHCl_3$/2-propanol (3:1). The organic layer was washed with brine, dried, and evaporated to give a crystalline residue, which yielded after treatment with MeOH 6.1 g (85%) of **8***a*. An analytical sample was recrystallized with MeOH; mp 282–286°C (dec.); $[\alpha]_D^{25}$ −116.9° (*c* 0.95, DMSO); ir (KBr): 3400 (broad,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

OH), 3280 (NH); nmr (DMSO-$d_6$) δ: 6.48 (m, 2H, ArH), 6.96 (d, 1H, ArH, $J$ = 8 Hz); ei ms *m/e*: 257 ($M^+$). *Anal.* calcd. for $C_{16}H_{19}NO_2$: C 74.68, H 7.44, N 5.44; found: C 74.40, H 7.65, N 5.36.

*(+)-2-Hydroxymorphinan-6-one (**8**b)*

Preparation of this compound from **7***b* in the same scale and manner as described above afforded 6.2 g (86%) of **8***b*. An analytical sample was obtained by recrystallization from MeOH; mp 281–284°C (dec.); $[\alpha]_D^{25}$ +117.6° (*c* 1.03, DMSO). *Anal.* calcd. for $C_{16}H_{19}NO_2$: C 74.68, H 7.44, N 5.44; found: C 74.40, H 7.63, N 5.68.

*(±)-2-Hydroxymorphinan-6-one (**8**)*

Preparation of this compound from 3.5 g **7** in the same manner as described above afforded 2.45 g (78%) of **8**. An analytical sample was obtained by recrystallization from MeOH; mp > 270°C (dec.). *Anal.* calcd. for $C_{16}H_{19}NO_2 \cdot 0.5H_2O$: C 72.15, H 7.57, N 5.26; found: C 72.29, H 7.28, N 5.31.

*(−)-2-Hydroxy-*N*-methylmorphinan-6-one (**9**a)*

A mixture of 5.5 g (21.4 mmol) of **8***a*, 5.5 g (40.4 mmol) of $NaOAc \cdot 3H_2O$, 17.6 mL of 37% formaline, and 1.5 g 10% Pd/C catalyst was hydrogenated in 150 mL 2 *N* AcOH at 50 psi and room temperature for 2 h. The mixture was filtered, washed with 2 *N* AcOH, the filtrate was basified with concentrated aqueous $NH_3$ and extracted with a total amount of 200 mL $CHCl_3$/2-propanol (3:1). The organic layer was washed with $H_2O$, dried, and evaporated to give a foam, which after crystallization from MeOH yielded 5.4 g (93%) **9***a*. An analytical sample was formed by recrystallization from MeOH; mp 115–117°C; $[\alpha]_D^{24}$ −130.2° (*c* 0.89, DMF); ir (KBr): 3400 (OH), 1705 (CO) $cm^{-1}$; nmr (DMSO-$d_6$) δ: 2.24 (s, 3H, $NCH_3$), 6.48 (m, 2H, ArH), 6.92 (d, 1H, ArH, $J$ = 8 Hz), 8.92 (s, 1H, OH); ci ms *m/e*: 272 ($M^+ + 1$). *Anal.* calcd. for $C_{17}H_{21}NO_2 \cdot CH_3OH$: C 71.25, H 8.31, N 4.62; found: C 71.26, H 8.73, N 4.43.

*(+)-2-Hydroxy-*N*-methylmorphinan-6-one (**9**b)*

Preparation of this compound from **8***b* on the same scale and manner as described above afforded 5.3 g (91%) **9***b*. An analytical sample was recrystallized from MeOH; mp 115–117°C; $[\alpha]_D^{24}$ +130.9° (*c* 0.95, DMF). *Anal.* calcd. for $C_{17}H_{21}NO_2 \cdot CH_3OH$: C 71.25, H 8.31, N 4.62; found: C 70.83, H 8.31, N 4.50.

Wolff–Kishner reduction of this material carried out in the usual way afforded the known (+)-2-hydroxy-*N*-methylmorphinan (4); mp 182–184°C (MeOH); $[\alpha]_D^{25}$ +40.8° (*c* 0.92, MeOH) (lit. (4) mp 181–183°C ($Et_2O$); $[\alpha]_D^{25}$ +41.4° (*c* 0.45, MeOH)).

*(±)-2-Hydroxy-*N*-methylmorphinan-6-one (**9**)*

Preparation of this compound from 2.5 g **8** essentially as described above yielded 2.2 g (83%) **9**. An analytical sample was prepared by recrystallization from 2-propanol; mp 240–242°C (dec.). *Anal.* calcd. for $C_{17}H_{21}NO_2$: C 75.24, H 7.80, N 5.16; found: C 74.93, H 7.85, N 5.11.

*(−)-2-Methoxy-*N*-methylmorphinan-6-one (**10**a)*

A mixture of 300 mg (1.1 mmol) of **9***a*, 300 mg (2.2 mmol) of anhydrous $K_2CO_3$, and 380 mg (2.2 mmol) of phenyltrimethylammonium chloride in 20 mL anhydrous DMF was stirred at 80°C (bath temperature) under argon for 6 h. The mixture was filtered, washed with $CHCl_3$, and the filtrate was evaporated. The residue was dissolved in $CH_2Cl_2$, washed with 1 *N* NaOH and brine, dried, and evaporated to give a crystalline solid, which was recrystallized from isopropyl ether to yield 210 mg (67%) of **10***a*. An analytical sample was recrystallized from MeOH; mp 149–151°C; $[\alpha]_D^{24}$ −125.8° (*c* 0.97, $CHCl_3$); ir (KBr): 1705 (CO) $cm^{-1}$; nmr ($CDCl_3$) δ: 2.44 (s, 3H, $NCH_3$), 3.74 (s, 3H, $OCH_3$), 6.66 (m, 2H, ArH), 7.14 (d, 1H, ArH, $J$ = 8 Hz); ei ms *m/e*: 285 ($M^+$). *Anal.* calcd. for $C_{18}H_{23}NO_2$: C 75.75, H 8.12, N 4.91; found: C 75.51, H 8.09, N 4.89.

*(+)-2-Methoxy-*N*-methylmorphinan-6-one (**10**b)*

Preparation of this compound from **9***a* on the same scale and essentially as described above yielded 200 mg (63%) of **10***b*. An analytical sample was prepared by recrystallization from MeOH; mp 150–152°C; $[\alpha]_D^{24}$ +126.0° (*c* 1.08, $CHCl_3$). *Anal.* calcd. for $C_{18}H_{23}NO_2$: C 75.75, H 8.12, N 4.91; found: C 75.93, H 8.19, N 4.89.

*(−)-2-[(1-Phenyl-1*H*-tetrazol-5-yl)oxy]-*N*-methylmorphinan-6-one (**11**a)*

A mixture of 3.7 g (13.6 mmol) of **9***a*, 3.7 g (26.8 mmol) of anhydrous $K_2CO_3$, and 2.6 g (14.4 mmol) of 5-chloro-1-phenyl-1*H*-tetrazole in 40 mL anhydrous DMF was stirred at room temperature under argon atmosphere for 18 h. The mixture was filtered, washed with $CHCl_3$, and the filtrate was evaporated. The residue was dissolved in $CH_2Cl_2$ and extracted with 10% aqueous tartaric acid. The aqueous layer was washed with $Et_2O$, rendered alkaline with concentrated NaOH, and extracted with $CH_2Cl_2$. The organic layer was washed with brine, dried, and evaporated to give 5.4 g (95%) of **11***a* as an oil, which was used for the next step without further purification. An analytical sample was obtained by crystallization with AcOEt; mp 133–134°C; $[\alpha]_D^{24}$ −80.1° (*c* 1.03, $CHCl_3$); ir (KBr): 1705 (CO) $cm^{-1}$; nmr ($CDCl_3$) δ: 2.38 (s, 3H, $NCH_3$), 7.04–7.78 (m, 8H, ArH); ei ms *m/e*: 415 ($M^+$). *Anal.* calcd. for $C_{24}H_{25}N_5O_2$: C 69.38, H 6.07, N 16.85; found: C 69.66, H 6.25, N 16.68.

*(+)-2-[(1-Phenyl-1*H*-tetrazol-5-yl)oxy]-*N*-methylmorphinan-6-one (**11**b)*

This compound was prepared from 2 g of **9***b* essentially as described above, yielded 2.8 (91%) of **11***b* as an oil, which was used for the next step without further purification. An analytical sample was obtained by crystallization with AcOEt; mp 132–134°C; $[\alpha]_D^{24}$ +80.4° (*c* 1.15, $CHCl_3$). *Anal.* calcd. for $C_{24}H_{25}N_5O_2$: C 69.38, H 6.07, N 16.85; found: C 69.51, H 5.93, N 17.08.

*(−)-*N*-Methylmorphinan-6-one (**12**a) (1)*

To a solution of 4.0 g (9.6 mmol) of crude **11***a* in 50 mL of glacial acetic acid were added 8.0 g 10% Pd/C catalyst. This mixture was hydrogenated at 50 psi at room temperature for 24 h. The catalyst was filtered off, washed with glacial acetic acid, and the filtrate was evaporated. The residue was dissolved in $H_2O$, rendered alkaline with concentrated NaOH, and extracted with $CH_2Cl_2$. The organic layer was washed with brine, dried, and evaporated to give a crystalline solid, which was treated with isopropyl ether to yield 1.9 g (77%) of **12***a*. An analytical sample was recrystallized with isopropyl ether; mp 165–167°C (lit. (1) mp 164–166°C); $[\alpha]_D^{25}$ −135.8° (*c* 0.86, $CHCl_3$) (lit. (1) $[\alpha]_D^{26}$ −137.8° (*c* 0.92, $CHCl_3$)); ir and nmr were identical with an authentic sample.

*(+)-*N*-Methylmorphinan-6-one (**12**b)*

This compound was prepared from 2.7 g of crude **11***b* essentially as described above, yielded 1.2 g (72%) of **12***b*. An analytical sample was recrystallized with isopropyl ether; mp 165–167°C; $[\alpha]_D^{24}$ +136.1° (*c* 1.01, $CHCl_3$). *Anal.* calcd. for $C_{17}H_{21}NO$: C 79.96, H 8.29, N 5.49; found: C 79.93, H 8.32, N 5.36.

# Mechanistic studies in strong acids. VIII.[1] Hydrolysis mechanisms for some thiobenzoic acids and esters in aqueous sulfuric acid, determined using the excess acidity method[2]

ROBIN A. COX AND KEITH YATES

*Department of Chemistry, University of Toronto, 80 St. George St., Toronto, Ont., Canada M5S 1A1*

Received July 6, 1982

ROBIN A. COX and KEITH YATES. Can. J. Chem. **60**, 3061 (1982).

The excess acidity method has been applied to hydrolysis rate data, obtained as a function of medium composition, for four thiobenzoic acids, thioacetic acid, eight ethyl thiolbenzoates, and eight ethyl thionbenzoates in aqueous sulfuric acid. The mechanistic behaviour thus revealed has both similarities to and differences from that of a typical ester like ethyl benzoate, which gives benzoic acid by an A-2 reaction involving two water molecules in weak acid, and by A-1 acylium ion formation in strong acid. The thioacids follow this behaviour, except that the A-2 process involves three water molecules, and that the mechanistic changeover occurs in 60% rather than 80% acid. The A-2 process for the ethyl thiolbenzoates is slow; the major hydrolysis mechanism is acylium ion formation, not in an A-1 reaction but by a concerted A–$S_E2$ process involving both proton transfer to sulfur and carbon–sulfur bond breaking. The major proton transfer agent is the undissociated sulfuric acid molecule. The thionbenzoate esters, in contrast, undergo very fast A-2 hydrolysis; so fast, in fact, that the initial protonation of sulfur is the rate-determining step in acids more dilute than about 62% w/w. It appears that proton transfer to sulfur is a comparatively slow process.

ROBIN A. COX et KEITH YATES. Can. J. Chem. **60**, 3061 (1982).

On a appliqué la méthode d'acidité en excès aux données de vitesse d'hydrolyse, obtenues en fonction de la composition du milieu, de quatre acides thiobenzoiques, à l'acide thioacétique, à huit thiolbenzoates d'éthyle et à huit thionbenzoates d'éthyle dans l'acide sulfurique aqueux. Le mécanisme ainsi révélé ressemble et diffère à la fois de celui d'un ester typique tel le benzoate d'éthyle qui conduit à l'acide benzoique selon une réaction de type A-2 qui implique deux molécules d'eau en présence d'un acide faible et selon une formation d'ion acylium de type A-1 en présence d'un acide fort. Les thioacides ont ce même comportement à l'exception du fait que le mécanisme de type A-2 implique trois molécules d'eau et que ce changement de mécanisme se produit dans un milieu acide à 60% plutôt qu'à 80%. Le processus A-2 est lent dans le cas des thiolbenzoates d'éthyle. Le mécanisme principal d'hydrolyse est la formation de l'ion acylium, non pas selon une réaction de type A-1 mais selon un mécanisme concerté du type A–$S_E2$ qui implique à la fois un transfert de proton sur le soufre et une rupture de la liaison carbone–soufre. Le principal agent de transfert du proton est la molécule d'acide sulfurique non dissocié. Les esters thionbenzoates au contraire, subissent une hydrolyse très rapide du type A-2. Cette hydrolyse est si rapide qu'en fait la protonation initiale du soufre est l'étape déterminante dans un milieu acide dont la dilution est supérieure à 62% w/w environ. Il semble que le transfert de proton sur le soufre est comparativement un processus lent.

[Traduit par le journal]

## Introduction

The excess acidity method has proved to be of considerable value in determining the details of mechanistic behaviour for reactions in aqueous acid media, particularly sulfuric acid (1–4). To date it has been applied to acid-catalyzed enolizations (2), to the hydrolyses of some crowded benzoate esters (3), to aromatic nitrations (5), and to benzamide, methylbenzimidatium ion, and lactam hydrolyses (4). In this paper the method is applied to the hydrolysis reactions undergone by four thiobenzoic acids (**1**), by thioacetic acid (**2**), by eight ethyl thiolbenzoates (**3**), and by eight ethyl thionbenzoates (**4**), in aqueous sulfuric acid.

All of these compounds give the parent carboxylic acid as product, and previous studies (6–8), using the *r*-parameter (9) and transition-state activity coefficient (10) methods, have suggested that, following a pre-equilibrium protonation step, they probably all hydrolyze either via an $A_{Ac}2$ mechanism involving water (preferred by **4**), or by acylium ion formation (preferred by **3**), depending on the acid concentration (6–8).

## Experimental

The protonation $pK_{SH^+}$ and $m^*$ values for **1***b*, **1***c*, and **3***c*–**3***h* were obtained from ionization ratio (*I*) data (7, 8) using eq. [1];

$$[1] \quad \log I - \log C_{H^+} = m^*X + pK_{SH^+}$$

values of *X* and log $C_{H^+}$ were available (11), and these were corrected to the measurement temperature, 5°C or 10°C (7, 8), as

[1]Parts I–VII are refs. 16–18 and 1–4.

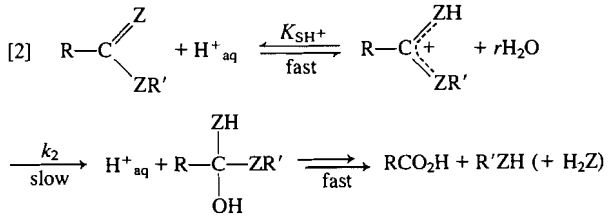
described previously (3). log $I$ data could not be obtained for **1***a*, **1***d*, **3***a*, and **3***b* (7, 8); for these p$K_{SH^+}$ was obtained from p$\sigma$ plots by extrapolation, and $m^*$ was assumed to be the averages of the **1***b*–**1***c* and **3***c*–**3***h* slopes. These were used to calculate the required protonation correction terms, log $[C_S/(C_S + C_{SH^+})]$, see eqs. [5], [7], [10], and [13]; p$K_{SH^+}$ was corrected to the reaction temperature, if necessary, by assuming that $\Delta G^0 = \Delta H^0$ for the protonation process, as before (3, 4). The 25°C values given in Tables 2 and 3 have been corrected in this way. For **4** p$K_{SH^+}$ and $m^*$ had previously been derived (11); thioacetic acid **2** was assumed to be unprotonated, which is reasonable on the basis of the very small protonation correction terms found for thiobenzoic acid, **1***c*.

Observed rate constants as a function of sulfuric acid concentration at 25°C, $k_\psi$, were available for **3** and **4** (6, 7), as were data at 50°C and two other temperatures for **1** and **2** (8). Temperature-corrected log water activities and log bisulfate ion concentrations in molarity units were those used before (3, 4); log sulfuric acid activities at 25°C were obtained from Giauque *et al.* (12) and converted to molarity units. The computer program used to separate individual processes, in those cases where mixed mechanisms were found, was that used previously (3, 4). Straight lines were fitted using standard least-squares analysis techniques. The $\sigma$ and $\sigma^+$ values were taken from Hammett (13). $\sigma^+$ was used in correlations except for the methoxy substituent, where an average of $\sigma$ and $\sigma^+$ was used, previous experience having found this to be the best compromise for sulfuric acid solutions (14).

## Kinetic analysis

*A-2 Mechanism*

For a typical $A_{Ac}2$ hydrolysis (1, 3), reaction [2],[3]



[3] $$k_\psi(C_S + C_{SH^+}) = k_2 a_{SH^+} a_{H_2O}{}^r / f_\ddagger$$

the observed pseudo-first-order rate constant $k_\psi$ is given by eq. [3], if the nucleophile is water; $a$ = activity, $C$ = molar concentration, $f$ = molar activity coefficient, and $r$ is the number of water molecules involved in bond making/breaking processes at the transition state (1, 4, 9). Substituting $a_{SH^+} = a_S a_{H^+}/K_{SH^+} = C_S C_{H^+} f_S f_{H^+}/K_{SH^+}$ into eq. [3], gathering terms and taking logs gives eq. [4] (1).

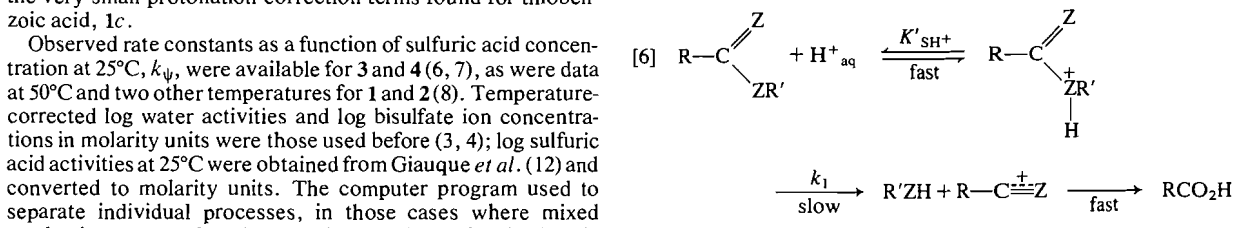
[4] $$\log k_\psi - \log [C_S/(C_S + C_{SH^+})] - \log C_{H^+} = \log (k_2/K_{SH^+}) + r \log a_{H_2O} + \log (f_S f_{H^+}/f_\ddagger)$$

It has been shown previously that the assumption $\log (f_S f_{H^+}/f_\ddagger) = m^\ddagger \log (f_S f_{H^+}/f_{SH^+})$ is valid (1), and since $\log (f_S f_{H^+}/f_{SH^+}) = m^* \log (f_{B^*} f_{H^+}/f_{B^*H^+}) =$ $m^*X$, where $X$ is the excess acidity for a standard base B* (11, 15), eq. [4] becomes eq. [5]. For A-2 reactions $m^\ddagger{}_2 \simeq 1$ is typical (1).

[5] $$\log k_\psi - \log [C_S/(C_S + C_{SH^+})] - \log C_{H^+} = \log (k_2/K_{SH^+}) + r \log a_{H_2O} + m^\ddagger{}_2 m^* X$$

*A-1 Mechanism*

Similar reasoning to the above results in eq. [7] for an $A_{Ac}1$ hydrolysis, reaction [6]. Protonation is



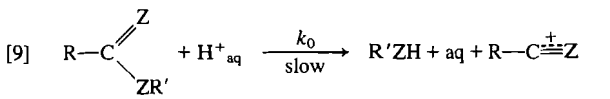
[7] $$\log k_\psi - \log [C_S/(C_S + C_{SH^+})] - \log C_{H^+} = \log (k_1/K'_{SH^+}) + m^\ddagger{}_1 m^{*\prime} X$$

at the ester Z rather than the carbonyl Z, represented by $K'_{SH^+}$ and $m^{*\prime}$ rather than $K_{SH^+}$ and $m^*$; however, the latter is still the most favoured protonation site (1, 3, 6, 7), and the amount of substrate "locked up" in the carbonyl- or thiocarbonyl-protonated form is accounted for by the protonation correction term, log $[C_S/(C_S + C_{SH^+})]$. For A-1 reactions $m^\ddagger{}_1 > 1$ is typical, values of 2–3 not being uncommon (1).

*A–$S_E2$ Mechanism*

If the initial protonation in reaction [2] is slow, $k_0$, reaction [8] can easily be derived (1). If the protonation in reaction [6] is involved in the rate-determining step, as shown in reaction [9], then eq. [10] is the result. For both of these $m^\ddagger{}_0 < 1$

[8] $$\log k_\psi - \log C_{H^+} = \log k_0 + m^\ddagger{}_0 m^* X$$



[10] $$\log k_\psi - \log [C_S/(C_S + C_{SH^+})] - \log C_{H^+} = \log k_0 + m^\ddagger{}_0 m^{*\prime} X$$

(1), which is a useful criterion for distinguishing eq. [8] or eq. [10] (A–$S_E2$) from eq. [7] (A-1). Distinguishing these from A-2 mechanisms is straightforward insofar as the water or bisulfate ion activity is not involved (1–4).

However, A–$S_E2$ mechanisms involve general acid catalysis, and protonated water is not the strongest acid in concentrated sulfuric acid solutions (16). Catalysis by undissociated $H_2SO_4$ molecules (16–18), and even by $H_3SO_4{}^+$ in really strong

[3]In reaction [2] and subsequent reactions R = substituted phenyl (or methyl), Z = O or S, and ZR′ = OEt, SEt, or SH.

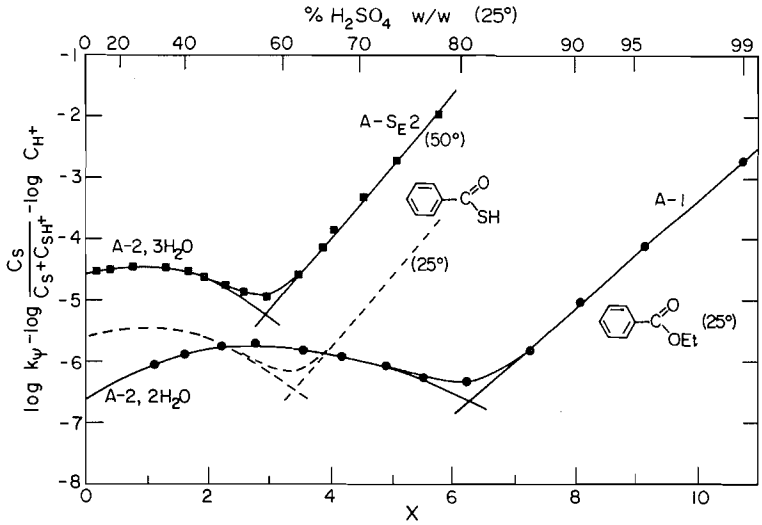


FIG. 1. Excess acidity plots for the hydrolyses of ethyl benzoate at 25°C (6) and thiobenzoic acid at 50°C (with an extrapolation to 25°C), in aqueous $H_2SO_4$.

acid (16), has been observed before, and deserves consideration here. From reaction [11] derivation

[11] 
of eq. [12] with the activity coefficient term log

$$[12]\quad \log k_\psi - \log [C_S/(C_S + C_{SH^+})] - \log a_{H_2SO_4} = \log k_0 + \log (f_S/f_\pm)$$

$(f_S/f_\pm)$ is straightforward. Regarding the latter, since $\log (f_S f_{H^+}/f_\pm) = m^\pm m^* X$, if $\log f_{H^+}$ is linear in $X$ then $\log (f_S/f_\pm)$ is too. Values of $a^*_{H^+}$, obtained (19) on making the Boyd assumption (20),[4] are available as a function of acid molarity for several acid systems (19). From these, $\log f^*_{H^+}$ (= $\log a^*_{H^+}$ − $\log C_{H^+}$) was derived and plotted against $X$. This graph was accurately linear, 0.9998 over 22 points with slope 2.10 ± 0.01, over the 5–70% $H_2SO_4$ range in which $\log a^*_{H^+}$ has been measured. Thus the assumption that $\log (f_S/f_\pm)$ is also linear in $X$ is very reasonable, and eq. [12] becomes eq. [13].

$$[13]\quad \log k_\psi - \log [C_S/(C_S + C_{SH^+})] - \log a_{H_2SO_4} = \log k_0 + mX$$

[4]The Boyd assumption is that $\log f_{TEA^+}$ is invariant with acidity, $TEA^+$ being the tetraethylammonium cation; $\log f^*_{H^+} = \log (f_{H^+}/f_{TEA^+})$.

## Results

A typical ester like ethyl benzoate hydrolyzes according to reaction [2] in acid more dilute than, and reaction [6] in acid more concentrated than, 80% $H_2SO_4$, as we have shown elsewhere (1, 3). The A-2 reaction involves two water molecules (3). Ethyl benzoate hydrolysis rate data (1, 6) are plotted according to eqs. [5] and [7] in Fig. 1; $k_\psi$ was separated into its components according to $k_\psi = k_{A\text{-}2} + k_{A\text{-}1}$ using an available computer program (3).

The thioacids **1** and **2** (8) exhibited very similar behaviour to this, except that three rather than two water molecules were found to be involved in the A-2 process (e.g. $r = 3.3 \pm 0.4$ for thiobenzoic acid, taken as a fixed value of 3 in subsequent calculations). Also the switchover to the acylium ion mechanism occurred in more dilute acid, about 60%. This behaviour is illustrated for thiobenzoic acid at 50°C in Fig. 1, together with an extrapolation to 25°C for direct comparison with ethyl benzoate.

Data at several temperatures were available for **1***c* and **2** (8), and this permitted calculation of standard-state activation parameters (i.e. values in water at 25°C) as described previously (3, 4). These are given in Table 1, together with the previously obtained methyl benzoate numbers (3), for comparison; included in Table 1 are the $m^\pm$ and $m^*$ slopes. Where possible $m^\pm_2$ and $\Delta H^\pm$ (i.e. $k_2$ in eq. [5]) are separated from $m^*$ and $\Delta H^0$ ($K_{SH^+}$ in eq. [5]); independent measurements of $pK_{SH^+}$ could be made in most cases (see Experimental section), which gave $m^*$ and enabled estimation of $\Delta H^0$ on

[a]$\Delta H$ in kcal/mol, $\Delta S$ in entropy units, all at 25°C. Superscript 0 refers to the protonation, see text.
[b]$\Delta S^0 = 0$ is assumed for the pre-equilibrium protonation.
[c]See text. Probably A–$S_E$2 for the thioacids, with $\Delta H = \Delta H^{\ddagger}$, $\Delta S = \Delta S^{\ddagger}$, and $m = m^{\ddagger}{}_0 m^{*\prime}$; reaction [9] and eq. [10]. Probably A-1 for methyl benzoate, with $\Delta H = \Delta H^{\ddagger} - \Delta H^{0\prime}$, $\Delta S = \Delta S^{\ddagger}$ $(-\Delta S^{0\prime})$, and $m = m^{\ddagger}{}_1 m^{*\prime}$; reaction [6] and eq. [7].

the reasonable assumption that $\Delta S^0 \simeq 0$ for the protonation (3, 4). The other thioacids were only studied at 50°C; Table 2 gives the $pK_{SH^+}$ and $m^*$ values of **1***a*–**1***d*, together with the results of applying the various rate equations to the hydrolysis data obtained for them (8).

The question arises as to whether the acylium ion reaction for these substrates is A-1 (reaction [6]) or A–$S_E$2 (reaction [9]). Although $m^*$ for protonation at SH could not be measured, $m^*$ for known sulfur protonations averages 1.3 (11). Thus $m^{\ddagger}$ for the acylium ion reaction would be less than one, in three out of four cases for the thiobenzoic acids **1** (Table 2), and for thioacetic acid as well (Table 1). This is indicative of A–$S_E$2 rather than A-1 reaction according to the criteria given above. Also the activation entropies for **1***b* and **2** are negative (Table 1), as compared to methyl benzoate, which gives the positive value typical of an A-1 process (3, 4).[5]

The rate data obtained for the ethyl thiolbenzoates **3** are plotted as a function of $X$ in Fig. 2. Comparison of Figs. 1 and 2 shows that the A-2 reaction is far less important for **3**. However, the dominant reaction is not an A-1 process, since the right-hand parts of the Fig. 2 curves are not linear in $X$. Neither is it an A-2 reaction; no water or bisulfate ion mechanism could be found which fitted the data on the basis of equations similar to eq. [5].

The only remaining possibility is an A–$S_E$2 rate-determining proton transfer, and transfer from protonated water can be ruled out, at least over most of the acidity region covered by Fig. 2, as the above kinetic analysis shows that the Fig. 2 plots should be linear in $X$ in this case too. Thus the proton transfer must be from undissociated $H_2SO_4$ molecules, reaction [11] above, and eq. [13] should apply. This was in fact found to be the case for **3** in the strong acid region, as can be seen from Fig. 3.

The slopes and intercepts of the Fig. 3 graphs, together with the basicities of **3**, are given in Table 3.

The choice of medium for a reaction rate LFER was not straightforward; the Table 3 intercepts refer to pure water, which contains no free $H_2SO_4$ and in which the preferred hydrolysis mechanism is reaction [2] rather than reaction [11]. Extrapolation to 100% $H_2SO_4$ is not possible because $X$ is not known at this point (11), and in any case the strongest catalyzing acid in pure $H_2SO_4$ is $H_3SO_4^+$ rather than $H_2SO_4$ (16). Accordingly, an arbitrary value of 90% $H_2SO_4$ was chosen for the LFER, as indicated in Fig. 3; the resulting $\rho$ was $-3.95 \pm 0.13$ (0.997, 8 compounds).

From Figs. 2 and 3, it is apparent that, although the reaction [11] mechanism applies over most of the acidity range, other mechanisms are important in the weak acid region. The parent compound **3***d* has sufficient data points in this region to permit their evaluation. It was found that two additional mechanisms were required to fit the experimental data, an A-2 reaction involving two water molecules in the aqueous acid region (the reaction [2] mechanism above), and an A–$S_E$2 reaction with protonated water as the catalyzing acid in the 50-70% $H_2SO_4$ region, reaction [9]. Separation of the various mechanisms was again possible, and their contribution to the overall hydrolysis rate data for ethyl thiolbenzoate is illustrated in Fig. 4. Some evidence is apparent from Fig. 3 for additional low acidity mechanisms for **3***a*–**3***c* also, but the data were insufficient for adequate quantification.

The rate data obtained for **4**, the ethyl thionbenzoates (6, 7), are plotted against $X$ in Fig. 5.[6] These graphs curve downward, typical of A-2 reactions involving water (1, 4); a reaction [2] mechanism seems reasonable and eq. [5] should apply. In Fig. 6[6] the data are plotted according to eq. [5] assuming the involvement of two water molecules. Good linearity is apparent for the acidity region above

[5]A referee has commented that determination of the kinetic solvent isotope effect should enable these two possibilities to be more clearly distinguished.

[6]In Figs. 5 and 6 the $y$-axis numbers refer to the curve for the parent compound (H) only. The other curves are displaced by one log unit from the preceding one, in order to avoid superimposition.

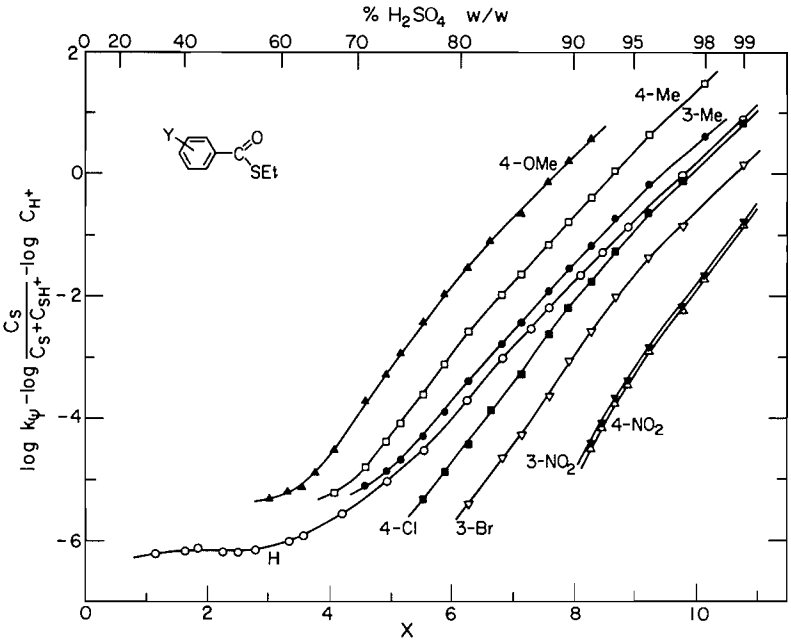

FIG. 2. Excess acidity plots for the hydrolyses of some ethyl thiolbenzoates in aqueous $H_2SO_4$ at 25°C (6, 7).

62% $H_2SO_4$, which is evidence for the applicability of the reaction [2] mechanism in this region; the reaction is fast for **4**, as compared to **1** and ethyl benzoate.

All of the Fig. 6 curves deviate somewhat at low acidity. However, the deviant points in Fig. 6 all show good linearity in $X$, as can be seen from Fig. 5. This means that, below 62% in acidity, the rate-determining process is no longer an A-2 reaction, but an A-1 or A–$S_E2$ one. For the parent compound **4***d* the slope against $X$, $m^{\neq}{}_0 m^*$, is 0.82 ± 0.02; using the known $m^*$ of 1.39 (11) $m^{\neq}{}_0 = 0.58$ is obtained. The other compounds evidently behave similarly. This number is quite typical for an A–$S_E2$ reaction with protonated water as the catalyzing acid (1). The most obvious explanation is that the A-2 reaction for these compounds is sufficiently fast that the initial protonation on sulfur becomes rate-determining at acidities well below the $pK_{SH^+}$ of the substrate (equivalent to 73% $H_2SO_4$ for **4***d* (11)), see reaction [2], and that the rate equation that applies is eq. [8]. The rate constants obtained for **4** according to eqs. [5] and [8] are given in Table 4.

[c]Extrapolated from ρσ relationship (Table 5).
[d]Average of measured values in this column.

The curve for the parent compound **4***d* also deviates at high acidity (above 90% $H_2SO_4$), see Fig. 6. This could be due to the onset of a thioacylium ion mechanism, or to bisulfate ion taking over from water in the reaction [2] A-2 mechanism, as has been observed in the hydrolysis of benzamide (4). With only two points available deciding between these two is difficult, but the observed $m^{\neq}$ values offer a clue, being ~0.9 for the A-1/A–$S_E2$ and ~1.2 for the A-2/$HSO_4^-$ processes. The latter mechanism seems the most reasonable.

Comparison between the various basicities and rates is facilitated by the summary Table 5, which mainly concerns the unsubstituted parent compounds. Also given are the intercept and slope data for ethyl benzoate (1, 6), together with that extrapolated to 25°C for thiobenzoic acid, see Fig. 1. Included are the data for the other two hydrolysis mechanisms for ethyl thiolbenzoate, illustrated in Fig. 4; the more sophisticated treatment in this paper supercedes that previously given for ethyl thiolbenzoate and ethyl thionbenzoate (1). Table 5 also contains the several ρ values obtained using data for the substituted compounds; the data are rather sparse for the thioacids, but reasonable values could be obtained in most other instances.

## Discussion

The rate constants and basicities provided by the excess acidity method can be usefully compared, e.g. in deriving ρ values, since they are all extrapolated to the same standard state, the hypothetical ideal 1 *M* acid solution in water which is also the standard for pH measurements (11). The $m^*$ and $m^{\neq}$ slopes can also provide useful information (1).

Looking first at the substrate basicities, the stability of the protonated form is seen to decrease in the series PhCOSEt > PhCOSH > PhCOOEt > PhCSOEt, as shown by the more negative $pK_{SH^+}$ values in Table 5. In the same series the decreasing

[a]Intercepts of Fig. 5, see eq. [8]. Only the parent compound had sufficient data points to enable proper statistical evaluation; log $k_0$ = −6.784±0.047, $m^*_0 m^*$ = 0.810±0.019. This slope was then assumed to apply to all the other compounds.
[b]Obtained from the Fig. 6 slopes and intercepts using known $m^*$ and $pK_{SH^+}$ values (11); see eq. [5]. Values in 1 *M* $H_2O$.
[c]Could not be evaluated.

ρ values show that the degree of internal resonance in the carbonyl/thiocarbonyl system increases, i.e. stabilization from the phenyl ring becomes less important, so that the latter would seem to be the more important acid weakening/base strengthening effect of the two. Carbonyl oxygen protonation has the characteristic $m^* = 0.6$–$0.7$ (1, 11), compared to 1.4 for thiocarbonyl sulfur protonation.

The A-2 reaction [2] which these substrates undergo has the reactivity order thionesters > thioacids > esters > thiolesters (Table 5). Deferring the thioacids for later consideration, this order is reasonable on the basis of substrate basicity, the most difficult to protonate (thionesters) being the most reactive, presumably on the basis of enhanced carbon electrophilicity caused by the decreased positive charge dispersal into the phenyl ring noted above. Esters, thionesters, and thiolesters all react with two water molecules ($r = 2$) as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

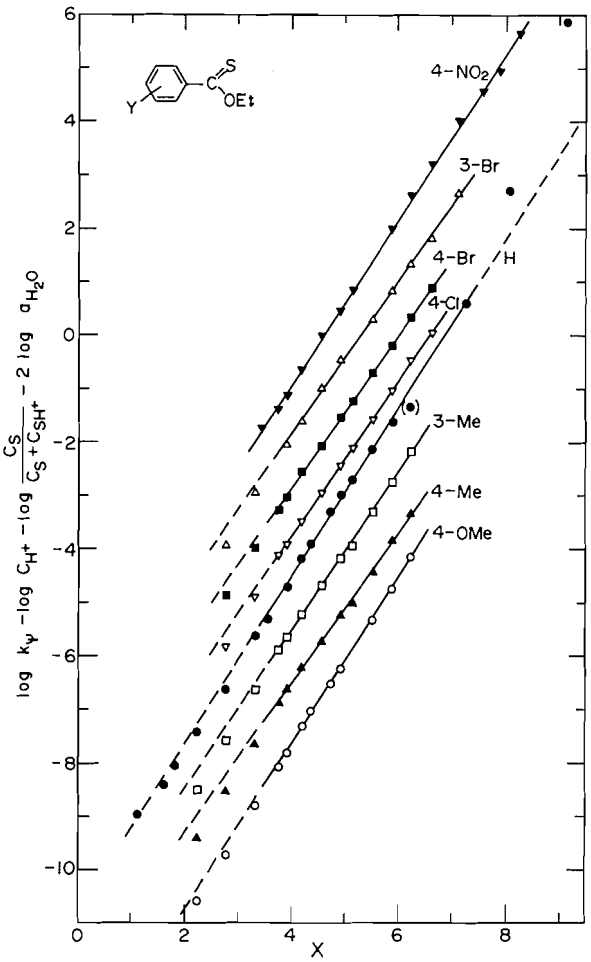

FIG. 6. Plots on the basis of eq. [5] for the hydrolyses in Fig. 5.[6]

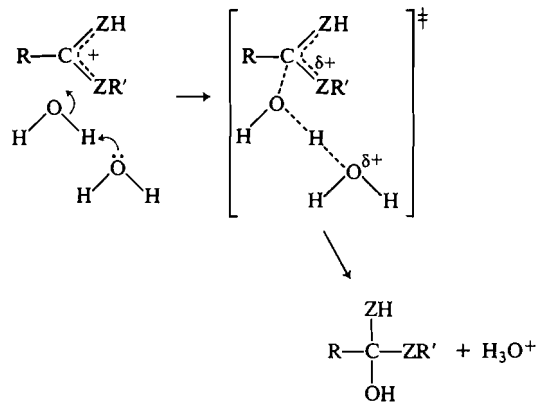
shown in reaction [14] (3). Support for the charge dispersal into the medium indicated by reaction [14] comes from the small positive ρ values. $m^{+}{}_{2}$ encompasses the range 0.8–1.3 (Tables 1, 2, 4, and 5) typical of A-2 reactions (1); ethyl thiolbenzoate

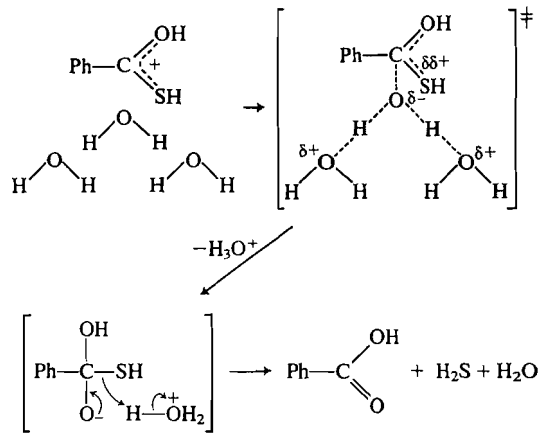
[14]



seems slightly low at 0.74 (Table 5), but since this value was derived using few measurements on only one compound (see Fig. 4) it should not perhaps be taken too seriously.

The thioacid A-2 reactions, however, are different. They involve three water molecules rather than two, the reactions are faster than the basicities would predict and the hydrolysis is characterized by a large positive ρ (1.6). Their activation enthalpies are lower than that for methyl benzoate (Table 1) and the entropies of activation are more negative at −48 eu. The cyclic 3 $H_2O$ mechanism previously suggested for amide hydrolysis has activation entropies of about this magnitude (4), but that is a positive species → positive species reaction which is not likely to produce a large ρ. Also, in the tetrahedral intermediate sulfur will not be so basic as nitrogen, which becomes protonated in the mechanism cited (4). One possibility that suggests itself for the thioacids is mechanism [15]. This would give a larger positive ρ, reflecting increased positive charge dispersal in the transition state, and would give enhanced reactivity (low $\Delta H^{\ddagger}$'s) since the entity reacting with the carbon electrophile is more negative in character. Also, the thioacids are the only substrates in the study which do not have a bulky ethyl group, perhaps providing "room" for the third water molecule to act and serving to explain why the thioacids react in this way and the thiolesters, for instance, do not. If this mechanism is correct the product of mechanism [15] would

[15]



react very quickly, as shown, and presumably the reaction would be essentially irreversible. Thus $^{18}O$ exchange into the substrate would not be predicted to occur. Evidence, however, is lacking.

Acylium ion formation, the mechanism favoured in stronger acid media, can involve either stepwise or concerted proton transfer, reaction [16]. The stepwise path is the familiar $A_{Ac}1$ ester hydrolysis

mechanism (3), characterized by positive entropies of activation and $m^{\neq} > 1$, see Table 1. However, the thiolesters and thioacids prefer the concerted pathway, with small negative entropies of activation, see above; either "$H^+$" or $H_2SO_4$ can be the general acid, depending on the medium. Both pathways have large negative ρ values, −3 to −4 (Table 5), indicative of concentration of positive charge at the acylium centre in the transition state in both cases, which suggests the concerted nature of the proton transfer/bond breaking process in the A-$S_E$2 reaction. Not much information can be obtained from the slopes of eq. [13] quoted in Table 3, as there is nothing with which to compare them. They are all, however, less than one.

Acylium ion formation is much faster for those substrates with —SH and —SEt groups: see the activation enthalpies in Table 1, the relative rates in Table 5, the earlier switchover to acylium ion formation illustrated in Fig. 1, and the dominance of this process for the thiolesters in Figs. 2 and 4. Thus the kinetic basicity of sulfur seems much higher than that of oxygen, which is reasonable on the basis of the polarizable or "soft" nature of sulfur as compared to oxygen. Most of the activation energy for the stepwise path is probably the energy required for the initial unfavourable protonation on the ether oxygen.

Thioacylium ions were not observed in this work. The thionesters are potentially capable of

[16]

reacting in this way, but in fact react by the A-2 mechanism, with two water molecules up to about 85% $H_2SO_4$, and probably with one bisulfate ion after that point. These substrates are so reactive towards nucleophilic addition that the initial protonation at sulfur becomes rate-determining at acidities below 62%; compare $\log k_0 = -6.78$ with $\log (k_2/K_{SH^+}) = -7.33$ in Table 5. This reaction has a $\rho$ of $-0.3 \pm 0.2$ (Table 5), compared to the $\rho$ for equilibrium protonation of 1.0, i.e. rather less than half a positive charge is present at the transition state. This is in passable agreement with the observed $m^{\neq}_0$ of $0.58 \pm 0.02$, indicating approximate half-transfer of the proton at this point (1). It is interesting that proton transfer to sulfur is involved in the slow step of the reaction at least some of the time, for all three types of sulfur-containing substrate in the study.

# L'enrobage moléculaire: complexation du cation sodium par le dibenzo-24-couronne-8[1,2]

MICHEL BISNAIRE, CHRISTIAN DETELLIER[3] ET DOMINIQUE NADON

*L'Institut Ottawa–Carleton de recherche et d'études avancées en chimie, Campus de l'université d'Ottawa, Ottawa, Ont., Canada KIN 9B4*

Reçu le 9 juillet 1982

MICHEL BISNAIRE, CHRISTIAN DETELLIER et DOMINIQUE NADON. Can. J. Chem. **60**, 3071 (1982).

Nous avons étudié la structure et la microdynamique en solution du complexe dibenzo-24-couronne-8 – perchlorate de sodium par rmn du Na-23 et du C-13. Dans l'ensemble des solvants étudiés (acétone, acétonitrile, pyridine, nitrométhane, carbonate de propylène et chloroforme-*d*) ainsi que dans les mélanges binaires acétone/pyridine, acétonitrile/nitrométhane, carbonate de propylène/méthanol, la couronne entoure le cation sodium, expulsant de sa couche de coordination anion conjugué ou molécules de solvant. La mesure des temps de relaxation quadripolaire en Na-23 et dipôle–dipôle en C-13 nous a permis de calculer le temps de corrélation effectif du complexe en solution dans le chloroforme-*d* ($65 \pm 11$ ps) et la constante de couplage quadripolaire du Na-23 dans tous ces solvants et mélanges de solvant (0.8–1.2 MHz). La couche de coordination du sodium est complètement figée un laps de temps supérieur au temps de corrélation réorientationnel.

MICHEL BISNAIRE, CHRISTIAN DETELLIER, and DOMINIQUE NADON. Can. J. Chem. **60**, 3071 (1982).

Structure and microdynamics in solution of the dibenzo-24-crown-8 – sodium perchlorate complex have been studied by Na-23 and C-13 nmr. In all solvents (acetone, acetonitrile, pyridine, nitromethane, propylene carbonate, and chloroform-*d*) and in the binary mixtures acetone/pyridine, acetonitrile/nitromethane, propylene carbonate/methanol, the crown wraps around the sodium cation and expels the conjugate anion and the solvent molecules from the cation coordination sphere. Measurements of Na-23 quadrupolar and C-13 dipole–dipole relaxation times give the effective correlation time of the complex in $CDCl_3$ solution ($65 \pm 11$ ps) and the Na-23 quadrupolar coupling constant in all those solvents and binary mixtures (0.8–1.2 MHz). The sodium coordination shell is completely frozen during a time superior to the reorientational correlation time.

## Introduction

Voilà maintenant quinze années, depuis la classique étude de Pedersen (1), que la classe de composés appelée éthers-couronne connaît une vogue importante, tant pour ses applications en chimie organique que pour ses propriétés de transport ionique membranaire. Ces molécules, complexant sélectivement les cations alcalins, les dissimulent aux yeux de l'anion conjugué, augmentant d'autant ses potentialités réactives. C'est l'activation anionique, et en dérive l'application de ces composés aux réactions organiques, tant en solution homogène (3), qu'en catalyse par transfert de phase (4–6).

Pourtant, ces ligands macrocycliques, n'offrant au cation qu'une cavité bi-dimensionnelle, lui laissent tout loisir de s'apparier à l'anion conjugué, d'un côté ou l'autre de la couronne. C'est là un écueil majeur à l'utilisation vraiment efficace des éthers-couronne en activation anionique (5). Les cryptands (7) surmontent cet écueil en offrant au cation la possibilité de se nicher au creux d'une molécule macrobicyclique, l'isolant parfaitement du reste de la solution. Les structures cristallographiques de quelques complexes entre cations alcalins et grands éthers-couronne ont montré que ceux-ci peuvent aussi se replier à l'entour du cation, le séparant de l'anion conjugué, à l'instar des cryptands. C'est le cas de l'assemblage entre le dibenzo-30-couronne-10 et KSCN (8) ou KI (9) où le composé couronne s'enroule autour du cation dans une conformation du type "balle de tennis" de symétrie $C_2$ (10). Nous nous intéressons à cerner la structure et la microdynamique en solution des complexes entre cations alcalins et grands éthers-couronne.

La rmn du noyau métallique lui-même est une sonde très utile pour déterminer l'environnement immédiat du cation en solution (11). Popov et ses collaborateurs ont étudié récemment, par la mesure des déplacements chimiques des noyaux Na-23 ou Cs-133, la complexation de ces cations par de grands éthers-couronne (12, 13). Le système formé par le tétraphénylborate de sodium et le dibenzo-24-couronne-8 (DB24C8) (**1**) a retenu notre atten-

tion: les déplacements chimiques, qui montrent la formation d'un complexe de stoéchiométrie 1:1, sont peu sensibles à la nature des trois solvants étudiés (13), suggérant l'enveloppement du cation par la couronne.

## Partie expérimentale

Le dibenzo-24-couronne-8 a été obtenu chez Parish Chem. Co. ou synthétisé selon la procédure de Pedersen (1) et a été séché sous vide à 60°C pendant plusieurs heures. Le perchlorate de sodium (Aldrich 99 + %) a été séché à 70°C sous 1 Torr pendant une vingtaine d'heures. Les solvants ont été séchés selon des procédures publiées (13, 16) et stockés sur tamis moléculaire 4 Å.

Les spectres rmn ont été obtenus à l'aide d'un spectromètre Varian FT-80 opérant à 21.04 MHz pour le Na-23 et à 20.0 MHz pour le C-13. Les déplacements chimiques du Na-23 ont été mesurés par rapport à une solution de NaCl 3 *M* dans $D_2O$, et le verrouillage assuré soit par du benzène-$d_6$ dans un tube coaxial, soit par du $D_2O$ externe. Dans tous les cas, les déplacements chimiques sont exprimés par rapport à NaCl à dilution infinie dans $H_2O$, après correction pour la concentration en chlorure de sodium de la référence et pour la différence éventuelle du solvant deutéré de verrouillage. Les raies observées étaient toutes de forme lorentzienne.

La mesure des temps de relaxation $T_1$ en C-13 a été effectuée sur des échantillons dégazés, à l'aide de la séquence d'inversion–recouvrement 180°–τ–90°, le temps de recyclage étant supérieur dans tous les cas à quatre fois le temps de relaxation à mesurer. L'effet nucléaire Overhauser a été mesuré par la technique du découplage en retenue.

La solution du complexe dans le chloroforme deutéré a été préparée par dissolution de quantités stoéchiométriques de DB24C8 et de perchlorate de sodium dans l'acétone, évaporation de ce solvant et dissolution du complexe dans $CDCl_3$.

Les viscosités des solutions ont été mesurées à l'aide d'un viscosimètre de type Desreux–Bishoff (14) sous enceinte thermostatée à 297 K, la température de la sonde rmn. Le volume du complexe DB24C8–sodium a été mesuré par le volume d'eau déplacé par un modèle moléculaire de type CPK, enrobé parfaitement de Parafilm pour garantir son étanchéité. Conway et Ayranci (15) ont montré que cette méthode, simple et astucieuse, se révèle très puissante dans la détermination des volumes moléculaires de molécules neutres, auxquelles nous pouvons assimiler ce complexe. Le volume moléculaire du complexe ainsi mesuré vaut 1.9 ± 0.1 nm³.

## Résultats et discussion

Les déplacements chimiques en Na-23 caractéristiques du cation sodium complexé par le dibenzo-24-couronne-8 dans une série de solvants sont présentés dans le tableau 1. Dans toute la gamme des solvants étudiés le déplacement chimique reste compris dans une fourchette de 1 ppm, à l'exception du mélange binaire méthanol – carbonate de propylène, de fraction molaire 0.15 en carbonate de propylène, qui s'en écarte légèrement. Les paramètres caractérisant la basicité de ces solvants, et particulièrement le nombre de donicité (20), balaient une large gamme allant d'un solvant de nombre de donicité (DN) nul, tel le chloroforme, à un solvant bon donneur tel la pyridine (DN = 33). Il est à noter pourtant que la constante de formation du complexe est très faible dans d'autres solvants bons donneurs tels le diméthylsulfoxyde ou la *N*,*N* diméthylformamide (13).

Comme il a été montré que le déplacement chimique du sodium-23 est relié linéairement au nombre de donicité du solvant dans lequel est dissous le perchlorate ou le tétraphénylborate de sodium (21), l'incorporation ne fut ce que d'une molécule de solvant dans la première couche de coordination du cation devrait provoquer une variation de déplacement chimique nettement plus conséquente que celle expérimentalement observée. D'autre part, le déplacement chimique est insensible à la nature de l'anion. Ainsi, lors de la complexation, toutes les molécules de solvants sont expulsées de la couche de coordination du sodium. Les largeurs de raie à mi-hauteur caractéristiques du cation sodium complexé par le DB24C8 sont également indiquées dans le tableau 1. Elles se rangent d'une quarantaine de Hz (AN, Ac) à plus de deux cents Hz (PC). Dans des conditions de rétrécissement extrême, la largeur de raie d'un noyau quadripolaire est fournie par l'équation [1]

$$[1]\quad \frac{1}{T_q} = \pi \nu_{\frac{1}{2}} = \frac{3}{40}\,\frac{2I+3}{I^2(2I-1)} \times \left(1+\frac{\eta^2}{3}\right)\left(\frac{e^2qQ}{\hbar}\right)^2 \tau_c$$

où $T_q$ est le temps de relaxation quadripolaire, $I$ le nombre de spin, $\eta$ un paramètre d'asymétrie, $q$, le gradient de champ au site du noyau, $Q$ le moment quadripolaire et $\tau_c$ le temps de corrélation caractéristique de la relaxation quadripolaire. Dans le cas du Na-23 ($I = 3/2$), pour un paramètre d'asymétrie nul, la relation devient (22):

$$[2]\quad \frac{1}{T_q} = \pi \nu_{\frac{1}{2}} = \frac{2\pi^2}{5}\chi^2 \tau_c$$

où

$$\chi = \frac{e^2qQ}{\hbar}$$

$\chi$ peut donc être calculé à partir de la largeur de raie expérimentale en Na-23, si le temps de corrélation $\tau_c$ est connu. Si ce temps de corrélation, caractéristique de la fluctuation du gradient du champ, prend son origine dans un mouvement purement réorientationnel, c'est-à-dire si le temps de vie d'une couche de coordination bien définie du cation sodium est long vis-à-vis du temps caractéristique

TABLEAU 1. Déplacements chimiques et largeurs de raie Na-23 du complexe DB24C8–sodium

| Solvant[a,b] | Anion[c] | δ(ppm)[d] | $\nu_{\frac{1}{2}}$(Hz)[e] |
|---|---|---|---|
| NM | $ClO_4^-$ | −7.9 | 65(±3) |
| NM | $B\phi_4^-$ | −7.7 | |
| AN | $ClO_4^-$ | −8.8 | 39(±2) |
| AN | $B\phi_4^-$ | −8.4 | |
| AC | $ClO_4^-$ | −8.4 | 38(±2) |
| Py | $ClO_4^-$ | −8.9 | 109(±4) |
| Py | $B\phi_4^-$ | −8.8 | |
| Py/THF | $ClO_4^-$ | −7.9 | 102(±4) |
| PC | $ClO_4^-$ | −8.0 | 225(±8) |
| MeOH/PC | $ClO_4^-$ | −7.0 | 66(±3) |
| $CDCl_3$ | $ClO_4^-$ | −8.0 | 123(±4) |

[a]NM = nitrométhane, AN = acétonitrile, Ac = acétone, Py = pyridine, Py/THF: mélange pyridine–tétrahydrofuranne, de fraction molaire 0.60 en pyridine, PC = carbonate de propylène, MeOH/PC = mélange méthanol – carbonate de propylène de fraction molaire 0.15 en méthanol.

[b]Dans ces solvants, seul un complexe de stoéchiométrie 1:1 se forme, avec une constante de formation supérieure ou égale à $10^3$ (13, 16), ce que nous avons vérifié dans le cas du perchlorate par une étude de la variation du déplacement chimique et de la largeur de raie du Na-23 en fonction du rapport [couronne]/[$Na^+$] dans NM, AN, Py/THF, Py et Ac (17). Dans tous les cas, un rapport 2:1 en [couronne]/[sodium] conduit à l'obtention de plus de 99% de sodium complexé.

[c]$ClO_4^-$: ce travail, $B\phi_4^-$: tétraphénylborate (réf. 13).

[d]Mesuré par rapport à NaCl dans $H_2O$ à dilution infinie, toutes corrections effectuées: voir partie expérimentale; ±0.1 ppm.

[e]Largeur de raie à mi-hauteur du signal Na-23 du cation sodium complexé par le DB24C8.

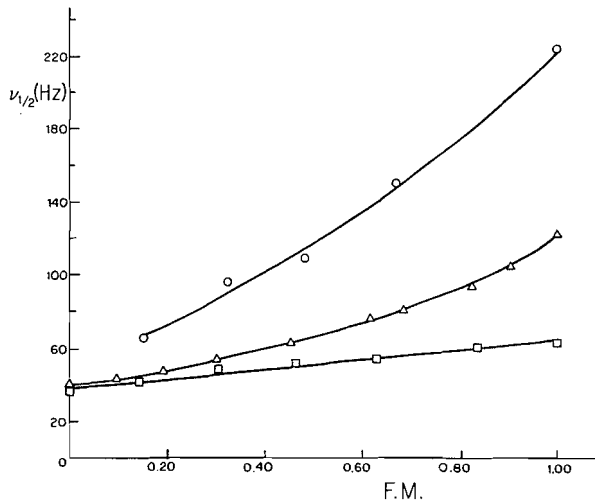

FIG. 1. Largeurs de raie à mi-hauteur ($\nu_{\frac{1}{2}}$) du sodium-23 pour le complexe $Na^+$–DB24C8 en fonction de la fraction molaire des mélanges binaires acétonitrile/nitrométhane (□), acétone/pyridine (△) et méthanol/carbonate de propylène (○). La trop faible solubilité du complexe dans le méthanol explique l'absence de points expérimentaux dans la zone des fractions molaires en méthanol de 0 à 0.15. La concentration en $NaClO_4$ est de 0.010 *M*, celle en DB24C8 de 0.020 *M*, dans tous les cas.

de la réorientation moléculaire, le temps de corrélation obéit à la relation de Debye–Stokes–Einstein, fournie par l'equation [3]

$$[3] \quad \tau_c = \frac{4}{3}\pi a^3 \frac{\eta}{kT} f_r$$

où $a$ est le rayon moléculaire, $\eta$ la viscosité du milieu[4] et $f_r$ le coefficient de microviscosité (23). La symétrie de la couche de coordination du cation se reflétant dans $\chi$, sa constance au long des solvants étudiés permettra à la largeur de raie d'être proportionnelle à la viscosité du solvant, uniquement (24–26). Effectivement, c'est ce que l'on observe. Les solvants peu visqueux (AN, $\eta$ = 0.335 cP; Ac, $\eta$ = 0.343 cP) fournissent une raie fine (40 Hz), les solvants plus visqueux (Py, $\eta$ = 0.955 cP, PC, $\eta$ = 2.41 cP) une raie large. Nous avons testé davantage cette invariance de $\chi$: lorsque le complexe est plongé dans un mélange binaire de deux solvants comportant des sites donneurs différents, tels la pyridine et l'acétone, le maintien de molécules de solvant dans la couche de coordination du cation produira un gradient de champ très dissymétrique, la variation de la constante de couplage quadripolaire au long du mélange binaire et la non-linéarité de $\nu_{\frac{1}{2}}$ avec $\eta$. La figure 1 montre la variation de la largeur de raie du Na-23 en fonction de la composition de mélange binaire pour trois paires de solvants: acétone et pyridine, nitrométhane et acétonitrile, carbonate de propylène et méthanol. Quant au test, il est concluant: on obtient d'excellentes relations linéaires entre la largeur de raie et la viscosité de ces solutions dans tous les cas (Fig. 2). La régression linéaire est même excellente pour l'ensemble des points expérimentaux ($\rho$ = 0.989 pour les 22 points). Une conclusion en découle: dans tous ces environnements, soumise à des pressions internes diverses, à la présence de solvants de donicités différentes, la couche de coordination du cation sodium reste remarquablement constante. Qui plus est, elle est rigide dans le domaine de temps de la réorientation moléculaire: l'orientation de chaque interaction $Na^+$ .... O, figée dans ce domaine de temps, ne fluctue que par la réorientation globale de la supramolécule. Quelle est la valeur de $\chi$? La connaissance de $\tau_c$ dans l'équation [2] nous permettrait son calcul. Puisque, comme nous venons de le montrer, $\tau_c$ est d'origine purement réorientationnelle, il peut être égalé aux temps de corrélation réorientationnels mesurés sur d'autres noyaux de la supramolécule, comme les C-13 du ligand. Cette approche a été décrite par Kintzinger et Lehn (27), et leur avait permis de calculer les constantes de couplage quadripolaires $\chi$ du cation sodium encagé

[4]Ne pas confondre $\eta$, la viscosité, avec le paramètre d'asymétrie de l'équation [1], malencontreusement nommé habituellement $\eta$, lui aussi.

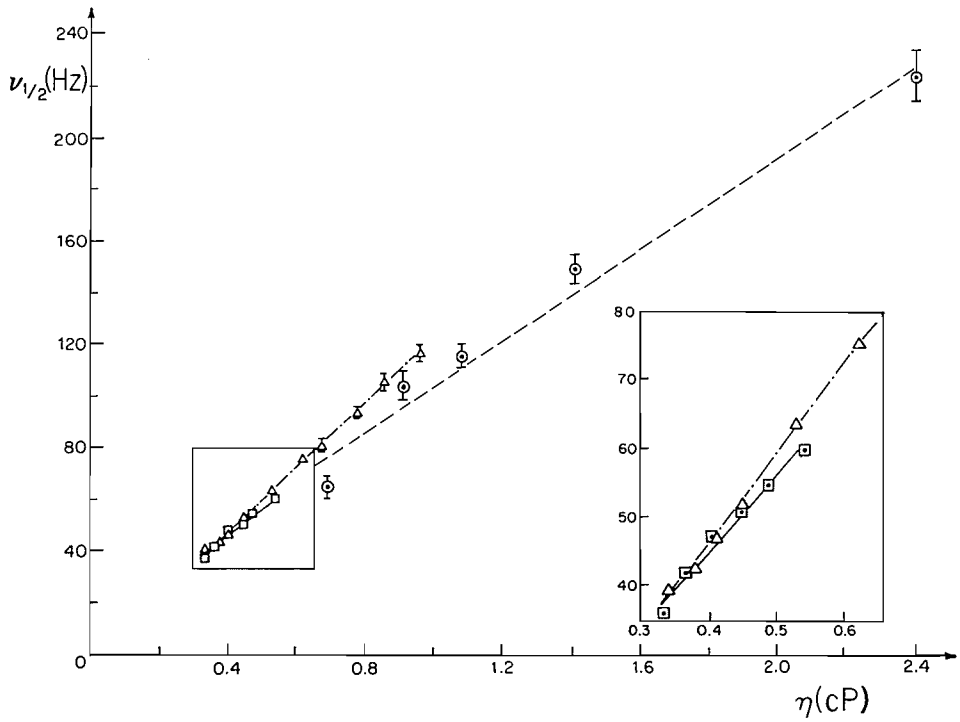

FIG. 2. Largeurs de raie à mi-hauteur ($\nu_{\frac{1}{2}}$) du sodium-23 en fonction de la viscosité ($\eta$) pour le complexe sodium - dibenzo-24-couronne-8 en solution dans divers mélanges binaires: –○–: mélange carbonate de propylène/méthanol (le coefficient de corrélation linéaire, $\rho$, est égal à 0.994 pour 5 points); –.–.△–.–: mélange acétone/pyridine ($\rho$ = 0.999 pour 10 points); –□–: mélange acétonitrile/nitrométhane ($\rho$ = 0.984 pour 7 points). Pour plus de clarté, la portion de graphique correspondant au mélange acétonitrile/nitrométhane est agrandie. La droite de régression sur l'ensemble des points expérimentaux, correspondant aux 6 solvants, n'est pas indiquée. Son équation est $\nu_{\frac{1}{2}} = 93.7\ \eta + 11.4$ ($\rho$ = 0.989 pour 22 points).

dans des cryptands. La vitesse de relaxation dipôle–dipôle de noyaux C-13 suit la relation [4]

$$[4]\quad \frac{1}{T_1^{DD}} = N_H\ \gamma_C^2\ \gamma_H^2\ \hbar^2\ r_{CH}^{-6}\ \tau_{eff}$$

où $N_H$ est le nombre d'hydrogène directement attachés au C-13, $\gamma_C$ et $\gamma_H$ sont les rapports gyromagnétiques des noyaux C-13 et H-1 et $r_{CH}$ est la longueur de la liaison C—H, dans le cas de carbones protonés où les contributions provenant d'hydrogènes non directement liés peuvent être ignorées (28). Pour des molécules de la taille du complexe étudié, la contribution dominante au temps de relaxation mesuré est d'origine dipolaire. En fait, c'est le cas à 80–90% comme nous l'avons vérifié par la mesure de l'effet nucléaire Overhauser (nOe) (tableau 2), et $T_1^{DD}$ a été calculé par l'équation [5] (27)

$$[5]\quad T_1^{DD} = T_1^{obs} \cdot \frac{1.98}{(nOe)_{obs}}$$

Compte tenu des erreurs de mesure, le temps de corrélation réorientationnel effectif, $\tau_{eff}$ est pratiquement constant pour les différents carbones (tableau 2). La différence notée entre les carbones aromatiques et les carbones éthérés, à la limite de l'erreur expérimentale, peut provenir de la réorientation anisotrope de la supramolécule. Il est à noter également que les valeurs de $T_1$ que nous mesurons sont en bon accord avec des valeurs précédemment publiées (18, 19) pour les complexes formés entre KSCN et le DB30C10 ou le DB18C6, où il apparaissait également une rigidité de la couronne après la complexation. Le temps de corrélation moyen obtenu est de 65 ± 11 ps, et, grâce à l'équation [2], la valeur de $\chi$ en dérive: 1.2 MHz dans $CDCl_3$. Nous avons déterminé le volume moléculaire du complexe (1.9 ± 0.1 nm$^3$) (voir partie expérimentale). L'équation [3] fournit ainsi une valeur pour le coefficient de microviscosité (23) égale à 0.24. Lorsque les molécules de solvant et de soluté sont de même taille, ce coefficient est égal à 0.17 (23). Pour des solutés de rayon moléculaire 0.5 nm, Kintzinger et Lehn trouvaient un coefficient de 0.20 (27). Dans le cas du complexe étudié le rayon moléculaire égale 0.77 nm et un coefficient de 0.24 est logique. L'équation [3] nous a ainsi permis de calculer $\chi$ pour l'ensemble des solvants étudiés. [a] Ce travail.
[b] Les déplacements chimiques sont exprimés en ppm, par rapport au tétraméthylsilane interne (±0.05 ppm).
[c] Le déplacement chimique du carbone aromatique non protoné est 148.05.
[d] L'estimation de l'erreur sur $T_1^{obs}$ est de ±10%.
[e] Erreur: ±5%.
[f] Calculé à l'aide de l'équation [4], en utilisant une valeur de $r$ égale à 0.1085 ± 0.0005 nm. L'erreur estimée sur $\tau_{eff}$ est de ± 15%. La moyenne de $\tau_{eff}$ sur les cinq valeurs est 65 ± 11 ps (voir discussion).
[g] Référence 18; solvant $CDCl_3$ à 320 K.
[h] La numérotation des carbones du DB30C10 est analogue à celle utilisée pour **1**.
[i] Référence 19; solvant $CD_2Cl_2$.

TABLEAU 3. Constantes de couplage quadripolaire du $Na^+$-23 complexé

| Solvants[a] | NM | AN | Ac | Py | Py/THF | PC | MeOH/PC | $CDCl_3$ |
|---|---|---|---|---|---|---|---|---|
| χ (MHz)[b] | 0.8 | 0.9 | 0.9 | 0.9 | 1.1 | 0.8 | 0.8 | 1.2 |

[a] Signification des abréviations: voir tableau 1.
[b] Calculé selon l'équation [3] sauf pour $CDCl_3$ où χ a été calculé selon l'équation [2] (voir texte); l'estimation de l'erreur sur χ est 20%.

tableau 3 fournit ces valeurs pour les solvants purs. Il est à noter que χ est constant également dans toute la gamme de chaque mélange binaire étudié. Cette valeur de χ est à comparer à celle déterminée dans le cas du cryptand 2,2,2 (1.0 MHz) où le cation sodium est niché dans une cavité tapissée de 6 atomes d'oxygène. Les cryptands 2,2,1 ou 2,1,1 fournissaient au sodium un environnement moins symétrique, reflété par la valeur de χ (1.4 et 2.2 MHz, respectivement) (27). De plus, les déplacements chimiques sont comparables: −8 et −11 ppm respectivement pour le DB24C8 et le cryptand 2,2,2: un argument étayant la théorie de Deverell (29, 30) de la proportionalité de la constante de couplage quadripolaire à la partie paramagnétique de la constante d'écran $\sigma_p$. Il a été récemment montré, dans une série de solvants aminés, une corrélation similaire confirmant cette théorie très peu testée jusqu'à présent (26).

En somme, le DB24C8 s'enroule autour du cation sodium, excluant de la couche de coordination du cation anion ou molécules de solvant. L'agrégat supramoléculaire sodium–DB24C8 a une structure bien définie, figée un laps de temps supérieur à $10^{-10}$ s, régie par des facteurs configurationnels et conformationnels (31). La détermination de la constante de couplage quadripolaire du sodium en solution et sa relation au déplacement chimique par une approche du type de celle que nous avons suivie, en immergeant l'ion dans une structure moléculaire le protégeant de tout autre environnement nous promettent d'avoir accès aux paramètres de solvatation et de complexation d'une manière nette et précise (32).

## Remerciements

Nous remercions le Conseil de Recherches en Sciences Naturelles et en Génie du Canada (CRSNG) pour son soutien financier. L'un de nous (D.N.) remercie également le CRSNG pour l'octroi d'une bourse de recherche d'été. Nous remercions le Dr R. R. Fraser pour des discussions stimulantes et M[r] Raj Capoor pour son experte assistance technique.

# The influence of crown ethers on the kinetics of E1cB and E2 β-elimination reactions of di(4-nitrophenyl)fluoroethanes with sodium methoxide in methanol

KENNETH T. LEFFEK AND GRZEGORZ SCHROEDER[1]
*Chemistry Department, Dalhousie University, Halifax, N.S., Canada B3H 4H6*
Received March 23, 1982

KENNETH T. LEFFEK and GRZEGORZ SCHROEDER. Can. J. Chem. **60**, 3077 (1982).

The addition of crown ethers 1,4,7,10,13-pentaoxacyclopentadecane (15C5) and 1,4,7,10,13,16-hexaoxacyclooctadecane (18C6) in quantities equimolar to the base, to β-elimination reactions of 1,1,1-trifluoro-2,2-di(4-nitrophenyl)ethane and 1-fluoro-2,2-di(4-nitrophenyl)ethane promoted by sodium methoxide in methanol, has been investigated. In the E2 reaction of the monofluoro compound, the crown ethers caused no change in the kinetic order and only small changes in the second-order rate constants and activation parameters. The primary deuterium isotope effect was also unaltered by the presence of crown ethers.

For the $(E1cB)_R$ reaction of the trifluoro compound, no change in kinetic order was found, but slightly larger rate constant changes and an increase in the isotope effect from $k_H/k_D$ = 1.0 to 1.25 at 25°C was observed. This is interpreted as an alteration in mechanism from $(E1cB)_R$ towards $(E1cB)_I$.

KENNETH T. LEFFEK et GRZEGORZ SCHROEDER. Can. J. Chem. **60**, 3077 (1982).

On a étudié l'addition d'éthers couronnes pentaoxa-1,4,7,10,13 cyclopentadécane (15C5) et hexaoxa-1,4,7,10,13,16 cyclooctadécane (18C6) en quantités équimoléculaires à la base lors des réactions d'élimination β du trifluoro-1,1,1 di(nitrophényl-4)-2,2 éthane et du fluoro-1 di(nitrophényl-4)-2,2 éthane favorisées par le méthylate de sodium dans le méthanol. Dans le cas de la réaction de type E2 du composé monofluoré, les éthers couronnes ne changent pas l'ordre cinétique et ne provoquent que de faibles variations des constantes de vitesse d'ordre deux et des paramètres d'activation. La présence des éthers couronnes n'affecte pas l'effet isotopique primaire du deutérium.

On n'a pas trouvé de changement dans l'ordre cinétique de la réaction de type $(E1cB)_R$ du composé trifluoré, mais on a observé des variations légèrement plus prononcées de la constante de vitesse et une augmentation de l'effet isotopique de $k_H/k_D$ = 1,0 à 1,25 à 25°C. On interprète ceci comme étant une évolution du mécanisme de $(E1cB)_R$ vers $(E1cB)_I$.

[Traduit par le journal]

## Introduction

The effect of crown ethers as additives to alkoxide promoted β-elimination reactions is emerging as an additional tool for the elucidation of the character of the transition states of these reactions (1–8). Recently Alunni *et al.* (1) concluded, from the effect of the addition of dicyclohexyl-18-crown-6 ether to 1-chloro and 1-bromo-1,2-diphenylethane eliminations induced by potassium *tert*-butoxide in *tert*-butanol, that the nonassociated $t\text{BuO}^-$ reacted via a transition state which had smaller bond breaking of the carbon–halogen bond and the same carbon–hydrogen bond breaking as the transition state for the associated base, $t\text{BuO}^-\text{K}^+$. The smaller carbon–halogen bond breaking was at variance with earlier work (3, 5). It was noted (1) that the crown ether may give rise to differences between the associated and dissociated base–solvent systems other than simply increasing the base strength.

In a previous study (9), we attempted to define the general effect, including solvation changes, of crown ethers on β-elimination reactions by studying the addition of 1,4,7,10,13-pentaoxacyclopentadecane (15C5) and 1,4,7,10,13,16-hexaoxacyclooctadecane (18C6) to reactions of some *p*-chlorophenylethanes promoted by sodium ethoxide and *tert*-butoxide in the corresponding alcohol solvents. In these reactions the crown ethers produced various effects, in some cases increasing the second-order rate constant and in other cases decreasing it. Similarly, the changes in the activation parameters, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ followed no simple pattern.

It is to be expected that, in addition to bringing about a dissociation of the alkoxide base ion-pairs, crown ethers might affect the mechanism of β-elimination reactions in different ways depending upon the mechanism of the reaction in the absence of crown ethers. We have, therefore, investigated the influence of crown ethers for two β-elimination reactions, one which follows the $(E1cB)_R$ mechanism and another which has a symmetrical E2 state. The base sodium methoxide in methanol was chosen in order that the effect of crown ether on base association would be minimized, since $\text{Na}^+\text{OCH}_3^-$ is largely dissociated in dilute solution (10), so that we could observe the influence of crown ethers other than their base dissociation effect. This type of control experiment does not seem to have been performed, but it is important in the interpretation of rate constant and isotope effect changes induced by crown ethers in reac-

tions involving alkoxide bases which are highly associated in the absence of crown ethers.

## Results and discussion

1,1,1-Trifluoro-2,2-di(4-nitrophenyl)ethane was shown to react with sodium methoxide in methanol by the $(E1cB)_R$ mechanism (11) and in a recent reinvestigation (12) 1-fluoro-2,2-di(4-nitrophenyl)-ethane was found to follow a concerted E2 mechanism with a symmetrical transition state with the same base–solvent system. Pseudo first-order rate constants were determined for the β-elimination of HF from these two substrates and their $1d_1$ deuterated analogues promoted by a large excess of sodium methoxide in methanol, in the presence of the crown ethers 15C5 and 18C6 in concentrations equal to that of the methoxide. The second-order rate constants were calculated from plots of the first-order constants vs. base concentration. In all cases these plots were linear, indicating a kinetic order of unity in methoxide for the reaction in the presence of crown ethers. The rate constant measurements for the trifluoro compound in the absence of crown ethers were repeated and the present work gave values about 15% lower than those previously determined (11). The present measurements were made by following the increase in absorbance at 338 nm, the isobestic point for the subsequent reaction of the olefin, whereas the earlier measurements were made at 325 nm, the absorbance maximum of the olefin product. The activation parameters are also slightly different from our previously published results, but by amounts less than the experimental uncertainties. The rate constants are shown in Tables 1 and 2 and the activation parameters in Table 3.

The ion-pair dissociation constant for sodium methoxide in methanol is about $0.02_5$ mol $L^{-1}$ (10), from which it can be calculated that the degree of dissociation of the base in these reactions varies from 83% at $5 \times 10^{-3}$ $M$ to 98% at $0.5 \times 10^{-3}$ $M$ sodium methoxide. For a carbenium ion reacting with sodium methoxide, it was shown (10) that the active base is the free methoxide ion. Also, for some β-elimination reactions with sodium ethoxide, McLennan determined (13) the rate constant for the free ethoxide ion to be more than 4 times greater than that for the sodium ethoxide ion-pair in ethanol. From these studies and the fact that our plots of $k_{2H}$ and $k_{2D}$ vs. base concentration are linear, it may be deduced that the elimination reactions proceed via the dissociated methoxide ion. Therefore, the rate change which may be expected if the crown ethers merely result in the complete dissociation of the base is an increase of about 25%.

The results in Tables 1 and 2 show that both crown ethers have very similar effects on the second-order rate constants, giving an increase of about 100% for the $(E1cB)_R$ reaction of the trifluoro compound and a small decrease (30% or less) for the E2 reaction of the monofluoro compound. For the trifluoro compound a small isotope effect, $k_H/k_D \sim 1.25$ at 25°C, is introduced by the crown ethers, but for the E2 reaction of the monofluoro compound the crown ethers have no effect at all on the

*Reference 12.

isotopic rate ratio of 4.7 to 4.8 at 25°C. This latter observation confirms a similar one by Alunni *et al.* for E2 reactions (1). Thus, the crown ethers do not affect the transition state of the E2 reaction with respect to the C—H bond breaking, but give rate constants about 50% less than would be predicted for complete dissociation of the alkoxide base. This is a very small change compared to the rate enhancements by factors of up to 250 found when crown ethers are added to reactions involving highly associated bases (1, 3). The small decrease in rate is probably due to changes in the solvation of the transition state around the C—F bond, brought about by the complexing of the sodium cation with the crown ether, which inhibits the C—F bond breaking process. The 18-crown-6 ether has practically no effect at all on the activation parameters of the E2 reaction of the monofluoro compound, but the 15-crown-5 produces a compensating decrease in $\Delta H^{\ddagger}$ and an increase in negative $\Delta S^{\ddagger}$.

For the $(E1cB)_R$ mechanism, shown in eq. [1], the inequality $k_{-1}[BH] \gg k_2$ is assumed for the steady-state approximation for $S^-$ to yield the rate

$$[1] \quad B^- + SH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} S^- + BH \xrightarrow{k_2} P + F^-$$

equation [2]. Since BH is the solvent methanol, the

$$[2] \quad \frac{d[P]}{dt} = \frac{k_1k_2}{k_{-1}} \frac{[B^-][SH]}{[BH]}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

$(ElcB)_R$ mechanism shows no primary deuterium isotope effect.

At the other extreme, when $k_2 \gg k_{-1}[BH]$, the mechanism $(ElcB)_I$ operates and the rate equation is [3]. For this mechanism the magnitude of $k_H/k_D$

$$[3] \quad \frac{d[P]}{dt} = k_1[B^-][SH]$$

is predicted (14) to be between 2 and 8.

A small isotope effect of 1.25 could appear if the added crown ethers changed the relative magnitudes of $k_{-1}[BH]$ and $k_2$. If $k_2$ is increased relative to $k_{-1}[BH]$ the mechanism would change from $(E1cB)_R$ towards $(E1cB)_I$ introducing an isotope effect.

Normally the carbanion is probably appreciably associated with sodium ions in ion-pairs, but in the presence of crown ethers where the $Na^+$ ions are complexed, the carbanion would be in the form of free ions and thereby both $k_{-1}[BH]$ and $k_2$ would be increased. However, the overall activation energy is decreased (Table 3) by 1.5 to 2 kcal $mol^{-1}$. Thus, the height of the energy barrier for loss of $F^-$ from the carbanion is decreased and $k_2$ is, therefore, increased to a greater extent than $k_{-1}[BH]$, altering the mechanism from $(E1cB)_R$ towards $(E1cB)_I$. The source of the decrease in $\Delta H^{\ddagger}$ may be that there is no energy requirement to break up the carbanion ion-pair to allow the negative charge to transfer to a fluorine atom.

It is presumed that the magnitude of $k_1$ would not be altered by the crown ethers, since we have seen from the E2 case that C—H bond breaking is unaffected by crown ether addition.

It is concluded that crown ethers added to an E2 β-elimination have only a small effect, other than the change in the dissociation of the alkoxide base. In the $(E1cB)_R$ case, however, crown ethers can bring about a change of mechanism to some extent, towards the $(E1cB)_I$ mechanism. It is, therefore, a kinetic tool which should be used with care at this extreme of the spectrum of β-elimination mechanisms.

## Experimental

The fluoroethanes were prepared as described previously (11, 12). The 15-crown-5 ether (Aldrich) was purified by distillation at reduced pressure and the 18-crown-6 ether (Aldrich) was recrystallized from hexane, mp 39–40°C.

The kinetic runs were carried out with a Unicam SP800 spectrophotometer, using the technique previously described (11).

Received March 15, 1982

PAWEŁ KAFARSKI, BARBARA LEJCZAK, PRZEMSŁAW MASTALERZ, JERZY SZEWCZYK, and CZESŁAW WASIELEWSKI. Can. J. Chem. **60**, 3081 (1982).

Diastereoisomeric mixtures of phosphonodipeptides, prepared from racemic dialkyl 1-aminoalkanephosphonates, were separated by ion-exchange column chromatography. Phosphonodipeptides were found to be much more readily available from dialkyl 1-aminoalkanephosphonates than from the corresponding free acids and the mixed carboxylic – carbonic anhydride method was found to be the most effective one.

PAWEŁ KAFARSKI, BARBARA LEJCZAK, PRZEMSŁAW MASTALERZ, JERZY SZEWCZYK et CZESŁAW WASIELEWSKI. Can. J. Chem. **60**, 3081 (1982).

On a séparé des mélanges disastéroisomères de phosphonodipeptides, préparés à partir d'amino-1 alcanephosphonates de dialkyles racémiques, par chromatographie sur colonnes échangeuses d'ions. On a trouvé que les phosphonodipeptides sont plus facilement accessibles à partir des amino-1 alcanephosphonates de dialkyles qu'à partir des acides libres correspondants et on a trouvé que la méthode des anhydres mixtes de l'acide carbonique est la plus efficace.

Peptides of aminoalkanephosphonic acids are now receiving considerable interest because some representatives of this class were found to repress bacterial growth at very low concentration levels (1–5).

Although the mechanism of molecular action of phosphonopeptides is quite well established (1, 3, 6, 7), their biochemistry is little known and several important metabolic aspects await elucidation. Progress in this field should be facilitated by increased availability of pure diastereoisomers of phosphonodipeptides.

We wish to report a simple and effective method for the separation of diastereoisomeric phosphonodipeptides by means of ion-exchange column chromatography. Since literature data on the synthesis of dipeptides containing *P*-terminal aminoalkanephosphonic acids are scarce (8–15), we have also described the routes for their preparation followed in this study.

*Synthesis of phosphonodipeptides*

We have prepared the peptides **1** by condensation of *N*-phthaloyl-, *N*-formyl-, or preferably *N*-benzyloxycarbonylamino acids **2** with 1-aminoalkanephosphonic acids as well as with their dialkyl esters.

The literature data and our observations on the preparation of phosphonodipeptides from free 1-aminoalkanephosphonic acids indicate that the yields of the coupling step are usually low or moderate. Moreover the use of bulky *N*-protected amino acids drastically decreases the reaction yield. Thus, following the methods of Martell and co-workers (11), we were unable to prepare dipep-

[b]$c$ = 2%, 1 $N$ NaOH.

tides containing *N*-terminal valine or leucine, while the peptides of phenylalanine were obtained in 5–10% yield.

Also, the active ester method gave low yields of the desired products (10–15). Our studies with *p*-nitrophenyl and cyanomethyl esters of *N*-phthaloylamino acids confirmed the observations that free aminoalkanephosphonic acids are particularly unsuitable as substrates for the synthesis of phosphonodipeptides.

We were able to obtain much better results using the dialkyl 1-aminoalkanephosphonates (16) instead of free acids. Thus, the desired peptides were prepared by condensation of *N*-protected amino acids **2** with dialkyl 1-aminoalkanephosphonates **3** (the methyl, ethyl, and isopropyl esters can be used interchangeably without noticeable effect on yields or purity of products) by means of the dicyclohexylcarbodiimide (DCC) or, preferably, the mixed carboxylic – carbonic anhydride (MCA) method. The DCC method often gave the corresponding *N*-acylureas, the side products of the reaction, in relatively high yields (about 30%). Conventional removal of the blocking groups yielded the peptides listed in Table 1.

*Separation of diastereoisomeric phosphonodipeptides*

Using ion-exchange column chromatography for purification of the phosphonodipeptides **1**, we have observed a separation of diastereoisomers. There appears to be no evidence for preparative separation of diastereoisomeric dipeptides in the literature, although there are reports describing analytical separation of carboxylic peptides (17, 18). Diastereoisomeric phosphonodipeptides have never been separated by ion-exchange chromatography.

Thus, mixtures of diastereoisomeric phosphonodipeptides, prepared from racemic 1-aminoalkanephosphonates, were placed on a Dowex 50W ($H^+$ form) 100–200 mesh column and simple elution with water yielded quantitatively the pure diastereoisomers (Table 2). Using a 200 × 20 mm column

we were able to separate 0.7 to 2.0 g portions of the mixture of diastereoisomers.

Specific rotation values shown in Table 2 indicate that there is a correlation of relative rotation for the pairs of diastereoisomers and the retention factor, the isomers of higher positive rotation being eluted faster. According to the general rule (19, 20), validated recently also for phosphonopeptides (21), the peptides which are eluted faster may be considered as possessing *S,S* (L,D) configuration. The tentative configurations proposed in Table 2 result from relative mobilities of the diastereoisomers on the Dowex column as well as on tlc plates.

In the case of peptides of 1-aminoethanephosphonic acid, our assignments are in accordance with those reported by the La Roche group (4, 22, 23) for *N*-L-alanyl-, *N*-L-valyl-, and *N*-L-leucyl-1-aminoethanephosphonic acids (see footnotes to Table 2).

## Experimental

The melting points were determined on a Koeffler apparatus and are uncorrected. The structure of the prepared peptides was confirmed by means of ir and nmr spectroscopy.

*Preparation of phosphonodipeptides by means of the MCA method*

*From* N-*benzyloxycarbonylamino acids (Method A)*

A solution of 0.01 mol of *N*-benzyloxycarbonylamino acid and 1.5 cm³ of triethylamine in 30 cm³ of dry chloroform was cooled to about −5°C and treated with 1.0 cm³ (0.011 *M*) of ethyl chloroformate. After 30 min, 0.011 mol of ester **3** was added and the solution was left to reach room temperature, then the solution was slowly heated to the boiling point. The resulting solution was washed successively with water, 5% hydrochloric acid, water, saturated solution of sodium bicarbonate, and water. Finally it was extracted with brine and dried over sodium sulphate. The solvent was distilled off and the oily residue representing crude peptide **4** was dissolved in 20 cm³ of 40% hydrogen bromide in glacial acetic acid solution and left overnight. Then acetic acid and excess of hydrogen bromide were removed under reduced pressure, the oily residue was dissolved in water and extracted with ether to remove benzyl bromide, and the solvent was stripped off under the reduced pressure. The residue was then dissolved in absolute ethanol and the crude peptide was precipitated with propylene oxide or pyridine.

Chromatographically pure products were obtained upon crystallization from water–ethanol or water–acetone mixtures.

*From* N-*phthaloylamino acids (Method B)*

The condensation of phthaloylamino acids with esters **3** and isolation of phthaloylated peptides **4** was carried out as described for crude *N*-benzyloxycarbonylpeptides **4**. The crude phthaloylated peptides were first dephthaloylated by boiling for 1 h with hydrazine hydrate in ethanol and *P*-alkyl groups were then removed with hydrogen bromide in acetic acid. Pure peptides were isolated as described above.

*From* N-*formylamino acids (Method C)*

The procedure for the preparation of *N*-formylpeptides **4** was identical as described for *N*-benzyloxycarbonylpeptides. Crude peptides were first deformylated with hydrogen chloride in methanol and then *P*-alkyl groups were removed with hydrogen bromide in glacial acetic acid solution. Pure peptides were isolated by standard procedure.

*Preparation of phosphonodipeptides by the DCC method (Method D)*

*N*-Protected amino acid **2** (0.005 mol) and 0.8 cm³ of triethylamine were dissolved in 20 cm³ of dry chloroform and 0.005 mol of diethyl 1-aminoalkanephosphonate was added. Then 0.005

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

mol, i.e. 1.03 g, of dicyclohexylcarbodiimide was added and the mixture was left overnight. After filtration of the formed dicyclohexylurea the peptide was obtained as in Method A.

*Separation of diastereoisomers – a typical example*

Crude (without crystallization) *N*-L-valyl-1-aminoethanephosphonic acid (1.0 g) was chromatographed on a 200 × 20 mm Dowex 50W X8 ($H^+$ form) 100–200 mesh column with water as eluent. The elution was monitored by ninhydrin reaction. Fractions of 16 $cm^3$ were collected. The *S*,*S*-dipeptide was obtained from fractions 106–200 and weighed 420 mg. The *S*,*R*-diastereoisomer was eluted from 225 up to 700 fractions; 460 mg of this isomer was obtained. The yield of pure diastereoisomers was 88%.
