Excess methanethiol was passed into a solution of sodium ethoxide in ethanol (10 mL) (from 13.8 mg sodium). To the solution was added 3-methylthio-1-phenyl-2,1-benzisothiazolium iodide (230 mg, 0.6 mmol), and the mixture warmed until homogeneous. The resulting red solution was treated with charcoal, filtered, and evaporated. The red oil was chromatographed and gave a red and a pale yellow band. The red band on elution gave a red oil which had properties consistent with **8***b* (73%). It was not analysed. The nmr spectrum, δ: 2.80 (3H, s), 6.83–8.40 (9H bands), 9.50–10.03 (1H, broad, the hydrogen bonded NH). The mass spectrum $M^+$ 259, M calcd. 259.

The pale yellow band on elution gave a pale yellow crystalline solid, mp 113°C, identical to a sample of **10** prepared below (5%).

Prolonged treatment of **8***b* with sodium methanethiolate did not produce any of the acridine **10**. Instead a polymeric material was obtained.

*9-Methylthioacridine (10)*

9-Chloracridine (2.13 g, 10 mmol) was treated with excess sodium methanethiolate in methanol (prepared from sodium methoxide and methanethiol) and stirred 4 h. Dilution with water and work-up afforded pale yellow crystals, mp 113–114°C (lit. (17) mp 113–114°C) (81%).

Y. HARIMA, H. KURIHARA, Y. NISHIKI, S. AOYAGUI, K. TOKUDA, and H. MATSUDA. Can. J. Chem. **60**, 445 (1982).

Potential-sweep voltammetric and potential-step chronoamperometric experiments were made at −50°C with solvated electrons in methylamine containing LiCl, KI, or CsI. The dissociation rate constants of the ion pairs, $(M^+ \cdot e_s^-)$, M being alkali metal and $e_s^-$ free solvated electron, were greater than $10^3\ s^{-1}$. The pseudo-first-order rate constant of the dissociation of $K^-$ into the one-electron species, $e_s^-$ and $(K^+ \cdot e_s^-)$ in rapid equilibrium, was determined as $40\ s^{-1}$ by chronoamperometry with 0.5 *M* KI solutions. The formation constants of $K^-$ from the one-electron species determined by chronoamperometry and voltammetry were $4.5 \times 10^4\ M^{-1}$ and $5.6 \times 10^4\ M^{-1}$, respectively. An addition of a small amount of ammonia to methylamine caused a decrease in the formation constant of $K^-$ and an increase in its dissociation rate constant. The appendix deals with a theoretical treatment of chronoamperograms for an electrode process preceded by the dissociation of a dimer. The boundary value problem was solved by the explicit finite difference method and the analytical method which was based on the concept of reaction layer.

Y. HARIMA, H. KURIHARA, Y. NISHIKI, S. AOYAGUI, K. TOKUDA et H. MATSUDA. Can. J. Chem. **60**, 445 (1982).

Opérant à −50°C, on a procédé à des expériences voltammétriques à variation linéaire de potentiel et chronoampèrométriques à saut de potentiel avec des électrons solvatés dans de la méthylamine contenant du LiCL, du KI ou du CsI. Les constantes de vitesse de dissociation des paires d'ions, $(M^+ \cdot e_s^-)$, M étant le métal alcalin et $e_s^-$ l'électron solvaté libre, sont plus grandes que $10^3\ s^{-1}$. On a établi que la constante de vitesse de dissociation de pseudo premier ordre de $K^-$ en espèces mono-électroniques, $e_s^-$ et $(M^+ \cdot e_s^-)$ en équilibre rapide, est égale à $40\ s^{-1}$, en faisant appel à la chronoampèrométrie sur des solutions à 0.5 M de KI. Les constantes de formation de $K^-$, telles que déterminées par chronoampèrométrie et voltammétrie, sont respectivement égales à $4.5 \times 10^4\ M^{-1}$ et $5.6 \times 10^4\ M^{-1}$. L'addition de petites quantités d'ammoniac à la méthylamine a provoqué un accroissement de la vitesse de dissociation de l'espèce bi-électronique et une décroissance de sa constante de formation. L'appendice présente un traitement théorique des chronoampérogrammes pour un processus d'électrode qui est procédé par la dissociation d'un dimère. On a résolu le problème de la valeur aux limites par la méthode de la différence finie explicite et la méthode analytique qui est basée sur le concept de la couche de réaction.

## Introduction

Since Hart and Boag (1) in 1963 revealed the presence of solvated electrons in water by generating them with pulse radiolysis and detecting them with spectroscopy, this technique has developed quickly as a powerful tool to investigate solvated electrons in various media, especially those of extremely short lifetimes. Extensive kinetic studies on the formation of chemical species composed of alkali metal cation, $M^+$, and free solvated electron, $e_s^-$, in amines and ethers have been carried out by means of this technique (2–8).

In a previous paper (9) we reported an electrochemical investigation of solvated electrons in methylamine containing an excess alkali metal halide, and concluded that the same solute species as had been proposed in the pulse radiolysis studies on alkali metal – methylamide solutions (2) were present: they were $e_s^-$, the ion pair of $e_s^-$ and $M^+$, $(M^+ \cdot e_s^-)$, and alkali metal anion, $(M^+ \cdot 2e_s^-)$ or $M^-$. In our electrochemical experiments $e_s^-$ and $(M^+ \cdot e_s^-)$ were recognized as species having one excess electron, and $M^-$, two excess electrons. They were termed the one- and the two-electron species, respectively, and the solvated electron species or the solvated electrons, generically. This paper deals with potential-sweep voltammetry and potential-step chronoamperometry of the anodic oxidation of solvated electrons in methylamine and methylamine–ammonia mixtures in order to obtain the rate constants of the dissociation of $(M^+ \cdot e_s^-)$ and $M^-$ as well as the formation constants of $M^-$. A part of the results has been reported in a preliminary note (10).[2]

## Experimental

The test solutions used contained solvated electrons and one of the supporting electrolytes, 0.5 *M* LiCl, 0.5 *M* KI, and 0.1 *M*

CsI, in methylamine or methylamine–ammonia mixed solvents. The mixtures were prepared by distillation of a required amount of ammonia into the cell containing a methylamine base solution. The procedures of solvent purification and base solution preparation were described previously (9, 11). Solvated electrons were generated by electrolysis with the cell of Fig. 1 in ref. 11, when their exact concentration must be known, and otherwise with the cell of Fig. 1 in ref. 9. The concentration thus known is the total concentration defined by $c_t = [e_s^-] + [(M^+ \cdot e_s^-)] + 2[M^-]$, where the brackets refer to the concentration in molarity. Tungsten electrodes were used as the working electrode (9–12). Potential-sweep voltammetric and potential-step chronoamperometric experiments were performed in the way described previously (12). In the former experiments the electrode potential was scanned anodically from the equilibrium potential, $E_{eq}$. In the latter ones it was stepped by +50–100 mV from $E_{eq}$ to the limiting current region. The lowest step height was used in the case of low $c_t$ in order to minimize the effect of capacity current. The current–time curves were recorded with a Kawasaki Electronica HR-1200 transient memory and a Riken Denshi F-3DP X-Y recorder. Measurements were made at −50 ± 1°C.

## Results

### *Potential-sweep voltammetry with methylamine solutions*

When $c_t$ and the sweep rate $v$ were below 0.1 m$M$ and 1 V s$^{-1}$, respectively, the potential-sweep voltammograms of 0.5 $M$ LiCl and 0.1 $M$ CsI solutions exhibited features characteristic of the diffusion-controlled electron-transfer process whose number of electron transferred, $n$, is one, as in the case of liquid ammonia solutions (12). In those of 0.5 $M$ KI solutions, however, the difference between $E_{eq}$ and the potential at which the anodic current peak occurs, $E_p$, became greater than 17 mV, a value close to the theoretical value of 16.4 mV which an electrode reaction of $n = 1$ is expected to have at −50°C, when $c_t$ was increased beyond ca. 0.01 m$M$. The $E_p - E_{eq}$ value at a given $c_t$ came to deviate from the theoretical value with increasing $v$. Furthermore, the plot of the peak current $i_p$ vs. $v^{1/2}$ at low $v$ values fitted a straight line through the origin, whereas it bent downwards with increasing $v$. The same behaviour of the $i_p$ vs. $v^{1/2}$ relation has been observed in experiments with an Na–$NaClO_4$ solution of hexamethylphosphoric triamide and attributed to the slow dissociation of some associated species of $e_s^-$ competing with the electron transfer process (13).

Solvated electrons generated by the pre-electrolysis of base solutions decomposed gradually during measurements. They were most unstable in LiCl solutions and most stable in KI solutions. Figure 1 shows a typical $i_p$ change with time in a 0.5 $M$ LiCl solution. No anodic current attributable to the oxidation of any decomposition products of solvated electrons was observed at potentials between 0 and 1.5 V referred to the respective initial $E_{eq}$'s.

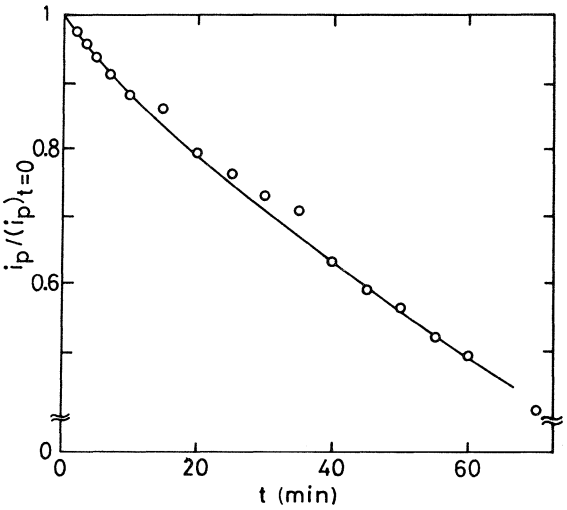

FIG. 1. Decomposition rate of solvated electrons in a 0.5 $M$ LiCl solution of methylamine at −50°C observed by potential-sweep voltammetry. Sweep rate: 50 mV s$^{-1}$.

### *Potential-step chronoamperometry with methylamine solutions*

Figure 2 shows $i_l t^{1/2}$ vs. log $t$ plots, $i_l$ being the limiting current density in potential-step chronoamperometry, obtained with 0.5 $M$ LiCl solutions whose $c_t$ values range from 0.05 to 1 m$M$. In all the curves the $i_l t^{1/2}$ value was independent of time, as in liquid ammonia (11, 12). This fact suggests that the electrode reaction should be a simple diffusion-controlled process. The $i_l t^{1/2}$ values for 0.1 $M$ CsI solutions within the time range of 5 to 600 ms were also almost invariable, when $c_t$ was below ca. 0.1 m$M$. However, an attempt to obtain information on the dissociation kinetics of $Cs^-$ was unsuccessful because of serious ohmic drop error due to high current densities caused by the use of solutions of high $c_t$ where $Cs^-$ is predominant. On the basis of these findings and the reaction schemes proposed previously (9), it is concluded that the lower limit of the rate constant $k_1$ for the dissociation of the ion pairs, $(Li^+ \cdot e_s^-)$ and $(Cs^+ \cdot e_s^-)$, is about $10^3$ s$^{-1}$, which is the reciprocal of the effective rise-time of the potentiostat under the experimental conditions employed.

Figure 3, a reproduction of Fig. 2 in ref. 10, shows $i_l t^{1/2}$ vs. log $t$ plots obtained with 0.5 $M$ KI solutions whose $c_t$ is below 0.1 m$M$. In the lowest curve corresponding to region I in Fig. 1 of ref. 10, the $i_l t^{1/2}$ values are independent of time as in LiCl and CsI solutions. This fact suggests that the $k_1$

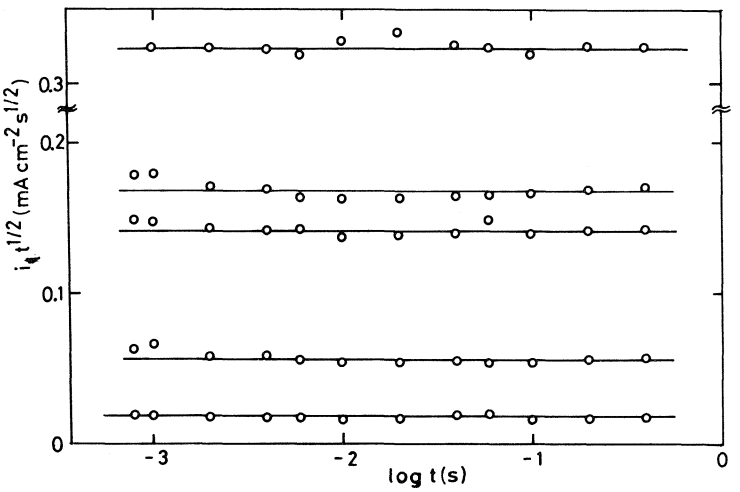

FIG. 2. $i_l t^{1/2}$ vs. log $t$ plots in potential-step chronoamperometry for solvated electrons in 0.5 $M$ LiCl solutions of methylamine at −50°C; $0.05 < c_t(\mathrm{m}M) < 1$.

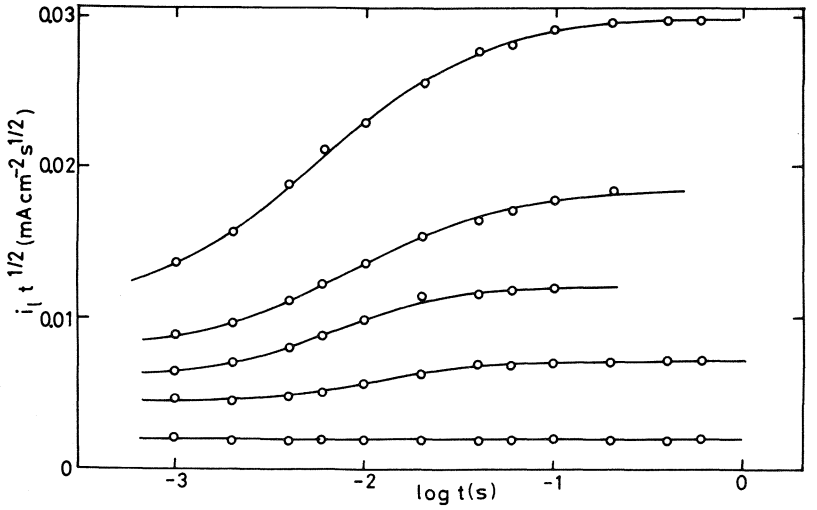

FIG. 3. $i_l t^{1/2}$ vs. log $t$ plots in potential-step chronoamperometry for solvated electrons in 0.5 $M$ KI solutions of methylamine at −50°C; $0.005 < c_t(\mathrm{m}M) < 0.1$.

value for $(K^+ \cdot e_s^-)$ should also be greater than $10^3$ $s^{-1}$. In solutions of higher $c_t$, where $K^-$ coexists with the one-electron species, each $i_l t^{1/2}$ vs. log $t$ curve has two plateaux and a transient region between them. The $i_l t^{1/2}$ values at the left and the right plateaux are denoted by $(i_l t^{1/2})_1$ and $(i_l t^{1/2})_2$, respectively. The transition region comes to be extended on both sides with increasing $c_t$. The current density at the left plateau is considered to be controlled by the diffusion of the one-electron species. The increase in $i_l t^{1/2}$ with time in the transition region may be attributed to the kinetic current (14) due to the formation of the one-electron species from $K^-$:

$$[1] \quad K^+ + K^- \underset{}{\overset{k_2}{\rightleftharpoons}} 2(K^+ \cdot e_s^-), (K^+ \cdot e_s^-) \underset{K^+ + e_s^-,\ e_s^- \rightarrow e_m^-}{\overset{k_1 > 10^3\ s^{-1}}{\rightleftharpoons}}$$

where $k_2$ is the second-order rate constant and $e_m^-$ the electron in electrode metal. In solutions of $c_t > 0.1$ m$M$, the $i_l t^{1/2}$ vs. log $t$ plots were irreproducible. It may be interpreted in terms of potassium metal deposition onto the electrode surface, as was the irreproducibility of the $-E$ vs. log $i$ plots at highly negative potentials (9). Details of the $i_l t^{1/2}$ vs. log $t$ curves for solutions of low $c_t$ are shown in

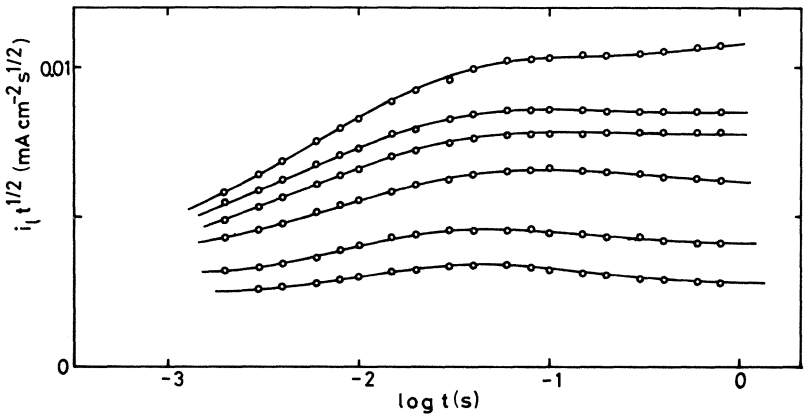

FIG. 4. Detailed plots for $i_l t^{1/2}$ vs. log $t$ in potential-step chronoamperometry for solvated electrons in 0.5 $M$ KI solutions of methylamine at −50°C; $0.005 < c_t(\mathrm{m}M) < 0.03$.

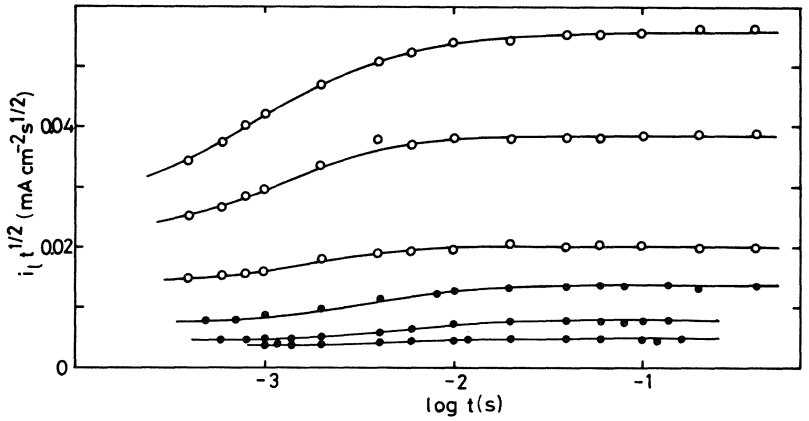

FIG. 5. $i_l t^{1/2}$ vs. log $t$ plots in potential-step chronoamperometry for solvated electrons in 0.5 $M$ KI solutions of (●) methylamine–ammonia (2.5 mol%) ($0.01 < c_t(\mathrm{m}M) < 0.04$) and (○) methylamine–ammonia (5.0 mol%) ($0.04 < c_t(\mathrm{m}M) < 0.15$).

Fig. 4. Each curve exhibited a broad peak at about 50 ms.

*Potential-step chronoamperometry with methylamine–ammonia mixed solutions*

Figure 5 shows $i_l t^{1/2}$ vs. log $t$ plots for solutions containing 0.5 $M$ KI and solvated electrons of various concentrations in methylamine–ammonia mixtures whose ammonia contents are 2.5 and 5.0 mol%. A comparison between Figs. 3 and 5 shows that the transition region of the $i_l t^{1/2}$ vs. log $t$ curve shifts to the left with increasing ammonia content. No such region was observed when ammonia content exceeded 10 mol%. In Fig. 6 are compared the normalized $i_l t^{1/2}$ vs. log $t$ plots for solvated electron solutions providing nearly equal $(i_l t^{1/2})_2$ values in pure methylamine and mixed solvents. The increasing shift of the transition region with increasing ammonia content explains why no transition region was observed when the pure ammonia solvent was used (11, 12).

$D_l$ *values in methylamine solutions of 0.5* M *KI and 0.1* M *CsI*

The results of the previous potential-sweep voltammetric (9) and the present potential-step chronoamperometric experiments suggests that the electrode reaction scheme in the region of $n = 1$ in methylamine should be exactly identical with that in liquid ammonia (12). Consequently, the diffusing species is a composite of $e_s^-$ and $(M^+ \cdot e_s^-)$ in rapid equilibrium. Its diffusion coefficient $D_l$ is given by the following equation (11):

$$[2] \quad D_l = ([e_s^-]D_e + [(M^+ \cdot e_s^-)]D_{ip})/([e_s^-] + [(M^+ \cdot e_s^-)]) = (D_e + K_1 D_{ip})/(1 + K_1)$$

with

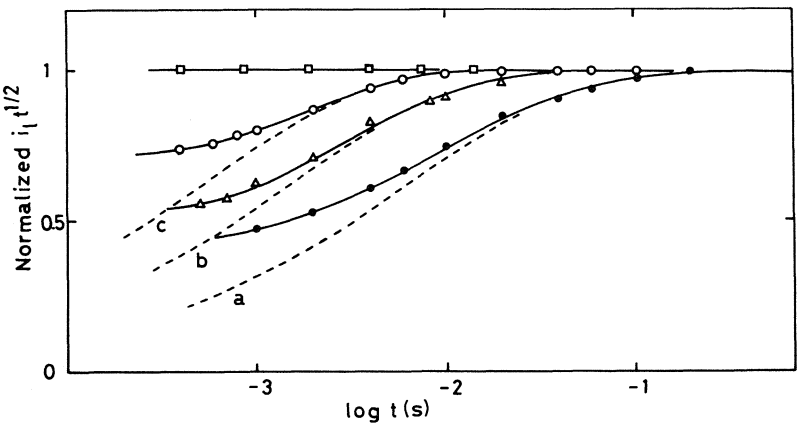

FIG. 6. Normalized plots of $i_l t^{1/2}$ vs. log $t$ for solvated electrons in 0.5 $M$ KI solutions of (●) methylamine, (△) methylamine–ammonia (2.5 mol%), (○) methylamine–ammonia (5.0 mol%), and (□) methylamine–ammonia (> 10 mol%). Broken lines are theoretical curves calculated from eq. [18] with $\alpha$ = (*a*) 15, (b) 67, and (c) 180 $s^{-1}$.

[3] $K_1 = [(M^+ \cdot e_s^-)]/[e_s^-]$

where $D_e$ and $D_{ip}$ are respectively the diffusion coefficients of $e_s^-$ and $(M^+ \cdot e_s^-)$. The $D_1$ values in methylamine were obtained by determining $c_t D_1^{1/2}$ voltammetrically and/or chronoamperometrically and $c_t$, which is practically equal to $[e_s^-] + [(M^+ \cdot e_s^-)]$, coulometrically.

The recovery ratio of solvated electrons in 0.5 $M$ KI solutions was approximately 71%, when determined by coulometric reoxidation which took about 100 min. Since each experimental run, i.e. the electrolytic generation of solvated electrons and the measurement of $c_t D_1^{1/2}$, took no more than 10 min, the decomposition of solvated electrons might affect the $D_1$ value to only a negligible extent. The $D_1$ values obtained by potential-step chronoamperometry and potential-sweep voltammetry were $4.1 \times 10^{-5}$ $cm^2$ $s^{-1}$ and $3.9 \times 10^{-5}$ $cm^2$ $s^{-1}$, respectively. The mean value of $4.0 \times 10^{-5}$ $cm^2$ $s^{-1}$ is used as the $D_1$ value in the 0.5 $M$ KI solution of methylamine at −50°C.

Figure 7 shows $c_t D_1^{1/2}$ vs. $c_t$ plots in 0.1 $M$ CsI solutions at −50°C obtained by potential-sweep voltammetry with sweep rates of 50 and 75 mV $s^{-1}$. All experimental points lie on a straight line. A $D_1$ value of $1.2 \times 10^{-5}$ $cm^2$ $s^{-1}$ could be obtained from its slope, but this might be the lower limit since the decomposition rate of solvated electrons in this solution was faster than in KI solutions.

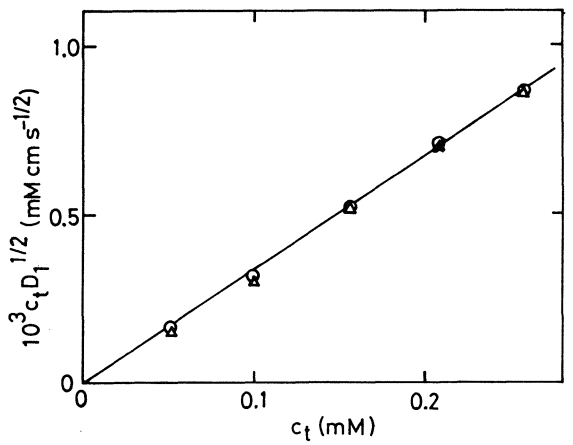

FIG. 7. Plots of $c_t D_1^{1/2}$ vs. $c_t$ for solvated electrons in 0.1 $M$ CsI solutions of methylamine at −50°C. $c_t D_1^{1/2}$ values are obtained by potential-sweep voltammetry with sweep rates of (○) 50 and (△) 75 mV $s^{-1}$. The $c_t$ values are determined coulometrically.

## Discussion

*Formation constant of two-electron species*

The electrode reaction of solvated electron species, $\varepsilon_{sol}$, is written in the form

[4] $n e_m^- \rightleftharpoons \varepsilon_{sol}$

When $n = 1$, $\varepsilon_{sol}$ is the one-electron species, i.e. a mixture of $e_s^-$ and $(M^+ \cdot e_s^-)$ in rapid equilibrium, and when $n = 2$, it is the two-electron species, presumably $M^-$ in the case of methylamine solutions.

The potential-sweep voltammograms in the regions of $n = 1$ and $n = 2$ are expressed respectively by the following equations (12):

[5] $E = -(RT/F) \ln i + (RT/2F) \ln v + A_1$

with

[6] $A_1 = E_1^0 + (RT/F)\{\ln F + \ln (FD_1/RT)^{1/2}\}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

and

$$[7] \quad E = -(RT/2F) \ln i + (RT/4F) \ln v + A_2$$

with

$$[8] \quad A_2 = E_2^0 + (RT/2F)\{\ln 2F + \ln(2FD_2/RT)^{1/2}\}$$

where $D_2$ is the diffusion coefficient of $M^-$. $E_1^0$ and $E_2^0$ are respectively the formal standard potentials of the electrode reaction [4] when $n = 1$ and 2 and they are defined respectively at $[e_s^-] + [(M^+ \cdot e_s^-)] = 1\,M$ and $[M^-] = 1\,M$. The difference between them can be given by the following equation, similar to the case where the two-electron species is $(M^+ \cdot e_s^-)_2$ (11):

$$[9] \quad E_1^0 - E_2^0 = -(RT/2F) \ln K_2$$

with

$$[10] \quad K_2 = [M^-]/([e_s^-] + [(M^+ \cdot e_s^-)])^2$$

The quantity $K_2$ is the formation constant of $M^-$ from the one-electron species and can be determined with the experimental values for $A_1, A_2, D_1$, and $D_2$. The $K_2$ value of $K^-$ in a 0.5 $M$ KI solution was $5.6 \times 10^4\ M^{-1}$, when the known values of $A_1 = -2.76$ V (9), $A_2 = -2.73$ V (9), and $D_1 = 4.0 \times 10^{-5}$ cm$^2$ s$^{-1}$ were used together with the $D_2$ value of $1.0 \times 10^{-5}$ cm$^2$ s$^{-1}$. The $D_2$ value was chosen by taking account of the diffusion coefficient of $K^+$ in methylamine, $1.5 \times 10^{-5}$ cm$^2$ s$^{-1}$, estimated from the mobility of $K^+$ in liquid ammonia (15) and the viscosities of liquid ammonia and methylamine (16).

The formation constant of $K^-$ was also obtained by analyzing the chronoamperometric results of Fig. 3. Since $(i_1t^{1/2})_1$ and $(i_1t^{1/2})_2 - (i_1t^{1/2})_1$ are attributed to the diffusion-controlled currents for the one- and the two-electron species, respectively, they can be written as follows:

$$[11] \quad (i_1t^{1/2})_1 = (F/\pi^{1/2})([e_s^-] + [(M^+ \cdot e_s^-)])D_1^{1/2}$$

and

$$[12] \quad (i_1t^{1/2})_2 - (i_1t^{1/2})_1 = (2F/\pi^{1-2})\,[K^-]D_2^{1/2}$$

Combining eqs. [11] and [12], one obtains

$$[13] \quad \{(i_1t^{1/2})_2 - (i_1t^{1/2})_1\}/(i_1t^{1/2})_1 = (2\pi^{1/2}/F)(D_2^{1/2}/D_1)K_2(i_1t^{1/2})_1$$

From the slope of the linear plot of $\{(i_1t^{1/2})_2 - (i_1t^{1/2})_1\}/(i_1t^{1/2})_1$ vs. $(i_1t^{1/2})_1$ in Fig. 8, the formation constant of $K^-$ was evaluated as $4.5 \times 10^4\ M^{-1}$.

The agreement between these $K_2$ values is satisfactory. This fact strongly suggests that the two-electron species in potential-sweep voltammetry should be identical with the slow-dissociating species in potential-step chronoamperometry.

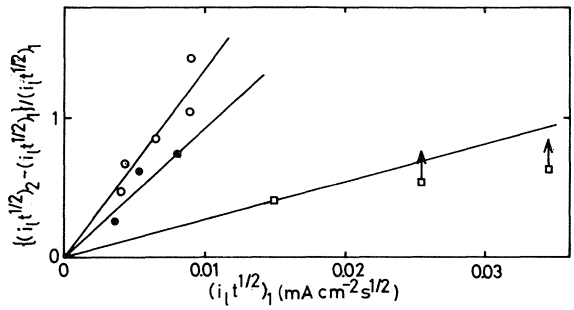

FIG. 8. Plots for obtaining the $K_2$ values in (○) methylamine, (●) methylamine–ammonia (2.5 mol%), and (□) methylamine–ammonia (5.0 mol%). (⇧) indicates a lower limit value.

Figure 9 shows the relative concentrations of the one- and the two-electron species at various $c_t$ values calculated with $K_2 = 5 \times 10^4\ M^{-1}$. The curves for $e_s^-$ and $(K^+ \cdot e_s^-)$ could not be drawn because the $K_1$ value was unavailable. A comparison between this illustration and the similar one obtained with liquid ammonia solutions (11) shows that the two-electron species prevails at much lower $c_t$ values in methylamine than in liquid ammonia.

From the previous potential-sweep voltammogram (9), the approximate value for the formation constant of $Cs^-$ in methylamine was estimated as $5 \times 10^2\ M^{-1}$, by using $A_1 = -2.76$ V, $A_2 = -2.77$ V, $D_1 = 1.2 \times 10^{-5}$ cm$^2$ s$^{-1}$, and $D_2 = 10^{-5}$ cm$^2$ s$^{-1}$. In a similar manner, the upper limit of the formation constant of $Li^-$ was evaluated to be $2 \times 10^1\ M^{-1}$. The order of magnitude of the $K_2$ values of these two-electron species in methylamine is thus as follows:

$$Li^- < Cs^- < K^-$$

It is noted that this is opposite to the solubility order (17) of these alkali metals.

*Dissociation rate constant of potassium anion*

The boundary value problem of the following electrode reaction in potential-step chronoamperometry was solved by the explicit finite difference method and, though applicable only in limited circumstances, the analytical method based on the reaction layer concept of Koutecky (see Appendix):

$$[14] \quad B \overset{k}{\rightleftharpoons} 2A,\ A \pm e_m^- \rightarrow C$$

where $k$ is the first-order rate constant[3] for the dissociation of B defined by $-d[B]/dt = k[B]$.

[3]In a preliminary note (10), the pseudo-first-order rate constant $k_2[K^+]$ for the dissociation of $K^-$ was defined by $-2d[B]/dt = k[B] \equiv (k_2[K^+])\,[B]$. The difference in definition should cause a difference in the $k_2[K^+]$ value by a factor of two.

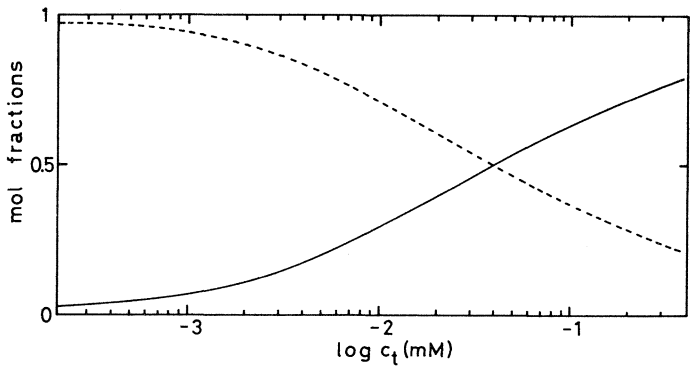

FIG. 9. Mole fractions of (------) the one-electron species and (——) the two-electron species in 0.5 *M* KI solutions of methylamine at −50°C calculated from the $K_2$ value.

The analysis of the electrode reaction of our present concern, reaction [1], can be reduced to that of reaction [14] because of the pseudo-first-order nature of the dissociation reaction of $M^-$ in the presence of a large excess of $M^+$ and the rapidity of the ion-pairing reactions. The chemical species B and A correspond respectively to $K^-$ and the composite one-electron species whose concentration and diffusion coefficient are $[e_s^-] + [(K^+ \cdot e_s^-)]$ and $D_1$, respectively. Then $k$, $K$, and $\alpha$ are given respectively by the following relations:

$$[15] \quad k = k_2[K^+]$$

$$[16] \quad K = K_2$$

and

$$[17] \quad \alpha = (2/3\pi)(D_1/D_2)\{([e_s^-] + [(K^+ \cdot e_s^-)])D_1/2D_2 + [K^-]\}^{-1/2} K_2^{-1/2} \times k_2[K^+]$$

Figure 10 shows the theoretical curves of $\Phi(\alpha t)$ vs. $\alpha t$ obtained by the explicit finite difference method. Each of them has a peak as do the experimental curves for $i_l t^{1/2}$ vs. log $t$ in Fig. 4. In Fig. 11 the two experimental curves at the bottom of Fig. 4 are fitted with the theoretical ones. The best fit was obtained with $k = 37\,s^{-1}$ in both cases, when the following experimental data were used: $D_1 = 4 \times 10^{-5}\,cm^2\,s^{-1}$, $D_2 = 1 \times 10^{-5}\,cm^2\,s^{-1}$, $K_2 = 5 \times 10^4\,M^{-1}$ and $[e_s^-] + [(K^+ \cdot e_s^-)] = 6.7 \times 10^{-3}$ and $8.3 \times 10^{-3}$ m*M* for the lowest and the upper curves, respectively. Those concentrations were determined from the $i_l t^{1/2}$ values at the left plateaux of the corresponding curves in Fig. 4.

Under the specific condition of $[K^-] \gg [e_s^-] + [(K^+ \cdot e_s^-)]$, the analytical method leads to the following expression for $i_l t^{1/2}$:

$$[18] \quad i_l t^{1/2} = (2F/\pi^{1/2})[K^-]D_2^{1/2}\Phi(\alpha t)$$

with

$$[19] \quad \alpha = (2/3\pi)(D_1/D_2)K_2^{-1/2}k_2[K^+][K^-]^{-1/2}$$

The uppermost curve of Fig. 3 was normalized and compared with the theoretical curves calculated from eq. [18] with various $\alpha$ values. The best fit was obtained with $\alpha = 20\,s^{-1}$. The disagreement at low $i_l t^{1/2}$ values, which is typically shown by curve (a) in Fig. 6, may be attributed to the condition $[B_0] \gg [A_0]$. It could not be fulfilled in our experiments because of inevitable metal deposition at $c_t >$ 0.1 m*M*. The same applies to curves (b) and (c). From eq. [19] with this $\alpha$ value the pseudo-first-order rate constant for the dissociation of $K^-$ was evaluated as $40\,s^{-1}$ in a 0.5 *M* KI solution of methylamine at −50°C. The agreement between the two $k_2[K^+]$ values is satisfactory.[4]

By using the $k_2[K^+]$ value of $40\,s^{-1}$, the rate constant for the formation of $K^-$ from the one-electron species, $kK = k_2[K^+]K_2$, was evaluated as $2 \times 10^6\,M^{-1}\,s^{-1}$. It is about three orders of magnitude smaller than the value in ethylamine, obtained with the pulse radiolysis technique, $6.2 \times 10^9\,M^{-1}\,s^{-1}$ (4). This is consistent with the finding that the formation process of $K^-$ in methylamine is too slow to be followed by this technique (2).

*Dissociation rate constants of the two-electron species in methylamine–ammonia mixed solvents*

It is evident from eq. [19] that the increase in the dissociation rate constant of $K^-$, $k_2[K^+]$, is not the only reason for the shift of the transition regions in Fig. 6 towards shorter times, because the quantities, $[K^-]$, $D_1/D_2$, and $K_2$, can also vary with the solvent composition. However, the change in $[K^-]$ cannot be responsible for the shift since the $i_l t^{1/2}$ vs. log $t$ plots in Fig. 6 were compared at nearly equal

[4]This fact suggests that eq. [18] can be used to determine $k_2[K^+]$ even when $[K^-] \simeq [e_s^-] + [(K^+ \cdot e_s^-)]$. The results of chronoamperometry with mixed solvents will be discussed on the basis of eq. [18].

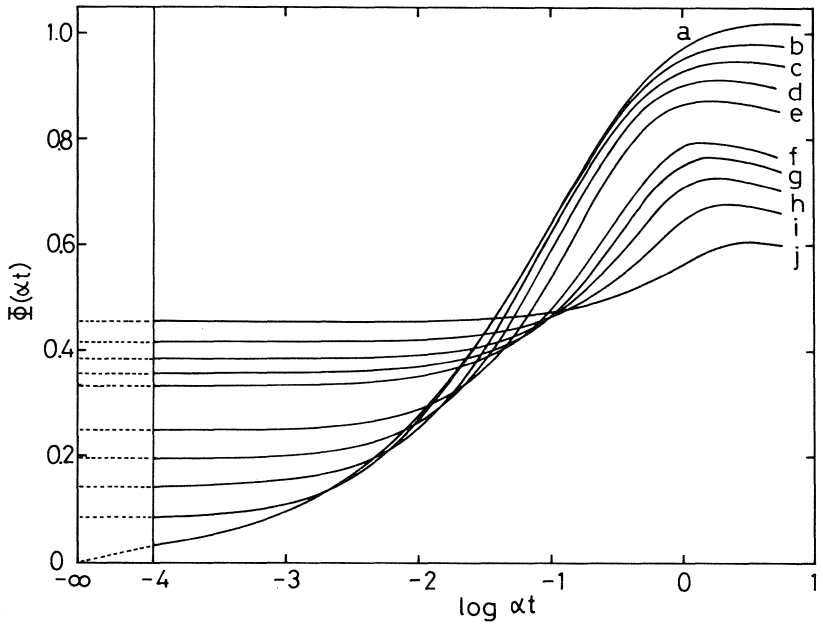

FIG. 10. $\Phi(\alpha t)$ vs. $\alpha t$ curves for $D_B/D_A = 0.25$ obtained by the explicit finite difference method with [B]/[A] = (b) 10, (c) 5, (d) $10^{1/2}$, (e) 2, (f) 1, (g) 0.8, (h) 0.6, (i) 0.4, and (j) 0.2. Curve a is obtained by the analytical method with [B]/[A] = ∞.

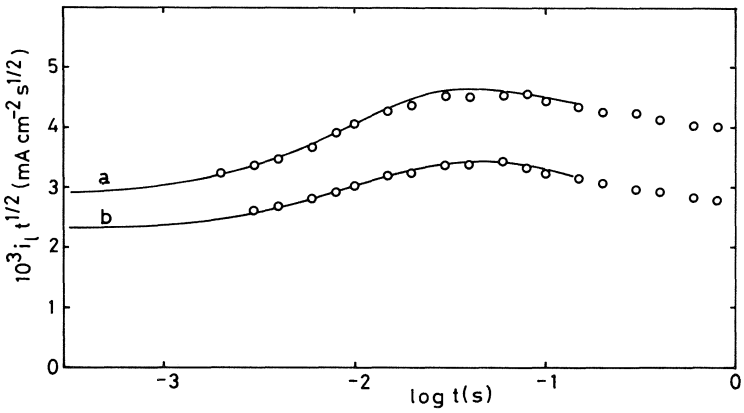

FIG. 11. Simulation analysis for obtaining the $k_2[K^+]$ value. Experimental points are reproductions of the lower two curves in Fig. 4. Solid lines are calculated by using the theoretical curves of Fig. 10 with $k_2[K^+] = 37\ s^{-1}$, $D_1 = 4.0 \times 10^{-5}\ cm^2\ s^{-1}$, $D_2 = 1 \times 10^{-5}\ cm^2\ s^{-1}$, $K_2 = 5 \times 10^4\ M^{-1}$, and $[e_s^-] + [(K^+ \cdot e_s^-)] =$ (a) $8.3 \times 10^{-3}$ m$M$ and (b) $6.7 \times 10^{-3}$ m$M$.

$(i_1 t^{1/2})_2$ values, i.e. $[K^-]$ values. The change in $D_1/D_2$ caused by the solvent composition change may also be unimportant since it ranges between the values of ca. 3 in pure ammonia (11) and 4 in pure methylamine.

The $K_2$ values in mixed solvents were obtained by using the slopes of the $\{(i_1 t^{1/2})_2 - (i_1 t^{1/2})_1\}/(i_1 t^{1/2})_1$ vs. $(i_1 t^{1/2})_1$ plots in Fig. 8 and a constant $D_1/D_2$ value of 4. The values for $\alpha$ and, consequently, $k_2[K^+]$ were obtained from eq. [18] using the uppermost curve for each solvent composition in Fig. 5 in order that the condition $[B_0] \gg [A_0]$ might be satisfied as fully as possible. In Table 1 are listed the values for $\alpha$, $K_2$, and $k_2[K^+]$ in mixed and pure solvents. An increase in ammonia content caused a decrease in $K_2$ as well as an increase in $k_2[K^+]$. According to eq. [19] both changes operate as factors to shift the transition region to shorter times.

The nature of the ion pairs in various solvents has recently been discussed on the basis of the hyperfine structure of the esr spectrum and the third absorption band observed in pulse radiolysis of solvents of relatively low polarity (18). It led to the conclusion that the atomic character of the ion pairs increased with the decreasing dielectric con-

stant of the solvent. The increase in the atomic character means the decrease in the solvent-separated nature. The values for the dipole moment and the dielectric constant of ammonia, 1.47 D and 22, are greater than those of methylamine, 1.27 D and 15. Consequently, the solvent-separated nature of the two-electron species may become enhanced by the addition of ammonia to methylamine. The increase in dissociation rate constant of the two-electron species caused by the addition of ammonia to methylamine may be interpreted on this basis. The idea of the solvent-separated nature of the two-electron species employed here is consistent with the model proposed for the associated species in alkali metal – ammonia solutions (19).

## Appendix

This appendix describes a theoretical treatment of chronoamperometric curves for an electrode process preceded by the dissociation of a dimer, the general scheme of which is expressed as

[A1] $B \underset{}{\overset{k}{\rightleftharpoons}} 2A,\ A \pm ne_m^- \rightarrow C$

Under the condition of linear diffusion, our boundary value problem is given by

[A2] $\partial[B]/\partial t = D_B\partial^2[B]/\partial x^2 - k([B] - K[A]^2)$

[A3] $\partial[A]/\partial t = D_A\partial^2[A]/\partial x^2 + 2k([B] - K[A]^2)$

with the initial and boundary conditions:

[A2] $$\begin{cases}[A] = [A_0],\ [B] = [B_0] = K[A_0]^2 \text{ for } t = 0,\ x > 0 \text{ and } t > 0,\ x \rightarrow \infty \\ [A] = 0,\ \partial[B]/\partial x = 0,\ D_A\partial[A]/\partial x = i_l/nF \text{ for } t > 0,\ x = 0\end{cases}$$

where $[A_0]$ and $[B_0]$ represent respectively the concentrations of A and B in the bulk of the solution and B is assumed to be electroinactive.

Since it is difficult to solve this nonlinear problem analytically, a digital simulation method outlined by Feldberg (20) was employed. The discretization of time and space into a number of increments of duration $\Delta t$ and JMAX space elements of equal size $\Delta x$, respectively, and transformation of eqs. [A2]–[A4] leads to explicit finite difference equations. Current density is calculated from the concentration of A in the first space element adjacent to the electrode, $C_A$, by using

[A6] $\text{CDNORM} = (\Delta t/\Delta x)(i/nF)/[B_0] = 2DD_AC_A(1)$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

in terms of the dimensionless quantities defined by

$$[A5]\quad \begin{cases} C_A(J) = [A_J]/[B_0],\ C_B(J) = [B_J]/[B_0],\ DD_A = D_A\Delta t/(\Delta x)^2 \\ DD_B = D_B\Delta t/(\Delta x)^2,\ \text{RATE} = k\Delta t,\ \text{EQ} = [B_0]/[A_0] = (k[B_0])^{1/2} \end{cases}$$

where $[A_J]$ and $[B_J]$ denote the concentrations of A and B in the $J$-th space element, respectively. The concentrations in the $J$-th space element are modified according to the following equations,

$$[A7]\quad \begin{cases} C_A'(1) = C_A(1) + DD_A[C_A(2) - C_A(1)] - \text{CDNORM} + 2\ \text{REAC}\ (1) \\ C_B'(1) = C_B(1) + DD_B[C_B(2) - C_B(1)] - \text{REAC}\ (1) \end{cases}$$

$$[A8]\quad \begin{cases} C_A'(J) = C_A(J) + DD_A[C_A(J+1) - 2C_A(J) + C_A(J-1)] + 2\ \text{REAC}\ (J) \\ C_B'(J) = C_B(J) + DD_B[C_B(J+1) - 2C_B(J) + C_B(J-1)] - \text{REAC}\ (J) \\ \qquad\qquad \text{for } 2 < J < \text{JMAX} \end{cases}$$

with

$$[A9]\quad \text{REAC}\ (J) = \text{RATE}\ [C_B(J) - \text{EQ}^2 C_A(J)^2] \text{ for } 1 < J < \text{JMAX}$$

where the primed quantities are evaluated at time $t + \Delta t$ while the unprimed ones are evaluated at $t$ and JMAX is taken as $6(D_A t)^{1/2}/\Delta x$. For each iteration of the time loop, $I = t/\Delta t = 1, 2, 3, \ldots$, values of a dimensionless function, $\Phi$, and a variable, $\xi$, are calculated. They are defined by

$$[A10]\quad \Phi = (\pi t/D_B)^{1/2}(i_l/nF)\{[A_0](D_A/D_B) + 2[B_0]\}^{-1}$$

and

$$[A11]\quad \xi = \alpha t$$

with

$$[A12]\quad \alpha = (2k/3\pi)(D_A/D_B)[K\{[A_0](D_A/2D_B) + [B]\}]^{-1/2}$$

Calculations were made on a computer FACOM M160 for various values of ratios $D_B/D_A$ and $[B_0]/[A_0]$ as parameters. The FORTRAN program is available from the authors (K.T. and H.M.) on request. Figure 10 shows variations of $\Phi$ with $\alpha t$ for a particular case of $D_B/D_A = 0.25$.

When the condition $[B_0] \gg [A_0]$ prevails and a steady-state condition for A is assumed in the reaction layer of thickness $\mu$, i.e.,

$$[A13]\quad \partial[A]/\partial t = 0 \text{ and } [B] = \text{const for } 0 < x < \mu$$

eqs. [A2]–[A4] are converted to an integral equation. Introducing a function

$$[A14]\quad f = [A] + 2(D_B/D_A)[B]$$

and using eq. [A13], we have

$$[A15]\quad \partial f/\partial t = D_B\partial^2 f/\partial x^2$$

and

$$[A16]\quad D_A d^2[A]/dx^2 + 2k([B] - K[A]^2) = 0 \text{ for } 0 < x < \mu$$

Following the procedure used by Koutecky and Hanus (21), we obtain an integral equation with respect to $(i_l/nF)$:

$$[A17]\quad (i_l/nF)^{4/3} = \{(8kD_A)^{2/3}/(9K)^{1/3}\}\{(D_A/2D_B)[A_0] + [B_0] - (1/2(\pi D_B)^{1/2}) \int_0^t (i_l/nF)/(t-u)^{1/2} du\}$$

Introducing the dimensionless variable $\xi$ defined by eq. [A11] and $\Psi$ defined by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

[A18] $\Psi(\xi) = (i_l/nF)(3/8kD_A)^{1/2}K^{1/4}\{[A_0](D_A/2D_B) + B_0]\}^{-3/4}$

into eq. [A17], we have

[A19] $[\Psi(\xi)]^{4/3} = 1 - \int_0^{\xi}(\xi - \eta)^{-1/2}\Psi(\eta)d\eta$

From eqs. [A10], [A11], and [A18], it is easily seen that

[A20] $\Phi(\xi) = \pi\xi^{1/2}\Psi(\xi)$

Equation [A19] was solved by the use of numerical integration. Variation of $\Phi$ with $\alpha t$ its also shown in Fig. 10 (curve a); $\Phi$ has a maximum value of 1.0192 at $\alpha t = 2.34$.

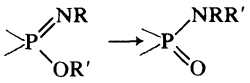
Reçu le 13 mai 1981

MARIE ROSE MARRE, MICHEL SANCHEZ, JEAN FRANÇOIS BRAZIER, ROBERT WOLF et JACQUES BELLAN. Can. J. Chem. **60**, 456 (1982).

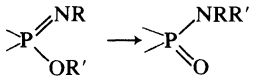
Nous avons préparé, suivant la réaction de Staudinger, douze iminophospholanes (**1–12**) à cycle dioxa (**1–4**), oxaza (**5**, **6**) et diaza (**7–12**). Ces derniers composés n'ont jamais conduit au dimère diazadiphosphétidine quelle que soit la nature du substituant sur l'atome d'azote imino. Pour les composés à cycle tétraméthyl dioxaphospholane (**1**, **2**, **4**) le réarrangement thermique



se produit avec l'atome d'oxygène intracyclique. Enfin l'action du méthanol sur ces dérivés, a mis en évidence une différence de comportement: addition conduisant à la pentacoordination pour les composés à cycle pinacolique, associations intermoléculaires de type pont hydrogène pour les dérivés à cycle diazaphospholane.

MARIE ROSE MARRE, MICHEL SANCHEZ, JEAN FRANÇOIS BRAZIER, ROBERT WOLF and JACQUES BELLAN. Can. J. Chem. **60**, 456 (1982).

Using the Staudinger reaction, we have synthesized twelve iminophospholanes (**1–12**) with dioxa (**1–4**), oxaza (**5**, **6**), and diaza (**7–12**) ring systems. We have never observed any phosphazene bond dimerization with diazaphospholane compounds, whatever the nature of the group on the imino atom. For the tetramethyl dioxaphospholane compounds (**1**, **2**, **4**), the thermal rearrangement



occurs with the intracyclic oxygen atom. Last of all, the reactivity of the phosphazene bond with methanol differs according to the nature of the ring: addition leading to the pentacoordinated species in pinacolic compounds, intermolecular associations (hydrogen bonding) in diazaphospholane derivatives.

## Introduction

Depuis les travaux de Staudinger et Meyer (1) et ceux plus récents de Zhmurova et Kirsanov (2), la chimie des organo-phosphorés tétracoordonnés à liaison phosphazène ( ) s'est largement développée. L'essor des iminophosphanes (3*a*) et surtout des polycyclophosphazènes (3*b*) a marqué la dernière décennie tant par le nombre de réactions originales que par la grande diversité des applications, par exemple dans le domaine des polymères (4) ou des antimitotiques (5).

La liaison phosphazène s'apparente aux liaisons phosphoylure ( ), phosphoryle (  ) ou thiophosphoryle ( ). De par sa réactivité, on lui connait beaucoup d'analogies avec la liaison phosphoylure, en particulier la réaction de type Wittig (6). Les divergences sont toutefois nombreuses. Parmi celles-ci, citons deux exemples.

(*i*) La réaction de dimérisation [1], très courante dans la chimie des iminophosphanes (7), est inconnue dans celle des ylures.

[1] 
Monomère Dimère

(*ii*) La réaction d'addition de réactifs à hydrogène mobile (XH) qui a été observée dans les phosphoylures (8), reste exceptionnelle dans les iminophosphanes.

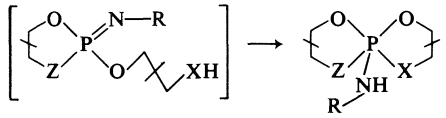
Des travaux récents (9) ont cependant montré que cette réaction d'addition [2] pouvait s'appliquer dans certains cas à la liaison $\rangle P{=}N{-}$:

[2] 
Sur ce thème, nous avons apporté notre contribution (10) en démontrant qu'une addition intramoléculaire dans un intermédiaire iminophosphane conduisait à un amino-phosphorane:



L'objet de cet article est d'exposer et de discuter les particularités de la réaction de synthèse de douze nouveaux iminophospholanes. Sur ces composés, nous avons par ailleurs étudié l'action du méthanol et montré la diversité du comportement de la liaison phosphazène suivant la nature du cycle branché sur l'atome de phosphore.

## Résultats et discussion

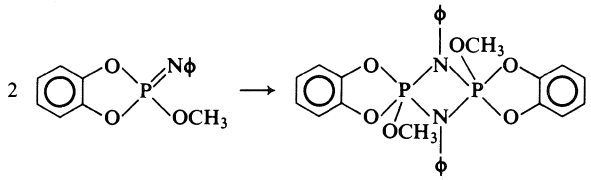
I. *Réaction générale de synthèse, choix des substrats phosphorés*

La réaction de Staudinger (1) (schéma [3]), action d'un azoture sur un composé du phosphore tricoordonné, est la voie d'accès aux iminophosphanes utilisée dans la préparation de la totalité de nos composés. Simple dans son principe, cette réaction présente l'avantage de se dérouler dans des conditions douces de température. De plus, l'avancement de la réaction peut être contrôlé par le dégagement d'azote correspondant:

[3] $R_3P + N_3R' \rightarrow [R_3P{=}N_3R'] \xrightarrow{-N_2} R_3P{=}NR'$

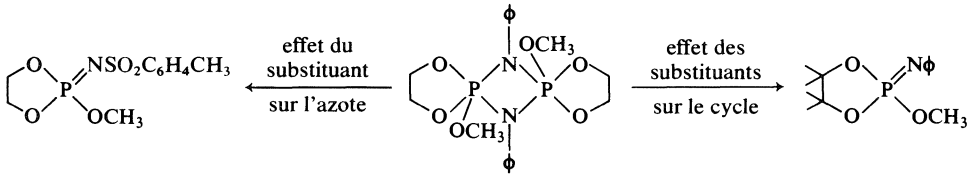
Trois azotures (R′ = $-C_6H_5$, $-SO_2-C_6H_4-CH_3$, $-C_2H_5$) ont été opposés à des substrats phosphorés monocycliques. Dans le choix de ces derniers, nous avons été confrontés à une difficulté inhérente à la nature même de la liaison phosphazène, à savoir la dimérisation spontanée du produit attendu en diazadiphosphétidine (réaction [1]).

La frontière dimère ($P^V$) ⇆ monomère ($P^{IV}$) est très sensible à la polarisation de la liaison P=N (*7a*). Celle-ci dépend de la nature des substituants: le seul remplacement d'un substituant sur l'atome de phosphore suffit par exemple à stabiliser l'une ou l'autre des deux formes. C'est ainsi que le cycle orthophénylène dioxaphospholane, par l'effet électroattracteur des atomes d'oxygène, accentue la polarité $P^{\delta+}-N^{\delta-}$ de la liaison phosphazène et entraîne la dimérisation (*7b*):

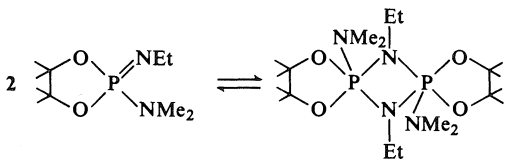


Il en est de même du cycle dioxaphospholane; toutefois, en passant au cycle tétraméthyldioxaphospholane (pinacolique), les substituants méthyle contrebalancent l'effet d'électronégativité des oxygènes et stabilisent la structure monomère.

La présence d'un substituant électronégatif sur l'azote est aussi un facteur favorable à la forme monomère. Les trois exemples suivants résument ce qui précède:



Nous avons également mis récemment (11) en évidence l'équilibre:



C'est en tenant compte de toutes ces observations que nous avons préparé douze dérivés monocycliques possèdant l'une des trois sortes de cycle: dioxa, oxaza et diaza-phospholanes. Il est remarquable de noter que ces derniers sont les seuls pour lesquels nous n'avons pas observé de forme dimère, quel que soit le substituant sur l'azote imino.

L'ensemble des composés synthétisés et étudiés

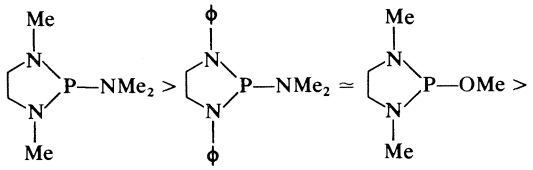
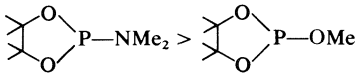
figurent dans le tableau 1. Nous y avons reporté les principaux paramètres de rmn de $^{31}P$, $^{1}H$, et les conditions de préparation.

II. *Particularités de la réaction de Staudinger rencontrées dans la préparation des iminophospholanes*

1. *Réactivité relative des phosphanes et des azotures*

Dans la préparation des différents iminophospholanes, nous avons constaté que la réactivité du phosphane sur l'azoture est très différenciée quand on passe d'une famille de dérivés à une autre. Ainsi, pour un même azoture ($\phi N_3$ par exemple), les dérivés à cycle diazaphospholane se révèlent plus réactifs que ceux ayant un cycle dioxaphospholane. De plus la présence d'un substituant $NMe_2$ accroît la réactivité du phosphane. Ces observations situent donc les diméthylamino diazaphospholanes comme les phosphanes les plus réactifs que nous ayons utilisés. Les atomes d'azote, par effet donneur d'électrons, augmenteraient la nucléophilie de l'atome de phosphore, ce qui expliquerait ainsi l'ordre décroissant de réactivité rencontré:

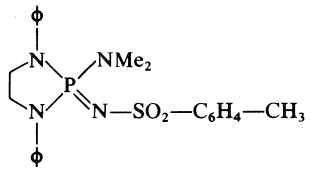




Le deuxième facteur intervenant dans la réaction de Staudinger est lié au caractère électrophile de l'azoture. Celui-ci est d'autant plus grand que les substituants présents sur la fonction azoture sont électroattracteurs. Ainsi la réactivité de ces substrats varie dans l'ordre suivant:

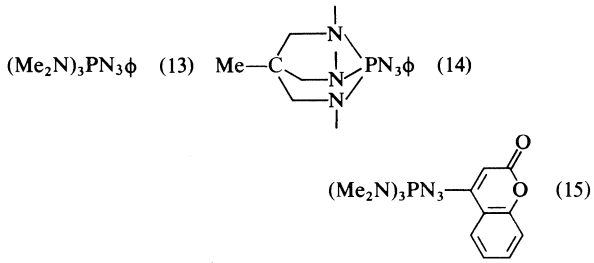
$$Me—C_6H_4—N_3 > C_6H_5—N_3 > C_2H_5—N_3$$

Ces deux facteurs agissent dans le même sens dans la préparation de **12**, synthétisé dans des conditions douces, avec un excellent rendement.

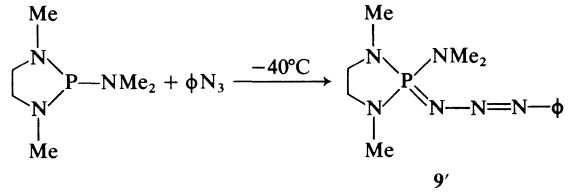


**12**

Dans l'étude de la réactivité des phosphanes vis-à-vis des azotures, nous avons cherché à mettre en évidence l'adduit triazène (phosphane-azoture) intermédiaire de la réaction de Staudinger (12). Ce type de dérivés existe, un petit nombre d'exemples, pour lesquels l'atome de phosphore est entouré de quatre atomes d'azote, ayant été décrits dans la littérature:



La relation entre basicité du phosphore dans les $P(NR_2)_3$ et stabilité de l'adduit avec $C_6H_5N_3$, établie par Kroshefsky et Verkade (14), nous laissait supposer que le cas le plus favorable pour que cet adduit soit stabilisé pourrait être **9′**.

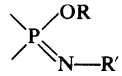


**9′**

En fait, cet adduit est un intermédiaire très labile, qui, dès sa formation, se décompose rapidement pour conduire à l'iminophosphane **9**. Nous avons pu toutefois le caractériser à basse température ($\delta^{31}P = +41$). Il semble que l'adduit triazène, dans les autres composés phosphorés étudiés ici, relèverait plus de l'état de transition que de l'intermédiaire de réaction.

2. *Réarrangement thermique iminophosphane – ester aminophosphorique*

Dans le tableau 1, nous constatons que les $\delta^{31}P$ des mélanges réactionnels bruts des composés **1**, **2**, **7** qui présentent tous le motif:



comportent deux valeurs: l'une appartenant à un signal intense (90%) situé à champ fort, est attribuable à l'iminophosphane recherché, l'autre, située à champ plus faible, résulte de la présence d'une entité phosphorylée[1] qui s'est formée en

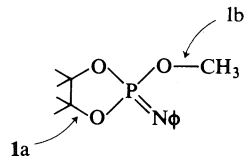
[1]Selon Kroshefsky et Verkade (14), la variation de $\delta^{31}P$ vers les champs faibles est caractéristique du passage $\geq P=N- \rightarrow \geq P=O$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

faible proportion (10%) au cours de la synthèse.

Cette forme phosphorylée provient du réarrangement thermique qui assure la migration du groupe R′ de l'alcoxy vers l'atome d'azote imino, formant ainsi une liaison phosphoryle thermodynamiquement plus stable que la liaison phosphazène.

[4] 
Ce type de réarrangement a été étudié tant en série acyclique (16) que cyclique (17). Dans cette dernière famille, nous avons étudié plus précisément le comportement du composé **1** qui peut s'isomériser thermiquement suivant les deux voies 1a et 1b en fonction des deux ruptures de liaison O—C possibles, cyclique (pour 1a) et exocyclique (pour 1b):



**1**

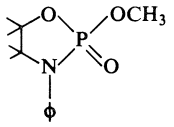
Une solution de **1** dans le toluène-$d_8$, est chauffée à 100°C pendant 40 h. En rmn de $^{31}P$ nous observons la disparition totale du signal appartenant à **1** ($\delta$ = 4,5) et la croissance de deux signaux d'inégale intensité, l'un à $\delta$ = 12,5 (70%) l'autre à $\delta$ = 14,6 (30%). Ces signaux sont attribuables à deux entités phosphorylées: la première existait déjà et sa concentration a augmenté notablement, la seconde s'est formée au cours du chauffage prolongé. Nous l'avons facilement identifiée comme étant le composé **1***b* synthétisé par la réaction [5]:

[5] 
**1***b*

La concordance des paramètres de rmn de $^{31}P$ ($\delta$ = 14,5) et de $^1H$ (doublet P—N—$CH_3$ $\delta$ = 3,0, $J$ = 10 Hz) entre le produit synthétisé et celui qui apparait en solution démontre sa formation à partir de **1** au cours du chauffage.

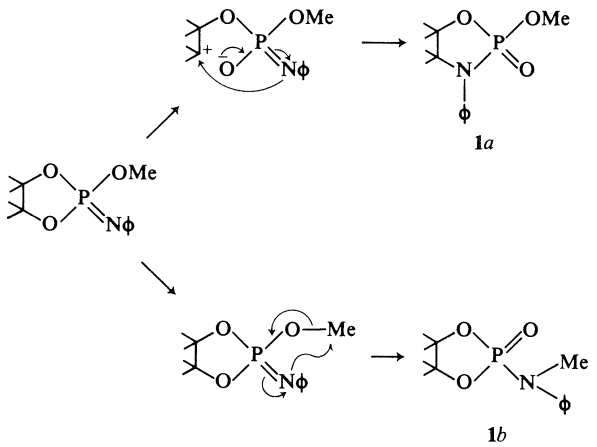
L'entité à $\delta$ = 12,5 appartient à l'isomère **1***a* qui résulte de l'ouverture du cycle tétraméthyldioxaphospholane. En effet la présence d'un doublet $OCH_3$ ($\delta$ = 3,37, $^3J_{HP}$ = 11,5 Hz) prouve que l'isomérisation thermique n'a pas touché le motif P—$OCH_3$. De plus, les signaux $CH_3$ du cycle pinacolique se sont modifiés très sévèrement: ils se présentent sous la forme de quatre signaux, différents des deux singulets du composé **1**.

Ces arguments nous amènent à proposer pour **1***a* la structure suivante:



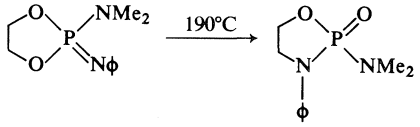
**1***a*

Il est intéressant de noter que, des deux réarrangements thermiques qui conduisent à **1***a* et **1***b*, c'est le premier qui est favorisé. Cela peut résulter de la stabilité relative des deux carbocations qui se forment dans les intermédiaires lors de la rupture de la liaison O—C du cycle (dans **1***a*) ou exocyclique (dans **1***b*). La stabilisation du carbocation tertiaire est la "force motrice" qui conduit préférentiellement à **1***a* par un réarrangement intracyclique.



**1***b*

Gilyarov *et al.* (17) a décrit un réarrangement de ce type à des températures plus élevées:



Il est manifeste que, dans notre cas, la substitution du cycle dioxaphospholane par des groupes $CH_3$, abaisse la barrière d'isomérisation thermique de telle sorte que le réarrangement phosphazène → phosphoryle intervient à des températures plus basses.

III. *Addition du méthanol aux iminophospholanes*

Rappelons tout d'abord les travaux antérieurs (9*a*, 10) qui ont montré le caractère quasi général

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

de la réaction d'addition intramoléculaire d'une fonction alcool (ou amine) sur la liaison P=N. Dans le cas où la réaction est menée de manière intermoléculaire elle n'est plus aussi générale; Cadogan *et al.* (*9b*) l'obtiennent encore dans le cas très particulier des α diols qui réagissent sur des iminodioxaphospholanes. Dans notre travail, nous allons mettre en lumière une différence importante de réactivité selon la nature du cycle dans lequel est inséré le phosphore: on peut ainsi classer en deux groupes les comportements rencontrés, suivant qu'on assiste au passage du phosphore à la pentacoordination, ou qu'il y a conservation de la tétracoordination, avec seulement associations moléculaires.

1. *Addition avec passage à la pentacoordination*

Elle a lieu pour les composés (**1**, **2** et **4**) possèdant le cycle tétraméthyl dioxaphospholane. Nous allons présenter en détail l'expérience réalisée avec le composé **1**.

A une solution de **1** dans le toluène-$d_8$, portée à −40°C, nous avons ajouté une quantité équimolaire de $CH_3OH$ à la même température. L'évolution du mélange réactionnel est suivie par rmn de $^{31}P$ de −40°C à +30°C. Le tableau 2 présente les δ des différents signaux observés sur les spectres et leur évolution en fonction de la température. La lecture de ce tableau nous amène à faire les commentaires suivants.

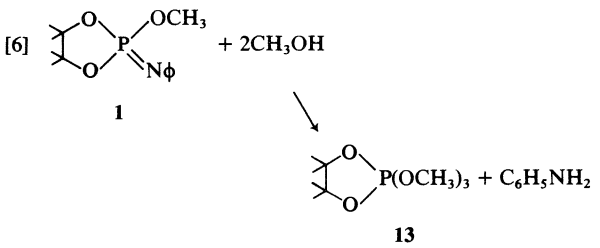
(*i*) Les signaux $\delta_2$ et $\delta_3$ qui apparaissent à champ fort lors de l'addition de $CH_3OH$ sont représentatifs de phosphoranes, l'entité $\delta_2 = -54{,}6$ étant le pentaoxyphosphorane **13** décrit par Bartlett *et al.*

TABLEAU 2. Réaction du méthanol sur l'iminophospholane **1** en solution dans le toluène, dans l'intervalle de température −40°C +30°C, par rmn $^{31}P$

| $n^a$ | T(°C) | $\delta_1$ | $\delta_2$ | $\delta_3$ | Intensités relatives des signaux |
|---|---|---|---|---|---|
| 0 | −40 | 5,9 | | | |
| | +30 | 5,5 | | | |
| 1 | −40 | 9,2 | | −57,5 | |
| | −30 | 8,3 | | −57,3 | |
| | −10 | 6,3 | | −57,3 | |
| | 0 | 6,3 | | −57,2 | $I_3/I_1 = 10$ |
| | +10 | 6,2 | −54,6 | −57,0 | |
| | +30 | 6,0 | −55,0 | −57,0 | $I_2/I_1 = 1$ $I_3$ faible |
| 2 | 0 | 6,4 | −55,4 | −57,3 | $I_2$ faible |
| | +10 | | −55,2 | −57,2 | $I_3/I_2 = 0{,}5$ |
| | +20 | | −55,0 | −57,0[b] | $I_3/I_2 = 0{,}05$ |
| 5 | +20 | | −55,0[c] | | |

[a] $n$ = nombre de moles de $CH_3OH$ par mole de **1**.
[b] Disparition totale deux heures après l'addition.
[c] Apparition d'un signal à δ = −60, dix jours après l'addition.

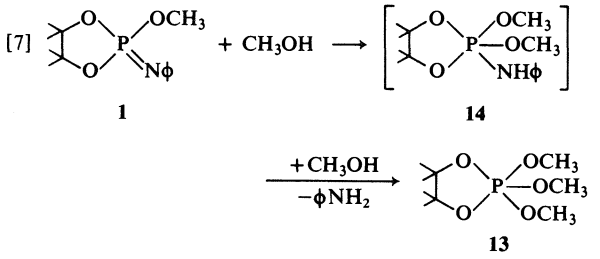
(18). Ce composé est le produit thermodynamique de la réaction [6]:



L'aniline formée au cours de la réaction a été caractérisée par chromatographie en phase vapeur. De plus **13** a été préparé suivant la réaction [6].

(*ii*) Le signal à $\delta_3 = -57$ correspond à un intermédiaire **14** résultant de l'addition de $CH_3OH$ sur **1**, stable jusqu'à la température de 0°C. Dans ces conditions la réaction n'est pas totale; en élevant la température, le méthanol en excès dans le milieu réagit sur l'intermédiaire **14** pour conduire au phosphorane **13**. Le dérivé **14** disparait complètement à la température ambiante; seuls le produit de départ et le produit thermodynamique sont, à cette température, présents dans le milieu.

L'addition de deux moles de $CH_3OH$ pour une mole de **1**, confirme les observations précédentes: dès 0°C, le produit final est décelé par rmn de $^{31}P$. Quatre heures après l'addition, à 20°C, la réaction est pratiquement totale. L'addition d'un excès de méthanol fait apparaître, après une dizaine de jours, une entité phosphoranique qui résonne à δ = −60 ppm et qui correspond vraisemblablement à: $P(OMe)_5$ (19).



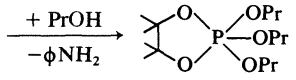
Cette interprétation des spectres de rmn de $^{31}P$ est résumée par le schéma [7] ci-dessus, qui se trouve confirmé par l'étude de la réaction en rmn protonique: l'intermédiaire aminophosphorane **14** est décelé à basse température (−20°C) à partir du doublet (δ = 4,80, $J_{HP}$ = 8,0 Hz) dû au proton P—N*H*-ϕ. Ce doublet, présent jusqu'à la température ambiante, disparait totalement quelques heures après l'addition du méthanol. La rmn protonique montre également la présence d'aniline dans le milieu dès −20°C ($\delta_{H_2N}$ = 4,26) prouvant

ainsi la formation du pentaoxyphosphorane **13** dès cette température.

La même étude par rmn de $^{31}P$ et de $^{1}H$ a été réalisée avec l'iminophosphane **2**: les résultats obtenus dans le cas de **1** sont entièrement confirmés. Ainsi l'intermédiaire aminophosphorane **15** résonne en $^{31}P$ à $\delta = -60{,}1$. Cet intermédiaire a une durée de vie suffisamment longue pour être observé (en rmn de $^{31}P$) à la température ambiante pendant une dizaine d'heures. Le pentaoxyphosphorane **16** donne un signal à $-58{,}3$ qui apparaît dès l'addition du propanol. La figure 1 illustre ces observations: en rmn protonique les trois entités **2**, **15** et **16** peuvent être identifiées au cours du temps par l'évolution des signaux du groupe $CH_2$—O—P.

[8] 

2 15



16

Pour le composé **4** à la température ambiante, nous n'avons pas observé de réaction d'addition sur la liaison phosphazène qui aurait conduit à **17**. La première étape de la réaction est en fait l'alcoolyse de la liaison P—$NMe_2$ qui donne le dérivé **1**. Celui-ci évolue comme nous l'avons vu précédemment vers le produit thermodynamique **13**.

[9] 

4

Le schéma [9] ci-dessus montre bien que **13** se forme par la voie (a) et non (b). La réaction d'addition est plus lente que la réaction d'alcoolyse de telle sorte qu'en défaut de méthanol, on observe toujours dans le milieu la présence des trois entités **4**, **1** et **13**. L'action de 3 moles de $CH_3OH$ sur une mole de **4** conduit à la seule formation de **13**.

2. *Associations intermoléculaires avec conservation de la tétracoordinance du phosphore*

Nous avons étudié l'action du méthanol sur la série des six diazaiminophosphanes (**7** à **12**) en suivant, par rmn de $^{31}P$, l'évolution d'une solution dans le toluène du dérivé phosphoré, en présence de quantités croissantes de méthanol. L'ensemble des résultats est reporté dans le tableau 3. Nous constatons pour tous ces composés, à l'exception de **12**, qu'il y a un déplacement progressif du signal de résonance du phosphore vers les champs faibles. En aucun cas, nous n'avons observé de signal dans le domaine des phosphoranes ($\delta \sim -60$). Ce comportement particularise les diazaiminophosphanes vis-à-vis des autres composés de ce travail.

Le déplacement chimique de $^{31}P$ varie notablement avec l'addition d'alcool. La variation la plus importante est obtenue avec **11** alors que pour **10**; elle est très faible et nulle pour **12**. La valeur limite de $\delta^{31}P$ intervient pour un excès d'alcool de l'ordre de 3 à 5 fois la quantité du dérivé phosphoré. Après évaporation du méthanol et mise en solution dans le toluène, on retrouve le même déplacement chimique qu'avant l'addition.[2] Ces observations s'interprètent bien comme résultant d'interactions faibles, de type liaison hydrogène, entre les sites basiques de l'iminophosphane considéré et le proton du méthanol. Cette association se retrouve également avec d'autres réactifs à proton acide tels

[2]Dans les composés **9** et **11**, l'addition du méthanol donne, après plusieurs jours, de nouvelles entités du phosphore tétracoordonné (voir partie expérimentale).

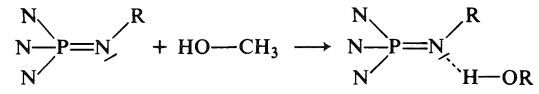
que le phénol,[3] et des solvants ($HCCl_3$) pour lesquels on enregistre également une variation du $\delta^{31}P$ vers les champs faibles.

Ainsi, par le biais de l'addition du méthanol aux diazaiminophosphanes et la variation de $\delta^{31}P$ qui en résulte, on retrouve les propriétés basiques de la liaison phosphazène. Celles-ci ont été très étudiées, par différentes méthodes, dans les aryliminophosphanes diversement substitués ($\phi_3P{=}N{-}C_6H_4X$) (20). Nous mêmes avons montré, par spectroscopie infrarouge dans les dérivés acycliques **18** et **19**, qu'il s'établissait une liaison hydrogène entre le proton du méthanol et l'atome d'azote imino.[4]

$\phi_3P{=}N\phi$ **18** $(CH_3O)_3P{=}N\phi$ **19** $(Me_2N)_3P{=}N\,\phi$ **20**

Les trois dérivés acycliques ci-dessus donnent d'ailleurs le même phénomène de variation de $\delta^{31}P$ en présence de $CH_3OH$. Dans le tableau 3, on notera que **20**, qui a le même environnement atomique que les dérivés cycliques étudiés, subit un $\Delta\delta$ de l'ordre de 10 unités, c'est à dire parmi les plus fortes variations enregistrées.

Les modèles moléculaires étudiés ici présentent trois sites azotés de basicité différente. Mais, de même qu'en série carbonée l'atome d'azote imino est plus basique que celui d'une amine, en série phosphorée, cet atome présente également une forte basicité accentuée par la polarisation de la liaison P=N en $P^{\delta+}{-}N^{\delta-}$ (21). Il est donc raisonnable d'admettre que l'association par liaison hydrogène se produit préférentiellement avec cet atome d'azote, formant un complexe de type 1/1 (22):



Cette association a pour effet d'accroître la charge effective ($\delta+$) sur P, d'où l'observation du déplacement du signal de résonance de $^{31}P$ vers le domaine des phosphoniums. Le fait d'observer un seul

[3]La variation de $\delta^{31}P$ est d'autant plus forte que le donneur de proton est plus acide. Par exemple, l'addition du phénol sur **11** entraine un $\Delta\delta$ de 17,4 ppm.

[4]R. Mathis, N. Zenati et M. Sanchez, travail en cours.

[a] $n$ = nombre de moles de $CH_3OH$ par mole d'iminophospholane.
[b] Solution dans le chloroforme.

signal en rmn de $^{31}P$ prouve l'existence d'un équilibre dynamique. La possibilité d'associations plus complexes de type 1/2 (réactif phosphoré/solvant) n'est pas à exclure; seule une étude quantitative (détermination des constantes d'équilibre) permettra de préciser le phénomène.

Rappelons que la basicité de la liaison phosphoryle a été également très étudiée (23); en rmn du phosphore la complexation avec R—OH se traduit par une variation notable de $\delta^{31}P$. Cette variation a servi de critère à Mayer et Gutmann (24), dans le cas de $Et_3P{=}O$, pour évaluer les propriétés électrophiles des solvants (D: donicité). D'une manière analogue, en considérant la variation de $\delta^{31}P$ ($\Delta\delta = \delta^{31}P_{CH_3OH} - \delta^{31}P_{Tol}$) comme critère de basicité du motif P=N d'iminophosphanes, nous pouvons établir un ordre relatif de basicité. Dans les composés étudiés, pour les mêmes ligands autour de P, nous observons l'ordre décroissant suivant, qui s'interprète bien avec l'effet inductif du substituant sur l'atome d'azote imino:

$$\text{>P=N—Et} > \text{>P=N—}\phi > \text{>P=N—Tos}$$

Il est intéressant de noter pour les trois dérivés ci-dessus le même ordre de réactivité vis-à-vis de réactifs électrodéficients tel que l'acétylène dicarboxylate de méthyle (DMA) (15): **11** réagit à la température ambiante plus facilement que **10**, qui nécessite un chauffage prolongé, alors que **12** est sans action sur le DMA.

En conclusion, nous avons synthétisé douze nouveaux iminophosphanes possèdant un cycle à cinq chaînons. Pour la famille de dérivés à cycle

diazaphospholane, la présence des substituants azotés est un facteur de stabilisation de la forme monomère iminophosphane quel que soit la nature du groupe présent sur l'azote imino.

L'existence, sur un même modèle, de liaisons P—O (simple) et P=NR est favorable à la réaction de réarrangement iminophosphane → phosphoryle. Dans le cas des composés à cycle tétraméthyldioxaphospholane (**1**, **2**, **4**) un tel réarrangement se produit par voie thermique, à des températures peu élevées, et conduit préférentiellement à l'isomère à cycle oxazaphospholane par introduction de l'azote imino dans le cycle pentagonal. Enfin l'action du méthanol a montré des différences de comportement de la liaison phosphazène. Avec les composés à cycle tétraméthyldioxaphospholane, l'addition du méthanol conduit aux dérivés phosphoraniques. Avec les dérivés à cycle diazaphospholane, des interactions intermoléculaires par liaison hydrogène ont été mises en évidence traduisant ainsi la forte basicité de l'azote imino.

Ceci confirme bien que la nature des substituants présents sur les atomes d'azote et de phosphore influe sur la délocalisation des charges de la liaison P=N, expliquant ainsi les réactions d'addition ou d'association du méthanol.

## Partie expérimentale

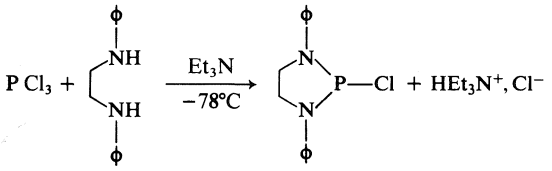
Les spectres de rmn du proton ont été enregistrés à 60 et 100 MHz sur des appareils Varian (T-60 et HA-100). En résonance de $^{31}P$ nous avons utilisé un appareil Perkin–Elmer (R-32) fonctionnant à 36,4 MHz en transformée de Fourier. Les déplacements chimiques sont comptés positivement à champ faible à partir de la référence externe ($H_3PO_4$, solution à 85%). Les points de fusion ont été déterminés sur banc Koffler et sont donnés sans correction. Les solvants utilisés dans les réactions chimiques: toluène, chlorure de méthylène, benzène, éther, acétonitrile et diméthylformamide ont été purifiés selon les techniques usuelles.

Nous avons préparé, en suivant les modes opératoires décrits dans la littérature, le phényle azoture (25), l'éthyle azoture (26) et le tosyle azoture (27). Les réactifs phosphorés quant à eux ont été synthétisés soit à partir de réactions mises au point au laboratoire (28) soit à partir de résultats de la littérature (29); c'est ainsi que nous avons réalisé la synthèse de quatre nouveaux diazaphospholanes.

I. *Préparation des réactifs du phosphore tricoordonné*

1. *Chloro-2,*N,N′ *diphényl-1,3 diazaphospholane-1,3,2*

Nous avons mis en oeuvre la réaction ci-dessous en suivant un mode opératoire proposé par Ramirez *et al.* (30).



Dans un ballon tricol muni d'un réfrigérant, d'une ampoule isobare, on place sous atmosphère d'argon 13,7 g (0,1 mol) de $PCl_3$ en solution dans 300 cm³ d'éther. La solution refroidie à −78°C est maintenue en agitation permanente. On ajoute goutte à goutte une solution de 21,2 g (0,1 mol) de *N,N′* diphényl éthylènediamine dans 300 cm³ d'éther. A la fin de l'addition, 20,2 g (0,2 mol) de triéthylamine sont ajoutés rapidement; le chlorhydrate précipite et le mélange réactionnel sous agitation est ramené à la température ambiante. Après filtration et évaporation du solvant on obtient un solide blanc qui est lavé à l'éther et séché (Rdt: 90%); F: 140°C; rmn $^{31}P$ ($CHCl_3$): δ = 137,5.

2. *Méthoxy-2,*N,N′ *diphényl-1,3 diazaphospholane-1,3,2*

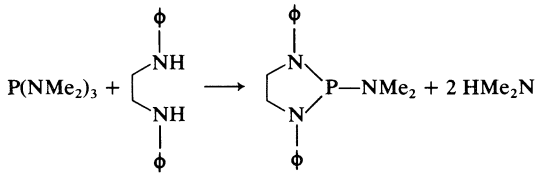
Ce composé est préparé par alcoolyse du dérivé chloré précédent, en présence de triéthylamine. La réaction se déroule à la température ambiante en 24 h; elle conduit avec un rendement quantitatif au composé attendu; F = 100°C; rmn $^{31}P$ ($CHCl_3$): δ = 103,9; rmn $^1H$ ($CDCl_3$): δ = 3,3 (d, $^3J_{H-P}$ = 8 Hz, 3H, $CH_3O$—), δ = 3,9 (m, 4H, $CH_2$—$CH_2$—).

3. tert-*Butylamino-2,*N,N′ *diphényl-1,3 diazaphospholane-1,3,2*

A une solution de 2,8 g (1 × $10^{-2}$ mol) du dérivé chloré, on ajoute à la température ambiante, un excès (2,2 g soit 3 × $10^{-2}$ mol) de *tert*-butylamine fraichement distillée. Le mélange réactionnel sous atmosphère inerte est maintenu en agitation pendant 12 h. On porte alors le mélange à 0°C puis on ajoute 200 cm³ d'éther pour faire précipiter la totalité du chlorhydrate de *tert*-butylamine. Après filtration et évaporation du solvant, on obtient un solide qui est lavé à l'éther puis séché sous vide (Rdt: 80%); F = 120°C; ir (sol. KBr) $\nu_{N-H}$ = 3350 cm⁻¹; rmn $^{31}P$ ($CHCl_3$): δ = 81; rmn $^1H$ ($CDCl_3$) δ = 1,1 (s, 9H, *t*-butyl), δ = 2,5 (singulet large, H—N), δ = 3,5 (m, 4H, —$CH_2$—$CH_2$—).

4. *Diméthylamino-2,*N,N′ *diphényl-1,3 diaza phospholane-1,3,2*

Ce composé a été préparé suivant la réaction:



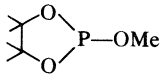
A partir d'un mode opératoire décrit antérieurement (30), on traite 8,15 g (5 × $10^{-2}$ mol) de tris(diméthylamino)phosphane par 10,6 g (5 × $10^{-2}$ mol) de diamine en solution dans 150 cm³ de toluène. Après 10 h de chauffage au reflux du solvant, la réaction est terminée (la quantité théorique de diméthylamine déplacée a été dosée). On obtient avec un bon rendement (85%) le diazaphospholane; F = 145°C; rmn $^{31}P$ (toluène): δ = 97,6; rmn $^1H$ (tol-$d_8$): δ = 2,5 (d, $^3J_{H-P}$ = 10 Hz, 6H, $N(CH_3)_2$), δ = 3,6 (m, 4H, —$CH_2$—$CH_2$—).

II. *Préparation des iminophospholanes*

Nous décrirons deux préparations-types correspondant aux composés **1** et **11** relevant des deux familles dioxa et diaza iminophospholanes.

1. *Tétraméthyl-4,4,5,5,*N *phényl-2, méthoxy-2, dioxaimino-phospholane-1,3,2 (composé 1)*

Dans un ballon tricol muni d'un agitateur magnétique, d'un réfrigérant relié à un volumètre, on place sous atmosphère d'argon 5,8 g (3,5 × $10^{-2}$ mol) de:



en solution dans 100 cm³ de toluène. On ajoute lentement à l'aide d'une seringue 4,2 g (3,5 × $10^{-2}$ mol) de phényl azoture

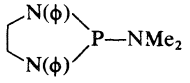
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

pur. Dès l'addition on observe un dégagement gazeux ($N_2$). On achève la réaction en chauffant le mélange réactionnel 1 h à 80°C. Extraction du solvant et purification par distillation: $Eb_{10^{-3}}$ = 92°C (Rdt = 80%). Le spectre de rmn $^{31}P$ du distillat montre la présence d'une impureté phosphorylée ($\delta$ = 12,5) celle-ci est éliminée en recristallisant le produit dans un mélange de $CH_2Cl_2$ et de pentane ($\delta$ $^{31}P$ = 5,3); F = 52°C.

Suivant le même mode opératoire nous avons préparé les iminophospholanes **2** ($Eb_{10^{-3}}$ = 108–110°C), recristallisé dans un mélange de benzène et d'hexane, **3** recristallisé dans le benzène (F = 120°C), **4** recristallisé dans le toluène et **5** produit peu soluble qui précipite à la fin de la réaction.

2. *Diméthylamino-2,*N,N′ *phénylamino-1,3,*N *éthylimino-2, diazaiminophospholane-1,3,2 (composé 11)*

A l'aide du même appareillage que celui décrit précédemment, on traite 2,85 g ($10^{-2}$ mol) du dérivé phosphoré



en solution dans 50 cm³ d'acétonitrile (ou de toluène) par 1,4 g d'éthyle azoture en excès ($2 \times 10^{-2}$ mol). Pour que la réaction soit totale (quantité d'azote dégagée 230 cm³), il est nécessaire de chauffer le mélange à 50°C pendant 1 h. Après évaporation du solvant on obtient un solide qui est lavé à l'hexane et séché sous vide (Rdt: 80%); F = 120°C. Les diaza iminophospholanes-1,3,2, **6** à **12** ont été préparés dans des conditions comparables à celles que nous venons de décrire pour **11** (voir tableau 1).

III. *Réaction d'isomérisation de 1 par voie thermique*

Dans une première approche cette réaction a été suivie par rmn du phosphore et du proton. La procédure est la suivante: dans un tube de rmn on place $2 \times 10^{-2}$ mol d'iminophospholane **1** en solution dans 0,5 cm³ de toluène-$d_8$. On enregistre les premiers spectres de référence; le tube est alors porté à une température constante de 100°C, des enregistrements sont effectués à intervalles de temps réguliers. On observe sur les spectres ainsi enregistrés l'apparition progressive de signaux dûs à deux nouvelles entités phosphorées; après 40 h de chauffage la disparition des signaux appartenant à **1** est totale et les deux composés **1***a* (70%) et **1***b* (30%) présentent les paramètres spectroscopiques suivants: **1***a*: rmn $^{31}P$: $\delta$ = 12,5; rmn $^1H$ (tol-$d_8$): $\delta$ = 3,38 (d, $^3J_{H-P}$ = 11,8 Hz, 3H, $CH_3$—O—), $\delta$ = 1,03 (s, 6H, $CH_3$—C—), $\delta$ = 1,08 (s, 6H, $CH_3$C); rmn $^1H$ (tol-$d_8$ + pyr-$d_5$): $\delta$ = 3,50 (d, $^3J_{H-P}$ = 11,6 Hz, 3H, $CH_3$—O—), $\delta$ = 1,08 (s, 6H, $CH_3$—C—), $\delta$ = 1,14 (s, 3H, $CH_3$—C—), $\delta$ = 1,22 (s, 3H, $CH_3$—C—); **1***b*: rmn $^{31}P$: $\delta$ = 14,5; rmn $^1H$ (tol-$d_8$): $\delta$ = 2,90 (d, $^3J_{H-P}$ = 9,5 Hz, 3H, $CH_3$—N), $\delta$ = 1,14 (s, 6H, $CH_3$—C—), $\delta$ = 1,18 (s, 6H, $CH_3$—C—).

Si la solution est laissée dans le tube, à la température ambiante, pendant plusieurs jours, on observe aucune évolution des spectres; par contre un chauffage prolongé (100 h) provoque une décomposition des produits avec apparition de signaux nouveaux d'intensité non négligeable dans les spectres de rmn protonique. Dans une deuxième approche, nous avons tenté d'isoler, sans succès, le composé **1***a* par chromatographie sur plaque de silice. Suivant la même méthode nous avons suivi l'isomérisation thermique de **2** en **2***a* ($\delta$ $^{31}P$ = 11,7). Enfin pour le composé **4** la forme phosphorylée **4***a* n'est pas présente dans le produit brut; par chauffage à 100°C nous avons caractérisé par rmn de $^{31}P$ sa formation ($\delta$ = 18,9).

IV. *Réactions avec le méthanol*

1. *Cas des composés à cycle diazaphospholane (7 à 12)*

Suivant une procédure analogue à celle que nous venons de décrire, nous avons suivi par rmn du phosphore et du proton le comportement d'une solution de $2 \times 10^{-3}$ mol d'iminophospholane dans 0,5 cm³ de tol-$d_8$ lorsqu'on ajoute des quantités croissantes (de 1 à $5 \times 10^{-3}$ mol) de méthanol. Les spectres sont enregistrés avant et après chaque addition; on s'est bien assuré que le signal en rmn de $^{31}P$ ne se déplace pas dans un intervalle de temps de l'ordre de 15 min. Lorsque la variation du déplacement de $^{31}P$ atteint son maximum, on évapore le méthanol puis le produit est remis en solution. On enregistre alors un dernier spectre pour lequel on retouve le même $\delta^{31}P$ qu'avant addition de $CH_3OH$. Ces manipulations ont été réalisées dans un temps de l'ordre de 10 h, à la température ambiante. A l'exception des composés **9** et **11** aucune évolution n'est constatée dans un temps supérieur à 24 h. Pour ces deux composés si le mélange iminophospholane (1 mol) – méthanol (3 mol) est laissé à la température ambiante pendant plusieurs jours on observe l'apparition progressive de signaux nouveaux, autres que celui du composé de départ, dans le domaine des atomes de phosphore tétracoordonné.

Pour **9** les signaux qui apparaissent sur le spectre de rmn de $^{31}P$ se stabilisent en intensité un mois après l'addition de méthanol; ils sont situés aux $\delta$ suivants: $\delta_1$ = 23,5, $\delta_2$ = 18,0, $\delta_3$ = 14,1 $\delta_4$ = 10,0. Après évaporation de $CH_3OH$, quatre entités phosphorées sont caractérisées: $\delta_1$ = 18,9 (composé **9**), $\delta_2$ = $\delta_3$ = 13,9, $\delta_4$ = 9,4. La rmn protonique montre sans ambiguité l'absence totale de signaux de type $OCH_3$ et une grande multiplicité des signaux correspondants à des protons $H_3C$—N; enfin dans deux expériences quantitatives effectuées sur 1 g ($0,4 \times 10^{-2}$ mol) d'iminophospholane pour 0,4 g ($0,4 \times 10^{-2}$ mol) de méthanol, en solution dans le toluène, nous n'avons pas observé de réaction de méthanolyse comparable à [9] et qui interviendrait par coupure de la liaison P—N($CH_3$) exocyclique.

L'étude de **11** confirme les observations faites sur **9**; 24 h après l'addition de 3 moles de méthanol sur une mole d'iminophospholane, le spectre de rmn de $^{31}P$ présente en plus du signal dû à **11** ($\delta$ = 19) un deuxième signal d'égale intensité à $\delta$ = 23,3. La rmn de $^1H$ montre bien que le méthanol n'a pas réagi sur **11**: absence de signaux de type $H_3C$—O, existence de trois doublets $H_3C$—N—P ($^3J_{H-P}$ = 10 Hz) aux $\delta$ suivants: $\delta_1$ = 2,50 (45%), $\delta_2$ = 2,30 (10%), $\delta_3$ = 2,25 (45%) et de trois triplets dus au $H_3C$ du groupe P=N—$CH_2$—$CH_3$ ($^3J_{H-H}$ = 7 Hz) aux $\delta$: $\delta_1$ = 1,40, $\delta_2$ = 1,10 et $\delta_3$ = 0,90.

Ces premiers résultats laisseraient supposer que les nouvelles entités phosphorées qui apparaissent au cours du temps, proviennent d'une ouverture du cycle diazaphospholane (**9** ou **11**) de départ. Les travaux en cours devraient permettre de préciser ces observations.

2. *Cas des composés à cycle dioxaphospholane (1, 2 et 4)*

L'étude de l'évolution au cours du temps et à différentes températures par rmn ($^{31}P$ et $^1H$) a été réalisée sur une solution dans le toluène deutérié (0,5 cm³) de $2 \times 10^{-3}$ mol de l'iminodioxaphospholane **1** en présence de $4 \times 10^{-3}$ mol de méthanol. A −20°C l'intermédiaire anilino phosphorane **14** a été caractérisè en solution: $\delta$ $^{31}P$ = −57,4, rmn $^1H$ $\delta$ = 4,82 (d, 1H, H—N—P, $^2J_{H-P}$ = 8 Hz), $\delta$ = 3,47 (d, 3H, $H_3CO$—P, $^3J_{H-P}$ = 12 Hz). Lorsque la solution est laissée quelques heures à la température ambiante le spectre protonique ne présente plus que les signaux caractéristiques du pentaoxyphosphorane **13** et ceux de l'aniline qui s'est formée dans le milieu.

*Préparation du tris méthoxy-2 tétraméthyl-4,4,5,5, dioxa-1,3 phosphorane-2 (13)*

On traite 4 g ($15 \times 10^{-3}$ mol) de **1** en solution benzènique (30 cm³) par 1 g ($31 \times 10^{-3}$ mol) de méthanol. Le mélange est laissé à la température ambiante pendant 10 h. Extraction du solvant et purification par distillation; $\delta$ $^{31}P$ = −55 (litt. (18) $\delta$ = −54,3); rmn $^1H$ ($CDCl_3$) $\delta$ = 3,54 (d, 9H, $H_3C$—O—P, $^3J_{H-P}$ = 13 Hz), $\delta$ = 1,05 (s, 12H, $H_3C$—C).

L'action du propanol sur l'iminodioxaphospholane **2** a été

également suivie par rmn comme dans le cas de **1**; la figure 1 donne une illustration de l'évolution des signaux correspondant aux protons méthylèniques du groupe P—$OC_3H_7$. L'intermédiaire **15** et le pentaoxyphosphorane **16** ont été aisément caractérisés en solution; **15**: $\delta$ $^{31}P = -60,1$; rmn $^1H$ ($C_6D_6$): $\delta$ = 4,90 (d, 1H, H—N—P, $^2J_{H-P}$ = 9 Hz), $\delta$ = 3,80 (q, 4H, —$CH_2$—O—P, $^3J_{H-H} = {}^3J_{H-P}$ = 6 Hz); **16**: $\delta$ $^{31}P = -58,3$; rmn $^1H$ ($C_6D_6$): $\delta$ = 3,89 (q, 6H, —$CH_2$—O—P, $^3J_{H-H} = {}^3J_{H-P}$ = 6 Hz), $\delta$ = 1,12 (s, 12H, $H_3C$—C).

Enfin l'imino dioxaphospholane **4** a été également soumis à l'action des deux alcools $CH_3OH$ et $n$-$C_3H_7OH$ dans les proportions 1:3. Dans chaque cas on observe la disparition du doublet dû aux protons $(CH_3)_2N$—P ($\delta$ = 2,49, $^3J_{H-P}$ = 10,6 Hz) et l'apparition conjointe d'un singulet dû aux $CH_3$ de la diméthylamine ($\delta$ = 2,14). Lors de l'addition du méthanol le spectre obtenu à la température ambiante est celui du phosphorane **13** alors que dans le cas de l'addition du propanol le spectre obtenu est celui du phosphorane **16** (voir ci-dessus).

# Effective interactions for the configurations $3d^34p + 3d^24s4p + 3d4s^24p$ in the first spectrum of titanium

C. ROTH

*Department of Mathematics, McGill University, Montreal, P.Q., Canada H3A 2K6*

Received July 13, 1981

C. ROTH. Can. J. Chem. **60**, 469 (1982).

Energy levels and Lande $g$-factors for the configurations $3d^34p + 3d^24s4p + 3d4s^24p$ in the first spectra of titanium were calculated and compared with experimental values. The calculations were done in intermediate coupling taking into account explicitly the interactions between configurations, as well as *complete* effective interactions of the core, and effective interactions $d$–$p$.

Due to the insertion of the various effective interactions and a successful starting point based on a general treatment of the odd configurations in the first spectra of the iron group, there was excellent agreement between the experimental and calculated levels.

On fitting 164 levels using 28 free interaction parameters a mean error of only 117 $cm^{-1}$ was obtained, i.e., about 0.3% average difference between the experimental and calculated levels. The experimental and calculated $g$-factors corresponded very closely.

C. ROTH. Can. J. Chem. **60**, 469 (1982).

On a calculé et comparé aux valeurs expérimentales les niveaux d'énergie et les facteurs $g$ de Lande des configurations $3d^34p + 3d^24s4p + 3d4s^24p$ du premier spectre du titane. On a fait les calculs pour un couplage intermédiaire en tenant compte explicitement des interactions entre les configurations ainsi que des interactions effectives complètes du noyau et des interactions effectives $d$–$p$.

L'accord entre les niveaux expérimentaux et calculés est excellent en raison de l'insertion des diverses interactions effectives et un point de départ approprié basé sur le traitement général des configurations impaires des premiers spectres du groupe du fer.

On a obtenu une erreur moyenne de seulement 117 $cm^{-1}$ c'est à dire environ 0,3% pour 164 niveaux en utilisant 28 paramètres d'interaction libre. Les facteurs $g$ calculés et expérimentaux sont très voisins.

## Introduction

For the odd configurations in the spectra of the iron group, both strong and weak configuration interactions are significant. The former arise when the perturbing and perturbed configurations are energetically close to each other and there is strong coupling of the configurations by the Coulomb field. These are taken into account by *explicitly* considering the configurations $3d^34p$, $3d^24s4p$, $3d4s^24p$ and the electrostatic interactions between them. Weak interactions occur when the perturbing configurations are well separated from the perturbed configuration, and the coupling of the Coulomb field is weak.

The individual weak interactions may not be significant, but their cumulative influence may be quite large, due to the increasing density of states as the continuum is approached. As it would be completely futile to consider each of these effects individually, the aim should be to modify the energy matrices of the principal configurations so that the major part of *all* the weakly perturbing configurations be included.

By first order perturbation theory, different configurations do not interact. In second order only those configurations which differ in the quantum numbers of at most two electrons interact. Bacher and Goudsmit (1) have shown that the terms of the configuration $l^n$ may be expressed as linear combinations of the terms of $l^2$, so that the perturbation of $l^n$ by all the configurations differing from it by the state of two electrons, and being distant from it, can be accounted for by suitably modifying the terms of $l^2$. Hence these perturbations can be described by two-body effective interactions.

The first correction of this kind for the configurations $d^n$ was the $\alpha L(L+1)$ correction introduced by Trees (2, 3), in the configurations $3d^54s$ of Mn(II) and Fe(III). Trees introduced his correction empirically, but Racah (4) showed that the above effects can be described by a model or effective interaction of the form

$$2\alpha(l_1 \cdot l_2) + \beta q_{12}$$

where $q_{12}$ is the seniority operator (5). For the configuration $d^n$ this becomes

$$\alpha[L(L+1) - 6n] + \beta Q$$

where

$$Q(n,\nu) = (1/4)\,(n-\nu)\,(4l+4-n-\nu)$$
$$= (1/4)\,(n-\nu)\,(12-n-\nu)$$

is the total seniority operator. Here $n$ is the number of $d$ electrons in the configuration $d^np$, $\nu$ is the seniority of the $d^n$ core term, and $l$ is 2 as we are dealing with $d$ electrons. The constant $-6n\alpha$ is usually incorporated into the height of the configuration. Racah (4) showed that the $\alpha L(L+1)$ and

the $\beta Q$ corrections form a complete set of two-body effective interactions for the $d^n$ configurations. This is due to the fact that together with the Slater integrals $F_0(d^2)$, $F_2(d^2)$, and $F_4(d^2)$, they form a set of five independent parameters that can represent the five terms of $d^2$.

Bacher and Goudsmit (1) also showed that if the far-lying perturbing configuration differs from $l^n$ by the state of only one electron, its effect can be described by expressing the terms of $l^n$ as linear combinations of $l^3$, and modifying the values of these terms. Hence in the linear theory, the Hamiltonian in this case must be augmented by additional three-body interactions.

Rajnak and Wybourne (6) obtained explicit formulas for the effective interactions representing the perturbation of an $l^n$ configuration by far-lying configurations differing from it by one or two electrons or holes.

Rohrlich (7) calculated the energy levels for the configurations $3d^34p$ and $3d^24s4p$ of TiI. He considered the spectrum in the *LS* approximation by taking into account the interaction between the cores $3d^3$ and $3d^24s$, but only as a perturbation to the calculated terms. He obtained an rms error of 1109 $cm^{-1}$.

Roth (8), by taking into account explicitly the three configurations $3d^34p$, $3d^24s4p$, and $3d4s^24p$, the electrostatic interactions between them, and the spin–orbit interactions, but *excluding* the effective interactions (with the exception of the $\alpha$ correction), obtained an rms error of 261 $cm^{-1}$.

At about the same time, Smith and Siddall (9), independently treating the configurations $(3d + 4s)^34p$ in *LS* coupling, obtained an rms error of 355 $cm^{-1}$.

In this project were included the electrostatic and spin–orbit interactions of the individual configurations $3d^34p$, $3d^24s4p$, and $3d4s^24p$; the explicit electrostatic interactions between configurations $3d^34p$–$3d^24s4p$, $3d^24s4p$–$3d4s^24p$, and $3d^3$-$4p$–$3d4s^24p$; and the *complete* two- and three-body effective interactions of the core *d* electrons, as well as two-body mixed effective interactions between the 3*d* and 4*p* electrons.

The value of $\Delta$ is also given by the least-squares routine. The same derivatives can be used for several variations in the least squares, either imposing different conditions on the parameters, inserting the experimental levels with different assignments, or even rejecting some levels from consideration. The parameters of that variation which yielded the best results were used to perform new diagonalizations. This iterative process was continued until mathematical convergence was attained. In the present project four complete iterations were required.

The initial values of the radial parameters were used to multiply the algebraic matrices on tape and the resulting matrices were diagonalized. Besides the eigenvalues, the diagonalization routine also yields the derivatives of the eigenvalues with respect to the parameters, the squares of the eigenvectors (percentage compositions), and the calculated Lande *g*-factors. The appropriate experimental levels were then fitted to the eigenvalues, and using the derivatives obtained in the diagonalization, least-squares optimization calculations were performed. In these calculations, the improved values of the theoretical energy levels, the corrected values of the parameters including their statistical deviations, and the sum of the squares of the differences between the observed and the calculated levels, were obtained. The rms error is then defined as

$$\Delta = \sqrt{\frac{\sum_{i=1}^{n} \Delta_i^2}{n - m}}$$

where the $\Delta_i$'s are the differences between the observed and calculated levels, $n$ is the number of known levels, and $m$ is the number of free parameters. The mean error is quite different from the mean deviation

$$\delta = \sqrt{\frac{\sum_{i=1}^{n} \Delta_i^2}{n}}$$

as the former takes into account the statistical effect of the number of free parameters. Hence in order for a new parameter to have physical significance, it should cause an essential decrease in the rms error, and not simply a decrease in the mean deviation.

## Parameters

The algebraic matrices of $(d + s)^3p$ comprise the electrostatic and spin–orbit interaction matrices of the configurations $d^3p$, $d^2sp$, and $ds^2p$; the electrostatic interactions between configurations $d^3p$–$d^2sp$, $d^2sp$–$ds^2p$, $d^3p$–$ds^2p$; the complete two- and three-body effective interactions of the core *d* electrons, as well as two-body mixed effective interactions between the *d* and *p* electrons. The energy matrix is then a linear combination of these matrices, the coefficients of which are parameters to be discussed below. Unprimed quantities denote the configuration $d^3p$, primes denote $d^2sp$, and double primes denote $ds^2p$.

For personal use only.

$A, A', A''$ = the heights of the configurations:

$$S' = A' - A, \; S'' = A'' - A$$

$B, B'$ = linear combinations of the Slater parameters $F^2(d,d)$ and $F^4(d,d)$:

$$B = \frac{1}{441}[9F^2(dd) - 5F^4(dd)] = F_2(dd) - 5F_4(dd) \quad (10)$$

$C, C'$ = multiples of the Slater parameter $F^4(d,d)$:

$$C = \frac{5}{63}F^4(dd) = 35F_4(dd) \quad (10)$$

$G_{ds}$ = the parameter of the $d$–$s$ interaction in the configuration $d^2sp$:

$$G_{ds} = \frac{1}{5}G^2(ds) \quad (5)$$

$F_2, F_2', F_2''$ = parameters of the direct part of the $d$–$p$ interaction:

$$F^2 = \frac{1}{35}F^2(dp) \quad (10)$$

$G_1, G_1', G_1''$ = parameters of the exchange part of the $d$–$p$ interaction:

$$G_1 = \frac{1}{15}G^1(dp) \quad (10)$$

$G_3, G_3', G_3''$ = parameters of the exchange part of the $d$–$p$ interaction:

$$G_3 = \frac{3}{245}G^3(dp) \quad (10)$$

$G_{ps}$ = the parameter of the $p$–$s$ interaction in the configuration $d^2sp$:

$$G_{ps} = \frac{1}{3}G^1(ps) \quad (11)$$

$H$ = the parameter of the $d^3$–$d^2s$ interaction:

$$H = \frac{R^2(dd,ds)}{35} \quad (5)$$

$H'$ = the parameter of the $d^2s$–$ds^2$ interaction, defined the same as $H$.

$J$ = the parameter of the direct part of the $d^3p$–$d^2sp$ interaction:

$$J = \frac{R^2(dp,sp)}{5} \quad (12)$$

$J'$ = the parameter of the direct part of the $d^2sp$–$ds^2p$ interaction, defined the same as $J$.

$K$ = the parameter of the exchange part of the $d^3p$–$d^2sp$ interaction:

$$K = \frac{R^1(dp,ps)}{3} \quad (12)$$

$K'$ = the parameter of the exchange part of the $d^2sp$–$ds^2p$ interaction, defined the same as $K$.

$G^*$ = the parameter of the $d^3p$–$ds^2p$ interaction:

$$G^* = \frac{R^2(dd,ss)}{5} \quad (5)$$

$\zeta_d, \zeta_d', \zeta_d''$ = parameters of the spin–orbit interactions of the $d$ electrons.

$\zeta_p, \zeta_p', \zeta_p''$ = parameters of the spin–orbit interaction of the $p$ electron.

$\alpha, \alpha'$ = parameters of the $L(L+1)$ correction.

$\beta, \beta'$ = parameters of the $Q$ correction.

$T, T'$ } parameters of the three-body effective
$T_x, T_x'$ } interactions of the core $d$ electrons.

$T$ is the parameter which fully represents the perturbation of $3s^23d^n$ by $3s3d^{n+1}$, while $T_x$ is an additional independent parameter, which is required to make the set of three-body effective interaction parameters complete (13).

$F_1, F_1', F_1''$ = parameters of the direct part of the effective interaction between $d$ and $p$ electrons.

$G_2, G_2', G_2''$ = parameters of the exchange part of the effective interaction between $d$ and $p$ electrons.

The two-body effective Hamiltonian for interactions between $d$ and $p$ electrons is given by (13)

$$H_{\text{eff}}^2 = -\sum_t F_t \sum_{i\neq j}(u_i^{(t)}\cdot v_j^{(t)}) - \sum_t G_t \sum_{i\neq j}(z_i^{(t)}\cdot \tilde{z}_j^{(t)}),$$

where $u^{(t)}$, $v^{(t)}$, $z^{(t)}$, and $\tilde{z}^{(t)}$ are tensor operators of order $t$ whose only non-vanishing reduced matrix elements are

$$(nl||u^{(t)}||nl) = 1$$
$$(n'l'||v^{(t)}||n'l') = 1$$
$$(nl||z^{(t)}||n'l') = 1$$
$$(n'l'||\tilde{z}^{(t)}||nl) = 1$$

The coefficients of $F_t$ in the configuration $d^np$ are found by calculating the matrix elements

$$(d^n(\nu_1 S_1 L_1)pSLJM\,|\sum_{i\neq j}(u_i^{(t)}\cdot v_j^{(t)})\,|d^n(\nu_1' S_1' L_1')pS'L'J'M')$$

Since this involves the reduced matrix element $(p||v^{(t)}||p)$, $t$ may take only the values 0, 1, and 2 because of the triangular relationship $\delta(1,t,1)$ between the two $p$ angular momenta and $t$. For $t$ equal to 0 and 2 the Slater parameters are included

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

elsewhere, and thus the only new direct effective parameter is $F_1$.

Similarly for $G_t$, the calculation of the matrix elements

$$(d^n(v_1S_1L_1)pSLJM\,|\sum_{i\neq j}(z_i^{(t)}\cdot\tilde{z}_j^{(t)})\,|d^n(v_1'S_1'L_1')pS'L'J'M')$$

is required.

Due to the reduced matrix element $(d||z^{(t)}||p)$ with the triangular relation $\delta(2,t,1)$, $t$ may take on the values 1, 2, or 3. Since $G_1$ and $G_3$ are already included elsewhere, the only new exchange effective parameter is $G_2$.

The Lande $g$-factors were also computed. Whenever observed $g$-factors exist, they provide useful information to help fit the experimental levels.

The initial values of the parameters $B, B', C, C', G_{ds}, F_2, F_2', F_2'', G_1, G_1', G_1'', G_3, G_3', G_3'', G_{ps}, H, H', J, J', K, K', G^*, \zeta_d, \zeta_d', \zeta_d'', \zeta_p, \zeta_p', \zeta_p'', \alpha$, and $\beta$ were taken as the values obtained for titanium in the general treatment of the configurations $3d^n4p + 3d^{n-1}4s4p + 3d^{n-2}4s^24p$ by the author (13). The initial values of $T$, $T_x$, $F_1$, and $G_2$ were taken as 0.

The initial values of $A$ and $A'$ were obtained by considering the terms $^5F$ and $^5G$ whose electrostatic interaction matrices are of order 2. They are given by (14, 15)

$$^5F\begin{bmatrix} A-15B+3F_2-6G_1-26G_3+12\alpha & -\frac{3\sqrt{5}}{5}(K-J) \\ \frac{-3\sqrt{5}}{5}(K-J) & A'-8B'-2G_{ds}-3F_2'-G_1'-16G_3'-G_{ps}+12\alpha' \end{bmatrix}$$

$$^5G\begin{bmatrix} A-15B-F_2-10G_1-10G_3+12\alpha & \frac{\sqrt{5}}{5}(K-J) \\ \frac{\sqrt{5}}{5}(K-J) & A'-8B'-2G_{ds}+F_2'-9G_1'-4G_3'-G_{ps}+12\alpha \end{bmatrix}$$

Using the initial values in Table 1 below and the experimental centers of gravity of the terms $z^5G$, $z^5F$, $y^5G$, and $y^5F$ which are 16 202 cm$^{-1}$, 17 046 cm$^{-1}$, 26 726 cm$^{-1}$, and 28 767 cm$^{-1}$, respectively (16), we obtain by evaluating the sums and differences of the eigenvalues, the following average values

$$A = 38\,276\ \text{cm}^{-1}$$

$$A' = 32\,264\ \text{cm}^{-1}$$

It was shown (13) that the centers of gravity of the terms $d^2sp$ and $ds^2p$ are given by

$$M'(d^2sp) = A' + \frac{7}{9}(C' - 2B) - 2(G_1' + \frac{7}{2}G_3') - G_{ds} - \frac{1}{2}G_{ps} + \frac{32}{3}\alpha' + \frac{1}{9}\beta' + \frac{980}{9}T' + 2G_2'$$

$$M''(ds^2p) = A'' - (G_1'' + \frac{7}{2}G_3'') - 6\alpha'' + 70T'' + G_2''$$

Then again from ref. 13, using

$$D'' = M'' - M' = 11\,532\ \text{cm}^{-1}$$

we obtain initially

$$A'' = 40\,102\ \text{cm}^{-1}$$

The values of the parameters are listed in Table 1.

In order to obtain well-defined values for the parameters in the least-squares the parameters $F_2, F_2', F_2''; G_1, G_1', G_1''; G_3, G_3', G_3''; \zeta_d, \zeta_d', \zeta_d''; \zeta_p, \zeta_p', \zeta_p''$ were in arithmetic progression. The parameters $H', J', K', G^*$ were fixed at their values in the diagonalization; whereas the parameters $\alpha$, $\beta$, $T$, $T_x, F_1, G_2$ were respectively equal for the different configurations.

The above values of the parameters compare favorably with those obtained by the author using Hartree–Fock calculations (13).

## Discussion

The configurations $(d + s)^3p$ comprise 92 theoretical terms splitting into 212 levels. In AEL (16),

74 terms splitting into 175 levels are assigned to the configurations $3d^34p + 3d^24s4p$. In addition, 11 odd terms splitting into 28 levels are given without a definite configuration designation. However, in the original work of Russell (17), only the term $w^1G$ was given with no configuration designation. Russell attributed the terms $w^3H$, $p^3D$, $t^3G$, $g^3F$, and $n^3D$, with no configuration designation in AEL, to configurations containing a $5p$ electron. Russell assigned the terms $s^3F$, $q^3D$, and $v^1D$, with no configuration designation in AEL as $3d^3(b^2D)4ps^3F$, $3d^3(b^2D)4pq^3D$, and $3d^3(a^2P)4pv^1D$, respectively. He assigned the term $3d^24s(a^2S)4pt^3P$ of AEL to the configuration $3d4s^24p$.

In the final least-squares, 65 experimental terms splitting into 164 levels were included. The six levels of the terms $s^3G$ and $p^3F$ found by Wilson and Thekaekara (18) and corroborated by Banks *et al.* (19) were included in the calculations. In the least-squares with 28 free parameters the mean error was only 117 $cm^{-1}$.

This value is a great improvement compared to that of 355 $cm^{-1}$ obtained by Smith and Siddall (9). There are several reasons for this very significant decrease. Contrary to Smith and Siddall, who claim that neither effective interactions nor the spin–orbit interactions are important, it turns out that *both* are indeed *very* significant. By including the spin–orbit interactions the mean error was reduced from 342 $cm^{-1}$ to 261 $cm^{-1}$ (8). Smith and Siddall (9), required the parameters $H'$, $J'$, $K'$, and $G^*$ to be respectively equal to $H$, $J$, $K$, and $G_{ds}$, whereas it was shown by the author (13), using Hartree–Fock calculations, that these assumptions are unjustified. Further, by including the various effective interactions, having reliable initial parameters based upon a general treatment (13), and neglecting levels that either belong to or are very strongly perturbed by the configurations $(3d + 4s)^35p$, we are able to obtain the very low final value of 117 $cm^{-1}$ for the rms error.

It should be emphasized that if the configurations with a $5p$ electron are not included in the computations, and if one retains those terms that suffer very large perturbations from these configurations (deviations in excess of 1000 $cm^{-1}$), unwelcome distortions in the parameters may occur. This may explain, for example, why Smith and Siddall's (9) results for $B$ and $B'$ have the very high values of 763 $cm^{-1}$ and 952 $cm^{-1}$, compared with our values of 547 $cm^{-1}$ and 653 $cm^{-1}$, respectively.

Table 2 compares the experimental and calculated levels and $g$-factors.

The column "Theoretical designation" gives the assignments of the calculated levels. For $d^3sp$, as the $p$–$s$ interaction is much stronger than the $d$–$s$ interaction, the coupling scheme is $d^{n-1}(v_1S_1L_1)sp(^{1,3}P)SL$. Whenever terms of the parent $d^m$ have different seniorities these are denoted by the letters $A$ and $B$, the lower calculated term being designated by $A$, and the seniorities summed for each level. Whenever a calculated term has a corresponding experimental term, the letters $z, y, x, \ldots$ are used as in AEL (16). The terms of $d^3p$ are differentiated from those of $ds^2p$ by using an asterisk with the latter terms.

In the column "Experimental designation" the experimental level assignments are given only if different from the calculated designations.

In the column "Percentage" the three highest contributions are specified, provided the lowest is greater than 4%.

The observed and calculated levels, as well as their differences, "O − C", are in $cm^{-1}$.

TABLE 2. Observed and calculated levels of TiI $(3d + 4s)^3 4p$

| Designation | | | | Level | | | $g$ | |

The columns "Obsd $g$" and "Calcd $g$" give the experimental and calculated $g$-factors respectively.

Below 44000 $cm^{-1}$ there are 76 experimental terms splitting into 185 levels in AEL. The following 13 terms, which split into 27 levels, were rejected in the final least-squares:

| | | | | |
|---|---|---|---|---|
| 1. | $3d^24s(b^2P)4p$ | $y^3S$ | at | 35439.43 $cm^{-1}$ |
| 2. | $3d^3(a^2G)4p$ | $t^3F_{C.G.}$ | at | 38576.37 $cm^{-1}$ |
| 3. | $3d^3(a^2G)4p$ | $x^1G$ | at | 38959.53 $cm^{-1}$ |
| 4. | $3d^3(a^2P)4p$ | $w^1D$ | at | 39265.80 $cm^{-1}$ |
| 5. | $3d^3(a^2P)4p$ | $r^3D_{C.G.}$ | at | 40728.70 $cm^{-1}$ |
| 6. | | $w^1G$ | at | 40883.30 $cm^{-1}$ |
| 7. | $3d^3(a^2H)4p$ | $u^3G_{C.G.}$ | at | 41397.82 $cm^{-1}$ |
| 8. | | $w^3H_{C.G.}$ | at | 41903.49 $cm^{-1}$ |
| 9. | | $q^3D_{C.G.}$ | at | 42243.52 $cm^{-1}$ |
| 10. | | $p^3D_{C.G.}$ | at | 42304.49 $cm^{-1}$ |
| 11. | $3d^24s(a^2S)4p$ | $w^1P$ | at | 42927.55 $cm^{-1}$ |
| 12. | | $r^3F_{C.G.}$ | at | 43624.79 $cm^{-1}$ |
| 13. | | $v^1D$ | at | 43710.28 $cm^{-1}$ |

From Table 2, the calculated value of the term $^3P(^1P)y^3S$ is 33984 $cm^{-1}$. Thus, if the experimental term $y^3S$ were inserted into the least-squares the deviation would be around 1500 $cm^{-1}$. As this deviation is about 13 times the mean error, and furthermore, since the term $y^3S$ has only combinations with the terms $a^3P$ and $b^3P$ (16), it was excluded.

The terms $3d^3(a^2G)4pt^3F$, $3d^3(a^2G)4px^1G$, $3d^3(a^2P)4pw^1D$, and $3d^3(a^2P)4pr^3D$ were excluded as the deviations would be exceedingly large (800–1000 $cm^{-1}$). It is felt that most of this effect is due to the interactions with the configurations $(3d + 4s)^35p$.

Russell does not attribute to $w^1G$ any definite configuration designation, and furthermore, he mentions that "this term depends on only three faint lines and may not even be real". This conclusion is verified by our results, since to all the calculated levels in the vicinity of $w^1G$ there correspond other experimental levels.

From the combinations found by Russell for the levels of $u^3G$, it is apparent that it is a valid term. However, if assigned to the theoretical term $(^2H)^3G$, the deviation would be around $-1500$ $cm^{-1}$. As this deviation is considerably higher than for the other terms, and since the experimental term $u^3G$ is high enough in order to conceivably belong to $(3d + 4s)^35p$, it was excluded.

As the three theoretically predicted terms $^3H$ of $(3d + 4s)^34p$ correspond to $z^3H$, $y^3H$, and $x^3H$, the term $w^3H$ is superfluous. Russell suggested that the term $w^3H$ may be assigned to configurations containing a $5p$ electron. However, in the configurations $(3d + 4s)^34p$, the term $3d^24s(b^2G)4pz^3H_{C.G.}$ at 31930 $cm^{-1}$ is higher by 13330 $cm^{-1}$ than the term $3d^24s(a^4F)4pz^5D_{C.G.}$ at 18600 $cm^{-1}$. Thus $w^3H$ cannot be assigned to $3d^24s(b^2G)5pw^3H$, since the experimental term $3d^24s(a^4F)5pv^5D$ is higher than $w^3H$ (16). Thus the levels of $w^3H$ probably belong to $3d^24s(a^4F)5px^5G$.

If either the term $q^3D_{C.G.}$ at 42243.52 $cm^{-1}$ or the term $p^3D_{C.G.}$ at 42304.49 $cm^{-1}$ were fitted to the only possible calculated term in that vicinity, $3d4s^24p^3D$, the deviations would be around $-1000$ $cm^{-1}$. Hence one of these two terms belongs to the configurations $(3d + 4s)^35p$, and the other is strongly affected by it. Thus both were excluded. Similar conclusions hold for the terms $3d^24s(a^2S)4pw^1P$, $r^3F$, and $v^1D$, as well as for most other terms above 44000 $cm^{-1}$. However, the six levels of $s^3G$ and $p^3F$ in the 47000 $cm^{-1}$ range have very low deviations.

In the configuration $(3d + 4s)^34p$, the lowest six terms are $[d^{2,3}F + (sp)^3P]^{3,5}D, F, G$. It is conceivable that the terms $u^3G$, $w^3H$, $v^5D$, $p^3D$, $r^3F$, and $t^3G$ belong to the lowest terms of $(3d + 4s)^35p$, with the following assignments: $(^3F + {}^3P)$: $z^3D(p^3D)$, $z^3F(r^3F)$, $z^3G(t^3G)$, $z^5D(v^5D)$, $z^5F(u^3G)$, $z^5G(w^3H)$.

In parentheses are the corresponding terms with a $4p$ electron. The term $p^3D$ was chosen over $r^3D$, according to a suggestion already made by Russell (17).

From Table 2 it is evident that the purity of many levels is low. In many cases, the mixing involves eigenfunctions of levels of both configurations $3d^34p$ and $3d^24s4p$, and in some instances even all three configurations.

The lowest calculated levels with no corresponding experimental levels are the levels $^3P(^3P)^1S$ and $^1D(^3P)^3P_0$ at 25356 $cm^{-1}$ and 25593 $cm^{-1}$, respectively.

There was excellent agreement between the experimental and calculated Lande $g$-factors. Hesse (20) has obtained the $g$-factors of the levels of $x^3F$, to four-figure accuracy. These values correspond closely to the calculated values.

All 212 calculated energy levels and $g$-factors are given in Table 2.

# The relation of physical properties of alkanes to connectivity indices: a molecular explanation

JOHN T. EDWARD

*Department of Chemistry, McGill University, 801 Sherbrooke St. West, Montreal, P.Q., Canada H3A 2K6*

Received July 30, 1981

JOHN T. EDWARD. Can. J. Chem. **60**, 480 (1982).

Additive schemes for calculating the molar volumes and heats of vaporization of liquid alkanes from increments characteristic of the numbers and different types of carbon atoms (primary, secondary, tertiary, quaternary), of the mole fraction $Z_g$ of *gauche* conformations, and (where necessary) of other steric factors have been developed. It is suggested that schemes for correlating physical properties of alkanes with connectivity indices $^m\chi_t$ are successful because these indices are also correlated with numbers and types of carbon atoms and with $Z_g$.

JOHN T. EDWARD. Can. J. Chem. **60**, 480 (1982).

On a développé des schémas additifs pour calculer les volumes et les chaleurs de vaporisation molaires des alcanes liquides à partir d'incréments caractéristiques de la quantité et des types d'atomes de carbone (primaire, secondaire, tertiaire, quaternaire), de la fraction molaire des conformations gauches, $Z_g$, et (lorsque c'est nécessaire) d'autres facteurs stériques. On pense que les schémas de corrélation des propriétés physiques des alcanes avec les indices de connectivité $^m\chi_t$ sont utiles parce qu'ils permettent aussi d'établir une corrélation avec la quantité et les types d'atomes de carbone et avec $Z_g$.

It has long been recognized that many physical properties of alkanes such as boiling point correlate roughly with the number $n$ of carbon atoms in the molecule. However, the boiling points of isomeric alkanes having the same $n$ differ, and obviously the branching or connectivity of the carbon network must also be taken into account. In fact, it was found by Randić (1) that the boiling point and other physical properties correlate well with a "branching index", which later became the first-order "connectivity index" $^1\chi$ (2). $^1\chi$ is dependent on both $n$ *and* the extent of branching of the molecule.

Better correlations are generally obtained using additional connectivity indices $^m\chi_t$ (3). A full treatment of the calculation and uses of $^m\chi_t$ is given in a book by Kier and Hall (2); here we can give only a brief discussion. To calculate any $^m\chi_t$ we consider the organic molecule (in the present case an alkane) as a graph with the $n$ carbon atoms as vertices and $m(= n - 1)$ bonds as edges (hydrogen atoms are suppressed). The graphs of ethane **1**, propane **2**, butane **3**, and isobutane **4** are shown in Scheme 1, with the valence (≡ number of skeletal bonds) δ of each vertex indicated on the graph. A graph may be made up of subgraphs of various types $t$ (path P, cluster C, path/cluster PC, chain (cycle) CH). Each connectivity index $^m\chi_t$ is evaluated as the sum of terms over all the possible subgraphs of $m$ edges. The subgraphs for $^0\chi$ consist of the vertices only (no edges), and $^0\chi$ is defined by

$$[1] \quad {}^0\chi = \sum_{i=1}^{n} \delta^{-1/2}$$

Values of $^0\chi$ for the alkanes **1**, **2**, **3**, and **4** are shown in Scheme 1. The subgraphs for $^1\chi$ consist of the individual edges, terminating in vertices of valence $\delta_i$ and $\delta_j$, and $^1\chi$ is defined by

$$[2] \quad {}^1\chi = \sum_{i=1}^{m} (\delta_i \delta_j)^{-1/2}$$

Values of $^1\chi$ for **1**, **2**, **3**, and **4** are also shown in Scheme 1.

Higher-order connectivity indices are obtained by summing up contributions from higher-order subgraphs. With $m \geq 3$, a differentiation of subgraphs into types P, C, and CH becomes possible (**3** is made up of paths *abc* and *bcd*, and **4** of *abc*, *abd*, and *dbc* having $m = 2$, whence $^2\chi_P$ may be calculated for these isomers; *abcd* of **4** represents the simplest possible cluster). For our present purposes it suffices that $^m\chi_t$ indices encode information about branching, so that generally isomers of identical $n$ have at least some $^m\chi_t$ different (compare $n$, $^0\chi$, and $^1\chi$, for **3** and **4** in Scheme 1).

Among the physical properties of organic compounds correlated with $^m\chi_t$ by Kier, Hall, and their associates (2) are heats of atomization, molar refractions, molar polarizabilities, diamagnetic susceptibilities, heats of vaporization, boiling points, liquid densities, water solubilities, and partition coefficients; among biological properties are anesthetic potencies, nonspecific narcotic activities, inhibition of various enzymes, vapour toxicities, toxicities against the red spider, and antimicrobial activities. Thus for a set of 46 alkanes for which

| $^0\chi$ | 2.000 | 2.707 | 3.414 | 3.577 |
| $^1\chi$ | 1.000 | 1.414 | 1.914 | 1.732 |

SCHEME 1

data were considered to be of the highest quality, the liquid density $d$ in g mL$^{-1}$ at 20°C was given by

$$[3]\quad d = 0.7955 - 0.4288/^1\chi + 0.0131^3\chi_P - 0.0079^5\chi_P + 0.0051^4\chi_{PC} + 0.0035^5\chi_{PC}$$

(correlation coefficient $r = 0.9971$, standard deviation $s = 0.0024$) and for a set of 44 alkanes the heat of vaporization $\Delta H_{vap}$ in kcal mol$^{-1}$ was given by

$$[4]\quad \Delta H_{vap} = 0.567 + 1.752^1\chi + 1.301^2\chi - 0.415^4\chi_P - 0.437^5\chi_P - 0.266^6\chi_P - 2.091^3\chi_C + 3.051^4\chi_C$$

($r = 0.9999$, $s = 0.042$).

Regarding the last equation, Kier and Hall write: "We consider this to be a remarkable achievement ... It would be desirable to analyse each coefficient and $^m\chi_t$ variable in terms of intermolecular forces". A start in this direction is made in the present paper, in which it is shown that the densities and heats of vaporization of the alkanes considered by Kier and Hall may be calculated by simple additive schemes *if the molar concentrations of* gauche *conformations* $Z_g$ (4, 5) *are taken into account.*

## An additive scheme for calculating molar volumes of alkanes

We shall calculate, not densities, but what is equivalent, molar volumes $V(\equiv M/d$, $M$ being the molecular weight) of the neat alkanes at 20°C, since a scheme making use of $Z_g$ has proven successful in calculating the partial molal volumes $\bar{V}°$ of alkanes in carbon tetrachloride (4). The corresponding equation for $V$, expanded to take account of several steric factors besides $Z_g$, is

$$[5]\quad V = V_c + \sum_1^m n^k I^k + \sum_1^r m^p S^p$$

where $V_c$ is a constant term (the "co-volume"), $I$ is the volume increment for the groups $CH_3$, $CH_2$, CH, and quaternary[1] C into which the alkane may be dissected, $n$ is the number of such groups, $S$ is a steric term for certain especially crowded groupings, and $m$ is the number of such groupings in the molecule.

The most pervasive steric effect comes from the contraction in volume ($S^1$ in Table 1) associated with the presence of one gauche conformation ($Z_g = 1$) in 1 mol of alkane. Most of the values of $Z_g$ given in Table 2 have been reported already (4–7); others were calculated by standard methods (4, 5). In applying [5], $Z_g$ becomes $m^1$. In calculations of $\bar{V}°$ (4), the other steric terms $S^2$, $S^3$, and $S^4$ (7) were not needed because highly branched hydrocarbons were not examined. Now they become necessary for some of the compounds in Table 2, and are then indicated in the table.

A least-squares fitting of the experimental data in Table 2 to [5] yields a $V_c$ of 17.375 mL mol$^{-1}$ and values of $I$ and $S$ given in Table 1. The steric terms are all associated with a diminution in volume, and all involve arrangements in which the van der Waals surfaces of parts of the molecules would be compressed if the conformations of the carbon network were maintained in ideal diamond-lattice conformations. However, it is probable that little compression of the van der Waals surfaces takes place, and that instead the torsional angles of the carbon network depart from ideal values (8); the reduction in volume most probably comes from a congestion of atoms in certain parts of the molecule, and is discussed further below.

The agreement between most experimental and calculated values of $V$ in Table 2 is highly satisfactory, in view of the simplicity of the model; the particular cases for which agreement is less satisfactory are considered later.

## Molecular basis of effect of structure on V

The volume $V$ occupied by 1 mol of liquid hydrocarbon is made up partly of the van der Waals volumes of the molecules, and partly of empty volumes between them (9). Models of alkane molecules show that hydrogen atoms completely envelope the carbon skeleton (9), and so in any additive scheme it is reasonable to assign a constant volume to the carbon atom (3.40 mL mol$^{-1}$ (4)), and variable volumes to the hydrogen atoms to include the variable empty volumes associated

TABLE 1. Parameters (in mL mol$^{-1}$) for calculation of molar volume $V$ by [5]

| Group | $I$ | Steric effect | $S$ |
|---|---|---|---|
| $-CH_3$ | 24.803 | g ($S^1$) | −2.055 |
| $=CH_2$ | 16.526 | $g^+g^-$ or $g^-g^+$ ($S^2$) | −0.878 |
| $\equiv CH$ | 9.671 | 2,2,3-$Me_3$ ($S^3$) | −1.286 |
| | | 2,2,3,3-$Me_4$ ($S^4$) | −3.565 |

[1]For reasons already discussed (4), $I$ for quaternary carbon is given the value of 3.40 mL mol$^{-1}$.

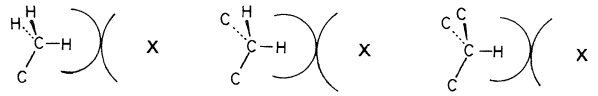
with them. On this basis, the increment for the single hydrogen atom depends on the type of carbon to which it is attached, being 7.13 mL mol$^{-1}$ for $CH_3$ (p) hydrogen, 6.56 mL mol$^{-1}$ for $CH_2$ (s) hydrogen, and 6.27 mL mol$^{-1}$ for CH (t) hydrogen.

If we regard the van der Waals volume of the hydrogen atom as being relatively constant, at about 3.43 mL mol$^{-1}$ (9), then the diminishing empty volume associated with hydrogen atoms in the order p > s > t may be explained by the increasing intermolecular attraction in the order p < s < t, so that another molecule X has a greater tendency to remain in the neighbourhood of methine hydrogen, for example (and thereby reduce the empty volume), than in the neighbourhood of methyl hydrogen. This can be understood by a consideration of **5**, **6**, and **7** in Scheme 2. The attraction of X to the portion of the molecular surface covered by methyl hydrogen atoms will be determined by the other atoms shown in **5**; because the energy of attraction falls off as the sixth power of the distance, other atoms of the molecule will be too distant to have any influence. Since carbon is more polarizable than hydrogen, attraction should increase in the order **5** < **6** < **7**, as carbon replaces hydrogen in the sphere in which interatomic attractive forces are appreciable. When considering $\bar{V}^\circ$ of a hydrocarbon in a solvent such as carbon tetrachloride (4), X is $CCl_4$; when considering $V$ of the neat hydrocarbon, X is a portion of a contiguous hydrocarbon molecule.



5 6 7

SCHEME 2

### An additive scheme for calculating $\Delta H_{vap}$

Like the molar volume $V$, the enthalpy of vaporization $\Delta H_{vap}$ of alkanes must also depend on the strength of the attractive forces holding the molecules together in the liquid. According to the picture above, this varies over the molecular surface, according to whether the surface is covered by methyl, methylene, or methine hydrogen atoms. It seems likely that the same steric factors $S^1$, $S^2$, $S^3$, and $S^4$ which increase density will also increase molecular attraction, so that the enthalpy of vaporization should be given by the equation

$$[6] \quad \Delta H_{vap} = \sum n^k H^k + \sum m^l S^l$$

where $n$ is the number of hydrogen atoms of a particular type (p, s, or t) and $H$ is the enthalpy increment associated with this type of atom. A least-squares fitting of the experimental data of Table 2 to [6] yields the parameters of Table 3, and using these parameters the calculated values of $\Delta H_{vap}$ in Table 2 are obtained. These agree with the experimental values fairly well (though less well than values calculated from [4]). The steric effects are all positive, as expected, except for $S^2$, which is essentially negligible.

### Failures of the additivity schemes

The degree of success of [5] and [6] is remarkable in view of the naiveté of the model adopted. Thus, if we examine the scale drawing in Fig. 1, we can see that while A and B are not too dissimilar to **5** and **6** (respectively) of Scheme 2, D and E are quite dissimilar, and that more atoms than those shown in **5**, **6**, and **7** are involved in attracting X to the hydrocarbon molecule. This would also be true as the steric effects $S^1$, $S^3$, and $S^4$ crowd atoms of the alkane together, and would explain why these effects are negative for $V$ and positive for $\Delta H_{vap}$. However, with the increased accumulation of branches on the chain, the molecule becomes stiffer, and one can imagine that shape effects, which could only be recognized by a study of individual molecules in their preferred conformations, might become important. Such shape effects could result in some molecules packing together in the liquid more snugly than usual,[2] and so having both $V$ smaller and $\Delta H_{vap}$ greater than expected (i.e. having $\Delta V = V_{exptl} - V_{calcd}$ negative and $\Delta\Delta H_{vap} = \Delta H_{vap(exptl)} - \Delta H_{vap(calcd)}$ positive), and other molecules of awkward shape packing together less well than usual, and having $\Delta V$ positive and $\Delta\Delta H_{vap}$ negative. In Fig. 2 $\Delta\Delta H_{vap}$ is plotted against $\Delta V$ for the fourteen worst cases in Table 2 (Nos. 10, 12, 18, 19, 26, 29, 30, 36, 38, 44, 45, 50, 51, 52), which have $\Delta H_{vap}$ differing by more than 0.1 kcal mol$^{-1}$, or $V$ by more than 0.6 mL mol$^{-1}$ from calculated values. The points do indeed cluster about a line of negative slope, as required by the simple-minded considerations above; the scatter of points is considerable, but is to be expected, since both $\Delta V$ and $\Delta\Delta H_{vap}$ are small differences between large numbers, and the effect of experimental error is magnified.

[2]The evidence in this paper does not support the idea that *n*-alkanes above *n*-octane pack together in the liquid in such a way as to favour the all-extended conformation, with a consequent reduction of $Z_g$ from the value noted in the spherical solvent, carbon tetrachloride.

TABLE 3. Parameters (in kcal mol$^{-1}$) for calculation of heat of vaporization $\Delta H_{vap}$ by [6]

| Type of H atom | $H$ | Steric effect | $S$ |
|---|---|---|---|
| —$CH_3$ (p) | 0.446 | g ($S^1$) | 0.036 |
| =$CH_2$ (s) | 0.595 | $g^+g^-$ or $g^-g^+$ ($S^2$) | −0.008 |
| ≡CH (t) | 0.678 | 2,2,3-$Me_3$ ($S^3$) | 0.090 |
| | | 2,2,3,3-$Me_3$ ($S^4$) | 0.264 |

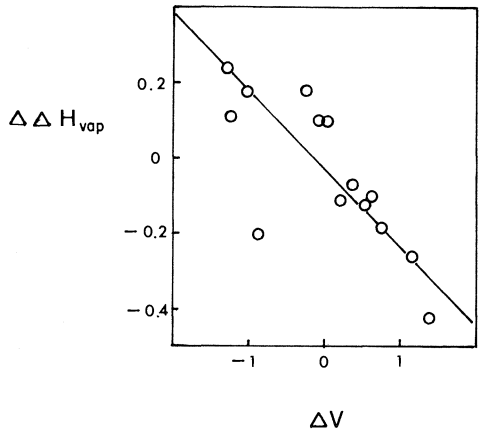

FIG. 2. Relation of $\Delta\Delta H_{vap}$ (in kcal mol$^{-1}$) to $\Delta V$ (in mL mol$^{-1}$).

## Relation of explanations based on molecular additivity to those based on connectivity

We now attempt to relate the empirical equations [3] and [4] based on connectivity to those ([5] and [6]) based on simple additivity schemes.

We may first note that $^0\chi$ is correlated to $n$ with $r = 0.991$; $^1\chi$ to $n$ with $r = 0.978$, and higher order connectivity indices to $n$ with continually decreasing $r$ (ref. 2, p. 250). In fact[3] we can write

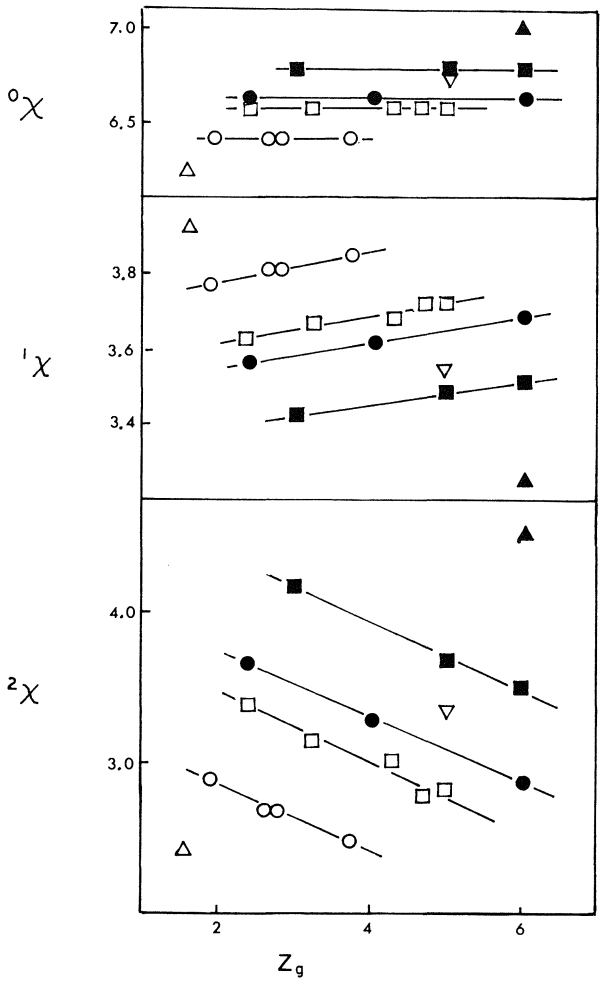

FIG. 3. Variation of $^m\chi$ of isomeric octanes with $Z_g$. Numbers of different types of carbon atoms ($n_p, n_s, n_t, n_q$) are as follows: △: 2,6,0,0 ($C_8$); ○: 3,4,1,0 (2-$MeC_7$, 3-$MeC_7$, 4-$MeC_7$, 3-$EtC_6$); □: 4,2,2,0 (2,3-$Me_2C_6$, 2,4-$Me_2C_6$, 2,5-$Me_2C_6$, 3,4-$Me_2C_6$, 2-Me-3-$EtC_5$); ●: 4,3,0,1 (2,2-$Me_2C_6$, 3,3-$Me_2C_6$, 3-Me-3-$EtC_5$); ▽: 5,0,3,0 (2,3,4-$Me_3C_5$); ■: 5,1,1,1 (2,2,3-$Me_3C_5$, 2,2,4-$Me_3C_5$, 2,3,3-$Me_3C_5$); ▲: 6,0,0,2 (2,2,3,3-$Me_4C_4$).

[7] $$n = n_p + n_s + n_t + n_q$$

[8] $$^0\chi = n_p + \frac{n_s}{\sqrt{2}} + \frac{n_t}{\sqrt{3}} + \frac{n_q}{\sqrt{4}}$$
$$= n_p + 0.707n_s + 0.578n_t + 0.500n_q$$

and for straight chain alkanes (which contain only p and s carbon atoms) having $n \geq 4$

[9] $$^1\chi = 0.457n_p + 0.500n_s$$

[3]Equations [8] and [9] have been obtained by simple inspection of tables of $^m\chi_t$ values (ref. 2, p. 240); doubtless they can be derived by appropriate manipulation of [1] and [2].

For personal use only.

Consequently, the different $\chi$ values give different weights to the contributions of $CH_3$, $CH_2$, CH, or quaternary carbon atoms, a feature also found in the additive schemes of [5] and [6]. Furthermore, when we consider isomers having the same $n_p$, $n_s$, $n_t$, and $n_q$, $^1\chi$ and $^2\chi$ are roughly linear with $Z_g$, as illustrated for the isomeric octanes in Fig. 2 *B* and *C*. Figure 2*A* shows that $^0\chi$ is independent of $Z_g$, and depends only on $n_p$, $n_s$, $n_t$, and $n_q$, as required by [8].

We can accordingly see that the various $^m\chi_t$ terms encode information, in varying proportions, about *both* the nature and number of carbon atoms in the alkanes *and* the degree of folding of the molecule ($Z_g$). This answers in part the problem raised by Kier and Hall (ref. 2, p. 221): "The difficulty encountered in considering molecular connectivity is that there is not yet a developed intuition as to what familiar structural characteristics are described by $^1\chi$, $^2\chi^v$, $^5\chi_p{}^v$, etc." It might prove profitable to examine the other physical properties of alkanes which correlate with various mixtures of $^m\chi_t$ to see whether they too can be accommodated by simple additive schemes making use of $n_p$, $n_s$, $n_t$, $n_q$, and $Z_g$.

# Thermochemistry of ion exchange and particle interaction in clay suspensions

LAURIER L. SCHRAMM[1] AND JAN C. T. KWAK
*Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3*

Received January 7, 1981[2]

LAURIER L. SCHRAMM and JAN C. T. KWAK. Can. J. Chem. **60**, 486 (1982).

The measurement of enthalpies of ion exchange for a number of homovalent and heterovalent exchange pairs by titration calorimetry is described. A self-consistent addition to previous measurements on such systems is reported. In addition to the enthalpies of ion exchange the heats of tactoid formation and breakdown were observed. The apparent heat of tactoid formation for the Na–Ca exchange pair is estimated to be −4.9 kJ per equivalent of ion exchange.

LAURIER L. SCHRAMM et JAN C. T. KWAK. Can. J. Chem. **60**, 486 (1982).

On décrit la mesure des enthalpies d'échanges d'ions d'une série de paires d'échanges homovalent et hétérovalent par titrage calorimétrique. On rapporte une addition auto-cohérente qui complète les mesures antérieures relatives à de tels systèmes. En plus des enthalpies d'échanges d'ions, on a observé les chaleurs de formation et de décomposition tactoide. On a évalué à −4,9 kJ par équivalent d'échanges d'ions la chaleur apparente de formation tactoide pour la paire d'échanges Na–Ca.

[Traduit par le journal]

## Introduction

Thermodynamic quantities provide useful information about interactions in clay suspensions. Although the usefulness of calorimetry in clay research has been demonstrated, relatively few studies have been carried out on the thermochemistry of ion exchange reactions in suspension. One reason for the scarcity of data in this connection is the low heat of reaction that characterizes the ion exchange process. As a result, careful calorimetric techniques are required to adequately determine the enthalpies of exchange.

Homshaw and Chaussidon (1) used calorimetry to study the distribution of water in montmorillonite samples of low water concent and to show the strong effect of water on the arrangement of clay plates. A number of studies have been concerned with measuring heats of immersion in water of clays. For example Keren and Shainberg (2, 3) measured heats of immersion of Na- and Ca-montmorillonite and mixed Na/Ca-montmorillonite. Keren and Shainberg found that the interplate adsorption process is different from that which takes place on external surfaces. These authors separated the heat of immersion into contributions from hydration reactions and from ion mixing and tactoid formation. They concluded that a strongly exothermic condensation of plates to form tactoids is the driving force for the demixing of adsorbed ions.

The more common studies involving calorimetry applied to clays have been concerned with observing ion exchange reactions, usually only to provide data for comparison with the results of the temperature dependence of equilibrium constant or selectivity coefficient measurements. Early measurements were made on H-form clays (4, 5). These experiments raise some uncertainty as to the proper interpretation of results when taking into account the possibility of acid attack of the clay lattice and the accompanying changes in surface composition. Another significant problem with such measurements is that the effect of the large heat of formation of water (H-form clay is titrated with base) makes it difficult to determine accurately the relatively small heat effect of the actual ion exchange reaction. Despite these difficulties, Martin and Laudelout (4) obtained heats of exchange by correcting the measured heat for the heats of formation of water, neutralization of $Al(H_2O)_6^{3+}$ (in aged clay), exchange of $Al^{3+}$ by the titrant cations, dilution of the base and gelation (from changes in aggregation). The values thus obtained are in reasonable agreement with values which they obtained directly by adding the appropriate salt to a clay suspension and correcting for a first small amount of reaction. The values obtained also agree with the results they obtained from the method of common final states in which equivalent amounts of reactants were mixed with clay, first with one ion on the clay and then the other, with a correction for the difference in apparent molal enthalpy of the two salts at their final concentration. The enthalpy change obtained in this fashion and from the previous methods is the value corresponding to the simple reaction:

*Parentheses indicate that $\Delta H°$ is for the reverse reaction, as actually measured.
†Determined by neutralization.
‡Determined by the common final state method.
§Determined by exchange in dilute suspension.
¶Determined using a separate determination of the equilibrium state.

The results of Martin and Laudelout for each of these methods are included in Table 1 (columns *1–3*), in which the results of a number of calorimetric studies on comparable montmorillonite samples are listed. Given the difficulties in interpretation inherent in the heat of neutralization method (column *1*), many authors use sensitive microcalorimeters to determine directly the small thermal changes in exchange reactions such as

[2] $Na^+ + Li\text{-clay} \rightarrow Na\text{-clay} + Li^+$

Gast *et al.* (6, 7), Laudelout *et al.* (8), and Van Bladel (9) used the method of common final states with a Calvet microcalorimeter to determine $\Delta H°$ for ion exchange reactions. Their results are summarized in Table 1. In a series of papers Maes *et al.* (10–12) reported enthalpies of ion exchange using an LKB batch microcalorimeter and a method in which a salt was added to a clay suspension and the equilibrium state determined separately. Some of their results are also included in Table 1. These authors also followed the changes in enthalpy of ion exchange on montmorillonite of varying degrees of charge density (prepared using the Hofmann–Klemen effect, ref. 13). The variation in $\Delta H°$ observed with changing charge density was explained on the basis that the enthalpy effects are due to differences in partial dehydration of the counterion.

While most of the results cited were measured by a batch technique using very small cells, titration calorimetry has also been applied to the study of clay suspensions (5) and, for example, humic acid solutions (14). Ewin, Erno, and Hepler (15) describe the application of titration calorimetry to the study of clay suspensions. The titration mode has advantages in simplicity of operation, low-cost instrumentation, and efficiency since the equivalent of a large number of batch experiments can be obtained in a single run, at least when considerations of reaction kinetics can be managed appropriately. An added advantage of the method is its potential to yield not only the enthalpy of exchange, but also the exchange selectivity coefficient and the cation exchange capacity of the clay. We have used the method of Ewin, Erno, and Hepler to measure the heat effect of ion-exchange reactions in relatively dilute montmorillonite suspensions, employing the titration calorimeter built and described by these authors (15). In order to obtain more detailed data for one particular exchange reaction, that of Na–Ca exchange, a second, commercial titration calorimeter (the LKB 8700-2, LKB Instruments, Malmo, Sweden) more suited to the measurement of heat evolved during discrete additions of titrant was used. A difficulty arising in the use of these titration calorimeters, and especially with the LKB unit, is the lack of efficient stirring of clay suspensions containing added electrolyte. The use of a flow microcalorimeter (Sodev Inc., Sherbrooke, P.Q.), which might in principle overcome this difficulty, was also investigated. The main advantage of the flow microcalorimeter would be its ability under steady state conditions to continuously detect thermal changes, thus yielding results equivalent to a large number of static measurements and using only very small volumes of suspension. Although we could demonstrate the sensitivity of the flow microcalorimeter in detecting heat effects from ion-exchange reactions in dilute clay suspensions, experimental difficulties besetting the method finally forced us to abandon this technique.

## Experimental

*Materials*

A sample of montmorillonite, API No. 27 (Ward's Natural Science Establishment) from Belle Fourche, South Dakota (Kerr *et al.*, ref. 16), was ground to −270 mesh. Samples (30 g) were converted to the sodium form by washing three times in 500 mL each 1 *M* NaCl. A sample of bentonite (Fisher Scientific), used for several measurements, was used as received and converted to the sodium form in the same fashion. Total equilibration time was in excess of 70 h. Preliminary desalting was accomplished by decanting and diluting until 1 L of stable suspension was obtained. This suspension was allowed to stand until the > 2 μm equivalent spherical diameter fraction had settled out. The final suspension was desalted by an ultrafiltration/dialysis procedure described previously by Schramm and Kwak (17). This suspension before final desalting was about 1.2 w% in clay and 0.05 *M* in NaCl. Briefly, the procedure consists of passing the suspension through porous hollow fibers at a slightly elevated pressure so that dissolved salts are efficiently removed via ultrafiltration and dialysis simultaneously. The same apparatus was used to convert the sodium form clay into other ionic forms (17). In this method no clay compaction of any kind takes place and the suspension concentration remains the same throughout the desalting, conversion, and final desalting steps. The final suspensions were freeze dried for storage.

The clay samples prepared by this method, or any method involving washing with water to remove salts, are subject to hydrolysis. As a result, the clays are not homoionic but from approximately 90% to 100% homoionic (18). This is a necessary disadvantage in working with suspensions at low ionic strengths. It was found that the total charge density of the clay is not affected by our procedures (18).

*Apparatus and methods*

The titration calorimeter used to obtain most of the enthalpy of exchange data has been described in detail by Ewin, Erno, and Hepler (15). Briefly, the reaction vessel is a 250 mL polypropylene beaker fitted with a Teflon lid, and suspended in a stainless steel canister which in turn was submerged in a constant temperature bath. In our experiments, the bath was maintained at 25.00°C. A stirrer, thermistor, heater, and titrant delivery tube are passed through the Teflon lid. The temperature outside the beaker was maintained constant to ±0.001°C. In our experiments a syringe pump delivered titrant at a rate of 1.126 ± 0.002 mL/min through 1.5 mm id Teflon tubing, 90 cm of which was coiled inside the constant temperature bath. Stirring was by a glass, multibladed stirrer. The output from the thermistor bridge was amplified and measured on a Keithley 160 B digital multimeter and on a stripchart recorder.

In each determination 2 g of montmorillonite (M27) in the appropriate ionic form was suspended in 200 mL of distilled water and titrated with a solution of 0.1 *M* in the chloride salt of the cation to be exchanged. Enthalpies of dilution were measured in separate experiments and subtracted from the enthalpies of ion exchange.[3] Titrant is added continuously from point *b* to point *c*. As the titration continues the heat effects observed at each point in time depend upon the enthalpy of ion exchange for the surface exchangeable composition present at that time, the selectivity coefficient and the exchange reaction rate. If we assume instantaneous equilibrium and an enthalpy of ion exchange and selectivity coefficient which are independent of the surface exchangeable composition, both the enthalpy of ion exchange and the selectivity coefficient can be obtained from a thermogram. For strongly favoured reactions a linear thermogram results and the enthalpy of ion exchange alone is determined.

Temperature data were taken at intervals along the curve *b*–*c* illustrated in Fig. 1. The raw data were then corrected, point by point, for the heat of dilution of the salt (and any associated instrumental heat effects) and for any change in stirring (background) slopes (shown as regions *a*–*b* and *c*–*d*). In the calculations for each run at least 20 points were taken from the region *b*–*c*. Typically, these titrations correspond to adding about 1 mmol of titrant to 2 mequiv of titrate (clay suspension). The heat gained or lost was calculated using the heat capacity of the suspension as measured before and after each run. For the

[3]Most of the enthalpies of dilution used in this study were measured by Dr. G. J. Ewin at the University of Lethbridge.

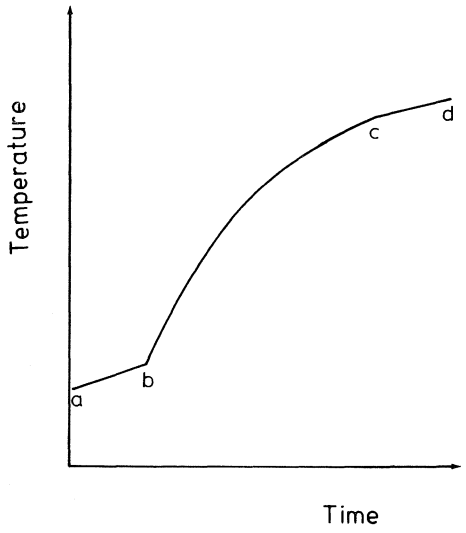

FIG. 1. Illustration of the shape of a typical thermogram as obtained from the continuous calorimeter (arbitrary units).

ion exchange reaction, $\Delta H°$ was assumed to be independent of the surface exchangeable composition. In using a molal selectivity coefficient it is not necessary to choose a special standard state (such as the homoionic solid in contact with an infinitely dilute solution of the corresponding salt). Rather, we take clay plus its counterions as an electrolyte and choose the hypothetical electrolyte solution of unit activity as the standard state. In order to calculate $\Delta H°$ and $K$ values for each thermogram, an initial guess at the value of $K$ is made, the corresponding equilibrium concentrations of competing species calculated, and from the measured heat $\Delta H°$ values for each point on the thermogram are obtained. By refining our choice of $K$ values in an iterative procedure a $K$ value which yields the most nearly constant value for $\Delta H°$ throughout the exchange reaction is obtained. For nearly linear thermograms the exchange reaction can be assumed to proceed to completion and $\Delta H°$ was calculated directly from the number of equivalents of titrant added. The entire group of calculations was carried out using a computer program written by Ewin. A further discussion of the instrumentation and data analysis of this type of calorimetry has been given elsewhere (19).

For additional Na-clay + $CaCl_2$ exchange experiments, use was made of the LKB model 8700-2 precision calorimetry system fitted for titration calorimetry with a Metrohm–Herisau motor buret.[4] This well known instrument has a 100 mL glass reaction cell immersed in a thermostat. In our experiments the temperature was maintained at 25.00°C. The configuration and principle of operation of the instrument are essentially the same as for the calorimeter described above, except that for the LKB the thermistor bridge is balanced manually after each addition of titrant. Stirring in the reaction cell was achieved by means of a small rotating gold clamp normally used to hold glass ampoules (for batch calorimetry). Stirring proved to be the limiting factor for the amounts of clay and salt solution which could be used in this instrument. The stirrer used could not disperse the thixotropic gel formed when sufficient $CaCl_2$ is added to a 2% suspension of Na-montmorillonite.

In each determination 2 g of Na-montmorillonite (M27) suspended in a total volume of 90.0 mL was placed in the cell and titrated stepwise with up to 10.0 mL 0.1 $M$ $CaCl_2$. After each titrant addition, time was allowed to ensure complete equilibration. Heat capacities were measured before and after each titration, but due to experimental difficulties associated with insufficient stirring, only the former was used in the calculations. Each titration took about 7 h to complete. The heat of dilution of $CaCl_2$ and other heat contributions were determined separately.

[4]This calorimeter was also made available to us by Dr. L. G. Hepler of the University of Lethbridge.

## Results and discussion

A summary of the measured enthalpies of ion exchange (reaction [1]) obtained from continuous titrations (Ewin, Erno, Hepler calorimeter) is given in Table 2. We do not report the selectivity coefficients of the exchange reactions because of the fairly large relative uncertainties associated with these quantities in the case of uni-univalent exchanges. However, the uncertainties in the enthalpy of exchange determinations are large enough to cover completely the influence of the relative error in the $K$ values observed. Uncertainties as reported for $\Delta H°$ partly stem from this source of error. That the data are self-consistent can be seen from Fig. 2. Additivities for all the reactions hold within the sum of the uncertainties reported. Referring to Table 1, it is clear that the values obtained for the ion exchange reactions fall within the range of literature values obtained for ion exchange on similar montmorillonite samples. From Tables 1 and 2 it can be seen that the enthalpies of ion exchange are very small, the largest values being observed for the endothermic ion exchanges of monovalent cations by divalent cations. For the heterovalent ion exchange reactions there are several reported values for enthalpies of exchange calculated from the temperature dependence of $\Delta G°$ (e.g. refs. 20, 21) but as might be inferred from Table 1 there are few direct experimental $\Delta H°$ data available. The value obtained here for the K–Ca exchange, +8.4 ± 0.3 kJ/equiv is in good agreement with the value of

TABLE 2. Enthalpies of ion exchange measured by titration calorimetry

| A-clay → B-clay | $\Delta H°$ (kJ/equiv) | Number of titrations |

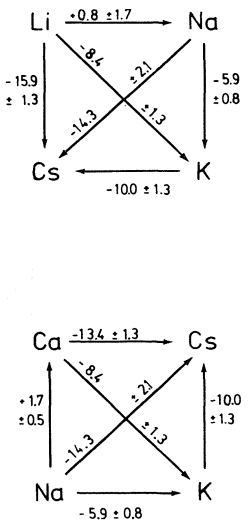

FIG. 2. Additivity diagrams for the measured enthalpies of ion exchange (kJ/equiv) on montmorillonite (M27). The arrows indicate the direction of reaction actually measured.

+8.1 kJ/equiv calculated by Hutcheon (20). The value obtained for the Na–Ca exchange, +1.7 ± 0.5 kJ/equiv is close to those measured by Maes and Cremers (10) for two montmorillonites: +1.72 and +1.4 kJ/equiv. Other values have been calculated or observed for this reaction, however. Tymochowicz (21) calculated 4.8321 kJ/equiv and Laudelout *et al.* (8) measured 5.10 kJ/equiv. This latter value agrees with that which can be inferred from these authors' other values in Table 1, column *1*, i.e. 5.6 kJ/equiv. Ewin *et al.* (15), using the same instrument and methods as in the present work, found a value of +1.7 ± 0.4 kJ/equiv in agreement with the present work and that of Maes and Cremers. Ewin *et al.* (15) observed values of −5.3 ± 0.4 and −18.4 ± 0.8 kJ/equiv for the Na–K and Na–Cs exchanges respectively. These values again are in good agreement with those of the present work, and somewhat more exothermic than the literature values tend to be.

A comparison of all the data presented indicates that while the homovalent exchange reactions are fairly well described, there is some variability in the data reported for heterovalent exchanges. Maes and Cremers (10) note that for heterovalent exchange reactions there seems to be some "partial and apparent irreversibility ... which seems to be restricted to the bivalent-rich end of the composition scale." In view of our earlier observations (22) concerning particle size changes in the same surface exchangeable composition range, it is worth examining in this context the features of some of the actual thermograms obtained.

In a separate paper (22) we describe the variations in the numbers of clay plates per aggregate (tactoid) as a function of surface ionic composition. It is observed that there are fairly narrow regions of surface ionic fraction over which these tactoids form or break down. Figure 3 shows the variation in tactoid size for the Na–Ca exchange pair, as determined from light scattering measurements, in terms of the relative number of plates per tactoid, $N$ ($N$ is relative to the Li-form having $N = 1$). A somewhat similar curve is observed for the Na–Cs exchange reaction (22). If we interpret the sharp rise in $N$ below Na equivalent fractions of 0.2 as a region of tactoid formation, we might expect this tactoid formation to influence the measured exchange enthalpies. The thermograms obtained for the homovalent exchanges are all fairly regularly shaped curves giving no indication of any additional enthalpy changes at any point, even in systems where considerable tactoid size changes are known to occur. As an example, Fig. 4 shows a typical curve, in this case for the Na–Cs exchange reaction. Considering the amount of $Cs^+$ added, the region of tactoid formation which occurs during this particular exchange reaction (22) is contained in this figure but no region of altered slope appears; hence any associated enthalpy effects are apparently too small to affect the curve. One other reaction

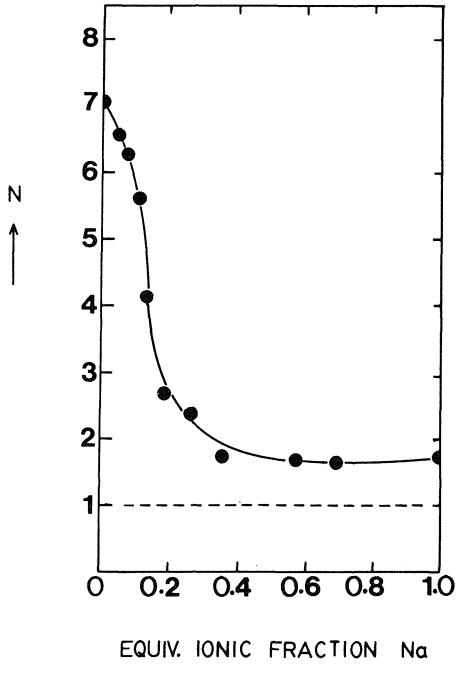

FIG. 3. Graph of relative plate numbers per tactoid versus surface ionic fraction of ions for exchange of Na with Ca on montmorillonite.

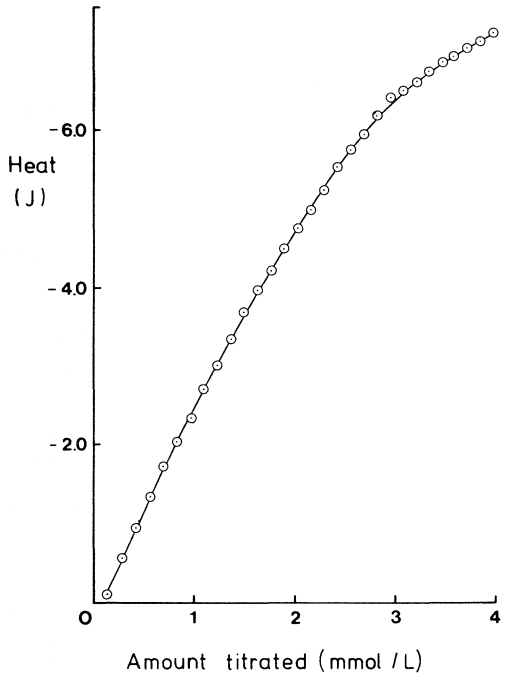

FIG. 4. Thermogram (continuous titration) obtained for the Na–Cs exchange reaction on 1.98 g of Na-montmorillonite (M27). The vertical axis shows the measured heat corrected for the heat of dilution of the titrant CsCl. The horizontal axis gives the amount of CsCl added.

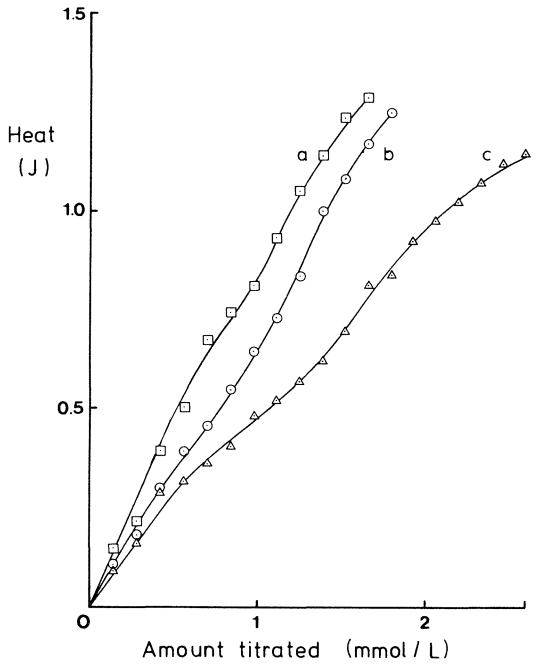

FIG. 5. Thermograms obtained for the Na–Ca exchange on (*a*) 2.12, (*b*) 0.95, and (*c*) 2.11 g of Na-montmorillonite (M27). The vertical axis gives the measured heat corrected for the heat of dilution of the titrant $CaCl_2$. The horizontal axis gives the amount of $CaCl_2$ added.

studied which should include the effect of tactoid formation is the Na–Ca exchange. The thermograms obtained for this case are given in Fig. 5. Since the value of $K$ for the Na–Ca exchange is fairly large, the thermogram curves should be nearly linear and in any case of regularly decreasing slope. It is clear that for each curve there is a region of distinctly altered slope, in each case covering a region corresponding to the same surface composition. It is evident that were these regions of altered slope not present the curves would indeed have the expected shape. For each titration an exothermic change in slope occurred at $\bar{X}_{Ca} = 0.15 \pm 0.03$ (equivalent fraction) and the original slope was regained at $\bar{X}_{Ca} = 0.4 \pm 0.1$. On the other hand, Fig. 3 indicates that under equilibrium conditions tactoids form over the region $\bar{X}_{Ca} = 0.5$–$0.7$. Our present results point to an initial formation of tactoids in regions of high *local* $Ca^{2+}$ concentrations caused by inadequate stirring. These tactoids then may not disperse quickly enough during the rest of the titration. The aggregation indicated by the enthalpy change does continue to the point where it *is* favoured at equilibrium. As has been reported by Shainberg and Kaiserman (23), tactoid formation is very fast, while tactoid breakdown can take place in the order of minutes: enough time to cause the observed effects. The heat effect causing the shift in the curves shown in Fig. 4 can be estimated by extrapolating the "regular" portions of the curve below $\bar{X}_{Ca} = 0.15$ and above $\bar{X}_{Ca} = 0.4$. Using this method we can estimate both (*a*) the overall $\Delta H°$ which would result were the observed irregularity in the thermograms not present, and (*b*) a "$\Delta H$ of tactoid formation". The average $\Delta H°$ of ion exchange would then be about +1.9 kJ/equiv compared to 1.7 kJ/equiv from Table 2. This is in fact within the estimated uncertainty of the earlier value. The "heat of tactoid formation" from curve (*c*) in Fig. 5 is in the order of −0.5 kJ/equiv of ion exchange over the range of ion exchange in which it was observed. If the tactoid formation was due to high local concentrations of titrant, then the units become meaningless and we can conclude only that the reaction to form tactoids is exothermic and of the order of a kJ or so per equivalent of exchange reaction. The exothermic nature of tactoid formation is expected and will be discussed later.

In the exchange of $Ca^{2+}$ by $K^+$ illustrated in Fig. 6, a change in slope over a narrow region of surface coverage is again observed. In this case the change in slope is endothermic and is interpreted to be the result of tactoid breakdown as $K^+$ ions penetrate

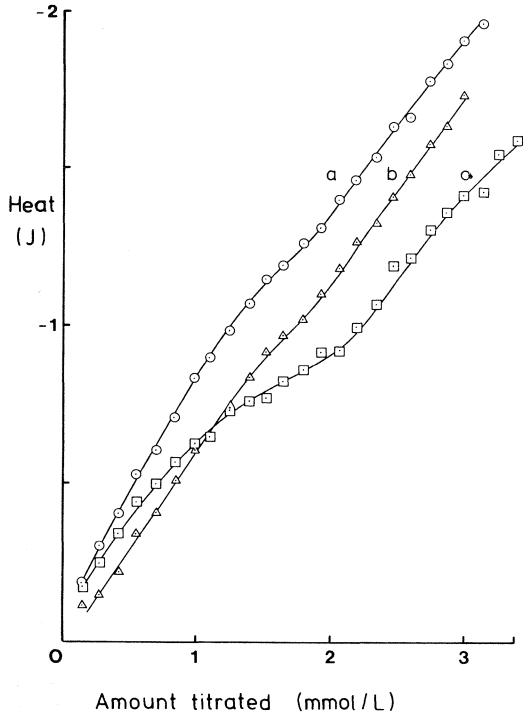

FIG. 6. Thermograms obtained for the Ca–K exchange on (*a*) 1.52, (*b*) 1.99, and (*c*) 2.89 g of Ca-montmorillonite (M27). The vertical axis gives the measured heat corrected for the heat of dilution of the KCl.

the tactoids. Using the value of selectivity coefficient which was fitted to the overall Ca–K thermogram ($K_{Ca/K} = 5 \times 10^{-2}$), and the surface equivalent fraction value required for tactoid breakup predicted from previous work (22), the total KCl concentration for breakup should be 0.001 *M* for curve (*c*) in Fig. 6, as observed. Similarly, significant enthalpy effects due to tactoid breakdown should disappear in the concentration range 0.002–0.003 *M* for curve (*c*), again, as observed.

While the observed enthalpies of tactoid formation and breakdown are not of sufficient magnitude to invalidate the enthalpy data for ion exchange presented here, they may contribute a significant error to measurements made using more sensitive methods or calorimeters (e.g. the Calvet or LKB batch microcalorimeters).

*Stepwise titrations*

Based on the results presented so far, in which apparent heats of tactoid formation and breakdown were observed but could not be quantified, it was of interest to determine whether allowing more time for equilibration would produce the same results, or results in closer agreement with expectations, based on a consideration of tactoid formation. While such measurements could in principle be made with the continuous calorimeter, the LKB calorimeter was considered to be more convenient for this purpose. As an example, Fig. 7 shows a thermogram obtained from a series of steps in the titration of $CaCl_2$ into a Na-montmorillonite (M27) suspension. Resistance values were converted to temperatures directly without correction for heats of leakage, stirring etc., except to the extent that they are the same for the reaction and dilution experiments. Comparison of the values thus obtained with those calculated by the Regnault–Pfaundler method (24) indicated that this was sufficient.

It can be seen from Fig. 7 that at a certain point (ca. $\bar{X}_{Ca} = 0.7$) the endothermic heat of exchange has diminished somewhat, and that by $\bar{X}_{Ca} \approx 0.9$ a definite exothermic apparent heat of exchange is observed. If the enthalpy of exchange as determined from the first addition of titrant is subtracted from each of the apparent enthalpies of exchange at each step in the titration, then (having corrected for the heat of dilution) an approximate heat of tactoid

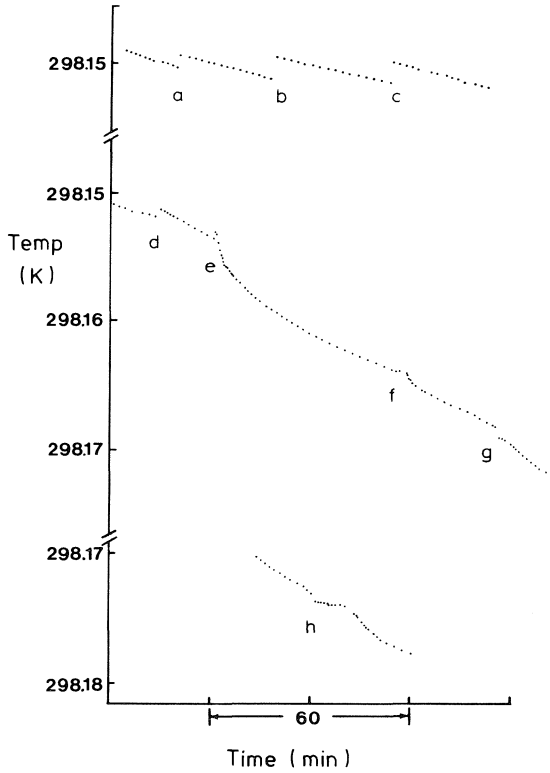

FIG. 7. Thermogram obtained from an LKB calorimeter titration of Na-montmorillonite with $CaCl_2$. In this case temperature is plotted versus time. Additions of titrant are 1 mL at points *a*, *d*–*h* and 2 mL at points *b* and *c*. Note changes in scale, the three segments are all from the same thermogram.

For personal use only.

formation per equivalent of ion exchange is obtained. This quantity, averaged over two separate titrations, is plotted in Fig. 8 as a function of surface ionic fraction sodium, assuming $K$ is large. This curve has the same features as Fig. 3 and shows that under conditions where equilibrium can be attained, the heat effect associated with tactoid formation apparently is indeed observed, and at about the same surface fractions as are other tactoid related properties. The enthalpies for Na–Ca exchange are:

$$\Delta H^\circ_{\text{exchange}} = +1.9 \pm 0.2 \text{ kJ/equiv}$$

$$\Delta H^\circ_{\text{tactoid formation}} = -4.9 \text{ kJ/equiv of ion exchange}$$

The enthalpy of ion exchange is in good agreement with the value obtained using the continuous calorimeter (+1.7 kJ/equiv, see above) and with the results of Ewin *et al.* (15) and Maes and Cremers (10). The apparent heat of tactoid formation is expressed per equivalent of ion exchange reaction for the region of ion exchange in which it is observed. The exothermic character of the reaction is in agreement with the previous results as will be discussed.

*On tactoid formation*

The results presented so far have demonstrated that tactoid formation and breakdown is accompanied by significant heat changes. The reaction to form tactoids is exothermic and for the Na–Ca reaction a value of −4.9 kJ/equiv of ion exchange was determined. So far as the authors are aware the only previous observations of such heat effects have been made by Keren and Shainberg (3) and Goulding and Talibudeen (25). In measuring heats of immersion of montmorillonite, Keren and Shainberg (3) noticed a difference between the heat of immersion for a "chemical" mixture of Na/Ca montmorillonite and for a "physical" mixture. They proposed that the difference gives a heat of mixing of Na and Ca on the montmorillonite surfaces and measured −5.8 kJ/equiv for the formation of the mixed surface composition. Keren and Shainberg apparently observed the same effect as in the present work and the two values agree quite well considering the uncertainty involved in estimating them. In fact, it will not be easy to separate the heat of demixing of the ions on the surfaces from the heat of tactoid formation, since the reactions are intimately connected. However, in physical terms, since the demixing ions are already adsorbed, it seems reasonable to expect that the observed heat is largely due to the tactoid formation itself. Goulding and Talibudeen interpreted the heat effect as arising from a separate homogeneous group of exchange sites within the mineral.

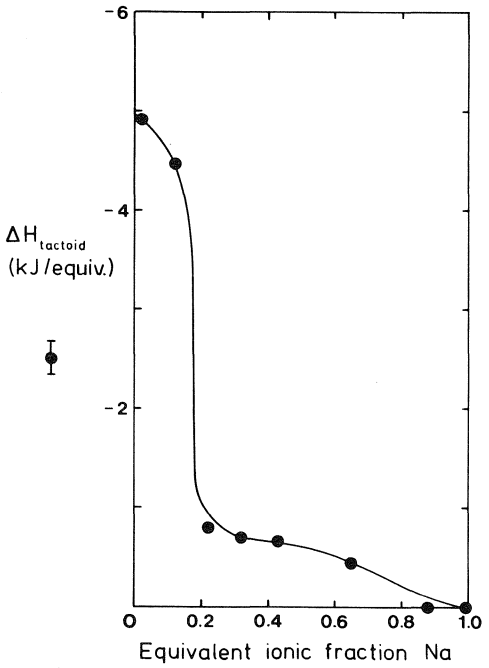

FIG. 8. Plot of observed heat of tactoid formation as a function of surface coverage for the Na–Ca exchange. The units of $\Delta H_{\text{tactoid}}$ are kJ/equiv of ion exchange reaction. An estimate of the experimental reproducibility is given along the axis.

That the reaction should be exothermic follows from the facts that the free energy is lower for plates in tactoids and that the $\Delta S$ term for the reaction will be negative. As concluded by Keren and Shainberg (3) it seems that the heat release is the driving force for the demixing of adsorbed ions.

We conclude that titration calorimetry provides a convenient method for the determination of enthalpies of ion exchange in clay suspensions. Both continuous and stepwise titration calorimeters produce self-consistent results which are in general agreement with literature data. For heterovalent ion exchange reactions the continuous titration method was found to suffer from the effects of inefficient stirring. The results indicate that some kind of batch or stepwise series of measurements in clay suspensions are necessary to establish that equilibrium properties are indeed being measured when expanding clay minerals are studied. Both instruments (methods) were limited in the end by the stirring efficiency. Because of this the final few percent of Na–Ca exchange could not be observed calorimetrically using either technique.

The positive values of $\Delta H^\circ$ obtained for the heterovalent $M^+$–$M^{2+}$ exchanges indicate that these

reactions are entropy driven, in agreement with the conclusions of Ewin *et al.* (15). Considering the enthalpy only, tactoid formation apparently also favours the $M^+$–$M^{2+}$ exchange, since we find tactoid formation to be enthalpy driven (the entropy of tactoid formation is expected to be negative, i.e. opposing tactoid formation). Tactoid formation may lead to complications in clay suspension calorimetry since during the addition of salt solution high local concentrations of exchanging counterions may cause premature tactoid formation, with reestablishment of equilibrium taking as long as several minutes.

In stepwise titration calorimetry we have observed the heat effects of tactoid formation and breakdown in the same regions of surface composition of the exchanging ions as can be predicted from light scattering and viscosity measurements (22). We were able to estimate the enthalpy change accompanying tactoid formation in the Na–Ca exchange on montmorillonite at −4.9 kJ/equiv of ion exchange, in remarkable agreement with the only other known (indirect) determination of this heat effect (3). This means, in the worst possible case, that if for instance in titration calorimetry one were to titrate Ca-montmorillonite with NaCl (notice this is the opposite of the exchange reaction reported in Table 2) only to the point where 20% or so of the Ca ions is replaced, the observed enthalpy of exchange would be positive rather than negative as expected from Table 2, and in the order of +1 kJ/equiv.

A. B. P. LEVER, I. M. WALKER, and P. J. MCCARTHY. Can. J. Chem. **60**, 495 (1982).

The single crystal polarised spectra, at 10 K, of a series of nickel(II) complexes containing the *cis*-chromophore $NiN_4O_2$ are reported. The four N ligands are provided by the diamines *N,N'*-diethylethylenediamine or *meso*-stilbenediamine, and the two O ligands by chelating nitrate or nitrite ion. The spectra are assigned in the point group $C_{2v}$(III). The energies are calculated within the Normalised Spherical Harmonic Hamiltonian and the Orbital Angular Overlap formalisms. The parameters so derived are consistent with previous experience obtained with *trans*-analogs once the small bite of the chelating nitrite ligand is accounted for.

A. B. P. LEVER, I. M. WALKER et P. J. MCCARTHY. Can. J. Chem. **60**, 495 (1982).

Opérant à 10 K, on a mesuré les spectres polarisés de monocristaux d'une série de complexes de nickel(II) contenant le chromophore $NiN_4O_2$ *cis*. Les diamines, *N,N'*-diéthylènediamine ou la meso stilbènediamine, constituent les quatre ligands azotés alors que la chélation des ions nitrate ou nitrite fournissent les deux ligands oxygénés. On attribue les spectres au groupe de symétrie $C_{2v}$(III). On a calculé les énergies à l'intérieur de l'Hamiltonien d'harmonie sphérique normalisée et des formules de recouvrement angulaire d'orbitale. Les paramètres ainsi obtenus sont en accord avec les expériences antérieures obtenues avec les analogues *trans* dès qu'on tient compte de la petite interaction du ligand nitrite chelatant.

[Traduit par le journal]

## Introduction

During the past ten years the electronic spectra of tetragonal complexes of a range of metal ions have been extensively studied (1–8). Complexes with chromium(III), nickel(II), and copper(II) are now particularly well understood (1) while those of cobalt(II) seem to have been studied less often (2, 3, 6). These complexes generally belong to a class of *trans*-octahedral species of general formula $ML_4Z_2$ of $D_{4h}$, or $ML_4ZZ'$ of $C_{4v}$ symmetry. The spectra have generally been treated in terms of the crystal field theory (9), the orbital angular overlap (OAM) model (10, 11), or the normalised spherical harmonic Hamiltonian (NSH) procedure (8, 12).

The earlier literature contains very few examples of systematic studies of complexes of symmetry lower than axial. The reasons for this omission are primarily the difficulty in assigning such spectra unequivocally, and the difficulty in fitting a limited number of observed transitions to the rather lengthy Hamiltonian which appears necessary for such systems.

The best early work on a rhombic six-coordinate complex appears to be the study by Meredith and Palmer (13*a*) on the nickel bis[histidinate], in which cryogenic temperatures, polarised light, and known crystal axes were used to definitively assign all the spin-allowed bands in $C_{2v}$(III) symmetry (12).

With the rising popularity of the Orbital Angular Overlap theory, a growing number of studies of low symmetry complexes are now appearing from the research groups of Gerloch (13*b*), Bertini (13*c*,*d*), and others. An extensive compilation of data and OAM parameters for low symmetry systems has recently appeared (13*e*).

In this article, we discuss single crystal polarised electronic spectra for a series of *cis*-octahedral nickel(II) complexes of general formula $M(diamine)_2(Z)_2$ where diamine is *meso*-stilbenediamine (*ms*-stien), or *sym-N,N'*-diethylethylenediamine (*s*-$Et_2$en) and $(Z_2)$ is bidentate (O,O) chelating nitrate or nitrite ion. Several of these spectra have already appeared in conjunction with our analysis of the vibronic spectrum of the nitrite ion (14). The *d*–*d* spectra of these complexes have unique features, such as their dichroism, which distinguish them from the analogous *trans* complexes. However, the OAM and NSH parameters derived from the *cis* systems parallel in a remarkable way those derivable from the *trans* systems.

## Experimental

The substituted diamines, supplied by Koch-Light (UK), were distilled and stored over KOH pellets. All other materials were of reagent grade. The preparation of the nitrito complexes has already been reported (15).

The preparation of crystals and the methods employed to obtain spectra have also been previously reported (5, 6, 15–18). $Ni(s\text{-}Et_2en)_2(NO_3)_2$ was prepared by the stoichiometric reaction

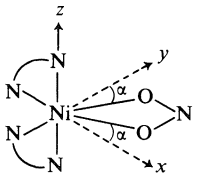
of *N,N'*-diethylethylenediamine with nickel nitrate in ethanol. Metal analyses, performed by EDTA back-titration (14) were satisfactory for all complexes.

## Results

X-Ray structures exist for [Ni(*s*-$Et_2$en)$_2$($O_2$N)]X, where X is nitrite (**I**) (19) or tetrafluoroborate (**II**) (15), and for [Ni(*ms*-stien)$_2$($O_2$N)]$NO_2$ (**III**) (20). These demonstrate a *cis*-octahedral cation as shown in an idealised fashion in **A**. In general, all the



**A**

N—Ni—N angles are within a few degrees of 90°, while the O—Ni—O angle is close to 60°. The deviation of each Ni—O vector from the *x* or *y* axes is measured by the angle α. The point group is $C_{2v}$(III) (12).

The complex Ni(*s*-$Et_2$en)$_2$($NO_3$)$_2$ (**IV**) has electronic spectroscopic features (see Fig. 1) very similar to those of the previously published nitrite complexes (14) suggesting that it also has a *cis* structure. Moreover, the infrared spectrum of this species shows combination bands consistent with the presence of both bidentate bound and ionic nitrate (21). The corresponding nitrite complex (**I**) has two cationic groups in the asymmetric unit (19). The nitrate complex (**IV**) appears to be similar in that the combination infrared spectrum consists of

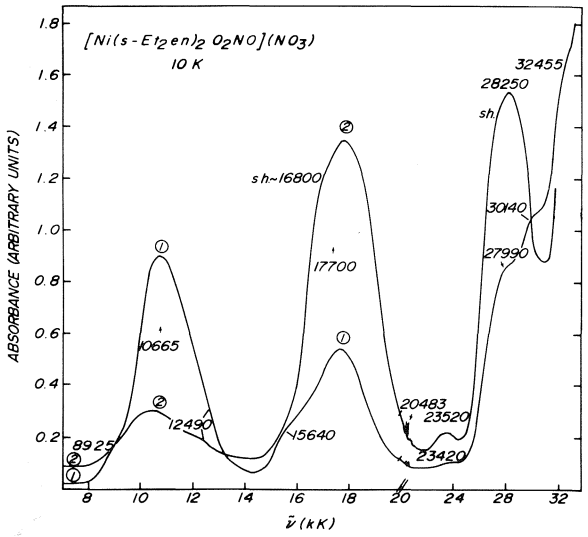


FIG. 1. Polarised crystal spectra of Ni(*s*-$Et_2$en)$_2$($NO_3$)$_2$ at 10 K, in two orthogonal polarisations. Note the change in horizontal scale at 20 kK.

two pairs of weak peaks (at 1719, 1768, and 1730, 1773 $cm^{-1}$) indicative of a pair of slightly different bidentate bound nitrate groups (21), and a sharp spike at 1756.5, with a shoulder at 1754 $cm^{-1}$ suggesting two slightly different ionic nitrate groups. We tentatively suppose therefore that the nitrate complex (**IV**) is isostructural with the cation shown in **A**.

We display single crystal polarised spectra of two of the four nickel(II) complexes at 10 K in Figs. 1, 2. The remaining spectra were reported in our discussion of their vibronic spectra (Figs. 1–5 in ref. 14). The utility of presenting such data obtained along orthogonal extinction axes has been discussed elsewhere (5). In general, with these low symmetry systems, the space groups frequently do not permit unambiguous assignments based solely on dichroism.

We note in Figs. 1–2 (and in ref. 14) that the lower two orbital triplets in cubic symmetry are each split in these derivatives. The very weak feature near 8500 $cm^{-1}$ is regarded to be a genuine crystal field feature and not a vibrational overtone because (*a*), it is absent from the electronic spectrum of Ni(*s*-$Et_2$en)$_2$($NCS)_2$ (5), (*b*), very narrow overtones seen in such species as Ni(*s*-$Et_2$en)$_2$($H_2O)_2^{2+}$ (5) are quite different from the broad bands seen here, and (*c*), calculations suggest that a crystal field band should indeed be observed here.

## Discussion

The principal features of the spectra below 20 kK must arise primarily from spin-allowed *d*–*d* transitions to the components of the $^3T_{1g}(F)$ octahedral parents in $C_{2v}$ symmetry. Except in complex **IV** the components of the $^3T_{1g}(P)$ multiplet are obscured by internal nitrite absorption. Spin singlet transitions may appear as weak features near 12–15 kK. It is evident, however, that the energies of these various spin-allowed components cannot be identified with assurance *a priori*. For this reason we do not believe it profitable to attempt to fit the spectra by allowing all parameters to vary freely, especially as the number of observable parameters does not significantly exceed the number of variables.

Prior experience suggests that OAM parameters can be transferred from one complex to another if the bonding is fairly ionic, rather than significantly covalent, and in the absence of important steric effects (22). This appears to be the situation here. Therefore, the OAM parameters derived from analogous *trans*-nickel(II) complexes (5, 7) should serve in this *cis* case also.

In an initial attempt to fit the spectra we, therefore, adopted the values $\sigma_N$ ca. 4200, $\sigma_O$ ca.

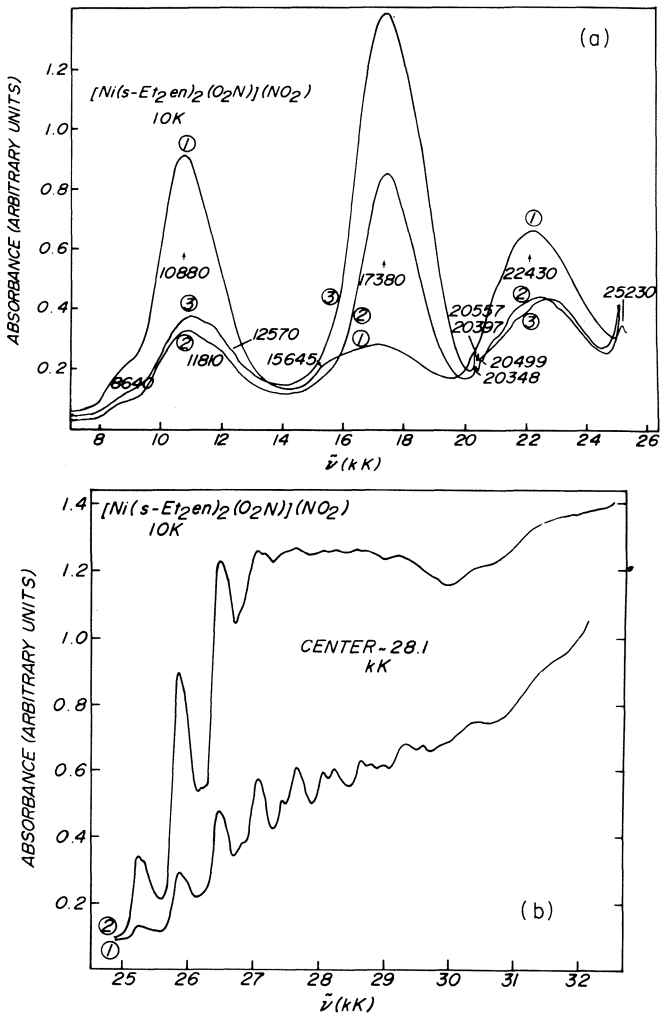

FIG. 2. Polarised crystal spectra of (Ni(*s*-$Et_2en)_2(O_2N)$) $NO_2$ at 10 K. (*a*) Region 7 500–25 000 $cm^{-1}$, three orthogonal polarisations are shown. (*b*) Region 25 000–32 000 $cm^{-1}$, two orthogonal polarisations are shown.

2400, $\pi_O$ ca. $\pm 500$, $\pi_N = 0\,cm^{-1}$, appropriate for *trans*-nickel(II) octahedral complexes and calculated the *d*-orbital energies in these complexes assuming an angle of 59.4° for the nitrite bite ($\alpha$ = 15.3°, see Appendix). Since the nitrito group is not ortho-axial, there is no constraint that in-plane $\pi$ bonding be equal to out-of-plane $\pi$ bonding. In face, we assume, in common with others (23) that in-plane $\pi$ bonding is negligible and write the corresponding OAM parameters equal zero. This is also necessary if the problem is to be tractable considering the small number of observables.

Calculated transition energies fall very close to the observed peaks and shoulders in these various spectra. Iteration around the initial choice of OAM parameters provides a good fit to the spectra as displayed in Table 1. The resulting OAM parameters (Table 2) fall well within the range of parameters expected for a fairly ionic six-coordinate nickel(II) complex with nitrogen and oxygen ligands. In the nitrate complex (**IV**) transitions to the components of the $^3T_{1g}(P)$ state can also be observed and are fitted moderately well.

The NSH approach has been used with other distorted octahedral nickel(II) complexes and for comparison purposes we report the NSH parameters for these complexes. This was achieved by mapping the NSH onto the OAM parameters (see Appendix). The NSH data have the advantage that, given a correct assignment, the parameter values are defined by the spectra and do not require knowledge of the angle $\alpha$ which may vary from one complex to another.

It is important to decide whether this assignment

[a] The calculated spectra should be compared with the data shown in Figs. 1–4. Not all features illustrated in these figures are listed in this table. The calculated energies of the components of the $^3T_{1g}(P)$ term are as follows: I, 26000 ($A_2$), 27970 ($B_1$), 28075 ($B_2$); II, III, 26170 ($A_2$), 28170 ($B_1$), 28220 ($B_2$); IV, 26845 ($A_2$), 28450 ($B_2$), 28620 ($B_1$).
[b] Calculated using $D_{4h}$ matrices.
[c] Tentative assignment.

TABLE 2. NSH and OAM parameters for complexes I, II, III, and IV[a]

| Parameter | Value | | |
|---|---|---|---|
| | I | II, III | IV |
| DQ | 28424 | 27690 | 28423 |
| DS | 2500 | 2500 | 3300 |
| DT | 4246 | 4138 | 3712 |
| DM | −2708 | −2582 | −2136 |
| DN | 4356 | 4209 | 4900 |
| *B* | 850 | 900 | 900 |
| *C* | 3100 | 3000 | 2860 |
| $DQ_{ax}$ | 38472 | 37483 | 37208 |
| $DQ_{eq}$ | 23400 | 22794 | 24031 |
| $\sigma_N$ | 4500 | 4400 | 4700 |
| $\sigma_O$ | 2500 | 2400 | 2400 |
| $\pi_O$ | 500 | 500 | 1000 |

[a] The reader is reminded that the calculation is based on only three OAM parameters. All other radial parameters are calculated therefrom. The numbers so derived are reported here without being rounded off; however, it is recognised that the final digit will not be significant.

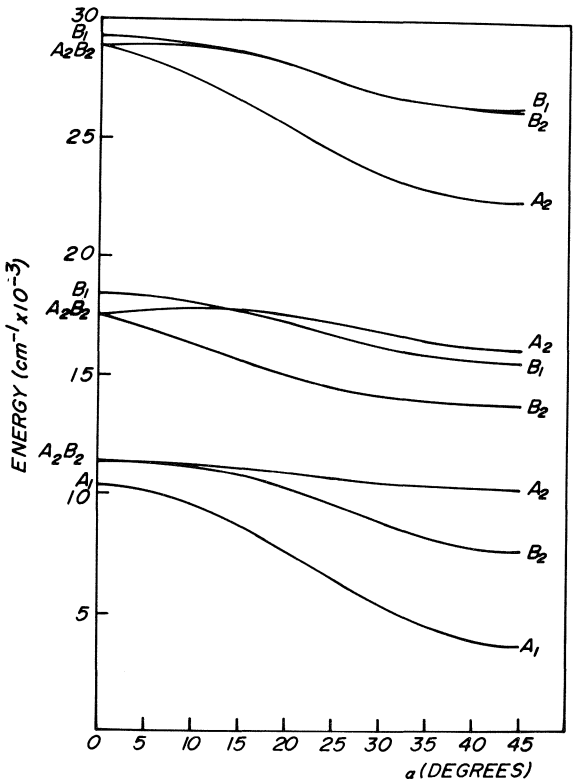

FIG. 3. The dependence of the energy of the states in $C_{2v}$(III) symmetry as a function of the angle α (see (A)). The baseline is the $^3B_1$ ground term energy. This scheme assumes $\sigma_N = 4500$, $\sigma_O = 2400$ and $\pi_O = 500\,cm^{-1}$. An angle of α near 15° is appropriate for the nitrite complexes discussed here.

is internally consistent since others are clearly feasible. Unfortunately the very low symmetry of these complexes precludes the direct use of dichroism to unequivocally assign excited state labels. In Fig. 3 we display the energy sequence for the splitting of the octahedral orbital triplets in these systems as a function of distortion angle α. The spectra show intensities largely independent of temperature, implying that electronic rather than vibronic selection rules are operative (14). All transitions are electronically allowed except for $^3B_2 \leftarrow {}^3A_1$ which is electronically forbidden but vibronically allowed. Our complexes possess α = 15.3° at a region of the diagram (Fig. 3) where there is close accidental degeneracy of two levels, thereby reducing the resolution of the spectra.

Generalising for these nickel(II) complexes, we note the following: (*i*) The weak band near 8.5 kK – 9 kK is assigned to the allowed transition to $^3A_1$ whose energy to first order is 10 Dq. The position of this transition is defined by the $NiN_2O_2$ plane. (*ii*) The $^3E(T_{2g})$ state splits into the $A_2$ and $B_2$ states. Transition to the former is electronically allowed, but is forbidden to the latter. However, the splitting is predicted to be small. Both bands lie inside the

envelope observed near 11 kK. (*iii*) Transition to the second $^3B_2$ level is observed weakly near 15–16 kK. Evidently it is allowed vibronically. (*iv*) Additional shoulders in the spectra of some of these complexes near 11.5–13 kK are reasonably assigned as spin singlet transitions (5). (*v*) The dichroism while it does not provide us with unequivocal assignment must nevertheless be itself internally consistent. Thus the transitions to the two $^3A_2$ levels within the *F* term, for example, should show maximum intensity in the same polarisation, not in different polarisations. Using complex **I** as an example, the internal consistency of the dichroism can be demonstrated.

In polarisation 1 (Fig. 2) the intense peak at 10.88 kK must be assigned to the $^3A_2$ component, since the other transition is orbitally forbidden. The strongest feature near 17 kK in this polarisation is also assigned to $^3A_2$. In the other two polarisations the strong peak at 17.38 kK must then be assigned to $^3B_1$. This has no counterpart near 11 kK so absorption here is relatively weak. It is rather strange that, considering polarisation 1, the intensity of the lower energy $^3A_2$ transition should be greater than that of the higher $^3A_2$ transition; this may arise because their octahedral parentage is different. We note that other rather distorted nickel(II) complexes also exhibit this unusual intensity reversal (24). This dichroism is very different from that generally observed with the usual *trans*-nickel (diamine)$_2X_2$ complexes with tetragonal distortion (1*f*, 5, 7). We may conclude that OAM parameters similar to those employed for analogous *trans*-nickel(II) $NiN_4O_2$ species can reproduce the dominant features in the electronic spectra of these *cis*-complexes. The resulting parameters, optimised to fit these spectra, are entirely reasonable.

Even so, we cannot conclude that the assignments demonstrated in Table 1 are unequivocally correct, but do regard that it is consistent with all available information at this time. Such low symmetry complexes have been rarely studied. A larger data base of such systems must be accumulated before further conclusions may be drawn. Clearly there is a great deal of chemical information within the spectra of such complexes and their analysis is certainly worthwhile.

In closing, we note that we have extended these studies to another class of *cis*-nickel(II) complexes, those with the general formula Ni(*s*-$Et_2$en)$_2$(LL) where (LL) is bidentate maleate, succinate, phthalate, malonate. These complexes are freely soluble in such non-polar solvents as dichloromethane providing strong evidence for a mononuclear, and necessarily *cis*-structure. Unfortunately, we have not been able to grow sufficiently large crystals for single crystal study. The solution spectra of these complexes appear close to octahedral (22) which would be anticipated in keeping with the smaller splitting of the octahedral orbital triplets. Certainly they show less structure than the *trans*-$NiN_4O_2$ analogs; thus even solution spectra may serve to distinguish *cis* from *trans* isomers in this series of complexes.

## Appendix

The N.S.H. Hamiltonian (12) appropriate for these $C_{2v}$(III) complexes is given by:

$$\mathcal{H} = \mathrm{DQ}|A_{1g}O(i)|^4_{Oh} + \mathrm{DS}|E_g(\theta)|^2_{Oh} + \mathrm{DT}|E_g(\theta)|^4_{Oh} + \mathrm{DM}|T_{2g}(xy)|^2_{Oh} + \mathrm{DN}|T_{2g}(xy)|^4_{Oh}$$

Since it possesses five variables, and we must add a sixth, the Racah $B$ parameter, it is of limited value with this data set, unless the number of variables can be reduced. By mapping onto the OAM model we note that the DM and DN parameters are not linearly independent, but have a fixed ratio independent of the angle $\alpha$. Moreover within the approximation used here (only three OAM parameters) the values of DM and DN are, in fact, defined by the values of DQ, DS, and DT, and the angle $\alpha$.

(*A*) General OAM matrix elements:

$$\langle z^2|\hat{O}|z^2\rangle = 2.5\sigma_N + 0.5\sigma_O$$
$$\langle 1/\sqrt{2}(xz + yz)|\hat{O}|1/\sqrt{2}(xz + yz)\rangle = 3\pi_N + \pi_O(1 + \sin 2\alpha)$$
$$\langle 1/\sqrt{2}(yz - xz)|\hat{O}|1/\sqrt{2}(yz - xz)\rangle = 3\pi_N + \pi_O(1 - \sin 2\alpha)$$
$$\langle xy|\hat{O}|xy\rangle = 2\pi_N + \sigma_O(1.5 \sin^2 2\alpha) + \pi_O'(2 \cos^2 2\alpha)$$
$$\langle x^2 - y^2|\hat{O}|x^2 - y^2\rangle = 1.5\sigma_N + \sigma_O(1.5 \cos^2 2\alpha) + \pi_O'(2 \sin^2 2\alpha)$$
$$\langle xy|\hat{O}|z^2\rangle = -\sigma_O((\sqrt{3}/\sqrt{2}) \sin 2\alpha)$$

($\pi_O'$, the in-plane $\pi$ bonding, is set equal to zero in our calculations).

(*B*) Mapping:

The zero reference energies of the OAM and NSH models differ from one another and are initially unknown. Mapping is achieved by equating sums and differences from which the zero reference energies cancel.

Since the mapping is independent of the number of electrons, the problem may be kept simple by working with $d^1$. The $d^1$ NSH energies may be used directly from Table VIII of ref. 12. The $d^1$ OAM energies are just those shown in (*A*) above.

Utilising the above procedure we derive, neglecting $\pi_N$ and $\pi_O'$ (in-plane $\pi$ bonding)

$$\mathrm{DQ} = \sqrt{21}\{(6/5)\sigma_N + \sigma_O((3/5) - (3/4) \sin^2 2\alpha)) - (2/5)\pi_O\}$$
$$\mathrm{DS} = \sigma_N - \sigma_O + \pi_O$$
$$\mathrm{DT} = \sqrt{15}\{(3/10)\sigma_N + \sigma_O[(21/20) \sin^2 2\alpha - (3/10)] - (2/5)\pi_O\}$$
$$\mathrm{DM} = \{-\sqrt{6}\sigma_O + \sqrt{3}\pi_O\} \sin 2\alpha$$
$$\mathrm{DN} = \{(9/\sqrt{10})\sigma_O + (6/\sqrt{5})\pi_O\} \sin 2\alpha$$

and the axial and equatorial field parameters:

$$\mathrm{DQ}_{ax} = \sqrt{21}\{(9/5)\sigma_N + \sigma_O[(27/20) \sin^2 2\alpha] - (6/5)\pi_O\}$$
$$\mathrm{DQ}_{eq} = \sqrt{21}\{(9/10)\sigma_N + \sigma_O[(9/10) - (9/5) \sin^2 2\alpha]\}$$

(*C*) The NSH parameters for $d^2$, $d^3$, $d^7$, and $d^8$ ions in $C_{2v}$(III) symmetry are reported in Table XI of ref. 12. Unfortunately there are some errors in the labelling of various rows of this table. To permit accurate use of this table, we correct these errors here. Within the body of the table, the following rows should be replaced as follows:

| | | | |
|---|---|---|---|
| Row 3 | $T_1 1 + (P)$ | $T_1 1 + 0.14548\mathrm{DQ} + 0.17143$ DS $- 0.06148$ DT $+ 0.19795\mathrm{DM} - 0.05324$*DN | |
| Row 4 | $T_1 1 + (P)$ | $T_2 1 -$ $- 0.22131$*DS $- 0.14286$*DT $+ 0.25555\mathrm{DM} + 0.12372$ DN | |
| Row 10 | $T_1 0(P)$ | $A_2 2 -$ $- 0.25555\mathrm{DM} + 0.16496$ DN | |
| Row 12 | $T_1 0$ | $A_2 2 -$ $- 0.12778\mathrm{DM} + 0.08248$ DN | |
| Row 13 | $A_2 2 -$ | $A_2 2 - 0.43644\mathrm{DQ}$ | |

# Apparent carbon–carbon bond cleavage in an epoxide. 2,3,4,5,6-Hexachloro-12-oxopentacyclo[5.4.1.1.$^{8,11}$.0$^{3,10}$.0$^{5,9}$]tridecane; a minor product from the acid treatment of endrin[1,4,5]

Received May 11, 1981

JOHN W. APSIMON, KAZU YAMASAKI, ALAIN FRUCHIER, ALFRED S. CHAU, and CAROL P. HUBER. Can. J. Chem. **60**, 501 (1982).

The treatment of *endrin* (**1**) with sulfuric acid produces ketoendrin **2** and from 6 to 8% of another product that we show to be 2,3,4,4,5,6-hexachloro-12-oxapentacyclo[5.4.1.1.$^{8,11}$.0$^{3,10}$.0$^{5,9}$]tridecane **3**, based initially on spectral evidence and confirmed by a single crystal X-ray diffraction study. The formation of **3** involves an apparent and unusual carbon–carbon single bond cleavage in an epoxide accompanied by cycloaddition to a proximate carbon–carbon double bond. This transformation probably proceeds by the route outlined in ref. 1. Some of the observed nmr parameters of **3** are discussed in the light of its structure and a comparison is made with the observed spectra for endrin (**1**).

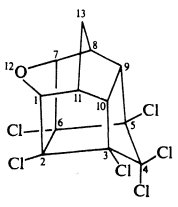
JOHN W. APSIMON, KAZU YAMASAKI, ALAIN FRUCHIER, ALFRED S. CHAU et CAROL P. HUBER. Can. J. Chem. **60**, 501 (1982).

L'*endrine* (**1**) réagit dans l'acide sulfurique en produisant la cétoendrine (**2**) ainsi que 6 à 8% d'hexachloro-2,3,4,4,5,6 oxa-12 pentacyclo[5.4.1.1.$^{8,11}$.0$^{3,10}$.0$^{5,9}$]-tridécane (**3**) dont la structure avait été proposée initialement sur la base de données spectrales et que nous avons confirmée par diffraction de rayons X sur un monocristal. La formation du composé **3** implique apparemment un clivage inusité d'une liaison simple carbone–carbone d'un epoxyde accompagné d'une cycloaddition avec la double liaison carbone–carbone à proximité. Cette transformation se fait probablement selon la voie suggérée dans la référence 1. On discute, à la lumière de sa structure, de quelques paramètres observés en rmn et on établit des comparaisons avec les spectres observés dans l'endrine (**1**).

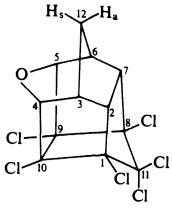
[Traduit par le journal]

During a study of the nuclear magnetic resonance spectral properties of the rearrangement products of polychlorocyclodiene insecticides, we have systematically examined the transformation products of endrin **1**. Thus, with sulfuric acid, endrin **1** yields ketoendrin **2** (2) together with a minor product (6–8%) to which we have previously assigned structure **3** (1) based on spectral evidence.[6,7] We now report confirmation of this proposal based on further nmr studies and a single crystal X-ray diffraction study.

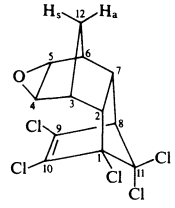
[1]For a preliminary communication see ref. 1.
[2]To whom inquiries may be addressed.
[3]Professor Associé, USTL 1976–1977.
[4]NRCC No. 19793.
[5]The numbering system used for **3** in this article varies in order to aid the reader. Thus, the IUPAC derived numbering system is shown in **3***a* while the numbering system used in the nmr spectral discussion in the text is shown in **3***b*. This choice is made since it is essential to our arguments that comparison be made to endrin **1**. This comparison is best appreciated if the two numbering systems correspond. The crystallographic work unfortunately uses another set of numbers to locate the atoms in the two independent molecules found in the unit cell. This system is indicated in Fig. 1.



*3a*



*3b*



*1*

[6]The assignments for H-12a and H-12s in Table 1 of this reference should be reversed as should the attributions to C-3/C-6 and C-2/C-7 in Table 2. This is amplified in the later discussion.
[7]A referee has correctly pointed out that the formation of **3** does not really involve C—C bond cleavage in an epoxide. Rather, if our proposed mechanism for the formation of **3** from **1** is correct (1), then the C—C bond cleavage occurs after epoxide C—O bond cleavage. The final product appears only as the net effect of C—C bond cleavage.

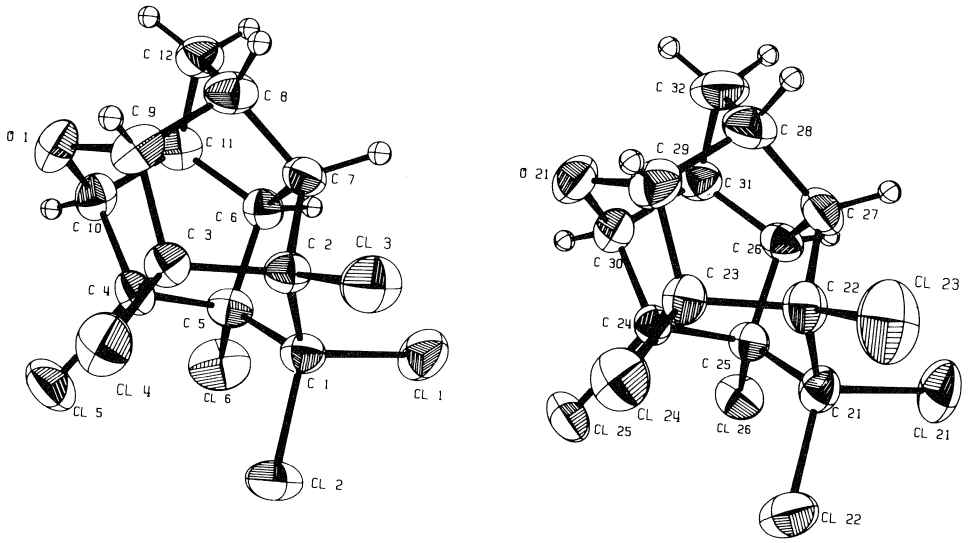

FIG. 1. ORTEP views of the two crystallographically independent molecules of **3**. The thermal ellipsoids enclose 50% probability (5).

*X-ray structural studies*

The results indicated that two independent molecules exist per asymmetric unit in the crystal of **3**. Views of these as established by the X-ray analysis are shown in Fig. 1. Final atomic parameters are listed in Table 1, and bond lengths and bond angles are given in Table 2. The C—H bond distances vary from 0.89 to 1.04 Å with mean 0.96 Å, and the bond angles involving hydrogen atoms vary from 103 to 122°, with mean 112°. The angles involving hydrogens are expected to be larger than 109° in compensation for the small angles formed by the heavier atoms in five-membered rings.

As in other related structures (endrin (3), aldrin (3), and dieldrin (4)), the molecules have essentially mirror symmetry with the mirror planes here defined by C(1), O(1), and C(12) and by C(21), O(21), and C(32). Agreement is reasonably good between chemically related bonds and angles in individual molecules as well as between corresponding values in the two molecules. Allowing for differences in the molecular structures, agreement between bond lengths and angles in the present structure and equivalent values in endrin, aldrin, and dieldrin is satisfactory.

The five-membered rings are all in envelope conformation and the six-membered ring is in the boat form. Because of the formation of bonds between the hexachloro system and what was the epoxide ring in endrin, the present molecule is more nearly spherical and more compact than endrin or dieldrin. The distances Cl(3)···Cl(6), Cl(2)···C(12), and O(1)···Cl(1) in this structure are 5.51, 5.98, and 5.82 Å respectively, while the corresponding Cl···Cl and Cl···epoxide oxygen distances in endrin and dieldrin are 5.47 and 5.52 (Cl···Cl) and 6.78 and 7.36 Å (Cl···O).

A parallel study of the nmr spectra of **3** was undertaken and some data are presented here. Using the computer program LACX (6) we have examined the eight spin system of **3** taking into account the inherent symmetry of the molecules. This calculation involved about 1000 observable transitions and provides the first complete analysis of this type of compound. Figure 2 shows the experimental 250 MHz proton nmr spectrum compared to the calculated spectrum after iteration. The signal for the 12s proton in the experimental

spectrum is broader compared to the simulated version where we did not introduce any small nonmeasurable long-range couplings. This accounts also for the difference in resolution between the signals for $H_4$ and $H_5$ in the two spectra since irradiation indicates these couplings to be present. Table 3 presents the chemical shifts and coupling constants for **3** and compares these data with those reported for endrin **1** (7).

The availability of the X-ray data for **3** and **1** (3) enables us to make the following comments comparing the nmr spectra of both compounds.

1. The value of $J_{12s,12a}$ is larger in **3** than in endrin (absolute value). In the former, it is close to the cyclohexane value (−12.6 Hz). The X-ray data show clearly that in **3** the $H_{12s}$—C—$H_{12a}$ angle is 108° (i.e. close to the tetrahedral angle), whereas in endrin (**1**) this angle is 123°. The relief of strain on formation of the five-membered tetrahydrofuran ring in **3** is evident here.

2. The value of $J_{3,4}$ is larger in **3** than in endrin (**1**) (8.6 Hz vs. 0.9 Hz). These values are unexceptional when the dihedral angles $H_4$—$C_4$—$C_3$—$H_3$ are examined (8.5° in **3***a* and 51° in endrin). The same Karplus-type agreement can be seen for $J_{2,3}$ (5.1 Hz in **3***a* and 2.5 Hz in endrin) where the dihedral angles are 22.5° and 65° respectively.

3. The modified geometry of **3** resulting from the epoxide C—C bond opening and the consequent relief of strain is further demonstrated by the observed coupling constants for $J_{3,12a}$ and $J_{3,12s}$ as follows. In **3** the $H_{12a}$—$C_{12}$—$C_3$—$H_3$ dihedral angle is 50° with a $J_{3,12}$ being 3.7 Hz and in endrin the corresponding angle is 71° reflected by a coupling constant of 1.3 Hz. The $H_{12s}$—$C_{12}$—$H_3$ dihedral angle in **3***a* is 70° with $J_{3,12s}$ being 1.3 Hz; in endrin this angle becomes 61° and $J_{3,12s}$ is 2.0 Hz.

4. The unambiguous assignment of the $H_{12a}$ and $H_{12s}$ signals can be made by a shift reagent study (8) for endrin (**1**) and **3**. The results obtained are outlined in Table 4. Assuming the oxygen atom is involved as the major complexation site with $Eu(fod)_3$, the assignments are self evident.

5. It is to be noted that the signal for $H_{12a}$ is more sensitive to the transformation of endrin (**1**) to **3** than that for $H_{12s}$, even though this proton is more proximate to the site of chemical change (0.50 ppm and 0.16 ppm downfield shifts respectively). One interpretation of these results is that the major contribution to the shielding of $H_{12}$ is the epoxide-group ring-current which is destroyed on conversion of endrin (**1**) to **3**; whereas for $H_{12s}$ the major shielding contribution arises from the proximate oxygen atom.

It is apparent from the above observations that **3**

suffers much less angular strain than the parent endrin (**1**) and its derivatives.

The formation of **3** is of mechanistic interest but at this stage we can make no further comment to that made in our preliminary communication (1) except to stress that this compound arises only via the acid-catalysed route.

## Experimental

*Reaction of endrin (1) with sulfuric acid*

Endrin (5 g) was dissolved with stirring in concentrated sulfuric acid (65 mL) and allowed to stand for 48 h. The resulting clear solution was poured into ice water (300 mL). The crystalline precipitate obtained was filtered and washed with aqueous sodium bicarbonate (saturated) and water. Preparative thin layer chromatography on silica gel plates eluted with benzene/5% acetone provided, after isolation in the usual manner, ketoendrin **2** (4.1 g) and **3** (0.34 g), mp 286°C. A sample was recrystallized twice from $CCl_4$ for analysis; $M^+$ (mass spectral): 381. *Anal.* calcd. for $C_{12}H_8OCl_6$: C 37.84, H 2.12, O 4.30, Cl 55.9; found: C 37.93, H 2.12, O 4.20, Cl 55.57. See text for nmr spectral data. All chemical operations were standard. Mass spectra were determined on an AE1 MS 10 spectrometer at Trent University, Peterborough, Ontario. The nmr spectra were originally determined on a Varian T-60 and XL-100 spectrometer at Carleton University. The 250 MHz nmr spectra were recorded on a CAMECA spectrometer at the Faculté de Pharmacie de Marseilles.

Crystal data are:

Monoclinic, space group $P2_1/c$, $a$ = 13.680(1), $b$, 8.515(2), $c$ =

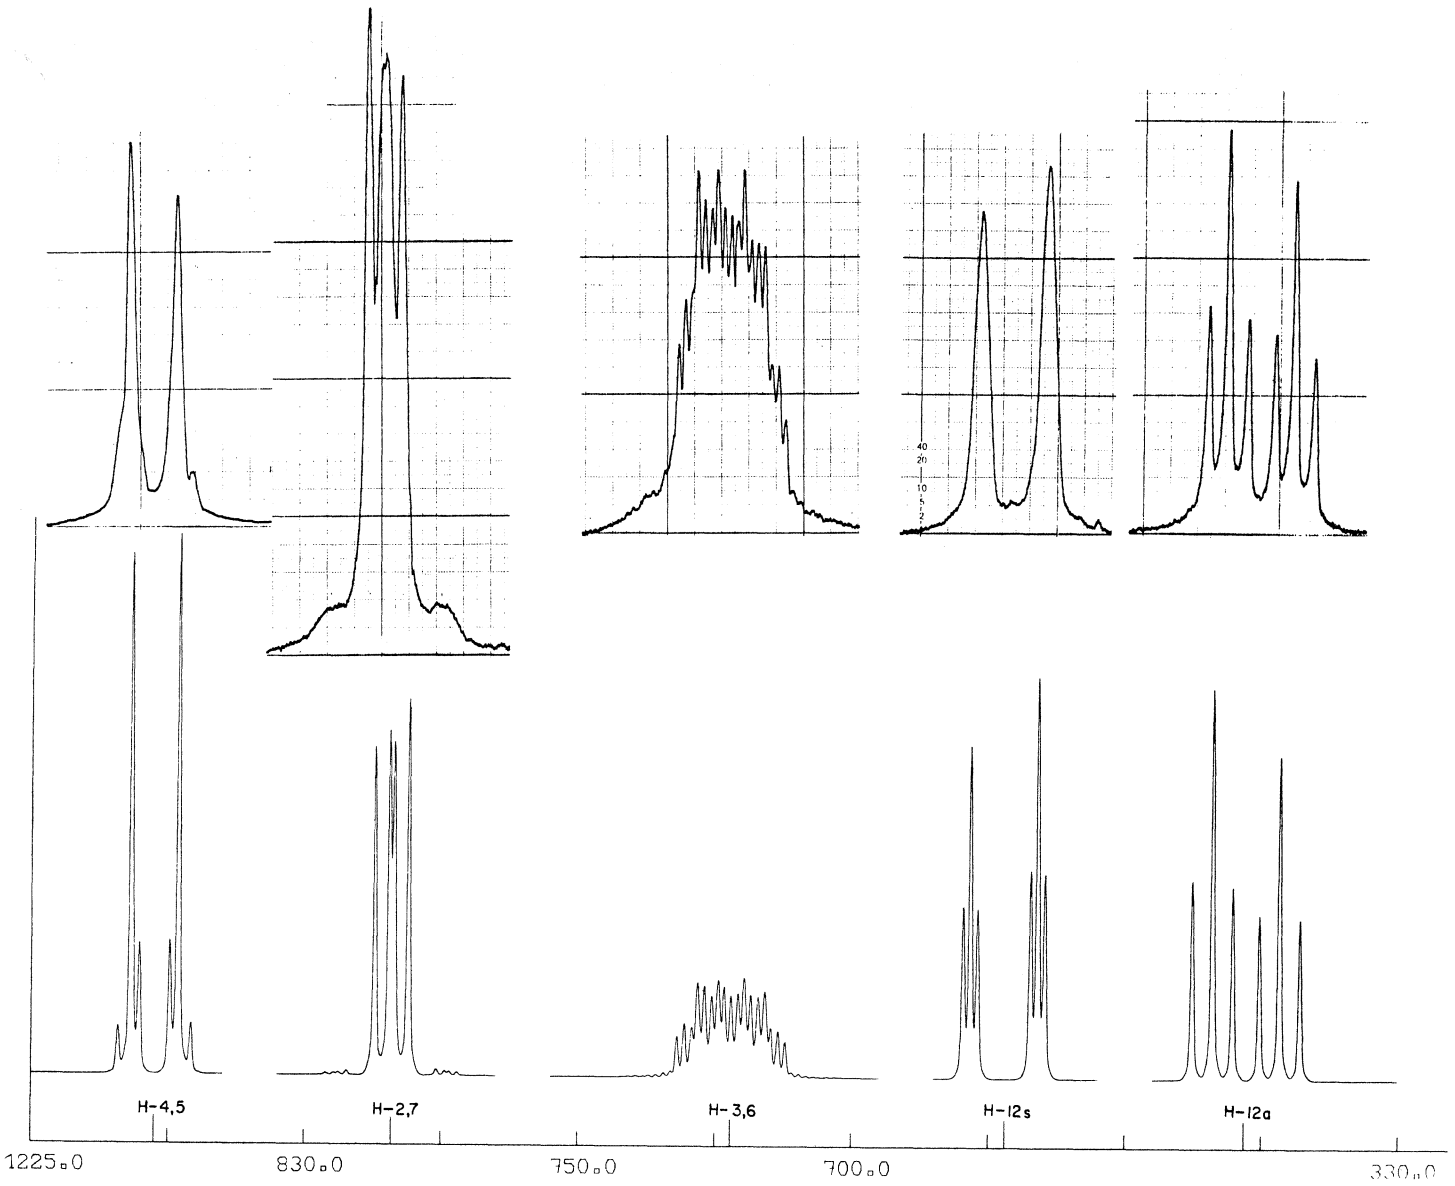

FIG. 2. Experimental 250 MHz $^1$H nmr spectrum of **3** compared with simulated spectrum using LACX. (Note: this spectrum presentation shows only the peaks observed, omitting the baselines in between signals. No effort has been made to equalize the amplitudes of the signals. The multiplicities only are of interest.)

[a] See footnote 6.
[b] Double irradiation experiments seem to indicate that a small coupling exists which has not been measured.
[c] The authors assumed this value to be zero, presumably due to symmetry.

TABLE 4. Shift reagents comparison studies ($Eu(fod)_3$) on endrin and the title compound, **3**. Chemical shifts are present in ppm from internal TMS at 100 MHz

| | Endrin | | Compound **3** | |
|---|---|---|---|---|
| | Chem. shifts | Rel. bound shifts | Chem. shifts | Rel. bound shifts |
| $H_2$ and $H_7$ | 3.22 | 100 | 3.26 | 100 |
| $H_3$ and $H_6$ | 2.89 | 170 | 2.89 | 128 |
| $H_4$ and $H_5$ | 3.30 | 421 | 4.81 | 397 |
| $H_{12a}$ | 0.93 | 150 | 1.43 | 104 |
| $H_{12s}$ | 1.79 | 379 | 1.95 | 251 |

25.963(2) Å, β = 115.71(3)°, $V$ = 2724.9 Å$^3$, $d_x$ = 1.857 g cm$^{-3}$, $Z$ = 8 (two independent molecules per asymmetric unit) (λ(Cu-Kα$_1$) = 1.54051, λ(CuKα$_2$) = 1.54433 Å), μ(CuKα) = 114.1 cm$^{-1}$.

The material crystallized from $CCl_4$ as clear colourless prisms. Data were collected from a specimen with maximum dimensions 0.30 × 0.15 × 0.40 mm, mounted parallel to the elongation direction (along *b*). Precession photographs showed monoclinic symmetry with systematic absences (0*k*0) with *k* odd, and (*h*0*l*) with *l* odd. Intensity data and cell dimensions were measured on a Picker diffractiometer using Ni-filtered Cu radiation. The θ/2θ scan mode was employed in measuring intensity data; the (2θ) scan speed was 2° min$^{-1}$, scan ranges were 2.0° for 0 < 2θ < 100°, 3.0° for 100 < 2θ ≤ 130°, and a 20 s background count was taken at the end of each scan. Of the 4611 independent reflections accessible in this range in two octants (*hkl* and $\bar{h}kl$) of reciprocal space, 3383 were considered "observed" on the basis of having net counts ≥ 15 and at least 10% of the total background count. Lorentz and polarization corrections were applied, and absorption corrections were made using a Gaussian integration formula; maximum and minimum transmission factors were 0.282 and 0.054 respectively.

The structure was solved by the symbolic addition procedure, and refined by block-diagonal least-squares calculations minimizing $\Sigma w(|F_o| - |F_c|)^2$. The nonhydrogen atoms were refined with anisotropic thermal parameters, and the hydrogen atoms were refined isotropically. The weighting scheme was $w = 1.0$ if $|F_o| < 35.0$, otherwise $w = (35.0/F_o)^2$, and six reflections were assigned zero weight in the later least-squares cycles. (Three (−1 1 3, −1 2 5, and −2 2 8) were affected by extinction and three (−2 0 6, 1 1 0, and 2 4 0) seemed to be Renninger reflections.) Scattering factor values for Cl, O, C, and H were taken from International Tables for X-ray Crystallography, Vol. IV (9). The Cl scattering curve was corrected (9) for the real part ($\Delta f' = 0.348$) of anomalous dispersion. In the last refinement cycle all shifts were less than one-third of their respective estimated standard deviations, and the mean (shift/esd) was 0.05. The final $R$ value for all (3383) observed reflections was 0.039. A difference map calculated from the final structure factors[8] showed 15 significant peaks (none larger than 0.40 e/Å$^3$), all of which occurred near Cl atom sites, most in locations consistent with lone-pair electron density. Computations were performed with the NRCC set of crystallographic computer programs (10).

JOHN W. APSIMON, RICK P. SEGUIN, and CAROL P. HUBER. Can. J. Chem. **60**, 509 (1982).

The title compound was made following a projected synthetic route to pentacyclic triterpenes. The key step in the route is the alkylative trapping of the enolate derived from the enol trimethylsilyl ether **8**. The stereochemical consequence of this reaction is confirmed by a single crystal X-ray structure determination on **4**, which although of no further utility in the projected synthesis, nevertheless served as a useful template for this determination. In this way, ongoing work in a parallel series of compounds rests on a firm stereochemical footing.

JOHN W. APSIMON, RICK P. SEGUIN et CAROL P. HUBER. Can. J. Chem. **60**, 509 (1982).

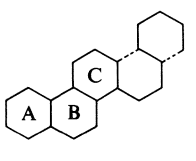
On a préparé le composé mentionné dans le titre en suivant une méthode de synthèse prévue pour les triterpènes pentacycliques. L'étape principale est le piègeage par alkylation de l'énolate provenant de l'énol de l'éther triméthylsilylé (**8**). On confirme la conséquence stéréochimique de cette réaction en déterminant la structure par diffraction de rayons X sur un monocristal du composé **4**, pour lequel on ne prévoit pas d'autre utilité au cours de la synthèse mais qui n'en demeure pas moins un modèle très utile pour cette détermination. De ce point de vue, les travaux en cours sur des séries parallèles reposent sur une base stéréochimique solide.

[Traduit par le journal]

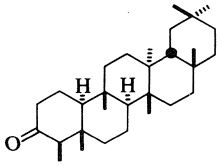
## Introduction

During the past several years we have examined several ring construction sequences in our synthetic approaches to pentacyclic triterpenes.[4] In this brief article we describe an approach via the ABC-fragment plus side chain-route as outlined in **1** aimed at providing species such as friedelin **2** and related compounds.

Although this particular work proved fruitless in providing pentacyclic (or tetracyclic) species capable of conversion to triterpenoids, it nevertheless revealed a crucial stereoselective step necessary for the pursual of a parallel series. Thus, our synthetic sub-goal was compound **3** envisioned as arising as shown in Scheme 1 in the retrosynthetic sense.



**1**



**2**

We describe here the preparation of the title compound **4** and its single crystal X-ray structure determination. In our hands this material could not be further elaborated to compound **7**. In view of this singular failure we have abandoned this route in favour of a closely related study in which the side-chain *gem*-dimethyl groups are absent. These studies will be the subject of a future report from these laboratories when completed.[5]

The condensation of **5** and **6** in this case was envisioned as presenting no real problem in view of established precedent and the improved alkylation characteristics of trimethylsilylvinyl ketones (6). In the event, the trimethylsilyl enol ether **8** was obtained by lithium – liquid ammonia reduction of **5** followed by trapping of the enolate with trimethyl-

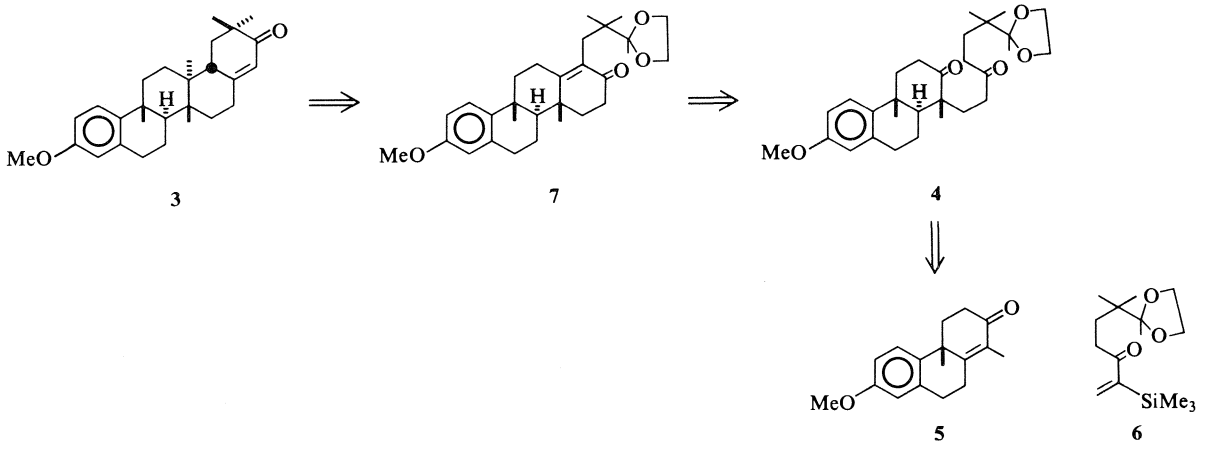
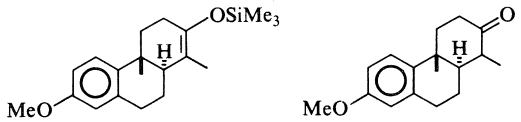


SCHEME 1

silyl chloride. Regeneration of the lithium enolate by reaction of purified **8** with methyllithium, followed by treatment with the trimethylsilylvinyl ketone **6**, provided a modest yield of **4** (42%) after isolation. Experiments aimed at the direct trapping of the enolate of **8** formed in the reductive process led to a low yield of **4** (<20%). By recycling ketone **9**, also isolated in this reaction, the yield can be raised to about 65–70%.



**8** **9**

The structure would appear to be secure on the basis of precedent (2) and benzene-induced solvent shifts observed in the proton nmr spectra of these compounds (3). However, in view of the potential pivotal position of these compounds in the control of other chiral centres in the developing synthetic route and the pleasing fact that **4** was crystalline, we performed a single crystal X-ray study on this material.

The vinyl ketone **6** was prepared as outlined in Scheme 2. This route is straightforward and requires no further comment other than the experimental details described later and to point out that the transformation of the nitrile to the aldehyde as shown worked best using the three-step procedure involving hydrolysis to the carboxylic acid, reduction to the primary alcohol, and oxidation back to the aldehyde (conditions *d* in Scheme 2).

With compound **4** on hand, many attempts were made to effect the aldol-type cyclization to **7** using a large variety of bases and acids. Under no conditions could we detect any cyclization products. Comparison of the structure of our substrates with the multitudinous systems described in the literature (7) suggested that the *gem*-dimethyl group, although seemingly distant from the reaction site, plays a role in the poor reactivity of this compound towards cyclization. Examination of molecular models of the correct enolate derived from **4** reveals that approach of this along a trajectory allowing for ready cyclization (1, 3) is sterically congested in the conceivable conformational modes for the respective transition states.

At this stage we abandoned this work for the more promising bis-normethyl series (**4** less the *gem*-dimethyl groups).[5]

*X-ray crystal structure of* ***4***

Final parameters for the nonhydrogen atoms are listed in Table 1.[6] Figure 1 gives the numbering scheme used in the analysis, and shows that the molecule is in the extended conformation. The final bond lengths not involving H atoms are shown in Fig. 2, and are unexceptional. The C—H bond lengths vary from 0.92 to 1.07 Å, with average 0.98 Å, and their esd's are between 0.019 and 0.041 Å. Endocyclic torsion angles are shown in Fig. 3. Ring A is planar within ±0.003 Å, ring B is in the half-chair conformation, and ring C is in the twist-boat form. The B/C ring junction is *trans*. Repulsion between the 1,3 diaxial methyl groups increases the C(25)—C(9)—C(8), C(9)—C(8)—C(14), and C(8)—C(14)—C(26) bond angles to 113.3, 113.2, and 113.5° respectively and results in an angle of 37.2° between the C(9)—C(25) and C(14)—C(26) vectors. Repulsion between O(2) and C(26) seems to affect the pertinent geometry less;

[6]Tables of final parameters for the hydrogen atoms, of bond angles, and of observed and calculated structure amplitudes are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont. Canada K1A 0S2.

SCHEME 2. Reagents: *a*, *t*-BuOK, *t*-BuOH, $\overset{}{=}\!\!\backslash$ CN : *b*, *p*-TsOH, $HOCH_2CH_2OH$, benzene, azeotropic removal $H_2O$: *c*, diBAL—H, $H_3O^+$: *d*, KOH, $HOCH_2CH_2OH$, reflux; $LiAlH_4$, THF; pyridinium chlorochromate (PCC)/, $CH_2Cl_2$: *e*, $CH_2{=}CHBrSiMe_3$, Mg, THF: *f*, PCC, $CH_2Cl_2$, NaOAc.

the O(2)—C(13)—C(14) and C(13)—C(14)—C(26) angles are increased by only about 1° from expected values. The O(2)—C(13)—C(14)—C(26) torsion angle is 30.4°, but a decrease in this would lead towards the less favorable boat conformation.

The dioxolane ring is envelope shaped, with C(21) displaced 0.42 Å from the exact plane formed by O(4), O(5), C(22), C(23).

The molecules are held in the crystal structure by van der Waals forces; there are no hydrogen bonds or other short intermolecular contacts.

*Conclusion*

Although this study did not lead to polycyclic materials capable of conversion to triterpenoids, the work performed, coupled with the X-ray structural analysis, provides concrete proof for the hitherto generally accepted stereochemical consequences of the lithium–ammonia reduction of fused enones and the subsequent trapping of the enolates formed as the trimethylsilyl ether followed by alkylation of the regenerated enolate. This observation places the ongoing stereo- and regio-selective routes in these laboratories on a firm basis.

## Experimental

Melting points were determined on a Fisher hot stage or Buchi model SMP-20 and are uncorrected. The nmr spectra were obtained on a Varian T-60, Varian EM-360, or Varian XL-100 spectrometer with tetramethylsilane (TMS) as internal standard. Chemical shifts are expressed in the δ scale and the following abbreviations apply: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. Infrared spectra were determined on a

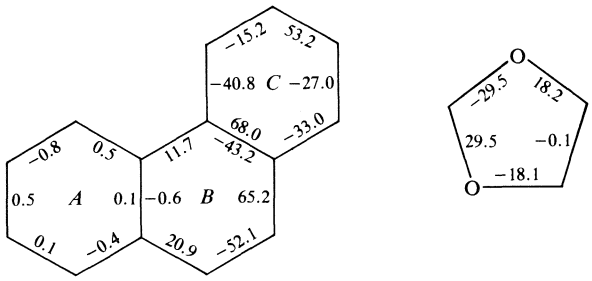

FIG. 3. Endocyclic torsional angles.

Perkin–Elmer 237B grating spectrophotometer. Mass spectra were obtained on an AE-1 MS-12 spectrometer at Trent University, Peterborough, Ont. Combustion analyses were performed by Canadian Microanalytical Laboratories, Guelph, Ontario and Spang Microanalytical Laboratory, Eagle Harbour, MI. Thin layer chromatograms (tlc) were run using precoated plates from E. Merck Reagents (silica gel 5-254, 0.25 or 2.0 mm layer thickness).

The term "work-up" refers to separation of aqueous and organic phases, neutralization of the organic phase by washing with dilute mineral acid or saturated bicarbonate as required, followed by a wash with aqueous brine, drying ($MgSO_4$ or $Na_2SO_4$), and rotary evaporation of the organic solvents.

*1,4aβ-dimethyl-7-methoxy-2-trimethylsilyloxy-3,4,4a,9,10,10aα-hexahydrophenanthrene (8)*

Dry ammonia (150 mL) was stirred for 15 min with 166 mg (23.7 mmol) of lithium metal followed by the addition of a solution of tricyclic enone **5** (2) (2.05 g, 8.0 mmol) in dry THF (150 mL) with 590 mg of *tert*-butanol as proton donor. The reaction mixture was stirred for 10 min and then the excess lithium carefully quenched by addition of small amounts of solid sodium benzoate until the dark blue color disappeared. The ammonia was removed under water aspirator vacuum pressure with the aid of a warm (40°C) water bath. Dry THF (50 mL) was added at such a point as to prevent the enolate/ammonia solution from evaporating to dryness. This was followed by the addition of 3.3 mL of a 1:1 v/v mixture of chlorotrimethylsilane and triethylamine (previously centrifuged to remove solid $Et_3N{\cdot}HCl$). The solution was stirred at room temperature for 2 h, followed by addition of pentane and work-up (sodium bicarbonate and brine wash). The pentane was removed, the residue taken up in benzene and filtered on a Florisil pad using benzene as eluant. Column chromatography using 40% benzene in petroleum ether 30–60°C accomplished separation of the silyl enol ether isomers. The desired $\Delta^1$-isomer (**8**) was isolated as an oil (1.37 g, 52%); nmr δ ($CDCl_3$): 0.2 (s, 9H, Si—*Me*), 1.05 (s, 3H, C-4a Me), 1.66 (broad s, 3H C-1 Me), 3.8 (s, 3H, -OMe), 6.6–7.4 (m, 3H, ArH); ms *m/e* (rel. int.): $M^+$ at 330 (27), 175 (15), 174 (100), 159 (15), 87 (15), 73 (40). *Anal.* calcd. for $C_{20}H_{30}SiO_2$: C 72.68, H 9.15, Si 8.50; found: C 72.88, H 9.21, Si 8.88.

The $\Delta^2$-isomer crystallized on standing (~8%), mp 34°C; nmr ($CDCl_3$) δ: 1.35 (d, 3H, C-1 Me), 4.85 (m, 1H, vinyl H); $M^+$ (mass spectrometer): 330.

*1β,4aβ-Dimethyl-7-methoxy-1α-(7',7'ethylene ketal-6',6'-dimethyl-3'-ketooctyl)-3,4,4a,9,10,10aα-hexahydro-2-(1H)-phenanthrone (4)*

Crystalline silylenol ether **8** (300 mg, 0.91 mmol) was dissolved in dry dimethoxyethane (8 mL) and titrated with methyllithium to a triphenylmethane indicator endpoint. The solution was stirred for 0.5 h and cooled to −78°C. Vinyl ketone **6** (300 mg, 1.09 mmol, 1.2 equiv.) in DME (4 mL) was added, followed by stirring for 10 min at −78°C, then allowing the mixture to warm to room temperature with stirring for 5 h. Addition of ammonium chloride and work-up gave 550 mg of a yellow viscous oil. Preparative tlc (10% ethyl acetate–benzene) gave diketone **4** (230 mg, 42%) which was crystallized from aqueous methanol, mp 156°C; $\bar{\nu}_{max}$: 1695–1705 (broad, C=O) $cm^{-1}$; nmr ($CDCl_3$) δ: 1.0 (s, 6H, 2-Me), 1.2 (s, 3H, Me), 1.35 (s, 6H, 2-Me), 3.8 (s, 3H, O-Me), 4.0 (s, 4H, ketal $CH_2$), 6.6–7.4 (m, 3H, Ar—H); ms *m/e*: 470 $M^+$ (0.05). *Anal.* calcd. for $C_{29}H_{42}O_5$: C 74.01, H 8.99, $M^+$ 470; found: C 73.80, H 9.13, $M^+$ 470.

*5,5-Ethylenedioxy-4,4-dimethylhexanenitrile*

3-Methyl-2-butanone (30 g, 0.34 mol) in dry *tert*-butanol (80 mL) and potassium metal (367 mg, 0.03 equiv.) were stirred for 45 min at room temperature and the acrylonitrile (14.2 g, 0.26 mol) added dropwise over a period of 1 h. Stirring was continued for a further 1 h; *tert*-butanol was removed and 0.7 mL of acetic acid in 100 mL of water was added. Work-up and vacuum distillation gave the keto-nitrile. Ketalization in the usual manner afforded the above nitrile (34.3 g, 68% based on acrylonitrile); $\bar{\nu}_{max}$ (neat): 2250 (CN) $cm^{-1}$; nmr ($CDCl_3$) δ: 1.0 (s, 6H, *gem* × di-Me), 1.25 (s, 3H, C-6 Me), 4.0 (s, 4H, ketal $CH_2$); $M^+$ 183; $C_{10}H_{17}O_2N$ requires $M^+$ 183.

*5,5-Ethylenedioxy-4,4-dimethylhexanal*

The above nitrile (14.5 g, 78 mmol) in 2 L of dry toluene was cooled to −10°C and diisobutylaluminum hydride (633 mL of 25.2% solution in toluene) was added dropwise. The reaction was allowed to warm to room temperature and stirred for 40 h. Saturated ammonium chloride (2 L) was added, followed by cooling to 0°C, and addition of ice-cold sulfuric acid (150 mL in 500 mL $H_2O$). Ether extraction, work-up, and filtration through a Florisil pad furnished pure aldehyde (5.3 g, 37%); $\bar{\nu}_{max}$ 1700 $cm^{-1}$; nmr ($CDCl_3$) δ: 0.98 (s, 6H, 2C-4 Me), 1.25 (s, 3H, C-6 Me), 3.95 (s, 4H, ketal $CH_2$), 9.8 (t (fine splitting), 1H, C*H*O); $M^+$ 186; $C_{10}H_{18}O_3$ requires $M^+$ 186.

Alternatively, the nitrile, (29.6 g, 1.6 mmol) was refluxed overnight with potassium hydroxide (20 g) in ethylene glycol (200 mL). Saturated brine was added and the aqueous layer extracted with ether (isolate nitrile starting material) and then carefully acidified with 50% hydrochloric acid at 0°C to pH 0.5. Rapid extraction with ether and chloroform, washing the extracts with brine and drying, gave the acid (28 g ~ 90%); $\bar{\nu}_{max}$ (neat): 3400–3500 (broad, $CO_2H$), 1710 (C=O) $cm^{-1}$; nmr ($CDCl_3$) δ: 9.95 (s broad, 1H, $CO_2H$). Prolonged treatment, elevated temperatures, or lower pH values led to extensive deketalization. The acid (27 g) in 350 mL of dry ether was then added dropwise to a suspension of lithium aluminum hydride (14.6 g, 0.386 mol) in ether (450 mL) and the mixture stirred for 5 h at room temperature. Addition (sequentially) of water (14.6 mL), 3*N* sodium hydroxide (14.6 mL), and water (43.8 mL) with continued stirring, furnished the ketal alcohol (29.4 g, 88%) which was stirred with pyridinium chlorochromate (46.5 g, 1.5 equiv.) in dichloromethane (300 mL) at room temperature for 15 h. Addition of ether, repeated ether washing of the solids, and filtration through Florisil gave, after removal of solvent, the aldehyde (20 g, 75%) identical in all respects to that prepared above.

*6,6-Dimethyl-7,7-ethylenedioxy-2-trimethylsilyl-3-oct-1-enone (6)*

α-Bromovinyltrimethylsilane (9) (29.4 g, 0.164 mol, 1.25 equiv.) was stirred in THF (40 mL) with dry magnesium turnings for 0.5 h at room temperature and then at reflux for 1 h followed by cooling to 0°C. The above aldehyde (24.4 g, 0.131 mol) in ether (60 mL) was added, the solution was allowed to warm up to room temperature and stirred overnight. Saturated ammonium chloride was added and the reaction worked up and filtered on Florisil. Column chromatography (10% ethyl acetate/benzene)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

gave the allylic alcohol (26.3 g, 70%); nmr ($CDCl_3$) δ: 0.95 (s, 6H, 2C-6 Me), 0.1 (s, 9H, Si-$Me_3$), 1.25 (s, 3H, C-8 Me), 3.95 (s, 4H, ketal $CH_2$), 5.4 (d, 1H, vinyl H), 5.8 (d, $J$ = 3 Hz, vinyl H).

The allylic alcohol (500 mg, 1.75 mmol), pyridinium chlorochromate (0.564 g, 1.5 equiv.), and sodium acetate buffer (143 mg, 1.0 equiv.) were stirred for 3 h at room temperature in dichloromethane (6 mL). Addition of ether and ether washing of the tarry precipitate followed by filtration through a Florisil pad gave ketone **6** (450 mg, 90%); $\bar{\nu}_{max}$: 1665 (C=O) $cm^{-1}$; nmr ($CDCl_3$) δ: 0.1 (s, 9H, $SiMe_3$), 1.25 (s, 3H, C-8 Me), 3.95 (s, 4H, ketal $CH_2$), 6.05 (t, 1H, vinyl H), 6.45 (t, 1H, vinyl H); ms $M^+$ at 284, 139 (10.9), 88 (7.5), 87 (100), 75 (16.5), 73 (28.5). *Anal.* calcd. for $C_{15}H_{28}SiO_3$: C 63.34, H 9.92, Si 9.87; found: C 63.37, H 9.84, Si 9.85.

*X-ray data collection*

The compound was crystallized from methanol/water as clear, colourless parallelopipeds. The specimen used for data collection had approximate dimensions 0.5 × 0.2 × 0.5 mm. Crystal data are as follows.

$C_{29}H_{42}O_5$ f.w. 470.6

Triclinic, $a$ = 12.843(2), $b$ = 17.427(3), $c$ = 7.012(3) Å, α = 119.47(2), β = 106.03(3), γ = 85.37(4)° (based on λ(CuKα$_1$) = 1.54051 and λ(CuKα$_2$) = 1.54433 Å), $V$ = 1310.3(7) Å$^3$. $Z$ = 2, $\rho_c$ = 1.193 g cm$^{-3}$, space group $P\bar{1}$, μ(CuKα) = 6.4 cm$^{-1}$.

Cell dimensions and intensity data were measured at room temperature on a four-circle diffractometer using Ni-filtered Cu radiation. The cell parameters were derived by a least-squares procedure from 2θ values of 12 carefully-centered high-angle reflections. Relative intensities were measured using θ/2θ scans with (2θ) scan ranges of 2–3°. All 4430 independent reflections in a hemisphere of reciprocal space (2θ ≤ 130°) were measured, of which 3824 were considered "observed". The remainder, with net counts less than 10 (deca-) counts or less than 1/10 of the total background count, were classified as "unobservably weak" and omitted from the least-squares refinement. The intensities of two "check" reflections were monitored at frequent intervals during the data collection, and indicated no crystal deterioration. Lorentz and polarization corrections were made, and an extinction correction ($g/u$ = 0.336 × 10$^{-5}$) was applied during the refinement stage.

The structure was solved by the symbolic addition procedure, and refined by block-diagonal least-squares calculations minimizing $\Sigma\, w(|F_o| - |F_c|)^2$. The hydrogen atoms were all located on a difference map and were refined isotropically while nonhydrogen atoms were refined anisotropically. Scattering factor values for C, H, O were taken from International Tables for X-ray Crystallography, Vol. IV (10). The weighting scheme used was $w = 1/[1 + \{(|F_o| - P_2)/P_1\}^2]$ with $P_1$ = 10.0, $P_2$ = 3.0. Ten reflections were given zero weight during the later stages of refinement because of poor structure-factor agreement; the largest discrepancies among these appear to be due to undercorrection for extinction. In the final least-squares cycle, the mean (shift/estimated standard deviation) was 0.06 and the largest shift was 0.3σ. The final $R$ value was 0.051 for all observed reflections. A difference Fourier synthesis calculated from the final structure factors showed no peaks higher than 0.25 e/Å$^3$.

Computer programs of Ahmed *et al.* (11) and Johnson (8) were used in the analysis.

# Complexes of substituted benzothiazoles 4. Nickel(II) complexes of the bidentate benzothiazoles 1,2-bis(2-benzothiazolyl)benzene and 1,2-bis(2-benzothiazolyl)ethane

LAURENCE KENNETH THOMPSON,[1] JOHN CHARLES THOMAS RENDELL, AND GEORGE CHARLES WELLON

*Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7*

Received May 29, 1981

LAURENCE KENNETH THOMPSON, JOHN CHARLES THOMAS RENDELL, and GEORGE CHARLES WELLON. Can. J. Chem. **60**, 514 (1982).

The nickel coordination chemistry of two potentially bidentate bis-benzothiazole ligands is compared. 1,2-Bis(2-benzothiazolyl)-benzene (OBT), which has an *o*-phenylene bridge, forms square planar derivatives with $NiX_2$ (X = I, $ClO_4$, $BF_4$), octahedral derivatives with $NiX_2$ (X = NCS, $NO_3$), and five-coordinate derivatives with $NiX_2$ (X = Cl, Br). 1,2-Bis(2-benzothiazolyl)ethane (BBTE), which has an ethylene bridge, forms tetrahedral derivatives with $NiX_2$ (X = Cl, Br, I) and an octahedral complex with $Ni(NO_3)_2$. Although both ligands are capable of tetrahedral coordination about a cobalt centre, the apparent preference of tetrahedral coordination with nickel complexes of BBTE seems unusual. The only difference between the two ligands lies in the bridging group between the benzothiazole rings. Structural assignments are supported by ligand field and infrared spectra, magnetic data, and an X-ray structure of the complex $[Ni(BBTE)Br_2]$, which has been shown to have a distorted tetrahedral stereochemistry.

LAURENCE KENNETH THOMPSON, JOHN CHARLES THOMAS RENDELL et GEORGE CHARLES WELLON. Can. J. Chem. **60**, 514 (1982).

On compare la chimie de coordination du nickel de deux ligands bis-benzothiazoles, potentiellement bidentates. Le bis(benzo-2 thiazolyl)-1,2 benzène (OBT), qui a un pont *o*-phénylène, forme des dérivés plan carrés avec $NiX_2$ (X = I, $ClO_4$, $BF_4$), des dérivés octaédriques avec $NiX_2$ (X = NCS, $NO_3$) et des dérivés pentacoordonnés avec $NiX_2$ (X = Cl, Br). Le bis(benzo-2 thiazolyl)-1,2 éthane (BBTE), qui a un pont éthylène, forme des dérivés tétraédriques avec $NiX_2$ (C = Cl, Br, I) et un complexe octaédrique avec $Ni(NO_3)_2$. En dépit du fait que les deux ligands peuvent avoir une coordination tétraétrique autour du centre cobalt, la préférence apparente pour une coordination tétraédrique avec les complexes de nickel du BBTE semble inhabituelle. La seule différence entre les deux ligands réside dans le groupe qui fait le pont entre les cycles benzothiazoles. Les déterminations de structure s'appuient sur le champ de ligand et les spectres infrarouges, les données magnétiques et la structure, déterminée par diffraction de rayons X, du complexe $[Ni(BBTE)Br_2]$ qui ont révélé la stéréochimie tétraédrique déformée de ce complexe.

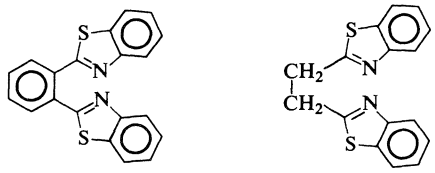
## Introduction

Histidine imidazole figures prominently at the active sites of numerous metalloprotein and metalloenzyme systems. The type 1 copper centres in such enzymes as plastocyanin (1) and azurin (2) contain imidazole groups, as well as sulphur donor groups. We have investigated a number of polyfunctional pseudoimidazole ligand systems in which the donor groups have included benzimidazoles, benzothiazoles, and imidazolines, all of which are nitrogen donors similar to histidine (3–7). The bisbenzothiazole ligand 1,2-bis(2-benzothiazolyl)-benzene (OBT; Fig. 1) behaves as an $N_2$ donor towards cobalt(II), copper(II), and zinc(II) salts, with the formation of four-coordinate pseudo-tetrahedral and square planar and six-coordinate derivatives (4). An X-ray structural determination revealed that an almost square planar $CuN_2Cl_2$ chromophore exists in the case of the complex $[Cu(OBT)Cl_2]$ (8). Little tendency towards tetrahedral coordination with copper was observed for this system. The bis-imidazoline ligands 1,2-bis(2′-imidazolin-2′-yl) benzene (LP) and 1,2-bis(2′-imidazolin-2′-yl)ethane (LE) form square planar bis-ligand complexes with nickel salts while cobalt complexes are for the most part tetrahedral (3).



OBT BBTE

FIG. 1. Structure of 1,2-bis(2-benzothiazolyl)benzene, OBT and 1,2-bis(2-benzothiazolylethane, BBTE.

In this study we have investigated the nickel coordination chemistry of the two closely related bis-benzothiazole ligands, OBT and BBTE (Fig. 1; BBTE = 1,2-bis(2-benzothiazolyl)ethane). These ligands are similar to LP and LE except that the imidazoline groups are replaced by benzothiazoles. Reaction of OBT with nickel(II) salts produced several square planar and octahedral derivatives, but in addition, in the case of the chloro- and bromo-complexes spectral and other data suggest the formation of square pyramidal dimers. contrast, BBTE produces four-coordinate 1:1 halide derivatives which appear to be tetrahedral, a structural difference which must in part be a function of the bridging entity between the benzothiazole rings. A six-coordinate nitrate derivative is also formed, which appears to be analogous to the OBT derivative and shows that although in general BBTE seems to prefer a tetrahedral bite it can be accommodated at a nickel centre with an N—Ni—N angle of around 90°.

## Experimental

Electronic spectra were recorded on a Cary 17 spectrometer and infrared spectra were obtained with a Perkin-Elmer model 283 spectrometer. Magnetic susceptibilities were obtained at room temperature by the Faraday method with a Cahn model #7600 Faraday Magnetic Susceptibility system, coupled to a Cahn gram electrobalance. Microanalyses were carried out by Canadian Microanalytical Service, Vancouver. Metal analyses were determined by Atomic Absorption with a Varian techtron AA-5 after digestion of the samples in concentrated $HNO_3$ or aqua-regia.

*Nickel complexes of OBT and BBTE*

OBT and BBTE were synthesized according to the procedure of Rai and Braunwarth (9).

*$[Ni_2(OBT)_2Cl_4]\cdot(CH_3)_2CO$ (I)*

OBT (0.75 g; 2.2 mmol) was dissolved in hot acetone (50 mL) and $NiCl_2\cdot 6H_2O$ (0.52 g; 2.2 mmol) dissolved in hot ethanol. The two solutions were mixed and refluxed for 30 min. After 5 min a pale orange solid formed. The product was filtered, washed with acetone, and dried *in vacuo* at 80°C for 3 h.

*$[Ni_2(OBT)_2Br_4]\cdot EtOH$ (II)*

OBT (0.75 g; 2.2 mmol) was dissolved in ethanol (15 mL) and triethylorthoformate (TEOF) (10 mL) added. $NiBr_2\cdot 3H_2O$ (2.0 g; 7.3 mmol) was dissolved in ethanol (30 mL), the two solutions mixed and heated on a steam bath. As the volume reduced, an orange semicrystalline solid formed. The product was filtered, washed with TEOF, diethylether, and dried *in vacuo* at 80°C for 3 h.

*$[Ni(OBT)I_2]$ (III)*

OBT (0.52 g; 1.5 mmol) was dissolved in hot acetone (35 mL). $NiI_2$ (0.54 g; 1.5 mmol) was dissolved in hot acetone (50 mL) and the solution filtered into the solution of the ligand. The mixture was refluxed until dark green crystals began to form. The product was filtered, washed with acetone, and dried *in vacuo* at 80°C for 3 h.

*$[Ni(OBT)_2(NCS)_2]$ (IV), $[Ni_2(OBT)_2(NCS)_4(H_2O)_2]\cdot(CH_3)_2CO$ (V)*

OBT (0.75 g; 2.2 mmol) was dissolved in hot ethanol (15 mL) and added to a solution of $Ni(NCS)_2$ (0.19 g; 1.1 mmol) in ethanol (50 mL). The mixture was refluxed for 1/2 h and the volume of the solution reduced to approximately 2 mL. Acetone (10 mL) was added and the green solution allowed to stand overnight. A green crystalline product (**IV**) was obtained, which was filtered, washed with ethanol/petroleum ether (30/70), and dried *in vacuo* at 80°C for 3 h. The 1:1 thiocyanate complex **V** was prepared similarly using equimolar quantities of ligand and metal salt.

*$[Ni(OBT)(NO_3)_2]\cdot\frac{1}{2}(CH_3)_2CO$ (VI)*

OBT (0.52 g; 1.5 mmol) was dissolved in ethanol (30 mL). $Ni(NO_3)_2\cdot 6H_2O$ (0.44 g; 1.5 mmol) was dissolved in ethanol (30 mL), and the two solutions mixed and refluxed for 1/2 h. The volume of the resulting green solution was reduced to about 2 mL and acetone added until a light green solid formed. The product was filtered, washed with acetone, diethyl ether, and dried *in vacuo* at 80°C for 3 h.

*$[Ni(OBT)_2](ClO_4)_2\cdot 2H_2O$ (VII), $[Ni(OBT)_2](BF_4)_2\cdot 2H_2O\cdot 2(CH_3)_2CO$ (VIII)*

OBT (0.52 g; 1.5 mmol) was dissolved in hot ethanol (20 mL) and $Ni(ClO_4)_2\cdot 6H_2O$ ( 0.28 g; 0.75 mmol) was dissolved in hot ethanol (30 mL). The solutions were mixed and refluxed for 1/2 h. On reducing the volume of the solution a yellow–orange solid began to form. Acetone was added to aid precipitation and the product filtered, washed with acetone, and dried *in vacuo* at 80°C for 3 h. $[Ni(OBT)_2](BF_4)_2\cdot 2H_2O\cdot 2(CH_3)_2CO$ was prepared similarly using acetone as solvent.

*$[Ni(BBTE)X_2]$ (X = Cl, Br) (IX, X), $[Ni(BBTE)I_2]\cdot EtOH$ (XI), $[Ni(BBTE)(NO_3)_2]\cdot\frac{1}{2}EtOH$ (XII)*

BBTE (0.75 g; 2.5 mmol) was dissolved in hot ethanol (50 mL), $NiCl_2\cdot 6H_2O$ (1.8 g; 7.5 mmol) was dissolved in hot ethanol (50 mL), and the two solutions mixed. TEOF (10 mL) was added and the mixture heated under vacuum until the solution volume was reduced sufficiently to produce purple crystals. The reaction mixture was warmed for an additional 2 h and the product filtered, washed with TEOF, petroleum ether and dried *in vacuo* at 80°C for 3 h. The bromide, iodide, and nitrate complexes were prepared similarly.

Analytical data for all the complexes are given in Table 1. Physical measurements on the nickel complexes of OBT and BBTE were possible only in the solid state because of their general insolubility in common solvents and also their solvolytic instability. Also none of the OBT complexes could be obtained in a crystalline form suitable for X-ray analysis.

## Results and discussion

The chloride and bromide complexes (**I**, **II**) have electronic spectra which are not typical of square planar, octahedral, or tetrahedral nickel(II) derivatives. They are paramagnetic compounds with major absorptions around 12 000 and 21 000 $cm^{-1}$ (Cl) and 11 000 and 20 000 $cm^{-1}$ (Br) (Table 2; Fig. 2). Five-coordinate trigonal bipyramidal nickel(II) derivatives with nitrogen ligands in general have some absorption below 10 000 $cm^{-1}$ with up to five major absorptions in the spectrum. For the trigonal bipyramidal complex $[Ni(Me_6tren)(NCS)]NCS\cdot H_2O$ absorptions are observed at 7 700, 13 200, 16 200, 12 100, 24 600 $cm^{-1}$. A similar spectrum is observed for $[Ni(Me_6tren)Br]Br$ with the band positions shifted to slightly lower energy (10). It seems unlikely therefore that **I**, **II** have trigonal bipyramidal structures. However, a square pyramidal stereochemistry at nickel seems quite plausible. Systems of the type $[Ni(dtp)_2am]$ (dtp = $(C_2H_5O)_2PSS^-$; am = secondary amine, pyridine, quinoline) (11, 12) are reported to have square pyramidal structures and exhibit two major absorptions around 13 000 and 21 000 $cm^{-1}$.

The infrared spectra of compounds **I**, **II** are similar, except in the low energy region (Table 3).

TABLE 1. Analytical and other data

| Compound | Colour | Found (%) C | H | N | M | Calcd. (%) C | H | N | M |

A single band in the chloro-complex, assigned to terminal Ni—Cl stretch, occurs at 300 $cm^{-1}$, while for the bromo-derivative a similar band occurs at 236 $cm^{-1}$. Other absorptions at 238, 245 $cm^{-1}$ (Cl) and 219 $cm^{-1}$ (Br) are assigned to bridging nickel halogen stretch. The similarity of the electronic spectra of these complexes with known square pyramidal systems and the presence of infrared bands attributable to both terminal and bridging nickel–halogen bonds suggests a square pyramidal dimeric structure for **I** and **II** involving halogen bridges. The presence of single absorptions associated with terminal nickel–halogen stretch also indicates *trans*- rather than *cis*-dimeric structures (Fig. 3). The other isomer involving a *trans*-arrangement of terminal metal halogen bonds in which a non-equatorial arrangement of ligands would exist is considered unlikely on steric grounds.

The iodide complex (**III**) exhibits three major bands in its mull transmittance spectrum. The high energy absorption at 27 800 $cm^{-1}$ is clearly charge transfer in origin while the other bands at 18 500 and 10 400 $cm^{-1}$ can be associated with a square planar iodo-derivative (13, 14). The diamagnetic nature of this system also supports the square planar structure.

The thiocyanate complexes (**IV**, **V**) exhibit typically octahedral mull transmittance spectra (Table 2) although in both bases the $\nu_3$ transition appears

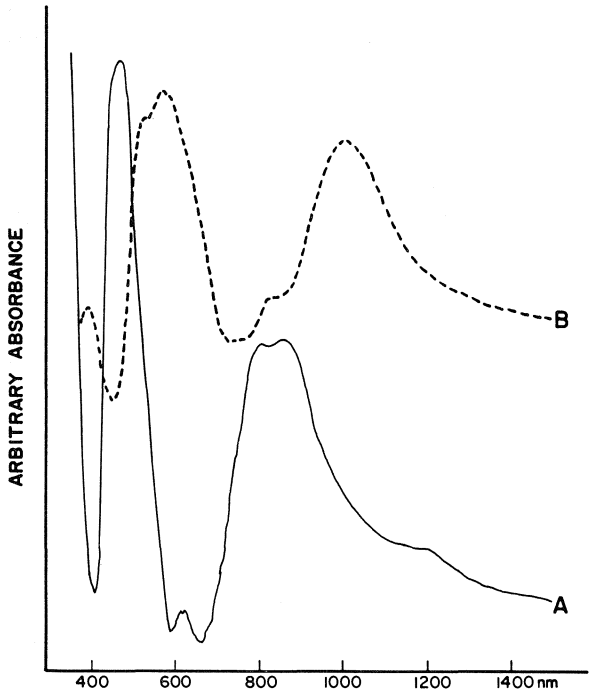

FIG. 2. Electronic spectra (mull transmittance) of $[Ni_2(OBT)_2Cl_4]\cdot(CH_3)_2CO$ (*A*) and $[Ni(BBTE)Cl_2]$ (*B*).

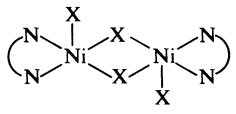

FIG. 3. Proposed structure for $[Ni_2(OBT)_2X_4]$ (X = Cl, Br).

to be hidden among high energy charge transfer absorptions. Although stereochemically compounds **IV** and **V** appear to be similar, in other respects they differ structurally. The 1:2 complex $[Ni(OBT)_2(NCS)_2]$ (**IV**) exhibits CN stretching bands at 2095 and 2106 $cm^{-1}$, associated with two *cis*-isothiocyanate groups. Other bands at 296 and 310 $cm^{-1}$, assigned to Ni—N stretch, are also consistent with such an arrangement. Consequently a *cis*-octahedral structure involving a $NiN_6$ chromophore is indicated for this system. The 1:1 thiocyanate complete (**V**) exhibits a more complex infrared spectrum in the CN stretching region. Three bands are observed at 2100, 2117, and 2140 $cm^{-1}$. The 2140 $cm^{-1}$ band is too high in energy to be associated with a terminally bound isothiocyanate and a thiocyanate bridge is suggested. The two lower energy absorptions appear to be more typical of terminally bound thiocyanate. In light of the stoichiometry of the complex and the fact that it has a pseudo-octahedral stereochemistry a di-μ-thiocyanate bridged dimeric structure appears to be

TABLE 3. Infrared data ($cm^{-1}$)* and magnetic data

reasonable with a *trans*-arrangement of OBT ligands and two *cis*-terminal thiocyanates. The remaining coordination sites appear to be occupied by water molecules as indicated by infrared absorptions at 3340 and 3390 $cm^{-1}$ (Fig. 4). Molecular models indicate that the isomer involving a *cis* non-equatorial arrangement of OBT ligands is unlikely because of steric crowding.

The nitrate complex $[Ni(OBT)(NO_3)_2]\cdot\frac{1}{2}(CH_3)_2CO$ (**VI**) exhibits mull transmittance bands typical of pseudo-octahedral nickel(II) (Table 2). Nitrate fundamental infrared absorptions (Table 3) suggest the presence of bidentate nitrate (15) and this is confirmed by the appearance of just two bands in the combination ($\nu_1 + \nu_4$) region separated by 32 $cm^{-1}$ (16). A *cis*-octahedral structure is therefore suggested involving one coordinated OBT and two bidentate nitrate groups.

The nickel perchlorate and tetrafluoroborate derivatives of OBT (**VII**, **VIII**) are clearly square planar in structure involving two bidentate ligands acting as $N_2$ donors. No clearly defined *d–d* bands are observed below 25 000 $cm^{-1}$ in their mull transmittance spectra (Table 2) where one might reasonably expect to see such absorptions due to a square planar $NiN_4$ chromophore and it is assumed that they are buried beneath high energy charge transfer bands. The diamagnetism of **VII** and **VIII** (Table 3), coupled with infrared data (Table 3) indicating the ionic role of the perchlorate and tetrafluoroborate groups confirms the square planar nature of these systems.

The nickel coordination chemistry of the ethylene bridged bis-benzothiazole BBTE (Fig. 1) differs markedly from that of OBT. It has not been found possible to synthesize square planar derivatives of BBTE. In fact with nickel perchlorate and tetrafluoroborate no significant complex formation was observed. $NiX_2$ (X = $ClO_4$, $BF_4$) and BBTE were reacted in ethanol/TEOF with warming but on cooling the ligand crystallized out and no complexes were formed. In the cases involving nickel halide complexes forcing conditions were required to effect complex formation. Excess metal salt was employed in each case under anhydrous conditions using TEOF and the mixtures were heated until the product crystallized from the hot solution. The products are solvolytically unstable and if the reaction solutions are cooled before the product is allowed to crystallize only the ligand is obtained.

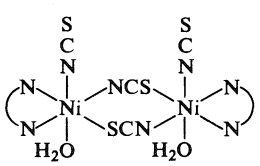

FIG. 4. Proposed structure for $[Ni_2(OBT)_2(NCS)_4(H_2O)_2]\cdot(CH_3)_2CO$.

Highly coloured paramagnetic derivatives are obtained with nickel halides, $NiX_2$ (X = Cl, Br, I) (**IX–XI**). Two major areas of absorption are observed in their mull transmittance spectra (Table 2; Fig. 2) corresponding to the $\nu_2$ and $\nu_3$ transitions associated with tetrahedral nickel (**II**). A high energy absorption at 17 900 $cm^{-1}$ in the case of the iodo-complex is associated with iodine-to-metal charge transfer. In each case two infrared absorptions associated with nickel halogen stretch are observed (Table 3) consistent with a pseudo-tetrahedral stereochemistry. The nitrate complex $[Ni(BBTE)(NO_3)_2]\cdot\frac{1}{2}EtOH$ (**XII**) exhibits electronic spectral bands typical of a pseudo-octahedral nickel(II) system (Table 2) and nitrate combination bands in the infrared (Table 3) separated by 50 $cm^{-1}$ indicate the presence of two bidentate nitrate groups. Structurally therefore the nitrate derivatives of both OBT and BBTE appear to be analogous.

Crystal field splittings for the pseudo-tetrahedral halide complexes are very similar, but it is somewhat surprising that the *Dq* values rise slightly in the series Cl < Br < I. The Racah parameter *B* decreases as expected (Cl > Br > I) reflecting more covalent character in the complexes as the size of the halogen increases. The $\nu_2$ transition increases in energy in the series Cl < Br < I while the $\nu_3$ transition decreases in energy (Cl > Br > I). It was not possible to observe the $\nu_1$ transition in any of these complexes. The slight increase in $\nu_2$ may reflect a distortion towards a square planar stereochemistry as the size of the halogen increases. In the case of the bromo-complex X-ray data indicate a somewhat flattened tetrahedron. This slight increase in $\nu_2$ appears to be responsible for the slight increase in *Dq* in the series Cl < Br < I. In the tetrahedral complexes $Ni(Ph_3PO)_2X_2$ (X = Cl, Br, I) $\nu_2$ decreases slightly in the series Cl > Br > I paralleling the trend in *Dq* (17). The complex $Ni(BBTE)Br_2$ has a crystal field splitting comparable with that of the tetrahedral complex Ni(2,3-dimethylpyridine)$_2Br_2$ (*Dq* = 540 $cm^{-1}$). However, the dimethylpyridine complex has more covalent character ($\beta$ = 0.75) (18).

A comparison of the two ligands, both of which act as $N_2$ donors and form seven-membered chelate rings, reveals a possible reason why square planar $NiN_4$ derivatives are not formed in the case of BBTE. The only difference between the two ligands lies in the bridging unit which is an *o*-disubstituted

For personal use only.

benzene in OBT and an ethylene, $—CH_2CH_2—$, in BBTE. Molecular models indicate that two OBT ligands fit, without serious steric problems, in a *trans*-configuration about a square planar metal centre but that axial coordination would be effectively prevented by the proximity of two α benzene ring protons per ligand to the fifth and sixth coordination sites. (A *cis*-configuration proposed in the case of the complex $[Ni(OBT)_2(NCS)_2]$ also seems reasonable.) The formation of a similar bis-ligand derivative involving BBTE seems less likely in either a *cis*- or a *trans*-configuration because of potential steric interactions between ethylene bridge protons and α benzene ring protons. Although molecular models indicate that a square planar mono-ligand system involving BBTE is reasonable, the fact that tetrahedral derivatives predominate may be a consequence of the larger ethylene bridge, which is more flexible than the *o*-phenylene bridge present in OBT and which can accommodate a larger bite about the metal centre.

An X-ray structural investigation of the complex $[Ni(BBTE)Br_2]$ confirms the pseudo-tetrahedral nature of this molecule (Fig. 5) (19).

Crystal data for $C_{16}H_{12}Br_2N_2S_2Ni$ fw = 514.5 Space group $A2/a$, $a$ = 19.401(1), $b$ = 7.7995(4), $c$ = 13.340(1) Å, β = 122.280(4)°, $V$ = 1706.6 Å$^3$, $Z$ = 4, $D_c$ = 1.996 g cm$^{-3}$, μ = 9.9 mm$^{-1}$, molecular symmetry, 2-fold axis. (CuKα radiation, $\lambda\alpha_1$ = 1.54056 Å)

Selected bond lengths and bond angles are listed in Table 4.

The N—Ni—N angle is very close to the tetrahedral angle but the Br—Ni—Br angle is significantly larger than 109½° and the tetrahedron itself is somewhat compressed. Bond lengths to the nickel centre and in the ligand itself are considered to be normal and the molecule has a two-fold symmetry axis through the nickel centre and a torsional angle of 99.1° in the ethylene bridge.

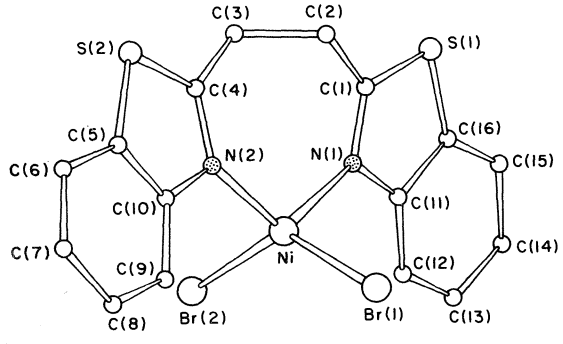

FIG. 5. X-ray structure for $[Ni(BBTE)Br_2]$ ($R$ = 0.027).

TABLE 4. Selected bond lengths and bond angles for $C_{16}H_{12}Br_2N_2S_2Ni$ (esd in parentheses)

| Bond | Length (Å) | Bonds | Angle (deg) |
|---|---|---|---|
| Ni—Br(1) | 2.3631(5) | Br(1)—Ni—Br(2) | 131.79(4) |
| Ni—N(1) | 2.010(3) | Br(1)—Ni—N(1) | 105.40(7) |
| N(1)—C(1) | 1.297(5) | Br(1)—Ni—N(2) | 101.83(8) |
| C(1)—C(2) | 1.484(5) | N(1)—Ni—N(2) | 109.6(1) |
| C(2)—C(3) | 1.541(8) | | |

The tetrahedral structure observed for this system and also for the corresponding chloro- and iodo-complexes seems somewhat unusual on two counts; nickel does not usually have a strong preference for tetrahedral geometries, although in some cases steric factors influence the situation, and also other bidentate pseudo-imidazole ligands have been shown to form only square planar and octahedral complexes with nickel even with a system involving an ethylene bridge. In earlier work we have shown that for the ethylene bridged bis-imidazoline LE (3) square planar bis-ligand complexes are formed with nickel halides, while cobalt derivatives, $Co(LE)X_2$ (X = Cl, Br, I, NCS), are tetrahedral. X-ray data confirm that the cobalt derivative $Co(LE)I_2$ has a tetrahedral structure in which the seven-membered chelate ring has similar dimensions to that in $Ni(BBTE)Br_2$ and the torsional angle in the ethylene bridge is 113.6° (20). BBTE also forms tetrahedral derivatives, $Co(BBTE)X_2$ (X = Cl, Br, I, NCS), with cobalt salts (21).

The formation of 1:1 tetrahedral derivatives of BBTE with the nickel halides appears, in part, to be a function of the ethylene bridge, which is somewhat larger and more flexible than an *o*-phenylene bridge and so would allow the ligand to span two tetrahedral coordination sites more readily than OBT. Also the size of the benzothiazole groups themselves must be taken into account. They are larger than the imidazoline rings found in LE and could be responsible for a steric effect which is helping to stabilize the tetrahedral structure. There appear to be no other steric phenomena in the structure, e.g., hydrogen bonding contacts, which could contribute to the stability of the tetrahedral arrangement. The crystal field strengths of the two ligands must of necessity be very similar and so it is unlikely that electronic effects are responsible for the enhanced stability of the tetrahedral stereochemistry in the cases of the BBTE complexes.

# 1-Pyrazolyl phosphazenes and their complexes with palladium(II) chloride and platinum(II) chloride

KEITH D. GALLICANO AND NORMAN L. PADDOCK

*Department of Chemistry, The University of British Columbia, 2035 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6*

Received June 25, 1981

KEITH D. GALLICANO and NORMAN L. PADDOCK. Can. J. Chem. **60**, 521 (1982).

The chlorophosphazenes $(NPCl_2)_{3-6}$ and the phenylchlorophosphazenes *gem*-$N_3P_3Ph_4Cl_2$ and *gem*-$N_3P_3Ph_2Cl_4$ react with pyrazole, 3-methylpyrazole, and 3,5-dimethylpyrazole to give $(NPpz_2)_{3-6}$, $[NP(Mepz)_2]_{3-5}$, $[NP(Me_2pz)_2]_{3,4}$, $N_3P_3Ph_4(Mepz)_2$, $N_3P_3Ph_4(Me_2pz)_2$, and $N_3P_3Ph_2(Me_2pz)_4$. Infrared and nmr spectroscopy show the pyrazolyl group to be an electron-withdrawing substituent on the phosphazene ring, resembling a halogen rather than an amino-group. The pyrazolyl group also acts as a donor through its pyridinic nitrogen atom, both intramolecularly and in the formation of the complexes *gem*-$N_3P_3Ph_4(Me_2pz)_2 \cdot PdCl_2$, *gem*-$N_3P_3Ph_2(Me_2pz)_4 \cdot PdCl_2$, $N_3P_3(Me_2pz)_6 \cdot 2PdCl_2$, $N_3P_3(Me_2pz)_6 \cdot 2PtCl_2$, and $N_3P_3(Me_2pz)_6 \cdot 3PdCl_2$. No bonding between the metal and a nitrtogen atom in the ring was detected.

KEITH D. GALLICANO et NORMAN L. PADDOCK. Can. J. Chem. **60**, 521 (1982).

Les chlorophosphazènes $(NPCl_2)_{3-6}$ et les phénylchlorophosphazènes *gem*-$N_3P_3Ph_4Cl_2$ et *gem*-$N_3P_3Ph_2Cl_4$ réagissent avec le pyrazole, le méthyl-3 pyrazole et le diméthyl-3,5 pyrazole pour donner les composés suivants: $(NPpz_2)_{3-6}$, $[NP(Mepz)_2]_{3-5}$, $[NP(Me_2pz)_2]_{3,4}$, $N_3P_3Ph_4(Mepz)_2$, $N_3P_3Ph_4(Me_2pz)$ et $N_3P_3Ph_2(Me_2pz)_4$. La spectroscopie infrarouge et la RMN montrent que le groupe pyrazolyle est un substituant électroattracteur du cycle phosphazène ressemblant plutôt à un halogène qu'à un groupe amino. Le groupe pyrazolyle agit également comme donneur par l'intermédiaire de son atome d'azote à la fois de façon intramoléculaire et lors de la formation des complexes *gem*-$N_3P_3Ph_4(Me_2pz)_2 \cdot PdCl_2$, *gem*-$N_3P_3Ph_2(Me_2pz)_4 \cdot PdCl_2$, $N_3P_3(Me_2pz)_6 \cdot 2PdCl_2$, $N_3Pe(Me_2pz)_6 \cdot 2PtCl_2$ et $N_3P_3(Me_2pz)_6 \cdot 3PdCl_2$. On n'a pas décelé de liaison entre le métal et l'atome d'azote dans le cycle.

[Traduit par le journal]

## Introduction

The phosphazene ring normally acts as an acceptor to substituent groups with unshared electrons. The electron transfer from such ligands as the dimethylamido-group shortens the exocyclic bonds, makes the phosphorus atom to which they are attached less electrophilic, and accentuates the donor properties of the nitrogen atoms in the phosphazene ring. The properties of the pyrazolyl group as a substituent (Fig. 1*a*) are different, in that the formally unshared electrons on nitrogen form part of the aromatic sextet, and their reduced availability for transfer to the phosphazene ring is diminished still further by an adjacent pyridinic nitrogen atom, which is more electronegative than carbon. The same conclusion applies to other heteroaromatic rings, and the validity of the basic concepts is confirmed by a study of the rates of hydrolysis of *N*-acylazoles (1), which increase both with the number of nitrogen atoms in the ring and with their separation, as expected theoretically.

One object of the present work was to compare the general properties of the pyrazolylphosphazenes with those of other phosphazene series, so as to clarify the electronic interactions between azole and phosphazene rings. A second object was to examine their coordination behaviour, to see how far the concentration of charge within the azole ring might shift the donor site from the phosphazene ring to the exocyclic groups. Among heteroaromatic rings, pyrazole is particularly appropriate, because of the stability conferred by chelation in its most usual coordination (Fig. 1*b*). We give below details of the preparation of the series of 1-pyrazolylphosphazenes shown in Fig. 2. The complexes *gem*-$N_3P_3Ph_4(Me_2pz)_2 \cdot PdCl_2$ (**7***a*) and *gem*-$N_3P_3Ph_2(Me_2pz)_4 \cdot PdCl_2$ (**7***b*) were prepared from $PdCl_2$ and **6***b* and **5** respectively, **1***c* gave $N_3P_3(Me_2pz)_6 \cdot 2PtCl_2$ (**8***b*) with $PtCl_2$ and $N_3P_3(Me_2pz)_6 \cdot 2PdCl_2$ (**8***a*) and $N_3P_3(Me_2pz)_6 \cdot 3PdCl_2$ (**9**) with $PdCl_2$. The spectroscopic results confirm the conclusion of a preliminary report (2), and show (*i*) that the pyrazolyl group is an electron-withdrawing substituent, and (*ii*) that coordination occurs exclusively at the pyrazolyl groups, as in Fig. 1*b*.

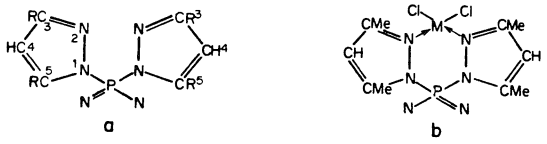

FIG. 1. (*a*) Numbering scheme of pyrazolyl group L. (*b*) Coordination scheme.

## Results and Discussion

All the pyrazolylphosphazenes are crystalline

white solids, that either melt or decompose above 200°C. They are stable to moist air, insoluble in acetonitrile and acetone, increasingly soluble (especially the methyl derivatives) in tetrahydrofuran, diethyl ether, benzene, and chloroform. The pyrazolylphenylphosphazenes are soluble in aromatic solvents.

Spectroscopic information on **1**–**6** is given in Tables 1 and 2. The proton nmr spectra show that the pyrazolyl groups on a particular phosphorus atom are magnetically equivalent. The 3- and 5-positions are differentiated. If $R^3$ and $R^5$ are identical, and contain protons which couple to $H^4$, $R^5$ is identified through the larger coupling constant $J_{4,5}$, arising from the greater double bond character of $C^4$—$C^5$. In the series **1***a*–**4***a*, the order H(5) > H(3) > H(4) for $\delta_H$ was confirmed by comparing the $^{31}$P-decoupled spectra to those of the corresponding methylpyrazolyl compounds (Table 1). The same order is found in $Ppz_3$ and $PhPpz_2$ (11); in $(Me_2N)_2Ppz$ (12) the H(3) resonance is at low field. The methyl signals themselves appear as sharp singlets. The lower-field methyl resonance in **1***c*, **2***c* is arbitrarily assigned to Me(5) by analogy with **1***a*–**4***a*. The peak separation $\Delta = \delta_H R(5) - \delta_H R(3)$ varies with solvent and temperature. Some typical results for **5** are shown in Table 3. Similar phenomena are observed in the spectra of (trimethylsilyl)pyrazoles (13) and in phosphino- and phosphinato-azoles (11). In the former, an intramolecular migration of the $Me_3Si$ group has been suggested to account for the coalescence of the 3- and 5-substituent resonances upon increasing the temperature. The behaviour of the pyrazolylphosphazenes is evidently different, because the coalescence is unsymmetrical, and in $CCl_4$ the bands separate when the temperature is increased. The significantly larger separations found for aromatic

solvents is probably a result of the interaction of the induced magnetic fields of the solvent and the pyrazole ring.

The $^{31}P$ chemical shifts (Table 1) vary with ring size in qualitatively the same way as in other phosphazene series; shielding is greater in the tetramer than in the trimer, and is greater for compounds with the more electronegative ligands. A similar statement applies to $\nu_{as}$ (P=N). Both criteria suggest that the pyrazolyl group resembles the more electronegative ligands F, Cl, Br, in withdrawing electrons from the phosphazene ring, rather than the methyl- or dimethylamido-groups which release them. Table 2 shows that the introduction of $PPh_2$ groups increases the shielding of neighbouring $Ppz_2$ groups, as expected.

The mass spectra of the trimeric pyrazolyl derivatives are similar to those of the halogen-derivatives, in that the parent ion is dominant; the appearance of metastable peaks shows that $R_2pz$ groups are lost consecutively. The significant difference is that the intensity of the parent peak of the pyrazolyls decreases rapidly with increase in ring size; no parent ion was found in the spectrum of **4***a* (Fig. 3). It is probable that the transannular attack, suggested as an explanation for the formation of $N_3P_3$ fragments from $N_6P_6Cl_{12}$ (14), would be facilitated by the good donor properties of the pyrazolyl groups. A similar interaction could account for the low yield obtained in the preparation of the pyrazolylphosphazenes, as discussed below.

All the pyrazolylphosphazenes, **1–6** were prepared from the chlorophosphazene and an excess of the pyrazole in THF or benzene, triethylamine

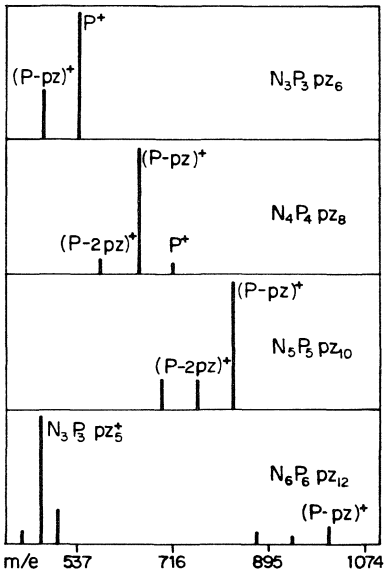

FIG. 3. The mass spectra of **1***a*–**4***a*. The mass numbers of the parent ions are marked; the individual base peaks are given the same intensity. Fragments less abundant than 5% of the base peak are omitted.

being used as an acceptor for hydrogen chloride. Triethylamine hydrochloride was precipitated almost quantitatively, and was variably contaminated by unidentified by-products. The yields of pyrazolylphosphazenes were also variable. They decreased with increase in the size of the phosphazene ring, and with the excess of the pyrazole and triethylamine; broadly speaking, by those changes in reaction conditions which would facilitate parasitic attack of a pyrazolyl group, free or combined, on phosphorus. In agreement, and with the exception of the trimeric derivatives (in which the ring is too small to allow transannular attack), methylation of the pyrazole ring also reduces the yield. Within the same molecule (reaction [1]), nucleophilic attack is made easier by an increase in electron density at the pyridinic nitrogen atom, the greater flexibility of the larger rings, and the partial

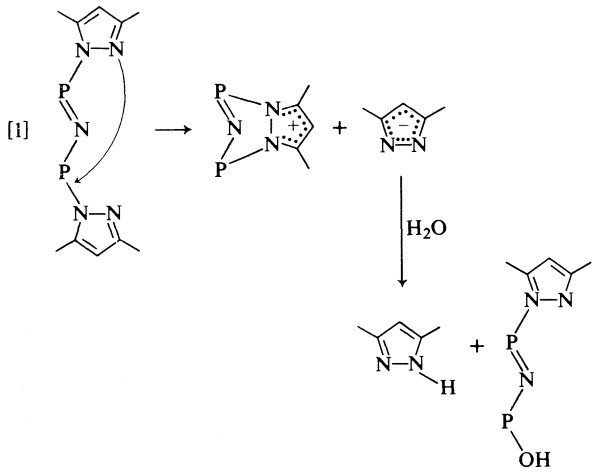
For personal use only.



positive charge on phosphorus induced by the substituent. A similar intermolecular reaction is clearly also possible; either would account for the large amounts of $Me_2pzH$ and MepzH recovered (with near-quantitative formation of $Et_3N{\cdot}HCl$) in their reactions with $(NPCl_2)_{5,6}$. In the later stages of this investigation, it was found that benzene was a better solvent than tetrahydrofuran, in that smaller amounts of by-products were formed and yields were improved. Such compounds as $[NP(Me_2pz)]_5$ could probably be obtained by using it.

The reaction appears to resemble that of catechol with the chlorophosphazenes (15), in which, also, the precipitation of $Et_3N{\cdot}HCl$ in high yield is accompanied by ring degradation; in this case no cyclic derivative of larger size than the trimer could be obtained. No such difficulties are found with the reaction of the phenylchlorophosphazenes with the pyrazoles, in which the reactivity of $PCl_2$ groups to nucleophiles is drastically reduced. The reactions of *gem*-$N_3P_3Ph_2Cl_4$ and *gem*-$N_3P_3Ph_4Cl_2$ are slow, those of the latter especially so, but by-products are absent and the yields are excellent.

The chemical properties of the pyrazolylphosphazenes are consistent with the general concepts developed above. As reported earlier (2), and confirmed here for **2***b*, they are cleaved by HCl more easily than are the dimethylamidophosphazenes, but qualitatively appear to be more stable to hydrolysis than is the trimeric imidazolide $N_3P_3Im_6$ (16); similarly, *N*-acetylimidazole is hydrolysed faster than *N*-acetylpyrazole (1). Since, also, pyrazolylphosphines are hydrolysed faster than are pyrrolylphosphines (17), it is likely that the first stage in the reaction is the protonation of the pyridinic nitrogen (16, 17). For the pyrazolylphosphazenes, its completion is aided by both the induced partial positive charge on phosphorus, and the slight extension (relative to dimethylamidophosphazenes) of the exocyclic P—N bond (2).

The donor sites of phosphazenes are almost always the nitrogen atoms in the ring, whether the acceptor group is a proton (18) or a metal ion (19), even when the use of other sites might reduce steric strain (20). Exceptionally, quaternisation of dimethylamidophosphazenes can occur exocyclically (21), and one tungsten carbonyl complex is known in which the metal is bound to ring and exocyclic nitrogen atoms (22). The structures of the five complexes reported here (Fig. 4) have been established spectroscopically, the numerical detail being given in Table 4.

The low electrical conductivities of **7***a*, *b*; **8***a*, *b* in nitromethane reported in the Experimental part show that ionisation plays no important part in determining the stereochemistry. The ν(Pd—Cl) frequencies in **7***a*, **7***b* are assigned to the $A_1$ (sym) and $B_1$ (asym) vibrations of a *cis*-coordinated $PdCl_2$ group of symmetry $C_{2v}$, by comparison with the spectra of *cis*-$PdCl_2(py)_2$ (23), *cis*-$PdCl_2(im)_2$ (24), and *cis*-$PdCl_2(Me_2pzH)_2$ (25), and the broad lines found in the spectra of **8***a*, **8***b*, and **9** are also more in accord with this type of coordination than with a *trans*-configuration, for which a single sharp line would be expected. Coordination at the nitrogen atoms of the phosphazene ring of **7***a* is ruled out by the magnetic equivalence of the two $Me_2pz$ groups. The $^{31}P$ spectrum of **7***a* is of the ABX type, the two $PPh_2$ phosphorus atoms being distinguished. The molecule is therefore stereochemically rigid, in the form shown in Fig. 4; the more downfield $PPh_2$ resonance is assigned to the phosphorus atom $P_A$ closest to the $PdCl_2$ unit. Compound **7***b* introduces a new feature, in that it contains four pyrazolyl groups and coordination might occur at two pyrazolyl groups on the same, or different, phosphorus atoms. The $^1H$ nmr spectrum shows two sets of pyrazolyl groups, consistent with both possibilities. The ABX pattern of the $^{31}P$ spectrum excludes the second possibility, which would require an $A_2X$

pattern. The nmr evidence does not distinguish between the two isomers shown (Fig. 5).

Apart from the substitution of platinum for palladium, the empirical formulae of **8***a* and **8***b* are the same, and their $^1H$, $^{31}P$, and infrared spectra suggest that they are isostructural. The $^{31}P$-decoupled $^1H$ nmr spectrum of **8***a* shows six singlets of equal intensity in the methyl region and three singlets of equal intensity in the H(4) region, corresponding to three non-equivalent sets containing two $Me_2pz$ groups each. The $^{31}P$ nmr spectrum of **8***a* is of the ABC type (Fig. 6), which is uniquely consistent with the schematic stereochemistry of Fig. 4. If the boat-shaped complexed pyrazolyl groups were turned towards one another, the two sets of $Me_2pz$ groups would be magnetically equivalent; a doublet and a triplet would be seen in the $^{31}P$ spectrum, and there would be two resonances of intensity ratio 2:1 for H(4), and at most four methyl resonances.

The introduction of a third metal atom simplifies the spectra. The infrared spectrum of **9** is almost identical to that of the ligand, particularly in the region of 1200 $cm^{-1}$, where $\nu_{as}$(P=N) remains

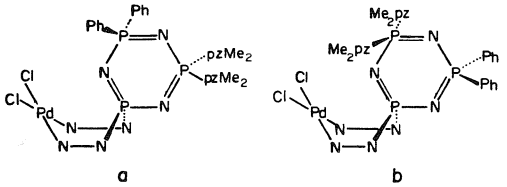

FIG. 5. Alternative structures of **7***b*.

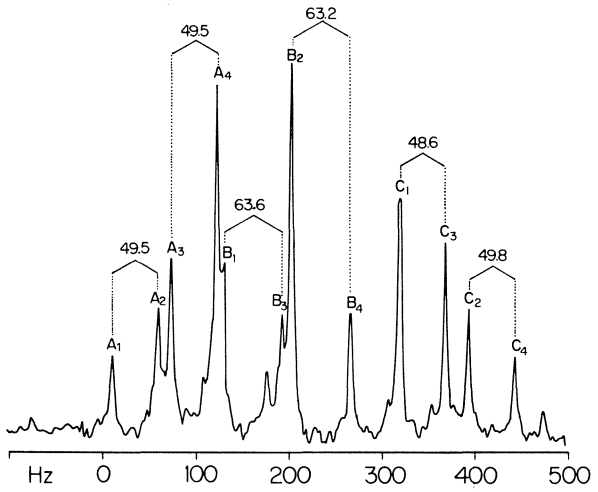

FIG. 6. The $^1H$-decoupled $^{31}P$ nmr spectrum of **8***a* (40.5 MHz, $CDCl_3$). Analysis, by method of ref. 35, in Table 4.

single, suggesting that the complex has a high symmetry. The symmetrical nature of the coordination is confirmed by the pair of singlets in the methyl region of the proton spectrum and by the singlet in the $^{31}P$ spectrum. The H(4) resonance remains as a broad unresolved band, in contrast to the observable couplings of ~ 4.0 Hz apparent in the spectra of the other palladium derivatives. The schematic stereochemistry is therefore that shown in Fig. 4.

We can conclude that in all the complexes, as in other pyrazolyl complexes of the same metals (26), the palladium or platinum has its normal square

planar coordination, that coordination occurs through two pyrazolyl groups on the same phosphorus atom, and that, where there is more than one coordination group in the same molecule, the boat-shaped groups are oriented in the same direction; successive addition of metal halides takes place in the sense **7** → **8** → **9** of Fig. 4. The infrared spectra show no evidence of additional coordination of the metal to the nitrogen atoms of the phosphazene ring, which would be expected to lower ν(M—Cl) by 15–20 $cm^{-1}$ (27). Such a lowering is in fact found in the complexes of **5** with $ZnCl_2$ and with $CoCl_2$, to be reported later in detail. The coordination chemistry of the Pd, Pt complexes confirms the spectroscopic results on the ligands, that the pyrazolyl group is an electronegative substituent on the phosphazene ring, which withdraws electron density sufficiently strongly to overcome the normal coordination properties of the phosphazene ring.

## Experimental

The chlorophosphazenes $(NPCl_2)_{3-6}$ (5) and the phenylchlorophosphazenes *gem*-$N_3P_3Ph_4Cl_2$ (28) and *gem*-$N_3P_3Ph_2Cl_4$ (29) were prepared as described in the literature. Pyrazole, 3-methylpyrazole, and 3,5-dimethylpyrazole (Aldrich) were purified by sublimation or distillation. Diethyl ether and tetrahydrofuran were distilled from sodium/benzophenone, benzene and xylene from $LiAlH_4$, and dichloromethane from $P_2O_5$. Methanol was dried over 4A molecular sieves, and acetonitrile and triethylamine over $CaH_2$. Standard methods (30) were used to make *cis*-bis(benzonitrile)dichloroplatinum (II) and *trans*-bis(benzonitrile)dichloropalladium (II). The pyrazolylphosphazenes were dried at 110°C.

Infrared spectra, calibrated against polystyrene, were obtained from Nujol or hexachlorobutadiene mulls on CsI or polyethylene plates, using Perkin-Elmer 457 or 225 spectrophotometers. Mass spectra were recorded at 70 eV on Varian (Atlas) CH 4-B and (for compounds with m.w. > 1000) Kratos AEI MS-902 mass spectrometers. Nuclear magnetic resonance spectra were run on Varian XL-100 ($^1H$, 100 MHz; $^{31}P$, 40.5 MHz), HA-100 ($^1H$, 100 MHz), and Nicolet-Oxford H-270 ($^1H$, 270 MHz) spectrometers. Double resonance techniques were used for $^{31}P$–$^1H$ decoupling (31). Conductance measurements were made with a Wayne Kerr Universal Bridge, Model B221A on solutions in nitromethane, ~ $10^{-3}$ *M*.

*$N_3P_3(pz)_6$ (1a)*

A solution of pyrazole (1.62 g, 23.8 mmol, 25% excess) and triethylamine (2.11 g, 20.9 mmol, 10% excess) in 50 mL THF was added dropwise to a stirred solution of $N_3P_3Cl_6$ (1.10 g, 3.16 mmol) in 60 mL THF. After heating under reflux for 24 h, the white precipitate (3.32 g) was filtered off, and the part soluble in chloroform (2.50 g) was identified as $Et_3N{\cdot}HCl$ (96%). Some of the product (0.15 g) was crystallised from the concentrated and cooled filtrate. The solvent was removed, and the residual white solid was heated at 110°C/0.1 Torr for 2 h, to remove traces of $Et_3N{\cdot}HCl$ and the excess of pyrazole. Crystallisation from acetonitrile yielded a further 0.15 g, of **1***a* (total 18%) as colourless prismatic needles, decomp. 268°C. *Anal.* calcd. for $C_{18}H_{18}N_{15}P_3$: C 40.2, H 3.4, N 39.1; found: C 40.1, H 3.3, N 39.2.

*$N_4P_4(pz)_8$ (2a)*

In a similar but faster reaction, 1.06 g of $N_4P_4Cl_8$ gave $Et_3N{\cdot}HCl$ (2.30 g, 92%), insoluble by-products (1.318 g) and **2***a* (0.30 g, 20%), which was recrystallised from acetonitrile/1,2-dichloroethane; decomp. 361°C. *Anal.* found: C 40.6, H 3.3, N 39.4.

*$N_5P_5(pz)_{10}$ (3a)*

By a similar method, but with a reduced excess of pyrazole (10%) and triethylamine (5%), $N_5P_5Cl_{10}$ (3.89 g, 6.7 mmol) gave a clear colourless oil, which was dissolved in 100 mL 1:1 acetonitrile/toluene and passed through a column of alumina. Slow evaporation of the solvent yielded colourless crystals (2.71 g, 45%) of **3***a*; decomp. 249°C. *Anal.* found: C 40.5, H 3.4, N 38.8.

*$N_6P_6(pz)_{12}$ (4a)*

The reaction product from $N_6P_6Cl_{12}$ (2.13 g, 3.1 mmol) was crystallised from acetonitrile/1,2-dichloroethane as **4***a* (0.692 g, 21%); decomp. 316°C. *Anal.* found: C 40.4, H 3.3, N 38.9.

*$N_3P_3(Mepz)_6$ (1b)*

3-Methylpyrazole (2.40 g, 29.2 mmol, 6% excess) and triethylamine (3.08 g, 30.4 mmol, 10% excess) were heated under reflux with $N_3P_3Cl_6$ (1.60 g, 4.6 mmol in 110 mL THF for 24 h. The $Et_3N{\cdot}HCl$ and by-products were filtered off, and the solvent removed *in vacuo*. The semisolid residue was washed with acetonitrile and crystallised from acetonitrile/1,2-dichloroethane as **1***b* (0.87 g, 30%); mp 213–218.5°C. *Anal.* calcd. for $C_{24}H_{30}N_{15}P_3$: C 46.4, H 4.9, N 33.8; found: C 46.7, H 4.9, N 33.9.

*$N_4P_4(Mepz)_8$ (2b)*

In a similar reaction, the product from $N_4P_4Cl_8$ (1.52 g, 3.3 mmol) was recrystallised from acetonitrile as **2***b* (1.60 g, 59%); mp 253.5–255°C. *Anal.* found: C 46.5, H 4.8, N 33.5. Hydrogen chloride was bubbled into a benzene solution of **2***b* (0.12 g, 0.15 mmol) for 10 min. The clear colourless solution was heated under reflux for 10 min and the solvent removed. The product was a mixture of $N_4P_4Cl_8$ and MepzH·HCl.

*$N_5P_5(Mepz)_{10}$ (3b)*

In a similar preparative experiment with $N_5P_5Cl_{10}$, the colourless oily product was identified by $^1H$ nmr spectroscopy as a mixture of 3-methylpyrazole and **3***b*. The pure compound was not isolated.

*$N_3P_3(Me_2pz)_6$ (1c)*

From $N_3P_3Cl_6$ (1.66 g, 4.8 mmol), 3,5-dimethylpyrazole (3.21 g, 33.3 mmol), and triethylamine (3.18 g, 31.4 mmol) in 115 mL THF, a white solid product (1.92 g) was obtained, which was crystallised from acetonitrile/1,2-dichloroethane as colourless blocks of **1***c*, 58%; mp 253.5–254.5°C. *Anal.* calcd. for $C_{30}H_{42}N_{15}P_3$: C 51.1, H 6.0, N 29.8; found: C 51.1, H 5.9, N 29.7. The product was also obtained in 91% yield by using benzene as a solvent, and a 5% excess of both triethylamine and 3,5-dimethylpyrazole. No by-products were found.

*$N_4P_4(Me_2pz)_8$ (2c)*

From $N_4P_4Cl_8$ (1.86 g, 4.0 mmol), 3,5-dimethylpyrazole (3.50 g, 36.4 mmol, 13% excess) and triethylamine (3.58 g, 35.4 mmol) in 115 mL THF, a colourless product was obtained, which was crystallised from benzene as **2***c*, 0.303 g; 8%, mp 222.5°C (gels). *Anal.* found: C 51.3, H 6.1, N 29.7. The yield was improved (to 17%) and the quantity of by-products diminished, by using the theoretical quantity of the pyrazole.

gem-*$N_3P_3Ph_2(Me_2pz)_4$ (5)*

A solution of 3,5-dimethylpyrazole (0.85 g, 8.9 mmol) and triethylamine (0.99 g, 9.8 mmol) in 50 mL THF was added to a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

stirred solution of *gem*$N_3P_3Ph_2Cl_4$ (0.96 g, 2.2 mmol) in 70 mL THF, and the mixture heated under reflux for 8 days. The white precipitate consisted solely of $Et_3N{\cdot}HCl$. The solvent was evaporated from the filtrate, leaving a clear pale yellow oil which solidified on standing. Residual $Et_3N{\cdot}HCl$ and 3,5-dimethylpyrazole were removed by sublimation *in vacuo*, and the residue crystallised from acetonitrile/1,2-dichloroethane as colourless needles of **5** (1.34 g, 90%); mp 217.5–219°C. *Anal.* calcd. for $C_{32}H_{38}N_{11}P_3$: C 57.4, H 5.7, N 23.0; found: C 57.1; H 5.6, N 22.8.

gem-$N_3P_3Ph_4(Me_2pz)_2$ (**6***b*)

In a similar but slower reaction, *gem*-$N_3P_3Ph_4Cl_2$ (1.50 g, 2.9 mmol), 3,5-dimethylpyrazole and triethylamine (both in 10% excess) in 120 mL xylene were heated under reflux for 8 days, when 81% of the pyrazole had reacted. The product was crystallised from acetonitrile/1,2-dichloroethane as colourless blocks of **6***b* (1.10 g, 73%); mp 211–212.5°C. *Anal.* calcd. for $C_{34}H_{34}N_7P_3$: C 64.5, H 5.4, N 15.5; found: C 64.7, H 5.4, N 15.5.

gem-$N_3P_3Ph_4(Mepz)_2$ (**6***a*)

The product from a similar reaction of *gem*-$N_3P_3Ph_4Cl_2$ in 80 mL xylene was obtained as an adduct with acetonitrile. The acetonitrile was removed by heating the powdered crystals at 100°C/0.1 Torr for 3 h, giving **6***a* (0.77 g, 71%) mp 203–208°C. *Anal.* calcd. for $C_{32}H_{30}N_7P_3$: C 63.5, H 5.0, N 16.2; found: C 63.4, H 5.0, N 16.0.

gem-$N_3P_3Ph_4(Me_2pz)_2{\cdot}PdCl_2$ (**7***a*)

A solution of $PdCl_2(PhCN)_2$ (0.045 g, 0.12 mmol) in 10 mL dichloromethane was filtered into a stirred solution of **6***b* (0.070 g, 0.11 mmol) in 5 mL dichloromethane. The solution gradually became orange, and deposited a yellow precipitate during 24 h at room temperature. The precipitate was crystallised from chloroform as **7***a* (0.081 g, 90%); decomp. 250°C. *Anal.* calcd. for $C_{34}H_{34}Cl_2N_7P_3Pd$: C 50.4, H 4.2, N 12.1; found: C 51.0, H 4.1, N 11.6. $\Lambda_M$(nitromethane) = 1.21 $cm^2$ $ohm^2$ $mol^{-1}$.

gem-$N_3P_3Ph_2(Me_2pz)_4{\cdot}PdCl_2$ (**7***b*)

In a similar experiment, in which benzene was used as a solvent, **5** with an excess of $PdCl_2(PhCN)_2$ yielded an orange solid, which was recrystallised from chloroform as orange needles of **7***b* (34%); decomp. 225°C, *Anal.* calcd. for $C_{32}H_{38}Cl_2N_{11}P_3Pd$: C 45.4, H 4.5, Cl 8.4, N 18.2; found: C 45.2, H 4.4, Cl 8.1, N 17.9. $\Lambda_M$(nitromethane) = 3.41 $cm^2$ $ohm^{-1}$ $mol^{-1}$.

$N_3P_3(Me_2pz)_6{\cdot}2PtCl_2$ (**8***b*)

In a slower reaction, a suspension of **1***c* (0.101 g, 0.14 mmol) in 30 mL benzene was heated under reflux with $PtCl_2(PhCN)_2$ (0.203 g, 0.43 mmol) for 7 days. The yellow precipitate was filtered off, washed with 50 mL benzene, and crystallised from chloroform/benzene as **8***b* (0.076 g, 43%); mp 275–280°C. *Anal.* calcd. for $C_{30}H_{42}Cl_4N_{15}P_3Pt_2$: C 29.1, H 3.4, N 17.0; found: C 29.5, H 3.4, N 15.7. The sample contained traces of benzene which could not be removed by heating it *in vacuo*. $\Lambda_M$(nitromethane) = 1.68 $cm^2$ $ohm^{-1}$ $mol^{-1}$.

$N_3P_3(Me_2pz)_6{\cdot}2PdCl_2$ (**8***a*)

The similar reaction of **1***c* with $PdCl_2(PhCN)_2$ was complete after 4 days. The dull yellow solid was crystallised from chloroform/benzene as orange blocks of **8***a* (80%); decomp. 250°C. *Anal.* calcd. for $C_{30}H_{42}Cl_4N_{15}P_3Pd_2$: C 34.0, H 4.0, Cl 13.4, N 19.8; found: C 34.1, H 4.8, Cl 13.8, N 19.5. Alternatively, the reaction was carried out in dichloromethane (**1***c*:Pd = 1:2) for 16 h. The orange solution was concentrated and added to a large volume of hexane. The yellow solid was filtered off and washed with benzene: yield 99%. $\Lambda_M$(nitromethane) = 2.26 $cm^2$ $ohm^{-1}$ $mol^{-1}$.

$N_3P_3(Me_2pz)_6{\cdot}3PdCl_2$ (**9**)

In the above reactions, no more than two $MCl_2$ groups could be introduced because the complexes were insoluble in benzene. The better solvent dichloromethane allowed further reaction. A solution of $PdCl_2(PhCN)_2$ (0.145 g, 0.38 mmol) in 30 mL dichloromethane was filtered into a solution of **1***c* (0.085 g, 0.12 mmol) in 3 mL dichloromethane. The orange solution was heated under reflux for 24 h, concentrated to 3 mL, and added dropwise to a large volume of hexane. The orange–yellow solid was filtered off and crystallised from dichloromethane as **9** (0.143 g, 96%); decomp. 250°C. *Anal.* calcd. for $C_{30}H_{42}Cl_6N_{15}P_3Pd_3$: C 29.1, H 3.4, N 17.0; found: C 29.9, H 3.8, N 16.6.

Received July 7, 1981

R. FAGGIANI, H. E. HOWARD-LOCK, C. J. L. LOCK, B. LIPPERT, and B. ROSENBERG. Can. J. Chem. **60**, 529 (1982).

The structure of *cis*-dichlorodiammine-*trans*-dihydroxoplatinum(IV), $PtCl_2(OH)_2(NH_3)_2$, has been determined by X-ray diffraction. The tetragonal space group, $P4_2/n$ has cell dimensions $a = 7.328(4)$, $c = 11.362(5)$ Å and has four formula units in the cell. Intensities were measured using MoKα radiation and a Syntex $P2_1$ diffractometer. The crystal structure was determined by standard methods and refined to $R_1 = 0.0460$, $R_2 = 0.0639$ based on 447 independent reflections. The platinum atom has roughly octahedral coordination and Pt—Cl, Pt—N, Pt—O distances (2.306(4), 2.00(1), 2.00(1) Å) are normal. The crystal is held together by hydrogen bonds, and the vibrational spectra have been correlated with observed features of the hydrogen bonding.

R. FAGGIANI, H. E. HOWARD-LOCK, C. J. L. LOCK, B. LIPPERT et B. ROSENBERG. Can. J. Chem. **60**, 529 (1982).

On a déterminé, par diffraction de rayons X, la structure du dichorodiamine-*cis* dihydroxo-*trans* platine(IV), $PtCl_2(OH)_2(NH_3)_2$. Le cristal appartient au groupe d'espace tétragonal $P4_2/n$; les dimensions de la maille sont: $a = 7{,}328(4)$, $c = 11{,}362(5)$ Å et comporte quatre unités par maille. On a mesuré les intensités en utilisant la radiation MoKα et un diffractomètre Syntex $P2_1$. On a résolu la structure du cristal par des méthodes normales et on l'a affiné jusqu'à une valeur conventionnelle de $R_1 = 0{,}0460$ et de $R_2 = 0{,}0639$ à partir de 447 réflexions indépendantes. L'atome de platine a grossièrement une géométrie de coordination octaédrique et les distances Pt—Cl, Pt—N, Pt—O (2,306(4), 2,00(1), 2,00(1) Å) sont normales. Le cristal est maintenu par des liaisons hydrogènes et on a fait correspondre les spectres de vibration aux caractéristiques de la liaison hydrogène.

[Traduit par le journal]

## Introduction

Since the original report on the antitumor activity of two platinum(IV) compounds, *cis*-$Pt(NH_3)_2Cl_4$ and $Pt(en)Cl_4$ (1), relatively little work has been done on the field of cancerostatic Pt(IV) complexes until recently. It had earlier been suggested that Pt(IV) complexes might be superior to Pt(II) compounds because of membrane transport properties (2). It was further assumed that the antitumor activity of Pt(IV) involves reduction inside the cell to the corresponding Pt(II) complexes with loss of the two *trans* ligands. Such an assumption is reasonable and it has been verified that ascorbic acid and cysteine, for example, can reduce Pt(IV) to Pt(II) (3). In a recent systematic study, Tobe *et al.* examined the differences in solubility, toxicity, and antitumor activity between *cis*-$Pta_2Cl_2$ (with a = amine) and *cis*-$Pta_2Cl_2(OH)_2$ (4). As a result no clear-cut structure–activity relation emerged, yet it became obvious that for a = $NH_3$ the compound *cis*-dichlorodiammine-*trans*-dihydroxyplatinum(IV), $PtCl_2(NH_3)_2(OH)_2$, in the test systems used, was clearly superior to *cis*-$Pt(NH_3)_2Cl_2$, the most widely used Pt-compound in cancer treatment of humans presently.

We were interested in this compound both for its antitumor activity and for structural comparison with hydroxo-bridged complexes of Pt(II) we isolated recently (5). Hydroxo-complexes of tetravalent platinum exist in a wide variety both with terminal and bridging hydroxo groups (6), yet only for two such compounds are crystallographic data available at present (7, 8).

## Experimental section

The compound was prepared as described previously (9). Elemental analysis (Glabraith Laboratories): H 2.50, N 8.35, O 9.72, Pt 58.56, Cl 21.29; calcd: H 2.39, N 8.40, O 9.58, Pt 58.4, Cl 21.23.

Solubility in $H_2O$: ~635 mg/100 mL at room temperature. The deuterated compound was prepared by recrystallization from boiling $D_2O$.

Infrared spectra were recorded on Perkin Elmer 577 and 580 grating spectrometers from 4000 to 180 $cm^{-1}$ as KBr and CsI pellets and from 4000 to 300 $cm^{-1}$ as Nujol mulls (KBr plates). The spectra were calibrated against polystyrene. Raman spectra were obtained from polycrystalline samples between 1800 and 150 $cm^{-1}$ on a Coderg PH1 spectrometer with a He–Ne Laser (Spectraphysics) and calibrated against Laser plasma lines.

*Collection of the X-ray diffraction data*

A crystal, homogeneous under the polarizing microscope, was used for crystallographic studies. Precession photographs

showed the crystal was tetragonal and unit cell parameters were obtained from least squares fit of $\chi$, $\Phi$, and $2\theta$ for 15 reflections in the range $11° < 2\theta < 26°$ recorded on a $P2_1$ diffractometer using graphite-monochromated MoK$\alpha$ radiation ($\lambda$ 0.71069 Å at 20°C). Crystal data and other numbers related to the data collection are given in Table 1. The density was not determined but was shown to be greater than 3.0 since the crystal sank in aqueous thallium formate solution of that density. Intensity data were recorded on a Syntex $P2_1$ diffractometer using a coupled $\theta$(crystal) – $2\theta$(counter) scan. The methods of selection of scan rates and initial data treatment have been described (10, 11). Corrections were made for Lorentz-polarization effects and absorption.

*Solution of the structure*

The coordinates of the platinum atom were found from a three-dimensional Patterson synthesis, and a three-dimensional electron density difference synthesis revealed the remaining non-hydrogen atoms. All atoms were given anisotropic temperature factors and further refinement using full-matrix least-squares minimizing $\Sigma w(|F_o| - |F_c|)^2$ was terminated when the maximum shift/error was 0.01. No attempt was made to locate the hydrogen atoms. Corrections were made for extinction using the method of Larson (12). Throughout the refinement, the scattering curves were taken from ref. 13 and anomalous dispersion corrections from ref. 14 were applied to the curves for platinum and chlorine. The atom parameters are listed in Table 2.[2]

## Results and discussion[3]

The molecule is shown in Fig. 1 and selected interatomic distances are given in Table 3. The bond lengths (Pt—O, 2.00(1), Pt—N; 2.00(1), Pt—Cl, 2.306(4) Å) agree well with those found previously in Pt(IV) compounds (Pt—N range, 1.97(4) to 2.068(17) Å, Pt—Cl range 2.26 Å to 2.309(6) Å, Pt—O, 1.96 Å) (7, 15, 16). Because of the errors it is not possible to differentiate between these values and those observed previously by us for Pt(II) compounds (17), but overall, it appears that the mean distances for the Pt(IV) complexes are about 0.05–0.1 Å shorter than corresponding values in Pt(II) complexes. All angles are close to the 90° or 180° expected for an octahedral complex.

The packing of the molecule within the cell is shown in Fig. 2. The molecules are arranged in layers centred at $z = 0$, $z = 1/4$. The lattice is held together by an extensive hydrogen bonding network, but it is not possible to decide unambiguously which atoms are hydrogen bonded since there are six distances in the range expected for hydrogen bonds (two short N···O, two medium O···Cl, two long, N···Cl) but only four hydrogen atoms (three on $NH_3$, one on OH). A consideration of probable interactions, distances, and angles suggests that the hydrogen bonds are probably disordered with two N—H···O (strong), one N—H···Cl (disordered, weak), and one O—H···Cl (disordered, medium). Within the layers, the sets of molecules related by the $\bar{4}$ axis are held together by the relatively strong $NH_3$···O bonds (N···O, 2.88(2) Å) and the somewhat weaker OH···Cl bonds (O···Cl, 3.39(1) Å). The very weak $NH_3$···Cl bonds (N···Cl, 3.48(1) Å) bind molecules along ***c*** related by the $4_2$ axis. In addition, the molecules in the ***c*** direction are arranged so that dipolar interactions will be maximized.

Infrared and Raman spectra are reported in Table 4, and the modes have been assigned by comparison with *cis*- and *trans*-$Pt(NH_3)_2Cl_4$ (18, 19), *cis*- and *trans*-$[Pt(NH_3)_4Cl_2)]Cl_2$ (18) $Pt(NH_3)_6Cl_4$, *mer*-$[Pt(NH_3)_3Cl_3]Cl{\cdot}H_2O$, $K[Pt(NH_3)Cl_5]{\cdot}H_2O$, $[Pt(NH_3)_5Cl]Cl_3{\cdot}H_2O$ (20, 21), *cis*-$Pt(NH_3)_2Cl_2$ (21, 22), and $K_2[PtCl_4(OH)_2]$ (23) and on the basis of the arguments given below. The isolated $(NH_3)_2PtCl_2$-

[2]All calculations were carried out on CDC6400 and CYBER 170/730 Computers. Initial data treatment used programs from the X-Ray 76 package (27). The structure was solved using the Fourier program, SYMFOU, and full-matrix least-squares program, CUDLS, written internally by Rutherford and Stephens, respectively. Diagrams were prepared using ORTEP-II (28).

[3]A table of the moduli of $F_o$ and $F_c$ is available on request, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a] The form of the anisotropic thermal ellipsoid is $\exp[-(\beta_{11}h^2 + \cdots + 2\beta_{12}hk + \cdots)]$ and $U_{ij}$ was obtained from $\beta_{ij} = 2\pi^2 b_i b_j U_{ij}$ where $b_i$ are the reciprocal lattice vectors.
[b] Standard deviations of the least significant figures are given here and in subsequent tables in parentheses.

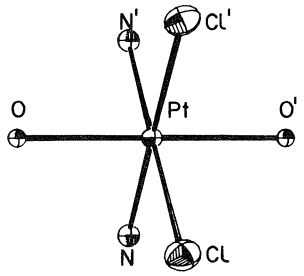

FIG. 1. The molecule *cis*-dichlorodiammine-*trans*-dihydroxoplatinum(IV).

$(OH)_2$ molecule is of point group $C_{2v}$ if $NH_3$ and OH are treated as monoatomic groups, but the site symmetry of $(NH_3)_2PtCl_2(OH)_2$ is reduced to $C_2$ in the crystal. The vibrational modes can be classified, in a first approximation, into those caused by the $NH_3$ and OH ligands and those caused by the $N_2PtCl_2O_2$ skeleton. The latter will be considered first.

The normal modes expected for the $N_2PtCl_2O_2$ system, having $C_2$ site symmetry, are $8A + 7B$, all both infrared- and Raman-active. The stretching modes for this skeleton are distributed as follows: $\nu(Pt—Cl) = A + B$, $\nu(Pt—N) = A + B$, and $\nu(Pt—O) = A + B$. A classification of the skeletal stretching vibrations on a site group approach is reasonable for most of the bands observed, since a multiplicity of bands as expected in a factor group analysis is not observed (c.f. Table 4). Because of the low solubility of the title compound in the solvents used, Raman polarization studies could not be performed and thus no definitive assignment of bands to particular symmetry species was possible. The two Pt—Cl stretching vibrations are observed at 335 and 350 $cm^{-1}$ in the ir spectrum and at 338 and 347 $cm^{-1}$ in the Raman spectrum. They are almost unaffected by deuteration, thus indicating that they are not significantly coupled to Pt—N modes of the same symmetry. The Pt—Cl stretching vibrations absorb in the range observed for other complexes of Pt(IV) with chloro ligands *trans* to $NH_3$ groups (18, 19).

For Pt—N and Pt—O modes of the same symmetry coupling must be taken into consideration, since $NH_3$ and OH have not only almost identical point masses but also identical distances to platinum (2.00 Å) in our compound. Comparison with other complexes of Pt(IV) suggests that Pt—N and Pt—O stretching vibrations can be expected at very similar energies (Pt—N range, 512–603 $cm^{-1}$ (18–22), Pt—O, 540, 548 $cm^{-1}$ (23)). The relatively low energy Pt—O stretching modes in $[(CH_3)_3Pt(OH)]_4$ (340 and 430 $cm^{-1}$ (24)) do not contradict the above assumption because of the relatively weak Pt—O bond (2.22 Å) and its partially ionic character (8*a*). Pt—N, Pt—O stretching modes are observed in the ir spectrum of the title compound at 575, 558, 457, and 420 $cm^{-1}$. The highest frequency band can be observed only under high resolution (1.3 $cm^{-1}$) and is, with lower resolution, buried under the strong 558 $cm^{-1}$ band. In the Raman spectrum, bands are observed 578, 550, 535, 448, and 410 $cm^{-1}$. There is one band more than predicted by $C_2$ site symmetry considerations in both the ir and Raman spectra in the range expected for Pt—N and Pt—O stretching vibrations. Moreover, the demanded "coincidence" between the bands at 457 (ir) and 448 (Raman), 420 (ir) and 410 (Raman),

558 (ir) and 550 $cm^{-1}$ (Raman) is poorer than with those of the higher frequency bands (578 (575) and 535 (535 $cm^{-1}$)) and the Pt—Cl modes. The intensity of the ir band at 457 $cm^{-1}$ indicates the latter is a fundamental, and it is not possible to determine the position of the 448 $cm^{-1}$ Raman bands with high accuracy because of its low intensity and the steep slope of the baseline. We assume that the 457 (ir) and the 448 $cm^{-1}$ (Raman) bands are actually coincident, and thus the 420 (ir) and the 410 $cm^{-1}$ (Raman) bands are interpreted as combination bands of skeletal deformation modes (cf. Table 4). An alternative interpretation, namely that factor group coupling causes splitting of one or two (if coupled intramolecularly) skeletal stretching vibrations and results in noncoincidence seems unreasonable because such splittings are usually considerably smaller than those observed (35 $cm^{-1}$ in ir, 38 $cm^{-1}$ in Raman). In the spectra of the deuterated compound the identification of five of the six expected skeletal stretching modes is straightforward since the three high frequency bands and the Pt—Cl modes (in the ir spectrum not resolved) coincide reasonably well. The most prominent change in the ir spectrum of the deuterated compound is the "disappearance", or at least considerable loss of intensity, of the original 457 $cm^{-1}$ band. In the 400–500 $cm^{-1}$ range of the ir-spectra of the deuterated compound, only a weak and broad band around 450 $cm^{-1}$ (KBr, CsI pellet) is observed, and the corresponding band in the Nujol mull (448 $cm^{-1}$) is even weaker. In the same range of the Raman spectrum only one distinct band of low intensity is observed at 434 $cm^{-1}$, though there are several other features at 418, 458, 469, 480, and 490 $cm^{-1}$ whose intensities, however, are too low to interpret them unambiguously as real bands. It is therefore not possible to identify the "missing" sixth band of the skeletal stretching modes with certainty.

Because of vibrational coupling between the Pt—N and Pt—O stretching motions and because hydrogen bonding affects these two motions differently, these vibrations cannot be unambiguously assigned without a detailed force constant analysis. Nevertheless, we suggest a tentative way of estimating which of the two stretching motions (Pt—N or Pt—O) makes the predominant contribution to each band, based on the fact that the Pt—N and Pt—O skeletal stretching vibrations are shifted to a different degree upon deuteration. The very strong Raman band at 578 $cm^{-1}$ is shifted to 567 $cm^{-1}$ in the deuterated species (567/578 = 0.981), the very strong Raman band from 535 $cm^{-1}$ to 502 $cm^{-1}$ (502/535 = 0.938), and the most intense ir band at 558 $cm^{-1}$ is shifted to 538 $cm^{-1}$ giving an isotopic shift of 0.964. Treating $NH_3/ND_3$ and OH/OD, respectively, as point masses vibrating against the heavy Pt-mass, and assuming no coupling, the isotopic/normal frequency ratios should approximate the value $\sqrt{17/20} = 0.922$ for $ND_3/NH_3$ and $\sqrt{17/18} = 0.972$ for OD/OH platinum vibrations. Therefore, we suggest the band at 535 $cm^{-1}$ (Raman), 538 $cm^{-1}$ (ir) is caused mainly by a Pt—N stretching motion and the 578 $cm^{-1}$ band (Raman), 575 $cm^{-1}$ (ir) is caused mainly by a Pt—O motion.

The Raman bands observed below the Pt—Cl stretching modes are listed in Table 4. No attempt was made to classify these skeletal deformation bands.

The ir spectrum above 600 $cm^{-1}$ consists of the absorptions of the individual $NH_3$ and OH group vibrations and combination and overtone vibrations, respectively. The stretching vibrations of the OH groups are well separated from those of the $NH_3$ ligands and appear at 3515 $cm^{-1}$ with multiple slight shoulders between 3495 and 3350 $cm^{-1}$. These shoulders, as well as their shifts in the spectrum of the deuterated compound ($\nu_{OH}/\nu_{OD}$ = 1.352), indicate some hydrogen bonding between hydroxo protons and chloro ligands. The PtO—$H_1$ bending vibration appears at 1039 $cm^{-1}$ in the ir spectrum of the undeuterated compound and at 773 $cm^{-1}$ in the deuterated compound. The position of this vibration falls in the range observed also for δ(PtO—H) modes in *trans*-$K_2[PtCl_4(OH)_2]$ (23) and in a series of hydroxo bridged complexes of Pt(II) (5) as well as other metal complexes containing terminal hydroxo groups (25).

[a] Infrared intensities: vs = very strong, s = strong, m = medium, w = weak, vw = very weak, sh = shoulder, br = broad, sp = sharp.
[b] Raman intensities relative to strongest Raman band at 578 (567) $cm^{-1}$ with arbitrary intensity 10.
[c] Only observable in KBr and CsI spectra.
[d] Bands below 300 $cm^{-1}$ only observable in CsI spectra.
[e] Typically δPt—N occurs at ~200 $cm^{-1}$; δPt—Cl at ~170 $cm^{-1}$.

The $NH_3$ stretching vibrations cover a rather large range with distinct bands at 3260 and 3170 $cm^{-1}$ and a broad, unresolved band centered around 3000 $cm^{-1}$. The last is caused by the ammine protons hydrogen bonded to oxygen atoms of neighbouring molecules whereas the two former are probably caused by the NH weakly bonded to Cl. The absorptions of the degenerate deformation modes of the $NH_3$ ligands appear at 1606, 1585, and 1551 $cm^{-1}$, those of the symmetric deformation modes as a single band at 1361 $cm^{-1}$. The somewhat higher positions of these bands in $Pt(NH_3)_2Cl(OH)_2$ compared to *cis*-$Pt(NH_3)_2Cl_4$ (18) are interpreted in terms of strong intermolecular hydrogen bonding between NH and O. The splitting of the degenerate deformation modes in $Pt(NH_3)_2Cl_2(OH)_2$

is preserved in the spectrum of the deuterated compound; this supports our interpretation of differing ammine protons.

There are two bands of approximate equal intensity at 966 and 907 $cm^{-1}$ in the ir spectrum of our compound, which, because they are shifted upon deuteration, are attributed to $NH_3$ vibrations. $NH_3$ rocking frequencies are known to be very sensitive to both the nature and the oxidation state of a metal (26) and thus a shift to higher energy is expected when *cis*-$Pt(NH_3)_2Cl_2^-$ ($\rho_r(NH_3) = 805, 790\ cm^{-1}$) (22) is compared to a closely related Pt(IV) complex. Even higher frequencies for $NH_3$ rocking vibrations are expected and observed for positively charged complexes of Pt(IV) (18, 20–22). The high positions for the $NH_3$ rocking modes in our complex, $Pt(NH_3)_2Cl_2(OH)_2$, undoubtedly are caused by hydrogen bonding. We assign the 966 band to the strongly-hydrogen bonded ammine protons and the other band to the weakly bonded one. The sharp shoulder at 917 $cm^{-1}$ is interpreted as the overtone of the 457 $cm^{-1}$ skeletal vibration. The $NH_3$ rocking frequencies are shifted in the deuterated compound to 725 and 695 $cm^{-1}$. The former band is observed only in spectra obtained from samples in discs KBr and CsI spectra since it falls under the Nujol absorption in this range.

# Conjugative interactions in 1-methylpyrrol-2-yl derivatives of the cyclic phosphazenes $(NPF_2)_n$ ($n$ = 3–6): the crystal and molecular structure of 1-methylpyrrol-2-ylheptafluorocyclotetraphosphazene

RAJENDRA D. SHARMA, STEVEN J. RETTIG, NORMAN L. PADDOCK, AND JAMES TROTTER

*Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6*

Received April 27, 1981

RAJENDRA D. SHARMA, STEVEN J. RETTIG, NORMAN L. PADDOCK, and JAMES TROTTER. Can. J. Chem. **60**, 535 (1982).

1-Methylpyrroles, in which the 2-position is occupied by a pentafluorocyclotriphosphazenyl (**1***a*), heptafluorocyclotetraphosphazenyl (**1***b*), nonafluorocyclopentaphosphazenyl (**1***c*), or undecafluorocyclohexaphosphazenyl group (**1***d*), have been prepared from 2-lithio-1-methylpyrrole and the corresponding fluorophosphazene. Crystals of **1***b* are monoclinic, $a$ = 17.300(2), $b$ = 5.0281(3), $c$ = 16.902(2) Å, β = 108.904(4)°, $Z$ = 4, space group $P2_1/n$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R$ = 0.038 and $R_w$ = 0.047 for 1167 observed reflections. The $N_4P_4$ ring is nearly planar. The P—N bond lengths (corrected for libration) range from 1.524(5) to 1.562(5) Å with a mean value of 1.541(17) Å, and the mean ring angles are 122.9(20)° at phosphorus and 146.4(23)° at nitrogen. The geometry of the 1-methylpyrryl group shows no unexpected features, but the P—C bond (1.756(5) Å) is significantly shorter than in typical P-phenyl derivatives, and the P—F bond at the same atom is comparatively long (1.561(4) Å). Conjugative electron release from the pyrryl group, involving $p_\pi$–$d_\pi$ bonding, is indicated both by these geometrical features and by the appearance of intramolecular charge transfer bands in the electronic spectra of **1**(*a*–*d*).

RAJENDRA D. SHARMA, STEVEN J. RETTIG, NORMAN L. PADDOCK et JAMES TROTTER. Can. J. Chem. **60**, 535 (1982).

La réaction du lithio-2 méthyl-1 pyrrole avec un fluorophospazène approprié conduit à des méthyl-1 pyrroles dans lesquels on trouve en position 2 soit un pentafluorocyclotriphosphazényle (**1***a*), soit un heptafluorocyclotétraphosphazényle (**1***b*), soit un nonafluorocyclopentaphosphazényle (**1***c*) ou undécafluorocyclohexaphosphazényle (**1***d*). Les cristaux du composé **1***b* appartiennent au groupe d'espace $P2_1/n$ avec $a$ = 17,300(2), $b$ = 5,0281(3) $c$ = 16,902(2) Å, β = 108,904(4)°, $Z$ = 4. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R$ = 0,038 et $R_w$ = 0,047 pour 1167 réflexions observées. Le cycle $N_4P_4$ est presque plan. Les longueurs de liaison P—N corrigées pour la libration varient de 1,524(5) à 1,562(5) Å avec une valeur moyenne de 1,541(17) Å alors que les angles moyens de cycle sont de 122,9(20)° au niveau du phosphore et de 146,4(23)° au niveau de l'azote. La géométrie du groupe méthyl-1 pyrrole ne révèle aucune caractéristique imprévue; toutefois la liaison P—C (1,756(5) Å) est d'une façon significative beaucoup courte que dans les dérivés P-phényles typiques alors que la liaison P—F au niveau du même atome est comparativement longue (1,561(4) Å). Les caractéristiques géométriques et l'apparence de bandes de transfers de charge intermoléculaires dans les spectres électroniques de **1**(*a*–*d*) indiquent que la libération conjuguée d'électron à partir du groupe pyrole, fait intervenir une liaison $p_\pi$–$d_\pi$.

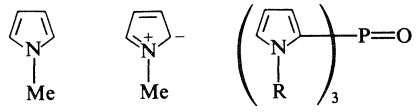
## Introduction

Although the inductive effect of substituents on a phosphazene ring has been recognized for some time, conjugative interactions are less well established. The Taft $\sigma_{R^0}$ parameters of fluorophosphazenyl groups are similar to those of cyano- or nitro-groups (1), but the electronic spectrum of a phenyl group is little changed by attachment to a phosphazene ring (2), and the results of a photoelectron spectroscopic investigation are in better agreement with the transmission of the electronic effects of a phenyl group through the σ-bond system (3).

The bonding system in phosphazenes is closely analogous to that in phosphoryl compounds, in which, again, the spectroscopic evidence (4) indicates only weak $p_\pi$–$d_\pi$ bonding between phenyl and phosphoryl groups. Electronic delocalization on to phosphorus is limited by the relatively high electronegativity of carbon, and in general the chemical and spectroscopic evidence for conjugation to a phosphoryl group, reviewed elsewhere (5),



**2***a* **2***b* **3**

is strongest for electron-releasing substituents. The pyrryl group is a good electron donor, because canonical forms of pyrrole like **2***b* make an important contribution to its electronic structure; experimentally, the first ionization energies of pyrrole (8.20 eV) (6) and especially 1-methylpyrrole **2** (7.95 eV) (7) are significantly less than that of benzene (9.25 eV) (8). As a consequence of the conjugative charge transfer to phosphorus, the tri(pyrryl) phosphine oxides **3** show an intense low frequency band in their electronic spectra (9), similar to that found in formyl- and acetyl-pyrroles (10), which is attributed to $p_\pi$–$d_\pi$ bonding (9).

In the expectation that phosphazenyl and phosphoryl groups would behave similarly, we have prepared the 1-methylpyrrol-2-yl fluorophosphazenes $N_nP_nF_{2n-1}\cdot C_4H_3NMe$, ($n$ = 3–6, **1***a*–*d*), and

have measured their electronic spectra. Since it is conceivable that any conjugation found in this way might be confined to the upper state of the electronic transition, we have also determined the crystal structure of **1***b*, to see whether its geometry might show evidence of conjugation in the ground state.

## Experimental

The fluorocyclophosphazenes $(NPF_2)_n$ ($n$ = 3–6) were prepared by the fluorination of the corresponding chlorides with activated KF. *N,N,N′,N′*-Tetramethylethylenediamine (TMEDA) was stirred over $CaH_2$ for 24 h and distilled at reduced pressure. Diethyl ether was heated with sodium benzophenone under reflux for 12 h, and distilled. 1-Methylpyrrole (Aldrich) was distilled at reduced pressure. All operations were carried out in an atmosphere of dry nitrogen. Ultraviolet spectra were obtained on a Cary 17 spectrophotometer, and nmr spectra were obtained using the following instruments; Varian XL100 ($^1$H, $^{31}$P), Varian CFT20 ($^{13}$C), Bruker WH 400 ($^{13}$C), and Varian EM 360/390 ($^{19}$F).

*Reaction of 2-lithio-1-methylpyrrole with hexafluorocyclotriphosphazene*

An equimolar mixture of *n*-butyllithium (2.2 *M* in hexane, 7.4 mL) and TMEDA (1.89 g, 16.3 mmol) was added dropwise to a solution of 1-methylpyrrole (1.32 g, 16.3 mmol) in 40 mL ether. The resulting solution was added dropwise to a stirred solution of hexafluorocyclotriphosphazene (4.12 g, 16.5 mmol) in 40 mL ether at −20°C. Lithium fluoride was precipitated immediately, and was filtered off (0.425 g, 16.4 mmol) after 2 h at −20°C and 6 h at room temperature. The solvent and the TMEDA were removed at 5 Torr, and the yellow liquid was fractionated at 0.02 Torr to give two components, boiling at 30°C, 50°C. They were purified by gas–liquid chromatography at 180°C: Varian A90P, column 2 ft × 0.25 in, SE30 on 60–80 mesh Chromosorb A treated with HMDS, retention times 3 and 7 min. The major component (50%) was identified as 1-methylpyrrol-2-ylpentafluorocyclotriphosphazene, **1***a*. *Anal.* calcd. for $C_5H_6F_5N_4P_3$: C 19.4, H 1.9, N 18.1; found: C 19.5, H 1.9, N 18.0. The minor component (20%) was bis(1-methylpyrrol-2-yl)tetrafluorocyclotriphosphazene, **4**, a colorless oil which slowly crystallized. *Anal.* calcd. for $C_{10}H_{12}F_4N_5P_3$: C 32.3, H 3.2, N 18.9; found: C 32.6, H 3.3, N 18.7.

The monosubstituted derivatives of $N_4P_4F_8$, $N_5P_5F_{10}$, and $N_6P_6F_{12}$ were prepared similarly. The yield of each was variable in different experiments, but always exceeded 50%. **1***b*, mp 37°C; *Anal.* calcd. for $C_5H_6F_7N_5P_4$: C 15.3, H 1.5, N 17.8; found: C 15.5, H 1.5, N 17.7. **1***c*; *Anal.* calcd. for $C_5H_6F_9N_6P_5$: C 12.6, H 1.3, N 17.6; found: C 12.8, H 1.2, N 17.7. **1***d*; *Anal.* calcd. for $C_5H_6F_{11}N_7P_6$: C 10.7, H 1.1, N 17.5; found C 11.0, H 1.1, N 17.3. Compounds **1***a*,*c*,*d* are liquid at room temperature.

*X-ray crystallographic analysis of* **1***b*

Colorless crystals of **1***b* were obtained from hexane. A crystal ca. 0.19 × 0.28 × 0.48 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo Kα Radiation (λ = 0.71073 Å). Crystal data at 22°C are:

$C_5H_6F_7N_5P_4$ fw = 393.0

Monoclinic, $a$ = 17.300(2), $b$ = 5.0281(3), $c$ = 16.902(2) Å, β = 108.904(4)°, $V$ = 1391.0(2) Å$^3$, $Z$ = 4, $\rho_c$ = 1.877 g cm$^{-3}$, $F(000)$ = 776, μ(Mo Kα) = 5.43 cm$^{-1}$. Absent reflections: $h0l$, $h + l \neq 2n$ and $0k0$, $k \neq 2n$ uniquely indicate the space group $P2_1/n$ (non-standard setting of $P2_1/c$, $C_{2h}^5$, No. 14).

Intensities were measured with graphite-monochromated Mo Kα Radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.18–10.06° min$^{-1}$ over a range of (1.00 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 50°. The intensities of three check reflections, measured every 5000 s throughout the data collection, remained constant within 2%.

After data reduction, no absorption correction was made in view of the low value of μ. Of the 2430 independent reflections measured, 1167 (48%) had intensities greater than 3σ($I$) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with $S$ = scan count and $B$ = background count.

The structure was solved by direct methods. The positions of the four phosphorus atoms were determined from an $E$-map and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R$ = 0.047, a difference map gave positions for all six hydrogen atoms which were included in subsequent cycles of refinement with isotropic thermal parameters. The scattering factors of ref. 11 were used for non-hydrogen atoms and those of ref. 12 for hydrogen atoms. Anomalous scattering factors from ref. 13 were used for the P atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. Convergence was reached at $R$ = 0.038 and $R_w$ = 0.047 for 1167 reflections with $I \geq 3\sigma(I)$. For all 2430 reflections $R$ = 0.111 and $R_w$ = 0.055. The function minimized was $\sum w(|F_o| - |F_c|)^2$, $R = \sum ||F_o| - |F_c|| / \sum |F_o|$ and $R_w = (\sum w(|F_o| - |F_c|)^2 / \sum w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum

parameter shifts corresponded to 0.01 and 0.16 σ respectively. The mean error in an observation of unit weight was 1.466. A final difference map showed no unusual features. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (14). The rms standard error in the temperature factors $\sigma U_{ij}$ (derived from the least-squares analysis) is 0.0036 Å$^2$. The molecule as a whole does not behave as a rigid body, but can be broken down into five smaller rigid groups consisting of the four phosphorus tetrahedra and the pyrrole group plus P(1) (rms $\Delta U_{ij} = 21, 14, 19, 14$, and $44 \times 10^{-4}$ Å$^2$ respectively, details in Table 3).[1] The appropriate bond distances have been corrected for libration (15), using shape parameters $q^2$ of 0.08 for all atoms involved. Corrected bond lengths appear in Table 4 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 5. Intra-annular torsion angles defining the conformation of the phosphazene ring are listed in Table 6.

The corrections to the bond lengths in this case are much larger than those usually obtained from this type of analysis, but in view of the high degree of thermal motion in this low-melting compound the corrections seem realistic. Simple riding-motion analysis yields even larger corrections.

## Results and discussion

The occurrence and extent of conjugation between a phosphorus atom and its substituents is a long-standing and important problem. We are concerned here with compounds in which phosphorus is tetrahedrally 4-coordinated. In so far as the 3*s* and 3*p* orbitals are totally used in σ-bonding, conjugation involves the 3*d*-orbitals of phos-

[1]The structure factor table, Table 2 (anisotropic thermal parameters) and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

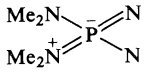
phorus. A considerable amount of structural information has been systematized on the basis of the competitive sharing of a pair of $d_\pi$-orbitals, doubly degenerate in $T_d$ symmetry (16). The better donors take the bigger $\pi$-share, and the exocyclic P—N bonds in, for instance, $(NP(NMe_2)_2)_{3,4}$ (17, 18) are short (mean values 1.652(4), 1.678(9) Å) and the $PNMe_2$ groups are close to planarity, in agreement with a substantial contribution to bonding in the sense of **5**. Since the carbon atoms in pyrrole carry no formally unshared pair of electrons, the 1-methylpyrrol-2-yl group should release electrons to a phosphazene ring, but less strongly than a dimethylamido group.



**5**

Pyrrolyl derivatives prepared from $(NPCl_2)_{3,4}$ have been reported previously (19), but few details are available, and the position of substitution in the pyrrole ring is unknown. In the present work, the use of 1-methylpyrrole in conjunction with TMEDA (20) was expected to restrict substitution to the 2-position. The patterns of the $^1H$ and $^{13}C$ shifts of **1***a–d* (Tables 7, 8)[2] are substantially independent of the size of the phosphazene ring, and show that the 2-substitution expected from the preparative method and proved crystallographically for **1***b* is uniform within the series. The shifts of Table 7 were assigned by comparison with those of other 2-substituted pyrroles (21). The resonances of H3 and H5 are shifted downfield from those of 1-methylpyrrole (22), the relationship being approximately that of 2-formylpyrrole to pyrrole (21). In the $^{13}C\{^1H\}$ spectra of **1***a–d*, the $CH_3$ resonance is a singlet, and that of C2 is split into two doublets by phosphorus and fluorine; its assignment is unambiguous. The other assignments are made comparatively (23), C4 at the highest field, and C3 to high field of C5. Comparison of the relative shifts (Table 8) with those of other substituted pyrroles (23) shows that the effect of a 2-(fluorophosphazenyl) group on C3 and C5 is similar to that of a 2-formyl group (relative shifts 13.2, 10.9 ppm respectively). The exceptionally high value of $J_{PC2}$ has no obvious interpretation, but a comparable value (224 Hz) for $J_{PC}$ was found for 3-fluorophenylpentafluorocyclotriphosphazene, and it may be typical of the bond between an aromatic and a phosphazene ring.

The $^{19}F$ spectra consist of doublets for the PFX and $PF_2$ groups, the former being at lower field, as in other mono-substituted fluorophosphazenes (1, 24). As for the analogous fluorophenyl derivatives, two types of $PF_2$ groups are found for **1***c,d*. The $^{31}P$ spectra of **1***a–d*, similar to those of the dimethylamido derivatives, are more complex, and have not been analysed completely. Their main features are given in Table 7. Taken in conjunction with the $^{13}C$ spectra, the $^{19}F$ and $^{31}P$ spectra show that the fluorophosphazenyl group withdraws electrons from C3 and C5, possibly concentrating them more on C2 than on P(1), but a more detailed discrimination of the electronic effects is not possible.

The electronic spectra are more informative. Pyrrole itself has two $\pi-\pi^*$ bands, at 207.5 nm (25) and 183 nm (26). 1-Methylpyrrole has a strong band at 213 nm (9); the vacuum ultraviolet region has apparently not been examined. Both bands of pyrrole are shifted to longer wavelength by electron-withdrawing groups capable of conjugation, such as 2-formyl (279, 246 nm), 1-methyl-2-formyl (280, 246 nm) (10), 2-nitro (335, 231 nm) (21), and 1-methyl-2-cyano (248, 230.5 nm) (27). Inductive shifts are much smaller. The charge transfer nature of the low frequency band has been established by the study of solvent effects (10, 28) and of ν(CO) (29), and confirmed theoretically (10, 28). The higher frequency band is also of the $\pi-\pi^*$ type, but its detailed nature is less certain (10). Two intense bands also appear in the spectrum of the pyrrol-2-yl phosphine oxides (9), similar to those of 2-formylpyrrole, but at higher frequency. The comparability of the pairs of bands in the acylpyrroles and the phosphine oxides in both position and intensity makes it highly likely that the transitions have the same cause, and argues in favour of conjugation in the pyrrylphosphine oxides (10). On this basis, conjugation is stronger in the heteroaryl com-

[2]In Tables 7, 8, and subsequent text, the standard numbering scheme of the pyrrole ring (denoted by unparenthesized numerals, e.g. C3, H3) is used to facilitate comparison with other work.

pounds than in their phenyl-phosphoryl counterparts, though it is appreciably weaker than to a carbonyl group.

As Table 9 shows, the spectra of 1*a–d* are similar to those of the phosphine oxides **3**, but the shift of the low energy band to longer wavelength (relative to 1-methylpyrrole, **2**) is slightly reduced. A similar statement applies to the intensities. The results again indicate conjugative bonding, comparable to but slightly weaker than that to the phosphoryl group, perhaps reflecting the lower electronegativity of nitrogen compared to oxygen. The spectra show another interesting feature, in the small but significant oscillations in $\lambda_{max}$ of the longer wavelength band. They show the same type of variation with ring size as the ionization energies of the fluorophosphazenes themselves (30).[3] Since the oscillation is small, the conjugative perturbation induced by the pyrryl group may not extend far beyond the phosphorus atom to which it is attached. The position of the shorter wavelength band is independent of ring size, at 220 nm. In nitropyrroles (28) the corresponding band has contributions from the local excitation of both the pyrrole ring and the nitro-group, and in the phosphazenyl derivatives, the shorter wavelength band is perhaps the less likely to be affected by ring size. Further work is required both on the nature of this band and, for the band at longer wavelength, the extent of conjugation within the phosphazene ring, possibly by the *ab initio* methods used to assess the σ- and π-interactions of a pyrryl group with organic substituents (31).

Although these measurements establish a conjugative connection between the pyrryl and phosphazenyl rings, they do not show the relative extent of charge transfer in the ground and excited state of the molecules. The molecular structure of 1*b* (Fig. 1, Tables 4, 5) is more informative. All the intermolecular distances exceed normal van der Waals distances, so that the molecule can be considered in

[3]The photoelectron spectra of 1*a–d* (38) show that the two highest occupied orbitals of 1-methylpyrrole are stabilized by the fluorophosphazenyl groups by 0.9 and 0.6 eV respectively, but conjugation need not be restricted to the ground state.

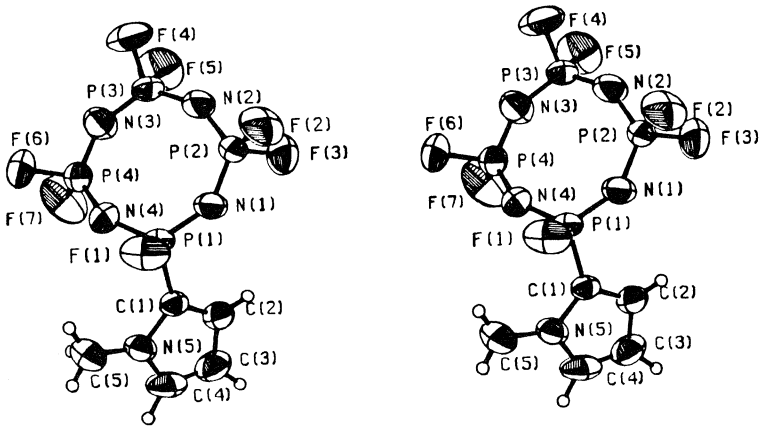

FIG. 1. Stereo view of the 1-methylpyrrol-2-ylheptafluorocyclotetraphosphazene molecule; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

isolation. In pyrrole itself, the N—C2, C2—C3, C3—C4, C4—C5, and N—C5 distances are 1.370(1), 1.382(5), 1.417(3), 1.382(5), and 1.370(1) Å respectively (32). The corresponding distances in **1***b* are 1.386(7), 1.376(9), 1.396(8), 1.353(10), and 1.363(8) Å and those in the related molecule (*E*)-2-methyl-3-(pyrrol-2-yl)prop-2-enal (33) (in which exocyclic conjugation also occurs) are 1.37(1), 1.39(1), 1.40(1), 1.35(1), and 1.37(1) Å. Substitution of pyrrole at C2 results in a slight decrease in the mean[4] C—C distance to 1.378(22) from 1.394(27) Å. It is noteworthy that in both the above 2-substituted pyrroles the C4—C5 distance is significantly shortened, rather than lengthened as would be expected to result from contribution by resonance forms such as **2***b*.

In the phosphazene part of the molecule, the changes from the structure of $N_4P_4F_8$ (34) are a little larger but more significant. The $N_4P_4$ ring itself is close to planarity (deviations from the mean plane; mean 0.062, max. 0.122(6) Å), and the sum of the ring angles at phosphorus and nitrogen is 1077.0(10)°, against 1080° required for a planar eight-membered ring. The temperature factors are large, and the ring must be regarded as conformationally flexible. The mean $PF_2$ angles (97.6(1)°) are slightly smaller than in $N_4P_4F_8$ (99.9(5)°), corresponding to the increase of the ring angle at phosphorus from 122.7(10)° to 123.9(4)°; the mean angle at nitrogen is 146.4(24)°, compared with 147.2(14)° in $N_4P_4F_8$. The replacement of fluorine by the less electronegative 1-methylpyrrol-2-yl group has several characteristic geometrical effects, whose general nature in related compounds is discussed elsewhere (35). The *endo*-angle at P(1) is decreased to 120.0(3)° and the *exo*-angle (C—P—F) increased to 104.3(2)°. The ring bonds to P(1) (1.562(1) Å) are lengthened by 0.027(12) Å relative to the other ring bonds (mean P—N excluding P(1) = 1.535(12) Å), and the P(1)—F(1) bond (1.561(4) Å) is lengthened (relative to the mean length in the $PF_2$ groups of 1.536(7) Å) by 0.025(8) Å. In phenylphosphazenes, the length of the P—C bond is close to 1.800 Å; relatively, P—C in **1***b* is shortened by 0.044 Å, to 1.756(5) Å. This reduction is chemically significant, but less than that expected for a formal double bond; in $Ph_3P{=}CH_2$, the length of the ylidic bond is 1.661(2) Å (36). Similar geometrical relationships are found in all-*trans* $N_4P_4(NMe_2)_4F_4$ (37), in which the strong exocyclic conjugation shortens P—N (*exo*) to 1.621(5) Å, the $PNMe_2$ group being nearly planar. The mean *endo*- and *exo*-angles at phosphorus in this compound are 122.3(5)° and 105.3(8)° and the mean (ring) P—N and the P—F bond lengths are 1.557(11) and 1.566 (11) Å respectively (37).

The general conclusion is that conjugative interactions to a phosphorus centre depend upon electron donation to it from the ligand, which increases in the order phenyl < 1-methylpyrryl < dimethylamido. Electron release from the 1-methylpyrryl group to acceptor groups decreases in the order acyl > phosphoryl > fluorophosphazenyl. The crystallographic results on **1***b* show a moderate degree of conjugative stabilization in the ground state, and the electronic spectra show that the acceptor level in the phosphazene has homomorphic character. Conjugation to a phosphoryl centre was earlier supposed (9) to involve 3*d*-orbitals at phosphorus, and the present results are consistent with that view; any appreciable use of a 3*p* orbital

[4]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

at phosphorus would reduce both *endo*- and *exo*-angles there. The interaction is not restricted to a single *d*-orbital, and $\pi$-interactions are not likely to introduce any large barrier to rotation about P(1)—C(1). In this respect, the conjugation differs from that of an acyl group.

# Bimolecular production of proton bound dimers in the gas phase. A low pressure ion cyclotron resonance technique for examination of solvent exchange equilibria and determination of single molecule solvation energetics

J. W. LARSON,[1] R. L. CLAIR, AND T. B. MCMAHON

*Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2*

Received October 13, 1981

J. W. LARSON, R. L. CLAIR, and T. B. MCMAHON. Can. J. Chem. **60**, 542 (1982).

A scheme is presented whereby sequences of fast bimolecular gas phase ion molecule reactions in mixtures containing $(CHF_2)_2O$ may be used to generate proton bound dimer species at low pressures in an ion cyclotron resonance spectrometer. Using competitive solvent switching reactions it is demonstrated that solvent exchange equilibria may be readily established and from the thermochemical data derived from such equilibria accurate relative single molecule solvation energetics obtained.

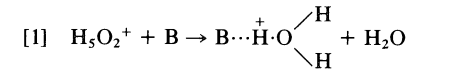
J. W. LARSON, R. L. CLAIR et T. B. MCMAHON. Can. J. Chem. **60**, 542 (1982).

On présente un schéma d'après lequel on peut utiliser les suites de réactions bimoléculaires rapides ion–molécule en phase gazeuse dans des mélanges contenant le $(CHF_2)_2O$ pour produire des espèces dimères liées par le proton à de faibles pressions dans un spectromètre à résonance de l'ion dans un cyclotron. Faisant appel à des réactions compétitives d'échange du solvant, on démontre que les équilibres d'échange du solvant peuvent être facilement établis; à partir des données thermo-chimiques déduites de ces équilibres, on peut obtenir les énergies de solvatation relative d'une molécule unique de façon précise.

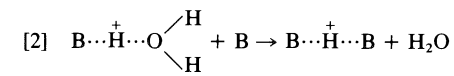
[Traduit par le journal]

A detailed knowledge of the nature of ion–solvent interactions is central to the understanding of the behaviour of ions in solution and of the reasons for differences between relative stabilities and reactivities of ions in the gas phase versus solution. Fortunately, several mass spectrometric techniques are available which allow examination of ion–neutral interactions and, as Kebarle has noted recently, relative solvation energetics of solution phase ions can generally be inferred from relative enthalpies of attachment of the first solvent molecules to ions in the gas phase (1). Thus the examination of gas phase ions co-ordinated to one or more solvent molecules becomes an extremely valuable means of understanding solvent effects on stability and reactivity (see, for example, ref. 2). Such examinations are usually not possible in trapped ion ion cyclotron resonance experiments because of the low pressures necessarily involved (3). However, we have recently demonstrated that the dihydrated proton, $H_5O_2^+$, may be rapidly and efficiently generated by a sequence of rapid bimolecular reactions in $H_2O$–$(CHF_2)_2O$ mixtures (4). In the present communication we wish to report experiments in which the chemistry of ternary mixtures containing $(CHF_2)_2O$ may be used to examine solvent exchange equilibria of proton bound dimer ions and thus provide a means whereby ion cyclotron resonance spectroscopy may be used to examine these important phenomena.

As shown previously (4) gas phase ion–molecule reactions in $H_2O$–$(CHF_2)_2O$ mixtures lead rapidly to production of the proton bound dimer of water, $H_5O_2^+$. If a ternary mixture is used containing $H_2O$, $(CHF_2)_2O$, and an n-donor base, B, of greater base strength than water, solvent displacement reactions, [1] and [2], are observed.



[1] $H_5O_2^+ + B \rightarrow B\cdots\overset{+}{H}\cdot O(H)(H) + H_2O$



[2] $B\cdots\overset{+}{H}\cdots O(H)(H) + B \rightarrow B\cdots\overset{+}{H}\cdots B + H_2O$

If the species B is of comparable base strength to water, a solvent switching equilibrium may be established and the relative free energies of solvation of $H_3O^+$ and $BH^+$ by single molecules of $H_2O$ and B obtained. For example, in mixtures of $CH_2O$, $H_2O$, and $(CHF_2)_2O$ the equilibria of [3] and [4] are established, as demonstrated by the experimental data shown in Fig. 1. From these data equilibrium constants of $K_3 = 3.9$ and $K_4 = 1.0$ may be obtained

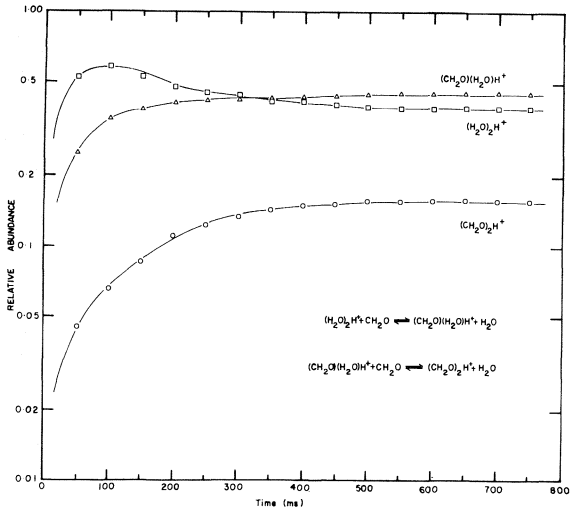

FIG. 1. Variation of relative abundances of proton bound dimers in a 3:3:1 mixture of $(CHF_2)_2O$:$H_2O$:$CH_2O$ at a total pressure of $1.4 \times 10^{-6}$ Torr following a 70 eV, 6 ms ionizing electron beam pulse.

[3] $H_5O_2^+ + CH_2O \rightleftharpoons H_2C{=}O\cdots\overset{+}{H}\cdots OH_2 + H_2O$

[4] $H_2C{=}O\cdots\overset{+}{H}\cdots OH_2 + CH_2O \rightarrow H_2C{=}O\cdots\overset{+}{H}\cdots O{=}CH_2 + H_2O$

which yield free energy changes of $\Delta G_3 = -0.8 \pm 0.1$ kcal mol$^{-1}$ and $\Delta G_4 = 0.0 \pm 0.1$ kcal mol$^{-1}$. Entropy changes for the solvent exchange equilibria may be estimated from changes in rotational entropy due to overall symmetry changes between reactants and products and translational entropy changes. Rotational entropy changes due to changes in moments of inertia have been calculated using the theoretically calculated geometries of $H_5O_2^+$, $CH_2OHOH_2^+$, and $(CH_2O)_2H^+$. The $\Delta S_{rot}$ thus determined have been found to be smaller than entropy changes due to translation and symmetry and have thus been ignored. Vibrational entropies and hence vibrational entropy changes are expected to be minor. Neutron diffraction analysis (5) reveals that solid state $H_5O_2^+$ is a species of $C_{2v}$ symmetry with a linear O···H···O bond in which each oxygen assumes a pyramidal arrangement of hydrogens with the opposing terminal hydrogens in a *trans* configuration. This is in contrast to the more stable species of $D_{2d}$ symmetry found on the basis of *ab initio* calculations (6). More recent calculations using larger basis sets show, however, that the energy difference between the $C_{2v}$ and $D_{2d}$ forms is very small (7) and on the basis of the greater entropy of the $C_{2v}$ form, this species may be the lowest in free energy and hence dominate in the gas phase also. The proton bound dimer of formaldehyde and water has been shown to be of $C_s$ symmetry (8) and further to be the most stable geometrical isomer of molecular formula $CH_5O_2^+$. Thus any rearrangement from the proton bound dimer species to other isomeric forms is unlikely. The proton bound dimer of formaldehyde has been shown by *ab initio* calculation to be of $C_{2v}$ symmetry (9). These symmetries taken with translational entropy changes give rise to estimates of the overall entropy change for these equilibria of $\Delta S_3 = +0.7$ cal mol$^{-1}$ K$^{-1}$ and $\Delta S_4 = -2.3$ cal mol$^{-1}$ K$^{-1}$. These entropy changes combined with the experimentally determined free energy changes yield values for the enthalpy changes of the two reactions of $\Delta H_3 = -0.6 \pm 0.1$ kcal mol$^{-1}$ and $\Delta H_4 = -0.7 \pm 0.1$ kcal mol$^{-1}$. The results obtained for reaction [3] are in good agreement with those of other authors using flowing afterglow (10, 11) and ion cyclotron resonance techniques (12). The only other determination of thermochemical data for reaction [4] is also in good agreement with the present result (10).

In similar fashion to the chemistry of $H_2O$–$(CHF_2)_2O$ mixtures, we have found that mixtures of $(CHF_2)_2O$ with n-donor bases, B, in favourable cases lead to production of proton bound dimer ions, $BHB^+$, via analogous bimolecular sequences. In such cases binary solvent mixtures can also lead to observation of solvent exchange equilibria. For example, in the 11:10:1 mixture of $(CHF_2)_2O$:-$(CH_3)_2CO$:THF shown in Fig. 2 the solvent exchange equilibria, reactions [5] and [6], may be obtained.

[5] $[(CH_3)_2CO]_2H^+ +$  $\rightleftharpoons (CH_3)_2C{=}O\cdots\overset{+}{H}\cdots$  $+ (CH_3)_2CO$

[6] $(CH_3)_2C{=}O\cdots\overset{+}{H}\cdots$  $+$ 

 $+ (CH_3)_2CO$

From the steady state ionic abundances at long reaction times equilibrium constants $K_5 = 43.5$ and $K_6 = 5.6$ may be calculated which yield free energy changes of $\Delta G_5 = -2.2 \pm 0.1$ kcal mol$^{-1}$, and $\Delta G_6 = -1.0 \pm 0.1$ kcal mol$^{-1}$. Using symmetry considerations and translational entropy differences the overall entropy change for each reaction may be estimated as $\Delta S_5 = 1.1$ cal mol$^{-1}$ K$^{-1}$ and $\Delta S_6 = -1.7$ cal mol$^{-1}$ K$^{-1}$ to yield overall enthalpy changes of $\Delta H_5 = -1.9 \pm 0.1$ kcal mol$^{-1}$ and $\Delta H_6 = -1.5 \pm 0.1$ kcal mol$^{-1}$. As in the $H_2O$–$CH_2O$ case the higher entropy of the mixed proton bound dimer

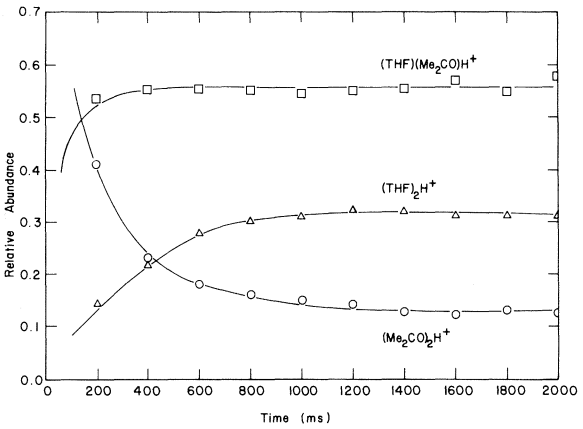

FIG. 2. Variation of relative abundances of proton bound dimers in an 11:10:1 mixture of $(CHF_2)_2O$:$(CH_3)_2CO$:THF at a total pressure of $2 \times 10^{-6}$ Torr following a 70 eV, 6 ms ionizing electron beam pulse.

due to its lower symmetry contributes significantly to the dominant intensity of this ion.

From the enthalpy data for these two cases it may be seen that the more basic molecule is the more strongly co-ordinating solvent for both protonated species involved. Thus $CH_2O$ "solvates" both $CH_2OH^+$ and $H_3O^+$ more strongly than does $H_2O$, and THF "solvates" both protonated THF and protonated acetone more strongly than does acetone. This correlation of solvating ability with gas phase basicity is a generally observed phenomenon (13).

From the above examples it is evident that at low pressures in the ion cyclotron resonance spectrometer using bimolecular reaction sequences associated with the ion chemistry of $(CHF_2)_2O$ a wide range of solvent switching equilibria may be studied. We are currently extending our studies to obtain binding energetics of proton bound dimers for a variety of solvents intermediate in basicity between water and ammonia to obtain a more complete understanding of the effects of basicity and heteroatom identity on these important quantities.

Thus $CH_2O$ "solvates" both $CH_2OH^+$ and $H_3O^+$ more strongly than does $H_2O$, and THF "solvates" both protonated THF and protonated acetone more strongly than does acetone. This correlation of solvating ability with gas phase basicity is a generally observed phenomenon (13).

From the above examples it is evident that at low pressures in the ion cyclotron resonance spectrometer using bimolecular reaction sequences associated with the ion chemistry of $(CHF_2)_2O$ a wide range of solvent switching equilibria may be studied. We are currently extending our studies to obtain binding energetics of proton bound dimers for a variety of solvents intermediate in basicity between water and ammonia to obtain a more complete understanding of the effects of basicity and heteroatom identity on these important quantities.

# The isolation and structure of phyllanthostatins 2 and 3[1]

GEORGE R. PETTIT,[2] GORDON M. CRAGG, DEVENS GUST, AND PETER BROWN[3]

*Cancer Research Institute and Department of Chemistry, Arizona State University, Tempe, AZ 85287, U.S.A.*

Received November 9, 1981

GEORGE R. PETTIT, GORDON M. CRAGG, DEVENS GUST, and PETER BROWN. Can. J. Chem. **60**, 544 (1982).

A new antineoplastic glycoside, phyllanthostatin 2, and a related glycoside, phyllanthostatin 3, have been isolated from the Central American tree, *Phyllanthus acuminatus* and their structures assigned as **1***c* and **2** respectively.

[1]Contribution 82 of the series Antineoplastic Agents. For previous contribution (contribution 81) see ref. 1.

The *Phyllanthus* genus (Euphorbiaceae) occurs in tropical areas and contains species purported to be useful in treatment of tubercular ulcers, sores, malaria, ring-worm, jaundice, and diarrhoea (*P. niruri*) (2–7), and as a diuretic (*P. discoides* (8–10) and *P. moderospotensis* (11)). Three species, *P. emblica* L., *P. niruri* L., and *P. urinoria* L., have been used in the primitive medical treatment of cancer.

We recently summarized the isolation and complete characterization of the antineoplastic glycosides, phyllanthostatin 1 (**1***a*), and phyllanthoside (**1***b*), from roots of the Central American tree *Phyllanthus acuminatus* Vahl (12). We now report that further detailed studies (guided by the murine P388 lymphocytic leukemia in vitro and in vivo bioassay, PS system) (12) of companion glycosides in *P. acuminatus* have revealed the presence of two new antineoplastic constituents designated phyllanthostatins 2 (**1***c*) and 3 (**2**). Initial biological evaluation of phyllanthostatins 2 and 3 against the PS leukemia has resulted in, respectively, 43% (at 12 mg/kg and $ED_{50}$ 0.12 μg/mL) and 41% (at 80 mg/kg) life extensions.

A recollection (1978) of *P. acuminatus* roots (81.5 kg) from Costa Rica was extracted employing

our new 1:1 methylene chloride – methanol procedure (12). The methylene chloride fraction (475 g) was further separated by a solvent partition sequence (9:1 → 4:1 → 3:2 methanol–water with ligroin → carbon tetrachloride → methylene chloride) (13) and a 38 g aliquot of the chlorinated hydrocarbon fractions (254 g) was subjected to careful separation by column chromatography (Sephadex LH-20 → silica gel) (12). Finally, chromatography on reverse phase (RP-2) silica (70 → 20% aqueous methanol gradient) afforded 0.10 g of phyllanthostatin 2 (**1***c*) as a colorless amorphous solid: mp 134–136°C; $[\alpha]_D^{24}$ +9.33° (*c* 0.75, $CHCl_3$); $\lambda_{max}$ (MeOH) nm (log ε): 216 (4.28), 222 (4.21), and 278 (4.38); ir (KBr) $\nu_{max}$: 3470, 1750, 1730, 1710, 1640, 1452, 1380, 1311, 1257, 1171, 1075, and 770 $cm^{-1}$; FD mass spectrum *m/e*: 821 ($M^+$ +H). Additional silica gel chromatography yielded 0.26 g of phyllanthostatin 3 (**2**) as a colorless amorphous solid: mp 126–130°C; $[\alpha]_D$ +15.7° (*c* 0.76, $CHCl_3$); $\lambda_{max}$ (MeOH) (log ε): 216 (4.25), 222 (4.18), and 278 (4.35) nm; ir (KBr) $\nu_{max}$: 3450, 1755, 1730, 1700, 1640, 1455, 1380, 1311, 1258, 1175, 1070, and 772 $cm^{-1}$; FD mass spectrum *m/e*: 323 ($M^+$ +H).

Comparison of the spectral data[4] recorded for phyllanthostatin 2 (**1***c*) and phyllanthoside (**1***b*, ref. 12) indicated a difference in one of the disaccharide 6-deoxy-D-glucose units. The nmr signal arising from one of the 6-deoxy-D-glucose methyl groups in **1***b* ($^1H$ nmr: d at 1.28 ppm; $^{13}C$ nmr 17.48 ppm) was replaced by a signal due to a $CH_2OH$ group ($^1H$ nmr: dd at 3.83 ppm; $^{13}C$ nmr 61.90 ppm appearing as a triplet in the off-resonance decoupled spectrum) in **1***c*. When $^1H$ nmr decoupling studies revealed that the $CH_2OH$ moiety was located at position S-5, it was apparent that one of the 6-deoxy-D-glucose units of phyllanthoside was replaced by glucose. Therefore structure **1***c* was assigned to phyllanthostatin 2.

Phyllanthostatin 3 (**2**) was found to differe significantly from phyllanthoside (**1***b*, ref. 12) in the

[4]The spectral and elemental microanalytical data were quite consistent with the assigned structures and will be summarized in a future full report. Instrumental analyses were performed using Varian-MAT 731, Bruker WH-90, and Bruker WH-400 instruments. We wish to thank Drs. R. R. Inners, P. D. Ellis, J. A. McCloskey, and J. Witschel, Jr. for expert assistance with these measurements.

aglycone moiety but possesses an identical disaccharide portion. The AB quartet at 2.92 and 2.95 ppm in the $^1$H nmr spectrum of **1***b* due to the epoxide methylene protons was replaced by two doubled doublets at 3.51 and 4.01 ppm in the spectrum of glycoside **2**. Analogous marked differences were apparent in the $^{13}$C nmr spectra. The signals due to C-7 and C-14 (71.00 and 50.01 ppm in **1***b*) of the phyllanthoside epoxide occurred instead at 85.27 and 66.61 ppm respectively in glycoside **2**. Less pronounced changes were observed in the chemical shift values of C-1, C-6, C-8, and C-9. These observations, together with mass spectral and elemental analytical data, established that phyllanthostatin 3 was a vicinal 7,14-diol counterpart of the 7,14-epoxide phyllanthoside. Therefore structure **2** was assigned to phyllanthostatin 3.

Further antineoplastic evaluation of phyllanthostatins 2 and 3 is underway in the U.S. National Cancer Institute's program.

# Nucleic acid related compounds. 37. Convenient and high-yield syntheses of *N*-[(2-hydroxyethoxy)methyl] heterocycles as "acyclic nucleoside" analogues[1]

MORRIS J. ROBINS AND PETER W. HATFIELD[2]

*Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received July 13, 1981

MORRIS J. ROBINS and PETER W. HATFIELD. Can. J. Chem. **60**, 547 (1982).

Treatment of 1,3-dioxolane with acetyl bromide gave (2-acetoxyethoxy)methyl bromide (**2***a*) in 88% yield. A number of pyrimidines and three chloropurines were trimethylsilylated and coupled with **2***a*. The respective *N*-1 and *N*-9 alkylated products (obtained in 79–89% yields) were deacetylated to give *N*-[(2-hydroxyethoxy)methyl] heterocycles. The 6-amino or 6-chloro substituent of the 2-amino-6-substituted-purine derivatives was hydrolyzed smoothly with adenosine deaminase to give 9-[(2-hydroxyethoxy)methyl]guanine (acycloguanosine), the potent antiviral agent.

MORRIS J. ROBINS et PETER W. HATFIELD. Can. J. Chem. **60**, 547 (1982).

Le dioxolanne-1,3 réagit avec le bromure d'acétyle en donnant le bromure de (acétoxy-2 éthoxy)méthyle (**2***a*) avec un rendement de 88%. On a couplé ce produit **2***a* avec un certain nombre de pyrimidines et trois chloropurines sur lesquelles on a fixé un groupement triméthylsilyle. Les produits alkyles respectivement *N*-1 et *N*-9 (obtenus avec des rendements allant de 79 à 89%), soumis à une désacétylation conduisent à des hétérocycles substitués par des groupes *N*-[(hydroxy-2 éthoxy)méthyle]. On a hydrolysé, dans des conditions douces en utilisant la désaminase d'adénosine, les substituants amino-6 ou chloro-6 des dérivés de l'amino-2 purine substitué en position 6 pour obtenir la [(hydroxy-2 éthoxy)méthyl]-9 guanine (acylguanosine), un agent antiviral puissant.

[Traduit par le journal]

A surge of interest in the application of nucleosides and acyclic nucleoside analogues as antiviral agents is underway. The well known 5-iodo-2′-deoxyuridine has been in clinical use for over a decade and 5-trifluoromethyl-2′-deoxyuridine has been employed. Approval of 9-(β-D-arabinofuranosyl)adenine (araA) for treatment of human herpes encephalitis has been given. Potent antiviral activity has been reported for 1-(β-D-ribofuranosyl)-1,2,-4-triazole-3-carboxamide (ribavirin), (*E*)-5-(2-bromovinyl)-2′-deoxyuridine, and 1-(2-fluoro-2-deoxy-β-D-arabinofuranosyl)-5-iodocytosine (FIAC) (2). Schaeffer and co-workers had prepared 9-(hydroxyalkyl)adenine derivatives as putative inhibitors of adenosine deaminase and found that 9-[(2-hydroxyethoxy)methyl]adenine was a substrate of the enzyme (3). They later reported the synthesis and potent antiviral activity of the acycloguanosine analogue, 9-[(2-hydroxyethoxy)-methyl]guanine (4). This agent has been carried into clinical trials (5). Other types of "acyclic nucleoside" analogues have been reported by De Clercq and Holý (6), Barrio and co-workers (7), Ogilvie and Gillen (8), McCormick and McElhinney (9), and ourselves (10).

Schaeffer employed alkylation of 6-chloropurine with (2-benzyloxyethoxy)methyl chloride to give the *N*-9 product in 44% yield. Ammonolysis and hydrogenolytic debenzylation gave 9-[(2-hydroxyethoxy)methyl]adenine (3). A similar sequence using 2,6-dichloropurine and (2-benzoyloxyethoxy)methyl chloride (41% yield) gave acycloguanosine (4). Barrio and co-workers studied reactions of chloro- and methylthio-substituted purines with (2-trimethylsilyloxyethoxy)methyl iodide (**7***a*). Alkylations proceeded in 50–80% yields at −63°C with this reagent (**7***a*,*c*). Two very recent abstracts noted work on related pyrimidine acyclonucleosides (11, 12).[3]

We have developed methods for the convenient and high-yield syntheses of *N*-[(2-hydroxyethoxy)-methyl] heterocycles. Acetolysis of 1,3-dioxolane (**1**) (see Scheme 1) gave (2-acetoxyethoxy)methyl acetate (**2***c*) as reported (13). However, treatment of trimethylsilylated pyrimidines with **2***c* in the presence of tin(IV) chloride according to the glycosylation procedure of Vorbrüggen (14) gave ~ 50% yields of *N*-1 products. Similar results have been noted recently (12). We repeated the cleavage

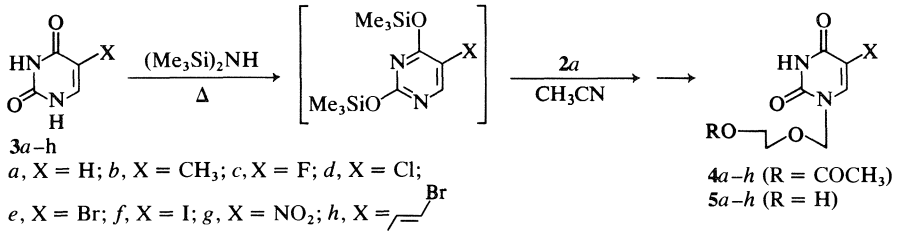


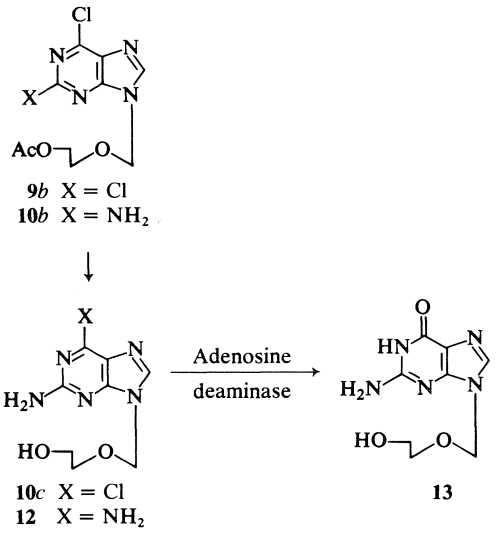
SCHEME 2

of **1** with trimethylsilyl iodide at −78°C (*7a*). However, this preparation was sensitive to moisture and temperature. The failure to isolate an alkylating agent (*7b*) necessitated repetitious *in situ* generation, and attempted use of this preparation with the sodium salt of adenine was not successful. Treatment of **1** with acetyl chloride in the presence of sulfuric acid gave (2-acetoxyethoxy)methyl chloride (**2***b*) contaminated with a tenacious by-product. Coupling yields using this preparation were depressed.

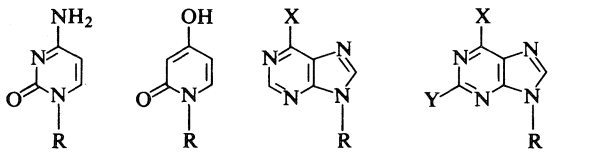
Treatment of **1** with neat acetyl bromide gave pure (2-acetoxyethoxy)methyl bromide (**2***a*) in 88% yield as a readily distilled colorless oil. Storage of **2***a* in a refrigerator for several months with frequent use resulted in no apparent decomposition. Trimethylsilylation of a series of uracils (**3***a–h*) (see Scheme 2), whose nucleosides are of biological interest (2), and *in situ* coupling with **2***a* in dry acetonitrile proceeded without difficulty. The same procedure was applied successfully to cytosine (**6***a*) and 3-deazauracil (4-hydroxy-2-pyridinone) (**7***a*) (see Fig. 1). The *N*-1 derivatives (**4***a–h*, **6***b*, **7***b*) were obtained regiospecifically in yields of 79–88% after recrystallization.

Analogous trimethylsilylation of 6-chloro- (**8***a*), 2,6-dichloro- (**9***a*), and 2-amino-6-chloropurine (**10***a*) and treatment with **2***a* in the presence of mercury(II) cyanide resulted in *N*-9 coupling to give **8***b*, **9***b*, and **10***b* (83–89% conversions). Use of this silylation/mercuric cyanide procedure (15) enhanced yields and effectively eliminated the *N*-7 isomers normally found in alkylations of purine sodium salts (*7c*). However, this method did not give high yields with adenine (**11***a*). Alkylation of the adenine anion with **2***a* in purified DMF gave 75% of 9-[(2-acetoxyethoxy)methyl]adenine (**11***b*). The coupling results and characterization data are summarized in Table 1 and spectral data in Table 2. Deacetylation of these compounds with methanolic ammonia or sodium methoxide occurred readily. Data for the deprotected acyclonucleosides (**5***a–h*, **6***c*, **7***c*, **10***c*, **11***c*) are summarized in Tables 3 and 4.

High-temperature ammonolysis of the 2-chloro group was required previously to prepare acycloguanosine (4, *7c*). Analogous ammonolysis of **9***b* at 150°C gave 2,6-diamino-9-[(2-hydroxyethoxy)-methyl]purine (**12**) (see Scheme 3). Adenosine deaminase was known to effect hydrolytic deamination and dechlorination at C-6 of related purine nucleosides (16) and 6-amino-9-[(2-hydroxyethoxy)methyl]purine (**11***c*) (3). Treatment of **12** with this enzyme effected clean conversion to 9-[(2-hydroxyethoxy)methyl]guanine (**13**). A route to this antiviral drug then was developed that employed convenient ambient temperature and pressure conditions. Mild deprotection of **10***b* followed by enzymatic dechlorination of **10***c* gave



SCHEME 3



Series: *a*, R = H; *b*, R = $CH_2OCH_2CH_2OCOCH_3$;
*c*, R = $CH_2OCH_2CH_2OH$

For personal use only.

acycloguanosine (**13**) in 76% yield overall for the 3-step sequence (**10***a* → **10***b* → **10***c* → **13**).

This study has provided convenient procedures for the high-yield syntheses of *N*-[(2-hydroxyethoxy)methyl] heterocycles. The facile preparation of (2-acetoxyethoxy)methyl bromide from 1,3-dioxolane provided a stable alkylating bromomethyl ether. Coupling of a number of silylated bases with this agent proceeded smoothly. Adenosine deaminase effected hydrolytic deamination or dechlorination at C-6 of the purine acyclonucleosides to give a mild synthetic route to the antiviral guanine compound (17).

## Experimental

*General*

Melting points were determined on a Reichert microstage block and are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer. The high-field nmr laboratory of this department obtained $^1$H spectra on Varian 100, Bruker WH-200, and WH-400 spectrometers. The $^{13}$C nmr spectra were measured at 22.6 MHz with proton decoupling on a Bruker HFX-90 instrument. Tetramethylsilane was used as internal standard for all nmr data. The mass spectra (ms) laboratory of this department measured EI spectra on an AEI MS-50 instrument with coupled computer analysis at 70 eV using direct probe sample introduction. Compounds that failed to give a molecular ion peak were examined by chemical ionization (ammonia gas) with an AEI MS-12 instrument at 70 eV. Elemental analyses were determined by the microanalytical laboratory of this department.

Evaporations were effected at room temperature with a Buchler rotary evaporator equipped with a Dewar "Dry-Ice" condenser under water tap or mechanical oil pump vacuum. Reagent grade acetonitrile and *N*,*N*-dimethylformamide (DMF) were refluxed with and then distilled from $P_2O_5$ into oven-dried flasks. Adenosine deaminase (adenosine aminohydrolase, E. C. 3.5.4.4) was purchased from Sigma Chemical Co. (crude, Type II). Silica gel for column chromatography was J. T. Baker 5-3405 and thin-layer chromatography was performed on small glass plates coated with E. Merck silica gel PF-254 for tlc using solvent systems (A) 10% MeOH in $CHCl_3$ or (B) EtOAc/*n*-PrOH/$H_2O$ (4:1:2) upper phase.

Solvent systems for recrystallization were: A, chloroform with diffusion of diethyl ether; B, methanol with diffusion of ether; C, 2-propanol with diffusion of ether; D, dichloromethane with diffusion of ether; E, methanol; F, methanol–water; G, 95% ethanol; H, acetone with diffusion of *n*-pentane; I, 2-propanol; J, ethanol–water. "Diffusion crystallization" is described in ref. 18.

*(2-Acetoxyethoxy)methyl bromide (***2***a)*

Freshly distilled acetyl bromide (13.0 g, 106 mmol) was stirred magnetically with cooling in an ice bath while 7.4 g (100 mmol) of 1,3-dioxolane (**1**) was added slowly. A rapid exothermic reaction occurred giving quantitative conversion to **2***a* (as judged by $^1$H nmr). Vacuum distillation of this material gave 17.4 g (88%) of **2***a*, bp 58–60°C/0.1 Torr; $^1$H nmr ($CDCl_3$) δ: 2.10 (s, 3, $COCH_3$), 3.88 ($A_2B_2$m, 2, $AcOCH_2CH_2$), 4.27 ($A_2B_2$m, 2, $AcOCH_2CH_2$), 5.72 (s, 2, $OCH_2Br$); $^{13}$C nmr ($CDCl_3$) δ: 20.80 ($CH_3CO$), 62.14 ($AcOCH_2CH_2$), 69.22 ($AcOCH_2CH_2$), 75.60 ($OCH_2Br$), 170.69 ($CH_3CO$); ms (CI) *m*/*z*: 214, 216 ($M^+$ + 18 [$^{79}$Br, $^{81}$Br]). *Anal.* calcd. for $C_5H_9BrO_3$: C 30.48, H 4.60, Br 40.55; found: C 30.55, H 4.59, Br 40.72.

For personal use only.

*Coupling Method A*

*1-[(2-Acetoxyethoxy)methyl]uracil (4a)*

To a suspension of 168 mg (1.5 mmol) of uracil (**3***a*) in 5 mL of hexamethyldisilazane was added a drop of chlorotrimethylsilane and the stirred mixture was heated at reflux with exclusion of moisture until a clear solution was obtained. Excess silylating reagent was removed *in vacuo* with protection against moisture. The residual clear oil was dissolved in 15 mL of dry acetonitrile and cooled to 0°C. A solution of 197 mg (1 mmol) of (2-acetoxyethoxy)methyl bromide (**2***a*) in 5 mL of dry acetonitrile was added slowly with stirring. The solution was allowed to stir for 2 h while warming to room temperature at which time tlc(A) indicated complete reaction. Volatile materials were evaporated *in vacuo*. The resulting yellow oil was chromatographed on a column (3 cm diameter) of 20 g of silica gel using 2% MeOH/$CHCl_3$ for elution. Fractions containing **4***a* were combined and evaporated. The residue was crystallized from $CHCl_3$ with diffusion of $Et_2O$ to give 181 mg (79%) of pure **4***a* with the physical and analytical data recorded in Tables 1 and 2.

This procedure was used to couple 1.5 mmol samples of **3***b–h* and **6***a*, and 1.1 mmol of **7***a* with 1 mmol of **2***a* to give **4***b–h*, **6***b*, and **7***b* as indicated in Tables 1 and 2. In the case of **3***f* → **4***f*, rigorous removal of the coupling by-product $Me_3SiBr$ was necessary in order to avoid deiodination of **4***f* to given contaminating **4***a* during processing and recrystallization.

*Coupling Method B*

*9-[(2-Acetoxyethoxy)methyl]-2-amino-6-chloropurine (10b)*

A stirred mixture of 187 mg (1.1 mmol) of 2-amino-6-chloropurine (**10***a*), 45 mg of $(NH_4)_2SO_4$, and 5 mL of hexamethyldisilazane was heated at reflux for 3 h with exclusion of moisture. Volatile materials were evaporated *in vacuo* with protection against moisture. The residue was stirred with 15 mL of dry benzene and 344 mg of $Hg(CN)_2$ was added. This mixture was stirred at reflux under a dry nitrogen atmosphere for 30 min. A solution of 197 mg (1 mmol) of (2-acetoxyethoxy)methyl bromide (**2***a*) in 5 mL of benzene was added and reflux was continued for 2 h. The mixture was cooled, 150 mL of $CHCl_3$ was added, and the organic phase was washed with 30 mL of saturated $NaHCO_3/H_2O$ followed by 30 mL of 1 *M* $KI/H_2O$. The organic solution was dried over $Na_2SO_4$, filtered, and evaporated to give 239 mg (84%) of an oil that was homogeneous by tlc(A). This product was crystallized from $CHCl_3$ with diffusion of $Et_2O$ to give pure **10***b* with the physical and analytical data given in Tables 1 and 2.

This procedure was used to couple 1.1 mmol samples of **8***a* and **9***a* to give **8***b* and **9***b* as indicated in Tables 1 and 2.

*Coupling Method C*

*9-[(2-Acetoxyethoxy)methyl]adenine (11b)*

To a stirred solution of 149 mg (1.1 mmol) of adenine (**11***a*) in 25 mL of dry (and *amine-free*) DMF was added 29 mg (1.2 mmol) of NaH. After evolution of hydrogen had ceased, the mixture was cooled to −63°C and a solution of 197 mg (1 mmol) of (2-acetoxyethoxy)methyl bromide (**2***a*) in 5 mL of DMF was added slowly. The stirred mixture was allowed to warm slowly to room temperature over a period of 2 h, 0.5 mL of 1 *M* $NaHCO_3/H_2O$ was added, and volatile materials were evaporated *in vacuo*. The residue was chromatographed on a column (30 g) of silica gel using 5% MeOH/$CHCl_3$ for elution. Appropriate fractions were combined and evaporated to give 188 mg (75%) of an oily product. This material was crystallized from $CHCl_3$ with diffusion of $Et_2O$ to give pure **11***b* with physical and analytical data as indicated in Tables 1 and 2.

*Deprotection Method A*

*2-Amino-6-chloro-9-[(2-hydroxyethoxy)methyl]purine (**10**c)*

A 226 mg (0.79 mmol) sample of **10***b* was added to 40 mL of MeOH saturated with $NH_3$ at −10°C. The flask was stoppered tightly and the solution was stirred for 5 h at room temperature. Thin-layer chromatography(A) indicated that complete deprotection of **10***b* had occurred. Volatile materials were evaporated and the resulting solid was recrystallized from 2-propanol to give 168 mg (87%) of pure **10***c* with physical and analytical data as indicated in Tables 3 and 4.

*Deprotection Method B*

*5-Fluoro-1-[(2-hydroxyethoxy)methyl]uracil (5*c*)*

To 60 mL of dry MeOH was added 0.23 g (10 mmol) of sodium metal. After hydrogen evolution was complete, 1.476 g (6 mmol) of **4***c* was added and stirring was continued for 2 h at room temperature. Thin-layer chromatography(A) indicated that complete deprotection of **4***c* had occurred. Amberlite IR-120 ($H^+$) resin was added until the solution was neutral to moist pH paper. The mixture was filtered, the resin washed with MeOH, and the combined filtrate evaporated. The colorless residual powder was recrystallized from MeOH–$H_2O$ to give 1.175 g (96%) of pure **5***c* with physical and analytical data as indicated in Tables 3 and 4.

*9-[(2-Hydroxyethoxy)methyl]guanine (acycloguanosine) (**13**) (4, 7c)*

A. *From 2-amino-6-chloro-9-[(2-hydroxyethoxy)methyl]-purine (10c)*

To a solution of 110 mg (0.45 mmol) of **10***c* in 25 mL of aqueous phosphate buffer (0.05 *M*, pH 7.5) was added 30 mg of adenosine deaminase. The reaction mixture was stirred magnetically at room temperature and monitored by tlc(B) until complete hydrolytic dechlorination had occurred. The crude product could be obtained directly by crystallization from the concentrated reaction mixture. However, a convenient purification procedure employed adsorption of the product from the aqueous medium on a carbon column (18), washing the column with water, and elution of **13** with 35% $CH_3CN/H_2O$. Evaporation of the appropriately pooled fractions, recrystallization of the solid from EtOH–$H_2O$, and thorough drying of the product *in vacuo* over $P_2O_5$ gave 88 mg (87%) of pure **13** with physical and analytical data as indicated in Tables 3 and 4.

B. *From 9-[(2-acetoxyethoxy)methyl]-2,6-dichloropurine (9b)*

A solution of 510 mg (1.67 mmol) of **9***b* in 15 mL of liquid ammonia was sealed in a Parr steel bomb and heated at 150°C for 3 days. After cooling, the bomb was vented and tlc(B) indicated complete conversion to the 2,6-diamino product (**12**) (none of the 6-amino-2-chloropurine analogue was detected). The residue was purified on a column of silica gel using 10% MeOH/$CHCl_3$ for elution to give 350 mg (93%) of oily **12**. This material was treated with adenosine deaminase as described above (A. **10***c* → **13**) to give 312 mg (89%) of pure **13**.

C. *Overall from 2-amino-6-chloropurine (**10**a)*

A 187 mg (1.1 mmol) sample of **10***a* was coupled with 197 mg (1 mmol) of **2***a* as described under Coupling Method B. The oily **10***b* obtained was treated by Deprotection Method A to give a crude solid, **10***c*, that was subjected directly to adenosine deaminase as described above (A. **10***c* → **13**). The resulting carbon column-purified product was recrystallized and dried to give 172 mg (76% overall from **2***a*) of pure **13**.

# Nucleic acid related compounds. 38. Smooth and high-yield iodination and chlorination at C-5 of uracil bases and *p*-toluyl-protected nucleosides[1]

MORRIS J. ROBINS, PHILIP J. BARR,[2] AND JERZY GIZIEWICZ[3]

*Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received July 13, 1981

MORRIS J. ROBINS, PHILIP J. BARR, and JERZY GIZIEWICZ. Can. J. Chem. **60**, 554 (1982).

Treatment of uracil bases and protected nucleosides with iodine monochloride (ICl) gave the corresponding 5-iodouracil products in over 95% purified yields. Analogously facile chlorination was effected with iodobenzene dichloride ($PhICl_2$). Protection of the nucleosides as *p*-toluyl esters provided reactants that were soluble in organic solvents and crystallized readily in high yields.

MORRIS J. ROBINS, PHILIP J. BARR et JERZY GIZIEWICZ. Can. J. Chem. **60**, 554 (1982).

Les bases du type uracile et les nucléosides protégés réagissent avec le monochlorure d'iode (ICl) en donnant les produits iodo-5 uraciles correspondants avec un rendement en produits purs supérieur à 95%. D'une façon analogue, on a pu faire facilement une chloration à l'aide du dichlorure d'iodobenzène ($PhICl_2$). La protection des nucléosides par un groupe ester *p*-tolyle fournit des réactifs solubles dans les solvants organiques et qui peuvent être cristallisés facilement avec d'excellents rendements.

A number of 5-substituted uracil derivatives, especially 2′-deoxyuridines, have been investigated extensively in the experimental and clinical treatment of neoplastic and viral diseases (2–4). The 5-fluorouracil and 2′-deoxyuridine compounds are potent inhibitors of cell growth and 5-fluorouracil has been used widely in the clinical treatment of cancer (2). The related 5-iodo-2′-deoxyuridine has been in clinical use as a herpes antiviral drug for over a decade (3). Recently (*E*)-5-(2-bromovinyl)-2′-deoxyuridine has been reported to have extraordinary activity and selectivity against herpes type I viruses (4, 5). There is strong current interest in the study of 5-substituted-2′-deoxyuridine 5′-monophosphates as mechanism based inhibitors of the crucial anabolic enzyme thymidylate synthetase (see ref. 6 and references therein).

We recently have devised an efficient route to uracil nucleosides with a functionalizable carbon chain at C-5 via the palladium–copper catalyzed coupling of terminal alkynes with 5-iodouracil compounds (7). A second reported coupling of terminal alkynes (as their chlorozinc derivatives) with a protected 5-iodo-2′-deoxyuridine gave the 5-(1-alkynyl) derivatives in variable yields (8). Both of these syntheses utilize 5-iodouracil precursors. The availability of the iodo compound in high yield is especially important when beginning with the expensive 2′-deoxyuridine.

Prior reports on the direct iodination of uridine, 2′-deoxyuridine, and their nucleotides have frequently employed the classical iodine/nitric acid/organic solvent mixture of Prusoff *et al.* (9). More recently, iodination of 5-mercuriuridine derivatives in aqueous alcohol has been described (10). However, these procedures can give troublesome by-products with resulting moderate yields of the purified 5-iodo compounds. The use of *N*-iodosuccinimide with pyrimidine nucleosides has been reasonably successful (11) and iodine monochloride has given moderate yields of uracil nucleosides with "unnatural" sugars (12).

We have found that treatment of uracil compounds with iodine monochloride under appropriate conditions gives clean conversion to the 5-iodo derivatives. Yields of the purified products depend primarily on the ease of crystallization. Treatment of 1-methyluracil (**1***b*) (see Scheme 1) with 2 equivalents of ICl in methanol at 50°C gave 5-iodo-1-methyluracil (**2***b*) in 95% yield after purification. Analogous treatment of uridine (**1***c*) and 2′-deoxyuridine (**1***d*) gave the corresponding 5-iodo nucleosides **2***c* and **2***d* in 82% and 76% yields.

Protection of the sugar hydroxyl groups as *p*-toluyl esters gave the organic soluble and readily crystallized derivatives **1***f* and **1***g*. Treatment of 2′,3′,5′-tri-*O*-*p*-toluyluridine (**1***f*), 3′,5′-di-*O*-*p*-toluyl-2′-deoxyuridine (**1***g*), and 1-(2,3,5-tri-*O*-*p*-toluyl-β-D-arabinofuranosyl)uracil (**1***h*) with 1.5 equivalents of ICl in dichloromethane at reflux gave 96%, 98%, and 95% crystallized yields of the 5-iodo products **2***f*, *g*, and *h*. Synthetic and characterization data are given in Table 1.

Chlorination of uracil compounds has been effected previously using elemental chlorine (13) or

SCHEME 1

*N*-chlorosuccinimide in acetic acid (14, 15) to provide the 5-chlorouracils in moderate yields. A new procedure that utilizes hydrogen chloride and *m*-chloroperoxybenzoic acid has been described very recently by Ryu and MacCoss (16).

We have found that treatment of uracil compounds with 1.2 equivalents of iodobenzene dichloride in warm acetic acid solutions gives rapid and clean conversion to the 5-chloro products. Treatment of 1-methyluracil (**1***b*) with $PhICl_2$ in acetic acid at 80°C for 15 min gave 94% of purified 5-chloro-1-methyluracil (**3***b*). Analogous treatment of 3′,5′-di-*O*-*p*-toluyl-2′-deoxyuridine (**1***g*) gave 94% of the purified 5-chloro nucleoside (**3***g*). Other examples and data are given in the table.

This investigation has determined convenient access to the readily crystallized *p*-toluyl esters of uridine, 2′-deoxyuridine, and their 5-chloro and 5-iodo analogues. High-yield iodination and chlorination of uracil bases and protected nucleosides have been achieved using iodine monochloride and iodobenzene dichloride, respectively. These procedures complement known methods for efficient access to the corresponding 5-fluoro (17) and 5-bromo (18) series. The precursor 5-iodouracils (**2**) now are readily available for coupling with terminal alkynes (7).

## Experimental

*General*

General procedures and instrumentation used are given in ref. 1. Melting points were determined on a Gallenkamp block apparatus in open capillary tubes and are uncorrected. Iodine monochloride (ICl) was purchased from Aldrich Chemical Co. and used directly without purification. Iodobenzene dichloride (phenyliodine(III) chloride, $PhICl_2$) was prepared as described by Lucas and Kennedy (19). Crystallization solvents used are: A, product dissolved in a minimum volume of hot $CHCl_3$ and ~5 volumes of MeOH added, followed by chilling at −18°C (further crops obtained by concentration and chilling of the mother liquor); B, MeOH (with addition of $Et_2O$ for additional crops); C, MeOH–$H_2O$; D, MeOH.

*Method A*

*3′,5′-Di*-O-p-*toluyl-2′-deoxyuridine* (**1**g)

A magnetically stirred solution of 11.4 g (0.05 mol) of 2′-deoxyuridine (**1***d*) in 250 mL of dry pyridine was cooled to 0°C and 17 g (0.11 mol) of freshly distilled *p*-toluyl chloride was added slowly. The solution was allowed to warm to room temperature, heated at 50°C for 2 h, and evaporated *in vacuo* to give a white solid mass. Chloroform (400 mL) was added and the organic phase was washed with 2 × 300 mL of 1 *M* $H_2SO_4/H_2O$, 2 × 300 mL of $H_2O$, dried over $Na_2SO_4$, filtered, and evaporated to ~150 mL. Methanol (~750 mL) was added and the resulting colorless crystalline mass was filtered. The filtrate was reduced to a small volume and chilled at −18°C to give further crystalline product. The combined crystals were dried to give 21.8 g (94%) of **1***g*, mp 215–217°C; $^1H$ nmr ($Me_2SO$-$d_6$) δ: 2.40 (br, 6, two $CH_3$'s), 4.50 (m, 3, H-4′,5′,5″), 5.58 (m, 2, H-3′ and H-5), 6.28 (t, 1, H-1′), 7.3–7.9 (m, 9, H-6 and aromatic), 11.39 (br, 1, NH).

*Method B*

*5-Iodo-1-methyluracil* (**2**b)

Iodine monochloride (6.5 g, 0.04 mol) was added to a stirred suspension of 2.52 g (0.02 mol) of 1-methyluracil (**1***b*) in 40 mL of MeOH and the resulting solution was heated at 50°C for 1.5 h. Separation of a crystalline mass occurred and tlc indicated complete conversion of **1***b* → **2***b*. The mixture was filtered and the crystals were washed with $Et_2O$. The combined filtrate and washings was chilled at 0°C for several hours and a second crop of crystals was collected to give 4.77 g (95%) of **2***b* after drying. This product had mp 220–224°C; $^1H$ nmr ($Me_2SO$-$d_6$) δ: 3.25 (s, 3, $CH_3$), 8.17 (s, 1, H-6), 11.74 (br, 1, NH).

*Method C*

*5-Iodo-3′,5′-di*-O-p-*toluyl-2′-deoxyuridine* (**2**g)

A stirred solution of 16.3 g (0.035 mol) of **1***g* and 8.53 g (0.0525 mol) of ICl in 300 mL of $CH_2Cl_2$ was heated at reflux for 2 h. Thin-layer chromatography indicated complete conversion of **1***g* → **2***g*. The solution was cooled, diluted with 200 mL of $CH_2Cl_2$, and decolorized (ICl) by careful washing with the *minimum* required volume of 2% $NaHSO_3/H_2O$ solution. The organic phase was washed with $H_2O$, dried over $Na_2SO_4$, filtered, and evaporated. The residue was dissolved in a minimum volume of hot $CHCl_3$, MeOH (~5 volumes) was added, and the mixture was chilled at −18°C to give (in three crops) 20.3 g (98%) of crystalline **2***g*, mp 195–196°C.

*Method D*

*5-Chloro-3′,5′-di*-O-p-*toluyl-2′-deoxyuridine* (**3**g)

Iodobenzene dichloride (825 mg, 3 mmol) was added to a stirred solution of 1.16 g (2.5 mmol) of **1***g* in 15 mL of acetic acid at 80°C. Stirring was continued at 80°C for 15 min and tlc indicated complete conversion of **1***g* → **3***g*. The mixture was evaporated *in vacuo*. Repeated addition and evaporation of MeOH/$H_2O$ and then MeOH gave 1.21 g (97%) of **3***g* as a white powder. This product was dissolved in a minimum volume of hot $CHCl_3$, MeOH (~5 volumes) was added, and the mixture was chilled at −18°C to give (in two crops) 1.17 g (94%) of crystalline **3***g*, mp 214–215°C.

Reçu le 19 mars 1981[1]

ELZBIETA KOZLOWSKA-GRAMSZ et GÉRARD DESCOTES. Can. J. Chem. **60**, 558 (1982).

L'addition photochimique des nitrènes sur les éthers vinyliques cycliques et les sucres insaturés permet d'aboutir en présence d'alcool aux produits d'alcoolyse d'aziridines intermédiairement formées. La réactivité et la stéréosélectivité de cette addition sont discutées. L'application de cette réaction à la synthèse d'aminosucres est décrite.

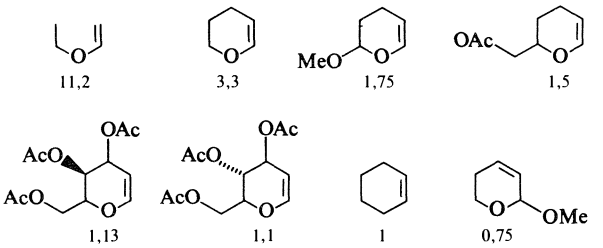
ELZBIETA KOZLOWSKA-GRAMSZ and GÉRARD DESCOTES. Can. J. Chem. **60**, 558 (1982).

The photochemical addition of nitrenes to cyclic vinylic ethers and unsaturated sugars, in the presence of alcohols, gave the products of alcoholysis of the aziridine intermediates. The reactivity and stereoselectivity of this addition is discussed. The application of this reaction to the synthesis of aminosugars is described.

Les nitrènes constituent des espèces intermédiaires électrophiles très réactives vis-à-vis de sites nucléophiles et en particulier des oléfines (1). L'utilisation des nitrènes pour la synthèse d'aziridines a fait l'objet de très nombreuses recherches et l'étude de la stéréosélectivité de l'addition constitue une des méthodes d'approche du mécanisme réactionnel (2–4). Les éthers vinyliques et plus spécialement le dihydropyranne présentent des insaturations électroniquement riches qui ont été relativement peu étudiées dans leurs réactions avec les nitrènes. Les travaux de Brown et Edwards (5) et de Steiner (6) ont montré que l'obtention d'aziridines était possible avec le dihydropyranne mais l'étude stéréochimique de cette réaction et les applications éventuelles à la synthèse d'aminosucres n'ont pas été abordées. Ce mémoire présente une étude de la réactivité des éthers vinyliques cycliques vis-à-vis des nitrènes, une description de la stéréosélectivité de l'addition des nitrènes sur ces substrats et des applications pour la synthèse d'aminosucres à partir de sucres insaturés.

## *I. Réactivité relative des éthers vinyliques cycliques et sucres insaturés*

Les éthers utilisés de type **1** sont mis en réaction avec l'azidoformiate d'éthyle soumis à une photolyse durant 18 h à 25°C. La comparaison des vitesses de disparition de **1** lors de l'addition compétitive des nitrènes permet par rmn ou cpv de préciser les réactivités relatives (voir Partie expérimentale) qui s'établissent selon la séquence suivante:



Cette séquence confirme principalement: (*i*) la plus grande réactivité des éthers vinyliques cycliques plus riches en électrons comparée à celle du cyclohexène ou d'un acétal insaturé; (*ii*) l'influence défavorable d'ordre vraisemblablement stérique des substituants en α ou en β des insaturations sur leur réactivité vis-à-vis des nitrènes.

Cependant, les faibles différences observées permettent d'envisager cette réaction pour la synthèse d'aminosucres. L'étude de la stéréosélectivité d'une telle addition a donc été entreprise.

## *II. Stéréosélectivité de l'addition des nitrènes sur 1*

### *1. Identification structurale des produits d'addition*

L'analyse rmn des produits obtenus par addition des nitrènes sur **1** permet de déterminer les configurations relatives des substituants du cycle, en particulier d'après le déplacement chimique et le couplage du proton acétalique (tableau 1).

Avec le dihydropyranne (**1***a*), l'effet anomère oriente la conformation de **5***a cis* avec un groupe alcoxy axial ($\delta_{H\text{-}1} = 4{,}7$ ppm, $J_{H\text{-}1\text{–}H\text{-}2} = 3$ Hz) quel que soit le solvant, alors que **3***a trans* modifie son

*Valeurs estimées d'après la cpv analytique et corrigées par rapport aux valeurs erronées données dans la note préliminaire (10).

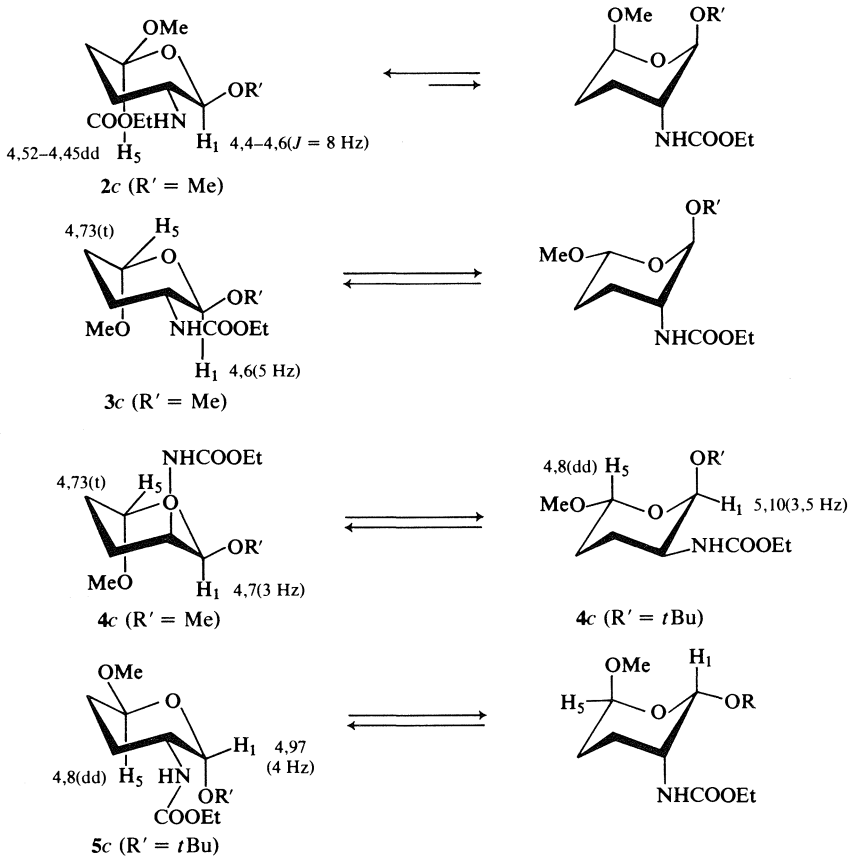
équilibre conformationnel selon le solvant ($J_{H-1-H-2}$ de 3,5 dans le chloroforme à 6 Hz dans le DMSO-$d_6$). Par contre, les hydroxyuréthannes isomères dont l'un avait été précédemment décrit (5) ont été détectés et identifiés (*cis*/*trans* = 5:1) montrant également l'influence prédominante de l'effet anomère dans l'équilibre de ces isomères.

Pour le composé **1***b*, le blocage de la conformation permet d'identifier les produits d'addition de type *trans* diéquatorial ou diaxial grâce aux couplages respectifs pour $J_{H-1-H-2}$ de 8 Hz et 1,5 Hz. Le dérivé de type *cis* isolé **5***b* (R′ = *t*Bu) présente un groupe alcoxy axial ($\delta_{H-1}$ = 5,02 et $J_{H-1-H-2}$ = 3 Hz).

Des observations de type analogue permettent d'attribuer les configurations et conformations des produits d'addition d'après le tableau 1 avec **1***c*.

Cependant, si les dérivés **2***c* (R′ = Me, *t*Bu) de type "*trans*" sont aisément identifiés d'après $J_{H-1-H-2}$ ~ 8 Hz, d'après la forme du signal de H-5 (dd) et la présence d'un seul signal méthoxy, les autres composés d'addition présentent des problèmes d'analyse conformationnelle résumée dans les équilibres ci-dessous. Les critères rmn $^1H$ utilisés sont les déplacements chimiques et les couplages de H-1, la forme du signal de H-5 et sont complétés par les données rmn $^{13}C$ (Tableau 1). D'après ces

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.



indications, **2***c* est dans une conformation privilégiée de type *C*1.

De même, **3***c* (R' = Me), **4***c* (R' = Me) et **5***c* (R' = *t*Bu) présenteraient un équilibre conformationnel déplacé vers les formes *C*1 alors que **4***c* (R' = *t*Bu) adopterait plutôt une conformation de type 1*C*. Les attributions pour chaque carbone acétalique n'ont pas été effectuées.

Dans le cas des sucres insaturés (**1***d* et **1***e*) quelques précédentes données de rmn $^1$H (7) ont été complétées par notre étude rmn $^{13}$C (tableau 1) pour l'établissement des configurations des produits d'addition obtenus. On n'observe pas de produit d'addition de type **4***d* ou **4***e* (β-*manno* et β-*talo*). Les autres isomères sont identifiés d'après le déplacement chimique et le couplage du proton anomère. En outre, les données cmr indiquent des variations de déplacements chimiques du carbone anomère répétitives puisque: (**3** − **5**) = 3,4 ppm; (**3** − **2**) = 1,6 à 1,7 ppm.

L'ensemble de ces données rmn permettent d'identifier sans ambiguité les isomères **2**, **3** et **5** en série *gluco* et *galacto* (8).

*2. Influence des conditions opératoires*

Divers facteurs expérimentaux ont été étudiés sur l'orientation stéréochimique des additions de nitrènes sur les éthers vinyliques de type **1** qui permettent de préciser: l'orientation initiale de l'attaque du nitrène: A/B, et l'addition *cis* ou *trans* des groupes azotés et oxygénés.

Si les effets de températures (15°C à 45°C) et de concentrations (éther/azidure = 1:1, 1:2) paraissent limités, les différentes données stéréochimiques pour la photolyse "directe" en présence d'alcools (méthode a) montrent que l'attaque du nitrène selon la voie A est privilégiée. Cette influence est limitée si $R_6$ est en position équatoriale (**1***b*) alors que pour $R_6$ préférentiellement axial selon l'effet anomère (**1***c*) (9), la stéréoorientation est beaucoup plus marquée. La gène stérique qui se développe lors de la formation de l'aziridine selon la voie B permet de justifier l'approche préférentielle selon la voie A. Néanmoins, dans le dernier cas, la *trans*-addition de l'alcool est moins importante. Cette observation sera retrouvée dans le cas de certains sucres insaturés (**1***e*) utilisés dans ce même type de réaction. L'amélioration de la stéréo sélectivité (*trans*-addition) est obtenue avec l'emploi d'un alcool encombré (*t*BuOH).

La réaction de **1***a* avec l'azidoformiate de méthyle permet d'aboutir à un intermédiaire de type aziri-

For personal use only.

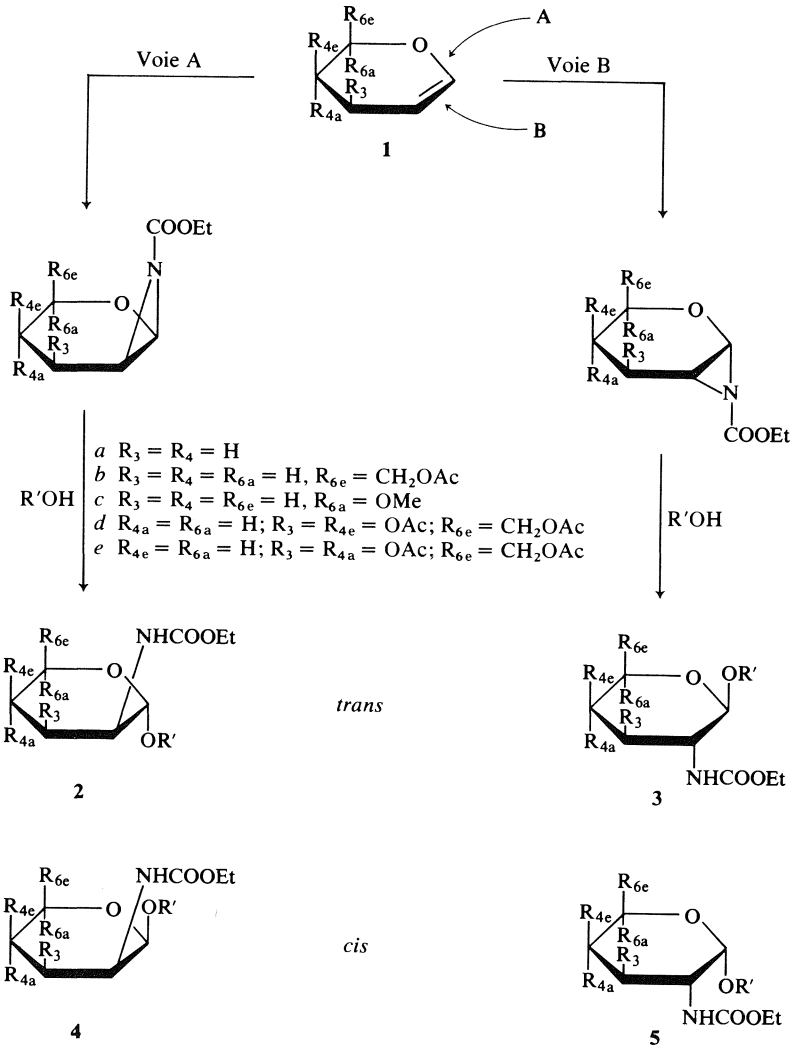

SCHÉMA 1

dine instable isolé par distillation (60°C/5 Torr) ($\delta_{H\text{-}1}$ = 5,95 ppm, $J$ = 6,5 Hz; $\delta_{H\text{-}2}$ = 3,95 ppm) qui donne par addition ultérieure d'alcool les mêmes produits d'alcoolyse que précédemment (tableau 2, méthode b).

La comparaison des résultats de photolyse "directe" avec ceux de réaction "photosensibilisée" (nitrènes à l'état triplet) (1, 4) montre que la présence de photosensibilisateurs diminue nettement les rendements en produits d'addition (avec apparition d'autres produits non isolés). Par contre, la stéréoorientation de l'attaque du nitrène à l'état triplet (rapport A/B) est accrue et le taux d'isomère 2*b* (R' = Me) est augmenté par rapport à la photolyse "directe". On peut expliquer ces différences de résultats par une addition non concertée des nitrènes à l'état triplet sur l'insaturation suivie d'une fixation d'alcool pour conduire aux alcoxyuréthannes de type préférentiellement *cis* en fonction de l'effet anomère. Ainsi, l'ensemble de ces données semble montrer que l'addition des nitrènes sur **1** par la photolyse "directe" dans nos conditions particulières se déroule préférentiellement par l'intermédiaire de nitrène à l'état singulet.

### *III. Application à la synthèse d'aminosucres*

L'obtention d'aminosucres par voie directe à partir des sucres insaturés constitue une intéressante synthèse qui a été récemment utilisée (7) dans des conditions ioniques (addition de *N*-chloroamide catalysée par le chlorure chromeux suivie d'une réaction de type Koenigs–Knorr). Les conditions photochimiques d'addition de nitrènes en présence d'alcools précédemment décrites permettaient d'envisager une synthèse "in one pot" de ces mêmes aminosucres avec une stéréosélectivité satisfaisante.

TABLEAU 3. Stéréosélectivité de l'addition des nitrènes sur **1***d* et **1***e*

| | Rdt global % | *trans* **2** | *trans* **3** | *cis* **4** | *cis* **5** | B/A | *trans*/*cis* % |
|---|---|---|---|---|---|---|---|
| **1***d* | 42 | 5 | 26 | — | 11 | 7,4 | 75 |
| **1***e* | 42 | 4 | 4 | — | 34 | 9,5 | 18 |

Les essais effectués avec le tri-*O*-acétyl-3,4,6-D-glucal (**1***d*) et le tri-*O*-acétyl-3,4,6-D-galactal (**1***e*) permettent de montrer l'intérêt de cette méthode (tableau 3). En effet, dans les deux cas, l'attaque du nitrène se fait très nettement selon la voie B. Cette approche montre donc l'influence prédominante du groupe $R_3$ = OAc en position quasiéquatoriale comme précédemment observé dans d'autres conditions.[2] Cette stéréoorientation permet ensuite d'obtenir par *trans*-addition de l'alcool, le β-D-aminoglucopyranoside **3***d* majoritaire (plus de 60% du mélange). Par contre, dans le cas du D-galactal **1***e*, si l'approche du nitrène selon la voie B est encore plus marquée, l'addition *cis* du méthanol devient prépondérante puisque l' α-D-aminogalactopyranoside **5***e* devient le composé majoritaire (plus de 80% du mélange). Cette différence de comportement des intermédiaires dérivés de **5***d* et **5***e* doit se justifier par la participation du groupe $R_{4a}$ = OAc qui faciliterait l'ouverture de l'aziridine intermédiaire et favoriserait la formation du dérivé de *cis*-addition répondant à l'effet anomère.

[2]B. Gross, communication personnelle.

*Conclusion*

La photolyse de l'azidoformiate d'éthyle en présence d'alcool sur les éthers vinyliques cycliques et sucres insaturés de type **1** conduit à la formation directe des produits d'alcoolyse d'aziridines intermédiaires. Si l'addition du nitrène est stéréoorientée selon les substituants du cycle, l'ouverture est régiospécifique et stéréosélective avec formation des produits de *trans*-addition prépondérants. Ces additions sont utilisables pour la synthèse d'amino sucres et sont étudiées pour l'obtention d'aminodisaccharides.

## Partie expérimentale

Les points de fusion non corrigés ont été déterminés sur un appareil Buchi. Les spectres rmn ont été tracés à température ambiante avec un appareil Varian A 60 et un Brucker WP 80 CW. Les spectres de masse ont été effectués sur un appareil VG Micromass 70-70 F (70 eV). Les séparations chromatographiques ont été réalisées sur colonne de silice avec un éluant de type pentane – acétate d'éthyle ou selon les indications données ci-dessous.

*Procédé a: Photolyse "directe" en présence d'alcool*

On place dans un photoréacteur en quartz 0,005 mol d'éther vinylique anhydre avec 0,01 mol d'azidure ($ROCON_3$) fraiche-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

ment distillé dans 3 mL d'alcool (méthanol ou tertiobutanol). L'irradiation avec une lampe Hanovia moyenne pression de 450 W est effectuée sous azote durant une période de 24 à 60 h à une température maintenue à 25°C. L'évolution de la réaction est suivie par ir avec la disparition des bandes caractéristiques des groupes azido ($\nu_{max}$ = 2120–2170 $cm^{-1}$). Après évaporation de l'alcool, le mélange est chromatographié sur silicagel. Dans certains cas (**1***e*), le mélange est chromatographié en hplc sur colonne "Lichroprep" Si 60 (5–20 μm) détection réfractométrique; éluant:acétate d'éthyle – hexane 30:70; 2 mL/min). La séparation du produit d'insertion du nitrène sur les alcools (EtOCONHOR′) est facilement obtenue dans les fractions de tête chromatographiques.

*Procédé b: Photolyse suivie d'addition d'alcool*

La photolyse est effectuée sans alcool dans les mêmes conditions que précédemment sans solvant pendant 36 h. L'alcool (méthanol ou tertiobutanol) est ensuite additionné (3 mL) au mélange qui est agité durant une heure. Les produits sont détectés par chromatographie en phase vapeur (à partir de **1***a* et **1***b*) et directement comparés avec ceux précédemment décrits.

*Photolyse photosensibilisée*

On opère de la même façon que précédemment (procédé a ou b) pour les réactions photosensibilisées en rajoutant 0,02 mol d'acétophénone ou d'acétone et en utilisant un filtre Pyrex. La photolyse poursuivie par les méthodes spectrales ou chromatographiques précédentes a été réalisée.

*Photoaddition compétitive*

On irradie un mélange d'oléfines, par exemple de 0,0025 mol de dihydropyranne et de 0,0025 mole de cyclohexène, en présence de 0,005 mol d'azidoformiate d'éthyle durant 18 h à 25°C sans solvant ou en présence de 1,5 $cm^3$ de $CH_2Cl_2$. La concentration restante des deux composés insaturés est mesurée au bout de cette période par rmn ou par chromatographie en phase gazeuse.

*Produits d'addition sur le dihydropyranne* **1**a (**2**a, **5**a)

R′ = H: composés partiellement décrits par la référence 5.

R′ = Me: composés décrits par la référence 7.

DOMINIQUE ADES, MICHEL FONTANILLE et JACQUES LEONARD. Can. J. Chem. **60**, 564 (1982).

La polymérisation anionique en masse de l'α-méthyl styrène (αMS) a été réalisée en utilisant comme amorceur le *tert*-butyllithium (*t*-BuLi) avec ou sans *N*,*N*,*N'*,*N'*-tétraméthyl éthylène diamine (TMEDA). En absence de TMEDA, les centres actifs formés se dégradent rapidement à 62°C tandis qu'ils sont relativement plus stables à 25°C. En présence de TMEDA, la stabilité des centres actifs est beaucoup plus grande mais elle est fonction de l'ordre dans lequel le *t*-BuLi et la TMEDA sont ajoutés à l'αMS. La stabilité des centres actifs est aussi fonction du rapport $r$ = [TMEDA]/[*t*-BuLi] et les meilleurs résultats sont obtenus pour un rapport égal à un. A température élevée, on observe l'apparition d'espèces qui absorbent à 390 et 424 nm et un élargissement de la répartition des masses molaires. Ces observations sont interprétées comme étant le résultat d'une réaction de transfert au monomère ou au polymère dégradé.

DOMINIQUE ADES, MICHEL FONTANILLE, and JACQUES LEONARD. Can. J. Chem. **60**, 564 (1982).

The anionic bulk polymerization of α-methylstyrene (αMS) has been carried out using *tert*-butyllithium (*t*-BuLi) as initiator with or without *N*,*N*,*N'*,*N'*-tetramethylethylenediamine (TMEDA). In absence of TMEDA, the "living ends" are rapidly deactivated at 62°C whereas they are relatively more stable at 25°C. The "living ends" are much more stable in presence of TMEDA; however, their stability is a function of the order in which *t*-BuLi and TMEDA are added to αMS. The stability of "living ends" is also a function of the ratio $r$ = [TMEDA]/[*t*-BuLi] and best results are obtained with a one to one ratio. At high temperature, the formation of species with absorption bands at 390 and 424 nm and the broadening of the molecular weight distribution are observed. These results are explained in terms of a transfer reaction to the monomer or to the deactivated polymer.

## Introduction

La polymérisation anionique de l'α-méthyl styrène représente l'exemple typique d'une polymérisation réversible et les études cinétiques et thermodynamiques de cette polymérisation en solution ont fait l'objet de nombreux travaux. Cependant, tel n'est pas le cas de la polymérisation anionique en masse même si l'absence d'un composant (le solvant) devrait simplifier l'étude de ce système de polymérisation. Les difficultés inhérentes aux manipulations des systèmes de polymérisation en masse et les anomalies observées au cours de cette polymérisation, comme l'absence de dépropagation et l'accroissement des quantités de polymère obtenu avec augmentation de la température dans un certain domaine de températures, peuvent expliquer le petit nombre d'études sur le sujet (1, 2).

Avant de pouvoir utiliser les données de la polymérisation en masse pour en déterminer les paramètres thermodynamiques, une connaissance approfondie de ce système est nécessaire pour en établir les conditions de réversibilité. Comme première étape de ce travail, nous présentons une étude sur la stabilité des centres actifs qui va de pair avec la réversibilité de la polymérisation. A cette fin, nous avons utilisé comme amorceur le *tert*-butyllithium (*t*-BuLi) seul ou complexé avec la *N*,*N*,*N'*,*N'*-tétraméthyl éthylène diamine (TMEDA). Cet amorceur est facile à mettre en œuvre, est soluble en milieu hydrocarboné et mène à la formation de chaînes monofonctionnelles.

## Partie expérimentale

Afin de réaliser cette étude dans les meilleures conditions de stabilité des centres actifs, nous avons utilisé les techniques expérimentales de travail sous haut vide mises au point par Fontanille et Sigwalt (3).

1. *Purification des réactifs*

α-*Méthyl styrène* (αMS) (Merck)

Distillation sur colonne à bande tournante, sous pression réduite (= 100 Torr), immédiatement suivie d'un séchage sur miroir de potassium. Un début de polymérisation a lieu et le monomère non polymérisé est récupéré sous vide et mis en présence de *n*-BuLi. Dès que l'amorçage est effectif, le monomère est distribué par distillation sur paroi froide, dans des tubes gradués. L'α-méthyl styrène, dont la pureté est testée par cpv, contient moins de 100 ppm d'impuretés non réactives.

t-*BuLi* (Aldrich)

La purification, à partir d'une solution dans l'hexane est réalisée par évaporation du solvant suivie d'une sublimation. Le *t*-BuLi sublimé est redissous dans de l'hexane purifié et

For personal use only.

distribué dans des "bulles" fragiles à partir desquelles le solvant est à nouveau évaporé. Le dosage est effectué sur une "bulle" témoin, par addition de diphényl-1,1 éthylène et dosage spectrophotométrique des carbanions diméthyl-3,3', diphényl-1,1' butyl lithium ($\varepsilon = 16\,000$ mol$^{-1}$ L cm$^{-1}$) (4).

*N,N,N',N'-tétraméthyl éthylène diamine* (TMEDA) (Merck)
La purification est effectuée par distillation sous azote dans une colonne à bande tournante suivie d'un séchage sur $CaH_2$ puis sur un miroir de sodium et sur *n*-BuLi. La distillation dans des tubes capillaires étalonnés est effectuée par condensation sur paroi froide.

2. *Techniques d'étude*
La stabilité des centres actifs est déterminée par spectrophotométrie visible–uv (Cary 118 C). Les polymérisations sont effectuées directement dans la cellule de spectrophotométrie. Il convient de signaler que la prise en masse dans la cellule ne conduit à son bris que si une élévation de température supérieure à 10°C est imposée au système. Le polymère "vivant" est désactivé par addition d'une solution de méthanol dans le toluène.

Pour des raisons d'opportunité, les distributions de masses molaires ont été déterminées par gpc dans le trichlorobenzène (TCB) à 140°C en présence de stabilisants. La distribution très étroite des masses molaires de certains échantillons montre que, même à cette température, aucune dégradation des polymères ne se produit. L'absence de dégradation a, en outre, été vérifiée sur un échantillon maintenu à 140°C dans le TCB pendant 24 h.

Les $\overline{M}_n$ ont été mesurées par osmométrie ou par tonométrie suivant la gamme de masses molaires.

## Résultats et discussion

1. *Stabilité des centres actifs lithiés en l'absence de complexant*

La réaction d'addition du *t*-BuLi sur l'α-méthyl styrène en masse à 25°C, peut être suivie par mesure de la densité optique *D* du maximum d'absorption du carbanion à 321,5 nm. Nous donnons ci-dessous (Fig. 1) les courbes permettant de suivre l'évolution des concentrations en centres actifs au cours du temps, pour deux concentrations initiales en *t*-BuLi ($7{,}4 \times 10^{-3}$ *M* et $11{,}4 \times 10^{-3}$ *M*) et à la température de 25°C.

Les courbes montrent que l'amorçage est pratiquement terminé au bout de 20 min mais qu'une légère dégradation a déjà eu lieu. La durée de 1/2 vie est environ de 5 h, ce qui est du même ordre de grandeur que le temps de prise en masse du système.

L'étude prolongée de la stabilité des centres actifs à la température ambiante permet de constater que $D_{321,5}$ tend vers une valeur asymptotique différente de zéro. Nous avions initialement pensé que cela pouvait provenir d'un effet de gel, mais ce phénomène a été observé aussi en présence de TMEDA, dans des conditions où la prise en masse n'a pas lieu.

La décroissance de la concentration en centres actifs est beaucoup plus rapide lorsque la température s'élève, et à 60°C la durée de demi-vie n'est que de quelques minutes et il n'y a pas d'apparition de nouvelles espèces décelables par spectrophotométrie uv–visible.

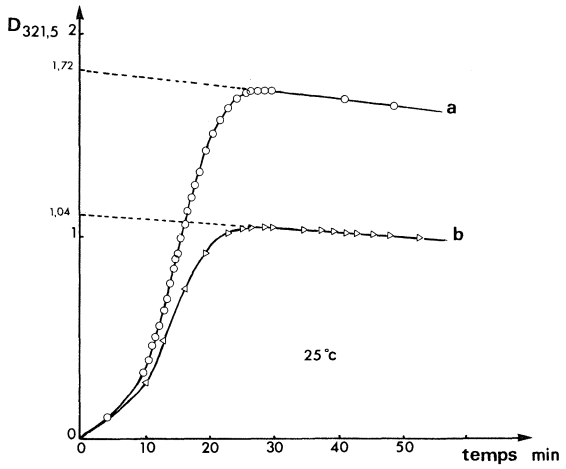

FIG. 1. Evolution de $D_{321,5}$ pour deux concentrations en amorceur à 25°C. (a): [*t*-BuLi] = 0,0114 *M*; (b): [*t*-BuLi] = 0,0074 *M*.

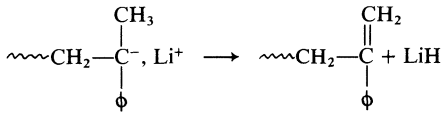
La dégradation peut être décrite par la réaction suivante:



dont l'existence est corroborée par l'apparition d'un léger trouble (LiH) en fin de réaction; l'absorption uv vers 304 et 314 nm du polymère désactivé caractérise la présence des insaturations. Ce résultat ne concorde pas avec le mécanisme proposé par Margerison et Nyss (5), lequel fait intervenir la formation d'une espèce indénique par cyclisation intramoléculaire pour des conditions de polymérisation très différentes.

La valeur asymptotique non nulle de $D_{321,5}$ résulterait de l'addition de l'ion hydrure formé à l'α-méthyl styrène résiduel. L'ensemble des deux réactions peut donc être considéré comme un transfert au monomère et la stabilité observée n'est qu'apparente, la stabilité réelle étant inférieure.

Une étude de la réversibilité de la polymérisation ne peut donc pas être entreprise avec des centres actifs dont la stabilité est si faible.

2. *Stabilité des centres actifs lithiés en présence de TMEDA*

(a) *Rôle de la TMEDA*

Cette diamine tertiaire a souvent été utilisée pour accélérer la polymérisation d'un certain nombre de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

For personal use only.

monomères: éthylène (6), dienes (7), styrène (8), ... en milieu hydrocarboné.

Son rôle peut être schématisé comme suit: dans les hydrocarbures, les composés organolithiés sont fortement agrégés (9) et la complexation de la diamine au cation $Li^+$ favorise leur désagrégation.

Il a été montré par Hélary et Fontanille (8) que l'espèce organométallique ainsi complexée est plus réactive que l'espèce agrégée et moins réactive que l'espèce non agrégée non complexée.

Selon le domaine de concentration en centres actifs, l'addition de la diamine peut donc provoquer soit une accélération (concentration élevée) soit un ralentissement (concentration faible) de la polymérisation.

Pour la polymérisation anionique de l'α-méthyl styrène avec contre ion $Li^+$ et sans agent complexant, l'équilibre entre espèces agrégées et non agrégées doit être influencé par la présence du groupement méthyle et la constante de désagrégation doit être supérieure à celle du polystyryl$^-$,$Li^+$.

L'addition de la TMEDA doit donc se traduire par une stabilité plus grande des centres actifs, à une concentration plus élevée que celle qui a été déterminée pour le polystyryl$^-$,$Li^+$ (8). Cet effet stabilisant vis-à-vis de la réaction de polyaddition doit aussi se manifester vis-à-vis de la désactivation et nous avons recherché les conditions dans lesquelles la réactivité des centres actifs et leur stabilité dans le temps sont compatibles avec la réversibilité et l'étude cinétique de la polymérisation.

(b) *Influence du mode de préparation des centres actifs sur leur stabilité*

Deux méthodes ont été utilisées pour préparer les centres actifs.

*1ère Méthode*: addition du *t*-BuLi à l'αMS en masse puis, lorsque l'amorçage est complet (voir Fig. 1), addition de la TMEDA dans le rapport $r$ = [TMEDA]/[*t*-BuLi].

*2ème Méthode*: addition du *t*-BuLi au mélange (TMEDA + αMS), la quantité de TMEDA étant déterminée par la quantité de *t*-BuLi.

Nous avons établi que, quel que soit le processus choisi, les masses molaires mesurées sont voisines de celles calculées à partir de la concentration en centres actifs. Sur le plan spectrophotométrique, toutes les espèces décelables présentent initialement un maximum d'absorption à 330 nm (espèce A); au cours du temps, apparaît lentement une espèce absorbant à 390 nm (espèce B) avec ou sans formation d'un point isosbestique selon la valeur de $r$ et la méthode retenue (Figs 2a et 2b). La concentration de cette deuxième espèce passe par un maximum, puis décroît très lentement.

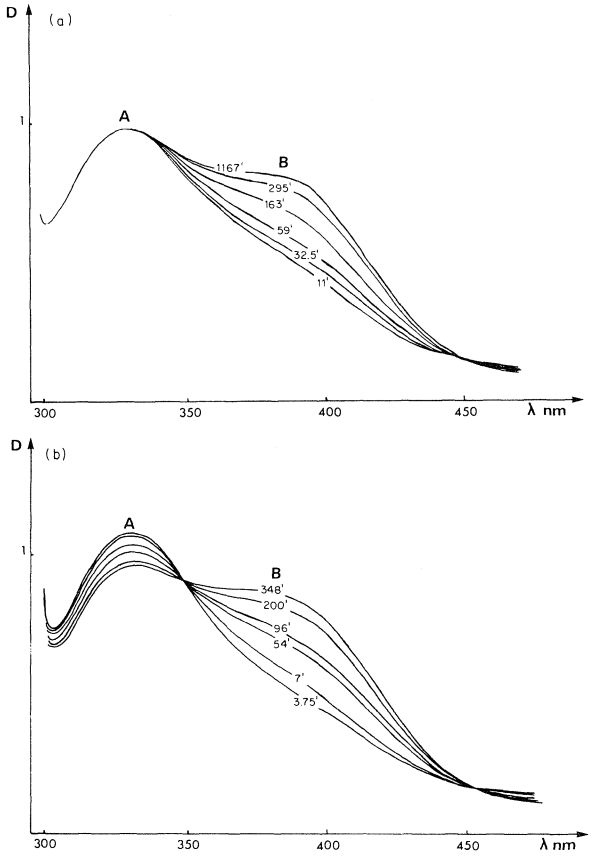

FIG. 2. Evolution spectrale postérieure à l'amorçage à 25°C formation de l'espèce B. (a): (αMS + *t*-BuLi) puis TMEDA. [*t*-BuLi] = 6,95 × $10^{-3}$ *M*; (b): (αMS + TMEDA) puis *t*-BuLi. [*t*-BuLi] = 6,60 × $10^{-3}$ *M*.

L'examen des Figures 2a et 2b montre que, quelle que soit la méthode d'amorçage utilisée, les espèces A se forment rapidement soit à partir du *t*-BuLi, soit à partir du poly(α-méthyl styryl)$^-$,$Li^+$. Par la deuxième méthode, l'espèce B prend naissance à partir de A (point isosbestique).

L'analyse de la distribution des masses molaires par gpc montre que, lorsque la polymérisation est lente, la distribution est élargie et asymétrique (Fig. 3), ce qui était prévisible en raison des évolutions spectrales.

Nous avons retenu la première méthode pour l'amorçage des polymérisations ultérieures. Il convient d'ores et déjà de remarquer que les espèces ainsi formées sont apparemment stables pendant des durées très supérieures à celles de la polymérisation.

(c) *Influence du rapport* r = *[TMEDA]/[t-BuLi] sur la stabilité*

Pour la plupart des expériences réalisées, les concentrations initiales en amorceur sont du même

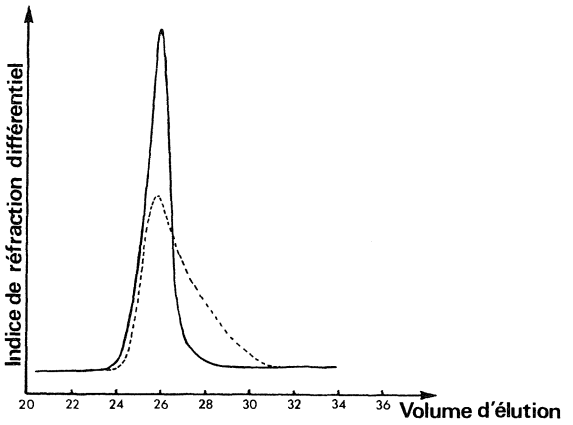

FIG. 3. Les chromatogrammes gpc d'échantillons de poly-(αMS) obtenus à 25°C, pour $r = 2$, par amorçage selon des deux méthodes: ——— *t*-BuLi puis amine; ---------- amine puis *t*-BuLi.

ordre de grandeur ($\simeq 7 \times 10^{-3}$ *M*). Nous avons fait varier le rapport $r$ entre 0,50 et des valeurs très élevées (jusqu'à 208!).

Ainsi que le montre la Fig. 4, la variation de densité optique à 330 nm (maximum d'absorption des espèces de type A) ne dépend que peu de la value de $r$. Néanmoins, il convient de remarquer que la valeur de la densité optique à 330 nm résulte de la simultanéité de plusieurs phénomènes: consommation des espèces A par la réaction de dégradation; contraction de la solution, liée à la polymérisation; reformation éventuelle d'espèces A à partir des formes dégradées susceptibles de réagir avec le monomère résiduel; et absorption non nulle à 330 nm des espèces résultant de la dégradation. Pour cette dernière raison, les valeurs de la Fig. 4 sont celles obtenues après déconvolution des spectres en chacun de leurs constituants.

L'appréciation de la stabilité doit donc tenir compte de ces différents facteurs. Nous constatons en outre que la densité optique à 330 nm atteint

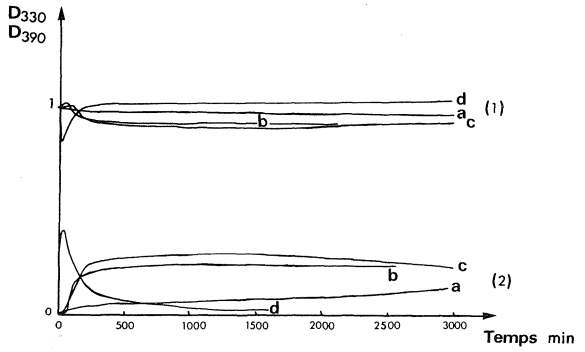

FIG. 4. Influence du rapport $r$ à 25°C sur l'évolution des maximums d'absorption à 330 nm (courbes 1) et à 390 nm (courbes 2). (a): $r = 0,5$; (b): $r = 1$; (c): $r = 2$; (d): $r = 25$.

rapidement une valuer asymptotique dépendant légèrement de $r$ et de la température de l'expérience.

Dans le cas de $r = 1$, on constate que l'abaissement de concentration maximal est de l'ordre de 10% à la température ambiante et seulement de 5% environ au moment de la prise en masse. On peut donc considérer comme négligeable la variation de concentration en centres actifs A pour les 30 premiers % de conversion.

Nous reviendrons ultérieurement sur l'éventuelle reformation de centres actifs à partir des espèces dégradées.

(d) *Influence de la température*

L'influence prépondérante de la température sur la position de l'équilibre polymère ⇄ monomère dans le cas de la polymérisation de l'αMS, nous a conduit à étudier la stabilité des centres actifs aux températures supérieures à la température ambiante.

Nous avons étudié la stabilité des centres actifs à des températures voisines de la température-plafond du système. Dans ces conditions, la polymérisation n'est que partielle et la contraction de volume peut être négligée.

*Pour* r = *1*

*A 75°C* (Fig. 5a), $D_{330}$ décroît de 30% de la valeur initiale, jusqu'à un palier qui est atteint au bout de 2 jours environ. Une observation prolongée du système fait apparaître une décroissance ultérieure de $D_{330}$, avec apparition d'une nouvelle espèce dont le $\lambda_{max} = 424$ nm (espèce C).

*A 62°C* (Fig. 5b), $D_{330}$ décroît de 80% avant d'atteindre le palier mais, si le système est porté à 75°C, il se produit une augmentation de la densité optique du maximum d'absorption principal. Cette augmentation est limitée et suivie d'une nouvelle décroissance simultanée de l'apparition de l'espèce C.

*Pour* r = *0,5* (Fig. 5c)

Le comportement est similaire, les évolutions sont toutefois plus lentes. Après 40 jours on ajoute du monomère. On observe d'abord un effet de dilution puis une évolution lente des espèces.

Pour les deux valeurs de $r$ retenues, une attente suffisamment longue permet de n'observer qu'un seul pic à 424 nm.

(e) *Nature des différentes espèces formées*

La concentration de l'espèce B croît avec $r$ jusqu'à $r = 2$, les vitesses d'apparition et de disparition de ces espèces sont d'autant plus rapides que $r$ est grand (Fig. 4).

Lorsque les polymérisations sont réalisées dans des conditions telles que la prise en masse n'inter-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

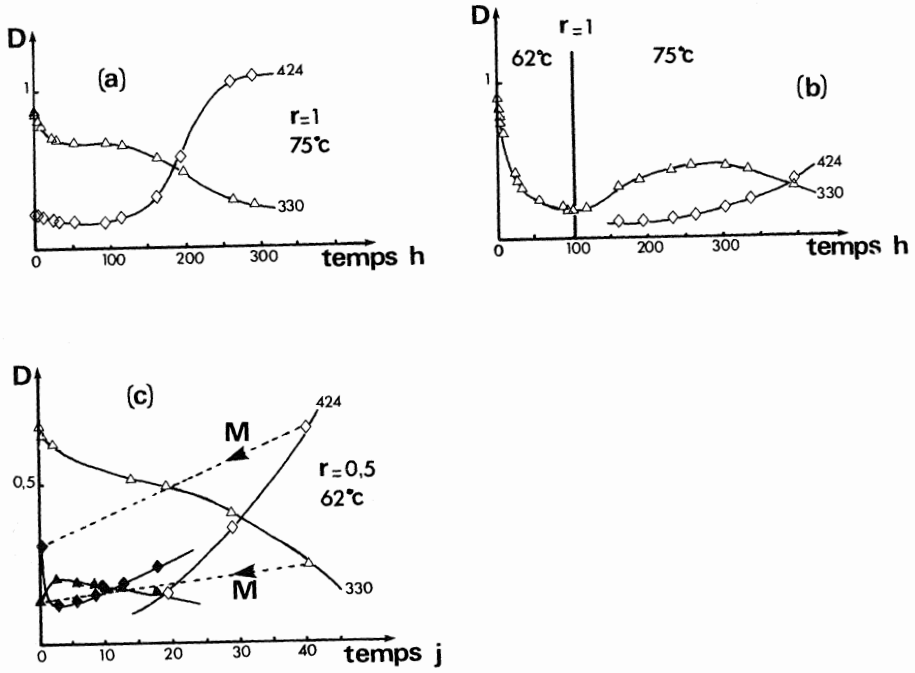

FIG. 5. Evolution de $D_{330}$ et $D_{424}$ pour différentes températures et rapports $r$. (a): $r = 1$ à 75°C; (b): $r = 1$ à 62° et 75°C; (c): Effect de dilution sur l'intensité des maximums: △◇ évolution des spectres au cours de 40 jours; ▲◆ après 40 jours et après addition de monomère. L'effet de dilution est indiqué par le pointillé.

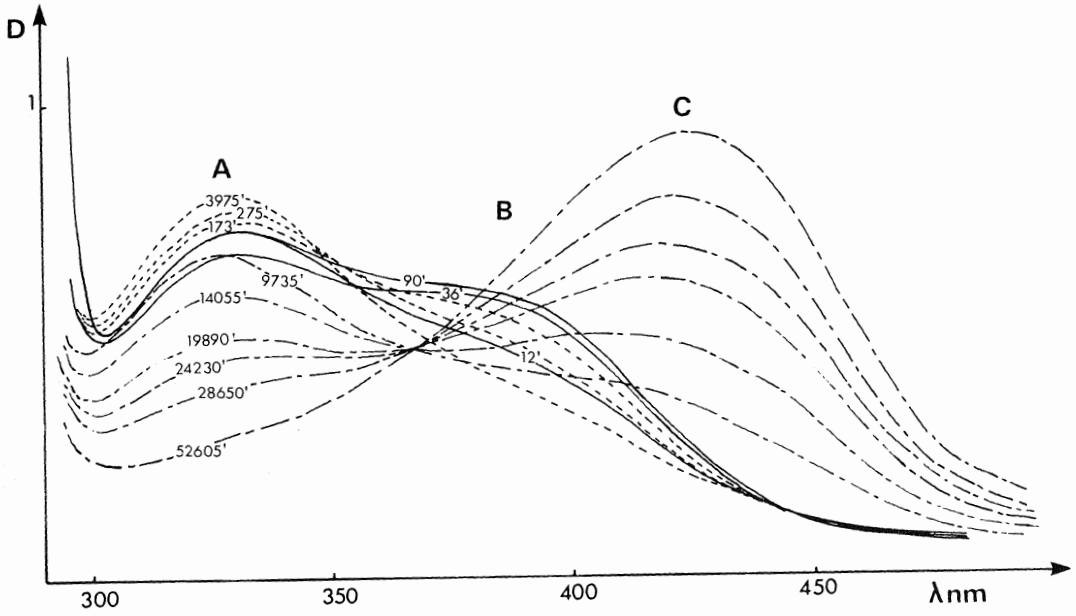

FIG. 6. Evolution spectrale des différentes espèces, obtenue pour $r = 208$ à 25°C; $t = 0$ correspond à l'addition du TMEDA au système amorcé selon la première méthode ($[t\text{-BuLi}]_i = 16 \times 10^{-3}$ équiv./L).

vient pas ou n'intervient que très lentement (haute température ou $r$ élevé), l'espèce C apparaît. La Figure 6 montre une évolution spectrale complète à partir de l'espèce A. Les deux points isosbestiques observés démontrent que B se forme à partir de A ainsi que C et que ce dernier n'est décelable que lorsqu'il n'y a pratiquement plus d'espèces B visibles.

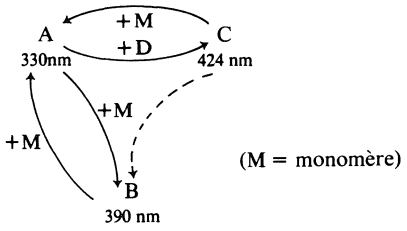
L'hypothèse rendant le mieux compte de ces observations consiste à admettre l'existence de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

deux réactions de dégradation simultanées conduisant respectivement à B et à C.

Par ailleurs, nous avons constaté que l'addition de monomère à un système vieilli dans lequel seule l'espèce C est décelable et dans lequel la concentration de monomère doit être faible, provoque la diminution de la concentration de C et la réapparition soit des espèces A, soit des espèces B selon la valeur de $r$ (Fig. 5c).

L'ensemble de nos observations peut s'expliquer par le schéma suivant:



D'après les données de la littérature (10–12), la structure probable de l'espèce C est de type phénylallylique.

L'espèce B absorbant à 390 nm résulterait de l'arranchement d'un proton allylique du monomère par l'espèce A. Cette réaction serait concurrentielle de l'addition.

Les concentrations relatives des espèces B et C dépendraient de leur réactivité respective vis-à-vis du monomère résiduel ainsi que de la concentration de ce dernier.

Le retour aux espèces de type A se produit par addition 1,3 du monomère sur les carbanions phényl allyliques B et C. Une réaction analogue, en présence d'agents complexants, a été précédemment signalée pour différents systèmes (10–12). La nouvelle espèce cylique formée présente une structure électronique très proche de celle de l'espèce A et doit donc absorber sensiblement à la même longueur d'onde. Elle doit aussi pouvoir s'additionner au monomère pour redonner l'espèce A ou

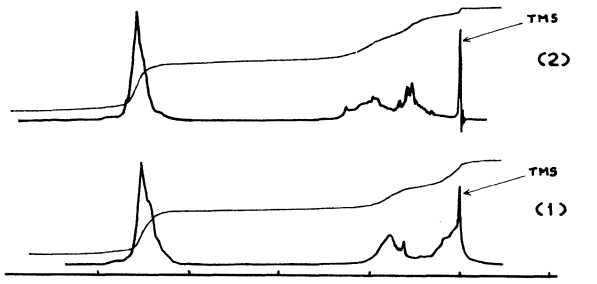


FIG. 7. Les spectres rmn $^1H$ à 60 MHz dans $CDCl_3$. Spectre 1: Polymère issu d'une polymérisation à −10°C. Spectre 2: Oligomères totaux issus d'une réaction conduite à 62°C.

même lui arracher un proton pour redonner l'espèce B. L'ensemble de ce schéma réactionnel est sur plusieurs points semblable à celui proposé par Comyn et Glasse (13).

Ces réactions peuvent être considérées comme des transferts au monomère ou au polymère conduisant à des irrégularités de structure cycliques. Nous avons observé des spectres de rmn $^1H$ très différents pour le poly(αMS) de haute masse molaire d'une part et pour des oligomères résultant d'un transfert important d'autre part (Fig. 7).

(f) *Evaluation du transfert*

Il ne faut pas perdre de vue que, pour réaliser une étude cinétique faisant intervenir un équilibre polymérisation–dépolymérisation, la constante de la concentration en centres actifs est une condition nécessaire mais non suffisante. Selon les schémas réactionnels que nous avons proposés, il se forme des extrémités de chaînes saturées et des cycles situés topochimiquement le long des chaînes qui bloquent la dépolymérisation et perturbent ainsi les équilibres thermodynamiques.

Le taux des irrégularités de structure est proportionnel à l'importance du transfert et les méthodes que nous avons retenues pour son évaluation consistent à comparer les masses molaires expérimentales aux masses théoriques et à mettre en évidence par gpc le défaut d'isomolécularité.

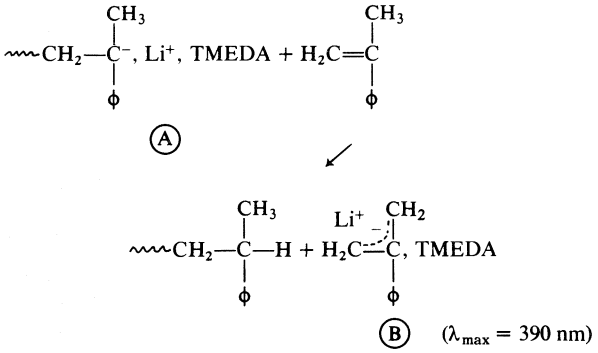
[a]Nombre obtenu par osmométrie.
[b]Nombre obtenu par tonométrie.

Chaque transfert contribue à l'élargissement de la courbe de répartition des masses molaires. Cette tendance s'accentue lors des transferts au monomère où chaque transfert divise par deux la masse molaire.



Une solution initiale est distribuée en 8 ampoules d'égale concentration en centres actifs en présence de TMEDA avec $r = 0{,}5$. Chacune d'elles est maintenue à une certaine température pendant une durée déterminée, puis désactivée par le méthanol. Le polymère formé est récupéré par évaporation du monomère résiduel et analysé par gpc. Les résultats correspondants sont exprimés dans le Tableau 1 et par la Fig. 8.

Il apparaît ainsi que la distribution des masses molaires et l'accord avec les masses molaires théoriques varient avec la température de la polymérisation. Pour les expériences réalisées au-dessous de 25°C environ, la répartition des masses molaires est étroite et leur valeur mesurée est en bon accord avec la valeur théorique.

Par contre, dès 35°C, on décèle un élargissement et une dissymétrie de la courbe de répartition qui peut être imputable au transfert.

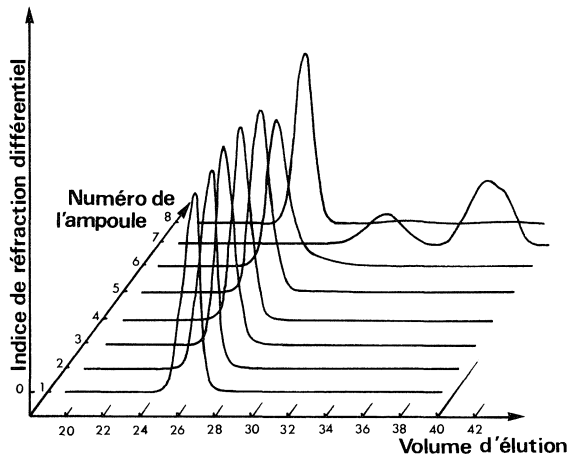


FIG. 8. Chromatogrammes gpc de poly(αMS) préparés à différentes températures (voir Tableau 1).

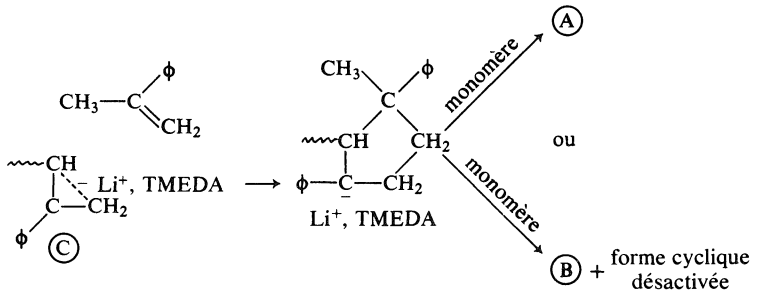

## Conclusion

Nous avions recherché les conditions dans lesquelles une étude cinétique de la polymérisation en masse de l'αMS est possible. Nous avons montré que la présence de TMEDA dans le rapport $r$ = [TMEDA]/[Li] = 1 induit une stabilisation du système qui permet de négliger la dégradation jusqu'à une température voisine de 35°C. Au delà de cette température, le transfert au monomère ou au polymère devient important et l'étude cinétique devra en tenir compte.

## Remerciements

# High yield "one-pot" synthesis of 2-hydroxy-3-methylcyclopent-2-en-1-one and related compounds

GEORGE M. STRUNZ AND G. SANKAR LAL

*Maritimes Forest Research Centre, Canadian Forestry Service, Department of the Environment, P.O. Box 4000, Fredericton, N.B., Canada E3B 5P7*

Received October 1, 1981

GEORGE M. STRUNZ and G. SANKAR LAL. Can. J. Chem. **60**, 572 (1982).

A convenient "one-pot" modification of a conventional synthetic route affords 2-hydroxy-3-methylcyclopent-2-en-1-one and related compounds in high overall yields.

GEORGE M. STRUNZ et G. SANKAR LAL. Can. J. Chem. **60**, 572 (1982).

Une modification très simple d'une synthèse conventionnelle conduit, sans isoler les intermédiaires, au produit hydroxy-2-méthyl-3-cyclopentèn-2-one-1 et d'autres produits apparentés avec des bons rendements.

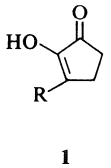
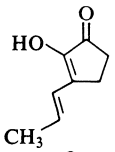
An interest in synthetic pyrethroids (1) with alcohol components derived from 2-hydroxy-3-substituted-cyclopent-2-en-1-ones (cf. refs. 2, 3) prompted us to seek a versatile and efficient synthetic route to the latter class of compounds. In large part because of the importance conferred on it by its organoleptic properties, 2-hydroxy-3-methylcyclopent-2-en-1-one (**1**, R = $CH_3$), a flavour constituent of coffee aroma (4) and maple syrup (5), has been a popular synthetic target: more than a score of papers describing syntheses of this and related compounds have been published (6).[1] The majority, according to Cookson and Smith (6*b*) "suffer from low yields, multistep procedures, and/or expensive reagents."



**1**



**2**

One of the earlier synthetic approaches, employed by Litchenberger and Litchenberger (7), Hesse and Bücking (8), and Gianturco and Friedel (9), appealed to us by virtue of its simplicity and because it allowed the introduction of a wide variety of substituent groups, R. The synthesis involves alkylation of 3,5-dicarboalkoxycyclopentane-1,2-dione, obtained by condensation of glutaric and oxalic acid esters. Subsequent hydrolysis and decarboxylation afford the 3-alkyl-2-hydroxycyclopent-2-en-1-one.

We have found that by the simple expedient of conducting these reactions sequentially in one flask, without isolation of intermediates, yields are substantially increased. (Additional modifications, such as the use of dimethylformamide as solvent for the alkylation and aqueous phosphoric acid for the hydrolysis–decarboxylation, were also found to be advantageous.) Using this modified procedure, **1** (R = $CH_3$) is obtained in an overall yield of 80% based on dimethyl glutarate. To our knowledge this is the highest yield reported for synthesis of 2-hydroxy-3-methylcyclopent-2-en-1-one from simple readily available noncyclic precursors.

Results for some related compounds prepared by the same procedure are presented in Table 1.

[1]The compound is available from several commercial sources.

## Experimental

The standard procedure is exemplified by the synthesis of **1** (R = $CH_3$).

*2-Hydroxy-3-methylcyclopent-2-en-1-one (1, R = $CH_3$)*

A solution of diethyl oxalate (11.65 g, 0.080 mol) in anhydrous ether (50 mL) was added during 30 min, by dropping funnel, to sodium methoxide (3.60 g, 0.067 mol) in a 100 mL two-neck flask fitted with a reflux condenser. Operations were conducted in an atmosphere of dry nitrogen, and the mixture was stirred and cooled in an ice-bath throughout the addition. When the initially formed lumps had broken down to give a smooth slurry, a solution of dimethyl glutarate (2.13 g, 0.013 mol) in anhydrous ether (10 mL) was added dropwise with stirring and cooling over a period of 30 min. Stirring was continued for 1 h while the mixture was allowed to warm to 22°C. The flask was then fitted for distillation and the apparatus was wrapped with glass wool.

The reaction mixture was gently heated on an oil bath until the ether was removed. The temperature was then gradually raised to 120°C. After 3 h at 120°C, the temperature was raised to 140°C where it was maintained for 14 h.

The residue was allowed to cool, and the apparatus was again fitted with a dropping funnel and reflux condenser. A solution of methyl iodide (3.78 g, 0.027 mol) in dry dimethylformamide (50 mL) was added to the residue, and the mixture was stirred at 22°C under nitrogen for 16 h, then heated under reflux for 2 h. Dimethylformamide and excess methyl iodide were removed by distillation *in vacuo*, and the product was refluxed with 42% aqueous phosphoric acid (50 mL) for 72 h.

The acidic aqueous mixture was extracted with ether (5 × 40 mL) and the extracts, after drying and evaporation of solvent, yielded a crude crystalline product. Elution with hexane–ace-

# On the origin of regioselectivity in the photorearrangement of 4,4-diphenyl-2,5-cyclohexadiene systems. Synthesis and photochemistry of 4,4-diphenyl-γ-thiopyran and -γ-thiopyran-1,1-dioxide[1,2]

DENIS GRAVEL[3] AND CHRISTIAN LEBOEUF[4]

*Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1*

Received August 28, 1981

DENIS GRAVEL and CHRISTIAN LEBOEUF. Can. J. Chem. **60**, 574 (1982).

The synthesis from diphenylmethane of 4,4-diphenyl-γ-thiopyran and 4,4-diphenyl-γ-thiopyran-1,1-dioxide is described. Upon direct photolysis at 254 nm the γ-thiopyran derivative undergoes rearrangement to a mixture of 5,6-diphenyl-2-thiabicyclo-[3.1.0]hexene and 2,4-diphenyl-α-thiopyran. The corresponding 1,1-dioxide derivative on the other hand undergoes, upon direct photolysis at 254 nm or sensitized (acetone) photolysis at 350 nm, rearrangement to 6,6-diphenyl-2-thiabicyclo[3.1.0]hexene-2,2-dioxide accompanied by a solvent addition product: 3-methoxy-4,4-diphenyl-2,3-dihydro-γ-thiopyran-1,1-dioxide. The results, along with those observed for 4,4-diphenyl-γ-pyran studied in this series, and other literature results are rationalized in terms of Zimmerman's reacting chromophore simulation using the Möbius–Hückel concept to evaluate competing excited state energies of the isoconjugate chromophores.

DENIS GRAVEL et CHRISTIAN LEBOEUF. Can. J. Chem. **60**, 574 (1982).

La synthèse à partir du diphenylméthane des diphényl-4,4-γ-thiopyranne et diphényl-4,4-γ-thiopyranne-1,1-dioxyde est rapportée. Lors de la photolyse directe à 254 nm le dérivé γ-thiopyranne se réarrange en un mélange de diphényl-5,6-thia-2-bicyclo[3.1.0]hexene et de diphényl-2,4-α-thiopyranne. Le dérivé 1,1-dioxyde correspondant d'autre part subit, lors de la photolyse directe à 254 nm ou sensibilisée (acétone) à 350 nm, un réarrangement en diphényl-6,6-thio-2-bicyclo[3.1.0]hexene-2,2-dioxyde accompagné d'un produit d'addition du solvant, le méthoxy-3-diphényl-4,4-dihydro-2,3-γ-thiopyranne-1,1-dioxyde. Les résultats ainsi que ceux observés pour le diphényl-4,4-γ-pyranne étudié dans cette série ainsi que d'autres résultats puisés de la littérature sont rationalisés en terme de la "simulation du chromophore en réaction" de Zimmerman, utilisant le concept de Möbius–Hückel pour évaluer les énergies en compétition des chromophores isoconjugués excités.

## Introduction

Previously we reported (1) on the photochemistry of 4,4-diphenyl-γ-pyran (**1***a*) which upon irradiation undergoes a di-π-methane rearrangement (2) to yield the corresponding *trans-endo*-5,6-diphenyl-2-oxabicyclo[3.1.0]hexene (**2***a*) as primary photoproduct, along with a series of secondary products which were characterized and interrelated (see Scheme 1).

As stated earlier (1*a*), our aim in undertaking these studies was to investigate some cyclic di-π-methane systems of general structure (**1**) where the two π moieties in the ring are joined by a heteroatom. Such models should provide a further test of the generality of the rearrangement, provide further insight into its mechanism, and also give access to new heterobicyclo[3.1.0] systems **2** and/or **3** and their chemistry. The interesting mechanistic aspect contributed by our original study (1*a*) on compound **1***a* was the observation of an absolute regioselectivity in the reaction, i.e., rearrangement takes place solely with phenyl–vinyl (P–V) bonding (path a) to yield the corresponding phenyl migrated oxabicyclo[3.1.0] product **2***a*; none of the alternative *gem*-diphenyl oxabicyclo[3.1.0] product **3***a* could be found, which shows that vinyl–vinyl (V–V) bonding (path b) does not take place, at least to any significant extent (see Scheme 2) in that system.

These results are to be compared (*vide infra*) with the well documented fundamental systems **1***b* and **1***c* studied by Zimmerman *et al.* (3, 4), which are also totally regioselective in their behavior: **1***b*, where X = C=CH$_2$, yields exclusively via path a the phenyl migrated bicyclo[3.1.0] product **2***b*, of the same *trans-endo* stereochemistry as **2***a* (3), whereas **1***c*, where X = C=O, yields exclusively via path b the *gem*-diphenyl bicyclo[3.1.0] product **3***c* (4); rearrangements following this particular path have been termed Type A rearrangements by Zimmerman (4).

The present study deals with the preparation and photochemistry of two new compounds of general structure **1**, namely: 4,4-diphenyl-γ-thiopyran (**1***d*), where X = S, and 4,4-diphenyl-γ-thiopyran-1,1-dioxyde (**1***e*), where X = SO$_2$. The first compound should yield information regarding the possible influence of the nature of the heteroatom on the

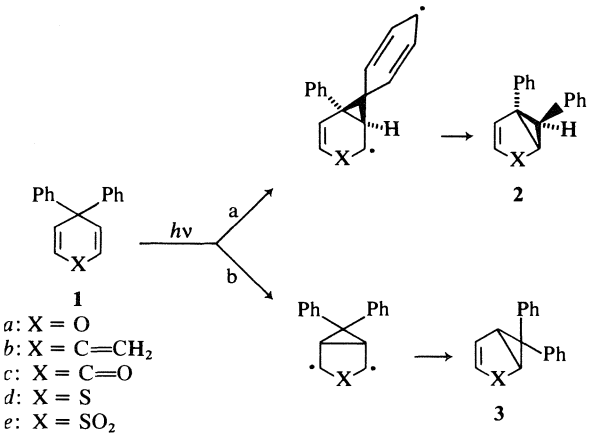
regioselectivity of the rearrangement while the second should provide information regarding the possible influence on the regioselectivity of (*i*) the electronegativity of group X and/or (*ii*) the presence or absence of unshared electrons on group X.



SCHEME 2. Odd-electron representation of *a priori* possible reaction pathways in the 4,4-diphenyl-2,5-cyclohexadiene system.

## Results

### *Synthesis of γ-thiopyrans 1*d *and 1*e

As exemplified (1*a*) by our synthesis of 4,4-diphenyl-γ-pyran (1*a*), our approach to the problem of gaining access to heterocyclic compounds of general structure **1** has been to synthesize the tetramethoxydiacetal derivative of 3,3-diphenylglutaraldehyde (**4**), which is a general synthon for our purpose.

Hence, in the present case, treatment of a dichloromethane solution of diacetal **4** by a gaseous mixture of hydrogen sulfide and hydrogen chloride leads to the 2,6-dihalotetrahydrothiopyran intermediate **5** which is immediately treated with *N*,*N*-dimethylaniline at 160°C to lead directly to the desired 4,4-diphenyl-γ-thiopyran (1*d*) with a 60% yield after purification (see Scheme 3). Compound 1*d* presents in its mass spectrum a molecular ion at *m/e* 250; in the nmr, a multiplet at 7.2 ppm in the form of a broadened singlet, characteristic of the phenyl protons, and an AB quartet centered at 6.0 ppm ($J_{AB}$ = 10.5 Hz) for the vinyl protons; the thioenol ether linkages are characterized in the ir by an absorption at 1600 $cm^{-1}$; finally, compound 1*d* shows in the uv a $\lambda_{max}$ at 240 nm with an ε of 1470 and a second $\lambda_{max}$ at 285 nm with an ε of 1090.

The corresponding sulfone 1*e* was obtained in a 93% yield by oxidation of thiopyran 1*d* with ruthenium tetroxide (5). The mass spectrum of sulfone 1*e* is devoid of a molecular ion peak at *m/e* 282, however, an ion at $M - 64$ corresponds to the loss of $SO_2$ by the molecular ion; furthermore, elemental analysis confirms the molecular formula $C_{17}H_{14}O_2S$ for the sulfone. In the nmr, the phenyl groups are characterized by a narrow multiplet at 7.35 ppm and the vinyl protons appear in the form of an AB quartet centered at 6.70 ppm ($J_{AB}$ = 12 Hz). In the infrared, two intense absorptions at 1295 and 1115 $cm^{-1}$ confirm the presence of the sulfone group.

*Preparative scale photolysis of thiopyran 1*d *and characterization of photoproducts*

Irradiation for 2 h of a $10^{-3}$ *M* solution of thiopyran **1***d* in anhydrous ether leads to a mixture of photoproducts. Preparative scale thin layer chromatography (tlc) on silica gel allows the recovery of the two main fractions: the first being composed of unreacted starting material **1***d* (7%) and the second, (55%), apparently composed of a mixture of 5,6-diphenyl-2-thiabicyclo[3.1.0]-hexene (**2***d*†)[5] and 2,4-diphenyl-α-thiopyran (**6**) (see eq. [1]). This mixture is unfortunately unstable

[1] 

Photolysis of 4,4-diphenyl-γ-thiopyran (**1***d*)

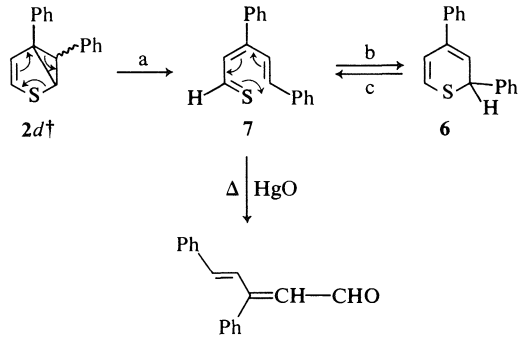
at room temperature and was not amenable, in our hands, to separation into its components.

In the nmr, the mixture of sulfides shows signals characteristic of both structures, i.e. a complex region from 2.1 to 3.7 ppm is typical of cyclopropane protons such as in **2***d*† and also of similar bicyclo[3.1.0] systems (6) such as 5,6-diphenyl-2-oxabicyclo[3.1.0]hexene (**2***a*) (1*a*). An AB system centered at 6.40 ppm ($J$ = 10.5 Hz) could be attributed to the 5,6 vinyl protons of α-thiopyran **6** while a multiplet at 5.80 ppm could very well be a superimposition of the vinyl AB system of the thiabicyclo[3.1.0] derivative **2***d*† and a doublet or multiplet expected for the vinyl proton in the 3-position of α-thiopyran **6**. A doublet at 4.85 ppm $J$ = 8 Hz could be attributed to $H_2$ in the same molecule and finally a broad signal centered at 7.35 ppm is characteristic of the phenyl groups in both compounds.

The formation of such a mixture of photoproducts from γ-thiopyran **1***d* is *a priori* in accord with the expected behavior of these systems (see Scheme 2) as far as the formation of the bicyclo[3.1.0] derivative **2***d*† is concerned. On the other hand, as we have shown in a previous paper (1*a*) and as was observed (6) in a study of the addition of carbenes to furans and thiophenes prior to our work, 2-heterobicyclo[3.1.0]hexenes are labile at room temperature or with acid and are known to rearrange to the corresponding open chain unsaturated aldehyde or thioaldehyde as illustrated in Scheme 1.

[5]The dagger (†) should be taken to indicate unspecified stereochemistry.

In our case, this immediately suggests that the expected primary photoproduct, the thiabicyclo-[3.1.0] derivative **2***d*†, could either thermally or photochemically have evolved to the corresponding thioaldehyde **7** which could have equilibrated [6] with α-thiopyran **6** in competition with decomposition and/or polymerization. With this hypothesis in mind and in the hope of obtaining a more stable and characterizable product we applied a desulfurization procedure reported by Corey and Shulman (7) in their study of the thio-Claisen rearrangement. According to the authors (7), carrying out the rearrangement by heating in the presence of red mercuric oxide allows trapping of the resulting thioaldehyde and conversion to the corresponding aldehyde in high yield. When this procedure was applied to the mixture (**2***d*† + **6**), the known (1*a*) 3,5-diphenylpentadienal (**8**) was obtained in a 63% yield and as a mixture of two stereoisomers[7] (see Scheme 4). Presumably, the thermal processes a, b, and c are initiated at 110–115°C and the intermediate thioaldehyde[7] trapped and converted to aldehyde **8**; a possible electrophilic catalysis by mercury on path a is highly probable since conversion of 2-oxabicyclo[3.1.0]hexenes to the corresponding unsaturated aldehydes is known to be also acid catalyzed (1*a*, 6).



SCHEME 4. Conversion of photoproduct mixture **2***d*† + **6** to fully characterizable 3,5-diphenylpentadienal (**8**).

In the nmr, the 3,5-diphenylpentadienal (**8**) presents a pair of doublets at 10.30 ppm ($J$ = 8 Hz) and 9.50 ppm ($J$ = 8 Hz) having respective relative intensities of 0.8H and 0.2H characteristic of an aldehyde mixture; at 7.72 ppm and 6.80 ppm, a pair of AB doublets ($J$ = 16 Hz) of relative intensities 1H characteristic of the 4,5 vinyl protons in a *trans*

[6]In support of this hypothesis, Jackson (6) has reported that, upon standing at 0–5°C, 3-chloro-2-thiabicyclo[3.1.0]hexene isomerizes to 6-chloro-2*H*-thiopyran.

[7]The ratio of isomers in the resulting mixture is different from that observed in the photolysis of γ-pyran **1***a* (see Scheme 1).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

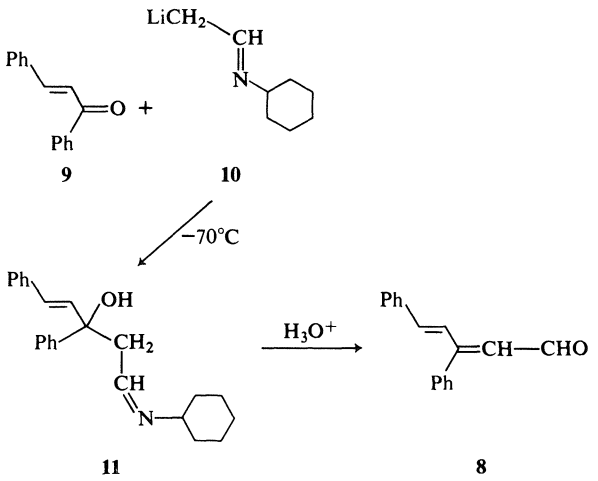
arrangement; at 7.40 ppm the phenyl groups appear in the form of a complex pattern; further upfield at 6.25 and 6.18 ppm appears another pair of doublets ($J$ = 8 Hz), having a relative total intensity of 1H, characteristic of the vinyl proton on carbon-2. The nmr spectrum is therefore in accord with that expected for a mixture of 2,3-*cis*-4,5-*trans* and 2,3-*trans*-4,5-*trans*-3,5-diphenylpentadienals (**8**). The ultraviolet spectrum is typical of such a conjugated system with a $\lambda_{max}$ at 334 nm ($\varepsilon \simeq$ 18 000) (1).

*Synthesis of authentic 3,5-diphenylpentadienal (8)*

In our previous paper (1*a*), the mixture of 3,5-diphenylpentadienal (**8**) was correlated chemically with authentic methyl 3,5-diphenylpentanoate using tlc and vpc techniques. In the present paper we sought a more direct and absolute proof of structure of the aldehyde mixture and embarked on a synthesis of the desired compound.

The most direct approach to synthesize the unsaturated aldehyde **8** is by formylolefination of chalcone (**9**). All attempts having failed using 2,2-ethylenedioxyethylenetriphenylphosphonium ylid (8), we attempted an alternative method developed by Wittig and Reiff (9) using metallated Schiff bases to effect aldol condensation as a route to α,β-unsaturated carbonyl compounds. This method presumably is superior to phosphorus ylids when ketones are used as starting material and greatly superior when conjugated ketones are used as starting material. Hence, we were most gratified to find that Wittig and Suchanek (10) had already reported the condensation of the lithium anion of ethylidenecyclohexylamine (**10**) with chalcone (**9**) which leads to the desired 3-hydroxy-3,5-diphenylpent-4-enylidenecyclohexylamine (**11**) when the reaction is carried out at −70°C; at room temperature, however, the main product isolated is that of the conjugate addition on the enone **9**. Although Wittig and Suchanek (10) had not reported the hydrolysis–dehydration step to the desired unsaturated aldehyde **8**, we envisaged that treatment by aqueous oxalic acid which has been used with success in many other cases (9) should also be applicable in this case. In the event, our assumption proved correct and the synthesis was carried out successfully (see Scheme 5 and Experimental).

The authentic 3,5-diphenylpentadienal (**8**), obtained in a 35% yield starting from ethylidenecyclohexylamine, presents in its mass spectrum a molecular ion at *m/e* 234 and a $M - 29$ peak typical of aldehydes. The infrared is characterized by an intense conjugated carbonyl absorption at 1660 $cm^{-1}$. In the nmr, there appears the typical pair of



SCHEME 5. Synthesis of authentic 3,5-diphenylpentadienal (**8**).

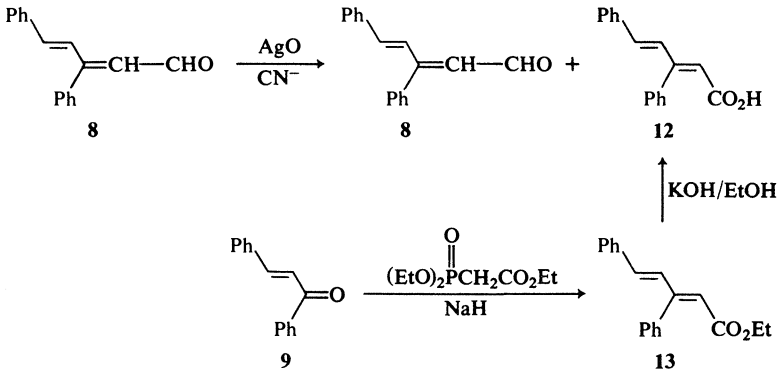
doublets at 10.18 ppm ($J$ = 8 Hz) and 9.40 ppm ($J$ = 8 Hz) but this time with respective relative intensities of 0.2H and 0.8H, i.e. proportions exactly opposite to those observed in the mercuric oxide experiment described above. Aside from the observed discrepancies in the signal intensities, the general aspect of the spectra regarding chemical shifts was identical.

The present correlation, although chemically sound, was not totally satisfactory to us because the different product ratios in each mixture prevented their full comparison by nmr and ir. We were therefore happy to find that *trans-trans*-3,5-diphenylpentadienoic acid (**12**) and its 2,3-*cis*-4,5-*trans* isomer had been reported in the literature (11) and were separated by crystallization. We thus required a smooth method to efficiently convert the 3,5-diphenylpentadienal mixture of isomers **8** to the corresponding mixture of acids.

*Oxidation of the 3,5-diphenylpentadienal mixture of isomers 8 and correlation with authentic* trans–trans-*3,5-diphenylpentadienoic acid (12)*

For the conversion of the unsaturated aldehyde mixture **8** to the corresponding acids we chose a method described by Corey *et al.* (12) as useful for such conversions and which gives little or no isomerization (see below). The method involves the use of silver oxide as oxidizing agent in presence of cyanide ions. When this procedure was applied to the mixture of unsaturated aldehydes **8** obtained from the mercuric oxide experiment (see Scheme 4), there was obtained a 1:1 mixture of 3,5-diphenylpentadienoic acid (**12**) and unreacted unsaturated aldehydes **8** (see Scheme 6).

Much to our surprise, the acid obtained was



SCHEME 6. Structure correlation of 3,5-diphenylpentadienoic acid (**12**)

unique and had the *trans-trans* stereochemistry while the unreacted unsaturated aldehyde had exactly the opposite isomer ratio to the starting aldehyde mixture, i.e. the aldehydic proton at 10.20 ppm had a relative integration of 0.2H while that at 9.40 ppm had 0.8H. This ratio, however, is exactly that obtained in the unambiguous synthesis of the aldehydes by the Wittig and Suchanek (10) procedure (see Scheme 5); hence, quite by chance, we were in a position to compare the nmr spectra of identical isomer ratios of 3,5-diphenylpentadienal (**8**) originating from the mercuric oxide desulfurization experiment (see Scheme 4) and from the unambiguous synthesis route (see Scheme 5); these proved identical in all respects.

The original desired correlation having thus been obtained (by coincidence) there was no further great need to prepare the *trans-trans* acid **12** but this was done for the sake of completeness using triethylphosphonoacetate and chalcone (**9**) (11) (see Scheme 6). The *trans-trans* ethyl ester **13** obtained by chromatography was saponified to the desired authentic *trans-trans* acid **12** which proved identical in all respects to the *trans-trans* acid **12** obtained by oxidation of the aldehyde mixture **8** using the silver oxide – cyanide method (12) (see Experimental).

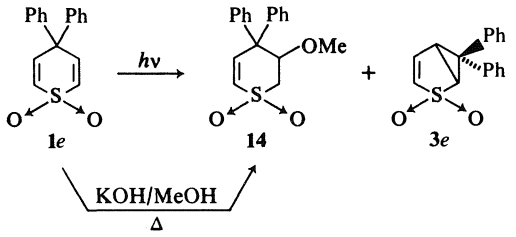
With the structure of aldehyde **8** now firmly established, it can safely be concluded that photorearrangement of 4,4-diphenylthiopyran **1***d* involves phenyl migration, most probably by a di-π-methane rearrangement resulting from a phenyl–vinyl (P–V) bonding interaction (see path a, Scheme

*Preparative scale photolysis of 4,4-diphenylthiopyran-1,1-dioxide (1e) and characterization of photoproducts*

In a typical experiment, irradiation for 1 h at 254 nm of 500 mL of a $3.5 \times 10^{-3}$ *M* methanol solution of sulfone **1***e* leads to a mixture of photoproducts. Preparative scale tlc on silica gel allows the recovery of 3 products: (*i*) unreacted starting sulfone **1***e*, 52%; (*ii*) 5-methoxy-4,4-diphenyl-5,6-dihydrothiopyran-1,1-dioxide (**14**) 13%; (*iii*) 6,6-diphenyl-2-thiabicyclo[3.1.0]hexene-2,2-dioxide (**3***e*), 15% (see Scheme 7).

Like the starting sulfone **1***e*, the methanol photoadduct **14** does not show a molecular ion in its mass spectrum but an ion at $M - 64$ is in accord with the loss of $SO_2$. In the ir, intense bands at 1300, 1125, and 1085 $cm^{-1}$ are characteristic of the $SO_2$ group and the C—O bond. The nmr, on the other hand, presents a narrow multiplet at 7.26 ppm for the aromatic protons; the two vinyl protons appear in the form of a singlet at 6.46 ppm while $H_5$ appears as a doublet of doublets ($J_1 \simeq 11.5$ Hz, $J_2 \simeq 2.5$ Hz) at 4.67 ppm. The methoxyl singlet appears at 3.33 ppm, in the midst of a complex signal extending from 3.53 to 2.93 ppm and due to the methylene group α to the sulfone. The structure of the proposed methoxysulfone **14** was corroborated by synthesis, *vide infra*.

The third and most relevant (for this study) product isolated shows in its mass spectrum a molecular ion at *m/e* 282 and an ion at $M - 64$ corresponding to the loss of $SO_2$, typical in this series; a microanalysis corroborated fully the molecular formula of $C_{17}H_{14}O_2S$. The ir spectrum clearly shows the presence of a sulfone group by



SCHEME 7. Photolysis of 4,4-diphenyl-γ-thiopyran-1,1-dioxide (**1***e*).

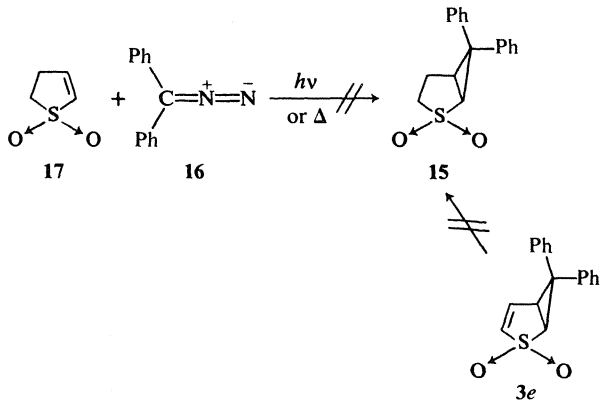

SCHEME 8. Attempted correlation of photoproduct **3e** by way of its dihydroderivative **15**.

characteristic absorptions at 1300 and 1140 $cm^{-1}$. In the nmr, the aromatic protons appear in the form of a narrow multiplet at 7.25 ppm. The vinyl proton $H_4$, β to sulfone, gives rise to a doublet of doublets centered at 6.88 ppm ($J_{3,4} \simeq 6.5$ Hz and $J_{4,5} \simeq 3.0$ Hz), while $H_3$, α to sulfone, gives rise to a doublet of doublets centered at 6.16 ppm ($J_{3,4} \simeq 6.5$ Hz and $J_{1,3} \simeq 1.5$ Hz); the cyclopropyl proton $H_1$ appears also as a doublet of doublets centered at 3.49 ppm ($J_{1,5} \simeq 6.5$ Hz and $J_{1,3} \simeq 1.5$ Hz) and $H_5$ as a doublet of doublets at 3.29 ppm ($J_{1,5} \simeq 6.5$ Hz and $J_{4,5} \simeq 3.0$ Hz).

Due to the all-importance of establishing absolutely and unambiguously the relative position of the phenyl groups on the bicyclic sulfone **3e** because it holds the key to the question of regioselectivity in this system, we attempted, but quite unsuccessfully, to synthesize the 3,4-dihydro derivative **15** of the bicyclic sulfone **3e** (see Scheme 8). We carried out the decomposition of diphenyldiazomethane **16** (13) in the presence of 2,3-dihydrothiophene-1,1-dioxide **17** (14) both photochemically (15) and thermally (16) but unfortunately could not isolate any of the desired bicyclic sulfone **15**.

Confronted with the impossibility of readily preparing authentic bicyclic sulfone **15** for correlation, we had to rely solely on nmr to determine the structural features of bicyclic sulfone **3e**. Although the spectrum described above is perfectly clear and consistent with the structure proposed (**3e**), we nevertheless must dissipate any possibility of error in establishing the structure. In order to do so, we present in Table 1 a series of pertinent nmr values taken from our work (1*a*) and that of Zimmerman *et al.* (3*b*, 17). Inspection shows clearly that all structures originating from phenyl migration present $H_6$ as a doublet as a result of coupling with $H_1$. *No* other coupling with any other proton of the skeleton has ever been observed. Also, $H_4$ in these structures only shows coupling to $H_3$. On the other hand, it is also readily apparent that bicyclic sulfone **3e** has an nmr which is very closely related to structures originating from vinyl migration (i.e. *gem*-diphenyl compounds); indeed, in these structures, $H_4$ or $H_5$ always appears as a doublet of doublets with $J_{4,5} \simeq 2$–3 Hz.

Hence it is now clear that the bicyclic sulfone **3e** bears a *gem*-diphenyl group on carbon-6 and stems from a vinyl–vinyl (V–V) interaction in the mechanism (see path b, Scheme 2).

*Preparation of authentic 5-methoxy-4,4-diphenyl-5,6-dihydrothiopyran-1,1-dioxide (**14**)*

A sample of authentic methoxysulfone **14** was prepared by Michael-type addition (19) of methanol to the cross-conjugated sulfone **1e** (see Scheme 7). The desired compound **14** was obtained in a 30% yield after a methanolic solution of sulfone **1e** was heated to reflux for 98 h in the presence of potassium hydroxide. The authentic methoxysulfone **14** was identical in all respects to that isolated from the photolysis (see Experimental).

*Sensitization experiments*

It has long been established by Zimmerman *et al.* (2) that constrained di-π-methane systems rearranging via a π–π* excited state normally proceed through the triplet state as a more efficient pathway; reaction through the singlet is also observed but is much less efficient.[8]

In the present case and in the case of our earlier work on 4,4-diphenylpyran **1a** (1) it is to be expected, on the basis of the structure–multiplicity relationship cited above, that the systems **1a**, **1d**, and **1e** should rearrange preferably via the triplet state.

Since we have already reported, in collaboration with Durocher and co-workers (1*b*), that pyran **1a** and thiopyran **1d** have lowest triplet states of π–π* configuration and respective energies of 77.8 and 76.4 Kcal/mol, it became apparent that acetone could be a useful sensitizer to carry out these studies. Although the sulfone **1e** does not phosphoresce at 77 K it should be safe to assume that its triplet is of π–π* configuration and energy comparable to that of **1a** and **1d**.

Acetone has a triplet energy of 79–82 Kcal/mol (20, 21) which puts it slightly above the energy of the acceptors. Hence, the conditions chosen for

[8]It will be recalled that unconstrained systems rearrange via the singlet excited state because in these systems the triplets deactivate by the so-called "free rotor effect" which is more efficient than the competing di-π-methane rearrangement.

[a]This compound was reported in the literature (*4b*) but the nmr data did not seem to correspond to those of **3*e***. We therefore repeated the photolysis of 4,4-diphenylcyclohexadienone (**1*c***) (18), isolated the reported bicyclo[3.1.0]hexenone photoproduct **3*c***, mp 138–139°C (lit. (18) 140°C) and herein report its nmr.

sensitization were to use acetone as solvent and 350 nm light in Pyrex vessels. Acetone absorbs only slightly at this wavelength, but pyran **1*a***, thiopyran **1*d***, and sulfone **1*e*** do not.

In a preliminary test, however, we irradiated solutions of pyran **1*a***, thiopyran **1*d***, and sulfone **1*e*** in anhydrous ether using 350 nm lamps (Rayonet) and Pyrex vessels. It was found that **1*a*** and **1*e*** are inert while thiopyran **1*d*** reacts to give the usual products; this is most probably due to the emission of a small amount of 300 nm light by the lamp and, since thiopyran **1*d*** has an $\varepsilon = 800\ M^{-1}\ cm^{-1}$ at 300 nm (*1b*), direct excitation takes place. Attempts to filter out this stray light using a 2 in. × 2 in. 320 nm 0-transmittance filter window even prevented pyran **1*a*** in acetone as sensitizer from reacting; this was most probably due to a lack of radiation energy reaching the sample due to the small size of the

window and not to a filter effect. Be that as it may, we abandoned the idea of sensitizing the thiopyran **1***d* reaction because it could not be realized under the best unambiguous conditions.

The preparative scale sensitized photolysis of pyran **1***a* was carried out in 1:1 acetone – *tert*-butanol solution using 350 nm lamps and a Pyrex vessel. The structures of the products isolated corresponded fully to those obtained by direct photolysis (**1***a*) (see Experimental).

As stated above, due to the nonphosphorescence of sulfone **1***e* we assumed a triplet energy of 76–78 Kcal/mol and used acetone as sensitizer. The experiment was carried out using the sensitizer as solvent, 350 nm lamps, and a Pyrex vessel. The bicyclo[3.1.0] product **3***e* isolated from the reaction was identical in all respects to that isolated from the direct irradiation (see Experimental).

These sensitization experiments therefore show that the lowest $\pi$–$\pi^*$ triplet $T_1$ can be the excited state by which rearrangement takes place in pyran **1***a* and sulfone **1***e*. These results are fully in accord with the structure–multiplicity relationship scheme proposed by Zimmerman and co-workers (2). Although we have no direct experimental results to that effect, it would seem reasonable to suggest, on the basis of Zimmerman's scheme (2) and the spectroscopic and photochemical results we have in this homologous series, that thiopyran **1***d* can most probably also undergo the rearrangement via its lowest $\pi$–$\pi^*$ triplet $T_1$. These results and considerations of course do not exclude the singlet $S_1$ as responsible for the rearrangement but according to the scheme (2) it should be less efficient than the triplet.

## Discussion

The results reported above have shown that di-$\pi$-methane systems in the 4,4-diphenyl-2,5-cyclohexadiene series, where the vinyl moieties are bound by a heteroatom, rearrange to yield *phenyl migrated products via phenyl–vinyl (P–V) bonding, when the heteroatom bears unshared electrons*; this is the case for the 4,4-diphenylpyran **1***a* and thiopyran **1***d*. On the other hand, the results also show that *when the heteroatom bears no unshared electrons* as in the case of 4,4-diphenylthiopyran-1,1-dioxide **1***e*, *the rearrangement leads to a vinyl migration product (type A) via vinyl–vinyl (V–V) bonding* (see Table 2).

In an effort to broaden the scope of the discussion we will take into consideration the rearrangement results of other 4,4-diphenyl-2,5-cyclohexadiene systems which have been reported in the literature (see Table 2); these are: the thoroughly studied 1-methylene-4,4-diphenyl-2,5-cyclohexadiene (**1***b*) (3), which has been shown by Zimmerman to give phenyl migration via phenyl–vinyl (P–V) bonding in a di-$\pi$-methane rearrangement; 4,4-diphenylcyclohexadienone **1***c* (4), which has been shown by the same author to give Type A rearrangement via vinyl–vinyl (V–V) bonding; and 1-hydroxy-4,4-diphenyl-2,5-cyclohexadiene (**1***f*) (22), which has been shown indirectly (see note at bottom of Table 2) to give Type A rearrangment via vinyl–vinyl (V–V) bonding. We have also included in the table two recent cases studied by Zimmerman and Diehl (23) to determine the controlling factors governing the differing reactivity between dienone **1***c*, triene **1***b*, and its 4,4-dimethyl analog. These are: 1-dicyanomethylene-4,4-diphenyl-2,5-cyclohexadiene (**1***g*) and 1-diphenylmethylene-4,4-diphenyl-2,5-cyclohexadiene (**1***h*), which in the first case leads to $\alpha,\alpha$-dicyano-3,4-diphenyltoluene (**18**) via phenyl–vinyl (P–V) bonding, while the second leads to 2-diphenylmethylene-6,6-diphenylbicyclo[3.1.0]hex-3-ene (**3***h*) via vinyl–vinyl (V–V) bonding in a Type A rearrangement.

Finally, we have included the interesting case of 4,4-disubstituted 4-sila-2,5-cyclohexadienones (**19**) (24) which yield ring contracted cyclopentenones (**20**) via vinyl–vinyl bonding in a presumed Type A rearrangement, where the zwitterionic intermediate would undergo a nucleophilic attack from the solvent to yield the corresponding cyclopentenone **20** rather than collapse to the usual type A product, the corresponding bicyclo[3.1.0] derivative. This type of interception of the Type A rearrangement by solvent attack on the intermediate zwitterion has already been observed in other cases (25).

In order to shed light on the problem of regioselectivity in the rearrangement of these 4,4-diphenyl-2,5-cyclohexadiene systems we must try to understand the factors which control the preferred mode of $\pi$–$\pi$ interaction and, eventually, bridging as depicted in a simplified fashion in Scheme 2.

In the present case, inspection of Table 2 reveals that compounds **1***a*, **1***b*, **1***d*, and **1***g*, where X = O, C=$CH_2$, S, and C=$(CN)_2$ respectively, give phenyl–vinyl (P–V) bonding while compounds **1***c*, **1***e*, **1***f*, **1***h*, and **19**, where X = C=O, $SO_2$, CH(OH), C=$CPh_2$, and C=O respectively, give vinyl–vinyl (V–V) bonding. For the purpose of our discussion we will try to adapt Zimmerman's "reacting chromophore simulation" concept (26) to the molecules at hand bearing in mind that it was developed and used mainly for benzobarrelene and aliphatic, i.e. non-2,5-cyclohexadienic, di-$\pi$-methane systems. It is important to remember here that excitation energy tends to localize in a mini-

mum energy MO and that "electronically excited species react by pathways minimizing energy as the reaction coordinate is traversed" (23). Although both the theoretical (27) and the empirical (28) approaches have been used by the authors we will consider here the latter. To do so, we must estimate the energy of the coupled isoconjugate chromophores as the π moieties begin to interact, i.e. the various vinyl–vinyl (V–V) and phenyl–vinyl (P–V) coupled chromophores. Normally this should be done for the excited singlet chromophores and for the corresponding triplets since some reactions are efficient via the singlet while others are efficient via the triplet. Unfortunately, however, this refinement of the method cannot be applied here because too few of the required energies are available in the literature. Let us nevertheless proceed and identify these coupled chromophores; they are represented in Scheme 9.

It is readily apparent from the scheme that, while phenyl–vinyl (P–V) bonding gives rise to various β-substituted styrenes, vinyl–vinyl (V–V) bonding gives rise to a most interesting series of fundamental five-membered ring chromophores which fall

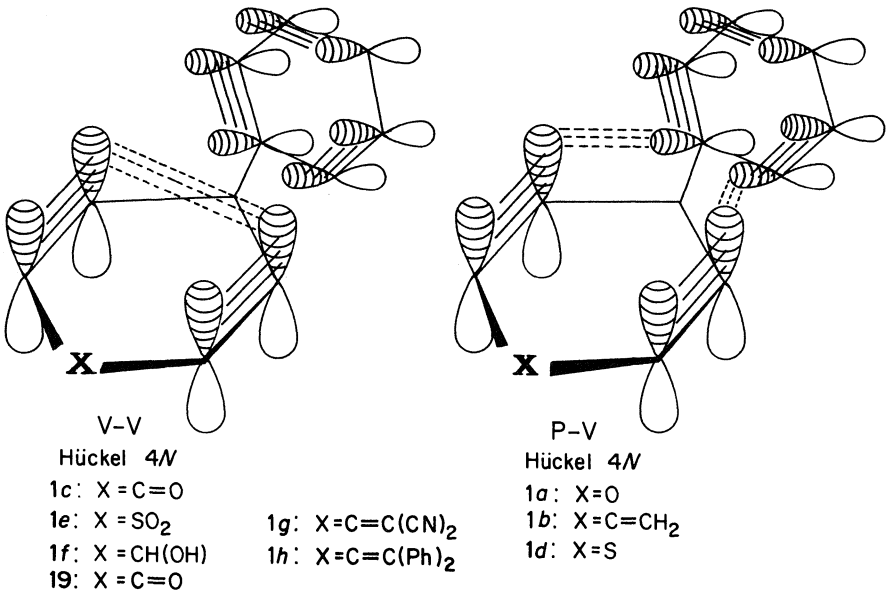

FIG. 1. Possibility of formation of Hückel arrays in V–V versus P–V coupled chromophores.

into two main categories. Firstly there are those which, according to Hückel's $4N$ vs. $4N + 2$ rule (29) or perhaps more appropriately the "Möbius–Hückel concept" developed by Zimmerman[9] (30), should show some aromatic character in the ground state and antiaromatic character in the excited state; they arise from the doubly starred compounds in Scheme 9. Secondly there are those which should show antiaromatic character in the ground state and aromatic character in the excited state; they arise from the singly starred compound in the same scheme. It is also important to note at this point that, apart from two exceptions, **1***g* and **1***h*, the V–V coupled chromophores arising from the doubly starred compounds (i.e. those that should show antiaromatic character, therefore high energy, in the excited state) correspond to an observed P–V regioselectivity and those from the starred compounds (i.e. those that should show aromatic character, therefore low energy, in the excited state) correspond to an observed V–V regioselectivity. In other words, it appears that using the Möbius–Hückel concept of aromaticity and antiaromaticity one may be able, for "*simple*" *cyclically conjugated coupled chromophores*, to evaluate the excited state energy with respect to that of the competing β-substituted styrene-coupled chromophore and thus, on the basis of energy localization, to predict the regioselectivity of the rearrangement.

Furthermore, it becomes readily apparent, upon consideration of molecular models, that phenyl–vinyl (P–V) overlap could also take place in these systems to conceivably generate another set of "*cyclically conjugated coupled chromophores*" whose excited state energies could also be evaluated using the aromaticity concept. Figure 1 illustrates in a generalized fashion the two competing interactions, i.e. V–V versus P–V, where cyclical conjugation takes place through a *p*-type lobe on X when X = O, C=$CR_2$, C=O, or S, and directly through space between lobes 2 and 5 when X = $SO_2$ or CH(OH). Some comments are, however, in order here before we proceed further with the discussion: (1) there should be no problem in applying the Möbius–Hückel concept (30) in the case of **1***a* and **1***d* since Aihara (32) has shown that Hückel's $4N + 2$ rule can still be applied to all heteroannulenes containing single heteroatoms; (2) also, cases **1***e* and **1***f* should be amenable to discussion by the same concept (30) since V–V or P–V coupling generates homoconjugated annulenes to which again Hückel's rule may be applied (32*b*); (3) finally, cases **1***b*, **1***c*, **1***g*, **1***h*, and **19**, upon V–V or P–V coupling, generate cyclic arrays of overlapping orbitals which at first glance should be treatable by the aromaticity rules above; however, Anh has pointed out the pitfalls of indiscriminately applying these rules to systems which are not monocyclic or which are generated by leaving out

[9]Dewar, using his nonbonding MO perturbation method, has arrived at the same conclusion and therefore Anh refers to the "Dewar–Zimmerman rule" (31).

For personal use only.

of the cyclic array one or more *p*-lobes (31, 33). It is therefore possible that some erroneous conclusions or predictions could be made upon simple application of Hückel's $4N + 2$ rule to these cases. It is nevertheless interesting to note that Aihara's calculations also show that the "rule" can be applied to annulenones and methylene annulenes (32).

Returning to Fig. 1, and inspecting the basis set orbitals for the cyclic Hückel arrays generated upon V–V versus P–V overlap, it can readily be seen that *when X has a* p*-lobe which contains the charge of one or more electrons, the V–V array then behaves as a 6(4*N + 2*) electron system which should be destabilized (antiaromatic) in the excited state, whereas the P–V array behaves as a 12(4*N*) electron system which should be stabilized (aromatic) in the excited state*. Therefore, it can reasonably be predicted that compounds **1***a* (X = O), **1***b* (X = C=$CH_2$), **1***d* (X = S), and **1***h* (X = C=$CPh_2$) should give preferential P–V bonding, which is the case with one exception, **1***h* (X = C=$CPh_2$), most probably attributable to the breakdown of the rule as pointed out by Anh (31, 33) because of the extended conjugation outside of the cyclic array (*vide supra*).

On the other hand, *when X has a* p*-lobe which is practically devoid of electronic charge due to polarization* such as in **1***c* (X = $C^{\delta+}$=$O^{\delta-}$), **1***g* (X = $C^{\delta+}$=$C^{\delta-}(CN)_2$, and **19** (X = $C^{\delta+}$=$O^{\delta-}$), *or when X has no* p*-lobe* as in **1***e* (X = CH(OH)) and **1***f* (X = $SO_2$), *then the V–V arrays possible* in **1***c*, **1***g*, and **19** *as well as the homoconjugated V–V arrays possible* in **1***e* and **1***f* behave as 4(4N) *electron systems which should be stabilized (aromatic) in the excited state, whereas the corresponding P–V arrays behave as 10(4*N + 2*) electron systems which should be destabilized (antiaromatic) in the excited state*. Therefore, it can reasonably be predicted that compounds **1***c*, **1***g*, **1***e*, **1***f*, and **19** should give preferential V–V bonding, which is the case, again with one exception, namely **1***g*, which, as in **1***h*, has conjugation outside of the cyclic arrays considered (*vide supra*).

In conclusion we have expanded in this work the list of 4,4-diphenyl-2,5-cyclohexadiene systems which give either di-π-methane or Type A rearrangement and have proposed a reasonable explanation for the regioselectivity observed in all but two cases, which is based on the Möbius–Hückel concept (30) of evaluating the relative energies of cyclic arrays of overlapping orbitals in competing processes. Although the proposed explanation is qualitative and will require eventual MO calculations, it has the merit of rationalizing for the first time, using a single concept, the problem of regioselectivity in the di-π-methane and dienone (Type A) rearrangements of 4,4-diphenyl-2,5-cyclohexadiene systems.

## Experimental

The silica gel used for all analytical and preparative (20 × 40 cm) tlc is of the G/UV 254 grade from Machery–Nagel. The melting points were taken on a "Büchi" apparatus and are uncorrected. The ir spectra were recorded on a Perkin–Elmer model 710-B apparatus. The routine nmr spectra were recorded either on a Varian A-60 or EM-360 model apparatus, while the high resolution spectra were taken on a JEOL 100 MHz, JNM-4H-100 apparatus. The reported chemical shifts are expressed on the δ scale in ppm and tetramethylsilane was used as internal reference. The letters s, d, t, q, and m are used as abbreviation for singlet, doublet, triplet, quartet, and multiplet. The uv spectra were recorded on a Bausch and Lomb Spectronic 505. The high resolution mass spectra were obtained on an AEI model MS-902 apparatus while the low resolution spectra were obtained on a Hitachi–Perkin–Elmer model RMU-6-D apparatus. All photolyses were carried out using a "Rayonet" photochemical reactor equipped with 16 "monochromatic" lamps emitting either at 254, 300, or 350 nm according to the case.

Finally, the reported microanalyses were done by Midwest Microlab, 6000 East 46th Street, Indianapolis, IN 46226, U.S.A.

*4,4-Diphenyl-γ-thiopyran (***1d***) (ref. 1a)*

A stirred solution of 1,1,5,5-tetramethoxy-3,3-diphenylpentane (**4**) (**1***a*, 34) (51.4 g, 0.15 mol) in 500 mL of dichloromethane is treated at room temperature by a 2:1 gaseous mixture of hydrogen chloride and hydrogen sulfide during a period of 2 h. The excess gas is flushed by a stream of nitrogen during 15 min. The solvent is then immediately evaporated and the crude 2,6-dichloro-4,4-diphenyltetrahydro-2,3,5,6-thiopyran (**5**) heated to reflux during a period of 3 h in 400 mL of *N*,*N*-dimethylaniline.

The reaction mixture is diluted with 300 mL of ether and the solution washed with 10% HCl and then with water. The organic layer is dried over anhydrous magnesium sulfate, filtered, and the solvent evaporated. The crude product obtained is purified by column chromatography over silica gel (8 cm × 80 cm) using hexane as eluent to yield 22.3 g (60%) of 4,4-diphenyl-γ-thiopyran (**1***d*) as a white solid, mp 83°C; ir ($CHCl_3$): 1600 $cm^{-1}$; uv (ethanol 95%): $\lambda_{max}$ = 240 nm (ε ≃ 1470) and $\lambda_{max}$ = 285 nm (ε ≃ 1090); nmr ($CDCl_3$): 7.20 (narrow m, 10H) and 6.00 (pair of d, AB, $J_{AB}$ = 10.5 Hz, $\Delta\nu_{AB}$ = 19 Hz, 4 H). Mass spectrum, calculated mass: 250.0815, measured mass: 250.0795.

*4,4-Diphenyl-γ-thiopyran-1,1-dioxide (***1e***)*

A solution of 4,4-diphenyl-γ-thiopyran (**1***d*) (5 g, 20 mmol) in 100 mL of carbon tetrachloride is added to a suspension of ruthenium dioxide (*n* $H_2O$) (100 mg) in 20 mL of water (5). A solution of 125 mL of 10% sodium periodate in water (58 mmol $NaIO_4$) is then added over a period of 20 min. The resulting suspension is then stirred at room temperature during 3 h. The excess of ruthenium tetroxide (formed *in situ*) is destroyed by addition of a few mL of isopropanol. A portion of 100 mL of chloroform is added to the reaction mixture which is then filtered and the organic phase separated from the aqueous phase. The latter is extracted with 2 portions of 50 mL of chloroform. The organic extracts are combined, dried over anhydrous magnesium sulfate, and the solvent evaporated to yield 5.25 g (93%) of crude product. Purification by crystallization from chloroform–hexane gives a white solid, mp 213.5–

For personal use only.

214°C; ir ($CHCl_3$): 3040, 1645, 1295, and 1115 $cm^{-1}$; uv (ethanol 95%): $\lambda_{max}$ = 235 nm ($\varepsilon \simeq 850$) and $\lambda_{max}$ = 260 ($\varepsilon \simeq 240$); nmr ($CDCl_3$): 7.35 (narrow m, 10H) and 6.70 (pair of d, AB, $J_{AB}$ = 12 Hz, $\Delta\nu_{AB}$ = 5 Hz, 4H). Mass spectrum: base peak at *m/z* 218 (M − $SO_2$). *Anal.* calcd. for $C_{17}H_{14}O_2S$: C 72.31, H 5.00, S 11.36; found: C 72.16, H 4.90, S 11.14.

*Preparative scale photolysis of* **1***d and characterization of photoproducts*

*Photolysis*

Two solutions of 500 mg of thiopyran **1***d* in 500 mL of anhydrous ether ($10^{-3}$ *M*) are irradiated at 254 nm during 2 h and the reaction monitored by tlc. The solvent is evaporated *in vacuo* without heating and the crude mixture separated on 20 preparative tlc plates using ether–hexane (1.5:98.5) as eluent. The products are extracted from the silica gel by successive washings with 75 mL anhydrous ether at room temperature.

The first fraction, 70 mg (7%), is identified as unreacted thiopyran **1***d* by nmr and tlc. The second fraction, 550 mg (55%), is identified as a mixture of 5,6-diphenyl-2-thiabicyclo[3.1.0]-3-hexene (**2***d*) and 2,4-diphenyl-(2*H*)-thiopyran (**6**) by nmr ($CDCl_3$): 7.35 (narrow m), 6.40 (pair of d, AB, $J_{AB}$ = 10.5 Hz, $\Delta\nu_{AB}$ = 11Hz), 5.80 (m), 4.85 (d, *J* = 8 Hz), and 3.70 to 2.10 (m).

*Desulfurization (7) of the photoproduct mixture* **2**d *and* **6**

A solution of the mixture of photoproducts **2***d* and **6** (480 mg, 1.9 mmol) in 200 mL of diglyme is heated to 110–115°C for 30 min in the presence of 1.5 g of commercial red mercuric oxide in the form of a fine powder (Malinckrodt). The reaction mixture is filtered and evaporated to dryness *in vacuo*. The residue is taken up with dichloromethane and separated on 10 preparative tlc plates using ether–hexane (1:4) as eluent. The silica bearing the product of $R_f$ 0.55 is scraped and washed with three portions of 125 mL of anhydrous ether to yield, after evaporation, 285 mg (63%) of a mixture of two 3,5-diphenylpentadienal stereoisomers (**8**); uv (ethanol 95%): $\lambda_{max}$ = 334 nm ($\varepsilon \simeq 18\,000$); nmr ($CDCl_3$): 10.30 (d, *J* = 8 Hz, 0.8H), 9.50 (d, *J* = 8 Hz, 0.2H), 7.72 (d, *J* = 16 Hz, 1H), 7.40 (m, 10H), 6.80 (d, *J* = 16 Hz, 1H), 6.25 (d, *J* = 8 Hz), and 6.18 (d, *J* = 8 Hz).

*Synthesis of authentic 3,5-diphenylpentadienals (8)*

*Condensation of the lithium anion of ethylidenecyclohexylamine (10) with chalcone (9)* (ref. 10)

Condensation of the lithium anion of ethylidenecyclohexylamine (**10**) with chalcone (**9**) is carried out in anhydrous ether at −78°C under argon, following the procedure of Wittig and Suchanek (10). The desired 3-hydroxy-3,5-diphenylpent-4-enylidenecyclohexylamine (**11**) is obtained as an unstable solid (64%, lit. (10) 65%) which is submitted to hydrolysis without further purification (see next procedure); nmr ($CDCl_3$): 7.68 (t, *J* ≃ 3.5 Hz, 1H), 7.33 (m, 10H), 6.46 (pair of d, AB, $J_{AB}$ = 16 Hz, $\Delta\nu_{AB} \simeq$ 10 Hz, 2H), 2.87 (d, broadened, *J* ≃ 3.5 Hz, 3H), and 1.43 (m, broad, 11H).

*Hydrolysis of 3-hydroxy-3,5-diphenylpent-4-enylidenecyclohexylamine (11) to 3,5-diphenylpentadienals (8)*

The β-hydroxy-alkylidenamine **11** from the previous experiment (10.7 g), oxalic acid (54 g, 0.6 mol), and water (250 mL) are heated to 100°C during a period of 2 h. The solution is cooled and extracted three times with 200 mL of ether. The organic layer is washed with aqueous $Na_2CO_3$, with water, dried over anhydrous magnesium sulfate, and evaporated. The crude oily product thus obtained (7.1 g) is purified by column chromatography over silica gel (5 cm × 50 cm), using ether–hexane (1:9) as eluent, to yield the desired authentic 3,5-diphenylpentadienal (**8**) as a mixture of isomers (4.25 g, 35% overall); ir ($CHCl_3$): 3040, 2750, 1660, and 1610 $cm^{-1}$; uv (ethanol 95%): $\lambda_{max}$ = 334 nm ($\varepsilon \simeq 18\,000$); nmr ($CDCl_3$): 10.18 (d, *J* = 8 Hz, 0.2H), 9.40 (d, *J* = 8 Hz, 0.8H), and 7.60 to 6.10 (m, 13H). Mass spectrum: molecular ion at *m/z* 234, loss of -CHO at *m/z* 205, tropylium ion at *m/z* 91, base peak at *m/z* 77 (probably $C_6H_5^{\cdot+}$).

*Chemical correlation of 3,5-diphenylpentadienal (8) with* trans–trans-*3,5-diphenylpentadienoic acid (12)*

*Oxidation of 3,5-diphenylpentadienals (8)*

According to the procedure of Corey *et al.* (12), silver oxide (1.22 g, 9.1 mmol) which has been freshly prepared and dried at 50°C for 30 min under 0.5 Torr, is suspended in 1.5 mL of dry methanol and treated rapidly with a solution of 3,5-diphenylpentadienal (**8**) (220 mg, 0.94 mmol) in 3 mL of methanol. A solution of sodium cyanide (231 mg, 4.7 mmol) in 12 mL methanol is then slowly added. Once the addition is completed, a solution of 0.8 mL of glacial acetic acid in 0.5 mL of methanol is added and the reaction mixture stirred for 3 h at room temperature, after which it is acidified with concentrated HCl, further stirred for a few minutes, filtered, and evaporated to dryness. The residue is taken up in 50 mL of ether and washed once with 30 mL of water. The aqueous layer is then extracted twice with 25 mL of ether; the ethereal layers are combined, dried over magnesium sulfate, and evaporated to yield 210 mg of a mixture of acid and aldehyde in a 1:1 ratio as shown by nmr; nmr ($CDCl_3$): 10.70 (s, broad, 0.5H), 10.25 (d, *J* = 8 Hz, 0.2H), 9.45 (d, *J* = 8 Hz, 0.3H), 8.70 to 6.10 (m, 12.5H), and 5.87 (s, 0.5H).

The mixture is separated by column chromatography on silica gel (2 cm × 25 cm), using chloroform–hexane (1:4) as eluent, to yield: (a) 90 mg of 3,5-diphenylpentadienal (**8**) as a mixture of isomers, *identical by nmr with the mixture of authentic 3,5-diphenylpentadienals (8) prepared above*; (b) 95 mg of crude 3,5-diphenylpentadienoic acid; recrystallization from dichloromethane–hexane yields the pure *trans-trans* acid **12**, mp 145–146°C, *identical with an authentic sample (mp 145–146.5°C) prepared as described below, mixture mp 145–146°C*; nmr ($CDCl_3$), see below.

*Preparation of authentic* trans–trans-*3,5-diphenylpentadienoic acid* **12**

trans–trans-*Ethyl-3,5-diphenylpentadienoate (13)* (ref. 11)

The title compound **13** is obtained, following the procedure of Bergman and Solomonovici (11), by treating chalcone (**9**) (4.16 g, 0.02 mol) with the anion of triethylphosphonoacetate. The crude oily product (5.61 g) obtained could not be separated by vacuum distillation and was therefore chromatographed on silica gel (5 cm × 50 cm) using chloroform–hexane (1:4) as eluent to yield pure *trans-trans*-ethyl-3,5-diphenylpentadienoate (**13**) (1.10 g, 20%, lit. (11) 52%); nmr ($CDCl_3$): 8.58 (d, AB, $J_{AB}$ = 16 Hz, $\Delta\nu_{AB}$ = 117 Hz, 1H), 7.40 (narrow m, 10H), 6.61 (d, AB, $J_{AB}$ = 16 Hz, $\Delta\nu_{AB}$ = 117 Hz, 1H), 5.83 (s, 1H), 4.27 (q, *J* = 7 Hz, 2H), and 1.33 (t, *J* = 7 Hz, 3H).

trans–trans-*3,5-Diphenylpentadienoic acid (12)* (ref. 11)

Saponification of the above ester **13** (160 mg, 0.58 mmol) using KOH in 95% ethanol yields, after work-up and recrystallization from dichloromethane–hexane, pure *trans-trans*-3,5-diphenylpentadienoic acid (133 mg, 93%), mp 145–146.5°C (lit. (11) mp 145°C); ir ($CHCl_3$): 3500–2500, 1680, and 1610 $cm^{-1}$; nmr ($CDCl_3$): 12.18 (s, 1H), 8.50 (d, AB, $J_{AB}$ = 16 Hz, $\Delta\nu_{AB}$ = 111 Hz, 1H), 7.45 (narrow m, 10H), 6.63 (d, AB, $J_{AB}$ = 16 Hz, $\Delta\nu_{AB}$ = 111 Hz, 1H), and 5.86 (s, 1H): Mass spectrum: molecular ion at *m/z* 250, loss of -OH at *m/z* 233, loss of -$CO_2$H at *m/z* 205 (base peak), tropylium at *m/z* 91, $C_6H_5^{\cdot+}$ at *m/z* 77.

*2,3-*cis*-4,5-*trans*-3,5-Diphenylpentadienoic acid*

It is possible to obtain the 2,3-*cis* isomer of the acid **12** simply by recrystallizing the crude saponification product above in a minimum of hot hexane. This procedure was repeated and the pure 2,3-*cis* isomer was obtained, mp 160–162°C; ir ($CHCl_3$):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

3600–2500, 1670, and 1610 $cm^{-1}$; nmr ($CDCl_3$): 11.76 (s, 1H), 7.36 (m, 10H), 7.06 (d, AB, $J_{AB}$ = 16 Hz, $\Delta\nu_{AB}$ = 39 Hz, 1H), 6.36 (d, AB, $J_{AB}$ = 16 Hz, $\Delta\nu_{AB}$ = 39 Hz, 1H), and 6.05 (s, 1H). Mass spectrum: molecular ion at *m/z* 250, loss of -OH at *m/z* 233, loss of $-CO_2H$ at *m/z* 205 (base peak), tropylium at *m/z* 91, $C_2H_5^{\cdot+}$ at *m/z* 77.

*Preparative scale photolysis of* 1e *and characterization of photoproducts*

*Photolysis*

A solution of 500 mg of the thiopyran-1,1-dioxide **1e** in 500 mL of methanol ($3.5 \times 10^{-3}$ *M*) is irradiated during 1 h at 254 nm and the reaction monitored by tlc. The solvent is evaporated *in vacuo* and the crude product mixture separated on 10 preparative tlc plates using dichloromethane–hexane–acetone (15:9:1) as eluent. Three major products are thus obtained: (a) unreacted starting sulfone **1e** (52%); (b) a solvent addition product, 5-methoxy-4,4-diphenyl-5,6-dihydrothiopyran-1,1-dioxide (**14**) (13%), which is obtained as a mixture with starting material and purified by crystallization in dichloromethane–hexane, mp 161–162.5°C; ir ($CHCl_3$): 3040, 2960, 1600, 1300, 1125, and 1085 $cm^{-1}$; nmr ($CDCl_3$): 7.26 (narrow m, 10 H), 6.46 (s, 2H), 4.67 (dd, $J_1 \simeq 11.5$ Hz, $J_2 \simeq 2.5$ Hz, 1H), 3.33 (s), and 3.53–2.93 (s and m, 5H). Mass spectrum: no molecular ion present at *m/z* 314, loss of $CH_3OH$ and $SO_2$ at *m/z* 218, loss of $CH_3OH + SO_2 + C_2H_2$ at *m/z* 192 (base peak).

This material was identical in all respects (nmr, ir, mixture mp) to an authentic sample prepared as described further below. (c) The third fraction isolated was purified by crystallization from dichloromethane–hexane, mp 210°C (dec.), and identified as 6,6-diphenyl-2-thiabicyclo[3.1.0]-3-hexene-2,2-dioxide (**3e**) (15%); nmr ($CDCl_3$); 7.25 (narrow m, 10H), 6.88 (dd, $J_{3,4} \simeq 6.5$ Hz, $J_{4,5} \simeq 3.0$ Hz, 1H), 6.16 (dd, $J_{3,4} \simeq 6.5$ Hz, $J_{1,3} \simeq 1.5$ Hz, 1H), 3.49 (dd, $J_{3,4} \simeq 6.5$ Hz, $J_{1,3} \simeq 1.5$ Hz, 1H), and 3.29 (dd, $J_{1,5} \simeq 6.5$ Hz, $J_{4,5} \simeq 3$Hz, 1H). Mass spectrum: very weak molecular ion peak at *m/z* 282, loss of $SO_2$ at *m/z* 218, loss of $HSO_2$ at *m/z* 217 (base peak). *Anal.* calcd. for $C_{17}H_{14}O_2S$: C 72.31, H 5.00, S 11.36; found: C 72.00, H 5.11, S 11.20.

*Preparation of authentic 5-methoxy-4,4-diphenyl-5,6-dihydrothiopyran-1,1-dioxide (14)*

A solution of 500 mg of 4,4-diphenylthiopyran-1,1-dioxide (**1e**) in 100 mL of anhydrous methanol is heated to reflux for 98 h in presence of five KOH pellets and under a nitrogen atmosphere. The mixture is diluted with 75 mL of chloroform and 75 mL of water; the two phases are separated and the aqueous layer extracted with 150 mL of chlorform. The organic extracts are combined, dried over anhydrous magnesium sulfate, and evaporated to dryness. The desired β-methoxysulfone (**14**) is formed in a 30% yield as shown by nmr. Three successive recrystallizations from dichloromethane–hexane yield pure authentic 5-methoxy-4,4-diphenyl-5,6-dihydrothiopyran-1,1-dioxide (**14**), mp 161–162.5°C, identical in all respects to the solvent addition photolysis product; mixture mp 161°C. The nmr and ir are identical to those of the photolysis product, see above.

*Preparation of authentic 6,6-diphenylbicyclo[3.1.0]-3-hexene-2-one (3c)* (ref. 18)

A solution of 500 mg of 4,4-diphenylcyclohexadienone (**1c**) (4) in 100 mL of anhydrous ether ($2.03 \times 10^{-2}$ *M*) is irradiated during 75 min at 300 nm. The photolysis mixture is separated on 10 preparative tlc plates and eluted with chloroform. This separation yields 270 mg of a mixture of starting dienone (**1c**) (45%) and bicyclic enone **3c** (55%), both having the same $R_f$ under these conditions. Recrystallization from dichloromethane–hexane yields the desired authentic 6,6-diphenylbicyclo[3.1.0]-3-hexene-2-one (**3c**), mp 135–138°C; sublimation at 110°C under 0.15 Torr gives mp 138–139°C (lit. (18) mp 140°C); ir ($CHCl_3$): 3065 and 1690 $cm^{-1}$. The nmr ($CDCl_3$) is less well resolved than that reported and this was the reason for preparing an authentic sample following the published procedure (4); nmr ($CDCl_3$): 7.41 (dd, $J_1 \simeq 2.5$ Hz, $J_2 \simeq 6.3$ Hz, 1H), 7.20 (narrow m, 5H), 7.17 (narrow m, 5H), 5.55 (d, $J \simeq 6.3$ Hz, 1H), 3.24 (dd, $J_1 \simeq 2.5$ Hz, $J_2 \simeq 5$ Hz, 1H), and 2.81 (d, $J \simeq 5$ Hz, 1H). These data are fully in accord with the published structure **3c**.

*Sensitized photolyses in acetone*

*Preliminary qualitative sensitized photolyses of pyran* 1a, *thiopyran* 1d, *and sulfone* 1e

The irradiation in a Pyrex vessel of 10 mg portions of compounds **1a**, **1d**, and **1e**, in 10 mL of anhydrous ether and using 350 nm light, shows that after 5 h of irradiation pyran **1a** and sulfone **1e** do not react and therefore do not absorb light, while thiopyran **1d** reacts and therefore absorbs light under these conditions. In the case of **1a** and **1d** the reaction is monitored by tlc on silica gel using ether–hexane (3:97) as eluent, while in the case of **1e** the eluent was dichloromethane–hexane–acetone (15:9:1).

*Preparative sensitized photolysis of 4,4-diphenylpyran (1a) in acetone*

A solution of 500 mg of title compound **1a** in 400 mL ($5.2 \times 10^{-3}$ *M*) of a 1:1 mixture of acetone and *tert*-butanol is distributed in sixteen 30 mL Pyrex tubes and irradiated during 20 h using 350 nm light. The solvent is evaporated and the residue taken up in 25 mL of anhydrous ether. The later is treated with an ethereal solution of diazomethane, prepared from Diazald (Aldrich), until the evolution of nitrogen has ceased. The excess reagent is destroyed by the addition of 2–3 drops of glacial acetic acid. The resultant ethereal solution is washed with 10% aqueous NaOH, with water, dried over magnesium sulfate, and evaporated to dryness. The residue is separated on 5 preparative tlc plates by eluting twice with ether–hexane (6:94). This procedure allows the recovery of the following two products, which we have reported earlier (1*a*) in the unsensitized photolysis, with the exception that in the present case the mixture of photoacids is obtained as methyl esters. (a) 3,5-Diphenylpentadienal (**8**), mixture of isomers. This material was identical in all respects with the compound which we obtained from the direct photolysis (1*a*) and also with the authentic material (**8**) reported herein (*vide supra*). (b) *trans*-Methyl-3,5-diphenylpent-2-enoate, isolated in the form of a clear oil, identical (tlc, ms, and nmr) with an authentic sample prepared as described below.

*Preparation of authentic* trans*-methyl-3,5-diphenylpent-2-enoate*

A solution of *trans*-ethyl-3,5-diphenylpent-2-enoate (1*a*) (840 mg, 3 mmol) in 10 mL of methanol, previously treated with 25 mg of sodium metal, is heated to reflux over molecular sieves 4A for a period of 24 h. After evaporation of the solvent, the residue is taken up in ether; the latter is washed with water, dried over anhydrous magnesium sulfate, filtered, and evaporated to yield 800 mg (100%) of authentic *trans*-methyl-3,5-diphenylpent-2-enoate in the form of a clear oil; nmr ($CDCl_3$): 7.36 (narrow m, 5H), 7.16 (narrow m, 5H), 6.03 (s, 1H), 3.70 (s, 3H), and 3.53–2.56 (m, AA'MM' portion of a AA'MM'X system, 4H). Mass spectrum: molecular ion at *m/z* 266, loss of $-OCH_3$ at *m/z* 235, loss of $CH_3OH$ at *m/z* 234, loss of $-CO_2CH_3$ at *m/z* 207, tropylium ion at *m/z* 91 (base peak).

*Preparative sensitized photolysis of 4,4-diphenylthiopyran-1,1-dioxide (1e)*

A solution of 500 mg of the title compound **1e** in 400 mL of "Spectrograde" acetone ($3.9 \times 10^{-3}$ *M*) is distributed in sixteen 30 mL Pyrex tubes and irradiated during 20 h using 350 nm light.

The solvent is evaporated and the residue separated on 5 preparative tlc plates eluting with dichloromethane–hexane–acetone (15:9:1) to yield the previously characterized (*vide supra*) 6,6-diphenyl-2-thiabicyclo[3.1.0]-3-hexene-1,1-dioxide (**3***e*) as a solid, mp 210°C (dec.), after recrystallization from dichloromethane–hexane. The nmr, in this case obtained on a Brucker Spectrospin 90 MHz apparatus using a $^1H$ probe and Fourier transform, and the mass spectra were identical in all respects with those of compound **3***e* isolated in the direct photolysis (*vide supra*).

# Optical and Raman spectra of single crystals of perylene-TCNQ charge transfer complexes

A. D. BANDRAUK,[1] K. D. TRUONG,[1] AND C. CARLONE[2]

*Groupe de recherche sur les semiconducteurs et diélectriques, Faculté des Sciences, Université de Sherbrooke, Sherbrooke, P.Q., Canada J1K 2R1*

Received August 12, 1981

A. D. BANDRAUK, K. D. TRUONG, and C. CARLONE. Can. J. Chem. **60**, 588 (1982).

Optical transmission and reflection measurements are reported for the quasi one dimensional solids perylene-TCNQ (P1T1) and (perylene)$_3$-TCNQ (P3T1) in the region from 300 to 1200 nm. Raman spectra of single crystals of both compounds were obtained from 20 to 3000 cm$^{-1}$. With 457.9 nm excitation, combinations and overtones of perylene are observed for the first time. A complete Raman spectrum of perylene and its deuterated homologue including librations is thus obtained via selective resonance enhancement of that molecule.

A. D. BANDRAUK, K. D. TRUONG et C. CARLONE. Can. J. Chem. **60**, 588 (1982).

On rapporte les mesures de transmission optique et de réflexion des solides quasi unidimensionnels pérylène-TCNQ (P1T1) et (perylène)$_3$-TCNQ(P3T1), dans la région allant de 300 à 1200 nm. On a obtenu les spectres Raman d'un monocristal des deux composés de 20 à 3000 cm$^{-1}$. Grâce à une excitation à 457,9 nm, on a pu observé pour la première fois les combinaisons et les harmoniques du pérylène. On a alors obtenu un spectre Raman complet du pérylène et de son homologue deutéré incluant les librations par l'intermédiaire d'une augmentation sélective de la résonance de la molécule.

[Traduit par le journal]

## I. Introduction

Compounds involving the molecule tetracyanoquinodimethane (TCNQ) are of current interest to solid state physicists, chemists, and materials scientists because they exhibit remarkable physical properties (1). In this work we study the optical properties of the compounds formed between TCNQ and perylene. At present, two such compounds are known to exist: perylene-TCNQ and (perylene)$_3$-TCNQ denoted as P1T1 and P3T1 respectively. From X-ray work (2), the former belongs to the class of one dimensional compounds in which the donor (perylene) and acceptor (TCNQ) alternate along one crystal axis in a monoclinic lattice. Some optical properties (3, 4), an infrared spectrum (3) and a partial Raman spectrum (5) of the powders in KBr pellets have been studied. The P3T1 compound has only been recently synthesized (3). Its structure is now known from the X-ray work (6). It seems appropriate to describe its structure as unidimensional chains of units of $P_2T$ intercalated by single perylene molecules in a triclinic lattice, Fig. 1. Some optical, infrared, and partial Raman spectra were reported simultaneously with P1T1 powders (3–5) from KBr measurements.

Both compounds are known to have very low electric conductivities (7, 8) ($< 10^{-9}$ ($\Omega$ cm)$^{-1}$) and are therefore classified as insulators since their ground state is neutral whereas the first electronic excited state is a charge transfer (CT) band (1, 9).

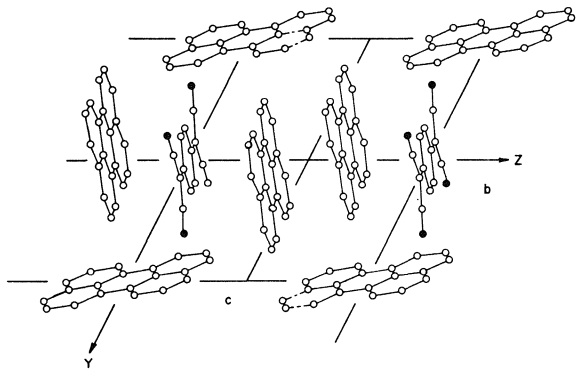

FIG. 1. Disposition of perylene and TCNQ molecules in the *bc* (*zy*) crystal plane of the P3T1 complex.

Since single crystal optical studies were lacking on these two systems, we present here detailed *polarization* transmission and reflection measurements on P1T1 crystals and polarized reflection measurements on P3T1 crystals. This enabled us to establish precisely the polarization of the electronic absorption bands present in these two solid compounds. Finally, the Raman spectra of single crystals of both complexes are also investigated. By working with individual surfaces and at lower temperatures, resolution was significantly increased. We thus report more Raman transitions, including previously undetected overtones and combinations of perylene and deuterated perylene molecules ($P_d$) in P3T1. This second order spectrum is readily excited with a 457.9 nm laser line. It is worth noting that the complexed perylenes do not fluoresce at

this and other laser frequencies, as opposed to pure solid perylene for which a resonant Raman spectrum is impossible to obtain (10). The present single crystal work allowed the investigation of the Raman spectrum down to $20\,cm^{-1}$, i.e., in the region of molecular librations. This work is partly motivated by the recent discovery that under pressure, neutral organic CT complexes such as those studied here can undergo reversible phase transitions to an ionic ground state (11). The present detailed spectroscopic study of perylene TCNQ complexes should contribute to a better understanding of these and other organic materials.

## II. Experimental

The method of compound preparation and of crystal growth has been given (3, 5).

The P1T1 crystals were needle shaped, between 3 and 10 mm long. For the optical measurements, several crystals were shattered in order to make them thinner. One such fragment, about 50 μ long and about 5 μ thick was used for the transmission and reflection measurements in Figs. 2 and 3.

The P3T1 crystals were much larger, about 2 × 3 × 4 mm. Several of the crystals grew into the shape of the unit cell, i.e. well-defined parallelepipeds. It was impossible to obtain transmission measurements as the crystals were too thick, but we took normal incidence reflection. The neutral perylene band at 450 nm was always found on the two larger surfaces, but never on the smaller one. Similarly, the second order Raman spectrum of the neutral perylene molecule appeared on the same two larger surfaces, but never on the smaller one. The axes were identified this way.

The electronic spectra were taken on Nanometer Spectrometers. In the visible, the Nano Spec/105 had a resolution of 1 nm, and in the infrared the Nano/IONIR had a resolution of 2 nm. The equipment used to obtain the Raman spectrum is standard and has been described previously in our KTCNQ work (12). All spectra were taken at 90° scattering. Excitation was via a Spectra Physics Model 170 Argon in laser. A Jobin-Yvon Ramanor HG2S monochromator equipped with a scrambler was used for spectral analysis.

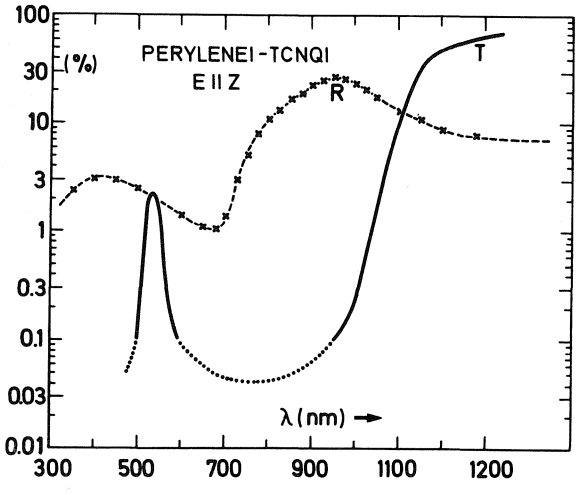

FIG. 2. Polarized transmission (T) and reflection (R) spectra of P1T1 single crystals along the $z$ axis (stacking axis).

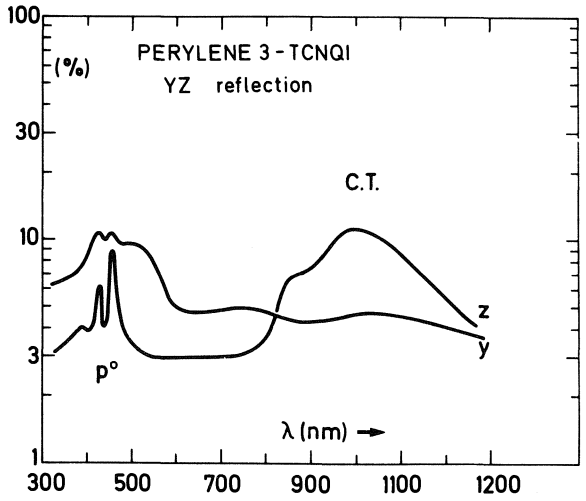

FIG. 3. Polarized reflection spectra of P3T1 single crystals along the $yz$ surface, $z(y)$ is direction of incidence and reflection.

## III. Optical data

In planar molecules, those transitions between states composed of linear combinations of π orbitals perpendicular to the plane of the molecule have their transition moment in the plane of the molecule, and this moment can be resolved into the long axis (LA) or short axis (SA) component. Charge transfer bands, in which the electron hops from the donor planar molecule to the acceptor planar molecule, have their moments perpendicular to the planes. The planes of the molecules are usually not exactly perpendicular to the crystal axis. In P1T1, the angle is 86° (2), so that one can distinguish the nature of the transitions by orienting the exciting field parallel or perpendicular to the axis. Thus, one sees from Fig. 2 where the incoming and outgoing field is parallel to the axis, that there are two parallel electronic bands (with respect to the crystal axis). The reflectivity peaks occur at 410 and 950 nm. The first occurs in the region of the in-plane-polarized electronic absorptions of TCNQ and perylene (13, 14) and probably is a second charge-transfer band. The high reflectivity at 950 nm for the parallel band is established as due to the first CT band in P1T1 since no such absorption occurs in isolated molecules (3). The polarization of this band determines therefore the stacking axis ($z$ axis), perpendicular to the molecular planes.

In the case of P3T1 complex (Fig. 3) we see that the maximum in the CT band is shifted to 1000 nm

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

with a weak shoulder at 900 nm. A more complicated structure must be expected since now two perylenes interact with one TCNQ. Again, following the crystal axis designations in Fig. 1, the stacking axis ($z$ axis) for the $P_2T$ units was thus determined for any crystal. The sharp reflection peaks in the 450 nm region are readily attributed to the isolated perylenes, denoted by $P^0$, which are parallel to the $z$ axis and hence perpendicular to the $P_2T$ units (6). Based on these and other surface polarization measurements, we were able to assign appropriate crystal surfaces following the axis notation in Fig. 1. Thus a $yz$ surface contains flat isolated perylenes ($P^0$) and $P_2T$ units perpendicular to it, so that reflection along the $y$ axis (Fig. 3) exhibits the peaks of the free perylenes ($P^0$) excited along their short axis (SA) and a broad spectrum from the $P_2T$ units which are excited along their long axis (LA). In Table 1, we present the various molecular transitions excited depending on the polarization of the exciting and emitted light. These results will be used to analyse the polarized Raman spectra presented below.

## IV. Raman spectra

### *(a) High frequency modes*

We present in Fig. 4 the frequency dependence of the Raman spectrum of intramolecular modes in the region 1000–2200 $cm^{-1}$ for single crystals of P1T1 and $P_d$1T1 where $P_d$ is deuterated perylene. The spectra in both figures correspond to $\rho\rho$ polarization where $\rho$ stands for either $x$ or $y$, (i.e. perpendicular to the stacking axis and therefore essentially in-plane with the molecular axes). Measurements done for $zz$ polarization, (i.e., perpendicular to the molecular axes) gave the same frequency dependence but with much weaker signals as expected. As in the case of our previous powder spectra taken in KBr (5), there is a selective enhancement of the perylene vibrations as one increases the argon laser frequency. Comparing with the KBr results we note that firstly, one obtains better resolution for single crystals. Thus, the 1454 $cm^{-1}$ C=C stretching vibration (15) of TCNQ always appears as a doublet in the single crystals of both compounds. This structure was suppressed in the powder spectra. Furthermore, it was found from the KBr work that the perylene vibrations were much more intense than the TCNQ modes at 457.9 nm excitation. For the isolated crystals this effect is less pronounced, both intensities being comparable at this excitation for the perylene and deuterated perylene complexes. Since this was surface dependent, the KBr results represent an orientational average of the polarization dependent intensities in the single crystal. It is worth noting that the vibrational frequencies are unshifted, in the single crystals and KBr, since the ground state is neutral and very little perturbed by environments.

We made the same measurements on P3T1 and $P_d$3T1 crystals and reached the same conclusion in so far as the first-order spectrum is concerned. Thus in Fig. 5 we represent the frequency dependence of the Raman spectra of the intramolecular modes of P3T1 in single crystals form for $yy$ polarization. From Table 1 and Fig. 1, this polarization corresponds to exciting neutral perylenes $P^0$ along their short axis (SA) and the $P_2T$ units along their long axis (LA). Measurements for $xx$ polarizations showed only TCNQ vibrations, indicating from Table 1 that perylene excitation along their short axis is negligible. Thus the spectra in Fig. 5 correspond essentially to the $P_2T$ units. Since there are twice as many perylenes as compared to P1T1 the resonance effects for perylene are much more important than for the monometric units, Fig. 3. Furthermore, a triplet structure appears well defined for the perylene vibrations at 1299 and 1568 $cm^{-1}$ and a doublet at 1366 $cm^{-1}$. Measurements were done at low temperatures to obtain better resolution for the frequencies reported in Tables 2 and 3. Measurements of scattering with $zz$ polarization corresponding to excitation of $P^0$ (LA) only (Table 1) showed the *same* frequencies and splittings. We thus conclude that the uncomplexed perylene, $P^0$, and the complexed perylene P, are indistinguishable in frequencies as far as Raman spectra are concerned. This is in agreement with the conductivity measurements (8) which indicate a neutral covalent group state for P1T1 and P3T1 compounds. It is worth noting that the deuterated perylene shows an isotopic intensity effect when comparing the equal perylene triplet in Fig. 5*a* to the equivalent unequal triplet in Fig. 5*b* for the deuterated perylene.

Since the P3T1 compound gave a strong resonant Raman spectrum for the perylene as compared to the usual fluorescence of pure perylene in the

TABLE 1. Expected optical transitions from the (perylene)$_3$-TCNQ surfaces*

| Surface | Electric field direction | Transition excited |
|---|---|---|
| $yz$ | $y$ | $P^0$ (SA), T (LA), P (LA) |
| | $z$ | $P^0$ (LA), CT |

457.9 nm excitation region (10), we observed many overtones and combinations of perylene at that excitation frequency. This is the first observation of these frequencies in perylene. We show the complete spectra in Fig. 6, where we show two different temperature measurements to ascertain that the lines in $P_d$3T1 at 1020 and 1212 $cm^{-1}$, Table 3, were actually *difference* vibrations, i.e., $\nu = \nu_1 - \nu_2$ where $\nu_2$ is a low frequency vibration excited thermally with negligible population at low temperatures. This explains the temperature dependence of these two lines and their frequencies. The same phenomenon was observed at 2375 $cm^{-1}$ ((2 × 1537) − 340) and at 2570 $cm^{-1}$ (1550 + 1357 − 340) in Fig. 6*b*. Assignments are made in Tables 2 and 3 from the known frequencies of the now well-established fundamentals of TCNQ (15) and perylene (5, 10). We remark that this overtone spectrum was not obtainable at reasonable laser powers for P1T1 crystals. Furthermore, this second order spectrum was excited *mainly* on the *yz* surface, for which all perylenes have their long axis in the direction of the external field. Finally, no TCNQ second order spectrum was observed at 457.9 nm, indicating once more the high selectivity of this resonance effect.

The sharpening of these broad overtones and combinations as a function of temperature are indicative of a second order spectrum since if the two phonons involved have opposite momentum, each phonon's wave vector spans the entire Bril-

louin zone (16). Phonon scattering will decrease at lower temperatures, thus inducing sharper lines.

*(b) Low frequency modes*

The selective resonance scattering from the perylene and deuterated perylene molecules at the laser wavelength of 457.9 nm was also used to identify the low frequency modes of these molecules, Figs. 6 and 7. Thus, the sharp lines at 37 and 65 $cm^{-1}$ in both compounds decrease rapidly in intensity with increasing laser frequency and are easily attributed to TCNQ as for solid TCNQ (15). The line at 110 $cm^{-1}$ is weak in both solid perylene (10) and solid TCNQ (15). The most interesting features are the two lines at 195 (189) and 227 (209) $cm^{-1}$ where the frequencies in parentheses correspond to $P_d$. The 195 $cm^{-1}$ was found to be very weak in pure perylene and the other line was not detected (10). Considering the appearance of overtones of the higher frequency modes at 457.9 nm excitation, Fig. 6, we assign these last two lines as overtones and combinations of low frequency modes of perylene, Table 4. The nature of these modes remains to be established. From the crystal structure, Fig. 1, each TCNQ has $C_i$ site symmetry, so that we can expect $3A_g$ librations and no translation in the Raman spectrum for these molecules (15). For the perylene molecules we have two different site symmetries. The free molecules, $P^0$, are at $C_i$ sites and therefore give $3A_g$ librations as TCNQ. The P molecules in the $P_2T$ units are at $C_1$ sites and will give $3A_g$ librations and $3A_g$ translations each. The moments of inertia of the TCNQ molecule are respectively 0.8 ($I_x$), 2.6 ($I_y$), and 3.3 ($I_z$) $\times 10^{-37}$ g $cm^2$ where *z* is perpendicular to the molecular plane. For perylene, these are 1.33 ($I_x$), 3.25 ($I_y$), and 3.99 ($I_z$) $\times 10^{-37}$ g $cm^2$. Thus for isotropic librations, the assignments of three TCNQ librations at 75, 96, and 155 $cm^{-1}$ agrees reasonably with the ratio of the reciprocals of the square roots of the moments, i.e., 1:1.2:2. For perylene, this ratio should be 1:1.1:1.75. The assignments in Table 4 agree qualitatively with this ratio. Due to the similarity in values of the $I_y$ and $I_z$ moments, for T and P, there will be considerable overlap of lines and the assignments cannot be absolute. With this in mind, we present also in Table 4 frequencies of phonons we obtained for pure TCNQ and pyrene-TCNQ crystals. All these low frequency modes belong to TCNQ as no pyrene vibrations were observed at 457.9 nm excitation. Considerable overlap is seen to occur between perylene and TCNQ librations in the 70–85 $cm^{-1}$ region and the 100–110 $cm^{-1}$ regions, so that these modes must be

†This mode is very weak at 37 K and increases with temperature.

strongly coupled. In addition, there may be some mixing with low frequency internal modes as has been suggested recently (18).

## Conclusion

We have presented above optical and Raman spectra of single crystals of P1T1 and P3T1. The optical electronic spectra enabled us to establish the polarization axes in the crystals, so that in the case of P3T1 we were able to infer which perylenes are excited. Raman spectra as a function of excitation frequency show that perylene and its deuterated analogue show selective resonance enhancements at 457.9 nm. In fact, at this wavelength we have obtained for the first time overtone and combination spectra of P and $P_d$ (deuterated). Combinations and overtones were also observed for the librations of perylene in P3T1. Polarization studies of the Raman spectra show that the free perylene and the complexed perylene in P3T1 are indistinguishable in frequencies so that P–T interactions must be very weak. The polarized optical spectra were essential for the differentiation of the excitation of these two different perylenes.

These results should be very useful in studying the pressure dependence of the neutral to ionic phase transition thought to occur in these and similar organic materials. Thus by increasing the pressure along the $P_2T$ stacking axis ($z$ axis, Fig. 1), one should observe a gradual change in the properties of complexed perylenes as opposed to the free molecules. Such measurements are now in progress as well as temperature dependent measurements of the frequencies and widths of the low frequency modes in order to understand the lattice dynamics of these interesting organic materials.

# Carbon-13 nuclear magnetic resonance studies of organotellurium compounds. II. Chemical shift trends

RAJ. K. CHADHA AND JACK M. MILLER

*Chemistry Department, Brock University, St. Catharines, Ont., Canada L2S 3A1*

Received July 21, 1981

RAJ. K. CHADHA and JACK M. MILLER. Can. J. Chem. **60**, 596 (1982).

$^{13}C$ nmr chemical shifts are reported for some aromatic and aliphatic tellurium compounds. For a given organic group, the shift of the $C^1$ atom varies in the order $RTeCl_4^- \gtrsim RTeCl_3 > R_2TeCl_2 > R_2Te > R_2Te_2$, as expected from electronegative considerations. The $C^2$ atom experiences an opposite trend while the $C^3$ and $C^4$ atoms of the ring experience smaller changes. The chemical shifts of *para*-substituted aromatic tellurium compounds do not show additivity of contributions from the substituents.

RAJ. K. CHADHA et JACK M. MILLER. Can. J. Chem. **60**, 596 (1982).

On rapporte les déplacements chimiques en rmn du $^{13}C$ de quelques composés aromatiques et aliphatiques du tellure. Pour un groupe organique donné, le déplacement de l'atome $C^1$ varie dans l'ordre $RTeCl_4^- > RTeCl_3 \gtrsim R_2TeCl_2 > R_2Te > R_2Te_2$ que l'on peut prévoir sur la base de considérations d'électronégativité. L'atome $C^2$ subit une tendance inverse alors que les atomes $C^3$ et $C^4$ ne subissent que de faibles changements. Les déplacements chimiques des composés aromatiques du tellure substitués en para ne présentent pas de contributions d'additivité de la part de ces substituants.

## Introduction

$^{13}C$ chemical shift measurements have been found to reflect total carbon atom electron density and, therefore, they have been particularly useful as probes for the study of organometallic compounds. In recent years there have been many publications on $^{13}C$ nmr studies of organometallic compounds (1–4). However, the available data on tellurium compounds are limited compared with those for sulphur and selenium compounds (5–14). We have recently reported our studies on $^{13}C$ nmr spectra of phenyl and *p*-methoxyphenyl tellurium compounds (15). We now report here $^{13}C$ chemical shift data for *p*-phenoxy, *p*-methyl, *p*-chloro, and *p*-bromo phenyl tellurium compounds and some aliphatic tellurium compounds.

## Results and discussion

$^{13}C$ chemical shifts are recorded in Table 1. Assignments of the aromatic signals were based on previous studies (8, 15). The assignments in compounds of the type RR'Te and $RR'TeCl_2$ were made by comparison with assignments in $R_2Te$, $R'_2Te$, and their dichlorides. Where the C signals from R and R' are close together, the assignment should be considered tentative. Assignments of aliphatic signals were made by comparison with assignments in closely related compounds (16).

Examination of Table 1 reveals that the effect of change in tellurium substituent is most strongly observed at $C^1$, to which the tellurium is directly attached, less so at $C^2$ (*ortho*) and $C^4$ (*para*), and least at $C^3$ (*meta*). Plots of the shifts of $C^1$ (tellurium compound) versus $C^1$ (carbon *para* to X in $C_6H_5X$) (Fig. 1) for these compounds show a general linear correlation ($r = 0.99$) with a slope of 1.4. For a given organic substituent, $C^1$ chemical shifts vary according to the number of chlorine atoms attached to tellurium, $RTeCl_4^- \gtrsim RTeCl_3 > R_2Te > R_2Te_2$. On going from tetrachloroaryltellurates to ditellurides, there is a decreasing positive charge on tellurium which corresponds to a decrease in the polarity of the Te—C bond. Magnetic anisotropic effects originating in the tellurium substituents are not expected to vary much in this closely related series; moreover, they are expected to be small (8). Thus the polarity of the C—Te bond appears to have the largest effect on the $C^1$ resonance. $C^1$ chemical shifts of compounds **1**, **2**, **6**, **7**, and **20** are also dependant upon the inductive effect of $—NEt_2$ and $—CH_2COCH_3$.

Figure 1 also shows that there is a linear relationship between $\delta C^2$ (aromatic tellurium compounds) and $\delta C^2(C_6H_5X)$ with a slope of 1.9. For a particular R, $\delta C^2$ changes in the opposite direction, i.e., $RTeCl_4^- \simeq RTeCl_3 < R_2TeCl_2 < R_2Te \simeq R_2Te_2$. A similar curve for $C^4$ signal gives a slope of 1.0.

The substituent shifts ($\Delta\delta^{13}C$ values) are calculated by using $\delta^{13}C$ values for aromatic hydrocarbons obtained on the same instrument under similar experimental conditions and are recorded in parentheses in Table 1. The use of $\Delta\delta^{13}C$ *para* values as a probe for understanding the $\pi$ inductive effects of the substituents in aromatic rings has been very well established (4, 17). The generally upfield shift of $\Delta\delta^{13}C^4$ in the case of diaryl tellurides and ditellurides suggests that $C^4$ in the Te derivative is shielded compared to the aromatic

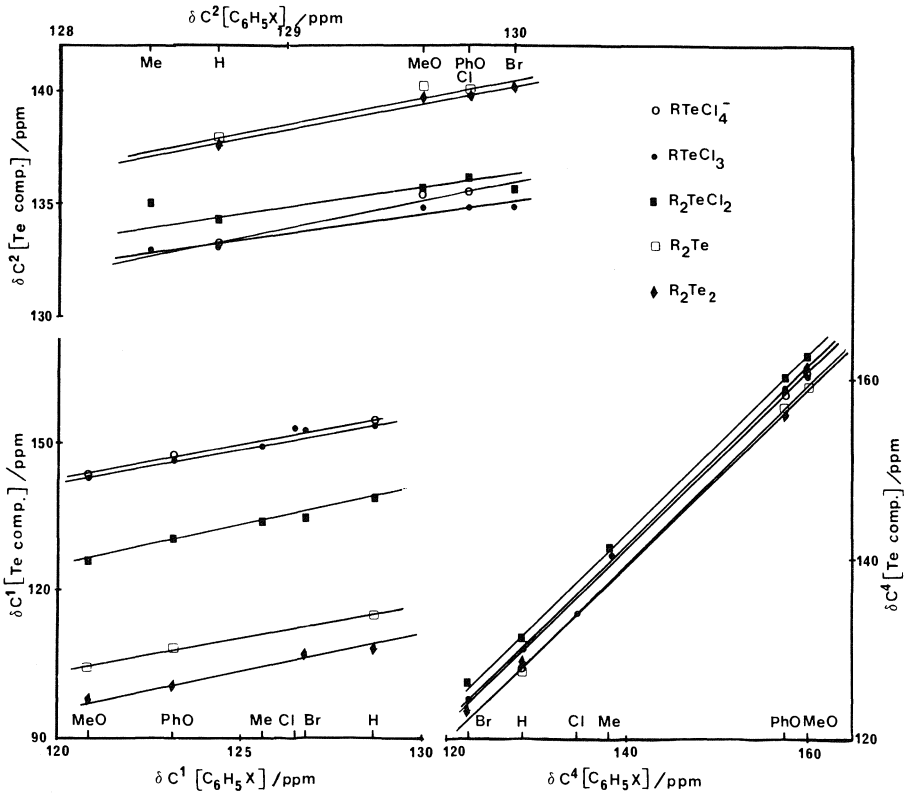

FIG. 1. Plots of $\delta C^n$ ($n$ = 1, 2, 4) for $C_6H_5X$ vs. $\delta C^n$ for organotellurium compounds. Data for X = H and MeO are taken from ref. 18.

hydrocarbon. The downfield shift for $\Delta\delta^{13}C^4$ for organotellurium halides suggests that the tellurium substituents are $\pi$ acceptors in nature.

The deviations of chemical shift values ($\Delta\Delta\delta^{13}C$) from the values calculated according to additivity principles (16) are presented in Table 2. The failure of additivity is clearly evident for $C^1$ and $C^2$, in particular, from this table. Kalabin *et al.* (6) suggested on the basis of the dipole moments and Kerr's constants that the failure of additivity in *p*-substituted aromatic selenium compounds is due to the deviation of the conformation of the molecule from coplanarity, which occurs with a decrease in the strength of the *para*-substituent X. The signs of $\Delta\Delta\delta^{13}C^1$ for different *para*-substituents on the aromatic ring in tellurium compounds (Table 2) are similar to the corresponding substituents in selenium compounds studied by Kalabin *et al.* (6). This similarity between selenium and tellurium compounds suggests that the factor affecting non-additivity in tellurium compounds may also be conformational, though there is not much information available from the dipole moment data (18–21).

For the aliphatic compounds it can be seen that the $C^1$ resonances in the tellurides and ditelluride show an upfield shift whereas in the tellurium halides, it shows a downfield shift, dependant upon the halogens attached to the tellurium atom.

*Coupling constants*

In some of the aliphatic compounds $^{125}$Te satellites are observed. The values lie in the range 127–168 Hz and are of the same order of magnitude as the reported $^1J$ (Te—C) value of 158.5 ± 0.5 Hz in $Me_2Te$ (22) and 118–146 Hz in pentane-2,4-dione tellurium(II) compounds (9). Two bond coupling constants have been observed in some cases and it appears that $^2J$ depends upon steric as well as electronic factors.

## Experimental

$^{13}$C nmr spectra were obtained on a Bruker WP-60FT NMR according to the method described previously (15).

A majority of the compounds studied are described in the literature (23–25). *p*BrPh(Ph)$TeCl_2$ was prepared by refluxing an equimolar mixture of *p*BrPh$TeCl_3$ and $Ph_3SnCl$ in toluene for 2 h. After removing any suspended impurity by filtration, ligroin

# Excited states of acrolein: *ab initio* model studies on α,β-unsaturated carbonyl compounds

KATHERINE VALENTA AND FRIEDRICH GREIN

*Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2*

Received August 11, 1981

KATHERINE VALENTA and FRIEDRICH GREIN. Can. J. Chem. **60**, 601 (1982).

As an explanation of the stereochemistry of photoaddition between α,β-unsaturated carbonyl compounds and olefins, Wiesner suggested that the excited state of the α,β-unsaturated carbonyl compound is pyramidal at the β-carbon. It is shown by *ab initio* SCF and CI studies that for acrolein in the $^1n\pi^*$, $^3n\pi^*$, and $^3\pi\pi^*$ excited states the β-carbon remains planar. In addition, vertical excitation energies for the $^1n\pi^*$ and $^1\pi\pi^*$, and adiabatic excitation energies for the $^1n\pi^*$ and $^3n\pi^*$ states of *trans*-acrolein have been calculated.

KATHERINE VALENTA et FRIEDRICH GREIN. Can. J. Chem. **60**, 601 (1982).

Pour expliquer la stéréochimie de l'addition photochimique des composés carbonylés α,β-insaturés sur des oléfines, Wiesner suggère que l'état excité du composé carbonylé α,β-insaturé est pyramidal au niveau du carbone en β. On montre par des calculs *ab initio* SCF et des études CI que dans les états excités $^1n\pi^*$ et $^3\pi\pi^*$ de l'acroléine, le carbone β reste plan. De plus, on a calculé les énergies d'excitation verticale des états $^1n\pi^*$ et $^1\pi\pi^*$ et les énergies d'excitation adiabatique des états $^1n\pi^*$ et $^3n\pi^*$ de l'acroléine *trans*.

[Traduit par le journal]

## 1. Introduction

In the photoaddition of allene and other olefins to α,β-unsaturated carbonyl compounds for the synthesis of polycyclic bridged natural products examples are found where the allene approaches from the more sterically hindered side of the enone. In order to explain this, Wiesner (1) proposed a general rule for predicting the stereochemistry of such photoadducts. He postulated that the excited state of the enone is the controlling factor of the reaction, and that in this excited state the β-carbon inverts to select the more stable configuration. Since then, other studies were found in agreement with this rule (2, 3).

At the basis of Wiesner's empirical rule is a consideration of the change in charge distribution of α,β-unsaturated carbonyl compounds upon excitation. According to Corey (4), the lowest excited singlet state ($^1n\pi^*$) is positively charged at the α-carbon, and negatively at the β-carbon. Placing the negative charge of the β-carbon into an orbital suggests a pyramidal structure of the β-carbon in the excited state (reaction [1]). The orbital accommodating the negative charge is directed upwards or downwards depending on steric effects.

If the geometry of the excited state is not the controlling factor of the reaction, then the configuration controlling species would have to be found in the reaction subsequent to the excitation. Corey *et al.* (4) and de Mayo and co-workers (5) postulated that in this reaction a π-complex is formed between the excited carbonyl compound and the olefin. This complex then becomes a diradical which cyclizes to form the product.

[1] 

Photoexcitation from the ground state of α,β-unsaturated carbonyl compounds will initially lead to the $^1n\pi^*$ excited state (see ref. 6 for acrolein, ref. 4 for other compounds). Since rapid intersystem crossover may occur to either $^3n\pi^*$ or $^3\pi\pi^*$ (4, 6, 7), the geometries of these two excited states are also of interest.

In this study, theoretical methods are used in order to determine whether or not the above-mentioned excited states of α,β-unsaturated carbonyl compounds are pyramidal at the β-position. We have restricted ourselves to the smallest such compound, acrolein (Fig. 1).

In its ground state acrolein is planar, with the *trans*-isomer more stable than the *cis*-isomer. The singlet $n\pi^*$ transition has been observed at 3860 Å, and is well characterized (8, 9). In both the ground state and the $^1n\pi^*$ state, the out-of-plane vibrational modes $\nu_{15}$ and $\nu_{16}$ have been assigned, the

former being the formyl CH wag, the latter being the vinyl $CH_2$ wag. Brand and Williamson (8) found that $\nu_{15}'/\nu_{15}'' = 644/980$, and $\nu_{16}'/\nu_{16}'' = 582/959$. So upon excitation, the vinyl hydrogen wagging mode decreases more than the formyl wagging mode, which is quite unusual. The corresponding potential curve is broadened or may even have a double minimum, in which case the vinyl out-of-plane configuration of the $^1n\pi^*$ state would be more stable.

A weak system at 4060 Å has recently been assigned to correspond to the transition from the ground state of *cis*-acrolein to the singlet $n\pi^*$ state of *cis*-acrolein (10). Similarly, at 4322 Å a transition to $^3n\pi^*$ of *cis*-acrolein has been observed (11). In the $n\pi^*$ excited states, the *cis*-isomer of acrolein appears to be more stable than the *trans*-isomer.

Becker *et al.* (6) suggested that in the lowest $\pi\pi^*$ triplet state twisting about the carbon–carbon double bond may occur, leading to intersystem crossover to the ground state. Their semiempirical PPP-CI calculations indicated that $^3\pi\pi^*$ is most stable at a 90° twist angle. This was subsequently confirmed by minimal basis *ab initio* SCF calculations of Devaquet and co-workers (12, 13). Dykstra (14) considered the possibility that the $^3\pi\pi^*$ state of acrolein is rotated about the CC single bond, with a minimum energy between the *cis* and *trans* form. However, due to the mixing of $\pi\pi^*$ with $n\pi^*$ for nonplanar acrolein, and in the absence of CI calculations, no definite conclusions could be reached.

The out-of-plane motion of the hydrogen atom at the α-carbon was studied by Devaquet (13), and was found to increase the energy. However, it was noted that for cyclic systems (such as cyclohexenone) a smaller ethylenic twist accompanied by an out-of-plane motion of the hydrogen attached to the α-carbon might stabilize the system in $^3\pi\pi^*$.

In summary, there is no conclusive spectroscopic or theoretical evidence for α,β-unsaturated carbonyl compounds to be pyramidal at the β-carbon in any of the excited states. However, only very limited studies have been performed in the past, and more work needs to be done.

In the present work, our ultimate goal is the study of the pyramidal nonplanarity at the β-position of the singlet $n\pi^*$, triplet $n\pi^*$, and triplet $\pi\pi^*$ states of *trans*-acrolein. In addition, we obtained vertical excitation energies for the singlet $n\pi^*$ and $\pi\pi^*$ states, optimized the geometries of the planar $^1n\pi^*$ and $^3n\pi^*$ species of *trans*-acrolein, and obtained the adiabatic excitation energies of these states.

## 2. Results and Discussion

Self-consistent-field (SCF) calculations were performed in the restricted Hartree–Fock formalism, using the (9*s*5*p*/4*s*2*p*) contracted Gaussian basis set according to Dunning (15) for C and O, and the (4*s*/2*s*) basis for H. The configuration-interaction (CI) method of Buenker and Peyerimhoff (16–18) was used. In this method, single and double excitations of a set of reference configurations are generated, and those configurations are selected for the final CI diagonalization which give energy contributions in excess of a properly chosen threshold value $T$. Only CI energy values extrapolated to $T \rightarrow 0$ will be given.

### *A. Vertical excitation energies of singlet states*

CI calculations at the experimental ground state geometry of acrolein ($R_{C_1C_2} = 1.36$ Å, $R_{C_2C_3} = 1.46$ Å, $R_{C_3O} = 1.22$ Å, 120° bond angles (19) were used; a more recent and more accurate ground state geometry (20) is $R_{C_1C_2} = 1.345$ Å, $R_{C_2C_3} = 1.470$ Å, $R_{C_3O} = 1.219$ Å, $R_{C-H} = 1.084$–$1.108$ Å, $H_1C_1H_2 = 118°35'$, $H_1C_1C_2 = 121°27'$, $H_2C_1C_2 = 119°58'$, $C_1C_2H_3 = 122°50'$, $C_1C_2C_3 = 119°50'$, $C_2C_3H_4 = 115°6'$, $C_2C_3O = 123°16'$) were performed for the $^1A'$ ground state, and the $^1A''(n\pi^*)$ and $^1A'(\pi\pi^*)$ excited states. Ground state SCF orbitals were used, with the ground state SCF energy being −190.6949 hartree. The four lowest energy orbitals $1a'$–$4a'$ were "frozen", and the four highest orbitals $37a'$–$40a'$ were excluded from any possible occupancy. The selection threshold was 50 μhartree. Here, and in all following CI calculations, configurations with a coefficient greater than 0.15(absolute) were included as reference (or main) configurations.

The results are given in Table 1. The vertical excitation energy for $^1n\pi^*$ is 4.37 eV, and for $^1\pi\pi^*$ 7.53 eV. The experimental values are 6.5 eV for the vertical excitation energy to $^1\pi\pi^*$ (21, 22). For $^1n\pi^*$, no experimental value could be found. Other theoretical values for $^1n\pi^*$, all obtained by SCF methods, are 4.44 eV (23) and 2.77 eV (14). A recent theoretical CI value for the vertical excitation energy to $^1\pi\pi^*$ is 7.52 eV (24), in close agreement with our results.

Vertical excitation energies to $^3n\pi^*$ and $^3\pi\pi^*$ were calculated by Lucchese *et al.* (25), using double ζ basis sets and CI methods. Their results are 3.38 eV for $^3n\pi^*$ and 3.97 eV for $^3\pi\pi^*$.

### *B. SCF geometry optimizations on planar $^1n\pi^*$ and $^3n\pi^*$ states*

Both the singlet and the triplet $n\pi^*$ states can be dealt with by SCF methods provided the molecule

is planar. Cyclic geometry optimizations on *trans*-acrolein in the $^1n\pi^*$ and $^3n\pi^*$ states were performed, varying the carbon–carbon and carbon–oxygen distances, but fixing the carbon–hydrogen distances at 1.09 Å, and all bond angles at 120°.

The results are given in Table 2. The minimized SCF energies are −109.6275 hartree for $^1n\pi^*$, and −190.6295 hartree for $^3n\pi^*$. A reversal of the C—C and C—O bond characters with respect to the ground state can be noticed. For both states the terminal C—C bond changes into a single bond, whereas the intermediate C—C bond becomes a double bond. Our results for $^1n\pi^*$ are in good agreement with experimental results (9) (Table 2), except for the C—O distance which is optimized to be much larger than experimental. However, according to Brand and Williamson (8), the experimental C—O distance may be as high as 1.35 Å.

Another experimental confirmation of the single bond – double bond interchange in the excited state is the barrier to internal rotation as reported by Brand and Williamson (8). For the $^1n\pi^*$ excited state, the barrier to rotation about the terminal C—C bond is 2700 $cm^{-1}$, whereas it is 5300 $cm^{-1}$ for the central C—C bond.

Our findings differ significantly from those of Dykstra (14) (also in Table 2), who obtained little change in the carbon–carbon distances upon excitation to the $n\pi^*$ states. His CO distance, however, is similar to ours. Dykstra used the same basis set as used in this work (probably scaled, since his SCF energies are lower), but he used bond angles that were optimized for the ground state ($C_1C_2C_3$ = 123.4°, $C_2C_3O$ = 121.4°, $H_1C_1H_2$ = 116.5°, $C_1C_2H_3$ = 116.3°, $C_2C_3H_4$ = 116.2°, see Fig. 1) instead of our uniform 120° bond angles. Dykstra's geometry parameters gave a higher energy than ours when checking for the discrepancy in results (using our basis set).

### C. *Adiabatic $n\pi^*$ excitation energies of planar trans-acrolein*

CI calculations were performed at the optimized geometries of $^1n\pi^*$ and $^3n\pi^*$, using the respective SCF molecular orbitals (MO). The selection threshold was again 50 μh, and the active orbital space the same as before.

SCF and CI adiabatic excitation energies are given in Table 3. The CI values are in reasonable agreement with experimental values for the transitions to excited states of *trans*-acrolein (since *cis*-acrolein in $^1n\pi^*$ and $^3n\pi^*$ is at lower energy than *trans*-acrolein, the cited excitation energies are not fully adiabatic). Dykstra (14), by SCF methods, obtained 2.01 eV for $^1n\pi^*$ and 1.81 eV for $^3n\pi^*$, whereas Lucchese *et al.* (25) obtained 2.68 eV for the adiabatic transition to $^3n\pi^*$, using Dykstra's optimized geometry that was discussed earlier. The same authors obtained a CI value of 2.86 eV for the adiabatic transition energy to $^3\pi\pi^*$.

### D. *Nonplanar methylene group studies*

In this section, the main problem of this paper will be addressed. Is acrolein (and other α,β-unsaturated carbonyl compounds) in any one of the $n\pi^*$ or $\pi\pi^*$ excited states pyramidal at the β-position? The two methylene hydrogens $H_1$ and $H_2$ will be moved below the plane of the molecule towards a tetrahedral arrangement. Three deformation angles were considered, starting with the planar geometry and going partially to a tetrahedral structure.

Due to a reduction in the symmetry of nonplanar acrolein, from $C_s$ to $C_1$, the SCF method is only capable of handling the lowest singlet state (ground state) and the lowest triplet state, which should be mainly $^3n\pi^*$, but has some admixture of $^3\pi\pi^*$. For simplicity we continue calling this state $^3n\pi^*$.

SCF and CI studies on the out-of-plane motions of the methylene group were conducted in the following way: The $H_1C_1H_2$ angle was reduced gradually from 120° to 115°, in such a way that α

| 38.13 | 15.94 | 3.01 | 3.51 | 5.27 | 4.64 |

was always kept equal to β (Fig. 1). Values for γ (the angle the $CH_2$ group makes with the plane of the rest of the molecule) were 0° (planar), 10°, 25°, and 38.13° ($\alpha = \beta = 115°$; a tetrahedral arrangement corresponds to $\gamma = 54.7°$). Thus, γ fixes the angles of bending unambiguously. For all states considered, the same bond distances, namely the ones optimized for $^1n\pi^*$, and the same bond angles were used. The reason for taking the same bond distances is that the optimized bond distances for $^3n\pi^*$ differ little from those of $^1n\pi^*$ (Table 2), and the $^3\pi\pi^*$ distances optimized by Dykstra (14) are also very similar. For the ground state, these bond distances are of course inadequate; however, the ground state is only a necessary ingredient for the CI calculations, and of no particular interest to the methylene nonplanarity studies. In all cases SCF orbitals for $^3n\pi^*$ were used. In the CI calculations the frozen MOs were as previously described while the highest ten MOs were excluded from possible occupations. Due to inconsistencies in the extrapolated CI energies at a threshold of 50 μhartree, a lower selection threshold of 20 μhartree had to be chosen.

For the singlet states, the lowest root (#1) corresponds to the ground state, and the second root to $^1n\pi^*$. For triplet states, root 1 correlates with $^3n\pi^*$, and root 2 with $^3\pi\pi^*$. Therefore, CI calculations on the $^1A$ and $^3A$ states, with 2 roots each, give results for all states of interest in the study of the methylene nonplanarity of acrolein.

Details of the CI calculations, and SCF and CI energies are given in Table 4. Five or six main configurations were used. The important results are summarized in Table 5. The conclusion is quite clearly that neither the initial state reached in the photoexcitation process, nor any of the triplet states that might be reached through intersystem crossover, have a pyramidal $CH_2$ group in the case of *trans*-acrolein. The CI energy barrier to the maximum deformation calculated is 3.0 kcal/mol for $^1n\pi^*$, 5.3 for $^3n\pi^*$ and 4.6 for $^3\pi\pi^*$.

As expected, the deformation barrier is much larger for the ground state (this should be true even

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

with good ground state bond distances). The calculated SCF values for $^3n\pi^*$ are similar to the CI values, but generally smaller.

### 3. Conclusion

According to the results presented for acrolein, none of the excited states of interest are pyramidal at the β-carbon. However, the energy barriers to becoming pyramidal are small, and certainly much smaller than for the ground state.

In the absence of any experimental evidence, and in light of the theoretical work presented here, it is reasonable to assume that α,β-unsaturated carbonyl compounds are planar or twisted at the β-carbon position, but not pyramidal. Therefore, the reason for Wiesner's empirical rule, stated in the Introduction, cannot be found in the geometry of the excited species of the carbonyl compound, and must be determined somehow by the subsequent reaction of the α,β-unsaturated carbonyl compound in the excited state with the olefin.

Considering that Wiesner's rule, relating the stereochemistry of the product to the geometry of the excited state of the carbonyl compound, works in all cases studied so far, one has to conclude that at the initial stages of the reaction with the olefin, the excited carbonyl compound does indeed pyramidalize at the β-position seeking the sterically less-hindered configuration. Due to the low energy barrier for pyramidalization, sufficient energy for this process should be available.

According to previously mentioned experimental evidence, one might assume that the α,β-unsaturated carbonyl compound, after initial photo excitation to $^1n\pi^*$, rapidly crosses over to a lower-lying triplet state, either $^3n\pi^*$ or $^3\pi\pi^*$. Bunce, Ridley, and Zerner (26) presented interesting experimental and theoretical results on *p*-quinones. They proposed that in these systems photo-cycloaddition with an olefin will lead to oxetane formation if the lowest triplet was $n\pi^*$, whereas cyclobutane will be formed if the lowest triplet was $\pi\pi^*$. This also follows from qualitative arguments if one assumes that the $n\pi^*$ excitation is mainly localized at the carbonyl group, whereas $\pi\pi^*$ is localized at the terminal C—C bond. Since in the reactions studied by Wiesner cyclobutane adducts are formed, this would imply that $^3\pi\pi^*$ is lower that $^3n\pi^*$. Although this is not the case for acrolein (but the two energies are close), it might be true for larger such compounds. (For steroidal ketones it was found that $^3\pi\pi^*$ is the lowest triplet state (27).) Bunce *et al.* also pointed out that the ordering of the triplet states is extremely sensitive to substitution.

Besides addressing the problem of a pyramidal β-carbon in excited states of acrolein, CI values were obtained for the singlet $n\pi^*$ and singlet $\pi\pi^*$ vertical excitation energies. Geometry optimizations for $^1n\pi^*$ and $^3n\pi^*$ gave bond distances corresponding to single bond – double bond reversals, similar to values previously obtained for the $^3\pi\pi^*$ state of acrolein. Corresponding calculated adiabatic excitation energies are in good agreement with experimental values.

### Acknowledgments

We are much obliged to Professor K. Wiesner for suggesting this problem, and for many valuable discussions. We also thank Dr. M. Zerner for his interest, and for pointing out useful references. Financial support from the Natural Sciences and Engineering Research Council of Canada and the University of New Brunswick is gratefully acknowledged. One of us (K.V.) would like to acknowledge the support of the Natural Sciences and Engineering Research Council in the form of a postgraduate scholarship, and the University of New Brunswick for support in the form of the Magee Postgraduate Merit award.

We are grateful to one of the referees for helpful comments.

# Sterically hindered aromatic compounds. XI. Spectral and product studies of the decomposition of *N*-nitrosoacetanilides

L. Ross C. Barclay[1] and Julian M. Dust[2]

*Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0*

Received September 28, 1981

L. Ross C. Barclay and Julian M. Dust. Can. J. Chem. **60**, 607 (1982).

Decomposition of *N*-nitroso-2,4,6-tri-*tert*-butylacetanilide (**1**) in benzene forms products 2,4,6-tri-*tert*-butylphenyl acetate (**3**), 3-(3,5-di-*tert*-butylphenyl)-2-acetoxy-2-methylpropane (**4**), and hydrocarbons 3-(3,5-di-*tert*-butylphenyl)- and 1-(3,5-di-*tert*-butylphenyl)-2-methylpropene (**5** and **6**) explained by a reactive aryl cation (**2**), the rearranged products (**4**, **5**, **6**) originating from a 1,5-hydride shift from an *ortho tert*-butyl group in **2**. In contrast, decomposition of **1** in triethylamine forms products 1,3,5-tri-*tert*-butylbenzene (**10**), 2,4,6-tri-*tert*-butylacetanilide (**15**), and 2-(3,5-di-*tert*-butylphenyl)-2-methylpropanal oxime (**13**), expected of a free radical pathway. Electron spin resonance evidence is given for intermediates formed by rearrangement of the 2,4,6-tri-*tert*-butylphenyl radical and spin trapped by the nitroso group of **1**. CIDNP and esr studies on the dediazoniation of *N*-nitrosoacetanilide and aniline in the presence of tertiary amines support the proposed electron transfer mechanism. The results are briefly discussed in terms of the role of steric effects and electron transfer in the dediazoniation of nitrosoacetanilides and diazonium salts.

L. Ross C. Barclay et Julian M. Dust. Can. J. Chem. **60**, 607 (1982).

La décomposition du *N*-nitroso tri-*tert*-butyl-2,4,6 acétanilide (**1**) dans le benzène conduit à la formation de l'acétate de tri-*tert*-butyl-2,4,6 phényle (**3**), de (di-*tert*-butyl-3,5 phényl)-3 acétoxy-2 méthyl-2 propane (**4**) et des (di-*tert*-butyl-3,5 phényl)-3 et (di-*tert*-butyl-3,5 phényl)-1 méthyl-2 propènes (**5** et **6**) dont on explique la formation à l'aide d'un cation aryle réactif (**2**), les produits de transposition (**4**, **5** et **6**) proviennent d'un déplacement-1,5 d'un hydrure provenant d'un groupement *tert*-butyle *ortho* dans **2**. Par opposition, la décomposition de **1** dans la triéthylamine conduit à la formation de tri-*tert*-butyl-1,3,5 benzène (**10**), de tri-*tert*-butyl-2,4,6 acétanilide (**15**) et de l'oxime du (di-*tert*-butyl-3,5 phényl)-2 méthyl-2 propanal (**13**) dont la formation est prévue pour un processus radicalaire. Les données de la rpe suggèrent la présence d'intermédiaires formés par une transposition du radical tri-*tert*-butyl-2,4,6 phényle qui est piégé par le nitroso de **1**. Des études de CIDNP et rpe sur la dédiazotation du *N*-nitrosoacétanilide et de l'aniline en présence d'amines tertiaires est en accord avec le mécanisme de transfert d'électron proposé. On discute brièvement des résultats obtenus en termes du rôle des effets stériques et des transferts d'électrons lors de la dédiazotation des nitrosoacétanilides et des sels de diazonium.

[Traduit par le journal]

## Introduction

The aromatic dediazoniation reaction has been the subject of renewed interest by a number of investigators (1–12). The variety of reactive intermediates involved: diazonium ions (5), aryl cations (6–8), nitrogen – aryl cation molecule – ion pairs (1, 9, 10), aryl radicals (2), and benzynes (3, 4, 11), have attracted considerable interest as have newer methods of deamination of arylamines for synthetic purposes (12).

Earlier (13) we studied the aprotic diazotization of hindered amines, such as 2,4,6-tri-*tert*-butylaniline, with butyl nitrite. The results of spin trapping of the hindered aryl radical and derived radicals from this reaction together with product analysis were rationalized on the basis of a predominantly radical pathway for the dediazoniation. On the other hand, oxygenated compounds accounted for at least 50 per cent of the products; these probably arise by ionic pathways, and the usual question arises as to the relationship between the free radical and cationic pathways. To provide some answers to this question we selected *N*-nitroso-2,4,6-tri-*tert*-butylacetanilide (**1**) for dediazoniation studies. This compound will undergo the reaction without added reagents and is therefore a "cleaner" system for studying the effect of varying conditions such as the presence of an electron transfer medium on the reactive intermediates involved and products formed. Some spectroscopic studies (CIDNP) will also be reported for the comparable decomposition of *N*-nitrosoacetanilide (NNA) in order to further explore the relationships between the various pathways involved in the dediazoniation (i.e. cationic, electron transfer, and free radical).

## Results

### A. *Product analysis*

#### 1. *Decomposition of **1** in benzene*

The nitroso compound (**1**) proved to be slow to decompose in benzene at room temperature or even at 80°C. The major products found are given in Table 1. They can readily be explained by a cationic mechanism involving combination of an aryl cation (**2**) with the acetate anion and rear-

TABLE 1. Products from decomposition of *N*-nitroso-2,4,6-tri-*tert*-butylacetanilide in benzene[a]

| Compound | % Yield |
|---|---|
| 2,4,6-Tri-*tert*-butylphenyl acetate **3** | 70.1 |
| 3-(3,5-Di-*tert*-butylphenyl)-2-methylpropene **5**[b] and 1-(3,5-di-*tert*-butylphenyl)-2-methylpropene **6**[b] | 15.9 |
| 3-(3,5-Di-*tert*-butylphenyl-2-acetoxy-2-methylpropane **4**[c] | 7.2 |

[a]Under nitrogen at 80°C for six days. Yields were determined by isolation using preparative tlc.
[b]Hydrocarbon **5** was the major component (as in ref. 13), according to nmr analysis.
[c]The structure is tentatively assigned from spectroscopic properties.

TABLE 2. Products from decomposition of *N*-nitroso-2,4,6-tri-*tert*-butylacetanilide in triethylamine[a]

| Compound | % Yield |
|---|---|
| 2,4,6-Tri-*tert*-butylacetanilide[b] **15** | 40.0 |
| 1,3,5-Tri-*tert*-butylbenzene **10** | 20.0 |
| 2-(3,5-Di-*tert*-butylphenyl)-2-methylpropanal oxime **13** | 18.3 |
| 2,4,6-Tri-*tert*-butylaniline | 2.5 |
| Hydrocarbons **5** and **6** | Trace |
| Unidentified mixture[c] | 11.0 |

[a]Under nitrogen at 80°C for 8 h. Compound **15** was isolated by filtration. The other products were separated and isolated yields determined by preparative tlc.
[b]Precipitated from reaction, filtered, and weighed.
[c]Comparison of the nmr spectrum of this mixture with that of the dimer of **12** (17) indicates that the mixture may consist of a mixture of dimers of nitroso compounds **12** and **17**, 3 peaks upfield at 1.30, 1.35, and 1.49 (*gem*-dimethyl, and *tert*-butyls), 2.55 (benzylic-$CH_2$), near 4.1 and 4.2 (—$CH_2$—NO—NO—), and two sets of multiplets at 7.2 and 7.58 (aromatic).

rangement of this aryl cation via a 1,5 hydride shift with subsequent carbonium ion reactions as outlined in Scheme 1.

It is interesting to contrast our observed rearrangement of **2** with cyclialkylations observed for other *ortho*-alkyl aryl cations (15) including that generated from the diazonium salt of 3-amino-4-*tert*-butyl-5-nitrobenzoic acid (16). Cyclialkylation in **2** would undoubtedly be hindered by an *ortho-tert*-butyl group.

2. *Decomposition of **1** in triethylamine*

The decomposition of **1** proceeded more rapidly in triethylamine than in benzene and the products (Table 2) are remarkably different. These products are explained by an electron transfer mechanism[3] operating between the aryl diazonium ion (or possibly the aryl cation **2**) and triethylamine to yield the 2,4,6-tri-*tert*-butylphenyl radical **7** and derived hydrocarbon radicals **8** and **9**. The products such as 1,3,5-tri-*tert*-butylbenzene (**10**), oxime (**13**), and 2,4,6-tri-*tert*-butylacetanilide (**15**) could then follow by hydrogen atom transfers (**7** to **10**) and radical trapping by the substrate **1** (or derived products, i.e. **17**) according to the proposal given in Scheme 2.[4] This scheme is somewhat speculative in that not all of the products or radical intermediates have been found. Nevertheless it does account for the rather large proportion of 2,4,6-tri-*tert*-butylacetanilide (**15**) found, since there are two routes for its formation: **11** → **14** → **15** and **16** → **14** → **15**.

The oxime **13** (derived from a spontaneous rearrangement of the nitroso compound **12**) was observed earlier (17) from the photorearrangement of 2,4,5-tri-*tert*-butylnitrosobenzene and its formation here is consistent with a radical pathway such as that shown. One would also expect to find some rearranged nitroso compound (**17**, or derived dimers) and this appears to be present in the "unidentified mixture" (Table 2).

[3]A referee has pointed out that there are two possibilities for the electron transfer. It may be either a "free" transfer or by a homolytic dissociation of the diazoaminonium cation formed from diazonium ion + triethylamine as a steady state intermediate.

[4]The intermediates **7**, **8**, and **9** were detected earlier in a kinetic study (14). The bracketed species are postulated ones, while the others (**16** and **17**) are reported herein by esr observations (*vide infra*).

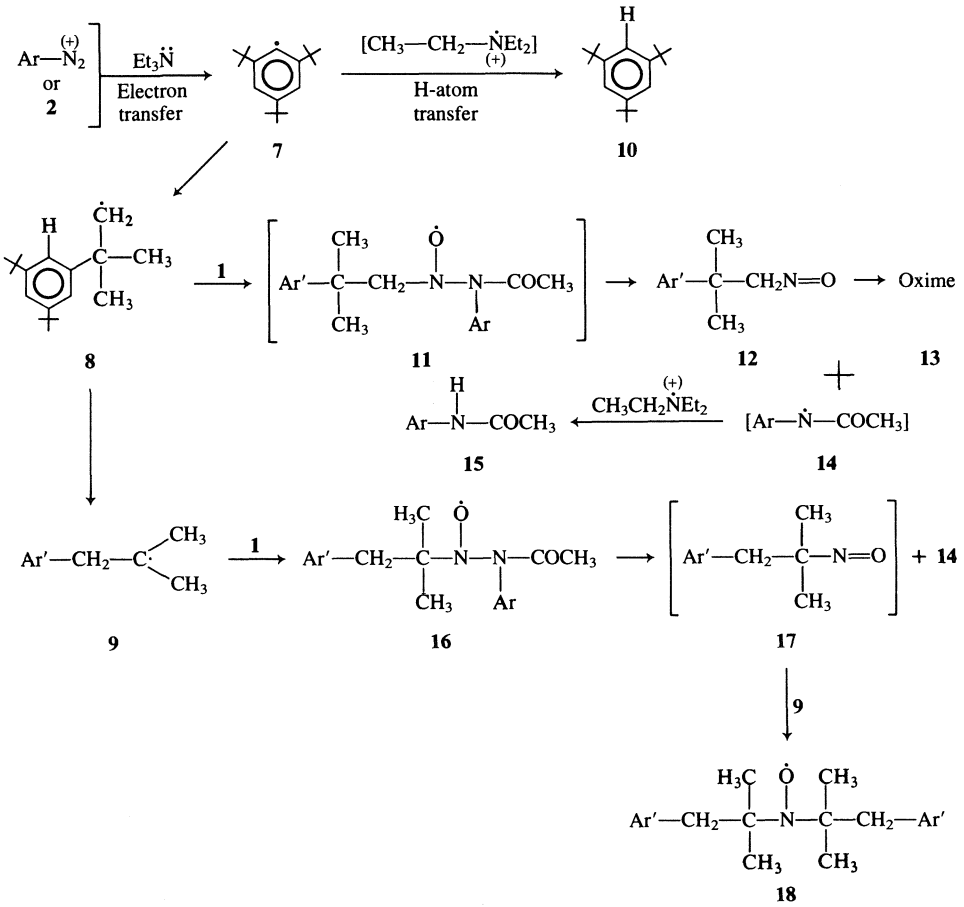

SCHEME 2

B. *Spectroscopic studies*

The pathways shown in Scheme 2 include a number of nitroxide radicals which should be detectable by esr measurements. In addition the proposed electron transfer from triethylamine to the diazonium ion or aryl cation is somewhat unusual. It was desirable to check the validity of this electron transfer and for this purpose we turned to chemically induced dynamic nuclear polarization (CIDNP), since a hydrocarbon (**10** from **2** or benzene from nitrosoacetanilide) formed from a radical pair as proposed is expected to exhibit polarization in the nmr experiment.

1. *Electron spin resonance*

The results from esr observations on the dediazoniations of **1** and nitrosoacetanilide (NNA) are given in Table 3. Earlier (13), we observed the formation of nitroxide radical **16** from **1** in methylene chloride. When this experiment was carried out in the presence of triethylamine (No. 2), the typical triplet of triplets for **16** appeared immediately upon addition of this base and the signals were much more intense and persistent than with **1** alone (No. 1). After longer contact time (3 hours) at room temperature, the spectrum of **16** was replaced by a single triplet assigned to the nitroxide radical (**18**). These results are entirely consistent with the proposal in Scheme 2 for the interconversions **9** → **16** → **17** → **18**. Separate attempts to observe the 2,4,6-tri-*tert*-butylacetanilino radical (**14**) (Scheme 2) by photolysis of the amide with di-*tert*-butylperoxide or oxidation of the amide with lead dioxide were not successful. The proposed **14** may abstract hydrogen readily from solvent or reagents as proposed in Scheme 2.

The effect of triethylamine indicates that it is acting as an electron donor. The earlier (13) observation of the radical (**16**) from **1** alone was probably a result of a minor route of decomposition of an intermediate diazoanhydride Ar—N=N—O—N=N—Ar →Ar· + $N_2$ + ·O—N=N—Ar according to the Rüchardt mechanism (21). An electron donor could cut in on that pathway by forming the

[a]Studies were carried out by scanning the substrate alone in degassed ($N_2$ purged) solvent and then adding the reagent and recording spectra.
[b,c]NNTBA = *N*-nitroso-2,4,6-tri-*tert*-butylacetanilide, NNA = N-nitrosoacetanilide, TEA = triethylamine, TPA = triphenylamine, TMP = *N*,*NN*′,*N*′-tetramethylparaphenylenediamine. Reactions were generally carried out on one mmol of substrate. The mole ratios of substrates to reagents are shown in parentheses.
[d,e]A combination of signals including *d* + *e* results; *d* is observed by adding NNA to TMP and *e* by adding TMP to NNA.
[f]The spectrum was the same as that for the $\overset{(+)}{TMP}\cdot$ (radical cation) generated independently according to ref. 19 or 20.
[g]The triplet for $(C_6H_5)_3\overset{(+)}{N}\cdot$ exhibited partly resolved fine structure due to coupling with aryl hydrogens. The reported $a_N$ has varied from 8.55 in $CH_2Cl_2$ (24) to 10.16 in liquid $SO_2$ (25).

TABLE 4. CIDNP observations of dediazoniations

| No. | Substrate[a] | Reagent[b] | Solvent | Temperature°C[d] Initial | CIDNP | (time/min) | Polarization observed |
|---|---|---|---|---|---|---|---|
| 1 | NNA | TEA | — | −22 | 0 | — | [e] |
| 2 | NNA | — | $C_6D_6$ | 10 | 30 | (1) | Benzene E |
| | | | | | 50 | (4) | Benzene E, biphenyl E |

| 8 | Aniline | BONO/TMP | — | 30 | 30 | (2) | Benzene E |

[a,b]NNA = *N*-nitrosoacetanilide, TEA = triethylamine, TMP = *N*,*N*,*N*′,*N*′-tetramethyl-paraphenylenediamine, BONO = butylnitrite.
[c]Biphenyl was added as an internal reference to detect the polarized form.
[d]The temperatures include the initial setting of the nmr probe and the temperature (higher) when CIDNP was observed and the corresponding elapsed time is given in parentheses.
[e]Ordinary benzene was observed, i.e. no CIDNP.

unstable aryl diazenyl radical directly from the diazonium ion

$$Ar{-}\overset{(+)}{N}_2 \xrightarrow[\text{donor}]{\text{electron}} [Ar{-}N{=}N\cdot] \xrightarrow{-N_2} Ar\cdot$$

We did not observe the $Et_3\overset{(+)}{N}\cdot$ radical cation shown in this pathway, presumably because it would rapidly undergo the transformation $Et_3\overset{(+)}{N}\cdot \xrightarrow{\dot{H}\ \text{transfer}}$ $CH_3CH{=}\overset{(+)}{N}Et_2$. However, when aromatic amines such as triphenylamine or tetramethylparaphenylenediamine (22) were used, their radical cations were readily observed in the esr (Nos. 3, 4, 5). These observations were extended to the parent compounds *N*-nitrosoacetanilide which yielded both the known hydrazoxyl radical (23) and the aromatic radical cation ($TMP\overset{(+)}{\cdot}$) (No. 5a, 5b).

2. *Chemically induced dynamic nuclear polarization (CIDNP)*

The CIDNP observations during dediazoniations are outlined in Table 4. Treatment of *N*-nitrosoacetanilide (NNA) with triethylamine in the cold (No. 1) resulted in slow formation of unpolarized benzene. Slow reactions of diazonium ions do not lead to CIDNP effects (26). This may be attributed to the resulting slow formation of radicals (phenyl) which then react comparatively quickly so that they reside in the solvent cage for shorter periods than required for polarization (27, 28). Similarly we found that *N*-nitroso-2,4,6-tri-*tert*-butylacetanilide (**1**) underwent very slow decomposition even at 80°C and did not exhibit CIDNP up to 110°C in perdeuterotoluene, nor at 140°C in cyclohexanone.

Decomposition of NNA at elevated temperatures (30–50°C) resulted in both polarized benzene and polarized biphenyl (Table 4, Nos. 2 and 3) (see Fig. 1). On the other hand, decomposition of NNA in the presence of electron transfer reagents gave only polarized benzene (Nos. 4 and 5) (see Fig. 2). Similarly the dediazoniation of aniline with butyl nitrite in the absence or presence of amines (Nos. 6–8) gave benzene as the only detectable polarized species by our method. Polarized benzene and substituted benzenes have been found in CIDNP studies of various dediazoniations (29–33), including pyrolysis of NNA in acetonitrile at low field (34), whereas spin polarized biphenyl from these systems is unusual and was not reported in CIDNP studies even when biaryls were formed in significant yields (33). Both polarized benzene and biphenyl were reported in $^{13}C$ CIDNP studies of the decomposition of diazoaminobenzene where the enhanced absorption of two carbons of biphenyl was assigned to cage recombination of two phenyl radicals (35). However, spin polarized biphenyl was not found in the $^1H$ CIDNP study of the same system (36).

Our CIDNP emissions for benzene in the *absence* of electron donors (i.e. Nos. 2, 3, and 6) can be accounted for by spin selection using the radical pair model (27, 28), where radical pairs such as $[ArN_2\cdot\ \cdot ON_2Ar]$ and $[Ar\cdot\ \cdot ON_2Ar]$ originate from the diazoanhydride according to the Rüchardt (21) mechanism. When organic bases are present as electron donors (Nos. 1, 4, 5, 7, and 8), the electron pairs involved are probably of the types $[Ar{-}\overset{(+)}{N}_2\cdot\ \cdot N{-}R_3]$ and $[Ar\cdot\ \cdot\overset{(+)}{N}{-}R_3]$. (In the latter pair the different *g* factors as required for the emission polarization are 2.00277 (37) and 2.00306 $TMP\overset{(+)}{\cdot}$.)

The polarized biphenyl, observed in certain experiments in the *absence* of organic bases (Nos. 2 and 3), could arise from attack of phenyl radicals, which escape the cage, on the solvent perdeutero-

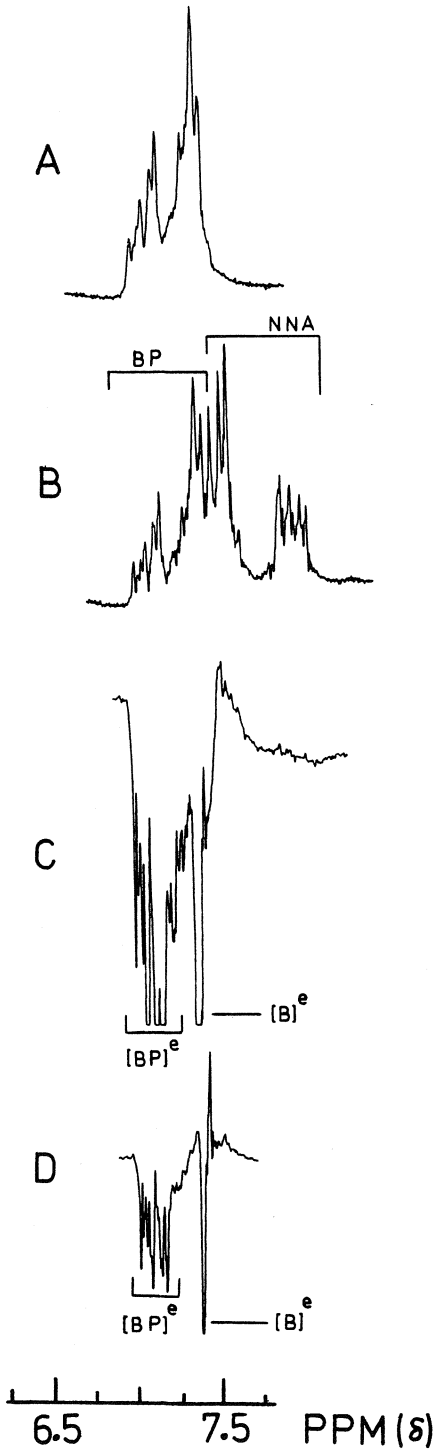

FIG. 1. $^1$H nmr spectra of aromatic protons during the decomposition of *N*-nitrosoacetanilide (NNA) in the presence of biphenyl as internal reference. Spectra were measured in $C_6D_6$ with TMS reference. A. Spectrum of biphenyl. B. Initial spectrum of NNA with biphenyl recorded at 10°C. C. Spectrum recorded at 50°C after 5 min, showing CIDNP emissions for biphenyl, [BP]$^e$, and benzene, [B]$^e$; both off scale. D. Spectrum recorded at reduced amplitude after 6 min at 50°C, showing CIDNP emissions for biphenyl, [BP]$^e$ and benzene [B]$^e$.

benzene. This known (3, 21) scavenging reaction of phenyl radicals could give a polarized product.[5]

## Discussion

These current results permit some conclusions on the role of steric effects and the effect of an electron transfer medium on the pathway of aryl dediazoniations.

1. In the absence of an effective electron transfer agent, the pyrolysis of *N*-nitroso-2,4,6-tri-*tert*-butylacetanilide (**1**) in benzene proceeds mainly by a cationic pathway through the very reactive 2,4,6-tri-*tert*-butylaryl cation (**2**). The major products from this reaction (Table 1) result from a hydride transfer from an *ortho tert*-butyl group via a five-membered transition state followed by subsequent rearrangements (Scheme 1). Similar rearrangements observed earlier (13) during the aprotic diazotization of 2,4,6-tri-*tert*-butylaniline were rationalized on the basis of free radical rearrangements based on esr evidence (e.g. spin trapping of the 2,4,6-tri-*tert*-butylphenyl radical (**7**)). It is more likely that those rearrangements were also cationic in nature, especially those forming oxygen containing products.

2. The *ortho tert*-butyl groups in **1** significantly retard its decomposition (compared to the unsubstituted NNA). This is most probably due to the severe steric restrictions exerted on the four-membered transition state required for the rearrangement of **1** $\rightarrow$ Ar—N=N—O—$\overset{\overset{O}{\|}}{C}$—$CH_3$ (4). On the other hand, the derived hindered diazonium ion Ar—$\overset{(+)}{N}_2$, once formed, is subject to the steric compression of two *ortho tert*-butyl groups and its decomposition may be sterically accelerated. This latter effect was confirmed in a qualitative manner by studying the decomposition of 2,4,6-tri-*tert*-butylphenyl diazonium nitrate. A suspension of this salt in ethyl ether appeared to be stable for several hours below −50°C. A sample of this suspension exhibited an infrared absorption band at 2250 cm$^{-1}$ for Ar—$\overset{(+)}{N}\equiv N$ *when handled rapidly*.

[5]It appears that our nmr method does not distinguish between the proposed product $C_6H_5$–$C_6D_5$, and biphenyl.

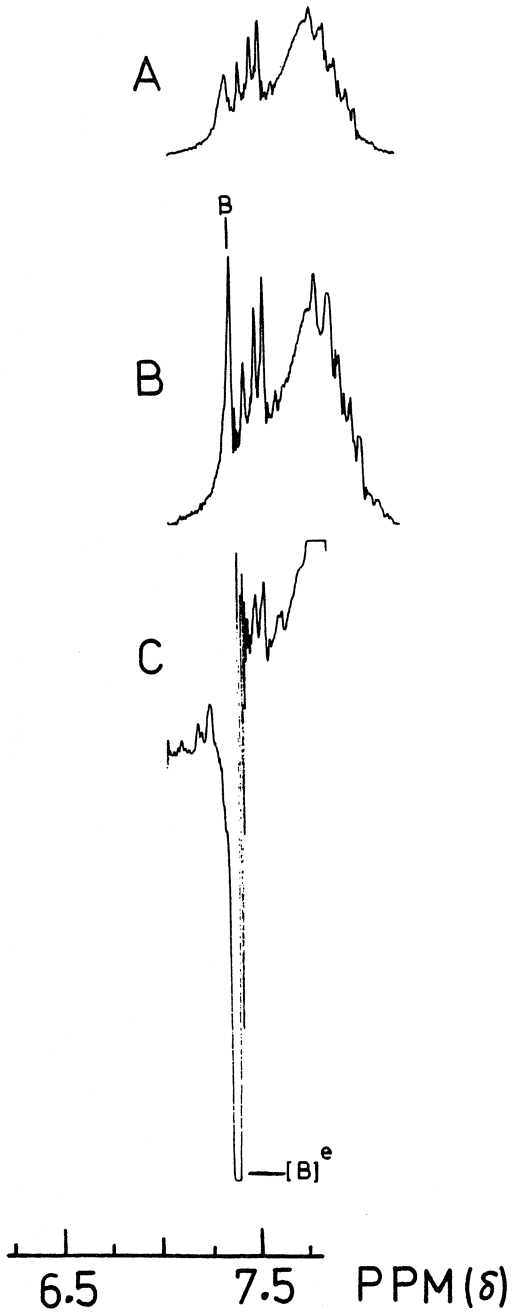

FIG. 2. $^1$H nmr spectra of aromatic protons during the decomposition of *N*-nitrosoacetanilide (NNA) in the presence of *N*,*N*,*N*,*N*-tetramethylparaphenylenediamine. Spectra were measured in $C_6D_6$ with TMS reference. A. Initial spectrum of NNA recorded at 10°C. The upfield portion is only partially resolved. B. Spectrum recorded after 2 min at 10°C, showing a trace of benzene, B, formed. C. Spectrum recorded after 3 min at 50°C, showing the CIDNP emissions for benzene, [B]$^e$, off scale.

Repetitive scans of this band indicated rapid decomposition of the salt at 25°C so that it was completely decomposed in five minutes. This contrasts with the rather *slow* decomposition observed for **1** in boiling benzene. This result is consistent with the proposed rapid ionic decomposition of the hindered Ar—$\overset{(+)}{N}_2$ (Scheme 1) as the main dediazoniation pathway.

3. The presence of tertiary amines as electron transfer agents switches the decomposition of **1** from an ionic to a free radical pathway. The products are accounted for by free radical reactions (Table 2, Scheme 2)[6] which are consistent with intense signals for radicals trapped as nitroxides such as **16** and **18**, as well as the signals for the expected amino cation radicals (e.g. $(C_6H_5)\overset{(+)}{N}\cdot$ and TMP$\overset{(+)}{\cdot}$, Table 3). CIDNP observations (Table 4) on the decomposition of NNA (and aprotic diazotization of aniline) in the presence of tertiary bases are also consistent with a pathway involving rapid electron transfer resulting in a radical pair of the type

$$[Ar—N_2\cdot \quad \cdot\overset{(+)}{N}—R_3]$$

The relatively uncomplicated nmr signal in the aromatic region on decomposition of NNA in triethylamine (a singlet for benzene is observed after the emission period) indicates that this may be a simple and efficient synthetic method for carrying out the well-known hydrodediazoniation reaction. Our failure to observe CIDNP signals for the decomposition of **1** is probably due to the relatively slow decomposition of **1**.

Our results for the hindered system (**1**) provide some insight into the role of steric effects on the dediazoniation reaction. This is a somewhat specialized system and our conclusions cannot readily be generalized. Nevertheless, the fact that radicals are trapped while at the same time products form from ionic pathways, in these and earlier (13) studies, indicates that ionic and radical reactions are independently occurring as shown in simplified form in Scheme 3. More detailed arguments in

[6]An alternative scheme suggested by a referee involves the radical $Et_2N\dot{C}HMe$ in the decomposition in triethylamine. It could form by rapid hydrogen abstraction from $Et_3N$ according to the following chain reaction sequence:

$$Ar\cdot + Et_3N \rightarrow ArH + Et_2N\dot{C}HMe$$
$$Et_2N\dot{C}HMe + Ar\overset{(+)}{N}_2 \rightarrow ArN{=}N\cdot + Et_2\overset{(+)}{N}{=}CHMe$$
$$ArN{=}N\cdot \rightarrow Ar\cdot + N_2$$

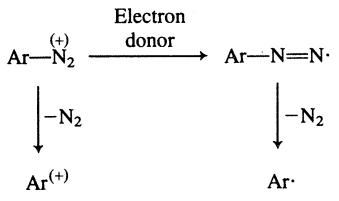

SCHEME 3

favour of a similar scheme have been given by Bunnett and co-workers (38).

## Experimental

*Materials and methods*

*N*-Nitroso-2,4,6-tri-*tert*-butylacetanilide (**1**) was prepared as described (13) and purified by preparative tlc immediately before use. *N*-Nitrosoacetanilide was prepared as described (39) and stored at −20°C over potassium hydroxide pellets. 2,4,6-Tri-*tert*-butylphenyldiazonium nitrate was prepared by the reaction of 2,4,6-tri-*tert*-butylaniline with nitric oxide (40). *N*,*N*,*N*′,*N*′-Tetramethylparaphenylenediamine and triphenylamine were reagent grade. All solvents were reagent grade, distilled before use. Triethylamine was distilled from 1% phenylisothiocyanate before use. Perdeuterobenzene and perdeuterotoluene of minimum isotopic purity 99 at.% deuterium were obtained from Merck, Sharpe and Dohme. The tlc separations were carried out on 20 × 20 cm and 0.5 mm-thick plates of silica gel using benzene eluant. The nmr measurements were made with a Varian EM360-L spectrometer and ir spectra were determined on a Perkin–Elmer 467 spectrometer. Electron spin resonance spectra were recorded on a Varian E-3 spectrometer using an esr reactor tube as previously described (13) and the $g$ values measured relative to that of tetracene in sulfuric acid, $g = 2.002604$ (41). Melting points were determined on a hot stage and are uncorrected.

*Product studies*

In a typical decomposition, a solution of **1** (931 mg, 2.80 mmol) in 50 mL of benzene or triethylamine was heated under a nitrogen atmosphere in an oil bath at 80°C until the carbonyl absorbance of the starting material (ir 1750 $cm^{-1}$) had disappeared. Experiments in triethylamine precipitated the highly insoluble 2,4,6-tri-*tert*-butylacetanilide (mp 270°C, lit. (13) mp 273°C) which was removed by filtration. The solvent was removed under reduced pressure and the residue separated on a number (e.g. 10) of preparative tlc plates. The products were identified, where applicable (e.g. hydrocarbons **5** and **6**, 2,4,6-tri-*tert*-butylacetanilide, 2-(3,5-di-*tert*-butylphenyl)-2-methylpropanal oxime **13**), by comparison of their nmr and ir spectra and melting points with those previously found (13, 17). 2,4,6-Tri-*tert*-butylphenyl acetate (**3**), the major product from **1** in benzene, gave mp 100–102°C (lit. (42) mp 101–102°C), ir band at 1780 $cm^{-1}$ for C=O ester, and nmr bands at δ 1.34 (s, 27H, 3 × $(CH_3)_3C$-), 2.25 (s, 3H, $CH_3COO$-), and 7.25 (s, 2H, aryl H). The minor product from this reaction, rearranged acetate (**4**), was separated from other compounds (e.g. **3**) by repeated preparative tlc. There was not sufficient sample for a complete analysis. Its ir spectrum showed a band at 1760 $cm^{-1}$ for C=O ester, and nmr bands at δ 1.33 (s, 18H, 2 × $(CH_3)_3C$-), 1.54 (s, 6H, $(CH_3)_2C$-), 2.23 (s, 3H, $CH_3COO$-), 2.54 (s, 2H, $CH_2$-), and 7.20 (m, 3H, aryl H).

*Chemically induced dynamic nuclear polarization*

Samples were prepared by rapidly dissolving the *N*-nitrosoacetanilide or aniline (1 mmol) in the cold solvent (0.40 mL of perdeuterobenzene, perdeuterotoluene, or triethylamine containing 50 μL tetramethylsilane) at approximately 0°C. The sample was degassed in the cold in the nmr tube by bubbling with nitrogen. The tube was sealed and the contents frozen in liquid nitrogen. The tube was warmed to −30°C in a methanol–liquid nitrogen bath just before placing in the nmr probe. The temperature of the probe was varied (usually from 10° to 50°C for samples in the deuterated solvents and −25° to 30°C for samples in triethylamine) and rapid repetitive scans were made through the aromatic proton region with the instrument locked on TMS. Benzene was confirmed as a product by peak enhancement on addition of benzene after the CIDNP effect was over. To confirm the presence of polarized biphenyl, a decomposition was carried out with biphenyl present (0.1 mmol to 1 mmol of *N*-nitrosoacetanilide). The ordinary biphenyl absorption was matched (and subsequently lost) by the intense polarized biphenyl emission.

# La dissolution du chlorure cuivreux formé par oxydation électrochimique du cuivre

ROBERT-LOUIS BROSSARD

*Institut de recherche d'Hydro-Québec, C.P. 1000, 1800 Montée Ste-Julie, Varennes (Qué.), Canada J0L 2P0*

Reçu le 27 juillet 1981

ROBERT-LOUIS BROSSARD. Can. J. Chem. **60**, 616 (1982).

La dissolution du chlorure cuivreux, formée par oxydation électrochimique du cuivre immergé en solution aqueuse avec LiCl dissout, a été étudiée. Le pH était compris entre 3 et 5 alors que la concentration en LiCl dissous a été variée de $2{,}36 \times 10^{-2}$ *M* à $16{,}5 \times 10^{-2}$ *M*. Le produit de corrosion accumulé sur l'électrode est constitué de cristaux de nantokite (CuCl) formés par précipitation.

La présence de ce précipité contribue à l'enrichissement local de la solution qui est dans un état voisin de la saturation près de l'électrode. Cet enrichissement se traduit par une tension d'électrode en circuit ouvert bien caractéristique. Elle est approximativement égale à −40 mV (/ECS) sur une électrode en stationnaire. La dissolution complète du CuCl coïncide, pour sa part, à une chute rapide de la tension. Cette chute de tension a permis de définir le temps de transition $\tau$ à partir duquel la vitesse de dissolution du CuCl a été calculée. Par exemple, la vitesse de dissolution est de $0{,}15 \pm 0{,}01$ mC $s^{-1}$ $cm^{-2}$ en courant équivalent pour une électrode stationnaire en présence de $2{,}36 \times 10^{-2}$ *M* de LiCl dissous. Elle est aussi constante jusqu'à la disparition complète du précipité.

Par ailleurs, l'utilisation de l'électrode à disque tournant a mis en évidence que la dissolution est entièrement dominée par la diffusion d'une espèce ionique en phase liquide. Les résultats expérimentaux sont compatibles avec la présence de $CuCl_2^-$ comme espèce diffusante.

---

ROBERT-LOUIS BROSSARD. Can. J. Chem. **60**, 616 (1982).

We have studied the dissolution of copper chloride formed by the electrochemical oxidation of copper immersed in aqueous lithium chloride. The pH was maintained between 3 and 5 while the concentration of LiCl in solution was varied between $2.36 \times 10^{-2}$ *M* to $16.5 \times 10^{-2}$ *M*. The corrosion product accumulating on the electrode consists of crystals of nantokite (CuCl) formed by precipitation.

The presence of this precipitate contributes to the local enrichment of the solution which is close to saturation near the electrode. This enrichment is revealed by an electrode voltage in a well characterized open circuit. This current is about −40 mV (/ECS) on a stationary electrode. The complete dissolution of CuCl coincides with a rapid drop in voltage which allows the transition time $\tau$ to be defined from which the speed of dissolution of CuCl has been calculated. For example, the speed of dissolution is $0.15 \pm 0.01$ mC $s^{-1}$ $cm^{-2}$ in a current equivalent for a stationary electrode in the presence of $2.36 \times 10^{-2}$ *M* of dissolved LiCl. This is also constant until the complete disappearance of the precipitate.

In another study, the use of a rotating disc electrode shows that the dissolution is completely dominated by the diffusion of ionic species in the liquid phase. The experimental results are compatible with the presence of $CuCl_2^-$ as the diffusing species.

[Journal translation]

## 1. Introduction

La corrosion du cuivre en solution aqueuse est intimement liée à la nature des anions présents dans la solution (1) avec lesquels il a tendance à former de nombreux complexes (2–4). En présence d'ions chlorures, notamment, la dissolution anodique du cuivre s'accompagne généralement de la formation de complexes comme le $CuCl_2^-$ et le $CuCl_3^{2-}$, selon la concentration en $Cl^-$ (5–9). Il a aussi été clairement établi que la vitesse de dissolution du cuivre est contrôlée par la diffusion des ions dans la phase liquide (5–12), le cuivre ayant habituellement une valence de +1.

Par ailleurs, le chlorure cuivreux est susceptible de précipiter à la surface de l'électrode (7, 9–11, 13). La seule étude actuellement disponible dans la littérature au sujet de la dissolution du CuCl formé par précipitation électrochimique sur une électrode de cuivre a été réalisée en solution aqueuse contenant 2 *M* de HCl (7). Une méthode optique a permis de suivre, de façon qualitative, le gradient de concentration des différentes espèces ioniques près de la surface d'une électrode en stationnaire. L'étape déterminante de la dissolution du CuCl est attribuée à la diffusion du $CuCl_2^-$ dans la phase liquide. Enfin, il a été observé que la dissolution du CuCl, formé par voie non électrochimique, est contrôlée par la diffusion d'un complexe dans la solution (14). La solution contenait entre 0,11 et 0,89 *M* en NaCl dissous.

Le présent travail, pour sa part, se propose d'approfondir en utilisant une approche originale, l'étude de la dissolution du CuCl fraîchement formé à partir de l'oxydation électrochimique du cuivre en solution aqueuse. Les solutions aqueuses contiennent entre $2{,}36 \times 10^{-2}$ *M* et $16{,}49 \times 10^{-2}$ *M* de LiCl dissous.

## 2. Partie expérimentale

### 2.1 *La cellule et ses accessoires*

Les cellules électrochimiques utilisées étaient d'un type conventionnel avec une électrode de travail en cuivre, une contre-électrode en platine platinée et une électrode de référence au calomel saturé. La solution en contact avec la contre-électrode était séparée de la solution mère par du verre fritté

alors que l'électrode de référence était immergée dans la partie supérieure du capillaire de Luggin dont l'extrémité venait à près de 1 mm de la surface de l'électrode en cuivre.

L'électrode de cuivre (Ventron Corp., 99,99%) se présentait sous la forme d'un fil de 0,64 cm de diamètre, d'une plaque de 1 cm × 2 cm ou d'un disque de 0,95 cm de diamètre; la surface de l'échantillon était de ~ 0,5 $cm^2$, ~ 4 $cm^2$ et 0,71 $cm^2$ respectivement. Le fil et la plaque étaient en position verticale tandis que le disque était en position horizontale. Les échantillons n'ont subi aucun traitement thermique préalable, tandis qu'une eau triplement distillée a été utilisée dans la préparation des solutions.

2.2 *La préparation des essais*

Un barbotage d'argon de 6 h précédait l'immersion de l'électrode de travail dans la solution. Les solutions étaient légèrement acides, le pH étant compris entre 3 et 5, et contenaient entre 1 et 7 g/L de LiCl. Un tampon à base de phtalate de potassium a été utilisé pour stabiliser le pH.

La méthode utilisée par Shoesmith et Lee (16) a été retenue pour le polissage du cuivre: l'échantillon était poli mécaniquement par abrasion avec du papier au carbure de silicium pour se terminer par un polissage avec une pâte de diament de 1 μ. L'échantillon était alors rincé à l'alcool, à l'acétone puis à l'eau distillée avant sont immersion.

2.3 *Les techniques expérimentales utilisées*

Les courbes cyclovoltammétriques ont été obtenues par les méthodes courantes. Un générateur de Tacussel G-STP2C, couplé à un potentiostat Wenking # 771068FR05, permettait de faire varier de façon continue ou brusque la tension de consigne imposée à l'électrode de cuivre. Un coulomètre Koslow Sci. Co. # 541 servait à mesurer la quantité d'électricité qui traversait l'électrode de travail durant l'oxydation et la réduction.

Par ailleurs, l'oxydation et la réduction en mode potentiostatique, i.e. à tension d'électrode constante, ont été effectuées en l'absence de toute agitation sur une électrode de travail stationnaire. Le cas échéant, l'agitation était imposée par barbotage d'un gaz inerte ou par rotation de l'électrode durant les périodes en circuit ouvert seulement.

Enfin, l'approche expérimentale mise au point pour la mesure de la vitesse de dissolution du chlorure cuivreux est décrite plus loin tandis que toutes les valeurs de la tension d'électrode sont données par rapport à l'électrode au calomel saturé.

## 3. Résultats expérimentaux et discussion

3.1 *Formation de la nantokite*

L'examen de l'enregistrement cyclovoltammétrique, reproduit à la figure 1, est représentatif du comportement de l'électrode de cuivre. L'accroissement de la vitesse de dissolution ($i_a$) est détectable au delà de −50 mV (/ECS). Pour des valeurs de tension croissantes, cet accroissement est continu de sorte que 4,1 mA/$cm^2$ coïncide avec + 100 mV.

Par ailleurs, $i_a$ est légèrement inférieur lors du balayage de retour tandis qu'un courant de réduction ($i_c$) est observé lorsque la tension franchit −15 mV. $i_c$ passe par un maximum de 4 mA/$cm^2$ environ pour devenir négligeable lorsque la tension atteint −180 mV, environ.

Dans ce cas, les quantités d'électricité mises en jeu sont de 48,5 mC/$cm^2$ en anodique ($Q_{oxy}$) contre

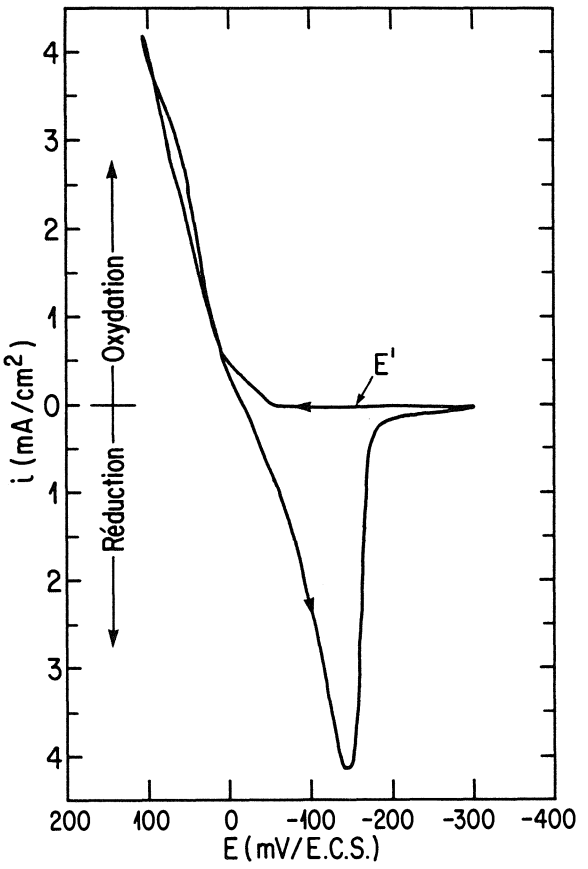

FIG. 1. Courbe de polarisation cyclovoltammétrique sur un fil de cuivre. E': tension du cuivre en circuit ouvert. Balayage à 10 mV/s. LiCl: 1 g/L, pH = 4.

32,5 mC/$cm^2$ en cathodique ($Q_{red}$). Le rapport $Q_{red}/Q_{oxy}$ est alors de 0,67. Ce comportement est généralement associé à la réduction d'un film peu ou pas protecteur formé durant le balayage anodique (15).

Le produit de corrosion qui s'accumule sur l'anode a été examiné par le microscope optique et à balayage ainsi que par diffraction aux rayons-X. Ces examens ont montré des cristaux de nantokite (CuCl) qui s'enchevêtrent pour recouvrir partiellement une surface sous-jacente à l'aspect rugueux (Fig. 2) et qui correspond au cuivre. On remarque, aussi, que les cristaux de nantokite sont souvent de forme tétraédrique. Dans l'exemple reproduit à la fig. 2, la portion de surface couverte par le précipité est de l'ordre de 0,5.

L'ensemble de ces observations suggère que la dissolution du cuivre est relativement uniforme tandis que les cristaux sont le résultat de la précipitation du CuCl suite à l'enrichissement de la solution en $Cu^+$ et en $Cl^-$ près de l'électrode.

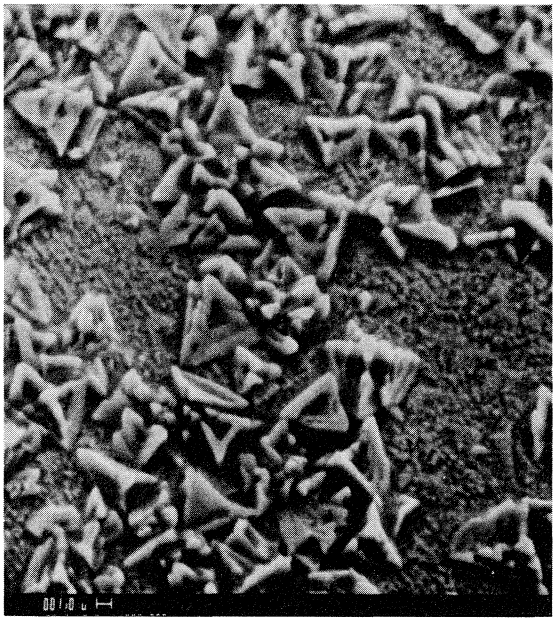

FIG. 2. Aspect de la surface de l'anode de cuivre en présence de nantokite. Tension imposée: +50 mV, durant 8 min.

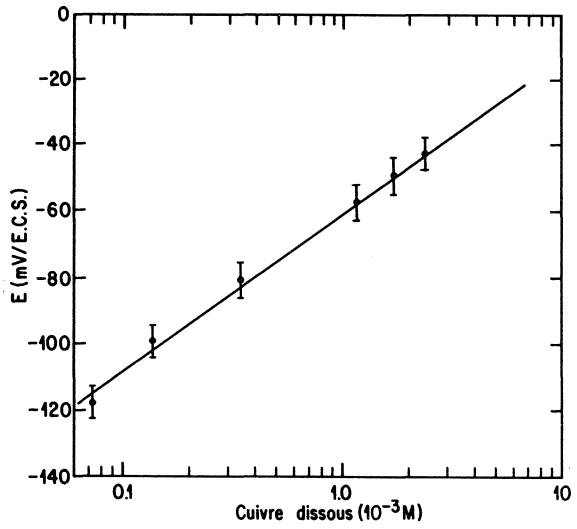

FIG. 3. Tension de l'électrode de cuivre en circuit ouvert ($E_{co}$) en l'absence de précipité en fonction de la concentration en cuivre dissous. LiCl: 1 g/L, pH = 4, solution désaérée.

### 3.2 *Passivation transitoire du cuivre*

La dissolution du CuCl, dès le retour en circuit ouvert, est susceptible de contribuer à l'enrichissement local de la solution. Il est alors prévisible que la tension du cuivre traduise cet enrichissement local.

La tension en circuit ouvert ($E_{co}$) du cuivre, en l'absence de précipité à sa surface, est représentée en fonction de la concentration en cuivre dissous à la fig. 3 tandis que $E_{co}$ du cuivre, en présence de précipité formé à sa surface, est donnée en fonction du temps à la fig. 4. $E_{co}$ du cuivre en présence de précipité présente deux plateaux. Le premier plateau se situe à −40 mV environ; cette valeur est voisine de la tension théorique de −10 mV qui correspond à l'équilibre Cu/CuCl (2). Par ailleurs, la saturation de la solution en $CuCl_2^-$ en présence de 1 g/L de LiCl dissous est de $1{,}34 \times 10^{-3}$ *M* d'après les valeurs thermodynamiques (2). Cette concentration de $1{,}34 \times 10^{-3}$ *M* en cuivre coïncide à $E_{co}$ égal à $-54 \pm 5$ mV (Fig. 3). Il est alors raisonnable d'envisager que la solution est dans un état proche de la saturation près de l'électrode alors recouverte de précipité.

Près du temps de transition τ, une baisse rapide de la tension se manifeste et un deuxième plateau est atteint au-delà de τ (Fig. 4). La tension du deuxième plateau dépend de la concentration en cuivre dissous au coeur de la solution. Quant au temps de transition τ, il est défini en suivant la même procédure que Shoesmith et Lee (16) pour l'étude de films d'oxydes de cuivre métastables.

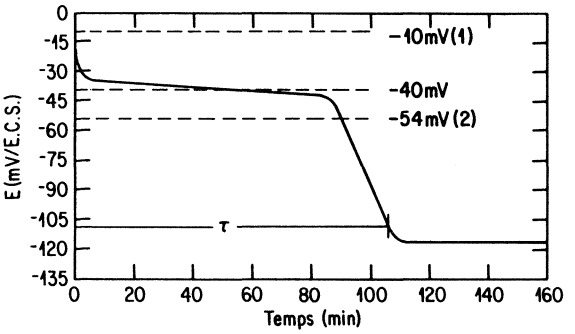

FIG. 4. Tension de l'électrode de cuivre en circuit ouvert après la formation de CuCl. *E*: tension d'électrode en circuit ouvert. LiCl: 1 g/L, pH = 4, solution désaérée. (1) $E_{co}$ théorique de l'équilibre Cu/CuCl; (2) $E_{co}$ pour $1{,}34 \times 10^{-3}$ *M* en cuivre dissous (Fig. 3).

De plus, l'examen de la surface au microscope a mis en évidence la disparition graduelle du produit de corrosion entre $t = 0$ et $t = \tau$ (Fig. 5a, b, c) tandis que le cuivre est complètement à nu à partir de τ (Fig. 5d, e).

La dissolution du précipité doit aussi se traduire par une augmentation de la concentration en cuivre dissous au sein de la solution jusqu'au temps $t = \tau$. Comme le montre l'example reproduit à la figure 6, la concentration en cuivre augmente de façon quasi linéaire avec le temps. L'enrichissement en cuivre ralentit en approchant de τ pour cesser au-delà de τ. Ce comportement incite à croire que la vitesse de dissolution de la nantokite est constante dans le temps jusqu'au voisinage du temps de transition.

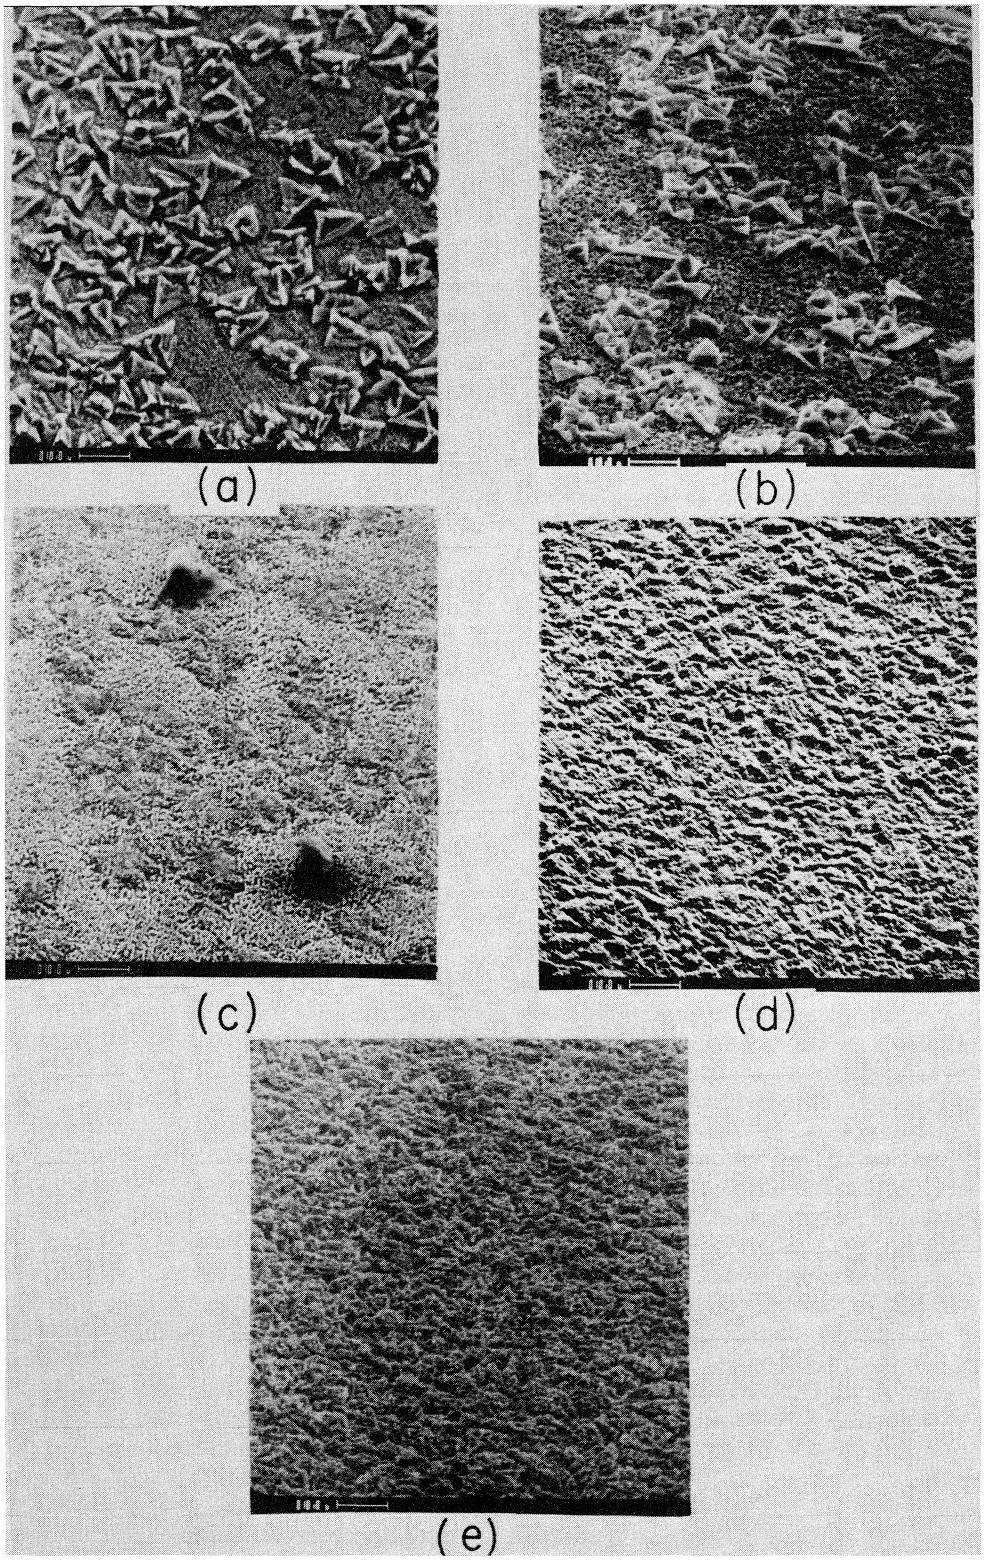

FIG. 5. Apparence de la surface de l'électrode durant la dissolution du CuCl. Condition d'oxydation: + 50 mV durant 8 min. LiCl: 1 g/L, pH = 4. Les durées d'immersion sont: (a) 0,05 $\tau$, (b) 0,40 $\tau$, (c) 0,91 $\tau$, (d) 0,99 $\tau$, (e) 1,17 $\tau$.

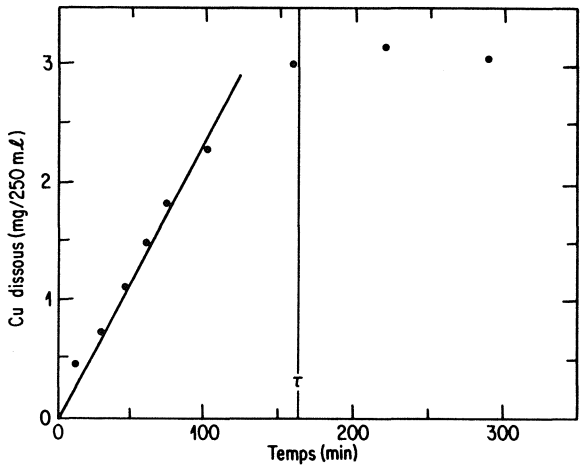

FIG. 6. Enrichissement de la solution en cuivre durant la dissolution de la nantokite. Concentration en cuivre obtenue à l'aide de la spectroscopie par absorption atomique.

### 3.3 *Mesure de la quantité de CuCl présent sur le cuivre*

La surface du cuivre était complètement à nu au départ. L'échantillon subissait, dans un premier temps, une oxydation électrochimique par enclenchement d'une tension anodique. La valeur de + 50 mV a été choisie. Un second enclenchement à −300 mV, destiné à réduire le précipité, suivait immédiatement l'oxydation. Les charges électriques mises en jeu durant l'oxydation ($Q_{oxy}$) et la réduction $(Q_{red})_{t=0}$ étaient mesurées.

Dans ces conditions, la réduction du précipité dépasse rarement 1 min. Le courant devient négligeable au pied de la vague de réduction, ce qui suggère la réduction complète du précipité. L'absence de précipité a été confirmée à partir de l'examen de la surface au microscope et de la mesure de la tension d'électrode en circuit ouvert. Le comportement du CuCl soumis à une réduction rappelle celui du $Cu(OH)_2$ en solution alcaline (16).

Par ailleurs, la charge de réduction $(Q_{red})_{t=0}$ dépend de la charge en oxydation ($Q_{oxy}$) tandis que le rapport $(Q_{red})_{t=0}/Q_{oxy}$ est constant lorsque les conditions d'oxydation demeurent les mêmes et ce, malgré les variations importantes de $Q_{oxy}$ (Fig. 7) qui ont été observées. Dans cet exemple, les charges $Q_{oxy}$ et $(Q_{red})_{t=0}$ ont été mesurées pour plusieurs cycles successifs oxydation–réduction avec +50 mV imposé durant 8 min en oxydation et −300 mV imposé durant 5 min en réduction.

En l'absence d'agitation, le rapport $(Q_{red})_{t=0}/Q_{oxy}$ demeure voisin de 0,5 tandis que $Q_{oxy}$ est compris entre 1100 et 2350 mC/cm². Ce rapport tend a diminuer lorsque l'agitation de la solution devient plus intense. La perte qui correspond à $Q_{oxy} - (Q_{red})_{t=0}$ est attribuée à la non précipitation d'une partie du cuivre qui va en solution, à la dissolution partielle du précipité et, enfin, au fait observable à l'oeil nu que des cristaux de nantokite ne sont pas retenus à la surface de l'électrode. Ainsi, la constance du rapport $(Q_{red})_{t=0}/Q_{oxy}$ permet de déduire la quantité de précipité présent en terme de charge $Q_{red}$ à partir de la valeur de $Q_{oxy}$.

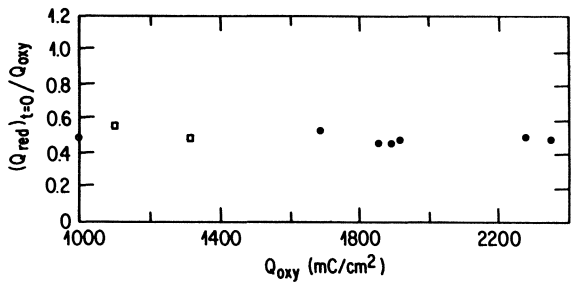

FIG. 7. Rapport $(Q_{red})_{t=0}/Q_{oxy}$ en fonction de $Q_{oxy}$ pour deux échantillons différents. $Q_{oxy}$: quantité d'électricité impliquée durant l'oxydation. $(Q_{red})_{t=0}$: quantité d'électricité obtenue par réduction complète du CuCl immédiatement après oxydation. $E_{oxy}$ = +50 mV durant 8 min; $E_{red}$ = −300 mV durant 5 min.

Le rapport $(Q_{red})_{t=0}/Q_{oxy}$ varie sensiblement d'un échantillon à l'autre même si les conditions expérimentales sont rigoureusement les mêmes. Par conséquent, ce rapport a été déterminé pour chaque immersion et $Q_{red}$ a été calculé à partir de $Q_{oxy}$.

### 3.4 *Vitesse de dissolution de la nantokite sur une électrode stationnaire*

On a vu, d'une part, que la quantité de précipité présent à la surface de l'échantillon est calculable et que, d'autre part, la dissolution du CuCl en circuit ouvert s'achève complètement au temps de transition τ. De plus, l'enrichissement de la solution en cuivre est quasi-linéaire avec le temps jusqu'en τ (Fig. 6); ce qui est compatible avec une vitesse de dissolution ($v$) constante. La vitesse $v$, en courant équivalent, est donc évaluable à partir du rapport $(Q_{red})_{t=0}/\tau$. Les mesures de $v$, à partir de cette approche, ont données 0,14 mC $s^{-1}$ $cm^{-2}$ en courant équivalent pour 1 g/L de LiCl dissous.

Par ailleurs, la constance de $v$ a été vérifiée à partir de la réduction à −300 mV du précipité après des durées variables de séjour en circuit ouvert (Fig. 8.). La différence entre $(Q_{red})_{t=0}$ et $(Q_{red})_{t=t}$ est associée à la perte de nantokite durant le temps $t$ où l'électrode est en circuit ouvert. La pente de la droite obtenue, qui correspond à $v$ en courant équivalent, est ici de 0,16 mC $s^{-1}$ $cm^{-2}$. La perte en nantokite cesse au temps τ où la dissolution du précipité est complète.

Enfin, on a observé que la vitesse de dissolution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

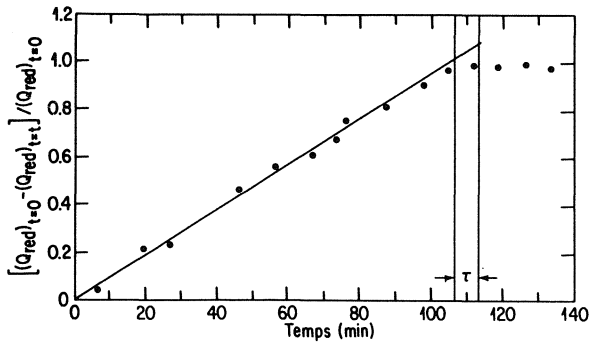

FIG. 8. Quantité de précipité qui passe en solution durant la période en circuit ouvert. $(Q_{red})_{t=0}$: quantité d'électricité disponible par réduction du CuCl immédiatement après formation du précipité. $(Q_{red})_{t=t}$: quantité d'électricité obtenue par réduction du précipité après le temps $t$. $(Q_{red})_{t=0} - (Q_{red})_{t=t}$: quantité de précipité qui va en solution durant le temps $t$.

est intimement liée à l'agitation de la solution réalisée à l'aide d'un barbotage d'un gaz inerte, par exemple, ainsi qu'à la position de l'électrode par rapport à la verticale alors que $v$ est maximum en position verticale et minimum à l'horizontal. L'utilisation d'une électrode à disque tournant en cuivre a permis de fixer les conditions d'agitation et d'établir que la vitesse de dissolution est contrôlée par la diffusion en phase liquide.

### 3.5 *Influence de l'agitation*

Les enregistrements de la tension en circuit ouvert en fonction du temps, reproduits à la figure 9, confirment l'influence déterminante de l'agitation pour des vitesses de rotation comprises entre 4 et 100 t/s. La vitesse de dissolution du CuCl, calculée à partir de la variation de la tension transitoire du cuivre en circuit ouvert, est donnée en fonction de la racine carrée de la vitesse de rotation de l'électrode (Fig. 10) où ω est compris entre 1 et 100 t/s.

L'augmentation linéaire de $v$ avec la racine carrée de ω est caractéristique d'un processus de dissoluton entièrement contrôlé par la diffusion dans la phase liquide (17). En langage mathématique:

[1] $$v = K\omega^{\frac{1}{2}}$$

avec

[2] $$K = 0{,}62\, nFD^{2/3}\nu^{-1/6}(C_s - C_0)$$

où ν correspond à la viscosité de la solution. $C_s$ et $C_0$ représentent la concentration de l'espèce considérée en surface et au sein de la solution, respectivement.

Ainsi, le coefficient de diffusion $D$ est calculable à partir de la relation [2] selon

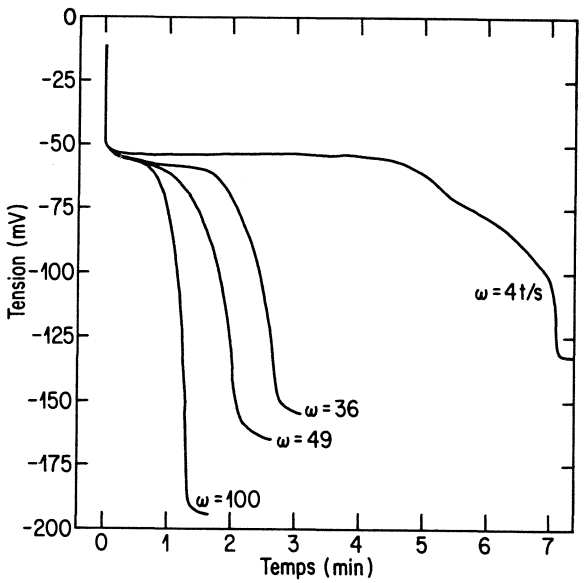

FIG. 9. Influence de la vitesse de rotation de l'électrode sur la tension en circuit ouvert. ω: vitesse de rotation de l'électrode en tours par seconde. pH = 4, LiCl = 5 g/L, $A$ = 0,71 cm².

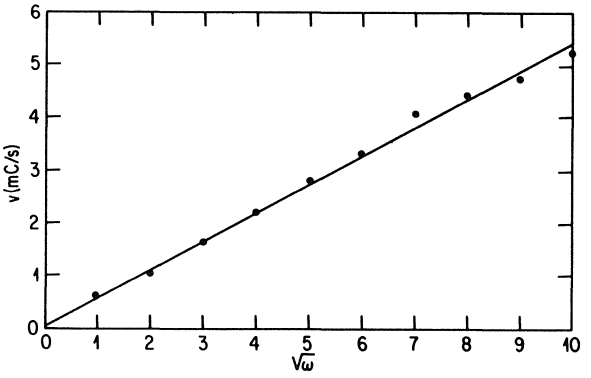

FIG. 10. Vitesse de dissolution en fonction de $\sqrt{\omega}$. $v$: vitesse de dissolution du CuCl en courant équivalent; pH = 4, LiCl = 5 g/L, $A$ = 0,71 cm².

[3] $$D = 2{,}05\, K^{3/2}\nu^{1/4}(nF)^{-3/2}(C_s - C_0)^{-3/2}$$

Par ailleurs, on a vu que la solution au voisinage de l'électrode est saturée en ion cuivreux (Figs. 2, 3, 9) tandis que le cuivre dissous doit exister sous forme de $CuCl_2^-$ dans la gamme de concentration en $Cl^-$ considérée (5, 14). La formation du $CuCl_2^-$ à partir de la nantokite est compatible avec la réaction globale:

[4] $$CuCl + Cl^- \rightleftarrows CuCl_2^-$$

La saturation en $CuCl_2^-(C_s)$, évaluée à partir des valeurs des enthalpies libres de formation standard (2) pour la réaction [4], est donnée en fonction de la concentration en LiCl dissous (Tableau 1). Pour sa

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

TABLEAU 1. Saturation en $CuCl_2^-$ en fonction de la concentration en LiCl dissous

| LiCl dissous (g/L) | $C_s$ ($10^{-3}$ $M$)[a] |
|---|---|
| 1 | 1,34 |
| 2 | 2,68 |
| 3 | 4,02 |
| 5 | 6,7 |
| 7 | 9,38 |

[a]Saturation évaluée à partir des valeurs des enthalpies libres de formation standard (2) pour la réaction [4].

part, ν est égal à $0,96 \times 10^{-2}$ cm²/s (18, 19) contre 1 pour $n$ alors que $C_o$ est estimée négligeable par rapport à $C_s$.

Le rapport $v/\omega^{\frac{1}{2}}$ ou $K$ obtenu avec l'électrode à disque tournant est donné en fonction de la concentration en LiCl dissous à la figure 11. A l'aide de la relation [3], on trouve $D = 0,6 \times 10^{-5}$ cm²/s tandis que $D_{CuCl_2^-}$ généralement admis dans la littérature est compris entre 1 et $0,6 \times 10^{-5}$ cm²/s (20, 21).

De plus, rappelons que

$$[5] \quad C_s = K_e[Cl^-]$$

où $K_e$ est la constante à l'équilibre de la réaction [4] égale à 0,057 [2]. La combinaison des relations [2] et [5] avec $C_o \ll C_s$ conduit à:

$$[6] \quad K = 0,62\, nFD^{2/3}\nu^{-1/6}K_e[Cl^-]$$

Par conséquent, le rapport $v/\omega^{\frac{1}{2}}$ ou $K$ doit être proportionnel à $[Cl^-]$ dans le cas où la réaction [4] est envisagée. Ce qui est tout à fait conforme à nos mesures expérimentales (Fig. 11). Il est aussi prévisible que l'influence du pH entre 3 et 5 soit marginale (Fig. 12). Ainsi l'ensemble des résultats expérimentaux s'expliquent de façon cohérente à partir de la présence du $CuCl_2^-$ comme espèce ionique qui diffuse.

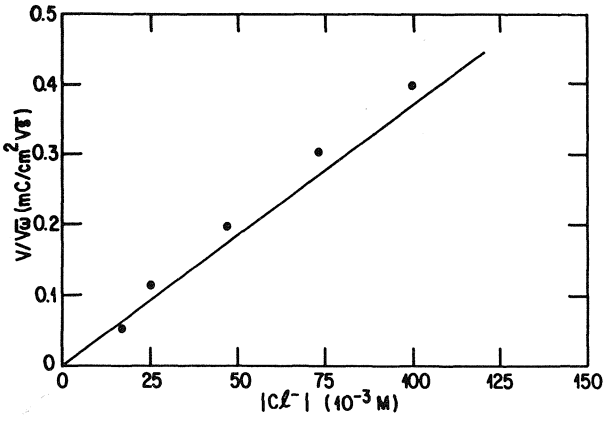

FIG. 11. Rapport $v/\omega^{\frac{1}{2}}$ en fonction de la concentration en LiCl dissous. Ces résultats ont été obtenus à l'aide de l'électrode à disque tournant.

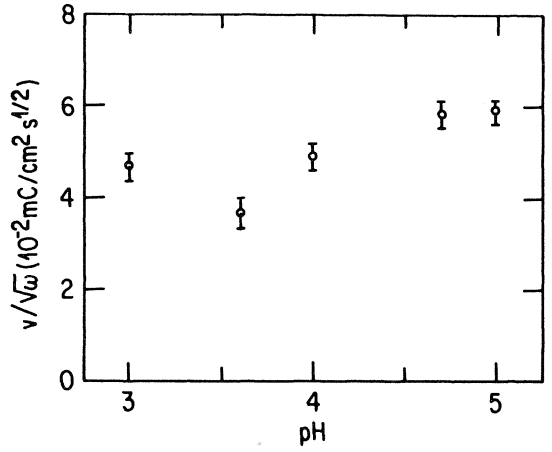

FIG. 12. Influence du pH sur la vitesse de dissolution de la nantokite. LiCl = 1 g/L.

## 4. Conclusion

1. La présence de chlorure cuivreux, formé par précipitation à la surface de l'électrode de cuivre, contribue à l'enrichissement local de la solution qui est alors dans un état voisin de la saturation en cuivre dissous. Cet enrichissement se traduit par une tension d'électrode bien caractéristique qui tombe dès la dissolution complète du précipité.

2. La vitesse de dissolution du précipité est constante jusque dans les instants qui précèdent sa dissolution complète. Elle est indépendante du pH entre 3 et 5 mais est proportionnelle à la concentration en $Cl^-$.

3. La dissolution de la nantokite est entièrement dominée par la diffusion d'une espèce ionique qui se déplace depuis l'électrode jusqu'au coeur de la solution. Les résultats expérimentaux s'expliquent entièrement à partir de la présence du $CuCl_2^-$ comme espèce ionique qui diffuse.

4. La mesure de la vitesse de dissolution du CuCl à partir de la détermination du temps de transition τ est un outil simple et efficace qui donne accès à l'étude de films peu épais fraîchement formés par oxydation électrochimique.

## Remerciements

# The Schmidt reaction of anthraquinones

CECILY A. FLEMMING, SHAM S. GANDHI, MARTIN S. GIBSON,[1] AND EDWARD H. RUEDIGER
*Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1*

Received August 26, 1981

CECILY A. FLEMMING, SHAM S. GANDHI, MARTIN S. GIBSON, and EDWARD H. RUEDIGER. Can. J. Chem. **60**, 624 (1982).

Schmidt reaction (sodium azide/sulfuric acid) of 1,5- and of 1,8-dichloroanthraquinones gives, in each case, both of the theoretically possible lactams (2,3,5,6-dibenzoazepin-4,7-diones). Two of the four theoretically possible lactams have been identified from Schmidt reaction of 1- and 2-chloroanthraquinones respectively. Methods used include: (a) preferential hydrolysis of one lactam and identification of the isomeric aminoanthraquinone formed on cyclodehydration of the resulting amino acid; (b) identification of the isomeric aminoanthraquinone(s) formed on direct treatment of a lactam (or mixture of lactams) by sulfuric acid; (c) cleavage by potassium *tert*-butoxide of the amino acid formed by preferential hydrolysis of one lactam and identification of the resulting benzoic acid as its methyl ester.

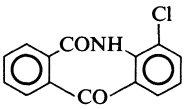
CECILY A. FLEMMING, SHAM S. GANDHI, MARTIN S. GIBSON et EDWARD H. RUEDIGER. Can. J. Chem. **60**, 624 (1982).

Les dichloro-1,5 et -1,8 anthraquinones soumises à la réaction de Schmidt (azoture de sodium/acide sulfurique) conduisent chacun aux deux lactames qui sont theoriquement possibles (dibenzo-2,3,5,6 azépinediones-4,7). On a identifié deux des quatres lactames pouvant provenir de la reaction de Schmidt sur les chloro-1 et chloro-2 anthraquinones respectivement. Les méthodes utilisées comprennent: (a) l'hydrolyse préférentielle d'un lactame et l'identification de l'aminoanthraquinone isomère formée par la cyclodeshydratation de l'acide amine formé; (b) l'identification des aminoanthraquinones isomères formées par la réaction directe du lactame (ou d'un melange de lactames) avec l'acide sulfurique; (c) l'utilisation du *tert*-butylate de potassium pour cliver l'acide aminé formé par l'hydrolyse préferentielle d'un lactame et l'identification de l'acide benzoique résultant sous forme d'ester méthylique.

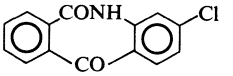
[Traduit par le journal]

Substituted 2-aminobenzophenones are of interest as sources of various heterocyclic compounds, including acridones (1, 2). The reports of Caronna and Palazzo that five monosubstituted anthraquinones react with sodium azide in concentrated sulfuric acid (Schmidt reaction) to give in each case a single lactam (2,3,5,6-dibenzoazepin-4,7-dione) are thus of interest since these lactams can be hydrolyzed to the corresponding 2-aminobenzophenone-2′-carboxylic acid (3, 4). Structures were assigned to these lactams and were supported in three cases by hydrolysis and alternate cyclodehydration to the corresponding aminoanthraquinone. In particular, the lactams obtained from 1- and 2-chloroanthraquinones were formulated as **1** and **2** respectively.

Schmidt reaction of a number of alkyl-substituted 1,4-benzo- and naphthoquinones has similarly been reported to give single lactams (5). However, structures were incorrectly assigned and in the course of correction it was noted that lactam mixtures were produced in some reactions (6, 7). It was concluded that these Schmidt reactions proceeded primarily under steric control, with electronic effects exerting a minor influence. Preferential attack occurred at the more hindered, less basic carbonyl group, followed by preferential migration of the larger attached substituent with loss of nitrogen.



**1**



**2**

Our objectives have been to verify, or otherwise, the course of the Schmidt reaction of 1- and 2-chloroanthraquinones, and to extend the study to 1,8- and 1,5-dichloroanthraquinones.

Schmidt reaction of 1-chloroanthraquinone gave a lactam product in high yield. It was, however, immediately apparent from thin-layer chromatography (tlc) and mass spectrometry that this product was a mixture of two or more lactams (four being theoretically possible) with closely related $R_f$ values. It was in fact possible by careful chromatography to separate two lactam fractions which for discussion we designate as lactam **A** (mp 178–180°C) and, in slightly larger quantity, lactam **B** (mp 227–229°C). This separation could, in effect, also be achieved by partial hydrolysis of the crude mixture using 2% ethanolic potassium hydroxide when lactam **A** was preferentially hydrolyzed. The amino acid thus produced (from lactam **A**) was heated with sulfuric acid to effect cyclization to the corresponding anthraquinone (3, 4). This gave a material (ca. 20%) which was separated by chromatography into 1-amino-2-chloroanthraquinone and lactam **A**, alternate products of cyclization of 2-amino-3-chlorobenzophenone-2′-carboxylic acid.

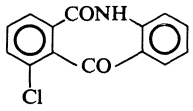
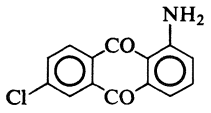
These are evidently derived from **1** as reported previously (4).

Lactam **B** was hydrolyzed using 25% aqueous potassium hydroxide. Cyclization of the resulting amino acid using sulfuric acid gave a material (ca. 30%) which on chromatography gave an aminoanthraquinone fraction and lactam **B**. The former was tentatively identified as (impure) 1,8-aminochloroanthraquinone since a mixture mp with the alternative 1,5-isomer showed depression; tlc and mass spectral characteristics were not sufficiently definitive to corroborate this identification. With this proviso, lactam **B** may be formulated as:

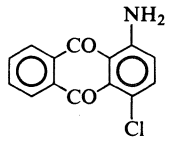


LACTAM B

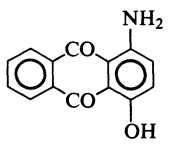
The case of 2-chloroanthraquinone also presents the possibility of four isomeric lactams being produced, of which **2** is one. Schmidt reaction gave a lactam mixture in good yield. The product showed simply a broad spot on tlc and, while assumed to be a mixture, did not lend itself to chromatographic separation or to attempts at preferential hydrolysis. In an attempt to identify (some of) the lactams present, this mixture was submitted to direct treatment with sulfuric acid (8). This gave a complex mixture (tlc) containing none of the starting lactams. Chromatography gave, in order of elution, compounds **3**, **4**, and **5**, each of which was



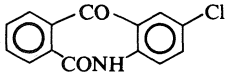
3



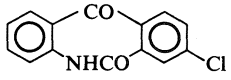
4



5



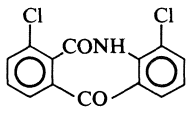
6



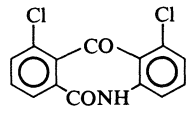
7

identified by comparison with authentic samples; recovery was ca. 50%. Compound **5** is evidently an artifact arising from hydrolytic displacement of chlorine either before or after formation of **4**. These compounds would have lactam **6** as precursor and compound **3** would similarly be derived from lactam **7**. Caronna and Palazzo's lactam **2** or the fourth possible isomer may have been present in the crude lactam mixture, but we obtained no evidence on this point.

The cases of 1,8- and 1,5-dichloroanthraquinones are in principle more tractable in that each of the quinones can yield at most two lactams. Schmidt reaction of 1,8-dichloroanthraquinone gave a mixture of two isomeric lactams (tlc) in good yield. Partial hydrolysis of this mixture with 2% ethanolic potassium hydroxide gave the (unhydrolyzed) lactam of slightly lower $R_f$ value and, after acidification, an amino acid derived from the other lactam. The lactam mixture was treated directly with sulfuric acid (8) and the product was chromatographed giving 1-amino-2,5-dichloroanthraquinone together with the lactam of lower $R_f$ value. A separate experiment confirmed that the lactam of lower $R_f$ value was only slightly affected under these reaction conditions. The quinone was evidently derived from **8** (lactam of higher $R_f$) since **9** (lactam of lower $R_f$) could not give a quinone without substituent displacement. The lactam of lower $R_f$ was hydrolyzed separately using 25% aqueous potassium hydroxide and the resulting amino acid was treated with sulfuric acid. Reversion to the lactam occurred, consistent with its formulation as **9**; interestingly, formation of 3-



8



9

chlorophthalic anhydride as a minor product was observed. The amino acid from **8**, similarly treated, gave the aforementioned quinone, together with **8** and 3-chlorophthalic anhydride (tlc, mass spectrum).

Implicit in methods of identifying these difficultly separable isomeric lactams by direct treatment with sulfuric acid or by preferential hydrolysis to an amino acid followed by treatment with sulfuric acid is the assumption that only direct cyclization to a quinone, where possible, occurs; i.e. there is no electrophilic displacement (or migration) of chlorine, nor do quinones arise by dismutation/recombination reactions. There are additional practical

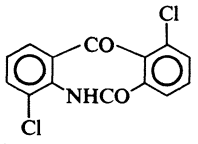
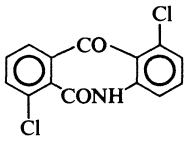
For personal use only.

problems of low yields and the absence of reference quinones for comparison as well as similarities in properties of isomeric quinones. For the Schmidt reaction of 1,5-dichloroanthraquinone, we have therefore developed an alternative approach. This reaction gave a mixture of two isomeric lactams, **10** and **11**, with closely related $R_f$ values. The lactam



**10**



**11**

of higher $R_f$ was preferentially hydrolyzed on treatment of the mixture with 2% ethanolic potassium hydroxide. The amino acid thus obtained is a substituted benzophenone and should thus be amenable to base cleavage to substituted benzoic (or phthalic) acids. Since cleavage of 2-chloro- and 2-carboxybenzophenones has been found to occur mainly on the side of the carbonyl group closer to the substituent (9), examination of cleavage product(s) should permit identification of the amino acid and hence of the precursory lactam. The amino acid in question was successfully cleaved by potassium *tert*-butoxide in 1,2-dimethoxyethane and the acid(s) isolated were converted to the methyl ester(s). Examination of the methyl ester(s) by gas–liquid chromatography (glc), using methyl 2- and 3-chlorobenzoates as standards, revealed the presence of the latter but none of the former ester. This is consistent only with the formulation of the preferentially hydrolyzed lactam as **10** and the other lactam as **11**. This method is reasonably convenient and likely to be useful in cases where the requisite anthraquinones are not available as standards for application of the earlier procedures for assigning lactam structures (3, 4, 8).

The synthetic usefulness of the Schmidt reaction of substituted anthraquinones is thus marred by the production of difficultly separable isomers rather than single lactams as previously reported (3, 4). Isomer production is a feature in common with the Schmidt reaction of some 1,4-benzo- and naphthoquinones (6, 7).

## Experimental

The ir spectra are quoted for KBr discs. The $^1$H nmr spectra were obtained on a Bruker WP-60FT spectrometer (60 MHz; tetramethylsilane as internal standard). Mass spectra were determined with an AEI MS-30 double-beam spectrometer; *m/e* values are reported for the lowest isotopic species (relative intensities in parentheses).

The tlc and plate chromatography were performed on silica gel; glc was carried out on an F and M Laboratory Chromatograph Model 700 using a six-foot column of diethylene glycol succinate on Chromosorb (80–100 mesh); column temperature 150°C, flow rate 40 mL/min.

Purity of all samples was checked before use. Commercial 1-amino-5-chloroanthraquinone was purified by plate chromatography, followed by sublimation, and had mp 221°C (lit. (10) mp 215–217°C); 1-amino-8-chloroanthraquinone was a prepared sample and had mp 225–229°C (lit. (10) mp 225–227°C), but was not quite pure.

*Schmidt reaction of 1-chloroanthraquinone*

To a stirred solution of the quinone (11.0 g) in concentrated $H_2SO_4$ (160 mL) was added $NaN_3$ (9.75 g) in portions so as to maintain a reaction temperature of 40–50°C. Stirring was continued at 40–50°C for 4 h and the mixture was then poured into water to give an off-white solid (10.6 g), mp 185–190°C, consisting apparently of two or more isomeric compounds (tlc, mass spectrum) similar in $R_f$ value.

A sample (1.0 g) of the crude product was chromatographed (silica gel, benzene). Elution gave lactam **A** (i.e. **1**) as a colorless solid (325 mg), mp 178–180°C (after crystallization from aqueous $Me_2SO$); ir: 3185, 1670 and 1655 cm$^{-1}$; $^1$H nmr ($Me_2SO$-$d_6$) δ: 10.09–10.04 (br s, 1H, exchangeable with $D_2O$); mass spectrum *m/e*: 257 ($M^+$, 75), 256 (M − H, 100), 229 (M − CO, 75), 222(M − Cl, 5), 201 (M − 2CO, 17), 166 (M − 2CO − Cl, 25), 139 (166 − HCN, 15). *Anal.* calcd. for $C_{14}H_8ClNO_2$: C 65.26, H 3.13, Cl 13.76, N 5.44; found: C 64.90, H 3.21, Cl 13.46, N 5.57.

Further elution gave lactam **B** as a colorless solid (500 mg), mp 227–229°C (after crystallization from aqueous $Me_2SO$); ir: 3180, 1670, and 1655 cm$^{-1}$; $^1$H nmr ($Me_2SO$-$d_6$) δ: 11.2 (br s, 1H, exchangeable with $D_2O$); mass spectrum *m/e*: 257 ($M^+$, 90), 256 (100), 229 (70), 222 (33), 201 (38), 166 (45), 139 (23). *Anal.* calcd. for $C_{14}H_8ClNO_2$: C 65.26, H 3.13, Cl 13.76, N 5.44; found: C 65.21, H 3.14, Cl 13.84, N 5.54.

*Hydrolysis of the foregoing lactams*

(a) A sample of the crude lactam mixture (5.0 g) from the previous experiment was boiled with 2% ethanolic KOH solution (100 mL) for 15 min. When cool, the solution was filtered and the filtrate was poured into water. The precipitated solid was crystallized from aqueous $Me_2SO$ to give the unhydrolyzed lactam **B** (2.45 g), mp 225–227°C, identical with the reference sample (mixture mp, tlc, ir spectrum).

The ethanolic filtrate from the hydrolysis was carefully acidified (concentrated $H_2SO_4$). Next day, the precipitated solid was collected and crystallized from aqueous ethanol to give 2-amino-3-chlorobenzophenone-2′-carboxylic acid (1.1 g), mp 180–181°C (lit. (11) mp 188°C); ir: 3465, 3345, 1690, and 1650 cm$^{-1}$; mass spectrum *m/e*: 275 ($M^+$). *Anal.* calcd. for $C_{14}H_{10}ClNO_3$: C 60.99, H 3.66, Cl 12.86, N 5.08; found: C 60.94, H 3.67, Cl 12.73, N 5.09.

(b) The lactam **B** (1.3 g, mp 225–227°C) was boiled with 25% aqueous KOH solution (60 mL) for 15 min and the solution was then filtered. When cool, the solution was carefully acidified (concentrated $H_2SO_4$) and left to stand overnight. The precipitated solid was collected, dried, and crystallized from benzene to give 2-amino-6′-chlorobenzophenone-2′-carboxylic acid (450 mg), mp 152–153°C; ir: 3460, 3345, 1720, and 1690 cm$^{-1}$; mass spectrum *m/e*: 275 ($M^+$). *Anal.* calcd. for $C_{14}H_{10}ClNO_3$: C 60.99, H 3.66, Cl 12.86, N 5.08; found: C 60.97, H 3.74, Cl 12.81, N 5.08.

*Treatment of the foregoing amino acids with concentrated sulfuric acid*

(a) A solution of 2-amino-3-chlorobenzophenone-2′-carboxylic acid (400 mg, mp 181–183°C) in concentrated $H_2SO_4$ (2.0 g) was slowly heated to 140–145°C and this reaction temperature was maintained for 6 h. When cool, the mixture was poured into ice-cold water. The precipitated solid (75 mg, mp 175–177°C),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

which apparently contained two components (tlc), was chromatographed on silica gel using benzene/petroleum ether as eluant. An orange solid (50 mg) was collected which crystallized from benzene/petroleum ether to give orange needles of 1-amino-2-chloroanthraquinone, mp 192–193°C (lit. (4) mp 197–198°C), identical with an authentic sample (mixture mp, tlc, mass spectrum); mass spectrum *m/e*: 257 ($M^+$).

Further elution (benzene) gave lactam **A** (**1**) (15 mg), mp 175–177°C, after crystallization from aqueous $Me_2SO$, identical with the reference sample (mixture mp tlc, ir spectrum).

(b) A solution of 2-amino-6′-chlorobenzophenone-2′-carboxylic acid (250 mg, mp 151–153°C) in concentrated $H_2SO_4$ (3.0 g) was heated slowly to 160–165°C and this temperature was maintained for 7 h. Isolated as in (a) above, the product (70 mg), which apparently contained two components (tlc), was chromatographed on silica gel (benzene/petroleum ether). This gave a brownish red solid (35 mg) which was crystallized twice from benzene to give red needles, mp 212–217°C, slightly contaminated with lactam **B** (mp 227–230°C); a mixture mp with 1,5-aminochloroanthraquinone was 189–210°C.

Further elution (benzene) gave lactam **B** (30 mg), mp 225–227°C after crystallization from aqueous $Me_2SO$, identical with the reference sample (mixture mp, tlc, ir, and mass spectra).

*Schmidt reaction of 2-chloroanthraquinone*

2-Chloroanthraquinone (16.5 g) was treated as for the 1-isomer above to give a crude product (14.8 g) consisting of two or more components with almost identical $R_f$ values. The mass spectrum suggested the presence of isomeric lactams (*m/e* 257; $M^+$). Attempts at chromatographic separation were unsuccessful as were attempts at preferential hydrolysis which gave presumably a mixture of amino acids with similar $R_f$ values.

A sample of the crude lactam mixture (6.0 g) was heated with concentrated $H_2SO_4$ (90 g) at 160–170°C for 6 h. When cool, the mixture was poured into ice-cold water and the purple solid (1.7 g) was filtered off, and dried.

A sample (900 mg) of the purple solid, shown by tlc to be a complex mixture, was chromatographed on silica gel using benzene/petroleum ether (1:3) as eluant. First eluted was 1-amino-6-chloroanthraquinone **3** (40 mg) as a red solid, mp 206–208°C (from nitrobenzene) (lit. (12) mp 210–211°C), identical with an authentic sample (mixture mp, tlc, mass spectrum); mass spectrum *m/e*: 257 ($M^+$). Continued elution with benzene/petroleum ether (1:1) gave 1-amino-4-chloroanthraquinone **4** (70 mg), mp 182–184°C (from toluene) (lit. (13) mp 179–180°C), identical with an authentic sample (mixture mp, tlc, mass spectrum); mass spectrum *m/e*: 257 ($M^+$). Finally, benzene eluted 1-amino-4-hydroxyanthraquinone **5** (315 mg) which crystallized from benzene/petroleum ether as violet needles, mp 210–212°C (lit. (14) mp 215°C), identical with an authentic sample (mixture mp, tlc, mass spectrum); $^1H$ nmr ($CDCl_3$) δ: 13.55 (s, 1H, -OH); mass spectrum *m/e*: 239 ($M^+$).

*Schmidt reaction of 1,8-dichloroanthraquinone*

Treatment of 1,8-dichloroanthraquinone (13.8 g) as above gave an off-white solid (12.9 g), mp 230–233°C, which apparently contained two isomeric lactams, **8** and **9** (tlc).

A sample of the lactam mixture (2.5 g) was heated with concentrated $H_2SO_4$ (35 g) at 140–145°C for 7 h. A portion (1.0 g) of the resulting brown solid, which was apparently a mixture of two components (tlc), was chromatographed on silica using toluene/petroleum ether (1:1) as eluant to give 1-amino-2,5-dichloroanthraquinone as orange-red needles (100 mg), mp 182–183°C (from toluene); mass spectrum *m/e*: 291 ($M^+$, 100), 263 (20), 239 (7), 237 (10), 200 (15), 173 (12), 164 (24), 127 (12), and 88 (12). *Anal.* calcd. for $C_{14}H_7Cl_2NO_2$: C 57.73, H 2.40, Cl 24.05, N 4.81; found: C 57.48, H 2.40, Cl 23.84, N 4.70.

Further elution gave lactam **9** (650 mg), mp 306–308°C, identical (mixture mp, ir spectrum, tlc) with the lactam of corresponding mp described below. A sample of this lactam (200 mg), similarly treated with $H_2SO_4$, was recovered (140 mg) in slightly impure form, a trace of a second compound being indicated by tlc.

*Hydrolysis of the foregoing lactams (8 and 9)*

(a) The crude lactam mixture (5.8 g) was boiled with 2% ethanolic KOH solution (65 mL) for 15 min, and unhydrolyzed material was collected as before. Crystallization from aqueous $Me_2SO$ gave lactam **9** (2.1 g), mp 306–308°C (homogeneous by tlc). An analytical sample had mp 313–315°C (from ethanol); mass spectrum *m/e*: 291 ($M^+$, 100), 290 (53), 263 (93), 256 (81), 235 (24), 228 (14), 200 (41), 173 (16), and 164 (43). *Anal.* calcd. for $C_{14}H_7Cl_2NO_2$: C 57.56, H 2.42, N 4.80; found: C 57.51, H 2.47, N 4.83.

The hydrolysis filtrate was carefully acidified ($H_2SO_4$). Next day, the yellow solid (1.45 g) was collected and crystallized from ethanol to give 2-amino-3,3′-dichlorobenzophenone-2′-carboxylic acid, mp 170–171°C; mass spectrum *m/e*: 309 ($M^+$). *Anal.* calcd. for $C_{14}H_9Cl_2NO_3$: C 54.22, H 2.92, Cl 22.86, N 4.52; found: C 54.37, H 2.94, Cl 23.09, N 4.45.

(b) Lactam **9** (700 mg, mp 306–308°C) was boiled with 25% aqueous KOH solution (30 mL) for 30 min and the solution was then filtered. When cool, the solution was carefully acidified ($H_2SO_4$). The gummy solid was collected, dried, and crystallized from benzene to yield yellow flakes of 2-amino-6,6′-dichlorobenzophenone-2′-carboxylic acid (450 mg), mp 179–180°C; mass spectrum *m/e*: 309 ($M^+$). *Anal.* calcd. for $C_{14}H_9Cl_2NO_3$: C 54.22, H 2.92, Cl 22.86, N 4.52; found: C 54.18, H 2.99, Cl 22.81; N 4.50.

*Treatment of the foregoing amino acids with concentrated sulfuric acid*

(a) The amino acid (70 mg, mp 170–171°C) derived from **8** was heated in concentrated $H_2SO_4$ (1.5 g) at 140–145°C for 6 h. This gave a brown solid (40 mg) consisting (tlc and mass spectra) of 1-amino-2,5-dichloroanthraquinone, 3-chlorophthalic anhydride, and lactam **8**.

(b) The amino acid (100 mg, mp 179–180°C) derived from **9** when similarly treated gave a near colourless solid (30 mg), shown (tlc and mass spectra) to consist of 3-chlorophthalic anhydride and lactam **9**. Chromatographic separation followed by sublimation gave the anhydride (6 mg), mp 126–127°C (lit (15) mp 126°C); ir: 1810 and 1750 (C=O) $cm^{-1}$; mass spectrum *m/e*: 182 ($M^+$).

*Schmidt reaction of 1,5-dichloroanthraquinone*

Treatment of 1,5-dichloroanthraquinone (8.5 g) as above gave a creamy-white powder (8.78 g) which apparently contained two isomeric lactams, **10** and **11** (tlc).

The lactam mixture (8.78 g) was boiled with 2% ethanolic KOH solution (100 mL) as before and unhydrolyzed material was filtered off. The filtrate was carefully acidified ($H_2SO_4$). The resulting gum was extracted with ethanol (35 mL), a small amount of insoluble solid being combined (tlc) with the unhydrolyzed material collected previously. The ethanolic solution was diluted with water and the resulting yellow solid was collected and crystallized from aqueous ethanol to give 2-amino-2′,3-dichlorobenzophenone-6′-carboxylic acid (3.2 g) as yellow spikes, mp 182–184°C; mass spectrum *m/e*: 309 ($M^+$). *Anal.* calcd. for $C_{14}H_9Cl_2NO_3$: C 54.22, H 2.92, Cl 22.86; found: C 54.13, H 2.96, Cl 23.07.

Crystallization of the unhydrolyzed lactam fraction from ethanol gave **11** (4.2 g) as white prisms, mp 321–322°C; mass spectrum *m/e*: 291 ($M^+$, 84), 290 (82), 263 (100), 256 (88), 235 (62), 200 (88), 173 (33), and 164 (85). *Anal.* calcd. for $C_{14}H_7Cl_2NO_2$: C 57.56, H 2.42, Cl 24.27; found: C 57.63, H 2.38, Cl 24.05.

*Cleavage of 2-amino-2',3-dichlorobenzophenone-6'-carboxylic acid*

The amino acid (1.6 g, mp 182–184°C) was added to a mixture made by adding water (0.28 g, 16 mmol) to a rapidly stirred solution of potassium *tert*-butoxide (5.8 g) in 1,2-dimethoxyethane (50 mL) under nitrogen. The mixture was stirred at 20°C for 3 h and then poured into water (250 mL). The solution was washed with ether (washings discarded), acidified (concentrated $H_2SO_4$), and then extracted with ether (3 × 50 mL). The combined ether extracts were washed with saturated aqueous $KHCO_3$ solution (2 × 50 mL). The bicarbonate washings were carefully acidified (concentrated HCl) and extracted with ether (2 × 50 mL). The ether solution was washed with water, dried ($Na_2SO_4$), and the solvent evaporated to give a light yellow residue (1.3 g). This mixture was esterified by refluxing in methanol (25 mL) and concentrated $H_2SO_4$ (2 mL) for 3 h. The mixture was then poured into water and extracted with ether. The ether was washed with saturated aqueous $KHCO_3$ solution (to remove any unreacted acid), then with water, and dried ($Na_2SO_4$).

The ethereal solution was then concentrated and the residue analyzed by glc. This showed the presence of methyl 3-chlorobenzoate (by comparison with an authentic sample).

## Acknowledgements

We are greatly indebted to Dr. G. Hallas (University of Leeds) for a sample of 1-amino-4-hydroxyanthraquinone and to Imperial Chemical Industries Ltd. (Dyestuffs Division) for research samples of several aminochloroanthraquinones. Financial support from the N.S.E.R.C., and from the Government of Ontario for graduate scholarships (to E.H.R.), is gratefully acknowledged.

# Structure of the Cornubert ketone

GEORGE R. PETTIT[1] AND EVAN G. THOMAS

*Cancer Research Institute and Department of Chemistry, Arizona State University, Tempe, AZ 85287, U.S.A.*
*and Department of Chemistry, University of Maine, Orono, ME 04473, U.S.A.*

Received August 11, 1981

GEORGE R. PETTIT and EVAN G. THOMAS. Can. J. Chem. **60**, 629 (1982).

The self-condensation of cyclohexanone in diethyl ether catalyzed by sodium amide has been found to provide a one-step route to pyran **3**. Evidence is presented that the Cornubert ketone formed by this reaction corresponds to ketol **2** which readily rearranges under dehydrating conditions to afford pyran **3**. Structural elucidation of pyran **3** was achieved by a combination of degradative (**3** → **5***b*), synthetic (**8** → **5***b*), and spectral methods. Xanthene **7**, a key dehydrogenation product of ketol **2**, was converted by selective reduction to dihydropyran **5***b*. The five-step synthesis of dihydroxypyran **5***b* from 1-carbomethoxycyclopentanol (**8**) provided unequivocal evidence for the structure assigned pyran **3** and xanthene **7**.

GEORGE R. PETTIT et EVAN G. THOMAS. Can. J. Chem. **60**, 629 (1982).

On a trouvé que l'auto-condensation de la cyclohexanone dans l'éther, catalysée par l'amidure de sodium, fournit une voie d'accès en une étape au pyranne **3**. On prouve que la cétone de Cornubert, formée par cette réaction, correspond au cétol **2** qui se transpose facilement en pyranne **3** dans des conditions de déshydratation. On a caractérisé le pyranne **3** en faisant appel à une combinaison de méthodes de dégradation (**3** → **5***b*), de synthèse (**8** → **5***b*) et spectrales. Par réduction sélective, on a transformé le xanthène **7**, un produit fondamental de déshydrogénation du cetol **2**, en dihydropyranne **5***b*. La synthèse en 5 étapes du dihydropyranne **5***b* à partir du carbométhoxy-1 cyclopentanol (**8**) fournit la preuve sans équivoque de la structure attribuée au pyranne **3** et au xanthène **7**.

[Traduit par le journal]

Over 50 years ago, while investigating the alkylation of cyclohexanone with methyl iodide using sodium hydride or amide, Cornubert (1) found that a simple mixture of the ketone, sodium amide, and diethyl ether yielded a new substance ($C_{18}H_{28}O_2$) melting at 186°C. After 2 h at 150°C in acetic anhydride – sodium acetate solution the new ketone was recovered unchanged. Failure of this attempt at acetylation suggested an ether group and the new ketone was formulated as tetrahydropyran **1**. In our previous study (2) of cyclohexanone intramolecular condensation reactions, mild treatment with sodium methoxide – dimethylformamide was found to yield a ketone ($C_{18}H_{28}O_2$) melting at 186.5–187°C. Chemical and physical evidence culminating in an X-ray crystal structure determination led to the definitive assignment of structure **2** (2).

To ascertain whether the Cornubert ketone (mp 186°C) actually corresponded to ketol **2**, attempts were made to repeat the sodium amide – ether experiment as originally (but briefly) outlined. The only $C_{18}$ product obtained (and in poor yield) using the original (1) fractional distillation (to 145°C at 0.5 Torr) procedure for isolation was pyran **3** (mp 40.5–41.5°C). Previously (2) we obtained the same pyran (**3**) by potassium hydrogen sulfate dehydration (at 190–200°C) of ketol **2**. Presumably Cornubert actually obtained ketol **2** instead of tetrahydroxy pyran **1** and depending on the isolation conditions, especially elevated temperatures, the ketol was easily rearranged (**2** → **4**) and dehydrated (**4** → **3**).[2]

Evidence for this conclusion was obtained by subjecting the reaction mixture prepared from cyclohexanone, sodium methoxide, and dimethylformamide, and known to yield ketol **2**, to an analogous fractional distillation. By this means a good yield of pyran **3** was obtained. Although the distillation procedure for obtaining **3** proved to be capricious and was not reproducible, it did seem likely that pyran **3** would be the principal result of subjecting ketol **2** to pyrolytic dehydration. By means of this evidence and that noted in the sequel, the structure of pyran **3** was unequivocally established.

[2]Cyclization of a 1,5-diketone to a 4*H*-pyran system is analogous to the intramolecular condensation reaction observed when dimedone aldehyde derivatives are heated under acid conditions (**i** → **ii**; see ref. 3*a*–*c*).

a:$(CH_3)_2NCHO$, $NaOCH_3$, RT, 5 days; b: $NH_3$, $NaNH_2$; c: $CH_3OH$, HCl, Δ, 12 h; d: 5% $Rh/Al_2O_3$, $H_2$; e, 5% $Rh/Al_2O_3$, $H_2$, $CH_3CH_2OH$, 50 psi, RT, 12 h–3 days.

Both the infrared and proton magnetic resonance spectra of pyran **3** were quite compatible with this assignment. Furthermore, partial reconversion to ketol **2** via the hypothetical 1,5-diketone **4** was realized by hydrolysis of pyran **3** in methanol containing concentrated hydrochloric acid. The main product was ketal **5***a*, and its infrared spectrum showed absorption at 1678 $cm^{-1}$ typical of a dihydropyran.

Complete reduction of pyran **3** employing palladium-catalyzed hydrogenation consumed two moles of hydrogen and provided ether **6**. Selective hydrogenation of pyran **3** using 5% rhodium-on-aluminum oxide led to dihydropyran **5***b*. Meanwhile, in a parallel study of the ketol **2** structure problem (2), xanthene **7** was found to be one of the three products formed by dehydrogenation over 10% palladium-on-carbon (at 290°C). Firm evidence for the structure of xanthene **7** was not obtained until the following experiments were completed. Reduction of xanthene **7** with 5% rhodium-on-aluminum oxide and hydrogen gave as main product dihydropyran **5***b* accompanied by a small quantity of ketol **2**. Isolation of the latter substance suggested that pyran **3** is an important intermediate in the course of hydrogenation and an alternative synthesis of dihydropyran **5***b* was considered necessary.

The route selected for a confirming synthesis was initiated by preparation of 1-carbomethoxycyclopentanol (**8**) by a method developed by Burger and Bennet (4). Cyclopentanone cyanohydrin, obtained by treating cyclopentanone bisulphite addition product with potassium cyanide, was hydrolyzed with concentrated hydrochloric acid to 1-hydroxycyclopentanoic acid. After esterification (Fischer) the ester was treated with *o*-methoxyphenylmagnesium bromide in tetrahydrofuran. The new glycol (**9**, 63%) was converted to the spirocyclohexanone **10** by a pinacol rearrangement (81.5% yield) with iodine in acetic acid. Wolff–Kishner reduction of ketone **10** proved to be somewhat more eventful. In addition to the expected methyl ether (**11**, 34% yield) a minor (13%) product was found to be xanthene **7**.[3]

The next step was intended to yield diketone **4** by a Birch reduction sequence. Attempts at reducing anisole **11** by lithium in liquid ammonia containing *tert*-butyl alcohol according to the Dryden (5)[4] variation of the Birch reduction proved unsuccessful. The Birch reduction appeared to proceed well in only one of the aromatic rings and efforts to hydrolyze the resulting enol ethers to an α,β-unsaturated ketone gave a mixture of ketones unsuitable for the synthetic objective. So the attractive alternative of first demethylating and then reducing the resulting bisphenol (**12**) to a cyclohexanol that could be oxidized to diketone **4** was evaluated. Simple cleavage with hydrobromic or hydriodic acids in hot acid led to mixtures. A reasonable conversion to phenol **12** was realized with refluxing 47% hydriodic acid. In model experiments with bis(2-methoxyphenyl)methane a mixture of sodium and pyridine gave the corresponding bisphenol in 80% yield. When this technique (6) was applied to ether **11** only poor yields of phenol **12** were obtained.

In order to reduce the possibility of competing hydrogenolysis during reduction of phenol **12** a rhodium catalyst was chosen for the reduction step (7). Perhaps due to steric difficulties presented by

[3]Except for two preliminary attempts, which were unsuccessful, to prepare xanthene by subjecting both bis(2-hydroxyphenyl)methane and bis(2-methoxyphenyl)methane to reaction with potassium hydroxide in diethylene glycol at 190°C, no further effort was devoted to the scope of this potentially useful route to certain diaryl ethers.

[4]By this procedure any trace amount of iron that would catalyze a competing reaction between lithium and the *tert*-butyl alcohol is removed by distilling the ammonia (see ref. 5)

f: THF, $N_2$, 10°C, RT, 12 h; g: $I_2$, $CH_3CO_2H$, Δ, 5 min, RT, 12 h; h: 85% $NH_2NH_2$, $(HOCH_2CH_2OCH_2)_2$, KOH, 195°C; i: 47% HI, Δ, 9 h; j: Na, Py, $N_2$, Δ, 6 h; k: $RuO_2 \cdot x\ H_2O$, $CH_3CH_2OH$, 1500 psi, 60°C, 43 h.

the spirocyclohexane ring, hydrogenation of bisphenol **12** with 5% rhodium-on-aluminum oxide as catalyst proved unsatisfactory (incomplete reduction). Since hydrogenolysis can also be minimized by using ruthenium oxide as catalyst (8), application of this method at 1500 psi afforded in one step dihydropyran ***5b***, albeit in low (15%) yield. The specimens of dihydropyran ***5b*** obtained by ruthenium oxide catalyzed hydrogenation of bisphenol **12** and by rhodium – aluminum oxide catalyzed hydrogenation of pyran **3** and xanthene **7** were found to be identical.

Completion of the above synthetic interconversions and interpretation of the various physical measurement results firmly established pyran **3** as an important product that may result from the intramolecular self-condensation of cyclohexanone and related ketones.

## Experimental

All solvent extracts of aqueous solutions were dried over anhydrous magnesium sulphate. Ether refers to diethyl ether. Solvents employed for chromatography were redistilled and basic alumina refers to either Merck "Suitable for Chromatography" or Alcoa F-20 grades. All melting points are uncorrected. Instruments employed for determining the ultraviolet (95% ethanol solution), infrared (in potassium bromide unless otherwise noted), $^1H$ nmr (deuteriochloroform solution), $^{13}C$ (deuteriochloroform solution with tetramethylsilane as reference), and mass (electron impact) spectra have been outlined in the introduction to the experimental section of ref. 2. We are pleased to thank Drs. C. L. Herald, R. Hill, G. Slomp, R. O. Mumma, and J. Witschel, Jr. for assistance with these measurements. Other general aspects of this experimental section also appear in ref. 2.

*1',2',3',4',5',6',7',8'-Octahydro-spiro[cyclohexane-1,9'-xanthene] (3)*

*Method A*

Without benefit of details the experiment (that gave a substance melting at 186°C) reported by Cornubert (1) entailing the auto-condensation of cyclohexanone in liquid ammonia solution containing sodium amide was repeated. A mixture of cyclohexanone (20 g), 1.38 g of sodium amide (prepared from 0.815 g of sodium and excess liquid ammonia containing ferric nitrate), and anhydrous ether (80 mL) was stirred (under dry nitrogen) at ca. 25°C for three days. The reaction mixture was cautiously decomposed (in a nitrogen atmosphere) with water, extracted with ether, and purified by distillation. The fraction (0.60 g) boiling at 135–142°C and 0.5 Torr was crystallized from ethanol to afford 0.085 g of plates, mp 34–40.5°C. Recrystallization from ethanol brought the melting point to 40.5–41.5°C, undepressed upon admixture with a sample of 1',2',3',4',5',6',7',8'-octahydro-spiro[cyclohexane-1,9'-xanthene] (**3**) prepared by method B and previously (2). Comparison infrared spectra confirmed the mutual identity.

*Method B*

Cyclohexanone (98.0 g, 1.0 mol) was dissolved in 300 mL of anhydrous *N,N*-dimethylformamide. Freshly prepared sodium methoxide (81.0 g, 1.5 mol) was added and the mixture vigorously stirred with cooling (ice-bath). After the temperature was lowered to 10°C it was allowed to rise to ca. 25°C and stirring was continued five days. The sodium methoxide was removed by filtration and the solvent and unreacted cyclohexanone were removed by distillation (atmospheric pressure). Vacuum distillation of the residue gave a fraction (36.9 g) boiling at 148.5–152°C and 1.3 Torr which crystallized from ethanol giving two crops of plates, 22.4 g (mp 40–41.5°C) and 3.1 g (mp 39.5–40.5°C). The first fraction was recrystallized twice from ethanol to afford a pure specimen of pyran **3** (tetranitromethane gave a red-brown color); $\nu_{max}$ ($CCl_4$): 1694, 1660, 1228, and 1180 $cm^{-1}$; $^1H$ nmr δ: 1.52–1.67 (18H, m), 2.16 (8H, m); $^{13}C$ nmr δ: 22.68 (2C), 23.95 (2C), 24.01, 25.64 (2C), 26.22 (2C), 27.46 (2C), 34.44 (2C), 36.00, 114.48 (2C, C=C), 145.18 (2C, =C—O); mass spectrum *m/e*: 258 ($M^+$), 250, 229, 215 (base peak), 207, 202. *Anal.* calcd. for $C_{18}H_{26}O$: C 83.66, H 10.14, O 6.18; found: C 83.64, 83.52; H 9.99, 10.01; O 6.39.

Preparation of pyran **3** by this procedure was not routinely reproducible.

*Acid hydrolysis of 1',2',3',4',5',6',7',8'-octahydro-spiro-[cyclohexane-1,9'-xanthene] (3)*

To a solution of pyran **3** (1.0 g) in 20 mL methanol was added five drops of concentrated hydrochloric acid. After 12 h at reflux the solution was diluted with an equal volume of water, the products were extracted with ether, and the extract was concentrated to about 2 mL. Upon cooling, crystalline plates (0.190 g) separated and melted at 185–186°C. The melting point upon admixture with spiro*[3,4-cyclohexano-4-hydroxybicyclo-[3.3.1]nonan-9-one-2,1'-cyclohexane] (2)* was undepressed. The mother liquor yielded *1',2',3',4',4a',5',6',7',8',9a'-decahydro-spiro[cyclohexane-1,9'-9a'-methoxy xanthene]* (***5a***) as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

plates (mp 79–79.5°C) following three recrystallizations from methanol; $\nu_{max}$: 1678, 1146, 1130, 1090 $cm^{-1}$. *Anal.* calcd. for $C_{19}H_{30}O_2$: C 78.57, H 10.41, *Mol. Wt.*: 290.43; found: C 78.35, H 10.08; *Mol. Wt.* (Rast): 263.

*1',2',3',4',4a',5',6',7',8',8a',9a',10a'-Dodecahydro-spiro-[cyclohexane-1,9'-xanthene] (**6**)*

A solution of pyran **3** (2.0 g) in 95% ethanol (75 mL) was shaken with platinum oxide (Adams catalyst 0.10 g) in a Towers atmospheric pressure hydrogenation apparatus for 12 h. The hydrogen uptake (corrected for catalyst) was 372 mL (the volume calcd. for two double bonds was 359 mL). The crude sample (1.85 g, mp 63–73°C) of tetrahydropyran **6** was purified by recrystallization from ethanol. Three recrystallizations yielded rhombahedra; mp 99.5–100.5°C; $\nu_{max}$: 1100, 1056, 1005 (C—O) $cm^{-1}$. *Anal.* calcd. for $C_{18}H_{28}O$: C 82.38, H 11.52; found: C 82.38, H 11.64.

*Catalytic hydrogenation of spiro[cyclohexane-1,9'-xanthene] (**7**)*

A 0.74 g sample of xanthene **7** (mp 56–57°C) was dissolved in absolute ethanol, 5% rhodium-on-alumina (0.80 g) was added, and the mixture was hydrogenated (50 psi, room temperature, Parr Shaker) for 3 days. To a solution of the crude hydrogenation product in 95% ethanol (15 mL) was added concentrated hydrochloric acid (0.5 mL). After heating 2 h at reflux the mixture was diluted with an equal volume of water, neutralized by adding 5% aqueous sodium bicarbonate, and extracted with ether. The ether was evaporated and the residual oil was triturated with hexane. The remaining solid (0.04 g) gave a melting point of 187–188°C that was undepressed upon admixture with a sample of spiro*[3,4-cyclohexano-4-hydroxybicyclo-[3.3.1]nonan-9-one-2,1'-cyclohexane]* (**2**). Comparison infrared spectra (KBr) confirmed the identity as ketol **2**.

The hexane-soluble portion of the hydrolyzate (0.39 g) was chromatographed on 15 g of basic alumina (Alcoa). A colorless oil (0.39 g) eluted by hexane was crystallized from methanol yielding prisms (0.150 g) of *1',2',3',4',4a',5',6',7',8',9a'-decahydro-spiro[cyclohexane-1,9'-xanthene]* (**5***b*, mp 79–82°C). Two recrystallizations from ethanol afforded dihydropyran **5***b* as prisms melting at 82–82.5°C (Kofler hot stage); $\nu_{max}$: 1672, 1228, 1194, 1172 $cm^{-1}$. *Anal.* calcd. for $C_{18}H_{28}O$: C 83.02, H 10.84; found: C 83.06, H 10.65, 10.79.

*Hydrogenation of 1',2',3',4',5',6',7',8'-octahydro-spiro-[cyclohexane-1,9'-xanthene] (**3**)*

To a solution of pyran **3** (0.50 g) in absolute ethanol (100 mL) was added 5% rhodium-on-alumina and the mixture was hydrogenated (Parr Shaker, room temperature) at 49 psi for 12 h. The crude oily product crystallized (0.31 g, mp 50–55°C) from ethanol. One recrystallization from ethanol gave prisms, mp 80–81.5°C, and another raised the melting point to 83.5–84°C which was not depressed upon admixture with *1',2',3',4',4a',-5',6',7',8',9a'-decahydro-spiro[cyclohexane-1,9'-xanthene]* (**5***b*) from the hydrogenation of spiro[cyclohexane-1,9'-xanthene] (**7**). Comparison infrared spectra confirmed the mutual identity.

*Di(2-methoxyphenyl)-(1-hydroxycyclopentyl)methanol (**9**)*

The Grignard reagent prepared from magnesium turnings (24.3 g, 0.566 mol), *ortho*-bromoanisole (105.8 g, 0.566 mol, bp 114–115°C and 22 Torr), and tetrahydrofuran under nitrogen, was cooled to 10°C and a solution of 1-carbomethoxycyclopentanol (**8**, 27.1 g, 0.189 mol) (4) in tetrahydrofuran was slowly added (over 15 min) with stirring. The reaction mixture was stirred at room temperature for 12 h and heated at reflux for 6.5 h. The tetrahydrofuran was replaced by benzene and the solution was poured onto ice (500 mL) – concentrated sulfuric acid (50 mL). Following extraction with chloroform the insoluble portion was collected and treated (steam-bath) for 30 min with 6 *N* hydrochloric acid (100 mL). The hydrolyzate was extracted with chloroform and both chloroform extracts were combined, washed with 5% sodium bicarbonate, and solvent was removed. The residual oil was washed with cold (10°C) hexane and the insoluble crude product (42.0 g) was crystallized from ethanol–acetone yielding a crystalline solid (33.9 g, 54.7%), mp 179–180°C. Recrystallization from ethanol gave diol **9**: mp 180.5–181°C (Kofler hot stage); $\lambda_{max}$: 272.4 ($\log \varepsilon = 3.55$), 278.4 ($\log \varepsilon = 3.52$) nm; $\nu_{max}$: 3460 (-OH), 1596, 1580, 1486 (aromatic), 1240 (aryl ether), 1034 ($-OCH_3$), 770 (1,2-disubstituted phenyl) $cm^{-1}$. *Anal.* calcd. for $C_{20}H_{24}O_4$: C 73.14, H 7.37; found: C 73.55, 73.40; H 7.39, 7.69.

*2,2-Bis(2-methoxyphenyl)cyclohexanone (**10**)*

To a solution of diol **9** (36.1 g) in hot glacial acetic acid (250 mL) was added iodine (0.250 g), and the solution was heated at reflux for 5 min, then poured onto ice. The mixture was left at room temperature for 12 h and the crude product was collected by filtration. Recrystallization from acetone afforded 28.0 g (81.8%) of ketone **10** melting at 108–111°C. Another recrystallization from ethanol yielded an analytical specimen as plates; mp 110.5–111.5°C (capillary); $\lambda_{max}$: 278 ($\log \varepsilon = 3.80$), 300 (shoulder, $\log \varepsilon = 2.92$) nm; $\nu_{max}$: 1724 (C=O), 1240 (aryl ether), 1025 ($-OCH_3$), (*o*-substituted phenyl) $cm^{-1}$. *Anal.* calcd. for $C_{20}H_{22}O_3$: C 77.39, H 7.14; found: C 77.07, H 7.10.

*Wolff–Kishner reduction of 2,2-bis(2-methoxyphenyl)-cyclohexanone (**10**)*

A mixture of ketone **10** (18.2 g), sodium hydroxide (7.4 g), 85% hydrazine hydrate (24 mL), and diethylene glycol (144 mL) was heated at reflux for 30 min. The reflux temperature was then raised to 190°C by removing water and excess hydrazine by distillation. Heating was continued at this temperature for 4.5 h. The reaction mixture was poured into water and concentrated hydrochloric acid was added until a red litmus test was obtained. Products were isolated in a chloroform solution, washed with 5% aqueous sodium bicarbonate, and dried. The solvent was removed *in vacuo* leaving a crude oil (19.0 g) which was dissolved in ether and the solution was extracted with 5% aqueous potassium hydroxide. After solvent removal the residual oil (14.5 g) was dissolved in hot ethanol and upon cooling *2,2-bis(2-methoxyphenyl)cyclohexane* (**11**) (4.5 g, mp 92–95°C) crystallized. Another crystallization from ethanol raised the melting point to 96–96.5°C. The mother liquor residual oil (10.0 g) was chromatographed on basic alumina (Alcoa). The fraction (1.82 g, mp 53.5–55°C) eluted by hexane was recrystallized from ethanol giving plates melting at 55–56°C and identical (by comparison infrared spectra and undepressed mixture melting point) with *spiro[cyclohexane-1,9'-xanthene]* (**7**) obtained from the dehydrogenation of ketol **2**.

A fraction (1.34 g, mp 96–97°C) containing cyclohexane **11** was obtained by elution with 1:9 benzene–hexane. Two recrystallizations from ethanol gave an analytical sample: mp 96.5–97.5°C (Kofler hot stage); $\lambda_{max}$: 281 ($\log \varepsilon = 3.56$), 274 ($\log \varepsilon = 3.56$) nm; $\nu_{max}$: 1594, 1580, 1490 (phenyl), 1248 (aryl ether), 1030 ($-OCH_3$), 764, 750 (1,2-disubstituted phenyl) $cm^{-1}$. *Anal.* calcd. for $C_{20}H_{24}O_2$: C 81.04, H 8.16; found: C 81.07, H 8.30.

*Demethylation of bis(2'-methoxyphenyl)cyclohexane (**11**)*

*Method A. With hydriodic acid*

A mixture of *bis(2-methoxyphenyl)cyclohexane* (**11**, 2.0 g), 47% hydriodic acid (20 mL), and glacial acetic acid (40 mL) was heated at reflux for 9 h, cooled to room temperature, and poured onto ice. An ether extract of the product was washed with 10% aqueous sodium hydroxide and concentrated to an oil (0.93 g neutral fraction). The combined sodium hydroxide extract was acidified with concentrated hydrochloric acid and the acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

fraction was isolated in ether. Sublimation of the acid fraction (0.625 g) led to 0.585 g of bis(2′-hydroxyphenyl)cyclohexane (**12**) which did not depress the melting point of phenol **12** prepared by Method B and both specimens showed identical infrared spectra.

*Method B. With sodium*

A mixture of *bis(2′-methoxyphenyl)cyclohexane* (**11**, 1.50 g), sodium (0.92 g), and dry pyridine (10 mL) was heated (nitrogen atmosphere) at reflux for 6 h. After cooling to room temperature excess sodium was removed by cautiously adding, in succession, pyridine, 1:1 pyridine–water, and water. A neutral fraction (0.90 g, mp 84–88°C), obtained by extracting the mixture with ether, was identified as unreacted starting material. The aqueous phase was adjusted to pH 6 (Hydrion paper) with hydrochloric acid and an acidic fraction (0.178 g) was isolated in ether and recrystallized three times from hexane. The analytical sample of phenol **12** melted at 111–111.5°C (Kofler hot stage); $\lambda_{max}$: 282.5 (log ε = 3.98), 277 (log ε = 3.99) nm; $\nu_{max}$: 3390 (-OH), 1366 (phenol), 768, 755 (1,2-disubstituted phenyl $cm^{-1}$. *Anal.* calcd. for $C_{18}H_{20}O_2$: C 80.56, H 7.51; found: C 80.57, 80.71; H 7.52, 7.53.

*Catalytic hydrogenation of bis(2′-hydroxyphenyl)cyclohexane (**12**)*

A mixture of bisphenol **12** (0.168 g), absolute ethanol (25 mL), and 60.13% ruthenium oxide (0.200 g) (8)[5] was hydrogenated at 1500 psi and 60°C for 43 h (Magnadash autoclave with 250 mL bomb container). The crude product (0.132 g of oil) was chromatographed on basic alumina (5 g). The fraction (0.026 g) eluted by hexane was crystallized from absolute ethanol to provide *1′,2′,3′,4′,4a′,5′,6′,7′,8′,9a′-decahydro-spiro[cyclohexane-1,9′-xanthene]* (**5***b*) as prisms, mp 82–83°C. A mixture melting point with the product (**5***b*) obtained from hydrogenation of spiro[cyclohexane-1,9′-xanthene] (**7**) was undepressed. The infrared spectra (KBr) of both samples were identical.

*2,2-Diphenylcyclohexane (**14**)*

A mixture composed of 2,2-diphenylcyclohexanone (**13**, prepared by the method of Burger and Bennet (4), 3 g, mp 101–102°C), 85% hydrazine hydrate (5 mL), diethylene glycol (25 mL), and potassium hydroxide pellets (3 g) was heated at reflux for 30 min. The reaction temperature was raised to 195°C by removing water and excess hydrazine by distillation and maintained there for 45 min. After cooling to room temperature, the mixture was poured into water (150 mL) and the crude product isolated in ether. The ether solution was concentrated to an oil which was chromatographed on 90 g of basic alumina. Hydrocarbon **14** (1.64 g, mp 45–46.5°C) was eluted by hexane and recrystallized from ethanol giving plates melting at 47–47.5°C (Kofler hot stage); $\lambda_{max}$: 269 (log ε = 2.71), 262 (log ε = 2.86), 255 (log ε = 2.80) nm; $\nu_{max}$ ($CCl_4$): 1600, 1504, 1495 (phenyl), 1452 ($CH_2$), 700 (phenyl) $cm^{-1}$. *Anal.* calcd. for $C_{18}H_{20}$: C 91.47, H 8.53; found: C 91.52, H 8.59.

# Enolates de β-cétoesters: conformations et stabilités des formes dissociées

C. CAMBILLAU[1] ET F. GUIBE[2]

*Groupe de Recherche No 12, C.N.R.S., B.P. 28, 94320 Thiais, France*

Reçu le 24 avril 1981[3]

C. CAMBILLAU et F. GUIBE. Can. J. Chem. **60**, 634 (1982).

La conformation d'énolates de β-cétoesters a été étudiée par $^1$H rmn et par conductimétrie. Nous avons comparé les dissociations des énolates de $K^+$ de β-cétoesters acycliques qui peuvent à priori adopter une quelconque des quatre conformations *ZE*, *ZZ*, *EE* ou *EZ* avec ceux de β-cétoesters hémicycliques (carbéthoxy-2 cyclopentanone, acétyl-2 γ-butyrolactone) qui ne peuvent en adopter qu'un nombre limité. Les résultats montrent que la conformation *EE* est plus stable que les conformations *ZZ* et *EZ*. Ce résultat, qui implique que les énolates acycliques dissociés sont de conformation *EE*, est confirmé par rmn du proton. Ces résultats expérimentaux ont été complétés par des calculs *ab-initio* STO-3G effectués sur l'anion du formylacétate de méthyle et sur celui de la formylacétone, son analogue dicétonique. La méthode de titrage conductimétrique par le cryptand (2,2,2), utilisée pour déterminer les coefficients de dissociation des énolates de $K^+$ dans le DMSO est discutée en détail.

C. CAMBILLAU and F. GUIBE. Can. J. Chem. **60**, 634 (1982).

The problem of the conformation of β-ketoester enolates has been investigated through $^1$H nmr studies and through conductimetric studies. We have compared the dissociative properties of the $K^+$ enolates of acyclic β-ketoesters which can a priori adopt any possible *ZE*, *ZZ*, *EE*, or *EZ* conformations and of hemicyclic β-ketoesters (2-carbethoxycyclopentanone, 2-acetyl γ-butyrolactone) in which geometrical constraints excluded some of them. The results lead to the conclusion that the *EE* conformation is more stable than either the *ZZ* or *EZ* ones. Confirmation of this point, which implies that the acyclic dissociated enolates exist in the *EE* conformation, is afforded by $^1$H nmr spectroscopy. Those experimental results have been complemented with *ab initio* STO-3G calculations performed on the methyl formylacetate anion and on the formylacetone anion (the diketonic analog). The method of conductimetric titration by cryptand (2,2,2) used for the determination of the dissociation coefficient of $K^+$ enolates in DMSO is discussed in some detail.

Outre son intérêt propre, la connaissance de la conformation des énolates de composés β-dicarbonylés est importante à plusieurs titres.

De la conformation adoptée par l'énolate dépend, en effet, la stéréosélectivité (*Z*, *E*) du produit obtenu dans des réactions mettant en jeu les atomes d'oxygène du système mésomère (*O*-alkylation, *O*-acylation) (1). Par ailleurs, les équilibres conformationnels de ces énolates sont très sensibles aux interactions avec l'environnement (cation, solvant, etc...) et de ce fait, ils constituent une sonde commode pour étudier la structure des solutions, en relation ou non avec des problèmes de réactivité (1–5).

Comme pour les énolates de composés β-dicarbonylés en général, quatre conformations (6) sont à priori possible pour les énolates de β-cétoesters: une conformation en *U* (*ZE*), une conformation en *W* (*EZ*) et deux conformations en *S* ("Sickle Shaped"): *S-cis* (*ZZ*) et *S-trans* (*EE*)[4] (Fig. 1).

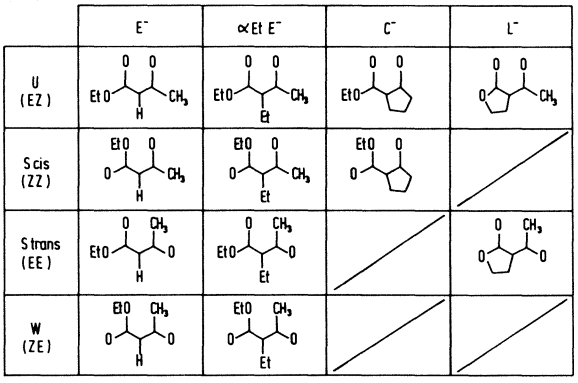

FIG. 1. Conformations que peuvent théoriquement présenter les énolates de l'acétylacétate d'éthyle ($E^-$), de l'α-éthyl-acétylacétate d'éthyle (αEt-$E^-$), de la carbéthoxy-2-cyclopentanone ($C^-$), et de l'acétyl-2-butyrolactone ($L^-$).

La structure en *U* des énolates au contact du cation est en accord avec les résultats des études de rmn du proton ou du $^{13}$C (4, 8, 9). Elle a récemment pu être observée directement par diffraction des rayons X sur des espèces monomères (paires d'ions solvatées extérieurement par des éthers couronnes)[5] (2, 10) ou dimères (ions triples du lithium) (11).

[1]Ce travail fait partie de la thèse d'Etat de C. Cambillau (13).

[2]Auteur à qui la correspondance doit être adressée.

[3]Revision reçu le 9 novembre 1981.

[4]Contrairement à la terminologie *E* et *Z*, la terminologie *U*, *W* et *S* présente l'avantage de rester invariante en passant de la série des β-cétoesters à la série des β-dicétones, et sera donc utilisée de préférence dans la suite de cet article. Les termes *S-cis* et *S-trans* appliqués ici aux énolates de β-cétoesters font référence à la position relative de l'oxygène pseudo-cétonique et du groupement carbalkoxy, en accord avec la terminologie originale de Miller *et al.* (7) concernant les esters ou éthers d'énols de composés β-dicétoniques.

[5]Pour le complexe [$CH_3COCHNaCO_2Et$, 15-couronne-5] (résultat non publié) voir réf. 12.

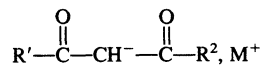
Cette structure en *U* est conservée en solution dans le THF pour la paire d'ions (2), et dans $CH_2Cl_2$ ou même le DMSO pour l'anion triple (11). Ces résultats sont facilement expliqués par la stabilité du cycle chélate ($C_3O_2^-$ $M^+$).

Le problème de la conformation des énolates dissociés ou en interaction lâche avec leur cation n'est pas aussi bien documenté. Aucune structure d'énolate alcalin dans une conformation non chélatante n'a été observée aux rayons X. Dans le cas de solutions d'acétylacétonates alcalins ($R^1 = R^2 = CH_3$), Raban *et al.* ont montré sans ambiguité par rmn ($^1H$ ou $^{13}C$) que l'ion dissocié adopte une conformation en *S* (4). Toujours par rmn, Ershov et coll. ont montré que les énolates de β-cétoesters (8) ($R^1$ = H ou $CH_3$, $R^2$ = OR) ou de β-cétoaldéhydes (9) ($R^1$ = H, $R^2 = CH_3$) devaient



exister sous une forme "transoïde" *W* ou *S*; ces conformations sont toutes deux compatibles avec la géométrie "*trans*" des éthers d'énol (1) obtenus dans les réactions d'alkylation en milieu dissociant.

Nous présentons ici nos résultats concernant la conformation d'énolates de composés β-dicarbonylés. Afin de préciser les stabilités relatives des diverses conformations, nous avons étudié comparativement les énolates de composés linéaires (acétylacétate d'éthyle, E; α-éthyl-acétylacétate d'éthyle, αEt-E) pour lesquels toute conformation est a priori possible, et des énolates de β-cétoesters cycliques (carbéthoxy-2 cyclopentanone, C; acétyl-2 γ-butyrolactone, L) qui ne peuvent en adopter qu'un nombre restreint (voir Fig. 1). Les techniques utilisées sont la rmn et la conductimétrie. Cette étude expérimentale a été complétée par des calculs théoriques (*ab initio* STO-3G) sur des molécules modèles afin de préciser les facteurs de stabilité des différents conformères.

## I. Conductimétrie

*Présentation de la technique utilisée*

Nous avons étudié la dissociation des énolates de potassium de E ($E^-K^+$), αEt-E ($\alpha Et\text{-}E^-K^+$), C ($C^-K^+$) et L ($L^-K^+$) dans le DMSO à 25°C au moyen de la méthode de *titrage conductimétrique* par le cryptand (2,2,2) proposée initialement par Collmann *et al.* (13). Cette méthode consiste à étudier la conductivité de l'électrolyte d'abord sans complexant, puis en présence de quantités croissantes de celui-ci, jusqu'à obtention d'un plateau de conductivité (Fig. 2). Elle permet de travailler facilement dans une gamme de concentrations

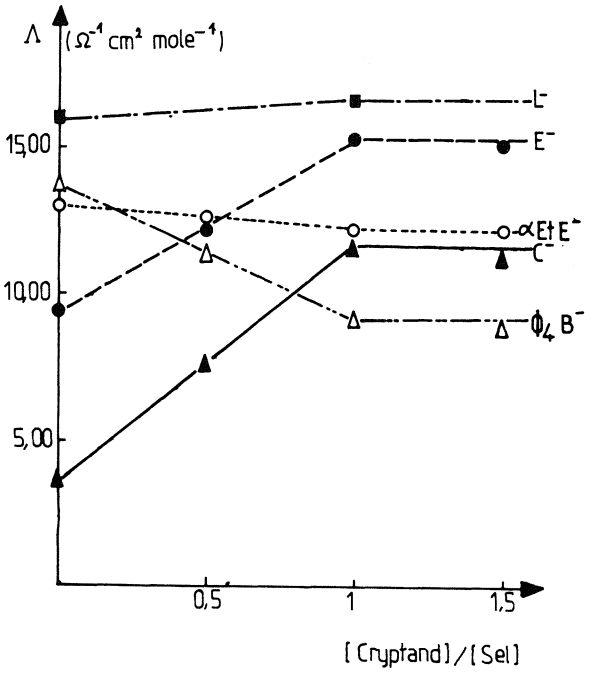


FIG. 2. Courbes de conductivité de quelques énolates de composés β-dicarbonylés et de $Ph_4B^-K^+$ 0,1 *M* dans le DMSO à 25°C, en fonction du nombre d'équivalents de cryptand (2,2,2) ajoutés. (L: acétyl-2-butyrolactone; E: acétylacétate d'éthyle; C: carboéthoxy-2-cyclopentanone; αEt-E: α-ethyl-acétyl-acétate d'éthyle).

inaccessibles à la conductimétrie classique. A partir des valeurs de conductivité équivalente $\Lambda_i$ au point initial (sans complexant) et $\Lambda_{pl}$ (au plateau) il est possible de calculer le coefficient α de l'électrolyte au point initial. Les valeurs $\Lambda_i$ et $\Lambda_{pl}$ obtenues sur un sel totalement dissocié dans le milieu en présence ou non de complexant permet d'effectuer les corrections de mobilités entre le cation et son cryptate. Notons que cette méthode ne s'applique qu'en milieu nettement dissociant (l'électrolyte crypté doit être totalement dissocié) et qu'elle ne permet d'accèder qu'à une valeur approchée de α (l'influence de la force ionique sur la mobilité des ions est négligée). L'ensemble de cette technique est discuté plus en détail dans l'annexe conductimétrique.

*Résultats et discussion* (Fig. 2, Tableau 1)

Pour les quatre énolates de $K^+$ étudiés, comme pour le tétraphénylborate de $K^+$, le plateau de conductivité est atteint dès un équivalent de cryptand ajouté (Fig. 2). Ceci est en accord avec les résultats obtenus par infrarouge (ir) sur des solutions de $E^-K^+$ dans le THF et le DMSO, montrant que, dès un équivalent de cryptand (2,2,2) ajouté,

TABLEAU 1. Résultats conductimétriques concernant quelques énolates de composés β-dicarbonylés et $\phi_4B^-K^+$ en solution 0,1 *M* dans le DMSO à 25°C

| Composé | $\Lambda_{sel}$[a] | $\Lambda_{pl,\,sel\,+\,(2,2,2)}$[a] | $\frac{\Lambda_{pl,sel\,+\,(2,2,2)}}{\Lambda_{pl,\phi_4B^-K^+\,(2,2,2)}}$ | $\alpha \times 100$ | $10^3 \times K_d$ |

[a]Λ: $\Omega^{-1}$ cm$^2$ mol$^{-1}$.

l'énolate est entièrement dans une conformation non chélatante (2). Les valeurs de conductivité au plateau $\Lambda_{pl}$ des énolates étudiés augmentent dans l'ordre $C^- \simeq$ αEt-$E^- < E^- < L^-$ correspondant aux tailles respectives des anions. Les constantes de dissociation croissent dans l'ordre $C^- < E^-$[6] < αEt-$E^- \sim L^-$. Ces données font apparaître trois faits significatifs et qui seront discutés successivement en se référant aux stabilités intrinsèques des diverses conformations possibles pour les énolates ainsi qu'aux interactions stériques qu'elles impliquent : (*i*) l'énolate acyclique $E^-$ non substitué sur le carbone central est moins dissocié que son homologue éthylé αEt-$E^-$. (*ii*) De tous les énolates étudiés $C^-$ est celui qui présente la plus faible tendance à la dissociation. (*iii*) La tendance à la dissociation des énolates $L^-$ et αEt-$E^-$ est pratiquement la même.

Les constantes de dissociation des énolates $E^-K^+$ et αEt-$E^-K^+$ sont à peu près dans le rapport 0,16 ($\Delta\Delta G \simeq 1{,}1$ kcal). La substitution de l'hydrogène sur le carbone central par le groupement éthyle se traduit donc par une tendance accrue à la dissociation. Des phénomènes analogues ont été récemment mis en évidence par Raban et Haritos (4*b*) dans l'étude par rmn du $^{13}C$ des énolates de lithium β-dicétones. Ils s'expliquent par la déstabilisation du conformère en *U* (donc de la forme associée) due aux interactions stériques 1–2 entre le substituant sur le carbone central et les groupements terminaux (Schéma 1).

Ainsi l'énolate de lithium de l'α-méthylacétyl acétone ($R^1 = R^2 = R^3 = CH_3$) présente une constante $K_d$ dans le méthanol 100 fois supérieure à celle de l'acétylacétonate. On remarque que l'effet de substituant observé dans la série des β-dicétones est donc beaucoup plus marqué que dans la série des β-cétoesters. Ceci pourrait s'expliquer par le fait que les énolates de dicétones α-substituées présentent deux interactions alkyl–alkyl 1–2 *contigues*, ce qui limite les possibilités de déformation de la molécule permettant de les soulager. Dans le cas de β-cétoesters, l'une de ces interactions alkyl–alkyl est remplacée par une interaction alkyl–alkoxy beaucoup moins sérieuse. Un effet de cation peut aussi être envisagé: dans le cas des énolates de lithium, les oxygènes du cycle chélate sont beaucoup plus fortement liés au cation que dans le cas des énolates de potassium ce qui doit impliquer des contraintes géométriques plus rigoureuses.[7]

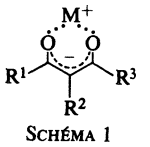

SCHÉMA 1

Dans la série des énolates hémicycliques, la faible dissociation de $C^-$ par rapport à $L^-$ (rapport des constantes de dissociation: 0,027, $\Delta\Delta G \simeq 2{,}15$ kcal) s'explique probablement en partie par le fait que le passage du chelate à la forme *S-cis* dans le cas de $C^-$ ne s'accompagne pas de la suppression d'une interaction alkyl–alkyl 1–3 défavorable comme cela est le cas lors du passage du chélate à la forme *S-trans* de $L^-$. Ceci ne saurait cependent être le seul facteur en cause. La constante de dissociation de $C^-$ est également plus faible, d'un facteur

[6]La valeur de α obtenue ici par conductimétrie concorde avec celle tirée de l'examen de spectres infrarouge (2, 12). Une décomposition graphique des absorptions ($\upsilon_s$CO) de la paire d'ions de contact et de l'ion libre indique la présence d'environ 35–45% de l'ion libre pour une solution 0.1 *M* dans le DMSO. Ainsi qu'il est indiqué dans l'annexe conductimétrique les valeurs de α obtenues par conductimétrie sont probablement légèrement surestimées.

[7]Des données récentes de Olmstead et Bordwell (23) vont à l'appui de cette dernière hypothèse. Le rapport des constantes de dissociation des énolates alcalins de l'acétylacétone et de l'α-méthylacétylacétone mesurées par ces auteurs dans le DMSO est en effet de 0,25 pour $K^+$, 0,08 pour $Na^+$ et 0,04 pour $Li^+$ (note ajoutée à la correction des épreuves).

environ 7 ($\Delta\Delta G \simeq 1{,}15$ kcal), que celle de l'énolate $E^-$ qui ne porte pas de substituant sur le carbone central et dont il est prouvé plus loin, notamment par rmn, qu'il adopte la conformation en *S-trans* à l'état dissocié. Ceci montre sans ambiguité que la conformation *S-cis*, dans laquelle l'atome d'oxygène du groupement éthoxy fait face à l'atome d'oxygène du groupement pseudo-cétonique est intrinsèquement défavorable. Ce résultat est corroboré par les calculs *ab initio* présentés plus loin.

Les valeurs très voisines de $K_d$ obtenues avec αEt-$E^-$ et $L^-$ $K^+$ plaident en faveur d'une structure commune *S-trans* pour ces deux énolates, l'énolate cyclique $L^-$ ne pouvant adopter la conformation en *W*. Sur la base de ces seules données conductimétriques, on ne peut exclure totalement la possibilité de coexistence des deux formes *W* et *S-trans* pour l'énolate acyclique; simplement, la forme *W* ne saurait être largement prédominante, auquel cas αEt-$E^-K^+$ serait nettement plus dissocié que $L^-K^+$. La forte dissociation de αEt-$E^-K^+$ comparée à celle de $C^-K^+$ avait déjà été mise en évidence par Rhoads et Holder (14) sur les sels de sodium dans le DMSO, mais elle avait été interprétée en termes de stabilités relatives de conformères *W* pour αEt-$E^-$ et *S-cis* pour $C^-$. La possibilité pour αEt-$E^-$ d'adopter la conformation *S-trans* n'avait pas été prise en considération.

## II. Etude par rmn du proton

L'étude conductimétrique à elle seule ne permet pas de trancher définitivement le problème de la conformation des énolates non cycliques. Nous l'avons donc étayée d'une étude par rmn du proton à basse température dans le méthanol-$d_4$ en comparant les déplacements chimiques de groupements méthyles des énolates $E^-$ et $L^-$. Les déplacements chimiques des protons des groupements éthoxy ne sont pas suffisamment sensibles à la conformation de l'énolate et cette étude n'a pu être étendue avec profit à l'énolate $C^-$.

*Enolate de l'acétyl γ-butyrolactone* ($L^-M^+$)
(Fig. 3, Tableau 2)

Le spectre d'une solution de $L^-K^+$ dans le méthanol à −30°C présente deux signaux pour le $CH_3$: l'un à 1,87 ppm, l'autre à 2,21 ppm. L'addition d'INa à cette solution fait croître le pic à 1,87 ppm. Une dilution de moitié d'une solution de $L^-Li^+$ fait croître celui à 2,21 ppm. Le premier pic correspond donc à un chélate et le second à l'ion relaché.

*Enolates de l'acétylacétate d'éthyle* ($E^-M^+$)
(Fig. 3, Tableau 2)

Le spectre de $E^-K^+$ dans MeOH à −30°C présente pour le $CH_3$ une absorption à 1,78 ppm et une autre à 2,20 ppm. L'addition d'INa à cette solution de $E^-K^+$ fait diminuer le pic à 2,20 ppm alors que l'addition de quantités croissantes de 15-couronne-5 à une solution de ENa le fait augmenter.

Nous concluons que le pic à 2,20 ppm correspond à $E^-$ relaché et celui à 1,78 ppm au chélate. Les déplacements observés sont identiques à ceux de la littérature (9).

La comparaison des intensités relatives des pics observés pour $E^-$ $K^+$ et $L^-$ $K^+$ montre que $L^-$ $K^+$ est beaucoup plus dissocié que $E^-$ $K^+$ ce qui est en accord avec les résultats conductimétriques.

La présence d'un seul pic $CH_3$ pour l'énolate relaché de l'acétylacétate d'éthyle montre que celui-ci existe sous une seule forme *W* ou *S-trans*; en effet à basse température les différents conformères d'énolates de composés β-dicarbonylés ne s'équilibrent pas rapidement à l'échelle de temps de la rmn ainsi qu'en témoigne par exemple la non-équivalence des deux méthyles terminaux du conformère *S-trans* de l'ion acétylacétonate (4*a*). Un seul pic pour $E^-$ relaché (δ = 2,18 ppm) est également observé par Esakov et coll. dans le DMF à −60°C (9).

La quasi identité, à 0,01 ppm près, des déplacements chimiques des groupements $CH_3$ de $E^-$ et $L^-$ observée ici indique par ailleurs que la conformation unique de $E^-$ relaché doit être du type *S-trans*. Raban *et al.* (15) ont montré que le groupement méthyle de l'énolate relaché de l'hexanedione-2,4 à structure en *S* présente des déplacements chimiques différents dans les deux conformères *EZ* et *ZE*. Un Δδ encore plus important (0,38 ppm) est observé pour les deux groupements méthyle non équivalents de l'énolate en *S* de l'acétylacétone (Schéma 2).

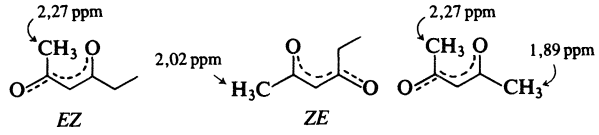

SCHÉMA 2

Dans les deux conformères en *S* de l'anion de l'hexanedione comme dans celui de l'anion de l'acétylacétone, les groupements méthyle sont situés très différemment par rapport au pseudo-carbonyle de l'extrémité opposée de la molécule et les différences de déplacement chimiques observées en rmn sont vraisemblablement le reflet de l'anisotropie magnétique de ce dernier (15). Il est bien établi, dans le cas des composés carbonylés α,β-insaturés et porteurs d'un méthyle en β, que les

| | $L^-K^+$ + INa | (b) | 1,90 | 12 | 2,22 | 88 |
| 4 | $L^-Li^+$ | (a) | 1,90 | 89 | 2,23 | 11 |
| | $L^-Li^+$ (C/2) | (b) | 1,89 | 78 | 2,22 | 22 |

protons méthyliques résonnent à champ plus fort en série *trans* qu'en série *cis* (16). Il a de plus été montré que l'effet de déblindage observé en série *cis* était associé à une conformation *S-cis* du groupement carbonyle (Schéma 3) (voir ref. 17*a*; pour une analyse semblable concernant les protons oléfiniques en β des cétones α,β-insaturées voir ref. 17*b*).

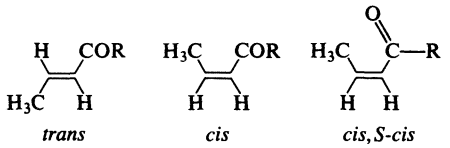

SCHÉMA 3

En accord avec ces données concernant des molécules neutres, on observe dans la série des énolates que le méthyle du conformère *EZ* de l'anion de l'hexanedione-2,4, maintenu dans le voisinage du pseudo-carbonyle, résonne à champ plus faible que le méthyle du conformère *ZE* dirigé vers l'extérieur de la molécule.

Dans le conformère en *W* de $E^-$ le groupement méthyle occupe vis à vis du pseudo-carbonyle de la partie opposée de la molécule une position éloignée, assez similaire à celle du méthyle de la forme *ZE* de l'hexadionate ou du méthyle extérieur de la forme *S-trans* de l'ion acétylacétonate et radicalement différente de celle du méthyle de la forme *S-trans* de $L^-$. Ce dernier occupe par contre une position équivalente à celle du méthyle de la forme *EZ* de l'hexadionate et du méthyle intérieur de la forme *S-trans* de l'acétylacétonate (Schémas 2 et 4). Sur la base de l'identité des déplacements chimiques observés pour $E^-$ et $L^-$, il est donc raisonnable d'exclure la conformation en *W* pour l'énolate $E^-$ et de conclure à l'existence d'une conformation *S-trans* analogue à celle de $L^-$.

Les déplacements chimiques à champ fort, δ < 2 ppm, des groupements méthyles de $E^-$ et $L^-$ sous forme de chélate sont en accord avec les données de la littérature (4, 8, 9, 15). Le Δδ de 0,09 ppm observé sur le chélate de $E^-$ et celui de $L^-$ est significatif et peut s'expliquer par un effet de substituant sur le carbone central du motif conjugué. Une différence de déplacement chimique très voisine (0,07 ppm) est observée par Esakov entre les chélates de l'acétylacétate d'éthyle et de l'α-méthyl-acétylacétate d'éthyle dans le DMF (9). A l'état relaché, l'énolate de l'α-méthyl-acétylacétate présente un δ($CH_3$) identique à celui de $E^-$ (9), ce qui est aussi en faveur d'une conformation *S-trans* pour le dérivé substitué sur le carbone central.

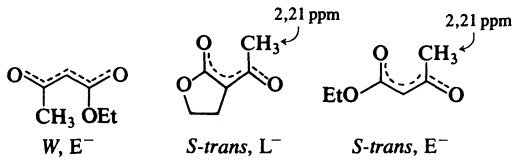

SCHÉMA 4

## III. Calculs théoriques

Les calculs théoriques (*ab initio* STO-3G) ont été réalisés à l'aide du programme Gauss 70. Les carbanions modèles choisis pour cette étude sont ceux du dimalonaldéhyde, de l'acide formylacétique et du formyl acétate de méthyle. Dans tous les cas les atomes appartenant ou directement attachés au système délocalisé $C_3O_2^-$ ont été pris dans le même plan;[8] les longueurs de liaison C—O et C—C du système délocalisé ont été fixées arbitrairement à 1,30 et 1,40 Å respectivement et les angles de liaison autour des atomes de carbone à 120°. Les paramètres géométriques standard ont été utilisés pour les autres parties des molécules (18).

[8]Les structures cristallines des complexes $E^-M^+$ – couronne montrent que le motif $C_3O_2^-$ est plan (2).

TABLEAU 3. Energie calculée (*ab initio* STO-3G) pour les carbanions du malonaldehyde, de l'acide formylacétique et du formylacétate de méthyle dans diverses conformations

| Anion | | *E* (en ua) | Energie relative[a] (en kcal) |
|---|---|---|---|
|  | *ZZ* (*U*) | −261,397 292 | +8,35 |
|  | *ZE* (*S*) | −261,409 667 | +0,58 |
|  | *EE* (*W*) | −261,410 597 | 0 |
|  | *EZ* (*U*) | −335,262 107 | +7,25 |
|  | *ZZ* (*S-cis*) | −335,266 130 | +4,72 |
|  | *EE* (*S-trans*) | −335,275 269 | −1,01 |
|  | *ZE* (*W*) | −335,273 653 | 0 |
|  | *EE* (*S-trans*) | −373,853 607 | −1,12 |
|  | *ZE* (*W*) | −373,851 820 | 0 |

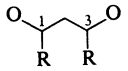
[a]Le conformère en *W* étant pris comme référence pour chacun des trois énolates.

Le tableau 3 rassemble les valeurs de l'énergie totale obtenues pour les différents conformères étudiés.

Dans tous les cas où il a été calculé (anions du dimalonaldéhyde et de l'acide formylacétique) le conformère en *U* apparaît très destabilisé en absence de cation ainsi que l'on pourrait s'y attendre sur la base de simples considérations électrostatiques (répulsion $O^1$–$O^2$). Le même phénomène s'observe, bien qu'à un degré moindre, pour le conformère *S-cis* de l'anion de l'acide formylacétique (répulsion $O^1$ – oxygène du groupement hydroxy) dont l'énergie calculée est supérieure de 0,00914 ua (5,73 kcal) à celle du conformère *S-trans*.

Concernant les stabilités respectives des formes *S-trans* et *W*, le calcul donne la forme *W* plus stable ($\Delta E$ = 0,58 kcal) dans le cas de l'énolate du malonaldehyde tandis que pour les énolates de l'acide formylacétique et de son ester méthylique utilisés comme modèles d'énolates de β-cétoesters la forme *S-trans* est favorisée ($\Delta E$ = 1,01 et 1,10 kcal respectivement). L'ordre de stabilité des deux formes ainsi trouvé est en accord avec les données expérimentales aussi bien en ce qui concerne l'énolate du malonaldéhyde (19) que celui du formylacétate de méthyle (8). Les différences d'énergie calculées sont cependant faibles et compte tenu du caractère fragmentaire des calculs réalisés ici (absence d'optimisation des paramètres géométriques, utilisation d'une base minimale pour la description des anions) un tel accord est peut être fortuit. Compte tenu de l'étroite parenté de structure des divers énolates étudiés, on peut cependant considérer comme vraisemblablement significative la tendance à la stabilisation, mise en évidence par le calcul, de la forme *S-trans relativement à la forme W* lorsque l'on passe de l'énolate du malonaldéhyde aux énolates de β-cétoesters.[9]

En résumé les résultats de ces calculs montrent que dans la série des énolates de β-cétoesters les facteurs purement électroniques sont nettement défavorables à la conformation *S-cis* et tendraient à favoriser la forme *S-trans* par rapport à la forme *W*. Ceci n'exclut pas la possibilité d'intervention d'autres facteurs, de nature stérique ou liés aux phénomènes de solvatation par exemple. Notamment les interactions stériques entre substituants placés en position 1 et 3 de la molécule, qui jouent



un rôle important dans la série des dicétones (*4b* et références citées) pourraient encore constituer dans le cas des β-cétoesters un facteur non négligeable de déstabilisation du conformère en *W*.

[9]Parmi les facteurs responsables des stabilités respectives des diverses formes, on peut penser que la répulsion électrostatique s'exerçant entre les deux oxygènes chargés négativement du système mésomère joue un rôle important. De ce point de vue, le passage de la forme *S-trans* à la forme en *W* doit s'accompagner d'un gain de stabilité dans la mesure où les deux atomes d'oxygène sont plus éloignés dans la seconde conformation (4,68 Å contre 4,01 Å avec les paramètres géométriques utilisés ici). Dans le cas des énolates de β-cétoesters cependant, la diminution de la répulsion électrostatique entre les deux atomes $O^1$ et $O^2$ du système délocalisé consécutive au passage *S-trans* → *W* est en partie compensée par l'augmentation de la répulsion électrostatique entre l'atome d'oxygène $O^1$ et l'atome d'oxygène $O^3$ du groupement alkoxy; ceci pourrait expliquer la déstabilisation relative du conformère en *W*. A titre d'illustration, si l'on se base sur les charges nettes données par le calcul *ab initio* STO-3G pour les atomes d'oxygène $O^1$, $O^2$ et $O^3$ on trouve, pour le passage *S-trans* → *W*, un gain de stabilité électrostatique d'environ 2 kcal/mol dans le cas de l'anion du formaldéhyde alors qu'il est inférieur à 1 kcal/mol dans le cas de l'anion du formylacétate de méthyle.

## Partie expérimentale

*Matières premières*

La préparation des énolates alcalins de l'acétylacétate d'éthyle a déjà été décrite (3). La même préparation a été suivie pour les énolates des autres composés β-dicarbonylés.

Le cryptand (2,2,2) (Kryptofix (2,2,2), Merck) a été utilisé tel quel. La 15-couronne-5 (Borregard) a été purifiée sur colonne d'alumine. $\phi_4B^-K^+$ et $I^-Na^+$ ont été sèchés dans un dessicateur sous vide à 80°C pendant une nuit.

Le DMSO a été distillé sous pression réduite avant utilisation, et le méthanol-$d_4$ utilisé tel quel.

*Appareils*

L'étude conductimétrique a été réalisée sur un conductimètre Philips PW 9501/01 équipé d'une cellule de mesure PR 9512/00 possèdant une constante de 0,685 $cm^{-1}$. La fréquence utilisée (2000 Hz) permet des mesures dans la gamme de $\chi$ de $10^{-4}$ à 0,1 $\Omega^{-1}$ $cm^{-1}$.

Les spectres de rmn à basse température ont été réalisés sur un Varian A 60D (60 MHz).

## Remerciements

Nous remercions le Dr J. Corset, Maître de Recherche au C.N.R.S. pour de fructueuses discussions, et Mme M. Ourevitch pour l'enregistrement des spectres rmn.

## Annexe conductimétrique

*Dosage conductimétrique à l'aide du cryptand (2,2,2)*

Il est admis en première approximation que la mobilité des ions est indépendante de la concentration en espèces ioniques dans le milieu. Les conductivités équivalentes $\Lambda_i$ du tétraphénylborate de $K^+$ et de l'énolate de $K^+$ étudié en l'absence de cryptand sont alors donnés par les relations

$$[1] \quad \Lambda_{i,EK} = \alpha\lambda_{E^-} + \alpha\lambda_{K^+}$$

$$[2] \quad \Lambda_{i\phi_4BK} = \lambda_{\phi_4B^-} + \lambda_{K^+}$$

$\alpha$ désignant le coefficient de dissociation de l'énolate et les $\lambda$ les conductivités ioniques équivalents des ions.

En présence de cryptand l'énolate est totalement dissocié et les conductivités équivalentes au plateau sont égales à:

$$[3] \quad \Lambda_{pl,EK} = \lambda_{E^-} + \lambda_{K^+ \text{ crypté}}$$

$$[4] \quad \Lambda_{pl,\phi_4BK} = \lambda_{\phi_4B} + \lambda_{K^+ \text{ crypté}}$$

Des équations [1]–[4] on tire la relation [5] utilisée pour la détermination approchée du coefficient de dissociation des énolates:

$$[5] \quad \alpha_{approx.} = \frac{\Lambda_{i,EK}}{\Lambda_{pl,EK} + \Lambda_{i,\phi_4BK} - \Lambda_{pl,\phi_4BK}}$$

L'équation [5] est de la forme:

$$\alpha = \frac{\Lambda_{i,EK}}{\Lambda_{pl,EK} + C}$$

$C = \Lambda_{i,\phi_4BK} - \Lambda_{pl,\phi_4BK}$ étant le terme correctif qui permet de tenir compte de la variation de la mobilité de l'ion $K^+$ consécutive à sa cryptation. Notons qu'elle est différente de l'équation proposée par Collmann *et al.* (13)

$$\alpha = \frac{\Lambda_{i,AM}}{\Lambda_{pl,AM}} \times C'$$

où le terme correctif $C'$ est égal au rapport $\Lambda_{i,\phi_4BM}/\Lambda_{pl,\phi_4BM}$

La conductivité équivalente d'un électrolyte n'est pas en réalité indépendante de sa concentra-

TABLEAU 4. Paramètres conductimétriques calculés pour les différents énolates (estimation) en tenant compte de l'effet de la concentration en espèces ioniques sur la mobilité des ions (cf. Annexe conductimétrique)

| Enolate | $\Lambda^\circ$ | $\alpha \times 100$ | $K_d$ |
|---|---|---|---|
| $E^-K^+$ | 36,93 | 35,1 | $19 \times 10^{-3}$ |
| $\alpha EtE^-K^+$ | 33,25 | 65,3 | $123 \times 10^{-3}$ |
| $C^-K^+$ | 32,62 | 14,3 | $2,1 \times 10^{-3}$ |
| $L^-K^+$ | 38,47 | 65,5 | $124 \times 10^{-3}$ |
| $\phi_4B^-K^+$ | 29,63 | | |
| $E^-K^+$ crypté | 31,53 | | |
| $E^-K^+$ crypté | 27,22 | | |
| $\phi_4B^-K^+$ crypté | 24,23 | | |
| $\alpha EtE^-K^+$ crypté | 27,85 | | |
| $E^-K^+$ crypté | 33,07 | | |

tion $c$ dans le milieu. Dans le cas d'un électrolyte complètement dissocié et pour des valeurs de $c$ suffisamment faibles, la variation de $\Lambda$ en fonction de $c$ est donnée par la relation d'Onsager (20, 21)

$$[6] \quad \Lambda = \Lambda^0 - a\sqrt{c}$$

Pour un électrolyte incomplètement dissocié, cette relation devient:

$$[7] \quad \Lambda = \alpha\,(\Lambda^0 - a\sqrt{\alpha c})$$

Le dosage conductimétrique par le cryptand (2,2,2) peut alors être traité de la façon suivante. Pour l'énolate en l'absence de cryptand nous avons la relation:

$$\Lambda_{i,EK} = \alpha\,(\Lambda^0{}_{EK} - a\sqrt{\alpha c})$$

soit

$$\alpha = \frac{\Lambda_{i,EK}}{\Lambda^0{}_{EK} - a\sqrt{\alpha c}}$$

La conductivité équivalente limite $\Lambda^0{}_{EK}$ de l'énolate de potassium peut être exprimée en fonction des conductivités équivalentes limites de l'énolate crypté et du tetraphényl borate de $K^+$ en présence et en l'absence de cryptand, en effet:

$$\Lambda^0{}_{EK} = \lambda^0{}_{E^-} + \lambda^0{}_{K^+} = \lambda^0{}_{E^-} + \lambda^0{}_{K^+\,\text{crypté}} + \lambda^0{}_{K^+} + \lambda^0{}_{\phi_4B^-} - \lambda^0{}_{\phi_4B^-} - \lambda^0{}_{K^+\,\text{crypté}}$$

et

$$\Lambda^0{}_{EK} = \Lambda^0{}_{EK\text{crypté}} + \Lambda^0{}_{\phi_4BK} - \Lambda^0{}_{\phi_4BK\text{crypté}}$$

et finalement:

$$[8] \quad \alpha = \frac{\Lambda_{i,EK}}{\Lambda^0{}_{EK\text{crypté}} + \Lambda^0{}_{\phi_4BK} - \Lambda^0{}_{\phi_4BK\text{crypté}} - a\sqrt{\alpha c}}$$

A la concentration choisie dans cette étude (0,1 *M*) les déviations par rapport à la loi d'Onsager sont déjà souvent substantielles (22). Il nous a néanmoins paru intéressant de calculer les nouvelles valeurs de $\alpha$ à l'aide de la relation [8] afin *d'estimer* l'importance des approximations faites dans le traitement initial (relation [5]). Les valeurs des conductivités équivalentes limites $\Lambda^0$ des électrolytes complètement dissociés ont été calculées à l'aide de la relation [6], la pente limite de Onsager:

$$a = \frac{8{,}20 \times 10^5\,\Lambda^0}{(DT)^{3/2}} + \frac{82{,}4}{n\,(DT)^{1/2}}$$

étant prise égale à:

$$a = 0{,}5\,\Lambda^0 + 35{,}6$$

dans le DMSO à 25°C ($n = 19{,}6 \times 10^{-3}$ poise et $D = 46{,}6$). $\alpha$ est ensuite calculé à l'aide de la relation [8] et par ajustement successif en prenant pour valeur de départ la valeur $\alpha_{app}$ obtenue à l'aide de [5].

Les valeurs de $\Lambda^0$, $\alpha$ et $K_d$ ainsi obtenues sont résumées dans le tableau 4. Notons que la valeur de $\alpha$ pour l'énolate $E^-M^+$ ($\alpha = 0{,}35$) trouvée ici est cohérente avec le résultat de spectroscopie ir pour une même solution qui donne $\alpha \simeq 0{,}40$ (12).

Les valeurs de $\alpha$ calculées selon [8] sont inférieures aux valeurs de $\alpha$ calculées selon [5]. Comme il était prévisible, l'écart maximum est observé dans le cas de l'énolate $C^-$ le moins dissocié (0,143 contre 0,22 soit un écart relatif de 35%). Les valeurs des constantes $K_d$ de dissociation sont diminuées d'un facteur voisin de 2 pour $E^-$, $\alpha$Et-$E^-$ et $L^-$ et d'un facteur 3 pour l'énolate $C^-$. Les approximations faites dans le traitement initial conduisent donc indiscutablement à surestimer la tendance à la dissociation des électrolytes étudiés. Elles ne remettent néanmoins pas en cause les conclusions tirées dans cette étude puisque celles-ci étaient basées non sur les valeurs absolues des constantes $K_d$ mais sur leur variation d'un énolate à l'autre.

En contre partie de son caractère approximatif, la méthode du titrage conductimétrique par le cryptand a pour avantage sa facilité de mise en œuvre; surtout elle nous a permis de travailler à une concentration élevée (0,1 *M*), où les énolates présentaient encore une forte tendance à l'association. Dans ces conditions, les variations de $K_d$ se sont traduites par des variations relatives de $\alpha$ importantes et ont donc pu être observées sans risque d'erreurs expérimentales.

# The biosynthesis of retronecine

GUNNAR GRUE-SØRENSEN AND IAN D. SPENSER[1]

*Department of Chemistry, McMaster University, Hamilton, Ont., Canada, L8S 4M1*

Received October 8, 1981

GUNNAR GRUE-SØRENSEN and IAN D. SPENSER. Can. J. Chem. **60**, 643 (1982).

An experiment with putrescine, doubly labelled intramolecularly, with $^{15}N$ and $^{13}C$ at the adjacent C-atom, demonstrates that a $C_4$–N–$C_4$ compound with $C_{2v}$ symmetry serves as a precursor of retronecine, the most common base of the Senecio alkaloids. The $C_4$–N–$C_4$ compound is, in turn, generated from two ornithine-derived precursor units. This was demonstrated by a degradation sequence whereby the distribution of label from [5-$^{14}$C]-, [5-$^{3}$H]-, and [4-$^{3}$H]ornithine within retronecine was fully accounted for.

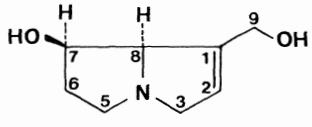
GUNNAR GRUE-SØRENSEN et IAN D. SPENSER. Can. J. Chem. **60**, 643 (1982).

Une experience, avec de la putrescine doublement marquée avec du $^{13}C$ et du $^{15}N$ sur l'atome de carbone voisin, permet de démontrer que le précurseur de la rétronecine, la base la plus commune des alcoloïdes du Senecio, est un composé $C_4$–N–$C_4$ de symétrie $C_{2v}$. Le composé $C_4$–N–$C_4$ est pour sa part généré à partir de deux unités ayant des dérivés de l'ornithine comme précurseurs. Ceci a été démontré par une séquence de dégradation grâce à laquelle on a pu expliquer complètement la distribution des [5-$^{14}$C]-, [5-$^{3}$H]- et [4-$^{3}$H]ornithines dans la rétronécine.

[Traduit par le journal]

## Introduction

Retronecine (**1**) is the most common of the necine bases of the Senecio alkaloids (1–5). Nonrandom incorporation of carbon-14 from ornithine (6–8) putrescine (6, 8), spermidine (8), and spermine (8) as well as carbon-13 from putrescine (9) into retronecine provides experimental support for the postulate of Sir Robert Robinson (10) that the pyrrolizidine skeleton of the Senecio alkaloids is generated from two $C_4$ units related to ornithine.



**1**

The manner in which the two ornithine-derived $C_4$ units are incorporated into retronecine is still in question. There is general agreement that one quarter of the activity derived from [2-$^{14}$C]ornithine (6,7) and from [5-$^{14}$C]ornithine (3, 6, 8) resides at C-9 (isolated as formaldehyde (6, 8) or as iodoform (7)). The location of the remaining activity is in dispute, however.

On the one hand, it is reported (8) that retronecine derived from [5-$^{14}$C]ornithine in *Senecio isatideus* contains one quarter of its label at C-5 (isolated together with C-6 and C-7 as β-alanine). If the assumption is made that the activity which is not accounted for by degradation is located at C-3 (25%) and C-8 (25%), this result suggests that two ornithine-derived $C_4$ units enter retronecine, each in symmetrical fashion. Putrescine (**3**), which originates from ornithine (**2**) or from arginine (11), is a nondissymmetric ($C_{2v}$) molecule whose intermediacy would lead to the observed labelling pattern. Label from (1,4-$^{13}C_2$)- and from (2,3-$^{13}C_2$)-putrescine is indeed incorporated into retronecine, leading to equal enrichment, within experimental error, at C-3,-5,-8, and -9, and at C-1,-2,-6, and -7, respectively (9), as expected. This distribution of label has been regarded also as an indication of the intermediacy of a "symmetrical dimeric" intermediate (Scheme 1, Route A) such as **6**. In fact, the same distribution of label would be obtained by a route (Scheme 1, Route B) which excludes a "symmetrical dimeric" intermediate.

On the other hand, it is claimed (7) that retronecine derived from [2-$^{14}$C]ornithine, in the same Senecio species, is not labelled either at C-3 or at C-5, and that the remaining activity (ca. 75%) resides at C-8. This result suggests that two nonidentical ornithine-derived $C_4$ units enter retronecine, each in nonsymmetrical fashion.

The two sets of results are clearly incompatible.

We have re-investigated the biosynthesis of retronecine in *Senecio vulgaris* (common groundsel).

To clarify the question of the distribution of label derived from ornithine, we have devised a degradation sequence which permits assay of label at each of the four crucial positions of retronecine, C-3, C-5, C-8, and C-9 (Scheme 2). By means of this degradation we have determined the mode of incorporation into retronecine of activity from [5-$^{14}$C]ornithine and from [4-$^{3}$H,5-$^{14}$C]- and [5-$^{3}$H,5-$^{14}$C]ornithine, as well as from a $^{3}$H,$^{14}$C-labelled sample of spermidine.

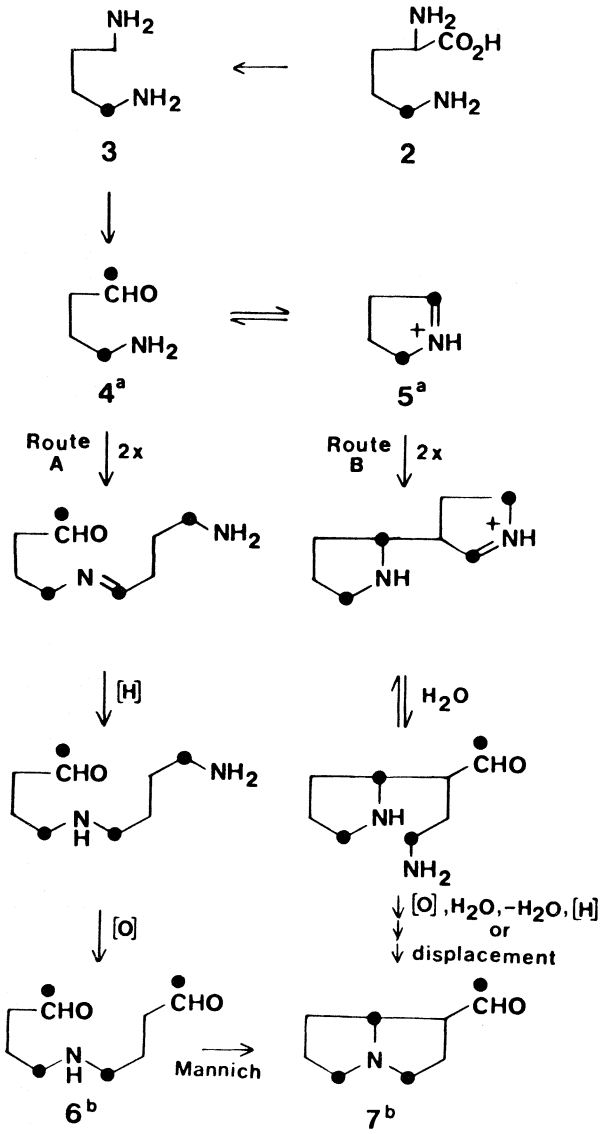


SCHEME 1. Two routes from ornithine into retronecine. Route A, via a symmetrical (i.e., nondissymmetric, $C_{2v}$) intermediate (**6**); Route B, via dissymmetric ($C_1$) intermediates. (a) Formulae **4** and **5** of labelled "monomeric" intermediates represent a 50/50 mixture of two singly labelled species. (b) Formulae of all labelled "dimeric" intermediates and of **7** represent mixtures of four singly labelled and four doubly labelled species, whose relative contribution is determined by the relative quantities of labelled and unlabelled putrescine available to the plant during the period of biosynthesis.

Furthermore, to show whether or not a "symmetrical dimeric" intermediate lies on the pathway to retronecine, we have determined the mode of incorporation of intramolecularly doubly $^{13}C,^{15}N$-labelled putrescine by means of $^{13}C$ nmr.

From our results we conclude that a "symmetrical dimeric" intermediate, $C_4$–N–$C_4$, generated from two L-ornithine-derived[2] "monomer" units, lies on the biosynthetic route. Whether or not these "monomer units" are "symmetrical" (i.e. nondissymmetric) cannot be decided with certainty on the basis of existing evidence.

## Methods and results

The plant species used in this study was *Senecio vulgaris* (common groundsel), a tough and persistent weed which re-appears every spring in the rose beds on the McMaster campus, much to the annoyance of the grounds supervisor, who each year has his staff do their utmost to eradicate it. During the summer months of 1978, 1979, and 1980, when these experiments were carried out, he was persuaded to tolerate the plants in a few unobtrusive locations until they were transferred to the greenhouse for use in our investigation.

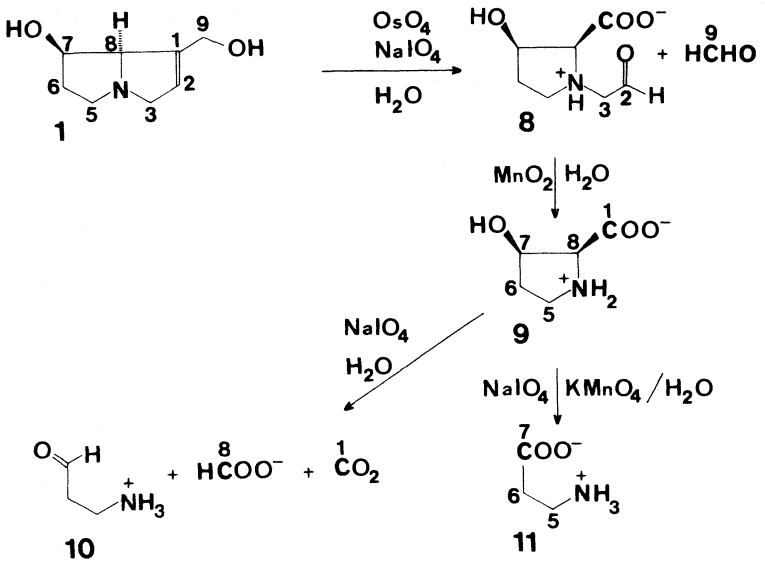
In 8 separate tracer experiments specifically labelled samples of ornithine (Experiments 1–4), putrescine (Experiment 5), spermidine (Experiment 6), and 1-pyrroline (Experiments 7 and 8) were administered to *S. vulgaris* by the wick method. In each of the experiments with radioactive tracers (Experiments 1–4, 6, 8) approximately 30 plants were used; in the experiments with stable isotopes (Experiment 5, $^{13}C,^{15}N$; Experiment 7, $^{2}H$) approximately 130 plants were used. In Experiment 5, plants were grown in contact with labelled substrate for two weeks. In all other cases the experiments lasted 3–5 days. Experimental details are summarized in Table 1.

Work-up of the plants yielded a mixture of alkaloids (senecionine, seneciphylline, and retrorsine (13–15)) and a mixture of the corresponding *N*-oxides. Retronecine (**1**) was isolated from the alkaloid mixture after hydrolysis and from the *N*-oxides after reduction and hydrolysis. Labelled samples of retronecine were obtained in the experiments with ornithine (Experiments 1–4), putrescine (Experiment 5), and spermidine (Experiment 6). The experiments with 1-pyrroline did not yield labelled alkaloids (Experiments 7 and 8).

The distribution of label within retronecine derived from radioactive precursors (Experiments 1–4, 6) was determined by the degradation sequence shown in Scheme 2. The distribution of label within retronecine derived from ($^{13}C,^{15}N$)putrescine was determined by $^{13}C$ nmr.

The degradation sequence shown in Scheme 2

[2]That the precursor is L-ornithine follows from the results of an investigation, to be published separately, of the relative efficiencies of incorporation of label from L- and D-ornithine, by a method previously developed (12) for establishing the chirality of precursor product relationships in intact systems.



SCHEME 2. Degradation of retronecine.

[a]The $^3H/^{14}C$ ratio was determined as follows. The solutions containing the two tracers were combined, diluted to 10 mL, and thoroughly mixed. Approximately 100 μL of the diluted solution was withdrawn and added to a solution containing the appropriate nonradioactive compound (200–500 mg) (Experiments 2–4, DL-ornithine monohydrochloride; Experiment 6, spermidine trihydrochloride, Experiment 8, DL-proline), which was then re-isolated and crystallized to constant activity and $^3H/^{14}C$ ratio.

permits individual assay of activity at each of the four predicted sites, C-3, C-5, C-8, and C-9. Oxidation of retronecine with periodate/osmium tetroxide (6) yields formaldehyde (C-9) (isolated as dimethone) and an amino acid, presumably **8**, which was not isolated but was further oxidized with manganese dioxide to yield L-cis-3-hydroxyproline[3] (**9**) (C-1,-5,-6,-7,-8). Periodate oxidation of the latter gave formic acid (C-8) (isolated as *N*-formyl-α-naphthylamine) and 3-aminopropanal (**10**) which was not isolated but oxidized with permanganate to β-alanine (**11**) (C-5,-6,-7) (isolated as *N*-phthaloyl-β-alanine). This degradation permits assay also of tritium at C-9 (formaldehyde), at C-8 (formic acid), and at C-5 + C-6 (β-alanine), and less directly, at C-7 (L-*cis*-3-hydroxyproline minus β-alanine minus formic acid) and at C-2 plus C-3 (retronecine minus L-*cis*-3-hydroxyproline minus formaldehyde).

In some instances the samples of retronecine obtained from alkaloids and alkaloid-*N*-oxides were each degraded separately (Experiments 4 and 6), in other cases only the sample obtained from the alkaloids was degraded (Experiments 2 and 3), and in one case (Experiment 1) the retronecine samples from the two sources were combined before degradation. The samples of retronecine derived from DL-[5-$^{14}$C]ornithine (Experiments 1–4) and from [1,4-tetramethylene-$^{14}C_2$]spermidine (Experiment 6) showed a characteristic labelling pattern (Table 2). In each case, formaldehyde (C-9), formic acid (C-8), and β-alanine (C-5,-6,-7) each accounted for one quarter of the $^{14}$C-activity of the intact retronecine molecule, within experimental error. L-*cis*-3-Hydroxyproline (C-1,-5,-6,-7,-8) accounted for one half of the $^{14}$C-activity. The distribution of label from DL-[5-$^{3}$H]- and from L-[5-$^{3}$H]ornithine (Experiments 2 and 3, respectively) was identical within experimental error (Table 3). Formaldehyde (H atoms at C-9) and formic acid (H atom at C-8) each accounted for approximately one fifth of label, β-alanine (H atoms at C-5 plus C-6) for one third, and L-*cis*-3-hydroxyproline (H atoms at C-5,-6,-7,-8) for one half of the $^{3}$H-activity of intact retronecine.

The distribution of label from L-[4-$^{3}$H]ornithine (Table 3, Experiment 4) was different. Formaldehyde (H-atoms at C-9) and formic acid (H-atom at C-8) were essentially inactive. β-Alanine (H-atoms at C-5 plus C-6) accounted for half the activity of the intact retronecine, L-*cis*-3-hydroxyproline (H-atoms at C-5,-6,-7,-8) for three quarters. The distribution of label within the two samples of retronecine isolated in this experiment, one from the alkaloids (4*A*), the other from the *N*-oxides (4*O*), was identical (Table 3).

The two corresponding retronecine samples, 6*A* and 6*O*, derived from the experiment with spermidine (Experiment 6) did not show identical distributions of tritium activity (Table 3), even though the $^{14}$C distribution was identical in the two samples (Table 2). In the sample obtained from the *N*-oxides, formate (H at C-8) and β-alanine (H at C-5 and C-6) each accounted for one quarter of the $^{3}$H-activity, formaldehyde (H at C-9) for somewhat more than one quarter and L-*cis*-3-hydroxyproline (H at C-5,-6,-7,-8) for one half. A different $^{3}$H-distribution was observed in the case of the other retronecine sample from this experiment (Table 3). As will be shown in the discussion this discrepancy illustrates an experimental pitfall in the use of intermolecularly doubly $^{3}$H,$^{14}$C-labelled samples.

The sample of retronecine, labelled with $^{13}$C and $^{15}$N, which was obtained in Experiment 5 was analyzed by means of $^{13}$C nmr. The precursor, used in this experiment, (1-$^{13}$C,1-$^{15}$N)putrescine dihydrochloride, was synthesized in 3 steps from intramolecularly doubly labelled cyanide (90 at.% $^{13}$C, 99 at.% $^{15}$N,K$^{13}$C$^{15}$N) (Scheme 3). Reaction of 1-bromo-3-phthalimidopropane (**12**) with the cyanide yielded 4-phthalimidobutyronitrile (**13**) which was reduced catalytically (Raney nickel). Acid hydrolysis then gave (1-$^{13}$C,1-$^{15}$N)putrescine dihydrochloride (**15**). This was mixed with [1-$^{14}$C]-putrescine dihydrochloride and administered to 133 plants over a period of 13 days. The alkaloids were isolated (16) and purified by column chromatography. Hydrolysis gave a mixture of retronecine hydrochloride and retronecine *N*-oxide (17, 18) in the ratio 1 to 5, as determined by $^{13}$C nmr (19) (Table 4). Reduction and work-up under exclusion of oxygen gave retronecine hydrochloride which was chemically ($^{13}$C nmr) and radiochemically pure. Four positions within retronecine, C-3,-5,-8, and -9, were equally enriched in $^{13}$C (Fig. 1, Table 4). Furthermore, the $^{13}$C nmr signals due to C-3 and C-5 each showed a doublet (due to $^{13}$C,$^{15}$N coupling) superimposed on a singlet. The ratio, area of doublet/area of singlet, for C-3 was identical with that for C-5 (Fig. 2, Table 5).

Administration to *S. vulgaris* of labelled samples of 1-pyrroline did not yield labelled alkaloids (Experiments 7 and 8). The samples of 1-pyrroline, a compound which is chemically labile (20, 21), were

[3]The stereochemistry of this degradation product provides confirmation of the established configuration at C-7 and C-8 of retronecine.

[d]$(1.09\,(A_E/A_{NA})-1) \times 1.1\%$.
[e]The average specific incorporation per carbon atom is [(¼) (1.17 + 1.50 + 1.61 + 1.58)/(90/2) × 100% = 3.3%, where (90/2) at.% $^{13}$C is the average enrichment at each terminal position of putrescine.

prepared by oxidation of DL-proline with periodate (22).

## Discussion

Tracer experiments with $^{14}$C-labelled (6–8) and $^{13}$C-enriched (9) substrates provide evidence which tends to support the prediction of Robinson (10) that the carbon atoms of the $C_4$–N–$C_4$ skeleton of retronecine are derived from two $C_4$ units, both of which ultimately originate from the $C_4$ chain, C-2,-3,-4,-5, of ornithine. The steps of the route from ornithine into the retronecine skeleton are almost totally unexplored, however. Before an attempt can be made to define some of the stages of the pathway, the following questions must be answered.

Does the route from ornithine (**2**) into the $C_4$ chains, i.e., C-9,-1,-2,-3 (chain B) and C-5,-6,-7,-8 (chain A) of retronecine (**1**), pass through a nondissymmetric intermediate (e.g., free putrescine (**3**)), or are the intermediates dissymmetric?

Do the two $C_4$ chains originate from ornithine by a common route, i.e., are they formed from a common intermediate, or is each generated from a different ornithine-derived $C_4$-intermediate?

Does the route include a "dimeric" intermedi-

C: difference spectrum (A minus B).

ate, $C_4$–N–$C_4$, which is nondissymmetric, or are all such intermediates dissymmetric?

Published experimental results (6–9) yield data which are incomplete and mutually contradictory. The present experiments were intended to resolve these questions.

The answers to the questions concerning the nature of the monomer precursor(s) of the $C_4$ units must be looked for in the labelling pattern within retronecine derived from specifically labelled ornithine. Experiments with C-labelled putrescine, a nondissymmetric ($C_{2v}$) molecule, cannot provide an answer, since incorporation of putrescine must, of structural necessity, take place in "symmetrical" fashion, as indeed it does (9). Furthermore, even though label from putrescine is incorporated into retronecine (6, 8, 9), it does not necessarily follow that ornithine, the precursor of putrescine, also enters retronecine in "symmetrical" fashion. It is well documented that putrescine is incorporat-

ed into hyoscyamine "symmetrically" (23–26), as a matter of structural necessity, but that ornithine enters "nonsymmetrically" (27).[4]

Label from [2-$^{14}$C]ornithine (6, 7) as well as from [5-$^{14}$C]ornithine (6, 8) was found at C-9 of retronecine, obtained from the alkaloids isolated from *Senecio douglasii* and *S. isatideus*. In each case one quarter of the total specific activity of retronecine was found at this site. This was interpreted to show that C-2 and C-5 of ornithine become equivalent before entering chain B of retronecine and to suggest that chain B is derived from a nondissymmetric $C_4$ intermediate, such as putrescine. Yet, a degradation product regarded as representing C-3 of retronecine, the second site within chain B which should have carried label if chain B were derived from a "symmetrical" precursor, was not radioactive when a sample of retronecine derived from [2-$^{14}$C]ornithine was degraded (7). The mode of entry of label into the A chain is similarly in dispute. On the one hand it is reported that retronecine from [5-$^{14}$C]ornithine contains one quarter of its label at C-5 (isolated, together with C-6,-7 as β-alanine) (8), on the other hand a degradation product regarded as representing C-5 of retronecine was nonradioactive, and another, thought to be derived from C-7,-8, accounted for three quarters of the specific activity of retronecine derived from [2-$^{14}$C]ornithine (7). The reported labeling patterns are summarized in Scheme 4 (Figs. A–D).

The results shown in Figs. A and C (Scheme 4) (6) led to the inference that chain B is derived from a "symmetrical" $C_4$-intermediate, and left open the origin of chain A. The results shown in Fig. D (Scheme 4) (8), together with the assumption that the rest of the activity, not accounted for by degradation, is divided equally between C-3 and C-8, suggested that chain A as well as chain B are "symmetrically" derived and that they originated from a common source. The results shown in Fig. B (7) on the other hand, appeared to show that chains A and B were derived independently and nonsymmetrically.

As will be shown in the sequel none of these inferences are valid, for different reasons.

It was apparent that the first step towards the resolution of these experimental contradictions was a reliable degradation permitting independent assay of radioactivity at each of the four crucial positions, C-3,-5,-8, and -9 of retronecine, and not merely at C-5 and -9, as hitherto. Such a degradation (Scheme 2) has now been employed to determine the distribution of label in samples of retronecine obtained from a mixture of the alkaloids retrorsine, senecionine, and seneciphylline, as well as from their *N*-oxides, isolated in four experiments from *S. vulgaris* to which DL-[5-$^{14}$C]-ornithine had been administered (Experiments 1–4, Table 1). The distribution of $^{14}$C within the samples of retronecine (Table 2) is shown in Fig. E, Scheme 4.

In each case formaldehyde (C-9) and formic acid (C-8) each accounts for one quarter of the $^{14}$C activity of the intact retronecine molecule, within

[4]Analogously, incorporation of lysine into piperidine alkaloids such as sedamine (28) and anabasine (29, 30) takes place "nonsymmetrically", while incorporation of cadaverine, the decarboxylation product of lysine, takes place "symmetrically" (31). A possible explanation of this apparent paradox has been advanced (32).

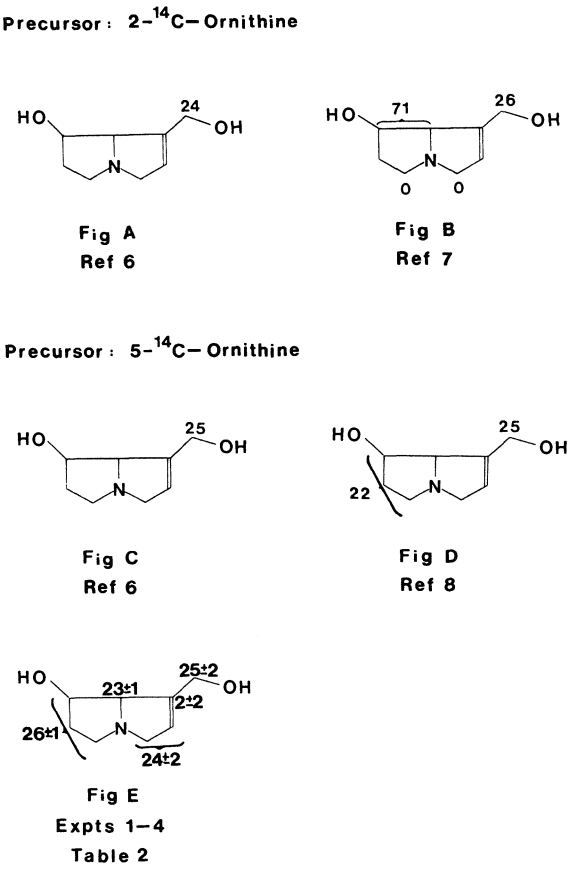
experimental error. L-*cis*-3-Hydroxyproline (C-1,-5,-6,-7,-8) accounts for one half of the $^{14}C$ activity, that is, one quarter must be present at one or more of C-1,-5,-6,-7. Since all of this activity is accounted for by β-alanine (C-5,-6,-7), C-1 must be unlabelled. The remaining quarter of the activity of the intact molecule must be present at C-2 and/or C-3 (by difference: retronecine minus formaldehyde (C-9; 25%) minus L-*cis*-3-hydroxyproline (C-1,-5,-6,-7,-8; 50%)). It is a reasonable supposition, based on structural relations, that a quarter of the activity resides at C-5 (and that C-6 and C-7 are unlabelled) and that a quarter of the activity resides at C-3 (and that C-2 is unlabelled). Thus, the four crucial sites, C-9,-3,-5, and -8, account for the activity of the intact molecule and are equally labelled. This result confirms and completes two of the earlier reports (6, 8) and controverts the third one (7).[5]

It would appear at first glance that the observed distribution of label proves that each of the $C_4$ units of retronecine is derived from ornithine via a nondissymmetric intermediate, and that the two $C_4$ units originate from a common source. The distribution is indeed consistent with such a derivation, but there are several other possibilities. The crucial problem which must be solved before the distribution of label can be interpreted is whether among the "dimeric" intermediates, $(C_4)_2N$, there is one that is nondissymmetric or not. Only in the absence of a nondissymmetric dimeric intermediate does the observed distribution prove that the two $C_4$ monomer units are necessarily derived from a common "symmetrical" intermediate, such as free putrescine (Scheme 5A).

If a "symmetrical dimeric" intermediate is implicated in the pathway, then in addition to such a derivation from a common symmetrical intermediate (Scheme 5B) several other routes into the product are possible. These are summarized in Schemes 5C, D, and E. Several other derivations of the two monomer units are excluded by the observed distribution pattern.



SCHEME 4. Distribution of label from [$^{14}$C]ornithine in retronecine. Figs. A, B, C, D: Reported partial distribution (6, 7, 8). Fig. E. Distribution of label from [5-$^{14}$C]ornithine, now determined.

In order to permit further interpretation of the labelling pattern from [5-$^{14}$C]ornithine it is thus necessary to determine whether or not a nondissymmetric "dimer" of the type $C_4$–N–$C_4$ plays a part in retronecine biosynthesis.

An answer to this question may be obtained, in principle, by a feeding experiment with 1-pyrroline, or with the corresponding open chain compound, 4-aminobutanal, substrates derivable from ornithine. Incorporation of labelled samples of either of these compounds by one or the other of the two routes shown in Scheme 1 would lead to recognizably different labelling patterns (Scheme 6). Feeding experiments with (2-$^2$H)-1-pyrroline (Experiment 7) and [5-$^3$H,5-$^{14}$C]-1-pyrroline (Experiment 8) were unsuccessful, however. Incorporation of tracer into retronecine in either experiment was too low for accurate determination by $^2$H

[5]It is likely that the erroneous results (7) have their basis in the chemistry of the degradation reactions that were employed. Ozonolysis of a Hofmann base leads to formaldehyde not only from the methylene carbon atom of the vinyl group but also from the *N*-methyl groups (33). It must be assumed that the apparent lack of radioactivity in the formaldehyde, derived from C-3 and C-5 by ozonolysis of Hofmann bases, was due to dilution of active formaldehyde derived from these carbons by inactive formaldehyde derived from the *N*-methyl groups, to yield samples whose radioactivity was beyond the limits of detection. Furthermore, evaluation of the contribution to a product of material from more than one site within the molecule (e.g. acetate from C-6,-5 and C-3,-2, as well as from C-9,-1, in the Kuhn–Roth oxidation of the second stage Hofmann base) is too uncertain for determining distribution patterns of radioactivity, as are reactions which yield $CO_2$ from a multiplicity of carbon atoms.

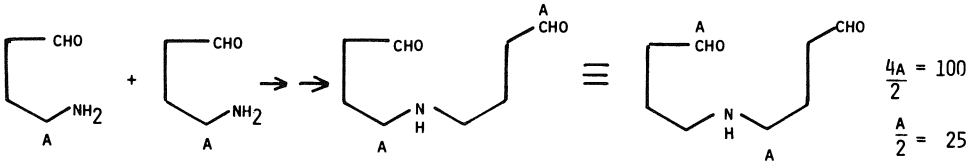
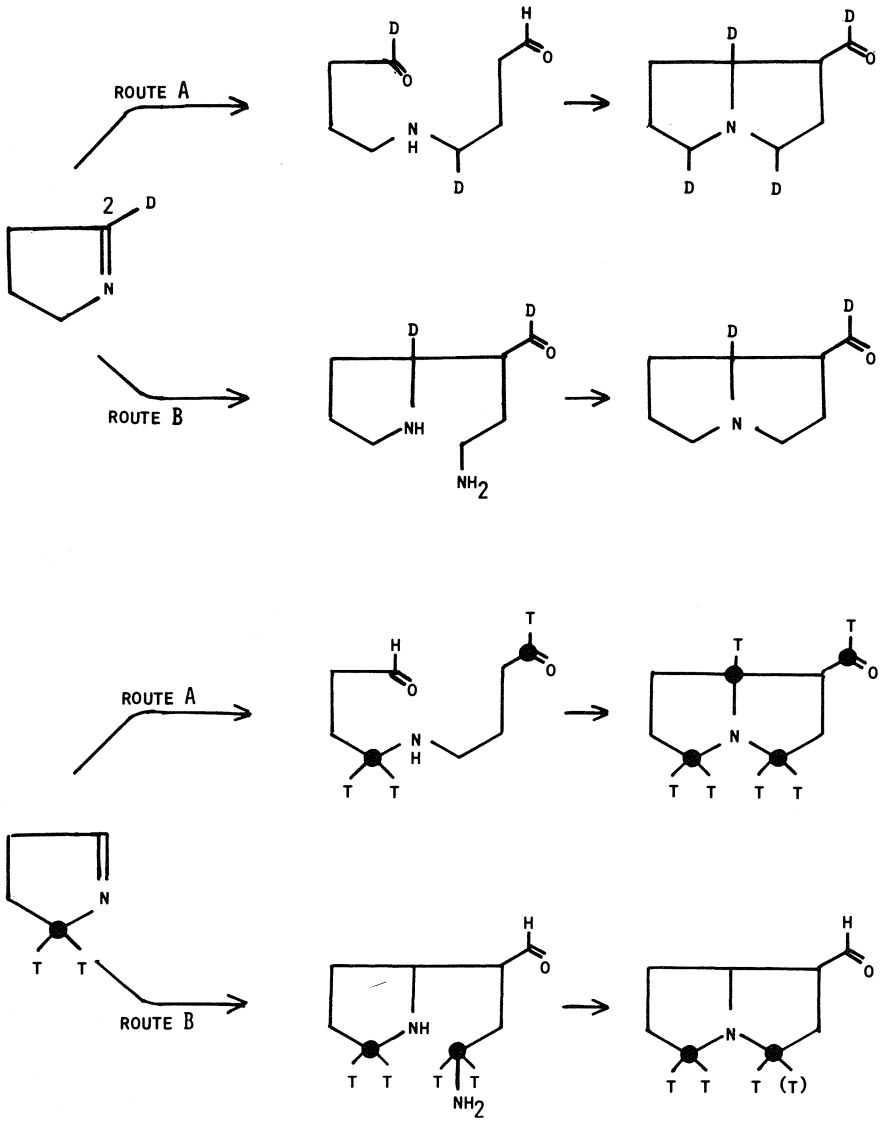


SCHEME 5. Five possible modes of incorporation of [5-$^{14}$C]ornithine-derived $C_4$ units which account for the observed distribution of label in retronecine (i.e. 25% of total specific radioactivity at each of C-3, C-5, C-8, and C-9).



SCHEME 6. Predicted distribution of label from (2-$^2$H)- and from [5-$^3$H]-1-pyrroline within retronecine.

nmr spectroscopy and liquid scintillation counting, respectively. 1-Pyrroline thus may not be an intermediate of biosynthesis. It is more likely, however, that the administered 1-pyrroline did not reach the site of biosynthesis. 1-Pyrroline rapidly polymerizes at basic and neutral pH (20, 21) and the polymer may not be available as a substrate for biosynthesis. In Experiment 8 the crude alkaloid fraction contained an unidentified component, not observed in other experiments, which accounted for ca. 90% of the total radioactivity of the fraction. This may have been a self-condensation product of 1-pyrroline.

Another possible way of establishing whether or not a nondissymmetric "dimeric" intermediate is involved in the pathway to retronecine is by studying the distribution of label from doubly $^3$H,$^{14}$C-labelled ornithines. The incorporation patterns, predicted for retronecine derived from [4-$^3$H,5-$^{14}$C]- and [5-$^3$H,5-$^{14}$C]ornithine, by Routes A and B (Scheme 1), via "nonsymmetrical" and via "symmetrical" monomer units, are summarized in Scheme 7.

The distribution of $^3$H within the samples of retronecine from [4-$^3$H]-ornithine (Experiment 4) and [5-$^3$H]ornithine (Experiments 2, 3), which were administered in admixture with [5-$^{14}$C]ornithine to provide an internal reference standard, was de-

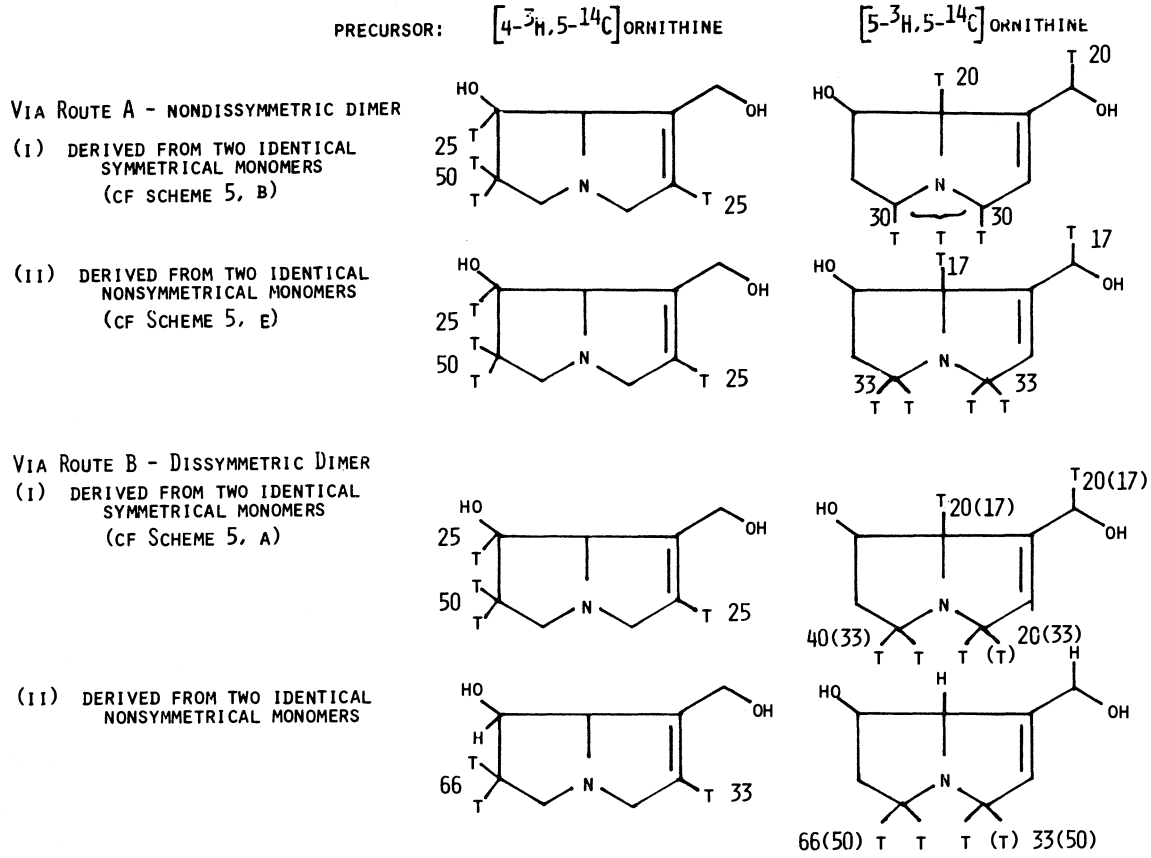

SCHEME 7. Predicted distribution of tritium from [4-$^3$H]- and [5-$^3$H]ornithine within retronecine.

duced from the radioactivity of the products of chemical degradation of these samples (Table 3).

The labeling pattern of $^3$H within the two samples of retronecine derived from L-[4-$^3$H]ornithine was essentially identical and is shown in Fig. F, Scheme 8. No tritium is present at C-9 (formaldehyde) or at C-8 (formic acid). Three quarters of the tritium is accounted for by the hydrogen atoms at C-5,-6,-7, and -8 (L-*cis*-3-hydroxyproline), one half by those at C-5,-6 (β-alanine). Assuming no migration of label from the initial C-4 position of ornithine to C-5 in the course of biosynthesis, tritium is then located at positions C-2 (25%, 1H), C-6 (50%, 2H), and C-7 (25%, 1H) of retronecine. This distribution is consistent with three of the four patterns shown in Scheme 7, and eliminates the fourth. Retention of tritium at C-7 demonstrates that introduction of the hydroxyl group does not involve a keto or enol intermediate.

The distribution of label within the two samples of retronecine from this experiment, derived from the alkaloids, present as such, and from the *N*-oxides (Experiment 4*A* and 4*O*, respectively, Table 3), was identical. If the ease of oxidation of retronecine during the work-up in Experiment 5 (see later) is any guide, the conversion of free alkaloids to *N*-oxides within the plant may well be a nonenzymatic process.

The labeling pattern of $^3$H within the samples of retronecine derived from DL-[5-$^3$H]- and L-[5-$^3$H]ornithine, identical in all but one value[6] (Experiments 2 and 3, Table 3) is shown in Fig. G, Scheme 8. Approximately one fifth of the total label was present at C-9 (formaldehyde) and one fifth at C-8 (formic acid).[6] Half of the tritium is accounted for by the hydrogen atoms at C-5,-6,-7, and -8 (L-*cis*-3-hydroxyproline) and one third by those at C-5,-6 (β-alanine).

The observed distribution of tritium lies within the range of two of the four predicted distribution patterns (Scheme 7, AI, AII, BI). A choice among them on the basis of the experimental data would

[6]The low value for the formic acid in Experiment 3 may have been due to contamination of the product by a nonradioactive contaminant.

SCHEME 8. Observed distribution of tritium from [4-$^3$H]- and [5-$^3$H]ornithine within retronecine.

appear to be unwarranted. It is unfortunate that the sample of DL-[5-$^3$H]ornithine was contaminated with [4-$^3$H]ornithine (See Table 1, footnote *e*). If the observed values are corrected for this contamination, on the basis of the experimental results of the experiment with [4-$^3$H]ornithine (Experiment 4, above), the resulting values correspond closely to three of the predicted distributions (Scheme 7, AI, or AII ≡ BI).

One tritium is present at each of C-9 and C-8 and three or four, respectively, are shared equally among C-3 and C-5. Only one of the hydrogen atoms at the prochiral site, C-9, is labelled. This is predicted by a pathway (Route A, Scheme 1) which involves oxidation of a primary amino function at C-9 to yield an imine which is subsequently hydrolyzed to an aldehyde. The possibility that each of the two sites, C-3 and C-5, accounts for one and a half tritium atoms would support the intermediacy of a nondissymmetric dimer, $C_4$–N–$C_4$, generated from two identical nondissymmetric ornithine-derived monomer units (Scheme 5B). Two other derivations of the nondissymmetric dimer are also consistent with this distribution, however.

The possibility that, on average, 1.5 tritium atoms are located at each of C-3 and C-5 requires comment. Route A (Scheme 1) predicts a reduction step during which a hydrogen atom is introduced at the imino group carbon atom of an intermediate which in subsequent steps is converted into a compound with $C_{2v}$ symmetry. A tritium-labelled compound of this type would be composed of various tritiated species in which, on averaging, 3 labelled hydrogen atoms are shared by the two carbon atoms which are destined to become C-3 and C-5 of retronecine. If this interpretation is correct then the two labelled centres, C-3 and C-5, must be chiral in some of the contributing labelled species and must be of opposite configuration (α and β) at C-3 and C-5. This inference has yet to be tested.

The inference that a nondissymmetric dimer serves as an intermediate rests on values obtained by correcting experimental data. The experimental data themselves did not permit a direct and clearcut differentiation among two sets of predicted values both of which were within experimental range. For this reason the conclusions drawn from the experiments with [5-$^3$H]ornithine must be regarded as tentative. A further experimental approach was sought to solve the problem of the symmetry of the "dimeric" intermediate in a conclusive manner.

In the third attempt to answer the question concerning the intermediacy of a nondissymmetric dimer, we exploited the fact that retronecine contains a single nitrogen atom. If this nitrogen atom, like the carbon atoms, were derived from ornithine, then, assuming a unique route of retronecine biosynthesis, only one of the three C-atoms, C-3, C-5, or, less likely, C-8, can be transferred from a precursor into retronecine without ever having been separated from direct attachment to nitrogen.

Maintenance of a C—N bond in the conversion of a suitably labelled precursor into a product can be recognized by $^{13}$C or $^{15}$N nmr techniques (34–37). If the retronecine obtained in an experi-

ment with an appropriately $^{13}C—^{15}N$ labelled precursor contains a single $^{13}C—^{15}N$ bond, transferred intact from a labelled substrate, then all $(C_4)_2N$ intermediates must have been dissymmetric. If two intact $^{13}C—^{15}N$ bonds appear in the product, a nondissymmetric $C_4–N–C_4$ intermediate must have served as a stage of the biosynthetic route.

A substrate, intramolecularly doubly labelled, with $^{15}N$, as well as with $^{13}C$ at the adjacent C atom, would be suitable for such an experiment. A doubly labelled sample of ornithine or of any other compound known to be incorporated into retronecine (e.g. putrescine) could be used for such an experiment.

(1-$^{13}$C,1-$^{15}$N)Putrescine dihydrochloride was synthesized from K$^{13}$C$^{15}$N, with isotopic enrichments of 90 at.% $^{13}C$ and 99 at.% $^{15}N$ (Scheme 3). To obviate the possibility of a multiplicity of couplings in the $^{13}C$ nmr spectrum of the biosynthetic product, the putrescine was labelled only at one of the C—N termini.

A large amount (472 mg) of (1-$^{13}$C,1-$^{15}$N)putrescine dihydrochloride was used in the hope of achieving $^{13}C$ enrichment above natural abundance high enough for quantitative assay. In order to minimize a change in the internal environment of the plants due to this large quantity of extraneous material, the compound was administered in small doses over a prolonged period (13 days). Simultaneous administration of $^{14}C$-labelled putrescine served as an independent check on the incorporation of substrate into retronecine. The plants were growing actively at the end of the 13-day period and had not sustained any evident damage.

An unexpectedly low yield of alkaloid was obtained in the feeding experiment with putrescine (Experiment 5), and a problem, not encountered when larger amounts of alkaloids were handled, was the partial oxidation of the pyrrolizidine moiety to the corresponding *N*-oxide during work-up, when oxygen-free conditions were not employed. As it turned out, the isolation of retronecine-*N*-oxide, the product of this oxidation, was useful in that comparison of the signals in the $^{13}C$ nmr spectra of retronecine hydrochloride and *N*-oxide served as an independent check on the assignment of the signals. There has been some confusion in the assignment of signals in the $^{13}C$ nmr spectra of the pyrrolizidine alkaloids (38, 39). Our own findings (Table 4) are in agreement with those of Barreiro *et al.* (19).

Reduction of the alkaloid *N*-oxides and further work-up under exclusion of oxygen yielded retronecine hydrochloride which was chemically and radiochemically pure. The specific incorporation of substrate per $C_4$ unit of retronecine, as determined by assay of radioactivity, was 3.3%.[7,8]

The $^{13}C$ nmr spectrum of the retronecine sample (Fig. 1 and Table 4) shows that, as expected, four of its eight carbon atoms are enriched in $^{13}C$, to an equal extent. The average specific incorporation per $C_4$-unit, based on $^{13}C$ nmr data (Table 4), is 3.3%, identical with the value obtained from $^{14}C$ assay.

To enhance the resolution of the signals due to the enriched carbon atoms, the number of Hz per data point was decreased tenfold from 1.5 to 0.15, and the acquisition time was correspondingly increased from 0.68 to 6.8 s. The spectrum thus obtained (Fig. 2 and Table 5) comprises the signals due to C-3,-5,-7,-8, and -9, of which only that due to C-7 is a nonenriched singlet. The other four signals show higher multiplicity, reflecting the different labelled species present in the retronecine hydrochloride isolated from the feeding experiment with (1-$^{13}$C,1-$^{15}$N)putrescine.

Most noticeable are the signals due to C-3 and C-5, which each appear as a doublet superimposed on a singlet. The coupling constants are different from one another. This shows that the doublets are due to $^{13}C–^{15}N$ coupling ($^{13}$C-3,$^{15}$N, 5.1 Hz; $^{13}$C-5,-$^{15}$N, 4.4 Hz) and do not arise from $^{13}$C-5,$^{13}$C-3 coupling.

The ratio of the areas of singlet and of doublet, due to enrichment above natural abundance, for each of the two signals, is identical (ca. 28/72). This shows that the $^{13}C—^{15}N$ moiety of putrescine had been transferred intact into positions C-3,N and C-5,N of retronecine to an equal extent, that is, that the retronecine contains equimolar amounts of two species, one of which is labelled at C-3,N, the other at C-5,N. The simplest interpretation of this result is that a nondissymmetric "dimeric" intermediate, $C_4–N–C_4$, such as **6**, lies on the pathway to retronecine. Two other, less likely, possibilities, which exclude a nondissymmetric "dimeric" intermediate, cannot be entirely ruled out, however. One is the intermediacy of a dissymmetric compound, capable of undergoing a degenerate sigmatropic rearrangement (e.g. $NH_2CH_2CH_2CH_2CH_2$-$N{=}CHCH_2CH_2CH_2NH_2$), the other is the occur-

[7] $\dfrac{\text{Molar specific activity of retonecine (dpm/mmol)} \times \frac{1}{2}}{\text{Molar specific activity of putrescine (dpm/mmol)}} \times$

$$100 = \frac{3.4 \times 10^6}{5.2 \times 10^7} \times \frac{10^2}{2} = 3.3.$$

[8] An account of this experiment has appeared in a preliminary communication (40). More recently the results of a similar experiment were reported independently (44).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

rence of two independent pathways fortuitously yielding equal amounts of the two labelled species.

Disregarding these remote possibilities, the nmr evidence thus suggests that a nondissymmetric "dimeric" intermediate is implicated in the biosynthesis of retronecine. As discussed earlier, this leaves open four variants (Scheme 5B, C, D, E) of the mode whereby $C_4$ monomer units combine to yield the $C_4$–N–$C_4$ skeleton.

One of these four possibilities can be eliminated on the basis of a feature of the nmr spectrum which has yet to be discussed, the signal due to C-9. The $^{13}C$ enrichment at this signal is composed of a singlet and a doublet, 72:28 in area. The doublet is due to coupling between C-9 and C-8, and the singlet/doublet ratio is a measure of the contribution to the $^{13}C$-labelled retronecine of molecules enriched in both $C_4$ chains. The fact that such doubly enriched retronecine molecules are found eliminates from further consideration the possibility shown in Scheme 5D, which considers that only one of the two $C_4$ chains is derived from ornithine. No doubly enriched retronecine molecules would occur if this were its mode of origin.

The ratio of the areas singlet/doublet in the signal due to C-9 reflects the dilution of the administered doubly labelled putrescine by natural abundance material produced endogenously by the plant. The observed ratio corresponds to that expected if the administered putrescine were diluted with 63% of its own weight of natural abundance material (40).

The C-9,C-8 coupling is barely observable at C-8, presumably due to superimposed low intensity coupling to $^{15}N$ and C-3. Coupling due to C-8,C-3 or C-5,C-3 (through $^{15}N$) is not observed. Their intensities are presumably low and their contribution to the singlet and doublet integrals of C-3 and C-5 insignificant.

Coupling between C-3 and C-9 does not appear since the labelling pattern in the substrates precludes the possibility of formation of a retronecine molecule, doubly labelled in one $C_4$ chain.

The three remaining possibilities for the origin of the $C_4$–N–$C_4$ unit of retronecine cannot be differentiated on the basis of the experiment with (1-$^{13}C$,1-$^{15}N$)putrescine. In each case the retronecine that would be formed from this precursor would be predicted to yield an nmr spectrum showing C-8,C-9 coupling.

However, an experiment with (5-$^{13}C$,5-$^{15}N$)-ornithine would distinguish between the derivation shown in Scheme 5E (no C-8,C-9 coupling, if retronecine were generated from two identical ornithine-derived dissymmetric $C_4$ units) and those shown in Schemes 5B and C. Such an experiment is in hand.

The final experiment to be mentioned, a study of the incorporation of spermidine into retronecine (Experiment 6), does not contribute to the main thesis of this paper, but provides an illustration of one of the pitfalls which may be encountered in the use of intermolecularly $^3H$,$^{14}C$-doubly labelled substrates in biosynthetic studies. The incorporation of label from [1,4-tetramethylene-$^{14}C$]spermidine into retronecine has been previously reported (8). Presumably it serves as a source of putrescine or of 4-aminobutanal, or both.

A sample of [1-tetramethylene-$^3H$,1,4-tetramethylene-$^{14}C$,8-trimethylene-$^3H$]spermidine was administered, retronecine was obtained from the alkaloids and from the *N*-oxides that were isolated, and the samples were degraded to establish the labelling pattern.

The distribution of $^{14}C$ in the two samples was unexceptional (Experiment 6, Table 2). One quarter of label of each sample was present at each of C-9,-8,-5, and -3. However, the distribution of tritium (Experiment 6, Table 3) differed significantly from that observed in the experiment with [5-$^3H$]ornithine (Experiments 2, 3, Table 3), in that, in both spermidine-derived samples C-3 and C-5 each made the same contribution to the total activity as C-8, whereas in the ornithine-derived samples C-3 and C-5 each accounted for 50% more label than C-8. The observed distribution of label in retronecine derived from the labelled spermidine is readily explicable if the latter were first oxidized to the corresponding aldehyde, OTC—$CH_2$—$CH_2$—$CH_2$—NH—$CH_2$—$CH_2$—$CT_2$—$NH_2$ (11, 41), which then yields as the sole labelled product which enters retronecine, 4-amino-[1-$^3H$]butanal, OTC—$CH_2$—$CH_2$—$CH_2$—$NH_2$. The distribution is also explicable, somewhat less readily, if degradation of the spermidine had yielded both [1-$^3H$]-putrescine, $NH_2$—$CT_2$—$CH_2$—$CH_2$—$CH_2$—$NH_2$, and 4-amino-[4-$^3H$]butanal, $NH_2$—$CT_2$—$CH_2$—$CH_2$—CHO (11). The experiment thus raises questions concerning the mode of degradation of spermidine in *S. vulgaris* rather than answering questions regarding the biosynthesis of retronecine. Further work is required to clarify this problem.

What is of more immediate interest is the difference in the distribution of tritium observed in the two spermidine-derived samples of retronecine, 6*A* and 6*O* (Table 3). These samples differed in the relative contribution which C-9 (formaldehyde) makes to the total activity. In both cases this is higher than the contribution made by tritium at C-8 (formic acid). An explanation for this finding must be sought in an isotope effect or a reverse isotope effect in one of the reactions involved in the

TABLE 6. $^3H/^{14}C$ ratios in retronecine and its degradation products, derived from Expt. 6

| | Sample 6*O* degraded without further chromatography | Sample 6*A* degraded after further chromatography | Difference % |
|---|---|---|---|
| Retronecine | $\frac{23.4}{5.11} = 4.6$ | $\frac{31.0}{8.31} = 3.7$ | −20 |
| Retronecine HCl | $\frac{23.0}{5.07} = 4.5$ | $\frac{30.0}{8.03} = 3.7$ | −18 |
| Formaldehyde dimethone | $\frac{7.2}{1.23} = 5.8$ | $\frac{11.5}{1.95} = 5.9$ | +2 |
| L-*cis*-3-Hydroxyproline | $\frac{11.0}{2.47} = 4.5$ | $\frac{13.1}{4.01} = 3.3$ | −27 |
| *N*-Formyl-1-naphthylamine | $\frac{5.3}{1.23} = 4.3$ | $\frac{5.6}{1.88} = 3.0$ | −30 |
| *N*-Phthaloyl-β-alanine | $\frac{5.5}{1.23} = 4.5$ | $\frac{7.0}{1.97} = 3.6$ | −20 |

formation of retronecine from the "symmetrical dimeric" intermediate, e.g., in the ring closure or in the reduction of the aldehyde function at C-9 to a carbinol.

The differences of distribution within the two samples were due to isotope fractionation in the course of the chromatographic purification of the retronecine samples. The sample isolated from the free alkaloids was chromatographed more extensively than that isolated from the *N*-oxides. When originally isolated, both retronecine samples were radiochemically pure and each showed a $^3H/^{14}C$ ratio 4.6. The retronecine sample derived from the *N*-oxides was degraded without further chromatography. The retronecine sample from the free alkaloids, $^3H/^{14}C$ 4.6, was chromatographed on a silica gel column with chloroform–methanol – concentrated ammonia (74:24:2). The retronecine-containing effluent was collected in several fractions which maintained the specific activity with respect to $^{14}C$ but differed in $^3H/^{14}C$ ratio, which rose from 2.9 to 5.2 and then leapt to 20 in the final retronecine-containing fraction. Retronecine with a $^3H/^{14}C$ ratio of 3.7, isolated from the combined early fractions, was degraded (Tables 2 and 3). Table 6 shows the $^3H/^{14}C$ ratios of the various degradation products derived from the two retronecine samples.

It is evident that the $^3H/^{14}C$ ratio within the samples of formaldehyde (i.e. within C-9 of the two retronecine samples) is the same, i.e., no loss of $^3H$, relative to $^{14}C$, has occurred at this position in the course of chromatography. The other breakdown products, representing samples containing tritium adjacent to the basic nitrogen, have all suffered loss of tritium, relative to $^{14}C$. It would appear that the discrimination of the $^{14}C$-labelled, i.e., the protonated species, versus the tritiated species is a function of small differences in the $pK_a$ due to replacement of $^1H$ by $^3H$ at the carbon atoms adjacent to nitrogen. Such small differences in $pK_a$ are evidently sufficient to cause separation of the two species in the course of chromatography, particularly when the pH of the eluent is numerically close to the $pK_a$ of the dissociating group in question.

Experiments whose interpretation is based on a measurement of $^3H/^{14}C$ ratios must be designed in such a way that such isotope fractionation is avoided.

## Experimental

*Synthesis of (1-$^{13}C$,1-$^{15}N$)putrescine dihydrochloride (**15**)*

1-Bromo-3-phthalimidopropane (**12**) (1.94 g, 7.24 mmol), dissolved in *N*,*N*-dimethylformamide (7.2 mL), was added to a solution of potassium ($^{13}C$,$^{15}N$)cyanide (90.6 at.% $^{13}C$, 99.4 at.% $^{15}N$, Prochem) (0.48 g, 7.16 mmol) in water (2.4 mL). The mixture was heated on a steambath for 90 min. After cooling to 25°C and addition of water (70 mL) the reaction mixture was extracted with ether (2 × 70 mL). The combined ether extracts were re-extracted with water (70 mL) and dried over anhydrous sodium sulfate. Filtration and evaporation of solvent *in vacuo* yielded an oil (1.08 g). Repeated extraction of the combined aqueous phases with ether (2 × 70 mL) and washing of the ether extracts with water (35 mL) gave, upon evaporation of solvent *in vacuo*, an additional 0.18 g. The total yield of crude 4-phthalimidobutyro-(1-$^{13}C$,1-$^{15}N$)nitrile (**13**) was 1.26 g (5.83 mmol, 81%); $^1H$ nmr[9] ($CDCl_3$) δ: 8.95–8.65 (m, 4H), 3.80 (t, $J$ = 6.5 Hz, 2H), 2.60–2.35 (m, 2H), 2.25–1.75 (m, 2H) ppm; $^{13}C$ nmr[10] ($CDCl_3$) δ: 118.8 (d, $J_{^{13}C,^{15}N}$ = 17.6 Hz) ppm; ms *m/e*: 217 (2.3%), 216 (10.5%), 215 (1.3%), 161 (26%), 160 (100%), 105 (15%), 104 (14%), 77 (17%), 76 (22%).

Crude 4-phthalimidobutyro-(1-$^{13}C$,1-$^{15}N$)nitrile (**13**) (1.24 g,

[9]Recorded at 90 MHz on a Varian EM390 spectrometer.

[10] $^{13}C$ nmr spectra were recorded at 20.15 MHz in the Fourier mode on a Bruker WP 80 spectrometer with proton noise decoupling.

5.74 mmol) was dissolved in acetic anhydride (7 mL) and added to Raney-Ni (0.5 g, BDH, stabilized, washed with ethanol (2 × 20 mL) and acetic anhydride (10 mL)) in acetic anhydride (5 mL). Hydrogenation was carried out with vigorous stirring at 90°C and 1 atm for 15 h. The reaction was followed by tlc (silica gel, ethyl acetate): 4-phthalimidobutyronitrile (**13**), $R_f$ 0.75, and 4-phthalimido-1-acetamidobutane (**14**), $R_f$ 0.15 (monitored with uv-light). The reaction mixture was centrifuged and the supernate concentrated *in vacuo* to an oil. Hydrochloric acid (25 mL, 6 *M*) was added and the mixture kept in a sealed flask at 92°C for 20 h. Upon cooling to 25°C the mixture was seeded with phthalic acid crystals and kept at 5°C for 1 h. Phthalic acid was removed by centrifugation, washed with hydrochloric acid (2 × 10 mL, 6 *M*), and the supernatant liquids evaporated to dryness *in vacuo*. The residue was dissolved in sodium hydroxide (20 mL, 1 *M*), and the solution was saturated with sodium chloride and extracted with 1-butanol (5 × 20 mL). Hydrochloric acid (2 mL, 6 *M*) was added to the combined extracts and the mixture was evaporated to dryness and dried *in vacuo* over calcium chloride. The crude (1-$^{13}$C,1-$^{15}$N)putrescine dihydrochloride (**15**) (954 mg) was recrystallized from water/ethanol. Yield, 544 mg (3.34 mmol); $^1$H nmr[9] ($D_2O$) δ: 4.0–3.8 (m, 0.9 H), 3.2–3.0 (m, 2.2 H), 2.4–2.2 (m, 0.9 H), 2.0–1.7 (m, 4.0 H) ppm, $J_{^{13}C,H\text{-}1}$ = 143 Hz; $^{13}$C nmr[10] ($D_2O$) δ: 40.3 (d, $J_{C\text{-}1,N}$ = 4.4 Hz), 25.11 (d, $J_{C\text{-}2,C\text{-}1}$ = 37 Hz), 25.15 (s, C-3) ppm.

*Synthesis of (2-$^2$H)-1-pyrroline*

DL-(2-$^2$H)Proline (98 at.%, Merck, Sharp and Dohme) (294 mg, 2.53 mmol) was dissolved in sulfuric acid (20 mL, 0.1 *M*) and sodium metaperiodate (635 mg, 2.97 mmol) in water (10 mL) was added. The mixture was kept in the dark for 16 h. After cooling to 0°C a saturated solution of barium chloride dihydrate (863 mg, 3.53 mmol) in water was added. A saturated solution of sodium bicarbonate was added until the pH was 7.5. The ice-cold reaction mixture was filtered (Celite) and the pH was immediately adjusted to 6.5 with dilute hydrochloric acid. The mixture was immediately used for feeding (experiment 7).

*Synthesis of [5-$^3$H,5-$^{14}$C]-1-pyrroline*

Sodium metaperiodate (13.2 mg, 0.062 mmol) was added to a solution containing L-[5-$^3$H]proline (see Table 1), DL-[5-$^{14}$C]-proline (see Table 1), and L-proline (5.6 mg, 0.049 mmol) in sulfuric acid (0.5 mL, 0.1 *M*). The mixture was left in the dark for 23 h. A solution of barium chloride dihydrate (17.9 mg, 0.073 mmol) in water (0.5 mL) was added and the mixture centrifuged. The precipitate was washed with water (1 × 0.5 mL) and to the combined supernatant liquids was added a solution of sodium bicarbonate (3.5 mg, 0.042 mmol) in water (0.5 mL). Centrifugation and washing of the precipitate with water (1 × 0.5 mL) gave a solution (pH ca. 6) which was immediately used for feeding (experiment 8).

*Administration of tracers to* Senecio vulgaris

The plants used in this study were collected on the McMaster University Campus, keeping as much of the original soil around the roots as possible, and transferred to the greenhouse, where they were allowed to acclimatize for 2–10 days. The plants used in the feeding experiments were 15–30 cm tall. Tracer solution was administered by the wick method.

*Experiment 5*

The mixture of (1-$^{13}$C,1-$^{15}$N)putrescine dihydrochloride (90 at.% $^{13}$C, 99 at.% $^{15}$N, *vide supra*) (472 mg, 2.90 mmol) and [1-$^{14}$C]putrescine (68 μCi, see Table 1)[11] in water (50 mL) was administered to 133 plants over a period of 13 days (July). An equal volume of tracer solution was administered each day.

*Experiments 1–4, 6–8*

Tracer solution was administered in a single dose. The plants were allowed to grow in contact with tracer for various lengths of time before being harvested (see Table 1).

*Extraction of alkaloids*

The procedure described is typical for the experiments with radioactive substrates (Experiments 1–4, 6, 8). In the experiments with stable isotopic tracers (Experiments 5, 7) the amounts used were twice those given below. The plants were harvested and the fresh plant material was immediately ground in a blender with methanol and extracted in a Soxhlet extractor with methanol (approx. 10 h). The extract was concentrated *in vacuo*. Sulfuric acid (50 mL, 1 *M*) was added to the residue and the mixture extracted with ether (3 × 50 mL). The aqueous phase was basified to pH ca. 9 with concentrated ammonium hydroxide and extracted with chloroform (4 × 50 mL). The chloroform extracts were dried over anhydrous sodium sulfate, filtered, and concentrated *in vacuo* to yield a mixture of crude alkaloids. The composition of the mixture was determined by $^1$H nmr (42) and tlc (silica gel, $CHCl_3$/MeOH/concentrated $NH_4OH$; 85:14:1) using Dragendorff's reagent (43*a*) for visualization (retrorsine $R_f$ 0.40; seneciphylline $R_f$ 0.73; senecionine $R_f$ 0.73). These alkaloids accounted for 0–10%, 40–50%, and 50–60%, respectively of the mixture.

The aqueous phase from the chloroform extractions was partly concentrated *in vacuo* to remove excess ammonia. The mixture was acidified to pH ca. 1 with concentrated sulfuric acid and stirred with zinc dust (ca. 2 g) for 30 min. Excess concentrated ammonium hydroxide was added and the mixture extracted with chloroform (4 × 50 mL). The extracts were dried over anhydrous sodium sulfate, filtered, and concentrated *in vacuo* to yield a mixture of crude alkaloids originating from the alkaloid *N*-oxides. The composition of the mixture fell within the limits given above. The aqueous phase from the chloroform extractions was kept for the isolation of ornithine (see Footnote 2).

*Isolation of retronecine*

*Experiment 5*

Each of the two mixtures of the crude alkaloids (*vide supra*) was applied to a column of silica gel 40 (Merck, 70–230 mesh, 25 × 1 cm) and eluted with $CHCl_3$/MeOH/concentrated $NH_4OH$ (90:9:1). The fractions containing the alkaloids were identified by tlc (*vide supra*) and evaporated to dryness *in vacuo*. The yield of crude alkaloids was 47 mg.

Water (1.3 mL) and barium hydroxide octahydrate (186 mg, 0.59 mmol) were added to the crude alkaloids and the mixture heated with stirring on a steambath for 10 min. Sulfuric acid (50% v/v) was added at 20°C to pH ca. 1, the mixture was centrifuged, the precipitate washed with water (3 × 1 mL), and the combined supernate and washings were applied to an ion exchange column (Dowex 2-X8, $OH^-$-form, 5 mL). The eluate was acidified with dilute hydrochloric acid and the solution was evaporated to dryness *in vacuo*. The residue was a mixture (17 mg) of retronecine hydrochloride and retronecine *N*-oxide (1:5, as determined by $^{13}$C nmr, see Table 4).

This mixture was dissolved in hydrochloric acid (1 mL, 1 *M*) and stirred with an excess of Zn dust for 1 h. The mixture was centrifuged, the precipitate washed with water (2 × 1 mL), and the combined supernatant solutions applied to an ion exchange column (Dowex 50W-X4, $H^+$-form, 3 mL). The column was washed with degassed water until the eluate was neutral, then with oxygen-free ammonium hydroxide (3 *M*). The basic eluate (ca. 10 mL) was collected under nitrogen and evaporated to dryness *in vacuo*. The residue was immediately acidified with hydrochloric acid (2 mL, 0.1 *M*) and evaporated to dryness *in*

[11] The radioactivity of the putrescine dihydrochloride which was administered to the plants was determined after recrystallization to constant activity. Specific activity 5.2 × $10^7$ dpm/mmol; total activity administered: 5.2 × $10^7$ dpm/mmol × 2.9 mmol = 1.5 × $10^8$ dpm = 68 μCi.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

*vacuo* to yield retronecine hydrochloride (13 mg, 0.068 mmol). The $^{13}C$ nmr spectrum (see Table 4) showed no signals other than those of retronecine hydrochloride. The specific radioactivity of this material ($3.4 (\pm 0.1) \times 10^6$ dpm per mmol) did not change with repeated recrystallizations from ethanol/acetone, indicating that the sample was radiochemically pure.

*Experiment 7*

The two crude alkaloid fractions (*vide supra*) were separately applied to a Merck silica gel prepacked column (size B) and eluted with $CHCl_3$/MeOH/concentrated $NH_4OH$ (90:9:1) with continuous monitoring of the effluent at 254 nm. The fraction from 35–55 min (flow rate 2.7 mL/min) containing senecionine and seneciphylline (1:1) was collected and evaporated to dryness *in vacuo*. Yield 168 mg (from "free" alkaloids) and 87 mg (from alkaloid *N*-oxides). The two samples were combined and recrystallized from methanol to yield a mixture (177 mg) of senecionine (0.25 mmol) and seneciphylline (0.28 mmol). A 13.8 MHz $^2H$ nmr spectrum ($CHCl_3$, 42 000 scans, pulse width 35 μs, acquisition time 2.0 s) of a saturated solution (ca. 75 mg/mL) showed a line due to the natural abundance of $^2H$ in the chloroform used as solvent. Work-up was discontinued.

*Experiments 1–4, 6, 8*

The two crude alkaloid fractions (*vide supra*) were worked up separately. A typical experiment will be described. To a crude alkaloid fraction was added crude retrorsine (200 mg, 0.57 mmol), water (4 mL), and barium hydroxide octahydrate (650 mg, 2.06 mmol) and the mixture was heated on a steambath with stirring for 10 min. Sulfuric acid (50%, v/v) was added till the pH was ca. 1, and barium sulfate was removed by centrifugation. The supernate was extracted with ether continuously for 24 h. The aqueous phase was applied to an ion exchange column (Dowex 2-X8, $OH^-$-form, 10 mL) and eluted with water. The basic eluate was collected and evaporated to dryness *in vacuo*. The residue was chromatographed on a Silica Gel column (Baker, 60–200 mesh, 50 × 0.7 cm) with $CHCl_3$/MeOH/concentrated $NH_4OH$ (74:24:2) with continuous monitoring of the effluent at 254 nm.[12] The fraction containing retronecine was collected and evaporated to dryness *in vacuo* to yield crude retronecine (103 mg, 0.66 mmol). Addition of excess dilute hydrochloric acid, evaporation to dryness *in vacuo*, and repeated recrystallization from ethanol/acetone yielded retronecine hydrochloride (50 mg, 0.26 mmol). Nonradioactive retronecine hydrochloride (52 mg, 0.27 mmol) was added, the mixture applied to an ion exchange column (Dowex 2-X8, $OH^-$-form, 10 mL), and eluted with water. The basic eluate was evaporated to dryness *in vacuo*. Recrystallization from acetone yielded retronecine (63 mg, 0.41 mmol), mp 119–120°C (lit. (6) mp 119–120°C).

Retronecine (60 mg, 0.39 mmol) was dissolved in excess dilute hydrochloric acid, the solution was evaporated to dryness *in vacuo*, and the residue recrystallized from ethanol/acetone to yield retronecine hydrochloride (68 mg, 0.35 mmol), mp 163–164°C (lit. (16) mp 164°C).

*Degradation of retronecine hydrochloride (Experiments 1–4, 6)*

*Carbon-9 as formaldehyde*

A solution of retronecine hydrochloride (63 mg, 0.33 mmol), osmium tetroxide (4 mg, 0.01 mmol), and sodium metaperiodate (223 mg, 1.04 mmol) in water (2.5 mL) was allowed to stand 2 h at 25°C. Part of this solution (0.15 mL) was added to a solution of 5,5-dimethylcyclohexane-1,3-dione (28 mg, 0.20 mmol) and sodium bicarbonate (8 mg, 0.10 mmol) in water (7 mL). After 2 h at 25°C the precipitate was isolated, washed with water (2 × 2 mL), and recrystallized from ethanol/water to yield formaldehyde dimethone: 4 mg (0.014 mmol, 71%), mp 190–191°C (lit. 43*b*) mp 189°C).

*Carbon-1 and carbons 5–8 as* L-cis-*3-hydroxyproline*

The remaining part of the oxidation mixture (2.35 mL, *vide supra*) was applied to an ion exchange column (Dowex 50W (50-4X200), $H^+$-form, 3 mL). The column was washed with water until the eluate was neutral, and was then eluted with aqueous pyridine (1 *M*). The basic eluate (ca. 15 mL) was concentrated *in vacuo* to 1.0 mL. After addition of manganese dioxide (300 mg, 3.45 mmol) the mixture was stirred with a magnetic bar in a stoppered flask 24 h (or more, if necessary) at 25°C. The course of the reaction was followed by tlc (silica gel, 1-BuOH/AcOH/$H_2O$; 2:1:1), *N*-(2′-oxoethyl)-L-*cis*-3-hydroxyproline, $R_f$ 0.5 (visualized with iodine vapor) and L-*cis*-3-hydroxyproline, $R_f$ 0.3 (visualized with iodine vapor (weak reaction) and ninhydrin (yellow)). The reaction mixture was centrifuged and the supernate applied to an ion exchange column (Dowex 50W (50-4X200), $H^+$-form, 3 mL). The column was washed with water and then eluted with aqueous pyridine (1 *M*). The basic eluate (ca. 15 mL) was evaporated to dryness *in vacuo*, to yield crude L-*cis*-3-hydroxyproline (26 mg, 0.20 mmol, 64%). Recrystallization from water/ethanol yielded 14 mg (0.114 mmol, 34%).

$[\alpha]_D^{25}$ −96° ± 1° (*c* 1.0, $H_2O$) (lit. (45) $[\alpha]_D^{25}$ −102.7° ± 1.5° (*c* 1.0, $H_2O$)); $^1H$ nmr ($D_2O$): δ and *J* values identical with those given for DL-*cis*-3-hydroxyproline (46).

*Carbon-8 as formic acid*

L-*cis*-3-Hydroxyproline (8 mg, 0.061 mmol) and sodium metaperiodate (31 mg, 0.145 mmol) were dissolved in water (0.7 mL). The solution was kept 2 h at 25°C, sulfuric acid (1.1 mL, 0.1 *M*) was then added, and the reaction mixture was solidified by immersing the reaction flask into liquid nitrogen. The frozen mixture, now kept at room temperature, was then submitted to sublimation (0.1 Torr) and the sublimate collected in a flask cooled in liquid nitrogen. The sublimate was allowed to warm to room temperature and the resulting solution was basified to pH 8 with dilute sodium hydroxide (0.1 *M*) and concentrated *in vacuo* to 1.0 mL. 1-Naphthylamine hydrochloride (14 mg, 0.078 mmol) and *N*-ethyl-*N*′-3′-(dimethylamino)propylcarbodiimide hydrochloride (40 mg, 0.21 mmol) was added and the mixture was stirred 15 min. Hydrochloric acid (1 mL, 1 *M*) was added and the mixture was extracted with ether (3 × 1 mL). The ether extracts were evaporated to dryness and the product, *N*-formyl-1-naphthylamine, recrystallized from benzene/hexane: 8 mg (0.047 mmol, 77%), mp 139°C (lit. (47) mp 141–142°C).

*Carbons 5–7 as* β-*alanine*

L-*cis*-3-Hydroxyproline (16 mg, 0.122 mmol) and sodium metaperiodate (107 mg, 0.50 mmol) were dissolved in water (0.75 mL) and allowed to stand at 25°C for 1 h. Potassium permanganate (1.0 mg, 0.006 mmol) was added and the temperature kept at 75°C for 20 min. The reaction mixture was cooled to 25°C, the pH was adjusted to ca. 8 with sodium bicarbonate, and *N*-carbethoxyphthalimide (36 mg, 0.16 mmol) was then added. The mixture was stirred for 10–15 min and then extracted with chloroform (2 × 2 mL). The aqueous phase was acidified with hydrochloric acid (0.5 mL, 1 *M*) and extracted with chloroform (2 × 2 mL). The chloroform extract was evaporated to dryness *in vacuo* and the residue recrystallized from water. Yield of *N*-phthaloyl-β-alanine: 4 mg (0.018 mmol, 15%), mp 151–152°C (lit. (48) mp 152°C).

*Determination of radioactivity*

Radioactivity was assayed by liquid scintillation counting (Beckman LS 9000 Liquid Scintillation System). All samples counted were recrystallized to constant specific radioactivity,

[12]It is of the utmost importance to collect the *whole* fraction containing retronecine to avoid partial separation of $^3H$-containing from $^{14}C$-containing retronecine molecules. Differences in distribution of label within the two samples of retronecine in experiment 6*A* and 6*O* were due to isotope fractionation in the course of chromatographic purification (see Discussion).

dissolved in Aquasol (New England Nuclear), and counted in triplicate, if possible, under comparable conditions of quenching. Confidence limits shown in the tables are standard deviation from the mean.

## Acknowledgments

We thank Dr. D. H. G. Crout, University of Exeter, for a generous sample of retrorsine. This investigation was supported by a grant from the Natural Sciences and Engineering Research Council of Canada. One of us (I.D.S.) thanks the Scientific Affairs Division of the North Atlantic Treaty Organization for the award of a Senior Fellowship.

# Regiospecific addition of benzeneselenenyl halide to 1,1-disubstituted olefins[1]

PAK-TSUN HO[2] AND RALPH J. KOLT

*Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received August 24, 1981

PAK-TSUN HO and RALPH J. KOLT. Can. J. Chem. **60**, 663 (1982).

The reaction of benzeneselenenyl halide with a variety of 1,1-disubstituted olefins under controlled conditions yields regiospecifically the anti-Markovnikov adducts which have been converted into the synthetically useful vinyl halides and allyl halides.

PAK-TSUN HO et RALPH J. KOLT. Can. J. Chem. **60**, 663 (1982).

L'halogènure de benzenesélényle réagit avec différentes oléfines disubstituées en position 1,1 dans des conditions controlées pour conduire de manière régiospécifique à des adduits du type anti-Markonikov. On transforme ces derniers en halogènure vinyliques et allyliques qui sont très utiles en synthèse.

[Traduit par le journal]

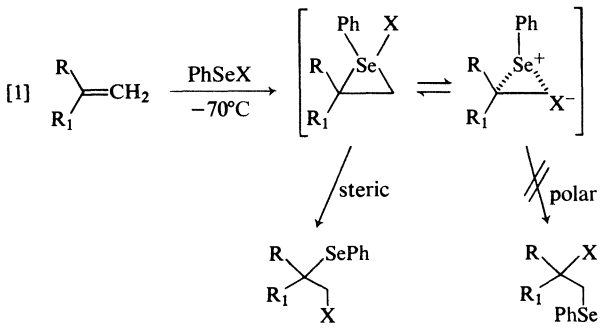
For personal use only.

Organolselenium compounds have become increasingly important reagents for organic synthesis, because selenides can be converted into olefins in high yield under relatively mild conditions. The reaction of areneselenenyl halides with carbon–carbon double bonds which provide an easy route to selenides has received considerable attention (1). This reaction is observed to be a clean anti-stereospecific addition, but is characterized by low regiospecificity (1*a*, 2). Most studies of the addition have mainly been concerned with simple olefinic hydrocarbons. It has been observed that the reaction of some 1,1-disubstituted alkenes with benzeneselenenyl halide yielded the Markovnikov adducts (3, 4). Recently, it has also been shown that addition of benzeneselenenyl halide to simple monosubstituted terminal olefins produced the unstable anti-Markovnikov adducts with high regioselectivity (5). It seems that the nature of the products obtained from the reaction of olefins with benzeneselenenyl halide is sensitive to the substituted pattern of alkenes. We are interested in the reaction between benzeneselenenyl halide and alkenes that arose from the need of substituted allylic halide for our synthetic effort. We report herein our findings with experimental detail along the lines.

Addition of benzeneselenenyl halide to 1,1-disubstituted alkenes under controlled conditions gives the anti-Markovnikov adducts and is highly regiospecific. When a solution of benzeneselenenyl chloride (1 equiv) in dichloromethane was added dropwise to a stirring solution of methylenecyclohexane **1** in dichloromethane at −70°C under argon, a single adduct was obtained quantitatively. The $^1$H nmr spectrum of the product showed a singlet at 3.76 ppm for two protons deshielded by a chlorine atom and indicated that only the anti-Markovnikov adduct was formed within the experimental limit of our $^1$H nmr analysis. The adduct could survive at −16°C and isomerized slowly at room temperature to its isomer. A new signal at 3.43 ppm (singlet, 2 H, —$CH_2$SePh) appeared in its $^1$H nmr spectrum, which suggested the anti-Markovnikov product had rearranged to the Markovnikov regioisomer. The reaction of methylenecyclopentane **2**, methylenecyclobutane **3**, 2-methyl-3-propenyl benzoate **4**, 3-chloro-2-methyl propene **5**, and the optically active olefinic lactone **6** with benzeneselenenyl chloride under the same conditions all yielded the anti-Markovnikov adducts (Table 1). This observation is similar to the results reported by Raucher (5).



It is of note that under the reaction conditions as described above, the effect of solvent for the reaction is not observed. Thus, the addition of benzeneselenenyl chloride to a solution of olefins in polar solvent such as acetonitrile at −45°C yielded the same anti-Markovnikov adduct as dichloromethane was used as solvent for the reaction. Further, it is worth noting that the introduction of

[a]For $^1$H nmr analysis, all reactions were carried out in an nmr tube using deuterated solvents.
[b]Pure products were obtained either by tlc or by glc.

functional groups to the 1,1-disubstituted olefins results in a remarkable increase of the stability of the anti-Markovnikov adduct. A crystalline adduct **12** could be prepared from the olefinic lactone **6** at room temperature and was stored at 0°C for several days without significant isomerization.

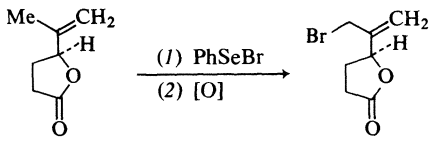
The result clearly indicates that temperature is the key factor in determining the product with anti-Markovnikov orientation. The addition of benzeneselenenyl halide to olefin presumably involves the formation of a bridged selenurane intermediate (reaction [1]). Which of the two carbon atoms in the intermediate will be attacked by the nucleophilic halide will probably depend on the polar and steric factors. The quantitative formation of anti-Markovnikov product under the reaction conditions strongly suggests that at low temperature the steric factor is preferred and leads to regiospecific formation of the product. Moreover, the use of a polar solvent such as acetonitrile for the reaction does not affect the product composition further supports our view that the reaction carried out at low temperature is not determined by polar factors.

For further characterization, the anti-Markovnikov adduct was converted into the allyl chlorides and vinyl chlorides by simple oxidative elimination process. Typically, the adduct obtained by the reaction of olefines with benzeneselenenyl chloride at −70°C was not isolated and subsequent oxidation elimination with *m*-chloroperbenzoic acid in the presence of pyridine was carried out in the same pot at −70°C. The products were isolated by distillation. The results are summarized in Table 1.

The regiospecificity of the reaction of olefins with benzeneselenenyl chloride described above will provide a simple method for the preparation of substituted allyl chlorides from 1,1-disubstituted alkenes, although the selectivity in the elimination of PhSeOH is rather low. However, it is expected

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

that this weakness could be improved by using benzeneselenenyl bromide instead of chloride for the reaction. The reaction of benzeneselenenyl bromide with the optically active olefinic lactone **6** under the same conditions gave 80% yield of the allyl bromide **24** contaminated about 15% of the vinyl bromide.



**6** **24**

## Experimental

Melting points were determined on a Reichert hot stage apparatus and are uncorrected. Optical rotations were measured with a Perkin-Elmer Model 141 automatic polarimeter at room temperature. Infrared spectra were of chloroform solution and $^1$H nmr spectra were of deuteriodichloromethane with TMS as an internal reference. A Varian Autoprep Model A-700 gas chromatograph was used in the glc experiment. Thin-layer and preparative-layer chromatography was done using silica gel containing a fluorescent indicator ($G_{254}$).

*General procedure for reaction of benzeneselenenyl chloride with olefins*

*(a) Preparation of the adduct*

A solution of benzeneselenenyl chloride (3.1 mmol) in dichloromethane (6 mL) was added dropwise to a stirring solution of olefins (3 mmol) in dichloromethane (10 mL) at −70°C under argon. Stirring was continued until the orange colour disappeared (10 min).

*(b) Oxidative elimination*

The above adduct obtained at −70°C was not isolated, but was subsequently oxidized with *m*-chloroperbenzoic acid (1.1 equiv) in the presence of pyridine (2 equiv) in the same pot at −70°C. The reaction mixture was stirred at −70°C for 2 h and kept at room temperature overnight. The mixture was diluted with dichloromethane. The solution was washed with 5% sodium metabisulfite, 2% hydrochloric acid, 10% sodium carbonate, and water. Evaporation of the solvent gave the crude product which was purified either by bulb-to-bulb distillation or by chromatography on silica gel.

*Reaction of methylenecyclohexane **1** with PhSeCl*

(*a*) $^1$H nmr of the adduct **7** ($CD_2Cl_2$): δ 1.65 (m, 10 H), 3.76 (s, 2H, —$CH_2Cl$), and 7.32 ppm (m, 5 H aromatic). The adduct **7**, which was left at room temperature overnight, isomerized completely to its Markovnikov isomer. $^1$H nmr ($CD_2Cl_2$): δ 1.73 (m, 10 H), 3.38 (s, 2 H, —$CH_2SePh$), 7.42 ppm (m, 5 H, aromatic).

(*b*) The elimination product from **7** was obtained by distillation (bp 40–45°C at 80 Torr) in 74% yield as a mixture, which was separated by glc to give 96% of compound **13** and 4% of compound **14**. $^1$H nmr of compound **13** ($CDCl_3$): δ 2.21 (m, 4 H, allylic protons), and 5.74 ppm (broad s, 1 H, olefinic proton). *Anal.* calcd. for $C_7H_{14}Cl$: C 64.37, H 8.49, Cl 27.14; found: C 64.47, H 8.57, Cl 27.13. $^1$H nmr of compound **14** ($CDCl_3$): δ 3.95 (s, 2 H, —$CH_2Cl$), and 5.84 ppm (broad s, 1 H, olefinic proton). *Anal.* calcd. for $C_7H_{14}Cl$: C 64.37, H 8.49, Cl 27.14; found: C 64.42, H 8.57, Cl 27.19.

*Reaction of methylenecyclopentane **2** with PhSeCl*

(*a*) $^1$H nmr of the adduct **8** ($CD_2Cl_2$): δ 1.68 (m, 8 H), 3.82 (s, 2 H, —$CH_2Cl$), and 7.38 ppm (m, 5 H, aromatic).

(*b*) The elimination product **15** was obtained in 50% yield. Compound **15** was identical with the sample prepared from known procedure (6). $^1$H nmr ($CDCl_3$): δ 2.62–1.67 (m, 6 H), 4.17 (s, 2 H, —$CH_2Cl$), and 5.76 ppm (broad s, 1 H, olefinic proton).

*Reaction of methylenecyclobutane **3** with PhSeCl*

(*a*) $^1$H nmr of the adduct **9** ($CD_2Cl_2$): δ 2.41 (m, 6 H), 3.79 (s, 2 H, —$CH_2Cl$), and 7.31 ppm (m, 5 H, aromatic).

(*b*) The elimination product from **9** was obtained by distillation (bp 70°C at 120 Torr) in 57% yield based on the 80% commercial material as a mixture, which was separated by glc on a 20% Carbowax column at 100°C to give 65% of compound **16** and 35% of compound **17**. Their $^1$H nmr spectra were identical with the authentic samples respectively (7). $^1$H nmr of compound **16** ($CDCl_3$): δ 2.45 (m, 4H), 4.03 (s, 2 H, —$CH_2Cl$), and 5.95 ppm (broad s, 1 H, olefinic proton). $^1$H nmr of compound **17** ($CDCl_3$): δ 2.03 (q, 2 H), 2.64 (m, 4 H, allylic protons), and 5.69 ppm (5, 1 H, olefinic proton).

*Reaction of 2-methyl-3-propenyl benzoate **4** with PhSeCl*

(*a*) $^1$H nmr of the adduct **10** ($CD_2Cl_2$): δ 1.42 (s, 3 H, $CH_3$), 3.88 (q, 2 H, —$CH_2Cl$), and 4.46 ppm (s, 2 H, Ph—C(=O)—O—$CH_2$).

(*b*) The elimination product from **10** was obtained by distillation (bp 46–50°C at 5 × $10^{-2}$ Torr) in 80% yield as a mixture, which was separated by chromatography on silica gel to give 87% of compound **18** and 13% of compound **19**. For compound **18**: ir ($CHCl_3$): 1720 $cm^{-1}$ (benzoate); $^1$H nmr ($CDCl_3$): δ 4.15 (s, 2 H, —$CH_2Cl$), 4.93 (s, 2 H, Ph—C(=O)—O—$CH_2$—), and 5.38 ppm (m, 2 H, >C=$CH_2$); *Anal.* calcd. for $C_{11}H_{11}O_2Cl$: C 62.72, H 5.22, Cl 16.82; found: C 62.83, H 5.11, Cl 16.77.

*Reaction of 3-chloro-2-methyl propene **5** with PhSeCl*

(*a*) $^1$H nmr of the adduct **11** ($CD_2Cl_2$): δ 1.41 (s, 3 H, —$CH_3$), 3.78 (q, 2 H, —$CH_2Cl$), 3.92 (q, 2 H, —$CH_2Cl$), and 7.32 ppm (m, 5 H, aromatic).

(*b*) The elimination product from **11** was obtained by distillation (bp 45–50°C at 75 Torr) in 56% yield as a mixture, which was separated by glc on a 20% OS-136 column at 110°C to yield 76% of compound **20** and 24% of compound **21**. Their spectra were identical with the literature reported respectively (8). $^1$H nmr of **20** ($CDCl_3$): δ 4.19 (s, 4 H, —$CH_2Cl$), and 5.32 ppm (s, 2 H, >C=$CH_2$). $^1$H nmr of **21** ($CDCl_3$): δ 1.89 (s, 3 H, methyl), 4.21 (s, 2 H, —$CH_2Cl$), and 5.98 ppm (broad s, 1 H, olefinic proton).

*Preparation of the olefinic lactone **6***

(*a*) A solution of the lactonic acid chloride (24.9 g, 0.163 mol) in tetrahydrofuran (75 mL), prepared from L-glutamic acid (9), was added over 20 min to a solution (−10°C) of dimethyl cadmium, prepared from the reaction of methylmagnesium bromide (0.216 mol) with anhydrous cadmium chloride (20.8 g, 0.113 mol) in tetrahydrofuran (250 mL) under argon. The reaction mixture was stirred at −10°C for an additional 8 h, at which time 4 *N* aqueous sulfuric acid (50 mL) was added slowly and the mixture was stirred for 30 min. It was extracted with dichloromethane (3 × 200 mL). The extracts were washed with 5% sodium carbonate and water, and dried over anhydrous magnesium sulfate. Removal of the solvent gave the methyl ketone lactone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

(14.5 g, 70% yield), which was pure enough for further reaction $[\alpha]_D$ −11.9° (c 1.0, $CHCl_3$); ir ($CHCl_3$): 1725 (ketone) and 1785 cm$^{-1}$ (lactone); $^1$H nmr ($CDCl_3$): δ 2.25 (s, 3 H, —C(=O)—$CH_3$), and 4.90 ppm (m, 1 H, —C(=O)—O—CH(—O—C(=O)—)—).

(*b*) A solution of the methyl ketone lactone (2.56 g, 20 mmol) in tetrahydrofuran (10 mL) was added over 15 min to a Wittig reagent, prepared by the reaction of methyltriphenylphosphorium bromide (7.6 g, 21 mmol) in tetrahydrofuran (30 mL) with *n*-butyl lithium (20 mmol) at −78°C under argon. The reaction mixture was stirred at room temperature for 2 days, after which time the mixture was diluted with ether (200 mL), and the solid was filtered. Evaporation of the solvent gave a residue which was chromatographed on silica gel (100 g) to yield the pure olefinic lactone **6** (1.3 g) in 51% yield. $[\alpha]_D$ +6.3° (c 1.3, chloroform); ir ($CHCl_3$) 1775 cm$^{-1}$ (lactone); $^1$H nmr ($CDCl_3$): δ 1.75 (s, 3 H, $CH_3$), and 4.97 ppm (m, 3 H, $>C{=}CH_2$ and —CH(—O—C(=O)—)—). *Anal.* calcd. for $C_7H_{10}O_2$: C 66.64, H 7.99; found: C 66.56, H 8.01.

*Reaction of olefinic lactone **6** with PhSeCl*

(*a*) The crystalline adduct **12** was a mixture of two diastereoisomers (7:3 based on $^1$H nmr analysis), which was stable at 0°C for several days. $^1$H nmr ($CDCl_3$): δ 1.18 (s, 3 H, $CH_3$), 3.73 (q, 2 H, —$CH_2$Cl), 4.76 ppm (m, 1 H, —CH(—O—C(=O)—)—).

(*b*) The elimination product was a mixture which was separated by preparative tlc on silica gel to give 65% of the allyl chloride **22** and 35% of the vinyl chloride **23**. For compound **22**: $[\alpha]_D$ +9.7° (c 1.8, chloroform); ir ($CHCl_3$): 1778 cm$^{-1}$ (lactone); $^1$H nmr ($CDCl_3$): δ 4.10 (s, 2 H, —$CH_2$Cl), 5.07 (broad t, 1 H, —CH(—O—C(=O)—)—), 5.36 ppm (broad d, 2 H, $>C{=}CH_2$). *Anal.* calcd. for $C_7H_9ClO_2$: C 52.35, H 5.65, Cl 22.08; found: C 52.29, H 5.79, Cl 22.23.

*Reaction of olefinic lactone **6** with PhSeBr*

The product, prepared under the same conditions as described in the general procedure, was obtained in 80% yield as a mixture, which could be purified by chromatography on silica gel using benzene and ethyl acetate (10:1) as the solvent. $^1$H nmr of the allyl bromide **24** ($CDCl_3$): δ 4.01 (s, 2 H, —$CH_2$Br), and 5.39 ppm (broad d, 2H, $>C{=}CH_2$); ir ($CHCl_3$): 1778 cm$^{-1}$ (lactone); $[\alpha]_D$ +8.6° (c 1.7, methanol).

# Lanthanide complexes of potentially heptadentate Schiff base ligands

ELMER C. ALYEA, ABDUL MALEK,[1] AND ANGELOS E. VOUGIOUKAS

*Guelph-Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, University of Guelph, Guelph, Ont., Canada N1G 2W1*

Received July 6, 1981

ELMER C. ALYEA, ABDUL MALEK, and ANGELOS E. VOUGIOUKAS. Can. J. Chem. **60**, 667 (1982).

The potentially heptadentate trianionic Schiff base ligands derived from tris(2-aminoethyl)amine and 3 mol of (substituted) salicylaldehyde react with lanthanide metal nitrates to form neutral 1:1 compounds of formula Ln(X-Saltren). Physicochemical measurements are described for the following complexes: Ln = La, Pr, Nd, Eu, Gd, Dy, Ho, Yb, X= 3,5-$Cl_2$; Ln = La, X = 5-Cl and 5-$NO_2$; and the analogous complexes, M = Sc, Y, Co, X = 3,5-$Cl_2$. Discussion of the spectroscopic data focuses on far infrared ν(Ln—O) and ν(Ln—N) bands, $^1$H nmr pseudocontact shifts and hypersensitive *f–f* transitions.

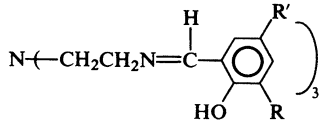
ELMER C. ALYEA, ABDUL MALEK, and ANGELOS E. VOUGIOUKAS. Can. J. Chem. **60**, 667 (1982).

Les ligands du type base de Schiff potentiellement heptadentates et trianioniques provenant de la réaction de la tris(amino-2 éthyl) amine avec trois moles de salicylaldehyde (substitué) réagissent avec les nitrates des métaux de la série des lanthanides en formant des composés neutres 1:1 de formule Ln(X-Saltren). On a effectué les mesures physicochimiques sur les complexes suivants: Ln = La, Pr, Nd, Eu, Gd, Dy, Ho, Yb, X = $Cl_2$-3,5; Ln = La, X = Cl-5 et $NO_2$-5 ainsi que sur des complexes analogues, M = Sc, Y, Co, X = $Cl_2$-3,5. La discussion des données spectroscopiques porte sur les bandes ν(Ln—O) et ν(Ln—N) dans l'infrarouge lointain, sur la rmn du $^1$H des réactifs de pseudo déplacement et sur les transitions hypersensibles *f—f*.

[Traduit par le journal]

## Introduction

Studies of metal complexes involving ligands having seven potential donor atoms are relatively rare (1). The number of Schiff base complexes of the lanthanide elements is similarly limited to a few reports (2). In the present work, we accordingly explore the ligating properties of potentially heptadentate Schiff base ligands (**I**) with several trivalent lanthanide metals.

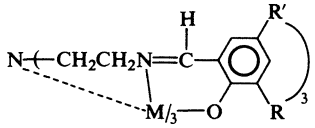


R = H, R′ = H $H_3$Saltren (**I***a*)
R = H, R′ = $NO_2$ $H_3$5-$NO_2$Saltren (**I***b*)
R = H, R′ = Cl $H_3$5-ClSaltren (**I***c*)
R = Cl, R′ = Cl $H_3$3,5-$Cl_2$Saltren (**I***d*)

Earlier work in our laboratory (3) described the synthesis of these trianionic ligands derived from tris(2-aminoethyl)amine(tren) and 3 mol of (substituted) salicylaldehydes and the characterization of M(3,5-$Cl_2$Saltren) (M = Cr, Fe, La), where $H_3$3,5-$Cl_2$Saltren represents tris(3,5-dichlorosalicylidene-2-iminoethyl)amine (**I***d*). The present trivalent metal complexes, prepared according to [1]

[1] $M(NO_3)_3 + H_3X$—Saltren + 3NaOAc → M(X—Saltren) + $3NaNO_3$ + 3HOAc

are expected to have structures represented by the following:



## Experimental

*Chemicals*

Tris(2-aminoethyl)amine was purchased from Ames Laboratories, Inc., salicylaldehyde was a J. T. Baker product, and the substituted salicyladehydes were obtained from the Eastman Kodak Co. The hydrated lanthanide metal nitrates were obtained from Alfa Inorganics Inc. These chemicals and all solvents were used without further purification.

*Physical measurements*

Elemental analyses were performed by Guelph Chemical Laboratories, Inc., Guelph. Infrared spectra were recorded for Nujol mulls between KBr plates (4000–400 $cm^{-1}$ region) and polythene plates (500–100 $cm^{-1}$ region) using Beckman Acculab-6 and Perkin-Elmer 180 spectrophotometers, respectively. A Cary 14 spectrophotometer was used to obtain the electronic spectral data, either as mulls on filter paper or in dimethylsulfoxide using 10 cm cells and ca. $10^{-2}$ *M* solutions. Proton nmr spectra were obtained by Dr. A. Woon-Fat on a Bruker WH-60 FT instrument using dimethylsulfoxide-$d_6$ solutions with TMS as internal standard. Conductivity measurements were made on dimethylsulfoxide solutions with a Beckman Model RC-18A conductance bridge and a cell with platinized electrodes and a cell constant of 0.20.

*Preparation of the complexes*

A solution of the Schiff base ligands (1.0 mmol), hydrated metal nitrate (1.0 mmol), and sodium acetate (1.0 mmol) in absolute ethanol/2,2-dimethoxypropane was stirred and refluxed overnight. The precipitated product was collected by

filtration, washed with absolute ethanol, then dried over $P_4O_{10}$ for 3 h *in vacuo* at 100°C. The analytical data for the new complexes are given in Table 1. The complexes do not melt, but char at temperatures above 290°C.

## Results and Discussion

A series of lanthanide metal complexes of the potentially heptadentate trianionic Schiff base ligands (**I***d*) has been prepared as an extension of our earlier work (3) on M(3,5-$Cl_2$Saltren) (M = Cr, Fe, La). For comparative purposes, other metal complexes of **I***d*, namely for M = Sc, Y and Co, as well as lanthanum complexes of **I***b* and **I***c* were also synthesized. The instability of ligand **I***a* toward hydrolysis prevented isolation of the analogous lanthanide metal complexes. We had noted earlier that related Schiff base ligands obtained by the condensation of tren with β-diketones are even more susceptible to hydrolysis of the azomethine linkages; however, the *in situ* isolation of lanthanide shift reagents of this type was reported (4) during the present investigation. Other workers have also recently described the preparation and properties of several first-row metal (**III**) complexes of ligands **I***a* and **I***c*; in particular, X-ray analysis has established essentially octahedral [$M(N_3O_3)$] geometries for M(5-ClSaltren) (M = Cr, Mn, and Fe) (5). The present work focuses on the spectroscopic characterization of the lanthanide complexes Ln(3,5-$Cl_2$Saltren) (Ln = La, Pr, Nd, Eu, Gd, Dy, Ho, Yb) with some comparative data being provided for the complexes M(3,5-$Cl_2$Saltren) (M = Cr, Fe, Co, Sc, and Y).

The new complexes have low solubilities in common organic solvents, necessitating the use of dimethylsulfoxide for solution measurements. Such solutions are non-conducting, with molar conductance values of less than 1 mho $cm^2$, confirming the neutral formulation of the complexes. The mass spectrum of La(3,5-$Cl_2$Saltren) showed the parent ion corresponding to the monomer but attempts to obtain the mass spectra of the other lanthanide metal complexes proved unsatisfactory. In spite of the attempts to dehydrate the complexes by using 2,2-dimethoxypropane as a reagent and by drying the products *in vacuo*, the presence of lattice water was indicated in a few cases by elemental analysis (Table 1) and broad infrared bands at ca. 3400 $cm^{-1}$. The existence of lattice water was verified by other workers (5) in the X-ray analyses of M(5-ClSaltren)·$3H_2O$ (Cr, Mn, and Fe).

### *Infrared studies*

The bands near 1600 $cm^{-1}$ associated with the ν(C=N) and ν(C=C) stretching frequencies change in profile in the complexes as compared to those observed for the isolated ligands, with the significant lowering in frequency of the main band also indicating coordination via the azomethine nitrogen atom. The trianionic nature of the ligands in the complexes is shown by the absence of the broad weak hydroxyl bands (3600–2200 $cm^{-1}$) displayed by the free ligands. All of the complexes showed very similar infrared spectra above 500 $cm^{-1}$ and, therefore, far-infrared spectra were recorded (to 100 $cm^{-1}$) in an attempt to assign ν(Ln—O) and ν(Ln—N) vibrational modes. There is a paucity of such assignments in the literature, though it appears that ν(Ln—O) and ν(Ln—N) might be expected in the 500–300 $cm^{-1}$ and 300–200 $cm^{-1}$ regions, respectively (6). Some confirmation of this expectation was obtained by recording the far-infrared spectra of two known lanthanide metal complexes of 8-hydroxyquinoline, whose donor atom environments are similar to those in

[c]Values taken from ref. 10(*a*).

our Schiff base ligand of interest. For Nd(oxin)$_3$ and Eu(oxin)$_3$, prepared according to Aly (7), bands near 485 cm$^{-1}$ and 365 cm$^{-1}$ that do not occur in the spectrum of 8-hydroxyquinoline may be assigned to ν(Ln—O). The band near 200 cm$^{-1}$, of greatly increased intensity as compared to the 191 cm$^{-1}$ band in 8-hydroxyquinoline, may more tentatively be assigned to a ν(Ln—N) mode (8). Such assignments are comparable to those made previously for M(oxin)$_3$ (M = Al, Fe, Co) (9). Similarly, comparison of the far-infrared spectra of the Ln(3,5-$Cl_2$Saltren) complexes with the spectra of the uncoordinated ligand and of lighter metal complexes (Table 2, Fig. 1) allows the tentative assignment of ν(Ln—O) and ν(Ln—N) vibrational modes. Several strong metal-sensitive bands in the 300–450 cm$^{-1}$ region are probably associated with ν(Ln—O) since lanthanide metal isopropoxides and β-diketonates also show strong bands in the same range (6, 10). Of the bands at lower frequency, those near 270 cm$^{-1}$ and 200 cm$^{-1}$ appear to be likely candidates for the ν(Ln—N) modes (6). Although the complexes M(3,5-$Cl_2$Saltren) (M = Sc, Cr, Co, Fe) are undoubtedly six-coordinate (5), the apparent decrease in frequency of the far-infrared bands associated with ν(Ln—O) and ν(Ln—N) nevertheless does not allow a choice in assigning either six- or seven-coordination to these new lanthanide complexes. A comparison of ν(M—O) and ν(M—N) modes between the lighter elements and the lanthanide elements is invalidated by the great difference in covalency expected in the metal complexes.

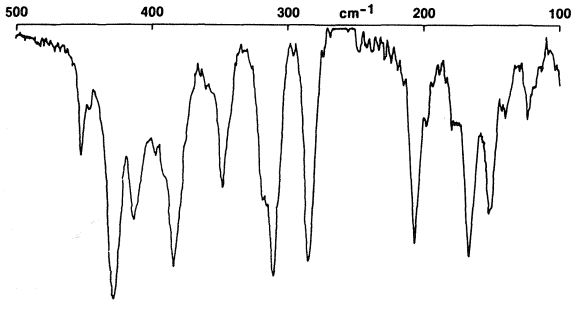

FIG. 1. Far-infrared spectrum of Yb(3,5-$Cl_2$Saltren).

*Electronic transitions*

An intense intraligand transition occurs for all of the M(3,5-$Cl_2$Saltren) complexes at ca. 26 000 cm$^{-1}$, with the slight metal dependence signifying the charge-transfer origin of the band. Solid-state spectra show a prominent shoulder centered near 23 000 cm$^{-1}$ which obscures observations of either *d–d* or *f–f* transitions in this region. Strong bands observed near 18 000 cm$^{-1}$ for the iron(III) complexes of ligands **I** are probably also of charge-transfer (phenol → iron(III)) type (11), but the weaker shoulder near 18 000 cm$^{-1}$ for the chromium(III) complexes of **I** may be the expected (11) $\nu_1$ transition for octahedral chromium(III) complexes since no shoulder to the 26 000 cm$^{-1}$ band is found for the Sc(3,5-$Cl_2$Saltren) and La(3,5-$Cl_2$Saltren) complexes. Similarly, the weak band at 16 400 cm$^{-1}$ observed in the solid state spectrum of Co(3,5-$Cl_2$Saltren) may be attributed to the octahedral transition expected (5, 11) in this region, since X-ray analysis has confirmed this geometry for

| Yb | $^2F_{7/2}$ | $^2F_{5/2}$ | 10 300 | 10 280<br>10 580 |

[a]All complexes have a ligand band at ca. 26 000 $cm^{-1}$ in DMSO, and additionally a shoulder in the 22 700–25 600 $cm^{-1}$ region in the solid state.
[b]Four peaks are observed in this region.
[c]Several peaks are observed, see Fig. 2. The pattern of peaks is distinctly different from those observed for either $Nd(NO_3)_3 \cdot 5H_2O$ or $Nd_2O_3$.
[d]Bands observed by fluorescence spectroscopy, see text.
[e]Assignments are tentative, broad multiplets in ultraviolet region expected.

M(5-ClSaltren)$\cdot 3H_2O$ (M = Cr, Mn, Fe) (5). The absence of a shoulder to the intense 26 000 $cm^{-1}$ ($\varepsilon \approx 2 \times 10^3$ $mol^{-1}$ L $cm^{-1}$) band for dimethylsulfoxide solutions of the Ln(3,5-Saltren) complexes doubtless implies an increase in coordination number upon dissolution, since the complexes are also insoluble in other common organic solvents.

Changes in the intensity and fine structure of certain "hypersensitive" absorption bands in the absorption spectra of trivalent lanthanide complexes have been related to changes in the symmetry of the ligand field around the lanthanide ions (12). Accordingly, the occurrence of such *f–f* transitions was observed in the solid state for the Ln(3,5-$Cl_2$Saltren) complexes to allow a comparison with those bands reported for the aqueous $Ln^{3+}$ ions (Table 3). A qualitative indication of significant covalency in the ligand-to-metal bonds, as compared to the aquo ions, is given by calculations of the nephelauxetic parameter β for the complexes. For example, the red shift of 350 $cm^{-1}$ for the Ho(3,5-$Cl_2$Saltren) complex represents a nephelauxetic effect of 0.98. More quantitative information on the degree of covalency and site symmetry in the complexes via a comparison of oscillator strengths of these hypersensitive bands is precluded by the low solubility of the complexes, even in dimethylsulfoxide.

The coordination number of neodymium has been related to the shape and intensity of the hypersensitive transition, $^4I_{9/2} \rightarrow {}^4G_{5/2}$, $^2G_{7/2}$, which occurs near 17 000 $cm^{-1}$ (12, 13). Thus, $Nd(NO_3)_3 \cdot 5H_2O$, known to be 10-coordinate (14), shows a single solid state visible band at 17 400 $cm^{-1}$. A prominent shoulder at 17 500 $cm^{-1}$ to the more intense 17 300 $cm^{-1}$ band is observed in the visible spectrum of Nd(oxin)$_3$. An assignment of either 6- or 7-coordination is possible for this 8-hydroxyquinoline complex by comparison with the spectral profiles of tri-β-diketonate complexes (and their adducts) studied by Karraker (13). Because of the similarity in donor atom environment between ligands **I** and 8-hydroxyquinoline, the spectrum of Nd(3,5-$Cl_2$Saltren) was expected to be similar. Although the shoulders on the high energy side of the hypersensitive transition centered at 17 000 $cm^{-1}$ (see Fig. 2) signify a low coordination number, the more extensive splitting indicates a lower symmetry site for the $Nd^{3+}$ ion. Whether or not this low symmetry environment results only from the (expected) trigonal field imposed by a pseudooctahedral environment or from the additional asymmetry due to coordination by the apical nitrogen atom cannot be ascertained from the visible spectra. An X-ray analysis of a Ln(3,5-$Cl_2$Saltren) complex has been initiated in order to answer the question of apical nitrogen coordination. The observance of less extensive splitting of the $^4I_{9/2} \rightarrow {}^4G_{5/2}$, $^2G_{7/2}$ transition for Nd(3,5-ClSaltren) in dimethylsulfoxide solution is compatible with an increase in coordination number. It is

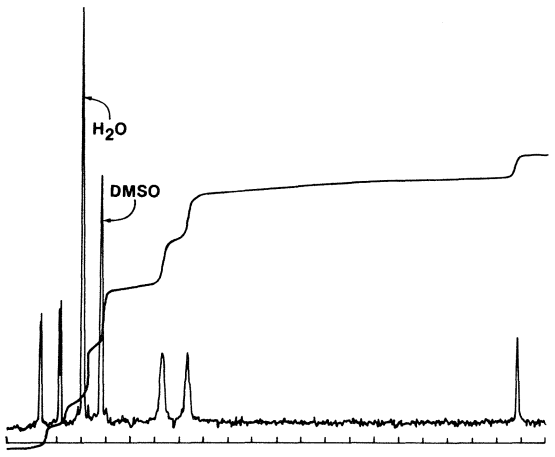

FIG. 3. Proton nmr spectrum of Eu(3,5-$Cl_2$Saltren) in dimethylsulfoxide-$d_6$ solution.

worth noting that an asymmetric tetramethylurea complex of neodymium, $Nd(tmu)_5(F_3CSO_3)_3$, also presumably either 6- or 7-coordinate, shows similar splitting of this hypersensitive band (15).

Hypersensitive transitions in europium complexes are often observed by fluorescence spectroscopy, with information on the local symmetry of the $Eu^{3+}$ ion coming from the number of $^5D_0 \rightarrow {}^7F_J$ transitions. For example, the single $^5D_0 \rightarrow {}^7F_1$ transition observed at 17 000 $cm^{-1}$ is compatible with other evidence for octahedral coordination in $Eu(tmu)_6(CF_3SO_3)_3$ (15). A lower symmetry site for the europium ion in Eu(3,5-$Cl_2$Saltren) is implied by the presence of several peaks in the 16 000–17 800 $cm^{-1}$ region. These peaks are superimposed upon a broad fluorescence band centred at 20 000 $cm^{-1}$ which is also observed for the other Ln(3,5-$Cl_2$Saltren) complexes. Consideration of the possible allowed components for the $^5D_J \rightarrow {}^7F_J$ transitions in the feasible crystal field symmetries (16) does not allow an unambiguous assignment of the coordination number in Eu(3,5-$Cl_2$Saltren).

TABLE 4. $^1$H nmr spectra for (3,5-$Cl_2$Saltren)

[b]Peaks due to undeuterated dimethylsulfoxide occur at 2.52 for the free ligand and in the range 2.52–2.59 for the lanthanide complexes.

### $^1$*H nmr studies*

Proton nuclear magnetic resonance spectra were recorded for the Ln(3,5-$Cl_2$Saltren) complexes in order to characterize the ligating ability of the ligand. As indicated for the diamagnetic lanthanum complex in Table 4, coordination of the azomethine nitrogen atom results in an upfield shift of the azomethine proton, with the magnitude of the shift being comparable to a solvent shift (3). For the paramagnetic praseodymium, neodymium, and europium compounds, well-resolved spectra are observed (Table 4, Fig. 3) which exhibit large pseudocontact shifts (17). As expected from the distance–shift relationship, the azomethine proton undergoes the greatest shift, with a shielding difference of about 42 ppm between the signals for the europium (upfield) and the two other lanthanide complexes (downfield). The well-resolved resonance peaks due to the ethylene and aromatic protons ($^4J$ = 2.9 Hz for the Eu case) indicate a rigid chelated structure with potential, after modification to improve solubility and eliminate proton peaks, for applications as lanthanide shift reagents. Investigations are underway with suitably modified analogous ligands.

# Electrophilic cyclization of polyene allylsilanes. Synthesis of albicanyl acetate

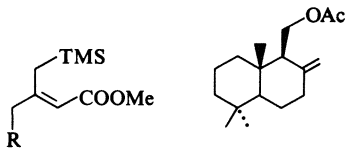
ROSEMARY J. ARMSTRONG, FRANCIS L. HARRIS,[1] AND LARRY WEILER[2]

*Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6*

Received December 28, 1981

ROSEMARY J. ARMSTRONG, FRANCIS L. HARRIS, and LARRY WEILER. Can. J. Chem. **60**, 673 (1982).

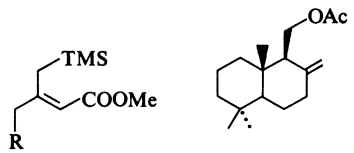
The allylsilanes **5** (*a*, R =  ; *b*, R =  ) were prepared by a nickel(II) catalyzed coupling of trimethylsilylmethylmagnesium chloride with the enol phosphate of the corresponding β-keto esters. Stannic chloride and mercuric trifluoroacetate effected a cyclization of **5**. The product from **5***b* was converted into the marine natural product, albicanyl acetate (**1**).



**5** **1**

ROSEMARY J. ARMSTRONG, FRANCIS L. HARRIS et LARRY WEILER. Can. J. Chem. **60**, 673 (1982).

On a préparé les allylsilanes **5** (*a*, R =  ; *b*, R =  ) grâce à un couplage, catalysé par le nickel(II), du chlorure de triméthylsilylméthylmagnesium avec le phosphate de l'énol des β-cétoesters correspondants. Le chlorure stannique et le trifluoroacétate mercurique ont un effet sur la cyclisation du composé **5**. On a transformé le produit obtenu à partir du composé **5***b* en acétate d'albicanyle (**1**), un produit naturel marin.



**5** **1**

[Traduit par le journal]

Recent studies on the synthesis of allylic silanes and their cyclization (1) prompt us to report our results on the synthesis of carboxylated allylsilanes and their cyclization which has led to a synthesis of the marine sesquiterpene, albicanyl acetate (**1**) (2). In 1975, Fleming and co-workers found that the allylsilane **2** cyclized cleanly to the exocyclic product **3** (eq. [1]) (3). We were intrigued about the possibility of extending this concept to the cyclization of polyolefinic esters and acids.

[1] 

**2** **3**

The esters **5***a* and **5***b* were synthesized from methyl acetoacetate as shown in eq. [2]. The β-keto esters **4** (4) were prepared by the alkylation of the dianion of methyl acetoacetate (5) with γ,γ-dimethylallyl bromide and geranyl bromide respec-

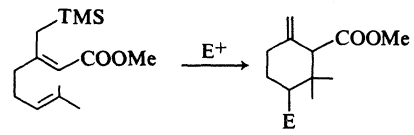
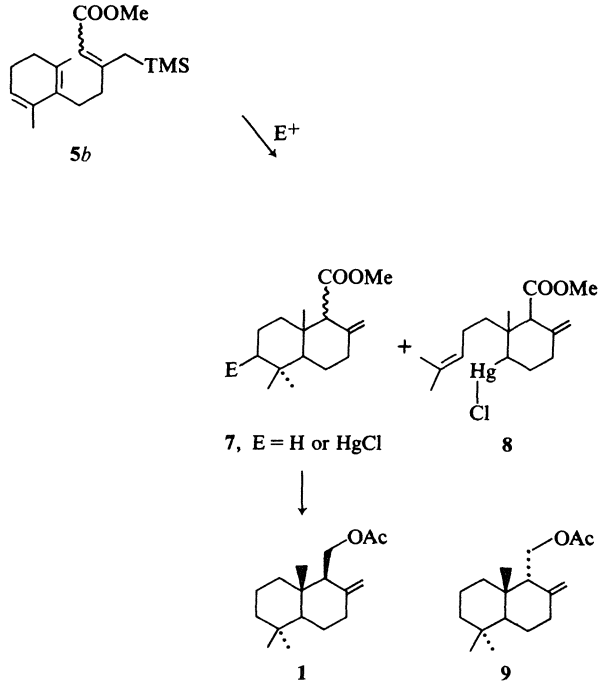
tively. Compounds **4***a* and **4***b* were converted into the *Z*-enol phosphates (6) in 95–100% yield. The enol phosphates were reacted with trimethylsilylmethylmagnesium chloride and nickel(II) bisacetylacetonate catalyst[3] (7) to give mainly the *Z*-allylsilanes **5** in 70–80% yield. The stereoselectivity was estimated from the $^1$H nmr of **5***a* (*E*/*Z* = 1:20) and **5***b* (*E*/*Z* < 1:20). In addition we have prepared the *E*-enol phosphate from β-keto ester **4***b*[4] and coupled it with trimethylsilylmethylmagnesium chloride using $Ni(acac)_2$ catalyst to give **5***b* in 76% yield (*E*/*Z* = 7:3). The stereospecificity in this coupling is very different from that recently reported by Casey *et al.* for β-halo enoate esters (8).

We have studied a variety of electrophilic cyclizations of **5** and at this time note the results with Lewis acids and mercuric trifluoroacetate. Treatment of a $CH_2Cl_2$ solution of ester **5***a* with stannic chloride at 0°C gave the exocyclic alkene **6** (E = H) in ca. 90% yield. A gc analysis of the crude reaction product showed that ratio of exocyclic to endocyclic product was 7:1. Prolonged exposure of the reaction mixture to stannic chloride lead to isomerization of **6** (E = H) to the endocyclic β,γ-unsaturated compound. The ester **5***a* gave the organomercury product **6** (E = HgCl) in 84% yield on cyclization with mercury trifluoroacetate in nitromethane followed by an aqueous brine workup (9).



**5***a* **6**, E = H or HgCl

Cyclization of **5***b* (>95% *Z*) in $CH_2Cl_2$ with stannic chloride at −56°C gave the 9β- and 9α-isomers **7** (E = H) in almost quantitative yield. The ratio of 9β-**7**/9α-**7** as determined by gc was 4:1. The structure of the major isomer was determined by reduction ($LiAlH_4$), chromatographic purification (10), and acetylation ($Ac_2O$, py, DMAP) to give (±)-albicanyl acetate (**1**) in 70% yield. The synthetic albicanyl acetate was identical to a natural sample (2) in spectral and chromatographic comparisons. The mercuric trifluoroacetate cyclization (9) of **5***b* gave a mixture of 9β- and 9α-**7** (E = HgCl) and monocyclic product **8**. The mixture could be purified by flash chromatography (10) to give 55–65% of the bicyclic products **7** (E = HgCl) and ca. 10% of **8**. The bicyclic products were analyzed by reduction ($LiAlH_4$) and acetylation ($Ac_2O$, py, DMAP) to give a mixture of (±)-albicanyl acetate (**1**) and its C-9 epimer **9** in a yield of 65–70% (**1**/**9** = 73:27).



**5***b* **7**, E = H or HgCl **8** **1** **9**

The mixture of **5***b* containing mainly the 2*E* isomer (*E*/*Z* = 7:3) was cyclized with mercuric trifluoroacetate, reduced, and acetylated as above in 85% overall yield. A vpc analysis of the acetates showed that the ratio of **1**/**9** was 18:82. Thus the $Hg^{2+}$ cyclization of the 2*E* and 2*Z* isomers of **5***b* is stereospecific and it would appear that the 9β-ester partially isomerizes to the 9α-ester under the cyclizing conditions or in the hydride reduction.

In summary the allylsilane activates conjugated esters in polyene cyclizations and they can be used to selectively produce exocyclic alkenes in electrophilic cyclizations initiated by protons or mercuric trifluoroacetate.[5]

[3]The coupling of β-phosphoryloxy alkenoate esters with Grignard reagents can be effected with Cu(I) or Ni(II) catalysts (J. P. Barnier, F. L. Harris, and L. Weiler, unpublished results). This extends the utility of our earlier reported alkene synthesis (ref. 6).

[4]The *E*-enol phosphates of β-keto esters can be prepared from the corresponding β-keto esters using triethylamine or 4-dimethylaminopyridine as base and a small amount of HMPA in the solvent system (F. W. Sum, Ph.D. Thesis, University of British Columbia, Vancouver, B.C., 1979 and W. McKay, F. W. Sum, and L. Weiler, unpublished results).

[5]All new compounds were characterized by ir, nmr, mass spectroscopy, and high resolution mass measurement or elemental analysis.

**Acknowledgements**

We are grateful to the Natural Sciences and Engineering Research Council of Canada for financial support, to Professor R. J. Andersen and J. Hellou for spectra and samples of albicanyl acetate, and to Professor E. J. Corey for details on their mercuric trifluoroacetate cyclization (ref. 9). One of us (R.J.A.) is grateful to the Canadian Commonwealth Scholarship and Fellowship Plan for the award of a graduate scholarship.

Ronald B. Kelly, Mary Lou Harley, Sandra J. Alward et Percy S. Manchand. Can. J. Chem. **60**, 675 (1982).

On décrit la synthèse totale du diterpènoïde naturel désoxy-2 stémodinone (**3**) et celle du diterpènoïde ayant la structure **2** ("stémodinol"). Le diterpène synthétique **2** ne correspond pas tout à fait à un échantillon authentique du "stémodinol". On a trouvé que l'échantillon authentique est de la stémarine à laquelle on a attribué par erreur la structure **2** dans la littérature. Il semble donc que le diterpène représenté par la structure **2** n'est pas d'origine naturelle.

[Traduit par le journal]

Recently we described (1) a total synthesis of the structurally unique diterpenoid stemarin (**1**) (2). This synthesis featured photoaddition of allene to an α,β-unsaturated ketone and two subsequent skeletal rearrangements. At the same time (1) we anticipated the completion of syntheses of stemodinol (**2**) (3) and related terpenoids (3, 4) and alphidicolin (5) by a similar strategy.[1] We now wish to describe syntheses of (±)-stemodinol (**2**) and the related diterpenoid (±)-2-desoxystemodinone (**3**) (2) as anticipated.

[1]For syntheses of aphidicolin and the stemodane diterpenoids by entirely different approaches see refs. 6 and 7 respectively.

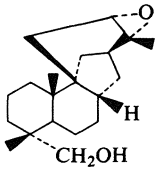
9 R = $COOCH_3$
10 R = $CH_2OH$



11

During our synthesis of stemarin (**1**) (1) we encountered a pair of epimeric keto alcohols, **4** and **5**. The former was chosen for conversion into stemarin on the basis of stereochemical considerations and it was predicted (1), on the same basis, that **5** could readily be converted into stemodinol (**2**). The validity of this prediction has now been demonstrated by the successful conversion of **5** into **2** and **3** as described in the sequel.[2]

The keto alcohol **5** (mp 191°C; spectral properties similar to **4** (1)) was converted, quantitatively, into the thioketal **6** (mp 177–178°C; nmr δ: 3.17 (m, 4H, ethylene of ketal)) which, on treatment with Raney nickel, afforded (97%) the alcohol **7** (mp 130°C; ir: 3500 (OH) and 1705 (ester) $cm^{-1}$; nmr δ: 3.56 (m, 1H, H—C—OH)). The latter was converted into the gummy tosylate **8** (nmr δ: aromatic protons 7.20–7.85) in which the tosylate group was *anti* and periplanar to the bond (a), the required stereoalignment for the desired rearrangement (*vide infra*).

When **8** was heated at 60°C in DMSO in the presence of methyl sulfinyl carbanion (8), it was transformed, by migration of bond (a) and elimination of hydrogen, into the olefin **9** (oil; ir (film): 1730 (ester) and 1650 (olefin) $cm^{-1}$; nmr δ: 1.55 (d, $J$ = 2 Hz, 3H, vinylic methyl and 4.94 (m, H, vinylic proton)), which was reduced quantitatively with $LiAlH_4$ to the olefinic alcohol **10** (oil; ir (film): 3350 (OH) and 1625 (olefin) $cm^{-1}$; nmr δ: 3.07 and 3.38 (doublets, $J$ = 11 Hz, 1H each, $CH_2$—OH)).

Epoxidation of **10** with *m*-chlorobenzoic acid gave the oily epoxide **11** (68%; nmr δ: 1.27 (s, 3H, methyl attached to oxirane ring)). The oxirane ring was assigned the α-configuration on the basis of conversion of **11** into 2-desoxystemodinone (**3**) (2) (*vide infra*). Finally, reduction of **11** with $LiAlH_4$ afforded the racemic diterpenoid **2** (mp 160°C; ir: 3510 and 3350 (OH) $cm^{-1}$; nmr δ: 0.82, 1.00 and 1.11 (singlets, 3H each, tertiary methyls), 3.07 and 3.37 (doublets, $J$ = 11Hz, 1H each, $CH_2$—OH)).

The synthetic diterpenoid (**2**) was clearly *not identical* with a sample of "stemodinol" from natural sources. Eventually, by comparison with authentic stemarin (**1**), it was discovered that the sample of naturally occurrring stemodinol (3) which we received was in fact stemarin (**1**).[3] To the best of our knowledge the diterpenoid having structure **2** ("stemodinol") has not been isolated from natural sources.

We were now faced with the necessity of demonstrating the validity of structure **2** for our synthetic diterpenoid, a task which was complicated by our inability to produce crystals of **2** or its derivatives suitable for X-ray crystallographic analysis. Eventually this task was accomplished in the following manner. The tosylate **12** of **2** was reduced with $LiAlH_4$ and the product (**3**) was shown to be identical (ir, nmr, ms, and silica gel tlc) with an authentic sample of the naturally occurring 2-desoxystemodinone (2), the structure of which has been unequivocally shown to be **3**.[4] The assignment of the $CH_2OH$ group in **2** to the α-orientation follows from the fact that **2** and stemarin have been synthesized from common intermediates (1). Thus, the conversion of **2** to **3** proves that structure **2** is correct for our synthetic diterpenoid and constitutes a total synthesis of 2-desoxystemodinone (**3**).

**Acknowledgments**

We thank the Natural Sciences and Engineering

[2]Throughout, the ir spectra (in Nujol unless specified) and the nmr spectra (in $CDCl_3$) are entirely consistent with assigned structures. Satisfactory elemental analyses were obtained for all crystalline compounds and correct molecular ions were found in the mass spectra of the remaining compounds.

[3]Professor C. D. Hufford, University of Mississippi, University, Mississippi, concurs with the results of our comparison.

# The microwave spectrum, harmonic force field, structure, and dipole moment of propiolyl chloride[1]

R. WELLINGTON DAVIS[2] AND M. C. L. GERRY

*Department of Chemistry, The University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6*

Received October 1, 1981

R. WELLINGTON DAVIS and M. C. L. GERRY. Can. J. Chem. **60**, 679 (1982).

The microwave spectra of four isotopic species of propiolyl chloride, HCCCOCl, have been measured for their ground and $v_9 = 1$ excited vibrational states. Values for the rotational constants, quartic centrifugal distortion constants, chlorine nuclear quadrupole coupling constants, and the molecular dipole moment have been obtained. The centrifugal distortion constants have been combined with vibrational wavenumbers from the literature to calculate an approximate harmonic force field. Effective and ground state average structures of the most abundant isotopic species, $H^{12}C^{12}C^{12}C^{16}O^{35}Cl$, are presented.

R. WELLINGTON DAVIS et M. C. L. GERRY. Can. J. Chem. **60**, 679 (1982).

On a mesuré les spectres micro ondes de quatre espèces isotopiques de chlorure de propiolyle, HCC≡COCl, dans les états vibrationnels fondamental et excité, $v_9 = 1$. On a obtenu les valeurs suivantes: les constantes de rotation, les constantes de distorsion centrifuge quartique, les constantes de couplage quadrupolaire nucléaire du chlore et le moment dipolaire moléculaire. On a combiné les constantes de distorsion centrifuge aux nombres d'ondes vibrationnelles, obtenues dans la littérature, afin de calculer un champ de force hamonique approximatif. On présente la structure moyenne réelle à celle à l'état fondamental de l'espèce isotopique la plus abondante: $H^{12}C^{12}C^{12}C^{16}O^{35}Cl$.

## Introduction

The acid halide derivatives of simple carboxylic acids have been extensively studied using microwave spectroscopy. The molecules include the acid fluorides and acid chlorides of formic acid (1, 2), acetic acid (3, 4), cyclopropanecarboxylic acid (5, 6), and propionic acid (7, 8). A logical and interesting extension is to the corresponding derivatives of propiolic (propynoic) acid, one of the simplest planar carboxylic acids. These molecules are of especial interest as the parent propiolic acid has a very large acid dissociation constant (9, 10) compared to those of aliphatic, olefinic, or aromatic carboxylic acids. At 20°C, for example, the acid dissociation constants of the three-carbon propionic and propiolic acids are $1.35 \times 10^{-5}$ and $1.36 \times 10^{-2}$ respectively. This difference has been attributed to the strong electron-withdrawing properties of the ethynyl group (11) relative to those of other hydrocarbon substituents. As well, the propiolyl halides are the simplest acid halides in which the carbonyl bond is conjugate to a carbon–carbon triple bond. Therefore it would not be surprising if the —COX groups in the propiolyl halides had somewhat different structures from those found for other acid halides.

This paper deals with the microwave spectrum and structure of one such derivative: propiolyl chloride. Several recent reports have dealt with its synthesis and with other spectroscopic investigations. Augdahl *et al.* (12) prepared propiolyl chloride from the parent acid by halogenation with 1,1-dichlorodimethyl ether, recorded the infrared and Raman spectra and assigned all vibrational fundamentals. Balfour, Grieg, and Visaisouk described a synthesis from propiolic acid and phosphorus pentachloride (13). Subsequently Balfour *et al.* analysed the vibrational spectrum of propiolyl chloride-*d* (14) and observed the near ultraviolet spectra of the normal and deuterated species (15). Two rather incomplete normal coordinate analyses have been made for propiolyl chloride. In the first study the mean amplitudes of vibration were reported without details of the corresponding force field (16). A second analysis gave values for the force constants but unfortunately did not use non-redundant symmetry coordinates (17). Finally, a preliminary account of the microwave spectrum has been published (18).

The rotational spectra of a few molecules structurally similar to propiolyl chloride have been investigated. These have included the spectra of propiolic acid (19, 20) and propiolyl fluoride (21), both of which were shown to be planar. The corresponding aldehyde, propynal, was first studied by Howe and Goldstein (22) who assigned a few low $J$ lines of the normal isotopic species and measured the dipole moment. A complete structure for propynal was later determined by Costain and

Morton (23). Their microwave results showed that the carbon chain in propynal has a bend of approximately 1.5°. This result has since been confirmed by a combination of the microwave results with electron diffraction data (24). The deviation from linearity, if any, of the carbon chains of other propiolyl-type molecules is an interesting problem which has not previously received attention.

In the present study of propiolyl chloride four isotopic species have been investigated. Their spectra have been analysed to yield values for the rotational constants, quartic centrifugal distortion constants, and nuclear quadrupole coupling constants. The molecular dipole moment has also been obtained. Using an assumed structure for the ethynyl group the remaining structural parameters have been calculated from the ground state effective moments of inertia. Further, the centrifugal distortion constants have been combined with existing vibrational data to determine an approximate force field. Again, having assumed a structure for the ethynyl group, the average rotational constants have been used to calculate the average structure in the ground vibrational state.

## Experimental methods

The samples of normal propiolyl chloride and propiolyl chloride-*d* were both kindly supplied by Dr. W. J. Balfour. They had been prepared by the reaction of propiolic acid and $PCl_5$ (13). Since propiolyl chloride readily decomposes at room temperature the samples were stored at liquid nitrogen temperature; for manipulations on a vacuum line the storage vessel was held at dry ice temperature.

Transitions were measured in the frequency regions 12.5–18 and 26.5–40 GHz, using a 100 kHz Stark modulated spectrometer with a 10 ft X-band cell. All measurements were made with the Stark cell wrapped in dry ice, with sample pressures of 0.3–3.0 Pa. Under these conditions the sample was quite stable in the cell. Although the infrared and Raman spectra of these samples showed the presence of an $OPCl_3$ impurity (14), this molecule was too involatile in these conditions to be detected in the microwave spectrum.

## Observed spectra and assignments

The spectrum of propiolyl chloride is very rich, and has both *a*- and *b*-type transitions with roughly equal intensities. The transitions show chlorine quadrupole hyperfine structure. The initial assignments were of the $J = 6 \leftarrow 5$ and $7 \leftarrow 6$ *a*-type R branches, which gave preliminary rotational constants. From these constants more accurate predictions were made, and the bootstrap procedure described previously was then used to assign an increasing number of transitions (21). Spectra were assigned for the ground vibrational states of both normal and deuterated isotopic species containing $^{35}Cl$ and $^{37}Cl$. In addition, for all species except $DCCCO^{37}Cl$, transitions were assigned for an excited vibrational state. From relative intensities of the ground and excited state transitions the vibration was deduced to be at $150 \pm 50$ cm$^{-1}$, in good agreement with the measured frequency of the $\nu_9$ fundamental at 157 cm$^{-1}$ (12). In all cases the frequency fit was the chief criterion for the assignments, confirmed by the hyperfine structure.

The entire measured spectra were analysed, first for the nuclear quadrupole coupling constants, and then for the rotational and centrifugal distortion constants, using the methods described in the following section. Some representative observed transitions, along with their assignments and the splittings calculated using the derived quadrupole coupling constants, are given in Table 1. Table 2 contains the frequencies of all the observed rotational transitions with nuclear quadrupole hyperfine structure removed, along with their centrifugal distortion contributions.

## Analysis of the spectra

*1. Nuclear quadrupole coupling*

The chlorine nuclear quadrupole coupling could be accounted for using first-order theory (25). A least-squares fit was made of the observed splittings to the coupling constants $\chi_{aa}$ and $\chi_{bb} - \chi_{cc}$. The results are in Table 3, where account is taken of the fact that

$$\chi_{aa} + \chi_{bb} + \chi_{cc} = 0.$$

*2. Rotational and centrifugal distortion constants*

After the hyperfine structure had been subtracted from each rotational transition using the coupling constants of Table 3, the resulting unsplit line frequencies were then used to calculate the rotational constants and quartic centrifugal distortion constants. The *A* reduction of Watson's Hamiltonian in the $I^r$ representation (26) equation [1] below, was used; no sextic constants were required to fit the data.

$$[1]\quad \mathcal{H} = A\hat{J}_a^2 + B\hat{J}_b^2 + C\hat{J}_c^2 - \Delta_J\hat{J}^4 - \Delta_{JK}\hat{J}^2\hat{J}_a^2 - \Delta_K\hat{J}_a^4 - 2\delta_J\hat{J}^2(\hat{J}_b^2 - \hat{J}_c^2) - \delta_K\{\hat{J}_a^2(\hat{J}_b^2 - \hat{J}_c^2) + (\hat{J}_b^2 - \hat{J}_c^2)\hat{J}_a^2\}$$

Here $A$, $B$, $C$ are rotational constants; $\Delta_J$, $\Delta_{JK}$, $\Delta_K$, $\delta_J$, $\delta_K$ are quartic centrifugal distortion constants; $\hat{J}_a, \hat{J}_b, \hat{J}_c$ are components of the total angular momentum $\hat{J}$. For most species studied the data were used to obtain values for the rotational constants and all the quartic centrifugal distortion constants. For the $HCCCO^{37}Cl$ and $DCCCO^{35}Cl$ excited states, however, there were insufficient data available to perform centrifugal distortion analyses. In these latter two cases the distortion on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

each line was assumed to be the same as that calculated for the corresponding ground state transition, and was subtracted from the measured frequencies; the resulting frequencies were fit to the three rotational constants. The rotational and centrifugal distortion constants so determined are given in Table 4.

*3. Dipole moment*

Because both *a*- and *b*-type transitions were observed the components $\mu_a$ and $\mu_b$ are non-zero. Since the molecule is planar (see later), $\mu_c$ is zero. The values of $\mu_a$ and $\mu_b$, and hence the total dipole moment $\mu$, were determined using the Stark effects of the $M = 0$ component of the $3_{03} \leftarrow 2_{02}$ transition and the $M = 5$ and 6 components of the $6_{24} \leftarrow 6_{15}$ transition. In all three cases the Stark effects were second order, and were measured in the high field limit (with the Stark energies much bigger than the quadrupole energies). The spacing of the Stark electrode in the cell was measured using the $1 \leftarrow 0$ transition of OCS and Muenter's value of its dipole moment (27). Linear plots were obtained for the frequency shifts vs. the square of the electric field; their slopes are in Table 5. Also in Table 5 are the derived values of $\mu_a$, $\mu_b$, and $\mu$, along with estimated outside uncertainty limits. The most probable direction of $\mu$, on electronegativity grounds, is in Fig. 1.

*4. The harmonic force field and structure*

*(a) The effective structure*

The ground state principal moments of inertia and inertial defects of the four isotopic species of propiolyl chloride studied are given in Table 6. The ground state inertial defects are small positive numbers which show only small isotopic variations and therefore confirm that the molecule has a planar structure.

The limited isotopic data obtained for propiolyl chloride precluded the calculation of a full substitution structure. Therefore, in an initial structural refinement, a crude ground state effective geometry was calculated. Values for five bond lengths and four angles are required to define the structure of propiolyl chloride; the four angles can be chosen as ∠(H—C≡C), ∠(C≡C—C), ∠(C—C=O), and ∠(C—C—Cl). As no deviation from linearity has been found for an ethynyl group it is reasonable to assume that ∠(H—C≡C) = 180°; this reduces the number of structural parameters to be determined to eight. Table 6 contains values for twelve ground state principal moments of inertia. Because the molecule is planar, however, only eight of these (two for each isotope) are independent. Therefore further assumptions are required to derive a meaningful structure. Since the C—H and C≡C distances have been found to be nearly identical in a wide range of acetylenic molecules (23, 28–39) values of 1.057 ± 0.002 Å and 1.206 ± 0.003 Å were initially assumed for these bond lengths; only for fluoroacetylene (29) do the C—H and C≡C distances lie outside these ranges.

[a]Here $F$ and $F'$ are the labels for the initial and final states respectively.

Using the assumed ethynyl group geometry a series of effective structures was calculated for propiolyl chloride. The choice of "best" structure is subjective, however, because different results were obtained when either the *A* and *B* or, alternatively, the *B* and *C* rotational constants were used in the fit. Therefore the effective structure, given in the first column of Table 7, should be regarded with detachment; it was obtained using the ground state *A* and *B* rotational constants and assuming further that ∠(C≡C—C) = 180° and *r*(C—C) = 1.435 Å. When only the geometry of the ethynyl group was constrained somewhat different results were obtained. For example, by fitting the *A* and *B* rotational constants *r*(C—C), *r* (C=O), and *r*(C—Cl) distances of 1.430 Å, 1.200 Å, and 1.764 Å resulted; the corresponding values derived from a fit to the *B* and *C* rotational constants were 1.450 Å, 1.188 Å, and 1.760 Å. Further calculations showed that, with the present data set, the *r*(C—C) and *r*(C=O) distances are highly correlated; isotopic substitution of the carbonyl group would probably alleviate this difficulty. In both of these latter refinements very similar values were obtained for

the ∠(C≡C—C): 179.4° from the fit to the *A* and *B* rotational constants and 179.3° from the fit to the *B* and *C* constants (here an angle less than 180° indicates that the ethynyl group is bent away from the C—Cl bond and towards the C=O bond whereas in propynal the opposite was observed (23)). It was felt that a force field refinement and average structure calculation would be useful to determine whether this apparent bend of the carbon chain was an artifact caused by zero point vibrational effects. These calculations are described in the following two sections of this paper.

*(b) The harmonic force field*

To determine the average structure of propiolyl chloride it is necessary to calculate the harmonic contributions to the vibration–rotation α-constants from the harmonic force field. Although strictly speaking a complete force field is required, in practice it is sufficient to have good values for the more important force constants. In this work we have calculated an approximate force field by combining the available vibration wavenumbers

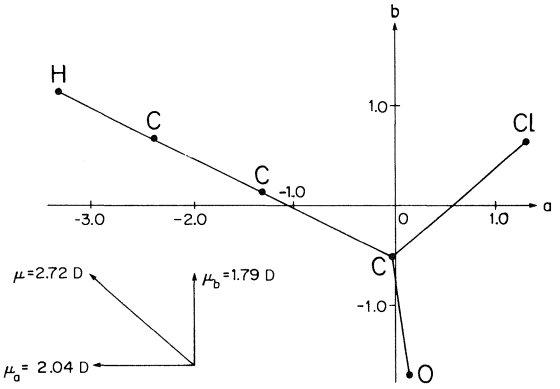

FIG. 1. The ground state average structure and dipole moment of H$^{12}$C$^{12}$C$^{12}$C$^{16}$O$^{35}$Cl in its principal in inertial axis system.

(12, 14, 15) with the centrifugal distortion constants. The chosen non-redundant symmetry coordinates, which transform as $9A' + 3A''$ in the point group $C_s$, are given in terms of the internal displacement coordinates in Table 8. The structure used was the effective structure of Table 7.

From the infrared spectrum of the gas (12) a complete set of vibrational wavenumbers was available for normal propiolyl chloride although the assignment of $\nu_5$ (H—C≡C in plane bend) was considered uncertain. Except for $\nu_7$, which showed a complex hot band structure, these wavenumbers were used directly with no corrections for anharmonicity being made; the Raman liquid value was adopted for $\nu_7$. Unfortunately the results for propiolyl chloride-*d* were less clear cut, partly because a weaker spectrum was obtained. For this species $\nu_{10}$ was not observed and gas phase values for $\nu_9$ and $\nu_{12}$ were unavailable (14). Because the corresponding gas and liquid values for the normal species were quite different the $\nu_9$ Raman liquid value for propiolyl chloride-*d* was discarded; instead, a value was taken from the ultraviolet spectrum (15). Additionally, $\nu_{12}$ for the deuterated species was taken to be 2 cm$^{-1}$ lower in the gas than

[f]The ethynyl group is bent away from the C—Cl bond.

in the liquid (observed shift for the normal species is 3 $cm^{-1}$) and, as for the normal species, the Raman liquid value was adopted for $\nu_7$. Except for $\nu_6$ (D—C≡C in-plane bend) the wavenumbers used for the remaining propiolyl chloride-*d* fundamentals were the reported gas infrared values (14). The previous assignment of $\nu_6$ to a band at 522 $cm^{-1}$ (14) seemed unlikely for several reasons. Firstly, this band showed no appreciable gas-to-liquid frequency shift whereas for normal propiolyl chloride (12) and propynal (40) the Raman liquid values are 20–25 $cm^{-1}$ higher than the gas infrared values. As well, the force field calculations suggested that $\nu_6$ and $\nu_{11}$ (D—C≡C out-of-plane bend) should be nearly degenerate and should occur at a somewhat higher frequency. Notably, a gas infrared band observed at 547 $cm^{-1}$ (assigned to $\nu_{11}$) is seen in the liquid at 570 $cm^{-1}$. No other band shows this behaviour; tentatively therefore $\nu_6$ and $\nu_{11}$ have been taken to be degenerate.

The force constants obtained in the present analysis are given in Table 9. Because of the limited data available the values of several force constants were fixed by analogy with other related molecules, reflecting structural differences (41, 42), and others were constrained to zero. In addition, the corresponding force constants defining the in-plane and out-of-plane H—C≡C and C≡C—C deformations were assumed to be equal. The values obtained for the various force constants appear reasonable in light of results for the related molecules acetylene (43), propyne (44), phosgene (41), and formic acid (45, 46); the value obtained for $F_{44}$ (C—C stretching force constant) does, however, appear low in comparison to the corresponding 5.50 mdyn $Å^{-1}$ value obtained for propyne (44).

Tables 10 and 11 demonstrate how well the present force field reproduces the observed data. Table 10 shows that the fit for the vibrational wavenumbers, with the possible exception of $\nu_9$, is satisfactory. Table 11 shows that the fit is also very good for the centrifugal distortion constants. Finally, a good harmonic force field should accurately predict the values of the ground and excited state inertial defects; the results of Table 12 show that this is the case here and, further, that the isotopic dependence of the ground state inertial defects is well accounted for. Although the results obtained are very pleasing, the force field given in Table 9 should be regarded as a preliminary result; with the many assumptions made, including the neglect of anharmonicity, it is evident that the uncertainties given in Table 9 underestimate the total errors in these parameters.

### *(c) The average structure*

The harmonic force field of Table 9 was used to calculate the harmonic parts of the α constants, and hence the ground state average rotational constants of the four isotopic species studied; these are given in Table 13. Because the inertial defects calculated using these $A_z$, $B_z$, and $C_z$ values are essentially zero (see Table 13), all twelve rotational constants were used to determine the ground state average structure. Again, since only eight of these were independent, it was necessary to assume a structure for the ethynyl group. The r(C—H) bond length was taken to be 1.055 Å ($r_s$ and $r_z$ values for propynal are 1.055 Å (23) and 1.054 Å (24) respectively) and the $r$(C≡C) length was taken to be 1.207 Å ($r_s$ and $r_z$ values for propynal are 1.209 Å (23) and 1.205 Å (24) respectively). The results of a least-

| | $F_{11,11} = 0.689(15)$ | | |
| | $F_{12,12} = 0.218(3)$ | | |

[a]Bond stretching force constants in mdyn Å$^{-1}$; stretch–bend interaction force constants in mdyn rad$^{-1}$; angle bending force constants in mdyn Å rad$^{-2}$.
[b]Uncertainties cited are standard errors in units of the last significant figures.
[c]No error cited indicates a constrained force constant. Force constants not cited were constrained to zero.
[d]The corresponding force constants defining the *A'* and *A"* H—C≡C and C≡C—C deformations were assumed to be equal. Specifically, the constraints made were: $F_{66} = F_{10,10}$; $F_{69} = F_{10,12}$, and $F_{99} = F_{12,12}$.

squares fit to the ground state average rotational constants are given in the last column of Table 7. They are shown pictorially in Fig. 1. In the structural refinements the ∠(C—C≡C) was not constrained and *r*(C—C) was varied by trial and error (at 0.0005 Å increments) to find the best fit: isotopic variations in the bond lengths were ignored. The standard deviation of the fit to the twelve rotational constants of Table 13 was 0.008 MHz, not significantly larger than the errors quoted for the effective ground state constants of Table 4; in view of the limited isotopic data available, however, this small standard deviation may not be meaningful. As well, because possible systematic errors have been ignored the least-squares standard errors almost certainly underestimate the total errors in the structural parameters; the uncertainties quoted in Table 7 represent five standard errors but do not indicate outside limits of error.

### 5. *Comments on the structure of propiolyl chloride*

Although the present results for propiolyl chloride are not definitive it is nevertheless interesting to compare the structures of propiolyl chloride and some related molecules; this has been done in Table 14. The results of Table 14 suggest that the

TABLE 10. Observed and calculated vibrational wavenumbers ($cm^{-1}$) of propiolyl chloride

| | $HCCCO^{35}Cl$ | | $DCCCO^{35}Cl$ | |
|---|---|---|---|---|
| Vibration | Observed[a] | Deviation | Observed[b] | Deviation |
| $A'$ $\nu_1$ | 3326 | −11.1 | 2609 | 7.8 |
| $\nu_2$ | 2131 | −8.2 | 2000 | 8.9 |
| $\nu_3$ | 1767 | −3.6 | 1772 | 1.6 |
| $\nu_4$ | 1003 | 0.0 | 994 | −5.9 |
| $\nu_5$ | 696 | −3.3 | 653 | 3.9 |
| $\nu_6$ | 655 | −1.4 | 547 | −0.6 |
| $\nu_7$ | 478 | 2.1 | 472 | 1.1 |
| $\nu_8$ | 414 | 3.6 | 404 | −1.2 |
| $\nu_9$ | 157 | 5.2 | 147 | 2.8 |
| $A''$ $\nu_{10}$ | 703 | 3.2 | (664)[c] | — |
| $\nu_{11}$ | 665 | 1.4 | 547 | 3.8 |
| $\nu_{12}$ | 224 | −2.3 | 214 | −2.2 |

[a]Taken from Augdahl *et al.* (12). The observed wavenumbers are gas infrared values except for $\nu_7$ which is a Raman liquid value. In the fits the uncertainty of $\nu_3$ was taken to be 1.5%; all other fundamentals were given uncertainties of 1% of the measured value.
[b]The observed wavenumbers are mostly gas infrared values (14); $\nu_7$ is a Raman liquid value and $\nu_{12}$ is an estimated gas phase value (216 $cm^{-1}$ in the Raman spectrum of the liquid (14)). A value for $\nu_9$ was taken from the ultraviolet spectrum (15). In the fits $\nu_6$ and $\nu_{11}$ were assumed to be degenerate but were given low weights; see text. In the fits $\nu_3$, $\nu_6$, and $\nu_{11}$ were given uncertainties of 2%, 5%, and 5% respectively; all other fundamentals were assigned uncertainties of 1% of the measured value.
[c]Calculated value. No experimental value was available.

[a]Obtained using the effective ground state rotational constants of Table 4 and the force field of Table 9.

C=O bond in propiolyl chloride is shorter than that in propynal. This is reasonable in view of results for $H_2CO$ (47), HCOCl (2), and $Cl_2CO$ (48) where C=O bond lengths of 1.207 Å ($r_z$), 1.188 Å ($r_s$), and 1.179 Å ($r_z$) have been obtained; as well, for $CH_3CHO$ (49) and $CH_3COCl$ (50) the corresponding values are 1.207 Å ($r_z$) and 1.185 Å ($r_z$). Therefore the C=O bond in propiolyl chloride might be expected to be 0.010–0.020 Å shorter than that in propynal; the results of Table 14, albeit imprecise, support this hypothesis. More marked are the variations in the C—Cl lengths; essentially identical bond distances have been determined for formyl chloride and propiolyl chloride while that found for acetyl chloride is somewhat longer. Kagarise (51) suggested that electronegative substituents should lower the contribution of nonbonded resonance structures such as $RCO^+Cl^-$; therefore the longest C—Cl bond would be expected for acetyl chloride because of the presence of the "electron-donating" methyl group. Similar arguments have been used to explain the trend in

TABLE 14. The structures of propiolyl chloride and related molecules[a]

the acid dissociation constants of the parent carboxylic acids (11). On this basis one might expect the C—Cl bond in propiolyl chloride to be slightly shorter than that found in formyl chloride; this very simple argument neglects, however, possible conjugative effects in propiolyl chloride. The remaining bond lengths in propiolyl chloride and propynal are apparently nearly equal.

In the case of the bond angles in acetyl chloride and propiolyl chloride it is seen that the ∠(C—C—Cl) is essentially identical in both molecules; the ∠(C—C=O) is in each case about 14° larger. Apparently the carbon chain in propiolyl chloride is more nearly linear than that found in propynal. Although this may be an experimental artifact the $r_0$ structure calculations lead to the same conclusion. More precise structural results for propiolyl chloride would require additional isotopic data.

# Coordination compounds of indium. Part 39. Some neutral adducts of $In_2Br_4$ and $In_2I_4$

MICHAEL J. TAYLOR,[1] DENNIS G. TUCK,[2] AND LUIS VICTORIANO
*Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4*

Received May 19, 1981

MICHAEL J. TAYLOR, DENNIS G. TUCK, and LUIS VICTORIANO. Can. J. Chem. **60**, 690 (1982).

The neutral indium(II) compounds $In_2X_4(Et_3P)_2$, $In_2X_4(TMED)_2$, and $In_2X_4(TMED)_2C_6H_6$ (X = Br, I; TMED = *N,N,N',N'*-tetramethylethylenediamine) have been prepared by the reaction of $InX_2$ and donor in benzene or toluene. With several other neutral donors, and in all systems involving $InCl_2$, decomposition to $In^0$ is the predominant process. Analysis of the vibrational spectra demonstrates that these structures involve $X_2In–InX_2$ kernels. Slight revisions are proposed to previous discussions of the infrared spectra of $In_2X_6^{2-}$ anions.

MICHAEL J. TAYLOR, DENNIS G. TUCK et LUIS VICTORIANO. Can. J. Chem. **60**, 690 (1982).

On a préparé les composés neutres de l'indium(II) $In_2X_4(Et_3P)_2$, $In_2X_4(TMED)_2$ et $In_2X_4(THED)_2$ $C_6H_6$ (X = Br, I; TMED = *N,N,N',N'*-tétraméthyléthylènediamine) en faisant réagir $InX_2$ avec un donneur dans le benzène ou le toluène. La décomposition en $In^0$ est la réaction principale avec plusieurs autres donneurs neutres et dans tous les systèmes qui impliquent $InCl_2$. L'analyse des spectres de vibration démontre que ces structures font intervenir les noyaux $X_2In–InX_2$. On propose une légère revision des discussion antérieures des spectres infrarouges des anions $In_2X_6^{2-}$.

## Introduction

In a number of previous publications from this laboratory we have commented on the dearth of information on the chemistry of the lower oxidation states of indium. Recent papers have described the development of synthetic routes to a number of neutral (1), cationic (2), and anionic (3) complexes of indium(I) and there does not seem to exist any barrier now, in principle, to the extension of such work to related systems. On the other hand, the chemistry of indium(II) still presents a number of challenging problems. The neutral dihalides are generally formulated as ionic dimers of mixed oxidation state, and a simple route to the preparation of these compounds (4) also lead to the development of synthetic routes to the first anionic complexes $In_2X_6^{2-}$ (5). These anionic species are structurally similar to the digallium salts which were reported some time ago (6), and for which structural information is available from X-ray crystallography (7, 8).

We now report the preparation of a small number of neutral adducts of the indium dihalides, which on the basis of the vibrational spectra are believed to contain indium–indium bonds. Again these are similar to the gallium analogues which were reported recently by Worrall *et al.* (9), although it appears that the symmetry and coordination number at the metal may not be the same for both sets of compounds.

## Experimental

### *General*

Spectroscopic and analytical procedures were as described previously (1). Indium dihalides were prepared from indium metal and indium trihalides (3). *N,N,N',N'*-Tetramethylethylenediamine (TMED) and other ligands were the commercially available materials used without further purification. Solvents were refluxed in sodium/benzophenone and distilled from the blue ketyl. All operations were performed in an atmosphere of pure, dry nitrogen.

### *Preparative*

The same general method was used in each case, with isolation procedures which varied according to the particular system. Approximately 2–3 mmol of the dihalide (calculated as the dimer) was placed in a Schlenk flask and 30–40 m of benzene syringed in through a rubber septum. The resultant suspension was frozen in liquid nitrogen, and a four-fold excess of monodentate, or two-fold excess of bidentate, ligand syringed in; solid ligands were dissolved in the minimum amount (5–10 mL) of benzene for this purpose. The liquid nitrogen cooling bath was removed, and the system stirred as soon as the melting of the solvent allowed. Magnetic stirring was continued for 20 min after the solvent had completely melted.

### *Isolation procedures*

*$InBr_2$/TMED:* The white suspension was filtered and the solid collected and dried. Analysis established the composition $InBr_2$(TMED) for this material. The mother liquors were allowed to stand over a period of 72 h, when large crystals (1.5 × 0.5 × 0.5 cm) were obtained, with further smaller (1 × 1 × 2 mm) crystals being obtained from the residual liquid after 24 h. These crystals had the composition $In_2Br_4(TMED)_2C_6H_6$ (see Table 1 for analytical results).

*$InI_2$/TMED:* A red colour, believed to indicate the presence of InI, was still apparent after stirring at room temperature for 2.5 h, and the mixture was therefore refluxed for 2 h. The yellow solid which separated on cooling was collected and dried, and found to have the composition $InI_2$(TMED). The filtrate was concentrated to 20 mL and a viscous brown liquid settled out on standing. This oil was separated and treated with 10 mL of light

ligroin (40–60°C bp) to yield a sticky yellow solid which was exhaustively pumped at room temperature. Analysis showed the composition of this material to be $In_2I_4(TMED)_2C_6H_6$.

*$InBr_2/Et_3P$:* When these two substances reacted in toluene at −40°C, a deep red solution initially formed but this rapidly changed colour, becoming yellow at about −20°C, and at room temperature, appreciable decomposition to the metal was noted. Addition of cold light ligroin to the solution at −20°C produced a white precipitate which was collected and dried; analysis gave the empirical formula $InBr_2 \cdot Et_3P$. The instability of this material prevented further investigation; in particular the infrared and Raman spectra presented no identifiable features.

*$InI_2/Et_3P$:* The green reaction mixture was concentrated to 20 mL by evaporation; after 2–3 h the orange crystalline material which was deposited was collected and dried. Further material was obtained by addition of light ligroin to the solution. Analysis showed this solid material to be $InI_2 \cdot Et_3P$.

*Other reactions*

Reactions between benzene solutions of $InBr_2$ and the ligands $Et_3N$, pyridine, 2,2′-bipyridine, and dimethylsulphoxide all gave indium metal in yields of 90% or larger, according to the disproportionation reaction

$$3InX_2 \rightarrow In^0 + 2InX_3$$

In the case of $InBr_2/Et_3P$, a substance of stoichiometry $InBr_3 \cdot 2Et_3P$ was recovered from the mother liquor, while $InBr_2 + Ph_3P$ yielded 100% InBr according to

$$In_2Br_4 \rightarrow InBr + InBr_3$$

Similar behaviour was observed with $InI_2$ and $Et_3N$, pyridine, 2,2′-bipyridine, $Ph_3P$, and bis(diphenylphosphino)ethane.

All attempts to make chloro-derivatives by the above methods from $InCl_2$ and a number of neutral donors resulted in disproportionation to indium metal.

## Results and discussion

*General*

The presence of coordinated ligands is apparent from the analytical results, and from infrared spectroscopy. The ir spectrum of neat TMED has bands *inter alia* at 1040 and 1275 $cm^{-1}$, which are shifted to 1025 and 1295 $cm^{-1}$ in the complexes, suggesting that they are related to the vibrations of the donor atom (10). Similarly bands at 1230 and 975 $cm^{-1}$ in the spectrum of $Et_3P$ (11) shift to 1265 and 995 $cm^{-1}$ in the complexes. $^1H$-nmr spectra of the products in deuteroacetonitrile also confirmed the presence of the ligands, without adding to our knowledge of the structures of the complexes. The magnetic susceptibilities of the solid materials (0.01–0.05 BM at 25°C) established them as diamagnetic. Rapid decomposition in suitable solvents prevented the measurement of molar conductivities.

TABLE 1. Analytical results[a]

| Compound | % In | % halogen |
|---|---|---|
| $In_2Br_4(Et_3P)_2$ | 29.0(29.3) | 41.0(40.7) |
| $In_2Br_4(TMED)_2$ | 32.7(29.4)[b] | 39.2(40.9)[b] |
| $In_2Br_4(TMED)_2C_6H_6$ | 26.8(26.7) | 37.3(37.2) |
| $In_2I_4(Et_3P)_2$ | 24.1(23.6) | 52.1(52.2) |
| $In_2I_4(TMED)_2$ | 23.6(23.7) | 52.9(52.4) |
| $In_2I_4(TMED)_2C_6H_6$ | 22.2(21.9) | 48.4(48.5) |

[a] Figures in parentheses indicate theoretical compositions.
[b] See text for discussion of these analyses.

Sharp aromatic resonances (7.20 ppm downfield from TMS) confirmed the presence of benzene in those products formulated as $In_2X_4(TMED)_2C_6H_6$. Neither nmr nor vibrational spectroscopy throws any light on the mode of interaction of benzene in the solid phase of such compounds, and only minor changes in other frequencies were noted on comparing analogous solvated and non-solvated compounds. This may indicate that the benzene is merely trapped in the crystal lattice with no strong interactions towards the metal centre, and in keeping with this, the crystalline materials slowly lose benzene and disintegrate on standing in an atmosphere of dry nitrogen, which frustrated attempts at X-ray structural analysis.

*Vibrational spectroscopy*

In view of the above results, we conclude that the most obvious structural analogues of these compounds are the $Ga_2Cl_4L_2$ compounds reported by Worrall *et al.* (9), and shown to involve Ga—Ga bonding. The presence of In—In bonds in the corresponding indium(II) anionic complexes also provides further indication of a metal–metal bonded structure, and in the absence of X-ray crystallographic data (see above) we now justify the formulation of the present compounds as In—In bonded dimers on the basis of vibrational spectroscopy.

As a preliminary, we first report some necessary revision to the previously published results for the $In_2X_6^{2-}$ anions. Despite the earlier report (5), we now find that these compounds dissolve in $CH_3CN$ with only slight decomposition, and that addition of $Et_2O$ yields good crystalline material. The vibrational spectra of these products are similar to those of the untreated materials, except that the highest frequency infrared features, at 332 $cm^{-1}$ for Cl, 235 $cm^{-1}$ for Br, and 186 $cm^{-1}$ for I, have disappeared; an additional feature is also observed at 135 $cm^{-1}$ for $In_2I_6^{2-}$. We suggest that such absorptions are actually due to tetrahaloindate(III) anion impurities (12). The simplified spectra of the $In_2X_6^{2-}$ anions are summarized in Table 2, from which it is clear that it is no longer necessary to invoke Fermi resonance in order to explain the spectra (cf. ref. 5). Other infrared frequencies, and the Raman spectra, which remain unchanged in the newly purified materials, are not affected. These

TABLE 2. The revised infrared spectra of $In_2X_6^{2-}$ anions, as $Bu_4N^+$ salts (in $cm^{-1}$)

| $In_2Cl_6^{2-}$ | $In_2Br_6^{2-}$ | $In_2I_6^{2-}$ | Assignment | Description |
|---|---|---|---|---|
| 292s | 207s | 162s | $E_u$ | ν(In—X) |
| 284sh | 185s | 135s | $A_{2u}$ | ν(In—X) |

revisions must have some effect on the values of the force constants and potential energy distributions, but do not change the general conclusions reached earlier about the $X_3In—InX_3^{2-}$ structure of these anions.

The Raman and ir features of $In_2X_4L_2$ (X = Br, I; L = TMED, $Et_3P$) are detailed in Table 3. The most prominent feature in the spectra of each of the $In_2X_4$ complexes is a strong Raman line which appears at 141 $cm^{-1}$ in $In_2Br_4(TMED)_2$, at 110 $cm^{-1}$ in $In_2I_4(TMED)_2$, at 116 $cm^{-1}$ in $In_2I_4(Et_3P)_2$. These values agree well with the frequencies for ν(In—In) in the corresponding anionic species $In_2X_6^{2-}$ (5), and the shift of this stretching mode with changes in net charge or coordination number follows the pattern already established for the analogous $Ga_2X_4$ species (9).

*Triethylphosphine complexes*

Once the presence of a metal-to-metal bond has been established, various ionic structures can be ruled out, but even then a number of different structural possibilities must be considered for the TMED complexes; we return to this point below. A structural formulation is most easily made in the case of $In_2I_4(Et_3P)_2$. The mutual exclusion rule identifies the species as centrosymmetric, and on this basis we propose a structure of $C_{2h}$ skeletal symmetry shown in Fig. 1. The vibrational representation for the stretching modes of this $In_2X_4P_2$ kernel is $3A_g + B_g + A_u + 2B_u$, in which the g-modes are Raman-active and all u-modes infrared-active. It was not possible to obtain satisfactory spectra for $In_2Br_4(Et_3P)_2$ (see Experimental), but the vibrational spectrum of $In_2I_4(Et_3P)_2$, given in Table 3, shows the ν(In—In) vibration, together with bands which are reasonably attributed to the four In—I stretching modes.

The assignment of phosphorus-to-metal stretching frequencies has generally raised some difficulties. Shobatake and Nakamoto (13) used metal isotope techniques for $NiX_2(Et_3P)_2$ and thus located ν(Ni—P) near 270 $cm^{-1}$. The spectra of $InX_3(R_3P)_2$ (X = Cl, Br, or I; R = Me or Et) did not reveal any obvious ν(In—P) modes (14), but a single-crystal study of $InCl_3(Me_3P)_2$ lead to the identification of the totally symmetric modes of this molecule, with ν(In—P) being assigned at 135 $cm^{-1}$ (15). This frequency seems rather low in terms of mass considerations, when compared to values of 307 $cm^{-1}$ for ν(In—Si) in $In(SiMe_3)_3$ (16), of 370–380 $cm^{-1}$ for ν(In—S) in a series of toluene-3,4-dithiol derivatives of indium (17), and of 319–339 $cm^{-1}$ for this mode in $InX_3 \cdot 2Et_2S$ (X = Cl, Br) (18). The situation is undoubtedly complicated by the possibility of mixing modes of like symmetry. The present spectra contain bands at 376 m (ir) and 333 m $cm^{-1}$ (R), shown elsewhere (13) to be δ(CCP) modes of the coordinated ligand. This leaves a weak ir band at 254 $cm^{-1}$, which we tentatively assign to ν(In—P).

*N,N,N′,N′-Tetramethylethylenediamine complexes*

In the TMED series, we first consider the In—halogen stretching region, where in all cases two Raman and two non-coincident ir features are found (Table 3). This suggests the presence of a centrosymmetric $In_2X_4$ unit, which requires the $In_2X_4N_4$ kernel to adopt a conformation similar to that in the $Et_3P$ analog. Inspection of the In—N stretching region, as defined by Mertz *et al.* (19), might argue against the presence of a centre of symmetry since all four features are coincident, or nearly so, but in the context of the above discussion, we attribute this to a lowering of the overall molecular symmetry caused by the hydrocarbon framework of the ligand.

The frequencies of coordinated TMED have been reported previously (20), and we assume that the ligand is functioning as a bidentate donor in the present complexes, as implied by the presence of four ν(In—N) frequencies. This requires the indium atoms in $In_2X_4(TMED)_2$ to be five-coordinate, and the shift in the ν(In—In) frequency from 116 $cm^{-1}$ in $In_2I_4(Et_3P)_2$ to 110 $cm^{-1}$ in $In_2I_4(TMED)_2$ is consistent with an increase in coordination number from four to five. This conclusion, and the identification of a centrosymmetric $In_2I_4$ unit, reveal notable differences between these indium complexes and the gallium compounds $Ga_2Cl_4(dioxane)_2$, in which the dioxane is monodentate, the metal atoms are four-coordinate, and the molecular symmetry approximately $C_{2v}$ (9). We note in this context that some examples of five-coordination at tin are known for Sn—Sn bonded compounds (21).

The mode of coordination of *N,N,N′,N′*-tetramethylethylenediamine requires some comment. As already noted, the expected bidentate coordination seems to be confirmed by the number of bands observed in the 350–500 $cm^{-1}$ region of the spec-

trum (ν(In—N)). This still leaves at least three possibilities to consider: (*a*) terminal TMED, (*b*) intermolecular bridging, and (*c*) intramolecular bridging. The second possibility can be rejected in view of the results for the 700–900 $cm^{-1}$ region of the infrared spectrum. Chelate-type diamines display two bands, assigned as $CH_2$ rocking vibrations at approximately 810 and 770 $cm^{-1}$, while intermolecular bridging leads to a *trans* conformation in the diamine, with ir bands at 870 and 790 $cm^{-1}$ (10, 20). Our materials show bands at 770w and 790s, implying a *cis* or *gauche* conformation of bidentate TMED, and the structures are accordingly written as $X_2$(TMED)InIn(TMED)$X_2$.

Some spectral features still remain unexplained after this analysis. Several of these can be ascribed to small amounts of impurities, as is the case of $In_2Br_4(TMED)_2C_6H_6$ where a Raman line at 197 $cm^{-1}$, and an ir feature at 236 $cm^{-1}$, point to the presence of $InBr_4^-$. Perhaps more interesting is the strong Raman line found at 129 $cm^{-1}$ in the spectrum of $In_2Br_4(TMED)_2$. The intensity and position of this feature suggest the presence of a second metal–metal bonded species, with the frequency of this vibration affected either by a higher coordination number, or by an increase of negative charge, or both. As can be seen from Table 1, the analyses for this material do not agree particularly well with the presumed composition, so that the presence of some unidentified second compound in the crude material is not unreasonable. Our interpretation has also neglected the presence of bending modes, which will be responsible for some of the features still unexplained in the assignments in Table 3.

*Reaction pathway*

Although the reaction is apparently the single addition of neutral ligand to indium dihalide, two significant factors must be recognized. The first is that few of the $InX_2^-$ ligand combinations investigated do in fact yield the desired product, and that in most cases disproportionation to $In^0$ and presumably $In^{III}$ species predominates. The second is that a deep-red or orange colour is formed on the

addition of either anionic (5) or neutral ligands (this work) to solutions of indium dihalide, which is compatible with the establishment of the equilibrium

$$In_2X_4 \rightleftharpoons InX + InX_3.$$

Since very little is known about the solution chemistry of indium(I) or indium(II) compounds in aromatic solvents, we are presently unable to rationalize these various observations, and work on these and related problems is continuing.

# Neutral complexes of the indium dihalides

IAN SINCLAIR AND IAN J. WORRALL

*Department of Chemistry, The University of Lancaster, Bailrigg, Lancaster LA1 4YA, England*

Received August 25, 1981

IAN SINCLAIR and IAN J. WORRALL. Can. J. Chem. **60**, 695 (1982).

The neutral complexes $In_2X_4 \cdot 2L$ (X = Cl, Br, I; L = 1,4-dioxan, tetrahydropyran, tetrahydrofuran, tetrahydrothiophene), $In_2X_4 \cdot 2L$ (X = Br, I; L = dimethylsulphide), $In_2X_4 \cdot 4L$ (X = Cl, Br, I; L = piperidine, piperazine, morpholine), and $In_2X_4 \cdot 4L$ (X = Br, I; L = pyridine, dimethylsulphoxide) have been prepared. Solid state Raman spectra indicate that the compounds contain indium–indium bonds.

IAN SINCLAIR et IAN J. WORRALL. Can. J. Chem. **60**, 695 (1982).

On a préparé les complexes neutres $In_2X_4 \cdot 2L$ (X = Cl, Br, I; L = dioxanne-1,4 tétrahydropyranne, tétrahydrofuranne, tétrahydrothiophène), $In_2X_4 \cdot 2L$ (X = Br, I; L = sulfure de diméthyle), $In_2X_4 \cdot 4L$ (X = Cl, Br, I; L = pipéridine, pipérazine, morpholine) et $In_2X_4 \cdot 4L$ (X = Br, I; L = pyridine, diméthylsulfoxyde). Les spectres Raman à l'état solide indiquent que ces composés contiennent des liaisons In–In.

## Introduction

Although the gallium halides $Ga_2X_4$ are ionic mixed oxidation state compounds they react with many ligands to form neutral gallium–gallium bonded complexes (1, 2). Recent crystal structure determinations have confirmed the presence of these bonds in $Ga_2X_4 \cdot 2$dioxan (X = Cl, Br) (1, 3) and $Ga_2Br_4 \cdot 2$pyridine (4). The use of the structurally similar indium and thallium dihalides to prepare neutral metal–metal bonded complexes of these elements is a logical extension to the gallium work and we here report the preparation of a number of neutral indium compounds which appear to be similar to their gallium analogues and contain indium–indium bonds.

A survey of previous work suggests that the indium dihalides are capable of forming both ionic and neutral complexes; aniline complexes of stoichiometry $InX_2 \cdot 2$aniline have been formulated In(aniline)$_4^+InX_4^-$ (5) and Russian workers have proposed that metal–metal bonds are present in the complexes $InX_2 \cdot 3NH_3$, $InX_2 \cdot 4NH_3$, $InI_2 \cdot 3EtNH_2$, and $InI_2 \cdot$bipy$\cdot 2EtNH_2$ (bipy = 2,2′-bipyridyl) although no structural evidence has been reported in support of these formulations (6). Very recently Tuck *et al.* (7) have reported the preparation of a number of ionic complexes with macrocyclic ligands and in the same paper state that they have prepared the neutral compounds, e.g. $In_2I_4 \cdot 2PEt_3$ and $In_2Br_4 \cdot 2$(tmen) (tmen = *NNN′N′*-tetramethylethylenediamine) although no details were given.[1]

## Experimental

*Purification of ligands and solvents*

Pyridine, piperidine, and morpholine were refluxed over KOH for 24 h and fractionally distilled from BaO. 1,4-Dioxan, dimethyl sulphide, tetrahydropyran, tetrahydrofuran, and tetrahydrothiophene were refluxed over LiH for 24 h and fractionally distilled. Dimethylsulphoxide was passed down a column of freshly activated alumina and fractionally distilled from BaO. Diethyl and xylene were refluxed over sodium wire for 24 h and fractionally distilled.

*Preparation of $In_2Br_4$ complexes*

(*a*) Dimethyl sulphide, dimethylsulphoxide, tetrahydrofuran, and tetrahydrothiophene complexes: A vial of powdered indium dibromide was opened in a nitrogen-filled dry-box and transferred to a round bottomed flask. The flask was evacuated on a vacuum line, cooled with liquid nitrogen, and ligand condensed on to the halide. This procedure was adopted for the preparation of most complexes. As the ligand melted the mixture was mechanically stirred; an orange compound, thought to be InBr, was initially precipitated and this reacted slowly to produce a colourless solution. On removal of excess ligand a white powder remained.

(*b*) Tetrahydropyran complex: A large excess of tetrahydropyran was condensed on to $InBr_2$ over a period of 2 h. The temperature was allowed to rise to the melting point of the ligand and the solution stirred for 1–2 min until a solution formed. This was then solidified by freezing and the excess ligand removed from the solid; a yellow powder remained. If the described conditions were not strictly adhered to then disproportionation to InBr and the soluble $InBr_3$ complex occurred.

(*c*) Morpholine and piperidine complexes: A large excess of ligand was condensed on to $InBr_2$ and the mixture slowly allowed to warm up to room temperature. After removal of excess ligand a white powder remained.

(*d*) Pyridine complex: This was prepared by the same method as described for the morpholine complex but the reaction temperature was maintained at −30°C. Above this temperature indium metal was deposited. The reaction yielded a white solid which was stable once the excess pyridine had been removed.

(*e*) Tetrahydrofuran complex: Excess ligand was condensed on to $InBr_2$, the mixture was shaken for 20 min and stirred for a further 4 h and after the removal of excess ligand a white solid remained.

(*f*) 1,4-Dioxan complex: The direct addition of this ligand to $InBr_2$ invariably produced InBr and $InBr_2 \cdot$dioxan. However, the complex was successfully prepared by the following indirect method: dry nitromethane was added to $InBr_2$, the orange solid, which initially formed slowly dissolved on stirring and on removal of the excess nitromethane a glassy substance remain-

*THP = tetrahydropyran, THF = tetrahydrofuran, THT = tetrahydrothiophene, DMS = dimethylsulphide, DMSO = dimethylsulphoxide.

ed. 1,4-Dioxan was then condensed on to the glass and a white solid formed; this was dried under vacuum.

(*g*) Piperazine complex: A dilute xylene solution of piperazine was added to a suspension of $InBr_2$ in xylene in an atmosphere of dry nitrogen. A white precipitate formed which was separated from the liquid by centrifugation. The white solid was washed with xylene and ether and dried under vacuum.

*Preparation of chloride and iodide complexes*

The preparative methods are very similar. In most reactions a precipitate initially formed and this is thought to be the monohalide, i.e. yellow (InCl) in chloride reactions and purple (InI) in iodide reactions. In the case of $In_2Cl_4$ we were unable to prepare complexes with pyridine, dimethylsulphide, or dimethylsulphoxide since decomposition to metal always occurred.

The indium dihalides were prepared from indium metal and indium trihalides (8–10).

*Raman spectra*

Spectra were recorded on solid samples using an Anaspec 81 L spectrometer and radiation of wavelength 541.5 nm. Spectra could only be obtained on two chloride compounds since the others decomposed in the laser beam even at very low power. Data are given in Table 2 together with the ions $In_2X_6^{2-}$ (12) in the range 100–400 $cm^{-1}$.

*Analytical data*

Indium was determined by atomic absorption spectrophotometry and halogen by Volhard's method. Data are given in Table 1.

## Results and discussion

Analytical results show that two types of compound are formed with stoichiometry $In_2X_4 \cdot 2L$ and $In_2X_4 \cdot 4L$; the former with O and S donors and the latter with N donors (with one exception: dimethylsulphoxide). The same stoichiometries have been reported by Brewer *et al.* for the analogous gallium compounds (11).

The possibility that the complexes have simple ionic structures of the type, e.g. $InL_4^+InX_4^-$ can be ruled out since the characteristic strong bands of the $InX_4^-$ ions are absent in their Raman spectra (Table 2). Conductivity measurements could not be obtained due to the instability of the complexes in the solvents used; however, such measurements have proved to be unreliable in some of the gallium analogues, e.g. conductivity measurements show that $Ga_2Cl_4 \cdot 2$dioxan is ionic in nitrobenzene solution whereas the solid state structure is covalent (1, 11).

The Raman spectra (in the range 100–400 $cm^{-1}$) of all known gallium–gallium species with ethane-like structures each consist of one very intense band together with a smaller number of weaker bands. The very intense band is associated with the gallium–gallium stretching mode and the weaker bands with gallium–halogen modes. In addition the position of the very intense bands in neutral complexes is very similar to observed bands in the parent halides; e.g. $Ga_2Cl_6^{2-}$ 233 $cm^{-1}$, $Ga_2Cl_4$·-

*vs = very strong, s = strong, m = medium, w = weak.

2dioxan 238 $cm^{-1}$; $Ga_2Br_6^{2-}$ 164 $cm^{-1}$, $Ga_2Br_4$·2dioxan 169 $cm^{-1}$, $Ga_2Br_4$·2pyridine 168 $cm^{-1}$ (1, 2). It is seen in Table 2 that the indium–halide complexes conform to a similar pattern and we therefore conclude that they have similar indium–indium bonded structures.

Band assignment is necessarily speculative due to the absence of X-ray crystallographic data and attempts to grow suitable crystals have so far been unsuccessful. In addition we were unable to measure low frequency infrared spectra. However, the very close similarity (with few exceptions) in the position of the very strong bands (italics in Table 2) compared with those observed for the parent anions $In_2X_6^{2-}$ (12), and in view of the recent assignments by Tuck *et al.* (16) for analogous bromide and iodide complexes we assign the strong bands to $\nu_{In—In}$. The positions of the intense bands are remarkably similar for each set of complexes, falling in the range 173 ± 4 $cm^{-1}$ for the chloride series, 143 ± 4 $cm^{-1}$ for the bromide series (excluding the dioxan and pyridine complexes), and 105 ± 5 $cm^{-1}$ for the iodide series. This constancy is perhaps surprising in view of (*a*) the apparent difference in coordination about indium in $In_2X_4$·2L and $In_2X_4$·4L and, (*b*) the large shifts observed in the mixed halide ions, e.g. $In_2Cl_4Br_2^{2-}$, $\nu_{In—In}$ = 163 $cm^{-1}$ and $In_2Cl_4I_2^{2-}$, $\nu_{In—In}$ = 147 $cm^{-1}$ (13). To fully explain these facts it is necessary to consider the mixing of the various modes and this is not possible with the available data. Mixing effects in analogous gallium systems have been previously discussed (1, 14).

The remaining higher bands are assigned to metal–halogen modes and their numbers will depend upon the symmetry of the molecules and their environments within the crystal, which are unknown. Of the three neutral gallium complexes of known structure, $Ga_2X_4$·2dioxan (X = Cl, Br) have $C_1$ symmetry and $Ga_2Br_4$·2pyridine $C_{2h}$, and their Raman spectra reflect these symmetry differences. No attempt is made here to deduce the symmetry of the indium complexes from the number of higher bands since these are generally of weak intensity and it is possible that in some cases not all bands have been observed (e.g. only the strong band was observed for $In_2I_4$·4pyridine), whilst in others an excess of bands may be due to trace impurities (e.g. in $In_2Br_4$·4pyridine the band at 180 $cm^{-1}$ may be due to $InBr_3$·3pyridine and the band at 192 to $InBr_4^-$).

Ligand bands were observed for all complexes and it is thought that the mode of coordination of morpholine is via nitrogen since the N—H frequency is lowered from 3340 $cm^{-1}$ in morpholine to 3286–3296 $cm^{-1}$ (15) in the complexes.

Since spectroscopic data provide strong evidence for the occurrence of indium–indium bonds in both 4:1 and 2:1 complexes we propose that both types are neutral and the 4:1 contains five coordi-

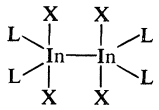
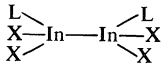
For personal use only.

nate indium and has the structure



and the 2:1 complexes are expected to be isostructural with their gallium analogues i.e.



Ligand strength appears to be the dominant factor here since all of the nitrogen donors examined and dimethylsulphoxide form 4:1 complexes whilst the weaker oxygen and sulphur donors form 2:1 complexes.

A comparison between the complexes formed by the similar sized ligands, dioxan and morpholine, emphasizes this point where 2:1 adducts are formed by the former and 4:1 by the latter.

# The electronic structure of cyclopentadienylindium

C. S. LIN AND DENNIS G. TUCK
*Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4*

Received July 20, 1981

C. S. LIN and DENNIS G. TUCK. Can. J. Chem. **60**, 699 (1982).

CNDO calculations have been carried out for the molecule $InC_5H_5$ of $C_{5v}$ symmetry. Overlap populations were calculated and compared with those for related species. The bonding between In and the organic moiety can be described as essentially a covalent interaction involving mainly indium 5*s* and 5*p* orbitals with ring $p_\pi$ orbitals. A lone pair on indium is a dominant feature of the structure, and is largely responsible for a (calculated) dipole moment of 4.75 D. The calculated orbital energies are compared with experimental photoelectron spectra.

C. S. LIN et DENNIS G. TUCK. Can. J. Chem. **60**, 699 (1982).

On a effectué des calculs CNDO pour la molécule de $InC_5H_5$ de symétrie $C_{5v}$. On a calculé le recouvrement des populations et on les a comparé à celui des espèces apparentées. On peut décrire la liaison entre In et la portion organique comme étant essentiellement une interaction covalente impliquant principalement les orbitales 5*s* et 5*p* de l'indium avec les orbitales $p_\pi$ du cycle. Le trait dominant de la structure est le doublet libre de l'indium, et il est grandement responsable d'un moment dipolaire (calculé) de 4,75 D. On a comparé les énergies calculées des orbitales aux spectres photoélectroniques expérimentaux.

## Introduction

Cyclopentadienylindium (CpIn), first prepared by Fischer and Hofmann (1) in 1957, is a molecule of some interest for at least two reasons. The first, and the more readily disposed of, is that it is the only readily accessible indium(I) compound which is soluble in common organic solvents, and as such is a useful starting point in the synthesis of indium(I) complexes (2, 3). The second reason is more apposite to this paper; the compound presents an interesting problem in structure and bonding, and the nature of the latter has been the subject of some discussion.

The structure of the molecule in the gas phase has been unambiguously established by the precise electron diffraction study of Shibata, Bartell, and Gavin (4). The results of their work are summarised in Fig. 1, which shows that the molecule indeed has the half-sandwich pentahapto-ligand structure originally postulated by Fischer (1, 5). In the crystalline state, the CpIn molecules line up in an almost linear head-to-tail fashion (6). Bartell *et al.* (4) have reviewed the various attempts to explain the bonding in this molecule (and in the isostructural (7) thallium species). The Fischer and Hofmann representation involves donation from the $\pi$-orbitals of $C_5H_5^-$ into the vacant 5*p* orbitals of $In^+$. Cotton and Reynolds (8) proposed an ionic structure, but Bartell *et al.* showed that this was incorrect, and in fact carried out overlap integral calculations which supported a covalent description of the In—$C_5H_5$ bonding.

In two recent publications, Cradock and Duncan (9) and Egdell, Fragala, and Orchard (10) have reported the He(I) and He(II) photoelectron spectrum of CpIn, with results which are in good agreement. The interpretation is based upon earlier studies of transition metal cyclopentadienyl sandwich compounds, which we believe to be an inappropriate model for CpIn. The present paper reports the results of CNDO calculations which lead to an analysis of the bonding and the electronic properties of the molecule.

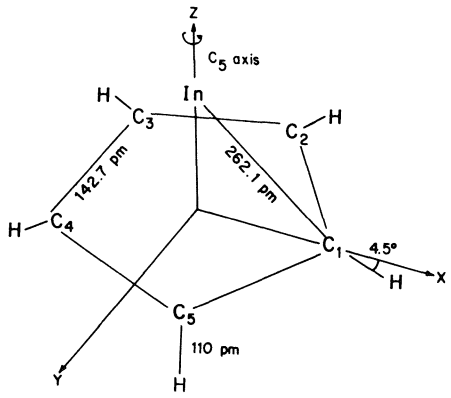

FIG. 1. Structural parameters and coordinate system for cyclopentadienylindium.

## Experimental

*Calculations and results*

Molecular orbitals and corresponding orbital energies were calculated by using the CNDO computer programme of Rinaldi (11), without optimization with respect to the molecular geometry. The theory (12), and the parameters used in the programme, are standard and well-documented and are not detailed here. The bond distances and angles used in this calculation are

| $\psi_8$ | | $0.10(s_1) + 0.27(x_1) - 0.31(x_2 + x_5) + 0.18(x_3 + x_4) - 0.13(y_2 - y_5) + 0.39(y_3 - y_4)$ | |
| $\psi_7$ | $0.27(s) - 0.21(z)$ | $+ 0.42(z_1 + z_2 + z_3 + z_4 + z_5)$ | |

[a]Atomic orbitals with coefficients less than 0.10 are omitted.

derived from the work of Bartell *et al.* (4); the values and the coordinate axes adopted are shown in Fig. 1.

The CNDO molecular orbital scheme gives rise to fourteen occupied orbitals; Table 1 lists the top seven of these with approximate descriptions. Electron densities in the atomic orbitals, and gross atomic electronic densities, are given in Table 2, and the breakdown of the overlap population in Table 3.

*Dipole moment*

The dipole moment of CpIn in toluene solution (approximately 0.01 mol $L^{-1}$) was determined on a WTW DM-01 instrument at a sample temperature of 40°C. The experimental value was $2.2 \pm 0.2$ D.

## Discussion

### *Bonding*

Table 2 demonstrates the conspicuous absence of ionic character in the bonding. The negative charge on the indium atom is only 0.059e, with the positive charges spread almost evenly among other atoms. Although the five carbon atoms are coplanar, the geometry of the molecule induces the conventional carbon π atomic orbitals ($2p_z$) to mix with the $2s$, $2p_x$, and $2p_y$ orbitals to some extent in order to bond with the indium and hydrogen atoms. As the result of indium–carbon bond formation, a slight build-up of electron density occurs in the space between indium and the plane of carbon atoms, as indicated by the values for $2p_z$ in Table 2. These densities are obviously siphoned off from carbon–carbon and carbon–hydrogen bonds, but since the shift is small, the effect on the ring σ-bonds is apparently negligible.

TABLE 2. Electron densities in atomic orbitals, and gross atomic electron densities, in CpIn

| Orbital | Electron density | | |
|---|---|---|---|
| | In | C | H |
| $s$ | 1.7773 | 0.9998 | 0.9956 |
| $p_x + p_y$ | 0.7364 | 1.9689 | — |
| $p_z$ | 0.5453 | 1.0238 | — |
| Sum | 3.0590 | 3.9927 | 0.9956 |

TABLE 3. Overlap population distribution in CpIn

| | Indium | | |
|---|---|---|---|
| | $5sp_z$ | $5p_x + 5p_y$ | Sum |
| Carbon | | | |
| $2s + 2p_x + 2p_y$ | 0.44 | 0.14 | 0.58 |
| $2p_z$ | 0.33 | 0.25 | 0.58 |
| Sum | 0.77 | 0.39 | — |

In order to analyze the results of the calculations, the overlap population $q_{kl}$ defined by Mulliken (13) was computed, with the following results.

(*a*) Bonding in the hydrocarbon ring. The overlap population for the C—C bond is 0.88, to be compared with the value of 0.55 for the C—C single bond in ethane (14). The resultant ratio of 1.60 is only fractionally lower than the comparable value of 1.67 for benzene, and quite close to that for the C—C bonds in the graphite ring (1.525). Bartell *et al.* (4) obtained a value of 1.40 by considering the equivalent resonance structures of CpIn. The overlap population in the C—H bonds of CpIn is 0.67, which is practically the same as the value of 0.678 for C—H in ethane (14).

The CNDO calculations of Del Bene and Jaffé (15) place the lowest π electron ionisation potential of cyclopentadiene, $e_1(\pi)$, at 9.94 eV. The calculated ionisation potential for the corresponding molecular orbitals in CpIn ($\psi_{12}$, $\psi_{13}$) is 12.54 eV. The difference of 2.60 eV gives a rough estimate of the additional binding energy for an electron in $e_1(\pi)$ due to the bonding of the ring to indium.

(*b*) Indium–carbon bond. Molecular geometry dictates that, in the first approximation, an $sp_z$

hybrid on the indium atom be bonded to the totally symmetric σ and π symmetry orbitals of the hydrocarbon ($\psi_7$, $\psi_{14}$), while the $5p_x$ and $5p_y$ orbitals are bonded to the doubly degenerate symmetry orbitals $e_1(\psi_{12}, \psi_{13})$. Although the differentiation between the σ and π atomic orbitals is not strictly valid because of the geometry of the molecule, the above bonding scheme is still essentially correct and is indeed substantiated by the CNDO calculations.

The lone pair ($\psi_{14}$; see below) accounts for 1.566e and 0.365e of the total electron densities of 1.777e and 0.545e in the $5s$ and $5p_z$ atomic orbitals of indium. Since this lone pair contributes little to the In—$C_5H_5$ bonding, only 0.211e and 0.18e in these respective atomic orbitals participate in the bonding to the organic group. By comparison, the entire electron density (0.368e) in both $5p_x$ and $5p_y$ is involved in the bonding ($\psi_{12}$, $\psi_{13}$). Despite the lower electron density available for bonding from the $sp_z$ hybrid, Table 3 shows that this orbital contributes twice as much towards the overlap population as do $5p_x + 5p_y$. In fact, it accounts for two-thirds of the total overlap population (i.e. bonding) between indium and $C_5H_5$, which is to be expected since in this system the $sp_z$ hybrid is what is traditionally regarded as a σ atomic orbital and overlaps effectively with the π orbitals of the hydrocarbon. This observation confirms the view of Bartell *et al.* (4) that an $sp_z$ hybrid on the metal plays an important role in the indium–carbon bonding. Table 3 also shows the σ atomic orbitals ($2s$, $2p_x$, $2p_y$) of the carbon atoms participating as strongly in the bonding to indium as do the $2p_z$ orbitals.

Overall then, while there is a slight shift of electron density from the σ-bonds of the cyclopentadienyl into the indium–carbon bond, as shown by the values for $2p_z$ in Table 2, there is virtually no interatomic transfer of electron density, so that the bonding is essentially covalent in nature. The metal–ring bonding involves both σ- and π-interactions, with the former predominating (Table 3).

(*c*) Lone pair on indium. The highest occupied orbital in the CNDO molecular orbital scheme ($\psi_{14}$) represents a large lone pair (1.93e) on the indium atom, pointing diametrically away from the Cp ring. It is predominantly $5s$ in character with approximately 18% contribution from $5p_z$ and only 3.5% from all other atoms. In fact, it is this lone pair of electrons which contributes most to the calculated molecular electric dipole moment of 4.75 D; since there is practically no transfer of electron densities between atoms, the component of dipole moment arising from the charges amounts to only 0.67 D, with the remaining 4.08 D coming from the lone pair. The theoretical value is much higher than the experimental value of 2.2 ± 0.2 D, not an unusual situation in CNDO calculations. The presence of a large lone pair has formed the basis for earlier discussions of certain aspects of the chemistry of CpIn (16, 17).

*Ionisation potentials*

Table 4 compares the experimental values for the ionisation potentials of CpIn with those derived from the CNDO calculations. The agreement is within the limits normally placed upon such calculations, with the differences ranging from about 1 eV for a lone pair orbital to several eV for a bonding molecular orbital, often increasing with the binding energy. This calculation brought forth two questions inherent to the interpretation of experimental photoelectron spectra on the basis of Koopman's theorem.

Firstly, while our CNDO calculation identifies the lowest ionisation potential of this molecule with the lone pair ($\psi_{14}$) on the metal atom, both Cradock and Duncan (9), and Egdell *et al.* (10) interpret this peak as originating from the doubly degenerate $e_1(\pi)$ of the organic moiety. These authors (9, 10)

based their interpretation on the photoelectron spectra of transition element metallocenes (18, 19). Symmetry consideration certainly would indicate that in a *sandwich* complex the lone pair on In should be exclusively *s* in character, and that the lowest ionisation potential should be for the removal of an electron from an $e_1(\pi)$ molecular orbital, but the same argument also clearly indicates that the bonding and electronic structure of indium in CpIn is so fundamentally different from that in a sandwich complex as to render invalid any interpretation of the spectrum of one system on the basis of the other.

Although several lines of argument can be cited to support our assignments, a CNDO calculation on a molecule of this complexity may well not be definitive (see below), and additional information is needed for clarification. The $C_{5v}$ symmetry of this molecule results in a number of pairs of molecular orbitals being doubly degenerate; the last column of Table 4 lists six such examples. Since these orbitals are partially responsible for the bonding in the framework of the cyclopentadienyl group (see Table 1), the removal of an electron from any one of them, and especially from $\psi_{12}$ or $\psi_{13}$, is likely to result in a loss of planarity in the $C_5$ ring of the resultant ion. This loss of co-planarity could induce a strong interaction among all the ionic states,[1] with consequent removal of the double degeneracies. It follows that Koopman's theorem cannot be expected to give a reliable description of the photoelectron spectra of a molecule of this type. A rigorous study taking into account these interactions is beyond the scope of CNDO, and must await more sophisticated calculations.

[1]The authors are grateful to a referee for pointing this out.

# An electron spin resonance study of organomercury radical complexes with *ortho*-quinones and vitamin C

DOUGLAS WEIR, DOUGLAS A. HUTCHINSON, JUDY RUSSELL, AND JEFFREY K. S. WAN

*Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6*

Received August 20, 1981

DOUGLAS WEIR, DOUGLAS A. HUTCHINSON, JUDY RUSSELL, and JEFFREY K. S. WAN. Can. J. Chem. **60**, 703 (1982).

Photochemical and thermal reactions of *ortho*-quinones and organomercury lead to the formation of a series of quinone–HgR$^{\bullet}$ radical complexes. Hyperfine splittings due to $^{199}$Hg isotope were resolved for the 3,5-di-*t*-butylbenzoquinone complexes. Photochemical reactions of vitamin C in ethanol with a number of mercuric salts produce a paramagnetic intermediate which is assigned to the ion-pair involving the ascorbate radical anion and the mercuric ion. In di-*n*-butyl mercury, photolysis of vitamin C leads to the formation of a radical complex similar to those of quinone–HgR$^{\bullet}$ but with a much smaller hyperfine coupling constant for $^{199}$Hg. A simple theoretical model using some MO calculations on the π system of these organometal–quinone radical complexes, which include the metal atom, was developed to account for the systematic experimental observations.

DOUGLAS WEIR, DOUGLAS A. HUTCHINSON, JUDY RUSSELL et JEFFREY K. S. WAN. Can. J. Chem. **60**, 703 (1982).

Les réactions photochimiques et thermiques des orthoquinones avec des organomercuriques conduisent à la formation d'une série de complexes radicalaires du type quinone–$^{\bullet}$HgR. On a résolu les dédoublements hyperfins provoqués par l'isotope $^{199}$Hg des complexes de la di-*tert*-butyl-3,5 benzoquinone. Les réactions photochimiques de la vitamine C dans l'éthanol avec un certain nombre de sels mercuriques produisent un intermédiaire paramagnétique identifié comme étant la paire d'ions provenant de l'anion radical ascorbate et l'ion mercurique. La photolyse de la vitamine C dans le di-*n*-butyl mercure conduit à la formation d'un complexe radicalaire semblable à ceux observées pour quinones–$^{\bullet}$HgR mais avec une constante de couplage hyperfin beaucoup plus faible pour le $^{199}$Hg. On a développé un modèle théorique simple, faisant appel à des calculs d'OM sur le système π de ces complexes radicalaires organométalliques–quinones et impliquant l'atome de métal, afin de tenir compte des observations expérimentales systématiques.

[Traduit par le journal]

## Introduction

In the past few years we have studied extensively the interactions of quinones and other dicarbonyl compounds with organometals, including the uranyl (1), the organomercury (2), the group IVB organometals (3), and the group VIB and group VIIB metal carbonyls (4). In many cases where chemically induced dynamic electron polarization can be detected (1, 3), the additional parameter of the spin–lattice relaxation time of the organometallic radical complexes affords supporting arguments of the extent of spin–orbit coupling of the heavy metal which contributes to the *g*-factor shifts. In order to understand the relative contributions to the *g*-shift, we have chosen here some model organomercury radical complex systems for further investigation. The photochemical reactions between quinones and organomercury are in themselves rather interesting, particularly due to the biological implication of organomercury compounds. In that regard we have also studied the reactions between organomercury and vitamin C (ascorbate) by esr spectroscopy. Ascorbate contains a carbonyl group and two adjacent hydroxylic groups and ascorbate is readily oxidized to a relatively stable free radical anion whose structure has been determined using esr spectroscopy and theoretical calculations (5). In this paper we report a systematic investigation of a number of organomercury–quinone radical complexes by esr and a simple theoretical approach, using some MO calculations on the π electron system of these organometal–quinone complexes which include the metal atom, to obtain some qualitative understanding of the *g*-factor shifts. The ability of vitamin C (ascorbate) to form radical complexes with some organomercury compounds is also illustrated in this report.

## Experimental

Procedures for sample preparations and the photochemical generations of the organometal radical complexes are similar to the method described previously (3). Electron spin resonance spectra were recorded on a Bruker 420 X-band spectrometer with a 100 kHz field modulation. The magnetic field was monitored by a Bruker nmr oscillator and the microwave frequency was measured by a Hewlett-Packard 5432 frequency counter. Magnetic field calibration was made using the potassium naphthalene ion-pair in THF as an external standard. All chemicals were used as received. THF was distilled twice over sodium and stored over sodium wire. The light source was a 200 W super pressure Hg lamp.

## Results and Discussion

### *1. The photochemical reactions of quinones with organomercury*

The photochemical reaction of organomercury compounds with *o*-quinones in THF gives unique

radical esr spectra. The radicals were relatively unstable at high temperatures. Among a number of quinones studied, no reaction was observed with acenaphthenequinone. With tetrachloro- and tetrabromo-*o*-benzoquinones the reaction required light to initiate but the photochemical reaction proceeded too rapidly with immediate destruction of any possible radical complexes, leaving only the esr spectra of the semiquinone radical anions observable. Organomercury radical complexes were observed for phenanthroquinone (PQ), 1,2-naphthoquinone (NQ), camphoroquinone (CQ), and 3,5-di-*t*-butyl-*o*-benzoquinone (DTBQ).

In the case of DTBQ reacting with dibenzyl mercury, the radical complex formed is relatively stable, even at room temperature. A typical esr spectrum of the benzyl mercury – DTBQ radical complex is shown in Fig. 1. The radical has a very low *g*-factor ($g = 1.9994$) and exhibits an esr spectrum which is composed of a strong central doublet of a proton hyperfine splitting of 2.70 G due to the *meta*-proton from the DTBQ moiety, and a pair of weak doublets of 22.7 G due to the interactions with the $^{199}Hg$ isotope (16.84%, $I = 1/2$). The other $^{201}Hg$ isotope (13.24%, $I = 3/2$) was not resolved in the spectrum. Although the hyperfine splittings from the benzyl protons in the organomercury moiety were not resolved, the identification of the radical complex with the following structure (**1**) is reasonable and consistent with previous assignments (2). For most of the other organomercury–quinone radical complexes studied, the $^{199}Hg$ splittings are very difficult to resolve. The observed esr parameters of the various organomercury–quinone radical complexes are given in Table 1.

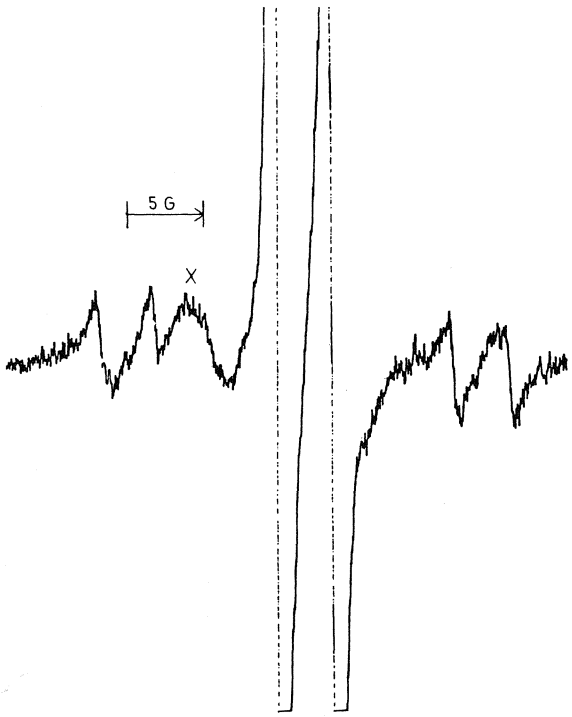

FIG. 1. The esr spectrum of the $DTBQ^{-\cdot}HgCH_2Ph$ complex in THF at −60°C. × marks the $DTBQ^{-\cdot}$ radical anion signal.

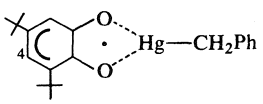

**1**

The observations of these radical complexes were sensitive to the reaction temperatures. With the noted exception of the benzyl mercury – DTBQ complex, temperatures above −50°C lead to rapid decomposition of the complexes. On the other hand, temperatures below −80°C inhibit the formation of the complexes. The best resolution in the esr spectra of the radical complexes was obtained for the 1,2-naphthoquinone complexes (Fig. 2).

The experimental esr parameters of the 1,2-naphthoquinone radical complexes with a variety of organometals are listed in Table 2. It is seen that for the mercury and the uranyl complexes the *g*-factor shift is large and negative as compared to other metals. Furthermore, the mercury complex has larger proton coupling constants but there is little change in the *g*-factors or proton coupling constants as the organic group on the mercury is varied. These observations will be discussed in more detail in section 4.

There are two possible mechanisms leading to the formation of these organomercury–quinone radical complexes. The first one involves a primary electron transfer process followed by secondary processes as outlined below:

$$[1] \quad Q + R_2Hg \xrightarrow[\text{or } \Delta]{h\nu} Q^{-\cdot} + R_2Hg^{+\cdot}$$

$$[2] \quad R_2Hg^{+\cdot} \rightarrow RHg^{+} + R^{\cdot}$$

$$[3] \quad RHg^{+} + Q^{-\cdot} \rightarrow RHg\text{–}Q^{\cdot}$$

In a previous study (2) of the exchange reaction between the quinone – alkali metal ion-pairs and methylmercury chloride, a similar radical ion mechanism has been proposed. Another earlier study (6) also suggested an electron transfer mechanism in the formation of complexes between DTBQ and triethylgermyl mercury. Direct spectroscopic evidence, however, is still lacking since the detection of the reactive $R_2Hg^{+\cdot}$ radical ion has yet to be achieved. On the other hand, it may be feasible to carry out the photochemical reaction at 77 K with an aim to trap pairwise the radical ions involved in

the primary electron transfer process [1]. Similar experiments have indeed been successfully performed with the quinone–organotin systems (7).

Until the electron transfer mechanism is unequivocally established, we must also consider the second possible mechanism which involves mainly the decomposition of the organomercury:

[4] $R_2Hg \xrightarrow[\text{or } \Delta]{h\nu} RHg^\bullet + R^\bullet$

[5] $RHg^\bullet + Q \rightarrow RHg\text{–}Q^\bullet$

The decomposition of $R_2Hg$ has been shown to involve free radicals in a CIDNP study (8) but it was recognized that the intermediate RHg• radical is likely to undergo further decomposition to yield R• and Hg with a rate constant greater than $10^9$ $s^{-1}$. This means that reaction [5] must proceed faster than $10^{-9}$ s which is most unlikely as the reaction in solution is probably at least diffusion-controlled.

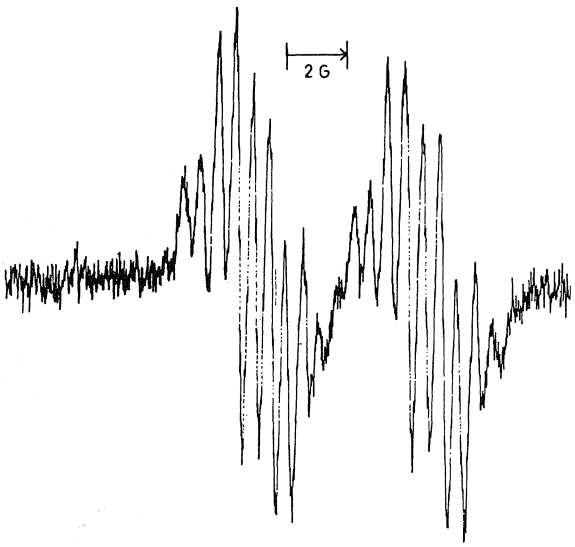

FIG. 2. The esr spectrum of the $NQ^{-\bullet}HgICH_3$ complex in THF at −80°C.

*2. The thermal reactions of quinones in di-*n*-butyl mercury solution*

In a separate series of investigation, liquid di-*n*-butyl mercury was used as solvent for the quinones. The thermal reaction proceeded well at 25°C leading to the esr observation of the radical complex which was found to be stable at room temperature for at least several hours. The thermal reaction involved three different quinones, PQ, NQ, and DTBQ and the corresponding radical complexes are given in Table 3. Among these three quinones PQ gave the weakest concentration of the radical complex. Both NQ and DTBQ gave very strong esr signals with $^{199}Hg$ splittings (Fig. 3). The $^{199}Hg$ coupling constant in these complexes is only about 6 G, much smaller compared to the 22 G observed in the DTBQ–$HgCH_2Ph^\bullet$ complex. This suggests that the Hg—O bonds are weaker in the quinone – aliphatic mercury complexes than those in the quinone – aromatic mercury.

*3. The reactions of vitamin C with mercury(II) salts*

Vitamin C contains functional groups which are structurally similar to *ortho*-quinones. When a degassed ethanol solution of L(+)-ascorbic acid (vitamin C) was photolysed within the esr micro-

wave cavity, a doublet signal with $g$ = 2.0057 and coupling constant of 1.85 G was observed (Fig. 4*a*). This is assigned to the ascorbate radical anion, consistent with literature reports (9). When a mercuric salt was added to the solution and again photolysed the ascorbate signal disappeared and in its place a new single line spectrum was observed (Fig. 4*b*). In all cases the $g$-factor of the new radical is slightly lower (2.0054, 2.0053, 2.0051 for Hg-$(SCN)_2$, $HgBr_2$, and $HgCl_2$, respectively) than the ascorbate radical anion value. In all the above three systems grey precipitate due to colloidal mercury appeared after prolonged irradiation. With mercuric acetate the precipitate appeared immediately upon irradiation and therefore no esr signal was detected. The new radical species formed in these mercuric salt systems were not thermally stable and they decayed immediately when the irradiation was terminated. The fact that colloidal mercury was formed upon prolonged irradiation points to the photoredox nature of the "complexation" in which successive electron transfer steps occurred (17). The radical complex observed is thus probably an ion-pair similar to that observed by Stegmann and co-workers (10) in the vitamin C – $Ph_2T10H$ system. The fact that the $g$-factor shift was so small from the free radical anion ruled out the drastic ring-opening in the complex. In the absence of observable $^{199}Hg$ hyperfine splitting and a significant $g$-shift, whether the ion-pair is a

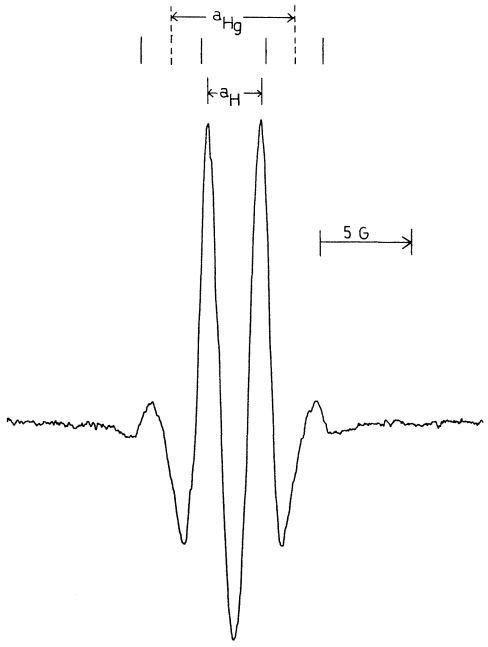

FIG. 3. The second derivative esr spectrum of vitamin C – $n$-butyl mercury in liquid di-$n$-butyl mercury at 25°C.

contact-pair or a solvent-separated pair cannot be established at this time.

When organomercury was added to an ethanol solution of vitamin C, photolysis failed to produce any observable mercury radical complexes. Since more stable mercury – quinone radical complexes have been obtained by using di-$n$-butyl mercury as solvent, the same technique was applied to the vitamin C system. There was no observable thermal reaction of vitamin C in liquid di-$n$-butyl mercury. However, upon irradiation of the system two doublet esr signals were observed. One set of the doublet at lower field can be identified as the well-known ascorbate radical anion, while the doublet at higher field with parameters $g$ = 1.9884 and $a_H$ = 5.84 G is typical for an organomercury

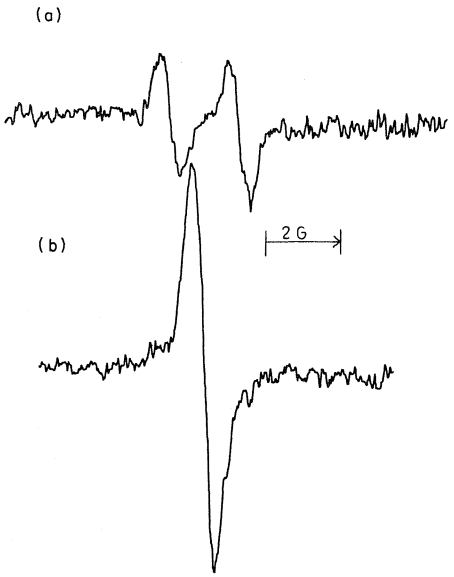

FIG. 4. The esr spectra at 25°C of (*a*) ascorbate radical anion in ethanol and (*b*) when a mercuric salt $Hg(SCN)_2$ was added.

radical complex to vitamin C. The larger proton coupling constant in the C-4 position of the ascorbate moiety is consistent with other observations involving T1–ascorbate complexes (10). These organomercury – ascorbate radical complexes probably have a structure similar to those of quinone–organomercury complexes, but the mercury–ascorbate complexes are much less thermally stable than the quinone analog.

### *4. Some theoretical considerations on the g-factor shifts of metal – quinone radical complexes*

In our systematic study of an extensive series of organometal – quinone radical complexes, we have found that while the uranyl and the organomercury complexes have very low $g$-factors, many of the other metal–quinone complexes have $g$-factors equal to or above the free electron value. For the uranyl–quinone complexes, we were able to obtain a good agreement with the experimental results by using a spin–orbit coupling model to account for the $g$-shifts (1). With a more extensive series of organomercury–quinone and mercury – vitamin C radical complexes reported in this paper, it is interesting to develop a simple theoretical model to account for their trend in $g$-factor shifts. In order to understand the relative contributions to the $g$-shift from the spin–orbit coupling of the metal and from the $d$–$p_\pi$-bonding mechanism proposed earlier for group IVB-substituted methyl and ethyl radicals (11, 12), we have performed some simple calculations on the $\pi$ electron system of these organometal–quinone complexes which include the metal atom.

We began by applying the elegant formulation on **G** tensor by Stone (13) and also followed his arguments in the treatment of the odd electron $\pi$ MO which is expressed as a linear combination of $p_z$ AO's. The final approximate expression for the $g$-factor of the metal–quinone complexes is

$$[6]\quad g \simeq g_e - \frac{4}{3\,\Delta\varepsilon_n}\sum_a |c_{an}|^2\zeta_a$$

where $g_e$ is the free electron $g$-factor and $\zeta_a$ is the spin–orbit coupling parameter, obtainable from spectroscopic results; all other symbols have their conventional meanings.

The energy differences for the atomic C $^3P_2$, $^3P_1$, $^3P_0$ levels are obtained from Moore (14); in atomic units the results are

$$\varepsilon(^3P_2) - \varepsilon(^3P_0) = 1.982 \times 10^{-4}$$

$$\varepsilon(^3P_1) - \varepsilon(^3P_0) = 0.7472 \times 10^{-4}$$

If the $^3P_2$, $^3P_1$, and $^3P_0$ are assigned the respective spin–orbit coupling parameters $\zeta_2$, $\zeta_1$, $\zeta_0$ with splittings $(1/2)\zeta_2$, $-(1/2)\zeta_1$, $-\zeta_0$, then

$$(1/2)\zeta_2 + \zeta_0 = 1.982 \times 10^{-4}$$

$$-(1/2)\zeta_1 + \zeta_0 = 0.7472 \times 10^{-4}$$

and

$$(5/2)\zeta_2 - (3/2)\zeta_1 - \zeta_0 = 0$$

The weighted average is $\zeta_C = 1.254 \times 10^{-4}$. A similar procedure for the oxygen atom gives $\zeta_O = 7.144 \times 10^{-4}$. The procedure for $Hg(..6s^16p^1)$ is somewhat different because the $^3P_1$ and $^1P_1$ levels can interact but the $^3P_2$ and $^3P_0$ levels have the same state vectors for Russell Saunders and *jj* couplings. Thus $\varepsilon(^3P_2) - \varepsilon(^3P_0)$ can be equated to $(3/2)\zeta_{Hg}$; from Moore (14) the result is $\zeta_{Hg} = 194.342 \times 10^{-4}$.

The coefficients $c_{an}$ of eq. [6] are estimated by a Hückel method; the Hg $6p_z$ orbital is included in the description of the $\pi$ states. The orbital energies $\varepsilon_n$ and coefficients $c_{an}$ are then obtained from eq. [7]:

$$[7]\quad (\gamma_a + x_n)c_{an} + \sum_{b\neq a} y_{ab}c_{bn} = 0$$

The parameters $\gamma_a$, $x_n$, and $y_{ab}$ are defined in terms of the atomic integrals $\alpha_a$, bond integrals $\beta_{ab}$, the standard carbon atomic integral $\alpha_C$, and standard benzene bond integral $\beta_B$ as follows:

$$[8]\quad \gamma_a = (\alpha_a - \alpha_C)/\beta_B;$$

$$x_n = (\alpha_C - \varepsilon_n)/\beta_B;$$

and

$$y_{ab} = \beta_{ab}/\beta_B \simeq \langle a|b\rangle/\langle a|b\rangle_B$$

where $\langle a|b\rangle_B$ is the value for benzene with a CC bond length of 1.397 Å.

A value of −2.505 eV is assigned to $\beta_B$ from the spectroscopic data. The negative of the ionization energy differences for O and C is assigned to $\alpha_O - \alpha_C$; a value of 0.9417 is then obtained for $\gamma_O$. The spectroscopic data for Hg allows one to write the following

$$\varepsilon_\infty - (\varepsilon(\mathrm{Hg}6s6p) - \zeta) = 5.76997 \text{ eV};$$

$$\varepsilon_\infty - (\varepsilon(\mathrm{Hg}6s6p) + (1/2)\zeta) = 4.97675 \text{ eV}$$

for the $^3P_0$ and $^3P_2$ levels. Consequently the $6p$ ionization energy of Hg is $\varepsilon_\infty - \varepsilon(\mathrm{Hg}6s6p) = 5.24116$ eV, from which $\gamma_{Hg} = -2.402$. The inner products of eq. [8] are evaluated from Slater orbitals for C and O. The radial part $R_{6p}(r)$ of the Hg $6p_z$ orbital is constructed from $(R_{31}(\rho_3) + cR_{53}(\rho_5))/(1 + c^2 + 2C(R_{31}, R_{53}))$, where $R_{31}$ and $R_{53}$ are associated Laguerre polynomials of the arguments

$$\rho_n = 2\,Zr/n,$$

$r$ in atomic units. The values $Z = 7.0$ and $c = 0.4$ are obtained by fitting $R_{6p}(r)$ to the Hg $6p$ wavefunction of Hay, Wadt, Kahn, and Bobrowicz (15).

It is convenient to rewrite eq. [6] as

$$[9] \quad g - g_e \simeq -\frac{4}{3\Delta\varepsilon_n}(w_{\mathrm{Hg},n}\zeta_{\mathrm{Hg}} + w_{O,n}\zeta_O + w_{C,n}\zeta_C)$$

where $w_{\mathrm{Hg},n}$, $w_{O,n}$, and $w_{C,n}$ respectively are the sums of the squares of the Hg, O, and C atom coefficients of the odd electron π MO $|n\rangle$. In order to determine the orbital for the odd electron, the number of electrons in the π system needs to be known. For the DTBQ–HgR· radical complex, the six aromatic C atoms and the two O atoms each contribute an electron to the π system. In the valence region of Hg there are seven electrons: four from the O atom lone pairs, two from Hg itself, and one from the R moiety bonded to Hg. Three $sp^2$ hybrids around Hg can accommodate six of the seven electrons so the remaining one is in the π system. From these arguments one concludes that the π system contains nine electrons; thus the odd electron is in the fifth πMO. Similarly NQ–HgR· complex contains thirteen electrons in the π system; the odd electron is in the seventh πMO. PQ–HgR· has a π system with seventeen electrons; the odd electron is in the ninth πMO. The results produced by these arguments, and the experimental $g$-shifts are shown in Table 4.

Although the calculated results for $(g - g_e)\Delta\varepsilon_n$ are negative, $g - g_e$ can be positive or negative depending on the signs of $\Delta\varepsilon_n$. For a semiquinone we follow Stone (16) and recognize that the most important contributing orbitals are occupied σMO's. Thus, after an average energy approximation is introduced, $\Delta\varepsilon_n$ is negative and $g - g_e$ is positive. When the quinone–HgR· complex is formed, the Hg atom has many unoccupied orbitals near the highest filled MO. An average energy approximation should now give a positive $\Delta\varepsilon_n$ and hence a negative $g - g_e$. In this way a qualitative understanding of the $g$-factor shifts is obtained for the metal–quinone complex.

A quantitative assessment of the experimental results is much more difficult to obtain from this simple model. The $\Delta\varepsilon_n$ term, however, should be comparable for all the quinone-HgR· complexes. The Hg spectroscopic data suggest that a value of ~1/4 atomic unit is reasonable for $\Delta\varepsilon_n$. As seen in Table 4 this does give reasonable $g$-shifts and they are in fair agreement with the experimental shifts obtained in the di-*n*-butyl mercury systems. In THF solvent with dibenzyl mercury, the NQ complex appeared to disagree with the predicted trend among the series of three quinone complexes. Our simple model is not capable of accounting for the solvent and other experimental effects which may result from using THF as solvent. Also we would refrain from applying this simple model quantitatively to the ascorbate–mercury radical complexes, as neither the π electron system nor the exact nature of the three oxygen atoms of the ascorbate in the interaction with the mercury would be comparable to the quinone systems.

We shall now turn to the $g$-factors of other organometal–quinone radical complexes. The respective $g$-factors for the $Ph_3Sn$— and $Ph_3Pb$— complexes with DTBQ are 2.0038 and 2.0032. The positive shifts of 0.0015 and 0.0009 here indicate that the Sn and Pb atoms coordinate to the quinone more loosely than does a Hg atom. In the absence of additional structural information it is plausible to assume a trigonal bipyramidal arrangement of the two O—Pb and three Ph—Pb bonds about Pb and the same arrangement for Sn. In such an arrangement the $\pi$ system contains two more electrons than the quinone–HgR$^\cdot$ complexes. In the valence region about Pb there are eleven electrons: four from Pb itself, three from the attached phenyl groups, and four from the two O atom lone pairs. The trigonal bipyramidal $sp^3d$ hybridization scheme gives $d_{3z^2-r^2}$ and three $sp^2$ hybrids to the $\sigma$ system and $p_z$ to the $\pi$ system: the $\sigma$ system contains four orbitals and the $\pi$ system contains one. Thus eight of the eleven valence electrons are accommodated in the $\sigma$ system and the remaining three are distributed in the $\pi$ system. Since the quinone moiety contains eight $\pi$ electrons there are a total of eleven electrons in the $\pi$ system. The odd electron occupies the sixth $\pi$MO in contrast to the fifth $\pi$MO for the nine $\pi$ electron quinone–HgR$^\cdot$ complex.

It is instructive to compare the Hg and O atom coefficients for the fifth and sixth $\pi$MO's of the HgR complex determined by eq. [7]. For the fifth $\pi$MO the respective Hg and O atom coefficients are 0.1313 and 0.4526; the corresponding numbers for the sixth $\pi$Mo's are 0.0725 and 0.1293. These results point the way to a reduced role for the metal atom in the Sn and Pb complexes. Conceivably the metal atom coefficient could have been lowered to the point where the binding to the quinone is slight and the occupied $\sigma$MO's of the quinone are more important than the unoccupied orbitals of the metal atom. This would produce a negative $\Delta\varepsilon_n$ and thus a positive $g - g_e$, as observed in the experiments.

We must re-emphasize that our simple model is developed mainly to account for some of the experimental observations among a large number of metal–quinone radical complexes investigated in this laboratory. The results of the calculations do favor a significant $g$-factor shift for the complexes involving the HgR moiety, and they also suggest that the other tin and lead complexes have much smaller $g$ shifts. Such a simple model does provide a qualitative understanding of some of the important esr parameters and as such is a valuable tool for the experimentalists.

# Synthesis and properties of some spin labeled long chain aliphatic acids

D. GALA, R. SCHULTZ, AND R. KREILICK

*Department of Chemistry, University of Rochester, Rochester, NY 14627, U.S.A.*

Received October 9, 1981

D. GALA, R. SCHULTZ, and R. KREILICK. Can. J. Chem. **60**, 710 (1982).

We have synthesized and characterized a series of spin labeled aliphatic acids with variable chain lengths between the nitroxide radicals and the carboxylic group. These molecules should be of general utility in labeling a variety of substrates which can react with the free carboxylic acid group. Variable temperature esr studies have been conducted with some of these molecules to characterize molecular motion as a function of solvent viscosity.

D. GALA, R. SCHULTZ et R. KREILICK. Can. J. Chem. **60**, 710 (1982).

On synthétisé et caractérisé une série d'acides aliphatiques portant un marqueur de spin et l'on a fait varié la longueur de la chaîne entre les radicaux nitroxydes et groupement carboxylique. Les molécules devraient être d'une utilité générale pour marquer un grand nombre de substrats qui peuvent réagir avec le groupement acide carboxylique libre. On a effectué des études de rpe à température variable à l'aide de ces molécules afin de caractériser leur mouvement moléculaire en fonction de la viscosité du solvant.

## Introduction

The electron spin resonance (esr) spectra of spin labeled molecules have been used to investigate motional correlation times of a variety of biologically important compounds (1). Nitroxide radicals are generally the label of choice because extensive theoretical work has been conducted to relate experimental spectra to motional correlation times (2). The motional correlation times may depend on steric interactions between the labeled reporter group and a biological substrate. If the nitroxide group can be attached to a drug molecule or enzyme with a variable length connecting chain, one is able to monitor changes in molecular correlation times as a function of the length of the spacer group between the drug or enzyme and the nitroxide label (3). Through analysis of changes in molecular motion as a function of the spacer group's length one can obtain information about the structure of a binding site. If the spacer group is short compared to the depth of the binding site, the nitroxide label's motion will be inhibited by steric interactions with the substrate while longer spacers may allow the nitroxide to extend out of the binding site resulting in greater mobility of the labeled group. If one determines the motional correlation time as a function of the length of the spacer group one obtains a measure of the depth of the binding site.

We have synthesized a group of spin labels in which a nitroxide label is bound to a carboxylic acid functional group via a variable length aliphatic chain (Fig. 1). The carboxylic acid groups of these molecules can be used to form either ester or amide linkages with a variety of different substrates. We have used these molecules to spin label both morphine and codeine through formation of ester linkages at the 3 and 6 positions. The labeled acids should prove to be of general utility in the synthesis of a variety of other types of labeled drugs or enzymes. The labeled molecules were synthesized by three related techniques. In method A (Fig. 1) the half ester, half acid chloride of a dicarboxylic acid was allowed to react with the amino group of 2,2,6,6-tetramethyl-4-aminopiperidine-1-oxy to form a molecule with both an amide and ester group. The ester was subsequently hydrolysed to form the desired product. In method B the acid function of the half ester of a dicarboxylic acid was condensed with the amino group of the nitroxide radical through use of *N*,*N'*-dicyclohexylcarbodiimide (DCC). Hydrolysis of the ester group again led to the formation of the desired labeled acid. In method C a dicarboxylic acid was directly condensed with the amino group of the nitroxide radical using DCC as a coupling reagent. The spin labeled acids were characterized by their ir spectra, their nmr spectra (after reduction of the nitroxide group), and by their esr spectra. A variable temperature esr study was conducted with two of the labeled acids to determine changes in motional correlation times as a function of solvent viscosity and the chain length of the spacer group.

## Methods and experimental

The spin labeled acids were synthesized by three different techniques. The choice of technique for a given molecule was dictated by availability of starting materials and the overall yield of the product. The three reaction schemes are illustrated in Fig. 1. The half esters of dibasic acids with $n$ = 2–4, 7 were commercially available, while only the diacids were available

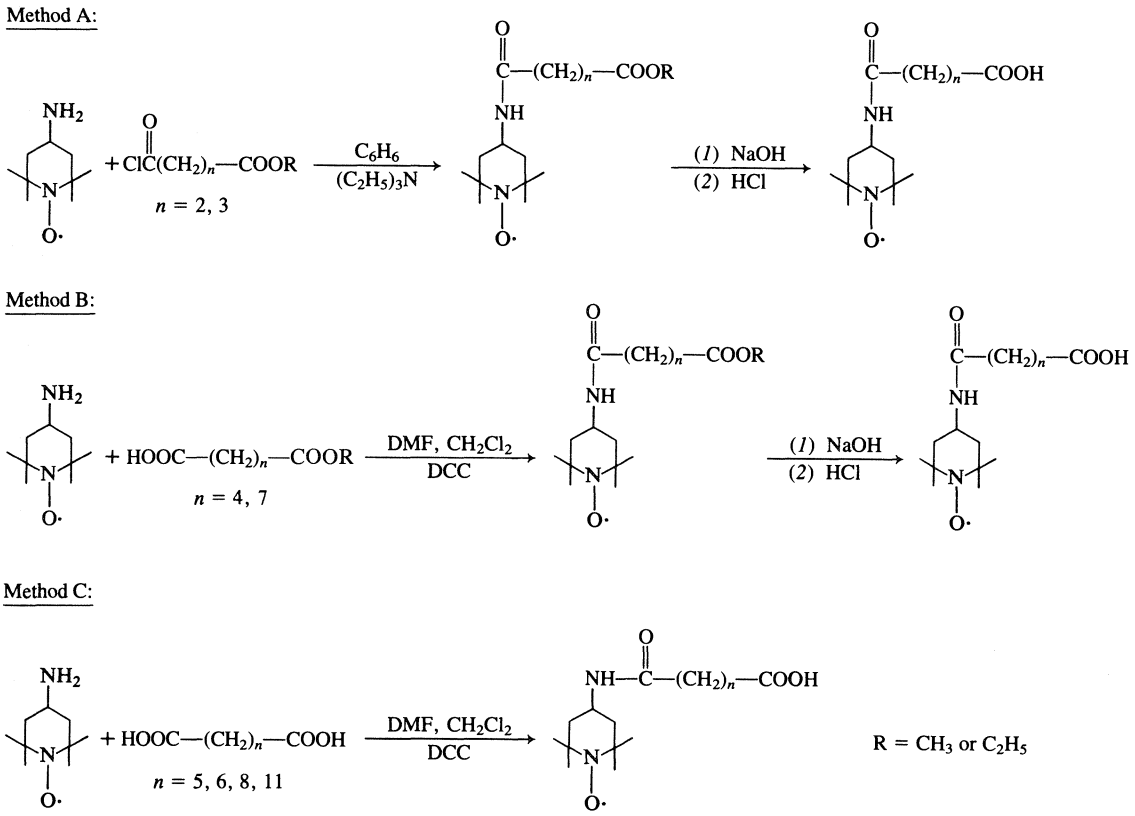

FIG. 1. Reaction schemes for synthesis of the spin labeled acids.

for the other chain lengths. The diacids can react with two molecules of the nitroxide label to yield a biradical and the yield of the desired product was lower than that from molecules in which one of the carboxylic acid groups was blocked with an ester linkage. Synthesis of the half esters of these molecules could have been carried out but the overall yield after this additional reaction would have been comparable to the yield obtained when the diacid was used directly.

All of the diacids and half acid esters were obtained from Aldrich Chemical Co. and used without further purification. The 2,2,6,6-tetramethyl-4-aminopiperidine-1-oxy was synthesized by the technique of Rozantsev (4). Illustrations of the techniques used in the various reaction sequences are given below.

*Method A: reaction of half ester, half acid chlorides (*n = *2, 3) with the nitroxide radical*

A solution of 0.23 g (1.4 mmol) of the nitroxide radical in 1 mL of dry benzene was slowly added to a stirred solution of 0.22 g (1.4 mmol) of ethylsuccinyl chloride in 1 mL of dry benzene and 0.5 mL of triethylamine (TEA) held at 0°C. The reaction mixture was allowed to come to room temperature and stirred for an additional 12 h. Thin-layer chromatography (silica gel, $CH_2Cl_2$ or EtOAc) indicated completion of the reaction. Two milliliters of benzene were added to the reaction mixture and the TEA·HCl was removed by filtration. The TEA·HCl was washed with two 5-mL aliquots of ether and these washings were combined with the original filtrate. The filtrate was evaporated to dryness under vacuum to yield 0.4 g (95%) of a red oil. This oil (spin labeled ethylsuccinate) was saponified without further purification. Attempts at washing the oil with water resulted in lower yields. The spin labeled ethylsuccinate (0.33 g, 1.09 mmol) was dissolved in 5 mL of 95% ethanol and a solution containing 0.80 g (20 mmol) of NaOH in a minimum amount of 50% ethanol was added. This solution was refluxed for 18 h and then the solvent was removed by vacuum evaporation. The resulting solid was dissolved in 20 mL of 2 *N* NaOH and this solution was washed with two 5-mL aliquots of chloroform. The solution was cooled to 0°C and the pH was adjusted to 2 by addition of 1 *N* HCl. The acidified solution was extracted with 20-mL aliquots of chloroform and two 20-mL aliquots of EtOAc. The combined extracts were dried over anhydrous $MgSO_4$ and the solvent was removed under reduced pressure to yield an orange solid. Recrystallization of this material from EtOAc and petroleum ether gave 0.24 g (80%) of yellow-orange spin labeled acid (mp 154–157°C). The overall yield for the two reactions to produce the desired product was 76%. In cases in which the half methyl ester of a dibasic acid was used as an initial reactant, methanol was used in place of ethanol in the saponification.

*Method B: reaction of half ester, half acids (*n = *4, 7) with the nitroxide radical*

A dicyclohexyl carbodiimide (DCC) solution containing 5.19 g (25 mmol) in 10 mL of $CH_2Cl_2$ was added to a stirred solution of 3.56 g (22.5 mmol) of mono-methyladipate in 5 mL of $CH_2Cl_2$ at 0°C. A white solid formed in about 15 min. A solution of 3.8 g (22 mmol) of the nitroxide radical in 10 mL of $CH_2Cl_2$ was slowly added to this mixture while the temperature was maintained at 0°C. The temperature was allowed to rise to room temperature

For personal use only.

and the mixture was stirred for 24 h. The precipitate was filtered, washed with two 10-mL aliquots of $CH_2Cl_2$, and the filtrate was vacuum evaporated to yield a thick red oil. This oil was dissolved in chloroform and quickly washed with 15 mL of water, 15 mL of 5% $NaHCO_3$, two additional 15-mL aliquots of water, and dried over anhydrous $MgSO_4$. Thin-layer chromatographic examination (silica gel, $CHCl_3$, EtOAc, and $CH_3OH$) showed that more than one component was present in this solution. The solution was concentrated under reduced pressure and the resulting red oil was separated on a silica gel column using either EtOAc or 10% $CH_3OH$ in $CH_2Cl_2$ as eluant to obtain 6.25 g (90%) of the spin labeled adipic acid methyl ester as a thick red oil. The ester was saponified using the general technique described under method A.

*Method C: reaction of diacids (n = 5, 6, 8, 11) with the nitroxide radical*

A solution of DCC (5.64 g, 27 mmol, in a minimum volume of dry DMF) was added to a stirred solution of 6.18 g (38 mmol) of pimelic acid in 10 mL of dry DMF at 0°C. A white crystalline precipitate formed in about 45 min. At this point 4.5 g (26 mmol) of the nitroxide radical in 5 mL $CH_2Cl_2$ was slowly added at 0°C. The reaction mixture was stirred at room temperature for 48 h and the white precipitate was removed by filtration. The precipitate was washed with three 10-mL aliquots of $CHCl_3$ and the combined filtrate was concentrated under vacuum. The resulting thick red oil was dissolved in 90 mL of $CHCl_3$ and insoluble white crystals were removed by filtration. The solution was extracted with three 60-mL aliquots of 10% NaOH and the NaOH extracts were combined, cooled to 0°C, and the pH was adjusted to 2 by titration with concentrated HCl. The acidified solution was extracted with four 60-mL aliquots of chloroform and two 60-mL aliquots of EtOAc. The extracts were washed separately with three 30-mL aliquots of water, dried over anhydrous $MgSO_4$, combined, and the solvent was removed by vacuum evaporation to yield 3.75 g (46%) of an orange-red solid (mp 105–121°C). Thin-layer chromatographic examination (silica gel, $CHCl_3$, EtOAc, $CH_3OH$, and 6% $CH_3OH$ in $CH_2Cl_2$) showed this solid to contain small amounts of impurity. The mixture was separated on a silica gel column with either 6% or 10% $CH_3OH$ in $CH_2Cl_2$ which yielded 2.05 g (25%) of the product. After evaporation of the eluant from the column one always obtained a thick red oil. Addition of about 5 mL of EtOAc to this oil yielded a crystalline product, mp 114–117°C. Recrystallization from EtOAc and petroleum ether yields pure spin labeled pimelic acid, mp 118–121°C.

*Nuclear magnetic resonance spectra*

In order to obtain high resolution nmr spectra of the molecules for analytical purposes, it is necessary to reduce the nitroxide radical to a hydroxyl amine. The reduction was carried out in an nmr sample tube in which 30 to 50 mg of a given spin label was dissolved in 1 mL of DMSO-$d_6$. A solution (15 μL) of 85% hydrazine was added as the reducing agent. The reduction led to formation of gas bubbles ($N_2$) and loss of color from the solution. The reaction was complete in 3–5 h and the nmr spectra were taken. All of the nmr spectra showed the following general characteristics: a sharp singlet with a shoulder (1.12 to 1.18 δ) from the 12 methyl protons on the piperidine ring, a broad doublet (7.8 to 8.0 δ) from the amide proton, and a group of overlapped lines (1.2 to 2.2 δ) whose area corresponded to the protons in the methylene chain. Addition of 0.25 mL of $CDCl_3$ to the solution revealed an additional peak from the single carboxylic acid proton (8.1–8.15 δ).

*Properties of specific labels*

*Compound* ***1***, $n = 2$, prepared by method A; yield 76%; mp 154–157°C; ir (KBr): 3475, 3000, 2960, 1740, 1645, 1555 $cm^{-1}$; nmr δ: 1.1 (12 H), 7.9 (1 H); *Anal.* calcd. for $C_{13}H_{23}N_2O_4 \cdot 1/2H_2O$: C 55.74, H 8.60, N 9.98; found: C 56.29, H 8.54, N 9.89.

*Compound* ***2***, $n = 3$, prepared by method A; yield 73%; mp 117–120°C; ir (KBr); 3460, 3000, 1710, 1625, 1575 $cm^{-1}$; nmr δ: 1.1 (12 H), 7.8 (1 H); *Anal.* calcd. for $C_{14}H_{25}N_2O_4 \cdot 1/2H_2O$: C 57.32, H 8.92, N 9.54; found: C 57.64, H 8.83, N 9.36.

*Compound* ***3***, $n = 4$, prepared by method B; yield 55%; mp 99–101°C; ir (KBr): 3340, 2970, 2880, 1695, 1610, 1560 $cm^{-1}$; nmr δ: 1.1 (12 H), 7.7 (1 H); *Anal.* calcd. for $C_{15}H_{27}N_2O_4$: C 60.18, H 9.09, N 9.36; found: C 60.19, H 9.15, N 9.20.

*Compound* ***4***, $n = 5$, prepared by method C; yield 25%; mp 118–121°C; ir (KBr): 3395, 2960, 2890, 1730, 1640, 1550 $cm^{-1}$; nmr δ: 1.15 (12 H), 7.4 (1 H); *Anal.* calcd. for $C_{16}H_{29}N_2O_4$: C 61.32, H 9.33, N 8.94; found: C 60.83, H 9.45, N 8.78.

*Compound* ***6***, $n = 7$, prepared by method B; yield 42%; mp 98–99°C; ir (KBr): 3380, 3340, 2940, 2860, 1720, 1630, 1560 $cm^{-1}$; nmr δ: 1.15 (12 H), 7.65 (1 H); *Anal.* calcd. for $C_{18}H_{33}N_2O_4$: C 63.31, H 9.74, N 8.20; found: C 63.41, H 9.88, N 8.16.

*Compound* ***7***, $n = 8$, prepared by method C, catalytic amounts of 4-dimethylpyridine were used in this reaction; yield 25%; mp 99–101°C; ir (KBr): 3350, 2935, 2860, 1700, 1610, 1565 $cm^{-1}$; nmr δ: 1.1 (12 H), 7.7 (1 H); *Anal.* calcd. for $C_{19}H_{35}N_2O_4$: C 64.19, H 9.92, N 7.88; found: C 63.74, H 10.14, N 7.67.

*Compound* ***8***, $n = 11$, prepared by method C, catalytic amounts of 4-dimethylpyridine were used in this reaction; yield 26%; mp 114–116°C; ir (KBr): 3380, 3320, 2935, 2860, 1720, 1630, 1560 $cm^{-1}$; nmr δ: 1.2 (12 H), 7.5 (1 H); *Anal.* calcd. for $C_{22}H_{41}N_2O_4$: C 66.46, H 10.36, N 7.05; found: C 66.17, H 10.67, N 6.95.

## Electron spin resonance spectra

The esr spectra of this group of radicals in solution at room temperature were essentially identical ($A(N) = 16.2$ G; $g = 2.005$ in 50:50 methanol–ethanol). Variable temperature studies of two of the radicals ($n = 2$ and 11) were conducted to obtain information about the rotational motion of the labels as a function of the viscosity of the solvent. Figure 2 shows spectra of these two radicals at a series of temperatures while Fig. 3 shows plots of the ratio of intensities of the high field to center line and the low field to center line as a function of temperature. The signal intensities are inversely proportional to the square of the linewidth and measurement of relative intensities gives a good measure of line broadening produced by incomplete averaging of anisotropic interactions. If the molecules tumble isotropically so that the components of the dipolar and $g$ anisotropy are averaged equally, one expects to observe the greatest broadening in the high field ($m = -1$) line, the second greatest broadening in the low field ($m = 1$) line, and the least broadening in the center line ($m = 0$) (5). The experimental results show the greatest broadening in the high field line, the second greatest broadening in the center line, and the least broadening in the low field line (Fig. 3).

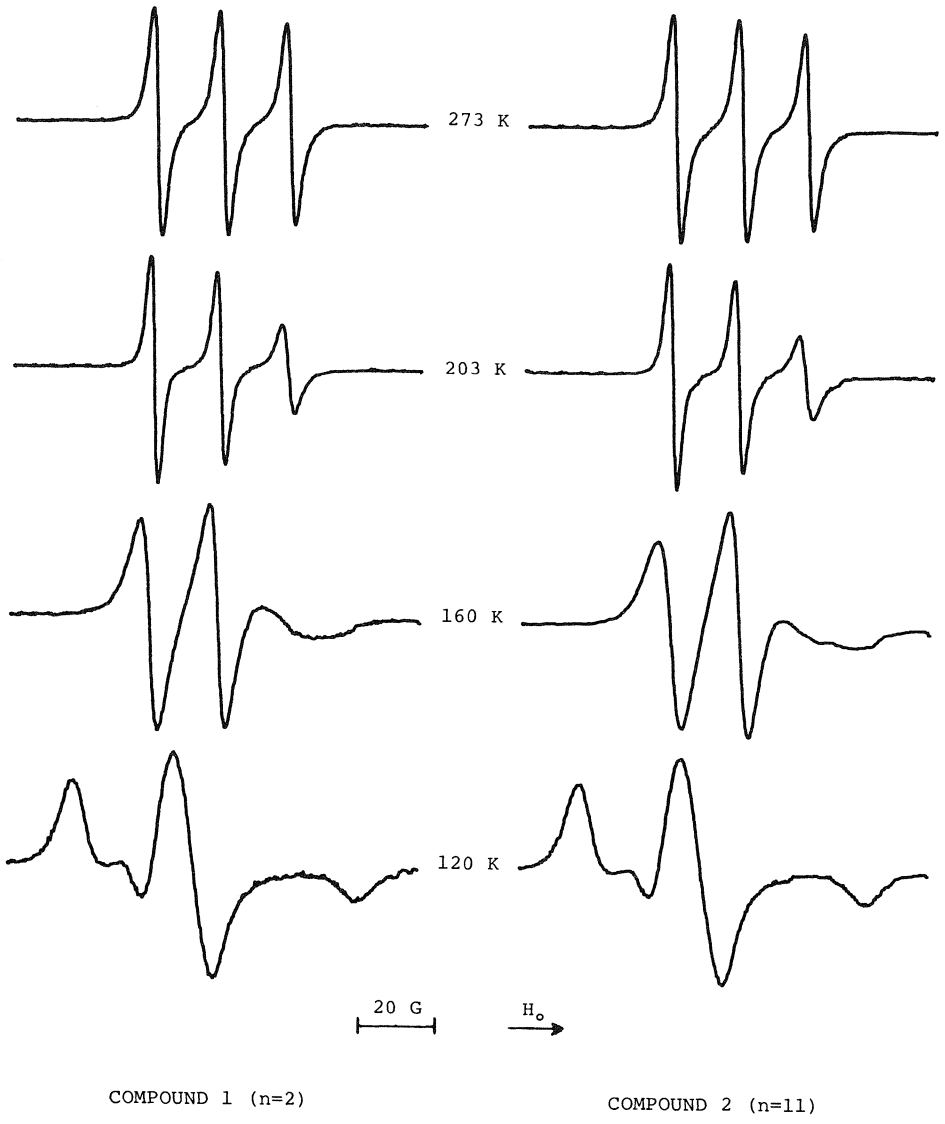

FIG. 2. The esr spectra of compound **1** ($n$ = 2) and compound **8** ($n$ = 11) in 50:50 methanol–ethanol as a function of temperature.

This type of behavior is observed when rotation around the $x$ axis (defined by the N—O bond direction) is preferred over rotation around the other two axes (6) (Fig. 4). The $x$ axis is roughly colinear with the direction (long axis) of the aliphatic connecting chain if this chain extends out into solution and is not wrapped back around the radical. This type of motion is often observed from labels with long chains which are introduced into lipid bilayers where motion around the long axis is much more facile than rotation around the other axes. The motion of the longer chain molecules ($n$ = 11) appears to be slightly slower than that of the short chain acid ($n$ = 2) at a given temperature, which may reflect differences in the steric bulk or configuration of the connecting chain. One cannot obtain values for motional correlation times from the simple formulas used for isotropic rotation and a complete lineshape analysis would be necessary to determine accurate correlation times.

## Conclusions

A group of spin labeled long chain aliphatic acids has been synthesized and characterized by their ir and esr spectra, by elemental analysis, and by the nmr spectra of hydroxyl amines formed by reduction of the radicals. The esr results indicate that molecules preferentially rotate around the $x$ mo-

# The basicity of phosphines

TIM ALLMAN[1] AND RAM G. GOEL[2]

*Guelph-Waterloo Centre for Graduate Work in Chemistry, Guelph, Ont., Canada N1G 2W1*

Received July 27, 1981

TIM ALLMAN and RAM G. GOEL. Can. J. Chem. **60**, 716 (1982).

The basicities of the triarylphosphines $P(4\text{-}XC_6H_4)_3$ (X = Cl, F, H, $CH_3$, $CH_3O$, $(CH_3)_2N$), $P(3\text{-}CH_3C_6H_4)_3$, and $P(2\text{-}CH_3C_6H_7)_3$ as well as the trialkylphosphines $P(t\text{-}Bu)_3$ and $PCy_3$ have been measured by the nitromethane titration method. The range of basicity available by aryl substitution is very large, being $pK_a = 8.65$ for X = $(CH_3)_2N$ to 1.03 for X = Cl. The most basic phosphine is $P(t\text{-}Bu)_3$ whose $pK_a = 11.40$. The measured basicities correlate well with $\sigma_p$, $\sigma^\phi$, and ν as well as with the lone pair ionisation potentials of the triarylphosphines. Generally the $^1H$, $^{31}P$, and $^{13}C$ nmr spectral parameters of the free and protonated phosphines do not correlate well with $pK_a$.

TIM ALLMAN et RAM G. GOEL. Can. J. Chem. **60**, 716 (1982).

Utilisant la méthode de titration au nitrométhane, on a mesuré les basicités de triarylphosphines $P(4\text{-}XC_6H_4)_3$ (X = Cl, F, H, $CH_3$, $CH_3O$, $(CH_3)_2N$), $P(3\text{-}CH_3C_6H_4)_3$ et $P(2\text{-}CH_3C_6H_7)$ et des trialkylphosphines $P(tert\text{-}Bu)_3$ et $PCy_3$. L'éventail des basicités disponibles pour la substitution des groupes aryles varie de $pK_a = 8{,}65$ pour X = $(CH_3)_2N$ à 1,03 pour X = Cl. La phosphine la plus basique est la $P(tert\text{-}Bu)_3$ dont le $pK_a = 11{,}40$. Les basicités mesurées sont en bon accord avec $\sigma_p$, $\sigma^\phi$ et ν ainsi qu'avec les potentiels d'ionisation des paires libres des triarylphosphines. D'une façon générale, les paramètres des spectres rmn du $^1H$, du $^{13}C$ et du $^{31}P$ des phosphines libres et protonées ne sont pas en accord avec les $pK_a$.

[Traduit par le journal]

## Introduction

Tertiary phosphines form stable complexes (1–4) with many main group Lewis acids as well as with transition metals in their various oxidation states. Due to very useful catalytic properties (5) of a number of phosphine complexes of transition metals, tertiary phosphines have become very widely studied ligands.

By analogy with the bonding of metal carbonyls, it has long been proposed that phosphines can act as σ donors as well as π acceptors (6–11). To test this hypothesis and to evaluate the electronic effects of phosphines on the properties of their complexes, tertiary phosphines with a variety of substituents on phosphorus have been synthesised and the electronic effects in their complexes have been investigated (1–4).

Tolman has proposed an empirical electronic parameter, ν, based on substituent group contributions, $\chi_i$, derived from the CO stretching frequency belonging to the $A_1$ mode of the complexes $Ni(CO)_3PR_3$ (7). These are intended to be a quantitative measure of electronic effects.

Other workers (8–13) have used the inductive and mesomeric effects of the substituents attached to phosphorus to infer the electronic effects of phosphines. For example, the magnitude of $^1J$(M—P) for complexes of tungsten(0) (8) and platinum(II) (9) with the phosphines $PR_nPh_{3-n}$ (R = alkyl, Ph = phenyl) increases as $n$ decreases but the opposite is true for some mercury(II) complexes (10). From these results it has been concluded (8–10) that the magnitude of $^1J(^{183}W—^{31}P)$ or $^1J(^{195}Pt—^{31}P)$ increases with decreasing basicity whereas the $^1J(^{199}Hg—^{31}P)$ values vary in the opposite manner. Using a Hammett-type relationship, Kabachnik and co-workers (14) have derived the substituent parameters $\sigma^\phi$ which have also been used as a measure of electronic effects of phosphines. It has been shown (15) that the reactivity of the complexes $IrCl(CO)L_2$ (L = triarylphosphine) toward oxidative addition of methyl iodide is linearly dependent upon the $\sigma^\phi$ values for the substituents at phosphorus.

Phosphines, like amines, are also Brønsted bases and the electronic effects of the substituents on the metal–phosphorus bond can be quantitatively measured in terms of the basicity of the phosphines toward a proton. It has been shown (16) that the half neutralisation potentials (HNP) for the water-insoluble phosphines in a non-aqueous solvent can be accurately correlated with their aqueous basicities. The $pK_a$ values for a number of trialkyl phosphines have been determined by this method (16).

As part of a systematic investigation of the electronic and steric effects in the phosphine complexes of $d^8$ and $d^{10}$ metals, the metal–phosphorus nuclear spin–spin couplings and/or metal–phosphorus stretching frequencies for the platinum(II) (17), mercury(II) (18), cadmium(II) (19), and silver(I) (20) complexes of tri-*tert*-butylphosphine,

tricyclohexylphosphine, and a number of substituted triarylphosphines have been examined in this laboratory. The most significant finding of these investigations is that, contrary to conclusions arrived at from earlier studies, the magnitude of $^1J$(M—P) for the *para* substituted triarylphosphine complexes of platinum(II) (17) as well as mercury(II) (18*g*) and cadmium(II) (19*b*) halides increase with increasing electron releasing power of the aryl group. It is therefore evident that $^1J$(M—P) is not simply related to the electron-donating abilities of phosphines, which are more reliably measured by their basicities towards a proton. Thus, the dependence of the spectral parameters and other properties of the complexes can be evaluated quantitatively from the knowledge of the relative $pK_a$ values of the phosphines. The $pK_a$ values for the ten phosphines used in the nmr studies have been determined in the present work. Correlations between the phosphine basicity and the $^1H$, $^{31}P$, and $^{13}C$ nmr spectral parameters of the phosphines as well as the $^1J(^{31}P—^1H)$ values for the protonated phosphines have also been examined. The topic of substituent contributions to the $^{31}P$ chemical shift has been dealt with by others (41).

## Results and discussion

### *(a) Basicities of phosphines*

The $pK_a$ values for the ten phosphines examined in this study are given in Table 1 along with some of their $^1H$ and $^{13}C$ nmr data. The $pK_a$ values for $P(c\text{-}C_6H_{11})_3$ and $P(4\text{-}CH_3OC_6H_4)_3$ are in good agreement with the values reported by Streuli (16*a*).

For the triarylphosphines the order of basicity is found to be the same as the order of the Hammett $\sigma_p$ and $\sigma_m$ parameters (21) for the substituents on the phenyl groups. $P(4\text{-}FC_6H_4)$ is found to be slightly more basic than $P(4\text{-}ClC_6H_4)_3$. This can be attributed to the more efficient conjugation of the non-bonding electrons on fluorine with the ring. In spite of the powerful inductive effect of fluorine, a significant amount of electron density is donated back to the ring. The three tritolylphosphines are all more basic than triphenylphosphine and their $pK_a$ values occur within a small range. The higher basicities of $P(4\text{-}CH_3OC_6H_4)_3$ and $P(4\text{-}(CH_3)_2\text{-}NC_6H_4)_3$ are expected because of the known electron donating abilities of the substituents. The two trialkylphosphines are significantly more basic than most of the triarylphosphines. They are, in fact, the most basic phosphines whose $pK_a$'s have been measured to date. The very high value for $P(t\text{-}C_4\text{-}H_9)_3$ compared to $P(c\text{-}C_6H_{11})_3$ is consistent with the greater electron-donating ability of the *t*-butyl groups.

It should be noted here that these results are not entirely consistent with some previous work, particularly with respect to the $pK_a$ value for $P(4\text{-}ClC_6H_4)_3$. Goetz and Sidhu (22) measured the $pK_a$'s of two classes of phosphines, $P(C_6H_5)_2(4\text{-}XC_6H_4)$ and $P(4\text{-}XC_6H_4)_3$, by a titration method using HCl in 80% ethanol/water. For the first class they found a good correlation between Hammett's constants and the measured $pK_a$ values. The latter class gave the order of decreasing basicity ($P(4\text{-}CH_3OC_6H_4)_3 > P(4\text{-}ClC_6H_4)_3 > P(C_6H_5)_3$, which is different from ours.

Using a different technique, Hopkins and coworkers (23) also studied several symmetrical 4-substituted triarylphosphines. Using an infrared technique, they measured the equilibrium constant

for eq. [1] by observing the free and H-bonded ν(OH) bands in dilute $CS_2$ solution.

[1] $F_3C\langle\bigcirc\rangle O{-}H + PAr_3 \overset{K}{\rightleftharpoons} F_3C\langle\bigcirc\rangle O{-}H\text{---}:PAr_3$

The rationale was that the more basic phosphines would H-bond more extensively to the phenol. This experiment gave an order of decreasing basicity of $P(4\text{-}CH_3OC_6H_4)_3 \gg P(4\text{-}CH_3C_6H_4)_3 > P(4\text{-}ClC_6H_4)_3 > P(C_6H_5)_3$.

While it is difficult to criticise the methodology of the former study, the latter is open to various interpretations. One possible explanation for the deviation of Hopkins' order from ours is that the substituents which are themselves capable of H-bonding (—Cl and —$OCH_3$) are doing so and raising the apparent basicities of the phosphines. In support of our study is one in which the equilibrium in the reaction of phosphines and tritylperchlorate (eq. [2]) was

[2] $Ar_3P + Ar_3{}^+C + ClO_4{}^- \leftrightharpoons Ar_3P^+{-}CAr_3 + ClO_4{}^-$

studied (24). The more basic phosphines shifted the reaction to the right to give an order of decreasing basicity:

$$P(4\text{-}CH_3C_6H_4)_3 > P(C_6H_5)_3 > P(4\text{-}ClC_6H_4)_3$$

Also in support of our work, and more directly comparable, is a protonation study by Grim and Yankowsky (11). They were able to qualitatively assign basicities to eighteen triarylphosphines based on whether the doublet due to the phosphonium proton could be seen by $^1H$ nmr after bubbling HBr(g) through $CH_2Cl_2$ solutions of the phosphines. Their results are consistent with our study; the phosphonium proton was most easily observed with the most basic phosphines.

Correlations of the basicities of phosphines with Hammett's $\sigma_m$, parameters (22) and to Tafts σ* parameters (16*b*) have been demonstrated. Correlations using these constants are not possible, however, when the groups attached to phosphorus are mixed alkyl–aryl or are not organic. The basicities of these other phosphines can be correlated with Kabachnik's $\sigma^\phi$ constants (14). These values are proportional to Hammett's σ constants for substituted aromatic groups but also include a wide range of alkyl, alkoxy, and halide groups. Because these constants are derived from the ionisation of phosphorus acids they should, at least in principle, be better constants to use with phosphorus compounds.

The correlation between $pK_a$ and $\sigma^\phi$ for the phosphines in this study is excellent (see Fig. 1). Mastryukova and Kabachnik (14) have pointed out that the data of Henderson and Streuli fall on one line when $\sigma^\phi$ is used rather than the three lines obtained when $pK_a$ is plotted vs. σ* (16*b*).

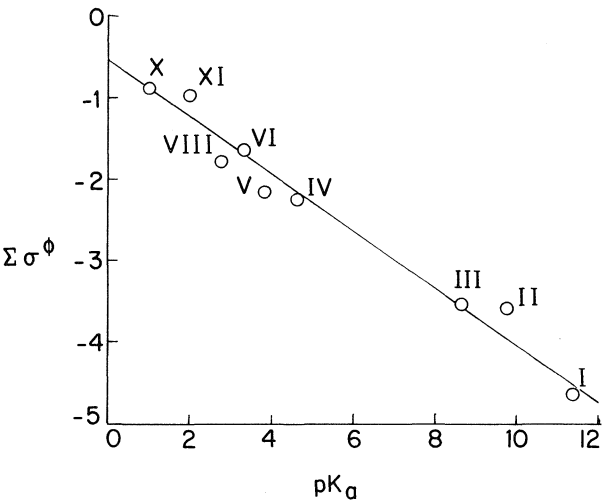

FIG. 1. Plot of Kabachnik's $\Sigma\sigma^\phi$ vs. $pK_a$. Numbers correspond to those in the tables.

$$\Sigma\sigma^\phi = -0.351pK_a - 0.540,$$
$$r = -0.986.$$

Tolman has proposed constants for the phosphines, $\chi_i$, which also reflect the changes in basicity very well (7*a*). In his paper Tolman gives a plot of $\chi_i$ vs. $\sigma^\phi$ which shows significant deviation from linearity in the region of low basicity, particularly in the region where the phosphites are found. As shown in Fig. 2, for the phosphine used in this study the correlation between $pK_a$ and $\chi_i$ is linear, probably because the range of basicities of our phosphines is smaller.

It is reasonable that the phosphorus lone pair ionisation potential (IP) should reflect the variations with ring substitution that we have seen by these other techniques. The lone pair IP of several 4-substituted triarylphosphines have been determined recently by ultraviolet photo-electron spectroscopy. Weiner and Lattman (25) found a good correlation between lone pair IP and $\sigma_p$ but point out that this implies that there are no major changes in hybridisation at phosphorus through the series. Another study (26) corroborates this by showing that while there may be good correlations within a series of closely related phosphines, it is not a good technique for determining the relative basicities of very different phosphines such as $PCl_3$ and $(P(C_6H_5)_3$. Indeed, while the IP of all the triarylphosphines used in this study correlate well with $pK_a$ (Fig. 3), the point for $P(t\text{-}C_4H_9)_3$ is far from the line. The C—P—C angle in the triarylphosphines is probably close to the 103.0° of $P(C_6H_5)_3$ (27) while the angle in $P(t\text{-}C_4H_9)_3$ is larger at 109° (26, 28).

*(b) Nuclear magnetic resonance data*

*(i) $^1J$(P—H) in the protonated phosphines*

Previous workers have generated the phosphonium ions by dissolving the phosphines in very strongly acid media such as 100% $H_2SO_4$ (12) or $HSO_3F$ (13) or by bubbling HBr(g) through solutions of the phosphines in $CH_2Cl_2$. We find that the ions can be observed easily in trifluoroacetic acid solution. The nmr data for these ions are given in Table 1.

The coupling constants decrease slightly in the triaryl series with increasing basicity as do the chemical shifts, but the correlation is poor. In light of the wide range of basicity in this series the small range of $^1J$(P—H) is surprising. The two trialkylphosphines give coupling constants that are significantly lower than the others. However, these data are consistent with those from previous studies (11–13); some selected data are presented in Fig. 4. It can be seen clearly that $^1J$(P—H) decreases with increasing basicity (decreasing $\Sigma\sigma^\phi$) of the phosphine or phosphite. Put it in another way, $^1J$(P—H) increases with increasing electronegativity of the substituents in a reasonably smooth manner. This trend is indeed well known for $^1J$(C—H) in various organic compounds. For example, $^1J$(C—H) decreases in the series $HCF_3 > HCCl_3 > HCBr_3 > HCI_3$. These results are consistent with Bent's rule (29) which states that *p* character tends towards the orbitals with the most electronegative substituents. Because the sum of *s* character of the carbon orbitals must be exactly 1,

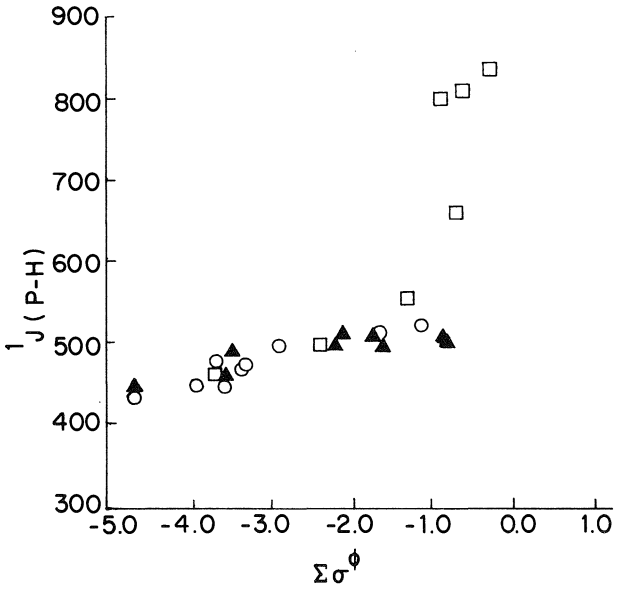

FIG. 4. Plot of $^1J$(P—H) of the protonated phosphines vs. p$K_a$. ▲, this study; ○, ref. 14, □, ref. 13.

For personal use only.

the C—H bond will have more *s* character in $HCF_3$ than in $HCCl_3$. The higher coupling constant implies that the Fermi contact mechanism is dominant in determining these coupling constants (30, 31). Extension of this reasoning to organophosphines is probably sound because no multiple bonding between phosphorus and hydrogen is possible and it has generally been accepted that M—H coupling is explained by this mechanism (32). Supporting this view is the observation that $^1J$(P—H) correlates well with the calculated charges on phosphorus and hydrogen in some protonated phosphites (33).

*(ii)* $^1$J*(P—C) in the free phosphines*

The observed trend in $^1J$(P—C) is not as easily explained. The Fermi contact term, although important, has been found to contribute less as the coupled atoms become heavier and where there is multiple bonding between them (34). If it is assumed that the sign of the coupling constant is merely a label defining the origin of the coupling and that it is the magnitude of the coupling constant that is important, then the trend in $^1J$(P—C) vs. p$K_a$ is not explicable in terms of changes in the Fermi contact term. Rehybridisation of phosphorus in accordance with Bent's rule would increase the *s* character of the P—C bond with increasing basicity of the phosphine thus giving a higher $^1J$(P—C). We see the opposite trend in the triaryl phosphine data in Fig. 5. These changes in the C—P—C angle are likely to be small, if indeed they do exist. So far, there are not enough crystallographic data to know. Much larger changes in hybridisation can be forced by including the phosphorus atom in a heterocyclic ring or by replacing an aryl group by cyclohexyl or *t*-Bu. It has been found that changes in $^1J$(P—C) are consistent with rehybridisation at phosphorus and the Fermi contact mechanism in such ring systems (35).

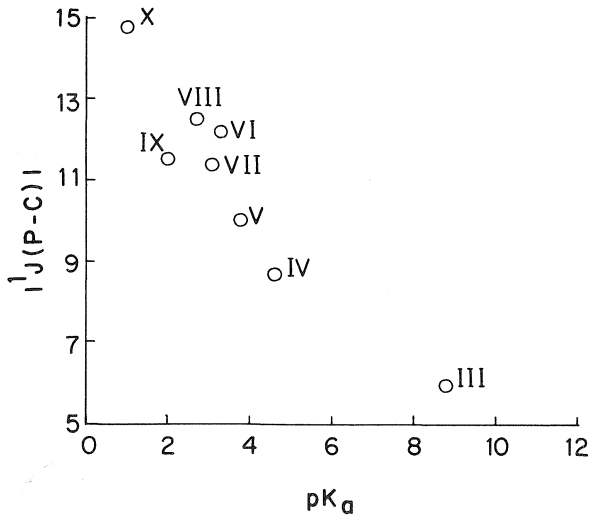

FIG. 5. Plot of $|^1J$(P—C)| vs. p$K_a$ for the triarylphosphines. Numbers correspond to those in the tables.

What can be learned from this is that the interpretation of coupling constants is by no means easy. The other factors in the Fermi contact expression, the electron density at the nucleus and the triplet excitation energy, can only be guessed at and the contributions of the orbital and dipolar mechanisms are unknown. It is likely that several contributions to the coupling constant are changing through the aryl phosphine series and not all in the same direction, thus, giving a correlation of $^1J$(P—C) with p$K_a$ which probably means very little by itself.

## Conclusions

We have shown that substituents on the phenyl rings of triarylphosphines can bring about large changes in the basicities of these phosphines. They should be useful for studies where electronic changes without significant concurrent steric changes are desired. The measured basicities correlate well with $\sigma_p$, $\sigma^\phi$, and $\nu$ as well as with the lone pair ionisation potentials for members of a series of similar phosphines. Generally, the nmr spectral parameters do not correlate well with the measured basicities and do not provide an alternate method of determining basicities. Of all the methods devised to date the nitromethane titration appears to be the most consistent and reasonable method for the measurement of basicities of phosphines.

## Experimental section

*(a) Materials*

Triphenylphosphine from Eastman Kodak was recrystallised twice from hot ethanol and dried *in vacuo*. Tris(4-dimethylaminophenyl) phosphine from Strem Chemicals was purified by recrystallisation from hot benzene under $N_2$. Tricyclohexylphosphine was used as received from Pressure Chemical Co. Tri-*tert*-butylphosphine was prepared as previously reported (40). All other phosphines were prepared as described in (*b*). Purity of each phosphine was established by melting point and $^1$H and $^{31}$P nmr spectral measurements and, except for tri-*tert*-butylphosphine and tricyclohexylphosphine, by elemental analysis. Trifluoroacetic acid from Eastman Kodak was distilled onto molecular sieves and stored in a desiccator. Reagent grade nitromethane and perchloric acid were used as received.

*(b) Synthesis of triarylphosphines*

The preparation of $P(4\text{-}ClC_6H_4)_3$ is described as a representative procedure for the preparation of the triarylphosphines. All glassware was oven-dried and flushed with dry dinitrogen before use. The starting material, 1-bromo-4-chlorobenzene (100 g, 0.52 mol) was dissolved in ~ 100 mL of reagent grade THF from a freshly opened bottle. This solution was slowly added to a 500 mL 3-necked flask containing magnesium turnings (12.7 g, 0.52 mol) and THF (~ 50 mL). The reaction started spontaneously after about 2–3 min. The reagent solution was added continu-

TABLE 2. Analytical data[a]

| | Compound | Melting point (°C) | C Calcd. | C Found | H Calcd. | H Found | δ($^{31}$P) (ppm) | δ($^{1}$H)$_{CH_3}$[b] (ppm) |
|---|---|---|---|---|---|---|---|---|
| I | P(*t*-$C_4H_9$)$_3$ | 27–29 | — | — | — | — | 56.7 | 3.12[c] |
| II | P(*c*-$C_6H_{11}$)$_3$ | 76–77 | — | — | — | — | 8.8 | — |

[a]The analytical data are in agreement with those in ref. 41.
[b]These methyl shifts are included because they are diagnostic and show significant shifts on coordination of the phosphine. All the aryl phosphines showed aromatic multiplets around δ = 7. The spectrum of **II** was an unresolved and very complex multiplet between δ = 1.0 and δ = 3.0.
[c]$^3J$(P—H) = 9.5 Hz.
[d]%N = 10.7 (calcd.) 11.2 (found).
[e]Quartet. $^5J$(P—F) = 4.4 Hz.

ously at a rate necessary to maintain reflux. The total time of addition was about 1 h. Using the same dropping funnel, a solution of $PCl_3$ (23.9 g, 0.17 mol, 15.2 mL) in 50 mL THF was prepared and added slowly, also at a rate necessary to maintain reflux. Up to this point all reactions were done under dry nitrogen. Enough water was added to produce two layers in the flask and the organic layer was removed and filtered. The aqueous portion was extracted twice with 50 mL portions of diethyl ether which were also filtered and added to the first organic portion. The aqueous portion was discarded and the organic solution was evaporated. The residue, which had a definite orange colour, was recrystallised from hot ethanol repeatedly until a white crystalline product was obtained. Elemental analyses were performed by Guelph Chemical Laboratory, Guelph, Ontario. Analytical data are given in Table 2 which also contains the $^{31}$P—{$^1$H} and $^1$H nmr data.

*(c) Determination of basicities*

The method of Streuli (16) was modified to suit the equipment and materials available in our laboratory. A solution of $HClO_4$ (0.2 *M*), prepared by adding reagent grade 70% $HClO_4$ (8.4 mL) to $CH_3NO_2$ (500 mL), was deoxygenated by bubbling dry $N_2$ through it for 30 min. Titrations were performed using a 5 mL self-filling burette attached to a source of $N_2$. The phosphines (~ 1 mmol per determination) were dissolved in $CH_3NO_2$ (100 mL) and the titration was followed using a Chemtrix digital pH–mV meter with a combination glass–calomel electrode. The best results were obtained when the electrode was allowed to sit in nitromethane a few hours before the titrations were performed. The endpoint was determined from a derivative plot and the half neutralisation potential (HNP) was recorded. Three separate determinations were made for each phosphine. Triphenylphosphine was used as a standard instead of diphenylguanidine. The difference, HNP(triphenylphosphine) − HNP(phosphine), was calculated. The ΔHNP used by Streuli is merely this value plus 573 mV which is the ΔHNP of triphenylphosphine when diphenylguanidine is used as a reference. This new value can now be used in the equation

$$pK_a = 10.12 - 0.0129(\Delta HNP)$$

where

$$pK_a = -\log_{10}[H^+][PR_3]/[HPR_3^+]$$

The value HNP(triphenylphosphine) was determined daily before the titrations. Tri-*tert*-butylphosphine, tricyclohexylphosphine, and tris(4-dimethylaminophenyl)phosphine were titrated under an atmosphere of oxygen-free nitrogen using deoxygenated solvent. The others were titrated in air. Smaller amounts (~ 0.3 mmol) of tricyclohexylphosphine and tris(4-dimethylaminophenyl)phosphine were used because of their low solubility in nitromethane.

Because of the possible ambiguity about the site of protonation of P(H-$(CH_3)_2NC_6H_4$)$_3$ the titration was continued past the first endpoint. A second equivalence point was found at four times the volume of titrant as for the first. Clearly the first endpoint was from the protonation of the phosphorus atom and the second was from the protonation of the nitrogen atoms.

The reproducibility of the titrations was equivalent to ± 0.05 $pK_a$ units.

*(d) Nuclear magnetic resonance measurements*

*(i) Measurements of $^1J$(P—H)*

The phosphonium ions were generated by dissolving the phosphines in dry trifluoroacetic acid to give clear colourless solutions. High phosphine concentrations tended to promote exchange of the phosphonium protons so that solutions were no more concentrated than necessary to observe the doublet due to the phosphonium proton. The $^1J$(P—H) values for the phosphonium ions of all the phosphines except tris(4-fluorophenyl)-phosphine were determined from their $^1$H nmr spectra measured at ambient temperature with a Varian T-60 nmr spectrometer using TMS as the internal reference. The $^1J$(P—H) value for protonated tris(4-fluorophenyl)phosphine was obtained from its $^{31}$P nmr spectrum run on a Bruker WP-60 FT nmr spectrometer using 85% $H_3PO_4$ as external reference.

*(ii) Spectra of the free phosphines*

All spectra but two ($^{13}$C of **VI** and **X**) were recorded on a Bruker WP-60 FT nmr spectrometer. The other two spectra were run on a Bruker WH-400 FT nmr spectrometer to remove the peak overlap which made assignments impossible in the low field spectra. The $^1$H and $^{13}$C spectra were run in $CDCl_3$ (aryl phosphines) or $C_6D_6$ (alkyl phosphines) using the deuterium lock and internal TMS as a reference. All $^{31}$P spectra were measured on concentrated $CH_2Cl_2$ solutions to which 10% v/v $C_6D_6$ was added to provide a deuterium lock. A capillary of 85% $H_3PO_4$ was used as an external reference. $^{13}$C and $^{31}$P spectra were proton decoupled using a broad band decoupler. All shifts are reported in the same sense; that is, positive shifts are to high frequency of the reference.

# Synthesis of 4,5-disubstituted imidazoles

GERRY KAVADIAS,[1] BING LUH, AND ROGER SAINTONGE
*Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1*

Received September 10, 1981

GERRY KAVADIAS, BING LUH, and ROGER SAINTONGE. Can. J. Chem. **60**, 723 (1982).

Introduction of a triphenylmethyl group on the nitrogen of imidazole-4,5-dicarboxylic acid esters or 4,5-dihydroxymethylimidazole resulted in deactivation of the functional group adjacent to the protecting group and allowed reactions to take place preferably or exclusively on the other functional group. Thus, dimethyl 1-triphenylmethylimidazole-4,5-dicarboxylate (**2**), on treatment with hydrazine and methylamine produced methyl 4-hydrazinocarbonyl-1-triphenylmethylimidazole-5-carboxylate (**3***a*) and methyl 4-methylaminocarbonyl-1-triphenylmethylimidazole-5-carboxylate (**3***b*), respectively. Reduction of **2** with lithium borohydride gave methyl 4-hydroxymethyl-1-triphenylmethylimidazole-5-carboxylate (**4***a*). Treatment of 4,5-dihydroxymethyl-1-triphenylmethylimidazole (**5***a*), with trimethylacetyl chloride and with acetic anhydride afforded 5-hydroxymethyl-4-trimethylacetoxymethyl-1-triphenylmethylimidazole (**6***a*), and 4-acetoxymethyl-5-hydroxymethyl-1-triphenylmethylimidazole (**6***c*), respectively. Oxidation of **5***a* with activated manganese dioxide produced the monoaldehydes **9** and **10** in a ratio of 11:1. A new mild process for deprotection of *N*-triphenylmethylimidazoles, compatible with acid sensitive groups in the molecule, is reported. The synthesis of several 4,5-disubstituted imidazoles is also described.

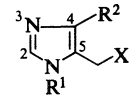
GERRY KAVADIAS, BING LUH et ROGER SAINTONGE. Can. J. Chem. **60**, 723 (1982).

L'introduction d'un groupe triphénylméthyle sur l'azote des esters de l'acide imidazoledicarboxylique-4,5 ou du dihydroxyméthyl-4,5 imidazole, provoque la désactivation du groupe fonctionnel voisin du groupe protecteur et induit des réactions préférentielles ou exclusives au niveau de l'autre groupe fonctionnel. Dans ces conditions, le triphénylméthyl-1 imidazoledicarboxylate-4,5 de méthyle réagit avec l'hydrazine ou la méthylamine pour donner soit l'hydrazinocarbonyl-4 triphenylméthyl-1 imidazolecarbonylate-1 de méthyle (**3***a*) ou le méthylaminocarbonyl-4 triphenylméthyl-1 imidazole carboxylate-5 de méthyle (**3***b*). Le composé **2**, en présence de borohydrure de lithium, conduit à l'hydroxyméthyl-4 triphénylméthyl-1 imidazolecarboxylate-5 de méthyle (**4***a*). Le dihydroxyméthyl-4,5 triphenylméthyl-1 imidazole (**5***a*) réagit avec le chlorure de triméthylacétyle ou l'anhydride acétique pour donner soit l'hydroxyméthyl-5 triméthylacetoxyméthyl-4 triphénylméthyl-1 imidazole (**6***a*) ou l'acétoxyméthyl-4 hydroxyméthyl-5 triphénylméthyl-1 imidazole (**6***c*). L'oxydation du composé **5***a* par le dioxyde de manganèse fournit les monoaldéhydes **9** et **10** dans un rapport de 11:1. On rapporte une nouvelle méthode de déprotection douce des *N*-triphénylméthylimidazoles qui est compatible avec les groupes sensibles aux acides. On décrit également la synthèse de plusieurs imidazoles substitués en positions 4 et 5.

[Traduit par le journal]

In a research project directed toward the syntheses of novel histamine H-2 receptor antagonists as potential antiulcer agents, structurally related to cimetidine (1), 4,5-disubstituted imidazoles of the general structure **1** were needed as intermediates.

Most syntheses of 4,5-disubstituted imidazoles are based on ring closure of α-diketones, α-hydroxy-, α-halogeno- or (under reducing conditions) α-oximinoketones. All these suffer from deficiencies such as difficulties in the syntheses of starting materials and low yields. Furthermore, the applicability of these processes is limited to the syntheses of products that can survive the vigorous conditions involved in the ring-closing step (2). It seemed of interest to investigate the possibility of an alternative synthesis which would utilize viable sources of starting materials with a preformed imidazole ring. This paper describes the synthesis of 4,5-heterodisubstituted imidazoles from the readily available dimethyl 4,5-imidazole dicarboxylate (**1**) and from 4,5-dihydroxymethyl imidazole (**5***b*).



**1**

$R^1$ = H; $R^2$ = $CO_2CH_3$, $CH_2OH$, CN, CHO, $CONHCH_3$, $CONHNH_2$, CH=CHCN; X = Cl, Br

The ester groups in **1** and the hydroxymethyl groups in **5***b* are chemically equivalent and therefore chemical modifications of these molecules invariably yield symmetrically disubstituted products. It appeared to us that the presence of a bulky triphenylmethyl group at the 1-position of dimethyl imidazole-4,5-dicarboxylate (compound **2**) would hinder reactions on the neighboring ester at C-5, thus permitting reactions to take place preferentially at the other ester group. For similar reasons, the reactivities of the hydroxymethyl groups in the protected diol **5***a* were expected to be influenced by the presence of the triphenylmethyl group.

The reactions of the protected ester **2** with nucleophiles are shown in Scheme 1. Treatment of dimethyl imidazole-4,5-dicarboxylate (3) with tri-

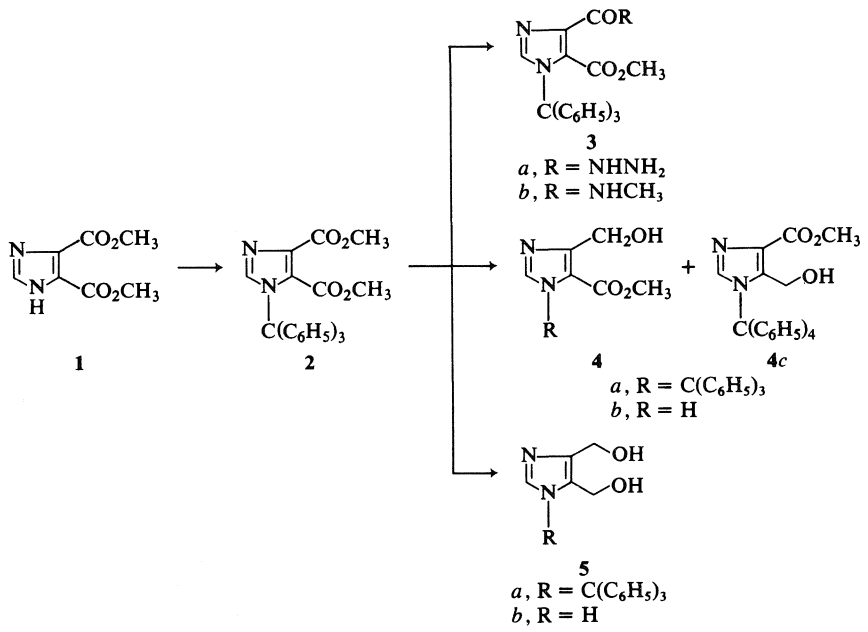

SCHEME 1

phenylmethyl chloride in dimethylformamide in the presence of triethylamine (4, 5) provided a 93% yield of dimethyl 1-triphenylmethylimidazole-4,5-dicarboxylate (**2**). When **2** was treated with a large excess of hydrazine (24 equiv.) in ethanol, the monohydrazide **3***a* was obtained in 94% yield. It is pertinent to note that similar reaction with the unprotected diester **1** yielded exclusively imidazole-4,5-dicarboxylic acid dihydrazide (6). Reaction of **2** with a large excess of methylamine in tetrahydrofuran–ethanol solvent mixture was also regiospecific and produced the monoamide **3***b*, exclusively. It was also possible to reduce one of the ester groups in **2** and produce the corresponding monoester. Thus, treatment of **2** with lithium borohydride in diglyme gave a 62% yield of the monoesters **4***a* and **4***c* in a ratio of 10:1, which upon removal of the triphenylmethyl group yielded the monoester **4***b*.

That the triphenylmethyl group in **3***a*, **3***b*, and **4***a* was correctly assigned to the nitrogen atom adjacent to the carboxymethyl group was supported by $^1$Hmr spectroscopy. The methyl groups of dimethyl imidazole-4,5-dicarboxylate (**1**) experienced the same chemical shift and appeared as a singlet at δ 3.8 (see Table 1). In compound **2**, the methyl groups appeared as sharp singlets at δ 3.87 (same region as in **1**) and 3.17. Due to the shielding influence of the triphenylmethyl group these resonance peaks were assigned to the methyl protons of the carboxymethyl groups at C-4 and C-5, respectively. The $^1$Hmr spectra of **3***a*, **3***b*, and **4***a* revealed that the sharp singlet at lower field (δ 3.8) had disappeared, while the singlet at higher field (δ 3.1–3.2) remained. Thus, the carboxymethyl group of these products must be adjacent to the triphenylmethyl group.

4,5-Dihydroxymethyl-1-triphenylmethylimidazole (**5***a*) was also found to be a viable intermediate for the synthesis of 4,5-heterodisubstituted imidazoles. The triphenylmethyl group in **5***a* appreciably decreased the reactivity of the adjacent hydroxyl group thus allowing reactions to take place preferably at the other hydroxyl group. Although the blocked diol **5***a* could be obtained from **5***b* by reaction with triphenylmethyl chloride, the difficulties involved in the preparation of **5***b* (7) by reduction of **1** with lithium aluminum hydride (mainly because of the extremely low solubilities of **1** in the permissible solvents) makes this process less desirable. It was found more convenient to prepare **5***a* by reduction of the diester **2** with lithium aluminum hydride in tetrahydrofuran. The high solubilities of **2** in THF and ether and the easily removable protective group makes this process attractive for the synthesis of **5***b* on a preparative scale.

It was possible to protect one of the hydroxyl groups in **5***a* while the other remained free for subsequent reactions (Scheme 2). Thus, treatment of **5***a* with trimethylacetyl chloride and with acetic anhydride produced the monoesters **6***a* (79%) and **6***c* (90%), respectively. When **6***a* was treated with thionyl chloride the chloride hydrochloride **7** was

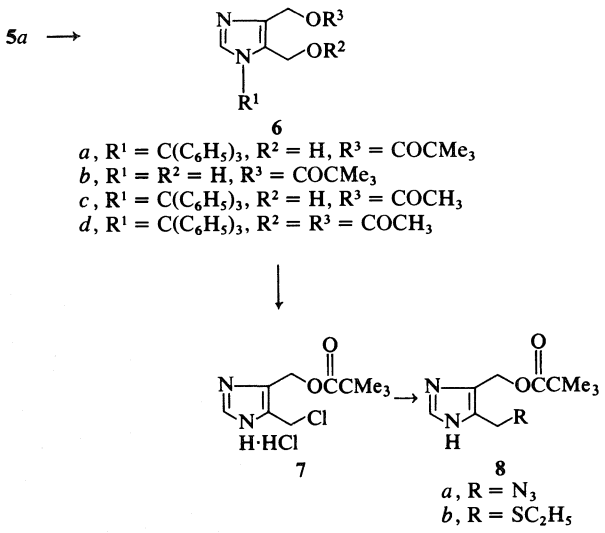
[a]Recorded at 60 MHz. Values expressed as ppm (δ). All spectra appeared as sharp singlets, unless otherwise noted. The coupling constants are recorded in Hz.
[b]Appeared in the region 7.1–7.5 together with the aromatic protons.
[c]Tr = $C(C_6H_5)_3$.

obtained in good yield (83.5%). Treatment of **7** with sodium azide in aqueous ethanol afforded a 91% yield of the azide ***8a***. The reaction of **7** with sodium ethanethiolate in water gave a good yield (75%) of the thioether ***8b***.

Oxidation of the diol ***5a*** with activated manganese dioxide (8) in boiling chloroform, conditions similar to those previously employed by Kelley and co-workers for the oxidation of an analogous product (5), gave a mixture of the isomeric monoaldehydes **9** and **10** in which compound **9** was the predominant isomer (92%). Several transformations of **9** giving rise to a variety of 4,5-heterodisubstituted imidazoles are apparent (Scheme 3). Thus, the reaction of **9** with ammonia in methylene chloride in the presence of activated manganese dioxide (8), a process described by Gilman (9), gave rise to the cyanocompound **11**. Treatment of **11** with thionyl chloride afforded **12** which on reaction with sodium 2-aminoethanethiolate produced **13**.



SCHEME 2

Extension of the side chain in **9** was possible by reaction of **9** and diethylcyanomethylphosphonate (10) giving rise to a mixture of the olefins **14** and **15** in a ratio of 2:1.

The assignment of structures for compounds **6***a*, **6***c*, and **9** as having the hydroxymethyl group next to the nitrogen atom carrying the triphenylmethyl group was made on the basis of $^1$Hmr studies. Examination of Table 1 reveals that the methylene groups in 4,5-dihydroxymethylimidazole (**5***b*) experience the same chemical shift and appear as a sharp singlet at δ 4.63. In 4,5-dihydroxymethyl-1-triphenylmethylimidazole (**5***a*), the methylene group at C-4 resonated in the same field as those in **5***b* and appeared as a singlet at δ 4.65 whereas the methylene group at C-5 was shifted to higher field and appeared as a singlet at δ 3.95. The $^1$Hmr spectra of **6***a*, **6***c*, and **9** revealed that the sharp singlet for the methylene of the hydroxymethyl group at δ 4.65 had disappeared, while the singlet in the region of δ 3.95 remained.

Excellent results were obtained in deblocking *N*-triphenylmethylimidazoles (i.e., compound **11***a*) using dilute hydrochloric acid solutions as has already been reported (4, 5). However, equally good results were obtained by simply refluxing ethanolic solutions of blocked imidazoles in the presence of water and a small amount of acetic acid. This process is compatible with acid-sensitive groups in the molecule. Compounds **4***b*, **5***b*, and **6***b* were prepared by this method in high yields.

In summary, we have shown that the commercially available imidazole-4,5-dicarboxylic acid can be conveniently converted to valuable and otherwise not easily accessible 4,5-disubstituted imidazoles by simple chemical processes.

## Experimental

The infrared spectra were recorded on a Unicam SP-200G grating ir spectrophotometer. The $^1$Hmr spectra were determined on a Varian EM 360 spectrometer using tetramethylsilane (for solutions other than deuterium oxide) and sodium 4,4-di-

methyl-4-silapentane-1-sulfonate (for solutions of deuterium oxide) as internal standards. Melting points are uncorrected and were determined on an electrothermal melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, IL. Thin layer chromatography (tlc) was carried out on pre-coated silica gel plates (E. Merck F-254). Reaction yields refer to products which showed a single spot on tlc plates.

*Dimethyl imidazole-4,5-dicarboxylate (**1**)*

This compound was prepared by a described procedure (3*b*). Recrystallization twice from water provided pure sample, mp 206–207°C. (lit., (3*a*), mp 200–202°C).

*Dimethyl 1-triphenylmethylimidazole-4,5-dicarboxylate (**2**)*

This compound was prepared according to the procedure described in the literature (4, 5) for the synthesis of *N*-triphenylmethylimidazoles. Thus, a mixture of dimethyl imidazole-4,5-dicarboxylate (11.0 g, 60 mmol), dry triethylamine (10.4 mL, 78 mmol), and dry dimethylformamide (75 mL) was blanketed with nitrogen and stirred at room temperature. To this mixture was added 19.5 g (70 mmol) of triphenylmethyl chloride in one lot. Soon after the addition, a white precipitate was formed; to facilitate stirring an additional 40 mL of dimethylformamide was added. The reaction was monitored by tlc on silica plates using 5% methanol in methylene chloride as eluent and was complete after 2 h. After stirring for an additional 2 h, the reaction mixture was poured over a mixture of crushed ice and water (600 mL). The solids were collected and washed with water. The partly dried product was dissolved in methylene chloride and the solution washed several times with water to eliminate unreacted diester **1**, dried, and evaporated. The residue was dissolved in $CHCl_3$ (50 mL), the solution diluted with petroleum ether (100 mL, bp 30–60°C), and the resultant solution allowed to crystallize at room temperature. The solids were collected by filtration to give 19.5 g of **2**, mp 202–205°C. The mother liquor was evaporated at reduced pressure and the residue was recrystallized from the same solvent system as above to provide an additional 4.5 g of **2** which were combined with the first crop to a total of 24 g (93%); ir (Nujol): 1720 $cm^{-1}$. *Anal.* calcd. for $C_{26}H_{22}N_2O_4$: C 73.22, H 5.19, N 6.57; found: C 73.24, H 5.52, N 6.57.

*Methyl 4-hydrazinocarbonyl-1-triphenylmethylimidazole-5-carboxylate (**3**a)*

To a stirred suspension of **2** (0.5 g, 1.18 mmol) in ethanol (2 mL) was added 0.9 mL (0.91 g, 28.4 mmol) of anhydrous hydazine and the reaction mixture stirred at room temperature for 40 min. Removal of the solvent by evaporation and recrystallization of solid residue from ethanol yielded 0.47 g (94%) of **3***a*, mp 240–242°C (decomp.); ir (Nujol): 3300, 1720, 1670, 1620, 1570 $cm^{-1}$. *Anal.* calcd. for $C_{25}H_{22}N_4O_3$: C 70.40, H 5.20, N 13.14; found: C 70.15, H 5.16, N 13.18.

*Methyl 4-methylaminocarbonyl-1-triphenylmethylimidazole-5-carboxylate (**3**b)*

A solution of **2** (1.0 g, 2.34 mmol) in tetrahydrofuran–ethanol solvent mixture (1:1, 45 mL) was saturated with methylamine (gas) and the reaction mixture stirred at room temperature for 48 h. The reaction was monitored by tlc on silica plates using ether–benzene (1:1) as eluent; after 48 h, the spot for **2** ($R_f$ 0.4) disappeared and a new spot of $R_f$ 0.24 (**3***b*) appeared. The reaction mixture was evaporated at reduced pressure. The solid residue was dissolved in acetone–chloroform mixture (1:10) and filtered through a pad of silica (4 cm long × 3.5 cm id) and the silica washed with the same solvent mixture (50 mL). The combined filtrate and washings were evaporated, the residue triturated with acetone–ether (1:2, 15 mL) and the crystalline material collected to give 0.85 g (85%) of **3***b* mp 211–213°C; ir (Nujol): 3380 (NH), 1730, 1680, 1570 $cm^{-1}$. *Anal.* calcd. for $C_{26}H_{23}N_3O_3$: C 73.30, H 5.44, N 9.87; found: C 73.09, H 5.34, N 9.78.

*Methyl 4-hydroxymethyl-1-triphenylmethylimidazole-5-carboxylate (**4**a)*

To a solution of sodium borohydride (0.57 g, 15 mmol) in dry diglyme (25 mL) was added anhydrous lithium bromide (1.3 g, 15 mmol) and the suspension was placed under a slow stream of nitrogen and stirred at room temperature for 30 min. To this mixture was added the diester **2** (2.13 g, 5 mmol) and the reaction mixture stirred at 25°C for 7 h, stored at 0°C overnight, and then stirred at 25°C for 5 h more. The reaction mixture was poured into cold water (200 mL) and the precipitate collected by filtration and washed with water. The solids were dissolved in methylene chloride, the solution extracted with water, dried, and evaporated to give 1.8 g of a syrup. Analysis of this product on tlc (silica, 10% MeOH–$CH_2Cl_2$) showed one major spot of $R_f$ 0.51 (**4***a*) and three minor spots of $R_f$ 0.46 (diol), 0.62, and 0.77 (**2**). The crude product was chromatographed on Alumina Act. II (Alumina Fluka for chromatography type 507C) (column size 13 × 1.8 cm id). Elution with ether–benzene (1:1) mixture removed the unreacted diester (0.32 g); subsequent elution with 2% methanol in methylene chloride gave 1.2 g (62%) of product which on tlc showed a major spot for **4***a* and a minor one of $R_f$ 0.62 (presumably the isomer of **4***a*). Further elution with 4% methanol in methylene chloride gave 0.2 g of the diol **5***a*.

The major fraction (**4***a* plus isomer) without further purification was used in the next reaction. A sample was recrystallized from 80% ethanol to afford **4***a*, mp 162–163°C; ir ($CHCl_3$): 3300, 1720 $cm^{-1}$. *Anal.* calcd. for $C_{25}H_{22}N_2O_3$: C 75.35, H 5.54, N 7.03; found: C 75.28, H 5.53, N 7.05.

*Methyl 4(5)-hydroxymethylimidazole-5(4)-carboxylate (**4**b)*

A solution of **4***a* (0.6 g) in 80% ethanol (10 mL) and glacial acetic acid (0.5 mL) was stirred under reflux for 45 min. Removal of the solvent by evaporation *in vacuo* left a solid which was partitioned between water (10 mL) and ether–hexane mixture (1:1, 10 mL). The organic phase containing triphenyl carbinol was separated and discharged; the aqueous phase was evaporated under reduced pressure to give 0.21 g (90%) of **4***b*. Recrystallization from ethanol yielded the analytical sample, mp 171–172°C. *Anal.* calcd. for $C_6H_8N_2O_3$: C 46.15, H 5.16, N 17.94; found: C 46.13, H 5.16, N 17.95.

*4,5-Dihydroxymethyl-1-triphenylmethylimidazole (**5**a)*

Dimethyl 1-triphenylmethylimidazole-4,5-dicarboxylate (58 g, 0.136 mol) was added in small portions to a stirred mixture of 9 g (0.237 mol) of lithium aluminum hydride in 1 L of dry tetrahydrofuran at 0°C under a nitrogen atmosphere. After the addition was completed (30 min) the cooling bath was removed and stirring was continued at room temperature for 3 h. The reaction mixture was cooled to 0°C and treated successively with 60 mL of water, 60 mL of 15% aqueous sodium hydroxide, and 60 mL of water. It was then filtered and the inorganic salts were washed with tetrahydrofuran. The combined filtrate and washings were evaporated under reduced pressure. The residue was dissolved in methylene chloride, the solution was washed with water, dried, and evaporated to give 38 g (75%) of **5***a*, mp 192–193°C; on tlc (silica, 10% methanol – methylene chloride), this product showed a single spot of $R_f$ 0.4. *Anal.* calcd. for $C_{24}H_{22}N_2O_2$: C 77.81, H 5.99, N 7.56; found: C 77.84, H 6.15, N 7.44.

In a larger scale experiment, the yield of **5***a* was 85%.

*4,5-Dihydroxymethylimidazole (**5**b)*

To a solution of **5***a* (1 g, 2.7 mmol) in 80% ethanol (10 mL) was added glacial acetic acid (0.5 mL) and the solution was refluxed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

for 1.5 h. Removal of the solvent *in vacuo* left a solid residue which was partitioned between water and ether. The ether phase containing triphenyl methanol was separated and discharged; the aqueous phase was evaporated to dryness at reduced pressure to give 0.33 g (98.5%) of crystalline **5***b*. Recrystallization from ethanol afforded the analytical sample, mp 165–166°C (lit. (7) mp 162–163°C).

*5-Hydroxymethyl-4-trimethylacetoxymethyl-1-triphenylmethylimidazole (**6**a)*

To a suspension of **5***a* (29.6 g, 80 mmol) in dry methylene chloride (250 mL) was added 8.3 g (124 mmol) of dry pyridine and the mixture, protected from moisture, was cooled in an ice bath while stirring. A solution of 10.25 g (85 mmol) of trimethylacetyl chloride in 100 mL of methylene chloride was added dropwise. After the addition was completed (10 min), the reaction solution was stirred at room temperature for 2.5 h and then stored at 0°C overnight. The reaction mixture was washed with water (3 × 200 mL), dried, and evaporated under reduced pressure to give a syrup which on tlc (silica, 10% acetone in methylene chloride) showed one major spot for **6***a* ($R_f$ 0.45), a minor spot for unreacted **5***a* ($R_f$ 0) and three other unidentified minor spots ($R_f$ 0.62, 0.82, and 0.92). This product was dissolved in acetone – methylene chloride solvent mixture (1:10, 200 mL) and the solution filtered through a pad of silica (10 cm × 4 cm id) and the silica bed washed with the same solvent system (200 mL). By this treatment, the unreacted **5***a* was removed. The filtrate and washings were combined and evaporated to give 31 g of crystalline product. Recrystallization from benzene (70 mL) – petroleum ether (175 mL, bp 90–120°C) afforded 21.6 g (59.5%) of **6***a*, mp 157–159°C. The mother liquor was evaporated and the residue was chromatographed on silica using acetone–chloroform solvent mixture (1:10) as eluent to provide an additional 7 g of **6***a*. The two crops were combined to a total yield of 28.6 g (79%); ir ($CHCl_3$): 3580, 1720 $cm^{-1}$. *Anal.* calcd. for $C_{29}H_{30}N_2O_3$: C 76.62, H 6.65, N 6.16; found: C 77.03, H 6.49, N 6.16.

*4(5)-Hydroxymethyl-5(4)-trimethylacetoxymethylimidazole (**6**b)*

To a solution of **6***a* (2.0 g, 4.4 mmol) in 80% ethanol (20 mL) was added glacial acetic acid (1 mL) and the resultant solution was heated under reflux for 1 h and then evaporated to dryness at reduced pressure. The residue was chromatographed on a wet column of silica (12 cm × 1.8 cm id) using 5% methanol in chloroform as eluent to give 0.89 g (95%) of **6***b* as a syrup which crystallized on standing. This product showed on tlc (silica, 10% MeOH – $CH_2Cl_2$) a single spot of $R_f$ 0.2. Recrystallization from methylene chloride – ether solvent mixture afforded the analytical sample, mp 97–99°C: ir ($CHCl_3$): 3200, 1720 $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{16}N_2O_3$: C 56.59, H 7.60, N 13.20; found: C 56.55, H 7.62, N 13.15.

*4-Acetoxymethyl-5-hydroxymethyl-1-triphenylmethylimidazole (**6**c)*

To a suspension of **5***a* (0.925 g, 2.5 mmol) in 5 mL of methylene chloride was added 0.4 mL (5 mmol) of dry pyridine and 0.3 mL (3.2 mmol) of acetic anhydride and the mixture stirred at room temperature for 3 h. Methylene chloride (50 mL) was added and the resultant solution was washed with water (3 × 50 mL), dried, and filtered. Removal of the solvent *in vacuo* gave 1.0 g of solids which on tlc (silica, 10% acetone in chloroform) showed a major spot of $R_f$ 0.23 (**6***c*) and two minor spots of $R_f$ 0 and 0.4 (**5***a*). This product was purified by column chromatography on silica using acetone–chloroform mixture (1:3) as eluent to provide 0.92 (90%) of crystalline **6***c*. Recrystallization from ethanol afforded the analytical sample, mp 192–193°C; ir ($CHCl_3$): 3580, 3460, 1727 $cm^{-1}$. *Anal.* calcd. for $C_{26}H_{24}N_2O_3$: C 75.70, H 5.86, N 6.79; found: C 75.60, H 5.85, N 6.80.

*5(4)-Chloromethyl-4(5)-trimethylacetoxymethylimidazole hydrochloride (**7**)*

A mixture of **6***a* (5.0 g, 11 mmol) and thionyl chloride (25 mL) was stirred at 23°C for 10 min and then heated under reflux for 30 min. Removal of the excess thionyl chloride *in vacuo* left a syrupy residue which partly solidified on trituration with ether (50 mL). The ether was removed by evaporation. The residue was dissolved in 95% ethanol (5 mL), the solution was diluted with ether (60 mL) and allowed to crystallize at room temperature. The crystalline product was collected, washed with ether, and dried to give 2.15 g (83.5%) of **7**, mp 275–280°C (decomp.); $^1$Hmr ($CD_3OD$–$CD_3COCD_3$) δ: 1.2 (s, 9H, $CMe_3$), 5.03 (s, 2H, $CH_2Cl$), 5.37 (s, 2H, $CH_2O$), 9.17 (s, 1H, H-2). *Anal.* calcd. for $C_{10}H_{15}ClN_2O_2 \cdot HCl$: C 44.96, H 6.04, N 10.49, Cl 26.14; found: C 44.81, H 5.94, N 10.47, Cl 25.60. In a larger scale experiment, the yield of **7** was 90%.

*5(4)-Azidomethyl-4(5)-trimethylacetoxymethylimidazole (**8**a)*

To a solution of sodium azide (0.52 g, 8 mmol) in 4 mL of aqueous ethanol (50%) was added a solution of **7** (0.534 g, 2 mmol) in 2 mL of 90% ethanol. After stirring at room temperature for 18 h the reaction mixture was diluted with water (10 mL) and extracted with methylene chloride (4 × 10 mL). The combined extracts were washed with water, dried, and evaporated to give 0.45 g (91%) of **8***a* as a syrup which crystallized on trituration with ether. This product showed on tlc (silica, 5% MeOH – $CH_2Cl_2$) a single spot of $R_f$ 0.35. Recrystallization from ether afforded the analytical sample, mp 88.5–89°C; ir (Nujol): 2100 ($N_3$) 1730 $cm^{-1}$ (CO); $^1$Hmr ($CDCl_3$) δ: 1.17 (s, 9H, $COMe_3$), 4.43 (s, 2H, $CH_2N_3$), 5.13 (s, 2H, $CH_2O$), 7.70 (s, 1H, H-2). *Anal.* calcd. for $C_{10}H_{15}N_5O_2$: C 50.62, H 6.37, N 29.52; found: C 50.26, H 6.42, N 29.63.

*4(5)-Ethylthiomethyl-5(4)-trimethylacetoxymethylimidazole (**8**b)*

Ethanethiol (0.6 mL, 8 mmol) was added to 1 mL of 4 *N* aqueous sodium hydroxide and the solution was placed under a nitrogen atmosphere and cooled in an ice bath. To this solution was added 0.534 g (2 mmol) of **7** and the reaction mixture was stirred at room temperature for 2 h. The solvent was removed by evaporation and the residue partition between water and methylene chloride. The organic phase after drying was evaporated to dryness, and the residue was chromatographed on silica gel (10 g) using 5% methanol in methylene chloride as eluent to give 0.396 g (75%) of **8***b* as an oil; ir (neat): 1710 $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 1.17 (s, 9H $CMe_3$), 1.20 and 2.50 (t and q for $SCH_2CH_3$), 3.80 (s, 2H, $CH_2S$—), 5.10 (s, 2H, $CH_2O$), 7.67 (s, 1H, H-2). The hydrochloride salt of **8***b* had mp 147–149°C. *Anal.* calcd. for $C_{12}H_{20}N_2O_2 \cdot HCl$: C 49.22, H 7.23, N 9.57; found: C 49.18, H 7.19, N 10.15.

*4-(5-Hydroxymethyl-1-triphenylmethyl)imidazolecarboxaldehyde (**9**) and 5-(4-hydroxymethyl-1-triphenylmethyl)imidazolecarboxaldehyde (**10**)*

The procedure described by Kelley and co-workers (5) for the synthesis of 4-(*N*-triphenylmethyl)imidazole carboxaldehyde was used as follows. A mixture of 29.2 g (73.5 mmol) of **5***a* and 47 g (540 mmol) of activated manganese dioxide (8) and 1 L of dry and ethanol-free chloroform was refluxed with mechanical stirring for 1.5 h. Fresh manganese dioxide (47 g) was added and refluxing continued for an additional 1.5 h. The hot reaction mixture was filtered through a Celite pad and the solids were washed with chloroform (300 mL). The combined filtrate and washings were evaporated *in vacuo* and the residue was triturated with ether (100 mL). The solids were collected to give 25 g of crude product which on tlc (silica, 10% acetone – $CHCl_3$) showed 3 spots of $R_f$ values 0.50 (major, **9**), 0.23 (minor, **10**), and 0. The crude product was chromatographed on a silica column

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

(700 g), eluted successively with methylene chloride, 5% acetone – methylene chloride, and 10% acetone – methylene chloride to give 17.9 g (62%) of crystalline **9**. The analytical sample obtained by recrystallization from methylene chloride had mp 177.5–178.5°C; ir ($CHCl_3$): 3350, 1675 $cm^{-1}$. *Anal.* calcd. for $C_{24}H_{20}N_2O_2$: C 78.24, H 5.47, N 7.60; found: C 77.85, H 5.60, N 7.43. Further elution of the column with 1:1 acetone – methylene chloride solvent mixture gave 1.6 g (5.5%) of the isomer **10**, mp 160–164°C; ir ($CHCl_3$); 3350, 1660 $cm^{-1}$. *Anal.* calcd. for $C_{24}H_{20}N_2O_2$: C 78.24, H 5.47, N 7.60; found: C 77.39, H 5.50, N 7.58.

*4-Cyano-5-hydroxymethyl-1-triphenylmethylimidazole (**11**a)*

A described general procedure (9) was used as follows. To a solution of 1.3 g (3.36 mmol) of **9** in 60 mL methylene chloride was added 2.6 g molecular sieves (type 4A) and the mixture was stirred at room temperature. Ammonia (gas) was bubbled into the reaction mixture for 10 min then 2.6 g of activated manganese dioxide (8) was added and the mixture was stirred at room temperature for 2 h while the bubbling of ammonia was maintained. The reaction mixture was filtered and the solids were washed with methylene chloride (50 mL). The combined filtrate and washings were evaporated to give 1.3 g of an oil which crystallized from methylene chloride – ether mixture to give 0.52 g of **11***a*, mp 170–172°C. From the mother liquor, after evaporation and crystallization of the residue as above, an additional 0.17 g of **11***a* was obtained. The two crops were combined to a total yield of 0.69 g (48%); ir (Nujol): 3350, 2240 $cm^{-1}$; $^1$Hmr ($CDCl_3$–$CD_3OD$) δ: 7.4 (m, 16H, ArH and H-2), 3.85 (s, 2H, $CH_2$). *Anal.* calcd. for $C_{24}H_{19}N_3O$: C 78.88, H 5.24, N 11.50; found: C 78.28, H 5.24, N 11.55.

*4(5)-Cyano-5(4)-hydroxymethylimidazole hydrochloride (**11**b)*

To a solution of **11***a* (2.14 g, 5.45 mmol) in methanol (25 mL) was added 2.5 *N* hydrochloric acid (4, 5) (12 mL) and the resulting solution was heated at 40°C for 1 h and then evaporated under reduced pressure. The solid residue was dissolved in water (15 mL) and the solution extracted with ether (2 × 20 mL). The aqueous phase was evaporated to dryness to give 0.82 g (94%) of **11***b* as a solid. Recrystallization from an ethanol–ether solvent mixture afforded the analytical sample mp 180–182°C; ir (Nujol): 2200 (CN) $cm^{-1}$; $^1$Hmr (DMSO-$d_6$) δ: 4.98 (s, 2H, $CH_2O$), 8.04 (s, 1H, H-2). *Anal.* calcd. for $C_5H_5N_3O$·HCl: C 37.63, H 3.16, N 26.33; found: C 37.52, H 3.18, N 26.22.

*5(4)-Chloromethyl-4(5)-cyanoimidazole hydrochloride (**12**)*

A mixture of 1.6 g (4.4 mmol) of **11***a* and 35 mL of thionyl chloride was refluxed for 20 h. The reaction mixture was evaporated to dryness and flashed with chloroform (3 × 20 mL). The residue was extracted with ether (3 × 45 mL) and methylene chloride (25 mL) and the organic extracts were discharged. The solid product was collected to give 0.44 g (56%) of **12**; ir (Nujol): 2600, 2220 $cm^{-1}$; $^1$Hmr ($D_2O$) δ: 8.83 (s, 1H, H-2), 4.95 (s, 2H, $CH_2$). *Anal.* calcd. for $C_5H_4N_3Cl$·HCl: C 33.73, H 2.83, N 23.61; found: C 33.54, H 2.81, N 23.62.

*4(5)-Cyano-5(4)-[(2-aminoethyl)thiomethyl]imidazole (**13**)*

To a solution of 2 *N* sodium ethoxide in ethanol (7 mL) was added a solution of 0.785 g (5 mmol) of 2-aminoethanethiol hydrochloride in 7 mL of ethanol and the mixture was placed under a nitrogen atmosphere and stirred at −10°C for 25 min. To this mixture was added dropwise over a period of 15 min a solution of 0.63 g (3.5 mmol) of **12** in 7 mL ethanol. After the addition of **12** was completed, the cooling bath was removed and the reaction mixture stirred at room temperature for 4 h. Removal of the solvent by evaporation left a residue which was purified by chromatography on a column of Rexyn 102 resin ($NH_4^+$ form, 10 cm long × 2 cm id). The column was eluted successively with water (50 mL), 0.1 *N* ammonium hydroxide (50 mL), and 0.2 *N* ammonium hydroxide (50 mL). The fractions of eluent containing the product were combined and evaporated to give 0.25 g (42.5%) of **13** as a syrup. This product showed on tlc (silica, ammonia–methanol–water, 0.5:9:0.5) a single spot of $R_f$ 0.7; $^1$Hmr ($D_2O$) δ: 7.66 (s, 1H, H-2), 3.90 (s, 2H, $CH_2S$), 2.86 (m, 4H, $SCH_2CH_2N$). *Anal.* calcd. for $C_7H_{10}N_4S$: C 46.13, H 5.53, S 17.59; found: C 46.09, H 5.49, S 17.49.

*Preparation of compounds **14** and **15***

A mixture of 0.811 g of 50% sodium hydride – oil suspension (16.9 mmol) and 20 mL of dry benzene was cooled in an ice bath while stirring under an atmosphere of nitrogen. To this mixture was added dropwise 1.43 mL (8.85 mmol) of diethylcyanomethylphosphonate and, after the addition was completed, the mixture stirred at 0°C for 5 min. This solution was transferred into a dropping funnel and added dropwise to a stirred solution of 2.96 g (8.05 mmol) of the aldehyde **9** in 260 mL of dry benzene at 45°C. After the addition was completed, the reaction mixture was stirred at 45°C for 20 min under a nitrogen atmosphere. After cooling to room temperature, the reaction solution was washed with brine (200 mL), the organic phase separated, and the aqueous phase extracted with chloroform (50 mL). The combined extracts were washed with brine, dried, and evaporated to give 1.9 g (61%) of a syrup. This product showed on tlc (silica, ether) two spots of $R_f$ 0.38 (*trans*-isomer **14**) and 0.23 (*cis*-isomer **15**). The ratio of *trans*- to *cis*-isomer in the mixture was 2:1 as determined by $^1$Hmr. The two isomers were separated by chromatography on a column of silica gel (150 g) eluted successively with ether, ether – methylene chloride mixture (1:1), and methylene chloride. The *trans*-isomer **14** had mp 171–172°C; ir ($CHCl_3$): 3570 (OH), 2220 (CN), 1620 (C=C) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 7.53 (d, 1H, C=CH, $J$ = 16 Hz), 7.3 (m, 16H, ArH and H-2), 6.00 (d, 1H, C=CH, $J$ = 16 Hz), 4.06 (d, 2H, $CH_2OH$, $J$ = 6 Hz on exchange with $D_2O$ gives a singlet), 1.45 (t, 1H, OH, $J$ = 6 Hz, disappears on exchange with $D_2O$). *Anal.* calcd. for $C_{26}H_{21}N_3O$: C 79.77, H 5.40, N 10.73; found: C 79.69, H 5.39, N 10.79. The *cis*-isomer **15** had mp 181–182°C; ir ($CHCl_3$): 3570 (OH), 2220 (CN), 1625 (C=C) $cm^{-1}$; $^1$Hmr ($CDCl_3$) δ: 7.24 (m, 17H, ArH, H-2 and *CH*=CHCN), 5.24 (d, 1H, C=*CH*CN, $J$ = 11.8 Hz), 4.07 (s, 2H, $CH_2OH$). *Anal.* calcd. for $C_{26}H_{21}N_3O$: C 79.77, H 5.40, N 10.73; found; C 79.78, H 5.41, N 10.80.

# Molecular orbital structures of sulfones

RUSSELL J. BOYD[1] AND JEFFREY P. SZABO
*Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3*

Received October 6, 1981

RUSSELL J. BOYD and JEFFREY P. SZABO. Can. J. Chem. **60**, 730 (1982).

*Ab initio* molecular orbital calculations are reported for several cyclic and acyclic sulfones. The geometries of $XSO_2Y$, where X, Y = H, F, or $CH_3$ are optimized at the STO-3G* level. Similar calculations are reported for the smallest cyclic sulfone, thiirane-1,1-dioxide, as well as the corresponding sulfoxide, thiirane-1-oxide, and the parent sulfide, thiirane. Where comparison with experiment is possible, the agreement is satisfactory. In order to consider the possibility of substantial differences between axial and equatorial S—O bonds in the gas phase, as observed in the crystal structure of 5*H*,8*H*-dibenzo[*d*,*f*][1,2]-dithiocin-1,1-dioxide, STO-3G* calculations are reported for a six-membered ring, thiane-1,1-dioxide, and a model eight-membered ring. Limited geometry optimization of the axial and equatorial S—O bonds in the chair conformations of the six- and eight-membered rings leads to bond lengths of 1.46 Å with the difference being less than 0.01 Å.

RUSSELL J. BOYD et JEFFREY P. SZABO. Can. J. Chem. **60**, 730 (1982).

On rapporte des calculs *ab initio* d'orbitales moléculaires relatifs à plusieurs sulfones cycliques et acycliques. Au niveau STO-3G*, on a amélioré les géométrie de $XSO_2Y$ où X, Y = H, F ou $CH_3$. On rapporte des calculs analogues pour la sulfone cyclique la plus petite, le thiiranne dioxyde-1,1, ainsi que pour le sulfoxyde correspondant, le thiiranne oxyde-1, et le sulfure apparenté, le thiiranne. L'accord est satisfaisant là où il a été possible d'établir des comparaisons. On rapporte des calculs STO-3G* pour les cycles à 6 chaînons, thianne dioxyde-1,1 et pour un cycle modèle à 8 chaînons dans le but d'envisager la possibilité de différences notables entre les liaisons S—O axiales et équatoriales en phase gazeuse telles qu'observées dans la structure du crystal du 5*H*,8*H*-dibenzo[*d*,*f*][1,2]dithiocinne dioxyde-1,1. Une optimisation limitée de la géométrie des liaisons S—O axiales et équatoriales de la forme chaise des cycles à 6 et à 8 chaînons conduit à des longueurs de liaison de 1,46 Å, avec une différence inférieure à 0,01 Å.
[Traduit par le journal]

## Introduction

The crystal structure (1) of 5*H*,8*H*-[*d*,*f*][1,2]-dithiocin-1,1-dioxide indicates that the eight-membered ring is a pseudo-chair in which the "pseudo-axial" S—O bond is significantly shorter (1.352 Å vs. 1.475 Å) than its "pseudo-equatorial" analogue. Somewhat smaller differences have been observed (2) for $\gamma$-$SO_3$ in the solid state. In this paper we consider the possibility of similar anomalies in the gas phase. To this end, we have carried out extensive *ab initio* molecular orbital (MO) calculations on cyclic and acyclic sulfones.

## Method

Standard single determinant *ab initio* molecular orbital theory, according to which closed-shell species are treated by the spin-restricted Hartree-Fock (RHF) procedure (3), has been used throughout. All calculations were carried out using the Gaussian 76 program (4) on a CDC CYBER 170-720 computer. The STO-3G* basis set (5) in which a manifold of five *d*-type functions, consisting of one second-order Gaussian each, is added to the minimal STO-3G basis set for second row atoms has been used. The minimal STO-3G basis set (6) has been used for hydrogen and first-row elements. We have chosen the STO-3G* basis set because previous studies (5, 7–9) have demonstrated the importance of including *d* functions on second-row atoms in hypervalent molecules. Moreover, the STO-3G* basis set offers a convenient compromise between minimal (5) and larger *sp* basis sets (5, 9) on the one hand and extended plus polarization basis sets (9, 10) on the other.

Geometry optimization was carried out for each molecule. In a few cases model geometries were assumed or part of the molecule was constrained to the experimental structure. For example, model methyl groups, $r$(CH) = 1.09 Å and $\angle$HCH = 109.5°, were adopted to reduce the requirements for computer time. Except where noted otherwise, all calculated structures reported in this paper should be within 0.002 Å and 0.2° of their true theoretical (at the STO-3G* level) geometries. In many cases the geometrical parameters have been determined to within 0.001 Å and 0.1°.

### *Acyclic sulfones*

In order to establish the reliability of *ab initio* calculations on sulfones at the STO-3G* level we begin our discussion with some simple molecules which contain the $SO_2$ functional group. The calculated equilibrium geometries of $XSO_2Y$, where X, Y = H, F, or $CH_3$, are illustrated in Fig. 1. The theoretical geometries are compared with the available (11) gas phase structural data in Table 1. In agreement with experimental evidence (11, 12) and semi-empirical MO calculations (13), the lowest

[a]Bond lengths in Å, angles in deg.
[b]Structures are identified in Fig. 1.
[c]Experimental data from ref. 11 and references therein.

energy conformations of the methyl sulfones (**4**, **5**, and **6**) have a staggered arrangement about the C—S bonds. The agreement between the calculated and observed geometries of **3**, **5**, and **6** is satisfactory and is quite typical of calculations at the STO-3G and STO-3G* levels (5, 10, 14, 15). Two features of the calculated bond lengths are worth noting: all bonds are over-estimated, by about 0.03 Å on average, and the effect of substituents is qualitatively reproduced.

The STO-3G* total energies of the simple sulfones are listed in Table 2. From the computed energies of the eclipsed conformers at the bond lengths and angles of the equilibrium geometries we estimate the barriers to rigid rotation[2] of **4**, **5**, and **6** to be 2.0, 2.3, and 1.8 kcal/mol, respectively.[3] These values are low but in qualitative agreement with the observed barriers of 3.4 (12) and 2.5 (17) in **5** and **6**, respectively. The low value obtained for **6** relative to **4** is contrary to the trends observed for substituted ethanes where replacement of a H atom by a F atom raises the barrier (18). However, not all barriers are raised by fluorine substitution. For example, the observed barriers (18) in $CH_3$—CHO and $CH_3$—CFO are 1.16 and 1.04 kcal/mol, respectively. Similarly the barriers of 1.70 and 1.56 kcal/mol in $CH_3$—$SiH_3$ and $CH_3$—$SiH_2F$, respectively, are consistent with the trends observed here for the theoretical barriers of the sulfones. Unfortunately sulfone **4** has not been reported.

With reference to the net atomic charges listed in Table 2 we observe that the effect of fluorine substitution on the S and O charges in the series $H_nSO_2F_{2-n}$ and $(CH_3)_nSO_2F_{2-n}$ is essentially additive. Similar additivity relationships are apparent for the $(CH_3)_nSO_2H_{2-n}$ series. The charges listed in Table 2 are based on the Mulliken population analysis procedure (19). We conclude this section by emphasizing that the additivity of net charges at the STO-3G* level is not complemented by a corresponding set of bond additivity rules.

*Cyclic sulfones*

Before discussing the question of anomalous S—O bond lengths in cyclic sulfones we consider the smallest cyclic sulfone, namely, thiirane-1,1-dioxide **7**. The STO-3G* equilibrium geometry of **7** is shown in Fig. 2 together with the equilibrium

[2]Our estimate, which corresponds to geometric model B of Radom and Pople (16), would be slightly lower for flexible rotation.

[3]The barrier for simultaneous rotation of the two methyl groups of **5** is estimated to be 6.0 kcal/mol whereas the value of 2.3 kcal/mol given above is for the rotation of a single methyl group.

**8** and **9** agrees with the microwave spectroscopic values of 1.590 (20), 1.504 (21), and 1.492 Å (22), respectively. The lengthening of the S—O bond in **8** relative to **7** is less pronounced at the STO-3G* level than in the experimental structures (1.483 for **8** vs. 1.439 Å for **7**). The major discrepancy occurs for the C—S bond of **9**. The microwave values are 1.731, 1.822, and 1.819 Å for **7**, **8**, and **9**, respectively. We note that **7**, **8**, and **9** form a sequence in which the S atom is modified in a regular fashion. Successive removal of the two O atoms converts the hypervalent S atom of **7** to the divalent S atom of **9**.

With a minimal basis set it is essential to include *d* orbitals on hypervalent S atoms in order to obtain reasonable bond lengths. For divalent S, the STO-3G values of the S—H bond lengths are in better agreement with experiment than the STO-3G* values. In general the effect of including *d* orbitals on S in a minimal basis set is to shorten H—S and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

C—S bonds in acyclic divalent molecules by about 0.01 to 0.02 Å. This is apparent from the work of Collins *et al.* (5) on $H_2S$ and $CH_3SH$ where the calculated H—S, C—S, and S—H bond lengths are in better agreement with experiment at the STO-3G level than at the STO-3G* level. Our results on **9** show a similar but somewhat greater effect: 1.773 (STO-3G) vs. 1.744 Å (STO-3G*) for the C—S bond. In the case of disulfides, —S—S—, we have found that the effect of including *d* orbitals on S is an order of magnitude greater than in divalent sulfides involving hydrogen and/or first-row atoms (23). Although we will not discuss the three-membered rings further, we should point out that Hoffmann *et al.* (24) have reported a detailed analysis of the bond lengths of these molecules. On the basis of extended Hückel calculations they propose a bonding picture in which the molecules are described as complexes of an ethylene with S, SO, or $SO_2$.

Two larger systems have been considered. As an example of a six-membered ring we chose thiane-1,1-dioxide (thiacyclohexane-1,1-dioxide) (**10**) (see Fig. 3). Starting with a model geometry, $r$(CS) = 1.82, $r$(CC) = 1.53, $r$(CH) = 1.09, bond angles approximately 109.5° and dihedral angles near 180°, we carried out a limited geometry optimization for the axial and equatorial S—O bonds in the chair conformation. Our conclusion is that the STO-3G* optimized bond lengths for our model geometry are 1.46 Å and that the differences are less than 0.01 Å.

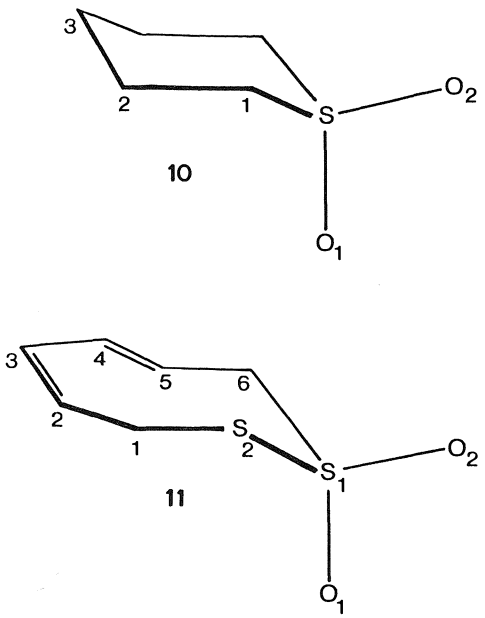

FIG. 3. Structural formulas of six- and eight-membered rings containing the sulfone functional group.

Thus the axial *and* equatorial S—O bonds of **10** are predicted to be essentially equal in the gas phase. The computed total energy and net atomic charges of **10** are listed in Table 3. We observe a slightly greater charge on the axial O atom than on the equatorial O atom and a small increase in the polarity of the S—O bonds relative to the three-membered ring **7**.

The molecule mentioned in the Introduction contains a S atom adjacent to the sulfone group. In order to determine the effect of an adjacent S atom we chose an eight-membered ring **11** as a convenient model. With the coordinates of the atoms in the ring chosen from the crystallographic data of Wahl *et al.* (1), the S—O bond lengths were optimized. As in the case of **10**, the optimized bond lengths turned out to be 1.46 Å with the difference being less than 0.01 Å. Thus, even when we include a S atom adjacent to the sulfone functional group, we find no significant difference between the axial and equatorial S—O bonds. On the strength of the *ab initio* calculations reported in this paper we do not expect anomalies in the gas phase similar to those reported (1, 2) in the solid state on the basis of X-ray diffraction studies. If such anomalies exist then they are presumably associated with crystal packing forces. Here we should like to point out that a X-ray crystal structure determination (25) of 4,4,-*a*-dihydro-5,7-dimethylpyrido[1,2-*d*][1,5,2]dithiazine-1,1,3,3-tetroxide indicates that the S—O bonds of the sulfone functional group are essentially identical. Moreover, the same molecule contains a second $SO_2$ group adjacent to a N atom. The second $SO_2$ group, like the first, contains two essentially equal S—O bonds. And finally we should like to mention that complementary calculations (26, 27) on the importance of *d*-functions in the basis set and the deformability of sulfur moities when crystal forces are present have been reported. In conclusion, we do not expect axial and equatorial S—O bond lengths to differ significantly in the gas phase.

# The solvolysis of *trans*-1,2-diphenyl-2-phenylthio[1-$^{13}$C]vinyl tosylate in anhydrous or aqueous acetic acid

CHOI CHUCK LEE, CHARLES Y. FIAKPUI, AND J. WILSON QUAIL

*Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0*

Received July 30, 1981

CHOI CHUCK LEE, CHARLES Y. FIAKPUI, and J. WILSON QUAIL. Can. J. Chem. **60**, 735 (1982).

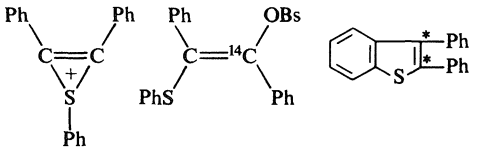
The acetolysis of *trans*-1,2-diphenyl-2-phenylthiol[1-$^{13}$C]vinyl tosylate (**2**-OTs-1-$^{13}$C) under anhydrous conditions (HOAc–$Ac_2O$–NaOAc) gave *trans*-1,2-diphenyl-2-phenylthio[1,2-$^{13}$C]vinyl acetate (**2**-OAc-1,2-$^{13}$C) as product. The label was scrambled equally over C-1 and C-2 and there was no detectable amount of *cis*-product. These results are consistent with the involvement of an intermediate sulfur-bridged thiirenium ion in the reaction. Solvolysis of **2**-OTs-1-$^{13}$C in 70% HOAc – 30% $H_2O$ containing 3 equiv. of NaOAc gave 1,2-diphenyl-2-phenylthio[1,2-$^{13}$C]ethanone (α-phenyl-α-(phenylthio)acetophenone) (**5**-1,2-$^{13}$C) and 1,2-diphenyl[1,2-$^{13}$C]ethanone (desoxybenzoin) (**6**-1,2-$^{13}$C) as major and minor products, respectively. The $^{13}$C-label in both of these ketones was again equally distributed over C-1 and C-2. Further studies with unlabeled **2**-OTs showed that its solvolysis in aqueous HOAc gave, besides ketones **5** and **6**, some benzil and diphenyl disulfide. It was also found that **6**, benzil, and diphenyl disulfide were derived from the initial product **5**. A possible mechanism for these conversions is proposed.

CHOI CHUCK LEE, CHARLES Y. FIAKPUI et J. WILSON QUAIL. Can. J. Chem. **60**, 735 (1982).

L'acétolyse du tosylate de diphényl-1,2 phénylthio-2 vinyle [$^{13}$C-1] *trans* (OTs-**2** $^{13}$C-1) dans des conditions anhydres (AcOH–$Ac_2O$–AcONa) conduit l'acétate (AcO-**2** $^{13}$C-1,2) de diphényl-1,2 phénylthio-2 vinyle [$^{13}$C-1,2] *trans*. Le marqueur est réparti également entre C-1 et C-2 et il n'y pas de produit *cis*. Ces résultats sont en accord avec la participation d'un ion thiirénium intermédiaire ayant un soufre en position de pont au cours de la réaction. La solvalyse du tosylate (**2**-OTs $^{13}$C-1) dans une solution aqueuse de AcOH à 70% contenant 3 équivalents de AcONa conduit à la diphényl-1,2 phenylthio-2 éthanone [$^{13}$C-1,2] (α-phenyl α-(phénylthio) acétophénone) (**5**-$^{13}$C-1,2) comme produit majoritaire et à la diphényl-1,2 éthanone [$^{13}$C-1,2] (déoxybenzoine) (**6**-$^{13}$C-1,2) comme produit secondaire. Le marqueur $^{13}$C dans ces deux cétones se distribue également entre $C_1$ et $C_2$. Des études plus poussées avec un tosylate **2**-OTs non marqué révèlent que la solvolyse dans AcOH aqueux donne en plus des cétones **5** et **6**, un disulfure de benzyle et un disulfure de diphényle. On a également trouvé que ces disulfures proviennent du produit initial **5**. On propose un mécanisme qui explique ces transformations.

[Traduit par le journal]

The possible involvement of the sulfur-bridged thiirenium ion, such as **1**, as a reaction intermediate in the addition of sulfenyl derivatives to alkynes or in the solvolysis of 2-arylthiovinyl sulfonates has been reviewed by Modena and co-workers (1, 2). Among the evidence in support of **1** was the finding that a labeled substrate such as *trans*-1,2-diphenyl-2-phenylthio[1-$^{14}$C]vinyl brosylate (**2**-OBs-1-$^{14}$C), when treated in $CHCl_3$ saturated with gaseous $BF_3$, gave the cyclized product, 2,3-diphenylbenzo[*b*]-thiophene (**3**), which showed that substantial equilibration of the two ethylenic carbon atoms has taken place (3, 4).



**1** **2**-OBs-1-$^{14}$C **3**

In addition to the study on the formation of **3** from **2**-OBs-1-$^{14}$C, effected in the absence of any nucleophile, a demonstration of the complete scrambling of the label between C-1 and C-2 in the substitution product from a labeled 2-arylthiovinyl sulfonate would give further support to the thiirenium ion as a reaction intermediate. Thus we have undertaken an investigation on the solvolysis of *trans*-1,2-diphenyl-2-phenylthio[1-$^{13}$C]vinyl tosylate (**2**-OTs-1-$^{13}$C) in anhydrous or aqueous HOAc.

The synthesis of **2**-OTs-1-$^{13}$C was carried out using procedures analogous to those employed in the preparation of **2**-OBs-1-$^{14}$C (4) as outlined in Scheme 1. Modena and co-workers (4) have shown that the **2**-OBs-1-$^{14}$C synthesized in this way was *trans* and that the label was located solely at C-1. The $^{13}$C nmr spectrum of the labeled **2**-OTs-1-$^{13}$C, showing an intense C-1 absorption at 144.0 ppm, also confirmed that the $^{13}$C-label was located solely at C-1.

In preliminary experiments with ordinary **2**-OTs, solvolysis in HOAc–$Ac_2O$ (9:1 by volume) containing 3 equiv. of NaOAc gave the acetate product, the $^1$H nmr spectrum of which showed a single peak for the $CH_3$ protons of the acetate group, indicating the formation of only the *trans*-isomer, **2**-OAc (5–7). In the solvolysis of **2**-OTs-1-$^{13}$C, the acetate product was reduced with $LiAlH_4$ to give a mixture of *erythro*- and *threo*-1,2-diphenyl-2-phenylthio[1,2-$^{13}$C]ethanol (**4**-1,2-$^{13}$C) for $^{13}$C nmr analy-

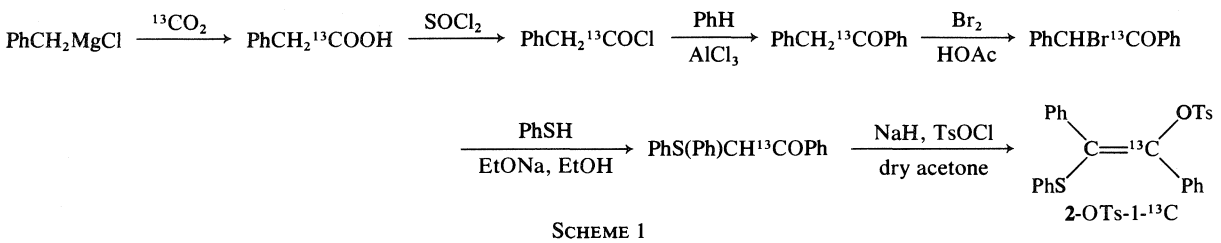

SCHEME 1

sis. It was intended that a quantitative measurement of the $^{13}C$ contents at C-1 and C-2 might be carried out using the method of relative intensities with respect to a suitable internal standard as was done in the reaction of triphenyl[2-$^{13}C$]vinyl or trianisyl[2-$^{13}C$]vinyl bromide with HOAc–AgOAc (8, 9). In these studies (8, 9) the sum of some of the aromatic absorptions of the triphenylvinyl system or the $CH_3O$ absorption of the trianisylvinyl system, which contained $^{13}C$ in its natural abundance, was used as the internal standard for the quantitative $^{13}C$ determination.

In the present work, the $^{13}C$ nmr spectrum of the unlabeled **4** from the reduction of **2**-OAc is shown in Fig. 1*A*. The C-1 and C-2 absorptions of the major diastereomer appear at 74.8 and 59.4 ppm, respectively, while those of the minor diastereomer appear at 76.1 and 60.9 ppm. Probably, the *erythro* isomer, with the OH and PhS groups as well as the two phenyl groups *trans* in the antiperiplanar conformation, constituted the major component, since the *threo* isomer would have the two phenyl groups *gauche* in the antiperiplanar conformation. The $^{13}C$ nmr spectrum of **4**-1,2-$^{13}C$ from the **2**-OAc-1,2-$^{13}C$ derived from the solvolysis of **2**-OTs-1-$^{13}C$, with about 20% $^{13}C$ enrichment, in HOAc–$Ac_2O$ containing 3 equiv. of NaOAc at 148 ± 2°C for 10 h, is given in Fig. 1*B*. It is seen that the intensities of the C-1 and C-2 absorptions are essentially the same in the spectrum of the unlabeled **4** as well as in the spectrum of **4**-1,2-$^{13}C$. These results indicate that the $^{13}C$-label is distributed essentially equally over C-1 and C-2, and it is not necessary to use an internal standard for the calculations as was done with the labeled triphenylvinyl and trianisylvinyl systems (8, 9). The same equal distribution of the label over C-1 and C-2 was observed when similar acetolyses of **2**-OTs-1-$^{13}C$ in HOAc–$Ac_2O$–NaOAc at 148 ± 2°C were carried out for 4 or 7 instead of 10 h. In all of these three experiments, the reaction likely had reached completion since the specific rate constant for the acetolysis of **2**-OTs in the presence of added NaOAc at 151°C was reported to be $81.3 \times 10^{-5}$ $s^{-1}$ (7). The finding that the scrambling of the label over C-1 and C-2 did not change with reaction time would suggest that the acetolysis product was stable when heated under anhydrous conditions in HOAc–$Ac_2O$–NaOAc. The present results on the equal distribution of the label over C-1 and C-2 in the substitution product, the formation of the *trans*-acetate with no detectable amount of the *cis*-isomer, and the earlier observation of Modena and co-workers (3, 4) on the equilibration of the label over the two ethylenic carbons in the cyclized product **3** all are consistent with and hence provide support for the thiirenium ion as a reaction intermediate (1, 2).

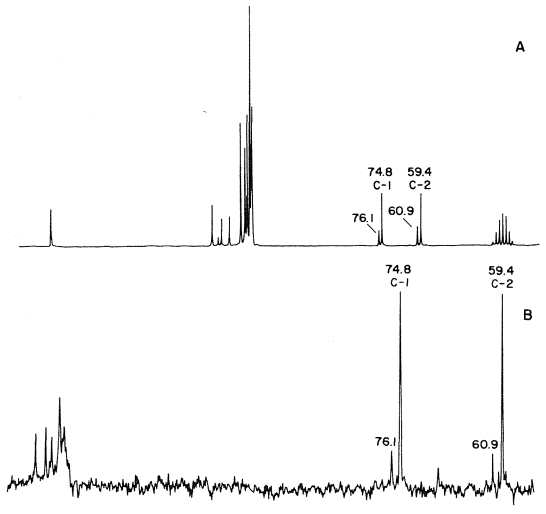

FIG. 1. $^1H$-decoupled $^{13}C$ nmr spectra in acetone-$d_6$ of the mixture of *erythro*- and *threo*-1,2-diphenyl-2-phenylthioethanols (**4**) derived from the reduction of ordinary *trans*-1,2-diphenyl-2-phenylthiovinyl acetate (2-OAc) (*A*), and of the mixture of *erythro*- and *threo*-1,2-diphenyl-2-phenylthio[1,2-$^{13}C$]ethanols (**4**-1,2-$^{13}C$) derived from the acetolysis of 20% enriched **2**-OTs-1-$^{13}C$ in HOAc–$Ac_2O$–NaOAc (*B*). (The chemical shifts in Figs. 1 and 2 were measured using the center peak of the acetone-$d_6$ absorptions at 28.05 ppm as internal reference.)

In previous work in this laboratory on solvolytic studies with labeled triphenylvinyl and trianisylvinyl bromides, one of the solvent systems employed was 70% HOAc – 30% $H_2O$ (by volume) (10, 11). In the present work, 70% HOAc – 30% $H_2O$ (to be called 70% HOAc or aqueous HOAc) was also utilized in solvolytic studies with **2**-OTs-1-$^{13}C$. The chief product from the reaction of **2**-OTs

| 5 | NaOAc (3 equiv.) | 24 | 89 | 11 | — |
| 6 | NaOAc (30 equiv.) | 24 | 67 | Trace | 33[b] |
| 7 | $HClO_4$[c] | 72 | 62 | 38 | — |

[a]Based on the $^1H$ nmr absorptions of the C-2 H's of **5** and **6** and the acetate H's of **2**-OAc.
[b]This would be the amount of **2**-OAc that survived under the conditions of Expt. 6. When only 3 equiv. of NaOAc was employed, apparently any **2**-OAc that might have been formed was likely all hydrolyzed to **5**.
[c]5.0 mL of 70% $HClO_4$ added to 50 mL of 70% HOAc – 30% $H_2O$.

in 70% HOAc was α-phenyl-α-(phenylthio)acetophenone (1,2-diphenyl-2-phenylthioethanone) (**5**). No acetate product, **2**-OAc, was detectable except when the reaction was carried out in the presence of a large excess of NaOAc. Interestingly, another product, usually a minor one, was obtained along with **5**, and it was identified as desoxybenzoin (1,2-diphenylethanone) (**6**). The relative yields of these products from solvolyses of **2**-OTs in aqueous HOAc under different conditions are given in Table 1. It is seen from Table 1 that the extent of formation of **6** rose with increasing reaction time, and furthermore, the presence of NaOAc or $HClO_4$, respectively, apparently could decrease or increase its formation.

When the labeled **2**-OTs-1-$^{13}C$ was solvolyzed in 70% HOAc in the presence of 3 equiv. of NaOAc at 148 ± 2°C for 4 h (conditions of Expt. 3, Table 1), followed by $LiAlH_4$ reduction of the product mixture, the major product, ketone **5**-1,2-$^{13}C$, was converted to the mixture of *erythro*- and *threo*-alcohols **4**-1,2-$^{13}C$ and the minor product, ketone **6**-1,2-$^{13}C$, was converted to1,2-diphenyl[1,2-$^{13}C$]-ethanol (**7**-1,2-$^{13}C$). The expanded aliphatic region of the $^{13}C$ nmr spectrum of the mixture of alcohols, **4**-1,2-$^{13}C$ and **7**-1,2-$^{13}C$, obtained from this experiment, is given in Fig. 2*B*, while the $^{13}C$ nmr spectrum of the unlabeled **7** is shown in Fig. 2*A*. From the essentially equal intensities of the C-1 and C-2 absorptions, it may be concluded that the $^{13}C$-label is distributed equally over C-1 and C-2 in both the major and minor products, ketones **5**-1,2-$^{13}C$ and **6**-1,2-$^{13}C$. Similar results indicating an equal distribution of the label over C-1 and C-2 in both **5**-1,2-$^{13}C$ and **6**-1,2-$^{13}C$ were also observed when **2**-OTs-1-$^{13}C$ was solvolyzed in 70% HOAc in the presence of 3 equiv. of NaOAc at 148 ± 2°C for 7 or 24 h (conditions of Expts. 4 and 5, Table 1).

Since the scrambling of the label over C-1 and C-2 remained the same in both **5**-1,2-$^{13}C$ and **6**-1,2-$^{13}C$, even though the relative amount of **6** that was formed was higher with a longer reaction time (Table 1), it is possible that the minor product, **6**-1,2-$^{13}C$, was formed from the initial product, **5**-1,2-$^{13}C$. It has also been noted from Table 1 that the formation of **6** was favored by the presence of a strong acid, and the *p*-toluenesulfonic acid liberated during the solvolysis of **2**-OTs could be such an acid. In some control experiments, ketone **5** in 70% HOAc containing 1 equiv. of TsOH was heated at 148 ± 2°C for 24 and 74 h, and indeed it was found that about 10 and 20%, respectively, of the ketone **5** was converted to desoxybenzoin (**6**), confirming the idea that **6** could be formed from the initial product **5**.

The detection of **5** and **6** as described above were based chiefly on the absorptions in the aliphatic regions of their $^1H$ and $^{13}C$ nmr spectra. On a closer examination of the carbonyl region of some of the $^{13}C$ nmr spectra of the products from the solvolysis of **2**-OTs in aqueous HOAc, such as the product from Expt. 7, Table 1, which contained some added $HClO_4$, besides the absorptions at 194.8 and 197.7 ppm attributable to the carbonyl groups of **5** and **6**, respectively, there was a third peak at 194.6 ppm, which was very near the 194.8 ppm absorption of **5**. It was shown subsequently that this third component was due to the carbonyl absorption of benzil. The presence of benzil among the products has actually been observed previously in the decomposition in $CH_3NO_2$ of *trans*-1,2-diphenyl-2-phenylthiovinyl and *trans*-1,2-diphenyl-2-*p*-tolylthiovinyl 2,4,6-trinitrobenzenesulfonates (12).

Since benzil was most readily observed in Expt. 7 (Table 1) with $HClO_4$ present in the reaction mixture, there is the possibility that benzil was derived from the oxidation of benzoin. It is known

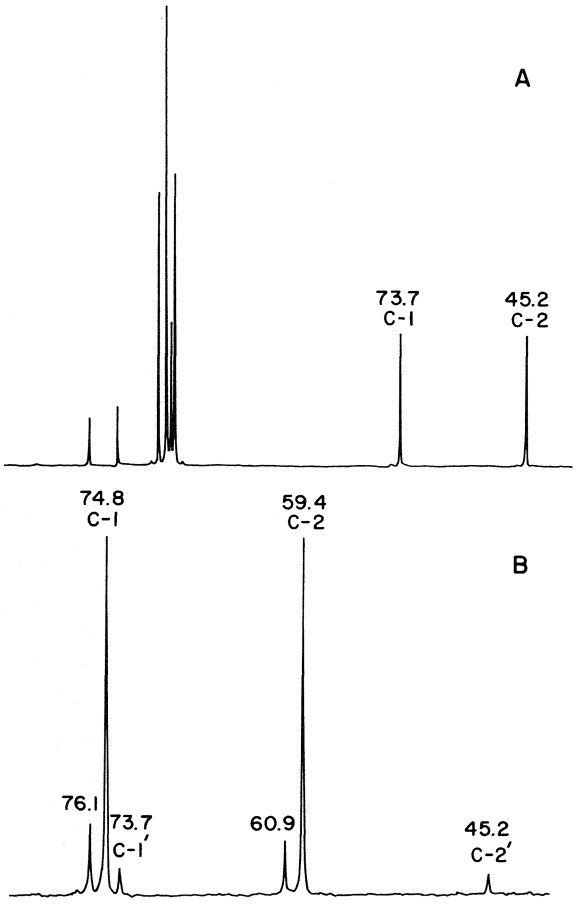

FIG. 2. $^1$H-decoupled $^{13}$C nmr spectra in acetone-$d_6$: *A* is the spectrum of ordinary 1,2-diphenylethanol (**7**); *B* is the expanded aliphatic region of the mixture of *erythro*- and *threo*-alcohols **4**-1,2-$^{13}$C and the alcohol **7**-1,2-$^{13}$C derived from the solvolysis of **2**-OTs-1-$^{13}$C in 70% HOAc in the presence of 3 equiv. of NaOAc at 148 ± 2°C for 4 h; the peaks marked C-1′ and C-2′ are due to **7**-1,2-$^{13}$C.

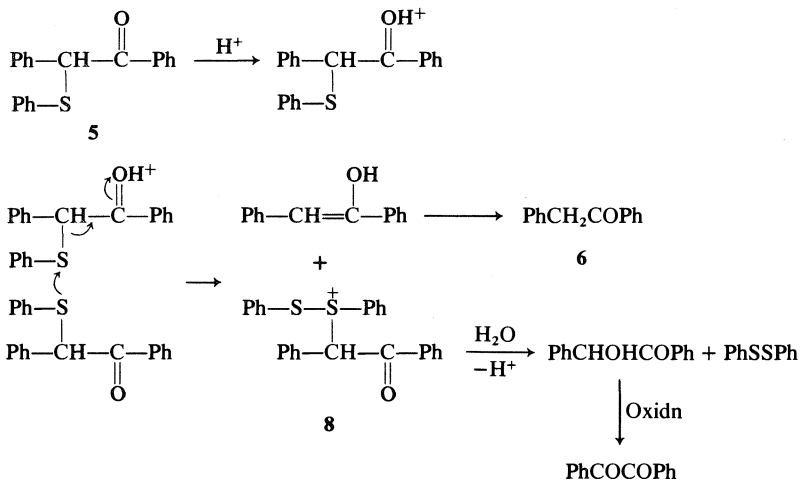
that vinyl sulfides (thioenol ethers) can be hydrolyzed to give ketones (13, 14). The enol form of **5** would be a thioenol ether and its hydrolysis would give rise to benzoin. Thus under the conditions of solvolysis of **2**-OTs in 70% HOAc, some benzoin might be formed and it in turn might be converted to benzil and desoxybenzoin (**6**). To test this possibility, ketone **5** in 70% HOAc containing 1 equiv. of TsOH and 1 equiv. of benzoin was heated at 148 ± 2°C for 24 h, but there was no significant increase in the 10% conversion of **5** to **6** which was observed in a similar control experiment without the presence of benzoin. Even when **5** in 70% HOAc containing 1 equiv. each of TsOH, benzoin and $C_6H_5SH$, the latter being added as a possible reducing agent, was treated in the same way at 148 ± 2°C for 24 h, there was again no significant increase in the conversion of **5** to **6**. Hence it must be concluded that the desoxybenzoin (**6**) obtained as a minor product in the present studies did not arise from benzoin.

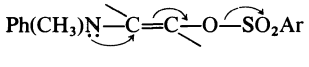
Besides **5**, **6**, and benzil, diphenyl disulfide has also been obtained as another product in the solvolysis of **2**-OTs in aqueous HOAc. In the work with **2**-OTs-1-$^{13}$C, the solvolysis products were treated with $LiAlH_4$ to give the alcohols **4**-1,2-$^{13}$C and **7**-1,2-$^{13}$C. Purification of these alcohols involved their passage through an alumina column. The unwanted materials were first eluted with a mixture of petroleum ether and ether before the desired alcohols were eluted with ether alone. It was from the petroleum ether – ether eluate that diphenyl disulfide was first detected. This disulfide has also been reported previously as among the products from the decomposition of *trans*-1,2-diphenyl-2-phenylthiovinyl 2,4,6-trinitrobenzenesulfonate in $CH_3NO_2$ (12) and from the solvolysis of *trans*-2-phenylthio-1,2-di-*p*-tolylvinyl 2,4,6-trinitrobenzenesulfonate in acetone–methanol (6). When 1.0 g of **2**-OTs in 50 mL of 70% HOAc was heated at 148 ± 2°C for 96 h, the products, **5**, **6**, benzil, and diphenyl disulfide, respectively, were isolated in yields of 22, 21, 11, and 13%. When ketone **5** in 70% HOAc containing 1 equiv. of TsOH was heated at 148 ± 2°C for 72 h, desoxybenzoin (**6**), benzil, and diphenyl disulfide were also obtained, indicating that these products resulted from subsequent reactions of the initial product **5**.

From the above results, it can be concluded that the solvolysis of **2**-OTs in 70% HOAc gave, via the thiirenium ion **1**, α-phenyl-α-(phenylthio)acetophenone (**5**) as the initial product. With labeled **2**-OTs-1-$^{13}$C as substrate, the label would be scrambled equally over C-1 and C-2. Upon being heated in the reaction mixture, part of the initial product **5** could be converted to desoxybenzoin (**6**), benzil, and diphenyl disulfide. To account for the formation of **6**, benzil, and diphenyl disulfide from **5**, a possible mechanism as given in Scheme 2 may be tentatively suggested. The processes outlined in Scheme 2 would be consistent with the finding that acidic and aqueous conditions are necessary to bring about these conversions. A key step is the suggestion that the phenylthio group of a second molecule of **5** could act as a reducing agent on a protonated **5** to give rise eventually to desoxybenzoin (**6**) and the sulfonium ion **8**. A nucleophilic displacement by $H_2O$ on ion **8** would give diphenyl disulfide and benzoin, with the latter being oxidized to benzil. Under the conditions of the present solvolytic studies with **2**-OTs, a possible oxidizing agent could be the liberated sulfonic acid. Indeed a test experiment has shown that some benzil was



SCHEME 2

isolated after a mixture of benzoin and TsOH was heated in 70% HOAc. The processes responsible for the formation of **6**, benzil, and diphenyl disulfide could, of course, be much more complex than the reactions outlined in Scheme 2. It has been found, for example, that in the solvolysis of β-aminovinyl sulfonates (15), an oxygen–sulfur cleavage in the sulfonate group via



as a transition state gave benzil as one of the products. Such a process conceivably could also play a role in the solvolysis of β-phenylthiovinyl sulfonates.

## Experimental

trans-*1,2-Diphenyl-2-phenylthio[1-*$^{13}$*C]vinyl tosylate (2-OTs-1-*$^{13}$*C)*

**2**-OTs-1-$^{13}$C was synthesized using a series of reactions as given in Scheme 1. The various steps involved were similar to those already reported in the literature (4, 16). The procedures for the steps leading to the carbonyl-labeled desoxybenzoin from $^{13}CO_2$ were essentially the same as those employed for the preparation of the carbonyl-labeled desoxyanisoin (16). The remaining reactions were carried out using procedures described by Modena and co-workers (4), with slight modifications involving the use of HOAc (16) instead of $CCl_4$ (4) as solvent in the bromination of the desoxybenzoin, and the use of *p*-toluenesulfonyl chloride instead of *p*-bromobenzenesulfonyl chloride in the final step to give the tosylate instead of the brosylate. The desired product, **2**-OTs-1-$^{13}$C, after crystallization from dichloromethane–pentane, melted at 140–141°C (lit. (7) mp 139–140°C), $^1$H nmr δ($CDCl_3$) 2.30 ($CH_3$, s, 3H), 6.80–7.60 (arom., m, 19H).

*Acetolysis under anhydrous conditions*

In a typical experiment, a mixture of 400 mg (0.87 mmol) of **2**-OTs-1-$^{13}$C (about 20% $^{13}$C enrichment) and 210 mg (2.6 mmol) of NaOAc in 30 mL of HOAc–$Ac_2O$ (9:1 by volume) in a sealed tube was heated in an oil bath at 148 ± 2°C for 10 h. The resulting material was poured into $H_2O$ and extracted 3 times with $CHCl_3$. The extract was washed successively with $H_2O$, a $NaHCO_3$ solution, and then $H_2O$. After drying over $MgSO_4$, removal of the solvent gave about 250 mg of crude product. In preliminary trials with ordinary **2**-OTs, the crude product was crystallized from methanol to give 50–55% yields of *trans*-1,2-diphenyl-2-phenylthiovinyl acetate (**2**-OAc), mp 88°C (lit. (7) mp 86°C), $^1$H nmr δ($CDCl_3$) 1.90 ($CH_3$, s, 3H), 6.90–7.80 (arom., m, 15H).

The crude acetate product from the labeled **2**-OTs-1-$^{13}$C was reduced twice successively (9, 17) with $LiAlH_4$ in anhydrous ether to give the mixture of *erythro*- and *threo*-1,2-diphenyl-2-phenylthio[1,2-$^{13}$C]ethanol (**4**-1,2-$^{13}$C). The **4**-1,2-$^{13}$C obtained after the $LiAlH_4$ treatments was purified by passage through a 30 cm × 2 cm diameter column packed with adsorption alumina. The unwanted material was first eluted with a 7:3 mixture of petroleum ether (bp 40–60°C) and ether before the product, **4**-1,2-$^{13}$C, was recovered by elution with ether. The $^{13}$C nmr spectrum of the *erythro*- and *threo*-alcohols, **4**-1,2-$^{13}$C, obtained from this experiment, is given in Fig. 1*B*, while the spectrum of the unlabeled **4** from the reduction of ordinary **2**-OAc is shown in Fig. 1*A*.

*Solvolysis in 70% HOAc – 30% $H_2O$*

In a typical experiment, a mixture of 300 mg (0.65 mmol) of **2**-OTs-1-$^{13}$C and 160 mg (2.0 mmol) of NaOAc in 50 mL of 70% HOAc in a sealed tube was heated in an oil bath at 148 ± 2°C for 4 h. The resulting material was worked up as described in the acetolysis under anhydrous conditions to give 200 mg of oil as crude product. Preliminary experiments with unlabeled **2**-OTs showed that under these conditions the crude product contained α-phenyl-α-(phenylthio)acetophenone (**5**) and desoxybenzoin (**6**) in a relative ratio of 95:5.

The crude product from the reaction with **2**-OTs-1-$^{13}$C was dissolved in ether and pentane was added to precipitate out unwanted materials which may contain some unreacted tosylate. After the removal of the precipitate and evaporation of the solvent, the residual oil containing **5**-1,2-$^{13}$C and **6**-1,2-$^{13}$C was treated once with $LiAlH_4$ in anhydrous ether to give the *erythro*- and *threo*-alcohols, **4**-1,2-$^{13}$C, and 1,2-diphenyl[1,2-$^{13}$C]ethanol (**7**-1,2-$^{13}$C), which were recovered after purification through an alumina column as described earlier. The aliphatic region of the $^{13}$C nmr spectrum of the mixture of labeled alcohols obtained in this experiment is shown in Fig. 2*B*, while the $^{13}$C nmr spectrum of a pure sample of ordinary **7** is given in Fig. 2*A*.

For personal use only.

The identification of ketones **5** and **6** in various experiments with ordinary **2**-OTs were based on their $^1H$ and $^{13}C$ nmr spectra, and these spectral data are as follows: α-phenyl-α-(phenylthio)acetophenone (**5**), $^1H$ nmr δ($CDCl_3$) 5.85 (CH, s, 1H), 7.15–7.65 (arom., m, 13H), 7.80–8.15 (arom., m, H *ortho* to CO, 2H); $^{13}C$ nmr δ($CDCl_3$) 60.3 (CH), 128.0, 128.1, 128.9, 133.1, 133.4 (arom.), 134.1, 135.7, 136.6 (quat. arom.), 194.8 (CO). Desoxybenzoin (**6**), $^1H$ nmr δ($CDCl_3$) 4.25 ($CH_2$, s, 2H), 7.20–7.60 (arom., m, 8H), 7.90–8.20 (arom., m, H *ortho* to CO, 2H); $^{13}C$ nmr δ($CDCl_3$) 45.6 ($CH_2$), 126.9, 128.7, 129.6, 133.2 (arom.), 134.3, 136.2 (quat. arom.), 197.7 (CO).

*Product determinations*

A solution of 1.00 g (2.2 mmol) of **2**-OTs in 50 mL of 70% HOAc in a sealed tube was heated at 148 ± 2°C for 96 h. The resulting material was poured into $H_2O$ and extracted with ether. The extract was washed with a $NaHCO_3$ solution and then with $H_2O$. After drying over $MgSO_4$, removal of the solvent gave 0.55 g of crude products which were separated by passage through an alumina column. The first fraction was eluted with a 6:1 (by volume) mixture of petroleum ether (bp 40–60°C) and ether to give 60 mg (13%) of diphenyl disulfide, mp 56–58°C (lit. (12) mp 55–58°C); its mass spectrum showed the molecular ion at *m/e* 218 as expected. The second fraction was eluted with a 3:1 mixture of petroleum ether – ether to give 90 mg (21%) of desoxybenzoin (**6**) which melted alone or on admixture with an authentic sample at 50°C. Its $^1H$ and $^{13}C$ nmr absorptions are given in the preceding section. The third fraction was eluted with a 2:1 mixture of petroleum ether – ether to give 150 mg (22%) of α-phenyl-α-(phenylthio)acetophenone (**5**), mp 82–83°C (lit. (18) mp 83–84°C). Again its $^1H$ and $^{13}C$ nmr absorptions are given in the preceding section. The fourth fraction was eluted with a 1:1 mixture of petroleum ether – ether to give 50 mg (11%) of benzil which melted alone or on admixture with an authentic sample at 95°C, $^1H$ nmr δ($CDCl_3$) 7.30–7.80 (arom., m, 6H), 7.90–8.20 (arom., m, H *ortho* to CO, 4H).

When a mixture of 1.40 g (4.6 mmol) of ketone **5** and 90 mg (4.7 mmol) *p*-toluenesulfonic acid in 50 mL of 70% HOAc in a sealed tube was heated at 148 ± 2°C for 72 h, after the usual work up, separation of the products through the alumina column gave 180 mg (18%) of diphenyl disulfide, 300 mg (33%) of desoxybenzoin (**6**), and 100 mg (10%) of benzil.

When a mixture of 1.00 g (4.7 mmol) of benzoin and 2.70 g (14 mmol) of TsOH in 50 mL of 70% HOAc in a sealed tube was heated at 148 ± 2°C for 72 h, the usual work up and product separation gave 200 mg (20%) of benzil.

# Effect of hydrogen bonding on the π-electronic absorption spectra of some bicyclic secondary amines

TAPAN GANGULY AND SUKHENDU B. BANERJEE[1]

*Optics Department, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 700032, India*

Received June 25, 1981

TAPAN GANGULY and SUKHENDU B. BANERJEE. Can. J. Chem. **60**, 741 (1982).

Spectral shift and change in the intensity of electronic absorption bands of bicyclic molecules, 1,2,3,4-tetrahydroquinoline (THQ) and 1,2,3,4-tetrahydroisoquinoline (THIQ), on hydrogen bond formation in binary and ternary solutions were investigated. Roles of factors contributing to the spectral changes such as change in configuration of the molecules and σ–π interaction are discussed in this paper.

TAPAN GANGULY et SUKHENDU B. BANERJEE. Can. J. Chem. **60**, 741 (1982).

Dans cet article on examine en détail le décalage spectral et le changement dans l'intensité des bandes d'absorption des molécules bicycliques 1,2,3,4-tétrahydroquinoline (THQ) et 1,2,3,4-tétrahydroisoquinoline (THIQ) suivant la formation de le liaison hydrogène en solutions binaires et ternaires.

On discute les rôles des facteurs comme le changement dans la configuration des molécules et l'interaction σ–π contribuants aux changements mentionnés ci-dessus.

## Introduction

Several authors have discussed hydrogen bonding in secondary amines acting either as proton donors (1, 2) or as proton acceptors (3–5). The present work concerns the hydrogen bonding behaviour and π-electronic absorption spectra of 1,2,3,4-tetrahydroquinoline (THQ) and 1,2,3,4-tetrahydroisoquinoline (THIQ) in binary and ternary solutions in *n*-heptane and dioxane. The infrared absorption of the molecules in *n*-heptane and dioxane was also measured to get corroborative evidence about intermolecular hydrogen bond. Both these molecules, THQ and THIQ, are bicyclic secondary amines with the NH-group in the ring that has non-aromatic bonds. The hydrogen bonding in such molecules has not been studied earlier. It was felt that study of π-electronic spectral changes effected through intermolecular hydrogen bond formation might provide useful information about change in configuration of the molecules and σ–π conjugation. In this paper the results are described.

## Experimental

Chemically pure compounds of THQ (ρ = 1.055 g/mL; bp 251°C) and THIQ (ρ = 1.0642 g/mL; bp 232°C) supplied by Fluka, Switzerland and dioxane supplied by Messers British Drug House, London were used after distillation under reduced pressure. The solvent *n*-heptane, obtained from E. Merck, was of spectroscopic purity and was used without further purification. The electron absorption spectra were measured with a Hilger U.V. spectrophotometer. Infrared spectra were recorded with a Beckman IR-2OA Spectrophotometer fitted with a grating monochromator. The experimental details were as described earlier (6). The spectral data and the measured thermodynamic quantities are given in Tables 1–4.

[1]To whom all correspondence should be addressed.

## Calculations

Dioxane and *n*-heptane were the proton acceptor and the inert solvent respectively. The concentration of dioxane was increased in steps and in every step the concentration of THQ or THIQ was kept fixed at a very low value ($\sim 10^{-4}$–$10^{-5}$ mol/L) compared to that of dioxane.

The association equilibrium constant ($K$) was calculated by the equation described by Ketelaar *et al.* (7)

$$[1]\quad \frac{1}{\varepsilon - \varepsilon_f} = \frac{1}{C}\,\frac{1}{\varepsilon_b - \varepsilon_f}\,\frac{1}{K} + \frac{1}{\varepsilon_b - \varepsilon_f}$$

where ε = apparent molar extinction coefficient for THQ in solution in which dioxane concentration is $C$, $\varepsilon_f$ = molar extinction coefficient of the non-hydrogen bonded molecule and $\varepsilon_b$ = molar extinction coefficient for the hydrogen bonded molecule. All these extinction coefficients refer to a given frequency. Molar extinction coefficient $\varepsilon_b$ for the hydrogen bonded species was calculated for every frequency from [2] which can be readily deduced from [1].

$$[2]\quad \varepsilon_b = \varepsilon + \frac{\varepsilon - \varepsilon_f}{KC}$$

The hydrogen-bonded curves were obtained by plotting $\varepsilon_b$ against ν (in $cm^{-1}$) (6, 8, 9).

On plotting $1/(\varepsilon - \varepsilon_f)$ against $1/C$, straight lines were obtained and upon extrapolating them to the point $1/(\varepsilon - \varepsilon_f) = 0$, the values of $K$ were obtained.

The free energy ($\Delta F$), the energy of hydrogen bond formation ($\Delta H$), and the $f$-values were calcu-

lated from the familiar relations,

[3] $\Delta F = -RT \ln K$

[4] $\Delta H = -\dfrac{R\,\mathrm{d} \ln K}{\mathrm{d}(1/T)}$

and

[5] $f = 4.32 \times 10^{-9} \int \varepsilon d\nu$

A plot of $R \ln K$ versus $1/T$ yielded straight lines whose slope gave $\Delta H$. The method of least-squares was used for calculating $\Delta H$ and $K$.

## Results and discussion

In $n$-heptane solution THQ exhibits two systems of absorption bands in the regions 2750 Å to 3170 Å and 2320 Å to 2620 Å (Fig. 1 (*a*) and (*b*)). When the

($1.584 \times 10^{-4}$ mol $L^{-1}$ THQ in *n*-heptane). *I*, $c_{dioxane} = 0$; *II*, $c_{dioxane} = 0.1$ mol $L^{-1}$; *III*, $c_{dioxane} = 0.3$ mol $L^{-1}$; *IV*, $c_{dioxane} = 0.5$ mol $L^{-1}$; *V*, hydrogen bonded curve (only the upper portions of the curves near the peaks are shown). (*b*). Ultraviolet absorption curves for THQ (at 302 K) (transition II). ($1.584 \times 10^{-5}$ mol $L^{-1}$ THQ in *n*-heptane); *I*, $c_{dioxane} = 0$; *II*, $c_{dioxane} = 0.08$ mol $L^{-1}$; *III*, $c_{dioxane} = 0.2$ mol $L^{-1}$; *IV*, $c_{dioxane} = 0.3$ mol $L^{-1}$; *V*, $c_{dioxane} = 0.5$ mol $L^{-1}$; *VI*, hydrogen bonded curve (only the upper portions of the curves near the peaks are shown).

proton acceptor solvent dioxane is added to the binary solution of THQ in *n*-heptane, bands of the both absorption systems shift towards the longer wavelength side (Table 1). The observed red shifts of the two systems are characteristic of a $\pi^* \leftarrow \pi$ transition and both systems may be logically assigned to such transition. Moreover, probability of excitation of a nitrogen non-bonding electron to $\pi$-orbital of the aromatic ring will not be high because the nitrogen atom is in the non-aromatic ring 2 and separated by a bond from the aromatic ring 1 (inset in Fig. 1). In the spectrum of THIQ in *n*-heptane one $\pi$-electronic band system in the region 2500 Å to 2760 Å is observed (Fig. 2) and the bands do not undergo any red shift worth noting when dioxane is added to the THIQ–*n*-heptane solution. For THQ the integrated absorption $\int \varepsilon d\nu$ increases, with the addition of proton acceptor dioxane (Table 2), tending to a constant value at high dioxane concentration (>0.5 mol/L). The corresponding change in the case of THIQ is, however, very small. Since *n*-heptane comprises the bulk of the ternary solution in which the relative concentration of dioxane is low, the effect of change of polarity, without H-bonding, will not be of any great significance and the observed spectral changes should presumably be attributed to intermolecular hydrogen bonding involving THQ (or THIQ) and dioxane molecules. The linear graph obtained from the plot of $1(\varepsilon - \varepsilon_f)$ versus $1/C$ (Figs. 3 and 4)

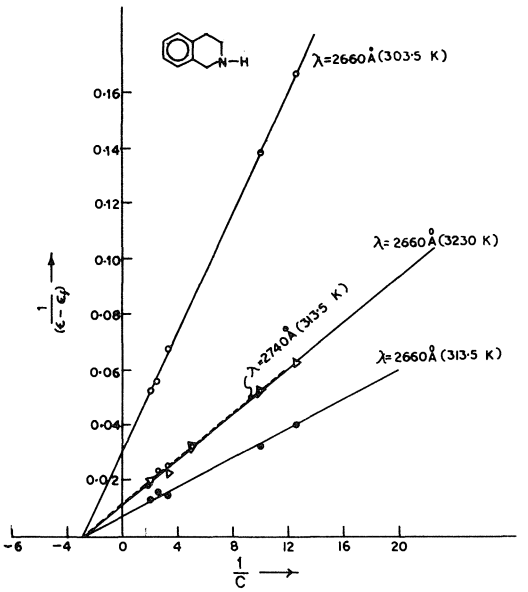

FIG. 4. Plot of $1/(\varepsilon - \varepsilon_f)$ vs. $1/C$ for the determination of *K* in the THIQ system.

further indicates occurrence of 1:1 hydrogen bonded complex.

To get complementary evidence of an intermolecular N—H···O bond, the infrared spectra of THQ and THIQ in *n*-heptane and dioxane were recorded and the absorption curves are presented in Fig. 5(*a*) and (*b*). For THQ in *n*-heptane solution (Fig. 5(*a*)) the free ν(N—H) band can be located at 3430 $cm^{-1}$. When dioxane is added to the solution a second band which may be reasonably assigned to vibration of bonded N—H, appears at 3380 $cm^{-1}$ (Fig. 5(*a*)). In the presence of an excess amount of dioxane in the ternary mixture, this band predominates over the 3430 $cm^{-1}$ band whose intensity becomes vanishingly small. In the infrared spectra of THIQ, the free ν(N—H) band is at 3320 $cm^{-1}$. This value of free ν(N—H) for THIQ in which the N—H group is in the non-aromatic ring and separated from the aromatic ring by intervening bonds, is closer to the value expected for an aliphatic amine (10). Addition of dioxane results in a small but finite red shift of 20 $cm^{-1}$, indicating formation of intermolecular bond, though weak, between THIQ and dioxane.

From Table 4 it is seen that for THQ and THIQ, the oscillator strength of bonded molecules ($f_b$) is larger than that of free molecules ($f_f$). However, some interesting points are brought to light if the enthalpy of hydrogen bond and the change in intensity of absorption, expressed as $f_b/f_f$ or $\Delta f$, for

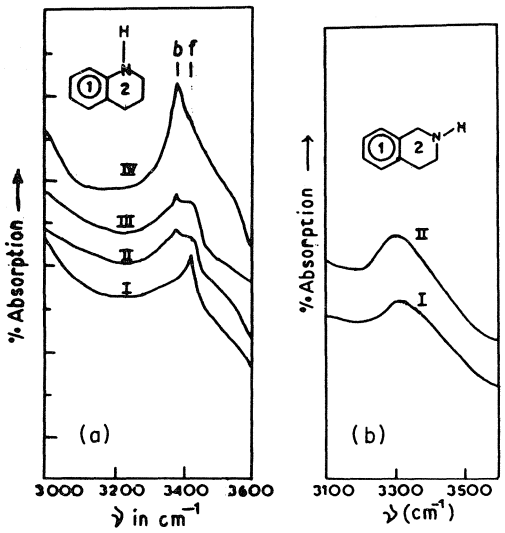

FIG. 5(*a*). Infrared absorption curves for THQ (at 298 K) (1.58 × $10^{-2}$ mol $L^{-1}$ THQ in *n*-heptane): *I*, $c_{dioxane} = 0$; *II*, $c_{dioxane} = 0.5$ mol $L^{-1}$; *III*, $c_{dioxane} = 0.6$ mol $L^{-1}$; *IV*, excess dioxane. (*b*). Infrared absorption curves for THIQ (at 298 K) (1.59 × $10^{-2}$ mol $L^{-1}$ THIQ in *n*-heptane): *I*, $c_{dioxane} = 0$; *II*, excess dioxane.

THQ, THIQ, and *o*-toluidine, a primary amine, presented in Table 5 are examined. Taking up first the molecules of THQ and *o*-toluidine, it is seen that the energy of the hydrogen bond ($\Delta H$) in the case of THQ is nearly half of that in the case of *o*-toluidine. This is as expected because secondary amines are known to be much weaker hydrogen bonding agents than primary amines (11, 12). Interestingly, the increase in *f*-value is much greater for the weaker hydrogen bonding THQ molecule than for the *o*-toluidine molecule. The spectral shifts observed for the two molecules are of comparable magnitude.

The alicyclic ring in tetraline is known to have cyclohexene-like distorted chair structure (13). According to Aroney and Le Fèvre (14), with the valencies of the nitrogen atom disposed pyramidally and the C—C—C angles tetrahedral, a chair structure need be considered for piperidine molecule, where the N—H bond may be axial or equatorial, and they had concluded that piperidine in benzene solution contains 80% or more of the axial form. The non-aromatic ring 2 of THQ (inset in Fig. 1(*a*)) could be assumed to have a similar structure and the π-character of the non-bonding electrons on N-atom should be different from that of the toluidine molecule where the nitrogen atom, as in aniline, uses $sp^2$ orbitals. From proton magnetic resonance studies Booth (15) actually proposed for THQ a mixture of rapidly inverting half-chair structure and made the tentative suggestion that equal proportions of axial and equatorial

TABLE 5. Comparison of enthalpy of hydrogen bond and change in *f*-value for THQ, THIQ, and *o*-toluidine

| System | $-\Delta H$ (kcal $mol^{-1}$) | $f_b/f_f$ | $\Delta f$ |
|---|---|---|---|
| THQ | 2.49 | 1.326 (Transition I) | 0.015 |
| | | 1.444 (Transition II) | 0.093 |
| *o*-Toluidine (6) | 4.92 | 1.178 (Transition I) | 0.007 |
| | | 1.360 (Transition II) | 0.077 |
| THIQ | 1.22 | 1.142 (Transition I) | 0.001 |

conformations might be present. In connection with the changes observed in the spectrum of THQ in *n*-heptane–dioxane solution several possibilities deserve attention. The intermolecular hydrogen bond may bring about change in conformational equilibrium of the THQ molecule with the N—H bond tending to deviate from the axial position. As the intensification of the spectra indicates larger resonance or larger participation of nitrogen nonbonding electrons of the alicyclic-like ring in the π-electronic system of ring 1 (inset in Fig. 1 (*a*)), it appears that the lone pair electrons may possibly have gained some *p*-character consequent upon the new conformation in which the C—NH group may be more coplaner with the ring 1 so that the nitrogen atom is favourably placed to allow for large overlap of lone pair with carbon $p\pi$-electrons. Further, since the formation of intermolecular hydrogen bond leads to an increase in σ-electron density on the nitrogen atom (6, 8, 9, 16, 17), another contributing factor may be increased σ–π interaction, whose role in explaining spectral characteristics of bicyclic molecules has been stressed by previous authors (18, 19).

The situation is different in THIQ (inset in Fig. 2) in which the N—H group is away from the aromatic ring 1 separated by intervening bonds and is shielded by charge clouds of hydrogen atoms on both sides. In this molecule the weak intermolecular hydrogen bond resulting from addition of dioxane to *n*- heptane–THIQ solution produces no noticeable spectral shift or intensification of the spectrum.

# Large hydrophobic interactions with clearly defined geometry. A dimeric steroid with catalytic properties

J. PETER GUTHRIE, PATRICIA A. CULLIMORE, ROBERT S. MCDONALD, AND STELLA O'LEARY

*Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7*

Received May 27, 1981

J. PETER GUTHRIE, PATRICIA A. CULLIMORE, ROBERT S. MCDONALD, and STELLA O'LEARY. Can. J. Chem. **60**, 747 (1982).

The steroid dimer α,α′-bis(17β-(4′-imidazolyl)-11-keto-5α-androstan-3β-amino)-*p*-xylene, **3**, has been synthesized by reductive amination of 17β-(4′-imidazolyl)-5α-androstane-3,11-dione by *p*-xylenediamine in the presence of sodium cyanoborohydride, and by reductive amination of terephthalaldehyde by 3β-amino-17β-(4′-imidazolyl)-5α-androstan-11-one. The second method is stereochemically unambiguous; the first is not. Compound **3** acts as a catalyst for the hydrolysis of 3-arylpropionate esters of 3-hydroxy-4-nitrobenzoic acid. For the phenanthryl propionate the rate enhancement relative to imidazole is 200-fold, and the rate enhancement relative to the hypothetical rate for the propionate reacting with the steroid by the same transition state geometry is 3000-fold. The slope of a plot of log $k_{corr}$ vs. π for the reaction of **3***b* with aryl propionate esters was 0.83; the corresponding slope for **12** was 0.39. This provides a design parameter for the construction of artificial enzymes.

J. PETER GUTHRIE, PATRICIA A. CULLIMORE, ROBERT S. MCDONALD et STELLA O'LEARY. Can. J. Chem. **60**, 747 (1982).

On a synthétisé le α,α′-bis-((imidazolyl-4′)-17β céto-11 5α-androstane amino-3β) *p*-zylène, **3**, par amination réductrice de la (imidazolyl-4′)-17β 5α-androstanedione-3,11 par la *p*-xylènediamine en présence de cyanoborohydrure de sodium et par amination réductrice du téréphtalaldéhyde par l'amino-3β (imidazolyl-4′)-17β 5α-androstanone-11.

La deuxième méthode est stéréochimiquement sans ambiguité; la première ne l'est pas. Le composé **3** est un catalyseur pour l'hydrolyse des esters aryl-3 propionates de l'acide hydroxy-3 nitro-4 benzoique. Dans le cas du phénanthryl-3 propionate l'augmentation de la vitesse relative à l'imidazole est égale à 200 alors qu'elle est égale à 3000 par rapport au propionate qui réagirait avec le stéroïde en passant par un état de transition qui aurait la même géométrie. La pente de la courbe de log $k_{corr}$ en fonction π pour la réaction du composé **3***b* avec les esters arylpropionates est de 0,83; la pente correspondante est de 0,39 pour le composé **12**. Ceci fournit un paramètre de conception pour la construction d'enzymes artificiels.

[Traduit par le journal]

## Introduction

We have previously (1) reported studies of the imidazolyl steroid, **1**, which can act as a catalyst, in aqueous solution, for active esters **2***a–d*, and which shows a marked specificity for esters with a hydrophobic acyl group, such as **2***b–d*, with **2***d* being the best substrate found so far. Careful analysis of the kinetic behavior of these reactions showed that there was a potential rate enhancement, due to favorable hydrophobic interactions between steroid and ester, of as much as 156-fold for a phenanthrene ring interacting with the steroid, but that much of this was masked by unavoidable rate-retarding steric effects in the vicinity of the reaction center, so that only a 3.6-fold rate enhancement was observable. In related studies of enolization catalyzed by **1** (2) it was found that the same hydrophobic effect was present and the steric retardation was less, so that more of the potential effect became apparent; in fact a 110-fold rate enhancement relative to imidazole was directly observable.

A clear conclusion from these experiments was that in order to get a large rate enhancement for ester hydrolysis, a greater area of hydrophobic contact between substrate and catalyst was essential. A conceptually simple way to achieve such an increased area of contact would be to use dimeric steroids such as **3** or **4**, with two steroid moieties linked by a *p*-xylylene bridge. Space filling models (CPK) suggested that this sort of dimeric steroid would allow a phenanthryl (or smaller) aromatic system to intercalate snugly, but without crowding or strain.

Clearly, **4** is the more desirable catalyst, because the additional amines allow for more positive charges at the pH where the imidazolyl groups are catalytically active (ca. pH 8) and so allow greater solubility in water. Unfortunately, serious difficulties were encountered in trying to prepare **4** from **1**, and it seemed advisable to study a more accessible steroid, in order to test the validity of our hypothesis that a dimeric steroid would show much larger rate effects.

As anticipated, **3** was relatively accessible by reductive amination as shown in Scheme 1. Preliminary studies, using the material prepared by this route, showed that it was indeed much more effective as a catalyst for the hydrolysis of esters **2***b–d* than **1**, although it was only very sparingly soluble in water. Unfortunately, the high resolution nmr spectrum gave grounds for profound suspicion that it was not stereochemically homogeneous; see Fig. **1**(b). The 100 MHz $^1$H nmr spectrum taken at the time this work was carried out showed only a slight splitting of the signal attributed to the xylene

aromatic CH protons. These studies have had to be regarded as preliminary because of doubts about the stereochemical nature and purity of the dimer at the 3-positions of the steroid residues. Nonetheless it was possible to examine the pH dependence of the kinetic behavior of the material prepared in this way, and to study the catalytic properties of this dimer as a model for the stereochemically unambiguous material.

It appeared necessary to prepare **3** by a different route, free of stereochemical ambiguity. This has now been accomplished, by the route shown in Scheme 2. We will refer to the material prepared according to Scheme 1 as **3***a*, and material prepared according to Scheme 2(b) as **3***b*. We are now able to report the results of studies of the reactions of **3***a* and **3***b* with **2***a*–*d*.

This work leads to large hydrophobic effects for which there is very little structural uncertainty. It is our hope that these results will be of interest both to other students of enzyme models, and also to those concerned with the theory of hydrophobic interactions.

## Results

*Synthesis of* **3**a

Reductive amination, using sodium cyanoborohydride, served to link *p*-xylenediamine, **5**, with 17β-imidazolyl-5α-androstane-3,11-dione, **6** (prepared as previously described (4)), to give the dimeric steroid, **3**. This material was isolated as the tetrahydrochloride salt, and was purified by chromatography. The purified material was chromatographically homogeneous, and had an nmr spectrum consistent with the anticipated structure, except that a spectrum recorded at 100 MHz showed splitting of the signal from the phenyl ring protons. In a symmetrical dimer of constitution **3***a* these protons would all be equivalent. It therefore appears that either we have a mixture of compounds or one of the amines was generated with axial and one with equatorial geometry. The salt was of limited, though adequate, solubility in water, but the solubility decreased markedly as the pH was raised above 6.

*Kinetics with* **3**a

The kinetics were carried out under pseudo-first-order or approximately pseudo-first-order conditions; it was sometimes necessary to have a ratio of reagent concentrations closer to unity than is desirable in order to maintain an adequate absorbance change. Most kinetics were done with steroid in excess, although for PPA-HNB[1] as substrate some runs were done with substrate in excess. Considerations discussed in an accompanying paper (3) suggest that in some cases our treatment of the data is oversimplified; unfortunately it is not possible to apply the more sophisticated methods recently developed for this purpose to the data reported in the present paper, because the data were recorded some years ago before our laboratory was equipped with digitizing data-capture apparatus, and consequently the number of data points is too small.

The experimental conditions and the parameters describing the data are contained in Table 1. As is shown in Fig. 2, there is a concentration dependence for the apparent second-order rate constants for the larger substrates, which means that true values can only be determined at rather low concentrations. The limiting concentration, below which the rate constant is independent of reagent concentrations, is a function of the nature of the substrate and in particular of the size of the hydrophobic portion of the substrate. We attribute this behavior to aggregation and/or precipitation of steroid by substrate. The inherent reactivity of the

[1]Abbreviations used: monomer = **12**; dimer = **3**; ACE-HNB = **2***a*, HCA-HNB = **2***b*, NPA-HNB = **2***c*, PPA-HNB = **2***d*.

3a

SCHEME 1

three substrates, as measured by rate of reaction with imidazole, is identical.

The apparent rate constant for reaction of the steroid with an aryl ester substrate is expected to be a function of pH as a result of protonation of the imidazole groups. As a working hypothesis we have assumed that the two imidazole groups in **3** act independently, and that both have the same $pK_a$ as imidazole itself (or the imidazole in **1**). This leads to the following equation for the observed rate constant (provided that both the amino groups remain fully protonated, i.e. pH ≦ 8.

$$[1] \quad k_{obs} = k(1 + K/[H^+])/([H^+]/2K + 1 + K/2[H^+])$$

where $k$ is the rate constant per free imidazole of **3**, and $K$ is the microscopic ionization constant for an imidazolium group in **3**. The available data at three pH values are fitted by this equation using the measured $pK_a$ value for **1**, which is essentially the same as for imidazole, and a value for $k$ picked to give the best fit. For NPA-HNB the data are in reasonable accord with this simple picture, although unfortunately the precision is not high enough for a stringent test. For PPA-HNB the rate constants at pH values higher than 7.1 actually decrease with increasing pH; see Table 1. We interpret this to mean that we were not working at low enough concentrations at these higher pH values, and that with a lower net charge on the dimeric steroid, the critical concentration below which aggregation would interfere with the kinetics was lower than the accessible limit in concentration when these experiments were done.

*Synthesis of* **3**b

The synthesis is outlined in Scheme 2(b): corticosterone was converted to **8** as previously described (4). In order to obtain **9** by a Birch reduction it was necessary to increase the solubility of **8** in nonpolar aprotic solvents. Compound **8** itself is very soluble in methanol, but only sparingly soluble in THF or other ether solvents. Accordingly **8** was alkylated using benzyl chloride to give a mixture of isomeric *N*-benzyl derivatives. These could be separated by crystallization, but the mixture was generally used for the reduction. The benzylated material was, as expected, quite adequately soluble in THF for our purposes, and was submitted to reduction by a solution of sodium in liquid ammonia. When the reaction was judged to be complete on the basis of tlc analysis, excess sodium was destroyed using ammonium chloride. Work-up gave **9** contaminated with **8** and some of the overreduced material with a 3-hydroxyl group. Although **9** could be crystallized, it proved easier to perform the purification at the next stage of the synthesis. The stereochemistry of the reduction followed the expected course, giving the α-isomer, as judged by the $^{13}C$ nmr. The chemical shift of C-19 is very sensitive to the stereochemistry at carbon-5 (5). Compound **9** was readily converted to the oxime **10**, which could be crystallized to give

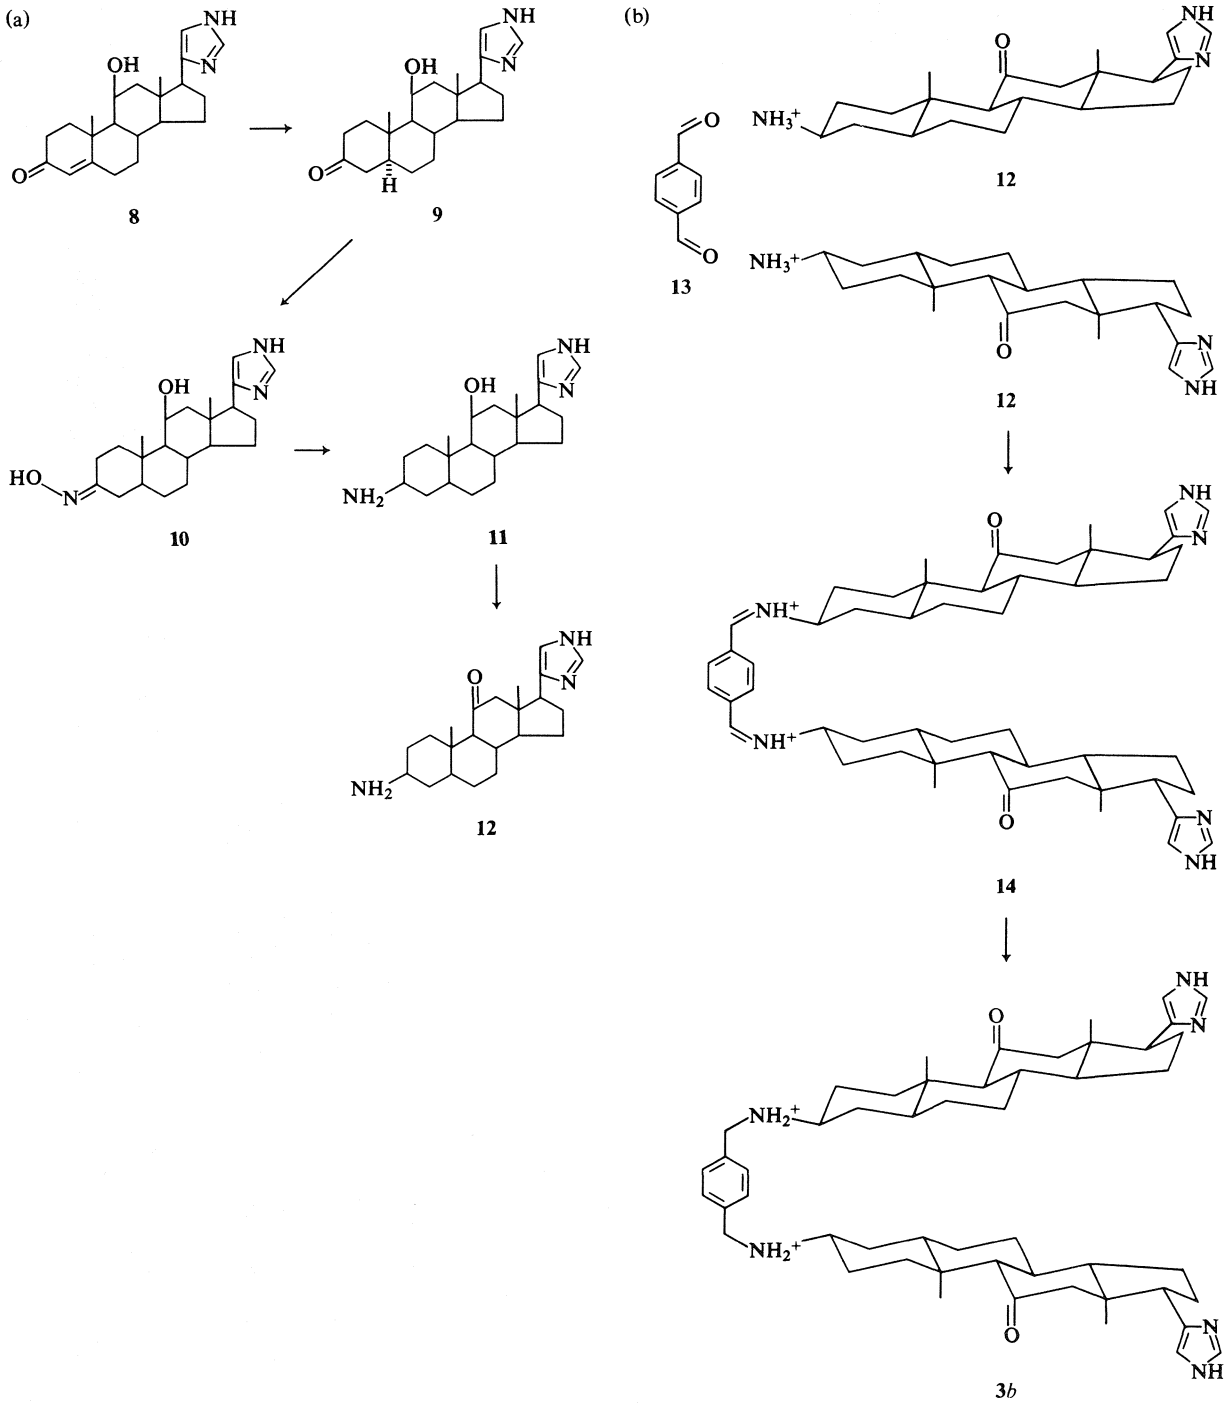

SCHEME 2

material free of C=C-containing contaminants. Reduction of the oxime using sodium – *n*-propanol gave **11**, which was purified by low pressure chromatography. This reaction is expected (6) to give the 3-β (equatorial) amine.

The stereochemistry was confirmed by examination of the 200 MHz $^1$H nmr spectrum of the DCl salt of **12** in $D_2O$, which showed a broad signal at 3.6 δ attributed to the C(3)-H, with $\Delta\nu_{1/2} \simeq 30$ Hz. There is a one-proton triplet overlapping this signal

[a]Estimate of the uncertainty in the data based on scatter about the least-squares lines. $\sigma^2$ = (weighted sum of squares of residuals)/(degrees of freedom). A value of $\sigma$ = 0.002 is expected for absorbance values in the range encountered in these experiments.
[b]Weighted average.
[c]Corrected for the uncatalyzed hydrolysis, assuming that NPA-HNB and HCA-HNB undergo uncatalyzed hydrolysis at the same rate at pH 7.1 (as they do at pH 8 (1)).
[d]Not included in the calculation of the average.

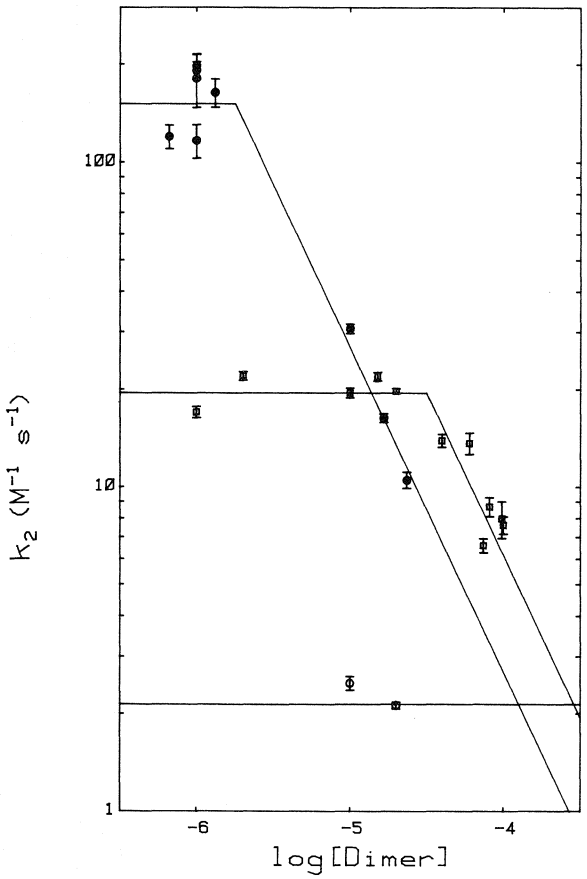

FIG. 2. Concentration dependence of rate constants for the reaction of **3** with HCA-HNB (○), NPA-HNB (□), and PPA-HNB (●). log $k_2$ as a function of log [steroid dimer concentration].

so that $\Delta\nu_{1/2}$ is imprecise, but it is unquestionably > 20 Hz, and ≫ 8 Hz, the value expected if the $NH_3^+$ were axial (7). Thus the stereochemistry is as desired. The C(3)-H was not distinguishable from the mass of skeletal proton signals in the spectrum of the neutral molecule in $CD_3OD$. In the spectrum of the DCl salt in $D_2O$ this peak is well resolved from the skeletal proton signals, but is almost coincident with a triplet; these two signals integrate for a total of 2 protons. There is also a one-proton doublet at 3.07 δ and a two-proton doublet at 2.56 δ; the latter may actually be the two central peaks of an AB quartet. These signals had been seen earlier in the spectrum of 17β-(4-imidazolyl)-5α-androstane-3,11-dione (4), but had not been as well separated or resolved at 100 MHz. Other steroids in this series, lacking the 11-keto group, did not show this pattern of three low-field signals.

Oxidation of **11** by $Cr^{VI}$ in acetic acid, with alkaline work-up by the procedure of Mueller and DiPardo (8), gave **12**, which could be crystallized from acetonitrile. After various trials at reductive dimerization, it was found best to prepare the diimine by reaction in benzene–ethanol, with azeotropic removal of water, followed, after removal of solvent, by reduction in DMF using sodium cyanoborohydride and trifluoroacetic acid. The crude dimer was purified by low pressure chromatography. It was homogeneous by tlc, and gave clean $^1H$ and $^{13}C$ nmr spectra. The molecular ion could be seen in the mass spectrum, although it was rather weak, and gave the expected exact mass.

*Kinetics with* **3**b

For all reactions we have given the parameters for empirical equations which describe the data; in each case the fit was by weighted least squares (9). Despite the fact that we could fit the data reasonably well by a suitable equation, it frequently happened, as will be described below, that there is no theoretical justification for the form of equation used, so that the parameters have no simple interpretation. We report these parameters as a way of summarizing the empirical facts concisely, since the primary data are voluminous.

*Monomer and ACE-HNB*

The conditions for these reactions are shown in Table 2; it will be apparent that the reactions are second order because the concentrations of monomer and ester are comparable. Although the data could be fitted reasonably well to an integrated first-order equation, with parameters given in Table 2, the fit was not ideal and there was no theoretical justification for the use of this equation. The difficulty is that there is a competing uncatalyzed hydrolysis, and also hydrolysis of the acetyl imidazole formed from reaction of monomer with ester, leading to regeneration of catalyst.

$$\text{Ester} \xrightarrow{k_1} \text{acid} + \text{aryloxide}$$

$$\text{Steroid} + \text{ester} \xrightarrow{k_2} \text{acylimidazole} + \text{aryloxide}$$

$$\text{Acylimidazole} \xrightarrow{k_3} \text{acid} + \text{steroid}$$

In the absence of a closed-form integrated rate law which could be fitted to the observable data, a new method for extracting the rate constants is required. In an accompanying paper (3) we report two methods for accomplishing this task. In one, numerical integration is used to provide calculated absorbance values corresponding to a set of parameters, and to allow numerical evaluation of the derivatives needed for least-squares refinement of the parameters. Another method uses numerical differentiation of the original data to give a curve from which the rate constants can be extracted. It was concluded that the second method, based on differentiation of the absorbance time curve, was generally preferable.

In the present case we calculate the quantity:

$$[2] \quad z = (\mathrm{d}x/\mathrm{d}t)/(a - x) = k_1 + k_2 (b - y)$$

where $x$ = absorbance − initial absorbance; $a$ = total change in absorbance at completion; $b$ = initial concentration of imidazole; $y$ = concentration of acylimidazole. In calculating the slope, $\mathrm{d}x/\mathrm{d}t$, one must compromise between taking slopes from few points, and accepting high noise levels, and taking slopes involving more points and inevitably smoothing out some of the information, particularly at the beginning of the reaction where we are especially interested in the instantaneous slope. We have generally compromised on 5 or 7 points per instantaneous slope. In several cases we examined the consequences of varying the number of points used to ensure that no major changes in the results would ensue. Inevitably $z$ has large uncertainties at long times where both numerator and denominator are small.

For the situation of ACE-HNB and monomer a plot of $z$ vs. $t$ shows a fall in $z$ followed by a rise to approximately the initial value. From the initial value of $z$,

$$z_0 = k_1 + k_2 b$$

we can determine $k_2$ given $k_1$ and $b$. From the position of the minimum in $z$, $k_3$ can be determined, since we have shown (10) that

$$[3] \quad k_3 = [(A_\infty - A_{\min})/\Delta\varepsilon][(z_0 - k_1)/b] \; [(z_0 - k_1)/(z_0 - z_{\min}) - 1]$$

The value so calculated for $k_2$ was $0.823 \pm 0.021$ $M^{-1}$ $s^{-1}$ (weighted average); for $k_3$ the weighted average was $1.45 \pm 0.15 \times 10^{-4}$ $s^{-1}$. The value for $k_1$ used in these calculations was that measured previously in this laboratory (1). The decline in $z$ from its initial value to the minimum did not obey first-order kinetics since both ester and steroidal imidazole concentrations were changing during the time required by this process. Therefore no simple fit of a curve to the data was possible.

*Monomer plus HCA-HNB*

The conditions for these experiments are as given in Table 2; all runs were under pseudo-first-order conditions. For these reactions, fitting the data to the appropriate integrated equation gave the parameters listed in Table 2. The weighted average value for $k_2$ is $1.37 \pm 0.06$ $M^{-1}$ $s^{-1}$;

*Monomer plus NPA-HNB*

The conditions for these reactions are given in Table 2. For all reactions, the conditions are pseudo-first-order, and the data would be fitted to the simple exponential form of the integrated rate equation. The weighted average value of $k_2$ was $2.04 \pm 0.38$ $M^{-1}$ $s^{-1}$.

*Monomer plus PPA-HNB*

All of the reactions were studied under pseudo-first-order conditions, as described in Table 2. For all of these reactions the second-order rate constant could be calculated from the least-squares parameters. There is a disturbing scatter to the values, and we sought for any trend with concentration, but careful scrutiny shows that the range of scatter is the same at high or low ester concentrations, and for high or low monomer concentrations. The weighted average value was $5.42 \pm 1.36$ $M^{-1}$ $s^{-1}$.

*Dimer plus HCA-HNB*

These reactions were all studied with ester in excess; the conditions are specified in Table 2. It is not proper to assume that the uncatalyzed reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

is pseudo-zero-order during the time that the acylation reaction is occurring because the latter reaction is not fast enough relative to hydrolysis. Nonetheless, the data could be fitted reasonably well to a simple exponential plus linear equation, and the corresponding parameters are given in Table 2. Analysis of the data by our derivative treatment led to values for the rate constants. In the present case, a plot of $z$ vs. $t$ showed a decline to a constant value with no apparent recovery at longer times during the period for which the reaction was followed. This corresponds to establishment of a steady state. It is a fair approximation to take the approach to steady state as pseudo-first-order, and this allows a simple analysis of the data. As we have shown (3):

$$[4]\quad z = k_1 + k_2 b - [k_2^2 ab/(k_2 a + k_3)] + [k_2^2 ab/(k_2 a + k_3)]\exp[-(k_2 a + k_3)t] = z_{\text{final}} + \Delta z \exp(-\kappa t)$$

where:

$$\Delta z = k_2^2 ab/(k_2 a + k_3)$$

$$\kappa = k_2 a + k_3$$

Then

$$k_2 = \sqrt{\kappa \Delta z/ab}$$

$$k_3 = \kappa - k_2 a$$

$$k_1 = z_0 - k_2 b$$

An advantage of this approach is that it gives an independent estimate for $k_1$, which can be measured in a separate experiment, and so provides a test of internal consistency. As is shown in Table 2, there is some scatter, but the data give $k_2 = 12.36 \pm 1.36$, $k_1 = 8.3 \pm 1.3 \times 10^{-6}$ s$^{-1}$, and $k_3 = 1.10 \pm 0.43 \times 10^{-4}$ s$^{-1}$. Direct measurement (1) gives $k_1 = 8.7 \times 10^{-6}$ s$^{-1}$, in satisfactory agreement.

*Dimer plus NPA-HNB*

These data were treated in the same way as for the dimer plus HCA-HNB reactions. The first run was clearly aberrant and was not included in the averaging. The rate constants obtained were $k_2 = 95 \pm 19\ M^{-1}$ s$^{-1}$ and $k_1 = 3.7 \pm 1.9 \times 10^{-5}$ s$^{-1}$. This latter value somewhat deviates from the directly measured value of $1.11 \times 10^{-5}$ s$^{-1}$. However, the $k_1$ value calculated is actually a small difference between two large numbers, $z_0$ and $k_2 b$, so that it is inherently imprecise and subject to systematic errors. An alternative estimate can be made from the steady-state value of $z$, since $k_3$ was not distinguishable from zero in these experiments. (The value calculated from eq. [4] was negative.) The steady-state value of $z$ was $1.35 \pm 0.36 \times 10^{-5}$ s$^{-1}$, an average of 7 values. This value agrees reasonably well with the directly measured value of $k_1$.

*Dimer plus PPA-HNB*

The conditions for these experiments are given in Table 2. Runs at ester concentrations near $10^{-5}$ $M$ led to rate constants not much larger than were obtained for NPA-HNB, leading to suspicions that aggregation of the substrate or aggregation of substrate and dimer was leading to spuriously low reactivity. Accordingly reactions were carried out under pseudo-first-order conditions with $10^{-7}$ $M$ substrate and $10^{-6}$ $M$ dimer. These experiments were at the limit of the barely possible with our instrumentation, and required use of a digitizer to give a ten-fold amplification by longer data sampling, in addition to using ten-centimeter cells. We were severely limited by artefacts, generally involving bubble formation on the optical surfaces. In order to get information from this very noisy kind of experiment we did multiple runs, nine in all, and sought ways to average the replicate runs.

Plots using data to 10 000 s and a uniform scale were constructed for the 8 runs, and showed that in almost all cases the absorbance change was over in 5000 s, and had the form expected for a simple exponential; i.e. first-order behavior. One run showed a continuous increase in absorbance to a much larger overall absorbance change than could be rationalized in terms of the known extinction coefficient. Another showed an anomalously slow change, with much less absorbance change in the usual time period than the rest of the experiments. These two runs were deleted from the set. The total absorbance change was small, and there was considerable variation in the final absorbance value; in order to pool the data into one set, it was necessary to put them on a common scale. This was done by calculating the final absorbance for each run as the average of the observed absorbance values from 5000 to 10 000 s, and then calculating the difference between this final value and the observed value for times less than 5000 seconds, (absorbance$_\infty$ − absorbance$_t$). These differences were pooled into one large data set, which could then be fitted by least squares. Since the scatter in the data is considerable, and we recognize that we are at the limits of our techniques, we have examined the range of rate constants which might be consistent with the data by drawing the extreme lines which could fall within the range of the experimental points plotted in first-order fashion; see Fig. 3. In effect we are taking the scatter as a measure of the

true uncertainty in the data and are calculating possible error limits to supplement the probable error limits suggested by least squares. This approach leads to limits of $265 < k_2 < 639$. Taking the least-squares rate constant as the best estimate, and the higher value for the error implied by these limits, we conclude that $k_2 = 377 \pm 262\ M^{-1}\ s^{-1}$.

Although we believe that we have satisfactorily extracted the rate constant for the reaction of dimer and PPA-HNB, this treatment is necessarily less convincing than we would prefer. The value obtained is roughly consistent with the rest of our results, as will be seen below, and with the conclusion that unambiguous results can only be obtained at the very low concentrations used, or else at still lower concentrations which at present are not experimentally feasible.

## Discussion

*Stereochemistry of* **3**a

In planning the synthesis of **3**, we were guided by reports that the normal stereochemical result of reductive amination of a steroidal 3-one using cyanoborohydride is generation of an equatorial amine (10). Although this indeed seems to be the case for simple reductive aminations, it does not appear to have been so for the reaction of interest. A possible rationalization which presents itself for reductive amination leading to a 3α-amino residue is that the first reductive amination might follow the predicted course, but that the second might well involve reaction of a dimeric molecule which, if the conformation were one with the two steroids in contact, would not allow the reducing agent to attack the iminium ion from the α-surface, thus forcing reaction to occur from the β-surface.

*Kinetics with* **3**a

An approximate measure of the hydrophobic rate enhancement can be obtained by calculating the ratio of the rate constants at pH 7.1 for the reactions of **3** and imidazole with each substrate. When the logarithms of these ratios are plotted vs. the π (11) hydrophobicity parameter a straight line is obtained (Fig. 4). This simple treatment ignores the possibility of reaction by a nonhydrophobically-stabilized transition state (1), but seems appropriate for the rather crude kinetics and sizeable rate enhancements obtained in these experiments. The slope of the plot is 0.77, which is substantially larger than the value obtained for **1**, namely 0.47 (1). The intercept of the plot corresponds to $k_{rel} = 0.095$, a value considerably less than 1.0; we interpret this to mean that if a substrate with no hydrophobic binding group, i.e. the propionate ester, were to react with the same geometry as for the arylpropionate esters, it would be much slower to react with the steroid than with imidazole in the

For personal use only.

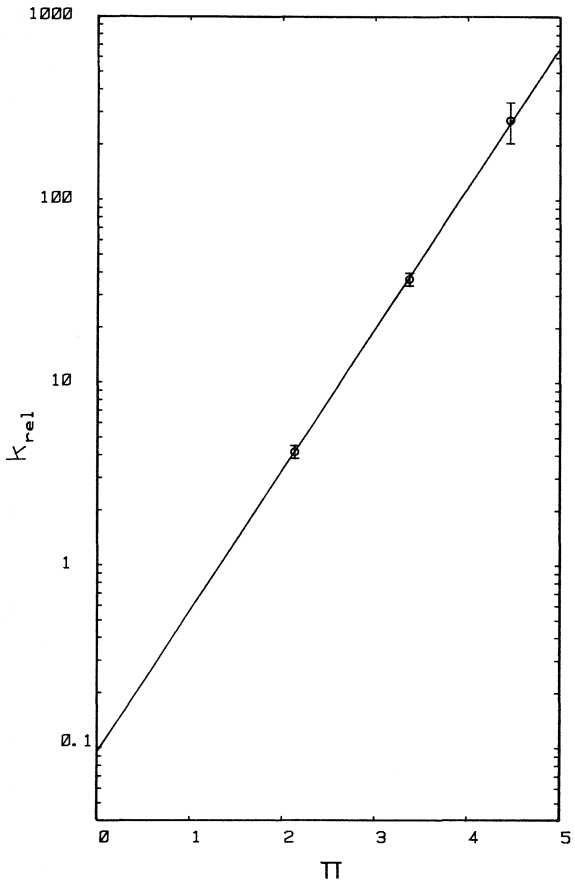

FIG. 4. Relative rate constants (imidazole as standard) for **3** reacting at pH 7.1 with HCA-HNB, NPA-HNB, and PPA-HNB, as a function of $\pi$, the hydrophobicity parameter. The line is fitted by least squares, and has slope = 0.77 and intercept = 0.095.

model reaction. Inspection of molecular models supports this interpretation, since in addition to intermolecular crowding there is an eclipsing interaction of the two methylenes linking aryl and acyl groups (1). This eclipsing interaction, which cannot be avoided if covalent attack and hydrophobic contact are both to occur, destabilizes the transition state and cancels part of the potential hydrophobic stabilization. Although a long extrapolation is involved, it appears that the observed rate enhancement for PPA-HNB of 273-fold for **3** relative to imidazole is only a part of the potential which would be realized if there were no strain, and that this potential could be as large as $10^3$–$10^4$. We observe a value for the rate enhancement of 2900-fold, if we take the intercept from Fig. 3 as the reference point; and 273-fold if we take the rate constant for imidazole as the reference point. As we have argued before (1), we think the former value is the better measure of the potential hydrophobic effect.

Interpretation of the kinetics results with **3***a* is subject to various caveats, since the conditions used were often not truly pseudo-first order, the steroid was of uncertain stereochemistry, and the solutions may not have been sufficiently dilute (because of the impossibility of using lower concentrations). Nevertheless, the experiments do show that markedly larger rate enhancements are available using a dimeric steroid than could be obtained using a monomeric steroid. Furthermore, they serve as guides to the concentration ranges which are likely to be possible for simple kinetic behavior, and demonstrate that the simplest expectations about pH dependence appear to be correct.

*Stereochemistry of* **3**b

This synthesis, although more roundabout, has led to a material which is unambiguously of the desired stereochemistry, since the key stereochemical point, the configuration at C-3, is established by a reaction which is well known to be very stereoselective (6), and the stereochemistry could be confirmed by nmr spectroscopy. As shown in Fig. 1(b), the nmr of **3***b* is consistent with the conclusion that it is homogeneous since there is no sign of splitting of the signal attributed to the benzene ring protons although, despite chromatography and crystallization, there appears to be a small amount of impurity present; this was revealed by the 200 MHz spectrum, but was not apparent at 100 MHz.

*Kinetics with* **3**b

Drawing on the work with the closely related material, **3***a*, which was studied initially, we can confidently expect that experiments at pH 8 will give near maximal rate constants for reaction of dimer and substrates. The conditions were chosen to allow direct comparison with the previous studies of **1**. Because there are important electrostatic interactions in the transition states from **1** and **2***a–d* (1) which are missing in the analogous transition states from **3***b* and **2***a–d*, because of the change from 11-β-amino to 11-keto, we have also studied the reactions of the analogous monomeric steroid **12**. The rate constants evaluated in this work, Table 2, can be analyzed to give a measure of the hydrophobic stabilization of the transition state.

We have previously argued (1) that the imidazolyl steroids always have accessible to them the option of reacting with the substrates in conformations where there is little contact between the steroid and the hydrophobic portion of the substrate, and that such a reaction mode should have a

rate constant very similar to that for the acetate, for which hydrophobic stabilization is not possible. The apparent rate constant for a substrate with a hydrophobic acyl substituent is then the sum of a contribution for transition states with no hydrophobic stabilization, and one with hydrophobic stabilization. The latter transition state is favored by the lowering in free energy consequent upon having hydrocarbon residues in contact with each other, freeing water molecules from contact with hydrocarbon, but is disfavored by certain forms of strain, chiefly eclipsing interactions, which must be introduced to satisfy the geometrical constraints for simultaneous hydrophobic interaction and nucleophilic attack.

When we plot the logarithms of the rate constants for reaction of the monomer with HCA-HNB, NPA-HNB, and PPA-HNB, all corrected by subtracting the rate constant for reaction with ACE-HNB to allow for the nonhydrophobically-stabilized contribution, we find that there is a plausibly linear relationship with the $\pi$ parameter (11). For the rate constants for reaction of the dimer, we first divide by 2 to correct for the statistical factor favoring the dimer, and then correct for the nonhydrophobic transition state by subtracting the rate constant for the reaction with ACE-HNB, which is assumed to be the same as that for the monomer. At the accessible concentrations of **3***b* its contribution to the rate of reaction of ACE-HNB would be undetectable. When the logarithms of these corrected rate constants are plotted as a function of $\pi$ we find another linear relationship. In Fig. 5, both sets of data are plotted; the lines were determined by weighted least squares with the condition imposed that the lines have a common intercept. In imposing the condition of a common intercept we are assuming that for both reactions the same imidazole nitrogen is used and that the geometries of the transition states for the reactions of the esters would be identical (1). This is the simpler assumption, although it is possible that the more hindered imidazole nitrogen plays a more important part in the reactions of **3***b* than in those of **12**. The lines are in satisfactory, though not marvellous, accord with the data. It should be noted that despite the very low concentrations which were used for the experiments involving dimer and PPA-HNB, it remains possible that we have not reached concentrations low enough to give the true rate constant. Since the points for dimer plus HCA-HNB and NPA-HNB imply a steeper line and a larger rate constant for PPA-HNB, this is a serious source of concern. The slopes of the lines are 0.40 for the monomer and

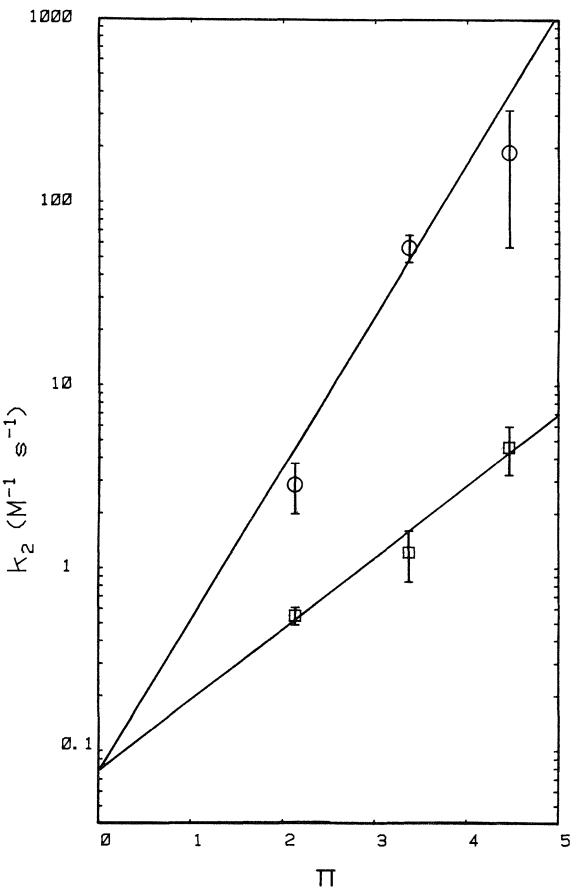

FIG. 5. Corrected second-order rate constants for the reaction of **12** and **3***b* with **2***b*–*d*, as a function of $\pi$. The lines were fitted by least squares with the imposed constraint of a common intercept; the intercept corresponds to $k_{corr} = 0.078$; slope for **3***b* = 0.83; slope for **12** = 0.39. (□) Reaction of **12** with **2***b*–*d*; (○) reaction of **3***b* with **2***b*–*d*.

0.83 for the dimer. The fact that the line for the dimer has a slope twice as great as that for the monomer is in accord with expectation, since twice as much of the surface area of the aromatic ring should be removed from contact with water by the dimer.

A further complication is that these steroidal imidazoles have two imidazole nitrogens, which differ in degree of steric hindrance, and also in suitability for reaction with hydrophobic stabilization. For the best hydrophobic stabilization of the transition state, molecular models suggest that the more hindered nitrogen (N-3 of the imidazolyl group) must react. Studies with an analog of **1**, in which N-1 of the imidazolyl group was isopropylated and unable to react, showed that such a steroid was markedly less reactive than **1** itself, and therefore that **1** reacts almost exclusively at the less hindered nitrogen (1). By analogy we conclude that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

**12** reacts at the less hindered nitrogen. We cannot tell which nitrogen is used by **3*b***, but can state, based on examination of models, that for either **12** or **3*b***, hydrophobic contacts are better if reaction occurs by the more hindered nitrogen. Since the hydrophobic stabilization is clearly much larger for **3*b*** than for **12**, it is possible that the fraction of reaction involving the more hindered nitrogen is greater, and thus that the slope of the plot of the logarithm of the corrected rate constant vs. $\pi$ could be greater than twice that for the monomer, and the intercept smaller than that for the monomer.

The intercept of the plots in Fig. 5 is interpreted as the logarithm of the rate constant for reaction with a hypothetical substrate with no hydrophobic binding group by a transition state geometrically identical to that used by the substrates with aromatic binding groups. It is thus an accessible but very improbable transition state for the reaction of the propionate ester. If we use this hypothetical rate constant as our reference point, we can easily calculate the potential rate enhancement, from hydrophobic stabilization, as 2800-fold for phenanthryl as binding group. The actual rate enhancement can be calculated using the rate constant for the observed reaction of imidazole as reference point as 200-fold. This clearly bears out the expectations which led to the synthesis of **3*b***.

There is only a small amount of ambiguity possible concerning the geometry of the transition state for the reaction of **3*b*** with PPA-HNB. The size of the rate enhancements observed, compared to the behavior seen with **1** and **12**, absolutely requires that the phenanthrene ring be interacting with two steroid residues. The imidazole nitrogen must be attacking the ester carbonyl at the transition state. These constraints plus the very limited amount of rotational freedom in substrate and nucleophile specify the transition state within strict bounds, even if they do not completely specify it.

We conclude that hydrophobic binding with an area equivalent to the upper and lower surfaces of phenanthrene, which is by simple geometry similar to the total surface area of benzene, is sufficient to give a stabilization equivalent to ca. 3000-fold in rate constant. This provides a suitable design parameter for any one wishing to construct an artificial enzyme. The major defect of **3*b*** as an enzyme model is its very low solubility, which leads to severe difficulties in performing experiments and makes many experiments impossible. We are encouraged by the present results to continue our efforts to prepare **4**, which should be at least as good as a catalyst, and much more soluble in water.

## Experimental

*Methods*

Nuclear magnetic resonance spectra were recorded using Varian XL-200, XL-100, HA-100, and T-60 spectrometers, generally in $CD_3OD$ with tetramethylsilane as internal standard. For spectra in $D_2O$, the sample was converted to its DCl salt and evaporated several times from $D_2O$ to remove exchangeable protons and excess DCl. For these spectra the solvent (HOD) peak was used as internal standard; since the concentrations were low ($\simeq$ 5 mg per 0.3 mL) and no excess DCl was present, the solvent peak will not be perturbed. The $^{13}C$ nmr spectra were run for many of the steroids synthesized in this project. From the noise decoupled and off-resonance decoupled spectra it was possible to make a partial assignment of the spectra (12). It was, in general, not possible to make a complete assignment and the results, given in Table 3, indicate this ambiguity. For **3*b*** there were further problems, because the sample was rather small and the solvent peaks caused more serious interference than for the other compounds. Nevertheless, although only a very partial assignment was possible, it is clear that peaks assigned to carbons well removed from the linking xylyene group were essentially unperturbed relative to the monomer. Infrared spectra were recorded using a Beckman Acculab 4 spectrophotometer. Mass spectra were recorded on a Varian MAT 311A spectrometer. Low-pressure chromatography of intermediates in the synthesis of **3*b*** was carried out using Glenco apparatus, including linear-gradient mixing chambers, at a gauge pressure of ca. 13 psi; the column packing was Merck Silica PF254. Thin-layer chromatography was on plates coated with Merck Silica GF254 or on Analtech Silica Gel GF precoated tlc plates. Imidazole-containing compounds were detected on tlc plates by spraying with a freshly prepared solution of diazotized sulfanilic acid in aqueous methanol.

*Materials*

Sodium cyanoborohydride (Aldrich) was purified according to Borch *et al.* (10). Acetonitrile for kinetics solutions was purified by passage through a column of Woelm neutral alumina, Grade I. Tetrahydrofuran was dried by distillation from sodium/benzophenone ketyl. Distilled water was redistilled from alkaline permanganate in an all-glass apparatus.

p-*Xylenediamine*

Phthalamide was converted to its potassium salt following the Organic Syntheses procedure (13). Potassium phthalimide, 14.2 g (76.4 mmol), was suspended in 200 mL dry DMF and stirred for 15 min while protected from moisture. Then $\alpha,\alpha'$-dibromo-*p*-xylene (Aldrich), 10 g (37.9 mmol), was added cautiously in portions. When all of the dibromide had been added the mixture was heated at 65°C with rapid stirring for 90 min, then allowed to cool to room temperature and stirred for 2 days. Thin-layer chromatography showed no remaining dibromide. The mixture was poured into a separatory funnel containing water and $CHCl_3$; the product proved to be almost insoluble in $CHCl_3$ and was isolated by filtration. Yield 14.3 g, 95%; mp 276–278°C (lit. (14) mp 279–280°C; (15) mp 272–273°C). The diphthalimide, 13 g (33 mmol), in 100 mL ethanol and 10 mL hydrazine hydrate (200 mmol) was heated at reflux for 5.5 h (a further 50 mL ethanol was added after 0.5 h because the mass became too thick to stir) and let stand at room temperature overnight. The ethanol was evaporated *in vacuo*, 50 mL of water was added and evaporated to remove excess hydrazine, and then the solid mass was treated with 100 mL 2 *N* HCl, with stirring and warming at 60°C for 15 min. Filtration yielded 14.5 g phthalhydrazide, mp 342–343°C (lit. (16) mp 342–344). The filtrate was concentrated to about 100 mL, cooled, and filtered to give 3.0 g *p*-xylenediamine dihydrochloride, mp > 360°C; nmr

($D_2O$): 4.33 (4H), 7.64 (4H). Concentration of the mother liquor gave a second crop of yellowish crystals, 1.95 g, and then a third crop of 1.0 g. Total yield 6 g, 85%.

*α,α′-Bis(17β-(4-imidazolyl)-11-keto-5α-androstan-3β-amino)-p-xylene,* **3**

*p*-Xylenediamine dihydrochloride (151 mg; 0.722 mmol) and 120 mg NaOAc (1.46 mmol) were dissolved in 30 mL methanol; then 17-β-(4-imidazolyl)-androstane-3,11-dione (4), 509 mg (1.44 mmol), in 5 mL methanol was added with stirring; then sodium cyanoborohydride, 104 mg (1.64 mmol), was added. The solution was stirred for 36 h. Thin-layer chromatographic analysis suggested that the reaction was incomplete, so 10 mg diamine (0.05 mmol) and 8.6 mg NaOAc (0.1 mmol) were added and stirring continued for another 36 h. Concentrated HCl, 4 mL, was added to destroy excess reducing agent; the mixture was filtered and the precipitate rinsed with methanol. The filtrate was partitioned between water and ethyl acetate. On addition of base the aqueous layer deposited a gummy precipitate. This was filtered off and the filtrate was extracted using ethyl acetate – methanol. The extracts were evaporated and the residue and the gummy precipitate were taken up in methanol and acidified with HCl. The solution was filtered and evaporated to dryness to give the crude hydrochloride salt of the dimer. The salt would not crystallize, so it was taken up in methanol, basified using KOH, and adsorbed onto 1 g silicic acid (Mallinkrodt 2847). Chromatography at atmospheric pressure on 10 g silicic acid, starting in ether and moving in a step gradient to 20% methanol in ether, gave fractions which were predominantly dimer with traces of contaminants. These fractions were pooled, concentrated, and converted to the hydrochloride salt.

*17β-(N-Benzyl-4′-imidazolyl)-11β-hydroxy-4-androsten-3-one,* N-*benzyl-***8**

Compound **8** (prepared from corticosterone (Sigma Chemical Co.) as previously described (4)), 10 g; (28 mmol), dissolved in 90 mL methanol, was treated with 3.3 mL (29 mmol) benzyl chloride and 2.44 g (29 mmol) sodium bicarbonate at reflux until tlc analysis (80:20 $CHCl_3$–$CH_3OH$) showed that the reaction was over. The solution was filtered through sintered glass and evaporated. The residue was purified by low-pressure chromatography, eluting with 90:10 $CHCl_3$–$CH_3OH$, to give 6.26 g *N*-benzyl-**8**, and 1.8 g *N*-benzyl-**8** contaminated by benzyl methyl ether. The latter fraction was purified by partitioning between $CHCl_3$ and a large volume of aqueous 2 *N* $H_2SO_4$. The combined aqueous layers were basified (concentrated $NH_3$) and extracted using ethyl acetate; evaporation of the organic extracts, after drying ($Na_2SO_4$), gave 0.87 g *N*-benzyl-**8**. The total yield of *N*-benzyl-**8** was 7.13 g, 57%. A small portion of *N*-benzyl-**8** was purified by crystallization giving two different materials, which were identified as positional isomers. Crystallization from toluene–cyclohexane gave material of mp 223.5–226.5°C (dec); ir ($CHCl_3$), $\nu_{C=O}$: 1665 $cm^{-1}$; $^1H$ nmr, δ: 7.64 (br s), 6.86 (br s, imidazole ring protons), 7.28 (m, phenyl protons), 5.69 (s, C(4)-H), 5.19 (s, benzylic methylene protons), 4.36 (m, C(11)-H), 1.48 (s, C(19)-$H_3$), 0.80 (s, C(18)-$H_3$), 2.76–0.58 (steroid skeletal protons). The second isomer crystallized from $CHCl_3$; mp 153–160°C (dec); $^1H$ nmr, δ: 8.97 (s), 7.88 (s, imidazole ring protons), 7.42 (s, phenyl protons), 5.66 (s, C(4)-H), 5.41 (s, benzylic methylene protons), 4.36 (m, C(11)-H), 1.46 (s, C(19)-$H_3$), 0.82 (s, C(18)-$H_3$), 2.88–0.72 (steroid skeletal protons); ms (70 eV) *m/e*: 444.27723 (calcd. for $C_{29}H_{36}N_2O_2$: 444.27766).

*17β-(4′-Imidazolyl)-5α-androstan-11β-ol-3-one,* **9**

The isomeric mixture of *N*-benzyl-**8**, 2.82 g (6.3 mmol), dissolved in 100 mL of dry THF, was added dropwise to a solution of sodium, 0.64 g (27.2 mmol) dissolved in 400 mL distilled liquid ammonia. Stirring was continued after addition was complete, and samples of the mixture were analyzed by tlc (80:20 $CHCl_3$–$CH_3OH$). When the reaction was judged to be complete, $NH_4Cl$, 2.0 g (37 mmol), was added and the ammonia was allowed to evaporate. The residue was partitioned between ethyl acetate and 1 *N* aqueous $NH_3$. The organic layers were combined, dried over $Na_2SO_4$, and evaporated to give 2.24 g crude product, which was found to be contaminated by **8**. A small portion was purified by crystallization from methanol, mp 261–263.5°C (dec); $^1H$ nmr ($CD_3OD$), δ: 7.54 (s), 6.77 (s, imidazole ring protons), 4.32 (m, C(11)-H), 1.30 (s, C(19)-$H_3$), 0.78 (s, C(18)-$H_3$), 2.76–0.58 (steroid skeletal protons); ms (70 eV) *m/e*: 356.24636 (calcd. for $C_{22}H_{32}N_2O_2$: 356.24636).

*3-Oximino-17β-(4′-imidazolyl)-5α-androstan-11β-ol,* **10**

Crude **9**, 1.4 g (3.9 mmol), and hydroxylamine hydrochloride, 1.4 g (20 mmol), were dissolved in 15 mL pyridine and allowed to react at room temperature. Analysis by tlc, 80:20 $CHCl_3$–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

$CH_3OH$, showed that reaction was complete by the time the reagents were completely dissolved. Although two isomeric products were detected, the initial product at room temperature was more than 90% one material. Heating led to equilibration of the two products. The reaction mixture was partitioned between $CHCl_3$ and 1 *N* aqueous $NH_3$. The combined organic extracts were dried ($Na_2SO_4$) and evaporated to give 1.16 g crude product. This could be crystallized from methanol to give white flakes, mp 183–185°C; $^1$H nmr, δ: 7.53 (s), 6.77 (s, imidazole ring protons), 4.29 (m, C(11)-H), 1.15 (s, C(19)-$H_3$), 0.75 (s, C(18)-$H_3$), 2.76–0.45 (steroid skeletal protons); ms (70 eV) *m/e*: 371.25748 (calcd. for $C_{22}H_{33}N_3O_2$: 371.25726).

*3β-Amino-17β-(4'-imidazolyl)-5α-androstan-11β-ol,* ***6***

Pure **5**, 0.249 g (0.67 mmol), suspended in 15 mL *n*-propanol, was treated with 0.61 g (40 equiv.) sodium, added in portions. When analysis by tlc, 80:20 $CHCl_3$–$CH_3OH$, showed that the reduction was complete, the solution was cooled, and partitioned between $CH_2Cl_2$ and 1 *N* aqueous $NH_3$. The organic extracts were dried ($Na_2SO_4$) and evaporated. The crude product was purified by low pressure chromatography, eluting with 80:20 $CHCl_3$–$CH_3OH$ to which had been added 2% $NH_3$. The yield of **11** after chromatography was 0.22 g; crystallization from methanol gave material of mp 153–154.5°C; $^1$H nmr, δ: 7.53 (s), 6.77 (s, imidazole ring protons), 4.30 (m, C(11)-H), 1.05 (s, C(19)-$H_3$), 0.72 (s, C(18)-$H_3$), 2.83–0.58 (steroid skeletal protons); ms (70 eV) *m/e*: 357.27793 (calcd. for $C_{22}H_{36}N_3O$: 357.27799).

*3β-Amino-17β-(4'-imidazolyl)-5α-androstan-11-one,* ***12***

Compound **11**, 0.240 g (0.67 mmol), dissolved in 14 mL glacial acetic acid, was treated with 0.62 mL (1.24 mmol) 2 *N* aqueous $H_2SO_4$, followed by 0.4 mL (0.8 mmol) Jones reagent. The reaction was followed by tlc, 1 *N* $NH_3$ in $CH_3OH$. When no more **11** was detectable, 0.5 mL 2-propanol was added to quench residual $Cr^{VI}$. The reaction was then worked up using the method of Mueller and DiPardo (8) which avoids the usual difficulties encountered with alkaline $Cr^{III}$ solutions. Partitioning between $CH_2Cl_2$ and 1 *N* aqueous $NH_3$, drying of the organic extracts, and evaporation gave 0.229 g (96%) crude product. Crystallization from acetonitrile gave crystals which charred on heating; ir ($CHCl_3$) $\nu_{C=O}$: 1703 $cm^{-1}$; $^1$H nmr in $CD_3OD$, δ: 7.57 (s), 6.82 (s, imidazole ring protons), 2.96 (t, $J$ = 9 Hz), 2.46 (d, $J$ = 12 Hz), 2.12 (d, $J$ = 11 Hz, skeletal protons perturbed by the 11-keto group), 1.02 (s, C(19)-$H_3$), 0.42 (s, C(18)-$H_3$), 3.18–0.60 (steroid skeletal protons); $^1$H nmr of the DCl salt in $D_2O$ at 200 MHz, δ: 9.03 (s), 7.74 (s, imidazolium ring protons), 3.6 (broad, $\Delta\nu_{1/2} \simeq$ 30 Hz, C(3)-αH), 3.59 (t, $J$ = 10 H), 3.07 (d, $J$ = 12 Hz), 2.56 (d, $J$ = 12 Hz, skeletal protons perturbed by the 11-keto group), 1.43 (s, C(19)-$H_3$), 0.91 (s, C(18)-$H_3$), 2.9–1.5 (steroid skeletal protons); ms (70 eV) *m/e*: 355.26186 (calcd. for $C_{22}H_{33}N_3O$: 355.26234).

*α,α'-Bis(17β-(4'-imidazolyl)-11-keto-5α-androstan-3β-amino)-p-xylene,* **3***b*

A three-necked flask fitted with a thermometer, stopper, and a Soxhlet extractor charged with 3A molecular sieves was charged with 70 mL of a 70:30 mixture of absolute ethanol and dry benzene. The mixture was refluxed for several hours to dry the system, and then purified **12**, 0.100 g (0.28 mmol), and terephthalaldehyde (Aldrich, recrystallized before use), 0.018 g (0.13 mmol), were added. The reaction mixture was refluxed for 24 h; during this time a white solid precipitated. The solvent was then removed by evaporation and replaced with dry DMF. (Karl Fischer titration using a Photovolt Aquatest II water meter showed 0.02% water.) Sodium cyanoborohydride, 0.365 g (0.58 mmol), was added and the suspension was stirred for a few minutes. Trifluoroacetic acid was then added dropwise until a clear solution was obtained; the total volume added was about 70 μL. The solution was partitioned between $CH_2Cl_2$ and 2 *N* aqueous $H_2SO_4$. The aqueous extracts were neutralized using $NaHCO_3$, made basic with $NH_3$, and extracted using $CH_2Cl_2$. The organic extracts were dried ($Na_2SO_4$) and evaporated to give 0.103 g crude product (90%). Purification by low-pressure chromatography using 0.3 *M* $NH_3$ in $CH_3OH$ as eluant gave pure ***3b***, but the recovery after chromatography was only about 22%. Compound ***3b*** charred without melting; $^1$H nmr in $CD_3OD$ at 100 MHz, δ: 7.56 (s), 6.80 (s, imidazole ring protons), 7.34 (s, phenyl protons), 6.80 (s, benzylic methylene protons), 2.96 (br t, $J$ = 9 Hz), 2.50 (d, $J$ = 12 Hz), 2.14 (d, $J$ = 12 Hz, skeletal protons perturbed by the 11-keto group), 1.02 (s, C(19)-$H_3$), 0.41 (s, C(18)-$H_3$), 3.12–0.58 (steroid skeletal protons); $^1$H nmr of the DCl salt in $D_2O$ at 200 MHz, δ: 9.05 (s), 7.73 (s, imidazolium ring protons), 7.98 (s, xylylene ring protons), 4.71 (s, benzylic $CH_2$), 3.6 (broad peak plus a triplet with $J$ = 10 Hz, C(3)-H plus a proton perturbed by the 11-keto group), 3.07 (d, $J$ = 12 Hz), 2.54 (d, $J$ = 12 Hz, skeletal protons perturbed by the 11-keto group), 1.44 (s, C(19)-$H_3$), 0.91 (s, C(18)-$H_3$), 2.9–1.5 (steroid skeletal protons); ms (70 eV): the molecular ion could be seen at *m/e* 812 although it was rather weak; its *Exact Mass* could be determined as *m/e*: 812.57102; calcd. for $C_{52}H_{72}N_6O_2$: 812.57164. Two major fragments were determined; *m/e*: 458.31733 (calcd. for $C_{30}H_{40}N_3O$: 458.31712), and *m/e*: 354.25385 (calcd. for $C_{22}H_{32}N_3O$: 354.25452).

*Substrates*

Compounds **2***a–d* were prepared as previously reported (1), and purified by crystallization. All showed satisfactory nmr spectra (recorded in acetone-$d_6$).

*Kinetics*

Reactions were followed using a Gilford Model 240 spectrophotometer, with the cell compartment temperature maintained at 25.0 ± 0.1°C using a Braun Thermomix II circulator for experiments with ***3a*** or a Neslab Exacal 300 circulator for experiments with ***3b***. For dilute solutions, 10-cm cells were used with a Gilford Model 2470 sample chamber. For more concentrated solutions, 1-cm cells were used. Hamilton microsyringes, 10 μL or 100 μL, were used for measuring volumes less than 1 mL. Reactions were initiated by adding the required volume of substrate solution to an equilibrated solution containing buffer, nucleophile, and the amount of acetonitrile needed to give a final concentration of 3.2% v/v. The pH of each reaction solution was measured at the end of the reaction.

Stock solutions of substrates were prepared in acetonitrile. The reaction solvent was aqueous buffer, pH 7.1, 7.5, or 8.0, ionic strength 0.097 *M*, with 0.0097 *M* phosphate or 0.0097 *M* Tris, and 3.2% acetonitrile. These conditions are the same as were used for the studies of steroid **1** (1). Reaction of the substrates was followed by monitoring the formation of the 3-hydroxy-4-nitrobenzoate dianion at 420 nm. For experiments involving ***3b***, data were collected using a digitizer constructed in this department, and stored on punched paper tape.

A $10^{-4}$ *M* stock solution of ***3a*** was prepared by dissolving 5.00 mg dimer as the tetrahydrochloride, $KH_2PO_4$ (68.17 mg), and KCl (290.0 mg), in 45 mL glass-distilled water, and adjusting the pH to 7.00 with sodium hydroxide. The solution was then diluted to 50.0 mL. Kinetics solutions were prepared by dilution from this stock.

A stock solution of ***3b***, $1 \times 10^{-4}$ *M* in pH 7 phosphate buffer was prepared. To our surprise this solution was not completely clear, but showed slight turbidity which became noticeable as the pH was adjusted from the initial low value; this became apparent about pH 6.7. No such turbidity was seen at this concentration of ***3a***. Since much of the available supply of dimer ***3b*** was in this solution, and the insoluble material was, and remained, very finely divided, we went ahead and used it as a

stock, mixing well before removing a sample for dilution. For kinetics this solution was diluted at least 50- and generally 100-fold into pH 8 buffer. No visible turbidity was ever detected in the diluted solutions. When Tris buffer was used, solutions were never kept more than one week.

# Determination of rate constants when analytical integration of the rate law is not possible: approaches based on numerical differentiation and numerical integration

J. PETER GUTHRIE

*Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7*

Received May 27, 1981

J. PETER GUTHRIE. Can. J. Chem. **60**, 765 (1982).

Two methods for deriving rate constants from absorbance–time data when the rate laws cannot be integrated in closed form are presented, and their use illustrated. One method uses least-squares fitting to the curve obtained by numerical integration of the rate law. The other involves analysis of the numerically evaluated derivative with respect to time of the absorbance–time curve. This allows calculation of rate constants in a direct fashion, either from the initial and minimum values of a function of the derivative or by fitting the decrease in the value of this function to a first-order rate equation when this is suitable. The advantages and disadvantages of the methods are discussed. The illustrations are from recent studies of the reactions of steroidal imidazoles with aryl esters. The derivative method appears to be superior, and of potentially wide utility.

J. PETER GUTHRIE. Can. J. Chem. **60**, 765 (1982).

On présente deux méthodes de dérivation des constantes de vitesse à partir des données d'absorption en fonction du temps lorsqu'il est impossible d'intégrer les lois de vitesse de façon convenable; on illustre ces méthodes. Une méthode utilise l'ajustment des moindres carrés à la courbe obtenue par l'intégration numérique de la loi de vitesse. L'autre implique une analyse numérique de la dérivée, évaluée en fonction du temps, de la courbe d'absorption vs temps. Ceci permet de calculer directement les constantes de vitesse soit à partir des valeurs initiales et minimales d'une fonction de la dérivée ou en ajustant la diminution de la valeur de cette fonction à une équation de première ordre si c'est approprié. On discute des avantages et des inconvénients de ces méthodes. Les exemples d'application portent sur des études récentes des réactions d'imidazoles stéroidaux avec des esters aryliques. La méthode de la dérivée semble supérieure et d'une grande utilité potentielle.

## Introduction

Although integrated forms for various rate laws are given in standard textbooks (1, 2), considerations of practicality strongly favor the use of first order or pseudo-first order kinetics whenever possible. The rational basis for this deep seated prejudice is shown by the fact that for any network of first order processes, it is possible to derive an analytical solution, although this may be of well nigh intractable complexity if the network is not small (1–3). No such analytical solution is possible for networks of higher order reactions, or even for many simple cases of mixed first and second order reactions. We recently stumbled upon one such deceptively simple situation, where the rate law for the situation symbolized below:

[1] $A \xrightarrow{k_1} P_1 + P_2$

[2] $A + B \xrightarrow{k_2} C + P_1$

[3] $C \xrightarrow{k_3} B + P_2$

is given by:

[4] $dx/dt = k_2(a - x)(b - y) + k_1(a - x)$

[5] $dy/dt = k_2(a - x)(b - y) - k_3 y$

where $a$ is the initial concentration of A, $b$ is the initial concentration of B, $x$ is the concentration of $P_1$, and $y$ is the concentration of C. Astonishingly enough this simple set of equations is quite intractable to integration, and remains so even if $k_3 = 0$.

We have developed two methods for extracting rate constants from data for such reaction systems, which we feel will be of some general usefulness. Accordingly we report the methods here with illustrative examples taken from the studies reported in the accompanying paper (7), in which the need for these methods arose. This paper is concerned with the methodology for solving such kinetics problems.

## Mathematical methods

One response to this situation of rate laws which cannot be integrated in closed form, i.e. in terms of well-known standard functions, is to attempt numerical integration (9, 10). We have tried this approach, and found that it is indeed possible to achieve reasonable simulations of the observed behavior, but the approach is not fully satisfactory for determination of the kinetic parameters by least squares, as will be discussed below. We have also developed methods for determining rate constants from the data by first calculating the instantaneous rates of reaction at each data point, and then deducing the rate constants from the differential forms of the rate law.

One is faced with a general problem in extracting rate constants for a system such as the present one in that calculation of the observable values, here absorbance as a function of time, requires specification of more parameters than could be defined by the observed curve. Intuitively it is clear that a straight line is specified by two parameters, and that data which, with some degree of scatter, lie distributed about a straight line allow determination of two parameters but no more. Similarly an exponential curve is specified by three parameters, and data distributed about an exponential curve allow determination of three parameters but no more. For any set of data there is a very limited number of parameters which can be determined by fitting an equation to the data. Since concentrations of reagents, rate constants, initial absorbances, etc. all affect the observable quantity, and almost all are invariably only approximately known, it is very likely that more theoretically significant numerical values are required to calculate a set of data than there are parameters which can be determined by fitting to the data. In the case of reactions described by reactions [1]–[3], numerical calculation requires that one specify not less than seven quantities, none of which is known exactly, and all of which will affect the quality of the fit. These quantities are: the two initial concentrations, the three rate constants, the initial absorbance, and the change in extinction coefficient for conversion of the starting material into the product. However, the experimental data imply a curve which is not sufficiently complicated to define seven parameters. The actual number of parameters defined by the curve is hard to state reliably in the absence of an analytical expression fitting it well, but three or four parameters give fairly good fits. If an analytical expression were known, it might have, say, four parameters, which were functions of the seven theoretical quantities.

The least-squares procedure for fitting an equation to data requires derivatives for $(y_{obs} - y_{calcd})$ with respect to each of the parameters (4, 5). If no analytical form of the integrated rate law is available it is possible to determine these derivatives analytically by determining $(y_{obs} - y_{calcd})$ for the current set of parameters, and then for a set where one parameter is changed by a small amount, say 1%. The change in $(y_{obs} - y_{calcd})$ divided by the change in the parameter is an approximation to the derivative with respect to that parameter. This must then be done for each parameter. Each value of $y_{calcd}$ needed for this calculation must be determined by numerical integration from the differential form of the rate law. We have written a computer program in FORTRAN, using a modified form of the Euler method (6) to perform the integration and evaluate the calculated absorbance at each time for which a value was recorded. In this method the value of a concentration $C_n$ at one time is used to calculate the value at a later time $C_{n+1}$ as:

$$C_{n+1} = C_n + (1/2)[(dC/dt)_n + (dC/dt)_{n+1}]\Delta t$$

The procedure can be iterated to give an improved value, but two iterations seems to be sufficient. Least-squares fitting was carried out using the Marquardt algorithm (4), which leads to more rapid convergence when the initial estimates for the parameters are not close to the best values. The calculations were carried out on a Xitan microcomputer. The quality of the fit was tested in two ways. The first involved calculating $\sqrt{[\Sigma(y_{obs} - y_{calcd})^2 \times (\text{weight})/(\text{degrees of freedom})]}$, which Deming (5) calls $\sigma_{ext}$ and which is a measure of the scatter of points about the line fitted to them; for a good fit it should be comparable to the anticipated experimental error in the points. The second involved plotting the results on a Hewlett-Packard 7225A plotter, for visual examination of the fit.

A disadvantage of numerical integration as a basis for least-squares fitting is that it is very hard to see which parts of the data actually define the individual rate constants.[1] This may be contrasted with the situation seen for example in first order kinetics, where it is quite clear that data from late in the reaction, say the ninth or tenth half-lives, principally determine the infinity value; that data from the first part of the reaction principally determine the initial value, and the initial slope, which depends both on the rate constant and on the total change in the quantity being followed; and that the rate constant is determined by data defining the curvature between the initial and final lines, over the first two–three half-lives which are followed. For data of high precision, later stages of the reaction will contribute to defining the rate constant. For reactions following the mechanism of [1]–[3], when integration in closed form is not possible, it is clear that $k_1$ and $k_3$ will be most important at long times, and that $k_1$ and/or $k_2$ will be important at short times, but it is not easy to see which portion of the data define which rate constant, even when all three rate constants are important, and even more when one may be unimportant. By contrast we may

[1]NOTE ADDED IN PROOF: Since this manuscript was accepted for publication, we became aware of a paper (11) which addressed the problem of which parts of a set of data determine particular parameters, for systems where all of the parameters are specified by the data.

consider a closely related situation where integration in closed form is possible. For the system described by reactions [1]–[3], if [B] ≫ [A] so that [B] was essentially constant, then $k_3$ would not matter, the kinetics would be simple and the rate law would become

$$OD = OD_0 + (a\Delta\varepsilon)\{1 - \exp[-(k_1 + k_2 b)t]\}$$

Here six theoretical quantities would still be required to specify the observed OD–time curve, namely: two concentrations, $a$ and $b$; two rate constants, $k_1$ and $k_2$; the initial OD, and the change in extinction coefficient. However, these would be grouped into three parameters which could be determined from the data. This situation, that numerical integration must use all of the theoretically required quantities, without grouping them into composite parameters, means that there is no obvious way to tell whether a particular rate constant is actually specified by the data. As we will see there can easily be cases where there is strong covariance of parameters, so that least-squares fitting can lead to values quite different from the optimum if a parameter which is not well determined by the data is allowed to vary. Furthermore, numerical integration is a rather slow procedure, and the least-squares method based upon it converges slowly in our experience.

A simpler method, which leads to a convenient solution to this problem, involves calculation of instantaneous derivatives from the experimental absorbance–time data. This calculation is practical if one has many points (generally 200 per run in the present case) and the data are in computer readable form so that the calculations can all be done automatically. There are problems of noise which pose limitations for this approach, and one must compromise between taking slopes from few points, and accepting high noise levels, and taking slopes involving more points and inevitably smoothing out some of the information, particularly at the beginning of the reaction where we are especially interested in the instantaneous slope. In the present case we calculate the quantity:

$$[6] \quad z = (dx/dt)/(a - x) = k_1 + k_2 (b - y)$$

Inevitably this quantity becomes very noisy at long times where both numerator and denominator are small. It is also inevitable that uncertainties in "$a$" have serious effects on "$z$" and quantities derived from it. However, this error becomes major only for long times as $(a - x)$ becomes small. We have found that in many cases the derivative method leads to a convenient solution, and allows one to see what part of the data define the derived rate constants.

One must recognize that there are also disadvantages to the derivative method. In the case where the decrease in $z$ is second order we really use only a small part of the data; the early points to estimate $z_0$, and points around the minimum to estimate $z_{min}$ and $t_{min}$. Since the calculated derivatives have substantial errors, quantities calculated from them are necessarily imprecise. Set against these disadvantages are the advantages of a more direct extraction of rate constants, and the possibility of a more intuitive recognition of whether the rate constants are truly determined by the data.

In applying the derivative method, two situations can be recognized which require different treatment of the data. If only one of the two reagent concentrations, [A] and [B], changes appreciably during the time that $z$ decreases to its minimum, the kinetics for this decline will be pseudo-first order. If it is [B] which is constant, then the kinetics will be simple and can be dealt with by traditional methods. If both change, then the kinetics will be second order and intractable. If $z$ is either constant after the minimum has been reached or else increases slowly, then a linear approximation will lead to useful simplification in the case where the decrease to the minimum is pseudo-first order in [A]. The increase must be slow enough that the steady state approximation remains good if this is to be a useful approach.

Listings of the computer programs DERIV3 and RIGLSQ6 have been deposited as supplementary material.[2] These programs were written in Small Systems Services FORTRAN IV.

## Results

In a study reported in the accompanying paper (7) of the reaction of the steroidal imidazoles, **1** and **2**, with a variety of substrates of general formula **3**, we were forced to study the kinetics under conditions where the concentrations of both reagents were comparable, and the rate of the uncatalyzed reaction was comparable with the rate of the bimolecular reaction of interest. In some cases regeneration of the nucleophile, $k_3$, was clearly important, in other cases it clearly was not. Thus the situation described above arose, and we were faced with the problem of extracting the values for $k_2$ which were the object of the exercise.

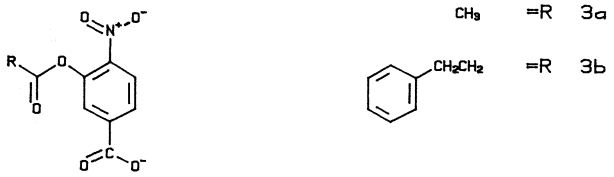
2



3a, b

The first case considered involves the reaction of **1** and ACE-HNB.[3] Despite the fact that the kinetics were known to be complex, it was possible to get plausible fits to either a first order or a second order integrated rate law by non-linear least squares (4, 5), as shown in Figs. 1 and 2.

Least-squares fitting making use of numerical integration can be employed, and also leads to a plausible fit as shown in Fig. 3.

It turned out that the values obtained for the parameters were strongly dependent upon the number and the identity of the parameters allowed to vary. Figure 3 shows the results when $[A]_0$, $k_2$, and $k_3$ were determined by least-squares, while the other four quantities were held constant. Very similar fits were obtained when $[A]_0$, $k_1$, $k_2$, and $k_3$ were determined by least-squares, but then $k_1$ rose to a value three times the independently measured value (8) and $k_2$ fell, with only a small change in the quality of the fit; see Table 1. As one would expect for this behavior, the correlation coefficient (4) for

[3]Abbreviations used: ACE-HNB = acetyl hydroxynitrobenzoate, **3***a*; HCA-HNB = hydrocinammoyl hydroxynitrobenzoate, **3***b*.

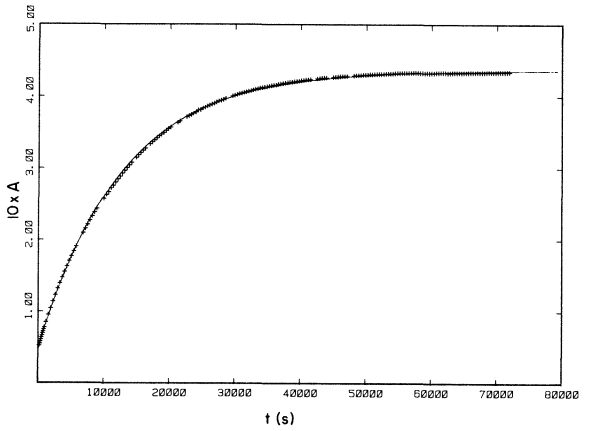


FIG. 1. Reaction of $9.77 \times 10^{-5}$ *M* ACE-HNB with $9.69 \times 10^{-5}$ *M* **1** fitted to a first order integrated rate law; $y = a_1 + a_2 \exp(-a_3 t)$, with $a_1 = 4.37$, $a_2 = -3.89$, $a_3 = 0.0000798$.

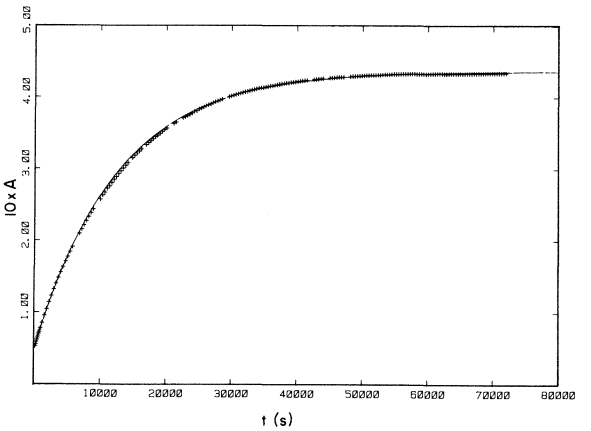

FIG. 2. Reaction of $9.77 \times 10^{-5}$ *M* ACE-HNB with $9.69 \times 10^{-5}$ *M* **1** fitted to a second order integrated rate law; $y = a_1 + a_2[\exp(a_3 t) + 1]/[\exp(a_3 t) + a_4]$, with $a_1 = 0.476$, $a_2 = 3.894$, $a_3 = 7.95 \times 10^{-5}$, $a_4 = 0.0158$.

$k_1$ and $k_2$ from the least-squares fit was large and negative: $-0.9982$. To obtain the observed infinity value the product of $[A]_0$ and $\Delta\varepsilon$ had to be decreased by 8%; whether $\Delta\varepsilon$ was decreased by this amount or held to the experimental value (7) while $[A]_0$ was allowed to vary made little difference in the quality of the fit; see Table 1.

Finally it is possible to apply the derivative method; in this case a plot of $z$ vs. $t$, e.g., Fig. 4 shows a fall in $z$ followed by a rise to approximately the initial value. The initial value of $z$, $z_0$, is equal to $k_1 + k_2 b$; if $k_1$ and $b$ are known then $k_2$ can be calculated. In effect we are using initial rates to determine $k_2$, with an extrapolation procedure to give an improved estimate for the initial rate. From the position of the minimum it is possible to deduce

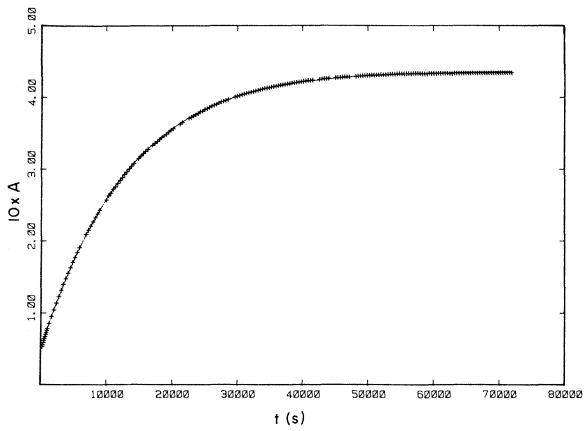

FIG. 3. Reaction of 9.77 × $10^{-5}$ *M* ACE-HNB with 9.69 × $10^{-5}$ *M* **1** fitted by least-squares using numerical integration; held constant were $[B]_0 = 9.69 \times 10^{-5}$ *M*, $10 \times A_0 = 0.477$, $\Delta\varepsilon = 4320$, $k_1 = 1.19 \times 10^{-5}$; determined by least-squares were $[A]_0 = 9.00 \times 10^{-5}$ *M*, $k_2 = 0.761$ $M^{-1}$ $s^{-1}$, and $k_3 = 3.19 \times 10^{-4}$ $s^{-1}$.

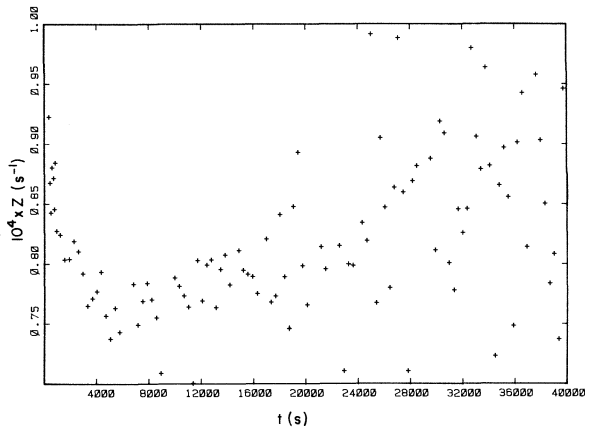

FIG. 4. Reaction of 9.77 × $10^{-5}$ *M* ACE-HNB with 9.69 × $10^{-5}$ *M* **1**. Plot of $z = (dA/dt)/(\Delta A_\infty - \Delta A_t)$; $10 \times \Delta A = 4.368$, $10 \times A_0 = 0.477$.

a value for $k_3$. At the minimum:

[7] $$dy/dt = 0.0 = k_2(a - x_{min})(b - y_{min}) - k_3 y_{min}$$

[8] $$y_{min} = -(z_{min} - k_1 - k_2 b)/k_2 = (z_0 - z_{min})/k_2$$

[9] $$k_3 = k_2(a - x_{min})(b - y_{min})/y_{min} = [(A_\infty - A_{min})/\Delta\varepsilon][(z_0 - k_1)/b][(z_0 - k_1)/(z_0 - z_{min}) - 1]$$

The value for $k_1$ used in these calculations was that measured previously in this laboratory (8). The decline in $z$ from its initial value to the minimum did not obey first order kinetics since both ester and steroidal imidazole concentrations were changing during the time required by this process. Therefore no simple fit of a curve to the data was possible. Using the experimental value for $k_1$ (8), and the values for $k_2$ and $k_3$ derived from the $z$ vs. $t$ curve as described above, as well as independent values for the concentrations, extinction coefficients, and initial absorbance, we calculated the curve in Fig. 5 by numerical integration.

Another situation arose in the reaction of **2** with HCA-HNB (7), where the ester was in excess. The data could be fitted to eq. [10]:

[10] $$Abs = a_1 + a_2 \exp(-a_3 t) + a_4 t$$

see Fig. 6. However, this was not a very satisfactory way to handle the data because the contribution of $k_2 b$ to the observed rate was rather close to the contribution of $k_1$. The data could be fitted by least squares using our numerical integration procedure with the results shown in Fig. 7.

For this fit three parameters were allowed to vary: $[A]_0$, $k_2$, and $k_3$. Allowing $k_1$ to vary as well made little change in either the parameters or the quality of the fit. Analysis of the data by our derivative treatment led to values for the rate constants. In the present case, a plot of $z$ vs. $t$, Fig. 8, showed a decline to a constant value with no apparent recovery at longer times during the period for which the reaction was followed. This corresponds to the establishment of a steady state. The following analysis would also apply if there were a slow increase in $z$ after the decrease to the minimum. It is a fair approximation to take the ap-

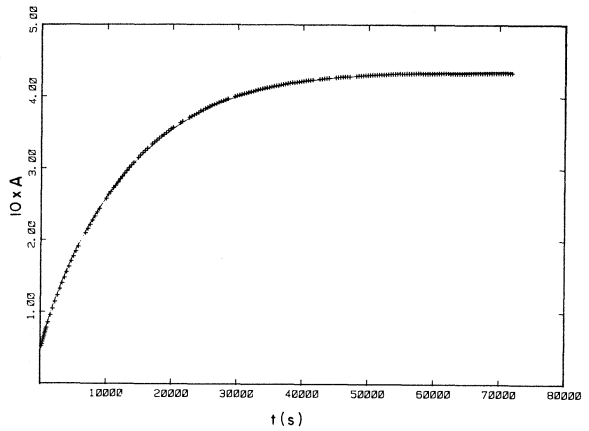

FIG. 5. Reaction of $9.77 \times 10^{-5}$ $M$ ACE-HNB with $9.69 \times 10^{-5}$ $M$ **1**. The curve is drawn by numerical integration using parameters based on the derivative method. $[A]_0 = 9.77 \times 10^{-5}$ $M$, $[B]_0 = 9.69 \times 10^{-5}$ $M$, $10 \times A_0 = 0.477$, $\Delta\varepsilon = 3983$, $k_1 = 1.19 \times 10^{-5}$ s$^{-1}$, $k_2 = 0.823$, $k_3 = 1.45 \times 10^{-4}$ s$^{-1}$.

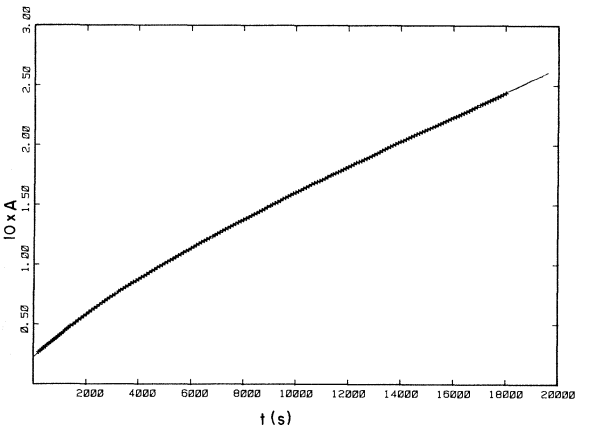

FIG. 6. Reaction of $2.25 \times 10^{-5}$ $M$ HCA-HNB with $1.16 \times 10^{-6}$ $M$ **2** in 10 cm cells, fitted to the equation $y = a_1 + a_2 \exp(-a_3 t) + a_4 t$, with $a_1 = 0.632$, $a_2 = -0.406$, $a_3 = 2.37 \times 10^{-4}$, and $a_4 = 1.01 \times 10^{-4}$.

proach to steady state as first order, since at the time that the minimum value in $z$ is attained, only about 20% of the ester has reacted, and this allows a simple analysis of the data. Equation [5] becomes:

$$[11] \quad dy/dt = k_2 a(b - y) - k_3 y = k_2 ab - (k_2 a + k_3)y$$

After integration

$$[12] \quad y = [k_2 ab/(k_2 a + k_3)]\{1 - \exp[-(k_2 a + k_3)t]\}$$

$$[13] \quad z = k_1 + k_2 b - [k_2^2 ab/(k_2 a + k_3)] + [k_2^2 ab/(k_2 a + k_3)]\{\exp - [(k_2 a + k_3)t]\} = z_{\text{final}} + \Delta z \exp(-\kappa t)$$

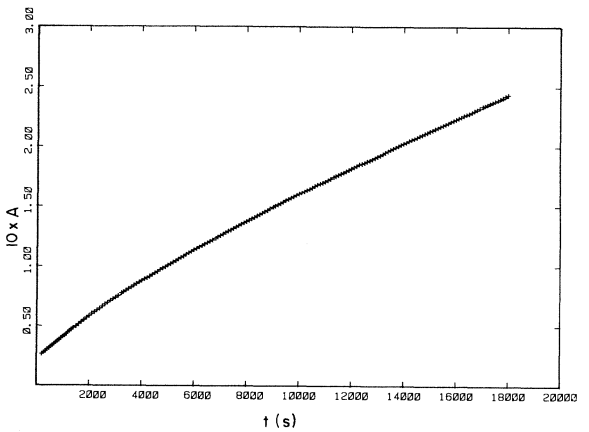

FIG. 7. Reaction of $2.25 \times 10^{-5}$ $M$ HCA-HNB with $1.16 \times 10^{-6}$ $M$ **2** in 10 cm cells, fitted by least-squares using numerical integration; held constant were $[B]_0 = 1.16 \times 10^{-6}$ $M$, $10 \times A_0 = 0.233$, $\Delta\varepsilon = 4320$, and $k_1 = 9.74 \times 10^{-6}$ s$^{-1}$; fitted by least-squares were $[A]_0 = 2.37 \times 10^{-5}$ $M$, $k_2 = 7.53$ $M^{-1}$ s$^{-1}$, and $k_3 = 4.33 \times 10^{-5}$ s$^{-1}$.

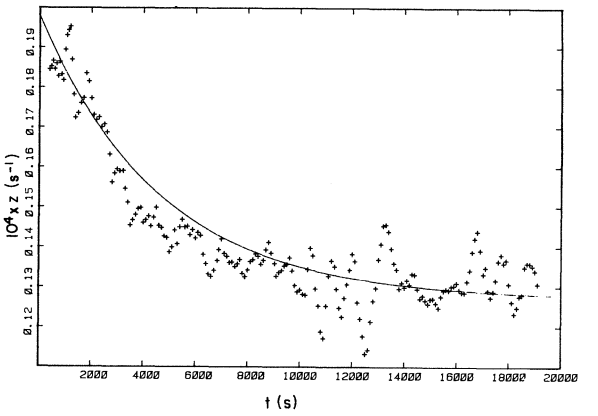

FIG. 8. Reaction of $2.25 \times 10^{-5}$ $M$ HCA-HNB with $1.16 \times 10^{-6}$ $M$ **2** in 10 cm cells, derivative plot; $z$ was calculated using $10 \times \Delta A_\infty = 9.72$ and $10 \times A_0 = 0.233$. The line was fitted by least-squares $z = a_1 + a_2 \exp(-a_3 t)$, with $a_1 = 0.127$, $a_2 = 0.074$, and $a_3 = 0.000201$.

where

$$\Delta z = k_2^2 ab/(k_2 a + k_3)$$
$$\kappa = k_2 a + k_3$$

Then

$$[14] \quad k_2 = \sqrt{\kappa \Delta z / ab}$$

$$[15] \quad k_3 = \kappa - k_2 a$$

$$[16] \quad k_1 = z_0 - k_2 b$$

An advantage of this approach is that it gives an independent estimate for $k_1$, which can be measured in a separate experiment, and so provides a test of internal consistency. $\Delta z$ can be as large as

$k_2b$ for $k_3$ negligibly small and can be zero if $k_3 \gg k_2a$. Thus the magnitude of $z_0$ relative to $k_1$ gives an idea of how well $k_2b$ is defined by $z_0$, and the magnitude of $\Delta z$ relative to $k_2b$ gives an idea of how well $k_3$ is defined. The smallest possible value for $z_{final}$, when $k_3 \simeq 0$, is $k_1$; thus if $z_{final}$ does not fall close to $k_1$ one cannot expect $k_1$ to be well defined by the data. Similarly if $z_0 \gg k_1$, so that it is mostly determined by $k_2b$, one cannot expect $k_1$ to be well defined by eq. [16]. Figure 9 shows that numerical integration based on rate constants derived as just described gives a satisfactory fit to the data.

Figure 9 also illustrates an interpretational hazard when calculating absorbance–time curves from parameters calculated indirectly, and not by direct fitting to the data. For this reaction error analysis based on the least-squares fit to the $z$ vs. $t$ plot leads to $k_1 = 1.07 \pm 0.10 \times 10^{-5}$ s$^{-1}$. If this value is used (Fig. 9*b*) the fit looks rather poor. On the other hand if a value for $k_1 = 1.04 \times 10^{-5}$ s$^{-1}$ is used (Fig. 9*a*) the fit looks excellent. The difference is much less than the uncertainty in $k_1$.

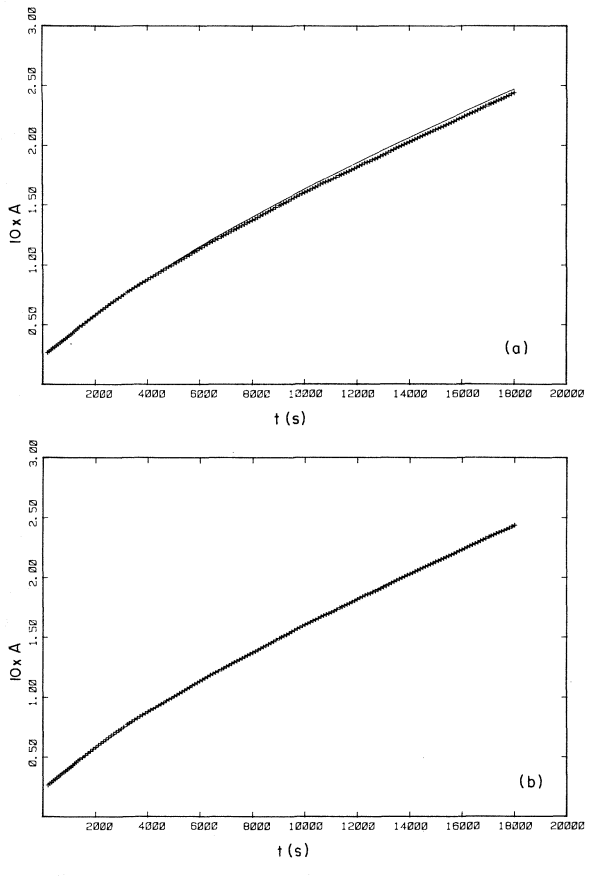

FIG. 9. Reaction of $2.25 \times 10^{-5}$ *M* HCA-HNB with $1.16 \times 10^{-6}$ *M* **2** in 10 cm cells, line calculated by numerical integration using parameters from the derivative fit; $[A]_0 = 2.25 \times 10^{-5}$ *M*, $[B]_0 = 1.16 \times 10^{-6}$ *M*, $10 \times A_0 = 0.233$, $\Delta\varepsilon = 4320$, $k_2 = 7.70$ $M^{-1}$ s$^{-1}$, $k_3 = 4.47 \times 10^{-5}$ s$^{-1}$, and $k_1 = 1.07 \times 10^{-5}$ s$^{-1}$ (9*a*) or $1.04 \times 10^{-5}$ s$^{-1}$ (9*b*).

Various methods for determining parameters by fitting procedures based on numerical integration of rate laws have been reported (9, 10); the method reported here is convenient for simple reaction systems but not unique. We are not aware of any report of approaches analogous to the derivative method reported here.

## Conclusions

When it is not possible to obtain an integrated rate law in analytical form, either of the methods described in this paper can be used to obtain the rate constants. We prefer to use the derivative method although sometimes it may be preferable to use least-squares based on numerical integration. In the latter case one must be very careful because the parameters in the least-squares fit need not all be specified by the data, and may show striking covariance.

# Flow $^1$H nmr study of the rapid nucleophilic addition of amino acids to 4-formylpyridine

LIANG K. TAN AND MICHAEL COCIVERA[1]

*The Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1*

Received June 26, 1981

LIANG K. TAN and MICHAEL COCIVERA. Can. J. Chem. **60**, 772 (1982).

Rapid addition of primary amino acids and imidazole to 4-formylpyridine to form carbinolamine intermediates in water has been studied by means of stopped-flow $^1$H nuclear magnetic resonance spectroscopy. The equilibrium constant $K_n$ for this process was determined using stopped-flow uv spectroscopy. For the amino acid D,L-alanine and its derivatives, D,L-alanine methyl ester and D,L-alanylglycine, $K_n$ does not appear to correlate with $K_a$, the acid dissociation constant. Values of $k_n$, the addition rate constant, appear to be independent of pH and buffer concentration for these nucleophiles. The limited data indicate that the variation in rates of nucleophilic addition to 4-formylpyridine cannot be accounted for in terms of p$K_a$, $K_n$ or related to systematic changes in structure of the nucleophile. As a group, the primary amino acid D,L-alanine and its derivatives have comparable $k_n$ values within a factor of two in spite of their different p$K_a$ values. Imidazole, an aromatic secondary diamine, has a $k_n$ value that is 10 to 20 times larger than these primary amines and has a relatively small $K_n$ value. At the same time, its $k_n$ value is comparable to that found previously for sarcosine, a secondary acyclic amino acid having substantially larger p$K_a$ and $K_n$ values. The nucleophilic addition step of the primary amino acid and derivatives is rapid relative to the subsequent dehydration and prototropic shift steps. It occurs in a pH range at which pyridine nitrogen protonation is negligible.

LIANG K. TAN et MICHAEL COCIVERA. Can. J. Chem. **60**, 772 (1982).

Faisant appel à la spectrocopie de rmn du $^1$H à flux stoppé, on a étudié l'addition rapide des acides aminés primaires et de l'imidazole sur la formyl-4 pyridine en vue d'obtenir les intermédiaires du type carbinolamine dans l'eau. On a déterminé la constante d'équilibre $K_n$ de cette réaction en utilisant la spectroscopie uv découlement à flux stoppé. Dans le cas de D,L-alamine et de ses dérivés, l'ester méthylique de la D,L-alanine et de la D,L-alanylglycine, il n'existe pas de relation en $K_n$ et $K_a$, la constante de dissociation de l'acide. Les valeurs de $K_n$, la constante de vitesse d'addition, semblent être indépendantes du pH et de la concentration du tampon de ces nucléophiles. Des données limitées indiquent que la variation de vitesse de l'addition nucléophile sur la formyl-4 pyridine ne peut être reliée à p$K_a$, à $K_n$ ou à des changements systématiques apparents dans la structure du nucléophile. En tant que groupe, l'acide aminé primaire D,L-alanine et ses dérivés ont des valeurs de $k_n$ qui sont comparables puisqu'elles ne varient pas plus que du simple au double même si les valeurs de leur p$K_a$ sont différentes. L'imidazole, une diamine secondaire aromatique, a une valeur de $k_n$ qui est de 10 à 20 fois plus élevée que celles des amines primaires, alors que son $K_n$ est relativement faible. En même temps, la valeur de $k_n$ est comparable à celle trouvée antérieurement pour la sarcosine, un acide aminé secondaire acyclique ayant des valeurs de p$K_a$ et $K_n$ nettement plus élevées. L'étape d'addition nucléophile de l'acide aminé primaire et des ses dérivés est rapide par rapport aux étapes de déshydratation et de glissement protopiques subséquentes. Elle se produit dans un domaine de pH où la protonation de l'azote de la pyridine est négligeable.

## Introduction

Nucleophilic addition of amino acids to 4-formylpyridine (FPY) and its analogues has been used as a model reaction to probe the details of enzymatic reactions involving pyridoxal phosphate (1–3). These studies indicate that imine formation proceeds through a tetrahedral intermediate (1). At high pH equilibration between the aldehyde and this intermediate is rapid relative to the subsequent dehydration step (1, 2) and it has been possible to measure the equilibrium constant for a variety of nucleophiles (2, 4). Measurement of the rate of addition has been reported only for secondary amines for which the reaction with FPY does not proceed beyond the carbinolamine intermediate (2).

In the present paper, we report rate data for the rapid addition of primary amino acids to FPY to form carbinolamine intermediates (CA), which do, in fact, undergo subsequent dehydration. By means of stopped-flow nmr it has been possible to measure the exchange broadened proton nmr resonance of the aldehyde proton of FPY from which $k_n$ and $k_{-n}$ can be calculated for the equilibrium

[1] 

FPY CA

in which $RNH_2$ is alanine (ALN), alanine methyl ester (AME), and alanylglycine (AGY). The details of the subsequent steps are to be reported in the following paper.

## Experimental

*Chemicals*

4-Formylpyridine (FPY) was vacuum distilled and stored over molecular sieves at −25°C. Imidazole was recrystallized

twice from benzene. Diazobicyclooctane (DABCO) was sublimed at reduced pressure. Benzyl alcohol, spectrograde acetonitrile, D,L-alanine (ALN), D,L-alanine methyl ester hydrochloride (AME), and D,L-alanylglycine (AGY) were used without purification. The last two compounds were stored at −25°C. The oxazolidine of 4-acetylpyridine was prepared from 4-acetylpyridine (vacuum distilled) and 2-amino-2-methyl propanol-ol as described previously (5). Deionized water was distilled in an all-glass apparatus.

*Solutions*

In order to avoid possible heavy metal catalyzed reactions of FPY, $1 \times 10^{-4}$ *M* sodium ethylenediamine tetraacetate was included in all solutions. To reduce the possibility of decomposition of FPY and AME, which are not stable for long periods at high pH, these compounds were added only after the solutions had been brought close to the desired pH value; then the final minor pH adjustments were made. Solutions were buffered with imidazole, phosphate, or DABCO at an ionic strength of 1.3 *M* (KCl). A Radiometer PHM 63 digital pH-meter was used. The pD value was obtained by adding 0.4 to the pH meter reading of the $D_2O$ solution (6).

*Exchange reaction*

Proton exchange data were obtained at 30°C by measuring the line width of the broadened signal of the aldehyde proton of FPY relative to that for the signal due to the aromatic protons of benzyl alcohol, which was used as an internal reference to monitor changes in chemical shift and magnetic field homogeneity. Stopped-flow was employed to measure the nmr spectra (7, 8) because CA undergoes dehydration at a substantial rate as described in the following paper (8*c*). To conserve material, the line width was measured as a function of time during this dehydration reaction. Consequently, the exchange rate and, therefore, the line width was time-dependent since it is related to the concentration of FPY and amino acid as described below. The concentration of these reactants at the time of each line width measurement was simulated using rate constants and rate equations presented in the following paper (8*c*).

*Equilibria*

The acid dissociation equilibrium constant $K_a$ for the amino acids in $H_2O$ were measured at 30°C and an ionic strength of 1.3 *M* (KCl) by titration to half neutralization with standardized NaOH. In the case of AME, nmr was used to verify that no significant hydrolysis had occurred during the measurement.

The equilibrium constant for hydration of FPY, $K_h$ ($\mu = 1.3$ *M* KCl) in $H_2O$ and $K_h'$ in $D_2O$, was determined by measuring the areas of the proton nmr signals due to the aldehyde proton of FPY and the corresponding proton of the hydrate of FPY. For these measurements solutions were buffered with phosphate and DABCO in the pH range 6.5 to 8.7 and in the pD range 8.0 to 9.7.

The equilibrium constant $K$ for the addition step to form carbinolamine was determined at 30 ± 1°C as described previously (4) using a D-110 Durrum stopped-flow spectrophotometer equipped with an oscilloscope. The reaction was followed as a function of time over a period of 20 ms at a wavelength of 280 nm. Extrapolation to zero time gave the absorbance of aldehyde remaining at equilibrium. The absorbances of nucleophiles and CA at this wavelength were also taken into account in this determination.[2] The molar absorptivity of CA is assumed to be the same as that for the structurally similar oxazolidine of 4-acetylpyridine.[3] The $pK_a$ of CA for each nucleophile was estimated according to the previous method (5, 9) by adjusting the $pK_a$ value for the corresponding nucleophile for substituent effects using $\sigma^*$ values.[4] The $pK_a$ values obtained in $H_2O$ and 5.4, 3.4, and 3.7 for CA derived from ALN, AME, and AGY, respectively. The rate of addition of each amino acid is too fast to be measured by stopped-flow uv. For ALN and AGY, $K$ was determined at pH 10.2 (0.200 *M* DABCO). For AME $K$ was determined at pH 7.5 (0.100 *M* imidazole); at this pH ester hydrolysis is not an important factor during the period of the determination. For each nucleophile four concentrations were employed. The value for $K$ does not take hydration of the aldehyde into account, i.e., $K$ = [CA]/[N] ([aldehyde] + [hydrate]) in which [N] is the nucleophile free base concentration. The equilibrium constant $K_n$ based on eq. [1] is calculated using the expression $K_n = K(1 + K_h)$.

## Results and discussion

Figure 1 illustrates the 100 MHz proton nmr spectra in $D_2O$ at pD 9.7 (0.400 *M* DABCO, $\mu = 1.3$ *M* KCl) at 30°C: (*A*) 0.604 *M* FPY; and (*B*) mixture of 0.302 *M* FPY and 0.100 *M* AGY. Only the portion of the spectrum downfield from the HDO signal is illustrated. In Fig. 1*A* the signals labeled *a* and *h* are due to the aldehyde proton of FPY and the corresponding proton of the hydrate of FPY, respectively. The reference signal is labeled *r*. The remaining signals are due to the ring protons of the aldehyde and its hydrate. Note in Fig. 1*B* that signal *a* is broadened but has not shifted. Furthermore, the position and width of signal *h* appears unaffected by the presence of AGY. These results permit two conclusions. First, the equilibrium given by eq. [1] is fast enough to affect the nmr line shape and is in the slow exchange category since the position of signal *a* does not change (10). If the exchange were fast relative to δ, the chemical shift between the two exchanging sites, the signals of the two sites would coalesce to form one signal having a weighted chemical shift (10). Thus in contrast with Fig. 1*B*, the broadened signal should have been observed upfield from signal *a* by about 0.64 ppm,[5] for fast exchange. Second, the hydration equilibrium is slow on the nmr time scale since both the aldehyde and hydrate signals are observed in Fig. 1*A*. Furthermore, the presence of AGY does not increase the line width of the hydrate signal

[2]Molar absorptivities of AME and AGY are found to be 0.04 and 0.19 $M^{-1}$ cm$^{-1}$ respectively at λ 280 nm, μ 1.3 *M* (KCl), and 30°C; molar absorptivity of ALN is negligible under these conditions.

[3]Molar absorptivity of oxazolidine of 4-acetylpyridine is found to be 11.6 ± 1.0 $M^{-1}$ cm$^{-1}$ at λ 280 nm, μ 1.3 *M* (KCl), and 30°C.

[4]Since $\sigma^*$ for $-CH_2Py$ is not available, it is obtained from $pK_a$ values for 4-(dimethyl amino methyl)pyridine ($pK_a = 7.66$) and trimethylamine ($pK_a = 9.81$), giving a value of 0.65.

[5]This value is calculated assuming the chemical shift for the carbinolamine is about the same as that for the hydrate, as has been found previously (see ref. 8*a*). A comparable value is estimated by the method of Shoolery (see ref. 11).

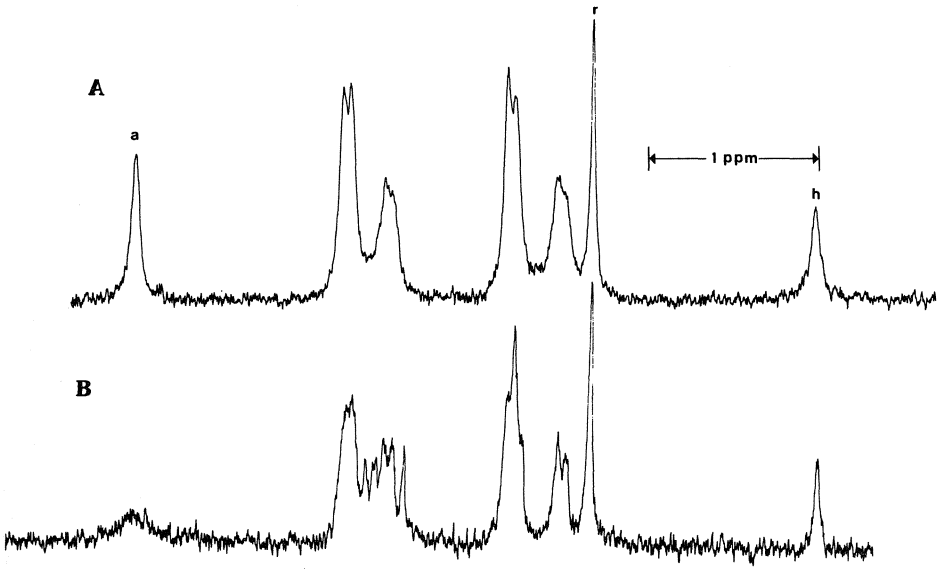

FIG. 1. Partial $^1H$ nmr spectra at 100 MHz in $D_2O$ at pD 9.7 buffered by 0.400 *M* DABCO at 30°C with 1.3 *M* ionic strength. Magnetic field increases from left to right. About 20% acetonitrile was used as an internal lock signal. *A*. portion of the spectrum downfield from the lock signal for a solution containing 0.602 *M* FPY; *B*. same region for a reaction mixture containing 0.301 *M* FPY and 0.100 *M* AGY initially, scan starts immediately after the flow of the liquid is stopped and takes about 4 min to complete. Assignment of signals: *a*, aldehyde proton of FPY; *h*, corresponding proton for hydrated FPY; *r*, ring protons of benzyl alcohol used as an internal line width and chemical shift reference; unlabeled signals are due to the ring protons of the aldehyde and hydrate forms of FPY in *A*, plus product in *B*. During the measurement of the aldehyde proton resonance very little dehydration has occurred.

and, therefore, does not increase the rates for hydration/dehydration. Consequently, the excess line width of the aldehyde signal has no contribution from the hydration reaction.[6]

As a result, the excess line width observed for the aldehyde signal in $D_2O$ in the presence of AGY appears to be due solely to the addition reaction [1], and $k_n$ and $k_{-n}$ are calculated using the analysis for slow exchange between two sites (5, 8*b*, 10). In this case the excess line width in rad/s is equal to $1/\tau_{FPY}$, and $1/\tau_{FPY} = k_n[AGY]$ since $\tau_{FPY}$ is the average lifetime for the aldehyde proton. [AGY] is the concentration of AGY free base. For these calculations, the excess line width has been corrected for variations in magnetic field homogeneity by means of an internal reference line width (benzyl alcohol) as described previously (5). The corresponding signal due to CA is not observed because it is small and broad (about 1/5 the area for the signal due to the aldehyde proton of FPY). Consequently the value for $k_{-n}$ is calculated using the value for $K_n$ and $k_n$. Consistent with slow exchange is the fact that $\delta\tau$ is 5, in agreement with the requirement that $\delta\tau$ should be about 4 or larger (10).[7]

When $H_2O$ is the solvent, the excess line width again appears to be due to slow exchange for AGY, ALN, and AME addition to FPY. However, at low pH the signal shift calculated on the basis of fast exchange is small (around 0.1 ppm or less) because the concentration of nucleophile free base is low under the conditions employed. Consequently the chemical shift measurements do not provide conclusive information about the exchange rate. As a result, the solvent deuterium isotope effect is used to decide between slow and fast exchange at low pH.

For fast exchange in $H_2O$, the ratio $(k_n^{H_2O}/k_n^{D_2O})$ is 31 and 25 for AGY at pH 7.4 and 7.5, respectively.[8] There appears to be no precedent for such large

[6]On the other hand, this hydration reaction is fast relative to the dehydration of CA, i.e., both the addition and hydration equilibria for FPY are maintained during the dehydration of CA.

[7]For this calculation, the value for $\delta$ is 2520 rad/s (see footnote 5) and $\tau$ is calculated using $1/\tau = k_n[AGY] + k_{-n}$ (see refs. 5 and 10).

[8]For this calculation, the chemical shift $\delta$ between the signals of the two sites is estimated as described above. The uncertainty in the chemical shift is unlikely to exceed 0.5 ppm. Consequently, the error in $k_n$ for $H_2O$ solvent is unlikely to exceed 25%. The line width for CA in the absence of exchange is assumed to be equal to the one for the hydrate of FPY since aldehyde–hydrate exchange is slow at this pH.

solvent deuterium isotope effects. For example, for the analogous reaction involving hydrolysis of *meta*- and *para*-substituted 2,2,2-trifluoro-*N*-methylacetanilides via a carbinolamine intermediate none of the various steps in the mechanism is found to have a solvent isotope effect that exceeds 3.0 (12). Similar results are found for hydrolysis of *para*-substituted benzoylimidazoles (12). Consequently, when $H_2O$ is the solvent it appears that the excess line width in the presence of AGY is due to slow exchange rather than fast exchange. In view of the close similarity in structure between the three nucleophiles, we conclude that the slow exchange interpretation also applies at low pH for ALN and AME.

Imidazole also undergoes nucleophilic addition to FPY; however, the rate is fast relative to the chemical shift δ between the signals due to the two exchanging sites because the line width and the position of the broadened signal depend on the concentration of imidazole at pH 8.2. Because the equilibrium constant for the addition appears to be small and the concentration of imidazole could not be increased conveniently above 0.8 *M*, only a semiquantitative value for $K_n$ and δ were obtained by successive approximation using eq. [1] and $\delta_C - \delta_{FPY} = p\delta$ in which $p$ is the proton fraction for CA and $\delta_C$ is the chemical shift of the coalescence signal. As a result, the values for $k_n$ must also be considered to be semiquantitative.

To determine $k_n$ for the amino acid nucleophiles when imidazole is used to buffer the solutions, it is necessary to include the effect of the imidazole equilibrium on the line width of the aldehyde signal as well as on the concentration of the amino acid free base. Because nucleophilic substitution at the tetrahedral carbon atom of CA is expected to be substantially slower than nucleophilic addition to the aldehyde carbon, addition by amino acid and imidazole can be treated as separate competitive exchange processes. Consequently, the contribution to the line width made by each exchange process is additive (10). This consideration also applies to the aldehyde–hydrate exchange, whose contribution increases as the pH increases. As discussed above, to calculate $k_n$ from this excess line width, it is necessary to know the concentration of amino acid free base in equilibrium with its corresponding CA. In the presence of imidazole, this concentration was calculated by including the imidazole addition equilibrium as well as the two acid–base equilibria. If the concentration of amino acid free base is not adjusted in this manner, the $k_n$ value calculated from the excess line width is about 18 and 26% larger than the ones listed in Table 1 for AGY and AME, respectively.

Values for $K_n$, $k_n$, and $k_{-n}$ are listed in Table 1 along with the $pK_a$ for each nucleophile. As has been found previously, there appears to be no direct correlation between $K_n$ and $K_a$ (4, 5). In agreement with our $K_n/(1 + K_h)$ values of 2.3[9] and 0.3 $M^{-1}$ for ALN and imidazole, respectively,[10] Sander and Jencks measured values of 2.1[9] and 0.3 $M^{-1}$, respectively (4).

Values of $k_n$ listed in Table 1 are calculated using a linear dependence between $1/\tau$ and the concentration of nucleophile. Temperature jump studies of the addition of sarcosine and piperazine to FPY indicate both a linear and nonlinear term for $1/\tau$ (2); however, a ten-fold variation in nucleophile concentration was possible in these studies, and the nonlinearity becomes apparent at the high concentrations. In the present study a maximum of only about a four-fold variation in concentration was possible because of the limitations in accuracy of nmr line width measurements for this system. Within these limitations, a nonlinear term was not observed. In addition, the nature and concentration of the buffer appear to have no effect on the rate of addition. Thus, varying the concentration of imidazole or DABCO from 0.4 *M* to 0.8 *M* had no effect on the value of $k_n$ for the amino acid nucleophiles. Likewise comparison of the results for phosphate vs. imidazole or imidazole vs. DABCO in Table 1 indicates no dependence on the nature of the buffer. Similar results have been found previously for the addition of various α-nucleophiles to a variety of ketones (5, 7, 8*b*).

Correlation between $k_n$ or $k_{-n}$ and $K_a$ or $K_n$ for the various nucleophiles is not apparent in Table 1. Considering only the amino acids including sarcosine for which the $pK_a$ is 10.03 and $K_n$ is 5.0 $M^{-1}$ (2*b*), the rate constants again do not appear to correlate with either $K_a$ or $K_n$. Thus a plot of log $k_n$ or log $k_{-n}$ vs. $pK_a$ or log $K_n$ is not linear. For this consideration, we calculate an average $k_n$ value of about $5 \times 10^4$ $M^{-1}$ $s^{-1}$ for sarcosine assuming $1/\tau$ has a linear dependence on the nucleophile concentration for data at pH 10.65 (2*b*).

This value of $k_n$ for sarcosine is about 10 times the one for ALN despite the fact that both amino

[9]These values differ from the one obtained kinetically (see ref. 1*a*).

[10]Although there are several reports concerning $K_h$ none refers to the conditions employed in our study. Furthermore, there is quite a spread in values, ranging from 1.28 to 0.67 (see refs. 2*a*, 4, and 14). For these reasons, we have determined the value listed in Table 1 as described above.

TABLE 1. Equilibrium and kinetic data for nucleophilic addition to 4-formylpyridine at 30°C and $\mu = 1.3\ M$ (KCl)

| Nucleophile[a] | $pK_a$ | $K_n$ ($M^{-1}$) | pH[b] | Buffer | $k_n \times 10^{-3}$ [c] ($M^{-1}\ s^{-1}$) | $k_{-n} \times 10^{-3}$ ($s^{-1}$) |

acids have nearly identical values for $pK_a$ and $K_n$. On the other hand, piperazine, whose second $pK_a$ is about the same as the one for sarcosine, has been found to add to FPY 20 to 40 times faster than sarcosine with a $K_n$ of about 10 times the value for sarcosine (2). Comparison of the data for AGY indicates that there is little or no solvent deuterium isotope effect. This result is similar to that for the analogous reaction in which hydroxide ion adds to substituted *N*-methyltrifluoroacetanilides to form a tetrahedral intermediate. For this system the solvent ($H_2O/D_2O$) deuterium isotope effect is about 1.3 for the addition step (12).

In summary the limited data for the rates of nucleophilic addition to FPY indicate that the variations cannot be accounted for in terms of $pK_a$, $K_n$, or related to systematic changes in structure of the nucleophile. As a group, the primary amino acid and its derivatives, ALN, AME, and AGY, have comparable $k_n$ values within a factor of 2 in spite of their different $pK_a$ values. Imidazole, an aromatic secondary diamine, has a $k_n$ value that is 10 to 20 times larger than these primary amines and has a relatively small $K_n$ value. At the same time, its value is comparable to that for sarcosine, a secondary acyclic amino acid having substantially larger $pK_a$ and $K_n$ values. But the sarcosine rates are 20 to 40 times smaller than those for piperazine, a cyclic, nonaromatic diamine (2). In view of these variations in rates with structure of the nucleophile, it seems that primary amino acids are more suitable for model studies of the details of the addition step involving pyridoxal phosphate. Since the $pK_a$ of FPY is 4.77 (15), the rapid rate of addition of the primary amino acid and derivatives to FPY at high pH could mean that protonation of the ring nitrogen of pyridoxal in the apoenzyme of transaminase need not be a requirement for the addition step. Subsequent protonation may occur prior to the prototropic shift as has been suggested earlier (1*d*). The details of the subsequent steps involving these amino acids and FPY are to be reported in the following paper.

# Amino acid addition to 4-formylpyridine and its quaternized salt: transamination

LIANG K. TAN AND MICHAEL COCIVERA[1]

*The Guelph-Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1*

Received June 26, 1981

LIANG K. TAN and MICHAEL COCIVERA. Can. J. Chem. **60**, 778 (1982).

Flow and stopped-flow $^1H$ nuclear magnetic resonance spectroscopy of aqueous solutions have been used to study the reaction between 4-formylpyridine or 4-formyl-1-methylpyridinium iodide and D,L-alanine as well as its methyl ester and D,L-alanylglycine. Because resolved signals can be observed for the alanyl-$CH_3$-proton resonance of the amine, the aldimine, and the ketimine, the time dependence of each species was followed, and the sequence of steps leading to transamination could be studied. As was found previously with alanine, the conversion of aldimine to ketimine appears to be too slow to be detected when 4-formylpyridine is reacted with alanine (pH range to 10) or alanyl methyl ester (pH range 7 to 8). For these systems reaction proceeds until an equilibrium between aldimine and reactants is established. Because the equilibrium constant for the addition step is measured separately, the constant for the equilibrium $K_d$ between carbinolamine and aldimine could be determined. The rate constants for the forward and reverse steps of this equilibrium are independent of buffer but depend on pH. For alanylglycine between pH 7.2 and 7.7, the same process was found to occur. However between pH 8.2 and 10.1, the aldimine derived from this amine undergoes a prototropic shift to form the corresponding ketimine with a rate constant that depends on the concentration of DABCO at each pH. Thus, the change from α-carboxylate anion of alanine (or other amino acids studied previously) to the uncharged α-amide of alanylglycine causes a distinct increase in the rate of prototropic shift when 4-formylpyridine is the electrophile. For the more reactive 4-formyl-1-methylpyridinium iodide, aldimine to ketimine conversion was found to occur for alanine and alanylglycine. During reaction of the latter, a broad nmr signal occurs. This signal may be due to the dihydropyridine structure suggested for an intermediate detected spectrophotometrically for the reaction involving alanine or glycine.

LIANG K. TAN et MICHAEL COCIVERA. Can. J. Chem. **60**, 778 (1982).

On a utilisé la spectroscopie de rmn du $^1H$ en solution aqueuse à écoulement et à flux stoppé, pour étudier la réaction entre la formyl-4 pyridine ou l'iodure de formyl-4 méthyl-l pyridinium et la D,L-alanine, son ester méthylique et la D,L-alanylglycine. En raison du fait que l'on peut observer des signaux résolus pour la résonance du proton $CH_3$ de l'alanyle de l'acide aminé, de l'aldimine et de la cétimine, on a pu étudier l'évolution de chaque espèce en fonction du temps et on a pu déterminer la succession d'étapes conduisant à la transamination. Tel que trouvé antérieurement avec l'alanine, la transformation de l'aldémine en cétimine semble être trop lente pour être décelée lorsque la formyl-4 pyridine réagit avec l'alanine (pH allant jusqu'à 10) ou l'ester méthylique de l'alanine (pH allant de 7 à 8). Pour ces systèmes, la réaction évolue jusqu'à un équilibre entre l'aldimine et les réactifs. On peut déterminer la constante d'équilibre $K_d$ entre la carbinolamine et l'aldimine puisque la constante d'équilibre de l'étape d'addition est mesurée séparément. Les constantes de vitesse des étapes directe et inverse de cet équilibre ne dépendent pas du tampon, mais dépendent du pH. On a trouvé que dans le cas de l'alanylglycine, la même réaction se produit à un pH compris entre 7,2 et 7,7. Cependant à un pH compris entre 8,2 et 10,1 l'aldimine provenant de cet amine subit un glissement prototropique pour conduire à la cétimine correspondante avec une constante de vitesse qui dépend de la concentration en DABCO à chaque pH. Ainsi, le passage de l'anion carboxylate de l'analine (ou d'autres acides aminés étudiés.

[Traduit par le journal]

## Introduction

Model systems consisting of pyridoxal analogues have been used to probe the mechanism of enzyme catalysed transamination involving amino acids (1–3). Since the model reaction consists of a number of steps, some of which involve species not detectable by uv–visible spectrophotometric techniques, we have undertaken a flow and stopped-flow $^1H$ nmr study of nucleophilic addition of amino acids to 4-formylpyridine (FPY) and 4-formyl-1-methylpyridinium iodide (FMP) in $H_2O$ and $D_2O$ at 30°C. In the previous paper (4), line width measurements were used to obtain $k_n$ and $k_{-n}$ for the forward and reverse steps of the rapid pre-equilibrium in which the carbinolamine intermediate (CA) is formed as shown in Scheme 1. In this scheme Py denotes the pyridyl group and R, the carboxylate or substituted carboxyl group.

The purpose of the present paper is to report the results of a study of the subsequent reactions involving dehydration of CA to form aldimine which in some cases (depending on the amino acid and pH) undergoes a prototropic shift to form the *syn* (SKM) and *anti* (AKM) ketimine. Alanine (ALN), alanine methyl ester (AME), and alanylglycine (AGY) were used as nucleophiles to determine the effect of the three forms of the α-carboxyl group. Time-dependent nmr spectra provide information about the values for the rate constants for the steps following the pre-equilibrium indicated in the scheme. Values are dependent on pH and the nature of the α-carboxyl group. For example, $k_{ps}$ and $k_{pa}$ are too small at pH 7 to 8 to detect the ketimine for any of the amino acids except for AGY

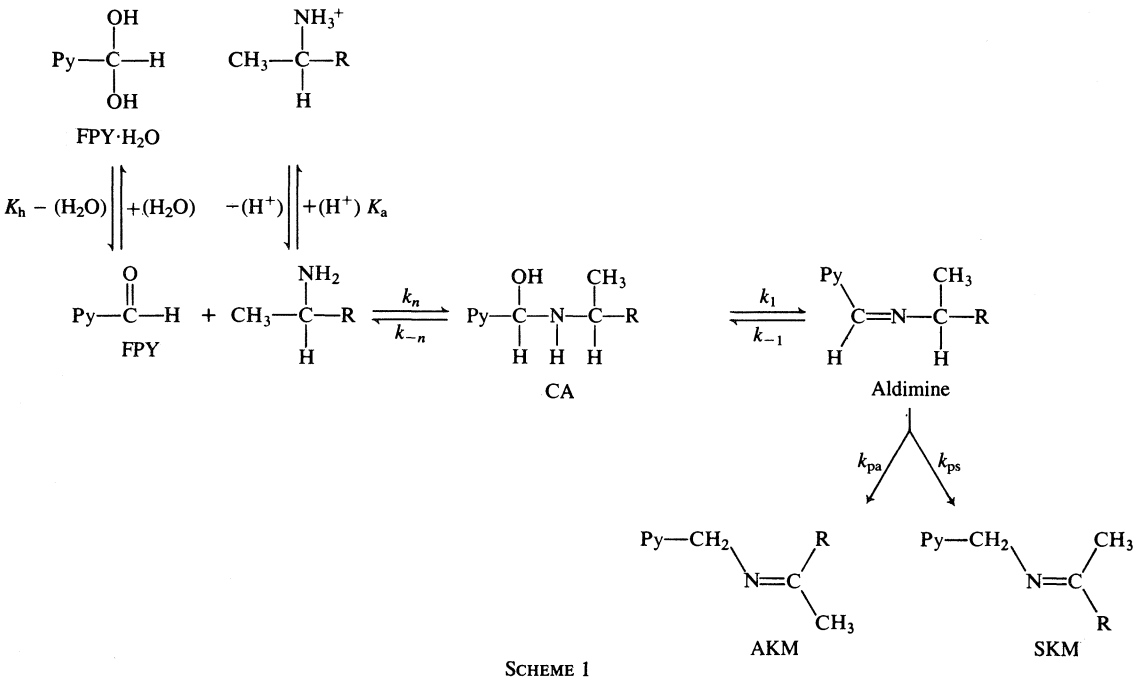

SCHEME 1

at large buffer concentrations. The aldimine slowly decays for AGY but the ketimine is not detected below pH 7.7, perhaps because it hydrolyzes. At higher pH, around 9.5, SKM and AKM are observed for AGY but not for the other amino acids. In previous work, which included only amino acids and no peptides, the prototropic shift was not observed when FPY was used (1*a*).

When the more reactive aldehyde FMP is used, SKM and AKM are observed for the nucleophiles ALN and AGY. In the case of AGY, the prototropic shift appears to occur via an intermediate that is associated with a broadened $^1$H nmr signal. In the corresponding uv–visible study of the reaction between FMP and ALN or glycine, an intermediate was also detected and suggested to be the dihydropyridine tautomer of the carbanion derived from the aldimine by removal of the proton α to the carboxylate group (1*c*). This structure has also been suggested for an intermediate observed spectrophotometrically in an enzymatic reaction involving serine transhydromethylase and alanine (5).

## Experimental

*Chemicals*

4-Formylpyridine (FPY) was vacuum distilled and stored over molecular sieves at −25°C. Imidazole was recrystallized twice from benzene. Diazabicyclooctane (DABCO) was sublimed at reduced pressure. Dimethylsulfoxide (DMSO) was purified by partial crystallization at 5°C and stored over molecular sieves. *t*-Butyl alcohol was distilled prior to use. Spectrograde acetonitrile, D,L-alanine (ALN), D,L-alanine methyl ester (AME) hydrochloride, and D,L-alanylglycine (AGY) were used without purification. The last two compounds were stored at −25°C. 4-Aminomethylpyridine was distilled under reduced pressure. 4-Formyl-1-methylpyridinium iodide (FMP) was prepared from FPY and methyl iodide in dry benzene. The orange–red product was washed with ether, dried, and hydrated in air. The hydrate is a stable pale yellow crystalline material melting at 110–112°C; mp 114–116°C was found previously (6). Deionized water was distilled in an all-glass apparatus prior to use.

*Solutions*

In order to avoid possible heavy metal catalyzed reaction of FPY and FMP, $1 \times 10^{-4}$ *M* sodium ethylene diamine tetraacetate was included in all solutions. To reduce the possibility of decomposition of FPY and AME, which are not stable for long periods at high pH, these compounds were added only after the solutions had been brought close to the desired pH value; then the final minor pH adjustments were made. FMP undergoes side reactions as discussed below. Solutions were buffered with imidazole, sodium phosphate, and DABCO at an ionic strength of 1.3 *M* (KCl). A Radiometer PHM 63 digital pH-meter was used. For $D_2O$ solution, pD was obtained by adding 0.4 to the meter reading (7). Equilibrium constants were measured previously (4).

*Kinetic measurements*

Rate data were obtained by measuring the time dependence of $^1$H nmr spectra at 100 MHz using a Varian HA 100-15 spectrometer equipped with a stopped-flow system described earlier (8). Equal volumes of reactant solutions were mixed at 30 ± 0.3°C. The change in pH after mixing was followed as a function of time. In most cases, there was an immediate drop of 0.1 to 0.4 pH units, depending on the initial pH. After this initial decrease, the pH remained constant to within ±0.03 pH units

during the dehydration and subsequent reaction steps. For each of these steps, the nmr signals due to the product and reactant could be observed in the $CH_3$-region of the spectrum upfield from the $H_2O$ internal lock signal. Thus, the $CH_3$-proton resonance of the amino acid and corresponding $CH_3$-signals of the aldimine and ketimine (*syn* and *anti*) were observed, and their time dependences were obtained by repetitive scanning of each signal. $CH_3$-proton resonance of DMSO or *t*-butyl alcohol served as the chemical shift and intensity internal reference.

## Results and discussion

### *4-Formylpyridine*

Figure 1 illustrates the proton resonance region upfield from the internal $H_2O$ lock signal at 30°C for: *A*, a solution containing 0.100 *M* AGY at pH 9.7 buffered with 0.400 *M* DABCO and an ionic strength of 1.3 *M* (KCl); *B* and *C*, reaction mixture containing initial concentrations of 0.412 *M* FPY and 0.100 *M* AGY at different stages of reaction as indicated in the figure caption.

Assignment of the signals is given in the figure caption. Figure 1*B* illustrates that the $CH_3$-proton resonance of AGY (doublet)[2] and the corresponding $CH_3$-proton resonances of the aldimine (doublet)[3] and the *syn* and *anti* isomers of the ketimine (singlets) are clearly resolved. Thus, by repetitive scanning of each resonance, it has been possible to follow the time dependence of each species as illustrated in Fig. 2.

Figure 2 indicates that the aldimine decomposition rate is sufficiently slower than its formation so that these two reactions can be treated separately. Furthermore the *syn* and *anti* isomers of the ketimine appear to react very slowly. These general features apply when AGY is used as the nucleophile in the pH range 8.2 to 10.1. The rate of formation of the ketimine decreases as the pH decreases so that the ketimine is not observed in the pH range 7.2 to 7.7 (except at pH 7.7 with 0.6 *M* DABCO). Under these conditions, the equilibrium between CA and aldimine (Scheme 1) is attained.

The spectra observed for ALN in the pH range 8.1 to 10.3 and AME in the pH range 6.7 to 8.0 are similar to Fig. 1*B* except that the *syn* and *anti* isomers of the ketimine are not observed, i.e., the prototropic shift is very slow for these nucleophiles. AME could not be studied above pH 8.0 because ester hydrolysis becomes significant. Thus we cannot rule out the possibility that the prototropic shift could have an appreciable rate for this nucleophile at higher pH. At any rate, it is clear that ALN does not undergo this reaction whereas AGY does. The absence of any significant conversion of aldimine to ketimine has been reported for reaction of a variety of amino acids (including ALN) with FPY (1*a*). Consequently, the results for AGY are generally in contrast with those for amino acids.

As with AGY at low pH, the equilibria in Scheme

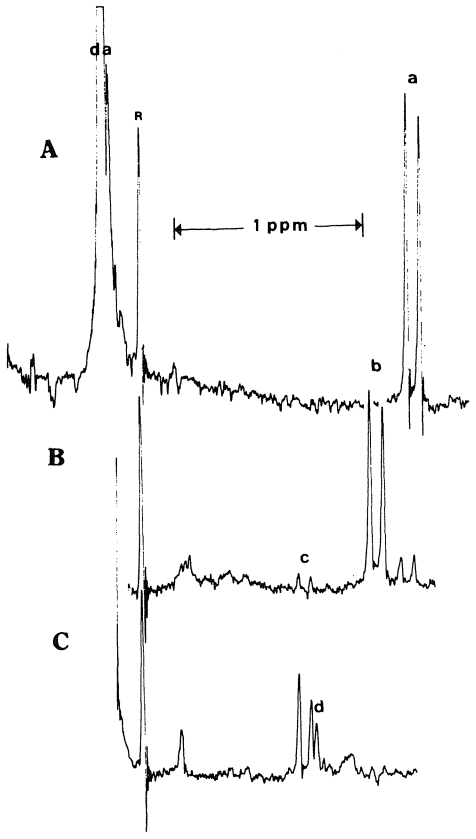

FIG. 1. Partial $^1H$ nmr spectra at 100 MHz obtained upfield from the $H_2O$ lock signal at pH 9.7, 30°C, and 1.3 *M* ionic strength (KCl) using static spinning samples. Magnetic field increases from left to right: *A*, aqueous solution containing 0.100 *M* AGY and 0.400 *M* DABCO; *B*, same as *A* except 0.412 *M* FPY present initially, doublet *a* recorded 1.9 min after mixing; *C*, same as *B*; the two signals labeled *c* were recorded 34 min after mixing. Assignment and chemical shift (relative to TMS) of signals: *a*, $CH_3$-proton of AGY, doublet, 1.32 ppm (this chemical shift is pH dependent, decreasing from 1.57 to 1.28 ppm as the pH is increased from 7.2 to 10.1, respectively); *b*, corresponding $CH_3$-protons of the aldimine derived from AGY, doublet, 1.37 ppm (the corresponding aldimine derived from ALN and AME occurs at 1.35 and 1.38 ppm, respectively); *c*, ketimine $CH_3$-protons, *anti*-singlet, 1.79 ppm and *syn*-singlet, 1.74; *R*, $CH_3$-protons of DMSO (internal reference), singlet 2.62 ppm; *da*, protons of DABCO; and *d*, unidentified product, this signal ultimately becomes the largest in the region of the spectrum.

[2]This doublet also contains a contribution from the corresponding $CH_3$-proton resonance of CA. However, the exchange process involving CA and AGY does not affect line width or position, as might be anticipated since the chemical shift between the exchanging sites is probably small.

[3]The isomers of the aldimine do not give separate $CH_3$-proton signals. Presumably the double bond is separated from the $CH_3$-group by too many bonds to have an effect.

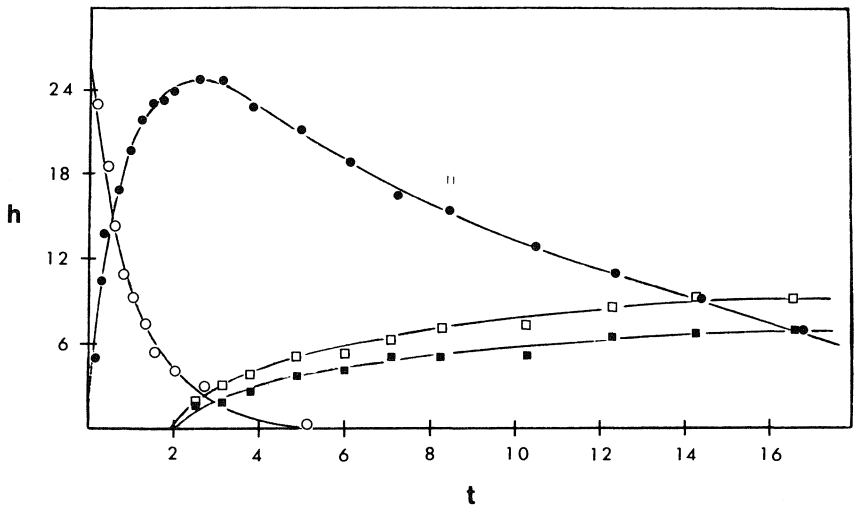

FIG. 2. Time dependence for the $CH_3$-proton signal heights of species occurring during the reaction after mixing at 30°C and ionic strength 1.3 *M* (KCl). Solution contains 0.401 *M* FPY and 0.100 *M* AGY initially at pH 9.7 buffered by 0.400 *M* DABCO. Symbols: *h*, height of signal; *t*, time in min; ○, AGY; ●, aldimine; □, *anti* ketimine; ■, *syn* ketimine. The lines, which have no theoretical significance, are drawn merely to aid in following the behavior of each species. Assignment of *syn* and *anti* isomer is based on ref. 14.

1 are attained with ALN and AME at all pH values employed; and $K_1 = k_1/k_{-1}$, the constant for the equilibrium between CA and the aldimine, can be calculated from the ratio of the signal intensities for the amino acid and its corresponding aldimine using $K_a$ and $K_n$ values reported in the preceding paper (4). Values of $K_1$ for ALN listed in Table 1 indicate that the nmr data provide reasonably precise values over a wide range of pH. When imidazole is the buffer, $K_n'$ for the addition of imidazole to FPY is also included in the calculation of $K_1$ (4). Comparison of the ALN values indicates that $K_1$ is the same when either DABCO or imidazole is the buffer. The average $K_1$ values for ALN, AME, and AGY are 101 ± 15, 93 ± 16, and 66 ± 10, respectively.

For the ALN–FPY system, comparison of our equilibrium data with previous work is possible. A value of 270 $M^{-1}$ has been reported for the equilibrium constant for the overall equilibrium, ALN + FPY ⇌ aldimine (1*a*). Correction of this value by multiplying by the factor ($K_h$ + 1) to take into account the equilibrium hydration of FPY gives a value of 520 $M^{-1}$ which agrees well with our value of 450 $M^{-1}$ calculated as $K_nK_1$. The value of $K_h$, the equilibrium constant for hydration of FPY, is 0.93 (4).[4]

For the cases in which the $K_1$ equilibrium occurs, $k_1$ and $k_{-1}$ have been calculated from time dependence for the amino acid signal decay or the aldimine signal growth using

$$[1] \quad \ln\left(\frac{[N_T] - [N_T]_e}{[N_T]_0 - [N_T]_e}\right) = -(k_1 + k_{-1})\beta t$$

in which β is $K_aK_n[FPY]/(K_aK_n[FPY] + [H^+] + K_a)$, $[N_T]$ is the total concentration of the nucleophile at time $t$ including all degrees of protonation, the subscripts 0 and e denote initial and equilibrium values, and [FPY] is the equilibrium concentration of the aldehyde at time $t$ based on the hydration and nucleophilic addition equilibria (Scheme 1). In this treatment protonation of CA has not been included because the $pK_a$ of protonated CA is estimated to be substantially lower than the pH employed (4). Equation [2], in which β is time dependent, must be used because the rapid pre-equilibrium provides significant concentrations of FPY and CA; and, therefore, the time dependence cannot be treated as either a pure first order or second order process. Similar expressions have been employed in previous nmr studies, and it was found that this approximation causes less than a 10% error provided the concentration of one reactant is at least twice that of the other (8*c*), as is the case in the present study. In practice, values for $(k_1 + k_{-1})$ listed in Table 1 were calculated using a linear regression program written for a Hewlett-Packard HP-65 calculator.[5] The errors and scatter indicated in this table for ALN are typical of the data for AME and AGY, also. Each value is an average of three to five determinations. The $(k_1 + k_{-1})$ values are independent of DABCO concentration but increase as the pH decreases. Similar behavior is observed for AME in the pH range 6.7 to 8.0 with imidazole.[5] As discussed above, AGY was used in two pH ranges (7.2–7.7 and 8.2–10.1) and equilibration with the aldimine could be observed only at the lower pH range, presumably because the aldimine–ketimine conversion is very slow in this pH range. Thus in this pH range $(k_1 + k_{-1})$ was calculated according to eq. [1]; in the higher range, $k_1$ was calculated according to a similar equation in which the $k_{-1}$ step was excluded. Over both pH ranges, $k_1$ for AGY appears to be independent of buffer concentration (0.20 to 0.35 *M* phosphate, 0.40 to 0.80 *M* imidazole, and 0.40 to 0.80 *M* DABCO) but dependent on pH, increasing as the pH decreases.[6] Consequently for the three nucleophiles, ALN, AGY and AME, the dehydration/hydration of CA appears to depend on the concentration of hydronium ion. Values of $k_1^+$ listed in Table 2 are obtained by linear regression using the equation, $k_1 = k_1^0 + k_1^+[H_3O^+]$. For ALN and AME the correlation coefficient is greater than 0.99; and for AGY it is greater than 0.98. The intercept $k_1^0$ for ALN is substantially larger than the values for the other two nucleophiles. The reason for this difference is not clear. On the other hand, the large variation in $k_1^+$ values for the nucleophiles may be related to protonation of CA as has been suggested by French and Bruice (1*a*). Thus the $k_1^+$ values in Table 2 have the same meaning as the $k_1/K_a''$ values reported by these workers who define $k_1$ and $K_a''$ to be the dehydration rate constant and the acid dissociation constant, respectively, for $CAH^+$, the protonated form of CA. Comparison with this previous work is possible only for ALN for which a $k_1/K_a''$ value of $2.5 \times 10^8$ $M^{-1}$ $s^{-1}$ was reported. The large difference between this value and the one in Table 2 probably results because the kinetic analysis used in the previous work did not include hydration of FPY.[7]

In spite of this difference in magnitude, the two studies agree that the rate of dehydration of $CAH^+$ makes a significant contribution to the overall rate of formation of the aldimine. Furthermore it ap-

[5]Equation [1] represents an additional approximation since the term $(k_1 + k_{-1})$ should really be $(k_1 + k_{-1}/\beta)$. A correction for this approximation is made by calculating $k_1$ as $\beta K_1 (k_1 + k_{-1})/(\beta K_1 + 1)$. This correction is small for ALN and AGY, a maximum of about 10% at low pH. However, the maximum correction is about 56% for AME.

[6]For AME $K_1$ and $(k_1 + k_{-1})$ data were obtained for 22 pH and buffer concentration combinations in the pH range 6.7 to 8.0. For AGY, data were obtained for 18 and 14 pH and buffer concentration combinations in the pH ranges 7.2 to 7.7 and 8.2 to 10.1 respectively.

[7]For the same reason, their equilibrium constant for ALN + FPY ⇌ CA differs from our value, which agrees with the one determined by Sanders and Jencks (see refs. 4 and 9).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

pears this rate is about the same for the three nucleophiles, i.e., $k_1^+K_a''$, the first order rate constant for dehydration of $CAH^+$, has nearly the same value despite the difference in the $pK_a$ values of the nucleophiles. For this consideration, the absolute value of $k_1^+K_a''$ for each $CAH^+$ cannot be determined accurately because the acid dissociation constant $K_a''$ is not known for these intermediates, although it may be estimated as described previously (10). Nevertheless, using $pK_a$ data in Table 2, one can calculate $k_1^+K_a$, which is expected to be proportional to $k_1^+K_a''$. The $k_1^+K_a$ values listed in Table 2 are all nearly identical. This similarity would indicate that $CAH^+$ dehydrates at nearly the same rate for the three nucleophiles if the difference between $K_a$ and $K''$ were due to identical substituent effects in the three cases.

In contrast, the intercept $k_1^0$, which can be assigned to dehydration of the unprotonated carbinolamine, depends on the nature of the nucleophile with AGY having a substantially smaller value than the other two. It would be useful to have results for other nucleophiles to determine the factors affecting this step. As indicated in Table 2, the solvent deuterium isotope effect for $k_1$ has been determined at only one pH–pD value. In view of the complications involved in the interpretation of solvent deuterium isotope effects (11), any discussion seems premature.

Although imidazole appears to add to FPY (4, 9), there is no evidence to indicate that formation of the imidazole–FPY adduct enhances the rate of aldimine formation for the various nucleophiles. In addition, our results give no indication that imidazole adds to the aldimine to form a complex similar to the one observed during the reaction between pyridoxal and α-aminophenylacetic acid (12).

For the AGY–FPY system at low pH, the aldimine slowly decays after equilibrium between this imine and CA has been attained. Because this decay is slow under these conditions, it was not followed to completion. Nevertheless, a sufficient fraction of the reaction was followed to indicate that it is first order in aldimine and that the first order rate constant increases as the concentration of imidazole is increased. The signals due to the expected *syn* and *anti* ketimine products, which are observed at high pH (see below), are not observed in this pH range, presumably because ketimine formation is rate limiting.[8] Consequently, although it seems likely that ketimine formation is the main reaction for the aldimine, the possible occurrence of competing reactions cannot be ruled out. For this reason, the values for the first order rate constants are not listed for this pH range. They are about a factor of 200 smaller than the values at pH 9.7 with DABCO buffer as discussed below.

At high pH in the range 8.2 to 10.1, evidence for the prototropic shift for the system AGY–FPY is more conclusive. As indicated in Figs. 1 and 2, the *syn* and *anti* isomers of the ketimine are observed. Although aldimine to ketimine interconversion has been observed when more reactive electrophiles such as FMP (1*c*) and 4-formyl-3-hydroxypyridine (1*b*) are used, this process was not detected previously when FPY was reacted with amino acids (1*a*). While it is interesting to speculate about the reasons for the effectiveness of the peptide relative to the amino acids in promoting this step, other systems should be studied to obtain more information.

Both isomers react at a slower rate than they are formed. Presumably this decomposition involves hydrolysis of the ketimine to form pyruvoylglycine and 4-aminomethylpyridine, neither of which are detected. Our failure to detect 4-aminomethylpyridine is due to the fact that its signals occur in the same regions as other stronger signals. Pyruvoylglycine undergoes ring closure under basic conditions to form γ-hydroxypyrrolidone carboxylic acid (13). Although several signals having suitable time dependences are observed, none has been assigned conclusively to this acid. Consequently, because the products have not been identified and because the rates are very slow, kinetic studies of the reaction of ketimine have not been pursued.

On the other hand, the slow rate of decay of ketimine in comparison with its growth permits the measurement of $k_{pa}/k_{ps}$, which is assumed to be equal to the AKM/SKM ratio of $CH_3$-proton signal intensities.[9] Because this ratio was found to be constant over the time the reaction was followed, we cannot decide if the prototropy occurs under kinetic or thermodynamic control. Previous work with the glycine–pyruvate system indicates that the rate of forward and reverse steps of the *syn–anti* equilibrium is comparable to the nmr time scale at nucleophile concentrations larger than those used in the present study (15). For the AGY–FPY system, the line width of the *syn* and *anti* signals gives no indication of an exchange process. Values of $k_{pa}/k_{ps}$ ratio listed in Table 3 are averages over the reaction period.

[8]At higher pH, ketimine decomposition is rate limiting. The transition appears to occur around pH 7.7 since ketimine can be detected only when DABCO concentration is 0.6 *M* and greater, see below.

[9]Assignment of *syn* and *anti* $CH_3$-proton resonance signals is based on ref. 14.

Because the rate of conversion of aldimine to ketimine is slower than the dehydration of CA, the decay of the aldimine was studied using static spinning samples. Analysis according to first order reaction provides values for the sum of the rate constants ($k_{ps} + k_{pa}$) that are listed in Table 3. These values depend on pH and total DABCO concentration. However, this dependence appears to be more complicated than a first order dependence on buffer concentration because the intercept is negative, the value increasing with pH until it is positive at pH 10.1. This behavior may indicate a nonlinear dependence on buffer concentration. Unfortunately, it is not possible to test this behavior by using buffer concentrations lower than 0.4 *M* because the pH cannot be controlled adequately below this concentration. Consequently, because of the limited buffer concentration range employed, a detailed nonlinear analysis is not reported here. Suffice it to say that the limited data can be fit to the equation, $(k_{pa} + k_{ps}) = k_p'[\text{DABCO}]_T + k_p''[\text{DABCO}]_T^2$. This equation is used assuming that catalysis by hydroxide ion may be neglected. Because the error due to this approximation is not known and only three concentrations are employed at each pH, the calculated values should be considered semiquantitative and sufficient only to indicate trends. For each pH, plots of $(k_{pa} + k_{ps})/[\text{DABCO}]_T$ vs. $[\text{DABCO}]_T$ are linear with correlation coefficients of 0.98 or greater. The value for $k_p'$ increases as the pH increases and the general base catalytic constant, $k_p^{GB}$, which is obtained as $k_p'(K_a + [H_3O^+])/K_a$, has a value of 0.32 ± 0.02 $M^{-1}$ min$^{-1}$ in the pH range 9.2 to 10.1. General base catalysis has also been observed in aldimine–ketimine conversions in studies of more active aldehydes such as FMP or 3-hydroxy-4-formylpyridine (1*b*,*c*). For these systems, it has been suggested that the base is involved in removal of the methine proton of the aldimine. A similar mechanism is consistent with the present results.

[a]pH after mixing.
[b]Total concentration after mixing, includes all degrees of protonation.
[c]Total initial concentration of FPY after mixing, includes its hydrate form. The total initial concentration of AGY after mixing is 0.100 *M* for all runs, includes all degrees of protonation.
[d]Obtained from the ratio of the $CH_3$-proton signal height of AKM and SKM. Each value is an average of 3 mean values from 3 runs. Each mean value from each run is the average of several ratios at different time.
[e]At this pH, using concentrations of DABCO lower than 0.6 *M* leads to no formation of ketimine.

The value for $k_p''$ decreases as the pH increases from 8.2 to 10.1, at which the value is very close to zero. Although the data are semiquantitative, this trend appears real. A mechanism to account for this behavior is not obvious. In the study of the transamination reaction involving α-aminophenylacetic acid and pyridoxal, catalysis by imidazole was found to depend on the square of the imidazole concentration at low concentration but not at high concentration of imidazole (12). This behavior was interpreted as evidence for a preequilibrium formation of a complex of aldimine with imidazole and imidazolium ion followed by an intracomplex bifunctional acid–base catalysis of the prototropic shift. Complex formation does not appear to apply to the AGY–FPY system because there is no evidence that the rate becomes independent of DABCO concentration at high concentration. On the other hand, complex formation is not necessarily needed for bifunctional catalysis. For example, termolecular terms determined in the enolization of ketones have been attributed to bifunctional acid–base catalysis (16). The DABCO results are not strongly indicative of bifunctional catalysis because $k_p''$ does not exhibit the expected dependence on pH, i.e., a maximum value should be observed when pH equals p$K_a$ (9.4) of DABCO. Instead, the value decreases monotonically as pH increases from 8.2 to 10.1. This effect could not be studied below pH 8.2 because there is no clear indication that ketimine formation is the only path available to the aldimine, i.e., as mentioned above, the reaction is slow and ketimine is not observed below pH 7.7. Even at this pH, ketimine can be detected only when the DABCO concentration is 0.6 *M* or greater, indicating that ketimine may not be formed faster than it is hydrolysed below this concentration. Consequently in this pH range there is no certainty that the decay of aldimine leads solely to ketimine.

### *4-Formyl-1-methylpyridinium iodide*

The reaction of 4-formyl-1-methylpyridinium iodide (FMP) with ALN or AGY could not be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

studied quantitatively because FMP decomposes in the pH range employed (pH 9–10). The rate of this decomposition appears to increase with increase in FMP concentration as well as buffer and nucleophile concentrations. Thus this decomposition competes with nucleophilic addition by ALN or AGY. The FMP concentration dependence indicates that this decomposition may not be important at the concentrations employed in previous studies (1*c*). At any rate, because the nmr study requires FMP concentrations in the range 0.1 to 0.4 M, this reaction becomes important. Therefore, the nmr study has been used to obtain only qualitative information.

First we find that FMP is extensively hydrated so that the aldehyde proton resonance cannot be detected. This hydration has been alluded to previously (1*c*). The rate of hydration/dehydration appears to be slow on the nmr time scale because the position and width of the hydrate methine proton resonance are not affected when the nucleophile is added. Since, by analogy to FPY, nucleophilic addition to the aldehyde form of FMP is expected to be sufficiently rapid to cause line broadening, an increase in line width and/or a change in position of the hydrate signal is expected if hydration/dehydration is also rapid. With available information it is not possible to decide whether dehydration of the hydrate or dehydration of CA is the rate limiting step in aldimine formation.

Although reasonably precise first order rates of formation of aldimine can be obtained based on the time dependence of the $CH_3$-proton resonance of the amino acids, their meaning is unclear because FMP, whose concentration is usually three times that for the amino acid, disappears completely while about 20% of the amino acid remains at the end of the reaction.

Qualitatively it appears that ketimine formation occurs according to Scheme 1, but the concentration of the aldehyde form of FMP is very low. In addition, in the case of ALN–FMP, the hydrolysis of the ketimine is clearly established by detection of the $CH_3$-proton resonance of pyruvate anion. Identification of this signal supports the previous evidence that pyruvate anion is formed as a result of hydrolysis of ketimine derived from ALN (1*c*). Based on intensities, it appears that about a 50% conversion of ALN to pyruvate ion occurs at pH 9.6 in the presence of DABCO in about 30 min, compared with 78% in about 5 h at half neutralization of ALN in the absence of DABCO reported previously (1*c*).

For AGY–FMP, the reaction mechanism appears similar; however, the signal due to the hydrolysis product has not been assigned for the reasons mentioned in the previous section. In Fig. 3, the $CH_3$-region of the spectrum for the AGY–FMP system obtained 17 min after mixing illustrates the appearance of a broad signal in addition to those due to the aldimine and AGY. This broad signal occurs in the presence of DABCO or imidazole[10] in the pH range 9 to 10. It decays more rapidly in the presence of DABCO, but the rate appears to be substantially slower than the hydrolysis rate of the ketimine of ALN. An unambiguous assignment of this signal cannot be made. However, it is possible that this signal may be associated with the dihydropyridine structure (DHP) in eq. [2] suggested earlier to account for the absorbance maxima observed at 500 and 600 nm for the FMP–glycine

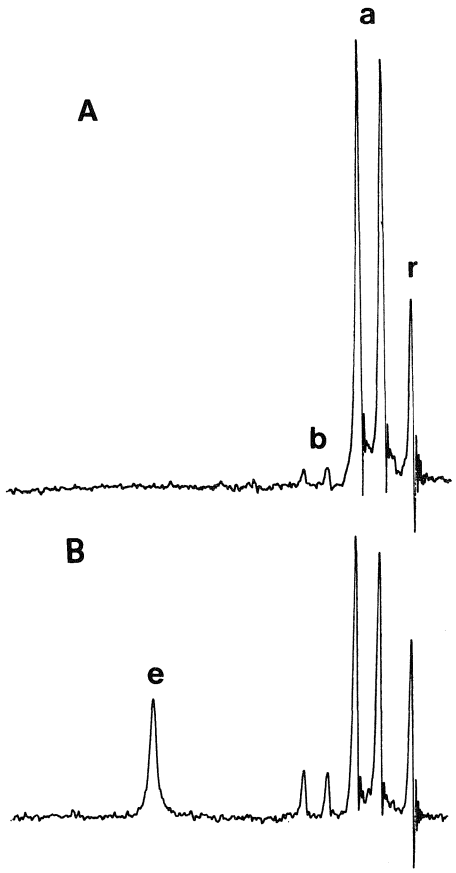

FIG. 3. Partial $^1H$ nmr spectrum of an aqueous reaction mixture containing 0.400 *M* FMP and 0.200 *M* AGY at pH 9.5. Except for the gain, the nmr conditions are identical to those for Fig. 1 as are the labels. This figure is photographically reduced less than Fig. 1 and the chemical shift between signals *e* to *r* is 0.77 ppm. In addition, *r* denotes the $CH_3$-proton resonance of *t*-butyl alcohol, and *e* is not identified conclusively, see text. *A*, Scan is started immediately after mixing, and *r* is recorded 60 s after start; *B*, scan started 17.4 min after mixing.

[10]The pH drop is 0.1 and 0.3 in the presence of DABCO and imidazole, respectively.

and FMP–ALN systems, respectively (1*c*). Thus, the signal may be due to the DHP methyl group attached to the $sp^2$ hybridized carbon. It is broadened because of restricted rotation about the carbon–nitrogen bond. The fact that this signal decays more rapidly in the presence of DABCO than in the presence of imidazole may indicate that conversion of DHP to ketimine is acid catalyzed, i.e.,

[2] 

since the fraction of acid form of imidazole ($pK_a$ = 7.24) is very small in this pH range whereas it is appreciable for DABCO ($pK_a$ = 9.40).

For the ALN–FMP system detection of a corresponding signal has not been established conclusively, although some very weak signals have been observed. This result does not necessarily contradict those of the spectrophotometric study (1*c*) since a large molar absorptivity would permit detection of DHP at concentrations too small for nmr detection in a single scan. In addition the enhanced reactivity of ALN vs. AGY may have several factors: (*1*) the negative charge of the α-carboxylate reduces the stability of DHP and the corresponding ketimine resulting in more rapid conversion to hydrolysis product (pyruvate anion); (*2*) unreacted ALN acts as a general acid catalyst in eq. [2].

Received October 9, 1981

G. W. BUCHANAN and J. B. STOTHERS. Can. J. Chem. **60**, 787 (1982).

$^{15}N$ nuclear magnetic resonance chemical shifts are shown to be highly sensitive to site-selective diamagnetic metal ion binding for the nucleosides adenosine, cytidine, and guanosine. Conclusions regarding preferred complexation sites are compared with results derived from other physical measurements, and with expectations based on electron density calculations.

G. W. BUCHANAN et J. B. STOTHERS. Can. J. Chem. **60**, 787 (1982).

On a montré que quelques ions diamagnétiques induisent sélectivement des grandes changements des déplacements chimiques dans l'rmn de l'azote-15 pour les nucléosides adenosine, cytidine et guanosine. Les conclusions concernant les sites d'attachement préferés sont comparés avec les résultats d'autres méthodes physiques et avec les calculs basés sur les densités électroniques.

## Introduction

The importance of metal ion interactions with nucleotide components is now well recognized. Subtle features of metal – nucleic acid binding are deemed responsible for the toxic behaviour of some metal complexes and the antineoplastic behaviour of others (1).

Among the available techniques which have been applied in this field are Raman and Raman difference spectroscopy (2), as well as $^{1}H$, $^{13}C$, $^{31}P$, $^{7}Li$, and $^{35}Cl$ nmr (3). For the mononucleotide AMP, $^{15}Nmr$ has recently been used to study paramagnetic $Mn^{+2}$ binding, via $T_1$ and linewidth measurements (4). No changes in $^{15}N$ chemical shifts, however, were apparent upon binding, although the [Mn]/[AMP] ratio was relatively low.

By contrast, no studies have been reported using $^{15}Nmr$ to monitor *nucleoside* – metal ion binding, despite the fact that ions such as $Hg^{+2}$ are known to form complexes of high stability with nucleosides, and the primary binding sites have often been postulated to be one or more of the nitrogen sites of the nucleoside bases (3).

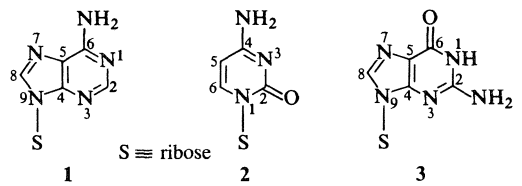
We wish to report that large chemical shift changes are found in the $^{15}N$ spectra of nucleosides on addition of up to one molar equivalent concentration of $HgCl_2$ and $Zn(NO_3)_2$, and that additional information regarding nitrogen site selectivity is thus available. Dimethyl sulfoxide has been used as solvent, since relatively high concentrations of metal ions and nucleosides can be achieved in this medium.

[1]Author to whom correspondence should be addressed.

## Results and discussion

Specifically, the nucleosides adenosine **1**, cytidine **2**, and guanosine **3** have been examined in the presence of $HgCl_2$, $Zn(NO_3)_2$, and $Ba(NO_3)_2$.

The $^{15}N$ chemical shifts for the nucleosides



**1** **2** **3**

themselves in DMSO-$d_6$ solution have been reported previously (5), and our data (Table 1) are in excellent agreement with the earlier work.

Our choice of metal ions was made for several reasons. Firstly, there is general agreement (6–10) that $HgCl_2$ binds strongly to endocyclic ring nitrogens of nucleosides in DMSO solution. Our studies, therefore, were aimed mainly at establishing the degree of perturbation of the $^{15}Nmr$ spectra due to the binding interactions. Furthermore $Hg^{+2}$ classifies as a "soft" metal ion species, its bonding being more covalent in nature than that for "harder" metals.

The $Zn^{+2}$ ion was chosen since it also has a known affinity for endocyclic nitrogens of nucleosides (11, 12), but is otherwise "harder" than $Hg^{+2}$. Finally $Ba^{+2}$ was selected as an example of a "hard" ion, its mode of bonding normally being ionic rather than covalent.

The effects of added $HgCl_2$ and $Zn(NO_3)_2$, up to one molar equivalent, on the $^{15}N$ resonances of the

*DMSO-$d_6$ solutions.

three nucleosides are shown in Figs. 1–6. In all cases, $Ba(NO_3)_2$ induced maximal shift changes of less than 0.3 ppm, and accordingly these results are not plotted.

(a) *Adenosine: $HgCl_2$ addition*

Results in Fig. 1 show that the N-1 resonance of adenosine is most affected by $HgCl_2$ addition, there being a 9.5 ppm *upfield* shift upon addition of 1 molar equivalent of $Hg^{+2}$. The N-7 resonance experiences a minor upfield shift also (1.2 ppm), while the remaining three $^{15}N$ resonances for N-3, N-9, and the $NH_2$ are shifted downfield on addition of 1 molar equivalent $HgCl_2$.

In this context it is interesting to recall the results of protonation of adenosine, also in DMSO solution, using TFA as a proton source (5). It was found that the N-1 $^{15}N$ resonance shifted *upfield* by 72.6 ppm after 1.6 equivalents of TFA were added. By contrast, all other $^{15}N$ resonances were affected to a much lesser extent, and all were shifted downfield, the values being 1.9, 3.3, 8.2, and 9.9 ppm for N-3, N-7, N-9, and the $NH_2$ respectively (5).

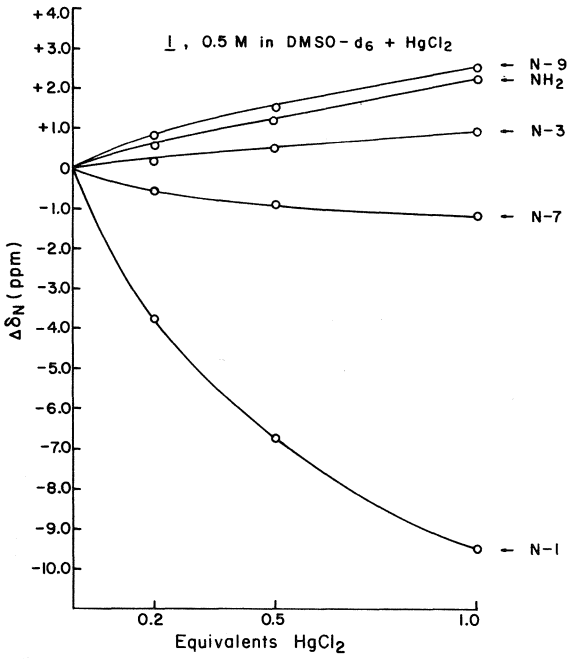

FIG. 1. $^{15}N$ chemical shift changes as a function of added metal ion. + sign denotes increased δ value (downfield shift); − sign denotes decreased δ value (upfield shift); **1** + $HgCl_2$.

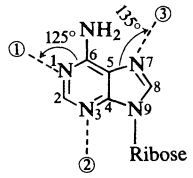
For pyridine, protonation induces an upfield shift of about 97 ppm in the $^{15}N$ resonance (5). Thus the upfield shift of N-1 of adenosine can be taken as evidence for this position being the preferred protonation site.

Similarly, one can argue that N-1 is the preferred site of mercuration in adenosine. The fact that N-7 also shifts upfield upon $HgCl_2$ addition suggests that N-1 is not, however, an exclusive complexation site. For the remaining three nitrogens of **1**, the smaller downfield shifts are most likely due to the involvement of these positions in conjugation with a metallated N-1 (or N-7) site (5).

It is interesting to compare these conclusions with theoretical predictions (13) of preferred binding sites of adenosine, based on electron density calculations. Results of these calculations are depicted below, with the circled numbers indicating, in order, the preferred complexation sites.



For mercuration and protonation, N-1 does indeed appear to be the preferred site. There is, however, an experimental preference for N-7 over N-3 as the second most likely mercuration site, in contrast to the predictions of the theory.

(b) *Adenosine: $Zn(NO_3)_2$ addition*

As is shown in Fig. 2, the induced $^{15}N$ shifts upon $Zn(NO_3)_2$ addition are largest for the N-7 site (upfield by 7.5 ppm after 1 molar equivalent added). The N-1 resonance is also shifted upfield, but to a smaller extent (1.6 ppm). The N-3 and N-9 resonances are essentially unaffected, while the $NH_2$ is deshielded by 1.4 ppm.

Based on these data, one is led to suggest that $HgCl_2$ and $Zn(NO_3)_2$ solutions with adenosine may contain *different mixes* of N-1 vs. N-7 metallated complexes, the N-1 site being preferred by $Hg^{+2}$, while $Zn^{+2}$ prefers N-7.

It is instructive to note that previous studies (3) of adenosine–$HgCl_2$ and $Zn(NO_3)_2$ complexes, which made use of $^1H_1$, $^{13}C$, and Raman difference spectra, suggested that this is indeed true, although no distinction between relative nitrogen site preferences was possible.

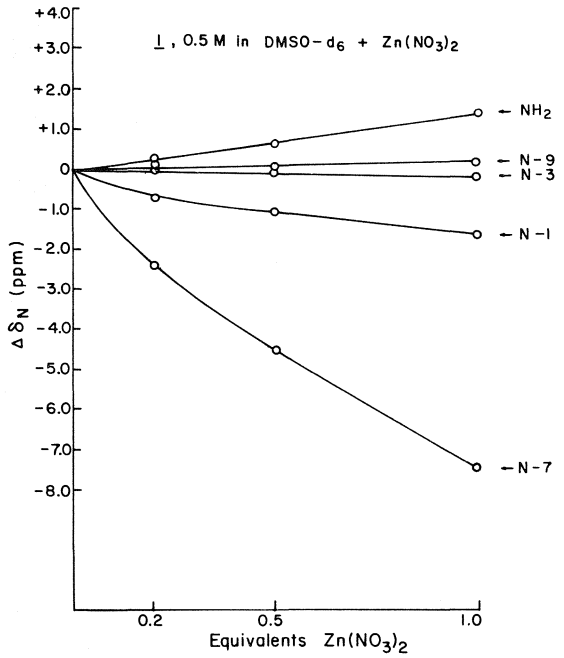


FIG. 2. 1 + $Zn(NO_3)_2$.

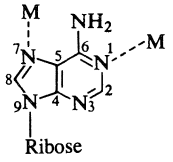
Another explanation for the upfield shifts of both N-1 and N-7 of **1** upon metalation is the possible formation of a dimetalated species, as shown below.



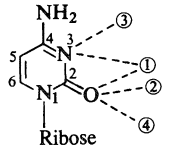
The existence of such a complex has recently been suggested by Farrell (14) for adenosine complexes with $Pt^{II}$. If such a species did exist, however, one might expect more nearly equivalent upfield shifts for N-1 and N-7 of **1** upon addition of the metal ions.

(c) *Adenosine: $Ba(NO_3)_2$ addition*

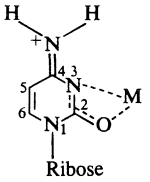
Raman difference and $^{13}$Cmr spectra of adenosine in the presence of "hard" metal species such as $Ba(NO_3)_2$ indicate no binding (3), and the negligible $^{15}$N chemical shift changes induced upon addition of this salt are consistent with this situation.

(d) *Cytidine: $HgCl_2$ and $Zn(NO_3)_2$ addition*

For cytidine, the primary binding site is calculated (13) to be a chelated position between the carbonyl oxygen and N-3 as shown below.



The large upfield shifts at N-3 of **2** induced by both $HgCl_2$ and $Zn(NO_3)_2$, as shown in Figs. 3 and 4 respectively, are consistent with a binding site which preferentially involves this nitrogen. The accompanying downfield shift of the $NH_2$ upon complexation is reminiscent of the effect of protonation (5), where it was postulated that the deshielding of this nitrogen was due at least in part to its interaction with the complexed N-3 position via resonance donation, as depicted below for metalated cytidine.



The N-1 resonance of **2** experiences an upfield shift which is less than 10% of that seen for the N-3 absorption. The fact that it is upfield however, suggests that N-1 is also a metalation site, although to rather a minor extent.

Once again it is interesting to compare the effects of metalation with protonation. Upon addition of 1.6 equivalents of TFA, the N-3 resonance of cytidine shifts upfield by 64.8 ppm, while the $NH_2$ is deshielded by 20.8 ppm, and N-1 undergoes a minor shielding of 2.9 ppm (5). This ratio of 22.4 :

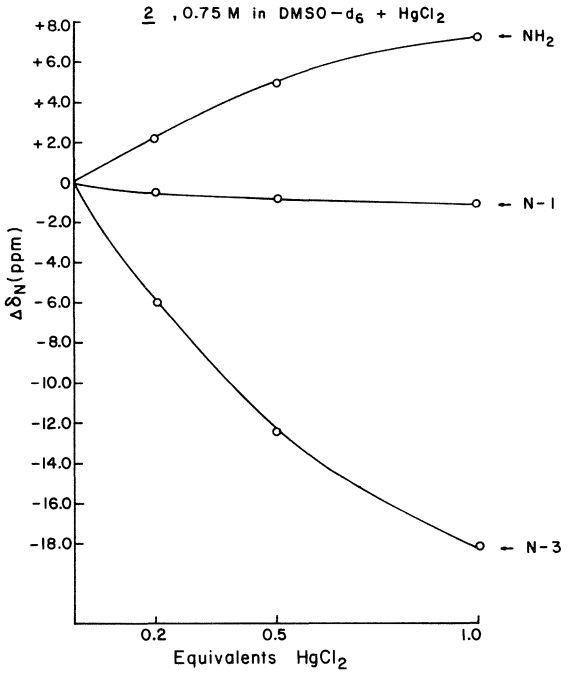


FIG. 3. 2 + $HgCl_2$.

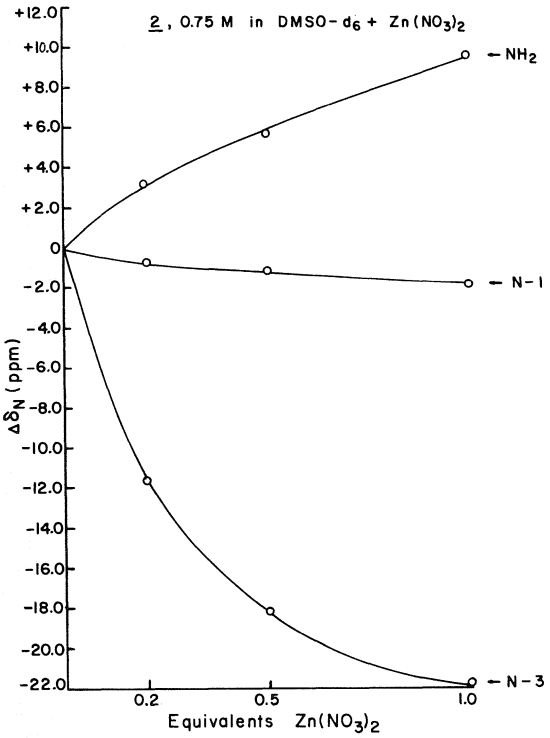

FIG. 4. 2 + $Zn(NO_3)_2$.

7.2 : 1.0 for the induced $^{15}N$ shifts upon protonation is remarkedly similar to the mercuration shift ratio, namely 18.0 : 7.4 : 1.0 (Fig. 3) and the directions of individual induced shifts are the same for protonation and mercuration.

It is unfortunate that the protonation work (5) did not include data for 1.0 equivalent of TFA added, so that highly detailed quantitative comparisons with metalation are not meaningful here.

For $Zn(NO_3)_2$ addition to cytidine (Fig. 4), the induced shifts are somewhat larger than for $HgCl_2$, but the trends are similar.

(e) *Cytidine: $Ba(NO_3)_2$ addition*

We find that $Ba(NO_3)_2$ appears not to bind at a nitrogen of cytidine since no appreciable induced $^{15}N$ shifts are apparent. This result is in agreement with previous conclusions (8), drawn from $^{13}Cmr$ and Raman data, that $Ba^{+2}$ binds preferentially to the carbonyl oxygen of cytidine.

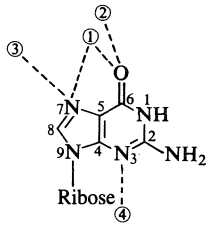
Generally, the earlier results (3) indicate that the site of attachment of metal ions to cytidine depends on the nature of the metal ion. "Hard" metals such as $Ba^{+2}$ bind to the carbonyl oxygen, while soft metals and $H^+$ bind to N-3. In the case of $Zn^{+2}$, binding at both N-3 and the carbonyl oxygen has been suggested.

From the $^{15}N$ results herein, one can conclude that there is certainly N-3 binding for $Hg^{+2}$ and $Zn^{+2}$, while attachment of $Ba^{+2}$ to the carbonyl oxygen does not perturb the magnetic environment at any of the nitrogen atoms enough to influence their chemical shifts.

(f) *Guanosine: $HgCl_2$ and $Zn(NO_3)_2$ addition*

The induced $^{15}N$ shifts (Figs. 5 and 6) clearly show that N-7 is the preferred nitrogen for $Hg^{+2}$ and $Zn^{+2}$ complexation. The pronounced upfield shifts of N-7 are reminiscent of its shift upon protonation (5), as are the directions and magnitudes of the minor changes seen for the remaining four nitrogens.

For guanosine, the primary binding site is calculated (13) to be a chelated position involving the carbonyl oxygen and N-7 as shown below.



The minor upfield shifts seen for N-3 of **3** upon metalation are consistent with this site being a potential, but less favored, site of complexation than N-7.

(g) *Guanosine: $Ba(NO_3)_2$ addition*

The lack of pronounced $^{15}N$ shift changes upon $Ba^{+2}$ addition indicates that primary $Ba^{+2}$ complexation is not at nitrogen. Presumably this "hard"

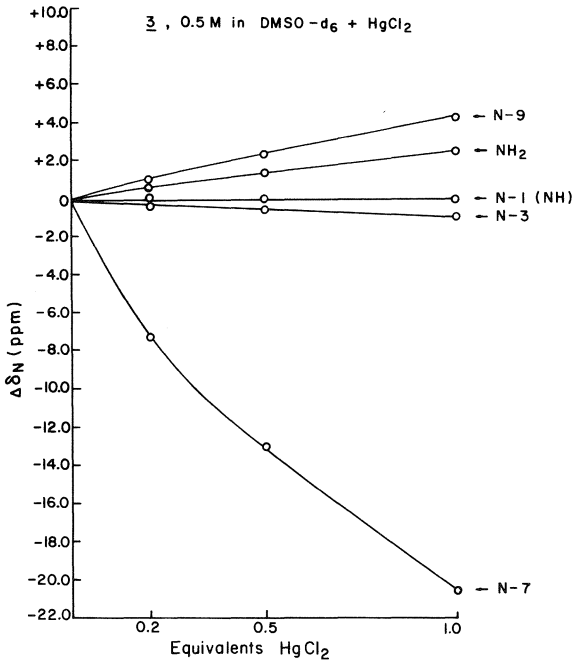


FIG. 5. 3 + $HgCl_2$.

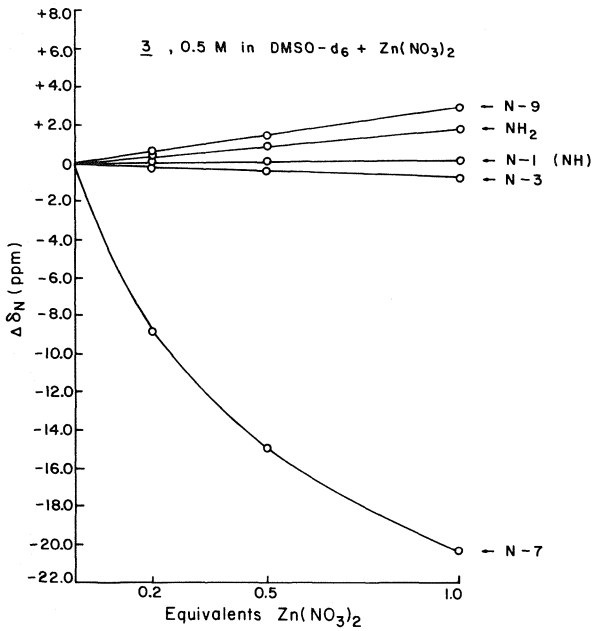

FIG. 6. 3 + $Zn(NO_3)_2$.

ion prefers the carbonyl oxygen, but no $^{13}C$ or Raman data are presently available to check this point.

## Conclusions

It is apparent from this work that $^{15}N$mr chemical shift changes provide a useful addition to the available methods for monitoring metal ion – nucleoside binding. There appears to be a general upfield shift for metalated nitrogen, and the preferred sites of mercuration in the three nucleosides studied here parallel the well-established protonation sites.

Further work in this area using $^{15}N$ relaxation times could be envisaged by analogy to that recently carried out for nucleotide – paramagnetic ion interactions (4).

Extension to aqueous solutions is planned, although the lower solubilities of the materials in aqueous media will retard experiments somewhat. Based on $^{13}C$ and Raman spectra (11, 15) it has been suggested, however, that, with the exception of N-1 of guanosine, similar complexes are formed between these nucleosides and metal ions in $H_2O$ as in DMSO solution.

## Experimental

(a) *Materials*

Samples of adenosine, cytidine, and guanosine were obtained from Sigma Chemical Company, St. Louis, MO 63178, U.S.A. and were used without further purification.

Mercuric chloride was Fisher Certified ACS grade and used without additional purification, as were $Ba(NO_3)_2$ and $Zn(NO_3)_2$. Dimethylsulfoxide-$d_6$ was purchased from Stohler Isotope Chemicals, Montreal 101, Quebec, Canada, and Merck, Sharp & Dohme of Canada Ltd., Pointe Clair – Dorval, Quebec.

(b) *Spectra*

For all resonances except those of protonated nitrogens, natural abundance $^{15}N$ spectra were obtained on a Bruker WH-400 nmr spectrometer at a frequency of 40.54 MHz using facilities at the Southwestern Ontario High Field NMR Centre, Guelph, Ontario. Sample size was 10 mm, and spectra were recorded using inverse gated $^1H$ decoupling in order to eliminate effects of differential nuclear Overhauser effects. Typical pulse angles were 40° and delay times of 30 s were employed. Satisfactory signal to noise ratios were obtained after 300–500 scans. Typical spectral widths were 12 000 Hz.

$^{15}N$ chemical shifts for the protonated nitrogens were obtained on a Varian XL-200 spectrometer at 20.27 MHz. The refocussed INEPT sequence (16, 17) was used. Employing $^1J_{NH} = 91$ Hz, the delays were $\tau = 2.75$ ms ($\frac{1}{4}J$) and $\Delta = 4.12$ ms ($\frac{3}{8}J$), and the $\pi/2$ pulses were 26 μs for $^{15}N$ and 40.5 μs for $^1H$ respectively. A recycle time of 2 s was used. Samples were run in 10 mm tubes.

Chemical shifts were measured relative to external saturated aqueous $NH_4Cl$ and then converted to the standard $^{15}N$ scale in ppm relative to $NH_3$ using a conversion constant of +27.3 ppm (18).

Linewidths of nitrogen resonances did not increase appreciably upon metalation, indicating that the rate of exchange between metalated and free nucleoside is fast on the nmr timescale.

# Charge distributions and chemical effects. XXVII. Molecular energies of carbonyl compounds and ethers, a calculation involving the charges of the bond-forming atoms

S. FLISZÁR AND M. T. BÉRALDIN

*Département de Chimie, Université de Montréal, Montréal (Qué), Canada H3C 3V1*

Received June 26, 1981

S. FLISZÁR and M. T. BÉRALDIN. Can. J. Chem. **60**, 792 (1982).

Energy calculations are presented for carbonyl compounds and ethers by applying the equation $\varepsilon_{ij} = \varepsilon_{ij}^0 + a_{ij}\Delta q_i + a_{ji}\Delta q_j$ which describes individual bond contributions in terms of electronic charge increments $\Delta q$ at the bond-forming atoms $i$ and $j$, relative to atomic charges in selected reference bonds with energies $\varepsilon_{ij}^0$. At a molecular level, the sum $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ accounts for virtually the entire energy variations due to charge redistributions accompanying isodesmic structural changes. Coulomb-type interactions between nonbonded atoms play only a minor role in that respect. Using charges derived from $^{13}C$ and $^{17}O$ nmr shift-charge correlations, calculated and experimental energies agree within 0.16 kcal/mol (average deviation).

S. FLISZÁR et M. T. BÉRALDIN. Can. J. Chem. **60**, 792 (1982).

Les énergies d'une série d'aldéhydes, de cétones et d'éthers ont été calculées au moyen de l'équation $\varepsilon_{ij} = \varepsilon_{ij}^0 + a_{ij}\Delta q_i + a_{ji}\Delta q_j$ décrivant la contribution individuelle de chaque lien en termes des variations de charges $\Delta q$ des atomes liés $i$ et $j$, par rapport aux charges atomiques d'un lien de référence d'énergie $\varepsilon_{ij}^0$. Au niveau moléculaire, la somme $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ représente la presque totalité de la variation d'énergie due aux redistributions électroniques accompagnant les changements de structure isodesmiques. Les interactions Coulombiennes entre atomes non liés ne jouent qu'un rôle très secondaire. A l'aide de charges déduites de corrélations avec les déplacements chimiques en rmn pour les noyaux $^{13}C$ et $^{17}O$, le calcul conduit à un bon accord avec les énergies expérimentales, l'erreur moyenne étant de 0.16 kcal/mol.

## Introduction

The simplest "theoretical" description of a molecule, its structural formula featuring the chemical bonds, still represents the single most valuable "material" support for the discussion of a number of problems regarding chemical transformations and molecular properties. Because of the undisputed qualities of this type of description, much can be gained (namely, in simplicity) with the use of a theoretical approach retracing the essential features linked to the concept of chemical bonds.

While, of course, a molecule is a distinct entity which can be characterized in a number of manners, the constituent atoms retain much of their "atomic" properties. In fact, a molecule can be considered as a collection of "atoms" with energies differing from their free state values (1–3). These energy differences are, for each individual atom, a measure for the process of becoming part of the molecule and contain a portion of the molecular binding energy. Alternatively, in an entirely equivalent description, molecules can be regarded as assemblies of "chemical bonds" whose energies depend in a subtle way on the bond-forming atoms, namely, on their electron populations (2). This type of description, resulting from an appropriate energy partitioning, leads to a bond by bond insight into the various factors contributing to the stability of a molecular edifice and appears to be most suited for its analysis in terms of electron distributions.

Fascinating new information can be extracted in this way. For example, in the study (2) of linear and branched paraffins and in compounds containing chair or boat cyclohexane rings it appeared that 0.001 electron (= 1 me) added to hydrogen stabilized a CH bond by 0.632 kcal/mol whereas 1 me added to carbon had a stabilizing effect of 0.247 on a CH bond and of 0.488 kcal/mol on a CC bond. It follows therefrom that any electron enrichment on carbon atoms at the expense of electron populations at the hydrogen atoms results in a gain in molecular stability, which is well reflected in comparisons between isomers or conformers. In the present study, we examine carbon–oxygen bonds in ethers and carbonyl compounds, in order to learn how these and the remaining parts of the molecules are affected by intramolecular electron redistributions accompanying structural changes. While consideration is given to the theoretical interpretation of the energetic aspects related to the individual bonds, we also offer comparisons with experimental results, namely, with enthalpies of formation.

## Bond energies

The following considerations apply to molecules at equilibrium, in their hypothetical vibrationless state at 0 K. The portion of the total atomization energy associated with the *ij* bond (i.e., the "bond energy" $\varepsilon_{ij}$) is given by eq. [1] (2)

[1] $$\varepsilon_{ij} = K_i^{\text{mol}} Z_i(\partial\varepsilon_{ij}/\partial Z_i) + K_j^{\text{mol}} Z_j(\partial\varepsilon_{ij}/\partial Z_j) + (K_i^{\text{at}} - K_i^{\text{mol}})\, V_{\text{ne}}(\text{free atom } i)/v_i + (K_j^{\text{at}} - K_j^{\text{mol}}) V_{\text{ne}}(\text{free atom } j)/v_j$$

where $Z_i$ is the nuclear charge of atom $i$, $v_i$ the number of atoms attached to it, and $V_{\text{ne}}$ its nuclear–electronic potential energy. For isolated atoms, the $K_i^{\text{at}}$ constants are $E_i^{\text{at}}/V_{\text{ne}}$(free atom $i$) with $E_i^{\text{at}}$ = energy of atom $i$. Similarly, $K_i^{\text{mol}}$ is $E_i^{\text{mol}}/V(i, \text{mol})$ where $E_i^{\text{mol}}$ is the energy of an atom $i$ being part of a molecule and $V(i, \text{mol})$ the total (nuclear–electronic and nuclear–nuclear) potential energy involving nucleus $Z_i$. Detailed numerical analyses have indicated that the $K_i^{\text{mol}}$'s are, indeed, constants for the individual atoms, regardless of hybridization or type of bonding in a molecule (3, 4). They are most conveniently deduced from Hartree–Fock total energies, $E$, and the orbital energies ($\nu$ = orbital occupation) of homonuclear diatomics, by means of eq. [2].

[2] $$(3 - 1/K_i^{\text{mol}})\, E = \Sigma\nu\varepsilon^{\text{orb}}$$

When applied to isolated atoms, eq. [2] permits the calculation of $K_i^{\text{at}}$. The validity of eq. [1] is determined only by the validity of apportioning the molecular atomization energy into bonded and nonbonded terms, i.e., ultimately, by the very existence of chemical bonds (2). Equation [2], on the other hand, is exact in Hartree–Fock theory provided, of course, that all quantities are evaluated at equilibrium geometry (3, 5). The $K_i^{\text{at}}$ and $K_i^{\text{mol}}$ constants, deduced from the appropriate Hartree–Fock calculations (3, 6, 7), are indicated in Table 1.

The $\partial\varepsilon_{ij}/\partial Z_i$ derivatives for use in eq. [1] can be extracted from SCF calculations, by means of eq. [3].

[3] $$Z_i\Sigma_j(\partial\varepsilon_{ij}/\partial Z_i) \simeq V_{\text{ne}}(\text{free atom } i) - V(i, \text{mol})$$

This approximation (2) is certainly valid when the interactions between nonbonded atoms are much smaller than those between bonded atoms. With the selection of a convenient set of "model" bonds, we only need to calculate a limited number of "reference" derivatives, $\partial\varepsilon_{ij}^0/\partial Z_i$, which correspond to the $\varepsilon_{ij}^0$ energies of the reference bonds, e.g., the CC and CH bonds of ethane. The results (Appendix I) are indicated in Table 1.

Using now these results, derived from [5*s*3*p*|3*s*] calculations, we deduce the corresponding theoretical $\varepsilon_{ij}^0$ energies by means of eq. [1]. Of course, any error in their evaluation leads to systematic deviations which are magnified by the number of their occurrence in a molecule. An empirical refinement, using experimental atomization energies, yields the "best" $\varepsilon_{ij}^0$'s which are compared in Table 2 with their theoretical counterparts.

TABLE 1. Theoretical parameters for use in eq. [1]

| Parameter (au) | Source |
|---|---|
| $K_H^{\text{at}} = K_H^{\text{mol}} = 1/2$ | References 2, 3 |
| $K_C^{\text{at}} = 0.4276$ | Clementi and Roetti (6), eq. [2] |
| $K_C^{\text{mol}} = 0.4287$ | Reference 3 |
| $K_O^{\text{at}} = 0.4201$ | Clementi and Roetti (6), eq. [2] |
| $K_O^{\text{mol}} = 0.4213$ | Cade and Wahl (7), eq. [2] |
| $E$ (free at. C) = −37.8558 | From the sum, $-\Sigma$IP, of the ionization potentials (8), using 1 au = 27.2106 eV |
| $E$ (free at. O) = −75.1102 | |
| $\partial\varepsilon_{CH}/\partial Z_H = 0.153$ | Ethane, ref. 2 |
| $\partial\varepsilon_{CH}/\partial Z_C = 0.027$ | Ethane, ref. 2 |
| $\partial\varepsilon_{CC}/\partial Z_C = 0.012$ | Ethane, ref. 2 |
| $\partial\varepsilon_{CO}^0/\partial Z_C = -0.049$ | Diethylether, Appendix I |
| $\partial\varepsilon_{CO}^0/\partial Z_O = 0.036$ | Diethylether, Appendix I |
| $\partial\varepsilon_{CO}^0/\partial Z_C = -0.077$ | Acetone, Appendix I |
| $\partial\varepsilon_{CO}^0/\partial Z_O = 0.071$ | Acetone, Appendix I |

TABLE 2. Energy terms of selected reference bonds

| Reference molecule | Bond | Energy ($\varepsilon_{ij}^0$), kcal/mol: Theor. (eq. [1]) | "Best" |
|---|---|---|---|
| Ethane | CC | 69.3 | 69.63 |
| Ethane | CH | 106.9 | 106.81 |
| Diethylether | CO | 80 | 79.78 |
| Acetone | CO | 181 | 179.40 |

The partial derivatives $\partial\varepsilon_{ij}^0/\partial Z_i$, which are bound to the conditions set by the Hellmann–Feynman theorem used for deriving eq. [1] (implying, namely, constant electron densities), are valid only for the molecules to which they refer. This, of course, holds also for the $\varepsilon_{ij}^0$ energies: they cannot be simply transferred to other molecules. Indeed, the simple transfer of bonds from one molecule to another implies transferring the bond-forming atoms, including their electron clouds, at the sacrifice of preserving molecular electroneutrality (2). The appropriate charge renormalization leads to the following expression for the energy contribution of an *ij* bond (2)

[4] $$\varepsilon_{ij} = \varepsilon_{ij}^0 + a_{ij}\Delta q_i + a_{ji}\Delta q_j$$

where $\Delta q_i$ and $\Delta q_j$ are the increments in net atomic charge with respect to the charges of the atoms $i$ and $j$ in the reference bond. The sum over all the *ij* bonds gives the "bonded" contribution to the energy of atomization, i.e.,

[5] $$\Delta E_a^{*\text{bonds}} = \Sigma\varepsilon_{ij}^0 + \Sigma_i\Sigma_j a_{ij}\Delta q_i$$

TABLE 3. Calculation of $a_{ij}$ (eq. [6])

| Atom | $N_i$ (e) | $\partial E_i/\partial N_i$ | $\partial^2 E_i/\partial N_i^2$ | $r_{ij}$ (Å) | $a_{ij}$ (au) |
|---|---|---|---|---|---|
| H (1*s*) | 1.0117 | −0.195 | | 1.08 (CH) | $a_{HC} = -1.007$ |
| C (2*s*) | 1.44 | −0.735 | 0.45 | 1.08 (CH) | $a_{CH} = -0.394$ |
| | | | | 1.53 (CC) | $a_{CC} = -0.777$ |
| | | | | 1.43 (CO) | $a_{CO} = -1.135$ (ether) |
| C (2*p*) | 1.97 | −0.200[a] | 0.37 | 1.08 (CH) | $a_{CH} = -0.276$ (carbonyl-C) |
| | | | | 1.53 (CC) | $a_{CC} = -0.659$ (carbonyl-C) |
| | | | | 1.22 (CO) | $a_{CO} = -1.182$ (carbonyl-C) |
| O (2*p*) | 4.023 | −0.316 | 0.50 | 1.22 (CO) | $a_{OC}$[b] $= -1.065$ (carbonyl-O) |
| | 3.995 | −0.331 | | 1.43 (CO) | $a_{OC}$[c] $= -0.804$ (ether) |

[a]The selection of the appropriate $\partial E_i/\partial N_i$ derivatives presents no difficulties for $sp^3$ carbon and oxygen atoms because *ab initio* population analyses clearly show the involvement of 2*s* electrons in the former case (2) and of 2*p* electrons in the latter (14). At carbonyl-C atoms, however, mainly 2*p* populations are affected by substitution. The appropriateness of this choice for $\partial E_i/\partial N_i$ is discussed in the text.
[b]Value for acetone. The $a_{OC}$'s for carbonyl groups must be recalculated for each compound of interest, using eq. [6].
[c]For the more negative oxygens, we find $a_{OC} = -0.800$ au (see text).

featuring the effects due to changes in net atomic charges with respect to the charges of the atoms forming the reference bonds. The $a_{ij}$'s are given by the formula (2)

$$[6] \quad a_{ij} = \frac{1}{v_i}\frac{K_{Av}^{mol}}{K_i^{mol}}\left[\left(\frac{\partial E_i}{\partial N_i}\right)^0 - \frac{1}{2}\left(\frac{\partial^2 E_i}{\partial N_i^2}\right)^0 \Delta q_i\right] - K_{Av}^{mol} Z_j^{eff} < r_{ij}^{-1} >^0$$

in which $v_i$ is the number of atoms bonded to $i$ and $K_{Av}^{mol}$ is the molecular average of the $K_i^{mol}$'s, which can be taken at 3/7. Moreover, $Z_i^{eff}$ is the effective nuclear charge of atom $j$, in the spirit of the Politzer–Parr electron partitioning into core and valence region (9), e.g., $Z^{eff}(C) \simeq 4$ and $Z^{eff}(O) \simeq 6$ au. Finally, $< r_{ij}^{-1} >^0$ is the average inverse distance from nucleus $i$ to the $N_j$ electrons of atom $j$, which is approximated by the inverse internuclear distance $(r_{ij}^{-1})_{nn}$. The first and second derivatives of the energy of atom $i$ with respect to its population $N_i$ are conveniently obtained from SCF-Xα theory (10). For hydrogen and $sp^3$ carbon atoms, the appropriate values are those of ref. 2. The results for C and O 2*p* electrons were deduced using the "frozen core" α values given by Schwarz (11), i.e., $\alpha_C = 0.75928$ and $\alpha_O = 0.74447$ (Table 3).[1]

So far, we have deduced the theoretical parameters required for numerical applications of eqs. [4] and [5], namely, the reference bond terms $\varepsilon_{ij}^0$ (Table 2) and the $a_{ij}$ coefficients (Table 3). We now must find a convenient way to determine the $\Delta q_i$'s which are also required in the study of molecular energies using eqs. [4] and [5].

### Approximations for $\Delta q_i$

Atomic charges can, in principle, be derived from molecular wave functions using an appropriate partitioning scheme, but this is a horse of another color (12). In practice, under favorable conditions, one can take advantage of $^{13}C$ and $^{17}O$ nmr information. For $sp^3$ carbon atoms it was shown that a linear shift–charge relationship is remarkably accurate (13) and, moreover, that the theoretical charges satisfying it correspond to the same definition as those satisfying eq. [5] (2). Hence, using charges deduced from $^{13}C$ nmr data, eq. [5] was found to agree with experimental energies within 0.16 kcal/mol (average derivation).

Following the same approach, we use the relationship (2)

$$[7] \quad \Delta q_C = -0.148\ \delta_C \text{ (me)}$$

where $\delta_C$ is the shift relative to the atom chosen as reference in the calculation of $\Delta q_C$. Interestingly, the same relation applies, at least as a valid approximation, also to the α-carbons in ethers and to carbonyl-C atoms provided, of course, that the references are chosen in an appropriate manner. This point is verified by comparisons with experimental results (given below) but in this case our knowledge concerning the precision of eq. [7] is limited by the accuracy of the experimental data used in this type of verification. Furthermore, *ab initio* calculations on ether oxygen atoms indicate that the $\Delta q_O/\delta_O$ slope is ~1.8 times that of the $\Delta q_C/\delta_C$ slope determined under identical conditions, giving (14)

$$[8] \quad \Delta q_O(\text{ether}) = -0.267\delta_O \text{ (me)}$$

Finally, for carbonyl oxygen atoms we use

$$[9] \quad \Delta q_O(\text{carbonyl}) = 2.7\ \delta_O \text{ (me)}$$

In contrast with eqs. [7] and [8] which are based on theoretical electron populations, this relationship is deduced from, and justified by, a numerical

[1]We thank Dr. B. N. McMaster, who carried out these SCF-Xα calculations.

analysis involving experimental energies, as explained further below: while not ranking at the same degree of confidence as eqs. [7] and [8], eq. [9] appears to represent at least a reasonable approximation.[2]

For the hydrogen atoms, we deduce the sum $\Sigma\Delta q_H$ from the condition $\Sigma_i q_i = 0$. The result is

$$[10]\quad \Sigma\Delta q_H = -(\Sigma\Delta q_{C\alpha} + \Sigma\Delta q_{C\neq\alpha} + \Sigma\Delta q_O) - (n_{C\alpha}q_{C\alpha}^0 + n_O q_O^0) - (n_{C\neq\alpha}q_C^0 + n_H q_H^0)$$

where Cα and C≠α stand for C atoms adjacent to, viz. nonadjacent to oxygen and $n_i$ is the number of $i$ atoms in the molecule. Finally, $q_{C\alpha}^0$ and $q_O^0$ are for acetone or diethylether, whichever is the appropriate reference, and $q_C^0$, $q_H^0$ are the ethane C and H net charges, 35.1 and −11.7 me, respectively (2). The sum $n_{C\alpha}q_{C\alpha}^0 + n_O q_O^0$ gives $2q_{C\alpha}^0 + q_O^0 \simeq 67.7$ me for diethylether and $q_{C\alpha}^0 + q_O^0 \simeq -7.2$ me for acetone, from charge normalization (Appendix II).

Attention must be given to the difference $\Delta q_{C\alpha}^0 = q_{C\alpha}^0 - q_C^0$. Indeed, for CO bonds the reference is $q_{C\alpha}^0$ but in calculations of CC and CH bonds, including those involving α-carbons, the appropriate reference is $q_C^0$. $\Delta q_{C\alpha}^0$ cannot be simply deduced from the appropriate $^{13}C$ nmr shifts, as oxygen appears to introduce an "extra" downfield shift at α-carbons, estimated at ~ 41.7 ppm in the case of the ethers (16). Assuming here that this shift, which could be due in part of the electric field of the oxygen dipole, is not primarily a carbon charge effect, we estimate the latter by subtracting tentatively 41.7 ppm from the observed α-carbon-shifts (60, viz. 199 ppm from ethane for diethylether (16) and acetone (17), respectively). It turns out that the $\Delta q_{C\alpha}^0 \simeq -2.7$ (ether) and $\Delta q_{C\alpha}^0 \simeq -23$ me (acetone) values obtained in this fashion (eq. [7]) are reasonable: atomization energies calculated with these $\Delta q_{C\alpha}^0$ values differ from their experimental counterparts by ~0.35 kcal/mol (average deviation). A refinement involving experimental energies yields, as described below, $\Delta q_{C\alpha}^0 = -3.84$ me for diethylether and −21.1 me for acetone. Of course, not too much importance should be attached to these estimates since they may, in part, correct for minor uncertainties associated with the $a_{ij}$'s, with eqs. [7]–[9], and with the evaluation of vibrational and thermodynamic data used in this analysis. Clearly, the difficulties are now in the evaluation of fraction of kcal/mol uncertainties, thus preventing us temporarily from further improving the calculations. This is best seen by examining experimental results.

[2] *Ab initio* calculations (14) reveal that carbonyl oxygen atoms behave quite like ethylenic $sp^2$ carbons, in that any increase of electronic charge is reflected in an upfield shift. For the latter, the charge/shift slope is ~ −11.7 times that of alkane carbon atoms (15) giving $\Delta q_C \simeq 1.7\delta_C$, a result which is of the same order as that expressed by eq. [9].

### Comparisons with experimental energies

In addition to the energy $\Delta E_a{}^{*\text{bonds}} = \Sigma\varepsilon_{ij}$ contributed by the chemical bonds, we also consider the small "nonbonded" part, $\Delta E_{nb}{}^* = -E_{nb}{}^*$, of the atomization energy:

$$[11]\quad \Delta E_a{}^* = \Delta E_a{}^{*\text{bonds}} - E_{nb}{}^*$$

Regarding $E_{nb}{}^*$, Del Re (18) has shown that a valid approximation in σ systems is Coulombic in nature, i.e.

$$[12]\quad E_{nb}{}^* = (1/2)\sum_{kl}^{nb} q_k q_l / r_{kl}$$

where $q_k$ and $q_l$ are the net charges of nonbonded atoms at a distance $r_{kl}$. For carbonyl compounds, results derived from eq. [12] should be interpreted with some reservations and are used on a tentative basis.

So far we have considered molecules in their hypothetical vibrationless state. Actual molecules, at some temperature $T$, contain zero-point (ZPE) and thermal vibrational energies ($E_{vibr}$). These were deduced from experimental and calculated fundamental frequencies ν, i.e., in the harmonic oscillator approximation,

$$[13]\quad \text{ZPE} = N_{Av}(1/2)\Sigma_i h\nu_i$$

and, using Einstein's function,

$$[14]\quad E_{vibr} = N_{AV}\Sigma_i h\nu_i \exp(-h\nu_i/kT)/[1 - \exp(-h\nu_i/kT)]$$

Interpolation formulas had to be used in cases for which no or insufficient spectral data are presently available (Table 4). With these results and the

TABLE 4. Zero-point and heat-content energies (kcal mol$^{-1}$)[a]

| Molecule | ZPE | $H_T - H_0$ | Estimated ZPE + $H_T - H_0$ |
|---|---|---|---|
| $CH_3CHO$ | 33.58 | 3.07 | |
| $(CH_3)_2CO$ | 50.59 | 4.00 | |
| $(C_2H_5)_2CO$ | 86.68 | 4.84 | |
| $(CH_3)_2O$ | 49.91 | 2.74 | 52.55 (−0.10) |
| $CH_3OC_2H_5$ | 65.75 | 4.11 | 70.19 (0.33) |
| $CH_3OiC_3H_7$ | 82.74 | 4.92 | 87.83 (0.17) |
| $(C_2H_5)_2O$ | 82.82 | 4.94 | 87.83 (0.07) |
| $C_2H_5OiC_3H_7$ | 99.59 | 5.81 | 105.47 (0.07) |
| $(iC_3H_7)_2O$ | 116.65 | 6.67 | 123.11 (−0.21) |
| Tetrahydropyran | 88.83 | 4.04 | |
| 1,4-Dioxane | 74.61 | 3.87 | |

[a]Results deduced from eqs. [13] and [14] using the vibrational analyses of acetaldehyde and acetone (20*a*) and diethylketone (20*b*). For the ethers, the ir and Raman spectra are taken from refs. 20*c* and 20*d*, for dimethylether. The "estimated" values are deduced from the approximation ZPE + $H_T - H_0$ = 52.55 + 17.64($n_C$ − 2); the differences between these estimates and those based on spectroscopic evidence are given in parentheses.

appropriate enthalpies of formation of the gaseous atoms (19), $\Delta H_f^0$ $(A_i)$ = 170.89 (C), 52.09 (H), and 59.54 kcal/mol (O), one relates the atomization energies $\Delta E_a$* to the standard molecular enthalpies of formation, $\Delta H_f^0$ (298.15, gas), by means of the formula

$$[15]\quad \Delta E_a^* = \Sigma n_i[\Delta H_f^0\ (A_i) + 5RT/2] + \mathrm{ZPE} + (H_T - H_0) - \Delta H_f^0$$

in which $H_T - H_0 = E_{vibr} + 4RT$ is the increase in enthalpy of non-linear molecules due to their warming up from $T = 0$ to $T = T$. Eqs. [13]–[15] are instrumental in the calculation of "experimental" $\Delta E_a$* energies.

The theoretical sums $\Sigma\varepsilon_{ij}$ can be deduced from bond by bond calculations of the individual $\varepsilon_{ij}$'s (eq. [4]). A detailed example is worked out in Appendix III. For homologous series, like those studied here, it is easy and convenient to derive general formulas. For the carbonyl compounds listed below we obtain

$$[16]\quad \Sigma_i\Sigma_j a_{ij}\Delta q_i = \lambda_1\Sigma N_{CC}\delta_C + \lambda_2\Sigma\delta_{C\neq\alpha} + \lambda_3\delta_{C\alpha} + \lambda_4\delta_O + n_C a_{HC} q_H^0 + \Delta q_{C\alpha}^0\,(a_{C\alpha C}N_{CC}^{\alpha} + a_{C\alpha H}N_{CH}^{\alpha} - a_{HC}) - a_{HC}q_O^0$$

where[3] $\lambda_1 = a_{CC} - a_{CH} = 0.0356$, $\lambda_2 = 4a_{CH} - a_{HC} = 0.0529$, and $\lambda_3 = 2a_{C\alpha H} + a_{CO} - a_{HC} = 0.0675$ kcal mol$^{-1}$ ppm$^{-1}$ (using eq. [7] and 1 au = 627.51 kcal/mol). Because of the large variations of $\Delta q_O$, $a_{OC}$ (eq. [6]) and $\lambda_4 = a_{OC} - a_{HC}$ must be calculated in each case of interest. $a_{OC}$ varies between −1.081 au ($CH_3CHO$) and −1.041 au ($iC_3H_7COiC_3H_7$). $N_{CC}$ is the number of CC bonds formed by the C atom whose shift is $\delta_C$, $N_{CC}^{\alpha}$ and $N_{CH}^{\alpha}$ are the number of CC, viz. CH, bonds involving α carbons. Similarly, one obtains for dialkylethers that

$$[17]\quad \Sigma_i\Sigma_j a_{ij}\Delta q_i = \lambda_1\Sigma N_{CC}\delta_C + \lambda_2\Sigma\delta_{C\neq\alpha} + \lambda_3'\Sigma\delta_{C\alpha} + \lambda_4'\delta_O + (n_C - 2)a_{HC}q_H^0 + \Delta q_{C\alpha}^0\,(a_{CC}\Sigma N_{CC}^{\alpha} + a_{CH}\Sigma N_{CH}^{\alpha} - 2a_{HC}) - a_{HC}q_O^0$$

with $\lambda_1$ and $\lambda_2$ as above and $\lambda_3' = 3a_{CH} + a_{CO} - a_{HC} = 0.1217$ kcal mol$^{-1}$ ppm$^{-1}$. $\lambda_4' = 2a_{OC} - a_{HC}$ is 0.1007 kcal mol$^{-1}$ ppm$^{-1}$ for $a_{OC} = -0.804$ au ($\delta_O < 0$) or 0.0994 kcal mol$^{-1}$ ppm$^{-1}$ for $a_{OC} = -0.800$ ($\delta_O > 0$). Equations [16] and [17] enable an empirical evaluation of the respective $\Delta q_{C\alpha}^0$'s (−21.1 and −3.84 me for acetone and diethylether, respectively) and, therefrom, of $q_O^0$ (−21.2 for acetone and 5.18 me for diethylether, as indicated in Appendix II). The appropriate shift values are reported in Table 5.

[3]The $a_{C\alpha C} - a_{C\alpha H} = a_{CC} - a_{CH}$ term appearing in this calculation does not depend on $\partial E/\partial N$. A possible error associated with this derivative in the treatment of carbonyl-C atoms would result in a constant error for all carbonyl compounds and, hence, in a distortion in the estimate of $\varepsilon_{CO}^0$.

[a]The $\delta_{C\neq\alpha}$ data (16, 21*a*) are relative to ethane (5.8 ppm from TMS) and the $\delta_{C\alpha}$ shifts are from acetone for carbonyl compounds (21*a*), viz. diethylether for the ethers (16). The $^{17}O$ shifts (16, 17) are relative to acetone and diethylether for the carbonyl compounds and ethers, respectively. The $\Sigma N_{CC}\delta_C$ term includes both, $\delta_{C\alpha}$ and $\delta_{C\neq\alpha}$. The tetrahydropyran and 1,4-dioxane $^{13}C$ data are taken from Stothers (21*a*) and the $^{17}O$ results are extracted from ref. 21*b*.

The calculation of $\Delta E_a$*$^{bonds}$ (eq. [5]) is now straightforward. An estimate of the small non-bonded contributions is obtained from eq. [12] and the approximations outlined in Appendix II. The theoretical atomization energies $\Delta E_a$* derived in this fashion are seen to agree within ~0.16 kcal/mol (average deviation) with their counterparts deduced from experimental results using eq. [15] (Table 6). While this sort of agreement prevents us from retracing minor uncertainties associated with our approximations, it also appears that reliable predictions can be made in a number of cases (Table 7).

The quality of calculated enthalpies rests, of course, largely with the approximations involved in the estimate of ZPE + $H_T - H_0$ energies. The use of vibrational energies constructed on the basis of regular group increments may be regarded acceptable in simple cases like those investigated here.[4] It remains, however, that one should refrain from extrapolations in highly crowded systems until these are adequately supported by spectroscopic evidence. With these reservations in mind, our predicted $\Delta H_f^0$ values should represent reasonably good estimates.

[4]Similar situations are described for saturated hydrocarbons (22).

[a]The estimated ZPE + $H_T - H_0$ energies are 105.47 and 123.11 kcal/mol, respectively, for the $C_5H_{12}O$ and $C_6H_{14}O$ ethers, using the approximation indicated in Table 4. The nmr data are taken from ref. 16.

## Conclusions

The atomization energy of a vibrationless molecule, a true molecular property describing chemical binding, is largely controlled by an energy term reflecting the effects of atomic charges. This is best seen in comparisons between isomers, e.g. $C_2H_5$-CHO vs. $(CH_3)_2CO$ or $nC_3H_7CHO$ vs. $CH_3$-$COC_2H_5$, where the charge redistributions accompanying the structural changes account for virtually the entire variations in molecular energies. Nonbonded Coulomb interactions play only a minor role in that respect.

The effect of adding 0.001 electron (i.e., $\Delta q_i = -1$ me) to an atom is given by theory (eq. [4]): the $a_{ij}$'s (eq. [6]) indicate that 1 me added to hydrogen stabilizes a CH bond by 0.632 kcal/mol, whereas 1 me added to carbon stabilizes a CC bond by 0.488, a CH bond by 0.247, an ether-CO bond by 0.712 and a carbonyl-CO bond by 0.742 kcal/mol. Similarly, an electron enrichment of 1 me at an oxygen atom stabilizes an ether-CO bond by ~0.505 and a carbonyl-CO bond by ~0.668 kcal/mol, the precise values depending on the oxygen net charges. These results answer a number of questions regarding charge-related energy effects. Consider, for example, a charge decrease of 1 me at a hydrogen atom in favor of a carbonyl oxygen atom, causing a loss in stability of 0.632 kcal/mol at the CH bond involved

and a gain of 0.668 kcal/mol at the CO bond, for a net gain of 0.036 kcal/mol. This example shows that, *under circumstances which can be evaluated from the* $a_{ij}$*'s, a transfer of electronic charge accompanying isomerization can result in a relatively small change in total stability while the "location" of a certain portion of the overall stability is shifted from one part of the molecule to another*. Of course, this type of reasoning applies only to comparisons involving molecules at equilibrium. With this understanding, the example just presented could apply to a comparison between, say, propanal and propanone, the latter compound being the more stable one (by ~6.1 kcal/mol in $\Delta E_a$* energy), which is largely, but not exclusively, traced back to an electron enrichment at the oxygen atom of the ketone at the expense of electronic charge at the hydrogen atoms. In a way, *the alkyl hydrogen atoms play the role of a reservoir of electronic charge which, under appropriate circumstances depending on molecular geometry, is called upon for stabilizing bonds other than CH bonds, with a net gain in molecular stability*. (This conclusion holds whenever the sum $\Sigma_j a_{ij}$, measuring the stabilization of all the bonds formed by atom $i$ by an electronic charge added to it, is more negative than $a_{HC}$). So, for example, if we are asked why adamantane is more stable than twistane (by 9.1 kcal/mol in $\Delta E_a$* energy), the answer is that the largest part by far of this energy difference is due to the fact that adamantane has less electrons on the H atoms and, consequently, more on the C atoms, than twistane. It is certainly pleasing that this new insight derives *exclusively* from basic and clearly identified physical concepts, namely (*i*) the Politzer–Parr partitioning of molecular energies in terms of "atomic-like contributions" (23) which emphasizes the dependence of atomic and molecular energies upon the electrostatic potentials at the nuclei; (*ii*) the relationships between energy components (1, 3), of which Politzer's approximations (4) are an important part and, finally, (*iii*) the reduction of the problem of molecular energies to its electrostatic aspects, featuring the role of local charges (2).

The single most important difficulty encountered in our approach rests with the accurate calculations of atomic charges. If it was not for this reason, the calculation of the $\Sigma_i \Sigma_j a_{ij} \Delta q_i$ terms would, indeed, be very simple. Presently, the calculations are still somewhat involved because we have to resort to normalization procedures in order to make up for the lack of a comprehensive knowledge of atomic charges. In turn, the use of general formulas, in which hydrogen charges do not appear explicitly, makes it possible to describe large classes of compounds in terms of atoms other than hydrogen, whose charges can be extracted from correlations with nmr shifts. While lacking the elegance of a purely theoretical approach, the judicious use of carefully established charge–nmr shift correlations fulfills its goals, although the significance or generality of such correlations is presently not known. Fortunately, encouraging theoretical progress is being made in the area of charge calculations: since it became clear that the CH polarity in simple alkanes is (13, 24) $C^+H^-$ (at variance with most results derived from Mulliken population analyses), new powerful and realistic methods (25) are converging toward this type of result which is part of the present charge analyses. Extention of the present theory to other classes of molecules (alcohols, acetals, etc.) can be envisaged as a powerful means of studying large molecules of biological interest, which would normally lie outside the range of computational feasibility. This hope seems justified by the close agreement between calculated and experimental energies, for a body of ~80 molecules (0.16 kcal/mol, average deviation).

## Appendix I

The $\partial\varepsilon_{ij}/\partial Z_i$ derivatives were deduced from eq. [3], using the atomic ground state energies and the appropriate $K^{at}$ values (Table 1) giving the free atom values $V_{ne} = -88.5309$ (C) and $-178.7912$ au (O). For the α carbons in diethylether ($\Delta q_C = -3.84$ me) and acetone ($\Delta q_C = -21.1$ me) we calculate $\partial\varepsilon_{ij}/\partial Z_i = \partial\varepsilon_{ij}{}^0/\partial Z_i + a_{ij}\Delta q_i/K_i{}^{mol}Z_i$ (from eqs. [1] and [4]), giving $2\partial\varepsilon_{CH}/\partial Z_C + \partial\varepsilon_{CC}/\partial Z_C = 0.0683$ au (diethylether) and $2\partial\varepsilon_{CC}/\partial Z_C = 0.0368$ au (acetone). The nuclear–nuclear repulsions, $\Sigma_{j\neq i}Z_j/r_{ij}$, deduced from STO-3G optimized geometries, are 9.8107 (α-C of diethylether), 9.2843 (ether-O), 9.1275 (acetone-α-carbon) and 6.3853 au (acetone-O). With these values, eq. [3] gives $\partial\varepsilon_{CO}{}^0/\partial Z_C = -[24.6342 + V_{ne}\,(C, mol)/Z_C]$ and $\partial\varepsilon_{CO}{}^0/\partial Z_O = -[15.8166 + V_{ne}\,(O, mol)/2Z_O]$ for diethylether, as well as $\partial\varepsilon_{CO}{}^0/\partial Z_C = -[23.9195 + V_{ne}\,(C, mol)/Z_C]$ and $\partial\varepsilon_{CO}{}^0/\partial Z_O = -[28.7342 + V_{ne}\,(O, mol)/Z_O]$ for acetone.

The theoretical results were obtained from GTO $(9s\,5p|6s) \rightarrow [5s\,3p|3s]$ calculations using Dunning's exponents (26) and optimum contraction vectors (27), i.e. 42111 for C(*s*) and O(*s*), 311 for C(*p*), O(*p*), and 222 for H(*s*). The "Gaussian 76" program (28) was used. The $V_{ne}\,(i, mol)/Z_i = 1/r$ results are $-24.4910$ (α-C), $-31.6277$ (O) for diethylether, and $-23.7504$ (α-C), $-28.7351$ au (O) for acetone, but a rescaling is necessary before they can be used in eq. [4] together with "experimental" free atom values. This rescaling involves experimental total energies of ethane ($-79.8439$), dimethylether ($-155.0922$), and acetone ($-193.2336$ au), as well as calculated $\gamma = (V_{ne} + 2V_{nn})/E_{mol}$ ratios (3), i.e., respectively, $\gamma = 2.3192$, 2.3459, and 2.3424. Using the appropriate $V_{nn}$ values, i.e., in the same order, 42.2663, 83.8112, and 119.0759 au, we estimate the corresponding $V_{ne}$ energies on a scale approaching the experimental one and find $V_{ne} = -269.7066$ (ethane), $-531.4532$ (dimethylether), and $-690.7822$ au (acetone). Next, we calculate the nuclear–electronic potential energy for each individual atom of this set of molecules and collect the contributions of atoms of the same chemical species. For example, $\Sigma V_{ne}(C) = -403.6756$, $\Sigma V_{ne}(H) = -54.2347$ and $V_{ne}(O) = -229.8811$ au are, respectively, the total contributions of the C, H, and O atoms in acetone. Their sum is scaled as follows to match the total $V_{ne}$ value estimated above from the experimental energy, $403.6756f_C + 54.2347f_H + 229.8811f_O = 690.7822$. Similarly, using the appropriate results for ethane and dimethylether (3), we write $228.1297f_C + 40.0624f_H = 269.7066$ and $252.6870f_C + 49.6558f_H + 226.7787f_O = 531.4532$. The $f_C = 1.0038$ and $f_O = 1.0025$ factors deduced in this fashion are used to rescale the $V_{ne}\,(i, mol)$ results indicated above (giving, e.g., $V_{ne} = -24.5841$ for the α-carbon in diethylether), which are now used in eq. [3] for obtaining the $\partial\varepsilon_{ij}/\partial Z_i$ derivatives. Because of the uncertainties (0.02%) in the γ's, we have also explored the results by assuming ethane, dimethylether, and acetone γ values of 2.3188, 2.3455, 2.3421 and 2.3197, 2.3461, 2.3426, satisfying the constraint that the energy of acetone is correctly reproduced. The selected average $f_C = 1.00386$ and $f_O = 1.00243$ factors give the results reported in Table 1. The point is that this rescaling which did not involve diethylether in a first place also yields the correct $\varepsilon_{CO}{}^0$ energy for this molecule. For comparison, using only $[5s3p|3s]$ results, including $V_{ne}(C, at) = -87.9484$ and $V_{ne}\,(O, at) = -177.8148$ au, we obtain (eq. [3]) that $\partial\varepsilon_{CH}{}^0/\partial Z_H = 0.121$, $\partial\varepsilon_{CH}{}^0/\partial Z_C$

$= 0.025$, $\partial\varepsilon_{CO}^0/\partial Z_C = 0.013$, $\partial\varepsilon_{CO}^0/\partial Z_C = -0.042$, $\partial\varepsilon_{CO}^0/\partial Z_O = 0.058$ (ether), $\partial\varepsilon_{CO}^0/\partial Z_C = -0.074$, and $\partial\varepsilon_{CO}^0/\partial Z_O = 0.123$ au (acetone), revealing that the main distortion occurs in the evaluation of the oxygen atoms.

A final assessment of the precision of eq. [1] and the validity of the approximation, eq. [3], for deducing $\partial\varepsilon_{ij}/\partial Z_i$ values must await considerably more sophisticated *ab initio* results. So far we have only established the general validity of our approach within the limits of the uncertainties associated with the *ab initio* evaluation of the various energy components. Our rescaling is made to remain internally consistent with the detailed features of the *ab initio* results on which they are based and has the merit that the resulting molecular energies and their components are set on the same footing as the energies of the isolated atoms, which are taken at their experimental values. The overall consistency of our results can thus, as it should, be demonstrated at a level which is close to experimental accuracy. It remains, however, that this rescaling still represents a delicate procedure because of the extreme accuracy required.

## Appendix II

The calculation of the carbon and oxygen net charges is straightforward, using eqs. [7]–[9] and the appropriate references $q_{C\alpha}^0$, $q_O^0$ and $q_{C\neq\alpha}^0 =$ 35.1 me. The charges of C atoms other than adjacent to O closely parallel those of the parent hydrocarbons (16, 17) and it seems reasonable to anticipate a similar behavior also for the H atoms attached to them. In alkanes, the H and C charges are monotonically related one to another, with different lines for primary and secondary atoms. These lines are easily deduced using the "inductive" charges (28, Table 2, 13) with $q_C^0$ (ethane) = 35.1 me and $n = -4.4122$, which insures the correct scaling of atomic charges, giving (in me units) 35.1 (C), −11.70 (H) for ethane, 33.64 (C), −12.10 (H) for propane-$CH_3$, 32.37 (C), −12.47 (H) for isobutane-$CH_3$, and 31.20 (C), −13.05 (H) for neopentane-$CH_3$. For $CH_2$ charges, it is found: 33.48 (C), −14.09 (H) for propane, 32.28 (C), −14.62 (H) for butane, and 30.82 (C), −15.01 (H) for the central $CH_2$ of *n*-pentane. In this manner it follows for di-*tert*-butylether ($\delta_{C\neq\alpha} = 26.0$ ppm from ethane) that $q_{C\neq\alpha} = 31.25$ and $q_H = -13.02$ me, on the average. Moreover ($\delta_{C\alpha} = 7.7$ ppm from the α-C of diethylether), $q_{C\alpha} = q_{C\alpha}^0 - 1.14$ and ($\delta_O = 69.5$ ppm from diethylether) $q_O = q_O^0 - 18.56$ me. It follows from charge normalization that $q_O^0 + 2\,q_{C\alpha}^0 \simeq 67.7$ me. Similarly, one obtains for acetone ($\delta_{C\neq\alpha} = 22.2$ ppm from ethane) that $q_{C\neq\alpha} = 31.81$, $q_H = -9.40$ and $q_{C\alpha}^0 + q_O^0 \simeq -7.2$ me. With the appropriate $\Delta q_{C\alpha}^0 = q_{C\alpha}^0 - q_C^0$ values determined from eqs. [16] and [17], we find $q_{C\alpha}^0 \simeq 31.26$ and $q_O^0 \simeq 5.18$ me for diethylether and $q_{C\alpha}^0 \simeq 14.0$ and $q_O^0 \simeq -21.2$ me for acetone. The charges of H atoms attached to α-carbons are deduced from charge normalization. This admittedly crude (but realistic) assignment of H charges is straightforward in most cases and a comparison of the trends in the sets of molecules studied here facilitates their reasonable, balanced assessment. The important point is that the uncertainties associated with these estimates (usually $< 0.1$ me) have virtually no effect on the evaluation of nonbonded interaction (eq. [12]).

## Appendix III

The following example illustrates the use of eq. [4]. For di-*n*-propylether, $\delta_O = -10.0$ ppm gives $\Delta q_O = 2.67$ and $q_O = 7.85$ me; $\delta_{C\alpha} = 6.8$ ppm gives $\Delta q_{C\alpha} = 1.01$ and $q_{C\alpha} = 30.25$ me. These $\Delta q_O$ and $\Delta q_C$ values, relative to the reference which is diethylether, are used in the calculation of the CO contributions, giving $\varepsilon_{CO} = 79.15$ kcal/mol. For the β and γ C atoms, the shifts (relative to ethane) are 17.6 and 5.0 ppm, respectively, giving $\Delta q_{C\beta} = -2.60$ and $\Delta q_{C\gamma} = -0.74$ me, i.e., $q_C = 32.50$ (β) and 34.36 me (γ). With these $\Delta q_C$'s, eq. [4] gives $\varepsilon_{CC} =$ 71.26 kcal/mol. For the $C_\alpha$—$C_\beta$ bond, we use again $\Delta q_{C\beta} = -2.60$ me, and $\Delta q_C = 30.25 - 35.1 = -4.85$ me relative to ethane for the α-carbon, and obtain $\varepsilon_{CC} = 73.265$ kcal/mol. The $\Delta q_C = -4.85$ me value is also used in the calculation of the corresponding $\varepsilon_{CH}$ contributions. The total net charge on C and O amounts to 202.07 me, meaning that the average H charge is −14.434 me, i.e., $\Delta q_H = -2.734$ me relative to ethane, for an average $a_{HC}\Delta q_H$ contribution of 1.727 kcal/mol. The calculation of all the $\varepsilon_{CH}$'s is now straightforward and the sum of all $\varepsilon_{ij}$'s can be derived without the detailed knowledge of the distribution of charges among the individual H atoms.

# The Lewis acid complexes of α,β-unsaturated carbonyl and nitrile compounds. A nuclear magnetic resonance study

RONALD F. CHILDS,[1] D. LINDSAY MULHOLLAND, AND ALAN NIXON

RONALD F. CHILDS, D. LINDSAY MULHOLLAND, and ALAN NIXON. Can. J. Chem. **60**, 801 (1982).

1:1 Complexes of a range of Lewis acids with crotonaldehyde (**1**) have been systematically investigated by $^1H$ and $^{13}C$ nmr spectroscopy. Lewis acids employed were: $BF_3$, $BCl_3$, $BBr_3$, $SnCl_4$, $TiCl_4$, $SbCl_5$, $AlCl_3$, $EtAlCl_2$, $Et_2AlCl$, $Et_3Al_2Cl_3$, and $Et_3Al$. Chemical shift changes in $^1H$ nuclei remote from the Lewis acid group were found to be remarkably regular and consistent. The study has been extended to tiglaldehyde (**2**), pent-3-en-2-one (**3**), cyclohexenone (**4**), methyl crotonate (**5**), and crotonitrile (**6**) and the relationships between the chemical shift differences associated with complexation of these have been explored.

RONALD F. CHILDS, D. LINDSAY MULHOLLAND et ALAN NIXON. Can. J. Chem. **60**, 801 (1982).

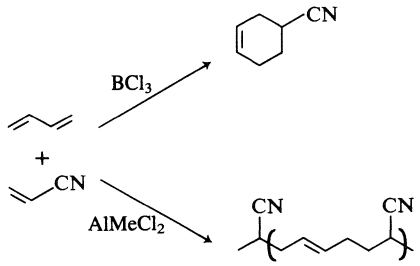
On a étudié d'une façon systématique des complexes 1:1 de divers acides de Lewis avec le crotonaldéhyde (**1**) en faisant appel à la rmn du $^1H$ et du $^{13}C$. On a utilisé les acides de Lewis suivants: $BF_3$, $BCl_3$, $BBr_3$, $SnCl_4$, $TiCl_4$, $SbCl_5$, $AlCl_3$, $EtAlCl_2$, $Et_2AlCl$, $Et_3Al_2Cl_3$ et $Et_3Al$. On a trouvé que les changements dans les déplacements des $^1H$ qui sont loins de l'acide de Lewis sont très réguliers et consistants. On a étendu l'étude au tiglaldéhyde (**2**), à la pentène-3 one-2 (**3**) à la cyclohexène-2 one (**4**), au crotonate de méthyle (**5**) et au crotonitrile (**6**); on a étudié les relations entre les différences de déplacements chimiques associés avec la complexation.

[Traduit par le journal]

## Introduction

Many reactions of unsaturated carbonyl and nitrile compounds are catalysed by Lewis acids. These include, for example, catalysed Diels–Alder reactions (1), alternating copolymerizations (2), the ene reaction (3), [2 + 2] cycloadditions (4), linear additions (5), aldol condensations (6), and several photoreactions (7). Despite the obvious importance of these catalysed reactions there is not yet a satisfactory explanation of how these reactions proceed and in particular what factors determine the course of the reaction. Take for example the competing catalysed Diels–Alder and alternating copolymerization reactions. Suggestions have been put forward to account for the Lewis acid catalysis of both of these reactions (8, 9). However, none of these suggestions can satisfactorily account for the reaction of butadiene with acrylonitrile which can give predominantly either the Diels–Alder product or alternating copolymer depending on the choice of Lewis acid.

The initial step in catalysis of these reactions by a Lewis acid appears to be complexation of the unsaturated carbonyl or nitrile compounds with the Lewis acid. Complexes of this type have been studied by a wide variety of techniques and it is generally accepted that bonding takes place through the electronegative atoms, oxygen or nitrogen, in the class of Lewis bases studied here (10). Subsequently, the base which has been activated by complexation undergoes attack by another reactant in the component mixture. The structure and properties of the intermediate complex appear to be crucial in determining reactivity and selectivity. The possibility that the charge distribution within the complex could significantly affect the chemistry of these systems led us to investigate this property in particular. Despite limitations, nmr remains one of the few methods available for the investigation of charge distribution in organic molecules (11). We have therefore undertaken and report here a systematic study of the $^1H$ and $^{13}C$ nmr spectra of a series of these complexes with the expectation that the chemical shifts observed at remote nuclei would provide a reasonably reliable indication of the relative charge induced on the base as a whole. It should be noted that the nmr spectra of some complexes of α,β-unsaturated carbonyl compounds have been reported previously under a variety of conditions (12–14).



## Results

The unsaturated bases used in these studies are the aldehydes, crotonaldehyde **1** and tiglaldehyde

**6**

These bases were selected as examples of important classes of compounds which undergo the type of catalysed reactions above. For the most part, these bases also have readily and unambigously assignable signals in their nmr spectra. The exception to this is **4**; however, in this case the vinyl signals can be clearly differentiated. Most of the complexes derived from these bases were also sufficiently stable at −20°C for study. The acids used in this study were $BF_3$, $BCl_3$, $BBr_3$, $SbCl_5$, $TiCl_4$, $SnCl_4$, $AlCl_3$, and various ethylaluminum chlorides. Methylene chloride and chloroform (for some $^{13}C$ spectra) were employed as solvents. It is known that these solvents do not react with the Lewis acids (15).

The 1:1 complexes were prepared by adding a known weight of the base to a cooled solution of the Lewis acid (~ 0.3 *M*) in an nmr tube.

The data obtained are given in Tables 1–8. In each case the difference in chemical shift between the complex and the free base is quoted (Δδ = δ complex − δ free base; Δδ is positive for a downfield shift).

TABLE 1. $^1H$ chemical shift differences (Δδ) of crotonaldehyde **1** on complexation with various Lewis acids[a]

| | Proton Δδ (ppm) | | | |
|---|---|---|---|---|
| Lewis acid | H1 | H2 | H3 | H4 |
| $BBr_3$ | 0.11 | 0.93 | 1.49 | 0.51 |

[b]At −60°C. Chemical shifts of uncomplexed base: δ = 2.26 (1-$CH_3$), 6.03 (H2), 6.89 (H3), 1.94 (H4). Acid written in monomeric form for simplicity.

## Discussion

### *Crotonaldehyde complexes*

The 2-, 3-, and 4-proton resonances of crotonaldehyde were all found to be shifted downfield on complexation. The magnitude of the shift of the H3 resonance of **1** on complexation was observed to be greatest, while those of H2 and H4 were found to be smaller but linearly related to those of H3. This is clearly shown in Fig. 1 where the Δδ's of H2 and H4 are plotted against Δδ H3 as the Lewis acid is varied. The complexation-induced shift of H1 appears to vary randomly.[2]

There are several possible conformations for the

[2]It is important to be sure of the identity of the Lewis acid with which complexation is occurring. The coincidence of all the resonance shifts obtained with the pairs of acids $AlCl_3$ and $EtAlCl_2$ suggests that, under these reaction conditions, complexation of crotonaldehyde was taking place to the same Lewis acid species, i.e., $AlCl_3$, because of disproportionation. Disproportionation of $EtAlCl_2$ on reaction with Lewis bases has been previously reported (12).

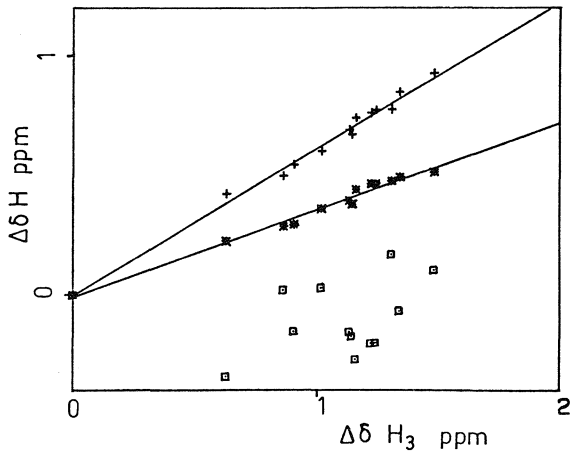

FIG. 1. $^1$H chemical shift differences of the protons of crotonaldehyde, **1**, versus the 3-proton chemical shift difference on complexation with various Lewis acids. (+, Δδ H2/Δδ H3; *, Δδ H4/Δδ H3; ⊡, Δδ H1; Δδ H3.)

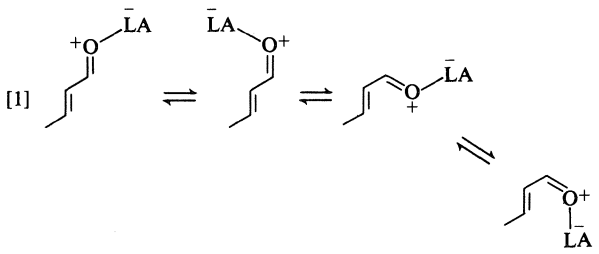
complexes of **1**, see eq. [1]. Crotonaldehyde itself adopts the *s-trans* conformation and it is likely that the same conformational preference is maintained on complexation. O-protonated crotonaldehyde exists in the C, O-*E* configuration and, because the Lewis acids used here are larger than a proton, it is most probable that the same configuration is pre-

ferred. As such it will be noted that the Lewis acid is *syn* to the aldehydic proton and removed spatially from the remaining protons of the crotonaldehyde. It is possible that local anisotropy effects are important in determining the chemical shift of H1 in the Lewis acid complexes.

A similar regularity of induced chemical shift was found with the $^{13}C$ nmr spectra of these complexes, Fig. 2.[3] (The number of acids used in this study was less than that used for the $^{1}H$ nmr work because of limited solubility of some of the complexes.) The shifts of the carbonyl carbon resonances appear to be random and unrelated to the corresponding shifts of the C3 resonance.



A noteworthy feature of the $^{13}C$ chemical shifts is the upfield shift of the C2 resonance on complexation. This shift is linearly related to the shifts of C3 and C4 but is in the opposite direction. $^{13}C$ chemical shift differences have been taken to give an indication of the change in electron density (11) and therefore it appears that electron density is increased at C2 on complexation but reduced particularly at C3 and somewhat at C4. Similar upfield shifts of C2 resonances have been reported for unsaturated esters (16), ketones (17), ethers (18), and imines (19) on complexation or protonation.

Not only are the Lewis-acid induced chemical shift differences of the $^{13}C$ and $^{1}H$ resonances of crotonaldehyde linearly related within each series but linear relationships also occur between the two series, Fig. 3.[3] Apart from the C1 and H1 resonances, a good correlation exists between the carbon and proton chemical shift differences of the 2, 3, and 4 positions. The slopes of the lines vary considerably, C2/H2 = $-3.6 \pm 0.8$; C3/H3 = $22 \pm 3$; C4/H4 = $8 \pm 2$. There are both theoretical arguments and some empirical evidence to suggest that, at least within related series of compounds, there are linear relationships between both induced $^{1}H$ and $^{13}C$ chemical shifts and charge (20). Specific values for $\Delta\delta^{13}C/\Delta\delta^{1}H$ vary but are usually found to be ca. 16. The slope parameters of the linear relationships reported here for specific carbon–proton pairs differ greatly from this value. It follows that carbon and proton chemical shift differences cannot both be taken as reliable indicators of charge induced at a specific site. This problem is highlighted by the difference in sign between the chemical shift differences of C2 and H2.

If, as seems likely, the carbon chemical shifts are more directly related to charge, the linear relationship between proton and carbon chemical shift differences is a useful result as it allows the prediction of carbon chemical shift differences based on the measurement of proton chemical shift differences. Direct $^{13}C$ measurements are limited in many cases because of poor solubility of the complexes.

It has been suggested that there is a correlation between the algebraic difference ($\Delta\delta$ C3 − $\Delta\delta$ C2) and $\Delta\delta$ C1 for a number of related complexes of unsaturated carbonyl compounds (21). No such relationship was found here for the Lewis acid complexes of crotonaldehyde.

*Extension to other bases*

The effect of various Lewis acids on the $^{1}H$ nmr spectrum of tiglaldehyde follows a very similar pattern to that described above. A similar linear relationship exists between the $\Delta\delta$'s of H4 and the 2-$CH_3$ group with $\Delta\delta$'s of H3, and again there appears to be no correlation of the shifts of H1. In Fig. 4 the $\Delta\delta$'s of the various H's in tiglaldehyde are plotted against those of corresponding $\Delta\delta$'s of crotonaldehyde. Slopes are $0.92 \pm 0.04$, $1.03 \pm 0.07$, and $0.90 \pm 0.18$ for the lines due to H1, H3, and H4 respectively. The closeness to unity of these slopes indicates that the systems are behaving almost identically.

While such parallel behavior might be expected between the two aldehydes, it also exists between crotononitrile, **6**, and crotonaldehyde, Fig. 5.[3] Thus the shifts induced on the H2, H3, and H4 resonances of crotononitrile are also linearly related to those of the corresponding $^{1}H$ resonances of crotonaldehyde as the Lewis acid is varied. In this case the slope of the line is $0.66 \pm 0.15$.

The ketones **3** and **4** differ in behavior from the aldehydes and crotononitrile. Cyclohexenone is the simplest system to examine initially as it has to exist in an *s-trans* conformation because of its ring structure. In this case, plotting $\Delta\delta$ H3 of cyclohexenone against $\Delta\delta$ H3 of crotonaldehyde again leads to a straight line (slope = $0.88 \pm 0.11$) which goes

[3]Figs. 2, 3, 5, 7, 8, 9 are available as supplementary material, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2. Slopes, intercepts, and correlation coefficients are summarized in Table 9.

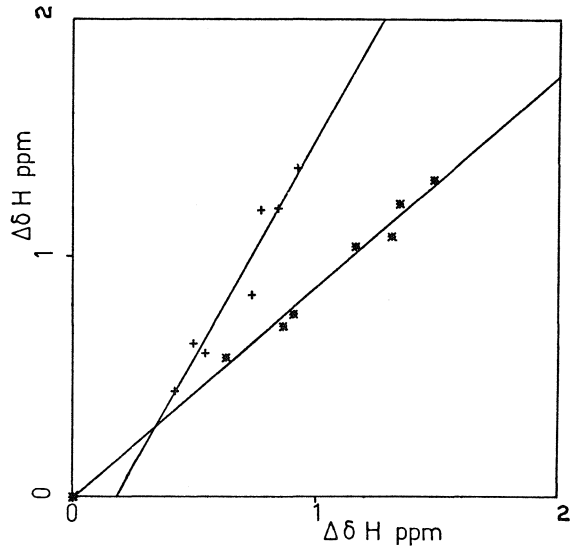

FIG. 6. $^1$H chemical shift differences of the protons of cyclohex-2-enone, **4**, versus the $^1$H chemical shift differences of the corresponding protons of crotonaldehyde, **1**, on complexation with various Lewis acids. (+, Δδ H2; *, Δδ H3.)

through the origin (Fig. 6). On the other hand, the corresponding points of the H2 Δδ's do not lie on this line. A linear relationship still exists but there is a much greater sensitivity to the change of Lewis acid (slope = 1.80 ± 0.22). The line correlating the H2 resonances no longer goes through the origin.

Azzarro and co-workers (13) have shown that the $BF_3$ complex of cyclohexenone exists in two conformations with approximately equal proportions of each. The barrier to interconversion of these two conformations is sufficiently low that, at the temperature used for our studies, it is not possible to detect separate signals from each. However, the Lewis acid grouping in **4** (*E*) is close to H2 and a

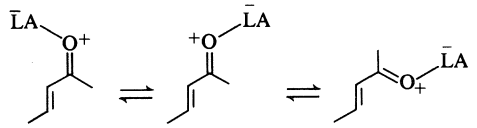
4(*E*) 4(*Z*)

through-space deshielding of this proton might be anticipated (13).

Pentenone shows a similar but diminished pattern of behavior to that of cyclohexenone, Fig. 7.[3] The Δδ's of H3 and H4 are linearly related to those of H3 and H4 crotonaldehyde (slope = 0.90 ± 0.13). However, the Δδ plot of the H2 resonance is steeper than the others and does not go through the origin. In this case the deviation of the plot of the Δδ's of the H2 resonances from the normal Δδ line is less than that observed with cyclohexenone, due to the greater conformational freedom of this complex. It is known that the pentenone itself can exist in both *s-cis* and *s-trans* conformations. It is likely that pentenone when complexed with a Lewis acid exists in three of the four possible conformations. It has not been possible to freeze out interconversions between these conformations to determine which is preferred. In one of these conformations a through-space deshielding of H2 could occur.



Additional support for the suggestion that the anisotropy of the Lewis acid can affect the resonance position of H2 comes from an analysis of the results obtained with methyl crotonate **5**, Fig. 8.[3] Once more as the Δδ's of methyl crotonate proton resonances are plotted against the corresponding crotonaldehyde values the Δδ's of the H3 and H4 resonances exhibit a linear relationship (slope = 0.63 ± 0.16) while the Δδ's of the H2 resonances show a very much steeper linear relationship which does not go through the origin (slope = 2.14 ± 0.20). Consideration of the possible conformations of the complexed methyl crotonate indicates that only two are reasonable.

The "U" conformation of the complexed ester should be of higher energy as has been established in the case of the protonated carboxylic acids (22). The other two sickle and "W" conformations both

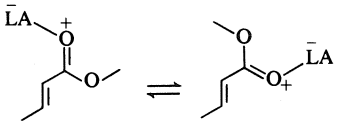


TABLE 10. Lewis acid scale based on Δδ-values of H3 resonances of various bases[a]

[a]Derived from values in Tables 1–6 and from slope parameters quoted in text. Values were obtained from six Lewis bases except where stated.
[b]Crotonaldehyde was the only Lewis base employed.
[c]Values obtained with all Lewis bases except tiglaldehyde.
[d]Values obtained with all Lewis bases except tiglaldehyde and pentenone.

have strong steric interactions between the H3 proton and the group on the adjacent oxygen. Therefore it is likely that the H2 nucleus of **5** is in close proximity to the Lewis acid and is further deshielded as a result.

The suggestion of a similar origin for the effects of the Δδ's of the H2 proton resonances of cyclohexenone and methyl crotonate is confirmed by the linear relationship which exists between them, Fig. 9.[3] It is interesting that no anomalous deshielding of the C2 resonances of the Lewis acid complexes of methyl crotonate is observed.

## Conclusions

A remarkable feature of the above results is the regularity of the linear relationships which exist for the Lewis acid induced shifts of the H3, H4, C3, and C4 resonances of all the bases. The induced shifts of nuclei closer to the site of bonding with the Lewis acid (H1 and C1) appear to be influenced by local anisotropy, the signals of the remote atoms (H3, C3, H4, and C4) are not significantly affected by this and therefore both the $^1H$ and $^{13}C$ nuclei seem to reflect the change in electron distribution associated with complexation. Although the Δδ $^1H$ values in **1** and **2** show little, if any, correlation with the Δδ values of other protons, they are not random. This is demonstrated by the good correlation between the Δδ $^1H$ values for these two bases. Complexation-induced shifts of the C2 and H2 atoms are also regular but appear to be comprised of two components, viz., through-bond and through-space deshielding, with the magnitude of the latter component being determined by conformation.

If indeed a linear relationship exists between

induced charge and chemical shift difference, even if the constant of proportionality differs for specific nuclei, then it follows that the choice of Lewis acid influences only the magnitude of the atomic charges induced on the bases and not their distribution.

With all the bases used in this study, linear relationships were found for the shifts induced by complexation with Lewis acids. This means it is possible to set up a Lewis acid scale based upon any or all of these bases in which the acids are ranked on the basis of the magnitude of the induced shift of the H3 resonance. Such a scale is shown in Table 10. The order of Lewis acids, so obtained, is at considerable variance with that found by another group whose results were obtained by deducing complex formation constants from enthalpy measurements (14). It remains to be seen whether reactivity and/or regioselectivity in catalyzed reactions of these bases will follow any such scale.

The bases used here vary in their response to complexation with a Lewis acid. This is shown by the various slope parameters found in plotting $\Delta\delta$ H3 of a particular base against the comparable shift difference of crotonaldehyde. These slope parameters do not necessarily reflect the basicity of the Lewis base, but are to be indicative of the relative charge induced at the 3-position. They could therefore be of importance in predicting reactivity after complexation.

## Experimental

*General*

A number of $^1$H nmr spectra were obtained on a Varian HA-100 spectrometer operating at 100 MHz and fitted with a variable temperature probe controlled by a Varian V-6040 controller. Chemical shifts were measured using a Varian V-4315 frequency counter relative either to TMS or $CH_2Cl_2$ and to a precision of $\pm$ 0.01 ppm. The remaining $^1$H nmr spectra were recorded on a Bruker WP.80 Pulsed Fourier Transform spectrometer operating at 80 MHz. Where the use of TMS as an internal standard was impractical, shifts were measured relative to $CH_2Cl_2$ (HA-100) or to the central resonance of $CHDCl_2$ (WP.80) and were estimated relative to TMS by adding 5.40 ppm. No significant difference in chemical shifts was observed for repeat runs with separately-prepared samples or by using different instruments.

$^{13}$C spectra were obtained on either a Bruker WH.90 or a Bruker WH.80 Pulsed Fourier Transform spectrometer operating at 22.6 MHz and 20.1 MHz respectively. All spectra were obtained at 253 K except those containing alkyl aluminums, which were run at 213 K.

*Materials*

The Lewis bases, which are commercially available materials, were distilled and stored over activated 4A molecular sieves. A further distillation *in vacuo* immediately before use afforded compounds which were >99.5% pure by gas chromatography and in which no impurities were observed by $^1$H nmr. All manipulations were carried out under an atmosphere of dry nitrogen.

The liquid Lewis acids were distilled under reduced pressure. Early fractions were discarded. Later fractions were sealed in small dry glass ampoules until required. Again, all manipulations were carried out under an atmosphere of dry nitrogen. Gaseous Lewis acids ($BF_3$, $BCl_3$) were distilled from trap to trap in a dry glass vacuum line.

Methylene chloride was purified by the method of Jones and Wood (23).

*Preparation of nmr samples*

The nmr samples were prepared under dry nitrogen by adding an appropriate quantity of Lewis base through a rubber septum cap to a solution of Lewis acid in methylene chloride which was cooled to 195 K, except in the case of the gaseous Lewis acids, $BF_3$ and $BCl_3$, which were dispensed in a precalibrated vacuum line system. The stoichiometry of the resulting solution was such that there was a 10 to 100% excess of the Lewis acid present. $^1$H and $^{13}$C nmr spectra were recorded at −20°C, or at −60°C in the case of alkylaluminums to minimize side reactions. Complete complex formation was checked by comparing samples with different ratios of Lewis acid to the base. Only in the case of crotononitrile was there any question about the completeness of the reaction; however, under the conditions used here more than 95% of the base was complexed.

# Lewis acid adducts of α,β-unsaturated carbonyl and nitrile compounds. A calorimetric study

RONALD F. CHILDS,[1] D. LINDSAY MULHOLLAND, AND ALAN NIXON
*Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1*

Received July 20, 1981

RONALD F. CHILDS, D. LINDSAY MULHOLLAND, and ALAN NIXON. Can. J. Chem. **60**, 809 (1982).

Enthalpies of complexation of the α,β-unsaturated Lewis bases crotonaldehyde, **1**; methyl crotonate, **2**; mesityl oxide, **3**; and crotononitrile, **4**; with each of the Lewis acids $SnCl_4$, $TiCl_4$, $SbCl_5$, and $BCl_3$ were measured in solution in $CH_2Cl_2$. The results indicate that while a qualitative agreement exists in the ranking of Lewis acids for each of the Lewis bases, there is only a modest quantitative correlation. Similarly, when compared with an nmr-derived Lewis acid scale, the enthalpies were found to agree with the qualitative ranking of Lewis acids, but exhibited only a poor correlation.

RONALD F. CHILDS, D. LINDSAY MULHOLLAND et ALAN NIXON. Can. J. Chem. **60**, 809 (1982).

On a mesuré, en solution dans le $CH_2Cl_2$, les enthalpies de complexation des bases de Lewis α,β-non saturées, crotonaldehyde (**1**), crotonate de méthyle (**2**), oxyde de mésityle (**3**) et crotononitrile (**4**) avec chacun des acides Lewis suivants: $SnCl_4$, $TiCl_4$, $SbCl_5$ et $BCl_3$. Les résultats indiquent que des accords qualitatifs permettent d'ordonner chaque acide de Lewis pour chacune des bases de Lewis; toutefois la corrélation quantitative n'est que modeste. De la même manière, si on compare les enthalpies avec une échelle d'acide de Lewis dérivée de la rmn, on peut qualitativement ordonner les acides de Lewis mais la corrélation est faible.

Lewis acids are used to catalyse a variety of synthetically useful reactions of α,β-unsaturated carbonyl and nitrile compounds. In a previous paper we have reported a systematic examination of the nmr spectra of the complexes formed between some of these unsaturated bases and Lewis acids and have proposed an acid scale which, it was suggested, reflected the amount of charge induced at C3 of the base on complexation (1).

There has been much discussion about and many attempts at correlating Lewis acid/Lewis base interactions (2). These include, among others, the hard/soft concepts introduced by Pearson (3), the donor/acceptor numbers of Gutmann (4), Drago's E/C equation (5), and theoretical treatments of Mulliken and Pearson (6) and Klopman (7). The equilibrium constant or the heat of reaction is generally used to measure the strength of a Lewis acid/base reaction.

In our attempts to quantify the catalytic effects of Lewis acids on the reactions of unsaturated carbonyls and nitriles, it seemed of interest to compare the nmr-based scale mentioned above with the strength of the acid/base interaction. As complex formation was essentially complete for nearly all the systems we had studied it seemed appropriate to base such a comparison on the heats of reaction. There have been some previous reports of the measurement of the $\Delta H$ for reaction of unsaturated bases with Lewis acids (8) but insufficient for a meaningful comparison with our nmr-based scale. We report here a range of calorimetric measurements of these systems and examine the correlations with the nmr scale.

## Results and discussion

### *Calorimetric measurements*

Ideally the enthalpy measured should be that of the interaction of the acid and base in the gas phase. However, since solvation energies are likely to be small in inert solvents, the gas phase conditions can be approximated by taking the heat of molecular complexation to be the difference in molar heats of solution of the base in a solution of the Lewis acid and that in the same solvent with no acid present (4, 9–11).

The solution calorimeter used was a modified version of a design of Arnett and Petro (10). The precision of the calorimeter was checked by measuring the enthalpy of reaction of water with $FSO_3H$ (measured $-12.23 \mp 0.08$ kcal/mol, literature $-12.2 \mp 0.1$ (12) and $-11.95 \mp 0.04$ kcal/mol (13)). Further checks were made by measuring the heat of solution of various bases in a $SbCl_5/C_2H_4Cl_2$ solution and comparing with literature values.

Methylene chloride was used as the solvent with the unsaturated carbonyl and nitrile compounds of interest in this study. This solvent is inert to the Lewis acids used. The bases used were crotonaldehyde, **1**; methyl crotonate, **2**; mesityl oxide, **3**; and crotononitrile, **4**. The heats of reaction of each of these bases with $BCl_3$, $SbCl_5$, $TiCl_4$, and $SnCl_4$ were measured and the results shown in Table 1.

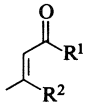
TABLE 1. Enthalpies of complexation ($\Delta H$) of α,β-unsaturated bases with various Lewis acids[a]

| Lewis base | $-\Delta H$ (kcal/mol) $BCl_3$ | $SbCl_5$ | $TiCl_4$ | $SnCl_4$ | $-\Delta H_2$[c] |
|---|---|---|---|---|---|
| Crotonaldehyde | 24.4±0.3 | 21.2±0.4 | 14.0±0.6 | 12.2±0.4 | 0.78±0.3 |
| Methyl crotonate | 19.9±0.4 | 18.0±0.4 | 13.6±0.7 | 6.1±0.3 | 0.64±0.05 |
| Mesityl oxide | 25.4±0.3 | 24.3±0.5 | 17.9±0.3 | 12.1±0.2 | 0.60±0.02 |
| Crotononitrile | 19.2±0.2 | 15.3±0.3 | 11.5±0.3 | (5.6±0.2)[b] | 0.60±0.04 |

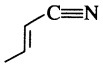
[a]As defined by equation given in Experimental. In dichloromethane solution at 295 K.
[b]Value corrected for incomplete complexation. Measured value = 3.8 ± 0.1 kcal/mol.
[c]Heat of solution of base in $CH_2Cl_2$.

*Nature of complexes formed*

Before discussing these heats of reaction it is important to establish the nature of the complexes formed. In all measurements the Lewis acid was held in excess and 1:1 complexes were formed (1). Checks were made for complete complexation by running $^1H$ nmr spectra at 25°C on solutions of comparable concentrations to those used in the calorimetry. In all but one case, variation of the acid to base ratio did not alter the chemical shifts of the resonances of the base indicating that the base was essentially completely complexed.



1 $R^1 = R^2 = H$
2 $R^1 = OCH_3$, $R^2 = H$
3 $R^1 = R^2 = CH_3$



4

The one exception was crotononitrile and $SnCl_4$, where considerable variation was detected, Table 2. From a plot of $1/\Delta\delta$ of H3 against the reciprocal of the Lewis acid concentration (Fig. 1), the equilibrium constant was found to be 5.31 L $mol^{-1}$.[2] The value of the equilibrium constant found here for **4** and $SnCl_4$ corresponds well with that reported by Brown and Kubota (14) for benzonitrile/$SnCl_4$ ($K$ = 4.17 L $mol^{-1}$).

Under the calorimetric conditions used the magnitude of the equilibrium constant between **4** and $SnCl_4$ is such that only some 58% of **4** would be complexed. This contrasts markedly with the $^1H$ nmr measurements at −20°C reported earlier (1) where it appeared that essentially all of **4** was complexed. The entropy term for this equilibrium was found to be −16 eu. Using the linear enthalpy/entropy relationship of Laane and Brown (15), a value of −22 eu might be expected.

*Enthalpy correlations*

Plots of the enthalpies of reaction of the Lewis acids with the Lewis bases against the nmr-derived scale (1) are shown in Fig. 2. Each of the bases shows a qualitative correlation between the enthalpies and nmr rating of the Lewis acids. In each case the ranking of the Lewis acids is the same. However, with the exception of mesityl oxide, the correlations are not very good quantitatively.

If the nmr scale we advanced previously is indeed indicative of the amount of positive charge

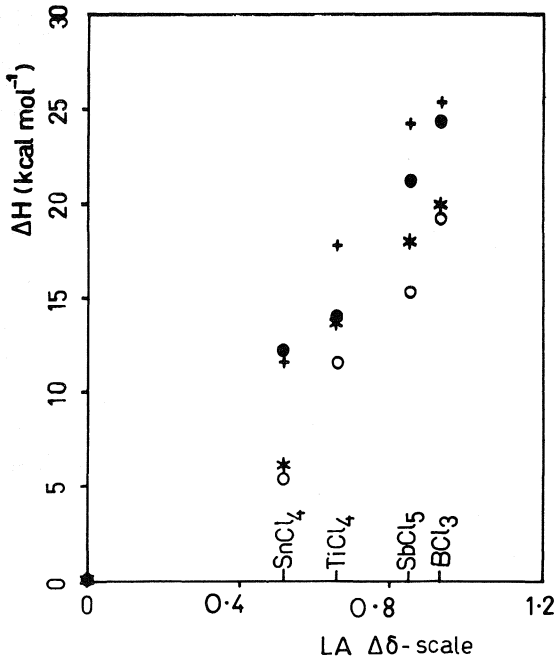

FIG. 2. Plots of the enthalpy of reaction of Lewis acids with crotonaldehyde (●); mesityl oxide (+); methyl crotonate (★); and crotononitrile (○) against nmr Lewis acid scale.

induced on the carbon framework of these unsaturated bases on complexation, then qualitatively this is related to the heat of formation of the complexes. It should be stressed, however, that the Lewis acids selected for this study are all simple inasmuch as they are monomeric in solution. No correlation would be anticipated with dimeric systems such as $Al_2Br_6$ or the alkylaluminum halides unless allowance was made for the heats of dissociation of the Lewis acids.

In the nmr work it was found that each base had a different sensitivity (slope parameter) to change of the Lewis acid. Thus crotonaldehyde was much more sensitive to change of the Lewis acid than pent-3-en-2-one. Crotononitrile was found to be the least sensitive. There appears to be no correlation between the calorimetric data presented in this paper and these base slope parameters. As can be seen from Fig. 2, the slopes of the $\Delta H$ vs. nmr scale plots for all the bases used are qualitatively the same.

In conclusion, it remains to be seen whether the parameters measured for these Lewis acid complexes of the unsaturated bases can be used to predict reactivity in their catalysed reactions.

## Experimental

*General*

All materials were purified as described previously (1). The $^1$H nmr spectra were obtained on a Bruker WP 80 Fourier Transform spectrometer operating at 80 MHz equipped with a Bruker B-VT 1000 variable temperature controller. Samples were run at 25°C in $CD_2Cl_2$ as solvent.

*Equilibrium measurements for crotononitrile/$SnCl_4$*

A series of samples of **4** (0.04 *M*) in $CD_2Cl_2$ (0.3 mL) were prepared and $SnCl_4$ added to them such that the acid concentration varied between 0.2 to 0.8 *M*. The $^1$H nmr chemical shifts of **4** were measured at 25°C and are shown in Table 1. The equilibrium constant was estimated from a slightly modified Benesi–Hildebrand plot (16). The slope is given by $1/\Delta\delta oK$ (where $\Delta\delta o$ is the chemical shift of the complex relative to the free base) and the intercept is given by $1/\Delta\delta o$. The slope was $0.48 \mp 0.02$ mol/L and intercept $2.55 \mp 0.05$ giving a value of $K = 5.31 \mp 0.19$ L mol$^{-1}$ (16). All other combinations of Lewis acids – bases used in this study gave invariant chemical shift differences on comparable changes of the Lewis acid concentration.

*The calorimeter* employed was based on the design by Arnett and Petro (10) with the following modifications. The calorimeter vessel was reduced in size to approximately 125 mL. As a result, the volume of solvent used could be reduced to 60 mL. The bottom of the vessel was made flat except for a V-shaped indentation which acted as a bearing for the Teflon tip of the stirrer. This allowed better immersion of the glass probes containing the thermistor and heaters. The reduction in volume of solvent caused an increase in sensitivity of the calorimeter, decreasing the heat input for balance and calibration runs. For the balance and calibration heaters, Philips metal film precision resistors type MR 25 F (50 ohm) were used. These were in series and mounted in 5 mm od Pyrex glass tubes partially filled with liquid paraffin as a heat transfer fluid. The resistance of these heaters was carefully monitored during use, but heat transfer was found to be so effective that no significant change in resistance took place even with prolonged use. Two 12-V lead–acid accumulators acted as power supplies. These were independently connected to the balance and calibration heaters and the applied voltage was measured using a digital multimeter (Keithley 169). The duration of the calibration heating cycle was measured to 0.01 s using an interconnected digital timer.

*Calorimetric procedure*

The dried calorimeter vessel was charged with dried $CH_2Cl_2$ (60 mL) and blanketed with nitrogen. The Lewis acid was added to the calorimeter with a syringe so as to give a 0.2 to 0.3 *M* solution. (At least two completely independent runs were carried out for each acid/base combination with different acid concentrations being used in each.) The calorimeter was balanced by adjusting the balance heater at ca. 25°C and a series of at least eight electrical calibrations was conducted.

The Lewis base (5–20 mg) was added using a weighed 25 μL syringe. The enthalpies quoted in Table 2 are the arithmetic

mean of at least six injections carried out over two separate runs. A typical set of results is shown in Table 3. To obtain the heat of complexation a separate experiment was conducted in which no Lewis acid was added to the calorimeter and the heat of solution subtracted from the previous value. ($\Delta H_{compl.} = \Delta H_1 - \Delta H_2$ where $\Delta H_{compl.}$ = heat of complexation; $\Delta H_1$ = heat of solution of base in $CH_2Cl_2$ containing the Lewis acid; $\Delta H_2$ = heat of solution of base in $CH_2Cl_2$ solution.) A further set of electrical calibrations was carried out at the end of the run.

# *Ab initio* SCF MO calculations on the reactions of OH radical with pyridine and pyridinium ion

M. C. ANTHONY, W. L. WALTZ, AND P. G. MEZEY

*Department of Chemistry and Chemical Engineering and the Saskatchewan Accelerator Laboratory, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0*

Received October 30, 1981

M. C. ANTHONY, W. L. WALTZ, and P. G. MEZEY. Can. J. Chem. **60**, 813 (1982).

Relative energies of various products formed in the reaction of pyridine and pyridinium ion with the hydroxyl radical are calculated using non-empirical SCF MO techniques. The favourable electron delocalization in the *meta*-products, rather than the electrophilic character of the OH radical is the determining factor of relative stabilities. Calculated energy barriers along approximate reaction paths correlate with the available experimental information.

M. C. ANTHONY, W. L. WALTZ et P. G. MEZEY. Can. J. Chem. **60**, 813 (1982).

On a calculé les énergies relatives des divers produits qui se forment au cours de la réaction de la pyridine et de l'ion pyridium avec le radical hydroxyle en faisant appel à des techniques OM SCF non empiriques. Le facteur qui détermine les stabilités relatives est la délocalisation favorable des électrons dans les produits meta plutôt que le caractère électrophile du radical OH. Les barrières d'énergies calculées le long des coordonnées approximatives de la réaction sont en bon accord avec les informations expérimentales disponibles.

[Traduit par le journal]

## Introduction

Within recent years, a very large number of experimental investigations have focused on the reactions of hydroxyl radical in aqueous media with nitrogen heterocyclic materials (1). This interest has been engendered in part by the recognition of the general importance of such reactions with respect to radiation biology and chemistry and some nonradiolytic biological processes (refs. 2–4 and references therein). Theoretical calculations pertaining to nitrogen heterocyclic compounds have provided useful insight into the processes associated with tautomerization and protonation (5–10). In this report, theoretical methods have been used to study the reaction of OH with one of the simplest of such heterocyclic compounds, namely pyridine and its protonated form, pyridinium ion. Whereas ground and excited states of pyridine and pyridinium ion have been studied earlier using theoretical methods (11–13), to our knowledge no such studies on reactions with OH radical have been reported.

The choice of this system is appropriate from the perspective that considerable, recent experimental information is available concerning the reactions of hydroxyl radical with pyridine, substituted pyridines, and related benzene systems (14–19). Investigations have also been undertaken into the effects associated with protonation and metal ion complexation (16, 17, 20–22). Such effects can be quite marked as exemplified by the observation that pyridine is about a hundred times more reactive towards OH than is its protonated form (16, 20). For pyridine systems and related benzene entities, their reactions with hydroxyl radical lead in general to OH addition at the aromatic ring to yield radical species. There can be a considerable level of specificity as to the reaction site, even though in some cases the second-order rate constants for these reactions approach values usually characteristic of diffusion-controlled processes. For example, pyridine with four possible reaction sites (nitrogen; carbons at the *ortho*, *meta*, and *para* positions) has an overall reaction rate constant of $4.5 \times 10^9\ M^{-1}\ s^{-1}$ (20), and in situ radiolysis–esr results indicate that OH addition occurs at the *meta* positions to an extent of 80% or more. A recent study involving time-resolved measurements using pulse radiolysis and final product analysis has corroborated this finding (19).

In the interpretation of the site specificity for pyridine systems and substituted benzene compounds, emphasis has been placed on the electrophilic character of OH and on the assumed preference of reaction at the least electron deficient positions of the aromatic ring. On this basis, reaction at the nitrogen position would seem to be quite favorable. Aside from the results of an earlier pulse radiolysis – optical absorption investigation (16), the more recent reports have not provided indications of reaction at the pyridine nitrogen (18, 19). The foregoing suggests that other factors must contribute to the site selection.

To approach this aspect from a new perspective, we have undertaken theoretical calculations on various model reactions and on the stabilities of the

isomeric radical products. The OH addition to pyridine and its protonated form has been analysed in terms of the energetic stability, and points along the theoretical potential energy surface have been calculated near the assumed reaction paths. While possible effects due to solvent interaction have not been studied, the results are nevertheless in agreement with the experimental observations with regard to the specificity of OH addition and to the relative order of reactivity between pyridine and pyridinium ion.

## Method of calculations

In analyzing the site-specificity of OH addition to both pyridine and its protonated form, the total energies of all the isomeric hydroxypyridine radicals formed in these reactions have been calculated using an *ab initio* SCF MO method. In the calculations, the geometry of the intermediate radical has been assumed to be tetrahedral. A similar assumption has been employed by Imamura and Hirao (23) in a study on benzene systems. For our calculations, experimental parameters (24) have been taken for the geometry of pyridine, and the same geometry has been used as the initial guess for geometry optimization and for all the hydroxypyridine radicals. The series of neutral, ionic, and radical species studied in this work are shown in Fig. 1, and the specific numbering of atoms in the four most important species is given in Fig. 2.

For the reaction path calculations, all the parameters in the reactants and products are optimised and are given in Figs. 3 and 4. Using these optimised parameters, total energies as functions of both C—OH and C—H bond lengths have been calculated along assumed reaction paths, keeping the rest of the geometrical parameters fixed.

An STO-3G minimal basis set was used in all the RHF and UHF calculations using versions of either the Gaussian70 (25) or the MonsterGauss (26) programs, modified for the 36 bit computerword of the DEC-2060 computer of the University of Saskatchewan.[1]

## Results and discussion

Addition of OH to pyridine and to pyridinium ion can occur at four different positions of the ring. The remaining two positions in the ring can be treated as symmetrically identical to one of these positions.

[1]An efficient integral package, utilizing all 36 bits for the storage of integral labels has been developed (27) that will double the maximum size of molecules which can be studied with the new versions of these programs. The new programs will enable us to extend our studies to larger models, using larger, e.g. 4-31G, basis sets.

In earlier studies, the electronic charge distribution has been regarded as the dominant factor in explaining site-specificity of OH addition. The calculated gross charges on all these ring atoms are given in Table 1 (note that not all digits listed in the tables are physically significant, nevertheless they are quoted for the sake of numerical comparisons within the theoretical models). The order of electron density on these atoms is calculated as N > *meta*-C > *para*-C > *ortho*-C. If the specificity of OH addition to ring atoms of pyridine is associated primarily with electrophilicity, as suggested by earlier studies, then its addition to N atom is expected to be the most favoured process. Experimentally this has not been found to be so.[2] According to our calculations of the total energies, the *meta* position is the most preferred site (in agreement with experiment) with nitrogen being the site of second preference. The calculated total energies of all the isomeric hydroxypyridine radicals are given in Table 2. Based upon these energy values, the preferential order for OH addition at the different positions of the ring is *meta*-C > N >> *para*-C > *ortho*-C. For the carbon-based sites, the order appears to be in accord with the reported experimental observations (18, 19).[3] Given this and the calculated lower bound for the corresponding activation energy (see later), an experimental re-examination of the apparent lack of reaction at the nitrogen site may be warranted.

Total energies of the various products of OH addition to pyridinium ion are given in Table 3. By comparing these energy values, the order of site preference for OH addition to protonated pyridine can be given as *meta*-C >> *para*-C > *ortho*-C > N. Evidently, by protonation of pyridine, the selectivity of OH addition changes considerably as now addition to N atom is the least favoured position in contrast to nitrogen being the second preferred site in the unprotonated form. In both cases the *meta* position is the most favourable site. In the protonated form, this preference is much more pronounced. Similarly, it is also found amongst the non-radicals, **VI–IX** and **XV–XVIII**, that the two *meta* compounds (**VI** and **XV**) and the nitrogen-based OH adduct (**IX**) are of the lowest total energy as shown in Tables 2 and 3. It should be noted, however, that the calculated wavefunction for negative ion **IX** is *not* a stable solution of the closed shell Hartree–Fock equations, since the HOMO energy is positive. Such positive HOMO energies, although inconclusive in the strict sense, often indicate a physical instability of the system. Even if the ion does exist, the calculated energy value is less reliable than the rest of the calculated total energies.

With regard to the site-specificity, it is germane to note that among the radical species, the only two forms with calculated atomic spin densities of consistently alternating signs along the molecular skeleton are the two *meta*-substituted species, **II** and **XI**. Such sign alternation of spin densities indicates a high degree of delocalization of the odd electron, which shows an apparent correlation with the exceptional stability of the *meta*-species. The calculated spin densities of **II** and **XI** are listed in Table 4. The favourable delocalization in the meta hydroxypyridine radical (**II**) is also indicated by the calculated dipole moment which is smallest for this

TABLE 2. Calculated electronic and total energies of pyridine and different isomeric hydroxypyridine radicals and molecules

| Molecules/ radicals | Electronic energy (au) | Total energy (au) |
|---|---|---|
| **I** | −449.54088 | −243.63840 |
| **II** (*meta*) | −609.81489 | −317.98024 |
| **III** (*ortho*) | −630.37346 | −317.52033 |
| **IV** (*para*) | −631.09525 | −317.59866 |
| **V** (N)[a] | −613.13425 | −317.90943 |
| **VI** (*meta*) | −592.40234 | −317.46054 |
| **VII** (*ortho*) | −594.26303 | −317.43222 |
| **VIII** (*para*) | −595.36195 | −317.45357 |
| **IX** (N)[b] | −616.01537 | −317.65202 |

[a]Radical **V** shows an extremely flat potential along the N pyramidal inversion coordinate. The results in the table refer to the optimum oxygen out-of-plane angle of 28.7°; however, the planar form ($E_{el}$ = −612.21048 au, $E_{tot}$ = −317.90456 au) lies only 3 kcal/mol above this form.
[b]Ion **IX** has one more H atom than molecules **VI–VIII**.

[2]While it was suggested in an earlier study that OH attack at the nitrogen site may occur (16), more recent investigations give no definite indications of this occurrence (18, 19).

[3]In the text of ref. 19, the order is given as quoted above, although in the abstract, the positions of *para* and *ortho* are reversed.

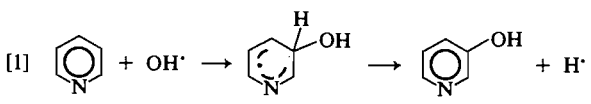
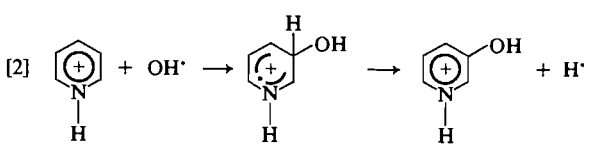
species (**II**: 1.48 D, **III**: 6.56 D, **IV**: 5.14 D, **V**: 1.53 D).

These results suggest that the most preferred products for OH addition to pyridine and to pyridinium ion can be given by reactions [1] and [2].





Although the two dehydrogenation reactions, which are portrayed as being subsequent to the OH additions, have not been observed experimentally, we have nevertheless considered them for the sake of completeness to the theoretical model. Approximate reaction paths have been calculated for all four reaction steps in reactions [1] and [2]. The total energies at the equilibrium (optimized) geometries of all species involved in the above equations are listed in Table 5. The calculated total energies along the approximate reaction paths are shown in Figs. 5–8. Since the reaction paths themselves are not fully optimized, the calculated activation energies, $E_A$, are less accurate than the net energy differences, $\Delta E$:

TABLE 5. Total energies of the completely optimized molecules, radicals, and ions

| Species | Total energy (au) |
|---|---|
| **I** | −243.63840 |
| **II** | −318.04995 |
| **VI** | −317.47048 |
| **X** | −244.07547 |
| **XI** | −318.46263 |
| **XV** | −317.90411 |
| OH | −74.36489 |
| H | −0.46658 |

[3] **I** + OH → **II**
$E_A \cong$ 11 kcal/mol, $\Delta E$ = 29 kcal/mol

[4] **X** + OH → **XI**
$E_A \cong$ 16 kcal/mol, $\Delta E$ = 14 kcal/mol

[5] **VI** + H → **II**
$E_A \cong$ 7 kcal/mol, $\Delta E$ = 71 kcal/mol

[6] **XV** + H → **XI**
$E_A \cong$ 14 kcal/mol, $\Delta E$ = 58 kcal/mol

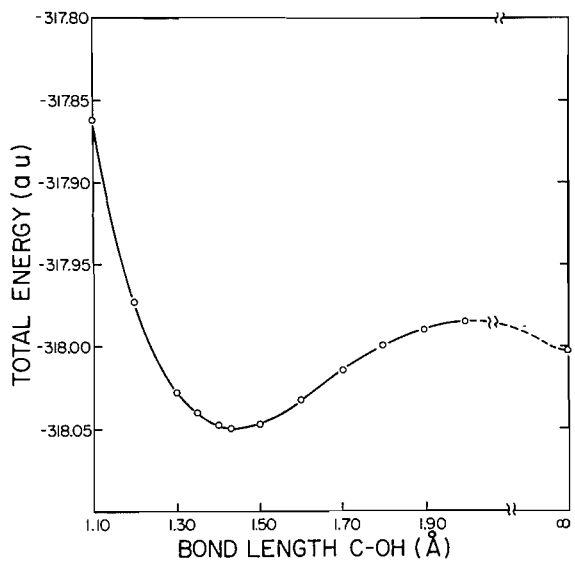


FIG. 5. Calculated approximate energy profile for the reaction of pyridine (**I**) with hydroxyl radical. The assumed reaction path is along the C—O stretching coordinate.

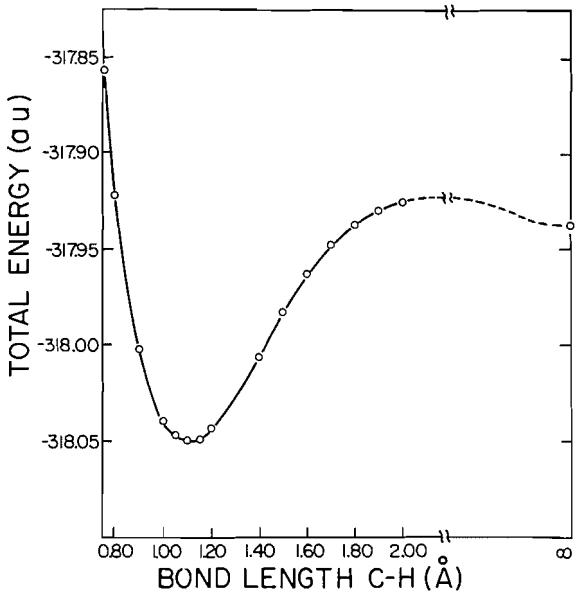

FIG. 6. Calculated approximate energy profile for the reaction of 3-hydroxypyridine (**VI**) with H atom. The assumed reaction path is along the C—H stretching coordinate.

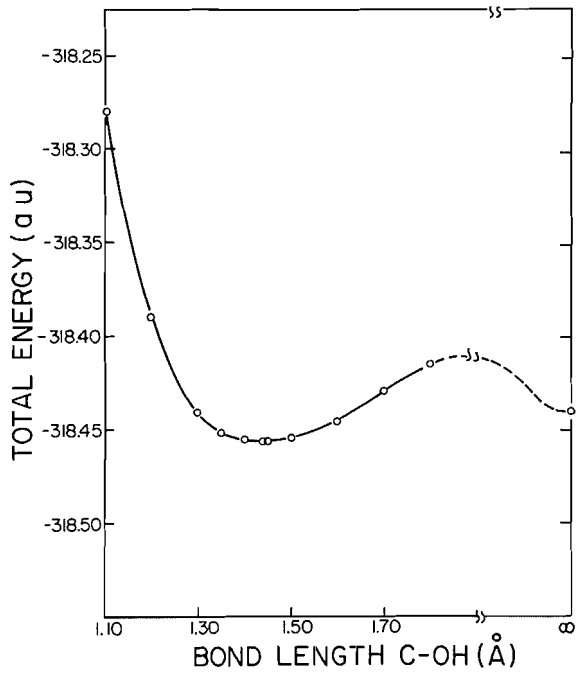

FIG. 7. Calculated approximate energy profile for the reaction of pyridinium ion (**X**) with hydroxyl radical. The assumed reaction path is along the C—O stretching coordinate.

The above results also provide information on the activation energy for the **I** + ·OH → **V** process. Since the total energy of the N-based OH-adduct **V** lies more than 44 kcal/mol above that of the *meta* adduct **II**, the activation energy for the **I** + ·OH → **V** process must be at least 15 kcal/mol, which is certainly larger than that of the **I** + ·OH → **II** process.

The above reactions correspond to processes proceeding from *right to left* along the approximate reaction profiles shown in Figs. 5–8, where a linear approach along the direction of the corresponding chemical bond has been assumed. That is, they refer to hydroxyl or hydrogen *addition* processes. The calculated approximate activation energies are consistently lower for neutral pyridine than for the pyridinium ion. This result is in good agreement with conclusions drawn from experiments, indicating a higher degree of reactivity towards OH for pyridine as compared to pyridinium ion. The corresponding reactions of H atom with hydroxypyridine (**VI** and **XV**) have not apparently been investigated experimentally; however, H atom has been found to be more reactive towards pyridine than pyridinium ion (28).

The calculated protonation energies for the closed-shell species are as follows:

[7] **I** + $H^+$ → **X**
$\Delta E$ = 274 kcal/mol

[8] **VI** + $H^+$ → **XV**
$\Delta E$ = 269 kcal/mol

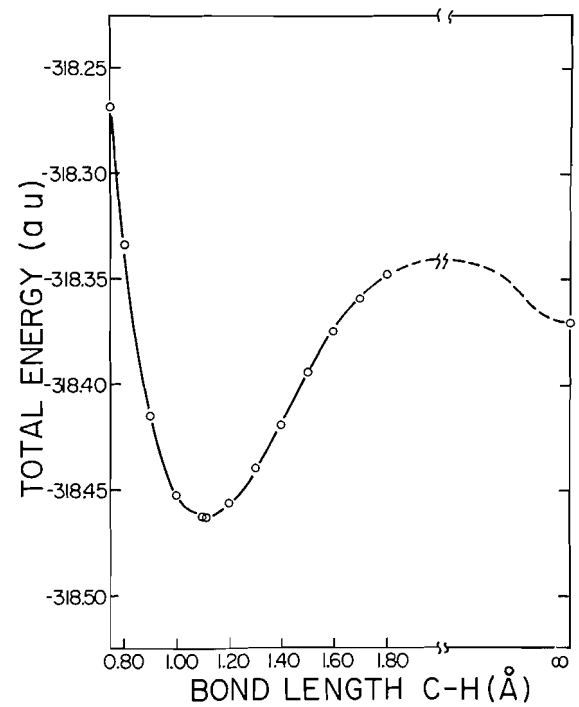

FIG. 8. Calculated approximate energy profile for the reaction of 3-hydroxypyridinium ion (**XV**) with H atom. The assumed reaction path is along the C—H stretching coordinate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

[9] **VII** + $H^+ \rightarrow$ **XVI**
$\Delta E$ = 275 kcal/mol

[10] **VIII** + $H^+ \rightarrow$ **XVII**
$\Delta E$ = 272 kcal/mol

The protonation energies are the largest for **I** and **VII**. The three carbon-based OH adducts show similar protonation energies with the largest difference being about 6 kcal/mol. Although, as pointed out above, the calculated results for ion **IX** are unreliable, the energy values suggest that protonated form **XVIII** is much more stable than **IX**.

All these calculated protonation energies are significantly lower than those calculated for various thymine and cytosine tautomers (at least by 8 kcal/mol with respect to thymine and by 16 kcal/mol with respect to cytosine tautomers [8]). Protonated forms of the above nucleotide bases and their tautomeric forms are apparently more stable than protonated forms of the above pyridine derivatives.

## Conclusions

Relative stabilities, atomic spin densities, and approximate reaction paths have been calculated for various neutral, ionic, and radical species involved in the reactions of neutral and protonated pyridines with the OH radical. The *meta* product is clearly favored among both neutral and protonated pyridine species. As opposed to earlier suggestions, the site specificity of OH radical addition is not determined solely by the electrophilic character of OH, and by the assumed preference of reaction at the least electron deficient ring positions. Rather, the advantageous delocalization of the odd electron in the *meta*-species appears to play a major role in determining the order of relative stabilities and product preference.

With the new, extended versions of the two *ab initio* programs (27), capable of handling larger (e.g. 4-31G) bases for the molecules studied and also for larger models, further studies are in preparation.

Received October 14, 1981

JOHN F. KINGSTON and ALEX G. FALLIS. Can. J. Chem. **60**, 820 (1982).

Two new $C_{26}$ steroid $\Delta^{1,4}$-dien-3-ones **5** and **6** with 12β oxygen functions have been isolated from the soft coral *Gersemia rubiformis* and their structures elucidated from their spectral data and chemical transformations.

JOHN F. KINGSTON et ALEX G. FALLIS. Can. J. Chem. **60**, 820 (1982).

On a isolé les deux nouveaux stéroides en $C_{26}$, **5** et **6**, du type hydroxy-12β diène-$\Delta^{1,4}$ one-3, à partir des coraux mous *Gersemia rubiformis* et on a élucidé leur structure en se basant sur des données spectrales et des transformations chimiques.

[Traduit par le journal]

## Introduction

As part of our investigation of local marine natural products we have examined a number of marine invertebrates inhabiting the cold waters off Newfoundland and Labrador. These studies have included several soft corals of the order Alcyonacea (Phylum Cnidaria (Coelenterata), Class Anthozoa, Subclass Octocorallia) and one of these, the sea raspberry, *Gersemia rubiformis* (Pallas) has afforded novel steroids possessing a vinyl side chain and/or a cross conjugated dienone functionality in ring A (1, 2), such as structure **1**. Warm water relatives of these species have provided a rich source of various natural products including sesqui- and diterpenes (3) and compounds related to **1** have been identified in a South Pacific alcyonacean coral (4), a Hawaiian telestacean octocoral (5), and a Mediterranean gorgonian coral (6).

In spite of the wide distribution of $C_{26}$ 3β-hydroxy sterols in marine invertebrates (7) more highly functionalized skeletons are less common, although the dienone **2** has been isolated from a sponge (8) and recently the peroxide **3** was identified in a nudibranch and a sea pen (9). A rare example of a $C_{12}$ hydroxylated marine steroid, the polyoxygenated compound 24-methylcholestan-3β,5α,6β,12β,25-pentol 25-monoacetate (**4**), was found in an alcyonacean coral (10). We report herein the isolation from *Gersemia rubiformis* and structure elucidation of two unusual $C_{26}$ steroids, 12β-hydroxy-24-norcholesta-1,4,22-trien-3-one (**5**) and its acetate **6**. In addition to the rare $C_{12}$ oxygen functionality they comprise the first examples of marine steroids of more than 21 carbons which incorporate the $\Delta^{1,4}$-dien-3-one functionality in ring A.

## Results and discussion

Samples of *Gersemia rubiformis* collected at Admiral's Cove and Bay Bulls, Newfoundland were freeze dried and extracted with acetone. Fractionation of the extract by column chromatography and several tlc steps afforded the alcohol **5** and acetate **6** in 0.009% and 0.008% of the dry weight of the animal.

The molecular formula for the alcohol $C_{26}H_{38}O_2$ was established by high resolution mass spectrometry. The infrared absorptions at 1660, 1620, and 1595 $cm^{-1}$ were characteristic of the presence of the cross conjugated C-3 ketone in ring A (1) as was the uv spectrum ($\lambda_{max}$ 244 nm, $\varepsilon$ = 12 000). The $^1H$ nmr spectrum contained a pattern typical of $\Delta^{1,4}$-dien-3-ones (1) and was assigned as follows. A doublet at δ 7.03 ($J$ = 10 Hz), representing the single proton at C-1, was coupled with a second proton at C-2 which appeared as a doublet of doublets at δ 6.22 ($J$ = 10, 2 Hz). The C-4 proton appeared as a broadened singlet at δ 6.07 ($W_{1/2}$ = 4 Hz) due to coupling with the C-2 proton and the C-6 methylene function. The presence of an hydroxyl group was indicated by the infrared absorption at 3400–3600 $cm^{-1}$ and the large $M - 18$ peak at $m/e$ 364 corresponding to loss of water from the parent ion in the mass spectrum. The secondary nature of the alcohol was established from the signal of the proton on the hydroxyl carbon in the $^1H$ nmr spectrum which appeared at δ 3.40 as a doublet of doublets ($J$ = 10, 5 Hz) and confirmed by the doublet assigned to this carbon at δ 78.6 in the off-resonance $^{13}C$ nmr spectrum. An additional multiplet at δ 5.35 in the $^1H$ nmr spectrum representing two protons suggested the presence of an additional disubstituted double bond and singlets at

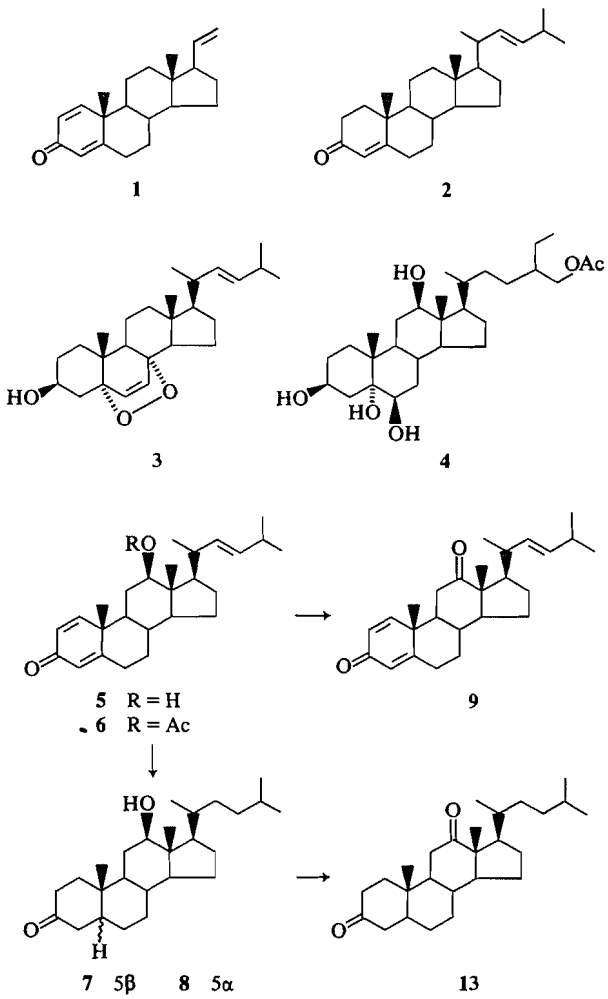
δ 0.74 (3H) and δ 1.20 (3H) were assigned to the C-18 and C-19 methyl groups respectively. In the 400 MHz spectrum the C-21 methyl group appeared as a doublet ($J$ = 6 Hz) at δ 1.02, while the C-25 and C-26 methyl groups gave rise to a common doublet ($J$ = 6 Hz) at δ 0.95 representing six hydrogens. A single proton multiplet at δ 2.25 was assigned to the C-24 proton; irradiation at this frequency caused the doublet at δ 0.95 to collapse to a singlet and resulted in partial collapse of the vinyl proton multiplet at δ 5.35. These experiments demonstrated that this double bond was adjacent to two secondary methyl groups and requires that the olefin function be located in the side chain at C-22. The correctness of this assignment was confirmed by ozonolysis of the acetate **6** to give, amongst other products, iso-butyraldehyde which was characterized as its 2,4-DNP derivative and identified by comparison with an authentic sample. This double bond gave rise to a weak infrared absorption at 970 $cm^{-1}$ consistent with the *trans* configuration.

Since the side chain contains no secondary positions, the alcohol function must be in the steroid ring system. The position of this group was determined as follows. Hydrogenation of **5** over 5% Pd/C afforded a 3:1 ratio of **7** and **8**. The mass spectrum established the molecular formula $C_{26}H_{44}O_2$ and displayed a base peak at $m/e$ 271 corresponding to loss of water plus a saturated $C_7H_{15}$ side chain confirming that the hydroxyl function was attached to a ring position, either C-6, 7, 11, 12, 15, or 16. Oxidation of **5** with Jones' reagent afforded the diketone **9** whose infrared spectrum contained a new carbonyl absorption at 1705 $cm^{-1}$ typical of a cyclohexanone. In addition, the ultraviolet spectrum was unchanged from the starting material and unaffected by addition of base. These data ruled out part structures **10** and **11** and eliminated positions 15 and 16 from further consideration. Thus the alcohol substituent must be located at either C-11 or C-12. It was anticipated that an 11-keto function should significantly deshield the olefinic C-1 proton and this was shown to be the case by the preparation of trione **12** from 11α-hydroxyprogesterone by dehydrogenation with DDQ followed by Jones' oxidation. In this 11-keto compound the C-1 proton doublet occurred at δ 7.68, while in contrast, this signal for **9** appeared at δ 6.85. Thus the hydroxyl group was not located at C-11 and could be tentatively assigned to C-12.

Steroids possessing C-12 ketones and 17-alkyl side chains undergo a characteristic mass spectral fragmentation involving ring D loss and hydrogen transfer from C-20 to the C-12 ketone, resulting in a



fragment corresponding to loss of the side chain plus 40 mass units (11). This fragment is masked in **9** due to the dominant loss of ring A by bisallylic cleavage to give an ion at $m/e$ 122 typical of $\Delta^{1,4}$-3-ketosteroids. When the reduced keto-alcohols **7** and **8** were oxidized with Jones' reagent to the 3,12-diketone **13**, the mass spectrum of this material displayed, as the largest fragment, $C_{16}H_{23}O_2$ from loss of the side chain plus 40 mass units thereby establishing the location of the oxygen functionality at C-12.

The stereochemistry of the hydroxyl group was ascertained from the $^1H$ nmr spectrum of **5**. The C-12 proton appeared at δ 3.40 as a doublet of doublets due to one axial–axial coupling ($J$ = 10 Hz) and one axial–equatorial coupling ($J$ = 5 Hz) with the C-11 hydrogens, and thus established that this proton was axial and hence the hydroxyl group equatorial (β).

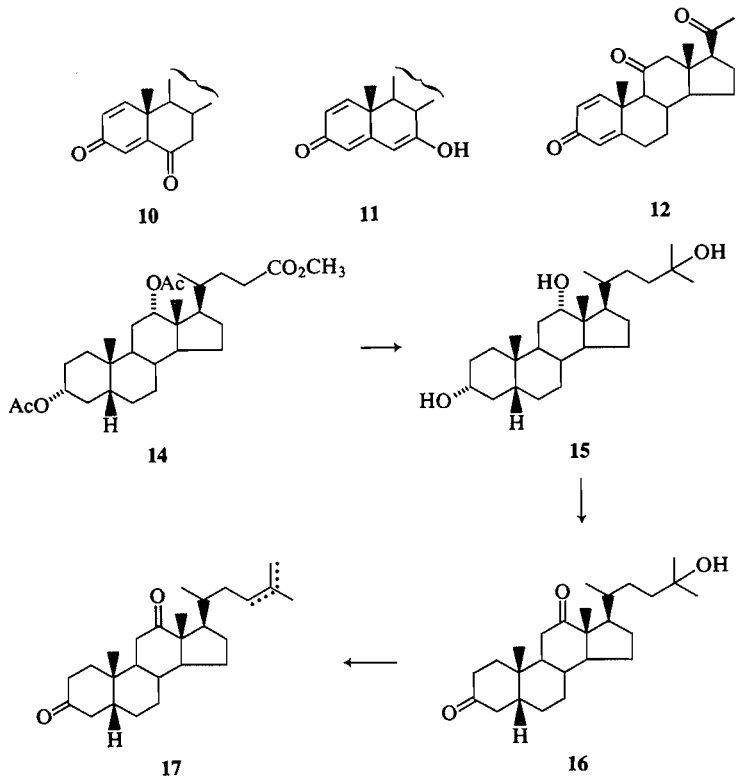
For personal use only.



Final confirmation of the correctness of the structural assignment was provided by synthesis of an authentic sample of the 5β isomer of **13** as follows. The triester **14** was treated with excess methyllithium to give the triol **15** which was oxidized with Jones' reagent to the 3,12-diketoalcohol **16**. Elimination of water proceeded smoothly at room temperature in acetic acid containing $BF_3 \cdot Et_2O$. The resulting mixture of olefins **17** was hydrogenated over 5% Pd/C to provide the desired 24-nor-5β-cholesta-3,12-dione which was identical with the major isomer of **13**, separated by glc, prepared from the natural product.

The acetate **6** displayed characteristic infrared carbonyl absorption at 1735 $cm^{-1}$ and a methyl singlet at δ 2.09 in the $^1H$ nmr spectrum. The C-12 proton appeared at δ 4.60 as a doublet of doublets ($J$ = 5, 10 Hz) and the mass spectrum displayed a tiny molecular ion (*m/e* 424), and a large fragment at *m/e* 364 due to loss of acetic acid. The remaining spectral data were similar to those of the alcohol **5**. Treatment of **5** with acetic anhydride in pyridine afforded **6** which was identical in all respects with the naturally occurring acetate.

## Experimental

Melting points were determined in capillary tubes with a Thomas–Hoover Uni-Melt apparatus or a Fisher–Johns melting point apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 237B grating spectrophotometer, and were calibrated with the 2850 and 1601 $cm^{-1}$ bands of polystyrene film. Ultraviolet spectra were recorded on a Perkin–Elmer 202 uv–visible spectrophotometer and were calibrated with the 279.4 nm band of a Holmium oxide filter. Proton magnetic resonance spectra were measured at 80 MHz with a Bruker Model WP80 spectrometer employing a chloroform lock. Signal positions are reported in ppm downfield from tetramethylsilane (δ scale) as an internal standard, the number of protons, multiplicity, coupling constants, and proton assignments are indicated in parentheses. The 400 MHz spectrum was recorded on the Bruker WH 400 spectrometer at the University of Alberta. Mass spectra were determined on a Hitachi Perkin–Elmer RMU 6E or Varian MAT 311A instrument using an ionization energy of 70 eV. Gas–liquid chromatographic analyses were conducted on a Hewlett–Packard 402B gas chromatograph equipped with a column (3 m × 6 mm id) containing 1.5% OV-17 supported on Gas Chrom Q using helium as the carrier gas. Thin-layer chromatographic analyses were carried out on commercial pre-coated silica gel plates with fluorescent indicator (Eastman Kodak Silica gel 13181). Preparative thin-layer chromatography was conducted on 20 × 20 cm glass plates coated with silica gel $PF_{254+366}$ type 60 (E. Merck).

Solutions in organic solvents were dried over anhydrous magnesium sulphate and stripped of solvent with a Büchi rotary evaporator connected to a water aspirator.

*Isolation of 12β-hydroxy-24-norcholesta-1,4,22-trien-3-one (5) and 12β-acetoxy-24-norcholesta-1,4,22-trien-3-one (6)*

Samples of *Gersemia rubiformis* were collected at Admiral's Cove and Bay Bulls, Newfoundland. The acetone extract of the freeze dried animals was fractionated by liquid chromatography on silica gel using a stepped gradient of hexanes/chloroform/

2-propanol. The acetate **6** and alcohol **5** were contained in separate fractions which eluted with chloroform/2-propanol (97:3). Fractions rich in the alcohol were subjected to further column chromatography on silica gel (toluene/acetone, 9:1) followed by preparative tlc on alumina (toluene/acetone, 3:1). Final purification by preparative tlc on silica gel (hexanes/2-propanol, 9:1) afforded the alcohol **5** as a colourless oil (0.009% of dry weight); uv (MeOH)$\lambda_{max}$: 244 nm, $\varepsilon$ = 12 000; ir ($CHCl_3$) $\nu_{max}$: 3600–3400 (O—H), 1660 (C=O), 1620, 1595 (C=C), 970 (C=C—H) $cm^{-1}$; $^1H$ nmr ($CDCl_3$, 400 MHz) $\delta$: 0.74 (3H, s, C-18 methyl), 0.95 (6H, d, $J$ = 6 Hz, C-25 and C-26 methyls), 1.02 (3H, d, $J$ = 6 Hz, C-21 methyl), 1.20 (3H, s, C-19 methyl), 2.25 (1H, m, C-24 H), 3.40 (1H, dd, $J$ = 5, 10 Hz, C-12 H), 5.35 (2H, m, —CH=CH—), 6.07 (1H, s, $W_{1/2}$ = 4 Hz, C-4 H), 6.22 (1H, dd, $J$ = 10, 2 Hz, C-2 H), 7.03 (1H, d, $J$ = 10 Hz, C-1 H); $^{13}C$ nmr ($CDCl_3$) $\delta$: 186.2 (C-3), 168.5 (C-5), 155.2 (C-1), 136.3, 132.3 (C-22, C-23), 127.8, 124.2 (C-2, C-4), 78.6 (C-12), 57.2, 53.5, 51.1, 48.1, 43.4, 37.7, 34.4, 33.1, 32.9, 32.4, 31.2, 24.2, 24.0, 22.7, 22.6, 22.4, 18.7, 8.6; ms *m/e* (%): 382(1), 364(39), 349 (11), 321(45), 267(23), 243(22), 122(49), 121(100). *Exact Mass* calcd. for $C_{26}H_{38}O_2$: 382.2872; found: 382.2867.

Fractions rich in the acetate were purified by column chromatography on silica gel (toluene/acetone, 9:1) and preparative tlc on alumina (toluene/acetone, 9:1) and silica gel (hexanes/2-propanol, 19:1) to afford the acetate **6** as a colourless oil (0.008% of dry weight); uv (MeOH) $\lambda_{max}$: 244, $\varepsilon$ = 11 800; ir ($CHCl_3$) $\nu_{max}$: 1735 (C=O, acetate), 1660 (C=O), 1620, 1600 (C=C), 970 (C=C—H) $cm^{-1}$; $^1H$ nmr ($CDCl_3$, 80 MHz) $\delta$: 2.09 (3H, s, acetate Me), 4.60 (1H, dd, $J$ = 5, 10 Hz, C-12 H), 5.3 (2H, m, —CH=CH—), 6.05 (1H, bs, $W_{1/2}$ = 5 Hz, C-4 H), 6.20 (1H, dd, $J$ = 10, 2 Hz, C-2 H), 6.94 (1H, d, $J$ = 10 Hz, C-1 H); ms *m/e* (%): 424(1), 364(59), 349(15), 321(63), 267(26), 243(24), 122(61), 121(100).

Both the alcohol **5** and acetate **6** were accompanied by a C-27 homolog present as about 5% of the mixture which was separated from the main $C_{26}$ compound by glc.

*Acetylation of 5*

The alcohol **5** (3.0 mg, 8.1 μmol) was treated with acetic anhydride (0.5 mL) in pyridine (0.5 mL) at 23°C for 18 h. Water (5 mL) was added and the resulting mixture was extracted with chloroform (2 × 5 mL). The chloroform extract was washed with water (5 mL) and dried ($MgSO_4$). The solvent was removed under reduced pressure and the resulting crude product purified by preparative tlc on alumina (toluene/acetone, 4:1) to afford the acetate **6** (3.0 mg, 90%) identical to the naturally occurring compound by chromatographic (tlc, glc) and spectral ($^1H$ nmr, ir, uv, ms) comparison.

*Ozonolysis of 6*

Ozone was bubbled for 20 min through a solution of **6** (5.0 mg, 12 μmol) in 2-propanol (3 mL) at −78°C. Dimethyl sulphide (50 μL, 670 μmol) was added and the resulting solution was warmed to 0°C before a solution (2 mL, 0.1 *M*, 200 μmol) of 2,4-dinitrophenylhydrazine in phosphoric acid and ethanol (12) was added. After standing for 18 h at 23°C the resulting precipitate was collected by filtration, dissolved in chloroform (20 mL), and dried over $MgSO_4$. The crude product obtained by removal of the chloroform was fractionated by preparative tlc on silica gel (toluene/2-propanol, 98:2). One of the fractions obtained ($R_f$ 0.60–0.65) was the 2,4-dinitrophenylhydrazone of isobutyraldehyde (1.2 mg, 42%), identical by tlc, mixture melting point, and all spectral data with an authentic sample.

*Hydrogenation of 5*

A solution of **5** (16.5 mg, 43.2 μmol) in ethyl acetate (5 mL) was hydrogenated at atmospheric pressure over 5% Pd/C (7.2 mg) at 23°C for 19 h. After removal of the catalyst and solvent the crude product was purified by preparative tlc on silica gel (toluene/ethyl acetate, 9:1) to afford a 3:1 mixture (glc) of **7** and **8** as a clear oil (11.4 mg, 68%); ir ($CHCl_3$) $\nu_{max}$: 3600–3400 (O—H), 1705 (C=O) $cm^{-1}$; $^1H$ nmr ($CDCl_3$) $\delta$: 2.0–2.8 (4H, bm, —$CH_2COCH_2$—), 3.4 (1H, m, C-12 H); ms *m/e* (%): 388(1), 370(57), 355(7), 299(28), 272(31), 271(100), 247(28). *Exact Mass* calcd. for $C_{26}H_{44}O_2$: 388.3341; found: 388.3366.

*Jones' oxidation of 5*

A solution of **5** (5.5 mg, 14 μmol) in acetone (1 mL) was treated with 3 drops of Jones' reagent and stirred for 10 min at 23°C. Water (10 mL) was added and the resulting mixture was extracted with chloroform (3 × 10 mL). The chloroform extract was dried over $MgSO_4$ and the solvent removed under reduced pressure. The crude product obtained was purified by preparative tlc on silica gel (toluene/acetone, 85:15) to afford **9** (2.9 mg, 53%); uv (MeOH) $\lambda_{max}$: 244 nm, $\varepsilon$ = 12 000, no change with addition of aqueous NaOH; ir ($CHCl_3$) $\nu_{max}$: 1705, 1660 (C=O), 1620, 1600 (C=C) $cm^{-1}$; $^1H$ nmr ($CDCl_3$) $\delta$: 5.28 (2H, m, —CH=CH—), 6.08 (1H, bs, $W_{1/2}$ = 4 Hz, C-4 H), 6.23 (1H, dd, $J$ = 10, 2 Hz, C-2 H), 6.85 (1H, d, $J$ = 10 Hz, C-1 H); ms *m/e* (%): 380(21), 311(13), 269(28), 259(19), 177(28), 161(43), 147(31), 135(70), 122(29), 121(100). *Exact Mass* calcd. for $C_{26}H_{36}O_2$: 380.2715; found: 380.2726.

*Jones' oxidation of 7 and 8*

The mixture of **7** and **8** (8.0 mg, 20.6 μmol) obtained from the hydrogenation of **5** was oxidized with Jones' reagent as described above. The crude product obtained was purified by preparative tlc on silica gel (toluene/acetone, 9:1) to afford **9** (6.0 mg, 75%); ir ($CHCl_3$) $\nu_{max}$: 1705 $cm^{-1}$; ms, *m/e* (%): 386(100), 371(5), 287(11), 261(16), 247.1686(68) ($M^+$ − side chain − 40 mu, $C_{16}H_{23}O_2$, calcd. 247.1698), 121(12). *Exact Mass* calcd. for $C_{26}H_{42}O_2$: 386.3185; found: 386.3174.

*24-Nor-5β-cholesta-3α,12α,24-triol (15)*

A solution of 5β-cholanic acid-3α,12α-diol diacetate methyl ester (**14**) (269 mg, 0.550 mmol Steraloids) in ether (20 mL) was cooled to 0°C under an atmosphere of nitrogen. A solution of methyllithium (1.7 *M*, 5 mL, 8.5 mmol) in ether was added dropwise over a period of 5 min with stirring. The resulting cloudy solution was stirred at 0°C for 15 min, warmed to 23°C for 15 min, and cooled again to 0°C before the addition of 20 mL of water. Ether was added to bring the volume of the organic phase to 100 mL and this phase was washed with water until neutral to litmus (3 × 5 mL), and dried over $MgSO_4$. Removal of the solvent afforded **15** (221.7 mg, 98%), mp 82–85°C, which was used in the next step without further purification; ir ($CHCl_3$) $\nu_{max}$: 3700–3300 (O—H) $cm^{-1}$, no carbonyl; $^1H$ nmr ($CDCl_3$) $\delta$: 3.55 (1H, m, C-3 H), 3.97 (1H, m, C-12 H); ms *m/e* (%): 388(26), 370(29), 355(13), 352(16), 332(21), 314(56), 273(29), 271(16), 255(58), 97(100). *Exact Mass* calcd. for $C_{26}H_{44}O_2$ ($M^+ - H_2O$): 388.3341; found: 388.3331.

*24-Hydroxy-24-nor-5β-cholesta-3,12-dione (16)*

Jones' reagent was added dropwise with stirring to a solution of the triol **15** (990.7 mg, 0.224 mmol) in acetone (2 mL) until a deep orange colour persisted. After stirring for 15 min water (10 mL) was added and the resulting mixture was extracted with chloroform (3 × 20 mL). The crude product obtained after drying ($MgSO_4$) and solvent removal was purified by preparative tlc on silica gel (toluene/acetone, 4:1) to afford **16** (54.3 mg, 60%), mp 157–158°C; ir ($CHCl_3$) $\nu_{max}$: 3700–3300 (O—H), 1705 (C=O) $cm^{-1}$; ms *m/e* (%): 402(9), 387(15), 384(97), 328(100), 315(16), 297(12), 96(22). *Exact Mass* calcd. for $C_{26}H_{42}O_3$: 402.3134; found: 402.3123.

*$\Delta^{23}$- and $\Delta^{24}$-24-nor-5β-cholesten-3,12-dione (17)*

A solution of **16** (22.5 mg, 56.0 μmol) in glacial acetic acid (2 mL) at 23°C was treated with boron trifluoride etherate (0.5 mL) and the resulting solution was stirred for 1 h before dilution with chloroform (30 mL). Enough aqueous NaOH (1 *M*) was added, with vigorous shaking, to bring the aqueous phase to pH 8. The phases were separated and the organic phase was washed with water (20 mL) and dried over $MgSO_4$. The crude product obtained by removal of the solvent was purified by preparative tlc on silica gel (toluene/acetone, 9:1) to afford the mixture of dehydrated products **17** (13.0 mg, 61%), mp 138–140°C; ir ($CHCl_3$) $\nu_{max}$: 1705 (C=O) $cm^{-1}$, no O—H; $^1H$ nmr ($CDCl_3$) δ: 5.12 (~1–2H, m, olefinic H); ms *m/e* (%): 384(100), 328(24), 315(36), 297(31), 273(26). *Exact Mass* calcd. for $C_{26}H_{40}O_2$: 384.3028; found: 384.3039.

*24-Nor-5β-cholesta-3,12,-dione (13)*

The mixture of olefins **17** (5.7 mg, 15 μmol) was hydrogenated for 18 h at atmospheric pressure over 5% Pd/C (10 mg) in ethyl acetate (5 mL). The crude product obtained after removal of the catalyst and solvent was purified by preparative tlc on silica gel (toluene/acetone, 9:1) to afford the crystalline 5β isomer of **13**, mp 133–134°C; chromatographic (tlc) and spectral data were identical to the mixture of 5α and 5β-**13** obtained from the natural product; glc was identical to the 5β isomer. *Exact Mass* calcd. for $C_{26}H_{42}O_2$: 386.3185; found: 386.3185.

# Synthesis of cedranoid sesquiterpenes. II. Functionalization at carbon 12[1]

PETER YATES AND KENNETH E. STEVENS

*Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1*

Received October 9, 1981

PETER YATES and KENNETH E. STEVENS. Can. J. Chem. **60**, 825 (1982).

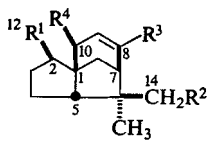
Dimethyl 6,6-dimethyl-7-oxotricyclo[3.2.1.$0^{2,8}$]octane-1,8-dicarboxylate (**6**) undergoes homoconjugate addition with lithium diphenylcuprate to give dimethyl 3-hydroxy-4,4-dimethyl-*exo*-8-phenyl-*cis*-bicyclo[3.3.0]oct-2-ene-1,2-dicarboxylate (**12***a*), which on monodecarboxymethylation, ozonolysis, and esterification with diazomethane gives dimethyl 6,6-dimethyl-7-oxo-*cis*-bicyclo-[3.3.0]octane-1,*exo*-2-dicarboxylate (**15**). Reaction of **6** with diethylaluminum cyanide gives dimethyl *exo*-8-cyano-3-hydroxy-4,4-dimethyl-*cis*-bicyclo[3.3.0]oct-2-ene-1,2-dicarboxylate (**16**), which on hydrolysis and esterification with diazomethane also gives **15**. Sensitized photolysis of dimethyl 5-oxo-6,6-dimethylbicyclo[2.2.2]octa-2,7-diene-2,3-dicarboxylate (**19**) gives dimethyl 4,4-dimethyl-3-oxotricyclo[3.2.1.$0^{2,8}$]oct-6-ene-1,8-dicarboxylate (**20**), which on reduction with lithium in ammonia gives dimethyl 6,6-dimethyl-7-oxobicyclo[3.3.0]oct-3-ene-1,*exo*-2-dicarboxylate (**31**); conversion of **31** to its 2-ene isomer **32** followed by catalytic hydrogenation gives **15** and its *endo*-2 epimer **33**.

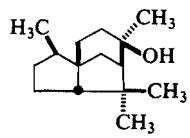
PETER YATES et KENNETH E. STEVENS. Can. J. Chem. **60**, 825 (1982).

Le diméthyl-6,6 oxo-7 tricyclo[3.2.1.$0^{2,8}$] octanedicarboxylate-1,8 de méthyle (**6**) subit une addition homoconjuguée du diphénylcuprate de lithium pour donner l'hydroxy-3 diméthyl-4,4 phényl-8-*exo* bicyclo[3.3.0] octène-2 dicarboxylate-1,2-*cis* de méthyle (**12***a*) qui par monodécarboxyméthylation, ozonolyse et estérification par le diazométhane conduit au diméthyl-6,6 oxo-7 bicyclo[3.2.0] octanedicarboxylate-1,2-*exo* de méthyle (**15**). La réaction de **6** avec du cyanure de diéthylaluminium fournit le cyano-8-*exo* hydroxy-3 diméthyl-4,4 bicyclo[3.3.0] octène-2 dicarboxylate-1,2-*cis* de méthyle (**16**) qui, par hydrolyse et estérification par le diazométhane, conduit aussi à **15**. La photolyse sensibilisée de l'oxo-5 diméthyl-6,6 bicyclo[2.2.2] octadiène-2,7 dicarboxylate-2,3 de méthyle (**19**) fournit le diméthyl-4,4 oxo-3 tricyclo[3.2.1.$0^{2,8}$] octène-6 dicarboxylate-1,8 de méthyle (**20**) qui, par réduction par le lithium dans l'ammoniac, conduit au diméthyl-6,6 oxo-7 bicyclo[3.3.0] octène-3 dicarboxylate-1,2-*exo* de méthyle (**31**); la conversion de **31** dans son isomère ène-2 (**32**), suivie par une hydrogénation catalytique, conduit à **15** et à son épimère 2-*endo* (**33**).

[Traduit par le journal]

The cedranoid sesquiterpenes are a group of naturally occurring compounds and their congeners that have the tricyclo[5.3.1.$0^{1,5}$]undecane skeleton, of which the simplest members are α-cedrene (**1**) and cedrol (**2**) (2).[2] A variety of more highly oxygenated compounds have also been isolated, such as laccishellolic acid (**3**) (4) and shellolic acid (**4**) (5).





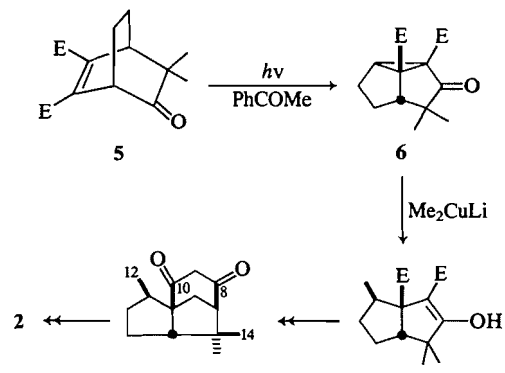
**1** $R^1 = R^3 = CH_3$, $R^2 = R^4 = H$

**3** $R^1 = R^3 = CO_2H$, $R^2 = H$, $R^4 = OH$

**4** $R^1 = R^3 = CO_2H$, $R^2 = R^4 = OH$

**2**

Several total syntheses of compounds **1** and **2** have been achieved (6, 7), but none of compounds **3** and **4**. We have recently designed a new synthesis of (±)-cedrol (**2**) that it was hoped could subsequently be elaborated to provide syntheses of the more highly oxygenated cedranoid sesquiterpenes, including **3** and **4** (1, 8). This synthesis (Scheme 1) has as key steps the photochemical oxa-di-π-rearrangement of the bicyclo[2.2.2]octenone **5** to the tricyclo[3.2.1.$0^{2,8}$]octanone **6** and reaction of lithium dimethylcuprate with the latter to give the homoconjugate addition product **7** [cf. ref. 9]. The bicyclo[3.3.0]octanone **7** was converted in five steps to the β-diketone **8**, which had earlier been prepared by Stork and Clarke by a different route and transformed into cedrol (**2**) (6). The desired elaboration of this approach requires the incorporation of oxygenated functions at C-12 and C-14 in **8** and appropriate manipulations of the ketonic functions at C-8 and C-10. We report now on progress



**5** **6** **8** **7**

SCHEME 1 (E = $CO_2Me$)

[1]For a preliminary account of part of this work, see ref. 1.

[2]At least four systems of numbering of the cedrene skeleton have been used; that in **1** is in accord with the IUPAC rules (3).

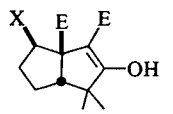
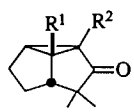
towards the attainment of the first of these objectives.

With the intention of introducing a latent carboxylic acid group in place of the C-12 methyl group of **8**, we first attempted to effect the homoconjugate addition of a vinyl group to **6** by treatment with lithium divinylcuprate reagents. However, the use of a large variety of reagents and conditions that had previously been used for the conjugate addition of a vinyl group to α,β-unsaturated carbonyl compounds (see Experimental) failed to effect homoconjugate addition.[3] Nor could such addition be effected with lithium diisobutylhex-1-enylmethylalanate (12) or with the potassium or thallous derivatives of diethyl malonate (9, 13). Attempted homoconjugate addition of an allyl group with allytrimethylsilane and titanium tetrachloride (14) led instead to homoconjugate addition of chloride ion to give **9**, which showed the typical strong ir bands at 6.06 and 6.21 μm of the enolized β-keto ester system of homoconjugate addition products from **6**. We subsequently found that the same product is formed in the presence of titanium tetrachloride alone. The failure to add an allyl group indicates that, while the ethylenic bond of allyltrimethylsilane may be relatively nucleophilic (15), chloride ion is a much better nucleophile under the conditions used. It is possible that in the case of conjugate addition to α,β-unsaturated ketones (14), conjugate addition of chloride also occurs, but is reversible.



**9** X = Cl, E = $CO_2Me$
**10** X = Br, E = $CO_2Me$



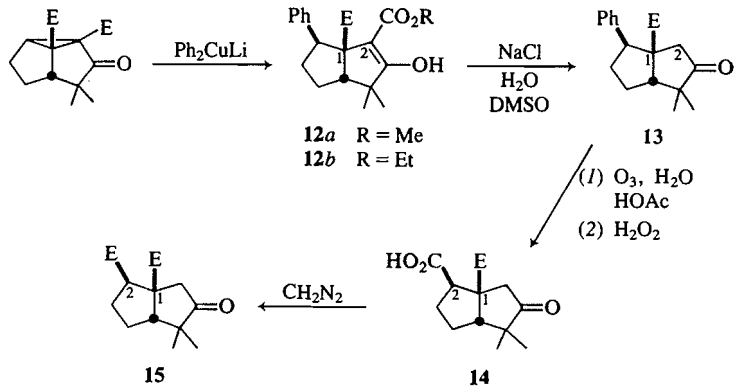
**11***a* $R^1 = (C_6H_5C{\equiv}C)_2COH$, $R^2 = CO_2Me$
**11***b* $R^1 = CO_2Me$, $R^2 = (C_6H_5C{\equiv}C)_2COH$

The recent report (16*a*; see, however, ref. 16*b*) of the homoconjugate addition of Grignard reagents to spiroactivated cyclopropane rings (9) led us to investigate the reaction of **6** with phenylethynylmagnesium bromide in ether. At 2°C a voluminous white precipitate formed immediately and work-up gave two products in approximately equal amounts. When the reaction was conducted at −75°C for 9 hours and then at 2°C for 11 hours, one of these products was formed almost exclusively. This was shown to be a homoconjugate addition product by strong bands in its ir spectrum at 6.06 and 6.19 μm (*vide supra*) and identified as the hydrogen bromide adduct **10**. It was prepared independently by treatment of **6** with hydrogen bromide in dichloromethane. While the other product was not fully characterized, it is tentatively assigned structure **11***a* or **11***b* on the basis of the of the following spectroscopic data and mechanistic considerations. Its ir spectrum with a single band in the carbonyl-stretching region at 5.79 μm suggested that opening of the cyclopropane ring had not occurred; this spectrum also showed a band at 3.07 μm attributable to a strongly hydrogen-bonded hydroxyl group. Its $^1H$ nmr spectrum showed that only one methyl ester group remained (δ 3.67 ppm (s, 3H)) and that two phenyl groups had been incorporated into the molecule. We suggest that the keto and C-1 ester groups or the two ester groups of **6** act as a powerful bidentate ligand and that the precipitate is a magnesium bromide complex of **6** or **10**, either of which could lead to **10** on work-up. As in the precipitation of magnesium bromide from Grignard reagents by dioxane (17), bis(phenylethynyl)magnesium remains in solution and reacts with uncomplexed **6** at 2°C, but not at −75°C. Weight is lent to these suppositions by the observation that treatment of **6** with a solution of bis(phenylethynyl)magnesium, prepared by the addition of dioxane to a solution of phenylethynylmagnesium bromide, at 4°C gives exclusively **11***a* (or **11***b*).

Eventually success was achieved in the introduction of a carboxylic acid function into **6** by the route shown in Scheme 2. Reaction with lithium diphenylcuprate led to homoconjugate addition of a phenyl group to give **12**, whose ir spectrum showed strong bands at 6.09 and 6.25 μm. Life was still not without its complications, however, since the $^1H$ nmr spectrum of this product showed that it was a ~2:1 mixture of the methyl and ethyl esters **12***a* and **12***b* (see Experimental). The ethyl ester **12***b* is considered to be formed by exchange of ethoxide for methoxide in the C-2 ester group of **12***a*; the ethoxide ion most probably has its origin in a slow reaction of phenyllithium with ether, for the phenyllithium was obtained commercially as a solution in ether and benzene (30:70).[4] It is of interest that although reaction of **6** with lithium dimethylcuprate gives, together with the homoconjugate product, small amounts of two stereoisomeric bicyclo[3.2.1]octan-3-ones formed by reduction (8), there

[3]In the course of other work (10) it has recently been observed that lithium divinylcuprate reagents fail to effect conjugate addition of a vinyl group to cholest-4-en-3-one, although this compound undergoes conjugate addition with lithium dimethyl- and diethylcuprate (11).

[4]Compare the slow reaction of *n*-butyllithium with tetrahydrofuran to give butane, ethylene, and the lithium enolate of acetaldehyde (18).



SCHEME 2 (E = $CO_2Me$)

was no evidence for the formation of reduction products in the case of its reaction with lithium diphenylcuprate; this was unexpected since the two cuprates have similar reactivities towards α,β-unsaturated ketones (19). Attempts to separate **12***a* and **12***b* were unsuccessful and the mixture was therefore subjected to monodecarboalkoxylation with sodium chloride in aqueous dimethyl sulfoxide (20) to give the single product **13**. This showed in its ir spectrum a single band in the carbonyl-stretching region at 5.80 μm as expected. Its $^1H$ nmr spectrum showed two one-proton doublets ($J$ = 19 Hz) at δ 2.46 and 3.60 ppm, characteristic of the C-2 protons in this system (cf. the corresponding decarbomethoxylation product from **7**: δ 2.09 (d, 1H) and 3.35 ppm (d, 1H) ($J$ = 20 Hz)); the signal of the methyl ester protons appears at δ 3.21 ppm as a result of shielding of these protons by the phenyl group. This shielding is in accord with the *exo* configuration assigned at C-8 in **12** and **13**, which is also based on analogy with the configuration established at this carbon in **7** (8). Ozonolysis of **13** in aqueous acetic acid followed by oxidative work-up (cf. ref. 21) gave the carboxylic acid **14**, which was characterized as the diester 15. The ir spectrum of this had a single peak in the carbonyl-stretching region at 5.78 μm, and its $^1H$ nmr spectrum included two three-proton singlets at δ 3.67 and 3.71 ppm and two one-proton doublets at δ 2.34 and 3.62 ppm ($J$ = 19 Hz). The *exo* configuration of **14** and **15** at C-2 follows from their formation from **13** and is corroborated by the synthesis of the C-2 epimer of **15** (*vide infra*).

A second route from **6** to **15** is shown in Scheme 3; this process involved homoconjugate addition to **6** and proceeded more expeditiously and in better yield than by the route of Scheme 2. Reaction of **6** with diethylaluminum cyanide in toluene gave the nitrile **16** (cf. ref. 22). The introduction of a nitrile group into the product was signalled by a band at 4.46 μm in its ir spectrum and a singlet at δ 120.0 ppm in its sford $^{13}C$ nmr spectrum. The presence of the enolized β-keto ester was vouchsafed by strong bands at 6.01 and 6.17 μm in their spectrum of the product and a one-proton singlet at δ 10.52 ppm in its $^1H$ nmr spectrum. Attempts to convert **16** directly to **15** led to complex mixtures of products, and this transformation was therefore carried out in two steps. Decarboxylation as before gave **17** and treatment of this with boiling methanol containing sulfuric acid (cf. ref. 23) gave **15** as the major product, identical with the product obtained by the route in Scheme 2. A minor product was also formed in this reaction and is assigned structure **18** on the basis of its origin and its spectra. Its ir spectrum showed bands at 5.62 (m) and 5.79 (s) μm assigned to the carbonyl-stretching vibrations of the five-membered cyclic imide and five-membered cyclic ketonic groups together with an N—H stretching band at 3.02 μm. Its $^1H$ nmr spectrum showed two one-proton doublets at δ 2.38 and 3.22 ppm ($J$ = 19 Hz) indicating that the bicyclo[3.3.0]-octan-3-one system was intact, and a broad one-proton singlet at δ 8.69 ppm (absent after $D_2O$ treatment) confirming the presence of an NH group; this spectrum also revealed the absence of methoxyl protons. The conversion of **17** to **15** and **18** most probably occurs by the pathways shown in Scheme 4 (cf. ref. 24).

A third approach to **15** was undertaken in an entirely different fashion.[5] Irradiation of the dienone **19**, the precursor of **5** (8), with acetophenone as photosensitizer gave one major and two minor products (Scheme 5). The major product was identified by its spectra and further transformations (*vide infra*) as the di-π-methane rearrangement product **20**. Its ir spectrum showed a single band in the carbonyl-stretching region at 5.77 μm. Its $^1H$

[5]We thank Miss Shirley Stiver for suggesting this route.

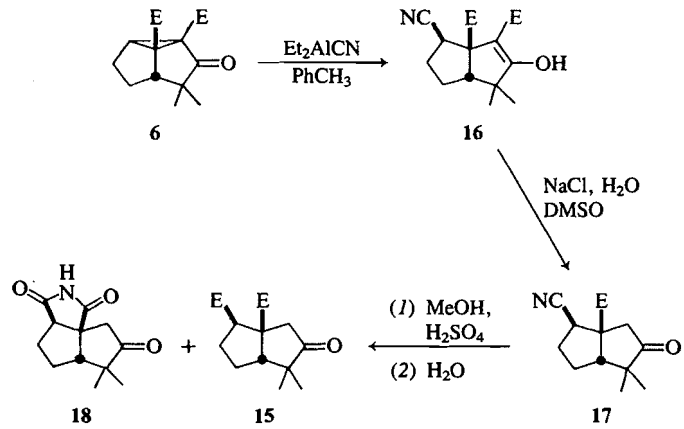
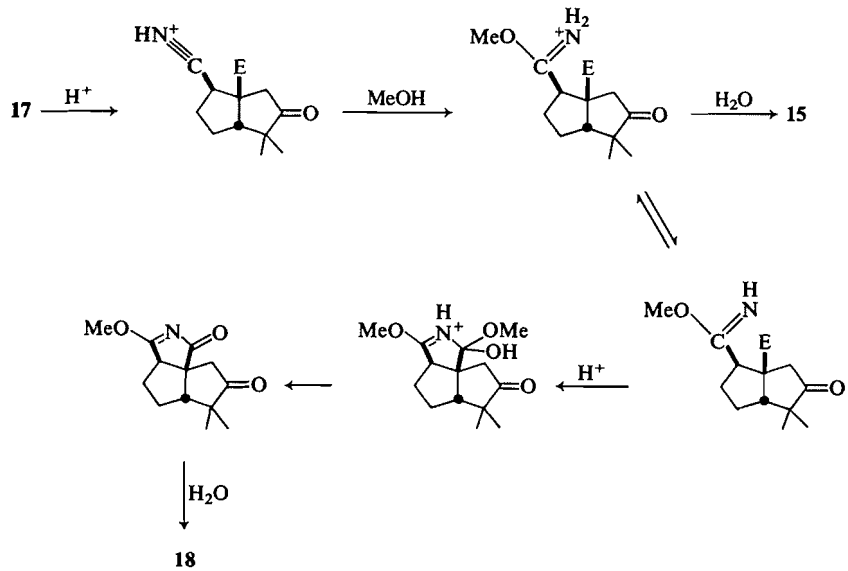
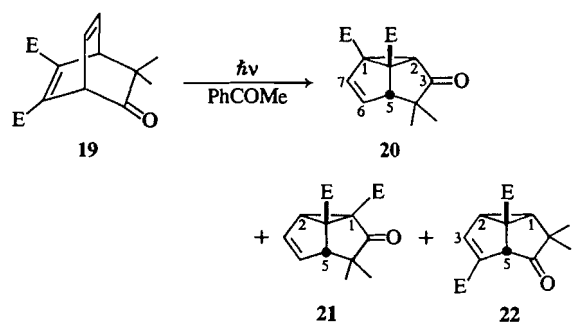


SCHEME 3 (E = $CO_2Me$)



SCHEME 4 (E = $CO_2Me$)

nmr spectrum (in deuteriochloroform) showed two two-proton multiplets at δ 3.5–3.7 and 5.7–6.0 ppm; the former is assigned to the C-2 and C-5 protons, and the latter to the olefinic protons. In benzene–deuteriochloroform the higher field multiplet was resolved into a one-proton singlet at δ 3.62 ppm, assigned to the C-2 proton, and a one-proton doublet at δ 3.38 ppm ($J$ = 2.5 Hz), assigned to the C-5 proton; the lower field multiplet was resolved into a one-proton doublet at δ 5.74 ppm ($J$ = 5.5 Hz), assigned to C-7 and a one-proton doublet of doublets at δ 5.51 ppm ($J$ = 5.5, 2.5 Hz), assigned to C-6. The observed coupling constants are in excellent agreement with those observed for a C-3 methylene analogue of **20** (25). One of the minor products is considered to arise by an oxa-di-π-methane rearrangement in analogous fashion to the formation of **6** and to have structure **21**. Its ir and $^1H$ nmr spectra were similar to those of **20**, the latter spectrum (in deuteriochloroform) showing two two-proton multiplets at δ 3.4–3.7 ppm and



SCHEME 5 (E = $CO_2Me$)

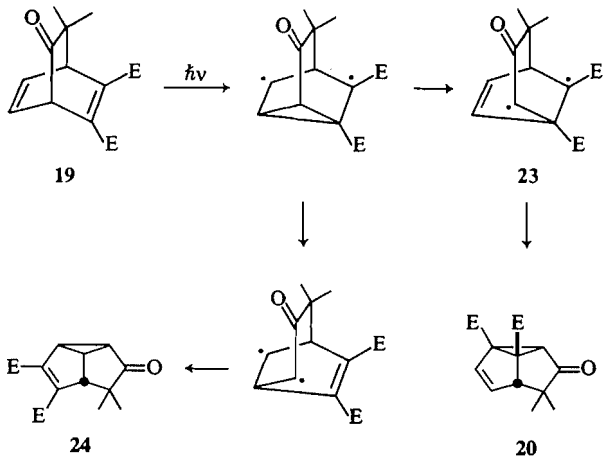
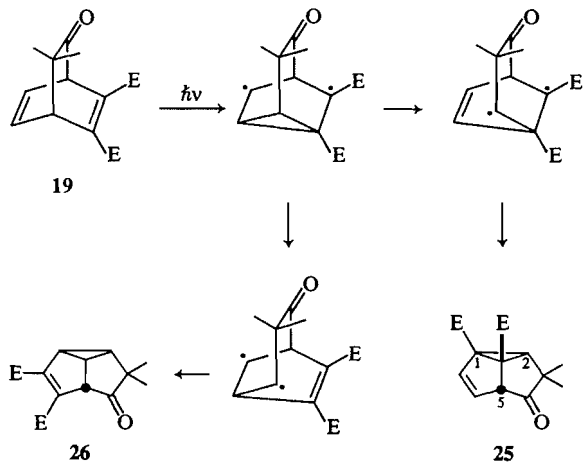


SCHEME 6 (E = $CO_2Me$)



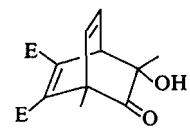
SCHEME 7 (E = $CO_2Me$)

5.6–5.95 ppm.[6] We shall return subsequently to the proposed structure **22** of the other minor product.

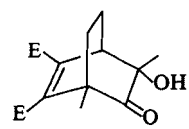
Compound **19** is capable of giving four different di-π-methane rearrangement products, **20** and **24–26** (Schemes 6 and 7), and two different oxa-di-π-methane rearrangement products, **21** and **28** (Schemes 8 and 9) (26).

The preference of bicyclo[2.2.2]octadienone derivatives to undergo di-π-methane rather than oxa-di-π-methane rearrangements has been observed previously, but there has been little discussion concerning its origin. The suggestion has been made that this is due to preemptive homoconjugation of the diene moiety, based on the observation that the $n \rightarrow \pi^*$ absorption band of **29** is lower in intensity than that of **30** (27). It may be noted that benzobicyclo[2.2.2]octadienone derivatives, in which the homoconjugate interaction between the aromatic π system and the olefinic double bond is expected to be reduced relative to that in bicyclo[2.2.2]octadienone derivatives without the benzene ring, undergo oxa-di-π-methane rearrangement on triplet-sensitized irradiation (28). The regioselectivity of both the di-π-methane rearrangement of **19** leading to **20** and its oxa-di-π-methane rearrangement leading to the minor product **21** may be interpreted in terms of the greater stabilization of diradicals **23** (Scheme 6) and **27** (Scheme 8) relative to the related diradicals that lead to other di-π-methane and oxa-di-π-methane rearrangement products, respectively. Similar directing influences have been proposed to account for the observed regioselectivity in di-π-methane rearrangements of 5,6-benzo-2-azabicyclo[2.2.2]-5,7-dien-3-one derivatives (29; cf. also ref. 25).

The spectra of the other minor product did not correspond with expectation for any of the other possible primary products **24–26** and **28**. Its ir spectrum showed bands at 5.81 (s) and 6.19 (w) μm suggestive of an α,β-unsaturated carbonyl group. Its $^1H$ nmr spectrum showed a one-proton doublet ($J$ = 2.5 Hz) at δ 6.83 ppm: this proton is coupled with a proton that gives rise to a doublet of doublets at δ 2.99 ppm ($J$ = 2.5, 7.5 Hz), which is also coupled with a proton giving rise to a doublet at δ 2.69 ppm ($J$ = 7.5 Hz); in addition a one-proton singlet appeared at δ 4.29 ppm. On the basis of these data this product is considered to have structure **22**, with assignment of the proton signals referred to above to the C-3, C-2, C-1, and C-5



29



30

protons, respectively. This product may arise from a secondary photochemical reaction of the primary product **20** as shown in Scheme 10. A closely related thermal transformation has been reported (30).

We return now to the conversion of **20** to **15**. This was effected by the route shown in Scheme 11. Reduction with lithium in liquid ammonia and ether cleaved the C-1—C-2 bond to give **31**; the crude product was oxidized with sodium dichromate and sulfuric acid since some reduction of the ketonic group also occurred. The product was obtained as a single epimer at C-2, which is considered to be the

[6]This structure is preferred over structure **25** (*vide infra*), because the latter would be expected to give rise in its $^1H$ nmr spectrum to C-2 and C-5 proton signals with more widely separated chemical shifts, with the C-2 proton signal at higher field and the C-5 proton signal at lower field.

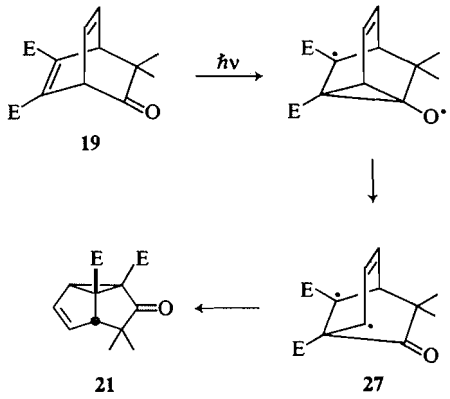
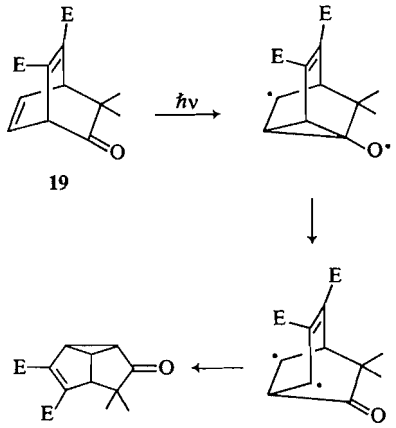
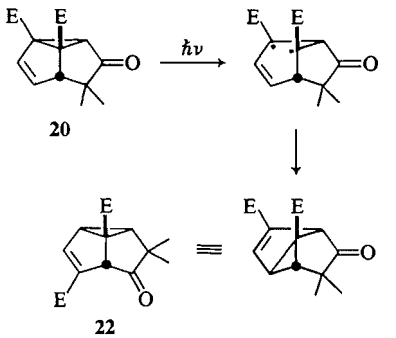


SCHEME 8 (E = $CO_2Me$)



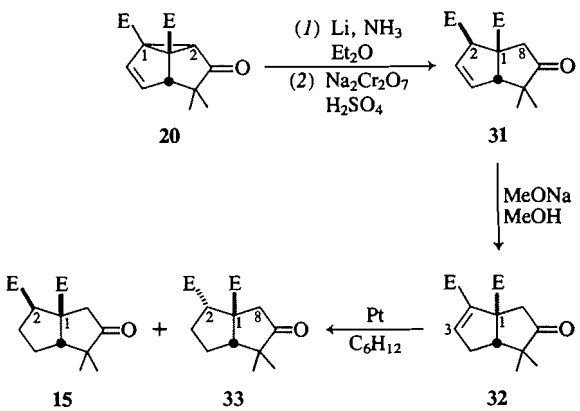
SCHEME 9 (E = $CO_2Me$)



SCHEME 10 (E = $CO_2Me$)

more stable *exo* epimer **31**. Its ir spectrum showed a carbonyl-stretching band at 5.78 μm and its $^1H$ nmr spectrum showed two one-proton doublets ($J$ = 18.5 Hz) at δ 2.20 and 3.02 ppm, characteristic of the C-8 protons in this system, and a two-proton multiplet at δ 5.8 ppm arising from the olefinic protons. Treatment of **31** with methanolic sodium methoxide gave the isomeric α,β-unsaturated ester **32**, whose ir spectrum included a strong band at 5.83 μm and a weak band at 6.13 μm. Its $^1H$ nmr spectrum showed a one-proton triplet ($J$ = 2 Hz) at δ 6.89 ppm, assigned to the C-3 proton. Catalytic hydrogenation of **32** over palladium/carbon in methanol at atmospheric pressure gave exclusively **15**, identical with the diester obtained by the routes in Schemes 2 and 3. Hydrogenation over platinum in cyclohexane gave mixtures of **15** and a new compound, assigned the C-2 epimeric structure **33**.[7] The reaction was exceedingly capricious and the product mixture had variable ratios of **33** and **15**, ranging up to 19:1. The ir and $^1H$ nmr spectra of the two epimers were very similar; a critical difference in the latter spectra was that in the spectrum of **33** the lower field doublet of the two one-proton doublets ($J$ = 19 Hz) at δ 2.14 and 3.18 ppm arising from the C-8 protons exhibited a further small coupling ($J \sim 1$ Hz). This signal is assigned to the *exo* C-8 proton and the additional coupling is attributed to $^4J$ long range coupling with the proton at C-2. Examination of molecular models shows that the "W" relationship between the *exo* C-8 and C-2 protons required for such $^4J$ coupling (31) is possible only if the C-2 proton has the *exo* configuration, i.e., the ester group at C-2 has the *endo* configuration. Molecular models also show that delivery of hydrogen to **32** would be expected to occur from the less hindered *exo* face, leading to **33**. The exclusive formation of **15** in some cases and its formation in variable amounts in others may be due to epimerization of **33** by adventitious acid or base or by the catalyst itself (32).

We have thus attained our objective of functionalization of the carbon designed to become *exo* C-12 in the cedranoid sesquiterpenes by three different methods. The last method has provided in



SCHEME 11 (E = $CO_2Me$)

[7]This product was not entirely freed of **15** and was obtained as a solid with a wide melting range.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

addition a potential route to *endo* C-12 functionalized cedranoid sesquiterpenes, which also have been obtained from natural sources.

## Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The ir spectra were taken in $CHCl_3$ solution and the $^1H$ and $^{13}C$ nmr spectra in $CDCl_3$ solution. Analytical thin layer chromatography was carried out on 0.25 mm silica gel Q6-F plates from Quantum Industries. Preparative thin layer chromatography was carried out on 20 × 20 cm plates coated with 0.5 mm, 1 mm, or 2 mm silica gel layers (Merck Kieselgel 60 $PF_{254}$ containing gypsum). Medium pressure liquid chromatography was carried out on a Merck silica gel 60 prepacked column (Size B) operated at a pressure of ~5 psi. Solutions were dried over magnesium sulfate and concentrated on a Büchi "Rotovapor < R >" rotary evaporator under water aspirator pressure. Solvents used for work-ups and chromatography were either distilled or were of ACS Reagent Grade quality.

*Attempted homoconjugate addition of an alkenyl group to dimethyl 6,6-dimethyl-7-oxotricyclo[3.2.1.0$^{2,8}$]octane-1,8-dicarboxylate (**6**)*[8]

*(i). With lithium divinylcuprate reagents*

A solution of vinyllithium in tetrahydrofuran (THF) (1.56 *M*; 0.70 mL, 1.09 mmol) was added to a cold (−45°C), stirred slurry of cuprous iodide (109 mg, 0.57 mmol) in ether (4 mL) containing isopropyl sulfide (260 μl, 212 mg, 1.79 mmol) under argon (33). The mixture was warmed to −15°C to −20°C for 15 min, and then rapidly cooled to −75°C, producing a light grey-green solution containing some black solid. A solution of **6** (8) (99 mg, 0.37 mmol) in ether (1 mL) was added. The mixture was stirred at −75°C for 10 min and at 4°C overnight, and then 50% saturated aqueous $NH_4Cl$ (10 mL) was added. The layers were separated, and the aqueous phase was extracted with ether (2 × 10 mL). The combined organic solutions were washed with saturated aqueous $NH_4Cl$ (10 mL), dried, and concentrated to give a yellow oil (68 mg). No vinyl proton signals were apparent in the $^1H$ nmr spectrum of this material, which consisted mostly of unconsumed **6**. Attempted reaction in tetrahydrofuran produced the same result.

The following reagents (34) also failed to effect homoconjugate addition of a vinyl group to **6**: $LiCu(CH{=}CH_2)$ in ether or THF, $LiCu(CH{=}CH_2)_2$ in ether or $THF/(CH_3)_2S$, $LiCu(CH{=}CH_2)_2$ in ether/$(n\text{-}C_4H_9)_3P$, $LiCu(CH{=}CH_2)_2{\cdot}P(n\text{-}C_4H_9)_3$ in ether or THF/pentane, $LiCu[C{\equiv}CC(CH_3)_2OCH_3](CH{=}CH_2)$ in ether or THF, $LiCu[C{\equiv}CCH_2N(CH_3)_2](CH{=}CH_2)$ in triethylamine, $LiCu(CH_3)(CH{=}CH_2)$ in ether or THF, $CH_2{=}CHMgBr/CuI$ in THF, $(CH_2{=}CH)_4(CH_3)Cu_3Mg_2Br_2$ in THF.

*(ii). With lithium diisobutylhex-1-enylmethylalanate*

A solution of diisobutylaluminum hydride in toluene (25% by weight; 265 μL, 0.42 mmol) was added to a stirred solution of 1-hexyne (48 μL, 34 mg, 0.41 mmol) in toluene (5.0 mL) under nitrogen at room temperature. The resulting solution was warmed to 40–60°C for 45 min and then cooled to 0°C. A solution of methyllithium – lithium bromide complex in ether (1.33 *M*; 310 μL, 0.41 mmol) was added, producing a white gelatinous precipitate and a colorless solution. The mixture was stirred at 0°C for 20 min and was then allowed to warm to room temperature. A solution of **6** (100 mg, 0.38 mmol) in toluene (10 mL) was added, and the mixture was stirred at room temperature for 22 h. Ice (~15 g) was added, followed by aqueous 10% HCl (10 mL). The mixture was stirred for 1 h, the layers were separated, and the aqueous phase was extracted with ether (2 × 10 mL). The organic phases were combined, washed with saturated aqueous NaCl (10 mL), dried, and concentrated to give a yellow oil (97 mg), which was found to be **6** almost exclusively.

*Reaction of **6** with titanium tetrachloride. Formation of dimethyl* exo*-8-chloro-3-hydroxy-4,4-dimethyl-*cis*-bicyclo[3.3.0]oct-2-ene-1,2-dicarboxylate (**9**)*[8]

Titanium tetrachloride (100 μL, 0.91 mmol) was added to a stirred solution of **6** (202 mg, 0.76 mmol) in dichloromethane (4.0 mL) under nitrogen. The solution was stirred for 30 min, remaining homogeneous but gradually turning deep red. Saturated aqueous $NH_4Cl$ (10 mL) was added, and the resulting mixture was extracted with ether (2 × 10 mL). The combined ethereal extracts were dried and concentrated to give **9** (212 mg, 0.70 mmol, 92%) as a pale yellow powder. Crystallization from pentanes gave large, white crystals, mp 102–104°C; ir $\lambda_{max}$: 5.80, 6.06, 6.21 μm; $^1H$ nmr δ: 1.08 (s, 3H), 1.12 (s, 3H), 1.2–2.3 (m, 4H), 2.7–3.1 (m, 1H), 3.65 (s, 3H), 3.75 (s, 3H), 4.2–4.5 (m, 1H), 11.93 (s, 1H); ms *m/e*: 304 (3), 303 (*M* + 1; 3), 302 (8). *Anal.* calcd. for $C_{14}H_{19}O_5Cl$: C 55.54, H 6.33, Cl 11.71; found: C 55.70, H 6.44, Cl 11.72.

Treatment of **6** with allyltrimethylsilane and titanium tetrachloride in dichloromethane (14) gave **9** in good yield as the only product.

*Reaction of **6** with phenylethynylmagnesium bromide. Formation of **10** and **11**a or **11**b*[8]

A solution of ethylmagnesium bromide in ether (1.75 *M*; 240 μL, 0.42 mmol) was added to a stirred solution of phenylacetylene (46 μL, 0.42 mmol) in ether (2.0 mL) under nitrogen. The clear homogeneous solution was stirred at room temperature for 30 min and then cooled to 2°C. A solution of **6** (100 mg, 0.38 mmol) in ether (1.0 mL) was added, producing a large amount of white precipitate. The mixture was stirred for 1 h at 2°C, after which aqueous 10% HCl (10 mL) was added. The resulting mixture was shaken with ether (20 mL), and the ethereal layer was washed with saturated aqueous NaCl (10 mL), dried, and concentrated to give a yellow oil (122 mg). The $^1H$ nmr spectrum of this oil showed it to contain phenylacetylene and a ~1:1 mixture of **10** and **11***a* or **11***b* (*vide infra*).

*Reaction of **6** with hydrogen bromide. Formation of dimethyl* exo*-8-bromo-3-hydroxy-4,4-dimethyl-*cis*-bicyclo[3.3.0]-oct-2-ene-1,2-dicarboxylate (**10**)*

Anhydrous hydrogen bromide was bubbled slowly into a cold (0°C), stirred solution of **6** (419 mg, 1.58 mmol) in dichloromethane (20 mL). After 2.5 h analytical thin layer chromatography indicated that no **6** remained. The solution was poured onto ice (~40 g). When all the ice had melted the layers were separated, and the aqueous phase was extracted with dichloromethane (2 × 10 mL). The combined organic solutions were washed with water (10 mL), saturated aqueous $NaHCO_3$ (10 mL), and saturated aqueous NaCl (10 mL). They were dried and concentrated to give a white powder (508 mg). Crystallization from pentanes – ethyl acetate (2:1 v/v) gave **10** (397 mg, 1.14 mmol, 72%) as white crystals, mp 112.5–115.5°C; ir $\lambda_{max}$: 5.80, 6.06, 6.19 μm; $^1H$ nmr δ: 1.12 (s, 3H), 1.16 (s, 3H), 1.3–2.5 (m, 4H), 2.75–3.15 (m, 1H), 3.74 (s, 3H), 3.83 (s, 3H), 4.25–4.60 (m, 1H), 11.02 (s, 1H); $^{13}C$ nmr δ: 19.9 (q), 27.4 (t), 27.9 (q), 38.1 (t), 44.3 (s), 51.3 (q), 52.0 (q), 55.1 (d), 56.6 (d), 65.3 (s), 99.4 (s), 170.8 (s), 173.7 (s), 182.4 (s); ms *m/e*: 348 (1), 346 (1). *Anal.* calcd. for $C_{14}H_{19}O_5Br$: C 48.43, H 5.52, Br 23.01; found: C 48.41, H 5.52, Br 23.01.

*Reaction of **6** with bis(phenylethynyl)magnesium. Formation of **11**a or **11**b*[8]

Dioxane (0.8 mL, 9.38 mmol) was added to a solution of phenylethynylmagnesium bromide prepared by the reaction of a

[8]These experiments were conducted under rigorously anhydrous conditions under a positive pressure of argon or nitrogen.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

solution of ethylmagnesium bromide in ether (0.81 *M*; 11.2 mL, 9.07 mmol) with a solution of phenylacetylene (1.0 mL, 9.11 mmol) in ether (20 mL) under nitrogen. After 30 min the mixture was filtered under nitrogen through a sintered glass frit. The filtrate was titrated as 0.09 *M* in bis(phenylethynyl)magnesium.

A solution of **6** (50 mg, 0.19 mmol) was added with stirring to this solution (2.5 mL, 0.23 mmol), cooled to 4°C under nitrogen. After 4 h aqueous 10% HCl (10 mL) was added, and the resulting mixture was washed with ether (20 mL). The organic layer was washed with saturated aqueous NaCl (10 mL), dried, and concentrated to give a yellow oil (65 mg). This contained only a small amount of phenylacetylene, little or no **6**, and a single major product tentatively identified as **11***a* or **11***b*; ir $\lambda_{max}$: 3.07 (m), 5.79 μm; $^1$H nmr δ: 0.94 (s, 3H), 1.39 (s, 3H), 3.67 (s, 3H), 6.85–7.64 (m, > 10H).

*Methyl 4,4-dimethyl-3-oxo-*exo*-8-phenyl-*cis*-bicyclo[3.3.0]-octane-1-carboxylate (**13**)*

A solution of phenyllithium in ether–benzene (30:70 v/v) (1.9 *M*; 12.0 mL, 22.8 mmol) was added over ~20 min to a cold (5°C), stirred slurry of cuprous iodide (2.18 g, 11.4 mmol) in ether (20 mL) under argon.[8] Stirring for 1 h at 0–5°C gave a homogeneous dark green solution of lithium diphenylcuprate. A solution of **6** (1.00 g, 3.76 mmol) in ether (15 mL) was added and stirring was continued for 4 h. Aqueous 10% HCl (25 mL) was added to the cold solution, and the resulting mixture was stirred for a further 30 min and then suction-filtered. The layers of the filtrate were separated and the aqueous phase was extracted with ether (3 × 10 mL). The organic phases were combined and washed with saturated aqueous $NaHCO_3$ (10 mL), 1 *M* aqueous $Na_2S_2O_3$ (10 mL), and saturated aqueous $NH_4Cl$ (10 mL) made slightly basic by the addition of concentrated aqueous $NH_3$. The organic solution was dried and concentrated to give a yellow oil (1.76 g). The $^1$H nmr spectrum of this material included two singlets at δ 11.2 and 11.4 ppm, in a ratio of ~2:1, which are assigned to the enolic protons of **12***a* and **12***b*, respectively. This spectrum also showed a singlet at δ 3.18 ppm, assigned to the C-1 carbomethoxy groups of both **12***a* and **12***b*, a singlet at δ 3.78 ppm, assigned to the C-2 carbomethoxy group of **12***a*, and a quartet ($J$ = 7 Hz) at δ 4.25 ppm, assigned to the carboethoxy group of **12***b*. The ir spectrum of this crude product showed strong bands at 5.83, 6.09, and 6.25 μm.

This material was stirred and heated (96°C) in dimethyl sulfoxide (8 mL) containing water (500 μL, ~27.8 mmol) and sodium chloride (413 mg, 7.1 mmol) for 6 h. The mixture was allowed to cool to room temperature and was then diluted with water (20 mL). The resulting solution was extracted with ether (4 × 10 mL). The ethereal extracts were combined, washed with water (5 × 10 mL), dried, and concentrated to leave a yellow solid (1.22 g). Crystallization from ether gave **13** (521 mg); medium pressure liquid chromatography of the mother liquors with hexanes – ethyl acetate (7:1 v/v) as eluent gave a further quantity of **13** (175 mg; total: 696 mg, 2.43 mmol, 65% from **6**). Further recrystallizations from 10% ethyl acetate – pentanes gave **13**, mp 125–127°C; ir $\lambda_{max}$: 5.80 μm; $^1$H nmr δ: 1.02 (s, 3H), 1.08 (s, 3H), 1.2–2.5 (m, 5H), 2.46 (d, $J$ = 19 Hz, 1H), 2.8–3.2 (m, 1H), 3.21 (s, 3H), 3.60 (d, $J$ = 19 Hz, 1H), 7.21 (s, 5H); $^{13}$C nmr δ: 18.9 (q), 27.3 (q), 29.7 (t), 31.3 (t), 46.4 (t), 49.0 (s), 51.7 (q), 57.2 (s), 57.8 (d), 59.9 (d), 127.0 (d), 127.6 (d), 128.1 (d), 139.6 (s), 175.8 (s), 219.9 (s); ms *m/e*: 286 (62). *Anal.* calcd. for $C_{18}H_{22}O_3$: C 75.50, H 7.74; found: C 75.27, H 7.77.

*Dimethyl 6,6-dimethyl-7-oxo-*cis*-bicyclo[3.3.0]octane-1,*exo*-2-dicarboxylate (**15**)*

Ozonized oxygen was bubbled through a solution of **13** (207 mg, 0.72 mmol) in glacial acetic acid (21.5 mL) and water (3.5 mL) for 3 h at room temperature. The solution eventually acquired a very faint blue color. It was allowed to stand at room temperature for 2 h, treated with 30% hydrogen peroxide (0.5 mL), and then allowed to stand at room temperature overnight. The solvents were removed by distillation (0.5 Torr) at room temperature, and the residue was dissolved in a mixture of ether (20 mL) and ethyl acetate (10 mL). The solution was extracted with saturated aqueous $NaHCO_3$ (3 × 10 mL). The basic extracts were combined, and made strongly acidic by the addition of concentrated $H_2SO_4$, and extracted with ethyl acetate (3 × 10 mL). The latter extracts were combined, washed with saturated aqueous NaCl, dried, and concentrated to give a colorless oil (130 mg). Molecular distillation (100°C/0.1 Torr) gave **14** (85 mg, 0.33 mol, ~46%) as a colorless oil containing trace impurities; ir $\lambda_{max}$: 2.7–4.0 (br), 5.73 μm; $^1$H nmr δ: 1.02 (s, 3H), 1.08 (s, 3H), 1.6–3.0 (m, 6H), 2.35 (d, $J$ = 19.5 Hz, 1H), 3.59 (d, $J$ = 19.5 Hz, 1H), 3.70 (s, 3H), 10.80 (br s, 1H); $^{13}$C nmr δ: 19.6 (q), 27.3 (q), 28.9 (t), 29.2 (t), 46.1 (t), 48.6 (s), 52.5 (q), 54.2 (s), 57.5 (d), 58.5 (d), 176.0 (s), 178.5 (s), 220.2 (s).

Ethereal diazomethane was added to a cold (0°C) stirred solution of crude **14** (72 mg, ~0.28 mmol) in methanol (5 mL) until the yellow color of the reagent persisted. The solution was allowed to stand at room temperature until all the diazomethane had evaporated. Concentration of this solution gave **15** (76 mg, ~0.28 mmol, ~100%). Preparative thin layer chromatography with elution with 2:1 cyclohexane – ethyl acetate ($R_f$ 0.46), followed by sublimation (70°C/0.05 Torr), and crystallization from ethyl acetate – pentanes gave **15** as a white solid, mp 63–65°C; ir $\lambda_{max}$: 5.78 μm; $^1$H nmr δ: 1.04 (s, 3H), 1.09 (s, 3H), 1.3–2.4 (m, 4H), 2.34 (d, $J$ = 19 Hz, 1H), 2.4–3.0 (m, 2H), 3.62 (d, $J$ = 19 Hz, 1H), 3.67 (s, 3H), 3.71 (s, 3H); $^{13}$C nmr δ: 19.6 (q), 27.3 (q), 29.0 (t), 29.4 (t), 46.2 (t), 48.5 (s), 51.8 (s), 52.4 (q), 54.1 (s), 57.7 (d), 58.4 (d), 172.7 (s), 176.0 (s), 219.6 (s); ms *m/e*: 268 (13). *Anal.* calcd. for $C_{14}H_{20}O_5$: C 62.67, H 7.51; found: C 62.85, H 7.59.

*Dimethyl* exo*-8-cyano-3-hydroxy-4,4-dimethyl-*cis*-bicyclo-[3.3.0]oct-2-ene-1,2-dicarboxylate (**16**)*[8]

A solution of diethylaluminum cyanide in toluene (1.57 *M*; 4.8 mL, 7.54 mmol) was added by means of a syringe equipped with a wide bore needle to **6** (995 mg, 3.74 mmol) in a round-bottomed flask equipped with a magnetic stirring bar, septum, and nitrogen inlet. The resulting solution was stirred at room temperature for exactly 2 h. It was then poured cautiously into a mixture of aqueous 10% HCl (50 mL) and ice (50 g). The resulting mixture was stirred for 1 h and extracted with ether (3 × 20 mL). The combined organic extracts were washed with saturated aqueous NaCl (10 mL), dried, and concentrated to give a white powder. Crystallization from ethyl acetate gave **16** (609 mg, 2.08 mmol, 56%). Further recrystallization gave white crystals, mp 135–137.5°C; ir $\lambda_{max}$: 4.46 (w), 6.01, 6.17 μm; $^1$H nmr δ: 1.12 (s, 3H), 1.17 (s, 3H), 1.30–3.05 (m, 6H), 3.79 (s, 3H), 3.83 (s, 3H), 10.52 (s, 1H); $^{13}$C nmr δ: 19.7 (q), 28.2 (q), 29.1 (t), 32.6 (t), 40.1 (d), 44.4 (s), 51.4 (q), 52.5 (q), 58.6 (d), 61.8 (s), 100.2 (s), 120.0 (s), 169.7 (s), 173.9 (s), 181.0 (s); ms *m/e*: 294 (*M* + 1; 7), 293 (9). *Anal.* calcd. for $C_{15}H_{19}O_5N$: C 61.42, H 6.53, N 4.78; found: C 61.32, H 6.49, N 4.69.

*Methyl* exo*-8-cyano-4,4-dimethyl-3-oxo-*cis*-bicyclo[3.3.0]-octane-1-carboxylate (**17**)*

A mixture of **16** (303 mg, 1.03 mmol) and NaCl (86 mg, 1.47 mmol) in dimethyl sulfoxide containing water (175 μL, 9.72 mmol) was stirred and heated (94°C) under nitrogen for 5 h. After cooling, the mixture was extracted with ether (30 mL), and the extract was washed with water (4 × 10 mL). The ethereal solution was dried and concentrated. The residual oil was molecularly distilled (107°C/0.025 Torr) to give **17** (166 mg, 0.71 mmol, 69%) as a colorless, viscous oil; ir $\lambda_{max}$: 4.46 (w), 5.85 μm; $^1$H nmr δ: 1.06 (s, 6H), 1.25–2.35 (m, 4H), 2.25 (d, $J$ = 19.5 Hz, 1H), 2.55–3.1 (m, 2H), 3.62 (d, $J$ = 19.5 Hz, 1H), 3.91 (s, 3H);

*Reaction of* ***17*** *with methanol and concentrated sulfuric acid. Formation of* ***15*** *and* ***18***

A mixture of **17** (197 mg, 0.84 mmol), methanol (16 mL), and concentrated $H_2SO_4$ (5.4 mL) was stirred and heated (90°C) for 26 h under nitrogen. After the mixture had cooled to room temperature, water (20 mL) was added and the methanol was removed by distillation at reduced pressure (15 Torr). The residue was extracted with ether (5 × 10 mL). The combined ethereal extracts were washed with saturated aqueous $NaHCO_3$ (10 mL) and saturated aqueous NaCl (10 mL), dried, and concentrated to give a colorless oil (136 mg). Repeated extraction of the aqueous phases with ether gave an additional quantity of crude product (31 mg). Crystallization from a mixture of toluene and pentanes gave crude **18** (19 mg, 0.09 mmol, 11%). Further crystallization gave pure **18**, mp 153.5–154.5°C; ir $\lambda_{max}$: 3.02 (m), 5.62 (m), 5.79, 7.46 (m), 8.61 (m) μm; $^1$H nmr δ: 1.06 (s, 3H), 1.29 (s, 3H), 1.6–2.3 (m, 4H), 2.38 (d, $J$ = 19 Hz, 1H), 2.5–3.1 (m, 2H), 3.22 (d, $J$ = 19 Hz, 1H), 8.69 (br s, 1H); ms *m/e*: 221 (45). *Mol. Wt.* calcd. for $C_{12}H_{15}O_3N$: 221.1052; found (ms): 221.1048.

Concentration of the original mother liquor followed by molecular distillation (90°C/0.05 Torr) gave **15** (92 mg, 0.34 mmol, 41%), mp 63–65°C, whose spectra were identical with those of the sample of **15** prepared from **13** (*vide supra*).

*Sensitized photolysis of* ***19****. Formation of dimethyl 4,4-dimethyl-3-oxotricyclo[3.2.1.0$^{2,8}$]oct-6-ene-1,8-dicarboxylate (****20****), 21, and 22*

A solution of **19** (1.10 g, 4.17 mmol) in acetophenone (freshly distilled; 110 mL) was degassed with nitrogen for 3 h. The solution was then irradiated in a Rayonet–Srinivasan–Griffin Photochemical Reactor equipped with eleven low pressure 350 nm RPR lamps for 34 h. The solvent was removed by distillation at 0.25 Torr. The oily residue was chromatographed (medium pressure liquid chromatography with hexanes – ethyl acetate (5:1 v/v) as eluent; fraction size ~10 mL) to give:

| | | |
|---|---|---|
| fraction | 24 | **21** (20 mg, 0.08 mmol, 2%) |
| | 25 | **20** and **21** |
| | 26–30 | **20** (540 mg, 2.05 mmol, 49%) |
| | 31–33 | **20** and **22** |
| | 34–37 | **22** (52 mg, 0.20 mmol, 5%) |

Samples of compounds **20–22** for analysis were recrystallized from ethyl acetate – hexanes.

Compound **20**, mp 84–85°C; ir $\lambda_{max}$: 5.77 μm; $^1$H nmr δ: 0.95 (s, 3H), 1.27 (s, 3H), 3.5–3.7 (m, 2H), 3.80 (s, 6H), 5.7–6.0 (m, 2H); δ ($C_6H_6$/$CDCl_3$): 0.78 (s, 3H), 1.12 (s, 3H), 3.38 (d, $J$ = 2.5 Hz, 1H), 3.48 and 3.50 (two s, 6H), 3.62 (s, 1H), 5.51 (dd, $J$ = 5.5, 2.5 Hz, 1H), 5.74 (d, $J$ = 5.5 Hz, 1H); $^{13}$C nmr δ: 17.9 (q), 25.4 (q), 47.7 (d), 52.6 (q), 52.8 (q), 53.7 (s), 56.4 (s), 58.0 (d), 62.6 (s), 127.4 (d), 136.5 (d), 167.1 (s), 168.3 (s), 209.0 (s); ms *m/e*: 264 (5). *Anal.* calcd. for $C_{14}H_{16}O_5$: C 63.63, H 6.10; found: C 63.50, H 6.25.

*Dimethyl 6,6-dimethyl-7-oxo-*cis*-bicyclo[3.3.0]oct-3-ene-1,*exo*-2-dicarboxylate (****31****)*[8]

Lithium wire (37 mg, 5.33 mmol) was added to a stirred solution of **20** (282 mg, 1.07 mmol) in ether (5 mL) and liquid ammonia (10 mL) under nitrogen. After ~40 min, all the lithium appeared to have reacted, and after a further 20 min, solid ammonium chloride was added. The ammonia was allowed to evaporate at room temperature, after which water (10 mL) was added. The phases were separated and the aqueous layer was extracted with ether (3 × 10 mL). The combined ethereal solutions were washed with saturated aqueous NaCl, dried, and concentrated to leave a colorless oil (217 mg). This was dissolved in benzene (5 mL), and the solution was stirred for 6 h with 10 mL of a solution of sodium dichromate dihydrate (1.2 g, 4.03 mmol) in acetic acid (5 mL), concentrated $H_2SO_4$ (6 mL), and water (19 mL). The phases were separated and the aqueous phase was extracted with ether (3 × 10 mL). The combined organic solutions were washed with water (10 mL), saturated aqueous $NaHCO_3$ (2 × 10 mL), and saturated aqueous NaCl (10 mL), dried, and concentrated to give **31** (92 mg, 0.35 mmol, 33%) as a colorless oil, which crystallized on standing. Recrystallization from ethyl acetate – hexanes gave white crystals, mp 72–73°C; ir $\lambda_{max}$: 5.78 μm; $^1$H nmr δ: 1.06 (s, 3H), 1.09 (s, 3H), 2.20 (d, $J$ = 18.5 Hz, 1H), 3.02 (d, $J$ = 18.5 Hz, 1H), 3.3–3.5 (m, 1H), 3.69 (s, 3H), 3.81 (s, 3H), 4.3–4.5 (m, 1H), 5.6–6.0 (m, 2H); $^{13}$C nmr δ: 22.1 (q), 26.3 (q), 41.5 (t), 47.9 (s), 52.0 (q), 52.9 (q), 55.2 (s), 58.4 (d), 65.2 (d), 128.4 (d), 131.4 (d), 171.6 (s), 175.7 (s), 218.7 (s); ms *m/e*: 266 (5). *Anal.* calcd. for $C_{14}H_{18}O_5$: C 63.15, H 6.81; found: C 62.96, H 6.85.

*Dimethyl 6,6-dimethyl-7-oxo-*cis*-bicyclo[3.3.0]oct-2-ene-1,2-dicarboxylate (****32****)*[8]

Compound **31** (68 mg, 0.26 mmol) ws stirred at room temperature under nitrogen for 1 h in a solution prepared by the reaction of sodium (15 mg, 0.65 mg atom) with methanol (2 mL). The resulting solution was poured into water (10 mL), and the mixture was extracted with ether (3 × 10 mL). The ethereal extracts were combined, washed with saturated aqueous NaCl (10 mL), dried, and concentrated to give **32** (56 mg, 0.21 mmol, 81%) as a colorless oil, which crystallized on standing. Purification by preparative thin layer chromatography with elution with cyclohexane – ethyl acetate (2:1 v/v) gave **32** ($R_f$ 0.41), which crystallized from ethyl acetate – pentanes (~1:10 v/v) to give white needles, mp 84–85°C; ir $\lambda_{max}$: 5.78, 5.83, 6.13 (w) μm; $^1$H nmr δ: 1.06 (s, 3H), 1.11 (s, 3H), 2.39 (d, $J$ = 20 Hz, 1H), 2.4–3.2 (m, 2H), 3.56 (d, $J$ = 20 Hz, 1H), 3.77 (s, 3H), 6.89 (t, $J$ = 2 Hz, 1H); $^{13}$C nmr δ: 20.6 (q), 26.6 (q), 34.5 (t), 42.9 (t), 48.8 (s), 51.8 (q), 52.9 (q), 57.0 (d), 58.1 (s), 138.8 (s), 145.2 (d), 163.9 (s), 174.5 (s), 219.3 (s); ms *m/e*: 266 (6). *Anal.* calcd. for $C_{14}H_{18}O_5$: C 63.14, H 6.81; found: C 62.86, H 6.83.

*Catalytic hydrogenation of* ***32****. Formation of dimethyl 6,6-dimethyl-7-oxo-*cis*-bicyclo[3.3.0]octane-1-*endo*-2-dicarboxylate (****33****) and* ***15***

Compound **32** (17 mg, 0.06 mmol) was hydrogenated at atmospheric pressure over platinum (22 mg) in cyclohexane (3 mL) for 3 h at room temperature. The catalyst was filtered off and the filtrate was concentrated to give a colorless oil (9 mg) which solidified on standing. Sublimation (< 90°C/0.1 Torr) gave **33** (8 mg, 0.03 mmol, 50%) as a white solid, which was crystallized from pentanes – ethyl acetate;[7] ir $\lambda_{max}$: 5.78 μm; $^1$H nmr δ: 1.03 (s, 3H), 1.06 (s, 3H), 1.5–2.2 (m, 4H), 2.14 (d, $J$ = 19 Hz, 1H), 2.4–3.0 (m, 2H), 3.18 (dd, $J$ = 19, ~1 Hz, 1H), 3.69 (s, 3H), 3.82 (s, 3H); ms *m/e*: 268 (16).

Similar hydrogenation of **32** (12 mg) over 10% palladium/carbon (5.5 mg) in methanol (4 mL) gave a product (11 mg) whose $^1$H nmr spectrum showed it to be **15**; the presence of **33** could not be detected.

# Ene-type adducts from the reaction of 4-phenyl-1,2,4-triazoline-3,5-dione with β-alkyl *s-cis* enones[1]

NORMAN ROBERT HUNTER,[2] BERT PAUL KRAWCHUK, AND JANICE DEBORAH SHILOFF[3]

*Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2*

Received July 8, 1980[4]

NORMAN ROBERT HUNTER, BERT PAUL KRAWCHUK, and JANICE DEBORAH SHILOFF. Can. J. Chem. **60**, 835 (1982).

The adducts from the reaction of 4-phenyl-1,2,4-triazoline-3,5-dione with a number of α,β-unsaturated ketones have been isolated and characterized. The reaction generally proceeds with migration of the double bond to the β,γ-position and is highly chemoselective towards reaction with enones which have, or can assume, an *s-cis* conformation.

NORMAN ROBERT HUNTER, BERT PAUL KRAWCHUK et JANICE DEBORAH SHILOFF. Can. J. Chem. **60**, 835 (1982).

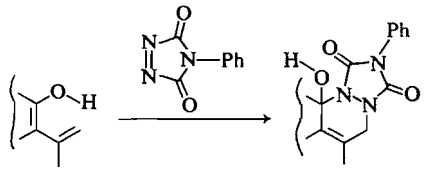
On a isolé et caractérisé les adduits provenant de la réaction de la phényl-4 triazoline-1,2,4 dione-3,5 avec un certain nombre de cétones α,β non saturées. La réaction procède généralement par la migration de la liaison double vers la position β,γ et elle est très chémosélective vis-à-vis les énones qui ont, ou qui peuvent prendre, une conformation *s-cis*.

[Traduit par le journal]

## Introduction

Recently Sammes (2) reviewed the photocatalysed enolization reaction which occurs for a wide variety of phenones. In many cases the dienol formed in the photoenolization process has sufficient stability to be observed spectroscopically, and in other cases the dienol has been trapped in a Diels–Alder cycloaddition reaction with an appropriate dienophile (3). Our interest in the photoenolization of α,β-enones (4) led us to attempt the trapping of transient dienols from β-alkyl α,β-unsaturated ketones with a reactive dienophile. We chose to study (+)-pulegone (see Table 1, compound **4**) since it does not undergo deconjugation upon photolysis.[5] At the outset of our investigation, there was no evidence of a dienol formed upon photolysis of β-alkyl α,β-enones but we anticipated that if a dienol were formed it could be trapped with a highly reactive dienophile such as 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD)[6] (Scheme 1).

PTAD has been shown to be one of the most reactive dienophiles known (for a summary of the use of triazolinediones as dienophiles see ref. 7) and seemed to be an appropriate choice for the trapping experiments.



SCHEME 1

When these trapping experiments were attempted, however, it soon became apparent that the product (a mixture of diastereomers **12***a* and **12***b*, see Table 1) did not arise from a route involving that outlined in Scheme 1, but rather via an ene reaction involving ground state (+)-pulegone.

The ene reaction has been studied thoroughly and reviewed for both the inter- and intramolecular cases (refs. 8 and 9, respectively). However, only one case of a probable ene reaction of a β-alkyl α,β-enone (specifically isophorone) has been reported in the literature (10). The results of the PTAD – (+)-pulegone reaction prompted us to investigate the reaction of PTAD with a variety of other β-alkyl enones.[7] Pirkle and Stickler (11) had earlier observed the ene reaction of PTAD with alkenes. Corey and Snider (12) have also used PTAD as an enophile in a synthesis of prostaglandins, and Magnus and co-workers (13) have recently reported the reaction of PTAD with allylsilanes.

## Results and discussion

A total of eleven different β-alkyl α,β-enones

[1]A portion of this work appeared as a preliminary communication (1).

[2]Author to whom enquiries should be addressed.

[3]Taken in part from the M.Sc. thesis of J. D. S., August, 1977.

[4]Revision received December 2, 1981.

[5]N. R. Hunter, unpublished studies.

[6]Shortly after our trapping attempts Tada and Miura (5) demonstrated the existence of a transient dienol from several β-disubstituted α,β-enones by a deuterium exchange and low temperature infrared studies. Subsequently, Noyori *et al.* (6) reported the isolation of a stable dienol from photolysis of 1-acetylcyclooctene.

[7]Subsequent to the completion of this study, Professor T. R. Hoye, University of Minnesota, informed us of his investigation of the reaction of PTAD with a number of α,β-unsaturated ketones and esters. The results of his study, which is complimentary to ours, have been reported recently (24). We thank Professor Hoye for his exchange of information.

were chosen for our investigation of their reaction with PTAD. These compounds were either prepared according to literature procedures or obtained commercially (see Experimental). For each compound used in the study a standard reaction procedure was used as described in the Experimental.

The yield for each adduct is recorded in Table 1 and is based on an analytically pure sample obtained by recrystallization of the crude reaction mixture. No attempt has been made to optimize the yield for individual reactions. Yields of 75 to 80% are readily obtained after one recrystallization. All of the structures assigned to the adducts are in complete agreement with the spectral and analytical data which are summarized in the table.

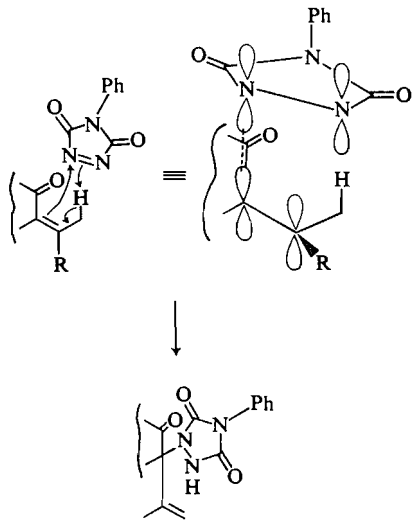
In contrast to the compounds listed in the table the other three enones chosen (3-methylcyclohex-2-en-1-one, 3,3,5-trimethylcyclohex-2-en-1-one, and 3-phenylbut-3-en-2-one) were recovered unreacted after treatment with PTAD under standard conditions.

These results, coupled with the observation that piperitenone (**5**) reacts only at the enone site which has an *s-cis* methyl, indicate the preferential reactivity of PTAD with the β-methyl group of those compounds which have, or can assume, an *s-cis* geometry. The reaction of acetylcyclohexene (**2**) with PTAD gave the adduct **10** which could arise from a regular ene reaction as first reported by Pirkle and Stickler (11).

Our results of the reaction of PTAD with enones (and those of Hoye[7]) reveal that the reaction proceeds with a high degree of regioselectivity. Thus, the acyclic case (**1**) and the exocyclic cyclohexenones (**3**, **4**, **5**, and **6**) all react with the introduction of the PTADH moiety at the α-position and movement of the double bond out of conjugation (cf. **9**, **11**, **12***a*, **12***b*, **13**, and **14**).

In contrast, however, the isopropylidenecyclopentanone (**7**) reacts with opposite regiochemistry (cf. **15**) where the double bond moves into conjugation in the five membered ring and the PTADH functionality becomes attached at the original β-carbon of the enone system. Similarily, but less efficiently, the enone **8** yields **17**. This latter example is the only case where a mixture of double bond isomers was obtained.

From a mechanistic point of view one can speculate about several possible modes of reaction of PTAD with these enones. Such mechanistic speculation, however, must account for several unique features of the reaction. Firstly, the high degree of site selectivity whereby, with the exception of compounds **10**, **15**, and **17**, the PTADH moiety becomes attached to the α-position to the carbonyl can be explained by a normal ene reaction (Scheme 2) with a secondary orbital overlap between the carbonyl group of the enone and the carbonyl–nitrogen system of the PTAD. The formation of compounds **10**, **15**, and **17** can then be considered to arise from a normal ene reaction leading to the thermodynamically more stable conjugated enone. This argument is particularly cogent for compounds **15** and **17**. A second observation which must be explained is the necessity for an *s-cis* conformation of the β-alkyl group in the enone. Once again the normal ene reaction (Scheme 2) may be used to explain the reactivity observed. For systems where the β-alkyl group cannot adopt an *s-cis* conformation the secondary overlap explained above is not possible in any interaction which would lead to an ene reaction of the β-alkyl group.



SCHEME 2

The necessity of an *s-cis* conformation of the enones represents a parallel between our results and the recently reported reaction of singlet oxygen with α,β-unsaturated ketones and lactones (14). (For recent discussions of the mechanism of the singlet oxygen ene reaction see refs. 15 and 16.) It is worth noting here that Greene has reported on the mechanism of the ene reaction and cycloaddition of triazolinediones with simple alkenes (25).

As a result of our investigation, a new method for introduction of a nitrogen functionality at the α-position of a ketone is possible. This reaction has potential application both for effecting deconjugation of α,β-enones and also for selective oxidation of these compounds.

## Experimental

The infrared spectra were recorded on a Perkin–Elmer Model 700 spectrometer as methylene chloride solutions. Proton magnetic resonance spectra were recorded on a Varian Anaspect EM 360 spectrometer using deuterochloroform as solvent and tetramethylsilane as internal standard. Chemical shifts are recorded as values in ppm relative to TMS ($\delta_{TMS} = 0$ ppm). Mass spectra were measured with a Finnigan 1015 quadrupole mass spectrometer. Melting points were determined on a Fisher–Johns melting point apparatus. Column chromatography was done utilizing Camag DSF-5 silica gel containing 5% calcium sulfate. All organic extracts were dried over magnesium sulfate and solvents were removed *in vacuo* using a rotary evaporator. Solvents were used as obtained from commercial sources. Elemental analyses were done by Chemalytics Inc., Tempe, Arizona.

*4-Phenyl-1,2,4-triazoline-3,5-dione (PTAD)*

4-Phenyltriazole (prepared according to Cookson *et al.* (17)) was oxidized to PTAD using *N*-bromosuccinimide according to the procedure of Wamhoff and Wald (18).

*Enones for PTAD–adduct formation*

Isopropylidenecyclopentanone (**7**) was prepared by condensation of acetone and cyclopentanone according to the literature procedure (19). Isopropylidenecyclohexanone (**3**) was prepared from ethyl 2-cyclohexanone carboxylate (Aldrich) according to the procedure of Mukherjii *et al.* (20). 2-Cyclopentylidenecyclopentanone (**8**) was prepared from cyclopentanone following the literature method (21). The procedure of Reese (22) was used to prepare 2-cyclohexylidenecyclohexanone (**6**) from 2-(1-cyclohexyl) cyclohexanone (23). Mesityl oxide (**1**), 1-acetyl-1-cyclohexene (**2**) and (+)-Pulegone (**4**) were obtained from Aldrich Chemical Company. Piperitenone (**5**) was obtained as a gift from Dr. J. J. Beereboom, Pfizer Inc., Groton, Connecticut.

*Typical procedure for the preparation of PTAD–enone adducts*

*Reaction of PTAD with piperitenone (5): formation of adduct 13*

To a solution of piperitenone (1.50 g, 10.0 mmol) in 15 mL of ethyl acetate at ambient temperature was added 1.75 g (10.0 mmol) of 4-phenyl-1,2,4-triazoline-3,5-dione. The reaction mixture was placed in the refrigerator at ~3°C for 2 h. At the end of that time the bright red color of PTAD had disappeared. After filtration to remove a small amount of white precipitate, pentane (10 mL) was added with stirring and the resulting precipitate was filtered, washed with cold benzene (20 mL), and dried under suction. The crude product was recrystallized from a small volume of ethyl acetate to give the adduct **13** (1.79 g, 5.51 mmol; 55%) with mp 171–173°C. Complete spectral data for **13** is recorded in the table.

All other adducts were prepared and purified in a similar way with the only variable being the reaction time (20 min to 1 day).

## Acknowledgements

Dr. J. J. Beereboom is thanked for a generous gift of piperitenone. Dr.'s Jim Charlton and Ted Edwards are thanked for discussion concerning possible mechanisms for the reaction. The University of Manitoba Research Board and the Natural Sciences and Engineering Research Council of Canada (formerly the National Research Council) are thanked for financial support.

Reçu le 30 juin 1981

MONIQUE SAVIGNAC, PAUL CADIOT et FRANÇOIS MATHEY. Can. J. Chem. **60**, 840 (1982).

La metallation par le *tert*-butyllithium de composés comportant l'enchaînement $P^V—CH_2—CH_2—SR$ se traduit par l'élimination du groupe SR (R = H, $CH_3$) qui est suivie de l'addition du *tert*-BuLi. L'application de cette réaction d'élimination–addition aux oxydes de phosphines fonctionnels $(C_6H_5)_2P(O)CH_2Z$ (Z = CN, COOEt) a permis de synthétiser des composés γ-diphosphorylés fonctionnels originaux. Ceux-ci se dissocient en milieu basique suivant un mécanisme inverse à celui de leur formation qui a été mis en évidence par réaction du mélange réactionnel sur le *para*-chlorobenzaldéhyde pour donner le *para*-chlorocinnamate d'éthyle.

MONIQUE SAVIGNAC, PAUL CADIOT, and FRANÇOIS MATHEY. Can. J. Chem. **60**, 840 (1982).

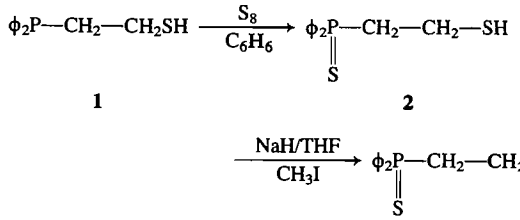
The *tert*-butyllithium metallation of compounds containing the group $P^V—CH_2—CH_2—SR$ proceeds by elimination of the group SR (R = H, $CH_3$) followed by addition of *tert*-BuLi. Application of this addition–elimination reaction to functionalized phosphine-oxides $\phi_2P(O)CH_2Z$ (Z = CN, COOEt) leads to the synthesis of γ-diphosphorylated compounds. These dissociate in basic medium following a mechanism which is the reverse of their formation as shown by treatment of the reaction mixture with *p*-chlorobenzaldehyde to give ethyl *p*-chlorocinnamate.

[Journal Translation]

Jusqu'à ce jour les composés β-thioéthylphosphorés ont fait l'objet de travaux limités à la préparation (1) et l'emploi en chimie de coordination (2) de β-thioéthylphosphines. À la suite de nos résultats sur les propriétés de ces coordinats trivalents (2*a*) nous avons entamé une étude des propriétés des espèces tétracoordinées correspondantes, oxydes et sulfures.

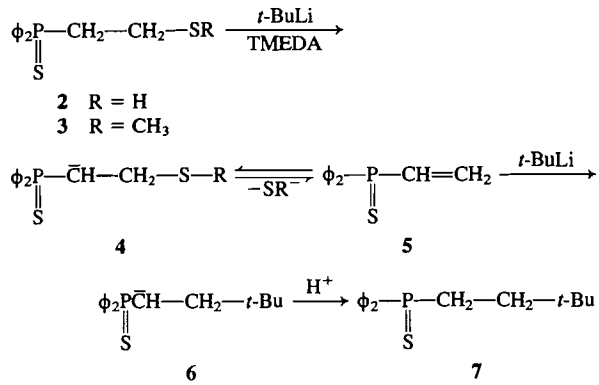
## A. *Réactivité anionique des sulfures de β-thioéthyldiphényl phosphines*

En présence de soufre élémentaire la β-thioéthyldiphényl phosphine (1*a*) **1** est convertie en sulfure **2** dont la méthylation conduit au thioéther **3** avec des rendements élevés.



**1** **2** **3**

La métallation en position α du groupe thiophosphoryle des composés **2** et **3** nécessite l'emploi d'une base forte. Le *n*-butyllithium dans le tétrahydrofuranne (THF) nous ayant donné des résultats peu interprétables, nous lui avons substitué le complexe *tert*-butyllithium – TMEDA dans l'hexane. L'addition soit de **2** soit de **3** au complexe *tert*-BuLi/TMEDA à −40°C provoque l'apparition immédiate d'une coloration orangée-vif stable jusqu'à 0°C. Après hydrolyse et traitement en parallèle des deux réactions, un même composé **7** est obtenu correspondant pour **2** à la substitution du groupe —S—H par le groupe *tert*-BuLi et pour **3** à la substitution du groupe —$SCH_3$ par le même groupe *tert*-BuLi. La formation d'un même composé **7** à partir de **2** ou de **3** trouve probablement son origine dans un mécanisme d'élimination–addition représenté sur le schéma suivant:



**2** R = H
**3** R = $CH_3$

**4** **5** **6** **7**

À la formation de l'anion lithien **4** succède l'apparition du vinylique **5** par élimination d'un

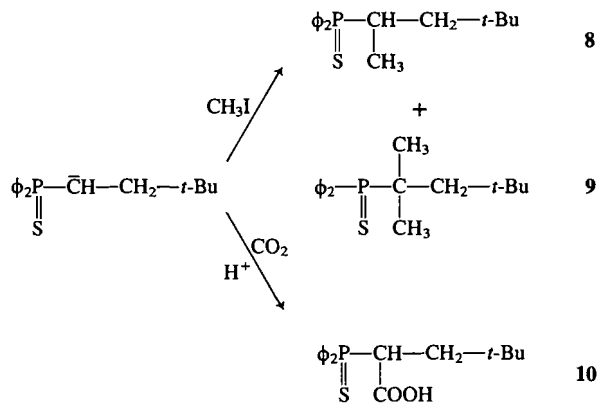
anion thiolate ($S^{2-}$ ou $RS^-$), elle-même suivie de l'addition nucléophile du *tert*-BuLi pour engendrer un nouveau carbanion **6** dont la protonation fournit **7**. La vinylphosphine **5** est soumise à une réaction réversible d'élimination–addition qui est déplacée vers la formation de **6** par consommation progressive de **5** par le *tert*-BuLi.

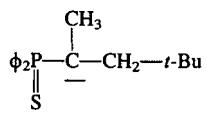
Des additions identiques sur le même type de composé ont déjà été décrites (3). D'autre part la réversibilité de l'addition des anions thiolates sur les composés vinyliques du phosphore a également été mise en évidence lorsque ceux-ci sont substitués en α par un groupe attracteur (4).

Nous avons vérifié que le processus d'élimination–addition est indépendant de la température (entre −60° et −10°C); en outre l'étape d'addition du *tert*-BuLi doit être plus rapide que l'étape d'élimination puisque lorsqu'on opère en défaut de *tert*-BuLi (1 mole au lieu des deux moles nécessaires) on récupère après hydrolyse un mélange de **7** et de produit de départ (**2** ou **3**). L'anion α-lithié **6** peut être alkylé **8** ou carbonaté **10** (3).



Le produit brut de méthylation **8** contient une petite quantité de produit diméthylé **9** (environ 5%) dont la présence est décelée par spectrométrie de masse.

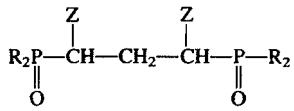
La présence de **9** peut être attribuée à la formation d'un nouvel anion en α du phosphoré **11** résultant d'un échange entre **6** et **8**.



**11**

B. *Application de l'élimination–addition à la préparation de composés γ-diphosphorylés fonctionnels*

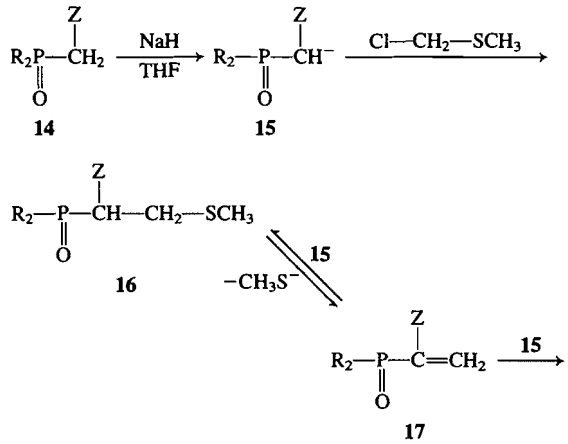
Les résultats précédents ont été étendus à la préparation de nouvelles espèces diphosphorylées de formule générale **13** dont à notre connaissance aucune synthèse n'avait été décrite.



**13**

*a* R = ϕ Z = CN
*b* R = ϕ Z = COOEt
*c* R = EtO Z = COOEt

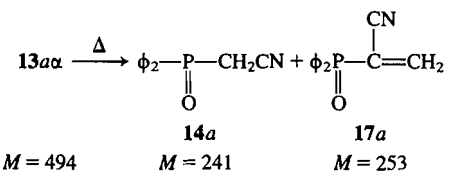
Le précurseur fonctionnel **14** est un phosphonate ou une phosphine susceptible de donner dans des conditions douces (NaH/THF) l'anion correspondant **15**. La condensation de cet anion **15** sur le



chlorométhylthiométhyléther conduit à **16** générateur en milieu basique du dérivé vinylique **17** sur lequel le précurseur anionique **15** vient s'additionner pour conduire après protonation à l'espèce **13**.

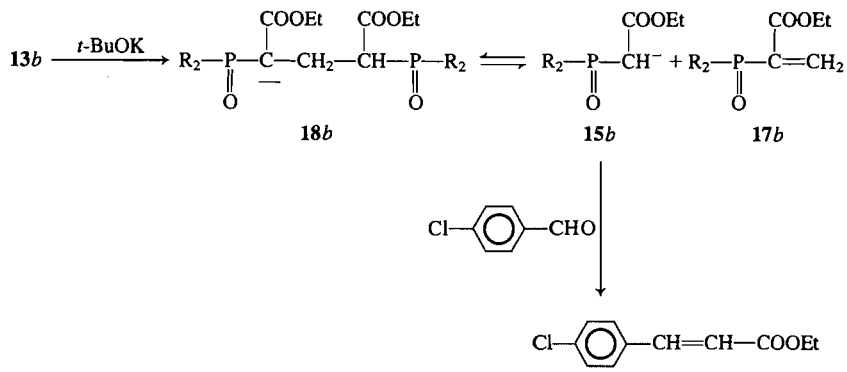
Dans cette réaction c'est l'anion **15** qui induit l'élimination de **16** en **17**, puis le thiométhylate de sodium formé l'entretient, la rendant irréversible. Lorsque Z = COOEt, le composé **13***b* ou **13***c* représente le produit unique; lorsque Z = CN on isole également une faible quantité du composé β-sulfuré **16***a*. Sa présence confirme la réversibilité des processus concurrents d'addition du méthylthiolate et de l'anion **15***a*.

Les composés **13** sont isolés sous la forme d'un mélange sensiblement équimoléculaire de deux diastéréoisomères **13** (α + β). Dans le cas de **13***a* un des diastéréoisomères **13**α (α correspond au dias-



**14***a* **17***a*

$M = 494$ $M = 241$ $M = 253$



téréoisomère le moins déblindé en rmn $^{31}P$) est isolable par cristallisation dans l'acétate d'éthyle. Il a été complétement caractérisé (rmn: $^{1}H$, $^{31}P$, $^{13}C$; sm; analyse).

En spectrométrie de masse l'interprétation la plus plausible de sa décomposition consiste en une dissociation inverse du processus de formation.

Ce schéma de dissociation a été également vérifié avec **13***b* et **13***c*.

C. *Interconversion en milieu basique des composés isomères γ-diphosphorylés* ***13*** α,β

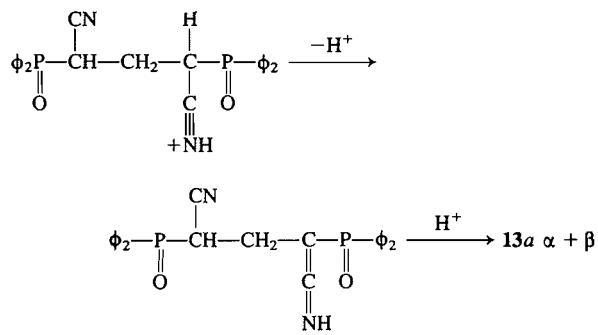
La réaction a été étudiée sur le mélange de diastéréoisomères **13***b* (α + β). En présence de *tert*-BuOK dans le THF, le mélange des deux diastéréoisomères conduit aux monanions **18***b* qui se dissocient réversiblement en phosphoré vinylique **17***b* et anion **15***b*. Cette dissociation inverse du processus de formation est pleinement confirmée en piègeant l'anion **15***b* par le *p*-chlorobenzaldéhyde. On obtient comme seul produit de réaction le *p*-chlorocinnamate d'éthyle "*trans*"; quant à **17***b* il polymérise.[1]

Cette réaction consomme préférentiellement un des diastéréoisomères. Après hydrolyse on récupère du produit de départ non transformé qui n'est plus un mélange équimoléculaire de diastéréoisomères mais contient très majoritairement l'un deux. Ce nouveau mélange traité par le *tert* BuOK dans le THF redonne le mélange équimoléculaire initial résultant de l'action de NaH sur **14**. Il n'y a donc pas d'influence notable du contre-ion sur le processus d'interconversion. Il semble que l'un des isomères de **13***b* soit préférentiellement métallé par *tert* BuOK pour des raisons stériques ou de solubilité ce qui expliquerait sa consommation préférentielle.

Dans le cas des diastéréoisomères **13***a* nous observons un phénomène d'interconversion identique; le diastéréoisomère pur **13***a*α mis en solution dans le THF en présence de *tert* BuOK subit une interconversion rapide pour donner le mélange équimoléculaire des diastéréoisomères **13***a* (α + β).

D. *Isomérisation du composé γ-diphosphorylé* ***13***a*α en milieu acide*

Le diastéréoisomère **13***a*α s'isomérise en milieu acide en un mélange équimoléculaire des diastéréoisomères α et β. Cette équilibration a été réalisée en 24 h à 20°C en solution chloroformique ou en une heure en solution faiblement acétique de chlorure de méthylène. Dans le chlorure de méthylène pur cette transformation est quasiment inexistante au bout d'une semaine. Il est vraisemblable que l'acide chlorhydrique toujours présent dans $CHCl_3$ ou l'acide acétique conduisent à la protonation de la fonction nitrile suivie de l'épimérisation progressive du carbone porteur du groupe fonctionnel.



E. *Conformation du diastéréoisomère* ***13***a*α*

La conformation du diastéréoisomère **13***a*α peut être définie par étude de son spectre de rmn $^{13}C$. En solution dans $CDCl_3$ les carbones en α du phos-

[1]Un essai de préparation de **17***b* a été effectué en adaptant le mode opératoire correspondant à la préparation du méthyl-2 (diéthylphosphono)acrylate (4). L'action du formaldéhyde sur l'oxyde de diphénylphosphino-méthyl carbéthoxyéthyl par chauffage pendant 8 h conduit après traitement à l'alcool correspondant qui par déshydratation en présence d'APTS fournit le composé vinylique **17***b*. Il n'a jamais pu être isolé car il polymérise spontanément lors de sa purification.

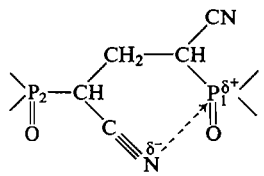
phore porteurs des groupes nitriles apparaissent (31, 65 ppm) sous la forme d'un doublet de doublet ($^1J_{PC}$ = 60,3 Hz et $^3J_{PC}$ = 8,2 Hz). A l'examen des courbes liant l'angle dièdre C—C—C—P au $^3J_{PC}$ (5) nous aurions dans notre cas un angle dièdre de 130°. Une disposition rigoureusement "*trans*" des groupes fonctionnels $P_1$ et CH(CN)—$P_2$ autour de la liaison CH(CN)—$CH_2$ correspondrait environ à $^3J_{PC}$ de 15 Hz comme on aurait pu également le supposer sur la base d'argument purement stérique. Nous proposons donc une certaine stabilisation de la disposition "*cis*" par interaction de l'azote du groupe nitrile avec le phosphore positif du phosphoryle.



L'étude ir en solution dans le chloroforme des vibrations $\nu_{C\equiv N}$ dans $CH_3CN$, **14***a*, **13***a* va dans le sens de cette interprétation:

| | $\nu_{C\equiv N}$ cm$^{-1}$ | $\Delta\nu$ |
|---|---|---|
| $CH_3CN$ | 2291 | |
| **14***a* | 2252 | 39 |
| **13***a* | 2241 | 11 |

L'importance de cet abaissement supplémentaire nous semble difficile à expliquer par un simple effet inductif à travers quatre liaisons carbone–carbone mais est en faveur d'une intéraction directe à travers l'espace du type de celle figurée sur le schéma.

*Conclusion*

L'étude des espèces β-thioéthylphosphines tétracoordinées a permis de dégager deux faits importants: (*i*) une généralisation du phénomène d'élimination–addition en milieu basique sur les dérivés comportant l'enchaînement $P^V$—$CH_2$—$CH_2$—Nu; et (*ii*) du point de vue synthètique il ouvre la voie à la préparation de nouvelles molécules originales γ-diphosphorylées par un processus relativement simple.

## Partie expérimentale

Les spectres rmn $^1$H sont enregistrés sur Varian T 60 et XL 100; le tetraméthylsilane (TMS) est utilisé comme référence interne; le solvant est $CDCl_3$ sauf lorsque le contraire est précisé.

*Sulfure du diphénylphosphino-2 éthanethiol 2*

Il est préparé par addition du diphénylphosphino-2 éthanethiol (**1**) (10 g) à une suspension de soufre en fleur en quantité équimoléculaire dans le benzène à 0°C. Après retour à température ambiante en 30 min, le solvant est évaporé et l'huile est reprise par l'éther de pétrole (30–60°C). L'huile cristallise; *m* = 8,7 g (Rdt = 80%).

*Méthylation du sulfure de diphénylphosphino-2 éthanethiol 3*

Le sulfure de diphénylphoshino-2 éthanethiol (2 g; 0,0071 mol) dans 20 mL de THF est ajouté à une suspension de 0,35 g (0,0071 mol + 5%) d'hydrure de sodium dans 30 mL de THF. Le mélange est agité 1 h à température ambiante, puis 1,1 g (0,0071 mol + 5%) d'iodure de méthyle dans 10 mL de THF sont ajoutés. Après une heure d'agitation à température ambiante, la solution est hydrolysée (20 mL), puis extraite par l'éther éthylique (3 × 50 mL). Après séchage et évaporation on obtient 1,8 g de **3** (86,7%). Ce produit est utilisé brut; rmn $^1$H, δ: 1,83 (s, $CH_3$), 2,6 ($(CH_2)_2$), 7,4 (massif Ph) ppm.

*Réaction du sulfure de diphénylphosphino-2 éthanethiol avec le* tert-*butyllithium*

Au complexe *t*-BuLi/TMEDA (15,5 cm$^3$/2,59 g; 0,0213 mol) préalablement formé dans 40 mL d'hexane, on ajoute à −40°C, 2 g (0,0071 mol) de **2** en solution dans un minimum de $C_6H_6$ (~10 mL). Une coloration orangée-vif se développe. La métallation est poursuivie pendant 1 h à −40°C.

A. *Hydrolyse*

On additionne à la solution ramenée à température ambiante 30 mL d'une solution aqueuse d'HCl (3 *N*). On extrait à l'éther éthylique (3 × 50 mL), lave au carbonate, sèche et évapore. On obtient 1,25 g de sulfure diméthyl-1,1 diphénylphosphino-3 butane **7** (58%, *F* = 136°C); rmn $^1$H, δ: 0,9 (s, $C(CH_3)_3$), 1,4 (m, $CH_2$), 2,4 (m, $CH_2$), 7,8 (m, Ph) ppm. *Anal.* calc. pour $C_{18}H_{23}PS$: C 71,25; H 7,61; P 10,26%; trouvé: C 71,3; H 7,5; P 9,7%.

B. *Méthylation*

À la solution ramenée à température ambiante, on additionne un large excès de $CH_3I$ (4 g, 0,028 mol). On agite la solution jusqu'à décoloration totale (~1 h), hydrolyse par HCl 3 *N* (30 mL), puis extrait à l'éther (3 × 50 mL). Le produit brut est purifié par chromatographie sur colonne de silice (hexane/$Et_2O$ 80:20). On obtient 0,6 g (Rdt 25%) de sulfure de diphénylphosphino-1 triméthyl-1,3,3 butane, **8** (*F* = 110°C); rmn $^1$H, δ: 0,7 (s, $C(CH_3)_3$), 1,29 (q, $J_{HP}$ = 20 Hz, $J_{HH}$ = 6,7 Hz, $CH_3$), 1,44 (m, $CH_2$), 2,74 (m, CH), 7,72 (m, Ph) ppm; *m/e*: 316(M). *Anal.* calc. pour $C_{19}H_{25}PS$: C 72,15; H 7,9; P 9,8%; trouvé: C 71.9; H 7,8; P, 9,4%.

C. *Carbonatation*

Dans un verre de Dewar contenant de l'éther saturée de $CO_2$ par de la carboglace sèche, on additionne rapidement la solution du carbanion, puis abandonne une nuit. Le lendemain on décante, lave la phase aqueuse à l'éther (3 × 50 mL), acidifie ($H_2SO_4$ concentré), puis extrait à l'éther éthylique (3 × 50 mL), sèche et on concentre: on obtient un produit cristallisé blanc **10** qui est comparé à un échantillon authentique préparé selon la référence 3.

*Réaction du sulfure de diphénylphosphino-2 éthanethiométhyl éther avec le* tert-*butyllithium*

Au complexe *t*-BuLi/TMEDA (9,2 cm$^3$/1,5 g; 0,0123 mol) préalablement formé dans 40 mL d'hexane, on additionne à −40°C 1,8 g (0,0061 mol) de sulfure de diphényl phosphino-2 éthanethiométhyl ether en solution dans le minimum de $C_6H_6$ (~10 mL). La solution prend une coloration orangée-vif. On l'abandonne 1 h à −40°C.

A. *Hydrolyse*

Cette solution est hydrolysée par HCl 3 *N* (30 mL), puis extraite à l'éther éthylique. Après dessication et évaporation du

solvant, on obtient un composé cristallisé ayant les mêmes caractéristiques physiques que le sulfure de diméthyl-1,1 diphénylphosphino-3 butane **7**; $m$ = 0,67 g (35%).

B. *Méthylation*

On laisse la solution remonter à la température ambiante, puis on ajoute un large excès de $CH_3I$. La solution est agitée jusqu'à décoloration complète et hydrolysée par HCl 3 *N* (30 mL), puis extraite par l'éther éthylique (3 × 50 mL). Le produit brut obtenu est purifié par chromatographie sur colonne de silice (hexane/$Et_2O$ 80:20); $m$ = 0,22 g (12%). Il présente les mêmes caractéristiques physiques que **8**.

*Préparation des oxydes de diphosphines* ***13***

*Mode opératoire général*

Nous le décrivons pour R = Ph, Z = COOEt; **13***b*: 14,4 g (0,05 mol) d'oxyde de diphénylphosphinométhyl carbéthoxyéthyl **14***b* dans 50 mL de THF sont ajoutés à température ambiante à une suspension de 2,4 g (0,05 mol + 5%) de NaH dans 20 mL de THF. Après 30 min d'agitation à température ambiante, on additionne 4,83 g (0,05 mol) de chlorométhylthiométhyl ether dans 10 mL de THF. Le mélange réactionnel est progressivement chauffé à 65°C, un abondant précipité de NaCl apparait. Après 3 h à 64°C on hydrolyse (40 mL) et extrait à l'éther éthylique (3 × 50 mL). Le produit brut obtenu est purifié par chromatographie sur colonne de silice (acétate d'éthyle). On obtient un mélange de diastéréoisomères; $m$ = 4 g (Rdt = 42%), $F$ = 154°C; rmn $^1$H, δ: 0,65 (t, $CH_3$), 2,3 (m, $CH_2$), 3,5 (m, $CH_2(CH_3—CH_2)$ et CH), 7,35 (massif Ph) ppm; rmn $^{31}$P, δ: +27,0, + 28,3 ppm; *m/e*: 588 (M). *Anal.* calc. pour $C_{33}H_{34}P_2O_6$: C 67,34; H 5.78; P 10.54%; trouvé: C 67,0; H 5,77; P 9,90%.

*Pour R = Ph, Z = CN* ***13***a *(0,05 mol)*

Par chromatographie sur colonne de silice (acétate d'éthyle) on sépare en tête **16***a*: $m$ = 1,1 g; $F$ = 140°C; rmn $^1$H, δ: 2,18 (s, S—Me), 2,78 (m, $CH_A$—SMe), 3,15 (m, $CH_B$—SMe), 3,68 (m, CH), 7,8 (m, Ph) ppm; rmn $^{31}$P, δ: +23,82 ppm; *m/e*: 301 (M). *Anal.* calc. pour $C_{16}H_{16}NOPS$: C 63,78; H 5,3; P 10,29%; trouvé: C 63,56; H 5,22; P 9,66%. Puis **13***a* pur par cristallisation dans l'acétate d'éthyle: $m$ = 4,15 g, $F$ = 260°C; rmn $^1$H, δ: 2,3 (m, $CH_2$), 3,94 (m, CH), 7,7 (m, Ph) ppm; rmn $^{31}$P, δ: +24,8, +26,1 ppm; *m/e*: 494 (H). *Anal.* calculé: C 70,44; H 4,85; P 12,55%; trouvé: C 70,17; H 4,82; P 11,93%.

*R = EtO, Z = COOEt* ***13***c *(0,05 mol)*

Purification par chromatographie sur colonne de silice (acétate d'éthyle); $m$ = 4,18 g (Rdt = 56%); rmn $^1$H; δ: 1,43 (m, $CH_3$), 2,48 (m, $CH_2$), 3,11 (m, CH), 4,19 (m, $CH_2—CH_3$) ppm; *m/e*: 460 (M).

*Equilibration en milieu basique des composés diphosphorylés* ***13***b

A une suspension de 0,56 g de *t*-BuOK dans 20 mL de THF on additionne un mélange de 2,94 g (0,005 mol) de **13***b* et de 0,830 g (0,0625 mol) de *para*-chlorobenzaldéhyde en solution dans 50 mL de THF. La solution devient limpide puis un précipité apparaît progressivement ($Ph_2P—\overset{\overset{O}{\|}}{O}K$). On hydrolyse par 30 mL d'eau, puis extrait par l'éther éthylique (3 × 50 mL). Après dessication et évaporation on obtient 0,2 g de *para*-chlorocinnamate d'éthyle. Après purification le *para*-chlorocinnamate d'éthyle est comparé à un échantillon authentique.

Received August 12, 1981

TED SCHAEFER, RUDY SEBASTIAN, and RODERICK E. WASYLISHEN. Can. J. Chem. **60**, 845 (1982).

A partial analysis of the 400 MHz $^1$H nmr spectrum of isopropylcyclopropane yields 8.6 ± 0.2 Hz for the vicinal proton–proton coupling constant between a cyclopropyl proton and the methine proton of the isopropyl group. The fractional population of the *s-trans* conformer is estimated as 0.65 ± 0.10 at 300 K, in reasonable agreement with molecular mechanics and INDO MO computations of the energies of the *gauche* and *trans* forms.

The conformational preference of this molecule is similar to that in *n*-butane and in vinylcyclopropane but contrasts with that in biisopropyl and bicyclopropyl.

TED SCHAEFER, RUDY SEBASTIAN et RODERICK E. WASYLISHEN. Can. J. Chem. **60**, 845 (1982).

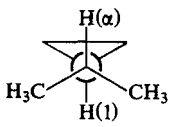
Une analyse partielle du spectre rmn du $^1$H à 400 MHz de l'isopropylcyclopropane permet d'établir à 8.6 ± 0.2 Hz la constante de couplage vicinale entre un proton du cyclopropane et le proton méthine du groupe isopropyle. On évalue à 0.65 ± 0.10 la fraction de la population dans la conformation *s-trans*; cette valeur est en bon accord avec des calculs de mécanique moléculaire et INDO MO des énergies des formes *gauche* et *trans*.

La préférence conformationnelle de cette molécule se rapproche de celles du *n*-butane et du vinylcyclopropane mais elle diffère de celles observées avec le biisopropyl et le bicyclopropyl.

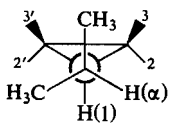
[Traduit par le journal]

## Introduction

The electronic and conformational properties of many cyclopropane derivatives have been studied (1, 2). An exception is isopropylcyclopropane (IPCP) for which an empirical force-field (3) predicts the *trans* conformation, **1**, as 380 cal/mol (1 cal ≡ 4.184 J) more stable than either of the two *gauche* forms, **2**. Apparently the only experimental data are the Raman spectra in the liquid and solid phases (4). These are interpreted to mean that only one conformation is present in both phases, probably **1**.



**1**



**2**

Here the $^1$H nmr spectrum at 400 MHz is analyzed in enough detail to yield the vicinal coupling, $^3J$, between the methine proton of the isopropyl group and the ring proton. Its magnitude places limits on the conformer distribution.

## Experimental

A 3 mol% solution of IPCP (Chemical Samples Co.) in benzene-$d_6$ was degassed by the freeze–pump–thaw technique and sealed into a 5 mm od nmr sample tube. At 305 K and 100.00 MHz the methyl protons resonate at 6.19 ppm upfield of $C_6H_6$, which itself resonates at 7.15 ppm to low field of internal tetramethylsilane. Accordingly, allowing for small temperature and concentration variations, $\delta_{CH_3}$ is 0.96 ± 0.02 ppm. Decoupling experiments on a WH90 spectrometer did not yield tractable spectra.

The $^1$H nmr spectrum was obtained on a WH400 (University of Guelph) spectrometer at 297 K, utilizing four 20 μs pulses, an acquisition time of 6.55 s, a sweep width of 2500 Hz with 16384 real points and quadrature phase detection. The centerband occurred at 400.1348 MHz. Homonuclear decoupling experiments were also performed.

INDO MO FPT (5) computations utilized an Amdahl 470/V7 system.

## Results and discussion

### *Spectral analysis*

The linewidth of the observed peaks was about 0.8 Hz, part of which at least arises from long-range couplings over four and five bonds. Of the 50 observed peaks, 45 were used in a 12-spin iterative analysis with the computer program NUMARIT (6). The 2084 calculated transitions occurred as 175 groups, each group spanning 0.05 Hz. In all, 289 transitions were assigned to observed peaks. Starting parameters were taken from those for very similar compounds, like 2-hydroxyethyl- and 2-bromoethylcyclopropane (7). The two *cis* vicinal couplings in the $CH_2CH_2$ fragment were set at 9.1 and 9.3 Hz (7), the latter for the protons *trans* to the isopropyl group. These couplings were not allowed to vary during the iteration.

The spectral parameters in Table 1 are probably

accurate to 0.2 Hz, about 6 times their standard deviations. The couplings interior to the cyclopropyl moiety lie within about 0.1 Hz of those observed for closely related molecules (7). Figure 1 displays the observed and calculated spectra for the unique cyclopropyl proton and the pair of protons *cis* to it, H-2.

*Conformational distribution*

The crucial parameter is $^3J_{1\alpha} \equiv {}^3J = 8.6_4 \pm 0.2_2$ Hz (error is six times the standard deviation). The derived fractional populations, $P_t$ and $P_g$, of the *trans* and *gauche* conformers are most sensitive to the value of $^3J_t$ in **1**. This can be seen as follows.

If the *gauche* conformers each have the same entropy as the *trans* form, then $P_t/P_g = 0.5 \exp(-\Delta H^0/RT)$ and $P_t + P_g = 1$. The observed $^3J$ is related to $P_t$ by $P_t = (8.6_4 - J_g)/(J_t - J_g)$. It is easy to show that, for 2.0 Hz $\leq J_g \leq$ 3.0 Hz, $P_t$ varies by 0.04 at most for a given $J_t$ in the range 8.6 Hz $\leq J_t \leq$ 13.0 Hz. Accordingly, a reliable $J_t$ is needed, estimates being made as follows.

$^3J$(H, $CH_3$) in a cyclopropane derivative is 6.2 Hz (8). An INDO MO FPT calculation, using a standard geometry (9) for the methyl group, the electron diffraction geometry for the cyclopropane fragment (10), and 1.54 Å for the exocyclic C—C bond, gives $J_t = 17.0$ and $J_g = 2.47$ Hz. Adjustment of these numbers to $J_t = 13.6$, $J_g = 2.5$ Hz or to 14.5 and 2.1 Hz, reproduces the observed coupling. Again, a standard geometry for the isopropyl group, together with the geometry above, yields INDO values of $J_t = 16.9$ and $J_g = 2.30$ Hz. In many compounds, INDO overestimates $J_t$ rather more than $J_g$. For example, in propene $(J_t + 2J_g)/3$ is 6.47 Hz whereas $J_t$ and $J_g$ are calculated (11) as 16.2 and 3.2 Hz.

In alkyl derivatives of ethene (12), it was estimated that a *lower* limit of $J_t$ is 11.1 Hz. The orbital used by a carbon atom in cyclopropane to bond to an alkyl carbon atom is very nearly $sp^2$ hybridized (7, 13, 14), implying that $J_t$ in IPCP is not less than 11.1 Hz. In *trans*-butadiene and *s-trans*-vinyl cyclopropane $J_t$ is thought to be 11.0 Hz and $J_g$ is then 1.85 Hz (15, 16). In 1,1,2,2-tetraphenylethane, $J_t$ is 11.3 Hz (17).

If, then, in IPCP 2.0 Hz $\leq J_g \leq$ 3.0 Hz and 11.0 $\leq J_t \leq$ 13.0 Hz, one has $0.56 \leq P_t \leq 0.74$. It is probable that $P_t = 0.65 \pm 0.10$.

These estimates assume "rigid" *gauche* and *trans* conformers insofar as averaging over torsional states (18, 19) *within* the conformers is ignored. The barriers to interconversion of the conformers are calculated as about 3 kcal/mol (3) so that at 300 K the simple approach may underestimate $P_t$ by as much as 0.05 (20). A variable temperature study would have to include the averaging procedure in a classical or quantum mechanical way (20). For reasons of spectral complexity, such a study should be done on the compound in which all but the two relevant protons are replaced by deuterium nuclei.

Molecular mechanics (3) favor the *trans* form by 380 cal/mol, whereas the present INDO results have this preference as 720 cal/mol. These numbers, if taken as enthalpies, give $P_t$ as 0.49 and 0.65, respectively. The INDO approximation of MO theory finds a reasonable conformational preference for phenylcyclopropane (2). The empirical force-field method (3) yields the dihedral angle as 52° in the *gauche* form. Such a number suggests $J_g$ as closer to 3 than to 2 Hz, implying $P_t$ as nearer 0.7

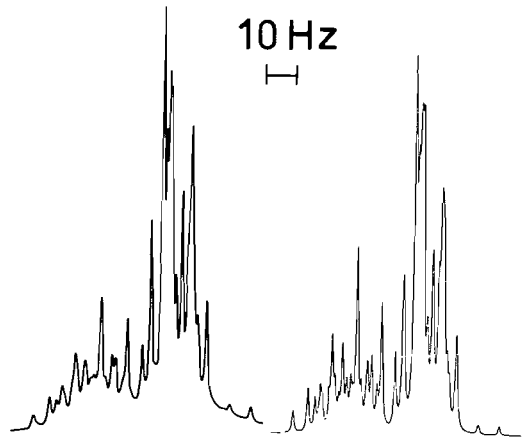

FIG. 1. The observed and calculated spectra of H-1 and H-2 (see **2** in text) at 400.135 MHz for a 3 mol% solution of isopropylcyclopropane in benzene-$d_6$. The calculated spectrum takes the parameters in Table 1 and assumes a linewidth, $\Delta\nu_{1/2}$, of 0.80 Hz. A $\Delta\nu_{1/2}$ of 1.0 Hz for H-1 produces closer agreement for this proton. Much of the width may arise from long-range coupling to the methyl protons. The digital resolution is 0.153 Hz/point. H-2 is more shielded than H-1 by 26.3 Hz.

TABLE 1. Spectral parameters for isopropylcyclopropane in benzene-$d_6$ at 297 K and 400.135 MHz

| Parameter[a,b] | Value | Parameter[a] | Value |
|---|---|---|---|
| $\nu_{CH_3}$ | −3.302(30) | $^3J_{12}$ | 8.250(29) |
| $\nu_a$ | −111.093(24) | $^3J_{13}$ | 4.969(27) |
| $\nu_1$ | −234.585(21) | $^3J_{23'}$ | 5.525(24) |
| $\nu_2$ | −260.901(20) | $^3J_{22'}$ | 9.1 |
| $\nu_3$ | −391.781(20) | $^3J_{33'}$ | 9.3 |
| $^3J_{(\alpha,CH_3)}$ | 6.714(18) | $^2J_{23}$ | −4.303(22) |
| $^3J_{1,\alpha}$ | 8.637(36) | Root mean square error | 0.169 |

[a] The numbers in parentheses give the standard deviations in the last two significant figures.
[b] The shifts are in Hz relative to an arbitrary zero. Approximate shifts in Hz at 400.135 MHz relative to internal TMS are obtained by *addition* of 384.1 Hz. H-3 therefore resonates upfield of TMS by about 0.02 ppm.

than 0.55 (a $P_t$ of 0.65 also fits $J_t = 11.5$ and $J_g = 3.3$ Hz).

From the detailed nmr and infrared studies of biisopropyl and bicyclopropyl by Lüttke and coworkers (21–23), it follows that the *gauche* forms are favored by enthalpies of about 0.1 kcal/mol. By way of contrast, for IPCP the *trans* conformation is distinctly favored by an energy similar to the energies favoring the *trans* forms in *n*-butane and vinylcyclopropane ($^3J$ in the latter is 8.3 Hz near room temperature (24), and is 8.6 Hz in IPCP). For an extensive discussion of the torsional potentials in all these compounds, see (3).

The INDO MO dipole moments are $\mu_t = 0.07_3$ and $\mu_g = 0.08_5$ D, suggesting that solvent perturbations of the conformational equilibrium are small for IPCP.

# Kinetics of the oxidation of diphenyl sulfide with hydrogen peroxide catalyzed by sodium metavanadate[1]

YOSHIRO OGATA[2] AND KAZUSHIGE TANAKA

*Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan*

Received April 6, 1981[3]

YOSHIRO OGATA and KAZUSHIGE TANAKA. Can. J. Chem. **60**, 848 (1982).

The oxidation of diphenyl sulfide ($Ph_2S$) by hydrogen peroxide in the presence of a catalytic amount of sodium metavanadate ($NaVO_3$) has been studied kinetically by means of iodometry of hydrogen peroxide. The reaction rate is expressed as: $v = k[NaVO_3]_{st}[Ph_2S]^2$, when the concentration of catalyst is very low and $[Ph_2S]_0/[H_2O_2]_0 > 2$, where $[\ ]_{st}$ and $[\ ]_0$ mean stoichiometric and initial concentration, respectively. The effective oxidant may consist of polymeric as well as monomeric peroxyvanadate in view of the effect of concentration of catalyst on the rate. The main oxidizing species at low concentration of catalyst seems to be diperoxyvanadate $VO_5^-$. The rate constant $k_2$ in $v = k_2[Ph_2S]^2$ tends to decrease with initial concentration of $H_2O_2$, which is present in excess of the catalyst. A probable mechanism for the oxidation is discussed.

YOSHIRO OGATA et KAZUSHIGE TANAKA. Can. J. Chem. **60**, 848 (1982).

Faisant appel à l'iodométrie du peroxyde d'hydrogène, on a réalisé une étude cinétique de l'oxydation du sulfure de biphényle ($Ph_2S$) par le peroxyde d'hydrogène en présence d'une quantité catalytique de métavanadate de sodium ($NaVO_3$). On exprime la vitesse de la réaction par l'équation: $v = k[NaVO_3]_{st}[Ph_2S]^2$, lorsque la concentration du catalyseur est très faible et lorsque $[Ph_2S]_M/[H_2O_2]_0 > 2$ où $[\ ]_{st}$ et $[\ ]_0$ signifiient respectivement les concentrations stochiométriques et initiales. L'oxydant effectif peut être le peroxyvanadate sous la forme polymérisée aussi bien que sous la forme monomère compte tenu de l'effet de la concentration du catalyseur sur la vitesse. Pour une faible concentration du catalyseur, l'oxydant principal semble être de dipéroxyvanadate $VO_5^-$. La constante de vitesse $k_2$ dans l'expression $v = k_2[Ph_2S]^2$ tend à diminuer avec la concentration initiale de $H_2O_2$ qui est en excès par rapport au catalyseur. On discute du mécanisme probable de l'oxydation.

[Traduit par le journal]

## Introduction

Vanadic acid is converted to its peroxy acids on treatment with $H_2O_2$. Beg and Ahmad (1) have reported on the kinetics and mechanism of epoxidation of maleic and fumaric acids by $H_2O_2$ catalyzed by sodium orthovanadate, in which the main oxidant is monoperoxyvanadic acid $H_3VO_5$. On the other hand, Modena and co-workers have reported the oxidation of sulfides with *tert*-butyl hydroperoxide (2) or $H_2O_2$ (3) in the presence of bis(acetylacetonato) oxovanadium(IV) $VO(acac)_2$ in alcohol (ROH) as solvent, where the main oxidant is said to be complexed monoperoxyvanadic acid $VO(OR)_2OOH$ produced by conversion of $VO(OR)_3$. These reports, however, paid little attention to the rate of diperoxyvanadic acid.

The treatment of metavanadate with $H_2O_2$ produces peroxy acids consisting mainly of diperoxyvanadate $VO_5^-$ and polymeric peroxyvanadate (4), so that these peroxyvanadates may participate in this oxidation. The present paper describes the rate data and some factors influencing the rate for the $NaVO_3$-catalyzed oxidation of diphenyl sulfide by hydrogen peroxide in 98 wt.% methanol (with 2 wt.% water).

[1] $Ph_2S + H_2O_2 \xrightarrow{NaVO_3} Ph_2SO + H_2O$

## Results and discussion

### *Peroxyvanadate*

Generally, metavanadate ion is known to exist mainly as $V_3O_9^{3-}$ in neutral solution (5). The ion $V_3O_9^{3-}$ is converted to monoperoxyvanadate ion $VO_3^+$ and diperoxyvanadate ion $VO_5^-$ on treatment with hydrogen peroxide as follows (6).

[2a] $V_3O_9^{3-} \xrightarrow{3\,H_2O_2,\ 6H^+} 3\,VO(O_2)^+$

[2b] $V_3O_9^{3-} \xrightarrow{6\,H_2O_2} 3\,VO(O_2)_2^-$

Here, the formation of $VO_5^-$ is influenced by $[H^+]$ (see eq. [3]). But the main species present in the system with $< 0.015\ M$ $H_2O_2$ seems to be $VO_5^-$ based on the fact that the color of the reaction mixture is yellow, that no decomposition of $H_2O_2$ is observed on standing for ca. 8 h at 25°C, and that the rate becomes first-order with respect to substrate ($Ph_2S$) by addition of strong acid ($H_2SO_4$) as stated later.

The identification of $VO_3^+$ and $VO_5^-$ by means of polarography and uv spectroscopy failed because of the complex reaction at the electrode (7) and partial overlapping of the spectra (8), respectively.

*Kinetics*

The oxidation of diphenyl sulfide gave diphenyl sulfoxide together with a small amount of diphenyl sulfone (eq. [1]). Most of our kinetic experiments were done under conditions in which the formation of diphenyl sulfone was negligible; i.e., in the presence of a large excess of sulfide over $H_2O_2$. The rate was followed by iodometry of active oxygen, since the rate constants $k_2$ (in $v = k_2[Ph_2S]^2$) calculated by the iodometry were practically in agreement with those calculated on the basis of the consumption of $Ph_2S$, determined by means of glc; i.e., $6.52 \times 10^{-4}\ M^{-1}\ s^{-1}$ (by iodometry) and $6.15 \times 10^{-4}\ M^{-1}\ s^{-1}$ (by glc).

Though vanadate is a weak oxidant, diphenyl sulfide is oxidized by neither metavanadate nor $H_2O_2$ alone in this solvent (98 wt.% methanol) at 25°C. The spontaneous decomposition of $H_2O_2$ is negligible under these conditions.

The effect of initial concentration of diphenyl sulfide on the rate was examined, the results being shown in Table 1. The rate is expressed as $v = k_2[Ph_2S]^2$, if $[Ph_2S]_0/[H_2O_2]_0 > 2$ and $[H_2O_2]_0 \sim 1.15 \times 10^{-2}\ M$. This result is different from that of sodium tungstate, where the rate expression $v = k_1[Ph_2S]$ is observed. The term $[Ph_2S]^2$ in the rate expression suggests that peroxyvanadate and diphenyl sulfide form a 1:1 coordination complex, $(VO_5{-}Ph_2S)^-$, which may act as a strong oxidant for $Ph_2S$.

If $[Ph_2S]_0$ is lower than $2 \times 10^{-2}\ M$, further oxidation giving a considerable amount of $Ph_2SO_2$ occurs, by which the rate constant decreases.

*Effects of concentration of catalyst and $H_2O_2$*

The effect of the initial concentration of sodium metavanadate $[NaVO_3]_0$ relative to that of $H_2O_2$, which is in large excess to $NaVO_3$, is shown in Fig. 1. The rate constant ($k_2$ in $v = k\,[Ph_2S]^2$) increases with $[NaVO_3]_0$, but the increase is not linear after $5 \times 10^{-4}\ M$ $NaVO_3$. This fact suggests that polymeric diperoxyvanadate, which is a weaker oxidant, may exist in analogy to polymeric vanadate; the extent of polymerization of vanadate is known to increase with its concentration (4).

The effect of the initial concentration of hydrogen peroxide is shown in Fig. 2. As apparent from the figure, the rate constant decreases gradually with increasing $[H_2O_2]_0$. The rate expression $v = k_2[Ph_2S]^2$ is valid at $[Ph_2S]_0/[H_2O_2]_0 > 2$, but when $[Ph_2S]_0/[H_2O_2]_0 < 1/2$, little reaction occurs.

If $[Ph_2S]_0/[H_2O_2]_0 < 2$ and $[H_2O_2]_0$ is kept constant, the rate constant $k_2$ increases with the concentration of $Ph_2S$. These results suggest the presence of a complex consisting of $H_2O_2$, $Ph_2S$, and $VO_5^-$ at the transition state. We found that there is no effect of $[H_2O_2]_0$ on the rate constant, if sodium tungstate is used instead of sodium metavanadate; hence the interaction between hydrogen peroxide and peroxyvanadate is characteristic of vanadate and it may be ascribed to the hydrogen-bonded association of $H_2O_2$ with peroxyvanadate. Since diperoxyvanadate $VO_5^-$ seems to be a highly charge-delocalized anion (3), it is possible that it may associate with $H_2O_2$ more readily than peroxytungstate. In analogy to $H_2O_2$, the addition of a small amount of water to the reaction system retards the rate markedly; for example, $6.52 \times 10^{-4}$

[a] $v = k_2[Ph_2S]^2$.

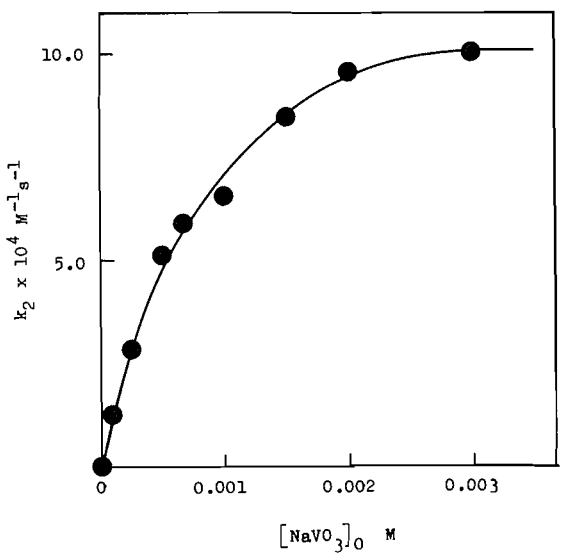

FIG. 1. Effect of $[NaVO_3]_0$ on $k_2$ ($M^{-1}\ s^{-1}$) for $NaVO_3$-catalyzed oxidation of $Ph_2S$ with $H_2O_2$ in 98 wt.% MeOH at 25°C. $[Ph_2S]_0 = 2.5 \times 10^{-2}\ M$, $[H_2O_2]_0 = 1.20 \times 10^{-2}\ M$.

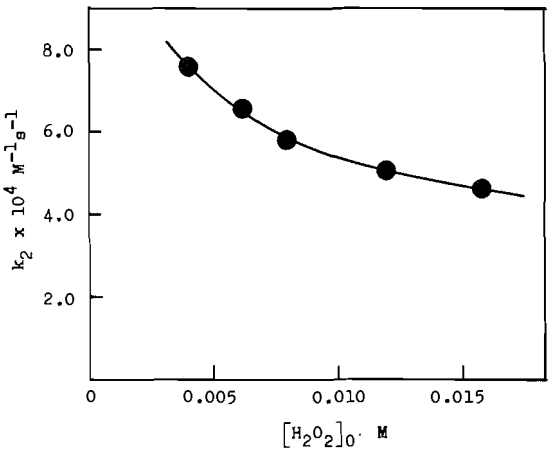

FIG. 2. Effect of $[H_2O_2]_0$ on $k_2$ ($M^{-1}$ $s^{-1}$) for $NaVO_3$-catalyzed oxidation of $Ph_2S$ with $H_2O_2$ in 98 wt.% MeOH at 25°C. $[Ph_2S]_0 = 2.5 \times 10^{-2}$ $M$, $[NaVO_3]_0 = 0.5 \times 10^{-3}$ $M$.

$M^{-1}$ $s^{-1}$ in 98 wt.% MeOH–$H_2O$ and $3.69 \times 10^{-4}$ $M^{-1}$ $s^{-1}$ in 96 wt.% MeOH–$H_2O$. This fact also supports the deactivation of peroxyvanadate with hydrogen-bonded association. It is known that $VO_5^-$ is converted to other peroxyvanadates such as $HV(O)(O_2)_3^{2-}$ or $HV(O)_2(O_2)_2^{2-}$ etc. by an increase of $[OH^-]$ (6). Since $H_2O_2$ is almost neutral (very weak acid), $VO_5^-$ does not seem to be converted to the above peroxyvanadates by a large excess of $H_2O_2$. On the other hand, though $VO_5^-$ is converted to $VO_3^+$ by an increase of $[H^+]$, the conversion into $VO_3^+$ is negligible at this acidity, since there is no change of the rate order and no decomposition of $H_2O_2$ is observed on addition of $H_2SO_4$ (see below).

*Effects of additives*

Effects of additives ($H_2SO_4$, $Ph_2SO$, and $H_2O$) are shown in Table 2. The rate constants did not vary on addition of $4.0 \times 10^{-3}$ $M$ diphenyl sulfoxide. On addition of $1.5 \times 10^{-3}$ $M$ sulfuric acid to the reaction mixture, the rate expression becomes $v = k_1[Ph_2S]$, i.e., not second-order, but first-order in the substrate. The addition of $H_2SO_4$ makes the decomposition of $H_2O_2$ appreciable, and it changes the color of the reaction mixture from yellow to orange. These facts suggest that monoperoxyvanadate is a main oxidizing agent under acidic conditions, as will be explained below.

(a) Monoperoxyvanadate $VO_3^+$ is red and diperoxyvanadate $VO_5^-$ is yellow (9). The observed change of colors to orange by addition of $H_2SO_4$ is ascribed to the increasing content of $VO_3^+$.

(b) Modena and co-workers have reported that the $H_2O_2$ oxidation and the decomposition of $H_2O_2$ occur via $VO(OR)_2OOH$, which is equivalent to $VO_3^+$, according to the equation:

$$VO_3^+ + 2\,RO^- \xrightarrow{H^+} VO(OR)_2OOH.$$

The rate of oxidation by $VO(OR)_2OOH$ is first-order in substrate just like our $H_2SO_4$–$NaVO_3$–$H_2O_2$ oxidation. Hence, the main oxidant in the $H_2SO_4$–$NaVO_3$–$H_2O_2$ system may be $VO_3^+$.

(c) There is an equilibrium between monoperoxyvanadate and diperoxyvanadate, as shown in eq. [3], and the equilibrium constant has been reported (10).

[3] $$VO_3^+ + H_2O_2 \rightleftarrows VO_5^- + 2H^+$$

The increase of the acidity shifts the equilibrium to the left, thus $[VO_3^+]$ increases, so that the main oxidizing species in strong acid solution would be $VO_3^+$. An increase of $H_2SO_4$ concentration over $1.5 \times 10^{-3}$ $M$ resulted in the rapid decomposition of $H_2O_2$, thus leading to inaccurate rate constants, while addition of $2.8 \times 10^{-3}$ $M$ NaOH inhibited the reaction. The oxidation in the range between $1.5 \times 10^{-3}$ $M$ $H_2SO_4$ and $2.8 \times 10^{-3}$ $M$ NaOH gave a complex rate expression because of the participation of mono- and diperoxyvanadium complexes.

On addition of $H_2O$ to the reaction mixture, the rate constant becomes small. This fact supports the deactivation of peroxyvanadate with hydrogen-bonded association as stated above.

*Mechanism*

The above facts suggest the following mechanism for the oxidation in neutral 98 wt.% methanol at very low concentrations of sodium metavanadate with negligible concentration of polyperoxyvanadates.

[4] $$VO_5^- + nH_2O_2 \underset{\text{fast}}{\overset{K_{n,a}}{\rightleftharpoons}} (VO_5^-)(H_2O_2)_n$$

[5] $$(VO_5^-)(H_2O_2)_n + Ph_2S \underset{\text{fast}}{\overset{K_{n,b}}{\rightleftharpoons}} (VO_5\text{–}Ph_2S)^-(H_2O_2)_n$$

[6] $$(VO_5\text{–}Ph_2S)^-(H_2O_2)_n + Ph_2S \xrightarrow[k_n]{\text{slow}} Ph_2SO + (VO_4\text{–}Ph_2S)^-(H_2O_2)_n$$

[7] $$(VO_4\text{–}Ph_2S)^-(H_2O_2)_n + H_2O_2 \xrightarrow{\text{fast}} (VO_5\text{–}Ph_2S)^-(H_2O_2)_n + H_2O$$

Equation [4] shows the hydrogen-bonded association of $H_2O_2$ with $VO_5^-$. In view of the rate equation, this aggregated complex seems to form a 1:1 coordination complex with diphenyl sulfide (eq.

[d] Weight %.

[5]) and this complex seems to react with another molecule of diphenyl sulfide to give diphenyl sulfoxide (eq. [6]). The bulky $Ph_2S$ molecule would permit the second molecule of $Ph_2S$ to attack on the peroxy oxygen atom but not on the vanadium atom. Since monoperoxyvanadate seems to be unstable in this system, $(VO_4–Ph_2S)^-(H_2O_2)_n$ formed in eq. [6] would be rapidly converted to $(VO_5–Ph_2S)^-(H_2O_2)_n$ by excess $H_2O_2$ (eq. [7]).

This mechanism involving a rate-determining attack of complex $(VO_5–Ph_2S)^-(H_2O_2)_n$ on diphenyl sulfide to form diphenyl sulfoxide leads to a rate expression as follows.

$$[8] \quad v = \sum_{i=0}^{n} k_i[(VO_5–Ph_2S)^-(H_2O_2)_i][Ph_2S] = \sum_{i=0}^{n} k_i K_{i,a} K_{i,b}[H_2O_2]^i[VO_5^-][Ph_2S]^2$$

Here, $K_{0,a} = 1$ and $k_i$ represents the $i$th rate constant, $K_{i,a}$ the $i$th equilibrium constant of eq. [4], and $K_{i,b}$, the $i$th equilibrium constant of eq. [5]. Since $NaVO_3$ reacts rapidly with $H_2O_2$ and since the uv spectrum of peroxyvanadates does not change with increasing concentration of $H_2O_2$ which is present in excess of the catalyst, $NaVO_3$ may be completely converted to peroxyvanadates (mainly $VO_5^-$). Hence, the stoichiometric initial concentration of $NaVO_3$ is approximated as: $[NaVO_3]_0 \simeq [VO_5^-]_{st}$. On the other hand, the association of $VO_5^-$ with $H_2O_2$ at various molar ratios is expressed as:

$$[9] \quad [VO_5^-]_{st} = \sum_{i=0}^{n} K_{i,a}[H_2O_2]^i[VO_5^-]$$

Introduction of eq. [9] into eq. [8] leads to

$$[10] \quad v = \sum_{i=0}^{n} k_i K_{i,a} K_{i,b}[H_2O_2]^i\{[VO_5^-]_{st} - \sum_{i=1}^{n} K_{i,a}[H_2O_2]^i[VO_5^-]\}[Ph_2S]^2$$

Also, the reactivity of free $VO_5^-$ is much reduced by association with $H_2O_2$, i.e.,

$$k_0K_{0,b} \gg k_1K_{1,a}K_{1,b}[H_2O_2] + \cdots + k_nK_{n,a}K_{n,b}[H_2O_2]^n;$$

consequently,

$$\sum_{i=0}^{n} k_iK_{i,a}K_{i,b}[H_2O_2]^i \simeq k_0K_{0,b}$$

Hence,

$$[11] \quad v \simeq k_0K_{0,b}\{[VO_5^-]_{st} - \sum_{i=1}^{n} K_{i,a}[H_2O_2]^i[VO_5^-]\} \times [Ph_2S]^2 = k_2[Ph_2S]^2$$

This expression is consistent with the experimental results. The apparent rate constant $k_2$ decreases with increasing $[H_2O_2]_0$, since the concentration or the sum of concentrations of associated peroxyvanadates, i.e.,

$$\sum_{i=1}^{n} K_{i,a}[H_2O_2]^i[VO_5^-]$$

increases with $[H_2O_2]_0$.

On the other hand, in the presence of $H_2SO_4$, the following mechanism may be operating as a main pathway as stated above.

$$[12a] \quad V_3O_9^{3-} + 3H_2O_2 + 6H_2SO_4 \rightleftarrows 3VO_3^+ + 6H_2O + 6HSO_4^-$$

$$[12b] \quad VO_3^+ + Ph_2S \rightarrow VO_2^+ + Ph_2SO$$

But the direct oxidation with acidic $H_2O_2$ and spontaneous decomposition of $H_2O_2$ render the reaction kinetics complex. It has been reported (10) that both peroxy species $VO_3^+$ and $VO_5^-$ participate in the oxidation of iodide ion in the $[H^+]$ range of 0.1–1.0.

## Experimental

*Materials*

Methanol was purified by fractionation (bp 66–67°C) and it was used as 98 wt.% solvent to make the oxidation system homogeneous. Diphenyl sulfide was purified by vacuum distillation (bp 118–119°C, 4 Torr). Sodium metavanadate was of commercial, guaranteed reagent grade, quality.

*Kinetics*

A mixture of $NaVO_3$ and $H_2O_2$ in 98 wt.% MeOH was kept standing at 25°C for 5 min, then the reaction was started by addition of $Ph_2S$. Aliquots were taken out at appropriate intervals of time, and their peroxide contents were determined iodometrically. The concentrations of $Ph_2S$ were calculated based on the $H_2O_2$ concentration after subtraction of metavanadate concentration. The consumption of $Ph_2S$ was measured by glc (a Yanagimoto G 180 gas chromatograph with FID) with a column (2.5 mm × 1 m) packed with PEG 20M.

# Synthesis and vibrational study of a 1:1 stoichiometric complex of hydronium tetrafluoroborate and 1,4,7,10,13,16-hexaoxacyclooctadecane (18-crown-6)

ROBERT CHÊNEVERT,[1] ANDRÉ RODRIGUE, MARIE PIGEON-GOSSELIN, AND RODRIGUE SAVOIE[1]

*Département de chimie et Centre de recherche sur les atomes et les molécules, Université Laval, Québec (Qué.), Canada G1K 7P4*

Received September 18, 1981

ROBERT CHÊNEVERT, ANDRÉ RODRIGUE, MARIE PIGEON-GOSSELIN, and RODRIGUE SAVOIE. Can. J. Chem. **60**, 853 (1982).

The macrocyclic ether 1,4,7,10,13,16-hexaoxaoctadecane (18-crown-6) has the remarkable property of being able to transfer the hydronium ($H_3O^+$) ion from an aqueous solution to an organic medium. This property has been used to synthetize a 1:1 stoichiometric complex of this ether with hydronium tetrafluoroborate. This complex is very stable (mp 145°C) and dissolves readily, without decomposition, in solvents such as $CHCl_3$. The presence of the $H_3O^+$ and $BF_4^-$ ions in the complex has been confirmed by chemical analysis, and by $^1H$ nmr, Raman, and ir spectroscopy. The vibrational spectra indicate that a conformational change of the crown ether takes place in the complex over the temperature range −50°C to −100°C. The symmetry of the crown ether, which appears to be relatively high at room temperature, is considerably reduced below the transition temperature.

ROBERT CHÊNEVERT, ANDRÉ RODRIGUE, MARIE PIGEON-GOSSELIN et RODRIGUE SAVOIE. Can. J. Chem. **60**, 853 (1982).

L'éther macrocyclique 1,4,7,10,13,16-hexaoxaoctadécane (18-crown-6) possède la propriété remarquable de pouvoir transférer l'ion hydronium ($H_3O^+$) d'une solution aqueuse à un milieu organique. Cette propriété a été utilisée pour préparer un complexe de stoéchiométrie 1:1 de l'éther avec le tétrafluoroborate d'hydronium. Ce complexe très stable (pf 145°C) se dissout sans décomposition dans des solvants tels que le $CHCl_3$. La présence des ions $H_3O^+$ et $BF_4^-$ dans le complexe a été démontrée par analyse chimique, et par spectroscopie $^1H$ rmn, ir et Raman. Les spectres de vibration ont mis en évidence dans le complexe un changement de conformation de l'éther dans le domaine de température s'étendant approximativement de −50°C à −100°C. La symmétrie de l'éther couronne, assez élevée à température ambiante, serait fortement diminuée au-dessous de la température de transition.

## Introduction

Macrocyclic polyethers have a remarkable complexing ability, not only for alkali metal ions, but also for ammonium (1), guanidinium (2), and sulfonium ions (3), as well as for mercury and cadmium halides (4). Evidence of complexation between crown ethers and diazonium and benzoyl cations has also been reported (5). These cyclic ethers further form complexes with neutral organic molecules such as dimethyl acetylenedicarboxylate (6), thiourea (7), acetonitrile (8), and nitro compounds (9). Izatt and co-workers (10) have characterized a complex between hydronium perchlorate and dicyclohexyl-18-crown-6 (*cis-syn-cis* isomer) by infrared spectroscopy. We report here on the formation and characterization of a 1:1 stoichiometric complex between hydronium tetrafluoroborate and 1,4,7,10,13,16-hexaoxacyclooctadecane (18-crown-6, hereafter referred to as EOc6, as it corresponds to a cyclic hexamer of ethylene oxide).

## Experimental

The complex studied here was first obtained during a study of the complexation of nitronium tetrafluoroborate by the cyclic ether EOc6 in tetrahydrofuran; addition of water produced a precipitate which was later identified as the complex reported here. It was later discovered that the complex could be prepared in a more straightforward manner, by the addition of fluoroboric acid (40%) to a solution of the crown ether in tetrahydrofuran. In contrast to most hydronium salts which have low melting points and are highly hygroscopic, the crown ether hydronium complex as well as the oxonium complex described previously (10) are very stable to moisture and can be kept indefinitely at room temperature. The melting temperature of $EOc6.H_3O^+.BF_4^-$ (145°C) is much higher than that of the ligand (40°C).

The one-to-one stoichiometry of the $H_3O^+.BF_4^-$ and EOc6 components in the complex was established by dissolution of the salt in water followed by titration of the acid content by NaOH 1 *N* with phenolphthalein as an indicator. Elemental analysis for C, H, and F was consistent with the suggested formulation ($C_{12}H_{27}O_7BF_4$; calcd: C 38.94, H 7.35, F 20.53; found: C 39.20, H 7.33, F 20.77).

The Raman spectra were recorded on a microcomputer-controlled Spex Model 1400 spectrometer (11), using the 514.5 nm exciting line from a Spectra Physics Model 165 argon ion laser. The measurements were taken by steps of 1 $cm^{-1}$, with an integration time typically set at 1.5 s per point. The spectral slit width was generally adjusted to 1 $cm^{-1}$ and the laser power at the sample was fixed at 450 mW. The polycrystalline solid complex as well as the solutions were studied in glass capillary cells. For low-temperature measurements, down to −100°C, the sample cell was fixed in the center of an evacuated cylindrical jacket and cooled with a flow of cold nitrogen gas. The spectra at liquid nitrogen temperature were obtained with the sample cell placed in a copper holder fixed at the tip of a cold finger in a liquid nitrogen cryostat.

In the infrared study, Nujol and hexachlorobutadiene mulls contained between Irtran-4 windows were used. The spectra were recorded on a Perkin-Elmer Model 621 spectrophotometer, at a scanning speed of 0.4 $cm^{-1}$/s and a spectral slit width of 3 $cm^{-1}$. The low-temperature spectra were obtained with the same mulls as above, using a conventional liquid nitrogen cryostat.

In both the infrared and Raman studies, the temperature was monitored by a copper–constantan thermocouple linked to a Fluke digital thermometer. In each case the temperature was maintained within ±3°C of any desired value, either by adding controlled amounts of liquid nitrogen to the cryostat in the infrared, or by adjusting the flow on coolant gas in the Raman experiments. The frequencies reported in this study are believed to be accurate to ±2 $cm^{-1}$ for sharp peaks, the infrared spectrometer having been calibrated with a standard indene solution and the Raman instrument with a neon discharge lamp.

The $^1H$ nmr spectra were taken on a Bruker HX-90 (90 MHz) with tetramethylsilane as an internal standard or, for $^{13}C$, on a Bruker WP-80 spectrometer working at 20 MHz.

The microanalyses were performed by Dr. C. Daessle, Organic Microanalysis, Montreal.

## Results and discussion

The EOc6 ether was found to be able to transfer the hydronium tetrafluoroborate ion pair from an aqueous phase to an organic medium (dichloromethane, chloroform, tetrahydrofuran). To the best of our knowledge, this is the first observation of a direct liquid–liquid phase transfer of the hydronium ion from an aqueous solution to an organic phase. This process is obviously of great interest and work is continuing along that line. Preliminary results indicate that other cyclic ethers, such as dicyclohexyl-18-crown-6, dibenzo-18-crown-6, and 15-crown-5 also share the complexing ability of EOc6 towards the $H_3O^+$ ion, although it appears more difficult to isolate complexes of definite composition with these other ethers.

The Raman spectra of the complex in solution and as a polycrystalline powder are reproduced in Fig. 1, together with the spectrum of the uncomplexed ether which is shown for comparison purposes. The infrared spectra of mulled samples of the complex have also been recorded and the frequencies of the observed bands are given in Table 1, along with those of the Raman peaks.

The $^1H$ nmr spectrum of the EOc6.$H_3O^+$.$BF_4^-$ complex in solution in $CDCl_3$ contains only two peaks; the first at 3.77 ppm is slightly shifted with respect to that of the free ether (3.67 ppm), whereas the second consists of a sharp singlet near 11 ppm and is characteristic of the $H_3O^+$ ion (12). The latter, which is not present in the corresponding spectrum of the deuterated complex, has an integrated area which is consistent with the presence of the three hydrogen atoms of the hydronium ion. On the other hand, the proton decoupled $^{13}C$ nmr spectrum of the complex in solution in $CDCl_3$ contains but a very sharp singlet at 70.10 ppm, slightly shifted from the signal obtained from the uncomplexed ether (70.76 ppm). The relative simplicity of the nmr spectra suggests for the complex in solution a rather soft structure, the $H_3O^+$ ion being able to move around so that the six oxygen atoms of the ether share equally, on the average, the possible hydrogen bonds formed between the hydronium ion and the ligand.

The ionic nature of the EOc6.$H_3O^+$.$BF_4^-$ complex is confirmed by its infrared and Raman spectra, which also provide some information on its structure. It is helpful in this regard to compare the vibrational spectra of the complex with that of the uncomplexed cyclic ether, in both the crystalline state and in chloroform solution.

The molecular structure of the uncomplexed hexaether in the crystal departs significantly from the regular ($D_{3d}$) crown conformation (13). It assumes a rectangular shape of symmetry $C_i$, with three different kinds of —O—$CH_2$—$CH_2$—O— units. This low symmetry is reflected in the Raman spectrum (Fig. 1*A*, see also ref. 14), which is appreciably more complicated than those of various crystalline polyether complexes, such as KSCN, RbSCN, and CsCN (15), in which the ether adopts the $D_{3d}$ conformation (16). The same is true of the KBr complex, which has also been extensively studied by infrared spectroscopy (15, 17, 18).

The Raman spectrum of EOc6 dissolved in $CHCl_3$ (Fig. 1*B*) closely resembles that in $CH_3OH$ (14). Simplification of the spectrum occurs upon dissolution, even after taking into account the general broadening of the bands. It therefore appears that the molecule, on the average, has a more symmetrical structure in solution, although this structure probably fluctuates widely between various different conformations. The absence in the Raman spectrum of the solute of the strong band present at 414 $cm^{-1}$ in the spectrum of the solid is worth mentioning, as it may be characteristic of the rectangular structure adopted by the ether in the crystal.

The presence of the $H_3O^+$ ion in the crystalline complex, as well as in the solution in $CHCl_3$, is readily established from the characteristic bands of the hydronium ion (see, for example, ref. 19 and references cited therein) present in the infrared spectra. The two stretching modes ($\nu_1$ and $\nu_3$) give a very strong and broad band centered at 2850 $cm^{-1}$ (Fig. 2), whereas the asymmetric bending mode ($\nu_4$) occurs near 1650 $cm^{-1}$. The band due to the symmetric bending mode ($\nu_2$), which normally occurs near 1100 $cm^{-1}$, is overlapped by a very strong band of the $BF_4^-$ ion. However, its first overtone gives a characteristic band at 2150 $cm^{-1}$. These frequencies are almost identical to those found in the dicyclohexyl-18-crown-6.$H_3O^+$.$ClO_4^-$ complex (10), whose structure is probably quite

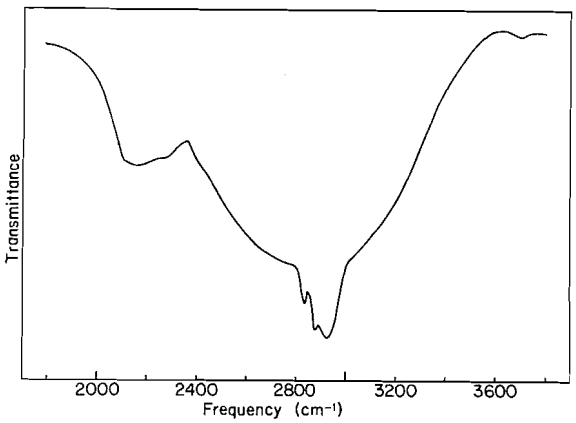

FIG. 2. High-frequency region of the infrared spectrum of 18-crown-6. $H_3O^+.BF_4^-$ complex mulled in hexachlorobutadiene at 28°C, showing the strong band of $H_3O^+$ near 2850 $cm^{-1}$.

similar to that of the complex discussed here. Raman bands due to the weak $H_3O^+$ scatterer were not detected in the Raman spectra of the complex, although this ion has been shown to give a measurable Raman spectrum in various acids (19, 20). It should also be mentioned that the solid monohydrate of tetrafluoroboric acid, $HBF_4.H_2O$, is ionised ($H_3O^+.BF_4^-$) in its crystalline form (21).

The vibrational frequencies of the tetrahedral $BF_4^-$ ion are well known from previous spectroscopic studies of this species in aqueous solution, molten salts (22), and crystalline salts of alkaline metals (23). The very sharp peak due to the totally symmetric stretching mode ($\nu_1$) is particularly evident at 765 $cm^{-1}$ in the Raman spectra of the EOc6 complex (Fig. 1 *C–E*), even in the case of the $CHCl_3$ solution where it emerges from a broader peak due to the solvent. This mode is normally infrared-inactive, but it is responsible for a very weak band detectable in the infrared spectrum at liquid nitrogen temperature. This points to a slight departure from tetrahedral symmetry in the solid, at least at low temperature.

The symmetric bending mode ($\nu_2$) of $BF_4^-$ gives but a weak peak at 369 $cm^{-1}$ in the spectrum of the solid at room temperature. At liquid nitrogen temperature, however, this band is split into a doublet at 368/374 $cm^{-1}$. This probably results from the anisotropy of the local field surrounding the $BF_4^-$ ions in the solid, which also suggests some distortion of these ions in an asymmetric environment. The $\nu_4$ bending mode, which normally occurs in the 520–535 $cm^{-1}$ range, is difficult to single out in the present study due to the presence of other bands from the ether in this same region. The weak band present at 536 $cm^{-1}$ in both the infrared and Raman spectra most likely belongs to this vibration, but it is not possible to establish whether the nearby peaks at 520 and 550 $cm^{-1}$ in the Raman are components of this triply degenerate mode or if they belong to the ether.

The asymmetric stretching mode of the tetrafluoroborate ion ($\nu_3$) is responsible for a very strong absorption band in the 1100 $cm^{-1}$ region of the infrared spectrum. As in crystalline $KBF_4$, $RbBF_4$, and $CsBF_4$ (23), this band is characterized by a submaximum near 1040 $cm^{-1}$ and a very strong reflection shoulder on its high frequency side. This region of the spectrum is extremely complex, due to the interaction between $\nu_3$ and the first overtone of $\nu_4$, and because of the presence of the $\nu_2$ bending mode of the $H_3O^+$ and a strong band from the cyclic ether. The $\nu_3$ band of $BF_4^-$ is weak in the Raman spectrum of the complex, and it cannot be singled out from other bands in this region.

Comparison of the spectrum of the ether complex in solution in $CHCl_3$ (Fig. 1*C*) with that of a solution of the uncomplexed ether (Fig. 1*B*), shows that a noticeable sharpening of the Raman bands occurs upon complexation, along with intensity changes, particularly in the 1450 and 2900 $cm^{-1}$ region. This indicates that the structure of the complex is relatively more rigid than that of the uncomplexed ether and, also, that the conformation of the ether in the complex is modified with respect to the average conformation of the free molecule. On the other hand, the Raman spectra of the complex in solution (Fig. 1*C*) and in the crystalline state (Fig. 1*D*) are very similar, which means that the $EOc6.H_3O^+.BF_4^-$ units have basically the same structure in both conditions. One also notices that the Raman bands of the crystalline complex at room temperature are generally broader than those of the crystalline cyclic ether (Fig. 1*A*). Although the exact significance of this observation is not clear, the possibility that some degree of disorder exists in the crystalline complex cannot be discarded.

The room temperature Raman spectrum of the $EOc6.H_3O^+.BF_4^-$ crystalline complex is very similar to those of various complexes in which the ether is known to have the regular crown geometry of $D_{3d}$ symmetry (14, 15, 24). However, some extra bands are observed in the present case, which suggest some departure from this ideal conformation. For example, whereas three Raman-active modes ($A_{1g} + 2E_g$) are predicted, and generally observed in other spectra, for the $CH_2$ twisting modes in the 1330–1400 $cm^{-1}$ region, at least four bands are present in this region of the spectrum of the hydronium complex. One also notes a splitting of the skeletal breathing mode, which gives a doublet at 874/883 $cm^{-1}$ in the present case, as compared to a singlet in the 860–870 $cm^{-1}$ region

with other compounds. Departure from the $D_{3d}$ symmetry is even more evident when the infrared spectra are compared. Those of the very symmetric complexes, such as that with KBr, in which the $K^+$ ion is located at the center of the crown ether cavity, contain but two major bands in the 800–1000 $cm^{-1}$ region (15, 17), whereas two doublets are observed at 820/842 and 949/973 $cm^{-1}$ in the spectrum of the hydronium complex. This type of splitting is too important to be explained by an intermolecular vibrational coupling effect and, also, unlikely to be caused by a purely crystalline field perturbation.

The vibrational spectra of the hydronium complex at liquid nitrogen temperature (Fig. 1*E* and Table 1) differ markedly from those at room temperature. The vibrational bands are much sharper at low temperature and the number of components in each region of the spectrum is considerably increased. Although the observed spectral changes occur gradually with the lowering of the temperature, they mostly take place in the range −55°C to −95°C (Fig. 3). The modifications of the spectra can only be interpreted in terms of a lowering of the symmetry of the ether molecules at low temperature. This, in turn, is most likely accompanied by a change in the structure of the crystal.

It is possible, using known structural data, to build a satisfactory model of the EOc6.$H_3O^+$.$BF_4^-$ complex, which would be consistent with its vibrational spectra. EOc6 is known to be a particularly good complexing agent for metal ions, which interact with its oxygen atoms. When the ionic radius of the metal is appropriate, such as with $K^+$, the ether adopts the $D_{3d}$ conformation and the ion sits at the center of the molecular cavity. Larger ions, such as $Cs^+$ and $Rb^+$, are displaced from the mean plane of the ether, although the latter retains its $D_{3d}$ conformation, whereas with a smaller ion such as $Na^+$ the ether folds itself around the positively charged particle (16). Assuming an average dimension for the EOc6 molecule in its $D_{3d}$ conformation (16) and for the $H_3O^+$ ion ($r$(O—H) = 1.02 Å, ∠ H—O—H = 110°), one finds that the hydronium ion can fit easily within the ether cavity. However, it is to be expected in this case that the $H_3O^+$ ion will orient itself so as to form three OH···O hydrogen bonds, using alternate oxygen atoms of the ether. These three atoms can be those above the mean plane of the ether, as shown in Fig. 4, or the three below, this latter possibility being probably more favorable in view of the relative orientation of the lone pairs on these atoms. It is also possible that both types of complex exist at room temperature, given the relative broadness of the vibrational bands noted above.

The $BF_4^-$ ion is obviously associated electrically with the EOc6.$H_3O^+$ complex and it is likely that, at least in solution, it will take a position so as to maximize its interactions with the hydrogen atoms of the $H_3O^+$ ion. This is most easily done through the cavity of the host ether, with the resulting $H_3O^+$.EOc6.$BF_4^-$ aggregate being best described as a "crown ether-separated ion pair", analogous to the $RNH_3^+$. crown ether.$A^-$ complexes obtained with primary amines (25). The vibrational spectra indicate that the $BF_4^-$ ion in the complex is little distorted from tetrahedral symmetry, contrary to the situation which prevails with isolated $M^+BF_4^-$ ion pairs isolated in rare gas matrices (26). This suggests that the $H_3O^+$–$BF_4^-$ interactions in the complex are not very directional in nature, which may result in the molecular rotation of the $BF_4^-$ ions being relatively free in solution and even in the room temperature solid.

We have mentioned above that the hydronium ion is small enough to fit into the cavity of the crown ether. In fact, it would fit very loosely into this cavity when the crown ether is in its $D_{3d}$ conformation. In this case, assuming equivalent linear hydrogen bonds between the $H_3O^+$ ion and three alternate oxygen atoms of the ether, the O····O distances in the complex can be estimated at 2.95 Å. Such a large value would only be consistent with very weak hydrogen bonds, which could not account for the stability of the complex. Moreover, using known relations between the ν(O—H) frequency and the O····O distances in H-bonded systems (19, 27), the 2850 $cm^{-1}$ value for the room temperature solid leads to an approximate distance of 2.65 Å.

There are many ways in which the O····O distances between the $H_3O^+$ ion and the cyclic ether can be diminished. First, one can consider the case where the ether would essentially retain its $D_{3d}$ geometry, with the hydronium ion moving about in the cavity so as to form at any given time two strong and one weak hydrogen bonds. In this situation, there would be two different types of oxygen atoms in the ether molecule, those which are statistically H-bonded with the hydronium ion, and the other three which are not involved in hydrogen bond formation. The symmetry of the ether molecule would then be statistically $C_{3v}$. Also possible is a symmetric distortion of the ether, in which three alternate oxygen atoms are forced towards each other, which would also lower the symmetry of the complex to $C_{3v}$. This type of symmetry is interesting because it would be consistent with the room temperature vibrational spectra of the complex, which suggest a structure of relatively high symmetry, related to the $D_{3d}$ conformation of the ether

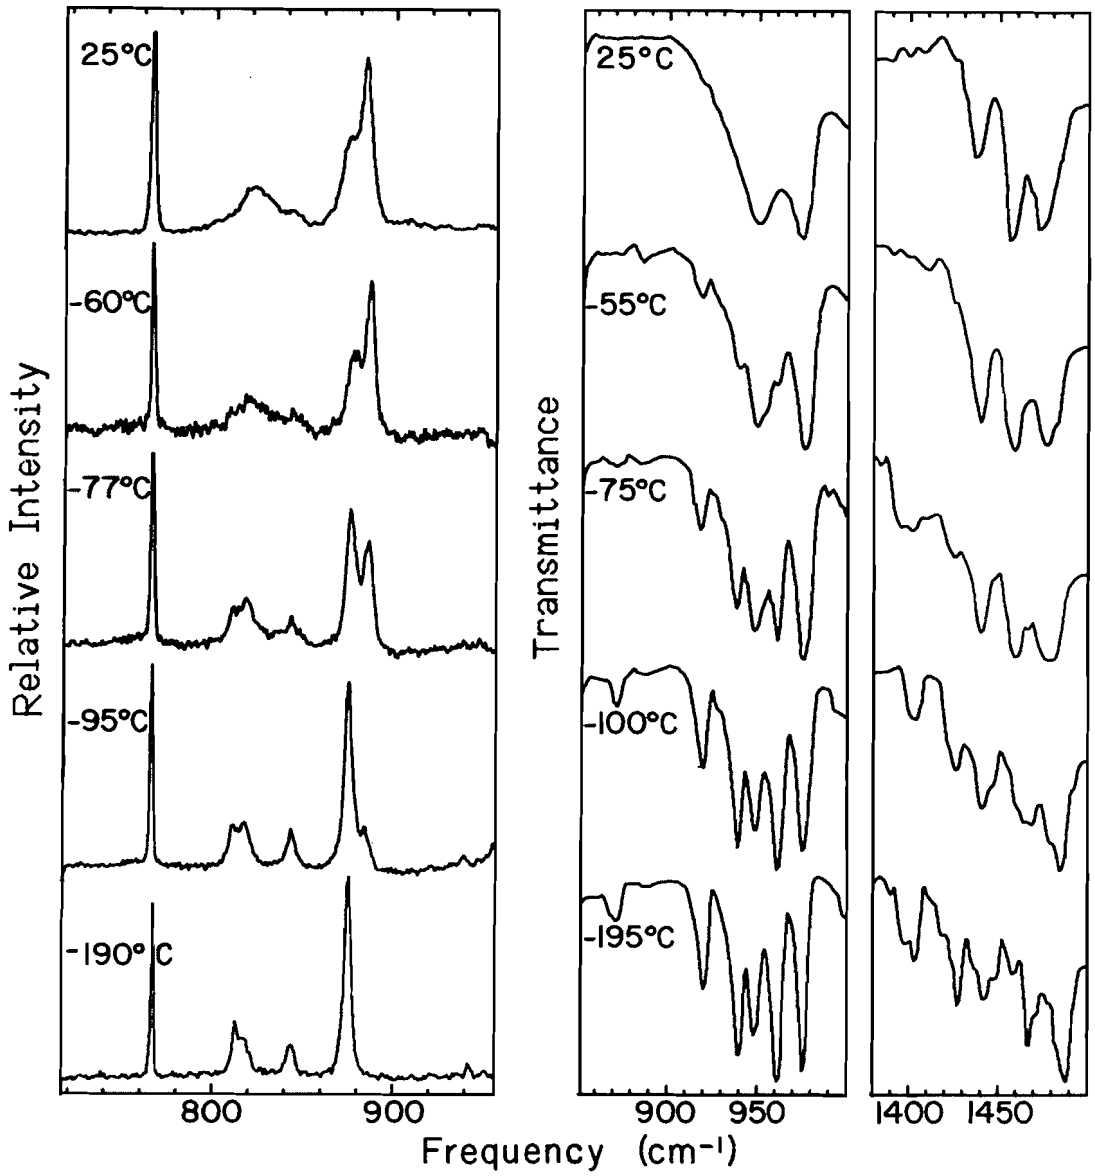

FIG. 3. Selected regions of the Raman (left) and infrared (right) spectra of the 18-crown-6.$H_3O^+$.$BF_4^-$ complex as a function of temperature.

moiety. The extra bands observed in the spectra could be readily explained on this basis, as the predicted number of active vibrational components would be approximately doubled by a lowering of the ether symmetry to $C_{3v}$. For example, whereas three non-coincident Raman- ($A_g + 2E_g$) and infrared- ($A_{2u} + 2E_u$) active modes are predicted for each of the $\delta(CH_2)$ (1430–1500 $cm^{-1}$ region), $\omega(CH_2)$ (1330–1430 $cm^{-1}$ region), and $tw(CH_2)$ (1230–1330 $cm^{-1}$ region) modes in the case of a $D_{3d}$ conformation, six coincident infrared- and Raman-active components ($2A_1 + 4E$) are expected in each region for a molecule of $C_{3v}$ symmetry.

From a theoretical point of view, lowering the symmetry of the crown ether molecule from $D_{3d}$ to $C_{3v}$ by bringing three of the six oxygen atoms closer together is not energetically favorable. This type of perturbation would force the other three oxygen atoms in the molecule to be pushed outwards, and bring strain into the cycle as the torsion angle about the C—C bonds increases from their ideal 60° value and that about the C—O bonds gets smaller than 180°. The strain brought into the cycle would then have to be more than compensated by the extra stability resulting from the formation of the three hydrogen bonds, each with an energy of ~7 kcal

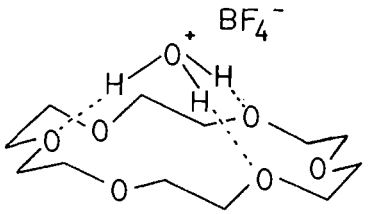

FIG. 4. Schematic representation of the 18-crown-6.$H_3O^+$.$BF_4^-$ complex.

$mol^{-1}$, as deduced from the frequency of the ν(O—H) stretching mode (27). The changes observed in the spectra upon lowering the temperature point to a very low symmetry of the crown ether moiety below the transition temperature. In the present scheme, it would seem that lowering the temperature causes the O···O distances to become shorter (the ν(O—H) frequency decreases to 2700 $cm^{-1}$), which results in the strain in the cyclic ether ring becoming more important than the gain in stability resulting from the formation of the three hydrogen bonds. At this point some folding of the ether molecule would take place, thus lowering the symmetry of the complex, possibly to $C_s$. In this low symmetry, all of the fundamental vibrations of the ether become simultaneously infrared- and Raman-active, which would account for the complexity of the vibrational spectra in the low temperature phase of the crystal. The very sharp lines in the spectra at liquid nitrogen temperature indicate that, whatever the structure of the crystal, it is not disordered as seems to be the case in the higher temperature modification.

The strange behavior of the 874/883 $cm^{-1}$ Raman doublet with temperature (Fig. 3) is noteworthy. The fact that one of the two components appears to grow at the expense of the other with decreasing temperature suggests a shift of equilibrium between two different conformers which would be simultaneously present in the solid at room temperature. This, however, is not supported by the other features in the spectra. These suggest only a gradual change of conformation of the complex as the temperature is lowered. In most cases, new bands gradually appear in the spectra upon going through the transition, and the disappearance of the 883 $cm^{-1}$ Raman band appears to be accidental. It is possible that the splitting of the skeletal breathing mode at high temperature is caused by Fermi resonance between this mode and an overtone or combination mode involving a low frequency skeletal bending mode.

It should finally be mentioned that a slow conformational change has been shown to occur between −90°C and −140°C in a complex of 18-crown-6 with $Cs^+BF_4^-$ (28). However, due to the size and spherical shape of the $Cs^+$ ion, it is doubtful that this change is in any way related to that observed here with the hydronium complex.

Reçu le 28 août 1981

JEAN-PAUL CANSELIER, SERGE DOMENECH, ŠTEFAN STANKOVSKY et SABINE GAUTIER. Can. J. Chem. **60**, 862 (1982).

Comme dans le cas des donneurs benzéniques, les spectres électroniques d'absorption des complexes moléculaires formés par les hétérocycles pentagonaux soufrés ou oxygénés, simples ou condensés, avec le TCNE (ou la DDQ) font apparaître le plus souvent deux bandes de transfert de charge. Dans de nombreux exemples étudiés, la détermination précise des fréquences d'absorption nécessite une méthode de résolution. Les résultats obtenus sont utilisés dans des corrélations avec les potentiels d'ionisation des donneurs d'une part, et avec la réfringence des solvants apolaires d'autre part.

JEAN-PAUL CANSELIER, SERGE DOMENECH, ŠTEFAN STANKOVSKY, and SABINE GAUTIER. Can. J. Chem. **60**, 862 (1982).

As with benzenoid donors, the electronic absorption spectra of the molecular complexes of simple or condensed sulfur or oxygen-containing five-membered heterocycles with TCNE (or DDQ) often show two charge-transfer bands. In many cases, the knowledge of the actual frequencies requires a technique of resolution. The results so obtained are correlated with the ionization potentials of donors on the one hand, and the refractivity of nonpolar solvents on the other hand.

## 1. Introduction

L'étude physico-chimique des hétérocycles soufrés (en particulier celle des thiophènes condensés) trouve des applications dans l'hydrodésulfuration des résidus pétroliers lourds. Les travaux que nous avons entrepris sur le caractère aromatique de ce type d'hétérocycles (1, 2) et, parallèlement, sur l'adsorption de certains de ces composés sur un catalyseur d'hydrodésulfuration (3) sont maintenant poursuivis par l'examen de leur pouvoir donneur d'électrons. Celui-ci se manifeste entre autres dans la formation de complexes moléculaires faibles, dont le spectre électronique d'absorption présente une ou plusieurs bandes supplémentaires, appelées "bandes de transfert de charge" (4–7). Selon la théorie de Mulliken et Person (6), les fréquences de transfert de charge $\nu_{TC}$ donnent lieu à une corrélation avec les potentiels d'ionisation $I_D$ des donneurs pour les complexes d'un même accepteur, ou avec les affinités électroniques $E_A$ des accepteurs lorsqu'on travaille sur un seul donneur:

$$[1] \quad h\nu_{TC} = I_D - E_A + (G_0 - G_1) + \frac{\beta_0^2 + \beta_1^2}{I_D - E_A + (G_0 - G_1)}$$

$G_0$ représente l'énergie résultant des interactions de non-liaison entre A et D et $G_1$ l'énergie d'attraction coulombienne[3] entre $A^-$ et $D^+$. Les intégrales $\beta_i$, ayant la dimension d'une énergie, peuvent être explicitées par un calcul de perturbation du second ordre (6, 7).

D'après une autre approche, partant de la théorie des orbitales moléculaires (8), la bande de transfert de charge de plus basse fréquence observée a pour origine une transition entre la plus haute orbitale occupée (H.O.) du donneur et la plus basse orbitale vacante (B.V.) de l'accepteur, les niveaux d'énergie correspondants n'étant pratiquement pas perturbés par la formation du complexe. Bien qu'approximatives, ces justifications théoriques vont nous permettre une analyse des spectres de transfert de charge surtout en ce qui concerne le nombre et la nature des transitions observées.

## 2. Résultats expérimentaux. Traitement des bandes multiples

Les donneurs d'électrons considérés sont des hydrocarbures et des hétérocycles appartenant aux familles A à F (composés modèles et dérivés substitués **1** à **28** avec X = $CH_2$, O, S; Y = $CH_2$, S) (cf. Tableau 1), certains composés aromatiques de référence comportant un, deux ou trois cycles bénzéniques (**29** à **42**), et quelques donneurs saturés à paire électronique libre: **43** à **47**.

Nous avons choisi d'autre part des accepteurs d'électrons bien connus et figurant parmi les plus puissants répertoriés jusqu'ici (7, 9): le tétracyanoéthylène (TCNE), qui offre de plus l'avantage

d'être incolore, et la dichloro-2,3 dicyano-5,6 benzoquinone (DDQ).

*(a) Mesure de $\lambda_{max}$*

Les spectres des complexes moléculaires en solution ont été enregistrés à l'aide d'un spectrophotomètre Beckman DBG. Les mesures ont été effectuées dans trois principaux solvants: le dichlorométhane, le chloroforme et le tétrachlorure de carbone. Malgré certains résultats interprétés en termes d'interactions spécifiques avec les hydrocarbures benzéniques (10, 11) ce dernier solvant nous paraît être le seul solvant non polaire capable de dissoudre suffisamment les composés polycycliques et les accepteurs d'électrons.

Les longueurs d'onde des bandes de transfert de charge avec le TCNE mesurées au(x) maximum(s) d'absorption apparent(s) ($\lambda_{max}$) sont rassemblées dans le tableau 1, qui renferme aussi certaines données tirées de la littérature.

Le tableau 2 rassemble les mesures effectuées sur les complexes de la DDQ dans le dichlorométhane et dans le tétrachlorure de carbone. La DDQ présente un maximum d'absorption à 388 nm (dans $CH_2Cl_2$) qui perturbe dans de nombreux cas la deuxième bande de transfert de charge (bande de plus haute fréquence).

Les valeurs de $\lambda_{max}$ sont données à 2 nm près environ:[4] en nombre d'ondes, cet écart correspond à une incertitude comprise entre 0,05 kK (à 650 nm) et 0,15 kK (à 350 nm). L'examen du tableau 1 montre cependant qu'entre différents auteurs les écarts sont parfois supérieurs à 2 nm.

*(b) Prévision des bandes multiples*

Une étude préliminaire de la structure électronique $\pi$ (selon Hückel) des donneurs et des accepteurs envisagés (13, 42) a montré que les deux H.O. des composés de types C et D sont assez proches en énergie ($\Delta\chi_i < 0{,}25\beta$). Les dérivés benzéniques mono- ou disubstitués possèdent la même propriété. Les deux H.O. des composés A et F sont un peu plus espacées, mais, seuls parmi les donneurs $\pi$ envisagés ici, le benzène et l'hexaméthylbenzène, plus symétriques (groupe $D_{6h}$), présentent une dégénérescence de leurs plus hauts niveaux énergétiques, les orbitales correspondantes appartenant à la représentation irréductible $E_{1g}$. Par ailleurs, d'après la spectroscopie de photoélectrons dans l'ultraviolet (SPU), les deux premiers potentiels d'ionisation des composés A à F, souvent assez rapprochés, font bien intervenir des orbitales moléculaires (o.m.) $\pi$ (Tableau 1).

En revanche les deux B.V. du TCNE et de la DDQ sont relativement éloignées (42*b*) de sorte que les transitions les moins énergétiques susceptibles de produire les bandes de transferts de charge doivent mettre en jeu deux o.m. du donneur et une seule o.m. de l'accepteur. Effectivement la majorité des complexes du TCNE considérés laissent apparaître deux bandes de transfert de charge inégalement espacées, même sur l'échelle des nombres d'ondes. Si l'on se réfère aux structures cristallines connues (7, 43), les associations ainsi formées ne possèdent pas en général un haut degré de symétrie, et l'application du critère de symétrie ne diminue pas le nombre de bandes prévu par la théorie (42*b*). L'unique maximum apparent observé avec les donneurs **7**, **12**, **18**, **19**, **22**, **30–32** et **42** recouvre donc deux bandes.

*(c) Forme et résolution des bandes de transfert de charge*

Dans l'analyse des spectres les bandes symétriques sont généralement représentées par des courbes de Gauss ou de Lorentz–Cauchy comportant trois paramètres: les coordonnées $x_0$ et $y_0$ (nombre d'ondes et densité optique) du maximum et la largeur à mi-hauteur $\Delta x_{\frac{1}{2}}$. La principale différence entre les deux représentations réside dans l'importance en surface des traînées latérales, beaucoup plus grande avec le modèle de Lorentz–Cauchy.

En fait, les bandes de transfert de charge, telles qu'on les observe en solution, constituent l'enveloppe d'une structure fine due à la vibration d'élongation totalement symétrique ("respiration") du complexe. Elles résultent donc de la combinaison de courbes gaussiennes élémentaires, généralement considérées comme symétriques sur l'échelle des fréquences (44). Si la fréquence de respiration est assez élevée, les niveaux vibrationnels excités de l'état électronique fondamental sont très peu peuplés et les courbes élémentaires représentent des transitions vibrationnelles $0 \rightarrow v'$ (principe de Franck–Condon). La bande enveloppe sera, par conséquent, très dissymétrique. Au contraire, si la

[4]Les bandes étant larges, la détermination de leur sommet est effectuée par la méthode du point milieu (41).

fréquence de respiration est basse ($\bar{\nu} = 115\,cm^{-1}$ pour le complexe mésitylène–TCNE, par exemple (45)) la possibilité de transitions $1 \rightarrow 0$, $1 \rightarrow 1$, ... et même $2 \rightarrow 0$, $2 \rightarrow 1$, ... diminuera la dissymétrie de la bande observée. Le facteur $B$ de Briegleb et Czekalla (46) caractérise la dissymétrie des bandes de transfert de charge:

$$[2] \quad B = \frac{\bar{\nu}_h - \bar{\nu}_1}{2(\bar{\nu}_{max} - \bar{\nu}_1)}$$

$\bar{\nu}_{max}$, $\bar{\nu}_h$ et $\bar{\nu}_1$ désignent respectivement les nombres d'ondes au maximum d'absorption et à mi-hauteur ($\bar{\nu}_h > \bar{\nu}_1$).

La représentation par des courbes de Gauss asymétriques a été utilisée par Jørgensen (47) en spectrophotométrie des complexes métalliques. Le modèle de Fraser et Suzuki (48), plus complet, a été préféré par certains auteurs (24, 49).

Afin d'identifier les paramètres des bandes élémentaires, nous avons choisi pour notre part un algorithme fondé sur la méthode des moindres carrés associée à l'utilisation d'une fonction de référence, et que préconisent d'ailleurs Fraser et Suzuki (48*b*). Le facteur $B$ est alors imposé et pris identique pour les deux transitions d'un même complexe.[5] Il reste donc à identifier trois paramètres par bande: la hauteur, la position du sommet et la largeur relative, et l'algorithme consiste à modeler les bandes expérimentales sur la courbe de référence au moyen de trois transformations ponctuelles: une translation et deux affinités.

La fonction de référence choisie doit être la plus représentative possible des bandes à séparer. Nous avons retenu comme références les bandes de plus basse fréquence données par les complexes **28**–TCNE et **37**–TCNE en raison de la similitude structurale de ces donneurs avec de nombreux composés étudiés (présence du motif $C_6H_5$—S ou $(C_6H_5)_2S$) ainsi que les bandes uniques des complexes du TCNE avec les donneurs **33** et **47**. La méthode de résolution est présentée en annexe. A titre d'illustration, nous avons représenté sur la figure 1 les spectres expérimentaux et calculés des complexes **13**–TCNE et **19**–TCNE.

Nous avons examiné systématiquement l'influence de la fonction de référence sur le traitement de 60 spectres. Les valeurs des paramètres obtenues à l'aide des quatre fonctions de référence, pour les deux exemples de la figure 1, sont consignées dans le tableau 3. L'écart quadratique moyen entre le spectre expérimental et le spectre calculé[6] est voisin dans ces deux cas de $5 \times 10^{-3}$. L'abscisse d'un sommet est déterminée à 0,2 kK près et l'écart sur $\bar{\nu}$ ne dépasse pas cette valeur. Les hauteurs $h_1$ et $h_2$ sont plus sensibles au choix du modèle. Les nombres d'ondes de transfert de charge $\bar{\nu}_{max}$ obtenus après résolution sont rassemblés dans le tableau 4.

[5]Contrairement à ce que considèrent certains auteurs, la valeur de $B$ est souvent légèrement inférieure à 1,19 et varie quelque peu suivant le complexe examiné.

[6]Pour l'ensemble des spectres calqués sur la fonction de référence **37**–TCNE, les valeurs limites de $S_{min}$ sont $1{,}35 \times 10^{-3}$ et $1{,}25 \times 10^{-2}$ (cf. Annexe).

## 3. Interprétation et discussion

*(a) Corrélation des fréquences de transfert de charge avec les premiers potentiels d'ionisation des donneurs*

Les premiers potentiels d'ionisation verticaux des donneurs étudiés, mesurés par spectroscopie de photoélectrons uv (SPU), figurent dans le tableau 1. L'incertitude sur cette grandeur, souvent inférieure ou égale à 0,05 eV, peut atteindre 0,1 eV, notamment lorsque les pics sont mal séparés, ce qui nécessiterait une résolution.

Nous avons appliqué la relation [1] sous l'une des formes simplifiées suivantes:

$$[1'] \quad h\nu_{TC} = I_D - C_1 + \frac{C_2}{I_D - C_1}$$

$$[1''] \quad h\nu_{TC} = aI_D - b$$

aux séries de valeurs obtenues au cours de ce travail et trouvées dans la littérature. Les paramètres $C_1$, $C_2$, $a$ et $b$ ainsi identifiés sont rassemblés dans le tableau 5. La figure 2 illustre graphiquement certains de ces résultats. On s'aperçoit immédiatement que le traitement des données par le modèle [1'] n'apporte guère d'amélioration par rapport à l'équation [1'']. Les complexes étudiés dans le

[b] Solvant $CH_2Cl_2$.
[c] Solvant $CHCl_3$.

dichlorométhane au cours de ce travail donnent franchement une droite de pente égale à l'unité. Ce cas mis à part, il n'apparaît pas de différence notable entre nos résultats d'une part et la totalité des points issus de ce travail et de la littérature d'autre part. On a affaire à première vue à une dispersion quasi-statistique provenant des incertitudes expérimentales et du grand nombre de points considéré. Les irrégularités constatées ne dépendent pas de l'accepteur (voir ci-dessous) et ne sont pas imputables au solvant; la corrélation entre les nombres d'ondes (en kK) observés dans le tétrachlorure de carbone et ceux obtenus dans le dichlorométhane est en effet meilleure que celle de la figure 2:

[3] $\bar{\nu}_{CCl_4} = \bar{\nu}_{CH_2Cl_2} + 0{,}14$ (32 points; $\rho = 0{,}997$)

Le regroupement des donneurs par familles paraît difficile; on remarque toutefois que les points correspondant aux donneurs *n* (**43** à **47**) sont bien alignés. Mais certains autres donneurs se placent très près de cette droite, ce qui ne suffit évidemment pas à prouver leur caractère *n*. Finalement, pour distinguer l'écart théorique à la corrélation d'une part, de la dispersion d'origine expérimentale d'autre part, il vaut sans doute mieux s'intéresser aux points les plus éloignés de la droite des moindres carrés: on découvre alors sans surprise la position de **33**, le plus fort donneur π envisagé ici, et pour lequel l'approximation de Mulliken peut ne plus être suffisante.

De la relation [1″] on tire l'écart théorique $\Delta\bar{\nu}$ entre les sommets des bandes relatives à un même donneur:

$$[4] \quad \Delta\bar{\nu} = \frac{a}{hc} . \Delta I_D$$

ou

$$[4'] \quad \Delta\bar{\nu}(\text{kK}) = 8{,}066\, a . \Delta I_D(\text{eV})$$

L'exploitation des 24 résultats concernant l'ensemble des donneurs étudiées dans $CCl_4$ au cours de ce travail conduit à la droite de régression d'équation:

$$[4''] \quad \Delta\bar{\nu}(\text{kK}) = 7{,}530\, \Delta I_D(\text{eV}) \quad (\rho = 0{,}952)$$

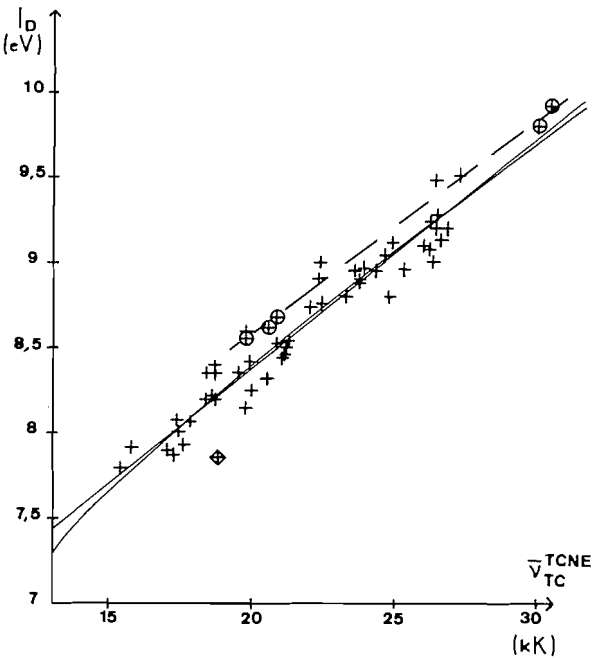

FIG. 2. Corrélation $\bar{\nu}_{TC}^{TCNE} = f(I_D)$; solvant $CCl_4$, ce travail; ⊕ donneurs *n*; ⊕ donneur **33**.

TABLEAU 5. Paramètres $C_1$ et $C_2$ de la corrélation [1'] $a$ et $b$ de la corrélation [1''] (énergies exprimées en eV)

| Accepteur | Solvant | Origine | Nombre de points | $C_1$ (eV) | $C_2$ (eV)[2] | $a$ | $b$ | $\rho$[a] |
|---|---|---|---|---|---|---|---|---|
| TCNE | $CCl_4$ | Ce travail (tous donneurs) | 56 | 6,16 | 0,52 | 0,91 | 5,13 | 0,966 |
| | $CCl_4$ | Ce travail (donneurs n) | 5 | | | 0,97 | 5,86 | 0,999 |
| | $CCl_4$ | Ce travail + littérature | 80 | 6,21 | 0,64 | 0,85 | 4,66 | 0,971 |
| | $CH_2Cl_2$ | Ce travail | 10 | 6,03 | 0,04 | 1,00 | 6,05 | 0,974 |
| | $CH_2Cl_2$ | Littérature | 38 | 6,29 | 0,87 | 0,83 | 4,47 | 0,956 |
| | $CHCl_3$ | Ce travail | 11 | 6,28 | 0,56 | 0,91 | 5,23 | 0,972 |
| | $CHCl_3$ | Littérature | 10 | 6,39 | 0,94 | 0,83 | 4,50 | 0,961 |
| DDQ | $CH_2Cl_2$ | Ce travail + littérature | 11 | 6,58 | 0,79 | 0,72 | 3,76 | 0,878 |
| | $CCl_4$ | Ce travail + littérature | 10 | 6,56 | 0,78 | 0,77 | 4,19 | 0,898 |

[a] Coefficient de corrélation des droites d'équation [1''].

on constate que l'erreur commise sur la pente est inférieure à 3% (8,066 $a$ = 7,340). Cette étude confirme ainsi que les deux bandes de transfert de charge observées sur un même spectre (éventuellement après résolution) proviennent bien des H.O. 1 et 2 du donneur.

*(b) Influence de l'affinité électronique de l'accepteur*

Le dernier terme de la relation [1] est petit devant les autres. Appliquée à un seul donneur formant des complexes avec deux accepteurs A et A', cette égalité devient, $G_1$ étant approximativement constant:

$$[5] \quad \bar{\nu}_{TC}{}^{A} - \bar{\nu}_{TC}{}^{A'} = \frac{1}{hc}(E_{A'} - E_A)$$

Les travaux de Page et coll. (50) et de Chen et Wentworth (51) ont permis d'établir une liste d'affinités électroniques absolues pour les accepteurs d'électrons. Si l'on admet pour le TCNE la valeur mesurée ($E_{TCNE}$ = 2,88 eV (50)), nos résultats spectrophotométriques dans le tétrachlorure de carbone conduisent à:

$$E_{DDQ} = 3{,}08\ \text{eV}$$

Avec le même point de départ ($E_{TCNE}$) et à l'aide de valeurs de $\lambda_{max}$ dans le dichlorométhane tirées en grande partie de la littérature (Tableaux 1 et 2), on trouve:

$$E_{DDQ} = 3{,}14\ \text{eV}$$

Les valeurs ainsi obtenues sont très voisines de celles recalculées par Chen et Wentworth (51) à l'aide de la corrélation [1] ($E_{TCNE}$ = 2,77 eV; $E_{DDQ}$ = 3,13 eV).

*(c) Influence du solvant*

Les spectres des complexes formés par quatre des donneurs avec le TCNE ont été pris dans une gamme de solvants assez étendue en polarité et en polarisabilité, eu égard à la réactivité du TCNE.

Les donneurs choisis correspondent à trois cas de spectres différents: une seule bande (**29**), deux bandes partiellement résolues (**13** et **16**) et deux bandes donnant un seul maximum apparent (**19**). Les résultats relatifs au benzène (**29**) sont tirés en partie de la littérature. Les équations publiées par Davis (52) et par Rao (53) dans des mises au point récentes, pour rendre compte des interactions soluté–solvant non spécifiques, soulignent la complexité des phénomènes mis en jeu.

Examinons si l'effet de solvant sur la fréquence de transfert de charge $\nu_{max}$ peut être traduit par la formule de McRae (54):

$$[6] \quad \bar{\nu}_{max} - \bar{\nu}_{max}{}^{0} = (AL_0 + B)\frac{n^2 - 1}{2n^2 + 1} + C\left(\frac{\varepsilon - 1}{\varepsilon + 2} - \frac{n^2 - 1}{n^2 + 2}\right)$$

$\bar{\nu}_{max}{}^{0}$ caractérise le complexe à l'état gazeux; $n$ et $\varepsilon$ désignent respectivement l'indice de réfraction et la constante diélectrique du solvant. $(AL_0 + B)$ et $C$ sont des constantes. Dans le cas des solvants non polaires ($n^2 \simeq \varepsilon$) cette relation se réduit à:

$$[6'] \quad \bar{\nu}_{max} - \bar{\nu}_{max}{}^{0} = (AL_0 + B)\frac{n^2 - 1}{2n^2 + 1}$$

Les droites obtenues sont représentées sur la figure 3 et les valeurs des paramètres $(AL_0 + B)$ et $\bar{\nu}_{max}{}^{0}$ sont rassemblées dans le tableau 6. On peut admettre comme incertitudes 0,5 kK sur la pente et 0,1 kK sur l'ordonnée à l'origine, sauf pour $\bar{\nu}_2$ de **16** où l'incertitude est environ deux fois plus grande.

Dans les cas étudiés ici l'influence du solvant est identique sur les deux bandes, ce qui confirme l'interprétation faisant intervenir plusieurs états électroniques d'un même complexe. Les complexes

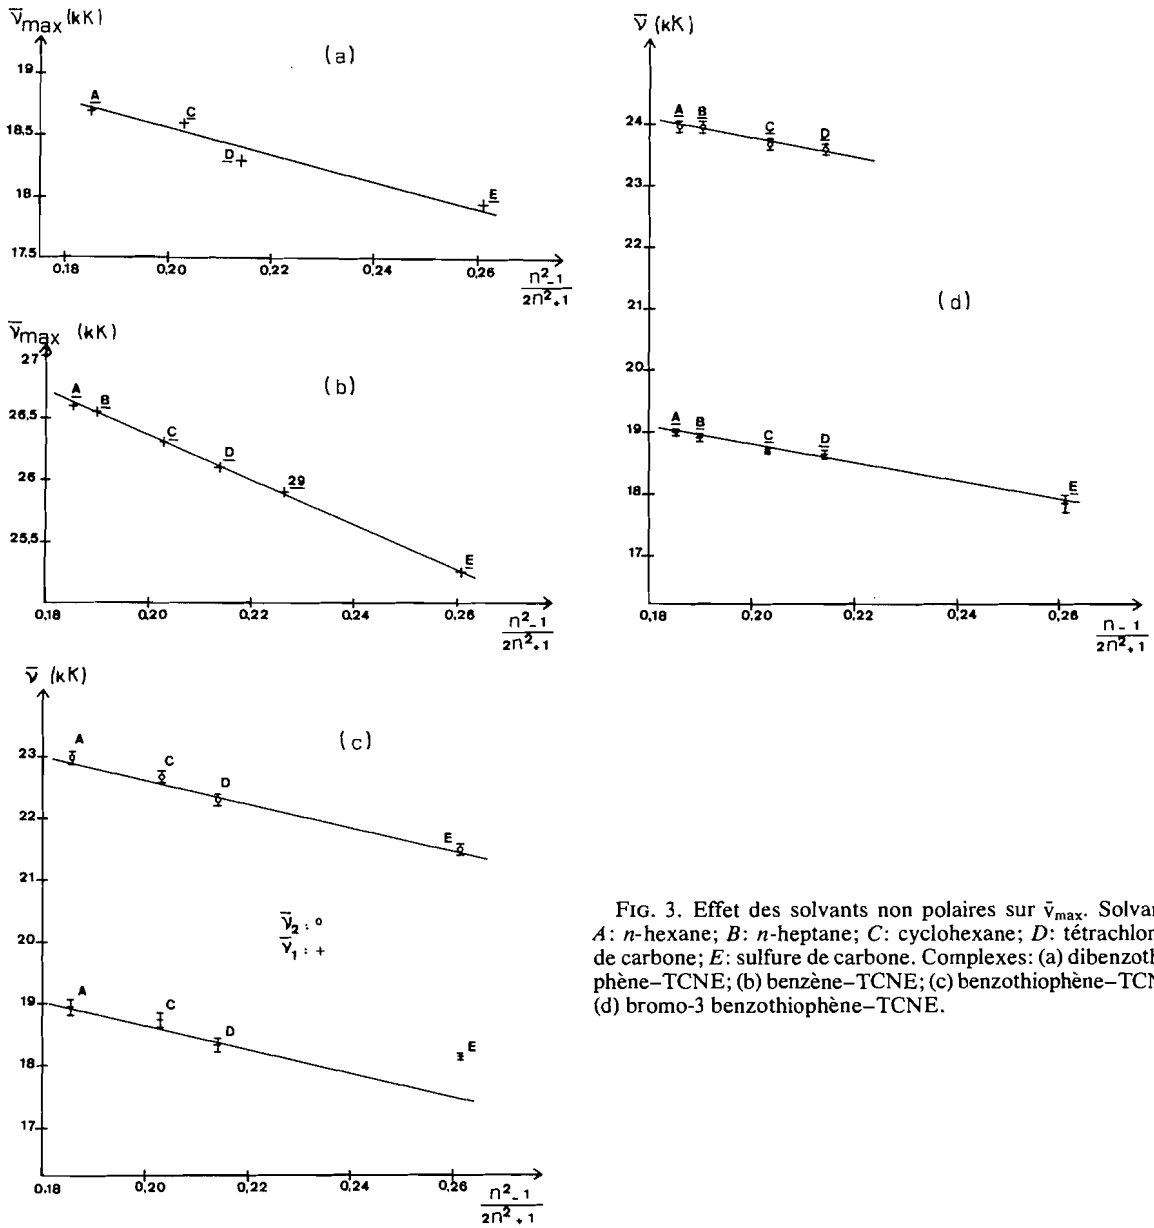

FIG. 3. Effet des solvants non polaires sur $\bar{\nu}_{max}$. Solvants: *A*: *n*-hexane; *B*: *n*-heptane; *C*: cyclohexane; *D*: tétrachlorure de carbone; *E*: sulfure de carbone. Complexes: (a) dibenzothiophène–TCNE; (b) benzène–TCNE; (c) benzothiophène–TCNE; (d) bromo-3 benzothiophène–TCNE.

des hétérocycles soufrés conjugés se comportent donc exactement comme ceux des hydrocarbures aromatiques (55, 56): le déplacement bathochrome observé dans les solvants non polaires, et augmentant avec la réfringence du solvant, est caractéristique des solutés non polaires (forces de dispersion) ou des solutés peu polaires, dont le moment dipolaire augmente de l'état fondamental à l'état excité (forces d'induction).[7]

[7]La comparaison de ces résultats avec ceux rassemblés par Trotter (57) semble bien montrer que la compression interne et l'effet de champ ne sont que le côté pile et le côté face d'une même réalité.

On peut appliquer la relation [1″] aux fréquences $\nu_{max}^0$ calculées et s'apercevoir que ces grandeurs se classent normalement aux incertitudes expérimentales près, en fonction des potentiels d'ionisation ($a = 1{,}03$; $b = 5{,}81$; $\rho = 0{,}98$).

Essayons maintenant de déterminer $C$ par voie graphique, il suffit pour cela de tracer:

$$[6''] \quad \bar{\nu}_{max} - (AL_0 + B)\frac{n^2-1}{2n^2+1} = f\left[\left(\frac{\varepsilon-1}{\varepsilon+2}\right) - \left(\frac{n^2-1}{n^2+2}\right)\right]$$

TABLEAU 6. Influence du solvant sur $\bar{\nu}_{max}$

| No | Composé donneur | $AL_0 + B$ (kK) | $\nu_{max}^0$ (kK) |
|---|---|---|---|
| **13** | Benzothiophène | $\bar{\nu}_1$: −19 | 22,45 |
| | | $\bar{\nu}_2$: −19 | 26,5 |
| **16** | Bromo-3 benzothiophène | $\bar{\nu}_1$: −15 | 21,7 |
| | | $\bar{\nu}_2$: (−15) | 26,9 |
| **19** | Dibenzothiophène | −11 | 20,75 |
| **29** | Benzène | −18 | 29,9 |

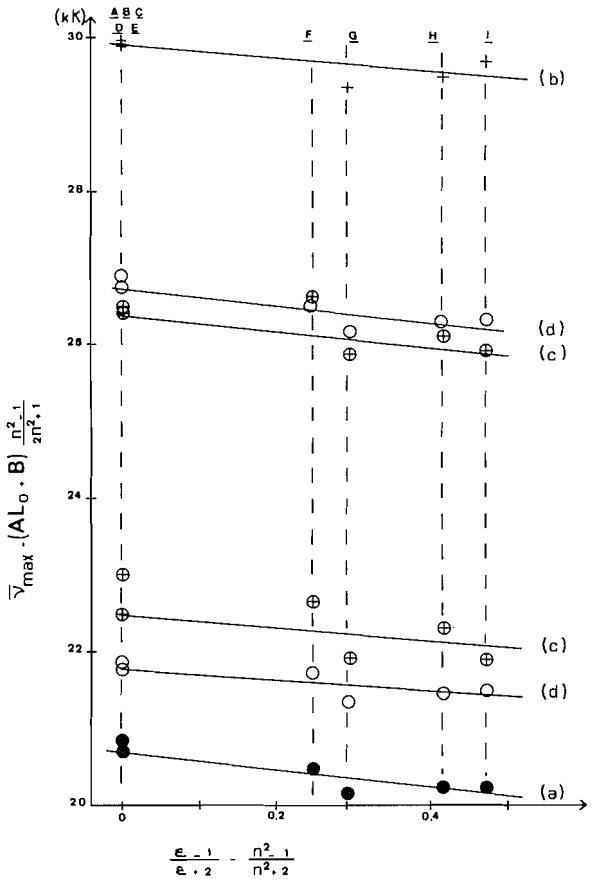

FIG. 4. Effet des solvants polaires sur $\bar{\nu}_{max}$. Solvants: *F*: dibromo-1,2 éthane, *G*: chloroforme, *H*: tétrachloro-1,1,2,2 éthane, *I*: dichlorométhane. Complexes (voir Fig. 3).

Au vu de la figure 4, on constate que les solvants halogénés saturés conduisent à des valeurs faiblement négatives de $C$ ($C \simeq -0{,}5$ kK) comme dans le cas du complexe naphtalène–TCNE (56). Ceci s'explique par le fait que le deuxième terme de la relation [6] rend compte des interactions soluté–solvant du type dipôle de solvant – dipole de soluté (forces d'orientation) et que le paramètre $C$ peut s'exprimer en fonction des moments dipolaires du complexe à l'état fondamental ($\mu_f$) et à l'état excité ($\mu_e > \mu_f$) selon

$$[7] \quad C = \frac{2\mu_f(\mu_f - \mu_e)}{a^3}$$

$a$ représente le rayon de la cavité du solvant.

On ne peut donc pas conclure à une solvatation spécifique des complexes dans ce groupe de solvants. On peut estimer au contraire que la structure électronique des complexes étudiés n'est pratiquement pas influencée par des milieux continus comme ceux considérés ici.

**Remerciements**

Les auteurs remercient Monsieur le Professeur Gilot pour l'intérêt qu'il a porté à ce travail et pour les discussions fructueuses auxquelles ces résultats ont donné lieu.

## Annexe. Méthode de résolution des bandes

La fonction de référence est traitée en premier lieu. Le spectre enregistré (linéaire en $\lambda$) est discrétisé à intervalles de 5 nm. Ces données sont converties en nombres d'ondes et subissent une première interpolation quadratique qui espace régulièrement les abscisses (0,1 kK): deux interpolations sont pratiquées ultérieurement de façon que la fonction de référence en coordonnées réduites comporte 101 points équidistants en abscisses, le sommet de la courbe coïncidant avec le point 51.

Le spectre à résoudre est alors introduit sous forme discrétisée; les abscisses sont transformées comme plus haut au moyen de la première interpolation. Ce spectre est assimilé à la somme de deux courbes[8] présentant le même rapport $B$. Un premier calcul est réalisé à partir de six paramètres d'essai (hauteur, position et largeur des bandes) et des deux paramètres fixes qui caractérisent la ligne de base, supposée linéaire (densités optiques aux deux extrémités). On utilise la méthode des moindres carrés appliquée aux fonctions non linéaires (méthode de Gauss–Newton); l'écart quadratique moyen $S$ est minimisé au sixième chiffre significatif près au cours d'un calcul itératif. Une convergence plus probable et plus rapide est assurée par l'intervention d'un facteur de relaxation et d'un facteur d'échelle eux-mêmes optimisés au fur et à mesure des itérations.

Un tableau[9] présente en détail des exemples de résultats obtenus. $S_{min}$ est la valeur minimale de $S$ pour laquelle on arrête le calcul, et le paramètre de largeur $(\Delta\bar{\nu}_{\frac{1}{2}})_i$ de la bande $i$ représente en fait la largeur à mi-hauteur de cette bande (en kK) divisée par la largeur à mi-hauteur de la bande de référence $(\Delta\bar{\nu}_{\frac{1}{2}})_{réf}$ exprimée en abscisses réduites (unités arbitraires).

[8]Nous ne traitons pas l'extrémité de la bande présente vers le bleu et appartenant au spectre d'un des réactifs. La pente en est très grande et le nombre de points insuffisant. C'est pourquoi nous avons discrétisé les spectres à partir d'une longueur d'onde au-delà de laquelle l'influence de cette bande est négligeable.

# Synthesis of (±)-lineatin by the photochemical cycloaddition of allene to anhydromevalonolactone

WILLIAM R. MCKAY, JIM OUNSWORTH, PHAIK-ENG SUM, AND LARRY WEILER[1]

*Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6*

Received October 14, 1981

WILLIAM R. MCKAY, JIM OUNSWORTH, PHAIK-ENG SUM, and LARRY WEILER. Can. J. Chem. **60**, 872 (1982).

(±)-Lineatin (**1**), the aggregation pheromone of an ambrosia beetle, was synthesized in five steps from anhydromevalonolactone (**5**) in 10% overall yield. The key step in the synthesis was a photochemical cycloaddition of **5** and allene. This photolysis produced two regioisomers (ca. 3:2) and efforts to improve the regioselectivity by varying the photolysis conditions or substituents on the allene were unsuccessful.

**1** **5**

WILLIAM R. MCKAY, JIM OUNSWORTH, PHAIK-ENG SUM et LARRY WEILER. Can. J. Chem. **60**, 872 (1982).

Nous avons préparé la ±-linéatine (**1**), la phéromone d'aggrégation d'une abeille de type Ambrosia, en réalisant une synthèse en 5 étapes à partir de l'anhydromévalonolactone (**5**) avec un rendement global de 10%. L'addition photochimique du composé **5** sur une allène est l'étape principale de cette synthèse. Cette photolyse conduit à deux régioisomères (environ 3:2) et nous avons vainement tenté d'améliorer la régiosélectivité en changeant les conditions d'hydrolyse ou en faisant varier les substituants sur l'allène.

**1** **5**

[Traduit par le journal]

Female ambrosia beetles, *Trypodendron lineatum*, produce an attractant aggregation pheromone while boring into fallen timber and cut lumber. The active pheromone, called lineatin, was isolated from frass and its structure was proposed to be **1** or **2** (1). Subsequently, Borden *et al.* reported three

**1** **2**

very low yielding syntheses of the pheromone which allowed them to demonstrate that lineatin in fact has structure **1** (2). Recently, Slessor *et al.* (3) and Mori and Sasaki (4) have reported more efficient syntheses of **1** and both groups have been able to resolve one of their synthetic intermediates to provide the optically active pheromone. In this paper we report a short synthetic route to lineatin (**1**) and offer some observations on the photochemical addition of allenes to α,β-unsaturated lactones.

A major challenge in the synthesis of **1** is the construction of the unusual tricyclic acetal skeleton. Our retrosynthetic analysis of this problem is shown in Scheme 1. The critical point in the synthesis of an intermediate such as **3** appeared to be the construction of a cyclobutane with the correct regio- and stereochemistry. We also considered the cyclobutanone **4** derived by oxidation of **3** as a potential synthetic intermediate, since it was expected that reduction of the ketone in **4** should occur preferentially from the *exo* face to yield **3**. This route would only require a regioselective cyclobutanone formation. Finally we sought a synthetic route starting from anhydromevalonolactone (**5**) because of its ready availability (see below).

A convenient method to construct cyclobutane rings employs a [2 + 2] cycloaddition. Although ketenes can be added to trisubstituted olefins, they are not known to add to electron deficient olefins (5) such as **5**. Therefore we chose to investigate a photochemical [2 + 2] reaction of **5** and an appropriate alkene to generate the desired cyclobutane. Photolysis of lactone **5** and ethylene gave the cycloadduct **6** in 70% yield (eq. [1]) (6). Indeed a number of alkenes undergo a photochemical [2 + 2] cycloaddition to α,β-unsaturated lactones (6*b*).

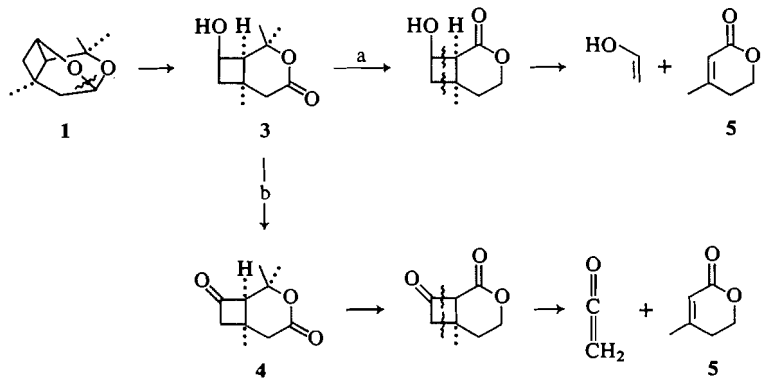
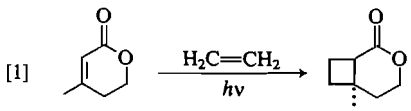
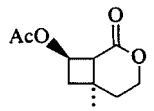


SCHEME 1. Possible retrosynthetic analyses for lineatin (**1**)

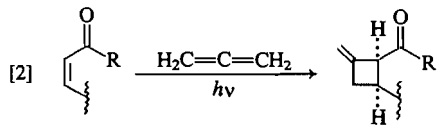
Unfortunately there are very few reports on the cycloaddition of heteroatom substituted alkenes to conjugated lactones. The photolysis of **5** and vinyl acetate gave only 4% of the adduct **7** (2). For these reasons, we considered the cycloaddition of allene and **5** as the key step in the synthetic plan.



There are a number of examples of the photochemical [2 + 2] cycloaddition of allene to α,β-unsaturated ketones and aldehydes (7). In all cases the methylenecyclobutane produced has the *cis* stereochemistry for cyclic olefinic starting materi-



als, and in almost all cases the regioselectivity is that shown in eq. [2] (7). This is precisely the stereochemistry we would require to synthesize a cyclobutanone such as **4** from lactone **5**. Before the initiation of this work we were not aware of any photochemical addition of allene or its derivatives to an α,β-unsaturated lactone. During the course of our work Baker *et al.* reported an intramolecular



photolysis of a substituted allene and a lactone (8) (see below).

Anhydromevalonolactone (**5**) was conveniently synthesized from methyl vinyl ketone (6*b*, 9, 10). This procedure involves the dehydration of mevalonolactone by distillation from potassium bisulfate (6*b*). Usually the crude dehydration product was a mixture of α,β- and β,γ-unsaturated lactones. This mixture could be isomerized to the α,β-isomer **5** by redistillation from potassium bisulfate or more conveniently by a $RhCl_3$ catalyzed isomerization (11).

Irradiation (Vycor filter) of an acetone solution of lactone **5** and allene gave a mixture of 1:1 cycloaddition products in approximately 80% yield. The photolysis products could not be separated by thin layer or column chromatography. However, two components in the mixture were barely separable by capillary column gas chromatography. The ratio of the two products was ca. 3:2. In addition, the 270 MHz $^1H$ nmr spectrum of the photolysis product had two methyl singlets at δ 1.26 and 1.24 (relative intensity ca. 3:2). The photoadducts were not epimerized by base, thus each contained a *cis* fused cyclobutane. The structures of the photoadducts were determined from the following two ozonolysis experiments. First, ozonolysis of the photolysis mixture in methanol gave **8** and **9**; the ester **8** was the major product. Ozonolysis of the photolysis mixture in dichloromethane gave the cyclobutanones **9** and **10**. The

cyclobutanone **10**, although difficult to purify, was the major compound.

The results from the ozonolysis experiments and the failure of base to epimerize the adducts prove that the major photolysis product is the desired methylenecyclobutane **11** but a substantial amount of the isomeric methylenecyclobutane **12** is produced in the photolysis (eq. [3]). The low selectivity surprised us in view of the wealth of examples demonstrating the regioselective addition of allene to a variety of α,β-unsaturated ketones and aldehydes (7). It was clear that our photolysis conditions were different from those for enone additions, hence the photolysis in eq. [3] may be occurring by a different mechanism than the enone examples

[3] 

5 11 12

3:2

(eq. [2]). For example, the enone photolyses are usually carried out in ether or hydrocarbon solvents with a Pyrex filter (7). Presumably the enone is excited by direct irradiation and the reaction may proceed through the π,π* triplet (12). In the photolysis of lactone **5** (eq. [3]) the acetone is acting as a triplet sensitizer. Because the π,π* triplet of an α,β-unsaturated ester is of higher energy than the n,π* triplet (13) it may be that the lactone photolysis involves the n,π* triplet. A second possibility is that both types of photolysis reactions involve the same triplet but that the oxygen of the lactone changes the shape of the frontier orbitals involved and thus the regioselectivity of attack.

However, before these arguments are taken too far we should note that the photochemical cycloaddition of allene to 3-methylcyclohexenone gives a 4:1 mixture of regioisomers (eq. [4]) (14). In addition, Baker *et al.* have recently reported an intramolecular photolysis of an allenic α,β-unsaturated lactone to give two regioisomeric products (eq. [5]) (8). However, photolysis of the allenic enone in eq. [6] is highly regioselective (15). Thus the factors controlling the regioselectivity in these reactions are very subtle.

[4] 

4:1

The summary of several experiments which were carried out in an effort to improve the regioselectivity in the photolysis (eq. [3]) is given in

[5] 

2.5:1

Table 1. The ratio of the regioisomers **11**:**12** was determined by 270 MHz $^1$H nmr. The tertiary methyl group in these isomers has a resonance at δ 1.26 and 1.24 respectively. First we note that the ratio of **11**:**12** did not change significantly with

[6] 

temperature (runs 1 and 2) or using xanthone as a triplet sensitizer (run 3). Finally in runs 4–6 the polarity of the solvent was varied. In dichloromethane and dichloroethane solvents the regioselectivity was essentially the same as in pure acetone. However in methanol solvent (run 4) the regioselectivity did change but in the wrong direction. In addition the total yield of photoadducts was substantially lower in methanol (run 4). We were unable to improve the regioselectivity in eq. [3] by altering the photolysis conditions.

TABLE 1. Photolysis of lactone **5** and allene

| Run | Solvent | Sensitizer | Temperature (°C) | Yield (%)[a] | **11**:**12**[c] |
|---|---|---|---|---|---|
| 1 | Acetone | | 25 | 82 | 5:3 |
| 2 | Acetone | | −78 | 83[b] | 3:2 |
| 3 | Dichloromethane | 0.07% Xanthone | −78 | 60 | 4:3 |

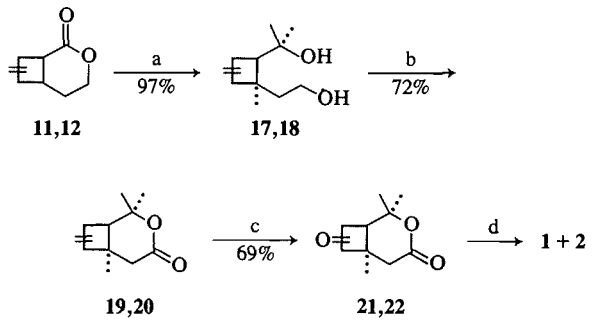
[7]

Then we turned to a study of the photochemical [2 + 2] cycloaddition of substituted allenes to lactone **5**. Since our synthetic plan involved eventual oxidative cleavage of the exocyclic double bond in the methylenecyclobutane, if the exocyclic carbon bore a substituent it would be lost in such a reaction. Phenylallene and 3,3-diphenylallene polymerized when photolyzed in acetone solutions of **5**. At −78°C, 3,3-dimethylallene did not undergo a photochemical addition to the conjugated lactone **5** in acetone. However, at 0°C a photochemical cycloaddition did occur to produce the adducts **13–15** (eq. [7]). The structures of these adducts were determined by ozonolysis of the photolysis mixture in methanol and gas chromatography – mass spectroscopic analysis of the products.

The mixture of photoadducts was ozonized as above and the mixture of products obtained was separated into three peaks by gc and these peaks had parent ions at *m/e* 186, 214, and 182. We could not detect any gc fraction with *m/e* 154 in the mixture. The ratio of the three components (by gc) in the ozonolysis mixture was **13***a*:**14***a*:**15***a* = 16:24:51. The product from the desired isomer **13** was the minor one. All of our efforts to control the regioselectivity in the photochemical cycloaddition were thwarted.

Since the adducts **11** and **12** could not be easily separated we continued the synthesis with the mixture of isomers as follows. On treatment with excess methyllithium, **11** and **12** gave the diols **17** and **18** in almost quantitative yield. These diols were oxidized (16) to the lactones **19** and **20** in 70–75% yield, which were then ozonized to give the keto lactones **21** and **22** in ca. 70% yield. Diisobutylaluminum hydride reduction of **21** and **22** followed by an acid work-up gave a mixture of (±)-lineatin (**1**) and its isomer **2** in a crude yield of 95%. The crude product could be distilled at 110°C/20 Torr. It has been shown that the isomer **2** has no biological activity (17) and the mixture of **1** and **2** is attractive to *T. lineatum* in field trapping studies.[2] In addition, these two products, **1** and **2**, were readily separated by column chromatography; however, their high volatility led to significant loss of material. Nonetheless, pure (±)-lineatin (**1**) could be isolated in 23% yield and the isomer **2** in 13.5% yield.



(a) MeLi, $Et_2O$, 0°C; (b) $CrO_3 \cdot 2py$, $CH_2Cl_2$;
(c) $O_3$, $CH_2Cl_2$, −78°C, then $Me_2S$, −78°C → 25°C; (d) DIBAL, then $H^+$

SCHEME 2. Synthesis of (±)-lineatin (**1**)

It is clear from the earlier structural (1) and synthetic studies (3, 4) on lineatin that the 100 MHz $^1H$ nmr spectral data was not sufficient evidence to differentiate structures **1** and **2**. Experiments with nmr shift reagents were also inconclusive (1). The 270 MHz $^1H$ nmr spectra of **1** and **2** are sufficiently resolved (Figs. 1 and 2) that decoupling experiments can be carried out and an essentially complete assignment of the $^1H$ nmr spectra of **1** and **2** obtained (Table 2). A summary of the coupling constants obtained from the decoupling experiments is given in Table 3. The chemical shifts in lineatin (Table 2) are within the range of values

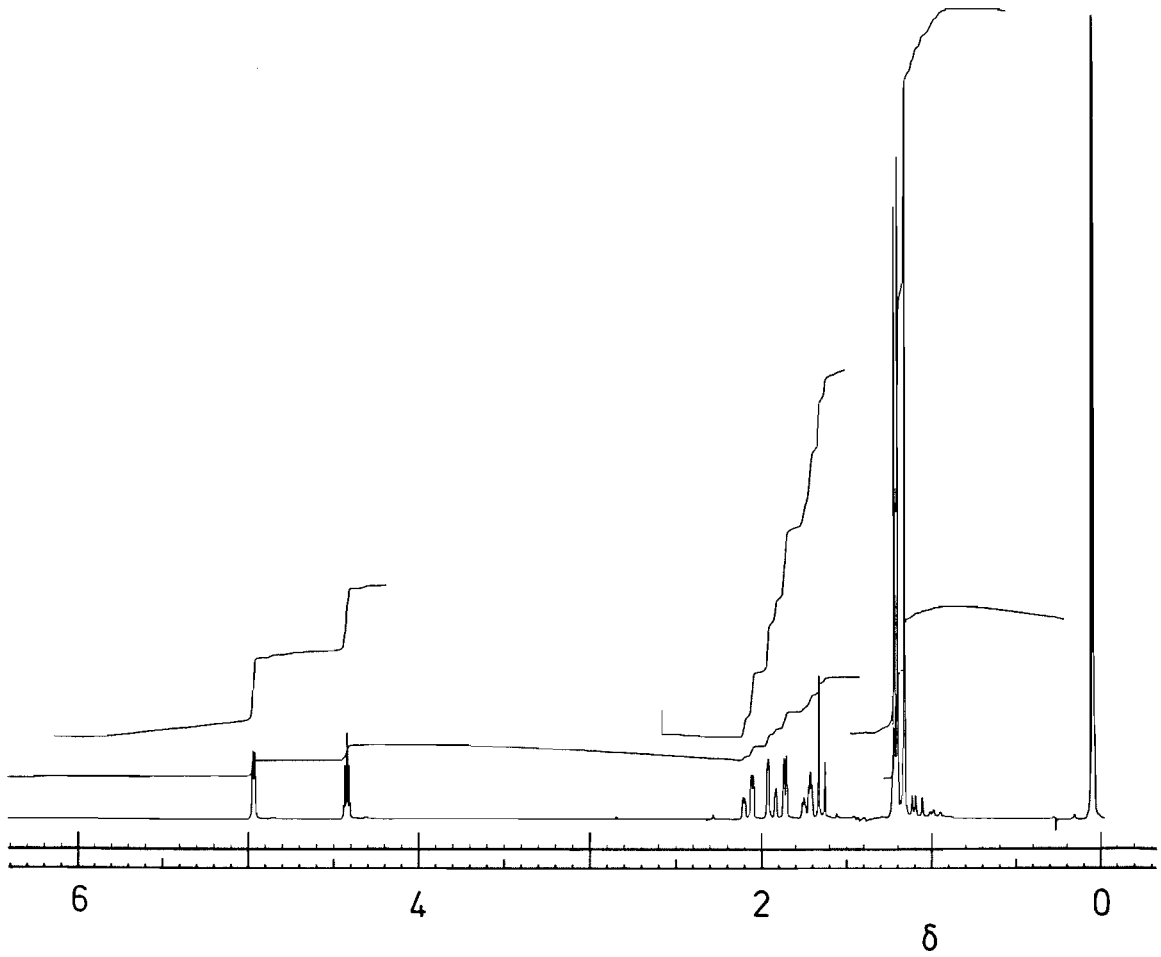

FIG. 1. 270 MHz $^1$H nmr spectrum of lineatin (**1**).

found in model systems. On the other hand there are some unusual shifts in the isomer **2** (Table 2). First $\delta_{5a}$ is rather low for a cyclobutyl methylene hydrogen. Models indicate that **2** adopts a conformation in which $H_{5a}$ and methyl(b) are forced rather close together. Thus we would suggest that the low chemical shift of $H_{5a}$ in **2** is due to a van der Waals deshielding (18) of $H_{5a}$ by the methyl(b). Incidentally we use this same argument to assign the lowest-field methyl singlet to b. The second unusual chemical shift in **2** is the very high field resonance of $H_{8a}$ which may be due to a shielding effect of 0–9 (See ref. 18, p. 80).

The coupling constants in **1** and **2** (Table 3) also show some differences which highlight the structural differences between **1** and **2**. In lineatin (**1**) we find a long range coupling between $H_{6b}$ and $H_{8b}$, and in **2** there is a long range coupling between $H_4$ and $H_6$. In each molecule the hydrogens involved in

the long range coupling and the intervening carbons can adopt a *W* configuration (19). Hence we find that the high-field $^1$H nmr data can be used to differentiate structures **1** and **2**.

## Experimental

*General*

Unless otherwise stated the following are implied. Gas–liquid chromatography (glc) was performed on a Hewlett Packard Model 5831A gas chromatograph, using a 6 ft × 1/8 in. column of 3% OV 17 on Chromosorb W. The 60 MHz proton nuclear magnetic resonance spectra were recorded on a Varian Associates Model T-60, the 100 MHz spectra were recorded on a Varian Associates Model HA-100 or Model XL-100, and the 270 MHz spectra were recorded on a homebuilt high resolution nmr spectrometer consisting of an Oxford Instruments' 63.4 KG magnet. Chemical shifts in ppm are reported using δ scale with tetramethylsilane (TMS) as internal reference. Signal multiplicity, integrated area, and coupling constants are indicated in parentheses. Infrared spectra were recorded on either a Perkin–Elmer model 700 or 710B spectrophotometer. Solution spectra were performed using a sodium chloride solution cell of 0.2 mm thickness. Absorption positions are given in $cm^{-1}$ and are calibrated by means of the 1601 $cm^{-1}$ band of polystyrene. Low resolution mass spectra were determined on a Varian/Mat model CH4B mass spectrometer. High resolution mass measurements were obtained using Kratos-AEI model MS902 or model MS50 instrument. The gc–ms data were obtained with a Hewlett Packard 5700 gc interfaced with a Varian/Mat 777 mass spectrometer. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver.

Analytical thin layer chromatography (tlc) plates and preparative tlc plates were prepared from silica gel GF-254 from E. Merck Co. Preparative tlc plates were of about 1 mm in thickness. Column chromatography was carried out with 100–200 mesh silica gel from Davision Chemical or with 230–400 mesh silica gel from BDH according to the procedure of Still *et al.* (20). Plates were visualized under long and short wavelength ultraviolet radiation and were developed by iodine.

Solvents and reagents used were of either Reagent grade or Certified grade. Solvents were distilled before use. The petroleum ether used was of boiling range ca. 30–60°C. Dry solvents or reagents, where indicated, were prepared as follows: ethyl ether (ether) and tetrahydrofuran (THF) by refluxing over lithium aluminum hydride followed by distillation; dichloromethane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

($CH_2Cl_2$) by distillation from phosphorus pentoxide; pyridine by distillation from barium oxide followed by storage over potassium hydroxide pellets; acetone by distillation from and storage over anhydrous magnesium sulfate; and methanol by refluxing over magnesium methoxide followed by distillation.

Methyllithium (in ethyl ether) was obtained from Aldrich Chemical Company, Inc., and standardized by titration against 1.0 *M tert*-butanol in benzene using 1,10-phenanthroline as indicator.

*3-Methyl-5-hydroxy-2-pentenoic acid δ-lactone (5) (6a)*

A mixture of 10.4 g (80 mmol) of mevalonolactone and 13.6 g of potassium hydrogen sulfate was heated under vacuum for 1 h and distilled at 72–78°C/0.9 Torr to give 8.0 g of colorless liquid. The nmr of the distilled liquid showed it to be a mixture of dehydrated products. The mixture of products was refluxed with 0.2 g (0.76 mmol) of rhodium(III) chloride trihydrate (11) in ethanol (50 mL) for 24 h, allowed to cool, then diluted with water and extracted with dichloromethane. The dichloromethane extract was dried over anhydrous magnesium sulfate, filtered, and the solvents removed under reduced pressure to give 8.0 g (89%) of 3-methyl-5-hydroxy-2-pentenoic acid δ-lactone (**5**). This material was shown to be 94% pure by glc. The spectral data below were the same as those reported for this compound (6*a*); ir ($CHCl_3$): 1650 and 1725 $cm^{-1}$; nmr ($CDCl_3$) δ: 2.01 (br s, 3H), 2.37 (t, $J$ = 6 Hz, 2H), 4.33 (t, $J$ = 6 Hz, 2H), and 5.73 (m, 1H); mass spectrum *m/e* (relative intensity): 41(10), 53(12), 54(44), 55(11), 82(100) and 112(59).

*Photoaddition of 3-methyl-5-hydroxy-2-pentenoic acid δ-lactone (5) to allene*

A solution of 17.8 g (0.445 mol) of allene and 10.0 g (0.089 mol) of 3-methyl-5-hydroxy-2-pentenoic acid δ-lactone (**5**) in 200 mL of degassed acetone was irradiated with a 450 W Hanovia high pressure mercury arc at −78°C for 4 h through a Vycor filter. At the end of the irradiation the solvent was removed by distillation under reduced pressure to give 12.2 g (90%) of crude product. This product was purified by flash column chromatography (20) using silica gel (230–400 mesh) and a mixture of petroleum ether and ethyl acetate (3:2, v/v) as eluent to give 11.3 g (83%) of a mixture of photoadducts: 1-methyl-7-methylene-4-oxa-*cis*-bicyclo[4.2.0]octan-5-one (**11**) and 1-methyl-8-methylene-4-oxa-*cis*-bicyclo[4.2.0]octan-5-one (**12**). The material was shown to be a 3:2 mixture of **11** and **12** respectively by 270 MHz nmr and by glc (using a 23.2 m × 0.28 mm id whisker-walled column coated with Carbowax 20 M).[3] Since separation of the individual components of the photoadduct mixture was very difficult, the sequence was carried through on the mixture. The fraction isolated by the above chromatography was further distilled at 120°C/0.8 Torr (Kugelrohr) and was characterized by the following; ir ($CHCl_3$): 1725 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.25 (s, 3H), 1.8 (m, 2H), 2.6 (m, 1H), 2.95 (m, 1H), 3.4 (m, 1H), 4.4 (m, 2H), and 4.9 (m, 2H); mass spectrum: (*a*) high resolution calcd. for $C_9H_{12}O_2$: 152.0838; found 152.0845 amu; (*b*) low resolution *m/e* (relative intensity): 41(13), 67(10), 77(27), 79(39), 91(20), 93(100), 94(24), 95(10), 107(21), 109(22), 124(15), 137(30), and 152(40). *Anal.* calcd. for $C_9H_{12}O_2$: C 71.03, H 7.95; found: C 70.77, H 8.16.

*Addition of methyllithium to photoadducts 11 and 12*

A solution of 8.0 g (52.60 mmol) of photoadducts **11** and **12** in ca. 20 mL of anhydrous ethyl ether was added dropwise to an ice-cooled flask containing 120 mL (210 mmol) of 1.75 *M* methyllithium in ethyl ether. The mixture was stirred at 0°C for 2 h and the excess methyllithium was decomposed with a saturated aqueous solution of ammonium chloride. The ether layer was separated and the aqueous layer extracted several times with ethyl acetate. The combined extracts were dried over anhydrous magnesium sulfate, filtered, and the solvents were removed under reduced pressure to give 9.35 g (97%) of a mixture of diols **17** and **18** which could not be separated by tlc. The crude mixture was pure enough for the next reaction. A small sample of the mixture of products was chromatographed on a 20 × 20 cm silica gel coated plate, thickness 1 mm, using a mixture of ethyl acetate and petroleum ether (7:1, v/v) as eluent. A thick colorless oil was isolated and characterized by the following data; ir ($CHCl_3$): 1680, 3420, and 3620 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.23 (s, 3H), 1.30 + 1.33 (ss, 6H), 1.8–2.4 (m, 4H), 2.6 (m, 1H), 3.7 (br m, 2H), and 4.8 (br m, 2H); mass spectrum: (*a*) high resolution calcd. for $C_{11}H_{20}O_2$: 184.1463; found: 184.1462 amu; (*b*) low resolution *m/e* (relative intensity): 41(45), 43(100), 53(13), 55(33), 59(95), 67(24), 79(27), 83(72), 85(36), 86(32), 105(19), 107(34), 111(59), 121(49), 123(30), 135(60), 151(34), and 166(15) (P − $H_2O$).

*Oxidation of mixture of diols 17 and 18*

A sample of 31.2 g (312 mmol) of chromium trioxide was added to a stirred solution of 49.32 g (624 mmol) of anhydrous pyridine (16) in ca. 30 mL of anhydrous dichloromethane. The chromium trioxide – pyridine complex was stirred at room temperature for 25 min. Then a solution of 9.20 g (50 mmol) of the mixture of diols **17** and **18** in ca. 5 mL of anhydrous dichloromethane was added in one portion. A tarry, black precipitate separated immediately. After stirring for 4.5 h at room temperature, the solution was decanted from the reaction, and the dichloromethane removed under reduced pressure. The residue was diluted with ethyl ether and the reaction flask rinsed several times with ethyl ether. The combined ether layers were filtered through a bed of Celite, washed with ice-cold dilute hydrochloric acid, aqueous sodium bicarbonate solution, brine, dried over anhydrous magnesium sulfate, and filtered. The solvents were removed under reduced pressure to give 7.60 g (84%) of a mixture of 2,2,6-trimethyl-8-methylene-3-oxa-*cis*-bicyclo[4.2.0]octan-4-one (**19**) and 2,2,6-trimethyl-7-methylene-3-oxa-*cis*-bicyclo[4.2.0]octan-4-one (**20**). The crude products were purified by column chromatography using silica gel (100–200 mesh) and a mixture of petroleum ether and ethyl acetate (2:3, v/v) as eluent. The fraction isolated from this chromatography was homogeneous by tlc analysis, and was shown to be a 3:2 mixture of **19** and **20** by nmr and glc (using a 23.4 m × 0.28 mm id whisker-walled column coated with Silar 10C).[3] Since separation of the individual components from the mixture was very difficult, the next sequence of steps was carried through on the mixture. The mixture from the chromatography was further distilled at 100°C/1.0 Torr (Kugelrohr) to afford 6.5 g (72%) of a mixture of **19** and **20** which was characterized by ir ($CHCl_3$): 1680 and 1725 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.35, 1.42 and 1.47 (ss, 9H), 2.4 (m, 5H), and 4.9 (m, 2H); mass spectrum: (*a*) high resolution calcd. for $C_{11}H_{16}O_2$: 180.1150; found: 180.1158 amu; (*b*) low resolution *m/e* (relative intensity): 41(33), 43(69), 79(77), 80(90), 93(32), 109(24), 121(20), 123(31), 125(31), 139(14), 165(10), and 180(17). *Anal.* calcd. for $C_{11}H_{16}O_2$: C 73.30, H 8.95; found: C 73.10, H 8.95.

*Ozonolysis of alkenes 19 and 20*

A stream of ozone and oxygen was bubbled through a solution of 6.93 g (38.5 mmol) of a mixture of compounds **19** and **20** in ca. 250 mL of anhydrous dichloromethane at −78°C until the solution turned blue. Excess dimethylsulfide was added slowly. The reaction mixture was allowed to stir at −78°C for 20 min, warmed slowly to room temperature, washed with water, dried over anhydrous magnesium sulfate, and filtered. The solvents

[3]We wish to thank Professor A. C. Oehlschlager and Dr. H. Pierce, Jr., Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada, for the glc analysis of this compound.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

were removed under reduced pressure to give 6.27 g (89%) of crude product which was purified by column chromatography using silica gel (100–200 mesh) and a mixture of petroleum ether and ethyl acetate (1:1, v/v) as eluent. The fraction isolated from this chromatography gave 4.8 g (69%) of a mixture of 2,2,6-trimethyl-3-oxa-*cis*-bicyclo[4.2.0]octan-4,8-dione (**21**) and 2,2,6-trimethyl-3-oxa-*cis*-bicyclo[4.2.0]octan-4,7-dione (**22**). The mixture of products could not be separated by tlc and was characterized by the following spectral data; ir ($CHCl_3$): 1730 and 1785 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.32 and 1.40 (ss, 3H), 1.53 (s, 6H), and 2.2–3.2 (m, 5H); mass spectrum: (*a*) high resolution calcd. for $C_{10}H_{14}O_3$: 182.0943; found: 182.0953 amu; (*b*) low resolution *m/e* (relative intensity): 40(27), 41(60), 42(20), 43(78), 44(38), 51(10), 53(32), 54(17), 55(33), 59(10), 67(35), 68(47), 69(30), 70(14), 77(14), 79(30), 81(53), 82(26), 83(28), 95(25), 96(100), 97(79), 98(42), 123(46), 125(89), 126(23), 141(19), 167(8), and 182(6).

*(±)-Lineatin (1) and 3,3,7-trimethyl-2,9-dioxatricyclo-[4.2.1.0$^{4,7}$]nonane (isolineatin) (2)*

A solution of 5.0 g (27.5 mmol) of a mixture of ketones **21** and **22** in anhydrous ether (100 mL) was cooled to −60°C and a solution of 60 mL (1.0 *M* in hexane, 60 mmol) of diisobutylaluminum hydride in hexane was added dropwise under nitrogen. The reaction mixture was stirred at −60°C for 1 h, and saturated ammonium chloride (100 mL) was added. The reaction mixture was warmed to 0°C and acidified by dilute hydrochloric acid. Stirring was continued for an additional 1 h and the mixture was extracted several times with ether. The combined extracts were washed with aqueous sodium bicarbonate solution, dried over anhydrous magnesium sulfate, filtered, and the solvents removed under reduced pressure to give 4.3 g (95%) of crude product. The material was shown to be a 1.6:1 mixture of 3,3,7-trimethyl-2,9-dioxatricyclo[3.3.1.0$^{4,7}$]nonane (**1**) (±-lineatin) and 3,3,7-trimethyl-2,9-dioxatricyclo[4.2.1.0$^{4,7}$]nonane (**2**) (isolineatin) by glc. Purification was achieved by flash column chromatography (20) using silica gel (230–400 mesh) and a mixture of petroleum ether and ethyl ether (3:2, v/v) as eluent. Two components were isolated from this chromatography, and these were, in order of elution, (±)-lineatin (**1**) (1.05 g, 23%) and 3,3,7-trimethyl-2,9-dioxatricyclo[4.2.1.0$^{4,7}$]nonane (**2**) (0.615 g, 13.5%). All the spectral data of compound **1** were similar to those published by MacConnell *et al.* for (±)-lineatin (**1**) and **2** (1). This synthetic (±)-lineatin (**1**) was distilled at 110°C/20 Torr (Kugelrohr) and was characterized by; ir ($CCl_4$): 838, 875, 905, 920, 960, 1000, 1020, 1078, 1100, 1125, 1170, 1185, 1210, 1225, 1245, 1318, 1345, 1365, 1380, 1385, 1455, 1470, 2880, 2940, and 2975 $cm^{-1}$; nmr (100 MHz, $CCl_4$) δ: 1.08 (s, 3H), 1.12 (s, 3H), 1.14 (s, 3H), 1.55–2.1 (m, 5H), 4.34 (t, $J$ = 4 Hz, 1H), and 4.86 (d, $J$ = 3.5 Hz, 1H); nmr (270 MHz, $CCl_4$) δ: 1.12 (s, 3H), 1.16 (s, 3H), 1.17 (s, 3H), 1.61 (d, $J$ = 10.5 Hz, 1H), 1.69 (dt, $J$ = 10.5, 4 Hz, 1H), 1.83 (d, $J$ = 4 Hz, 1H), 1.91 (dd, $J$ = 12, 4 Hz, 1H), 2.04 (dd, $J$ = 12, 4 Hz, 1H), 4.38 (t, $J$ = 4 Hz, 1H), and 4.93 (d, $J$ = 4 Hz, 1H); mass spectrum: (*a*) high resolution calcd. for $C_{10}H_{16}O_2$: 168.1150; found: 168.1148 amu; (*b*) low resolution *m/e* (relative intensity): 41(44), 43(43), 55(44), 69(34), 83(58), 85(100), 96(84), 97(47), 107(68), 109(51), 111(85), 125(56), 140(12), 153(8), and 168(10). *Anal.* calcd. for $C_{10}H_{16}O_2$: C 71.39, H 9.59; found: C 71.52, H 9.76.

3,3,7-Trimethyl-2,9-dioxatricyclo[4.2.1.0$^{4,7}$]nonane (**2**) was distilled (Kugelrohr) at 110°C/20 Torr and was characterized by the following spectral data; ir ($CCl_4$): 660, 700, 850, 895, 905, 925, 938, 960, 970, 980, 990, 1000, 1018, 1040, 1050, 1080, 1100, 1115, 1140, 1160, 1178, 1195, 1205, 1220, 1238, 1255, 1295, 1300, 1325, 1345, 1360, 1365, 1382, 1435, 1455, 1470, 2875, 2950, and 2980 $cm^{-1}$; nmr (100 MHz, $CCl_4$) δ: 1.03 (s, 3H), 1.19 (s, 3H), 1.34 (s, 3H), 1.7–2.45 (m, 5H), 3.86 (t, $J$ = 4 Hz, 1H), and 5.23 (d, $J$ = 4 Hz, 1H); nmr (270 MHz, $CCl_4$) δ: 1.08 (s, 3H), 1.23 (s, 3H), 1.39 (s, 3H), 1.33 (dd, $J$ = 12, 4 Hz, 1H), 1.9 (m, 2H), 2.09 (d, $J$ = 12 Hz, 1H), 2.35 (ddd, $J$ = 13, 9, 4 Hz, 1H), 3.93 (t, $J$ = 4 Hz, 1H), and 5.32 (d, $J$ = 4 Hz, 1H); mass spectrum: (*a*) high resolution calcd. for $C_{10}H_{16}O_2$: 168.1150; found: 168.1152 amu; (*b*) low resolution *m/e* (relative intensity): 41(37), 43(30), 55(23), 67(13), 69(37), 71(17), 79(14), 81(18), 83(14), 91(45), 92(29), 93(13), 95(22), 97(16), 105(16), 107(22), 109(100), 120(15), 125(15), 124(60), 125(20), 130(16), 166(6), and 168(1). *Anal.* calcd. for $C_{10}H_{16}O_2$: C 71.39, H 9.59; found: C 71.19, H 9.59.

*Photoaddition of 3-methyl-5-hydroxy-2-pentenoic acid δ-lactone (5) to 3,3-dimethylallene*

A solution of 0.73 g (10.7 mmol) of 3,3-dimethylallene (Aldrich) and 0.80 g (7.13 mmol) of 3-methyl-5-hydroxy-2-pentenoic acid δ-lactone (**5**) in 30 mL of degassed acetone was irradiated with a 450 W Hanovia high pressure mercury arc at 0°C for 4 h through a Vycor filter. At the end of the irradiation the solvent was removed under reduced pressure to give 1.55 g of crude product. This product was purified by flash chromatography (20) using silica gel (230–400 mesh) and a mixture of ethyl acetate and petroleum ether (1:3, v/v) as eluent to give 0.69 g (53%) of a mixture of photoadducts. This mixture was found to contain three main components by glc in the ratio 13:20:65. These were subsequently shown by the following ozonolysis experiment to correspond to compounds **13**, **14**, and **15** respectively.

*Ozonolysis of alkenes 13, 14, and 15*

A stream of ozone and oxygen was bubbled through a solution of 0.25 g (1.4 mmol) of a mixture of compounds **13**, **14**, and **15** in 25 mL of anhydrous methanol at −78°C until the solution turned blue. Excess dimethylsulfide was added slowly. The reaction mixture was allowed to stir at −78°C for 20 min, warmed slowly to room temperature, washed with water, dried over anhydrous magnesium sulfate, and filtered. The solvents were removed under reduced pressure to give 0.14 g (ca. 50% yield) of a mixture of compounds. This mixture was shown by gc–ms to contain compounds with *m/e* 186(13*a*), 214(**14***a*), and 182(**15***a*) in the ratio 16:24:51 (glc ratios) respectively.[4]

# Clathrate and other solid phases in the tetrahydrofuran–water system: thermal conductivity and heat capacity under pressure

RUSSELL G. ROSS[1] AND PER ANDERSSON
*Department of Physics, University of Umeå, 901 87 Umeå, Sweden*

Received September 15, 1981

RUSSELL G. ROSS and PER ANDERSSON. Can. J. Chem. **60**, 881 (1982).

Solid phases in the tetrahydrofuran–water (THF–$H_2O$) system were investigated in the temperature range 100–260 K and at pressures up to 1.5 GPa. Thermal conductivity, $\lambda$, and heat capacity per unit volume, $\rho c_p$, were measured, using the transient hot-wire method. We made measurements on solid phases having nominal compositions THF·17$H_2O$, THF·7.1$H_2O$, and THF·4.6$H_2O$, which we refer to as phases $\alpha$, $\beta$, and $\gamma$, respectively. Phase $\alpha$ is known to be a structure II clathrate hydrate, and $\lambda$ for this phase was found to be similar to other crystalline solids which are glass-like in relation to their thermal properties. Low-energy excitations are known to be relevant to the properties of glass-like solids, and, in the case of phase $\alpha$, were probably rotational vibrations of the THF guest molecules. Phase $\beta$ was similar, and we inferred that it was probably a structure I clathrate hydrate. Phase $\gamma$ behaved nearly like a normal crystal phase at low temperatures, but $\lambda$ became almost independent of temperature near melting. At 1.1 GPa and 130 K, we found evidence that phase $\alpha$ transformed, on pressurization, to a metastable modification which may be a new high-density form of clathrate hydrate. The astrophysical implications of our results were mentioned briefly.

RUSSELL G. ROSS et PER ANDERSSON. Can. J. Chem. **60**, 881 (1982).

On a étudié les phases solides dans le système tétrahydrofuranne–eau (THF–$H_2O$) dans un intervalle de température allant de 100 à 260 K et des pressions allant jusqu'à 1,5 GPa. On a mesuré la conductivité thermique, $\lambda$, et la capacité calorifique par unité de volume, $\rho c_p$, en utilisant la méthode du fil chaud transitoire. Nous avons effectué ces mesures sur des phases solides ayant des compositions nominales de THF·17$H_2O$, THF·7,1$H_2O$ et THF4,6$H_2O$ que nous désignons respectivement comme phases $\alpha$,$\beta$ et $\gamma$. On sait que la phase $\alpha$ a une structure II d'hydrate de clathrate et on a trouvé que, pour cette phase, $\lambda$ est semblable à celui d'autres solides cristallins qui ressemblent à des verres si l'on tient compte de leurs propriétés thermiques. On sait que les excitations de faible énergie sont reliées aux propriétés des solides ressemblant à des verres et, dans le cas de la phase $\alpha$, ce sont probablement des vibrations–rotations des molécules-hôtes de THF. La phase $\beta$ est semblable et nous en déduisons qu'elle a probablement une structure I d'hydrate de clathrate. La phase $\gamma$ se comporte presque comme une phase cristalline normale à basse température, mais $\lambda$ devient presqu'indépendant de la température au voisinage du point de fusion. A 1,1 GPa et 130 K, nous avons trouvé des indications à l'effet que la phase $\alpha$ se transforme, sous pression, en une forme métastable qui peut être une nouvelle forme d'hydrate de clathrate à haute densité. Nous mentionnons brièvement les implications astrophysiques de nos résultats.

[Traduit par le journal]

## 1. Introduction

We report here the first detailed measurements of the thermal properties of a clathrate hydrate. The properties we measured were thermal conductivity and heat capacity per unit volume. The system we studied was tetrahydrofuran–water (THF–$H_2O$), and we investigated three intermediate solid phases occurring at different compositions. One of these phases is known to be a clathrate hydrate, and we found evidence to suggest that a second one is as well. By way of introduction, our aim in the present section is to provide information both on clathrate hydrates, and on thermal properties of nonmetallic solids. Structural disorder, and its effects, will be a recurring theme.

### *1.1 Clathrate hydrates*

Clathrate solids (1) are a class of multi-component solid phase in which the major component, the host, encages individual guest molecules of the minor component(s). When the host is $H_2O$, the resulting clathrate solids are referred to as clathrate hydrates. Various properties of clathrate hydrates have been described in a detailed review by Davidson (2) on which the present introductory remarks are based. We consider here only binary systems yielding simple clathrate hydrates in which guest molecules of a single chemical species are encaged by a structure of $H_2O$ molecules of the host. The host molecules are hydrogen-bonded to each other, and form structures which may be described as "ice-like". A guest molecule may be considered to undergo relatively free rotational vibrations within its cage (3).

For almost all clathrate hydrates studied to date, the host molecules have a crystal structure which is of either one of two types, referred to as structure I and structure II. Structure I clathrate hydrates have been found for guest molecules (or atoms) up to about 0.53 nm in diameter, and structure II for guest molecules having diameters in the range 0.56–0.66 nm. Some examples are known where

guest molecules of about 0.55 nm diameter can form clathrate hydrates of either structure I or II. Structure I clathrate hydrates may be formed in principle in the range of composition from $M \cdot 5\frac{3}{4}H_2O$ to $M \cdot 7\frac{2}{3}H_2O$, where M represents a guest molecule. This compositional range reflects varying degrees of occupancy by guest molecules of the two sizes of cage available in the host structure. Structure II clathrate hydrates always seem to occur in a very narrow range of composition near $M \cdot 17H_2O$. This composition corresponds to full occupancy of large cages only.

The clathrate-forming system under investigation here is THF–$H_2O$. One reason for selecting this system was that samples were easy to prepare. Under normal conditions of temperature and pressure, THF is a liquid and binary samples can be prepared by simple mixing weighed amounts of the components. Guest species which are gaseous under normal conditions of temperature and pressure cannot be handled using our present experimental arrangements. In addition, the THF–$H_2O$ system has been relatively thoroughly investigated by previous workers. Dyadin *et al.* (4) determined the phase diagram over the whole range composition, at temperatures 240–320 K and at pressures up to 0.9 GPa. Figure 1 has been drawn to show the essential features of their results. They detected four intermediate solid phases at nominal compositions $THF \cdot 17H_2O$, $THF \cdot 7.1H_2O$, $THF \cdot 4.6H_2O$, and $THF \cdot 2.2H_2O$. For convenience, we shall refer to these phases as α, β, γ, and δ, respectively. Phases α, β, and γ were investigated in the present work. Phase α is known to be a structure II clathrate hydrate (5) which probably has a precise composition (6) $THF \cdot 16.86H_2O$. The existence of a structure II clathrate hydrate in this system is consistent with the structural generalizations previously described, since the diameter of the THF molecule is about 0.59 nm. However, Fig. 1 shows that phase α is stable only at a fairly low pressure. The possibility of the formation of other clathrate hydrate structures at high pressures will be considered later. Phases β and γ, for which no structural data are available, have been assigned (4) an experimental uncertainty of $\pm 0.3H_2O$ in composition, and are asserted to have a narrow range of composition. It can be seen from Fig. 1 that, at suitable pressures, all phases α, β, and γ can be formed by the procedure of congruent freezing of a liquid solution. We generally followed such a procedure in order to obtain the simplification of a single-phase solid sample.

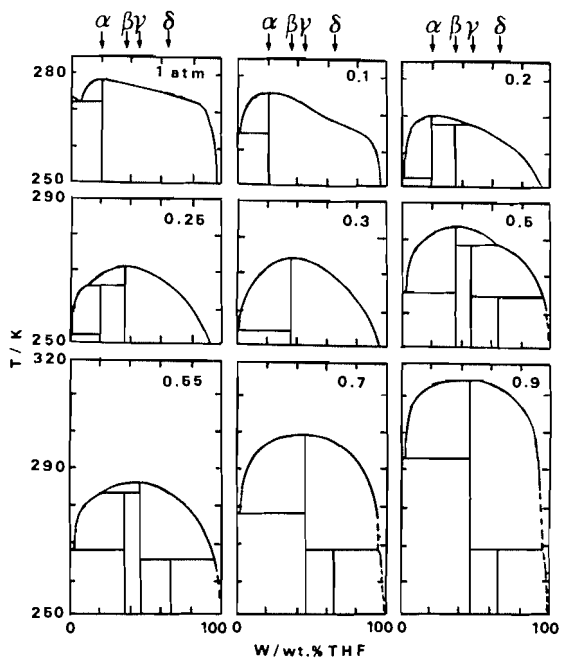

FIG. 1. Phase diagram of THF–$H_2O$ system, after Dyadin *et al.* (4). Solid phases have nominal compositions $THF \cdot nH_2O$ with $n$ = 17, 7.1, 4.6, and 2.2 for phases α, β, γ, and δ, respectively. Pressure for each isobaric section in GPa (except at 1 atm).

### *1.2 Thermal properties of nonmetallic crystals and glasses*

We now describe some simple and basic ideas in connection with the thermal properties of nonmetallic solids, in particular, molecular solids. It is well-known that specifically molecular properties exhibited in the gas phase are modified to a relatively small extent on transition to a solid phase. We shall therefore assume, in connection with the crystallography of molecular solids, that molecules may be regarded as the effective structural units.

We may distinguish several different types of internal motion in a molecular solid. One type of motion will be associated with the collective movement of the whole molecules and will correspond to the plane-wave solutions familiar from an elementary analysis of the lattice dynamics of a simple solid. The acoustic modes of the resulting dispersion relation should be of importance for the conduction of heat. Lattice optic modes and intramolecular vibrations also need to be taken into account, in principle.

In discussing the thermal conductivity, λ, it is usual to start with the Debye formula (7)

$$[1] \quad \lambda = \frac{1}{3} Cvl$$

In eq. [1], $C$ is the heat capacity per unit volume, $v$ the phonon velocity, and $l$ the phonon mean free

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

path. An expression of the form of eq. [1] should pertain for each of the lattice modes of vibration, but in practice we shall ignore optic modes by using the argument that they are expected to have a negligibly small phonon velocity. Although no detailed theoretical model (8) has yet been developed specifically for the thermal conductivity of complex molecular solids, it seems reasonable to assume that eq. [1] may be applied, and that only the acoustic modes carry heat. Thermal resistivity will arise from processes which scatter phonons. We shall present evidence which suggests that, in a clathrate hydrate, such processes may include motion of guest molecules.

As a preliminary to a more detailed view of the thermal conductivity of a molecular solid, we consider first the simplest possible analysis (7) for two idealized materials: a structurally-perfect crystalline solid of monatomic basis, and a structurally-disordered glass. We shall use eq. [1] to predict the form of $\lambda(T)$, where $T$ is the temperature.

For the structurally-perfect crystal, the thermal resistivity at high temperatures is considered to arise entirely from three-phonon umklapp processes. The density of other phonons with which a given phonon can interact is taken to be $\propto T$, from the high-temperature limit of the Planck distribution function, so $l \propto 1/T$. The heat capacity is taken to be constant at its classical value, and the temperature dependence of $v$ is ignored. The resulting theoretical prediction is $\lambda \propto 1/T$, and a more detailed treatment (9) gives the same result. The prediction is expected to be valid for $T \gtrsim$ the Debye temperature, $\theta_D$. As is well-known, the predicted form of $\lambda(T)$ is found in practice for many real crystals, including some molecular crystals (10).

For a glass, on the other hand, a common approximation is to take $l$ to be a temperature-independent constant, the value of which is fixed at a relatively small value as a result of structural disorder. Three-phonon umklapp processes are considered to make a negligible contribution to the total thermal resistivity. The temperature dependence of $v$ is ignored, and $C(T)$ is assumed to be described by a Debye model. The temperature dependence of $\lambda$ is then predicted to be similar to that of $C$, i.e., $\lambda$ increases modestly with $T$. Real glasses show approximately the predicted behaviour.

Even for the very simplest models, an outstanding difference to be emphasized between a perfect crystal and a glass is in the sign of $d\lambda/dT$; negative for a perfect crystal ($d \ln \lambda/d \ln T = -1$), and positive for a glass. It is also found empirically that $\lambda$(glass) is relatively small and close to $\lambda$(liquid) (11), whereas $\lambda$ usually shows a dramatic increase on freezing to a normal crystalline phase (8).

Recently, thermal properties of glasses at low temperature have been the subject of considerable experimental and theoretical investigation; see ref. 12 and references cited therein. In particular, for the thermal conductivity, a plateau at about 10 K is found to be superposed on a general increase of $\lambda$ with $T$. This and other features of the thermal properties are generally considered to be associated with the existence of low-energy, localized excitations, but detailed theoretical interpretation of the plateau is still controversial (12–14).

A related but somewhat surprising result which is by now established is that there are essentially-crystalline solids whose thermal properties are very similar to those just described for glasses. Such solids are also known to exhibit some form of structural disorder, and will be referred to here as glass-like (in relation to thermal properties). Data on the thermal properties of these solids has recently been summarized by Ackerman *et al.* (15). Further relevant references are refs. 16 to 18. As for glasses, appropriate localized excitations are invoked (15) to account for the observed thermal properties of glass-like solids.

From the discussion in section 1.1, we might expect that a clathrate hydrate would be a glass-like solid, and we shall present evidence to support this view. We shall further attempt to associate the low-energy excitations, relevant to the thermal conductivity, with the rotational vibrations of the guest molecules. Since our experiments were made at $T > 100$ K, our results complement those of previous investigations (15) which were mainly concerned with very low temperature conditions. A preliminary report of some of our results has already appeared (19).

### *1.3 Thermal conductivity of a two-phase system*

Methods for estimating the thermal conductivity of a two-phase mixture must also be mentioned briefly. This topic has been discussed by Parrott and Stuckes (7). In general, we tried to ensure that our sample was single-phase, but sometimes we were fairly sure that a second phase was present. In the latter case, we assumed that the thermal conductivity of the mixture could be calculated using the formula due to Maxwell. The input data required in the calculation were the thermal conductivities of each of the phases, and their volume fractions. The result was probably a good approximation when the volume fraction of one of the phases was small, but less satisfactory when the volume fractions of the two phases were nearly equal.

## 2. Experimental details

The thermal conductivity, $\lambda$, and the heat capacity per unit volume, $\rho c_p$, were measured simultaneously using the transient hotwire method. $c_p$ is the specific heat capacity at constant pressure, and $\rho$ is the mass density. Details of the method have been given elsewhere (10). Measurements were made in the temperature range $T = 100$–$260$ K and at pressures $P = 0.1$–$1.5$ GPa. Such ranges exceed, to a modest degree, those of the known phase diagram (4) (Fig. 1). Our investigation was concentrated on phases $\alpha$, $\beta$, and $\gamma$.

Samples were prepared by mixing at room temperature and pressure weighed quantities of spectroscopic grade THF and doubly-distilled water. A sample of liquid solution was poured into the Teflon cell of our piston-cylinder high pressure apparatus, and frozen, normally congruently, by cooling at the appropriate pressure. Overall compositions were calculated using the measured weights of the components.

Accuracy was $\pm 3\%$ in $\lambda$ and $\pm 10\%$ in $\rho c_p$.

## 3. Results

Our results for congruent freezing temperatures of phases $\alpha$, $\beta$, and $\gamma$ agreed to within 2 K with the known phase diagram (4). In all cases, we observed about 4 K supercooling, followed by an arrest. Such behaviour indicates unambiguously that a first-order liquid $\rightarrow$ solid transition occurred on cooling, and excludes the possibility of glass formation.

Data for $\lambda$ and $\rho c_p$ are shown in Figs. 2–6. There are no previous results available for comparison. Equations were fitted where appropriate, and the resultant coefficients are given in Tables 1 and 2.

We also made measurements for the liquid-phase solutions, but for simplicity these data have been omitted from the figures. In addition, for technical reasons discussed elsewhere (20), our measurements for liquids are less accurate than for solids. We can, however, obtain approximate values for the ratio $\lambda$(solid)/$\lambda$(liquid) at congruent freezing, and the results were values 1.07, 1.04, and 1.20 in connection with phases $\alpha$, $\beta$, and $\gamma$ respectively.

We investigated a number of solid samples under various conditions, according to the following outline:

(*i*) All samples had a composition at or near that expected for phase $\alpha$, $\beta$, or $\gamma$.

(*ii*) For each of these phases, we made isobaric measurements under conditions of thermodynamic equilibrium at the pressure we employed for congruent freezing, which was 0.1, 0.3, or 0.55 GPa for phase $\alpha$, $\beta$, or $\gamma$ respectively. For phase $\gamma$, isobaric measurements were also made at pressures of 0.91 and 1.4 GPa. The former pressure is known from the phase diagram (Fig. 1) to correspond to thermodynamic equilibrium, and it appears from our measurements that the latter pressure does as well. Results for isobaric measurements under conditions of themodynamic equilibrium are described in section 3.1.

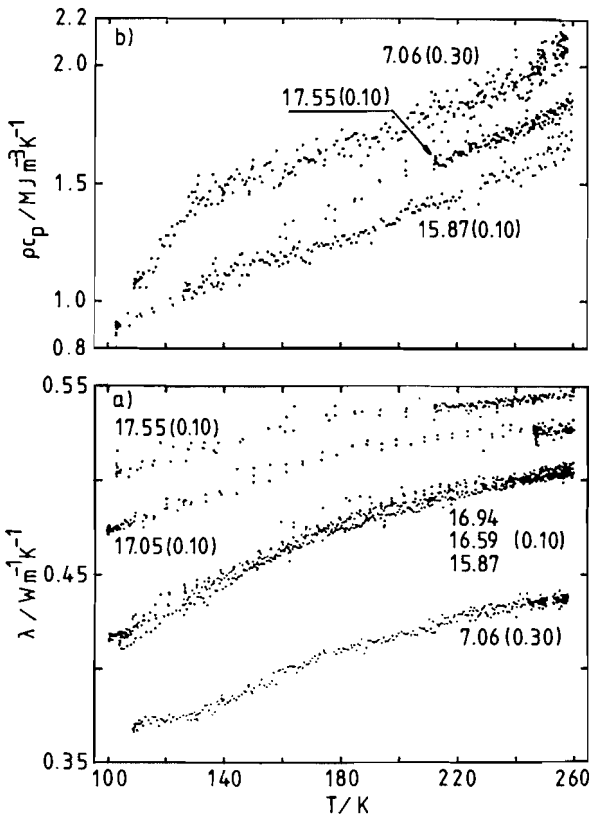

FIG. 2. Isobaric temperature dependence of (*a*) thermal conductivity $\lambda$ and (*b*) heat capacity per unit volume $\rho c_p$. Data for samples of composition THF·$n$H$_2$O at pressure $P$/GPa labelled $n(P)$.

(*iii*) In another series of experiments, samples of composition appropriate to each of phases $\alpha$, $\beta$, and $\gamma$ were cooled at the pressure employed for congruent freezing, and then pressurized isothermally at 130 K to about 1.5 GPa. At 1.1 GPa, there was evidence that phase $\alpha$ transformed to what we shall call phase $\alpha'$. Results for isothermal compression at 130 K are described in section 3.2.

(*iv*) Phases $\alpha'$ and $\beta$ were probably metastable at 1.4 GPa and low temperatures, and reliable measurements could only be made up to 200 K. Results for isobaric measurements on these metastable phases are described in sections 3.2.4 and 3.2.2 respectively.

(*v*) Phases $\alpha$ and $\beta$ could be compressed under equilibrium conditions at 240 K, and the corresponding results for isothermal measurements are described in section 3.3

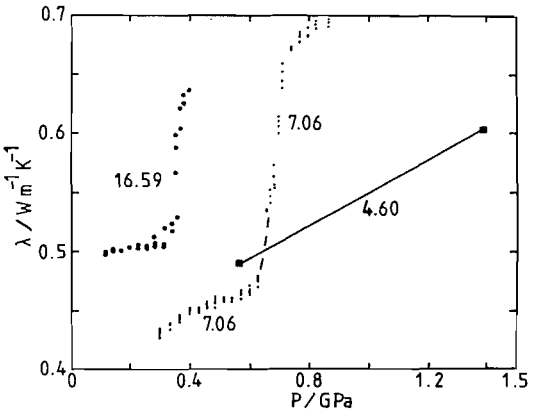

FIG. 5. Isothermal pressure dependence of thermal conductivity $\lambda$ at 240 K. Data for samples of composition THF·$n$$H_2O$ labelled $n$.

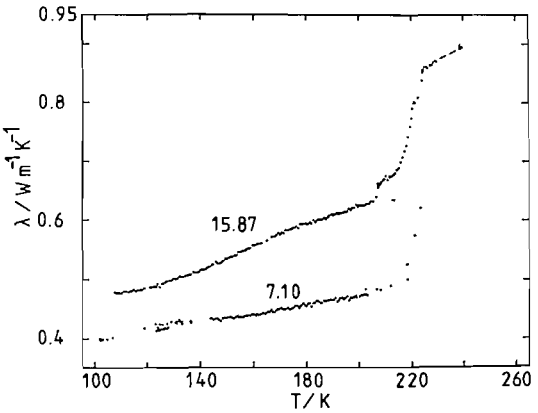

FIG. 6. Isobaric temperature dependence of thermal conductivity $\lambda$ at 1.4 GPa. Data for samples of composition THF·$n$$H_2O$ labelled $n$.

The figure shows that $\lambda(T)$ had the same general form for all these samples, and that it was similar to that for a glass.

The measured values of $\lambda(T)$ were essentially identical for samples in the range of composition from THF·15.87$H_2O$ to THF·16.94$H_2O$. Since phase $\alpha$ is known (6) to have a narrow range of composition at about THF·16.9$H_2O$, these samples should consist either of phase $\alpha$ or of phase $\alpha$ + a small proportion of a THF-rich phase. For $T \gtrsim$ 170 K, the THF-rich phase will consist (4, 21) of liquid solution, whereas at lower temperatures it is most likely to be pure solid THF. The normal freezing point of pure THF is 164.76 K (22). Whether solid or liquid, the presence of a small proportion of THF-rich phase should have a very small effect on $\lambda$. This is because the THF-rich phase is expected to have a value of $\lambda$ quite close to that of phase $\alpha$. It was stated earlier that we found $\lambda$(phase $\alpha$)/ $\lambda$(liquid) $\approx$ 1.07 for liquid solution of the same composition as phase $\alpha$. In the case of pure solid THF, $\lambda \approx 0.65$ W m$^{-1}$ K$^{-1}$ at 130 K and low

pressure.[2] From the data shown in Fig. 2, there was no evidence that freezing of the THF-rich phase, which probably occurred at about 170 K, had any significant effect on the measured value of $\lambda$. We therefore conclude that $\lambda(T)$ for phase $\alpha$ is closely approximated by the data shown in Fig. 2(*a*) for samples in the range of composition from $THF{\cdot}15.87H_2O$ to $THF{\cdot}16.94H_2O$.

Similarly, samples of composition $THF{\cdot}17.05H_2O$ and $THF{\cdot}17.55H_2O$ were expected to contain a small proportion of ice Ih, but, by contrast, the presence of the latter should have a relatively large effect on $\lambda$ since $\lambda$(ice Ih)/$\lambda$(phase $\alpha$) $\approx$ 5. To show this effect in more detail, we can estimate $\lambda$ for a two-phase mixture using the Maxwell formula (7). At a temperature of about 250 K, we take $\lambda$(phase $\alpha$) $\approx$ 0.5 W m$^{-1}$ K$^{-1}$ from present work, and $\lambda$(ice Ih) $\approx$ 2.5 W m$^{-1}$ K$^{-1}$ from previous work (23). We ignore any difference of density (6) between the two phases. An increase of molecular concentration by $0.5H_2O$ above the exact composition of phase $\alpha$ then implies a volume ratio (ice Ih):(phase $\alpha$) $\approx$ 1:35. Use of the Maxwell formula then yields a corresponding increase in $\lambda$ of 5%, which was about what was observed experimentally. Supporting evidence for the presence of ice Ih in the sample of composition $THF{\cdot}17.55H_2O$ was our observation of a response in $\lambda(T)$, as usually found for a phase transition, at the temperature of the (phase $\alpha$)–(ice Ih)–(liquid) eutectic.

*3.1.2 Phase* $\beta$

Figure 2(*a*) also includes data for $\lambda(T)$ at 0.3 GPa for a sample of composition $THF{\cdot}7.1H_2O$, which we assumed consisted entirely of phase $\beta$. As for phase $\alpha$, the form of $\lambda(T)$ for phase $\beta$ is similar to that for a glass.

*3.1.3 Phase* $\gamma$

Figure 3 shows our results along various isobars for a sample of composition $THF{\cdot}4.6H_2O$, which we assumed consisted entirely of phase $\gamma$. The form of $\lambda(T)$ for phase $\gamma$ is evidently very different from that for phases $\alpha$ and $\beta$ (Fig. 2), and closer to what would be expected for a normal crystalline phase. At 0.55 GPa, a weak maximum in $\lambda(T)$, and minimum in $\rho c_p(T)$, were detected at a temperature of about 130 K. These features became less pronounced with increasing pressure. We shall argue later that they can most plausibly be regarded as an artifact of the transient hot-wire method. Our results at 260 K indicated that the region of stability of phase $\gamma$ in the phase diagram (Fig. 1) can be extended to at least 1.4 GPa at this temperature.

*3.2 Isothermal compression at 130 K, and metastability*

Figure 4 shows our results for isothermal compression of phases $\alpha$, $\beta$, and $\gamma$ at a temperature of 130 K. Only data for $\lambda(P)$ are shown. With an exception to be noted in the following paragraph, $\rho c_p$ had a value of about 1 MJ m$^{-3}$ K$^{-1}$ for all phases and $P$–$T$ conditions indicated in Fig. 4.

*3.2.1 Phase* $\alpha$

We begin with a consideration of samples of composition $THF{\cdot}15.87H_2O$ and $THF{\cdot}17.05H_2O$, which were both expected to consist mostly of phase $\alpha$. Both of these samples showed evidence for a phase transition (which we have referred to as $\alpha \rightarrow \alpha'$) at a pressure of about 1.1 GPa, but discussion of this transition is deferred until later (section 3.2.4). The phase $\alpha \rightarrow \alpha'$ transition was accompanied by an increase of about 25% in $\rho c_p$.

Our first concern is with $\lambda(P)$ at pressures up to 1.1 GPa. It seems reasonable to conclude from section 3.1 that $\lambda(P)$ shown in Fig. 4 for the sample of composition $THF{\cdot}15.87H_2O$ closely represented the behaviour of phase $\alpha$. For reasons which will become apparent shortly, this composition was deliberatly selected so that we could be quite sure that the sample did not include any ice. A small proportion of THF-rich second phase was expected to be present in this sample, but we conclude that it would have a small effect on the total $\lambda$. The

[2] R. G. Ross and P. Andersson. Unpublished work.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

argument in support of this conclusion was given earlier in discussing $\lambda(T)$ for this sample; namely, that $\lambda$ for the THF-rich second phase which was present was close to that for phase $\alpha$. At 130 K, the THF-rich second phase was most likely to be pure solid THF, although there is no direct evidence for this from the known phase diagram (Fig. 1). For solid THF at 130 K and low pressures, $\lambda \approx 0.65$ W m$^{-1}$ K$^{-1}$ and $d\lambda/dP \approx 0.79$ W m$^{-1}$ K$^{-1}$ GPa$^{-1}$.[2]

The constitution of the sample of composition THF·17.05$H_2O$ was considered earlier (section 3.1.1), where we concluded that it almost certainly contained a small proportion of ice as a second phase. The main evidence from our experiments for such a mixture of phases in this sample was that calculations using the Maxwell formula yielded about the same composition dependence of $\lambda$ as was observed experimentally.

We shall now attempt to show that the presence of a small proportion of ice phase in this sample is consistent with the observed form of $\lambda(P)$. The main point to be emphasized is that $\lambda$(ice Ih)/$\lambda$(phase $\alpha$) $\approx$ 5. Thus, even a relatively small proportion of ice Ih can have a relatively large effect on the total $\lambda$, and its pressure dependence. Ice Ih is known (23) to have a negative value of $d\lambda/dP$. Figure 4 and Table 2 show that $d\lambda/dP$ for the sample of composition THF·17.05$H_2O$ was very small, and in fact slightly negative, at pressures up to about 0.8 GPa. This behaviour was probably caused by the ice Ih phase present. Furthermore, in the pressure range 0.8–1.1 GPa, $\lambda$ decreased relatively rapidly with pressure. Such a decrease could be due to a gradual transformation of the ice Ih second phase to one or more of the high pressure modifications, such as ice III or ice V. The latter are known (23) to have absolute values of $\lambda$ which are smaller than that of ice Ih by a factor about 2. However, there are no data available to provide direct evidence for transitions from ice Ih to other modifications on pressurization at 130 K.

*3.2.2 Phase* $\beta$

Figure 4 and Table 2 include data for $\lambda(P)$ at 130 K for a sample of composition THF·7.1$H_2O$, which we assumed consisted entirely of phase $\beta$. $d\lambda/dP$ was positive, and there was no evidence for any phase transition at pressures up to the maximum of 1.5 GPa. The phase diagram (Fig. 1) leads us to expect that phase $\beta$ was probably metastable with respect to other phases for $P \gtrsim 0.6$ GPa. When phase $\beta$ was warmed at a pressure of 1.5 GPa, we found the form of $\lambda(T)$ which is shown in Fig. 6 for the sample of composition THF·7.1$H_2O$. Up to a temperature of about 200 K, this form is similar to that found for phase $\beta$ at a pressure of 0.3 GPa (Fig. 2). At higher temperatures, $\lambda$ increased rapidly, probably due to a transition to an equilibrium configuration of phases. A consequence was internal damage to the cell, and termination of the run at this point.

*3.2.3 Phase* $\gamma$

A sample of composition THF·4.6$H_2O$ was assumed to consist entirely of phase $\gamma$. Low-temperature pressurization experiments were carried out for this sample at temperatures of 110 and 150 K. These temperatures were selected so as to be below and above the weak maximum in $\lambda(T)$ which we found for phase $\gamma$ at about 130 K (Fig. 3). The resultant isothermal measurements showed no significant difference between the two temperatures. These measurements, together with data deduced from Fig. 3, yield the results for phase $\gamma$ shown in Fig. 4 and Table 2.

*3.2.4 Phase* $\alpha'$

We now return to a consideration of the behaviour of phase $\alpha$ in the region of 1.1 GPa at 130 K. Figure 4 shows that $\lambda$ increased discontinuously by about 10%, and we also found that $\rho c_p$ increased discontinuously by about 25%. In addition, thermocouple response in the cell indicated evolution of heat, on increase of pressure. In our type of experiments, such observations are normally associated with a first-order phase transition. We shall therefore assume that at a pressure of about 1.1 GPa, phase $\alpha$ transformed to what we have referred to as phase $\alpha'$. It is recognized that phase $\alpha'$ may be single-phase but metastable, or perhaps consist of a mixture of phases, and we now examine some possibilities for the latter.

The phase diagram (Fig. 1) suggests that phase $\alpha$ was probably metastable with respect to other phases for $P \gtrsim 0.3$ GPa. Thus, under conditions of thermodynamic equilibrium and at, say, 0.9 GPa, phase $\alpha$ would be expected to dissociate to yield phase $\gamma$ + an ice phase. The latter would be expected to be ice VI, on the basis of the known phase diagram for ice (24). The same mixture of phases should be the stable equilibrium configuration for $P \gtrsim 1.1$ GPa, since we have found (Fig. 3) that phase $\gamma$ is stable up to at least 1.4 GPa. Let us suppose that phase $\alpha'$ is actually a mixture of phase $\gamma$ + ice VI. At 130 K and 1.4 GPa, $\lambda$(phase $\gamma$) $\approx$ 0.84 W m$^{-1}$ K$^{-1}$ from present work, and we estimate $\lambda$(ice VI) $\approx$ 3 W m$^{-1}$ K$^{-1}$ from previous work (23, 25). The value of $\lambda$ for phase $\gamma$ gives a lower limit for $\lambda$(mixture), whatever the volume fractions in the mixture we have supposed to exist. If we take the volume fraction of phase $\gamma$ to be 0.44, as suggested by the phase diagram, the Maxwell

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

formula (7) yields $\lambda$(phase $\gamma$ + ice VI) $\approx$ 1.9 W m$^{-1}$ K$^{-1}$. All predictions of $\lambda$(mixture) which involve phase $\gamma$ are substantially larger than the value 0.51 W m$^{-1}$ K$^{-1}$ found experimentally for phase $\alpha'$. We conclude, therefore, that phase $\alpha'$ is very unlikely to consist of a mixture of phase $\gamma$ and ice VI. A similar conclusion is reached if we assume phase $\alpha$ to undergo a less probable dissociation to give a mixture of phase $\beta$ + ice VI, in equal volume fractions. If we take $\lambda$(phase $\beta$) $\approx$ 0.42 W m$^{-1}$ K$^{-1}$, from present work, the Maxwell formula then yields $\lambda$(phase $\beta$ + ice VI) $\approx$ 1 W m$^{-1}$ K$^{-1}$. The final result is that no phase mixture suggested by the phase diagram yields an estimate for $\lambda$(mixture) which is close to the value found experimentally for phase $\alpha'$.

It seems to us most likely that phase $\alpha'$ was a single phase, formed by a first-order transition from phase $\alpha$ on pressurization, but probably metastable with respect to a mixture of phase $\gamma$ and ice VI. When phase $\alpha'$ was pressurized to 1.42 GPa, cooled to 110 K, and then warmed, we obtained the results which are included in Fig. 6 for the sample of composition THF·15.87$H_2O$. We found $d\lambda/dT$ for this sample to be positive, up to temperatures of about 200 K, so from the form of $\lambda(T)$ phase $\alpha'$ must be included in the same group as phases $\alpha$ and $\beta$. For $T > 200$ K, $\lambda$ increased rapidly, probably in the course of a transition to an equilibrium configuration of phases. A consequence was internal damage to the cell, and termination of the run at this point.

*3.3 Isothermal compression at 240 K*

Results for pressurization of various samples at a temperature of 240 K are shown in Fig. 5. In all cases, we expected that the system was close to thermodynamic equilibrium.

*3.3.1 Phase* $\alpha$

For the sample of composition THF·16.59$H_2O$, pressure was increased until there was evidence that a phase transformation had taken place, as indicated by the rapid increase of $\lambda$ shown in Fig. 5 at a pressure of about 0.3 GPa. According to the phase diagram (Fig. 1), the transformation to be expected is a compositional dissociation of phase $\alpha$ to yield phase $\beta$ + a high pressure ice, presumably ice III (24). With the assumption that this dissociation indeed occurred, we may estimate $\lambda$ for the resulting mixture, using the Maxwell formula. We assume the volume fraction of ice III to be 0.45, and take $\lambda$(phase $\beta$) $\approx$ 0.44 W m$^{-1}$ K$^{-1}$ (Fig. 2, sample THF·7.06$H_2O$) and $\lambda$(ice III) $\approx$ 1.0 W m$^{-1}$ K$^{-1}$ (25). The resulting prediction for the mixture is $\lambda$ = imentally.

*3.3.2 Phase* $\beta$

Results for the pressurization of phase $\beta$ at 240 K are also shown in Fig. 5. The rapid increase of $\lambda$ for pressures greater than about 0.6 GPa we associate with a compositional dissociation of phase $\beta$. According to the phase diagram (Fig. 1), we expect phase $\beta$ to dissociate at about this pressure to yield phase $\gamma$ + a high pressure ice modification. At a pressure of 0.8 GPa, the latter should almost certainly be ice VI (24). We shall again use the Maxwell formula, at this pressure, to calculate $\lambda$ for the assumed mixture. From Fig. 5, we take an interpolated value, $\lambda$(phase $\gamma$) $\approx$ 0.52 W m$^{-1}$ K$^{-1}$ (sample of composition THF·4.6$H_2O$), and $\lambda$(ice VI) $\approx$ 1.7 W m$^{-1}$ K$^{-1}$ (23). The phase diagram (Fig. 1) indicates that ice VI should be the dispersed phase, and, although the density of phase $\gamma$ is not known, we estimate the volume fraction of ice VI as about 0.21. The Maxwell formula then yields the value $\lambda$(mixture) $\approx$ 0.68 W m$^{-1}$ K$^{-1}$, compared with 0.69 W m$^{-1}$ K$^{-1}$ found experimentally.

## 4. Discussion

All of the solid phases we have investigated in the THF–$H_2O$ system have interesting and somewhat unusual thermal properties. We shall be concerned with discussing mainly the temperature and pressure (volume) dependences of $\lambda$.

$\lambda(T)$ for phases $\alpha$, $\alpha'$, or $\beta$ is similar to that for a glass (12) or for a glass-like solid (15). An obvious assumption is that this behaviour arises from structural disorder, at least for phase $\alpha$ which is known to be a structure II clathrate hydrate. Our experiments did not extend to sufficiently low temperatures to determine whether or not a plateau in $\lambda$ exists for a clathrate hydrate.

The only data for $\lambda$ for clathrate hydrates are due to Stoll and Bryan (26). These workers measured the magnitude of $\lambda$ for a propane hydrate (structure II) and a methane hydrate (structure I). In both cases, they found $\lambda \approx 0.4$ W m$^{-1}$ K$^{-1}$ at a temperature of 275 K. The pressure was of order 1 MPa for the propane hydrate and 10 MPa for the methane hydrate. The temperature dependence of $\lambda$ was not determined.

The results available from our work and that of Stoll and Bryan (26) lead to the preliminary conclusion that $\lambda$ for a clathrate hydrate always has a value of about 1/2 W m$^{-1}$ K$^{-1}$ near 300 K and at low pressures. If such uniformity in the magnitude of $\lambda$ indeed exists generally for clathrate hydrates, then it may correspond to a similar uniformity which is known to pertain for glasses (12) and other glass-like solids (15).

Both the magnitude of $\lambda$, and its temperature dependence, suggest that phase $\beta$ should be regarded as a clathrate hydrate. If so, it is probably structure I, on the basis of composition, although

no structural data are available. In fact, phase β is only stable under pressure (Fig. 1). As suggested by Dyadin *et al.* (4), structure II may become less stable than structure I under pressure, even for a guest molecule having a diameter as large as that of THF (0.59 nm). The largest diameter of guest molecule previously known to form a structure I clathrate hydrate was about 0.55 nm (2), but this was at low pressure.

We shall now discuss each phase in more detail.

*4.1 Phase α*

We have tried a number of mathematical forms to fit our data for $\lambda(T)$ of phase α. The results are shown in Figs. 7 and 8. We keep in mind that this structure II clathrate hydrate can probably be appropriately regarded as a glass-like solid (15).

We first made use of eq. [1]. If we take the mean free path $l$ and the velocity $v$ to be independent of $T$, then all of the temperature dependence of λ must come from $C$. As described in section 1.2, it is reasonable to take only the acoustic modes into account, so we use a model for $C$ since our measured $C$ values probably included additional contributions from optic and intramolecular modes. Figure 7 shows that a relatively poor fit is obtained using an Einstein model for $C$, with Einstein temperature $\theta_E = 190$ K. The root-mean-square deviation, $F$, was $6.3 \times 10^{-3}$ W m$^{-1}$ K$^{-1}$. Indistinguishable results were obtained using the high-temperature approximation for a Debye model, with $\theta_D = 248$ K. Evidently, the temperature dependence of λ is not well approximated by the temperature dependence of $C$.

If we assume $\lambda \sim T^n$, then Fig. 7 shows that a better fit is obtained ($F = 3.2 \times 10^{-3}$ W m$^{-1}$ K$^{-1}$). We get $n = 0.22$, but have no independent means of estimating this exponent. An exponent of about 0.6 may be deduced for the glass-like solid $KFeF_3$ (17). If we use eq. [1] and write $(vl) \sim T^m$, then Fig. 7 shows that we can obtain a good fit to the data ($F = 2.5 \times 10^{-3}$ W m$^{-1}$ K$^{-1}$), which is not surprising since there are three parameters. We used an Einstein model for $C(T)$. The parameters had values $\theta_E = 91$ K and $m = 0.17$. According to this fitting procedure, the product $vl$, and presumably $l$, decreased with decreasing $T$. This is contrary to the likely variation if some form of phonon–phonon interaction determined the thermal resistivity. Moreover, the corresponding change of $l$ of about 18% from 100 to 260 K evidently cannot be accounted for by linear thermal expansion, which is only (3) ~1% over this range of temperature.

An interesting and somewhat surprising result is shown in Fig. 8. Empirically, we find that the form $\lambda \sim \exp(-T_0/T)$ provides a good fit to the data ($F = 3.3 \times 10^{-3}$ W m$^{-1}$ K$^{-1}$). The characteristic temperature, $T_0$, required to fit the data turns out to be about 37 K, and we now examine the significance of this value.

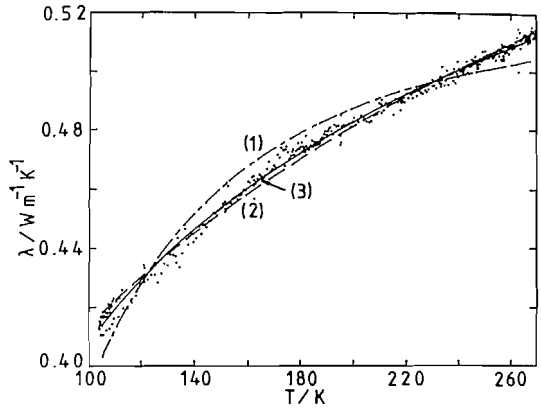

FIG. 7. Isobaric data for thermal conductivity λ of sample of composition THF·16.59$H_2O$ at 0.10 GPa fitted to equations of form: (*1*) $C(T)$, (*2*) $T^n$, (*3*) $C(T)\,(vl)^m$.

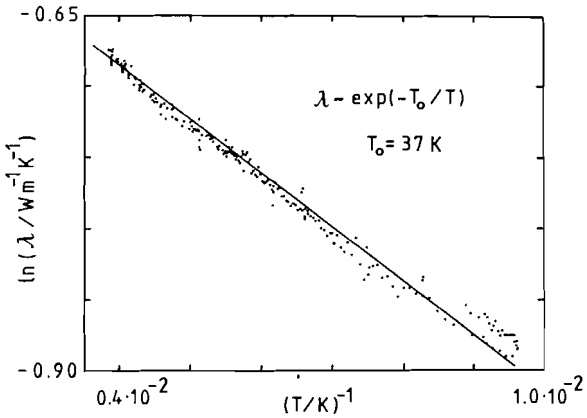

FIG. 8. Isobaric data for thermal conductivity λ of sample of composition THF·16.59$H_2O$ at 0.10 GPa fitted to equation of form ln (λ/W $m^{-1}$ K$^{-1}$) ~ $(-T_0/T)$.

In recent far-infrared spectroscopic measurements on phase α at low temperatures, Bertie and Jacobs (3) found that a principal absorption assigned to rotational vibrations of the THF molecules occurred at a wave number of about 25 cm$^{-1}$. The corresponding energy, expressed in terms of temperature, is $T_{RV} = 36$ K. Whilst the agreement between this temperature and $T_0$ may be fortuitous, it strongly suggests to us that rotational vibrations of the guest molecules have a predominant influence on the conduction of heat. Since the localized guest molecules obey Maxwell–Boltzmann statistics (27) the degree of excitation of rotational vibrations will be $\propto \exp(-T_{RV}/T)$, which is similar to $\lambda(T)$. Thus, it appears that heat

transport in this clathrate hydrate occurs by lattice vibrations which couple, perhaps inelastically (13, 14), with the rotational vibrations of the THF guest molecules, and that $\lambda$ is proportional to the degree of excitation of these vibrations. We infer that rotational vibrations of THF guest molecules are probably a specific example of low-energy excitations of the general type expected (15) to affect the thermal properties of glass-like solids.
