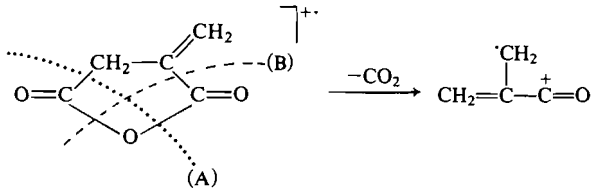
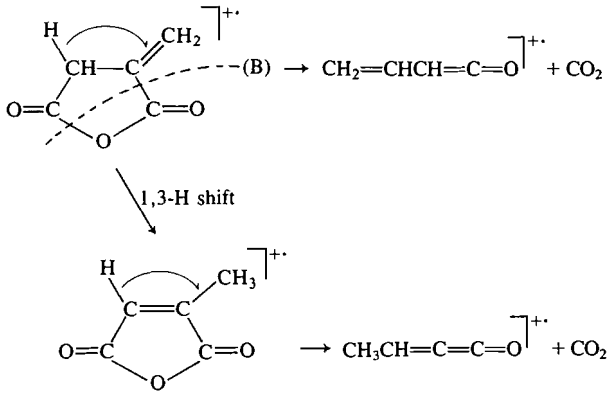
This proposal cannot be demonstrated by labelling experiments, but the CA mass spectrum of the *ion-source* generated $[C_4H_4O]^{+\cdot}$ ions from this reaction can most satisfactorily be reproduced from a 2:3 mixture of the CA mass spectra of [vinylketene]$^{+\cdot}$ and the branched ketene. $[C_4H_4O]^{+\cdot}$ ions of lower internal energy, derived from molecular ions fragmenting in the first field-free region, display CA mass spectra for which a respective 3:2 summation suffices, indicating a higher proportion of the thermodynamically more stable species.

*[Buta-1,2-dienone]*$^{+\cdot}$

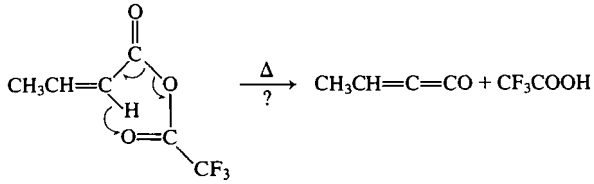
Identification of this ion proved difficult because of the lack of precursor molecules which might predictably yield it upon dissociative ionisation. The neutral ketene has not been described, but its homologue, propadienone, $CH_2{=}C{=}C{=}O$, resulted from the gas phase pyrolysis of the mixed anhydride of acrylic and trifluoroacetic acids.[4] By analogy, the anhydride of crotonic and trifluoroacetic acid might be expected to yield the desired ketene. However, the IE of the $C_4H_4O$ species derived from the pyrolysis of $CH_3CH{=}CH{-}CO{-}O{-}COCF_3$ was only 8.07 eV, i.e. *lower* than the IE of vinylketene (8.31 eV (9)) and thus excluding *its* generation. Consequently this pyrolysis may well yield the expected product whose IE should be lower than that of vinylketene. So far, however, the characterisation of the ionised $C_4H_4O$ pyrolysis product by its CA mass spectrum could not be performed because of the lack of a pyrolytic inlet system for the instrument (ZAB-2F) with which CA mass spectra were measured. However, three precursor molecules were examined which have major *m/z* 68 $[C_4H_4O]^{+\cdot}$ ions in their mass spectra whose structure may indeed be that of ionised buta-1-2-dienone. Loss of $CH_2O$ from $[CH_2{=}C{=}CHCOOCH_3]^{+\cdot}$ and loss of $CO_2$ from itaconic and citraconic anhydrides produce $[C_4H_4O]^{+\cdot}$ ions with identical CA mass spectra (see Table 1) which we propose is that of $[CH_3CH{=}C{=}C{=}O]^{+\cdot}$. The assignment is based on the following arguments. Consider the two *direct* $CO_2$ eliminations from ionised itaconic anhydride.



Only mode A leads *directly* to a stable product ion as shown above. However, this $[C_4H_4O]^{+\cdot}$ ion is *not* generated because its CA mass spectrum (and its charge-stripping [CS] mass spectrum, see below) is markedly different from that of the observed product ion. Note for example, the absence of *m/z* 54 (loss of $:CH_2$) and the relative prominence of *m/z* 53 (loss of $CH_3{\cdot}$). Mode B would yield, at least initially, a highly unstable linear ion and would not be expected to compete with mode A; it could also generate $[O{=}CH{-}CH{=}C{=}CH_2]^{+\cdot}$ but the observed CA mass spectrum rules this out. However, the following two simple *rearrangements* in ionised itaconic and citraconic anhydrides would yield product ions having $\Delta H_f$ lower than that of the branched ketene:



Route B, the formation of [vinylketene]$^{+\cdot}$, can be rejected (CA and CS mass spectra). The second reaction proceeds via ionised citraconic anhydride and thereby accounts for the observed daughter ions from the two anhydrides having the same characteristics; the 1,2-H shift shown in the second step leads to [buta-1,2-dienone]$^{+\cdot}$. Note that *without* rearrangement, loss of $CO_2$ from citraconic anhydride would generate [methylcyclopropenone]$^{+\cdot}$,

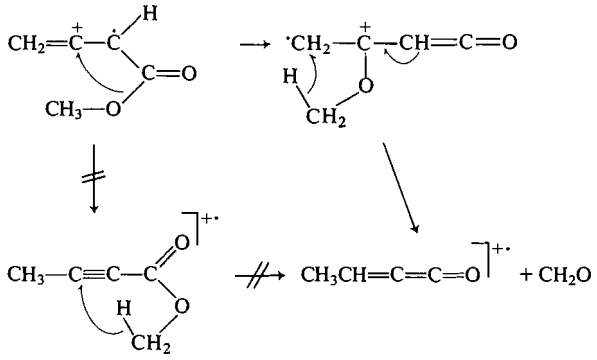


[4]This was obtained by measurement of the AE for the metastable peak *m/z* 112 → *m/z* 68 by a comparative method (34).

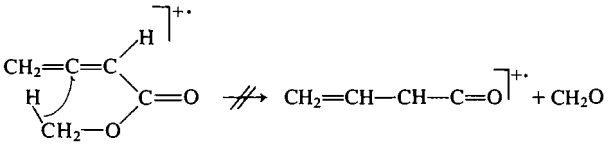
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

a reference ion whose CA mass spectrum is closely similar to that of the observed daughter ion. The latter, however, *cannot* have the cyclic structure because the $\Delta H_f[C_4H_4O]^{+\cdot}$ values derived from AE measurements (AE *m/z* 68 from citraconic anhydride = 10.68 eV. $\Delta H_f$(neutral) = −106.8 kcal mol$^{-1}$ (12), $\Delta H_f(CO_2)$ = −94.1 kcal mol$^{-1}$ (14). $T_{min}$ from metastable peak *m/z* 112 → *m/z* 68 = 0.3 eV, whence $\Delta H_f[C_4H_4O]^{+\cdot} \leq 226$ kcal mol$^{-1}$. AE *m/z* 68 from itaconic anhydride = 10.95 ± 0.15 eV,[3] $\Delta H_f$(neutral) = −104 kcal mol$^{-1}$ (8), $T_{min}$ = 0.36 eV, whence $\Delta H_f[C_4H_4O]^{+\cdot} \leq 234$ kcal mol$^{-1}$) are all significantly below that of ionised [methylcyclopropenone] ($\Delta H_f$ = 240 kcal mol$^{-1}$ (4)). This conclusion is reinforced by the observation that CS mass spectra of the $[C_4H_4O]^{+\cdot}$ ions generated from the ester and the anhydrides are dissimilar — see Table 2. It should be noted that CS mass spectra have successfully been used to differentiate between cyclic and acyclic isomers which are indistinguishable by means of their CA mass spectra (3, 16). That [methylcyclopropenone]$^{+\cdot}$ and the proposed product ion $[CH_3—CH=C=C=O]^{+\cdot}$ have some closely related characteristics is also exemplified by observations on their loss of CO, where the $[C_3H_4]^{+\cdot}$ product ions in both cases consist largely of [propyne]$^{+\cdot}$, rather than the more stable [allene]$^{+\cdot}$ ion. A recent CA study (15) showed how these isomeric $[C_3H_4]^{+\cdot}$ ions may be distinguished from both their CA and CS mass spectra; additional work by ourselves (17) leads us to conclude that the presence of a methyl group within an unsaturated $C_3$ system is a prerequisite for [propyne]$^{+\cdot}$ generation.

Another route to $[CH_3CH=C=C=O]^{+\cdot}$ involves the loss of $CH_2O$ from the ionised methyl ester of allene carboxylic acid (base peak in the normal mass spectrum), for which we propose the following mechanism:



The 1,3-methoxy shift is analogous to the 1,3-hydroxy migration in $[CH_2=C=CHCH_2OH]^{+\cdot}$ (6) and yields [buta-1,2-dienone]$^{+\cdot}$ as shown above. The alternative route via an allene–yne rearrangement (see also below) cannot be involved, because directly ionised $CH_3C{\equiv}CCOOCH_3$ does not lose $CH_2O$. Note that a simple reaction mechanism yielding [vinylketene]$^{+\cdot}$ could be envisaged:



but is unable to compete with the methoxy shift.

The remaining ions will be grouped as keto–enol tautomeric pairs.

*Ionised methylethynylketone and its enol [HC≡C—C(OH)=CH$_2$]*

The $\Delta H_f$[ketone]$^{+\cdot}$ was obtained from its IE = 10.25 eV, $\Delta H_f[CH_3COC{\equiv}CH]$ = +7.4 kcal mol$^{-1}$,[5] leading to $\Delta H_f[CH_3COC{\equiv}CH]^{+\cdot}$ = 244 kcal mol$^{-1}$. The CA mass spectrum is dominated by ions resulting from simple bond cleavages, *m/z* 53 $[HC{\equiv}C—\overset{+}{C}O]$ and *m/z* 43 $[CH_3\overset{+}{C}O]$.[6]

For the enol, $\Delta H_f[HC{\equiv}C—C(OH)=CH_2]^{+\cdot}$ = 217 kcal mol$^{-1}$ was obtained from the AE *m/z* 68 from $HC{\equiv}C—COCH_2CH_2CH_3$, the method normally used to obtain $\Delta H_f$ values for enol ions (5) (AE *m/z* 68 = 10.08 eV, $\Delta H_f[HC{\equiv}CCOCH_2CH_2CH_3]$ = −2.6 kcal mol$^{-1}$,[4] $\Delta H_f[C_2H_4]$ = +12.4 kcal mol$^{-1}$ (12)). That there is little, if any, communication between the tautomeric ions follows from a comparison of the CA mass spectrum of the keto ion with that of the enol ion (Table 1). The latter was also generated via a 2π + 2π cycloreversion reaction from ionised 1-ethynyl cyclobutanol (loss $C_2H_4$) and similarly from 1-ethynylcyclopentanol (loss $C_3H_6$).

*Aldehyde ions and their enols*

Scheme 1 shows these ions and their proposed interrelationships. $\Delta H_f$ values and CA mass spectra are shown in Table 1. From their CA mass spectra it can be seen that allene aldehyde (**1**) does not communicate with its isomer (**2**); this is in keeping with the behaviour of the analogous allenic and acetylenic esters discussed above. The CA mass spectrum of (**2**) is dominated by H atom loss, a simple cleavage having an energy requirement

[5]Values for $C_t$—(CO), CO—($C_l$)(C), and CO—($C_l$)(H) of +25.6, −35, and −33 kcal mol$^{-1}$ were used in these $\Delta H_f$ estimations.

[6]AE *m/z* 53 = 11.14 eV, which with $\Delta H_f[CH_3^{\cdot}]$ = 34 kcal mol$^{-1}$ (14) leads to $\Delta H_f[C_3HO^+]$ = 230 kcal mol$^{-1}$.

TABLE 2. Charge stripping spectra of some $[C_4H_4O]^{+\cdot}$ ions

| m/z | $68^{2+}$ | $67^{2+}$ | $66^{2+}$ | $65^{2+}$ | $40^{2+}$ | $39^{2+}$ | $38^{2+}$ |
|---|---|---|---|---|---|---|---|

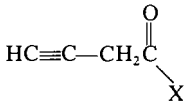
For personal use only.

($\Delta H_f[CH_3C{\equiv}C{-}\overset{+}{C}{=}O] + \Delta H_f[H]^{\cdot} = 254$ kcal mol$^{-1}$)[7] similar to that for the rearrangement leading to $[CH_3{-}C{\equiv}CH]^{+\cdot} + CO$ ($\Delta H_f[C_3H_4]^{+\cdot} + \Delta H_f[CO] = 257$ kcal mol$^{-1}$ (14)). The latter daughter ion in the normal mass spectrum of **2** was shown to have the structure $[CH_3{-}C{\equiv}CH]^{+\cdot}$ from its CA and CS mass spectra (15) (see also above).

Allene aldehyde, **1**, shows little $H^{\cdot}$ loss in its CA mass spectrum, in which *m/z* 40 is the second most abundant ion. It is noteworthy that for **1**, *m/z* 40 in its normal mass spectrum has the $[allene]^{+\cdot}$ structure.

Aldehyde **3** could not be studied directly; all attempts at synthesis failed. However, several related compounds of general formula



X = $CH_3$, $C_2H_5$, OH, and $OCH_3$, displayed mass spectral characteristics which indicated that a facile rearrangement to their allenic analogue preceded fragmentation; such behaviour has also been observed in the

$$HC{\equiv}C{-}CH_2{-}OCH_3^{+\cdot} \rightleftharpoons H_2C{=}C{=}CHOCH_3^{+\cdot}$$

system (18). The $\Delta H_f$ for ion **3** can be estimated by assuming that the IE will be typically aldehydic, similar to that of butanal = 9.85 eV (14), $\Delta H_f[HC{\equiv}CCH_2CHO] = 20.1$ kcal mol$^{-1}$ (8), whence $\Delta H_f[HC{\equiv}CCH_2CHO]^{+\cdot} \simeq 247$ kcal mol$^{-1}$. We propose that the CA mass spectrum of **3** will be closely similar to that of **1**.

The CA mass spectrum of the ionised cyclic aldehyde, **4**, is clearly very different from that of all other isomers and is characteristic of its structure (Table 1). Unfortunately a reliable value for its IE could not be measured; the compound polymerised very readily and it could only be introduced into a mass spectrometer in small quantities from dilute solution in $CH_2Cl_2$.

Two of the aldehydes, **3** and **1**, have enol tautomers, **5** and **6** respectively. The two ethyl ethers $HC{\equiv}C{-}CH{=}CH{-}O{-}CH_2CH_3$ and $CH_2{=}C{=}C{=}CH{-}OCH_2CH_3$ have intense *m/z* 68, $[C_4H_4O]^{+\cdot}$ peaks in their normal mass spectra. By analogy with the behaviour of $[CH_2{=}CH{-}O{-}CH_2CH_3]^{+\cdot}$, which generates $[CH_2{=}CHOH]^{+\cdot} + C_2H_4$ via a β-hydrogen shift, it may be argued that the above ethers will generate the desired enols upon loss of $C_2H_4$ by dissociative ionisation. $\Delta H_f[C_4H_4O]^{+\cdot}$ from $HC{\equiv}C{-}CH{=}CH{-}OCH_2CH_3 = 220$ kcal mol$^{-1}$ (from AE = 9.22 eV; $\Delta H_f[HC{\equiv}CCH{=}CH{-}OCH_2CH_3] = 20.1$ kcal mol$^{-1}$ (8), $\Delta H_f[C_2H_4] = 12.5$ kcal mol$^{-1}$ (14)). Note that the narrow metastable peak for this process is of simple Gaussian-type with $T_{0.5} = 0.024$ eV, indicating that the reverse reaction is unlikely to have any appreciable energy requirement and thus the derived $\Delta H_f$ will not be significantly greater than the thermochemical $\Delta H_f$. The CA mass spectra of this ion generated both metastably and in the ion source are the same and remarkably close to that of **1**; furthermore, the same composite metastable peaks, shown in Fig. 1, are observed for CO loss from **1** and the $[C_4H_4O]^{+\cdot}$ ions derived from $[HC{\equiv}C{-}CH{=}CH{-}OCH_2CH_3]$. We conclude that the latter $[C_4H_4O]^{+\cdot}$ ions have the enol-structure **5** and that **1** must be able rapidly to rearrange to **5** at or very close to the [allene–aldehyde] IE. This rearrangement could readily take place via a 1,5-H shift rather than via enolisation of **3**.

**6**, the enol of **1**, generated as described above, has $\Delta H_f = 222$ kcal mol$^{-1}$ (AE *m/z* 68 from $CH_2{=}C{=}C{=}CHOCH_2CH_3 = 8.74$ eV; $\Delta H_f$[neutral] = 33.4 kcal mol$^{-1}$ (8), $\Delta H_f[C_2H_4] = 12.4$ kcal mol$^{-1}$ (14)). The metastable peak for the fragmentation *m/z* 96 → *m/z* 68 was of simple Gaussian type, $T_{0.5} = 0.045$ eV, and so no significant correction for excess energy is likely to be necessary. Its CA mass spectrum is significantly different from those of **1** and **5**, as is the metastable peak shape for CO loss (see Fig. 1). We conclude therefore that this ion exists as a stable species in the gas phase. The molecule $HC{\equiv}C{-}CH(C_3H_7)CHO$ does not generate **5** by dissociative ionisation (loss of $C_3H_6$ via a McLafferty rearrangement) but produces a $[C_4H_4O]^{+\cdot}$ ion whose CA mass spectrum is identi-

[7]AE *m/z* 67 from $CH_3C{\equiv}CCOOCH_3 = 10.70$ eV; $\Delta H_f[CH_3C{\equiv}CCOOCH_3] = -43.3$ kcal mol$^{-1}$ (8[4]), $\Delta H_f[CH_3O] = 1.4$ kcal mol$^{-1}$, $\Delta H_f[H^{\cdot}] = 52.1$ kcal mol$^{-1}$ (14).

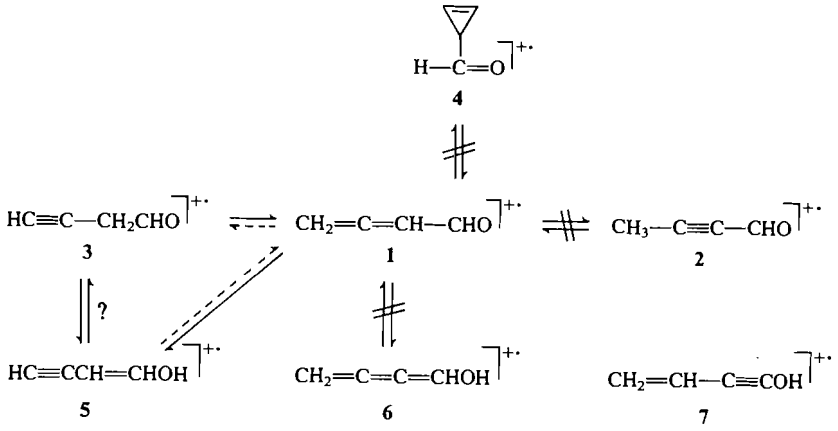

SCHEME 1

cal with that of **6**. It is concluded that the molecular ion undergoes an -yne to allene isomerisation before dissociation.

Generation of the last ion shown in Scheme 1, $[CH_2{=}CH{-}C{\equiv}C{-}OH]^{+\cdot}$, **7**, was achieved by the dissociative ionisation of $CH_2{=}CH{-}C{\equiv}C{-}OCH_2CH_3$, by analogy with the behaviour of the two ethers described above. Although the metastably fragmenting ions from this ether clearly produced ionised [vinylketene]$^{+\cdot}$ (as described above), the CA mass spectrum of the ion-source generated ions was completely different from all others shown in Table 1, and we propose that at the higher energies, the desired species is produced.

We have attempted in this study to develop criteria for the identification of fifteen isomeric $[C_4H_4O]^{+\cdot}$ ions, using many of the currently available techniques for investigating ion structures in the gas phase. Although the CA mass spectra shown in Table 1 may be readily explained in terms of the given ion structures, identification of the latter relied heavily on the establishing of ionic heats of formation to assist in their proper designation. The CA mass spectra *alone* would have been very difficult to interpret. Only two pairs of isomers showed closely similar CA mass spectra, namely, $[CH_3{-}CH{=}C{=}C{=}O]^{+\cdot}$ and [methylcyclopropenone]$^{+\cdot}$, $[H_2C{=}C{=}CH{-}CHO]^{+\cdot}$ and $[HC{\equiv}C{-}CH{=}CH(OH)]^{+\cdot}$. The similarity of the former pair may well result from there being only a small (or no) energy requirement for opening the strained cyclopropene ring; a concomitant H-shift would readily produce $[CH_3{-}CH{=}C{=}C{=}O]^{+\cdot}$, via an exothermic reaction. The second pair of isomers could be envisaged as interconverting via a single 1,5-H shift, the acetylenic enol being thermochemically the more stable species.

The differences in $\Delta H_f$ for the keto–enol pairs deserve comment. For example, $\Delta(\Delta H_f)$ for the ions $[HC{\equiv}C{-}CH_2CHO]^{+\cdot}$ and $[HC{\equiv}C{-}CH{=}$

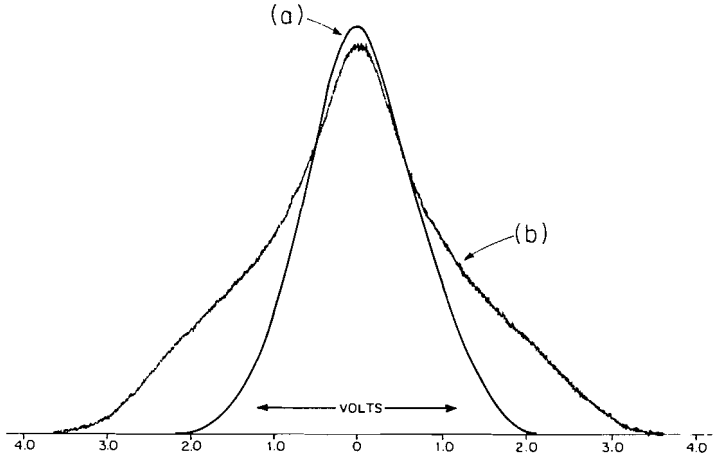

FIG. 1. Metastable peaks for loss of CO from (*a*) $[CH_2{=}C{=}C{=}CHOH]^{+\cdot}$ and (*b*) $[HC{\equiv}C{-}CH{=}CHOH]^{+\cdot}$ and/or $[CH_2{=}C{=}CHCHO]^{+\cdot}$.

$CHOH]^{+\cdot}$, 25 kcal mol$^{-1}$, is very similar to that for the analogous pair $[CH_2{=}CH{-}CH_2CHO]^{+\cdot}$ ($\Delta H_f$[ion]$^{+\cdot} \simeq 202$ kcal mol$^{-1}$ from IE $\sim$ 9.6 eV, $\Delta H_f$(neutral) = $-19.7$ kcal mol$^{-1}$, by additivity (8)) and $[CH_2{=}CH{-}CH{=}CHOH]^{+\cdot}$, $\Delta H_f$ = 176 kcal mol$^{-1}$ (6). For the ketone $[CH_3COC{\equiv}CH]^{+\cdot}$ and its enol a stabilisation of similar magnitude was observed. The relatively small stabilisation found between $[CH_2{=}C{=}CH{-}CHO]^{+\cdot}$ and $[CH_2{=}C{=}C{=}CHOH]^{+\cdot}$ is in keeping with the loss of conjugative stabilisation in going from the en–al to the cumulene–ol. This situation is analogous to that of ionised acrolein, $[CH_3{=}CHCHO]^{+\cdot}$, and its enol $[CH_2{=}C{=}CHOH]^{+\cdot}$; $\Delta H_f[CH_2{=}CHCHO]^{+\cdot}$ = 215 kcal mol$^{-1}$; from IE = 10.11 eV (19), $\Delta H_f[CH_2{=}CHCHO]$ = $-17.7$ kcal mol$^{-1}$ (8). For the enol $\Delta H_f[CH_2{=}C{=}CHOH] = 4 \pm 1$ kcal mol$^{-1}$ (by additivity (8)) and an IE of $9.1 \pm 0.1$ eV (assumed to be similar to that of vinyl alcohol, 9.1 eV (20)) whence $\Delta H_f[CH_2{=}C{=}CHOH]^{+\cdot} = 214 \pm 3$ kcal mol$^{-1}$. For this pair, the enol ion may have a higher $\Delta H_f$ than its keto tautomer, the first example of reversed thermodynamic stability between such ionised tautomers. The situation arises from the large difference between the $\Delta H_f$ values for the neutral compounds.

## Experimental

*Synthesis of compounds*

The purity and, where necessary, the structure of the compounds synthesized was checked by nmr spectroscopy.

*Vinyloxyethyne* ($CH_2{=}CHOC{\equiv}CH$) was prepared by the method of Brandsma and Arens (21).

*5,6-Dihydro-2-pyrone* ($\overline{CH_2{-}CH_2{-}CH{=}CH{-}COO}$) was prepared from 3-butenoic acid and paraformaldehyde as described in ref. 22.

*Trifluoroacetic*-trans-*crotonic anhydride* ($CF_3{-}COO{-}CO{-}CH{=}CH{-}CH_3$) was prepared from *trans*-crotonic acid chloride and the sodium salt of trifluoroacetic acid by the general procedure of ref. 23.

The *methylester of butadienecarboxylic acid* ($CH_2{=}C{=}CHCOOCH_3$) was synthesized from the acid and diazomethane (24). The acid was prepared from allene, *n*-butyllithium, and $CO_2$ (25).

*Methylcyclopropenone* ($\overline{CO{-}C(CH_3){=}CH}$) was synthesized by the method of Breslow and Altman (26).

*Hex-1-yn-3-one* ($CH_3CH_2CH_2COC{\equiv}CH$) was prepared by oxidation of hex-1-yn-3-ol (27).

*1-Ethynylcyclobutanol* ($\overline{CH_2{-}CO(C{\equiv}CH)CH_2{-}CH_2}$) was prepared by the reaction of ethynylmagnesium bromide with cyclobutanone (25).

*1-Ethynylcyclopentanol* ($\overline{CH_2{-}CO(C{\equiv}CH)CH_2CH_2CH_2}$) was synthesized similarly using cyclopentanone.

*1-Ethoxybut-1-en-3-yne* ($HC{\equiv}C{-}CH{=}CHOC_2H_5$) was prepared from 1,4-diethoxybut-2-yne with sodium amide in liquid ammonia (27).

*Buta-2,3-dienal* ($CH_2{=}C{=}CHCHO$) was prepared by adding 1-ethoxybut-1-en-3-yne to excess 2 *N* ortho-phosphoric acid at $-10$°C. The reaction is complete in about 5 min, after which the crude aldehyde (containing water, ethanol, and traces of starting material) was collected in a $CO_2$/acetone trap at reduced pressure (15 mm Hg). The purified aldehyde (repetitive trap-to-trap distillations) has physical properties identical with the sample prepared in ref. 28 by a more laborious procedure.

*1-Ethoxybut-3-en-1-yne* ($CH_2{=}CH{-}C{\equiv}C{-}O{-}C_2H_5$) was prepared by elimination of *p*-toluene sulfuric acid from 1-ethoxybut-1-yn-4-tosylate (25, 29).

*Cycloprop-3-ene carboxaldehyde* ($\overline{HC{=}CHCHCHO}$) was prepared by irridation of pyridazine-*N*-oxide (30). The sample was purified by gas chromatography using a 10% OV-17 column at room temperature.

*Ethoxybutatriene* ($CH_2{=}C{=}C{=}CHOC_2H_5$) was synthesized from 1,4-diethoxybut-2-yne and ethyllithium in ether followed by hydrolysis (25).

*(2-n-Propyl)-butadienal* ($CH_2{=}C{=}C(CHO)C_3H_7$) was obtained by treatment of dilithiated hex-1-yne (31) with dimethyl formamide at $-50$°C. After 30 min the reaction mixture was hydrolysed with 1 equiv. of 1 *N* HCl and extracted with ether. Evaporation of the solvent yielded the desired product b.p. 55°/10 mm in a 50% yield.

(2-*n*-Propyl)-but-3-yne-1-al ($HC{\equiv}C{-}CH(CHO)C_3H_7$) was obtained by the same reaction using excess of 2 *N* HCl.

The propargylic aldehyde easily isomerises into the allenic form (see above) with traces of base formed during hydrolysis. This isomerisation is prevented by slowly pouring the reaction mixture into vigorously stirred excess of acid. However, this procedure yields a large amount of polymer from which the desired aldehyde was isolated in low yield (10%).

All other compound were commercially available and checked by gcms and nmr analysis.

Ionisation and appearance energies were measured using energy selected electrons (32). Metastable peaks (33) and collisional activation mass spectra (18) were measured by conventional means.

CA spectra of metastably generated ions were obtained using a ZAB-2F mass spectrometer; metastable peaks arising from dissociations in the first field-free region were selected by their apparent mass and the transmitted species were then subjected to collisional excitation in the second field-free region.

# $^{125}$Te Fourier transform nuclear magnetic resonance studies of tellurium compounds

RAJ K. CHADHA AND JACK M. MILLER[1]

*Chemistry Department, Brock University, St. Catharines, Ont., Canada L2S 3A1*

Received February 24, 1982

RAJ K. CHADHA and JACK M. MILLER. Can. J. Chem. **60**, 2256 (1982).

$^{125}$Te nmr spectra of a number of organotellurium compounds and inorganic tellurium salts are reported. The tellurium shielding has been found to be dependent upon the nature and number of electronegative substituents bonded to tellurium and where applicable, upon the *para* substituents on the phenyl ring. Possible reasons for the observed broad line widths are discussed.

RAJ K. CHADHA et JACK M. MILLER. Can. J. Chem. **60**, 2256 (1982).

On rapporte les spectres de RMN du $^{125}$Te de plusieurs composés organotelluriques et de plusieurs sels inorganiques du tellure. On a trouvé que le blindage du tellure dépend de la nature et du nombre de substituants électronégatifs liés au tellure et des substituants en position *para* du cycle phényle, quand le cas se présente. On discute des raisons éventuelles qui expliquent la largeur des lignes observées.

## Introduction

Studies in the field of $^{77}$Se nmr of inorganic and organic selenium compounds are rapidly increasing (1–8). In contrast, $^{125}$Te nmr investigations have received little attention (9–14), though the nuclear properties of $^{125}$Te are more favourable for nmr studies than those of $^{77}$Se. For example, $^{125}$Te is approximately 4.5 times more sensitive than $^{77}$Se and spin–lattice relaxation times for the $^{125}$Te are 4 to 6 times shorter than those for the $^{77}$Se (15). $^{125}$Te nmr spectroscopy has recently been utilised to study the exchange reactions (16) and the characterisation of metal complexes (17) in solution. These studies demonstrate the usefulness of this technique for the understanding of grossly complex and relatively unknown solution nature of the tellurium compounds (13, 14, 18). Examination of literature shows that $^{125}$Te chemical shift values of only limited categories of organotellurium compounds with different environments of tellurium have been reported (14, 19, 20), and more results are required before there is a thorough understanding of the trends in the chemical shifts. We, therefore, present the $^{125}$Te chemical shift data of some unsymmetric diaryltellurium dichlorides, aryltellurium trihalides, and some ionic tellurium salts, the categories which have received relatively less attention.

## Results and discussion

$^{125}$Te chemical shifts, using neat $Me_2Te$ as an external reference, are recorded in Table 1. Data already available in the literature have established the chemical shift range to be ~5000 ppm (13, 14, 21). The compounds studied here cover a range of 1530 ppm. Inspection of Table 1 reveals that $^{125}$Te chemical shifts are sensitive to the oxidation state of tellurium, amount of the ionic character in the Te—X bond, and the *para* substituent present in the phenyl ring. Similar trends were shown by selenium compounds (6), though the tellurium shifts are much more sensitive to the nature of substituents than are the selenium shifts. This observation is similar to the one made earlier (20). It is suggested that for heavy atom nuclei including selenium, the paramagnetic contribution ($\sigma_p$) to the shielding is dominant. The expression used for the paramagnetic term also involves the mean inverse cubes of the valence *p*- and *d*-electron–nuclear distances. Since this distance increases on going from selenium to tellurium, it may account for larger chemical shift values for tellurium than for selenium, and consequently, the tellurium shifts appear to be more sensitive than the selenium shifts to the nature of the substituents. However, the chemical shift values change significantly with *para* substituents on the aromatic ring, separated from tellurium by five interatomic bonds and about 6.2 Å (22) in space. This suggests that neighbouring atom electronic effects contribute significantly to the paramagnetic shielding. The chemical shifts show slight dependence upon solvent and concentration. Therefore, the solute–solvent interaction also has a slight contribution to the $\sigma_p$. This is consistent with earlier observation (21).

The downfield shift of *p*-$BrC_6H_4(Ph)Te$ and highfield shift of *p*-$MeOC_6H_4(Ph)Te$ as compared to $Ph_2Te$ (19) suggest that the tellurium nucleus is strongly deshielded (or shielded) by electron-withdrawing (or releasing) substituents on the phenyl

ring. Similar observation was made in case of tellurol esters (23). No clear trend is observed in diaryltellurium dichlorides, or in diaryl ditellurides (21), while an opposite order is found in aryltellurium trichlorides. Figure 1 shows that there is an approximately linear relationship between $^{125}$Te chemical shifts of aryltellurium trichlorides and Swain and Lupton parameter, $\sigma_p^+$, of the *para* aromatic substituents (24) except for the *p*-phenoxy derivative for which resonance effect may be important. Downfield chemical shifts for electron-releasing substituents are observed. It is not clear why the two series should have completely opposite orders. Organotellurium trichlorides are known to be capable of forming stable solvates (25) in strongly donating solvents, such as $CH_3CN$ and DMSO, and subsequent change in solute–solvent interaction might have affected the observed difference. These compounds are not sufficiently soluble in other organic solvents. Therefore, nmr studies of unsolvated or weakly solvated species are not easily possible.

The line widths vary from 10 to several hundred Hz for the compounds studied here. Large line widths for organotellurium trihalides may be due to the association in solution (25). The spectra taken at −80°C in an attempt to observe separate signals from monomer and halogen-bridged dimer species resulted in, in many cases, the sharpening of the signals, but for only one compound, viz. $p\text{-}MeOC_6H_4TeCl_3$, could the splitting of the signal be observed. However, $^{125}$Te chemical shifts show a slight downfield shift (of the order of 0.05 ppm/°C) when measured at −80°C. The consistency with which reduced temperature gave narrower lines indicates that relaxation is predominantly by the spin-rotation mechanism, as was concluded by Granger and Chapelle (26). A slight component of the line broadening can also arise from the fluctuations of the temperature during long accumulation,

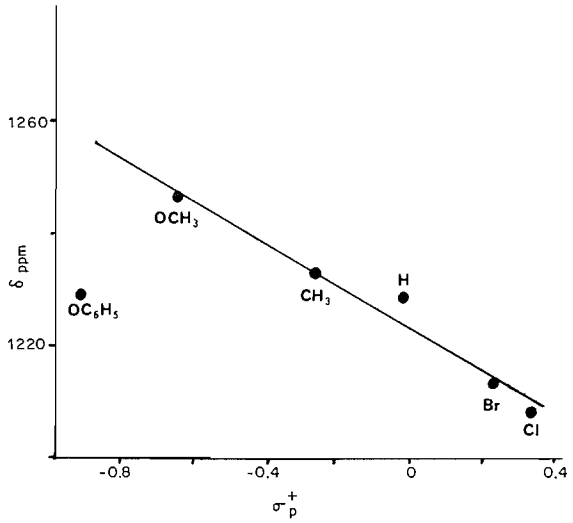

FIG. 1. Substituent effects on the $^{125}$Te chemical shifts of *para*-substituted aryltellurium trichlorides.

particularly when the superconducting magnets are used (21). A temperature variation of ±1°C, which is likely in our experimentation, can contribute line broadening of the order of 12 Hz.

The tellurium atom attached to the phenyl ring having a *para* substituent can be coupled only to *ortho* or remotely separated *meta* protons. However, fine structure due to three or four bond couplings could not be observed because $^3J_{Te-H}$ or $^4J_{Te-H}$ is expected to be smaller (~6 Hz) (21) than the observed line widths.

## Experimental

$^{125}$Te nmr spectra were recorded at 126.2413643 MHz on a Bruker WH-400 Fourier Transform Multinuclear Magnetic Resonance Spectrometer using 50 kHz sweep widths (6.1 Hz/pt), using 50° pulses and repetition rate of 2 s for 100 scans. Typically 100–300 scans were obtained. The shifts were determined with an accuracy of ±0.1 ppm. The samples were saturated solutions in $CH_2Cl_2$ or 1:1 mixture of $CH_2Cl_2$ and DMSO in 10 mm tubes. No deuterium lock was necessary since the lines were relatively broad and acquisition time short. In some cases 27° spectra were not observed because of fast exchange between monomers and dimers.

The compounds, **1**, **3**, **4** (27), **6–9** (28), **10–19** (29, 30), **20** (31), **21–29** (32, 33), were prepared by the methods described earlier.

# Membrane transport systems. III. A mechanistic study of cation–proton coupled countertransport[1]

THOMAS M. FYLES,[2] VIRGINIA A. MALIK-DIEMER, CYNTHIA A. MCGAVIN, AND DENNIS M. WHITFIELD

*Department of Chemistry, University of Victoria, P.O. Box 1700, Victoria, B.C., Canada V8W 2Y2*

Received March 8, 1982

THOMAS M. FYLES, VIRGINIA A. MALIK-DIEMER, CYNTHIA A. MCGAVIN, and DENNIS M. WHITFIELD. Can. J. Chem. **60**, 2259 (1982).

The rate of extraction and transport of potassium ions from a basic aqueous solution into a chloroform membrane containing a macrocyclic polyether (crown ether) – carboxylic acid has been investigated as a function of the following variables: stirring rate, potassium ion concentration, crown ether concentration, proton concentration, buffer concentration and composition, and crown ether-to-potassium ion ratio. Two rate regimes are found, a "zero order" regime where transport rate depends only on the carrier concentration and a "consecutive first order" regime where transport rate depends on the concentration of a crown ether – potassium complex. The kinetic data, together with partition coefficient and interfacial surface tension data, indicate that the rate determining steps in ion extraction occur at the interface. A mechanism involving rate limiting adsorption of carrier or desorption of complex, depending on the experimental conditions, is shown to be consistent with all available data.

THOMAS M. FYLES, VIRGINIA A. MALIK-DIEMER, CYNTHIA A. MCGAVIN et DENNIS M. WHITFIELD. Can. J. Chem. **60**, 2259 (1982).

On a étudié la vitesse de l'extraction et de la transport des ions de potassium d'une phase aqueuse basique à travers une membrane chloroformique, qui contient un macrocycle (ether-couronne) – acide carboxylique, en fonction des paramétres suivants: la vitesse d'agitation des phases, la concentration de potassium, la concentration de macrocycle, la concentration de proton, la concentration et la composition de tampon et le rapport des concentrations de potassium et macrocycle. Il y a deux régimes cinétiques; celui d'un "ordre zero" où la vitesse n'est en fonction que de la concentration de macrocycle et celui d'un "ordre premier consécutif" où la vitesse est en fonction de la concentration d'un complex du macrocycle et potassium. Ces faits, avec les coefficients de partage chloroforme–eau et la tension de la surface d'interface, indiquent l'interface comme site des étapes lentes. On propose une mécanisme où les étapes lentes sont, soit l'adsorption du macrocycle, soit la désorption du complex selon des conditions expérimentaux. Toutes les observations sont consistantes à une telle mécanisme.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

We have recently described an artificial membrane transport system based upon derivatives of macrocyclic polyethers (crown ethers) which utilizes the coupled countertransport of cations and protons to "pump" alkali metal ions from dilute, basic solution, across a liquid membrane, to a more concentrated, acidic solution (1, 2). The system is presumed to function according to the schematic mechanism outlined in Fig. 1. Starting at the basic interface, proton–cation exchange occurs, the liposoluble complex diffuses to the acidic interface, and the reverse cation–proton exchange occurs to regenerate the carrier. The net result is the transport of a metal ion from the basic to the acidic side of the membrane coupled to the transport of a proton in the opposite direction. The system can act as a cation pump if the gradient in protons exceeds the gradient in the transported cation.

Our previous studies were concerned with the synthesis and characterization of the carriers and their alkali metal cation complexes (1) and with a general examination of the transport behaviour of

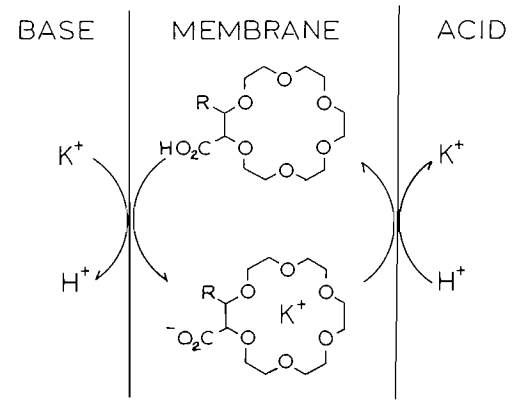

FIG. 1. A schematic mechanism for the carrier mediated countertransport of a metal ion and a proton.

the system (2). This report presents a kinetic examination of potassium ion transport by membrane systems incorporating one of the carriers previously described (**1**). Our goal was to develop a mechanism for ion extraction and transport by carriers of this type which would be useful in designing other carriers for cation–proton coupled countertransport membranes. It was assumed that the important step in the transport cycle is the

**2** $m = 3$
**3** $m = 7$

initial extraction of the ion from the aqueous phase; previously it was shown that extraction is typically, but not necessarily, rate limiting (2). The extraction kinetics of potassium picrate into 1,2-dichloroethane by dibenzo-18-crown-6 have been studied, and the process was shown to occur by an interfacial chemical reaction involving as intermediates the crown ether and its complex adsorbed to the interface (3). Although no other detailed studies have been reported for crown ether extractions nor for artificial membrane transport systems, it has been widely assumed that the key step in the extraction occurs at the interface with the carrier (extractant) in the organic phase and the ion in the aqueous phase (2, 4–6). A recent review concludes that interfacial chemical reactions are rate limiting for a wide variety of extractants and metal ions (7). We have therefore undertaken an examination of the kinetics of the ion extraction half of the transport cycle with a view to identifying the location and nature of the rate limiting step(s) in the process occurring within our transport system.

## Results and discussion

*Initial rate studies*

The transport of potassium by **1** exhibits two types of kinetic behaviour depending upon the initial ratio of carrier and metal ion (2). When the concentration of cation exceeds the concentration of carrier, the transport of metal ion is independent of the metal ion concentration ("zero order" regime). When the concentrations of cation and carrier are comparable, the kinetic behaviour can be described as a pair of consecutive first order reactions ("consecutive first order" regime).[3] At intermediate ratios, mixed order behaviour can be found. The rate of cation transport is not limited by diffusion (2) but is controlled by the rates of the extraction reactions (the "kinetic regime" of ref. 7). This conclusion was further tested by measuring the transport rate at various stirring rates for the three phases in the U-tube cell. Between 200 and 800 rpm, no variation in the observed rate could be detected provided the interface remained quiescent. At the standard rate of 400 rpm, the extraction is thus "kinetically controlled".[4]

The extraction may thus be regarded as a chemical reaction. In general, the rate of extraction as a function of observable concentrations is given by eq. [1].

$$[1] \quad \text{rate} = k[K^+(aq)]^p[HCr(org)]^c[H^+(aq)]^h$$

where $p$, $c$, and $h$ are the orders of the reaction for potassium, carrier, and protons respectively. In the zero order regime, $p = 0$ by definition and $h = 0$ from previously reported experiments (2); the value of $c$ was unknown (eq. [2]). In the consecutive first order regime, $p = 1$ by definition but the values of $c$ and $h$ were unknown (eq. [3]).

$$[2] \quad \text{rate} = k[HCr(org)]^c$$

$$[3] \quad \text{rate} = k[K^+(aq)][HCr(org)]^c[H^+(aq)]^h$$

The value of $c$ in eq. [2] was determined from a series of experiments in which the initial rates of reaction were determined as a function of the initial concentration of carrier. Taking the logarithms of both sides of [2] at $t = 0$ gives

$$[4] \quad \log(\text{rate}_0) = c \log([HCr(org)]_0) + \text{const}$$

where the subscript indicates initial values. This approach is feasible for the zeroth order regime as the system behaviour is relatively insensitive to the magnitude of the excess of potassium. Proton concentration was fixed by buffering. The cell thus consisted of: variable concentration of KCl (ten-fold excess over **1**); 0.125 *M* Tris,[5] 0.125 *M* Tris HCl[5] || variable concentration of **1** in $CHCl_3$ || variable concentration of KCl (ten-fold excess over **1**), 0.125 *M* $H_3PO_4$, 0.125 *M* $TEAH^+H_2PO_4^-$.[5] A graph of the initial transport rate data according to eq. [4] is given in Fig. 2 and shows a line of slope 1.02 ($r^2 = 0.995$) clearly indicating that, in the zero order regime, the transport of potassium is first order in carrier.

The situation for the consecutive first order regime is substantially more complex. Not only does the rate vary with carrier and proton concentrations, but the system collapses towards the zero

[3]Extraction of potassium from the basic phase is first order in potassium and is followed by a release step which is first order in "$[K^+(org)]$". Thus $[K^+(aq)] \xrightarrow{k_1} [KCr(org)] \xrightarrow{k_2} [K^+(aq)]$ describes the transport cycle.

[4]Two sets of experiments were performed; one was typical of the zeroth order regime ($[K^+]_0 = 5 \times 10^{-3}$ *M*, $[HCr]_0 = 5 \times 10^{-4}$), the other was typical of the consecutive first order regime ($[K^+]_0 = 1 \times 10^{-3}$ *M* = $[HCr]_0$). Both sets led to similar conclusions.

[5]Tris = tris(hydroxymethyl)amino methane, Tris HCl = hydrochloride salt of Tris, $TEAH^+ H_2PO_4^-$ = dihydrogenphosphate salt of triethanolammonium. pH of basic buffer = 8.25; pH of acidic buffer = 2.30.

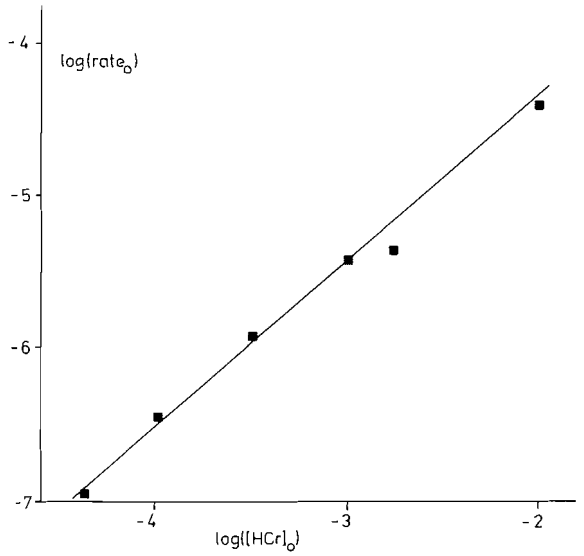

FIG. 2. A plot of log ($rate_0$) as a function of log ($[HCr]_0$) for the zero order transport of potassium by **1**. Log ($rate_0$) = −2.38 + 1.02 log ($[HCr]_0$); $r^2 = 0.995$. Units of rate are μmol $h^{-1}$, units of concentration are mol $L^{-1}$.

order regime if the potassium excess exceeds three-fold. The order in potassium is known by definition. Thus rearrangement of [3] and taking logarithms yields eq. [5].

$$[5] \quad \log\left(\frac{\text{rate}_0}{[K^+(aq)]_0}\right) = c \log([HCr(org)]_0) + h \log([H^+(aq)]_0) + \text{const}$$

The proton concentration may be imposed as constant by buffers, thus

$$[6] \quad \log\left(\frac{\text{rate}_0}{[K^+(aq)]_0}\right) = c \log([HCr(org)]_0) + \text{const}'$$

Furthermore, for a first order process, the initial rate is related to the first order rate constant for uptake of potassium ion ($k_1$obs) by definition [7] to give, on substitution, eq. [8].

$$[7] \quad \text{rate}_0 = k_1 \text{ obs } [K^+(aq)]_0$$

$$[8] \quad \log(k_1 \text{ obs}) = c \log([HCr(org)]_0) + \text{const}'$$

Equation [8] permits an evaluation of the order in carrier even though the concentration of potassium is allowed to vary. Experimentally, this permits the consecutive first order regime to be maintained by balancing the potassium and carrier concentrations. The cell thus consisted of: KCl, 0.125 *M* Tris, 0.125 *M* Tris HCl || variable concentration of **1** || KCl, 0.125 *M* $H_3PO_4$, 0.125 *M* $TEAH^+ H_2PO_4^-$ where $[K^+(aq)]_0 = [HCr(org)]_0$ or $[K^+(aq)]_0 = 1/3$

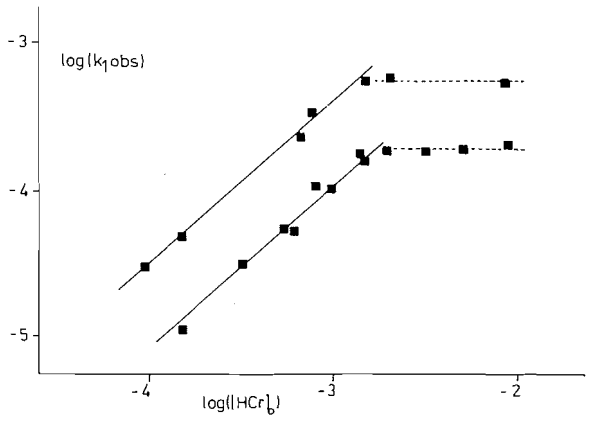

FIG. 3. A plot of log ($k_1$obs) as a function of log ($[HCr]_0$) for the consecutive first order transport of potassium by **1**. Upper curve: log ($k_1$obs) = −0.15 + 1.08 log ($[HCr]_0$); $r^2 = 0.995$; $3[K^+]_0 = [HCr]_0$. Lower curve: log ($k_1$obs) = −0.70 + 1.09 log $[HCr]_0$; $r^2 = 0.983$; $[K^+]_0 = ([HCr]_0)$. Units of $k_1$obs are $s^{-1}$, units of ($[HCr]_0$) are mol $L^{-1}$.

$[HCr(org)]_0$. A graph of the data according to eq. [8] is given as Fig. 3. The curves consist of two regions; the upper horizontal portions correspond to cells where potassium ion release on the acidic side of the membrane is rate limiting. The other portions have slopes of 1.08 ($r^2 = 0.995$) and 1.09 ($r^2 = 0.983$) indicating that uptake is first order in carrier. The separation between the curves corroborates this conclusion; a three-fold increase in the excess of carrier increases the observed rate constant by three-fold resulting in a log 3 separation of the curves at every point. This also indicates that potassium ion release is probably first order in carrier as well, since the log 3 separation continues between the upper portions of the curves.

By a similar analysis to that presented above, [5] may be rewritten as:

$$[9] \quad \log(k_1 \text{ obs}) = h \log([H^+(aq)]_0) + \text{const}'' = -h \log \text{pH}_0 + \text{const}''$$

if the initial carrier concentration is held constant. In principle the initial potassium ion concentration could vary, but this is not necessary as the consecutive first order regime is not as sensitive to pH as to changes in the carrier-to-potassium ion ratio. The cell consisted of: $1.5 \times 10^{-3}$ *M* KCl, Tris/Tris HCl buffers at various pH, Tris (total) = 0.25 *M* || $1.5 \times 10^{-3}$ *M* **1** in $CHCl_3$ || $1.5 \times 10^{-3}$ *M* KCl, 0.125 *M* $H_3PO_4$, 0.125 *M* $TEAH^+ H_2PO_4^-$. A graph of the transport data according to [9] is given as Fig. 4. At higher pH the cells had ion release as the rate determining step, hence were apparently zeroth order in pH. Below pH 8.2 the slope is 0.955 ($r^2 = 0.985$) indicating that in the consecutive first order

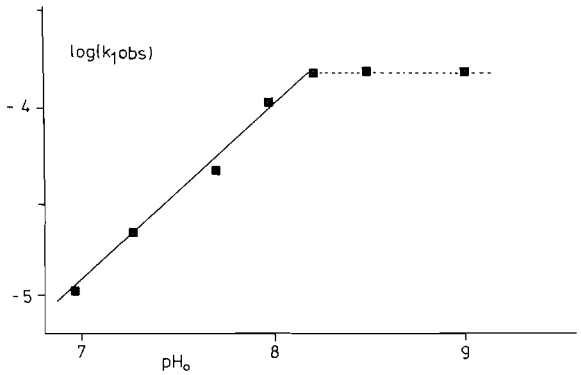

FIG. 4. A plot of log ($k_1$obs) as a function of $pH_0$ for the consecutive first order transport of potassium by **1**. Log ($k_1$obs) $= -11.64 + 0.995\ pH_0$; $r^2 = 0.985$.

regime, the uptake of potassium is inversely proportional to the proton concentration. Thus:

$$[10] \quad \text{rate} = k\,\frac{[K^+(aq)][HCr(org)]}{[H^+(aq)]}$$

for the consecutive first order regime. Equation [10] may be rearranged to an equivalent, but more revealing, form by consideration of two hypothetical partition equilibria, eqs. [11] and [12], which sum to the exchange equilibrium [13].

$$[11] \quad HCr(org) \rightleftharpoons Cr^-(org) + H^+(aq)$$

$$[12] \quad Cr^-(org) + K^+(aq) \rightleftharpoons KCr(org)$$

$$[13] \quad HCr(org) + K^+(aq) \rightleftharpoons KCr(org) + H^+(aq)$$

Equation [11] defines a type of acidity constant $K_a^*$ while [12] defines a type of complex formation constant $K_s^*$. The exchange equilibrium constant $K_e$ of [13] is thus given by [14].

$$[14] \quad K_e = K_a^* K_s^* = \frac{[H^+(aq)][KCr(org)]}{[K^+(aq)][HCr(org)]}$$

Rearrangement of [14] and substitution into [10] gives finally

$$[15] \quad \text{rate} = \frac{k[KCr(org)]}{K_a^* K_s^*} = k'[KCr(org)]$$

The result of this analysis is to demonstrate that in the consecutive first order regime, the rate of potassium ion uptake depends directly upon the concentration of the carrier–potassium complex. This is essentially the mechanism implied by Fig. 1. Additional checks were made of the effect of buffer type (phosphate, TEA, glycinate) and concentration (0.01 to 0.5 *M*) on observed transport rates in both kinetic regimes. There is no discernible effect of either of these variables.

*Partition equilibria and interfacial surface tension*

Several fundamental steps may be envisaged for the movement of an ion from water to within a complex in the organic phase and in principle any one could be rate limiting. However, complexation–decomplexation rates of crown ethers and other ionophores with alkali metal cations are known to be rapid in a variety of media (8–10), hence it is unlikely that the actual complexation step would be the slowest in this particular case. This is particularly true if the complexation occurs in a predominantly aqueous environment. Similarly, deprotonation of the ligand is unlikely to be rate limiting. More likely candidates for the rate limiting steps are reactions involving transfer across a phase boundary (partition) or adsorption–desorption reactions at an interface. Similar processes occur in extraction (7) and in phase transfer catalysis (11); in both cases the extractant remains within the organic phase and ion exchange reactions occur at the interface (12, 13).

Partition of the carrier between the two phases has been examined by two indirect methods. All partition equilibria strongly favour the carrier and its complexes in the organic phase, hence a direct determination of the partition coefficient **1** is analytically difficult. Direct determinations for a lower homolog of **1** (i.e. **2**) have been possible.

Consider the following equilibria:

$$[16] \quad HCr(aq) \rightleftharpoons HCr(org) \qquad P_{HCr} = \frac{[HCr(org)]}{[HCr(aq)]}$$

$$[17] \quad KCr(aq) \rightleftharpoons KCr(org) \qquad P_{KCr} = \frac{[KCr(org)]}{[KCr(aq)]}$$

$$[18] \quad HCr(aq) \rightleftharpoons Cr^-(aq) + H^+(aq)$$

$$[19] \quad K^+(aq) + Cr^-(aq) \rightleftharpoons KCr(aq)$$

Equations [16] and [17] define partition coefficients for HCr and KCr respectively, while [18] and [19] define the acidity and stability constants for complexation in the aqueous phase. For **2**, $pK_a = 3.60 \pm 0.2$ and $\log K_s(K^+) = 2.6 \pm 0.2$ in 0.1 *M* $(CH_3)_4NCl$ as determined from pH-metric titration using procedures previously described (1).

At a pH less than the $pK_a$, the carrier in the aqueous phase will be predominantly as the protonated form, and eq. [16] will describe the system to a first approximation. Solutions of **2** in chloroform were equilibrated with aqueous phosphoric acid and the equilibrium concentrations of HCr in both phases were determined by acid–base titration. In this manner $\log P_{HCr}$ was found to be $1.50 \pm 0.2$.

Manipulation of eqs. [16]–[19] (14) leads to an expression for the distribution of metal ions between two phases (eq. [20]).

$$[20] \quad \frac{[KCr(org)]}{[K^+(aq)]} \cong \frac{P_{KCr}K_sK_a}{P_{HCr}} \frac{[HCr(org)]}{[H^+(aq)]}$$

Values of $P_{HCr}$, $K_s$, and $K_a$ are given above, [HCr(org)] may be determined as described above by titration, $[H^+(aq)]$ may be calculated from the pH, and the metal ion distribution may be determined by atomic absorption analysis for potassium ion in the two phases, $P_{KCr}$ is the only unknown. Under conditions which closely resembled the initial conditions in a transport experiment, log $P_{KCr}$ was found to be $-0.7 \pm 0.3$.

The values of log $P_{HCr}$ and $P_{KCr}$ for **1** may be estimated by assuming a constant increment of log $P = +0.54$ per additional methylene group (15). Thus for **1** log $P_{HCr} = 6.9$ and log $P_{KCr} = 4.7$. One other value in this series has been directly determined; log $P_{HCr}$ for **3** was found to be $3.8 \pm 0.2$ (1). The calculated value for **3** is 3.66. The agreement is quite good although the extrapolation required for **1** may lead to greater errors (15).

Returning to the central question; is the carrier partitioned into the aqueous phase kinetically important under the transport conditions? The answer is likely not. At pH 8.25, $[K^+(aq)]_0 = 1.0 \times 10^{-3}\,M$ and $[HCr(org)]_0 = 1.0 \times 10^{-3}\,M$, the maximum concentration of KCr(aq) is calculated to be ca. $10^{-8}\,M$. In order to achieve μmol $h^{-1}$ transfer rates the partition equilibria would have to be established at rates of about $10^3\,h^{-1}$ (ca. $s^{-1}$). This is clearly not the case, as some distribution experiments required days to reach limiting values.

Further evidence ruling out kinetically important roles for HCr(aq) and KCr(aq) may be obtained from experiments conducted in H-tube cells (16). In the base of one arm was a solution of **1** in chloroform and in the other, chloroform with no carrier. Floating on these, and filling the cross of the H, was placed $1 \times 10^{-3}\,M$ KCl in pH 8.25 buffer. All compartments were stirred. The approach to equilibrium of the potassium in the aqueous phase was followed by analysis of aliquots for potassium. This process was complete within 8 h. However, even after 80 h, the two chloroform phases had not achieved equilibrium as determined by analysis of the two chloroform solutions by atomic absorption (for potassium) and acid–base titration (for carrier). By either criterion, virtually none of the carrier was transferred through the aqueous phase in this time. It follows that a partitioning of the carrier is insufficiently rapid to explain the transport rates.

Since the kinetically important carrier form is membrane bound, it is reasonable to suppose that the site of extraction is at the interface. Other extractants are known to be surfactants (7, 17) and the interfacial activity of simple crown ethers has been investigated (3, 18). The surfactant properties of **1**, under conditions similar to those encountered in the transport experiments, have been determined by measurement of the interfacial surface tension ($\gamma_i$) by the de Nöuy ring method (19). Due to the large amount of organic solute in the buffers, the value of $\gamma_i$ between pH 8.25 buffer and chloroform is low (5 dyne $cm^{-1}$). Quantitative data are thus rather imprecise but serve to give a qualitative insight into the behaviour of **1** at the interface. In the absence of potassium ions, the interfacial surface tension between pH 8.25 buffer and chloroform falls to less than 1 dyne $cm^{-1}$ at concentrations of **1** greater than $10^{-6}\,M$. The change in $\gamma_i$ occurs abruptly between $10^{-6}$ and $10^{-7}\,M$ in **1**. In the presence of $10^{-2}\,M$ KCl the abrupt decrease in $\gamma_i$ occurs at slightly higher concentrations of **1**, between $10^{-6}$ and $10^{-5}\,M$. At the concentrations used for transport the interface is likely to be completely saturated by the surfactant carrier, either as the anion $Cr^-$(i) or as the complex KCr(i).

The Gibbs equation [21] (19) relates the change in $\gamma_i$ with concentration to the surface excess of the surfactant (Γ).

$$[21] \quad \Gamma = -\frac{1}{RT}\left(\frac{d\gamma_i}{d \ln c}\right)$$

where Γ is the surface excess of the solute considered and $c$ is its concentration. The data are insufficiently reliable to give accurate values for the final term in [21]; they are, however, sufficient to provide an estimate of about $-5$ dyne $cm^{-1}$ per decade as a minimum value. The surface excess of **1** is calculated to be ca. $9 \times 10^{-11}$ mol $cm^{-2}$ by [21] which can be converted to a value of 185 $Å^2$/molecule as the area occupied at the interface. The area per molecule may be estimated from CPK models to be about 200 Å for an "edge-on" orientation and about 250 $Å^2$ for a "face-on" orientation. The interface probably consists of a fully condensed monolayer of carrier between the aqueous and chloroform phases, with the alkyl chains extending to the organic solvent.

If the carboxylate and the complex are both strongly adsorbed to the interface, the protonated carrier is much less strongly adsorbed. Interfacial

surface tension measurements for pH 2.3 buffer and chloroform reveal that $\gamma_i$ remains constant to carrier concentrations above $10^{-3}\,M$ and only reaches a limiting value at $5 \times 10^{-2}\,M$. Under the transport conditions the acidic interface is unlikely to be saturated with carrier. At the basic interface the situation is more complex. The carrier, HCr, will have little tendency to adsorb; once at the interface, deprotonation and complexation can occur and the tendency for *desorption* will be small. The basic interface remains saturated throughout, *but not with the species whose concentration is experimentally varied.*

*Extraction mechanism*

The extraction mechanism likely in the case of ion extraction and transport by **1** is similar to those observed with other amphiphilic extractants (7). It involves adsorption of the carrier to the interface, a series of exchange equilibria, and desorption of the adsorbed complex into the organic phase. The sequence of primary steps is given below.

[22] $\mathrm{HCr(org)} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{HCr(i)}$

[23] $\mathrm{HCr(i)} \overset{K_a'}{\rightleftharpoons} \mathrm{Cr^-(i)} + \mathrm{H^+(aq)}$

[24] $\mathrm{Cr^-(i)} + \mathrm{K^+(aq)} \overset{K_s'}{\rightleftharpoons} \mathrm{KCr(i)}$

[25] $\mathrm{KCr(i)} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{KCr(org)}$

In principle any of the steps could be rate limiting; as argued above, protonation and complexation are likely to be fast. Thus the interfacial "concentration" of the various carrier species are interrelated through the equilibrium constants $K_a'$ and $K_s'$; i.e.

$$[26] \quad [\mathrm{HCr(i)}] = \frac{[\mathrm{KCr(i)}][\mathrm{H^+(aq)}]}{K_a' K_s' [\mathrm{K^+(aq)}]}$$

Further, for an interfacial area of 1.54 $\mathrm{cm^2}$ and an area per molecule of ca. 200 Å, the various interfacial species can never exceed one part in $10^{11}$ of the total amount of carrier present in a typical experiment. Thus, the interfacial species may be treated as steady-state intermediates, which gives an expression for the "concentration" of KCr(i) in terms of bulk concentrations; i.e.

$$[27] \quad [\mathrm{KCr(i)}] = \frac{k_1[\mathrm{HCr(org)}] + k_{-2}[\mathrm{KCr(org)}]}{\dfrac{k_{-1}[\mathrm{H^+(aq)}]}{K_a' K_s' [\mathrm{K^+(aq)}]} + k_2}$$

The rate of disappearance of potassium from the aqueous phase must equal the rate of formation of the complex in the memebrane, hence

$$[28] \quad \frac{-\mathrm{d}[\mathrm{K^+(aq)}]}{\mathrm{d}t} = \frac{\mathrm{d}[\mathrm{KCr(org)}]}{\mathrm{d}t} = (k_1 k_2 K_a' K_s' [\mathrm{K^+(aq)}][\mathrm{HCr(org)}] - k_{-1} k_{-2} [\mathrm{H^+(aq)}][\mathrm{KCr(org)}])/(k_{-1}[\mathrm{H^+(aq)}] + k_2 K_s' K_a' [\mathrm{K^+(aq)}])$$

The concentration of the complex in the bulk organic phase is initially zero and, by mass balance calculation, rarely exceeds 15% of the total amount of carrier present under normal transport conditions (2). The proton concentration is also low; thus the second numerator term of [28] is likely to be negligible for most circumstances. Two limiting cases are thus possible; one in which $k_{-1}[\mathrm{H^+(aq)}]$ is large with respect to $k_2[\mathrm{K^+(aq)}]\ K_a'\ K_s'$, giving eq. [29], and the converse, which leads to eq. [30].

$$[29] \quad \frac{-\mathrm{d}[\mathrm{K^+(aq)}]}{\mathrm{d}t} \approx \frac{k_1 k_2 K_a' K_s' [\mathrm{K^+(aq)}][\mathrm{HCr(org)}]}{k_{-1}[\mathrm{H^+(aq)}]}$$

$$[30] \quad \frac{-\mathrm{d}[\mathrm{K^+(aq)}]}{\mathrm{d}t} \approx k_1[\mathrm{HCr(org)}]$$

The result of this analysis is to show the relationship of the experimentally observed rate constants to the individual steps in the extraction process. Equation [29] corresponds to the consecutive first order regime. A comparison of [29] and [10] shows that the observed first order rate constant, $k_1$obs, is equal to the constants in [29]; i.e., $k_1 k_2 K_a' K_s'/k_{-1}$. In this regime, complex desorption is rate limiting. The absorption–desorption of HCr appears as an equilibrium constant given by $k_1/k_{-1}$.

Equation [30] corresponds to the zero order regime and a comparison with eq. [3] shows that the observed zero order rate constant $k_0$obs is equal to $k_1$. In this regime it is the adsorption of HCr to the interface which is rate limiting. As outlined above, the interface is likely to be saturated with $\mathrm{Cr^-(i)}$ and KCr(i); the rate limiting step may thus be the penetration of the protonated carrier into the monolayer of adsorbed carrier complex at the interface.

*Comparison with other transport systems*

To what degree is the mechanism presented above applicable to the numerous other membrane transport systems, both artificial and natural, which are known? Many artificial membrane transport systems have been shown to be rate limited by diffusion of the carrier and its complexes within the membrane (4, 20). The rate determining steps applicable to the mechanism above are thus sufficiently rapid to be treated as equilibria in the kinetic analysis (20). Although there have been no detailed studies of these systems under "kinetic control" (7), the behaviour of a typical transport system in which potassium picrate is transported by dibenzo-18-crown-6 (21) may be inferred from the extraction data (3). In this case two separate rate behaviours were noted. In the concentration range of $10^{-3}$ to $10^{-2}$ *M* in dibenzo-18-crown-6, the extraction closely resembles the consecutive first order regime of **1**, i.e., extraction apparently depends on the formation of a carrier–potassium complex. To higher concentration the extraction becomes zero order in carrier while data at lower carrier concentrations are not presented. Neither of the mechanisms discussed by the authors of ref. 3 will fit with the data presented above for the carrier **1**. However, the data of ref. 3 are consistent with a mechanism similar to the one presented above in which desorption of an interfacial carrier complex is rate limiting. Further study will reveal if the proposed mechanism is generally applicable in other cases as well. It is potentially a candidate in any case where the surfactant properties of the carrier alter on complex formation (22) and where the complexation rates are likely to be fast.

Comparisons with naturally occurring transport systems are unlikely to reveal any mechanistic similarities. There are, nonetheless, considerable kinetic similarities. Transport data in naturally occurring transport systems are commonly analysed using the Michealis–Menton equation developed for use in enzyme kinetics (23). The basic equation has many forms; the one due to Eadie and Hofstee (24, 25) (eq. [31]) gives the most reliable estimates of the parameters $V_{max}$ and $K_m$ (26, 27).

$$[31] \quad \text{rate}_0 = V_{max} - \frac{K_m(\text{rate})_0}{[K^+(aq)]}$$

where $V_{max}$ is the maximal rate of transport for a given concentration of carrier and $K_m$ is an apparent dissociation constant for the carrier complex. Initial rate data were obtained for the cell: variable concentration of KCl, 0.125 *M* Tris, 0.125 *M* Tris HCl || $5.0 \times 10^{-4}$ *M* in $CHCl_3$ || variable concentration of KCl, 0.125 *M* $H_3PO_4$, 0.125 *M* $TEAH^+$ $H_2PO_4^-$. The data are plotted according to [31] (Fig. 5). The intercept gives a value of $V_{max}$ = 4.1 μmol $h^{-1}$ ($4.1 \times 10^{-4}$ *M* $h^{-1}$)[6] and the slope gives $K_m = 6.1 \times 10^{-4}$ mol $L^{-1}$. Although this value of $K_m$ would be typical for a wide range of natural transport systems for potassium (23), the value of $V_{max}$ is several orders of magnitude lower than those found for biological systems. This is doubtless due to the difference between a thin bilayer membrane and the large volumes of the U-tube.

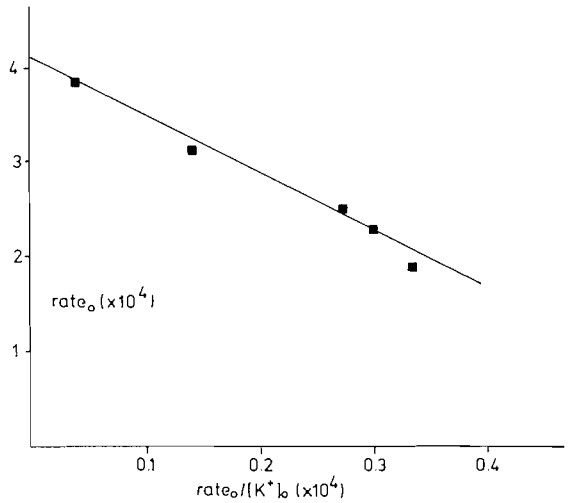

FIG. 5. A plot of initial transport rate of potassium as a function of $\text{rate}_0/[K^+]_0$ by $5 \times 10^{-4}$ *M* **1**. $\text{Rate}_0 = 4.10 \times 10^{-4} - 6.1 \times 10^{-4}$ ($\text{rate}_0/[K^+]_0$); $r^2 = 0.981$. Units of $\text{rate}_0$ are mol $L^{-1}$ $h^{-1}$, units of concentration are mol $L^{-1}$.

TABLE 1. Initial transport rates for the zero order transport of potassium by **1**[a]

| Entry | $[K^+(aq)]_0$[b] | $[HCr(org)]_0$[b] | Initial rate[c] |
|---|---|---|---|
| 1 | $1.0 \times 10^{-1}$ | $1.02 \times 10^{-2}$ | 41.2 |
| 2 | $3.0 \times 10^{-2}$ | $1.77 \times 10^{-3}$ | 4.22 |
| 3 | $1.0 \times 10^{-2}$ | $1.02 \times 10^{-3}$ | 3.91 |
| 4 | $5.0 \times 10^{-3}$ | $5.50 \times 10^{-4}$ | 1.34 |
| 5 | $3.0 \times 10^{-3}$ | $3.40 \times 10^{-4}$ | 1.24 |

As noted, $K_m$ is an apparent dissociation constant for the carrier complex. The apparent *association* constant, the reciprocal of $K_m$, has a value of log $(1/K_m) = 3.2$. This may be compared to the stability constants for complex formation in water (log $K_s = 2.6$) and in 90:10 methanol–water (log $K_s = 5.6$) (1). This serves to further corroborate the assertion that complexation occurs in a predominantly aqueous environment.

The values of $K_m$ and $V_{max}$ are of little fundamental importance as they depend on the concentration of the carrier. They do, however, provide a simple way to summarize the kinetic and thermodynamic behaviour of a carrier under a specified set of conditions. A more complete analysis would involve an evaluation of all the constants in eq. [28].

[p] Entries 1–6 and 10–15 appear as the lower line in Fig. 3, entries 16–21 appear as the upper line. Previous values (7–9) are included for comparison. Entry 22 lies on the upper line of Fig. 3 but outside the boundary of the graph. Entries 23–28 and entry 10 appear in Fig. 4. The negligible buffer effect is indicated by entries 29–31.

## Experimental

General methods for purification of carriers, kinetic analyses, and thermodynamic measurements were as previously described (1, 2). The reported kinetic data were usually determined in duplicate and in some cases triplicate. In addition, most experiments were conducted once in a preliminary fashion to determine optimal sampling times and analytical procedures; none of these experiments is included in the final values. Kinetic data are appended in Tables 1 and 2.

*Extraction equilibria*

An aqueous phase, 10 mL, with or without added potassium, and a chloroform solution of the carrier were stirred in a jacketed test tube at 25°C for a minimum of 48 h. The equilibrated phases were analysed for potassium ion content by atomic absorption and for carrier by acid–base titration. Aliquots of the aqueous phase were directly titrated with standard base. Endpoints were determined from the maxima in plots of the first derivative of the pH–volume curve. Separate endpoints for the carrier and $H_3PO_4$ were clearly identifiable. Aliquots of the organic phase were evaporated, taken up in 0.1 *M* KCl(aq), and titrated with standard base. Partition coefficients were calculated from this data as described in the text.

*Interfacial surface tension*

The aqueous phase (20 mL) and the chloroform solution of the carrier (20 mL) were allowed to stand at 20°C overnight before measurements were performed. The interfacial surface tension was measured using a Fisher Surface tensiometer. The scale was calibrated with standard weights and scale readings were corrected for buoyancy (28). Final values were the average of several measurements. Typical values were 0.125 *M* Tris, 0.125 *M* Tris HCl/chloroform: 5.0 ± 0.6 dyne $cm^{-1}$; 0.125 *M* Tris, 0.125 *M* Tris HCl/1 × $10^{-3}$ *M* **1** in chloroform: 0.9 ± 0.5 dyne $cm^{-1}$. Due to the low magnitude and large uncertainty the values obtained were of qualitative interest only.

## Acknowledgements

We thank V. A. Harris and M. E. Robinson for analytical assistance in the preliminary work and the Natural Sciences and Engineering Research Council of Canada and the University of Victoria for support of this project.

# The electrophilic addition of dimethylbromosulfonium bromide to conjugated enones: efficient synthesis of α-bromo enones

YUAN L. CHOW AND BERT H. BAKKER

*Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6*

Received January 21, 1982

YUAN L. CHOW and BERT H. BAKKER. Can. J. Chem. **60**, 2268 (1982).

Dimethylbromosulfonium bromide reacted readily with many enones at 0°C or lower to precipitate α-bromo-β-sulfonium conjugated enones. These salts eliminate a proton and dimethylsulfide readily with aqueous potassium carbonate to give excellent yields of α-bromo conjugated enones cleanly. The mechanism of the addition was explained by the bromonium ion initiated 1,4-addition followed by tautomerization of enol hypobromites.

YUAN L. CHOW et BERT H. BAKKER. Can. J. Chem. **60**, 2268 (1982).

Le bromure de diméthylbromosulfonium réagit facilement avec plusieurs énones à 0°C ou à une température plus basse pour donner un précipité formé d'énones conjuguées α-bromo-β-sulfonium. Ces sels, en présence de carbonate de potassium en solution aqueuse, perdent facilement un proton et le diméthylsulfure en donnant des α-bromo énones conjuguées à l'état pur, avec un excellent rendement. On explique le mécanisme d'addition par l'ion bromonium qui initie une addition 1,4 suivie d'une tautomérisation des hypobromites d'énol.

Dialkylbromosulfonium bromides are readily prepared from dialkylsulfides and bromine as relatively stable crystalline compounds (1–5) and their structures have been determined by X-ray analysis to have a S—Br bond (6). Dimethylbromosulfonium bromide is also formed from the interaction of dimethylsulfoxide with bromine or *N*-bromosuccinimide (7) in alcohols. This obviously involves an oxidation reaction by DMSO since it has been shown that HBr can catalyze the reduction of DMSO in the presence of $H_2O$ to give dimethylsulfide and bromine.

In recent years, much interest has been directed toward dialkylhalosulfonium halides, in particular $(CH_3)_2SBr^+Br^-$ because of its ready availability, as synthetic reagents for various transformations. Pummerer type rearrangement is probably the earliest known reaction in which α-halosulfides are the product (1). The reaction type involving nucleophilic substitution at the α-carbon has been reported (1, 7).

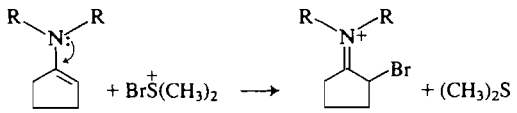
$$R-\overset{\overset{Br}{|}}{\underset{+}{S}}-CH_3 \quad X^- \rightarrow R-SBr + CH_3X$$

$$X = RO^-,\ OH^-,\ Br^-$$

However, nucleophilic attack at the cationic sulfur center is the more commonly observed reaction (3, 4, 8, 9). The reagent is also proposed as the donor of bromonium ion to electron-rich centers (5, 9). As shown by the reaction patterns, the reagents are versatile, but that also causes diversity of products. In some cases, control of the reaction conditions can promote a single reaction pathway enabling the reagents to be useful in synthetic chemistry.

$$Me_2\overset{+}{S}-Br + XH \rightarrow Me_2\overset{+}{S}-X + HBr$$

$$XH = R-OH\ (3);\ R_2NH\ (8),\ H_2C(CO_2R)_2\ (4),\ \text{epoxide}\ (9)$$



In pursuit of the application of dimethylbromosulfonium bromide in synthesis, we quite unexpectedly found that the reagent reacted efficiently and cleanly with certain α,β-unsaturated carbonyl compounds but not so efficiently with others. Our curiosity was further aroused by the fact that while the reagent was assumed to be an electrophile, it added efficiently to a so-called electron-poor conjugated double bond, in a manner very similar to electrophilic reactions. The addition reaction also led us to discover a simple way of preparing certain α-bromo-α,β-unsaturated carbonyl compounds in high yields and purity. This paper describes the chemistry pertaining to the synthetic processes and discusses the mechanism of the reactions.

## Results

While the yellow solid bromodimethylsulfonium bromide, $(CH_3)_2S \cdot Br_2$ (**1**), could be prepared by mixing dimethyl sulfide and bromine in an inert solvent, it was more convenient to make it in acetonitrile and react it with α,β-unsaturated

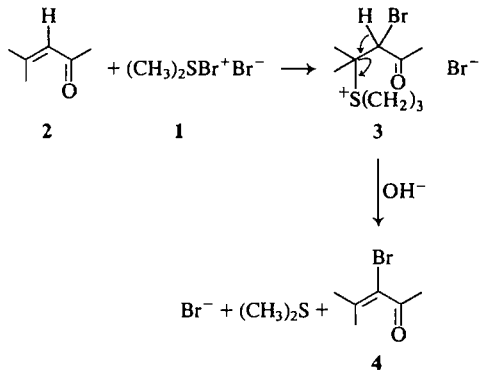
carbonyl compounds (**2**) *in situ* at temperatures lower than zero degrees. The rate of the reaction varied under these conditions depending on the degree of steric crowding and could be visually monitored by the changing of the yellow precipitate to a colorless solid which was identified as an α-bromo-β-dimethylsulfonium carbonyl compound (**3**). The sulfonium adducts **3** were stable enough at room temperature to be isolated and characterized by spectroscopic methods but not sufficiently stable for recrystallization. In aqueous solution the sulfonium adducts **3** underwent decomposition giving α-bromo enones **4** as the sole or the major product. However, simple dissolution of sulfonium adducts **3** in aqueous sodium bicarbonate solution resulted in a base catalyzed elimination of the α-proton and dimethylsulfide to provide, after extraction, excellent yields of practically pure α-bromo enones **4**.



The overall reaction could be represented by the scheme shown above. The yields and spectroscopic parameters of the sulfonium adducts **3** and bromo enones **4** prepared by this process are summarized in Tables 1 and 2. Simplicity of operation, good yields of products, and the absence of by-products characterize this procedure as a superior method over the direct addition of bromine and base-catalyzed elimination to introduce the α-bromo group into certain α,β-unsaturated carbonyl compounds. The latter method (10–13) generally yields some by-products and requires distillation and recrystallization to obtain the reasonably pure products. In addition, several stereochemical features associated with the course and the products of the addition and elimination require some comments.

The reactions of $(CH_3)_2S \cdot Br_2$ with vinylmethyl ketone and acrolein were instantaneous even at −40°C, as judged by the disappearance of the yellow solid, whereas those with mesityl oxide and 2-cyclohexenenone were slow and only reasonably rapid in the vicinity of 0°C. The reaction with other enones 3-penten-2-one, crotonaldehyde, and 2-cyclopentenone was rapid at intermediate temperatures, e.g., at −10°C to ≈ −20°C. These observations clearly indicated the operation of steric crowding during the course of addition. The sulfonium adducts derived from acrolein and crotonaldehyde showed no (or superficial) carbonyl peaks but strong hydroxyl absorptions in the 3500 $cm^{-1}$ region and were consistent with the *gem*-diol structure shown in **6** and **8**. This conclusion was supported by the lack of aldehydic signals in the 9–10 ppm region of the nmr spectra. However, in both cases, the sulfonium group was eliminated easily in the presence of bicarbonate, presumably occurring from the minor component of the aldehydic form in equilibrium with the hydrated form in solution. In aqueous solution, most of the sulfonium adducts **3** eliminated the sulfonium group slowly over a period of several days, except for **11** which, under nmr measurement conditions, did so rapidly to give 2-bromo-2-cyclopentenone **18**. While **9** is stable in storage, the copious amounts of **9** formed during the addition slowly decomposed when stirred at room temperature, by elimination of the sulfonium group, to give **16**, indicating steric acceleration. This may account for a lower yield of **18** (30–40%) when reaction was run at room temperature for a longer period.

The rates of $(CH_3)_2S \cdot Br_2$ addition to conjugated enones were significantly slower in less polar solvents. For example, the addition to acrolein in methylene chloride did not take place unless warmed to room temperature and took ten hours for the yellow color to disappear. It gave poorer yields of adduct **6**. In carbon tetrachloride the reaction was too slow at room temperature to be practical. The same trend was noted in the addition to mesityl oxide. In these cases, trimethylsulfonium bromide ($(CH_3)_3S^+Br$, singlet at 2.90 ppm) was formed in significant amounts.

The addition of $(CH_3)_2S \cdot Br_2$ to some conjugated enones naturally led to the question of the stereochemistry of the resulting sulfonium adducts which were, in turn, related to the stereochemical course of the reaction. While the stereochemistry of sulfonium adduct **11** could not be determined due to its instability in solution, that of 2-bromo-3-sulfonium cyclohexanone **10** obviously had the *trans*-configuration (diequatorial) as shown by the nmr doublet at 4.38 ppm with $J = 10$ Hz. However, the presence of ≈5% of

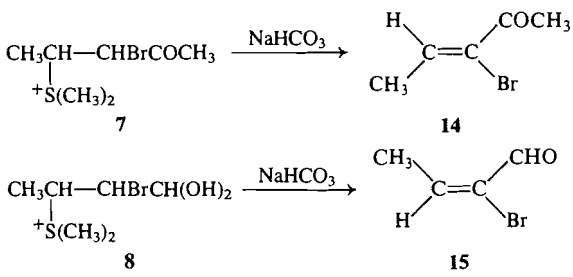
[a] The adducts were isolated as sulfonium bromides and their ir and nmr spectra were given.
[b] The ir spectra were taken in Nujol or as KBr pellets.
[c] The nmr spectra were taken in $D_2O$ using DSS as an internal standard.
[d] In $CF_3CO_2H$, it showed signals at 9.38 (broad s, 1H), 5.19 (t, 1H, 5 Hz), 4.10 (d, 2H, 5 Hz), 3.25 (s, 3H), 3.18 (s, 3H).
[e] The spectrum also showed weak signals at 5.30 (d, $J = 5$ Hz), 2.92 (s), 1.65 (s) for the minor isomer. In $CF_3CO_2H$ it showed two sets of signals in a 1:1 ratio.
[f] On standing at the room temperature, there emerged another set of signals at 5.18 (d, 4 Hz), 4.10 (m), 3.02 (s), 2.88 (s), 2.52 (3), 1.64 (d, 7 Hz).
[g] On dissolution in $D_2O$, the compound eliminated $(CH_3)_2S$ spontaneously and showed weak signals of these two singlets corresponding to the dimethylsulfonium group.

another isomer was suggested by a small spike at 3.00 ppm (for a $CH_3S^+$-signal). Sulfonium adduct **8** showed a major and minor set of nmr signals in $D_2O$ corresponding to the *erythro* and *threo* diastereoisomers. In trifluoroacetic acid, however, the two sets of signals were in the ratio of nearly 1:1. While 3-penten-2-one contained *trans* and *cis* isomers in a 10:1 ratio as shown by the nmr spectra, its sulfonium adduct **7** showed only one set of $^1H$ nmr signals in $D_2O$. This solution developed another set of signals, reaching a 1:1 ratio in two weeks. In trifluoroacetic acid solution, the change was much faster, reaching the equilibrium in four days. Assuming that the two sets of signals were derived from *erythro* and *threo* diastereoisomers, we must conclude isomerization occurred in solution. *It was noteworthy that the isomerization of 7 in $D_2O$ solution was not accompanied by deuterium exchanges at the α- and β-position.*



7 **14**

8 **15**

The base-promoted elimination of sulfonium adducts **7** and **8** also generates geometrical isomers of α-bromo enones **14** and **15**. The crude product obtained from base treatment of **8** showed a clear nmr spectrum in carbon tetrachloride for the single isomer **15**. The doublet at 2.14 ppm and the quartet at 7.18 ppm allowed us to assign the structure as shown. Another set of nmr signals developed gradually, reaching a 1:1 ratio after 3 days. This set

[a]The ir and nmr spectra were recorded in $CCl_4$ solution; for the latter TMS was used as an internal standard. The molecular ion peaks gave the correct molecular weight by high resolution mass spectrometry.
[b]In $CCl_4$ solution, the $^1H$ nmr spectrum exhibited weak signals (10%) for the minor component at 6.42 (q, 6.8 Hz), 2.60 (s), 2.00 (d, 6.8 Hz); no isomerization occurred under the conditions (10).
[c]In $CCl_4$ solution, the $^1H$ nmr spectrum showed signals for the minor component at 9.40 (s), 7.50 (q, 7 Hz), 2.01 (d, 7 Hz); the ratio of the corresponding signals reached 1:1 in 3 days.
[d]Melting point 68–69°C (lit. (11) mp 69–71°C).
[e]Melting point 34–35°C (lit. (12) mp 39–39.5°C).
[f]The low yield arose from volatility of **13** (13).

showed a singlet at 9.40 ppm, a quartet at 7.50, and a doublet at 2.01 ppm, and was assigned to the structure with alternative geometry isomeric to **15**. On the contrary, the elimination of the sulfonium group from **7** gave **14** as the major product, with about 10% of the alternative isomer as shown by gc–ms and $^1H$ nmr. The latter was more volatile and easily removed by evaporation. Compound **14** was stable in $CCl_4$ solution.

The reagent $(CH_3)_2S \cdot Br_2$ reacted with cinnamaldehyde slowly at 0°C (but not at −30°C) and with ethyl cinnamate only at room temperature to give dibromo adducts without a trace of the sulfonium adducts. The reagent failed to add to isophorone and maleic anhydride and reacted sluggishly with 4-cholesten-3-one. In the presence of ethyl acrylate, the reagent reacted very slowly at 0°C and gave a complex mixture.

## Discussion

The addition of $(CH_3)_2S \cdot Br_2$ to α,β-unsaturated carbonyl compounds is characterized by some unusual observations. Firstly, the addition occurs very rapidly even at −40°C in solid–solution mixture. Secondly, the rates of the addition are very sensitive to steric control, as seen by the failure to add to isophorone and 4-cholesten-3-one, and to electronic factors, as seen by the sluggish addition to conjugated esters. Thirdly, the reagent behaves as a bromine addition reagent with phenyl

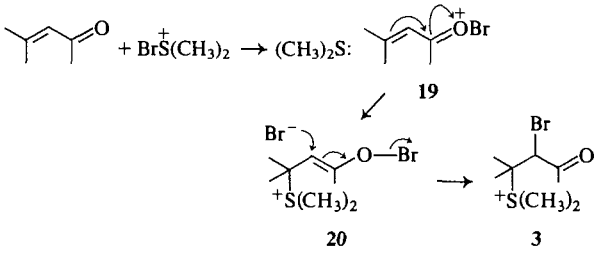
conjugated α,β-unsaturated carbonyl compounds. Fourthly, the reagent completely fails to react with maleic anhydride which is brominated readily by $Br_2$ in carbon tetrachloride (14). Fifthly, the addition is dramatically retarded in less polar solvents such as methylene chloride. Finally, the addition is regiospecific, giving α-bromo-β-sulfonium carbonyl compounds, and stereoselective, giving predominantly one isomer where relevant. The evidence described above appears to indicate that the addition occurs by a mechanism of brominium ion initiated electrophilic addition to the conjugated double bond (15), or that of dimethylsulfide initiated nucleophilic attack at the β-carbon similar to the Michael type 1,4-addition. However, the attack of bromonium ion at the electron deficient olefinic bond of enones is not likely, nor is the manifested reactivity order in agreement with such an assumption. The latter idea suffers from the assumption that dimethylsulfide attacks at a disubstituted β-olefinic carbon in the mesityl oxide case; indeed, dimethylsulfide initiated addition is unknown as far as we are aware.

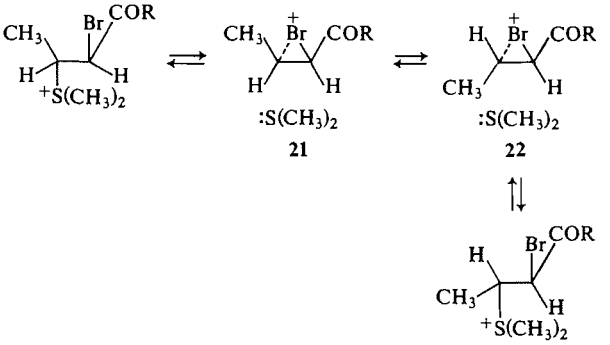
Alternatively, one may consider the sulfide cation radical (16) as the reactive species which initiates the addition by a chain process. Such a radical mechanism also suffers from inadequacy to explain dramatic solvent effects. Nor is it reasonable to use the sulfide cation radical to attack the β-carbon of a conjugated enone system. We have observed that the presence of air does not substantially alter the addition product pattern; this observation rules out the possibility of a radical mechanism.

The clue to the addition mechanism may rest on the reactivity order in which conjugated aldehydes react faster than conjugated ketones which, in turn, react faster than conjugated esters; that is, the more basic substrates react faster. It has been demonstrated that the addition of bromine to α,β-unsaturated ketones, aldehydes, and esters (and also other electron withdrawing groups) is catalyzed by acids involving the attack of the bromide (or an anionoid) at the β-carbon as the rate determining step (17). Reactivity is in the order of acrolein > crotonaldehyde >> cinnamaldehyde > ethyl cinnamate (18). We propose a similar mechanism as shown below to account for the addition. The reaction is initiated by the electrophilic attack of the brominium ion at the carbonyl oxygen to give the intermediate **19**. Such a mechanism can account for the observed regiospecificity and acceleration of the addition in polar solvent. In this mechanism the stereochemistry of the sulfonium adduct **3** is determined by tautomerization of the enol hypobromite **20** to **3** and may involve the attack of a bromide anion as a possible pathway. Therefore, irrespective of the *cis–trans* geometry of conjugated enones, the stereochemistry of the adducts **3** should be the same as determined by the tautomerization process as shown in the addition to 3-penten-2-one to give the single isomer **14**. It follows that the carbonyl group of conjugated esters is not as electron rich as that of conjugated enones to interact with $(CH)_2S—Br^+$ and therefore does not lead to a successful addition. Recently, the addition of bromine to conjugated enones has been reinvestigated in methylene chloride and from the reactivity pattern a similar mechanism has been proposed (19).



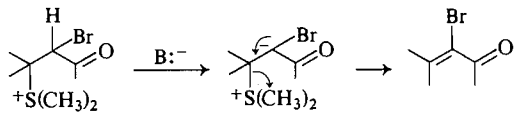
20 3

The observed isomerization of sulfonium adducts **7** and **8** from one diastereoisomer to the other in $D_2O$ solution must involve the breaking and reformation of a bond at a chiral center. That this bond is not a C—H bond at the α and β chiral carbon centers is demonstrated by the lack of deuterium exchange in $D_2O$. A mechanism involving unsymmetrically bridged bromonium ions **21** and **22** may account for the isomerization. The isomerization of **7** occurs much faster in trifluoroacetic acid and, indeed, **8** also isomerizes in this solvent.



21 22

The base-promoted elimination of sulfonium adduct **3** is most likely to occur by an E1cb mechanism via the anion **23** and, thus, the stereochemistry of α-bromoenone **4** is determined by the stereoelectronic balance around the developing double bond. This mechanism can account for the elimination of diastereomeric



3 23 4

mixtures of **8** to give only one isomer **15** which rearranged slowly in carbon tetrachloride solution. In contrast, **14** is stable under similar conditions. Conjugated enones with the α-bromo group are versatile dienophiles in the Diels–Alder reaction, giving highly regiospecific adducts (20–24).

## Experimental

Melting points were uncorrected. Reported nmr spectra were recorded on a Varian EM-360 or a Varian XL-100 and ir spectra with a Perkin–Elmer 457 spectrophotometer. Mass spectra were obtained with a Hewlett–Packard 5985 spectrometer. Gas chromatography was performed on a Varian 1400 instrument equipped with a SE-30 capillary column (45 ft × 0.28 mm). Reagent grade solvents were redistilled, and other chemicals were C.P. grade materials as supplied from commercial sources.

*Preparation of dimethylbromosulfonium bromide*

To a solution of dimethylsulfide (10 mL, 130 mmol) in methylene chloride (100 mL) cooled to −40°C under nitrogen, a bromine (15.01 g, 94 mmol) solution in methylene chloride (30 mL) was added in 30 min. A yellow precipitate formed immediately. The mixture was stirred for 10–20 min and ether (100 mL) was added. The precipitate was filtered, and washed with ether and pentane to afford bromodimethylsulfonium bromide (19.0 g, 91%).

*Addition of dimethylbromosulfonium bromide to conjugated enones*

Generally, the salt was formed *in situ* for the addition reaction. To a solution of dimethyl sulfide (1 to 2 mol equivalent) in acetonitrile (50–100 mL), cooled under nitrogen, a solution of bromine (≈ 20–100 mmol) in carbon tetrachloride (5 mL) was added, dropwise, at −40°C. The yellow precipitate was stirred at this temperature for 5 min and an enone (≈ 1–1.5 equivalent) was injected. Unhindered enones, such as vinylmethyl ketone or acrolein, reacted immediately at this temperature to give a colorless precipitate. Hindered carbonyl compounds, such as mesityloxide and 2-cyclohexenone, reacted at 0°C in 10–20 min to afford a colorless precipitate. To the mixture, ether (100 mL) was added. The precipitate was filtered and washed with ether and pentane and dried. The solid was generally stored in a freezing compartment.

*Preparation of 2-bromo-α,β-unsaturated carbonyl compounds*

A sulfonium salt (5–20 mmol) obtained from the above preparation was dissolved in 5% sodium bicarbonate solution (50–100 mL). The mixture was warmed for 10–15 min at room temperature and was extracted with methylene chloride. The methylene chloride solution was washed with water, dried, and evaporated to give the α-bromo enone. The product was pure enough to obtain the spectra shown in Table 2, but could be recrystallized or distilled. All α-bromo enones showed very intense molecular ion peaks which showed correct molecular weight by high resolution mass spectrometry.

*Synthesis of α-bromoacrolein (an example)*

Dimethylsulfide (5 mL) in acetonitrile (100 mL) was cooled at −40°C under nitrogen. Bromine (6 g) in carbon tetrachloride (5 mL) was added at −40°C to give the yellow precipitate. To this mixture acrolein (3 mL) was injected at −40°C, at which the yellow precipitate was changed to a white precipitate immediately. Ether (100 mL) was added to the mixture. The precipitate was filtered, washed, and dried on filter paper to give a white solid (8.0 g), mp 70–75°C(dec.). The solid was dissolved in water (50 mL) containing sodium bicarbonate (4.0 g). After warming up to 35°C for 15 min, the mixture was extracted with methylene chloride. The methylene chloride solution was worked up as usual and distilled over a short Vigreux column. The residue was distilled under a water pump vacuum to afford colorless α-bromoacrolein (1.85 g, 48% based on bromine); 45°C/25 Torr.

# Spin–spin coupling constants as indicators of the conformation of anthrone in solution

TED SCHAEFER, RUDY SEBASTIAN, TIMOTHY A. WILDMAN, AND HEATHER DETTMAN
*Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2*

Received March 17, 1982

TED SCHAEFER, RUDY SEBASTIAN, TIMOTHY A. WILDMAN, and HEATHER DETTMAN. Can. J. Chem. **60**, 2274 (1982).

The analyses of the $^1$H nmr spectra of fluorene, 2,7-dibromofluorene, and anthrone are reported. The benzylic couplings in these compounds are compared with those in indene and toluene. It is argued that the six-bond and five-bond couplings in anthrone are more compatible with a nonplanar than a planar central ring. The spectrum of the 2,7-dibromofluorene suggest that couplings between protons in different benzenoid rings are small, perhaps no larger than 0.05 Hz.

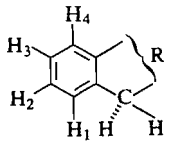
TED SCHAEFER, RUDY SEBASTIAN, TIMOTHY A. WILDMAN et HEATHER DETTMAN. Can. J. Chem. **60**, 2274 (1982).

On rapporte l'analyse des spectres de rmn du $^1$H du fluorène, du dibromo-2,7 fluorène et de l'anthrone. On a comparé les couplages benzyliques dans ces composés à ceux de l'indène et du toluène. On démontre que les couplages à travers six et cinq liaisons dans l'anthrone sont plus compatibles avec un cycle non plan qu'avec un cycle ayant un plan central. Le spectre du dibromo-2,7 fluorène suggère que les couplages entre protons de différents cycles benzénoides sont petits, peut-être pas plus grands que 0,05 Hz.

[Traduit par le journal]

## Introduction

The recent report of the complete analysis of the $^1$H nmr spectrum of indene, **1**, at 270 MHz (1) prompts an account of our analyses of the $^1$H nmr spectra of fluorene, **2**, and anthrone, **3**, (9,(10H)-anthracenone) at 100 MHz. Although the heavy atom skeletons of **1** and **2** are planar, and although **3**



**1** R = HC = CH
**2** R = $C_6H_4$
**3** R = $C_6H_4C$ = O

has been judged as planar by X-ray diffraction (2, 3), and as planar or very nearly planar by Kerr effect studies (4), the long-range spin–spin couplings to the methylene protons reported here for anthrone are most easily interpreted in terms of an inverting boatlike structure for the central ring.

## Experimental

The $^1$H nmr spectrum of a degassed, 10 mol% solution of fluorene in $CS_2$ was calibrated on an HA 100 spectrometer at a probe temperature of 350 K. The calibration and subsequent, interpolated peak frequency, procedure followed that described in detail recently (5). The $^1$H nmr spectrum of a degassed, 3.9 mol% solution of anthrone in $CDCl_3$ was also calibrated in the frequency sweep mode, as was that of a 2.0 mol% solution of 2,7-dibromofluorene in $CS_2$. No nmr evidence was found for anthrol in the former solution.

## Results and discussion

### *Spectral analyses*

The benzenoid ring proton spectra for fluorene and anthrone were analyzed with the computer program LAME (6, 7) with the assumption of no cross-ring coupling. Previous analyses of fluorene, fluorenone, and 1-methylfluorene also made this assumption with success (8–12). For 2,7-dibromofluorene this assumption was unnecessary (LAME-8 analysis) yet no strong evidence for cross-ring couplings could be found,. i.e., between protons in different benzenoid rings.

Figure 1 displays the calculated and observed ring proton spectra for 2,7-dibromofluorene. The observed peaks are somewhat broader (0.15 Hz) than normal and this *may* arise from some cross-ring coupling. The calculated spectrum with no cross-ring coupling agrees well with the observed peaks. Presumably any coupling across the five-membered ring is not larger than ca. 0.05 Hz.

The spectral parameters are found in Table 1.

### *The proton coupling constants within the benzenoid rings*

These couplings for fluorene in Table 1 agree very closely with those in indene (1), the mean difference being $0.04_4$ Hz for six couplings. The corresponding parameters for anthrone are quite different from those in fluorene. Recent rough analyses (13) of the $^1$H nmr spectra of a series of anthracene derivatives suggested that $^3J_{12}$ is 7.99 ± 0.15 Hz for nonplanar and 8.67 ± 0.10 Hz for planar molecules. For anthrone, $^3J_{12}$ was given as 7.5 Hz although nothing was stated about its conformation. In Table 1, the value of $^3J_{12}$ is 7.79(1) Hz, the error being taken as twice the standard deviation.

The benzenoid ring proton couplings expected for a relatively unstrained anthrone molecule might be approximated by those in 2-methylacetophenone (14). Acetophenone is probably planar in

[a]Fluorene as a 10 mol% solution in $CS_2$ and shifts in Hz at $100.001_2$ MHz to low field of internal TMS.
[b]A 2.0 mol% solution of 2,7-dibromofluorene in $CS_2$.
[c]Anthrone as a 3.9 mol% solution in $CDCl_3$.
[d]Numbers in parentheses are the standard deviations in the last one or two significant figures.

the ground state (15) but some degree of non-planarity of the heavy-atom skeleton is very likely induced by an *ortho* methyl substituent. The coupling constants (those for anthrone in parentheses) are 7.64(7.79), 7.39(7.27), 7.87(7.94), 1.30 (1.23), 1.44(1.46), and 0.47(0.59) Hz.

*Benzylic couplings*

In toluene the coupling over six bonds, $^6J_p^{H,CH_3}$, is represented by $-1.24 \sin^2\theta$, where $\theta$ is the angle by which the $\alpha$ C—H bond twists out of the benzene plane (16). This behaviour is reproduced almost exactly by INDO MO FPT calculations (17). In ref. 17 it is also implied that $^5J_m^{H,CH_3}$ consists of $\sigma$ and $\pi$ electron components and one may write

$$[1] \qquad {}^5J_m{}^{H,CH_3} = {}^5J^{\pi}{}_{90}\langle \sin^2\theta \rangle + {}^5J^{\sigma}{}_{180}\langle \sin^2(\theta/2) \rangle$$

Experimental data on toluene (18) and *m*-xylene (19,20) suggest $^5J^{\pi}{}_{90}$ as 0.38(4) Hz and $^5J^{\sigma}{}_{180}$ as 0.34(4) Hz. $^5J^{\pi}{}_{90}$ is the counterpart of $^6J^{\pi}{}_{90} = -1.24$ for the six-bond coupling, whereas $^5J^{\sigma}{}_{180}$ is the coupling for an all-*trans* arrangement of the five

For personal use only.

bonds intervening between the *meta* ring proton and the α proton. In toluene both averages over θ in [1] are 0.5.

In indene and fluorene θ is fixed to within small vibrational motions. For fluorene, simple trigonometry and the heavy-atom structure (21) allow the statement that θ varies between 57.9° and 61.5° as the methylene HCH angle ranges between 103.5° and 111.5°. For present purposes, θ will be assigned a value of 60° in fluorene. The same number will be assumed for indene.

$^6J$ in indene is $-0.66_2$ Hz (1), implying $^6J_{90}$ as $-0.88_3$ Hz, whereas in fluorene $^6J$ is $-0.77_7$ Hz, suggesting $^6J_{90}$ as $-1.04$ Hz, $\sin^2\theta$ being 0.75. Both values of $^6J_{90}$ are substantially smaller in magnitude than in toluene. This we take as an indication of ring strain rather than of a reduction caused by the electronegativity of the additional carbon atom attached to the methylene group (there is good evidence (16) that $^6J_{90}$ should not be reduced in magnitude by more than about 0.03 Hz by the presence of a second carbon).

Turning to $^5J$, for fluorene one may write (Table 1)

$$[2] \quad {}^5J_m{}^{H_2,CH_2} = 0.159 = {}^5J^{\pi}{}_{90} \sin^2 60° + {}^5J^{\sigma}{}_{180} \sin^2(60°/2)$$

$$[3] \quad {}^5J_m{}^{H_4,CH_2} = 0.389 = {}^5J^{\pi}{}_{90} \sin^2 120° + {}^5J^{\sigma}{}_{180} \sin^2(120°/2)$$

with the result that $^5J^{\pi}{}_{90}$ is $0.05_9$ Hz and $^5J^{\sigma}{}_{180} = 0.46_0$ Hz. Apparently the π electron contribution to $^5J$ is much smaller than in toluene. Again, the analogous couplings in indene are < 0.05 Hz and 0.20 Hz (1). If the former coupling is zero, then $^5J^{\pi}{}_{90}$ necessarily vanishes and equations of the type [2] and [3] are incompatible. For compatibility, one has $^5J^{\pi}{}_{90} + {}^5J^{\sigma}{}_{180} = 0.27$ Hz and the minimum magnitude of $^5J^{\pi}{}_{90}$ must be $0.06_6$ Hz if it is to be positive. However, the two couplings are then calculated as $0.10_0$ and $0.20_4$ Hz. Now, INDO MO FPT calculations on indene (1) yield reasonable values for $^4J_o{}^{H,CH_2}$ and $^6J_p{}^{H,CH_2}$. Normally, such calculations overestimate the *magnitude* of $^5J_m{}^{H,CH_2}$. For indene, they yield the two couplings as 0.21 and 0.55 Hz. Then $^5J_{90}$ and $^5J_{180}$ follow as 0.05 and 0.68 Hz, again emphasizing the very small π electron contributions to $^5J$ in indene and fluorene in contrast to experimental and theoretical indications for toluene. Whether peculiar coupling paths or some other mechanism could account for these results is unknown. It may be noted that the ratios of $^4J_o/^6J_p$ for these π electron dominated couplings are 0.80 ± 0.02 for indene, fluorene, toluene, and anthrone.

For anthrone, $^6J_p{}^{H,CH_2}$ is $-0.72_3$ Hz. If the molecule is planar, then $^6J_{90}$ is $-0.96_4$ Hz, a value much smaller in magnitude than in toluene, $-1.2_4$ Hz, or even fluorene, $-1.0_4$ Hz. Such a situation seems rather unlikely. However, if anthrone exists in the boat form which inverts rapidly on the nmr time scale, as does 9,10-dihydroanthracene (22, 23), then the extreme boat conformation is one in which one C—H bond of the methylene group has θ as ca. 90° and the other C—H bond has θ as ca. 30°. Rapid inversion between the two equivalent boat forms yields $\langle \sin^2\theta \rangle$ as 0.5 ($\sin^2 90° + \sin^2 30°$) or 0.625. Then $^6J_{90}$ becomes $-0.723/0.625$ or $-1.1_6$ Hz, a value much more consistent with that expected for an α-alkyl toluene (16) and for a central six-membered ring in anthrone.

Equations of type [2] and [3] yield $^5J^{\pi}{}_{90}$ as $0.35_2$ Hz and $^5J^{\sigma}{}_{180}$ as $0.24_7$ Hz for an inverting boat structure of anthrone. These numbers predict $^5J^{H,CH_3}$ as 0.30 Hz in toluene, whereas the observed value is 0.36 ± 0.02 Hz. Of course, according to the arguments above, this observed value should be somewhat larger because of the larger π (and possibly σ) electron contribution in toluene.

Again, in ethylbenzene $^5J_m{}^{H,CH_2}$ is 0.28 Hz (24). $^6J_p{}^{H,CH_2}$ is (−)0.45 Hz, implying (16) $\langle \sin^2\theta \rangle$ as 0.45/1.22 or 0.369. The π contribution to $^5J$ is then 0.369 × 0.352 or 0.130 Hz. This molecule prefers a conformation in which the $CH_3$ group lies in a plane perpendicular to the benzene plane (25*a*). If this were a fixed conformation, $\sin^2(\theta/2)$ averaged over the two methylene protons would be $\{\sin^2(150°/2) + \sin^2(30°/2)\}/2$ or 0.500. Free rotation would also yield an average of 0.5. Approximately then, the σ contribution to $^5J_m$ is 0.5 × 0.247 or 0.123 Hz, yielding a total $^5J_m{}^{H,CH_2}$ of $0.25_3$ Hz, perhaps within or very near the combined experimental error of all the measurements.

By way of contrast, assumption of a planar anthrone molecule yields $^5J^{\pi}{}_{90}$ and $^5J^{\sigma}{}_{180}$ as $0.31_5$ and $0.21_4$ Hz, respectively, a $^5J_m{}^{H,CH_3}$ in toluene of 0.26 Hz, and a $^5J_m{}^{H,CH_2}$ of 0.22 Hz in ethylbenzene, rather far from the observed couplings.

Now, as emphasized by a referee, the preceding derivation of $^6J_{90}$ as $-1.1_6$ Hz in anthrone assumes rapid inversion between boat conformations and also that conformations lying on the inversion path have negligible populations. An alternative hypothesis assumes a planar conformation with large amplitude vibrations, of the sort implied by recent molecular mechanics calculations on 9,10-dihydroanthracene (25*b*). Were anthrone to behave similarly, the molecular mechanics results in Fig. 3 of ref. 25*b* imply that the proper average value of $\sin^2\theta$ is, approximately, $\int_{\pi/6}^{\pi/2} \sin^2\theta d\theta$ or 0.740. Then

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

$^6J_{90}$ is $-0.723/0.740$ or $0.97_7$ Hz. The arguments above would reject this hypothesis. Similar remarks apply to the somewhat steeper energy profiles calculated by molecular orbital methods (25*b*).

Our central assumption, that $^6J_{90}$ in anthrone is larger in magnitude than in fluorene and that, indeed, it is closer to the magnitudes in toluene and its α-substituted derivatives, therefore suggests a double minimum potential for the inversion of anthrone in solution. Furthermore, the assumption implies that the barrier to inversion be somewhat larger than $kT$ at ambient temperatures.

This rather bold suggestion may be wrong. Nevertheless, it may have sufficient merit to interest those spectroscopists specializing in the interpretation of relatively low frequency vibrational bands.

*The X-ray data*

The anthrone crystal, although structurally disordered, has been studied extensively by X-ray diffraction (2, 3). Apparently, the molecule is planar in the solid. A large out-of-plane libration of the oxygen atom occurs (3). A boatlike central ring exists in crystals of 10-bromoanthrone (26). In 9,10-dihydroanthracene, successive substitution at the 9,10 positions can induce increased flattening of the central ring (23, 27). Packing forces in the crystal could be sufficient to perturb derivatives of 1,4-dihydrobenzene from their equilibrium geometry (28). Whether such perturbations occur for anthrone is a point of interest.

## Conclusions

The benzylic couplings in anthrone are most naturally interpreted in terms of an inverting, nonplanar, central ring. Additional evidence might be provided by experiments on geminal proton–proton coupling constants of the kind performed by Fraser and co-workers (29) on related compounds. The benzylic couplings in 9,10-dihydroanthracenes and 1,4-dihydronaphthalenes are needed to provide a necessary complement to homoallylic couplings (23, 30, 31) as conformational markers. Their extraction requires a more powerful spectrometer than used in this study.

# Use of the absolute method in neutron activation analysis: application to National Bureau of Standards coal and spinach

J. ST-PIERRE AND L. ZIKOVSKY

*Nuclear Engineering Institute, École Polytechnique, P.O. Box 6079, Stn. A, Montreal, P.Q., Canada H3C 3A7*

Received November 10, 1981[1]

J. ST-PIERRE and L. ZIKOVSKY. Can. J. Chem. **60**, 2278 (1982).

Absolute neutron activation analysis, which consists of gamma-ray counting and direct calculation of weights from nuclear constants, was applied to two National Bureau of Standards materials: coal (SRM 1632a) and spinach (SRM 1570). Al, As, Br, Cl, Co, Cr, Cs, Eu, Fe, Ga, K, La, Mg, Na, Sb, Sc, Sr, Ti, V, W, and Zn were instrumentally determined in these samples with accuracy ranging from −18 to +21% among elements for which reference values were available.

J. ST-PIERRE et L. ZIKOVSKY. Can. J. Chem. **60**, 2278 (1982).

L'analyse par activation neutronique absolue qui consiste à calculer directement des masses à partir des constantes nucléaires et des données obtenues par spectrométrie gamma a été utilisée pour analyser deux étalons du National Bureau of Standards: charbon (SRM 1632a) et épinard (SRM 1570). Dans ces étalons, nous avons dosé 21 éléments (Al, As, Br, Cl, Co, Cr, Cs, Eu, Fe, Ga, K, La, Mg, Na, Sb, Sc, Sr, Ti, V, W et Zn) d'une façon non-destructive et avec une exactitude qui a variée de −18 à +21% pour les éléments pour lesquels les valeurs certifiées étaient connues.

## Introduction

In our laboratory, the semi-absolute method (1) is used to analyze a great variety of samples by neutron activation. One drawback of this technique is the necessity of measuring the activation constants (1) for each gamma-ray peak, detector, and counting position used. Our gamma-ray library contains 2000 peaks and we are using 4 different detectors with 3 or more counting positions. This means that there are 24 000 values to be determined – a life-long endeavour. In order to eliminate this tedious work we started 2 years ago to develop an "absolute" method. This technique consists of absolute gamma-ray measurement and direct calculation of weights or concentrations from nuclear constants. Such a technique had been used earlier (2, 3) but, judging from the number of researchers which were using this method, it did not enjoy wide acceptance by neutron activation analysts, we believe, mostly because of the limited accuracy of the nuclear data (cross sections, isotopic abundances, etc.) at that time. This method was given a new impetus with the introduction of the $k_0$ standardization method (4, 5). Presently, the nuclear constants are much more reliable, which should rekindle a new interest in this technique. In this paper, the demonstration of the capability of this rejuvenated standardization method is described.

## Theory

In the absolute method, the weight $W$ of the element of interest is calculated from the corresponding gamma peak area $A$ using eq. [1]:

$$[1] \quad W = \frac{MA\lambda}{NF\sigma IG\eta\,(1 - \exp(-\lambda t_i))\,(1 - \exp(-\lambda t_c))\exp(-\lambda t_d)}$$

where $M$ is the atomic weight of the element, $\lambda$ is the radioactive constant, $N$ is Avogadro's number, $F$ is the neutron flux, $\sigma$ is the reaction cross section, $I$ is the isotopic abundance of the target nuclide, $G$ is the abundance of the gamma-ray counted, $\eta$ is the absolute counting efficiency for a given gamma-ray energy, and $t_i$, $t_d$, $t_c$ are the irradiation, decay, and counting times. In this equation $M$, $\lambda$, $N$, $\sigma$, $I$, $G$ are nuclear constants and only the detector efficiency $\eta$ needs to be measured, for different energies and counting positions. About 20 experimental points are needed for each detector efficiency curve, which reduces the 24 000 measurements to 240. The advantage of such an approach is evident.

## Experimental

The efficiency curves were established by using a calibrated source of $^{60}$Co and sources with well known gamma-ray intensities, in our case $^{152}$Eu, $^{75}$Se, $^{182}$Ta, and $^{165}$Dy.

An example of two such efficiency curves is shown in Fig. 1.

For the next step, a computer program called ANAS (Absolute Neutron Activation with SLOWPOKE) was written.

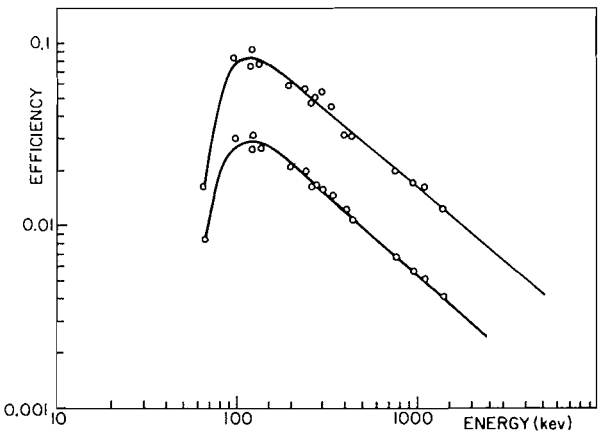

FIG. 1. Efficiency curves for the Ge(Li) detector at two sample–detector distances.

This program incorporates basic routines developed earlier (6) for the semi-absolute method but instead of activation constants it uses published nuclear data (7, 8) and the measured efficiency curves.

In order to assess the accuracy and precision of the absolute method, we applied this technique to two NBS standards: coal (SRM 1632a) and spinach (SRM 1570). Three aliquots of each of these standards were placed in 1 mL polyethylene vials and irradiated in the SLOWPOKE reactor for 30 s, 2 minutes, and 1 h with a neutron flux of $10^{11}$ or $10^{12}$ n/cm$^2$/s depending on the activity desired.

The decay times used vary from 20 s to 440 days and the irradiated capsules were counted for 30 to 30 000 s using a Ge(Li) detector with an active volume of 114 cm$^3$.

The counting positions were made reproducible by using plastic sample holders which keep the sample always at the same distance from the detector and on its axis.

## Results and discussion

Altogether 19 gamma-ray spectra were analyzed by the ANAS program and a large number of results were obtained. For some nuclides which emit gamma-rays of different energies, up to 16 values of the concentration were generated. These data were analyzed by another computer program which calculates an average and the standard deviation and where each value is weighted by the inverse of its statistical error.

Using these, it tries to identify subpopulations of results. If any can be found, it would indicate that at least some results are subject to a systematic error. The complete description of this program will be published later.

The final results are listed in Table 1; the values listed are the arithmetic means of the measured concentrations with the standard deviations of the measured values.

The results obtained agree reasonably well with the NBS certified values whenever these are available. A significant deviation from those values could be caused by a systematic error in the calibration curves and/or incorrect nuclear data. Since the differences are small, one can conclude

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

that these factors do not affect significantly the accuracy of the method for the samples studied and that the nuclear data used are of high quality.

The precision of the absolute method is somewhat lower than the precision obtained in the same conditions by the semi-absolute or relative methods. This is due mainly to the coincidence effects for certain gamma-rays. Some nuclides emit two gamma-rays in cascade. One such example is $^{56}$Mn with 1811 and 846 keV gamma-rays which can penetrate simultaneously into the detector and produce a sum pulse. Consequently, the concentration calculated from cascade gamma-rays will be lower than the real concentration because the counting efficiency is lower than the tabulated one. This effect diminishes with greater sample-to-detector distance but the sensitivity is also reduced, so it is better to apply corrections to the results. This problem was discussed by Crouthamel (9) and Girardi *et al.* (3).

On the other hand, when a peak with energy equal to the sum of the energies of cascade gamma-rays is used, the calculated concentration will be too high and hence corrections must also be applied.

Another fact that can affect the precision of the method is an error in the slope of the calibration curves. A small deviation in that slope can produce two different concentrations calculated from two peaks of the same radioisotope.

Matrix effects such as self-shielding and self-absorption can yield erroneous results and the method, as described, applies only to samples which are relatively transparent to neutrons and gamma-rays. We plan to take into account these two effects in a subsequent version of ANAS.

The method is valid for a standard sample volume of 1 mL and the sample shape which is determined by the inner dimensions of the irradiation vials. These have a diameter of 8 mm and height of 20 mm; for a different sample shape or volume counting geometry corrections would also be needed.

Despite these drawbacks, the absolute method can be a valuable tool in neutron activation analysis, particularly in conjunction with a very stable nuclear reactor such as SLOWPOKE. When this reactor is used, it is not necessary to measure the neutron flux for each irradiation, since it is very stable.

The irradiation positions in the reactor are very reproducible because of its design which is based on the pneumatic transport and gravity positioning of samples. This feature combined with negligible axial and small longitudinal variations of the neutron flux, makes SLOWPOKE a very suitable reactor for absolute neutron activation.

## Conclusion

The absolute method was used with accuracy ranging from −18 to +21% to determine nondestructively 22 elements in two NBS standards. This technique in conjunction with neutron activation constitutes a useful analytical tool by reducing considerably the number of tedious measurements which would be otherwise necessary. By better characterization of counting particularities of this method of standardization (gamma-ray coincidence), precision similar to that which is presently attainable with the semi-absolute or relative methods should be achievable. A very stable nuclear reactor such as SLOWPOKE is distinctly preferable for this technique.

*Ab initio* Hartree–Fock–Slater molecular orbital calculations on the planar tetrasulphur tetranitride dication $S_4N_4^{2+}$ reveal that it can be described as a fully delocalised 10 π-electron system. Overlap populations for the NS bonds suggest a bond order substantially stronger than in neutral $S_4N_4$. The strong uv/visible absorptions observed for $S_4N_4^{2+}$ at 346 and 262 nm are assigned to $n\pi_S \rightarrow \pi^*$ and $n\pi_N \rightarrow \pi^*$ excitations. The Hartree–Fock–Slater π-molecular orbital manifold is discussed in relation to simple HMO concepts.

MILAN TRSIC, WILLIAM G. LAIDLAW et RICHARD T. OAKLEY. Can. J. Chem. **60**, 2281 (1982).

Des calculs *ab initio* d'orbitales moléculaires de Hartree–Fock–Slater sur les dications planaires de tétraazoture de soufre, $S_4N_4^{2+}$, révèlent qu'on peut décrire ce cation comme étant un système pleinement délocalisé à 10 électrons π. Le recouvrement de populations des liaisons NS suggère un ordre de liaison substantiellement plus fort que dans le composé neutre $S_4N_4$. On attribue les fortes absorptions uv/visible observées pour le $S_4N_4^{2+}$ à 346 et 262 nm à des excitations $n\pi_S \rightarrow \pi^*$ et $n\pi_N \rightarrow \pi^*$. On discute des multiples d'orbitales moléculaires π de Hartree–Fock–Slater en relation avec des concepts simples de OMH.

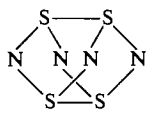
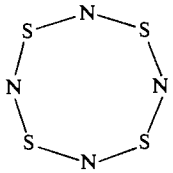
## Introduction

The unusual cage-like structure of tetrasulphur tetranitride **1** has long been of central interest in the study of binary SN species. A little over a decade ago Gleiter presented an intuitively appealing rationalization of its molecular structure by considering the π-system of an idealised planar $S_4N_4$ ring **2**



**1**



**2**

(1). In this view the 12 π-electron ground state of **2** would be orbitally degenerate and, as such, unstable with respect to Jahn–Teller distortion. Of the several possible symmetry changes that will break the orbital degeneracy of the ground state, the $D_{2d}$ conformation is the most attractive since, in the extended Hückel description, two antibonding π-MO's of **2** would be converted into cross-ring S—S σ-interactions. With the discovery of the planar $S_4N_4^{2+}$ dication in 1977 by Gillespie and co-workers (2), the structure/bonding relationships of Gleiter were strengthened. Implicit in his original analysis was the concept that a planar $S_4N_4^{2+}$ system, with 10 π-electrons, would be stable. In 1978, Michl recognized the spectroscopic consequences of such a π-electron distribution, and predicted the appearance of the MCD spectrum of $S_4N_4^{2+}$ (3). Very recently Sharma, Aubke, and Paddock have provided a specific and quantitative molecular orbital analysis of the $S_4N_4^{2+}$ species (4). Their extended Hückel and CNDO calculations yield orbital eigenvalues and Mulliken overlap populations which are crucial to the understanding of the system. Although these studies have enhanced our knowledge of the electronic make-up of $S_4N_4^{2+}$, it nevertheless has seemed appropriate to us to undertake an investigation of the species at the *ab initio* level. Our Hartree–Fock–Slater (HFS) calculations not only provide a confirmation, within the *ab initio* context, of many of the concepts developed by previous workers, but also allow the prediction of electronic excitation and total energies. In addition, a more detailed analysis of the charge density distribution and overlap populations permits a discussion of the HFS results in terms of elementary considerations of electronegativity and simple Hückel MO theory.

## Theoretical method

The Hartree–Fock–Slater method has been well documented in the literature, and efficient procedures for its implementation have been outlined and tested extensively by Baerends and co-

workers (5). Our application of the method to a variety of $S_xN_y^{z\pm}$ cages (6), rings (7), and chains (8) has provided satisfactory results. The calculations reported here were carried out using a single determinant closed shell state function and the double ζ basis of Clementi and Roetti (9) augmented with a sulphur 3*d* orbital with exponent 1.68 (10). Throughout the SCF calculations the core electrons were kept "frozen" in the manner described by Baerends and co-workers (11). An idealized planar $D_{4h}$ geometry with $d$(S—N) = 1.545 Å, $\hat{S}$ = 120°, and $\hat{N}$ = 150° was assumed for $S_4N_4^{2+}$. These parameters represent an average of those observed in a variety of $S_4N_4^{2+}$ salts (2*b*).

## Results and discussion

*Orbital energy levels*

The HFS molecular orbital energies (eigenvalues), atomic charges, and Mulliken overlap populations calculated for $S_4N_4^{2+}$ are shown in Table 1. Figure 1 illustrates the upper energy levels of the valence shell of $S_4N_4^{2+}$ along with the corresponding levels for the neutral $S_4N_4$ molecule (6). Since the representations $a_{2u}$, $b_{1u}$, $b_{2u}$, and $e_g$ are antisymmetric with respect to the molecular plane, it is clear that the ground state of the $S_4N_4^{2+}$ dication is a 10 π-system in our *ab initio* calculations. The calculated atomic charges on sulphur (0.69) and nitrogen (−0.19) indicate that the positive charge resides primarily on sulphur, as expected on electronegativity grounds. However, an analysis of the σ- and π-electron distributions of $S_4N_4^{2+}$ shows that the transfer of electrons is entirely within the π-system; in the σ-system $\rho_S^\sigma = \rho_N^\sigma = 4.0$, while for the π-MO's $\rho_S^\pi = 1.31$ and $\rho_N^\pi = 1.21$.[2] Thus if one arbitrarily assumes that 0.5 electron is lost from each sulphur atom in the ionization process $S_4N_4 \rightarrow S_4N_4^{2+} + 2e$ (1, 2), then an additional transfer of ~0.2 π-electron occurs during the formation of the $S_4N_4^{2+}$ π-bonding network.

The total NS overlap population of 0.61 is significantly larger than in $S_4N_4$ (0.49) and illustrates the strengthening of the skeletal bonds caused by oxidation of the neutral molecule (cf. NS → $NS^+$ + e effects the removal of a π*-electron and increases the net NS bond order from 2.5 to 3 (12)). Analysis of the orbital overlap populations reveals a π-contribution of 0.26 (approximately ½ of a π-bond), which is clearly larger than in $S_3N_3^-$ (0.16). By contrast, the σ-contributions for both species (0.35 in $S_4N_4^{2+}$ vs. 0.36 in $S_3N_3^-$) are almost identical.

[2]The lack of polarity in the σ-framework imparts to it a pseudo $D_{8h}$ symmetry. Thus several energy levels (e.g., $1b_{1g}$ and $1b_{2g}$) are approximately degenerate.

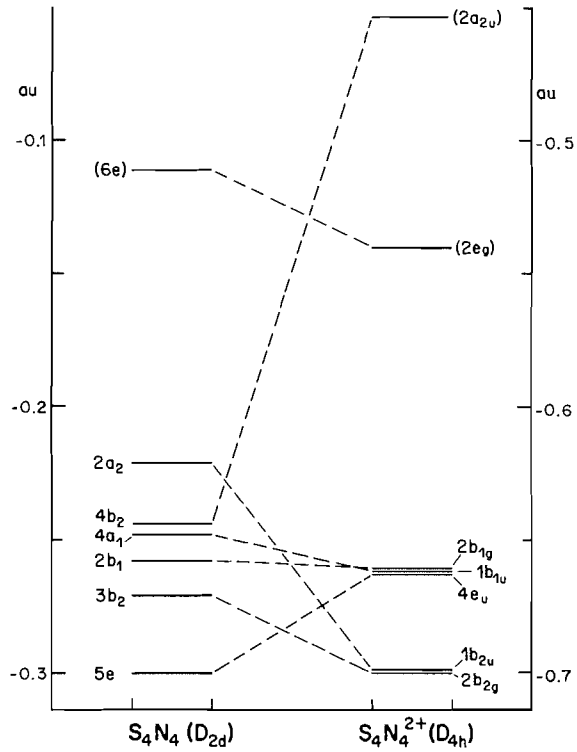

FIG. 1. Correlation diagram between the upper part of the energy level stack of $S_4N_4$ ($D_{2d}$) and planar $S_4N_4^{2+}$ ($D_{4h}$). Virtual orbitals are indicated by parentheses.

Thus the stronger bond in $S_4N_4^{2+}$ ($d$(S—N) = 1.53–1.57 Å) compared to $S_3N_3^-$ ($d$(S—N) = 1.58–1.62 Å) can be attributed to the strengthened π-network of the former, i.e. there are fewer occupied anti-bonding levels. Gillespie and co-workers (2*b*) have suggested the presence of a partial π-bond between nearest neighbour sulphurs, but little or no cross-ring interaction. However, our calculations indicate that there is essentially zero overlap between adjacent and remote pairs of sulphur atoms. Indeed, the highest occupied π-orbital $1b_{1u}$, which would presumably be a candidate for 1,3-SS-overlap in a valence bond approach, is strongly localised on sulphur, and the very weak overlap population that it has is anti-bonding in character.

Comparison of the HFS energy levels with the CNDO results of Paddock and co-workers reveals major similarities. In both cases there is a sulphur lone pair orbital $1b_{1u}$ at the Fermi surface (because of the choice of axes their subscripts 1 and 2 on the $b_u$ and $b_g$ representations are interchanged with ours), and at somewhat lower energy lies a nitrogen lone pair orbital $1b_{2u}$. The remaining occupied π-orbitals $1a_{2u}$ and $1e_g$ are well buried in the upper σ-levels and the two lowest unoccupied levels are the π-orbitals $2e_g$ and $2a_{2u}$. Perhaps the major distinction between the CNDO results and ours is the accumulation of several energy levels near the Fermi surface in the HFS case. This grouping of lone pair and antibonding orbitals at the top of the filled energy level stack seems typical of *ab initio* calculations on SN compounds.[3] This difference in the position of the σ-energy levels is reflected in a somewhat different characterization of the σ-orbitals themselves. We find a total of eight σ-bonding orbitals $1a_{1g}$, $1a_{2g}$, $1b_{1g}$, $1b_{2g}$, $1e_u$, and $2e_u$, with the eight remaining σ-orbitals divided between five lone pairs ($2a_{1g}$, $2b_{1g}$, $2b_{2g}$, and $3e_u$) and three anti-bonding orbitals ($3a_{1g}$ and $4e_u$). This description is reminiscent of Gillespie's characterization (2*b*) of the σ-system into eight bonding pairs and eight lone pairs (valence bond parlance does not recognize anti-bonding orbitals), but is in contrast to the CNDO picture of a dozen σ-bonding orbitals (4).

### Ab initio *vs. Hückel MO description*

Partitioning of the electrons of planar ring systems into σ- and π-networks, as we have done above, has a long history in carbocyclic systems, and retains its appeal in the present context. Indeed, the implications of simple Hückel molecular orbital (HMO) theory pervade much of the current understanding of the π-structure of cyclic SN systems. In any HMO treatment of the π-system of a cyclic molecule of general formula $(AB)_n$, the energy levels of the system are given by the roots of the secular determinant (14):

$$\begin{vmatrix} \alpha_A - E & 2\beta \cos l\pi/n \\ 2\beta \cos l\pi/n & \alpha_B - E \end{vmatrix} = 0$$

where $l = 0, \pm 1, \pm 2, \cdots \pm (n-1)/2$ ($n$ odd)

$l = 0, \pm 1, \pm 2, \cdots \pm n/2$ ($n$ even)

However, the form of the MO's will depend critically on the values of the Coulomb parameters $\alpha_A$ and $\alpha_B$, their relative magnitudes reflecting the electronegativity difference between the A and B sites. In sulphur–nitrogen rings, the choice of $\alpha_S$ and $\alpha_N$ is not obvious. Gleiter (1, 15) has proposed "a higher electronegativity of nitrogen compared to sulphur" (i.e. $\alpha_N < \alpha_S$) and refers to the atomic electronegativity scale of Pauling (16). By contrast, Gimarc and Trinajstić (17) have pointed out the potential applicability of the orbital electronegativities proposed by Streitweiser (18) (i.e. $\alpha_N > \alpha_S$). From our *ab initio* calculations (and from Paddock's CNDO work) it is apparent that the sulphur

[3]See, for example, our own results (6) and those of Palmer *et al.* (13) for $S_4N_4$.

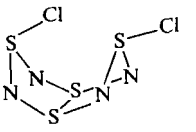
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

lone pair π-orbital $1b_{1u}$ lies above the corresponding nitrogen-based orbital $1b_{2u}$. From this energy level ordering one would conclude that nitrogen is more electronegative than sulphur ($\alpha_N < \alpha_S$). However, upon examination of the HFS π-electron density distribution, one finds (as mentioned earlier) a greater π-charge on sulphur ($\rho_S^\pi = 1.31$) than on nitrogen ($\rho_N^\pi = 1.21$). At the HMO level such a result can only be reproduced by choosing Coulomb parameters such that $\alpha_S < \alpha_N$, i.e. a sulphur which is more electronegative than nitrogen.

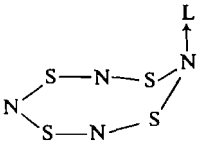
It is therefore apparent that the π-MO's of $S_4N_4^{2+}$ respond to a potential field that cannot be modelled by a single Hückel parameterization. This is not really surprising insofar as the lower π-levels are well buried in the stack and consequently sense a potential more characteristic of the core. By contrast the higher lying and more diffuse frontier orbitals $1b_{2u}$ and $1b_{1u}$ and the virtual levels $2e_g$ and $2a_{2u}$ see a potential which is more characteristic of a complete nitrogen and sulphur valence shell, for which the atomic electronegativity scale (i.e. $\alpha_N < \alpha_S$) is more appropriate. Simple Hückel concepts must therefore be used with caution. However, bearing this caveat in mind, useful information can be obtained by a suitable choice of parameters. If properties such as π-charge densities are desired, the *ab initio* charge distribution is best described at the Hückel level by setting $\alpha_S < \alpha_N$. However, if information concerning the composition and ordering of the frontier orbitals is required, as would be the case in the study of pericyclic reactions, the ratio $\alpha_S > \alpha_N$ will provide more meaningful results.

*Ionization of $S_4N_4$*

Before leaving the discussion of the molecular orbitals of $S_4N_4^{2+}$ we should comment on the proposition (1, 4, 15) that ionization of $S_4N_4$ to $S_4N_4^{2+}$ involves the $2a_{2u}$ orbital. Certainly this orbital has SS-bonding character in $S_4N_4$; removal of electrons from it would weaken the cross-ring interaction and could lead to the formation of a planar $S_4N_4^{2+}$. This concept is consistent with Fig. 1, which shows that the $2a_{2u}$ orbital of $S_4N_4^{2+}$, to which the $4b_2$ orbital of $S_4N_4$ has evolved, is noticeably destabilized. However, such a description has certain shortcomings. For example, upon oxidation of $S_4N_4$ with chlorine to give $S_4N_4Cl_2$, **3**, one of the S—S bonds of $S_4N_4$ is retained (19). As we have already noted, $S_4N_4$ itself has several orbitals located very near the surface which could be involved in the attack of electrophiles (e.g. $Cl^+$), and the retention of the cage shape in $S_4N_4Cl_2$ implicates the use of orbitals other than the $4b_2$ in the formation of the S—Cl σ-bonds. The structures of the Lewis acid adducts of $S_4N_4$, e.g. $S_4N_4.L$ (**4**, $L = BF_3$ (20), $SbCl_5$ (21), $FeCl_3$ (22), $AsF_5$ (23), $SO_3$ (24)) also pose an interesting question. Adduct formation through nitrogen effects structural changes similar to those caused by ionization, i.e. both cross-ring S—S bonds are lost, but it is hard to conceive of the $4b_2$ orbital being significantly perturbed by the N → L interaction. Instead the nitrogen lone pairs $2b_1$ and $4e$ seem more likely candidates for adduct formation.



3



4

In order to understand better the thermodynamics of the structural change which occurs upon the ionization of $S_4N_4$, we have calculated the energy of the $S_4N_4^{2+}$ cage ($D_{2d}$) formed by removing the two electrons from one of the three uppermost orbitals of $S_4N_4$: $2a_2$, $4a_1$, and $4b_2$. Although we have had difficulty in obtaining a fully converged state in the case of an empty $4b_2$ orbital, the energy of all of these cage dications is over 100 kcal/mol above that of the planar form. This rather significant stabilization of the latter reflects the energetic importance of the well developed π-system found in it. The high π-bond energy achieved in the planar structure is more than sufficient to offset the loss of cross-ring SS-bonding (25).

*Electronic spectrum of $S_4N_4^{2+}$*

The uv/visible spectrum of $S_4N_4^{2+}$ contains two major peaks with $\lambda_{max}$ at 346 and 262 nm (4). There is also a small shoulder near 300 nm on the latter peak. In order to assign the electronic excitations responsible for these absorptions we have calculated the oscillator strengths[4] of all symmetry-allowed transitions which correspond to a $\lambda_{max} > 200$ nm. Of these the $1b_{1u}$ ($n\pi_S$) → $2e_g$ ($\pi^*$) and $1b_{2u}$ ($n\pi_N$) → $2e_g(\pi^*)$ are dominant (see Table 2). There is in addition another allowed transition $4e_u$ ($\sigma^*$) → $2e_g$ ($\pi^*$) which has an oscillator strength of about 1% of the two major absorptions. The calculated energies[5] for the two intense transitions are 334 nm ($1b_{1u}$ → $2e_g$) and

[4]The dipole length – dipole velocity formula was employed for the calculation of transition moments. See ref. 26.

[5]Excitation energies have been obtained by adding 0.4 eV to the corresponding one-electron energy differences; this correction reproduces well the total energy differences calculated by the more expensive, and exact, transition state method (27) we used in refs. 7, 8. Theoretical and numerical justification for this correction will be published elsewhere.

TABLE 2. Electronic spectrum of $S_4N_4^{2+}$

| Transition | Polarization | $\lambda_{max}$ (nm) Observed[a] | $\lambda_{max}$ (nm) Calculated | Calculated oscillator strength (au) |
|---|---|---|---|---|
| $1b_{1u} \rightarrow 2e_g$ | Molecular plane | 346 | 334 | $2 \times 10$ |
| $4e_u \rightarrow 2e_g$ | $C_4$ axis | 300 | 331 | $1 \times 10^{-1}$ |
| $1b_{2u} \rightarrow 2e_g$ | Molecular plane | 262 | 262 | $1 \times 10$ |

[a]From ref. 4.

262 nm ($1b_{2u} \rightarrow 2e_g$), both of which compare remarkably well with the observed $\lambda_{max}$ values. The weak transition $4e_u \rightarrow 2e_g$ has a calculated energy of 331 nm, and we presume that the weak absorption near 300 nm corresponds to this excitation.

The above assignments provide theoretical confirmation of Michl's prediction for the MCD spectrum of $S_4N_4^{2+}$ (3). Treating $S_4N_4^{2+}$ as an 8-atom 10 $\pi$-electron perimeter one would expect two $\pi \rightarrow \pi^*$ transitions to be symmetry-allowed. These are indeed the two excitations which, according to our calculations, dominate the electronic spectrum. Both transitions give rise to a degenerate excited state and, according to the perimeter model (3), should give rise to a pair of positive *A*-terms in the MCD spectrum.

## Summary

*Ab initio* Hartree–Fock–Slater molecular orbital calculations on the $S_4N_4^{2+}$ dication confirm the description of its electronic structure in terms of a fully delocalised 10 $\pi$-electron system. The preference for the planar form of $S_4N_4^{2+}$ over a cage structure can be rationalized in terms of the strong $\pi$-network of the former, which is more than sufficient to counterbalance the loss of cross-ring sulphur–sulphur bonding in the cage. The electronic spectrum of $S_4N_4^{2+}$ provides a classic example of an 8-atom 10 $\pi$-electron perimeter, the two intense uv/visible absorptions being assigned to $n\pi_S \rightarrow \pi^*$ and $n\pi_N \rightarrow \pi^*$ transitions.

# Diazonium salts in photochemistry. I. Quenching of triplet photosensitizers[1]

J. C. SCAIANO AND NGUYEN KIM-THUAN[2]

*Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received March 11, 1982

J. C. SCAIANO and NGUYEN KIM-THUAN. Can. J. Chem. **60**, 2286 (1982).

Aromatic diazonium tetrafluoroborates have been shown to be excellent triplet quenchers. Typical rate constants obtained using laser flash photolysis are in the $1-10 \times 10^9 M^{-1} s^{-1}$ range in acetonitrile at 300 K. With most sensitizers the interaction leads to the dediazoniation reaction, via either energy transfer or electron transfer mechanisms. In the case of anthracene, where the rate constant for benzenediazonium tetrafluoroborate is $(5.4 \pm 0.3) \times 10^9 M^{-1} s^{-1}$, the reaction involves the transfer of an electron, leading to the formation of anthracene radical-cation, which has been characterized by absorption spectroscopy. High energy sensitizers, such as benzophenone, are believed to lead to aryl cations and nitrogen; the process may involve some degree of charge transfer, since it is somewhat faster when electron donating substituents are present in the diazonium salt.

J. C. SCAIANO et NGUYEN KIM-THUAN. Can. J. Chem. **60**, 2286 (1982).

On montre que les tétrafluoroborates de diazonium aromatiques sont d'excellents pièges à triplet. Les constantes typiques de vitesse obtenues en utilisant la photolyse flash au laser sont de l'ordre de 1 à $10 \times 10^9 M^{-1} s^{-1}$ dans l'acétonitrile à 300 K. Avec la plupart des sensibilisateurs, l'interaction conduit à une réaction de perte d'une molécule d'azote par l'intermédiaire de mécanismes de transfert d'énergie ou de transfert d'électrons. Dans le cas de l'anthracène, où la constante de vitesse du tétrafluoroborate de benzènediazonium est de $(5{,}4 \pm 0{,}3) \times 10^9 M^{-1} s^{-1}$, la réaction implique le transfert d'un électron et conduit à la formation d'un cation radicalaire anthracène, que l'on a identifié par la spectroscopie d'absorption. On pense que les sensibilisateurs à haute énergie, tels la benzophénone, conduisent à des cations aryliques et à l'azote; la réaction peut impliquer un certain degré de transfert de charge puisqu'elle est en quelque sorte plus rapide quand des substituants électrodonneurs sont présents dans le sel de diazonium.

[Traduit par le journal]

## Introduction

The involvement of diazonium salts in photochemical reactions has been the subject of a number of studies (1–22); however, many fundamental aspects remain, at best, obscure. For example, we find that, while photosensitized processes have been examined in several systems (8, 10–12, 14, 17, 19, 21–23), only in the case of singlet pyrene have a few rate constants been determined (12).

We have recently started work on a project involving the study of the mechanism and kinetics of a wide range of photoreactions of diazonium salts. We find that the total lack of knowledge of quenching rates, particularly in the case of the triplet state, makes any serious analysis of reaction mechanisms virtually impossible. Most photosensitizers induce the loss of molecular nitrogen from the diazonium salt; however, several mechanisms can lead to this result. For instance, energy transfer can lead to an heterolytic mechanism involving the intermediacy of aryl cations. On the other hand, electron transfer can lead to homolytic pathways via diazenyl radicals which decompose to give phenyl radicals and nitrogen. The photoreduction of diazonium salts can take place via a direct electron transfer from the excited sensitizer in the primary photochemical step, or through the involvement of photogenerated radical intermediates. For example, with sensitizers such as benzophenone (21), it is necessary to establish whether the primary photoprocesses involve the solvent (in cases such as methanol) or a direct interaction of the triplet sensitizer with the diazonium salt.

This study was undertaken in order to examine the kinetics of the interaction of a variety of triplet sensitizers, covering a range of molecular structures and triplet energies, with a few diazonium tetrafluoroborates having representative ring substituents. Rate constants were measured using nanosecond laser flash photolysis techniques. In a few cases we have also been able to gather some information concerning the detailed nature of the interaction; while mechanistic aspects are still poorly understood, our experiments provide a glimpse at some of the details, and perhaps complications, that can be expected in these systems.

## Results

All the experiments reported herein have been carried out in deaerated solution, using the pulses from a nitrogen or, occasionally, an excimer laser for excitation. In each system a complete transient spectrum (usually 300 to 760 nm) was recorded in the absence of quencher, as well as in the presence

of sufficient diazonium salt to make decay-via-quenching the predominant decay mode. Kinetic measurements were carried out by monitoring T–T absorptions at or near the corresponding maximum.

A few preliminary experiments with representative sensitizers showed that the tetrafluoroborate anion (sodium salt) is a very poor quencher by comparison with the diazonium salts (*vide infra*). For example, experiments with benzophenone and anthracene in acetonitrile–water at 300 K led to $k_q = (1.5 \pm 0.7) \pm 10^7$ and $< 3.6 \times 10^5 M^{-1} s^{-1}$, respectively. Thus, the rate constants discussed below cannot be attributed to quenching by free tetrafluoroborate anion, with the possible exception of benzil.

When attempting to carry out experiments on a variety of substituent and solvent effects, it is clear that all possible combinations cannot be examined, and little would be gained by trying to do so. Our systems were selected so that the quenching of all sensitizers used by the "parent" substrate, benzenediazonium tetrafluoroborate, was examined. The sensitizers used were mostly the same employed in other studies from this laboratory (24, 25); this should make the comparison of diazonium salts with other quenchers readily available. Substituent effects were examined mostly using benzophenone and anthracene as sensitizers. Acetonitrile was used as a "base" solvent, with a few experiments in other media. Experiments were carried out either using a flow system or static samples; the former are definitely more accurate, but they are also far more time consuming.

The measurement of the rate constant for benzophenone triplet quenching by benzenediazonium tetrafluoroborate in acetonitrile at 300 K is the only one described in detail here; the same approach was followed in all other systems. A $0.014 M$ solution of benzophenone in acetonitrile was examined in the laser photolysis system using the nitrogen laser; the choice of laser was based on the favorable ratio of extinction coefficients at 337.1 nm, which makes selective excitation of benzophenone possible. The transient spectrum (at 5 nm intervals) recorded immediately following the laser pulse was in full agreement with that reported for the benzophenone triplet (26) and which had already been recorded numerous times in our laboratory. When the full laser dose was used for excitation, the decay of the triplet, monitored at 525 nm, followed mixed first and second order kinetics, the latter reflecting triplet–triplet annihilation. Usage of suitable neutral density filters to attenuate the excitation laser dose led to predominant first order decay. The diazonium salts proved to be excellent quenchers, and in their presence the decay of the triplet followed clean pseudo-first order kinetics, with rate constant $k_{obs}$ given by:

[1] $$k_{obs} = \tau_0^{-1} + k_q[DS]$$

where $\tau_0$ is the triplet lifetime in the absence of quencher, $k_q$ is the rate constant for triplet quenching, and [DS] the concentration of diazonium salts. Figure 1 shows a plot according to eq. [1] and the insert a representative decay trace. As in most of the systems examined, the spectrum in the presence of diazonium salt, and after triplet decay was complete, was also recorded. A residual signal was detected at 375 nm. This signal is not due to benzophenone radical-cation and could be due to nitrylium ion (15), but it has not been characterized in detail yet. We note that in most cases these studies are limited to wavelengths at least 10 nm longer than that of the laser used for excitation, since most samples are not transparent at shorter wavelengths.

One exception to the problems mentioned above is the case of xanthone, which is strongly absorbing at 337 nm, but presents a window in the 300 nm region. For example, in the xanthone – *p*-methoxybenzenediazonium tetrafluoroborate system, it is possible to observe the bleaching of the quencher. Figure 2 illustrates this effect; the top part shows the decay of the triplet ketone, while the bottom part shows that the destruction of the diazonium salt is concurrent with the quenching process. At 300 nm the diazonium salt and triplet xanthone have significant absorption.

Another system where it is possible to monitor the bleaching of the diazonium salts is in the case of *p*-diethylaminobenzenediazonium tetrafluoroborate, where the absorption maximum is located at ~380 nm. Experiments with benzophenone showed, as in the case of xanthone described above, that bleaching of the quencher occurs concurrently with triplet decay.

Another type of transient phenomena that one can hope to detect in experiments of this type is the transfer of an electron from the sensitizer to the diazonium salt, i.e., reaction [5],

[2] $$S^* \xrightarrow{k_d} S$$

[3] $$S^* + DS \xrightarrow{k_3} S + DS$$

[4] $$S^* + DS \xrightarrow{k_4} S + Ar^+ + N_2$$

[5] $$S^* + DS \xrightarrow{k_5} S^{+\cdot} + Ar^\cdot + N_2$$

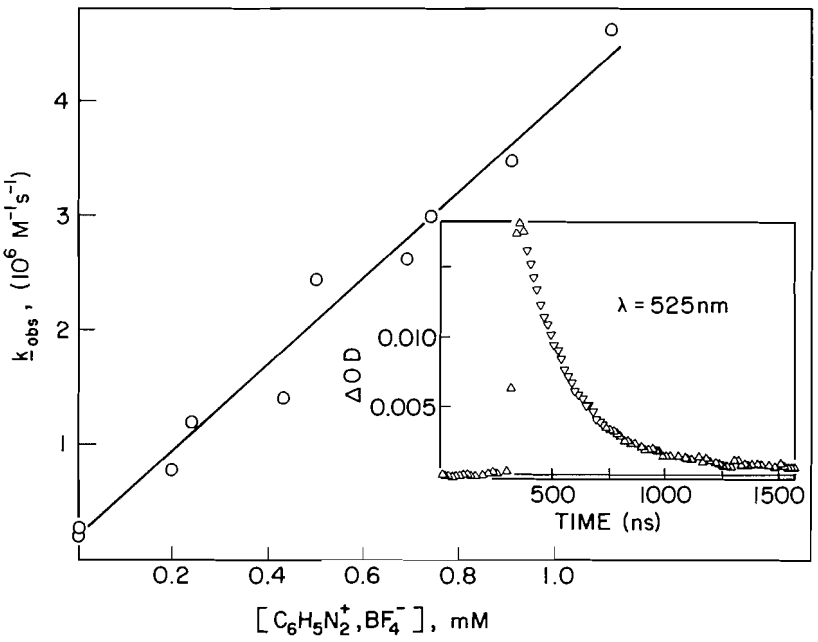

FIG. 1. Quenching of benzophenone triplets by benzenediazonium tetrafluoroborate in acetonitrile at 300 K, according to eq. [1]. *Insert*: Decay of benzophenone triplet monitored at 525 nm in the presence of 1.12 m*M* diazonium salt.

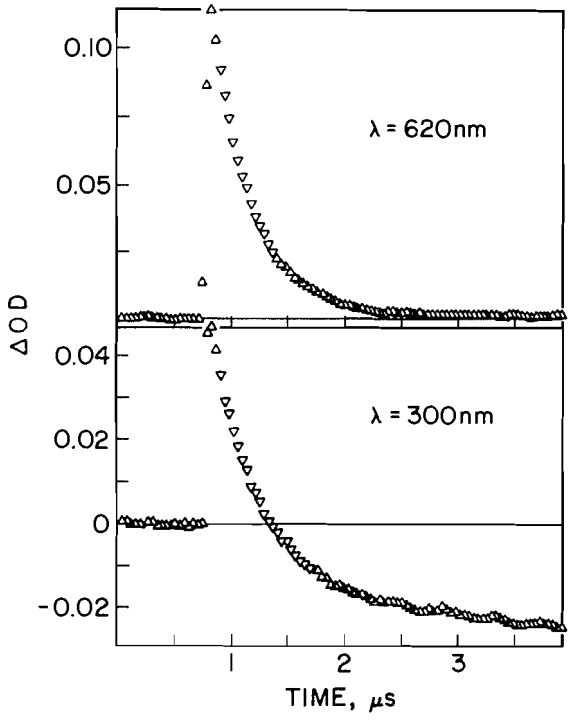

FIG. 2. Transient phenomena observed in the xanthone – *p*-methoxybenzenediazonium tetrafluoroborate (0.26 m*M*), monitored at two different wavelengths. *Top*: Decay of the triplet state. *Bottom*: Triplet decay with concurrent bleaching of the diazonium salt. The slow bleaching at the tail of this trace may be due to relatively minor free radical processes induced in this system.

where S* stands for triplet sensitizer, and reactions [3]–[5] have been written as a single step for simplicity. In fact, reactions [3] and [4] may involve an electronically excited diazonium salt, while reaction [5] probably involves a diazenyl radical (12, 27), which then loses molecular nitrogen. Further, the aryl cation produced in reaction [4] may not be initially in its ground state since, depending upon substitution, these may have singlet or triplet ground states (28, 29).

Occurrence of reaction [5] should lead to the formation of sensitizer-derived radical-cations. This has been observed in the case of anthracene, where the radical-cation shows a very characteristic absorption band at 720 nm (30). Figure 3 shows the transient spectra recorded before significant triplet decay and after the decay (predominantly via quenching) was complete. Time resolved studies showed that the formation of anthracene$^{+\cdot}$ occurred concurrently with triplet decay. From a knowledge of the extinction coefficients of the triplet state (31) and the radical-cation (30) it is possible to estimate the yield of the latter. From an estimated ratio of extinction coefficients of 4 or 5 (triplet-to-radical-cation, at the corresponding maxima (30, 31)), we estimate that the yields of electron transfer are close to quantitative in acetonitrile at 300 K, for benzene- and *p*-methoxybenzenediazonium tetrafluoroborates. It should be noted that estimates are not quantum yields, but rather, the fraction of quenching events that lead to

TABLE 1. Quenching of triplet sensitizers by diazonium tetrafluoroborates at 300 K

| Sensitizer ($E_T$)[a,b] | Diazonium salt[c] | Solvent | $\lambda_{ex}$, $\lambda_{mon}$, method[d] | $k_q$, $M^{-1}$ $s^{-1}$[e] |

complete electron transfer, i.e.,

$$[6]\quad \text{yield of radical-cation} = \frac{k_5}{k_3+k_4+k_5}$$

Other systems where the detection of $S^{+\cdot}$ could have been expected to be simple are the cases of phenanthrene and pyrene. For the former we could not detect any significant concentrations of radical-cation, suggesting that reaction [5] is unimportant.

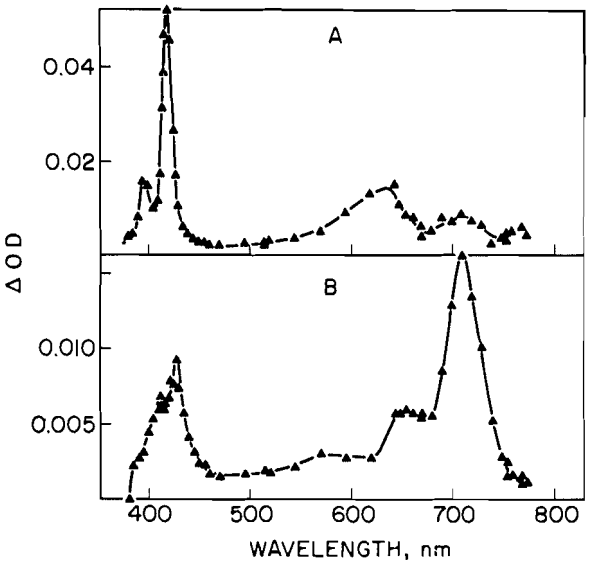

FIG. 3. Transient spectra recorded in the anthracene – *p*-methoxybenzenediazonium tetrafluoroborate (0.88 m*M*) in acetonitrile at 300 K. *Top*: Immediately after laser excitation. *Bottom*: 2.5 μs after excitation.

In the case of pyrene, the radical-cation can be detected, but the problem is complicated by the efficient biphotonic ionization of pyrene (32). This problem can be reduced by working at very low excitation doses, although this leads to a decrease in the signal-to-noise ratio. After a detailed study of the yields of radical cations as a function of laser dose, our conclusion is that $pyrene^{+\cdot}$ is formed rather inefficiently and that some of this radical-cation may in fact be the result of singlet quenching as suggested by Becker *et al.* (14), although overall ion formation is rather inefficient.

We have also carried out a detailed study of the uv–vis spectra of sensitizer – diazonium salt mixtures, since it has been reported that these systems can form electron donor–acceptor complexes (12). Typical equilibrium constants at 293 K in acetonitrile are somewhat below $1\,M^{-1}$ (e.g. for pyrene, anthracene, and phenanthrene). Our studies indicate no complex formation under the conditions of our experiments, typically involving both reagents in millimolar (and occasionally lower) concentrations.

## Discussion

The data in Table 1 clearly show that diazonium tetrafluoroborates are, in most cases, excellent triplet quenchers. Our studies using sodium tetrafluoroborate show that this property reflects the

behaviour of aryldiazonium cations, since the anion, $BF_4^-$, shows only very inefficient quenching. Our results also indicate a true intermolecular process, since complex formation has been shown to be unimportant in these systems.

The only example where the anion is likely to play a role is the case of benzil, where the quenching process is quite slow. The result is perhaps not surprising; benzil has a tendency to show very peculiar behaviour as a sensitizer (24), and it has been suggested that this may be the result of the dramatic structural differences between the ground and triplet states (24).

While one could be tempted to try to offer a comprehensive explanation for the triplet quenching mechanism, this seems rather difficult in view of the rather contradictory spectroscopic evidence on the triplet level of the diazonium compounds. For example, Zharkov and Kondratenko (33) have studied the absorption spectra of *para*-substituted benzenediazonium salts between 4.2 and 300 K; they claim that the long wave edge of the main absorption band is due to absorption to the lowest triplet level, which is a predissociative state. If this is correct, then one can expect the mechanism of triplet quenching to be similar to that proposed in the case of peroxides (24, 34), involving the transfer of energy to a dissociative state of the acceptor. The spectroscopic evidence does not seem consistent with the observation by Sukigara *et al.* (6) of well defined triplet phosphorescence in the case of the unsubstituted substrate, benzenediazonium tetrafluoroborate, with $\lambda_{max} = 412$ nm (77 K). Our own evidence indicates that if excited triplet diazonium salts are formed at all in solution at room temperature, their lifetimes must be extremely short, probably in the subnanosecond range, since the diazonium salt is bleached concurrently with triplet decay (see Fig. 2) and no new transients are observed following it. This is true of all systems examined, including 1-naphthalenediazonium tetrafluoroborate, where the presence of the naphthalene chromophore could be expected to lead to easily detectable triplets.

Our data suggest that electronic effects (see *para*-substituted substrates in Table 1) do not play a major role in determining the rate constants for triplet quenching, while steric effects (see *o*-toluene diazonium data in Table 1) could be of importance. Some small electronic effects are in fact observable; for example, in electron transfer processes, as is the case for anthracene triplet, the rate for benzenediazonium ion is ~2.3 faster than for the methoxy substituted derivative, while in the case of the electrophilic benzophenone triplet the situation is reversed. Solvent effects do not seem extensive; only water seems to reduce significantly the rate constants, at least in the case of xanthone. Futher studies in this area are certainly needed.

While it may be tempting to use free energy relationships to further interpret the data, these may be of very limited applicability in many of these systems. The majority of the rate constants measured are close to diffusion controlled, a fact that will tend to mask substituent effects. Further, some of the more informative substituents (such as nitro) can lead to enough absorption at the excitation wavelength (35) to make selective sensitizer excitation difficult, and ground state complex formation a definite possibility.

In the case of the sensitizers examined, we believe that the most common pathway is probably the fragmentation of the diazonium salt according to reaction [4], which occurs concurrently with the decay of the triplet sensitizer. Figure 2 illustrates this effect.

Full electron transfer from the sensitizer triplet seems to be a less common process, observed as an efficient reaction in the case of anthracene and to some degree in pyrene. It is possible that reaction [5] will be a favoured process for triplets with relatively low triplet energy and substantial electron donor ability. Naturally, anthracene is precisely a good representative of this group.

While electron transfer may not be a common pathway with high energy sensitizers, charge transfer may play a role in the transition state during the quenching process. As pointed out earlier, the reactivity changes observed in the case of benzophenone point in this direction; even the intermediacy of an exciplex is a definite possibility. Many sensitizers can form electron donor–acceptor complexes with the diazonium salts under favorable conditions (14), and this property is expected to be enhanced in the excited state.

Finally, as pointed out above, we have observed residual absorption signals in a number of systems after the quenching event and triplet decay are complete. Benzophenone and xanthone are two examples of this behaviour; these signals are likely to arise from reactions of aryl cations or of transients derived from them. The complete characterization of these species is beyond the scope of this report, but we hope to undertake the detailed study of some of these problems in the near future.

## Experimental

*Materials*

*p*-Diethylaminobenzenediazonium tetrafluoroborate was an Aldrich product, and was purified by recrystallization from acetonitrile by precipitation with ether. All other diazonium compounds were prepared from the corresponding amines by

standard procedures (36) and purified as indicated above. The solid samples were stored at −20°C, and freshly prepared solutions were used in the experiments.

*Spectra*

The uv–vis spectra of the samples were recorded in Varian 219 or Hewlett Packard 8450-A spectrometers.

*Laser flash photolysis*

The samples (under oxygen-free conditions) were excited with the pulses from a Molectron UV-24 nitrogen (337.1 nm, ~8 ns, up to 10 mJ) or a Lumonics TE-860-2 excimer (308 nm with Xe/HCl mixtures, ~4 ns, up to 80 mJ) laser. The samples were contained or flowed through Suprasil cells. In the case of the excimer laser the optical path was 7 mm and a flow system was essential because of its high power. In the case of the nitrogen laser the energy per pulse is considerably less and fresh static samples were, in some cases (see Table 1) regarded as acceptable; in these experiments the optical path was 3 mm. The signal from an RCA-4840 photomultiplier tube was terminated into 93 ohms. Each trace was initially stored in an R7912 Tektronix transient digitizer, and later transferred to a PDP 11/23 computer which controlled the experiment and provided suitable processing, storage, and hardcopy facilities. Further details have been given elsewhere (37).

# The total, stereocontrolled synthesis of a chemical precursor to (+)-thienamycin. A formal synthesis of the antibiotic[1]

STEPHEN HANESSIAN, DENIS DESILETS,[2] GEORGES RANCOURT,[3] AND REJEAN FORTIN

*Department of Chemistry, University of Montreal, Montreal, Qué., Canada H3C 3V1*

Received May 7, 1982

STEPHEN HANESSIAN, DENIS DESILETS, GEORGES RANCOURT, and REJEAN FORTIN. Can. J. Chem. **60**, 2292 (1982).

A total synthesis of a key lactone intermediate in the synthesis of (+)-thienamycin is described, based on a strategy that uses "chiral templates" derived from D-glucose.

STEPHEN HANESSIAN, DENIS DESILETS, GEORGES RANCOURT et REJEAN FORTIN. Can. J. Chem. **60**, 2292 (1982).

Il s'agit de la description d'une synthèse globale d'un intermédiaire lactone principal dans la synthèse du (+)-thiénamycine qui s'étaye sur une stratégie qui utilise des "matrices chirales" dérivées du D-glucose.

[Traduit par le journal]

Thienamycin (1) and related naturally occurring compounds are new-generation β-lactam antibiotics which are endowed with unique structures (2) and unusually potent antibacterial activity (3). Synthetic efforts in this area, mainly by the Merck group, have resulted in a number of elegant contributions culminating with the total synthesis of the racemic (4), as well as optically active (5) antibiotic. A number of other groups (6), including one at Merck (7), have reported on other approaches to the chiral backbone (in racemic form) of this intriguing structure.

We wish to report on the total synthesis of an optically active six-carbon segment encompassing the functionality and chirality represented by the upper half of the molecule. Our synthesis is based on the recognition of *hidden carbohydrate-type symmetry* in the target (8) as illustrated by the analysis in Scheme 1. Thus, successive bond disconnection at the double bond (C-2—C-3) and the β-lactam function (N-4—C-7) generates a six-carbon β-amino acid which can be related to a "chiral template" derived from a carbohydrate (8). Our synthesis starts with D-glucose and converges on a known lactone which has been previously used in the total synthesis of the racemic antibiotic (7). With the decoding of the hidden symmetry in the target, as depicted in Scheme 1, it is clear that the generation of a segment which encompasses all three asymmetric centers entails systematic modification of the original carbohydrate framework. Consideration of the chemistry involved presents a unique challenge in devising a regio- and stereospecific method for incorporating a carboxyl group or its equivalent at C-4 (carbohydrate numbering).

The starting material **1** for our synthesis already contains a 2-deoxy function (C-1 of the target) and can be prepared in large quantities via crystalline intermediates from D-glucose (9)[4] (Scheme 2). Deoxygenation at the terminal position as well as introduction of the potential amino group were effected via the bromo derivative **2**, $[\alpha]_D$ +140.2° (10), to give compound **3**, $[\alpha]_D$ +133°[5] in excellent overall yield. Thus, the desired deoxygenation pattern as well as the necessary functionality with the correct sense of chirality corresponding to C-5 and C-8 of the target were achieved by virtue of the highly predictive nature of the transformations. We were now faced with the deceptively simple task of introducing a carboxyl group or its equivalent at C-4 of "template" **3**. This proved to be a challenging goal, which we were able to achieve by considering ketenedithioacetals as carboxyl equivalents (12). Thus, oxidation (13) of **3** afforded the azidoketone derivative **4** which was treated with the anion from *O*,*O*-dimethyl formylphosphonate

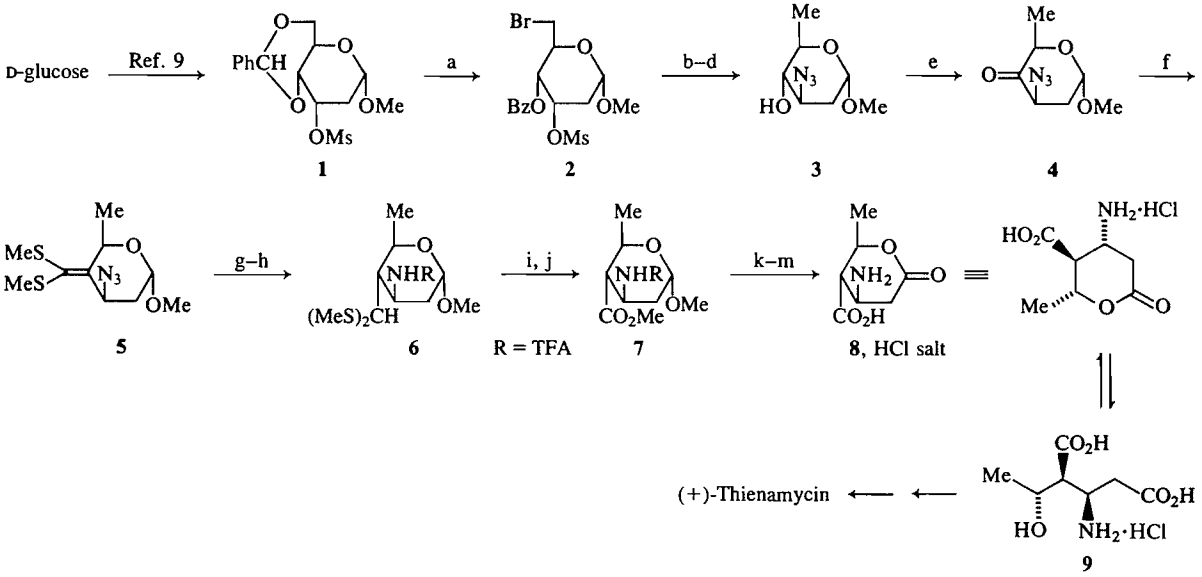

SCHEME 2. (a) NBS, $CCl_4$, $BaCO_3$, reflux, 95%; (b) Pd/C,$H_2$, EtOAc, 90%; (c) $n$-$Bu_4NN_3$, benzene, reflux, 85%; (d) NaOMe, MeOH, 93%; (e) pyridinium chlorochromate, $CH_2Cl_2$, 4 Å sieves, 95%; (f) $(MeO)_2POCH(SMe)_2$, BuLi, THF, −78°C → 25°C, 60%; (g) $LiAlH_4$, THF, 84%; (h) $(CF_3CO)_2O$, pyr., $CH_2Cl_2$, 87%; (i) $HgCl_2$, HgO, aqueous acetone, 76%; (j) $CrO_3$, acetone, $H_2SO_4$, 88%, then $CH_2N_2$, 90%; (k) 12 $N$ HCl, THF (2:5), 68%; (l) aqueous $Br_2$, MeCN, $CaCO_3$, 80%; (m) 12 $N$ HCl, reflux, then azeotropic evaporation from toluene at 50°C, 73%; evaporation at low temperature gave **9**.

$S$,$S$-dimethyl thioacetal (14) to give the ketenedithioacetal derivative **5** in a nonoptimized yield of 60%. With the incorporation of this useful functionality in regiospecific manner we were now ready to address the problem of selective functional group transformations and more importantly to achieve this with a high measure of stereocontrol. We reasoned that treatment of **5**, $[\alpha]_D$ +185.6°, with a reducing agent such as lithium aluminum hydride would reduce the ketenedithioacetal function[6] virtually stereospecifically from the β-side by virtue of prior coordination with the initially formed amine. Indeed, reduction of the azide function in **5** with lithium aluminum hydride followed by derivatization gave the $N$-trifluoroacetyl derivative **6**, $[\alpha]_D$ +120°, in good overall yield. With the regio- and stereochemical problems solved, there remained to change the oxidation

[6]For a related case, see ref. 15.

state of the dithioacetal derivative **6**. Routine manipulations led to the crystalline ester **7**, mp 174–175°C, $[\alpha]_D$ +112°, which was subjected to selective hydrolysis, oxidation, and deprotection to give the crystalline Melillo lactone **8**, mp 192–193°C (dec.) in optically active form.[7] Interestingly, in aqueous solution the lactone hydrochloride **8** was converted in major part to the open-chain acid form **9**, mp 136–138°C (from acetone), $[\alpha]_D$ +4.2° → +6.7°, 20 h ($H_2O$).[8]

As previously mentioned, the racemic form of lactone **8**, mp 184–186°C (dec.) and its open-chain monobenzyl ester were previously used in a total synthesis of (±)-thienamycin (7). The presently described synthesis should therefore provide access to the optically active thienamycin and constitutes a formal synthesis of the antibiotic.[9]

Received December 31, 1981

HUMBERTO CARPIO, EDVIGE GALEAZZI, ROBERT GREENHOUSE, ANGEL GUZMÁN, ESPERANZA VELARDE, YULIA ANTONIO, FIDENCIO FRANCO, ALICIA LEON, VIRGINIA PÉREZ, RAQUEL SALAS, DAVID VALDÉS, JACK ACKRELL, DIANE CHO, PASQUALE GALLEGRA, OTTO HALPERN, RICHARD KOEHLER, MICHAEL L. MADDOX, JOSEPH M. MUCHOWSKI, ANTHONY PRINCE, DEREK TEGG, T. CRAIG THURBER, ALBERT R. VAN HORN, and DOUG WREN. Can. J. Chem. **60**, 2295 (1982).

Several syntheses of the previously unknown 1,2-dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylic acid and various 5- and 6-substituted derivatives thereof have been devised. Some of these processes have been extended to the heretofore unreported 5,6,7,8-tetrahydropyrrolo[1,2-*a*]pyridine-8-carboxylic acid and 5,6,7,8-tetrahydro-9*H*-pyrrolo[1,2-*a*]azepine-9-carboxylic acid derivatives.

Two new processes were developed for the conversion of pyrroles into the corresponding pyrrol-2-acetic acid esters. Both processes were based on the use of the readily available ethoxalylpyrrole derivatives as the starting material. One sequence involved saponification of the α-keto ester, followed by Wolff–Kishner reduction of the crude α-keto acid salt and subsequent esterification of the acetic acid derivative thus produced. The second synthesis commenced with reduction of the 2-ethoxalpyrrole with sodium borohydride to the α-hydroxy ester, which was further reduced to the acetic acid ester with an equimolar mixture of triphenylphosphine and triphenylphosphine diiodide.

HUMBERTO CARPIO, EDVIGE GALEAZZI, ROBERT GREENHOUSE, ANGEL GUZMÁN, ESPERANZA VELARDE, YULIA ANTONIO, FIDENCIO FRANCO, ALICIA LEON, VIRGINIA PÉREZ, RAQUEL SALAS, DAVID VALDÉS, JACK ACKRELL, DIANE CHO, PASQUALE GALLEGRA, OTTO HALPERN, RICHARD KOEHLER, MICHAEL L. MADDOX, JOSEPH M. MUCHOWSKI, ANTHONY PRINCE, DEREK TEGG, T. CRAIG THURBER, ALBERT R. VAN HORN et DOUG WREN. Can. J. Chem. **60**, 2295 (1982).

On a réalisé plusieurs synthèses de l'acide dihydro-1,2 3*H*-pyrrolo-[1,2-*a*] pyrrole carboxylique-1 inconnu jusqu'à présent et de plusieurs de ses dérivés substitués en position 6. On a étendu quelques-unes de ces synthèses aux dérivés de l'acide tétrahydro-5,6,7,8 pyrrolo[1,2-*a*] pyridine carboxylique-8 et de l'acide tétrahydro-5,6,7,8 9*H*-pyrrolo[1,2-*a*] azépine carboxylique-9 non rapportés antérieurerement.

On a mis au point deux nouveaux procédés pour transformer des pyrroles en esters d'acides pyrroleacétique-2 correspondants. Les deux méthodes s'appuient sur l'utilisation, comme produit de départ, des dérivés de l'éthoxalylpyrrole facilement disponible. Une méthode fait appel à la saponification de l'α-cétoester suivi d'une réduction de Wolff–Kishner du sel de l'α-cétoacide brut et d'une estérificatin du dérivé d'acide acétique. La deuxième synthèse débute par la réduction de l'éthoxalyl-2 pyrrole, par le borohydrure de sodium, en α-hydroxy ester que l'on réduit ensuite en ester d'acide acétique avec un mélange équimolaire de triphénylphosphine et d'iodure de triphénylphosphine.

[Traduit par le journal]

In connection with a program related to the development of certain nonsteroidal antiinflammatory agents (1), methods were required for the synthesis of bicyclic carboxylic acids of the structural types encompassed by formula **1** ($n$ = 2–4). No examples of these specific compounds, with or without substituents in the aromatic ring, have ever been reported in the literature.[4] This publication describes several ways in which the synthesis of such compounds can be achieved.

Central to the synthetic studies described herein was the observation that the iodoethyl pyrrole derivative **3**,[5] obtained in very low overall yield

[1]Alternative nomenclature: 1,2-dihydro-3*H*-pyrrolizine-1-carboxylic acids.

[2]Contribution No. 600 from the Syntex Institute of Organic Chemistry.

[3]Author to whom enquiries concerning this paper should be addressed.

[4]Certain aspects of the research described in this paper have appeared in the patents cited in ref. 1.

[5]The synthesis of this compound was effected by the copper catalysed reaction of the THP ether corresponding to **2***a* with ethyl diazoacetate, followed by hydrolysis of the protecting group, conversion of the alcohol into the methanesulfonate, and displacement with sodium iodide.

from 1-(2-hydroxyethyl)pyrrole **2***a*, readily underwent cyclization to the pyrrolopyrrole derivative **1** ($n = 1$; $R^1$, $R^2$ = H, $R^3$ = $C_2H_5$) on reaction with sodium hydride in dimethylformamide (DMF) solution. Therefore the strategy was to devise efficient preparative routes to compound **3** and derivatives and homologues thereof.

The first successful approach to the desired compounds was based on a Hantzsch pyrrole synthesis. When bromocetaldehyde was added to an acetonitrile solution of the enamine derived from dimethyl acetonedicarboxylate and ethanolamine, and the solution thus obtained was heated at reflux temperature, the crystalline 1-substituted pyrrole dicarboxylic acid ester **4***a* was formed in 38–43% yield. This compound was converted into the methanesulfonate **4***b* which, after nucleophilic displacement with sodium iodide in acetonitrile, gave the iodide **4***c* in 90% overall yield from the alcohol. As expected, cyclization of the iodide to the bicyclic diester **5***a* was effected rapidly, and in high yield, in the presence of sodium hydride in DMF solution. The removal of the unwanted carboxyl group from **5***a* was accomplished by a three-step sequence which took advantage of the differing steric environment of the two ester moieties. Saponification of **5***a* with excess potassium hydroxide gave the dicarboxylic acid **5***b* which was selectively esterified at the less hindered

carboxyl group with 2-propanol under Fischer conditions. Thermal decarboxylation of the mono carboxylic acid **5***c* took place in a manner typical of pyrrole-3-carboxylic acids (2) to give *i*-propyl 1,2-dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylate **6***a* in 55% yield from the diester **5***a*. Alkaline hydrolysis of the air-sensitive ester gave the corresponding carboxylic acid **6***b* which was characterized as the stable, crystalline dicyclohexylammonium salt.

When propanolamine was substituted for ethanolamine in the Hantzsch pyrrole synthesis, the 1-(3-hydroxypropyl) diester **7***a* was obtained in 43–58% yield. This compound was subjected to a sequence of reactions analogous to that described above to provide 5,6,7,8-tetrahydropyrrolo[1,2-*a*]-pyridine-8-carboxylic acid **9***b* (see Tables 1 and 2).

One of the significant aspects of the above reaction sequences was that when a bromomethyl ketone was used as the halocarbonyl component, then depending on the conditions utilized to effect the Hantzsch reaction, pyrroles substituted in the 4- or the 5-position could be prepared. For example, slow addition of bromoacetone (2 equiv.) to a mixture of aqueous ethanolamine (10 equiv.) and dimethyl acetonedicarboxylate (1 equiv.) gave the pyrrole diester **4***d*, bearing a methyl group at C-4, as the major product. This substance was converted into *i*-propyl 6-methyl-1,2-dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylate **6***c*. Similarly, commencing with 1-bromo-2-butanone, 1-bromo-4-methoxy-2-butanone, and 1-bromo-5-methoxy-2-pentanone, the 6-substituted bicyclic acid esters **6***d*, **6***e*, and **6***g*, respectively (see Tables 1 and 2), were synthesized. In contrast, when the Hantzsch pyrrole synthesis was effected under nonaqueous conditions with bromoacetone or phenacyl bromide as the halocarbonyl components, the 5-substituted pyrrole diesters **10***a* and **10***d* were obtained as the principal products. These compounds were converted into the corresponding 5-substituted pyrrolopyrrole carboxylic acid derivatives **12***a* and **12***c*, via the usual reaction sequence.

The formation of isomeric pyrroles from a single set of starting materials merely through a minor variation of the reaction conditions indubitably is a reflection of a mechanistic change in the Hantzsch reaction. While it is probable that the pyrroles **4***a*, **7***a*, **10***a*, and **10***d* result from carbon alkylation of the enamine **13** in the expected sense, the mechanism of formation of the abnormal Hantzsch products (i.e., with the substituent at C-4) is less apparent. In this connection, it has recently been shown (3) that the optimum conditions for the formation of the 4-methyl compound **14** involve the simultaneous addition of a 1.5:1 molar ratio of chloracetone and dimethyl acetonedicarboxylate to a considerable excess (≥3.5 equiv.) of aqueous methylamine in a two phase system. Although other explanations are possible, it may be that these conditions favor the generation of a low concentration of a reactive intermediate, such as methylaminoacetone, which might be efficiently trapped in the Knorr sense (see ref. 2, pp. 52–57) to yield the vinylogous urethane **15**. This intermediate would be especially prone to a base catalyzed internal aldolization to the alcohol **16**, followed by an equally facile base catalyzed elimination of water therefrom, to yield the observed product.

The distinguishing feature of a second synthetic route to 1,2-dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylic acid derivatives was the sequential attachment of two carbon units, suitable for closure

to a 5-membered ring, at positions -1 and -2 of pyrrole. For the parent system the process commenced with the preparation of the known (4) 1-(2-hydroxyethyl)pyrrole **2***a* from 2,5-dimethoxytetrahydrofuran and ethanolamine, a synthesis which was much more convenient, and better yielding, than that described by Blicke and Blake (4). The alcohol was converted into the tetrahydropyranyl ether **17***a* which, on acylation with ethoxalyl chloride in the presence of pyridine, gave the α-keto ester **18***a*. This compound could also be prepared, in good yield, by the sodium hydride mediated alkylation of 2-ethoxalyl pyrrole (5) with the tetrahydropyranyl ether of bromoethanol. In addition, acylation of 1-(2-acetoxyethyl)pyrrole **17***b* (4) with ethoxalyl chloride provided the acetate **18***b*, a particularly useful precursor of the required bicyclic systems. Saponification of either **18***a* or **18***b*, followed by careful acidification at 0°C, permitted the isolation of the unstable α-keto acid **18***c*. In general, however, the crude carboxylic acid salt was directly subjected to the Huang–Minlon modification of the Wolff–Kishner reduction. The pyrrole acetic acid derivative **19***a* thus produced was converted, without purification, into the corresponding methyl ester **19***b* with methyl iodide, in DMF containing potassium carbonate (50–70% overall yield from α-keto esters **18***a* or **18***b*), or with ethereal diazomethane (53% overall from **18***a*). The transformation of this substance into the bicyclic methyl ester **6***h* was then accomplished, in the usual manner, via the methanesulfonate **19***c* and the iodide **19***d*.

The versatility of the above process proved to be considerable since, by appropriate modification of the reaction sequence, it was also possible to prepare analogues of **6***h* incorporating a methyl, methoxymethyl, chloro, or a bromo group at C-6. For example, the carbon atom destined to be the 6-methyl group in **6***i* was introduced by a Vilsmeier–Haack reaction on the keto ester **18***b*. Saponification of the 4-formyl-α-keto ester **18***d* so produced gave the carboxylic acid **18***e* which was transformed, in one step, into the 4-methylpyrrole-2-acetic acid derivative **19***e* by the modified Wolff–Kishner reduction.

The introduction of the methoxymethyl group was first effected by the hydrogen chloride promoted reaction of dimethoxymethane with the ethoxalyl pyrrole **18***b*, and subsequent methanolysis of a presumed (see below) intermediate chloromethyl compound. This reaction gave varying amounts of the expected 4-methoxymethyl pyrrole **18***f* and the corresponding alcohol **18***g* in

combined yields of 30–36%. Because of the capricious nature of the above reaction, an alternative route to the desired compounds, based on the methoxymethylation of 1-(2-chloroethyl)-2-ethoxyalylpyrrole **18***h* (prepared by acylation of 1-(2-chloroethyl)pyrrole **17***c*), was devised. This reaction sequence gave the expected 4-methoxymethyl pyrrole derivative **18***i* as the major product, together with minor amounts of the methyl ester **18***j* and the 4-hydroxymethyl compound **18***k* (converted into **18***i* by acid catalyzed methanolysis). The process was shown to proceed via the intermediate 4-chloromethyl compound **18***l* by elimination of the methanolysis step. Nucleophilic displacement of chloride ion in **18***i* with excess sodium acetate, in the presence of sodium iodide, gave a mixture of the 1-acetoxyethyl and 1-hydroxyethyl pyrrole derivatives **18***f* and **18***g* in a combined overall yield of 35–47% from 1-(2-chloroethyl)-2-ethoxalylpyrrole **18***h*. A small amount of the *N*-vinyl compound **20** was also formed in this reaction. Careful saponification of either **18***f* or **18***g* with potassium hydroxide in ethylene glycol at −5°C, followed by sequential Wolff–Kishner reduction and esterification of the crude potassium salt of the acetic acid **19***i* with methyl iodide, gave the methyl ester **19***j* in 58% yield overall.[6]

The introduction of chlorine or bromine at the required position was accomplished by the low temperature halogenation of the oxalyl compound **18***b* with sulfuryl chloride or bromine. In each case, in addition to the desired 4-substituted pyrrole derivatives **18***m* and **18***n*, lesser amounts of the pyrroles **22***a* and **22***b*, substituted at C-5 or at C-5 and C-6, were also isolated. Because of the concern that the halo moiety in **18***m* and **18***n* would not survive the drastic conditions of the Wolff–Kishner reduction, an alternative means of converting these α-keto esters into the corresponding acetic acid derivatives was devised. Thus, reduction with sodium borohydride at low temperature gave the secondary alcohols **23***a* and **23***b*, which were then reacted with equimolar amounts of triphenylphosphine and triphenylphosphine diiodide in boiling benzene (6). Whereas this resulted in the clean conversion of the 4-chloro alcohol **23***a* into the acetic acid ethyl ester **19***l*, under the same conditions **23***b* suffered the loss of the nuclear bromine atom as well. This difficulty was obviated, however, when the reaction was conducted at room temperature.[7] Finally, the acetates **19***l* and **19***p* were subjected to 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) catalyzed transesterification with methanol, which resulted in the formation of the *N*-hydroxyethyl methyl esters **19***m* and **19***q*.

The 4-substituted 1-(2-hydroxyethyl)pyrrole acetic acid esters **19***f*, **19***j*, **19***m*, and **19***q*, described above, were converted into the corresponding 6-substituted 1,2-dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylic acid derivatives **6***i* to **6***l*, in the usual manner, via the respective *N*-methanesulfonyloxyethyl or *N*-iodoethyl compounds.

A third and final approach to the desired bicyclic compounds was tactically identical to the second synthetic route, described above, except for the manner of the attachment of the two-carbon unit to C-2 of the pyrrole moiety. This operation was accomplished in a three-step sequence (7) which is exemplified below for the synthesis of the parent pyrrolopyrrole carboxylic acid derivative **6***h*. Thus, reaction of *N*-hydroxyethylpyrrole **2***a* with formaldehyde and dimethylamine hydrochloride gave the Mannich base **24***a* which was quaternized with dimethyl sulfate. The quaternary ammonium salt **25** ($n = 2$) was converted, without isolation, into the acetonitrile derivative **26***a* with hot aqueous sodium cyanide. The cyclization of this compound to **27***a* was then carried out in the usual

manner via the methane sulfonate **26***b* and the iodide **26***c*. Alkaline hydrolysis of the nitrile **27***a*, followed by reaction of the crude salt with methyl iodide, provided the previously described methyl ester **6***h*. In a similar manner, but commencing with *N*-hydroxypropylpyrrole **2***b* and *N*-hydroxybutylpyrrole **2***c*, were prepared 5,6,7,8-tetrahydropyrrolo[1,2-*a*]pyrrole-8-carbonitrile **27***b*, 5,6,7,8-tetrahydro-9*H*-pyrrolo[1,2-*a*]azepine-9-carbonitrile **27***c*, and the corresponding acid methyl esters **9***c* and **28***b*.

[6]A small amount of the decarbonylation product **21** was also isolated. If the saponification of **18***f* was effected with aqueous methanolic potassium hydroxide at 0°C, it became the major product.

[7]This synthesis of pyrrole acetic acid derivatives, which doubtless proceeds via the α-iodo ester and the enol phosphonium salt (8) corresponding thereto, has a considerable degree of generality.[8]

[a]Measured on a Bruker WM300 spectrometer operating at 300.133 MHz (spectral width 3600 Hz; pulse width 4 μs; pulse interval 5.4 s; scans 4; line broadening function −0.1 Hz; data points 32 000).
[b]The chemical shifts and coupling constants of the aliphatic protons of *6i* and *27a* were simulated as indicated in the experimental section.

The compounds described in this manuscript were fully characterized by the usual spectroscopic techniques (see introduction to experimental section), which included nmr spectra. A selection of the latter are found in Table 4 or in the experimental part. A complete compilation of the spectra (Tables 5 and 6) can be obtained from the Depository of Unpublished Data.[9] The nmr spectra of the nitriles **27***a* and **27***b* and the methyl esters **6***i* and **28***b* were also measured at 300 MHz. The absorptions for the protons of the ester **6***i* and the nitrile **27***a* were sufficiently chemically shifted from one another to permit a complete analysis of the spectra (see Table 3). This was not true for compounds **27***b* and **28***b*, and little useful information could be derived from the aliphatic region of these spectra.

Molecular models predict that the ring system of the 1-substituted 1,2-dihydro-3*H*-pyrrolo[1,2-*a*]-pyrroles should be nearly planar. The vicinal coupling constants, listed in Table 3, at the least show the expected trend of $J_{cis} > J_{trans}$, which is consistent with this prediction. Nevertheless, the *cis* and *trans* coupling constants do not differ as much as might be anticipated for a planar 5-membered ring, a situation which has been observed and discussed in detail elsewhere (9).

Finally, it is of some interest that the proton α to the carbomethoxy or the cyano substituent in compounds **6***i*, **27***a*, and **28***b* is long range coupled (0.5–1 Hz) to the adjacent pyrrole proton, a phenomenon which has previously been reported for various substituted pyrroles (10).

## Experimental

The melting points were determined in a Mel-Temp melting point apparatus and are corrected. The infrared spectra were measured with a Perkin–Elmer Model 237 grating infrared

[9]These tables are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

TABLE 4. Nuclear magnetic resonance spectra of some pyrrole derivatives[a]

| Compound | Chemical shifts δ (ppm) |
|---|---|
| **4***a* | 3.68 (s, 3H, $OCH_3$), 3.75 (s, 3H, $OCH_3$), 3.81–3.99 (m, 4H, $CH_2CH_2$), 4.11 (s, 2H, $CH_2CO$), 6.61 (q, 2H, $J_{AB}$ = 2.9 Hz, H-3,4) |
| **4***d* | 2.20 (s, 3H, $CH_3$), 3.62–3.97 (m, 4H, $CH_2CH_2$), 3.68 (s, 3H, $OCH_3$), 3.73 (s, 3H, $OCH_3$), 4.00 (s, 2H, $CH_2$), 6.35 (s, 1H, H-5) |
| **5***a* | 2.48–3.08 (m, 2H, $CH_2$), 3.71 (s, 3H, $OCH_3$), 3.74 (s, 3H, $OCH_3$), 3.93–4.31 (m, 3H, CH, $CH_2N$), 6.47 (m, 2H, H-5, 6) |
| **5***d* | 2.23 (s, 3H, $CH_3$), 2.42–3.07 (m, 2H, $CH_2$), 3.67 (s, 6H, 2 × $OCH_3$), 3.73–4.32 (m, 3H, CH, $CH_2N$), 6.27 (s, 1H, H-5) |
| **6***j* | 2.40–2.79 (m, 2H, $CH_2$), 3.25 (s, 3H, $CH_3OCH_2$), 3.63 (s, 3H, $OCH_3$), 3.75–4.05 (m, 3H, CH, $CH_2N$), 4.20 (s, 2H, $CH_3OCH_2$), 5.90 (s, 1H, H-7), 6.52 (s, 1H, H-5) |
| **6***k* | 2.37–2.75 (m, 2H, $CH_2$), 3.62 (s, 3H, $OCH_3$), 3.53–4.07 (m, 3H, CH, $CH_2N$), 5.85 (m, 1H, H-7), 6.45 (m, 1H, H-5) |
| **10***a* | 2.19 (s, 3H, 5-$CH_3$), 3.65 (s, 3H, $OCH_3$), 3.70 (s, 3H, $OCH_2$), 3.82 (m, 4H, $CH_2CH_2$), 4.03 (s, 2H, $CH_2$), 6.23 (m, 1H, H-4) |
| **11***a* | 2.13 (s, 3H, $CH_3$), 2.50–2.90 (m, 2H, $CH_2$), 3.63–4.22 (m, 3H, CH, $CH_2N$), 3.66 (s, 6H, 2 × $OCH_3$), 6.18 (s, 1H, H-6) |
| **18***i* | 1.40 (t, 3H, $J$ = 7.2 Hz, $CH_3$), 3.40 (s, 3H, $CH_3O$), 3.84 (t, 2H, $J$ = 5.7 Hz, $CH_2Cl$), 4.37 (s, 2H, $CH_3OCH_2$), 4.43 (q, 2H, $J$ = 7.2 Hz, $CH_2$), 4.63 (t, 2H, $J$ = 5.7 Hz, $CH_2N$), 7.16 (d, 1H, $J$ = 1.8 Hz, H-3 or H-5), 7.34 (d, 1H, $J$ = 1.3 Hz, H-5 or H-3) |
| **18***m* | 1.44 (t, 3H, $J$ = 7.2 Hz, $CH_3$), 2.07 (s, 3H, $CH_3CO_2$), 4.23–4.70 (m, 6H, 3 × $CH_2$), 7.00 (d, 3H, $J$ = 1.8 Hz, H-3 or H-5), 7.27 (d, 1H, $J$ = 1.8 Hz, H-5 or H-3) |
| **19***n* | 2.84 (s, 3H, $SO_2CH_3$), 3.60 (s, 2H, $CH_2CO$), 3.70 (s, 3H, $OCH_3$), 4.00–4.47 (m, 4H, $CH_2CH_2$), 5.98 (d, 1H, $J$ = 2.0 Hz, H-3), 6.64 (d, 1H, $J$ = 2.0 Hz, H-5) |

[a] Measured in deuteriochloroform. OH and NH groups were exchanged with deuterium oxide.

spectrophotometer. The ultraviolet spectra were recorded on a Perkin–Elmer Model 402 ultraviolet visible spectrometer. The $^1H$ nmr spectra were measured with a Varian T-60, a Varian HA-100, or a Bruker WM 300 nmr spectrometer and are expressed as parts per million (δ) from internal tetramethylsilane. The low resolution mass spectra were measured on Atlas CH-4, Varian-MAT CH-7, and AEI MS-9 spectrometers. The high resolution mass spectra were obtained with a Varian-MAT 311A mass spectrometer.

The 300 MHz nmr spectra of compounds **6***h* and **27***a* were simulated with an Aspect 2000 computer using the PANIC computer program (Bruker-Physik AG, Rheinstetten, Germany).

The term "dried" signifies dried over $Na_2SO_4$ throughout the experimental section.

*Synthesis of the 1-bromoalkan-2-ones*

(a) *1-Bromobutan-2-one*

This compound was prepared in the manner described by Catch *et al.* (11).

(b) *1-Bromo-4-methoxybutan-2-one*

A solution of the known (12) 3-methoxypropionyl chloride (1 mol) in dry $CH_2Cl_2$ (25 mL/g) was added to an ethereal solution of $CH_2N_2$ (2.5 mol, prepared from nitrosomethylurea) at −10°C. After 1 h at this temperature, the solvent was removed at 0°C by means of a stream of $N_2$. The crude diazoketone (ir ($CHCl_3$): 2120, 1636 $cm^{-1}$) was dissolved in $CH_2Cl_2$ (50 mL/g) and the solution was cooled to −70°C. A saturated solution of HBr gas in $CH_2Cl_2$ was then added dropwise, care being taken that excess HBr solution was not added. When the diazoketone had been consumed (tlc analysis), the temperature was lowered to −75°C and a stream of $N_2$ was passed through the solution until the solvent volume had been reduced to about one-third of the original. The remainder of the solvent was then removed *in vacuo* (≤25 mm) at room temperature. The residue was subjected to column chromatography on silica gel using EtOAc–hexane (5:95) as the eluting solvent. A lachrymatory, volatile oil (74% yield) remained; ir ($CHCl_3$): 1716 $cm^{-1}$; nmr ($CDCl_3$) δ: 2.87 (t, 2H, $J$ = 6.0 Hz), 3.33 (s, 3H), 3.67 (5, 2H, $J$ = 6.0 Hz), 3.94 (s, 2H). This compound was not characterized further.

(c) *1-Bromo-5-methoxy-2-pentanone*

To a solution of 4-methoxybutyric acid (ref. 13; 20.0 g, 169 mmol), in dry $CH_2Cl_2$ (50 mL), was added anhydrous DMF (0.5 mL) and $SOCl_2$ (21.4 g, 180 mmol). The solution was left at room temperature for 2 h and then the solvent was removed *in vacuo* (≤25°C). The residual oil was then added to excess ethereal $CH_2N_2$ at 0°C as described above. After the usual work-up the crude diazoketone was dissolved in ether and an ethereal solution of HBr gas was added thereto in the manner described above. When the diazoketone was no longer present the solvent was removed *in vacuo* (≤20°C) and the residue was subjected to column chromatography on silica gel (400 g) using $CH_2Cl_2$ (15:85) to elute the product. The eluate was evaporated at ≤20°C (≈20 Torr) to minimize loss of the volatile bromoketone (25.0 g, 76%); ir ($CHCl_3$): 1715 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.88 (quin., 2H, $J$ = 6.8 Hz), 2.74 (t, 2H, $J$ = 6.0 Hz), 3.29 (s, 3H), 3.37 (t, 2H, $J$ = 6.0 Hz), 3.88 (s, 2H). This compound (light sensitive) was not characterized further.

*1-(2-Hydroxyethyl)pyrrole* **2**a

Ethanolamine (400 g, 6.55 mol) was added with efficient agitation to glacial HOAc (720 mL), cooled in an ice–salt mixture at a rate such that the temperature was maintained at 15–25°C. When the addition was completed, 2,5-dimethoxytetrahydrofuran (200 g, 1.51 mol) was added in one portion, the reaction vessel was removed from the cooling bath and set up for downward distillation. The reaction flask was placed in an oil bath and the temperature was raised to 110–120°C, at which point distillation of a liquid commenced. After ca. 1.5 h at this temperature about 250 mL of a distillate had been collected. The residual liquid in the reaction vessel was cooled to room temperature, it was diluted with $H_2O$ (1.2 L), and extracted with $CH_2Cl_2$. The extract was washed successively with saturated aqueous solutions of NaCl and $Na_2CO_3$, it was dried, and then the solvent was removed *in vacuo*. The residue, which consisted mainly of the desired alcohol **2***a* and a lesser amount of the corresponding acetate **17***b*, was dissolved in MeOH (250 mL), 20 wt.% NaOH (200 mL) was added, and the solution was left at room temperature for 1 h. The solution was poured into saturated aqueous NaCl solution (2.5 L), the product was extracted into $CH_2Cl_2$, and the extract was dried. The solvent was removed *in vacuo* leaving an oil (117 g, 70%) which was spectroscopically identical to a specimen which had been prepared by the method of Blicke and Blake (4); uv (MeOH): 223 nm (ε 3900); ir ($CHCl_3$): 3605, 3490 $cm^{-1}$; nmr ($CDCl_3$) δ: 2.23 (s, 1H, OH), 3.50–3.93 (m, 4H, $CH_2CH_2$), 6.04 (m, 2H, H-3,4), 6.55 (m, 2H, H-2,5).

*1-(3-Hydroxypropyl)pyrrole* 2b

This compound was prepared from 3-aminopropanol (300 g, 3.99 mol) and 2,5-dimethoxytetrahydrofuran (150 g, 1.14 mol), in HOAc solution (540 mL), in the manner described above for compound **2***a*. After alkaline hydrolysis of the crude product obtained from this condensation, the hydrolysate was subjected to column chromatography on Florisil. The product (79.6 g, 45.6%) was eluted from the column with hexane–$CH_2Cl_2$ (3:1, then 1:1) and was of sufficient purity for use in subsequent reactions. For analysis a small amount of the material was distilled *in vacuo*, bp 65–67°C/0.2 Torr; uv (MeOH): 223 nm (ε 4570); ir ($CHCl_3$): 3436 $cm^{-1}$; nmr ($CDCl_3$) δ: 2.00 (m, 2H, $CH_2$), 3.55 (m, 2H, $CH_2O$), 3.95 (m, 2H, $CH_2N$), 6.10 (m, 2H, H-3,4), 6.61 (m, 2H, H-2,5); *Anal.* calcd. for $C_7H_{11}NO$: C 67.17, H 8.86, N 11.15; found: C 67.04, H 8.93, N 11.12.

*1-(4-Hydroxybutyl)pyrrole* 2c

This alcohol was prepared from 4-aminobutanol (ref. 14; 76.8 g, 860 mmol) and 2,5-dimethoxytetrahydrofuran (38.4 g, 290 mmol), in glacial HOAc solution (150 mL), in the manner described above. The product was obtained in 61% yield after purification by distillation *in vacuo*, bp 69°C/0.075 Torr; uv (MeOH): 224 nm (ε 3800); ir ($CHCl_3$): 3597, 3460 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.66 (m, 4H, $CH_2CH_2$), 3.56 (m, 2H, $CH_2O$), 3.86 (m, 2H, $CH_2N$), 6.10 (m, 2H, H-3,4), 6.60 (m, 2H, H-2,5); mass spectrum *m/e*: 139 ($M^+$); *Anal.* calcd. for $C_8H_{13}NO$: C 69.02, H 9.41, N 10.06; found: C 68.55, H 9.48, N 10.03.

This compound was further characterized by conversion into the 4-(4-nitrophenylazo) benzoate. To a stirred solution of the alcohol **2***c* (0.450 g, 3.2 mmol) in dry $C_6H_6$ (50 mL) containing pyridine (0.51 g, 6.4 mmol) was added 4-(4-nitrophenylazo) benzoyl chloride (ref. 15; 1.03 g, 3.5 mmol). After 40 min the mixture was evaporated to dryness *in vacuo* and the residue was passed through a column of neutral alumina (30 g, Fluka, Act. I) using $C_6H_6$ as the solvent. The product, after crystallization from $CH_2Cl_2$–MeOH, was obtained in 68% yield. A further crystallization from EtOAc gave the analytical specimen, mp 108–110°C; ir ($CHCl_3$): 1710, 1610, 1520, 1340 $cm^{-1}$; *Anal.* calcd. for $C_{21}H_{20}N_4$: C 64.27, H 5.14, N 14.28; found: C 63.97, H 5.15, N 14.24.

*1-(2-Tetrahydropyran-2-yloxyethyl)pyrrole* 17a

A solution of the alcohol **2***a* (3.0 g, 2.7 mmol) in anhydrous $CH_2Cl_2$ (50 mL), containing dihydropyran (6.8 g, 8.1 mmol), was cooled to −20°C and *p*-TsOH (0.073 g) was added. After 45 min at this temperature, pyridine (5 drops) was added, and then the mixture was partitioned between $H_2O$ and ether. The organic phase was washed with saturated NaCl solution, it was dried, and then the solvent was removed *in vacuo*. The residue was purified by column chromatography on Florisil (150 g) using hexane and hexane–ether (95:5) to elute the product (4.2 g, 81%) which had bp 87°C/2 Torr (slight dec.); uv (MeOH): 220 nm (ε 5130); nmr ($CDCl_3$) δ: 1.60 (m, 6H, $(CH_2)_3$ of THP), 3.25–4.12 (m, 6H, $NCH_2CH_2O$ and $OCH_2$ of THP), 4.43 (m, 1H, H-2 of THP), 6.03 (m, 2H, H-3,4), 6.60 (H-2,5); *Anal.* calcd. for $C_{11}H_{17}NO_2$: C 67.75, H 8.79, N 7.18; found: C 67.79, H 8.79, N 6.98.

*1-(2-Acetoxyethyl)pyrrole* 17b

A solution of the crude 1-(2-hydroxyethyl)pyrrole **2***a* (147 g; which contained some of the acetate **17***b*) in pyridine (415 mL), containing $Ac_2O$ (139 mL), was heated on a steam bath for 0.5 h. The solution was poured into $H_2O$ (1 L) and the product was extracted into EtOAC (3 × 1 L). The extract was washed successively with dilute HCl solution, brine, dilute $Na_2CO_3$ solution, and brine again. The extract was dried, the solvent was removed *in vacuo* and the residue was purified by column chromatography on Florisil using 1:1 hexane–$CH_2Cl_2$ as the developing solvent. The product (128 g) was identical to a sample prepared by the method of Blicke and Blake (4); uv (MeOH): 223 nm (ε 4170); ir ($CHCl_3$): 1741 $cm^{-1}$; nmr ($CDCl_3$) δ: 2.02 (s, 3H, $CH_3CO$), 3.92–4.37 (m, 4H, $CH_2CH_2$), 6.07 (m, 2H, H-3,4), 6.60 (m, 2H, H-2,5).

*1-(2-Chloroethyl)pyrrole* 17c

A mixture of 2,5-dimethoxytetrahydrofuran (150 g, 1.13 mol), 2-chloroethylamine hydrochloride (450 g, 3.88 mol), anhydrous NaOAc (450 g, 5.5 mol), and HOAc (560 mL) was heated with an oil bath, with mechanical stirring, in an apparatus set up for distillation. The oil bath was heated to 110°C, at which temperature distillation of a liquid took place. After 15 min at 110°C the mixture was cooled, poured into saturated salt solution, and the product was extracted into $CH_2Cl_2$. The extract was washed successively with saturated salt solution, saturated $Na_2CO_3$ solution, and saturated salt solution. The extract was dried, the solvent was removed *in vacuo*, and the residue was passed through a column of Florisil (800 g) using hexane as the solvent. The product (84 g, 57%) obtained in this way was sufficiently pure for synthetic purposes. For analysis, a small portion was distilled at 50°C/1.2 Torr; uv (MeOH): 219 nm (ε 4790); nmr ($CDCl_3$) δ: 3.66 (m, 2H, $CH_2Cl$), 4.06 (m, 2H, $CH_2N$), 6.10 (m, 2H, H-3,4), 6.63 (m, 2H, H-2,5); *Anal.* calcd. for $C_6H_8ClN$: C 55.60, H 6.22, Cl 27.36; found: C 55.44, H 6.23, Cl 27.11.

*Hantzsch pyrrole synthesis*

A. *Use of bromoacetaldehyde as α-halo carbonyl component. Synthesis of methyl 1-(2-hydroxyethyl)-3-methoxycarbonylpyrrol-2-acetate* 4a

A 250 mL 3-necked round bottomed flask containing a magnetic stirring bar and fitted with a $CaCl_2$-filled drying tube was connected directly (via one of the outer necks) by means of a receiver adapter and a 3 in. Liebig condensor to the acetal pyrolysis apparatus. This latter apparatus consisted of a 100 mL round bottomed flask topped with a 6 in. Vigreux column (bearing a thermometer) connected to the above-mentioned condensor.

The acetal pyrolysis flask was charged with oxalic acid dihydrate (15.6 g, 124 mmol) and bromoacetaldehyde diethyl acetal (11.82 g, 60 mmol). Ethanolamine (3.36 g, 55 mmol) was placed in the 3-necked flask, which was immersed in an ice bath. Dimethyl acetonedicarboxylate (8.7 g, 0.05 mol) was then added with stirring at 0–10°C. The enamine formed immediately. When the addition was completed, the cooling bath was removed and dry MeCN (100 mL) was added. The acetal pyrolysis part of the apparatus was now placed in an oil bath and the temperature thereof was raised to 150–160°C. The bromoacetaldehyde solution, which formed (bp 80–83°C/ca. 580 Torr pressure in Mexico City), distilled directly into the three-necked flask. When the temperature of the distillate had dropped below 80°C, the pyrolysis part of the apparatus was replaced by a reflux condensor fitted with a drying tube containing $CaCl_2$. The solution was heated at reflux temperature for 1 h. The solvent was removed *in vacuo*, MeOH (200 mL) and silica gel (20 g) were added to the residue, the MeOH was removed *in vacuo*, and the solid mixture was placed on top of a column of silica gel (200 g) packed in hexane. The column was eluted with hexane–EtOAc (4:1, 1 × 500 mL) and hexane–EtOAc (1:1, 9 × 500 mL). Fractions 2 and 3 contained dimethyl acetonedicarboxylate and nonpolar impurities, fractions 4–8 contained the crystalline pyrrole **4***a* (38–43%), which was recrystallized from ether–hexane. The physical constants for this compound are found in Tables 1 and 2.

The yield of the product was very dependent on the scale of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

the reaction. Thus, doubling the scale gave the pyrrole in about half the yield stated above.

*Methyl 1-(3-hydroxypropyl)-3-methoxycarbonylpyrrol-2-acetate* **7**a

This compound was prepared in the same manner as described above for the synthesis of **4***a* except that 3-amino-1-propanol was used in place of ethanolamine and the condensation between the dimethyl acetonedicarboxylate – 3-amino-1-propanol adduct and bromoacetaldehyde was conducted at room temperature for 16 h. The crude product was purified by column chromatography on silica gel, the column being developed successively with hexane, hexane–ether (4:1), and hexane–ether (1:4). The product was eluted from the column with the last solvent system, and then crystallized from $CH_2Cl_2$–hexane. See Tables 1 and 2 for physical constants.

B. *Utilization of 1-bromoalkan-2-ones as the α-halo carbonyl component*

(a) *Aqueous conditions*

The experimental procedures for the synthesis of compounds **4***d* and **4***g* were identical, except that 60% aqueous HOAc was used as the reaction solvent for the preparation of **4***g*. Compounds **4***j* and **4***l* were obtained by processes which differed somewhat from that used for **4***d* and **4***g* (see below) but were identical to each other, except that hexane–EtOAc (1:1) was used as the eluting solvent in the column chromatographic purification of **4***l*.

*Methyl 1-(2-hydroxyethyl)-3-methoxycarbonyl-4-methylpyrrol-2-acetate* **4**d

Dimethyl acetonedicarboxylate (1.74 g, 10 mmol) was added in one portion to ethanolamine (6 mL, 100 mmol) and $H_2O$ (5 mL) and the mixture was rapidly cooled to −10°C at which point bromoacetone (1.67 mL, 0.02 mol) was added in a dropwise manner. The temperature was allowed to rise, but not above 45°C. When the addition was completed the deeply colored solution was stirred at room temperature for 1 h and then the reaction was quenched by pouring it onto a mixture of crushed ice and 25% HCl. The solution was saturated with NaCl and the product was extracted into EtOAc. The extract was washed to neutrality with $H_2O$, dried, and then the solvent was removed *in vacuo*. The residue was subjected to column chromatography on silica gel using hexane–EtOAc (7:3) as the eluting solvent. The solid product (0.89 g, 35%) was crystallized from $CH_2Cl_2$–hexane for analysis. See Tables 1 and 2.

*Methyl 1-(2-hydroxyethyl)-3-methoxycarbonyl-(2-methoxyethyl)pyrrol-2-acetate* **4**j

To a stirred solution of ethanolamine (10 equiv.) and $H_2O$ (0.33 g/g ethanolamine) was added a mixture of 1-bromo-4-methoxybutan-2-one (1 equiv.) and dimethyl acetonedicarboxylate (1 equiv.) in a dropwise manner. A vigorous reaction took place but the temperature was not permitted to exceed 35°C. Fifteen minutes after the addition was completed, the reaction was worked up in the usual way. The desired pyrrole was obtained from the product mixture by column chromatography on silica gel using ether–hexane (5:1) as the eluting solvent.

(b) *Nonaqueous conditions*

*Methyl 1-(2-hydroxyethyl)-3-methoxycarbonyl-5-methylpyrrol-2-acetate* **10**a

A mixture of dimethyl acetonedicarboxylate (1 equiv.) and ethanolamine (1 equiv.) was stirred at room temperature for 10 min and then bromoacetone (3 equiv.) was added. The mixture was left at room temperature for 5 days, after which time it was subjected to column chromatography on silica gel. The desired product was eluted as an oil with a 1:1 EtOAc–hexane mixture.

*Methyl 1-(2-hydroxyethyl)-3-methoxycarbonyl-5-phenylpyrrol-2-acetate* **10**d

Ethanolamine (1 equiv.) and phenacyl bromide (2 equiv.) were added in succession to dimethyl acetonedicarboxylate (2 equiv.) in MeCN (1 mL/mmol phenacyl bromide) and the solution was heated at reflux temperature for 1.75 h. The solvent was removed *in vacuo* and a 1:1 mixture of $H_2O$ and HCl was added to the residue. After the usual work-up, the crude product was subjected to column chromatography on silica gel and the desired pyrrole was eluted with 1:1 EtOAc–hexane.

*Synthesis of the methanesulfonates*

All of the methanesulfonates described in this paper were prepared by the general procedure outlined below.

To a stirred solution of the hydroxy compound (1 equiv.) in anhydrous $CH_2Cl_2$ (10–20 mL/g of the alcohol), cooled to 0°C or lower (see Table 1), and containing triethylamine (1 equiv.), was added $CH_3SO_2Cl$ (1 equiv.) at a rate such that the temperature was maintained at 0°C or below. When the addition was completed, the mixture was stirred for the time and at the temperature specified in Table 1. The solution was washed successively with $H_2O$ and saturated salt solution, dried, and evaporated *in vacuo*. The residue was then purified by crystallization from the appropriate solvent system, or by column chromatography on silica gel. For the 6-chloro and 6-bromo compounds **19***n* and **19***r*, respectively, the methanesulfonate was eluted with hexane–EtOAc (7:3). The cyano methanesulfonates **26***e* and **26***g* were removed from the column with 9:1 and 7:2 hexane–$CH_2Cl_2$ mixtures.

*Synthesis of the 4-(4-nitrophenylazo) benzoate esters*

The syntheses of the 4-(4-nitrophenylazo) benzoate esters of compounds **10***d*, **19***j*, and **26***f* were effected in exactly the same manner as described for 1-(4-hydroxybutyl)pyrrole **2***c*, except that compound **19***j* was purified by column chromatography on Act. II neutral alumina and the ester was eluted with $C_6H_6$–EtOAc (9:1).

*Synthesis of the 1-(ω-iodoalkyl)pyrroles*

A solution of the methanesulfonate (1 equiv.) in anhydrous MeCN (10–40 mL/g methanesulfonate) containing dry NaI (2.3 equiv. for compounds **7***b*, **26***b*, and **26***e*; 10 equiv. for **4***h*; all others, 5 equiv.) was heated at reflux temperature for the time specified in Table 1. The solvent was evaporated to dryness *in vacuo*, $H_2O$ was added to the residue, and the product was extracted into $CH_2Cl_2$. The extract was washed with $H_2O$, dried, and evaporated *in vacuo*. The residue in some cases was analytically pure, in others the crude product was purified by crystallization from the appropriate solvent system or by column chromatography on silica gel using hexane–EtOAc (3:2 for **7***c* and 95:5 for **19***o*).

*Acylation of 1-substituted pyrroles with ethoxalyl chloride*

The α-keto esters **18***a*, **18***b*, and **18***h* were synthesized in the manner described below.

A solution of pyridine (1.1 equiv.) in anhydrous $CH_2Cl_2$ (25 mL/g) was added to a stirred solution of ethoxalyl chloride (1 equiv.) in $CH_2Cl_2$ (15 mL/g) at a rate such that the temperature was maintained at −20 to −25°C. Immediately thereafter, a solution of the 1-substituted pyrrole (1 equiv.) in $CH_2Cl_2$ (15 mL/g) was added at the same temperature. The solution was then stirred for the time and at the temperature specified in Table 1, after which time it was washed successively with dilute HCl and saturated aqueous NaCl solution. The $CH_2Cl_2$ solution was dried and evaporated *in vacuo*. The residue was subjected to column chromatography on Florisil. For compounds **18***a* and **18***h* the column was eluted successively with hexane, and hexane–ether (95:5, then 90:10); for compound **18***b* the product was eluted with hexane–EtOAc mixtures (95:5, then 80:20).

*Synthesis of 1-(2-tetrahydropyran-2-yloxy)-2-ethoxalylpyrrole* ***18a*** *by alkylation of 2-ethoxalylpyrrole with the tetrahydropyranyl ether of bromoethanol (ref. 16)*

To a stirred suspension of NaH (prepared by washing 50% NaH in mineral oil (7.9 g, 165 mmol) with hexane) in dry DMF (150 mL), maintained in a $N_2$ atmosphere, was added 2-ethoxalylpyrrole (5) (25.0 g, 150 mmol) in portions. After 0.75 h, the tetrahydropyranyl ether of bromoethanol (46.7 g, 224 mmol) was added and the solution was left at room temperature for 16 h. The solution was diluted with $C_6H_6$ and the mixture was washed well, first with $H_2O$ and then with saturated aqueous NaCl solution. The organic phase was dried and evaporated *in vacuo*. The residue was chromatographed on silica gel (600 g) using EtOAc–hexane (9:1) to elute the product (36.0 g, 81%) which was identical to that obtained by the acylation of 1-(2-tetrahydropyran-2-yloxy)pyrrole with ethoxalyl chloride.

*1-(2-Hydroxyethyl)pyrrole-2-glyoxylic acid* ***18c***

A solution of the tetrahydropyranyloxy ether **18***a* (10.0 g, 33.8 mmol) in 65% HOAc (150 mL) was stirred at 55°C for 2 h. The solvent was evaporated *in vacuo* and the residue was subjected to column chromatography on silica gel (300 g). The free hydroxy compound (6.1 g, 85%), which was eluted with hexane–EtOAc (4:1), was obtained as an oil (uv (MeOH): 303 nm (ε 9120); ir ($CHCl_3$): 3615, 3420, 1737, 1643 $cm^{-1}$; mass spectrum *m/e*: 211 ($M^+$)). The hydroxy compound was not characterized further; instead, it was converted directly to the carboxylic acid **18***c* as follows. A mixture of the above ester (4.75 g, 22.5 mmol) and $K_2CO_3$ (6.54 g), in 80% MeOH (100 mL), was heated at reflux temperature for 1 h. The mixture was evaporated to dryness *in vacuo*; $H_2O$ (4 mL) was added to the residue; the solution which resulted was cooled to 0°C and made acidic with concentrated HCl. The product was extracted into EtOAc, the extract was washed with saturated NaCl solution and dried. The solvent was removed *in vacuo* leaving a solid (3.84 g, 93%), which was crystallized from ether–EtOAc to give the very unstable α-oxocarboxylic acid **18***c*, mp 85–90°C (dec.), which was best characterized as the stable dicyclohexylammonium salt. This salt was prepared by adding the carboxylic acid (0.590 g, 3.2 mmol) to a stirred 1:1 MeOH–ether (10 mL) solution of dicyclohexylamine (0.634 g, 3.5 mmol). After 0.5 h, ether (25 mL) was added and the precipitated salt, mp 170–172°C (0.935 g, 80%), was collected by filtration, washed with ether, and dried *in vacuo*. It was recrystallized from ether–MeOH for analysis.

*Ethyl 1-(2-acetoxyethyl)-4-formylpyrrole-2-glyoxalate* ***18d***

Phosphorus oxychloride (35.1 g, 229 mmol) was added to dry DMF (17.3 g, 237 mmol), with stirring and cooling, at a rate such that the internal temperature was maintained at 10–20°C. When the addition was completed, the solution was stirred at room temperature for 15 min, and then it was mixed with anhydrous 1,2-dichloroethane (50 mL) and the mixture was cooled in an ice bath. When the internal temperature had reached 5°C, a solution of 1-(2-acetoxyethyl)-2-ethoxalylpyrrole **18***b* (10.0 g, 39.5 mmol) in 1,2-dichloroethane (50 mL) was added over a 0.5 h period. The mixture was then stirred at reflux temperature for 8 h, cooled to room temperature, and a solution of NaOAc·3 $H_2O$ (161 g, 1.18 mol) in $H_2O$ (220 mL) was added cautiously. The mixture was heated at reflux temperature with stirring for 15 min and after cooling the organic phase was separated and the aqueous phase was extracted with ether (3 × 100 mL). The combined organic phases were washed with saturated $Na_2CO_3$ solution and then dried. The solvent was removed *in vacuo* and the residue was chromatographed on Florisil (300 g) using hexane–EtOAc (95:5 and 90:10) to elute the oily product (7.5 g, 68%).

*1-(2-Hydroxyethyl)-4-formylpyrrole-2-glyoxylic acid* ***18e***

This carboxylic acid was obtained by hydrolysis of the ester **18***d* in the same manner as described for the synthesis of **18***c*, except that the reaction was conducted at room temperature for 14 h. The crude product (44% yield) was crystallized from acetone for analysis.

*1-(2-Acetoxyethyl)-2-ethoxalyl-4-methoxymethylpyrrole* ***18f*** *and 1-(2-hydroxyethyl)-2-ethoxalyl-4-hydroxymethylpyrrole* ***18g*** *from* ***18b***

Concentrated HCl (1.5 mL) was cooled to 0–5°C and $Ac_2O$ (6 mL) was added, at a rate such that the temperature did not exceed 5°C, over a 1.5 h period. The mixture was stirred at room temperature for 16 h and then dimethoxymethane (3 mL) and a solution of 1-(2-acetoxyethyl)-2-ethoxalylpyrrole **18***b* (1.00 g) in anhydrous $C_6H_6$ (6 mL) were added and the solution was heated at 63°C for 1.5 h. The solution was cooled to room temperature, MeOH (10 mL) was added, and the solution was stirred at room temperature for 16 h. The solvent was evaporated *in vacuo* and a saturated solution of $Na_2CO_3$ was added to the residue. The mixture was extracted with EtOAc, the extract was washed well with $H_2O$ and dried over $MgSO_4$. The solvent was removed *in vacuo* and the residue was subjected to tlc on silica gel using hexane–EtOAc (65:35) as the developing solvent. The acetate **18***f* (0.115 g, 10%) was obtained as an oil, while the alcohol **18***g* (0.255 g, 26%) was isolated as a solid which was crystallized from hexane.

When this reaction was carried out on a 158 mmol scale, compounds **18***f* and **18***g* were isolated in 17% and 12% yields, respectively.

*1-(2-Chloroethyl)-2-ethoxalyl-4-methoxymethylpyrrole* ***18i***, *1-(2-chloroethyl)-2-methoxalyl-4-methoxymethylpyrrole* ***18j***, *and 1-(2-chloroethyl)-2-ethoxalyl-4-hydroxymethylpyrrole* ***18k***

The reaction of 1-(2-chloroethyl)-2-ethoxalyl pyrrole with dimethoxymethane was carried out in exactly the same manner as described above for the synthesis of **18***f* and **18***g*. The mixture was separated by tlc on silica gel using hexane–EtOAc (4:1) as the developing solvent.

*1-(2-Chloroethyl)-2-ethoxalyl-4-chloromethylpyrrole* ***18l***

To isolate the title compound, a reaction was carried out in the normal manner but the MeOH treatment was not carried out. Instead, the reaction mixture was poured into dilute $Na_2CO_3$ solution. The mixture was extracted into EtOAc, the extract was washed to neutrality with $H_2O$, dried over $MgSO_4$, and evaporated *in vacuo*. The crude product was then subjected to tlc on silica gel (hexane–EtOAc (4:1)), which gave the 4-chloromethyl compound **18***l* as well as a small amount (9%) of the 4-hydroxymethyl compound **18***k* which resulted from the hydrolysis of the chloro compound during the chromatographic process.

*Synthesis of 1-(2-chloroethyl)-2-ethoxalyl-4-methoxymethylpyrrole* ***18i*** *by acid catalyzed reaction of* ***18k*** *with methanol*

A solution of the hydroxymethyl compound **18***k* (0.150 g) in anhydrous MeOH (5 mL) containing *p*-TsOH·$H_2O$ (0.005 g) was heated at reflux temperature for 1.5 h. The MeOH was removed *in vacuo* and $H_2O$ (5 mL) was added to the residue. The product was extracted into ether, the extract was washed with $H_2O$, dried over $MgSO_4$, and evaporated *in vacuo*. The crude product was purified by tlc on silica gel (hexane–EtOAc (4:1)), followed by crystallization from ether to give the 4-methoxymethyl compound **18***i* (0.110 g, 70%) identical to the material obtained as described above.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

*Acetolysis of 1-(2-chloroethyl)-2-ethoxalyl-4-methoxymethylpyrrole* ***18****i*

A mixture of the title compound **18***i* (40 g, 146 mmol), fused NaOAc (59.9 g, 730 mmol), and NaI (65.7 g, 438 mmol) in anhydrous DMF (500 mL) was heated at 65°C for 40 h. The reaction mixture was cooled to room temperature, poured into $H_2O$, and then extracted with $C_6H_6$. The extract was washed well with $H_2O$, dried over $MgSO_4$, and evaporated *in vacuo*. The residue (35 g) was subjected to column chromatography on silica gel (1.05 kg). Elution with hexane–EtOAc (85:15) gave, in succession, 1-vinyl-2-ethoxalyl-4-methoxymethylpyrrole **20** (4.3 g, 12%) as an oil, the 1-(2-acetoxyethyl) compound **18***f* (15.0 g, 35%), and the 1-(2-hydroxyethyl) compound **18***g* (7.0 g, 21%).

*1-(2-Acetoxyethyl)-2-ethoxalyl-4-chloropyrrole* ***18****m* *and 1-(2-acetoxyethyl)-2-ethoxalyl-5-chloropyrrole* ***22****a*

Recently distilled $SO_2Cl_2$ (13.7 mL, 170 mmol) was added at −70°C to a stirred solution of 1-(2-acetoxyethyl)-2-ethoxalylpyrrole **18***b* (40.5 g, 160 mmol) in anhydrous $CH_2Cl_2$ (900 mL). When the addition was completed, the solution was left to come to room temperature and after 2 h the solvent was removed *in vacuo*. The oily residue was taken up in $CH_2Cl_2$, the solution was washed to neutrality with $H_2O$ and dried. The solvent was evaporated *in vacuo* and the residual mixture (63 g) was separated by column chromatography on silica gel (800 g) using hexane–EtOAC (9:1) as the eluting solvent. In this way there was obtained the desired 4-chloro compound **18***m* (19.0 g, 41%) as an oil, the isomeric oily 5-chloro compound **22***a* (16.0 g, 34%), as well as some starting material (2.3 g).

*1-(2-Acetoxyethyl)-2-ethoxalyl-4-bromopyrrole* ***18****n* *and 1-(2-acetoxyethyl)-2-ethoxalyl-4,5-dibromopyrrole* ***22****b*

Bromine (3.0 mL, 58.3 mmol) was added in a dropwise manner to a stirred solution of 1-(2-acetoxyethyl)-2-ethoxalylpyrrole **18***b* (14.8 g, 58.3 mmol) in anhydrous $CH_2Cl_2$ (200 mL) at −75°C. After 2.5 h at this temperature, the temperature was left to reach ambient and the solvent was removed *in vacuo*. $CH_2Cl_2$ was added to the residue and the solution was washed successively with $H_2O$, 10% $NaHCO_3$ solution, and $H_2O$. The solution was dried, evaporated *in vacuo*, and the mixture (18.3 g) was separated by column chromatography on Florisil (1 kg) using hexane–EtOAc (9:1) as the eluting solvent. This gave the mono bromo compound **18***n* (10.9 g, 56%) as an oil, as well as lesser amounts of the crystalline dibrominated pyrrole **22***b* (4.8 g, 20%) and the starting material (2.1 g). These compounds were eluted from the column in the order **22***b*, **18**n, **18***b*. See Tables 1 and 2 for other data concerning the products.

*1-(2-Hydroxyethyl)pyrrol-2-acetic acid* ***19****a* *and methyl 1-(2-hydroxyethyl)pyrrol-2-acetate* ***19****b*

A solution of 85% KOH (85 g, 1.29 mol), in $H_2O$ (150 mL), was added with stirring to a cooled solution of the ester **18***b* (151 g, 0.597 mol), in MeOH (550 mL), at a rate such that the temperature did not exceed 15°C. The cooling bath was removed and after the mixture had reached ambient temperature it was stirred for a further 2 h. The solution was evaporated to dryness *in vacuo*, $C_6H_6$ was added to the residue, and the mixture was again evaporated *in vacuo*. This process was repeated 3–4 times to remove the $H_2O$. To the solid thus obtained was added diethylene glycol (500 mL) and 85% hydrazine hydrate (209 mL), and the mixture was heated in an oil bath at 100–110°C for 2 h in a nitrogen atmosphere. The solution was cooled to 40–50°C and solid 85% KOH (pellets, 225 g) was added carefully in small portions (vigorous foaming). The apparatus was set up for distillation and the mixture was slowly heated in an oil bath to 170–180°C. This temperature (internal temperature rose to 145°C) was maintained for 1 h 10 min, during which time a distillate (300 mL) was collected. The apparatus was then changed to allow boiling under reflux, at which temperature the reaction was maintained for 2 h. The mixture was cooled to room temperature, $H_2O$ (1.5 L) was added, and the solution was cooled to 0°C. Concentrated HCl (530 mL) was added in a dropwise manner at 0°C, which gave a solution with pH ca. 4. The product was extracted with EtOAc (3 × 2 L), the extract was washed with saturated salt solution, dried, and evaporated *in vacuo* to give the crude acetic acid **19***a* (105 g) as an oil.

A small portion of the crude carboxylic acid was converted into the crystalline dicyclohexylammonium salt, in ether, in the manner described for **18***c*. The crude salt was crystallized from $CH_2Cl_2$–ether (see Table 1).

To a solution of the above crude carboxylic acid in dry DMF (500 mL) was added $K_2CO_3$ (93.3 g) and MeI (180 g). The mixture was stirred at room temperature for 18 h, after which time it was poured into a large volume of saturated salt solution and ice. The product was extracted with $C_6H_6$ (3 × 2 L); the extract was washed with salt solution, dried, and evaporated *in vacuo*. The residue was purified by column chromatography on Florisil (1.2 kg). The product began to come off the column on elution with hexane–EtOAc (9:1) and was completely removed with a 3:2 mixture of these solvents. The ester was obtained as an oil (49–66% yield from **18***b*).

This ester could also be obtained by reaction of the crude carboxylic acid with excess ethereal $CH_2N_2$ (52–54% overall from **18***b*).

*1-(2-Hydroxyethyl)-4-methylpyrrol-2-acetic acid* ***19****e* *and methyl 1-(2-hydroxyethyl)-4-methylpyrrol-2-acetate* ***19****f*

The carboxylic acid **19***e* was prepared from the 4-formyl compound **18***d* in exactly the same manner as described above for the synthesis of **19***a*, except that ethylene glycol was used as the solvent for the Huang–Minlon version of the Wolff–Kishner reduction, and the ethylene glycol was removed *in vacuo*. The residual solid was dissolved in $H_2O$ and then worked up in the usual way to give the crude unstable carboxylic acid **19***e*, which was immediately converted into the methyl ester **19***f* with ethereal $CH_2N_2$.

Alternatively, it was not necessary to isolate the unstable acid **19***e*. Instead, after removal of the ethylene glycol *in vacuo*, the residual solid, containing the potassium salt of the carboxylic acid **19***e* (obtained from **18***d* (4.81 g)), was dissolved in DMSO (20 mL) and $H_2O$ (5 mL). MeI (31 mL) was added and, after 14 h at room temperature, water was added and the product was extracted with ether. The extract was washed with saturated salt solution, dried, and evaporated *in vacuo*. The product was purified by column chromatography on Florisil using hexane–EtOAc (95:5) to elute the desired ester **19***f*.

*Methyl 1-(2-hydroxyethyl)-4-methoxymethylpyrrol-2-acetate* ***19****j* *and methyl 1-(2-hydroxyethyl)-4-methoxymethylpyrrole-2-carboxylate* ***21***

A solution of 85% KOH (1.36 g, 20.7 mmol) in $H_2O$ (4 mL) was added to a stirred and cooled mixture of the α-keto ester **18***f* (3.00 g, 10.1 mmol) and ethylene glycol (120 mL, argon atmosphere) at a rate such that the reaction temperature did not exceed 0°C. The hydrolysis was complete in about ten minutes. At this stage, 85% hydrazine hydrate (1.7 mL) was added, the cooling bath was removed, and the mixture was heated at 100–110°C for 2.5 h. The solution was cooled to 40°C and 85% KOH (2.32 g) was added cautiously. The apparatus was set up for distillation, placed in an oil bath, and slowly heated to 170°C. During a 0.5 h period distillation occurred (90–120°C) and then vacuum was applied and ca. 10 mL of ethylene glycol was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

removed. The apparatus was set up for heating under reflux and the solution was heated at 145°C for 3 h. At the end of this time the major portion of the ethylene glycol was removed *in vacuo*, the mixture was cooled to 0°C, DMSO (40 mL) and MeI (8 mL) were added, and the solution was stirred at room temperature for 6 h. The solution was poured into $H_2O$, extracted with an EtOAC–ether mixture (1:1), and the extract was washed with saturated NaCl solution and dried over $MgSO_4$. The solvent was removed *in vacuo* and the residue was separated by tlc on silica gel using hexane–EtOAc (3:2) as the developing solvent. There was thus obtained the pyrrole carboxylic acid derivative **21** (0.160 g, 7%) and the desired pyrrole acetic acid derivative **19***j* (1.30 g, 57%), both as oils. The latter compound was characterized as the crystalline 4-(4-nitro)phenylazobenzoate.

*Sodium borohydride reduction of ethyl 1-(2-acetoxyethyl)-4-chloropyrrole-2-glyoxalate* ***18***m

$NaBH_4$ (23.7 g, 624 mmol) was added to 8% aqueous MeOH (325 mL) with stirring at −30°C. When the vigorous reaction had subsided, a solution of the α-keto ester **18***m* (40.0 g, 139 mmol) in MeOH (400 mL) was added at a rate such that the reaction temperature did not exceed −20°C. When the addition was completed, the solution was stirred for 2 h at −30°C and then a solution of HOAc (21.5 mL) in $H_2O$ (320 mL) was added. After an additional 1 h at −30°C the precipitated solid was collected by filtration and dissolved in $CH_2Cl_2$. This solution was washed with saturated NaCl solution, dried, and evaporated *in vacuo*. The solid alcohol **23***a* (33.2 g, 83%; homogeneous by tlc), which was obtained, was of sufficient purity to be used directly in the next step.

*Sodium borohydride reduction of ethyl 1-(2-acetoxyethyl)-4-bromopyrrole-2-glyoxalate* ***18***n

$NaBH_4$ (3.07 g, 81.2 mmol) was added at −50°C to 2.5% aqueous methanol (103 mL) and after 5 min a solution of the 4-bromo compound **18***n* (8.90 g, 26.7 mmol) in MeOH (40 mL) was added, with stirring, at a rate such that the reaction temperature did not exceed −40°C. After 1 h at −40°C, 50% HOAc was added until the solution was weakly acidic. The MeOH was removed *in vacuo*, the residue was shaken with EtOAc, and the organic phase was washed with saturated NaCl solution. After drying, the solvent was removed *in vacuo* and the residue was crystallized at low temperature from ether to give the alcohol **23***b* (6.0 g, 67%). This solid is very unstable at room temperature and must be stored in an evacuated vessel at −10°C.

*Synthesis of the ethyl 1-(2-acetoxyethyl)-4-halopyrrol-2-acetates* ***19***l *and* ***19***p *by reduction of the α-hydroxy esters* ***23***a *and* ***23***b

Triphenylphosphine (2 equiv.) was added to a stirred solution of $I_2$ (1 equiv.) in anhydrous $C_6H_6$ (15–25 mL/g $I_2$) maintained in an inert atmosphere. After 5–10 min, the α-hydroxy ester (1 equiv.) was added all at once. The mixture was then heated at reflux temperature for 2.5 h (**23***a*) or stirred at room temperature for 18 h (**23***b*). The mixture was filtered, the filtrate was washed well with NaCl solution, dried, and evaporated *in vacuo*. The chloro compound **19***l* was purified by column chromatography on Florisil using hexane–EtOAc (9:1) as the eluting solvent. The oily ester **19***l* (83% yield) must be stored in the cold in the presence of a few drops of $Et_3N$.

The bromo compound **19***p* was purified by column chromatography on silica gel using hexane–EtOAc (1:1 and 4:1) as the eluting solvent system. An oil (86% yield) was obtained which was even less stable than the chloro compound. It was best used immediately in the next step but could be stored safely at Dry-Ice temperature in the presence of a few drops of $Et_3N$.

*Methyl 1-(2-hydroxyethyl)-4-halopyrrol-2-acetates* ***19***m *and* ***19***q

A solution of the acetoxyethylpyrrole in anhydrous MeOH (10–15 mL/g of pyrrole) containing 1,5-diazabicyclo[4.3.0]non-5-ene (1–2 drops/5 mmol substrate) was left at room temperature in an inert atmosphere for the specified time. The solvent was removed *in vacuo*; the residue was taken up in EtOAc; the solution was washed with saturated salt solution, dried, and evaporated *in vacuo*. The residual oil was unstable at room temperature but could be stored at low temperature in an inert atmosphere if a few drops of $Et_3N$ was added.

*1-(ω-Hydroxyalkyl)-2-dimethylaminomethylpyrroles* ***24***a–c

The 1-(ω-hydroxyalkyl)pyrrole (1 equiv.) was heated to 50°C in an oil bath and a solution of $Me_2NH{\cdot}HCl$ (1.2–1.35 equiv.) in 37% aqueous HCHO (7–10 g/100 mmol pyrrole), which was prewarmed to 45°C, was added with stirring at a rate such that the reaction temperature did not exceed 60°C (ca. 1 h). The reaction mixture was then allowed to reach room temperature and stirring was continued for a further 2 h. At the end of this period, 20% NaOH (15.5–19 mL/100 mmol pyrrole) and $H_2O$ (40–60 mL/100 mmol starting pyrrole) were added and the product was extracted into $CH_2Cl_2$. The extract was washed with saturated salt solution, then with $H_2O$, and finally it was dried. The solvent was removed *in vacuo* and the residue was purified by distillation (**24***a*), by column chromatography on silica gel (**24***c*, hexane–EtOAc (1:1)), or by column chromatography on silica gel ($CH_2Cl_2$–MeOH (95:5)) followed by distillation (**24***b*).

*1-(ω-Hydroxyalkyl)pyrrol-2-acetonitriles* ***26***a, ***26***d, *and* ***26***f

Dimethyl sulfate (1.03–1.18 equiv.) was added to a stirred and cooled (0°C) solution of the 1-hydroxyalkylated-2-dimethylaminomethylpyrrole (1 equiv.) in acetone (5 mL/g pyrrole), maintained in a nitrogen atmosphere, at a rate such that the reaction temperature did not exceed 4°C. When the addition was completed, the solution was stirred at room temperature for 1 h and then a solution of NaCN (2.0–2.4 equiv.) in $H_2O$ (2.2 mL/g NaCN) was added. The apparatus containing the reaction mixture was set up for distillation and the reaction mixture was heated on a steam bath. Distillation was continued until the temperature of the reaction mixture reached 90–95°C. At this point the solution was heated at reflux temperature for 0.5 h. The reaction mixture was cooled to room temperature, and after dilution with $H_2O$ it was extracted with $CH_2Cl_2$. The extract was washed with half-saturated NaCl solution and after drying it was evaporated *in vacuo*. The residue was subjected to column chromatography on silica gel using hexane–EtOAc (3:2 for **26***a*, 85:15 for **26***d*, and 4:1 for **26***f*) to elute the product. Compounds **26***d* and **26***f* were further purified by distillation.

*Cyclization of the 1-(ω-iodoalkyl or ω-methanesulfonyloxyethyl)pyrrole diesters* ***4***c, ***4***f, ***4***i, ***4***k, ***4***m, ***7***c, ***10***c, *and* ***10***f *to the bicyclic diesters* ***5***a, ***5***d, ***5***g, ***5***j, ***5***m, ***8***a, ***11***a, *and* ***11***d, *respectively*

NaH (50% in mineral oil, or 100%; 1–1.2 equiv.) was suspended in anhydrous DMF (100–300 mL/g of NaH) and the mixture was cooled with stirring (inert atmosphere) to 0°C. The iodide or the methanesulfonate (1 equiv.) was added neat, in small portions, or as a solution in dry DMF for compound **10***f* (10 mL/g iodide). A vigorous evolution of hydrogen, in some cases accompanied by considerable foaming, took place. The solution was then stirred at the temperature and for the time indicated in Table 2. The reaction mixture was poured into a large volume of $H_2O$ and the product was extracted into $C_6H_6$ or EtOAc (compounds **5***j*, **5***m*, and **11***d*). The extract was washed successively with $H_2O$ and saturated salt solution and then it was dried and evaporated *in vacuo*. The residue was purified by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

crystallization (compounds **5***a* and **8***a*) or by column chromatography or tlc followed by crystallization. The following compounds were first purified by column chromatography on silica gel using the solvent systems indicated: **5***d*, **5***m*, **11***a* (hexane–EtOAc (7:3)); **5***j* (hexane–ether (4:1 to 1:4)). Compound **5***g* was purified by column chromatography on Florisil (hexane–EtOAc (9:1)) and the bicyclic diester **11***d* was obtained pure by tlc on silica gel using hexane–EtOAc (7:3) as the developing solvent.

The yields, physical constants, and spectroscopic properties of these compounds are given in Tables 2 and 5.

*Cyclization of the 1-(ω-iodoalkyl or ω-iodomethanesulfonyloxyalkyl)pyrrole acetic esters and acetonitriles* ***19***d, ***19***h, ***19***k, ***19***o, ***19***r, ***26***c, ***26***e, *and* ***26***g *to the bicyclic monoesters and bicyclic nitriles* ***6***h–l *and* ***27***a–c, *respectively*

A solution of the iodide or the methanesulfonate (1 equiv.) in dry DMF (1–10 mL/g substrate) was added with stirring at −5–15°C (inert atmosphere) to a suspension of NaH (1–1.2 equiv.) in dry DMF (20–120 mL/g of NaH). The reaction mixture was then stirred for the time and at the temperature shown in Table 2 and the reaction was worked up in the manner described above. $CH_2Cl_2$ was used as the extracting solvent for **27***a*, while $C_6H_6$ was utilized as the extractant for all of the other reaction products. Compounds **6***h*, **6***j*, and **6***l* were purified by tlc on silica gel using hexane–EtOAc (7:3 for **6***i* and **6***j*, 4:1 for **6***l*) as the developing solvent. Methyl 6-methyl-1,2-dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylate **6***i* was purified by column chromatography on Florisil using hexane–EtOAc (95:5) as the developing solvent. All of the other compounds were purified by column chromatography on silica gel using hexane–EtOAc to elute the desired material (9:1 for **6***k*, 10:1 for **27***a*, and 95:5 for **27***b*,*c*). Compounds **6***h*–*l* could be stored for extended periods at ≤ −20°C in the presence of a trace of $Et_3N$. The nitriles **27***a*–*c* were stable at ambient temperature.

*Saponification of the diesters* **5**a, **5**d, **5**g, **5**j, **5**m, **8**a, **11**a, *and* **11**d

A solution of the diester (1 mol) in MeOH or EtOH (10–50 mL/g of ester) containing $H_2O$ (5–20 mL/g of ester) and 85% KOH (3.8 mol) was heated at reflux temperature for the time stipulated in Table 2. The alcoholic solvent was removed *in vacuo* and the residual aqueous phase was extracted with ether. The basic aqueous layer was then cooled to 0°C and made acidic with 5 *N* HCl solution. If the dicarboxylic acid precipitated, it was collected by filtration, washed with $H_2O$, and dried *in vacuo*. If the dicarboxylic acid did not precipitate from solution, it was extracted with EtOAc. The extract was washed well with $H_2O$, dried, and evaporated *in vacuo*. The crystalline residue was recrystallized from a suitable solvent system for analysis (see Table 4).

*Synthesis of the monoisopropyl esters* **5**c, **5**f, **5**l, **5**o, **8**c, **11**c, *and* **11**f *by selective esterification of the corresponding dicarboxylic acids*

A solution or a suspension of the dicarboxylic acid in anhydrous *i*-PrOH (15–50 mL/g of diacid) was cooled to 0 to −10°C and HCl gas was bubbled through the *i*-PrOH until saturation was achieved. The solution was then left at ambient temperature for the time indicated in Table 2 and then the solvent was evaporated *in vacuo*. $C_6H_6$ was added to the residue and the mixture was evaporated to dryness *in vacuo* again. This process was repeated a total of three times and the solid residue was then crystallized from a suitable solvent.

Alternatively, after removal of the *i*-PrOH, the residue was dissolved in EtOAc, the resulting solution was washed well with $H_2O$, dried, and evaporated *in vacuo*. The residual solid was purified by crystallization.

Under the conditions described, the 6-ethyl substituted dicarboxylic acid **5***h* did not give the expected monoacidic ester **5***i*. Instead, *i*-propyl 6-ethyl-1,2-dihydro pyrrolo[1,2-*a*]pyrrole-1-carboxylate **6***d* was obtained directly, presumably as a result of the acid catalyzed decarboxylation of **5***i*.

*Decarboxylation of the dicarboxylic acid monoisopropyl esters* **5**c, **5**f, **5**l, **5**o, **8**c, **11**c, *and* **11**f

The carboxylic acid was heated, in an inert atmosphere, to a temperature (see Table 2) at which decarboxylation occurred at a rapid but controllable rate. In most cases the decarboxylation was effected in a distillation apparatus (in some cases, under a vacuum of 20–40 Torr) and the product distilled as it was formed. The purity of material obtained in this way was usually at least 95%. In some cases, it was more convenient to effect the decarboxylation without simultaneous distillation of the product. The product obtained in this way could then be purified by tlc on silica gel (e.g., **12***b*; hexane–ether (4:1)) or by column chromatography on silica gel (e.g., **6***a*; 200 mL fractions; elution with hexane (2 fractions), hexane–$C_6H_6$ (7:3, four fractions), hexane–$C_6H_6$ (1:1, eight fractions); product in fractions 7–14).

As mentioned above, the 6-ethyl substituted dicarboxylic acid monoisopropyl ester **5***i* was not observed, decarboxylation to **6***d* occurred during the acid catalyzed esterification. This compound was purified by tlc on silica gel using hexane–EtOAc (85:15) as the developing solvent.

All of these compounds were unstable to varying degrees in the presence of air and light. They could, however, be kept without decomposition for extended periods of time at low temperature (< −10°C) in the presence of a trace of $Et_3N$.

*1,2-Dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylic acid* **6**b *and 6-(2-methoxyethyl)-1,2-dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylic acid* **6**f

A solution of the *i*-propyl ester (1 equiv.) in MeOH (20 mL/g) and $H_2O$ (10 mL/g) containing 85% KOH (4 equiv.) was heated at reflux temperature for the time shown in Table 2. The MeOH was removed *in vacuo* and the aqueous alkaline residue was made acidic with 20% HCl. The product was extracted into EtOAc; the extract was washed with $H_2O$, dried, and evaporated *in vacuo*. The residual oil was dissolved in dry $C_6H_6$ and an equimolar amount of dicyclohexylamine was added. The solid which separated on standing was collected by filtration and crystallized from a suitable solvent system.

*5-Phenyl-1,2-dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylic acid* **12**c

A solution of the *i*-propyl ester **12***b* (0.60 g, 2.23 mmol) in MeOH (20 mL) and $H_2O$ (5 mL) containing $K_2CO_3$ (0.20 g, 1.45 mmol) was heated at reflux temperature in a nitrogen atmosphere for 1 h. After removal of the solvent *in vacuo*, $H_2O$ (20 mL) was added to the residue and the alkaline solution was extracted with ether. The aqueous phase was cooled to 0°C and made acidic with 4 *N* HCl. The product was extracted with saturated salt solution, dried, and evaporated *in vacuo*. Crystallization of the residue from EtOAc–hexane gave the pure carboxylic acid **12***c* (0.284 g, 56%), mp 162–163°C.

*Synthesis of methyl 1,2-dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylate* **6**h *and methyl 5,6,7,8-tetrahydropyrrolo[1,2-*a*]pyridine-8-carboxylate* **9**c *from nitriles* **27**a *and* **27**b, *respectively*

A solution of the nitrile (1 equiv.) in 95% EtOH (15–50 mL/g of nitrile) and $H_2O$ (1–2 mL/g of nitrile) containing 85% KOH (3–6 equiv.) was heated at reflux temperature for 3–9 hours. The

solvent was removed *in vacuo* and the residue was processed in a manner which depended on the substrate.

For the synthesis of **6***h* the above residue was dissolved in DMSO (5 mL/g of nitrile taken), the solution was cooled to 0°C, and MeI (4 mL/g of nitrile taken) was added. After stirring for 18.5 h at room temperature, the solution was poured into saturated NaCl solution and the product was extracted into $CH_2Cl_2$. The extract was washed with $H_2O$, dried, and evaporated *in vacuo*. The residual oil was subjected to column chromatography on Florisil using hexane–EtOAc (95:5) to elute the product (82%). The ester thus produced was identical to a sample prepared as described previously.

To prepare the methyl ester **9***c*, the residue described above, which in this case was mainly the crude, unstable carboxylic acid **9***b*, was diluted with $H_2O$ and the solution was made acidic with dilute HCl. The product was extracted with EtOAc, the extract was washed with $H_2O$, dried, and evaporated *in vacuo*. The residue was dissolved in $CH_2Cl_2$ and excess ethereal $CH_2N_2$ was added. The solvent was removed *in vacuo* and the residue was subjected to column chromatography as described above for **6***h*. The oily ester **9***c* (51%) was purified for analysis by tlc on silica gel using hexane–ether (1:1) as the developing solvent.

*5,6,7,8-Tetrahydro-9*H*-pyrrolo[1,2-*a*]azepine-9-carboxylic acid **28**a and methyl ester **28**b*

A solution of the nitrile **27***c* (1.00 g) in ethylene glycol (11 mL) and $H_2O$ (1.2 mL) containing 85% KOH (2.02 g) was heated in an oil bath at 118°C for 3 h. $H_2O$ was added, the solution was extracted with ether, and the aqueous phase was cooled to 5°C and made acidic with concentrated HCl. The product was extracted with EtOAc, the extract was washed with $H_2O$, dried, and evaporated *in vacuo*. The residue was recrystallized from EtOAc–ether to give the carboxylic acid **28***a* (1.03 g, 92%), mp 129–130°C.

The methyl ester was prepared by dissolving the carboxylic acid (2.9 g) in DMSO (25 mL) and $H_2O$ (5 mL), containing 85% KOH (1.11 g), and adding MeI (15 equiv.). After 18 h at room temperature, the reaction was worked up as described for **9***c* and the crude product was crystallized from $CH_2Cl_2$–hexane to give a solid (2.7 g, 89%), mp 56–57°C.

# The synthesis, characterization, and thermal isomerization of some 1,1,2,2-tetraarylcyclopropanes

DONALD R. ARNOLD,[1] DANIAL D. M. WAYNER, AND MASATO YOSHIDA
*Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3*

Received March 9, 1982

DONALD R. ARNOLD, DANIAL D. M. WAYNER, and MASATO YOSHIDA. Can. J. Chem. **60**, 2313 (1982).

The synthesis and spectral characterization of an extensive series of 1,1,2,2-tetraarylcyclopropanes are reported. The effects of substituents on the $^{13}$Cmr and $^{1}$Hmr chemical shifts are examined in detail. In a series of symmetrically substituted derivatives, the $^{13}$Cmr chemical shifts correlate with $\Sigma\sigma_R^0$. This correlation is only observed in cases where the $C_\alpha$—$C_\beta$ bond has no net polarity. Details of the thermal isomerization of those derivatives for which the possibility of *cis* and *trans* configurations exists are also reported. Trends in the Arrhenius parameters provide evidence for the biradical character of the transition state. Other data supporting the biradical character of the transition state are discussed.

DONALD R. ARNOLD, DANIAL D. M. WAYNER et MASATO YOSHIDA. Can. J. Chem. **60**, 2313 (1982).

On rapporte la synthèse et les caractéristiques spectrales d'une série importante de tétraaryl-1,1,2,2 cyclopropanes. On a examiné en détail l'effet des substituants sur les déplacements chimiques en rmn du $^{13}$C et du $^{1}$H. Dans les séries de dérivés substitués d'une façon symétrique, les déplacements chimiques du $^{13}$C correspondent à $\Sigma\sigma_R^0$. On observe cette corrélation uniquement dans les cas où la liaison C—$C_\beta$ n'a pas de polarité nette. On rapporte également les détails relatifs à l'isomérisation thermique de ces dérivés pour lesquels existe la possibilité de configuration *cis* et *trans*. La tendance des paramètres d'Arrhénius fournit la preuve du caractère biradicalaire de l'état de transition. On discute d'autres données qui appuient le caractère biradicalaire de l'état de transition.

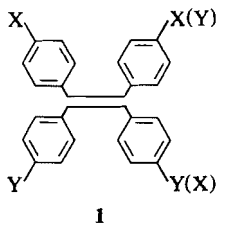
[Traduit par le journal]

## Introduction

We have reported the characterization of the ground and excited state surfaces for twisting about the double bond in tetraphenylethylene, and the effect of substituents on these surfaces (1). The results provided additional evidence for the 1,2-biradical character of the transition state for the thermal *cis–trans* isomerization of symmetrically substituted alkenes (1*a*, *c*, *e*, *g*, *i*, *l*).

The enhanced rate and significantly lower (8 kJ mol$^{-1}$) activation barrier for the thermal isomerization of the unsymmetrically substituted derivative 1*l* was attributed to merostabilization (1*a*). Direct irradiation of 1*a*, *c*, and *g* brought about efficient *cis–trans* isomerization. The sum of the quantum yields for *cis* to *trans* plus *trans* to *cis*

| | X | Y |
|---|---|---|
| *a* | $CH_3$ | H |
| *c* | $OCH_3$ | H |
| *e* | $OCH_3$ | $OCH_3$ |
| *g* | CN | H |
| *i* | CN | CN |
| *l* | $OCH_3$ | CN |



1

isomerization was essentially unity and the excited state ($S^1$) partitioned almost equally to the two isomers. In the case of 1*l*, however, the photostationary state significantly favoured the *trans* isomer and the efficiency of the *cis–trans* isomerization was greatly reduced. These differences were attributed to attractive dipolar forces between the methoxy and cyano substituted rings in the singlet excited state of this derivative (1*b*). The photosensitized (triplet–triplet energy transfer) isomerization of 1*a*, *c*, *g*, and *l* led to the same photostationary state, equal amounts of both isomers, for all four derivatives. However, the triplet energy of 1*l* was estimated to be about 8 kJ mol$^{-1}$ lower than the triplet energy of 1*a*, *c*, and *g*. This difference again was attributed to merostabilization (1*b*). The half-wave oxidation and reduction potentials of 1*a*, *c*, *e*, *g*, *i*, and *l* were found to correlate with the sum of the substituent parameters $\sigma^+$ and $\sigma^-$, respectively. These electrochemical data provided further information about the HOMO and LUMO of these alkenes, as well as further illustrating the effect of merostabilization on the stability of these radical-like (i.e. radical ion) species (1*a*).

This study has now been extended to the 1,1,2,2-tetraarylcyclopropane series. Our objective is to define the nature of the intermediates or transition states (the 1,3-biradicals and radical ions) that are involved in reactions of the 1,1,2,2-tetraarylcyclopropanes analogous to the previously studied tetraarylethylenes. Some of the

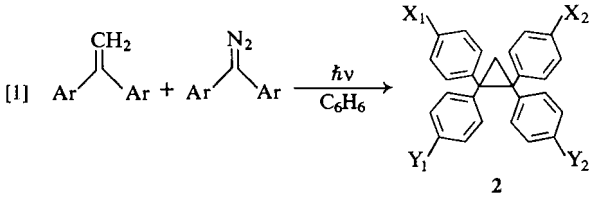
preliminary results have been published (2). In this paper we report the details of the synthesis, separation, purification, and spectral characterization of an extensive series of substituted 1,1,2,2-tetraarylcyclopropanes **2***a–m* (Table 1). All of these cyclopropanes, with the exception of the unsubstituted tetraphenyl derivative, are new compounds. In addition, this paper includes the details of the results of a study of the *cis–trans* thermal isomerization of the derivatives **2***c*, *g*, *j*, and *l* which were summarized in the preliminary communication (2*a*).

## Results and discussion

The tetraarylcyclopropanes were synthesized from the corresponding diaryldiazomethanes (3) and the 1,1-diarylethylenes (4), eq. [1].

In some cases, two routes were possible and both were tried. A better yield was obtained when the diarylmethylene bore the electron-donating substituents and the diarylethylene was substituted with the electron-withdrawing groups. For example, the yield of **2***j* was increased from 20% to 70% when the reactant pair was 4-methoxyphenylphenyldiazomethane and 1-(4-cyanophenyl)-1-phenylethylene. This relative reactivity is as expected (5).



**2**

Whenever configurational isomers were possible (**2***c*, *g*, *j*, and *l*), both *cis* and *trans* were obtained as an approximately equimolar mixture. Purification and separation of the isomers was achieved by medium pressure column chromatography on silica gel and/or by recrystallization. The composition of the isomeric mixtures could be determined conveniently by high pressure liquid chromatography.

The gross structures of the compounds **2***b–m* were inferred from their $^{13}$Cmr, $^1$Hmr, ir, and uv spectra and elemental analyses (or exact mass determination). Establishing the configuration of the isomeric pairs was straightforward in the case of **2***c*, *g*, and *l*. The cyclopropyl hydrogens are identical in the *trans* isomer of these derivatives, while an AB pair of doublets for these nonequivalent protons indicates the *cis* configuration.

Distinguishing *cis* from *trans* (**2***j*) was not trivial. The cyclopropyl hydrogens are obviously not equivalent in either isomer and the expected multiplet was observed for both. It seemed likely that an analysis of the nmr spectra, both $^{13}$C and $^1$H (Table 2), of this extensive series of analogous compounds would reveal some correlation upon which an assignment could be made. Furthermore, the nmr spectra of these compounds are of interest (6, 7). However, no correlation useful for assigning configuration to the isomers of **2***j* was evident.

The initial distinction between the *cis* and *trans* isomers of **2***j* rested on their relative thermodynamic stability (ref. 2*a* and Table 3). We knew that the thermal equilibrium in the case of **2***l* favoured the *trans* isomer. Therefore, the *cis* configuration was assigned to the more stable isomer of **2***j*. It

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

seems likely that through-space donor–acceptor interactions (8) between the cyano and methoxy substituted phenyl rings will stabilize the *cis* configuration of **2***j*. The magnitude of the equilibrium constant for **2***j* was, however, so small that the assignment was considered tentative (2*a*).

Confirmation of the structural assignment was provided by a complete X-ray analysis[2] of a single crystal of the less stable isomer (mp 134°C) which was shown to have the *trans* configuration of **2***j*.

*Substituent effects on the* $^{13}$*Cmr chemical shift*

The effect of ring substituents on the $^{13}$Cmr chemical shift (C-SCS) of a carbon α or β to the phenyl ring has been studied previously (6). It has been suggested that, in general, the $C_\alpha$-SCS are influenced primarily by the substituent Pauling electronegativity, $X_p$ (9), and to a lesser extent by resonance, $\sigma_R^0$ (6*c*–*e*). The data were treated in terms of a two parameter correlation plotting the $C_\alpha$-SCS against the substituent electronegativity and $\sigma_R^0$. The absolute magnitudes of the contribution of electronegativity ($\rho_{X_p}$) and resonance ($\rho_R$) cannot be compared since the substituent parameters $X_p$ and $\sigma_R^0$ are based on completely different energy scales. We can, however, obtain information about the relative importance of the two by comparing the ratios of $\rho_{X_p}$ to $\rho_R$. The results of Inamoto and co-workers (6*c*–*e*) clearly show that the relative magnitude of $\rho_{X_p}$ is much larger when $C_\alpha$ is *sp* or $sp^2$ than when $C_\alpha$ is $sp^3$ hybridized. Although they found a reasonable correlation using the two parameter approach for the *para*-substituted toluenes (**3**) ($r = 0.907$), we find that an even better correlation is obtained (Table 4) when their $C_\alpha$-SCS are plotted against $\sigma_R^0$ alone. Similar correlations were also observed for the 2-arylpropanes (**4**) and the arylcyclopropanes (**5**). We conclude that substituent electronegativity has some contribution to the $C_\alpha$-SCS for *sp* or $sp^2$ hybridized $C_\alpha$ but has a negligible effect when $C_\alpha$ is $sp^3$ hybridized. The effect of substitution on the $C_\beta$-SCS, on the other hand, has been interpreted as being dependent on the π-character of the $C_\alpha$—$C_\beta$ bond (6*e*) and on the dihedral angle between the plane of the aromatic ring and the $C_\alpha$—$C_\beta$ bond (6*b*).

Examination of the effect of aryl substituents on the $^{13}$C-SCS in the tetraarylcyclopropane series (Table 2) reveals that a complex mechanism for transmission of the substituent effects exists. Several important features can be pointed out. When all the data are considered, it is not surprising that no correlation is observed with $\Sigma\sigma_R^0$ in a one parameter Hammett plot. A two parameter Hammett plot, accommodating the effects of the α- and β-aryl substituents, also gives a poor correlation ($r = 0.80$). One surprising feature is that the $^{13}$C-SCS for the *cis* and *trans* isomers **2***c*, *g*, *j*, and *l* are virtually identical (at least for the quaternary cyclopropyl ring carbons). This implies that the influence of preferred conformations of the aryl rings is not as important as we had anticipated. If the series is limited to the symmetrically substituted derivatives **2***a*, *c*, *e*, *g*, *i*, and *l*, a good correlation is observed ($r = 0.97$) for a one parameter Hammett plot (Fig. 1). The slope of the correlation line in this case would actually be a composite ρ-value (i.e. $\rho = \rho_\alpha + \rho_\beta$ of a two parameter Hammett plot). Since the magnitude of ρ

| **5** | 2.00±0.27 | 0.96 |

[a]Correlation coefficient obtained from linear least-squares analysis.

is close to the ρ-value obtained for mono-arylcyclopropanes (Table 4), we are tempted to conclude that $\rho_\alpha$ is much greater than $\rho_\beta$. Although this may be the case, the evidence is not strong, since the absolute magnitude of $\rho_\alpha$ and $\rho_\beta$ is not known, only their sum is known; hence, the similarity may be fortuitous.

The $C_\alpha$—$C_\beta$ bond, in the symmetric derivatives, has no net polarity, thus the effect of a bond moment may account for the poor correlation obtained (10) when all of the derivatives are considered. The similarity in the trends observed for the tetraarylcyclopropane series and the toluene series indicates that the interaction of the cyclopropyl ring carbons with the aromatic ring is not fundamentally different than those interactions in the toluene series.

The $C_\beta(CH_2)$-SCS are much less sensitive to substitution (Table 2). Although the variation in chemical shift is only 1 ppm over the entire series, note that the $C_\beta(CH_2)$-SCS of the unsubstituted derivative **2***a* is at highest field, a result expected

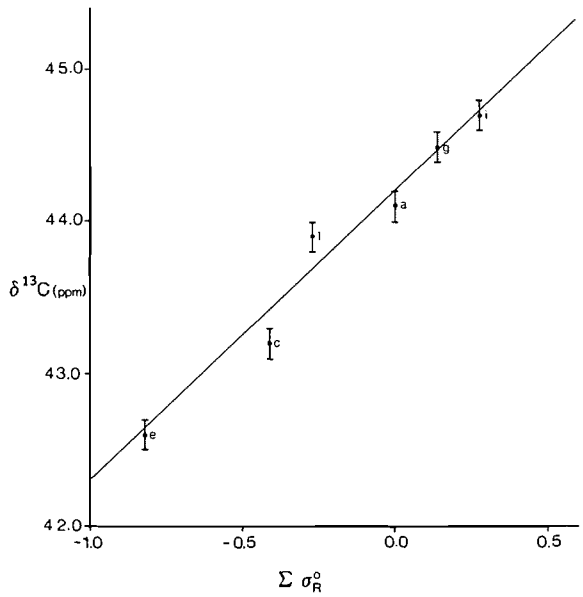

FIG. 1. Hammett plot of the $^{13}$C- CS of the symmetrical tetraarylcyclopropanes versus $\Sigma\sigma_R^0$.

considering the substituent electronegativity. This dependence is not observed for the less heavily arylated cyclopropane derivatives (**5**), or for the other phenylalkanes (**3**, **4**). The complex steric restrictions intrinsic to the tetraaryl series may be responsible for this anomalous behavior.

*Substituent effects on $^1$Hmr spectra*

The effect of the aryl substituents on the cyclopropyl ring proton chemical shifts has been studied previously (7) and our results are qualitatively similar. While correlation with substituent parameters is inadequate, the general trend observed is that the electron-donating substituents shield both methylene protons while the electron-withdrawing substituents deshield both. Table 2 shows the variation in chemical shift is only 0.3–0.4 ppm (~20 Hz) over the entire series. This effect is somewhat less than that reported for a series of *trans*-2-arylcyclopropanecarboxylic acids (7). This may be a result of different preferred conformations of the aryl ring with respect to the cyclopropane ring in the two series. The effect of the *para* substituents on the chemical shift of the cyclopropane methylene protons is additive. The *para*-methoxy substituent shifts the *cis*-methylene proton upfield by 0.07 ppm while the *trans*-methylene proton is shifted upfield by 0.04 ppm relative to the unsubstituted derivative (δ 2.54). In the case of the *para*-cyano substituent, the *cis*-methylene proton is shifted downfield by 0.1 ppm while the *trans*-methylene proton is shifted downfield by 0.02 ppm. The calculated values agree with the observed values to within 0.02 ppm (except **2***i* which appears 0.1 ppm upfield from the calculated value).

*Thermal isomerization*

The results for the thermal isomerization of **2***c*, *g*, *j*, and *l* have been summarized (ref. 2*a* and Table 3). The thermal *cis*–*trans* isomerization of **2** can be compared to the corresponding olefins (**1**), inasmuch as both involve the cleavage of a weak bond, a σ-bond for **2** and a π-bond for **1**. The trends in the activation energies as a function of substituent in **1** and **2** are remarkably similar. The lower activation barriers for **2** indicate a lower cyclopropane σ-bond strength compared to the olefin π-bond strength, about 20 kJ mol$^{-1}$ difference for these derivatives. Evidence for the biradical character of the transition state is obtained from an analysis of the substituent effects on the activation energy. If charge separation was involved at the transition state, the activation barrier of **2***j* would be expected to be lowered relative to the others. The lower barrier (9 kJ mol$^{-1}$) for **2***l* (and **1***l*) may be attributed to merostabiliza-

TABLE 5. The relationship between spin delocalization in the 1,3-biradical and the activation energy for thermal isomerization

[e]This work.

tion of the 1,3- (and 1,2-) biradical. The decrease in the preexponential factor (log *A*) in **2***l* is also consistent with the involvement of merostabilization. The merostabilized radical requires coplanarity of both rings and substituents; therefore, a decrease in the entropy of activation is expected (1*a*).

Further evidence for the biradical character of the transition state is obtained by comparing the activation barriers for the thermal isomerization of the series: **2**, *trans*-1,2-diphenylcyclopropane (**6**), 1-phenylcyclopropane-2-*d* (**5***d*), and cyclopropane-1,2-$d_2$ (**7**) (11). The differences in the activation energies reflect the relative σ-bond strengths. The bond strengths should parallel the extent of spin delocalization in the resulting radicals (i.e. transition state). A reasonable measure of spin delocalization can be obtained from spin density determinations for suitable model radicals. The α-hydrogen hyperfine coupling constant from the electron spin resonance spectrum is roughly proportional to the spin density at the carbon centre, and hence to the spin delocalization (12). The appropriate hydrocarbon radicals which adequately represent the transition state must also have at least one α-hydrogen. The series of model radicals with their corresponding spin densities are shown along with the activation energies for the cyclopropane thermal isomerization (Table 5). A plot of the activation energy versus the spin densities in the transition states (Fig. 2) reveals a good correlation ($r$ = 0.994). We have now confirmed the biradical character of the transition state in both **1** and **2**.

The difference in thermodynamic stability of these *cis* and *trans* isomers (Table 3) is small, less than 2.0 kJ mol$^{-1}$. Two factors (at least) influence the relative stability. Stabilization of the *trans* relative to the *cis* isomer may simply be the result of dipole–dipole interactions with the solvent. The difference in thermodynamic stability will increase as the difference in dipole moments between the

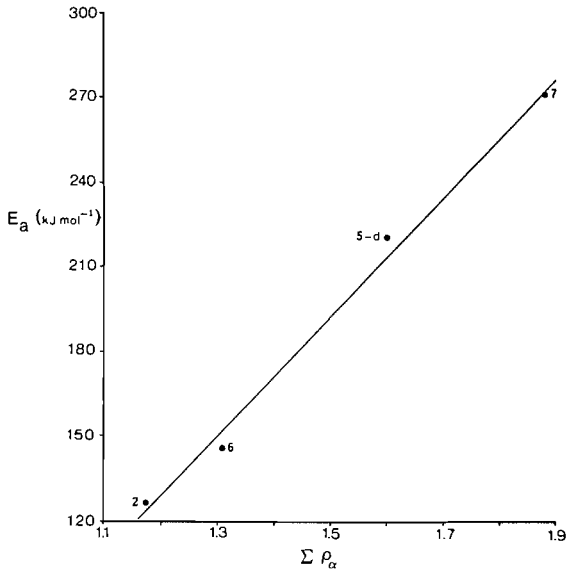

FIG. 2. Graph of activation energy ($E_a$) for cyclopropanes versus the estimated spin density ($\Sigma\rho_\alpha$) of the 1,3-biradical.

two isomers increases (1*a*). Intramolecular donor–acceptor interactions will also influence the relative stability of the two isomers. Electron-withdrawing substituents will lower the energy of the LUMO (i.e. lower the reduction potential) whereas electron-donating substituents will raise the energy of the HOMO (i.e., lower the oxidation potential). The difference in thermodynamic stability of the isomeric pairs will increase as the difference in redox potentials ($E^{ox}_{donor} - E^{red}_{acceptor}$) decreases. Evidence for intramolecular donor–acceptor interactions in similarly substituted cyclopropanes has been reported (8).

Although dipole–dipole interactions with the solvent can be used to rationalize the relative magnitudes of the equilibrium constants for **2***c*, *g*, and *l*, they do not predict the relative stability of *cis* and *trans* **2***j*. On the other hand, if intramolecular donor–acceptor interactions were solely responsi-

ble in determining $K_e$, then the equilibrium constant for **2***l* would be expected to be less than that for **2***g*. It is clear that both factors have an influence on the *cis–trans* equilibrium; it is difficult to assess the extent to which each is involved.

## Experimental

The $^1$Hmr and $^{13}$Cmr spectra were recorded on either a Varian T-60 or CFT-20 nmr spectrometer and are reported in parts per million (ppm) downfield from TMS. Infrared spectra were recorded on an air-purged Perkin–Elmer 180 grating infrared spectrometer and are reported in wavenumbers (calibrated against the 1601.8 $cm^{-1}$ absorption of polystyrene). Ultraviolet–visible absorption spectra were recorded on a Cary–Varian 219 absorption spectrometer and are reported in nanometers followed by the molar extinction coefficient. Elemental analyses were performed by Chemialytics, Inc. or Canadian Microanalytics, Inc., and agreed to within 0.3% of the calculated values. The melting points (uncorrected) were obtained on an Sybron Corporation Thermolyne melting point apparatus.

Bath temperatures for the thermal isomerization were maintained using a Fisher Proportional Temperature Control, and did not vary more than 0.5° during any particular run. The temperature was determined using a platinum resistance thermometer (Hewlett–Packard 2802A). Analyses of the cyclopropane mixtures were performed using a Tracor high performance liquid chromatograph which consists of a Tracor 995 isochromatographic pump, Model 970 variable wavelength absorbance detector, a Rheodyne model 7120 loop injection valve (20 μL volume), and a Hewlett–Packard model 7123A strip chart recorder, in conjunction with a Whatman Partisil PXS 10/25 analytical column. The hplc solvents were hexanes (Fisher reagent, distilled) and methylene chloride (Fisher reagent, distilled from phosphorous pentoxide). Peak areas were determined by cutting and weighing or multiplying height by half-width. The apparent mole fractions of the *cis* isomers (obtained by dividing the areas of the peak due to the *cis* isomer by the sum of the areas of both peaks) were converted to true mole fractions with working curves, which were simply plots of apparent vs. true mole fractions constructed with ten accurately weighed samples of "pure" *cis* and *trans* isomers.

The 1,1,2,2-tetraarylcyclopropanes were prepared by the addition of a diarylcarbene to a corresponding 1,1-diarylethylene in benzene. The diarylcarbenes were generated by the photolysis of the corresponding diaryldiazomethanes through a sodium nitrite filter. To reduce the formation of tetraarylazines, the diaryldiazomethanes were added to the olefin solutions in ten equal aliquots, allowing the colour to disappear between additions. The preparation of the diaryldiazomethanes and diarylolefins from the corresponding benzophenones has been described previously (3, 4). The tetraarylcyclopropanes were isolated by medium pressure chromatography or flash chromatography (13) and purified by recrystallization. The yields were generally greater than 60% except for **2***e* which was only 27%. The preparation of 1,1,2,2-tetraphenylcyclopropane has been reported previously (14). Details of the preparation, separation, purification, and characterization of each of the *para*-substituted derivatives are described below.

*1-(4-Methoxyphenyl)-1,2,2-triphenylcyclopropane (*2b*)*

Diphenyldiazomethane (0.9 g, 0.0046 mol) in 10 mL of benzene was added to 1-(4-methoxyphenyl)-1-phenylethylene (1.0 g, 0.0048 mol) in 20 mL of benzene (*vide supra*). After the photolysis was complete, the solvent was evaporated and the reaction mixture separated by medium pressure chromatography (silica gel, hexanes – methylene chloride gradient). The product was recrystallized three times from chloroform–methanol to give colourless plates (mp 145–146°C). Infrared (KBr): 3050 (m), 2839 (w), 1608 (m), 1512 (s), 1290 (m), 1246 (s), 1172 (s), 1028 (s), 798 (m), 699 (s); uv $\lambda_{max}$ (ethanol): 237 (20 000); $^1$Hmr $CDCl_3$) δ: 2.46 (d, 1H, $J$ = 0.1 Hz), 2.50 (d, 1H, $J$ = 0.1 Hz), 3.69 (s, 3H), 6.80 (m, 4H), 7.05 (m, 15H). *Anal.* calcd. for $C_{28}H_{24}O$: C 89.32, H 6.43; found: C89.50, H 6.38.

*1,2-Di(4-methoxyphenyl)-1,2-diphenylcyclopropane (*2c*)*

(4-Methoxyphenyl)phenyldiazomethane (1.5 g, 0.0067 mol) in 10 mL of benzene was added to 1-(4-methoxyphenyl)-1-phenylethylene (1.5 g, 0.0071 mol) in 20 mL of benzene (*vide supra*). After the photolysis was complete, the solvent was evaporated and the reaction mixture was separated by medium pressure chromatography (silica gel, hexanes – methylene chloride gradient). Rechromatographing the mixture of the *cis* and *trans* isomers (silica gel, hexanes – methylene chloride gradient) afforded pure samples of each. The *cis*-1,2-di(4-methoxyphenyl)-1,2-diphenylcyclopropane (*cis* **2***c*) was recrystallized from chloroform–ethanol to give colourless prisms (mp 139–141°C). Infrared (KBr): 3040 (w), 2833 (w), 1608 (m), 1510 (s), 1495 (m), 1447 (m), 1245 (s), 1033 (m), 826 (m), 697; uv $\lambda_{max}$ (ethanol): 236 (17 000); $^1$Hmr ($CDCl_3$) δ: 2.40 (d, 1H, $J$ = 5 Hz), 2.46 (d, 1H, $J$ = 5 Hz), 3.69 (s, 6H), 6.80 (m, 8H), 7.02 (m, 10H). *Anal.* calcd. for $C_{29}H_{26}O_2$: C 85.68, H 6.45; found: C 85.69, H 6.56.

The *trans*-1,2-di(4-methoxyphenyl)-1,2-diphenylcyclopropane (*trans* **1***c*) was recrystallized from chloroform–ethanol to give colourless prisms (mp 205–206°C). Infrared (KBr): 3030 (w), 2830 (m), 1606 (s), 1509 (s), 1457 (m), 1289 (m), 1241 (s), 1031 (s), 831 (m), 692 (m); uv $\lambda_{max}$ (ethanol): 235 (17 000); $^1$Hmr ($CDCl_3$) δ: 2.44 (s, 2H), 3.68 (s, 6H), 6.78 (m, 8H), 7.04 (m, 10H). *Anal.* calcd. for $C_{29}H_{26}O_2$: C 85.68, H 6.45; found: C 85.48, H 6.30.

*1,1-Di(4-methoxyphenyl)-2,2-diphenylcyclopropane (*2d*)*

Diphenyldiazomethane (1.2 g, 0.0062 mol) in 10 mL of benzene was added to 1,1-di(4-methoxyphenyl)ethylene (1.5 g, 0.0063 mol) in 20 mL of benzene (*vide supra*). The solvent was then evaporated and the reaction mixture separated by column chromatography (neutral alumina, hexane–benzene gradient). The product was recrystallized from chloroform–ethanol to give colourless prisms (mp 107–108°C). Infrared (KBr): 3030 (w), 2836 (w), 1608 (m), 1510 (s), 1290 (m), 1247 (s), 1179 (m), 1036 (m), 823 (m), 695 (m); uv $\lambda_{max}$ (ethanol): 236 (22 000); $^1$Hmr ($CDCl_3$) δ: 2.45 (s, 2H), 3.70 (s, 6H), 6.80 (m, 8H), 7.08 (m, 10H). *Anal.* calcd. for $C_{29}H_{26}O_2$: C 85.68, H 6.45; found: C 85.81, H 6.29.

*1,1,2,2-Tetra(4-methoxyphenyl)cyclopropane (*2e*)*

Di(4-methoxyphenyl)diazomethane (1.0 g, 0.004 mol) in 10 mL of benzene was added to 1,1-di(4-methoxyphenyl)ethylene (2.0 g, 0.008 mol) in 20 mL of benzene (*vide supra*). The solvent was then evaporated and the reaction mixture separated by flash chromatography (silica gel, methylene chloride). The product contained a trace amount of a fluorescent impurity which could be removed only by careful chromatography of the product and collecting the last few fractions as the compound eluted (basic alumina, hexane – methylene chloride gradient). The product was recrystallized from chloroform–hexanes to give colourless needles (mp 215.5–216°C). Infrared (KBr): 3030 (w), 2832 (m), 1605 (s), 1507 (s), 1461 (m), 1290 (m), 1241 (s), 1105 (m), 1031 (s), 837 (m), 748 (m); uv $\lambda_{max}$ (ethanol): 233 (32 000); $^1$Hmr ($CDCl_3$) δ: 2.34 (s, 2H), 3.70 (s, 12H), 6.74 (m, 16H). *Anal.* calcd. for $C_{31}H_{30}O_4$: C 79.83, H 6.45; found: C 79.81, H 6.37.

*1-(4-Cyanophenyl)-1,1,2-triphenylcyclopropane (*2f*)*

4-Cyanophenylphenyldiazomethane (1.0 g, 0.0046 mol) in 10 mL of benzene was added to 1,1-diphenylethylene (1.0 g, 0.0056 mol) in 20 mL of benzene (*vide supra*). The solvent was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

then evaporated and the reaction mixture separated by medium pressure chromatography (silica gel, hexane – methylene chloride gradient). The product obtained was recrystallized from chloroform–ethanol to give colourless plates (mp 175–176°C). Infrared (KBr): 3058 (m), 2228 (s), 1603 (s), 1492 (s), 1448 (s), 832 (m), 749 (m), 697 (s), 633 (m); uv $\lambda_{max}$ (ethanol): 243 (20 000), 260 (17 000); $^1$Hmr ($CDCl_3$) δ: 2.56 (d, 1H, $J$ = 6 Hz), 2.65 (d, 1H, $J$ = 6 Hz), 7.30 (m, 19H). *Anal.* calcd. for $C_{28}H_{21}N$: C 90.53, H 5.70; found: C 90.66, H 5.50.

*1,2-Di(4-cyanophenyl)-1,2-diphenylcyclopropane (2g)*

4-Cyanophenylphenyldiazomethane (0.20 g, 0.0009 mol) in 5 mL of benzene was added to 1-(4-cyanophenyl)-1-phenylethylene (0.20 g, 0.001 mol) in 5 mL of benzene (*vide supra*). The solvent was then evaporated and the reaction mixture separated by medium pressure chromatography (silica gel, hexanes – methylene chloride gradient). The *cis* isomer was recrystallized from chloroform–ethanol to give colourless needles (mp 201–202°C). Infrared (KBr): 3060 (w), 2227 (s), 1605 (s), 1496 (s), 1449 (m), 1400 (w), 1008 (m), 833 (m), 761 (m), 695 (s), 628 (m); uv $\lambda_{max}$ (ethanol): 241 (27 000), 255 (22 000); $^1$Hmr ($CDCl_3$) δ: 2.57 (d, 1H, $J$ = 6 Hz), 2.71 (d, 1H, $J$ = 6 Hz), 7.10 (m, 10H) 7.32 (m, 8H). *Anal.* calcd. for $C_{29}H_{20}N_2$: C 87.85, H 5.08; found: C 87.72, H 5.01.

The *trans* isomer was recrystallized from chloroform–ethanol to give colourless plates (mp 106–109°C). Infrared (KBr): 3060 (w), 2227 (s), 1606 (s), 1501 (m), 1444 (w), 1400 (w), 1008 (w), 849 (m), 701 (s), 675 (m), 621 (m); uv $\lambda_{max}$ (ethanol): 241 (27 000), 255 (20 000); $^1$Hmr ($CDCl_3$) δ: 2.65 (s, 2H), 7.15 (m, 10H), 7.22 (m, 8H). *Anal.* calcd. for $C_{29}H_{20}N_2$: C 87.85, H 5.08; found: C 87.69, H 4.99.

*1,1-Di(4-cyanophenyl)-2,2-diphenylcyclopropane (2h)*

Di(4-cyanophenyl)diazomethane (1.3 g, 0.0053 mol) in 10 mL of benzene was added to 1,1-diphenylethylene (1.0 g, 0.0056 mol) in 20 mL of benzene (*vide supra*). The solvent was then evaporated and the reaction mixture separated by column chromatography (neutral alumina, benzene). The produce was recrystallized from chloroform–ethanol to give colourless needles (mp 217–219°C). Infrared (KBr): 2222 (s), 1600 (s), 1495 (m), 1448 (m), 1398 (w), 828 (m), 738 (m), 705 (m), 569 (m); uv $\lambda_{max}$ (ethanol): 243 (26 000), 260 (20 000); $^1$Hmr ($CDCl_3$) δ: 2.64 (s, 2H), 7.10 (m, 10H), 7.26 (m, 8H). *Anal.* calcd. for $C_{29}H_{20}N_2$: C 87.85, H 5.08; found: C 87.96, H 5.28.

*1,1,2,2-Tetra(4-cyanophenyl)cyclopropane (2i)*

Di(4-cyanophenyl)diazomethane (0.5 g, 0.0020 mol) in 10 mL of benzene was added to 1,1-di(4-cyanophenyl)ethylene (0.5 g, 0.0022 mol) in 10 mL of benzene (*vide supra*). The solvent mixture was separated by medium pressure chromatography (silica gel, hexane – methylene chloride gradient). The yellow solid was recrystallized three times from chloroform–hexanes to give colourless plates (mp 233–234.5°C). Infrared (KBr): 3060 (w), 2227 (s), 1605 (s), 1502 (s), 1448 (w), 1405 (m), 1178 (w), 1005 (w), 851 (w), 752 (m), 630 (w); uv $\lambda_{max}$ (ethanol): 243 (56 000), 260 (38 000); $^1$Hmr ($CDCl_3$); δ: 2.68 (s, 2H), 7.20 (m, 16H). *Anal.* calcd. for $C_{31}H_{18}N_4$: C 83.41, H 4.04, N 12.56; found: C 83.11, H 3.82, N 12.51.

*1-(4-Cyanophenyl)-2-(4-methoxyphenyl)-1,2-diphenylcyclopropane (2j)*

4-Methoxyphenylphenyldiazomethane (0.5 g, 0.0022 mol) in 10 mL of benzene was added to 1-(4-cyanophenyl)-1-phenylethylene (0.5, 0.0024 mol) in 10 mL (*vide supra*). The solvent was then evaporated and the mixture separated by medium pressure chromatography (silica gel, hexanes – methylene chloride gradient). Rechromatographing the mixture of the *cis* and *trans* isomers afforded pure samples of each. The *cis* isomer was recrystallized from ethanol to give colourless prisms (mp 158–159°C). Infrared (KBr): 3050 (w), 2833 (w), 2222 (m), 1607 (m), 1512 (s), 1449 (m), 1405 (w), 1247 (s), 1178 (m), 1035 (m), 1005 (w), 832 (m), 700 (s); uv $\lambda_{max}$ (ethanol): 235 (24 000); $^1$Hmr ($CDCl_3$) δ: 2.47 (d, 1H, $J$ = 6 Hz), 2.57 (d, 1H, $J$ = 6 Hz), 3.64 (s, 3H), 7.0 (m, 18H); $^1$Hmr ($C_6D_6$) δ: 1.95 (d, 1H, $J$ = 6 Hz), 2.25 (d, 1H, $J$ = 6 Hz), 3.22 (s, 3H), 6.72 (m, 18H). *Exact Mol. Wt.* calcd.: 401.177955; found: 401.179314.

The *trans* isomer was recrystallized from ethanol to give colourless needles (mp 134–135.5°C). Infrared (KBr): 3050 (w), 2833 (w), 2222 (m), 1603 (m), 1509 (s), 1422 (m), 1403 (w), 1244 (s), 1180 (m), 1030 (m), 1001 (w), 837 (m), 698 (s); uv $\lambda_{max}$ (ethanol): 234 (25 000), 271 (13 000); $^1$Hmr ($CDCl_3$) δ: 2.53 (s, 2H), 3.69 (s, 3H), 6.77 (m, 4H), 7.10 (m, 14H); $^1$Hmr ($C_6D_6$) δ: 2.00 (d, 1H, $J$ = 7 Hz), 2.26 (d, 1H, $J$ = 7 Hz), 3.17 (s, 3H), 6.72 (m, 18H). *Exact Mol. Wt.* calcd.: 401.177955; found: 401.178917.

Crystals of *trans* **2j**, for the X-ray determination, were prepared by slow recrystallization from ethanol–chloroform.

*1-(4-Cyanophenyl)-1-(4-methoxyphenyl)-2,2-diphenylcyclopropane (2k)*

4-Cyano-4′-methoxydiphenyldiazomethane (1.5 g, 0.006 mol) in 10 mL of benzene was added to 1,1-diphenylethylene (2.1 g, 0.0117 mol) in 20 mL of benzene (*vide supra*). The solvent was then evaporated and the reaction mixture separated by chromatography (neutral alumina, hexane–benzene, 1:3). The product was recrystallized from methanol to give colourless prisms (mp 191–192°C). Infrared (KBr): 3040 (w), 2840 (w), 2227 (s), 1608 (s), 1513 (s), 1450 (m), 1398 (w), 1252 (s), 1182 (m), 1031 (m), 1000 (w), 836 (m), 703 (s); uv $\lambda_{max}$ (ethanol): 236 (21 000), 242 (18 000); $^1$Hmr ($CDCl_3$) δ: 2.53 (s, 2H), 3.64 (s, 3H), 7.01 (m, 18H). *Exact Mol. Wt.* calcd.: 401.177955; found: 401.178519.

*1,2-Di(4-cyanophenyl)-1,2-di(4-methoxyphenyl)cyclopropane (2l)*

4-Cyano-4′-methoxydiphenyldiazomethane (0.8 g, 0.0032 mol) in 10 mL of benzene was added to 1-(4-cyanophenyl)-1-(4-methoxyphenyl)ethylene (0.9 g, 0.0038 mol) in 20 mL of benzene (*vide supra*). The solvent was then evaporated and the reaction mixture separated by column chromatography (silica gel, hexanes–benzene gradient) to give a mixture of the *cis* and *trans* isomers. The two isomers were separated by medium pressure chromatography (silica gel, hexanes–benzene gradient). The *cis* isomer was recrystallized from chloroform–ethanol to give colourless needles (mp 157–158°C). Infrared (KBr): 2840 (w), 2230 (s), 1610 (s), 1516 (s), 1300 (m), 1250 (s), 1187 (m), 1136 (m), 850 (m), 753 (m), 596 (m); uv $\lambda_{max}$ (ethanol): 231 (52 000), 267 (32 000); $^1$Hmr ($CDCl_3$) δ: 2.43 (d, 1H, $J$ = 7 Hz), 2.66 (d, 1H, $J$ = 7 Hz), 3.70 (s, 6H), 7.00 (m, 16H). *Anal.* calcd. for $C_{31}H_{24}N_2O_2$: C 81.55, H 5.33; found: C 81.71, H 5.27.

The *trans* isomer was recrystallized from chloroform–ethanol to give colourless prisms (mp 95–96°C). Infrared (KBr): 2840 (w), 2228 (m), 1610 (s), 1513 (s), 1298 (m), 1250 (s), 1181 (m), 937 (m), 852 (m), 757 (w), 591 (w); uv $\lambda_{max}$ (ethanol): 233 (39 000), 262 (35 000); $^1$Hmr ($CDCl_3$) δ: 2.58 (s, 2H), 3.75 (s, 6H), 7.00 (m, 16H). *Anal.* calcd. for $C_{31}H_{24}N_2O_2$: C 81.55, H 5.33; found: C 81.38, H 5.31.

*1,1,-Di(4-cyanophenyl)-2,2-di(4-methoxyphenyl)cyclopropane (2m)*

Di(4-cyanophenyl)diazomethane (1.2 g, 0.0049 mol) in 10 mL of benzene was added to 1,1-di(4-methoxyphenyl)ethylene (1.2 g, 0.005 mol) in 20 mL of benzene (*vide supra*). The solvent was then evaporated and the reaction mixture separated by column chromatography (neutral alumina, benzene). The product was recrystallized from chloroform–ethanol to give colourless needles (mp 203–204°C). Infrared (KBr): 2840 (w),

2230 (s), 1608 (s), 1510 (s), 1452 (s), 1290 (m), 1250 (s), 1112 (w), 1028 (s), 850 (m), 756 (m); uv $\lambda_{max}$ (ethanol): 233 (37 000), 270 (14 000); $^1$Hmr ($CDCl_3$) δ: 2.53 (s, 2H), 3.71 (s, 6H), 7.00 (m, 16H). *Anal.* calcd. for $C_{31}H_{24}N_2O_2$: C 81.55, H 5.33; found: C 81.24, H 5.39.

*Thermal isomerization of* 2c, g, j, l: *kinetics*

Samples tubes were prepared from 5 or 7 mm Pyrex tubing which had been rinsed once with concentrated nitric acid, thrice with distilled water, soaked in 5% aqueous sodium hydroxide (1 h), rinsed again (three times) with distilled water, and then dried in an oven. Samples (in benzene) were degassed (three freeze–pump–thaw cycles) and sealed. Five tubes were then placed simultaneously in a preset insulated kinetic bath. The rates of approach to thermal equilibrium were studied over a 20° temperature range near 120°C. The temperature of the bath did not fall by more than 0.5° when the samples were introduced and recovered to its original value within 1.5 minutes. Samples were removed after specific time intervals and quenched immediately in an ice bath, opened, and analysed by hplc. The rate constants for thermal isomerization ($k_{c\rightarrow t} + k_{t\rightarrow c}$) and the equilibrium compositions were averages of two runs starting with both isomers.

The rate constants were determined by linear regression analysis of the mole fraction vs. time data (assuming first order kinetics), using the minitab II program (15). Arrhenius parameters were determined by the temperature dependence of the rate constants for thermal isomerization using a linear least-squares program.

# Kinetics and mechanism of barium tungstate crystal growth from sodium tungstate melts in platinum crucibles

BIMALENDU NARAYAN ROY[1] AND MANJU RANI ROY

*Department of Chemistry, University of Science and Technology, Kumasi, Ghana*

Received May 12, 1980

BIMALENDU NARAYAN ROY and MANJU RANI ROY. Can. J. Chem. **60**, 2321 (1982).

Kinetics and mechanism of barium tungstate crystal growth from sodium tungstate melts in platinum crucibles were investigated by DTA at crystallization temperatures $T_0$ = 800 to 1000°C by continuous cooling at rates $R_T$ = 0.67 to 3.37°C min$^{-1}$. During an induction period ($\bar{t}$) small crystallites ($\bar{l}$ = 0.003 to 0.03 cm) developed in the solution but the main growth occurred only after sufficient excess solute concentrations ($\Delta\bar{C}$) developed at the end of $\bar{t}$. For crystallizations <80%, the average crystal lengths ($l_\tau$) varied with the growth time ($\tau$) according to $l_\tau^2 = (\bar{l})^2 + 4k_{D_l}M\Delta\bar{C}$, $k_{D_l}$ being the diffusion rate constant and $M$ the metal salt molecular weight. The last 20% growth was rate-controlled only by the development rate of excess solute concentration.

BIMALENDU NARAYAN ROY et MANJU RANI ROY. Can. J. Chem. **60**, 2321 (1982).

Faisant appel à l'ATD, on a étudié la cinétique et le mécanisme de la croissance de cristaux de tungstate de baryum à partir de masse fondue de tungstate de sodium présents dans des creusets de platine; les températures de cristallisation s'étalent de $T_0$ = 800 à 1000°C et le taux de refroidissement continue varie de $R_T$ = 0,67 à 3,37°C min$^{-1}$. Au cours de la période d'induction ($\bar{t}$) des petits cristaux se développent dans la solution mais la croissance principale ne se produit que lorsqu'un excès suffisant de la concentration du soluté ($\Delta\bar{C}$) se manifeste à la fin de $\bar{t}$. Pour des cristallisations <80%, la longueur moyenne des cristaux ($l_\tau$) varie avec le temps de croissance selon l'équation $l_\tau^2 = (\bar{l})^2 + 4k_{D_l}M\Delta\bar{C}$ où $k_{D_l}$ est la constante de vitesse de diffusion et $M$ la masse molaire du sel métallique. Les derniers 20% de la croissance se font à une vitesse qui est contrôlée que par le taux d'évolution de la concentration du soluté en excès.

[Traduit par le journal]

## Introduction

In recent years crystallization kinetics of a large number of inorganic salts have been reported (1–10). In any crystallization from aqueous solutions or melts, the growth process may occur practically immediately after the onset of cooling or the system may exhibit induction periods of different lengths during which only the excess solute concentration develops without any significant growth — the actual growth occurs only after the induction period. In both cases, the growth mechanism may be identical but the kinetic relations will differ depending upon the length of induction periods.

For a diffusion-controlled crystal growth exhibiting induction periods, the rate of the main growth of the "major" side of the main crystal face at any growth time $\tau$ after the induction period ($\bar{t}$) would be expressed (11)

$$[1] \qquad dl_\tau/d\tau = \frac{2(\mathrm{Sh})DM\phi(\Delta C_{sol})_\tau}{l_\tau}(\rho_{sol}/\rho)$$

where Sh is the Sherwood function; $D$ is the diffusion coefficient of the metal salt cations; $M$ is the molecular weight of the solute; $\phi$ is the overall permeability factor; $\tau$ ($=t-\bar{t}$) is the actual growth time; $t$ is the total crystallization time; $l_\tau$ is the crystal length at $\tau$; $(\Delta C_{sol})_\tau$ is the residual excess solute concentration at $\tau$; and $\rho$ and $\rho_{sol}$ are the densities of the crystal and solution respectively. When the natural convection in an unstirred solution is poor, the dimensionless Sherwood function approximately equals 2 and then eq. [1] becomes (11)

$$[2] \qquad dl_\tau/d\tau = \frac{4DM\phi(\Delta C_{sol})_\tau}{l_\tau}(\rho_{sol}/\rho)$$

$$[3] \qquad = \frac{2k_{D_l}M(\Delta C_{sol})_\tau}{l_\tau}$$

where $k_{D_l} = 2D\phi(\rho_{sol}/\rho)$ is the rate constant for diffusion-controlled growth of the "wider" crystal face.

Generally, in crystallizations from melts, the excess solute concentration at any $\tau$ would be

$$[4] \qquad (\Delta C_{sol})_\tau = (\Delta C_\tau - W_\tau/M)$$

where $\Delta C_\tau$ is the overall excess solute concentration up to $\tau$ and $W_\tau$ is the crystal weight deposited at different growth time $\tau$. This equation may be written as

$$[5] \qquad (\Delta C_{sol})_\tau = (\Delta\bar{C} + R_c\tau - \beta l_\tau^3)$$

where $\Delta\bar{C}$ is the excess solute concentration up to $\bar{t}$; $R_c$ is the development rate of excess solute concentration; $N$ is the crystal number at any

crystallization time $t$; $f_s$ is a shape factor; and $\beta$ ($= N\rho f_s/M$) is a function of the crystal number. Combining eqs. [3] and [5]

$$[6] \quad dl_\tau/d\tau = 2k_{D_l}M(\Delta\bar{C} + R_c\tau - \beta l_\tau^3)/l_\tau$$

Integrating, one gets

$$[7] \quad l_\tau^2 = (\bar{l})^2 + A\tau + B\tau^2$$

where $\bar{l}$ is the maximum crystal length up to the end of $\bar{\imath}$, and for any $T_0$ and $R_T$, $A$ and $B$ are constants given by

$$A = 4k_{D_l}M\Delta\bar{C} - 4k_{D_l}M\beta\bar{l}^3$$
$$B = 2k_{D_l}MR_c$$

If $(\Delta C_{sol})_\tau \simeq \Delta\bar{C}$, eq. [3] becomes

$$[8] \quad dl_\tau/d\tau = 2k_{D_l}M\Delta\bar{C}/l_\tau$$

Integrating, one gets

$$[9] \quad l_\tau^2 = (\bar{l})^2 + A'\tau$$

where $A'$ ($= 4k_{D_l}M\Delta\bar{C}$) is a function of $\Delta\bar{C}$ and constant for any $T_0$ and $R_T$.

## Experimental

Barium tungstate was prepared *in situ* in sodium tungstate melts from equimolecular mixtures of the metal carbonate and tungsten trioxide. The saturated solutions were prepared at temperatures slightly higher than the initial crystallization temperature by heating for several hours inside a "Carbolite" electric furnace (Carbolite Co. Ltd., Sheffield, U.K.). These solutions were then cooled down rapidly to room temperature and the solidified melt was ground well and dried at 100°C for 24 h to remove any moisture absorbed during grinding. The requisite amount of this sample was then taken in a small platinum crucible inside a differential thermal analyser (No. 990, E.I. du Pont de Nemours & Co., Wilmington, DE, U.S.A.) and the temperature was gradually raised to slightly higher than the crystallization temperature $T_0$ at a rate of 20°/min. It was held constant at that temperature for sufficient time to ensure complete melting. Then the crystallization was carried out by gradually reducing the temperature from $T_0$ (=800 to 1000°C) down to below 300°C at cooling rates $R_T$ = 40, 120, and 200°C per h according to a pre-assigned automatic cooling programme. The temperatures were recorded automatically on the chart. The DTA curves were traced on standard millimeter graph papers.

From the DTA curves, the eutectic temperature ($T_e$) was determined as the initial melting temperature of the mixtures of metal tungstate and sodium tungstate. The degree of crystallization ($\alpha_t$) at different crystallization time ($t$) was calculated using $\alpha_t = A_t/A_{total}$, where $A_t$ is the area under the thermogram at any time $t$ and $A_{total}$ is the total area under the same thermogram. From these $\alpha_t$ values the length ($l_t$) of barium tungstate crystals at any time was estimated using $\alpha_t = (l_t/\bar{l}_t)^3$, where $l_t$ is the final crystal length. $l_t$ values were measured by optical microscopy from separate crystallization runs in the "Carbolite" electric furnace mentioned above (12).

The rates ($R_c$) of development of excess solute concentration were estimated from the product $aR_T$, where $a = dC/dT$, $C$ being the concentration. Induction periods ($\bar{\imath}$) were determined by extrapolation of the linear parts of the $l_t$ vs. $t$ plots back to the $t$-axis; the induction temperatures ($\bar{T}$) were then given by $\bar{T} = T_0 - R_T\bar{\imath}$. The actual growth time ($\tau$) and the overall excess solute concentration ($\Delta C_\tau$) at different $\tau$ were evaluated respectively from $\tau = t - \bar{\imath}$ and $\Delta C_\tau = C_0 - C_\tau$, where $C_0$ is the initial concentration and $C_\tau$ the concentration at $\tau$. The residual excess solute concentrations, $(\Delta C_{sol})_\tau$, were evaluated from eq. [4], and $W_t/M$ and the final overall excess solute concentrations, $\Delta C_f$, were respectively given by

$$W_\tau/M = N\rho f_s l_\tau^3$$

and

$$\Delta C_f = (C_0 - C_{eu})$$

where $C_{eu}$ is the solubility at the eutectic temperature ($T_{eu}$).

## Results

### *Development of supersaturation*

#### *Overall excess solute concentrations, residual excess solute concentrations, and total crystal weights*

The overall excess solute concentrations ($\Delta C_t$) increased linearly with cooling time $t$ and attained the maximum value, $\Delta C_f$, at the eutectic temperature. The total crystal weights $W_t/M$ increased significantly only after the induction periods. Some typical results for $\Delta C_t$ and $W_t/M$ are shown in Figs. 1 and 2. The amount of excess solute concentration developed at any $t$ and also the final amount was higher than those for barium tungstate crystallization under identical conditions from sodium tungstate melts in alumina crucibles (12).

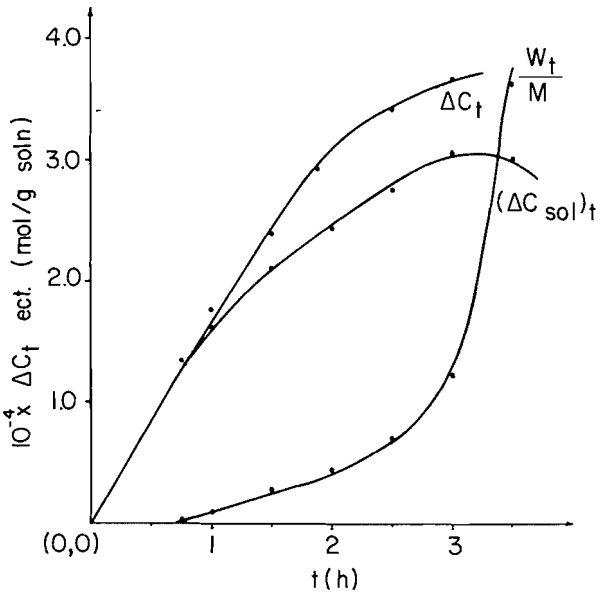

FIG. 1. Crystallization of barium tungstate from sodium tungstate melts at $T_0$ = 900°C and $R_T$ = 40°C/h. Overall excess solute concentrations ($\Delta C_t$), residual excess solute concentrations, $(\Delta C_{sol})_t$, and total crystal weights at different times ($W_t/M$ has no dimensions).

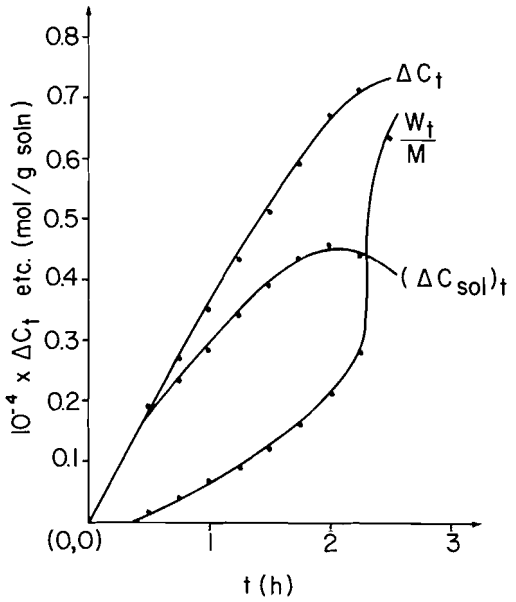

FIG. 2. Crystallization of barium tungstate from sodium tungstate melts at $T_0$ = 1000°C and $R_T$ = 120°C/h. Overall excess solute concentrations ($\Delta C_t$), residual excess solute concentrations ($\Delta C_{sol}$)$_t$, and total crystal weights at different times ($W_t/M$ has no dimensions).

The $\Delta C_t$ and $W_t/M$ values show that at the early stages the amount of residual excess solute concentrations was high. Total crystal weights were very low at the early stages; however, these weights increased with decreasing temperatures up to the time $t^*$ (over 75% crystallization), when all the excess solute deposited on the growing crystals and probably no further growth occurred. This was also observed in the case of barium tungstate crystallization from sodium tungstate melts in alumina crucibles (12).

Very little (or perhaps none at all) material deposited on the early nuclei until the excess solute concentrations in the solution attained some value $\Delta\bar{C}$ at temperature $\bar{T}$. As the crystallization proceeded, the residual excess solute concentrations in the solution at any $t$ deviated more and more from $\Delta C_t$, gradually reached the final value, and then sharply dropped to very low values at $t^*$.

*Critical time ($\bar{t}$), critical temperature ($\bar{T}$), and critical excess solute concentration ($\Delta\bar{C}$)*

Unlike the crystallization of barium tungstate from sodium tungstate melts in alumina crucibles (12), in this case short to medium induction periods were observed, which were ostensibly modified by the cooling rates but there was no direct relationship between $R_T$ and $\bar{t}$. During the induction periods, heterogeneous nuclei slowly formed onto the metal platinate particles within the solutions and probably very small crystallites grew on these nuclei up to the end of $\bar{t}$. Probably the growth kinetics of these crystallites were rate-controlled by a sluggish secondary mononuclear process (13), which was not the case in the crystallization of the same system in alumina crucibles (12).

*Kinetics of crystal growth after the induction periods*

It is well known that crystallization at high supersaturation is expected to be diffusion-limited. Also, the growth rate of metal salt crystals in unstirred low permeability solutions is generally controlled by the diffusion rate of metal salt ions into the growing crystal surfaces. As stated earlier, during the induction period probably very small crystallites grew on the early nuclei up to $\bar{t}$. Since there was no significant growth occurring during the induction period, sufficient amount of excess solute concentration accumulated at the end of $\bar{t}$ and then the main crystal growth occurred. The average crystal lengths ($l_\tau$) at any growth time $\tau$ after the induction periods were evaluated from the $l_t$ versus $t$ plots; $l_\tau^2$ values were then plotted against $\tau$ (Figs. 3–5). These plots were linear according to eq. [9] up to $l_\tau \simeq 0.48 l_f$; these linear relationships indicated that the growth process was probably diffusion rate controlled.

The $A'$ values were estimated for different crystallizations (Table 1). These values generally

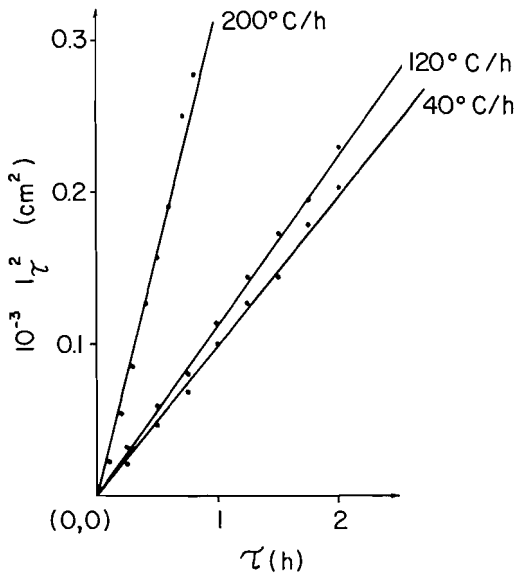

FIG. 3. Crystallization of barium tungstate from sodium tungstate melts at $T_0$ = 800°C; square of crystal lengths ($l_\tau^2$) at different growth times ($\tau$).

increased as $T_0$ and $R_T$ increased but there was no direct correlation.

*The final growth*

It is assumed that at growth times $\tau > \tau^*$ (over 75% crystallization) some fresh solute continued to separate out from the solution by further cooling but this was probably immediately used up by deposition on the already developed large crystals. Consequently, the residual excess solute concentrations were very low and the growth rates became dependent only on the development of further excess solute concentration effected by the decrease in temperature. For this,

$$[10] \quad l_\tau^3 = (l^*)^3 + b(\tau - \tau^*)$$

where $b$ (= $R_c/\beta$) is a constant. Then at $\tau = \tau^*$, $l_\tau = l^*$. This was observed experimentally.

# Alkylation of benzene by alkyl cations. Stability of the *tert*-butyl benzenium ion

D. K. SEN SHARMA, S. IKUTA,[1] AND P. KEBARLE[2]

*Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received March 4, 1982

D. K. SEN SHARMA, S. IKUTA, and P. KEBARLE. Can. J. Chem. **60**, 2325 (1982).

The kinetics and equilibria of the gas phase reaction [1] *tert*-$C_4H_9^+ + C_6H_6 =$ *tert*-$C_4H_9C_6H_6^+$ were studied with a high ion source pressure pulsed electron beam mass spectrometer. Equilibria [1] could be observed in the temperature range 285–325 K. van't Hoff plots of the equilibrium constants led to $\Delta H_1^0 = -22 \pm 2$ kcal mol$^{-1}$ and $\Delta S_1^0 = -49 \pm 5$ cal K$^{-1}$ mol$^{-1}$. The rate constants at 305 K were $k_{1f} = 1.5 \times 10^{-28}$ molecules$^{-2}$ cm$^6$ s$^{-1}$ and $k_{1r} = 2.9 \times 10^{-19}$ molecules$^{-1}$ cm$^3$ s$^{-1}$. *tert*-$C_4H_9C_6H_6^+$ dissociates easily via [lr] not only because of the low dissociation energy ($-\Delta H_1^0$) but also because of the unusually favorable entropy ($-\Delta S_1^0$). The occurrence of transalkylation reactions: *tert*-$C_4H_9C_6H_6^+$ + alkylbenzene = *tert*-$C_4H_9$ alkylbenzene$^+$ + benzene, was discovered in the present work.

D. K. SEN SHARMA, S. IKUTA et P. KEBARLE. Can. J. Chem. **60**, 2325 (1982).

On a étudié la cinétique et l'équilibre de la réaction en phase gazeuse [1] *tert*-$C_4H_9^+ + C_6H_6 =$ *tert*-$C_4H_9C_6H_6^+$ en faisant appel à un spectromètre de masse à faisceau d'électrons pulsés et ayant une source d'ions à haute pression. Les équilibres [1] peuvent être observés dans l'intervalle de température de 285–326 K. Les courbes de van't Hoff des constantes d'équilibre conduisent à $\Delta H_1^0 = 22 \pm 2$ kcal mol$^{-1}$ et à $\Delta S_1^0 = -49 \pm 5$ cal K$^{-1}$ mol$^{-1}$. Les constantes de vitesse à 305 K sont: $k_{1f} = 1{,}5 \times 10^{-28}$ molécules$^{-2}$ cm$^3$ s$^{-1}$ et $k_{1r} = 2{,}9 \times 10^{19}$ molécules$^{-1}$ cm$^3$ s$^{-1}$. L'ion *tert*-$C_4H_9C_6H_6^+$ se dissocie facilement via [lr] non seulement parce que l'énergie de dissociation est faible ($-\Delta H_1^0$] mais également par suite d'une entropie exceptionnellement favorable ($-\Delta S_1^0$). Dans cette étude, on a découvert la manifestation des réactions de transalkylation: *tert*-$C_4H_9C_6H_6^+$ + alkylbenzène = *tert*-$C_4H_9$ alkylbenzène$^+$ + benzène.

[Traduit par le journal]

## Introduction

The alkylation of benzene and other aromatic hydrocarbons by the electrophilic attack of alkyl cation intermediates is a classical condensed phase reaction. It is of interest in a very wide area. Thus it has played an important part in the development of the theory of carbonium ions in physical organic chemistry (1, 2) and, on the other end of the spectrum, it is an important industrial reaction for the production of alkyl benzenes. In the gas phase, the reactions are of analytical importance in chemical ionization mass spectrometry (3). Thus the often used reagent gases methane, propane, and isobutane produce $C_2H_5^+$, iso-$C_3H_7^+$, and *tert*-$C_4H_9^+$ respectively, as reagent ions. These become involved in alkylation reactions when the unknown is benzene or some other aromatic compound.

The present work describes results obtained from measurement of the kinetics and equilibria of the gas phase reaction [1] with a high pressure mass spectrometer. Reaction [1] represents an association of a carbenium ion, i.e. a Lewis acid with a $\pi$ Lewis base. Association reactions involving various alkyl cations and Lewis bases like $H_2O$, CO, RCl have been described in previous publications from this laboratory (4).

We believe that the present results are at least of partial interest to all areas mentioned above. They do represent also an addition to gas phase ion thermochemistry (5, 6).

$$[1] \quad \textit{tert}\text{-}C_4H_9^+ + C_6H_6 \underset{lr}{\overset{lf}{\rightleftarrows}} \textit{tert}\text{-}C_4H_9{\cdot}C_6H_6^+$$

## Experimental

The measurements were made with the pulsed electron beam high ion source pressure mass spectrometer used in earlier work (4–6). Pulsing of the electron beam permits time resolved detection of the ions. The temperature of the ion source is controlled by means of heaters embedded in the ion source block. The usual procedure of flowing the gas mixture in and out of the ion source was employed. In the absence of such flow an enrichment of the heavier neutral components in the ion source is expected because of the effusive loss of gas through the ion source slits.

In a reaction mixture containing methane as major gas (3 to 4 Torr) and known low pressures of isobutane and benzene where $p$ (isobutane) $\gg$ $p$ (benzene), a sequence of reactions occurs. The dominant ionization is of methane and the final ions in methane are $CH_5^+$ and $C_2H_5^+$. In the presence of isobutane, reactions [2] and [3] convert $CH_5^+$ and $C_2H_5^+$ to $C_4H_9^+$, which in turn reacts with benzene via the desired reaction [1].

$$[2] \quad CH_5^+ + \text{iso-}C_4H_{10} = CH_4 + C_4H_9^+ + H_2$$

$$[3] \quad C_2H_5^+ + \text{iso-}C_4H_{10} = C_2H_6 + C_4H_9^+$$

At suitably high temperatures, reaction [1] becomes reversible which allows the determination of equilibrium [1].

The ion–time dependence in a typical experiment leading to equilibrium is shown in Fig. 1. The equilibrium constants $K_1$ and their temperature dependence are displayed in Figs. 2 and 3. These results will be discussed in the next section. Here we wish to describe some observations which relate to the choice of concentrations used in the experiments. The data of Figs. 1–3 were obtained with methane 3 Torr, isobutane 1 Torr, and benzene in the 1 to 10 mTorr range. Initial experiments with much lower isobutane concentrations (e.g., isobutane 100 to 30 mTorr, benzene ~5 mTorr) led to anomalous results. A certain residual amount of $C_4H_9C_6H_6^+$ at equilibrium was observed to persist to much higher temperatures than could be expected from Fig. 3. For example, about 10% $C_4H_9C_6H_6^+$ was still observed at 152°C. The corresponding $C_5H_9^+$ was 50%, which leads to an equilibrium constant "$K_1$" = 25 ($Torr^{-1}$) ($p$(benzene) = 8 mTorr). The $K_1$ predicted from Fig. 3 for the same temperature is about four orders of magnitude smaller. Evidence cited below indicates that the residual $C_4H_9C_6H_6^+$ is not *tert*-butyl benzenium but the more stable isobutyl or *sec*-butyl benzenium, formed by the addition of the corresponding isomeric butyl cation to benzene.

Experiments at high temperature and low isobutane pressures showed that the residual $C_4H_9C_6H_6^+$ increased with benzene pressure but only up to a certain limiting concentration (~30%). Increase of the isobutane pressure led to a decrease of the residual butyl benzenium. Pressures above ~0.6 Torr isobutane caused the complete disappearance of the high temperature residual ion and these conditions led also to the normal equilibrium behavior at low temperatures (Figs. 1–3).

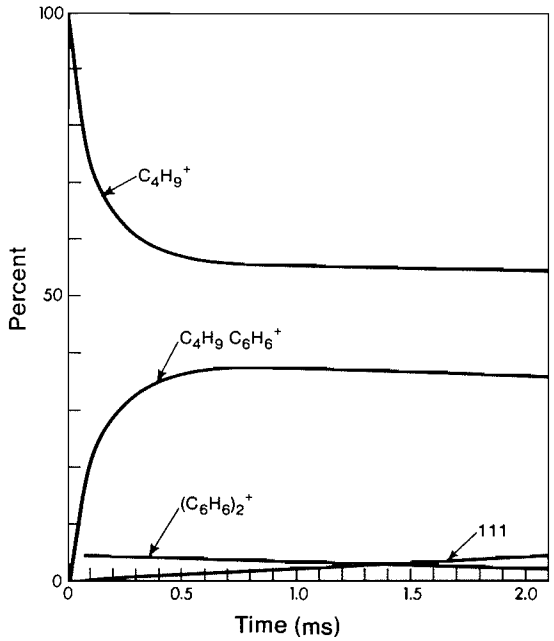

FIG. 1. Kinetics and equilibrium of reaction [1], $C_4H_9^+ + C_6H_6 = C_4H_9C_6H_6^+$. Reaction mixture employed: $CH_4$ 3 Torr, isobutane 1 Torr, benzene 4 mTorr, temperature 32°C. Rapid ion–molecule reactions in major gases methane and isobutane produce $C_4H_9^+$ as practically the only ion. $C_4H_9^+$ adds to benzene; however, reaction is reversible and reaches equilibrium after about 0.5 ms. Equilibrium constant $K_1$ = 170 $Torr^{-1}$ from data in this figure. Approximate rate constants for the forward and reverse direction of the reaction can also be obtained from this figure.

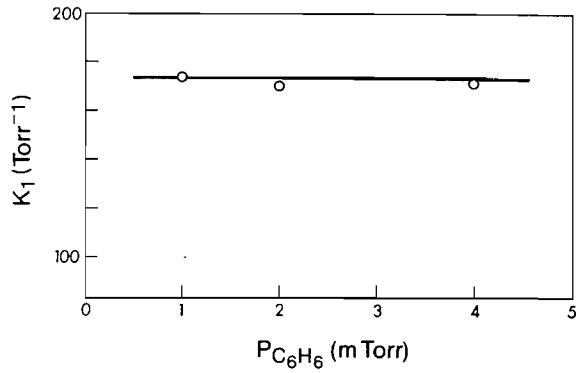

FIG. 2. Invariance of equilibrium constant $K_1$ with pressure of benzene. Temperature 32°C.

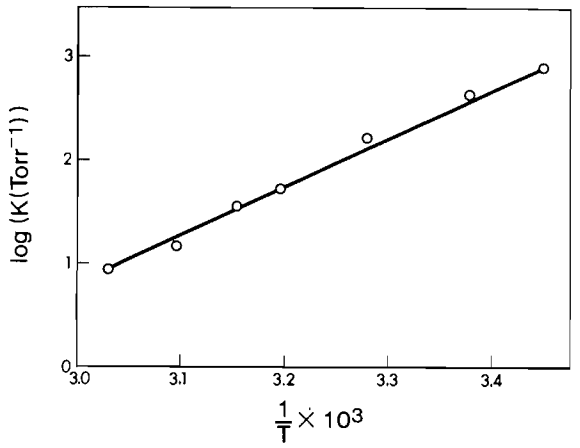

FIG. 3. van't Hoff plot of equilibrium constant $K_1$ obtained from equilibria measurements as illustrated in Fig. 1. Slope and intercept lead to $\Delta H_1^0 = -22 \pm 2$ kcal $mol^{-1}$, $\Delta S_1^0 = 49 \pm 5$ cal $K^{-1}$ $mol^{-1}$ given in Table 1.

Reactions [2] and [3] can produce not only *tert*-$C_4H_9^+$ but also another butyl isomer, x-$C_4H_9^+$. This isomer can either add to benzene giving the stable butyl benzenium by reaction [4] or be converted to *tert*-$C_4H_9^+$ by the hydride abstraction [5], reaction [5] being favored by a high isobutane to benzene ratio.

[4] $\text{x-}C_4H_9^+ + C_6H_6 = \text{x-}C_4H_9C_6H_6^+$

[5] $\text{x-}C_4H_9^+ + \text{iso-}C_4H_8 = \text{x-}C_4H_{10} + \textit{tert}\text{-}C_4H_9^+$

Experiments with $(CH_3)_3CD$ in methane showed that both $CH_5^+$ and $C_2H_5^+$ produced $C_4H_9^+$ *and* $C_4H_8D^+$. The $C_4H_8D^+/C_4H_9^+$ ratio observed for ethyl was approximately 2. The $C_4H_8D^+$ must be, at least initially, of the isobutyl structure. Evidence in the literature (9) suggests that the isobutyl cation is unstable (9*a*); however, the production of the unstable isobutyl was by electron impact (9*b*) and not the milder hydride abstraction occurring in the present work. The present work does not provide any evidence on the nature of the x-$C_4H_9^+$ except that it leads to an adduct that is more stable than *tert*-$C_4H_9C_6H_6^+$. *sec*-$C_4H_9^+$ will form a sufficiently stable benzenium ion to fit our experimental conditions. Thus, we observed that the *sec*-$C_3H_7C_6H_6^+$ ion, formed by the addition of *sec*-$C_3H_7^+$ to benzene, was stable at the elevated temperatures (150°C) at which the x-$C_4H_9C_6H_6^+$ was observed.

| [14] *tert*-$C_4H_9C_6H_6 + CH_3C_6H_5 = tert$-$C_4H_9 \cdot CH_3C_6H_5^+ + C_6H_6$ | $k_{14} \approx 10^{-11}$ molecules$^{-1}$ cm$^3$ s$^{-1}$ | |

[a] Enthalpies in kcal/mol, entropies in cal mol$^{-1}$ K$^{-1}$ at 300 K, standard state 1 atm.
[b] Present experimental work from van't Hoff plot in Fig. 3. Errors are estimated.
[c] Evaluated from eq. [7] $\Delta PA = 1.5$ kcal/mol from McIver and co-workers (10, 11); $\Delta H_f^?$: *tert*-butylbenzene = −7; benzene +19.8; isobutene −4.3 kcal/mol (13).
[d] Estimated (statistical thermodynamics) see text.
[e] From $\Delta H^0_{PT} = -10.1$ kcal/mol, $\Delta G^0_{PT} = -10.5$ kcal/mol (10–12); $\Delta H_f^?$: $C_3H_6$ = 4.9 kcal/mol; isopropylbenzene = 0.9 kcal/mol; $\Delta G_f^?$: $C_3H_6$ = 15 kcal/mol; isopropylbenzene = 32.7 kcal/mol (13, 14).
[f] From $\Delta H^0_{PT} = -21.7$ kcal/mol, $\Delta G^0_{PT} = -21.3$ kcal/mol, based on $\Delta H_f^?$ ($C_2H_5^+$) = 216 kcal/mol (10, 17); $\Delta H_f^?$ (ethylbenzene) = 7.1 kcal/mol, $\Delta G_f^?$ (ethylbenzene) = 31.2 kcal/mol (13, 14).
[g] Rate constants at 32°C. The rate constant $k_{1f}$ was assumed to be third order while $k_{1r}$ was assumed to be second order.

A mixture of methane (3 Torr) and isobutane (1 Torr) was used in the equilibria [1] determinations, rather than neat isobutane at 4 Torr, because an unknown trace impurity (probably $C_4H_8$) in the isobutane led to production of ions of mass 113 and 111. These were noticeable at long reaction times in runs undertaken below room temperature. Mass 113 is probably the $C_4H_9 \cdot C_4H_8^+$ while mass 111 results from dehydrogenation of mass 113.

## Results and discussion

A typical experimental result is shown in Fig. 1. The reaction mixture produces *tert*-$C_4H_9^+$ as essentially the only ion some microseconds after the electron pulse.[3] In the presence of a small concentration of benzene, reaction [1] is seen to occur. The reaction reaches equilibrium after

$$[1] \quad C_4H_9^+ + C_6H_6 \underset{lr}{\overset{lf}{\rightleftarrows}} C_4H_9C_6H_6^+$$

about 0.7 ms. Runs with higher benzene concentration led to a shift of the equilibrium to the right as required by the equilibrium expression [6]. The ion intensity ratio from

$$[6] \quad K_1 = \frac{P(C_4H_9C_6H_6)^+}{P(C_4H_9^+)\,P(C_6H_6)}$$

runs as in Fig. 1, in the steady region, at long reaction times, was substituted into equation [6]. An example of the invariance of $K_1$ with changing benzene pressure is shown in Fig. 2. The results in Fig. 1 illustrate the clean reaction conditions that can be achieved by proper choice of the reaction mixture. The ions of interest, $C_4H_9^+$ and $C_4H_9C_6H_6^+$, represent almost 95% of the total ions observed during most of the reaction time. The reactions leading to $C_4H_9^+$ in the selected reaction mixture are described in the experimental section.

Raising the ion source temperature shifted the equilibrium to the left as expected for an exothermic reaction like [1]. The equilibrium constants $K_1$ determined at different temperatures are shown in the van't Hoff plot Fig. 3. The thermodynamic data $\Delta H_1^0$, $\Delta G_1^0$, and $\Delta S_1^0$ obtained from the plot are given in Table 1. These results can be compared with calculated values obtained through eq. [7] and literature thermochemical data (10–14).

$$[7] \quad \Delta H_1 = \Delta H_{PT} - \Delta H_f^0(\text{iso-}C_4H_8) + \Delta H_f^0(C_4H_9C_6H_5) - \Delta H_f^0(C_6H_6)$$

$$[8] \quad C_4H_9^+ + C_4H_9C_6H_5 = \text{iso-}C_4H_8 + C_4H_9C_6H_6^+$$
$$\Delta H_8^0 = \Delta H_{PT}^0 = PA(\text{iso-}C_4H_8) - PA(C_4H_9C_6H_5)$$

$\Delta H_{PT}^0$ corresponds to the enthalpy for the proton transfer shown in eq. [8]. Analogous equations can be written also for $\Delta G_1^0$ and $\Delta S_1^0$. The proton affinity of butylbenzene has been determined from proton transfer equilibria by McIver and co-workers (10). The proton affinity of isobutene also has been determined by proton transfer equilibria (7, 8, 11, 12). Since only the proton affinity difference is required in eq. [7], one needs only the relative proton affinities, i.e., there is no need to use an absolute PA scale. Heats of formation for the neutrals are also available (13). The $\Delta H^0 = -22$ kcal/mol obtained from the van't Hoff plot is seen to be in relatively good agreement with the value of −21 kcal/mol obtained via eq. [7].

Immediately after the butylation, the proton may

[3] Since all subsequent discussion deals with *tert*-$C_4H_9$, the prefix *tert* will be omitted for brevity in all the subsequent text and formulas.

be expected to be in position 1, relative to the butyl group. The relative energies for different positions of the proton on the benzene ring should be similar to those in protonated toluene, for which Hehre and co-workers (15) have made STO-3G calculations. They found the following relative values 1(0); 2(−6.2); 3(−1.7); 4(−8.2), the numbers in brackets being the energies in kcal/mol. The proton affinity (10) of butylbenzene obtained from proton transfer equilibria should relate to the most stable position 4. The (approximate) agreement between $\Delta H_1$ from the equilibria [1] and the calculated $\Delta H_1$ from eq. [7] indicates that the proton in equilibria [1] was in the 2 or 4 position. One may expect considerable energy barrier(s) for the migration of the proton from the 1 to the 2 (and 4) position. The exothermicity of the butyl addition (proton in position 1) which should be around 12–15 kcal/mol is the only source that could provide the energy for the migration. Thus, we assume that the barriers are less than ~15 kcal/mol and the energy is provided by chemical activation.

Approximate rate constants $k_{1f}$ and $k_{1r}$ can be determined from runs like that shown in Fig. 1. These are shown in Table 1. It was assumed that the reaction is third order in the forward and second order in the reverse direction. The $k_{1f} \approx 10^{-28}$ cm$^6$ molecules$^{-2}$ s$^{-1}$ is very small when compared to other third order association reactions involving polyatomic reactants and exothermicities in the 20 kcal/mol range. The low rate constant, however, is not so surprising when one considers that the primary product of [1f] contains the proton in position 1 and thus has a considerably lower exothermicity than 20 kcal/mol. Furthermore, the formation of the adduct is connected with unusually unfavorable entropy, as will be shown below.

Table 1 gives enthalpy changes for the alkylation of benzene by the isopropyl and ethyl cation. These were calculated from equations analogous to [7] and corresponding thermochemical data. As expected, a rapid increase of exothermicity is observed for the series $C_4H_9^+$, *sec*-$C_3H_7^+$, $C_2H_5^+$.

It is possible to calculate the entropy change of the alkylation reactions with an equation analogous to [7] but involving the corresponding entropy terms. The $\Delta S$ changes for the proton transfer reactions are small and are generally estimated from the rotational symmetry numbers. The entropies for the neutrals were taken from Stull *et al.* (14). The calculated entropies for iso-$C_3H_7^+$ and $C_2H_5^+$ alkylation are shown in Table 1. Unfortunately a value for $S^0(C_4H_9 \cdot C_6H_5)$ is not available, so that $\Delta S_1^0$ could not be evaluated from eq. [7]. An estimate of $\Delta S_1^0$ can be made on the basis of equations for translational, rotational, and vibrational entropies from statistical mechanics. The translational and external rotation changes are easily evaluated and amount to $\Delta S^0_{tr} = -36.7$ and $\Delta S^0_{ext\ rot} = -15.2$. (All entropy values in cal K$^{-1}$ mol$^{-1}$.) Space models indicate that the internal rotation of the butyl group relative to $C_6H_6$ in $C_4H_9C_6H_6^+$ may be restricted to a torsional oscillation. The same is true for the internal rotations of the methyl groups. Taking this into account, one obtains a $\Delta S^0_{int\ rot} \approx -1.5$. The total $-\Delta S_1^0$, neglecting all vibrations, is 53.4. This value represents a maximum value for $-\Delta S_1^0$. Several soft vibrations created in the adduct $C_4H_9C_6H_6^+$ will reduce $-\Delta S_1^0$ by some 5–8 units, i.e. to the neighbourhood of 46 cal K$^{-1}$ mol$^{-1}$. This is the estimated value given in Table 1.

The (absolute) entropy changes for the alkylation of benzene are seen to increase rapidly in the order $C_2H_5^+$, *sec*-$C_3H_7^+$, $C_4H_9^+$. The $-\Delta S^0$ value for butyl is unusually large, the largest we have ever measured. The entropy changes for many association reactions fall around 25 cal/degree mol. This is particularly true for clustering reactions, i.e. ion–solvent molecule association (7). The large entropy loss in reaction [1] must be attributed to the relatively large mass and large moments of inertia of both benzene and $C_4H_9^+$ and to the very restricted motions of the butyl group in the $C_4H_9C_6H_6^+$ ion. The very adverse entropy change for reaction [1] contributes significantly to the lack of stability of the $C_4H_9C_6H_6^+$ which was seen to thermally decompose (see Figs. 1 and 3) already below room temperature. Species with a dissociation energy of 22 kcal/mol ($-\Delta H_1$) and more normal entropies remain stable to much higher temperatures.

In superacid solution Olah *et al.* (1*c*) have observed, by $^1$Hmr, that the protonated butylbenzene is stable at −78°C. However, "warming of the solution leads to immediate cleavage of the butyl group" i.e. the reverse of reaction [1]. From this description, it appears that the cleavage is considerably more facile in solution than in the gas phase. This difference probably is largely due to solvation effects, in particular the better solvation of the butyl cation when compared to the butyl benzenium ion.

The facile decomposition of $C_4H_9C_6H_6^+$ is obviously responsible for protolysis being the almost exclusive reaction in the mass spectral chemical ionization of butylbenzene (3) with strong Brönsted acids like $CH_5^+$ and $C_2H_5^+$. But even after the most gentle protonation, thermal decomposition by [1r] will occur at the 100°C temperature commonly used in C.I. ion sources. McIver and

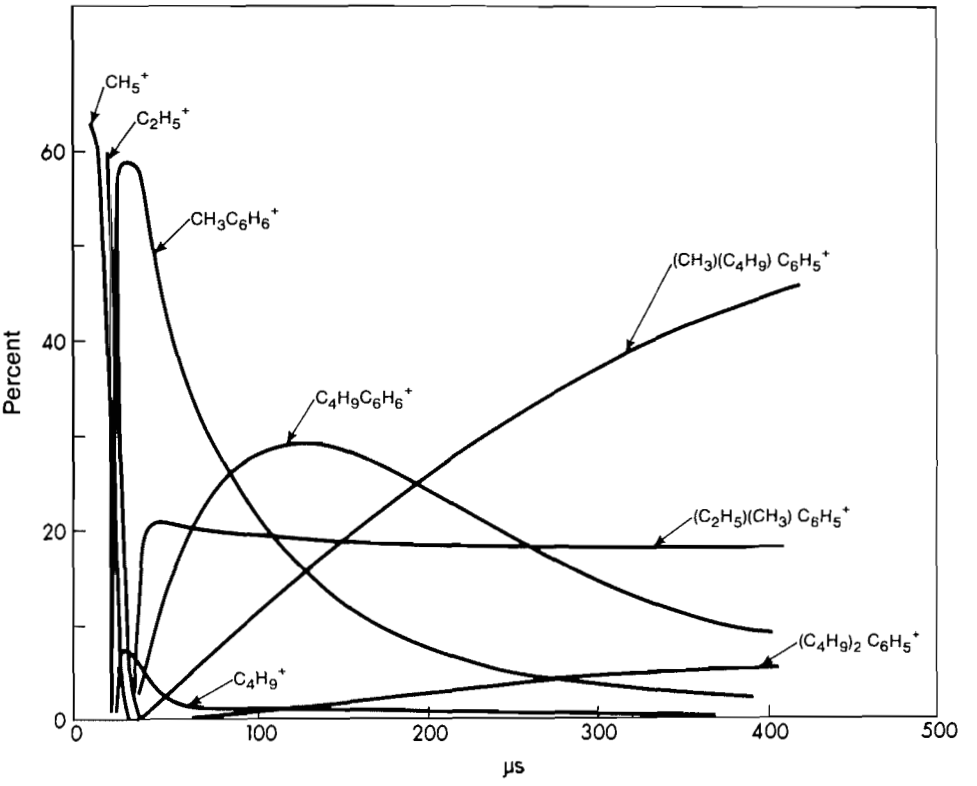

FIG. 4. Time dependence of major ions observed for reaction mixture: $CH_4$ 1.6 Torr, *tert*-butylbenzene 0.7 mTorr. Strongly exothermic protonation of butylbenzene by $CH_5^+$ and $C_2H_5^+$ leads almost exclusively to protolysis: $(C_4H_9C_6H_6^+)^* \longrightarrow C_4H_9^+ + C_6H_6$. The butyl ion produced by the above reaction alkylates the butylbenzene by reaction [10], $C_4H_9^+ + C_4H_9C_6H_5 = (C_4H_9)_2C_6H_5^+$. The doubly butylated benzenium ion is more stable than the monobutylated ion, i.e. $K_{10} \gg K_1$.

co-workers (10) were able to measure proton transfer equilibria involving butylbenzene only because, at the low pressures used in the ICR apparatus, the thermal activation required for [lr] is very much slower than the proton transfer reactions.

Some experiments were made in order to determine the fate of $C_4H_9C_6H_6^+$ produced by protonation of butylbenzene. The time dependence of the ions observed in two such experiments is shown in Figs. 4 and 5. A mixture of methane (1.6 Torr) with traces of butylbenzene (0.7 mTorr) was used in Fig. 4.

The proton transfer from the methane ions $CH_5^+$ and $C_2H_5^+$ is strongly exothermic and results in almost complete protolysis of the butylbenzene. The $C_4H_9^+$ created by the protolysis is seen

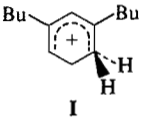
$$[9]\quad CH_5^+(\text{or } C_2H_5^+) + C_4H_9C_6H_5 = [C_4H_9C_6H_6^+]^* + CH_4\,(\text{or } C_2H_4)$$

$$[C_4H_9C_6H_6^+]^* \longrightarrow C_4H_9^+ + C_6H_6$$

to alkylate the butylbenzene in reaction [10] which is analogous to [1]. In comparing Figs. 1 and 4, which are for experiments at the same

$$[10]\quad C_4H_9^+ + C_4H_9C_6H_5 = (C_4H_9)_2C_6H_5^+$$

temperature, it becomes immediately obvious that the equilibrium constant $K_{10}$ is much larger than $K_1$, i.e. $K_1 \approx \geq 1.7 \times 10^2$ while $K_{10} \geq 3 \times 10^4$ ($Torr^{-1}$). This is an expected result. It has long been known, from condensed media experiments, that the stability of benzenium ions (cyclohexadienyl cations) increases as the number of alkyl substituents is increased (1, 2). This is due to the greater stabilization of the charge in the benzenium ions by the multiple alkyl substituents. A well-known consequence of this effect is the reduced synthetic utility of Friedel–Crafts alkylations, i.e. the difficulty in stopping the reaction at the single alkylation stage. The product of reaction [10] is most likely the most stable isomer, i.e. the *meta* dibutylbenzenium shown in structure **I**.



**I**

Not all of the protonated butylbenzene formed by reaction [9] suffers immediate dissociation; a small

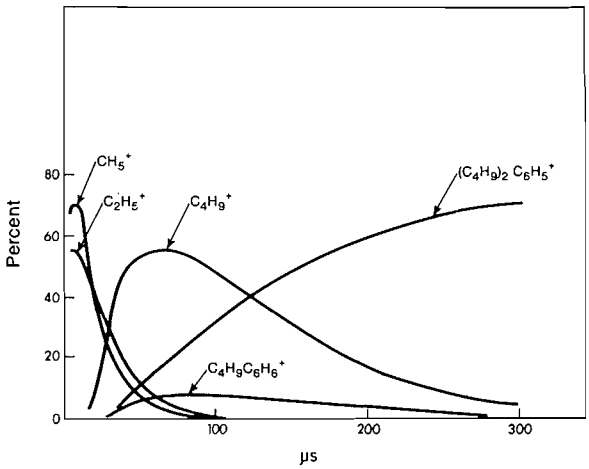

FIG. 5. Time dependence of major ions observed with reaction mixture: $CH_4$ 1 Torr, toluene 10 mTorr, *tert*-butylbenzene 0.5 mTorr. $CH_5^+$ and $C_2H_5^+$ rapidly protonate toluene. The protonated toluene proton transfers to butylbenzene [11] $CH_3C_6H_6^+ + C_4H_9C_6H_5 = CH_3C_6H_5 + C_4H_9C_6H_6^+$. Reaction [11] comes near equilibrium for longer reaction times. Some of the $C_4H_9C_6H_6^+$ decomposes to $C_4H_9^+$ by [lr]. The final major product $(CH_3)(C_4H_9)C_6H_5^+$ is formed by the addition of $C_4H_9^+$ to toluene [12] and also by the direct reaction [14], $C_4H_9C_6H_6^+ + CH_3C_6H_5 = (C_4H_9)(CH_3)C_6H_5^+ + C_6H_6$.

fraction becomes thermalized (see Fig. 4) and then gradually disappears by reactions [lr] and [15] to be discussed below.

The ion–time profiles shown in Fig. 5 were obtained with a gas mixture of the major gas methane (1 Torr) with toluene (10 mTorr) and butylbenzene (0.5 mTorr). For these conditions, proton transfer from $CH_5^+$ and $C_2H_5^+$ to toluene is rapid. The protonated toluene proton transfers to the butylbenzene by reaction [11]. Since the proton affinities of

[11] $CH_3C_6H_6^+ + C_4H_9C_6H_5 = CH_3C_6H_5 + C_4H_9C_6H_6^+$

toluene and butylbenzene are close, reaction [11] reaches equilibrium after $\sim 100\,\mu s$. This is demonstrated by the essentially constant ratio $[C_4H_9C_6H_6^+]/[CH_3C_6H_6^+] \approx 3$ at longer reaction times. This ratio taken together with the concentration ratio of the neutrals, [toluene]/[butylbenzene] = 20, leads to $K_{11} \approx 60$ and $\Delta G^0_{11} = -2.5$ kcal/mol in good agreement with McIver's (10) value of $-2.3$ kcal/mol. The butylbenzenium ion formed via (11) disappears gradually and is replaced by the two ions $(CH_3)(C_4H_9)C_6H_5^+$ and $(C_4H_9)_2C_6H_5^+$. These products can be created by reactions [12] and [13], the association of $C_4H_9^+$ with toluene and butylbenzene. The butyl$^+$ is formed by the thermal

[12] $C_4H_9^+ + CH_3C_6H_5 = C_4H_9CH_3C_6H_5^+$

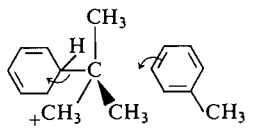
[13] $C_4H_9^+ + C_4H_9C_6H_5 = (C_4H_9)_2C_6H_5^+$

decomposition of the $C_4H_9C_6H_6^+$, i.e. reaction [lr]. Reactions [lr], [12], and [13] undoubtedly occur, evidence for this is the small, near steady state concentration of $C_4H_9^+$ observed in Fig. 5 over the whole duration of the $C_4H_9C_6H_6^+$ ion. This is consistent with $C_4H_9^+$ being produced by [lr] and disappearing by [12] and [13]. (A "burst" of $C_4H_9^+$ at short reaction times is due to protolysis of butylbenzene by $CH_5^+$ and $C_2H_5^+$.) Comparing the rate of $C_4H_9C_6H_6^+$ disappearance with the expected rate due to reaction [lr] (the rate constant $k_{lr}$ was determined from Fig. 1) one finds that the observed rate in Fig. 5 and other similar runs is much faster. Furthermore this rate was found to increase as the concentration of toluene and butylbenzene was increased. This is very strong evidence that reactions [14] and [15] are also occurring. The rate constants $k_{14}$ and $k_{15}$ could be estimated to be around

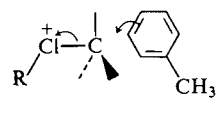
[14] $C_4H_9C_6H_6^+ + CH_3C_6H_5 = C_4H_9CH_3C_6H_5^+ + C_6H_6$

[15] $C_4H_9C_6H_6^+ + tert\text{-}C_4H_9C_6H_5 = (C_3H_9)_2C_6H_5^+ + C_6H_6$

$k_{14} \approx k_{15} \approx 10^{-11}$ molecules$^{-1}$ cm$^3$ s$^{-1}$ which is two orders of magnitude lower than the orbiting collision rates. Reactions [14] and [15] probably proceed via the intermediate shown in structure **II** (for toluene). While the positive charge in **II** is formally on the benzene ring, in actual fact a considerable fraction of the charge will be also on the butyl group. After all, in the dissociation [lr] all the charge ends up on the butyl group. Thus, one can visualize the butyl group involved in an electrophilic attack as in **II**. Reactions [14] and [15] via the complex **II** probably have no counterpart in solution where solvent assistance of the dissociation [lr] favors very much the route [lr] followed by alkylations [12] and [13]. Also, solvation of the $C_4H_9C_6H_6^+$ ion probably reduces the electrophilicity of the $C_4H_9$ group and thus its tendency to form an activated complex like **II**. Reactions [14], [15], and the intermediate **II** are somewhat analogous to the alkylation reactions of benzenes by alkyl chloronium ions observed in solution and recently also in the gas phase (16) (see structure **III**). The gas



**II**



**III**

phase chloronium ion reactions were found to proceed with rate constants much lower than the orbiting rates (16); i.e., the alkylations by butyl benzenium (**II**) and alkylchloronium (**III**) are both relatively slow reactions.

# Electronic spectroscopy of aromatic Schiff bases. V. Specific interactions involved between some typical benzylideneaniline molecules and small polar molecules

MICHEL BELLETETE[1] AND GILLES DUROCHER

*Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1*

Received February 18, 1982

MICHEL BELLETETE and GILLES DUROCHER. Can. J. Chem. **60**, 2332 (1982).

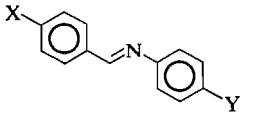
Fluorescence quantum yields ($\phi_F$), theoretical first-singlet radiative decay constants ($k_F^{(u)}$), and first-singlet non-radiative decay constants ($k_{nr}$) of some benzylideneanilines (BA) dissolved in methylcyclohexane have been obtained. High values of $k_{nr}$ are interpreted by the twisting of the molecules around the azomethine bond (C=N) in the first singlet excited state. The absorption spectra of some BA's have also been obtained in methylcyclohexane with various added amounts of polar molecules. BA's with strong electron-donor and/or strong electron-acceptor substituents in the *para* positions give rise to the formation of ground state complexes with small polar molecules. The stoichiometry of the complex is one BA molecule for two polar solvent molecules; when ethanol is used as a polar solvent, it is further involved in hydrogen bonding formation. The fluorescence spectra of 4-dimethylaminobenzylidene-4'-nitroaniline have been obtained in methylcyclohexane with various added amounts of polar species. The results are interpreted by the formation of exciplexes with polar compound. The Lippert–Mataga theory and the more generalized Kawski theory failed to explain the solute–solvent interactions disussed in this paper.

MICHEL BELLETETE et GILLES DUROCHER. Can. J. Chem. **60**, 2332 (1982).

Les rendements de fluorescence ($\phi_F$), les constantes de désactivation radiative théoriques de l'état premier singulet excité ($k_F^{(u)}$) et les constantes de désactivation non-radiatives de l'état premier singulet excité ($k_{nr}$) de certaines molécules de benzylidèneaniline (BA) dissoutes dans le méthylcyclohexane ont été obtenus. Les valeurs élevées de $k_{nr}$ obtenues sont expliquées par la torsion des molécules autour du lien azométhine (C=N) dans l'état premier singulet excité. Les spectres d'absorption de certaines molécules de benzylidèneaniline ont été mesurés dans le méthylcyclohexane avec différentes quantités ajoutées de molécules polaires. Les BA possédant des substituants électro-accepteurs puissants en position Y et/ou des substituants électro-donneurs en position X forment des complexes à l'état fondamental avec les molécules polaires. La stoïchiométrie de ces complexes est une molécule de BA pour deux molécules de solvant polaire; les complexes formés par l'éthanol impliquent la formation d'une liaison hydrogène. Les spectres de fluorescence de la molécule de diméthylamino-4 benzylidène nitro-4'-aniline ont été obtenus dans le méthylcyclohexane pour des additions successives de molécules polaires. Les résultats obtenus sont expliqués en termes d'interactions spécifiques à l'état excité (exciplexe). La théorie de Lippert-Mataga et la théorie plus généralisée de Kawski ne peuvent expliquer les interactions soluté–solvant discutées dans cet article.

## Introduction

The absorption spectroscopy of the *para*-substituted benzylideneanilines (BA) has been studied in recent years and for a review of the literature we refer the readers to parts I and II of this series of papers (1, 2). For band system II of some BA's, assigned to a charge transfer transition, very large excited state dipole moments have been obtained by using the Lippert–Mataga theory describing the solute–solvent interactions (2). On the other hand, the emission spectroscopy of these molecules was unexplored (3–6). Recently, we have shown the existence of luminescence from some BA's (7–9). The purpose of this paper is two-fold: first we want to study the photophysics of some of these BA's and secondly, we want to investigate the possibility of specific interactions taking place between BA's and polar solvents in their ground and/or excited states. The molecules studied here are the following using the same notations as described in an earlier paper (2).



| Compound | X | Y |
|---|---|---|
| **1** | H | H |
| **2** | $OCH_3$ | H |
| **3** | H | $NO_2$ |
| **4** | $OCH_3$ | $OCH_3$ |
| **5** | $OCH_3$ | $NO_2$ |
| **6** | $N(CH_3)_2$ | $NO_2$ |
| **7** | H | $OCH_3$ |
| **8** | $NO_2$ | H |
| **9** | $NO_2$ | $OCH_3$ |
| **13** | $NO_2$ | $NO_2$ |

## Experimental part

The BA's were synthesized and purified as described previously (1, 2). Methylcyclohexane, diethyl ether, acetonitrile, dimethylformamide, and ethanol were purified as described elsewhere (2); *n*-butylbromide (Eastman Kodak) was distilled twice and kept in the dark. Absorption spectra at room temperature have been recorded on Cary-14 and on B & L Spectronic-505 spectrophotometers. The areas under the absorption curves for the calculation of the $k_F^{(u)}$ values were

determined by using a program adapted on the "Data General Nova 3/12" minicomputer.

Absorption spectra at several temperatures and fluorescence spectra at room temperature were obtained on a Spex "Fluorolog" instrument model 1902, using a 450 W xenon-arc source. The temperature was varied with a "Polyscience Corporation" model 90 circulator bath using a mixture of water – ethylene glycol as the circulating fluid and connected to the 4-cell sample holder. The temperature (0°C to 60°C) of the samples was measured directly with a thermometer placed in a reference cell (±0.5°C). The fluorescence quantum yields were obtained relative to those of the 3H-indoles (10). Concentrations were varied from 2 to 5 × $10^{-5}$ mol $L^{-1}$ in the absorption and fluorescence studies.

## Results and discussion

### *I. Photophysics of some* p-*substituted BA's in a non-polar solvent*

The absorption spectra of the BA's studied here have been obtained at room temperature in cyclohexane and were published in part I of this series of papers (1). Fluorescence was detected only for molecules **2**, **4**, **6**, and **7**. The fluorescence spectra of these molecules at room temperature in methylcyclohexane are shown in Fig. 1. The intensity has been normalized. The absorption and fluorescence spectra do not show any vibrational structure and do not give rise to good mirror-image relationship as the absorption spectra from ref. 1 are wider than the fluorescence spectra in each case.

The fluorescence quantum yields of molecules **2**, **4**, **6**, and **7** have been measured. For the other molecules, $\phi_F$ was less than 0.0001, the experimental sensitivity limit of our instrumentation. Very small $\phi_F$ values were obtained for all molecules as shown in Table 1. The theoretical first singlet radiative decay constants ($k_F^{(t)}$) have been calculated using the approximate Forster relation (11) since the Strickler and Berg approach (12) necessitates the use of the fluorescence spectra which are not available for many of the molecules studied. The Forster relation is strictly valid only when fluorescence and absorption give good mirror image relationship. This is not the case for the BA molecules studied here and the $k_F^{(t)}$ calculations are thus only approximate and may vary by a factor of 2 as we have shown by application of the Strickler and Berg approach to the fluorescing molecules. Nevertheless, it is interesting to note that the variation in the $k_F^{(t)}$ values of these molecules follows (roughly) the variation in their ground state dipole moments (2).

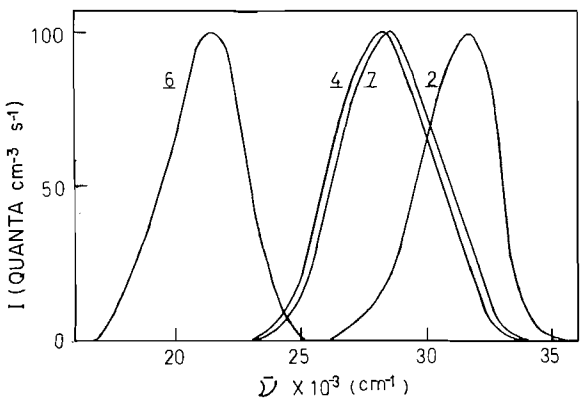

FIG. 1. Fluorescence spectra of molecules **2**, **4**, **6**, and **7** at room temperature in methylcyclohexane. All spectra have been normalized.

Obviously the non-radiative decay constant ($k_{nr}$) is the key parameter as far as the photophysical behaviour of the BA is concerned. Even if it seemed necessary that molecules which emit fluorescence possess a $k_F^{(t)}$ value higher than 3.0 × $10^8$ $s^{-1}$, it is not the only prerequisite since molecules **5** and **9** have shown no fluorescence emission (limit of detection of our apparatus). Such high non-radiative decay constants are difficult to assign to intersystem crossing from $S_1$ to $T_1$ since these rates from singlet $\pi\pi^*$ states vary normally between $10^6$ and $10^8$ $s^{-1}$ (ref. 11, p. 178). Moreover, very weak phosphorescence has been observed in low temperature matrices in only two of these molecules (8). Since the BA's are not rigid in their ground electronic states (1), the first excited singlet state is likely to be deactivated by the twisting of the molecules around the azomethine bond (C=N). This would explain the high values of $k_{nr}$ for all the BA molecules. Recently, Yoshida and Kobayashi have shown that various substituted *N*-benzylideneanilines are converted into their photo *Z*(*cis*) isomers upon irradiation by a high pressure mercury lamp (31). This photochemical behaviour has been correlated to that of stilbene derivatives.

On the other hand, Pinasias *et al.* have shown that the fluorescence quantum yields of *p*-substituted stilbenes increase by decreasing the temperature (13). The temperature-dependent process was attributed to twisting of the molecular parts around the ethylenic bond rather than to internal conversion. Moreover, Fisher *et al.* obtained the same results and gave the same interpretation for non-planar stilbene derivatives (14). Unfortunately, due to the fact that these highly polar BA's are only slightly soluble in non-polar solvents, dimerization of these BA's rapidly occurs in lowering the temperature and the free BA fluorescence is then rapidly quenched. On the other hand, the Stokes shifts ($\bar{\nu}_A - \bar{\nu}_F$) are rather small for molecules **2**, **4**, and **7** but nearly double for molecule **6**, so it might

TABLE 1. Photophysical properties of some *p*-substituted benzylideneaniline molecules in methylcyclohexane at room temperature

| Molecules | X | Y | $\bar{\nu}_A - \bar{\nu}_F$ ($cm^{-1}$) | $k_F^{(1)} \times 10^{-8}$ ($s^{-1}$) | $\phi_F$ | $k_{nr} \times 10^{-12}$ ($s^{-1}$) |
|---|---|---|---|---|---|---|
| **6** | $N(CH_3)_2$ | $NO_2$ | 4800 | 7.4 | 0.0014 | 0.53 |
| **5** | $OCH_3$ | $NO_2$ | — | 5.8 | <0.0001 | >6 |
| **2** | $OCH_3$ | H | 2200 | 3.0 | 0.0010 | 0.30 |
| **3** | H | $NO_2$ | — | 1.9 | <0.0001 | >2 |
| **1** | H | H | — | 1.9 | <0.0001 | >2 |
| **7** | H | $OCH_3$ | 2700 | 3.6 | 0.0001 | 4 |
| **8** | $NO_2$ | H | — | 1.3 | <0.0001 | >1 |
| **9** | $NO_2$ | $OCH_3$ | — | 3.3 | <0.0001 | >3 |
| **4** | $OCH_3$ | $OCH_3$ | 2200 | 5.2 | 0.0001 | 5 |
| **13** | $NO_2$ | $NO_2$ | — | 1.4 | <0.0001 | >1 |

be that the twisted internal charge transfer excited state involving the dimethylamino group in this molecule also plays a certain role in stabilizing the relaxed $S_1$ state before the fluorescence can occur (27, 28). Finally the 3H-indoles (planar analogs of the BA's), which are more rigid in their ground states and where the twisting of the molecules around the C=N double bond is avoided, show $k_{nr}$ values lower by four orders of magnitude in some cases compared to the BA's (10).

Furthermore, it is quite clear from Table 1 that the non-radiative decay constants of all the substituted BA's are higher by about one order of magnitude than that of stilbene (14) and tetraphenylethylene (29). This suggests that the excited state torsional motions are playing a more active role in the former molecules.

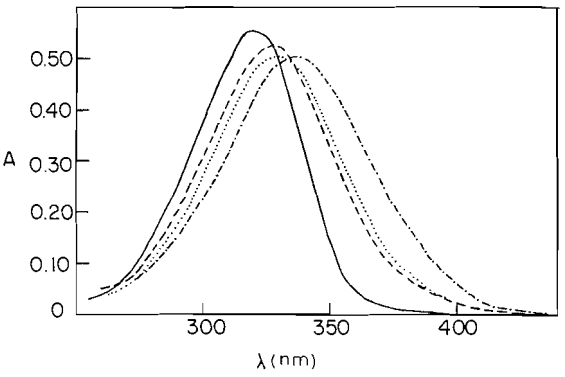

FIG. 2. Absorption spectra of 4-methoxybenzylidene-4'-nitroaniline (**5**) at room temperature in methylcyclohexane with various amounts of ethanol added (— 0.0 *M*, --- 0.188 *M*, ··· 0.273 *M*, ·····- 0.568 *M*).

*II. Ground state specific interactions (complexation)*

The absorption spectra of all the BA molecules studied here have been obtained at room temperature in methylcyclohexane with various added amounts of polar molecules like ethanol and acetonitrile. Some molecules clearly show ground state complexation with polar solvents.

*Molecule 5*

The absorption spectra of 4-methoxybenzylidene-4'-nitroaniline (**5**) have been obtained in methylcyclohexane at room temperature with various added amounts of polar molecules: ethanol ($\mu$ = 1.67 D), *n*-butylbromide ($\mu$ = 2.1 D), and acetonitrile ($\mu$ = 3.35 D). These three series of spectra show two important features: a large red shift of the absorption wavelength and the presence of an isosbestic point only at small concentrations of the polar molecules added as illustrated for the case of ethanol in Fig. 2. We have applied the Lippert–Mataga theory (2, 15, 16) to the solvent shifts and linear correlations have been obtained for the three solvents. However, the values of excited state dipole moment calculated using the different slopes were over 60 D for *n*-butylbromide and over 100 D for ethanol and acetonitrile. This proves that the solvent shifts are too large to be explained by generalized solute–solvent interactions and, furthermore, the existence of an isosbestic point in the spectra suggests that molecule **5** form a ground state complex with small polar molecules. We have also analyzed our solvent-induced frequency shifts according to the more general formula derived by Kawski (17) because, in these equations, the cavity is assumed to be an ellipsoid instead of a sphere, which is somewhat more realistic for the BA's. Linear correlations have also been obtained for the cases of ethanol and *n*-butylbromide as shown in Fig. 3. It is thus rather hazardous to use such plots (Lippert–Mataga and Kawski theories) in the calculation of excited state dipole moments without any meaningful look at all possible interactions involved.

In order to study the nature of the interactions involved in these complexes and specifically to investigate the possibility of hydrogen bonding

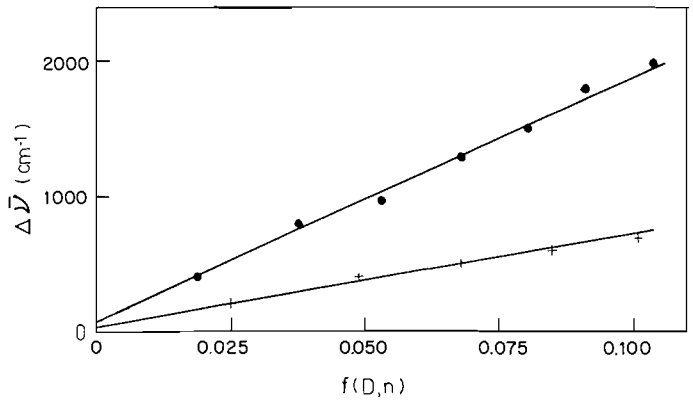

FIG. 3. Absorption solvent shifts for 4-methoxybenzylidene-4′-nitroaniline (5) (● ethanol, + *n*-butylbromide)

$$[24]\quad f(D, n) = \left(\frac{2n^2 + 1}{n^2 + 2}\right)^2 \cdot \left(\frac{D - 1}{2D + 1} - \frac{n^2 - 1}{2n^2 + 1}\right)$$

where $D$ is the dielectric constant and $n$ is the refractive index of the medium.

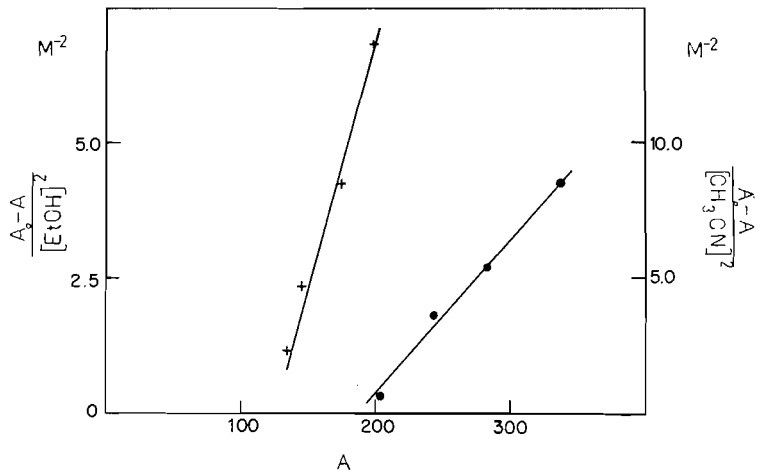

FIG. 4. Plots of $(A_0 - A)/[B]^2$ against $A$ for 4-methoxybenzylidene-4′-nitroaniline (5) in methylcyclohexane at 283 K. (The absorption wavelengths used were 300 nm for ethanol (●) and 290 nm for acetonitrile (+).)

between molecule **5** and ethanol, we recorded the absorption spectra with various amounts of ethanol and acetonitrile added at several temperatures and calculated the ground state equilibrium constant of the complex at each temperature using the following relation (18):

$$[1]\quad K[B]^n = \frac{A_0 - A}{A - A_F}$$

where $K$ is the ground state equilibrium constant, [B] is the concentration of polar molecules, $A_0$ is the absorbance at a particular wavelength in the absence of polar molecules, $A_F$ is the absorbance when all the molecules are complexed in the mixed solvent system, and $A$ is the absorbance of the sample in the presence of varying concentrations of polar molecules. Plots of $(A_0 - A)/[B]^n$ against $A$ have a slope of $K$, the equilibrium constant of the complex. Good linear correlations have been obtained only for $n = 2$, which is the number of polar molecules involved in the complex, giving rise to a stoichiometry of one molecule of **5** for 2 molecules of polar solvent. Figure 4 shows such correlations for ethanol and acetonitrile at 283 K and Table 2 gives the values of $K$ at several temperatures for ethanol and acetonitrile. Linear plots like those shown in Fig. 4 and with the same slope have been obtained by using absorption wavelengths between 290 nm and 315 nm for ethanol and between 280 nm and 300 nm for acetonitrile. The following ther-

TABLE 2. Thermodynamic parameters of the ground state molecular complexes of molecule **5**

| Ethanol | | | | Acetonitrile | | | |
|---|---|---|---|---|---|---|---|
| $T$ (K) | $K$ ($M^{-2}$) | $\Delta H^0$ (kJ mol$^{-1}$) | $\Delta S^0$ (J mol$^{-1}$ K$^{-1}$) | $T$ (K) | $K$ ($M^{-2}$) | $\Delta H^0$ (kJ mol$^{-1}$) | $\Delta S^0$ (J mol$^{-1}$ K$^{-1}$) |
| 273 | 43.5 | | | 284 | 179 | | |
| 283 | 26 | | | 294 | 145 | | |
| | | $-43\pm3$ | $-120\pm10$ | | | $-15\pm1$ | $-9\pm1$ |
| 297 | 11 | | | 306 | 102 | | |
| 306 | 6.6 | | | 329 | 74.6 | | |

modynamic relation was used to calculate the enthalpy and the entropy of the complexes:

$$[2] \quad \log K = -\frac{\Delta H^0}{2.303R}\frac{1}{T} + \frac{\Delta S^0}{2.303R}$$

Plots of log $K$ against $1/T$ give slopes of $-\Delta H^0/2.303R$ and an intercept $\Delta S^0/2.303R$. Such plots are shown in Fig. 5 and the values of $\Delta H^0$ and $\Delta S^0$ for ethanol and acetonitrile are given in Table 2.

It is worth pointing out that $\Delta H^0$ is much larger for the complex involving ethanol even if acetonitrile is much more polar than ethanol. This higher energy of formation of the complex in ethanol is responsible for its red-shifted electronic absorption in ethanol compared to acetonitrile. In the literature we find $\Delta H$ values between 1 kJ mol$^{-1}$ and about 18 kJ mol$^{-1}$ for complexes stabilized by dipolar interactions and from 8 kJ mol$^{-1}$ to 40 kJ mol$^{-1}$ for complexes involving hydrogen bonding interactions (19). We then propose that acetonitrile is involved in a complex mainly stabilized by dipole–dipole interactions. For the case of ethanol, dipolar interactions may also contribute to the binding in the complex but hydrogen bonding formation is certainly the most important factor involved in the formation of this kind of complex.

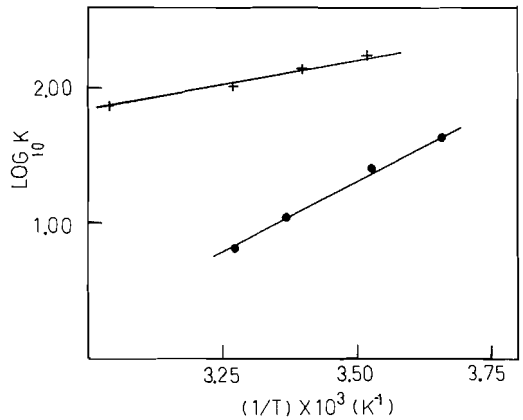

FIG. 5. Plots of log $K$ against $1/T$ for 4-methoxybenzylidene-4′-nitroaniline in methylcyclohexane (● ethanol, + acetonitrile).

Moreover, the entropy change is higher for the complex involving ethanol; this can be explained by the fact that complexes involving hydrogen bond interactions are much more ordered relative to those stabilized by dipolar interactions.

Thermodynamics alone cannot differentiate the sites of the complexation, but recently Lumry *et al.* (20) suggested that indole compounds possess two sites for complexation and that alcohols can serve as proton donor and also electron donor in the interactions with these type of compounds. Scheuer-Lamalle made some theoretical *ab initio* calculations of the electronic density on the substituted phenylimines (R′—CH=N—$C_6H_4$—R) and on the substituted benzaldimine molecules (R′—$C_6H_4$—CH=N—R) (21). She showed that for the phenylimines, the electronic charge on the nitrogen atom of the azomethine bond is practically independent of the substituents R and R′. On the other hand, benzaldimines, where R′ is an electron-donor substituent and R is an electron-acceptor substituent, show a net increase in the electronic charge on the nitrogen atom. By analogy, BA molecules where X is an electron-donor substituent and Y is an electron-acceptor substituent are expected to show the same behavior as that of the benzaldimines. These BA's thus have a negative nitrogen atom with one highly accessible electron lone pair and different positive sites on carbon atoms. Two sites of complexation are therefore also possible in BA's possessing electron-donor substituents in X position and electron-acceptor substituents in Y position. For complexes involving ethanol one molecule is certainly bound at the nitrogen site by hydrogen bonding interaction and the other molecule might be bound elsewhere in the BA by dipolar interactions. For complexes involving acetonitrile, the polar molecules are probably linked at the same positions as for ethanol but this time only dipolar interactions are involved in the stabilization of the complexes.

*Molecule* **6**

The absorption spectra of 4-dimethylamino-benzylidene-4′-nitroaniline (**6**) have been obtained in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

methylcyclohexane at room temperature with various added amounts of ethanol and *n*-butylbromide. Acetonitrile was not used due to the lack of miscibility with methylcyclohexane, less than 2%, which is not enough to observe significant changes in the absorption spectra. Figure 6 shows the case of ethanol and as for molecule **5**, an isosbestic point appeared this time at 385 nm which emphasizes the formation of a ground state complex. The equilibrium constant of the complexes have been calculated using eq. [1] and values of $K = 1.00 \pm 0.20\,M^{-2}$ and $K = 1.5 \pm 0.5\,M^{-2}$ have been obtained for the cases of ethanol and *n*-butylbromide, respectively. The stoichiometry of the complexes is one molecule of **6** for two molecules of polar solvent. By analogy with molecule **5**, the ground state complex is probably stabilized by dipolar interactions for *n*-butylbromide and by hydrogen bonding formation for ethanol. We have applied the Lippert–Mataga (2, 15, 16) and the Kawski (17) relations for the solvent shifts and this time no linear correlation has been obtained for either solvent.

*Molecule 3*

The absorption spectra of benzylidene-4′-nitroaniline have been obtained in methylcyclohexane at room temperature with different added amounts of ethanol and are illustrated on Fig. 7. It is clear there is ground state complexation and $K = 1.0 \pm 0.2\,M^{-2}$. Linear Lippert–Mataga and Kawski correlations have been obtained for the solvent shifts.

All the other BA's studied didn't seem to show any obvious specific interactions with ethanol in their ground electronic state. So only BA's with strong electron-acceptor substituents in the Y position and/or electron-donor substituents in the X position give rise to the formation of ground state

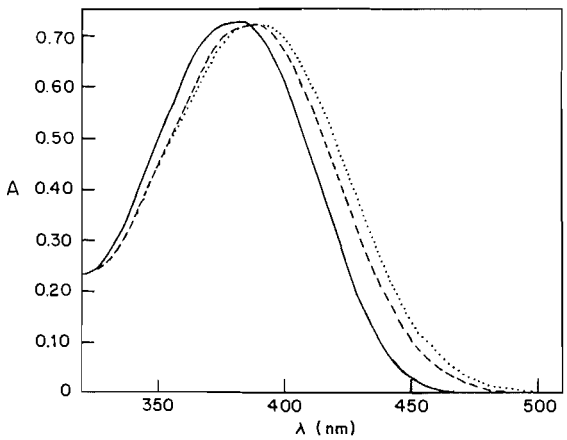

FIG. 6. Absorption spectra of 4-dimethylaminobenzylidene-4′-nitroaniline (**6**) at room temperature in methylcyclohexane with various amounts of ethanol added (— 0.0 *M*, --- 2.02 *M*, ··· 3.24 *M*).

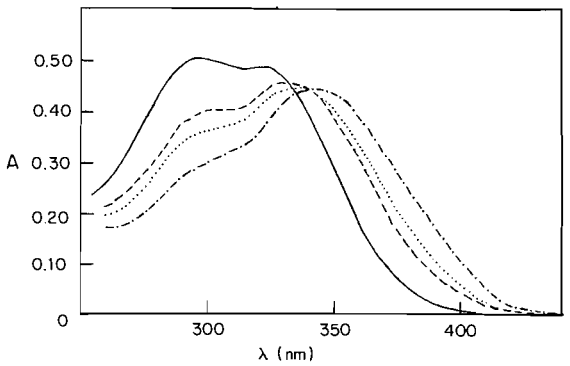

FIG. 7. Absorption spectra of benzylidene-4′-nitroaniline (**3**) at room temperature in methylcyclohexane with various amounts of ethanol added (— 0 *M*, --- 1.07 *M*, ··· 1.56 *M*, ·-·-·- 3.24 *M*).

complexes with small polar molecules. These molecules are likely not to be planar (2) in their ground states; for example, Kobayashi *et al.* (22) using CNDO/S CI calculations have shown that benzylidene-4′-nitroaniline is considerably twisted in its ground state. On the other hand, 4-nitrobenzylidene-4′-methoxyaniline, which is nearly planar (23), shows no evidence of ground state specific interactions. The planarity of the BA's does not seem to be a criterion as far as ground state complexation is concerned. The important factor seems to be the electron density at the different sites of the BA molecules; molecules with strong electron density on the N atom and electronic attraction centers at various C atoms form ground state complexes with small polar molecules. Due to the fact that a high electron density on the nitrogen atom of the azomethine bond favors the distortion of the phenylimine group (loss of planarity of the whole molecule) these BA's probably behave like bichromophores with their own interaction sites.

We have thus shown that the Lippert–Mataga and the more generalized Kawski theories sometimes give linear correlations for the solvent shifts even if ground state complexes exist. Thus these kinds of correlation cannot be used as criteria for the presence or absence of specific interactions with a particular polar solvent. For this reason, some of the excited state dipole moments of polar molecules published in the literature are to be used with caution, since ground state complexation with polar solvents might possibly occur.

### *III. Do any excited state specific interactions exist between BA's and polar solvents?*

Lippert calculated an excited state dipole moment for molecule **6** using absorption and fluorescence maxima in many solvents of different dielectric constants (3). He obtained a roughly linear correlation between $\bar{\nu}_A - \bar{\nu}_F$ and $f(D, n)$ (even if as

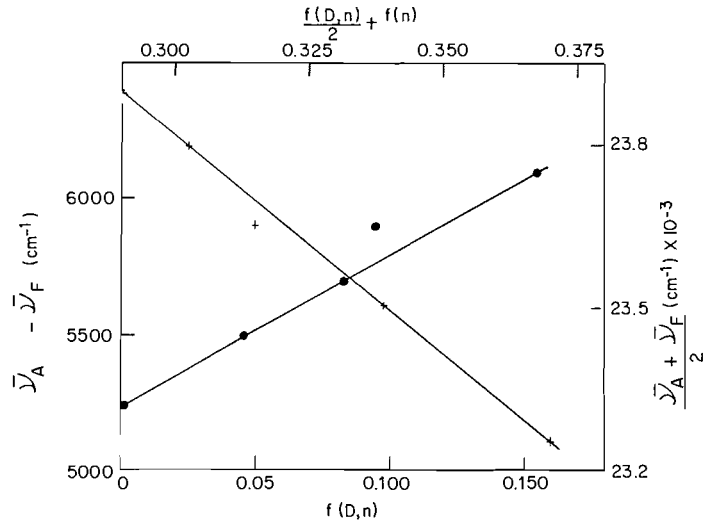

FIG. 8. Plots of $\bar{\nu}_A - \bar{\nu}_F$ vs. $f(D,n)$ (●) and $(\bar{\nu}_A + \bar{\nu}_F)/2$ vs. $f(D,n)/2 + f(n)$ (+) for the solvent shifts of 4-dimethylaminobenzylidene-4′-nitroaniline (**6**) in methylcyclohexane with various amounts of acetonitrile added.

[17, 24] $$f(D, n) = \frac{2n^2 + 1}{n^2 + 2} \cdot \left(\frac{D - 1}{D + 2} - \frac{n^2 - 1}{n^2 + 2}\right)$$

$$f(n) = \frac{3\,(n^4 - 1)}{2\,(n^2 + 2)^2}$$

where $D$ is the dielectric constant and $n$ is the refractive index of the medium.

we have shown above, some of the polar solvents used give rise to ground state complexation) and he obtained an excited state dipole moment of 38 D. To find out if specific interactions in the excited state exist, fluorescence spectra of molecule **6** have been measured at room temperature in methylcyclohexane with different added amounts of diethyl ether, *n*-butylbromide, dimethylformamide (DMF), acetonitrile, and ethanol. The Lippert–Mataga plots using absorption and fluorescence data (2, 15, 16) for the solvent shifts have been made and linear correlations have been obtained only for the cases of DMF and acetonitrile (8). The more generalized Kawski theory (17), using the absorption and fluorescence maxima, was also applied as used by Chama and Viallet (24) for the indole derivatives. Linear correlations were also obtained. Figure 8 shows the case of acetonitrile using the two main expressions given by Chama and Viallet (24).

In each case, the fluorescence intensity of molecule **6** first increases with increasing amounts of polar solvent to reach a maximum and then decreases with further addition of polar molecules. Moreover, the fluorescence is completely extinguished in pure acetonitrile and DMF. This is a behavior typical of exciplex formation followed by exciplex fluorescence quenching when the solvent polarity increases (25). Similar results have been obtained for the equivalent planar analog (3H-indole) where the fluorescence quantum yield and singlet lifetime are much larger and consequently allow us to interpret them in terms of exciplex formation with polar solvents (26). Finally, we have reported in an earlier paper (9) that the fluorescence of some benzylideneanilines (BA's), including molecule **6** and some 3H-indole molecules, shows a blue shift in EPA at 77 K compared to the same solutions at room temperature. At the time we interpreted these results in terms of an emission taking its origin from a non-completely relaxed Franck–Condon excited state due to the rigidity of the medium. However, EPA contains 16.6% of ethanol which we know now is undergoing ground state specific interactions with these solute molecules. At 77 K ground state complexes are favored and exciplexes are not likely to occur compared to the room temperature behavior. This would also explain the blue shift observed in EPA in going from room temperature to 77 K. If the excited ground state complex was responsible for the fluorescence, one would expect a red shift in going from room to lower temperatures. Moreover, the fluorescence intensity of molecule **6** dissolved in methylcyclohexane which contains 1% of DMF decreases exponentially with the reverse of the temperature between 180 K and 220 K. It was impossible to work at temperatures lower than 180 K due to dimerization of the solute molecules. For temperatures higher than 220 K the fluores-

For personal use only.

cence intensity reaches a saturation. This is also a typical fluorescence emission behaviour for an exciplex (30).

For all these reasons we think that molecule **6** forms exciplexes with polar molecules. In pure polar solvents with high dipole moments like acetonitrile and DMF, the exciplex is completely deactivated so that no fluorescence emissions are detected in these pure solvents.

For the other BA's, the fluorescence was too weak and it was then impossible to do the same kind of experiments. However, we can anticipate that BA's for which the first singlet excited state is charge transfer in nature (electron-donor in X and/or electron-acceptor in Y) will undergo exciplex formation with small polar molecules. Finally we have shown that the Lippert–Mataga and Kawski relations using absorption and fluorescence data may give linear correlations even though specific interactions exist in the ground and excited states.

## Conclusion

BA's show high values of first-singlet non-radiative decay constants ($k_{nr}$) which are interpreted by the twisting of the molecules around the azomethine bond (C=N) in the first-singlet excited state. BA's with strong electron-acceptor substituents in the Y position and/or strong electron-donor substituents in the X position give rise to specific interactions in the ground and/or excited states. This has been rationalized in terms of a highly distorted equilibrium geometry in the ground states of these molecules (a bichromophoric molecular type). Ethanol gives rise to hydrogen bonding formation with BA's and aprotic polar solvents give rise to complexes stabilized by dipolar interactions. Linear solvent shift plots from either the Lippert–Mataga theory or the more generalized Kawski theory are not criteria from which one can conclude that no specific interactions exist between the solute ground and/or excited states and the solvent molecules. Consequently these plots should be used with caution in order to obtain excited state dipole moments without any investigations on the interactions involved with each particular polar solvent used.

# Electron spin resonance study of $SO_2$ and CO on CuO–alumina

K. C. KHULBE AND R. S. MANN

*Department of Chemical Engineering, University of Ottawa, Ottawa, Ont., Canada K1N 9B4*

Received May 6, 1981[1]

K. C. KHULBE and R. S. MANN. Can. J. Chem. **60**, 2340 (1982).

The intensity of the $Cu^{2+}$ esr signal increased significantly on the addition of CO or $SO_2$, especially with $SO_2$, at room temperature to the preheated (at 400°C) and evacuated CuO–alumina catalyst. When the CO or $SO_2$ treated sample was evacuated at room temperature, the shape and intensity of the $Cu^{2+}$ esr line returned to their original values. The intensity of the $Cu^{2+}$ esr line decreased, but not to zero, on heating CuO–alumina either with CO or $SO_2$. In the case of $SO_2$, a new line appeared for the $SO_2^-$ ion which was not affected on evacuation. It seems that the $SO_2^-$ do not take part in the reduction of $SO_2$ with CO over the CuO–alumina catalyst.

K. C. KHULBE et R. S. MANN. Can. J. Chem. **60**, 2340 (1982).

L'intensité du signal de rpe de $Cu^{2+}$ augmente de façon significative, spécialement avec le $SO_2$, lors de l'addition de CO ou de $SO_2$ à température ambiante sur un catalyseur CuO–alumine préchauffé (à 400°C) sous vide. L'intensité et la forme du signal de rpe du $Cu^{2+}$ reviennent à leur valeur originale quand les échantillons traités au CO ou au $SO_2$ sont placés sous vide. L'intensité de la bande de rpe du $Cu^{2+}$ diminue, mais ne va pas jusqu'à zéro lorsqu'on chauffe le CuO–alumine soit avec de CO ou du $SO_2$. Dans le cas du $SO_2$, il apparaît une nouvelle ligne correspondant à l'ion $SO_2^-$ que le vide n'affecte pas. Il semble que l'ion $SO_2^-$ ne participe pas dans la réduction du $SO_2$ avec le CO sur un catalyseur de CuO–alumine.

[Traduit par le journal]

## Introduction

It was observed that CuO–alumina catalysts have an excellent efficiency for the formation of elemental sulfur when $SO_2$ was reduced with CO (1–3). The mechanism for this type of reaction can be studied by following the radical formation during adsorption of CO and $SO_2$ on the surface using an esr technique.

The nature of CO adsorption on a solid surface has been studied extensively in the last several years, primarily by infrared methods. Cordischi *et al.* (4) have discussed the formation of $C_2O_2^-$ radicals following adsorption of CO on MgO. Lunsford *et al.* (5, 6) and Khulbe and Mann (7) studied the formation of paramagnetic species during adsorption of $SO_2$ on several solids. However, no such effects are reported for CO or $SO_2$ adsorbed on CuO–alumina.

The preparation of the catalyst and techniques for the esr studies are described elsewhere (8). $SO_2$ and CO, each 99.5% pure, were supplied by Linde and Matheson respectively.

Figure 1(a) shows the esr spectra obtained for the 5% CuO–alumina catalyst at room temperature after it was evacuated and heated at 400°C for 4 hours. The spectrum is assigned to $Cu^{2+}$ ions. It is well known that although nearly all copper ions in the CuO–alumina system contribute to the magnetic susceptibility, only 2% contribute to the esr signals (9). It also has been reported that in the CuO–alumina system, depending on the composition and thermal treatment, copper complexes with $Cu^{3+}$, $Cu^{2+}$, and $Cu^+$ are formed (10) and $Cu^{2+}$ ion complexes are grouped into clusters on the support surface (11). When CO (200 Torr) was added at room temperature to the evacuated and previously heated CuO–alumina system, the shape of the line due to $Cu^{2+}$ ion changed. The intensity of the line almost doubled. It could be possible that CO adsorption modifies Cu–Cu interactions and thereby increases the fraction of total $Cu^{2+}$ seen by esr. However, other possibilities cannot be discarded. On evacuation of the sample for 5 minutes at room temperature, the shape and intensity of the $Cu^{2+}$ esr line returned to their original values.

On heating the CuO–alumina in the presence of CO (200 Torr) at 400°C for 2 minutes, the colour of the catalyst changed from green to grey. The intensity of the $Cu^{2+}$ ion signal decreased slightly after the addition. On heating for a further 2 hours, the catalyst colour changed to pitch black from grey and the concentration of $Cu^{2+}$ ions decreased. On prolonged heating with CO for 24 h at 400°C the esr spectrum of $Cu^{2+}$ remained. However, it is reported that when Cu–zeolite was heated in CO, the $Cu^{2+}$ signals decreased and finally disappeared (12). It is possible that while one particular type of $Cu^{2+}$ reacts with CO at high temperature (~400°C) another type does not. On evacuating the remaining CO, no change was observed in the $Cu^{2+}$ spectra.

When $SO_2$ was added to the CO–CuO–alumina

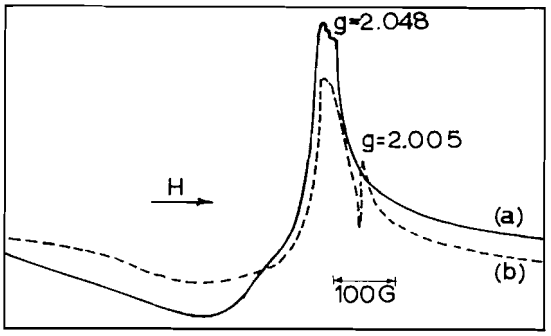

FIG. 1. (a) Electron spin resonance spectrum of $Cu^{2+}$ on the CuO–alumina catalyst; (b) spectrum obtained after the catalyst was exposed to $SO_2$ and heated at 400°C for 2 hours.

system at room temperature, the intensity of the $Cu^{2+}$ line increased slightly. On heating this system at 400°C for 10 min, the concentration of $Cu^{2+}$ ions decreased slightly and a new line at $g = 2.005$ appeared (Fig. 1(b)). This new line is attributed to $SO_2^{-\cdot}$ radical ions (6). The colour of the catalyst changed from black to yellowish black when heated for 24 h at 400°C. The yellowish colour may be due to the formation of elemental sulfur on reduction of $SO_2$ with CO (adsorbed CO which could not be removed from the surface). However, the $Cu^{2+}$ ion spectrum remained the same and the line at $g = 2.005$ increased sharply. On treating this system again with CO, though no effect was observed on the $Cu^{2+}$ ion spectrum, the line at $g = 2.005$ increased slightly. It seems that the $Cu^{2+}$ ions which contribute to the esr spectra do not take part in the CO + $SO_2$ reactions, though $SO_2$ reacts with CO in the presence of Cu ions and forms $SO_2^{-\cdot}$ radical ions on the surface, and elemental sulfur.

In another set of experiments with $SO_2$ was added at room temperature to a fresh CuO–alumina catalyst, previously evacuated at 400°C, the concentration of $Cu^{2+}$ increased markedly as shown by the esr spectra. This increase was greater than that which occurred when CO was added to the fresh catalyst under similar conditions. After evacuation at room temperature, the spectrum of the $Cu^{2+}$ ions reverted to its original shape and intensity. On heating (for 2 min at 400°C) $SO_2$–CuO–alumina ($SO_2$ evacuated at room temperature before heating) the intensity of the $Cu^{2+}$ ion spectrum decreased and the line for $SO_2^{-\cdot}$ at $g = 2.005$ (Fig. 1(b)) appeared. On prolonged heating (~14 h, 400°C), the concentration of $Cu^{2+}$ ions further decreased but not to zero. No change in the esr spectrum of the sample was observed after evacuation.

When CO was added to the evacuated $SO_2^{-\cdot}$–CuO–alumina system ($SO_2$ plus CuO–alumina heated at 400°C for 2 minutes), the intensity of the $Cu^{2+}$ line further decreased slightly. However, when this was heated at 400°C for 5 minutes, the intensity of the $SO_2^{-\cdot}$ signal ($g = 2.005$) increased markedly, though the concentration of $Cu^{2+}$ ions decreased further. On prolonged heating for 14 h at 400°C, the intensity of the $SO_2$ line increased and the concentration of $Cu^{2+}$ ions further decreased, but again not to zero. The colour of the catalyst changed from green to black with a yellowish tinge probably due to elemental sulfur.

Thus it seems that a particular type of $Cu^{2+}$ ions which contributes to the esr signal is not affected when treated with CO or $SO_2$, and that $SO_2^{-\cdot}$ ions do not take part in the reduction of $SO_2$ with CO.

# Composition effects on optical absorption spectra of solvated electrons in alcohol/water mixed solvents[1]

AH-DONG LEU, KAMAL N. JHA, AND GORDON R. FREEMAN

*Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received March 30, 1981

AH-DONG LEU, KAMAL N. JHA, and GORDON R. FREEMAN. Can. J. Chem. **60**, 2342 (1982).

Addition of a few percent of water to an alcohol has a relatively large effect on the shape of the optical absorption spectrum of solvated electrons in the liquid. This occurs whether the optical absorption energy in the pure alcohol is greater or smaller than that in water. Addition of up to 10 mol% of water causes $E_{Amax}$ in methanol and primary alcohols to decrease, while it increases in secondary and tertiary alcohols. At around 10 mol% water in primary alcohols $E_{Amax}$ passes through a minimum and increases again at higher water concentrations, reaching a plateau at about 30 mol% and remaining constant up to about 95 mol% water; over the last part of the composition range to pure water $E_{Amax}$ decreases slightly. The behavior in secondary and tertiary alcohols containing >30 mol% water is similar to that in primary alcohols. The width of the band at half height $W_{1/2}$ is divided at $E_{Amax}$ into "red side" and "blue side" portions $W_r$ and $W_b$, respectively. In methanol and in primary and secondary alcohols, addition of up to 30 mol% of water greatly reduces $W_b$ but has relatively little effect on $W_r$. At >30 mol% water $W_b$ and $W_r$ are similar to those in pure water. In tertiary butyl alcohol the band width is similar to that in pure water, so addition of water to the alcohol makes little change in the band width. The water/alcohol composition effects on the $e_s^-$ absorption band parameters are attributed to changes in solvent structure. This is especially evidenced by the minimum in $E_{Amax}$ at 10 mol% water in a primary alcohol. The changes in band asymmetry $W_b/W_r$ indicate that the types of electronic transition on the low and high energy sides of the band are different.

AH-DONG LEU, KAMAL N. JHA et GORDON R. FREEMAN. Can. J. Chem. **60**, 2342 (1982).

L'addition d'un faible pourcentage d'eau à un alcool a un large effet relatif sur la forme du spectre d'absorption optique des électrons solvatés dans le liquide. Ceci se produit si l'énergie d'absorption optique dans l'alcool pur est supérieure ou inférieure à celle dans l'eau. L'addition de quantité allant jusqu'à 10 mol% d'eau provoque une diminution de $E_{Amax}$ dans le méthanol et les alcools primaires, alors qu'il augmente dans les alcools secondaires et tertiaires. A environ 10 mol% d'eau dans les alcools primaires, $E_{Amax}$ passe par un minimum et augmente de nouveau avec des augmentations de concentrations en eau pour atteindre un plateau à environ 30 mol% alors qu'il demeure constant jusqu'à environ 95 mol% d'eau; à partir de là et jusqu'à l'eau pure, $E_{Amax}$ diminue légèrement. Le comportement, dans les alcools secondaires et tertiaires contenant >30 mol% d'eau, est semblable à celui dans les alcools primaires. La largeur de la bande à mi-hauteur $W_{1/2}$ est divisée à $E_{Amax}$ en deux parties: les "côté rouge" et "côté bleu" dénommés respectivement $W_r$ et $W_b$. Dans le méthanol et dans les alcools primaires et secondaires, l'addition de quantités allant jusqu'à 30 mol% d'eau réduit fortement $W_b$ mais a peu d'effet sur $W_r$. A 30 mol% d'eau, $W_b$ et $W_r$ sont identiques à ceux observés dans de l'eau pure. Dans l'alcool butylique tertiaire, la largeur de la bande est semblable à celle observée dans l'eau pure; l'addition d'eau à l'alcool ne provoque donc que peu de changement dans la largeur de la bande. On attribue les effets de la composition eau/alcool, sur les paramètres de bande d'absorption des $e_s^-$, à des variations de structure du solvant. Ceci est spécialement mix en évidence par le minimum de $E_{Amax}$ à 10 mol% d'eau dans un alcool primaire. Les variations dans l'asymétrie de la bande $W_b/W_r$ indiquent que les types de transition électronique du côté de faible et de forte énergie de la bande sont différentes.

[Traduit par le journal]

## Introduction

The energy levels of solvated electrons, as reflected in the energy of the optical absorption maximum $E_{Amax}$, are determined more by details of the liquid structure than by the dielectric constant or the molecular dipole moment (1, 2). The breadth $W_{1/2}$ and asymmetry $W_b/W_r$ of the optical absorption band are strongly related to the molecular structure of the solvent, but less emphasis had been placed on these band properties until recently. More information is needed about the dependence of the width and asymmetry on solvent structure.

The theoretical interpretation of the optical absorption spectrum requires a quantum statistical mechanical model that includes details of the liquid structure. Simons and co-workers have formulated the problem (3, 4), appropriately introducing the effects of fluctuations in solvent properties at an early stage of the model. Ultimately it was not possible to use realistic structure properties in the calculations. For example, the orientational disorder and the optical and electrical anisotropies of the molecules had to be neglected, and multibody interactions were still handled as sums of pair interactions (3, 4). Although much work remains to be done, an approach similar to that of Simons seems to be most promising for the next major advances in solvated electron theory.

The utility of developing a model by beginning with detailed observed spectral properties has been emphasized (5). The foundation of the model is therefore a relatively complete empirical description of the behavior of electrons in liquids. The present article deals with effects on the optical

absorption spectrum caused by mixing different hydroxylic solvents.

The absorption spectrum of solvated electrons in a binary solvent exhibits a single absorption band with a maximum at an energy $E_{Amax}$ that is intermediate to the values of $E_{Amax}$ in the pure components (6–20). In a mixed solvent such as an alkane and an alcohol the electrons are selectively solvated by the alcohol (10–16). Similarly, in mixtures of amines and alcohols (15), or an ether with an alcohol or water (17–20), the electrons are selectively solvated by the more polar solvent. The degree of selective solvation is assessed by the relative position of $E_{Amax}$ between those for electrons in the pure components, compared to the composition of the solvent. In a mixture of an amine and water (4) or ammonia and water (8, 9, 17), $E_{Amax}$ is slightly dominated by water. In solutions of an alcohol and water, earlier studies (6, 7) were not detailed enough to portray possible structural or selective solvation effects.

## Experimental

*Materials*

The methanol was Spectrophotometric Reagent Grade from Baker Chemical Co.; ethanol was Absolute Reagent Grade from U.S. Industrial Chemical Co.; 1-propanol, Certified Grade, Matheson, Coleman and Bell Co.; 2-propanol, Spectrophotometric Grade, Aldrich Chemical Co.; 1-butanol and 2-methyl-1-propanol (*i*-butyl alcohol) were Spectranalyzed Grade, Fisher Scientific Co.; 2-butanol and 2-methyl-2-propanol (*t*-butyl alcohol) were Analytical Reagent Grade, BDH Chemical Co.

Ethanol was used without further purification (21). Other alcohols and water were further purified as reported earlier from this laboratory (22, 23).

*Apparatus and techniques*

The optical system, irradiation facilities (22–24), and sample preparation (25) were described elsewhere. A Spectrosil cell of 1.0 cm optical path length was used for spectral measurements with 1.0 μs pulses of 1.8 MeV electrons ($9 \times 10^{16}$ eV/g) in the uv, visible, and ir regions. Appropriate Corning glass filters (26, 27) were placed in front of the optical cell and the monochromator. The dose per pulse was measured with 5 m*M* KCNS solution saturated with oxygen, using $G\varepsilon_{max} = 21\,000$ ($e_s^-$/100 eV *M* cm) at 478 nm (28). The irradiation temperature was 298.0 ± 0.5 K.

The solvated electron spectra were corrected for the decay during the pulse (24). The spectra at wavelengths < 400 nm were also corrected for absorbance due to radicals (24). This correction involved the assumptions that the net decay of radicals over the period of $t_{1/2}$ for $e_s^-$ was negligible, and that the decay of $e_s^-$ leads to negligible net formation of radicals. The second assumption probably leaves a residual error that causes the plotted absorbances to be low at $\lambda \lesssim 320$ nm, or $E \gtrsim 3.9$ eV, due to the formation of $R_2\dot{C}OH$ and $R_2\dot{C}O_s^-$, where R can be either H or an alkyl group (see spectra in section 4 of ref. 29).

## Results

*Alcohol/water solution*

The addition of water to an alcohol shifts the optical absorption energies of solvated electrons in a manner that depends on the nature of the alcohol. The energies at $E_{Amax}$ for electrons in water mixtures with methanol, ethanol, 1-propanol, 2-propanol, and 2-methyl-2-propanol are shown in Fig. 1. The behavior of these curves and those for the other alcohols studied may be summarized as follows. (*i*) For methanol, $E_{Amax}$ decreases gradually as mol% water increases to 30, then is approximately constant until 80%, then decreases again. (*ii*) For the primary alcohols (ethanol, 1-propanol, 1-butanol, and 2-methyl-1-propanol), $E_{Amax}$ decreases rapidly to a minimum at around 10 mol% water, then increases until ~30 mol% water, is approximately constant between 30 and 95 mol%, then decreases slightly to the value in pure water. (*iii*) For the secondary (2-propanol and 2-butanol) and tertiary (2-methyl-2-propanol) alcohols, $E_{Amax}$ is at its lowest for pure alcohol. It increases as mol% water increases to 50, then drifts gently upwards until 95 mol% is reached, then decreases slightly to the pure water value. In the region of 0 to ~30 mol% water, however, the

increase is more pronounced for tertiary than for secondary alcohols.

All the curves showed relatively rapid change between 0 and 10 mol% water, were essentially horizontal between 30 and 80 mol%, and had a negative slope between about 97 and 100 mol% water. For this reason the representative concentrations chosen to study solutions of the other alcohols were 10, 50, and 98 mol% water.

Aqueous solutions of eight $C_1$ to $C_4$ alcohols having different carbon skeletons were studied to find the effect of molecular structure. The spectrum parameters are listed in Table 1.

*Composition effect upon spectrum shape*

Representative spectra obtained for solvated electrons in methanol/water solutions are shown in Fig. 2. Plots of the spectrum parameters against composition are shown in Fig. 3. The optical absorption spectra for solvated electrons in alcohol/water solutions are skewed towards high energy. The skew decreases as mol% water increases.

The relation of $W_{1/2}$ (band width at half-height) to composition is shown in Fig. 4. For all the alcohols except 2-methyl-2-propanol, $W_{1/2}$ decreases relatively rapidly as mol% water increases to a certain point, then decreases gradually or levels off for the remainder of the curve. (*i*) For methanol and the primary alcohols, most of the decrease occurs up to 50 mol% water. (*ii*) For secondary alcohols, most of the decrease occurs up to 10 mol% water. (*iii*) For the tertiary alcohol, $W_{1/2}$ varies approximately linearly with composition, because the value is only slightly different in water than in the pure alcohol.

The behavior of $W_b$ (the part of $W_{1/2}$ on the blue side of absorption maximum) and of $W_r$ (the part on the red side) as a function of composition is shown in Fig. 5. The sharp decrease in $W_{1/2}$ is largely due

to the decrease of $W_b$; $W_r$ decreases only slightly as mol% water increases.

## Discussion

*Composition dependence of* $E_{Amax}$

The variations of $E_{Amax}$ with composition for methyl, ethyl, 2 isomers of propyl, and 4 isomers of butyl alcohol are summarized in Fig. 6. This figure shows non-ideal behavior in mixing alcohols with water. The overall composition dependence of $E_{Amax}$ can be divided into three categories, one for methyl, another for primary, and a third for secondary and tertiary alcohols. The addition of 3 mol% of any of the alcohols to water causes $E_{Amax}$ to increase slightly (Fig. 6).

The changes of $E_{Amax}$ indicate that the depth of the trap for the excess electron is changed, which we attribute qualitatively to changes in solution structure. Changes in solution structure are also indicated by the nonideal behavior of viscosities (30, 31) and excess enthalpies of mixing (32, 33).

water are in the following order: methanol ≳ primary alcohol > water > secondary alcohol > tertiary alcohol (Table 1). This indicates that the depths of the traps are in the same order. More extensive alkylation of the carbon connected to the —OH inhibits favorable orientation of the alcohol molecules around the electron, presumably because a greater disruption of the normal liquid structure would be required. Branching of the alkyl

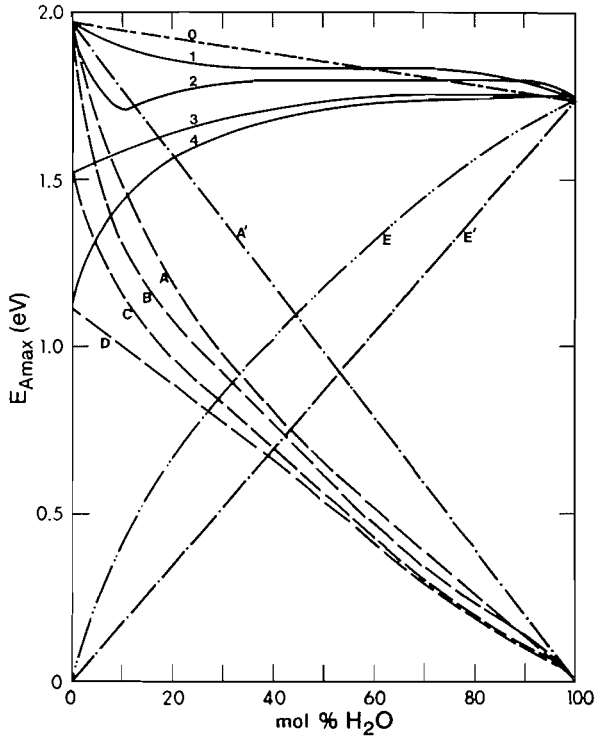

FIG. 7. Approximate resolution of $E_{Amax}$/composition curves. 298 K. Experimental: *1*, methanol; *2*, 1-propanol; *3*, 2-propanol; *4*, 2-methyl-2-propanol. Ideal solution line for methanol/water, *O*; ideal methanol component, *A'*; ideal water component, *E'*. *A*, *B*, *C*, *D*, and *E* are approximate actual component curves for the alcohols and water (see text). Shapes for other primary and secondary alcohols are similar to those of *2* and *3*, *B* and *C*, respectively.

chain at any position other than the carbon to which the —OH is attached makes little difference to the $e_{solv}^-$ optical spectrum. For example, the values of ($E_{Amax}$, $W_r$, $W_b$) in the branched 2-methyl-1-propanol (1.97, 0.57, 1.04) are similar to those in the unbranched 1-butanol (1.98, 0.53, 1.04), while the values in the branched 2-methyl-2-propanol are much lower (1.12, 0.30, 0.65). The large influence of the endgroup, which for alcohols is —C(—)—OH, on $E_{Amax}$ had been pointed out earlier (1) and was implicit in the relatively small dependence of $E_{Amax}$ on chain length for *n*-alkanols (13).

*(ii) Low and intermediate % water regions*

The complex shape of the curve for primary alcohols in Fig. 6 can be interpreted in terms of two tendencies, one to decrease $E_{Amax}$ and the other to increase it. These can then be applied to the solutions of the other alcohols.

Considering first the methanol and 1-propanol

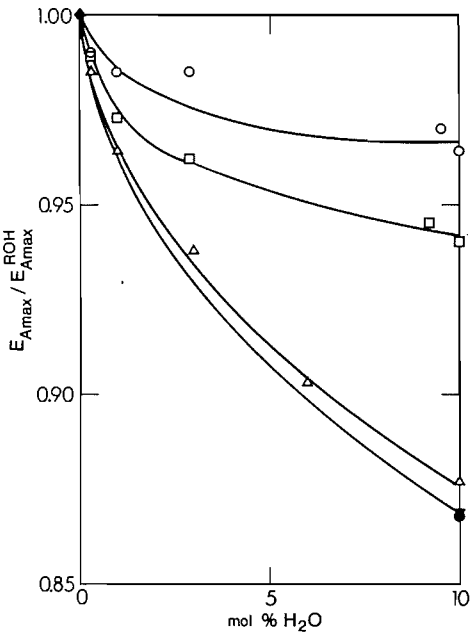

FIG. 8. Composition dependence of $E_{Amax}$ in primary alcohols at low water concentrations, normalized to the value in pure alcohol. 298 K. ○, methanol; □, ethanol; △, 1-propanol; ▽, 1-butanol; ●, 2-methyl-1-propanol; ◆, pure ROH.

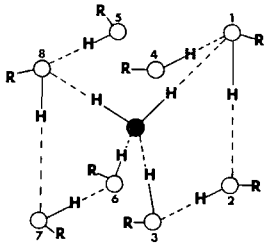

FIG. 9. Possible structure of ~10 mol% water/alcohol solution. ●, oxygen atom in water molecule; ○, oxygen atom in alcohol.

curves *1* and *2* in Fig. 7, ideal solution lines *O*, *A'*, and *E'* were drawn for reference. The observed behavior is distinctly nonideal. The similarity of the shape of curve *2* at >10% water to that of curves *3* and *4* indicates that the behavior of water is similar in all the alcohols. Water makes a greater than proportionate contribution to electron solvation, so curve *E'* should be shifted to about *E*. Curves *A* and *B* are then obtained by subtracting *E* from *1* and *2*, respectively. The alcohols make a less than proportionate contribution to electron solvation in the mixed solvents.

Although curve *E* is probably not the same from one alcohol to another, the general behavior is similar. Curves *C* and *D* were obtained by subtracting *E* from *3* and *4*, for 2-propanol and 2-methyl-2-propanol, respectively. For methanol curve *E* probably lies closer to *E'* than shown in Fig. 7, and for 2-methyl-2-propanol *E* probably lies farther away than shown. Curves *A* and *D* would then be respectively less and more concave than shown in Fig. 7.

Curves *A* to *E* in Fig. 7 indicate that the extra electrons favor sites that contain, or are influenced by, a water molecule. The relative flatness of curves *1* to *4* between about 30 and 90 mol% water indicates that the favored site does not change much over this concentration range. The site is apparently only slightly modified from one in pure water.

The relative amount of disturbance to the electron site caused by adding a small amount of water to a primary alcohol is related to the alkyl chain length. The ratio ($E_{Amax}/E^{ROH}_{Amax}$) decreases progressively more rapidly in the order methanol < ethanol < 1-propanol < 1-butanol ≈ 2-methyl-1-propanol (Fig. 8). It is not possible to say whether the main effect of water is to raise the ground state or to lower the energy of the excited state.

The minimum in $E_{Amax}$ at 10 mol% water in ethanol is observable in the data of Arai and Sauer (6), but they apparently attributed it to experimental scatter. This behavior in the primary alcohol/water solutions indicates that a particular structure exists in the 10% water solutions. If we interpret the minimum as a minimum in the strength of interaction between the excess electron and the solvent OH groups, one may speculate about water-nucleated hydrogen bonded structures such as the one in Fig. 9. This structure is based on considerations of ring polymer (34), octahedral (35), tetrahedral (36), and body centered cubic (37–39) models. Two tetramers of alcohol may be linked through one water molecule (Fig. 9), and the water molecule is occluded by eight alcohol molecules. The stacking together of these structures would be sensitive to the size and shape of the alkyl group, which is consistent with the spectral observations.

*(iii) Small amount of alcohol in water*

The addition of ~3% of any alcohol to water causes $E_{Amax}$ to increase slightly (Fig. 6). The addition of a small amount of a nonelectrolyte to water alters the liquid structure in a way that affects the viscosity (ref. 40, quoted in ref. 32, p. 67) and partial molar volume (41). The addition of a few mol% of ethanol to water increases the partial molar volume of water, and may therefore be considered to enhance the degree of order in the

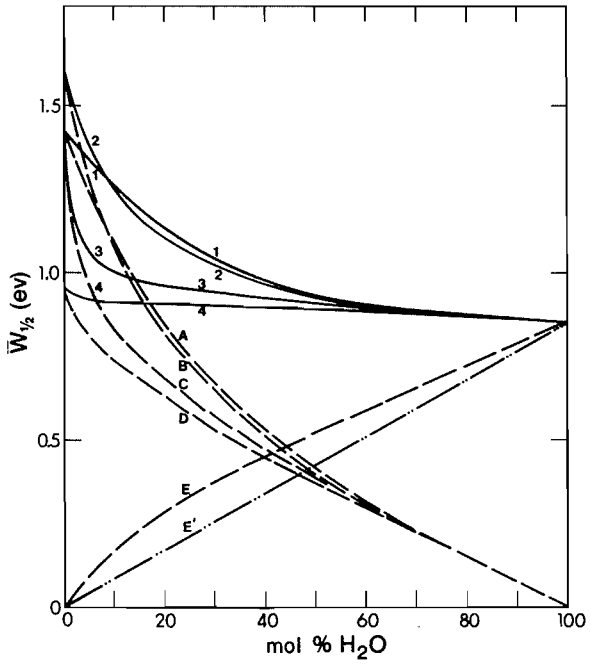

FIG. 10. Approximate resolution of $W_{1/2}$/composition curves. The labelling is the same as in Fig. 7, except that ideal lines *O* and *A'* are omitted. Shapes for other primary and secondary alcohols are similar to those of *2* and *3*, *B* and *C*, respectively.

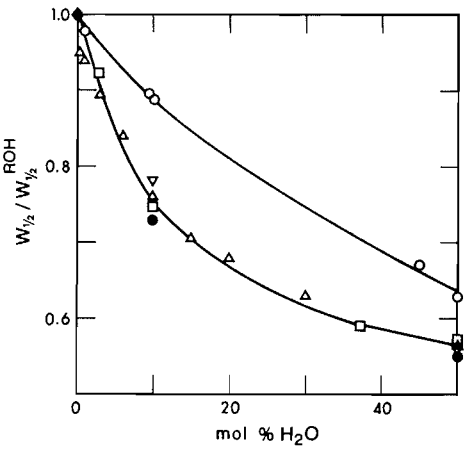

FIG. 11. Composition dependence of $W_{1/2}$ in primary alcohols at low water concentrations, normalized to the value in pure alcohol. The symbols are the same as in Fig. 8.

water structure (lattice-like hydrogen bonded structure). The addition of a few percent of 2-methyl-2-propanol to water also enhances the water structure, but neutron scattering measurements indicate that the structure bears no resemblance to ice (42); in the same system the value of $E_{Amax}$ for the first absorption peak of iodide ions increases over that in pure water (43), similar

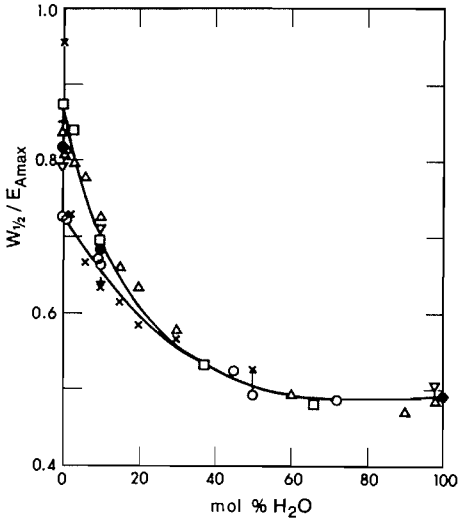

FIG. 12. Composition dependence of $W_{1/2}/E_{Amax}$. The symbols are the same as in Fig. 8 except that here ◆ represents pure water, plus: ×, 2-propanol; +, 2-methyl-2-propanol. At 50 and 98 mol% water the two extreme values of the ratio are shown; the values for the other five alcohols are scattered randomly between these extremes.

to the behavior of solvated electrons. In both cases the slight increase of $E_{Amax}$ is attributed to a small change of solvent structure in the electron or anion site, although it is not yet possible to give details of the change.

*Composition dependence of* $W_{1/2}$

The value of $W_{1/2}$ decreases with increasing water concentration (Fig. 4). Most of the decrease occurs upon the addition of the first 30 mol%. The exception is 2-methyl-2-propanol, in which the value of $W_{1/2}$ is similar to that in water. The sharpness of decrease in $W_{1/2}$ during the addition of the first 10 mol% water to the various alcohols is in the order secondary > primary > methanol > tertiary.

The $W_{1/2}$ curves reflect selective solvation of the electrons by water, as did $E_{Amax}$. By analogy with Fig. 7, the $W_{1/2}$ curves were tentatively divided into alcohol and water contributions (Fig. 10). The water contribution is something like *E*. The alcohol contributions *A* to *D* were approximated by subtracting *E* from the experimental curves *1* to *4*, respectively. Curve *E* for methanol probably lies closer to *E'*, while for 2-methyl-2-propanol *E* probably bulges farther away from *E'* than shown. The behavior is similar to that of $E_{Amax}$. However, the relative amount of disturbance to $W_{1/2}$ caused by adding water to ethanol is similar to that for the longer chain primary alcohols (Fig. 11), whereas for $E_{Amax}$ the behavior in ethanol was closer to that in methanol (Fig. 8).

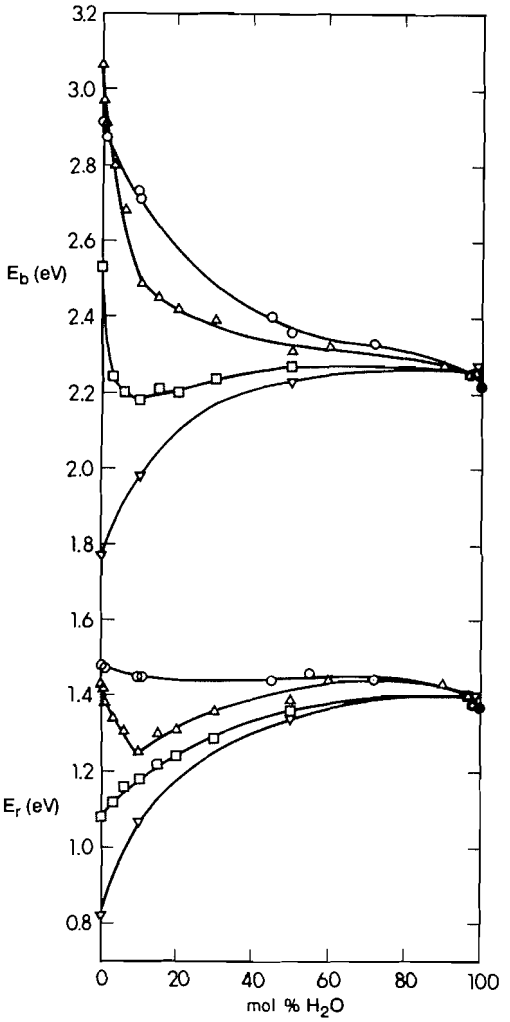

FIG. 13. Composition dependence of $E_r$ and $E_b$. ○, methanol; △, 1-propanol; □, 2-propanol; ▽, 2-methyl-2-propanol; ●, pure water. Shapes for other primary and secondary alcohols are similar to those of △ and □, respectively.

Upon addition of water the ratio $W_{1/2}/E_{Amax}$ decreases most rapidly for 2-propanol and least rapidly for methanol (Fig. 12). The values are the same within the experimental uncertainty for all the alcohols containing ≥ 30 mol% water.

The conclusion is that the band width is more readily disturbed by the addition of water to an alcohol than is $E_{Amax}$.

*Composition dependence of* $W_r$, $W_b$, $E_r$, *and* $E_b$

The shifts of the energies $E_r$ and $E_b$ on the respective red and blue sides of the absorption band at $0.5A_{max}$ are diagnostic of the spectral changes that occur when solvents are mixed. The values of $E_r$ and $E_b$ are related to those of other parameters by eqs. [1]–[3].

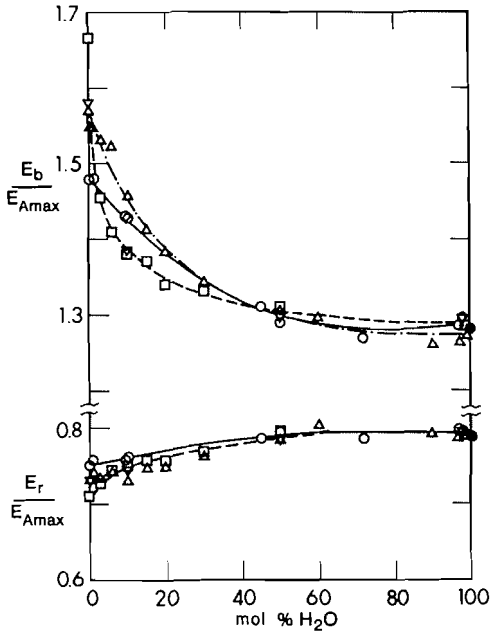

FIG. 14. Composition dependence of the ratios $E_r/E_{Amax}$ and $E_b/E_{Amax}$. The labelling is the same as in Fig. 13.

$$[1] \quad W_{1/2} = W_r + W_b = E_b - E_r$$

$$[2] \quad W_r = E_{Amax} - E_r$$

$$[3] \quad W_b = E_b - E_{Amax}$$

The uncertainties in $E_r$ and $E_b$ are ±0.01 eV, while those in $E_{Amax}$ and $W_{1/2}$ are ±0.02 eV.

The composition dependence of $W_{1/2}$ is generated mainly through $W_b$ (Fig. 5). This supports the interpretation that the low and high energy sides of the absorption band are determined by different processes (22). The low energy side is attributed to a bound–bound transition. The high energy tail presumably represents bound–continuum transitions. The greater width of the alcohol bands, relative to their values of $E_{Amax}$, may be due to a second, bound excited state. The second excited state might be associated with the relatively low scattering power of the alkyl groups, and easily upset by the presence of water.

The value of $E_b$ changes in quite a different manner from that of $E_r$ when water is added to methyl, a primary, or a secondary alcohol (Fig. 13). On going from methanol to water $E_b$ decreases by 0.7 eV while $E_r$ decreases by only 0.1 eV. In the 1-propanol solutions $E_r$ has a minimum at 10 mol% water. The behavior of $E_r$ is similar to that of $E_{Amax}$ for all the alcohol/water solutions. By contrast $E_b$ does not possess a minimum in the primary alcohol solutions, but does in those of 2-propanol (Fig. 13). In the 2-methyl-2-propanol solutions $E_r$ and $E_b$

behave similarly; both increase rapidly with increasing water content up to about 50 mol%, then change little up to about 95%, then decrease slightly to the values in pure water.

When the values of $E_r$ are normalized to those of $E_{Amax}$, the curves for the different types of alcohol cluster together (Fig. 14). The ratio $E_r/E_{Amax}$ *increases* by 5% (methanol) to 12% (2-propanol) between zero and 50 mol% water, then remains constant up to pure water. By contrast the ratio $E_b/E_{Amax}$ *decreases* by 15% (methanol) to 27% (2-propanol), then remains essentially constant up to pure water. This behavior indicates that above 30 mol% water the solvated electrons reside in sites that have characteristics only slightly different from those in pure water.

*Deductions from the water effects*

(*1*) The types of electronic transition are different on the low and high energy sides of the band.

(*2*) The greater breadth of the band in alcohols than in water has more to do with differences in the excited states than with differences in the ground states. These differences are greatly reduced by the addition of ~10 mol% of water to the alcohol.

(*3*) The liquid structure has a dominating effect on the optical absorption energies. The structure effect is clearly evident in the minimum of $E_{Amax}$ at 10 mol% of water in primary alcohol/water mixtures.

# Complexes of propyl mercury thiocyanates with cobalt, nickel, and zinc thiocyanate

P. P. SINGH AND V. P. SINGH

*Chemistry Department, M.L.K. College, Balrampur-271201 (U.P.), India*

Received November 27, 1981

P. P. SINGH and V. P. SINGH. Can. J. Chem. **60**, 2351 (1982).

RHgSCN (R = *n*-$C_3H_7$, *iso*-$C_3H_7$) react with $M(NCS)_2$ (M = Co(II), Ni(II), Zn(II)) to form compounds of general formula $(SCN)_2M(NCSHgR)_2$. Conductance measurements and infrared and electronic spectral studies indicate that M and mercury atoms are linked by bridging thiocyanate groups. Cobalt and zinc are tetrahedrally coordinated, whereas nickel is octahedral. With the exception of zinc analogs, these compounds form complexes with Lewis bases. Pyridine and nicotinamide form adducts of general formula $L_2(SCN)_2M(NCSHgR)_2$, while 2,2′-bipyridine and 1,10-phenanthroline form cationic–anionic complexes of formula $[M(L—L)_3][RHg(SCN)_2]_2$.

P. P. SINGH et V. P. SINGH. Can. J. Chem. **60**, 2351 (1982).

Le composé RHgSCN (R = *n*-$C_3H_7$, *iso*-$C_3H_7$) réagit avec $M(NCS)_2$ (M = Co(II), Ni(II), Zn(II)) en donnant des composés de formule générale $(SCN)_2M(NCSHgR)_2$. Les mesures de conductivité et les études des spectres infrarouges et électroniques indiquent que les atomes de M et de mercure sont liés par des groupes thiocyanates en position de pont. Le cobalt et le zinc sont coordonnés de manière tétraédrique tandis que le nickel est octaédrique. Ces composés, à l'exception des analogues contenant le zinc, forment des complexes avec les bases de Lewis. La pyridine et la nicotinamide forment des adduits de formule générale $L_2(SCN)_2M(NCSHgR)_2$ tandis que la bipyridine-2,2′ et la phénanthroline-1,10 forment des complexes cationiques–anioniques de formule $[M(L—L)_3][RHg(SCN)_2]_2$.

## Introduction

Recently (1) we have reported a new class of mixed metal compounds of the type $(SCN)_2M(NCSHgR)_2$ (M = Co(II), Ni(II) and R = phenyl) and their complexes. In order to determine the effect of change of phenyl group by *n*-propyl or isopropyl group on the mode of thiocyanate bonding, we report here the synthesis and characterization of another series of thiocyanates and their complexes.

## Experimental

*Materials and manipulations*

Reagent grade solvents were purified before use. *n*-$C_3H_7HgCl$ and *iso*-$C_3H_7HgCl$ were prepared using Grignard reagents. The chlorides were converted into thiocyanate by stirring an acetone solution of *n*-$C_3H_7HgCl$ with an acetone solution of KNCS in a 1:1 molar ratio. The precipitated KCl was filtered off and the filtrate was concentrated by evaporation under reduced pressure. On addition of water to the concentrate the thiocyanate was precipitated, filtered, washed with water, recrystallized from ethanol, and dried in vacuum. The isopropyl analog was similarly prepared.

*Anal.* calcd. for *n*-$C_3H_7HgSCN$: C 11.96, H 2.32, S 10.63, Hg 66.61, N 4.65; found: C 11.25, H 2.10, S 10.50, Hg 65.85, N 4.45, mp 95°C; yield 65%; ir (Nujol): 2165 (ν(CN)), 760 (ν(CS)), 430 $cm^{-1}$ (δ(NCS)).

*Anal.* calcd. for *iso*-$C_3H_7HgSCN$: C 11.96, H 2.32, S 10.63, Hg 66.61, N 4.65; found: C 11.30, H 2.15, S 10.55, Hg 65.95, N 4.25, mp 85°C; yield 65%; ir (Nujol): 2140 (ν(CN)), 750 (ν(CS)), 420 $cm^{-1}$ (δ(NCS)).

*Preparation of complexes $(SCN)_2M(NCSHgR)_2$ (M = Co(II), Ni(II), Zn(II); R = n-$C_3H_7$, iso-$C_3H_7$)*

*$(SCN)_2Co(NCSHgR)$*

1.75 g of $Co(NCS)_2$ (1 mmol) and 6.02 g of *n*-$C_3H_7HgSCN$ (2 mmol) were dissolved in 50 mL of ethanol and 100 mL of ethyl acetate, respectively. The solutions were mixed together and stirred for 20 h. The resulting blue precipitate was filtered, washed with ethanol, and dried in vacuum. The isopropyl analog was similarly prepared. The *n*-propyl derivative has mp 125°C and isopropyl has mp 140°C.

*$(SCN)_2Ni(NCSHgR)_2$*

A solution of 1.75 g of $Ni(NCS)_2$ (1 mmol) in 25 mL of methanol was mixed with a solution of 6.02 g (2 mmol) of *n*-$C_3H_7HgSCN$ in 100 mL of acetone, and the mixture was stirred for 24 h. The resulting grey precipitate was filtered, washed with acetone, and dried in a vacuum. The isopropyl analog was similarly prepared. The compounds were recrystallized from acetone. The *n*-propyl derivative melts at 155°C with decomposition and the isopropyl derivative melts at 165°C with decomposition.

*$(SCN)_2Zn(NCSHgR)_2$*

1.81 g of $Zn(NCS)_2$ (1 mmol) and 6.02 g of *n*-$C_3H_7HgSCN$ (2 mmol) were dissolved in 50 mL of ethanol and 100 mL of acetone, respectively. The solutions were mixed together and stirred for 20 h. The resulting white precipitate was filtered, washed with acetone, and dried in vacuum. The isopropyl analog was similarly prepared. Compounds were recrystallized from acetone. The *n*-propyl derivative has melting point 135°C and the isopropyl derivative has melting point 150°C.

*Preparation of adducts $L_2(SCN)_2M(NCSHgR)_2$ (L = pyridine, nicotinamide) and cationic–anionic complexes $[M(L—L)_3][RHg(SCN)_2]_2$ (L—L = 2,2′-bipyridine, 1,10-phenanthroline; M = Co(II), Ni(II))*

The complexes were prepared by mixing in stoichiometric ratios a suspension of the $(SCN)_2M(NCSHgR)_2$ in ethanol with a solution of the ligand in the same solvent and stirring the mixture for 24 h. Pink cobalt complexes and green nickel complexes were formed; they were filtered, washed with ethanol, and dried in vacuum. Complexes with pyridine and nicotinamide were recrystallized from acetone and 2,2′-bipyridine complexes

For personal use only.

were recrystallized from a mixture of ethanol and dimethylsulphoxide.

Alternatively, pyridine complexes were prepared by the following method. $Co(NCS)_2.2py$ was first prepared, recrystallized, and characterized. $Co(NCS)_2.2py$ (3.32 g) was dissolved in 100 mL of ethanol and mixed with 100 mL of an ethanol solution containing 6.02 g of $n$-$C_3H_7HgSCN$ and stirred. A pink compound was formed, filtered, washed with ethanol, recrystallized from acetone, and dried in vacuum. The isopropyl analog was similarly prepared.

Attempts to isolate adducts of oxygen donors such as tetrahydrofuran, dimethylsulphoxide, and dioxane were unsuccessful presumably because of their instability at room temperature.

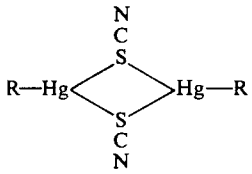
The adducts and cationic–anionic complexes which have been prepared are: $(py)_2(SCN)_2Co(NCSHg\ n\text{-}C_3H_7)_2$, $(py)_2(SCN)_2Co(NCSHg\ iso\text{-}C_3H_7)_2$, $(py)_2(SCN)_2Ni(NCSHg\ n\text{-}C_3H_7)_2$, $(py)_2(SCN)_2Ni(NCSHg\ iso\text{-}C_3H_7)_2$, $(nia)_2(SCN)_2Co(NCSHg\ n\text{-}C_3H_7)_2$, $(nia)_2(SCN)_2Co(NCSHg\ iso\text{-}C_3H_7)_2$, $(nia)_2(SCN)_2Ni(NCSHg\ n\text{-}C_3H_7)_2$, $(nia)_2(SCN)_2Ni(NCSHg\ iso\text{-}C_3H_7)_2$, $[Co(bipy)_3][(NCS)_2Hg\ n\text{-}C_3H_7]_2$, $[Co(bipy)_3][(NCS)_2Hg\ iso\text{-}C_3H_7]_2$, $[Ni(phen)_3][(NCS)_2Hg\ n\text{-}C_3H_7]_2$, and $[Ni(phen)_3][(NCS)_2Hg\ iso\text{-}C_3H_7]_2$.

Analyses of the complexes and various physical measurements were made as described earlier (1). The analytical, infrared spectral (50–2500 $cm^{-1}$) and electronic spectral data are available from the Depository of Unpublished Data.[1]

## Results and discussion

*$(SCN)_2M(NCSHgR)_2$ ($M$ = Co(II), Ni(II), Zn(II); $R$ = n-$C_3H_7$, iso-$C_3H_7$)*

The unit cell of RHgSCN may be centrosymmetric (2) having the following molecular units.



The solid phase infrared spectrum of $n$-$C_3H_7HgSCN$ shows bands at 2165 (ν(CN)), 760 (ν(CS)), 430 (δ(NCS)), 540 (ν(HgC)), and 220 $cm^{-1}$ (ν(HgS)). The position of (CN) and (CS) bands is considerably changed when spectrum is recorded in methanol. ν(CN) is observed at 2130 $cm^{-1}$ and ν(CS) at 690 $cm^{-1}$. This indicates that bridging through sulphur of thiocyanate in $n$-$C_3H_7HgSCN$ is absent in solution.

The analytical results of the complexes indicate that one molecule of $M(NCS)_2$ reacts with two molecules of RHgSCN to form a complex of general formula $(SCN)_2M(NCSHgR)_2$. On complex formation two bands at 2175 and 2080 $cm^{-1}$ appear for ν(CN), 790 and 680 $cm^{-1}$ for ν(CS), 460 and 435 $cm^{-1}$ for δ(NCS), and 212 and 205 $cm^{-1}$ for ν(Hg—SCN), and one band at 520 $cm^{-1}$ for ν(HgC). These changes indicate that the thiocyanate of RHgSCN becomes bridging on complex formation. A band in the ν(CN) region at 2080 $cm^{-1}$ is also observed in all complexes. This can be attributed to N-bonded thiocyanate arising from M—NCS and can be supported by analogy with the corresponding bands reported for $M(NCS)_2.2L$ (3). The position of ν(MN) and ν(CN) bands in $M(NCS)_2$ are not altered on complex formation.

The electronic spectra of $(NCS)_2Co(NCSHgR)_2$ show the presence of two intense bands due to $d$–$d$ transitions in the region 16550 $cm^{-1}$ and 7880 $cm^{-1}$. The position of these bands in solid and solution phase spectra remains the same, showing that there is no solvolysis. The bands in the region 16550 $cm^{-1}$ are assigned to $^4A_2 \rightarrow {}^4T_1(P)$ ($\nu_3$) and in the region 7880 $cm^{-1}$ to $^4A_2 \rightarrow {}^4T_1$ (F) ($\nu_2$). The $Dq$ values as calculated from $\nu_2$ and $\nu_3$ band positions (4) are in the range 454–459 $cm^{-1}$. Magnetic moment values are in the range 4.5–4.6 BM. These results confirm that cobalt has tetrahedral geometry. A $T_d$ local symmetry should produce one ir-active band for ν(MN), which is consistent with the observed number.

The electronic spectra of $(SCN)_2Ni(NCSHgR)_2$ show absorption bands in the region 27780 $cm^{-1}$, 16390 $cm^{-1}$, and 10150 $cm^{-1}$ which may be assigned to the transitions $^3A_{2g} \rightarrow {}^3T_{1g}$ (P) ($\nu_3$), $^3A_{2g} \rightarrow {}^3T_{1g}$ (F) ($\nu_2$), and $^3A_{2g} \rightarrow {}^3T_{2g}$ (F) ($\nu_1$), respectively. The position and assignments of these bands and magnetic moment values (2.90 BM) indicate that Ni(II) acquires octahedral geometry probably by coordinating thiocyanate groups of other molecules (5).

The $Dq$ values of $n$-propyl complexes of both cobalt and nickel are higher than the $Dq$ values of their corresponding isopropyl analogs. This shows that $n$-$C_3H_7HgSCN$ is a stronger base than $iso$-$C_3H_7HgSCN$. On the basis of $Dq$ values of $(SCN)_2Ni(NCSHgR)_2$ they can be placed in the spectrochemical series (1, 6): DMSO < $CH_3OH$ < DMF < $iso$-$C_3H_7NH_2$ < $n$-$C_3H_7NH_2$ < $C_6H_5HgSCN$ < $iso$-$C_3H_7HgSCN$ < $n$-$C_3H_7HgSCN$ < NCS < $NH_3$ < en < Dipy

*Adducts $L_2(SCN)_2M(NCSHgR)_2$ ($M$ = Co(II), Ni(II); $L$ = py, nia)*

The coordination number of cobalt in $(SCN)_2Co(NCSHgR)_2$ is four rather than its maximum six, hence the complexes have the capacity to form adducts with pyridine and nicotinamide. The nickel counterparts also form similar adducts by replacing with ligands the weak thiocyanate bridges in the

octahedral coordination sphere. Zinc analogs, however, decompose into their respective components on reaction with these Lewis bases.

Pyridine or nicotinamide reacts with $(SCN)_2Co(NCSHgR)_2$ to form pink adducts. They are non-conducting (55–63 $cm^{-1}$ mhos/mol) in dimethylformamide (7), and are partly dissociated in dimethylsulphoxide solution. On heating in vacuum pyridine is given off and the parent blue complexes $(SCN)_2Co(NCSHgR)_2$ are obtained. This shows that pyridine is linked to cobalt, changing its tetrahedral geometry to octahedral. Electronic spectra of $L_2(SCN)_2Co(NCSHgR)_2$ give three *d–d* transition bands in the range 20880–21100 $cm^{-1}$, 16300–16700 $cm^{-1}$, and 8700–8900 $cm^{-1}$ assignable to $^4T_{1g} \rightarrow {}^4T_{1g}$ (P) ($\nu_3$), $^4T_{1g} \rightarrow {}^4A_{2g}$ ($\nu_2$), and $^4T_{1g} \rightarrow {}^4T_{2g}$ ($\nu_1$) transitions, respectively. The $\mu_{eff}$ values are in the range 5.10–5.20 BM. The infrared spectra of the complexes show a negative shift in ν(Co—NCS) on adduct formation. These observations also support octahedral coordination geometry around cobalt (8). The $L_2(SCN)_2Ni(NCSHgR)_2$ adducts are also non-conducting in dimethylformamide and partly dissociated in dimethylsulphoxide solution. The pyridine in this case in not given off on heating in vacuum. Electronic spectra indicate the presence of three bands in the range 27000–29800 $cm^{-1}$, 16500–17500 $cm^{-1}$, and 10000–10800 $cm^{-1}$ assigned to $^3A_{2g} \rightarrow {}^3A_{1g}$ (P) ($\nu_3$), $^3A_{2g} \rightarrow {}^3T_{1g}$ (F) ($\nu_2$), and $^3A_{2g} \rightarrow {}^3T_{2g}$ (F) ($\nu_1$) transitions, respectively. The $\mu_{eff}$ values are in the range 2.95–3.15 BM. These results support an octahedral geometry around nickel.

Two bands at 2175 and 2081 $cm^{-1}$ for ν(CN), 790 and 680 $cm^{-1}$ for ν(CS), and 435 and 460 $cm^{-1}$ for δ(NCS) are observed in $(SCN)_2Co(NCSHgR)_2$. On adduct formation the position of the 2175 $cm^{-1}$ band is changed to about 2140 $cm^{-1}$, whereas the positions of the other bands remain unaltered. The negative shift in the band at 2175 $cm^{-1}$ is consistent with the change of tetrahedral coordination geometry around cobalt to octahedral on adduct formation. In addition to this, new bands at 280 $cm^{-1}$ and 125 $cm^{-1}$ which are assigned to ν(ML) and δ(L—M—L) are also observed. There is little or no change in ν(CN) in the case of $(SCN)_2Ni(NCSHgR)_2$ because nickel has octahedral coordination geometry in the complexes and adducts as well.

The proposed coordination of ligand is further supported by the fact that the organomercury compounds show little tendency to increase their coordination number (9), thus the pyridine or nicotinamide is preferentially coordinated to M. Far infrared spectra also do not show any absorption due to Hg—L bond stretching.

*Cationic–anionic complexes $[M(L—L)_3][RHg(SCN)_2]_2$ (M = Co(II), Ni(II); L—L = 2,2′-bipyridine, 1,10-phenanthroline)*

The molar conductance values of 2,2′-bipyridine and 1,10-phenanthroline complexes (122–140 $cm^{-1}$ mhos/mol) in dimethylformamide indicate that they are 1:2 electrolytes. The electronic spectra of cobalt complexes are consistent with octahedral stereochemistry, showing three bands in the range 21000–21100 $cm^{-1}$, 16400–16530 $cm^{-1}$, and 8770–8880 $cm^{-1}$ assigned to $^4T_{1g} \rightarrow {}^4T_{1g}$ (P) ($\nu_3$), $^4T_{1g} \rightarrow {}^4A_{2g}$ ($\nu_2$), and $^4T_{1g} \rightarrow {}^4T_{2g}$ ($\nu_1$) transitions, respectively. The $\mu_{eff}$ values (5.21–5.25 BM) also support the octahedral environment.

The electronic spectra of nickel complexes also indicate three bands in the range 29760–29850 $cm^{-1}$, 17480–17540 $cm^{-1}$, and 10150–10860 $cm^{-1}$ assigned to $^3A_{2g} \rightarrow {}^3A_{2g}$ ($\nu_3$), $^3A_{2g} \rightarrow {}^3T_{1g}$ ($\nu_2$), and $^3A_{2g} \rightarrow {}^3T_{2g}$ ($\nu_1$) transitions, respectively. The positions of these bands and $\mu_{eff}$ values (3.10–3.15 BM) support the octahedral environment around nickel. The infrared spectra of these complexes show two bands for ν(CN), ν(CS), δ(NCS), ν(Hg—SCN) and one band for ν(HgC). These bands are present at about 2060 and 2080 $cm^{-1}$, 705 and 710 $cm^{-1}$, 450 and 440 $cm^{-1}$, 205 and 215 $cm^{-1}$ and at 520 $cm^{-1}$, respectively. The positions of these bands indicate the linkage of thiocyanate through the S-end (10) and their number supports the presence of $[RHg(SCN)_2]^-$ having $C_{2v}$ symmetry. On the basis of these observations it can be presumed that the cation $[M(L—L)_3]^{2+}$ consists of a metal ion duly coordinated with three molecules of 2,2′-bipyridine or 1,10-phenanthroline and the anion consists of a tricoordinated mercury $[RHg(SCN)_2]^-$. Only one band is observed at about 265 $cm^{-1}$, assigned to ν(ML) (11), which supports $O_h$ symmetry for the cation.

Comparisons with $(SCN)_2M(NCSHgPh)_2$, where M = Co(II) and Ni(II), reveal (*1*) the alkyl mercury thiocyanates acquire a higher position in the spectrochemical series than the phenyl mercury thiocyanate, (*2*) $(SCN)_2M(NCSHgPh)_2$ form comparatively stable complexes with oxygen donors such as dimethylsulphoxide and tetrahydrofuran whereas the alkyl analogs form very unstable complexes, and (*3*) Ni(II) in the case of propyl complexes has an octahedral configuration $[Ni(L—L)_3]^{2+}$, whereas in the phenyl complexes it has a square planar configuration $[Ni(L—L)_2]^{2+}$.

Reçu le 12 février 1982

C. AGAMI, T. RIZK, R. DURAND et P. GENESTE. Can. J. Chem. **60**, 2355 (1982).

La réactivité comparée d'un certain nombre de couples d'isomères *cis/trans* de cétones bicycliques en série décalone-1 et décalone-2 (décalone-2 *trans* et *cis*; méthyl-10 décalone-2 *trans* et *cis*; méthyl-9 décalone-1 *trans* et *cis*; diméthyl-3,10 décalone-2 *trans*) sont étudiés dans le cas de l'addition nucléophile en milieu acide de l'hydroxylamine. Les résultats obtenus aussi bien sur les constantes de vitesse d'addition neutre ou acido catalysée font apparaître une réactivité toujours légèrement supérieure en faveur de l'isomère *trans* (× 2, 4). Ce résultat en accord avec l'hypothèse d'une attaque préférentielle équatoriale du nucléophile est dû aux facteurs conformationnels liés à l'existence dans l'isomère *cis* d'un équilibre stéroïde ⇌ non stéroïde.

C. AGAMI, T. RIZK, R. DURAND, and P. GENESTE. Can. J. Chem. **60**, 2355 (1982).

The relative reactivities of a number of *cis/trans* pairs of bicyclic ketones in the 1- and 2-decalone series (2-decalone; 10-methyl-2-decalone; 9-methyl-1-decalone; and 3,10-dimethyl-2-decalone) have been studied for the nucleophilic addition of hydroxylamine in acidic medium. The results obtained as well as the rate constants for neutral or acid catalysed addition always reveal a slight preference for the *trans*-isomer (× 2.4). This result agrees with the proposal that preferential equatorial attack of a nucleophile is caused by conformational factors related to a steroid ⇌ non-steroid conformation equilibrium in the *cis*-isomers.

## Introduction

Quelques travaux épars dans la littérature (1–6) rapportent des résultats principalement qualitatifs sur les différences de réactivités entre des composés bicycliques isomères *cis/trans*. Ces résultats sont souvent contradictoires, ce qui est probablement dû à la diversité des réactions examinées. Une étude cinétique de la réactivité comparée de couples de cétones bicycliques *cis* et *trans* en série décalone-1 et décalone-2 envers l'hydroxylamine a paru intéressante afin d'obtenir des indications sur l'influence des facteurs conformationnels intervenant dans ces différents isomères.

## Résultats et discussion

La réaction d'oximation a un mécanisme relativement complexe (7–10); elle se fait en deux étapes successives équilibrées tour à tour limitantes selon le pH du milieu. En milieu acide, l'étape d'addition de $NH_2OH$ sur la fonction carbonyle est lente et de plus, soumise à une catalyse acide spécifique. Ce n'est donc que dans ces conditions expérimentales bien précises (9, 10) que l'on peut mesurer correctement les constantes de vitesse $k_0$ et $k_{H^+}$ (Tableau 1) correspondant aux étapes d'addition neutre et acido catalysées.

Nous avons vérifié qu'il existait une bonne corrélation linéaire entre log $k_0$ et log $k_{H^+}$ pour les neuf cyclanones étudiées. La pente de la droite de régression obtenue est voisine de l'unité (pente = 0,86; coefficient de corrélation 0,97). Ce résultat indique que les effets de structure opèrent de la même façon sur $k_0$ et $k_{H^+}$; que les conclusions que l'on peut déduire pour rendre compte des variations de $k_0$ s'appliqueront donc également à celles de $k_{H^+}$.

L'examen du tableau de résultats fait apparaître une grande différence de réactivité entre la *trans* décalone-1 **6** et son dérivé méthylé **7** ($k_0^6/k_0^7 = 18{,}8$ soit $\Delta G = 7230$ J).

La présence d'un groupe méthyle en position axiale α conduit donc à un ralentissement important qui est du même ordre de grandeur que l'énergie conformationnelle habituellement affectée à ce substituant. Ce résultat confirme l'hypothèse d'une attaque équatoriale avec une structure d'état de

TABLEAU 1. Constantes de vitesse d'addition de l'hydroxylamine par la voie neutre $k_0$ ou acido catalysée $k_{H^+}$*

| Composé | | $k_0 10^{-3}$ L mole$^{-1}$s$^{-1}$ | $k_{H^+} 10^{-3}$ L mol$^{-2}$s$^{-1}$ | $k_{0\ trans}/k_{0\ cis}$ | *Réference* |
|---|---|---|---|---|---|
| **1** | | 9,0 | 20,5 | | 10 |
| **2** |  | 7,3 | 21,8 | 2,3 | |
| **3** |  | 3,1 | 8,3 | | |
| **4** |  | 5,7 | 15,2 | 2,5 | |
| **5** |  | 2,3 | 7,1 | | |
| **6** | | 6,0 | 15,2 | | 10 |
| **7** | | 0,32 | 0,92 | 2,3 | |
| **8** | | 0,14 | 0,42 | | |
| **9** |  | 0,96 | 2,1 | | |

*Toutes ces mesures ont été effectuées dans l'eau à 25,0 ± 0,1°C et à force ionique constante $\mu$ = 1,0 mol/L; l'erreur sur $k_0$ ou $k_{H^+}$ est inférieure à 2%.

transition qui ressemble au réactif, ce qui paraît désormais parfaitement admis sans que l'on puisse toutefois en donner une explication satisfaisante (11).

Les résultats font apparaître également pour les trois couples de cétones *cis* et *trans* étudiés **2–3**, **4–5** et **7–8** une réactivité supérieure et sensiblement constante de la forme *trans* respectivement égale à 2,3, 2,5 et 2,3.

Puisque dans le cas de l'addition de l'hydroxylamine sur les cétones l'état de transition ressemble aux réactifs, l'application stricte du principe de Curtin–Hammett entraîne que ce sont uniquement les intéractions stériques dans les différents états de transition des deux formes *cis* et *trans* qui doivent être prises en considération.

Ainsi, dans le cas des décalones-2 **2** et **3**, l'examen des différentes structures montre que parmi les trois structures *cis* stéroïde, *cis* non stéroïde et *trans*, vis à vis d'une attaque par la face équatoriale, deux d'entre elles, la non stéroïde et la *trans*, présentent le même encombrement alors que la structure stéroïde probablement minoritaire (12) est la plus encombrée puisqu'elle possède un substituant axial en $\gamma$.

Dans le cas des décalones-1 *cis* et *trans*, **7** et **8**, les trois structures présentent sensiblement le même encombrement vis à vis d'une attaque équatoriale dû au substituant axial en $\alpha$. Un effet identique se retrouve dans le cas des deux décalones-2 **4** et **5** possédant un méthyle angulaire.

Ces identités d'empêchement stérique sur les trois structures conduisent donc aux réactivités analogues observées. La réactivité légèrement plus importante de la forme *trans* est probablement due au fait que les formes *cis* existent en équilibre conformationnel sur la position duquel malheureusement existent beaucoup de résultats expérimentaux discordants.

Enfin, la comparaison des réactivités de **9** et **4** permet de mettre en évidence une différence due à la présence d'un groupe méthyle équatorial en $\alpha$ du groupe carbonyle voisine de 6. Ce ralentissement est probablement du aux effets stériques de torsion par éclipsage partiel de la liaison carbone–oxygène avec le groupement méthyle en équatorial (8).

Ces résultats montrent donc que la faible différence de réactivité entre les composés bicycliques isomères *cis*/*trans* peut parfaitement s'expliquer sur de simples bases conformationnelles. Ainsi que le prévoyait Johnson (1) dès 1943: "the causes of the differences in reactivity must be subtle" à propos de la réactivité comparée des décalones **7** et **8** envers la semi-carbazone.

## Partie expérimentale

A. *Obtention des substrats*

Les décalones sont préparées selon des modes opératoires déjà décrits: décalone-2 *trans* **2** et *cis* **3** (13), méthyl-10

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

décalone-2 *trans* **4** (14) et *cis* **5** (15), méthyl-9 décalone-1 *trans* **7** (16) et *cis* **8** (17), diméthyl-3,10 décalone-2 *trans* **9** (18).

Les cétones obtenues sont purifiées par chromatographie sur colonne de gel de silice. L'analyse par chromatographie en phase vapeur (Carbowax 20M) montre que leur pureté est dans chaque cas supérieure à 98%.

B. *Mesures cinétiques*

Les réactions d'oximation sont suivies par spectrophotometrie uv (Gilford 250) en mesurant l'augmentation de la densité optique due à l'apparition des oximes (220 nm) à 25,0 ± 0,1°C. L'eau est utilisée comme solvant, la force ionique maintenue constante $\mu$ = 1,0 mol/L pour les différentes acidités. Les concentrations en cétone et en chlorhydrate d'hydroxylamine sont respectivement de $2,5 \times 10^{-4} M$ et $0,5 M$, différentes concentrations en acide sont étudiées pour chaque cétone afin de déterminer $k_0$ et $k_{H^+}$ [HCl] = $0,5 M$ ($h_0 = 0,609$) et [HCl] = $0,05 M$ ($h_0 = 0,05$). Le mode de détermination de $k_0$ et $k_{H^+}$ a été décrit précédement (9).

# Stereospecific and practical syntheses of both *meso*-cyclopentane-1,2,3-tricarboxylic acids

PELAYO CAMPS[1] AND CARLOS JAIME

*Departamento de Química Orgánica, Facultad de Ciencias, Universidad Autónoma de Barcelona, Bellaterra, Barcelona, Spain*

Received January 13, 1982

PELAYO CAMPS and CARLOS JAIME. Can. J. Chem. **60**, 2358 (1982).

A stereospecific synthesis of both *meso*-cyclopentane-1,2,3-tricarboxylic acids, by using the 1,3-dimethoxytrimethylene bridge as two latent carboxyl groups, is described. A practical synthesis of these acids is also described.

PELAYO CAMPS et CARLOS JAIME. Can. J. Chem. **60**, 2358 (1982).

On décrit une synthèse stéréospécifique des deux acides *méso*-cyclopentanetricarboxyliques-1,2,3 qui utilise le pont diméthoxy-1,3 triméthylène comme groupes carboxyles latents. On décrit également une synthèse pratique de ces acides.

[Traduit par le journal]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

We have recently described the use of the 1,3-dimethoxytrimethylene bridge as two latent carboxyl groups (1). We describe in this communication the use of this latent functionality for the stereospecific synthesis of (1*R*,2*s*,3*S*)-cyclopentane-1,2,3-tricarboxylic acid, **1***a*, and (1*R*,2*r*,3*S*)-cyclopentane-1,2,3-tricarboxylic acid, **2***a*. To the best of our knowledge only one *meso*-cyclopentane-1,2,3-tricarboxylic acid, mp 169–170°C, has so far been described (2). It was obtained by heating the racemic form with acetic anhydride at 150°C, but its configuration was not assigned.

The starting product in our stereospecific synthesis was a mixture of stereoisomers of 2,4-dimethoxy-8-methylenebicyclo[3.2.1]octane, **3**, prepared in two steps from cyclopentanone in 34% overall yield (1, 3) (Scheme 1). Hydroboration of **3** followed by alkaline hydrogen peroxide oxidation gave a crude mixture of (2,4-dimethoxybicyclo[3.2.1]oct-8-yl)methanol, **4**, which was separated by low pressure column chromatography using silica gel (230–400 mesh) (4) as support to give **4***b* (67% yield) and **4***a* (14.9% yield).

The configuration of **4***b* was easily assigned because of the presence of two methoxyl absorptions in the $^1$H nmr spectrum and the observation of an intramolecular hydrogen bond in the ir spectrum. By decoupling experiments carried out on the $^1$H nmr spectrum of **4***a* in the presence of 0.39 equivalents of Eu(fod)$_3$ we obtained the following coupling constant values: $J_{1',8'} = 4.3$ Hz, $J_{2',3'\ endo} = 10.6$ Hz, $J_{2',3'\ exo} = 6.0$ Hz, and $J_{1,8'} = 8.0$ Hz (see Table 1). Assuming a chair conformation for the cyclohexane ring of **4***a* (5), the $J_{2',3'\ exo}$ and $J_{2',3'\ endo}$ values agreed with equatorial methoxyl groups, which, on the other hand, agreed with the stereoisomeric composition of the starting compound (1, 3, 5). The *syn*-stereochemistry[2] of the hydroxymethyl group in **4***a* was established on the basis of the $J_{1',8'}$ value. Table 1 collects coupling constant values in related systems (6–8). As can be seen from Table 1, the *syn*-stereochemistry of the substituent at C8 or C9 is systematically associated with a significant value of $J_{1,8}$ and $J_{5,8}$ in bicyclo[3.2.1]octane systems or $J_{1,9}$ in bicyclo[4.2.1]nonane systems, while the *anti*-stereochemistry is associated with a very small value of $J_{1,8}$ and $J_{5,8}$ or $J_{1,9}$.

Knowing the *syn*-stereochemistry of the hydroxymethyl group in **4***a* and **4***b*, the stereoisomeric mixture **4** was oxidized with Jones reagent to give *syn*-2,4-dimethoxybicyclo[3.2.1]octane-8-carboxylic acid, **5**, as a stereoisomeric mixture in 89% yield. The preparation of *anti*-2,4-dimethoxybicyclo[3.2.1]octane-8-carboxylic acid from **5** required the epimerization at C8. For convenience, the study of the epimerization reaction was carried out on **5***b*, prepared in 93% yield by Jones oxidation of **4***b*. Reaction of **5***b* with ethereal diazomethane gave the corresponding methyl ester **6***b*. Several attempts to epimerize **6***b* by using catalytic amounts of sodium methoxide or potassium *tert*-butoxide were fruitless. Refluxing **6***b* with 4–5 equivalents of potassium *tert*-butoxide in *tert*-butyl alcohol for 60 h, the acid **7***b* was obtained in 71.6% yield. Esterification of **7***b* with ethereal diazometh-

[1]Author to whom correspondence may be addressed. Present address, Departamento de Química Orgánica, Facultad de Ciencias Químicas San Sebastian, Universidad del País Vasco, Alza, San Sebastian, Spain.

[2]The terms *syn* and *anti* in 8-substituted bicyclo[3.2.1]octane and 9-substituted bicyclo[4.2.1]nonane derivatives refer in this context to the relation between the substituent at C8 or C9 and the larger ring to which it is attached, as it is used in refs. 7 and 8.

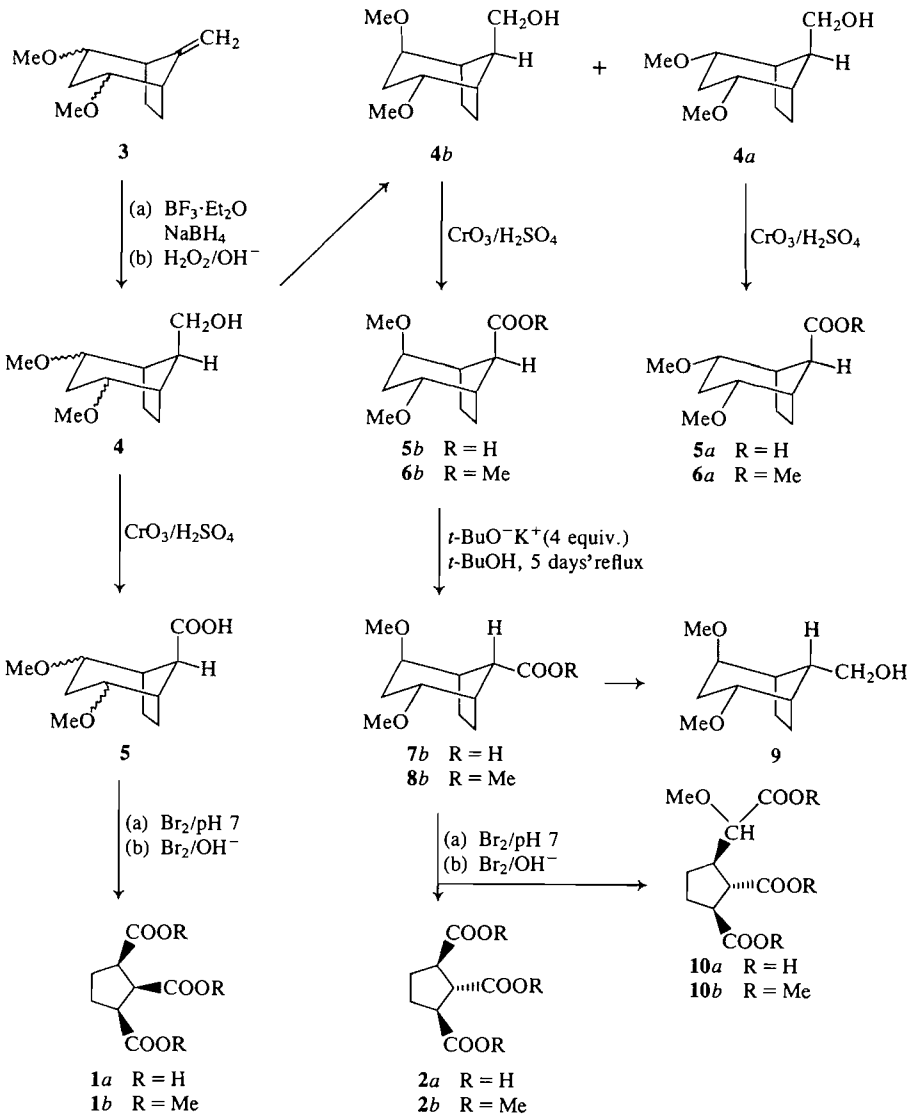

SCHEME 1

ane gave the corresponding methyl ester **8***b*, different from **6***b* (glc). Moreover, $LiAlH_4$ reduction of **8***b* gave the alcohol **9**, in which the *anti* stereochemistry of the hydroxymethyl group is clearly defined by the absence of intramolecular hydrogen bond (ir) and the small value of the coupling constants $J_{1',8'}$ and $J_{5',8'}$ (see Table 1).

It is noteworthy that the acid **7***b* and not its methyl ester **8***b* was the product obtained in the epimerization of **6***b*. The hydrolysis must take place after the epimerization of **6***b* because otherwise epimerization would not easily occur, and probably it implies breaking of the methyl–oxygen bond by nucleophilic attack of the *tert*-butoxide ion on the methyl of the ester function. Alternatively, as suggested by a referee, hydrolysis of a ketene intermediate would lead directly to the acid **7***b*.

We also prepared the ester **6***a*, by Jones oxidation of **4***a* and esterification of the corresponding acid **5***a* with ethereal diazomethane, but we did not attempt its epimerization, because we considered it more simple to carry out the final step of the sequence of Scheme 1 on **7***b*.

The bromine oxidation of the stereoisomeric mixture **5** gave, after esterification of the reaction

TABLE 1. Diagnostic coupling constants in 8-substituted bicyclo[3.2.1]octane and 9-substituted bicyclo[4.2.1]nonane derivatives

| | | |
|---|---|---|
|  |  |  |
| 4a $J_{1',8'} = 4.3$ Hz[a] | $J_{1,8} \sim J_{5,8} = 4$ Hz (ref. 6) | $J_{1,9} = 7$ Hz (ref. 7) |
| | |  |
| | | $J_{1,9} = 0$ Hz (ref. 7) |
|  |  |  |
| 4b $J_{1',8'} \sim J_{5',8'} = 4$ Hz[b] | $J_{1,8} = 5$ Hz (ref. 6) | $J_{1,9} = 7$ Hz (ref. 8) |
|  |  |  |
| 9 $J_{1',8'} \sim J_{5',8'} = 0$ Hz[a] | $J_{1,8} \sim J_{5,8} = 0$ Hz (ref. 6) | $J_{1,9} = 0$ Hz (ref. 8) |

[a]Value obtained from the $^1$H nmr spectrum in the presence of 0.39 equivalents of Eu(fod)$_3$.
[b]Approximate value obtained from the width of the H8′ absorption with simultaneous irradiation of the H1 protons.

product with ethereal diazomethane and chromatography, trimethyl (1*R*,2*s*,3*S*)-cyclopentane-1,2,3-tricarboxylate, **1***b*, in 18.7% yield. In the same way, bromine oxidation of **7***b* gave a crude product which, by crystallization from a small volume of 3 *N* HCl, afforded a solid, mp 169–171°C, that was characterized as *c*-3-(1-methoxyhydroxycarbonylmethyl)-*r*-1,*t*-2-cyclopentanedicarboxylic acid, **10***a* (21.5% yield). The mother liquors, esterified with ethereal diazomethane and chromatographed, gave trimethyl (1*R*,2*r*,3*S*)-cyclopentane-1,2,3-tricarboxylate, **2***b* (11.1% yield), plus dimethyl *c*-3-(1-methoxymethoxycarbonylmethyl)-*r*-1,*t*-2-cyclopentanedicarboxylate, **10***b* (7% yield).

The proposed structure for **10***a* and **10***b* comes from the spectroscopic and analytical data and mechanistic considerations. Thus, **10***b* showed in its $^1$H nmr spectrum three ester and one ether methoxyls at δ 3.75, 3.72, 3.70, and 3.43, respectively. There was also a doublet absorption ($J$ = 4 Hz) at δ 3.90 corresponding to one proton. The elemental analysis agreed for $C_{13}H_{20}O_7$. These facts pointed to a methyl α-methoxy-α-cyclopentylacetate substituted with two methoxycarbonyl groups in the cyclopentyl ring. The relative position of these substituents and the configuration were assigned on mechanistic grounds. Scheme 2 shows how **10***a* might have been formed.

In the fragmentation step the reaction might have followed a different course than we had observed on other substrates (1) (see Scheme 2). However, this fragmentation–elimination reaction requires the bonds to be broken (C3—C4 and C2—O) to adopt an antiperiplanar arrangement with respect to the C2—C3 bond, difficult to attain if the configuration at C2 is that shown.

No isomerization of **1***a* or **2***a* under the bromine oxidation conditions was expected. The 200 MHz $^1$H nmr spectra of **1***b* and **2***b* confirmed the expected configurations. Both spectra showed symmetrical absorptions for the annular protons as required by *meso*-compounds. The spectrum of **1***b* showed two clearly defined methoxyl absorptions, while only one was observed for **2***b*. The absorption corresponding to the C2 proton appeared in both cases as a triplet, shifted 0.1 ppm downfield for **2***b* with respect to **1***b* due to the shielding of the *cis*-methoxycarbonyl groups at C1 and C3. The most significant difference in both spectra corresponded to the methylene protons that appeared as two complex absorptions at δ 2.3 and 2.0 for **1***b* and as a complex one at δ 2.0 for **2***b*. A greater chemical shift difference must be expected for the methylene protons of **1***b* than for those of **2***b*. Similarly, the 50 MHz $^{13}$C nmr spectra of **1***b* and **2***b* confirmed the assigned configurations. The carbonyl absorptions of **1***b* appeared shifted 1.38 and 1.46 ppm upfield with respect to the corresponding absorptions of **2***b*, due to a greater γ-effect between the methoxycarbonyl groups in **1***b*. Moreover, the methylene carbons (C4 and C5) of **1***b* appeared shifted 3.76 ppm upfield with respect to the corresponding absorption of **2***b*. Assuming the $C_s$ envelope conformations of **1***b* and **2***b* to be the most stable (9), a greater γ-effect for the methylene carbons must be expected in **1***b* because of the axial methoxycarbonyl group at C2 (10).

Hydrolysis of **1***b* by reaction with dilute aqueous HCl gave (1*R*,2*s*,3*S*)-cyclopentane-1,2,3-tricarboxylic acid, **1***a*, in 97% yield, which after two crystallizations from 3 *N* HCl melted at 169–170°C. Esterification of a sample of **1***a* with ethereal diazomethane gave back **1***b*, showing that no isomerization had taken place during hydrolysis. In the same way, **2***b* was hydrolyzed to **2***a* in 95% yield, which after two crystallizations from 3 *N* HCl melted at 183–185°C. Esterification of a sample of **2***a* with ethereal diazomethane gave back **2***b*.

The melting point of **1***a* agrees with that of the described *meso*-cyclopentane-1,2,3-tricarboxylic acid. Since it is obtained under equilibration conditions by refluxing the racemic form with acetic anhydride, we expected it to be **2***a*, which

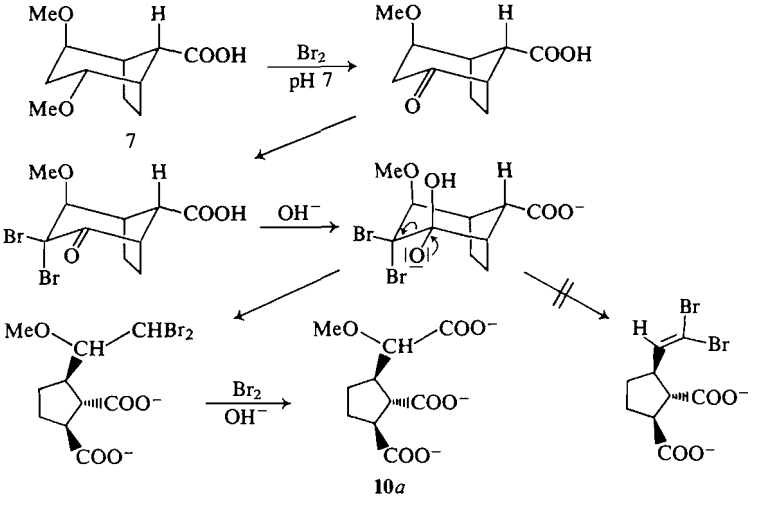
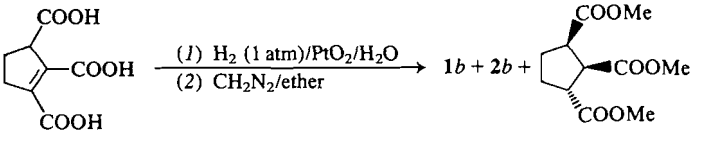


SCHEME 2



SCHEME 3

must be the thermodynamically more stable. However, it must not be the relative stabilities of these acids, but those of the species present in the reaction medium, that determine the preferred formation of one of them.

Compounds **1***b* and **2***b* were also prepared in a straightforward manner by hydrogenation (11) of the known cyclopentene-1,2,3-tricarboxylic acid (12), **11**, followed by esterification with ethereal diazomethane and column chromatography (Scheme 3).

As can be seen from Table 2, the best stereoselectivity in the hydrogenation of **11** was obtained by using Pt as catalyst. Moreover, a large proportion of **2***b* was always obtained. This product must arise from the hydrogenation of a product of double bond isomerization of **11**. Column chromatography of a mixture of **1***b*, **2***b*, and **12** (from a hydrogenation of **11** using Pt as catalyst) using silica gel as support and hexane–ether mixtures as eluent gave pure **1***b* (52% yield from **11**) and **2***b* (containing 6% **12** (nmr)) (11% yield from **11**). By reaction of a mixture of **1***b*, **2***b*, and **12** (from a Pd/C hydrogenation of **11**) with sodium methoxide in methanol, a 3:1 mixture of **2***b*/**12** was obtained, in agreement with the expected relative stabilities of the trimethyl cyclopentane-1,2,3-tricarboxylates.

Thus the use of the 1,3-dimethoxytrimethylene bridge as two latent carboxyl groups has allowed us to carry out a low yield, but stereospecific, synthesis of the acids **1***a* and **2***a* which, on the other hand, have been easily prepared stereoselectively from **11**.

TABLE 2. Ratios of stereoisomeric trimethyl cyclopentane-1,2,3-tricarboxylates obtained by hydrogenation of **11** in water at atmospheric pressure using different catalysts, followed by reaction with ethereal diazomethane

| Catalyst | 1*b* | 2*b* | 12 |
|---|---|---|---|
| 10% Pd/C | 44 | 42 | 14 |
| 5% Rd/C | 67 | 20 | 13 |
| Pt | 78 | 20 | Traces |

## Experimental

Infrared spectra were recorded on a Perkin–Elmer spectrometer model 720, mass spectra on a Hewlett–Packard spectrometer model 5930A. The $^1$H nmr spectra, unless otherwise stated, were taken at 60 MHz on a Perkin–Elmer R-12A spectrometer, while 200 MHz $^1$H spectra and 50 MHz $^{13}$C spectra were recorded on a Varian XL 200. Chemical shifts are given in ppm relative to internal TMS (δ scale). Melting points were determined on a Kofler hot-stage and are corrected.

syn-*(2,4-Dimethoxybicyclo[3.2.1]oct-8-yl)methanol, 4*

Into a three-necked 100 mL flask fitted with reflux condenser, addition funnel, thermometer, Ar atmosphere, and magnetic stirrer, 2.363 g of **3** (13 mmol) in 16 mL anhydrous DME and 0.182 g $NaBH_4$ (4.8 mmol) were introduced. The flask was immersed in a water bath at 20°C and 0.75 mL of boron trifluoride-etherate (6 mmol) in 5 mL anhydrous DME were slowly added (15 min) with stirring, keeping the temperature of the reaction mixture below 25°C. After 1 h stirring, the flask was immersed in an ice bath and 15 mL water and 15 mL aqueous 3 *N* NaOH were introduced. Then 6 mL of 30% $H_2O_2$ was slowly added and the mixture was stirred at room temperature for 1 h. In order to keep the reaction medium alkaline during the addition of $H_2O_2$, 1 mL more of aqueous 3 *N* NaOH was added. Water (25 mL) was added and the solution extracted with $CH_2Cl_2$ (4 × 20 mL). By removing the solvents at reduced pressure from the dried extracts (anhydrous $Na_2SO_4$), 2.364 g of crude product was obtained. The water phase was continuously extracted with ether for 24 h to give 0.236 g more of crude product, total 2.600 g. This crude product on chromatography through 50 g silica gel (230–400 mesh) (4) gave the following fractions: 0.150 g starting product (0.82 mmol) (hexane – ethyl acetate 98:2), 1.743 g of **4***b* (8.71 mmol), 0.073 g of a mixture of **4***b* and **4***a* (0.37 mmol), and 0.389 g of **4***a* (1.94 mmol) (ethyl acetate) (90.4% yield of **4***a* + **4***b* from reacted **3**). Boiling point of **4***a* and **4***b*, 185–190°C (oven)/15 Torr.

*Spectral and analytical data of [(1RS,2RS,4RS,5SR,8SR)-2,4-dimethoxybicyclo[3.2.1]oct-8-yl]methanol, 4*b

Infrared ($CHCl_3$), ν: 3650 and 3450 $cm^{-1}$. The relative intensities remained unchanged on dilution; $^1H$ nmr ($CDCl_3$), δ: 1.1–2.2 (broad, 7H), 2.2–2.5 (broad, 3H, part of this absorption changed on dilution), 3.2–3.8 (complex absorption), 3.33(s), 3.31(s) (total 8H), 3.95 (d, $J$ = 8 Hz, 2H); ms: 200($M^+$, 2), 181(4), 168($M^+$ – MeOH, 100), 150(29), 136(76), 101(MeO—$\overset{+}{C}$H—CH=CH—OMe, 76), 79(59), 71(MeO—$\overset{+}{C}$H—CH=$CH_2$, 76). *Anal.* calcd. for $C_{11}H_{20}O_3$: C 65.97, H 10.07; found: C 65.69, H 10.18.

*Spectral and analytical data of [(1R,2S,4R,5S,8s)-2,4-dimethoxybicyclo[3.2.1]oct-8-yl]methanol, 4*a

Infrared ($CHCl_3$), ν: 3650 and 3450 $cm^{-1}$. The relative intensities of these absorptions varied on dilution; $^1H$ nmr ($CDCl_3$), δ: 1.0–2.5 (broad), 1.85 (s, changed on dilution) (total 10 H), 3.2–3.7 (complex absorption), 3.30(s) (total 8H), 3.8(d, $J$ = 8 Hz, 2H); ms: 200($M^+$, 2), 181(6), 168($M^+$ – MeOH, 42), 151(25), 150(24), 136(25), 101(MeO—$\overset{+}{C}$H—CH=CH—OMe, 100), 71(MeO—$\overset{+}{C}$H—CH=$CH_2$, 59). *Anal.* calcd. for $C_{11}H_{20}O_3$: C 65.97, H 10.07; found: C 65.74, H 10.10.

*(1RS,2RS,4RS,5SR,8SR)-2,4-Dimethoxybicyclo[3.2.1]octane-8-carboxylic acid, 5*b

To a solution of 0.816 g of **4***b* (4.08 mmol) in 20 mL acetone, 2.2 mL of Jones reagent was slowly added and the mixture magnetically stirred at room temperature for 16 h. The solvent was removed at reduced pressure, water (20 mL) was added, and the mixture extracted with ether (7 × 15 mL). The ether extracts were dried over anhydrous $Na_2SO_4$ and the solvent removed at reduced pressure to give 0.815 g of **5***b* as a white solid, mp 106–109°C (ether–hexane) (3.81 mmol, 93% yield); ir($CHCl_3$), ν: 3700–2400(m), 1710(s) $cm^{-1}$; $^1H$ nmr ($CDCl_3$), δ: 1.1–2.3 (broad, 6H), 2.4–3.1 (broad, 3H), 3.2–4.4 (complex absorption), 3.30(s), 3.33(s) (total 8H), 9.07(broad, 1H); ms: 196($M^+$ – $H_2O$, 3), 182(11), 152(11), 101(MeO—$\overset{+}{C}$H—CH=CH—OMe, 100), 71(MeO—$\overset{+}{C}$H—CH=$CH_2$, 54). *Anal.* calcd. for $C_{11}H_{18}O_4$: C 61.66, H 8.74; found: C 61.58, H 8.54.

*(1R,2S,4R,5S,8s)-2,4-Dimethoxybicyclo[3.2.1]octane-8-carboxylic acid, 5*a

Compound **5***a* was prepared as described for **5***b*. From 0.147 g of **4***a* (0.73 mmol), 0.123 g of **5***a* (0.57 mmol, 78% yield) as a white solid, mp 159–163°C, was obtained; ir($CHCl_3$), ν: 3700–2400(s), 1700(s) $cm^{-1}$; $^1H$ nmr ($CDCl_3$), δ: 1.0–2.5 (broad, 6H), 2.5–3.0 (broad, 3H), 3.30–3.85 (complex absorption), 3.35(s) (total, 8H), 9.5 (broad, 1H); ms: 214($M^+$, 2), 199(1), 196(2), 182(13), 101(MeO—$\overset{+}{C}$H—CH=CH—OMe, 100), 71(MeO—$\overset{+}{C}$H—CH=$CH_2$, 54). *Anal.* calcd. for $C_{11}H_{18}O_4$: C 61.66, H 8.47; found: C 61.90, H 8.57.

syn-*2,4-Dimethoxybicyclo[3.2.1]octane-8-carboxylic acid, 5*

The stereoisomeric mixture **5** was prepared as described for **5***b*. From 0.824 g of **4** (4.12 mmol), 0.783 g of **5** (3.65 mmol, 89% yield) was obtained.

*Methyl (1RS,2RS,4RS,5SR,8SR)-2,4-dimethoxybicyclo[3.2.1]-octane-8-carboxylate, 6*b

An ethereal solution of diazomethane was added to 0.815 g of **5***b* (3.81 mmol) until the yellow color persisted. Then the solvent was removed at reduced pressure to give 0.802 g of **6***b* (3.52 mmol, 92% yield) as a liquid, bp 135–140°C (oven)/18 Torr; ir($CCl_4$), ν: 1740(s) $cm^{-1}$; $^1H$ nmr ($CDCl_3$), δ: 1.0–2.2 (broad, 6H), 2.2–3.0 (broad, 3H), 3.0–3.5 (complex absorption), 3.14(s), 3.22(s) (total 7H), 3.53 (s, 3H), 3.97 (ddd, $J$ = 2 Hz, $J'$ = 7 Hz, and $J''$ = 11 Hz); ms: 228($M^+$, 1), 213(1), 196($M^+$ – MeOH, 81), 181(22), 168(16), 153(22), 137(52), 136($M^+$ – MeOH – $HCO_2Me$, 100), 108($C_6H_5$—$OMe^+$, 56), 101(MeO—$\overset{+}{C}$H—CH=CH—OMe, 72), 71(MeO—$\overset{+}{C}$H—CH=$CH_2$, 61). *Anal.* calcd. for $C_{12}H_{20}O_4$: C 63.14, H 8.83; found: C 63.39, H 8.84.

*Methyl (1R,2S,4R,5S,8s)-2,4-dimethoxybicyclo[3.2.1]octane-8-carboxylate, 6*a

Compound **6***a* was prepared as described for **6***b*. From 0.070 g of **5***a* (0.33 mmol), 0.070 g of distilled **6***a* (0.31 mmol, 94% yield), bp 148–152°C (oven)/16 Torr, was obtained; ir($CCl_4$), ν: 1735(s) $cm^{-1}$; $^1H$ nmr ($CDCl_3$), δ: 0.8–2.4 (broad, 7H), 2.57 (broad, 2H), 3.2–3.7 (complex absorption), 3.28(s), 3.68(s) (total 11H); ms: 228($M^+$, 3), 213(3), 197(9), 196(33), 181(9), 168(7), 165(16), 164(12), 149(13), 137(41), 136(17), 101(MeO—$\overset{+}{C}$H—CH=CH—OMe, 100), 71(MeO—$\overset{+}{C}$H—CH=$CH_2$, 55). *Anal.* calcd. for $C_{12}H_{20}O_4$: C 63.14, H 8.83; found: C 63.00, H 8.90.

*(1RS,2RS,4RS,5SR,8RS)-2,4-Dimethoxybicyclo[3.2.1]octane-8-carboxylic acid, 7*b

In a 50 mL flask fitted with a reflux condenser with a $CaCl_2$ tube, 25 mL anhydrous *tert*-butyl alcohol and 1.360 g potassium (34.9 mmol) were introduced. After all potassium had reacted and the solution reached room temperature, 1.833 g of **6***b* (8.04 mmol) in 5 mL anhydrous *tert*-butyl alcohol was added and the solution heated under reflux for 60 h. After cooling, 175 mL water was added and the mixture extracted with $CH_2Cl_2$ (5 × 20 mL). The extracts were washed with water (2 × 5 mL) and dried over anhydrous $Na_2SO_4$ to give, after removing the solvent at reduced pressure, 0.188 g of an unidentified product. The aqueous phase was acidified with concentrated HCl and extracted with ether (5 × 50 mL). The ether extracts were dried over anhydrous $Na_2SO_4$ and the solvent removed at reduced pressure to give 1.232 g of **7***b* (5.76 mmol, 71.6% yield) as an oil that solidified on standing, mp 98–101°C (ethyl acetate – hexane); ir(KBr), ν: 3700–3200(s), 1720(s) $cm^{-1}$; $^1H$ nmr ($CDCl_3$), δ: 1.0–2.2 (broad, 6H), 2.6–2.9 (broad, 3H), 3.2–3.6 (broad), 3.27(s) (total, 8H), 11.1 (broad, 1H); ms: 196($M^+$ – $H_2O$, 0.5), 183(0.5), 103(MeO—$\overset{+}{C}$H—$CH_2$—$CH_2$—OMe, 13),

101(MeO—$\overset{+}{C}$H—CH=CH—OMe, 30), 71(MeO—$\overset{+}{C}$H—CH=$CH_2$, 100). *Anal.* calcd. for $C_{11}H_{18}O_4$: C 61.66, H 8.47; found: C 61.61, H 8.46.

*Methyl (1*RS,*2*RS,*4*RS,*5*SR,*8*RS*)-2,4-dimethoxybicyclo[3.2.1]-octane-8-carboxylate, 8*b

Compound **8***b* was obtained quantitatively from **7***b* as described for **6***b*, bp 135–140°C (oven)/16 Torr; ir($CCl_4$), v: 1730(s) $cm^{-1}$; $^1H$ nmr ($CDCl_3$), δ: 1.0–2.6 (broad, 6H), 2.6–2.9 (broad, 3H), 3.2–4.0 (broad), 3.30(s), 3.66(s) (total, 11H); ms: 213($M^+$ – Me, 1), 197(2), 196(7), 137(5), 105(5), 101(MeO—$\overset{+}{C}$H—CH=CH—OMe, 22), 71(MeO—$\overset{+}{C}$H—CH=$CH_2$, 100). *Anal.* calcd. for $C_{12}H_{20}O_4$: C 63.14, H 8.83; found: C 63.42, H 9.09.

*[(1*RS,*2*RS,*4*RS,*5*SR,*8*RS*)-2,4-Dimethoxybicyclo[3.2.1]oct-8-yl]methanol, 9*

In a 10 mL flask protected from moisture ($CaCl_2$ tube), 0.069 g $LiAlH_4$ (1.8 mmol), 3 mL ether, and 0.148 g of **8***b* (0.65 mmol) were introduced and the mixture was magnetically stirred at room temperature for 30 min. Wet ether (10 mL) was added and then 10 mL aqueous 0.1 *N* HCl. The ethereal phase was decanted and the aqueous one extracted with ether. By removing the solvent at reduced pressure from the dried ether extracts (anhydrous $Na_2SO_4$), 0.125 g of crude product was obtained. This product was chromatographed through 10 g silica gel (230–400 mesh) (4) to give 0.018 g of starting product (0.08 mmol), eluting with hexane – ethyl acetate 4:1, and 0.075 g of pure **9** (0.37 mmol, 66% yield from unrecovered **8***b*), eluting with hexane – ethyl acetate 1:1. Infrared ($CCl_4$), v: 3660 and 3450 $cm^{-1}$. The relative intensities varied on dilution; $^1H$ nmr ($CDCl_3$), δ: 0.9–2.5 (broad, 10H) (part of this absorption at δ 2.3 varied on dilution), 3.1–3.5 (complex absorption), 3.22(s), 3.38(d, $J$ = 8 Hz) (total 10H); ms: 168($M^+$ – MeOH, 6), 150(1), 138(2), 137(3), 136(2), 110(8), 103(MeO—$\overset{+}{C}$H—$CH_2$—$CH_2$—OMe, 37), 101(MeO—$\overset{+}{C}$H—CH=CH—OMe, 22), 91(15), 71(MeO—$\overset{+}{C}$H—CH=$CH_2$, 100). *Anal.* calcd. for $C_{11}H_{20}O_3$: C 65.97, H 10.07; found: C 65.84, H 10.44.

*Bromine oxidation of 5: trimethyl (1*R,*2*s,*3*S*)-cyclopentane-1,2,3-tricarboxylate, 1*b

In a 50 mL flask, 0.343 g of **5** (1.6 mmol), 32 mL of buffer solution of pH 7 (containing 10.4 mmol of $PO_4H_2^-$ and 13.4 mmol of $PO_4H^{2-}$), and 0.68 mL of bromine (13.2 mmol) were introduced. The flask was stoppered and the mixture magnetically stirred at room temperature for 68 h. Sodium hydroxide (3.92 g, 98 mmol) and 0.4 mL bromine (7.8 mmol) were introduced and stirring continued for 24 h more. The excess bromine was destroyed with solid $Na_2SO_3$, and the solution made acidic by addition of a mixture of ice and concentrated HCl. The solution was continuously extracted with ether for 13 days. The ether was removed at reduced pressure to give 0.330 g of a viscous crude that was treated with excess ethereal diazomethane. The solution was concentrated at reduced pressure and the residue distilled to give 0.245 g of a mixture (glc), bp 165–170°C (oven)/17 Torr. This mixture was chromatographed through 10 g silica gel (230–400 mesh) (4) to give, among other fractions, 0.072 g of **1***b* (0.3 mmol, 18.7% yield), eluting with hexane – ethyl acetate 4:1, bp 165–170°C (oven)/17 Torr; ir (film), v: 1730(s) $cm^{-1}$; 200 MHz $^1H$ nmr ($CDCl_3$), δ: 1.91–2.09 (complex m, 2H), 2.24–2.43 (complex m, 2H), 2.98–3.11 (complex m, 2H), 3.46(t, $J$ = 7 Hz, 1H), 3.65(s, 3H), 3.67(s, 6H); 50 MHz $^{13}C$ nmr ($CDCl_3$), δ: 25.66(C4 and C5), 47.46(C1 and C3), 49.20(C2), 51.89(C2—COO*Me*), 51.93(C1—COO*Me* and C3—COO*Me*), 172.30(C2—*C*OOMe), 172.80 (C1—*C*OOMe and C3—*C*OOMe); ms: 244($M^+$, 1), 213(63), 212(36), 184(12), 180(3), 153(43), 152($M^+$ – MeOH – HCOOMe, 90), 125(100), 124($M^+$ – 2HCOOMe, 100), 93(70). *Anal.* calcd. for $C_{11}H_{16}O_6$: C 54.05, H 6.60; found: C 54.16, H 6.68.

*Bromine oxidation of 7*b

In a 100 mL flask, 1.055 g of **7***b* (4.93 mmol), 56 mL of buffer solution of pH 7 (containing 1.67 mmol of $PO_4H_2^-$ and 2.00 mmol of $PO_4H^{2-}$), and 2.02 mL of bromine (39.5 mmol) were introduced. The flask was stoppered and the mixture magnetically stirred at room temperature for 63 h. Sodium hydroxide (18.96 g, 0.474 mol) and 0.63 mL of bromine (12.3 mmol) were added, and stirring continued for 24 h more. The excess bromine was destroyed with solid $Na_2SO_3$, the solution made acidic by addition of a mixture of ice and concentrated HCl, and extracted continuously with ether for 19 h. The ether was removed at reduced pressure to give 0.720 g of a viscous product that was dissolved in 1 mL of aqueous 3 *N* HCl. From this solution 0.261 g of a solid, mp 169–171°C, that was characterized as **10***a* (1.06 mmol, 21.5% yield), was obtained. The solvent was removed from the mother liquors at reduced pressure, and the residue was esterified with ethereal diazomethane to give, after removing the ether, 0.373 g of a liquid that was chromatographed through 20 g silica gel, eluting with hexane–ether 7:3, to give 0.134 g of **2***b* (0.55 mmol, 11.1% yield) and 0.085 g of **10***b* (0.34 mmol, 7% yield).

*Trimethyl (1*R,2s,3S)- *and (1*R,2r,3S)-*cyclopentane-1,2,3-tricarboxylate from 1-cyclopentene-1,2,3-tricarboxylic acid (12),* ***11***

A solution of 3.421 g of **11** (17.1 mmol) in 20 mL water was hydrogenated at atmospheric pressure using 0.600 g $PtO_2$ as catalyst (11). The catalyst was filtered and the residue washed with water (3 × 3 mL). The water was removed from the filtrate at reduced pressure to give 3.056 g of a viscous liquid that was esterified with ethereal diazomethane. By removing the ether, 3.191 g of a crude product was obtained, which was characterized (glc) as a 4:1 mixture of **1***b* and **2***b*, traces of **12** not being excluded. This crude product was chromatographed through 130 g silica gel using hexane–ether mixtures as eluent. The following fractions were obtained: 0.426 g of **2***b* contaminated with 6% **12** (nmr) (hexane–ether 7:3), 0.154 g of mixture of stereoisomers (hexane–ether 7:3), and 2.164 g of pure **1***b* (hexane–ether 6:4).

*Equilibration of a stereoisomeric mixture of trimethyl cyclopentane-1,2,3-tricarboxylate by reaction with sodium methoxide*

A mixture of **1***b*, **2***b*, and racemic trimethyl cyclopentane-1,2,3-tricarboxylate, **12** (1 g from a hydrogenation of **11** with 10% Pd/C and esterification with ethereal diazomethane), 0.246 g of anhydrous sodium methoxide, and 25 mL of anhydrous methanol was heated under reflux for 36 h. The mixture was neutralized with concentrated HCl, the volatile products removed at reduced pressure, and the residue treated with $CHCl_3$. By removing the chloroform at reduced pressure, 0.882 g of a mixture of **2***b* and **12** in the ratio 3:1 (nmr) was obtained.

# Towards a general scheme for estimating the heats of formation of organic ions in the gas phase. Part II. The effect of substitution at charge-bearing sites

JOHN L. HOLMES AND F. P. LOSSING

*Chemistry Department, University of Ottawa, Ottawa, Ont., Canada K1N 9B4*

Received May 6, 1982

JOHN L. HOLMES and F. P. LOSSING. Can. J. Chem. **60**, 2365 (1982).

The effects on ionic heats of formation of the multiple substitution of $-CH_3$, -OH, or $-OCH_3$ groups, in place of H atoms, are described. It is shown that for all three substituents, good linear correlations exist between $\Delta H_f$(ion) and the logarithm of the number of atoms in the ion (i.e. a quantity proportional to ionic size). The changes in $\Delta H_f$(ion) resulting from successive substitutions at a charge-bearing atom or π-system essentially depend only upon the specific nucleophilic character of the group and the size of the resultant ion. Examples are given of the utility of these correlations in estimating new ionic heats of formation.

JOHN L. HOLMES et F. P. LOSSING. Can. J. Chem. **60**, 2365 (1982).

On décrit les effets des chaleurs ioniques de formation lorsqu'on substitue à des atomes d'hydrogène les groupes $CH_3$, OH, ou $OCH_3$. On montre que, pour chacun des trois substituants, il existe de bonnes corrélations linéaires entre le $\Delta H_f$(ion) et le logarithme du nombre d'atomes dans l'ion (i.e. une quantité proportionnelle à la taille de l'ion). Les variations du $\Delta H_f$(ion) qui résultent des substitutions successives au niveau de l'atome porteur de la charge ou du système π, dépend en majeure partie du caractère nucléophile spécifique du groupe et de la taille de l'ion résultant. On donne des exemples de l'utilité de ces corrélations pour l'évaluation de nouvelles enthalpies ioniques de formation.

[Traduit par le journal]

## Introduction

In Part I of the work (1) we described a method for calculating the heats of formation, $\Delta H_f$, of organic radical cations belonging to homologous series. The generic equation for this method has the form $\Delta H_f(\text{ion}) = A - Bn + C/n$, where $n$ is the number of atoms in the ion and $A$, $B$, and $C$ are constants for the series. The latter were derived from experimental data for members of the unbranched homologous series. When a generic equation for a series has been derived, correction terms for chain-branching effects and double-bond position, etc., can be established. Although the method is empirical, the form of the equation properly reflects the fact that $\Delta H_f$(ion) is the sum of the $\Delta H_f$ of the neutral molecule and its ionization energy (IE). The $A - Bn$ part of the equation is analogous to the thermochemical additivity system of Benson *et al.* (2), which accurately reproduces the linear decrease in $\Delta H_f$(neutral) with increasing homologue size. The IE, however, is not linear in molecular size, but falls at a decreasing rate. Figure 1 shows the decrease in $\Delta H_f$(neutral), ionization energy, and $\Delta H_f$(ion) as a function of molecular size, which here is simply represented by the total

TABLE 1. Relative stabilization of radicals and ions (kcal mol$^{-1}$)

| Structure | $\Delta H_f(R^\cdot)$ | $D$(R—H) | Relative stability | $\Delta H_f(R^+)$ | $D(R^+—H^-)$ [a] | Relative stability |
|---|---|---|---|---|---|---|
| $H.CH_2—H$ | 34 (4) | 104 | 0 | 261 (4) | 313 | 0 |
| $H_3C.CH_2—H$ | 28 (5) | 100 | 4 | 216 (4, 6) | 271 | 42 |
| $HO.CH_2—H$ | −6.2 (7) | 96 | 8 | 169 (8) | 252 | 61 |
| $CH_3O.CH_2—H$ | −1.3 (7) | 94 | 10 | 157 (8) | 235 | 78 |
| $H_2N.CH_2—H$ | 36 (9) | 94 | 10 | 178 (10) | 218 | 95 |
| $N\equiv C.CH_2—H$ | 51 (11) | 88 | 16 | 286[b] | 305 | 8 |
| $H_2C=CH.CH_2—H$ | 39 (14) | 86 | 18 | 226 (15) | 256 | 57 |

[a] $\Delta H_f[H]^- = 34.7$ kcal mol$^{-1}$.
[b] From AE $m/z$ 40 from $CH_3CN$ = 14.01 (12), and $\Delta H_f[CH_3CN]$ − 15.4 kcal mol$^{-1}$ (13).

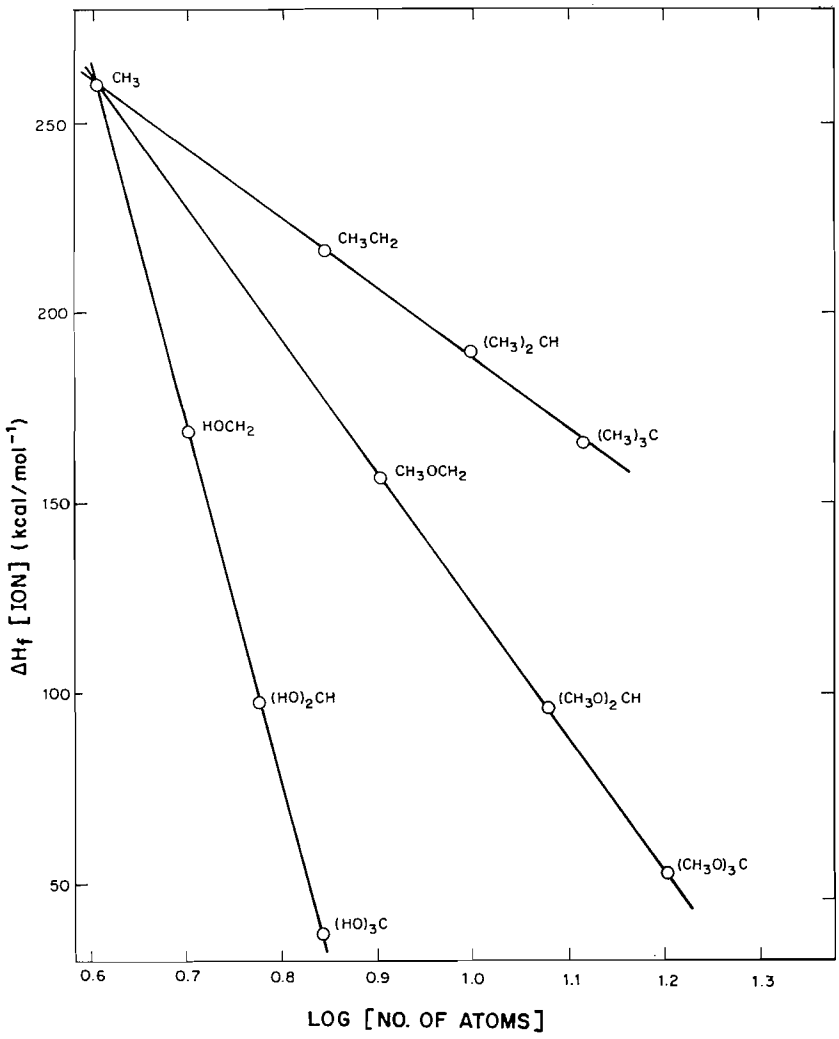

FIG. 3. $\Delta H_f$(ion) for successive substitution of -$CH_3$, -$OCH_3$, and -OH in $CH_3^+$ vs. log (no. atoms).

number of atoms in the ion. The data in Fig. 1 are for the *n*-alkanes, but other unbranched homologous series produce similar graphs. Figure 2 shows that the ionization energies of the members of linear homologous series decrease in an almost linear manner with the reciprocal of the number of atoms. It is evident therefore that the $\Delta H_f$ values for an homologous series of ions ($\Delta H_f$(ion) = $\Delta H_f$(neutral) + IE) can be closely reproduced by an equation of the form $\Delta H_f(\text{ion}) = A - Bn + C/n$. The inclusion of the appropriate correction terms for isomers, e.g. chain-branching, double-bond

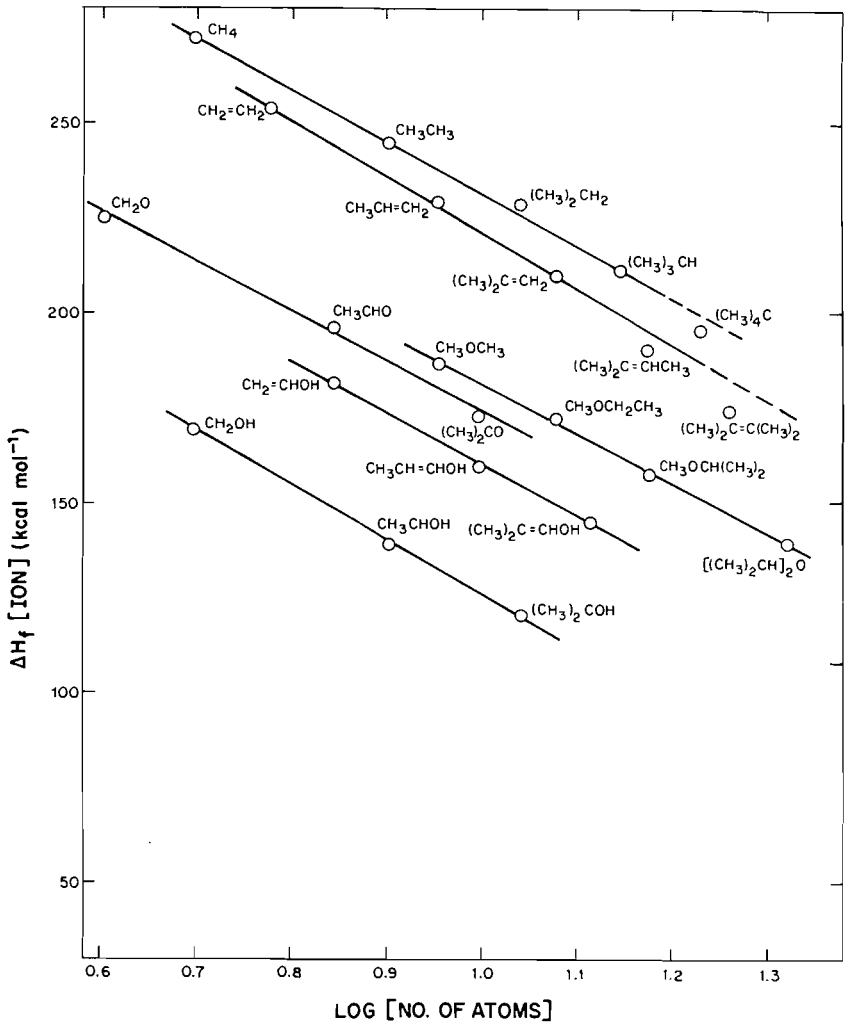

FIG. 4. $\Delta H_f$(ion) for successive substitution of -$CH_3$ at charge bearing sites in odd and even electron ions vs. log (no. atoms).

position, etc., permitted the fitting of almost all the calculated $\Delta H_f$ values to the experimental data to within $\pm 1$ kcal mol$^{-1}$ (1).

Although this method successfully reproduces the heats of formation of homologous radical cations, there are many ions of interest which cannot be described as members of homologous series, but which are nevertheless related structurally. For example, the even electron ions: $CH_3^+$, $CH_3\overset{+}{C}H_2$, $(CH_3)_2\overset{+}{C}H$, $(CH_3)_3\overset{+}{C}$, and the molecular ions of benzene, toluene, dimethyl benzene, trimethyl benzene, etc., are two such families of related ions. Here, a functional group, -$CH_3$, is successively substituted around, in the former case, a common charged site, and in the latter, a $\pi$-system bearing a delocalized charge. For such series the effect of substitution on $\Delta H_f$(ion) is conveniently and simply illustrated by plotting $\Delta H_f$(ion) against the logarithm of the number of atoms (i.e. molecular size). For many series of this kind, as shown in the present work, excellent straight-line relationships are found. Although this type of plot is also successful for the lower members of true homologous series, for higher homologues (above $C_8$) the experimental points fall increasingly below the line. The use of the generic equation avoids this error. The deviation occurs because for the higher homologues the ionization energies fall progressively more slowly, and the successive decreases in $\Delta H_f$(ion) become dominated by the *linear* decrease in $\Delta H_f$(neutral). The present work is concerned with the ionic stabilizing effects (represented here by reductions in $\Delta H_f$(ion)) of the multiple-substitution of -$CH_3$, -OH,

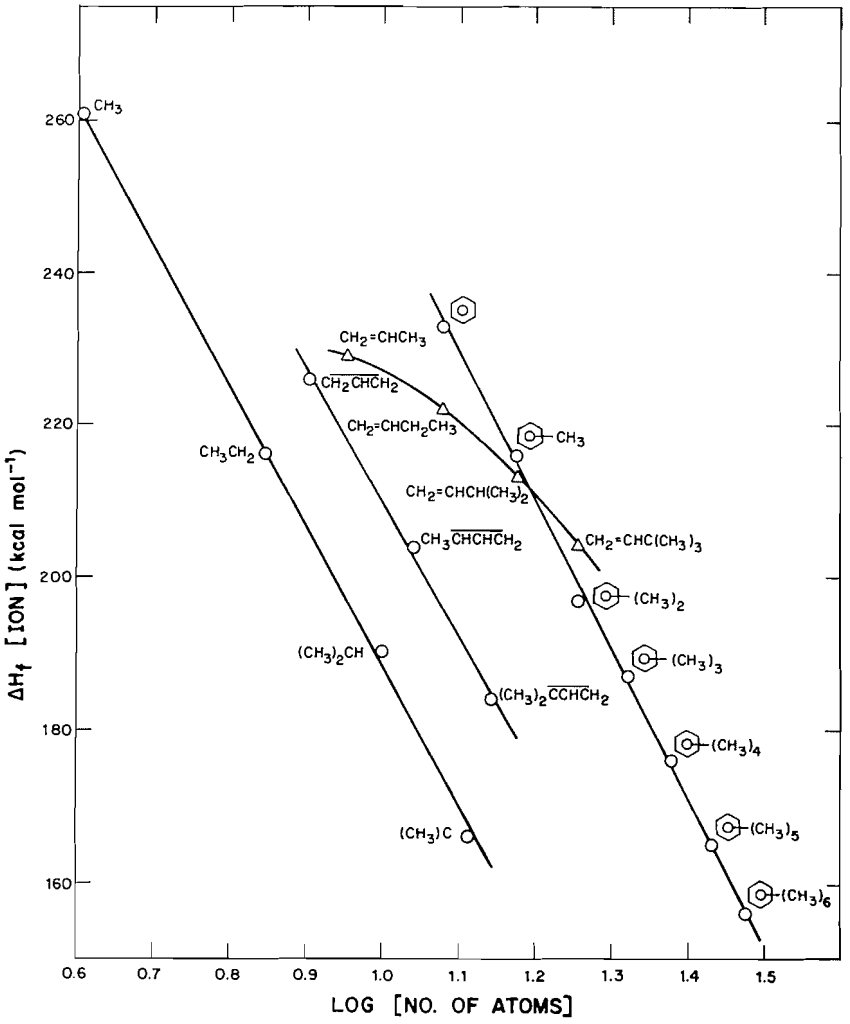

FIG. 5. $\Delta H_f$(ion) for successive substitution of -$CH_3$ at localized and delocalized charge sites (○) and at a site remote from the charge (△) vs. log (no. atoms).

and -$OCH_3$ groups around a common charge-bearing carbon atom or a variety of π-systems. The third type of series, in which the functional group is substituted at a formally uncharged site, will be discussed in a forthcoming publication.

## Experimental

The values of the heats of formation of ions used in this work are given in the Appendix. Most of these were taken from the recent literature, but some were measured in this laboratory by ionization or dissociative ionization of appropriate compounds by impact of a monoenergetic electron beam (3). The $\Delta H_f$(ion) values so obtained are briefly discussed in the Appendix.

## Discussion

The effects of substituent groups on the thermodynamic stability of organic ions has been the subject of intensive investigation for many years, particularly by studies of the relative rates of solvolytic reactions in the liquid phase. It is difficult directly to relate this enormous body of data to gas-phase ionic heats of formation because of solvation and other effects. However, the principal effects of substituent groups are well-understood in terms of the lowering of the energy of the incipient carbonium ion centre by charge delocalization. Substituent groups vary widely in their ability to provide such stabilization; their effects appear to involve both the effect of size and of specific nucleophilic character. These stabilizing effects can quantitatively be compared for radicals via the bond dissociation energies $D(RCH_2—H)$; for even-electron ions, the corresponding quantity in the charged species is the hydride ion affinity or heterolytic bond dissociation energy (HBDE), $D(R\overset{+}{C}H_2—H^-)$. As can be seen from Table 1, the stabilizing effects of various groups on a neutral $CH_3$ centre are greatly different from their effects

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

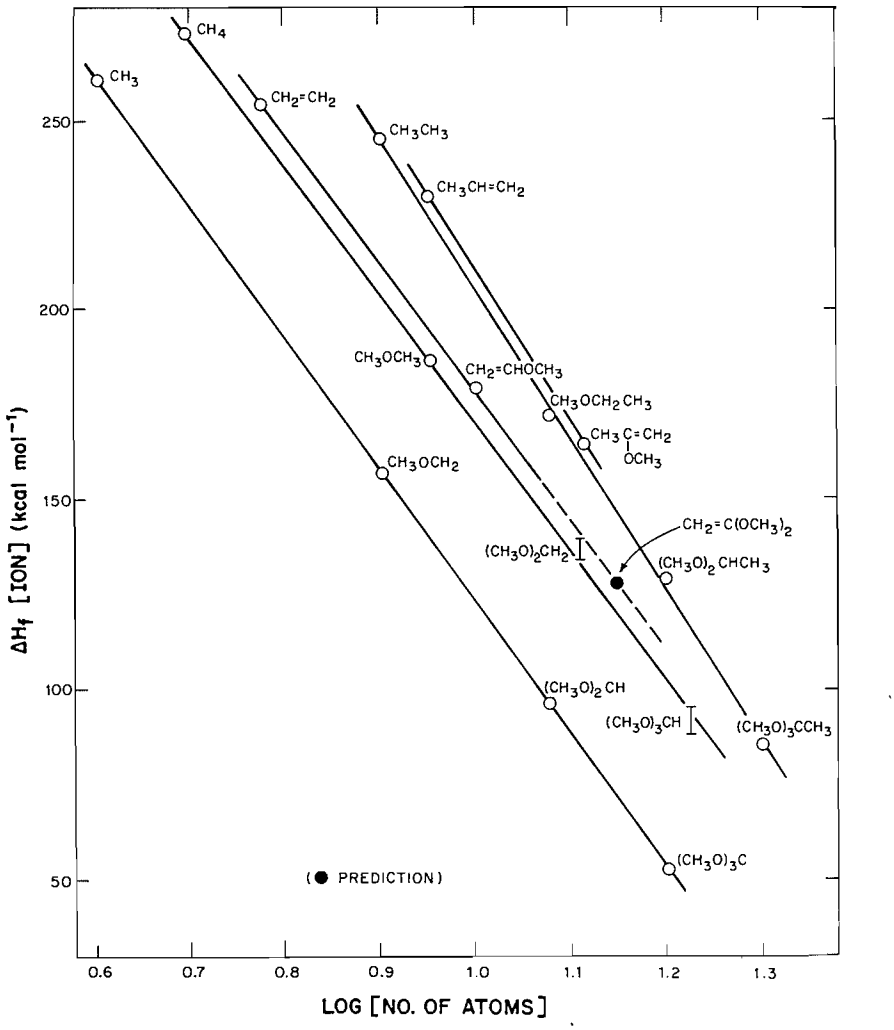

FIG. 6. $\Delta H_f$(ion) for successive substitution of -$OCH_3$ at charge bearing sites in odd and even electron ions vs. log (no. atoms).

on a *charged* centre. It is immediately evident that stabilizing effects are very much greater in ions than in neutrals. The interesting exception in Table 1 is -CN substitution, in which the ion is destabilized relative to the neutral radical. The relation between these effects and ionic abundances in mass spectra has been discussed qualitatively by many authors (see, for example, ref. 16) in terms of the familiar concepts of physical-organic chemistry.

In order to correlate the stabilizing effects of multiple-substitution for both odd- and even-electron ions, it is more convenient to use changes in $\Delta H_f$(ion) along such series, rather than HBDE comparisons. Our purpose here is to illustrate a method for estimating an unknown $\Delta H_f$(ion) from known members of its multiple-substitution series, rather than to make numerical comparisons of the stabilizing power of various substituent groups. As well as their predictive utility for missing members, these correlations can indicate a possible error in $\Delta H_f$ for a given member, or an incorrect structure assignment based on observations other than a $\Delta H_f$.

Figures 3 to 7 are plots of $\Delta H_f$(ion) versus the logarithm of the total number of atoms for members of multiple-substitution series. To facilitate comparison of different groups Figs. 3 to 6 are drawn on the same scale. Figure 3 shows the effect on ionic heat of formation of successive substitution of -$CH_3$, -$OCH_3$, and -OH in $CH_3^+$; data for all members are available (see Appendix). Good straight-line plots are obtained for each substituent. The OH-substitution line is steeper than that for -$OCH_3$, but it should be emphasized that this shows that -OH is the more effective stabilizing group *per atom*. Thus, when correlating ionic heats of formation, the *size* of the substituent group is an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

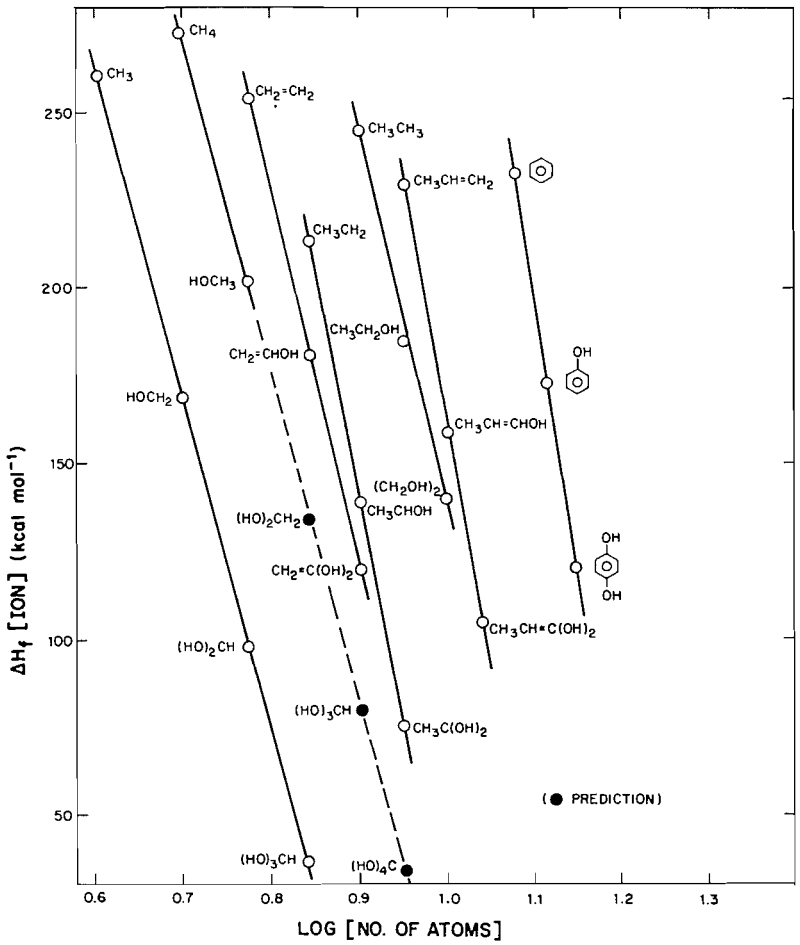

FIG. 7. $\Delta H_f$(ion) for successive substitution of -OH at charge bearing sites in odd and even electron ions vs. log (no. atoms).

important parameter, as well as its specific nucleophilic character.

Figure 4 shows six series for multiple substitution of $-CH_3$ at charge bearing sites in odd- and even-electron cations. Although, as mentioned above, the log plot begins to fail for the higher members of some series, it is evident that the slopes of the lines are closely similar. Thus to a first approximation $-CH_3$ substitution in a series produces an effect which is *only* dependent upon the *size* of the resultant ion.

In Fig. 5, the effect of $-CH_3$ substitution on $\Delta H_f$(ion) is illustrated for four multiple-substitution series. For three of these, the substitution is at either a charged carbon atom, or in contact with a charge-delocalized $\pi$-system, and the $\Delta H_f$(ion) values lie on good straight lines of approximately equal slope. In the fourth series (indicated by triangles in Fig. 5) the substitution is at a site *remote* from the charge, which here is localized in the double bond; the substitution of $-CH_3$ has in this case only a relatively small effect, the greater part of which arises from the changes in $\Delta H_f$(neutral). It is clear that for such remote substitutions, the present method will not give satisfactory estimates of $\Delta H_f$(ion).

Figure 6 similarly displays the effect of multiple-substitution of $-OCH_3$ for five series. One series has a missing member $[CH_2{=}C(OCH_3)_2]^{+\cdot}$, whose $\Delta H_f$(ion) can be predicted from the graph to be $\sim$ 127 kcal mol$^{-1}$.

In Fig. 7 the effect of successive substitution of -OH is illustrated for seven series of ions. The slopes of the lines are not quite identical but, nevertheless, the points are colinear for each series, permitting prediction of $\Delta H_f$-values. For instance, based on the line through the two available points for the series $CH_4$, $CH_3OH$, etc., one can predict that the heats of formation of the remaining members of this series, the as yet unknown ions $[(HO)_2CH_2]^{+\cdot}$, $[(HO)_3CH]^{+\cdot}$, and $[(HO)_4C]^{+\cdot}$, are approximately 134, 80, and 34 kcal mol$^{-1}$ respectively.

## Appendix: ionic heats of formation (kcal mol$^{-1}$)

Unless given below, all $\Delta H_f$ values are from ref. 15 and are $\Delta H_{f298}$ corrected, where appropriate, from $\Delta H_{f0}$.

Odd electron ions

| Species | $\Delta H_f$ | | Species | $\Delta H_f$ | |
|---|---|---|---|---|---|
| $(CH_3)_2C{=}CH_2$ | 209 | (1) | $CH_2{=}CHOCH_3$ | 179 | (18) |
| $(CH_3)_2C{=}CHCH_3$ | 190 | (1) | $CH_3OCH_2CH_3$ | 172 | (1) |
| $(CH_3)_2C{=}C(CH_3)_2$ | 174 | (1) | $CH_3OCH(CH_3)_2$ | 157 | (1) |
| $HOCH_2CH_2OH$ | 142 | [a] | $CH_2(OCH_3)_2$ | ~137 | [b] |
| $(CH_3)_2CO$ | 172 | (1) | $CH(OCH_3)_3$ | 90–95 | [c] |
| $CH_2{=}CHOH$ | 181 | (17) | $CH_3C(OCH_3)_3$ | ~86 | [d] |
| $CH_2{=}C(OH)_2$ | 120 | (18) | $C_6H_4(OH)_2$ | 120 | [e] |
| $CH_3CH{=}C(OH)_2$ | 105 | (18) | $CH_2{=}C(OCH_3)CH_3$ | 164 | [f] |

[a] $\Delta H_f[HOCH_2CH_2OH] = -92.6$ kcal mol$^{-1}$ (13), and IE (this work) = 10.16 eV.
[b] $\Delta H_f[CH_2(OCH_3)_2] = -83.2$ kcal mol$^{-1}$ (13) and IE ~ 9.5 eV(est.).
[c] $\Delta H_f[CH(OCH_3)_3] = -130.2$ kcal mol$^{-1}$ (13) and IE ~ 9.5 eV(est.).
[d] $\Delta H_f[CH_3C(OCH_3)_3] = -137$ kcal mol$^{-1}$ from additivity (2) and IE (this work) = 9.65 eV.
[e] $\Delta H_f$[1,4-dihydroxy benzene] = −63.4 kcal mol$^{-1}$ (13) and IE = 7.95 eV(19).
[f] From IE this work = 8.64 eV, $\Delta H_f[CH_2{=}C(OCH_3)CH_3] = -34.9$ kcal mol$^{-1}$ by additivity (2).

Even electron ions

| Species | $\Delta H_f$ | | Species | $\Delta H_f$ | |
|---|---|---|---|---|---|
| $CH_3$ | 261 | (4) | $CH_3C(OH)_2$ | 75 | [h] |
| $CH_3CH_2$ | 216 | (4, 6) | $CH_3CHOH$ | 139 | (8) |
| $(CH_3)_3CH$ | 191 | (4, 6) | $(CH_3)_2COH$ | 120 | (8) |
| $(CH_3)_3C$ | 166 | (4, 6, 20) | $CH_3OCH_2$ | 157 | (8) |
| $CH_2OH$ | 168 | (8) | $(CH_3O)_2CH$ | 97 | [i] |
| $CH(OH)_2$ | 98 | [g] | $(CH_3O)_3C$ | 53 | [j] |
| $C(OH)_3$ | 37 | [k] | | | |

[g] From proton affinity PA [HCOOH] = 178 kcal mol$^{-1}$ (21).
[h] From PA [$CH_3COOH$] = 187 kcal mol$^{-1}$ (21).
[i] From AE (this work) $m/z$ 75 $[C_3H_7O_2]^+$ from $CH_3CH(OCH_3)_2 = 9.74$ eV; $\Delta H_f[CH_3CH(OCH_3)_2] = -93.1$ kcal mol$^{-1}$ (13).
[j] From AE (this work) $m/z$ 105 $([C_4H_9O_3]^+$ from $(CH_3O)_3CCH_3 = 9.86$ eV and from $(CH_3O)_3CH = 10.22$ eV. $\Delta H_f[(CH_3O)_3CCH_3] = -141$ kcal mol$^{-1}$ and $\Delta H_f[(CH_3O)_3CH] = -130.2$ kcal mol$^{-1}$ (13).
[k] From AE (this work) $m/z$ 63 $[CH_3O_3]^+ = 11.72$ eV from diethyl carbonate; neutral fragments $C_2H_4$ and $CH_2{=}\dot{C}H$ ($\Delta H_f = 68$ kcal mol$^{-1}$ (11)).

Received December 22, 1981

R. H. MARCHESSAULT, SUZANNE COULOMBE, HIROMICHI MORIKAWA, and DANIELLE ROBERT. Can. J. Chem. **60**, 2372 (1982).

Exploded wood lignin (EXWL) was extracted from moist steam hydrolysed aspen (*Populus tremuloides*) wood using methanol. The lignin was examined by elemental analysis, gel permeation chromatography, infrared spectroscopy, proton and $^{13}C$ nmr. The observed nmr spectra were compared with those of aspen milled wood lignin (MWL). Typical composition of the material is $C_9H_{9.2}O_{2.7}(OCH_3)_{1.1}$. Assignment of all the signals in the nmr spectrum led to the conclusion that the explosion process causes cleavage of the β-aryl-ether bond. The weight average molecular weight was found to be 1700–1900 and the polydispersity 2.6. The finely divided exploded wood was soluble in 90% methanol/water mixtures to well beyond 20% by weight at room temperature.

R. H. MARCHESSAULT, SUZANNE COULOMBE, HIROMICHI MORIKAWA et DANIELLE ROBERT. Can. J. Chem. **60**, 2372 (1982).

Utilisant le méthanol, on a extrait la lignine de bois éclaté (LBE) de bois de peuplier (*Populis tremuloides*) hydrolysé par de la vapeur humide. On a étudié la lignine en faisant appel à l'analyse élémentaire, à la chromatographie par permation sur gel, à la spectroscopie infrarouge et rmn du proton et du $^{13}C$. On a comparé les spectres de rmn observés à ceux de la lignine du bois moulu de peuplier (LBM). La composition typique du produit est: $C_9H_{9,2}O_{2,7}(OCH_3)_{1,1}$. L'identification de tous les signaux du spectre de rmn conduit à conclure que le processus d'explosion provoque une rupture de la liaison éther en β du groupe aryle. Le poids moléculaire moyen est de 1700–1900 et la polydispersité est de 2,6. Le bois explosé finement divisé est soluble dans des mélanges à 90% méthanol/eau jusqu'à des concentrations allant au-delà de 20% en poids à la température ambiante.

[Traduit par le journal]

## Introduction

A new class of lignin material is appearing in the published literature at this time (1–3). The principal characteristics of these "emerging lignins" are: (*i*) extensive solubility in simple organic solvents and (*ii*) average molecular weights corresponding to oligomeric size molecules. By contrast, lignins from waste pulping liquors have been subjected to extensive exposure to base or acid and as a result may have undergone repolymerization (3) and chemical transformation. Certainly the sulphonic acid groups of the familiar lignosulfonates are known to result from the action of pulping reagents.

Milled wood lignin (MWL) is recognized as an isolated lignin which most closely resembles the true native lignin. The reported (4) molecular weight of 11 000 for the material extracted in dioxane or other neutral solvents and its characteristic nmr spectrum will be used as a reference material in this study.

It is important to note that lignin does not have a regular repeating unit. Nevertheless it is possible to characterize hardwood lignins by the fact that 65% of the interunit linkages are of the aryl-ether type (5). In general it is reported to be a non-linear macromolecule (4, 5). Basic differences between softwood and hardwood lignins relate to the presence of syringyl and guaiacyl groups in hardwoods while softwood lignin has only guaiacyl. Furthermore, in softwood lignins only 45% of the interunit bonds are of the β-aryl-either type.

In this study we will review characterization of organic solvent soluble lignin obtained by explosion of aspen wood (1, 2), which will be referred to as EXWL. The explosion process (6) is a steam hydrolysis at high temperature (220–240°C) and at 600 psi of wood materials followed by mechanical shock and quench to room temperature and atmospheric pressure. Due to the natural acidity of wood, the reaction takes place at acid pH. The process destructures and comminutes the wood tissue and rapidly terminates the chemical reactions underway. The product of this explosive hydrolysis is a finely divided cellulose which retains its intrinsic crystallinity but has been destructured in terms of wood morphology (1). The material is dark brown with a consistency of potting

soil with about 50% moisture. The various experiments which will be described below are based on a fractionation of the explosion product according to a published scheme (2) which involves: (*a*) water extraction to remove the hemicelluloses and some water soluble lignin; (*b*) alcohol extraction of lignin from the moist residue leaving celulose contaminated with a few percent of lignin and some hemicellulose.

## Experimental

*Lignin samples*

The aspen (*Populus tremuloides*) EXWL sample was prepared by methanol extraction of the moist (50% $H_2O$) exploded wood followed by fractional precipitation with distilled water and drying in air (1, 2). The EXWL was provided by E. A. DeLong of 15 Milne Crescent, Kanata, Ontario, Canada; the explosion process and fractionation follow a preferred description disclosed by him (6): "500–700 psi and 200–238°C (in particular 234°C) achieved in less than 60 s (preferably 45 s)".

*Ultraviolet and infrared spectroscopy*

Ultraviolet spectra of EXWL were recorded at a concentration of 0.0027% in methanol on a "Unicam SP 1700". Infrared spectra were recorded on a Beckman IR 4250 using the KBr disk method.

*Nuclear magnetic resonance spectroscopy*

$^1H$ nmr spectra were recorded at 250 MHz on a CAMECA spectrometer.

$^{13}C$ nmr spectra were recorded at 62.9 MHz on a BRUKER WM250 spectrometer using the FT mode. The protons were broad band decoupled. In both cases the samples were examined at a concentration of 14.5% in DMSO-$d_6$ and the spectra were recorded at a temperature of 333 K. All chemical shifts ($\delta$) are downfield from TMS.

*Intrinsic viscosity*

The intrinsic viscosities of EXWL were determined using an Ubbelohde viscometer. Measurements were made at 25°C at concentrations of 1.1% to 4.7% in methanol, acetone, and pyridine.

*Elemental analyses*

Lignin samples were analysed for C, H, O, and methoxyl content by Schwarzkopf Microanalytical Laboratory, Inc., New York, NY.

*Gel permeation chromatography*

Gel permeation chromatography was carried out using equipment made by Toyo-Soda (TS). The sample was dissolved in tetrahydrofuran at a concentration of 0.525%. Fractionation was achieved by using a combined column polystyrene gel (TSKG4000H8 + G2000H8 or G2500H8X2; Toyo-Soda, Tokyo, Japan) packed in a stainless steel tube (7.5 mm id × 120 cm long) and a sample flow-rate of 1.0 to 1.1 mL at room temperature. The eluant was monitored by differential refractometry (TSKRI-8) and light scattering (TSKLS0-8).

## Results

*Chemical composition of EXWL*

Based on elemental analysis (2), the typical composition of aspen EXWL is $C_9H_{9.2}O_{2.7}(OCH_3)_{1.1}$. Recently, Chua and Wayman (3) have reported aspen MWL of the composition of $C_9H_{8.70}O_{3.05}(OCH_3)_{1.47}$. This indicates that EXWL is a "modified" lignin and characteristically has a low methoxyl content.

The ultraviolet absorption spectrum of aspen EXWL has been reported previously (2). The spectrum is characteristic of phenolic compounds but the absorption maximum is observed at a higher wavelength (238 nm) than is reported for aspen lignin (6, 7). Table 1 lists the absorption coefficient ($E\%_{cm}$) of EXWL at various wavelengths. This table also contains the results of MWL of hardwoods and softwoods reported by Sarkanen *et al.* (8, 9). The absorption coefficient of EXWL is considerably higher than that of hardwood MWL throughout the region of 260 nm to 350 nm and higher or comparable to softwood MWL. The lower absorption coefficient of hardwood MWL at 280 nm, as compared to softwood MWL, is attributed to the presence of syringyl groups in the former lignin (9, 10). In hardwoods, lignins show a high absorption coefficient (maximum values in hardwood MWL in Table 1), which is attributed to the *p*-hydroxybenzoate groups in the lignins (13).

Typical infrared spectra of aspen EXWL are shown in Fig. 1. The spectra showed characteristic "lignin bands", e.g. at 1600 $cm^{-1}$ and 1510 $cm^{-1}$ which are due to aromatic groups (2). Depending on the explosion conditions the spectra showed a difference in the 1700–1750 $cm^{-1}$ region (see

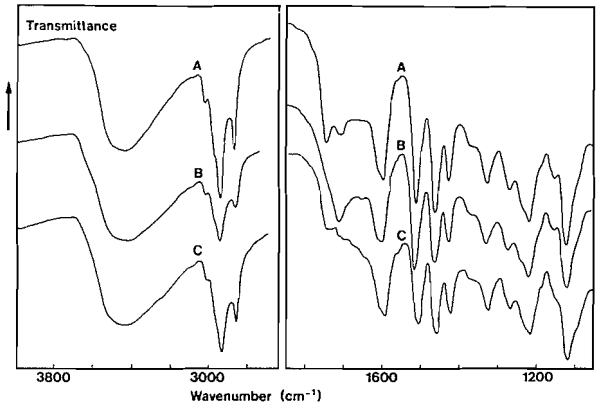

FIG. 1. Infrared spectra of aspen exploded wood lignins before (*A*, *B*) and after (*C*) saponification.

Fig. 1). In one case (spectrum *A*) two bands at 1710 $cm^{-1}$ and 1745 $cm^{-1}$ were observed while the latter band was very weak or not observed in the other (*B*). These bands are assigned to unconjugated carbonyl groups (11, 12). Saponification of EXWL with 0.1 *N* NaOH for 24 h at room temperature decreased the intensities of these bands but significant absorptions remained at these frequencies (*C*). This indicates the presence of unconjugated ketone and/or aldehyde groups as well as carboxyl ester groups in aspen EXWL. In the spectra of lignin preparations including MWL and solvolysis lignins, the bands observed at 1710–1750 $cm^{-1}$ are attributed to unconjugated carboxyl ester groups (6, 13) or unconjugated aliphatic or β-ketone groups (12, 14–18). It should be noted that in the reported lignin spectra the bands due to conjugated carbonyl groups are observed at 1660–1670 $cm^{-1}$ whereas only background absorption was detected in this region of the spectrum of EXWL.

The relative intensities of the unconjugated carbonyl bands in aspen EXWL were higher (about two times) than in the aspen MWL (6, 13). Based on differential infrared spectra of lignins in woods and pulps, Bolker (15, 19) has shown that unconjugated β-ketone groups in isolated lignins are formed during solvolytic isolation. Recently, Lora and Wayman (20) have shown that heating of aspen MWL at low pH increased the absorption intensity of the infrared band attributable to unconjugated β-keto and carboxylic acid groups in the lignin. Thus the results suggest that the explosion process causes some bond-breakage or bond rearrangement resulting in increased carbonyl groups in the lignin fraction.

The proton nmr spectra of MWL and EXWL from aspen are shown in Fig. 2 and assignments are made in Table 2. Comparison of the spectra shows the presence of typical lignin resonances (4, 21–24), e.g. signals *6* and *10*, respectively, are due to protons of methoxyl and aromatic groups. It is noteworthy that a weak, but distinct peak at 5.3 ppm is observable in EXWL, supporting the idea that phenyl coumaran structures are still present in this lignin (22, 26). The addition of $CF_3COOD$ shifted the hydroxyl protons (signal *5*) downfield (21, 25) whereas previously they resonated at 3.4 ppm. There are, nevertheless, important differences in the two spectra: (*i*) signals of saturated aliphatic side chain protons between 0.9 and 2.2 ppm are more intense in EXWL than in MWL which suggests that the side chains in $C_9$ units are saturated or reduced in EXWL; and (*ii*) signals between 4.2 and 5 ppm corresponding to H-α, H-β, and H-γ attached to carbons involved in aryl-ether bonds or hydroxyl bonds become very weak in EXWL. This suggests that β-O—4 linkages have been split and comparison of the $^{13}C$ spectra (see below) strongly supports this interpretation.

The $^{13}C$ nmr spectra of aspen MWL and EXWL are shown in Fig. 3. The assignment of the peaks in the spectra (Table 3) was made based on comparison with the results of lignin model compounds and native lignins reported by Nimz (5), Ludemann and Nimz (27), and Gagnaire and Robert (28). The nomenclature used in this study (Fig. 4) is the same as that used by previous authors (5).

*Carbonyl and carboxyl carbons*

Signal *2*, at 191.7 ppm, is strong in the EXWL spectrum but is very weak in the MWL spectrum, it can be assigned to α-carbon aldehyde groups in syringyl structure; this assignment is in keeping with the relatively greater intensity of signal *16* in EXWL. There are no carbonyl signals in EXWL spectrum towards 200 ppm which could be assigned to unconjugated ketone groups although the infrared spectrum indicates the presence of such groups. Signals *3*, *4*, and *5* between 160 and 169.5 ppm correspond to carboxylic carbons (as in esters) and they are particularly important in MWL but they are absent in EXWL.

*Aromatic carbons*

The major differences between the two spectra concern: (*i*) signal *6*, typical of C-3/C-5 carbons in etherified syringyl units, is definitely less intense in EXWL than in MWL; (*ii*) signal *8*, assigned to C-3

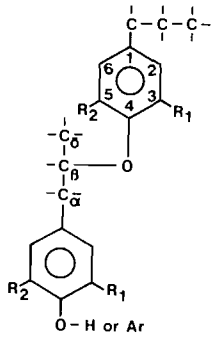

FIG. 4. The β-aryl-ether type (β-O—4) linkage in lignin (ref. 5). Guaiacyl unit: $R_1 = OCH_3$, $R_2 = H$; syringyl unit: $R_1 = R_2 = OCH_3$.

in non-etherified guaiacyl units and C-3/C-5 in non-etherified syringyl, is more intense in EXWL than in MWL; and (*iii*) signal *7*, assigned to C-4 in etherified guaiacyl units, disappears in the EXWL spectrum.

These observations indicate that EXWL is characteristically de-etherified as compared to MWL. This fact is confirmed in the EXWL spectrum by the near disappearance of signals *13* and *15*. On the other hand, signal *14* is relatively more intense in EXWL than in MWL which supports the idea that in addition to an increase of non-etherified units there is an increase of *p*-hydroxyphenyl units. This is confirmed by the somewhat lower methoxyl content for EXWL compared to MWL (cf. below).

*Aliphatic carbons*

Compared to MWL, signals *18*, *19*, and *21* in the EXWL spectrum are significantly weaker. Since these are assignable to C-β, C-α, and C-γ carbons of the propane side chains when β-O—4 linkages are present, the de-etherification must occur at the β-O—4 linkage as a result of the explosion process. This is a reasonable consequence of the predominance of α- and β-aryl-ether linkages (5) and their reported weakness of such linkages in lignin solvolysis studies (5, 29). It has also been reported (30) that the thermal stability of alkyl–aryl linkages is less in hardwoods than in softwoods which is in keeping with the lack of success of the explosion process with gymnosperms.

Methoxyl signals: the resolution of the spectrum allows observation of two distinct signals, *22* and *23*, which are assigned respectively to $—OCH_3$ syringyl and $—OCH_3$ guaiacyl groups; the chemical shifts of these signals and their multiplicity (quartets) support these assignments. An approximate quantitative estimation of the ratio $G_{OCH_3}/S_{OCH_3}$ yields 0.40 and 0.33 for MWL and EXWL, respectively, which suggests that slightly more guaiacyl moieties than syringyl are affected by the explosion process.

Finally, the peaks between 21 and 33 ppm which are due to aliphatic carbons are stronger in the EXWL spectrum than in that of MWL. Signal *26* corresponds to a $—CH_3$ group. This indicates the presence of a saturated propane side chain in EXWL which agrees with the proton nmr results as described above.

*Explosion temperature and chemical composition*

One of the important variables in the explosion process is the maximum temperature prior to pressure release ("explosion temperature"). Because of the short processing period it is not possible to achieve a true equilibrium state, hence pressure was set as rapidly as possible (~630 psi) while time was varied in a sequence of runs which probed the effect of explosion temperature. In no case was the total time more than 60 s. A series of lignin samples derived from exploded wood which had been prepared at different explosion temperatures was examined. These lignins were subjected to elemental and methoxyl analysis. The results of these analyses are shown in Figs. 5 and 6.

The most striking feature of the data is the sharp inflection in the curves at about 235°C. Since the process literature (6) states that 234°C is an optimum temperature for achieving desirable properties such as lignin solubilization and enzyme accessibility of the cellulose (2), the inflection point

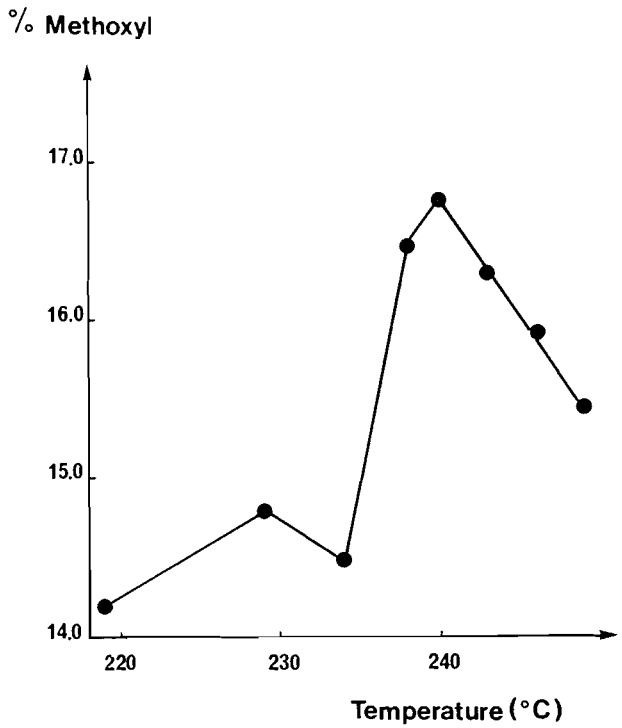

FIG. 6. Methoxyl content of aspen exploded wood lignin plotted against "explosion temperature".

probably has significance in terms of the combined chemical and morphological changes which are taking place. The variation in properties, however, reflects the variation in composition of the extracted lignin and no attempt is made to interpret these results since the total lignin in each sample was not analysed.

*Molecular weight distribution*

Based on the vapor phase method, the number-average molecular weight, $M_n$, of aspen EXWL was found to be 700 g/mol which roughly corresponds to four phenylpropane units (2).

The intrinsic viscosity, [η], values of EXWL in different solvents are listed in Table 4. In general these values are lower than those obtained for aspen autohydrolysis lignins (3) or other lignin preparations (31). The Huggins constant, $k'$ (see Table 4), and the intrinsic viscosities indicate that the "better solvent" for EXWL is in the order: pyridine > methanol > acetone.

A typical gel permeation chromatogram of EXWL is shown in Fig. 7 where the eluant was monitored by differential refractometry (RI) and light scattering (LS). The chromatogram can be divided into five fractions. Table 5 lists molecular

TABLE 4. Intrinsic viscosity, [η], of aspen exploded wood lignin expressed in dL/g; $k'$ is the Huggins constant

| Solvent | [η] | $k'$ |

weight ($M$) ranges (using polystyrene standards) of EXWL obtained by two different column systems. It is clear that about one-third of EXWL is "high" molecular weight ($M$ = 1300–7000) and about two-thirds have molecular weight less than 1300. From these data, the weight-average molecular weight, $M_w$, of EXWL was found to be 1700–1900 and thus the polydispersity, $M_w/M_n$, is 2.4 to 2.7. These molecular weight results and polydispersity estimates are much lower than observed for autohydrolysis lignins (3) or lignosulfonates (32) but similar to the values obtained for kraft lignins (33, 34).

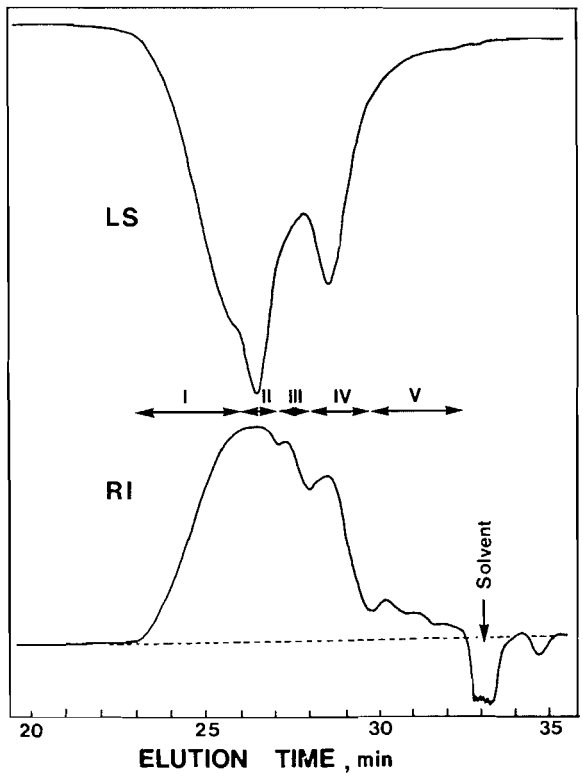

FIG. 7. Gel permeation chromatogram of aspen exploded wood lignin. The combined column (TSKG4000H8 + G2000H8) was used. Elution volume = 1.1 mL × elution time. See text for detail.

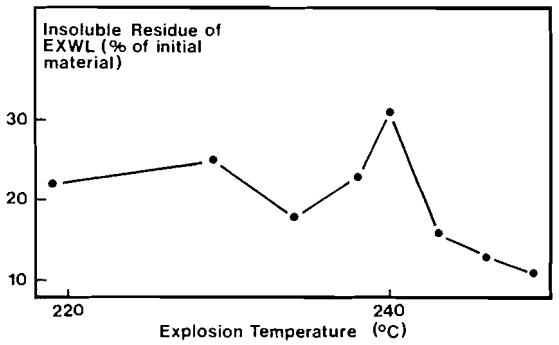

FIG. 9. Insoluble residue of aspen exploded wood lignin in 100% methanol plotted against "explosion temperature". The final concentration of lignin was about 1% and other conditions are as in Fig. 8.

*Solubility of EXWL*

The sample (0.05 to 1.0 g) was added to 5 mL of methanol containing 10% of water and allowed to stand for 24 h at room temperature with occasional stirring, after which the solution was warmed (at 40°C for 15 min) and then filtered. The concentration of the lignin in the solution was estimated from the amount of insoluble residue. From Fig. 8 it is clear that EXWL is dissolved almost linearly up to the concentration of 20% which was the maximum studied.

It should be noted that although the lignin preparations used here were obtained by extraction with methanol followed by precipitation and drying (see Experimental Section), they were found not completely soluble in 100% methanol (Fig. 9). This suggests some effect of drying on the lignin solubility and stresses the importance of water in methanol for achieving full solubility.

During the course of this work the solubility of EXWL in *N*-methylmorpholine *N*-oxide (MMNO), a new solvent for cellulosic materials (35, 36) was tested. The patent literature (36) vaguely specifies MMNO as a solvent for lignin as well as cellulose. A periodate lignin (kindly provided by D. A. I. Goring of the Pulp and Paper Research Institute of Canada) when tested by us was found to be insoluble in the MMNO monohydrate (Eastman Kodak). However, EXWL was soluble at least to 5% by weight in this solvent. Furthermore the exploded wood itself is also soluble in the same solvent and from this solution a thin film could be coagulated in $H_2O$. This film showed the typical characteristics of regenerated cellulose by infrared spectroscopy and X-ray analysis methods (37).

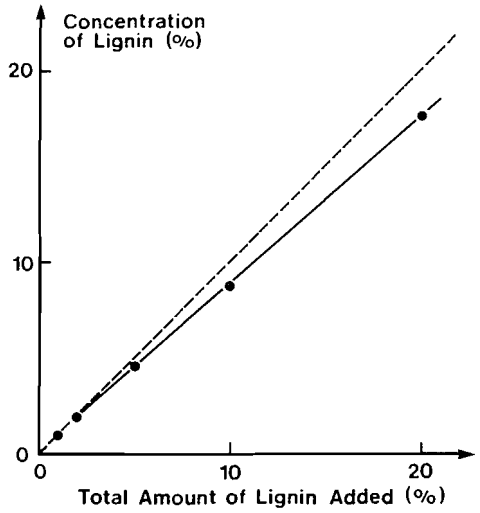

FIG. 8. Solubility of aspen exploded wood lignin in 90% methanol (see text).

## Discussion

The results of this study serve to show how critical reactor variables such as explosion temperature are likely to influence the chemical composition of lignin from the explosion process. Nevertheless the basic structure remains lignin and the compositional changes are of a quantitative nature only. This is important for those who plan biomass strategies especially in terms of chemical uses of lignin. In addition to the chemical composition variation, one can surely expect some changes in molecular weight and polydispersity as a function of explosion temperature. It is noteworthy that the polydispersity of the molecular weight of EXWL is less than reported for autohydrolysis lignin (3). This is not unexpected because the

For personal use only.

explosion reaction is likely to have been more homogeneous with less opportunity for repolymerization.

From comparative evaluation of the $^{13}C$ spectra for MWL and EXWL it has been possible to conclude that cleavage of the β-O—4 ether bonds has been extensive in the latter material. This will have the effect of increasing the hydrocarbon nature of the carbon chain attached to syringyl and guaiacyl units. At the same time, the concentration of phenolic hydroxyl groups is increased, hence the amphiphilic character of the lignin is heightened. This fact, along with the expected increase in solubility as the molecular weight is lowered (also due to β-O—4 bond cleavage), accounts for the unusual alcohol solubility of EXWL. This property alone could allow numerous applications for this lignin which have not been possible to consider with less soluble product. For example, usage of lignins as copolymerization oligomers is ideal when all starting reactants are soluble.

EXWL can be considered a typical biomass lignin, i.e., it is easily separable from the wood mass following a simple pretreatment of the wood. This pretreatment must unlock the nascent clasp between lignin and cellulose without major loss of their chemical identity. Pretreatment processes to create a "chemicals from wood" economy often depend on a subsequent microbiological transformation of carbohydrate polymers. To achieve high carbohydrate accessibility by enzymes in lignocellulosics the removal of lignin has generally been necessary (38). One of the properties of exploded wood is a remarkable increase in enzyme accessibility (1) of the carbohydrate fraction as a result of the pretreatment. Given the results of this study, it is clear that enzymatic accessibility of cellulose is due to destructuring of the composite relation of lignin matrix and fiber. More important still, the hydrolytic cleavage and high temperature induce a coalescence of the lignin into micron-size domains (1), leaving an accessible cellulose surface. With major restructuring of its topology, the lignin of exploded wood no longer blocks the access of enzymes to the inner cellulose surface of woody fibers (1, 39). Similarly, the substrate has enhanced accessibility to other reagents because the intimate cellulose/lignin interface has been largely eliminated.

## Acknowledgements

The authors acknowledge important assistance from Toshihiko Hanai and Jean St. Pierre of the Chemistry Department, University of Montreal. One of us (D.R.) is indebted to Professor D. Gagnaire, Director of the CNRS Institute, C.E.R.M.A.V., and to Dr. H. Chanzy of the Institute for stimulating encouragement in the development of this study. The work was supported by an NSERC thematic grant, by financial support from NRC's IRAP, and by the Ministère de l'Education du Québec. One of us (R.H.M.) profited from stimulating discussions and helpful criticism from S. Malhotra of Xerox Research Centre of Canada. Finally, we thank the Centre Grenoblois de Résonance Magnétique for providing the nmr facilities.

## Introduction

L'activité anticancéreuse de la sarkomycine (**1**, l'acide méthylène-2 oxo-3 cyclopentanoïque) est reliée à la présence de trois groupements vicinaux: carbonyle, méthylène exocyclique et carboxyle. Nous avons synthétisé cet antibiotique (1) ainsi que son analogue cyclohexanique (2). Le bis-nor-4,5 sarkomycine, (**2**, l'acide méthylène-2 oxo-3 cyclopropanoïque) est le plus petit cycle qui puisse porter ces trois fonctions. Ce composé peut être obtenu, en principe, par l'addition des carbènes ou des carbènoïdes aux oléfines convenablement substituées.

La liaison double exocyclique du produit **2** peut en principe être obtenue par isomérisation de la liaison double endocyclique du produit **3** avec des bases fortes par analogie en système cyclopentanique et cyclohexanique par exemple (3). Ceci permet donc d'envisager les trois synthèses suivantes: (*i*) l'addition du chlorométhylcarbène (**4**) à l'acétale du dicyano-2,2 cétène (**5**); (*ii*) l'addition du dichlorocarbène (**7**) au butyne-2 oate d'éthyle (**6**); (*iii*) l'addition du chlorocarbométhoxycarbène (**8**) au diéthoxy-1,1 propène (**9**); et une quatrième, la réaction de Wittig modifiée, semblable aux trois précédentes dans un contexte carbènique de ce travail entre (*iv*) l'époxy-2,3 butenoate d'éthyle (**10**) et le triphényldichlorométhyle phosphate (Schéma 1).

Les produits obtenus dans les quatre réactions devraient pouvoir être transformés par l'hydrolyse de CN, la décarboxylation du diacide geminal, le déblocage de la fonction acétale ou cétale, l'hydrolyse du système dichloro geminal, l'élimination de HCl, l'hydrolyse de l'ester et finalement l'isomérisation *endo–exo* de la liaison double en produit **2**.

## Résultats et discussion

Les carbènes s'additionnent très bien aux alcènes (4), cependant leur addition aux alcynes, possèdant un caractère moins nucléophile, s'effectue avec plus de difficulté. De plus, la nucléophilie des carbènes varie en fonction de leur substitution. Ainsi la réactivité d'une espèce carbènique avec l'accepteur de ce carbène dépend de la compatibilité (affinité) électronique respective. Les facteurs stériques imposent davantage de restrictions à cette réactivité, cependant, compte tenu des objectifs synthétiques, ce facteur devient important seulement dans le cas du produit **5**.

La protection de la fonction carbonyle dans la synthèse du produit **2** (ou **3**) par la route carbènique est nécessaire à cause de l'addition possible du carbène au carbonyle et pour protéger les cyclopropanones obtenues contre les réactions de la décarbonylation (5),polymérisation, etc. Dans les synthèses proposées, nous protégeons les fonctions carbonyles par des groupements dihalogéminaux ou par cétalisation.

### *(i) L'addition du chlorométhylcarbène (4) à l'acétale du dicyano-2,2 cétène (5)*

Cette route est complètement inefficace. Le produit **4** formé *in situ* ne réagit pas avec **5** mais donne exclusivement les produits de la polymérisation et d'homologation. Nous avons fait varier la température de la réaction de −50 à 25°C et le rapport de **4**/**5** de 10:1 à 40:1 sans succès. D'ailleurs, la réaction entre **4** et du tétracyano-1,1,2,2 éthylène, ne donne pas non plus le produit d'addition désiré. Cependant le produit **5** réagit avec le dichloro méthyllithium en donnant l'acétal du dicyano-1,1 chloro-2 cyclopropanone (**13**) avec un faible rendement de 2%. Le produit envisagé originalement, l'acétal du dicyano-1,1 chloro-2 méthyle-2 cyclopropanone (**14**), demeure cependant inaccessible à partir du produit **13** à

[1]Révision reçue le 14 mai 1982.

SCHÉMA 1

cause de l'incompatibilité du carbènoïde et de l'oléfine.

*(ii) L'addition du dichlorocarbène (7) au butyne-2 oate d'éthyle (6)*

Le butyne-2 oate d'éthyle (**6**), synthétisé d'après la méthode de Denny et Ross (6), réagit avec le dichlorocarbène **7** en formant l'ester éthylique de l'acide méthyl-2 dichloro-3,3 cyclopropanoïque (**15**) (rendement 15%). La formation du produit **15** n'est pas observée quand on remplace l'acétate de sodium par une solution de phényl bromodichlorométhyl mercure en présence de mailles moléculaires.

L'hydrolyse du produit **15** mène à l'ester éthylique de l'acide méthyl-2 oxo-3 cyclopropènoique (**20**) avec un rendement de 40%. Les produits majeurs des réactions de cette série sont des polymères. Les composés **15** et **20** montrent les signaux de groupement méthyl-2 dans le spectre de rmn à 2.18 et 0.92 respectivement. La présence du groupement *gem*-dichloro déplace le signal de l'ester de 3.66 à 4.22 ppm.

*(iii) L'addition du chlorocarbométhoxycarbène (8) au diéthoxy-1,1 propène (9)*

Ce carbène, préparé à partir du phényl dichlorocarbométhoxyméthyl mercure, offre la voie la plus prometteuse pour la préparation du système de bis-nor-4,5 sarkomycine. Les rendements de l'addition dans ce cas, ainsi que pour l'addition du carboéthoxycarbène à la même oléfine, sont de l'ordre de 40%. Il est donc évident que l'oléfine **9** possède un caractère nucléophile assez prononcé résultant de l'effet électrodonneur des groupements —$OC_2H_5$. Cependant la molécule **16** résiste à la deshydrohalogénation en vue d'obtenir le produit **20** avec des différentes bases utilisées. Tel est le cas aussi bien avant qu'après le déblocage de la fonction cétonique (polymères).

La même oléfine **9** réagit bien avec le carbométhoxycarbène (**11**) généré à partir du diazoacétate d'éthyle en donnant le produit modèle, l'ester éthylique de l'acide méthyl-2 diethoxy-3,3 cyclopropanoïque (**17**).

*(iv) La réaction de Wittig modifiée*

L'époxy-2,3 butanoate d'éthyle (**10**) réagit lentement avec la triphénylphosphine et le chloroforme en présence du *tert*-butanolate de potassium en formant l'ester éthylique de l'acide méthyl-2 dichloro-3,3 cyclopropanoïque (**19**). Cette réaction est une variante de la réaction de Wittig: la réaction classique mène à la formation des oléfines, cependant, l'époxyde soumis au traitement du réactif de Wittig donne le cyclopropane. Le rendement de cette réaction est de l'ordre de 50%. Le même produit, **19**, a été synthétisé par l'addition du dichlorocarbène au butène-2 oate d'éthyle (**18**). Il est à noter que l'utilisation de trichloroacétate de sodium est une source de carbène plus efficace que le phénylbromodichlorométhyl mercure. Le produit **19** traité en milieu acide donne immédiatement le produit **18** avec une perte de monoxyde de carbone.

Nous avons examiné la voie la plus simple menant à la formation du produit **3** en utilisant des carbènes. Le choix des carbènes nous semble être un facteur primordial dans la synthèse des dérivés cyclopropaniques. En plus de leur utilité indiscutable dans la synthèse des cycles à trois membres, ils montrent un certain degré de sélectivité envers l'adduit compte tenu des facteurs stériques et électroniques de ce dernier. La conversion du produit **3** en **2** qui demeure un point incertain de la synthèse fera l'objet d'une publication subséquante.

## Partie expérimentale

Les solvants ont été purifiés d'après les méthodes généralement utilisées.

Les spectres ir ont été obtenus avec un spectrophotomètre Perkin–Elmer, modèle 467, soit comme film sur plaques de NaCl soit en solution avec une cellule NaCl (données en $cm^{-1}$).

Les spectres rmn ont été enregistrés avec des appareils Varian T-60 et HR-220. Les déplacements chimiques, δ, sont exprimés en ppm (référence interne TMS) et les constantes de couplages vicinales, $J$, en Hz. Les lettres s, d, t, q et m signifient respectivement singulet, doublet, triplet, quadruplet et multiplet.

Les spectres de masse (sm) (70 eV, 250°C) ont été enregistrés à l'aide des spectromètres de masse Perkin–Elmer RMU-6D et Dupont CEC-21-491 munis d'une sonde à température variable (60–350°C).

La chromatographie sur colonne fut effectuée avec de l'alumine comme absorbant.

Le produit **5** fut synthétisé d'après la recette de Dickinson et Melby (11) (rmn: 4.84); le butyne-2 oate d'éthyle (**6**) d'après Denny et Ross (6) et Gaugh et Trippett (8) (rmn ($CDCl_3$): 2.03, (s, 3H, $CH_3$), 4.20 (q, $J$ = 7.6; 2H, $CH_2$—$CH_3$) et 1.30 (t, 3H, $CH_2$—$CH_3$, $J_{CH_2,CH_3}$ = 7.6)); le diéthoxy-1,1 propène (**9**) d'après le procédé de Walters et McElvain (9) (rmn ($CDCl_4$): 3.48 (q, 1H, $J$ = 6, C*H*), 1.53 (d, 3H, CH—$CH_3$), 3.65 (q, 2H, $CH_2$—$CH_3$) et 1.26 (t, 3H, $CH_2$—$CH_3$)) et l'époxy-2,3 butanoate d'éthyle (**10**) fut acheté chez Aldrich. Les carbènes **4**, **7** et **8** ont été synthétisés *in situ* d'après les méthodes décrites dans la littérature (4). La réaction de Wittig modifiée est modelée sur le procédé de Denny *et al.* (10).

Les nouveaux produits synthétisés **13**, **16**, **17**, **19** et **20** donnent une analyse élémentaire (C, H) satisfaisante. Ces analyses ont été effectuées sur l'appareil Beckman 915A du Département de génie de l'Université de Moncton (7).

Les chromatogrammes en phase vapeur (cpv) ont été enregistrés sur l'appareil Perkin–Elmer 990 en utilisant des colonnes: A 3% OV-1 sur Carbowax 80–120 (3 pi × 1/8 po) et B 3% SE-30 sur Chromosorb 80 (3 pi × 1/8 po).

*Acétal du dicyano-1,1 chloro-2 cyclopropanone (13)*

Dans un ballon à trois cols de 500 mL muni d'un agitateur magnétique, sous une atmosphère d'azote préséchée, fut ajouté du méthyllithium (0.1 mol) et du chlorure de méthylène anhydre (50 mL). Tout en refroidissant le mélange à environ −10°C (glace/NaCl), une solution de l'acétal du dicyano-2,2 cétène (**5**, 0.02 mol) en chlorure de méthylène anhydre fut ajoutée sur une période d'une demi-heure. La solution fut agité davantage pendant 20 h à la température ambiante.

Le mélange réactionnel fut filtré, lavé deux fois avec de l'eau distillée (25 mL), séché au sulfate de magnésium (20 g) et distillé sous pression réduite. Le produit **13** fut distillé à 90°C/0.07 Torr. Rendement.: 2%; ir: 2280, 1070, 720, 2950; rmn: 3.75 (s, 1H, C*H*Cl), 4.53 (s, 4H, $CH_2$); sm *m/z* (I%): 184 ($M^+$, 17), 186 ($M^+$ + 2, 7), 72 (100), 71 (61), 136 (50), 153 (32), 182 (13). *Anal.* calc. pour $C_7H_5O_2N_2Cl$: C 45.52, H 2.73; trouvée: C 45.23, H 2.2%

*Ester éthylique de l'acide méthyl-2 dichloro-3,3 cyclopropènoïque (15)*

Le butyne-2 oate d'éthyle (**6**, 0.03 mol) fut ajouté à une solution de diglyme (3.3 mL) en tétrachloroéthylène (13.0 mL) dans un ballon de 50 mL. Le mélange fut agité et chauffé à une température de 115°C. Ensuite, la quantité de 5.2 g de trichloroacétate de sodium (0.03 mol) fut ajoutée au mélange pendant une demi-heure. Le mélange fut maintenu à une température de 115°C pendant une demi-heure.

La solution fut refroidie, filtrée, et lavée avec de l'éthanol (100 mL, 95%). Le résidu, distillé sous pression réduite, a donné un produit **15**, 33–38°C/1.7 Torr. Rendement: 15%; ir: 760, 1700, 1900; cpv: $R_t$ 1.7 min (col. A); rmn: 2.18 (s, 3H, $CH_3$—C), 3.66 (q, $J$ = 7.2, 2H, $CH_2$—$CH_3$), 1.18 (q, 2H, $CH_2$—$CH_3$); sm *m/z* (I%): 194 ($M^+$, 33), 196 ($M^+$ + 2, 21), 198 ($M^+$ + 4, 5), 112 (100), 149 (37), 166 (21), 151 (20).

*Ester éthylique de l'acide méthyl-2 oxo-3 cyclopropènoïque (20)*

En suivant le procédé utilisé dans la synthèse de **15**, avec le butyne-2 oate d'éthyle, le mélange réactionnel fut chauffé à 125°C pendant 24 h, puis agité avec 100 mL d'eau dans une température ambiente.

La solution fut filtrée, lavée avec de l'eau distillée (25 mL) et de l'acide chlorohydrique (25 mL, 10%) et extrait avec du benzène (50 mL). Les extraits furent séchés avec le sulfate de magnésium anhydre (8.0 g), filtrés, et le solvant évaporé sous vide pour donner le produit **20** (p. eb. 42–45°/0.4 Torr). Rendement: 42%; ir: 1700, 1810, 1950; cpv: $R_t$ 4.1 min (col. A); rmn: 0.92 (s, 3H, $CH_3$), 4.22 (q, $J$ = 7, 2H, $CH_2$, $CH_3$), 1.30 (t, 3H, $CH_2$—$CH_3$); sm *m/z* (I%): 140 ($M^+$, 17), 112 (100), 95 (68), 94 (62), 43 (47), 67 (32). *Anal.* calc. pour $C_7H_8O_3$: C 60.00, H 5.71; trouvée: C 59.75, H 5.6%.

*Ester éthylique de l'acide méthyl-2 diéthoxy-3,3 cyclopropanoïque (17)*

L'acétal **9** (0.025 mol) fut introduit dans un ballon de 200 mL à trois cols contenant du cyclohexane (15 mL) et du sulfate de cuivre (0.4 g). Une solution de diazoacétate d'éthyle (0.10 mol) dans du cyclohexane (75 mL) fut ajoutée au mélange avec l'agitation vigoureuse, goutte à goutte. Le mélange réactionnel fut laissé au reflux pendant deux heures. Le mélange fut filtré, séché au sulfate de magnésium anhydre (5 g) et concentré sous vide.

Le mélange réactionnel fut distillé sous pression réduite. Le produit **17**, distillé à 140°C/0.4 Torr. Rendement: 44%; cpv: $R_t$ 6.2 min (col. B); rmn: 1.32 (d, 3H, $J_{CH_3CH}$ = 9.0, $CH_3$—CH), 1.22 (m, $J_{CH,CH}$ = 2.0, 1H, $CH_3$—C*H*), 2.78 (d, 1H, C*H*—CO), 4.13 (q, $J$ = 7.0, 4H, O$CH_2$—$CH_3$), 1.26 (t, 6H, O$CH_2$—$CH_3$), 3.54 (q, $J$ = 7.0, 2H, COO$CH_2$—$CH_3$), 1.18 (t, 3H, COO$CH_2$—$CH_3$); sm *m/z* (I%): 216 ($M^+$, 7), 161 (100), 188 (63), 187 (41), 170 (27), 142 (21). *Anal.* calc. pour $C_{11}H_{20}O_4$: C 61.11, H 9.33; trouvée: C 60.88, H 9.15.

*Ester méthylique de l'acide chloro-1 méthyl-2 diéthoxy-3,3 cyclopropanoïque (16)*

Le phényl (dichlorocarbométhoxyméthyl) mercure (0.02 mol) fut ajouté à un mélange de diéthoxy-1,1 propène (**9**, 0.03 mol) et de chlorobenzène (25 mL) dans un ballon à trois cols (muni d'un agitateur, d'un thermomètre ainsi que d'une entrée et d'une sortie d'azote séchée à l'hydroxyde de sodium). Le mélange réactionnel fut chauffé à reflux (135°C) pendant sept jours. Le produit **16** distille à 29°C/0.75 Torr. Rendement: 41%; cpv: $R_t$

3.0 min (col. A); rmn: 1.37 (d, $J = 4.0$, 3H, $CH_3$—CH), 2.22 (q, 1H, $CH_3$—CH), 3.40 (s, 3H, $OCH_3$), 4.18 (q, $J = 7.0$, 4H, $COOCH_3$—$CH_3$), 1.23 (t, 6H, $COOCH_2$—$CH_3$); sm *m/z* (I%): 236 ($M^+$, 17), 238 ($M^+ + 2$, 6), 93 (100), 200 (42), 181 (37), 205 (17). *Anal.* calc. pour $C_{10}H_{17}O_4Cl$: C 50.85, H 7.24; trouvée: C 50.65, H 7.0.

*Ester éthylique de l'acide méthyl-2 dichloro-3,3 cyclopropanoïque (**19**)*

*Méthode A*

Le triphénylphosphine (0.20 mol) fut ajouté au *tert*-butanolate de potassium (0.20 mol) et du heptane (250 mL) dans un ballon d'un litre. Le mélange fut refroidi dans un bain de glace et fut agité vigoreusement avec une agitation magnétique. Une solution comprenant du chloroforme (0.20 mol) dans du heptane (200 mL) fut ajoutée au mélange sur une période de 30 min. Le mélange réactionnel fut concentré sous vide à un volume d'environ 100 mL.

L'époxy-2,3 butanoate d'éthyle (**10**, 0.20 mol) fut ajouté au mélange réactionnel concentré et fut chauffé à 65°C pendant trois heures. Le mélange réactionnel fut distillé sous pression réduite. Le produit **19** distille à 28–29°C/0.15 Torr. Rendement: 53%; ir: 740, 1740; cpv: $R_t$ 4.4 (col. A); rmn: 1.38 (m, $J = 5.0$, $J = 1.2$, 3H, CH—$CH_3$), 3.18 (m, $J = 2.0$, 1H, $CH$—$CH_3$), 3.15 (m, 1H, $CH$—CO), 1.3 (t, 3H, $CH_2$—$CH_3$); sm *m/z* (I%): 196 ($M^+$, 31), 198 ($M^+ + 2$, 24), 200 ($M^+ + 4$, 6), 114 (100), 123 (43), 160 (40), 151 (21). *Anal.* calc. pour $C_7H_{10}O_2Cl_2$: C 42.64, H 5.12; trouvée: C 42.45, H 5.00. Analyse de Cl (tritrage $AgNO_3$) calc.: Cl 36.05; trouvée: Cl 35.1.

*Méthode B*

Le butène-2 oate d'éthyle (**18**, 0.035 mol) fut ajouté en solution de 30 mL du glyme au trichloroacétate de sodium (0.067 mol). Le mélange fut chauffé à reflux jusqu'à ce que l'évolution de $CO_2$ cesse. Le mélange réactionnel fut filtré et concentré sous vide puis distillé.

La spectrométrie de masse à température variable du mélange réactionnel a permis l'analyse détaillée des fractions obtenues par la distillation fractionnée. Le produit **19** distille à 40°C/0.3 Torr. Rendement: 17%.

## Remerciements

Nous désirons remercier le Conseil de Recherches de l'Université de Moncton pour l'appui financier accordé à ce travail et au Dr W. D. Jamieson (Conseil national de recherches du Canada, Atlantic Regional Laboratories, Halifax, N.-E.) pour l'enregistrement des spectres de masse des dérivés polychlorés avec la sonde à température variable (STCID). L'aide technique de MM. R. Coulombe, C. Vautour et R. Volpé est grandement appréciée.

# Assay of metallochromic dyes by weight titration with copper(II) using a copper(II) ion-selective electrode

B. KRATOCHVIL AND CARMELITA MAITRA

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received June 2, 1982

B. KRATOCHVIL and CARMELITA MAITRA. Can. J. Chem. **60**, 2387 (1982).

Twelve analytically useful chelating dyes were assayed by potentiometric titrations with copper(II). A copper ion-selective electrode served as end-point indicator. Use of a gravimetric titration system allowed microtitrations to be performed with relative standard deviations of the order of a percent.

B. KRATOCHVIL et CARMELITA MAITRA. Can. J. Chem. **60**, 2387 (1982).

Faisant appel à des titrations potentiométriques avec le cuivre(II), on a essayé douze colorants chélatants utiles en analyse. On a utilisé une électrode sélective pour les ions cuivriques comme indicateur de fin de réaction. L'utilisation d'un système de titrage gravimétrique permet de réaliser des microtitrages avec des déviations standard relatives de l'ordre de 1%.

Metallochromic dyes are widely used in chemical analysis. They serve as equivalence-point indicators in complexation titrimetry, as ligands forming species suitable for spectrophotometric or fluorimetric determinations of metal ions and anions, and as active components in liquid-membrane electrodes (1–4). For some applications knowledge of the purity of the dyes is necessary. Dye purity is important, for example, when measuring acid dissociation constants and metal stability constants (5–7), or when applying techniques such as the ion-increment method for the spectrophotometric measurement of free metal ion concentrations (8). In many other applications, such as indicators for titrations or as ligands for trace metal analysis by spectrophotometry, purity is not critical. Because removal of impurities is often difficult and tedious, their presence is tolerated wherever possible. Therefore most commercially available metallochromic dyes used in analysis contain moderate to high levels of both organic and inorganic impurities. Purification when done usually involves a combination of precipitation, column chromatography, or solvent extraction operations, and may require several days.

Present methods for the quantitative assay of metallochromic dyes include spectrophotometry (ref. 2, pp. 22–75, refs. 9, 10), chromatography (7, 12), and complexation, acid–base, and ion-pair extraction titrations. None of the available methods provide the speed, convenience, and precision desirable for routine analyses. Accordingly, we report here a procedure in which a standard solution of copper(II) is titrated with a solution of the dye under assay. A copper ion-selective electrode (ISE) is used to follow the titration. Most metallochromic dyes form stable complexes with copper(II), and the copper ISE provides a convenient, well-documented method of equivalence-point detection (10, 13, 14). The titrations were performed gravimetrically with small volumes of dilute solutions because of solubility limitations, and in some instances because only limited quantities of purified dye were available.

## Experimental

*Apparatus*

An Orion Model 94-29A cupric ion membrane elecrode was used as the indicating electrode. Measurements of pH were made with a Fisher glass electrode (Cat. #13-639-3). Potentials of the copper(II) and glass electrodes were measured relative to a Fisher Saturated Calomel Electrode (Cat. #13-639-52) with a Fisher Accumet Model 520 Digital pH/ion meter. The titrant was delivered from a 150-mL polypropylene bottle through a 1.6-mm id Tygon tube attached to a nipple near the base of the bottle. In operation, the bottle is placed on a Mettler Model PL-200 top-loading balance and the tube anchored to the balance housing 10 to 15 cm from the nipple with a small weight. The balance, the pH/ion meter and the valve (General Valve Corp., Part No. 2-26-900) controlling the addition of titrant, were interfaced[1] with a PDP 11/03 (Digital Equipment Corp.) minicomputer. Data readouts consisted of balance readings, weight increments of titrant delivered, corresponding electrode potential readings for each weight increment, and point-by-point titration slopes ($\Delta mV/\Delta g$).

Titrations were done in 200-mL polypropylene (Nalge Co., N.Y.) plastic beakers.

*Reagents and solutions*

The dyes were from various sources: Calmagite (CMG) (Fluka); Tiron, Xylenol Orange (XO), and Hydroxy Naphthol Blue (HNB) (Fisher Scientific Co., Fair Lawn, NJ); SNAZOXS,

Methylthymol Blue (MTB), and Eriochrome Blue SE (EBSE) (J. T. Baker Chem. Co., Phillipsburg, NJ); Alizarin Complexone (AC) and Eriochrome Black T (EBT) (Aldrich Chem. Co., Milwaukee, WI); and 1(2-Pyridylazo)-2-naphthol (*o*-PAN) (Eastman Organic Chemicals, Rochester, NY).

Titrant solutions were prepared (assuming 100% purity) to a weight molarity of about $2 \times 10^{-6}$ mol per g of solution. All dyes were analyzed as received except for CMG, which was analyzed both as received and after purification by a previously described method (9).

Stock copper(II) standard solutions were prepared by dissolving AR grade copper shot (Fisher Scientific Co., Fair Lawn, NJ) in a minimum amount of concentrated $HNO_3$. After dissolution and dilution with distilled $H_2O$, the weight of the final solution was obtained to determine the weight molarity, usually about $2.5 \times 10^{-5}$ mol Cu per g of solution.

All other reagents ($NH_4NO_3$, $NH_3$, $HNO_3$, $LiNO_3$, $CH_3CN$, and ethanol) were analytical reagent grade. Distilled water was used for all dilutions unless specified otherwise.

*Procedure*

From 0.1 to 0.25 g portions of stock copper solution (2 to $6 \times 10^{-6}$ mol) were weighed into separate beakers by difference from a Teflon-tipped glass syringe. Precisely 10 mL of 1 *M* $NH_3$ – 1 *M* $NH_4NO_3$ were added and the solution diluted to a total volume of about 100 mL. The pH of the final solution was approximately 9.3. The reference and copper indicating electrodes were inserted into the solution and the sample titrated with the dye solution. The solution was stirred magnetically throughout the titration.

Parameters for the titration, including rate of titrant delivery, equilibration time between addition of titrant increments and reading of potential, frequency of reading, allowable precision for potential and balance readouts, and end-of-titration potentials, were set using a program[1] written in FORTRAN. The actual titration was controlled by a second program,[1] also in FORTRAN. The point of greatest slope ($\Delta mV/\Delta g$) was selected as the end point for each titration.

Indicators which were not readily soluble in water (EBT, EBSE, AC, HNB) were dissolved in dilute (0.01 *M*) $NH_3$–$NH_4NO_3$ buffer. *o*-PAN, because of its insolubility in both $H_2O$ and $NH_3$–$NH_4NO_3$ buffer, was dissolved in 70:30 ethanol–$H_2O$ or $CH_3CN$–$H_2O$. For these titrations, the copper sample solutions and a salt bridge of 0.1 *M* $LiNO_3$ for the SCE were made up in the same solvent composition as used for the dye.

All titrations were done in a constant temperature room at an ambient temperature of 23.5°C.

## Results and discussion

Results of the titrations are shown in Table 1. The acid dissociation constants and the stability constants for Cu(II)–indicator complex formation have been included for ready reference in the discussion. Purities ranged from 36 to 93% except for HNB, which was only available crystallized onto sodium chloride for direct addition as a solid to titration solutions. The percentage of HNB in the sample was so low that several grams of sample were required to carry out the titration within the acceptable titrant weight range (perferably 1 to 10 g) (33). This resulted in a solution containing about 10% NaCl, in which the dye was insoluble. Addition of a small amount of $NH_3$–$NH_4NO_3$ buffer (~0.01 *M* final concentration) effected dissolution.

The sharpness of the titration end points determined the precision of the results. Examples of titration plots are shown in Fig. 1. Titrations with sharp end points included the *o*,*o*′-dihydroxyazo dyes: CMG, EBT, HNB, EBBR, and EBSE. All gave satisfactory precision. EBT and EBBR form 1:1 complexes with copper(II) with fairly high (16, 19, 22) stability constants. Combining ratios and stability constants for the other *o*,*o*′-dihydroxyazo dyes with copper(II) have not been reported, although all are known to form 1:1 complexes of moderate stability with $Ca^{2+}$ and $Mg^{2+}$ (15, 19, 21). The complexation equilibrium of AC with copper(II) does not appear to have been studied. XO and MTB have been reported to form $Cu_2In$, CuIn (1, 5, 29), and CuHIn (5) complexes. A recent study (27), however, reported for MTB the formation of $CuH_2In$ and $CuIn_2$ complexes but not $Cu_2In$. In our results, a plot of potential against weight of titrant did not show a second inflection even though the titrations were carried more than 100% past the 1:1 inflection point with both XO and MTB. The first inflections were drawn out for both, however. SNAZOXS and Tiron have been reported (20, 31) to form both CuIn and $CuIn_2$ complexes. A tendency to form a second weak complex with copper may be the cause of the drawn out end points and low precision observed for SNAZOXS and Tiron, and may have contributed to the poor end points for MTB and XO.

The titration of *o*-PAN in the mixed solvents proceeded as for the aqueous titrations. The precision was, however, poorer than that of the aqueous titrations of the *o*,*o*′-dihydroxyazo dyes. Coetzee and Istone (34) observed that the copper ISE malfunctioned in 100% acetonitrile as solvent but gave calibration plots similar to the aqueous system in mixtures of methanol, ethanol, 2-propanol, dimethylsulfoxide, propylene carbonate, or ethylene glycol with water. Rechnitz and Kenny (35), on the other hand, found the behavior of the electrode in acetonitrile to be similar to that in methanol.

As indicated in Table 1, SNAZOXS and Tiron were assayed at two concentrations. Increased precision was observed for both dyes at higher concentrations. Results at the two levels agreed well for SNAZOXS; agreement was less good with Tiron, but within experimental uncertainties for both. The higher precision at higher concentrations can be attributed to sharper end points for both dyes. Agreement between the two concentrations indicates the absence of bias in end-point selection at low concentrations.

All the plots of potential against weight of dye titrant obtained in this study were asymmetric. This has generally been observed (ref. 33, pp.

128–131, ref. 37) for complexometric titrations with ISE indication. Asymmetry in this type of titration with the copper ISE has been attributed to oxygen sensitivity of the copper electrode (38). In general, it has also been observed (37, 39, 40) that in titrations exhibiting asymmetric curves the equivalence point does not coincide with the inflection point, which could introduce systematic errors (ref. 33, pp. 128–131, ref. 37) if the peak in the first derivative plot were taken as the equivalence point. The error has generally been computed (11, 36, 37, 39, 40) to increase with an increase in the concentration of interfering ions, with a decrease in sample ion concentration (leading to non-Nernstian response), with an increase in dilution, and with a decrease in the completeness of the main reaction (low $K_{ML}$) (11, 37, 39, 40).

In this study, we selected as the end point that point corresponding to the highest slope ($\Delta mV/\Delta g$). We found this method to be the least subjective and the most reproducible. The magnitude of the error introduced by this approach could not be assessed for the commercial dyes owing to the unknown nature of the impurities present. However, the results obtained for purified CMG agreed within experimental error with previous analyses by two other methods (9). Accordingly, the method of end-point selection used here does not appear to introduce systematic error.

## Conclusions

The assay of chelating dyes by potentiometric titration with copper(II) has several advantages. One is that copper(II) reacts in a clean, stoichiometric way with most indicator ligands, forming 1:1 complexes with the dihydroxyazo dyes, and 2:1 copper-to-ligand complexes with sulfonephthaleins possessing two iminodiacetate groups attached to the phthalein unit. Another is that colored impurities which do not form complexes but would affect spectrophotometric measurements, such as unreacted starting material or coupled products not possessing chelating capability, do not interfere. A third is that the procedure is rapid and simple, so that it lends itself readily to monitoring of commercial lots of indicators, and to assessing various purification methods. Also, the titration may be performed in aqueous, nonaqueous, or mixed solvents. The method is well suited to automated weight titrations of milligram amounts of material.

M. CYGLER. Can. J. Chem. **60**, 2392 (1982).

4,7-Oxido-7-methyl-7-hydroxymethyl-2,2,6,6-tetramethylpiperidin-1-oxyl, $C_{12}H_{22}NO_3$, crystallizes in the monoclinic space group $P2_1/m$ with unit cell dimensions $a$ = 8.041(1), $b$ = 13.348(1), $c$ = 5.945(1) Å, $\beta$ = 95.90(1)°, $Z$ = 2. Intensity data were measured on a diffractometer and the structure solved by direct methods. The least-squares refinement converged at $R$ = 0.039 for 1304 reflections. Two enantiomeric molecules, differing in the position of the OH group, occupy the same site in the asymmetric unit (each with a probability of 0.5) giving rise to a disorder of the hydroxyl group. The piperidine ring adopts the usual chair conformation, with C—C—C—C torsion angles being intermediate between those observed for C(4) mono- and for bisubstituted nitroxypiperidine derivatives. The N—O bond is 1.282(2) Å long, and it makes an angle of 18.5(2)° with the CNC plane. Molecules are connected by O—H...O hydrogen bonds. The influence of the degree of substitution at C(4) on ring geometry is discussed.

M. CYGLER. Can. J. Chem. **60**, 2392 (1982).

L'oxydo-4,7 méthyl-7 hydroxyméthyl-7 tétraméthyl-2,2,6,6 pipéridineoxyl-1, $C_{12}H_{22}NO_3$, cristallise dans le groupe d'espace monoclinique $P2_1/m$ avec des dimensions de maille de: $a$ = 8,041(1), $b$ = 13,348(1), $c$ = 5,945(1) Å, $\beta$ = 95,90(1)°, $Z$ = 2. On a mesuré les données d'intensité à l'aide d'un diffractomètre, on a résolu la structure par des méthodes directes et on l'a affiné par la méthode des moindres carrés jusqu'à une valeur conventionnelle de $R$ = 0,039 pour 1304 réflexions. Deux molécules énantiomères qui diffèrent par la position du groupe OH occupent le même site dans l'unité asymétrique (chacune ayant une probabilité de 0,5) provoquant une augmentation du désordre du groupe hydroxyle. Le cycle pipéridine adopte la conformation chaise habituelle, avec des angles de torsion C—C—C—C intermédaires entre ceux observés pour des dérivés de nitroxypipéridine mono et bisubstitués en position C-4. La liaison N—O est longue 1,282(2) Å et forme un angle de 18,5(2)° avec le plan CNC. Les molécules sont reliées par des liaisons hydrogènes O—H...O. On discute de l'influence du degré de substitution en position C-4 sur la géométrie du cycle.

[Traduit par le journal]

## Introduction

Nitroxy radicals incorporated in the piperidine ring form stable radicals when shielded by bulky groups at adjacent ring carbon atoms. Conformations of various 2,2,6,6-tetramethylpiperidin-1-oxyl derivatives with different substituents at C(4) have been investigated by the X-ray diffraction method (1–15). The piperidine rings exhibited, with two exceptions, a chair conformation flattened at the nitrogen and distorted to varying extents by interactions of axial substituents. The two exceptions are 2,2,6,6-tetramethylpiperidin-4-one-1-oxyl (13, 14), which adopts a twist conformation in the crystal, and a derivative of 2,2,6,6-tetramethyl-5-methylenepiperidin-4-one-1-oxy with C(3) spiro connected to a system of fused rings (15), where a half-chair conformation was adopted. In the latter compound, two adjacent, $sp^2$ hybridized C atoms are largely responsible for such a conformation. The former molecule may be regarded as an analogue of cyclohexan-1,4-dione, which has also been shown to adopt a twist conformation in the solid state (16). Rozantsev, on the basis of measured dipole moments of 2,2,6,6-tetramethylpiperidin-4-one-1-oxyl, concluded that this molecule has a twist conformation in solution as well (17). Interestingly, however, the results of electron diffraction experiments performed in the gas phase were most consistent with that molecule adopting a chair form (18). It is evident that the carbonyl group greatly lowers the energy difference between chair and twist conformations. On the other hand, a hydroxyimine group bonded to C(4) does not destabilize the chair conformation to the same extent. It was shown that 2,2,6,6-tetramethyl-4-hydroxyimino-piperidin-1-oxyl (19) adopts a chair conformation in the crystal.

A series of 2,2,6,6-tetramethylpiperidine derivatives **1** with an exocyclic double bond at C(4) has recently been synthesized (20). Their imino groups were converted to nitroxy radicals by the standard procedure of oxidation with hydrogen peroxide in the presence of a catalyst (21).

During the oxidation of **1***a* the double bond also was oxidized, giving **2** (the title compound, mp 95.5–96.5°C). In other derivatives the double bond

*d*: R = $C(CH_3)C(CH_3)_2OH$

was retained, but the resulting compounds are liquids at room temperature. We have proceeded with the X-ray analysis of **2** in order to investigate the influence of the epoxide moiety on the conformation of the piperidine ring.

## Experimental

Crystal data are as follows:

$C_{12}H_{22}NO_3$ fw = 228.3

Monoclinic, $P2_1/m$, $a = 8.041(1)$, $b = 13.348(1)$, $c = 5.945(1)$ Å, $\beta = 95.90(1)°$, $V = 634.7$ Å$^3$, $Z = 2$, $d_x = 1.195$ g cm$^{-3}$, $\lambda(CuK_\alpha) = 1.54178$ Å, $\mu(CuK_\alpha) = 7.0$ cm$^{-1}$.

Dark red prisms were crystallized from a mixture of benzene and dimethyl sulfoxide. The data were collected at room temperature on an Enraf-Nonius CAD-4 diffractometer, using Ni-filtered $CuK_\alpha$ radiation and a crystal of dimensions 0.49 × 0.32 × 0.12 mm. An $\omega/2\theta$ scan technique was employed for reflections with $\theta$ angles in the range 1–76°. The scan width was $\Delta\omega = (0.7 + 0.2 \tan\theta)°$ and it was extended by 25% on either side for background counts. The aperture was $(2.5 + 0.5 \tan\theta)$ mm wide and 4 mm high. The maximum scan time was 120 s. The intensities of three standard reflections, monitored every 100 min, varied ±2% during the data collection and were used for appropriate scaling of intensities. Three other reflections were used as orientation controls and were measured every 60 reflections. The measured intensities were corrected for Lorentz and polarization factors but not for absorption.

Out of the total of 1382 independent reflections there were 1304 with $I > 1.5\,\sigma(I)$. The systematic absences observed on precession photographs indicated space group $P2_1$ or $P2_1/m$. Because the molecule lacks mirror symmetry and the unit cell contains only two molecules, the space group $P2_1$ was assumed to be correct despite the clearly centrosymmetric statistics of the normalized structure factors. Direct methods (MULTAN (22)) were applied in that space group and the solution with the highest figure of merit revealed an acceptable model. It possessed a plane of symmetry passing through N(1) and C(4), perpendicular to the *y*-axis, with two possible positions for a hydroxyl group on either side of the mirror plane. Accordingly, the space group assignment was changed to $P2_1/m$ and the hydroxyl O atom was refined with an occupancy factor of one-half. The block-diagonal least-squares refinement with isotropic and then anisotropic temperature factors reduced the *R* index to 0.100. A difference map revealed all the H atoms except that of the hydroxyl group. Two further cycles of refinement ($R = 0.047$) followed by another difference map permitted the location of the missing H atom. The final agreement indices are $R = 0.039$ and $R_w = 0.043$ for 1304 reflections. The weighting scheme used in the last few cycles was $w^{-1/2} = 12.0/|F_o|$ for $|F_o| > 12$, otherwise $w^{-1/2} = 1.0$. The mean and maximum shifts/esd for all atoms in the last least-squares cycle were 0.06 and 0.46, respectively. The scattering factor curves were taken from ref. 23.

All calculations were carried out with the NRC crystallographic computing programs by Ahmed, Hall, Pippy, and Huber (24). The final coordinates are listed in Table 1. Lists of anisotropic temperature parameters and of observed and calculated structure factors are available.[3]

## Results and discussion

The title compound, obtained by a nonstereospecific reaction, is racemic. Usually enantiomeric molecules are related by crystallographic symmetry or they occupy two distinct positions in the asymmetric unit. The enantiomeric molecules in the present structure differ only by the position of the terminal hydroxyl group. This group is involved in hydrogen bonding in the crystal. However, the geometry of that bond and other intermolecular contacts of the hydroxyl group are the same for both enantiomers. Consequently each enantiomeric molecule can occupy any particular site. The O(3) atom can thus be found with equal probability on either side of the molecule in the average unit cell, giving rise to the observed mirror

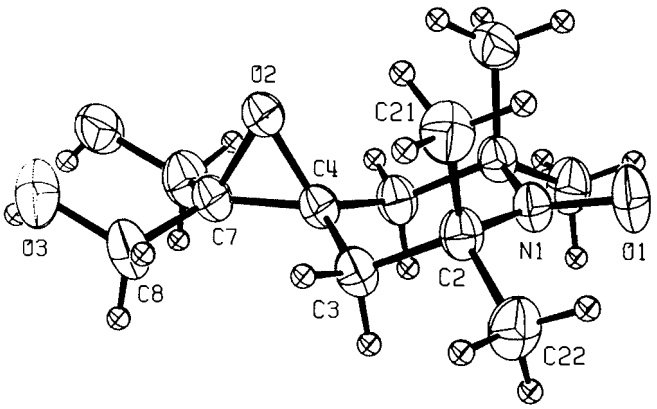

FIG. 1. View of the molecule with the numbering scheme. Both sites for the O(3) atom with occupancy factors 0.5 are shown.

symmetry. A somewhat similar case was described by Krishna Murthy and Vijayan (25), where two conformers, differing by a 180° rotation of a non-symmetrically substituted phenyl ring, occupied the same general position with partial occupancies, leading to a more symmetrical image of the molecule. In that case, however, van der Waals interactions were significantly different for the two conformers, leading to unequal occupancies (0.35 and 0.65).

*Piperidine ring*

A view of the molecule together with the numbering scheme is shown in Fig. 1. Bond lengths, valence, and torsion angles are shown in Fig. 2. The C—H distances, which are not given in Fig. 2, are in the range of 0.96(1) to 1.02(1) Å with the mean value of 0.99(2) Å. The piperidine ring adopts its usual chair conformation, flattened at the nitrogen atom. The O(2) atom of the epoxide ring is in an axial position in relation to the piperidine ring.

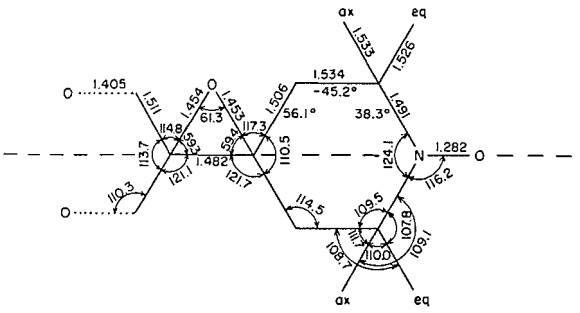

FIG. 2. Bond lengths (Å), valence, and torsion angles (deg). Estimated standard deviations are in the range: 0.002–0.003 Å for bonds; 0.08–0.14° for angles and 0.3° for torsion angles. The dashed line marks schematically the plane of symmetry of the molecule.

In Table 2, a compilation of some geometrical features of various 2,2,6,6-tetramethylpiperidin-1-oxyl derivatives is presented.

It may be stated that the ring becomes less puckered near the C(4) with increasing substitution at C(4). That effect is especially apparent for bisubstituted rings where the C—C—C—C ($\tau_3$) torsion angle is 8° smaller than in mono- and 10° smaller than in unsubstituted derivatives. The N—C—C—C ($\tau_2$) torsion angle also decreases as substitution at C(4) increases; the changes are, however, smaller than for $\tau_3$. No such correlation was observed for torsion angles around the N—C bonds. The C—N—C—C ($\tau_1$) torsion angle varies over a wide range and the average values for bi-, mono-, and unsubstituted derivatives are close.

The distance of 3.382(2) Å between the axial methyl groups is among the shortest found in this series of derivatives. The distance between the O(2) atom of the epoxide ring and the axial methyl groups is 3.307(2) Å, only slightly longer than contacts between the axial substituents in 4-ethynyl-4-hydroxy-2,2,6,6-tetramethylpiperidin-1-oxyl (—C≡...$C_{ax}$ = 2.283(4) Å (12)). Such a distance is attained in the present molecule by increased puckering at C(4). The C—C—C—C ($\tau_3$) torsion angle is between those observed for mono- and bisubstituted rings. The C—N—C—C ($\tau_1$) torsion angle has a larger value than observed in most other compounds; however, similar values have been observed (see Table 2). The endocyclic angles at methylene groups (114.5(1)°) are between those found in mono- and bisubstituted derivatives, e.g., 113.1(5)° in 2,2,6,6-tetramethylpiperidin-4-ol-1-oxyl (5), 113.0(3)° in carbonic acid di(4-hydroxy-2,2,6,6-tetramethylpiperidin-1-oxyl) ester (7) and 117.3(2)° in 4-ethynyl-4-hydroxy-2,2,6,6-tetramethylpiperidin-1-oxyl (12).

[a]α is the angle between the N—O bond and the CNC plane; $\tau_1$, $\tau_2$, and $\tau_3$ are endocyclic torsion angles in the piperidine ring.
[b]N⁺=O rather than N—O.

*Nitroxy group*

The geometry of the nitroxy group is normal (see Table 2); the N—O distance of 1.282(2) Å and the C—N—C angle of 124.1(1)° are within the range observed in other compounds. The C—N(O)—C group is not planar: the N—O bond forms an angle of 18.5(2)° with the CNC plane.

In a previous study (26) we pointed out that the $C_{ax}$—C—N and $C_{eq}$—C—C endocyclic angles reflect the bulkiness and position of the substituent at the N atom. The angles reported for 2,2,6,6-tetramethylpiperidin-1-oxyl derivatives, 109.0 and 108.9° respectively, agree well with those observed here (Fig. 2).

*Epoxide ring*

The epoxide ring, as found in this structure, is symmetrical, with both C—O bonds and both C—C angles being equal within experimental error. The exocyclic C—C—C angles are significantly larger than the O—C—C angles. While the former are very similar at both C(4) and C(7) (~121.4°), the latter are smaller at the terminal $CH_2OH$ group (114.8(1)°) than at the junction with the piperidine ring (117.3(1)°) due to the interaction of O(2) with the axial methyl groups.

Comparisons of the geometries of epoxide rings were previously made by Brisse *et al.* (27) and Foces-Foces *et al.* (28), and were based on 11 and 14 crystal structures, respectively. We have extended the analysis, using the Cambridge Crystallographic Database (29) and restricting ourselves to determinations with *R* factors less than 0.08 and esd's for C—C bond lengths less than 0.006 Å. The analysed set contained 170 epoxide fragments.[4] Table 3 presents some results of that comparison. The bond lengths and angles in the ring vary over quite a broad range. Mean values

TABLE 3. Summary of the epoxide ring geometry based on 170 structural fragments

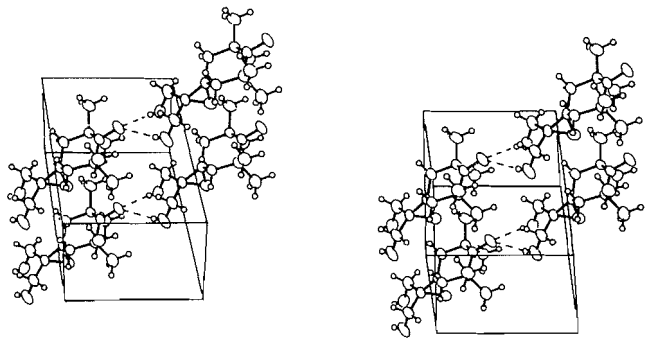

FIG. 3. Stereoview of the molecular packing. Molecules related by two-fold screw axis are omitted for better clarity of the drawing. Hydrogen bonds are marked with dashed lines.

obtained here do not differ significantly from those reported previously.

It was found that a fusion of an epoxide ring with a 5-membered ring or other strained system causes lengthening of the C—C bond (usually above 1.485 Å). Similar lengthening is also caused by $\pi$-donor substituents (e.g., phenyl or —C≡N) to the ring (30).

In the case of a double bond which is one bond away from the epoxide ring, the distal C—O bond in the ring tended to be shorter than the proximal one. A similar effect for a cyclopropane ring was analysed by Allen (31) from structural data. In the epoxide moiety that effect is, however, less pronounced. Out of 38 fragments in the analysed data set with a neighbouring C=O or —C=C— group, 19 showed significant shortening of distal C—O bonds, 11 showed no significant difference, and 8 showed significant lengthening of distal C—O.

*Molecular packing*

The molecules of the title compound are connected by hydrogen bonds between the hydroxyl group and nitroxyl oxygen into chains along the [101] direction (Fig. 3). The geometry of that bond is as follows: O(1)...O(3) = 2.766(3) Å, O(3)—H = 0.61(1) Å, H...O(1) = 2.16(1) Å, O(3)—H...O(1) = 174(4)°. The molecules are packed in such a way that the epoxide ring O(2) points toward the free space between equatorial methyl groups of a neighbouring molecule. The distance between O(2) and the closest H atoms of these methyl groups is 2.70(1) Å and the O(2)...N distance is 3.312(2) Å. The shortest intermolecular contact is between O(3) and the axial H atom at C(3) (2.56(2) Å). All H...H contacts are above 2.57 Å and those of other atoms are above 3.5 Å.

# Détermination de propriétés diélectriques de substances polaires: conditions d'applicabilité de l'équation d'Omini

LÉO DEGRÈVE, PAULO ROBERTO BROSSI PELISSARI ET MARIA MARCIA MURTA

*Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, 14100 Ribeirão Preto, São Paulo, Brésil*

Reçu le 5 janvier 1982

LÉO DEGRÈVE, PAULO ROBERTO BROSSI PELISSARI et MARIA MARCIA MURTA. Can. J. Chem. **60**, 2398 (1982).

Une équation qui permet de déterminer le moment dipolaire et la polarisabilité de substances polaires à partir de la mesure de la constante diélectrique de solutions de cette substance avec des solvants apolaires est testée avec différentes paires solvant–soluté. Les résultats indiquent que cette équation fournit de bonnes valeurs du moment dipolaire et de la polarisabilité si le solvant est choisi convenablement.

LÉO DEGRÈVE, PAULO ROBERTO BROSSI PELISSARI, and MARIA MARCIA MURTA. Can. J. Chem. **60**, 2398 (1982).

An equation which allows for the determination of the dipole moment and polarizability of polar substances via the dielectric constant of solutions of the substance in nonpolar solvents is tested using different solute–solvent pairs. The results indicate that this equation provides good values of the dipole moment and of the polarizability if the solvent is correctly chosen.

## Introduction

La détermination du moment dipolaire et de la polarisabilité de molécules est un problème assez ancien quand cette détermination peut être réalisée seulement en solution (voir, par exemple, réf. 2). Les difficultés qui apparaissent dans ces déterminations sont de divers types mais pour l'expérimentateur un problème crucial est celui de savoir quelle est la confiance qu'il peut prêter aux résultats. D'autre part, la simplicité de la manipulation expérimentale est importante aussi. Pour cela, nous nous proposons de tester et d'analyser les conditions d'applicabilité d'une équation publiée par M. Omini (1) qui permet de calculer le moment dipolaire et la polarisabilité d'une substance polaire à partir de la mesure de la constante diélectrique de solutions de diverses concentrations de cette substance avec un solvant apolaire.

Pour tester l'équation d'Omini, la constante diélectrique de mélanges binaires de quatre solvants apolaires et quatre solutés polaires a été mesurée en fonction de la concentration et en fonction de la température. Les moments dipolaires et les polarisabilités ont été calculés et analysés en les comparant aux résultats obtenus par d'autres méthodes afin de déterminer les meilleures conditions d'applicabilité de la théorie d'Omini.

## Partie expérimentale

Comme substances de travail, nous avons utilisé le tétrachlorure de carbone, le benzène, l'hexane normal, l'heptane normal, le chloroforme, le chlorobenzène, le 1-chloro-*n*-pentane et le 2-chloro-2 méthylpropane. Ces substances ont été purifiées suivant les techniques indiquées pour des mesures de propriétés diélectriques (3). La pureté de ces substances a été vérifiée par au moins deux des techniques suivantes: détermination de l'indice de réfraction, de la température d'ébullition, de la constante diélectrique, de la teneur d'eau ou par la spectroscopie infrarouge.

Les constantes diélectriques de solutions de fractions molaires du soluté polaire allant de 0 à 0,5 ont été mesurées à diverses températures entre 25 et 40°C. Les solutions ont été préparées par pesage et les titres molaires calculés directement à partir des masses des substances. Deux cellules de capacitance ont été employées: la première construite d'acier inoxydable et Teflon, la deuxième de laiton, sur lequel une couche d'or a été déposée électrolytiquement, et Teflon. La température a été mesurée hors de la cellule et ensuite une correction a été introduite à partir de la mesure de la température interne des cellules au moyen d'un thermocouple dont la mesure à son tour a été comparée avec celle d'un thermomètre de mercure standardisé. L'erreur finale des mesures de température est ainsi estimée comme étant $\pm 0{,}1°$. Les capacitances ont été mesurée avec un pont de capacitance Général Radio 1620A. De cette manière la précision des résultats expérimentaux est de l'ordre de 0,04%.

## Résultats

Afin de faciliter l'utilisation des résultats expérimentaux, nous avons mis ceux-ci sous la forme:

$$[1]\quad \varepsilon = (a_1 + a_2 f_2 + a_3 f_2^2 + a_4 f_2^3) \times t + b_1 + b_2 f_2 + b_3 f_2^2 + b_4 f_2^3$$

où les coefficients $a_1, \ldots, b_4$ sont obtenus par régression à partir des données expérimentales et $t$ est la température centigrade.

Les tableaux 1 et 2 réunissent les valeurs des $a$ et des $b$ obtenues. Dans le tableau 3, on trouve les

valeurs moyennes des constantes diélectriques à 0°C et leurs coefficients de température pour les solvants apolaires purs. Les tableaux 1 et 2 permettent de reproduire les données expérimentales avec un écart maximum de 0,01%. Le tableau 3 montre que la concordance entre nos résultats et les résultats publiés est bonne.

Pour appliquer l'équation d'Omini (1), les tableaux 1 et 2 ont été utilisés pour calculer les constantes diélectriques des solutions à 25,0, 30,0, 35,0 et 40,0°C pour sept fractions molaires distribuées régulièrement de 0,07 à 0,49 et pour $f_2 = 0$. La densité des solutions a été calculée par la relation: $\rho = f_1\rho_1 + f_2\rho_2$. Les données utilisées dans ce cas sont réunies dans le tableau 4. Etant donné que des différences entre les résultats pour les diverses températures ont été observées (par exemple, le moment dipolaire du chlorobenzène calculé à partir de la constante diélectrique de solutions de tétrachlorure de carbone a été calculé aux quatre températures comme étant de 1,80, 1,81, 1,83 et 1,84 $D$), nous avons introduit leur écart moyen dans le tableau récapitulatif des résultats, tableau 5.

TABLEAU 4. Densité, coefficient de température de la densité, polarisabilité et moment dipolaire des substances utilisées

## Discussion

Afin de faciliter l'analyse des résultats, les substances choisies comme tests ont des formes géométriques différentes, à savoir: globulaire, annulaire et en chaîne flexible. De cette manière, on peut espérer pouvoir séparer les effets spécifiques dûs à la géométrie des molécules, c'est-à-dire finalement dûs à la structure interne des solutions, des effets dûs à la méthode en soi.

L'analyse des résultats du tableau 5 montre immédiatement que les écarts entre les valeurs de $\mu$ et $\alpha_2$ calculées et publiés sont intolérables quand les solvants utilisés sont l'hexane ou l'heptane. Cela semble indiquer que la conformation des molécules de solvant joue un rôle extrêmement important dans la qualité des résultats et confirme que ce type de solvant doit être évité. Les résultats relatifs au chloroforme doivent être regardés avec une certaine réserve puisqu'il existe la possibilité de formation de complexes (8). Cependant le moment dipolaire du chloroforme déterminé à partir de la constante diélectrique de solutions de benzène se trouve dans une limite d'erreur raisonnable ce qui pourrait indiquer qu'aucun complexe ne se forme. Mais l'erreur de la polarisabilité est beaucoup trop grande. Les mêmes observations peuvent être faites au sujet du chlorure de butyle tertiaire.

En règle générale, l'erreur sur le moment dipolaire est beaucoup plus petite que l'erreur sur la polarisabilité. Cela peut s'expliquer par le fait que le moment dipolaire apparait, en réalité, au carré ce qui rapproche fortement les erreurs sur $\alpha_2$ et sur $\mu^2$. D'autre part, il n'existe aucune évidence de ce que le traîtement d'Omini surestime soit $\alpha_2$, soit $\mu$ au détriment de l'autre facteur puisque les erreurs sur $\alpha_2$, et sur $\mu$ sont aussi bien du même signe que de signes opposés. Cependant, il est bon de noter que seulement dans un cas l'erreur sur la polarisabilité est négative.

Les différences entre les résultats obtenus aux diverses températures ne sont pas significatives puisqu'elles sont de 0,28% par degré, en moyenne. Si on considère encore que quand la température augmente, les résultats calculés peuvent aussi bien augmenter que diminuer, on peut conclure qu'il s'agit de variations qui dépendent plus des erreurs expérimentales et de la technique de calcul que de la méthode en soi.

Quand la méthode d'Omini est utilisée en même temps que des méthodes computationnelles de recherche de l'écart minimum, $\sigma^2$, il faut prendre garde au fait que dans certains cas il apparaît un minimum secondaire comme le montre la figure 1 pour le mélange chloroforme/tétrachlorure de carbone.

La théorie d'Omini est rigoureusement exacte quand les indices de réfraction à longueur d'onde infinie sont égaux pour le solvant et pour le soluté (1). Afin de vérifier indirectement cette affirmation, on peut comparer la différence, en pourcentage, entre la polarisabilité du solvant et celle du soluté avec l'erreur, en pourcentage, commise sur l'évaluation du moment dipolaire (cette erreur est donnée dans le tableau 5). Cette comparaison est faite par la figure 2. Les droites relatives au

For personal use only.

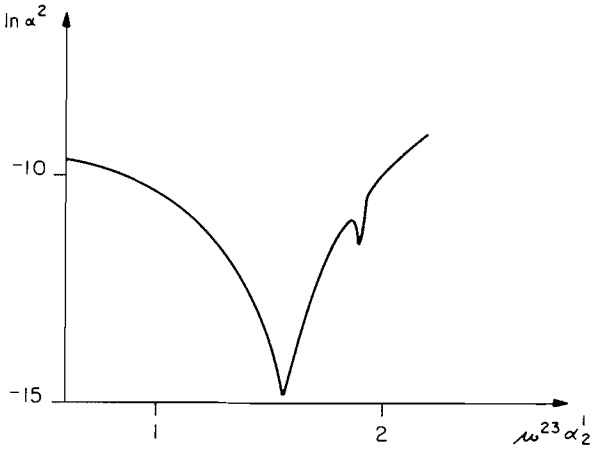

FIG. 1. Logarithme de l'écart quadratique en fonction des valeurs d'essai de la polarisabilité du soluté.

1-chloropentane et au 2-chloro-2 méthylpropane s'écartent de l'origine des axes, où l'erreur est nulle, probablement à cause des erreurs expérimentales. La droite du chlorobenzène s'écarte trop de l'erreur nulle pour qu'il n'y ait pas un autre facteur déterminant; il faut remarquer que les points où $\Delta\mu \approx 65\%$ sont ceux relatifs aux solutions d'hexane et d'heptane ce qui signifie que l'effet de la polarisabilité ne doit pas être considéré seul mais en même temps que les effets dûs aux configurations moléculaires, donc en même temps que les effets entropiques. Les coefficients angulaires de ces trois droites sont très voisins: leur moyenne est de $-0{,}36 \pm 0{,}04$ et la conséquence est qu'une différence de seulement 3% entre les polarisabilité du solvant et du soluté induit une erreur de 10% sur le moment dipolaire. Donc le coefficient angulaire de ces droites est une propriété intrinsèque de la méthode d'Omini appliquée dans des conditions qui ne sont pas exactement celles prévues dans son élaboration. Quant à l'ordonnée à l'origine, elle doit probablement dépendre de la conformation des molécules plus étroitement que le coefficient angulaire. Le coefficient angulaire de la droite du chloroforme est positif, donc de signe opposé aux trois autres. Cependant il faut remarquer que les deux points où $\Delta\mu = 77$ et 66%, qui provoquent la variation du signe, sont ceux où les solvants sont des chaînes flexibles. Cela confirmerait encore une fois que l'hexane et l'heptane ne sont pas des solvants adéquats. L'inversion du signe du coefficient angulaire est peut-être aussi un signal de l'existence de complexe.

Donc il semble que les affirmations d'Omini sur les polarisabilités se confirment puisque les résultats sont meilleurs quand celles-ci sont proches. Cependant la théorie d'Omini ne considère pas un facteur très important, à savoir la forme des molécules qui semble jouer un rôle très important dans la qualité des résultats comme le montre le tableau 6 obtenu à partir de deux méthodes qui tiennent compte de la forme non sphérique des molécules du soluté (6, 7). La constante diélectrique dépend, entre autres facteurs, de la distribution relative des molécules (9) de manière que l'influence de la forme des molécules sur la façon qu'elles ont de se situer dans l'espace (en moyenne) et donc sur leurs interactions est grande. Les variations conséquentes de la constante diélectrique influencent directement la qualité des résultats. Si on compare ce raisonnement avec une hypothèse fondamentale de la théorie d'Onsager (1, 2) qui est de situer un dipôle ponctuel au centre d'une cavité sphérique plongée

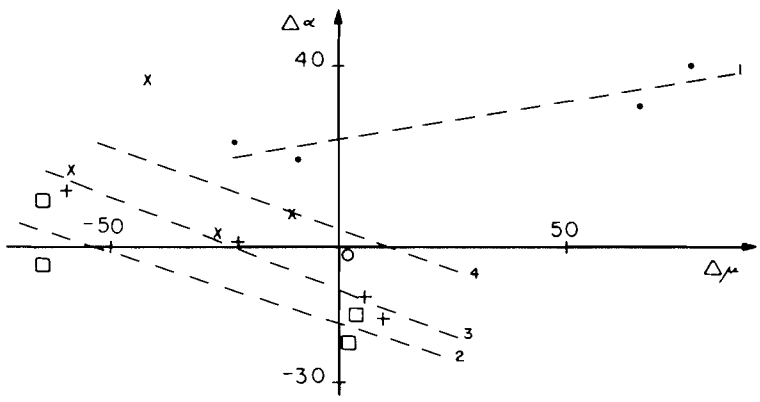

FIG. 2. Pourcentage de le différence depolarisabilité entre le solvant et le soluté en fonction du pourcentage d'erreur donné par la méthode d'Omini. dans un milieu diélectrique continu, on peut vérifier que le milieu sera "plus continu" si la forme des molécules permet un empilement très régulier ce qui est obtenu seulement avec des molécules de grande symétrie (9). Donc les solvants comme le tétrachlorure de carbone et le benzène doivent fournir les meilleurs résultats et les solvants en chaîne ouverte de mauvais résultats: cela est parfaitement confirmé par les résultats du tableau 5.

## Conclusion

La méthode d'Omini est d'application simple et donne de bons résultats pour estimer le moment dipolaire et la polarisabilité des substances polaires à partir seulement de mesures de la constante diélectrique de solutions. De manière générale, elle ne doit pas être appliquée avec des solvants dont la conformation moléculaire peut varier beaucoup et le solvant doit être choisi de manière à ce que sa polarisabilité soit proche de celle du soluté. Dans ces cas, les résultats seront entâchés d'erreurs de l'ordre de 10% au maximum.

# BEST — A new program for rigorous calculation of equilibrium parameters of complex multicomponent systems

RAMUNAS J. MOTEKAITIS AND ARTHUR E. MARTELL[1]

*Department of Chemistry, Texas A&M University, College Station, TX 77843, U.S.A.*

Received March 9, 1982

RAMUNAS J. MOTEKAITIS and ARTHUR E. MARTELL. Can. J. Chem. **60**, 2403 (1982).

The FORTRAN program BEST for the refinement of stability constants from potentiometric data measured on complex systems containing any number of interacting components is described. The core algorithm consists of computation by successive approximations of the pH values at each equilibrium point from an initial set of stability constants based on the equilibrium model. Each approximation results in adjustment of the equilibrium constants being refined in order to improve the fit between the calculated and observed pH values for all the data taken for the system under investigation. Novel features of the algorithm include total generality, minimization of errors with respect to pH, and the avoidance of customary classification labels such as "metal ion", "ligand", "hydroxides", "proton", etc. Several examples of applications to real systems are provided to illustrate the versatility of the program.

RAMUNAS J. MOTEKAITIS et ARTHUR E. MARTELL. Can. J. Chem. **60**, 2403 (1982).

On décrit le programme Fortran BEST, utilisé pour l'amélioration des constantes de stabilité obtenues à partir de données potentiométriques mesurées dans des systèmes complexes contenant des quantités variables de composants qui interagisent. L'algoarithme de base consiste en calculs par approximations successives des valeurs du pH à chaque point d'équilibre et un ensemble initial de constantes de stabilité d'un modèle d'équilibre. Chaque approximation provenant d'un ajustement des constantes d'équilibre est amélioré dans le but de faciliter l'insertion entre les valeurs de pH calculées et observées pour toutes les données relevées pour le système étudié. Les caractéristiques nouvelles de l'algoarithme comprennent une généralité totale, la minimisation des erreurs par rapport au pH et la suppression de la classification habituelle des marqueurs tels "ion métallique", "ligand A", "hydroxydes", "proton", etc. On fournit plusieurs exemples d'applications à des systèmes réels pour illustrer la versatilité du programme.

## Introduction

In a break with the traditional approaches described in the literature, a novel algorithm was recently reported (1) for the determination of any number of overlapping protonation constants from potentiometric titration data wherein the function being minimized is the sum of the squares of the differences between calculated and observed pH values. The main advantage of this new approach stems from the correct statistical treatment in which the mass balance quantities including the volume of titrant added are treated as known parameters while the pH represents the measured dependent variable that reflects the unique set of equilibrium protonation constants that most accurately describe the system. Therefore, minimization of the $\Sigma(pH_{calc} - pH_{obs})^2$ function does not only make chemical sense, but is the mathematically correct choice.

Several recent reviews have appeared which deal both specifically as well as comparatively with the various numerical and analytical methods and programs used in computer calculations of chemical equilibria and stability constants. The comprehensive reviews of Gans (2), Gaizer (3) and the survey by Leggett (4) discuss both popularly used programs and other approaches which had been employed in the determination of stability constants from potentiometric and other data. The common element among all programs surveyed is the choice of minimization of the calculated differences in one or more mass balance terms $T_M$, $T_L$, $T_H$, $T_{OH}$, $\bar{n}$, $v_{titrant}$. A second feature of most published programs is the specific identification and classification of the reacting components into categories such as "metal", "ligand", "proton", and "hydroxide". Legett (5) pointed out that general complexes of formulation $M_mH_j(OH)_kL_n$ are treated by the computer as coming from components M, L, H, $H_2O$ whose concentrations are constrained by the mass balance equations [1]–[3] and the equilibrium constant [4]. Different symbols are employed for each interacting component.

$$[1] \quad C_M = [M] + \Sigma m[M_mH_j(OH)_kL_n]$$

$$[2] \quad C_L = [L] + \Sigma n[M_mH_j(OH)_kL_n]$$

$$[3] \quad C_H = [H] - [OH] + \Sigma j[M_mH_jL_n] - \Sigma k[M_m(OH)_kL_n]$$

$$[4] \quad \beta_{mjkn} = \frac{[M_mH_j(OH)_kL_n][H]^k}{[M]^m[H]^j[H_2O]^k[L]^n}$$

It appears then that there are two drawbacks to the standard strategies employed in the computa-

tion of equilibrium constants: the choice (other than pH) of the variable being minimized and the usage of cumbersome notation labels which preclude straightforward generalization of the computation problem toward more complicated systems. The program BEST described in this work was written with the object in mind of eliminating these two drawbacks. BEST computes the equilibrium pH value at each equilibrium point and refines the chosen equilibrium constants accordingly, thus minimizing the discrepancies between the calculated and experimentally observed values of pH. The analytical mass balance algorithm depends entirely on the species stoichiometry entered in the input data and does not make a special *a priori* distinction between "metal", "ligand", "hydroxide", and "proton" components. In BEST, the explicit equations [1]–[3] have been replaced by a perfectly general and therefore mathematically more tractable mass balance equation [5] which states that the analytical concentration of a given component is always balanced by its distribution in all the equilibrating species, defined in eq. [6]. The sum of each component is taken over all of the species present, while the product of each species in [6] is taken over the range of all of the components.

$$[5] \quad T_{\text{component}} = \Sigma\gamma[\text{species}]$$

$$[6] \quad [\text{species}] = \beta\prod[\text{component}]^{\gamma}$$

## Mathematical background for program BEST

### *A. Solution of the equilibrium*

For a monophasic solution of $NC$ components and $NS$ species, the generalized mass balance equations in each component of concentration $T_{C_j}$ is

$$[7] \quad T_{C_j} = \sum_{i=1}^{NS} \gamma_{j,i}[S]_i$$

where

$$[8] \quad [S]_i = \beta_i \prod_{k=1}^{NC} [C]_k^{\gamma}{}_{k,i}$$

and $\gamma_{n,j}$ is the stoichiometric coefficient of component $n$ in species $i$, $[S]_i$ is the concentration of species $S_i$, and $\beta_i$ is the overall formation constant for species $i$ from its components C. The set of simultaneous equations [7] is solved most efficiently at each titration point by the Newton–Raphson method (6) by defining the set of $NC$ functions $F_j$ [9] such that $F_j \rightarrow 0$ when the correct concentration of the free components is obtained. The necessary Jacobian $NC \times NC$ determinant [10] is constructed through partial differentiation with respect to each component concentration, $C_j$. Likewise, $NC$ substitution determinants $D_j$ must be evaluated for the iterative process. For example $D_2$ is shown in eq. [11].

$$[9] \quad F_j = \sum_{i=1}^{NC} \gamma_{j,i}[S]_i - T_{C_j}$$

$$[10] \quad D = \begin{vmatrix} \frac{\delta F_1}{\delta C_1} & \frac{\delta F_1}{\delta C_2} & \cdots & \frac{\delta F_1}{\delta C_{NC}} \\ \vdots & \vdots & & \vdots \\ \frac{\delta F_{NC}}{\delta C_1} & \frac{\delta F_{NC}}{\delta C_2} & \cdots & \frac{\delta F_{NC}}{\delta C_{NC}} \end{vmatrix}$$

$$[11] \quad D_2 = \begin{vmatrix} \frac{\delta F_1}{\delta C_1} & F_1 & \cdots & \frac{\delta F_1}{\delta C_{NC}} \\ \vdots & \vdots & & \vdots \\ \frac{\delta F_{NC}}{\delta C_1} & F_{NC} & \cdots & \frac{\delta F_{NC}}{\delta C_{NC}} \end{vmatrix}$$

An initial estimate of the component concentration is refined by the Newton–Raphson method for simultaneous equations with the recursion formula [12]

$$[12] \quad C_j = C_j(\text{previous value}) - D_j/D$$

By convention it was chosen that $C_{NC}$ (when $j = NC$) represents the free hydrogen ion concentration.

### *B. Refinement of equilibrium constants*

The refinement of the basis set of stability constants each representing a species present is accomplished in the following series of steps.

(*1*) For the basis set solve the mass balance equations [7] using eqs. [12] as outlined above.

(*2*) Convert $C_{NC}$ to pH ($-\log C_{NC}$) at each equilibrium point. In effect this is a calculated pH curve.

(*3*) Perturb a small fraction of the basis set by an increment and repeat step *2*.

(*4*) Compare the effect of step *3* with regard to improvement of the fit to the experimental curve and repeat step *3* in the appropriate direction to affect further improvement.

(*5*) Repeat *4* and *3* until refinement of the basis set cannot be further improved.

## Discussion

The main advantage of program BEST is that it provides an easily accessible vehicle for the computation of pH values at each titration point in systems of any complexity. For example the binucleating ligand PXBDE (7) was studied in the

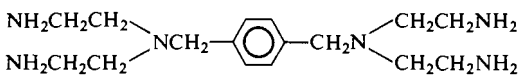
*The larger deviations near $a = 1$ and $a = 5$ are characteristic of the steeply sloping parts (inflection regions) of the potentiometric equilibrium curves.
†$a$ = moles base added per mole of metal ion present.

presence of added ethylenediamine (EN), or glycine, cobalt(II), and oxygen (8).



Tetrakis(2-aminoethyl)-α,α′-diamino-*p*-xylene (PXBDE)

Table 1 shows the results of the calculations on this complex system defined by the experimental parameters and the set of overall stability constants for the species shown in Table 2. The five components defining this system are Co(II), ethylenediamine, PXBDE, protons, and oxygen. Because the experiment was run under 1 atm of oxygen, that particular component was not listed per se, but its interaction is implied in species **24**. Species **23** is the unoxygenated binuclear mixed ligand complex while species **24** is the same species with a dioxygen bridge between the two cobalt centers. The input stability constant data had been obtained from separate experiments while only the stability constant of species **24** is determined in the calculation illustrated here. Species **2** is the hydrolysis constant for Co(II) and was taken from Smith and Martell (9). The protonation constants for ethylenediamine **4**, **5**, and PXBDE **7**, **8**, **9**, **10**, **11**, **12** were determined using program PKAS (1). The stability constants **13**, **14**, **15** between EN and Co(II) were determined using BEST anaerobically from titration under nitrogen. Species **16**, **17**, **18** were computed with BEST for 1:1 PXBDE:Co(II) equilibrium mixtures while **21** was determined for 1:2 PXBDE:Co(II) experiments also with BEST. Finally, in a series of experiments the mixed ligand species **22** and **23** were determined using BEST. These prior determinations are necessary in order

to compute the desired oxygenation equilibrium constant **24**.

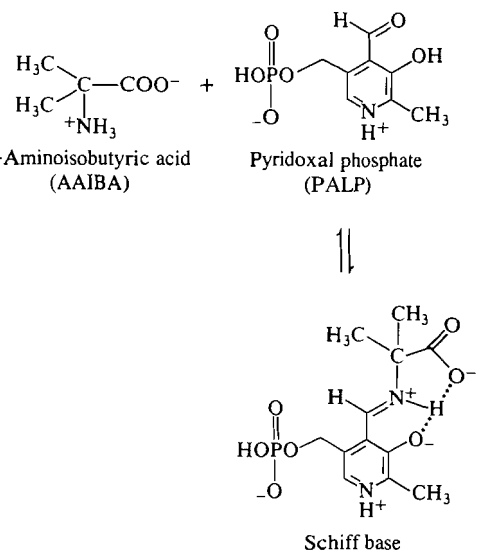
It is to be noted that the differences in the last column of Table 1 are very small and that there appears to be some deviation near $a$ values of about 1 and 5. The reason for these deviations is related to slight misbalance in the acid–base stoichiometry, for which small deviations are amplified many-fold in the regions of high slope. The standard deviation for overall fit is 0.023 log units. This, taken together with the excellent fit ($\ll 0.01$ pH) in the buffer regions, is indicative of a good equilibrium description of a very complex system. We believe that such refinement heretofore without any approximation was not possible for accurate determination of oxygenation constants.

Table 3 illustrates the added option that BEST offers: a complete species distribution for all of the titration points. The particular example shows point **27** at $a = 3.9$. The second column lists the actual concentration while the third column lists the percent with respect to the first component, Co(II).

Because of the generalized nature of the mass balance equation [7], program BEST may handle much more complex systems, such as those containing several ligands and many metal ions. Such equilibrium studies would be of interest for complex biological systems in proving out the predictions of multicomponent systems derived from separate studies of the components involved.

Furthermore, in these laboratories, BEST was applied to a determination of a Schiff base equilibrium shown in reaction [13], where α-aminoisobutyric acid forms a Schiff base with pyridoxal phosphate. This system was tractable because BEST does not require formal identification of components as "metal ions" or "ligands". As usual, the input parameters shown in Table 4 were used to obtain the very good fit $\sigma = 0.037$ shown in Table 5. It is to be noted that the experiment was performed on an initial volume of 3.00 mL of solution in a micro titration apparatus. In Table 4 the difference between **9** and **8** (11.88) represents the log protonation constant of the totally deprotonated Schiff base, while **10–9** and **11–10** (7.02 and 5.90) represent the next two protonation steps. This is the first report of a potentiometric determination of Schiff base equilibrium constants.

[13]



Other applications of BEST have been tested on a variety of gallium(III) complexes with multidentate ligands such as tetraethylenepentaamineheptaacetic acid (TPHA) (10), the study of

mixed dinuclear complexes of 1,4,7,13,16,19-hexaaza-10,22-dioxacyclotetracosane (BISDIEN) (11), and the mono and dinuclear Fe(III) complexes with 1,4-bis(2′,5′,5′-tricarboxymethyl-2′,5′-diazapentyl)benzene (PXED3A) (12), a bispentadentate ligand. The latter ligand–metal system possesses up to 25 species. The titrations themselves involve more than 100 data points. The most interesting finding is an intramolecularly bound oxide bridge in the dinegative species $Fe_2LO^{2-}$.

Two additional features of BEST deserve mention. The entire algorithm is written in single precision arithmetic, a fact which accounts for more rapid execution relative to the customary double precision routines found in older literature. Also, BEST computes the complete species distribution consistent with the current data base.

Figure 1 is a species distribution diagram of the Schiff base system described in Table 4. The computation was performed utilizing the same mathematical algorithm as found in BEST. In order to obtain this diagram, the pH was varied incrementally and the various quantities were calculated at each pH increment. However, both here and in the original refinement of the equilibrium constants, it was not necessary to invoke artificial approximations of any kind. Currently, program

BEST is DIMENSIONed for 7 components and 121 data points. Higher DIMENSIONing is limited only by the memory available on the MICROMATION Z64 microcomputer employed in the recent work carried out in this laboratory. This microcomputer is equipped with 64K RAM utilizing the Z-80A microprocessor and dual 8″ floppy disks with Chromemco software. Currently, adaptation of program BEST to the VAX-11/780 have improved computer run times by a factor of ~200.

# Rearrangement studies with $^{14}C$. XLVII. The decomposition of chain labeled or ring labeled trianisylvinylphenyltriazene

CHOI CHUCK LEE AND CRAIG A. OBAFEMI

*Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0*

Received April 1, 1982

CHOI CHUCK LEE and CRAIG A. OBAFEMI. Can. J. Chem. **60**, 2410 (1982).

Simultaneous reactions were carried out on the decomposition of the chain labeled trianisyl[2-$^{14}C$]vinylphenyltriazene (**1**-NNNHPh-2-$^{14}C$) and the ring labeled 1,2-dianisyl-2-*p*-[$^{14}C$]methoxyphenylvinylphenyltriazene (**1**-NNNHPh-2-methoxy-$^{14}C$) in HOAc, HOAc–NaOAc, or $CF_3CH_2OH$–$HClO_4$. In HOAc, the presence of increasing amounts of NaOAc resulted in decreasing extents of isotopic scrambling arising from 1,2-anisyl shifts in the trianisylvinyl cation, in agreement with previous observations. For decompositions in the less nucleophilic TFE, complete equilibration was observed, giving rise to 50.0% and 33.3% scramblings, respectively, for the chain and ring labels. When the data were expressed as % rearrangement, with the assumption that 100% rearrangement would correspond to 50.0% or 33.3% scrambling, respectively, for the chain or ring label, for each experiment under a given set of conditions, the % rearrangement was found to be equal in the chain and in the ring label. These results are discussed in conjunction with earlier data from the acetolysis of doubly labeled 1,2-dianisyl-2-*p*-[$^{14}C$]methoxyphenyl[2-$^{13}C$]vinyl bromide (**1**-Br-2-$^{13}C$-2-methoxy-$^{14}C$) which gave, depending on experimental conditions, either equal or unequal values for the % rearrangement in the chain and in the ring label.

CHOI CHUCK LEE et CRAIG A. OBAFEMI. Can. J. Chem. **60**, 2410 (1982).

On a effectué des réactions de décompositions simultanées dans le AcOH, le AcOH–AcONa ou le $CF_3CH_2OH$–$HClO_4$ du trianisyl [2-$^{14}C$] vinylphényltriazène (**1**-NNNHPh-2-$^{14}C$) marqué dans la chaîne et du dianisyl-1,2 *p*-[$^{14}C$] méthoxyphényl-2 vinylphényltriazène (**1**-NNNHPh-2-méthoxy-$^{14}C$) marqué sur le cycle. Dans le AcOH, la présence de quantités croissantes de AcONa provoque une diminution du taux de mélange isotopique provenant de glissements 1,2 des anisyles du cation trianisylvinyle; ceci est en accord avec des observations antérieures. Dans le cas des décompositions dans le TFE qui est moins nucléophile, on a observé une équilibration complète donnant lieu à des taux de mélanges respectivs de 50% et de 33% pour les composés avec une chaîne ou un cycle marqué. Quand on exprime les données en % de transposition, en se basant sur le fait qu'une transposition à 100% correspond à un mélange de 50,0% ou de 33,3% suivant que le marqueur est sur la chaîne ou sur le cycle, on trouve pour chaque expérience conduite dans un ensemble de conditions données que le % de transposition est le même que le marqueur soit dans la chaîne ou dans le cycle. On discute des ces résultats en fonction des données antérieures provenant de l'acétolyse du bromure de dianisyl-1,2 *p*[$^{14}C$] méthoxyphényl-2 [2-$^{13}C$] vinyle doublement marqué qui donne, suivant les conditions expérimentales, soit des valeurs égales ou inégales du % de transposition suivant que le marqueur est dans la chaîne ou dans le cycle.

[Traduit par le journal]

The acid catalyzed decomposition of triarylvinylphenyltriazene as a method of generating the triarylvinyl cation, presumably via the triarylvinyldiazonium ion, was first reported by Jones and Miller (1). Rearrangements arising from 1,2-aryl shifts across the double bond in the triarylvinyl cation were also observed by these workers. For example, the decomposition in HOAc of 1-phenyl-2,2-di-*p*-tolylvinylphenyltriazene gave 80% of the unrearranged 1-phenyl-2,2-di-*p*-tolylvinyl acetate and 20% of the rearranged 2-phenyl-1,2-di-*p*-tolylvinyl acetate and this rearrangement was completely suppressed by the presence of 10 molar equivalents of added KOAc (1). These findings were interpreted as being consistent with the formation of the free 1-phenyl-2,2-di-*p*-tolylvinyl cation which could undergo 1,2-tolyl shift to give the more stable 2-phenyl-1,2-di-*p*-tolylvinyl cation. The presence of the added more nucleophilic acetate ion would favor product formation from the unrearranged cation, thus decreasing or suppressing the extent of 1,2-shifts to give rearrangement. Similarly, isotopic scramblings arising from 1,2-aryl shifts in triarylvinyl cations derived from the decomposition in HOAc of trianisyl[2-$^{14}C$]vinylphenyltriazene or *cis*- and *trans*-1,2-dianisyl-2-phenyl[2-$^{14}C$]vinylphenyltriazenes have been reported from this laboratory (2, 3). In these studies, it was found that the presence of added NaOAc also decreased the extent of scrambling, in support of the formation of free triarylvinyl cations. Extensive studies on rearrangements of vinyl cations, largely generated from solvolyses, have also been carried out and the results have been summarized in recent reviews (4, 5).

Recently we have investigated the extents of isotopic scrambling in the acetolysis of trianisylvinyl bromide doubly labeled at C-2 with $^{13}C$ and at the methoxy carbon of one of the C-2 anisyl groups with $^{14}C$ (1,2-dianisyl-2-*p*-[$^{14}C$]methoxyphenyl[2-$^{13}C$]vinyl bromide, **1**-Br-2-$^{13}C$-2-methoxy-$^{14}C$). Since the scramblings for the $^{13}C$ and $^{14}C$ labels were measured by two independent methods, namely, $^{13}C$ nmr and $^{14}C$ radioactivity, it was found

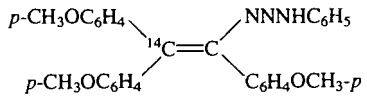
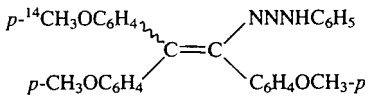
in preliminary trials that the scrambling results from reactions with 1-Br-2-$^{13}$C-2-methoxy-$^{14}$C were essentially the same as those from similar reactions with a 1:1 mixture of singly labeled trianisyl[2-$^{13}$C]vinyl bromide (1-Br-2-$^{13}$C) and 1,2-dianisyl-2-*p*-[$^{14}$C]methoxyphenylvinyl bromide (1-Br-2-methoxy-$^{14}$C) (6). When the acetolysis of 1-Br-2-$^{13}$C-2-methoxy-$^{14}$C was carried out in the presence of low concentrations of added salts, the "% rearrangements" for the chain label and the ring label were unexpectedly found to be unequal. On the other hand, in the presence of high salt concentrations, the % rearrangements for the chain and ring labels were equal, and it was suggested that ion-pairs and free ions, respectively, might be involved in the acetolysis of 1-Br-2-$^{13}$C-2-methoxy-$^{14}$C in the presence of low and high concentrations of added salts (6). Since the decomposition of vinylphenyltriazenes would proceed via the free vinyl cation, in the present work, simultaneous experiments were carried out with the chain labeled trianisyl[2-$^{14}$C]vinylphenyltriazene (1-NNNHPh-2-$^{14}$C) and the ring labeled 1,2-dianisyl-2-*p*-[$^{14}$C]methoxyphenylvinylphenyltriazene (1-NNNHPh-2-methoxy-$^{14}$C) in order to provide scrambling data for comparison with those obtained from the acetolysis of 1-Br-2-$^{13}$C-2-methoxy-$^{14}$C.



1-NNNHPh-2-$^{14}$C



1-NNNHPh-2-methoxy-$^{14}$C

The preparation of 1-NNNHPh-2-$^{14}$C was effected from the reaction of 1-Br-2-$^{14}$C with phenyl azide as previously described (2). Similarly, 1-NNNHPh-2-methoxy-$^{14}$C was obtained from the reaction of 1-Br-2-methoxy-$^{14}$C (6) with phenyl azide. The decomposition of these triazenes was carried out in HOAc, in HOAc containing different amounts of NaOAc, or in 2,2,2-trifluoroethanol (TFE) containing 0.1% $HClO_4$. The products of these decomposition reactions were the isotopically scrambled trianisylvinyl acetates, 1-OAc-1,2-$^{14}$C and 1-OAc-1,2-methoxy-$^{14}$C, or the trianisylvinyl trifluoroethyl ethers, 1-$OCH_2CF_3$-1,2-$^{14}$C and 1-$OCH_2CF_3$-1,2-methoxy-$^{14}$C. Ozonolysis of these products gave rise to dianisyl[$^{14}$C]ketone (2-$^{14}$C) (7), and the difference in the $^{14}$C activities between the product and 2-$^{14}$C gave the extent of scrambling of the label from C-2 to C-1. The results are summarized in Tables 1 and 2.

In the previous study on the decomposition of 1-NNNHPh-2-$^{14}$C in HOAc (2), scramblings of 37.8 and 38.4% were observed in duplicate runs, and the present results from Expts. 1 and 2, Table 1, are in complete agreement with the earlier data. In the earlier work (2), the presence of 1.7 molar equivalents of added NaOAc decreased the scramblings in these duplicate runs to 17.0 and 16.6%, again in agreement with the effects of added NaOAc in the results given in Table 1. A similar trend of decreasing extents of scrambling with increasing amounts of added NaOAc was also observed with the ring labeled substrate 1-NNNHPh-2-methoxy-$^{14}$C (Table 2) and such effects could be interpreted as indicating that the decomposition of trianisylvinylphenyltriazene gave rise to the dissociated "free" trianisylvinyl cation (2). When the decomposition of 1-NNNHPh-2-$^{14}$C or 1-NNNHPh-2-methoxy-$^{14}$C was carried out in TFE, a solvent of lower nucleophilicity (9), a longer lifetime for the trianisylvinyl cation would be possible and thus more extensive 1,2-anisyl shifts could occur resulting in a complete scrambling of 50.0% or 33.3%, respectively, in the decomposition of 1-NNNHPh-2-$^{14}$C or 1-NNNHPh-2-methoxy-$^{14}$C.

Since the maximum extent of scrambling from complete equilibration of the isotopic labels would be 50.0% or 33.3%, respectively, for the chain labeled trianisyl[2-$^{14}$C]vinyl cation or the ring labeled 1,2-dianisyl-2-*p*-[$^{14}$C]methoxyphenylvinyl cation (eqs. [1] and [2]), the scrambling data have been

[1] 

50.0% 50.0%

[2] 

66.7% 33.3%

expressed as "% rearrangement" based on the assumption that 100% rearrangement corresponds to the maximum scrambling of 50.0% or 33.3% (10). Thus the observed % scrambling could be converted to % rearrangement by multiplication with a

[a] The product from reaction in the HOAc or $CF_3CH_2OH$ medium was the scrambled trianisylvinyl acetate, 1-OAc-1,2-methoxy-$^{14}$C, or trianisylvinyl trifluoroethyl ether, 1-$OCH_2CF_3$-1,2-methoxy-$^{14}$C, respectively.
[b] Assayed as the oxime.
[c] Instead of ozonolysis, the trianisylvinyl acetate product was converted by $LiAlH_4$ treatment to 1,2,2-trianisylethanol followed by $KMnO_4$ oxidation to give $An_2CO$ (2, 8).

factor of 2 or 3, respectively, for the chain or ring label.

In the earlier work on the acetolysis of 1-Br-2-$^{13}$C-2-methoxy-$^{14}$C (6), when the reaction was carried out in the presence of high concentrations of added salts (e.g. 15 m$M$ substrate with 450 m$M$ NaOAc or 300 m$M$ NaOAc and 300 m$M$ $Et_4NBr$), the "% rearrangement" for the $^{13}$C chain label and for the $^{14}$C ring label from a given experiment were found to be equal, indicating a complete equilibration of the labels in the molecules that have undergone rearrangement. On the other hand, for experiments carried out with lower concentrations of added salt, the equality of the "% rearrangement" for the chain and ring labels was not observed and it was suggested (6) that under such conditions some of the 1,2-anisyl shifts could have occurred in the ion-pair stage. The presence of the counterion would give rise to a front side hindrance, resulting in an incomplete equilibration of the labels. When ionization could proceed further to the dissociated "free" ions in the more polar medium with high concentrations of added salts, the 1,2-shifts would not be hindered by any counterion and complete equilibration was attained.

Given in Table 3 are the mean scrambling data

[a] Mean values from Tables 1 and 2.
[b] Assuming that 100% rearrangement corresponds to 50.0% or 33.3% scrambling, respectively, for the chain or ring label.

from the decomposition of the chain labeled 1-NNNHPh-2-$^{14}$C or the ring labeled 1-NNNHPh-2-methoxy-$^{14}$C expressed as % rearrangement. It is readily seen that the % rearrangement is the same for the chain labeled or ring labeled substrate. In Expts. 1 and 2, for example, almost 76% of the trianisylvinyl cation has undergone rearrangement with complete equilibration of the labels, while the remaining 24% was captured by solvent without rearrangement. For the reactions in HOAc with the presence of increasing amounts of the more nucleophilic acetate ion (Expts. 3–5), the portion of trianisylvinyl cation that was captured without rearrangement was increased, thus decreasing the net extent of rearrangement. In that portion of the trianisylvinyl cation in which 1,2-anisyl shifts took place, complete equilibration of the labels was achieved since triazene decomposition gave rise to the free cation in which 1,2-shifts could occur without hindrance by the presence of a counterion. These results thus may be regarded as giving support to the previous conclusion (6) that in the acetolysis of 1-Br-2-$^{13}$C-2-methoxy-$^{14}$C, conditions which gave rise to equal values for the % rearrangement in the chain label and in the ring label would involve scrambling in the free cation, while conditions which gave unequal % rearrangement for the chain and ring labels likely involved some scrambling in the ion-pair stage.

Recently, Ikeda *et al.* (11) have investigated the process of 1,2-anisyl shifts in solvolytic reactions with 2,2-dianisyl-1-phenylvinyl bromide specifically labeled with *p*-[$^2H_3$]$CH_3O$ (methoxy-$d_3$) in the *cis* or *trans*-anisyl group. A slight preference was found for the migration of the anisyl group *trans* to the bromine in reactions with HOAc–NaOAc, HOAc–AgOAc, or TFE-2,6-lutidine. It was proposed that this preference for migration of the *trans*-anisyl group was due to the intervention of ion-pairs in the rearrangement process, with the leaving group as the counterion hindering the migration of the anisyl group *cis* to the bromine. This mechanism is essentially the same as that suggested by us in accounting for the unequal % rearrangement found for the chain and ring labels in the acetolysis of 1-Br-2-$^{13}$C-2-methoxy-$^{14}$C under conditions of low concentrations of added salts (6).

## Experimental

*Trianisyl[2-$^{14}$C]vinylphenyltriazene (1-NNNHPh-2-$^{14}$C) and 1,2-dianisyl-2-p-[$^{14}$C]methoxyphenylvinylphenyltriazene (1-NNNHPh-2-methoxy-$^{14}$C)*

The chain labeled 1-NNNHPh-2-$^{14}$C was prepared from 1-Br-2-$^{14}$C and phenyl azide as previously described (2). The ring labeled 1-NNNHPh-2-methoxy-$^{14}$C was obtained from a similar phenyl azide reaction with 1,2-dianisyl-2-*p*-[$^{14}$C]methoxyphenylvinyl bromide (1-Br-2-methoxy-$^{14}$C), the latter being obtained starting from desoxyanisoin and *p*-[$^{14}$C]methoxyphenylmagnesium bromide, again as previously described (6).

*Decomposition of triazene and degradation of the reaction product*

The decomposition of 1-NNNHPh-2-$^{14}$C or 1-NNNHPh-2-methoxy-$^{14}$C in HOAc or HOAc–NaOAc was carried out essentially as described by Lee and Ko (2). Typically, 670 mg (1.44 mmol) of 1-NNNHPh-2-$^{14}$C or 1-NNNHPh-2-methoxy-$^{14}$C and 118 mg (1.44 mmol) of NaOAc in 10 mL of glacial HOAc was stirred at room temperature for 10 min (Expt. 3). The resulting material was worked up as previously described (2) to give the product, trianisyl[1,2-$^{14}$C]vinyl acetate (1-OAc-1,2-$^{14}$C) which was either subjected directly to ozonolysis to give dianisyl-[$^{14}$C]ketone (2-$^{14}$C) (7) or converted by $LiAlH_4$ treatment to 1,2,2-trianisyl[1,2-$^{14}$C]ethanol followed by $KMnO_4$ oxidation to give 2-$^{14}$C.

For the decomposition in TFE–$HClO_4$, typically 69.8 mg (0.15 mmol) of 1-NNNHPh-2-$^{14}$C or 1-NNNHPh-2-methoxy-$^{14}$C was dissolved in 10 mL of TFE containing 0.01 mL of $HClO_4$ (Expt. 6). Evolution of $N_2$ occurred immediately. The mixture was stirred at room temperature for 10 min and then poured into $H_2O$. After extraction with ether, the extract was washed with $H_2O$, dried over $MgSO_4$, and upon removal of the ether 60 mg (90%) of crude product was obtained as an oil. Its nmr spectrum was the same as that of an authentic sample of trianisylvinyl 2,2,2-trifluoroethyl ether (1-$OCH_2CF_3$). The labeled product, 1-$OCH_2CF_3$-1,2-$^{14}$C, was diluted with authentic 1-$OCH_2CF_3$ and then degraded by ozonolysis (7) to give 2-$^{14}$C.

Authentic 1-$OCH_2CF_3$ was prepared from heating a solution of 2.0 g (4.7 mmol) of 1-Br and 1.5 g (14 mmol) of 2,6-lutidine in 40 mL of TFE in a sealed tube at 120°C for 12 h. The resulting material was worked up as described above in the decomposition of triazene in TFE to give an oily product which was repeatedly crystallized from EtOH–$H_2O$, yielding 1.6 g (77%) of pure 1-$OCH_2CF_3$, mp 103–104°C; $^1$H nmr δ($CDCl_3$): 3.70, 3.76, 3.82 (3s, $CH_3O$), 3.91 (q, $CH_2$), 6.5–7.1 (m, arom.). *Anal.* calcd. for $C_{25}H_{23}O_4F_3$: C 67.56, H 5.22; found: C 67.26, H 5.30.

# Preparation and crystal and molecular structure of ($\eta^3$-octamethylcyclotetraphosphazane-*P,P,P*)tricarbonylmolybdenum(0), [$\eta^3$-$(CH_3PNCH_3)_4$]Mo$(CO)_3$

KEITH D. GALLICANO, NORMAN L. PADDOCK, STEVEN J. RETTIG, AND JAMES TROTTER

*Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6*

Received March 9, 1982

KEITH D. GALLICANO, NORMAN L. PADDOCK, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **60**, 2415 (1982).

The synthesis and physical properties of the phosphazane complex [$\eta^3$-$(CH_3PNCH_3)_4$]Mo$(CO)_3$ are reported. Crystals of ($\eta^3$-octamethylcyclotetraphosphazane-*P,P,P*)tricarbonylmolybdenum(0) are monoclinic, $a$ = 8.6898(9), $b$ = 16.0987(8), $c$ = 14.1156(17) Å, $\beta$ = 98.321(6)°, $Z$ = 4, space group $Cc$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to $R$ = 0.020 and $R_w$ = 0.024 for 2286 reflections with $I \geq 3\sigma(I)$. The molybdenum atom is coordinated to three phosphorus atoms of the $(MePNMe)_4$ ligand and to three carbonyl ligands in a distorted octahedral geometry. The molecule has approximate mirror symmetry in the solid state. Important bond lengths (corrected for libration) are: Mo—P = 2.537(1), 2.467(1), and 2.513(1), Mo—C = 1.971(4), 2.002(4), and 1.978(4), mean P—N = 1.704(8) for coordinated P, 1.735(7) Å for uncoordinated P. The structural evidence indicates that the phosphazane is a weaker donor to Mo$(CO)_3$ than to three sulphur atoms, and that coordination withdraws electron density from the fourth phosphorus atom. The complex is fluxional in solution.

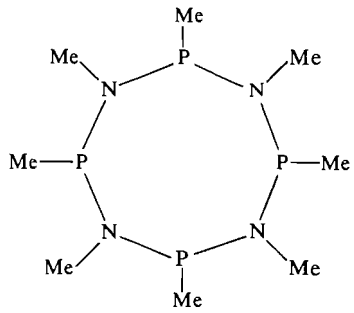
KEITH D. GALLICANO, NORMAN L. PADDOCK, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **60**, 2415 (1982).

On rapporte la synthèse et les propriétés physiques du complexe de phosphazane: [$\eta^3$-$(CH_3PNCH_3)_4$] Mo$(CO)_3$. Les cristaux de ($\eta^3$-octaméthylcyclotétraphosphazane-*P,P,P*)tricarbonylmolybolène(0) sont monocliniques et appartiennent au groupe d'espace $Cc$ avec $a$ = 8,6898(9), $b$ = 16,0987(8), $c$ = 14,1156(17) Å, $\beta$ = 98,321(6)°, $Z$ = 4. On a résolu la structure par les synthèses de Patterson et de Fourier et on l'a affiné par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de $R$ = 0,020 et de $R_w$ = 0,024 pour 2286 réflexions avec $I \geq 3\sigma(I)$. L'atome de molybolène est coordonné à trois atomes de phosphore du ligand (MePNMe) et à trois ligands carbonyle selon une géométrie octaédrique déformée. La molécule est approximativement symétrique à l'état solide. Les angles importants de liaison (corrigés pour la libration sont: Mo—P = 2,537(1), 2,467(1) et 2,513(1), Mo—C = 1,971(4), 2,002(4) et 1,978(4), angle moyen P—N = 1,704(8) pour le P coordonné et 1,735(7) Å pour le phosphore non coordonné. Les preuves structurales indiquent que le phosphazane est un plus faible donneur envers le Mo$(CO)_3$ qu'envers les trois atomes de soufre et que la coordination enlève la densité électronique du quatrième atome de phosphore. Le complexe est fluxionnaire en solution.

[Traduit par le journal]

## Introduction

The phosphazane $(MePNMe)_4$, **1**, was earlier prepared from methyldichlorophosphine and heptamethyldisilazane, and its crystal and molecular structure determined (1). Its reactions with sulphur to give $(MePNMe)_4S_3$ (2) and with acetylenic diesters (3) have been investigated; in both reactions, the phosphorus atoms are the donors. We have prepared the complex [$\eta^3$-$(CH_3PNCH_3)_4$]Mo$(CO)_3$, and have determined its crystal and molecular structure.



**1**

## Experimental

Molybdenum hexacarbonyl (0.178 g, 0.67 mmol) was added to **1** (0.202 g, 0.67 mmol) in 20 mL toluene at 70°C. The solution was stirred at this temperature under dry nitrogen for 18 h (higher temperatures cause decomposition), during which time a pale yellow solid precipitated. The product was filtered off, washed with toluene, and crystallized from acetonitrile as pale yellow blocks (0.080 g, 25%) of [$\eta^3$-$(CH_3PNCH_3)_4$]Mo$(CO)_3$, **2**. *Anal.* calcd. for $C_{11}H_{24}MoN_4O_3P_4$: C 27.5, H 5.0, N 11.7; found: C 27.2, H 5.2, N 11.6. **2** decomposed above 300°C, after turning brown at 180°C. Its mass spectrum (70 eV) showed the molecular ion and the stepwise loss of three carbonyl groups. $^1$H nmr parameters ($CDCl_3$, internal $Me_4Si$): $\delta(PCH_3)$ = 1.63, $\delta(NCH_3)$ = 2.88 (see Discussion). Infrared bands (Nujol mull): $\nu_{CO}$ = 1928 and 1828, 1817 cm$^{-1}$. Shoulder absorptions at 1854 and 1781 cm$^{-1}$ are attributed to solid state interactions.

*X-ray crystallographic analysis of* $[\eta^3\text{-}(CH_3PNCH_3)_4]Mo(CO)_3$

A crystal ca. 0.080 × 0.225 × 0.325 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo Kα$_1$ radiation (λ = 0.70930 Å). Crystal data at 22°C are:

$C_{11}H_{24}MoN_4O_3P_4$ fw = 480.18

Monoclinic, $a = 8.6898(9)$, $b = 16.0987(8)$, $c = 14.1156(17)$ Å, β = 98.321(6)°, $V = 1953.9(3)$ Å$^3$, $Z = 4$, $\rho_c = 1.632$ g cm$^{-3}$, $F(000) = 976$, μ(Mo Kα) = 9.11 cm$^{-1}$. Absent reflections: $hkl$, $h + k \neq 2n$ and $h0l$, $l \neq 2n$, space group $Cc$ ($C_s^4$, No. 9) from structure analysis.

Intensities were measured with graphite-monochromated Mo Kα radiation (λ = 0.71073 Å) on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.01–10.06° min$^{-1}$ over a range of (0.75 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 60°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within ±3.7%. After data reduction, an absorption correction was applied using the Gaussian integration method (4, 5). Transmission factors ranged from 0.876 to 0.933 for 96 sampling points. Of the 2846 independent reflections measured, 2286 (80.3%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with $S$ = scan count and $B$ = background count.

The systematic absences allow space groups $C2/c$ or $Cc$, the latter being indicated by the $E$-statistics, the Patterson function and by the number of molecules in the unit-cell. The positions of the Mo and P atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.028$, a difference map gave the positions of all 24 hydrogen atoms which were refined with isotropic thermal parameters in subsequent least-squares cycles. The scattering factors of ref. 6 were used for non-hydrogen atoms and those of ref. 7 for hydrogen atoms. Anomalous scattering factors from ref. 8 were used for the Mo and P atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. Convergence was reached at $R = 0.020$ and $R_w = 0.024$ for 2286 reflections with $I \geq 3\sigma(I)$. For all 2846 reflections $R = 0.037$ and $R_w = 0.024$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.10 and 1.02σ respectively. The mean error in an observation of unit weight was 1.122. A final difference map showed maximum fluctuations of ±0.90 e Å$^{-3}$ near Mo and less than ±0.2 e Å$^{-3}$ away from the Mo and P atoms. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Hydrogen atom coordinates and thermal parameters (Table 1*b*) have been deposited. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (9). The rms standard error in the temperature factors $\sigma U_{ij}$ (derived from the least-squares analysis) is 0.0017 Å$^2$. Analysis of all 23 non-hydrogen atoms gave rms $\Delta U_{ij}$ = 0.0081 Å$^2$ and indicated independent motion of the carbonyl oxygen and methyl carbon atoms. The 12 remaining core atoms were then analysed giving rms $\Delta U_{ij}$ = 0.0023 Å$^2$ and physically reasonable rigid-body parameters. The appropriate bond distances have been corrected for libration (10), using shape parameters $q^2$ of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of phosphazane and chelate rings are listed in Table 5. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 6–8) are included as supplementary material.

## Results and discussion

The $^1$H nmr spectrum of **2** shows that the molecule is fluxional in solution on the nmr time scale, the mean $PCH_3$ and $NCH_3$ signals, relative to those of **1**, being shifted upfield and downfield by 0.22 and 0.07 ppm respectively. $J_{PCH_3}$ is too small to be measured. The $(N)CH_3$ spectrum appears to be a doublet superimposed on a triplet, and was simulated by assuming equal coupling constants (3.2 Hz) to both pairs of phosphorus atoms. The carbonyl stretching frequencies are similar to, but slightly lower than, those of the $A_1$, $E$ bands (1949, 1835 cm$^{-1}$) in $(Ph_3P)_3Mo(CO)_3$ (11), consistent with some strengthening of the donor function of phosphorus by electron release from nitrogen.

There are no intermolecular contacts less than the sum of van der Waals radii in the crystal of **2**, so

[1]The structure factor table, Table 2 (anisotropic thermal parameters) and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

that the molecule may be considered in isolation. A stereoscopic view of it is shown in Fig. 1. The Mo atom is coordinated by three phosphorus atoms of the $(MePNMe)_4$ ligand and by three carbonyl ligands in a distorted octahedral geometry. Although the molecule has no strict crystallographic symmetry, it is nearly symmetrical about a plane through P(2)MoP(4), and, for the discussion, corresponding dimensions are averaged. In the complex, the crown conformation of the ligand is retained; the changes in its geometry caused by complex formation are discussed below.

In the ligand **1** (1), the configuration of the nitrogen atom is almost planar, the sum of the angles there being 357.1°, whereas the phosphorus atom is pyramidal, the sum of angles being 309.5°. The P—N bond, at 1.722(2) Å, is 0.05 Å shorter than would be expected for a single bond (12). The deficit, though smaller than in phosphazenes (0.09–0.16 Å) (13), represents significant $\pi$-bonding, arising from the acceptor properties of tervalent phosphorus. Such bonding is also found in non-cyclic molecules; in 1,1-bis(diphenylphosphino)-2,2-dimethylhydrazine, the sum of the angles at N(1) is 359.9(2)°, and the mean P—N bond length is 1.715(14) Å (14),[2] and in a diphenylphosphino-amino-substituted phosphetidine a short exocyclic P—N bond (1.691(11) Å) is associated with near planarity (359°) of the atoms attached to nitrogen (15).

Tri-coordination to molybdenum in **2** forms one six-membered and two four-membered rings, with

[2]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

some corresponding ring strain. The six-membered ring has a distorted boat conformation. Four-membered rings have also been found in the $Fe(CO)_3$ complex of a phosphetidine (16); in **2** they are both non-planar, that containing P(3) being somewhat more so than the other (see Table 5). The mean ring angle at N(1), N(2) (102.9(1)°) is 8.9° less than in **1**. Since this change is unaccompanied by changes in the lengths of the N—C bonds, the σ-hybrids at nitrogen do not lie along the bond directions, and the molecule must be regarded as strained at these points; the method of ref. 13 cannot be used for the assessment of π-contractions.[3] By the same argument, there is no indication of ring strain at the phosphorus atoms in **2**. The difference between the mean lengths of the P—C bonds to P(1), P(2), and P(3) (1.815(3) Å) and to P(4) (1.838(4) Å) is exactly that expected from the difference in N—P—C angle: mean 104.0(6)° at P(1), P(2), and P(3), 100.7(4)° at P(4). On the assumption of *s*/*p* hybridization, we can then calculate the composition and the direction of the lone pair orbital at each phosphorus atom.

Figure 2, calculated from the geometry around the phosphorus atoms, shows that the increased *p*-electron density in the P—Mo regions is attained partly at the expense of P(4) (in agreement with the reduced nucleophilicity found experimentally and spectroscopically at P(4) in the trisulphide (2)), and partly by an increased *s*-component in the ring

[3]As a comparison, the ring in $(MeNPMe)_4S_3$ is apparently unstrained. The especially large bond angles at N(2), N(3) (128.3(2), 129.9(2)°) are associated, through increased *p*-character of the exocyclic bonds, with the longest N—C bonds (1.497(6), 1.511(6) Å).

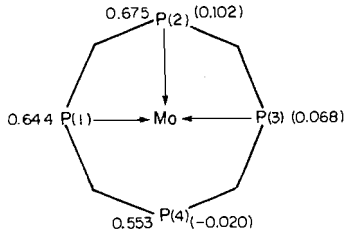

FIG. 2. Fractional $p$-electron density in the lone pair orbitals at phosphorus. Difference from density in the free ligand in parentheses.

bonds. This result is consistent with a reduction of the mean P—N bond length from 1.722(2) Å in **1** to 1.711(17) Å in **2**, a slight increase in the strengths of the bonds meeting at P(1), P(2), and P(3) (mean P—N = 1.704(8) Å) being achieved partly at the expense of P(4)—N (mean 1.735(7) Å). A similar but slightly larger effect is found in the trisulphide $(MePNMe)_4S_3$ (2), in which the ring bonds to the coordinated phosphorus atoms (means 1.688(13) Å) are shorter than those to the fourth atom (mean 1.740(9) Å). Whether assessed by bond angles or bond lengths, the electronic shifts induced by the $S_3$ and $Mo(CO)_3$ groups are qualitatively of the same type, sulphur being the stronger acceptor.

Some differences between the two structures are a consequence of the particular geometry of the $Mo(CO)_3$ group. Its coordination to the phosphazane framework necessarily introduces angular strain, discussed above for the angles at nitrogen, if normal bond lengths are to be preserved in the four-membered rings. Distortion at phosphorus is of another sort, the P—Mo bond directions deviating from the calculated lone pair directions by 23.6° at P(1) and P(3), and by 34.3° at P(2). The P—Mo—P angles are small (64.49(3), 85.12(3), and 64.75(3)°), but there may be no strain here. Certainly, there are other examples of small angles, such as P—Mo—P = 65.6(2)° in $(EtP)_5Mo(CO)_4$ (17) and 64.8(2)° in $(Ph_2PNEtPPh_2)Mo(CO)_4$ (18), and in $(Ph_2PNEtPPhNEtPPh_2)Mo(CO)_3$, **3** (19), the coordination geometry of the tridentate ligand is almost identical with that in **2**, even though the ligand is acyclic, the P—Mo—P angles being 65.0(1), 94.0(1), and 65.3(1)°.

The surprising feature of the structure of **2** is that P(2)—Mo (2.467(1) Å) is significantly shorter than P(1)—Mo, P(3)—Mo (mean 2.525(12) Å), opposite to the situation in **3** where the central P—Mo bond (2.527(4) Å) is significantly longer than the other two (mean 2.451(26) Å). This feature of **2** is consistent with the calculated $p$-electron densities and with the Mo—C distances, that to C(2) being significantly longer (2.002(4) Å) than those to C(1), C(3) (mean Mo—C = 1.975(4) Å), but there seems no obvious explanation. The difference does not appear to be caused by the electronic structure of the phosphazane since all three P=S bonds in the trisulphide are equal. It may simply be that elongation of the P(2)—Mo bond would increase the misalignment of the bond and lone pair directions, thereby reducing the P—Mo—P angle unacceptably, but a compromise of this type which strengthens a bond is unusual.

# The mechanism of sulphide oxidation by *Mortierella isabellina* NRRL 1757

HERBERT L. HOLLAND[1] AND IAN M. CARTER
*Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1*

Received March 26, 1982

HERBERT L. HOLLAND and IAN M. CARTER. Can. J. Chem. **60**, 2420 (1982).

A series of aryl substituted phenyl and benzyl methyl sulphides has been oxidized to the corresponding sulphoxides by *Mortierella isabellina* NRRL 1757. The oxygen atom introduced during this enzymic oxidation is derived from the atmosphere and not from water. The rates of oxidation have been determined by uv analysis, and correlated with the Hammett $p$. sigma constants for the phenyl methyl sulphide series. The value of $\rho = -0.67$ so obtained is interpreted in terms of a mechanism of oxidation at sulphur involving an electrophilic attack on the sulphide sulphur by the enzymic activated iron–oxygen complex, followed by conversion of the resulting sulphur cation to sulphoxide.

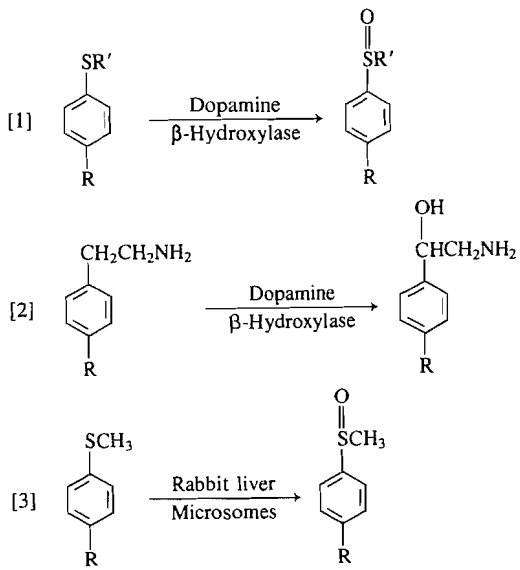
HERBERT L. HOLLAND et IAN M. CARTER. Can. J. Chem. **60**, 2420 (1982).

On a oxydé une série de méthylthio-benzènes et -phénylméthanes substitués en sulphoxydes correspondants à l'aide de la *Mortierella isabellina* NRRL 1757. L'atome d'oxygène introduit lors de cette oxydation enzymatique provient de l'atmosphère et non de l'eau. On a déterminé les vitesses d'oxydation par l'analyse uv et on les a relié aux constantes sigma $p$ de Hammett, dans le cas des méthylthiobenzènes. On interprète la valeur de $\rho = -0{,}67$ ainsi obtenue en fonction d'un mécanisme d'oxydation au niveau du soufre impliquant une attaque électrophile sur le soufre du sulfure par un complexe fer-oxygène activé enzymatiquement, suivi de la transformation sur cation soufré résultant en sulphoxyde.

[Traduit par le journal]

The enzymic oxidation of sulphides to sulphoxides and sulphones can be efficiently carried out by enzymes from mammalian (1–3) or microbial (4–6) sources. Early work in this area (4–6) was concerned largely with the stereospecificity of sulphoxide formation and metabolism by fungi, whereas more recent work (2, 3, 7, 8) has centered on an investigation of the mechanism of the oxidative reaction when carried out by enzymes from mammalian sources.

May *et al.* (7) found that dopamine β-hydroxlase, a copper-containing mono-oxygenase, can perform sulphoxidation of aryl substituted phenyl alkyl sulphides (eq. [1]), and that with this enzyme the reaction proceeds at rates which indicate a ρ value of −3.6 in the conventional Hammett plot. This value differs considerably from that shown by the same enzyme for β hydroxylation of substituted dopamine derivatives (eq. [2]), where a value of −0.4 was reported (7). These values were interpreted by May *et al.* (7) in terms of a mechanism of enzymic sulphoxidation similar to that of hydrogen peroxide oxidation of sulphides, where a ρ value of −1.13 was observed (9). The large difference in ρ values (−3.6 vs. −1.13) was not commented upon. However, the enzymic ρ value was obtained using only halo substituted and unsubstituted thioanisole, and because of the small range of σ values concerned should be regarded as an approximate value. The mechanistic proposal of May (Scheme 1) involves nucleophilic attack by



sulphur at an electron deficient activated oxygen intermediate. Hydroxylation, on the other hand, is proposed to proceed via neutral radical intermediates which would necessitate little charge separation in the transition state, a state of affairs consistent with the observed values.

In a parallel investigation, Oae and co-workers (2, 3, 8) have studied the sulphoxidation of substituted phenyl methyl sulphides by a cytochrome P-450 dependent enzyme preparation from rabbit liver (eq. [3]). Their kinetic data gave a $\rho^+$ value of −0.16; the low magnitude of this result, together with the results of model reactions with

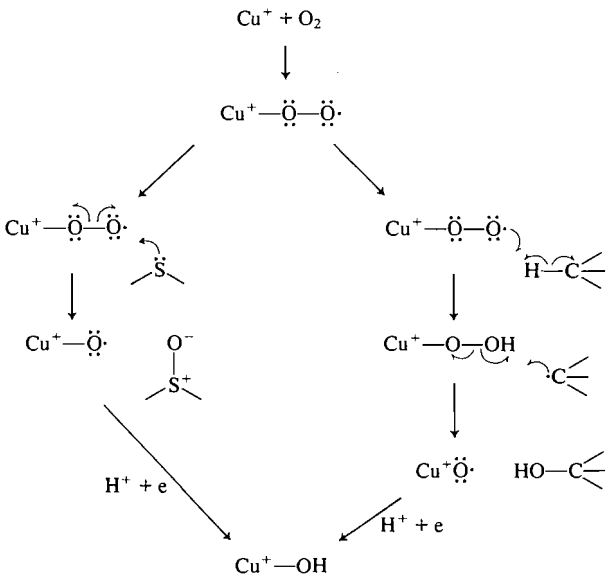
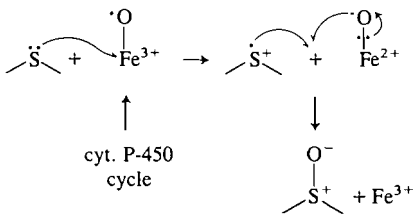


SCHEME 1. Proposed mechanism for sulphoxidation and hydroxylation by dopamine β-hydroxylase (7).

hydroxyl radical generating systems (10–12) and a study of the one-electron oxidation potentials of sulphides, led to the mechanistic proposal shown in Scheme 2, in which the rate determining step involves an activated iron–oxygen species. The correlation coefficients obtained in both the above studies are presented in Table 2.

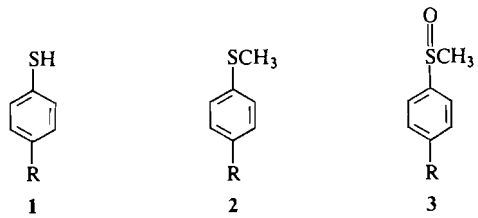


SCHEME 2. Proposed mechanism for sulphoxidation by rabbit liver microsomes (2, 3).

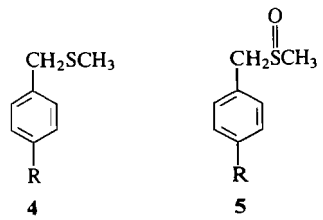
In the present study, we have investigated the sulphoxidation of a series of substituted methyl phenyl (**2**) and benzyl methyl (**4**) sulphides by the fungus *Mortierella isabellina* NRRL 1757 (eq. [4]). This fungus was chosen because it oxidizes sulphides of type **2** and **4** to the corresponding sulphoxides **3** and **5** in high yield and without any detectable further oxidation to sulphone (6); the formation of sulphone occurs to a greater or lesser extent with most of the other fungi reported to perform this reaction (13).

By performing incubations in $^{18}O$ labelled water and air (see Experimental) we have demonstrated that the enzyme catalysing the sulphoxidation of **2***a* shows one of the major characteristic properties of mono-oxygenases, in that the oxygen entering the substrate is derived directly from the atmosphere and not from the aqueous medium. However, other cofactor requirements for this reaction have not been investigated.

The rates of oxidation of sulphides **2** and **4** were determined by monitoring the release of sulphoxides **3** and **5** into the aqueous medium by ultraviolet spectral analysis. The uv data on which these analyses were based, together with the rates so obtained, are presented in Table 1. The following control experiments were performed. Firstly, a culture of fungus grown in the absence of sulphide was monitored over a 36 h period for the production of uv absorbing compounds which might interfere with the analysis: none were found. Secondly, calibration mixtures of sulphide **2***a* and sulphoxide **3***a* of varying composition were made up, and confirmed that the uv method gave reliable estimates of sulphoxide concentration. Thirdly,



**1–3** *a* R = H
*b* R = $CH_3$
*c* R = $C_2H_5$
*d* R = F
*e* R = Cl
*f* R = Br
*g* R = $NO_2$
*h* R = $OCH_3$



**4, 5** *a* R = H
*b* R = $CH_3$
*c* R = $NO_2$

confirmation of sulphoxide formation was obtained in all cases by both the isolation and characterization of sulphoxide from the incubation medium, and by comparison of the uv trace obtained at the termination of the kinetic runs with that of an authentic sample of sulphoxide. In no case was any

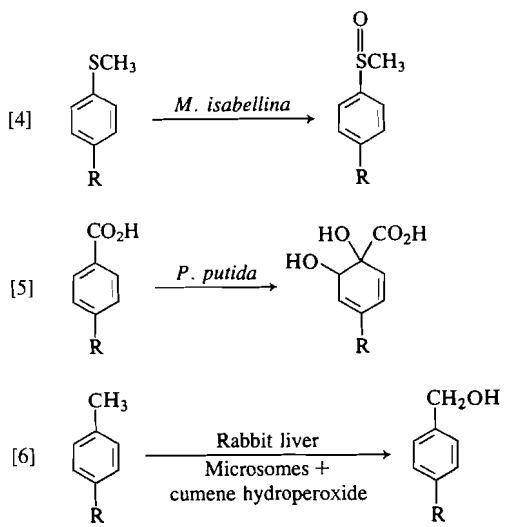
evidence obtained for the formation of a uv absorbing compound other than the sulphoxide.

The complexity of biological reactions, especially in systems involving membrane bound enzymes and very poorly soluble substrates, as is the case in the present study, often makes the interpretation of correlation analyses such as ρ values extremely complex. In an attempt to demonstrate that the variation in rate of sulphoxide production reported herein can be directly correlated to the rate of sulphide oxidation, we have studied the oxidation of the corresponding benzyl methyl sulphides **4** by *M. isabellina*.



The common rate observed for the oxidation of the different benzyl sulphides **4***a*–**4***c* confirms that the variation in rate observed in the case of the phenyl sulphides **2** is probably attributable to the electronic effect of the *para* substitutent, and not to the difference in size and/or polar nature of the groups concerned. The assumption that the rate of release of sulphoxide into the aqueous medium can be correlated with the rate of oxidation at sulphur, and is not attributable to other factors (such as membrane transport or cofactor oxidation), is based on the following arguments.

Firstly, although the rate determining step in enzymic sulphoxidation is unknown, in cytochrome P-450 dependent mono-oxygenase reactions the rate determining step is the decomposition of the cytochrome P-450 oxygen–substrate complex to products (14); and secondly, externally added sulphoxide is not taken up by the fungal mycelia, suggesting that the degree of association between sulphoxide and cell membrane is low. We therefore conclude that sulphoxide, on its release from the active site, is rapidly passed through the cell wall into the aqueous medium. This conclusion is supported by control experiments in which extraction of both the medium and fungal mycelia at various times after addition of sulphide indicates that sulphoxide is present only in the medium, and that little if any sulphoxide remains in the mycelia.

The Hammett plot obtained for sulphoxidation of the phenyl methyl sulphides **2** is presented in Fig. 1. With the exception of data for **2***b* (R = $CH_3$), **2***c*

TABLE 2. Hammett ρ values obtained for oxidation at sulphur and hydroxylation at carbon

*$\rho^+$ value.
†Source of a dioxygenase enzyme.

(R = $C_2H_5$), and **2***f* (R = Br), the points fall on a straight line with a value of −0.67 ($r$ = 0.994). The rates observed in our work, unlike those obtained by Oae and co-workers (2), do not correlate well with $\sigma^+$ values. The deviation of the rates for alkyl substituted sulphide oxidation from this value may reflect a change in the rate limiting step of the reaction, or a degree of hydrophobic interaction between substrate and fungal membrane not present for the other substrates involved. However, this phenomenon is not apparent for the oxidation of the corresponding benzyl sulphide. A comparison of this value with other ρ values for enzymic oxidation at sulphur (2, 3, 7, 8, 37) and carbon (7, 15, 16) is presented in Table 2. The reactions concerned are outlined in eqs. [1]–[7]. With the exception of eq. [1], all the enzymic processes have been proposed, on the basis of a low negative ρ value, to involve a mechanism in which there is not a high degree of electron demand

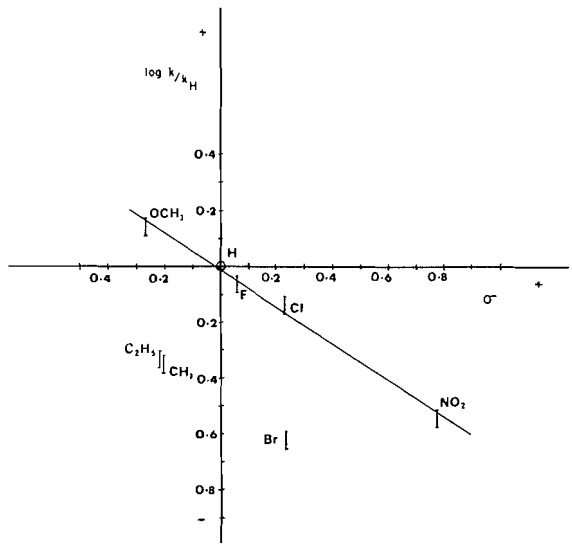

FIG. 1. The Hammett plot for sulphoxidation of phenyl methyl sulphides **2**.

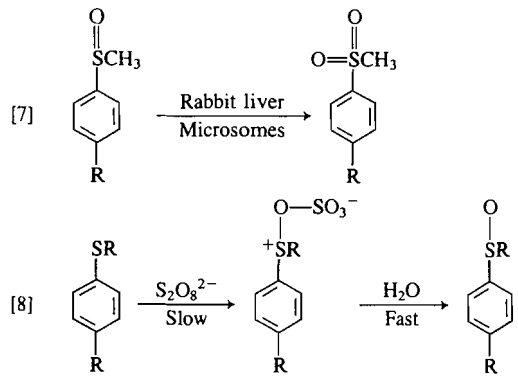

Reference 39

on the substrate in the transition state. In the case of hydroxylation at saturated carbon, a carbon radical intermediate has been proposed (16) (Scheme 3), whereas in the case of oxidation at sulphur, a radical cation species is the proposed intermediate (Scheme 2).

The ρ value of −0.67 obtained in the present study differs appreciably from those obtained using peroxide oxidants ($H_2O_2$, −1.13 (9), isoalloxazine hydroperoxide, −1.67 (38)), and that reported by May *et al.* (7) for dopamine β hydroxylase, −3.6 (but *vide supra* and ref. 38). However, it is close to the value reported by Srinivasan *et al.* (39) for oxidation by potassium persulphate (ρ = −0.87, $\rho^+$ = −0.56), in which the slow step is electrophilic attack at sulphide sulphur by the persulphate ion to form an intermediate sulphur cation (eq. [8]), and

also the value observed for the oxidation of sulphoxides to sulphones by *m*-chloroperoxybenzoic acid (−0.54) (24). Our data therefore do not strongly support the one-electron oxidation route proposed for the corresponding mammalian enzymic reaction (2, 3, 37) (Scheme 2), but indicate a transition state in which there is greater electron demand on sulphur. This is consistent with an electrophilic attack by the activated iron–oxygen enzymic complex on sulphur, analogous to that shown in eq. [8].

The relevance of the sulphur oxidation mechanism to the mechanism of hydroxylation at saturated carbon remains to be established, however. The values of ρ obtained for the latter reaction (Table 2) may not reflect the value for a normal cytochrome P-450 dependent mono-oxygenase. Equation [2] involves a copper dependent enzyme, eq. [4] refers to a dioxygenase, and eq. [6] involves the use of cumene hydroperoxide rather than oxygen as the ultimate oxidizing species. It is therefore apparent that definitive data for the carbon hydroxylation reaction are needed so that a more meaningful comparison with sulphur oxidation can be made.

## Experimental

*Apparatus, materials, and methods*

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with a Perkin–Elmer 237B spectrometer, and ultraviolet spectra with a Hitachi Perkin–Elmer 124 or Cary 14 spectrophotometer. Proton nmr spectra were obtained at 60 MHz with a Varian A-60 or Bruker WP-60, using $CDCl_3$ as solvent and TMS as internal standard, and $^{13}C$ nmr at 15.18 MHz with a Bruker WP-60, using $CDCl_3$ as solvent and TMS as internal standard. Mass spectra were obtained with an AEI MS 30 interfaced to a Kratos DS 55 data system: isotopic composition was determined by repeated data accumulation over the relevant ion region and application of the appropriate corrections for natural abundances; values are accurate to ± 0.5%. Column chromatography was performed on silica gel (60–200 mesh), and thin layer chromatography on Merck silica gel 60 F-254 (0–2 mm).

*Mortierella isabellina* NRRL 1757 was maintained on slopes composed of 4% malt agar.

*Preparation of substrates*

*p*-Toluenethiol (**1***b*), *p*-fluorobenzenethiol (**1***d*), *p*-chlorobenzenethiol (**1***e*), *p*-bromobenzenethiol (**1***f*), *p*-nitrobenzenethiol (**1***g*), thioanisole (**2***a*), and benzyl methyl sulfide (**4***a*) were commercial samples.

p-*Ethylbenzenethiol* (**1***c*) *and* p-*methoxybenzenethiol* (**1***h*)

These were prepared from the corresponding phenol by the method of Newman and Karnes (17), and gave satisfactory analytical (bp and spectral) data.

*Substituted thioanisoles;* **2**b–**2**h

These were made by alkylation of the corresponding thiophenols **1***b*–**1***h* by the method of Clark and Miller (18) and possessed physical properties similar to those reported (19, 20).

*Substituted phenyl methyl sulphoxides;* **3**a–**3**h

These were prepared from the corresponding sulphides **2** using sodium metaperiodate as oxidant (21), and exhibited spectral and physical properties consistent with those reported (22–27).

*Substituted benzyl methyl sulphides;* **4**b, **4**c

Compound **4***b* was prepared by reaction of the corresponding substituted benzyl chloride with methanethiol using the procedure described (28), and gave satisfactory analytical data (29, 30). *p*-Nitrobenzyl methyl sulphide (**4***c*) (31) was prepared from *p*-nitrobenzyl mercaptan (32) by alkylation with methyl iodide (18).

*Substituted benzyl methyl sulphoxides;* **5**a–**5**c

These were prepared from the corresponding sulphides **4** using sodium metaperiodate as oxidant (21), and exhibited spectral and physical properties consistent with those reported (29, 33, 34).

*Incubations with* Mortierella isabellina *NRRL 1757*

The fungus was grown in a medium composed of glucose (40 g), soybean meal (5 g), yeast extract (5 g), sodium chloride (5 g), and dibasic potassium phosphate (5 g) per litre of distilled water (35). One-litre Erlenmeyer flasks containing 150 mL of the above medium were sterilized, allowed to cool, and then inoculated from a growing slope of *M. isabellina*. The flasks were then placed on a 1 in. rotary shaker (150 rpm) at 25°C for 3 days. After this time, the fungus was removed by filtration and resuspended in distilled water (130 mL in each 1-L Erlenmeyer flask). For preparative studies, sulphide (100 mg in 1.15 mL ethanol) was added to each flask and incubation continued as above for 24–36 h. After this time, the fungus was removed by filtration and the filtrate extracted with chloroform. The extract was dried and evaporated, and then subjected to tlc and spectral analysis. Incubations of sulphides **2** and **4** gave the corresponding sulphoxides **3** and **5** as the only identifiable products.

*Measurement of kinetic data*

For kinetic studies, the mycelia from two flasks were combined and resuspended in 130 mL of distilled water in a single 1-L Erlenmeyer flask. Sulphide (100 mg in 1.15 mL ethanol) was added to each flask at time zero, and the flask returned to the rotary shaker at 25°C. Samples (1 mL) were removed by filtration at various time intervals, and diluted to 25 mL with spectroscopic grade methanol. This solution was then used for uv spectral analysis. The relative proportions of sulphide and sulphoxide were determined by the standard technique of two-component analysis (36), using the wavelengths and extinction coefficients listed in Table 1. The increase in sulphoxide concentration with time gave the rate constants reported for release of sulphoxide into the medium.

*Incubation in* $^{18}O$*-labelled water*

Fungus from one 1-L flask, grown as described above, was placed into 100 mL of $H_2{}^{18}O$ (1.5% enriched) in a 500 mL Erlenmeyer flask, and methyl phenyl sulphide (**2***a*) (100 mg) in ethanol (1 mL) added to the flask. The sulphoxide **3***a* isolated after a 36 h incubation was examined by mass spectrometry and found to contain no higher level of $^{18}O$ then a sample produced in a comparable experiment using unlabelled water.

*Incubation under an* $^{18}O$ *labelled atmosphere*

Fungus from one 1-L flask, grown as described above, was placed in a side arm attached to 500 mL Erlenmeyer flask. The main body of the flask contained 100 mL water and 100 mg methyl phenyl sulphide (**2***a*). Degassing was carried out by alternate freezing, pumping, and thawing. The flask was then filled with an $^{18}O$ enriched atmosphere (nominally 90% $^{18}O$), and sealed. The fungus was added from the side arm, and the sulphoxide **3***a* isolated after a 36 h incubation examined by mass spectrometry: isotopic content, $^{18}O$, 80%; $^{16}O$, 20%.

# Dihydropyridines in synthesis and biosynthesis. V.[1,2] Synthesis of pyridocarbazole alkaloids: olivacine and (±)-guatambuine

JAMES P. KUTNEY, MASAKI NODA, NORMAN G. LEWIS, BEATRICE MONTEIRO, DANUTA MOSTOWICZ, AND BRIAN R. WORTH

*Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6*

Received March 15, 1982

JAMES P. KUTNEY, MASAKI NODA, NORMAN G. LEWIS, BEATRICE MONTEIRO, DANUTA MOSTOWICZ, and BRIAN R. WORTH. Can. J. Chem. **60**, 2426 (1982).

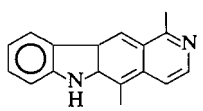
A synthetic route to the pyridocarbazole alkaloids, olivacine and guatambuine is described. The crucial step in the synthesis utilizes tricarbonylchromium(0) complexes of a suitable dihydropyridine system and illustrates the application of such complexes for the preparation of such alkaloids.

JAMES P. KUTNEY, MASAKI NODA, NORMAN G. LEWIS, BEATRICE MONTEIRO, DANUTA MOSTOWICZ et BRIAN R. WORTH. Can. J. Chem. **60**, 2426 (1982).

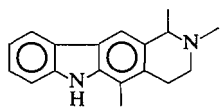
On décrit une voie d'accès aux alcaloides pyridocarbazole, olivacine et guatambuine. L'étape fondamentale de la synthèse utilise les complexes tricarbonylchrome(0) d'un système dihydropyridine convenable et illustre l'application de ces complexes à la préparation de tels alcaloides.

[Traduit par le journal]

The pyridocarbazole alkaloids, including olivacine (**1**) and guatambuine (**2**), have received considerable interest due to their promising antitumor activity (3–5). The total synthesis of representatives of this family of alkaloids has been the subject of numerous studies (6–21). Several of the synthetic approaches reported employed cyclization of pyridyl-substituted indoles to generate the linear pyridocarbazole skeleton. However, the yields obtained have generally been low.



**1**



**2**

Our interest in the stabilization and use of very reactive dihydropyridine systems led us to investigate the utility of tricarbonylchromium(0) complexes (e.g. **8**) in the synthesis of natural products (22, 23). Here we envisaged the complex **8** to provide a nucleophilic center at the indole-3 position, for appropriate substitution employing a one-carbon electrophile, and subsequent cyclization to the pyridocarbazole skeleton utilizing the masked enamine (dihydropyridine) unit (Scheme 1).

Condensation of 1-benzenesulphonylindole (**4**), readily derived from indole (**3**), with 4-acetylpyridine gave **5** which was readily hydrolyzed to **6** (19, 24). Iodomethylation of **6** provided the corresponding pyridinium salt **7** in high yield. Reduction of **7** with sodium borohydride and protection of the resulting dihydropyridine, in the usual manner (22), afforded the tricarbonylchromium(0) complex **8** as red crystals in 56% overall yield. High resolution $^1$Hmr revealed two sets of resonances, indicating the product as a mixture of two diastereoisomers in the ratio of 2:1 (see Experimental). As expected, in the major isomer the methyl group (δ 1.44) on the chiral center is in the more stable configuration, that is, on the opposite side of the bulky tricarbonylchromium group. These methyl protons (δ 1.88) of the other epimer being affected significantly by the deshielding property of the tricarbonylchromium group resonated as substantially lower field.

Reaction of complex **8** with the Vilsmeier reagent, prepared from DMF and $POCl_3$, formed an intermediate which on direct treatment with pyridine afforded a mixture of yellow products **12** and **13** in high yield. Considerable efforts were expended in attempting to separate this mixture by various chromatographic methods. Eventually a portion was separated by careful silica gel column chromatography to give sufficient material for characterization of the two compounds. The less polar minor compound was assigned the structure **13** based on its spectral properties (C4-H, broad doublet at δ 8.22, $J$ = 8 Hz; C1-H, singlet at δ 9.14). Clearly structure **14** must possess two doublets for the corresponding C3- and C4-vinyl protons. The major product **12** was isolated as the phosphate salt. Formation of **12** from **8** can be rationalized according to Scheme 1 (viz. **8** → **9** → **10** → **11**). The

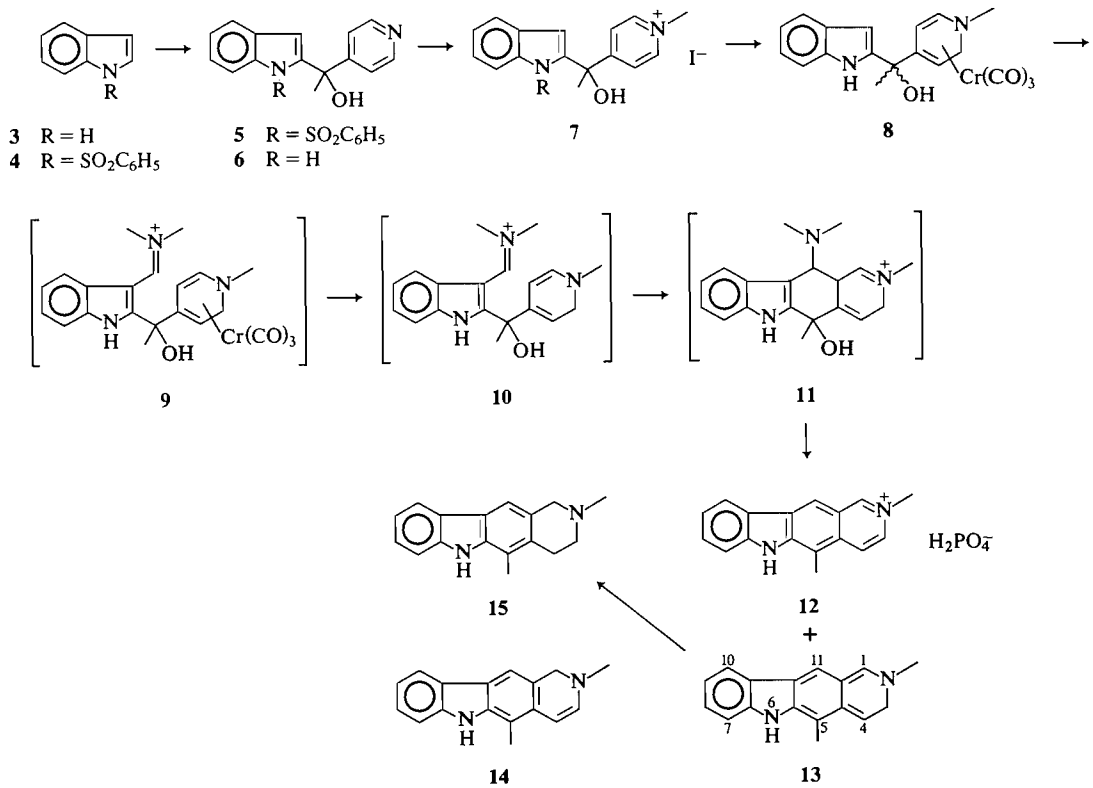

SCHEME 1

reduction product **13**, also isolated in this mixture, can be rationalized via a reductive process involving the dihydropyridine system generated from the complex **8**. However, direct evidence for this process is lacking. Reduction of the mixture **12** and **13** with sodium borohydride resulted in a single product 1-desmethylguatambuine (**15**) (89% yield from **8**). Similar reduction of a small sample of pure **13** also gave **15** as the product, thus supporting the structural assignment for **13**.

With the pyridocarbazole skeleton constructed (compounds **12** and **13**), subsequent elaboration of these intermediates to complete the syntheses of olivacine (**1**) and (±)-guatambuine (**2**) was achieved as shown in Scheme 2. Dehydrogenation of the mixture of **12** and **13** using Pd/C at 300°C afforded a mixture of unconverted **12** and the pyridine derivative **16**. The latter was easily separated from **12** which was also readily demethylated to **16** using triphenylphosphine in DMF or HMPA.

Reaction of **16** with methyllithium in dry THF and subsequent oxidation of the dihydropyridine intermediate with iodine provided olivacine (**1**) in 54% yield. Iodomethylation of **1** followed by reduction with sodium borohydride afforded (±)-guatambuine (**2**). Further confirmation of **1** and **2** was established by thin layer chromatography comparison with authentic samples.

These studies have provided a further demonstration of the utility of chromium tricarbonyl complexing in the stabilization of highly reactive dihydropyridine systems. This reactive dienamine generated *in situ* at an appropriate stage in the synthesis affords an interesting and efficient preparation of pyridocarbazole alkaloids.

## Experimental

Melting points were determined on a Kofler block and are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer in methanol solution. The wavelengths of absorption maxima are reported in nanometers (nm) with log ε in parentheses. Infrared (ir) spectra were measured on a Perkin–Elmer model 710 or 457 spectrophotometer as KBr disc. The absorption maxima are reported in wavenumbers ($cm^{-1}$), calibrated with respect to the absorption band of polystyrene at 1601 $cm^{-1}$. Proton magnetic resonance ($^1$Hmr) spectra were recorded on either a Varian HA- or XL-100 or a 270 MHz spectrometer with TMS as internal standard. The integrated peak areas, signal multiplicities, and proton assignments are given in parentheses. Low resolution mass spectra (ms) were determined on either an AEI MS-902 or an Atlas CH-4B spectrometer. High resolution mass spectra were measured on an AEI MS-902 instrument. Microanalyses were carried out by Mr. P. Borda of the Microanalytical Laboratory, University of British Columbia. Column chromatography utilized Merck silica gel 60 (70–230 mesh). Preparative and thin layer chromatography utilized Merck silica gel $GF_{254}$. As a matter of routine, all reagents and solvents were recrystallized or distilled before use.

*1-Benzenesulfonylindole (4)*

Potassium hydride (54 g, 22.1% (0.29 mol)) was added to a solution of anhydrous THF (150 mL) and HMPA (40 mL) at 0°C. To this mixture was added indole (23.4 g (0.2 mol)) in anhydrous THF (50 mL) over 30 min under nitrogen, which was then warmed to room temperature for 1 h. The mixture was cooled to 0°C and benzenesulfonyl chloride (41 g (0.23 mol)) was added dropwise. The mixture was stirred at room temperature for 20 h and poured into water and extracted with $CH_2Cl_2$. The organic extract was dried ($Na_2SO_4$) and concentrated. The precipitate was filtered to give **4** (35.5 g, 68%). Recrystallization of the product from $CH_2Cl_2$–hexane gave colourless needles, mp 78°C (lit. (23) mp 77.5–79°C).

*1-(1-Benzenesulfonyl indole-2-yl)-1-(4-pyridyl)-ethanol (5)*

*tert*-Butyllithium (40 mL (1.85 *M*), 75 mmol) was added dropwise to benzenesulfonylindole (**4**) (12.8 g, 50 mmol) in dry THF (270 mL) under nitrogen at 0°C. The reaction mixture was stirred at room temperature for 2 h, cooled to 0°C, and 4-acetylpyridine (13 mL, 118 mmol) was added dropwise. The resulting yellowish suspension was stirred overnight at room temperature and poured into water (200 mL) and extracted with $CH_2Cl_2$. The organic extracts were washed with water, dried ($Na_2SO_4$), and evaporated to give colourless crystals. The crystals were filtered and washed with acetone to give **5** (8.5 g, 48%). From the mother liquor crude **5** (2.5 g) was obtained. Recrystallization from acetone–$CHCl_3$ gave pure **5** (2.0 g, 17%), total yield 65%, mp 228–229°C (from $CHCl_3$) (lit. (23) mp. 229–230°C).

*Indole-2-yl-1-(4-pyridyl)-ethanol (6)*

The alcohol **5** (3 g, 7.96 mmol) was added to a 2 *M* methanol sodium hydroxide solution (500 mL) and heated for 4 h, cooled, and extracted with ether (600 mL). The organic extract was evaporated and recrystallized from $CHCl_3$ to give **6** (1.36 g, 72%), mp 218–221°C (lit. (23) mp 221°C); ir $\nu_{max}$: 3400, 3290, 1600; uv $\lambda_{max}$: 283 (3.86), 274 (3.92), 256 (3.95), 253 (3.92), 211 (4.53); $^1$Hmr (DMSO-$d_6$) δ: 1.88 (3H, s), 6.18 (1H, s, OH), 6.31 (1H, d, $J$ = 2 Hz, C3′-H), 7.40–6.80 (4H, m, ArH), 7.46 (2H, d, $J$ = 6 Hz, C3-H, C5-H), 8.49 (2H, d, $J$ = 6 Hz, C2-H, C6-H), 10.92 (1H, s, N*H*); ms *m/e*: 238 ($M^+$), 220, 205, 160. High resolution mass determination, calcd. for $C_{15}H_{14}N_2O$: 238.1106; found: 238.1123. *Anal.* calcd. for $C_{15}H_{14}N_2O$: C 75.63, H 5.88, N 11.76; found: C 75.55, H 5.70, N 11.95.

*Indole-2-yl-1-(4-pyridylmethiodide)-ethanol (7)*

The alcohol **6** (390 mg) was added to a solution of ethyl acetate (30 mL) and $CH_3I$ (2 mL). The suspension was heated at 50°C for 5 h. The resulting precipitate was removed by suction filtration to afford an amorphous powder **7** (554 mg, 89%), ir $\nu_{max}$: 3285, 1640; uv $\lambda_{max}$: 287 (3.63), 277 (3.85), 262 (4.06), 257 (4.07), 217 (4.70); $^1$Hmr (DMSO-$d_6$) δ: 1.98 (3H, s), 4.26 (3H, s, N—$CH_3$), 6.44 (1H, s, C3′-H), 6.72 (1H, s, O*H*), 7.56–6.82 (4H, m, ArH), 8.17 (2H, d, $J$ = 6.8 Hz, C3-H, C5-H), 8.93 (2H, d, $J$ = 6.8 Hz, C2-H, C6-H).

*The complexes 8*

$NaBH_4$ (5%) in ether (40 mL) and 2 *N* NaOH (15 mL) was added to the pyridinium salt **7** (570 mg, 1.5 mmol) in MeOH (15 mL) under nitrogen at 0°C. The two phase system was stirred vigorously for 50 min at 0°C. The aqueous layer was removed, and then the ether layer was washed briefly with 2 *N* NaOH (5 mL) and dried with anhydrous $Na_2SO_4$, $K_2CO_3$, and a small amount of KOH for 1 h at 0°C. The dried ether solution was added under nitrogen to a solution of trisacetonitriletricarbonyl chromium (1.5 equiv.) in dry ether at 0°C and the mixture was stirred for 3 h. The resulting red solution was filtered through previously degassed Florisil (20 g) with degassed dichloromethane under a nitrogen atmosphere to afford **8** as a mixture of diastereomers in the ratio of 2:1. Recrystallization of the red mixture with ether and petroleum ether (30–60°C) under nitrogen gave red needles (390 mg, 56%, mp 65–67°C (dec.)), which contained one mole equiv. of ether (by $^1$Hmr spectroscopy and microanalysis), ir $\nu_{max}$: 1941, 1866, 1821 $cm^{-1}$; uv ($Et_2O$)$\lambda_{max}$: 400 (3.61), 289 (3.87), 281 (3.93), 266 (3.96), 219 (4.53); $^1$Hmr ($C_6C_6$) δ: 1.14 (6H, t, $J$ = 7 Hz, methyl of ether) 1.30 (3H × 1/3, N—C*H*$_3$), 1.34 (3H × 2/3, N—C*H*$_3$), 1.44 (3H × 2/3, C*H*$_3$), 1.88 (3H × 1/3, C*H*$_3$), 1.99 (1H × 1/3, C6-H, bd, $J$ = 10 Hz), 2.09 (1H × 2/3, C6-H, bd, $J$ = 10 Hz), 2.56 (1H × 1/3, C6-H, bd, $J$ = 10 Hz), 2.68 (1H × 2/3, C6-H, bd, $J$ = 10 Hz), 2.62 (1H, OH, bs), 3.15 (1H, C5-H, bs), 3.31 (4H, q, $J$ = 7 Hz, methylene of ether), 4.34 (1H × 1/3, C2-H, bd, $J$ = 5 Hz), 4.45 (1H × 2/3, C2-H, bd, $J$ = 5 Hz), 5.61 (1H × 1/3, C3-H, dd, $J$ = 5 Hz, $J$ = 2 Hz), 5.84 (1H × 2/3, C3-H, dd, $J$ = 5 Hz, $J$ = 2 Hz), 6.14 (1H × 2/3, C3′-H, d, $J$ = 2 Hz), 6.38 (1H × 1/3, C3′-H, d, $J$ = 2 Hz), 7.25–7.35 (3H, C5′,6′,7′-H, m), 7.64–7.78 (1H, C4′-H, m), 8.28–8.56 (N*H*, bs); ms *m/e*: 390 ($M^+$), 376, 372, 362, 334, 320, 306, 288, 237 (100%). High resolution molecular weight determination, calcd. for $C_{19}H_{18}N_2O_4Cr$: 390.0701; found: 390.0704. *Anal.* calcd. for $C_{19}H_{18}N_2O_4Cr.C_4H_{10}O$: C 59.48, H 6.03, N 6.03; found: C 59.50, H 6.13, N 5.93.

*Formation of 12 and 13*

Vilsmeier reagent prepared from DMF (0.4 mL, 5.1 mmol), $POCl_3$ (0.24 mL, 2.6 mmol), and $CH_2Cl_2$ (0.32 mL) was added dropwise to a $CH_2Cl_2$ (5 mL) solution of the complex **8** (948 mg, 2.4 mmol) at −5°C under nitrogen. The mixture was stirred at 0°C for 2 h and then at room temperature for 20 min. After evaporation of the solvent, the residues were dissolved in pyridine (30 mL), and heated at 50–55°C for 5 h. Pyridine was removed and the resulting residue was purified by silica gel (30 g) column chromatography with $CH_2Cl_2$–MeOH (10:1) as eluant to afford a yellow mixture of **12** and **13** (727 mg, 91%, in ratio of ca. 7:3 by $^1$Hmr spectroscopy). This mixture was not readily resolved by various chromatographic methods. Eventually a portion (200 mg) was applied on a silica-gel column (30 g) and eluted carefully with $CH_2Cl_2$–MeOH (10:1). The less polar fractions contained mainly **13** which on recrystallization from ethyl acetate – MeOH gave **13** as yellow needles (40 mg), mp 312–315°C (dec.); ir $\nu_{max}$: 3127, 1660, 1620, 1604, 1595; uv $\lambda_{max}$: 378 (4.05), 312 (4.02), 304 (3.97), 282 (4.34), 235 (4.10); $^1$Hmr (DMSO-$d_6$) δ: 2.55 (3H, s, C*H*$_3$), 3.73 (3H, s, —NC*H*$_3$), 4.02 (2H, C2-H, bt, $J$ = 8 Hz), 7.2–7.8 (4H, C7, 10 – H, m), 8.22 (1H,

For personal use only.

C4-H, d, $J$ = 8 Hz), 8.5 (1H, C11-H, s), 9.14 (1H, C1-H, s), 12.22 (1H, bs, N*H*); ms *m/e*: 250 ($M^+$ +2), 249 ($M^+$ + 1, 100%), 248 ($M^+$), 247, 246, 232, 231, 207, 206, 204. High resolution molecular weight determination, calcd. for $C_{17}H_{16}N_2$: 248.1315; found: 248.1299. More polar fractions containing **12** were combined and concentrated to give the product as yellow needles (140 mg) (from EtOAc–MeOH), mp 297–300°C (dec.); ir $\nu_{max}$: 3150, 1643, 1625, 1610, 1582; uv $\lambda_{max}$: 234 (4.59), 245 (4.51), 280 (4.56), 298 (4.88), 350 (3.89); $^1$Hmr (DMSO-$d_6$) δ: 2.94 (3H, s), 4.46 (3H, s), 7.39 (1H, t, $J$ = 7.5 Hz, C9-H), 7.7–7.8 (2H, m, C 7 & 8 – H), 8.4–8.6 (3H, m, C3 & 4-H, C10-H), 9.11 (1H, s, C11-H), 9.93 (1H, s, C1-H), 12.32 (1H, N*H*). *Anal.* calcd. for $C_{17}H_{15}N_2.H_2PO_4.H_2O$: C 56.36, H 5.29, N 7.73; found: C 56.76, H 5.07, N 7.59.

*Dehydrogenation of a mixture of **12** and **13***

A mixture of **12** and **13** (0.2 g) was mixed with 20% Pd/C (0.2 g) and heated under nitrogen at 300–320°C for 30 min. The black solid was extracted with hot MeOH and the solvent evaporated. The residues were separated by silica gel column chromatography with $CH_2Cl_2$–MeOH as eluant. Elution with $CH_2Cl_2$–MeOH (10:1) afforded **16** (19 mg, 9.5% from complex **8**) as colourless prisms, mp 270–276°C (dec.) ($CH_2Cl_2$–pet. ether) (lit. (16) mp 290–292°C (dec.)); ir $\nu_{max}$: 3120, 1632, 1618, 1595; uv $\lambda_{max}$: 222 (4.41), 236 (4.30), 263 (4.60), 272 (4.73), 282 (4.84), 293 (4.85), 325 (3.74); $^1$Hmr ($CDCl_3$) δ: 2.82 (3H, s), 7.90 (1H, d, $J$ = 6 Hz, C4-H), 8.26 (1H, d, $J$ = 7 Hz, C11-H), 8.54 (1H, d, $J$ = 6 Hz, C3-H), 8.59 (s, C11-H), 9.44 (s, C1-H), 8.2–8.3 (1H, bs, N*H*); ms *m/e*: 232 ($M^+$ 100%), 231, 229, 204, 203. High resolution molecular weight determination, calcd. for $C_{16}H_{12}N_2$: 232.1001; found: 232.0992. *Anal.* calcd. for $C_{16}H_{12}N_2$: C 82.73, H 5.21, N 12.06; found: C 82.40, H 5.11, N 12.31.

Elution with $CH_2Cl_2$–MeOH (5:1) provided unreacted **12** (130 mg).

*Demethylation of **12***

The salt **12** (50 mg) and triphenylphosphine (46 mg, 0.176 mmol) were dissolved in DMF (5 mL) and refluxed under nitrogen for 86 h. After evaporation of solvent, the mixture was separated by silica gel column chromatography to give **16** (18 mg, 54%) and unreacted **12** (23 mg, 46%).

Alternatively, **12** (50 mg) and triphenyl phosphine (46 mg) were dissolved in HMPA (2 mL) and heated under nitrogen at 185–190°C for 5 h. The solvent was removed under reduced pressure and the residue separated by silica gel column chromatography to give the crude product **16** which was suspended in water and then extracted with ether. Evaporation of the ether extracts gave pure **16** (15 mg, 45%).

*N-Methyl-5-methyl-1,2,3,4-tetrahydro-6H-pyrido[4,3-b]carbazole (**15**)*

$NaBH_4$ (excess) was added to a MeOH solution (1 mL) of the mixture of **12** and **13** (10 mg) at 0°C and stirred for 1 h. After evaporation of solvent the residue was taken up in water and extracted with $CH_2Cl_2$. Concentration of the organic extracts gave **15** (7.5 mg, 89% from complex **8**), mp 205–207°C (from ether); ir $\nu_{max}$: 3320, 1613; uv $\lambda_{max}$: 232 (4.62), 238 (4.71), 248 (4.56), 259 (4.40), 287 (4.11), 297 (4.32), 326 (3.66), 340 (3.53); $^1$Hmr (DMSO-$d_6$) δ: 2.52 (3H, s), 2.69 (2H, bs, C3-H), 2.89 (2H, bs, C3-H), 3.17 (1H, s, C1-H), 3.41 (1H, s, C1-H), 3.65 (3H, bs, N—C*H*$_3$), 7.09 (1H, t, $J$ = 7.5 Hz, C9-H), 7.33 (1H, t, $J$ = 7.5 Hz, C8-H), 7.44 (1H, d, $J$ = 8.5 Hz, C7-H), 7.60 (1H, s, C11-H), 7.98 (1H, d, $J$ = 8.5 Hz, C10-H), 10.90 (1H, bs, N*H*); ms *m/e*: 250 ($M^+$), 249 (100%), 233, 207, 191. High resolution molecular weight determination, calcd. for $C_{17}H_{18}N_2$: 250.1471; found: 250.1449. *Anal.* calcd. for $C_{17}H_{18}N_2$: C 80.92, H 7.19, N 11.10; found: C 81.28, H 7.17, N 11.19.

Reduction of **13** (5 mg) with $NaBH_4$ (8 mg) under similar conditions also resulted in a single product **15** (3 mg) with physical properties identical to those above.

*1-Methyl-5-methyl-6H-pyrido[4,3-b]carbazole, olivacine (**1**)*

$CH_3Li$ solution (1 *M*, 0.75 mL) was added to a solution of **16** (35 mg) in dry THF (2 mL) at 0°C under nitrogen. The mixture was stirred at room temperature for 30 min and then refluxed for another 1 h. MeOH was added to quench excess $CH_3Li$ and then $I_2$ (38 mg) was added. After stirring of the mixture for 30 min, the solvent was removed and the residue triturated with water. The product was collected and purified by silica gel column chromatography to give **1** (20 mg, 54%) as yellow prisms (from ether), mp 303–306°C (dec.) (lit. GARETH A. MORRIS and LAURANCE D. HALL. Can. J. Chem. **60**, 2431 (1982).

Double Fourier transform ("2D") nmr methods allow the simultaneous measurement of proton and carbon-13 chemical shifts for each directly bonded carbon–proton pair in a molecule. As well as greatly increasing the number of different resonances that may be distinguished in the spectra of complex systems, the measurement of correlated proton and carbon-13 shifts allows the otherwise inaccessible proton shifts to be determined, and facilitates the assignment of conventional proton and carbon-13 spectra. Results are presented for glucose, maltose, maltotriose, α-cyclodextrin, β-cyclodextrin, and dextran T-10; reassignments are proposed for the carbon-13 spectra of maltose and maltotriose.

GARETH A. MORRIS et LAURANCE D. HALL. Can. J. Chem. **60**, 2431 (1982).

Les méthodes de la rmn faisant appel à une transformation double de Fourier ("2D") permettent de mesurer simultanément les déplacements chimiques du proton et du carbone-13 pour chaque liaison directe carbone–proton d'une molécule. Tout en permettant d'augmenter considérablement le nombre de résonances différentes que l'on peut distinguer dans les spectres des systèmes complexes, la mesure des déplacements chimiques du proton et du carbone-13 liés permet de déterminer les déplacements chimiques autrement inaccessibles du proton et facilite l'identification des spectres conventionnels du proton et du carbone-13. On présente les résultats relatifs au glucose, au maltose, au maltotriose, à l'α-cyclodextrine, à la β-cyclodextrine et au dextran T-10. On propose une identification nouvelle des spectres du carbone-13 du maltose et du maltatriose.

[Traduit par le journal]

## Introduction

The proton nmr spectra of carbohydrates in aqueous solution are always complex, and generally the only resonances that may be assigned easily are those of the anomeric protons, shifted to low field by the combined effects of two neighbouring oxygen atoms. Under favourable conditions, the use of homonuclear double resonance techniques at high magnetic fields can yield reasonably complete assignments of the proton spectra of mono- and disaccharides, but such experiments are extremely time-consuming and are difficult to extend to larger oligosaccharides. In contrast, the proton decoupled carbon-13 spectra of even the most complex natural polysaccharides are well dispersed, the problem being to assign the individual resonances thus resolved.

The purpose of this paper, and of the preceding paper in this series (1),[4] is to illustrate some of the possibilities of the heteronuclear double Fourier transform ("2D") nmr experiments that have been developed in the past few years (2, 3). The particular technique that has been explored is 2D chemical shift correlation (3, 4), which allows the proton chemical shifts of all protons directly bonded to carbon-13 to be determined in a single double Fourier transform experiment. It is possible to determine such information from series of coherent off-resonance decoupling experiments (5–9), but this method is usually slow, difficult, and limited in accuracy. Under favourable conditions, a series of selective decoupling experiments might be expected to require about two orders of magnitude more time for data collection than a normal decoupled spectrum, and ought to yield a limiting accuracy on proton chemical shift values of about ± 0.1 ppm. In contrast, the 2D nmr experiments to be described require about ten times as long for data acquisition as a normal fully decoupled carbon-13 spectrum, and can give proton shifts that are accurate to better than 0.01 ppm.

In 2D nmr a set of free induction decays $\mathbf{S}(t_2)$ is acquired using a pulse sequence containing a variable delay $t_1$, which is incremented for successive decays until a complete matrix $\mathbf{S}(t_1, t_2)$ has been built up. This matrix describes the behaviour of the total nuclear signal as a function both of the time $t_2$ after excitation, and as a function of the delay $t_1$ within the exciting pulse sequence. When this matrix is subjected to a double Fourier transformation, once with respect to $t_2$ and once with

respect to $t_1$, the result is a two-dimensional spectrum $S(f_1, f_2)$ which describes signal strength as a function of two independent frequencies $f_1$ and $f_2$. Signals are dispersed along the $f_2$ axis according to their resonant frequency during acquisition of the free induction decays, and are dispersed in $f_1$ according to their apparent frequency of oscillation during the delays $t_1$. The pulse sequence is chosen so as to give each of the resonances in a system different frequencies during the two periods $t_1$ and $t_2$, so that their signals are dispersed differently in the two domains of the two-dimensional spectrum. The $f_2$ domain reflects signal behaviour during "real time", but since it is only the nuclear signal at the *end* of the delay $t_1$ which governs the form of the 2D spectrum and not the signals's behaviour *during* $t_1$, signal dispersion in $f_1$ can be made to depend on characteristic frequencies of a spin system that are not measurable from normal spectra. The general techniques and background of 2D nmr and many of the pulse sequences used are described in refs. 2 and 3.

The pulse sequence used for obtaining heteronuclear chemical shift correlation 2D spectra is shown in Fig. 1. Its purpose is to generate decoupled carbon-13 free induction decays in which each carbon signal has been modulated as a function of $t_1$ by the chemical shift frequency of any proton to which it is directly bonded. After double Fourier transformation of the matrix of free induction decays acquired using this pulse sequence, a 2D spectrum is obtained in which one signal appears for each directly bonded carbon–proton pair in a molecule. The $f_1$ and $f_2$ coordinates of these signals are simply the displacement of the proton chemical shift from the proton transmitter frequency and the displacement of the carbon-13 chemical shift from the carbon-13 transmitter respectively, so that for each decoupled carbon-13 signal the chemical shift of any proton bound to that carbon can be determined by simple inspection of the 2D spectrum. Since only one signal appears for each CH group, the dispersion as a function of both the proton and the carbon-13 chemical shift means that a great increase in resolving power is obtained over the conventional spectra of carbon-13 or protons. The mode of action of the pulse sequence of Fig. 1 is discussed in detail in ref. 1, which draws heavily on the work of Ernst and co-workers (10, 11) and of Bodenhausen, Freeman, and co-workers (3, 13–15).

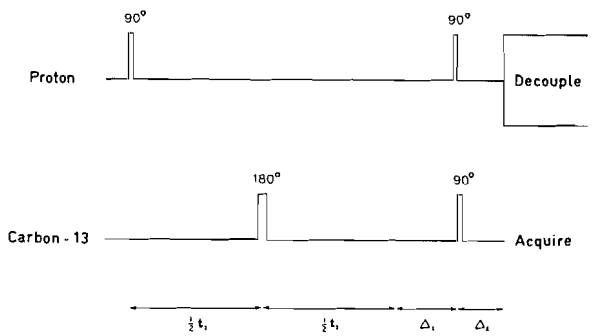

FIG. 1. Pulse sequence used for obtaining heteronuclear chemical shift correlation 2D spectra. For the experiments described $\Delta_1$ was 3 ms and $\Delta_2$ was 2.2 ms.

## Experimental

The instrument used in the work to be described was a home-built superconducting spectrometer operating at 270 MHz for protons and 67.9 MHz for carbon-13, based on a Bruker/Nicolet TT-23 console and an Oxford Instruments 6.3 T solenoid. Experiments were controlled and data processed with the standard NTCFT software package of a Nicolet 1180/293A' data system, equipped with a Diablo magnetic disc of 1.15 megabyte storage capacity. Time domain matrices $S(t_1, t_2)$ of 128 × 1024 or 2048 points were used, with spectral widths in the $f_1$ and $f_2$ domains of 1000 and 3500 Hz respectively.

Glucose (Fisher), maltose and maltotriose (Aldrich), and α-cyclodextrin (Eastman) were used as 10% solutions in $D_2O$ (Merck, Sharp and Dohme), two or three drops of *p*-dioxane (Fisher) in 3 mL of sample being used as internal reference for the proton and carbon-13 chemical shifts. β-cyclodextrin (Corn Products Co.) was used as a saturated solution in $D_2O$ at the experimental temperature of 22 ± 2°C. Dextran T-10 (Pharmacia) was used as a 10% solution in $D_2O$, with dioxane as internal reference; EDTA (ethylenediaminetetracetic acid sodium salt, G. Frederick Smith, approx. 10 mg in 3 mL) was added to scavenge paramagnetic ions which otherwise prevented resolution of the nonanomeric carbon-13 resonances. The chemical shifts of dioxane were taken as 3.76 ppm from internal TSP for protons, and 67.40 ppm from external TMS for carbon-13. Decoupled carbon-13 spectra for these samples required between 2 and 15 min for data acquisition, while the data for the 2D spectra took between 30 and 120 min to collect. A more detailed description of the experimental methods used is given in ref. 1.

## Results

The experimental chemical shift correlation 2D spectrum for α-cyclodextrin (**4**) is shown in Fig. 2. As expected, one peak appears for each CH group; in the methylene groups of dioxane and cyclodextrin C-6 both methylene protons have the same shift. The full stacked plot is time consuming to produce, and fails to make best use of the digitized information available, so for each correlation signal the appropriate cross-section through the $f_1$ domain has been obtained with enhanced digital resolution by zero-filling the appropriate interferogram prior to Fourier transformation. Since these traces summarize the information required from the 2D experiment, results from the series of compounds studied are presented in Figs. 3 to 7 as sets of $f_1$ traces, one for each carbon-13 signal in the 2D correlation spectrum.

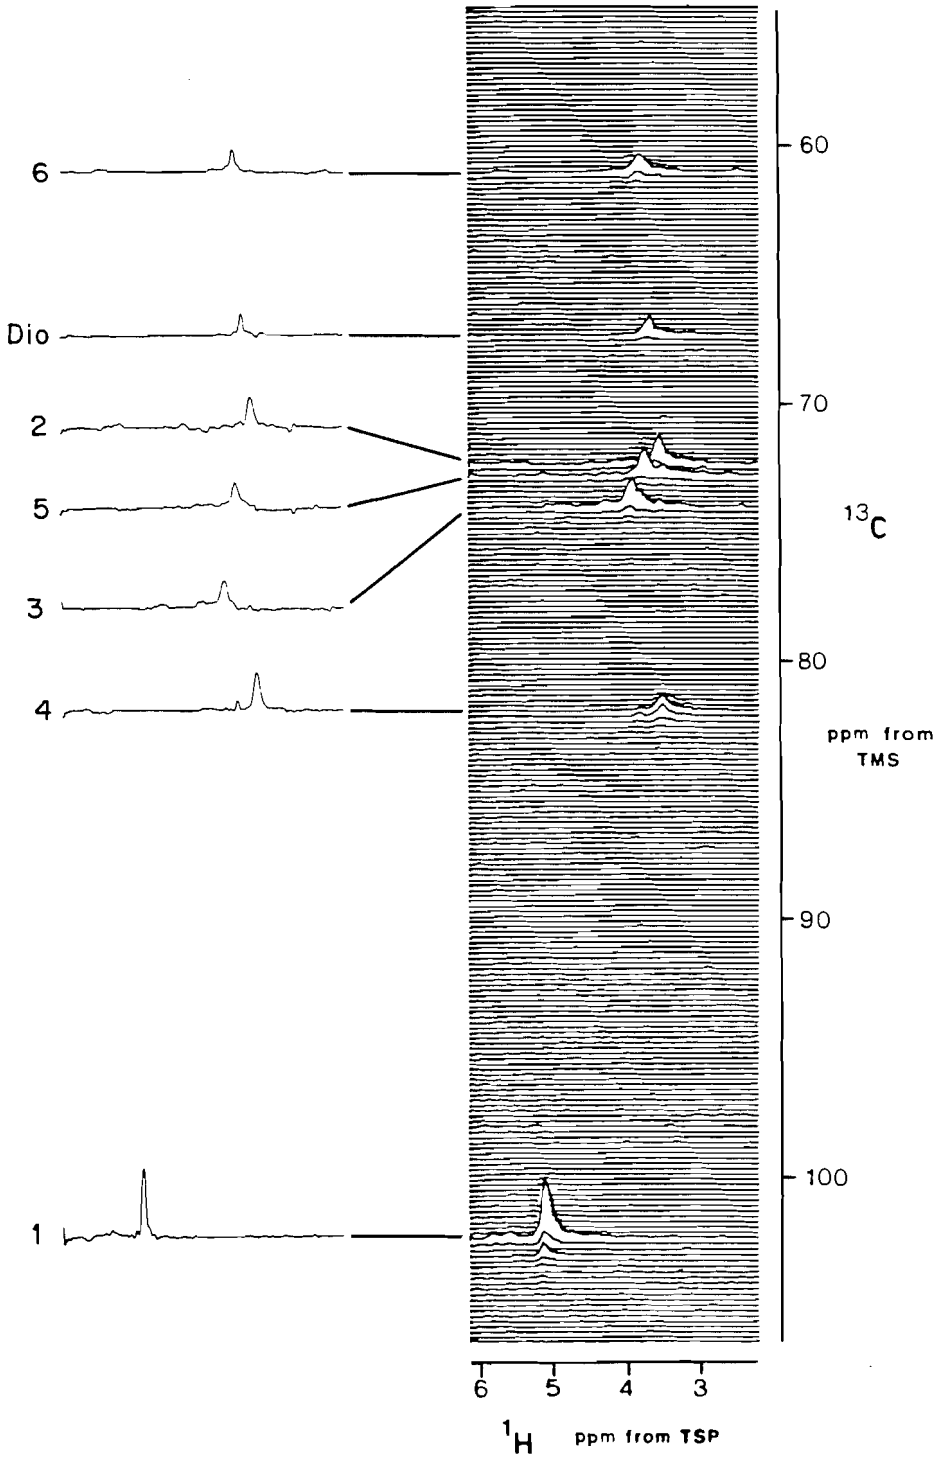

FIG. 2. Stacked plot of a chemical shift correlation 2D spectrum of α-cyclodextrin in $D_2O$, showing signal strength as a function of carbon-13 chemical shift (vertical or $f_2$ axis) and of proton chemical shift (horizontal or $f_1$ axis). Traces bearing signals have been recalculated using zero-filling to improve digital resolution, and are displayed to the left of the full 2D spectrum.

The proton and carbon-13 chemical shifts measured from the one- and two-dimensional spectra are listed in Table 1, together with the estimated standard deviations of the values given. Carbon-13 shifts were measured from the proton decoupled conventional spectrum, and proton shifts from cross-sections through the 2D spectrum. In the latter case interferograms were zero-filled three times before transformation (1); since the proton multiplet structure in $f_1$ is normally symmetrical about the proton chemical shift frequency, this procedure, coupled with parabolic interpolation to find the peak maximum, leads to a real improvement in the precision of measurement of the proton shift. Poor signal-to-noise ratio, overlap, and some types of strong coupling can degrade the accuracy of results, as indicated in Table 1. The sample of β-cyclodextrin (**5**) showed unusually wide carbon-13 lines, possibly due to contamination with paramagnetic ions, while the α-cyclodextrin spectra (Fig. 2) show the presence of a small amount of the β form. The traces shown in Figs. 3 to 7 are mostly presented in phase sensitive form, since this gives optimum precision, but, where carbon-13 signals overlap, the presence of strongly frequency-dependent phase shifts can necessitate the use of absolute-value display.

The assignments of the cyclodextrins and dextran T-10 in Table 1 are based on carbon-13 shifts reported by Colson, *et al.* (16), while those for glucose (**1**) follow Pfeffer *et al.* (17) and Dwek and co-workers (18). Several assignments have been proposed for maltose (**2**) and maltotriose (**3**) (16, 19, 20), but the experimental results obtained suggest a minor adjustment to the assignment of maltose, and a fairly radical reinterpretation of the

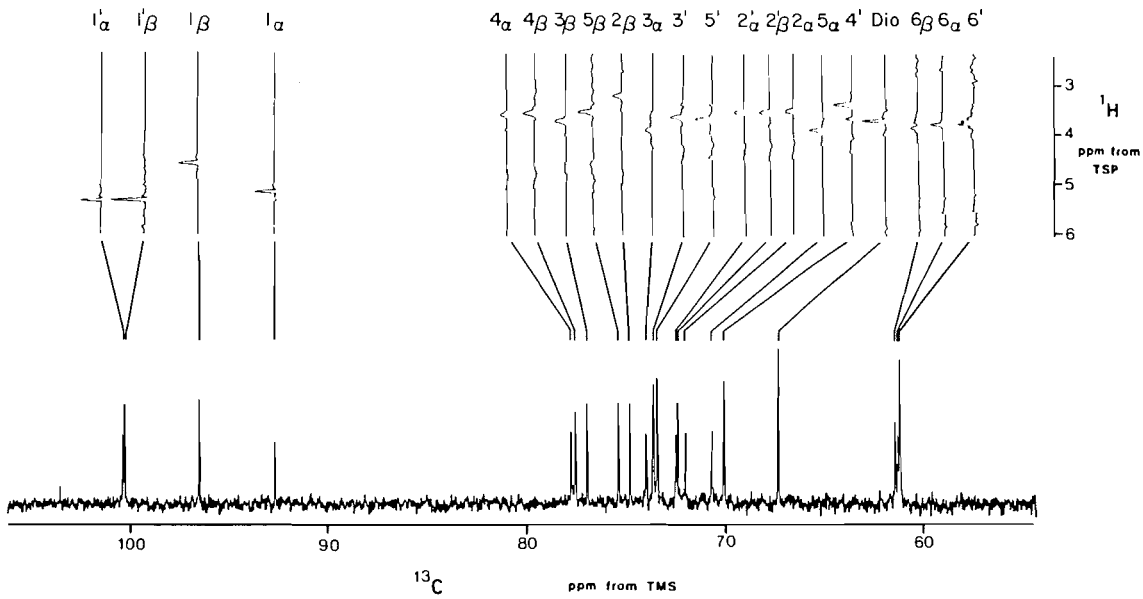

FIG. 3. Figures 3–7 show the experimental results for compounds **2** to **5** and for dextran T-10. The proton decoupled carbon-13 spectrum is shown horizontally, with traces through the $f_1$ domain of the 2D spectrum for each protonated carbon resonance shown displayed vertically. Figure 3 shows the experimental results for D-maltose (**2**).

spectrum of maltotriose.[5] The correlated proton and carbon-13 shifts measured for maltose are, with the minor exception of a reversal of α and β C-6 carbon signals, consistent with all the assignments of Colson *et al.* (16) except those of the 2′ and 5′ resonances. Their assignment implies a reversal of the proton shifts of these two sites compared to those of α-glucose, in contradiction to the partial assignment of the maltose proton spectrum carried out using proton continuous wave INDOR at 300 MHz by DeBruyn *et al.* (21). The exchange of the C-2′ and C-5′ assignments is borne out by the splitting of the reassigned C-2′ carbon-13 resonance due to the anomeric equilibrium at the

[5]During the preparation of this paper Heyraud *et al.* (Biopolymers, **18**, 167 (1979)) have published carbon-13 assignments for maltose and maltotriose identical to those derived here; we thank a referee for drawing this paper to our attention.

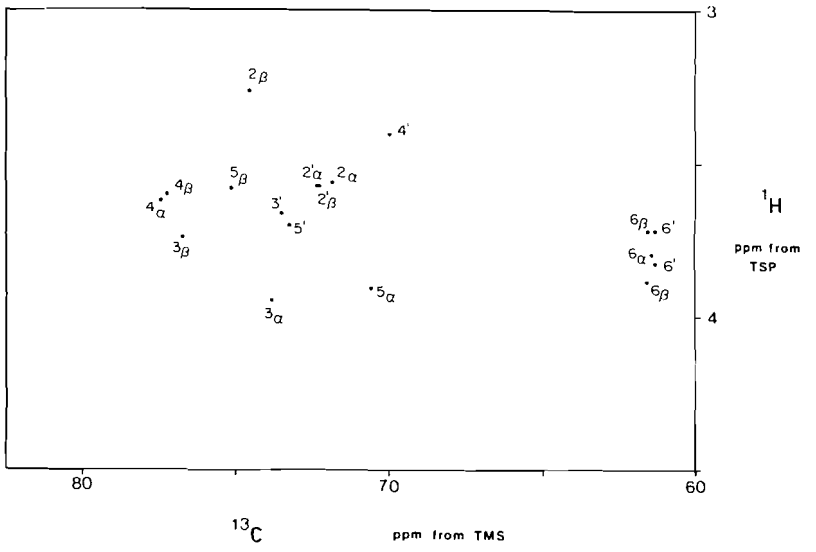

FIG. 8. Chemical shift correlation map for maltose (2).

reducing terminus of maltose, and is also consistent with approximate measurements of the carbon-13 deuterium induced isotope shifts for this system, made by the method of Pfeffer *et al.* (17).

The assignment of the carbon-13 spectrum of maltotriose is a particularly difficult problem to attack by conventional means, and affords a nice illustration of the advantages of using correlated proton and carbon-13 chemical shifts. Correlated shift data are most easily assessed when presented in the form of a shift map such as Fig. 8, for the proton and carbon-13 chemical shifts of maltose. The correlated shifts of maltose may be used as models for those of maltotriose, since the shifts of the reducing rings of maltose and maltotriose should be quite similar, as should those of the nonreducing termini of the two systems. Comparison between Fig. 8 and Fig. 9, the map for

maltotriose, confirms that the effects of interposing a third α-glucose ring between the nonreducing and the reducing termini are indeed sufficiently small that all of these resonances may be assigned by comparison. This leaves the problem of the central ring of maltotriose, in which the resonances have been perturbed by the formation of glycosidic linkages on both sides of the ring.

The effects of the formation of an α linkage on α-glucose may be deduced by comparison between the shifts of α-glucose and those of the nonreducing ring of maltose, and the effects of adding a glycosidic linkage to C-4 of α-glucose may be found from comparison with the α form of the reducing ring of maltose. To a first approximation these two sets of effects will be additive, so that the expected positions of the correlated shifts of the central ring resonances in Fig. 9 may be predicted by taking the vector sum of the α-glucose – maltose glucosyl and α-glucose – α-maltose glucose shift displacements, as illustrated in Fig. 10. The predicted shifts are more than accurate enough to complete the assignment of the maltotriose carbon-13 and proton resonances, the small deviations observed being attributable to the effects of conformation and concentration dependence.

In order to assess the viability of 2D shift correlation methods for polysaccharide systems, experiments were carried out on dextran T-10, a partially hydrolysed dextran linked predominantly $1\xrightarrow{\alpha}6$, with a mean molecular weight of about 10000. Even at room temperature, linewidths were sufficiently narrow for accurate proton and carbon-13 chemical shifts to be obtained, as can be seen from Fig. 7, provided that EDTA was added to prevent paramagnetic ions from binding to the dextran and broadening all the resonances. These results suggest that at higher sample temperatures it should be possible to study a wide range of polysaccharide systems by 2D shift correlation, with its attendant advantages of improved resolution and greater specificity for characterizing linkages and branching points.

As an illustration of the advantages of chemical shift correlation for the assignment of proton spectra, Fig. 11 a–c shows 270 MHz proton spectra of a 10% solution of maltotriose in $D_2O$. The inserts a and b show a 1 ppm region of the spectrum, with and without resolution enhancement, containing the 24 nonanomeric proton resonances. The assigned chemical shifts measured from the experimental data of Fig. 4 are given below trace b; few other methods are available for making such assignments.

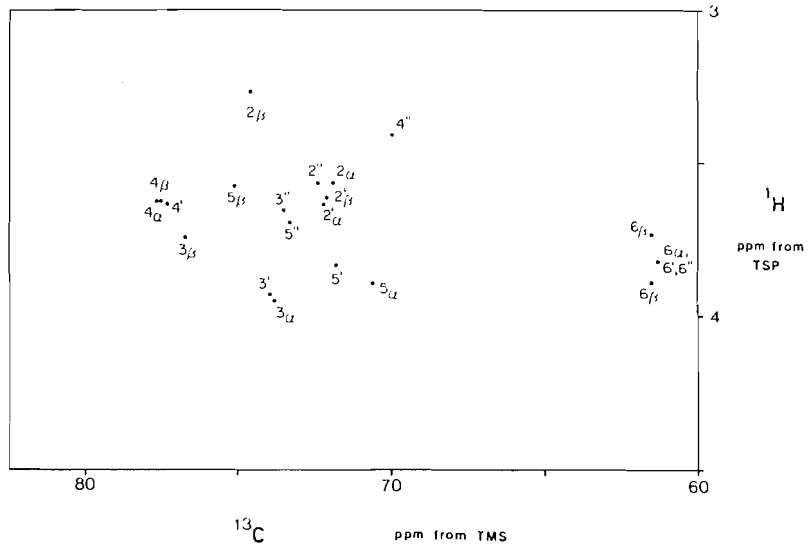

FIG. 9. Chemical shift correlation map for maltotriose (**3**).

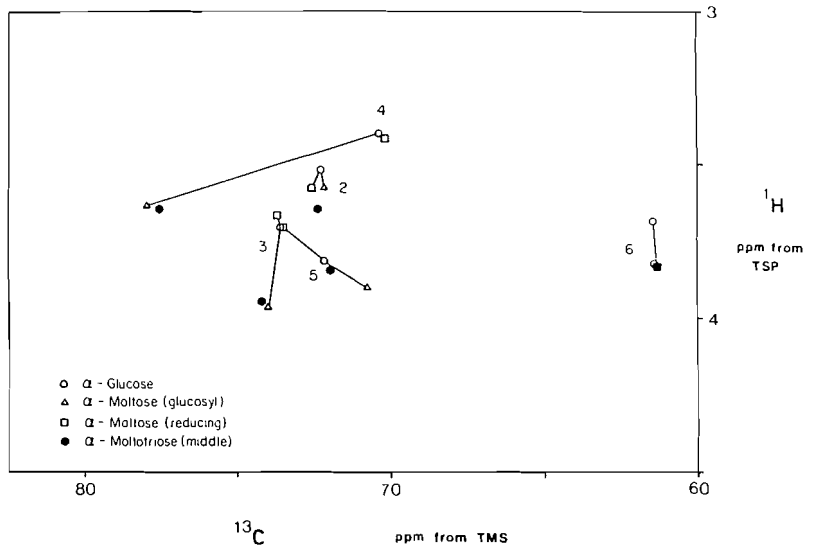

FIG. 10. Chemical shift correlation map for the α-glucose unit in free glucose, maltose, and maltotriose, showing the effect of glycosidic linkage formation.

## Discussion

The results reported here illustrate the utility of heteronuclear two-dimensional nmr spectroscopy in studying a range of typical carbohydrate systems. Proton chemical shifts have been reported for several systems which are very difficult to study by conventional proton nmr methods owing to the great complexity of their spectra, and in the case of maltotriose a new technique for the reliable assignment of complex carbon-13 spectra, particularly well suited to the assignment of oligomer spectra, has been illustrated. The advantages of heteronuclear 2D nmr methods in studying the structure of spectra are common to many other applications of 2D nmr: greatly improved resolution of signals, correlation of different nmr parameters, and measurement of parameters unobtainable by conventional methods. Chemical shift correlation by 2D nmr is a particularly attractive experiment since it is only about a factor of three less

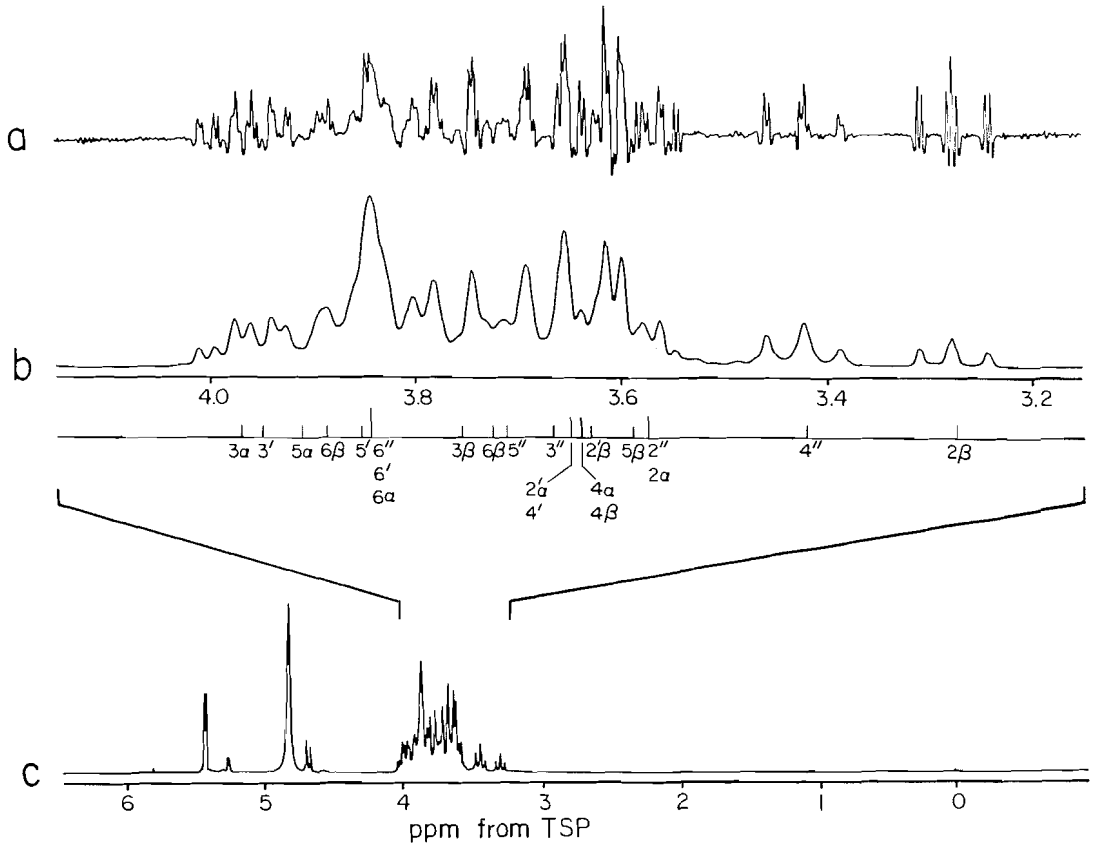

FIG. 11. 270 MHz proton spectra of a 10% solution of maltotriose in $D_2O$, showing (a) and (b) a 1 ppm section with and without resolution enhancement by "double exponential" multiplication of the form $\exp(+at)\exp(-bt^2)$, and (c) the full proton spectrum. Assignments shown under trace (b) indicate the chemical shifts for the 24 nonanomeric protons whose resonances fall in the expanded region, obtained for the experimental results of Fig. 5.

sensitive than normal decoupled carbon-13 nmr, as the carbon-13 signals observed actually originate with the stronger proton polarization, and the rate at which the pulse sequence of Fig. 1 may be repeated is governed not by the carbon-13 but by the proton spin-lattice relaxation time $T_1$. Thus a shift correlation experiment may be carried out in only a fraction of the time needed for a measurement of $T_1$, or for obtaining a set of coherently off-resonance decoupled carbon-13 spectra. The experiments described above were all carried out using instrumentation similar to many commercially available spectrometers; no modification of the software supplied with the computer system was necessary. The small price paid in increased complexity of the nmr experiment is more than offset by the advantages outlined above, which both facilitate the interpretation of nmr experiments on relatively simple systems and increase considerably the size and complexity of molecule that can be made to yield detailed proton and carbon-13 assignments.

## Acknowledgments

This work was supported by operating grants (A1905 to L.D.H.) from the Natural Sciences and Engineering Research Council of Canada and by an Izaak Walton Killam Postdoctoral Fellowship to G.A.M. Components for the spectrometer used were purchased with funds provided by the Chemistry Department and by the President's Emergency Research Equipment Fund, both of U.B.C. The expert assistance of Tom Markus in the construction of the spectrometer was warmly appreciated. A preprint of reference 15 was kindly supplied by Dr. G. Bodenhausen.

# One-electron photooxidation of carbazole in the presence of carbon tetrachloride. Part II. Carbon tetrachloride as a reaction medium. Use of ammonia after irradiation and during irradiation

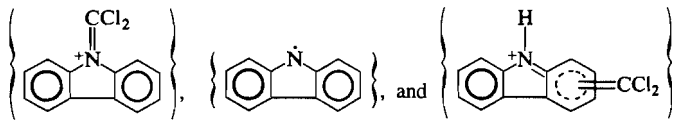
BOGUMIL ZELENT[1] AND GILLES DUROCHER

*Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1*

Received March 11, 1982

BOGUMIL ZELENT and GILLES DUROCHER. Can. J. Chem. **60**, 2442 (1982).

In part I of this series of papers we proposed the mechanism of electron transfer as the primary photochemical reaction in the carbazole – carbon tetrachloride system along with a secondary photochemical reaction initiated by transformations of the radical cation of carbazole in the solvent cage resulting in intermediates:

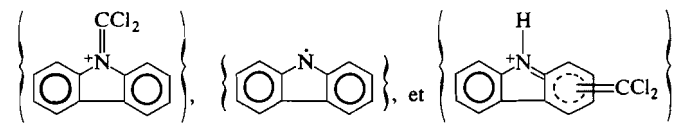


α β $\gamma_i$($i$ = 1, 2, 3, or 4)

In this paper we discuss the influence of ammonia, used *after* and *during* irradiation, on the mechanism of secondary transformation and the formation of thermodynamically stable products in the system studied. Such compounds as *N*-cyanocarbazole, 1-cyanocarbazole, and 3-cyanocarbazole have been formed as the main products during neutralization of the photolyte solution by ammonia gas. The mechanism of formation of these compounds has been explained by the chemical reaction of ammonia with cations α and $\gamma_i$. If ammonia is present in the solution of carbazole in $CCl_4$ during irradiation, such products as *N*,*N*′-dicarbazyl and *N*-cyanocarbazole are mainly formed along with 3-(*N*-carbazyl)carbazole, 3,9-di-(*N*-carbazyl)carbazole, and *N*-cyano-3-(*N*-carbazyl)carbazole. In such a case, reactions of radicals β are the determining factors in the secondary photochemical transformations. Radicals β are formed by the reaction involving ammonia with radical cations of carbazole. All the results in this paper have been discussed taking under consideration the influence of the reaction media on the mechanism of photochemical transformation of carbazole.

BOGUMIL ZELENT et GILLES DUROCHER. Can. J. Chem. **60**, 2442 (1982).

Dans la première partie de cette série d'articles nous avons suggéré que le mécanisme photochimique primaire lors de la réaction du carbazole et du tétrachlorure de carbone en était un de transfert électronique. La réaction photochimique secondaire consiste en la transformation du radical cation du carbazole dans la cage du solvant pour donner les intermédiaires suivants:



α β $\gamma_i$($i$ = 1, 2, 3, ou 4)

Dans cet article, nous discuterons de l'influence de l'ammoniac utilisé *après* et *avant* l'irradiation, sur le mécanisme secondaire de transformation et de formation de photoproduits thermodynamiquement stables. Lorsque l'ammoniac est ajouté après l'irradiation, le cyano-*N* carbazole, le cyano-1 carbazole et le cyano-3 carbazole ont été surtout obtenus. Ce résultat s'explique par la réaction de l'ammoniac avec les cations α et $\gamma_i$. Si au contraire, l'ammoniac est présent dans la solution du carbazole dans le $CCl_4$ au cours de l'irradiation, les produits suivants sont obtenus avec un bon rendement: dicarbazyl-*N*,*N*′ et cyano-*N* carbazole. Les produits suivants sont également obtenus: (carbazyl-*N*)-3 carbazole, di-(carbazyl-*N*)-3,9 carbazole et cyano-*N*(carbazyl-*N*)-3 carbazole. Les radicaux β sont alors impliqués dans la transformation photochimique. Ces radicaux β sont produits suite à la réaction de l'ammoniac avec les radicaux cations du carbazole. Tous les résultats sont discutés en tenant compte de l'influence du milieu réactionnel sur le mécanisme de la transformation photochimique du carbazole.

## Introduction

Among various halocarbons, carbon tetrachloride is most frequently used as a fluorescence quencher of different aromatic molecules (1–8). Studies of the mechanism of fluorescence quenching by halocarbons focused the attention of researchers upon the possibilities of photochemical reaction in the electron donor molecule – $CCl_4$ system. Therefore $CCl_4$ became used as the medi-

um or as the active component of the medium for photochemical reaction of many potential electron donors (8–16). Such studies not only strongly supported the electron transfer mechanism used to explain the fluorescence quenching but also depicted new possibilities of the application of an electron acceptor like $CCl_4$ in photochemical synthesis.

Because of its significant electron affinity (4), $CCl_4$ forms weak CT complexes with numerous electron donor molecules in their electronic ground state (2, 8, 13, 17–20). The excited states of aromatic molecules are therefore expected to be involved in charge transfer interactions with $CCl_4$ through exciplex formation. Low energy of the C—Cl bond in $CCl_4$ (21) and also the low activation energy of the dissociative process of electron attachment (22) promote the chemical activity of carbon tetrachloride. Therefore the electronic excitation of the electron donor molecule in the presence of $CCl_4$ is accompanied by the process of electron transfer to the $CCl_4$ molecule according to the scheme

$$e^- (\text{donor}) + CCl_4 \rightarrow \dot{C}Cl_3 + Cl^-$$

which is the primary photochemical process initiating complex reactions.

Among aromatic amines known as typical electron donors, carbazole turned out to be an interesting subject of studies of the photophysical and photochemical properties in the presence of halocarbon molecules. The carbazole–$CCl_4$ system in the electronic donor ground state did not show any significant interaction of electron donor–acceptor type. Nevertheless, such interactions appear in the first electronic excited singlet state of the carbazole molecule. This has been supported by studies on the photophysical properties of the carbazole–$CCl_4$ system in various media (1), as well as by the fact that fluorescence quenching of carbazole by $CCl_4$ is accompanied by a photochemical reaction (14). The proposed mechanism of the photochemical transformations in the carbazole–$CCl_4$ system has been discussed in detail in part I of this series of papers (15). This paper is a continuation of the discussion of the photochemical reactions involved in the carbazole–$CCl_4$ system, considering this time the influence of ammonia on the formation of the thermodynamically stable products after irradiation as well as the influence of ammonia on the mechanism and products during irradiation.

## Results and discussion

Irradiation of solutions of carbazole in carbon tetrachloride gives rise to the formation of both stable products such as hexachloroethane (**1**), *N*-trichloroethylenecarbazole (**2**), 1-chlorocarbazole (**3**), and 3-chlorocarbazole (**22**), as well as reactive transient photoproducts stable only in the $CCl_4$ medium. When, after irradiation of carbazole in $CCl_4$, the photolysis solution was saturated with ammonia gas to neutralize the formation of hydrogen chloride, the reactive products underwent transformation to the corresponding cyano derivatives of carbazole. It turned out that *N*-cyanocarbazole (**25**), 1-cyanocarbazole (**28**), and 3-cyanocarbazole (**29**) are the main products formed from these transformations (first column in Table 1). We have also performed the irradiation of carbazole solution in $CCl_4$ saturated with ammonia gas. In this case *N*,*N*'-dicarbazyl (**23**) and **25** are the main products of the reaction. We have also identified

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

the following compounds: 3,9-di-(*N*-carbazyl)carbazole (**24**), *N*-cyano-3-(*N*-carbazyl)carbazole (**26**), and 3-(*N*-carbazyl)carbazole (**27**) in addition to products **1**, **3**, **22**, **28**, and **29** (second column in Table 1).

All the isolated and identified products, using ammonia after and during irradiation, support the carbazole radical cation transformation mechanism that we proposed in part I (15).

These results, along with the known electron acceptor properties of $CCl_4$ as well as the photophysical properties of aromatic electron donor – $CCl_4$ systems (1–4), strongly support the mechanism of the primary photochemical reaction in the carbazole–$CCl_4$ system according to the following:

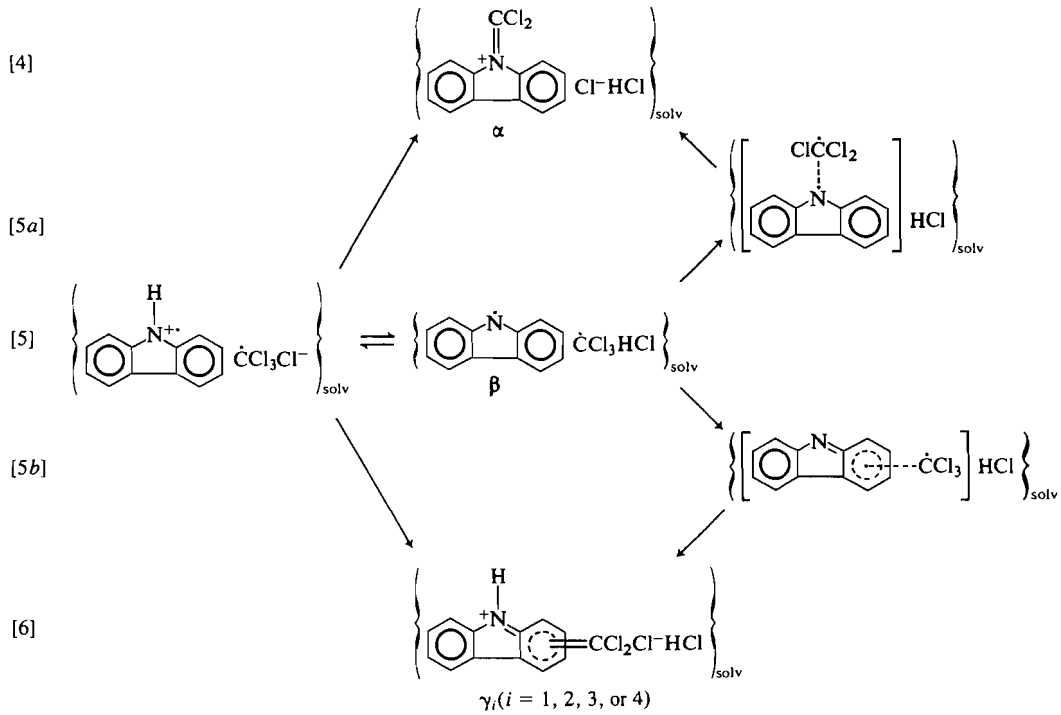
[1] $C + h\nu \rightarrow {}^1C^*$

[2] ${}^1C^* + CCl_4 \rightarrow {}^1(C^{\delta+}\cdots CCl_4{}^{\delta-})^*_{solv}$

[3] ${}^1(C^{\delta+}\cdots CCl_4{}^{\delta-})^*_{solv} \rightarrow [C^{+\cdot}\ Cl^-\ \dot{C}Cl_3]_{solv}$

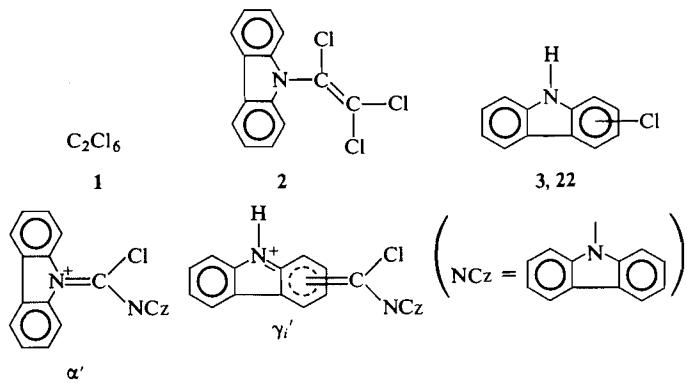
The electron transfer from the electronically excited carbazole molecule to the $CCl_4$ molecule in the excited CT complex (eq. [3]) gives rise to chemical transformation in the system studied. The radical cation of carbazole, chloride ion, and trichloromethyl radical are the primary products of the photochemical reaction.

The secondary reactions in the solvent cage are illustrated by the following scheme:



SCHEME 1

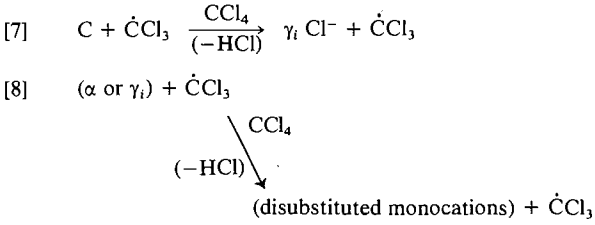
The possibilities of transformations of the carbazole radical cation are conditioned by the presence of trichloromethyl radical and chloride ion in the solvent cage. The reaction of the radical cation of carbazole with the trichloromethyl radical can occur with the participation of the nitrogen as well as the ring leading to the formation of the transient ionic products α and $\gamma_i$ (mainly with $i = 1$ or 3). The transformations of the radical cation of carbazole in the solvent cage are accompanied by the formation of thermodynamically stable molecules of hydrogen chloride (eqs. [4] and [6]). On the other hand, the radical cation of carbazole in the presence of chloride ion in the solvent cage can also split off a proton, transforming itself into the radical β. Reaction [5] is reversible (23, 24) because the N—H and H—Cl bond energies are about the same (~431 kJ $mol^{-1}$) (25). So, in the presence of HCl in the solvent cage, radical β can undergo inverse transformation to the carbazole radical cation or can react with the trichloromethyl radical. The reaction of radical β with radical $CCl_3$ can lead to cation α (eq. [5*a*]) as well as to cation $\gamma_i$ (eq. [5*b*]). In each of these reactions chloride ion is being split off.



Apart from the reactions in the solvent cage discussed above, both the radical cation of carbazole and the trichloromethyl radical, as well as intermediate products α, β, and $\gamma_i$, participate in the secondary reactions outside the solvent cage. This has been depicted by the nature of the photochemical compounds obtained, such as **1**, **2**, **3**, and **22**, as well as compounds α′ and $\gamma_i$′ which are of intermediate character. The formation mechanism of these products has been proposed and discussed previously (15) and we do not intend to go into further details here.

Acidic reaction media do not favour the formation of *N*,*N*′-dicarbazyl. The lack of this product can be interpreted by the low concentration of radicals β caused by the shift of the equilibrium of reaction [5] towards the radical cation of carbazole and by reactions [5*a*] and [5*b*].

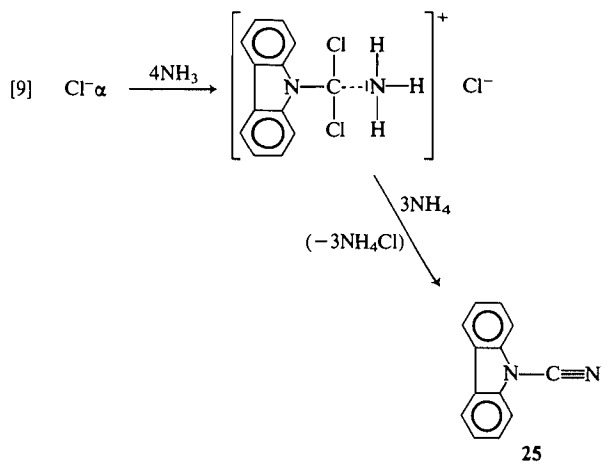
Photochemically generated trichloromethyl radicals initiate chain reactions in the solution according to the scheme:

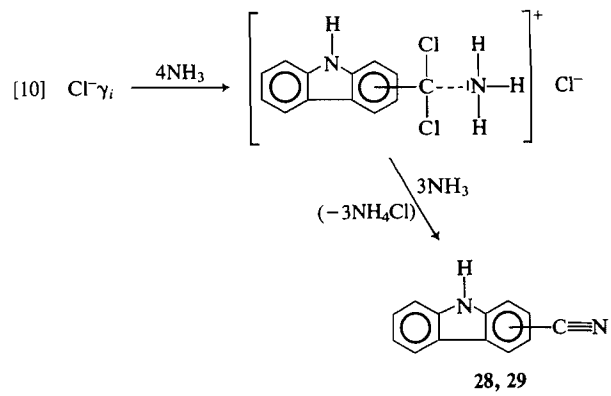


Significant photochemical activity of carbazole solution in $CCl_4$ can be explained by reactions [3] and [7]. Reaction [8] acts as a source of disubstituted monocations in the solution studied.

*Use of $NH_3$ after irradiation*

After saturation of the photolysis solution by ammonia gas, products such as **25**, **28**, and **29** appeared in addition to ammonium chloride among the other compounds of the reaction. This points to the fact that reactive transient products, stable in the $CCl_4$ medium, easily undergo reaction in the presence of ammonia to the corresponding cyano derivatives of carbazole. Therefore the formation of products **25**, **28**, and **29** can be presented by the following ammonolysis mechanism of intermediates α and $\gamma_i$:

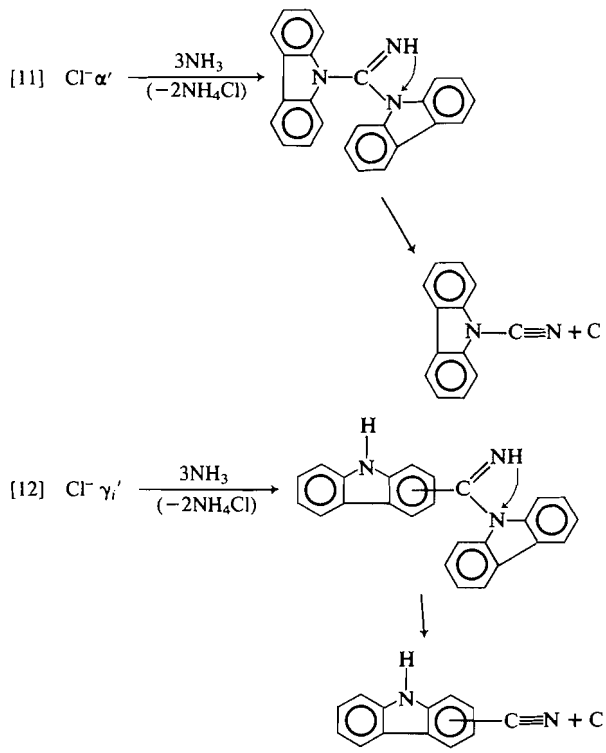




Reactions [9] and [10] are the main sources of these products. In a similar way, intermediates α′ and $\gamma_i$′ might undergo reaction in the presence of ammonia resulting in the corresponding (carboimino-*N*-carbazyl)carbazoles. These, in turn, can undergo rearrangement to cyano derivatives of carbazole.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

We propose the following scheme for these reactions:



The presence of ammonia in excess, acting as a good scavenger of HCl in the reaction medium, favours the course of reactions [9] to [12].

Decomposition of (carboimino-*N*-carbazyl)carbazoles to carbazole and cyano derivatives of carbazole in reactions [11] and [12] requires a certain activation energy. Therefore, at room temperature, it can take place only partially in the photolyte solution. This reaction occurs mainly on the surface of silica gel during chromatographic separation of products.

When nonactivated silica gel, containing the adsorbed water on its surface, was used, we found (carbo-*N*-carbazyl)carbazoles in the separation fractions. This confirms the presence of (carboimino-*N*-carbazyl)carbazoles in the mixture of products chromatographically analysed. The formation of (carbo-*N*-carbazyl)carbazoles in this case can only be explained by hydrolysis of (carboimino-*N*-carbazyl)carbazoles. Similar reactions have been discussed in the literature (26). We failed to isolate (carboimino-*N*-carbazyl)carbazoles because of the chemical properties mentioned above. The formation mechanism and the chemical properties of these compounds require extended studies.

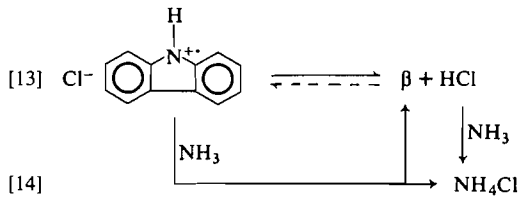
If the irradiated solution of carbazole in $CCl_4$ is saturated with ammonia gas the main reaction products are as follows: *N*-cyanocarbazole, 1-cyanocarbazole, and 3-cyanocarbazole. It is an indication of the fact that positions 1, 3, 6, 8 and 9(N) are likely to be favoured in the transformations of both the radical cation of carbazole and the carbazyl radical β in the solvent cage. The same principle of transformation for the radical cation of carbazole has been observed in the studies of electrochemical oxidation of carbazole (27). Similarly, the photolysis products of *N*-acetyl carbazole, being formed as a result of the reactions of carbazyl and acetyl radicals in the solvent cage (28), as well as the thermal rearrangement products of *N*,*N*′-dicarbazyl (29), strongly support the mechanism discussed for the reactions between the pair of radicals β and $CCl_3$. These experimentally observed chemical properties of the radical cation of carbazole as well as of radical β are in good agreement with theoretical estimations of the electron charge density in the carbazole molecule (27, 30) and in the carbazyl radical (28).

As we have shown before (15), the radical cation of carbazole can also undergo chemical transformations through positions 2 and 4 but with much less probability than through positions 1 and 3. It is presumably the reason for the low yields of 2-cyanocarbazole and 4-cyanocarbazole in the reaction medium studied. We failed to isolate these products in an amount sufficient for unambiguous identification. Similarly, because of the low yields, we did not manage to isolate dicyano derivatives of carbazole which can be formed as the result of ammonolysis of disubstituted monocations.

*Use of $NH_3$ during irradiation*

The course of photochemical transformations in the carbazole–$CCl_4$ system, discussed above, is radically changed in the presence of ammonia. This is indicated by the qualitative and quantitative composition changes of the photochemical reaction products. The products obtained (see Table 1) show the participation of the radicals β in the secondary reactions. Thus, it may be suggested that the reaction medium favours the formation of the radicals β. Therefore, the active role of ammonia in the reaction medium could be explained by the removal of hydrogen chloride from the reaction medium and also by interaction with the radical cation of carbazole out of the cage according to the following scheme:

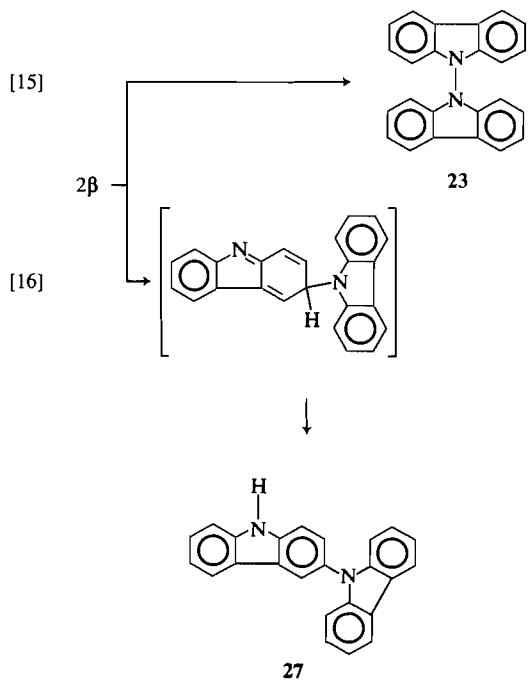
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.



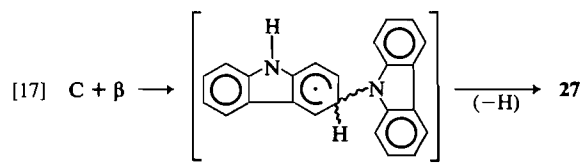
SCHEME 2

Scheme 2 explains the mechanism of formation of the radicals β in the reaction medium. Active interaction between ammonia and radical cations of aromatic amines is well known in the literature (10, 11, 31, 32). The results in these papers show that such interaction usually leads to the transformation of radical cations of aromatic amines to the corresponding radicals.

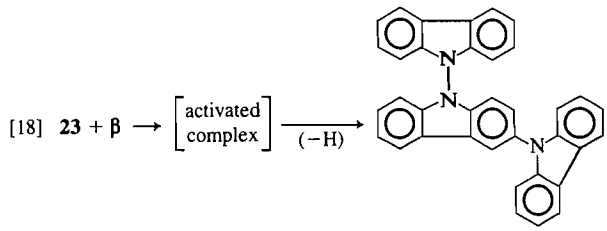
The reactions involving the recombination of radicals β explain explicitly the formation mechanism of such products as **23** and **27**:

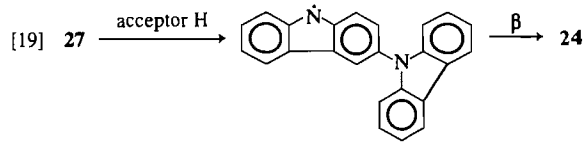


The interaction between radicals β and the carbazole molecule in the presence of hydrogen acceptor may also lead to the formation of product **27** according to reaction [17].

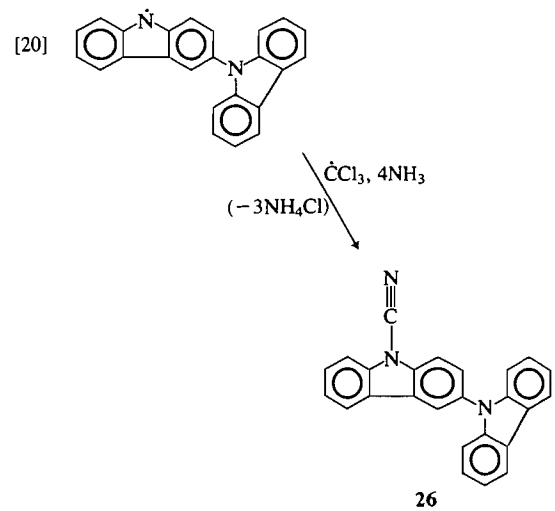


Because the medium favors radical reactions, products **23** and **27** partially undergo further transformation. This is indicated by the formation of product **24** according to reactions [18] and [19].

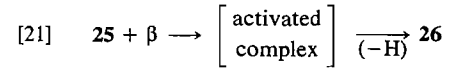




Radicals 3-(*N*-carbazyl)carbazyl appearing in reaction [19] can undergo not only the recombination reaction with radicals β forming trimer **24** but they can recombine with each other resulting in the tetramer 3,3′-di(*N*-carbazyl)-*N*,*N*′-dicarbazyl (33). In the reaction medium studied, radicals 3-(*N*-carbazyl)carbazyl, in the presence of trichloromethyl radicals, can also be the precursor of product **26** according to reaction [20].



Another possible formation mechanism of **26** can be described by reaction of radical β with *N*-cyanocarbazole:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Intermediate radical products as well as $CCl_4$ can be hydrogen acceptors in reactions [15]–[19] and [21].

Reactions [15]–[21] indicate the role played by radical β in the formation mechanism of products **23**, **27**, **24**, and **26**. Reactions involving radicals β have been thoroughly studied previously (33). Products **23**, **27**, and **24** are also formed during the chemical oxidation of carbazole with nickel peroxide (34). Thus, some analogies can be observed between photochemical and chemical oxidation of carbazole.

The products presented above along with results described in refs. 33 and 34 indicate that the production of radicals β is always accompanied by the formation of polycarbazoles according to the simplified scheme:

$$\beta \xrightarrow{\beta} (\text{dimers}) \xrightarrow[(-H)]{\beta} (\text{trimers}) \xrightarrow[(-H)]{\beta} \cdots$$

Furthermore these products prove also that radicals β outside the solvent cage take part in the reactions mainly at positions 3 and 9.

Intermediates α and $\gamma_i$ are also formed in the reaction medium studied; they are indicated by the formation of products **25**, **28**, and **29** described by reactions [9] and [10]. Products **28** and **29** are formed with low yields, while **25** as well as **23** are the main products of the discussed photochemical transformation of carbazole.

These studies of the photochemical reaction products lead to the assumption that the probability of transformation of the carbazole radical cation to form the intermediates α and $\gamma_i$ (eqs. [4] and [6] in the presence of ammonia decreases in favour of the formation of radical β (eq. [5]).

The significant yields of products **23** and **25** are connected with the high concentration of β radicals in the reaction medium. Product **23** is formed in reaction [15], while the formation of **25** can be explained by reaction [5*a*] which occurs mainly outside the solvent cage.

All the results discussed in parts I and II will serve as an excellent background for our future spectroscopic and quantitative studies of photochemical reactions in the carbazole–$CCl_4$ system.

## Experimental

*Apparatus*

The $^1$H nmr spectra have been measured with a Bruker WH-90 spectrometer operating at 90 MHz. Chemical shift values are given in a δ scale with respect to TMS as an internal standard. Infrared spectra were recorded on a Perkin–Elmer 710B infrared spectrophotometer and mass spectra were taken with a AE1 MS902 mass spectrometer.

*Materials*

Carbazole was an Eastman Organic Chemical and was used without any further purification. Carbon tetrachloride from American Chemicals was a Spectrograde quality and it was purified as described previously (15). Petroleum ether (boiling range 30–75°C) and benzene were distilled before use.

*General procedure*

Carbazole solution (0.005 *M*) in carbon tetrachloride was deoxygenated with oxygen-free argon and irradiated in a Pyrex Hanovia immersion-well reactor for 1 hour with an Hanovia 679A36 450 W medium-pressure mercury lamp. After irradiation, the solution of photolyte was saturated with ammonia gas, so that hydrogen chloride generated during the reaction was neutralized. Following that, the solution of photolyte was concentrated.

Irradiation of carbazole solution (0.005 *M*, 1 h) in carbon tetrachloride was also carried out in the presence of $NH_3$. A slow stream of ammonia gas was bubbled through the solution before and during irradiation. Hydrogen chloride generated during the photochemical reaction was thus removed from the reaction medium. When irradiation was finished, the solution of photolyte was concentrated.

The photochemical products were then analysed by tlc detected by uv (using Eastman–Kodak tlc plates, silica gel 13181) and separated by column chromatography. The columns were packed with silica gel (Kieselgel 60, Merck, particle size 0.040–0.063 mm). Developing systems consisted of petroleum ether (low boiling fraction) and ethyl ether or benzene. The developed distance on tlc plates was kept at 10 cm. Identified products, on the basis of their $^1$H nmr, ir, and mass spectra, have been listed in Table 1 and their $R_f$ values on tlc plates with silica gel are listed in Table 2.

*Spectral characteristics of the photochemical products*

*Hexachloroethane* (**1**): single crystals. The compound was identified as described previously (15).

N-*Trichloroethylenecarbazole* (**2**): crystalline solid and *1-chlorocarbazole* (**3**): crystalline solid. These compounds were identified as described previously (14, 15).

*3-Chlorocarbazole* (**22**): crystalline solid; ir (film) $\tilde{\nu}_{max}$: 3390 (vs, N—H), 1610 (w), 1590 (w), 1560 (w), 1460 (m), 1440 (s), 1430 (s), 1320 (m), 1280 (w), 1260 (m), 1230 (w), 1210 (vw), 1190 (w), 1095 (w), 1055 (m), 1040 (w), 1010 (vw), 990 (w), 915 (m), 865 (s), 800 (vs), 735 (s), 710 (s) cm$^{-1}$; $^1$H nmr (acetone-$d_6$) δ: 7.09–7.58 (m, 5H, arom), 8.11–8.22 (m, 2H, arom), 10.52 (s, br, 1H, N—H); ($CDCl_3$): 7.10–7.50 (m, 5H, arom), 7.90–8.15 (m, 2H, arom and 1H, N—H); mass spectrum (70 eV) (mol. wt. for $C_{12}H_8NCl$: 201.66), *m/e*: 203 ($M^+$, 30), 201 ($M^+$, 100), 167 (6), 166 (37), 165 (6), 164 (9), 140 (10), 139 (13).

N,N′-*Dicarbazyl* (**23**); crystalline solid. The compound was identified as described previously (14).

*3,9-Di-(*N*-carbazyl)carbazole* (**24**): crystalline solid; ir (film) $\tilde{\nu}_{max}$: 1615 (m), 1595 (m), 1575 (w), 1490 (s), 1475 (s), 1450 (vs), 1320 (m), 1305 (s), 1265 (m), 1225 (vs), 1160 (w), 1145 (w), 1105 (w), 1015 (m), 1000 (w), 990 (w), 960 (vw), 920 (w), 910 (w), 870 (vw), 840 (vw), 800 (m), 740 (vs), 715 (s) cm$^{-1}$; $^1$H nmr ($CDCl_3$) δ: 6.93–7.18 and 7.18–7.55 (2 complex m, 17H, arom), 8.10–8.29 (m, 5H, arom), 8.36 (d, $J$ = 1.5 Hz, 1H, arom); mass spectrum (70 eV) (mol. wt. for $C_{36}H_{23}N_3$: 497.60), *m/e*: 497 ($M^+$, 12), 332 (43), 331 (100), 330 (22), 329 (20), 167 (75), 166 (58), 165 (25), 140 (42), 139 (27).

N-*Cyanocarbazole* (**25**): crystalline solid. The compound was identified as described previously (14).

N-*Cyano-3-(*N*-carbazyl)carbazole* (**26**): crystalline solid; ir (film) $\tilde{\nu}_{max}$: 2220 (vs, C≡N), 1610 (w), 1580 (m), 1565 (w), 1485 (vs), 1470 (s), 1445 (vs), 1350 (w), 1320 (s), 1300 (s), 1260 (w),

*Notation of compounds is the same as in Table 1.

1220 (s), 1150 (w), 1135 (w), 1100 (w), 900 (w), 860 (vw), 830 (vw), 795 (m), 735 (vs), 710 (s), $cm^{-1}$; $^1H$ nmr ($CDCl_3$) δ: 7.17–8.22 (complex m, 15H, arom); mass spectrum (70 eV) (mol. wt. for $C_{25}H_{15}N_3$: 357.42), *m/e*: 357 ($M^+$, 100), 330 (11), 165 (30), 138 (8).

*3-(*N*-Carbazyl)carbazole* (**27**): crystalline solid; ir (film) $\tilde{\nu}_{max}$: 3385 (vs, N—H), 1610 (w), 1580 (m), 1560 (w), 1490 (vs), 1470 (s), 1455 (vs), 1445 (vs), 1360 (vw), 1320 (s), 1305 (s), 1260 (m), 1225 (vs), 1145 (m), 1130 (m), 1095 (vw), 1000 (w), 990 (w), 900 (m), 860 (vw), 825 (w), 795 (m), 740 (vs), 710 (s), $cm^{-1}$; $^1H$ nmr ($CDCl_3$) δ: 7.16–7.67 (m, 11H, arom), 7.95–8.30 (m, 4H, arom and 1H, N—H); (acetone-$d_6$): 7.18–7.87 (m, 11H, arom), 8.13–8.40 (m, 4H, arom), ~10.72 (broad band, 1H, N—H); mass spectrum (70 eV) (mol. wt. for $C_{24}H_{16}N_2$: 332.41), *m/e*: 332 ($M^+$, 100), 166 (34), 165 (27), 139 (12).

*1-Cyanocarbazole* (**28**): crystalline solid; ir (Nujol film) $\tilde{\nu}_{max}$: 3300 (s, N—H), 2200 (s, C≡N), 1615 (vw), 1595 (m), 1570 (vw), 1490 (w), 1425 (m), 1325 (w), 1315 (m), 1265 (w), 1235 (m), 1220 (w), 1205 (w), 1105 (w), 780 (w), 725 (s), 710 (s) $cm^{-1}$; $^1H$ nmr (acetone-$d_6$) δ: 7.19–7.83 (complex m, 5H, arom), 8.16, 8.24 and 8.40, 8.48 (2d, 2H, arom), 11.13 (s, br, 1H, N—H); ($CDCl_3$): 7.18–7.74 (complex m, 5H, arom), 8.04, 8.12 and 8.22, 8.30 (2d, 2H, arom), 8.97 (s, 1H, N—H); mass spectrum (70 eV) (mol. wt. for $C_{13}H_8N_2$: 192.22), *m/e*: 192 ($M^+$, 100), 191 (7.1), 165 (7.8), 164 (14.2), 138 (4.2), 96 (8.5).

*3-Cyanocarbazole* (**29**): crystalline solid; ir (Nujol film) $\tilde{\nu}_{max}$: 3275 (s, N—H), 2200 (s, C≡N), 1615 (w), 1590 (s), 1570 (vw), 1480 (w), 1395 (w), 1325 (w), 1315 (m), 1275 (w), 1230 (s), 1205 (w), 1190 (m), 1110 (w), 885 (m), 800 (s), 755 (w), 735 (m), 720 (s) $cm^{-1}$; $^1H$ nmr (acetone-$d_6$) δ: 7.19–7.69 (m, 5H, arom), 8.20, 8.29 (d, 1H, arom), 8.58 (s, 1H, arom), 10.92 (s, br, 1H, N—H); ($CDCl_3$): 7.24–7.73 (m, 5H, arom), 8.04, 8.13 (d, 1H, arom), 8.38 (s, 1H, arom), ~8.48 (s, 1H, N—H); mass spectrum (70 eV) (mol. wt. for $C_{13}H_8N_2$: 192.22), *m/e*: 192 ($M^+$, 100), 191 (11.3), 165 (13.4), 164 (17.4), 138 (7.1), 96 (15.6).

## Conclusions

Use of ammonia *after* irradiation of the carbazole solution in $CCl_4$ leads to the appearance of *N*-, 1-, and 3-cyanocarbazoles as the main products in the reaction mixture. The formation of these products indicates that chemical reaction take place between ammonia and intermediates α and $\gamma_i$. This strongly supports the proposed mechanism of transformations of the radical cation of carbazole.

When ammonia was used *during* irradiation of the carbazole solution in $CCl_4$ we obtained *N*,*N*'-dicarbazyl and *N*-cyanocarbazole as the main products in addition to 3-(*N*-carbazyl)carbazole, 3,9-di-(*N*-carbazyl)carbazole, and *N*-cyano-3-(*N*-carbazyl) carbazole. The formation of these products is closely connected with the reactions of radicals β. Radicals β along with intermediates α and $\gamma_i$ also serve as a proof for the presence of radical cations of carbazole in the photochemical reaction medium.

All the intermediate products of the photochemical reaction in the carbazole–$CCl_4$ system indicate that the primary photochemical process is the electron transfer from the singlet excited molecule of carbazole to the $CCl_4$ molecule in the excited CT complex, $^1(C^{\delta+}\cdots CCl_4{}^{\delta-})^*$. Furthermore, transformation of the primary photochemical reaction products depends not only on their particular type, but also on the nature of the reaction media used.

# Magnetic non-equivalence of fluorine atoms of a trifluoromethyl group

MOHSIN A. KHAN,[1] DONALD F. TAVARES,[2] AND ARVI RAUK
*Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4*

Received March 19, 1982

MOHSIN A. KHAN, DONALD F. TAVARES, and ARVI RAUK. Can. J. Chem. **60**, 2451 (1982).

The three fluorine atoms of *N,N*-dialkyl amide and chloride derivatives of 2-methoxy-2-phenyl-3,3,3-trifluoropropanoic acid are magnetically nonequivalent below −60°C and exhibit a clear ABC coupling pattern from which chemical shifts and geminal coupling constants are readily derived. The chemical shifts span a range of about 10 ppm and the geminal coupling constants average about 110 Hz. A five bond coupling of about 5 Hz is observed between the hydrogens of the methoxy group and one of the nonequivalent fluorine atoms of the trifluoromethyl group. Barriers to the hindered rotation about the single bond to the trifluoromethyl group are in the range 36–46 kJ/mol.

MOHSIN A. KHAN, DONALD F. TAVARES et ARVI RAUK. Can. J. Chem. **60**, 2451 (1982).

Les trois atomes de fluor du *N,N*-dialkylamide et du chlorure provenant de l'acide méthoxy-2 phényl-2 trifluoro-3,3,3 propanoique sont magnétiquement non équivalents en dessous de −60°C et présentent un modèle clair de couplage ABC duquel on déduit facilement les déplacements chimiques et les constantes de couplage géminal. Les déplacements chimiques s'étalent sur un intervalle de 10 ppm environ et les constantes de couplage géminal sont en moyenne de 110 Hz environ. On observe un couplage à travers 5 liaisons de 5 Hz environ entre les hydrogènes du groupe méthoxy et l'un des atomes de fluor non équivalent du groupe trifluorométhyle. Les barrières à la rotation encombrée autour de la liaison simple du groupe trifluorométhyle sont de l'ordre de 36 à 46 kJ/mol.

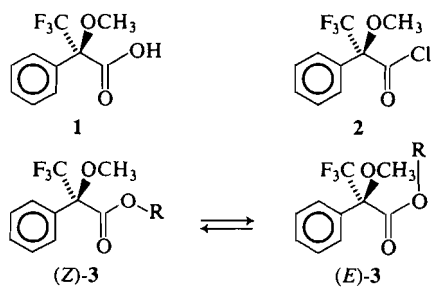
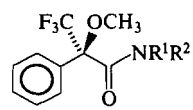
## Introduction

Fluorine nmr is an important technique in structural determination because of the extreme range (~800 ppm) of chemical shifts that are observed. $^{19}F$ chemical shifts and coupling constants have been used extensively to derive conformational and configurational information, much of it, however, in compounds in which the fluorine atoms are attached to rigid ring systems. In conformationally mobile systems, some information is lost due to averaging over structures, a consequence of the relatively long time scales of nmr experiments. Frequently, however, specific information may be obtained at temperatures at which conformation or group exchanges are slow on the nmr time scale.

The nmr spectral measurements of diastereomeric ester and amide derivatives of 2-methoxy-2-phenyl-3,3,3-trifluoropropanoic acid **1** have been routinely used for the determination of absolute configurations and optical purities of chiral alcohols and amines, after the pioneering work of Mosher and co-workers (1, 2). The esters, **3**, and amides of primary amines, **4** ($R^1$ = H), each display a single sharp fluorine resonance and mixtures of configurationally diastereomeric compounds often have separated signals for the $-CF_3$ groups, rendering assessment of relative abundances by integration facile. The conformational (or geometric) diastereoisomerism of which each of **3** and **4** ($R^1$ = H) is capable, namely (*Z*)-**3** ⇄ (*E*)-**3** and (*Z*)-**4** ⇄ (*E*)-**4**, is not evident in the ambient temperature nmr spectrum. Either the rate of interconversion is sufficiently rapid to average the signals of the geometric diastereomers or the equilibrium favours one of the isomers to the virtual exclusion of the other.





**4**

The former is unlikely, since it is known that rotation about the carbon–nitrogen bond of amides, including amides from primary amines (3), is hindered by a barrier of about 67–92 kJ/mol (3, 4). The corresponding barriers in esters are probably somewhat lower. For simple acetates and formates, barriers in the range 42–55 kJ/mol have been obtained by *ab initio* computations (5). Acyclic esters exist preferentially in the *Z*-conforma-

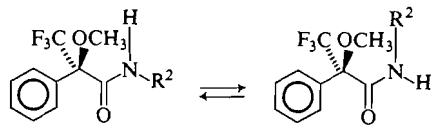
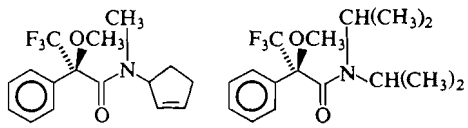
tion, (*Z*)-**3** (6, 7) which is at least 7.6 kJ/mol (the value for *tert*-butyl formate (7)) more stable than the *E*-conformer. *Ab initio* computations have yielded values in the range 17–35 kJ/mol in favour of the *Z*-form, e.g. (*Z*)-**3**, over the *E*-form, e.g. (*E*)-**3**, for methyl formate and methyl acetate (5, 8, 9). For amides of primary amines, the situation is similar. The carbon–nitrogen backbone in proteins has the *Z*-configuration, and simple acyclic *N*-monoalkyl amides also adopt the *Z*-conformation to the virtual exclusion of the other except in the case of formamides (10). For more complex *N*-monoalkyl amides, and for *N*,*N*-dialkyl amides, it is generally agreed that minimization of steric repulsions is the single most important factor which leads to a preference of one conformation over the other (11, 12) and this should be the case for **4** also.



(*Z*)-**4** ($R^1$ = H) (*E*)-**4** ($R^1$ = H)

Amides of chiral secondary amines, e.g. **4** ($R^1 \neq R^2 \neq$ H), present complications for the determination of absolute configurations or optical purities which arise from the fact that, in general, pairs of geometric diastereomers as well as configurational diastereomers are evident in the $^1$H nmr spectrum (13, 14), at ambient temperature. Indeed, the room temperature $^{19}$F nmr spectrum of amide **5**, pre-



**5** **7**

pared in connection with another study, shows two broad, unequal, overlapping absorptions. While multiple absorptions in the $^{19}$F nmr spectrum were expected, the breadth of the lines was not. We present below the analysis of several derivatives of **1**, namely **2**, **6**–**8**, in which nmr spectral changes are attributed to unusually high barriers to hindered rotation about the carbon–carbon single bond to the trifluoromethyl group.

**8**

## Experimental

*Materials*

Dimethylamine, diisopropylamine, and 2,6-dimethylpiperidine were commercial reagent grade, and were redistilled before use and their purity checked by glc (Porapak Q). The 2,6-dimethylpiperidine (Aldrich Chemical Co.) is the *cis*- or (*R*,*S*)-isomer as verified by $^{13}$C nmr spectroscopy (14). No trace of the *trans*- or (*d*,*l*)-isomer is detectable in the ambient temperature $^{13}$C spectrum.

*2-Methoxy-2-phenyl-3,3,3-trifluoropropanoyl chloride* (**2**)
(α-Methoxy-α-trifluoromethylphenylacetyl chloride)

Racemic and (+)-α-methoxy-α-trifluoromethylphenylacetic acids (Aldrich Chemical Co.) were converted to the corresponding acid chlorides by a modification of the published procedure (1) using a catalytic amount of dimethylformamide (15).

*Preparation of (±) and (+)-2-methoxy-2-phenyl-3,3,3-trifluoropropanamides*

(a). The amides of ammonia (**4**, $R^1 = R^2$ = H) and dimethylamine (**6**) were prepared according to the general procedure of Mosher (1) and were characterized by $^1$H nmr spectroscopy. Samples were diluted with the appropriate solvent for the $^{19}$F nmr spectroscopy experiments.

(b). The amides of diisopropylamine (**7**) and 2,6-dimethylpiperidine (**8**) required heating with the acid chloride for 3 h (reflux) followed by standing at room temperature for 18–20 h. The amides were characterized by $^1$H nmr and samples were diluted with the appropriate solvent for the $^{19}$F nmr experiments.

*Nuclear magnetic resonance experiments*

The $^{19}$F nmr spectra were recorded at 188.1 MHz on a Varian XL-200 spectrometer, equipped with a variable temperature controller (accurate to ±1°C). All spectra were referenced against TFA (trifluoroacetic acid) in $CDCl_3$ and converted to the ∂ scale (16) using the conversion factor: $\partial = \partial_{TFA} - 76.1$ ppm. For the temperature range +60°C to −65°C, $CDCl_3$ was used as the solvent; for the range −60°C to −128°C, $CFCl_3$ was used as the solvent and the instrument was run unlocked, using the same machine frequencies employed in the locked spectra and assuming no field drift.

## Results and discussion

### *Low temperature $^{19}$F nmr spectrum and parameters of the trifluoromethyl group*

The temperature dependence of the $^{19}$F nmr spectrum of **6** is typical of that of the other compounds and is shown in Fig. 1. At 22°C there is a single, somewhat broadened, resonance at δ = −71.3 ppm. Upon lowering the sample temperature, the signal broadens considerably and disappears at about −50°C, the coalescence temperature in both $CDCl_3$ and $CFCl_3$. At lower temperatures ($CFCl_3$) the signal reappears and sharpens into an ABC coupling pattern at −100°C. The observations must be due to hindered rotation about the C—$CF_3$

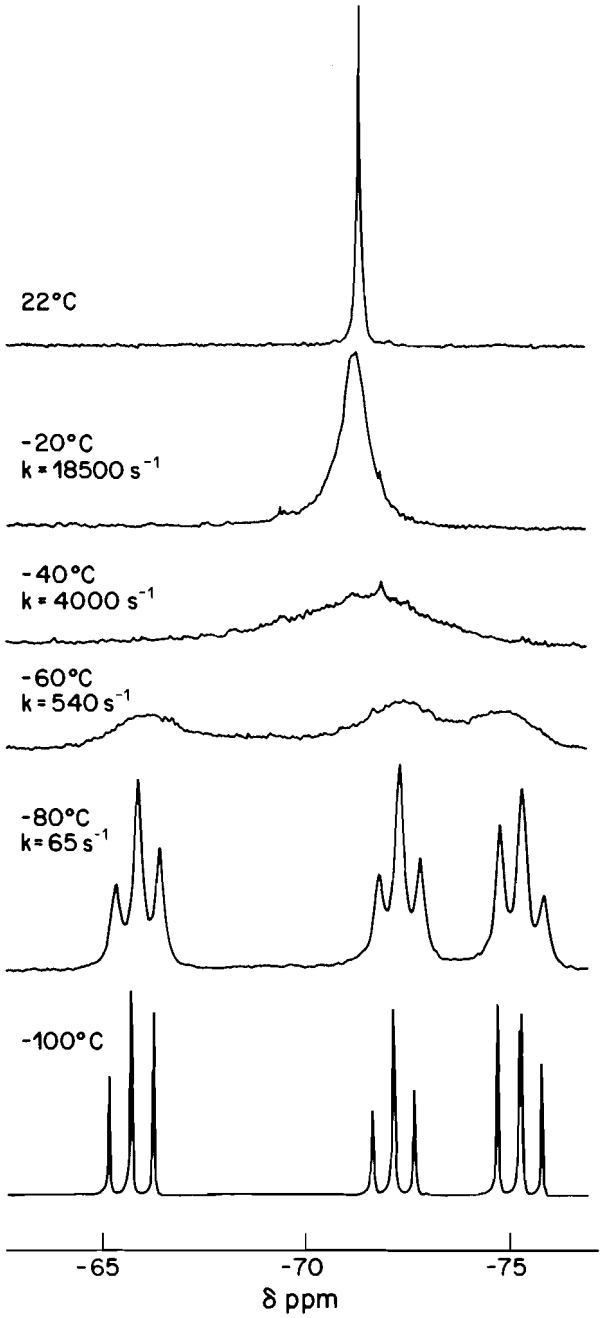

FIG. 1. The $^{19}F$ nmr spectra of **6** in the temperature range 23°C to −100°C. Rate constants were determined by lineshape fitting using DNMR3 (ref. 22). The spectra at the two lowest temperatures were recorded in $CFCl_3$, the rest in $CDCl_3$.

bond. The $^{19}F$ nmr spectral data of **6**, as well as **2**, **7**, and **8**, are given in Table 1. We refer to the individual fluorine resonances as $F_A$, $F_B$, and $F_C$ where $F_A$ is at highest frequency and $F_C$ at the lowest.

The nmr spectral data of all of the compounds of Table 1 have the following features in common. The $^1H$ nmr shows a five bond coupling, $^5J_{HF} = 2$ Hz, between the $CF_3$ group and the protons of the methoxy group. The long range coupling is highly stereospecific since only the middle fluorine ($F_B$) resonance displays broadening due to the (unresolved) coupling in the $^{19}F$ spectrum when $CF_3$ rotation is slow on the nmr time scale. In the case of **7**, the low temperature proton spectrum was recorded down to −80°C. The signal of the methoxy protons, initially a quartet, $^5J_{HF} = 1.9$ Hz, undergoes coalescence and then sharpens into a doublet, $^5J_{HF_B} = 4.7$ Hz. Since $(^5J_{HF_A} + {}^5J_{HF_B} + {}^5J_{HF_C})/3 = 1.9$ Hz, neither $^5J_{HF_A}$ nor $^5J_{HF_C}$ can exceed 1 Hz, thus confirming the stereospecificity of the long-range coupling to a single fluorine atom.

The average $CF_3$ chemical shift of all of the compounds is $-70.2 \pm 0.5$ ppm at low temperature. The narrowness of the observed range suggests that the local electronic and magnetic environment of the $CF_3$ group is similar in all cases. The median chemical shift difference $\langle \delta F_A - \delta F_C \rangle$ is 10.3 ppm ± 1.2 ppm. All of the observed geminal coupling constants $^2J_{FF}$ are in the range $111 \pm 8$ Hz. For each compound the same pattern is observed, namely $J_{AC} > J_{AB} > J_{BC}$.

Individual fluorine resonances arising from restricted rotation about a single bond to a trifluoromethyl group have been previously reported, first in 2,2,3,3-tetrachloro-1,1,1,4,4,4-hexafluorobutane (17) and then other halo alkanes (18, 19) and in several trifluoromethyl substituted phosphoranes (20, 21). The chemical shifts and coupling constants reported in Table 1 for derivatives of **1** are similar to those previously observed in the perhaloalkanes, although in the latter compounds, the chemical shift differences between the individual fluorine atoms of the $CF_3$ group are somewhat larger, 12–16 ppm (17–19).

*Barriers to the hindered rotation*

From the limiting values of chemical shifts and coupling constants, given in Table 1, and the temperature dependence of the lineshapes of the $^{19}F$ signals (e.g. **6**, Fig. 1), activation parameters were obtained for **2**, **6**, and **7** using the computer programme DNMR3 (22*a*) for rate constants. In each case, satisfactorily straight lines were obtained in a plot of $\ln(k/T)$ vs. $1/T$.

$$[1] \quad k = \left(\frac{k_B}{h} T\right) e^{-(\Delta H^{\ddagger} - T\Delta S^{\ddagger})/RT}$$

$\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ were obtained from the "least squares" lines. Free energies of activation, $\Delta G^{\ddagger}$,

| **2**[b] | −65.97 | −70.33 | −75.12 | 112.5 | 113.9 | 109.4 | −90 | 33.0 ±0.1[f] | 34.2±1.3[f] | 6.3±7.4[f] |
| **6**[c] | −66.09 | −72.26 | −75.67 | 108.9 | 117.1 | 106.1 | −50 | 40.46±0.01[g] | 35.8±0.5[g] | −21.0±2.4[g] |
| **7** | −64.95 | −71.64 | −74.68 | 107.8 | 118.1 | 106.4 | −10 | 47.25±0.04[h] | 44.1±0.5[h] | −11.8±2.2[h] |
| **8***a*[e] | −65.00 | −71.96 | −75.09 | 109.6 | 113.4 | 107.8 | −20 | 46[i] | | |
| **8***b*[e] | −63.92 | −70.20 | −75.43 | 107.5 | 118.3 | 104.9 | | | | |

[a]Values ($\partial$) are cited relative to $CFCl_3$ (16). The relative values are accurate to the level of significance shown.
[b]In $CFCl_3$ at −128°C.
[c]In $CFCl_3$ at −100°C.
[d]In $CDCl_3$ at −63.5°C.
[e]Relative abundance **8***a*/**8***b* = 2.0, in $CDCl_3$ at −63°C. These correspond to the geometric isomers which arise from rotation about the amide C(O)—N bond.
[f]Temperatures (°C) and rate constants ($s^{-1}$): −60, 45 000; −80, 4900; −100, 225; −110, 92; −115, 37; −120, 16.5.
[g]Temperatures (°C) and rate constants ($s^{-1}$): 0, 60 000; −20, 18 500; −40, 4000; −60, 540; −65, 390; −80, 65.
[h]Temperatures (°C) and rate constants ($s^{-1}$): 21, 20 000; 0, 5200; −20, 1020; −40, 142; −50, 56; −55, 27.
[i]Estimated using the Eyring equation (see text), $k_c \approx 1700\ s^{-1}$.

were obtained at the coalescence temperature $T_c$, using eq. [2]. Errors were estimated using eq. [3], following Binsch and Kessler (22*b*).

$$[2]\quad \Delta G^{\ddagger} = \Delta H^{\ddagger} - T_c \Delta S^{\ddagger}$$

$$[3]\quad \sigma(\Delta G^{\ddagger}) \approx |\sigma(\Delta H^{\ddagger}) - T\sigma(\Delta S^{\ddagger})|$$

The results are given in Table 1. For **8**, lineshape analysis could not be used because the low temperature $^{19}F$ spectra are complicated due to the presence of geometric (rotational) diastereomers. These occur as a consequence of rotation about the C(O)—N bond. The free energy of activation for **8** was estimated from the Eyring equation (eq. [4]), where an approximate rate constant, $k_c$, at the coalescence temperature, $T_c$,

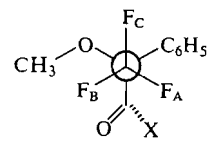
$$[4]\quad k_c = \left(\frac{k_B}{h} T_c\right) e^{-\Delta G^{\ddagger}/RT_c}$$

was obtained using DNMR3 and average limiting chemical shifts taken from Table 1. The values so obtained for **8** are: $\Delta G^{\ddagger} = 46$ kJ/mol, $T_c = -20$°C, $k_c = 1700\ s^{-1}$.

Barriers to hindered rotation about C—C single bonds have been the subject of several reviews (3, 23). Barriers to rotation about bonds of the $sp^3$–$sp^3$ type range from 11.7 kJ/mol (for ethane) to values as high as 140 kJ/mol, generally increasing with the size of the substituents. Barriers to rotation about bonds terminating in the $CF_3$ group are generally in the range 16–35 kJ/mol (17) (16.4 kJ/mol for $CF_3CF_3$) (24). Values obtained in the present study (Table 1) are somewhat higher than the norm but consistent with the high coalescence temperatures observed, and reflect the severe steric crowding of the substituents at the chiral centre. Indeed it is very difficult to prepare a spacefilling model of any of the compounds **2**–**8**.

*Stereochemistry of the individual fluorine resonances*

It would be of interest to assign the individual fluorine resonances in the chiral environment of the derivatives of **1**. Although an unambiguous assignment cannot be made at this time, several facts are consistent with the assignment shown in structure **9**, where $F_A$ is at highest frequency and X is Cl or a

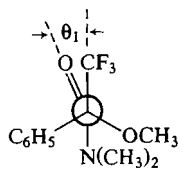


**9**

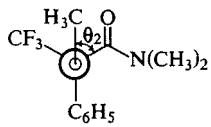
—$NR^1R^2$ group. In each of the compounds listed in Table 1, the individual fluorine atoms of the trifluoromethyl group are separated by about 10 ppm. $^{19}F$ chemical shifts have been related to the covalency of the bonding to fluorine and to the anisotropy of the charge distribution of the fluorine atom. A shift to low field (deshielding) due to the paramagnetic contribution is greatest in covalently bonded fluorine and is zero in the spherically symmetric $F^-$ ion (25). Although explicit calculation of the chemical shifts of fluorines in systems such as **1**–**8** is beyond our present capabilities, in order to obtain a measure of the amount of covalent character of the bonds to the three fluorine atoms, we have performed extensive geometry optimization by the MNDO method (26) on one of the conformers of **6**, shown below, which we judged from construction of spacefilling models most likely to correspond to the global minimum. Beginning with $\theta_1 = 0°$ and $\theta_2 = -60°$, and optimizing a total of 34 independent structural parameters (bond lengths, bond angles, and dihedral angles (only the internal geometry of the three methyl groups and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

the phenyl ring were constrained to standard values), the structure relaxed to $\theta_1 = 1°$ ($CF_3$ groups eclipsed to carbonyl group) and $\theta_2 = -50°$. The calculated anisotropies (27), $L(X)$, of the three fluorine atoms and bond orders (27), $B(C,F)$, of the bond to the fluorine atom can be used as indicators of covalent character. The calculated quantities for the three fluorine atoms (structure **9**) are $L(F_A) = 0.3458$, $L(F_B) = 0.3425$, $L(F_C) = 0.3404$, $B(C,F_A) = 0.9347$, $B(C,F_B) = 0.9289$, and $B(C,F_C) = 0.9253$. Although the differences in anisotropy and bond order appear to be small, direct application of the observed (25) correspondence between chemical shift and covalency yields the result that $F_A$ should be at highest frequency and $F_C$ at lowest.



*6a*



*6b*

The above result is consistent with the assignment of $F_B$ as the fluorine atom which is coupled to the protons of the methoxy group. The computations show the closest contact to be between $F_B$ and the methyl group, $r(F_B—CH_3O) = 2.50$ Å, compared to $r(F_A—CH_3) = 4.24$ Å and $r(F_C—CH_3O) = 3.18$ Å. The observed 5-bond F—H coupling is reminiscent of the stereospecific 5-bond F—F coupling reported by Weigert and Roberts (17), which was ascribed to "through space" or "direct" coupling, a mechanism which has substantial experimental support (28, 29). Although Weigert has urged restraint in the correlation of structure with "through space" coupling constants (19), the observed couplings $^5J_{F_B—H} = 4.3$ Hz in **6**, $^5J_{F_B—H} = 4.7$ Hz in **7** are very nearly those expected for $r(F_B—H) = 2.5$ Å using Myhre's curve which relates $J_{HF}$ to $r(F—H)$ (29).

# The solubilization of potassium permanganate by polyethylene glycols

DONALD G. LEE AND HASAN KARAMAN

*Department of Chemistry, The University of Regina, Regina, Sask., Canada S4S 0A2*

Received March 9, 1982

DONALD G. LEE and HASAN KARAMAN. Can. J. Chem. **60**, 2456 (1982).

The abilities of various cyclic and acyclic polyethers to solubilize potassium permanganate in organic solvents have been compared. In general, the cyclic compounds (crown ethers) are more effective than acyclic polyethers of comparable molecular weights. Each mole of 18-crown-6 is capable of solubilizing one mole of potassium permanganate in most solvents whereas the corresponding linear polymer, dimethyloctaethylene glycol, is much less effective, particularly in solvents of low polarity. Very long chain polymers are capable of complexing more than one mole of potassium ion per mole of polyether and thus bringing more than one mole of potassium permanganate into solution. A comparison with other studies on acyclic polyethylene glycols suggests that these structures would be helical with the oxygen complexed potassium ions inside and the permanganate anions arranged along the exterior.

DONALD G. LEE et HASAN KARAMAN. Can. J. Chem. **60**, 2456 (1982).

On a comparé les propriétés qu'ont divers polyéthers cycliques ou acycliques de solubiliser le permanganate de potassium dans des solvants organiques. En général, les composés cycliques (éthers couronnes) sont plus efficaces que les polyéthers acycliques de poids moléculaires comparables. Chaque mole d'éther-18 couronne-6 est capable de solubiliser une mole de permanganate de potassium dans la plupart des solvants alors que le polymère linéaire correspondant, le diméthyloctaéthylèneglycol, est beaucoup moins efficace, particulièrement dans les solvants de faible polarité. Les très longues chaînes de polymères peuvent complexer plus d'une mole d'ion potassium par mole de polyéther et solubilisent de ce fait plus d'une mole de permanganate de potassium. La comparaison avec d'autres études sur les polyéthylèneglycols acycliques suggère que ces structures peuvent être en hélice; les ions potassium, complexés par l'oxygène, sont à l'intérieur et les anions permanganates disposés à l'extérieur.

[Traduit par le journal]

## Introduction

The complexation of metal cations by polyethers is a well established method for solubilizing ionic reagents in organic solvents (1). Both cyclic (2) and acyclic (3) polyethylene glycols have been used to dissolve ionic reagents in organic solvents. The dissolved ionic reagents can then be used in a variety of chemical reactions (4).

Several synthetic procedures that utilize permanganate dissolved in organic solvents with the aid of polyethers have been reported (5) and in an attempt to optimize these procedures, as well as to obtain a better understanding of the fundamental principles involved, we have undertaken a quantitative study of the phase distributions of potassium permanganate in the presence of cyclic and acyclic polyethers.

## Experimental

*Materials*

The crown ethers were obtained from the Aldrich Chemical Co., the methoxypolyethylene glycols from Union Carbide Ltd., dimethyloctaethylene glycol from Prof. Herbert Lehmkuhl, and the trimethylsilanepolyethylene glycols from Dr. Gerd Rossmey. The solvents used were Fisher, spectro grade. Finely powdered potassium permanganate was obtained from the Carus Chemical Company.

*Extinction coefficients*

Since we intended to use its absorption spectrum to determine the concentration of permanganate in several solvents, it was first necessary to obtain extinction coefficients in each solvent.

TABLE 1. Extinction coefficients for permanganate in various solvents

| Solvent | 514 nm | 526 nm |
|---|---|---|
| Dichloromethane | 1720±30 | 2570±20 |
| Chloroform | 1710±30 | — |
| Benzene | 1750±40 | 2410±50 |
| Water | 1750±30 | 2410±40 |

In order to do this a solution of benzyltriethylammonium chloride ($1.60 \times 10^{-2}$ *M*) was prepared in the solvent under consideration and an aliquot (5 mL) was used to extract smaller volumes (0.2, 0.4, 0.6, 0.8, and 1.0 mL) of $1.65 \times 10^{-3}$ *M* aqueous potassium permanganate. (Benzyltriethylammonium chloride is a very efficient phase transfer agent for $KMnO_4$ and it was observed to be completely extracted from the aqueous solutions under these conditions.) The absorbances were then measured at two points (514 and 526 nm) and extinction coefficients obtained from the slopes of absorbance vs. concentration plots. This procedure was repeated at least three times for each solvent and the extinction coefficient for aqueous permanganate solutions was calculated similarly. The results are summarized in Table 1.

As the data indicate, extinction coefficients are the same in all of the solvents within the limits of experimental uncertainty. All measurements were subsequently made at 514 nm where the extinction coefficient was assumed to be 1740 L $mol^{-1}$ $cm^{-1}$. It was noted, however, that identical results were obtained in several cases where measurements were also made at 526 nm.

*Distribution ratios*

Distribution ratios relating to the ability of polyethers to bring solid $KMnO_4$ into solution were determined in the following manner. Initially, solid powdered potassium permanganate was extracted with solutions of polyethers and the number of moles of $KMnO_4$ which dissolved was determined spectrophotomet-

rically. The ratio of the number of moles of permanganate which had dissolved to the number of moles of polyether initially present ($[MnO_4^-]_{org}/[Polyether]_{initial}$) was designated by the symbol $K_R$. Under these conditions it may be assumed that permanganate exists in the organic solvents as an ion pair tightly associated with polyether complexed potassium ions (6).

In a typical experiment, five solutions containing different concentrations of polyether were prepared in a particular solvent and aliquots (5 mL) of each solution were added to test tubes containing an excess (0.1 g) of finely powdered potassium permanganate. After equilibrium had been established (vigorous shaking) the excess solid potassium permanganate was removed by centrifuging and the clear supernatant transferred to a cuvette. Absorbances at 514 nm were measured using a Unicam 500 SP spectrophotometer equipped with a thermostated cell compartment and $K_R$ values were obtained from plots of permanganate concentration vs. the initial concentration of polyether. A typical plot has been reproduced in Fig. 1.

## Results and discussion

The distribution ratios obtained when methylene chloride was used as the solvent have been collected in Table 2. An examination of the $K_R$ values reveals at least one surprising result; the longer chain polyethers are capable of solubilizing more than one mole of $KMnO_4$, with the longest polymers being capable of bringing an average of almost six moles of permanganate into solution. The quantity $n/K_R$ indicates the number of oxyethylene units required to solubilize one mole of $KMnO_4$. This value is lowest for the macrocyclic ethers, 18-crown-6 and dibenzo-18-crown-6, presumably because complexation constants are greater with preformed rings (7). It is apparent from the $K_R$ values that each of these crown ethers is capable of complexing one mole of potassium ion; however, two moles of 15-crown-5 are required per mole of $K^+$, suggesting that this complex exists as a sandwich with the cation situated between a pair of crowns (8, 9).

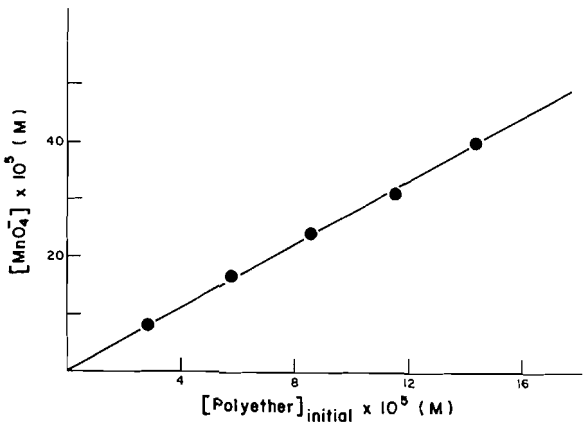

FIG. 1. A typical plot for the estimation of $K_R$ values. The system illustrated is $CH_3(OCH_2CH_2)_{44.7}OH$ in methylene chloride.

TABLE 2. Distribution ratios in methylene chloride[a]

| Polyether | $K_R$ | $n/K_R$[b] |

[a]At 25°C.
[b]$n$ = the average number of oxyethylene units.

Complexes of more than one mole of cation per mole of polyether are not unknown. For example, binuclear S-shaped complexes of KSCN with acyclic polyethers have been prepared and studied crystallographically (10). However, we are not aware of previously reported examples where as many as six cations were complexed by a single polyether.

Crystallographic studies have established that polyethylene glycols exist in the solid state as distorted helices containing about seven oxygens per loop (11). Consequently it is to be expected, when these compounds complex a salt in an organic solvent, that the oxygens would fold inward around the positive ion and the methylenes would form a nonpolar sheath projecting into the solvent (1). Since a crown with six oxygens is capable of complexing a potassium ion it might be expected that each loop of the helix could also accommodate one cation. However, if cations were situated within the cavity of the helix there would be a certain amount of electrical repulsion which would discourage the location of ions on adjacent loops. As a consequence it may be seen that as the number of cations per mole of polyether increases the number of oxyethylene units required per cation also increases.

It is apparent from a consideration of the data in Table 2 that the most important characteristic of the acyclic polyethers is the length of the chain and not the nature of the terminal "caps" (12), (see Fig. 2).

The ratios obtained when chloroform was used as the solvent are similar to those obtained with methylene chloride for the crowns but somewhat smaller for the acyclic polyethers. The latter may be due to the lower polarity of chloroform (13) which would increase the energy required to

TABLE 3. Distribution ratios ($K_R$) in various solvents[a]

solubilize an ion pair. This is further emphasized by the data in Table 3 from which it is clearly evident that the acyclic polyether complexes are more sensitive to changes in solvent polarity than are the crowns. The ability of dibenzo-18-crown-6 to function in solvents of low polarity (as compared to 18-crown-6) is somewhat decreased, possibly because the aromatic rings lend rigidity to the crown and withdraw electrons from the oxygens, thus decreasing its capability of complexing the potassium ions (14).

Although the effects of solvent changes on the magnitude of binding constants in homogeneous systems have been studied (15), the effects on phase changes of the type described here have been given less attention. However, when Brandstrom (6) studied the distribution of tetrabutylammonium salts between water and several organic solvents, he found that the smaller anions such as chloride were more easily extracted into chloroform than methylene chloride, but for ions in which the charge to mass ratio was small the reverse was true. For example, the salts of larger anions such as perchlorate and trinitrophenolate were more soluble in methylene chloride. The behavior of permanganate in the present study thus appears to be similar to that exhibited by other anions which can delocalize the negative charge over several oxygens.

Finally, it may be noted that these results lead to certain conclusions that have practical application to the oxidation of organic compounds in nonaqueous solvents. (*i*) The acyclic polyethers can be used as effectively to solubilize $KMnO_4$ as the more expensive crowns, provided that their lower efficiency is compensated for by use of longer chains. (*ii*) The concentration of permanganate in solution can be controlled by selection of an acyclic polyether of the appropriate length. A rough estimate of the concentrations to be expected can be obtained from interpolation of the data in Tables 2 and 3. (*iii*) Of the solvents studied, the use of methylene chloride resulted in the highest concentrations of potassium permanganate. The acyclic polyethers were all found to be completely incapable of solubilizing $KMnO_4$ in nonpolar solvents such as carbon tetrachloride or pentane.

Received March 25, 1982

M. BURTON, G. FOLCHER, H. MARQUET-ELLIS, P. RIGNY, and C. GIANNOTTI. Can. J. Chem. **60**, 2460 (1982).

The intermolecular exchange of cyclopentadienyl groups in the system $UCp_3$–$UCp_3Cl$ in THF solution between 170–300 K was investigated by $^1H$ nmr. The kinetic results show a bimolecular mechanism and suggest an electron transfer via the chlorine atom. This first example of a symmetrical exchange in the $U^{III}$–$U^{IV}$ system illustrates the lability of actinide organometallic compounds.

M. BURTON, G. FOLCHER, H. MARQUET-ELLIS, P. RIGNY et C. GIANNOTTI. Can. J. Chem. **60**, 2460 (1982).

L'échange intermoléculaire des groupes cyclopentadienyl dans le système $Cp_3U$–$Cp_3UCl$ en solution THF, entre 170 et 300 K a été étudié par rmn du proton. Les résultats cinétiques montrent qu'il s'agit d'un mécanisme bimoléculaire et suggère un transfert d'électron par l'intermédiaire d'un atome de chlore. Ce premier exemple d'échange symétrique $U^{III}$–$U^{IV}$ illustre la labilité de coordinence des composés organométalliques des actinides.

The study of exchange reactions provides particularly useful information in understanding the reactivity of organometallic complexes. In the specific case of uranium organometallics of the type $(C_5H_5)_3UX$ their relative inertness (1–3) is generally explained by saturation of the coordination sphere caused by three $\pi$ bonding $C_5H_5$ groups and a monodentate ligand, e.g. halogen or alkyl.

During previous work on the reduction of $U^{IV}$ cyclopentadienyls (5, 6) we noticed in the $^1H$ nmr the appearance of two reduced species well characterized by their optical and nmr spectra.

These two species have already been identified by Kanellakopulos *et al.* as $UCp_3$ and $UCp_3$.THF (4). We assigned the nmr data according to the published optical spectra. The reaction between $UCp_3$, which is most likely a dimer, and the adduct $UCp_3$.THF is not clearly understood. Nevertheless the observed optical spectrum of the product, which gives a singlet at 20 ppm, is very similar to $UCp_3$.THF. Here we present the unexpected behaviour of $UCp_3$.THF in the presence of $Cp_3UCl$, namely an exchange between the two molecules in THF solution at ambient temperature.

## Experimental

$UCp_3Cl$, $UCp_3CH_3$, and $UCp_3(iPr)$ were prepared and photolyzed according to the published procedure (6). In a typical experiment an equimolar quantity of $UCp_3Cl$ and $UCp_3CH_3$ in THF ($10^{-2}$ *M*) was photolyzed in an nmr tube. During irradiation the nmr signals for $UCp_3CH_3$ diminished while the signal for $UCp_3Cl$ was displaced upfield. A less easy method has also been employed in order to confirm the results: a careful reduction of $Cp_3UCl$ by $LiAlH_4$ in THF is achieved, the reaction followed by nmr to minimize the excess of reductant. The solution is filtered and the solvent removed; the resulting solid, vacuum dried, can be used to make THF solutions. The main disadvantage of this method is that the solid $Cp_3U$ (THF), which is not a well cristallized compound, does not dissolve entirely in THF at room temperature (as, for instance, reported in ref. 4).

In both cases, the relative concentration of $Cp_3U$THF and $Cp_3UCl$ was obtained by integration of the exchange peak and from the relationship $\nu - \nu_B = P_A(\nu_A - \nu_B)$ where $\nu$ represents the resonance frequency and $P$ the populations of the species in exchange. The nmr spectra were run on a Varian NV14 equipped with a variable temperature accessory. One resonance of THF was chosen as internal lock.

## Results and discussion

Figure 1 summarizes the behaviour of the Cp signal as a function of temperature between −16 and −76°C. It reveals a rapid exchange on the nmr timescale of Cp groups between $Cp_3U$ Cl and $Cp_3U$ from ambient temperature down to −50°C, and slow at less than −70°C. This exchange can be represented thus:

$$(A)\ Cp^*\ CP_2U\ Cl + (B)\ Cp_3U \rightleftharpoons Cp_3U\ Cl + Cp^*\ Cp_2U$$

remembering that species A and B have uranium in the IV and III oxidation states respectively.

The mechanism of this exchange can be understood by considering the parameters involved. Firstly, the reaction order can be found by plotting (Fig. 2) the line width at half height of the exchange peak as a function of the relative concentrations of the two species.

Two cases are considered.

(*a*) First order, $dA/dt = dB/dt = k_1A$

(*b*) Second order, $dA/dt = dB/dt = k_2\,A.B$

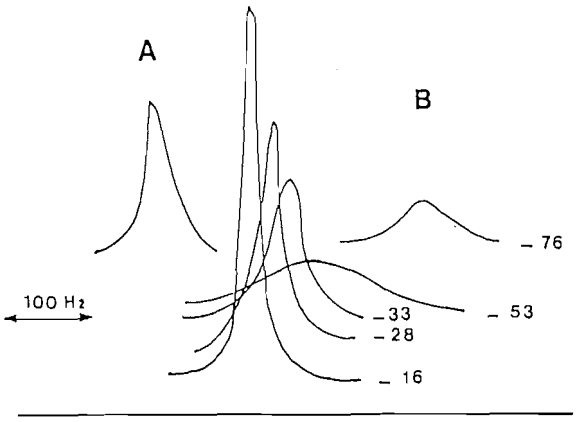

FIG. 1. The $^1H$ nmr spectra at 60 MHz of Cp in $Cp_3U$–$Cp_3U$ Cl system in THF. Temperature dependence.

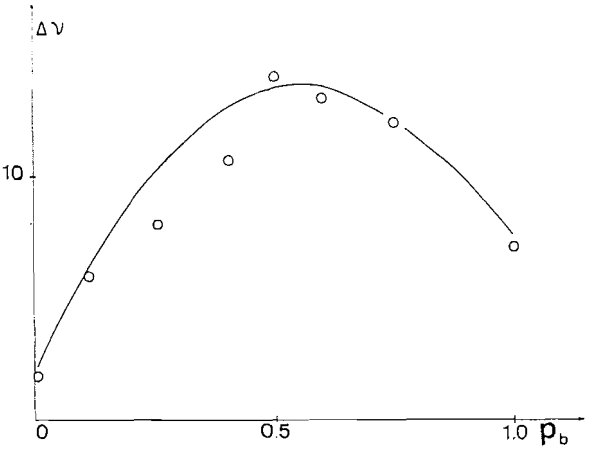

FIG. 2. Experimental (○) line width vs. $[UCp_3]/[UCp_3] + [UCp_3Cl]$. Solid line fits eq. [3] at room temperature.

In both cases $1/\tau = 1/\tau_A + 1/\tau_B$

Under rapid exchange conditions $2\pi\tau\Delta\nu \ll 1$. We can therefore employ the following expression (7)

$$[1] \quad \Delta = P_A \Delta_A^0 + P_B \Delta_B^0 + 4\pi^2 (\Delta\nu)^2 P_A P_B \tau$$

where $\Delta$ is the width at half height, $\Delta^0$ indicates the pure species in the absence of exchange, $\Delta\nu$ the difference in the resonance frequency between A and B, and $P_A$ and $P_B$ the respective populations of species A and B.

With first order kinetics,

$$[2] \quad \Delta = (1 - P_A)\Delta_B + P_A \Delta_A + P_A \frac{(1 - P_A)^2}{k_1} \times 4\pi^2 \Delta\nu^2$$

Assuming a second order reaction

$$[3] \quad \Delta = (1 - P_A)\Delta_B + P_A \Delta_A + P_A \frac{(1 - P_A)}{k_2 C} \times 4\pi^2 \Delta\nu^2$$

where $C$ is the total concentration of A and B.

Figure 2 is in good agreement with the expression depicting 2nd order kinetics. $\Delta_B$ is taken to be 7 Hz, the value for pure $UCp_3$, $\Delta_A$ is around 2 Hz and rapidly becomes negligible. $k_2 C$ is calculated to be $3.4 \times 10^5\ s^{-1}$.

The exchange is therefore second order with a rate constant of approximately $3 \times 10^6\ s^{-1}\ mol^{-1}$ at room temperature. The study as a function of temperature is shown in Figs. 1 and 3.

Figure 1 presents the behaviour of the exchange peak both in the region of rapid exchange (i.e. $2\pi\tau\Delta\nu \ll 1$) between −16 and −53°C and in the region of slow exchange (i.e. $2\pi\tau\Delta\nu \gg 1$) at temperatures below −76°C.

In the example chosen the populations $P_A$ and $P_B$ were equal to 0.4 and 0.6 respectively giving $1/\tau = 1/\tau_A + 1/\tau_B \sim 2.5/\tau_B$.

The formula [1] permits the calculation of $\Delta$ as a function of the temperature down to −50°C ($\Delta\nu$ is temperature variable but can be determined from the displacements of pure A and B in the same temperature range).

Thus for slow exchange we obtain $1/\tau_B = \pi(\Delta - \Delta^0)$ in which $\Delta^0$ represents the width in the absence of exchange and is negligible compared with $\Delta$.

Figure 3 demonstrates the linear variation in $\Delta$ as a function of $1/T$ from which the activation energy is calculated as 7.6 kcal $mol^{-1}$. Thus $\tau_B$ varies from 0.6 ms to 6 ms between −16°C and −50°C. The

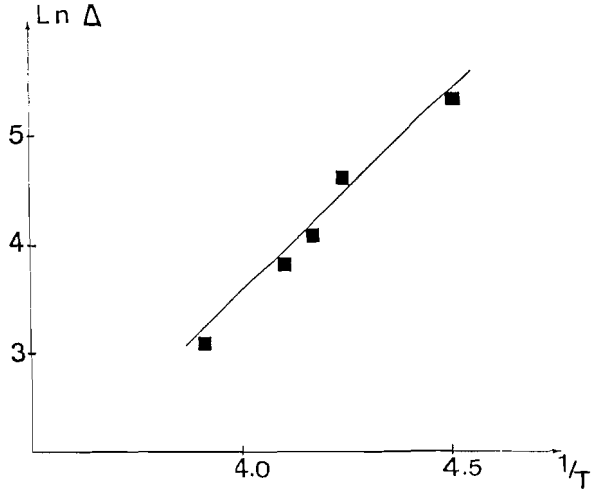

FIG. 3. Arrhenius plot of the line width of the Cp signal between −10 and −50°C.

values determined from the case of slow exchange are in good agreement with those calculated from rapid exchange. These values are less precise because the broad peaks observed do not fit exactly into a Lorentzian analysis. A more complete calculation would thus be necessary to determine better values of $\tau$.

From these measurements at slow exchange we have been able to deduce values for the bimolecular exchange constants $k_2$ ($k_2 = 1/2.5\,\tau\,[A]$) of $7 \times 10^4$ $s^{-1}\,mol^{-1}$ at $-16°C$, $7 \times 10^3$ $s^{-1}\,mol^{-1}$ at $-50°C$, and 50 $s^{-1}\,mol^{-1}$ at $-80°C$.

Two conclusions can be drawn from these results. It is the first example of symmetrical exchange demonstrated for $U^{3+}$ and the rate found is much greater than those encountered in other similar exchanges, in transition metal complexes for instance (8).

This rate must be interpreted in term of specificity of the uranium (or 5 f block elements) in an electron transfer mechanism and can be connected with the interesting properties of this ion as a reducing agent (9, 10). The molecular mechanism of this reaction suggests the presence of a complex $Cp_3U\text{-}Cl\ldots UCp_3(THF)$. In the bimetallic complex, the $Cl^-$ can be transferred from one uranium to the other.

Such a transfer achieves the electron exchange between the two uraniums and will give, on the Cp nmr spectrum, the measured broadening. A similar type of electron transfer by halogen bridge is known for several metal ion couples i.e. $Co^{3+}/Cu^{2+}$, $Fe^{3+}/Eu^{2+}$ (8); the assumed bimolecular complex is expected to be favoured by the facile enhancement of coordination number of the actinides. Thus $Cp_3U(THF)$ can easily give an adduct with $Cl^-$. On the other hand, it is well established (11, 12) in the case of β dicetonates that these complexes with high coordinance number are very labile; in this case it is assumed that the intermediate can undergo a very rapid decomposition.

# Simulation of edge effects in electroanalytical experiments by orthogonal collocation. Part 2. Theory for cyclic voltammetry

BERND SPEISER AND STANLEY PONS[1]

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received February 23, 1982

BERND SPEISER and STANLEY PONS. Can. J. Chem. **60**, 2463 (1982).

We showed in this paper the use of two-dimensional collocation to spatially discretize partial differential equations describing a model of cyclic voltammetric experiments under the influence of edge effects. The formal similarity of discretized equations for even very complicated mechanisms has been demonstrated by considering the oxidation scheme of phenol **I**. This similarity simplifies the writing and testing of computer programs used to calculate numerical simulation results. In fact, a change in mechanism normally only requires the exchange of a few FORTRAN statements while the main body of the program is untouched. We see this as one of the great advantages of our method which outweighs the difficulties encountered while assessing the features and behavior of a new type of a model, as this two-dimensional one. A thorough discussion of the numerical results for cyclic voltammetry simulations is given in part 4.

BERND SPEISER et STANLEY PONS. Can. J. Chem. **60**, 2463 (1982).

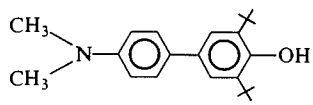
Nous montrons dans cette publication l'application d'une collocation bidimensionnelle aux équations différentielles partielles discontinues spatialement, décrivant un modèle d'expériences en voltamétrie cyclique sous l'influence des effets d'angle. On démontre la similitude formelle des équations discontinues, même dans le cas de mécanismes très compliqués, en considérant le mécanisme d'oxydation du phénol I. Cette similitude simplifie le développement et la vérification des programmes d'ordinateurs utilisés pour calculer les résultats de simulations numériques. En fait, un changement de mécanisme ne requiert normalement qu'un changement de quelques énoncés du langage Fortran tandis que le programme principal demeure inchangé. Nous percevons ceci comme un des grands avantages de notre méthode qui fait ressortir les difficultés rencontrées lorsqu'on détermine les caractéristiques et le comportement d'un nouveau type de modèle comme celui à deux dimensions. Dans la 4e partie de ce travail, on présente une discussion complète des résultats numériques des simulations en voltamétrie cyclique.

[Traduit par le journal]

## Introduction

We have used orthogonal collocation not only for the solution of linear diffusion problems but also for simulation of two-dimensional models (1, 2). Thus, it is possible to simulate edge effects on electroanalytical experiments using this fast and flexible numerical technique.

Cyclic voltammetry is one of the most commonly used electroanalytical methods and it might be of considerable interest to calculate the effects caused by edge diffusion on the $i/E$-curves. Lines and Parker (3) have observed an increase of $\Delta E_p$ when using microelectrodes and attributed this to edge effects, a conclusion which was confirmed by theoretical calculations by Heinze (4). Speiser and Rieker (5) found dramatic changes in cyclic voltammograms of 2,6-di-*tert*-butyl-4[4-dimethylaminophenyl]-phenol **I** in unbuffered, neutral acetonitrile when decreasing the electrode area from 0.29 $cm^2$ to 0.0022 $cm^2$. These experiments have also been explained in terms of edge diffusion. Up to now, however, it was not possible to simulate the complex mechanism describing the oxidation of **I** under the conditions of a finite circular disc electrode.



**I**

This paper expands the theory of two-dimensional orthogonal collocation to cyclic voltammetry and mechanisms as complex as the oxidation of **I**. It will only deal with the mathematics of the method, while a complete numerical analysis showing the usefulness of the derived equations will be given in part 4. This partition has been used because the analysis (which has to be done to validate the new two-dimensional collocation method) requires the discussion of many parameters. We point out, however, that this has to be done only once, while extension to more complicated mechanisms is obvious. Also, research on a comparison of the experimental results with **I** and numerical simulations is under way.

## Initial and boundary conditions

The initial and boundary conditions have been given by Nicholson and Shain (6) and used by Speiser and Rieker (7) in the context of orthogonal collocation for linear diffusion. Pons (8) simulated cyclic voltammograms under spherical diffusion conditions using orthogonal collocation.

For simulation of edge effects we employ our two-dimensional model of a finite, circular electrode of radius $r_0$ imbedded into an insulator body (1). The radius of the insulator may go to infinity.

We assume an EC mechanism:

[1] $$A \underset{+ne^{\ominus}}{\overset{-ne^{\ominus}}{\rightleftharpoons}} B \quad E^0, n$$

[2] $$B \rightarrow C \qquad k$$

where the diffusion controlled electron transfer is described by the formal potential, $E^0$, and the number of transferred electrons, $n$. The chemical step [2] proceeds with a rate constant $k$.

Fick's second law for the substrate A takes the form

[3] $$\frac{\partial c_A}{\partial t} = D\left[\frac{\partial^2 c_A}{\partial x^2} + \frac{1}{r}\frac{\partial c_A}{\partial r} + \frac{\partial^2 c_A}{\partial r^2}\right]$$

where $t$ is time and $x$ and $r$ are the distance coordinate perpendicular to the electrode and the radial coordinate respectively. The total diffusion is expressed as superimposition of a linear and a cylindrical term.

For species B and C eqs. [4] and [5] hold:

[4] $$\frac{\partial c_B}{\partial t} = D\left[\frac{\partial^2 c_B}{\partial x^2} + \frac{1}{r}\frac{\partial c_B}{\partial r} + \frac{\partial^2 c_B}{\partial r^2}\right] - kc_B$$

[5] $$\frac{\partial c_C}{\partial t} = D\left[\frac{\partial^2 c_C}{\partial x^2} + \frac{1}{r}\frac{\partial c_C}{\partial r} + \frac{\partial^2 c_C}{\partial r^2}\right] + kc_B$$

For convenience the diffusion coefficient of all species is set equal to $D$.

We assume that A is the only species present in the solution at the beginning of the experiment, its concentration being $c_A^0$. Thus, the initial conditions are

$t = 0,\ x \geq 0,\ r \geq 0$:

[6] $$c_A(x,r,0) = c_A^0$$

[7] $$c_B(x,r,0) = c_C(x,r,0) = 0$$

At a distance far from the electrode no concentration changes take place during the experiment. This yields the boundary conditions at $x \rightarrow \infty$ and $r \rightarrow \infty$

$t > 0,\ x \rightarrow \infty,\ r \geq 0$:

[8] $$c_A(\infty,r,t) \rightarrow c_A^0$$

[9] $$c_B(\infty,r,t) = c_C(\infty,r,t) = 0$$

$t > 0,\ x \geq 0,\ r \rightarrow \infty$:

[10] $$c_A(x,\infty,t) \rightarrow c_A^0$$

[11] $$c_B(x,\infty,t) = c_C(x,\infty,t) = 0$$

At the electrode surface the concentrations of A and B are given by [12] and [13], while [14] holds for species C:

$t > 0,\ x = 0,\ 0 \leq r \leq r_0$:

[12] $$\left(\frac{\partial c_A}{\partial x}\right)_{x=0} = -\left(\frac{\partial c_B}{\partial x}\right)_{x=0}$$

$$[13] \quad \frac{c_A(0,r,t)}{c_B(0,r,t)} = \exp\left[\frac{nF}{RT}(E^0 - E)\right] = \theta_{A/B} S_\lambda(t)$$

$$[14] \quad \left(\frac{\partial c_C}{\partial x}\right)_{x=0} = 0$$

Equation [13] reflects the special features of cyclic voltammetry if

$$[15] \quad \theta_{A/B} = \exp\left[\frac{nF}{RT}(E^0 - E_{start})\right]$$

and

$$[16] \quad S_\lambda(t) = \begin{cases} \exp[2(m-1)at_\lambda - at] & \text{for } 2(m-1)t_\lambda \le t \le (2m-1)t_\lambda \\ \exp[at - 2m\,at_\lambda] & \text{for } (2m-1)t_\lambda \le t \le 2m\,t_\lambda \end{cases} \qquad m = 1,2,\ldots$$

Here $F$, $R$, and $T$ have their usual meaning, $E_{start}$ is the starting potential of the scan, $t$ the time when the scan is reversed, $m$ the number of the present scan. A cycle consists of two scans. Finally $a$ is given by

$$[17] \quad a = \frac{nF}{RT} v$$

where $v$ is the scan rate, $dE/dt$.

There is no redox reaction at the insulator and hence no flux through this surface. Thus

$t > 0$, $x = 0$, $r > r_0$:

$$[18] \quad \left(\frac{\partial c_A}{\partial x}\right)_{x=0} = \left(\frac{\partial c_B}{\partial x}\right)_{x=0} = \left(\frac{\partial c_C}{\partial x}\right)_{x=0} = 0$$

At $r = 0$ there must be no flux in $r$-direction because our model is symmetric around $r = 0$:

$t > 0$, $x \ge 0$, $r = 0$:

$$[19] \quad \left(\frac{\partial c_A}{\partial r}\right)_{r=0} = \left(\frac{\partial c_B}{\partial r}\right)_{r=0} = \left(\frac{\partial c_C}{\partial r}\right)_{r=0} = 0$$

It is convenient (1) to divide the space in the $r$-direction into two parts, inside and outside of $r_0$. The concentration may be described by $c_1$ and $c_2$, respectively. The two concentration functions have to fulfill the conditions [20] and [21] at $r = r_0$ for all species.

$t > 0$, $x \ge 0$, $r = r_0$:

$$[20] \quad c_1(x,r_0,t) = c_2(x,r_0,t)$$

$$[21] \quad \left(\frac{\partial c_1}{\partial r}\right)_{r=r_0} = \left(\frac{\partial c_2}{\partial r}\right)_{r=r_0}$$

**Transformation to a dimensionless problem**

Equations [3]–[21] are transformed into a dimensionless problem by

$$[22] \quad X = x/L$$

$$[23] \quad c^*_{A1} = c_{A1}/c^0_A$$

$$[24] \quad c^*_{A2} = c_{A2}/c^0_A$$

$$[25] \quad c^*_{B1} = c_{B1}/c^0_A$$

$$[26] \quad c^*_{B2} = c_{B2}/c^0_A$$

$$[27] \quad c^*_{C1} = c_{C1}/c^0_A$$

$$[28] \quad c^*_{C2} = c_{C2}/c^0_A$$

[29a] $R = r/r_0 \qquad \text{for } 0 \leq r \leq r_0$

[29b] $R = (r - r_0)/(M - r_0) \qquad \text{for } r \geq r_0$

[30] $T' = at$

[31] $\alpha = kD/r_0^2$

Here $X$ is a dimensionless distance perpendicular to the electrode, $L$ is a distance from the electrode defined such that diffusion effects are negligible at all times, the $c^*$'s are dimensionless concentrations, $R$ and $R'$ are dimensionless coordinates in $r$-direction for the inner and outer functions respectively, while $M$ is defined as $L$ except it is a radial distance from the center of the electrode. The symbols $T'$ and $\alpha$ denote the dimensionless simulation time and rate constant respectively.

Thus, we get the dimensionless differential equations:

[32] $$\frac{\partial c^*_{A1}}{\partial T'} = \beta \frac{\partial^2 c^*_{A1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{A1}}{\partial R} + \beta' \frac{\partial^2 c^*_{A1}}{\partial R^2}$$

[33] $$\frac{\partial c^*_{B1}}{\partial T'} = \beta \frac{\partial^2 c^*_{B1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{B1}}{\partial R} + \beta' \frac{\partial^2 c^*_{B1}}{\partial R^2} - \alpha c^*_{B1}$$

[34] $$\frac{\partial c^*_{C1}}{\partial T'} = \beta \frac{\partial^2 c^*_{C1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{C1}}{\partial R} + \beta' \frac{\partial^2 c^*_{C1}}{\partial R^2} + \alpha c^*_{B1}$$

[35] $$\frac{\partial c^*_{A2}}{\partial T'} = \beta \frac{\partial^2 c^*_{A2}}{\partial X^2} + \frac{\sqrt{\beta'}\,\beta''}{\sqrt{\beta''} + \sqrt{\beta'}R'}\frac{\partial c^*_{A2}}{\partial R'} + \beta'' \frac{\partial^2 c^*_{A2}}{\partial R'^2}$$

[36] $$\frac{\partial c^*_{B2}}{\partial T'} = \beta \frac{\partial^2 c^*_{B2}}{\partial X^2} + \frac{\sqrt{\beta'}\,\beta''}{\sqrt{\beta''} + \sqrt{\beta'}R'}\frac{\partial c^*_{B2}}{\partial R'} + \beta'' \frac{\partial^2 c^*_{B2}}{\partial R'^2} - \alpha c^*_{B2}$$

[37] $$\frac{\partial c^*_{C2}}{\partial T'} = \beta \frac{\partial^2 c^*_{C2}}{\partial X^2} + \frac{\sqrt{\beta'}\,\beta''}{\sqrt{\beta''} + \sqrt{\beta'}R'}\frac{\partial c^*_{C2}}{\partial R'} + \beta'' \frac{\partial^2 c^*_{C2}}{\partial R'^2} + \alpha c^*_{B2}$$

where $\beta$ is given by

[38] $\beta = D/aL^2$

$\beta'$ contains only experimental parameters

[39] $\beta' = D/ar_0^2$

and

[40] $\beta'' = D/a(M - r_0)^2$

As in the case of the chronoamperometric simulations (1) we have two dimensionless parameters, here $\beta$ and $\beta''$. The parameter $\beta'$ is given by experimental parameters and thus the simulations will depend on $\beta'$ as, e.g., on $\alpha$.

The transformed initial and boundary conditions are given by

$T' = 0,\ 0 \leq X \leq 1,\ 0 \leq R \leq 1,\ 0 \leq R' \leq 1$:

[41] $c^*_{A1}(X,R,0) = c^*_{A2}(X,R',0) = 1$

[42] $c^*_{B1}(X,R,0) = c^*_{B2}(X,R',0) = c^*_{C1}(X,R,0) = c^*_{C2}(X,R',0) = 0$

$T' > 0,\ X = 1,\ 0 \leq R \leq 1$:

[43] $c^*_{A1}(1,R,T') = 1$

[44] $c^*_{B1}(1,R,T') = c^*_{C1}(1,R,T') = 0$

$T' > 0,\ X = 1,\ 0 \leq R' \leq 1$:

[45] $c^*_{A2}(1,R',T') = 1$

[46] $c^*_{B2}(1,R',T') = c^*_{C2}(1,R',T') = 0$

$T' > 0$, $0 \leq X \leq 1$, $R' = 1$:

[47] $c^*_{A2}(X,1,T') = 1$

[48] $c^*_{B2}(X,1,T') = c^*_{C2}(X,1,T') = 0$

$T' > 0$, $X = 0$, $0 \leq R \leq 1$:

[49] $$\left(\frac{\partial c^*_{A1}}{\partial X}\right)_{X=0} = -\left(\frac{\partial c^*_{B1}}{\partial X}\right)_{X=0}$$

[50] $$\frac{c^*_{B1}(0,R,T')}{c^*_{A1}(0,R,T')} = \theta_{A/B} S_\lambda(T')$$

with

[51] $$S_\lambda(T') = \begin{cases} \exp\,[2(m-1)T'_\lambda - T'] \\ \exp\,[T' - 2mT'_\lambda] \end{cases} \qquad m = 1,2,\ldots$$

where

[52] $T'_\lambda = at_\lambda$

[53] $$\left(\frac{\partial c^*_{C1}}{\partial X}\right)_{X=0} = 0$$

$T' > 0$, $X = 0$, $0 < R' \leq 1$:

[54] $$\left(\frac{\partial c^*_{A2}}{\partial X}\right)_{X=0} = \left(\frac{\partial c^*_{B2}}{\partial X}\right)_{X=0} = \left(\frac{\partial c^*_{C2}}{\partial X}\right)_{X=0} = 0$$

$T' > 0$, $0 \leq X \leq 1$, $R = 0$:

[55] $$\left(\frac{\partial c^*_{A1}}{\partial R}\right)_{R=0} = \left(\frac{\partial c^*_{B1}}{\partial R}\right)_{R=0} = \left(\frac{\partial c^*_{C1}}{\partial R}\right)_{R=0} = 0$$

$T' > 0$, $0 \leq X \leq 1$, $R = 1$ ($R' = 0$):

[56] $c^*_{A1}(X,1,T') = c^*_{A2}(X,0,T')$

[57] $c^*_{B1}(X,1,T') = c^*_{B2}(X,0,T')$

[58] $c^*_{C1}(X,1,T') = c^*_{C2}(X,0,T')$

[59] $$\left(\frac{\partial c^*_{A1}}{\partial R}\right)_{R=1} = \sqrt{\frac{\beta''}{\beta'}}\left(\frac{\partial c^*_{A2}}{\partial R'}\right)_{R'=0}$$

[60] $$\left(\frac{\partial c^*_{B1}}{\partial R}\right)_{R=1} = \sqrt{\frac{\beta''}{\beta'}}\left(\frac{\partial c^*_{B2}}{\partial R'}\right)_{R'=0}$$

[61] $$\left(\frac{\partial c^*_{C1}}{\partial R}\right)_{R=1} = \sqrt{\frac{\beta''}{\beta'}}\left(\frac{\partial c^*_{C2}}{\partial R'}\right)_{R'=0}$$

## Application of two-dimensional collocation

As in the case of chronoamperometry (1), we have to solve the system of second order partial differential equations [32]–[37] under the conditions [41]–[61] to get the dimensionless concentrations of species A, B, and C as functions of $X$, $R$ ($R'$), and $T'$. We use the two-dimensional collocation method outlined in part 1 of this series (1) to discretize eqs. [32]–[37] with respect to the grid of collocation points $(X_i, R_k)$ in the $X/R$-space.

We have shown (1) that the first and second derivatives of the concentration with respect to $x$ and $r$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

respectively at a collocation point $(x_i, r_k)$ may be expressed as

$$[62] \quad \left(\frac{\partial c}{\partial x}\right)_{x_i,r_k} = \sum_{j=1}^{N_x+2} A_{i,j}c(x_j,r_k,t)$$

$$[63] \quad \left(\frac{\partial^2 c}{\partial x^2}\right)_{x_i,r_k} = \sum_{j=1}^{N_x+2} B_{i,j}c(x_j,r_k,t)$$

$$[64] \quad \left(\frac{\partial c}{\partial r}\right)_{x_i,r_k} = \sum_{l=1}^{N_r+2} C_{l,k}c(x_i,r_l,t)$$

$$[65] \quad \left(\frac{\partial^2 c}{\partial r^2}\right)_{x_i,r_k} = \sum_{l=1}^{N_r+2} D_{l,k}c(x_i,r_l,t)$$

where $N_x$ and $N_r$ are the numbers of interior collocation points (chosen as the roots of an orthogonal polynomial (9)) in the $x$- and $r$-direction, respectively, and $A_{i,j}$, $B_{i,j}$, $C_{l,k}$, and $D_{l,k}$ are elements of matrices. The numerical values of those elements depend only on the degree and kind of the polynomial chosen for collocation (10). Thus, if the matrix elements have once been calculated they may be used for any problem. The degree of the polynomial used depends on the desired accuracy of the simulation.

Using eqs. [62]–[65] we may discretize the partial differential equations [32]–[37] in terms of the concentrations at the collocation points. If we introduce the boundary conditions [43]–[48] we arrive at eqs. [66]–[71].

$$[66] \quad \left.\frac{dc^*_{A1}}{dT'}\right|_{X_i,R_k} = \beta\left\{B_{i,1}c^*_{A1}(0,R_k,T') + B_{i,N_x+2} + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{A1}(X_j,R_k,T')\right\} + \beta'\left\{E_{1,k}c^*_{A1}(X_i,0,T') + E_{N_R+2,k}c^*_{A1}(X_i,1,T') + \sum_{l=2}^{N_R+1} E_{l,k}c^*_{A1}(X_i,R_l,T')\right\}$$

$$[67] \quad \left.\frac{dc^*_{B1}}{dT'}\right|_{X_i,R_k} = \beta\left\{B_{i,1}c^*_{B1}(0,R_k,T') + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{B1}(X_j,R_k,T')\right\} + \beta'\left\{E_{1,k}c^*_{B1}(X_i,0,T') + E_{N_R+2,k}c^*_{B1}(X_i,1,T') + \sum_{l=2}^{N_R+1} E_{l,k}c^*_{B1}(X_i,R_l,T')\right\} - \alpha c^*_{B1}$$

$$[68] \quad \left.\frac{dc^*_{C1}}{dT'}\right|_{X_i,R_k} = \beta\left\{B_{i,1}c^*_{C1}(0,R_k,T') + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{C1}(X_j,R_k,T')\right\} + \beta'\left\{E_{1,k}c^*_{C1}(X_i,0,T') + E_{N_R+2,k}c^*_{C1}(X_i,1,T') + \sum_{l=2}^{N_R+1} E_{l,k}c^*_{C1}(X_i,R_l,T')\right\} + \alpha c^*_{B1}$$

$$[69] \quad \left.\frac{dc^*_{A2}}{dT'}\right|_{X_i,R_k} = \beta\left\{B_{i,1}c^*_{A2}(0,R'_k,T') + B_{i,N_{R'}+2} + \sum_{j=2}^{N_{R'}+1} B_{i,j}c^*_{A2}(X_j,R'_k,T')\right\} + \beta''\left\{F'_{1,k}c^*_{A2}(X_i,0,T') + F'_{N_{R'}+2,k} + \sum_{l=2}^{N_{R'}+1} F'_{l,k}c^*_{A2}(X_i,R'_l,T')\right\}$$

$$[70] \quad \left.\frac{dc^*_{B2}}{dT'}\right|_{X_i,R_k} = \beta\left\{B_{i,1}c^*_{B2}(0,R'_k,T') + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{B2}(X_j,R'_k,T')\right\} + \beta''\left\{F'_{1,k}c^*_{B2}(X_i,0,T') + \sum_{l=2}^{N_{R'}+1} F'_{l,k}c^*_{B2}(X_i,R'_l,T')\right\} - \alpha c^*_{B2}$$

$$[71] \quad \left.\frac{dc^*_{C2}}{dT'}\right|_{X_i,R_k} = \beta\left\{B_{i,1}c^*_{C2}(0,R'_k,T') + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{C2}(X_j,R'_k,T')\right\} + \beta''\left\{F'_{1,k}c^*_{C2}(X_i,0,T') + \sum_{l=2}^{N_{R'}+1} F'_{l,k}c^*_{C2}(X_i,R'_l,T')\right\} + \alpha c^*_{B2}$$

with

$$[72] \qquad E_{l,k} = \frac{C_{l,k} + R_k D_{l,k}}{R_k}$$

and

$$[73] \qquad F'_{l,k} = \frac{\sqrt{\beta'}}{\sqrt{\beta''} + \sqrt{\beta'}\, R'_k}\, C'_{l,k} + D'_{l,k}$$

Primed matrix elements correspond to the outer discretization function. As in the case of chronoamperometry we have to substitute implicit equations for the unknown concentrations at the boundaries. The calculation of the $c^*_1(X_i,0,T')$, $c^*_1(X_i,1,T')$, $c^*_2(X_i,0,T')$, $c^*_1(0,R_k,T')$, and $c^*_2(0,R'_k,T')$ is essentially the same as for chronoamperometric simulations and we refer to part 1 of this series (1) for the derivations. They are (1):

$$[74] \qquad c^*_{A1}(X_i,0,T') = -\frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1} G_l c^*_{A1}(X_i,R_l,T') + \sum_{l=2}^{N_{R'}+1} C_{N_R+2,1} C'_{l,1} c^*_{A2}(X_i,R'_l,T') + C_{N_R+2,1} C'_{N_R+2,1}\right\}$$

$$[75] \qquad c^*_{B1}(X_i,0,T') = -\frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1} G_l c^*_{B1}(X_i,R_l,T') + \sum_{l=2}^{N_{R'}+1} C_{N_R+2,1} C'_{l,1} c^*_{B2}(X_i,R'_l,T')\right\}$$

$$[76] \qquad c^*_{C1}(X_i,0,T') = -\frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1} G_l c^*_{C1}(X_i,R_l,T') + \sum_{l=2}^{N_{R'}+1} C_{N_R+2,1} C_{l,1} c^*_{C2}(X_i,R'_l,T')\right\}$$

$$[77] \qquad c^*_{A1}(X_i,1,T') = c^*_{A2}(X_i,0,T') = \frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1} H_l c^*_{A1}(X_i,R_l,T') + \sum_{l=2}^{N_{R'}+1} C_{1,1} C'_{l,1} c^*_{A2}(X_i,R'_l,T') + C_{1,1} C'_{N_R+2,1}\right\}$$

$$[78] \qquad c^*_{B1}(X_i,1,T') = c^*_{B2}(X_i,0,T') = \frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1} H_l c^*_{B1}(X_i,R_l,T') + \sum_{l=2}^{N_{R'}+1} C_{1,1} C'_{l,1} c^*_{B2}(X_i,R'_l,T')\right\}$$

$$[79] \qquad c^*_{C1}(X_i,1,T') = c^*_{C2}(X_i,0,T') = \frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1} H_l c^*_{C1}(X_i,R_l,T') + \sum_{l=2}^{N_{R'}+1} C_{1,1} C'_{l,1} c^*_{C2}(X_i,R'_l,T')\right\}$$

$$[80] \qquad c^*_{C1}(0,R_k,T') = -\frac{1}{A_{1,1}} \sum_{j=2}^{N_x+1} A_{1,j} c^*_{C1}(X_j,R_k,T')$$

$$[81] \qquad c^*_{A2}(0,R'_k,T') = -\frac{1}{A_{1,1}}\left\{A_{1,N_x+2} + \sum_{j=2}^{N_x+1} A_{1,j} c^*_{A2}(X_j,R'_k,T')\right\}$$

$$[82] \qquad c^*_{B2}(0,R'_k,T') = -\frac{1}{A_{1,1}} \sum_{j=2}^{N_x+1} A_{1,j} c^*_{B2}(X_j,R'_k,T')$$

$$[83] \qquad c^*_{C2}(0,R'_k,T') = -\frac{1}{A_{1,1}} \sum_{j=2}^{N_x+1} A_{1,j} c^*_{C2}(X_j,R'_k,T')$$

with

$$[84] \qquad G_l = (C_{N_R+2,N_R+2} - C'_{1,1}) C_{l,1} - C_{l,N_R+2} C_{N_R+2,1}$$

and

$$[85] \qquad H_l = C_{1,N_R+2} C_{l,1} - C_{1,1} C_{l,N_R+2}$$

The values of $c^*_{A1}(0,R_k,T')$ and $c^*_{B1}(0,R_k,T')$ may be calculated from eqs. [49] and [50], yielding

$$[86]\qquad c^*_{A1}(0,R_k,T') = -\frac{\theta_{A/B}S_\lambda(T')}{A_{1,1}[1+\theta_{A/B}S_\lambda(T')]}\left\{A_{1,N_x+2}+\sum_{j=2}^{N_x+1}A_{1,j}[c^*_{A1}(X_j,R_k,T')+c^*_{B1}(X_j,R_k,T')]\right\}$$

and

$$[87]\qquad c^*_{B1}(0,R_k,T') = -\frac{1}{A_{1,1}[1+\theta_{A/B}S_\lambda(T')]}\left\{A_{1,N_x+2}+\sum_{j=2}^{N_x+1}A_{1,j}[c^*_{A1}(X_j,R_k,T')+c^*_{B1}(X_j,R_k,T')]\right\}$$

Now we may substitute [74]–[87] into eqs. [66]–[71] which gives us finally the discretized equations describing the time dependence of the concentration of all three species A, B, and C at the collocation points.

From [66] it follows, using [74], [77], and [86],

$$[88]\qquad \left.\frac{dc^*_{A1}}{dT'}\right|_{X_i,R_k} = \beta\left\{-\frac{B_{i,1}\theta_{A/B}S_\lambda(T')}{A_{1,1}[1+\theta_{A/B}S_\lambda(T')]}\left[A_{1,N_x+2}+\sum_{j=2}^{N_x+1}A_{1,j}[c^*_{A1}(X_j,R_k,T')+c^*_{B1}(X_j,R_k,T')]\right]+B_{i,N_x+2}+\sum_{j=2}^{N_x+1}B_{i,j}c^*_{A1}(X_j,R_k,T')\right.$$
$$\left.+\frac{\beta'}{G_1}\left\{I_{1,k}C'_{N_R+2,1}+\sum_{l=2}^{N_R+1}[J_{l,k}(C'_{1,1}-C_{N_R+2,N_R+2})-I_{1,k}C_{l,N_R+2}-I_{l,k}C_{1,N_R+2}]c^*_{A1}(X_i,R_l,T')+\sum_{l=2}^{N_{R'}+1}I_{1,k}C'_{l,1}c^*_{A2}(X_i,R'_l,T')\right\}\right.$$

where

$$[89]\qquad I_{l,k} = E_{N_R+2,k}C_{l,1} - E_{l,k}C_{N_R+2,1}$$

and

$$[90]\qquad J_{l,k} = E_{1,k}C_{l,1} - E_{l,k}C_{1,1}$$

If we combine [67] with [75], [78], and [87], we get

$$[91]\qquad \left.\frac{dc^*_{B1}}{dT'}\right|_{X_i,R_k} = \beta\left\{-\frac{B_{i,1}}{A_{1,1}[1+\theta_{A/B}S_\lambda(T')]}\left[A_{1,N_x+2}+\sum_{j=2}^{N_x+1}A_{1,j}[c^*_{A1}(X_j,R_k,T')+c^*_{B1}(X_j,R_k,T')]\right]\right.$$
$$\left.+\sum_{j=2}^{N_x+1}B_{i,j}c^*_{B1}(X_j,R_k,T')\right\}+\frac{\beta'}{G_1}\left\{\sum_{l=2}^{N_R+1}[J_{l,k}(C'_{1,1}-C_{N_R+2,N_R+2})-I_{1,k}C_{l,N_R+2}\right.$$
$$\left.-I_{l,k}C_{1,N_R+2}]c^*_{B1}(X_i,R_l,T')+\sum_{l=2}^{N_{R'}+1}I_{1,k}C'_{l,1}c^*_{B2}(X_i,R'_l,T')\right\}-\alpha c^*_{B1}$$

similarly [68] gives, with [76], [79], and [80],

$$[92]\qquad \left.\frac{dc^*_{C1}}{dT'}\right|_{X_i,R_k} = \frac{\beta}{A_{1,1}}\sum_{j=2}^{N_x+1}K_{i,j}c^*_{C1}(X_j,R_k,T')$$
$$+\frac{\beta'}{G_1}\left\{\sum_{l=2}^{N_R+1}[J_{l,k}(C'_{1,1}-C_{N_R+2,N_R+2})-I_{1,k}C_{l,N_R+2}-I_{l,k}C_{1,N_R+2}]c^*_{C1}(X_i,R_l,T')\right.$$
$$\left.+\sum_{l=2}^{N_{R'}+1}I_{1,k}C'_{l,1}c^*_{C2}(X_i,R'_l,T')\right\}+\alpha c^*_{B1}$$

For the outer function describing the concentration of species A it holds from [69], [77], and [81]

$$[93]\qquad \left.\frac{dc^*_{A2}}{dT'}\right|_{X_i,R'_k} = \frac{\beta}{A_{1,1}}\left\{K_{i,N_x+2}+\sum_{j=2}^{N_x+1}K_{i,j}c^*_{A2}(X_j,R'_k,T')\right\}$$
$$+\frac{\beta''}{G_1}\left\{L'_{N_{R'}+2,k}+\sum_{l=2}^{N_R+1}F'_{1,k}H_l c^*_{A1}(X_i,R_l,T')+\sum_{l=2}^{N_{R'}+1}L'_{l,k}c^*_{A2}(X_i,R'_l,T')\right\}$$

Equations [70], [78], and [82] combine to give

$$[94]\quad \left.\frac{dc^*_{B2}}{dT'}\right|_{X_i,R'_k} = \frac{\beta}{A_{1,1}}\sum_{j=2}^{N_x+1} K_{i,j}c^*_{B2}(X_j,R'_k,T') + \frac{\beta''}{G_1}\left\{\sum_{l=2}^{N_R+1} F'_{1,k}H_l c^*_{B1}(X_i,R_l,T') + \sum_{l=2}^{N_{R'}+1} L'_{l,k}c^*_{B2}(X_i,R'_l,T')\right\} - \alpha c^*_{B2}$$

Finally [71], [79], and [83] yield

$$[95]\quad \left.\frac{dc^*_{C2}}{dT'}\right|_{X_i,R'_k} = \frac{\beta}{A_{1,1}}\sum_{j=2}^{N_x+1} K_{i,j}c^*_{C2}(X_j,R'_k,T') + \frac{\beta''}{G_1}\left\{\sum_{l=2}^{N_R+1} F'_{1,k}H_l c^*_{C1}(X_i,R_l,T') + \sum_{l=2}^{N_{R'}+1} L'_{l,k}c^*_{C2}(X_i,R'_l,T')\right\} + \alpha c^*_{B2}$$

where we used

$$[96]\quad K_{i,j} = B_{i,j}A_{1,1} - B_{i,1}A_{1,j}$$

and

$$[97]\quad L'_{l,k} = F'_{l,k}G_1 + C_{1,1}C'_{l,1}F'_{1,k}$$

Thus, the system of six second order partial differential equations [32]–[37] has been converted into a set of $3N_x(N_R + N_{R'})$ simultaneous ordinary differential equations, [88] and [91]–[95]. After integrating this set we get the concentrations of species A, B, and C at the collocation points $(X_i,R_k)$ and $(X_i,R'_k)$ as a function of the simulation time $T'$.

One of the distinctive features of the orthogonal collocation approach can be seen from a comparison of eqs. [88] and [91]–[95]. Those formulae are very similar from a structural point of view. Furthermore, compared to the expressions describing the model of a chronoamperometric experiment (1), there are only few changes in the inner functions, while the outer functions are the same both for the models of cyclic voltammetry and chronoamperometry.

### Calculation of the current

Also, the calculation of the current is fully analogous to that performed for the chronoamperometric model. Again we have to integrate the flux over the part between 0 and $r_0$ on the $r$-axis

$$[98]\quad i = nFD\int_0^{r_0} 2\pi r\left(\frac{\partial c_A}{\partial x}\right)_{x=0} dr$$

Transforming the right hand side of eq. [98] into a dimensionless form we get

$$[99]\quad i = nFAc^0_A\sqrt{Da\pi}\sqrt{\frac{\beta}{\pi}}\,2\int_0^1 R\left(\frac{\partial c^*_{A1}}{\partial X}\right)_{X=0} dR$$

or, using Nicholson and Shain's current function (6),

$$[100]\quad \chi = \frac{i}{nFAc^0_A\sqrt{Da\pi}} = 2\sqrt{\frac{\beta}{\pi}}\int_0^1 R\left(\frac{\partial c^*_{A1}}{\partial X}\right)_{X=0} dR$$

The integration may be performed exactly by a quadrature method (ref. 9, p. 134), for we know the derivative $(\partial c^*_{A1}/\partial X)_{X=0}$ at all collocation points:

$$[101]\quad \chi = 2\sqrt{\frac{\beta}{\pi}}\sum_{l=1}^{N_R+2} Q_l R_l \frac{1}{1+\theta_{A/B}S_\lambda(T')} \times\left[A_{1,N_x+2} + \sum_{j=2}^{N_x+1} A_{1,j}c^*_{A1}(X_j,R_l,T') - \theta_{A/B}S_\lambda(T')\sum_{j=2}^{N_x+1} A_{1,j}c^*_{B1}(X_j,R_l,T')\right]$$

where the elements of the vector $\boldsymbol{Q}$ depend only on the degree and kind of the trial function in $r$-direction.

### Model mechanism for oxidation of I

It has been shown (11, 12) that the oxidation of **I** (denoted as A) may be described by an ECE-type mechanism, where protons released after the oxidation step are picked up by unoxidized phenol molecules giving the protonated form of **I**, $HA^{\oplus}$. The latter is oxidized at more positive potentials releasing two protons during reaction. The end product of both reactions is the stable phenoxenium cation, E, which is most probably formed from the neutral phenoxy radical, C, in a homogeneous redox reaction between C and the primary radical cation B (12). The intermediate D was not characterized further. The observation of changes in voltammograms of **I** with electrode size has been attributed to the protonation reaction $A \rightarrow HA^{\oplus}$ which causes a phenol-free layer in front of the electrode (5). The time after which phenol again reaches the electrode surface is decreased if more substrate diffuses into this layer due to edge effects.

$$A \underset{+e^{\ominus}}{\overset{-e^{\ominus}}{\rightleftharpoons}} B \qquad E^0_{A/B},\ n_1 = 1$$

$$B \longrightarrow H^{\oplus} + C \qquad k_1$$

$$H^{\oplus} + A \longrightarrow HA^{\oplus} \qquad k_2$$

$$HA^{\oplus} \underset{+e^{\ominus}}{\overset{-e^{\ominus}}{\rightleftharpoons}} D \qquad E^0_{HA^{\oplus}/D},\ n_2 = 1$$

$$D \longrightarrow 2H^{\oplus} + C \qquad k_3$$

$$B + C \rightleftharpoons A + E \qquad K_4 \gg 1,\ k_4/k_{-4} = K_4$$

$$C \underset{+e^{\ominus}}{\overset{-e^{\ominus}}{\rightleftharpoons}} E \qquad E^0_{C/E},\ n_3 = 1$$

With our two-dimensional simulation model it is now possible to include the effects of a finite disc into the calculations. This may also serve as a further example for the application of orthogonal collocation to electroanalytical problems. In this paper we show the derivation of the expressions for $dc^*/dT'$ for the species involved, while the comparison with experimental results will be reported in part 4 of this series.

The kinetic diffusion equations for the above model mechanism in dimensionless form are

[102] $$\frac{\partial c^*_{A1}}{\partial T'} = \beta \frac{\partial^2 c^*_{A1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{A1}}{\partial R} + \beta' \frac{\partial^2 c^*_{A1}}{\partial R^2} - \alpha_2 c^*_{H^{\oplus}1} c^*_{A1} - \alpha_{-4} c^*_{A1} c^*_{E1} + \alpha_4 c^*_{B1} c^*_{C1}$$

[103] $$\frac{\partial c^*_{B1}}{\partial T'} = \beta \frac{\partial^2 c^*_{B1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{B1}}{\partial R} + \beta' \frac{\partial^2 c^*_{B1}}{\partial R^2} - \alpha_1 c^*_{B1} - \alpha_4 c^*_{B1} c^*_{C1} + \alpha_{-4} c^*_{A1} c^*_{E1}$$

[104] $$\frac{\partial c^*_{C1}}{\partial T'} = \beta \frac{\partial^2 c^*_{C1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{C1}}{\partial R} + \beta' \frac{\partial^2 c^*_{C1}}{\partial R^2} + \alpha_1 c^*_{B1} + \alpha_3 c^*_{D1} - \alpha_4 c^*_{B1} c^*_{C1} + \alpha_{-4} c^*_{A1} c^*_{E1}$$

[105] $$\frac{\partial c^*_{H^{\oplus}1}}{\partial T'} = \beta \frac{\partial^2 c^*_{H^{\oplus}1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{H^{\oplus}1}}{\partial R} + \beta' \frac{\partial^2 c^*_{H^{\oplus}1}}{\partial R^2} + \alpha_1 c^*_{B1} + 2\alpha_3 c^*_{D1} - \alpha_2 c^*_{A1} c^*_{H^{\oplus}1}$$

[106] $$\frac{\partial c^*_{HA^{\oplus}1}}{\partial T'} = \beta \frac{\partial^2 c^*_{HA^{\oplus}1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{HA^{\oplus}1}}{\partial R} + \beta' \frac{\partial^2 c^*_{HA^{\oplus}1}}{\partial R^2} + \alpha_2 c^*_{A1} c^*_{H^{\oplus}1}$$

[107] $$\frac{\partial c^*_{D1}}{\partial T'} = \beta \frac{\partial^2 c^*_{D1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{D1}}{\partial R} + \beta' \frac{\partial^2 c^*_{D1}}{\partial R^2} - \alpha_3 c^*_{D1}$$

[108] $$\frac{\partial c^*_{E1}}{\partial T'} = \beta \frac{\partial^2 c^*_{E1}}{\partial X^2} + \frac{\beta'}{R}\frac{\partial c^*_{E1}}{\partial R} + \beta' \frac{\partial^2 c^*_{E1}}{\partial R^2} + \alpha_4 c^*_{B1} c^*_{C1} - \alpha_{-4} c^*_{A1} c^*_{E1}$$

[109] $$\frac{\partial c^*_{A2}}{\partial T'} = \beta \frac{\partial^2 c^*_{A2}}{\partial X^2} + \frac{\beta'' \sqrt{\beta'}}{\sqrt{\beta''} + \sqrt{\beta' R'}}\frac{\partial c^*_{A2}}{\partial R'} + \beta'' \frac{\partial^2 c^*_{A2}}{\partial R'^2} - \alpha_2 c^*_{H^{\oplus}2} c^*_{A2} - \alpha_{-4} c^*_{A2} c^*_{E2} + \alpha_4 c^*_{B2} c^*_{C2}$$

[110] $$\frac{\partial c^*_{B2}}{\partial T'} = \beta \frac{\partial^2 c^*_{B2}}{\partial X^2} + \frac{\beta'' \sqrt{\beta'}}{\sqrt{\beta''} + \sqrt{\beta' R'}}\frac{\partial c^*_{B2}}{\partial R'} + \beta'' \frac{\partial^2 c^*_{B2}}{\partial R'^2} - \alpha_1 c^*_{B2} - \alpha_4 c^*_{B2} c^*_{C2} + \alpha_{-4} c^*_{A2} c^*_{E2}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

[111] $$\frac{\partial c^*_{C2}}{\partial T'} = \beta \frac{\partial^2 c^*_{C2}}{\partial X^2} + \frac{\beta'' \sqrt{\beta'}}{\sqrt{\beta''} + \sqrt{\beta'} R'} \frac{\partial c^*_{C2}}{\partial R'} + \beta'' \frac{\partial^2 c^*_{C2}}{\partial R'^2} + \alpha_1 c^*_{B2} + \alpha_3 c^*_{D2} - \alpha_4 c^*_{B2} c^*_{C2} + \alpha_{-4} c^*_{A2} c^*_{E2}$$

[112] $$\frac{\partial c^*_{H\oplus_2}}{\partial T'} = \beta \frac{\partial^2 c^*_{H\oplus_2}}{\partial X^2} + \frac{\beta'' \sqrt{\beta'}}{\sqrt{\beta''} + \sqrt{\beta'} R'} \frac{\partial c^*_{H\oplus_2}}{\partial R'} + \beta'' \frac{\partial^2 c^*_{H\oplus_2}}{\partial R'^2} + \alpha_1 c^*_{B2} + 2\alpha_3 c^*_{D2} - \alpha_2 c^*_{A2} c^*_{H\oplus_2}$$

[113] $$\frac{\partial c^*_{HA\oplus_2}}{\partial T'} = \beta \frac{\partial^2 c^*_{HA\oplus_2}}{\partial X^2} + \frac{\beta'' \sqrt{\beta'}}{\sqrt{\beta''} + \sqrt{\beta'} R'} \frac{\partial c^*_{HA\oplus_2}}{\partial R'} + \beta'' \frac{\partial^2 c^*_{HA\oplus_2}}{\partial R'^2} + \alpha_2 c^*_{A2} c^*_{H\oplus_2}$$

[114] $$\frac{\partial c^*_{D2}}{\partial T'} = \beta \frac{\partial^2 c^*_{D2}}{\partial X^2} + \frac{\beta'' \sqrt{\beta'}}{\sqrt{\beta''} + \sqrt{\beta'} R'} \frac{\partial c^*_{D2}}{\partial R'} + \beta'' \frac{\partial^2 c^*_{D2}}{\partial R'^2} - \alpha_3 c^*_{D2}$$

[115] $$\frac{\partial c^*_{E2}}{\partial T'} = \beta \frac{\partial^2 c^*_{E2}}{\partial X^2} + \frac{\beta'' \sqrt{\beta'}}{\sqrt{\beta''} + \sqrt{\beta'} R'} \frac{\partial c^*_{E2}}{\partial R'} + \beta'' \frac{\partial^2 c^*_{E2}}{\partial R'^2} + \alpha_4 c^*_{B2} c^*_{C2} - \alpha_{-4} c^*_{A2} c^*_{E2}$$

where

[116] $$\alpha_j = k_j/a, \qquad j = 1, 3$$

[117] $$\alpha_2 = k_2 c^0_A/a$$

and

[118*a*] $$\alpha_4 = k_4 c^0_A/a$$

[118*b*] $$\alpha_{-4} = k_{-4} c^0_A/a$$

In addition to the initial conditions [41] and [42] we assume

$T' = 0, 0 \leq X \leq 1, 0 \leq R \leq 1, 0 \leq R' \leq 1$:

[119] $$c^*_{H\oplus_1}(X,R,0) = c^*_{H\oplus_2}(X,R',0) = c^*_{HA\oplus_1}(X,R,0) = c^*_{HA\oplus_2}(X,R',0) = c^*_{D1}(X,R,0) = c^*_{D2}(X,R',0) = c^*_{E1}(X,R,0) = c^*_{E2}(X,R',0) = 0$$

The boundary conditions now include

$T' > 0, X = 1, 0 \leq R \leq 1$:

[120] $$c^*_{H\oplus_1}(1,R,T') = c^*_{HA\oplus_1}(1,R,T') = c^*_{D1}(1,R,T') = c^*_{E1}(1,R,T') = 0$$

$T' > 0, X = 1, 0 \leq R' \leq 1$:

[121] $$c^*_{H\oplus_2}(1,R',T') = c^*_{HA\oplus_2}(1,R',T') = c^*_{D2}(1,R',T') = c^*_{E2}(1,R',T') = 0$$

$T' > 0, 0 \leq X \leq 1, R' = 1$:

[122] $$c^*_{H\oplus_2}(X,1,T') = c^*_{HA\oplus_2}(X,1,T') = c^*_{D2}(X,1,T') = c^*_{E2}(X,1,T') = 0$$

$T' > 0, X = 0, 0 \leq R \leq 1$:

[123] $$\left(\frac{\partial c^*_{HA\oplus_1}}{\partial X}\right)_{X=0} = -\left(\frac{\partial c^*_{D1}}{\partial X}\right)_{X=0}$$

[124] $$\frac{c^*_{HA\oplus_1}(0,R,T')}{c^*_{D1}(0,R,T')} = \theta_{HA\oplus/D} S_\lambda(T')$$

(where $\theta_{HA\oplus/D}$ is defined in analogy to $\theta_{A/B}$)

[125] $$\left(\frac{\partial c^*_{H\oplus_1}}{\partial X}\right)_{X=0} = 0$$

[126] $$\left(\frac{\partial c^*_{C1}}{\partial X}\right)_{X=0} = -\left(\frac{\partial c^*_{E1}}{\partial X}\right)_{X=0}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

[127] $$\frac{c^*_{C1}(0,R,T')}{c^*_{E1}(0,R,T')} = \theta_{C/E}S_\lambda(T')$$

$T' > 0$, $X = 0$, $0 < R' \leq 1$:

[128] $$\left(\frac{\partial c^*_{H\oplus 2}}{\partial X}\right)_{X=0} = \left(\frac{\partial c^*_{HA\oplus 2}}{\partial X}\right)_{X=0} = \left(\frac{\partial c^*_{D2}}{\partial X}\right)_{X=0} = \left(\frac{\partial c^*_{E2}}{\partial X}\right)_{X=0} = 0$$

$T' > 0$, $X \geq 0$, $R = 1$ ($R' = 0$):

[129] $$c^*_{H\oplus 2}(X,0,T') = c^*_{H\oplus 1}(X,1,T')$$

[130] $$c^*_{HA\oplus 2}(X,0,T') = c^*_{HA\oplus 1}(X,1,T')$$

[131] $$c^*_{D2}(X,0,T') = c^*_{D1}(X,1,T')$$

[132] $$c^*_{E2}(X,0,T') = c^*_{E1}(X,1,T')$$

[133] $$\left(\frac{\partial c^*_{H\oplus 1}}{\partial R}\right)_{R=1} = \sqrt{\frac{\beta''}{\beta'}}\left(\frac{\partial c^*_{H\oplus 2}}{\partial R'}\right)_{R'=0}$$

[134] $$\left(\frac{\partial c^*_{HA\oplus 1}}{\partial R}\right)_{R=1} = \sqrt{\frac{\beta''}{\beta'}}\left(\frac{\partial c^*_{HA\oplus 2}}{\partial R'}\right)_{R'=0}$$

[135] $$\left(\frac{\partial c^*_{D1}}{\partial R}\right)_{R=1} = \sqrt{\frac{\beta''}{\beta'}}\left(\frac{\partial c^*_{D2}}{\partial R'}\right)_{R'=0}$$

[136] $$\left(\frac{\partial c^*_{E1}}{\partial R}\right)_{R=1} = \sqrt{\frac{\beta''}{\beta'}}\left(\frac{\partial c^*_{E2}}{\partial R'}\right)_{R'=0}$$

$T' > 0$, $X \geq 0$, $R = 0$:

[137] $$\left(\frac{\partial c^*_{H\oplus 1}}{\partial R}\right)_{R=0} = \left(\frac{\partial c^*_{HA\oplus 1}}{\partial R}\right)_{R=0} = \left(\frac{\partial c^*_{D1}}{\partial R}\right)_{R=0} = \left(\frac{\partial c^*_{E1}}{\partial R}\right)_{R=0} = 0$$

Now, the set of equations [102]–[115] in connection with the initial conditions [41], [42], and [119] and the boundary conditions [43]–[50], [54]–[61], and [120]–[137] has to be solved.

After proceeding in the same manner as for the EC mechanism we arrive at

[138] $$\left.\frac{dc^*_{A1}}{dT'}\right|_{X_i,R_k} = \text{RHS [88]} - \alpha_2 c^*_{H\oplus 1}c^*_{A1} - \alpha_{-4}c^*_{A1}c^*_{E1} + \alpha_4 c^*_{B1}c^*_{C1}$$

[139] $$\left.\frac{dc^*_{B1}}{dT'}\right|_{X_i,R_k} = \{\text{RHS [91] without kinetic term}\} - \alpha_1 c^*_{B1} - \alpha_4 c^*_{B1}c^*_{C1} + \alpha_{-4}c^*_{A1}c^*_{E1}$$

[140] $$\left.\frac{dc^*_{C1}}{dT'}\right|_{X_i,R_k} = \beta\left\{-\frac{B_{i,1}\theta_{C/E}S_\lambda(T')}{A_{1,1}[1+\theta_{C/E}S_\lambda(T')]}\sum_{j=2}^{N_x+1}A_{1,j}[c^*_{C1}(X_j,R_k,T') + c^*_{E1}(X_j,R_k,T')] + \sum_{j=2}^{N_x+1}B_{i,j}c^*_{C1}(X_j,R_k,T')\right\} + \frac{\beta'}{G_1}\left\{\sum_{l=2}^{N_R+1}[J_{l,k}(C'_{1,1} - C_{N_R+2,N_R+2}) - I_{1,k}C_{l,N_R+2} - I_{l,k}C_{1,N_R+2}]c^*_{C1}(X_i,R_l,T') + \sum_{l=2}^{N_{R'}+1}I_{1,k}C'_{l,1}c^*_{C2}(X_i,R'_l,T')\right\} + \alpha_1 c^*_{B1} + \alpha_3 c^*_{D1} - \alpha_4 c^*_{B1}c^*_{C1} + \alpha_{-4}c^*_{A1}c^*_{E1}$$

[141] $$\left.\frac{dc^*_{H\oplus 1}}{dT'}\right|_{X_i,R_k} = \{\text{RHS [92] without kinetic term and } c^*_{H\oplus 1} \text{ substituted for } c^*_{C1}\} + \alpha_1 c^*_{B1} + 2\alpha_3 c^*_{D1} - \alpha_2 c^*_{A1}c^*_{H\oplus 1}$$

[142] $$\left.\frac{dc^*_{HA\oplus_1}}{dT'}\right|_{X_i,R_k} = \{\text{RHS [140] without kinetic terms and } c^*_{HA\oplus_1} \text{ substituted for } c^*_{C1},\ c^*_{D1} \text{ substituted for } c^*_E \text{ and } \theta_{HA\oplus/D} \text{ substituted for } \theta_{C/E}\} + \alpha_2 c^*_{A1} c^*_{H\oplus_1}$$

[143] $$\left.\frac{dc^*_{D1}}{dT'}\right|_{X_i,R_k} = \{\text{RHS [91] without kinetic term and } c^*_{D1} \text{ substituted for } c^*_{B1},\ c^*_{HA\oplus_1} \text{ substituted for } c^*_A \text{ and } \theta_{HA\oplus/D} \text{ substituted for } \theta_{A/B}\} - \alpha_3 c^*_{D1}$$

[144] $$\left.\frac{dc^*_{E1}}{dT'}\right|_{X_i,R_k} = \{\text{RHS [91] without kinetic term and } c^*_{E1} \text{ substituted for } c^*_{B1},\ c^*_{C1} \text{ substituted for } c^*_{A1} \text{ and } \theta_{C/E} \text{ substituted for } \theta_{A/B}\} + \alpha_4 c^*_{B1} c^*_{C1} - \alpha_{-4} c^*_{A1} c^*_{E1}$$

[145] $$\left.\frac{dc^*_{A2}}{dT'}\right|_{X_i,R'_k} = \text{RHS [93]} - \alpha_2 c^*_{H\oplus_2} c^*_{A2} - \alpha_{-4} c^*_{A2} c^*_{E2} + \alpha_4 c^*_{B2} c^*_{C2}$$

[146] $$\left.\frac{dc^*_{B2}}{dT'}\right|_{X_i,R'_k} = \{\text{RHS [94] without kinetic term}\} - \alpha_1 c^*_{B2} - \alpha_4 c^*_{B2} c^*_{C2} + \alpha_{-4} c^*_{A2} c^*_{E2}$$

[147] $$\left.\frac{dc^*_{C2}}{dT'}\right|_{X_i,R'_k} = \{\text{RHS [95] without kinetic term}\} + \alpha_1 c^*_{B2} + \alpha_3 c^*_{D2} - \alpha_4 c^*_{B2} c^*_{C2} + \alpha_{-4} c^*_{A2} c^*_{E2}$$

[148] $$\left.\frac{dc^*_{H\oplus_2}}{dT'}\right|_{X_i,R'_k} = \{\text{RHS [95] without kinetic term and } c^*_{H\oplus_2} \text{ substituted for } c^*_{C2}\} + \alpha_1 c^*_{B2} + 2\alpha_3 c^*_{D2} - \alpha_2 c^*_{A2} c^*_{H\oplus_2}$$

[149] $$\left.\frac{dc^*_{HA\oplus_2}}{dT'}\right|_{X_i,R'_k} = \{\text{RHS [95] without kinetic term and } c^*_{HA\oplus_2} \text{ substituted for } c^*_{C2}\} + \alpha_2 c^*_{A2} c^*_{HA\oplus_2}$$

[150] $$\left.\frac{dc^*_{D2}}{dT'}\right|_{X_i,R'_k} = \{\text{RHS [95] without kinetic term and } c^*_{D2} \text{ substituted for } c^*_{C2}\} - \alpha_3 c^*_{D2}$$

[151] $$\left.\frac{dc^*_{E2}}{dT'}\right|_{X_i,R'_k} = \{\text{RHS [95] without kinetic term and } c^*_{E2} \text{ substituted for } c^*_{C2}\} + \alpha_4 c^*_{B2} c^*_{C2} - \alpha_{-4} c^*_{A2} c^*_{E2}$$

Again, the close resemblance of all expressions may be noted. The current function in this model is determined by the fluxes of A, $HA^\oplus$, and C to the electrode

[152] $$\chi = 2\sqrt{\frac{\beta}{\pi}}\int_0^1 R\left[\left(\frac{\partial c^*_{A1}}{\partial X}\right)_{X=0} + \left(\frac{\partial c^*_{HA\oplus_1}}{\partial X}\right)_{X=0} + \left(\frac{\partial c^*_{C1}}{\partial X}\right)_{X=0}\right] dR$$

$$= 2\sqrt{\frac{\beta}{\pi}}\sum_{l=1}^{N_R+2} Q_l R_l \left[\frac{1}{1+\theta_{A/B}S_\lambda(T')}\left\{A_{1,N_x+2} + \sum_{j=2}^{N_x+1} A_{1,j} c^*_{A1}(X_j,R_k,T') - \theta_{A/B}S_\lambda(T')\sum_{j=2}^{N_x+1} A_{1,j} c^*_{B1}(X_j,R_l,T')\right\} + \frac{n_2}{n_1}\frac{1}{1+\theta_{HA\oplus/D}S_\lambda(T')}\right.$$

Received January 29, 1982

CONSTANTINOS A. TSIPIS, EVANGELOS G. BAKALBASSIS, VASSILIOS P. PAPAGEORGIOU, and MARIA N. BAKOLA-CHRISTIANOPOULOU. Can. J. Chem. **60**, 2477 (1982).

The chelating ability of 1,8-dihydroxyanthraquinone with the divalent metal ions Cu(II), Ni(II), Mn(II), and Zn(II) has been studied. The Cu(II) and Ni(II) metal ions gave both mononuclear and homobinuclear chelates, while Mn(II) and Zn(II) gave only the mononuclear chelates. It is therefore evident that 1,8-dihydroxyanthraquinone can coordinate to the divalent metal ions either through its monoanionic form as a chelating bidentate ligand or through its dianionic form as a chelating tridentate ligand. In the homobinuclear chelates each metal ion is bonded to two terminal oxygen atoms and shares two bridging oxygen atoms with the other metal ion. Most of the chelates were found to contain also molecules of water either as coordinated and/or as crystalline water. The mononuclear and homobinuclear chelates of Cu(II) and Ni(II) gave, on reaction with pyridine, adducts which are also discussed. The structure and bonding of these chelates are discussed in relation to their spectroscopic and magnetic data.

CONSTANTINOS A. TSIPIS, EVANGELOS G. BAKALBASSIS, VASSILIOS P. PAPAGEORGIOU et MARIA N. BAKOLA-CHRISTIANOPOULOU. Can. J. Chem. **60**, 2477 (1982).

On a étudié la propriété de la dihydroxy-1,8 anthraquinone de former des chélates avec les ions des métaux bivalents tels le Cu(II), le Ni(II), le Mn(II) et le Zn(II). Les ions Cu(II) et Ni(II) donnent à la fois des chélates mononucléaires et homobinucléaires, tandis que le Mn(II) et le Zn(II) donnent uniquement des chélates mononucléaires. Il est par conséquent évident que la dihydroxy-1,8 anthraquinone peut coordonner les ions des métaux divalents, soit sous sa forme monoanionique, comme un ligand chélatant bidentate, soit sous sa forme dianionique comme un ligand chélatant tridentate. Dans les chélates homobinucléaires, chaque ion métallique se lie à deux atomes d'oxygène terminaux et partage deux atomes d'oxygène en position de pont avec l'autre ion métallique. On a trouvé que la plupart des chélates contiennent également des molécules d'eau, soit sous forme coordonnée ou sous forme cristalline. On discute également des adduits provenant de la réaction des chélates mononucléaires et homobinucléaires du Cu(II) et du Ni(II) avec la pyridine. On discute de la structure et de la liaison de ces chélates en se basant sur les données spectroscopiques et magnétiques.

## Introduction

Quinones and their substituted derivatives have long been known to possess numerous chemically and biologically significant properties (1–3). It is not surprising then that these compounds have attracted considerable experimental and theoretical interest which has stimulated basic and applied research in several areas. Thus, quinones and their derivatives, either synthetic or naturally occurring, have been extensively utilized as acid–base indicators, pigments, and drugs. Also, they have found important applications in electrochemistry, analytical chemistry, and coordination chemistry. In the field of biology the interest has been focused on their antimicrobial and anti-tumor activity and some drugs based on quinones are now in use.

Since in most of the above applications of quinones and their derivatives their chelating ability plays an important role, the study of their metal chelates would be of great value in understanding mechanisms of their chemical and biological function. In fact, in the last few years a number of papers concerning the synthesis, characterization, thermal stability, and biological function of some metal chelates of hydroxybenzoquinones, hydroxynaphthoquinones, and hydroxyanthraquinones have been published (4–16). As far as we know, only one paper concerning the study of the chelating ability of 1,8-dihydroxyanthraquinone (chrysazin) with some divalent metal ions has been published (14). However, in this paper no details on the structure and bonding of the chelates are given, since the authors' interest was focused on the relation of the chelating ability of the ligand with its tumor-promoting activity.

This work is part of an effort to develop a better understanding of the structure and bonding of mononuclear and homobinuclear chelates of 1,8-dihydroxyanthraquinone (1,8-DHAQ) with some divalent metal ions, as well as to study their

ability to form adducts with nitrogeneous bases. This study is of considerable importance, from a biological point of view, since DNA contains nitrogen donor atoms and hence it could interact in a similar way with the metal chelates under investigation.

## Experimental

*Physical measurements*

Infrared spectra were recorded, in the region of 4000–250 $cm^{-1}$, on a Perkin-Elmer 467 spectrophotometer using KBr discs or Nujol mulls. Electronic spectra were obtained on a Perkin-Elmer Hitachi 200 spectrophotometer and on a Cary 17D spectrophotometer, using both freshly prepared solutions in DMF and Nujol mulls. Magnetic susceptibility measurements were done by the Faraday technique at different magnetic field strengths using $Hg[Co(SCN)_4]$ as the calibrant. Diamagnetic corrections were made using Pascal's constants. Carbon, hydrogen, and nitrogen were determined using a Perkin-Elmer 240 Elemental Analyzer.

*Starting materials*

All solvents were of reagent grade and were used without further purification in synthetic work. The 1,8-DHAQ ligand was obtained commercially from Sarsyntex and used without further purification.

*Preparation of the complexes*

*$Cu(C_{14}H_7O_4)_2$ (I), $Cu(C_{14}H_7O_4)_2(OH_2)_2$ (II)*: 0.96 g (4 mmol) of 1,8-DHAQ were dissolved in 200 mL of absolute ethanol and the solution was warmed to boiling and then was filtered while warm. To this warm light orange solution 20 mL of an ethanolic solution containing 0.4 g (2.0 mmol) of $Cu(CH_3COO)_2 \cdot H_2O$ were added slowly under continuous magnetic stirring. During the mixing of the two solutions, a brown–red solid precipitated. The mixture was left stirring at room temperature for 1 h and then was kept in a refrigerator overnight before filtering. The precipitate was washed several times with small portions of ethanol, acetone, and finally with diethyl ether until the washings were colourless and was dried in a vacuum desiccator over $P_2O_5$. It must be noted that compound II is isolated when we use an aqueous solution of $Cu(CH_3COO)_2 \cdot H_2O$.

*$Cu(C_{14}H_7O_4)_2(Py)(OH_2)$ (III)*: 0.3 g (0.55 mmol) of the bis-(1,8-dihydroxyanthraquinonato)copper(II) complex were dissolved in a mixture of 10 mL dimethylformamide and 10 mL pyridine under heating and the resulting solution was filtered while warm. The filtrate, after cooling, was diluted by gradual addition of 10 mL of distilled water and a red–brown precipitate formed. The precipitate was filtered off, washed several times with small portions of acetone and diethyl ether, and dried in a vacuum desiccator over $P_2O_5$.

*$Cu_2(C_{14}H_6O_4)_2$ (IV)*: to a boiling ethanolic solution of 0.88 g (4.4 mmol) of $Cu(CH_3COO)_2 \cdot H_2O$ in 40 mL of absolute ethanol, a hot solution of 0.96 g (4.0 mmol) of 1,8-DHAQ in 200 mL of absolute ethanol was added slowly under continuous magnetic stirring. During the mixing of the two solutions, a red–brown solid precipitated. The mixture was boiled for 10 min more and then it was left stirring for 1 h at room temperature. The precipitate was isolated by filtration, washed several times with small portions of ethanol, acetone, and finally with diethyl ether, and dried in a vacuum desiccator over $P_2O_5$.

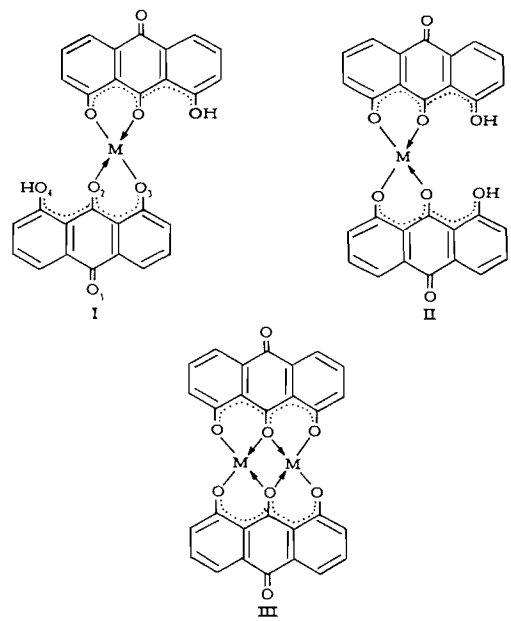
*$Cu_2(C_{14}H_6O_4)_2(Py)(OH_2)$ (V)*: 0.3 g (0.48 mmol) of the bis-(1,8-dihydroxyanthraquinonato)dicopper(II) complex was dissolved in a mixture of 15 mL dimethylformamide and 30 mL pyridine under heating. A brown–violet precipitate was formed and was isolated by filtration, washed with diethyl ether, and dried in a vacuum desiccator over $P_2O_5$.

*$Zn(C_{14}H_7O_4)_2$ (VI), $Mn(C_{14}H_7O_4)_2(OH_2)_2$ (VII), $Ni(C_{14}H_7O_4)_2(OH_2)_2$ (VIII)*: these compounds were obtained using a similar procedure. In all cases the hydrated metal acetates dissolved in the appropriate amount of ethanol were used as starting materials. The metal-to-ligand ratio used was 1:2. In cases where no precipitate appears immediately on mixing of the two solutions, the mixtures were left for longer periods or refluxed for about 4 h.

*$[Ni_2(C_{14}H_6O_4)_2(OH_2)_4] \cdot 2H_2O$ (IX), $[Ni_2(C_{14}H_6O_4)_2Py_2(OH_2)_2] \cdot 2H_2O$ (X)*: the dinickel complex was prepared according to the method used for the preparation of the dicopper complex. For the preparation of its 1:2 adduct with pyridine the following procedure was followed: 0.3 g (0.4 mmol) of the dinickel complex was dissolved in 30 mL of boiling pyridine and any undissolved material was removed by filtration. The filtrate was diluted with 200 mL of diethyl ether and was left in a refrigerator for 3 days. The dark violet precipitate formed was filtered, washed several times with small portions of diethyl ether, and dried under vacuum.

## Results and discussion

For the planar molecule of 1,8-DHAQ (symmetry group $C_{2v}$), which contains three oxygen donor atoms, one could expect coordination with divalent metal ions according to the following ways:



SCHEME 1. 1,8-DHAQ chelates of divalent metal ions.

In the isomeric structures **I** and **II** the 1,8-DHAQ acts, through its monoanionic form, as a chelating bidentate ligand forming with the metal ion a six-membered ring which is expected to be stabilized by a considerable delocalization of the $\pi$-electron density. In structure **III** the 1,8-DHAQ

*Figures in parentheses are the calculated values.

acts, through its dianionic form, as a chelating tridentate ligand forming binuclear metal chelates, which can be either homo- or heterobinuclear. In these chelates each metal ion is bonded to two terminal oxygen atoms and shares two bridging oxygen atoms with the other metal ion.

With the foregoing aspects in mind we could not understand why Van Duuren *et al.* (14) were able to isolate only the 1:2 metal-to-ligand chelates, although the authors, using Job's method, showed that 1,8-DHAQ gave 1:1 metal-to-ligand chelates. By varying the reaction conditions for the formation of the chelates we were able to isolate, in addition to the 1:2 chelates, homobinuclear chelates in the case of Cu(II) and Ni(II) metal ions, while Zn(II) and Mn(II) gave only the 1:2 chelates. The structures of these homobinuclear chelates as well as of their adducts with pyridine in relation to their spectroscopic and magnetic data will be discussed in the present paper. Also in the paper are included some known 1:2 mononuclear chelates, since no details on the structure and bonding of these chelates are given in the literature (14).

The analytical data for the compounds studied, their colours and yields are shown in Table 1. All compounds were fine powders or microcrystalline materials, stable in air, and do not melt up to 300°C. They were insoluble in most of the common organic solvents and water, but were soluble in DMF and DMSO and slightly soluble in methylene chloride. Most of the isolated compounds contain also molecules of water either as coordinated and/or as crystalline water. By heating the chelates at 50°C under vacuum (2 mm Hg) over $P_2O_5$ we found that only the chelates $Ni_2(C_{14}H_6O_4)_2(H_2O)_6$ and $Ni_2(C_{14}H_6O_4)_2(Py)_2(H_2O)_4$ showed weight changes. The weight changes observed correspond to the loss of two water molecules per molecule of each of the above chelates. Hence, two molecules of water are present as crystalline water in these chelates.

*Infrared spectra*

The most relevant absorption bands in the ir spectra of the studied compounds and their tentative assignments are shown in Table 2. Band assignments were based on the comparison method by considering the ir spectra of the chelates with different structures, as well as of the free ligand and its parent compound, anthraquinone. All the compounds showed a number of intense bands in the region 1200–1700 $cm^{-1}$, which are due to normal modes of vibration of the ligand affected by its coordination and hence are of great importance for the elucidation of its coordination mode. Parts of the ir spectra of some representative chelates are shown in Fig. 1.

The stretching frequency of the uncoordinated carbonyl group of the ligand is not affected by the coordination and its frequency $\nu(C\cdots O)_1$ is similar to that of the free ligand and its parent compound, anthraquinone (1690 $cm^{-1}$). In contrast, the coordinated carbonyl group, as well as the hydrogen bonded carbonyl of 1,8-DHAQ, gave absorption bands $\nu(C\cdots O)_2$ at lower frequencies relative to that of the uncoordinated carbonyl group. The difference $\nu(C\cdots O)_1 - \nu(C\cdots O)_2$, which amounts to some 60–90 $cm^{-1}$, depends slightly on the nature of the central atom and the type of the chelate. For the central atoms studied the difference decreases in the order: Cu > Zn > Ni > Mn > H and is higher in binuclear than in mononuclear chelates. All these observations could be easily explained on the basis of the expected structures **I** or **II** for the mononuclear chelates and structure **III** for the binuclear ones. The substitution of the hydrogen atom by the central metal ion results in higher shifting, because the metal ions are better electron density acceptors

than the hydrogen atom. The lowering of the metal ion's ability to accept electron density from the ligand by its coordination with pyridine in the adducts is also reflected from the lower values of the $\nu(C\cdots O)_1 - \nu(C\cdots O)_2$ differences.

Special attention should be paid to the region 1200–1250 $cm^{-1}$ in the ir spectra of the studied chelates, since some bands related to the bonding mode of the ligand occur in this region. It is well known (17–19) that in hydroxyanthraquinones the $\nu(C\cdots O)$ band occurs in the region 1200–1250 $cm^{-1}$. The position of this band indicates that the C—O bond has a fractional double bond character. The chelates in question gave the band due to $\nu(C\cdots O)_3$ and $\nu(C\cdots O)_4$ (for numbering see structure I) in the same region. If we assign this band to $\nu(C\cdots O)$ we would expect the band to show the following characteristics. For the mononuclear chelates, where the electron density distribution into the chelate ring containing the metal ion differs from that of the chelate rings containing the hydrogen bonds, two bands due to $\nu(C\cdots O)$ stretching must be observed [$\nu(C\cdots O)_3 \neq \nu(C\cdots O)_4$]. In contrast, for the homobinuclear chelates, where the electron density distribution into all the chelate rings formed is the same, only one band would be expected [$\nu(C\cdots O)_3 = \nu(C\cdots O)_4$].

Of interest and considerable importance is also

*The spectra were also obtained in solid state (Nujol mulls) and in some cases in $CH_2Cl_2$ or EtOH solutions in order to investigate the region of 30–50 kK of the spectra. In this region the Band I exists.
†sh = shoulder.
‡Figures in parentheses are the values of log $\varepsilon_{mol}$.

the region 300–700 $cm^{-1}$ of the ir spectra of the chelates under consideration. This region contains several absorptions with medium or weak intensities. Some of them are typical absorptions of the free ligand while the rest, which are sensitive to the central metal ion and the structure of the chelates, are attributed to the normal modes of vibration of the $MO_4$ and $M_2O_6$ moieties of the chelates. In order to make a reasonable assignment of these bands we used the comparison method. Thus, we have compared the ir spectra of the studied compounds with those of the corresponding acetylacetonate complexes, for which the absorption bands have been fully characterized on the basis of theoretical treatment (20–23). A similar pattern for the absorption bands in the region 300–700 $cm^{-1}$ for both classes of compounds has been observed, the only difference being the shifts of the bands. Such a shift must be expected on the basis of the different electron donor and acceptor abilities of the 1,8-DHAQ and the acetylacetonato ligands.

The number and the form of the bands due to M—O stretching for the 1:2 chelates are similar to those of the corresponding 1:2 metal acetylacetonates. Hence, since the 1:2 metal acetylacetonates have $D_{2h}$ symmetry we can conclude that our 1:2 chelates adopt structure **I** which also has $D_{2h}$ symmetry. On the basis of $D_{2h}$ symmetry we can assign the band in the region 450–550 $cm^{-1}$ to $\nu_{sym}$(M—O) stretching vibration (symmetry species $B_{1u}$) and the band in the region 310–360 $cm^{-1}$ to $\nu_{asym}$(M—O) stretching vibration (symmetry species $B_{2u}$). The third ir-active vibration (symmetry species $B_{3u}$) occurs at a lower frequency (below 300 $cm^{-1}$) and could not be observed in the present study. Both $\nu_{sym}$(M—O) and $\nu_{asym}$(M—O) bands of the chelates studied here are shifted to higher frequencies relative to the corresponding bands of the analogous acetylacetonates. This observation could be explained on the basis of the enhanced $\pi$-electron density delocalization into the chelate rings of the chelates under consideration over that in the metal acetylacetonates. The $\nu_{sym}$(M—O) and $\nu_{asym}$(M—O) are sensitive to the nature of the central metal ion. For the $\nu_{sym}$(M—O) band the following order of decreasing frequencies has been observed: Cu > Ni > Zn > Mn. This sequence is in accordance with the sequence observed for the stability constants of the chelates of these divalent metal ions with analogous oxygen donor ligands (20).

The only chelate which gave a different pattern for the $\nu$(M—O) bands was that of zinc(II). This is no doubt due to the ability of zinc(II) to adopt a tetrahedral and not a square planar geometry.

*Electronic spectra*

The positions of the band maxima and of discernible shoulders, as well as their log $\varepsilon_{mol}$ values, are given in Table 3.

In the region 30–50 kK a composite band (band I) occurs, which exhibits a maximum at about 40 kK and a shoulder at about 35 kK. Band I is not included in Table 3, as it was masked by the absorption of the solvent, but it was observed in the solid state spectra and in some cases in $CH_2Cl_2$ or EtOH solutions as well.

In the region 20–25 kK another intense multicomponent band (band II) occurs, which exhibits a main peak at about 23.0–23.5 kK and two shoulders, one on each side of the main peak, as well. Both bands I and II are attributed to intraligand transitions, which are the characteristic benzenoid and quinoid ET transitions of the ligand (24, 25).

In the region 15–25 kK an intense envelope type band (band III) occurs, which is absent in the spectra of the free ligand and the zinc(II) chelate as well. Band III is sensitive to the nature of the

central atom and the type of the chelate and has an intensity very close to the intensity of CT transitions. Hence we can assign band III to CT transitions which could be either of the L → M or L ← M type. The absence of band III in the spectrum of the zinc(II) chelate indicates that this band must be of the L → M type. If band III is an L → M CT band one could expect a shifting of the band (the main peak of band III is at 18–19 kK) to higher energies as the electron density on the central atom increases. In fact, this is the case for the chelates studied.

Finally, in the region 5–15 kK only the nickel(II) chelates exhibit a weak and broad absorption band (band IV). Band IV is characteristic of octahedral nickel(II) complexes and is attributed to the $^3T_{2g} \leftarrow {}^3A_{2g}$ electronic transition. For the tetragonally distorted complexes band IV splits into two well separated bands which are attributed to $^3B_{2g} \leftarrow {}^3B_{1g}$ and $^3E_g \leftarrow {}^3B_{1g}$ (26). The observed splitting of the band IV in the spectra of the nickel(II) chelates studied supports their distorted octahedral geometry. The 10 *Dq* values obtained are about 9.0 kK, very close to those of the octahedral nickel(II) complexes with oxygen donor ligands. The other two expected *d–d* transitions ($^3A_{2g} \leftarrow {}^3B_{1g}$, $^3E_g \leftarrow {}^3B_{1g}$) for the distorted octahedral nickel(II) complexes are obscured by the intense CT transitions and could not be observed. The same is also true for the expected *d–d* transitions ($^2A_g \leftarrow {}^2B_{1g}$; $^2B_{2g}$, $^2B_{3g} \leftarrow {}^2B_{1g}$) of the Cu(II) chelates of $D_{2h}$ symmetry (27–29).

It must be noticed that, after heating the homobinuclear nickel(II) chelates to remove the crystalline water, no spectral changes were observed. This fact indicates the existence of the same nickel chromophores before and after heating and hence the two molecules of water were present as crystalline water.

*Magnetic data*

The room temperature magnetic moments of the mononuclear chelates **I**, **II**, **III**, **VI**, **VII**, and **VIII** ($\mu_{eff}$ = 1.93, 2.10, 2.21, 0.00, 6.03, and 3.29 BM, respectively) are normal and in accordance with the proposed structures of the chelates (30). However, the room temperature magnetic data of the homobinuclear chelates obtained at different magnetic field strengths (Table 4) reflect a considerable spin–spin interaction between the unpaired electrons on the adjacent metal ions. The low magnetic moments observed both at low and high field strengths are indicative of the operation of antiferromagnetism in these compounds. On the other hand, the slight increase of the magnetic moments as the magnetic field strength decreases is indicative of the operation of ferromagnetism as well. Thus, the magnetic exchange phenomenon observed in the studied homobinuclear chelates is analogous to that observed in the case of other binuclear Cu(II) and Ni(II) chelates (31–35) and could be explained on the basis of the same mechanism. However, it must be noted that in the homobinuclear chelates studied, the magnetic data indicate a more favorable magnetic exchange which is dominated by antiferromagnetism than in the previously studied chelates (32–36). This could be expected on the basis of the better-developed π system on the 1,8-DHAQ ligand than in the 1,3,5-triketonato ligand.

Finally, it is worthwhile mentioning that the pyridine adducts gave high magnetic moments which in some cases were subnormal. The same was also observed previously (36) in the case of quinoline and isoquinoline adducts of the $Cu(acac)_2$ chelates.

# Correlations between spectroscopic properties of aromatic molecules and fragmentation rates of their metastable molecular ions in a mass spectrometer

ROBERT K. BOYD AND BORI SHUSHAN

*Guelph-Waterloo Centre for Graduate Work in Chemistry (Guelph Campus), University of Guelph, Guelph, Ont., Canada N1G 2W1*

Received August 10, 1981[1]

ROBERT K. BOYD and BORI SHUSHAN. Can. J. Chem. **60**, 2484 (1982).

Unexpected correlations have been found between spectroscopic (uv and nmr) properties of some aromatic systems (specifically polycyclic aromatic hydrocarbons and chlorinated biphenyls) and fragmentation rates of the corresponding metastable molecular ions in a field-free region of a mass spectrometer. The meaning of these empirical correlations is explored via the quasi-equilibrium theory of mass spectra. For the case of the polycyclic aromatic hydrocarbons for which more complete ancillary data are available, a reasonably self-consistent account of the correlations can be obtained via the ionisation energy as the crucial parameter. The case of the chlorinated biphenyls is less clear, due to a lack of subsidiary data. However, the best explanation available appears to involve a systematic shift in the energy deposition function with increasing steric interaction around the biphenyl linkage.

ROBERT K. BOYD et BORI SHUSHAN. Can. J. Chem. **60**, 2484 (1982).

On a trouvé des corrélations inattendues entre les propriétés spectroscopiques (uv et rmn) de quelques systèmes aromatiques (hydrocarbures aromatiques polycycliques et chlorobiphényles spécifiquement) et les vitesses de fragmentation des ions moléculaires métastables correspondants dans la région de libre champ d'un spectromètre de masse. On explore la signification de ces corrélations empiriques via la théorie de quasi équilibre des spectres de masse. Dans le cas des hydrocarbures aromatiques polycycliques, pour lesquels on dispose de données accessoires complètes, on peut obtenir une interprétation raisonnablement valable des corrélations par l'intermédiaire de l'énergie d'ionisation comme paramètre fondamental. Le cas des chlorobiphényles est moins clair, à cause du manque de données secondaires. Cependant, la meilleure explication disponible semble impliquer un glissement systématique dans la fonction d'énergie de précipitation avec une augmentation de l'interaction stérique autour de la liaison biphényle.

[Traduit par le journal]

## Introduction

In some recent work (1), devoted to exploiting the diagnostic capabilities of metastable ion studies in differentiating between isomeric chlorinated biphenyls (PCBs), a correlation was observed between the fragmentation intensities and the number of chlorine substituents *ortho* to the biphenyl linkage. This correlation, which had been noticed before (2) in the conventional mass spectra of these compounds, was attributed (2) to relief of steric strain in the molecular ions following expulsion of one or more chlorine atoms. In an attempt to improve upon this correlation, a parameter more sensitive to steric strain was sought. The so-called A-band of biphenyls (3) in the ultraviolet is attributed (3) to a transition to an excited state involving delocalisation over two quinonoid rings via a double-bond linkage. This view will be discussed more fully below, but clearly bulky *ortho* substituents will restrict the degree of attainable coplanarity, and thus affect the transition energy. An unexpectedly significant correlation was found (1) between the energy of the A-band transition for chlorinated biphenyls and the (M − 2Cl)/(M − Cl) intensity ratio in the metastable spectra (*B*/*E* linked scan for molecular ion as parent ion).

The original intent of seeking such correlations was to provide some partially predictive scheme to assist in cross-checking structures of chlorinated biphenyls other than the 31 standards (mono- through tetra-chloro substitution) which were available (1). However, the correlation thus found (1) was clearly of more fundamental significance. Accordingly, we have continued investigations of such correlations, and have extended them to include similar data obtained previously (4, 5) for polycyclic aromatic hydrocarbons (PAH). The latter correlations appear to be susceptible to a more satisfactory interpretation than those found for the PCBs.

## I. Polycyclic aromatic hydrocarbons

### *(a) Experimental results*

The raw data to be used here and the mass spectrometric techniques used to obtain them have been described previously (4, 5). The fragment ion intensities are those obtained for metastable molecular ions which fragmented in the first field-free region of a conventional double-focussing mass spectrometer. They were obtained as peak heights observed in linked scans at constant *B*/*E*, and thus correspond to the heights of the full metastable peaks (6).

The fragmentation reactions of molecular ions of PAH, which are of lowest appearance energy, correspond to loss of one and two hydrogen atoms. (The higher energy fragmentation reactions (5) do not show significant correlations.) The $(M - H)^+$ and $(M - 2H)^{+\cdot}$ intensities from metastable molecular ions *do* separately correlate fairly well with the transition energy of the so-called *p*-band (7) of the neutral PAH in the ultraviolet. This transition connects the $^1A$ ground state to the excited state designated $^1L_a$ in the free electron model of Platt (8). However, a slightly better correlation was found between the sum of the intensities $[(M - H)^+ + (M - 2H)^{+\cdot}]$ (normalised to the main-beam molecular ion intensity) and the *p*-band energy. This correlation for the 17 alternant aromatic hydrocarbons studied (5) is shown as Fig. 1. The two non-alternant hydrocarbons studied (5) (fluorene and fluoranthene) did not appear to fit the general trend, and have been omitted from Fig. 1. In Table 1 are listed the 17 alternant hydrocarbons studied (5), together with their molecular formulae and (0–0) *p*-band transition energies taken from Birks' monograph (9).

Before attempting any interpretation of Fig. 1, some background information will be useful. Previously (5), evidence was presented suggesting that the expulsion of hydrogen atoms from these PAH molecular ions is a stepwise process:

$$M^{+\cdot} \rightarrow (M - H)^+ + H^\cdot \rightarrow (M - 2H)^{+\cdot} + 2H^\cdot$$

It seems improbable (5) that loss of molecular hydrogen occurs in a single step. Thus, the $[M - H)^+ + (M - 2H)^{+\cdot}]$ may reasonably be regarded as a measure of the total intensity, on the timescale of the "metastable window" (see below), in the lowest energy reaction channel available to the PAH molecular ions.

The left hand curve in Fig. 1 correlates the data for the linear acenes plus perylene and benzoperylenes; the correlation coefficient for this set was found to be 0.96. The remaining compounds are correlated by the right hand curve of Fig. 1, with a correlation coefficient of 0.91. Both *cata*-condensed and *peri*-condensed PAH appear in both sets, so that this particular distinction appears to be of no significance in this regard.

*(b) Phenomenological identification of parameters underlying observed correlation*

The question to be faced concerns the connection between energy differences between *stationary* electronic states of neutral PAH molecules, on the one hand, and fragmentation *rates* of the corresponding molecular ions, on the other. In order to investigate this question, it is necessary to refer to some theory of fragmentation rate constants. Recently (10) Lorquet published a review of theories of unimolecular dissociation, particularly as applied to ions under collision-free conditions. It is not necessary to attempt here a summary of this scholarly perspective (10) in order to justify the present use of statistical theories of unimolecular fragmentation. Modern justifications of such theories, in particular of the so-called "energy randomisation" postulate underlying the use of a microcanonical rate constant $k(\varepsilon)$, are somewhat different (10) from those offered by the originators (11, 12). The most widely used statistical theory (Rice–Ramsperger–Kassel–Marcus or RRKM theory (11), alternatively quasi-equilibrium theory or QET (12)) leads to the following general expression for the microcanonical rate constant:

$$k(\varepsilon) = \left(\frac{\sigma}{h}\right) \frac{G^*(\varepsilon - \varepsilon_0)}{N(\varepsilon)}$$

where $\sigma$ is a symmetry factor, $N(\varepsilon)$ is the density of states, at internal energy $\varepsilon$, of the reactant, and $G(\varepsilon)$ is the integral of $N(\varepsilon)$ over the range $\varepsilon = 0$ to $\varepsilon$. The asterisk denotes a property of the transition state, i.e. to a system with one (usually vibrational)

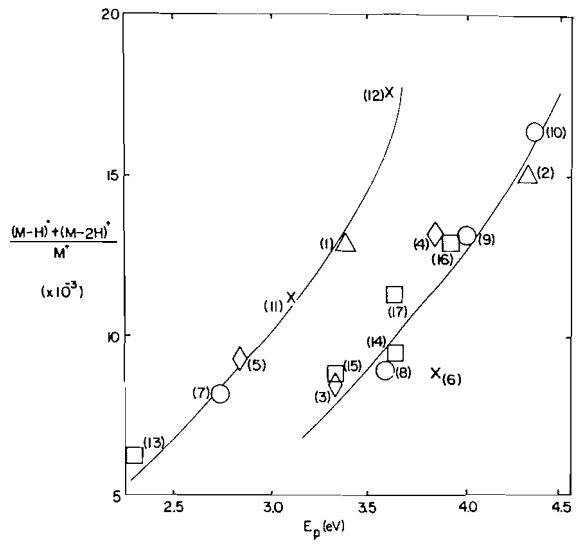

FIG. 1. Correlation of metastable ion fragmentation intensities ((M − 1) + (M − 2) peak heights in B/E linked scan spectra), with *p*-band energies for alternant hydrocarbons. Solid curves are least-squares fits, and the numbers designate the compounds (see Table 1). $E_p$ values are (0–0) energies (9). Isomeric series: △, $C_{14}H_{10}$; ◇, $C_{20}H_{12}$; ○, $C_{18}H_{12}$; □, $C_{22}H_{14}$; ×, single isomers. Numbers on symbols refer to code in Table 1.

degree of freedom removed. $\varepsilon_0$ is the critical energy for dissociation.

Quantitative evaluation of this expression requires detailed knowledge of the internal modes of both reactant and transition state. This would present a formidable problem for the reactants of interest in the present work. For qualitative purposes, it is common practice (13, 14) to use an oversimplified model involving $s$ degenerate classical, harmonic oscillators of frequency v; the RRKM expression then reduces to:

$$[1] \quad k(\varepsilon) = \nu\left(1 - \frac{\varepsilon_0}{\varepsilon}\right)^{s-1}$$

In the following discussion eq. [1] will be used. The qualitative conclusions thus reached can be re-expressed in terms of the full RRKM expression, but the arguments then become extremely wordy as a consequence of lack of specific knowledge of the internal mode properties underlying the quantities $N$ and $G^*$. (The parameters v and $s$ define $N$ and $G^*$ in this simplest conceivable model.) It will prove more convenient to transform to an energy scale $E$, measured relative to the zero-point energy of the neutral molecule:

$$[2] \quad E = \varepsilon + IE_a$$

where $IE_a$ is the adiabatic (0–0) ionisation energy. Then, eqs. [1] and [2] give:

$$[3] \quad k(E) = \nu[(E - AE_a)/(E - IE_a)]^{s-1}$$

where $AE_a$ is the adiabatic appearance energy for the product ion, i.e. the appearance energy without any kinetic shift contribution.

Now if the times $t_1$, $t_2$, $t_3$, $t_4$ represent, respectively, the ion-source residence time, the time of entry into the field-free region, the time of leaving the field-free region, and the time of arrival at the detector, it is straightforward to show that:

$$[4] \quad (M^+_{obs}/M^+_{tot}) = A\int_{IE_a}^{\infty} P(E)\exp[-k(E)t_4]dE$$

$$[5] \quad (F^+_{IS}/M^+_{tot}) = B\int_{IE_a}^{\infty} P(E)\{1 - \exp[-k(E)t_1]\}dE$$

$$[6] \quad (m^*/M^+_{tot}) = (F^+_{MS}/M^+_{tot}) = C\int_{IE_a}^{\infty} P(E)\{\exp[-k(E)t_3] - \exp[-k(E)t_2]\}dE$$

In eqs. [4]–[6], the various $F^+$ and $M^+$ are ion fluxes of product (fragment) ions and molecular (parent) ions, respectively. $M^+_{tot}$ is the total flux of molecular ions produced, while $M^+_{obs}$ is the flux which survives to the detector, and is measured as the molecular ion intensity in the conventional

mass spectrum. $F^+_{IS}$ is the flux of fragment ions produced within the ion source, and $F^+_{MS}$ that produced from metastable $M^+_{ions}$ within the field-free region, yielding an observed peak intensity m*. $A$, $B$, and $C$ are instrumental parameters which include such effects as ion transmission efficiency, detector response, use of peak heights instead of peak areas to measure intensities, etc. $P(E)$ is the normalised internal energy distribution function of the $M^+$ ions at the instant of creation; as such, it has non-zero values for $E > IE_a$, while $k(E)$ has non-zero values only for $E > AE_a$, in the absence of quantum effects. The lower limit of integration, in eqs. [5] and [6], could thus equally well be $AE_a$. The ordinate of Fig. 1 corresponds to $(m^*/M^+_{obs})$, i.e. to (eq. [6]/eq. [4]).

Strictly, all of $A$, $B$, $C$, $t_2$, $t_3$, $t_4$ are functions of the masses of the various ions. It does not seem conceivable that any of these parameters could be responsible for the regularities observed in Fig. 1, particularly in view of the differences observed between PAH isomers. Thus, the quantities $P(E)$, $\nu$, $s$, $IE_a$, and $AE_a$ remain for consideration. Two different quantities must be selected from these five to account for Fig. 1. The first, conveniently labelled parameter $X$, must correlate with $E_p$ to account for the smooth trends observed. The second (parameter $Y$) must account for the split into two clearly separated families of PAH (Fig. 1). Parameter $X$ will be sought first.

The quantities $P(E)$ and $\nu$ will now be considered as candidates for parameter $X$. Some indication of their potential in this regard can be obtained from a consideration of the conventional mass spectra (ion-source reactions), which are known (15) to be practically identical for isomeric PAH. Because of the relatively short residence time within the ion source, $F^+_{IS}$ must arise predominantly from fragmentations of molecular ions with large amounts of internal energy. If $E$ is large enough, $k(E)$ given by eq. [3] approaches the value $\nu$. With this approximation, eq. [5] becomes:

$$[7a] \quad (F^+_{IS}/M^+_{tot}) \approx B[1 - \exp(-\nu t_1)] \int_{EA_a + \bar{E}_{IS}}^{\infty} P(E)dE$$

$$[7b] \quad (F^+_{IS}/M^+_{obs}) = (B/A)\,(\exp \nu t_4)\,[1 - \exp(-\nu t_1)]$$

where $\bar{E}_{IS}$ is the average (assumed large) kinetic shift for molecular ions fragmenting in the ion source. Thus, the observed invariance of both $(F^+_{IS}/M^+_{tot})$ and $(F^+_{IS}/M^+_{obs})$ within an isomeric series of PAH would seem to imply that both $\nu$ and the integral in eq. [7a] are essentially constant. Strictly, the expression for $M^+_{obs}$ (eq. [4]) should account for *all* reactions of $M^+$; however, in the case of PAH, the loss of H atoms is easily the major fragmentation channel and the essentially qualitative conclusions to be drawn would not be affected by such a correction. Thus, these considerations provide some justification for discarding both $\nu$ and at least the high-energy tail of $P(E)$ as candidates for parameter $X$. It is also difficult to provide theoretical reasons to account for a simple correlation of either $\nu$ or $P(E)$ with $E_p$.

The parameter $s$ (eq. [3]) is somewhat nebulous (13, 14), but is generally between 30–50% of the total number of vibrational modes in the fragmenting ion; near the fragmentation threshold, this fraction can drop to about 20%. Unfortunately, it does not seem possible to deduce much phenomenological evidence for or against the suitability of $s$ as a candidate for parameter $X$. Again, it would be difficult to understand theoretically why an "effective number of oscillators" should correlate simply with $E_p$, particularly within an isomeric series.

The remaining possibilities for parameter $X$ are $AE_a$ and $IE_a$. The manner in which these quantities affect $k(E)$ and its convolution with $P(E)$ is illustrated qualitatively for the present case in Fig. 2. (This figure, and associated discussion, have been modified from a more general discussion given previously (13).) Nothing is known of the form of $P(E)$ (13, 14), and the only assumption made here is that $P(E)$ falls off to small values for both very large and very small values of $(E - IE_a)$. Then, since it is known (15) that the molecular ion $M^+_{obs}$ constitutes most of the ion current $M^+_{tot}$ (60% in the least favourable case listed (15)), the relative dispositions of the $P(E)$ and $k(E)$ curves in Fig. 2 must be such that $M^+_{obs}$ (= $M^+_0$ + $M^+_E$ in Fig. 2) accounts for the majority of the area under the $P(E)$ curve, as shown. The value of IE determines the general position along the $E$ axis of the $P(E)$ curve, while AE determines that of the $k(E)$ curve. Thus, it is clear from Fig. 2 that an increase in m* (i.e. $F^+_{MS}$, eq. [6]) can result from either a decrease in $AE_a$ or from an increase in $IE_a$. The only assumption required in reaching this conclusion was that concerning the very general form of $P(E)$; the requirement that $M^+_{obs}$ constitute the majority of $M^+_{tot}$ is derived from experimental observation (15).

Unfortunately, very little experimental information is available concerning the appearance energies of fragment ions of PAH. Some early data (16) for several PAH included only phenanthrene of those studied here (Table 1). Some additional AE values for $C_{18}H_{12}$ isomers were obtained more recently (5). All of these data (5, 16) were obtained

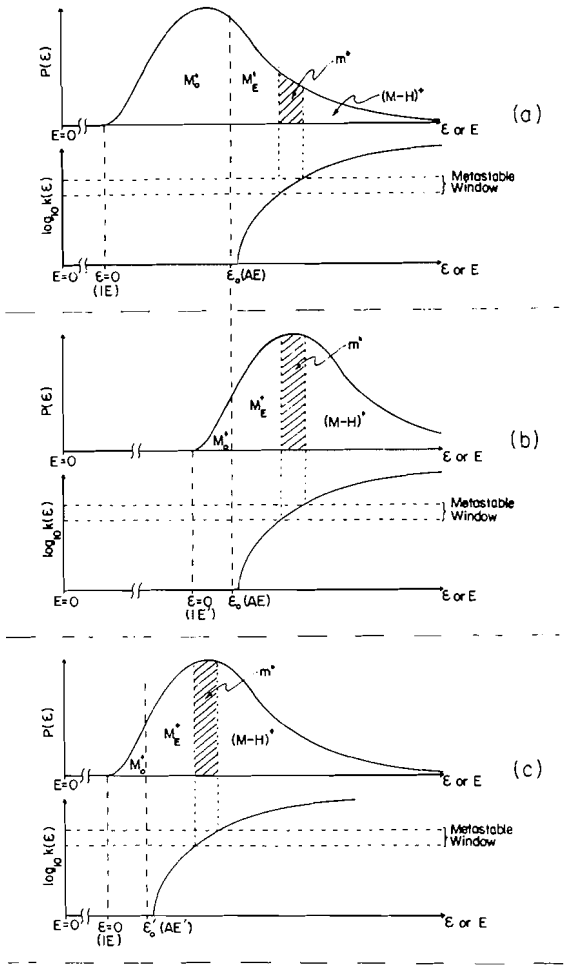

FIG. 2. Qualitative indication, of effects of changing ionization energy IE and appearance energy AE, on metastable peak intensity $m^*$. Internal energy deposition function $P(\varepsilon)$ is assumed to be a fixed function of $\varepsilon = (E - \mathrm{IE})$, while $k(\varepsilon)$ is given by eq. [3]. $M^+_0$, molecular ions with internal energy below reaction threshold; $M^+_E$, molecular ions with insufficient energy to react on instrumental timescale; m*, molecular ions with internal energies, and thus lifetimes, appropriate to fragmentation within the field-free region (metastable window); $(M - H)^+$, fragment ions formed within the ion source. (*a*) Low IE, high AE; (*b*) high IE, high AE; (*c*) low IE, low AE.

using unfiltered electron beams in conventional mass spectrometers, and are thus of low reliability. Nevertheless, the data thus obtained (5) for the appearance energies of $(M - H)^+$ fragments from $C_{18}H_{12}$ isomers are informative: tetracene, 14.5 eV; chrysene, 15.1 eV; triphenylene, 15.4 eV; 1,2-benzanthracene, 15.3 eV. (The last value was measured but not reported previously (5).) Thus, within this limited set of data, AE does *not* correlate with $E_p$ (Table 1). Probably the only significant difference observed within these AE values is that between the value for tetracene and the rest. Thus, this admittedly meagre evidence does suggest that $AE_a$ is probably not parameter $X$, but may correspond to parameter $Y$ which accounts for the separation of the acene series (plus perylene and the benzperylenes) from the other PAH studied (Fig. 1). This tentative proposal clearly requires further experimental test.

By elimination, then, $IE_a$ remains as the only candidate for parameter $X$. Accurate values of $IE_a$ have been obtained by Schmidt for a large number of PAH, using photoelectron spectroscopy (17–21). It was shown (20), for *cata*-condensed PAH only, that the lowest ionisation energies correlated well with $E_p$ values. The latter were estimated mostly from solution spectra taken at room temperature, with some empirical corrections applied for solvent shifts. In the present work the values of $E_p$ used were those corrected to the 0–0 transition by Birks (9); these values appear to be generally lower by about 0.1 eV than those used by Schmidt (17–21). The IE values obtained by Schmidt (17–21) are also 0–0 values ($IE_a$ values) since the first band in the photoelectron spectra generally showed well-resolved vibrational structure with a spacing (1300 $cm^{-1}$) very close to that observed in the *p*-bands. Figure 3 shows the correlation between the values of $IE_a$ and Birks' values (9) for the 0–0 *p*-band transition energies for the 17 PAH studied in the present work. This correlation,

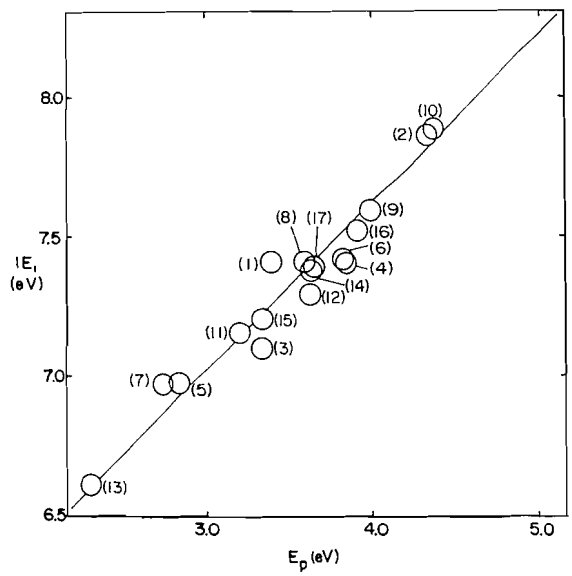

FIG. 3. Plot of ionisation energies for alternant PAH (data from photoelectron spectroscopy (17–21)) vs. *p*-band energies (9). Both are (0–0) transition energies. Solid line is least-squares fit (eq. [8]), and numbers designate the compounds (Table 1).

which refers to both *cata*- and *peri*-condensed PAH, may be expressed as:

[8] $IE_a/eV = 5.42(\pm 0.08) + 0.55(\pm 0.04)E_p$

The standard deviation is ±0.12 eV; correlation coefficient 0.96.

As emphasised previously (20), the quality of this and similar correlations is remarkable in view of the range of structural types of PAH, the varying degrees of non-planarity, etc. There is thus little doubt, in the present context, that $IE_a$ may be identified as parameter $X$, i.e. that parameter responsible for the correlation of metastable ion fragmentation rates with $E_p$. Identification of parameter $Y$, responsible for the split into two distinct families (Fig. 1), is much less certain though the data available do support the idea that $AE_a$ (eq. [3]) may be thus identified.

*(c) Theoretical considerations*

Since our original correlation between $E_p$ and metastable ion fragmentation intensities (Fig. 1) has now been reduced to one between $E_p$ and $IE_a$ (Fig. 3), some attempt must now be made to understand the latter. Simple Hückel theory of the π-electron system gives, for alternant PAH:

[9] $IE_i = -\alpha + m_i\beta$

[10] $E_i(HO,LU) = 2m_i\beta$

In eqs. [9] and [10], α and β have their usual significance in Hückel theory, and $m_i$ is the constant characteristic of the particular $(PAH)_i$. $IE_i$ is the ionisation energy corresponding to removal of an electron from the highest occupied Hückel MO. $E_i(HO,LU)$ denotes the energy for an electronic transition between the highest occupied and lowest unoccupied molecular orbitals. Then, eqs. [9] and [10] predict:

[11] $IE = -\alpha + 0.5E_p$

provided that the experimental IE and $E_p$ values may be identified with the theoretical quantities described above.

Simple Hückel theory thus correctly predicts the linear correlation between IE and $E_p$. The experimentally determined slope (eq. [8]) is reasonably close to that predicted (eq. [11]). Schmidt (20) showed that inclusion of electron repulsion effects in the spirit of self-consistent field theory, but without configuration interaction, sufficed to bring theoretical and experimental slopes into much better agreement. Presumably, when electron repulsion is included, the energies of the relevant configurations differ sufficiently to reduce the CI correction to a second-order effect (20). However, Schmidt (20) did not discuss the intercept which should correspond to the Coulomb integral (−α) for carbon. This quantity is *not* simply interpretable as the ionisation energy of an electron in the $p_z$ orbital of an isolated $sp^2$-hybridised carbon atom, but rather (22) as the mean of this ionisation energy and the corresponding electron affinity. The recommended values (22) of these latter parameters lead to a value of −5.7 eV for α, and thus to a theoretically predicted intercept of 5.7 eV for eq. [8]. The experimental value is thus slightly lower than that predicted by simple theory. However, the calculations of Schmidt (20) show that corrections for electron repulsion would act in the correct direction to also reduce this discrepancy. Thus, simple π-electron theory accounts remarkably well, on a semi-quantitative level, for the correlation between IE and $E_p$ (Fig. 3) and thus also in a more qualitative fashion for the relation (Fig. 1) between $E_p$ and the metastable ion fragmentation intensity.

There is nonetheless one conceptual problem remaining. This concerns the fact that Hückel theory considers the π-electron wavefunctions to be orthogonal to the wavefunctions describing the σ-framework. That is, the excess energy deposited in the π-electron system by the ionisation event cannot, according to the Hückel theory, be transferred to the σ-framework which is involved in the fragmentation reactions (fission of C—H bonds). However, this violation of a principal tenet of quasi-equilibrium theory (12) and other statistical theories of unimolecular reaction rates arises only if the simple Hückel theory is taken too seriously. For example, the (solution) electron spin resonance (esr) spectroscopy of the same PAH radical cations of interest here show hyperfine splittings due to the σ-bonded protons. The magnitudes of these hyperfine splittings can be well correlated (23) with spin densities (which usually (24) parallel "unpaired electron densities") calculated from the Hückel theory of the π-electrons. The accepted mechanism underlying the McConnel relationship (24) involves spin polarisation, which is unlikely to provide a means of transforming sizeable amounts of π-electronic energy to vibrational energy of the σ-framework. Nonetheless, the esr phenomenon does show that the Hückel theory can be extremely useful in correlating phenomena which apparently contradict the theory's primary postulate concerning orthogonality of the π and σ wavefunctions.

The question remains as to whether a theoretical approach less pragmatic than the Hückel theory might not provide additional insights. A successful approach to π electron energies has been devel-

TABLE 2. Resonance energies calculated by method of Herndon (30)

oped by Dewar and collaborators (22, 25), using a Pople-type SCF-MO method with allowance for σ-bond compression energies. A remarkably simple recipe, which reproduces the PAH resonance energies given by Dewar's method, has been devised by Herndon (26–29). This ingenious procedure, which involves only a simple count of Kekulé valence-bond structures, reproduces the resonance energies from SCF-MO calculations of Dewar (22, 25) to within an average deviation of ±0.04 eV, via the algorithm (29):

$$[12] \quad RE(M) = 1.185 \ln [CSC(M)]$$

where RE(M) is the resonance energy of the PAH molecule M, and CSC(M) is the "corrected structure count" of the Kekulé structures for M, as described by Herndon (26–29).

The interest in resonance energies, in the present context, arises from a suggestion, due originally to Franklin (16). An observed trend of increase in appearance energy for $(M - H)^+$ fragments for six PAH, with increasing resonance energy of the parent molecule, was interpreted in terms of the loss of a hydrogen atom from $M^{+\cdot}$ being accompanied by the opening of at least one aromatic ring (16). This suggestion was re-examined more recently (5) in terms of metastable-ion fragmentation intensities. Based only on the series of PAH compounds of formula $C_{18}H_{12}$ (Table 1), for which experimental resonance energies were available, it was concluded (5) that the metastable-ion intensities were consistent with loss of one H atom *not* destroying the aromatic system (i.e. the opposite conclusion to that of Franklin (16)), but that losses of 2H of $CH_3$ and of $C_2H_2$ *do* appear to disrupt the aromatic structure of the molecular ion; the latter two reactions *must* do so, of course. The availability of reliable theoretical values of resonance energy should permit some additional understanding of this particular point. More recently (30), Herndon has extended his procedure to the molecular ions (radical cations $M^{+\cdot}$) of PAH, and showed that the experimental ionisation energies could be reproduced to within ±0.16 eV by the simple formula:

$$[13] \quad [IE(M)1eV = 11.277 + RE(M) - 1.044 \ln [CSC(M^{+\cdot})]$$

The last term in eq. [13] was assumed by Herndon (30) to correspond to $RE(M^{+\cdot})$; this assumption is examined below, but for now will be assumed to be valid. Herndon (30) has calculated resonance energies, for both M and $M^{+\cdot}$, for most of the PAH studied here. Table 2 gives additional results obtained in the present investigation, including calculations undertaken for comparison with the original work (30).

Thus, it is now possible to test the proposed role of resonance energy, in controlling the energetics and rates of fragmentation reactions of metastable ions of PAH, in a more meaningful way. Unfortunately the results are disappointing. Figure 4 shows the best correlation found, that between the $(M - H)^+$ intensity (from metastable $M^{+\cdot}$) and $RE(M^{+\cdot})$. The data separate (Fig. 4) into isomeric series; all attempts to place these data on a common basis, by

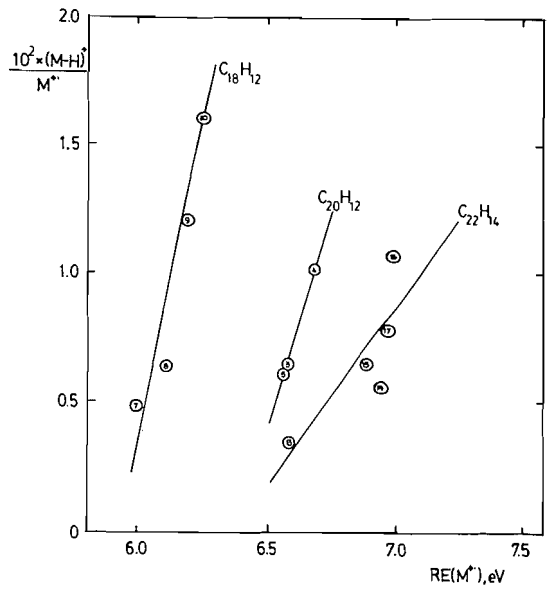

FIG. 4. Correlation between $(M^{+\cdot} \rightarrow (M - H)^+)$ metastable peak intensities (peak heights, *B*/*E*-linked scans) and resonance energies of $M^{+\cdot}$.

normalising RE($M^{+\cdot}$) to the number of $\pi$ electrons, or to the number of carbon–carbon bonds, or aromatic rings etc., produced scatter plots. More surprisingly, the data for $(M - CH_3)^+$ and $(M - C_2H_2)^{+\cdot}$ did not correlate at all with RE($M^{+\cdot}$), with the exception of the rather poor correlations for the $C_{18}H_{12}$ isomeric series shown previously (5). In view of our ignorance of the structures of these fragment ions, it is not possible to investigate *differences* in resonance energies between reactants ($M^{+\cdot}$) and products (e.g. $(M - C_2H_2)^{+\cdot}$) as a more suitable correlating parameter. The significance of the correlations shown in Fig. 4 is not clear, particularly in view of the correlations (of similar quality) with parameters reflecting steric strain (4, 5).

Finally, in this section, we wish to comment briefly on the physical interpretation of the remarkable empirical relation eq. [13]. The value of the constant term (11.277 eV) led Herndon (30) to propose that the ionisation energy of M is simply the *p*-ionisation energy of the $(sp^3;V_4)$ valence state of carbon (11.42 eV (31) or 11.30 eV (32), according to two different estimates), plus the resonance energy of M minus the resonance energy of $M^{+\cdot}$. This picture is not sensibly altered if the $\pi$-ionisation energy of a (tr tr tr $\pi$) valence state of carbon (11.19 eV (32)) is taken for comparison; this latter valence state seems intuitively more applicable to the present purpose than does the $(sp^3;V_4)$ valence state. In this notation, tr denotes a trigonal $sp^2$ hybrid orbital. In any event, a simple energy diagram (Fig. 5) connecting the various states involved shows that if Herndon's interpretation (30) is correct, there must exist some close correlations between various other parameters which are either purely fortuitous or result from relationships existing at a level more fundamental than that of the present discussion.

In fact, there appears to be no need to invoke valence states of C and $C^+$ at all. The ground-state ionisation energy of a carbon atom is 11.264 eV (33), very close to Herndon's (3) least-squares parameter (11.277 eV, eq. [13]); further, the localised bond energies used to define the reference state against which resonance energy is measured invariably involve formation of bonds from ground-state atoms. The localised bond energies used here are *not* the conventional energies of double and single carbon–carbon bonds, but rather the values derived by Dewar (25) for linear conjugated polyenes. These localised bond energies are additive, the $\pi$-contributions to the "single" bonds being absorbed into the empirical bond energies (34). Such "classical" polyenes are thus non-resonating, having only one single unexcited resonance structure, i.e. CSC(M) = 1, in Herndon's notation (26–30). From Fig. 5:

$$[14]\quad \mathrm{IE\ (eV)} = 11.264 + [\mathrm{LBE(M)} - \mathrm{LBE}(M^{+\cdot})] + \mathrm{RE(M)} - \mathrm{RE}(M^{+\cdot})$$

$$[15]\quad 1.044 \ln [\mathrm{CSC}(M^{+\cdot})] = \mathrm{RE}(M^{+\cdot}) - [\mathrm{LBE(M)} - \mathrm{LBE}(M^{+\cdot})]$$

The effect of the difference in localised bond energies (LBE) can presumably be accounted for within the parametrisation of eq. [13], and must presumably track the value of RE($M^{+\cdot}$) at least approximately.

Since eqs. [8] and [13] both hold, a linear relationship must hold between $E_p$(M) and ln [CSC($M^{+\cdot}$)]. Rather than plotting the data according to the combination of eqs. [8] and [13], a relationship analogous to that described by eq. [13] for IE was sought for $E_p$. The excited $\pi^*$ state reached in the transition characterised by $E_p$ is believed to be reasonably well described as a quinonoid structure, e.g. that in biphenyl as investigated theoretically by Hofmann (35). The number of Kekulé structures, for such an excited state, should be very close to half the number of structures for the corresponding radical cation and is exactly so for some of the simpler cases investigated by direct counting. Figure 6 shows [$E_p$(M) − RE(M)] plotted against ln [CSC(M*)], for the 17 PAH studied in the mass spectrometer (5) plus such diverse PAH as benzene, naphthalene, azulene, biphenyl, biphenylene, fluoranthene, and ovalene; also included in Fig. 6 are data for the linear conjugated polyenes containing one to six double bonds inclusive. It is important to note that the $E_p$ values used were those corresponding to the *maxima* in the absorption bands, *not* the 0–0 transition energies. The latter do not correlate well. For example, the 0–0 transition energy for the appropriate $\pi$–$\pi^*$ transition in ethylene ($S_0 \rightarrow S_1$) is about 4.7 eV, compared with about 7.6 eV at the band maximum (36), while this correction is only 0.1–0.2 eV at most for the larger PAH (9) which remain essentially planar in the excited state. A least-squares fit to the data in Fig. 6 gives:

$$[16]\quad E_p\ (\mathrm{eV}) = 7.01(\pm 0.92) + \mathrm{RE(M)} - 1.107(\pm 0.045) \ln [\mathrm{CSC(M^*)}]$$

(standard error = ±0.45 eV; correlation coefficient = −0.94).

This correlation is not as good as that obtained by Herndon (30) for the corresponding ionisation energies (eq. [13]). Nonetheless, the wide range of

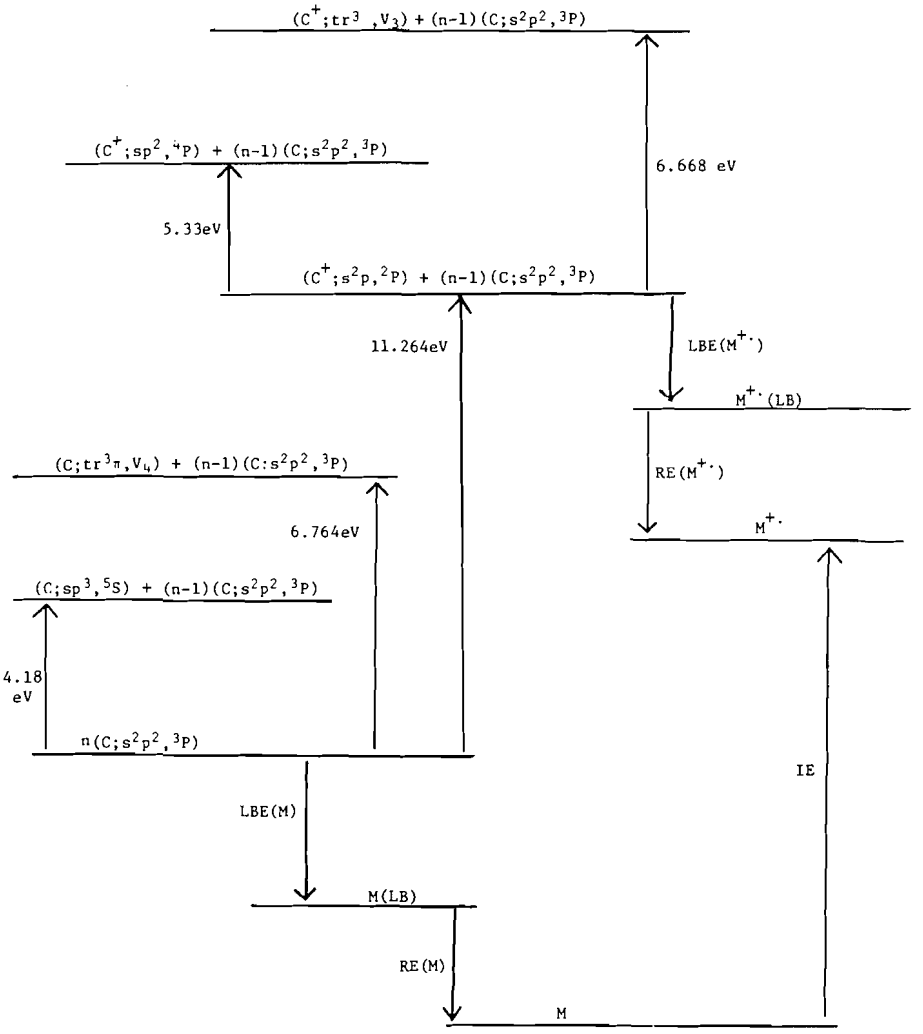

FIG. 5. Energy diagram (not to scale) showing relations between relevant states of C and of $C^+$, for a PAH molecule containing $n$ carbon atoms. (Hydrogen atoms omitted for clarity.) Energy differences between spectroscopically observed states from ref. 33; energies of valence states from ref. 32. Localised bond energies (LBE) for neutral M are values of Dewar (25) for conjugated linear polyenes, and resonance energies (RE) are defined relative to this reference state (see text). (Notation (tr) used for valence state description refers to trigonal $sp^2$ hybrid.)

acyclic and aromatic hydrocarbons (ethylene to ovalene) thus correlated seems remarkable. The use of vertical (band maximum) rather than adiabatic (0–0) transition energies is difficult to justify. A somewhat similar dilemma has been discussed previously (37). At least, eq. [16] permits an estimate of $E_p$ to be made for compounds (e.g. hexacene) which are photo-labile. Figure 1 then gives some indication of predicted metastable ion intensities.

## II. Polychlorinated biphenyls

*(a) Experimental results*

In the case of biphenyls, the absorption band in the ultraviolet, which corresponds ($^1L_a$ excited state) to the $p$-band in fused-ring PAH, is often referred to as the A-band (3). The separate correlations, with the band maximum $\lambda_A$, of $(M - Cl)^+/M^{+\cdot}$ and $(M - 2Cl)^{+\cdot}/M^{+\cdot}$ intensity ratios (metastable transitions, peak heights in linked scans at constant $B/E$ (1)) are shown in Figs. 7 and 8 (note the logarithmic scale in Fig. 7). The raw data have been described previously (1). In both cases, the data for the 3,3′- and 4,4′-dichlorobiphenyls fall well below the best (least-squares) polynomial fit to the data. However, when the $(M - Cl)^+/(M - 2Cl)^{+\cdot}$ ratio is statistically corrected, the overall correlation is greatly improved (Fig. 9). (A tetrachlorobiphenyl is statistically more likely to lose one Cl than is a dichlorobiphenyl, by a factor of 2,

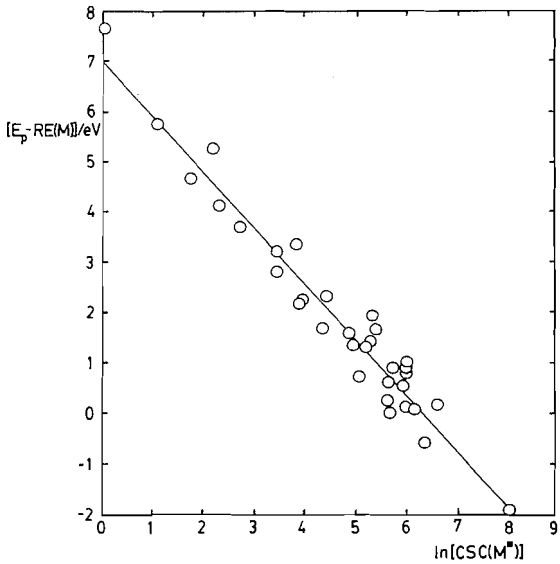

FIG. 6. Plot of ($E_p$ – RE) vs. ln [CSC(M*)], for a series of PAH (lower right of graph) and conjugated linear polyenes (upper left of graph). $E_p$ values correspond to band maxima (3, 9) (vertical transitions). Full line is least-squares fit (eq. [16]).

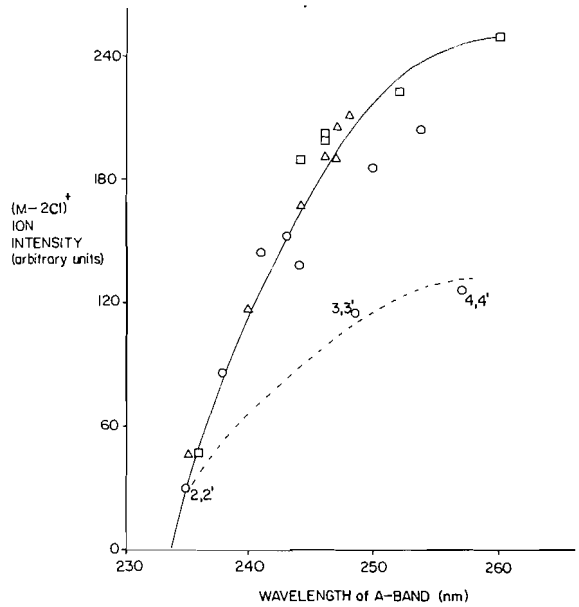

FIG. 8. Correlation of metastable peak heights (normalised to molecular ion = $10^5$), corresponding to $M^{+\cdot} \rightarrow (M - 2Cl)^{+\cdot}$, with $\lambda_A$. Symbols as in Fig. 7.

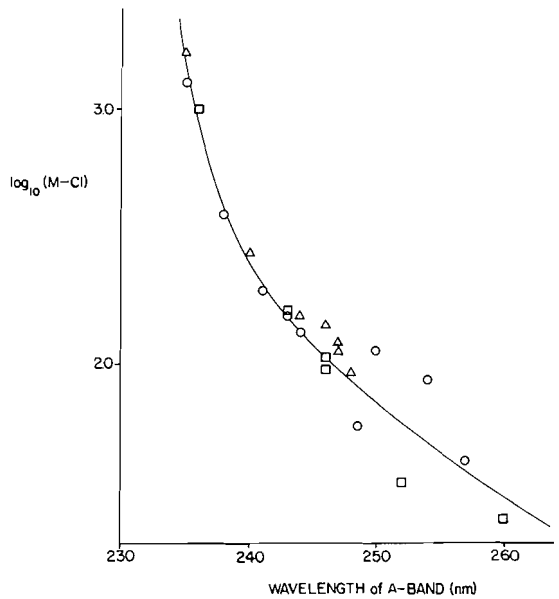

FIG. 7. Correlation of metastable peak heights (normalised to molecular ion = $10^5$), corresponding to $M^{+\cdot} \rightarrow (M - Cl)^+$ for PCB molecular ions, with $\lambda_A$. Circles, dichlorobiphenyls; triangles, trichlorobiphenyls; squares, tetrachlorobiphenyls.

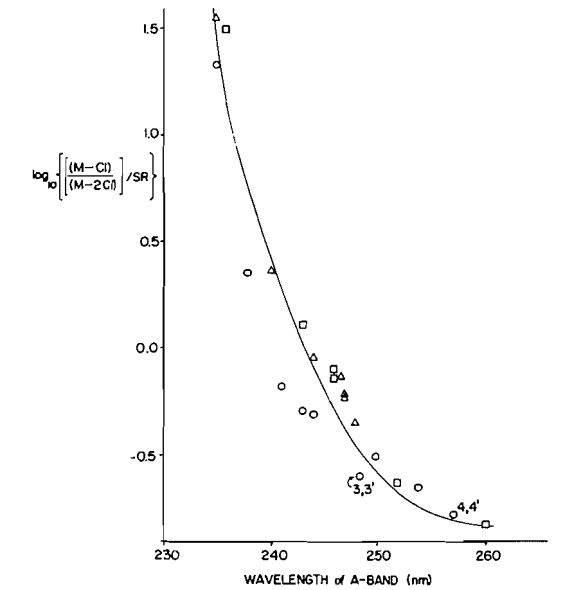

FIG. 9. Logarithmic plot of intensity ratio $(M - Cl)^+/(M - 2Cl)^{+\cdot}$ for metastable ion fragmentations, versus $\lambda_A$. SR is the ratio predicted on the basis of simple statistics (see text).

while the corresponding ratio for loss of two Cl is 6; the statistically predicted ratios (SR in Fig. 9) were calculated this way (1).) Figure 9 is similar to a correlation published previously (1), but plotted on a logarithmic scale in order to spread the data points. It is important to note that the following tetrachlorobiphenyl isomers are omitted from Figs. 7–9, due to the impossibility (1) of observing their A-band maxima: 2,2′,6,6′; 2,2′,5,6′; 2,2′,5,5′; 2,2′,4,5′; 2,2′,3,5′; 2,2′,3,3′. All of these contain three or four chlorine substituents *ortho* to the biphenyl linkage, or else contain two *ortho* chlorines plus at least one *meta* chlorine substituent to

For personal use only.

buttress the steric interaction. (In contrast, the 2,2′,4,4′-isomer gives a reasonably well-defined A-band (1).)

Recently (38), values of kinetic energy release have been measured from metastable peak widths, for expulsion of chlorine from molecular ions of PCBs. In the present work, only the $M^{+\cdot} \rightarrow (M - Cl)^+$ reactions were studied in this way. The technique used was a scan of accelerating voltage (39) yielding a series of peaks corresponding to reactions giving $(M - Cl)^+$ fragment ions containing $^{35}Cl$ only. For all PCBs containing two or more chlorine atoms, there are two such reactions, viz. loss of $^{35}Cl$ from molecular ions containing $^{35}Cl$ only, and loss of $^{37}Cl$ from molecular ions containing just one $^{37}Cl$ atom. The corresponding peaks are not well resolved from one another; an example is shown in Fig. 10. However, by assuming the peaks to be Gaussian (a reasonable approximation in the present case), it was possible to show that the low-energy half of the major peak (loss of $^{35}Cl$) is only marginally perturbed by the minor component. The correction to the major peak height was only about 5% in the case of tetrachlorobiphenyls (the worst case), while that to the half-height was negligible. Thus, by measuring the half-width at half-height, on the low-energy side of the major peak, and applying a small correction, reasonably reliable values of kinetic energy release were obtainable for these first field-free region reactions. The results obtained are shown in Table 3, together with results obtained previously (38). The latter were obtained (38) by a different technique which does not require the correction described above; the discrepancies will be discussed below. In agreement with previous findings (38), some of the peaks had a small foot on one side, corresponding to reactions leading to fragment ions of the selected mass via loss of a neutral fragment of approximate mass 30. This interference was completely absent in about half of the compounds studied, and may be due to some impurity.

Finally, $^{13}C$ nuclear magnetic resonance spectra were obtained for some of the compounds studied. The motivation for this work lay in previous findings (40) that deviations of chemical shifts, from values predicted from additivity relations, correlate with the degree of steric hindrance to free rotation about the biphenyl linkage. It was hoped that this data would provide more subtle information, concerning the lack of planarity in the ground-state molecule, than does the A-band maximum. The spectra were obtained on a Bruker WM250 Fourier transform spectrometer at 62.83 MHz, using full noise proton decoupling, at a temperature of 309 K. The samples were dissolved in chloroform-$d_1$, and chemical shifts were assigned relative to the central resonance of the chloroform-$d_1$ triplet as 77.30 ppm. The results obtained for four PCBs not previously investigated (40) are

shown in Table 4, together with values predicted from additivity relationships given previously (40). The assignments shown in Table 4 were made on the basis of relative values of observed chemical shifts compared with the calculated values, and on the basis of relative intensities where appropriate. Thus, for example, in 2,3-dichlorobiphenyl, C2 is the quaternary carbon furthest from a proton, and should thus correspond to the weakest signal observed. This is in accord with the chemical shift assignment.

*(b) Phenomenological interpretation of observed correlation*

Unfortunately, in the case of the PCBs, there is no information available concerning ionisation and appearance energies. The origins of the observed correlations (Figs. 7–9) are thus obscure, and the following discussion correspondingly more speculative than in the PAH case.

*(c) Theoretical considerations*

It is *not* assumed, in what follows, that the ionisation energy is the crucial parameter which correlates with both the molecular $^1L_a$ transition energies and the fragmentation rates of molecular ions of PCBs. In the PCB case, the phenomenon appears to be associated with steric interactions near the biphenyl linkage, and the best guess as to the key parameter turns out to be the internal energy distribution, $P(E)$.

It is possible to obtain some insight into this problem from the work of Wagner and Scheve (41), who constructed a potential energy diagram which accounted semi-quantitatively for the effects of *ortho*-chlorine substitution on singlet–triplet transitions of biphenyl. Based upon absorption and emission spectra, and their quenching characteristics, as well as on electron paramagnetic resonance spectra of the excited triplets, it was concluded (41) that the electronically excited state is planar, in contrast with the twisted ground-state equilibrium configuration for the gaseous molecule. Figure 11 has been drawn as a qualitative extension of the ideas of Wagner and Scheve (41) to include the molecular ion. The large increases in absorption transition energies, with increased *ortho* substitution, are due (41) to large increases in ground-state twisting and to the steep slopes of the excited state curves at larger values of the inter-ring dihedral angle. For present purposes, it is necessary to assume that the potential energy curve for the electronic ground state of the molecular ion is qualitatively similar to that for the relevant neutral excited state, as indicated in Fig. 11; this assumption is now discussed further.

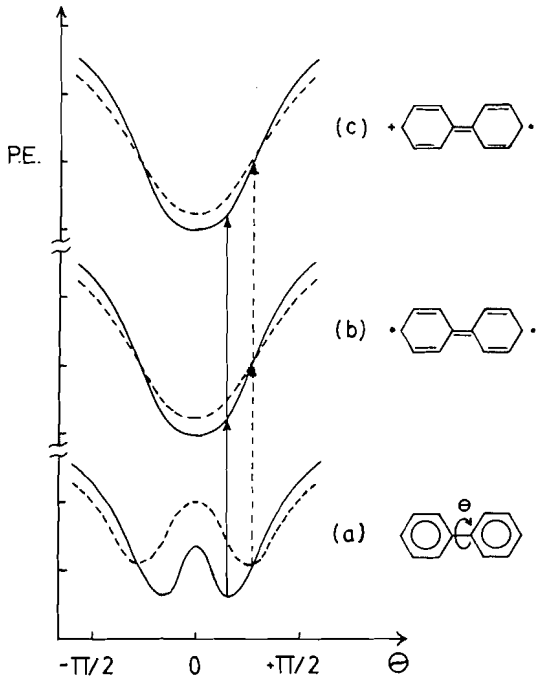

FIG. 11. Postulated form of potential energy, as a function of dihedral angle θ between the rings, for biphenyl (drawn after work of Wagner and Scheve (40)). Solid curves are for a biphenyl with little steric interaction around the biphenyl linkage, and dashed curves are for a case with appreciable interaction. (*a*) Curves for ground-state neutral molecules; (*b*) curves for $^1L_a$ excited states of neutral molecules; (*c*) curves for molecular ions.

The nature of the molecular orbitals in biphenyl have been investigated by Imamura and Hofmann (35), using a self-consistent field approach (π-electrons only). For a biphenyl molecule constrained to planarity, the molecular orbitals may be classified according to specified (35) symmetry properties with respect to two planes, one containing the long biphenyl axis and one perpendicular to it. A correlation diagram was constructed (35) to connect the levels of a planar biphenyl molecule with those of a molecule in which the planes of the rings are at 90° to one another. The four possible symmetries which arise for energy levels of planar biphenyl, along with their associated tendencies with respect to planarity or twisting, are: SA (tends to induce twisting), AS or AA (energy essentially independent of twist angle), and SS (tends to induce coplanarity of rings). The highest occupied level in ground-state biphenyl is SA, while the lowest unoccupied level is SS. While this description strictly applies to only planar biphenyl, the correlation diagram (35) indicates that at the equilibrium twist angle of about 40°, the highest occupied and lowest unoccupied levels do indeed correlate with these levels of the planar molecule.

The lowest excited state ($^1L_a$ in Platt's notation (9)) is due to the SA → SS excitation, and should thus (see above) induce a greater degree of planarity in the excited state. Calculations (35) indicate that the planar quinonoid valence bond structure for the excited state, shown in Fig. 11, is a reasonable description. For example, the calculated π bond order for the biphenyl bond is 0.26 in the ground state and 0.48 in the excited state (35). The molecular ion was not discussed (35), but removal of one electron from the highest occupied level (SA in planar biphenyl) should reduce the tendency towards twisting, though possibly to a lesser extent than in the neutral excited state in which the electron is excited to the SS level. However, an INDO/1 calculation (42) for planar geometry (all valence electrons included) has confirmed the essential conclusions (35) for the neutral ground state, and supports the planar quinonoid structure, with largely localised charge and spin densities, for the molecular ion as indicated in Fig. 11. For example, the π-bond order of the biphenyl bond is calculated (42) to be 0.49 in the molecular ion, while the spin densities at the *para* carbons are +0.45, close to theoretical maximum values. A more complete study of the geometries of neutral and ionised biphenyl is being undertaken (42), but these preliminary results do provide some support for the qualitative features of Fig. 11.

Thus the increasing degree of fragmentation of metastable molecular ions of PCBs, with increasing extent of chlorine substitution *ortho* to the biphenyl linkage, may be interpreted (Fig. 11) in terms of increasing the average twist angle in the ground state. This probably involves increasing both the twist angle at which a potential energy minimum occurs, and also increasing the barrier to internal rotation so that the potential minima represent increasingly preferred orientations. The present intent, in studying the $^{13}C$ nmr spectra of these compounds, was to obtain some insight into these rotational barriers. However, mere deviations from chemical shifts predicted from additivity relations (see ref. 40 and Table 4) were found to give very poor correlations with any of the other parameters, even for C-1 and C-1′, which are known (40) to display the largest of such deviations. In fact, the best available information on rotational barriers in PCBs, from nmr studies, appears to come from temperature dependences (40) of proton chemical shifts over the range 160 K to 340 K. These data (40) indicate rotational barriers of about 4–16 kJ $mol^{-1}$ for PCBs with no *ortho* substituents,

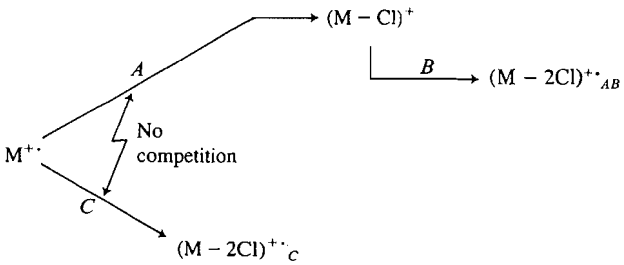
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

and of about 35 kJ $mol^{-1}$ or less for PCBs with at least one *ortho* substituent on each ring (40). PCBs with chlorine substituents on all four *ortho* positions displayed (40) no temperature dependence of proton chemical shift, and in the experimental temperature range (40) in solution are probably effectively locked into one conformation. If these solution data are transferable to the situation in the ion source (isolated molecules at ca. 500 K), they are of the correct magnitude to support the above proposal that increasing the degree of *ortho* substitution increases the internal rotational barrier, and thus the equilibrium fraction of molecules at or near the potential minima. Together with the postulated steeply sloping potential curves for the molecular ions (Fig. 11), this accounts, via appropriate change in $P(E)$, for the increased tendency to fragmentation actually observed for the metastable molecular ions of PCBs. (It should also be added that chlorine substitution on benzene is known (43) to split and shift the lowest band in the photoelectron spectra, so the complete picture is more complex.)

However, the correlations observed for the PCBs (Figs. 7–9) are more subtle than this, since the $(M - 2Cl)^{+\cdot}$ intensities *decrease* with increasing resistance to internal rotation, as indicated by the uv transition energy. The (generally more intense) $(M - Cl)^+$ fragment *does* increase in intensity, but some attempt seems necessary to examine the $(M - 2Cl)^+/(M - Cl)^{+\cdot}$ intensity ratio (Fig. 9). The study of kinetic energy release (Table 3) was undertaken as an extension of earlier work (38) aimed at elucidating the relationship between the mechanisms leading to these two fragment ions.

Comparison (Table 3) of $T$ values for the symmetrically substituted dichlorobiphenyls shows that the present values are generally higher than, but parallel reasonably well, values obtained previously (38). This is in accord with expectations based on the conclusion (38) that $T$ is here dominated by contributions from the kinetic shift $\varepsilon^{\neq}$. The present experiments involved appreciably shorter ion lifetimes, and thus presumably higher average energies for the fragmenting ions, than did the previous work (38). Much more disconcerting are the values obtained here for 3,3′,5,5′- and 3,3′,4,4′-tetrachlorobiphenyls. The MIKES technique used previously (38) is inherently more reliable than that available in the present work, but uncertainties in the correction applied (see above) are far too small to account for the observed discrepancies (Table 3). It was feared that we may have confused tetrachlorobiphenyl isomers while running the experiments, and obtained a different sample of the 3,3′,4,4′-isomer from an independent source. (We are indebted to Dr. N. J. Bunce for this sample.) The results obtained using this second sample were indistinguishable from those obtained using the commercial sample (Table 3). We thus cannot account for these discrepancies. (Discrepancies of a factor of about 3 have been observed previously (44) between $T$ values obtained for fragmentations occurring in the second field-free region of a ZAB-2F instrument, and values for first field-free-region reactions (45).) However, the present results do cast further doubt on the tentative categorisation into classes with and without multiple *meta*-chlorine substituents (38). Thus, the present data do *not* support the suggestion (38) that PCBs with several *meta*-chlorine substituents are necessarily associated with larger $T$ values. Indeed, there appears to be little useful information in Table 3. This is a disappointingly negative conclusion, but seems inescapable.

In fact, the most clearcut conclusions reached in the previous study (38) were based upon thermochemical arguments. In particular, to account for the observation that the $(M - Cl)^+$ fragment is generally (but not invariably (1, 46)) less intense than the $(M - 2Cl)^{+\cdot}$ fragment in fragmentations of metastable molecular ions of PCBs, while the situation is reversed for conventional mass spectra, it was necessary (38) to postulate two distinct mechanisms for formation of $(M - 2Cl)^{+\cdot}$ ions. One of these mechanisms must be a low-energy process which does *not* compete with formation of $(M - Cl)^+$ ions, while the other is a higher energy process (38). The simplest mechanism consistent with the available information appears to be the following:



Only those molecular ions with large amounts of internal energy (primarily those fragmenting in the ion source) will produce $(M - Cl)^+$ ions with sufficient energy to proceed via process $B$ to give $(M - 2Cl)^{+\cdot}_{AB}$ ions. These fragment ions need not have the same structure as those formed in the low-energy path $C$. The postulated situation is summarised in Fig. 12, where it is assumed that increase in steric interaction near the biphenyl

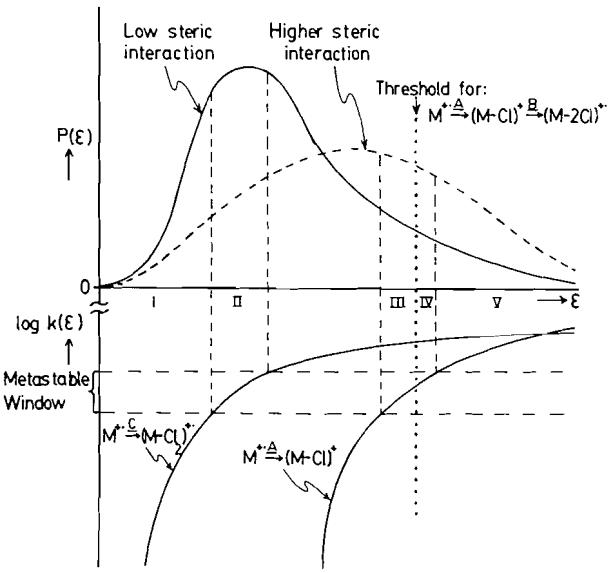


FIG. 12. Schematic illustration of effect of steric effects due to chlorine substitution *ortho* to biphenyl linkage of PCBs. The internal energy distributions $P(\varepsilon)$ are assumed normalised. Reactions *A* and *C* are assumed to not compete. A specified $k(\varepsilon)$ value is assumed, for simplicity, to define one unique ion lifetime (see also Fig. 2). Regions *I–V* denote the following: *I*, molecular ions; *II*, metastable ions giving $(M - 2Cl)^{+\cdot}{}_{C}$; *III*, metastable ions giving $(M - Cl)^{+}$; *IV*, metastable ions giving $(M - 2Cl)^{+\cdot}{}_{AB}$; *V*, ions fragmenting in ion source.

linkage shifts the $P(\varepsilon)$ distributions to higher energies, as discussed with reference to Fig. 11, but does not markedly alter the nature of the rate constants $k(\varepsilon)$. This is almost certainly an oversimplification, but no information on $k(\varepsilon)$ is available.

For simplicity, only one $P(\varepsilon)$ curve has been drawn for each of a "high" and "low" degree of steric interaction. (In fact, if processes *A* and *C* do not compete, there should be two $P(\varepsilon)$ curves for each case.) To account for the *decrease* in $(M - 2Cl)^{+\cdot}{}_{C}$ with increase in steric interaction (decrease in $\lambda_A$, Fig. 8), Region II (Fig. 12) must be on the low-energy side of the crossover point of the two $P(\varepsilon)$ curves. For similar reasons (Fig. 7), Region III must be to the high-energy side of this point. The $k(\varepsilon)$ curve for process *C* must be at lower energy, as described previously (38), and must therefore not compete directly with process *A*. Since at least some PCBs exhibit process *B* in metastable ion spectra (38, 46), the threshold for this process must be close to the region appropriate to process *A* for metastable ions.

Figure 12 represents an extension of earlier ideas (38), now including the observations summarised in Figs. 7 and 8 in the light of the discussion of Fig. 11. It is not yet clear, however, how to account for the remarkable success of Fig. 9 in correlating the $(M - 2Cl)^{+\cdot}/(M - Cl)^{+}$ ratio. Comparisons of ionisation efficiency curves for $M^{+\cdot}$, $(M - Cl)^{+}$, and $(M - 2Cl)^{+\cdot}$ with those for metastable transitions connecting these species could be informative. None of the above addresses itself, in any case, to more detailed mechanistic questions such as the extent of chlorine atom scrambling (46–48), or the involvement of 5-membered ring chloronium ion intermediates (2).

## Conclusions

The present work represents an attempt to understand some unexpected correlations found to exist between spectroscopic (uv) properties of neutral molecules and unimolecular fragmentation rates of their radical cations in the mass spectrometer. The work is necessarily speculative in part, but it has been possible to account for the existence, if not the precise form, of the correlations in the context of modern theories of physical organic chemistry. In the case of the fused-ring polycyclic aromatic hydrocarbons (PAH), it is clear that the crucial parameter which links the optical absorption energy to the ion fragmentation rate is the ionisation energy. The separation of the PAH correlation into two distinct well-defined families may tentatively be ascribed to a difference, in appearance energies for the ion fragments, between the linear acenes (plus two other species) and all the other PAHs studied. These conclusions appear to be consistent with modern theories of the π-electron systems in aromatic hydrocarbons.

In the case of the polychlorobiphenyls (PCBs), the conclusions reached are more tentative due to a lack of subsidiary information. However, it is possible to account for the existence of the correlations by analogy with the known photochemistry and photophysics of PCBs. The crucial feature here is the relative geometries of the ground and excited states; the ground state of the molecular ion of a PCB is expected to have a geometry similar to that of the neutral excited state involved in the photochemistry, and this has been confirmed by an INDO/1 calculation in the present work. These geometry differences manifest themselves in parallel trends in both the uv absorption energy and in the energy deposition function for the molecular ion.

The general conclusion is that these empirical correlations, which at first seemed to us sufficiently strange and unexpected as to be probably spurious coincidences, can be satisfactorily accommodated within accepted ideas of physical organic chemistry and unimolecular fragmentation theory.

# Isotope effects in nucleophilic substitution reactions. IV. The effect of changing a substituent at the α carbon on the structure of $S_N2$ transition states

KENNETH CHARLES WESTAWAY AND ZBIGNIEW WASZCZYLO
*Chemistry Department, Laurentian University, Sudbury, Ont., Canada P3E 2C6*

Received July 28, 1981[1]

KENNETH CHARLES WESTAWAY and ZBIGNIEW WASZCZYLO. Can. J. Chem. **60**, 2500 (1982).

Kinetic studies, secondary α-deuterium kinetic isotope effects, primary chlorine kinetic isotope effects (1), Hammett ρ values determined by changing the substituent in the nucleophile, and activation parameters have been used to determine the detailed (relative) structures of the transition states for the $S_N2$ reactions between *para*-substituted benzyl chlorides and thiophenoxide ion. A rationale for the U-shaped Hammett ρ plots observed when *para*-substituted benzyl compounds react with negatively charged nucleophiles is also presented.

KENNETH CHARLES WESTAWAY et ZBIGNIEW WASZCZYLO. Can. J. Chem. **60**, 2500 (1982).

On a utilisé des études cinétiques, des données relatives aux effets isotopiques cinétiques secondaires du deutérium en α et aux effets isotopiques cinétiques primaires du chlore (1), des valeurs ρ de Hammett déterminés en changeant les substituants du nucléophile et des paramètres d'activation pour déterminer les structures détaillées (relatives) des états de transition des réactions $S_N2$ entre les chlorures de benzyles substitués en position *para* et l'ion thiophénate. On présente également une explication raisonnable pour la forme en U des courbes de ρ de Hammett observées lorsque les composés benzyliques substitués en position *para* réagissent avec les nucléophiles chargés négativement.

## Introduction

Determining the effect of substituents on the structure of $S_N2$ transition states has been of interest for several years (1–6). Several different techniques, such as kinetic studies (2, 3), solvent effects (4), thermodynamic properties (4, 7), and kinetic isotope effects (1, 5, 6, 8–10), have been used in an attempt to determine how substituents affect transition state structure. In spite of these efforts, the influence of substituents is not understood. The major reason for this is that the structures of the transition states have not been determined in enough detail to indicate how the substituents alter all of the transition state bonds. In a recent study of substituent effects on $S_N2$ transition states, Westaway and Ali (6) showed that detailed transition state structures can be obtained from a combination of primary leaving group kinetic isotope effects, secondary α-deuterium kinetic isotope effects, and Hammett ρ values. The same criterion and others have been applied to the $S_N2$ reactions between *para*-substituted benzyl chlorides and thiophenoxide ion to determine how substituents at the α carbon affect the structure of an $S_N2$ transition state.

This series of reactions was studied for another reason. The reactions between *para*-substituted benzyl compounds and negatively charged nucleophiles invariably give curved (U-shaped) Hammett ρ plots with the minimum at the unsubstituted compound, i.e., the substrates, with electron donating substituents such as methoxy and methyl or electron withdrawing substituents such as chloro and nitro, react faster than the unsubstituted compound (2). This behaviour is observed regardless of the structure of the substrate, the leaving group, the solvent, or the nucleophile (11–18), i.e., it is a general phenomenon that is associated with the change in substituent. Although several explanations have been suggested for this unusual behaviour, the reason for the curvature in the Hammett plot is not known. The detailed knowledge of the $S_N2$ transition states for this series of reactions has allowed the authors to provide a rationale for the curved Hammett ρ plots that are observed for the reactions between negatively charged nucleophiles and *para*-substituted benzyl compounds.

## Results and discussion

Both of the objectives of this study, i.e., to determine (*i*) what changes occur in the structure of an $S_N2$ transition state when a substituent at the α carbon is altered, and (*ii*) why U-shaped Hammett plots are observed in the $S_N2$ reactions of benzyl compounds with negatively charged nucleophiles, were achieved by measuring the secondary α-deuterium kinetic isotope effects, the Hammett ρ values obtained by changing the substituent in the nucleophile, and the activation parameters for the reactions between *para*-substituted thiophenoxide ions and *para*-substituted benzyl chlorides in 0.250

*Kinetic studies*

The reactions between *para*-substituted thiophenoxide ions and *para*-substituted benzyl chlorides in 0.250 *M* lithium methoxide in methanol were followed by measuring the increase in the absorbance in a Beckman D.U. spectrophotometer. The second order rate constants measured at 0°C, 20°C, and 30°C are given in Table 1. The rate constants measured by the uv technique are in excellent agreement with those determined by Grimsrud (1) using a titrimetric method. With one exception (Y = $CH_3O$), the kinetic studies at 20°C produced good second order plots and gas chromatographic analyses of the reaction mixtures showed that the reactions were clean.

In the *para*-methoxybenzyl chloride reactions, however, slightly curved kinetic plots were observed at 20°C. The analysis of the products of the reaction revealed that a competing solvolysis of the substrate occurred, eq. [2]. A gas chromatographic analysis of the products from several different reactions showed that the solvolysis product, *para*-methoxybenzylmethyl ether, could be reduced to three percent of the product when the reaction was carried out at 0°C with a fivefold excess of the thiophenoxide ion, Table 2. Gas chromatographic analyses of reaction products from the reactions of *p*-methoxythiophenoxide ion and of *p*-chlorothiophenoxide ion with *p*-methoxybenzyl chloride also showed that the solvolysis product was reduced to 3 ± 1% of the product when the reactions were carried out at 0°C with a fivefold excess of thiophenoxide ion.

[a] These results are from 3 or 4 different analyses.

benzyl chloride reaction could not be determined gas chromatographically because the $S_N2$ product could not be separated from the 4,4′-ditolyldisulfide (the oxidation product of the unreacted *para*-methylthiophenoxide ion) which formed during the work-up of the product. Although the product could not be analyzed accurately, the area of the gas chromatographic peak associated with the solvolytic product was comparable to those observed in the reactions with the other nucleophiles. In addition, calculations of the product composition based on the measured second order rate constant and the first order rate constant ($k_1 = 8 \times 10^{-6}\ s^{-1}$, determined from a computer analysis of the other reactions) indicated that 2.8% of the product would be *para*-methoxybenzylmethyl ether.

These conditions were recognized as satisfactory for kinetic studies since an error in the experimentally determined secondary α-deuterium kinetic isotope effect and the Hammett ρ values caused by the small amount of solvolysis would be too small to be detected. Thus, the kinetic isotope effects, Hammett ρ values, and activation parameters measured for the series of reactions between the *para*-substituted thiophenoxide ions and *para*-substituted benzyl chlorides are clearly those associated with the $S_N$ reaction shown in eq. [1]. This ensures that any conclusions based on these results will be pertinent to the reactions under investigation.

*Proof of mechanism*

The kinetic studies, Table 1, provide strong evidence that the $S_N$ reactions between *para*-substituted thiophenoxide ions and *para*-substituted benzyl chlorides are $S_N2$ processes. The carbocation $S_N$ mechanisms such as the $S_N1$ ($S_N1$ Lim) mechanism ($k_1$ slow) and the other mechanisms where the $k_2$ or the $k_3$ step is the slow step of the reaction, eq. [3], can be ruled out because all of the reactions display clean second order kinetics and are first order in the substrate and in the nucleophile. This indicates that the nucleophile is involved in the transition state of the rate-determining step of the reaction. An additional indication that the S---$C_\alpha$ bond is forming in the transition state of these reactions is provided by the small Hammett ρ values found for all of the reactions in this study, Table 3. The Hammett ρ value for the protonation reactions of *para*-substituted thiophenoxide ions in methanol at 20°C is −1.99 (2). Thus, the magnitude of the ρ value should be approximately −2.0 for any reaction where the charge on sulfur has been totally destroyed in the transition state of the rate-determining step of the reaction. The small negative Hammett ρ values measured for the benzyl chloride reactions indicate that the change in charge on the sulfur atom is far from complete (S—$C_\alpha$ bond formation is only partially complete) in the transition state of the rate-determining step of these reactions. Obviously, this eliminates a carbocation mechanism where the $k_1$, the $k_2$, or the $k_3$ step is rate determining.

[3] $$RCl \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} R^+Cl^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} R^+\|Cl^- \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} R^+ + Cl^-$$
$$\begin{array}{ccc} ArS^- \downarrow k_4 & ArS^- \downarrow k_5 & ArS^- \downarrow k_6 \\ RSAr & RSAr & RSAr \end{array}$$

The $S_N2C^+$ type mechanism (with $k_4$ and/or $k_5$ and/or $k_6$ slow, eq. [3]) can also be eliminated. These mechanisms involve a fast, reversible rupture of the C—Cl bond followed by a rate-

determining step in which the ion pair or the carbocation reacts with the nucleophile. A mechanism in which the C—Cl bond ruptured in a fast and reversible step would display a small *equilibrium* chlorine isotope effect. Two different investigators have concluded that an equilibrium chlorine isotope effect would be 1.0037 and 1.0057 (19, 20). The much larger chlorine kinetic isotope effects of 1.00983 ± 0.00029 found by Grimsrud (1) for the reactions of thiophenoxide ion with *para*-substituted benzyl chlorides in the solvent system and at the temperature used in this investigation, show that the C—Cl bond is also breaking in the rate-determining step and not prior to it. These isotope effects clearly rule out all of the $S_N2C^+$ mechanisms.

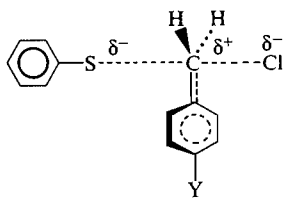
In conclusion, the large chlorine kinetic isotope effects, small Hammett ρ values, and good second order kinetics exclude all of the carbocation $S_N$ mechanisms and indicate that all of the reactions between the *para*-substituted thiophenoxide ions and *para*-substituted benzyl chlorides proceed via an $S_N2$ mechanism.[2] Thus, this system of reactions can be used to determine how different substituents at the α carbon affect the structure of the $S_N2$ transition state and to determine why U-shaped Hammett ρ plots are observed for these $S_N2$ reactions.

### Determination of transition state structures

In describing how changes in the *para* substituent affect the transition state structure for this series of $S_N2$ reactions, it is necessary to determine how these structural changes affect the bonding between the α carbon and the leaving group (chloride ion), the α carbon and the incoming nucleophile (sulfur of the thiophenoxide ion), as well as any changes in bonding between the α carbon and the benzene ring.

*Chlorine kinetic isotope effects*

One widely used method of determining the length of the α-carbon – leaving group bond in the transition state is to measure the leaving group heavy atom kinetic isotope effect. In one study, Grimsrud measured the leaving group chlorine kinetic isotope effects for the reactions of interest, i.e., the $S_N2$ reactions between thiophenoxide ion and *para*-substituted benzyl chlorides in 0.250 molar lithium methoxide in methanol at 20°C (1). The chlorine kinetic isotope effects were useful in this study because they indicated how the α-carbon – chlorine transition state bond was affected by a change in the *para*-substituent on the benzene ring. The chlorine kinetic isotope effects measured by Grimsrud are given in Table 4.



Although the standard deviation on the average kinetic isotope effect for this series of reactions exceeds the error ascribed to the individual kinetic isotope effects, the differences in the isotope effect caused by a change in the *para*-substituent are small and random. The simplest explanation is that the chlorine kinetic isotope effects are the same, or virtually the same, for all of the $S_N2$ transition states.

The interpretation of the effectively constant chlorine isotope effects observed for this series of reactions is not simple, however. Extensive theoretical calculations by Saunders (21) and Sims *et al.* (22) have shown that the magnitude of the leaving group chlorine isotope effect increases as the amount of C---Cl bond rupture increases (the bond order decreases) in the transition state of the rate-determining step. Thus, a larger chlorine isotope effect would indicate a longer C---Cl bond in the transition state of an $S_N2$ reaction. The almost constant chlorine isotope effects observed by Grimsrud suggest, therefore, that the C---Cl transition state bond length is not changed significantly when the *para*-substituent on the benzene ring is altered, i.e., that the C---Cl transition state bond has the same, or nearly the same, length for all the substituents.

TABLE 4. Chlorine kinetic isotope effects for the $S_N2$ reactions of thiophenoxide ion with *para*-substituted benzyl chlorides in 0.250 *M* lithium methoxide in methanol at 20°C

| *para*-Substituent "Y" | $k^{35}/k^{37}$[a] |
|---|---|
| $CH_3O$ | 1.01012 |
| $CH_3$ | 1.00963 |
| H | 1.00976 |
| Cl | 1.01013 |
| $NO_2$ | 1.00950 |
| | Average = 1.00983±0.00029[b] |

[a]The error on the individual kinetic isotope effects is ±0.00015.
[b]Standard deviation for the average kinetic isotope effect.

[2]It is worth noting that the second order kinetics, the small Hammett ρ value of −0.961, the small secondary α-deuterium kinetic isotope effect of 1.039, and the large chlorine kinetic isotope effect of 1.00950 clearly show that the *para*-nitrobenzyl chloride does not react via an electron transfer mechanism.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Although this explanation of the effectively constant isotope effects is the most obvious and straightforward, it is known that several other factors, in addition to the carbon–chlorine transition state bond order, affect the magnitude of a chlorine leaving group kinetic isotope effect. Theoretical calculations (28) indicate that (*i*) the force constant of the reacting (C—Cl) ground state bond, (*ii*) the nucleophile – α carbon transition state bond order, (*iii*) the amount of conjugation (π bond order) between the benzene ring and the α carbon in the transition state, (*iv*) changes in the reaction coordinate motion, i.e., from displacement by the nucleophile to displacement by the aryl group, and (*v*) solvation of the developing chloride ion all affect the magnitude of the isotope effect.

Although these effects influence the magnitude of the chlorine leaving group kinetic isotope effects in $S_N2$ reactions, fairly sophisticated calculations show that they are small with respect to the effect of a change in the C—Cl transition state bond order (28). For example, (*i*) the vibrational frequency of the C—Cl ground state bond decreases gradually from 680 $cm^{-1}$ in *para*-methoxybenzyl chloride to 625 $cm^{-1}$ for the *para*-nitrobenzyl chloride.[3] This means that the chlorine isotope effect would be slightly larger (the theoretical maximum isotope effect only changes by 0.0009 over the series) in the *para*-methoxybenzyl chloride reaction (29) (*vide infra*); (*ii*) a decrease in the nucleophile – α carbon transition state bond order leads to a slight decrease in the chlorine isotope effect (28). For example, decreasing the nucleophile – α carbon bond order from 1.00 to 0.40 only decreases the isotope effect by 0.001. Thus, a slightly smaller chlorine isotope effect would be expected for the *para*-methoxybenzyl chloride reaction (*vide infra*); (*iii*) increasing the amount of conjugation in the transition state causes a very slight increase in the isotope effect. For example, changing from 0% to 100% conjugation in a very loose transition state increases the isotope effect by less than 0.001 (28). Since the change in transition state π bond order is fairly small for all of the reactions in this series (*vide infra*), the changes in conjugation would have an extremely small effect on the isotope effect. A slightly larger isotope effect would be expected in the *para*-methoxybenzyl chloride reaction, however; (*iv*) changing the reaction coordinate motion from displacement by the nucleophile to displacement by the aryl group increases the isotope effect. In fact, increasing the contribution of displacement by the aryl group from 40% to 70% of the reaction coordinate motion can increase the isotope effect by as much as 0.001. In fact, this effect would be very small in this reaction series because very large changes in the reaction coordinate motion have almost no effect on the magnitude of the isotope effect when the C—Cl bond order is small in the transition state (28) (*vide infra*); (*v*) the solvation effect, i.e., the change in the solvation energy of the developing chloride ion, is thought to have the greatest effect on the magnitude of a chlorine kinetic isotope effect. If this were important, decreases in the C—Cl transition state bond order would not lead to a larger isotope effect. This would occur because the increased vibrational energy from the hydrogen bonding between the solvent, methanol, and the developing chloride ion would compensate for the loss of bonding in extending the C---Cl transition state bond. This means that the total bonding to the chloride ion and thus the magnitude of the isotope effect would not change when the C---Cl bond is more completely ruptured in the transition state. This idea, which was originally suggested by Thornton (23), has been substantiated by theoretical calculations by Sims and co-workers (24, 25). Sims' calculations show that strong solvation of the developing chloride ion in the transition state not only lowers the magnitude of the chlorine isotope effect, but also suggests that the chlorine kinetic isotope effect may be levelled in reactions with large amounts of C---Cl bond rupture in the transition state.

This levelling effect, although theoretically possible, seems unlikely in light of experimental results which show that very large *leaving group* chlorine kinetic isotope effects do not change significantly even with drastic changes in solvent, i.e., in cases where large changes in the solvation of the chloride ion would be expected. For example, changing the solvent from DMF where there is no hydrogen bonding to 97% aqueous methanol where hydrogen bonding should be important, only changes the chlorine isotope effects by an average of 0.0012 ± 0.0003 in the $S_N2$ reactions of *para*-substituted benzyl chlorides with 4-nitrophenoxide ion, 4-cyanophenoxide ion, or with azide ion (25). Moreover, changing the non-hydrogen bonding solvents, DMF or DMSO, to methanol in the $S_N2$ reaction between *n*-butyl chloride and thiophenoxide ion only changes the chlorine isotope effect by between 0.0002 and 0.0003 (20), i.e., by slightly more than the experimental error in the individual isotope effect. If the transition state structure of these reactions is not altered by a change in solvent as Westaway suggests (27), solvation by hydrogen bonding has a very small effect on the magnitude of the chlorine isotope effect even in reactions where

[3]J. W. Taylor, University of Wisconsin. Private communication.

For personal use only.

the C---Cl bond is mainly broken in the transition state and hydrogen bonding to the developing chloride ion would be expected to be important. These results suggest that hydrogen bonding to solvent does not influence the chlorine isotope effect in C---Cl bond breaking reactions significantly and it seems unlikely therefore, that the constant isotope effects are the effect of levelling, i.e., of changes in the solvation of the developing chloride ion.

Thus, although the magnitude of chlorine leaving group kinetic isotope effects can be affected by changes in the nucleophile – α carbon and benzene ring – α carbon (π) transition state bond orders, changes in the reaction coordinate motion, and changes in solvation of the developing chloride ion, theoretical calculations by Brubaker (28), and the solvent effects on *leaving group* chlorine kinetic isotope effects indicate that these effects are small with respect to those resulting from changes in the $C_\alpha$—Cl transition state bond order. Moreover, three of the five effects (*i*, *iv*, and *v*) should have an extremely small influence on the magnitudes of the isotope effects for this series of reactions and the other two effects (*ii* and *iii*) work in opposite directions. This means that the magnitude of the chlorine leaving group isotope effect is almost completely determined by the $C_\alpha$---Cl transition state bond order.

Finally, the chlorine leaving group kinetic isotope effects in other $S_N2$ reactions of *para*-substituted benzyl chlorides decrease when a more electron withdrawing substituent is placed on the benzene ring (*vide infra*). This shows that these isotope effects can respond to changes in transition state structure in $S_N2$ reactions. Thus, the constant chlorine isotope effects in the *para*-substituted benzyl chloride – thiophenoxide ion $S_N2$ reactions must indicate that the $C_\alpha$—Cl transition state bond order is not sensitive to changes in substituent and the best explanation of the effectively constant chlorine isotope effects found in the *para*-substituted benzyl chloride – thiophenoxide ion reaction series is that the $C_\alpha$—Cl bond is equally broken in all of the transition states of these reactions.

Finally, it is worth noting that the chlorine isotope effects are large. They are approximately 88% of the theoretical maximum chlorine isotope effect (29) and indicate that the $C_\alpha$---Cl transition state bonds are very long for all the *para*-substituted benzyl chlorides.

*Secondary α-deuterium kinetic isotope effects*

Once the substituent effect on the $C_\alpha$---Cl transition state bond had been determined, it was necessary to determine how the S---C transition state bond changes when the substituent on the benzyl chloride is altered. Westaway and Ali have recently shown that the magnitude of the secondary α-deuterium kinetic isotope effect can be related to the nucleophile – leaving group transition state distance in a closely related series of reactions (6). This is possible because the magnitude of secondary α-deuterium kinetic isotope effects in $S_N2$ reactions is primarily determined by the differences in the energy of the $C_\alpha$—H(D) out-of-plane bending vibrations in the initial and transition states (31, 34, 35). Since the point of structural change is four bonds away from the $C_\alpha$—H(D) bond, the frequencies of the $C_\alpha$—H(D) out-of-plane bending vibrations are the same (1450 ± 5 $cm^{-1}$) for all the *para*-substituted benzyl chlorides used in this study. This means that the differences in the transition state out-of-plane bending vibrations determine the magnitude of these isotope effects. The effect of transition state structure on the magnitude of the secondary α-deuterium kinetic isotope effect can be illustrated using eq. [4].

$$[4] \quad (k_H/k_D) = \exp \tfrac{1}{2}\left[\sum^{3n-6} \Delta u_i - \sum^{3n-7} \Delta u_i^{\ddagger}\right]$$

where $\frac{1}{2}\Delta u_i = \frac{1}{2}(u_{i_H} - u_{i_D})$ is the zero-point energy difference in the initial state and $\frac{1}{2}\Delta u_i^{\ddagger}$ is the corresponding difference in the transition state. The

$$\sum^{3n-6} \Delta u_i$$

term is the same for all of the reactants and thus a smaller secondary α-deuterium kinetic isotope effect would be observed when the

$$\sum^{3n-7} \Delta u^{\ddagger}$$

term is larger, i.e., when the steric crowding around the α carbon is greater in the transition state, the vibrational energy and zero-point energy difference for the $C_\alpha$—H(D) out-of-plane bending vibration are greater. Obviously, decreasing either or both of the S--$C_\alpha$ and $C_\alpha$---Cl bond lengths (the total S---Cl distance) in the transition state would increase the steric crowding around the α carbon and decrease the magnitude of the isotope effect. Thus, the magnitude of the isotope effect is related to the S---Cl distance in the transition states of these reactions, (refs. 6, 28, 36 and Fig. 1). Since the constant chlorine kinetic isotope effects indicate that the $C_\alpha$---Cl transition state bond length is the same for all the reactions, any change in the magnitude of the secondary α-deuterium kinetic isotope effect results from a change in the S---C transition state bond length. The secondary α-

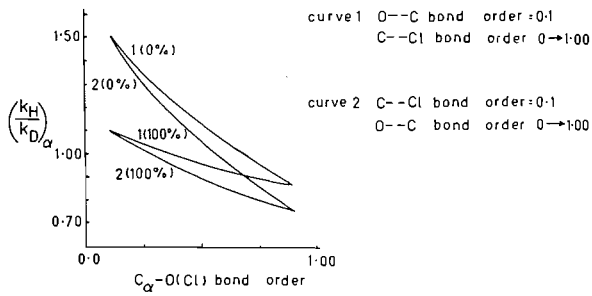

FIG. 1. The effect of conjugation between the α carbon and the benzene ring on the α carbon on the magnitude of the secondary α-deuterium kinetic isotope effect in the $S_N2$ reaction between alkoxide ion and benzyl chloride (28). The percent $C_\alpha$=Ar conjugation in the transition state is given in brackets for each curve.

deuterium kinetic isotope effects were measured for this series of reactions to determine how the S--$C_\alpha$ bond lengths changed when the structure of the substrate was altered.

The secondary α-deuterium isotope effects in the reactions between thiophenoxide ion and *para*-substituted benzyl chlorides were determined by a comparative technique, i.e., by reacting the undeuterated and deuterated[4] benzyl chlorides with thiophenoxide ion under identical conditions in separate experiments. The average rate constant for each was determined from between four and seven kinetic runs. Finally, since the secondary α-deuterium kinetic isotope effects in the reactions between thiophenoxide ion and *para*-methoxybenzyl chloride could only be measured at or below 0°C, the isotope effects for the *para*-methyl and unsubstituted benzyl chlorides were measured at 0° and 30°C to determine the temperature dependence of the isotope effect so that the magnitude of the isotope effect for the *para*-methoxybenzyl chloride reaction could be estimated at 20°C. The rate constants and isotope effects are given in Table 5.

An examination of the results in Table 5 shows that the magnitude of the isotope effect decreases as a more electron withdrawing substituent is placed on the benzene ring on the α carbon. This means that the S--Cl (nucleophile – leaving group) distance is shorter when a more electron withdrawing group is present in the substrate. Since the chlorine isotope effects show that the $C_\alpha$--Cl bond lengths are the same in all of the transition states, the S--$C_\alpha$ bond must be shorter in the transition state when a more electron withdrawing substituent is present on the benzene ring.

The only exception to this trend is found with the *para*-methoxybenzyl chloride reaction. The secondary α-deuterium kinetic isotope effects for the *para*-methyl and *para*-methoxybenzyl chloride reactions at 0°C are the same. Thus, the magnitude of the isotope effect for the *para*-methoxybenzyl chloride reaction at 20°C should be identical to the isotope effect for the *para*-methylbenzyl chloride reaction at 20°C., i.e., approximately 1.10 per $CD_2$ group or 1.05 per α-D. This means that the S--Cl distance and therefore, the S--$C_\alpha$ distance are equal in the two transition states in spite of the fact that the methoxy substituent is more electron donating than the methyl group. The chlorine and secondary α-deuterium kinetic isotope effects and the relative transition state structures suggested by these isotope effects are shown in Table 6.

The identical lengths of the S---$C_\alpha$ transition state bond for the reactions where the *para*-substituent is methoxy and methyl is difficult to explain because the more electron donating methoxy substituent would be expected to lead to a transition state with a longer S---$C_\alpha$ bond. This apparent inconsistency could be explained if the magnitude of the α-deuterium isotope effects were inversely related to the amount of $C_\alpha$=Ar conjugation in the transition state. One might expect this relationship would hold because an increase in conjugation means that the $C_\alpha$=Ar transition state bond order ($n^{\ddagger}_{C=Ar}$) is increased and thus the vibrational energy (force constant) for this bond would be greater. The $C_\alpha$—H out-of-plane bending force constants depend on the total bond order to the α carbon (25) and thus the

$$\sum^{3n-7} \Delta u_i^{\ddagger}$$

term (eq. [4]) would be larger and a smaller secondary α-deuterium isotope effect would be observed. In fact, theoretical calculations by Brubaker (28) on the $S_N2$ reactions between alkoxide ions and *para*-substituted benzyl chlorides suggest that this relationship should exist. Brubaker's calculations show that the magnitude of the isotope effect is smaller when conjugation with the aryl group on the α carbon is larger, i.e., when $n^{\ddagger}_{C=Ar}$ is greater, Fig. 1. The effect of increased conjugation is greater for looser transition states. For example, the isotope effect is reduced from 1.50 to 1.10 when the conjugation is increased from 0 to 100% for the loose transition state with $n^{\ddagger}_{C-Cl} + n^{\ddagger}_{C-O} = 0.2$, whereas a much smaller decrease from 0.89 to 0.77 is observed when the conjugation is increased from

[4]Nuclear magnetic resonance spectroscopy indicated that each deuterated benzyl chloride was 99% deuterated at the α carbon. A mass spectrometric analysis at low ionizing voltage indicated that the benzyl chlorides were between 98.6 and 99.1% deuterated (between 97.2 and 98.2% dideuterated) at the α carbon.

[a]Standard deviation.
[b]The standard error in the individual isotope effects is $1/k_D[(\Delta k_H)^2 + (k_H/k_D)^2 \times (\Delta k_D)^2]^{1/2}$ where $\Delta k_H$ and $\Delta k_D$ are the standard deviations for the rate constants for the undeuterated and deuterated substrates, respectively (30).

0 to 100% in a tight transition state with $n^{\ddagger}_{C-Cl} + n^{\ddagger}_{C-O} = 0.8$. These results indicate that looser transition states with greater conjugation could have secondary α-deuterium kinetic isotope effects comparable to or even smaller than those observed for tighter transition states where little or no conjugation is present.[5] Obviously, conjugation should be more important with the more electron donating *p*-$CH_3O$ substituent than the *p*-$CH_3$ substituent. When this factor is taken into consideration, it seems highly probable that the S---$C_\alpha$ transition state bond is longer for the transition state where the *para*-substituent is methoxy. If this argument is correct, the S---C bond becomes shorter as a more electron withdrawing substituent is added to the benzene ring for all transition states.

[5]One of the referees pointed out that the secondary α-deuterium kinetic isotope effects for various solvolysis reactions of 1-(*para*-methoxyphenyl)ethyl chloride and 1-phenylethyl chloride were identical. If an increase in conjugation decreases the magnitude of the isotope effect as is suggested, one would expect that the isotope effects for the 1-(*para*-methoxyphenyl)ethyl chloride solvolysis should be smaller than the isotope effects found for the unsubstituted substrate in the same reactions because conjugation should be more important in the 1-phenylethyl series where a carbocation intermediate is produced than in the benzyl series of $S_N2$ reactions.

The referee believes that the constant secondary α-deuterium kinetic isotope effects in the 1-phenylethyl series cast doubt on the proposed explanation. However, it appears that the constant α-deuterium isotope effects in the 1-phenylethyl series are unusual because the secondary β-deuterium kinetic isotope effects for these same reactions change markedly when the substituent is changed. Since these changes in the β-deuterium isotope effect are attributed to changes in mechanism and/or transition state structure, it is difficult to understand why the α-deuterium isotope effects in the 1-phenylethyl series are not altered by a change in substituent. We are unable to explain the very different trends in the secondary α-deuterium kinetic isotope effects for the carbonium ion solvolyses of the 1-(*para*-substituted phenyl)ethyl chlorides and the $S_N2$ reactions of the *para*-substituted benzyl chlorides.

*Hammett ρ values*

Although the relative lengths of most of the S---$C_\alpha$ transition state bonds can be given with some certainty, the difference between the S---$C_\alpha$ transition state bonds in the reactions of *para*-methoxy and *para*-methylbenzyl chlorides is based on an experimentally untested theory and there is no positive experimental proof that the S---$C_\alpha$ bond is indeed longer in the case where the *para*-substituent is methoxy. As a result, it was important to show that the S---$C_\alpha$ transition state bond actually becomes longer when the more electron donating methoxy substituent is added to the benzene ring. Westaway and Ali (6) have recently shown that the length of the nucleophile – α-carbon transition state bond in an $S_N2$ reaction can be determined by measuring the Hammett ρ values associated with changing the *para*-substituent on the nucleophile. The charge density on the sulfur atom of the nucleophile is obviously substrate independent and thus the variation in the Hammett ρ value must be the result of a different charge density on the sulfur atom in the transition state. The sulfur atom would experience only a small decrease in negative charge density in going to a transition state with a long S---$C_\alpha$ bond and thus the ρ value should be small and negative. If the nucleophile – α-carbon transition state bond is short (strong) on the other hand, only a small amount of negative charge would be on the sulfur atom of the nucleophile in the transition state. As a result, the change in charge on the sulfur atom in going from the thiophenoxide ion to the transition state is large and a large negative ρ value would be observed. Thus, a larger (more negative) ρ value indicates that the S---$C_\alpha$ bond is shorter in the transition state.

This technique was applied to the reactions of each of the substrates used in this study in order to confirm that the S---$C_\alpha$ bond shortens when more electron withdrawing substituents are present in

[a]Estimated from the data presented in Table 5.

the substrate. The *para*-substituent "Z" on the thiophenoxide ion was changed from $CH_3O$ to $CH_3$ to H and to Cl and the rate constant for the reaction of every nucleophile was measured with each of the substrates (Table 1). The Hammett ρ values and the correlation coefficients for each substrate are given in Table 3.

Unfortunately, the ρ value for the *para*-methoxybenzyl chloride reactions had to be determined from the rate constants at 0°C and estimated at 20°C. This was done by measuring the temperature dependence of the ρ value for the *para*-nitrobenzyl chloride reactions. This reaction series was chosen because the *para*-nitrobenzyl chloride had the largest ρ value and would therefore, be expected to show the greatest temperature dependence. The results in Table 3 show that the Hammett ρ value for the *para*-nitrobenzyl chloride reaction increases by eight percent when the temperature is reduced by 20°C. Assuming the same temperature dependence, the Hammett ρ value for the *para*-methoxybenzyl chloride reaction at 20°C would be −0.26.

The results in Table 3 show that the Hammett ρ value becomes more negative whenever a more electron withdrawing substituent is placed on the substrate. This indicates that the S---$C_\alpha$ transition state bond is shorter when a more electron withdrawing substituent is on the substrate. Thus, these results support the changes in the S---$C_\alpha$ transition state bond indicated by the variation in the secondary α-deuterium kinetic isotope effects. It is worth noting that the magnitude of the Hammett ρ value is much larger for the *para*-methylbenzyl chloride reaction than for the *para*-methoxybenzyl chloride reaction. This substantiates that the S---$C_\alpha$ bond is much longer in the latter transition state and confirms that the S--$C_\alpha$ bond shortens in all of the transition states when a more electron withdrawing substituent is placed on the benzene ring on the α carbon. This supports Brubaker's suggestion that the equal secondary α-deuterium isotope effects for the two reactions are due to a greater $C_\alpha$=--Ar bond order (conjugation) in the transition state of the *para*-methoxybenzyl chloride reaction.

Finally, it is interesting to try to provide a rationale for the above results, i.e., to explain why the S---C transition state bond becomes shorter whereas the C---Cl bond remains unchanged as a more electron withdrawing substituent is added to the benzene ring. One explanation is that the C---Cl bond is equally broken in all the transition states because the free energy required to displace the same leaving group is the same for each reaction. The change in the S---$C_\alpha$ bond could be qualitatively explained by assuming that the nucleophilic push required to rupture the C—Cl bond comes from a combination of electron density supplied by the nucleophile and electron density from the benzene ring bonded to the α carbon. When a strongly electron donating substituent is present on the benzene ring, the benzene ring supplies most of the electron density that is needed to push out the leaving group. In this case, little electron density is needed from the nucleophile and the nucleophile – α-carbon transition state bond is long. When an electron withdrawing substituent is on the benzene ring, little or no electron density will be provided by the benzene ring and most of the electron density required to rupture the C—Cl bond comes from the nucleophile. As a result, the nucleophile – α-carbon (S---$C_\alpha$) bond is much shorter in the transition state.

*Conjugation between the α carbon and the benzene ring*

Two different factors suggest that resonance between the α carbon and the benzene ring plays an important role in determining the structure of the transition states in the $S_N2$ reactions between thiophenoxide ion and *para*-substituted benzyl chlorides. Because the Hammett ρ value observed for the *para*-methoxybenzyl chloride reaction is smaller than the ρ value for the *para*-methylbenzyl chloride reaction, the S---$C_\alpha$ transition state bond is longer in the former reaction. Yet, identical secon-

dary α-deuterium isotope effects, which suggest that the S--$C_\alpha$ bonds are equally long in the two transition states, are observed for these two reactions. The identical isotope effects can be rationalized if $C_\alpha$=--Ar conjugation is greater in the *para*-methoxybenzyl chloride transition state. In addition, a consideration of the changes that occurred in the S---$C_\alpha$ and $C_\alpha$---Cl transition state bonds, when the substituent is altered, led to the suggestion that electron density from the nucleophile and electron density from the aryl group on the α carbon work in a complementary fashion in displacing the chloride ion. If these ideas are correct, $C_\alpha$=--Ar bonding plays a major role in determining transition state structure. It was important, therefore, to demonstrate that $C_\alpha$=--Ar conjugation has a major influence on the transition state structures of these $S_N2$ reactions.

Young and Jencks (37) recently showed that a modified Yukawa–Tsuno expression, eq. [5]:

$$[5] \quad \log (k/k_0) = \rho\sigma^n + \rho^r(\sigma^+ - \sigma^n)$$

can be used to determine the relative importance of polar and resonance effects in $S_N2$ reactions. The constants ρ and $\rho^r$ represent the sensitivity of the reaction to polar and resonance effects, respectively. The $\sigma^+$ substituent constant describes the interaction of the substituent with a carbonium ion, $\sigma^n$ represents the polar effect of the substituent (38), and $(\sigma^+ - \sigma^n)$ represents the ability of the substituent to donate electrons by resonance. The resonance effect of the substituent $(\sigma^+ - \sigma^n)$ decreases in the order methoxy > methyl > chloro. $(\sigma^+ - \sigma^n)$ is zero for the hydrogen and nitro substituents that do not donate electrons through resonance.

Equation [5] correlates the substituent effects on the reaction rates with the polar ($\rho\sigma^n$) and resonance ($\rho^r(\sigma^+ - \sigma^n)$) effects of the substituents. If resonance between the α carbon and the benzene ring is important in this reaction series, $\rho^r$ should be large. In fact, if the resonance effect is more important than the polar effect, $\rho^r$ will be larger than ρ. In the reaction series studied, the H and $NO_2$ substituents do not have a resonance effect and the Yukawa–Tsuno equation reduces to the simple Hammett equation for polar effects, eq. [6], for these two substituents.

$$[6] \quad \log (k/k_0) = \rho\sigma^n$$

A plot of log $k/k_0$ versus $\sigma^n$ for the *para*-hydrogen and *para*-nitro substituted benzyl chloride reactions at 20°C gives a line of slope = 0.94. When the other substituents are placed on the Hammett $\rho\sigma^n$ diagram, Fig. 2, the points corresponding to the

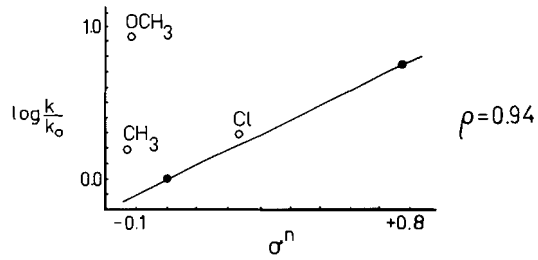

FIG. 2. Deviation of the rate constant for the *para*-methoxy, *para*-methyl, and *para*-chlorobenzyl chlorides from the log $(k/k_0) = 0.94\,\sigma^n$ plot.

*p*-$CH_3O$,[6] the *p*-$CH_3$, and the *p*-Cl benzyl chlorides show positive deviations from the ρ = 0.94 line. It is worth noting that the resonance effect (Δ log $k/k_0$) is much greater for *p*-$CH_3O$ (1.029) than for *p*-$CH_3$ (0.311) in agreement with the conclusion reached from the studies of the secondary α-deuterium isotope effects. The small deviation from the $0.94.\sigma^n$ line for the *p*-Cl substituent (0.058) is consistent with the overriding polar effect of this substituent. These deviations, which represent the resonance contribution of the substituents, can be evaluated from eq. [7].

$$[7] \quad \Delta \log (k/k_0) = \log (k/k_0) - 0.94\,\sigma^n = \rho^r(\sigma^+ - \sigma^n)$$

In fact, the slope of the Δ log $(k/k_0)$ versus $(\sigma^+ - \sigma^n)$ plot is $\rho^r = -1.67$. The standard deviation is ±0.08 and the correlation coefficient is 0.988.

The importance of the resonance effect is indicated by the relative sensitivity of the reaction series to the resonance and polar effects of the substituents. The larger absolute value of $\rho^r$, i.e., $|\rho^r/\rho| = |1.67/0.94| = 1.78$, indicates that the resonance effect is large in the reactions between thiophenoxide ions and *para*-substituted benzyl chlorides. This confirms that resonance ($C_\alpha$=--Ar bonding) is important in these reactions.

Once the values of ρ and $\rho^r$ had been determined, the Yukawa–Tsuno plot could be drawn, curve a, Fig. 3. The good linearity and high correlation coefficient of 0.985 illustrates that the Yukawa–Tsuno equation can be successfully applied to the data measured for this series of reactions. More important, however, is the information this treatment provides about the importance of conjugation between the α carbon and the aryl group.

Although the $\rho^r$ value was determined by using the three substituents with a significant electron

[6]The rate constant of 0.12 L/mol-s at 20°C reported by Grimsrud (1) was used because all of Grimsrud's other rate constants at 20°C were within experimental error of those determined in this work.

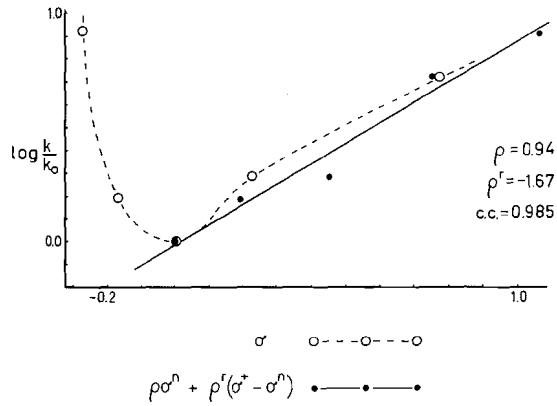

FIG. 3. The Yukawa–Tsuno plot (solid circles and line, curve a) and the Hammett plot (open circles and dotted line, curve b) for the $S_N2$ reactions between *para*-substituted benzyl chlorides and thiophenoxide ions at 20°C.

donating resonance effect, the large value of $\rho^r = -1.67$ suggests that conjugation is important in all of the transition states, i.e., even when the *para*-substituent "Y" is hydrogen and nitro. The nitro substituent is much more electron withdrawing than hydrogen, however, and the $C_\alpha$=Ar bond order would be expected to be much smaller in the *para*-nitrobenzyl chloride transition state than in the transition state where the substituent "Y" is hydrogen. This conclusion is supported by the work of Fuchs and Carlton (39) who studied the reactions of *para*-substituted benzyl chlorides and 3-nitro 4-substituted benzyl chlorides with thiosulfate ion in 60% aqueous acetone at 30°C and with water in 50% aqueous ethanol at 60°C. Application of the Yukawa–Tsuno equation to their data shows that the introduction of the 3-nitro group reduces the $\rho^r$ value from −3.99 to −0.96 for the reactions with thiosulfate ion and from −11.21 to −2.43 for the solvolysis reactions in aqueous ethanol. The large decrease in $\rho^r$ shows that the resonance with the α carbon (the $C_\alpha$=Ar transition state bond order) decreases when a more electron withdrawing substituent is added to the benzene ring of the substrate. However, $\rho^r$ is still finite for the 3-nitro 4-substituted benzyl chlorides and thus $C_\alpha$=Ar conjugation would be expected in all of the transition states investigated in this study.

The enthalpies of activation were determined for these reactions to (*i*) confirm that conjugation between the α carbon and the benzene ring was important in all of the transition states, and (*ii*) because these values could be used to demonstrate how the C=Ar bond length (conjugation) was related to the nucleophile – α-carbon bond lengths in these transition states. This approach requires two reasonable assumptions. The first assumption is that the enthalpy of activation ($\Delta H^\ddagger$) can be expressed in terms of an enthalpy of activation for each of the bonds that are made (the $C_\alpha$—S and the π bond between the α carbon and the benzene ring) or broken (the $C_\alpha$—Cl bond) in the transition state, eq. [8].

$$[8] \quad \Delta H^\ddagger = -\Delta H^\ddagger_{C=Ar} - \Delta H^\ddagger_{S-C} + \Delta H^\ddagger_{C-Cl}$$

The first two terms in eq. [8] are negative because the bond forming reactions reduce the magnitude of $\Delta H^\ddagger$. The second assumption is that the individual $\Delta H^\ddagger$ terms can be estimated using eq. [9].

$$[9] \quad \Delta H^\ddagger = \text{B.D.E.}\ (n^\ddagger - n_R)$$

where B.D.E. is the bond dissociation energy and $n^\ddagger$ and $n_R$ are the bond orders in the transition state and the reactant, respectively. Substituting the appropriate B.D.E. for the reacting bonds (69 kcal/mol for the C—Cl bond in benzyl chloride (40, 41), 59 kcal/mol for the benzyl C—S bond in benzylmethyl sulfide (41), and 63 kcal/mol for the π bond (42)) and $n_R$ values (1.00 for the C—Cl bond and 0.00 for the C—S and π bonds) in eq. [8] and rearranging gives eq. [10].

$$[10] \quad n^\ddagger_{C=Ar} = \frac{-\Delta H^\ddagger + 69(n^\ddagger_{C-Cl} - 1.0) - 59n^\ddagger_{S-C}}{63}$$

This means that $n^\ddagger_{C=Ar}$, the bond order of the π bond between the α carbon and the benzene ring in the transition state, could be estimated if values of $n^\ddagger_{C-Cl}$ and $n^\ddagger_{S-C}$ were known.

Although the exact values of $n^\ddagger_{C-Cl}$ and $n^\ddagger_{S-C}$ cannot be determined, they can be *estimated* from the magnitudes of the chlorine kinetic isotope effects and the Hammett ρ values observed for these reactions. Dividing the average chlorine isotope effect of 1.00983 ± 0.00029 by the theoretical maximum chlorine isotope effect of 1.0111 at 20°C indicates that the $C_\alpha$---Cl bond rupture is approximately 88% complete[7] (the $C_\alpha$---Cl bond order is approximately 0.12) in all of the transition states (29).

The $n^\ddagger_{S-C}$ for each reaction was *estimated* by dividing the Hammett ρ values obtained when the substituent on the nucleophile was changed (Table 3) by −1.99, the Hammett ρ value for the protonation of *para*-substituted thiophenoxide ions in methanol at 20°C (2). While the −1.99 is only an approximation for the ρ value that would be observed when the negative charge on sulfur is com-

[7]It is realized that this is a crude method of estimating the $C_\alpha$---Cl bond order. The theoretical maximum was calculated using the average $C_\alpha$—Cl stretching frequency of 650 $cm^{-1}$.

pletely destroyed in the transition state of a C—S bond forming reaction, the authors believe it is a good approximation because the charge on the sulfur atom is completely destroyed in the equilibrium and the substrates, solvent, and temperature are identical to those used in measuring the ρ values for the $S_N2$ reactions.

The enthalpy ($\Delta H^{\neq}$) and entropy ($\Delta S^{\neq}$) of activation for all but one of these reactions were determined from the rate constants measured at 0°C, 20°C, and 30°C, Table 1. The $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for the *para*-methoxybenzyl chloride reaction, on the other hand, were determined from the rate constants measured at −9.3°C, 0°C, and Grimsrud's rate constant at 20°C,[8] Table 1. The activation parameters and the calculated $n^{\neq}_{C-Cl}$, $n^{\neq}_{S-Cl}$, and $n^{\neq}_{C=Ar}$ are given in Table 7.

Although the bond orders in Table 7 are based on crude estimates and are only approximate, they illustrate two important features of these $S_N2$ transition states. First, all of the $n^{\neq}_{C=Ar}$ (π bond orders) are large. For example, the estimated $n^{\neq}_{C=Ar}$ is still 0.29 even in the transition state with the strongly electron withdrawing nitro substituent. This demonstrates that resonance between the benzene ring and the α carbon is important in all of these transition states and confirms the conclusion based on the use of the modified Yukawa–Tsuno equation.

The second observation is even more important, however. The linearity (the correlation coefficient is 0.994) of the $n^{\neq}_{C=Ar}$ versus $n^{\neq}_{S-C}$ plot, Fig. 4, demonstrates that $n^{\neq}_{C=Ar}$ varies inversely with $n^{\neq}_{S-C}$. This supports the qualitative relationship between the transition states that was suggested above, i.e., that electron density provided by the conjugation *and* the nucleophile are involved in displacing the leaving group and that the S--$C_\alpha$ transition state bond becomes shorter when a more electron withdrawing substituent is placed on the benzene ring and the conjugation decreases. This inverse relationship between the S---$C_\alpha$ and the $C_\alpha$=Ar bond orders means that the transition state structure is determined by the amount of $C_\alpha$=Ar conjugation in the transition state. This, in turn, suggests that the amount of conjugation should be related to the individual properties of each substituent. If this is true, the conjugation from the benzene ring should be related to the ρ value of the substituent on the benzene ring of the substrate. In fact, a good linear relationship is observed. A plot of $n^{\neq}_{C=Ar}$ versus the σ value of the *para*-substituent on the benzene ring has a correlation coefficient of 0.967, Fig. 5. This indicates that the resonance contribution of the benzene ring does vary as the

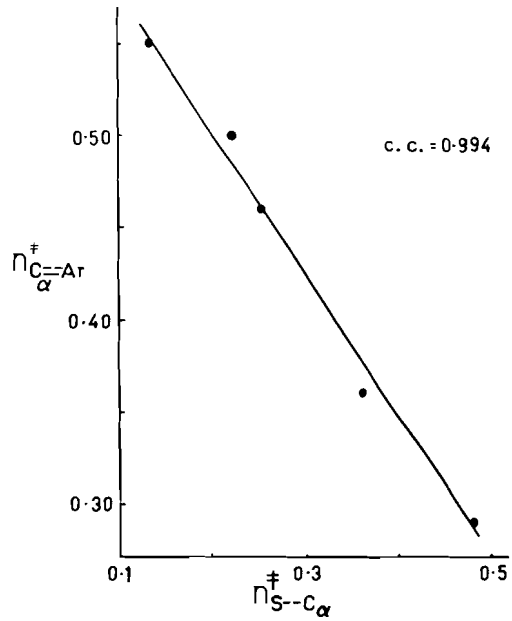

FIG. 4. The $C_\alpha$=Ar transition state π bond order (conjugation) versus the S---$C_\alpha$ transition state bond order for the $S_N2$ reactions between thiophenoxide ion and *para*-substituted benzyl chlorides.

[8]Grimsrud's rate constant at 20°C was only used because all other rate constants at 20°C were within experimental error of those reported by Grimsrud. The small error in $\Delta H^{\neq}$ for this compound (Table 7) also indicates that Grimsrud's rate constant was accurate.

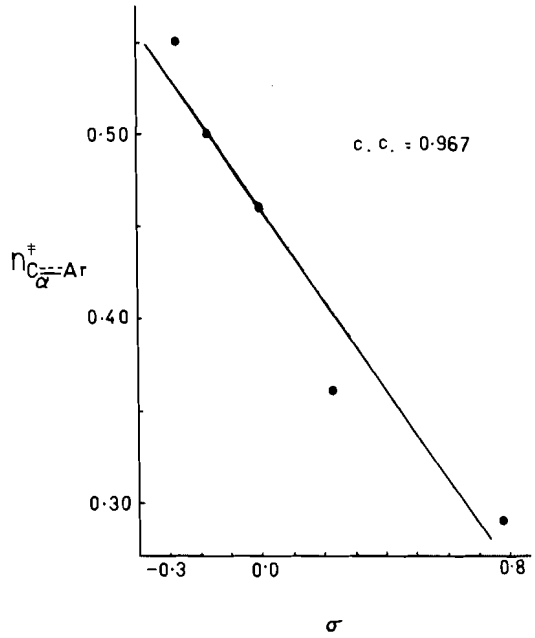

FIG. 5. A plot of the $C_\alpha$---Ar transition state π bond order versus the σ constant of the *para*-substituent "Y" in the reaction between *para*-substituted benzyl chlorides and thiophenoxide ions.

electron donating ability of the substituent. This in turn determines the S---$C_\alpha$ transition state bond order.

Combining the constant $C_\alpha$---Cl bond lengths with the shortening S---$C_\alpha$ bonds and the diminishing $C_\alpha$---Ar bond order, as the substituent on the substrate becomes more electron withdrawing, leads to detailed qualitative descriptions of the transition state structures in the reactions between thiophenoxide ion and *para*-substituted benzyl chlorides, Fig. 6. The plane of the benzene ring will be perpendicular to the S--$C_\alpha$--Cl axis so that the π electrons of the benzene ring can overlap with the partially filled orbitals on the α carbon. Finally, it is worth noting that the Hammett ρ values for the reactions of all the substrates are very small with respect to the −1.99 observed in the equilibrium reaction where the negative charge on the sulfur atom is completely destroyed (2). This indicates that the S--C transition state bonds are long in all cases. Since the chlorine (leaving group) isotope effects are large for all of the reactions, the C---Cl transition state bonds are also long. This means that all of the transition states are loose, i.e., are of the decreased total bonding (DTB) type.

### The effect of bond strength on transition state structure

The transition state structures in Fig. 6 show that the introduction of a more electron withdrawing substituent to the substrate shortens the nucleophile – α-carbon bond and reduces the conjugation between the α carbon and the benzene ring but does not alter the α-carbon – leaving group bond in the transition state. Having established the changes in the transition state structure, it was important to compare these results with those found for other similar reactions.

With one exception (49), the secondary α-deuterium kinetic isotope effects reported for the $S_N2$ reactions of several other benzyl substrates (5, 45–48) are smaller when a more electron withdrawing substituent is on the benzene ring. Moreover, this trend seems to be independent of the nucleophile and the solvent. Unfortunately, the smaller isotope effects found when a more electron withdrawing substituent is present only mean that the transition state is tighter, i.e., the nucleophile – leaving group distance is shorter, and there is no indication whether (*i*) the nucleophile – α-carbon bond, (*ii*) the α-carbon – leaving group bond, or (*iii*) both of these bonds are affected by the change in substituent. Thus, although our results agree with those found by other workers, these isotope effects do not give enough information so that one can determine whether the changes found in the benzyl chloride – thiophenoxide ion transition state structures are common to all reactions of benzyl substrates.

An examination of the chlorine kinetic isotope effects found for other $S_N2$ reactions of *para*-substituted benzyl chlorides showed that the chlorine isotope effects were independent of the *para*-substituent for some reactions but were substituent dependent in others. Obviously, the simple explanation presented above does not explain the changes in the transition state structure for all $S_N2$ reactions. For example, if one considers the reverse of the reactions studied, i.e., the displacement of thiophenoxide ion from benzylphenyl sulfide by chloride ion, the principle of microscopic reversibility states that the C---S bond (the α-carbon – leaving group bond) will shorten and that the Cl---C bond (the nucleophile – α-carbon bond) will remain unchanged when a more electron withdrawing substituent is on the benzene ring. This is opposite to the results given above, i.e., where the α-carbon – leaving group bond remained constant and the nucleophile – α-carbon bond shortened. Since the principle of microscopic reversibility must hold, another factor must play an important role in determining the changes in transition state structure. A consideration of this problem led to the conclusion that the relative bond strengths of the nucleophile – α-carbon and α-carbon – leaving group bonds are important in

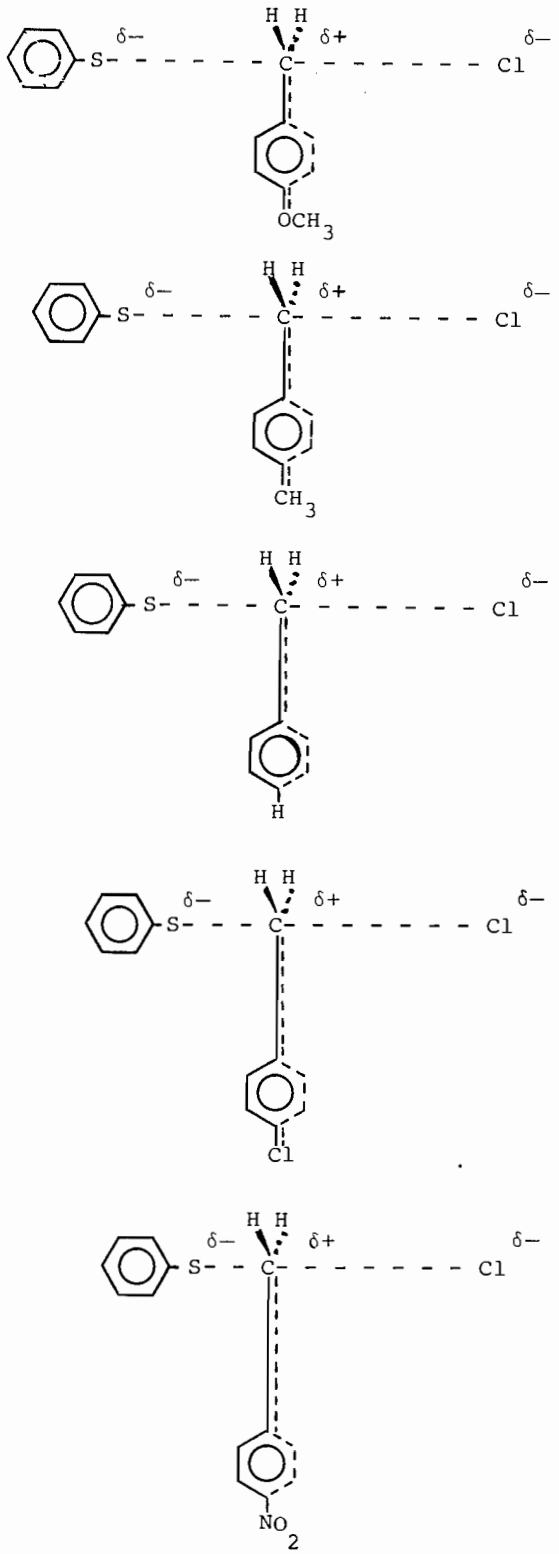

FIG. 6. The effect of changing the *para*-substituent on the transition state structure of the $S_N2$ reactions between thiophenoxide ion and *para*-substituted benzyl chlorides.

determining which reacting bond will be altered by a change in substituent. In fact, it is proposed that a change in the substituent on the α carbon will affect the length of the weaker reacting bond but will have considerably less or no effect on the stronger reacting bond in an $S_N2$ transition state. An examination of the chlorine isotope effects for other reactions supports this suggestion.

Reppond (26) studied the reactions of *para*-substituted benzyl chlorides with various nucleophiles in DMF and in 97% aqueous methanol and found that changing the substituent from *p*-$CH_3$ to *p*-$NO_2$ led to a significant decrease in the chlorine isotope effect, i.e., it decreased by 0.0013 in both solvents when the nucleophiles were *para*-cyano or *para*-nitrophenoxide ions. Constant chlorine isotope effects were observed in both solvents, however, when the nucleophile was azide ion. This is consistent with the above proposal because the C—Cl bond is weaker than the O—C bond, but stronger than the $N_3$—C bond (40). Grimsrud and Taylor (43) also found that the chlorine isotope effect decreased by 0.0012 as the substituent on the benzene ring was changed from *p*-$OCH_3$ to *p*-$NO_2$ in the reactions between *para*-substituted benzyl chlorides and phenoxide ion in methanol. Again, the weaker C—Cl bond changed when the substituent on the α carbon was altered. In addition, Hill and Fry (44) found that the chlorine isotope effect decreased by 0.0021 when the substituent on benzyl chloride was changed from *p*-$CH_3O$ to *p*-$NO_2$ for the reactions with cyanide ion and thiosulfate ion but remained constant for the solvolysis reactions in 80% aqueous dioxane. These results are expected because the NC—$C_\alpha$ and O—$C_\alpha$ bonds are stronger than the C—Cl bond, whereas the new $H_2\overset{+}{O}$—$C_\alpha$ bond is weaker than the $C_\alpha$—Cl bond (41). Grimsrud (1) also found constant chlorine isotope effects in the reactions of *para*-substituted benzyl chlorides with iodide ion, *n*-butylthiolate, and thiophenoxide ion. This also is consistent with the bond-strength hypothesis because both the I—C and the S—C bonds are weaker than the C—Cl bond. The one exception to this rule is the reaction series between *para*-substituted benzyl chlorides and methoxide ion in methanol, where essentially constant chlorine isotope effects are observed (1). This may be due to the fact that the attacking nucleophile is methanol. If this occurred, the new $CH_3$—$\overset{+}{O}$(H)—$C_\alpha$ bond would be the weakest bond in the transition state and the C—Cl transition state bond, and thus the chlorine isotope effects, should not be affected by a change in substituent.

In fact, all but one set of results are consistent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

with the bond strength postulate. Thus it is proposed that adding a more electron withdrawing substituent to the benzene ring of the substrate will lead to a transition state where the weakest reacting bond is shorter, the conjugation between the benzene ring and the α carbon is reduced, and the stronger reacting bond has not been altered significantly.

### Comparison of the experimental results and theoretical predictions

Once the actual transition state structures had been determined, the effect of changing a substituent at the α carbon could be compared with the theoretical predictions based on Thornton's reacting bond rule (50) and More O'Ferrall's energy surface (6, 51). According to Thornton's rule, the overall effect of a $S_N2$ reaction is comprised of the substituent effect on the perpendicular and the parallel vibrations of the transition state. For the perpendicular effect, introducing a more electron withdrawing substituent to the α carbon should lead to a tighter transition state with shorter S--C and C--Cl bonds. A more electron withdrawing substituent makes an increase in the parallel vibration easier for the S--C bond but more difficult for the C--Cl bond and no change in structure is predicted. Thus the overall effect is to shorten the S--C and C--Cl transition state bonds. This is obviously in discord with the experimental results because the C--Cl bond length is substituent independent. However, Thornton predicts that the parallel effect can be important when the two reacting bonds have different strengths. In these cases, Thornton states that the parallel effect will be determined from the substituent effect on the stronger reacting bond. Since the S—$C_\alpha$ bond is weaker (59 kcal/mol) than the $C_\alpha$—Cl bond (69 kcal/mol), the substituent effect on the parallel vibration will be determined from its effect on the $C_\alpha$---Cl bond. Since a more electron withdrawing substituent will make the C---Cl bond more difficult to stretch, shorter S--C and longer C--Cl transition state bonds are predicted. If the substituent effects on the perpendicular and parallel vibrations are equal, adding a more electron withdrawing substituent should lead to the changes in transition state structure that are observed experimentally, i.e., the transition state should have a shorter S---$C_\alpha$ and an unchanged $C_\alpha$---Cl bond. Although the experimental results are consistent with an equal parallel and perpendicular effect, this explanation seems surprising because the bond strengths only differ by 10 kcal/mol.

It is interesting that this approach also leads to the observed behaviour if one considers an $S_N2$ reaction where the nucleophile – α-carbon bond is stronger than the α-carbon – leaving group bond, e.g., the reaction between phenoxide ion and benzyl chloride. In this case, the parallel effect would be determined by the nucleophile – α-carbon (C—O) bond, i.e., adding a more electron withdrawing substituent would lead to a transition state with a longer nucleophile – α-carbon bond and a shorter α-carbon – leaving group bond. If the parallel and perpendicular effects are equally important, the overall effect would be little or no change in the nucleophile – α-carbon bond and a decrease in the α-carbon – leaving group bond length. In fact, the decreasing chlorine (leaving group) isotope effects found by Reppond (26) and Grimsrud and Taylor (43) in the $S_N2$ reactions between benzyl chlorides and phenoxide ions are consistent with this prediction.

Finally, it is worth noting that this is the only way that the experimental results and the predictions based on Thornton's reacting bond rule can be compatible. This suggests that the force constants of the two bonds and the parallel effect are more important in these $S_N2$ reactions than Thornton and the others predicted.

The More O'Ferrall method of predicting the substituent effect on the transition state structure is based on considering the substituent effect on the energy of the reactants, products, and two hypothetical intermediates: a carbonium ion and a pentavalent carbanion, Fig. 7. The upper curve represents the reaction coordinate for the *para*-nitrobenzyl chloride reaction and the lower curve is the reaction coordinate for the *para*-methoxybenzyl chloride reaction. The transition states for both these reactions are depicted by "b" and "a" respectively. All other transition states lie on the line connecting "a" and "b". This is required because the constant chlorine isotope effects indicate that the $C_\alpha$---Cl bond length (bond order) is the same for all transition states. The points "a" and "b" are drawn so that the $S_\alpha$---C transition state bond orders correspond to those estimated from the Hammett ρ values. This implies that the transition states are all product-like, i.e., they lie above the diagonal joining the two hypothetical intermediates, and are of the DTB type, i.e., they lie below the diagonal connecting the reactants and products.

The substituent effect on the transition state structure is determined by considering the substituent effect on the energies of both intermediates (a perpendicular effect) and the reactants and products (a parallel effect). The overall substituent

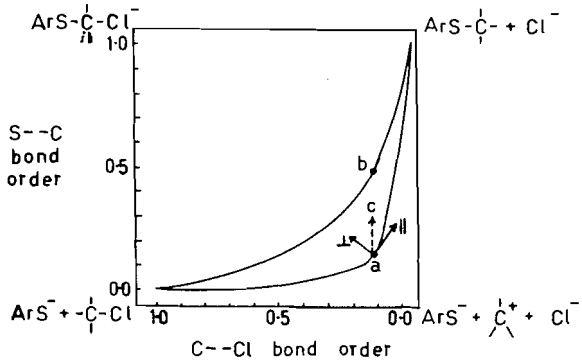

FIG. 7. The More O'Ferrall energy surface for the reactions between thiophenoxide ion and *para*-substituted benzyl chlorides.

effect is given by the resultant of the perpendicular and the parallel effect. Both the perpendicular and the parallel effect can be determined from the substituent effect on the transition state of the *para*-methoxybenzyl chloride reaction. A more electron withdrawing substituent at the α carbon will destabilize the carbonium ion (raise the bottom right corner) but stabilize the negatively charged adduct (lower the top left corner) thus creating a perpendicular shift (⊥) toward the adduct. The parallel effect is determined from the substituent effect on the vibrational frequencies of the C—Cl and S—C bonds in the reactants and products. Changing the substituent on benzyl chloride from $CH_3O$ to $NO_2$ leads to a decrease in the frequency of the C—Cl bond from 680 $cm^{-1}$ to 625 $cm^{-1}$. Thus, a more electron withdrawing substituent at the α carbon weakens the C—Cl bond, increases the energy of the reactant molecule, and raises the bottom left corner of the energy surface. The sulfur – benzyl carbon bond is weaker than the C—Cl bond and thus the same change in substituent ought to have a greater effect on the energy of the S—C bond and of the product molecule. Since the substituent effect should be in the same direction for the S—C and C—Cl bonds, a more electron withdrawing substituent would be expected to increase the energy of the product more than the energy of the reactant, i.e., the upper right corner will be raised more than the lower left corner. As a result, a more electron withdrawing substituent creates a parallel shift (||) toward the product. The unchanged C---Cl bond length and a shorter S---C bond that is actually observed experimentally (arrow c) is only predicted if the parallel effect is at least as large as the perpendicular effect. Again, the unusual importance of the parallel effect in this series of reactions is required if one is to obtain the experimental results. The authors are unable to rationalize the importance of the parallel effect in this series of reactions.

In conclusion, both Thornton's rule and More O'Ferrall's energy surface method can only predict the substituent effect at the α carbon if the parallel effect is equal to or greater than the perpendicular effect. The results of this study indicate that these theories will have to be modified, perhaps by considering the effect of the strengths of the nucleophile – α-carbon and α-carbon – leaving group bonds and/or the changing conjugation with the benzene ring on the α carbon, before they will be able to predict the substituent effects in $S_N2$ reactions correctly. As presently constituted, the theories do not predict (*i*) the importance of the parallel effect in these $S_N2$ reactions, (*ii*) the substituent effects found in this study nor those found in another detailed study of $S_N2$ transition states (6), nor (*iii*) the different substituent effects on the chlorine isotope effects in the $S_N2$ reactions of benzyl substrates.

## Curved Hammett plots

When *para*-substituted benzyl substrates react with negatively charged nucleophiles, U-shaped Hammett plots are always obtained (2, 16, 18, 39, 52–55). The observation that the minimum in these Hammett plots invariably occurs in the vicinity of the unsubstituted substrate regardless of the leaving group (18), the nucleophile (2), or the solvent (17), indicates that the U-shaped plots are a result of the properties of the substituent on the substrate. The Hammett plot obtained from the rate constants of the reactions between the negatively charged nucleophile, thiophenoxide ion, and *para*-substituted benzyl chlorides at 20°C is normal, i.e., it is U-shaped with a minimum when the *para*-substituent is hydrogen, Fig. 3, curve b.

The curvature of the Hammett plots has been attributed to three factors: (*i*) a change from an $S_N2$ to a carbonium ion $S_N$ mechanism as electron withdrawing substituents are changed to electron donating substituents (16, 56, 57); (*ii*) a change in transition state structure, i.e., a change in the relative importance of bond breaking and bond making in the transition state (2, 18, 53, 54); and (*iii*) a variable resonance effect of the substituents (58). All three explanations for the U-shaped Hammett plots will be considered in the light of the experimental results to determine which of these factors is responsible for the curvature.

Although a change in mechanism from a carbonium ion $S_N$ mechanism to an $S_N2$ mechanism has occurred in some reactions where curved Hammett plots have been found, it is not the explanation for

the curved Hammett plot in the reactions between thiophenoxide ion and *para*-substituted benzyl chlorides. The second order kinetics and small Hammett ρ values show that the S--C bond formation occurs in the transition state of the rate-determining step of the reaction. The large chlorine isotope effects demonstrate that the C---Cl bond is also breaking in the transition state of the rate-determining step. Since the S---C bond formation and the C---Cl bond rupture both occur in the slow step of the reaction, all of these reactions occur by an $S_N2$ mechanism. As a result, the curved Hammett plot observed for these reactions cannot be caused by a change in mechanism.

The curvature of the Hammett plots has also been attributed to changes in the relative amounts of bond formation and bond rupture in the transition state. The rationale for curvature follows. If the S---$C_\alpha$ bond order exceeds the $C_\alpha$---Cl bond order in the transition state (a product-like transition state), the α carbon will be less positively charged in the transition state than it was in the initial state. The reaction will be accelerated by electron withdrawing substituents and a positive ρ value (the slope of the log $(k/k_0)$ versus σ curve is positive) would be observed. For the reactant-like transition states, on the other hand, the α carbon will be more positively charged in the transition state because the electron density lost from the α carbon when the $C_\alpha$---Cl bond is weakened is not fully replaced by the partial formation of the S---$C_\alpha$ bond. In this case, the reaction will be accelerated by electron donating substituents and a negative ρ value (slope) would be observed. Thus, the Hammett plot should have a negative slope (ρ value) when electron donating substituents are present and the transition states are reactant-like, and a positive slope and product-like transition states when the substituents are electron withdrawing.

Three pieces of evidence suggest that this is not the explanation for the curved Hammett plot. First, the Hammett ρ values for substitution in the thiophenoxide ion suggest that the S---$C_\alpha$ bond orders range from approximately 0.13 to 0.48, Table 7, while the chlorine isotope effects indicate that the $C_\alpha$---Cl bond order is approximately 0.12 in all the transition states. Thus, the S---$C_\alpha$ bond order is greater than the $C_\alpha$---Cl bond order for all the substituents and all of the transition states are product-like. Obviously, the curved Hammett plot cannot be a result of changing from a reactant-like to a product-like transition state.

This conclusion is supported by an analysis of the enthalpies of activation. Even if one assumes that the S--$C_\alpha$ and $C_\alpha$---Cl transition state bond orders based on the Hammett ρ values and the chlorine isotope effects are wrong, and that the transition state does change from reactant-like when the *para*-substituents are $CH_3O$ and $CH_3$ to product-like when the substituents are Cl and $NO_2$, there would be a gradual increase in the total bonding to the α carbon as a more electron withdrawing substituent was added to the substrate. This gradual increase in bonding should lead to a gradual decrease in $\Delta H^{\ddagger}$ and, in fact, this is observed, Table 7. However, the changes that occur in the rate constants when the substituents are varied, i.e., the cause of the curvature in the Hammett plot, do not parallel the changes in the enthalpy of activation. Since the curved Hammett plot does not correlate with the enthalpies of activation which reflect the increase in the relative importance of bond making over bond breaking, it must be concluded that the curved Hammett plot is not a result of the changes in the relative importance of bond formation and bond rupture in the transition state.

Finally, if the curved Hammett plots were a result of changing the transition state structure from reactant-like to product-like, the position of the minimum in the Hammett plot should shift away from the reaction where the *para*-substituent is hydrogen when different nucleophiles, different leaving groups, and/or different solvents are used, i.e., since changes in the nucleophile, leaving group, or solvent would alter the structure of the transition state, the change from a reactant-like to a product-like transition state (the minimum) should occur when substituents other than hydrogen are present. Since the minimum in the U-shaped Hammett plots invariably occurs when the substituent is hydrogen, a change from reactant-like to product-like transition states cannot be the cause of the curvature in the Hammett plots.

The remaining possibility is that the curved Hammett plot is a result of a variation in the resonance effect. Young and Jencks (58) have demonstrated that the curved Hammett plot observed in the reversible reactions of bisulfate ion with *para*-substituted acetophenones can be attributed to a changing balance between the resonance and polar effects for different substituents. By using the modified Yukawa–Tsuno equation, the authors separated the polar and resonance effects of each substituent and evaluated the contribution of these effects to the reaction rate, e.g., the electron donating substituents ($p$-$CH_3O$, $p$-$CH_3$) stabilize the transition state mainly through a resonance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

effect whereas electron withdrawing substituents, such as $p$-$NO_2$, stabilize the transition state through a polar effect. An analysis of the results obtained in the benzyl chloride – thiophenoxide ion reaction show that the variable resonance effect of the substituents is responsible for the curvature in the Hammett plots. A good linear correlation between the rate constants and the resonance and polar contributions of the substituents was obtained when the modified Yukawa–Tsuno equation was applied to the rate constants obtained in this study, Fig. 3a. This confirmed that the curved Hammett plot observed in this reaction series is also a result of the resonance stabilization of the transition state by electron donating substituents on the benzene ring, and not of a change in mechanism or the relative importance of bond making and bond breaking in the transition state.

This explanation for the curvature is attractive for other reasons.

(*i*) When the modified Yukawa–Tsuno equation was applied to many $S_N2$ reactions of benzyl substrates with negatively charged nucleophiles, a good linear relationship was found (2, 39, 54). Thus, this explanation of the curved Hammett plots is general, i.e., it explains why curved Hammett plots are observed regardless of the nucleophile, the solvent, or the leaving group.

(*ii*) It relates the curvature of the Hammett plot to the individual properties of the substituents, i.e., it explains why the change in the slope is invariably around $p$-H. In the reactions of benzyl substrates with negatively charged nucleophiles, the upward curvature of the Hammett plot for electron withdrawing substituents occurs because transition states are stabilized by electron withdrawal through the polar effect. The α carbon in these reactions is less positively charged in the transition state than in the substrate because the decrease in the charge density on the α carbon that occurs when the C---Cl bond is weakened is more than compensated by charge density from the formation of the nucleophile – α-carbon bond.

The transition states with electron donating substituents are stabilized by a large resonance effect between the substituent and the benzene ring. In these cases, the electron density donated by resonance reduces the positive charge on the α carbon and stabilizes the transition state. As a result, these compounds react faster than the unsubstituted substrate and a U-shaped Hammett plot is observed. Since the change between electron donating (a strong resonance effect) and electron withdrawing substituents (a strong polar effect) occurs at hydrogen, this is where the minimum occurs in the Hammett plots.

(*iii*) It explains why linear Hammett plots are observed in $S_N2$ reactions where the resonance effect is absent (59, 60).

## Conclusions

The results of this study have shown that adding a more electron withdrawing substituent to the benzene ring in the $S_N2$ reactions between *para*-substituted benzyl chlorides and thiophenoxide ion leads to a transition state with a shorter S--$C_\alpha$ bond, less conjugation between the benzene ring and the α carbon, and virtually no change in the $C_\alpha$---Cl bond. The magnitude of the isotope effects and Hammett ρ values also suggest that the transition states are loose, and product-like.

The results of this and other studies have led the authors to conclude that the strengths of the nucleophile – α-carbon and α-carbon – leaving group bonds play an important role in determining substituent effects on transition state structure. The results suggest that the weaker reacting bond will be shortened and the conjugation reduced but that there will be little or no change in the stronger reacting bond in an $S_N2$ transition state when a more electron withdrawing group is added to the benzene ring of a benzyl compound.

A comparison of the results and the substituent effects predicted by Thornton's reacting bond rule and the More O'Ferrall energy surface method suggests that the parallel effect is of equal or greater importance than the perpendicular effect. This had not been predicted by these theories and it appears that this factor, as well as the strengths of the reacting bonds and the effect of conjugation with the α carbon, will have to be considered before these theories can predict the substituent effects in $S_N2$ transition states correctly.

These studies also suggest that the magnitude of the secondary α-deuterium kinetic isotope effect is significantly lower when conjugation between the aryl group and the α carbon is more important in the transition state. This means one must be careful in using the magnitude of these isotope effects to determine transition state structure in reactions where conjugation with the α carbon is possible.

Finally, this study has shown that the U-shaped Hammett plots observed when negatively charged nucleophiles react with benzyl compounds in $S_N2$ reactions are caused by a variation in the importance of resonance and polar effects of the substituents and not by a change in mechanism or the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

relative importance of bond formation and bond cleavage in the transition state.

## Experimental

*Preparation of materials*

All but one of the undeuterated *para*-substituted benzyl chlorides were commercially available. Each substrate was further purified by vacuum distillation or by recrystallization. The *para*-methoxybenzyl chloride was synthesized by treating an etherial solution of *para*-methoxybenzyl alcohol with concentrated hydrochloric acid (61). The pure product was unstable. As a result, it was stored in dry diethyl ether and distilled under reduced pressure immediately before use. All the deuterated benzyl chlorides, except the *para*-nitrobenzyl chloride, were synthesized by reducing the *para*-substituted methyl benzoates to the alcohols with lithium aluminum deuteride (62). The *para*-methyl and *para*-chlorobenzyl-1,1-$d_2$ alcohols were converted into the chloride with $PCl_5$ (63). The *para*-methoxybenzyl-1,1-$d_2$ alcohol was treated with concentrated hydrochloric acid in ether (61). Benzyl-1,1-$d_2$ chloride was prepared by treating benzyl-1,1-$d_2$ alcohol with Lucas reagent (62). The *p*-nitrobenzyl-1,1-$d_2$ chloride was prepared by nitrating benzyl-1,1-$d_2$ chloride with nitric acid in the presence of acetic anhydride (64).

Twenty grams of fuming nitric acid ($d$ = 1.5) was added slowly with stirring to 30 g of freshly distilled acetic anhydride at 5°C. The temperature of the solution was allowed to rise to 20°C and 5.0 g (0.04 mol) of benzyl-1,1-$d_2$ chloride was added dropwise. The temperature was kept at 20°C during the addition by adjusting the rate of addition and cooling. After all the benzyl-1,1-$d_2$ chloride had been added, the reaction mixture was stirred 8 h at room temperature and then poured onto 100 g of ice. The organic layer was separated and the aqueous layer was extracted with three 50-mL portions of ether. The ether extracts were combined with the organic layer, washed ten times with water, and then dried overnight with anhydrous magnesium sulfate. After the ether had been removed on the rotary evaporator, a distillation yielded 5.84 g of *para*-nitrobenzyl-1,1-$d_2$ chloride (bp 93–97°C at 1 Torr). The product was recrystallized once from methanol and twice from *n*-hexane to give 2.0 g (29%) of *para*-nitrobenzyl-1,1-$d_2$ chloride, mp 72.5–73.5°C. A mass spectrometric analysis at low ionizing voltage showed that the product was 97.2% dideuterated (98.6% deuterated) at the α carbon. The mass spectrometric analysis indicated that all the *para*-substituted benzyl chlorides were between 98.8 and 99.1% deuterated (97.6 to 98.2% dideuterated at the one position) (*vide infra*).

All of the *para*-substituted benzenethiols used in this study were purchased from Aldrich Chemical Company and purified by vacuum distillation. The *p*-Cl and *p*-$CH_3$ benzenethiols were further purified by recrystallization from petroleum ether (bp 60–80°C). The physical properties were in agreement with the literature values. The purified thiols were stored under nitrogen and used within one month.

*Kinetic measurements*

In a typical reaction "extra-dry" nitrogen was bubbled through a mixture of 2 g sodium methoxide and 1.5 L of anhydrous methanol for 0.5 h and then the methanol was distilled under a stream of "extra-dry" nitrogen. Approximately one liter of freshly distilled methanol was transferred into a glove bag. The paraffin oil was removed from approximately 2.7 g of lithium pellets (BDH) by immersing them in petroleum ether. The clean lithium was then transferred to a beaker containing petroleum ether and placed in the glove bag. The glove bag was sealed and purged twice with nitrogen. The oxide layer was removed from the lithium by swirling it in methanol until its surface became lustrous. The purified metal was slowly added to 800 mL of methanol. After the solution had cooled for one hour, two 10-mL samples were removed for titration. The lithium methoxide solution was transferred to a calibrated one-liter Erlenmeyer flask and stoppered tightly. The glove bag was opened and the two 10-mL samples titrated with 0.500 $N$ hydrochloric acid. Finally, sufficient methanol to make the final solution 0.250 $M$ in lithium methoxide was added to the lithium methoxide solution under a nitrogen atmosphere in the glove bag.

Once the correct concentration of lithium methoxide had been obtained, the glove bag was refilled with "extra-dry" nitrogen and a stirring bar and 75 mL of the 0.250 $M$ lithium methoxide solution were introduced into several reaction flasks. All the reaction flasks were stoppered, sealed with parafilm, and stored until they were used in a kinetic run. All the solutions were used within three weeks.

The kinetic runs were carried out in constant temperature baths maintained at 20.00 ± 0.02°C and 30.00 ± 0.02°C. The reactions at 0°C were carried out in a distilled water – ice bath. In a typical reaction, the reaction flask containing the 0.250 $M$ lithium methoxide – methanol solution was allowed to equilibrate at least one hour and then the parafilm seal was removed from the flask and a weighted amount of the nucleophile was introduced under a stream of "extra-dry" nitrogen. The liquid benzenethiols (*p*-H and *p*-$CH_3O$ benzenethiol) were accurately weighed in a gas-tight syringe stoppered with a rubber septum. The syringe and the septum were reweighed after the benzenethiol had been injected into the reaction flask. The weight difference gave the weight of the benzenethiol. The solid benzenethiols (*p*-methyl and *p*-chlorobenzenethiol) were weighed in a small glass vial. The glass vial containing the benzenethiol was simply dropped into the reaction vessel. When the nucleophile had dissolved in the solvent, a weighed amount of the substrate was added under a stream of "extra-dry" nitrogen and the electric timer was activated. The reaction flask was quickly stoppered with a greased adaptor fitted with a serum cap that was shielded from the methanol vapours by a piece of parafilm. The liquid benzyl chlorides (Y = H, $CH_3$, and $CH_3O$) were accurately weighed in a syringe fitted with a rubber septum. The *p*-chlorobenzyl chloride was melted in warm water and then weighed using the same technique. The solid *p*-nitrobenzyl chloride was accurately weighed and then dissolved in 1 mL of anhydrous methanol (distilled under nitrogen) in a small vial. The vial containing this solution was dropped into the reaction vessel. In the *p*-nitrobenzyl chloride reactions 0.253 $M$ lithium methoxide solution was used so that the final solution was 0.250 $M$ in lithium methoxide. Usually, fifteen 2-mL samples were withdrawn from the flask with a 2.5-mL Hamilton gas-tight syringe fitted with a 6 inch needle. The reaction was quenched by injecting each sample into a 25-mL volumetric flask containing approximately 15 mL of 95% ethanol and 4 mL of 0.2–0.3 $N$ sulfuric acid in ethanol. After every sample, "extra-dry" nitrogen was injected into the reaction flask to assure positive pressure inside the vessel and to prevent oxidation of the nucleophile (65). The samples were analyzed on a single-beam Beckman D.U. uv spectrophotometer. After the last sample had been taken, the reaction was left in the bath for ten half-lives, i.e., taken to completion, and then the infinity samples were analyzed.

In the reactions of the *para*-methyl, *para*-hydrogen, and *para*-chlorobenzyl chlorides at 0°C, the reaction flask was removed from the bath and left at room temperature so that these reactions would go to completion in a reasonably short

For personal use only.

time. After ten half-lives at room temperature, the reaction mixture was equilibrated for one hour at 0°C and then the infinity samples were taken.

At least 4 infinity samples were anlyzed for each reaction. The standard deviation for the average infinity absorbance ($A_\infty$) was generally ±0.002. The initial absorbance ($A_0$) was obtained by extrapolating an absorbance versus time plot to the $t = 0$. The maximum possible error of 0.005 in the $A_0$ value did not affect the value of the rate constant.

The nucleophile/substrate ratio was between 1.2 and 2.0 in all of the reactions involving the *p*-$CH_3$, *p*-Cl, and *p*-$NO_2$ benzyl chlorides and the concentrations of the nucleophile and the substrate were adjusted so that the half-life of the reaction was between 40 and 60 min for all of the reactions carried out at 20°C and 30°C and most of the reactions at 0°C. For some of the reactions at 0°C, however, the half-life was longer because the benzylphenyl sulfides were only sparingly soluble in the solvent at 0°C and low concentrations of the substrate had to be used so that the reaction mixtures were homogeneous.

The wavelength and dilution techniques used in studying the reactions were chosen so that two criteria were satisfied, i.e., so that (*i*) the change in absorbance during the reaction was a maximum, and (*ii*) the absorbance at infinity was below 0.80. With one exception, the wavelengths used in this study were between 255 and 270 nm although all of the reactions could have been followed at 265 nm. The reactions between *para*-nitrobenzyl chloride and thiophenoxide ions were monitored at 320 nm.

The second order rate constant was determined from the slope of the linear least-squares line of the log $[c_1 - x]/[c_2 - x]$ versus $t$ plot. $c_1$ is the initial concentration of the thiophenoxide ion and $c_2$ is the initial concentration of the substrate. $x$, the concentration of the substrate (product formed) in "$t$" seconds, is given by $x = c_2\,([A_t - A_0]/[A_\infty - A_0])$ where $A_0$ is the absorbance at $t = 0$, $A_t$ is the absorbance at time "$t$", and $A_\infty$ is the average absorbance at $t$ = infinity. If any kinetic point was more than twice the standard deviation from the least-squares line, the point was rejected and the calculations were repeated. Usually none of the points were rejected. The plots, which extended to between 50 and 80% of completion, were linear and had correlation coefficients greater than 0.999. The average rate constants were obtained from between 4 and 7 kinetic runs.

*Product analysis*

All but one of the *para*-substituted benzyl chlorides reacted with *para*-substituted thiophenoxide ions to give quantitative yields of the appropriate benzylphenyl sulfide in a clean $S_N2$ reaction (1). The $S_N2$ reaction between *para*-methoxybenzyl chloride and *para*-substituted thiophenoxide ions, however, was accompanied by a pseudo first order (solvolysis) reaction giving *para*-methoxybenzylmethyl ether. The percent ether in the product was determined in a gas chromatographic analysis performed on a Varian 3700 gas chromatograph fitted with a flame ionization detector and CDS 111 digital integrator. The injector and detector temperatures were maintained at 220°C and 300°C respectively. The $S_N2$ and solvolysis products in a 10 μL sample were separated by temperature programming an 8 ft × ⅛ in. column of 3% SE-30 on 100/200 mesh gas Chrom Q operating at a flow rate of 7.5 mL/min. The separation was achieved by maintaining the temperature at 100°C for 16 min and then increasing the temperature to 190°C at 80°C/min. The gas chromatograms from the reactions of *para*-methoxybenzyl chloride and *p*-$CH_3O$, *p*-H, and *p*-Cl substituted thiophenoxide ions at 0°C exhibited a very small peak at 13.3 min representing 3 ± 1 percent of the product, followed by 2 large peaks. The minor product in all cases was the *para*-methoxybenzylmethyl ether. The two large peaks were found to be the $S_N2$ product of the reaction and the oxidation product of the *para*-substituted thiophenoxide ion which formed during the work-up (65). The identity of all of the compounds was confirmed by comparing the retention times with authentic samples of each compound (66).

*Deuterium analysis*

The deuterium content of the deuterated *para*-substituted benzyl chlorides was determined in a mass spectrometric analysis at low ionizing voltage. In a typical analysis, the ionizing voltage was reduced until the $M - 1$ peak in the mass spectrum of the undeuterated benzyl chloride disappeared. The average ratio of the heights of the M+1/M peaks for the undeuterated benzyl chloride ($a/b$ in eq. [15]) was obtained by measuring the heights of the M and M+1 peaks from at least twelve different scans of the undeuterated benzyl chloride. The relative amounts of the monodeuterated ($d_1$) and dideuterated ($d_2$) benzyl chloride in the deuterated substrates were determined using the equation

$$[15] \quad H_{M^+} = d_2 + \left(\frac{a}{b}\right) d_1$$

$H_{M^+}$ is the height of the molecular ion peak for the deuterated compound and $d_1$ is equal to the height of the $M - 1$ peak (the molecular ion peak for the monodeuterated compound). The percentage dideuterated benzyl chloride in each deuterated substrate was calculated from at least twelve different scans. These analyses showed that the deuterated *para*-substituted benzyl chlorides were between 97.2 and 98.2 percent dideuterated at the one position. The remaining material was monodeuterated, i.e., no peaks were observed at the *m/e* for the molecular ion of the undeuterated compound.

GUSTAVO GARCIA, YVONNE GRILLASCA, JOAQUIN TAMARIS, ANDREW GREENE, and PIERRE CRABBÉ. Can. J. Chem. **60**, 2521 (1982).

An original approach for the synthesis from $PGA_2$ of C-10 substituted $PGE_2$ analogues is reported. A remarkable regio- and cyclo-selective Baeyer–Villiger reaction is described.

GUSTAVO GARCIA, YVONNE GRILLASCA, JOAQUIN TAMARIS, ANDREW GREENE et PIERRE CRABBÉ. Can. J. Chem. **60**, 2521 (1982).

On décrit la synthèse de nouvelles prostaglandines substituées en position 10 par une méthode originale. On rapporte une remarquable réaction d'oxydation de Baeyer–Villiger, qui est simultanément régio-, cyclo- et stéréosélective.

A number of modified prostaglandins have recently been obtained from naturally occurring $PGA_2$ (**1***a*) through chemical (1) and photochemical (2) transformations. In this communication a photochemical preparation from $PGA_2$ of new C-10 derivatives of $PGE_2$ not easily accessible by other routes is described.

Initial pilot reactions were performed with 15*R* $PGA_2$[2] from the marine corals *Plexaura homomalla*. Having established the appropriate reaction conditions, the sequence was applied to $PGA_2$ methyl ester with the 15*S* configuration.[3] $PGA_2$ methyl ester (**1***b*) in methylene chloride containing excess vinyl acetate, at −78°C under nitrogen, was irradiated with a Hanau TQ150 high pressure ultraviolet lamp equipped with a Pyrex filter. A mixture of stereoisomeric cycloadducts (**2***a*) ($[\alpha]_D$ +31° ($CHCl_3$); $\nu_{max}$ (neat): 3450, 1740 $cm^{-1}$, δ (in $CCl_4$, using TMS as a standard): 0.89 (t, 20-Me), 1.93 and 1.97 (s, OAc), 3.6 (s, $CO_2Me$), ca. 5.1–6.3 (m, vinylic H)) was obtained in 87% yield. There is ample precedent for the photochemical cycloaddition to the $\Delta^{10}$-double bond of $PGA_2$ under these conditions (2). No significant amount of any positional isomer, i.e., C-10′-acetoxy derivative, was found (3).

For the subsequent transformations of the cyclobutane ring, the C-15 hydroxyl group had to be appropriately protected. The *tert*-butyldimethylsilyl ether **2***b* ($\nu_{max}$ (neat): 1740 $cm^{-1}$; δ ($CCl_4$): 0.89 (20-Me, 15-*t*-Bu), 1.93 and 1.97 (s, OAc), 3.59 (s, $CO_2Me$), 4.00 (m, $\overset{|}{C}H—O—$), 5.15–5.67 (m, vinylic H); ms *m/e*: 548 ($M^+$), 517 ($M^+ - OMe$), 419 ($M^+ - t$-Bu)), obtained in quantitative yield from the isomeric mixture **2***a* by the usual procedure, proved to be the best of the several protecting groups examined. An essentially identical mixture (**2***b*) was obtained when the *tert*-butyldimethylsilyl ether **1***c*, readily prepared from **1***b*, was irradiated in the presence of vinyl acetate.

Hydrolysis of the C-11′ acetate of compound **2***b* with potassium carbonate in aqueous methanol for 30 min at 20°C gave selectively the corresponding alcohol **2***c*: $[\alpha]_D$ +19° ($CHCl_3$); $\nu_{max}$ (neat): 3450, 1740, 1600 $cm^{-1}$; δ ($CCl_4$): 0.88 (20-Me, 15-*t*-Bu), 3.7 (s, $CO_2Me$), 5.53 (m, *cis* vinylic H), 5.63 (m, *trans* vinylic H). Oxidation of the C-11′-hydroxyl group in **2***c* with pyridinium dichromate in dry methylene chloride (4) afforded the C-10,11 isomeric diketo derivatives in 76% yield: $[\alpha]_D$ −6° ($CHCl_3$); $\nu_{max}$ (neat): 1790, 1740–1735 $cm^{-1}$; δ

[1]Author to whom correspondence may be addressed.

[2]15*R* $PGA_2$ was obtained from the coral collected along the coast of Yucatan peninsula (Mexico).

[3]15*S* $PGA_2$ was collected along the coast of Cuba.

(CCl$_4$): 0.88 (20-Me, 15-*t*-Bu), 3.58 (s, $CO_2Me$), 4.03 (m, CHO—), 5.46 (m, *cis* vinylic H), 5.63 (m, *trans* vinylic H). Preparative tlc separation on silicagel (hexane–AcOEt, 3:1) of these stereoisomers provided 40% of the diketo derivative (**3**) and 60% of its α-isomer (**4**). Individual treatment of the diketones **3** and **4** with 2 equiv. of 30% hydrogen peroxide in aqueous acetic acid (5) at 0°C furnished the corresponding keto lactones **5***a* and **6***a* respectively in ca. 90% yield. A noteworthy feature of the Baeyer–Villiger reaction of these diketones is the apparently complete regio- (and cyclo-) selectivity observed.

The structure and stereochemistry of these bicyclic prostanoid lactones were established on the basis of their spectroscopic and chiroptical properties. The less polar isomer **6***a* displayed: $[\alpha]_D$ −12° ($CHCl_3$); $\nu_{max}$ (neat): 1790, 1740–1735 cm$^{-1}$; δ ($CDCl_3$): 0.89 (20-Me, *t*-Bu), 3.66 (s, $CO_2Me$), 4.2 (m, 15βH), 5.43 (m, *cis* vinylic H), 5.76 (m, *trans* vinylic H); ms *m/e*: 520 ($M^+$). The more polar lactone isomer **5***a* exhibited: $[\alpha]_D$ +2° ($CHCl_3$); $\nu_{max}$ (neat): 1790, 1740–1735 cm$^{-1}$; δ ($CDCl_3$): 0.92 (20-Me, *t*-Bu), 3.66 (s, $CO_2Me$), 4.2 (m, 15βH), 5.43 (m, *cis* vinylic H), 5.76 (m, *trans* vinylic H); ms *m/e*: 520 ($M^+$).

The salient feature of the nmr spectra is the signal associated with the C-11 proton. While in the lactone derivative **5***a* the C-11α proton appears at 5.03 ppm as a pseudo-triplet ($J$ = 4.5 Hz), in the lactone isomer **6***a* the 11β proton appears as a doublet of doublets at ca. 4.9 ppm with coupling constants $J_{H_{10,11}}$ = 5 Hz and $J_{H_{11,12}}$ = 8 Hz, thus supporting the γ-lactone stereochemical assignment.

The hydrolysis of both ethers **5***a* and **6***a* could be achieved directly in the acid medium at the end of the Baeyer–Villiger reaction, simply by diluting with water and leaving at room temperature for 2 h. The less polar α-lactone derivative **6***b* presented $\nu_{max}$ (neat): 3450, 1780, 1740 cm$^{-1}$; δ ($CDCl_3$): 0.89 (t, 20-Me), 3.66 (s, $CO_2Me$), 4.1 (m, 15βH), 5.4 (m, *cis* vinylic H), 5.73 (m, *trans* vinylic H); ms *m/e*: 406 ($M^+$). The more polar isomeric lactone **5***b* exhibited: $\nu_{max}$ (neat): 3450, 1780, 1740 cm$^{-1}$; δ ($CDCl_3$): 0.89 (t, 20-Me), 3.66 (s, $CO_2Me$), 4.13 (m, 15βH), 5.4 (m, *cis* vinylic H), 5.75 (m, *trans* vinylic H); ms *m/e*: 406 ($M^+$).

These stereochemical assignments were further supported by the CD curves. The C-10,11β lactone derivative **5***a* displayed an intense negative Cotton effect in the 300 nm region ($[\theta]_{292}$ −12350) (dioxane). Its C-10,11α stereoisomer **6***a* showed a weak negative Cotton effect CD curve in the same region ($[\theta]_{299}$ −4450) (dioxane). Similarly, the 15-alcohol of the β-isomer **5***b* exhibited a much stronger negative CD curve ($[\theta]_{302}$ −8555) (dioxane) than its α-counterpart **6***b* ($[\theta]_{294}$ −4245) (dioxane). These findings are in agreement with previous studies which have shown that C-10,11β cyclo-prostanoids display an intense negative Cotton effect in the 300 nm region (2).

Compound **6***b* is a $PGE_2$ derivative in which formally a C-10 acetic acid chain is cyclized with the C-11α hydroxyl. It is of interest to note that a recent report (6) mentions a Baeyer–Villiger oxidation of a similar system to yield the expected keto-lactone, along with the corresponding carboxymethyl enone resulting from lactone cleavage. Work in progress involves the conversion of $PGA_2$ to other PGE derivatives using this simple photochemical approach.

A theoretical study of the reaction coordinate for the coupling of phenyl radical with methyl anion, chloride and fluoride ions to yield the corresponding radical anion is carried out. In this process, σ and σ* MO's associated to the new bond are formed. The σ* MO is the lowest lying of the system for the radical anion formed in the coupling with chloride ion. With methyl anion and fluoride ion, σ and σ* MO's are also formed, but before they reach the equilibrium distance of the radical anion intermediate, the π* MO equals its energy with the incipient σ*, and from there on to the equilibrium distance, the odd electron stays in the π* MO.

HUGO VILLAR, EDUARDO A. CASTRO et ROBERTO A. ROSSI. Can. J. Chem. **60**, 2525 (1982).

On a réalisé une étude théorique des coordonnées de la réaction de couplage du radical phényle avec l'anion méthyle, les ions chlorure et fluorure qui conduit à l'anion radicalaire correspondant. Dans ce processus, il se forme des OM σ et σ* associés à la nouvelle liaison. L'orbitale moléculaire σ* est la plus basse orbitale liante du système d'anion radicalaire formé lors du couplage avec l'ion chlorure. Dans le cas de l'anion méthyle et de l'ion fluorure, il se forme également des OM σ et σ* mais avant qu'elles n'atteignent la distance d'équilibre de l'anion radicalaire intermédiaire, l'énergie de l'OM π* naissante devient égale à celle de l'OM σ* naissante et à partir de ce point jusqu'à la distance d'équilibre, l'électron célibataire demeure dans l'OM π*.

[Traduit par le journal]

## I. Introduction

During the last few years there has been a growing interest towards the chemical study of radical anions (1–4), because of their remarkable importance in organic electrochemistry and monomolecular nucleophilic substitution reactions. It is a well known fact that when radical anions of aromatic systems are attached to a nucleofugal group, they decompose to yield an aromatic radical and an anion corresponding to the nucleofugal group (5). The occurrence of such a reaction (6) as well as the decomposition rate depend to a great extent on the nature of the aromatic substrate, the presence of another substituent, and the position of the leaving group with respect to the substituents (2, 7).

Many experimental results indicate that during dissociation, the odd electron is transferred from a π* MO to a σ* MO (9, 10). This explanation would be an acceptable one when the σ* MO is associated to the nucleofugal – aromatic substrate bond, and that such a bond would be unstable. On the contrary, when the odd electron is located in a π* MO, the unstableness would spread over the whole molecule in general, and in a few cases, located on a particular bond (10). Consequently, the stable form of the radical anion could be assigned when the odd electron is in a π* MO, and its decomposition would take place by way of a transition to a σ* MO (11, 12). The coupling process (8) must correspond to an identical coordinate reaction as that of the decomposition (owing to the microscopic reversibility principle). Up to now, radical anions have been studied from a theoretical point of view by means of Hückel-like methods combined with PMO analysis (10). Then, as a natural following step, we deem appropriate to apply a somewhat more elaborate method which allows us to obtain a point-by-point information about the reaction coordinate, for elucidating the reasons responsible for the behavior of radical anions with respect to their relative stability as well as the correlation of their decomposition rates.

The purpose of this paper is to report the calculations of the reaction coordinate by INDO and CNDO/2 methods, for the coupling of phenyl radical with methyl, fluoride, and chloride anions. Theoretical results are then discussed in a comparative way with available experimental data.

## II. Calculation procedure

The molecular orbital calculations were made by the INDO method (13, 14) for toluene and fluorobenzene radical anions, while for chlorobenzene

radical anion the CNDO/2 method was chosen because of computer space limitations. We started the analysis of the reaction coordinate for $(Ph—CH_3)^{-\cdot}$ by determining the minimum total energy for each one of the reactants, i.e. $Ph^{\cdot}$ and $CH_3^-$. For the methyl anion we found an equilibrium distance $d_{C—H} = 1.130$ Å and a planar conformation. The equilibrium distances for $Ph^{\cdot}$ were determined by keeping up the $C_2$ symmetry axis. The values obtained are (see Fig. 1) $a = 1.370$ Å; $b = 1.405$ Å; $c = 1.380$ Å; and $d_{C—H} = 1.080$ Å. The reaction coordinate was simulated starting from the equilibrium values for the isolated species at an infinite distance. Then, from a value of 8 Å for the distance $d_{Ph^{\cdot}—CH_3}$ a linear variation of the angle HCH of the $CH_3$ group with $d_{C—C}$ was made up to reach the equilibrium distances in the radical anion. We give the potential curve in Fig. 2. We can see that the variation is regular, so we believe that the chosen mimicked reaction coordinate is a reasonable one. Figure 3 shows the energy of the frontier orbitals as functions of the reaction coordinate. For the radical anions $(Ph—F)^{-\cdot}$ and $(Ph—Cl)^{-\cdot}$ we simulated the reaction coordinate in a similar fashion, and potential curves (not reported here) are equivalent to that shown in Fig. 2. The energy of frontier orbitals as a function of the C—X distance for $(Ph—F)^{-\cdot}$ and $(Ph—Cl)^{-\cdot}$ are displayed in Figs. 4 and 5.

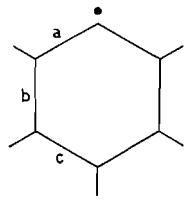

FIG. 1. Geometric parameters for phenyl radical.

## III. Analysis of results and discussion

These results demonstrate quantitatively that in the process of coupling of an aryl radical with a nucleophile, σ and σ* MO's are formed. As the reactants approach each other, σ decreases and σ* increases their energies, and two different situations can be found. If σ* is the lowest antibonding MO, such as in the coupling of $Ph^{\cdot}$ and $Cl^-$, the radical anion will be unstable and it can revert to the starting molecule. On the other hand, in the coupling of $Ph^{\cdot}$ with methyl anion or fluoride ion, σ and σ* MO's are also formed, but before reaching the equilibrium distances of the radical anions, the π* MO equals its energy with the incipient σ* MO, and from there on, σ* is always higher in energy than the π* MO, so that the radical anion formed is

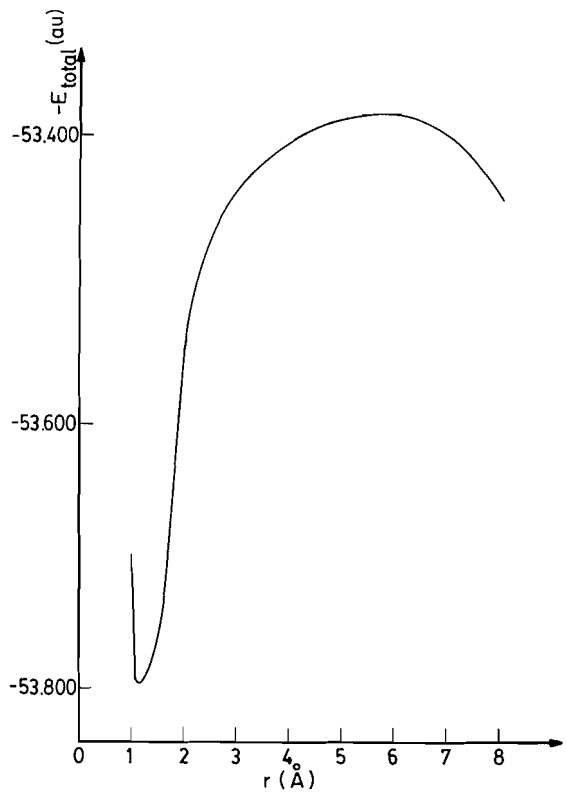

FIG. 2. Total energy curve for the $(Ph—CH_3)^{-\cdot}$ system as a function of the reaction coordinate.

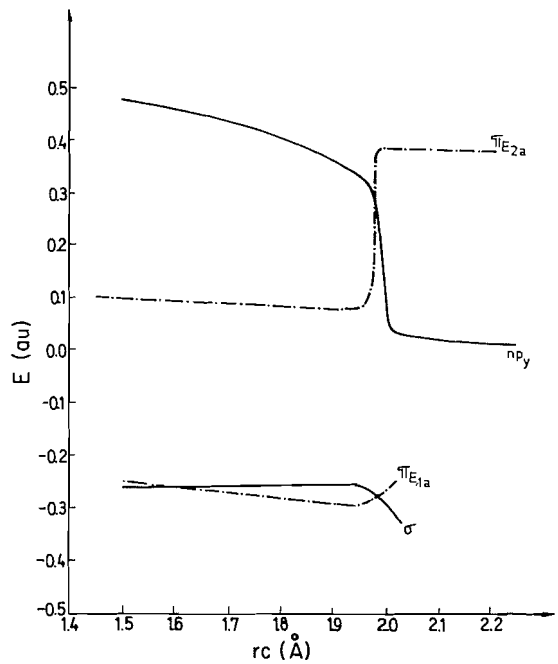

FIG. 3. Variation of the frontier orbital energies as a function of the reaction coordinate for the $(Ph—CH_3)^{-\cdot}$ system.

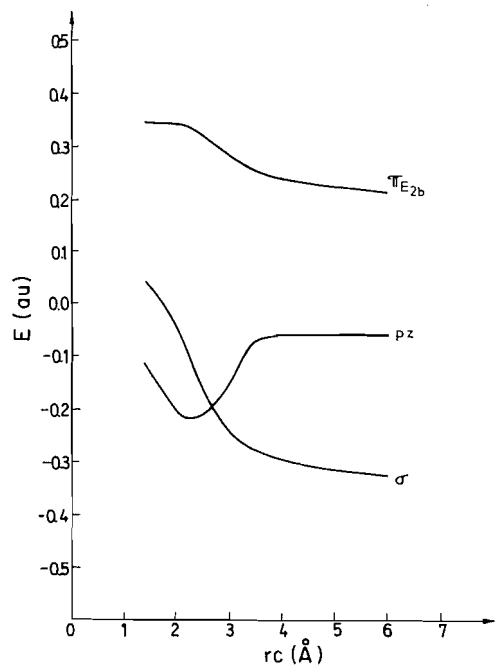

FIG. 5. Variation of the frontier orbital energies as a function of the reaction coordinate for the $(Ph—Cl)^{-\cdot}$ system.

a $\pi^*$ one. However, there is a difference between these two radical anions. Toluene radical anion does not decompose into reactants, but fluorobenzene radical does (5). From Figs. 3 and 4 we can see that the distance of the orbital crossing is farther from equilibrium in toluene than in the fluorobenzene radical anion. What eventually happens is that by internal conversion, the odd electron is transferred from the $\pi^*$ MO to the $\sigma^*$ MO, and this process is more probable the shorter the orbital crossing distance from the equilibrium. Vibrations of the radical anion provide the transfer mechanism between these orthogonal orbitals. That is to say, vibrations lower the symmetry momentarily and allows the states to mix (12). These results are in agreement with those found in $S_{RN}1$ reactions. Carbanionic nucleophiles couple with aryl radicals in a very efficient way, but coupling reaction with halide ions is not known, although the reverse reaction (5) is well known. The relative energies of the $\sigma^*$ and $\pi^*$ MO's in the coupling process in the $S_{RN}1$ mechanism are important not only with the halide ions, but also with nucleophiles derived from Te (15), As (16), and Sb (17), in which reversible coupling with aryl radicals leads to the scrambling of aryl rings. These results were ascribed to the low lying $\sigma^*$ MO's of the carbon–nucleophile bond formed (10).

# Fittig bislactones in cyclopentenone synthesis: short synthesis of methylenomycin B

GEORGE M. STRUNZ AND G. SANKAR LAL

*Maritimes Forest Research Centre, Canadian Forestry Service, Department of the Environment, P.O. Box 4000, Fredericton, N.B., Canada E3B 5P7*

Received May 18, 1982

GEORGE M. STRUNZ and G. SANKAR LAL. Can. J. Chem. **60**, 2528 (1982).

Treatment of the Fittig bislactone, 3-(1,1-dihydroxypropyl)glutaric acid di-γ-lactone, with methyllithium, followed by alkali, afforded 5-carboxymethyl-2,3-dimethylcyclopent-2-en-1-one. This compound on decarboxylation with lead tetraacetate afforded the antibiotic methylenomycin B.

GEORGE M. STRUNZ et G. SANKAR LAL. Can. J. Chem. **60**, 2528 (1982).

Le bislactone de Fittig, le di-γ-lactone de l'acide glutarique 3-(1,1-dihydroxypropyl), réagit avec le méthyllithium suivi par l'alkali pour fournir carboxyméthyl-5-diméthyl-2,3-cyclopentèn-2-one-1. La décarboxylation oxidative de ce composé par le tétraacétate de plomb fournit l'antibiotique méthylenomycine B.

The formation of bislactones of structure **1** by acylative decarboxylation of tricarballylic acid through the action of acid anhydrides was reported by Rudolf Fittig more than eighty years ago (1).[1] The reaction, which appears to be formally analogous to the more familiar Dakin–West reaction discovered later (2, 3), has been usefully exploited in natural product synthesis (4). Borohydride reduction under alkaline conditions of a Fittig bislactone (**1**, R = $C_8H_{17}$) gave *trans*-tetrahydro-2-octyl-5-oxo-3-furanacetic acid, a key intermediate in the synthesis of *dl*-avenaciolide by Parker and Johnson (4).

The arrangement of functionality in the bislactones is such that, for reaction with appropriate carbanion species, they might be regarded as masked enol lactones possessing a protected acetic acid side chain. These compounds could thus be potential precursors of 1,4-diketones, hence of substituted cyclopentenones, cf. refs. 5–7.

In this paper we report the realization of such a cyclopentenone synthesis, and its application in a short synthesis of the antibiotic methylenomycin B (8, 9), previously synthesized by Jernow *et al.* (9).[2]

Rather surprisingly, the reaction of propionic anhydride with tricarballylic acid did not give satisfactory yields of the required precursor **1** (R = $C_2H_5$) under conditions where acetic anhydride readily afforded the lower homologous bislactone, cf. refs. 3, 4. The desired conversion could, however, be effected in acceptable yield (53%) with catalysis by pyridine.

Treatment of **1** (R = $C_2H_5$) with slightly more than one equivalent of methyllithium gave a salt, which in principle can exist as an equilibrium mixture containing any or all of the species **2***a*–*c*. Without isolation, this intermediate was treated with aqueous ethanolic sodium hydroxide solution, affording, after chromatographic purification, the cyclized product **3**. The yield for the methyllithium reaction is profoundly influenced by the selection of an appropriate solvent system: it appears to be desirable to find a solvent from which the lithium salt **2** will separate as a fine powdery precipitate. In the present case the reaction was conducted in a 1:3 tetrahydrofuran–toluene mixture at −78°C. The overall yield of pure **3** obtained from **1** (R = $C_2H_5$) was 50%.

While a number of routes are conceivable for effecting the final conversion of **3** to **4** (e.g. Hunsdiecker, Curtius, and related reactions), the procedure developed independently by Rao and co-workers (10) and Ho and Wong (11) for preparing α-methylene lactones offered the most direct approach. This method is based on the Kochi oxidative decarboxylation of acids by lead tetraacetate in the presence of cupric acetate (12). Since the decarboxylation is believed to involve free radical as well as carbonium ion intermediates (12), its applicability in the present instance was not assured in view of the known propensity of methylenomycin B to spontaneous polymerization (8, 9). In the event, however, brief treatment of **3** with lead tetraacetate in refluxing benzene containing pyridine and a catalytic amount of cupric acetate gave, after chromatographic purification, the desired product **4** in 31% yield.

[1]Fittig employed the sodium salt of tricarballylic acid (1), but later investigators found that better yields of bislactones were obtained when the free acid was used (3), particularly if the reaction flask was previously washed with a strongly alkaline detergent (4).

[2]Since submission of this manuscript, reports of two other syntheses of methylenomycin B have been published (13, 14).

0008-4042/82/202528-03$01.00/0

Comparison of the spectroscopic characteristics of the product with published data (8, 9)[3] confirmed its identity with methylenomycin B. Like the earlier investigators (8, 9) we have also had to contend with the spontaneous polymerization of **4** during subsequent manipulations.

Further studies on the reaction of Fittig bislactones with organometallic reagents are in progress to investigate the scope of the reaction in cyclopentenone synthesis.

## Experimental

Melting points were determined on a hot-stage apparatus and are uncorrected. Infrared and ultraviolet spectra were recorded on Beckman Acculab 2 and DK-2A spectrophotometers respectively. Nuclear magnetic resonance spectra were run on a Varian T-60 instrument. Mass spectra were obtained with an Hitachi Perkin–Elmer RMU-6D mass spectrometer. High resolution mass spectra were provided by Mr. A. I. Budd, University of Alberta. Microanalyses were performed by Spang Microanalytical Laboratory, Eagle Harbor, MI.

*3-(1,1-Dihydroxypropyl)glutaric acid di-γ-lactone (1, R = $C_2H_5$)*

Tricarballylic acid (2.0 g, 11.4 mmol) was added to refluxing propionic anhydride (20 mL, distilled before use) containing pyridine (0.2 mL). The solution was heated under reflux, and carbon dioxide evolution was periodically monitored by the precipitation of carbonate from a solution of barium hydroxide. The initial, quite vigorous, evolution of carbon dioxide moderated after about 1 h, but it had still not ceased after 4.5 h when the reaction was terminated by distillation of the volatile material. The residue was dissolved in acetone and treated with activated charcoal. After removal of the charcoal by filtration, evaporation of the solvent *in vacuo* yielded a pale brown residue which crystallized on standing. Recrystallization from toluene afforded almost colorless crystals of **1** (R = $C_2H_5$) (1.03 g, 53%), mp 65–66°C; ir ($CHCl_3$): 1800 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.07 (3H, t, $J$ = 7 Hz), 2.06 (2H, q, $J$ = 7 Hz), 2.26–3.26 (5H, m); mass spectrum *m/e* (relative intensity) (ion) *inter alia*: 171.0642 (0.18) $(C_8H_{11}O_4)^+$, $(MH^+)$, 141.0186(38) $(C_6H_5O_4)^+$, 126.0682(6) $(C_7H_{10}O_2)^+$, 113.0241(15) $(C_5H_5O_3)^+$, 99.0081(22) $(C_4H_3O_3)^+$, 98.0732(62) $(C_6H_{10}O)^+$, 69.0344(7) $(C_4H_5O)^+$, 57.0365(100) $(C_3H_5O)^+$, 55.0204(31) $(C_3H_3O)^+$. *Anal.* calcd. for $C_8H_{10}O_4$: C 56.46, H 5.93; found: C 56.32, H 5.89.

*5-Carboxymethyl-2,3-dimethylcyclopent-2-en-1-one (3)*

A 100 mL three-necked round bottom flask equipped with a reflux condenser and a nitrogen inlet tube, a pressure equalizing dropping funnel, and a rubber septum stopper was charged with the bislactone **1** (R = $C_2H_5$) (2.0 g, 11.8 mmol). Anhydrous tetrahydrofuran (10 mL) was added through the dropping funnel under a nitrogen atmosphere, and when the bislactone was in solution, toluene (30 mL) was added. The flask was immersed in a Dry Ice – acetone bath, then an ether solution of methyllithium (containing 13.0 mmol) was added by syringe with magnetic stirring during 30 min, resulting in the separation of a fine precipitate. When the addition was complete the solvent was removed by distillation under reduced pressure. The residual lithium salt was heated at reflux under a nitrogen atmosphere for 16 h with a solution containing sodium hydroxide (2.4 g, 60 mmol) in water (20 mL) and ethanol (20 mL). After the alkali treatment, most of the ethanol was removed under reduced pressure, and the solution was adjusted with 50% hydrochloric acid to pH 2 and extracted with ether (5 × 30 mL). The ether solution was extracted with saturated sodium bicarbonate solution (5 × 25 mL). The aqueous phase was then made acidic by addition of 50% hydrochloric acid and extracted with ether (5 × 30 mL). After washing with water and drying over magnesium sulfate, the solvent was removed *in vacuo* to give a pale brown residue which crystallized on standing. The product was purified by chromatography on silica gel preparative layer plates (solvent system, acetone–toluene 1:3). In this manner the acid **3**

[3]We thank Dr. Jane Jernow, Hoffmann-La Roche Inc., Nutley, New Jersey for supplying us with the infrared spectrum of methylenomycin B.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

(990 mg, 50% from bislactone) was obtained as white crystals, mp 89–95°C; ir ($CHCl_3$): 3700–2400 (br), 1715–1700, 1650 $cm^{-1}$; uv $\lambda_{max}$ (EtOH): 234 nm (ε 11 300); nmr ($CDCl_3$) δ: 1.72 (3H, br s), 2.07 (3H, br s), 2.20–3.05 (5H + impurity, m), 9.42 (1H, br s); mass spectrum *m/e* (relative intensity) (ion) *inter alia*: 168.0785(77) $(C_9H_{12}O_3)^{\ddagger}$, (M‡), 151.0733(10) $(C_9H_{11}O_2)^+$, 150.0681(59) $(C_9H_{10}O_2)^{\ddagger}$, 124.0854(11) $(C_8H_{12}O)^{\ddagger}$, 123.0807(94) $(C_8H_{11}O)^+$, 122.0733(100) $(C_8H_{10}O)^{\ddagger}$, 109.0648(28) $(C_7H_9O)^+$, 108.0574(56) $(C_7H_8O)^{\ddagger}$, 107.0499(39) $(C_7H_7O)^+$, 95.0856(21) $(C_7H_{11})^+$, 94.0782(31) $(C_7H_{10})^{\ddagger}$, 93.0704(10) $(C_7H_9)^+$, 81.0705 (21) $(C_6H_9)^+$, 80.0624(27) $(C_6H_8)^{\ddagger}$, 79.0553(59) $(C_6H_7)^+$, 67.0555(24) $(C_5H_7)^+$, 55.0565(17) $(C_4H_7)^+$.

A sample was sublimed (65°C/ca. 0.2 Torr) for analysis: mp 94–97°C. *Anal.* calcd. for $C_9H_{12}O_3$: C 64.27, H 7.19; found: C 64.31, H 7.18.

*2,3-Dimethyl-5-methylenecyclopent-2-en-1-one: methylenomycin B (4)*

A 50 mL two-necked round bottom flask fitted with a reflux condenser, a nitrogen inlet, and a glass stopper was charged with the acid **3** (250 mg, 1.49 mmol), lead tetraacetate (1.120 g, 2.53 mmol), cupric acetate monohydrate (70 mg, 0.35 mmol), and pyridine (0.05 mL, 49.1 mg, 0.62 mmol). The system was purged with nitrogen and dry benzene (12.0 mL) was added. The mixture was stirred at 22°C for 30 min and was then heated under reflux for 25 min, after which it was poured into cold water (100 mL). The benzene layer was separated and the aqueous phase was extracted with methylene chloride (4 × 25 mL). The combined extracts were concentrated *in vacuo* to about 2 mL and applied to silica gel preparative layer plates for purification of the product (solvent system, toluene–ethyl acetate 5:95). In this manner **4** (56.8 mg, 31%) was obtained as a colorless oil, identified as methylenomycin B by comparison of spectra with published data (8, 9).[3] Infrared (neat film): 1690, 1660, 1625 $cm^{-1}$; uv $\lambda_{max}$ (EtOH) nm (ε): 241 (5800), 263 (sh 4200); nmr ($CDCl_3$) δ: 1.81 (br s, $CH_3$), 2.11 (br s, $CH_3$) 3.13 (br s, $—CH_2—$), 5.36, 6.07 (broad singlets, olefinic $CH_2$); all signals showing splitting due to coupling; mass spectrum *m/e* 122 (M‡).

While solutions of the product **4** in chloroform or methylene chloride could be stored for moderate periods (several days) in the refrigerator, removal of solvent resulted in polymerization; the resulting colorless material could not be redissolved in the same solvents. Jernow *et al.* (9) have observed that methylenomycin B forms a stable complex with 30% hydrogen peroxide solution, from which it may be recovered unchanged by solvent extraction. This provides an excellent means of storing methylenomycin B for longer periods.

## Acknowledgments

# Synthesis of some *N*- and *S*-glycosides of D-galactose bearing hydrazinocarbonyl and diazomethylcarbonyl functions in the aglycon

GILLES DUPUIS AND BENOÎT LECLAIR

*Département de Biochimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1H 5N4*

Received March 12, 1982

GILLES DUPUIS and BENOÎT LECLAIR. Can. J. Chem. **60**, 2531 (1982).

We describe the synthesis of *N*- and *S*-glycosides derived from D-galactopyranose in which the aglycon bears certain reactive groups. In a first series, the anomeric carbon is linked to an amino group that is acylated by a functionalized succinic acid chain. The terminal group of the aglycon moiety is a hydrazide function which can be converted by ultraviolet light irradiation into an azide and a nitrene. Alternatively, the terminal group is a diazoketone function which can be converted into a carbene, by ultraviolet light irradiation. A second series comprises glycosides of 1-thio-β-D-galactopyranose. The aglycon consists of a 6-carbon chain with a carboxylic end group. The latter has been converted into a hydrazide and diazoketone function. We show that the diazo group of the diazoketones (compounds **5** and **12**) is susceptible to decomposition by ultraviolet irradiation, being nearly quantitatively decomposed after 3 minutes. These compounds add to a growing list of hexose derivatives which can be used in the field of photoaffinity-labeling of the sugar binding sites of certain lectins and of hexose transport systems, or to prepare modified proteins or ligands for affinity chromatography.

GILLES DUPUIS et BENOÎT LECLAIR. Can. J. Chem. **60**, 2531 (1982).

Nous décrivons la synthèse de *N*- et *S*-glucosides dérivés du D-galactopyranose chez lesquels la portion aglycone porte certains groupements réactifs. Dans la première série de dérivés, le carbone anomérique est lié à un groupement aminé qui est acylé par un acide succinique fonctionnalisé. D'une part, la partie terminale de la portion aglycone est une fonction hydrazide qui peut être convertie en azide et en nitrène, après irradiation par la lumière ultraviolette. D'autre part, le groupement terminal de l'aglycone est une diazocétone qui peut être convertie en un dérivé carbène, par irradiation sous lumière ultraviolette. Dans la deuxième série de dérivés, nous avons préparé des glycosides du 1-thio-β-D-galactopyranose. La portion aglycone est une chaîne de six unités de carbone se terminant par un groupement carboxyle. Ce dernier a été converti en hydrazide ou en diazocétone. Nous montrons que le groupement cétodiazo des composés **5** et **12** est décomposé par irradiation ultraviolette. Trois minutes d'irradiation suffisent à décomposer les produits. Les composés décrits ici s'ajoutent à la liste de dérivés d'hexoses déjà décrits dans la littérature, lesquels peuvent être utilisés comme photo-marqueurs, du site de fixation de glucides chez des lectines et dans le système de transport des hexoses ou pour préparer des protéines modifiées ou des colonnes d'affinité ayant des glucides comme affinants.

## Introduction

The method of affinity-labeling has achieved success for determination of the nature of the amino acid residues located in the environment of the "active site" of biologically active proteins such as enzymes, antibodies, and others (1–3). This method is based on the synthesis of suitable reactive derivatives of the natural ligand or of molecules structurally related to it. The choice of derivatives is dictated by several factors such as reactivity, specificity of labeling, and stability in the medium used for reaction.

The design of affinity-labeling reagents has been extended to light-sensitive reagents (photoaffinity-labeling). This approach was pioneered by Westheimer and his group in their study of the active site of chymotrypsin (4). These workers used a diazo derivative which yielded a highly reactive nitrene after irradiation by light (5, 6).

Other types of derivatives have also been prepared. The ones used mainly are diazo and chloromethyl ketone derivatives or other activated forms of the carbonyl function (7, 8).

The choice of ligand is dictated by the properties of the protein to be modified. For instance in the case of lectins, a class of proteins which can specifically recognize monosaccharides or polysaccharidic structures (9, 10), synthesis of labeling probes would involve preparation of suitably modified glycosides. From a synthetic standpoint, the synthesis of monosaccharide derivatives appears to be the simplest route for affinity-labeling of lectins.

We have selected D-galactose as a model hexose and report the synthesis of derivatives wherein the anomeric carbon bears an aminoacyl chain or a *S*-alkyl chain. The compounds possess a hydrazide group which should be easily transformable into the corresponding azide (11) and nitrene groups (12), or a diazoketone function which can be transformed into the corresponding carbene, by ultraviolet irradiation (13).

## Results and discussion

### *Synthesis of 1-amino-β-D-galactopyranosides*

β-D-Galactopyranosylamine **2** (14) was *N*-acylated to give the methyl succinamido derivative **3**. This was done in a manner similar to the one described by Gordon *et al.* (15) for the synthesis of the ε-aminocaproyl derivative of β-D-galactopy-

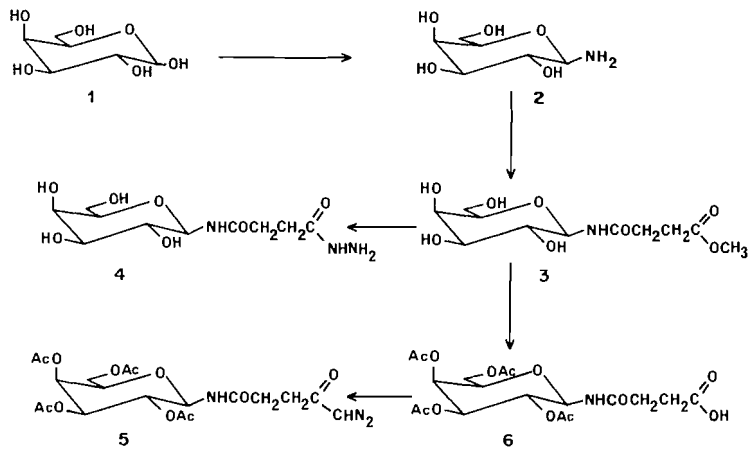

SCHEME 1

ranosylamine. Briefly, the mixed anhydride prepared from monomethyl succinate and isobutyl chloroformate constituted the necessary acylating agent which was allowed to react with compound **2** suspended in DMF.[1] Compound **3** was obtained crystalline in 70% yield. Attempts to prepare the analogous derivative of α-D-galactopyranosylamine failed. Treatment of compound **3** for two hours with hydrazine in refluxing methanol afforded a nearly quantitative yield of the crystalline hydrazide **4**.

In order to prepare the free acid from compound **3**, the latter was saponified by treatment with a methanolic solution of KOH, under reflux, for a brief period of time. Under these conditions, the methyl ester group was quantitatively cleaved, as evidenced by $^1$Hmr and ir spectra, whereas the amide bond remained intact. The oily compound was peracetylated with acetic anhydride in pyridine to afford compound **6**.

Several methods have been used to introduce the diazoketone function. These include conversion of the free acid into an acyl halide (16–20) and subsequent reaction with diazomethane or reaction of a mixed anhydride with diazomethane (21). We selected the mixed anhydride method because of simplicity of its application to **6**. The triethylammonium salt of **6** was treated with isobutyl chloroformate, and the ensuing mixed anhydride was mixed with an ether solution of freshly prepared diazomethane. Stirring the mixture at room temperature (overnight) gave only a low yield of conversion of the anhydride, as evidenced by the strong ir band at 1760 cm$^{-1}$. The mixture was therefore gently heated under reflux for 18 h, in the dark. An ir spectrum revealed complete disappearance of the 1760 cm$^{-1}$ absorption band and appearance of the characteristic diazo band at 2200 cm$^{-1}$ and a band at 1640 cm$^{-1}$ for the diazo ketone structure. These spectral features suggested a successful conversion of **6** into **5**.

The light sensitivity of diazo derivative **5** was investigated by irradiation of the compound with an ultraviolet lamp. The disappearance of the band at 254 nm was followed spectrophotometrically. A fifty percent decrease in optical density was observed after less than one minute, and nearly quantitative decomposition occurred after 3 minutes of irradiation.

*Synthesis of 1-thio-β-D-galactopyranosides*

Alkyl 1-thioaldopyranosides containing an amino, imido ester, aldehyde, or ester group at the terminal position of the aglycon have previously been reported (22–26). These compounds can be prepared by *S*-alkylation of 1-thioglycoses or by reaction of ethyleneimine with 1-thioaldose derivatives. Because of the demonstrated facility of the first approach (23), this method was selected in the present study.

A series of 1-thio-β-D-galactopyranose derivatives was generated by introduction of a medium size alkyl chain of six carbon units bearing the appropriate reactive functions. The starting material was 2,3,4,6-tetra-*O*-galactopyranosyl bromide (27) which was allowed to react with thiourea, as described by Bonner and Kahn (28). The ensuing crystalline hydrobromide salt **7** was quantitatively reduced to 2,3,4,6-tetra-*O*-acetyl-1-thio-β-D-galactopyranose **8** by treatment with sodium bisulfite at alkaline pH (29). The potassium thiolate of **8** was allowed to react with methyl 6-bromohexanoate, as

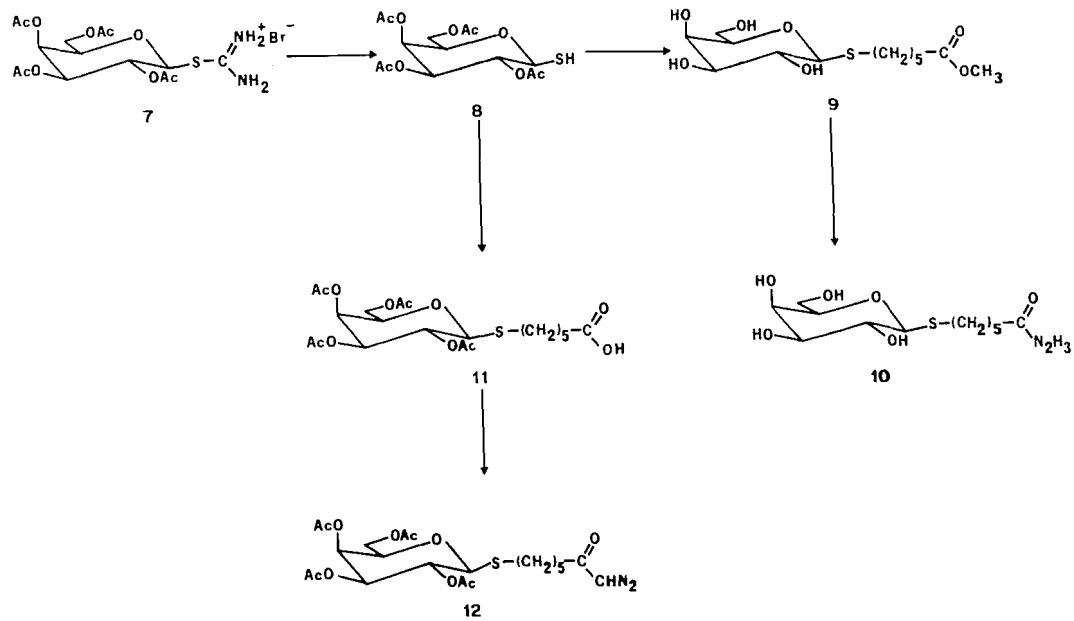

SCHEME 2

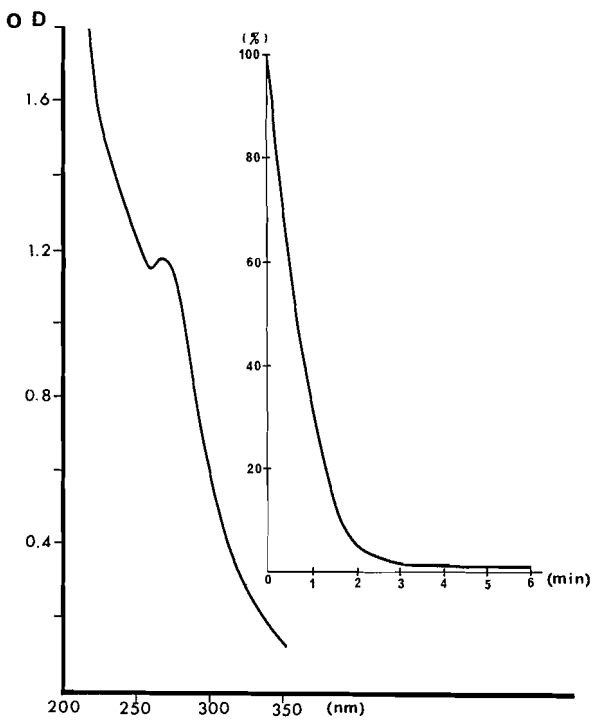

FIG. 1. Ultraviolet spectrum of 1-diazo-7-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosylthio)-2-heptanone (**12**) in ethanol. OD is the optical density. *N*-(2,3,4,6-Tetra-*O*-acetyl-β-D-galactopyranosyl)-5-diazo-4-oxopentanamide **5** had a spectrum identical to that of **12**. The insert shows the remaining proportion (%) of compound **12** as a function of time (min) of irradiation with a polychromatic ultraviolet lamp. The quantity of remaining compound was determined at 254 nm. The decomposition of compound **5** gave a similar curve.

described (25), and the oily product was deacetylated with sodium methoxide in methanol, to give the crystalline thioglycoside **9**. Reaction of **9** with hydrazine in refluxing methanol gave the crystalline hydrazine **10** (30).

The diazo ketone **12** was obtained in two steps from the peracetylated thiogalactose **8**. First, the free acid intermediate **11** was prepared by reaction of the potassium salt of compound **8** with potassium 6-bromohexanoate, followed by acidification. Compound **11** was then converted into the desired diazo derivative **12** by allowing the mixed anhydride prepared from **11** and isobutyl chloroformate to react with an excess of ethereal diazomethane, under reflux. The diazo derivative **12** was decomposed by ultraviolet irradiation as shown in Fig. 1. The kinetic course of decomposition was identical to that of compound **5**.

## Conclusions

Compounds prepared in this study should prove to be useful for affinity-labeling of lectins possessing a specificity for galactose such as those obtained from jequirity beans, peanuts, osage oranges, castor beans, and from *Bandeiraea simplicifolia* (10). It may be pointed out that the hydrazides **4** and **10** can probably be converted into the corresponding azides (11) affording the possibility of generating nitrenes, by irradiation (12). Furthermore, diazo derivatives such as compounds **5** and **12** should yield highly reactive carbenes, after irradiation (13), but they can also be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

transformed into halomethyl ketone derivatives by treatment with HBr or HCl (31). This transformation provides an additional tool for affinity-labeling studies. It is to be noted that compounds **5** and **12** are peracylated glycosides; however, the acetyl groups can be removed by treatment with sodium methoxide/methanol, without affecting the diazo function.

Sugar derivatives such as those described here can be used in biological systems apart from the study of the nature of lectin sugar binding sites. These may include the study of sugar transport systems in prokaryote and eukaryote cells (32, 33), the nature of the components involved in galactose-induced "puffing" of *Drosophila* giant chromosomes (34), etc. In addition, they represent further agents which can be used to prepare affinity columns (15, 35–37), to modify proteins by reaction with alkyl glycosides (11, 30, 38, 39), and to study cell adhesion to glycoside-modified solid surfaces and proteins (40).

## Experimental

D-Galactose was obtained from Sigma Chemical Co. (St. Louis, MO); other reagents were from Aldrich Chemical Co. (Milwaukee, WI) or from Fisher Scientific Co. or Canlab (Montreal).

All evaporations were performed under reduced pressure at 20–45°C, with a rotary evaporator. Melting points were determined in capillary tubes on a Tottoli apparatus (Brinkman Instruments, Rexdale, Ontario) and are not corrected. Thin layer chromatography was performed on silica gel G-coated glass plates. Plates were developed in the following system (v/v): I, chloroform – acetic acid – water (6:7:1); II, methanol–chloroform (1:1); III, acetone – petroleum ether 65–110°C (9:1); IV, benzene – ethyl acetate (5:1). Compounds were revealed by spraying the plates with dilute sulfuric acid followed by heating. Optical rotations were determined by Galbraith Laboratories (Knoxville, TN). The $^1$Hmr spectra were recorded on a Varian T-60 spectrometer; chemical shifts are presented in parts per million (δ) with reference to tetramethylsilane as internal standard. Infrared spectra were determined with a Perkin–Elmer spectrometer, model 457. Ultraviolet spectra were recorded on a Cary model 118 instrument.

*N-(β-D-Galactopyranosyl)-3-methoxycarbonylpropanamide (3)*

In a three-neck flask protected from moisture, monomethyl succinate (3.96 g; 30 mmol) was dissolved in DMF (50 mL), triethylamine (4.16 mL; 30 mmol) was added, and the solution was cooled at −5°C. Isobutyl chloroformate (3.94 mL; 30 mmol) was then added slowly, under stirring. The mixture was stirred for 20 min at −5°C, and then filtered, by suction, into a chilled (−5°C) flask containing a suspension of β-D-galactopyranosylamine ($R_f^I$, 0.21; mp 138°C (lit. (14) m.p. 137–138°C) (4.50 g; 25 mmol) in DMF (250 mL). The reaction mixture was stirred for 30 min at −5°C. It was then placed in an ice bath and stirred for 16 h at ambient temperature without removal of the bath. The solvent was evaporated and the oily product was crystallized from 1-butanol. Yield, 5.1 g (70%); mp 167°C; $R_f^I$, 0.33; $[\alpha]_D^{20}$ +11.3° (*c* 1, $H_2O$); $^1$Hmr ($D_2O$): 2.65 s (4H, $2CH_2$), 3.60 s (3H, $CO_2$—$CH_3$). *Anal.* calcd. for $C_{11}H_{19}NO_8$ (293.2): C 45.05, H 6.53, N 4.78; found: C 44.69, H 6.24, N 5.08.

*N-(β-D-Galactopyranosyl)-3-hydrazinocarbonylpropanamide (4)*

Compound **3** (0.5 g, 1.7 mmol) was dissolved in anhydrous methanol (3 mL) and absolute hydrazine (0.2 mL; 6.1 mmol) was added. The solution was heated under reflux for two hours. Cooling afforded crystals which were recrystallized from methanol. Yield, 0.48 g (95%); mp 236°C (dec.); $R_f^I$ 0.14; $[\alpha]_D^{20}$ = +7.8° (*c* 1, $H_2O$). *Anal.* calcd. for $C_{10}H_{19}N_3O_7$ (293.3): C 40.95, H 6.53, N 14.33; found: C 40.92, H 6.53, N 14.12.

*N-(2,3,4,6-Tetra-O-acetyl-β-D-galactopyranosyl)-3-carboxypropanamide (6)*

Compound **3** (1 g; 3.4 mmol) was dissolved in absolute methanol (5 mL) and a solution of KOH (2 g; 35 mmol) in anhydrous methanol (10 mL) was added. The mixture was heated under reflux for 8–10 min, cooled, acidified to pH 2.5 with 1 *N* HCl, and evaporated to dryness. Two successive evaporations of added methanol gave an oily residue which was dissolved in freshly distilled pyridine (5 mL), and acetic anhydride (5 mL) was added. The mixture was left at room temperature for 6 h. The suspension was filtered and the solvents were evaporated. Two successive evaporations of added methanol afforded a viscous material which was purified on a silicic acid column (2 × 30 cm) and equilibrated with chloroform. The desired product was eluted with 5% methanol in chloroform. The product was precipitated from chloroform by the addition of ether. Yield, 1.1 g (70%); mp 118–120°C; $R_f^{II}$ 0.3; $[\alpha]_D^{20}$ +27.8° (*c* 1, $CHCl_3$); $^1$Hmr ($CDCl_3$): 2.05 m (12 H, 4 $CH_3$—*CO*), 2.60 m (4H, 2 $CH_2$), 4.10 m (3H, $CHCH_2$—*OAc*), 5.20 m (3H, 3 CH—*OAc*), 11.50 s (1H, $CO_2H$). *Anal.* calcd. for $C_{18}H_{25}NO_{12}$ (447.39): C 48.32, H 5.63, N 3.13; found: C 48.56, H 5.66, N 3.44.

*N-(2,3,4,6-Tetra-O-acetyl-β-D-galactopyranosyl-5-diazo-4-oxopentanamide (5)*

Compound **6** (1.8 g; 4 mmol) was dissolved in a 4:1 mixture of THF/DMF (10 mL), the temperature was lowered to −5°C, and triethylamine (0.57 mL; 4 mmol) was added. Isobutyl chloroformate (0.53 mL; 4 mmol) was then added dropwise to the stirred mixture which was filtered after 15 min. the filtrate was transferred to a solution of diazomethane in ether (alcohol-free) (70 mL) contained in a polished-glass flask (Aldrich). The reaction mixture was protected from light and gently heated under reflux for 18 h. The solvent was evaporated and a slightly colored, oily residue was obtained. The ir spectrum showed the presence of the diazo function (2200 $cm^{-1}$), and of the carbonyl group of the acetyl (1740 $cm^{-1}$) and diazoketone (1640 $cm^{-1}$) functions, indicating that compound **5** was formed.

*S-(2,3,4,6-Tetra-O-acetyl-β-D-galactopyranosyl)-pseudothiouronium bromide (7)*

2,3,4,6-Tetra-*O*-acetyl-α-D-galactopyranosylbromide, mp, 88°C (lit. (27) mp 84–85°C) (13.2 g; 32 mmol), was dissolved in acetone (13 mL) and recrystallized thiourea (2.7 g; 35 mmol) was added. The mixture was boiled under reflux for 15 min and then allowed to cool. The crystals of **7** were filtered off and recrystallized from acetone and from 2-propanol. Yield, 12.9 g (83%); mp 172°C (lit. (22) mp 171–171.5°C); $R_f^{III}$, 0.24.

*5-(Methoxycarbonyl)pentyl-1-thio-β-D-galactopyranoside (9)*

2,3,4,6-Tetra-*O*-acetyl-1-thio-β-D-galactopyranose **8** was obtained by reduction of **7** according to the procedure of Černý *et al.* (29). The thio sugar (1.5 g; 4.12 mmol) was dissolved in acetone (20 mL) and an aqueous solution of $K_2CO_3$ (0.57 g; 4.12 mmol) was added. After 30 s the mixture was lyophilyzed. The rest of the procedure was done in a manner similar to that of Connolly *et al.* (25). The dry potassium salt of **8** was suspended in DMF (25 mL) and methyl 6-bromohexanoate (prepared from 6-bromohexanoic acid and etheral diazomethane) (0.8 g; 4

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

mmol) in DMF (5 mL) was added. The reaction mixture was stirred for 2 h at room temperature. The precipitate was removed by filtration and the solvent evaporated. The residue was dissolved in chloroform and the solution was washed with water. The organic phase was dried and evaporated. The product was an oil, as previously reported (25). For deacetylation, the product was dissolved in anhydrous methanol (5 mL) and 0.5 mL of 0.43 *M* $NaOCH_3$ in methanol was added. The mixture was stored in the dark for 18 h, at room temperature, then neutralized to pH 7.0 with *N* HCl and evaporated to dryness. The solid was dissolved in boiling ethyl acetate and the filtered solution deposited cyrstals on cooling. Yield, 0.67 g (50%, based on compound **8**); mp 96°C; $R_f^1$ 0.66; $[\alpha]_D^{20}$ −24.1° (*c* 1, $H_2O$); $^1$Hmr ($D_2O$): 1.50 m (6H, inner methylene groups of aglycon), 2.35 t (2H, $CH_2$—$CO_2CH_3$), 2.65 t (2H, $CH_2$—*S*), 3.55 m (7H, pyranosic protons), 3.60 s (3H, $CO_2$—$CH_3$). *Anal.* calcd. for $C_{13}H_{24}SO_7$ (324.4): C 48.13, H 7.46; found: C 48.42, H 7.36.

*6-(β-D-Galactopyranosylthio)hexanoic acid hydrazide (10)*

A solution of compound **9** (0.5 g; 1.54 mmol) in anhydrous methanol (3 mL) containing absolute hydrazine (0.2 mL; 6.1 mmol) was heated under reflux for 2 h and evaporated. Compound **10** was crystallized from ethanol. Yield, 460 mg (92%); mp 180°C (lit. (30) mp 182–183°C); $R_f$ 0.31; $[\alpha]_D^{20}$ − 26.7° (*c* 1, $H_2O$). *Anal.* calcd. for $C_{12}H_{24}N_2O_6S$ (324.4): C 44.43, H 7.46, N 8.64; found: C 44.32, H 7.36, N 8.44.

*1-Diazo-7-(2,3,4,6-tetra-O-acetyl-β-D-galactopyranosylthio)-2-heptanone (12)*

The carboxylic acid **11** was prepared from the potassium salt of **8** in a manner similar to that of compound **9**. Thus, the potassium salt of **8** (1.5 g; 4.1 mmol) was allowed to react with the potassium salt of 6-bromohexanoic acid (0.8 g; 4.1 mmol) in acetone–water (1:1 v/v, 20 mL). The mixture was stirred for two hours at room temperature, then acidified to pH 3 with *N* HCl and extracted with chloroform. The oil obtained after evaporation was purified on a silicic acid column (2 × 30 cm) equilibrated with chloroform. The desired compound **11**, an oil, was eluted with chloroform. Yield, 1.4 g (70%); $R_f^V$ 0.20; $[\alpha]_D^{20}$ − 8.6° (*c*, 1, $CHCl_3$); $^1$Hmr ($CDCl_3$): 1.50 m (6H, inner methylene groups of aglycon), 2.05 four s (12H, $4CO_2CH_3$), 2.30 t (2H, $CH_2$—$CO_2H$), 2.70 t (2H, *S*—$CH_2$), 4.00 s (2H, $CH_2$—*OAc*), 5.10 m (3H, CH—*OAc*), 11.20 s (1H, $CO_2H$).

A mixture of compound **11** (1.72 g; 3.6 mmol) and triethylamine (0.5 mL: 3.6 mmol) in THF (9 mL) was cooled to −5°C, and isobutyl chloroformate (0.47 mL; 3.6 mmol) was added in portions, with stirring. After 15 min, the mixture was filtered and added to an ethanol-free ether solution of diazomethane (24.5 mmol), in a "Vitro" flask (Aldrich). The reaction mixture was gently boiled under reflux for 18 h in the dark. Evaporation of the solvents gave **12** as an oil; ir (neat): 2100 (CH=N=N), 1640 (ketonic CO), and 1745 (ester CO); $^1$Hmr ($CDCl_3$): 1.60 m (6H, inner methylene groups of the aglycon), 2.10 four s (12H, 4 $CO_2$—$CH_3$), 2.50 t (2H, $CH_2$—*COCHN*$_2$), 2.89 t (2H, *S*—$CH_2$), 3.40 s (1H, $CHN_2$), 4.10 s (2H, $CH_2$—*OAc*), 5.20 m (CH—OAC).

*Deacetylation of compound 12*

Compound **12** (40 mg; 0.085 mmol) was dissolved in a minimum amount of anhydrous methanol and $NaOCH_3$ (0.010 mmol) in anhydrous methanol (25 μL) was added. The solution was stored in the dark for 8 h at room temperature, carefully neutralized to pH 4.5 with dilute acetic acid, and evaporated. The syrupy residue was dissolved in a small volume of anhydrous methanol and the suspension was centrifuged. Evaporation of the organic layer afforded an oily product which showed (ir) the characteristic bands of the diazo (2100) and the ketonic carbonyls (1640). In addition, the ultraviolet spectrum showed the characteristic maximum of absorption at 254 nm.

*Ultraviolet spectra and kinetics of decomposition of compounds 5 and 12*

The ultraviolet spectra of compounds **5** and **12** in ethanol (Fig. 1) showed an absorption maximum at 254 nm. Each compound was irradiated with an ultraviolet lamp ("Mineral light" UVSL 25, Ultraviolet Products, Inc., San Gabriel, CA) placed at 10 cm from the solutions. Spectra were recorded at various intervals, and the percentage of untransformed compound is plotted as a function of time of irradiation (Fig. 1). After 1 min of irradiation, approximately 70% of compounds **5** and **12** were decomposed. Complete photolysis was observed after 3 min of irradiation.

# The gas-phase thermal decomposition of cyclobutanol[1]

R. A. BACK

*Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received October 6, 1981[2]

R. A. BACK. Can. J. Chem. **60**, 2537 (1982).

The thermal decomposition of cyclobutanol has been studied in the gas phase in a static system at pressures from 3–6 Torr and temperatures from 250 to 450°C. The major products observed were ethylene and acetaldehyde, while *n*-butyraldehyde was a minor product. First-order rate constants based on ethylene formation in a Pyrex vessel conditioned by carbon deposition gave Arrhenius parameters of $A = 2.14\ (\pm 0.2) \times 10^{14}\ s^{-1}$ and $E = 57.3\ (\pm 1)$ kcal/mol. Under the same conditions, the ratio *n*-butyraldehyde/ethylene increased with decreasing temperature, corresponding to an activation energy of about 50 kcal/mol for butyraldehyde formation and a frequency factor about $10^4$ times lower than that for ethylene production. In an untreated Pyrex vessel the decomposition showed strong surface catalysis with much lower activation energies for both processes. It is suggested that both ethylene and *n*-butyraldehyde are formed from a common $\dot{C}H_2CH_2CH_2\dot{C}HOH$ biradical by cleavage and by hydrogen transfer through a 6-membered cyclic transition state respectively. The thermal decomposition is thus the reverse of the Type II and II′ processes observed in the photolysis of *n*-butyraldehyde.

R. A. BACK. Can. J. Chem. **60**, 2537 (1982).

On a étudié la décomposition thermique du cyclobutanol en phase gazeuse dans un système statique à des pressions variant de 3 à 6 Torr et à des températures allant de 250 à 450°C. Les produits majoritaires observés sont l'éthylène et l'acétaldéhyde tandis que le butyraldehyde est le produit secondaire. Les constantes de vitesse d'ordre un, évaluées à partir de la formation d'éthylène dans un récipient en pyrex traité au noir de charbon, permettent de déterminer les paramètres d'Arrhénius $A = 2{,}14\ (\pm 0{,}2) \times 10^{14}\ s^{-1}$ et $E = 57{,}3\ (\pm 1)$ kcal/mol. Dans les mêmes conditions, le rapport *n*-butyraldehyde/éthylène augmente lorsque la température diminue; ceci correspond à une énergie d'activation d'environ 50 kcal/mol pour le butyraldehyde.

[Traduit par le journal]

## Introduction

The thermal decompositions of cyclobutane and its derivatives have been very extensively studied (1). Simple unimolecular decomposition into two ethylene molecules (or substituted ethylenes) is the usual mode of decomposition, generally believed to proceed through a biradical intermediate formed by ring opening:

[1] $\square \longrightarrow -CH_2CH_2CH_2CH_2- \rightarrow 2C_2H_4$

In a few systems, alternative reactions of the biradical (other than isomerization) can compete with reaction [1]. In cyclobutanone, for example, minor products are cyclopropane and CO, although it is not clear whether they are formed from the same biradical which decomposes to yield ethylene and ketene, the main products, or by a totally different pathway (2). A better example is isopropenylcyclobutane, which forms 1-methylcyclohexene with a yield almost 80% of the normal fragmentation products by ring closure of an allylic resonance structure of the biradical (1, 3). A third and especially interesting example is the decomposition of *cis*-1,2-dimethylcyclobutanol. A brief account by Feit (4) reports two pairs of decomposition channels at 381°C, each pair proceeding through a common biradical and yielding not only the substituted ethylenes expected from fragmentation, but also the hexanone isomers formed by transfer of the O—H hydrogen through a cyclic six-membered transition state. The latter process is exactly the reverse of the biradical formation step postulated in the Norrish type II photochemical decomposition of these same ketones, and the fragmentation products are those observed in the latter processes in the gas phase (4). In the photolysis of the appropriate aldehydes and ketones (5, 6) isomeric cyclobutanols are produced, and it is clear that these photolyses and the thermal decomposition of the cyclobutanols are intimately related, and warrant further investigation.

No comparable studies of the thermal decomposition of cyclobutanol itself have been reported in the open literature, although a Ph.D. thesis on the subject was submitted to the University of Rochester in 1967 by P. M. Stacey, from the laboratory of the late W. D. Walters (7). Fragmentation to ethylene and acetaldehyde was the main decomposition path, and Arrhenius parameters based on carefully calibrated $\Delta p$ measurements were reported for the temperature range 405–445°C. *n*-Butyraldehyde was also observed to be a very minor product, but was not measured systematically. The present paper describes a more thorough study of the thermal decomposition, with measure-

ment of both product channels based on product analysis and covering a much wider range of temperature.

## Experimental

The decomposition was studied in a conventional static system, using a cylindrical Pyrex vessel about 3 cm in diameter and 10 cm long, with rounded ends, of about 55 $cm^3$ volume, mounted in a tube furnace controlled to ±0.5°C. In the first series of experiments no special treatment was given to the surface of the reaction vessel. In the second series, a light carbon coating was deposited on the surface by the pyrolysis of about 100 Torr of isobutene for 10 h at 450°C. To test for surface effects a similar vessel was used, packed with lengths of 5 mm od Pyrex tubing which increased the surface/volume ratio by a factor of 3. The reaction vessels were attached through a metal valve to a grease-free vacuum line. Pressure was measured by a quartz spiral gauge or a mercury manometer, and because the vacuum line was at ambient temperature, pressures of cyclobutanol were limited by its vapor pressure. The reaction was started by admitting the cyclobutanol vapor to the hot reaction vessel and terminated by opening the valve leading through a cold trap (77 K) to a Toepler pump. The entire sample, reagent and condensible and noncondensible products, was then transferred by Toepler pump to the pickup of a gas chromatograph for analysis. One of two columns was usually employed, either 6 m of Durapak phenylisocyanate on Porasil-C for hydrocarbon analysis, or 3 m of squalane on Celite for analysis of aldehydes and ketones, and duplicate experiments were made to obtain complete product analysis.

Cyclobutanol of stated purity 99+% was purchased from Aldrich Chemical Co. and used after rigorous degassing and simple trap-to-trap distillation. Very small amounts of ethylene and several other hydrocarbons remained, and traces of acetaldehyde and butyraldehyde were present. These impurities were all also products of the pyrolysis and small corrections were made to measured product yields.

## Results and discussion

*Reaction products*

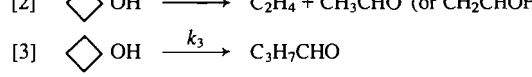
The major products of the decomposition under all conditions were ethylene and acetaldehyde, as found by Stacey (7). Vinyl alcohol would be expected from the simple decomposition analogous to reaction [1], but would not have been directly detected in the present experiments as it would have been strongly retained on the columns employed. In the untreated vessel ethylene and acetaldehyde were observed in approximately equal amounts except at the lowest temperature (250°C) where acetaldehyde was about 80% of the ethylene. In the conditioned vessel acetaldehyde was consistently less than the ethylene, ranging from 65 to 85%. Very recently it has been shown by mass spectrometry that vinyl alcohol is a major primary product of the pyrolysis of cyclobutanol vapor in a quartz tube at 950°C and about 1 mTorr pressure (8). The stability of vinyl alcohol has been a subject of some controversy, the isomerization being apparently very surface sensitive. It seems probable that vinyl alcohol was formed initially in the present experiments but mostly isomerized to acetaldehyde before analysis, more efficiently in the untreated vessel than in the conditioned one. Careful analysis on a β,β′-phenylnaphthylamine column showed that ethylene oxide, another possible isomer of vinyl alcohol, was not a product.

The only other product of any importance was *n*-butyraldehyde, which ranged in yield in the untreated vessel from about 15% of the ethylene at 250°C to about 4% at 450°C, and was rather less in the conditioned vessel.

Other minor products were $CH_4$ (0.2–0.9%), $C_2H_6$ (~0.1%), propylene (0.3–2.5%), butadiene (1.5–3.2%), and cyclobutanone (1–5%); yields in parentheses are ranges of initial values in the untreated vessel, relative to ethylene, between 250 and 450°C. Yields in the conditioned vessel were much less.

*Kinetics of the decomposition*

Production of ethylene and butyraldehyde can be described by two parallel first-order unimolecular reactions,



Rate constants based on yields of $C_2H_4$ and $C_3H_7$-CHO were independent of conversion up to about 10% and independent of pressure over the relatively narrow range of pressures employed (3–6 Torr). (A series of experiments in sealed untreated Pyrex tubes of ~10 $cm^3$ volume at higher pressures (~110 Torr) gave product yields and rate constants similar to those in the untreated fixed vessel.) At higher temperatures and higher conversions secondary decomposition of the aldehydes set in and yields of minor products increased.

Rates of decomposition were very much faster in the untreated reaction vessel, and less temperature dependent. Arrhenius plots of $k_2$, based on ethylene formation, are shown in Fig. 1. The Arrhenius parameters in the untreated vessel ($E$ = 32 kcal/mol, $A = 10^7$ $s^{-1}$) are much too low for a homogeneous reaction and the decomposition is obviously occurring on the surface. Values for the carbon-coated vessel of $E = 57.3 \pm 1$ kcal/mol and $A = 2.14\ (\pm 0.2) \times 10^{14}$ $s^{-1}$ on the other hand, are compatible with those observed for other homogeneous cyclobutane decompositions; the reduction in $E$ by about 5 kcal/mol from that for the parent cyclobutane seems reasonable for hydroxyl substitution. Experiments in a packed, conditioned reaction vessel with S/V increased by about a factor of 3 showed no significant change (Fig. 1) and

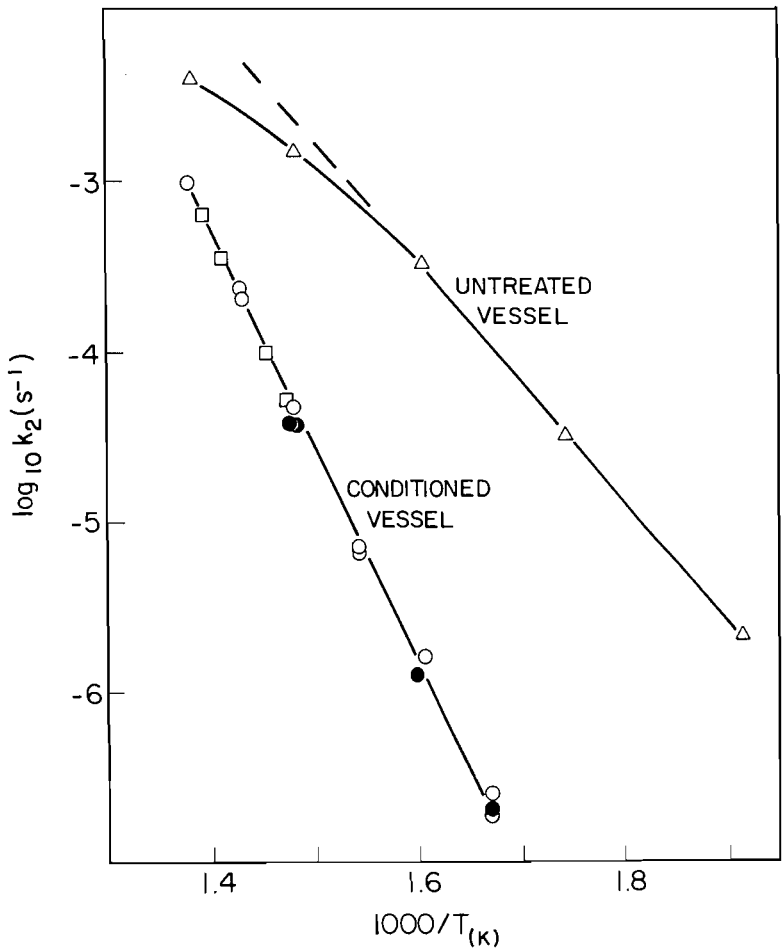

FIG. 1. Arrhenius plot of first-order rate constant $k_2$ for the thermal decomposition of cyclobutanol based on formation of $C_2H_4$. Stacey's data (Table XIV, ref. 7) = □.

it appears that the decomposition in the carbon-coated vessel was almost entirely homogeneous. Although alcohols are notoriously surface sensitive, the magnitude of the surface effect in cyclobutanol seems unusually large, with the rate of decomposition at 600 K almost 600 times faster in the clean vessel than in the carbon-coated one. Stacey (7) also found a large surface effect in the decomposition, which could be eliminated by seasoning the vessel by repeated prolonged pyrolysis of cyclobutanol or olefins. In such a seasoned vessel, Arrhenius parameters of $E = 60.1$ kcal/mol and $A = 1.28 \times 10^{15}$ s$^{-1}$ were obtained, independent of surface/volume ratio. While these values are substantially higher than ours, the actual rate constants on which they are based (plotted in Fig. 1) are in excellent agreement with the present data. Low Arrhenius parameters are generally suspect, since a variety of systematic errors (residual surface reaction, for example) tend in that direction. On the other hand, Stacy's data cover a narrow temperature range and depend on $\Delta p$ measurements at fairly high conversions, and on balance, our present Arrhenius parameters are probably more reliable.

Figure 2 shows Arrhenius plots of the product ratio $C_3H_7CHO/C_2H_4$ (i.e., $k_3/k_2$) for the treated and untreated reaction vessels; the ratio increases with decreasing temperature and is consistently higher and less temperature-dependent in the latter.

*Mechanism of the reaction*

The present observations point to a mechanism analogous to that suggested for 1,2-dimethylcyclobutane (4), shown in Fig. 3, which also shows the energetics of the decomposition. If the isomerization of the biradical is assumed to proceed with little or no activation energy, as seems probable,

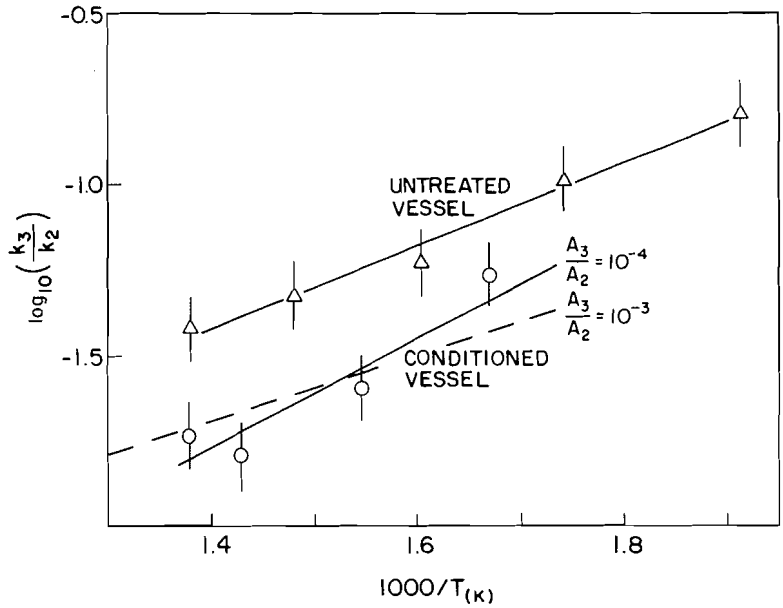

FIG. 2. Arrhenius plot of $k_3/k_2$, based on relative yields of *n*-butyraldehyde and ethylene.

the value of $E_2 - E_3 = 7.3$ derived from Fig. 2 for the conditioned vessel can be approximately equated to the activation energy for the decomposition of the biradical; from the value of $E_2 = 57.3$, the heat of formation of the biradical from cyclobutanol then becomes 50 (all energies in kcal/mol). These values are in reasonable accord with those calculated for similar systems by Benson *et al.* (1), making allowance for the effect of OH substitution. The value of $A_2/A_3 = \sim 10^4$ is at least 10 times larger than can reasonably be predicted from simple estimates of entropies of activation. The dashed line in Fig. 2 has been drawn to give $A_2/A_3 = 10^3$, and results in $E_2 - E_3 = 4.3$ kcal/mol. This seems a rather low activation energy for dissociation of the biradical, and perhaps a small barrier of 2 or 3 kcal/mol to the formation of the transition state for reaction [3], leaving 6 or 7 kcal/mol for dissociation, would be a happier solution. It is unfortunate that the low yields of *n*-butyraldehyde, its secondary decomposition, and possible surface effects, make the measurements of $k_2/k_3$ rather uncertain. The present system is a somewhat unusual example of a two-channel system in which the high-energy channel, reaction [2], predominates despite its higher energy requirements, because of a favourable frequency factor.

Feit (4) reported a ratio of methylbutylketone/propylene of about 8% for the decomposition of 1,2-dimethylcyclobutanol at 381°C; this is more than three times the analogous $C_3H_7CHO/C_2H_4$ ratio at the same temperature in the conditioned vessel in the present experiments. No temperature dependence of this ratio was reported and surface conditions were not specified, although the activation energy of 58 kcal/mol, based on disappearance of the cyclobutanol, was close to that found in the present study; the frequency factor was about 5 times larger.

Dehydration, a major mode of decomposition of some alcohols (9), does not seem to be important with cyclobutanol. The expected product, cyclobutene, would have been unstable at the temperatures of the decomposition, isomerizing to butadiene. The latter was a product in the untreated vessel, rising from 1.5% of the $C_2H_4$ at 250°C to 3.3% at 450°C; it was barely measurable in the conditioned vessel, less than 0.5% at the highest temperature. The other minor products, $CH_4$, $C_2H_6$, $C_3H_6$, and cyclobutanone were also almost negligible in the conditioned vessel. Their larger production in the untreated vessel probably came from free-radical reactions initiated at the surface; there was also a marked secondary formation of these products, probably from the decomposition of acetaldehyde and butyraldehyde.

The photolysis of *n*-butyraldehyde has been thoroughly studied, both in the gas phase and in solution, in a number of laboratories, most recently by Berces and co-workers (10). It was shown that both singlet and triplet excited states were precursors of ethylene, the type II photolysis product, and cyclobutanol, with both products presumed to arise from the $\dot{C}H_2CH_2CH_2\dot{C}HOH$ biradical

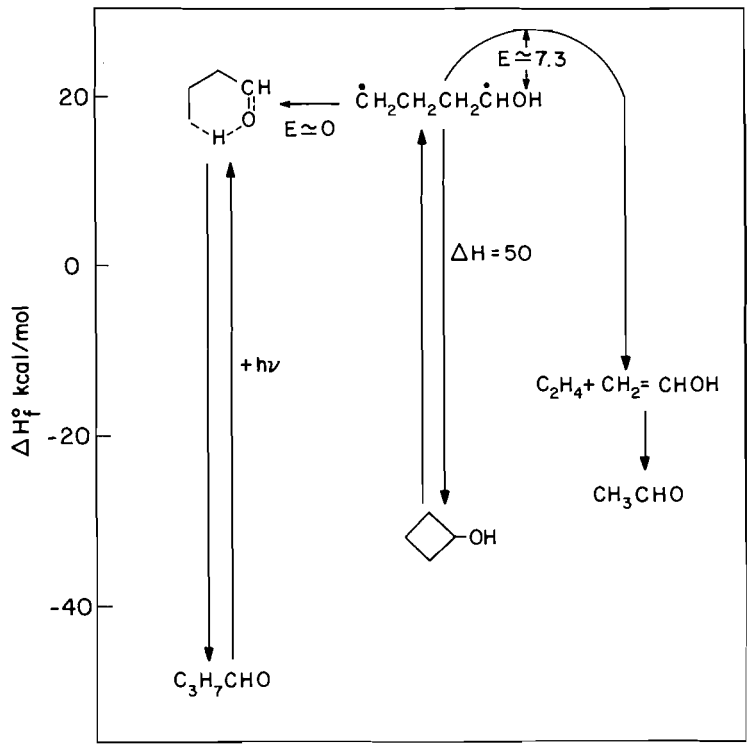

FIG. 3. Mechanism and energetics of the thermal decomposition of cyclobutanol.

formed by hydrogen transfer through a six-membered transition state (Fig. 3). The quantum yields of these products changed relatively little in going from the gas to the liquid phase, indicating that the biradical was formed directly from the excited singlet or triplet states rather than through a vibrationally excited ground state, and that vibrational excitation of the excited states was also not an important factor. In isooctane solution, the ratio $C_2H_4$/cyclobutanol (i.e., cleavage/ring closure) was 4.33, independent of temperature, while in the gas phase at 100 Torr the same ratio was 6.8 at room temperature. The difference between the gas phase and the solution, and a temperature dependence in the gas phase value, were attributed to a change in the singlet/triplet ratio, with the singlet yielding ethylene preferentially. The present study yields no information about ring closure in the cyclobutanol biradical, but Feit (4) in the thermal decomposition of *cis*-1,2-dimethylcyclobutanol at 381°C found appreciable *cis–trans* isomerization, indicating ring closure at a rate about one-third that of the cleavage to form propylene, i.e., cleavage/ring closure = 3.33. Making allowance for possible effects of methyl substitution, this value is close enough to those observed in the photolysis of *n*-butyraldehyde to support the contention that similar biradicals are intermediates in both systems.

# Pressure and fluence dependence in the decomposition of cyclobutanone vapor by a pulsed $CO_2$ laser[1]

R. A. BACK

*Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received November 6, 1981[2]

R. A. BACK. Can. J. Chem. **60**, 2542 (1982).

A re-examination of the decomposition of cyclobutanone vapor by a pulsed $CO_2$ laser over a range of pressure and fluence has shown that the apparent disagreement in previous measurements of the pressure dependence of the $C_3H_6/C_2H_4$ product ratio can be explained by differences in absorbed energy density. At low pressures of cyclobutanone, the energy of the decomposing molecules is apparently higher at low fluence than at high fluence, and an explanation is suggested in terms of a variation in the relative proportions of "collision-modified" and "collision-free" reactions with changing pressure and absorbed energy density.

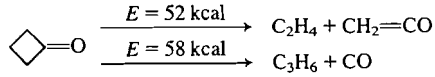
R. A. BACK. Can. J. Chem. **60**, 2542 (1982).

Une nouvelle étude de la décomposition de la cyclobutanone en phase vapeur par un laser déclenché à impulsion de $CO_2$, à diverses pressions et à divers fluence a montré que le désaccord apparent rapporté antérieurement relativement à l'effet de la pression sur le rapport de produit $C_3H_6/C_2H_4$ peut s'expliquer par des différences de densité d'énergie absorbée. A de faibles pressions de cyclobutanone, l'énergie des molécules en décomposition est apparemment plus élevée à faible fluence qu'à grand fluence; on suggère une explication en fonction de la variation des proportions relatives des réactions "modifiées par les collisions" et "sans collision" suivant la pression et la densité d'énergie absorbée.

[Traduit par le journal]

## Introduction

In the last several years, four reports from four different laboratories have described studies of the decomposition of cyclobutanone vapor induced by a pulsed $CO_2$ laser (1–4). While in all these studies decomposition was observed to follow the same two channels as seen in the thermal decomposition,



the ratio of these two channels and its dependence on cyclobutanone pressure varied considerably. In particular, Back and Back (1) found that $C_3H_6/C_2H_4$ increased sharply as the pressure was reduced below 2 Torr, while the three other groups (2–4) found that it decreased. This result was surprising, since conditions and procedures were roughly similar in these systems; we have therefore made further studies of the decomposition in an attempt to resolve these differences.

## Experimental

The reaction vessel was a brass cylinder 2 cm in diameter and 0.5 cm long, fitted with plane NaCl windows at each end. The laser beam was stopped down to give a diameter between 1.2 and 0.8 cm centered in the vessel. Two side tubes and valves permitted evacuation, filling with reagent, and direct pickup of total product and reagent for gc analysis. Source of reagent, gas handling, and analysis were otherwise as described previously (1). The laser was a Lumonics TEA laser similar to that described previously (1). It was used partially focussed with a 2 m f.l. Ge lens placed 60, 80, or 105 cm from the centre of the cell, thus giving slightly converging beams with three different incident fluences of about 1.6, 2.2, and 3.5 J/cm$^2$. The laser was tuned to the P(20) line in the 9.6 micron band (1046.9 cm$^{-1}$), the same frequency used in our previous study (1). (As correctly pointed out by Starov *et al.* (4) this frequency was erroneously reported as 1059 cm$^{-1}$ in ref. 1.)

## Results and discussion

The products were those observed previously, $C_2H_4$, cyclopropane, and propylene, the latter only significant at low pressure; ketene was not measured. In Fig. 1 is plotted the ratio $C_3H_6/C_2H_4$, where $C_3H_6$ is the sum of the cyclopropane and propylene, for the three fluences employed, together with curves representing the previous measurements. (The data of Starov *et al.* (4) are not shown, but lie close to those of Harrison *et al.* (2). Data from focussed beams reported previously from several laboratories (1–4) are also not shown and are not considered in the present discussion; the extreme conditions at the focus in these experiments (100% decomposition, high fluence and temperature, high probability of secondary reactions) we feel are not conducive to quantitative interpretation.)

It is evident that the present data effectively bridge the gap between the previously discordant results. Thus at the high fluence, the product ratio decreases with decreasing pressure, as observed by Harrison *et al.* (2), Koda and co-workers (3), and Starov *et al.* (4), while at the medium and low fluences the ratio turns upwards at low pressure in

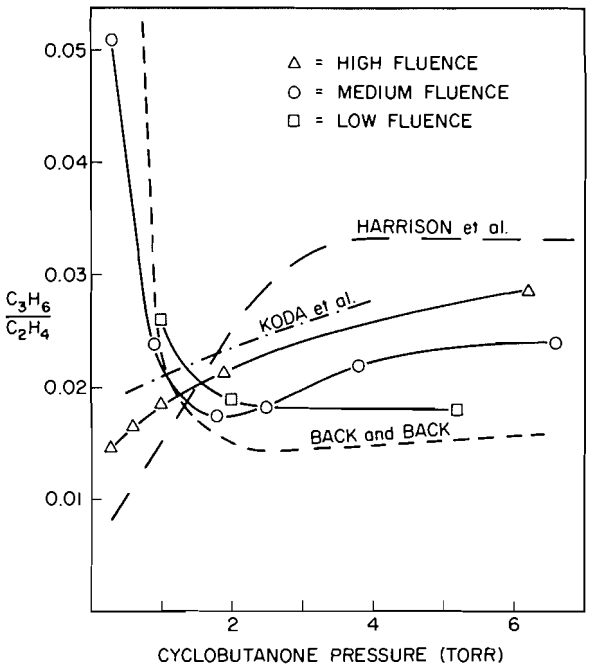

FIG. 1. Variation of the $C_3H_6/C_2H_4$ ratio with cyclobutanone pressure from the present study (points shown) and refs. 1–3 (curves only). $C_3H_6$ = cyclopropane + propylene.

agreement with previous measurements in this laboratory (1). There seems general agreement (1–4) that the product ratio at pressures above a few Torr measures simply the effective temperature of the decomposing cyclobutanone gas, which in turn reflects the absorbed energy density per pulse (J/cm³). If on this basis the 6 sets of data in Fig. 1 are placed in relative order of absorbed energy density,[3] there is seen to be a consistent systematic change in the pressure dependence of the $C_3H_6/C_2H_4$ ratio with changing absorbed energy density.

It appears that two opposing effects are superimposed, one causing a decrease in the product ratio as the pressure is decreased, the other causing an increase. At high fluence the former predominates, and at low fluence the latter; in our medium-fluence data both effects are evident, a decrease in the ratio down to about 2 Torr, and a sharp increase at lower pressures. If the $C_3H_6/C_2H_4$ ratio reflects the energy content of the decomposing cyclobutanone molecules, it must be concluded that at pressures below about 1 Torr, this energy content varies *inversely* with absorbed fluence.

Support for this conclusion also comes from the yields of propylene observed. It was first suggested by Blades (5) that propylene is formed in the cyclobutanone pyrolysis from the small fraction of cyclopropane molecules formed with sufficient vibrational excitation (> 65 kcal/mol) to isomerize, and which do so before they are deactivated by collision. Calculations by Koda *et al.* (3) based on the RRKM theory suggest that propylene is formed the same way in the laser-induced decomposition. In Fig. 2 are shown values of the ratio propylene/(propylene + cyclopropane) from the present experiments together with some previous data (1) not published before. From a value around 1 or 2% at high pressure, the ratio turns up sharply at low pressure at all fluences, but the lower the fluence, the greater the increase and the higher the pressure at which it begins. At 0.3 Torr, 75% of the cyclopropane isomerized to propylene at the medium fluence, while at the high fluence only 9% isomerized. The observations of Koda *et al.* (3) and Harrison *et al.* (2) that propylene was negligible at all pressures with the unfocussed laser are

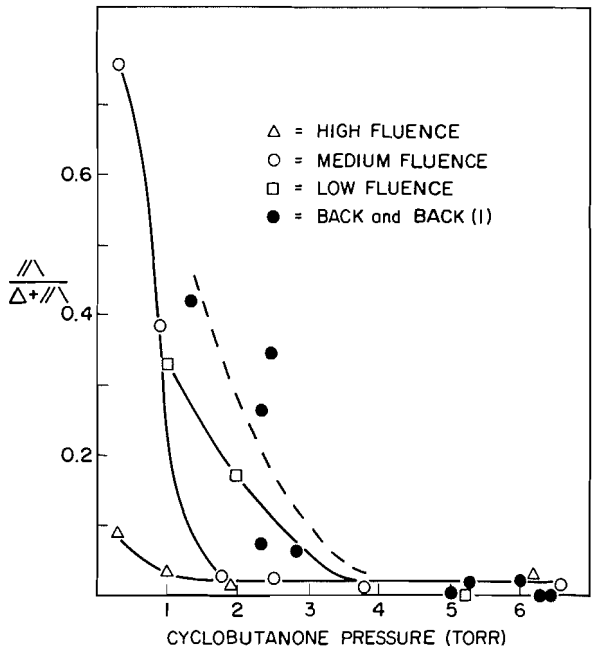

FIG. 2. Variation in the propylene/(total $C_3H_6$) ratio with cyclobutanone pressure from present work and ref. 1.

[3]Absorbed energy density, not incident fluence, is the critical parameter, not easily estimated in the absence of accurate absorption measurements and well-defined beam geometries. From the high-pressure $C_3H_6/C_2H_4$ ratios in Fig. 1, absorbed energy density was clearly much higher in ref. 2 than in ref. 1, although reported incident fluence was higher in the latter. The difference in this case is in the much stronger absorption of the 1073 $cm^{-1}$ radiation used by Harrison *et al.* compared to that of the 1046.9 $cm^{-1}$ radiation used in ref. 1 and the present study.

compatible with the data in Fig. 2, taking into account their higher absorbed energy densities. While there is some scatter in the data in Fig. 2, since absolute yields of propylene are small, they again suggest strongly that the energy content of the cyclopropane formed, and hence of the decomposing cyclobutanone molecules, varied inversely with fluence at low pressures.

In seeking an explanation of this somewhat paradoxical conclusion, it should be noted that the probability of decomposition depended very strongly on fluence at all pressures (Fig. 3). Thus for pressures of 1 Torr or lower, at low fluence, very few molecules decomposed per pulse, but apparently did so with very high energies; at high fluence many more decomposed but at much lower average energy. A tentative explanation can be suggested if the decomposition is treated as the sum of two processes. The first, which can be called the collision-modified process, is a complex dynamic competition involving interaction with the radiation field, collisional energy redistribution, decomposition, and cooling by expansion and conduction, such as has been modelled, for example, by Steel and co-workers (4). The second is a collision-free process, the decomposition of that small fraction of molecules that by statistical chance are directly pumped by the laser radiation to levels above the dissociation energy and dissociate before suffering appreciable energy loss by collision. At high pressure, only the first process is important, and it approximates in the limit to a thermal decomposition; the effective temperature, and hence the $C_3H_6/C_2H_4$ ratio, is roughly independent of pressure. As the pressure is decreased below a few Torr, the probability of decomposition via the first process decreases, for a variety of reasons, and as this is still the dominant process, the total probability of decomposition also decreases (Fig. 3). The average energy and hence the $C_3H_6/C_2H_4$ ratio for molecules decomposing by the first process also decreases, as predicted by Steel *et al.* (4). Probability of decomposition by the second process, on the other hand, increases with decreasing pressure as the time between collisions becomes longer and at some point this will become a significant fraction of the total decomposition. Because the rate of decomposition of an excited molecule increases sharply with its excess energy above the decomposition threshold, the collision-free process will be heavily weighted towards highly excited molecules which have a higher probability of decomposing before collision, and the effective "temperature" of decomposition and hence the $C_3H_6/C_2H_4$ ratio will be much higher

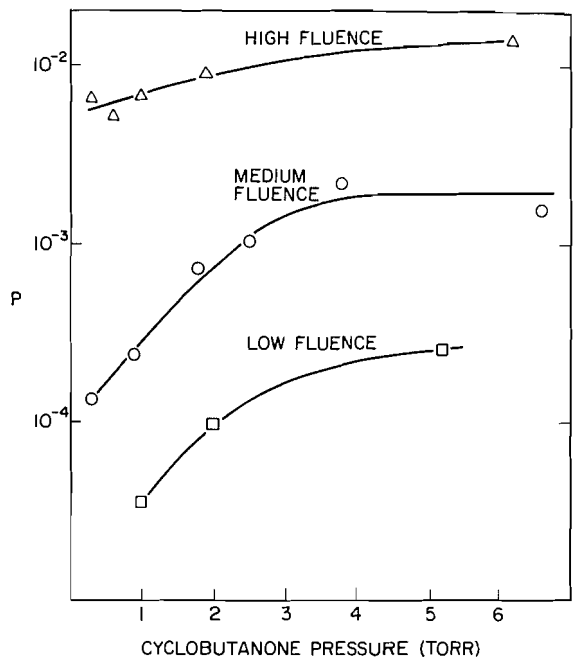

FIG. 3. Probability $P$ of decomposition of a molecule in the irradiated zone in a single pulse, as a function of cyclobutanone pressure.

than in the collision-modified process. We suggest therefore that the increase in this product ratio with decreasing pressure at low fluence (Fig. 1) may arise from an increasing proportion of collision-free decomposition sufficient to overcome the downward trend in the effective temperature of the collision-modified process. If now the probability of decomposition via the collision-modified process falls off less rapidly with decreasing pressure at high fluence than at low fluence (which appears to be borne out by the variation in the overall probability of decomposition shown in Fig. 3), then the collision-free decomposition becomes important at progressively lower pressures as the fluence is increased. In the experiments described in refs. 2–4 and at the highest fluence used in the present work, this has not yet occurred at the lowest pressure employed and the product ratio is still decreasing. In the very low pressure limit when the decomposition becomes completely collision-free, the $C_3H_6/C_2H_4$ ratio must of course revert again to a normal (i.e., direct) dependence on fluence, as dictated by common sense and any reasonable modelling of the system. As this limit is approached the ratio at low fluence will fall as the weighting in favour of the more highly excited molecules disappears; the high-fluence ratio may or may not actually increase, depending on factors affecting

For personal use only.

the pumping efficiency at low pressure, but the high-fluence and low-fluence curves must cross again before reaching the low-pressure limit.

In conclusion, the present study has demonstrated that previous experimental disagreement about the pressure dependence of the $C_3H_6/C_2H_4$ ratio in the laser-induced decomposition of cyclobutanone is real, but can be reconciled in terms of a complex dependence on absorbed energy density. A tentative mechanistic explanation is offered which appears to account reasonably well for most of the experimental observations, including the overall probability of decomposition and the variation of the $C_3H_6/C_2H_4$ and the propylene/cyclopropane ratios.

# Stereochemical studies. XI. Equilibria between δ-hydroxy-acids and δ-lactones in aqueous tetrahydrofuran. Relative stabilities of isomeric δ-lactones

JOHN T. EDWARD, ELLEN COOKE, AND THEMISTOCLES C. PARADELLIS
*Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6*

Received September 1, 1981[1]

JOHN T. EDWARD, ELLEN COOKE, and THEMISTOCLES C. PARADELLIS. Can. J. Chem. **60**, 2546 (1982).

The equilibrium constants $K'$ for the hydrolysis of 13 δ-lactones to hydroxy-acids in 54% (mol/mol) aqueous tetrahydrofuran at 25°C have been determined. The equilibrium constants for the isomerization of the five δ-lactones into their epimers, and for the isomerization of their hydroxy-acids into their epimers, have been calculated by the methods of conformational analysis. These calculated values are consistent with the experimental values of $K'$. Addition of methyl groups to a hydroxy-acid decreases $K'$ (the Thorpe–Ingold effect).

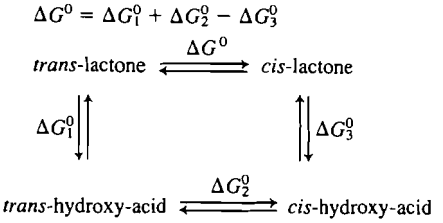
JOHN T. EDWARD, ELLEN COOKE et THEMISTOCLES C. PARADELLIS. Can. J. Chem. **60**, 2546 (1982).

On a déterminé les constantes d'équilibre $K'$ pour l'hydrolyse de 13 δ-lactones en 54% (mol/mol) tetrahydrofuran aqueux. Egalement on a calculé les constantes d'équilibre pour l'épimerisation de cinq δ-lactones, et pour l'épimerisation de cinq hydroxy-acides correspondantes, par les méthodes de l'analyse conformationelle. Les valeurs calculés sont cohérents avec les valeurs de $K'$. L'addition d'un groupement méthyl à un hydroxy-acide a pour résultat une diminution en $K'$ (l'effet Thorpe–Ingold).

## Introduction

The relative stabilities of two isomers such as *cis* and *trans*-decalin may be established by their direct equilibration over a suitable catalyst (1). In 50% sulfuric acid *trans*-1-oxa-2-oxohydrindane is converted completely into its *cis* epimer (2), and consequently we hoped to epimerize δ-lactones in hot formic acid. Some epimerization is indeed observed, but it is masked by the more extensive decomposition of the δ- into γ-lactones (3). Consequently, in the present paper we attempt to determine the relative stabilities of epimeric δ-lactones by an indirect method. A consideration of the thermodynamic cycle of Scheme 1 shows that the free energy change $\Delta G^0$ for the isomerization of a *trans* to a *cis* lactone is given by:

[1] $$\Delta G^0 = \Delta G_1^0 + \Delta G_2^0 - \Delta G_3^0$$



SCHEME 1

We have determined $\Delta G_1^0$ and $\Delta G_3^0$ for the equilibration of *trans* (**3**, **5**, **8**, **12** in Scheme 2) and *cis* lactones (**4**, **6**, **7**, **9**, **13**) with their hydroxy-acids in 54% (mol/mol) aqueous tetrahydrofuran, a solvent chosen because it dissolved all the lactones under study. Unfortunately, we were unable to find conditions under which the epimeric hydroxy-acids could be epimerized in this solvent, and so we have been forced to compute $\Delta G_2^0$ by the methods of conformational analysis. A few other δ-lactones (**1**, **2**, **10**, **11**) which did not belong to an epimeric pair were available, and their equilibration with their corresponding hydroxy-acids was also studied.

## Experimental

*Materials*

The lactones were prepared according to the literature (references in Scheme 2). The purity of the solid lactones was evident from satisfactory melting points. The purity of several liquid and low-melting solid lactones was checked by hydrolyzing them with a known excess of 0.100 *N* sodium hydroxide solution for 23 h, then back-titrating with 0.100 *N* hydrochloric acid solution. The purity was always found to be higher than 97%, which was judged adequate for our purposes.

Distilled water was redistilled in an all-glass apparatus, and passed through a deionizing resin immediately before use. Reagent-grade tetrahydrofuran from freshly-opened bottles was used; it was found that results were unchanged if the tetrahydrofuran was dried over calcium hydride and then passed through an alumina column.

*Experimental procedure*

The equilibration mixtures were prepared by weight, using a five-figure electric balance, to contain 0.050–0.100 *M* lactone, 0.010 *M* hydrochloric acid, tetrahydrofuran, and water. Aliquots (5–10 mL) were transferred to ampoules which were stoppered, cooled in ethanol – Dry Ice, sealed, and placed in a constant temperature bath at 25.0 ± 0.1°C. Samples of the solvent mixture (without lactone) were made up and sealed in ampoules to serve as blanks. After a week[2] the ampoules were opened, and aliquots (1.00–2.00 mL) were pipetted into 13 mL of water or 80% (v/v) tetrahydrofuran (depending on the solubility of the lactone) at 10°C and titrated with 0.100 *M*

[1]Revision received May 21, 1982.

[2]Equilibrium was generally reached in 1–2 days. Analyses after 2 weeks and 4 weeks gave the same results as after one week.

aqueous sodium hydroxide at 10°C under $CO_2$-free $N_2$, using a Sargent–Welch Model DR pH meter 530000 and combination electrode 530070-10. Separate experiments showed that under these conditions there was no appreciable hydrolysis of lactone to hydroxy-acid during titration. The precision of the titration procedure was estimated to be ±0.20%, and the accuracy ±0.50%, from experiments in which potassium acid phthalate solutions were sealed into ampoules, placed in the constant temperature bath, and then removed and titrated as above.

All equilibrations were done at least in duplicate, with two or three aliquots being titrated per sample.

## Results and discussion

*Determination of* $\Delta G_1^0$ *and* $\Delta G_3^0$

For the equilibrium

$$\text{Lactone (L)} + H_2O \rightleftarrows \text{Hydroxy-acid (HA)}$$

the equilibrium constant $K$ is given by

$$[2] \quad K = \frac{a_{HA}}{a_L a_{H_2O}} = \frac{c_{HA}}{c_L} \cdot \frac{\gamma_{HA}}{\gamma_L a_{H_2O}}$$

where $a$ stands for activity, $c$ for concentration, and $\gamma$ for activity coefficient. Because the concentration of water in the aqueous tetrahydrofuran solvent was in large excess of the concentration of lactone, it remained effectively constant during the equilibration reaction. Furthermore, if we make infinite dilution in 54% (*m*/*m*) aqueous tetrahydrofuran the standard state for the lactone and hydroxy-acid, $\gamma_{HA} \approx 1$ and $\gamma_L \approx 1$ for the low concentrations in our experiments, so that we can define an equilibrium constant $K'$ ($\equiv K a_{H_2O}$)

$$[3] \quad K' = c_{HA}/c_L$$

The experimental values of $K'$ are given in Table 1. The lactone **4** was available as the pure isomer, but **3** was available only in a 65:35 mixture of **3**/**4** (as established by nmr), and so the experimental errors for the values of $K'$ and of $\Delta G^0$ ($\equiv -RT \ln K'$) reported for **3** in Table 1 may be larger than for the other lactones. The same is true for the values reported for **5**, which was available only as a 83:17 mixture of **5**/**6**.

The smaller $K'$, the greater the tendency of the hydroxy-acid to cyclize. A scrutiny of the values of $K'$ in Table 1 shows that this tendency is enhanced by the addition of a methyl group (compare **1** and **2**; **3** and **5**; **4** and **6**; **7** and **10**; **11** and **12**), an example of the Thorpe–Ingold effect (10, 11*a*). However, the cyclization tendency is enhanced much more by fusion of the steroidal BCD ring system to the lactone ring: compare **11** and **8**.

*Calculation of* $\Delta G_2^0$ *for the isomerization of the hydroxy-acids*

The free energy differences between epimeric hydroxy-acids were calculated by conventional methods, assuming the following differences in enthalpy $\Delta H^0$ between axial and equatorial orientations.

1. Hydroxyl group, 0.9 kcal/mol.[3] A skew $CH_2\cdots OH$ or $CH_3\cdots OH$ interaction was assigned half this value, 0.45 kcal/mol.
2. Methyl, 1.8 kcal/mol (11*b*).
3. $CH_2CH_2CO_2H$, 2.1 kcal/mol.

Entropy differences were calculated on the assumption that the hydroxyl or $CH_2R$ group in an equatorial position has three rotational conformations, and hence an entropy of rotation of $R \ln 3$, and in the axial position only two conformations,[4]

[3]This can be only an educated guess, because thermodynamic studies of the equilibrium: axial-OH ⇄ equatorial-OH, have not been carried out in THF–$H_2O$, and the equilibrium is solvent-sensitive (12). However, it is a plausible value, lying between the value of 0.83 kcal/mol for the aprotic but polar solvent, 1,2-dimethoxyethane, and 1.09 kcal/mol for the protic 2-propanol (12).

[4]Eliel and Gilbert (12) have discussed the question of the population of rotational conformations (two "OH-outside", one "OH-inside") of axial hydroxyl, and advance evidence (persuasive but not definitive) that in nonpolar solvents each conformation may be equally populated. However, they also point out that the axial hydroxyl hydrogen can probably not bond readily to an acceptor solvent molecule from the "OH-inside" conformations, so that this conformation would be highly disfavored in the aqueous–organic solvent used in the present study.

TABLE 1. Thermodynamic parameters for δ-lactone – hydroxy-acid equilibria in 54% (*m*/*m*) aqueous tetrahydrofuran at 25°C

| Lactone | %Hydroxy-acid at equilibrium | $K'$ | $\Delta G^0$ (kcal/mol) |
|---|---|---|---|
| *trans*-γ,δ-Dimethyl-δ-valerolactone **1** | 41.5±0.2 | 0.71 | 0.20 |
| γ,γ,δ-Trimethyl-δ-valerolactone **2** | 22.0±0.1 | 0.28 | 0.75 |
| *trans*-1-Oxadecal-2-one **3** | 47.2±1.2[a] | 0.89 | 0.07 |
| *cis*-1-Oxadecal-2-one **4** | 57.1±0.2 | 1.3 | −0.17 |
| *trans*-10-Methyl-1-oxadecal-2-one **5** | 43.9±0.9[b] | 0.78 | 0.15 |
| *cis*-10-Methyl-1-oxadecal-2-one **6** | 16.8±0.2 | 0.20 | 0.95 |
| 6α-*tert*-Butyl-1-oxa-9α,10α-decal-2-one **7** | 64.5±0.7 | 1.8 | −0.35 |
| 6α-*tert*-Butyl-1-oxa-9α-10β-decal-2-one **8** | 44.1±0.2 | 0.79 | 0.14 |
| 6α-*tert*-Butyl-1-oxa-9β,10β-decal-2-one **9** | 57.9±0.25 | 1.4 | −0.19 |
| 6α-*tert*-Butyl-10α-methyl-1-oxa-9α-decal-2-one **10** | 40.0±0.2 | 0.67 | 0.24 |
| 4-Oxa-5α-estran-3-one **11** | 10.6±0.2 | 0.12 | 1.26 |
| 4-Oxa-5α-cholestan-3-one **12** | 9.0±0.1 | 0.099 | 1.37 |
| 4-Oxa-5β-cholestan-3-one **13** | 4.2±0.2 | 0.044 | 1.85 |

[a]A mixture of 65% **3** and 35% **4** (by nmr) had 50.7±0.2% hydroxy-acid at equilibrium; from the measurements with **4** (next line in table), 20.0±0.1% of this hydroxy-acid came from **4**, and hence 30.7±0.2% from **3**, whence the fraction of **3** hydrolysed to hydroxy-acid at equilibrium is 0.307/(0.65 − 0.307) = 0.472.
[b]Calculated in similar fashion after finding a mixture of 83% of **5** and 17% of **6** had 39.3±0.1% hydroxy-acid at equilibrium.

and hence has an entropy of rotation of $R \ln 2$ (13). At 25°C this effect will cause the OH or $CH_2R$ group in the equatorial position to be favored entropically by $RT(\ln 3 - \ln 2) = 0.24$ kcal/mol over the same group in the axial position.

The ring systems of the hydroxy-acids (HA), **7**-HA, **8**-HA, **9**-HA, **12**-HA, and **13**-HA formed by hydrolysis of lactones **7**, **8**, **9**, **12**, and **13**, can exist in essentially only one conformation, shown in Scheme 3, and hence calculation of the free energy differences between epimers of these hydroxy-acids is relatively straightforward. The enthalpic ($\Delta H^0$) and entropic ($T\Delta S^0$) contributions to the free energy differences between the epimers are listed in Table 2. From these values the free energies $\Delta G_2^0$ of the epimerization reactions were calculated, and are also given in the table.

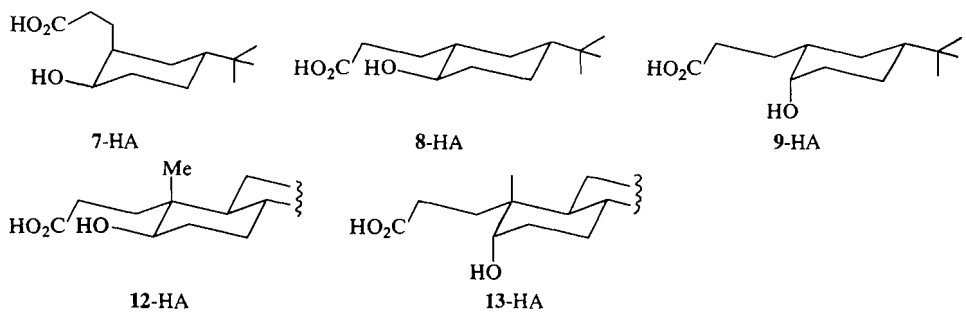
The computation of the free energy differences between the epimeric acids **14** and **15** (R = H) (Scheme 4), formed by opening the lactones **3** and **4**, is more difficult, because each ring system can exist in two conformations. Consequently, to obtain the free energy change for the epimerization:

TABLE 2. Thermodynamic parameters (in kcal/mol) for hydroxy-acids corresponding to lactones **7**, **8**, **9**, **12**, and **13**, and free energies of epimerization $\Delta G_2^0$

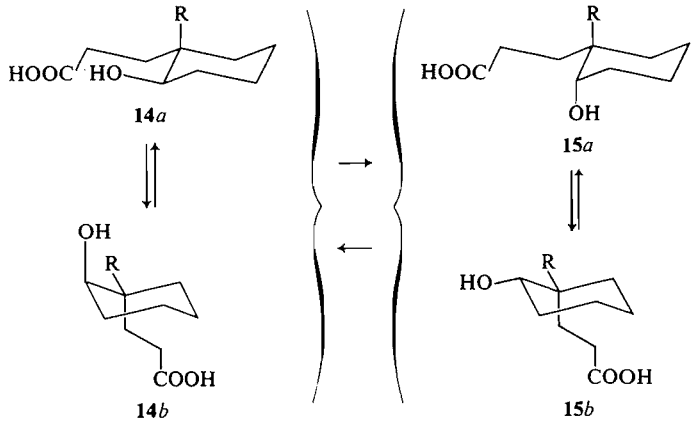
| | $\Delta H^0$ | | | | |
|---|---|---|---|---|---|
| Hydroxy-acid | $CH_2R$ | OH | $T\Delta S^0$ | $\Delta G^0$ | $\Delta G_2^0$ |
| **8**-HA | — | 0.45 | 0.24 | 0.21 | 0 |
| **9**-HA | — | 1.35 | 0 | 1.35 | 1.14[a] |
| **7**-HA | 2.1 | 0.45 | 0 | 2.55 | 2.34[b] |
| **12**-HA | — | 0.90 | 0.24 | 0.66 | 0 |
| **13**-HA | — | 1.35 | 0 | 1.35 | 0.69[c] |

[a]For **8**-HA ⇄ **9**-HA, given by $\Delta G^0$ (**9**-HA) − $\Delta G^0$ (**8**-HA).
[b]For **8**-HA ⇄ **7**-HA, given by $\Delta G^0$ (**7**-HA) − $\Delta G^0$ (**8**-HA).
[c]For **12**-HA ⇄ **13**-HA, given by $\Delta G^0$ (**13**-HA) − $\Delta G^0$ (**12**-HA).

**14** (R = H) ⇄ **15** (R = H), it is necessary first to calculate and take account of the mol fractions of the conformers **14***a* (R = H) and **14***b* (R = H), making up **14** (R = H), and of the mol fractions of the conformers **15***a* (R = H) and **15***b* (R = H), making up **15** (R = H). These mol fractions depend on the free energy differences $\Delta\Delta G^0$ between the two conformations (11*c*). Values of $\Delta G^0$ for each conformation were obtained by summing up the



SCHEME 3



SCHEME 4

different enthalpic and entropic contributions. These are given in Table 3, as well as the $\Delta\Delta G^0$ values derived from their differences, and thence the mol fractions $x_i$ of each conformation.

We may now consider the free energy change for the reaction: **14** (R = H) ⇄ **15** (R = H). Since more than 99% of **14** (R = H) exists in the conformation **14***a*, both the enthalpy and the entropy (i.e. the free energy) of **14** will be close to that of **14***a*, given in Table 3. The 0.6% of **14** present as the conformation **14***b* will raise the enthalpy and decrease the entropy very slightly, raising the free energy according to the equation (11*d*):

[4] $\Delta G^0 = \Sigma x_i \Delta G^0_i$

However, this very small increase in free energy coming from the presence of a trace of **14***b* (R = H) is counterbalanced by the decrease in free energy coming from the entropy of mixing $\Delta S^0_m$ (11*d*), given by the equation:

[5] $\Delta S^0_m = R \Sigma x_i \ln x_i$

The free energy change due to $\Delta S^0_m$ at 25°C is given in Table 4. The free energy of the epimeric hydroxy-acid **15** (R = H) also lies between those of its constituent conformers **15***a* (R = H) and **15***b* (R = H) (given in Table 3), but now it is favoured (with respect to **14** (R = H)) by a greater entropy of mixing (see Table 4). Summing up the various contributions listed in Table 4, we see that a free energy difference $\Delta G^0_2$ of 1.07 kcal/mol favours **14** (R = H) over its epimer **15** (R = H).

The free energy difference between **14** (R = Me) and **15** (R = Me), which also exist as mixtures of conformers, was calculated in similar fashion (see Tables 3 and 4).

*Relative stabilities of epimeric lactones:* $\Delta G^0$

With $\Delta G^0_1$ and $\Delta G^0_3$ from Table 1 and $\Delta G^0_2$ from Tables 2 and 4, it is possible to calculate $\Delta G^0$ for the hypothetical *trans* ⇄ *cis* lactone epimerization using eq. [1]. The values thus obtained are given in Table 5.

These values accord moderately well with the values $\Delta G^0_{calc}$ for the hypothetical epimerization reaction calculated by the usual rules of conforma-

TABLE 5. Free energy differences $\Delta G^0$ (in kcal/mol) of epimeric δ-lactones

| Reaction | $\Delta G^0$ from [1] | $\Delta G^0_{calc}$ |
|---|---|---|
| **3** ⇄ **4** | 1.3 | 1.4 |
| **5** ⇄ **6** | −0.5 | 0.05 |
| **8** ⇄ **9** | 1.4 | 1.5 |
| **8** ⇄ **7** | 2.8 | 2.5 |
| **12** ⇄ **13** | 0.2 | 0.3 |

tional analysis. To obtain $\Delta G^0_{calc}$ we calculate first $\Delta H^0$, and then $T\Delta S^0$, as follows.

We assume that all the lactone rings of **1** – **13** are in the half-chair conformation, with the ester linkage and the atoms attached to it coplanar or nearly so (14). We then count the number of skew interactions in each compound (or in each conformation, as in the case of **4** and **6** (Scheme 5), which can exist in two conformations *a* and *b*) and compute $\Delta H^0$ for each compound (Table 7) or each conformation (Table 6), assuming the following skew interaction enthalpies (in kcal/mol): C···C, 0.9; CO···C, 0.7 (11*e*, 15); O···C, 0.3.

In the case of the conformationally-mobile compounds **4** and **6**, $\Delta H^0$ lies somewhere between the values for each separate conformation, depending on the mol fractions $x_1$ and $x_2$ (11*d*):

$$[6] \quad \Delta H^0 = x_1 \Delta H_1^0 + x_2 \Delta H_2^0$$

The mol fractions in turn are determined by $\Delta H_1^0$ (it being assumed that the entropies of the various conformations are identical), and are given in Table 6 along with the values of $\Delta H^0$ calculated from eq. [6].

The differences $\Delta\Delta H^0$ between the enthalpies $\Delta H^0$ of the epimeric lactones are given in Table 7. These parallel (roughly!) the summed values $\Sigma\sigma$ of the $^{13}C$ chemical shifts, the latter being given in Table 8. For epimeric cyclohexane derivatives, Perlin and Koch (16) have shown that the net shielding of $^{13}C$ nuclei is higher in the more strained epimer. Thus a comparison of the summed values of the $^{13}C$ chemical shifts ($\Sigma\sigma$) of *cis* and *trans* 1,2-, 1,3-, and 1,4-dimethylcyclohexanes, where the enthalpy difference is 1.8 kcal/mol, showed differences $\Delta\Sigma\sigma$ of 26–30 ppm, $\Sigma\sigma$ being smaller in the more strained compound.[5] A similar comparison for epimeric cyclohexanols, where $\Delta\Delta H^0 \approx 0.9$ kcal/mol, showed $\Delta\Sigma\sigma \approx 16$ ppm. The similar relation shown between $\Delta\Sigma\sigma$ and our computed $\Delta\Delta H^0$ values increases our confidence in the latter.

Assuming no differences in entropy between epimers, the values of $\Delta G^0_{calc}$ for **8** ⇄ **9**, **8** ⇄ **7**, and **12** ⇄ **13** in Table 5 are obtained from the $\Delta\Delta H^0$ values of Table 7. However, the epimers **4** and **6** are stabilized by entropy of mixing (given by eq. [5]); this contribution is given in Table 6. The $\Delta G^0_{calc}$ values for **3** ⇄ **4** and **5** ⇄ **6** in Table 5 are obtained by subtracting the $T\Delta S^0$ values of Table 6 from the $\Delta\Delta H^0$ values of Table 7.

Considering the many approximations made, the agreement between $\Delta G^0$ and $\Delta G^0_{calc}$ in Table 5 is reasonably satisfactory except for the equilibrium **5** ⇄ **6**. The poor agreement in this case may have two reasons: (a) the $\Delta G_1^0$ value for **5** was obtained from the experimental value for a mixture of epimeric lactones **5**/**6** and from $\Delta G_3^0$ of **6**, and could suffer from cumulative experimental errors; (b) $\Delta G_2^0$ for the equilibration of the hydroxy-acids **14** (R = Me) and **15** (R = Me) (Scheme 4) could be seriously in error because of the abnormal behaviour of 1,1,2-trisubstituted cyclohexanes. Mursakulov *et al.* (17) showed that in equilibrations of such compounds the equatorial conformer is favoured to

[5]This is for shift values relative to TMS. Perlin and Koch measured shifts upfield from benzene, and under these circumstances their rule states that $\Sigma\sigma$ is *larger* for the more strained isomer.

a greater extent than would be predicted from first principles: that one of the skew repulsions of the equatorial conformer "somehow disappears". A tentative explanation was advanced, in which the axial group repelled the geminal equatorial group to an extent that the skew equatorial–equatorial interaction of the vicinal equatorial groups was reduced to zero. Applied to the equilibrium **14** (R = Me) ⇄ **15** (R = Me), this effect would reduce $\Delta H^0$ of both **14***a* (R = Me) and **15***b* (R = Me) by 0.45 kcal/mol. The effect of this, carried through the various calculations outlined above, would be to raise $\Delta G_2^0$ from 0.29 kcal/mol (Table 4) to 0.49 kcal/mol, and to increase $\Delta G^0$ for **5** ⇄ **6** from −0.5 kcal/mol to −0.3 kcal/mol, somewhat closer to the $\Delta G^0_{calc}$ of 0.05 kcal/mol (Table 5).[6]

The agreement between $\Delta G^0$ and $\Delta G^0_{calc}$ in Table 5 is as good as could be expected, in view of the fact that possible entropy contributions due to vibration, solvation, etc., have been ignored, and that a simple additive scheme has been used for computing enthalpy contributions. Obviously a more detailed study of the effect of changing solvent, temperature, etc., is required.

*The Thorpe–Ingold effect*

We have found experimentally that the change from R = H to R = Me in the hydroxy-acid **16** makes the formation of the lactone **12** easier than the formation of lactone **11** by 0.11 kcal/mol (see Table 1). The newly-introduced methyl group destabilizes both **16** (R = Me) and **12** by the introduction (*inter alia*) of an additional O···C skew interaction. However, it will be noted that, accepting our values for the HO···C (0.45) and the lactone O···C (0.3 kcal/mol) skew interactions[7] given above, the destabilization of **16** (R = Me) should be more serious than the destabilization of **12** by 0.15 kcal/mol. This would explain the experimental result, and may be *one* of the factors operating to bring about the Thorpe–Ingold effect. However, the explanation of the greater stabiliza-

[6] We are indebted to a referee for pointing out ref. 17, and the above argument based on it. The referee notes that a similar argument would raise $\Delta G_2^0$ of **12**-HA ⇄ **13**-HA, and thence $\Delta G^0$ of **12** ⇄ **13** (Table 5), but it seems likely that the distortions possible in a 1,1,2-trisubstituted cyclohexane which lead to the "disappearance" of one skew interaction in the equatorial conformer are not possible in the more rigid hydroxy-acid **12**-HA.

[7] In hydroxylic solvents it is reasonable that the HO···C skew interaction have a greater enthalpy than the ester-O···C interaction because of the greater solvation of the hydroxyl group.

Reçu le 17 décembre 1981[3]

C. CAMBILLAU, G. BRAM, J. CORSET et C. RICHE. Can. J. Chem. **60**, 2554 (1982).

La structure cristalline du complexe énolate de sodium de l'acétylacétate d'éthyle (AAE) – 15-couronne-5 ($E^-Na^+$–15C5) est décrite et comparée à celle précédemment publiée du complexe $E^-K^+$–18C6. Il s'agit dans les deux cas de paires d'ions de contact complexées extérieurement par la couronne. $Na^+$ sort du plan moyen de la couronne de 1,05 Å. La structure de ces complexes est conservée en solution dans le THF. Les résultats obtenus concernant l'addition de couronnes (C) aux énolates $E^-M^+$ en solution dans le THF (ir et cinétique) ou le DMSO (ir et conductimétrie) sont interprétés dans le cadre d'un système de quatre équilibres entre les quatre espèces ioniques: $E^-M^+$, $E^-||M^+$, $E^-M^+$–C et $E^-||M^+$ – C. Certaines valeurs de ces constantes d'équilibre ont été déterminées. À partir d'un certain excès de couronne, les deux espèces $E^-M^+$–C et $E^-||M^+$ – C restent seules en présence. La position de cet équilibre au plateau dépend fortement du solvant et du couple cation couronne. Certains résultats antérieurs dans la littérature, concernant l'alkylation des énolates de l'AAE sont rediscutés en fonction de cet équilibre au plateau.

C. CAMBILLAU, G. BRAM, J. CORSET, and C. RICHE. Can. J. Chem. **60**, 2554 (1982).

The crystal structure of the ethylacetoacetate (EAA) sodium enolate – 15 crown 5 complex ($E^-Na^+$–15C5) is described and compared with the $E^-K^+$–18C6 structure already published. Both entities are contact ion pairs externally complexed by the crown. The $Na^+$ cation is out of the mean plane of the crown (1,05 Å). The structure of both complexes is retained in THF solution. The effects observed upon addition of crowns to $E^-M^+$ enolates in THF solution (ir and kinetics) or DMSO solution (ir and conductivity) are discussed on the basis of an equilibrium between four ionic species: $E^-M^+$, $E^-||M^+$, $E^-M^+$–C, and $E^-||M^+$ – C. Some values of equilibrium constants have been determined. Of special interest is the simultaneous presence of the two species $E^-M^+$–C and $E^-||M^+$ – C when crown ether is added in excess. The position of the plateau equilibrium between these two species depends on the nature of the solvent, the cation, and the crown. Some previous results in the literature about alkylation of EAA enolates are rediscussed in relation to this plateau equilibrium.

Depuis une dizaine d'années, le chimiste organicien dispose de deux grandes classes de complexants macrocycliques des cations afin d'"activer" les anions: les éthers-couronnes monocycliques (1) et les cryptands bicycliques (2). L'effet de l'addition de cryptands à des sels alcalins semble à présent bien documenté: le cation est encapsulé[4] par le cryptand et toute interaction directe anion–cation disparaît (3, 4);[5] il s'ensuit une réactivité accrue de l'anion, comparable à celle de l'ion libre.

C'est le résultat que nous avons observé pour les solutions d'énolate de $K^+$ de l'AAE dans le THF ou le DMSO lors d'addition de cryptand (2,2,2) (5). L'addition de couronnes à des solutions de sels alcalins peut conduire à des structures et distributions d'espèces en solution fort différentes selon les cas (6, 7). En effet, la solvatation du cation dans le plan laisse alors subsister deux sites d'interaction possibles. Parmi les facteurs intervenant sur la structure des espèces, citons par exemple la polarité du milieu, les tailles respectives du cation et de la couronne, etc. ... Dans cet article, nous nous proposons de rationnaliser les phénomènes résultant de l'addition de couronnes à des solutions de sels alcalins. A cette fin, nous utiliserons comme substrats les énolates de $Na^+$ et $K^+$ de l'AAE ($E^-Na^+$, $E^-K^+$) complexés par les 15-couronne-5 (15C5) et 18-couronne-6 (18C6). Nous avons déjà montré dans un article précédent (5) que l'espèce très prédominante résultant de la complexation de $E^-K^+$ par la 8C6 dans le THF est une paire d'ions où le cation est complexé extérieurement par la

[2]Adresse actuelle: Laboratoire des Réactions Sélectives sur Supports, Université de Paris-Sud, Bât. 410, 91405 Orsay Cedex, France.

[3]Révision reçue le 8 juin 1982.

[4]Le cation n'est pas entièrement encapsulé lorsque son rayon est très supérieur à celui de la cavité du cryptand (8). Nous avons d'autre part mis en évidence un autre comportement "anormal" apparu lors de la complexation du sel de $Li^+$ de l'AAE par le cryptand (2,1,1): la formation d'ion triple (9).

[5]Selon la polarité du solvant, les espèces alors formées seront des paires d'ions lâches ou des ions dissociés.

SCHÉMA 1

couronne. La O-alkylation de cette espèce de structure en *U* ne devrait conduire qu'à un éther d'énol *cis* (4). En effet, l'obtention d'éther d'énol *cis* et *trans* dans les produits d'alkylation d'énolates de composés β-dicarbonylés (tels ceux de l'AAE) a été interprétée (11, 12) en invoquant une relation directe entre la structure des éthers d'énol et celle en *U* ou *W* des deux entités réactives: la paire d'ions chélate (*U*) et l'anion dissocié ou relâché que nous avons montré être de conformation *S-trans* (13).

Dans ce cadre, nous avons expliqué la présence abondante d'éther d'énol *trans* observée dans l'alkylation de $E^-K^+$ + 18C6 (5) en postulant un équilibre entre deux espèces complexées par la couronne: l'une serait la paire d'ions à cation couronnée en *U*, l'autre, de structure *S-trans* (13), existerait en faible quantité mais sa forte réactivité se traduisait par la présence d'éther d'énol *trans*. Cette deuxième espèce pourrait être, par exemple, une paire d'ions séparée par le solvant. Smid a montré l'existence d'un tel équilibre dans le cas de sels de fluorényl (6, 7). Nous présenterons dans une première partie la structure déterminée par diffraction des rayons X du complexe $E^-Na^+$–15C5 en la comparant à celle, déjà publiée, de $E^-K^+$–18C6 (14, 5). Nous utiliserons la conductrimétrie et la spectroscopie infrarouge dans le DMSO, solvant particulièrement dissociant, pour étudier l'état d'association de nos substrats. Dans le THF, solvant associant pour nos sels, nous compléterons l'étude ir par des résultats issus de mesures cinétiques interprétées grâce à un modèle (présenté en annexe). Nous discuterons enfin, en nous appuyant sur nos résultats, certaines conclusions erronées dans la littérature.

## I. Résultats

### *1. Structure cristalline du complexe $E^-Na^+$–15C5; comparaison avec celle de $E^-K^+$–18C6*

#### *(a) Structure générale des composés*

La structure du composé $E^-Na^+$–15C5 (Figs. 1 et 2) est celle d'une entité énolate (cation couronne) isolée dans la maille. Ce résultat confirme la structure du complexe $E^-K^+$–18C6 (14, 5) premier exemple de structure d'énolate alcalin non polymérique (15, 16). Le cation est lié d'un côté à l'anion énolate et de l'autre à la couronne ce qui permet de définir ces composés comme des paires d'ions de contact complexées extérieurement par la couronne. Dans les deux composés le cation sort du plan moyen de la couronne de 1,05 Å ($Na^+$) et 0,90 Å ($K^+$). Les distances atomes d'oxygène de l'énolate–cation (Fig. 2, Tableau 1) augmentant du sodium au potassium d'une valeur égale à la différence des rayons ioniques de ces cations. Le rayon que l'on peut calculer pour ces atomes d'oxygène chargés de l'énolate est très proche du rayon de van der Waals covalent de cet atome (1,34 et 1,36 Å pour 1,40 Å (19)). On en déduit que l'énolate est en contact de van der Waals avec son cation.

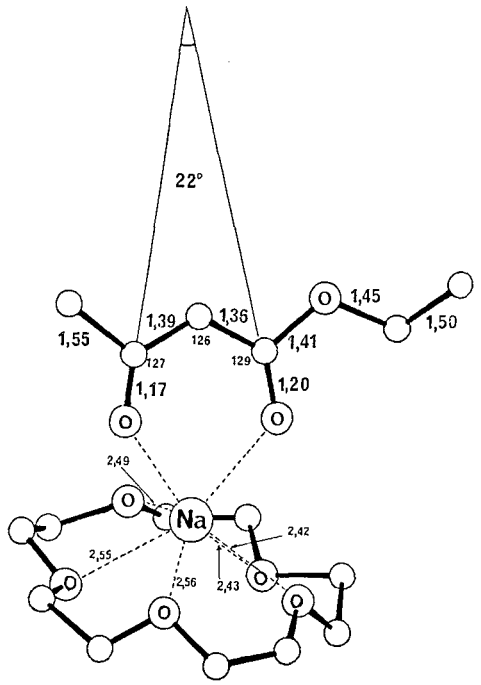

FIG. 1. Angles (degrés) et distances (Å) dans les complexes $E^-Na^+$–15C5 et $E^-K^+$–18C6.

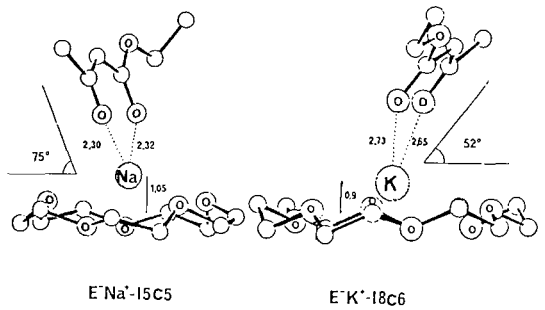

FIG. 2. Vue selon le plan moyen des couronnes, des complexes $E^-Na^+$–15C5 et $E^-K^+$–18C6 (distances en Å).

Les distances moyennes entre les oxygènes de la couronne et le cation augmentent avec le rayon ionique, du sodium (2,49 Å) au potassium (2,92 Å). Celles-ci sont supérieures de 0,1 à 0,2 Å à celles observées dans d'autres complexes où le cation est situé dans le plan de la couronne, $SCN^-K^+$–18C6 (2,80 Å) (17), $TsO^-K^+$–18C6 (2,81 Å) (18), et à celle de $I^-Na^+$ – Benzo-15C5, $H_2O$ (2,39 Å), complexe dans lequel le cation ne sort du plan de la couronne que de 0,15 Å (10). Il résulte de ceci que les oxygènes de la couronne et le cation ne sont plus au contact de van der Waals (Tableau 1). De plus, l'écart entre la valeur mesurée de la distance $O_{couronne}$—$M^+$ et la valeur calculée $r(M^+) + r(O)$,

TABLEAU 1. Distances ou rayon de van der Waals (Å) observés dans les complexes ENa–15C5 et EK–18C6

| | $Na^+$ | $K^+$ | $d(K^+ - Na^+)$ |
|---|---|---|---|
| $r_c(M^+)^a$ | 0,97 | 1,33 | 0,36 |
| $d(O_E^-M^+)^b$ | 2,31 | 2,69 | 0,38 |
| $r(O_E^-)$ | 1,34 | 1,36 | 0,02 |
| $d(O_CM^+)^c$ | 2,49 | 2,92 | 0,43 |
| $r(O_C)$ | 1,52 | 1,59 | 0,07 |

[a]Rayon ionique (19).

[c]$O_C$: oxygènes de la couronne.

passe de 0,12 Å pour $Na^+$ à 0,19 Å pour $K^+$ (Tableau 1). Les oxygènes de la 18C6 sont donc plus éloignée de $K^+$ que ceux de la 15C5 ne le sont de $Na^+$ du point de vue des sphères de van der Waals. Les conditions de stabilité stérique maximale de la couronne sont bien respectées dans le complexe $E^-K^+$–18C6 ou dans le complexe $SCN^-$-$K^+$–18C6 (17). En effet, le motif —C—O—C—C— est bien plan, et l'angle de rotation entre ce motif et les liaisons adjacentes est de 60°, ce qui assure aux hydrogènes une position décalée. Par contre, la 15C5 de par son manque de symétrie présente pour ces angles des écarts notables par rapport aux valeurs idéales: en particulier quatre atomes d'hydrogène sont éclipsés dans un motif $C_2H_4$ (17°) (Schéma 2).[6]

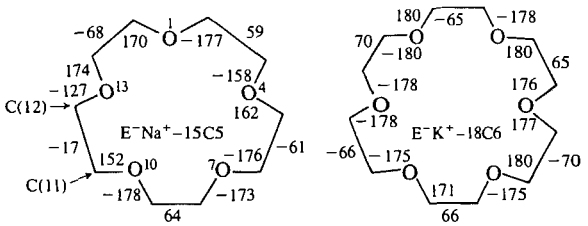

SCHÉMA 2 (Angles dièdres en degrés)

### *(b) Structure des anions énolates dans ces complexes*

Les longueurs et les angles des liaisons des énolates sont proches dans les deux complexes (Fig. 1). Il est remarquable que, malgré la dissymétrie générale de l'anion énolate de l'AAE, le motif $C_3O_2^-$ ait une symétrie presque $C_{2v}$ dans le complexe EK–18C6 et encore assez voisine de $C_{2v}$ dans le complexe ENa–15C5. La planéité de l'énolate dans le complexe EK–18C6 est rigoureuse, mais dans le complexe ENa–15C5, l'énolate présente deux déviations à cette planéité. L'une vient de la

[6]On observe dans la structure cristalline une forte agitation thermique au niveau de l'atome C(12). Ceci peut en fait correspondre à un désordre dynamique ou statique dû aux interactions défavorables dans la 15C5.

For personal use only.

conformation *gauche* du groupement éthyle dont l'angle de torsion est de 38 degrés, l'autre met en jeu le motif $C_3O_2^-$: l'angle entre ses deux moitiés est, en effet, de 7 degrés.

*2. Étude en milieu dissociant (DMSO)*

*(a) Énolates seuls*

En préalable à toute addition de couronne, nous avons examiné l'état initial des solutions de ENa et EK dans le DMSO. À cette fin, nous avons utilisé deux méthodes: le titrage conductimétrique par le cryptand (cf. Annexe et réf. 20) pour déterminer les coefficients de dissociation $\alpha$, et la spectroscopie infrarouge afin d'identifier les espèces en équilibre.

*Conductrimétrie*

La Figure 3 présente des courbes de titrage conductimétrique obtenues en ajoutant le cryptand (2,2,2) à des solutions de $\phi_4$BNa, $\phi_4$BK, ENa et EK dans le DMSO. Les cations de ces quatre sels sont complexés quantitativement par le cryptand puisqu'un plateau est atteint dès un équivalent de cryptand ajouté. À ce plateau, les conductivités des sels de $Na^+$ sont les mêmes que celles des sels de $K^+$, aux incertitudes de mesure prés. Ceci indique que les cations de ces sels entièrement dissociés ($Na^+$–(2,2,2)) et ($K^+$–(2,2,2)) ont une même mobilité. On peut alors calculer les valeurs de $\alpha$ pour ENa et EK 0,1 *M* dans le DMSO (cf. Annexe). On trouve respectivement $\alpha = 0{,}15$ et $\alpha = 0{,}45$.

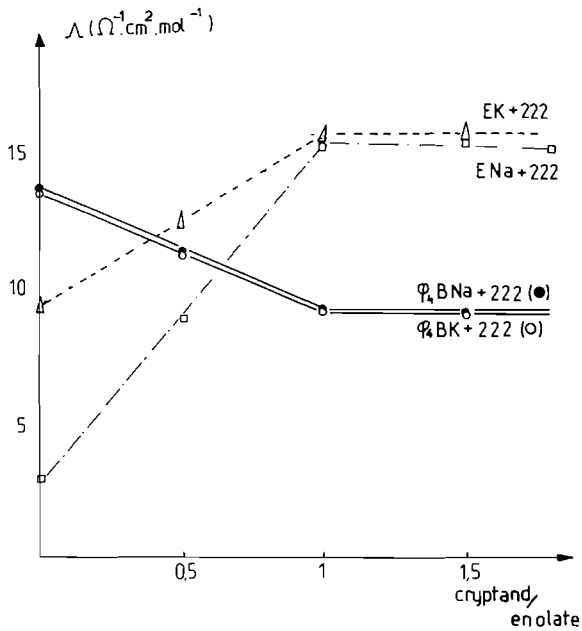

FIG. 3. Conductivités mesurées à 25°C pour des solutions 0,1 *M* dans le DMSO, de tétraphénylborates et d'énolates de $Na^+$ et $K^+$, seuls ou en présence de cryptands.

*Spectroscopie infrarouge*

Les spectres ir de ENa, EK et $E^-(K^+(2,2,2))$ en solution dans le DMSO sont présentés dans la Fig. 4. Les absorptions de $E^-(K^+(2,2,2))$ caractéristiques de l'énolate libre (5) à 1525 et 1637 $cm^{-1}$ se retrouvent en épaules dans le spectre de $E^-K^+$; par contre, seule la première est visible en très faible épaulement dans le spectre de $E^-Na^+$, ce qui corrobore le résultat conductrimétrique. Les bandes à 1474, 1514 et 1656 $cm^{-1}$ communes à $E^-Na^+$ et $E^-K^+$ appartiennent au cycle chélate $C_3O_2^-M^+$ des paires d'ions (5).

Les solutions de $E^-M^+$ dans le DMSO contiennent donc deux espèces en équilibre: la paire d'ions chélaté en *U*, et l'énolate dissocié:

$$E^-M^+, s \underset{}{\overset{K_d}{\rightleftharpoons}} E^- + M^+, s$$

avec

$$K_d(E^-Na^+) < K_d(E^-K^+)$$

*(b) Effet de l'addition de couronnes*

Nous avons mesuré la conductivité de solutions 0,1 *M* dans le DMSO de ENa, EK, $\phi_4$BNa et $\phi_4$BK lors de l'addition de 15C5 et 18C6 par la méthode précédemment décrite. Nous observons dans la Fig. 5 que les courbes conductrimétriques $\Lambda =$

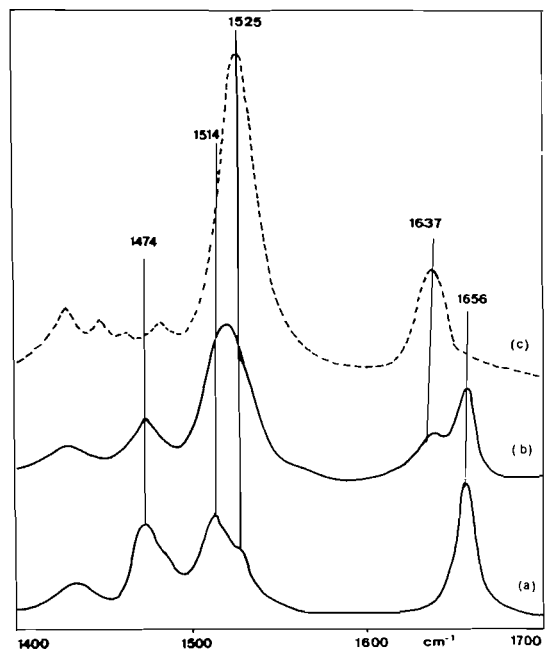

FIG. 4. Spectres infrarouges dans la zone 1500–1700 $cm^{-1}$ de $E^-Na^+$, $E^-K^+$, et $E^-(K^+(2,2,2))$ dans le DMSO. (a) $E^-Na^+$ 0,12 *M*; $1 \times c = 6{,}4 \times 10^{-7}$ mol $cm^{-2}$; (b) $E^-K^+$ 0,1 *M*; $1 \times c = 5{,}4 \times 10^{-7}$ mol $cm^{-2}$; (c) $E^-(K^+(2,2,2))$ 0,1 *M*; $1 \times c = 5{,}4 \times 10^{-7}$ mol $cm^{-2}$.

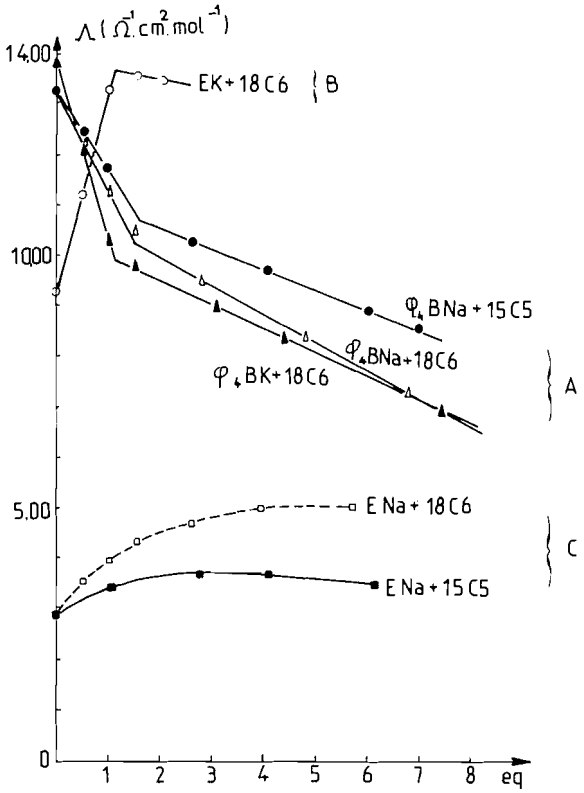

FIG. 5. Conductivités mesurées à 25°C, pour des solutions 0,1 *M* dans le DMSO, de tetraphénylborates et d'énolates de $Na^+$ et de $K^+$, en présence de 18C6 et de 15C5.

$f$(eq.) de $\phi_4B^-M^+$ sont décrites par 2 segments de droites successifs (courbe A). Un premier où la conductivité décroit rapidement ce qui traduit la diminution de mobilité du cation complexé. Un deuxième de pente plus faible rend compte d'une dilution et d'un accroissement de viscosité de la solution pour l'addition de quantités importantes de couronnes. L'abscisse de leur intersection indique le nombre d'équivalents de couronne nécessaires pour déplacer l'équilibre de complexation, sensiblement un équivalent; la valeur de la conductivité $\Lambda_1$ en ce point est celle des ions dissociés $\phi_4B^-$ et $M^+C$. Ces valeurs sont caractéristiques de la mobilité des cations complexés et suivent la séquence: $\lambda(Na^+–15C5) > \lambda(Na^+–18C6) > \lambda(K–18C6) > \lambda(K–(2,2,2))$ en accord avec les tailles de ces entités (Tableau 2). L'addition de 18C6 à une solution de EK dans le DMSO provoque d'abord une forte augmentation de la conductivité (courbe B). Puis, à partir de 1, 1 équivalent de couronne, la conductivité diminue légèrement pour les mêmes raisons citées précédemment. La conductivité $\Lambda_1$ correspondant au déplacement des équilibres de complexation du cation est *inférieure à celle de*

TABLEAU 2. Conductivités mesurées (en $\Omega^{-1}$ cm$^2$ mol$^{-1}$) pour des solutions 0,1 *M* dans le DMSO de tétraphénylborates et d'énolates de Na et de K en présence de couronnes. Rappel des valeurs en présence de cryptand (2,2,2) ($T^{re}$ = 25°C)

| Sel | (0,1 *M*) | C | Équiv. | Valeur limite |
|---|---|---|---|---|
| EK | 9,30 | 18C6 | 1,1 | 13,70 |
| $\phi_4$BK | 13,80 | 18C6 | 1,1 | 9,90 |
| EK | 9,30 | (2,2,2) | 1 | 15,30 |
| $\phi_4$BK | 13,70 | (2,2,2) | 1 | 9,15 |
| ENa | 2,90 | 15C5 | 1,1 | 3,40[a] |
| ENa | 2,90 | 18C6 | 1 | 3,95[a] |
| $\phi_4$BNa | 13,30 | 15C5 | 1,6 | 10,70 |
| $\phi_4$BNa | 13,30 | 18C6 | 1,5 | 10,25 |

[a]Cette valeur ne correspond pas à un plateau.

*$E^-(K^+–(2,2,2))$* (cf. Tableau 2) contrairement à ce que l'on attendrait pour un composé totalement dissocié puisque nous avons vu plus haut que $\lambda(K^+–18C6) > \lambda(K^+–(2,2,2))$. Cette valeur de $\Lambda_1$ traduit donc une *dissociation incomplète* de la paire d'ions au plateau. Le calcul (cf. Annexe) rend compte d'une dissociation de 85% de EK–18C6. L'énolate de sodium, beaucoup plus faiblement dissocié que EK présente un comportement fort différent. Nous voyons sur la Fig. 5 que l'addition du 15C5 ou de 18C6 ne provoque que de faibles augmentations de conductivités (courbes C). Il est intéressant de voir que la conductivité de ENa en présence de 18C6 est plus élevée que celle en présence de 15C5, pour une même quantité de couronne ajoutée. *La 18C6 est donc plus efficace que la 15C5 pour dissocier l'énolate de sodium.*

*Infrarouge*

L'addition de 0,5 à 1,1 équivalents de 18C6 à une solution de EK 0,12 *M* dans le DMSO provoque une augmentation des absorptions de l'ion libre (5) à 1637 et 1524 cm$^{-1}$ (Fig. 6), et une diminution de celles à 1656, 1473, 1214 cm$^{-1}$. Une addition supplémentaire de couronne ne modifie pas le spectre. Les équilibres de complexation sont donc totalement déplacés par addition de 1,1 équivalent de couronne, ce qui est en accord avec les résultats conductimétriques. Nous attribuons sur le spectre correspondant au plateau les absorptions à 1656, 1473, 1214 cm$^{-1}$, à l'espèce non dissociée $E^-K^+$–18C6 dans laquelle l'énolate chélate encore $K^+$ (5). La décomposition graphique des bandes à 1656 et 1637 cm$^{-1}$ du spectre au plateau, et la comparaison avec celle mesurée à 1637 cm$^{-1}$ pour $E^-(K^+(2,2,2))$ en solution dans le DMSO nous donne une valeur approchée du coefficient de dissociation de 0,80 proche de la valeur obtenue par dosage conductimétrique. La dissociation de ENa en présence de 18C6 (Fig. 6) est beaucoup plus faible que celle de EK. Nous trouvons les bandes de la paire d'ions à

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

1654, 1514, 1487 (ep), 1475, 1220 $cm^{-1}$. Les absorptions de l'énolate dissocié sont visibles en épaules à environ 1636 et 1524 $cm^{-1}$. Entre 2 et 11 équivalents de 18C6 ajoutés, le renversement d'intensité des épaules à 1524 et 1514 $cm^{-1}$ indique nettement une dissociation croissante de l'énolate; celle-ci reste faible, comme le confirme la courbe de dosage conductrimétrique. La 15C5, comme nous l'avons déjà remarqué lors de l'étude conductimétrique, est moins efficace que la 18C6 pour dissocier ENa. Les épaules à 1524 et 1636 $cm^{-1}$ sont très peu marquées, et la concentration en ion libre reste faible même en présence de six équivalents de couronne. (Ce spectre, très proche de celui de ENa, n'est pas présenté ici.)

L'existence de *deux espèces au plateau*, l'une associée, l'autre dissociée, mises en évidence tant en conductimétrie que par ir implique l'existence de l'équilibre **IV**:

$$\textbf{IV} \quad E^-M^+\text{–C,s} \overset{K_4}{\rightleftharpoons} E^- + M^+\text{–C,s}$$

En effet, cet équilibre est insensible à l'addition de couronne en excès:

$$K_4 = \frac{(E^-)(M^+\text{–C})}{(E^-M^+\text{–C})}$$

De plus, l'existence des équilibres **I** et **IV** implique celle des équilibres **II** et **III**, la complexation du cation pouvant en effet passer par la paire d'ions ou par le cation libre. Le modèle ci-dessous, à quatre équilibres, rend bien compte de nos résultats.

$$\begin{array}{ccc} E^-K^+, \text{DMSO} & \overset{K_1\,(\textbf{I})}{\rightleftharpoons} & E^- + K^+, \text{DMSO} \\ + & & + \\ 18C6 & & 18C6 \\ \Big\downarrow\Big\uparrow K_2 \;(\textbf{II}) & & K_3\;(\textbf{III})\Big\downarrow\Big\uparrow \\ E^-K^+\text{–18C6, DMSO} & \underset{(\textbf{IV})}{\overset{K_4}{\rightleftharpoons}} & E^- + K^+\text{–18C6, DMSO} \end{array}$$

### 3. *Études en milieu associant (THF)*

*Infrarouge*

Le spectre de $E^-Na^+$ en solution 0,1 *M* dans le THF présente de nombreuses bandes et épaules dans la région de 1400–1700 $cm^{-1}$ (Fig. 7). Un résultat analogue a été trouvé pour le spectre de $E^-K^+$ dans le THF (5). Il a été interprété par l'existence de deux espèces en équilibre: la paire d'ions solvatée et la paire d'ions faisant partie d'aggrégats. Cette conclusion peut être étendue à ENa dans le THF. Lors de l'addition de 15C5 ou de 18C6, le spectre se simplifie. Pour quatre équivalents de 15C5 et 12 de 18C6, on n'obtient plus que

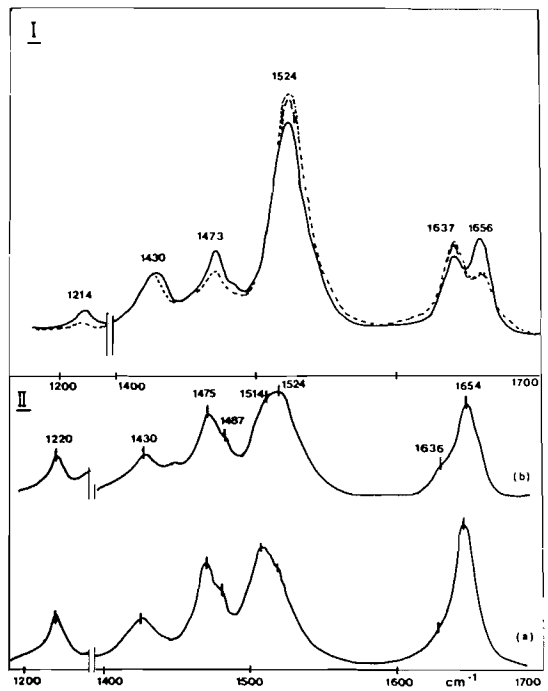

FIG. 6. I. Spectres d'absorptions ir de $E^-K^+$ en solution 0,12 *M* dans le DMSO-$d_6$, en présence de 0,5 (———), 1,1 (– – –) et 2,3 (---) équivalents de 18C6 ($1 \times c = 6{,}4 \times 10^{-7}$ mol $cm^{-2}$). II. Spectres d'absorptions ir de $E^-Na^+$ en solution 0,11 *M* dans le DMSO-$d_6$, en présence de (a) deux et (b) 11 équivalents de 18C6 ($1 \times c = 5{,}9 \times 10^{-7}$ mol $cm^{-2}$).

trois bandes caractéristiques du cycle chélate ($\nu_s$CO, $\nu_a$CC, $\nu_a$CO) à 1657, 1518 et 1472–1476 $cm^{-1}$. Les fréquences de ces absorptions sont proches de celles de ENa–15C5 cristallin que l'on trouve à 1663, 1525 et 1466 $cm^{-1}$. Comme dans le cas de $E^-K^+$ + 18C6, l'espèce existant au plateau est bien la paire d'ions couronnée. Rappelons que 2 équivalents de 18C6 sont nécessaires pour atteindre le plateau ir avec EK (5). Ainsi, l'ordre des affinités est:

$$\text{ENa} + 18C6 < \text{ENa} + 15C5 < \text{EK} + 18C6$$

*Cinétique d'alkylation*

La Figure 8 présente les résultats de l'alkylation par EtI de $E^-K^+$ en présence de 18C6 et de $E^-Na^+$ en présence des 15C5 et 18C6. À partir d'un certain nombre d'équivalents de couronne ajoutés, les constantes de vitesse ne varient plus: le plateau cinétique est donc atteint. Les constantes de vitesse d'alkylation au plateau ne dépendent pas de la couronne utilisée mais seulement du cation lié à l'énolate. Par contre, le nombre d'équivalents de couronne nécessaires pour atteindre le plateau dépend à la fois du cation et de la couronne étudiés (Fig. 8). Ainsi, il faut 1,5 à 2 équivalents de 18C6

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

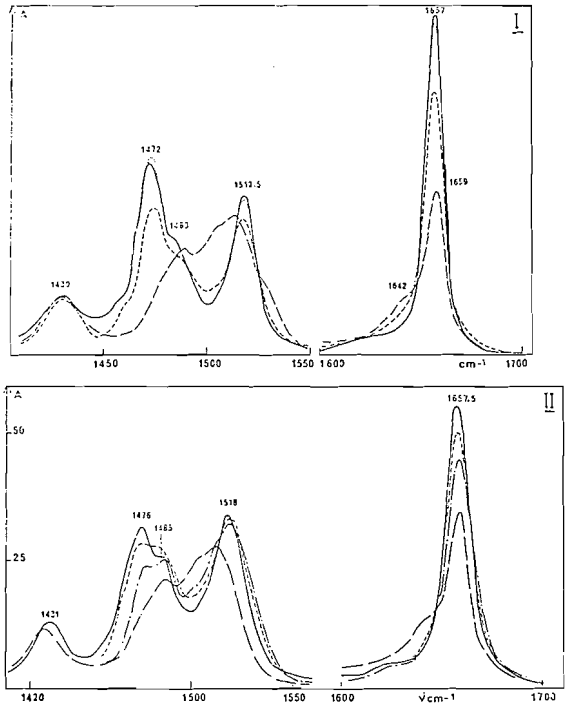

FIG. 7. Spectres d'absorptions ir de $E^-Na^+$ en solution dans le THF. I. En présence de 15C5. C/E = 0 (---); 1 (---); 5 (———); 10 (···). 1 × $c$: 5,4 × $10^{-7}$ mol $cm^{-2}$. II. En présence de 18C6. C/E: 0 (---); 2(—·—); 4 (---) et 12 (———). 1 × $c$: 5,4 × $10^{-7}$ mol $cm^{-2}$.

pour déplacer l'équilibre de complexation de EK, et respectivement 4 et 12 équivalents pour déplacer totalement les équilibres de complexation de ENa par les 15C5 et 18C6. Ces nombres d'équivalents nécessaires sont donc une mesure de l'affinité des différentes couronnes pour les paires d'ions $E^-M^+$. Ils recoupent bien les résultats infrarouge.

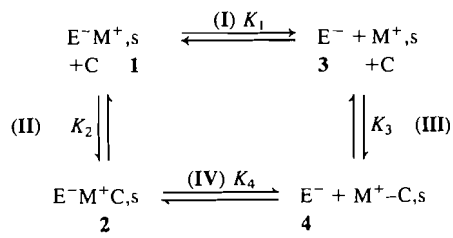
Nous avons en outre mesuré les constantes de vitesse d'alkylation par EtBr de EK et ENa en présence de 18C6 et de ENa en présence de 15C5 dans les conditions du plateau cinétique (Tableau 3). Comme dans le cas de l'alkylation par EtI, la valeur des constantes cinétiques au plateau ne dépend que du cation de l'énolate, et non de la couronne qui le complexe. Des quantités appréciables d'éthers d'énols apparaissent dans l'alkylation par EtBr de EK et ENa en présence de 18C6. L'isomère prépondérant est l'éther d'énol O-*trans*. Alors que les constantes cinétiques de ENa complexé par la 18C6 et la 15C5 sont très proches, la quantité d'éthers d'énols obtenue par alkylation du premier complexe est supérieure à celle obtenue pour le second. Dans le cadre du modèle représenté par l'équilibre **IV**, la connaissance de la constante globale d'alkylation $k_t$ et du pourcentage d'éthers d'énol O-*trans* permet d'obtenir la valeur de la constante de vitesse apparente de formation de l'éther d'énol *trans*: $k$ (O-*trans*). Si nous admettons que $E^-(K^+(2,2,2))$ est un bon modèle de l'espèce relâchée (ou dissociée) $E^-$, ($M^+$–C), α est donné par le rapport:

$$\alpha = \frac{k(\text{O-}trans)}{k_0(E^-(K^+ - (2,2,2))}$$

Les résultats du calcul de α (selon l'annexe 2) sont présentés dans le Tableau 4. Nous voyons que pour $E^-K^+$–18C6, α est de l'ordre de 0,3–0,5%. La valeur de α pour ENa–18C6 est supérieure à celle de ENa–15C5. Les valeurs, toutes inférieures à 1% expliquent que l'espèce dissociée (ou relâchée) ne puisse être détectée par spectroscopie ir.

## II. Discussion et conclusion

Nous discuterons nos résultats dans le cadre du modèle à quatre équilibres:



Dans le THF, les courbes d'accession au plateau ir et cinétique résultent principalement du déplacement de l'équilibre **II** vers la paire d'ions couronnée **2**. Nous excluons en effet le passage par les équilibres **I**, **III**, **IV** pour un système aussi associé que $E^-M^+$ dans le THF. La "rapidité" d'obtention du plateau cinétique ou ir traduit alors l'affinité de la couronne pour le cation chélaté selon la séquence:

THF $K_2(\text{ENa} + 18\text{C6}) < K_2(\text{ENa} + 15\text{C5}) < K_2(\text{EK} + 18\text{C6})$

Au plateau, les résultats cinétiques nous permettent de préciser que l'on est en fait en présence d'un équilibre (**IV**) entre paire d'ions couronnée et énolate relâché, cette dernière espèce, peu abondante, étant invisible par ir. Un modèle de calcul permet de trouver: $K_4$ (ENa + 15C5) < $K_4$ (ENa + 18C6) < $K_4$ (EK + 18C6).

Dans le DMSO, l'équilibre **I** est déjà appréciable initialement (on trouve **1** et **3**). Ceci implique que la complexation par la couronne doit pouvoir passer *à la fois* par les chemins **II** et **III**. Ainsi, aucune information ne peut a priori être recueillie sur les valeurs relatives de $K_2$ dans ce solvant. Cependant,

| E(K(2,2,2)) | 7,9 | 43 | 100 | 0 | 43 | 48 | 9 |

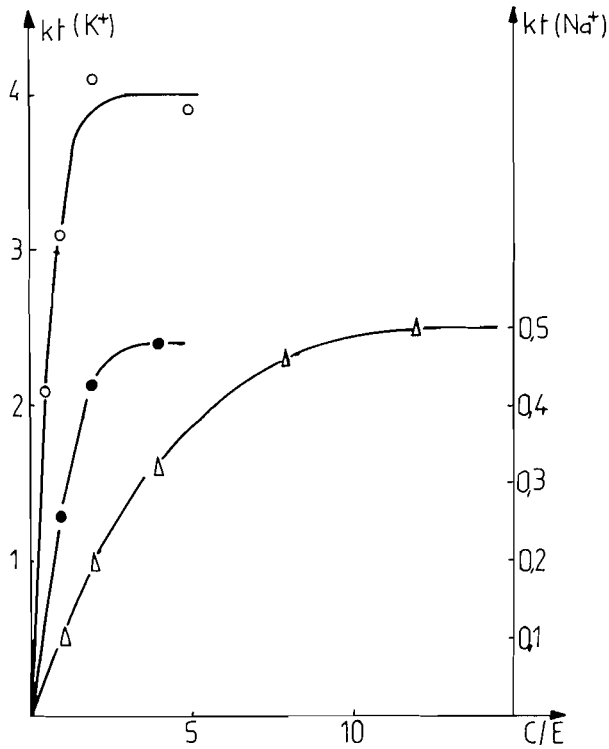

FIG. 8. Courbes $k_t = f$ (couronne/énolate) obtenues dans l'alkylation par EtI à 25°C dans le THF, de $E^-K^+$ 0,02 *M* en présence de 18C6 (○) et de $E^-Na^+$ 0,02 *M* en présence de 15C5 (●) ou de 18C6 (△). ($k_t$: $M^{-1}$ min$^{-1}$).

la complexation de EK aboutit à un plateau ir et conductimétrique qui traduit l'équilibre **IV** et permet d'accéder à $K_4$.

Les quatre constantes d'équilibre sont liées par la relation:

$$K_4 = K_1(K_3/K_2)$$

Comme dans ce cas $K_4 > K_1$ (Tableau 5), il découle que $K_3 > K_2$.

Ainsi l'affinité de la 18C6 pour $K^+$ solvaté est plus grande que pour $K^+$ dans la paire d'ions. Ceci peut être expliqué par une répulsion entre les oxygènes chargés de l'énolate et ceux de la couronne. Ce résultat était d'ailleurs attendu pour le cation $K^+$. A l'inverse, certains résultats de Smid (6, 7) montrent la grande difficulté pour une couronne à arracher $Na^+$ (libre) à sa sphère de solvant polaire (oxétane); elle choisit dans ce cas la complexation d'une paire d'ions de contact (anion = fluorényl) plus facile à désolvater. En est-il de même pour $E^-Na^+$?

Malheureusement les plateaux conductimétriques n'ont pu être obtenus pour $E^-Na^+$. Nous avons constaté simplement qu'à concentration identique en couronne, la dissociation de $E^-Na^+$ est plus forte avec la 18C6 qu'avec la 15C5. Sans les valeurs des constantes $K_4$, nous ne pouvons comparer la complexation par la 18C6 et la 15C5 de la paire d'ions et du cation libre.

Cependant, il serait intéressant de connaître *les valeurs relatives* de $K_4$ (ENa + 15C5) et $K_4$ (ENa + 18C6) dans le DMSO. Pour cela, deux assomptions sont nécessaires; nous admettrons: (*i*) que $K_2$ (ENa + C) dans le DMSO a les mêmes valeurs relatives que dans le THF, puisqu'il s'agit dans les deux cas de la complexation d'une paire d'ions de contact et que le rôle du solvant est moins important dans ce cas que dans celui de l'ion libre; (*ii*) que $K_3$ ($Na^+$–15C5) < $K_3$ ($Na^+$–18C6) comme il a déjà été observé dans des milieux dissociants ($H_2O$ ou MeOH) (2).

On obtient alors: $K_3$ (ENa + 15C5) < $K_3$ (ENa + 18C6) et $K_2$ (ENa + 15C5) > $K_2$ (ENa + 18C6) d'où $(K_3/K_2)$ (ENa + 15C5) ≪ $(K_3/K_2)$ (ENa + 18C6). Comme $K_3/K_2 = K_4/K_1$ et que $K_1$ est le même pour les 2 systèmes, $K_4$ (ENa + 15C5) ≪ $K_4$ (ENa + 18C6).

De ce fait, *la même séquence de* $K_4$ *est trouvée dans le THF et le DMSO:*

THF et DMSO:

$$K_4(\text{ENa} + 15\text{C5}) < K_4(\text{ENa} + 18\text{C6}) < K_4(\text{EK} + 18\text{C6})$$

Nous regroupons dans le Tableau 5 les valeurs

TABLEAU 4. Valeurs calculées à partir des résultats cinétiques, des coefficients de dissociation des complexes ENa–15C5, ENa–18C6 et EK–18C6 en solution 0,02 *M* dans le THF

des constantes (ou leurs grandeurs relatives) des équilibres **I**, **II** et **IV** dans le THF ou le DMSO.

La moins grande affinité apparente de la 15C5 pour ENa par rapport à celle de la 18C6 pour EK peut être expliquée par les résultats cristallographiques: la 15C5 ne peut, en effet, assumer une structure décalée régulière. La faible affinité de la 18C6 pour ENa peut s'expliquer par la perte de la structure régulière de la 18C6 d'une part, et certainement par le fait que, d'autre part, $Na^+$ et la couronne ne sont pas en contact de van der Waals. Remarquons enfin l'inversion de l'ordre des constantes $K_2$ et $K_4$ pour $E^-Na^+$:

$$K_2(E^-Na^+ + 15C5) > K_2(E^-Na^+ + 18C6)$$

$$K_4(E^-Na^+ + 15C5) < K_4(E^-Na^+ + 18C6)$$

Une telle inversion a été observée par Smid (6) pour le fluorényl–sodium.

Elle pourrait être expliquée par une intervention du solvant au niveau du complexe cation–couronne. Cette intervention serait moins nécessaire à la stabilisation du complexe $E^-Na^+$–C qu'à celle du complexe $Na^+$–C. La meilleure accessibilité du solvant au cation $Na^+$ via les sites apicaux de la 18C6 expliquerait alors ces résultats.[7]

L'ensemble de nos résultats montre avec quelle prudence l'effet de l'addition de couronnes doit être analysé avant de tirer des conclusions. Ils contredisent en effet les interprétations que Reutov et coll. ont émises dans une séries d'articles (21–23) consacrés à l'étude du même système que le nôtre.

D'une part, ces auteurs ont invoqué un équilibre en paires d'ions *de contact S-cis* et *W* pour expliquer l'obtention d'éther d'énols *cis* et *trans* à partir de $E^-M^+$ dans le dioxanne (21), ce qui est totalement contredit par nos résultats.

D'autre part, ils ont interprété l'existence d'un plateau cinétique lors de l'addition de 18C6 à $E^-M^+$ dans le DMF (22) ou dans d'autres solvants plus ou moins dissociants (23), par la *formation exclusive* des ions dissociés. Ainsi, les constantes cinétiques obtenues devaient être celles de l'ion dissocié plus ou moins solvaté. En fait, des constantes mesurées sont des constantes apparentes $\alpha \cdot k_i$ ($k_i$ = constante de l'ion libre) dépendant à la fois de la position de l'équilibre **IV** et de la réactivité de l'ion libre.

## III. Partie expérimentale

*1. Matières premières*

(a) La préparation des énolates ainsi que la purification des solvants des réactifs alkylants et des couronnes ont été décrits précédemment (5, 12).

*2. Mesures cinétiques*

Les techniques de mesures cinétique ainsi que leur traitement ont été décrits précédemment (5, 12). Il en est de même pour les dosages de produits d'alkylation effectués par cpg ou $^1$H-rmn.

*3. Structure cristalline de $E^-Na^+$–15C5*

L'addition de couronne 15C5 à une solution concentrée ($c$ = 0,2 *M*) d'énolate de sodium dans le THF conduit à l'apparition d'un précipité cristallisé en aiguilles fines. Un cristal de dimensions 0,5 × 0,3 × 0,2 mm obtenu par recristallisation dans le benzène (saturation 0,4 *M*) a été scellé dans un tube en verre de Lindeman.

*Données cristallographiques*

$C_6H_9O_3^-$, $C_{10}H_{20}O_5$, $Na^+$ $M = 372$

Orthorhombique, groupe spatial $P2_12_12_1$, $a$ = 9,150 (2), $b$ = 13,127 (3), $c$ = 16,566 (3) Å; $V$ = 1989,8 Å$^3$, $\rho_c$ = 1,3; $Z$ = 4, $\lambda$ = 1,5418 Å (Cu K monochromateur au graphite).

L'enregistrement des données de diffraction a été réalisé sur un diffractomètre Philips PW 1100 avec la radiation $K_\alpha$ du cuivre. Les intensités des trois réflexions de référence, mesurées toutes les 120 minutes, décroissaient avec le temps d'une manière isotrope (maximum 5%). Un facteur de décomposition a été calculé à partir des valeurs de ces intensités. Cette correction de décomposition, fonction du temps a été approchée par un polynome d'ordre quatre en utilisant la méthode des

[7]Un des rapporteurs suggère que le complexe ($Na^+$–18C6) adopte une conformation dans laquelle la 18C6 est repliée, comme dans le complexe ($H_2O$, $SCN^-Na^+$–18C6) (27). Un des deux sites apicaux serait alors solvaté par un oxygène de la couronne repliée, l'autre par le solvant. Cette conformation plus favorable au sens des contacts de van der Waals doit comporter cependant de fortes interactions répulsives dans la couronne, et si elle peut être préférée dans le cristal, rien ne permet d'affirmer qu'elle existe dans un solvant aussi basique que le DMSO. Nous ne pouvons donc trancher entre les deux structures suivantes du complexe $Na^+$– 18C6 en solution.

| Na ( ) | 5307 ( 3) | 3541 ( 3) | 6093 ( 2) | 4,6 |

moindres carrés. Sur un total de 1738 réflexions mesurées ($\theta < 68°$), 1038 répondant au critère $I > 3\sigma(I)$ (calculé à partir des erreurs statistiques de comptage) ont été considérées comme observées et utilisées lors de l'affinement des coordonnées de la structure.

La structure a été résolue par les méthodes directes à l'aide du programme MULTAN (24). Les coordonnées et les coefficients d'agitation thermique ont été affinés par la méthode des moindres carrés en minimisant l'expression $\Sigma w (|F_o| - |F_c|)^2$ où $w = 1/\sigma^2(F_o)$. Les atomes d'hydrogène ont été introduits dans les calculs de facteurs de structure en position idéale ($d_{C-H} = 1{,}0$ Å, $B_H = B_C$). Ceux du groupe méthyle C (17) ont été localisés sur une série de Fourier différence. Le facteur résiduel en fin d'affinement était de $R_w = 0{,}086$. Les facteurs de diffusion atomique ont été extraits des réfs. 25 (C, O, Na$^+$) et 26 pour H. Les coordonnées atomiques sont rassemblées dans le Tableau 6. On notera la forte agitation thermique générale qui se traduit par des valeurs élevées des $B$ équivalents (Tableau 6). Ceux-ci étant respectivement de: 4,6 (Na$^+$), 6,5 (énolate), 8,1 (oxygène de 15C5) et 12,3 (carbone de 15C5).[8]

*4. Enregistrement des spectres infrarouges*

Les spectres infrarouges sont enregistrés sur les spectrophotomètres Beckmann IR 12 et Perkin–Elmer 180. La résolution choisie est de 1 cm$^{-1}$. La précision des mesures est de $\mp$ 1 cm$^{-1}$. Les cuves utilisées pour les spectres de solutions sont en $CaF_2$, d'épaisseur allant de 8,5 à 2000 μ. Les spectres de solutions présentés ont été linéarisés.

*5. Étude conductimétrique*

Nous avons réalisé cette étude sur un conductivimètre Philips PW 9501/01 équipé d'une cellule de mesure PR 9512/00 possédant une constante de 0,685 cm$^{-1}$. La fréquence utilisée (2000 Hz) permet des mesures dans la gamme de 100 à 100000 $\times$ $10^{-6}\,\Omega^{-1}\,cm^{-1}$. La compensation de température est choisie et manuelle. Les solutions sont placées dans un récipient rodé sur lequel vient s'adapter l'électrode. Après 10 min de thermostatisation à 25°C (bain Haake uniterm R 21, $T^{re} \mp 0{,}05$°C), la valeur affichée de la constante de cellule est vérifiée, puis la valeur de la conductivité de la solution est lue.

## Annexes

*1. Annexe conductimétrique. Dosage conductimétrique à l'aide du cryptand (2,2,2)*

Cette technique présentée initialement par Collman *et al.* (20) a été modifiée et discutée plus en détail dans un de nos articles précédents. Nous en rappelons l'essentiel (13).

Il est admis en première approximation que la mobilité des ions est indépendante de la concentration en espèces ioniques dans le milieu. Les conductivités équivalentes $\Lambda_i$ du tétraphénylborate de $K^+$ et de l'énolate de $K^+$ étudié en l'absence de cryptand sont alors donnés par les relations

$$[1] \quad \Lambda_{i,EK} = \alpha(\lambda_{E^-} + \lambda_{K^+})$$

$$[2] \quad \Lambda_{i,\phi_4BK} = \alpha(\lambda_{\phi_4B^-} + \lambda_{K^+})$$

$\alpha$ désignant le coefficient de dissociation de l'énolate et $\lambda$ les conductivités ioniques équivalents des ions.

En présence de cryptand, l'énolate est totalement dissocié et les conductivités équivalentes au plateau sont égales à:

$$[3] \quad \Lambda_{pl,EK} = \lambda_{E^-} + \lambda_{K^+\,crypté}$$

$$[4] \quad \Lambda_{pl,\phi_4BK} = \lambda_{\phi_4B^-} + \lambda_{K^+\,crypté}$$

Des équations [1]–[4] on tire la relation [5] utilisée pour la détermination approchée du coefficient de dissociation des énolates:

$$[5] \quad \alpha_{approx.} = \frac{\Lambda_{i,EK}}{\Lambda_{pl,EK} + \Lambda_{i,\phi_4BK} - \Lambda_{pl,\phi_4BK}}$$

La même méthode a été appliquée dans le cas du titrage conductimétrique par les couronnes.

Dans le cas de $E^-K^+ + 18C6$ on a:

$$\Lambda_{11} = \lambda_{\phi_4B^-} + \lambda_{(K^+-18C6)} = 9{,}9\,\Omega^{-1}\,cm^2\,mol^{-1}$$

$$\Lambda_{12} = \lambda_{\phi_4B^-} + \lambda_{(K^+(2,2,2))} = 9{,}15\,\Omega^{-1}\,cm^2\,mol^{-1}$$

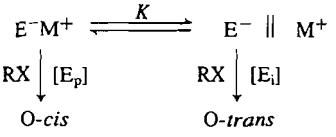
$$\Lambda_{13} = \lambda_{E^-} + \lambda_{(K^+(2,2,2))} = 15{,}3\,\Omega^{-1}\,cm^2\,mol^{-1}$$

$$\Lambda_{13} - \Lambda_{12} + \Lambda_{11} = \lambda_{E^-} + \lambda_{K^+-18C6} = 16{,}05\,\Omega^{-1}cm^2\,mol^{-1}$$

$$\Lambda_{1(E^-K^+ + 18C6)} = \alpha(\lambda_{E^-} + \lambda_{K^+-18C6}) = 13{,}7\,\Omega^{-1}\,cm^2\,mol^{-1}$$

$$\alpha = \frac{\Lambda_{1(E^-K^+ + 18C6)}}{\lambda_{E^-} + \lambda_{K^+-18C6}} = \frac{13{,}7}{16{,}05} = 0{,}85$$

*2. Annexe cinétique. À l'aide d'un modèle dissociatif: calcul de* $\alpha$



*Observés:* $k_t$, % O-*cis*, % O-*trans*
$k_{O_c}$ et $k_{O_t}$ déterminés.

$$[6] \quad \frac{dO_c}{dt} = k_{O_c} \cdot [E_t] \cdot [RX]$$

$$[7] \quad \frac{dOt}{dt} = k_{O_t} \cdot [E_t] \cdot [RX]$$

$k_{O_c}$ et $k_{O_t}$ sont des constantes apparentes mesurées expérimentalement.

Les constantes *vraies* font intervenir les concentrations en $E_p$ et $E_i$. Nous les nommerons $k_{O_p}$ et $k_{O_i}$:

$$[8] \quad \frac{dO_p}{dt} = k_{O_p} \cdot [E_p] \cdot [RX]$$

$$[9] \quad \frac{dO_i}{dt} = k_{O_i} \cdot [E_i] \cdot [RX]$$

$$[10] \quad k_{O_c} \cdot [E_t] = k_{O_p} \cdot [E_p] \qquad [6] \text{ et } [8]$$

$$[11] \quad k_{O_t} \cdot [E_t] = k_{O_i} \cdot [E_i] \qquad [7] \text{ et } [9]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

Or, le coefficient de dissociation $\alpha$ est tel que:

$$\alpha = [E_i]/[E_t] \quad \text{et} \quad 1-\alpha = [E_p]/[E_t]$$

d'où:

[12] $k_{O_c} = k_{O_p} \cdot ([E_p]/[E_t]) = k_{O_p} \cdot (1-\alpha)$

[13] $k_{O_t} = k_{O_i} \cdot ([E_i]/[E_t]) = k_{O_i}$

[14] $$\frac{O_c}{O_t} = \frac{k_{O_c}}{k_{O_t}} = \frac{(1-\alpha)}{\alpha} \cdot \frac{k_{O_p}}{k_{O_t}} \quad [12]/[13]$$

Or,

$$\frac{dO_c}{dt} + \frac{dO_t}{dt} = k_{O_c} \cdot [E_t] \cdot [RX] + k_{O_t} \cdot [E_t] \cdot [RX]$$
$$= k_{O_p} \cdot [E_p] \cdot [RX] + k_{O_i} \cdot [E_i] \cdot [RX]$$

[15] $k_{O_c} + k_{O_t} = k_{O_p} \cdot (1-\alpha) + k_{O_i}$

On obtient donc un système linéaire de deux équations à trois inconnues: $k_{O_p}$, $k_{O_i}$, et $\alpha$.

$$\frac{k_{O_c}}{k_{O_t}} = \frac{1-\alpha}{\alpha} \cdot \frac{k_{O_p}}{k_{O_i}}$$

$$k_{O_c} + k_{O_t} = k_{O_p}(1-\alpha) + k_{O_i}$$

En faisant l'hypothèse que:
$k_{O_i} \approx k_O$ ($E^-(K^+,2,2,2)$), on obtient un système de deux équations:

$$\alpha = \frac{k_{O_t}}{k_{O_i}} = \frac{k_{O_t}}{k_O(EK,2,2,2)}$$

avec

$$k_{O_t} = k_t \cdot \frac{\text{O total}}{\text{pr. total}} \cdot \frac{\text{O-}trans}{\text{pr. total}}$$

et $k_O(E^-(K^+(2,2,2)))$ étant déterminé expérimentalement par ailleurs (5).

# Absolute rate constants for hydrocarbon autoxidation. 32. On the self-reaction of 1,1-diphenylethylperoxyl in solution[1]

J. A. HOWARD, J. H. B. CHENIER, AND T. YAMADA[2]

*Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada, K1A 0R9*

Received May 6, 1982

J. A. HOWARD, J. H. B. CHENIER, and T. YAMADA. Can. J. Chem. **60**, 2566 (1982).

The major products of the self-reaction of 1,1-diphenylethylperoxyl have been determined from product studies of the autoxidation of 1,1-diphenylethane, induced decomposition of 1,1-diphenylethyl hydroperoxide, and decomposition of 2,2,3,3-tetraphenylbutane under an atmosphere of oxygen. Overall self-reaction is a complex free-radical process involving the intermediacy of 1,1-diphenylethoxyl and 1-phenyl-1-phenoxyethoxyl which undergo H-atom abstraction, β-scission and, in the case of the former radical, rearrangement. Hydroperoxide decomposition under an atmosphere of $^{36}O_2$ has shown that 1,1-diphenylethylperoxyl undergoes β-scission faster than α-cumylperoxyl at 303 K in solution. The values of the rate constants for self-reaction of $Ph_2C(Me)O_2\cdot$ relative to those for *tert*-butylperoxyl are, however, not affected by this reaction. Furthermore they are not affected to any appreciable extent by the efficiency with which $Ph_2C(Me)O\cdot$, formed in nonterminating self-reactions, escape from the solvent cage. They are influenced principally by the first-order rate of decomposition of $Ph_2C(Me)OOOOC(Me)Ph_2$.

J. A. HOWARD, J. H. B. CHENIER et T. YAMADA. Can. J. Chem. **60**, 2566 (1982).

On a déterminé les produits principaux de l'auto-réaction du diphényl-1,1 éthylperoxyle à partir d'études des produits provenant de l'auto-oxydation du diphényl-1,1 éthane, de la décomposition induite du diphényl-1,1 éthylhydroperoxyde et de la décomposition du tétraphényl-2,2,3,3 butane sous atmosphère d'oxygène. L'auto-réaction globale est un processus par radical libre complexe impliquant comme intermédiaire le diphényl-1,1 éthoxyle et le phényl-1 phénoxy-1 éthoxyle qui subissent une perte d'hydrogène, une scission β et, dans le cas du premier radical, une transformation. La décomposition de l'hydroperoxyde sous atmosphère de $^{36}O_2$ révèle que le diphényl-1,1 éthylperoxyle subit une scission β plus rapidement que l'α cumylperoxyle à 303 K en solution. Les valeurs de constantes de vitesse d'auto-réaction du $Ph_2C(Me)O_2\cdot$ par rapport à celles du *tert*-butylperoxyle ne sont pas, cependant, affectées par cette réaction. De plus elles ne sont pas affectées de façon appréciable par l'efficacité avec laquelle le $Ph_2C(MeO)\cdot$, formé lors d'auto-réactions intermédiaires, s'échappe de la cage du solvant. Elles sont principalement influencées par la vitesse de décomposition d'ordre un du $Ph_2C(Me)OOOOC(Me)Ph_2$.

[Traduit par le journal]

## Introduction

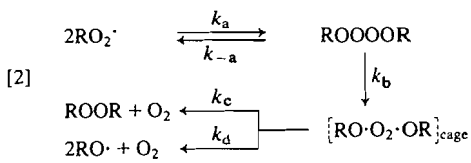
It has recently been re-established (1) that rates of self-reaction of α-cumylperoxyl in solution are second-order with respect to the radical concentration at 303 K and that, although β-scission of this radical (reaction [1]) occurs at this temperature, the steady-state concentration of cumyl is too low to influence the magnitude of the *overall* termination rate constant, $2k_t$, for autoxidation of cumene and the rate constant for self-reaction to give di-α-cumyl peroxide, $2k'_t$.

[1] $PhCMe_2O_2\cdot \rightleftarrows Ph\dot{C}Me_2 + O_2$

The related 1,1-diphenylethylperoxyl also decays with second-order kinetics in solution at 303 K and the values of $2k_t$ and $2k'_t$ for this radical are *both* approximately ten times larger than the corresponding rate constants for α-cumylperoxyl (2).

Recently Nangia and Benson (3) re-examined the kinetics and mechanisms for self-reactions of tertiary alkylperoxyls and concluded that the large values observed for the termination rate constants for α-cumylperoxyl and 1,1-diphenylethylperoxyl relative to the value for *tert*-butylperoxyl are the result of rather low efficiencies of cage escape for the more bulky α-cumyloxyl and 1,1-diphenylethoxyl relative to the high efficiency of cage escape for *tert*-butoxyl.

[2]



Thus they suggest that values of the rate constant ratio $k_c/k_d$ for R = $PhCMe_2$ and $Ph_2CMe$ are larger than $k_c/k_d$ for R = *t*-Bu. However, we found experimentally (1) that there is little or no difference in the values of this ratio for $PhCMe_2O_2\cdot$ and *t*-$BuO_2\cdot$ and that the differences in the magnitudes of $2k_t$ and $2k'_t$ for these two tertiary alkylperoxyls are due primarily to differences in the magnitude of the unimolecular rate constant for tetroxide decomposition, $k_b$.

Nangia and Benson (3) also concluded, from thermochemical calculations based on reasonable values of $\Delta H^0_f$ and $\Delta S^0_f$, that although β-scission of $PhCMe_2O_2\cdot$ is not important at ambient tempera-

tures under normal experimental conditions it can become important for $Ph_2CMeO_2\cdot$ at oxygen concentrations $< 10^{-3}\,M$. This is because of the difference in the stabilization energies of $PhC\dot{M}e_2$ and $Ph_2C\dot{M}e$ (3) and $\Delta H_f^0$ for $Ph_2C\dot{M}e$ was calculated to be about a factor of 12 times larger than $\Delta H_f^0$ for $PhC\dot{M}e_2$.

The present paper reports the results of a series of experiments similar to those reported previously for α-cumylperoxyl (1) designed to rationalize the difference in the kinetics for the second-order mutual reaction of α-cumylperoxyl and 1,1-diphenylethylperoxyl in solution and to estimate the importance of β-scission of 1,1-diphenylethylperoxyl at ambient temperatures, reaction [3], and the possible involvement of the reaction of 1,1-diphenylethylperoxyl with 1,1-diphenylethyl, reaction [4], in the overall chain termination process for autoxidation of 1,1-diphenylethane.

[3] $Ph_2C(Me)O_2\cdot \rightleftarrows Ph_2C\dot{M}e + O_2$

[4] $Ph_2C(Me)O_2\cdot + Ph_2C\dot{M}e \rightarrow Ph_2C(Me)OOC(Me)Ph_2$

In addition, this work also provides some quantitative information on the relative rates of H-atom abstraction and β-scission of 1,1-diphenylethoxyl and 1-phenyl-1-phenoxylethoxyl in solution at 303 K, radicals which are formed by nonterminating interactions of $Ph_2C(Me)O_2\cdot$.

## Experimental

*Materials*

1,1-Diphenylethane was prepared by reduction of 1,1-diphenylethylene (Aldrich) and purified by preparative gas–liquid chromatography. 1,1-Diphenylethyl hydroperoxide was prepared from 1,1-diphenylethanol and 30% $H_2O_2$ (4). 1,1-Diphenylethyl peroxide was prepared from 1,1-diphenylethyl hydroperoxide by the procedure of Bassey *et al.* (5). *o*-Benzoquinone was prepared by oxidation of catechol with lead oxide. No attempt was made to purify this compound and it contained a decomposition product as a major impurity. 2,2-Diphenyloxirane was prepared from 1,1-diphenylethylene via 1,1-diphenyl-2-bromoethanol (6). 1-Phenyl-1-phenoxyethyl hydroperoxide was prepared by autoxidation of phenyl α-methylbenzyl ether in the presence of *tert*-butyl hydroperoxide at 30°C. The hydroperoxide was not separated from the reaction mixture and it was concluded that the major product peak in the liquid phase chromatogram was the hydroperoxide. Phenyl benzoate was prepared from benzoyl chloride and phenol. 2,2,3,3-Tetraphenylbutane and di-*tert*-butyl hyponitrite had been prepared previously in our laboratory (1). Phenol, acetophenone, benzophenone, and 1,1-diphenylethanol were commercially available and were purified by standard methods. $^{36}O_2$ (99.1 at.%) was obtained from Merck, Sharpe and Dohme Canada Ltd.

*Product studies*

Oxidation and decomposition products were identified by a combination of gc–ms and hplc techniques as described previously (1). Yields of most of the oxygenated products were determined by reverse-phase hplc and were accurate to ~ ±10%. We did, however, experience difficulty measuring yields of 2,2-diphenyloxirane because it was produced in rather low yields and had a tendency to decompose during analysis.

## Results

*Products of autoxidation of 1,1-diphenylethane*

The major products of the di-*tert*-butyl hyponitrite initiated autoxidation of 1,1-diphenylethane at 303 K are 1,1-diphenylethyl hydroperoxide, 1,1-diphenylethanol, acetophenone, phenol, benzoquinones, 1,1-diphenylethyl peroxide, phenyl benzoate, and benzophenone and are consistent with the elementary reactions given in Scheme 1. The yields of these oxygenated products, formed under different experimental conditions, are given in Tables 1 and 2, and their total yield accounted for > 90% of the oxygen absorbed. 1-Phenyl-1-phenoxyethyl hydroperoxide and the unsymmetric peroxide, $Ph_2C(Me)OOC(Me)(OPh)Ph$, were not identified.

Autoxidation of 1,1-diphenylethane initially decelerates as oxygen is absorbed, probably because the steady-state concentration of chain-carrying peroxyls decreases because of reaction with the phenol produced in reaction [19]. Yields of $Ph_2C(Me)OOH$ were, therefore, lower than calculated from the oxidizability of $Ph_2CMeH$, $k_p/(2k_t)^{\frac{1}{2}} = 1.1 \times 10^{-3}\,M^{-\frac{1}{2}}\,s^{-\frac{1}{2}}$ (2), the average calculated rate of chain initiation, $R_i$, and the total reaction time.

*p*-Benzoquinone was positively identified as a reaction product while *o*-benzoquinone was not present in final reaction mixtures. There was, however, evidence for a decomposition product of the *ortho* isomer, suggesting that it was formed but was not stable under the reaction conditions. The

production of benzoquinones can be accounted for by reaction of phenol with peroxyls, reactions [21] and [22]. Yields of *p*-benzoquinone plus phenol were very similar to yields of acetophenone, indicating that *o*-benzoquinone was not formed in appreciable amounts. Interestingly, the yield of *p*-benzoquinone relative to the yield of phenol fell as the reaction proceeded, probably because

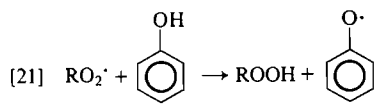
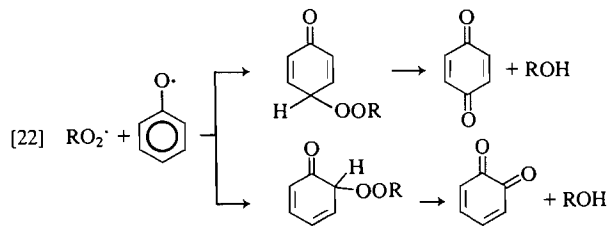
[b] Trace amounts of these products were formed.

phenoxyls reacted with $Ph_2C(Me)OOH$ to regenerate phenol, rather than with $Ph_2C(Me)O_2\cdot$ to give quinone.





Relative yields of products originating from $Ph_2C(Me)\dot{O}$ which escape the solvent cage, reaction [10*b*], to yields of 1,1-diphenylethyl peroxide formed in reaction [10*a*] are 2–4 which gives a rate constant ratio, $k_{10b}/k_{10a}$ of 1–2. From this ratio we can calculate that $Ph_2C(Me)\dot{O}$ are produced with an efficiency of 50–67% by decomposition of di-1,1-diphenylethyl tetroxide which is slightly less than the efficiency of 83–94% obtained for production of α-cumyloxyl by decomposition of di-α-cumyl tetroxide (1).

Yields of 1,1-diphenylethanol, acetophenone, phenyl benzoate, and benzophenone indicate that 1,1-diphenylethoxyl undergoes H-atom abstraction, β-scission, and rearrangement to give 1-phenyl-1-phenoxylethoxyl (reaction [13]) and that this latter radical undergoes H-atom abstraction and β-scission. The relative importance of these reactions can, however, not be assessed because the concentration of $Ph_2C(Me)OOH$, a reactive H-atom donating product, increases during autoxidation.

A further conclusion that can be drawn from the data in Table 1 is that relative yields of 1,1-diphenylethyl hydroperoxide to 1,1-diphenylethyl peroxide do not depend to any appreciable extent on the pressure of oxygen above the liquid in the range 0.4–10.3 atm. This implies that β-scission of $Ph_2C(Me)O_2\cdot$, reaction [3], is not sufficiently important to influence the chain length because if it did the ratio of hydroperoxide to peroxide would be reduced by a decrease in the oxygen pressure.

2,2-Diphenyloxirane is formed in trace amounts, probably by alkoxyl radical attack on the methyl group of 1,1-diphenylethyl hydroperoxide (see later) produced by extensive autoxidation.

*Induced decomposition of 1,1-diphenylethyl hydroperoxide under an atmosphere of* $^{36}O_2$

The yields of the major reaction products formed by induced decomposition of $Ph_2C(Me)OOH$ with thermally generated *tert*-butoxyls, reaction [23], in $CH_3CN$ and $C_6H_5Cl$ are given in Table 3.

[23] $t\text{-BuO}\cdot + Ph_2C(Me)OOH \rightarrow t\text{-BuOH} + Ph_2C(Me)O_2\cdot$

We were not able to estimate final concentrations of $Ph_2C(Me)OOH$ because PhC(Me)(OPh)OOH, a possible reaction product, could not be distinguished from $Ph_2C(Me)OOH$ by hplc analysis. It would, however, appear, from the high yields of $Ph_2C(Me)OH$ produced after reduction with $Ph_3P$, that a substantial concentration of $Ph_2C(Me)OOH$ was not decomposed by the same concentration of *tert*-butyl hyponitrite as was required to completely decompose $PhC(Me)_2OOH$. This suggests that the chain length for the induced decomposition of $Ph_2CMeOOH$ is less than that for $PhCMe_2OOH$. A reduction in the *overall* chain length could result from reaction of $Ph_2C(Me)O_2\cdot$ with phenol produced in the decomposition. That is, reaction

[a]Alcohol produced in the reaction and by reduction of excess $Ph_2C(Me)OOH$.
[b]It should be noted that the relative yields of this product are much more accurate than the absolute yields.
[c]Relative yields.

[21] competes with reaction [10$a$] as the major chain termination process.

The reaction products are consistent with the elementary reactions [5] to [20] except for 2,2-diphenyloxirane which is probably produced by alkoxyl attack at the methyl group of the hydroperoxide followed by an intramolecular $S_H2$ reaction by the carbon centred radical on the peroxide function.

[24] $RO\cdot + (C_6H_5)_2C(CH_3)COOH \rightarrow ROH + (C_6H_5)_2C(\dot{C}H_2)COOH$

[25] $(C_6H_5)_2C(\dot{C}H_2)COOH \rightarrow (C_6H_5)_2C(O)CH_2 + HO\cdot$

Analogous reactions probably account for the trace of 2-methyl-2-phenyloxirane produced by $t$-BuO· induced decomposition of $PhCMe_2OOH$ (1).

The relative yields of 1,1-diphenylethyl peroxide and *all* the products derived from $Ph_2C(Me)O\cdot$ which escape the solvent cage give $k_{10b}/k_{10a} \sim 8$–9, implying that $Ph_2C(Me)O\cdot$ are produced with a efficiency of ~ 90% by decomposition of 1,1-diphenylethyl tetroxide, a slightly larger value than that calculated from product yields of $Ph_2C(Me)H$ autoxidation.

When this reaction was conducted under an atmosphere of $^{36}O_2$ the gaseous oxygen at the end of the experiment contained 10% $^{32}O_2$, and $^{18}O$ enriched 1,1-diphenylethanol, acetophenone, phenol, and 2,2-diphenyloxirane were formed in the yields given in Table 4. A comparison of the yields of these compounds with the yields of the unenriched products reveals that $Ph_2C(Me)OH$, PhOH, and  were enriched to the extent of 88% whereas PhC(O)Me was only enriched to 75%. When these results are compared with the yields of $^{18}O$ enriched $PhCMe_2OH$ (1.25%) and PhC(O)Me (7–6%) produced from self-reaction of $PhCMe_2O_2\cdot$ under an atmosphere of $^{36}O_2$ (1) it is clear that $Ph_2C(Me)O_2\cdot$ undergoes β-scission faster than $PhCMe_2O_2\cdot$, a result which is consistent with the relative stabilization energies of $Ph_2\dot{C}Me$ and $Ph\dot{C}Me_2$ (3).

We have previously shown that the rate constant for β scission of a peroxyl ($k_\beta$) in the presence of its hydroperoxide, under an atmosphere of $^{36}O_2$, can very approximately be estimated from the expression

$$k_\beta = \frac{k_{dis}[R^{18}O^{18}O\cdot]\,[ROOH]}{[RO_2\cdot]}$$

In the present case R = $Ph_2CMe$, $k_\beta = k_3$ and $k_{dis}$, the rate constant for reaction of $Ph_2C(Me)O_2\cdot$ with $Ph_2C(Me)OOH$, can be assumed to be 570 $M^{-1}$ s$^{-1}$ at 303 K (7).

The average ratio of $^{18}O$ enriched product to normal product (excluding acetophenone) is 7.1, ignoring the small amount of $^{32}O_2$ evolved in the reaction. This ratio, in conjunction with an average hydroperoxide concentration of 0.425 $M$, gives $k_3 \sim 1700$ s$^{-1}$ which is ca. 3 orders of magnitude larger than the value of the rate constant for β-scission of $PhCMe_2O_2\cdot$. Again if we assume that $k_{-3} = 10^{9.5}$ $M^{-1}$ s$^{-1}$, the equilibrium constant for reaction [3] can be estimated to be $\sim 10^{6.3}$ $M^{-1}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

The steady-state concentration of $Ph_2\dot{C}Me$ at 1 atm of $O_2$ ($10^{-2}$ *M*) is, therefore, ca. $10^{-4.3}$[$Ph_2C(Me)O_2\cdot$] and if $k_4$ is $10^8$ $M^{-1}$ $s^{-1}$ (1) the rate of reaction [4] can be calculated to be $\sim 10^{3.7}$ $M^{-1}$ $s^{-1}$ which is negligible compared to the values of $2k_t = 1.35 \times 10^5$ $M^{-1}$ $s^{-1}$ and $2k_t' = 6.4 \times 10^4$ $M^{-1}$ $s^{-1}$ for $Ph_2C(Me)O_2\cdot$ at 303 K (2). However, as Nangia and Benson (3) have suggested, the rate of reaction [4] at 0.1 atm of $O_2$ is comparable to the rate of self-reaction of $Ph_2C(Me)O_2$.

The insignificance of reaction [4] at 303 K was confirmed by the observation that rates of autoxidation of cumene containing $Ph_2C(Me)OOH$ (0.38 *M*), i.e., under conditions where $Ph_2C(Me)O_2\cdot$ was the principal rate controlling chain carrying peroxyl, were independent of the oxygen pressure from 50 to 740 Torr.

*Products of 2,2,3,3-tetraphenylbutane decomposition in the presence of oxygen*

In order to investigate more fully the products of the self-reaction of $Ph_2C(Me)O_2\cdot$, $Ph_2\dot{C}Me$ was generated under an atmosphere of $O_2$ in $CH_3CN$ at 303 K by thermolysis of 2,2,3,3-tetraphenylbutane (TPB). Decomposition of TPB is a first-order process with a rate constant of $2.1 \times 10^{-6}$ $s^{-1}$ at 303 K and radicals are produced with an efficiency of 100%. An 18 m*M* solution absorbed oxygen with a rate of $9.5 \times 10^{-8}$ $M$ $s^{-1}$ which was close to the rate of production of $Ph_2\dot{C}Me$. Aliquots were taken periodically from the reaction and subjected to analysis by high performance liquid chromatography. The major reaction products and their yields after 23, 52.5, 73, and 95 h of reaction are given in Table 5 and are consistent with the elementary reactions [5]–[20] for the self-reaction of $Ph_2C(Me)O_2\cdot$ plus reaction of $Ph_2C(Me)O_2\cdot$ with a H-atom donor such as $CH_3CN$ or a reaction product such as phenol to give 1,1-diphenylethyl hydroperoxide. Di(1,1-diphenylethyl) peroxide was not observed because it had the same retention time as TPB under our analytical conditions.

TABLE 5. Products from thermal decomposition of 2,2,3,3-tetraphenylbutane in the presence of oxygen in $CH_3CN$ at 303 K

| Reaction time (h) | 23 | 52.5 | 75 | 95 |

[a]The yields in parentheses are for a decomposition that was only analysed after 95 h.

The low yield of benzophenone indicates that $Ph_2C(Me)O\cdot$ undergoes β-scission reaction [12], as well as H-atom abstraction [11] and rearrangement [13], but the rate of β-scission is relatively slow. Thus, the relative yields of 1,1-diphenylethanol and benzophenone give $k_{11}[RH]/k_{12} = 4.4$ and if $CH_3CN$ is the sole H-atom donor, RH = 19.14 *M* and $k_{11}/k_{12} = 0.23$. Unfortunately the absolute value of $k_{12}$ cannot be calculated because absolute rate constants for reaction of alkoxyls with $CH_3CN$ are not known. We did, however, find that cumyloxyl, produced by thermolysis of di-α-cumyl hyponitrite in $CH_3CN$, gave a ratio of α-cumyl alcohol to acetophenone = 0.2. This indicates, somewhat surprisingly, that $PhCMe_2O\cdot$ undergoes β-scission ~20 times faster than $Ph_2CMeO\cdot$.

As expected from reaction [19], the yield of phenol plus *p*-benzoquinone was approximately equal to the yield of acetophenone. The benzoquinone yield was, however, about ten times larger than the phenol yield, indicating substantial oxidation of phenol by peroxyls.

The relative yields of acetophenone and phenyl benzoate suggest that $k_{18}[RH]/k_{20} = 0.68$ and, if $CH_3CN$ is the H-atom donor, $k_{18}/k_{20} = 0.0355$. Thus $PhCMe(OPh)O\cdot$ undergoes β-scission ~ 6.5 times more readily than $Ph_2C(Me)O\cdot$.

## Conclusions

We can conclude from this study of the self-reactions of 1,1-diphenylethylperoxyl in solution that the reaction products are consistent with a complex series of free-radical reactions which involve the intermediacy of 1,1-diphenylethoxyl and 1-phenyl-1-phenoxylethoxyl. The former radical undergoes H-atom abstraction, β-scission, and rearrangement while the latter radical undergoes β-scission and H-atom abstraction.

The relative product yields agree with the products obtained from thermolysis of 2,2,6,6-tetramethyl-4-oxo-1-(1,1-diphenylethoxy) piperidine (8) and are more reliable than our earlier product studies of 2,2,3,3-tetraphenylbutane oxidation (9) and induced decomposition of 1,1-diphenylethyl hydroperoxide (10). This reflects the superiority of hplc over glc for the analysis of autoxidation products.

$Ph_2C(Me)O_2\cdot$ undergoes β-scission in solution at 303 K with a rate constant of ~1700 $s^{-1}$, compared with a value of ~2 $s^{-1}$ for $PhCMe_2O_2\cdot$, suggesting that there is ~4 kcal $mol^{-1}$ difference in the stabilization energies of $Ph_2\dot{C}Me$ and $Ph\dot{C}Me_2$. The

steady-state concentration of $Ph_2\dot{C}Me$ during autoxidation of $Ph_2CMeH$ is, however, not large enough to influence the overall termination rate constant at ambient temperatures.

$Ph_2C(Me)O\cdot$, produced by decomposition of 1,1-diphenylethyl tetroxide, escape the solvent cage with an efficiency > 50%, indicating that the nature of the alkyl moiety (R = *t*-Bu, $PhCMe_2$, $Ph_2CMe$) has very little influence on this efficiency. We can, therefore, conclude that differences in termination rate constants for *t*-$BuO_2\cdot$, $PhCMeO_2\cdot$, and $Ph_2CMeO_2\cdot$ are principally due to differences in the stability of the appropriate tetroxides towards irreversible homolysis. It should, however, be noted that phenol is a product of the autoxidation of 1,1-diphenylethane, and its rapid chain terminating reaction with chain carrying peroxyls could influence the *overall* termination rate constant after autoxidation has been in progress.

# Correlation of alkane solubilities in water with connectivity index

JOHN T. EDWARD

*Department of Chemistry, McGill University, 801 Sherbrooke St. West, Montreal, P.Q., Canada H3A 2K6*

Received February 10, 1982

JOHN T. EDWARD. Can. J. Chem. **60**, 2573 (1982).

The solubility of alkanes in water has been shown previously to be correlated both with the surface area of the molecular cavity containing the molecule in water, and the first-order connectivity index $^1\chi$ of the alkane; it is now shown that both the surface area and $^1\chi$ are dependent on the number of methyl, methylene, methine, and quaternary carbon groups in the alkane, modified by the degree of folding of the chain (as measured by $Z_g$).

JOHN T. EDWARD. Can. J. Chem. **60**, 2573 (1982).

On a montré antérieurement qu'on pouvait relier la solubilité des alcanes dans l'eau à la fois à la surface de la cavité moléculaire contenant la molécule dans l'eau et à l'indice de conductivité d'ordre un $^1\chi$ de l'alcane. Nous montrons maintenant que $^1\chi$ dépendent du nombre de méthyle, de méthylène, de méthine et des groupes de carbone quaternaire de l'alcane, modifiés par le degré d'enroulement de la chaîne (tel que mesuré par $Z_g$).

[Traduit par le journal]

Hansch (1) showed that the biological activities of a series of related compounds were sometimes partially, and sometimes totally, a function of the partition coefficients $P$ of the compounds between water and *n*-octanol. (Since to a good approximation $\log P$ is a linear function of $\log S$, where $S$ is the solubility of the compounds in water (2), this is equivalent to saying that in such cases the biological activity is partially or totally a function of $S$.) Hansch (1) produced a plausible model to explain such behaviour: the rate or the extent to which a compound passes through various lipoidal barriers to arrive at the target site in the organism varies with $P$. In some cases the biological activity also depends on the reactivity of the compound at the target site, and hence on a two-parameter equation involving Hammett or Taft's substituent constant $\sigma$ as well as $P$.

In an alternative approach Kier, Hall, and their colleagues (3–5) related biological activities (and many physical properties) of organic compounds to one or more connectivity indices $^m\chi_t$ (of order $m$ and type $t$). Connectivity indices depend on the topology of the molecule, and are briefly explained below; their physical significance has been unclear. For many activities and properties even the first-order connectivity index $^1\chi$ sufficed for a reasonable correlation.

The success of two radically different approaches suggests some underlying connection between them. In the present paper it is shown that for the particular case of alkanes, both the solubility $S$ in water and $^1\chi$ depend on the number of methyl, methylene, methine, and quaternary carbon atoms, modified slightly by the degree of chain folding as measured by the "*gauche* number" $Z_g$ (6, 7). (A similar argument was developed, but less completely, on the relation between $^m\chi_t$ and molecular volumes and heats of vaporization of alkanes (8); it seemed worthwhile to carry out the same exercise for $S$ (and by inference $P$) because of the central importance of $P$ in explanations of biological activity.)

## Relation of solubilities of alkanes to molecular cavity surface areas

The solubilities of alkanes in water decrease as the molecules become larger, because of the greater energy required to form a cavity for the molecule in the cohesive solvent (9–15), but there has been disagreement in the past as to whether this energy is proportional to the volume or the surface area of the cavity.[1] It is now generally agreed (11–14, 16) that the energy (and thence $\ln 1/S$) are correlated better with the surface area of the cavity,[2] but there has been less agreement on the

[1]The various ways in which the surface area and volume of a molecule may be defined have been discussed by Pearlman (16) in a penetrating and valuable review. For a homologous series of compounds the volume and surface area are linearly related.

[2]Counter to this consensus, Hansch and his colleagues (10) have recently claimed to find a better correlation between $\log P$ (and by inference $\log (1/S)$ (2)) and the molecular volume of hydrocarbons and apolar molecules. They obtained molecular volumes from the volume of water displaced by Corey–Pauling–Koltun (CPK) models of the molecules wrapped in flexible polyethylene. CPK models (17), like most space-filling models (18), seriously underestimate the van der Waals radius of hydrogen in order to allow models of slightly congested molecules to be made. This results in unrealistic volumes for most organic molecules, since hydrogen accounts for such a large proportion of their volume (73% in the case of propane: see Fig. 1).

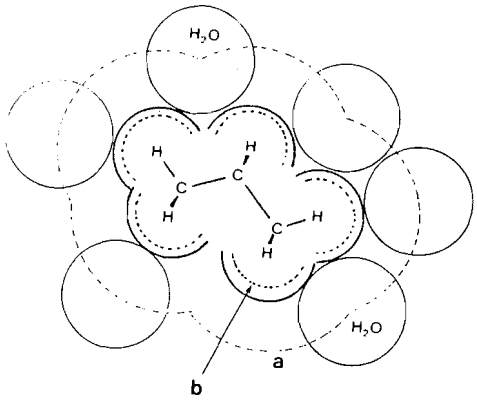

FIG. 1. Scale drawing of propane surrounded by water molecules, represented as spheres of radius 1.5 Å. Cavity surface according to (*a*) Hermann (ref. 12); (*b*) Leo, Hansch, and Jow (ref. 10).

best measurement of the cavity area.[3] It would now seem that the most plausible and successful model is that of Hermann (12). He defines the cavity surface area $A$ of a molecule in water as the area of the surface traced out by the centre of a water molecule (radius $r_w$ assumed to be 1.5 Å) rolling over the van der Waals surface (19) of the molecule. This is illustrated in Fig. 1 for propane. The solubilities of straight- and branched-chain and of cyclic alkanes are then found to correlate well with $A$ according to

$$[1] \quad kT \ln S = -b_0 A - C_0$$

where $b_0$ and $C_0$ are constants at a given temperature. This equation accounts for the fact that a branched-chain alkane, which has a lower $A$ but the same van der Waals volume and van der Waals surface area as its straight-chain isomer, has a greater solubility.

The cavity surface areas $A$ for 23 alkanes in their most extended conformation, calculated according to Hermann by a computer program with input information of bond lengths, bond angles, van der Waals radii of the atoms, and $r_w = 1.5$ Å for water, are given in Table 1.

Approximately the same values of $A$ are obtained by the equation

$$[2] \quad A = A_0 + \sum n_i A_i + \sum n_k S_k$$

where $A_0$ (= 115 Å$^2$) is a constant for all molecules (analogous to the constant covolume required in additive schemes for molecular volumes (7, 8)), $A_i$ is the surface increment from group $i$ (methyl, methylene, methine, or quaternary carbon), $n_i$ is the number of such groups, $S_k$ is the effect on the surface area of structural feature $k$, and $n_k$ is the number (integral or fractional) of such features. The values of the $A$ and $S$ parameters are given in Table 2, and were obtained by least-squares fitting of Hermann's values of $A$ to [2]. The data are sufficient to determine a unique value for $A_s$, but not for other values of $A_i$; $A_0 = 115$ Å$^2$ was chosen to keep $A_p$, $A_t$, and $A_q$ all positive.

The values of $A$ calculated by [2] and given in Table 1 take account of the fact that branched-alkanes, even in their most extended conformation, necessarily include one or more *gauche* arrangements. Thus the calculated value of $A$ for 2-methylbutane (2-MeC$_4$) is for conformation **1***a* (or equally its enantiomer **1***b*) having one *gauche* arrangement

**1***a* **1***b* **1***c*

($z_g = 1$: see ref. 7). In fact, in solution at 25°C these conformations are in equilibrium with a smaller amount of the conformation **1***c* ($z_g = 2$), so that the weighted-average *gauche* number $Z_g$ ($\equiv \sum x_i z_{g(i)}$, where $x_i$ is the mole fraction of conformation $i$ and $z_{g(i)}$ the number of *gauche* arrangements in it) of 2-methylbutane is 1.13 (19). This value of $Z_g$ (= $n_g$ in the symbolism of [2]) must be used in [2] to give the surface area of the cavity containing the average, as opposed to the maximally-extended molecule; the former surface area must then be used in [1].

The coiling of a molecule, as indicated by its $Z_g$, and even more cyclization of the molecule, reduce the area in contact with solvent water molecules. This is shown by the negative $S$ parameters in Table 2. Similar negative parameters (with magnitudes in the same relative order) are required in additive schemes of molecular volumes (21). The plot of log $S$ against $A$, as calculated by [2], is given in Fig. 2*B*, and shows how well the experimental data support [1]. (This is essentially the same as Fig. 2 in ref. 11, except that in this paper $A$ values were computed *ab initio* and not derived from [2].)

### Relation of solubilities of alkanes to first-order connectivity index $^1\chi$

Kier, Hall, and Murray (22) related the solubilities of alkanes to the changing topology of the molecules. The molecule is regarded as a graph, the atoms forming the vertices and the bonds the edges of the graph. Hydrogen atoms are suppressed, so that the five alkanes, ethane, propane, *n*-butane,

[3]Hansch *et al.* (9) equate the cavity surface area to the molecular surface area as calculated according to Bondi (19). Such a calculation yields identical cavity areas for straight- and branched-chain alkanes, and for this and other reasons is inadequate.

isobutane, and neopentane, are represented as shown in Scheme 1. Such graphs may be decomposed into subgraphs of differing orders $m$: zero order, consisting of single vertices; first-order, consisting of an edge joining two vertices; second-order, consisting of two edges linking three vertices; and so on.

The simple connectivity value $\delta_i$ of a vertex $i$ is the number of other vertices to which it is joined. Values of $\delta_i$ for the vertices of the five alkanes of Scheme 1 are shown in the scheme above the graphs. Kier and Hall (3) (following earlier work of Randic (23)) have defined connectivity indices $^m\chi$ based on the $\delta_i$ values of all the $n$ subgraphs of order $m$ into which a graph can be decomposed. The first-order connectivity index $^1\chi$ is defined by

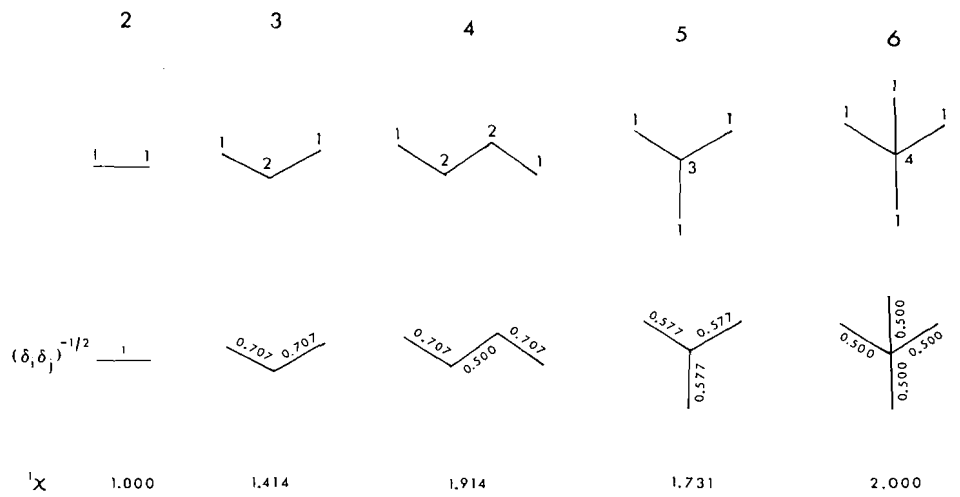
$$[3] \qquad {}^1\chi = \sum_{s=1}^{n} (\delta_i \delta_j)_s^{-1/2}$$

where $s$ identifies a first-order subgraph (an edge), $\delta_i$ and $\delta_j$ are the connectivity values at each end of an edge, and $n$ is the number of edges in the graph. In Scheme 1 the $(\delta_i \delta_j)_s^{-1/2}$ values are shown beside each edge for the five alkanes, and below are shown the $^1\chi$ values obtained by their summation.

Kier, Hall, and Murray (22) found that the solubilities of 18 alkanes in water follow fairly well the relation

$$[4] \qquad \ln S = -1.505 - 2.533\,{}^1\chi$$

(correlation coefficient $r = 0.958$; standard deviation $s = 0.511$). Considering the ease of calculating $^1\chi$ for any known structure, the success of [4], and of a large number of other equations relating physical properties to one or more $^m\chi_t$ values (3), must be considered quite striking. However, the agreement of the experimental data with [4] is distinctly inferior to its agreement with [1], as shown by a comparison of Fig. 2*A* with Fig. 2*B*. Furthermore, [1] is derived from thermodynamic theory, while [4] is an empirical relationship. Kier (5) says: "It is a tough challenge, looking for physical



SCHEME 1. Graphs of the alkanes ethane **2**, propane **3**, *n*-butane **4**, *iso*butane **5**, and neopentane **6**. Valencies $\delta_i$ of each vertex shown. meaning . . . [in] the connectivity indexes''. It was suggested earlier (8) that in an alkane $^1\chi$ is determined by the number and type of carbon atoms (methyl, methylene, methine, and quaternary carbon), modified by chain coiling; i.e. by precisely the factors determining the area of the cavity surface according to [2]. We now examine this suggestion in more detail.

## Relation of $^1\chi$ to numbers and types of carbon atoms and to structural features in alkane molecules

We first look at the sixteen non-cyclic alkanes of Table 1. These are made up of straight-chain compounds, alkanes having a methyl branch at position 2 or 3, alkanes having a *gem*-dimethyl group at position 2, and some mixed types.

Consider first propane and the higher *n*-alkanes. From an examination of **4** → **7** in Scheme 2, it is apparent that each additional $CH_2$ (secondary or *s*) increases $^1\chi$ of an *n*-alkane by 0.500. Subtracting 0.500 from $^1\chi$ (1.414) of propane leaves 0.914 for the two $CH_3$ (primary or *p*) groups, or 0.457 for each $CH_3$. Consequently, for propane and higher *n*-alkanes (and for cyclic alkanes, but not for ethane):

$$[5] \quad {}^1\chi = 0.457n_p + 0.500n_s$$

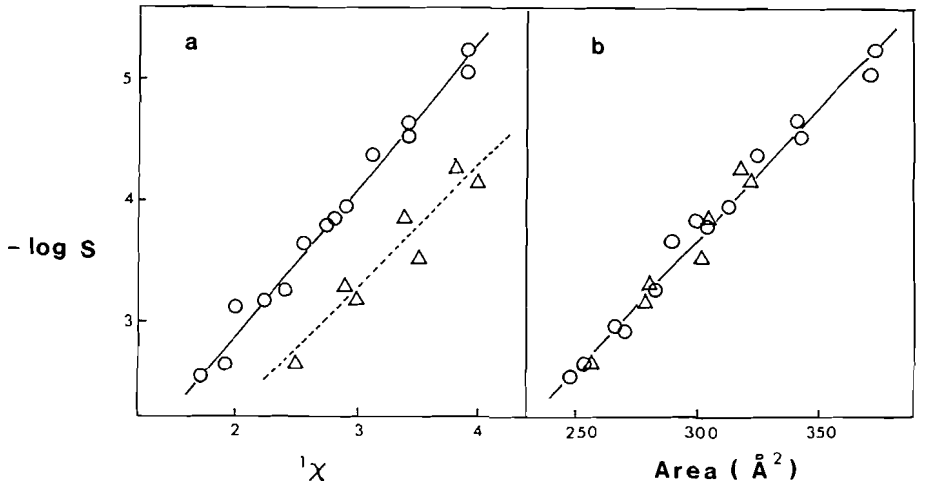

FIG. 2. Relation of molal solubility *S* to (*a*) connectivity index $^1\chi$, and (*b*) cavity surface area according to [2]. Symbols: ○, acyclic; △, cyclic alkanes.

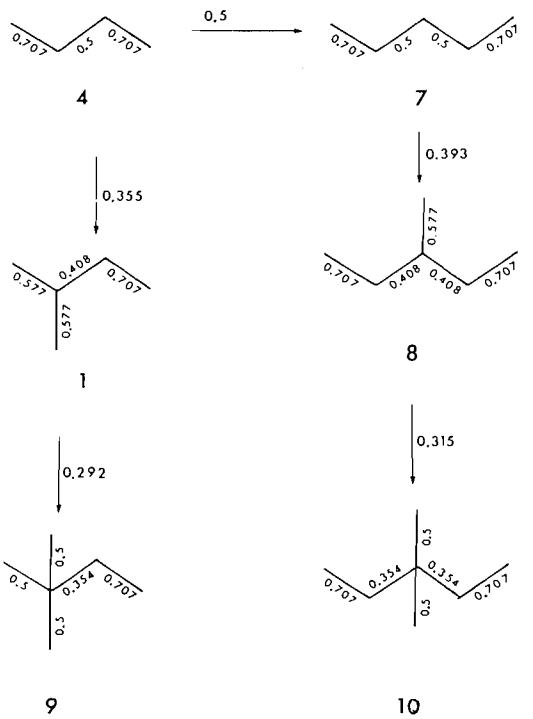

SCHEME 2. Increases in $^1\chi$ shown beside arrows, as carbon atoms are successively added to *n*-butane. Values of $(\delta_i\delta_j)^{-1/2}$ for each edge shown on graphs; $^1\chi$ values obtained by summation of $(\delta_i\delta_j)^{-1/2}$ terms.

(an equation advanced without proof previously (8)).

Looking now at **4** → **1** in Scheme 2, we see that adding a methyl group (*p*) at position 2 (and necessarily converting one $CH_2$ group (*s*) to CH (tertiary or *t*)) leads to an additional $(\delta_i\delta_j)^{-1/2}$ contribution to $^1\chi$ of 0.577 from the new bond, partially offset by diminutions in $(\delta_i\delta_j)^{-1/2}$ contributions from bonds 1,2 and 2,3, so that the overall change $\Delta^1\chi$ on going from **4** → **1** is 0.355. In terms of group contributions, the change may be represented by $p + t - s = 0.355$. Retaining $p = 0.457$ and $s = 0.500$, we obtain $t = 0.398$, so that for 2-methylbutane and higher homologues having a 2-methyl group

[6] $$^1\chi = 0.457n_p + 0.500n_s + 0.398n_t$$

Addition of a methyl group to the 3-position of **7** to give **8** results in $\Delta^1\chi = 0.393$, whence it may be shown, by arguments similar to those above, that for **8** and higher homologues having a methyl branch on a carbon atom at least two bonds away from the end of the chain (and for cyclic alkanes with a methyl branch)

[7] $$^1\chi = 0.457n_p + 0.500n_s + 0.436n_t$$

For 2,2-dimethylbutane (**9**) and higher homologues having a geminal 2,2-dimethyl group, similar arguments lead to

[8] $$^1\chi = 0.457n_p + 0.500n_s + 0.233n_q$$

and for 3,3-dimethylpentane (**10**) and higher homologues and for *gem*-dimethyl cyclic compounds to:

[9] $$^1\chi = 0.457n_p + 0.500n_s + 0.294n_q$$

These equations manifestly lack generality; other equations would be required for more highly branched compounds. However, they serve to demonstrate, for the limited number of classes of compounds considered above, that $^1\chi$ is determined by the number, suitably weighted, of $CH_3$, $CH_2$, and CH groups and of quaternary carbon atoms in an alkane, modified by connectivity differences (differences in site of branching).[4] Furthermore, the weighting of $CH_2$, CH, and quaternary carbon atoms (but not of $CH_3$) in [5]–[9], is in the same order as the weighting of the $A_i$ values of these groups in Table 2. Nevertheless, the diversity of structural types of alkanes in Table 1 is greater than that covered in [5]–[9], so that it is perhaps surprising that $(A_0 + \sum n_iA_i)$ for the 23 alkanes of Table 1 is roughly proportional to $^1\chi$. This is shown in Fig. 3*A*. Straight- and branched-chain alkanes lie close to one straight line, and cyclic alkanes close to another.

The structural features term $\sum n_kS_k$ of [2] (for the time-averaged molecule, not the artificially extended one whose $\sum n_kS_k$ values are given in Table 1) is also related to $^1\chi$. This is shown in Fig. 3*B*. *n*-Alkanes lie accurately on one straight line, cyclic compounds cluster about another one, the diverse branched compounds are scattered but show a general trend to increasing $\sum n_kS_k$ with increasing $^1\chi$. Overall, a fair correlation is found between $^1\chi$ and *A* (as calculated from [2]) as shown in Fig. 3*C*. It can be seen that non-cyclic alkanes lie about one straight line, cyclic alkanes about another.[5] Consequently, to the extent that $\log S$ is determined by *A*, as required by [1], we can expect $-\log S$ plotted against $^1\chi$ to lie on one of two straight lines: one for acyclic, one for cyclic alkanes. This we have already observed in Fig. 2*A*.

[4]It is possible that higher order $^m\chi$ functions are also determined by the number and weightings of various types of carbon atoms, but this remains to be demonstrated.

[5]Randic (23) has already pointed out a linear relationship between Hermann's cavity surface area and a "branching index" (which later became $^1\chi$), without discussing its molecular basis, and without pointing out the divergent behaviour of cyclic and acyclic alkanes.

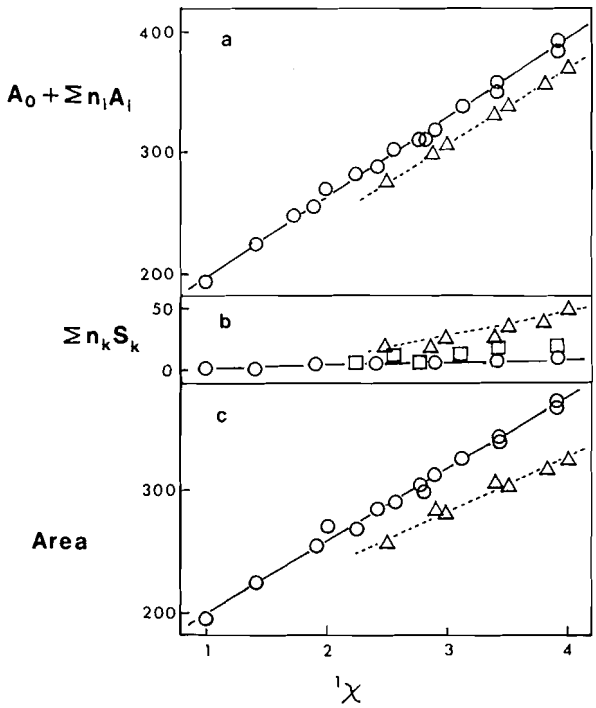

FIG. 3. Relation of cavity surface area terms of [2], and of total area (all in Å²), to first-order connectivity index $^1\chi$. In *a*, *b*, and *c*: △, cyclic alkanes. In *a* and *c*: ○, acyclic alkanes. In *b*: ○ *n*-alkanes; □, branched acyclic alkanes.

In summary, we can say that the solubility in water of alkanes (straight, branched, and cyclic) is related roughly to the first-order connectivity index $^1\chi$ because both are determined by the number and types of carbon atoms and the extent of chain coiling or cyclization. Heats of vaporization (which may be considered rough measures of molecular cohesiveness) and molecular volumes (measures of molecular bulk) are related to $^1\chi$ (and higher order $^m\chi_t$ values) for the same reasons (8). These are properties of central importance. Cramer (24) has shown by factor analysis that a large number of the properties of liquid compounds (activity coefficient, molar refractivity, boiling point, molar volume, magnetic susceptibility, dielectric constant, surface tension, viscosity, etc.) are linear functions of two orthogonal parameters (*B* and *C*) which he identifies with the "bulk" and "cohesiveness" of the individual molecules. To the extent that the latter parameters are linearly related to $^1\chi$ (or to mixtures of $^1\chi$ and other $^m\chi_t$ values), the various properties enumerated above should also be related to $^1\chi$. This may serve to adumbrate possible molecular explanations for the very large number of correlations discovered by Kier, Hall, and their collaborators (3), although this cannot be more than an article of faith until the molecular basis of the higher order connectivity indices is known.[6]

[6]In this article attention has been deliberately restricted to alkanes, because their conformational behaviour is uncomplicated. These compounds can be described solely by $^m\chi_t$ functions derived from simple numerical adjacency values δ of the carbon atoms. For compounds containing heteroatoms Kier and Hall (3) have developed valence molecular connectivity indices $^m\chi^v$, derived in similar fashion from valence delta $\delta^v$ values, which are based on the count of valence electrons participating in σ, π, and lone-pair orbitals in the atom, exclusive of bonds to hydrogen. Better correlations are often obtained using $^m\chi^v$ rather than $^m\chi$. At present a molecular explanation of these correlations seems remote.

# The direct electrochemical synthesis of neutral and anionic complexes of thorium(IV)

N. KUMAR AND DENNIS G. TUCK[1]

*Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4*

Received April 23, 1982

N. KUMAR and DENNIS G. TUCK. Can. J. Chem. **60**, 2579 (1982).

The electrochemical oxidation of thorium into solutions of halogen ($X_2$; X = Cl, Br) in acetonitrile yields the adducts $ThX_4.4CH_3CN$ in good yield. With solutions of $X_2 + R_4NX$, the products are $(R_4N)_2ThX_6$. Neutral chelate complexes such as $Th(acac)_4$ (acac = 2,4-pentanedionate) can also be prepared in a one-step synthesis from the metal, but cationic complexes could not be obtained by electrochemical methods.

N. KUMAR et DENNIS G. TUCK. Can. J. Chem. **60**, 2579 (1982).

L'oxydation électrochimique du thorium dans des solutions d'acétonitrile contenant des halogènes ($X_2$; X = Cl, Br) conduit à des adduits du type $ThX_4.4CH_3CN$ avec un bon rendement. Avec des solutions de $X_2 + R_4NX$, on obtient des produits du type $(R_4N)_2ThX_6$. On peut également préparer des chélates complexes neutres, tel $Th(acac)_4$ (acac = pentane dionate-2,4), en une seule étape à partir du métal, mais on n'a pas pu obtenir les complexes cationiques par des méthodes électrochimiques.

[Traduit par le journal]

## Introduction

The coordination chemistry of thorium, like that of other actinide elements, still reveals some surprising lacunae, despite the actual or potential industrial importance of these elements. The general chemistry of thorium is described in various reviews and standard texts (1–4), but few papers have appeared on the coordination chemistry in recent years, and these for the most part concerned with neutral or anionic derivatives of thorium tetrachloride or tetrabromide.

We now report work on the direct electrochemical oxidation of thorium metal into solutions of chlorine or bromine in acetonitrile. These experiments represent a natural extension of previous direct electrochemical syntheses of the neutral halides of various main group and transition metals (5–10). Solution phases of $X_2 + R_4NX$ yield salts of $ThX_6^{2-}$ anions (X = Cl, Br). We have also successfully snythesised $Th(acac)_4$ and similar compounds, again following earlier work (10), but attempts to prepare cationic complexes (11) were unsuccessful.

## Experimental

*Materials*

Thorium (Alfa Inorganics) was supplied as a rod and sliced into discs ca. 8 mm diameter and 1 mm thick. Acetonitrile (BDH Ltd.) was dried over phosphorus pentoxide and distilled under nitrogen before use. Neutral ligands and tetraalkylammonium halides were dried for 3–4 h at 105°C before use. Other reagents were used as supplied.

*Analysis and spectroscopy*

Thorium was determined by dissolving the complex and titrating the resultant solution at pH 2.1 against EDTA, using Alizarin S as indicator (12). Halogen analysis was by the Volhard technique. Microanalysis on selected compounds was carried out by Guelph Chemical Laboratories Ltd.

Infrared spectra were recorded on a Perkin-Elmer IR-18 instrument, and were used both to identify metal–halogen vibrations and to confirm the presence of neutral ligands or tetraalkylammonium cations.

*Electrochemical methods*

The electrochemical syntheses followed methods described in earlier publications (6–9). The solution phase, typically 50 mL in volume, was contained in a 100 mL tall-form beaker; the cathode was a platinum foil (1 × 1 cm) while a disc of thorium suspended on a platinum wire formed the anode. All preparations were carried out under an atmosphere of dry nitrogen. Details of the experimental conditions are given in Tables 1 and 2 and in the paragraphs below.

*Preparation of $ThX_4.4CH_3CN$ (X = Cl, Br)*

The final product of the electrochemical oxidation of thorium into bromine (2–4 g) in 50 mL acetonitrile was a solution of $ThBr_4$. Addition of diethyl ether led to the precipitation of $ThBr_4.4CH_3CN$ which was collected, washed with ether, and dried *in vacuo* at room temperature. The corresponding $ThCl_4.4CH_3CN$ was obtained with an electrolyte phase of acetonitrile containing dissolved chlorine, which was bubbled through the solution with nitrogen gas as a diluent (8). This adduct is insoluble in the reaction mixture and is simply collected, washed, and dried at the end of the experiment.

The compounds were identified by thorium and halogen analysis (Table 3), and by infrared spectroscopy. The $\nu(C\equiv N)$ mode of the ligand is found at 2280 $cm^{-1}$ in both species (c.f. 2273, 2278 $cm^{-1}$ reported by Bagnall *et al.* (13)); $\nu(M—Cl)$ is at 248 $cm^{-1}$, and $\nu(Th—Br)$ at 180 $cm^{-1}$ (c.f. 256 and 188 $cm^{-1}$, ref. 13).

The uncomplexed halides can be easily obtained by heating the acetonitrile adducts *in vacuo*, following the procedures of Bagnall *et al.* (13).

*Neutral adducts of $ThCl_4$ and $ThBr_4$*

Acetonitrile can be displaced from the tetrahalide complex by other ligands, so that the electrochemical synthesis also provides a route to other neutral adducts. In both systems, excess halogen remaining after the electrolysis was first removed by bubbling dry nitrogen through the solution for approximately 30 min.

In the case of $ThCl_4.4CH_3CN$, the suspension in acetonitrile

[g]Found: C 38.2, H 4.4; calcd: C 38.2, H 4.5.

was stirred with the appropriate ligand in excess for 1 h at room temperature. For $ThBr_4.4CH_3CN$, the solution in acetonitrile obtained from the electrolysis was used, after removing excess halogen. The products were then collected, washed, and dried in the usual way.

*Preparation of $ThX_6^{2-}$ salts (X = Cl, Br)*

In keeping with previous work (14), the electrochemical oxidation of thorium into acetonitrile solutions containing $R_4NX$ and $X_2$ (see Table 1) proceeded smoothly. At the end of the electrolysis, excess halogen was removed as described above, and the solution cooled to 0°C. In the case of X = Cl, R = Et, this caused precipitation of the salt $(Et_4N)_2ThCl_6$ which was collected, washed with diethyl ether, and dried *in vacuo*. For X = Br, R = Me, it was necessary to reduce the volume of the solution phase by ca. 25%, after which cooling produced crystals of $(Me_4N)ThBr_6$ which were collected, washed, and dried.

*Preparation of neutral chelate complexes*

The electrolyte phase for these syntheses consisted of an acetone solution of the appropriate parent acid (Table 2). After electrolysis, the solution was filtered in order to eliminate traces of solid impurity, and the solvent removed *in vacuo*. The resultant residue was dissolved in toluene and reprecipitated by the addition of petroleum ether; the final product was collected and dried *in vacuo*.

In addition to the known compounds $Th(acac)_4$ (acac =

For personal use only.

2,4-pentanedionate) and $Th(oxine)_4$ (oxine = 8-hydroxyquinolate), we also obtained $Th(tfha)_4$ (tfha = 1,1,1-trifluoroheptane-2,5-dionate). An attempt to prepare a salicylaldehyde derivative by this route was unsuccessful.

The $^1H$ nmr of $Th(acac)_4$ showed resonances at 1.17 ($CH_3$) and 4.67 (CH) ppm from TMS, in the intensity ratio 6:1, as required for a β-diketonate complex.

## Results and discussion

*Adducts of neutral halides*

The electrochemical synthesis of $ThX_4.4CH_3CN$ (X = Cl, Br) represents a convenient, rapid, and simple route to these compounds. The methods reported in the literature (3, 4) involve high temperature reactions to give $ThX_4$, which is then converted to the acetonitrile complex. The acetonitrile adducts, which are the primary products of the electrochemical synthesis, can be easily converted to other adducts as described above, or heated *in vacuo* to remove acetonitrile (13), and this latter sequence offers a simple pathway to the tetrachloride and tetrabromide. These systems have many parallels with earlier work on the preparation of acetonitrile and other adducts of the tetrahalides of titanium, zirconium, and hafnium (7).

It is worth noting here that the electrochemical oxidation of thorium into acetonitrile solutions of iodine gives rise to thorium(II) compounds (15). Such differences between iodine and the lighter halogens in stabilising low oxidation states have been noted previously in the case of copper (8) and indium (5).

The thorium(IV) adducts prepared electrochemically are for the most part identical in composition and spectral properties with those reported by earlier authors (13, 16, 17). Any discussion of the differences which do exist is beyond the scope of the present work.

*Anionic halogeno complexes*

The electrochemical oxidation of a metal into an non-aqueous solution of $R_4NX + X_2$ represents a simple one-step route to the tetraalkylammonium salts of $MX_n^{m-}$ anions (14), and we can now add thorium to the list of main group and transition metal elements for which this has been demonstrated. The salts $(Et_4N)_2ThCl_6$ and $(Me_4N)_2ThBr_6$ were obtained in good yield from the metal and in good crystalline form. Both compounds have been reported previously by Brown (18), who reacted $ThX_4$ (or $ThX_4.4CH_3CN$) with the appropriate tetraalkylammonium halide in boiling acetonitrile. The advantages of the electrochemical method are that it is a one-step reaction, starting from the metal, and that the thermal preparation of the tetrahalide is avoided.

*β-Diketonate and related complexes*

Following earlier work on the electrochemical preparation of $M(acac)_{2,3}$ species (10), and more recent studies of a range of similar cadmium complexes (19), we have investigated the direct synthesis of analogous thorium compounds. Both $Th(acac)_4$ and the related derivative of $CF_3CO-CH_2COC_3H_7$ were easily obtained in good yield by a route which appears simpler than those previously reported (20, 21), in that the number of steps is reduced. The corresponding oxinato complex $Th(oxine)_4$ was also obtained without the extra molecule of 8-hydroxyquinoline which is complexed to the thorium oxinate as the product of other syntheses of this compound, and which must be removed by pyrolysis (22).

*Cationic complexes*

In a previous publication (11), we described simple one-step syntheses of cationic complexes of a number of metallic elements with $CH_3CN$ or dimethylsulphoxide, using a mixture of the ligand with concentrated aqueous $HBF_4$ as the electrolyte; the products are then typically obtained as the salts $[ML_6](BF_4)_n$ (L = $CH_3CN$, dmso). Attempts to apply this method to the synthesis of the corresponding thorium species were unsuccessful. The anode rapidly became coated with a layer of white material, which effectively prevented further reaction. We believe that this material is a thorium fluoride species, formed by decomposition of the $BF_4^-$ anion at the electrode surface

[1] $BF_4^- \rightarrow BF_4^{\cdot} + e$

[2] $BF_4^{\cdot} \rightarrow BF_3 + F^{\cdot}$

[3] $nF^{\cdot} + Th \rightarrow ThF_n$

*Electrochemical efficiency*

As in previous work, we have measured the electrochemical yield ($E_F$), defined as moles of metal dissolved per Faraday of electricity. Such experiments are typically carried out at a constant current of 20 mA over 2 h.

For the $CH_3CN/X_2$ systems, we find $E_F = 0.27$ mol $F^{-1}$ for X = Cl, and 0.26 for X = Br. These values correspond to the anodic process

[4] $Th + 4X^- \rightarrow ThX_4 + 4e$

and are exactly in keeping with the products obtained from the acetonitrile solution, namely, the adducts of $ThCl_4$ and $ThBr_4$. Moreover, these $E_F$ values are equal within experimental error to those required for Faradaic behaviour, in sharp contrast to the results for other $M/X_2$ electrochemical systems (6–9) for which the values of $E_F$ were in the

range 1–10 mol $F^{-1}$. The reasons for these differences are not obvious at this point.

For the experiments involving β-diketonate or oxinate, the $E_F$ values were found to be

Th/Hacac $E_F = 0.18$ mol $F^{-1}$
Th/Htfha $E_F = 0.19$ mol $F^{-1}$
Th/Hoxine $E_F = 0.22$ mol $F^{-1}$

close to the value of 0.25 mol $F^{-1}$ required for an anode reaction such as

[5] $Th + 4acac^- \rightarrow Th(acac)_4 + 4e$

which implies the Faradaic behaviour found in other metal/β-diketonate electrolytic oxidations (10). As in such experiments, the formation of gas ($H_2$) at the cathode was noted. The rather low values of $E_F$ may imply a resistance of thorium metal to the oxidation reaction [5], with some anions being discharged without causing oxidation of the metal.

*General*

The electrochemical oxidation of thorium provides a simple room temperature reaction for the direct synthesis of a variety of thorium(IV) compounds in good yield (Table 3). We conclude that the electrochemical synthesis of thorium compounds could replace many of the earlier methods on the grounds of simplicity and convenience.

DOROTHY V. BAUTISTA, JOHN C. DEWAN, and LAURENCE K. THOMPSON. Can. J. Chem. **60**, 2583 (1982).

Mononuclear, binuclear, and trinuclear copper(II) complexes of the tetradentate ligands 1,4-di(2′-pyridyl) aminophthalazine (PAP) and 1,4-di(4′-methyl-2′-pyridyl) aminophthalazine (PAP4Me) and binuclear complexes of the tetradentate ligand 1,4-di(6′-methyl-2′-pyridyl) aminophthalazine (PAP6Me) are reported. In a series of binuclear carboxylate derivatives carboxylate bridges exist between copper centres in all cases and in some cases oxygen bridges (hydroxide or methoxide) are indicated. In all other polynuclear derivatives hydroxide bridges are anticipated on the basis of analytical, spectral, and magnetic data. The ligands exist as anionic groups in some binuclear carboxylate derivatives while in the other polynuclear systems neutral ligands are found. In reactions in aqueous solution protonated mononuclear derivatives are obtained for both PAP and PAP4Me in cases where solutions of the metal salts are inherently acidic, followed by polynuclear, neutral ligand complexes which form when the pH increases. Mononuclear protonated complexes are not obtained with PAP6Me, where steric factors may prevent the formation of such derivatives. Low magnetic moments (1.1–1.5 BM) are observed for most hydroxy bridged complexes while even lower values (<0.70 BM) are observed for two binuclear complexes of PAP6Me, indicating the possibility of strong antiferromagnetic exchange between metal centres. A preliminary X-ray investigation of the complex $[Cu_2(PAP4Me)(OH)(NO_3)_2(H_2O)_2]NO_3$ indicates a triple bridged binuclear structure including a bidentate nitrate bridge and a hydroxide bridge with an oxygen bridge angle of 115.2°.

DOROTHY V. BAUTISTA, JOHN C. DEWAN et LAURENCE K. THOMPSON. Can. J. Chem. **60**, 2583 (1982).

On a préparé les complexes mono-, bi- et trinucléaires du cuivre(II) des ligands tétradentates di(pyridyl 2′)-1,4 aminophtalazine (PAP) et di-(méthyl-4′ pyridyl-2′)-1,4 aminophtalazine (PAP4Me) et les complexes binucléaires du ligand tétradentate di(méthyl-6′ pyridyl-2′)-1,4 aminophtalazine (PAP6Me). Dans une série de dérivés carboxylates binucléaires, il existe dans tous les cas des ponts carboxylates entre les centres cuivre et, dans certains cas, on trouve des ponts oxygènes (hydroxyde ou méthylate). En se basant sur des données analytiques, spectrales et magnétiques, on prévoit qu'il existera des ponts hydroxydes dans tous les autres dérivés polynucléaires. Les ligands existent sous forme de groupes anioniques dans certains carboxylates binucléaires tandis que, dans d'autres systèmes polynucléaires, on trouve des ligands neutres. Lorsque les solutions de sels métalliques sont intrinsèquement acides, on obtient des dérivés mononucléaires protonés avec le PAP et le PAP4Me en solution aqueuses et des complexes polynucléaires de ligands neutres lorsque le pH augmente. On n'obtient pas de complexes mononucléaires protonés avec le PAP6Me alors que des facteurs stériques empêchent la formation de tels dérivés. On a observé de faibles moments magnétiques (1.1–1.5 BM) pour la plupart des complexes ayant un pont hydroxyde tandis qu'on observe des valeurs plus faibles (< 0.70 BM) pour deux complexes binucléaires du PAP6Me; ceci indique qu'il existe une possibilité d'un fort échange antiferromagnétique entre les centres métalliques. Une étude préliminaire du complexe $[Cu_2(PAP4Me)(OH)(NO_3)_2(H_2O)_2]NO_3$ par cristallographie de rayons X indique une structure binucléaire triplement pontée incluant un pont nitrate bidentate et un pont hydroxyde avec un angle du pont oxygène de 115,2°.

## Introduction

Binucleating ligands containing just nitrogen donor atoms have received some attention in recent years and have been based largely on substituted "diazine" type units. Polyfunctional ligands derived from hydrazine (1–3), pyrazole (4–8), pyridazine (4, 9–11), and phthalazine (4, 9, 11, 12–19) form transition metal complexes in which the metals are brought into close proximity because of the presence of the $N_2$, diazine, fragments in these systems. Antiferromagnetic exchange between the adjacent metal centres has been demonstrated in some of these complexes (4, 11, 13, 15, 16, 18) and catecholase activity has been shown with binuclear copper complexes of the binucleating ligand 1,4-di(2′-pyridyl) aminophthalazine (PAP) (Fig. 1). In a recent paper (21) binuclear copper complexes of the ligand 3,6-bis(2′-pyridyl) pyridazine are described and an X-ray structure of the chloro-derivative reveals a double bridge involving the pyridazine $N_2$ and a hydroxide. Binuclear complexes involving macrocyclic, nitrogen-containing ligands have also been synthesized (14, 22).

PAP has been shown to bind preferentially to two metal centres forming binuclear complexes with copper, cobalt, nickel, and zinc salts (13, 15, 16, 18, 19). Antiferromagnetic exchange exists between the metal centres in cobalt, nickel, and copper complexes of PAP (13, 15, 16, 18). PAP appears to be quite sensitive to protonation, even in mildly acidic solution, and as a result of the inherent acidity of aqueous and alcoholic solutions of certain commercially available metal salts, protonated

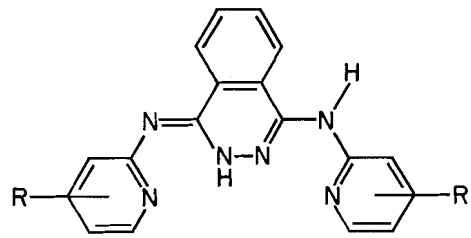

FIG. 1. PAP (R = H), PAP4Me (R = 4 methyl), PAP6Me (R = 6 methyl).

mononuclear (1:2) complexes are obtained as initial products, in certain reactions, followed by binuclear or polynuclear derivatives containing neutral ligand (18, 19).

In this paper we describe some copper complexes of PAP, which have not been previously reported, and some copper complexes of two closely related pyridyl phthalazines: 1,4-di(4′-methyl-2′-pyridyl) aminophthalazine (PAP4Me) and 1,4-di(6′-methyl-2′-pyridyl) aminophthalazine (PAP6Me). These ligands are previously unreported. Protonated mononuclear, neutral ligand binuclear and polynuclear complexes are obtained for PAP4Me, these systems bearing a close resemblance to counterparts with PAP itself, while for PAP6Me only binuclear complexes are obtained. The absence of any protonated mononuclear (1:2) complexes of the pyridyl phthalazine involving a methyl substituent in the 6-position on the pyridine ring is no doubt due to steric constraints imposed by such groups. However, in keeping with the general ability of PAP type ligands to act as weak bases, protonated ligand salts are produced in certain reactions involving PAP6Me. Preliminary X-ray structural details of the complex $[Cu_2(PAP\text{-}4Me)(OH)(NO_3)_2(H_2O)_2]NO_3$ are also reported.

## Experimental

Electronic spectra were recorded with a Cary 17 spectrometer and infrared spectra with a Perkin-Elmer Model 283 spectrometer. Magnetic susceptibilities were obtained at room temperature by the Faraday method using a Cahn Model #7600 Faraday Magnetic Susceptibility system, coupled to a Cahn gram electrobalance. Nuclear magnetic resonance spectra were run as solutions in deuterochloroform using a Bruker WP80 spectrometer and mass spectra were run using a Hitachi-Perkin Elmer RMU-6E with the direct insertion probe. Microanalyses were carried out by Canadian Microanalytical Service, Vancouver (C, H, N). Metal analyses were determined by atomic absorption with a Varian Techtron AA-5, after digestion of the samples in concentrated $HNO_3$ or aqua regia.

*Ligands*

PAP was prepared as described previously (13) but can also be prepared conveniently by the following procedure.

*1,4-Di(4′-methyl-2′-pyridyl) aminophthalazine (PAP4Me)*

1,3-Di(4′-methyl-2′-pyridyl) iminoisoindoline was prepared by fusing phthalonitrile (12.8 g, 0.100 mol) and 2-amino-4-methylpyridine (21.6 g, 0.200 mol) and maintaining a temperature of 220°C until ammonia evolution ceased (approximately 12 h). Extraction of the solid, which formed on cooling, into ethanol gave yellow crystals on recrystallization (yield = 24.2 g; 75%) (mp 164°C) (lit. 165–166°C, ref. 22).

The isoindoline (15.0 g, 0.050 mol) was dissolved in methanol (400 mL) under reflux, 85% hydrazine hydrate (8.0 mL) added, and the mixture refluxed for 15 h, or until ammonia evolution had essentially ceased. Filtration and reduction in volume led to the formation of a yellow crystalline product, which was recrystallized from ethanol (yield = 13.2 g, 84%) and dried at 80°C under vacuum for 3 h (mp 178°C). *Anal.* calcd. for $C_{20}H_{18}N_6$: C 70.2, H 5.26, N 24.6; found: C 70.2, H 5.45, N 24.3. Mass spectrum, major mass peaks (*m/e* (relative intensity)) 342 (100) P, 327 (10), 235 (23), 222 (25), 93 (68), 92 (95); $^1$H nmr ($CDCl_3$) (σ(relative intensity)) 2.33 (45) (singlet, $CH_3$), 6.68 (15) (doublet, pyridine $H_5$), 7.10 (7) (singlet, pyridine $H_3$), 7.7 (36) (multiplet, 1NH, *o*-phenylene $H_\beta$, pyridine $H_6$), 8.1 (15) (multiplet, *o*-phenylene $H_\alpha$), 8.75 (7) (broad singlet, 1NH). The observation of two different types of NH indicates that the ligand exists in chloroform solution in the tautomeric form illustrated in Fig. 1. Also the absence of a symmetric set of resonances attributable to a symmetrically disubstituted benzene ring indicates the presence of a tautomeric form of the ligand in which the phthalazine moiety is not bisected by a mirror plane. In the infrared spectrum two bands attributable to NH stretch are observed at 3270 and 3200 cm$^{-1}$, again supporting two different NH groups.

*1,4-Di(6′-methyl-2′-pyridyl) aminophthalazine (PAP6Me)*

PAP6Me was prepared in the same way as PAP4Me and obtained as a yellow crystalline solid which was recrystallized from ethanol and dried at 80°C, under vacuum, for 3 h (yield isoindoline = 41%; yield phthalazine = 83%) (mp 158–161°C). *Anal.* calcd. for $C_{20}H_{18}N_6$: C 70.2, H 5.26, N 24.6; found: C 69.9, H 5.37, N 24.3. Mass spectrum, major mass peaks (*m/e* (relative intensity)) 342 (100) P, 235 (24), 93 (84), 92 (90); $^1$H nmr ($CDCl_3$) (σ(relative intensity)) 2.52 (30) (singlet, methyl), 6.76 (10) (doublet, pyridine $H_5$), 7.52 (10) (doublet, pyridine $H_3$), approximately 7.8 (30) (poorly defined multiplet, *o*-phenylene $H_\alpha$, $H_\beta$, pyridine $H_4$), 8.75 (5) (NH). The NH resonance is very broad and an estimate of its integrated intensity suggests only one proton. Location of the second NH proton was unsuccessful, but it may be buried beneath the rather broad envelope of resonances in the range 6.7–8.05. The indication of two different types of NH suggests that the ligand exists in chloroform in the tautomeric form shown in Fig. 1. Also, unlike the isoindoline, whose nmr spectrum clearly shows an AA′BB′ splitting pattern associated with a symmetrically *o*-disubstituted benzene ring, the phthalazine shows an asymmetric set of resonances due to the fused benzene ring protons, indicating an unsymmetrical ligand involving two different types of NH. In the mull infrared spectrum a sharp, single absorption at 3400 cm$^{-1}$ suggests the possibility of just one type of NH in the solid state and a symmetrical tautomer probably involving hydrogen atoms bound to just the exocyclic nitrogen atoms.

*Copper complexes*

*$[Cu(PAPH)_2(NO_3)_2](NO_3)_2.0.5H_2O$ (I), $[Cu_3(PAP)_2(OH)_2(NO_3)_2](NO_3)_2.4H_2O$ (II)*

PAP (1.00 g; 3.18 mmol) was added to a solution of $Cu(NO_3)_2.3H_2O$ (0.770 g; 3.19 mmol) dissolved in water (200 mL) and the mixture refluxed for 2 h. The resulting green solution was filtered and allowed to stand at room temperature in a loosely covered beaker. Buff-coloured crystals (**I**) were obtained and after several days this product was filtered off, washed with ethanol and ether, and dried under vacuum and the mother

For personal use only.

liquor allowed to evaporate further. A second crop of buff crystals was obtained and the process repeated. A third crop of crystals contained I plus a green crystalline product (II) and finally green crystals (II) were obtained as the sole product in the fourth crop. The green product was recrystallized from water, washed with ethanol and ether, and dried under vacuum.

Pairs of products, including in each case a protonated mononuclear derivative and a polynuclear neutral ligand derivative, were obtained in a similar fashion from the reaction of $Cu(ClO_4)_2.6H_2O$ (**III**, buff; **IV**, green) with PAP in methanol or water and reactions of $Cu(NO_3)_2.3H_2O$ (**XV**, buff–yellow; **XVI**, blue), $Cu(ClO_4)_2.6H_2O$ (**XVII**, green–yellow; **XVIII**, green), and $Cu(BF_4)_2.6H_2O$ (**XIX**, green–yellow; **XX**, green) with PAP4Me in aqueous solution. In certain cases recrystallization of a product was effected from methanol and solvate molecules are found in the complex.

*$[Cu_2(PAP)$(p-tolylSCH$_2$COO)$_4].1.5H_2O$ (IX)*

$CuCO_3.Cu(OH)_2.H_2O$ (0.800 g; 3.35 mmol) and *p*-tolylthioacetic acid (2.34 g; 12.7 mmol) were added to methanol (150 mL) and the mixture refluxed for 15 min. PAP (1.00 g; 3.18 mmol) was added and the mixture refluxed for 1 h and the resulting green solution filtered. Reduction in volume of the solution did not produce a product and so the solvent was completely removed and the resulting green solid extracted with $MeOH/CHCl_3$ (50/50). On standing a green powder was formed, which was filtered, washed with ether, and dried under vacuum.

The other copper thio- and sulfoxy-carboxylate complexes (**V–VIII**, **X**, **XI**) were prepared similarly using stoichiometric amounts of copper carbonate and the appropriate carboxylic acid and obtained as green solids.

*$[Cu_2(PAP4Me)(OH)Cl_3].H_2O$ (XII)*

PAP4Me (1.00 g; 2.92 mmol) was added to a solution of $CuCl_2.2H_2O$ (3.23 g; 18.9 mmol) dissolved in water (100 mL) and the mixture refluxed for 1 h. A green precipitate formed which was filtered, washed with water, recrystallized from water, and dried under vacuum at room temperature.

The corresponding bromo-complex (**XIII**) and the copper chloride and copper bromide complexes of PAP6Me (**XXI**, **XXII**) were prepared similarly and obtained as green crystalline solids.

*$[Cu_2(PAP4Me)(CH_3COO)_2(OH)].H_2O$ (XIV)*

PAP4Me (1.00 g; 2.92 mmol) was added to a solution of cupric acetate (1.17 g; 2.96 mmol) dissolved in ethanol (300 mL) and the mixture refluxed for 45 min. The volume of the resulting green solution was reduced to approximately 100 mL and allowed to stand. A powdery khaki-green product was obtained which was recrystallized from methanol to give a khaki-green solid. The product was filtered off, washed with methanol and ether, and dried under vacuum at room temperature.

The copper acetate complex of PAP6Me (**XXIII**) was prepared similarly and obtained as a khaki-green powder.

*$[Cu_2(PAP6Me)(OH)(NO_3)_2]NO_3$ (XXIV)*

PAP6Me (0.500 g; 1.46 mmol) was dissolved under reflux in ethanol (100 mL). $Cu(NO_3)_2.3H_2O$ (0.688 g; 2.92 mmol) was dissolved in a mixture of ethanol (10 mL) and water (5 mL) and the solution added to the solution of the ligand. The resulting dark green solution was refluxed for 1 h and allowed to stand. A dark green product formed which was filtered, washed with ethanol and ether, and recrystallized from methanol.

*$[PAP6MeH_2](ClO_4)_2$ (XXV), $[Cu_2(PAP6Me)(OH)(H_2O)_2](ClO_4)_3.0.5H_2O$ (XXVI)*

PAP6Me (0.500 g; 1.46 mmol) was dissolved under reflux in ethanol (20 mL) and the solution added to a solution of $Cu(ClO_4)_2.6H_2O$ (1.08 g; 2.92 mmol) dissolved in water (30 mL). The resulting dark green solution was refluxed for 15 min and cooled. A light yellow powder formed (0.26 g) which was filtered off (**XXV**), washed with ethanol, and dried under vacuum. Reduction in volume of the mother liquor produced a dark green solid (0.48 g) which was filtered off (**XXVI**), washed with ethanol, and dried under vacuum.

Satisfactory analytical data have been obtained for these complexes and are reported in Table 1, which has been placed in the Depository of Unpublished Data.[2]

## Results and discussion

The new ligands described in this paper (PAP-4Me, PAP6Me; Fig. 1) are analogues of the parent pyridyl phthalazine (PAP) in which methyl groups have been introduced at the 4- and 6-positions of the pyridine ring. They are all prepared by a common synthetic route in which ring expansion of the isoindoline precursor is effected simply by reaction with hydrazine hydrate. The synthetic route to the isoindoline precursors involves the direct reaction of phthalonitrile and the appropriate 2-aminopyridine at high temperatures for periods of up to 12 h followed by extraction into ethanol. This direct fusion method, which we have used routinely for a number of years, provides good yields of the disubstituted isoindolines and is a more efficient procedure than previously reported syntheses involving phthalonitrile (23, 24) and 1,3-diiminoisoindoline (25) as starting materials. The synthesis of the 5-methyl isoindoline by this route was recently reported by Addison and coworkers (26).

### *Characterization of the complexes*

Previously reported copper complexes of PAP have included binuclear systems involving two metals bound to the same ligand (13) and mononuclear derivatives in which two bidentate ligands are bound to the same metal (19). Polynuclear derivatives involving three copper centres and a binuclear derivative involving two metals bound simultaneously to two tetradentate ligands have also been reported (19). In a series of binuclear copper carboxylate derivatives of PAP the $pK_a$ of the corresponding carboxylic acid determined whether or not the ligand was neutral or anionic. For acids whose $pK_a$ is greater than 3.8 complexes of the type $[Cu_2(PAP–H)(RCOO)_3]$ (PAP–H indicates anionic PAP involving loss of a proton) are formed, whereas for acids whose $pK_a$ is less than 3.8 complexes of the type $[Cu_2(PAP)(RCOO)_4]$, involving neutral ligand, are formed (13).

In an attempt to involve sulphur centres in the coordination sphere of the metal in binuclear systems of this sort, carboxylate complexes involv-

ing sulphur-containing carboxylic acids were synthesized. Instead of isolating the copper carboxylate itself the binuclear carboxylate complexes (**V–XI**) were synthesized by reacting ligand, copper carbonate, and the appropriate acid in a suitable solvent. Both 1:2:3 and 1:2:4 stoichiometries (ligand:metal:carboxylic acid) were used in synthesizing these compounds. However, two distinct compounds were obtained only in the case of phenylthioacetic acid and since a neutral ligand is indicated for **V**, in which three carboxylate groups are found, the remaining anionic charge can exist as either methoxide or hydroxide. The absence of any infrared absorption associated with OH suggests the former assignment. For the remaining systems only one compound formed regardless of the chosen stoichiometry.

The $pK_a$ values of the thio- and sulfoxyacetic acids fall in the range 2.6–3.5 and if the previous criterion for the type of complex formed were to apply then only derivatives of the type $[Cu_2(PAP)(RCOO)_4]$ or those involving neutral ligand should be formed. Neutral ligand derivatives are confirmed for all the carboxylate complexes in the solid state, with the possible exception of **VII**, by the presence of at least one charge transfer band at 27000 $cm^{-1}$ or higher (13). Although compound **VII** has a solid state charge transfer band at 27500 $cm^{-1}$, analytical and other data suggest an anionic derivative.

Previous studies have shown that the presence of an infrared band above 1000 $cm^{-1}$, associated with the ring breathing mode of the pyridine ring in PAP, indicates the coordination of this group to the metal centres (13). Absorptions in the range 1017–1025 $cm^{-1}$ (Table 2) for compounds **V–IX** indicate the involvement of the pyridine rings in coordination and suggest that PAP behaves as a tetradentate ligand. Similar absorptions could not be observed for compounds **X**, **XI** because of interfering bands associated with the sulfoxy groups.

Infrared absorptions found in the solid state in the range 1626–1345 $cm^{-1}$ for all the carboxylate complexes can be associated with both terminal and bridging carboxylate groups (13). Typically two absorptions occur around 1600 $cm^{-1}$, the one at higher energy being associated with the antisymmetric vibration of a terminal carboxylate while the lower energy absorption is associated with the antisymmetric mode of a bridging carboxylate. Other carboxylate bands occurring around 1400 $cm^{-1}$ are assigned to symmetric vibrations associated with both bridging and terminal carboxylates, although distinction between these bands is difficult. A comparison of the solid state spectra in this region with those obtained in chloroform solution (Table 2) indicates the possible disproportionation of certain species in solution. For compounds **VI** and **IX**, which contain four carboxylate groups, a new carboxylate band appears around 1700 $cm^{-1}$, which is not observed in the solid state (**VIII** was not soluble enough in chloroform to be studied), while the other carboxylate absorptions remain approximately the same. Since absorptions of this sort around 1700 $cm^{-1}$ can be associated with the free carboxylic acid itself it is suggested that these neutral tetracarboxylate derivatives dissociate via loss of one molecule of the appropriate carboxylic acid to form tricarboxylates, containing anionic ligand, in solution. This is supported by the observation of only one charge transfer absorption around 24000 $cm^{-1}$ associated with anionic PAP. There was no infrared evidence to indicate the involvement of the sulfur or sulfoxy groups in coordination to the metal centres in these complexes.

The solid state electronic spectra of the carboxylate complexes (Table 3) are in general characterized by a major absorption in the range 14500–16400 $cm^{-1}$ accompanied in many cases by a low energy shoulder. The spectra are very similar to those reported previously for related tri- and tetracarboxylate derivatives which were assigned square pyramidal coordination geometries (13). In the solid state charge transfer bands are observed in all cases at 27000 $cm^{-1}$ or above, signalling the presence of neutral ligand. These data can be rationalized reasonably in all cases except compound **VII** where analytical results indicate three carboxylate functions and the absence of a hydroxide group, thus suggesting an anionic ligand. Certainly in solution in chloroform this species appears to contain anionic ligand.

Magnetic moments, measured at room temperature (Table 3), appear normal for compounds **VI**, **VIII**, and **IX**, being in excess of the spin only value for copper(II), and indicate that any antiferromagnetic exchange between the metal centres is small. Efficient bridge exchange groups, e.g. oxygen centres, are therefore considered to be absent in these systems (27–29). Considerably reduced room temperature moments are observed for compounds **V**, **X**, and **XI** in keeping with the proposal that in addition to having phthalazine and carboxylate bridges the copper centres are also bridged by oxygen groups, viz. a methoxide in **V** and hydroxides in **X** and **XI**. For compound **VII**, a slightly reduced room temperature moment signals weaker exchange and the absence of an oxygen bridge. Proposed structures for the carboxylate complexes are given in Fig. 2. Compound **VII** may be a four-coordinate derivative but could also be five-

coordinate via intermolecular association involving the terminal carboxylates as was observed previously (13).

In a previous paper (19) we reported the formation of two different complexes from the reaction of copper tetrafluoroborate and PAP in aqueous solution: a mononuclear derivative, $[Cu(PAPH)_2(H_2O)_2](BF_4)_4$, containing protonated bidentate ligand, and a polynuclear, neutral ligand derivative which was formulated as a trinuclear system, $[Cu_3(PAP)_2(OH)_2](BF_4)(BF_3OH)_3.5H_2O$. The ease with which PAP became protonated, even in weakly acidic solutions, was shown to be the reason why such a mixture of compounds was formed. Surprisingly a similar situation arose in the reactions between copper nitrate and copper perchlorate with PAP (approximately 0.1 *M* solutions of copper nitrate and copper perchlorate have pH values of 3.7 each).

Buff-coloured protonated derivatives (**I**, **III**) were obtained as initial products from the reactions of copper nitrate and copper perchlorate with PAP in aqueous solution. The presence of up to four CN stretching vibrations in the infrared (Table 2) can be attributed to the presence of protonated PAP (19). The observtion of three nitrate combination bands (30) can be interpreted in terms of the presence of both ionic and monodentate nitrate and in keeping with the electronic spectrum (Table 3), it seems reasonable to assume a tetragonally distorted six-coordinate structure for **I** involving two axially bound monodentate nitrate groups and two in-plane bidentate protonated PAP ligands. The perchlorate derivative (**III**) appears to have an analogous square planar structure without the involvement of any axial ligand. Magnetic moments for these compounds are typical of mononuclear copper derivatives.

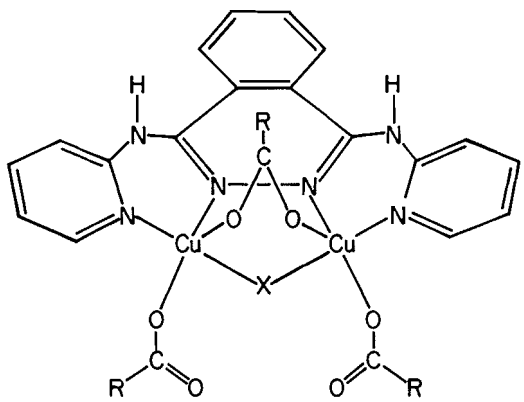

FIG. 2. Proposed structures for **V** (X = OMe), **X**, **XI** (X = OH), **VI**, **VIII**, **IX** (X = RCOO).

Additional green products (**II**, **IV**) are also obtained from both reaction mixtures, which do not contain protonated ligand. Two CN bands are observed in the infrared in each case, typical of neutral PAP. Nitrate combination bands indicate the presence of both ionic and monodentate nitrate in **II**, while for **IV** the $\nu_3$ perchlorate vibration, although it is slightly split, probably indicates ionic perchlorate. Pyridine ring breathing absorptions are observed for **II** in excess of 1000 $cm^{-1}$, indicative of the presence of tetradentate PAP (13), while for **IV** such absorptions are hidden by the perchlorate band. Elemental analyses suggest a metal-to-ligand ratio of 3:2 for **II** and **IV**, which requires the presence of two hydroxy groups to complete a charge balance. Rather broad infrared absorptions at 3400 $cm^{-1}$ (**II**) and 3525 $cm^{-1}$ (**IV**) are associated with water (**II**) and methanol (**IV**) and bridging hydroxy groups, probably involved in hydrogen bonding.

The electronic spectra of **II** and **IV** are very similar in the solid state involving three major absorptions and resemble very closely the spectrum of $[Cu_3(PAP)_2(OH)_2](BF_4)(BF_3OH)_3.5H_2O$ (19), suggesting a similar species. In general the binuclear copper complexes of PAP involve five-coordinate copper centres and only one major *d–d* band is observed in this region of the spectrum (13). The three prominent absorptions observed for **II** and **IV** therefore suggest the possible presence of more than one different stereochemistry for the copper centres in these systems. A reasonable suggestion for the structures of **II** and **IV** is illustrated in Fig. 3 in which two tetradentate ligands are bound simultaneously to three copper centres in a trinuclear arrangement. The central copper is six-coordinate being bound to the other two copper centres via phthalazine and hydroxy bridges. The outer two copper atoms are probably four-coordinate, the fourth coordination site being occupied by monodentate nitrates in **II** and methanol molecules in **IV**. Such a system can be rationalized spectroscopically by assuming that the highest energy *d–d* component can be associated with the two distorted square planar copper centres and that the two lower energy components can be asso-

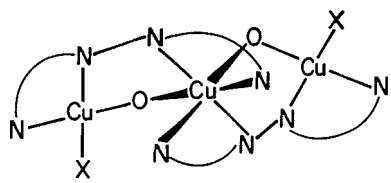

FIG. 3. Proposed structures for the cation in **II** (X = $NO_3$), **IV** (X = MeOH), **XVIII** and **XX** (X = $H_2O$).

ciated with a *cis*-$N_4O_2$ six-coordinate copper centre. Magnetic moments per copper centre for **II** and **IV** are quite low, indicating significant spin exchange, which would again support the presence of hydroxy bridges between the copper centres.

PAP4Me, which involves methyl substituents at the 4-position on the pyridine ring, forms similar copper complexes to those of PAP. This is perhaps not so surprising since substituents at the 4-position would not be expected to exert any unusual electronic or steric effects. Compounds **XII** and **XIII** are analogous to the PAP counterparts with hydroxy and halogeno bridges between the copper centres and reduced room temperature moments indicative of antiferromagnetic exchange (13, 31) (Fig. 2; X = OH, RCOO = halide). However, the moments are somewhat lower than those of the PAP analogues (Cl, $\mu$ = 1.60 BM; Br, $\mu$ = 1.66 BM) (13) which may indicate some structural modification at the binuclear centre in the systems.

The acetate complex **XIV** contains two acetate groups, according to elemental analysis, and has a low energy charge transfer absorption (13) indicative of the presence of anionic ligand (it is assumed that PAP and its simple methylated analogues will exhibit similar $\pi$–$\pi^*$ absorptions). In keeping with these data a hydroxy bridge is also implicated and although there is weak infrared evidence for the presence of such a group the low magnetic moment does indicate such a bridge. The high energy single *d*–*d* absorption (Table 3), present both in the solid state and solution, is consistent with a five-coordinate derivative. In the infrared, absorptions are observed both in the solid state and in chloroform solution consistent with the presence of both bridging and terminal carboxylate groups. A rather broad weak absorption around 3500 $cm^{-1}$ is associated with the hydroxide bridge and water molecule. Considering all the data a reasonable structure would involve a terminal carboxylate on one copper centre, a carboxylate and a hydroxide bridge, and a water molecule bound to the other copper centre (Fig. 2, X = OH, one terminal carboxylate replaced by $H_2O$). The formation of a hydroxy derivative in this case is seen as a result of the presence of water in the ethanol used to prepare the complex.

As in the case of PAP, two nitrate complexes are obtained. **XV** is clearly a protonated, mononuclear derivative which has a pseudo square planar structure according to both infrared and electronic spectral data. The presence of only one nitrate combination band at 1755 $cm^{-1}$ signifies the presence of ionic nitrate only. The blue neutral ligand species **XVI** appears to be a binuclear derivative, unlike its PAP counterpart. Infrared data suggest a hydroxy bridged species involving coordinated water and the complex absorption in the combination ($\nu_1 + \nu_4$) nitrate region suggests more than one type of nitrate group. The bands at 1751 and 1766 $cm^{-1}$ can be associated with monodentate nitrate and the band at 1753 $cm^{-1}$ with ionic nitrate. However, the high energy band at 1784 $cm^{-1}$ may be associated with a bridging bidentate nitrate (30).

Preliminary X-ray studies on this system (32) confirm the binuclear structure (Fig. 4) (Table 4) involving tetradentate PAP4Me, a hydroxide bridge, and a bidentate nitrate bridge. A second nitrate group is bound to Cu(2) with a bond length to O(2) of 2.034 Å. The interatomic distance Cu(2)—O(14) of 2.738 Å may indicate the nitrate group to be a weakly bound unsymmetrical bidentate chelating ligand giving rise to a distorted six-coordinate tetragonal structure around Cu(2). In a review of metal nitrate bonding (33) it is suggested that the nitrate group may be considered bidentate if the difference in the two closest metal–oxygen distances does not exceed 0.7 Å. The coordination geometry around Cu(1) can be considered to be tetragonal, six-coordinate with a long axial bond to O(16) of a water molecule. Of particular significance in the structure is the large bridge angle at O(1) (115.2°) and the metal–metal separation (3.138 Å). Full details of this structure will be published elsewhere.

We have recently examined the structure and magnetism of a series of complexes, $[Cu_2(PAP)(OH)X_3]$ (X = Cl, Br, $IO_3$) (34), and find that the binuclear centre can be tuned by varying the non-hydroxy bridge. The Cu—O—Cu bridge angle

| Cu(2)—O(14) | 2.738 | | |

is increased from 100° to 114° on replacing a chlorine bridge by an iodate bridge and the exchange integral increases from $-2J$ = 201 to $-2J$ = 335 $cm^{-1}$. Room temperature moments for these two systems are 1.66 BM (Cl) and 1.39 BM ($IO_3$). The low room temperature moment (1.12 BM) observed for **XVI** is consistent with the larger oxygen bridge angle for this nitrate bridged system and suggests the possibility of enhanced antiferromagnetic exchange.

The reaction of copper perchlorate and tetrafluoroborate with PAP4Me parallels the same reactions involving PAP. In both cases protonated, mononuclear derivatives, **XVII**, **XIX**, are produced which have pseudo-square planar structures involving bidentate, protonated PAP4Me. Also polynuclear derivatives, **XVIII** and **XX**, are obtained as final products in these reactions, which are analogues of **II** and **IV**, and are assumed to have the same basic structure (Fig. 3) but involving coordinated water at the four-coordinate copper centres.

Normal magnetic moments are observed for **XVII** and **XIX**, as would be expected for mononuclear derivatives, while the reduced moments observed for **XVIII** and **XX** are indicative of polynuclear species involving antiferromagnetic exchange. Three major absorptions are observed in the mull transmittance spectra of **XVIII** and **XX**, which can be associated with two different copper stereochemistries. Infrared data confirm the presence of protonated ligand in the mononuclear complexes **XVII** and **XIX** by the appearance of more than two νCN bands while for the polynuclear systems just two such bands are observed.

The introduction of a methyl group in the four position of the pyridine ring does not appear to have caused any major differences between the coordination chemistry of PAP and PAP4Me other than perhaps the formation of a binuclear nitrate complex with PAP4Me. However, a 6-methyl substituted ligand, in which the methyl group would be in a much better position to sterically influence the binuclear centre, might produce different complexes or analogues in which the dimensions of the binuclear centre might change.

Dark green binuclear products are obtained with copper chloride and bromide with PAP6Me (**XXI**, **XXII**) which appear to be analogues of the corresponding PAP and PAP4Me derivatives. Infrared absorptions observed at 3620 $cm^{-1}$ in both cases are indicative of the presence of a hydroxy bridge and other bands in the range 250–300 $cm^{-1}$ can be attributed to copper–halogen bonds. One major visible absorption is observed in each case which can be attributed to five-coordinate copper(II). On the surface these two compounds appear to have structures similar to their PAP and PAP4Me analogues (Fig. 2; X = OH, RCOO = halogen). However, the very low room temperature magnetic moments indicate the likelihood of enhanced magnetic exchange in these systems which can be seen as a result of the 6-methyl groups exerting a steric effect which forces the pyridine rings away from the binuclear centre thus increasing the metal–metal separation and the oxygen bridge angle. However, we await structural data and variable temperature magnetic studies to confirm this.

The copper acetate complex of PAP6Me (**XXIII**) appears to be similar to the acetate complex of PAP itself. A low energy charge transfer band (Table 3) indicates the presence of anionic ligand both in the solid state and in solution, while a single visible absorption, observed in the solid state spectrum at 16000 $cm^{-1}$, is consistent with a five-coordinate derivative. In methanol solution the $d$–$d$ absorption is observed at 17200 $cm^{-1}$, 1200 $cm^{-1}$ higher than in the solid state, suggesting the possibility of a change in stereochemistry. Carboxylate bands are observed in the infrared in the solid state (Nujol mull) at 1404 and 1585 $cm^{-1}$ which can be associated with the antisymmetric and symmetric vibrations of a bridging acetate. It was not possible to identify bands associated with terminally bound carboxylates. In chloroform solution four carboxylate bands can be picked out. Bands at 1575 and 1380 $cm^{-1}$ are associated with bridging carboxylate while the band at 1360 $cm^{-1}$ is assigned to the symmetric stretch of a terminal carboxylate. The band at 1700 $cm^{-1}$, which is absent in the mull spectrum, must be due to the "missing" antisymmetric stretch of a terminally bound carboxylate.

As with $Cu_2PAP(CH_3COO)_3$ (13), a loose intermolecular association is proposed between two terminal carboxylates on one binuclear complex with copper atoms on a neighbouring complex leading to a reduction in the antisymmetric frequency of the terminal carboxyl groups. This band is presumably hidden among the CN vibrations associated with the ligand itself in the solid state spectrum. The proposed intermolecular association would lead to a five-coordinate structure in the solid state (Fig. 5) but in solution, where the intermolecular association is broken, a four-coordinate system should exist. The observation of a *d–d* band in methanol at 17200 $cm^{-1}$ is certainly consistent with a four-coordinate system in which the stereochemistry at the copper centres is distorted square planar.

The binuclear nitrate complex (**XXIV**) is obtained from the reaction between copper nitrate and PAP6Me in aqueous ethanol. An infrared absorption at 3480 $cm^{-1}$ can be associated with a hydroxide bridge while nitrate combination bands are indicative of two types of nitrate (30). The absorption at 1750 $cm^{-1}$ indicates an ionic nitrate while absorptions at 1724 and 1757 $cm^{-1}$ suggest the presence of bidentate nitrate. The absence of a high energy nitrate combination band, indicative of the presence of a nitrate bridge, suggests a different structure for this complex than was observed for **XVI**. The *d–d* absorption in the solid state at 16400 $cm^{-1}$ can be associated with five-coordinate copper(II) and a five-coordinate binuclear structure is suggested in the solid state involving a hydroxy bridge and two bidentate nitrate groups (Fig. 6). The low magnetic moment of 1.20 BM suggests significant exchange and supports the proposed double bridged structure. In aqueous solution a much lower energy *d–d* absorption is observed, suggesting the formation of a solvated derivative.

In the reaction between copper perchlorate and PAP6Me in aqueous ethanol two products are

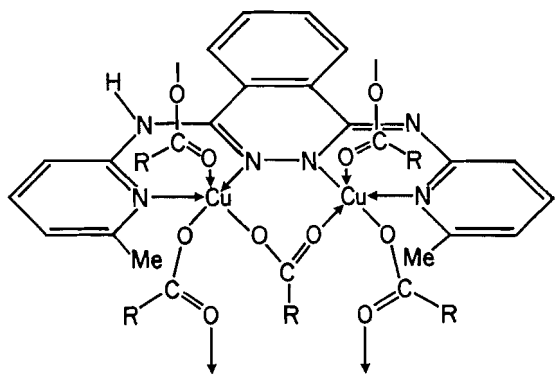

FIG. 5. Proposed structure for **XXIII**.

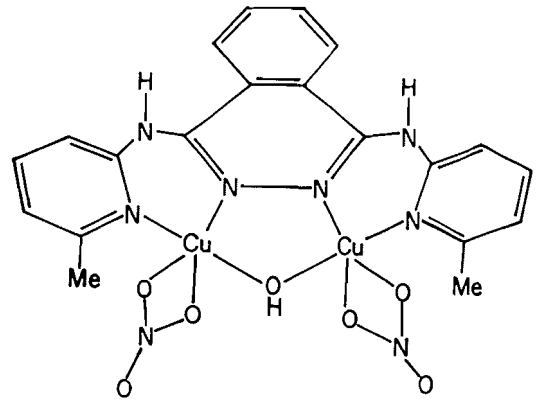

FIG. 6. Proposed structure for **XXIV**.

formed. Initially a yellow solid (**XXV**) is obtained followed by a green product (**XXVI**) on reduction of the volume of the mother liquor. **XXV** exhibits five infrared bands associated with CN stretch in the ligand and indicates the presence of protonated PAP6Me. This compound contains no metal and appears to be a diperchlorate salt in which the ligand is protonated at two sites (presumably both pyridine nitrogen atoms) (19). The formation of a salt of this type is a departure from the trend we have seen with the other systems in which, when the ligand acted as a base, mononuclear protonated complexes were formed. In the case of PAP6Me, however, the 6-methyl groups on the pyridine rings may exert enough of a steric influence that to form a mononuclear bis-bidentate ligand complex is not possible. Models suggest that this is so.

The green copper perchlorate complex (**XXVI**) is a binuclear derivative involving a hydroxide bridge and coordinated water. There is little evidence to suggest the involvement of perchlorate in the copper coordination sphere unless the slight splitting of the $\nu_3$ vibration is considered to be significant. In a recent paper Lippard and co-workers report the structure of a binuclear copper perchlorate complex of a binucleating macrocyclic ligand (35). In addition to a hydroxide bridge, a weakly bound bridging bidentate perchlorate group was also found to be present (Cu—O(perchlorate) ~ 2.6 Å). However, no infrared data were reported for the perchlorate group in this complex. Perhaps a rather weak splitting of $\nu_3$ would be expected in this case. The *d–d* absorption at 16700 $cm^{-1}$ (**XXVI**) is consistent with a four-coordinate system involving one coordinated water molecule per copper centre and a hydroxide bridge (Fig. 6; $NO_3$ replaced by $H_2O$) but the possibility of a five-coordinate derivative should not be ruled out.

Binuclear copper complexes involving antifer-

romagnetic exchange between metal centres are potential models for the binuclear oxygen-breathing protein hemocyanin and copper-containing oxidase enzymes, e.g. tyrosinase, laccase. Magnetic measurements on protein extracts indicate strong antiferromagnetic exchange between the copper(II) centres in Rhus vernicifera laccase ($-2J \geq 1000$ $cm^{-1}$) (36) and in oxyhemocyanin (Megathura crenulata; $-2J \geq 1250$ $cm^{-1}$) (37). Strong antiferromagnetic exchange is observed in binuclear copper systems involving single hydroxy bridges (29, 35, 38) and exchange increases with bridge angle (29, 34). An oxygen bridge from, e.g., tyrosine has been suggested as a super-exchange medium for both oxyhemocyanin (39) and enzymes containing Type III copper centres (35, 38) and other donor groups around the copper centres are thought to include histidine (38). With these properties in mind we see our complexes as potential models for such centres and are embarked on a program to investigate detailed magnetic and structural characteristics of some of our systems. We anticipate that varying the bridge groups between the copper centres and creating steric factors on the coordinated pyridine groups will alter the dimensions of the binuclear centre and vary the magnetic exchange.

The catecholase activity of the complex $[Cu_2(PAP)(OH)Cl_3]$ has already been demonstrated (20). Preliminary results indicate that this system also catalytically oxidizes ascorbic acid and that the complex $[Cu_2(PAP6Me)(OH)Cl_3]$ is also catecholase active. Reports on these studies will be published elsewhere.

Flowing afterglow measurements at 296 ± 2 K are reported which explore three aspects of the gas-phase acid–base chemistry of the methoxide anion. Firstly, the intrinsic reactivity of this ion has been determined from measurements of rate constants for solvent-free proton-transfer reactions with molecules more acidic than methanol including $CH_2{=}C{=}CH_2$, $C_6H_5CH_3$, $C_2H_5OH$, $C_2H_2$, $CH_3CN$, $CH_3COCH_3$, $CH_3CHO$, $CH_3NO_2$, and HCN. Secondly, equilibrium constant measurements have been performed for solvent-free proton-transfer reactions which provide a gas-phase scale of acidities for these molecules relative to the acidity of methanol. Finally, rate constants were measured for the reactions of these acids with methoxide ions solvated with up to three molecules of methanol. The results establish trends in reactivity as a function of step-wise solvation when relative acidity is preserved and when a reversal occurs in the relative acidity upon solvation.

GERVASE I. MACKAY, ASIT B. RAKSHIT et DIETHARD K. BOHME. Can. J. Chem. **60**, 2594 (1982).

On rapporte les mesures d'écoulement après incandescence à 296 ± 2 K qui explorent trois aspects de la chimie acide–base en phase gazeuse de l'anion méthanolate. Premièrement, on a déterminé la réactivité intrinsèque de cet ion à partir des mesures des constantes de vitesse de réactions de transfert de proton libre du solvant avec les molécules plus acides que le méthanol incluant: $CH_2{=}C{=}CH_2$, $C_6H_5CH_3$, $C_2H_5OH$, $C_2H_2$, $CH_3COCH_3$, $CH_3CHO$, $CH_3NO_2$ et HCN. Deuxièment, on a mesuré la constante d'équilibre des réactions de transfert de proton libre du solvant qui fournissent une échelle d'acidité en phase gazeuse de ces molécules par rapport à l'acidité du méthanol. Finalement, on a mesuré les constantes de vitesse des réactions de ces acides avec les ions méthanolates solvatés par un maximum de trois molécules de méthanol. Les résultats établissent les tendances de réactivité en fonction d'une solvatation par étape lorsque l'acidité relative est préservée et quand il se produit une inversion dans l'acidité relative lors de la solvatation.

## Introduction

Recent studies of gas-phase reactions of anions which have solution analogues have provided, for the first time, a direct quantitative measure of the *intrinsic* stability and reactivity of anions found in solution and an assessment of the absolute influence of solvation on these quantities. For example, gas-phase measurements of rate and equilibrium constants for solvent-free acid–base reactions of type [1]

[1] $B^- + AH \rightleftharpoons A^- + BH$

and solvated acid–base reactions of type [2]

[2] $B^-.S_n + AH \rightleftharpoons A^-.S_n + BH$

have provided both a measure of the absolute intrinsic reactivity and relative intrinsic basicity of anions as well as an indication of their perturbation by step-wise solvation. This has been illustrated by results obtained recently in our laboratory using the flowing afterglow technique for reactions of the hydroxide ion, an important base in solution (1, 2). Here we report an extension of our studies to the acid–base chemistry of the methoxide ion. Three aspects of this chemistry have been explored. Firstly, the intrinsic reactivity of the methoxide ion has been determined from measurements of rate constants for solvent-free proton-transfer reactions with molecules more acidic than methanol in the gas phase. Secondly, equilibrium constant measurements have been carried out for solvent-free proton-transfer reactions to provide a gas-phase scale of acidities of acids relative to the acidity of methanol. Finally, experiments were performed with methoxide ions solvated with up to three added methanol molecules which provide insight into the perturbation of the intrinsic reactivity and basicity of the methoxide ions by step-wise methanol solvation. The reagent acids were chosen to cover a range in overall energetics sufficient to establish the pattern of this perturbation which appeared to emerge from these studies.

## Experimental

The experiments were performed in a flowing plasma mass spectrometer (flowing afterglow) system. Details of the instrument together with the method of operation and data analysis have been elaborated elsewhere (3, 4). The anions were produced in a flowing plasma either by electron impact or by secondary ionization or ion–molecule reactions and were permitted to thermalize by collisions with a helium or hydrogen buffer gas to the ambient room temperature of 296 ± 2 K prior to entering the reaction region. The plasma was generated with ionizing electrons having energies in the range 35–70 eV. The filament emission of the electron gun was maintained at a fixed

[a]Rate constants and their estimated accuracies are given in units of $10^{-9}$ cm$^3$ molecule$^{-1}$ s$^{-1}$.

value in the range 0.5 to 1.5 mA. The ions present in the plasma were sampled through a small orifice mounted at the tip of a nose cone situated at the end of the reaction region and mass analysed with a quadrupole mass spectrometer. The observed variation in the ion signals as a function of neutral reagent addition provided the raw data from which the rate and equilibrium constants were determined. As has been the case in our previous studies, the buffer, source, and reagent gases or vapours were all of high purity.

Methoxide ions were generated by passing $CH_3OH$ into a He or $H_2$ buffer gas upstream of the filament at total pressures of ca. 0.4 Torr. The ions were solvated by reactions of type [3].

[3] $$CH_3O^-.(CH_3OH)_n + CH_3OH + He(H_2) \rightarrow CH_3O^-.(CH_3OH)_{n+1} + He(H_2)$$

The partial pressure of methanol was varied from ca. 0.005 to 2 mTorr in order to change the initial relative population of the cluster ions $CH_3O^-.(CH_3OH)_n$; $n$ was observed to take on values between 0 and 3 at the operating conditions of the experiments reported here. In deriving rate constants from the observed decays of $CH_3O^-.(CH_3OH)_n$, account was taken of the initial decay which could arise due to the depletion of the precursor ion $CH_3O^-.(CH_3OH)_{n-1}$. The magnitude of this depletion could be assessed in those studies in which the daughter ion $CH_3O^-.(CH_3OH)_n$ did not react with the added neutral reagent.

## Results

The rate and equilibrium constants measured in this study for acid–base reactions of types [1] and [2] are summarized in Tables 1 and 2. The sources of uncertainty have been described previously (3, 4). The following section provides a more detailed account of the measurements. They are presented in order of increasing acidity of the reagent acid.

### $H_2CCCH_2$

$CH_3O^-$ was established in both He and $H_2$ carrier gases at low methanol flows and moderately low pressures to avoid significant depletion of $CH_3O^-$ by clustering. Under these conditions the dominant source and sink of $CH_3O^-$ in the reaction region upon the addition of allene was the reversible reaction:

[4] $$CH_3O^- + H_2CCCH_2 \rightleftharpoons H_2CCCH^- + CH_3OH$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

We have reported elsewhere that the deprotonation of allene in this fashion is expected to establish the allenyl anion without subsequent 1,3-hydrogen migration to form the isomeric $CH_3—C{\equiv}C^-$ structure (5). A minor product (< 1%) of unknown origin was observed at $m/e = 38 (C_3H_2^-?)$ but it was sufficiently small to be ignored in the equilibrium analysis. The experiments provided values for $k_4 = (8.7 \pm 3.5) \times 10^{-10}$ cm$^3$ molecule$^{-1}$ s$^{-1}$, $k_4/k_{-4} = 1.36 \pm 0.41$ and $K_4 = 1.40 \pm 0.42$. The $CH_3O^-.CH_3OH$ in the reaction region did not react with allene, $k \leq 1 \times 10^{-12}$ cm$^3$ molecule$^{-1}$ s$^{-1}$. An extended analysis of the data confirmed that its presence did not prevent the determination of a reliable value for the true equilibrium constant of reaction [4]. Doubly and triply solvated methoxide ions were established at higher flows of methanol and these also did not react with allene.

One investigation was carried out in an attempt to determine the equilibrium constant for reaction [4] from the reverse direction. The $H_2CCCH^-$ ions were produced by proton transfer to $OH^-$ prior to the reaction region. At low additions of methanol the $CH_3O^-$ signal was observed to increase rapidly with an accompanying decline in the $H_2CCCH^-$ signal, indicating that proton transfer to $H_2CCCH^-$ from methanol is rapid and the major loss process for $H_2CCCH^-$ in the reaction region. The $CH_3O^-$ was observed to decline at large additions of methanol as a result of clustering. It was possible to fit the variations in the $H_2CCCH^-$ and $CH_3O^-$ signals using an extended analysis by incorporating the value for $k_4/k_{-4} = 1.36$ obtained from the forward study and a value of $k = 9.3 \times 10^{-27}$ cm$^6$ molecule$^{-2}$ s$^{-1}$ for the three-body rate constant of clustering determined from the decay of the $CH_3O^-$ signal at large methanol additions. This result provides additional confidence in the value of the equilibrium constant determined from the study in the forward direction.

The proton-transfer equilibrium

[5] $H_2CCCH^- + C_2H_2 \rightleftharpoons C_2H^- + H_2CCCH_2$

was investigated with the addition of acetylene into a He (or $H_2$) – $H_2CCCH_2$ – $H_2O$ plasma in which $H_2CCCH^-$ is produced initially by proton transfer from allene to $OH^-$ or directly by electron impact on allene. Small but negligible amounts of an ion at $m/e = 38$ were again observed to be produced. Analysis of the observed decay of the $H_2CCCH^-$ ion provided values for $k_5 = (7.0 \pm 1.8) \times 10^{-10}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ and $k_5/k_{-5} = (2.1 \pm 0.6) \times 10^3$. The ion signal ratio plots at high additions of $C_2H_2$ provided a value for $K_5 = (2.3 \pm 0.8) \times 10^3$. The flow of allene was varied from $2.17 \times 10^{17}$ to $2.4 \times 10^{19}$ molecules s$^{-1}$. No attempt was made to investigate this equilibrium from the reverse direction due to the large value of the equilibrium constant.

### $CH_3CCH$

Figure 1 shows the variation of the dominant negative ions resulting from the addition of propyne into a He–$CH_3OH$ plasma in which $CH_3O^-$ is initially a dominant negative ion. $C_3H_3^-$ is rapidly produced by the reaction

[6] $CH_3O^- + CH_3CCH \rightarrow C_3H_3^- + CH_3OH$

and it reacts further with propyne to produce $C_2H^-$, presumably by the nucleophilic-displacement reaction:

[7] $C_3H_3^- + CH_3CCH \rightarrow C_2H^- + C_4H_6$

Some production of $C_2H^-$ from the direct displacement by $CH_3O^-$ could not be excluded. The impurity ion $Cl^-$ and the cluster ion $CH_3O^-.CH_3OH$ are seen to be insensitive to the addition of propyne.

The deprotonation of propyne in reaction [6] may proceed either at the methyl or acetylenyl positions. The former will lead to an anion which rearranges to the allenyl anion (5):

[8] $^-CH_2—C{\equiv}CH \rightarrow CH_2{=}C{=}CH^-$

Further rearrangement to the more stable $CH_3—C{\equiv}C^-$ anion by 1,3-hydrogen migration involves a large activation barrier (6). Separate measurements have shown that deprotonation of propyne by $OH^-$ occurs predominantly at the methyl position so that most of the $C_3H_3^-$ produced in reaction [6] can be expected to be of the allenyl form. This implies that the reaction which introduces the observed curvature in the decay of $CH_3O^-$ is likely to be:

[9] $C_3H_3^- + CH_3OH \rightarrow CH_3O^- + CH_2{=}C{=}CH_2$

rather than the true reverse to reaction [6] which would regenerate propyne.

Reaction [7] was investigated separately in experiments in which $C_3H_3^-$ was produced from either allene or propyne by deprotonation with $OH^-$ (5). The measured rate constant was observed to be insensitive to the history of $C_3H_3^-$ and to have a value of $(8.0 \pm 2.0) \times 10^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$.

### $C_6H_5CH_3$

The study of reaction [10] was straightforward.

[10] $CH_3O^- + C_6H_5CH_3 \rightleftharpoons C_6H_5CH_2^- + CH_3OH$

Proton transfer was the only observed product channel proceeding with a rate constant of $(1.5 \pm 0.5) \times 10^{-9}$ cm$^3$ molecule$^{-1}$ s$^{-1}$. The cluster ion $CH_3O^-.CH_3OH$ was observed not to react rapidly with toluene, $k \leq 10^{-12}$ cm$^3$ molecule$^{-1}$ s$^{-1}$. No

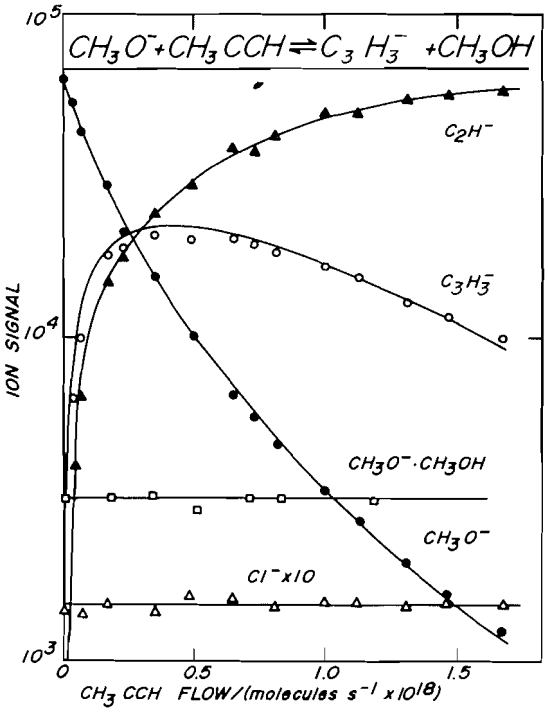

FIG. 1. The variation in dominant negative ions observed upon the addition of propyne into a He–$CH_3OH$ plasma in which $CH_3O^-$ is initially a dominant negative ion. $T = 296$ K, $P = 0.354$ Torr, $\bar{v} = 7.7 \times 10^3$ cm $s^{-1}$, $L = 59$ cm, and the $CH_3OH$ flow is $2.0 \times 10^{17}$ molecules $s^{-1}$.

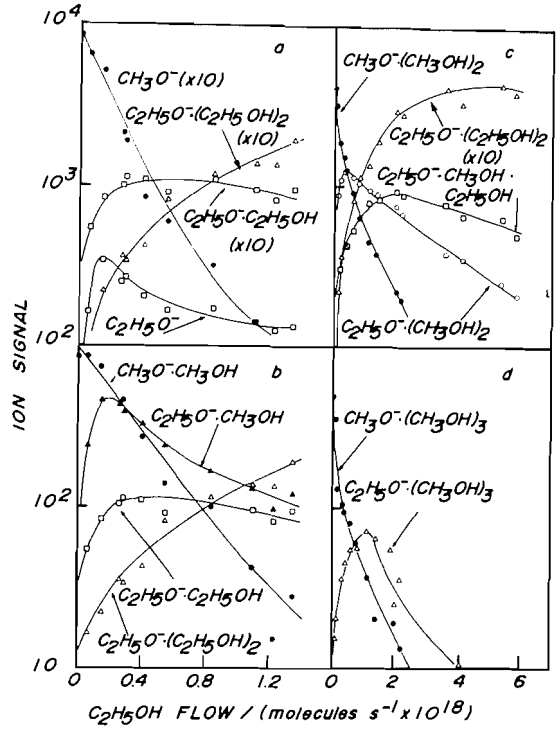

FIG. 2. A split view of observations recorded for the reactions of $CH_3O^-.(CH_3OH)_n$ with ethanol. The buffer gas is He. $T = 295$ K, $P = 0.333$ Torr, $\bar{v} = 8.1 \times 10^3$ cm $s^{-1}$, $L = 46$ cm, and the methanol flow is approximately $6 \times 10^{19}$ molecules $s^{-1}$.

evidence was found for competing and/or secondary reactions involving $C_6H_5CH_2^-$. Analysis of the observed $CH_3O^-$ decays under conditions approaching equilibrium provided a value for $k_{10}/k_{-10} = 1.4 \pm 0.5$ which is in exact agreement with the value for $K_{10} = 1.4 \pm 0.5$ obtained from ratio plot analyses under equilibrium conditions. Equilibrium was also approached from the reverse direction for which $C_6H_5CH_2^-$ was produced from the proton transfer between $OH^-$ and toluene. The decay of this ion at low methanol flows provided a value for $k_{10}/k_{-10} = 1.3 \pm 0.6$ while the equilibrium ion ratio led to a value for $K_{10} = 1.2 \pm 0.5$.

*$C_2H_5OH$*

The decays in the ion signals corresponding to $CH_3O^-$ and the solvated ions $CH_3O^-.CH_3OH$, $CH_3O^-.(CH_3OH)_2$, and $CH_3O^-.(CH_3OH)_3$ observed upon the addition of ethanol into a He–$CH_3OH$ plasma are shown in Fig. 2. Analysis of the data indicated that all of these ions react rapidly with ethanol in solvated acid–base reactions of type [11] with rate constants of $(3.3 \pm 1.0)$, $(2.9 \pm 1.0)$, $(1.2 \pm 0.4)$, and $(>0.2) \times 10^{-9}$ $cm^3$ $molecule^{-1}$ $s^{-1}$, respectively. The product ions $C_2H_5O^-.(CH_3OH)_n$ at $n = 0$ to 3 were observed to rise and then fall in concentration indicating further rapid reactions with ethanol. Evidently solvent exchange or "switching" reactions of type [12] were occurring. Both $C_2H_5O^-.C_2H_5OH$ and $C_2H_5O^-.CH_3OH.C_2H_5OH$ were observed to rise concomitant to the fall of the corresponding $C_2H_5O^-.(CH_3OH)_n$ species. $C_2H_5O^-.CH_3OH.C_2H_5OH$ was observed to displace still another methanol molecule according to reaction [13].

[11] $CH_3O^-.(CH_3OH)_n + C_2H_5OH \rightarrow C_2H_5O^-.(CH_3OH)_n + CH_3OH$

[12] $C_2H_5O^-.(CH_3OH)_n + C_2H_5OH \rightarrow C_2H_5O^-.(CH_3OH)_{n-1}.C_2H_5OH + CH_3OH$

[13] $C_2H_5O^-.CH_3OH.C_2H_5OH + C_2H_5OH \rightarrow C_2H_5O^-.(C_2H_5OH)_2 + CH_3OH$

Finally, the profiles in Fig. 2 also provide evidence for the occurrence of ethanol addition reactions of type [14] for $n = 0$ and 1. Taken together, the solvated proton-transfer reactions of type [11] appear to indicate sequences of solvent switching

[14] $C_2H_5O^-.(C_2H_5OH)_n + C_2H_5OH + He \rightarrow C_2H_5O^-.(C_2H_5OH)_{n+1} + He$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

and solvent addition reactions which combine to ultimately establish the ethoxide ion solvated exclusively by ethanol.

While the unsolvated proton-transfer reaction between $CH_3O^-$ and $C_2H_5OH$ did not appear to attain equilibrium under our operating conditions, an analysis of the dependence on ethanol flow of the solvated product to reactant ion ratios for reactions of type [11] for $n = 1$, 2, and 3 did indicate regimes of methanol and ethanol flow for which equilibrium appeared to be established. Figure 3 shows the attainment of equilibrium for the solvated proton-transfer reaction [15] as well as the

[15] $CH_3O^-.CH_3OH + C_2H_5OH \rightleftharpoons C_2H_5O^-.CH_3OH + CH_3OH$

ensuing solvent-switching reaction [16]. The linearity observed in the ion ratio plots for these

[16] $C_2H_5O^-.CH_3OH + C_2H_5OH \rightleftharpoons C_2H_5O^-.C_2H_5OH + CH_3OH$

two reactions provided values for $K$ of 7.6 ± 2.7 and 2.0 ± 1.0, respectively. For the higher solvated proton-transfer reactions of type [11] with $n = 2$ and 3, an analysis of the data indicated values for the equilibrium constants of approximately 4 and 1, respectively.

An unsuccessful attempt was made to approach equilibrium for the unsolvated proton-transfer reaction from its reverse direction by adding methanol into a He–$C_2H_5OH$ plasma in which $C_2H_5O^-$ was initially a dominant negative ion. However, equilibrium was again observed to be established for reactions [15] and [16]. The equilibrium constants deduced from the corresponding ratio plots were in good agreement with those derived from the forward study having values of 7.8 ± 3.9 and 2.5 ± 0.9, respectively.

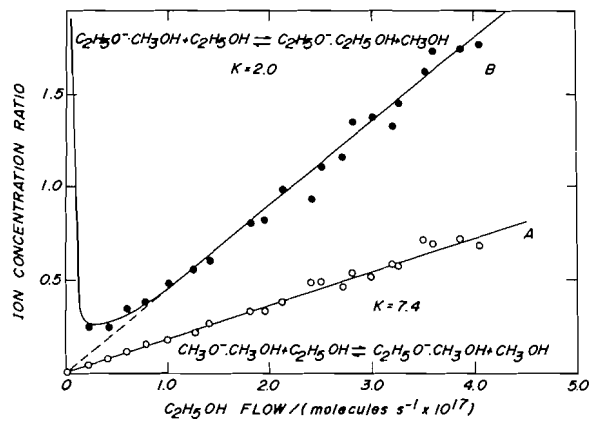

FIG. 3. The variation in ion concentration ratios observed upon the addition of ethanol into a He–$CH_3OH$ plasma. $T$ = 295 K, $P$ = 0.354 Torr, $\bar{v} = 8.4 \times 10^3$ cm $s^{-1}$, $L$ = 85 cm, and the flow of methanol is $4.09 \times 10^{17}$ molecules $s^{-1}$. Curve $A$: the ion concentration ratio $[C_2H_5O^-.CH_3OH]/[CH_3O^-.CH_3OH]$ divided by 10. Curve $B$: the ion concentration ratio $[C_2H_5O^-.C_2H_5OH]/[C_2H_5O^-.CH_3OH]$. The initial curvature arises from the production of $C_2H_5O^-.CH_3OH$ in the reaction region.

## $C_2H_2$

We have observed the proton-transfer reaction of $CH_3O^-$ with acetylene previously; it proceeded rapidly with a rate constant of $(1.6 \pm 0.4) \times 10^{-9}$ $cm^3$ $molecule^{-1}$ $s^{-1}$ (7) which was reproduced in the present studies. At the methanol flows used in the present experiments sufficient back reaction was introduced to allow the evaluation of the equilibrium constant for reaction [17] both from the ratios of ion and neutral concentrations at

[17] $CH_3O^- + C_2H_2 \rightleftharpoons C_2H^- + CH_3OH$

equilibrium and from the ratio of rate constants derived from the decay of $CH_3O^-$ and they were in good agreement. The values obtained were $(2.6 \pm 1.2) \times 10^3$ and $(2.7 \pm 1.1) \times 10^3$, respectively. Figure 4 shows data which provide a measure of the ratio of rate constants. The solvated species

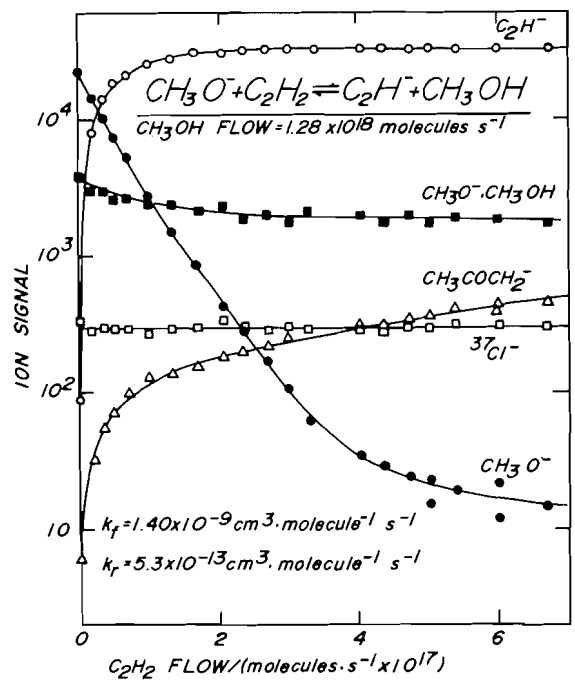

FIG. 4. The variation in dominant negative ions recorded upon the addition of acetylene into a He–$CH_3OH$ plasma in which $CH_3O^-$ is initially a dominant negative ion. The solid line through the $CH_3O^-$ decay represents a computer fit to the data with the values of the rate constants indicated. The initial decay in the $CH_3O^-.CH_3OH$ arises from the depletion of the $CH_3O^-$ source ion. $T$ = 298 K, $P$ = 0.317 Torr, $\bar{v} = 7.7 \times 10^3$ cm $s^{-1}$, and $L$ = 84 cm.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

$CH_3O^-.CH_3OH$ which was also observed to be present in the reaction region, failed to react with a measurable rate, $k \leq 1 \times 10^{-12}$ cm$^3$ molecule$^{-1}$ s$^{-1}$.

The reaction of the ethoxide anion

[18] $C_2H_5O^- + C_2H_2 \rightleftharpoons C_2H^- + C_2H_5OH$

could also be driven into equilibrium under quite similar operating conditions. Again there was good agreement between the ratio of rate constants, $k_{18}/k_{-18} = 17.0 \pm 6.8$ and the equilibrium constant derived from equilibrium concentrations, $K_{18} = 16.4 \pm 6.6$. The forward rate constant was determined to be $(1.4 \pm 0.4) \times 10^{-9}$ cm$^3$ molecule$^{-1}$ s$^{-1}$. One experiment was carried out in which $C_2H^-$ was produced in a $He/CH_4$ plasma in the absence of $C_2H_2$. The rate constant for the reverse reaction, $k_{-18} = 1.0 \times 10^{-10}$ cm$^3$ molecule$^{-1}$ s$^{-1}$, could then be evaluated directly from the slope of the $C_2H^-$ decay using Analysis A (3). This value, when coupled with the rate constant obtained from the forward study, provided a value for $k_{18}/k_{-18} = 14 \pm 8$. The cluster ion $C_2H_5O^-.C_2H_5OH$ became the dominant primary ion in the reaction region already at relatively low flows, $2 \times 10^{17}$ molecules s$^{-1}$. It was also observed not to react with $C_2H_2$, $k \leq 1 \times 10^{-12}$ cm$^3$ molecule$^{-1}$ s$^{-1}$.

With $(CH_3)_2CHO^-$ equilibrium was established already at the smallest measurable additions of $C_2H_2$. This precluded the determination of unique values for the forward and reverse rate constants for reaction [19].

[19] $(CH_3)_2CHO^- + C_2H_2 \rightleftharpoons C_2H^- + (CH_3)_2CHOH$

The measurements did, however, provide values for the ratio of rate constants $k_{19}/k_{-19} = 1.16 \pm 0.41$ and the equilibrium constant derived from equilibrium concentrations $K_{19} = 1.13 \pm 0.45$.

*$CH_3CN$*

We have reported previously that reaction [20]

[20] $CH_3O^- + CH_3CN \rightarrow CH_2CN^- + CH_3OH$

proceeds very rapidly with a rate constant at room temperature of $(3.5 \pm 0.9) \times 10^{-9}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ without any significant displacement to form $CN^-$ (8). Furthermore, the reaction could not be driven to equilibrium under our operating conditions. Consequently attempts were made to establish equilibrium for the less exoergic proton-transfer reaction [21]. Both He and $H_2$ were used as

[21] $C_2H^- + CH_3CN \rightleftharpoons CH_2CN^- + C_2H_2$

buffer gases and the $C_2H^-$ was produced either by electron impact on acetylene at ca. 40 eV or via the rapid proton transfer from $C_2H_2$ to $OH^-$ (9). Figure 5 shows a representative variation of dominant negative ions recorded upon the addition of

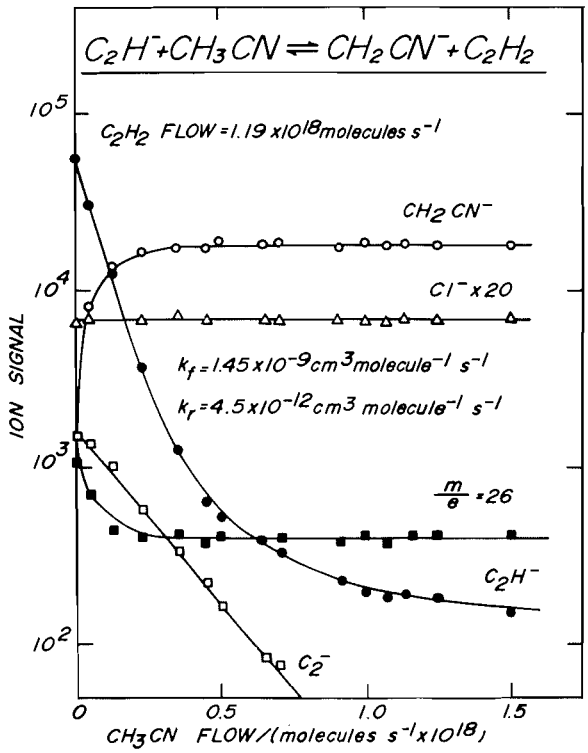

FIG. 5. The variation in dominant negative ions recorded upon the addition of $CH_3CN$ into a $He-C_2H_2$ plasma in which $C_2H^-$ is initially a dominant negative ion. The solid line through the $C_2H^-$ decay is a computer fit with the values of the rate constants indicated. $T = 295$ K, $P = 0.365$ Torr, $\bar{v} = 8.3 \times 10^3$ cm s$^{-1}$, and $L = 60$ cm.

acetonitrile into a $He-C_2H_2$ plasma in which $C_2H^-$ was initially a major ion. The majority of the $C_2H^-$ decay and accompanying increase in the $CH_2CN^-$ signal can be attributed to the proton-transfer reaction [21]. The initial decay in the mass 26 signal is due to the reaction of the $^{13}C^{12}CH^-$ isotope. The failure of the mass 26 ion signal to rise sets an upper limit of 0.5% to the production of $CN^-$ by nucleophilic displacement. The mass discrimination plots in all experiments exhibited excellent linearity over a range in $CH_3CN$ flow which was varied by over a factor of 200 and the mass discrimination factor was found to be independent of the $CH_3CN$ concentration and reaction length which had values of 59 and 85 cm. The application of our standard analyses to the curved $C_2H^-$ decays and the ratio plots led to values for the ratio of rate constants and the equilibrium constant, respectively, which agreed within the uncertainty of the measurements: $k_{21} = (1.5 \pm 0.4) \times 10^{-9}$ and $k_{-21} = (4.8 \pm 1.7) \times 10^{-12}$ cm$^3$ molecule$^{-1}$ s$^{-1}$, $k_{21}/k_{-21} = (3.1 \pm 0.9) \times 10^2$, and $K_{21} = (3.0 \pm 1.2) \times 10^2$. The weighted mean of the values for $k_{21}/k_{-21}$ and $K_{21}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

provides a best estimate of the true value for the equilibrium constant of $3.0 \times 10^2$ with a standard error of $\pm 0.7 \times 10^2$ for reaction [21].

The solvated cluster ions $CH_3O^-.(CH_3OH)_n$ with $n = 1$, 2, and 3 were observed not to react rapidly with $CH_3CN$, $k \leq 2 \times 10^{-12}$ cm$^3$ molecule$^{-1}$ s$^{-1}$. Apparently a reversal in the relative acidity of $CH_3OH$ and $CH_3CN$ occurs already at the addition of one solvent methanol molecule.

*$CH_3COCH_3$*

Figure 6 shows data which reveal the transition in kinetics with the stepwise solvation of $CH_3O^-$ with methanol in reactions of type [22].

[22] $CH_3O^-.(CH_3OH)_n + CH_3COCH_3 \rightarrow CH_3COCH_2^-.(CH_3OH)_n + CH_3OH$

The unsolvated methoxide ion reacts rapidly with a rate constant determined to be $(2.3 \pm 0.6) \times 10^{-9}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ but does not approach equilibrium. However, equilibrium was nearly achieved for the reaction of the singly solvated ion for which a slightly smaller rate constant of $(1.7 \pm 0.4) \times 10^{-9}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ was obtained, while the doubly and triply solvated species failed to react, $k < 2 \times 10^{-12}$ cm$^3$ molecule$^{-1}$ s$^{-1}$.

Since equilibrium could not be established for the solvent-free reaction of the methoxide ion with acetone, an attempt was made to approach an equilibrium in a proton-transfer reaction with the much less basic anion $CH_2CN^-$. The only product ion formed at low additions of acetone into a He–$CH_3CN$ plasma in which $CH_2CN^-$ was established by proton-transfer from $CH_3CN$ to $OH^-$ was $CH_3COCH_2^-$ so that the decay of $CH_2CN^-$ could be attributed to the proton-transfer reaction [23]. At large acetone additions the cluster-

[23] $CH_2CN^- + CH_3COCH_3 \rightarrow CH_3COCH_2^- + CH_3CN$

ing reaction [24] proceeded towards equilibrium. The product to reactant ion concentration ratio at

[24] $CH_3COCH_2^- + CH_3COCH_3 + He \rightleftharpoons CH_3COCH_2^-.CH_3COCH_3 + He$

equilibrium provided a value of $(1.5 \pm 0.5) \times 10^6$ (standard state = 1 atm) for the equilibrium constant of reaction [24]. A small amount of $CH_2CN^-.CH_3CN$ present initially was rapidly depleted by the solvated proton-transfer reaction [25].

[25] $CH_2CN^-.CH_3CN + CH_3COCH_3 \rightleftharpoons CH_3COCH_2^-.CH_3CN + CH_3CN$

An extended analysis of the data provided only a lower limit to the equilibrium constant for reaction [23] of 500. The initial decay of $CH_2CN^-$ provided a

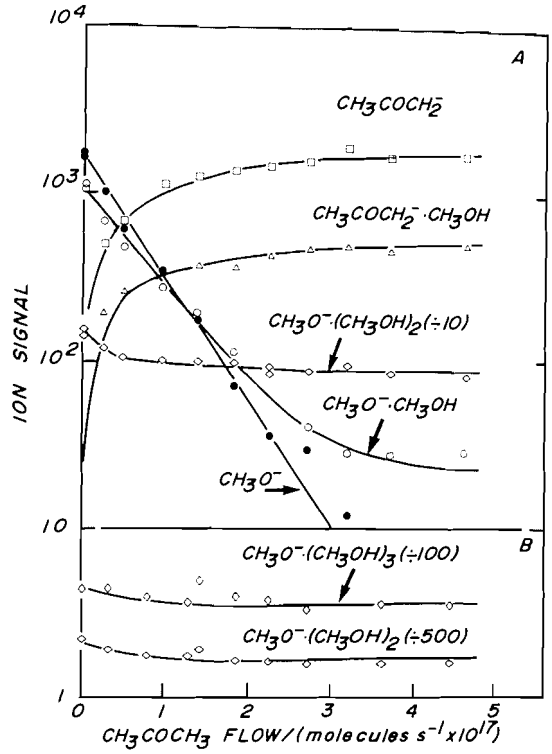

FIG. 6. Observations recorded for the reactions of $CH_3O^-.(CH_3OH)_n$ with acetone in a He buffer at a low flow ($A$: $\sim 5 \times 10^{17}$ molecules s$^{-1}$) and a high flow ($B$: $\sim 2 \times 10^{19}$ molecules s$^{-1}$) of methanol. $T = 295$ K, $P = 0.323$ Torr, $\bar{v} = 8 \times 10^3$ cm s$^{-1}$, and $L = 46$ cm.

forward rate constant for reaction [23] of $(3.0 \pm 0.9) \times 10^{-10}$ cm$^3$ molecule$^{-1}$ s$^{-1}$.

An attempt was also made to establish equilibrium for reaction [23] from the reverse direction. It was evident that $CH_3COCH_2^-$ does not react rapidly with $CH_3CN$ either by proton transfer or by $CN^-$ displacement: no significant increase was observed for the $m/e = 40$ and 26 ion signals. The cluster ion $CH_3COCH_2^-.CH_3CN$ was formed instead by the association reaction [26] for which the ion ratio plot at large flows of $CH_3CN$ indicated an equilibrium constant of $(1.0 \pm 0.5) \times$

[26] $CH_3COCH_2^- + CH_3CN + He \rightleftharpoons CH_3COCH_2^-.CH_3CN + He$

$10^7$ (standard state = 1 atm). Also the solvent-switching reaction [27] appeared to achieve

[27] $CH_3COCH_2^-.CH_3COCH_3 + CH_3CN \rightleftharpoons CH_3COCH_2^-.CH_3CN + CH_3COCH_3$

equilibrium with an equilibrium constant of $4 \pm 3$.

*$CH_3CHO$*

The solvent-free and singly-solvated methoxide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

ion were observed to react rapidly with acetaldehyde with rate constants of (2.0 ± 0.6) and (1.5 ± 0.6) × $10^{-9}$ $cm^3$ $molecule^{-1}$ $s^{-1}$. Both $^-CH_2CHO$ and $^-CH_2CHO.CH_3OH$ were observed as product ions in amounts which balanced the initial $CH_3O^-$ and $CH_3O^-.CH_3OH$ signals, respectively, in accordance with reaction [28].

[28] $CH_3O^-.(CH_3OH)_n + CH_3CHO \rightarrow {}^-CH_2CHO.(CH_3OH)_n + CH_3OH$

The reactions with $n = 2$ and 3 appeared not to proceed rapidly, $k < 1 \times 10^{-11}$ $cm^3$ $molecule^{-1}$ $s^{-1}$, and there was no significant production of $^-CH_2CHO.(CH_3OH)_n$ with $n = 2$ and 3. The $^-CH_2CHO$ reacted further, presumably to form the adduct $^-CH_2CHO.CH_3CHO$ which was observed to appear at larger additions of $CH_3CHO$ into the reaction region. The $^-CH_2CHO.CH_3OH$ appeared to react further by the solvent-switching reaction [29].

[29] $^-CH_2CHO.CH_3OH + CH_3CHO \rightarrow {}^-CH_2CHO.CH_2CHO + CH_3OH$

*$CH_3NO_2$*

The solvent free $CH_3O^-$ and the solvated $CH_3O^-.(CH_3OH)_n$ ions with $n = 1$ to 3 were all observed to react rapidly with nitromethane in reactions of type [30] with rate constants of (3.1 ± 0.8), (2.3 ± 0.7), (1.9 ± 0.6), and (1.3 ± 0.5) × $10^{-9}$

[30] $CH_3O^-.(CH_3OH)_n + CH_3NO_2 \rightarrow CH_2NO_2^-.(CH_3OH)_m + (n - m + 1)CH_3OH$

$cm^3$ $molecule^{-1}$ $s^{-1}$, respectively. We have reported previously a rate constant of (3.2 ± 0.8) × $10^{-9}$ $cm^3$ $molecule^{-1}$ $s^{-1}$ for the solvent-free reaction (10). All of the corresponding solvated product ions were observed to be produced, albeit $CH_2NO_2^-.(CH_3OH)_3$ appeared in only trace amounts. Also the product ion profiles provided evidence for the exchange of solvent in reactions of type [31] for $n = 1$ and 2, and the addition of

[31] $CH_2NO_2^-.(CH_3OH)_n + CH_3NO_2 \rightarrow CH_2NO_2^-.CH_3NO_2 + CH_3OH$

$CH_3NO_2$ to $CH_2NO_2^-$ according to reaction [32]. At the operating conditions of these experiments

[32] $CH_2NO_2^- + CH_3NO_2 + He \rightarrow CH_2NO_2^-.CH_3NO_2 + He$

there was no indication of the establishment of equilibrium in any of the reactions of type [30].

*HCN*

Figure 7 reveals the influence of methanol solvation on the reaction of methoxide ion with HCN. Rapid reactions of type [33] were observed

[33] $CH_3O^-.(CH_3OH)_n + HCN \rightarrow CN^-.(CH_3OH)_m + (n - m + 1)CH_3OH$

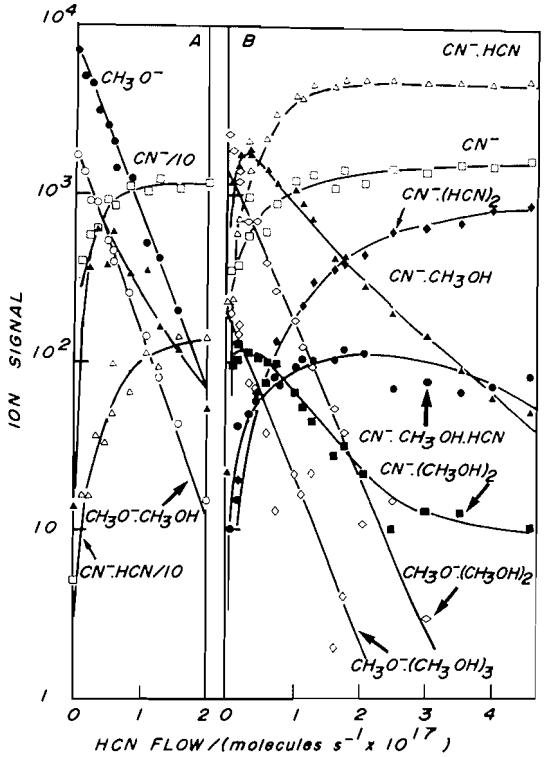

FIG. 7. A split view of observations recorded for the reactions of $CH_3O^-.(CH_3OH)_n$ with hydrogen cyanide at a low flow (*A*: ~1 × $10^{19}$ molecules $s^{-1}$) and a high flow (*B*: ~4 × $10^{19}$ molecules $s^{-1}$) of methanol. The buffer gas is He. $T = 296$ K, $P = 0.343$ Torr, $\bar{v} = 8.1 \times 10^3$ cm $s^{-1}$, and $L = 46$ cm.

for all of the $CH_3O^-.(CH_3OH)_n$ ions with the rate constants for $n = 0$, 1, 2, and 3 having values of (3.3 ± 0.8), (3.2 ± 1.0), (3.1 ± 1.0), and (3.0 ± 1.1) × $10^{-9}$ $cm^3$ $molecule^{-1}$ $s^{-1}$, respectively. The product ion profiles indicated further rapid solvent switching reactions of type [34] for $n = 1$ and 2 for

[34] $CN^-.(CH_3OH)_n + HCN \rightarrow CN^-.(CH_3OH)_{n-1}.HCN + CH_3OH$

which rate constants of (1.5 ± 0.5) and (1.4 ± 0.5) × $10^{-9}$ $cm^3$ $molecule^{-1}$ $s^{-1}$ were deduced. The reaction for $n = 2$ appeared to approach equilibrium (with an equilibrium constant > 1 × $10^3$) and was followed by further solvent exchange according to reaction [35] to completely eliminate $CH_3OH$ from the solvation shell of $CN^-$.

[35] $CN^-.CH_3OH.HCN + HCN \rightarrow CN^-.(HCN)_2 + CH_3OH$

## Discussion

*A. Intrinsic kinetics*

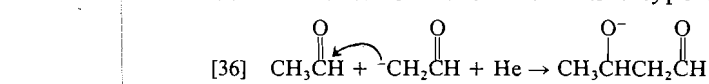
The room-temperature rate constants measured in this study for the reactions of solvent-free methoxide anions and several other unsolvated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

anions are summarized in Table 1. Protonation of the methoxide ion was observed to proceed rapidly in all cases with rate constants exceeding $8 \times 10^{-10}$ $cm^3$ $molecule^{-1}$ $s^{-1}$. The corresponding efficiencies determined from the ratios of the measured rate constant to the collision rate constant calculated using the AADO theory (11) all exceed 60%. The slowest and least efficient (10%) reaction measured was that between $CH_2CN^-$ and acetone which involves the protonation of a charge-delocalized anion.

Few other measurements are available for comparison. A rate constant of $6.58 \times 10^{-10}$ $cm^3$ $molecule^{-1}$ $s^{-1}$, which is about one-half of our room-temperature value, has been reported for the reaction of $CH_3O^-$ with toluene involving reagent ions with a laboratory energy of ca. 0.3 eV in a tandem spectrometer (12). An ion cyclotron resonance (ICR) measurement of the rate constant for this reaction resulted in a value of only $(2.0 \pm 0.2) \times 10^{-10}$ $cm^3$ $molecule^{-1}$ $s^{-1}$ (13) which is about seven times smaller than our value. Better agreement with the ICR results is obtained for the reaction of $CH_3O^-$ with ethanol for which the ICR measurements yielded $(1.2 \pm 0.3) \times 10^{-9}$ $cm^3$ $molecule^{-1}$ $s^{-1}$ (13).

Several new association reactions were identified in this study. Of particular note are reaction [24] and the analogous reaction with acetaldehyde. The clustering reactions may also be written as aldol-type condensations as in reaction [36]. Self-condensation reactions of this type are well



[36] $CH_3\overset{O}{\overset{\|}{C}}H + {}^-CH_2\overset{O}{\overset{\|}{C}}H + He \rightarrow CH_3\overset{O^-}{\overset{|}{C}}HCH_2\overset{O}{\overset{\|}{C}}H + He$

known in solution where they proceed readily in the presence of aqueous base.

### *B. Intrinsic energetics*

#### *Equilibrium constants*

The room-temperature equilibrium constants for the solvent-free proton-transfer reactions measured in this study and which provide the basis of the gas-phase scale of acidities derived below are also included in Table 1. The equilibrium constants for the three reactions of alkoxide ions with $C_2H_2$ supersede those reported a decade ago by Bohme and co-workers (14) in their first attempt to quantify differences in gas-phase acidities of organic compounds. These earlier flowing afterglow measurements, which relied on an inferior method for the measurement of concentrations of alcohol vapours, provided equilibrium constants of $3 \times 10$, $1 \times 10$, and 1 for the reactions of $CH_3O^-$, $C_2H_5O^-$, and $(CH_3)_2CHO^-$, respectively. They are to be compared with the current values of $(2.7 \pm 0.7) \times 10^3$, $17 \pm 4$, and $1.2 \pm 0.3$. With the exception of the results for the $CH_3O^-$ reaction, the agreement is within the experimental uncertainties of the two sets of measurements. The early results (15) for the reactions of $CH_3O^-$ with the allene and toluene, which provided limiting values for $K$ of $\lesssim 0.5$ and $\lesssim 1$ respectively, are also superseded by the present measurements, which yielded a value for $K$ of $1.4 \pm 0.3$ for both of these reactions.

Table 3 provides a comparison of our present and some earlier flowing afterglow results with those obtained by McIver and his colleagues with the pulsed-ICR mass spectrometer which operates at considerably different conditions of total pressure and reagent ion history, and a neutral gas and ion temperature which has been estimated to be 320 K (16). The agreement with the most recent ICR results reduced to apply at a temperature of 298 K (16) is within a factor of 2 in the majority of cases.

#### *Absolute and relative gas-phase acidities*

Bartmess and co-workers have recommended an absolute gas-phase acidity for methanol of 372.6 kcal $mol^{-1}$ (16) based on a standard enthalpy change and standard entropy change for the deprotonation of methanol of 379.2 kcal $mol^{-1}$ and 22.0 cal $mol^{-1}$ $K^{-1}$, respectively. In the same paper these authors have shown that the standard enthalpy change which can be derived from the best available values for $EA(CH_3O)$, $D(CH_3O—H)$, and IP(H) has an average value of 381.2 kcal $mol^{-1}$. We have adopted this latter value for the standard enthalpy change and recommend an absolute gas-phase acidity for methanol of $374.6 \pm 2$ kcal $mol^{-1}$. This value has been used as a reference for the assignment of the absolute gas-phase acidities indicated in Table 4 which also includes the differences in gas-phase acidity determined from the equilibrium constants measured with the flowing afterglow technique.

### *C. Influence of solvation on intrinsic kinetics and energetics*

Under our experimental operating conditions methanol solvent is added as a vapour in trace amounts (< 1%) to a flowing plasma of helium or hydrogen at low total presures (ca. 0.3 Torr). The reagent base, $B^- = CH_3O^-$, is produced by the ionization of methanol and allowed to build up a solvation shell upstream by successive methanol addition reactions to form ions of the type $CH_3O^-.(CH_3OH)_n$. These solvated ions then participate in reactions with the added acid, AH, as they enter the reaction region downstream. An ensuing solvated proton-transfer reaction of type

[e]Reference 19.
[f]Reference 20.

TABLE 4. Relative and absolute gas-phase acidities at 298 K, ΔGA and GA(AH) in kcal mol$^{-1}$, based on flowing afterglow measurements. The values in parentheses are those recommended by Bartmess, Scott, and McIver on the basis of pulsed-ICR mass spectrometer measurements (16)

| GA(AH) | AH | ΔGA |
|---|---|---|
| (345.8) | HCN | |
| | | 1.6±0.1 (1.3) |
| (347.1) | $H_2S$ | |
| (352.0) | $CH_3NO_2$ | |
| | | 0.4±0.1 (0.7) |
| (352.7) | $CH_3SH$ | |
| ≤362.8 (361.6) | $CH_3COCH_3$ | |
| | | >3.7 (2.8) |
| 366.5 (364.4) | $CH_3CN$ | |
| | | 3.4±0.2 (2.8) |
| 369.9 (367.2) | $C_2H_2$ | |
| | | 0.11±0.15 (0.3) |
| 370.0 (367.5) | $(CH_3)_2CHO$ | |
| | | 1.7±0.2 (2.3) |
| 371.6 (369.5) | $C_2H_5OH$ | |
| | | 4.5±0.2 (5.1) |
| 374.4 (372.3) | $C_6H_5CH_3$, $CH_2{=}C{=}CH_2$ | |
| | | 0.20±0.13 (0.3) |
| 374.6 (372.6) | $CH_3OH$ | |
| | | 4.7±0.2 (5.4) |

[2] may then establish the newly solvated species $A^-.(CH_3OH)_n$. In the time available in the reaction region these species in turn may optimize their stability by exchanging the methanol molecules in the solvation shell for the acid molecules, AH, or simply by adding the latter. Figure 8 shows a general scheme of the sequential solvated-ion chemistry which is implied by our measurements.

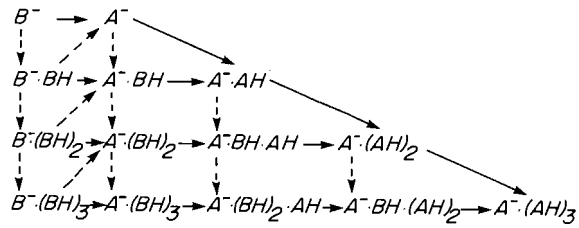

FIG. 8. A general scheme representative of the possible solvated ion chemistry proceeding under flowing afterglow conditions. The solid horizontal arrows represent solvated acid–base or solvent exchange reactions with AH. The solid diagonal arrows represent solvent addition reactions with AH. The dashed vertical arrows represent possible solvent addition reactions with BH. The dashed diagonol arrows represent possible solvated acid–base reactions with a concomitant "boiling off" of solvent BH.

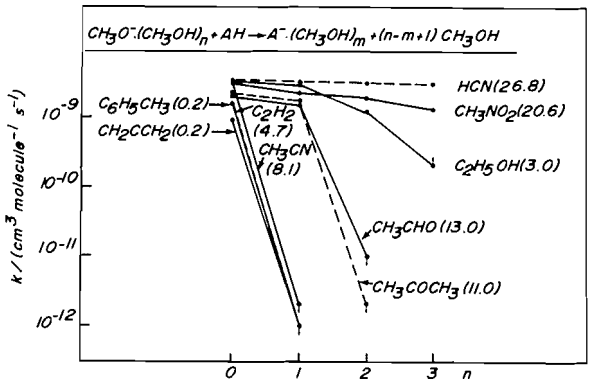

FIG. 9. Observed variations in the rate constants for the reactions of solvated methoxide ions with acids AH as a function of step-wise solvation. The values indicated in parentheses correspond to the relative intrinsic acidities of the acids AH and $CH_3OH$, i.e. $-\Delta G^0$ (in kcal $mol^{-1}$) for the solvent-free reactions at 298 K.

The chemical sequence indicated may be interrupted at any level of solvation depending on the nature of the added acid.

The rate constants obtained for the solvated proton-transfer reactions of the species $CH_3O^-.(CH_3OH)_2$ with the acids added in this study are summarized in Table 2 and presented graphically in Fig. 9. Solvation of $CH_3O^-$ is seen to lead to two extreme types of behaviour: (*a*) The addition of only one methanol molecule to the methoxide ion essentially closes the reactions of this ion with allene, toluene, acetylene, and methylcyanide. The rate constant is observed to drop dramatically by more than a factor of $\sim 10^3$ from an initial value of ca. $10^{-9}$ $cm^3$ $molecule^{-1}$ $s^{-1}$. (*b*) For the reactions of ethanol, nitromethane, and hydrogen cyanide the addition of three molecules of methanol does not reduce the rate by more than a factor of $\sim 10$. The reactions with acetone and acetaldehyde show an intermediate behaviour in that the sharp drop in rate is delayed until the addition of two molecules of methanol to the methoxide ion.

The remarkable divergence of the rate constants observed in this study can be accounted for by a consideration of the degree of stabilization of the reactant and product ions by solvation and their influence on overall reaction energetics. The rate of proton transfer can be expected to remain high upon solvation if the reaction remains exoergic. Conversely, a sharp drop in the rate can be anticipated if solvation renders the reaction endoergic. The solvent-free reactions are all exoergic: they span a range in $-\Delta G^0$, i.e. relative intrinsic acidity, from 0.2 to 26.8 kcal $mol^{-1}$. The free energy of solvation of $CH_3O^-$, which can be deduced to be approximately 17 kcal $mol^{-1}$ for the addition of the first methanol molecule (1), will act to decrease the reaction exoergicities and can lead to changes in the sign of $\Delta G^0$, i.e. reversals in relative acidity, and therefore reversals in the preferred direction of reaction unless it is offset by the solvation energy of the conjugate base produced. In other words, exoergicity will be preserved if the free energy of solvation of the conjugate base produced is comparable to or greater than the corresponding free energy of solvation of $CH_3O^-$ or if a lower free energy of solvation of the product base is offset by the exoergicity of the unsolvated reaction.

The carbanions produced by the deprotonation of allene and toluene, the two acids in this study with an intrinsic acidity almost identical to that of methanol, are expected to have free energies of solvation insufficient to compensate for the high solvation energy of $CH_3O^-$. The sharp drop in the rate of deprotonation observed upon the addition of just one molecule of solvent can therefore be interpreted as a manifestation of a reversal in the relative acidity of these two carbon acids and methanol. A similar situation seems to apply to the formation of $C_2H^-.CH_3OH$ and $CH_2CN^-.CH_3OH$ although the solvent-free reactions are somewhat more exoergic. Again a reversal in relative acidity appears to result after the addition of just one methanol molecule.

For the deprotonation of acetone and acetaldehyde by $CH_3O^-$ reversals also appear to occur but they are delayed by one additional molecule of solvent: the sharp decline in rate occurs at $n = 2$. In these cases the exoergicities of the solvent-free reactions are within 6 kcal $mol^{-1}$ of compensating for the high free energy of solvation of $CH_3O^-$. Also some of the negative charge on the anions produced from these two carbon acids is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

transferred to the oxygen which may result in some enhancement in the stability of the solvated species.

No reversals are observed for the deprotonation of nitromethane, hydrogen cyanide, and ethanol: reaction [2] remains rapid up to the addition of three methanol molecules to $CH_3O^-$. The intrinsic acidity of ethanol, an oxygen acid, is relatively close to that of methanol but in this case the order of acidity is preserved by the strong solvation of $C_2H_5O^-$. The intrinsic acidities of nitromethane and hydrogen cyanide are sufficiently high to offset the weaker anion–methanol interactions expected for $CH_2NO_2^-$ and $CN^-$. In fact, reactions of type [37] for AH = HCN or $CH_3NO_2$ in which some of

$$[37]\quad CH_3O^-.(CH_3OH)_n + AH \rightarrow A^-.(CH_3OH)_m + (n - m + 1)CH_3OH$$

the methanol is "boiled off" are exoergic at least for $n = 1$ and $m = 0$. Indeed the product spectra observed for these two reactions appear to be "shifted" in favour of lower degrees of solvation of $A^-$.

The clear pattern which has emerged from the trends in the rates of the acid–base reactions of the solvated methoxide ions which have been determined in this study and their dependence on the overall energetics of reaction is likely to be representative of the transition from the gas-phase to the solution in the rates of exothermic acid–base reactions generally and provides a vivid confirmation of expectations based on solution measurements.

# Theoretical prediction of protein antigenic determinants from amino acid sequences

SERAFIN FRAGA
*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T2G 2G2*
Received April 21, 1982

SERAFIN FRAGA. Can. J. Chem. **60**, 2606 (1982).

The locations of the antigenic determinants in a protein are predicted from its amino acid sequence by a modified Hopp–Woods method, proposed in this work, using both hydrophilicity and recognition factors. The amino acid – amino acid interaction energies, from which the recognition factors have been defined, have been evaluated by a semiempirical method, developed at this laboratory, using $1/R$ expansions parameterized on the basis of the results from accurate SCF calculations. The present procedure, which eliminates most of the uncertainties in the original Hopp–Woods method, leads to a very satisfactory prediction of the antigenic determinants.

SERAFIN FRAGA. Can. J. Chem. **60**, 2606 (1982).

On peut prévoir les sites des déterminants antigéniques d'une protéine à partir de la séquence d'acides aminés en faisant appel à une méthode modifiée de Hopp–Woods proposée dans ce travail et qui utilise à la fois l'hydrophilicité et les facteurs de reconnaissance. Utilisant une méthode semi-empirique mise au point dans ce laboratoire, qui fait appel aux expansions $1/R$ et en se basant sur les résultats obtenus à partir de calculs de champs auto-cohérants précis, on a évalué les énergies d'interaction entre acides aminés à partir desquelles on a défini les facteurs de reconnaissance. Le procédé actuel, qui élimine la plupart des incertitudes de la méthode originale de Hopp–Woods, conduit à une prévision très satisfaisante des déterminants antigéniques.
[Traduit par le journal]

## Introduction

The experimental prediction of protein antigenic determinants may be carried out either by synthesis of peptidic fragments (to be tested later for immunological activity) or by study of the influence of amino acid substitution in homologous series of proteins. Unfortunately both methods are time-consuming and difficult and therefore it is of considerable interest to develop a theoretical procedure for such a prediction, in which case the experimental work could be greatly reduced.

Hopp and Woods (1) have recently proposed one such method, based on a possible correlation with the hydrophilicity of the amino acids. This method, which only requires a knowledge of the amino acid sequence, leads always to the correct prediction of at least one antigenic determinant.

The reason, however, that this method may fail, usually predicting too large a number of regions with antigenic activity, may be found in the fact that the hydrophilicity, although an important factor, is probably not the only one. In particular, it would seem that the interaction between amino acids might also play a certain role.

The purpose of this work is then to investigate the possibility of modifying the Hopp–Woods method by consideration of the amino acid interactions.

## Preliminary work

The information required for the method proposed in this work consists of the amino acid sequence for the protein under study, the hydrophilicity factors for the individual amino acids, and the recognition factors corresponding to the interaction between individual amino acids.

The amino acid sequence for the protein under study will be available from experimental work and the hydrophilicity factors to be used are those of Levitt (2), as modified by Hopp and Woods (1).

The energies for the interaction between amino acids have been evaluated for this work using a recent formulation developed at this laboratory (3), based on $1/R$ expansions parameterized on the basis of the results of accurate self-consistent field calculations. The actual calculations involve a search of the minima in the configuration space by a steepest-descent procedure.

The calculations have been carried out for all the amino acids of interest and Table 1 collects the interaction energies corresponding to the most stable association of any two amino acids. For the purposes of this work, the recognition factor for a given amino acid has been defined as the average of the stabilization energies (in absolute value) of all the associations in which it is involved. The corresponding values are given in Table 2.

## Methodology

The procedure involves the determination of the hydrophilicity, recognition, and global profiles for the protein under study.

The determination of the hydrophilicity profile, using a modified Hopp–Woods procedure, in-

volves the following steps: (*a*) The set of six consecutive amino acid residues, at positions $i-2, i-1, i; i+1, i+2, i+3$ in the sequence of the protein, is considered to constitute the hexapeptide $h_i$. (*b*) Each hexapeptide in the protein is ascribed a hydrophilicity factor equal to the average of the hydrophilicity factors of its constituent residues. (*c*) The *i*-th amino acid residue is then ascribed a hydrophilicity factor equal to the average of the values corresponding to the hexapeptides $h_{i-1}$ and $h_i$. ($h_0$ is ascribed the value 0 and the values for $h_1$ and $h_2$ are obtained using four and five amino acids, respectively; the same considerations apply to the tail of the protein.) (*d*) The hydrophilicity factors obtained in this way are plotted vs. the sequence position, yielding the hydrophilicity profile of the protein.

The recognition profile is obtained in a similar fashion, using the recognition factors instead of the hydrophilicity factors, and the global profile is then defined by multiplication of the hydrophilicity and recognition factors corresponding to each sequence position in the protein.

For simplicity in their inspection, in the hydrophilicity and global profiles only the positive values are plotted. All the curves are smoothed by interpolation.

## Discussion of the results

Within the framework of the Hopp–Woods procedure, a region for which a peak is observed in the hydrophilicity profile is predicted to correspond (or to be adjacent) to an antigenic determinant. The argument is that the regions with high hydrophilicity will most probably appear on the surface of the protein, once it has adopted its tertiary structure.

The tertiary structure, however, will be stabilized not only by the interactions of the amino acid residues with the solvent but also by the interactions between residues in different regions of the peptidic chain. The final result will depend, therefore, on the relative values of all such interactions in each case and a complete *a priori* prediction is not possible unless a complete quantum-mechanical calculation is performed, with consideration of the aqueous environment.

An alternative may be found, however, for a theoretical prediction of antigenic determinants under the assumption that the amino acid – amino acid interactions are more important than the hydrophilicity in determining the tertiary structure, although a positive hydrophilicity is still a prerequisite for the corresponding region to appear on the surface of the protein (and perhaps be associ-

[a]The larger the recognition factor, the more easily is the amino acid recognized by any other.

ated with antigenic activity). The basic rules that have been developed (and found to be appropriate) are as follows: (*a*) The highest peak in the hydrophilicity profile will be assumed, as shown by Hopp and Woods (1), to correspond or to be immediately adjacent to an antigenic determinant. (*b*) The regions with negative hydrophilicity will never correspond to regions of antigenic activity. (*c*) The regions with positive hydrophilicity and high recognition will be assumed to lack antigenic activity. (*d*) Only those regions with positive hydrophilicity and low recognition will be assumed to correspond (or to be adjacent) to antigenic determinants.

In practice, the application of these rules is best carried out through a comparison of the hydrophilicity and global profiles. First, in the hydrophilicity profile the regions of positive hydrophilicity are ordered according to the decreasing magnitude of the highest peak within each region and then an equivalent ordering is performed in the global profile. A comparison of the two sets of ordering indices will then yield the required information: a region of high recognition (which is therefore to be discarded) will be characterized by a lower ordering index in the global than in the hydrophilicity profile. Among those regions whose ordering indices have remained the same or have increased, those which show an increase in the magnitude of their highest peaks (relative to the peak of the region of highest hydrophilicity) in the global profile by comparison to what it is in the hydrophilicity profile will alse be discarded. (Independently of recognition considerations, all the regions not including at least six residues will also be discarded.)

These rules have been tested for bovine basic myelin protein, hen egg-white lysozyme, sperm whale myoglobin, and tobacco mosaic virus protein. For simplicity in the discussion, the designations "waste" and "success" have been introduced: the waste of a prediction defines that fraction of experimental work that will be wasted when confirming the prediction, so that a waste of 0% indicates that all the predicted determinants possess activity; the success rate, on the other hand, gives the percentage ratio of the number of correctly predicted determinants over the number of known determinants.

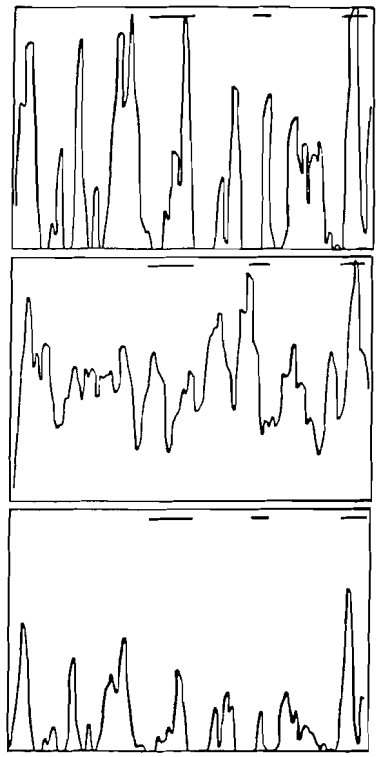

FIG. 1. Hydrophilicity (top), recognition (middle), and global (bottom) profiles for bovine basic protein. The horizontal lines at the top of each profile mark the positions of the known antigenic determinants.

The discussion (in which the regions with negligible hydrophilicity are not included) is as follows:

*(a) Bovine basic myelin protein (Fig. 1)*

It consists of 169 residues, with 4 sequential determinants (Eylar (4), Westall and Thompson (5)) at positions 64–73, 74–85, 113–121, and 153–166; for the discussion here, the first two determinants (which are adjacent) will be taken as one.

There are 10 regions of positive hydrophilicity and 7 determinants are predicted, corresponding to regions *2* (residues 17–23), *3* (residues 28–35), *5* (residues 43–64), *6* (residues 70–84), *7* (residues 95–107), *8* (residues 118–123), and *10* (residues 155–169), for a prediction with 57% waste and 100% success.

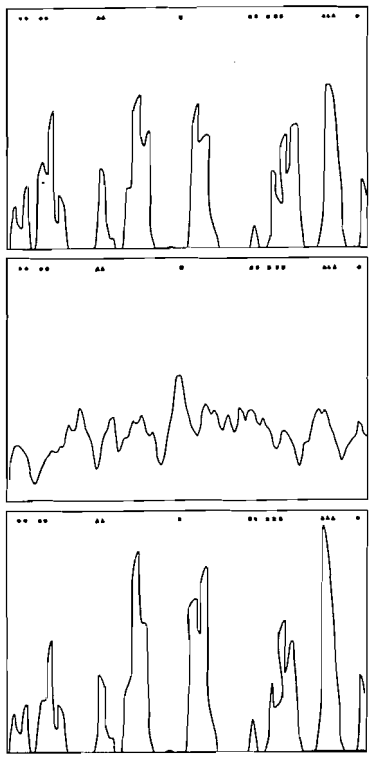

FIG. 2. Hydrophilicity (top), recognition (middle), and global (bottom) profiles for hen egg-white lysozyme. The symbols at the top of each profile mark the positions of the known antigenic determinants.

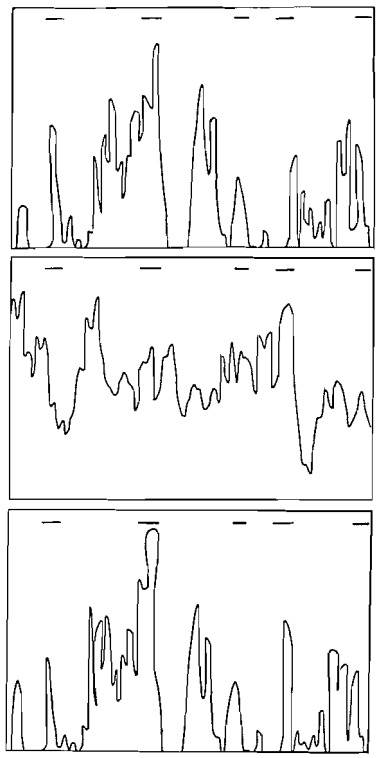

FIG. 3. Hydrophilicity (top), recognition (middle), and global (bottom) profiles for sperm whale myoglobin. The horizontal lines at the top of each profile mark the positions of the known antigenic determinants.

*(b) Hen egg-white lysozyme (Fig. 2)*

It consists of 129 residues, with 3 conformational determinants (Atassi and Habeeb (6), Atassi and Lee (7)) involving the residues (5, 7, 13, 14, and 125), (33, 34, 113, 114, and 116), and (62, 87, 89, 93, 96, 97), respectively.

There are 9 regions of positive hydrophilicity and 4 determinants are predicted, corresponding to regions *1* (residues 1–8), *2* (residues 11–21), *3* (residues 32–38), and *8* (residues 111–120), which correspond to the main components of the first two known determinants. This is a prediction with 0% waste and 67% success.

*(c) Sperm whale myoglobin (Fig. 3)*

It consists of 153 residues, with 5 sequential determinants (Atassi (8, 9)) at positions 15–22, 56–62, 94–99, 113–119, and 145–151.

There are 9 regions of positive hydrophilicity and 6 determinants are predicted, corresponding to regions *2* (residues 16–26), *3* (residues 32–65), *4* (residues 75–90), *5* (residues 93–103), *8* (residues 123–135), and *9* (residues 137–150), for a prediction with 33% waste and 80% success.

*(d) Tobacco mosaic virus protein (Fig. 4)*

It consists of 158 residues, with 3 sequential determinants (Anderer (10), Benjamini (11), and Milton and van Regenmortel (12)) at positions 62–68, 108–113, and 153–158.

There are 10 regions of positive hydrophilicity and 2 determinants are predicted, corresponding to regions *6* (residues 61–71) and *8* (residues 103–118), for a prediction with 0% waste and 67% success.

## Conclusions

The theoretical prediction of protein antigenic determinants should be based on calculations with consideration of the tertiary structure and the aqueous environment.

The results presented in this work indicate, however, that a simplified model, with consideration of both hydrophilic and recognition factors, constitutes a rather attractive alternative, because of its simplicity and high rate of success.

Although the above rules have been developed in a semi-empirical fashion, they may be easily rationalized by a semi-quantitative argument, taking

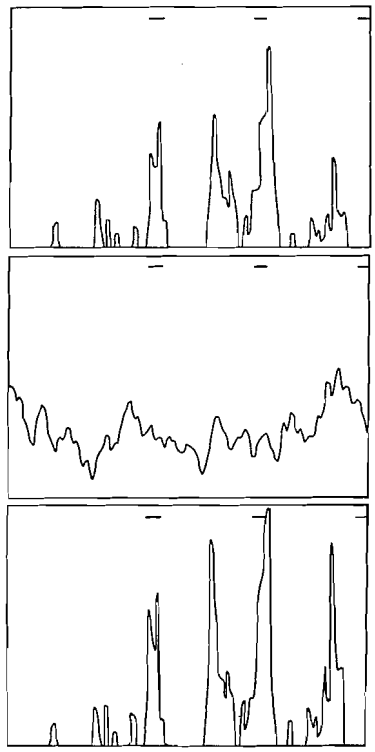

FIG. 4. Hydrophilicity (top), recognition (middle), and global (bottom) profiles for tobacco mosaic virus protein. The horizontal lines at the top of each profile mark the positions of the known antigenic determinants.

into account that the greater the recognition factor the more stable the association with another amino acid is.

As seen from Table 2, all amino acids have appreciable recognition factors and consequently it is understandable that those regions with low hydrophilicity will tend to arrange themselves within the interior of the protein, as this arrangement will lead to a more stable conformation. In fact, this consideration applies to all the regions with a high recognition, independently of their hydrophilicity so that only those regions of (relative) low recognition and high hydrophilicity remain as the likely candidates to appear on the surface of the protein.

As it is the case with any semi-empirical method, the usefulness of the present procedure should be based on its success rate and from that point of view it seems to constitute a powerful tool for the prediction of antigenic determinants.

The main limitation of this work arises from the neglect of conformational considerations, except as approximated through the use of recognition factors, and therefore it must be emphasized that conformational determinants cannot be predicted as such (i.e., the fact that several predicted sequential determinants may constitute part of a single conformational determinant will not be known from the results obtained).

It is expected, however, that recognition profiles may be of use in the prediction of some conformational characteristics (such as the existence of sharp bends) and this point will be examined in future work, as well as the influence of the aqueous environment.

TED SCHAEFER, RICHARD P. VEREGIN, REINO LAATIKAINEN, RUDY SEBASTIAN, KIRK MARAT, and JAMES L. CHARLTON. Can. J. Chem. **60**, 2611 (1982).

The temperature-dependent $^{19}F$ nmr spectra of 2,6-difluoroisopropylbenzene yield $\Delta G^{\ddagger}_{155}$, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ as 6.93 (5) kcal/mol, 6.1(1) kcal/mol, and −5.0 (8) cal/mol K, respectively, for the internal rotation of the isopropyl group about the $sp^2$–$sp^3$ carbon–carbon bond. The long-range spin–spin coupling constant over six bonds, $^6J_p^{H,CH}$, combined with the *J* method gives a twofold internal potential barrier of 5.0 ± 1.6 kcal/mol at 305 K. Although in this barrier range the *J* method suffers from large errors, the two methods yield comparable values for the barrier height. The lineshape method is inapplicable to 2,6-difluoroethylbenzene. The *J* method finds the preferred conformation and a twofold barrier of 6.0 ± 2 kcal/mol, again in a barrier region where this method is inaccurate. Relative to hydrogen, the fluorine substituents cause substantial increases in the barriers to internal rotation. Signs of the stereospecific couplings, $^4J_o^{F,CH}$, are determined.

TED SCHAEFER, RICHARD P. VEREGIN, REINO LAATIKAINEN, RUDY SEBASTIAN, KIRK MARAT et JAMES L. CHARLTON. Can. J. Chem. **60**, 2611 (1982).

La mesure de spectres de rmn du $^{19}F$ en fonction de la température du difluoro-2,6 isopropylbenzène permet d'obtenir les valeurs des $\Delta G^{\ddagger}_{155}$, $\Delta H^{\ddagger}$ et $\Delta S^{\ddagger}$ qui sont respectivement de 6,93 (5) kcal/mol, 6,1(1) kcal/mol et −5,08(8) cal/mol K pour la rotation interne du groupe isopropyle autour de la liaison carbone–carbone $sp^2$–$sp^3$. La constante de couplage à longue distance à travers six liaisons $^6J_p^{H,CH}$, combinée à la méthode *J* donne une barrière de potentiel interne binaire de 5,0 ± 1,6 kcal/mol à 305 K. Bien que dans cet ordre de grandeur, pour la barrière, la méthode *J* comporte de grandes erreurs, les deux méthodes donnent des valeurs comparables pour la hauteur de la barrière. La méthode de la forme des lignes ne peut s'appliquer dans le cas du difluoro-2,6 éthylbenzène. La méthode *J* permet d'établir la conformation préintégrée et une barrière binaire de 6,0 ± 2 kcal/mol; il s'agit encore d'une région de la barrière où cette méthode n'est pas précise. Par rapport à l'hydrogène, les substituants fluor provoquent une augmentation substantielle des barrières internes à la rotation. On a déterminé des signes de couplages stéréospécifiques $^4J_o^{F,CH}$.

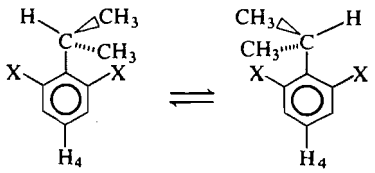
[Traduit par le journal]

## Introduction

According to the *J* method (1) the twofold barrier to rotation about the $sp^2$–$sp^3$ bond in isopropylbenzene is 1.95 ± 0.2 kcal/mol (1 cal ≡ 4.184 *J*). This method depends on the $\sin^2\theta$ dependence of $^6J_p^{H,CH}$ in **1** (X = H). A quantum mechanical hindered rotor model allows the calculation of the expectation value of $\sin^2\theta$ as a function of temperature, barrier, and reduced moment of inertia. Measurements of $^6J$ implies a value of $\langle\sin^2\theta\rangle$ according to $^6J = {}^6J_{90}\langle\sin^2\theta\rangle$, where $^6J_{90}$ is the magnitude of $^6J$ when the α C—H bond rotates out of the benzene plane by 90°.

When X = $CH_3$, the classical DNMR method and molecular mechanics calculations agree that the barrier is twofold (2) and much larger than in **1** (X = H). Lineshape analysis of the temperature-dependent $^1H$ nmr specra yields a free energy of activation, $\Delta G^{\ddagger}_{238}$, of 12.8 kcal/mol for the hindered rotation of the isopropyl fragment.

The DNMR method (3,4) depends on the dephasing of magnetization caused by the internal rotation. When the internal rotation rate increases



**1** **1**

sufficiently the dephasing process becomes more difficult to follow by DNMR. In consequence, very low barriers have not been measured by this technique, the lowest value being a $\Delta G^{\ddagger}_{93}$ of 4.2 kcal/mol (5). The *J* method suffers from an opposite disadvantage. As the barrier increases, the observed $^6J$ becomes less sensitive to $V_2$, particularly above about 3 kcal/mol.

It is desirable to apply both methods to the same barrier. When properly used, the lineshape method gives accurate $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ parameters (6). The J method has a different theoretical basis, has a relatively limited applicability at present, and yields a barrier parameter whose relationship to $\Delta G^{\ddagger}$ and its components is not immediately clear. If

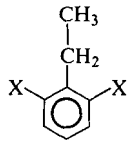
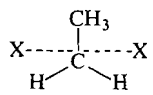
these two methods[1] were to yield compatible barrier parameters for the same process, the result might be taken as a severe test of the $J$ method.

Accordingly, the chosen molecule is one in which $^6J_p^{H,CH}$ is most sensitive to $V_2$. In **1** (X = F), $\langle \sin^2\theta \rangle$ varies between 0.5 and zero as $V_2$ increases from zero to infinity, respectively. Because fluorine is relatively small, there is the possibility that both $V_2$ and $\Delta G^{\ddagger}$ are measurable. Of course, the components of $\Delta G^{\ddagger}$ are also needed, implying measurements over a range of temperatures.

While the J method is not as general as DNMR in its applicability, it does have one significant advantage, exemplified by **2**. If X = H in **2**, the $J$ method shows that the preferred conformation, **2***a*, is the



**2**



**2***a*

one in which the methyl group lies in a plane perpendicular to the benzene ring ($\theta = 30°$ in $\sin^2\theta$). Hence DNMR is in principle inapplicable because there exists no Larmor frequency indicator of the internal reorientation rate.[2] By way of contrast, the $J$ method yields a $V_2$ of 1.2 ± 0.2 kcal/mol for rotation about the $sp^2$–$sp^3$ bond, in good agreement with a recent thermodynamic conclusion (1, 9).

In this paper **1** (X = F) and **2** (X = F) are investigated, the former by the two methods and the latter by the $J$ method. The results provide a comparison of the two methods and data on fluorine as a steric inhibitor of internal rotation of alkyl groups on a benzene ring.

## Experimental

*Synthesis*

Compound **1** (X = F) was prepared from 2,6-difluorobenzoic acid (Aldrich) via the methyl benzoate and treatment of the latter with methyl magnesium iodide in ether to give the alcohol. The alcohol was converted to the α-methylstyrene derivative with toluene-*p*-sulfonic acid. The alkene was hydrogenated in ethanol and extracted and purified by distillation to give **1** (X = F). Detials of the exact procedure are given in ref. 10.

Compound **2** (X = F) was prepared from 2,6-difluoroacetophenone (Maybridge) by a modification of the Wolff–Kishner method exactly as described in ref. 11. It was also synthesized by the palladium-catalyzed coupling (12) of tetramethyltin and 2,6-difluorobenzyl bromide (Maybridge). However, when using tetrakis(triphenylphosphine) palladium(0) as a catalyst as prescribed on p. 4996 of ref. 12, the characteristic blackening occurred only after some weeks.

*Samples*

All samples were prepared in 5 mm od diameter nmr tubes. They were degassed by the freeze–pump–thaw procedure, using as many as seven cycles, and were flame-sealed. For **1** (X = F) they included a 5 mol% solution in acetone-$d_6$ with a drop of $C_6F_6$, a 5 mol% solution in $CS_2$ with 4 mol% of tetramethylsilane, a 5 mol% solution in 1:1 v/v acetone-$d_6$ and isopentane, and an approximately 5 mol% solution in 1:1 v/v $CD_2Cl_2$ and isopentane. For **2** (X = F), a 2 mol% solution in $CCl_4$ containing 25% by volume of $C_6D_{12}$ and a 15 vol% solution in $CCl_4$ with 5 vol% TMS were prepared.

*Spectral measurements*

For **1** (X = F), the $^1$H nmr spectrum (acetone-$d_6$) at 90.020 MHz (centerband) was acquired in the FT mode on a WH-90 Bruker spectrometer in the manner described recently (13). A sweep width of 760 Hz and three separate experiments gave peak frequencies with an average deviation of 0.015 Hz. The $^{19}$F nmr spectra were obtained in a similar way at 84.670 MHz, except that the methyl protons were selectively decoupled, using a sweep width of 200 Hz. Average peak frequency variations were about 0.002 Hz. Multiple resonance $^1$H nmr experiments (14) utilized the $CS_2$ solution and an HA100 spectrometer in the frequency sweep mode.

Such experiments were also done for **2** (X = F) with the 15 vol% solution in $CCl_4$ on the HA100. The $^1$H nmr spectrum of **2** (X = F) in a 2 mol% solution in $CCl_4$–$C_6D_{12}$ was recorded on the WH-90 in the FT mode and gave linewidths of about 0.12 Hz. All these measurements were made at probe temperatures of 305 ± 1 K.

The variable temperature measurements of the $^{19}$F resonance of **1** (X = F) employed broadband decoupling of the protons on the WH-90 and frequency ranges of 500 to 1000 Hz. The temperature controller (B-VT-1000) was calibrated with a thermocouple in a dummy nmr tube and its dial readings agreed with the thermocouple to within ± 1 K. In order to reach 140 K the nitrogen gas stream was precooled by passing it through a copper coil immersed in liquid nitrogen before it reached the usual heat exchanger.

## Results and discussion

*Spectral analyses*

These employed the computer programs LAME (15, 16), MAOCON (17), NUMARIT (18), and DAVINS (19). The fully-coupled, 12-spin $^1$H nmr spectrum of **1** (X = F) at 305 K was analyzed to give the results in Table 1. The $^{19}$F nmr spectrum (methyl protons decoupled) was analyzed as part of a 6-spin system (Table 1). The double resonance experiments (14) designed to determine the signs of $^4J_o^{F,CH_\alpha}$ and $^5J_o^{F,CH_3}$ could be confirmed by partial simulations of the ensuing spectra with the computer program DOR (20). The magnitude of $^6J_p^{H,CH}$ was estimated from the partially resolved doublets in the H-4 region at 100 MHz together with a simulation of overlapping lorentzians with linewidths at half-height of 0.13 Hz, the width characteristic of single peaks in the H-3 region. An analysis of the digitized ring proton region of the

[1] Spin-lattice relaxation measurements also provide information on intramolecular reorientation processes. The barriers provided by this method are somewhat model dependent. A recent review (7) gives a thorough discussion of the strengths and pitfalls of this approach; for example, when applied to intrinsically small barriers.

[2] This restriction can sometimes be lifted by the use of liquid crystals as solvents (8), although their use has a number of disadvantages in DNMR studies. In particular, **1** and **2** have spin systems too large for this purpose.

spectrum obtained at 90 MHz (transferred from the Nicolet 1180 on the Bruker instrument to the Amdahl 470/V7 system via a telephone line) by the program Davins (19) gave another estimate of $^6J_p^{H,CH}$ (Table 1).

The $^1H$ nmr spectrum of **2** (X = F) was first partially analyzed as a 7-spin system (ignoring the methyl protons) with Maocon. This was followed by a 10-spin analysis with Numarit, with the results given in Table 2. Figure 1 displays the calculated and observed spectra of the methylene protons.

*Variable temperature pre-exchange lifetimes*

Pre-exchange lifetimes were extracted from the exchange-broadened proton-decoupled $^{19}F$ nmr spectra of **1** (X = F) by methods used in this laboratory for many years (21–27). The many possibilities of error in such extractions (6), particularly for two-site exchange between components of the doublet, have been thoroughly discussed and will not be repeated here. The detailed procedure can be found in ref. 10.

In brief, at 140 K the doublet separation is 290 Hz, but the doublets are already somewhat broadened by the rate process. The linewidth of internal $C_6F_6$ peaks was used as the linewidth expected in the absence of the rate process in **1**. The spectrum could be simulated as a function of the lifetime and of the chemical shift difference for a negligible rate of exchange. Above coalescence, which occurs very near 156 K, it was deemed correct to use a constant limiting internal chemical shift with a reference linewidth given by $C_6F_6$ and only one unknown parameter, the pre-exchange lifetime, $\tau$. In this way a temperature range of 60 K could be achieved, rather smaller than desired. Viscosity and/or solubility problems precluded measurements below 140 K, while at temperatures

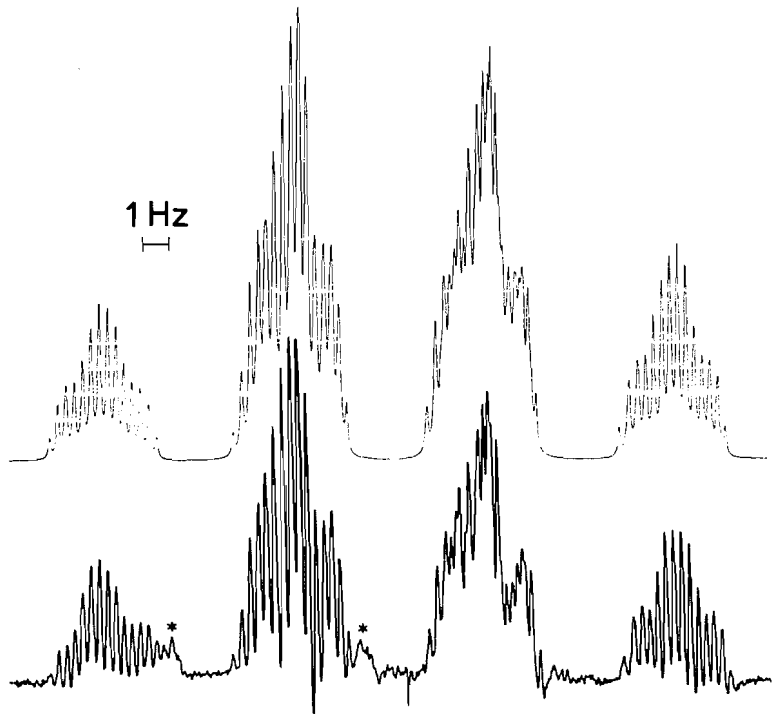

FIG. 1. The observed and calculated methylene proton $^1H$ nmr spectra at 90 MHz of a 2 mol% solution of 2,6-difluoroethylbenzene in a 25% v/v $C_6D_{12}/CCl_4$ solution at 305 K. The calculated spectrum has a linewidth at half-height of 0.12 Hz. Because the methylene protons form part of a 10-spin system and are coupled to all the other 8 spins, each peak in the spectrum contains many transitions. Impurity bands are indicated by asterisks. The many repeated spacings are ca. 0.3 Hz in magnitude.

above 200 K the exchange broadening was judged as too small for reliable work.

Observed spectra were compared with calculated lineshapes from a Versatic plotter, whose scale was ca. 25 × 60 cm and had been tested and adjusted for uniformity. Particular attention was paid to comparisons at 0.25, 0.50, and 0.75 of the maximum peak heights. In this way $\tau$ values, ranging from $1.46(4) \times 10^{-2}$ s at 140 K to $1.25(10) \times 10^{-5}$ s at 200 K, could be extracted.

Although one is dealing with a simple doublet, the Larmor frequency difference is substantial and some degree of accuracy in $\tau$ is attainable. Furthermore, different solvents give the same $\tau$ values to within experimental error. For example, at 180 K one has $\tau$ as $9.1(5) \times 10^{-5}$ s in the acetone–isopentane solvent and as $9.9(9) \times 10^{-5}$ s in the acetone solution.

*Activation parameters for* **1** *(X = F)*

These were extracted in the normal way. A plot of $\ln(1/\tau T)$ versus $1/T$ is shown in Fig. 2. An error propagation treatment, using the computer program ACTPAR (6), gave $\Delta G^{\ddagger}_{155}$ as 6.93(5) kcal/mol (within a degree or two of coalescence), $\Delta H^{\ddagger}$ as 6.1(1) kcal/mol, $\Delta S^{\ddagger}$ as −5.0(8) cal/mol K, $E_a$ = 6.5(1) kcal/mol, and $\log A = 11.9(2)$. A transmission coefficient of unity was assumed for the activated state. Another error analysis (24, 28) of $\Delta S^{\ddagger}$ gave 0.5 cal/mol K as its uncertainty. If the standard deviations are multiplied by two, one has $\Delta H^{\ddagger} = 6.1(2)$ kcal/mol and $\Delta S^{\ddagger} = -5.0(1.6)$ cal/mol K.

The negative value of $\Delta S^{\ddagger}$ may be compared with negative values of $\Delta S^{\ddagger}$ for a series of α,α-dihalo-2,6-dihalobenzenes and related compounds (21–27, 29, 30). The average value of $\Delta S^{\ddagger}$ for twelve sets of measurements is −3.9 cal/mol K. Considering that in the transition state the isopropyl group could lose more degrees of freedom than a $CHX_2$ (X = halogen), the present number of − 5 cal/mol deg is acceptable. $E_a$ and $\Delta H^{\ddagger}$ differ by about RT over the temperature range used for **1** (X = F).

*The twofold barrier,* $V_2$*, by the* J *method for* **1** *(X = F)*

The values of $^6J_p^{H,CH}$ obtained by the two approaches (Table 1) suggest $-0.08_9 \pm 0.03_0$ Hz. Utilization of $-1.20 \pm 0.02$ Hz for $^6J_{90}^{H,CH}$ (1) gives $\langle \sin^2 \theta \rangle$ as $0.07_4 \pm 0.02_6$. Figure 3 emphasizes the insensitivity of $\langle \sin^2 \theta \rangle$ to $V_2$ in this range of $V_2$ (the curve becomes much steeper for lower $V_2$). One

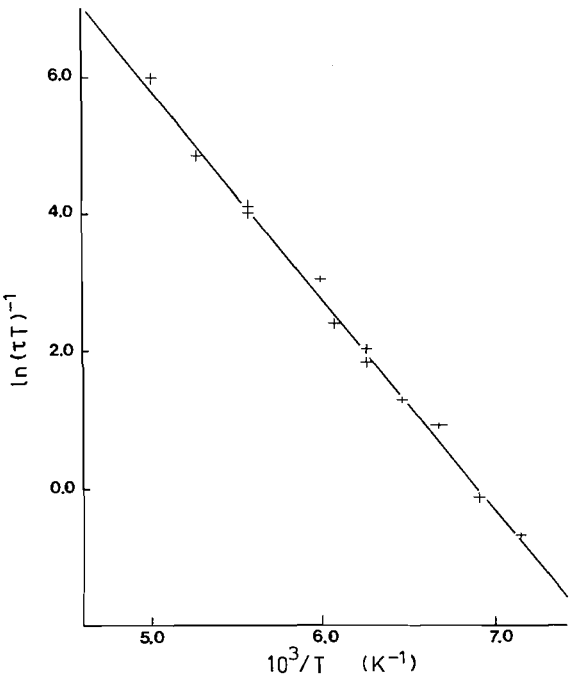

FIG. 2. A plot of $\ln(1/\tau T)$ versus $1/T$ for the internal rotation about the $sp^2$–$sp^3$ carbon–carbon bond in 2,6-difluoroisopropylbenzene between 140 and 200 K. The correlation coefficient is 0.998. An error propagation analysis yields $\Delta H^{\ddagger}$ as 6.1(1) kcal/mol and $\Delta S^{\ddagger}$ as −5.0(8) cal/mol K. $\Delta G^{\ddagger}_{155}$ is 6.93(5) kcal/mol, very near coalescence. Duplicate determinations of $\tau$ at the same temperature in the diagram employed different solvents.

has $V_2$ as 5.0 ± 1.6 kcal/mol, where the uncertainty is simply estimated from the projections of $\langle \sin^2 \theta \rangle$ onto the curve in Fig. 3.

$V_2$ is represented in the $J$ method by $0.5\ V_2(1 - \cos 2\theta)$. The hindered rotor calculations give the zero-point torsional energy of the ground state as 0.07 kcal/mol. The identification $\Delta H^{\ddagger} = V_2 + \Delta ZP$, where ΔZP is the zero-point energy of the transition state minus the zero-point energy of the ground state, allows an estimate of ΔZP as ca. 0.1 kcal/mol. To within experimental error, then, the two methods give the same barrier to internal rotation in **1** (X = F). Note that, *if* $\Delta S^{\ddagger}$ *were zero*, then $V_2$ would not agree with the subsequently *implied* $\Delta G^{\ddagger} = \Delta H^{\ddagger} =$ 6.9 kcal/mol.

This attempted overlap of the two methods has not been completely successful. By their very nature, the two methods must be somewhat inaccurate in the region of overlap. In the present instance, DNMR is more accurate than the $J$ method. The latter assumes a twofold cosine barrier and a hindered rotor model, the former an activated process. Molecular mechanics calculations on the isopropyl group confirm a twofold rotational barrier (2).

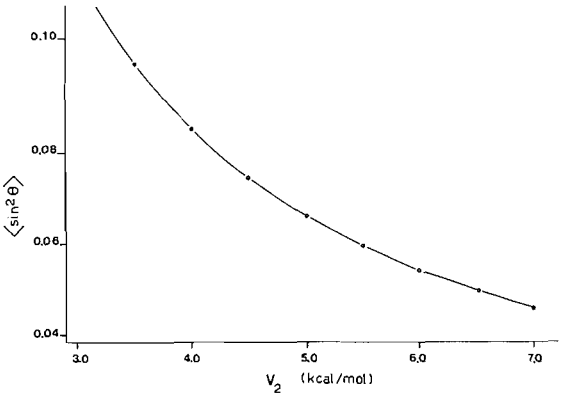

FIG. 3. Part of a plot of $\langle \sin^2 \theta \rangle$ versus $V_2$ for the rotation of the isopropyl group in 2,6-difluoroisopropylbenzene at 305 K. The hindered rotor model used a value of $0.9 \times 10^{-38}$ gm cm² for the reduced moment of inertia. The value of $\langle \sin^2 \theta \rangle$ is insensitive to this parameter. The basis set consisted of 51 free rotor functions. $\langle \sin^2 \theta \rangle$ varies between 0.5 for $V_2 = 0$ and 0.0 for $V_2 = \infty$ and is very insensitive to $V_2$ in the region depicted in this figure. The details of the calculations leading to figures such as this one can be found in ref. 1.

$V_2$ in isopropylbenzene is only 2 kcal/mol, so that two *ortho* fluorine substituents cause a substantial increase in the barrier. It is of interest whether a similar increase occurs in ethylbenzene on fluorine substitution.

### $V_2$ *in* **2** *(X = F) by the* J *method*

$^6J_p^{H,CH}$ is −0.338(12) Hz assuming an error equal to twice the difference between the values from the two analyses in Table 2. Taking $^6J_{90}$ as −1.22 ± 0.02 Hz (1) implies $\langle \sin^2 \theta \rangle$ as 0.277 ± 0.015. A reduced moment of inertia of $0.5 \times 10^{-38}$ gm cm², a basis set of 51 free rotor functions, and a $T$ of 305 K gives a tabulation[3] of $\langle \sin^2 \theta \rangle$ as a function of $V_2$. Again, because **2***a* is the preferred conformer, $\langle \sin^2 \theta \rangle$ approaches 0.25 in the high barrier limit and a large error in the derived value of $V_2$ is once more inevitable for the present molecule. One finds $V_2$ as 6.0 ± 2.0 kcal/mol.

Parenthetically one may note that $^6J_p^{H,CH_3}$ in 2,6-difluorotoluene[4] is −0.62 Hz, the same as in toluene (31), so that the $^6J_{90}$ employed above is correct (1). Further, the present result for $V_2$ in **2** (X = F) implies that $^6J_p^{H,CH}$ in **2** (X = Cl) lies very close to $0.25 \times {}^6J_{90}$ or −0.30 Hz. The observed value is −0.29 ± 0.02 Hz (32).

*If* the errors in the large $V_2$ values are disregarded, *then* the results in this paper suggest that the increase in the barrier on going from X = H to X = F in **1** and **2** is larger for the latter. The

[3]The values of $\langle \sin^2 \theta \rangle$ are rather insensitive to the reduced moment of inertia at this temperature.

[4]Unpublished work in this laboratory.

transitional conformation in **2** has a $CH_3$ group eclipsing the *ortho* C—F bond, while for **1** the high energy conformer has the α C—H bond at 90° to the benzene plane and therefore the two $CH_3$ groups lie in planes at 30° to the benzene plane. A molecular mechanics calculation would be very useful for these two molecules.

Whether the barriers in these molecules are entirely steric is not certain. One might, for example, speculate about the rotational angle dependence of hyperconjugative interactions of the C—H and C—C bonds in the sidechain with the π electrons of the ring. For a recent study of, and extensive literature references to, steric interactions and intramolecular rate processes see ref. 33.[5]

*Other long-range couplings*

Of particular interest are $^4J_o^{F,CH}$ and $^5J_o^{F,CH_3}$ in Tables 1 and 2. Their signs and magnitudes confirm an inadequacy in the INDO MO FPT computations for $^4J_o^{F,CH_3}$ in 2-fluorotoluene (35). The inadequacy may well arise from an improper account of the direct coupling mechanism. Synthesis of the requisite additional compounds is in hand and may allow an empirical delineation of the rotational angle dependence of $^4J_o^{F,CH}$ and of $^5J_o^{F,CH_3}$.

## Conclusions

For 2,6-difluoroisopropylbenzene the *J* method and DNMR appear to agree in their assessment of the internal barrier to rotation about the $sp^2$–$sp^3$ carbon–carbon bond. Therefore it can be said, tentatively in view of experimental and conceptual difficulties, that nmr spectroscopy as distinct from nmr relaxation methods can be used to measure barriers to internal rearrangements which range from near zero (*J* method) to as large as 30 kcal/mol (DNMR).

# Homonuclear one- and two-dimensional nuclear Overhauser effect experiments and spin-echo correlated spectroscopy. Application to prostaglandin $E_1$ and 6-keto-prostaglandin $E_1$[1]

GEORGE KOTOVYCH AND GERDY H. M. AARTS
*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received February 11, 1982

GEORGE KOTOVYCH and GERDY H. M. AARTS. Can. J. Chem. **60**, 2617 (1982).

Nuclear Overhauser effect one-dimensional and two-dimensional nuclear magnetic resonance experiments are reported for prostaglandin $E_1$. The two-dimensional nuclear Overhauser effect measurements are combined with spin-echo correlated spectroscopy in order to assign the complete high-field proton magnetic resonance spectrum of 6-keto-prostaglandin $E_1$. The advantages of these two-dimensional techniques are illustrated in these studies. It is also observed that the 6-keto-prostaglandin $E_1$ H-10α proton is substituted more readily by deuterium than are the other protons α to the keto groups.

GEORGE KOTOVYCH et GERDY H. M. AARTS. Can. J. Chem. **60**, 2617 (1982).

On rapporte des expériences en rmn sur l'effet Overhauser nucléaire à une et à deux dimensions pour la prostaglandine $E_1$. Les mesures de l'effet Overhauser nucléaire sont combinées avec la spectroscopie spin-écho de corrélation dans le but d'identifier le spectre complet de résonance magnétique du proton à haut champ de la céto-6 prostaglandine $E_1$. On illustre dans ces études les avantages de ces techniques à deux dimensions. On a également observé que le proton H-10α de la prostaglandine $E_1$ est substitué plus facilement par le deutérium que les autres protons en α des groupes cétoniques.

[Traduit par le journal]

Prostacyclin (Prostaglandin $I_2$, $PGI_2$) is the most potent inhibitor of platelet aggregation and a potent vasodilator (1, 2). It is unstable and rapidly hydrolyses to 6-keto-prostaglandin $F_{1\alpha}$. The metabolism of $PGI_2$ or 6-keto-prostaglandin $F_{1\alpha}$ by 9-hydroxy-prostaglandin dehydrogenase in human platelets leads to a more stable substance, 6-keto-prostaglandin $E_1$ (6-keto-$PGE_1$) (3) with similar biological activity to $PGI_2$ (4, 5). In our continuing studies of the structure–activity relationships of $PGI_2$ and its derivatives, we found it very difficult to analyze the complete proton magnetic resonance spectrum of 6-keto-$PGE_1$. Even at 400 MHz, due to the overlap of the multiplets in the high-field region, standard decoupling and one-dimensional nuclear Overhauser effect (nOe) measurements could not be used to assign all of the proton resonances. The complete assignment was possible by means of the combined two-dimensional nOe measurements and spin-echo correlated spectroscopy (SECSY).

The selective proton–proton one-dimensional (1D) nOe experiments have been extensively applied in the study of molecular structure and conformation (6–9). This experiment requires the measurement of the intensity change of a proton resonance upon saturating another proton. Two-dimensional nOe experiments have recently been developed for the investigation of cross-relaxation and chemical exchange processes (10–15). The advantages of this technique over the one-dimensional nOe experiment are (a) the simultaneous measurement of all the nOe's between closely-spaced protons in a molecule, and (b) the elimination of problems associated with the irradiation of multiplets that occur in crowded spectral regions, or that are partially resolved. In the present study, both advantages are illustrated.

The 2D nOe measurements have been combined with 2D correlated spectroscopy measurements (16, 17). The latter experiment represents a powerful technique for studying *J*-coupling connectivities (18–22). Combining these experiments yields valuable information on the nOe connectivities, as

[a]The H-8 and H-10α overlapping multiplets were simultaneously irradiated, as were the overlapping H-11 and H-15 multiplets. The observed nOe's were assigned to individual irradiated protons whenever possible on the basis of a molecular model. 1D nOe experiments were carried out on the multiplet at 1.2 to 1.7 ppm but the results are difficult to interpret due to the many overlapping proton resonances. The decoupling power levels were chosen in such a manner as to minimize the perturbation of neighboring multiplets.
[b]No nOe observed in the 2D experiment; w represents a weak 1D nOe.
[c]Weak 2D nOe's observed on expanded contour plots, or observed by taking cross sections parallel to the $F_1$ axis, are labelled c.s. $\tau_M = 0.5$ s.
[d]No nOe observed in the 1D experiment.

well as on the *J*-coupling connectivities for the molecule under study. In the present study, spin-echo correlated spectroscopy (SECSY) and the 2D nOe measurements have been combined to assign completely the high-field proton magnetic resonance spectrum of 6-keto-$PGE_1$. In addition, the nOe's obtained for prostaglandin $E_1$ ($PGE_1$) using both the 1D and 2D techniques are compared.

## Experimental

Prostaglandin $E_1$ was a gift from Dr. J. E. Pike, and 6-keto-$PGE_1$ was a gift from Dr. R. A. Johnson and Mr. Frank H. Lincoln of the Upjohn Company in Kalamazoo, MI, U.S.A. The nmr measurements were carried out on 0.06 *M* prostaglandin solutions in $CD_3OD$ (99.6%) (Merck, Sharp and Dohme). The $CD_3OD$ was vacuum distilled. Solutions of 6-keto-$PGE_1$ (0.06 *M*) were also prepared in phosphate buffer (0.20 *M* and 0.40 *M*) in $D_2O$ at a pH of 7.0 (uncorrected meter reading). All of the samples were degassed using the freeze–pump–thaw technique. Details of the sample preparation have been reported previously (23).

The nmr experiments were carried out in the Fourier transform mode using the Bruker WH-400/ DS nmr spectrometer and the Aspect 2000 data system. The chemical shifts are reported with respect to internal TMS. The one-dimensional measurements were obtained using 32K data points with a resolution of 0.244 Hz/pt or, in several cases, 0.305 Hz/pt. The resolution for the two dimensional nmr experiments was 2.05 Hz/pt in both dimensions, $F_1 = 525$, $F_2 = 2100$, using 512 and 2048 data points, respectively.

The one-dimensional nOe difference experiments were performed following standard procedures (23, 24). The two-dimensional nmr measurements were carried out using the Bruker software package (25). The 2D nOe experiment employs a sequence of three 90° pulses (90°–$t_1/2$ – 90°–$t_m$ – 90° – $t_1/2$-FID). The mixing time, $t_m$, is of central importance in measuring 2D nOe's. During this period, cross relaxation leads to exchange of magnetization between neighboring protons. The present experiments were carried out at several values of $t_m$ and the cross peaks were reproducible (15). The evolution time is $t_1$. The SECSY experiment employs two 90° pulses in the sequence (90°–$t_1/2$ – 90°–$t_1/2$-FID). The delay time $t_1/2$ after the last pulse allows both experiments to be represented in the same manner.

## Results

The results of the 1D nOe experiments for $PGE_1$ are presented in Table 1A. A contour plot of the 2D nOe experiment is presented in Fig. 1, and the data are summarized in Table 1B. The $PGE_1$ proton multiplets were assigned on the basis of standard decoupling, inversion recovery, and the 1D nOe experiments. In Fig. 1, the cross peaks are connected by the straight lines. Exchange of magnetization between any two protons, due to dipole–dipole interactions, is manifested by these cross peaks which indicate the presence of nOe's between the protons thus connected. For $PGE_1$ a wide range of $\tau_M$ values was used, from 0.1 s to 1.4 s. Extensive data handling procedures were used for the 2D nOe data to confirm the presence of weak cross peaks. These include taking cross sections parallel to the $F_1$ axis, and expanding the contour plots.

The results of the SECSY experiments performed on $PGE_1$ are shown in Fig. 2. Only the high-field region is shown as it illustrates the manner in which multiplets can be readily observed in regions of the spectrum where there is extensive multiplet overlap. The cross peaks in the SECSY experiment arise from proton–proton *J* connectiv-

For personal use only.

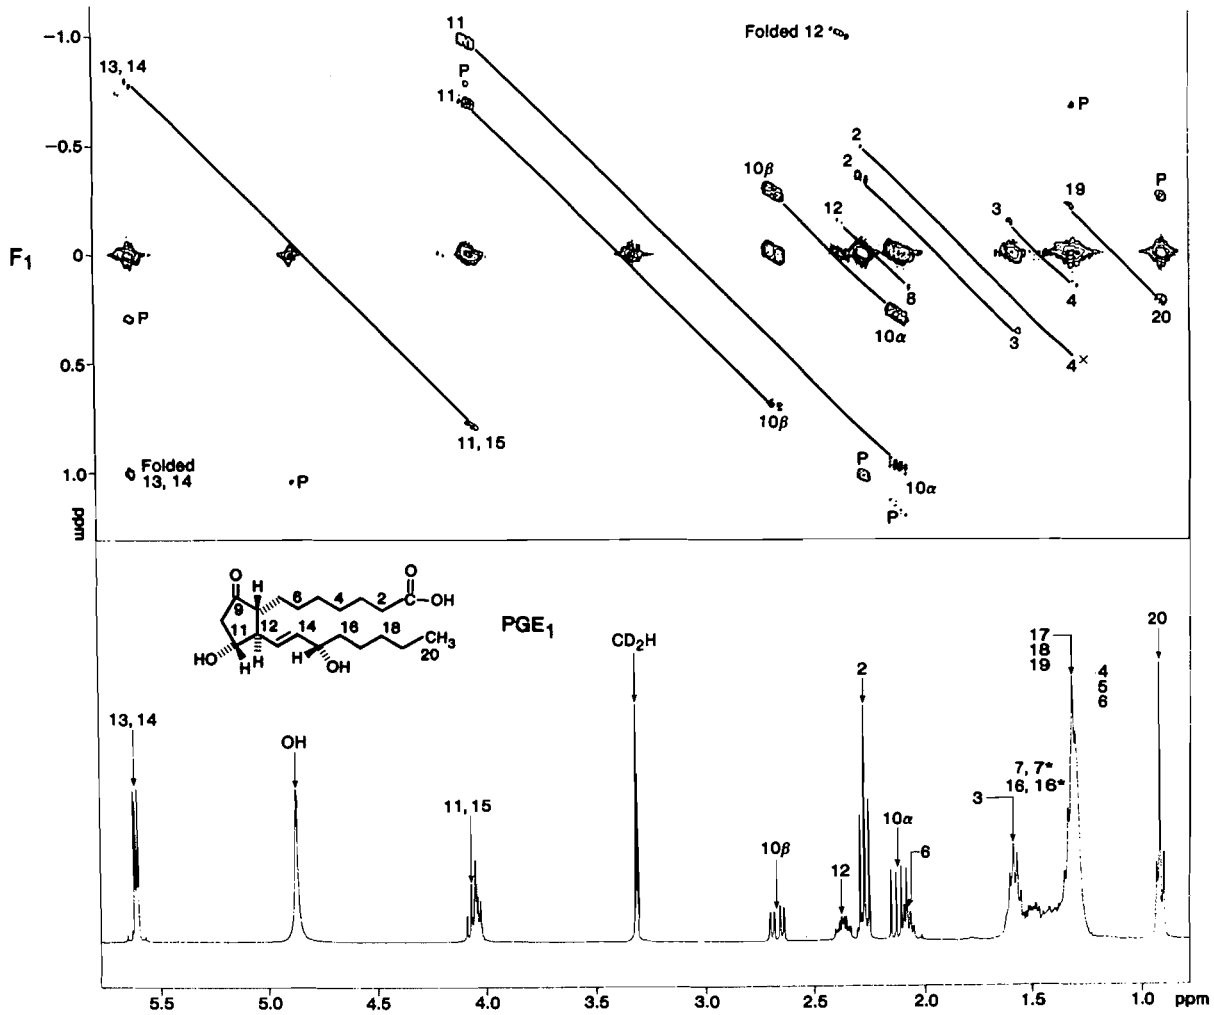

FIG. 1. *Top*. Contour plot of the proton–proton 2D nOe experiment for $PGE_1$ in $CD_3OD$ (0.06 *M*). The strong peaks on the horizontal axis passing through $F_1 = 0$ correspond to a 1D spectrum. The cross peaks are labelled and are connected with the solid lines, indicating nOe's between the nuclei whose resonances have the same chemical shift difference on the horizontal and vertical axes. Phantom peaks are labelled P (refs. 32 and 33). The × refers to the weak contour that was observed but not plotted. The $\tau_M$ was 0.5 s, 32 transients were accumulated and the total observation time was 21.4 h. The delay time between pulse sequences was 7.5 s. The FID's were multiplied by a sine bell function before Fourier transformation. The smaller spectral width along the vertical axis accounts for the folded contours. *Bottom*. The normal Fourier transform 1D spectrum obtained for $PGE_1$.

ities. The contour plot of the 2D nOe experiment for 6-keto-$PGE_1$ is combined with the contour plot for the SECSY experiment in Fig. 3. The top half of the contour plot (Fig. 3A) is for the 2D nOe experiment, while the bottom half (Fig. 3B) is for the SECSY experiment. At least two values of $t_m$ were used for the 2D nOe experiments. The cross peaks for both the 2D nOe and the SECSY experiments are labelled in Fig. 3 and are connected by the straight lines. In this way, protons which experience both the nOe and the *J* connectivities are connected. In Figs. 1–3 the straight lines intersect the horizontal axis at an angle of 135°.

For the 2D nOe experiments, as most of the nOe's are between *J*-coupled protons, transfer of magnetization by zero-quantum transitions cannot be excluded under the experimental conditions used (15, 26–28), which include phase cycling to eliminate multiple quantum transitions. Hence *J* cross peaks may also appear in the spectrum. For a quantitative interpretation of the 2D nOe data, the *J* cross peaks must be separated from the 2D nOe cross peaks. In view of the excellent agreement between the 1D nOe and the 2D nOe data for $PGE_1$, the qualitative interpretation of the 2D nOe data is valid.

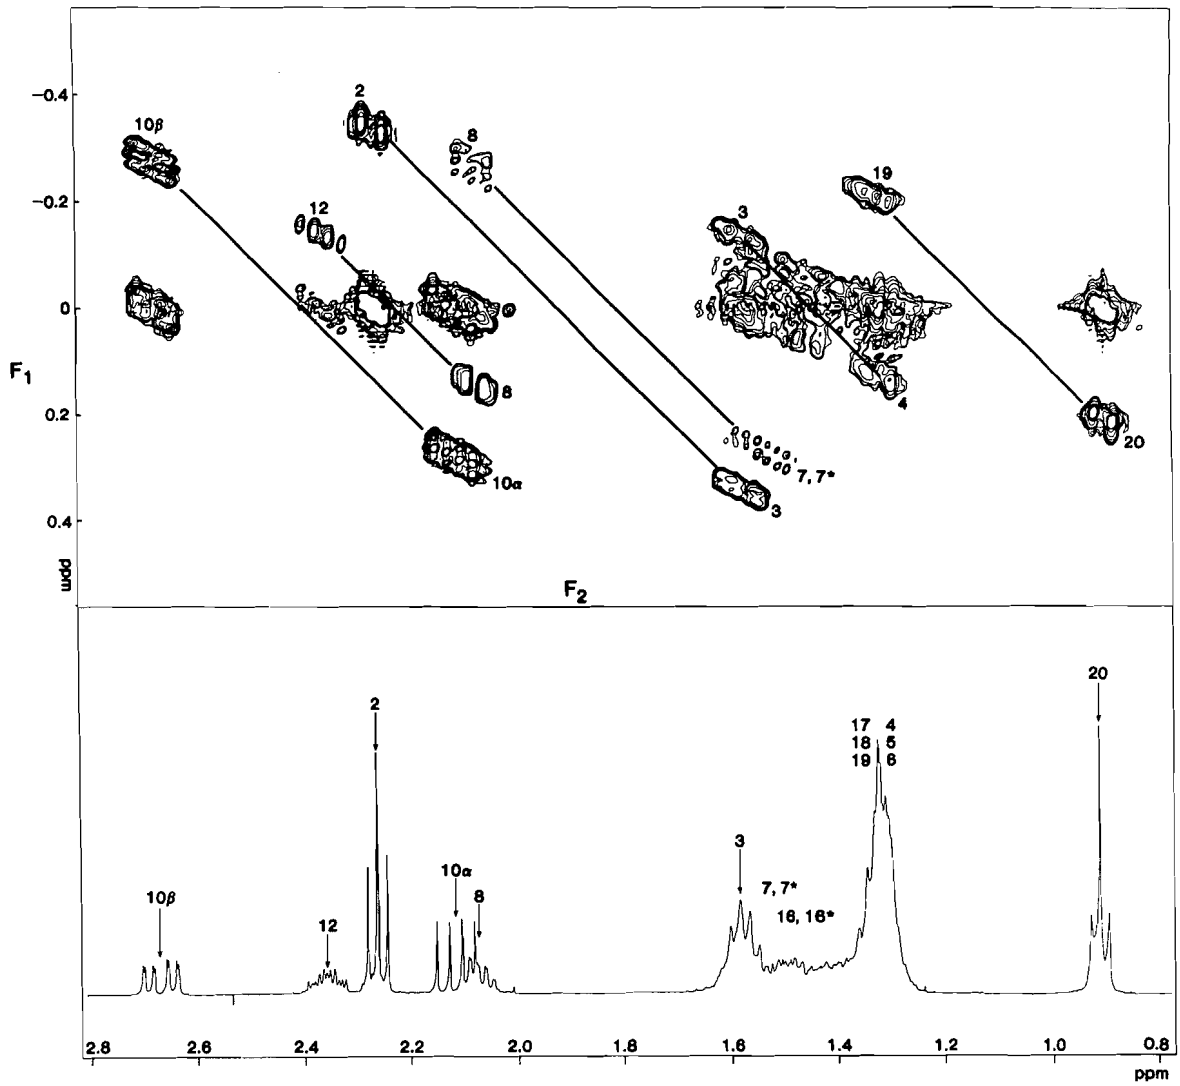

FIG. 2. *Top*. The contour plot for the SECSY experiment for $PGE_1$ in $CD_3OD$ (0.06 *M*). Only the high-field region is shown. The cross peaks are labelled and are connected by the straight lines. *Bottom*. The normal Fourier transform 1D spectrum obtained for $PGE_1$. Note the long-range H-10β to H-8 coupling constant.

The results of the nmr experiments carried out as a function of time on 6-keto-$PGE_1$ in 0.20 *M* phosphate buffer in $D_2O$ (pH 7.0) are shown in Fig. 4. By integrating these spectra, it is observed that after 28 hours the H-10α protons are substituted by deuterium to an extent of about 66%. In the same period of time, the total H-10β and H-7,7* multiplet decreases in intensity by one third of a proton, as does the H-5, H-8, and H-12 multiplet. After an extended period of time, further nmr measurements showed that protons H-10β and H-8 are also replaced by deuterium. Hence H-10α is substituted by deuterium more readily than are the other protons α to the keto groups.

The chemical shifts and coupling constants for $PGE_1$ and 6-keto-$PGE_1$ were calculated to first order with an accuracy of about ±0.010 ppm and ±0.20 Hz, respectively. These data are reported in Table 2 for the methanol solutions together with the coupling constants for 6-keto-$PGE_1$ in buffer solutions. Good agreement is observed between the coupling constants for both molecules in the methanol solutions, indicating similar conformations of the five-membered rings. The coupling constants for $PGE_1$ compare with those previously observed for $PGE_2$ in $CDCl_3$ (29).

## Discussion

The 1D nOe measurements have been extensively applied in our studies of prostacyclin (9),

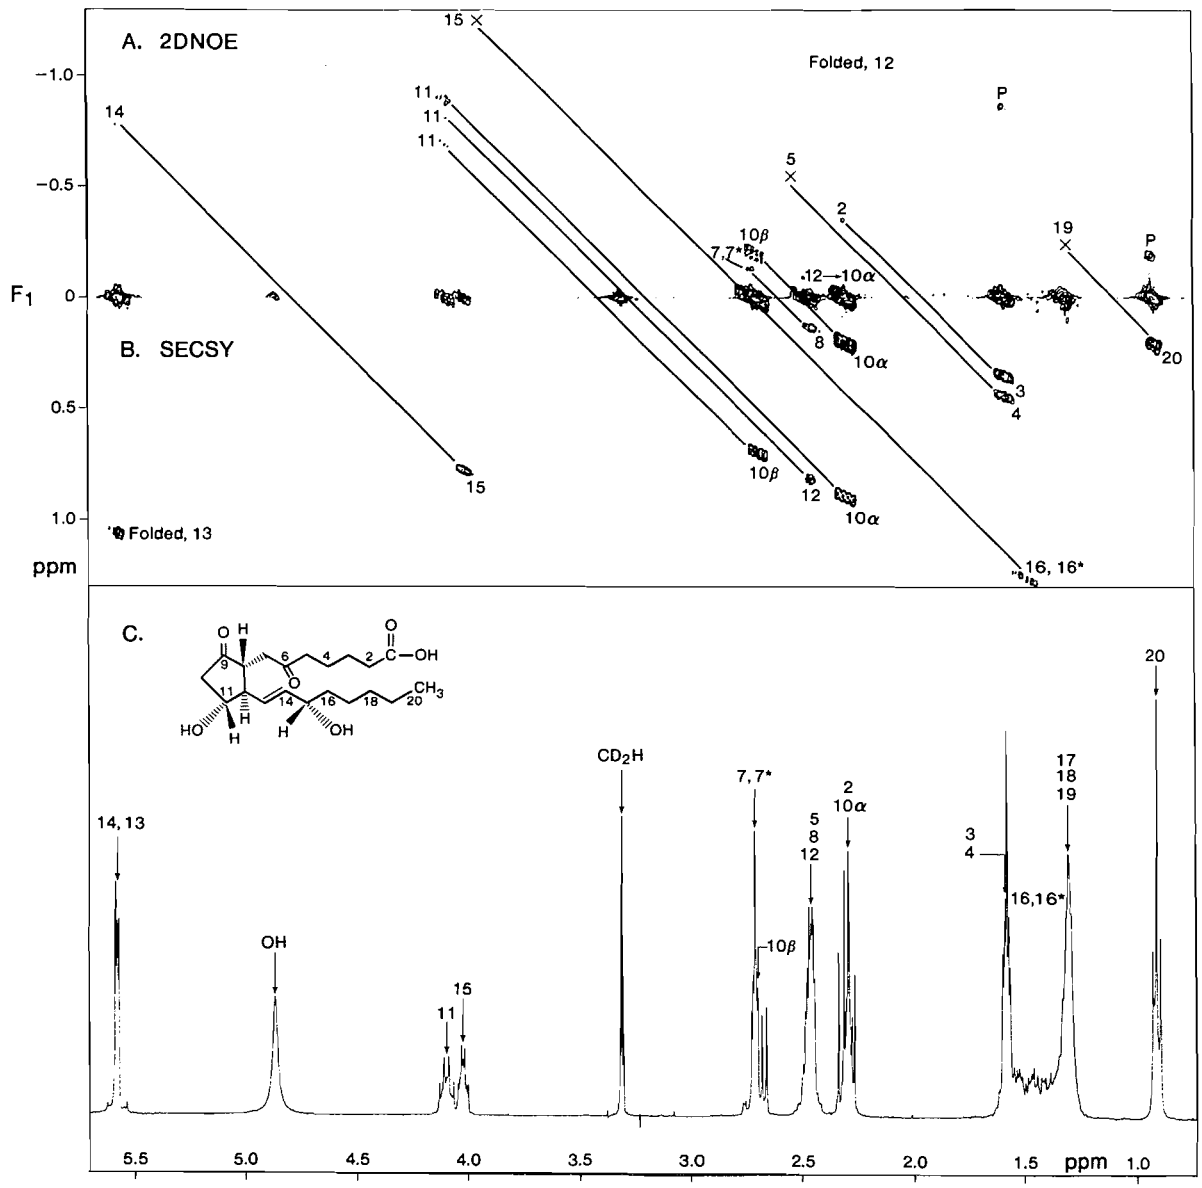

FIG. 3. The combined contour plot of the proton–proton 2D nOe experiment (2A) and the SECSY experiment (2B) for 6-keto-$PGE_1$. The cross peaks for both the 2D nOe and the SECSY experiments are labelled and are connected by the straight lines. Phantom peaks are labelled with a P. The × refers to contours that were observed but not plotted. For the 2D nOe experiment, $t_m$ equals 0.35 s. 32 transients were accumulated and the delay time between pulse sequences was 7.5 s. The FID's were multiplied by a sine bell function before Fourier transformation. The normal Fourier transform 1D spectrum obtained for 6-keto-$PGE_1$ is shown in C. The line assignments are indicated in the figure.

(6*R*)-prostaglandin $I_1$ (23), prostaglandin $E_2$ (29), (6*S*)-prostaglandin $I_1$ (30), and carboprostacyclin (31). These studies have now been extended to the 2D nOe experiment. A comparison of the data for $PGE_1$ in Table 1 shows the advantages of the 2D nOe experiment. The nOe from H-8 to H-12 is clearly visible, as is the nOe from H-10α to H-10β and H-11. On the other hand, in the 1D nOe experiment, both the H-8 and the H-10α protons must be simultaneously irradiated due to the overlapping multiplets. Then some of the observed nOe's can obviously be assigned to H-8 only, based on molecular model distances. However, the nOe's to H-10β, H-11, and H-12 are more difficult to assign. This was accomplished using the 2D nOe experiment. Finally, all of the observed nOe's in

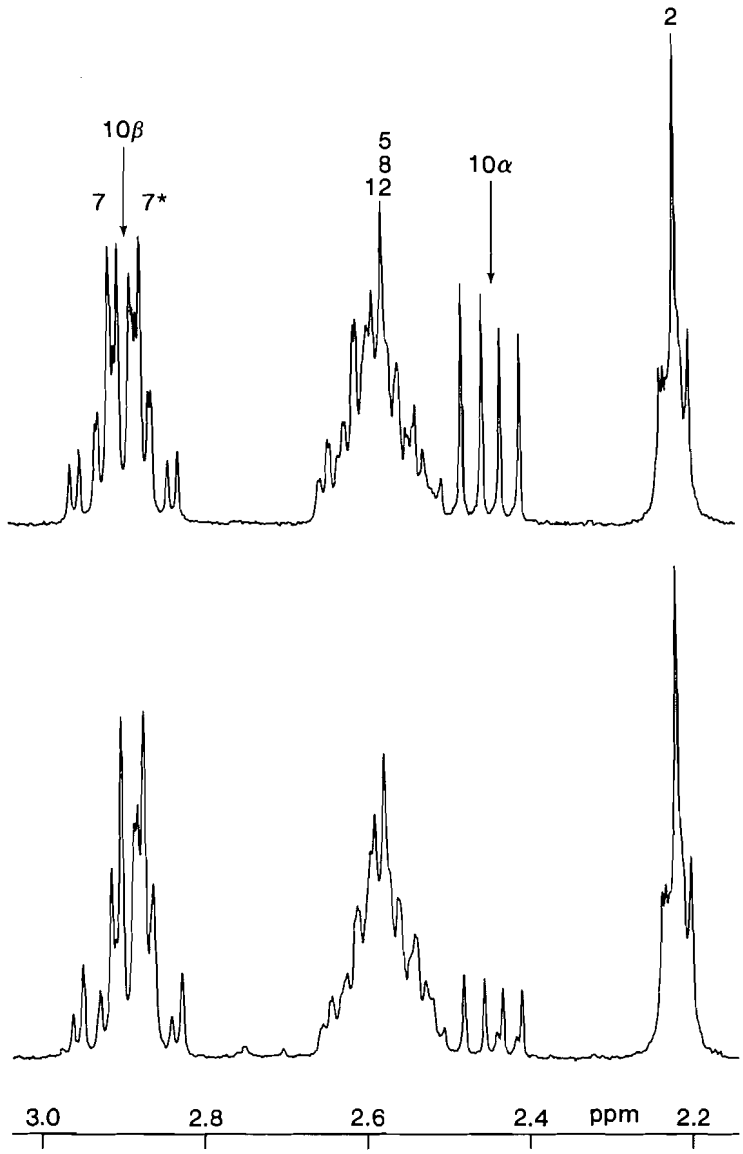

FIG. 4. Top spectrum: high-field region of the normal 1D spectrum observed for 6-keto-$PGE_1$ in phosphate buffer (0.20 *M*, pH 7.0) in $D_2O$. Bottom spectrum was obtained 28 h later.

the 2D experiment were obtained simultaneously, whereas seven experiments were required to obtain the 1D nOe data (in about the same time).

The SECSY experiment allows the determination of proton–proton *J*-connectivities. The great utility of this experiment is seen in Fig. 2. For example, the multiplet corresponding to the H-7,7* proton, which is coupled to H-8, is clearly evident in the top spectrum, whereas it would be impossible to observe this multiplet in the normal spectrum shown in the bottom of Fig. 2 due to the extensive multiplet overlap.

In view of the binding studies planned for 6-keto-$PGE_1$, a complete assignment of the proton magnetic resonance spectrum was required. This spectrum is shown in Fig. 3C for $CD_3OD$ solutions. A difficulty arises in the assignment of the proton resonances due to the extensive multiplet overlap in the high field region. Protons H-7, H-7*, H-5, and H-8 are difficult to assign by applying standard decoupling and 1D nOe techniques. In phosphate buffer, at a pH of 7.0, only the H-2 and H-10α proton multiplets no longer overlap and are thus simplified (Fig. 4). It was also observed that the

[a]The coupling constants in brackets, for 6-keto-$PGE_1$, are for the buffer solutions.
[b]Value obtained from 1D-nOe difference spectra.
[c]Value obtained from inversion recovery spectra.

H-10α proton was replaced by deuterium more readily than are the other protons α to the keto groups. However, the question of assigning the above-mentioned protons still remained.

The 2D nOe experiment combined with the SECSY experiment allowed this assignment to be carried out. The results of these two experiments, combined in one contour plot, are shown in Figs. 3A and 3B. Protons which experience both the nOe and the *J*-connectivity are connected by the straight lines. As seen from the figure, all of the expected nOe and *J* connectivities are present, for example, between H-10β and H-10α. In addition, separate contours are observed for H-7,7*, which can be distinguished from the H-10β contours. A connectivity is then established between H-7,7* and H-8 (at 2.45 ppm). The H-5 multiplet is also assigned a chemical shift of 2.45 ppm because a *J*-connectivity is observed from H-4 to H-5. Finally, the expected nOe between H-12 and H-10α is observed. Molecular models indicate that these two latter protons are in close spatial proximity. However, there is no coupling between H-12 and H-10α. Hence the combined 2D nOe and SECSY experiments lead to the assignment of H-5, H-7,7*, and H-8 and hence to the complete assignment of the 6-keto-$PGE_1$ spectrum as shown in Fig. 3C.

In summary, it can be readily seen that the combined 2D nOe and the spin-echo correlated spectroscopy (SECSY) experiments have proven to be of great value in the analysis of complex spectra.

# Kinetics and mechanisms of the oxidation of a nickel(II) oxime complex by cobalt(III) aquo ions in acidic aqueous media. Formation of a Ni(IV) complex

D. H. MACARTNEY[1] AND A. MCAULEY[2]

*Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2*

Received March 23, 1982

D. H. MACARTNEY and A. MCAULEY. Can. J. Chem. **60**, 2625 (1982).

The kinetics of the oxidation of a nickel(II) oxime complex to the corresponding nickel(IV) species by aquo cobalt(III) has been investigated in aqueous $CF_3SO_3H$ at various acidities (0.063–0.263 *M*) and temperatures (10.5–30.6°C). The inverse dependence of the rate constants on $[H^+]$ is attributed to a reaction pathway

$$CoOH^{2+} + Ni(II)(H_2L)^{2+} \xrightarrow{k_2} Co(II) + Ni(III)(H_2L)^{3+}$$

with $k_2 = 1.75 \times 10^4\ M^{-1}\ s^{-1}$, $\Delta H^{\ddagger} = 6.2 \pm 0.5$ kcal mol$^{-1}$, $\Delta S^{\ddagger} = -29.6 \pm 8.0$ cal deg mol$^{-1}$ ($K_h = 2 \times 10^{-3}\ M$ for the hydrolysis constant for cobalt(III)). The self-exchange parameter for the $Ni^{II}/Ni^{III}$-oxime couple ($k_{11} = 2.3 \times 10^3\ M^{-1}\ s^{-1}$, $\Delta G^{*} = 10.4$ kcal mol$^{-1}$) has been estimated from Marcus theory correlations. Comparisons are made between this value and the parameters determined for the Ni(II)/(III) tetra-aza macrocycle complexes.

D. H. MACARTNEY et A. MCAULEY. Can. J. Chem. **60**, 2625 (1982).

On a étudié la cinétique de l'oxydation du complexe de l'oxime de nickel(II) en nickel(IV) correspondant par le cobalt(III) aqueux, dans du $CF_3SO_3H$ aqueux à différentes acidités (0,063–0,263 *M*) et à différentes températures (10,5–30,6°C). On attribue au mécanisme réactionnel ci-dessous, l'influence inverse de $[H^+]$ sur la constante de vitesse

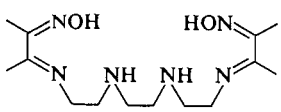
$$CoOH^{2+} + Ni(II)(H_2L)^{2+} \xrightarrow{k_2} Co(II) + Ni(III)(H_2L)^{3+}$$

avec $k_2 = 1{,}75 \times 10^4\ M^{-1}\ s^{-1}$, $\Delta H^{\ddagger} = 6{,}2 \pm 0{,}5$ kcal mol$^{-1}$, $\Delta S^{\ddagger} = -29{,}6 \pm 8{,}0$ cal deg mol$^{-1}$ ($K_h = 2 \times 10^{-3}$ pour la constante d'hydrolyse du cobalt(III)). On a évalué le paramètre d'auto-échange du couple $Ni^{II}/Ni^{III}$-oxime ($k_{11} = 2{,}3 \times 10^3\ M^{-1}\ s^{-1}$, $\Delta G^{*} = 10{,}4$ kcal mol$^{-1}$) à partir des corrélations de la théorie de Marcus. On a comparé ces valeurs entre elles et on déterminé les paramètres des complexes tétraazamacrocycles de Ni(II)/(III).

[Traduit par le journal]

## Introduction

There has been considerable recent interest in the formation of complexes of nickel in oxidation states higher than +2 (1–4). Attention has been paid principally to the use of tetra-aza macrocycles as ligands stabilising the ter-valent state. In these systems, there is evidence for the unpaired electron in the low-spin $d^7$ ion occupying a $d_z^2$ orbital since hyperfine interactions with axial ligands have been confirmed by esr studies (4, 5). There are, however, fewer complexes reported for the nickel(IV) state. Compounds containing di-oxime ligands have been prepared and studied (3, 6–8). Generally, a hexadentate ligand of the type **I** (3,14-dimethyl-4,7,10,13-tetraazahexadeca-3,13-diene-2,12-dione dioxime, $H_2L$) has been employed since pseudo-octahedral geometry is observed to be maintained in the $NiN_6$ complexes of nickel(II), (III), and (IV). The preparation of the Ni(IV) oxime by oxidation of the nickel(II) species has been carried out both electrochemically ($E^0(Ni^{IV}/Ni^{II}) = 0.95$ V) (8) or chemically with nitric acid (7). A similar chemical oxidation with $Ni(HL_1)^{2+}$ (where $HL_1$ represents the tridentate ligand 2-(2-aminoethyl)imino-3-butanone oxime) results in the Ni(IV) species $Ni(L_1)_2^{2+}$ which has been characterised by a crystal structure (9). Aqueous solutions of nickel(IV) complexes are stable for relatively long periods (weeks at 5°C) and, in keeping with the low-spin $d^6$ configuration, are of sufficient optical stability to be resolved (10).



**I**

In this paper, the kinetics and mechanism of the oxidation of $Ni(II)H_2L^{2+}$ by $Co(III)_{aq}$ are discussed. Since there is no change in the inner-sphere geometry of the reductant during the course of reaction, an outer-sphere mechanism is postulated. There has been increased use recently of the Marcus theory (11–14) to describe cross correlations of rate constants with free energy changes and also to derive self-exchange rates for reactants. We have used an approach of this type to attempt to

determine the rate of electron transfer for the Ni(II)/Ni(III) oxime couple.

## Experimental

*Reagents*

The oxime ligand, $H_2L$, was prepared by the condensation of butanedione monoxime with triethylenetetramine in ether. The nickel(II) oxime complex, $[Ni(H_2L)](ClO_4)_2$, was prepared by the addition of the ligand $H_2L$ to a methanol solution of $Ni(ClO_4)_2.6H_2O$ (7). The product was recrystallized from water and dried over $CaCl_2$. Analysis of the complex (Canadian Microanalytical Service) was satisfactory; observed (calculated) C 29.71 (29.49), H 5.02 (4.91), N 14.75 (14.70).

Solutions of hexaquocobalt(III) were prepared by the anodic oxidation of cobaltous perchlorate in perchloric acid (~5 *M*). The electrolysis was carried out near 0°C at a platinum electrode with $O_2$-free nitrogen passing through the solution. The stock solutions were analysed spectrophotometrically for Co(III) at 605 nm ($\varepsilon = 35.3\ M^{-1}\ cm^{-1}$) (15).

Owing to the insolubility of the nickel(II) oxime in perchlorate media, the kinetic studies were carried out in trifluoromethanesulphonic acid (Aldrich). The ionic strength of the reactant solutions was maintained at 0.50 *M* using lithium trifluoromethanesulphonate prepared by neutralising $CF_3SO_3H$ with lithium carbonate.

*Kinetic experiments*

The kinetic studies were made using a stopped-flow apparatus described previously (16). Thermostatting was maintained to within ±0.05°C in the temperature range 10.5–30.6°C. The reactions were followed by monitoring the formation of the nickel(IV) oxime product at 500 nm. All measurements were made under pseudo-first-order conditions of excess nickel(II) oxime concentrations. Plots of ln $(A_\infty - A_t)$ against time, derived from the absorbance data collected by a PCM-12 mini-computer, were linear for at least 3 half-lives. Rate constants were evaluated using a least-squares analysis of the slopes.

## Results

The visible spectrum of the products ($\lambda_{max}$ at 500 nm and 430 nm) of the oxidation of the nickel(II) oxime complex, $Ni(H_2L)^{2+}$, by $Co^{3+}$ in acidic aqueous media is consistent with the formation of a nickel(IV) species, $NiL^{2+}$ (7). The stoichiometry of the overall reaction

[1] $2Co^{3+} + Ni^{II}(H_2L)^{2+} \rightarrow 2Co^{2+} + Ni^{IV}L^{2+} + 2H^+$

was confirmed by a spectrophotometric titration ($\lambda$ = 500 nm) of 2.07 ± 0.10 mol of $Co^{3+}$ reacting per mol of the nickel oxime.

The observed rate constants exhibited a first-order dependence on the concentration of $Ni(H_2L)^{2+}$ as shown in Fig. 1. The second-order rate constants measured over the acid concentration range 0.063–0.263 *M* at five temperatures (10.5–30.6°C) are listed in Table 1. The rate constants were found to increase with decreasing hydrogen ion concentration. This inverse dependence is attributed to the hydrolysis of the $Co^{3+}$ ion ($pK_h = 2.7$) (15) rather than to a deprotonation of the oxime ligand in the $Ni(H_2L)^{2+}$ complex ($pK_1 = 5.9$, $pK_2 = 7.8$) at higher pH (7).

The rate law observed for the appearance of

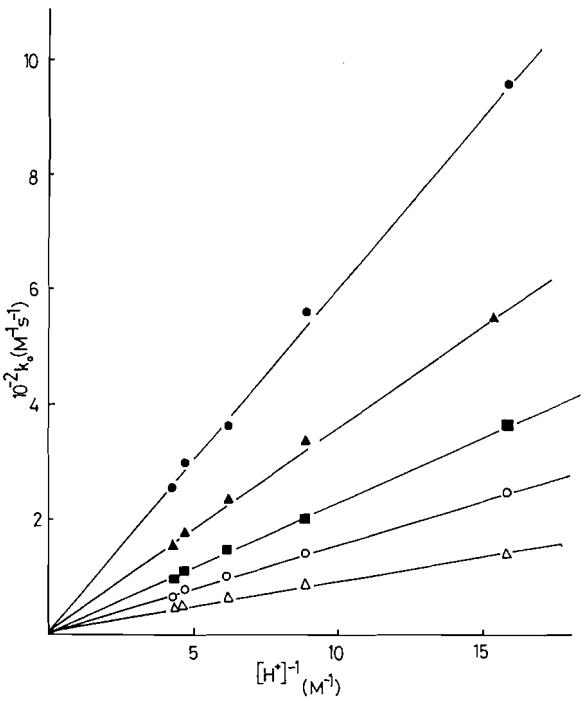

FIG. 2. A plot of $k_0$ against $1/[H^+]$ for the reaction of $Ni(H_2L)^{2+}$ with $Co^{3+}$ at several temperatures. △, $T$ = 10.5°C; ○, $T$ = 16.5°C; □, $T$ = 20.8°C; ▲, $T$ = 25.0°C; ●, $T$ = 30.6°C.

was noted, in general one standard deviation being greater than the intercept values obtained.

## Discussion

The observed rate laws may be derived from the following mechanistic scheme:

[3] $Co(H_2O)_6^{3+} \overset{K_h}{\rightleftharpoons} Co(H_2O)_5(OH)^{2+} + H^+$

[4] $Co^{3+} + Ni(II)H_2L^{2+} \xrightarrow{k_1} Co(II) + Ni(III)(H_2L)^{3+}$

[5] $Co(OH)^{2+} + Ni(II)H_2L^{2+} \xrightarrow{k_2} Co(II) + Ni(III)(H_2L)^{3+}$

[6] $Co(III) + Ni(III)L^{+} \xrightarrow{fast} Co(II) + Ni(IV)L^{2+}$

The rate law for the rate-determining one-electron oxidation may thus be written as

$$[7] \quad d[Ni(IV)L^{2+}]/dt = \frac{(k_1[H^+] + k_2K_h)}{([H^+] + K_h)} \times [Ni(II)]_t[Co(III)]_t$$

Under the conditions of study, $K_h$ (= $2 \times 10^{-3}$ $M$) < $[H^+]$ and since the intercept $k_1 < 10\ M^{-1}\ s^{-1}$ (Fig. 2), eq. [7] reduces to the form

$$[8] \quad d[Ni(IV)L^{2+}]/dt = \frac{k_2K_h}{[H^+]} [Ni(II)]_t[Co(III)]_t$$

where (eq. [2]) $a = k_2K_h$. The individual rate constants, $k_2$ (Table 2), have been derived using $K_h = 2 \times 10^{-3}$ $M$ (15) at 25°C while the dissociation constants at other temperatures were calculated using activation parameters (15, 17) associated with [3]; $\Delta H = 10 \pm 2$ kcal mol$^{-1}$ and $\Delta S = 21 \pm 8$ cal deg mol$^{-1}$. Specific rate constants were determined from a least-squares fit of the data in eq. [8] and are listed together with the corresponding activation parameters in Table 2.

The rate-determining step proposed is the one-electron oxidation (eq. [5]) to the nickel(III) species, $(Ni(III)H_2L)^{3+}$. From a knowledge of the proton equilibria for the nickel(II) complex (7) it is evident that only the fully protonated form is present under the conditions of the reaction. In the case of the nickel(III) ion, there is evidence (18) that in solutions of $[H^+] \sim 1.0\ M$ the species present is $Ni(III)HL^{2+}$. Above pH ~ 4 (p$K$ = 3.91) the deprotonated complex $Ni(III)L^+$ begins to predominate. In the present system, it is proposed that after electron transfer there is rapid dissociation to form $Ni(III)HL^{2+}$ (and possibly $Ni(III)L^+$). We have measured the acid-independent $Ni(IV)L^{2+}/Ni(III)L^+$ potential in *p*-toluenesulphonic acid media ($E^0$ = 0.64 V) and a rapid second oxidation to the nickel(IV) product is expected on the basis of the free energy changes involved.

It is of interest to note that in the corresponding oxidation of $Ni(cyclam)^{2+}$ (cyclam = 1,4,8,11-tetraazacyclotetradecane) (1) the sole reactive species is $CoOH^{2+}$. A hydroxide-mediated electron transfer within a specifically oriented outer-sphere precursor complex of $CoOH^{2+}$ and the square planar nickel(II) cyclam species has been suggested as an explanation.

The Marcus theory (11) for outer-sphere electron transfer reactions relates the free energy parameters for a cross-reaction ($\Delta G_{12}^0$, $\Delta G_{12}^*$) to the component self-exchange reactions ($\Delta G_{11}^*$, $\Delta G_{22}^*$). The relationship may be expressed in the form (19)

$$[9] \quad \Delta G_{12}^* = w + \lambda_{12}/4 + \Delta G_{12}^0/2 + (\Delta G_{12}^0)^2/4\lambda_{12}$$

TABLE 2. Specific rate constants and activation parameters* for the oxidation of $Ni(II)(H_2L)^{2+}$ by $CoOH^{2+}$

where $\lambda_{12} = 2(\Delta G_{11}^* + \Delta G_{22}^*)$, and $w$ is a parameter encompassing the work term associated with each of the free energy contributions. The work terms are usually small at an ionic strength $> 0.5\,M$ and, with reactants of the same charge type, tend to cancel each other out. Estimates for other reaction systems such as [5] may be derived using the expression (20)

$$w = 4.24 z_1 z_2 / r(1 + 0.329\, I^{1/2} r)$$

where $r$ is the distance of closest approach of the centres. Crystal data are not yet available for the nickel(II) oxime under study but bond lengths are available for a closely related complex (9), *bis*-2-(2-aminoethyl)imino-3-butanoneoximato nickel(II) which contains Ni—N, —oxime, —amine, and —imine groups and where the distorted octahedral geometry around the metal centre is retained on oxidation to Ni(IV). In the derivation of work terms the value of $r$ used was 10 Å. The activation free energy for the $CoOH^{2+/+}$ exchange has been measured previously (21) ($\Delta G_{22}^* = 11.2$ kcal mol$^{-1}$) and the reduction potential of $CoOH^{2+}$ may be estimated from that of the $Co^{3+}/Co^{2+}{}_{aq}$ couple (1.86 ± 0.02 V) (15) and the hydrolysis constants for the $Co^{3+}$ (p$K$ = 2.74) (15) and $Co^{2+}$ (p$K$ = 9.6) (22) aquo ions ($E^0{}_{CoOH^{2+/+}} = 1.44$ V).

Evidence favouring an outer-sphere reaction of $CoOH^{2+}$ with nickel(II)($H_2L$) may be presented by application of the cross reaction. Using the reaction of Ni(II)$(H_2L)^{2+}$ with Ru(bipy)$_3{}^{3+}$ in 1.0 $M$ *p*-toluenesulphonate medium, we have estimated (23) a value of 1.23 V for the reduction potential of the $Ni(H_2L)^{3+/2+}$ couple. From the resulting free energy change ($\Delta G^0 = -4.84$) for the $CoOH^{2+}$/$Ni(II)H_2L^{2+}$ system, a value of $\Delta G_{11}^* = 10.4 \pm 0.7$ kcal mol$^{-1}$ ($k_{11} = 2.4 \pm 1.6 \times 10^3\, M^{-1}\, s^{-1}$) may be obtained. A preliminary study of the oxidation of $Ni(II)H_2L^{2+}$ by a series of iron(III)–polypyridine complexes (23) yields a self-exchange parameter of $\sim 3 \times 10^3\, M^{-1}\, s^{-1}$. The exchange rate is also very similar to those derived recently by Lappin (18) for similar species. Using Co(phen)$_3{}^{2+}$ as reductant, he has derived $k_{11}$ values of $10^3\, M^{-1}\, s^{-1}$ and $2 \times 10^3\, M^{-1}\, s^{-1}$, respectively, for the Ni(HL)$^{2+/+}$ and $NiL^{+/0}$ exchanges. The Ni(II)/(III) oxime self-exchange parameters are close to those for the Ni(II)/(III) cyclam complexes ($1 \pm 0.3 \times 10^3\, M^{-1}\, s^{-1}$) (24). The oxime species retain an octahedral configuration in both oxidation states whereas a change from square-planar $Ni(II)L^{2+}$ to octahedral $NiL(OH_2)_2{}^{3+}$ occurs when L is a tetraaza macrocycle. The similarity in the self-exchange parameters suggests that there is only a small reorganisation energy associated with the change in geometry. There is also evidence that a square-planar–octahedral equilibrium (25) exists for these macrocycles and it may be that the axially solvated forms react in these outer sphere processes. Further kinetic studies on nickel(II) complexes with other cyclic and non-cyclic ligands will be helpful in examining the effects of ring size and geometry on the thermodynamics of electron exchange in these ions.

# The reaction of active nitrogen with fluoroethylenes

WILLIAM E. JONES AND MAHMOODA G. AHMED
*Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3*

Received April 13, 1982

WILLIAM E. JONES and MAHMOODA G. AHMED. Can. J. Chem. **60**, 2629 (1982).

The reactions of active nitrogen with the fluoroethylenes $C_2H_3F$, 1,1-$C_2H_2F_2$, $C_2HF_3$, and $C_2F_4$ have been investigated in a conventional flow system using a mass spectrometer to detect products and intermediate species. Addition of various gases (H, $H_2$, $NH_3$, $CH_4$, $N_2O$, $N_2(A^3\Sigma_u^+)$, and F) to the reacting mixtures provides evidence that both H and F atoms play significant roles in the reaction mechanisms, while $N_2A^3\Sigma_u^+$ does not. A brief discussion of possible mechanisms is presented.

WILLIAM E. JONES et MAHMOODA G. AHMED. Can. J. Chem. **60**, 2629 (1982).

On a étudié les réactions de l'azote actif avec les fluoroéthylènes $C_2H_3F$, $C_2H_2F_2$-1,1, $C_2HF_3$ et $C_2F_4$, dans un système à écoulement conventionnel et en utilisant un spectromètre de masse pour détecter les produits et les espèces intermédiaires. L'addition de différents gaz (H, $H_2$, $NH_3$, $CH_4$, $N_2O$, $N_2(A^3\Sigma_u^+)$ et F) au mélange réactionnel fournit la preuve que les deux atomes H et F jouent un rôle important dans le mécanisme réactionnel tandis que $N_2A^3\Sigma_u^+$ n'apporte aucune contribution. On discute brièvement des mécanismes possibles.

[Traduit par le journal]

## Introduction

The reactions of active nitrogen with hydrocarbons have been investigated by many workers. In particular, the reaction with ethylene has been studied extensively and several mechanisms have been suggested (1–5). In contrast, reports on the reactions of active nitrogen with fluoro-substituted ethylenes are scanty and there are considerable uncertainties about the mechanism of these reactions.

In an earlier study on the reaction of active nitrogen with perfluorinated olefins (6), a mechanism analogous to the early mechanism was proposed for the active nitrogen – hydrocarbon system (1). A bimolecular addition of a nitrogen atom to the fluorocarbon was suggested to be the initial step, which in the case of the tetrafluoroethylene reaction would be written as in [1].

$$[1] \quad N + C_2F_4 \rightarrow (C_2F_4N) \begin{cases} \rightarrow F_2CN + CF_2 \\ \rightarrow FCN + CF_3 \end{cases}$$

However, it is now believed that the mechanism of the hydrocarbon – active nitrogen reaction is not as simple as was suggested by Winkler and coworkers (1). Rather the reactions are considerably complicated by the involvement of hydrogen atoms and hydrocarbon radicals (2–5). More recently, Safrany and Jaster (4) proposed that the reaction of olefin with active nitrogen is initiated by hydrogen atoms rather than nitrogen atoms. This initiation step is alleged to produce alkyl radicals which are ultimately attacked by the N atoms. In light of this mechanism, one might suggest that hydrogen or fluorine atoms play a similar role in the reaction of fluoroethylene molecules with active nitrogen. Alternatively, it might be suggested in agreement with Merchand and Stringat (7), who studied the reaction with tetrafluoroethylene ($C_2F_4$), that the reaction is initiated by excited molecular nitrogen $N_2(A^3\Sigma_u^+)$. Involvement of excited state molecular nitrogen was also suggested by Johnson and Fontijn (8) in the final chemiexcitation step producing emission from the same reaction. This paper describes our attempts to determine whether either or both of the above possibilities are important.

## Experimental

Active nitrogen was produced in a conventional fast flow system by a 2450 MHz electrodeless discharge sustained by a 100 W Kiva MPG-2 generator. Hydrogen or fluorine atoms were also produced by 2450 MHz radiation from a Burdick MW/200 generator. Both nitrogen and hydrogen (or fluorine) gases could be activated simultaneously in separate discharge regions and introduced to the reaction flow tube. Typical flow conditions were: $N_2$, $1.2 \times 10^{-4}$ mol $s^{-1}$; $H_2$, $4.5 \times 10^{-5}$ mol $s^{-1}$; $F_2$ (1% in He), $1.5 \times 10^{-7}$ mol $s^{-1}$. The concentration of atomic nitrogen was measured by NO titration. The total pressure in the reaction tube was 0.95 Torr. The pressure in the mass spectrometer was approximately $2 \times 10^{-5}$ Torr. An ionization voltage of 23 eV was used to produce the ions.

The reaction tube was constructed from a 75 cm long 20 mm od Pyrex tube. The tube contained 9 multiperforated gas inlets spaced at various intervals along the tube. A portion of the reaction mixture passed directly into a T.O.F. mass spectrometer ionization chamber through a line of sight double pinhole system. The flow system, pinhole region, mass spectrometer, and data acquisition system are described in detail elsewhere (9).

Molecular nitrogen and hydrogen were obtained from Linde. Vinyl fluoride, 1,1-difluoroethylene, trifluoroethylene, methane, nitric oxide, and ammonia were supplied by Matheson. Nitrous oxide was a product of Canadian Liquid Air Limited. Tetrafluoroethylene was prepared by thermal decomposition of tetrafluoroethylene polymer boiling chips. All condensible

gases were purified by bulb-to-bulb distillation until no impurities could be detected mass spectrometrically. Nitrogen was purified by passing it through hot copper turnings and a liquid nitrogen trap.

## Results and discussion

Addition of fluoroethylene to active nitrogen produced a luminescent reaction flame about 10–15 cm in length. With $C_2H_3F$ and 1,1-$C_2H_2F_2$ the flame was greenish white, while with $C_2HF_3$ and $C_2F_4$ it was orange yellow. The *m/z* values of those positive ions attributable to products of the reactions are presented in Table 1.

Similar to the hydrocarbon – active nitrogen reactions a major product of the reaction of active nitrogen with $C_2H_3F$, 1,1-$C_2H_2F_2$, and $C_2HF_3$ was HCN (*m/z* 27). As the number of fluorine atoms in the ethylene molecule increase a decrease is observed in the relative amount of HCN produced and the peaks at *m/z* 50 ($CF_2{}^+$) and *m/z* 69 ($CF_3{}^+$) become progressively more important. If the fluoroethylene – active nitrogen reaction is truly analogous to the hydrocarbon – active nitrogen reaction, we might expect to obtain significant amounts of FCN as a product. A mass peak at *m/z* 45 in the reaction of 1,1-$C_2H_2F_2$, $C_2HF_3$, and $C_2F_4$ with active nitrogen probably corresponds to FCN. However, the relatively small amount of FCN produced could be due to its decomposition or its involvement in further reactions such as the formation of polymer. In the $C_2H_3F$ reaction, the *m/z* 45 peak is a major fragmentation peak of $C_2H_3F$ itself, which thus precludes the detection of FCN. For each of the fluorocarbons studied polymer was formed on the wall of the reaction tube as was found to be the case in earlier studies (6).

The reactions of active nitrogen with the fluoroethylenes are quite complex. The type and number of products formed, and the uncertainty about the initiation step make a quantitative study difficult. In an attempt to decide whether excited molecular nitrogen or species other than those present in active nitrogen played a significant role, we introduced a number of additives (H, $H_2$, F, $NH_3$, $N_2O$, $CH_4$, $N_2(A^3\Sigma_u^+)$) into the reacting mixtures. An indication of the effects of these additives on various product peaks is given in Figs. 1 to 3.

### *Effect of hydrogen atoms*

On addition of H atoms, the reaction of $C_2H_3F$ with active nitrogen was greatly enhanced, as evidenced by a sharp decrease in the length and increase in the intensity of the reaction flame. A

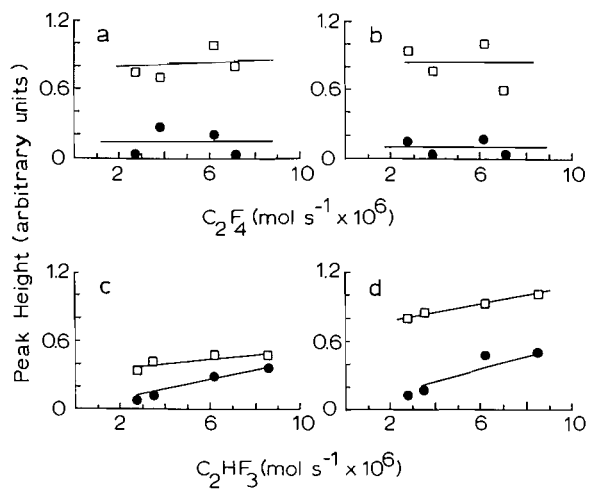

FIG. 2. Variation of major product mass peaks. (*a*) $CF_2^+$ in $C_2F_4$ reaction, (*b*) $CF_3^+$ in $C_2F_4$ reaction, (*c*) $FCN^+$ in $C_2HF_3$ reaction, (*d*) $CF_2^+$ in $C_2HF_3$ reaction. □, Active nitrogen with fluoroethylene. ●, Addition of $CH_4$ to reaction.

large decrease was also observed in the $N^+$ (from N) mass spectral peak, while a large increase was observed in the product peaks corresponding to $HCN^+$, $HF^+$, $CH_3^+$, $CH_4^+$, and $CH_3CN^+$. An example of this increase is given for the major product peak $HCN^+$ in Fig. 1*a*. A similar although not as pronounced effect was observed when H atoms were added to the 1,1-$C_2H_2F_2$ and $C_2HF_3$

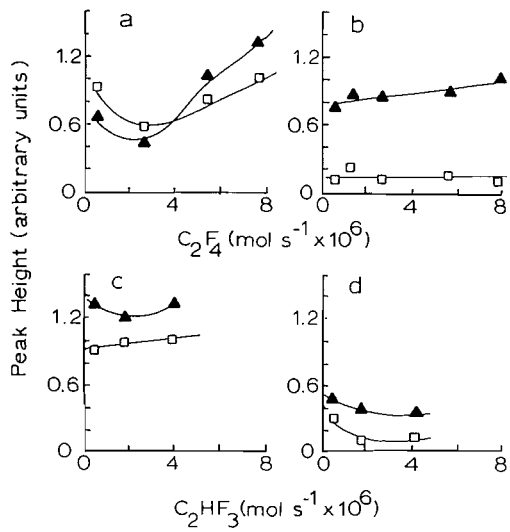

FIG. 3. Variation of major product mass peaks. (*a*) $CF_2^+$ in $C_2F_4$ reaction, (*b*) $CF_3^+$ in $C_2F_4$ reaction, (*c*) $CF_2^+$ in $C_2HF_3$ reaction, (*d*) $CF_3^+$ in $C_2HF_3$ reaction. □, Active nitrogen with fluoroethylene. ▲, Addition of F atoms to reaction.

reactions with active nitrogen. Figure 1*b* presents the effect on the $HCN^+$ peak for $C_2HF_3$.

In contrast to the above behaviour, product formation in the $C_2F_4$ – active nitrogen reaction was inhibited by the addition of H atoms. This inhibition may be on account of the presence of $H_2$ (see below) since the H atoms were present in an excess of molecular hydrogen. Results are shown for the two major product peaks, $CF_2^+$ and $CF_3^+$ in Fig. 1*c*, *d*.

*Effect of molecular hydrogen*

The addition of molecular hydrogen to the reaction of $C_2F_4$ with active nitrogen resulted in almost complete quenching of the reaction as evidenced by extinction of the reaction flame and decrease in product yields particularly at low flow rates of $C_2F_4$ (Fig. 1*b*, *c*). Although the reaction was quenched, the formation of small amounts of HF was noted on addition of $H_2$. Addition of $H_2$ to the $C_2HF_3$ reaction decreased product yields significantly at low $C_2HF_3$ flow rates, but had little effect at high $C_2HF_3$ flow rates (Fig. 1*b*). Addition of $H_2$ to 1,1-$C_2H_2F_2$ and $C_2H_3F$ appeared to have little effect on the reaction.

*Effect of ammonia and methane*

As with $H_2$, ammonia (Figs. 1*b*, *c*) and methane (Fig. 2*a*) essentially quenched the reaction of active nitrogen with $C_2F_4$, but did produce small amounts of HF. Ammonia (Fig. 1*d*) and methane (Fig. 2*b*) also severely inhibited the reaction with $C_2HF_3$. The reaction with 1,1-$C_2H_2F_2$ and $C_2H_3F$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

was not significantly affected by the addition of ammonia or methane.

*Effect of fluorine atoms*

The effect of fluorine atoms on the major product peaks of the reactions with $C_2F_4$ and $C_2HF_3$ are indicated in Fig. 3. When added to the $C_2F_4$ reaction, a very significant increase in the $CF_3^+$ product peak was observed (Fig. 3*b*), while the $CF_2^+$ product peak underwent a slight decrease at low $C_2F_4$ flow, and a slight increase at increased $C_2F_4$ flow. A shorter and brighter reaction flame was also noted on the addition of fluorine atoms. In the $C_2HF_3$ reaction a small increase in both the $CF_2^+$ and $CF_3^+$ peaks was observed.

*Effect of nitrous oxide*

The addition of $N_2O$ had very little effect on these reactions. No new detectable products were found nor did $N_2O$ quench the reactions as might have been expected if excited molecular nitrogen ($A^3\Sigma_u^+$) was an important initiating species.

*Addition of $N_2(A^3\Sigma_u^+)$*

Excited molecular nitrogen $N_2(A^3\Sigma_u^+)$ was produced from metastable Ar as described by Meyer *et al.* (10) and admitted to the $C_2F_4$ and $C_2HF_3$ active nitrogen reaction mixtures. This addition did not appear to affect either the reaction flame characteristics, or the type or amount of products formed.

Contrary to earlier suggestions (7, 8), it seems from the above observations that the effect of excited molecular nitrogen $N_2(A^3\Sigma_u^+)$ is minimal in initiating the reaction of active nitrogen with $C_2F_4$ or $C_2HF_3$. Both $NH_3$ and $N_2O$ are known to be efficient quenchers of $N_2(A^3\Sigma_u^+)$ (11). The large effect on the reaction by $NH_3$ seems to be contradictory to the observation of no effect by $N_2O$. This contradiction may be explained if fluorine atoms are considered to be an important species in these reactions. $NH_3$ reacts very rapidly with F atoms (12) while the reaction of F with $N_2O$ is very slow (12).

Additional evidence that F atoms play a role in these reactions is shown by the inhibiting effect of H and/or $H_2$, $H_2$, and $CH_4$ (all of which react rapidly, $k > 10^{13}$ cm$^3$ mol$^{-1}$ s$^{-1}$, with F (12)) on the reaction with $C_2F_4$ and to a lesser extent on the reaction with $C_2HF_3$ and by the formation of HF or increased amounts of HF with these additions. Further, the addition of F atoms to the reactions with $C_2F_4$ and $C_2HF_3$ enhanced the reaction.

This conclusion, that F atoms play an important role in the $C_2F_4$ and $C_2HF_3$ – active nitrogen reactions, is complementary to the earlier suggestions (2–5) that H atoms play a significant role in hydrocarbon – active nitrogen reactions. With some hesitation, it may be suggested that F atoms are the initiating species in these reactions much as H atoms have been suggested as the initiating species for hydrocarbon – active nitrogen reactions (4).

We can only speculate on the initiation step. If F atoms are the initiating species for the $C_2F_4$ reaction they must result from either reaction [2*a*] or [2*b*],

[2*a*] $N + N + C_2F_4 \rightarrow N_2 + C_2F_3 + F$ $\quad \Delta H = -427$ kJ mol$^{-1}$

[2*b*] $N_2^* + C_2F_4 \rightarrow N_2 + C_2F_3 + F$

where $N_2^*$ indicates some excited species of $N_2$ other than the $A$ state.[1] Alternatively, since the C=C bond is the weakest in $C_2F_4$ the initiation by N or $N_2^*$ might produce $CF_2$ radicals as in [3*a*] or [3*b*],

[3*a*] $N + N + C_2F_4 \rightarrow 2CF_2 + N_2$ $\quad \Delta H = -586$ kJ mol$^{-1}$

[3*b*] $N_2^* + C_2F_4 \rightarrow 2CF_2 + N_2$

followed by rapid reaction of atomic nitrogen with the $CF_2$ radicals.

Attack of the F atom on the fluorocarbon would produce an excited radical [4] which may directly dissociate

[4] $F + C_2F_4 \rightarrow [C_2F_5]^* \rightarrow CF_2 + CF_3$

or react with N atoms as in [5]

[5] $C_2F_5 + N \rightarrow F_2CN + CF_3$

These reactions will be followed by a series of rapid reactions involving the radicals and N or F atoms as in [6] to [11]. Such reactions can explain the rapid and complete reaction of nitrogen at very low concentrations of $C_2F_4$.

[6] $CF_3 + N \rightarrow F_2CN + F$ $\quad \Delta H = -69$ kJ mol$^{-1}$

[7] $CF_2 + N \rightarrow F_2CN$ $\quad \Delta H = -479$ kJ mol$^{-1}$

[8] $CF_2 + N \rightarrow FCN + F$ $\quad \Delta H = -258$ kJ mol$^{-1}$

[9] $CF_2 + F \rightarrow CF_3$ $\quad \Delta H = -410$ kJ mol$^{-1}$

[10] $F_2CN + N \rightarrow FCN + NF$ $\quad \Delta H = -90$ kJ mol$^{-1}$

[11] $NF + N \rightarrow N_2 + F$ $\quad \Delta H = -630$ kJ mol$^{-1}$

The rates of addition of H atoms to fluoroethylenes are known to be fast (13, 14), while the abstraction of an H or F atom by H are reported to

[1]Values of $\Delta H_f^0$ used in the calculation of heats of reaction were obtained from the National Bureau of Standards, Circular No. 26, except for: FCN, $-13 \pm 42$ kJ mol$^{-1}$ (ref. 15); $H_2CN$, $-180$ kJ mol$^{-1}$ (ref. 4); $F_2CN$, $-155$ kJ mol$^{-1}$; $C_2H_4F$, $-180$ kJ mol$^{-1}$; HFCN, $+47$ kJ mol$^{-1}$ (all calculated using MNDO, ref. 16).

be less likely processes (14). From the present observation that addition of H atoms greatly enhances the reactions $C_2H_3F$, 1,1-$C_2H_2F_2$, and $C_3HF_3$ with active nitrogen we suggest that hydrogen addition reactions initiate these reactions in the same way as proposed for hydrocarbon reactions (4). A set of possible reactions can thus be proposed for the hydrogen-containing fluorocarbons as shown in reactions [12] to [20].

[12] $C_2H_3F + H \rightarrow C_2H_4F$ $\Delta H = -280$ kJ mol$^{-1}$

[13] $C_2H_4F + N \rightarrow H_2CN + CH_2F$ $\Delta H = -139$ kJ mol$^{-1}$

[14] $\rightarrow HFCN + CH_3$ $\Delta H = -105$ kJ mol$^{-1}$

[15] $CH_3 + N \rightarrow H_2CN + H$ $\Delta H = -212$ kJ mol$^{-1}$

[16] $H_2CN + N \rightarrow HCN + NH$ $\Delta H = -197$ kJ mol$^{-1}$

[17] $CH_2F + N \rightarrow HFCN + H$ $\Delta H = -178$ kJ mol$^{-1}$

[18] $HFCN + N \rightarrow NH + FCN$ $\Delta H = -200$ kJ mol$^{-1}$

[19] $\rightarrow NF + HCN$ $\Delta H = -154$ kJ mol$^{-1}$

[20] $NH + N \rightarrow N_2 + H$ $\Delta H = -584$ kJ mol$^{-1}$

Similar sets of reactions could be proposed for 1,1-$C_2H_2F_2$ and $C_2HF_3$.

However, it is likely that both H atoms and F atoms play significant roles in the reaction of $C_2HF_3$ and to a lesser extent in the reaction of 1,1-$C_2H_2F_2$. In these reactions a mechanism would have to combine appropriate reactions from the H and F atom mechanisms.

# Isomérie *Z*–*E* des spirochromènes oxa- et thiazolidiniques-1,3 à deux atomes de carbone asymétriques. Comparaison avec les spirochromènes oxa- et thiaziniques-1,3 homologues

MICHEL MAGUET, YVES POIRIER ET ROBERT GUGLIELMETTI

*Laboratoire de synthèse organique, LA C.N.R.S. 322, Université de Bretagne Occidentale, Faculté des Sciences et Techniques, 6, Avenue V. Le Gorgeu, 29283 Brest Cedex, France*

Reçu le 4 février 1982

MICHEL MAGUET, YVES POIRIER et ROBERT GUGLIELMETTI. Can. J. Chem. **60**, 2635 (1982).

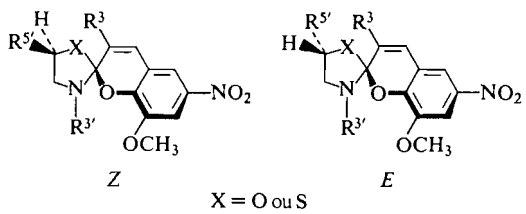
La synthèse de spirochromènes oxa- et thiazolidiniques-1,3 à deux atomes de carbone asymétriques en α de l'oxygène ou du soufre conduit généralement à un mélange de deux diastéréoisomères où la configuration *Z* prédomine. L'examen de modèles de Dreiding et l'application de l'équation de Karplus permettent une résolution satisfaisante de ce problème. Par contre, un seul isomère existe en séries tétrahydro-2,4,5,6 oxa- ou thiazinique-1,3 homologues. L'étude de la géométrie du cycle azoté prouve alors que la configuration peut être *Z* ou *E* selon que l'un des atomes de carbone asymétriques est en α ou en β de l'oxygène ou du soufre.

MICHEL MAGUET, YVES POIRIER, and ROBERT GUGLIELMETTI. Can. J. Chem. **60**, 2635 (1982).

The synthesis of oxa- and thiazolidine-1,3 spirochromenes with two asymmetric carbon atoms in an α position to oxygen or sulphur leads generally to a mixture of two diastereoisomers for which the *Z* configuration is predominant. Examination of Dreiding models and application of the Karplus equation allow a good solution of this problem. On the other hand, only one isomer exists in the 2,4,5,6-tetrahydro oxa- or thiazine-1,3 homolog compounds. The study of the geometry of the aza ring proves then that the configuration may be *Z* or *E* according to whether one of the asymmetric carbon atoms is in an α or β position to oxygen or sulphur.

## Introduction

L'un des aspects les plus originaux de la synthèse des spirochromènes oxa- et thiazolidiniques-1,3 **1** et **2** est l'obtention de deux diastéréoisomères *E* et *Z* quand ces composés présentent deux atomes de carbone asymétriques en α de l'atome d'oxygène ou de soufre (1, 2). Leur structure est la suivante:



Gruda *et al.* (3, 4) ont déjà signalé à propos de spirochromènes indoliniques asymétriquement substitués en position 3′ que l'étude de la cinétique de l'isomérisation *Z*–*E* est possible par la rmn $^1$H. C'est là une différence essentielle avec nos résultats. Nous avons constaté que les rapports **1***E*/**1***Z* et **2***E*/**2***Z* sont selon cette technique indépendants du temps et de la nature du solvant utilisé pour la réalisation du spectre. La séparation des deux diastéréoisomères – possible en série indolinique (4) – n'était pas notre motivation principale.[1] En effet, les spectres de rmn $^1$H à 250 MHz des mélanges *Z*/*E* sont suffisamment explicites pour permettre une approche de la géométrie des cycles oxa- et thiazolidiniques par le biais de l'équation de Karplus. Le même travail a été conduit dans le cas des spirochromènes tétrahydro oxa- et thiaziniques-1,3 de formules générales **3** et **4** pour lesquels on ne rencontre qu'un seul diastéréoisomère. Le présent mémoire concerne les deux points suivants.

1. L'identification du diastéréoisomère majoritaire.

2. L'approche de la stéréochimie des cycles azotés des composés **1**–**4**.

La résolution de ces deux problèmes est particulièrement intéressante. Nous avons montré en effet que la géométrie des photomérocyanines colorées produites par irradiation ultraviolette des spirochromènes dépend de la géométrie de ces derniers (5, 6). Il en résulte des répercussions au niveau des propriétés spectroscopiques et des applications potentielles de ces composés.

[1]La séparation des diastéréoisomères dans les séries oxazolidinique et thiazolidinique – irréalisable par cristallisation fractionnée – peut être envisagée grâce à la chromatographie liquide sous pression. L'ampleur des difficultés rencontrées ne nous a pas incité à développer nos recherches par cette technique.

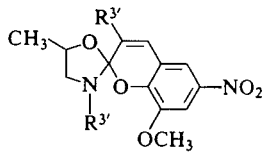
## Résultats et discussion

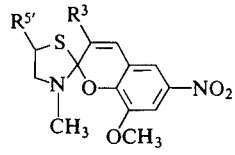
### I. *Spirochromènes oxa- et thiazolidiniques-1,3 1 et 2*

#### I.1 *Identification du diastéréoisomère majoritaire*

Les spirochromènes suivants ont été étudiés:



1



2

**1***a* $R^{3'} = CH_3$; $R^3 = C_2H_5$ **2***a* $R^{5'} = R^3 = CH_3$
**1***b* $R^{3'} = CH_3$; $R^3 = C_6H_5$ **2***b* $R^{5'} = CH_3$; $R^3 = OCH_3$
**1***c* $R^{3'} = CH_3$; $R^3 = OC_2H_5$ **2***c* $R^{5'} = t\text{-}C_4H_9$; $R^3 = CH_3$
**1***d* $R^{3'} = i\text{-}C_3H_7$; $R^3 = CH_3$ **2***d* $R^{5'} = t\text{-}C_4H_9$; $R^3 = i\text{-}C_3H_7$
**2***e* $R^{5'} = C_6H_5$; $R^3 = CH_3$
**2***f* $R^{5'} = OCH_3$; $R^3 = CH_3$

Les spectres de rmn $^1H$ ont été réalisés à 250 MHz et dans le deutériochloroforme (température de la sonde 20°C). Les figures 1 et 2 démontrent l'existence de deux diastéréoisomères pour les spirochromènes **1***a* et **2***a*. Les données les plus remarquables concernant les composés **1***a*–**1***d* et **2***a*–**2***f* sont groupées dans les Tableaux 1 et 2. Nous y indiquons les pourcentages des deux diastéréoisomères que nous désignons par *Min.* (minoritaire) et par *Maj.* (majoritaire). Le Tableau 2 montre que la proportion de *Maj.* va en augmentant (de 55 à 75%) avec l'encombrement soit de la position 5′ (spirochromènes **2***a*, **2***c* et **2***e*), soit des positions 3 et 5′ (spirochromène **2***d*). La détermination de la nature *Z* ou *E* du diastéréoisomère *Maj.* nécessite l'étude du dernier acte de la synthèse des spirochromènes, celui où la mérocyanine intermédiaire se referme selon le mécanisme généralement admis (7). On ne connaît pas la géométrie de cette entité fugace, mais il est vraisemblable que la partie azahétérocyclique se rapproche de celle des sels quaternaires par ses conformations possibles (8).

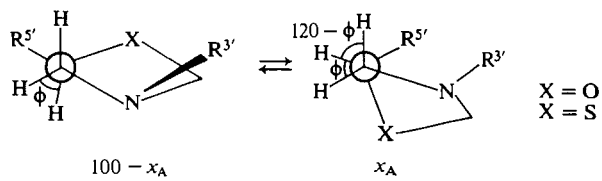
Sur cette base, nous avons réalisé un modèle de Dreiding de la mérocyanine **2**′*c* précurseur du spirochromène **2***c* (fig. 3).

Il est logique d'admettre que le groupement *tert*-butyle adopte une situation pseudo-équatoriale. S'il en était autrement, l'encombrement stérique serait tel, que la refermeture ne pourrait se faire que d'un seul côté, d'où formation d'un seul diastéréoisomère. Or, dans le cas où le groupement *tert*-butyle est pseudo-équatorial la refermeture conduisant à l'isomère *E* sera défavorisée par une gêne due à l'hydrogène pseudo-axial $H^{5''}$. Aucune gêne de ce type ne se rencontre dans une refermeture donnant le diastéréoisomère *Z*. Celui-ci sera donc majoritaire dans le cas du spirochromène **2***c*. Le raisonnement est identique pour **2***d* et **2***e*.

Le substituant $R^{5'}$ n'intervient donc dans la formation des deux diastéréoisomères que de manière indirecte. Lorsque $R^{5'} = CH_3$, la possibilité d'avoir ce substituant en situation pseudo-axiale n'est plus négligeable. La proportion de diastéréoisomère minoritaire *E* va augmenter dans les séries oxa- et thiazolidiniques (composés **1***a*–**1***d*, **2***a* et **2***b*). Le cas du spirochromène thiazolidinique **2***f* est particulier en raison de la formation d'un seul diastéréoisomère. Le calcul selon l'équation de Karplus montre que le substituant $R^{5'} = OCH_3$ est pseudo-axial dans ce composé (cf. Tableau 4). Le diastéréoisomère *E* se formera seul (cf. fig. 4).

#### I.2 *Approche de la stéréochimie des cycles oxa- et thiazolidiniques*

*I.2.1* Nous avons appliqué les travaux de Elguero et Fruchier (9) à la détermination de l'angle de torsion du fragment éthanique dans les spirochromènes **1** et **2**. On fait appel pour celà aux deux méthodes classiques basées sur l'équation de Karplus et où intervient soit la différence soit le rapport des constantes de couplage vicinal *cis* et *trans*. Ce mode de calcul permet de déterminer, outre l'angle de torsion $\phi$, la population $x_A$ du conformère avec $R^{5'}$ pseudo-axial (on fait abstraction dans l'équilibre ci-dessous de la partie chroménique des composés **1** et **2**).

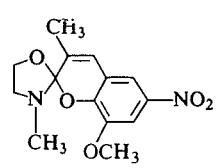


$100 - x_A$ $x_A$ X = O X = S

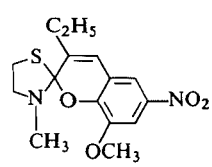
On admet que l'angle de pliage des deux conformères est le même. Ceci est faux car le conformère le plus encombré sera moins plié que l'autre. Néanmoins, il est intéressant de connaître les conséquences d'une telle hypothèse.

*I.2.2* La conduite des calculs selon la réf. 9 réclame la résolution des points suivants.

L'analyse du cas des spirochromènes oxa- et thiazolidiniques non substitués en 4′, 4″ et en 5′, 5″. Nous avons choisi pour cela les deux composés ci-dessous:



**1***e*



**2***g*

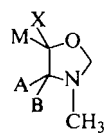
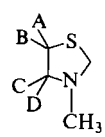
[a]δ en ppm/TMS, multiplicité, $J$(Hz), solvant $CDCl_3$ s: singulet, d: doublet, d de d: doublet de doublets, t: triplet, q: quadruplet, m: multiplet, *Min.*: minoritaire *Maj.*: majoritaire.

Les spectres de rmn $^1H$ ont été réalisés à 250 MHz dans le deutériochloroforme. Celui du spirochromène **1***e* est du type ABMX et celui du spirochromène **2***g* du type ABCD.

L'analyse du système ABCD est possible en faisant appel aux paramètres de la littérature. Nous avons choisi ceux déterminés par Wilson et Bazzone (10) pour la *tert*-butyl-2 thiazolidine-1,3. La simulation permet un premier affinage des données. L'itération au moyen du programme LAOCOON GP1 conduit aux valeurs du Tableau 3.





Pour le système ABMX, certains paramètres sont accessibles en analysant la partie MX. On procède encore par simulation et par itération. Les paramètres de rmn sont indiqués dans le Tableau 3.

TABLEAU 3. Déplacements chimiques et constantes de couplage pour les spirochromènes **1***e* et **2***g* (solvant $CDCL_3$), δ en ppm/TMS, *J* en Hz

| Composé | $\delta_X$ | $\delta_M$ | $\delta_A$ | $\delta_B$ | $J_{AB}$ | $J_{AM}$ | $J_{AX}$ | $J_{BM}$ | $J_{BX}$ | $J_{MX}$ | Erreur RMS |
|---|---|---|---|---|---|---|---|---|---|---|---|
| **1***e* | 4,33 | 4,04 | 3,35 | 3,28 | −7,56 | 9,93 | 8,12 | 7,08 | 1,99 | −7,45 | 0,231 |

| Composé | $\delta_A$ | $\delta_B$ | $\delta_C$ | $\delta_D$ | $J_{AB}$ | $J_{AC}$ | $J_{AD}$ | $J_{BC}$ | $J_{BD}$ | $J_{CD}$ | Erreur RMS |
|---|---|---|---|---|---|---|---|---|---|---|---|
| **2***g* | 3,58 | 3,46 | 3,18 | 3,05 | −9,2 | 11,39 | 6,22 | 6,99 | 0,92 | −9,59 | 0,124 |

TABLEAU 4. Détermination de l'angle ϕ et de la population $x_A$ du conformère pseudo-axial dans les spirochromènes oxazolidiniques **1** et thiazolidiniques **2** (*J* en Hz; *Min.*: minoritaire; *Maj.*: majoritaire)

| Spirochromènes | "Nature" du diastéréoisomère | $J_{cis}^{exp}$ | $J_{trans}^{exp}$ | Méthode des différences ϕ(°) | Méthode des différences $x_A$(%) | Méthode des rapports ϕ(°) | Méthode des rapports $x_A$(%) |
|---|---|---|---|---|---|---|---|
| **1***e* | — | 7,60 | 5,96 | 35 | 50 | 38 | 50 |
| **1***a* | *Min.* | 6,3 | 2,5 | 39 | 86 | 41 | 78 |
| | *Maj.* | 8,5 | 7,5 | 22 | ~0 | 30 | 22 |
| **1***b* | *Min.* | 7,5 | 3 | 30 | 75 | 35 | 69 |
| | *Maj.* | 8 | 8 | 26 | ~0 | 33 | 22 |
| **1***c* | *Min.* | 6,5 | 5,8 | 37 | 44 | 40 | 49 |
| | *Maj.* | 6 | 8 | 41 | 21 | 42 | 32 |
| **1***d* | *Min.* | 6,5 | 3,5 | 37 | 73 | 40 | 69 |
| **2***g* | — | 6,15 | 6,60 | 45 | 50 | 44 | 50 |
| **2***b* | *Maj.* | 6,8 | 9,5 | 36 | ~0 | 38 | 13 |
| **2***e* | *Min.* | 7 | 0 | 35 | 118 | 38 | 98 |
| **2***f* | — | 4 | 0 | 52 | 125 | 51 | 108 |

De même, selon la réf. 10, on prend pour **2***g*:

$$J_{trans} = \frac{J_{AD} + J_{BC}}{2} = 6{,}60\,\text{Hz};$$

$$J_{cis} = \frac{J_{AC} + J_{BD}}{2} = 6{,}15\,\text{HZ}$$

Le passage spirochromène non substitué – spirochromène $R^{5'}$ – substitué grâce aux incréments de structure relatifs à $R^{5'}$. Nous avons utilisé ceux déterminés par Abraham et Pachler (12).

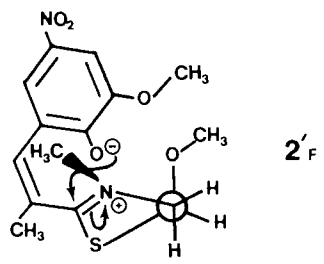

FIG. 4. Mise en évidence de la gêne stérique défavorisant une refermeture en diastéréoisomère *Z* pour le spirochromène **2***f*.

La détermination de $J_{cis}$ et de $J_{trans}$ pour les spirochromènes **1***a*–**1***d* et **2***b*, **2***e*, **2***f*. En accord avec les conclusions de divers auteurs (9, 13–15), nous avons admis qu'un substituant alkyle ou phényle blinde le proton vicinal en situation *cis* et le déblinde en situation *trans*. Nous avons vérifié l'exactitude de cette règle en étudiant des spirochromènes **1** et **2** à cycles oxa- et thiazolidiniques *cis* et *trans* diméthylés en positions 4′, 5′ (8).

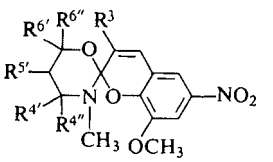
*I.2.3* Le Tableau 4 présente les résultats concernant les spirochromènes **1** et **2** dont les spectres de rmn $^1H$ se sont révélés totalement exploitables. On peut relever les points suivants: (*i*) l'accord entre les deux méthodes (rapports et différences) est excellent; (*ii*) les deux conformations de l'hétérocycle azoté sont énergétiquement équivalentes dans le cas des composés non substitués **1***e* et **2***g* ($x_A = 50\%$); (*iii*) le diastéréoisomère *Maj.* présente toujours le substituant $R^{5'}$ = alkyle ou aryle en situation pseudo-équatoriale ($x_A \sim 0$). La règle contraire s'applique au diastéréoisomère *Min.* Ceci confirme notre attribution d'une géométrie *Z* pour le *Maj.* Le groupement $R^{5'} = OCH_3$ du spirochromène thiazolidinique **2***f* occupe un site pseudo-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

axial ($x_A \sim 100\%$). C'est là une confirmation de la formation du seul diastéréoisomère *E* (cf. Paragraphe I.1); (*iv*) en raison du caractère approximatif de notre calcul, (on relève en effet des valeurs de $x_A$ supérieures à 100%), il est difficile de se prononcer quant aux angles $\phi$ de plissement des deux diastéréoisomères. Néanmoins, la tendance qui se dégage du Tableau 4 corrobore les conclusions tirées de l'examen des modèles de Dreiding pour l'identification des géométries *Z* ou *E*.

II. *Spirochromènes tétrahydro oxa- et thiaziniques-1,3, 3 et 4*

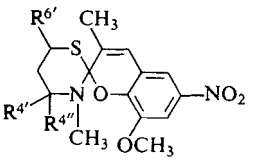
Les spirochromènes **3** et **4** suivants ont été étudiés:



**3**

**3***a* $R^{4'} = R^{4''} = R^{6'} = CH_3$; $R^{5'} = R^{6''} = H$, $R^3 = C_6H_5$

**3***b* $R^{4'} = R^{4''} = H$; $R^{5'} = R^{6'} = R^{6''} = R^3 = CH_3$



**4**

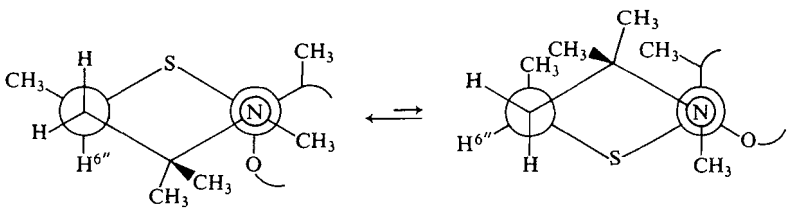
**4***a* $R^{4'} = R^{4''} = R^{6'} = CH_3$

**4***b* $R^{4'} = R^{4''} = H$; $R^{6'} = CH_3$

Le Tableau 5 regroupe les aspects les plus intéressants des spectres de rmn $^1H$ réalisés à 250 MHz et dans le deutériochloroforme (température de la sonde 20°C). Les quatre spirochromènes étudiés présentent un seul diastéréoisomère quelle que soit la position de l'un des atomes de carbone asymétriques par rapport à l'atome d'oxygène ou de soufre (en α: **3***a*, **4***a*, **4***b* ou en β: **3***b*). Nous avons déterminé la géométrie des cycles oxaziniques et thiaziniques afin d'interpréter ce fait qui différencie les séries à cinq chaînons **1** et **2** de celles à six **3** et **4**.

II.1 *Détermination de l'angle $\phi$ de torsion du cycle*

Les angles dièdres des protons vicinaux *gauches* sont calculés par application de la formule de Forrest et d'une équation de Karplus (16, 17). On trouve $\phi ae = \phi = 66°$ (**3***a*), 60° (**3***b*), 69° (**4***a*). La géométrie des cycles oxaziniques et thiaziniques s'écarte un peu de la forme chaise. On peut penser que l'inversion de cycle ne peut se réaliser par suite d'interactions de non-liaison prohibitives dans un conformère. Ainsi pour le spirochromène **4***a*, par exemple:



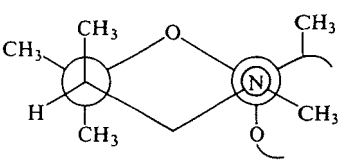
*C* ⟷ *C'*

La chaise *C'*, et, d'une manière plus générale, l'un des conformères possibles, sera toujours défavorisé en raison des interactions entre le substituant $R^3$ ($R^3 = CH_3$ pour **4***a*) et les substituants axiaux en positions 4', 4'' et 6', 6''. Par ailleurs, un conformère tel que *C'* avec le $CH_3$ en 6' axial peut être éliminé également au vu des constantes de couplage entre $H^{6''}$ et les autres protons. L'oxygène du cycle chroménique sera toujours axial et la chaise sera toujours du type *C*.

Le Tableau 5 indique que le proton équatorial est toujours le plus blindé que l'on considère les positions 4' et 4'' ou les positions 5' et 5'' dans les composés **3***a*, **3***b* et **4***b*. Ce fait n'est pas exceptionnel pour cette dernière position. Booth et Lemieux (18) le signalent à propos de tétrahydro oxazines. Ils l'attribuent à une relation 1,3 entre l'atome d'oxygène et l'atome de carbone portant les hydrogènes. Samitov *et al.* (19) concluent de même pour la diméthyl-3,4 phényl-6 tétrahydro-2,4,5,6 oxazine-1,3. Par contre, pour les autres positions, la règle est que le proton axial résonne à champ plus fort que l'équatorial. L'exception qui se rencontre ici pour la position 4', 4'' a été également signalée par Kazantsev *et al.* (20) au sujet de la triméthyl-3,5,6 phényl-6 tétrahydro-2,4,5,6 oxazine-1,3. Dans tous les cas, les auteurs admettent une conformation chaise.

II.2 *Identification du seul diastéréoisomère formé en séries oxazinique **3** et thiazinique **4***

On prendra le cas du spirochromène **3***b* pour exemple. Deux diastéréoisomères sont possibles:



*E*

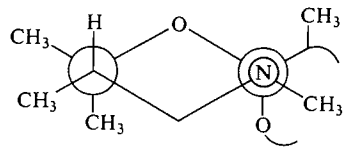
| | | 3,23–3,46 $H^{4''}$ ax. m | | | | | |

[a]δ en ppm/TMS, multiplicité, $J$(Hz); solvant $CDCl_3$; s: singulet; d: doublet; d de d: doublet de doublets; d de t: doublet de triplets; m: massif; ax: axial; eq.: équatorial.



*Z*

On élimine les autres conformères en accord avec les conclusions du paragraphe II.1.

La rmn $^1H$ indique que le substituant $R^{5'} = CH_3$ est équatorial (Tableau 5). Le diastéréoisomère *Z* est donc le seul à se former. Les spirochromènes **3***a*, **4***a* et **4***b* auront par contre la configuration *E*.

## Partie expérimentale

Les spirochromènes **1–4** sont des composés nouveaux dont nous avons déjà relaté la synthèse et les caractéristiques physiques de façon détaillée (1, 2, 21, 22). Les spectres de rmn $^1H$ à 250 MHz ont été enregistrés sur un appareil Cameca.

## Remerciements

Nous remercions vivement Mme le Professeur M. L. Martin (Faculté des Sciences de Nantes) pour ses conseils et son amicale collaboration à l'analyse des spectres ABCD et ABMX. Mme Mabon a réalisé les itérations (programme LAOCOON GP1). Nous remercions aussi Mlle J. Berger (Université d'Aix-Marseille III) pour la réalisation des spectres et Mrs. J. Elguero et A. Fruchier pour l'envoi du tableau permettant le calcul des angles de torsion en séries à cinq chaînons.

# Analyse par résonance magnétique nucléaire $^{13}C$ de la stabilité relative des spirochromènes et des mérocyanines dérivant du méthoxy-3 nitro-5 salicylaldéhyde

MICHEL MAGUET, MICHEL LE BACCON, YVES POIRIER ET ROBERT GUGLIELMETTI

*Laboratoire de synthèse organique, LA C.N.R.S. 322, Université de Bretagne Occidentale, Faculté des Sciences et Techniques, 6, Avenue Le Gorgeu, 29283 Brest Cedex, France*

Reçu le 3 mars 1982

MICHEL MAGUET, MICHEL LE BACCON, YVES POIRIER et ROBERT GUGLIELMETTI. Can. J. Chem. **60**, 2644 (1982).

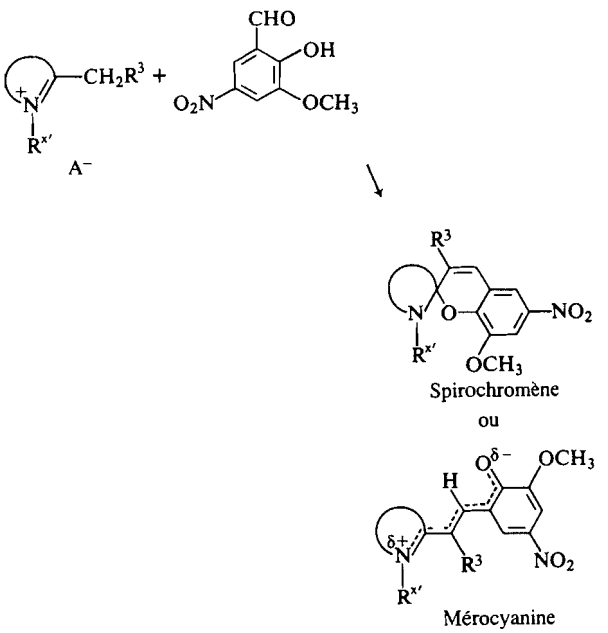
Les sels d'hétérocycloimmonium réagissent avec le méthoxy-3 nitro-5 salicylaldéhyde pour donner en général des spirochromènes ou des mérocyanines. Seuls ces derniers composés se forment en séries thiazolinique et benzimidazolinique. Le greffage d'une chaîne paraffinique sur les mérocyanines permet leur étude en rmn $^{13}C$. La confrontation de leurs spectres avec ceux des sels d'hétérocycloimmonium met en évidence une hyperconjugaison stabilisatrice en séries thiazolinique et benzimidazolinique. La série benzoxazolinique apparaît comme une série charnière : les stabilités des spirochromènes et des mérocyanines y sont voisines. On peut ainsi déterminer la valeur limite du déplacement chimique de l'atome de carbone concerné par la spiroannellation des mérocyanines.

MICHEL MAGUET, MICHEL LE BACCON, YVES POIRIER, and ROBERT GUGLIELMETTI. Can. J. Chem. **60**, 2644 (1982).

Heterocycloimmonium salts generally react with 3-methoxy 5-nitro salicylaldehyde to give spirochromenes or merocyanines. Only the latter compounds are obtained in the thiazolinic and the benzimidazolinic series. The linking of a paraffinic ring to the merocyanines allows their $^{13}C$ nmr study. The comparison of their spectra with those of heterocycloimmonium salts stresses a hyperconjugative effect in the thiazolinic and the benzimidazolinic series. The benzoxazolinic series appears to be in an intermediate position : the thermodynamic stabilities of spirochromenes and merocyanines are quite similar. The limiting value of the chemical shift of the carbon atom involved in the spiroannellation of merocyanines, can be approximately determined.

## Introduction

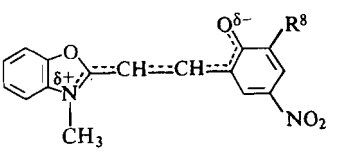
L'action des sels d'hétérocycloimmonium sur le méthoxy-3 nitro-5 salicylaldéhyde[1] peut être schématisée par l'équation suivante :



Les données de la littérature jointes aux résultats du laboratoire permettent de dégager trois cas possibles. Il peut y avoir : (*1*) formation de spirochromènes quel que soit $R^3$ et en particulier $R^3$ = H. C'est le cas des séries indolinique (1), pipéridinique et thiazinique-1,4 (2) ; (*2*) formation de spirochromènes pour $R^3 \geq CH_3$. Si $R^3$ = H, on isole une mérocyanine permanente. C'est le cas des séries benzothiazolinique (3,4) benzoxazolinique (5), oxa- et thiazolidinique-1,3, oxa- et thiazinique-1,3 (6–9) ; et (*3*) formation systématique d'une mérocyanine permanente quel que soit $R^3$ en séries thiazolinique (5) et benzimidazolinique (10).

On peut rencontrer des cas limites. Le comportement des mérocyanines benzoxazoliniques **1***a* et **1***b* en est un exemple.

Le spectre de rmn $^1H$ de **1***a* en solution dans le deutériochloroforme (fig. 1) et le spectre uv–visible de **1***b* en solution dans le toluène (fig. 2) montrent une refermeture de ces mérocyanines en spirochromènes. La généralisation des travaux de Veksler *et al.* (11) et de Zakhs *et al.* (12) par Sinkin *et al.* (13) conduit à la conclusion qu'un sel de méthyl-2



**1***a* $R^8 = CH_2OC_{16}H_{33}$
**1***b* $R^8 = OCH_3$

[1]Le méthoxy-3 nitro-5 salicylaldéhyde est très couramment utilisé dans ce genre de synthèse car il peut conduire à des spirochromènes dotés d'excellentes propriétés photochromiques et donc très intéressants au niveau des applications potentielles.

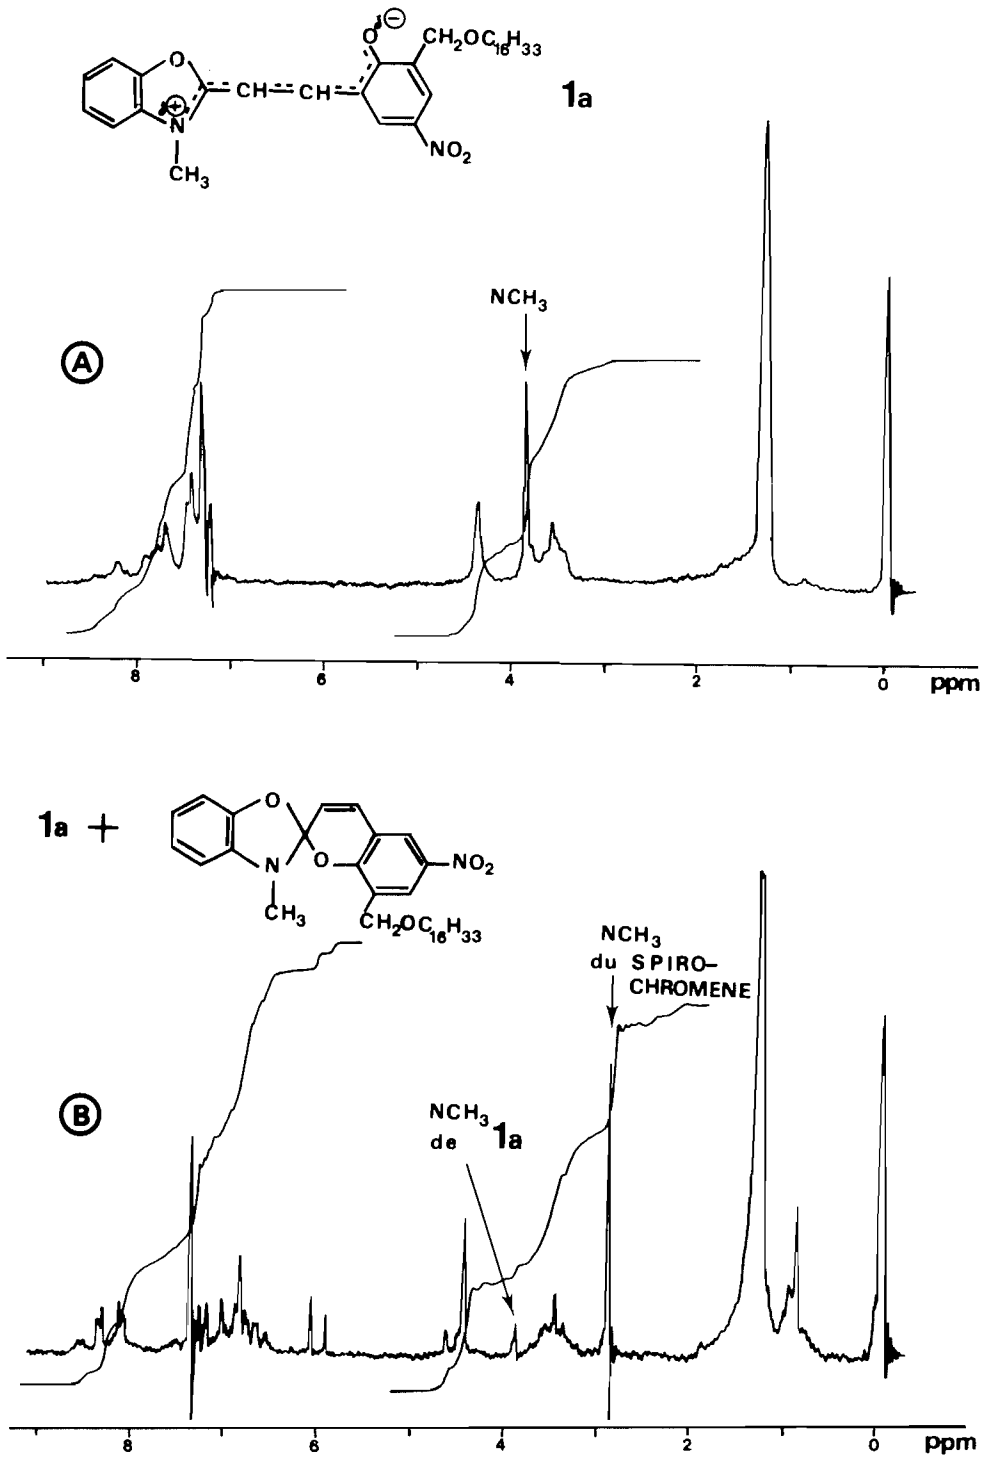

FIG. 1. Evolution du spectre de rmn $^1H$ de la mérocyanine 1*b* en solution dans $CDCl_3$. Spectre A: $t = 0$; spectre B: $t = 24$ h.

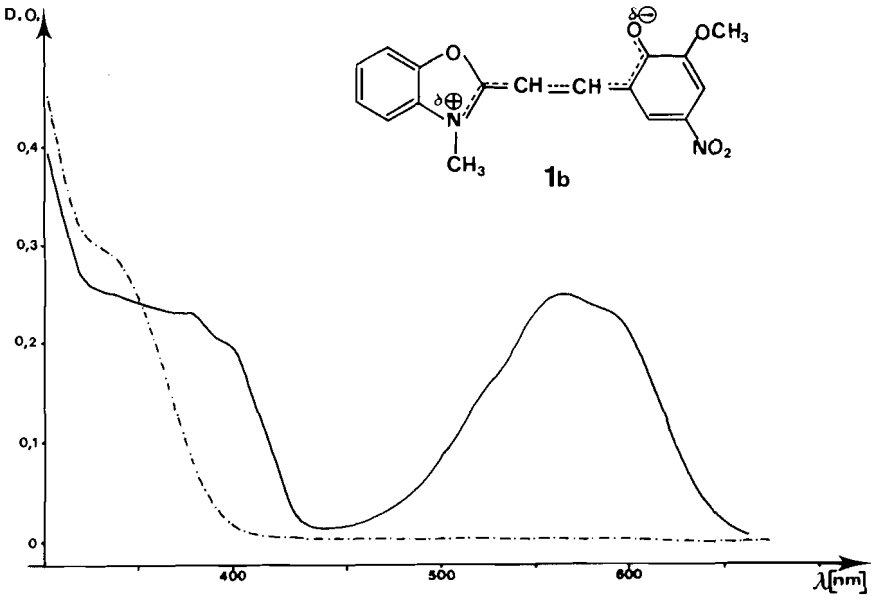

FIG. 2. Evolution du spectre uv–visible de la mérocyanine *1b* en solution dans le toluène (concentration inconnue en raison de la très faible solubilité). ——— Immédiatement après la mise en solution. —.—.—.— Après 24 h à l'obscurité (on peut revenir à l'état initial par irradiation uv).

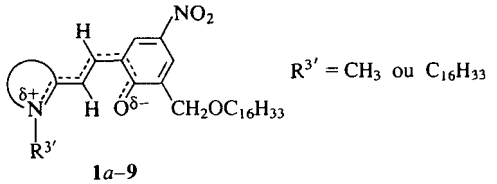
benzoxazolium ne peut donner de spirochromènes. Il y a là une contradiction avec nos résultats expérimentaux. Le problème de la stabilité relative des spirochromènes et des mérocyanines obtenus à partir du méthoxy-3 nitro-5 salicylaldéhyde se trouve ainsi posé. La rmn $^{13}C$ nous a semblé une méthode de choix pour parvenir à sa résolution, la refermeture d'une mérocyanine intéressant l'atome de carbone en α de l'atome d'azote.

La logique veut donc que l'on étudie en premier lieu les mérocyanines permanentes synthétisables dans la plupart des séries (les séries indolinique, pipéridinique et thiazinique-1,4 exceptées). La très faible solubilité de ce type de composé dérivant du méthoxy-3 nitro-5 salicylaldéhyde (e.g., la mérocyanine *1b*) est une difficulté insurmontable pour une étude en rmn $^{13}C$. Celle-ci est rendue possible par le greffage d'une chaîne paraffinique ($R^8$ = $CH_2OC_{16}H_{33}$). Les mérocyanines étudiées présentent la structure suivante :[2,3]



*1a–9*

[2]La numérotation des atomes de carbone dans ces mérocyanines ne correspond pas à la nomenclature officielle. Nous l'avons adoptée par souci de simplification.

[3]La justification de cette structure est donnée dans la partie expérimentale (paragraphe II.3).

Le remplacement du substituant $R^8 = OCH_3$ par le substituant $R^8 = CH_2OC_{16}H_{33}$ ne modifie pas les propriétés des mérocyanines (cf. figs. 1 et 2). Les composés ***1a–9*** sont donc des modèles acceptables pour notre travail.

## Résultats et discussion

### I. *Résonance magnétique nucléaire $^{13}C$ des mérocyanines permanentes 1a–9($R^3$ = H)*

Les spectres de rmn $^{13}C$ ont été réalisés dans le deutériochloroforme à la température ambiante. Le Tableau 1 regroupe les déplacements chimiques de la partie azahétérocyclique. Le Tableau 2 concerne la chaîne diméthinique et la partie phénolate. L'identification des carbones est facilitée par la comparaison des divers spectres, par l'intervention d'effets d'incréments connus (14) et par des résultats acquis au laboratoire (15, 16). Les atomes de carbone 3 et 4 du pont diméthinique ont été repérés grâce à des découplages sélectifs réalisés sur les mérocyanines **5**, **7** et **8**. On a pu ainsi établir que le proton éthylénique situé à champ fort est porté par le carbone sortant à champ faible et inversement. Ce résultat est en accord avec la structure proposée ci-dessus pour les mérocyanines ***1a–9*** et avec les données de la littérature (16). On retrouve également deux faits bien connus : l'alternance des densités électroniques sur le pont diméthinique (16, 17) et le déplacement chimique du carbone 8a (178 à 180 ppm, Tableau 2), bien plus proche de celui d'un atome de carbone de type

[a]δ $^{13}C$ des carbones de la partie hétérocyclique azotée. Solvant : $CDCl_3$. Enregistrement à 20°C. Solvant : DMSO-$d_6$. Enregistrement à 70°C (chiffres en italique).

phénolate que de celui d'un atome de carbone de type quinonique.

Hormis ces constatations classiques, on ne peut dégager des Tableaux 1 et 2 aucun argument étayant le fait que seules des mérocyanines sont stables dans les séries oxazolinique, thiazolinique et benzimidazolinique quel que soit $R^3$. Le seul déplacement chimique variant de façon significative est celui du carbone 2,2′ susceptible d'être le siège de la spiroannellation. La différence des valeurs entre la série oxazolinique (composé **6** ; δ = 163 ppm) et la série oxazinique (composé **4** ; δ =

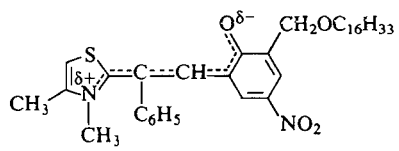
[a]$\delta$ $^{13}C$ des carbones de la chaine diméthinique et de la partie phénolate. Solvant : $CDCl_3$. (enregistrement à 20°C). Solvant : DMSO-$d_6$ : chiffres en italique (enregistrement à 70°C.
[b]Déplacements chimiques voisins : possibilité de permutation.

168,1 ppm) va dans le sens des constatations expérimentales. On peut y joindre la série benzimidazolinique (composé **9** ; $\delta$ = 150,7 ppm). Par contre, la série benzothiazolinique (composé **8** ; $\delta$ = 172,3 ppm) donne des spirochromènes contrairement à la série thiazolinique (composé **7** ; $\delta$ = 172,5 ppm). Ainsi la mérocyanine **10** ne peut se refermer bien que $\delta$C-2′ = 173,5 ppm (solvant $CDCl_3$).



**10**

Il est certain que l'étude de la mérocyanine **1***a* aurait pu être fructueuse. Malheureusement, la faible solubilité de ce composé et le fait qu'il évolue dans le temps (cf. figure 1) excluent la possibilité de déterminer $\delta$C-2′.

Les composés **1***a*–**9** ne sont donc pas des modèles suffisants pour prévoir la stabilité relative des spirochromènes et des mérocyanines au sein de chaque série. Nous avons alors choisi d'étudier les sels hétérocycliques qui conduisent à ces composé.

## II. *Résonance magnétique nucléaire $^{13}C$ de sels d'hétérocycloimmonium*

Nous avons groupé dans le Tableau 3 les spectres de rmn $^{13}C$ de divers sels quaternaires méthylés en 2 et à partir desquels on obtient uniquement des mérocyanines permanentes. Le Tableau 4 présente les déplacements chimiques du carbone 2 (ou 3 pour la série thiazinique-1,4) de sels pouvant conduire les uns à des spirochromènes, les autres à des mérocyanines. Le solvant choisi est le DMSO-$d_6$, certains sels étant peu solubles dans $CDCl_3$. On peut dégager les points suivants.

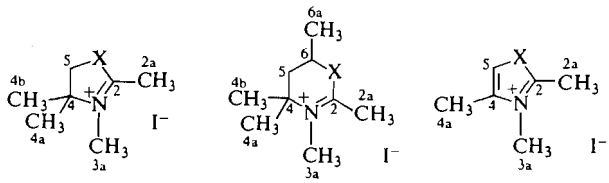
(*a*) Les sels méthylés en 2 (ou en 3) fournissent des formes fermées stables quand on a $\delta$C-2 (ou -3) > 191 ppm. Ceci se rencontre en séries thiazinique-1,4, pipéridinique et indolinique (composés **20**, **21**, **22**). On peut estimer importante la localisation de la charge positive sur le carbone siège de la refermeture.

(*b*) Quand pour un sel méthylé en 2, on a $\delta$ C-2 < 191 ppm, le seul composé à se former est une mérocyanine. C'est le cas des séries oxa- et thiazolidinique, oxa- et thiazinique-1,3, benzothiazolinique et benzimidazolinique (composés **11**–**14**, **26** et **27**).

(*c*) Les sels **18** et **19** (Tableau 4) substitués en -2 par un groupement éthyle présentent une valeur $\delta$C-2 < 191 ppm (187,3 ppm pour **19** et 174,3 ppm pour **18**). Ils conduiront néanmoins à des spirochromènes en raison du facteur stérique apporté par $R^3 = CH_3$.

(*d*) On relève pour les sels de thiazolium **23** et **24** des valeurs de $\delta$ C-2 égales à 177,3 et 179,3 ppm respectivement (Tableau 4), c'est-à-dire des chif-

TABLEAU 3. Spectrométrie[a] de rmn $^{13}C$ de sels d'hétérocycloimmonium conduisant à des mérocyanines permanentes



| Composés | Carbones | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | 2 | 2a | 3a | 4 | 4a | 4b | 5 | 6 | 6a |
|  **11** | 175,2 | 15,7 | 30,2 | 67,2 | 24,2 | | 82,2 | — | — |
|  **12** | 187,9 | 20,1 | 35,1 | 76,6 | 24,4 | | 42,8 | — | — |
|  **13** | 173,5 | 22,5 | 35,4 | 59,4 | 25,8 | 26,2 | 40,9 | 74,4 | 20,3 |
|  **14** | 182,3 | 27,4 | 33,9 | 64,0 | 24,9 | 27,1 | 43,0 | 39,3 | 20,1 |
|  **15** | 165,4 | 8,06 | 33,3 | 131,9 | 13,9 | — | 138,2 | — | — |
|  **16** | 171,2 | 16,6 | 36,9 | 145,8 | 13,9 | — | 117,1 | — | — |

[a] $\delta^{13}C$ en ppm/TMS. Solvant: DMSO-$d_6$.

fres supérieurs à celui (174,3 ppm) enregistré pour l'iodure d'oxazinium **18**. Or les tosylates **23** et **24** ne donnent que des mérocyanines permanentes telles que **10** (5). L'effet stérique compensateur de $R^3$ n'est plus suffisant dans ce cas. Pour interpréter ceci, il faut déterminer les déplacements chimiques des carbones 4 et 5 du cycle thiazolique. Ces valeurs sont accessibles grâce au découplage total, au découplage par faible bruit et à l'effet Overhauser (Tableau 4).

Le parallèle entre nos résultats et ceux de Faure *et al.*(18, 19) est mis en relief par le Tableau 5. L'atome de carbone 4 est toujours blindé quand on passe du thiazole au cation thiazolium. C'est le contraire pour le carbone 5. En accord avec les auteurs précédents, on peut envisager une important délocalisation de la charge positive sur l'ensemble de la molécule. Ceci rejoint les conclusions de Haake et Miller (20) selon lesquels la charge positive est répartie sur l'azote et surtout sur le soufre. Une forme sulfonium est la meilleure représentation de l'ion thiazolium.

Plus concrètement, Aldrich *et al.* (21) ont établi que dans l'ion triméthyl-3,4,5 thiazolium-1,3 l'atome de soufre porte une charge $q = 0{,}453$, alors que l'atome de carbone 2 est quasiment neutre ($q = 0{,}106$).

La comparaison des déplacements chimiques du carbone 2 (ou 2′) dans les Tableaux 1 et 3 ne peut être effectuée rigoureusement que s'ils se rappor-

TABLEAU 4. δEC des carbones[a] 2 (ou 3), 4 et 5 dans des sels d'hétérocycloimmonium alkylés en -2 ou en -3 conduisant à (a) des spirochromènes ; (b) des mérocyanines permanentes

| (a) | Composés | δC-2 | (b) | Composés | δC-2 | δC-4 | δC-5 |
|---|---|---|---|---|---|---|---|
| |  **17** | 193,4 | |  **23** | 177,3 | 146,3 | 118,5 |
| |  **18** | 174,3 | |  **24** | 179,3 | 149,2 | 120,2 |
| |  **19** | 187,3 | |  **25** | 170,7 | | |
| |  **20** | 191,3 | |  **26** | 177,1 | | |
| |  **21** | 195,2 | |  **27** | 153,1 | | |
| |  **22** | 196,5 | | | | | |

[a]δ$^{13}$C en ppm/TMS. Solvant: DMSO-$d_6$.

tent à des composés étudiés dans la même solvant. Nous avons examiné les spectres de rmn $^{13}$C des mérocyanines **2–9** dans le DMSO-$d_6$. La plupart de ces composés y sont peu solubles et l'enregistrement doit être réalisé à 70°C. Les résultats, quoique fragmentaires, montrent que le passage du sel (Tableau 3) à la mérocyanine (Tableau 1) s'accompagne d'un blindage du C-2 de 5,5 à 6,1 ppm en séries oxazolidinique, oxa- et thiazinique-1,3. Par contre, en séries oxazolinique et thiazolinique le déplacement chimique du C-2 dans le sel est voisin de celui du C-2′ dans la mérocyanine (0,8 ppm de différence pour **7**, 2,6 ppm pour **6**). Ainsi, la forme sulfonium mise en évidence pour les sels de thiazolium est envisageable pour les mérocyanines qui en dérivent. De plus, l'important blindage de C-5′ dans la mérocyanine **7** (111,8 ppm contre 117,1 ppm pour le sel **16**) est en faveur d'une hyperconjugaison du groupement méthyle. Cette résonance accrue pourrait stabiliser fortement les mérocyanines **7** (de même que **6**) et interdire leur refermeture en spirochromènes malgré un effet stérique favorable de $R^3$ = alkyle ou aryle. Une hyperconjugaison serait également envisageable dans les spirochromènes mais resterait limitée à la partie azahétérocyclique. Par contre, dans les mérocyanines, elle peut être étendue à l'ensemble de la molécule.

(*e*) La conclusion précédente s'applique à la série benzimidazolinique. En effet, le blindage de C-2 (δ = 153,1 ppm) dans l'iodure de benzimidazolium **27** peut s'expliquer par une dispersion de la charge positive sur les hydrogènes des groupements méthyle. Ceci a été avancé en série imidazolinique (21). Cette notion doit être étendue à la mérocyanine **9** (Tableau 3 ; δ C-2′ = 151,1 ppm) d'où une importante stabilisation.

(*f*) La valeur de δC-2 = 170,7 ppm (Tableau 4) pour l'iodure de benzoxazolium **25** apparaît comme

| **26** | (31) | 238 |
| **27** | (32) | 252 |

[a]Fin d'une plage de fusion de plusieurs degrés.

une valeur limite en dessous de laquelle un sel quaternaire ne conduira jamais quel que soit $R^3$ à un spirochromène stable en réagissant avec le méthoxy-3 nitro-5 salicylaldéhyde. Les mérocyanines **1***a* et **1***b* obtenues à partir de l'iodure **25** évoluent en solution (cf. figs. 1 et 2) vers des spirochromènes qui se décomposent quand on essaie de les isoler.

(*g*) De même que Kleinpeter et Borsdorf (22) nous avons classé l'acidité des hydrogènes du groupement méthyle en 2 pour les sels quaternaires des Tableaux 3 et 4. L'ordre est établi en fonction du déplacement chimique du carbone 2. Il est le suivant, par ordre décroissant d'acidité : cation indolinium > cation pipéridinium > cation thiazinium-1,4 > cation thiazolinium > cation thiazinium-1,3 > cation benzothiazolium > cation oxazolinium > cation oxazinium > cation thiazolium > cation benzoxazolium > cation oxazolium > cation benzimidazolium.

Il n'est pas étonnant de trouver dans les plus acides les cations ne possédant pas d'hétéroatomes en α du carbone 2. La délocalisation de la charge positive est moindre, comme cela a été constaté en série dihydroisoquinoléinium (12).

## Partie expérimentale

I. *Synthèse des sels*[4] *d'hétérocycloimmonium* ***11–27***

La synthèse des sels **11–14** et **17–19** a déjà été décrite (6–9). Nous avons appliqué le même mode opératoire à la préparation des autres iodures.

Les tosylates **23** et **24** sont obtenus en chauffant pendant 3 à 4 heures à 140°C, un mélange équi-moléculaire de thiazole et de tosylate de méthyle. Les sels sont alors isolés selon la technique employée pour les iodures. Les rendements sont quantitatifs. Ce sont des composés hygroscopiques à conserver au dessicateur. Les nouveaux sels sont rassemblés dans le Tableau 6 avec les références concernant la préparation des bases.

II. *Synthèse des mérocyanines* ***1–10***

II.1 *Synthèse du n-hexadécyloxyméthyl-3 nitro-5 salicylaldéhyde*

On ajoute à 0,1 mol (26,4 g) de n-hexadécylate de sodium en suspension dans 100 $cm^3$ de benzène, 0,1 mol (21,5 g) de chlorométhyl-3 nitro-5 salicylaldéhyde (33) dissoute dans le même volume de benzène. Le milieu réactionnel devient limpide assez rapidement. On chauffe alors au reflux pendant une heure. On filtre et concentre à sec. Le résidu repris par du benzène est chromatographié sur de l'alumine à 10% d'eau. L'élution avec un mélange benzène–éther de pétrole (70:30) fournit l'aldéhyde attendu. On le purifie par cristallisation dans le cyclohexane. C'est un solide beige fondant à 72°C. Le rendement ne dépasse pas 30%.

II.2 *Mérocyanines* ***2–10***

On dissout un mélange équimoléculaire de n-hexadécyloxyméthyl-3 nitro-5 salicylaldéhyde et de sel quaternaire dans le minimum d'éthanol anhydre. On rajoute la quantité stoechiométrique de pipéridine et on abandonne pendant 48 h à l'obscurité et à la température ambiante. On filtre le solide qui a précipité et on le sèche sous vide (on peut laver les mérocyanines **6**, **7** et **10** avec un peu d'éthanol. Eviter de le faire dans les autres séries en raison d'une solubilité importante).

II.3 *Mérocyanines* ***1****a et* ***1****b*

On opère dans du benzène anhydre à la température ambiante (avec le méthoxy-3 nitro-5 salicylaldéhyde (34) pour **1***b*). Après 48 h on recueille le solide formé. On le sèche, le lave avec de l'eau distillée puis de l'éthanol. On sèche à nouveau et on ne purifie pas davantage les mérocyanines **1***a* et **1***b*. La mérocyanine **1***b* est un solide brun vert, $F$ = 194°C ; Rdt : 36%.

Le Tableau 7 regroupe les mérocyanines préparées autres que **1***b*. Elles ne sont pas purifiables par cristallisation. Leur structure est confirmée par la spectroscopie de masse et par la rmn $^1H$ dans le deutériochloroforme. Quelques exemples de cette dernière (voir les formules, Tableau 1) sont présentés ci-dessous (δ en ppm, $J$ en Hz).

**3** : 0,87 (t mal résolu, 3H, chaîne paraffininque), 1,27 (s, chaîne paraffinique), 1,53 (s, $2CH_3$ géminés), 3,26 (s, $^+NCH_3$), 3,32 (s, $CH_2$ en α du soufre), 3,26–3,91 (m, 2H chaîne paraffinique), 4,46 (s, $CH_2$—$OC_{16}H_{33}$), 7,41 (d, *H4*, $J$ = 14), 8,12 (d, *H3*, J = 15), 7,92 (s, *H5* + *H7*).

**4** : 0,87 (t mal résolu, 3H, chaîne paraffinique), 1,28 (s, chaîne paraffinique), 1,48 et 1,52 (2s, $2CH_3$ géminés), 1,57 (d, $CH_3$ en α de l'oxygène, $J$ = 6), 1,80–2,20 (m, $CH_2$ en β de l'oxygène), 3,27

[4]Le sel nécessaire à l'élaboration de la mérocyanine **8** est obtenu en traitant le méthyl-2 benzothiazole par le tosylate de n-hexadécyle pendant 60 h en tube scellé à 140°C. Purification classique $F$ = 140°C. Rdt : 77%.

TABLEAU 7. Caractéristiques physiques des mérocyanines **1***a*–**10**

| Mérocyanines | *m/e* | Aspect | *F*(°C)[a] | Rdt (%) |
|---|---|---|---|---|
| **1***a* | 551 ($M^{\ddagger}+1$) | Poudre rouge brique | 141[b] | 39 |
| **2** | 530 ($M^{\ddagger}$) | Aiguilles rouges | 114[b] | 53 |
| **3** | — | Cristaux rouge foncé | 89 | 19 |
| **4** | 558 ($M^{\ddagger}$) | Aiguilles orangées | 150 | 47 |
| **5** | 575 ($M^{\ddagger}+1$) | Aiguilles rouge mordoré | 131 | 59 |
| **6** | 515 ($M^{\ddagger}+1$) | Cristaux rouge vif | 199 | 33 |
| **7** | 531 ($M^{\ddagger}+1$) | Cristaux rouge sombre | 231 | 69 |
| **8** | 777 ($M^{\ddagger}+1$) | Cristaux rouge mordoré | 190 | 43 |
| **9** | 564 ($M^{\ddagger}+1$) | Poudre vermillon | >260 | 88 |
| **10** | — | Cristaux rouge brique | 92[b] | 51 |

[a]Points de fusion déterminés au microscope Reichert à platine chauffante.
[b]Température repérant la fin d'une plage de fusion de quelques degrés.

(s, $^{+}NCH_3$), 3,55 (t, $OCH_2$—$C_{15}H_{31}$, $J = 6$), 4,20–4,70 (m, H en α de l'oxygène), 4,52 (s, $CH_2$—$OC_{16}H_{33}$), 7,64 (d, *H4*, $J = 14$), 8,07 (d, *H3*, $J = 14$), 8,02 (s, *H5* + *H7*).

**7** : 0,87 (t mal résolu, 3H, chaîne paraffinique), 1,29 (s, chaîne paraffinique), 2,37 (d, $CH_3$ éthylénique, $J = 1,5$), 3,40–3,80 (m, 2H, chaîne paraffinique), 3,72 (s, $^{+}NCH_3$), 4,48 (s, $CH_2$ $OC_{16}H_{33}$), 6,77 (q, H éthylénique, $J = 1,5$), 7.23 (d, H4, $J = 15$), 8,57 (d, *H3*, $J = 15$), 7,78 (d, *H7*, $J = 3$), 7,90 (d, *H5*, $J = 3$).

On relève une configuration *trans* au niveau du pont diméthinique. Le déblindage de *H3* est attributé à la proximité spatiale de l'oxygène phénolate (5, 16). Ceci est généralisable à toutes les mérocyanines **1***a*–**10**.

III. *Résonance magnétique nucléaire du carbone 13*

Les enregistrements en rmn $^{13}C$ des mérocyanines ont été réalisés sur un spectromètre JEOL de type FX 60 équipé d'un calculateur (JEC 980B) de 24 K.

Nous avons enregistré pour chaque composé, un spectre en découplage total (largeur d'impulsion 3 à 8 μs ; temps de répétition 1,2 s ou 1,5 s ; largeur spectrale = 4000 Hz ; nombre d'impulsions 1000 à 50 000) et un spectre en découplage par bruit de faible puissance (51 dB).

Les spectres des sels quaternaires et de la mérocyanine **10** ont été enregistrés sur un spectromètre JNM FX 100 équipé d'un calculateur de 32 K. Le découplage par faible bruit est réalisé par découplage total à 10 kHz de la fréquence de résonance du proton. La largeur spectrale est de 6250 Hz soit 250 ppm.

IV. *Spectres ultraviolet et visible*

L'évolution du spectre uv–visible de la mérocyanine benzoxazolinique **1***b* a été suivie sur un appareil Cary 219.

V. *Spectre de masse*

Les spectres de masse des mérocyanines ont été réalisés sur un appareil Nermag R 1010. La technique de l'impact électronique a été appliquée aux composés **2** et **4**. L'énergie des électrons est de 70 eV et la programmation de température va de 35 à 350°C à raison de 1,5°C par seconde. Les autres mérocyanines ne donnant pas d'ions moléculaires significatifs par impact électronique ont été analysées en désorption chimique. Le gaz réactant est l'ammoniac et la programmation du filament va de 0 à 300 mA à raison de 1,5 mA par seconde.

## Remerciements

Nous remercions vivement Mr. D. Picart (Laboratoire de Biochimie Faculté de Médecine, 22, rue C. Desmoulins, Brest, France) pour la réalisation et l'analyse des spectres de masse des mérocyanines.

# Nickel atom – ligand reactions: evidence for an unstable $\eta^3$-benzylnickel species from mixed-ligand cocondensations with nickel atoms[1]

J. Stephen Hartman[2] and Eric C. Kelusky

*Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1*

Received January 15, 1982

J. Stephen Hartman and Eric C. Kelusky. Can. J. Chem. **60**, 2654 (1982).

Detailed studies of nickel atom – benzyl halide cocondensation reactions, with and without a second organic ligand, have been carried out. Benzyl halides (X = Cl, Br) when cocondensed with nickel atoms at −196°C give no isolable organonickel product but only bibenzyl and nickel(II) halide, indicative of an initial unstable benzylnickel compound. Allyl chloride/benzyl chloride mixtures do not give the stable $\eta^3$-allylnickel chloride, but instead a highly-unstable sublimable yellow solid which apparently is the $\eta^3$-benzylnickel chloride dimer. All of this work indicates complexities in the initial metal atom interactions with the ligands. A further case is reported in which the presence of aluminosilicate insulating wool drastically changes the products obtained.

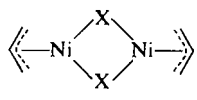
J. Stephen Hartman et Eric C. Kelusky. Can. J. Chem. **60**, 2654 (1982).

On a étudié en détail les réactions de cocondensation de l'atome de nickel avec l'halogénure benzyle en présence ou en l'absence d'un deuxième ligand organique. La cocondensation des halogénures de benzyle (X = Cl, Br) avec les atomes de nickel à −196°C ne permet pas de d'isoler des produits organonickels mais uniquement du bibenzyle et des halogénures de nickel(II) qui révèlent la formation initiale d'un composé benzylnickel instable. Les mélanges des chlorures d'allyle et de benzyle ne donnent pas le chlorure stable de $\eta^3$-allylnickel, mais conduisent de préférence à un solide jaune très instable, qui se sublime, et qui est apparemment un dimère de chlorure de $\eta^3$-benzylnickel. Tout ce travail indique la complexité des interactions initiales de l'atome métallique avec les ligands. On rapporte un autre cas où la présence d'une laine isolante alumino-silicate modifie profondément la nature des produits obtenus.

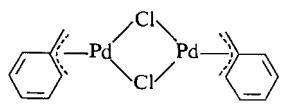
[Traduit par le journal]

## Introduction

In the last ten years metal atom – ligand cocondensation reactions have become an important synthetic technique (1–6). In an early study, allyl halides cocondensed with nickel atoms were shown to give the $\eta^3$-allylnickel halide dimers **I** (X = Cl, Br) in good yield (7). Palladium analogues of **I** can be prepared similarly (5), and benzyl chloride cocondensed with palladium has been shown to give the $\eta^3$-benzylpalladium chloride dimer **II** (8). Conventional synthetic techniques have been used to obtain $\eta^1$-benzylnickel chlorides stabilized with a variety of other ligands (9, 10).



**I**



**II**

We now report studies of mixed-ligand cocondensations with nickel, carried out with hopes of preparing the nickel analogue of **II** and nickel complexes containing both $\eta^3$-allyl and $\eta^3$-benzyl ligands. We find that the presence of allyl chloride facilitates formation of a benzylnickel species, not obtainable by cocondensing pure benzyl halide with nickel. We report here our studies of the formation of the highly-unstable benzylnickel species, and of related systems.

## Experimental

*Metal atom reactions*

The metal atom reactor was of a standard type (2, 4, 11), involving generation of metal atoms in an electrically-heated tungsten crucible (Sylvania Emissive Products) and cocondensation with the substrate on the walls of the reaction vessel, cooled with a liquid nitrogen bath. The apparatus is very similar to that of Fig. 3 of ref. 11. A highly detailed description of the procedure is given in ref. 11.

*Nickel with allyl bromide (7)*

Cocondensation of nickel (1.005 g) with 8.0 mL of allyl bromide at −196°C, followed by pumping off excess allyl bromide and sublimation of the red product at 70°C, gave **I** (X = Br, 1.47 g, 24%). The mass spectrum included clusters at *m/e* 360 (51) $[(C_3H_5)NiBr]_2^+$, 319 (16) $(C_3H_5)Ni_2Br_2^+$, 278 (25) $Ni_2Br_2^+$, 140 (100) $C_6H_{10}Ni^+$, 99 (88) $C_3H_5Ni^+$.

*Nickel with allyl chloride (7)*

Cocondensation of nickel (1.02 g) with 8.0 mL of allyl chloride at −196°C, followed by pumping off excess allyl chloride and sublimation of the red–brown product at 70°C, gave **I** (X = Cl; 1.12 g, 23.6%). The mass spectrum included clusters at *m/e* 272 $[(C_3H_5)NiCl]_2^+$, 231 $(C_3H_5)Ni_2Cl_2^+$, 190 $Ni_2Cl_2^+$, 99 $NiC_6H_{10}^+$.

*Nickel with benzyl chloride*

Nickel (0.953 g) was cocondensed with 25 mL of benzyl chloride at −196°C to give a deep red matrix. On warming the matrix colour disappeared. Excess benzyl chloride was pumped off and extraction with chloroform gave 0.52 g of bibenzyl (17.9%). $^1$H nmr: δ 2.93 (2H, s), δ 7.25 (5H, s). $^{13}$C nmr: 141.8,

TABLE 1. Minor products from allyl chloride/benzyl chloride/nickel cocondensation, as determined by gas chromatography/mass spectroscopy[a]

| Product | Mass spectral data |
|---|---|
|  | 132(46), 117(100), 91(61), 77, 65, 51[b] |
|  | 168(0.6), 166(1.6), 131(2), 127(12), 125(27), 117(11), 91(100), 77(7), 65(16), 51(11) |
|  | 170(1.4), 168(4.7), 133(5), 127(6.7), 125(16), 91(100), 77(6), 65(14), 51(9) |
|  | 174(3), 145(4), 131(23), 117(23), 91(100), 77(9), 65(15), 51(8) |

[a]GC/MS did not fully resolve all species. As a result all mass abundances are not reported.
[b]Literature values: 132(46), 117(100), 91(55), 77(14), 65(23), 51(26) (ref. 27).

128.5, 128.4, 125.9, and 37.9 ppm. Mass spectrum: *m/e* 182 (16), 104 (3), 91 (100), 65 (11), 51 (5), 39 (7).

Addition of 5 mL $Et_3P$ to the cocondensate at −196°C, followed by warming, gave bibenzyl and a red solid identified as $(Et_3P)_2NiCl_2$ by its mass spectrum: *m/e* 366 (trace) $NiCl_2(PEt_3)_2^+$, 331 (trace) $NiCl(PEt_3)_2^+$, 153 (12) $ClPEt_3^+$, 118 (100) $PEt_3^+$, 89 (45) $PEt_2^+$, 60 (31) $PEt^+$; $^1H$ nmr: 1.4 (3H, m), 1.7 (2H, m). The $^1H$ nmr of the crude mixture showed that the products were present in equimolar quantities.

*Aggregation or complexation of bibenzyl*

Whereas pure bibenzyl (mp 52°C) is easily sublimable under our workup conditions, the matrices obtained from nickel atom cocondensations involving benzyl halides gave a brown involatile solid which did not melt or sublime even at 70°C under high vacuum, and from which we recovered large quantities of bibenzyl by extraction with chloroform. An aggregation or complex of bibenzyl with nickel halide and/or with finely divided metallic nickel is indicated.

*Nickel with benzyl bromide*

Nickel (0.515 g) was cocondensed with 25 mL of benzyl bromide at −196°C to give a deep red matrix. The colour disappeared on warming. The excess benzyl bromide was pumped off; bibenzyl was recovered and identified by its $^1H$ nmr and mass spectrum, as above.

Addition of 5 mL $Et_3P$ to the cocondensate at −196°C, followed by warming, gave bibenzyl and a red solid identified as $(Et_3P)_2NiBr_2$ by its mass spectrum: *m/e* 454 (trace) $NiBr_2(PEt_3)_2^+$, 375 (trace) $NiBr(PEt_3)_2^+$, 197 (18.6) $BrPEt_3^+$, 118 (100) $PEt_3^+$, 89 (42) $PEt_2^+$, 60 (31) $PEt^+$. The $^1H$ nmr of the crude mixture showed that the bibenzyl and $NiBr_2(PEt_3)_2$ were present in equimolar amounts.

*Nickel with equimolar allyl chloride/benzyl chloride*

Cocondensation of nickel (0.955 g) with 25 mL of an equimolar mixture of allyl chloride and benzyl chloride at −196°C, followed by warming and pumping off the unreacted allyl and benzyl chloride, gave a highly air-sensitive yellow solid which was sublimed to a cold finger at 65°C. This decomposed slowly at ambient temperature to give bibenzyl, nickel chloride, and nickel metal, and could not be obtained in a pure form. (Bibenzyl and nickel(II) chloride do not sublime from our reaction mixtures and hence could only arise as decomposition products.) Repeated attempts to obtain the mass spectrum of the yellow solid under a variety of conditions gave only bibenzyl (parent ion: *m/e* 182). A gas chromatogram of a chloroform solution of the yellow solid on a 3% FE 30 on CHROM W column showed only bibenzyl (calibrated with a known sample). GC/MS analysis of the residue in the reaction vessel after sublimation, using a column with 3% 56 30/CHROM W/SPECIAL GC, showed predominantly bibenzyl and several other organic species which were present in yields of less than 0.5% (Table 1).

Trapping with 5 mL $Et_3P$ at −196°C yielded 0.495 g of bibenzyl and 1.039 g of $(Et_3P)_2NiCl_2$, both of which were identified by $^1H$ nmr and mass spectra, as above. Trapping with 10 mL triisobutylphosphine at −196°C yielded bibenzyl and red $(i\text{-}Bu_3P)_2NiCl_2$ in equimolar amounts, as determined by comparison of $^1H$ nmr integrals of the crude mixture. The $(i\text{-}Bu_3P)_2NiCl_2$ (26%) was identified by its $^{13}C$ nmr: 25.3 ppm (β-C), 25.6 (γ-C), 31.1 (α-C, d of d), and by its uv/visible spectrum (bands at 500, 402, 268, 251 mμ; known sample: 502, 406, 269, 247 mμ).

*Nickel with equimolar allyl chloride/benzyl bromide*

Cocondensation of nickel (1.33 g) with 25 mL of an equimolar mixture of allyl chloride and benzyl bromide at −196°C, followed by warming and pumping off the unreacted organic substrate, yielded two sublimable products: a yellow solid (subl. 65°C) and a red solid (subl. 70°C). The latter, identified from its mass spectrum as the $\eta^3$-allylnickel chloride dimer **I**, had $^{13}C$ nmr peaks at 56.0 and 105.4 ppm.

Addition of $Et_3P$ to a solution of the yellow solid in chloroform gave, in addition to metallic nickel, bibenzyl and $(Et_3P)_2NiBr_2$ as identified by the mass spectrum (*m/e* 454 (trace), 375 (trace), 197 . . . as above, for the nickel complex; *m/e* 182 (18), 104 (5), 91 (100), 65 (10), and 51 (7) for bibenzyl). The $^1H$ nmr of the crude mixture showed that the products were present in equimolar quantities.

The yellow solid could not be completely freed of **I** by sublimation; its $^{13}C$ spectrum showed the 56.0 and 105.4 ppm peaks of **I**, as well as bibenzyl peaks at 37.8, 125.9, 128.3, 128.4, and 141.7 ppm. Peaks assigned to the yellow solid occur at 41.4, 72.0, 126.6, 127.8, 130.6, and 132.2 ppm. These disappear with time as the bibenzyl peaks grow, and all peaks become broad due to the formation of paramagnetic nickel(II) bromide.

*Nickel with equimolar allyl bromide/benzyl bromide*

Cocondensation of nickel (1.102 g) with 25 mL of an equimolar mixture of allyl bromide and benzyl bromide at −196°C, followed by warming and pumping off the unreacted organic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

substrate, yielded a red solid (subl. 70°C) identified as the allylnickel bromide dimer, but no sublimable yellow solid. The remainder of the product in the reaction vessel, in addition to nickel metal, was identified as bibenzyl and nickel bromide, in approximately equimolar quantities.

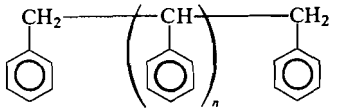
*Palladium with equimolar allyl chloride/benzyl chloride*

Cocondensation of palladium (0.852 g) with 25 mL of an equimolar mixture of allyl chloride and benzyl chloride at −196°C, followed by pumping off the unreacted organic substrate, yielded 0.184 g (6.3%) of the $\eta^3$-allylpalladium chloride dimer **II**, as identified by its mass spectrum (parent ion cluster at *m/e* 368) and $^1$H nmr (δ 3.03 (2H, d), 4.10 (2H, d), 5.40 (1H, m)). Also observed were very weak clusters at *m/e* 468 $(benzylPdCl)_2^+$ and 377 $(benzylPd_2Cl_2)^+$ and bibenzyl peaks (*m/e* 182, 91). Thus both $\eta^3$-allyl- and $\eta^3$-benzylpalladium chloride dimers form, but no peak could be detected at *m/e* 418 which would correspond to the parent ion of an analogous mixed allyl, benzylpalladium chloride compound.

*Nickel with benzyl halides, using Kaowool crucible insulation*

*(i) Nickel with benzyl chloride*

Cocondensation of nickel (0.86 g) with 26 g of benzyl chloride at −196°C in the presence of Kaowool crucible insulation gave a matrix which, when allowed to warm to ambient temperature, melted down the sides of the vessel and began to bubble, with evolution of hydrogen chloride (ir bands at 2875 cm$^{-1}$). After all volatiles were pumped off, 24.3 g of product was collected that was insoluble in all solvents used (pentane, chloroform, acetone, dimethylsulfoxide, acetonitrile). However, the addition of $Et_3P$ to the finely ground solid gave 1.42 g of $(Et_3P)_2NiCl_2$ (26.5% based on nickel; identified by mass spectrum and $^1$H nmr as above) and 23.8 g of insoluble white solid. This was identified by its mass spectrum as a mixture of polybenzylic species: *m/e* 632 (0.5), 542 (1), 452 (1.4), 362 (3), 272 (8), 181 (23), 179 (38), 91 (100). On slowly heating the mass spectrometer inlet the same peaks were present and also new peaks at higher mass appeared (*m/e* 722, 812, 902, and 992). These became larger as the inlet temperature was increased. These results, together with a fragmentation pattern indicative of a monosubstituted aromatic ring, suggest structures **III** ($n$ = 1–9).



**III**

Metastable scanning techniques (12, 13) confirm that the polybenzylic mass spectral peaks arise from separate species in the ionization chamber of the mass spectrometer rather than being fragments of a higher-mass parent ion. For a suspected parent ion, a $V$ scan (12) will determine whether it is itself a daughter of some higher-mass ion, while a $V^2/E$ scan (13) will determine its daughter ions. While the results (Table 2) require that the polybenzyls **III** are present in the mass spectrometer source, we cannot exclude the presence of less volatile higher polymers, or that the observed fragments might be formed in the source from the breakdown of a higher polymer.

*(ii) Nickel with benzyl bromide*

Cocondensation of nickel (0.52 g) with 25 mL of benzyl bromide at −196°C in the presence of Kaowool crucible insulation gave a red matrix. On warming to ambient temperature the red colour disappeared and hydrogen bromide was given off (ir bands at 2560 cm$^{-1}$). By workup methods similar to those used in the analogous benzyl chloride system, 3.46 g of polybenzylic product were obtained. Mass spectrum: *m/e* 632 (1), 542 (3), 452 (6), 362 (6), 361 (6), 272 (1), 271 (15), 182 (28), 181 (99), 91 (100).

TABLE 2. Metastable scanning techniques applied to suspected parent ions in the mass spectrum of a polybenzyl product

| Suspected parent ion *m/e* values | Parent ions (by $V$ scan) | Daughter ions (by $V^2/E$ scan)[a] |

[a]Errors are ±2 *m/e* units.

*(iii) Nickel with equimolar allyl bromide/benzyl bromide*

Cocondensation of nickel (0.62 g) with 25 mL of an equimolar allyl bromide/benzyl bromide mixture at −196°C in the presence of Kaowool crucible insulation gave an initial red matrix which on warming yielded hydrogen bromide and 2.17 g of a solid. Major peaks of the mass spectrum of the solid (Table 3) show that this is primarily a polybenzyl but that an allyl group or a bromine can become incorporated.

*Instrumentation*

Mass spectra were obtained on an AEI MS30 double beam spectrometer operating at 70 eV for most compounds, but at 19 eV for some of the less stable compounds. GC/MS runs were performed on a column with 3% 56 30/CHROM W/SPECIAL GC.

$V$ scans and $V^2/E$ scans, the two metastable scanning techniques used in this study, were carried out with the KRATOS metastable scan unit. Both follow decompositions in the field-free region between the ionization chamber and the electrostatic analyser of the MS-30 mass spectrometer. In the $V$ scan, the spectrometer is tuned to a peak of known mass (daughter ion $m_2^+$). The electrostatic analyser is held constant and the accelerating voltage $V$ is increased linearly. This gives the precursor or parent ions $m_1^+$ which give rise to that daughter ion (12). In the $V^2/E$ scan, the spectrometer is tuned to a peak of known mass; the electrostatic analyser voltage is then increased linearly while simultaneously $V$ is increased proportionally to the square of the electrostatic analyser voltage. This gives a spectrum which shows the peak the instrument was tuned to, and the daughter ions which arise from it (13).

Nuclear magnetic resonance spectra were recorded on a Bruker WP-60 Fourier Transform nmr spectrometer operating at 60 MHz ($^1$H) and at 15.08 MHz ($^{13}$C). $^{13}$C spectra were obtained using a 3759 Hz sweep width and 1.089 second acquisition time for an 8K FID. Thirty-degree pulses were used, with the Phase Alternating Pulse Sequence, and 5 W of proton noise decoupling were applied. Proton spectra were obtained with a 750 Hz sweep width and a 5.5 s acquisition time.

TABLE 3. Major mass spectral peaks of the polymeric nickel/allyl bromide/benzyl bromide/Kaowool reaction product

| | Composition: number of structural units incorporated | | |
|---|---|---|---|
| *m/e* | Benzyl | Allyl | Bromine |
| 182 | 2 | 0 | 0 |
| 222 | 2 | 1 | 0 |
| 260/262 | 2 | 0 | 1 |
| 222 | 3 | 0 | 0 |
| 312 | 3 | 1 | 0 |
| 362 | 4 | 0 | 0 |
| 402 | 4 | 1 | 0 |

*Materials*

Nickel pellets (99.95% purity) and palladium sponge (99.5% purity) were obtained from A. D. Mackay Limited. The allyl and benzyl halides (Aldrich) were used without further purification, although purity was checked by GC/MS. Toluene was purified by shaking with cold sulfuric acid, followed by washing with water, drying over phosphorus pentoxide, and distilling, with the first and last cuts being rejected. Chloroform was purified by predrying over calcium chloride and distilling from phosphorus pentoxide, the first and last cuts being rejected, and stored in the dark.

## Results and discussion

*(i) Single-ligand systems*

The cocondensation of benzyl chloride or benzyl bromide with nickel at −196°C gives an initial red matrix, similar to that observed in other arene–metal cocondensations (14) and interpreted as π-arene–metal complex formation, but on warming only bibenzyl and nickel(II) halide can be recovered. The presence of bibenzyl is consistent with the formation of an unstable benzylnickel complex. Trapping experiments, in which triethylphosphine is added to the initial matrix at −196°C in the hope of stabilizing an initially-formed organometallic linkage by incorporation of a phosphine ligand, give only bibenzyl and $(Et_3P)_2NiX_2$ (X = Cl, Br) on warming.

Similar cocondensations of a benzyl halide with nickel, but with the crucible surrounded by aluminosilicate insulating wool (Kaowool, available from Morganite Ceramic Fibers, Neston, England, is a stable high-temperature ceramic fiber with no organic binder, consisting principally of $Al_2O_3 \cdot 2SiO_2$), give on warming a mixture of nickel(II) halide, hydrogen halide, and polybenzyl species containing from three to at least nine benzyl units, as determined by mass spectroscopy. Covering of the insulation by brass foil gives only bibenzyl and nickel(II) halide, as in the absence of insulation. Klabunde and co-workers have recently reported similar major effects of crucible insulation on product distribution and yields in the synthesis of the $\eta^3$-benzylpalladium chloride dimer, **II**, and have demonstrated that pyrolysis reactions on the greatly increased surface area, when insulation is present, result in the production of organic free radicals from the substrate (14). Similar free radical processes are implicated here, although the products are different, i.e., polymer rather than the bibenzyl and toluene that were Klabunde's principal products. Hence crucible insulation was dispensed with in the mixed-ligand studies described below, despite the greater thermal losses involved.

The cocondensation of allyl chloride or bromide with nickel, with or without Kaowool insulation, gives the $\eta^3$-allylnickel halide dimers **I** in good yield, as reported by Piper and Timms (7).

*(ii) Mixed-ligand systems*

An equimolar mixture of allyl chloride and benzyl chloride, cocondensed with nickel atoms, does not give **I** but instead a hitherto-unreported yellow sublimable solid that decomposes very readily to bibenzyl, nickel(II) chloride, and nickel. Absence of decomposition products derivable from allyl chloride shows that the allyl group is not incorporated in the sublimable species. Addition of trialkylphosphines ($Et_3P$, $i$-$Bu_3P$) to the −196°C matrix yields equimolar amounts of bibenzyl and $(R_3P)_2NiCl_2$ but no other products.

An equimolar mixture of allyl bromide and benzyl bromide, cocondensed with nickel atoms, gives only the products which can be formed in the separate unmixed-ligand experiments, i.e., **I** (X = Br), bibenzyl, and nickel(II) bromide.

An intermediate mixed-ligand system, allyl chloride and benzyl bromide, when cocondensed with nickel gives two sublimable solids which can be separated by fractional sublimation: red **I** (X = Cl), and a yellow material which decomposes readily to give bibenzyl and nickel(II) bromide, and appears to be the bromine analogue of the sole product of the allyl chloride/benzyl chloride/nickel system. Addition of $Et_3P$ to a solution of this compound gives bibenzyl and $(Et_3P)_2NiBr_2$, identified by its mass spectrum.

Cocondensation of palladium atoms with an equimolar mixture of allyl chloride and benzyl chloride, followed by extraction with toluene, gives a yellow product identified as mainly $\eta^3$-allylpalladium chloride dimer from its mass spectrum. The mass spectrum also shows very weak clusters corresponding to the $\eta^3$-benzylpalladium chloride dimer **II** but none corresponding to a mixed allyl/benzylnickel chloride dimer.

*(iii) Structure of the unstable benzylnickel species*

Decomposition of the product of the allyl chloride/benzyl halide/nickel cocondensation reaction,

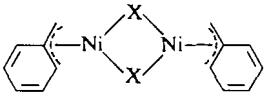
to give bibenzyl and nickel(II) halide in a 1:1 molar ratio as well as nickel metal but no other products, suggests structure **IV** (X = Cl, Br) analogous to **I** and **II**. Trapping experiments are consistent with this. However, the volatility of the product, greater than that of the allylnickel chloride dimer is anomalous and suggests that **IV** may vaporize as a monomer. Dissociation to the highly unstable monomer would be consistent with its extreme reactivity.



**IV**

Compound **II**, the palladium analogue of our proposed structure **IV**, also gives bibenzyl as a final product when reacted with $Et_3P$, but in the palladium case stepwise addition allows the isolation of an $\eta^1$-benzylnickel complex (15). An analogous but less stable $\eta^1$-benzylnickel complex is a likely intermediate in the reaction of **IV** with phosphines. Palladium species of this type tend to be much more stable than their nickel analogues (16).

Attempts to obtain mass spectra of **IV** showed only the presence of bibenzyl. A $^{13}C$ nmr spectrum was obtained on a deuterochloroform solution of **IV** (X = Br) but decomposition had already commenced and peaks attributable to bibenzyl were already larger than those of the unstable species. The peaks assigned to the unstable compound diminish on standing at ambient temperature, with corresponding growth of the bibenzyl peaks. The chemical shifts are reasonably consistent with those of other, similar $\eta^3$-allylmetal compounds (17–20) (Table 4). A complete assignment is difficult since peaks in the 125–133 ppm region are obscured by additional resonances, including the bibenzyl decomposition product. The peaks at 41.4 and 72.0 ppm are fully consistent with allylic bonding to nickel (21), and are difficult to account for in any other way.

The only previously-reported $\eta^3$-benzylnickel compounds appear to be **VI**. Compound **V** (X = Cl, Br) has been prepared by ethylene displacement from $(Ph_3P)_3Ni(C_2H_4)$ by benzyl halides (22). An $\eta^1 \rightleftharpoons \eta^3$ equilibrium in solution, with displacement of $Ph_3P$, was proposed on the basis of cryoscopic and $^1H$ nmr studies. These authors obtain decomposition products analogous to ours from their solutions (bibenzyl, $Ph_3P$, $(Ph_3P)_2NiX_2$, and nickel) but their complexes are considerably more stable. As in our work, no nickel-containing fragments were detected in the mass spectrum.

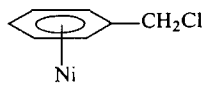
*(iv) Rationalization of product distributions*

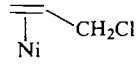
In metal atom – ligand cocondensations the interaction of metal atom and substrate first occurs on the freshly-formed cocondensation surface. The substrate and metal atoms are still mobile and the metal atoms are highly reactive, and in favourable cases a bond can form between metal atom and substrate. The initial organometallic species may then undergo further reactions, either at the cocondensation temperature or during warmup, to give the isolable products. Mobilities within the cocondensation matrix are important, especially when intermolecular reactions such as dimerization must occur, and are greatly affected by changes in attractive forces among the large excess of substrate molecules forming the matrix. Hence products and yields can be greatly changed by minor modifications to the matrix that affect mobility. For example, the use of *n*-hexane as substrate diluent in place of *n*-pentane when trimethylphosphine is cocondensed with iron atoms drastically decreases the yield of $HFe(CH_2PMe_2)(PMe_3)_3$ (1, 23), and the differing internal attraction of *n*-pentane and *n*-hexane, typified by their 35° difference in melting points, can explain this. Recent studies by Ozin and co-workers involving metal atom condensations in polymer matrices at temperatures much higher than −196°C have confirmed the importance of mobility effects (24). Aggregation of metal atoms to form colloidal metal can become predominant when mobility is either too low or too high, leaving a narrow temperature (i.e., mobility) range which favours desired products.

On the assumption that substrate melting points are indicative of mobilities in low-temperature matrices, our pattern of reactivities can be rationalized. The allyl halides have the lowest melting points of our organic substrates (allyl chloride, −134.5°C; allyl bromide, −119.4°C; benzyl chloride, −39°C; benzyl bromide, −3°C; acrylonitrile, −83.5°C). Hence the allyl halides form matrices of the highest mobility, favouring the formation of $\eta^3$-allynickel halide dimers by monomer diffusion. Benzyl halide matrices should be far less mobile, and the intitial monomeric benzylnickel halide probably decomposes before it can diffuse to form the less unstable dimer. Allyl halide/benzyl halide matrices should have intermediate mobilities, and dimerization of benzylnickel halide monomer is more likely to win out over monomer decomposition. Even here, a close balance of the two processes is apparently involved; the absence of **IV** from the allyl bromide/nickel bromide cocondensations might be the result of significantly lower mobility in this matrix, in accord with the higher melting points of the bromides compared to the analogous chlorides.

The absence of **I** from the allyl chloride/benzyl chloride cocondensation product might result from preferential formation of **VII** rather than **VIII** in the initial metal atom – ligand interaction. **VIII** is

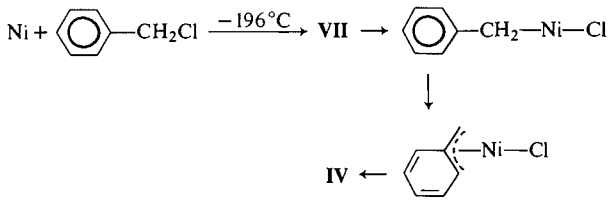


**VII**



**VIII**

known from the work of Ozin and Powers (25) and is stable up to −153°C. **VII** is the nickel analogue of the initial benzyl chloride – palladium species proposed by Klabunde *et al.* (8, 15). Once **VII** forms in preference to **VIII**, intramolecular rearrangement followed by dimerization would give **IV**, as in the analogous palladium system (8, 15):



Some **VIII** should form as well at −196°C, and a mixed $\eta^3$-allyl-$\eta^3$-benzylnickel halide dimer would be expected. No such species has been detected, but GC/MS analysis of the cocondensation residue, after sublimation of the volatile product, does show several organic species in addition to bibenzyl, all of which incorporate both allyl and benzyl fragments (Table 1). All of these products can be rationalized in terms of reactions of ligands in a mixed allylbenzylnickel compound.

A similar effect in inhibiting the formation of **I** has been observed in allyl bromide/acrylonitrile/nickel cocondensations. Neither **I**, nor the polymer obtained in acrylonitrile/nickel cocondensations, is obtained but instead a highly-unstable species which, from its decomposition products, appears to be a nickel complex containing both allyl and acrylonitrile groups (26). Metal atom cocondensation reactions with mixed ligands may hold many surprises even in cases in which the corresponding single-ligand reactions are well known.

# The lycoctonine family of alkaloids: a stereochemical revision[1]

O. E. EDWARDS

*Division of Chemistry, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R6*

AND

M. PRZYBYLSKA

*Division of Biological Sciences,, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R6*

Received April 6, 1982

O. E. EDWARDS and M. PRZYBYLSKA. Can. J. Chem. **60**, 2661 (1982).

A redetermination of the structure of des(oxymethylene)lycoctonine hydriodide has shown that a wrong choice had been made between the real and false mirror image peaks for the atoms of the 1-methoxyl group in the original pseudosymmetric Fourier synthesis. It has been demonstrated that lycoctonine samples from many sources are identical, and that no rearrangement took place in forming des(oxymethylene)lycoctonine. Hence all alkaloids that have been related to lycoctonine have a 1α-methoxyl group.

O. E. EDWARDS et M. PRZYBYLSKA. Can. J. Chem. **60**, 2661 (1982).

Une nouvelle détermination de la structure de l'iodhydrate du des(oxyméthylène) lycoctonine montre qu'on s'est trompé dans le choix des pics des images réelles et fausses dans un miroir des atomes du groupe méthoxy-1 dans la synthèse originale pseudosymétrique de Fourier. On démontre que les échantillons de lycoctonine, provenant de diverses sources, sont identiques et qu'il n'y a pas de transposition lors de la formation du des(oxyméthylène) lycoctonine. Ainsi tous les alcaloïdes qu'on a relié à la lycoctonine ont un groupe méthoxy en position 1 de configuration α.

[Traduit par le journal]

The skeleton, configuration of functional groups, and absolute stereochemistry of the diterpenoid alkaloid lycoctonine were determined by X-ray analysis of a simple derivative, des(oxymethylene)-lycoctonine hydriodide (1, 2). Subsequent chemical correlations resulted in assignment of structure and stereochemistry to the Delphinium alkaloids browniine (3), delpheline (4), and deltaline (5) and to the Aconite alkaloid chasmanine (6). This also provided the first direct chemical link between the two groups of alkaloids.

Total synthesis of chasmanine (7) and an X-ray structural analysis on its 14-*O*-benzoate hydrochloride (8) have since established beyond doubt that the C-1 configuration assigned to chasmanine in the above-mentioned work (6) was wrong, making it appear that the browniine–chasmanine correlation was in error. However, new X-ray analyses in our laboratories on lycoctonine transformation products (9, 10) have indicated that the error lay in the originally assigned configuration at C-1 in lycoctonine, and that all the alkaloids that have been related to lycoctonine, chasmanine, or browniine have 1α- methoxyl groups.[2]

## Results and discussion

In reexamining the question of the early assignment of configuration (1, 2) it seemed important to us to ensure that only one "lycoctonine" existed, i.e. that a stereoisomer had not been chosen for the X-ray analysis and that the alkaloids from the varied sources were identical. This has been done in part by comparison of X-ray powder patterns (12) and of other physical properties in our study of the alkaloids of *Inula royleana* (13). We now extend this with comparison of $^1$H nmr and $^{13}$C nmr spectra and X-ray powder patterns of the alkaloid and some of its transformation products from the early work in the 1950's and later work. Thus lycoctonine samples and derivatives from *D. consolida* L. (14), *D. brownii* Rydb. (*D. glaucum* S. Watts) (15), *D. elatum* L. (16), *D. ajacis* L. (now *Consolida ambigua* L.) (17), *D. barbeyi* Huth (18), and *Inula royleana* D. C. Prod. (13) were shown to be identical.

A second concern was whether the preparation of des(oxymethylene)lycoctonine proceeded without any stereochemical change. The gentle, nearly neutral conditions of the permanganate oxidation of lycoctonine, giving in part des(oxymethylene)-lycoctonam seemed unlikely to have epimerized C-1. Decarboxylation of lycoctonamic acid at 200°C gave the same compound (19*a*). But the more drastic lithium aluminum hydride reduction of des(oxymethylene)lycoctonam (refluxing dioxane) was more suspect. However, reoxidation of the resulting des(oxymethylene)lycoctonine gave a good yield of des(oxymethylene)lycoctonam iden-

tical with material obtained directly from lycoctonine.[3]

Clearly then, the anomaly lay in the original X-ray analysis of (+)-des(oxymethylene)lycoctonine hydriodide monohydrate (1, 2). The reexamination of this early determination was therefore undertaken. A crystal of the original sample was used to remeasure the data on a Nonius CAD-4 diffractometer with Ni-filtered Cu radiation. The unit-cell dimensions were corrected to: $a = 12.758(1)$, $b = 9.415(1)$, $c = 10.990(1)$ Å and $\beta = 97.81(1)°$. Out of 2644 measured reflections with $\theta \leq 70°$, 2012 were above threshold of $2\sigma(I_{net})$. The $\omega - 2\theta$ scanning method was used.

The space group is $P2_1$ and the structure had been solved by the heavy atom technique. The $x$ and $z$ coordinates of the iodine atom were derived from a Patterson projection. Its $y$ coordinate was assumed to be 0.250 and a three-dimensional Fourier synthesis was carried out using the phases based on the iodine contributions. This procedure imparted the symmetry of the centrosymmetric space group $P2_1/m$ by producing planes of symmetry at $y = 1/4$ and 3/4. The atomic peaks were therefore doubled and the choice between the real $(x, y, z)$ and the false mirror image peaks $(x, \frac{1}{2} - y, z)$ had been made on the basis of the examination of bond lengths and angles. In those days the computing facilities were rather poor and the refinement of the atomic coordinates thus derived had been limited to $F_o - F_c$ syntheses of the $h0l$, $0kl$, and $hk0$ zones, followed by the calculation of the $hkl$ structure factors. The $R$ index for 2162 observed reflections measured visually from Weissenberg films was 0.24.

The C(1) atom[4] had been situated close to the false plane of symmetry at $y = \frac{1}{4}$ in the original Fourier synthesis and the orientation of the ring A was such that the two symmetry related sets of peaks for O(1) and C(20) represented the α- and β-configurations of the 1-methoxy group. It appeared therefore that a wrong set of peaks was chosen for the real atoms in the interpretation of that synthesis. This was first tested by calculating structure factors, using new X-ray data, for observed reflections for two models: one with the previously published coordinates with 1-methoxyl in the β configuration and the other with the $y$ coordinates of C(1), O(1), and C(20) changed from 0.224, 0.080, and 0.039 to 0.276, 0.420, and 0.461, respectively. The $B$ value for all atoms in both cases was taken as 4.5 Å$^2$. The difference between the $R$ values was small (0.187 and 0.181, respectively), but it indicated that the second model with the 1α-methoxyl may be the correct one.

A difference synthesis carried out on the basis of structure factors, which had no contributions of 1-methoxy atoms, showed two weak peaks for each of the two configurations. Those for the α-configuration were, however, about 50% higher in intensity than those for β. Having adjusted the thermal parameters for different atoms and placed the 1-methoxy group in the α-configuration, the structure was refined by block-diagonal least-squares, minimizing $\Sigma w(|F_o| - |F_c|)^2$ with $w = 1/\{1 + [(|F_o| - 10)/15]^4\}$.

The refinement converged to $R = 0.085$ and $R_w = 0.098$. A difference map carried out close to the end of refinement showed residual density of only 0.4e Å$^{-3}$ at the positions for atoms of the methoxy group in both configurations. It was possible to locate all hydrogen atoms from difference syntheses except those of the disordered C(20) methyl group. The non-hydrogen atoms were refined anisotropically, but the parameters of the H atoms were fixed.

The atomic parameters are presented in Tables 1 and 2 and the bond lengths and the valency angles in Fig. 1. The $x$ and $z$ coordinates agree within 0.08 Å with the values published earlier, however, the $y$ coordinates show considerable differences, particularly for C(1), C(2), C(3), and O(7), as their refinement by two-dimensional difference maps had been seriously hampered by overlapping. The bond lengths for O(1)—C(1), C(4)—C(5), C(8)—C(9), and C(15)—C(16) have improved considerably and C(1)—C(11) increased from 1.50 to 1.57 Å.

The torsion angles are given in Fig. 1c. They are similar to those found in other aconitine and lycoctonine type alkaloids in which the boat form of the ring A is stabilized by the intramolecular hydrogen bonding (20–25). The projection of the structure is shown in Fig. 2, in which all the hydrogen-bonding parameters are presented. The molecule of water plays an important part in linking together neighbouring alkaloid molecules and the anion. The H ... I distances of 3.12 and 3.27 Å are only slightly shorter than the sum of the van der Waals radii of 3.35 Å. All other intermolecular contacts are normal.

To prove that this refined structure is the correct one, the effect on the refinement of changing of the 1-methoxy configuration back to β was studied. The H(11) atom was removed. The final $R$ values

[3]Variation in melting point range suggested that an isomer (*N*-acetyl?) was present in varying minor amounts in des(oxymethylene)lycoctonam but this was not evident in the nmr spectra.

[4]The numbering system corresponds to the generally accepted one for the $C_{19}$ diterpenoid alkaloids (19*b*), as is shown in **1**.

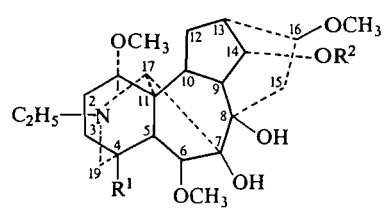
became appreciably higher ($R$ = 0.099 and $R_w$ = 0.123) and the bond lengths showed in general larger differences from the values obtained for the skeleton from more accurate X-ray determinations. The intermolecular contacts were satisfactory, but the O(1) ... H(22) and O(1) ... H(101) distances became unacceptably short. In addition, the final difference map showed peaks at positions for O(1) and C(20) in the α-configuration of ~2.0 and ~1.5e Å$^{-3}$, respectively.

In spite of the low accuracy of this redetermination, we can conclude that the β-configuration of the 1-methoxy group in the original analysis was wrong and that it is definitely α. This study has also shown that it would have been difficult to establish unambiguously the C(1) configuration in this derivative without recourse to better data and modern methods of refinement.

Thus lycoctonine has the structure and stereochemistry shown in **2** and browniine is represented by **3**. In a recent communication (26) Pelletier and co-workers have confirmed this revised stereochemistry by relating lycoctonine, browniine, delphatine, and delsoline through their methyl



**1** $R^1 = H$ $R^2 = CH_3$
**2** $R^1 = CH_2OH$ $R^2 = CH_3$
**3** $R^1 = CH_2OCH_3$ $R^2 = H$

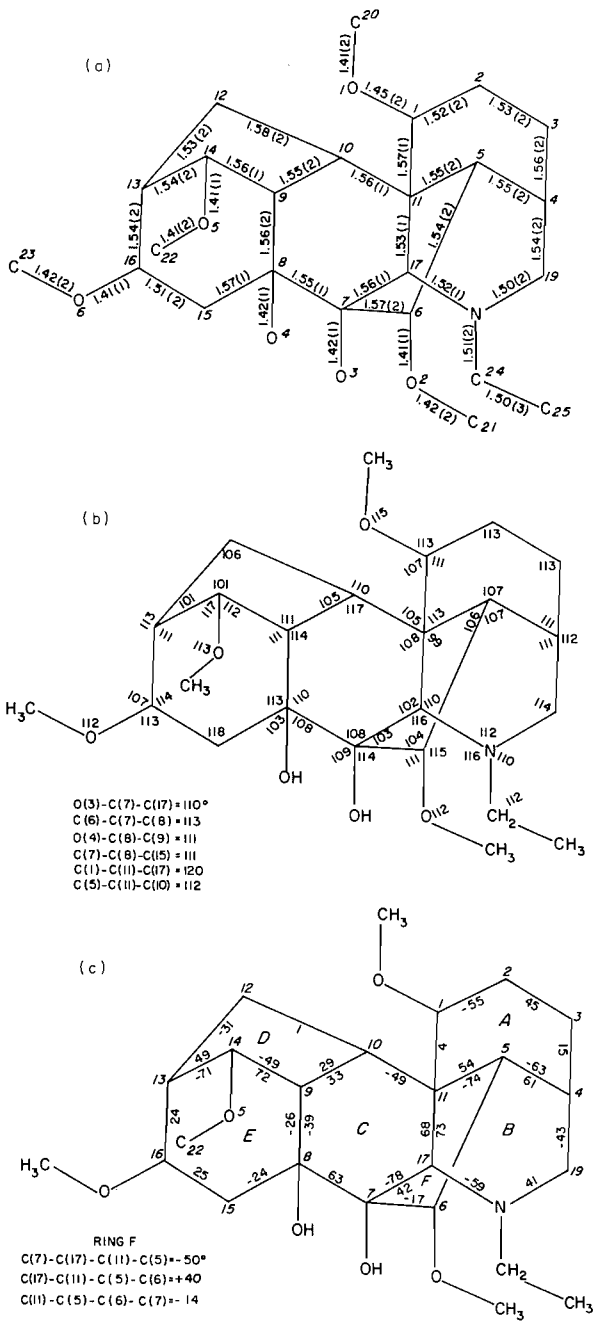

FIG. 1. (*a*) Bond lengths (Å) with their e.s.d.'s. (*b*) Valency angles (°); e.s.d.'s are 0.8 to 1.1° with the exception of those at C(2), C(3), and C(24) which are 1.3, 1.4, and 1.2°, respectively. (*c*) Torsion angles (°); e.s.d.'s are 0.5 to 0.9°.

ethers. Since delsoline has a 1α-hydroxyl group (27), the alkaloids with a 1-methoxyl group also have a 1α configuration.

Alkaloids which had been chemically correlated with lycoctonine, browniine, or delpheline, and which hence also require revision of their C-1 stereochemistry, are 14-*O*-acetylbrowniine (15*b*, 28), 14-*O*-acetyldelectine (29), *N*-acetyldelectine (30), ajacine (31), anthranoyllycoctonine (14, 15, 18, 32), 14-*O*-benzoylbrowniine (33), 14-dehydrobrowniine (33, 34), delbiterine (33), delectine (35), delectinine (35), delphatine (26, 28*b*, 36), deltaline (5, 37), dictyocarpine (38), elatine (37), lycaconitine (37, 39), methyllycaconitine (13, 37, 40), septentriodine (41), and tricornine (42).

A number of bases with 1-methoxyl groups have had their configurations assigned on the basis of their $^{13}C$ nmr spectra. Thus ajacusine (43), ajadine (43), and ambiguine (44) have chemical shifts for C-1 similar to lycoctonine and browniine (85 ± 2 ppm), while delcaroline (45) has a similar C-1 chemical shift to those of dictyocarpine and deltaline (79 ± 1 ppm), alkaloids with a 1α-hydroxyl group. However, no spectra seem to be available for 1β-methoxy alkaloids, so the assignments are open to question.

Since it should be possible to prepare methyl ethers of 1-epidelsoline (46), 1-epidelphisine (23), delphirine (47), and talatizidine (48), one should be able to ascertain whether a useful $^{13}C$ nmr shift difference exists between the epimers in both the lycoctonine and aconine series of alkaloids.

Other lycoctonine-type bases: delcorine (49), dehydrodelcorine (49), delcoridine (50), 6-deoxydelcorine (51), and ilidine (52) have been assigned 1α-methoxyl groups by interpretation of their mass spectra. The criterion was that 1-oxygenated bases with α configuration had low (less than 6%) ratios of the $M - 15$ to the $M - 31$ peaks while those with the β configuration had higher ratios (20–30%) (53). Since the examples used for the latter were lycoctonine and browniine, which are now shown to have 1α-methoxyl groups, this criterion is invalid. However, the apparent chemical correlation of delcorine with delphatine (26) seems to establish the correctness of these assignments.[5]

The revised configuration at C-1 vindicates the browniine–chasmanine correlation (6), which has often been questioned. The C-1 configurations of alkaloids which have been chemically related to chasmanine have already been corrected (54). New esters of browniine and dictyocarpinine have recently been isolated, but the corrected stereochemistry has been presented in ref. 55.

Two complex lycoctonine esters, avadharidine (56) and delsemine (57), are artifacts arising from ammonolysis of lycaconitine and methyllycaconitine, respectively, during isolation. Similarly, sep-

[5]This correlation has, to the best of our knowledge, not been documented.

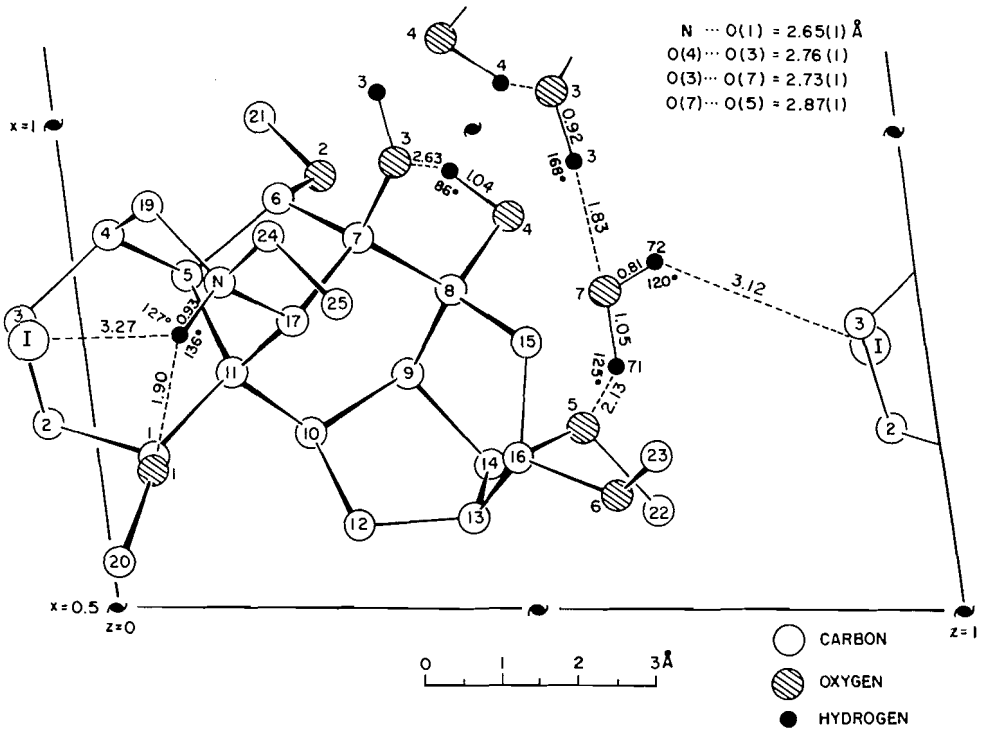

FIG. 2. A projection of the structure along the *b* axis. The hydrogen bonds are shown by broken lines.

tentrionidine (cashmiradelphine) (41, 58) and septentrionine probably are artifacts of methanolysis of lycaconitine and 8-*O*-methyllycaconitine, respectively.

## Experimental

Thin layer and preparative thin layer chromatography was done on silica gel plates with fluorescent indicator. Infrared spectra were obtained on a Perkin–Elmer Model grating spectrometer, $^1$H nmr spectra on a Varian EM 360 spectrometer, and $^{13}$C nmr spectra on a Brucker WP 80 spectrometer.

*Lycoctonine hydrate*

Early samples from Delphinium species (14, 15) and from *Inula royleana* (13) had identical $^1$H nmr spectra. In $C_6D_6$ (ca. 50 mg in 0.4 mL) it gave signals at δ 4.06 (1H, s), 3.87 (1H, s), 3.54 (1H, s), 3.32 (3H, s), 3.24 (3H, s), 3.16 (3H, s), 3.06 (3H, s), 1.17 (3H, t, $J$ = 7 Hz). In $CDCl_3$ the signals were at δ 4.04 (1H, s) 3.82 (1H, s), 3.42 (3H, s), 3.38 (3H, s), 3.32 (3H, s), 3.24 (3H, s), and 1.02 (3H, t, $J$ = 7 Hz).

Its $^{13}$C nmr spectrum in $C_6D_6$ had signals at δ 90.7, 88.5, 84.3, 84.0, 82.7, 77.6, 67.6, 64.9, 57.9, 57.7, 56.2, 55.7, 52.8, 51.1, 49.8, 48.9, 46.1, 43.3, 38.6, 38.0, 33.7, 31.7, 28.8, 26.1, 14.1 (25 carbons).

*Des(oxymethylene)lycoctonam*

Samples from permanganate oxidation of lycoctonine from *D. brownii* and *D. consolida* (19) were purified by preparative tlc on silica plates using 10% methanol in chloroform for development. They crystallized from ether as radiating clusters (pincushions) of rods, as isolated rods, or as prisms. The forms were interchangeable on recrystallization from acetone–ether. Some samples melted below 150°C, resolidified, sintered around 171°C, and melted completely by 181°C. The majority sintered at 171°C and melted by 180°C. Samples of prisms from early work on lycoctonine from Delphinium species (19) had mp 178–180.5°C. Similar prisms prepared from methyl lycaconitine from *Inula royleana* (13) had mp 179–181°C. The mixture mp of the two was 177–180°C.

The $^1$H nmr spectra of all samples of des(oxymethylene)lycoctonam in deuteriochloroform were identical. Because of the sensitivity of several chemical shifts to concentration, the spectra in deuteriobenzene were more difficult to reproduce exactly. The $^{13}$C nmr spectra of the different samples were identical as were the X-ray powder patterns of the same crystal forms.

$^1$H nmr ($CDCl_3$): a partially concealed multiplet near δ 4 (1H), 3.90 (1H, s, OH), 3.57 (1H, s), 3.42 (3H, s), 3.37 (3H, s), 3.20 (3H, s), 1.10 (3H, t, $J$ = 7 Hz); $^1$H nmr ($C_6D_6$): 4.34 (1H, m), 3.82 (1H, s), 3.58 (1H, s), 3.36 (3H, s), 3.10 (3H, s), 2.84 (3H, s), 2.78 (3H, s), 1.25 (3H, t, $J$ = 7 Hz); $^{13}$C nmr ($CDCl_3$): 170.3(s), 95.3(d), 85.9(s), 83.4(d), 82.0(d), 81.4(d), 76.4(s), 62.6(d), 58.8 (q), 57.5(q), 56.0(q), 55.2(q), 47.7(d), 47.1(d), 46.7(s), 44.8(d), 43.0(t), 42.7(d), 37.5(d), 32.8(t), 28.3(t), 25.0(t), 24.1(t), 11.8(q) (24 signals).

*Des(oxymethylene)lycoctonine*

A sample of methyllycaconitine from *Inula royleana* (13) was hydrolysed to give lycoctonine. This was oxidized to obtain des(oxymethylene)lycoctonam which was reduced to des(oxymethylene)lycoctonine (19*a*). The hydriodide of the base had mp 173°C and proved identical (mixture mp, $^1$H nmr spectrum, and X-ray powder patterns) with an old sample prepared from Delphinium sources (14, 15). The perchlorate of the base formed clusters of rectangular plates from methanol – ethyl acetate. This melted or sintered around 136°C, resolidified, and melted at 178–180°C. A dried sample gave only the higher mp. An old sample from lycoctonine from Delphinium species (14) had mp 181–183°C. The mixture mp was 180–181°C. The $^1$H nmr

spectra of the dried salts were identical as were their X-ray powder patterns.

The base gave a $^1$H nmr spectrum in $C_6D_6$ with signals at δ 3.92 (1H, s), 3.75 (1H, s), 3.50 (1H, s), 3.44 (3H, s), 3.16 (3H, s), 3.08 (3H, s), 2.94 (3H, s), 2.70 (1H, s), 1.17 (3H, t, $J$ = 7 Hz). Its perchlorate in $D_2O$–DSS solution gave $^1$H nmr signals at δ 3.9 (1H, s), 3.37 (3H, s), 3.35 (9H, s) and 1.25 (3H, t, $J$ = 7 Hz).

*Oxidation of des(oxymethylene)lycoctonine*

A solution of des(oxymethylene)lycoctonine (135 mg) was dissolved in 4 mL of acetone containing 0.5 mL of water and 0.05 mL of acetic acid. Powdered potassium permanganate was added in small portions with stirring, until an excess persisted for 30 min. The suspension was filtered, then the filtrate evaporated to small volume on a rotating evaporator. The residue was taken up in methylene chloride. After washing with aqueous sodium carbonate, then drying and distilling, the solution gave 145 mg of neutral product. This crystallized from ether–hexane giving 119 mg of crude des(oxymethylene)lycoctonam, which was purified on silica gel plates using 10% methanol in chloroform for development. The substance from the main zone (101 mg) crystallized as rods from acetone–hexane, mp 169–178°C. On recrystallization from the same solvent it formed clusters of rectangular prisms, mp 169–180°C, mixture mp with the product from permanganate oxidation of lycoctonine, 169–180°C. The $^1$H and $^{13}$C nmr spectra of the samples were identical.

# Étude de la réactivité des thiényldiazines: nitration et résonance magnétique nucléaire de $^{13}C$ dans $H_2SO_4$ concentré

JEAN BOURGUIGNON, STELLA CHAPELLE, PIERRE GRANGER ET GUY QUEGUINER[1]

*Laboratoire de Chimie Organique Hétérocyclique, Institut National Supérieur de Chimie Industrielle de Rouen, Faculté des Sciences et des Techniques de Rouen, 76130 Mont Saint Aignan, France*

Reçu le 23 février 1982

JEAN BOURGUIGNON, STELLA CHAPELLE, PIERRE GRANGER et GUY QUEGUINER. Can. J. Chem. **60**, 2668 (1982).

La réactivité des thiényldiazines **1** à **7** a été étudiée par l'intermédiaire de la réaction de nitration. Dans le but d'établir une relation entre la réactivité et la structure électronique de ces composés, nous avons enregistré et interprété leurs spectres de rmn $^{13}C$ dans $CDCl_3$ et dans $H_2SO_4$ concentré.

Les renseignements fournis par les spectres $^{13}C$ ont par ailleurs permis d'expliquer les réactivités relatives observées lors de réactions de concurrence entre les thiényldiazines **1** et **2**, **2** et **7**, **2** et **4**, **2** et **6**.

Cette méthode constitue une approche rarement utilisée pour étudier une substitution électrophile aromatique d'une molécule dans son milieu réactionnel.

JEAN BOURGUIGNON, STELLA CHAPELLE, PIERRE GRANGER, and GUY QUEGUINER. Can. J. Chem. **60**, 2668 (1982).

The reactivity of the thienyl diazines **1** to **7** has been studied by means of the nitration reaction. In order to examine any relationship between the reactivity and the electronic structure of these compounds, we have recorded their $^{13}C$ nmr spectra in $CDCl_3$ and in concentrated sulfuric acid.

The $^{13}C$ results are correlated to relative reactivities observed during competitive reactions between the thienyl diazines **1** and **2**, **2** and **7**, **2** and **4**, **2** and **6**.

This method is a rarely-used approach for the study of electrophilic substitution of a molecule in the reaction mixture.

Les systèmes bihétérocycliques constitués d'un cycle riche en électrons, le thiophène et d'un cycle pauvre en électrons ont particulièrement retenu l'attention des chercheurs depuis quelques années. La combinaison d'un cycle π-excédentaire et d'un cycle π- déficitaire se traduit, bien évidemment par une modification des propriétés respectives des deux cycles. C'est ainsi que Kauffmann *et al.* (1) ont réalisé une intéressante comparaison des réactivités électrophiles et nucléophiles de divers systèmes hétérocycliques assemblés.

Un certain nombre de réactions électrophiles ont été réalisées avec succès dans le cas d'autres systèmes bihétérocycliques constitués d'un thiophène et d'une diazine assemblés ou accolés, notamment par Gronowitz, Robba et coll. (2).

Les résultats décrits dans la littérature font apparaître que la réaction de nitration constitue un excellent modèle pour étudier et comparer la réactivité des systèmes bihétérocycliques assemblés ou accolés. C'est ce qui nous a conduit à l'appliquer à l'étude de la réactivité de thiényldiazines (3), de thiénodiazines (4) et de la (thiényl-2)-2 thiéno[2,3-*d*]pyrimidine (5). Ce dernier composé présente d'ailleurs la particularité d'être constitué d'un cycle diazinique à la fois assemblé et accolé à un cycle thiophénique.

Il est connu que la rmn de $^{13}C$ permet assez souvent d'obtenir des renseignements sur la densité électronique des systèmes π hétérocycliques en particulier. On admet souvent que le déplacement chimique d'un carbone donné est directement lié à la densité électronique à son niveau (6). C'est pourquoi nous avons décidé d'utiliser cette méthode pour compléter la discussion des résultats obtenus lors de la nitration des thiényldiazines **1** à **7**. Nous avons pour notre part enregistré les spectres de rmn de $^{13}C$ des composés étudiés tout d'abord dans $CDCl_3$ puis dans $H_2SO_4$ concentré. Dans ce dernier cas, les molécules étudiées se trouvent dans leur milieu réactionnel. Ceci constitue une approche utilisée pour la première fois, à notre connaissance, de la

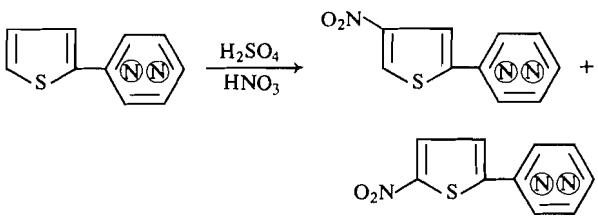
structure d'un système hétérocyclique soumis à une substitution électrophile aromatique dans l'acide sulfurique.

## I. Nitration des (thiényl-2)diazines

### 1. Résultats

La nitration se fait avec un excellent rendement et fournit un mélange en proportions variables du dérivé nitré en 4 et du dérivé nitré en 5 sur le cycle thiophénique (Tableau 1). L'obtention de ces deux isomères résulte de la compétition entre l'effet électroattracteur de la diazine protonée (3*c*), orienteur en *méta* (sommet 4) et la réactivité élevée de la position α du thiophène (sommet 5).



*Spectres de résonance magnétique nucléaire de* $^{13}C$

*(a) Spectres dans le deutériochloroforme*

L'attribution des divers signaux des carbones des composés étudiés **1** à **6** rassemblés, dans le Tableau 2 a été effectuée selon les données de la littérature ci-dessous: (*i*) utilisation des déplacements chimiques des cycles thiophénique et diazinique et des constantes de couplage $^1J$(C—H) relevées dans la littérature (7) qui permettent, entre autre, la distinction des carbones en α et en β du soufre; (*ii*) utilisation des constantes de couplage à longue distance $J$(C—H) et du découplage sélectif pour lever certaines ambiguïtés.

Dans le cas du composé **1**, l'attribution de déplacement chimique du carbone 5 pyridazinique à 126,6 ppm est basée sur le fait que $^2J_{C_5-H_4} \simeq 0$ et $^2J_{C_5-H_6} \simeq 5$ Hz (7*b*) conduisant à l'observation d'un doublet alors que le carbone 3 thiophénique à 126,4 ppm se présente sous forme d'un massif complexe à cause des valeurs de $^2J_{C_3-H_4}$ et $^2J_{C_3-H_5}$ de l'ordre de 5 et 8 Hz (7*a*).

Les carbones 3 et 4 du cycle thiophénique des composés **3**, **4** et **5** ont été différenciés par leurs $J$ longue distance qui conduisent à des largeurs de raie différentes. De plus dans le cas du composé **5**, nous avons vérifié l'attribution en effectuant un découplage sélectif: l'irradiation de H4 (δ = 7,16 ppm en rmn de $^1$H) permet d'observer un découplage total de la raie à 128,4 ppm alors que la raie à 125,3 ppm n'est que partiellement découplée et donne une constante de couplage résiduelle de 12 Hz ($\delta H_3$ = 7,42 ppm).

L'attribution des déplacements chimiques des carbones 3 et 5 du cycle pyrazinique du composé **6** a été effectuée par analogie avec les valeurs relevées pour la phényl pyrazine (7*e*).

Dans le cas du composé **7**, l'attribution des signaux correspondants aux carbones 2 et 5 du cycle thiophénique pourraît être inversée. Notre attribution est effectuée par analogie avec les résultats de la littérature (7*a*).

Les valeurs des déplacements chimiques des (thiényl-2)diazines dans $CDCl_3$ indiquées dans le Tableau 2 révèlent qu'il n'existe pas de différences importantes pour un carbone thiophénique donné lorsque l'on passe d'un composé à un autre. On note par exemple les écarts ci-dessous pour les déplacements chimiques des carbones 4 et 5 (choisis car ce sont les positions de nitration): carbone 5: de 127,3 à 130,2 ppm; carbone 4: de 127,6 à 128,5 ppm.

Ces écarts trop faibles ne nous permettent pas de comparer valablement la réactivité des thiényldiazines que nous avons soumises à la nitration. Cette réaction s'effectuant en milieu acide sulfurique concentré, nous avons alors décidé d'enregistrer les spectres des produits étudiés dans ce même milieu. On peut penser, en effet, que l'étude des spectres de $^{13}$C des (thiényl-2)diazines dans leur milieu réactionnel a plus de chances de fournir des renseignements intéressants concernant leur réactivité.

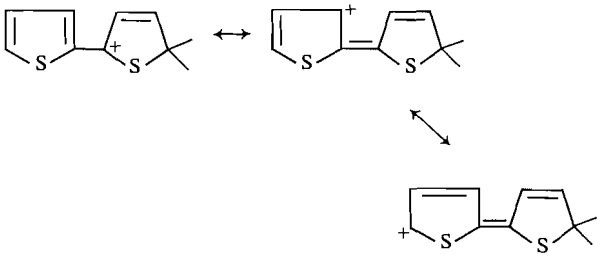
*(b) Spectres dans $H_2SO_4$*

Une étude préalable en rmn de $^1H$ nous a montré que certains composés étudiés se sulfonaient rapidement. C'est ainsi que nous avons rencontré de grandes difficultés pour enregistrer le spectre de $^{13}C$ du composé **1** (voir partie expérimentale).

D'une manière générale, l'interprétation des spectres des divers composés dans l'acide sulfurique a été déduite de l'examen des constantes de couplage et surtout de l'examen des variations de déplacements chimiques, en tenant compte des résultats obtenus par Pugmire et Grant (8) sur la mono ou la diprotonation des diazines. Les signaux sont fins, les déplacements chimiques sont mesurés sans ambiguïté (il ne se forme pas de produit sulfoné, il peut y avoir échange rapide entre les espèces monoprotonée ou diprotonée).

L'ensemble des résultats en milieu sulfurique concentré est présenté dans le Tableau 3. De ceux-ci on constate que: (*i*) les carbones du cycle pyrimidinique ont des déplacements chimiques très voisins de ceux observés pour le mono ou le dicathion pyrimidinium (8), et (*ii*) les carbones du cycle thiophénique ont des déplacements chimiques très comparables à ceux du cycle thiophénique dans le bithiényl-2,2′ protoné en milieu superacide (9). Les forts déblindages des carbones 3 et 5 sont attribués à la présence d'une charge positive sur les sommets correspondants dans les formules limites ci-dessous:



L'interprétation du spectre du composé **4** dans l'acide sulfurique pose un problème au niveau du carbone 5 du cycle thiophénique et du carbone 6 du cycle pyrimidinique. Si l'on s'en tient aux constantes de couplage observées, il semblerait (par analogie avec le composé **3**) que les déplacements chimiques de ces deux carbones seraient respectivement de 156 ppm et 148,7 ppm. Cette dernière valeur représente alors un blindage trop important du carbone pyrimidinique par rapport à son déplacement chimique dans $CDCl_3$ (8,4 ppm) au lieu de 1 à 2 ppm observés par Pugmire et Grant (8). C'est pourquoi nous avons finalement choisi l'interprétation indiquée dans le Tableau 3.

## 2. Discussion

La nitration des (thiényl-2)diazines **1** à **6** fournit un mélange de (nitro-4 et -5 thiényl-2)diazines avec, en général, un pourcentage plus élevé de l'isomère en 5. Or si on examine les déplacements chimiques des carbones correspondants dans $H_2SO_4$, on constate que le carbone 5 est toujours plus déblindé que le carbone 4. On a d'ailleurs l'ordre suivant $\delta C_4 < \delta C_3 < \delta C_5$. Cette situation est la conséquence de l'effet électroattracteur de la diazine qui s'exerce essentiellement sur les sommets 3 et 5.

Il n'apparaît donc pas de corrélation directe entre la réactivité préférentielle en 5 et le déplacement chimique du carbone correspondant.

Cependant la nitration fournit de 27% à 65% de dérivé nitré en 4 (voir Tableau 1).

L'obtention de ces dérivés nitrés est la conséquence de l'effet exercé par le cycle diazinique protoné orienteur en *méta*, qui entre en concurrence avec la réactivité élevée de la position α du cycle thiophénique.

Si on examine la différence des déplacements chimiques entre les carbones 5 et 4 du cycle thiophénique des diverses thiényldiazines (en solution dans $H_2SO_4$) et les pourcentages de (nitro-4 thiényl-2)diazines obtenus, on observe qu'il y a une bonne corrélation entre ces deux grandeurs.

Seul le composé **1** se trouve légèrement en dehors du classement proposé, mais il faut rappeler les difficultés rencontrés pour enregistrer son spectre dans l'acide sulfurique.

On peut estimer que plus l'écart des déplacements chimiques entre les deux sommets est élevé plus la réactivité en 5 est défavorisée par rapport à la réactivité en 4.

On peut donc penser qu'il est possible dans

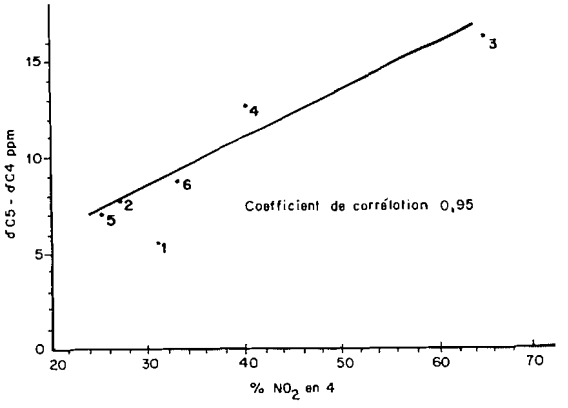


FIG. 1. δC5 – δC4 en fonction du % de dérivé nitré en 4 des (thiényl-2)diazines **1** à **6**.

TABLEAU 4. Réactions de concurrence entre les thiényldiazines

| Diazines de départ | Nitration de chaque diazine (%) | Rendement global[a] | |
|---|---|---|---|
| 1 + 2 | 50% 1 et 50% 2 | 91% | Position d'assemblage sur la pyridazine |
| 2 + 7 | 30% 2 et 70% 7 | 82% | Position d'assemblage sur le thiophène |
| 2 + 4 | 75% 2 et 25% 4 | 93,5% | Nature de la diazine |
| 2 + 6 | 60% 2 et 40% 6 | 86% | Nature de la diazine |

[a]Rendement global: voir partie expérimentale pour sa détermination.

certains cas de prévoir les réactivités relatives des sommets α et β de cycles thiophéniques diversement substitués en 2 à partir des différences de déplacement chimique de ces deux sommets α et β en milieu acide.

## II. Réaction de concurrences entre les thiényldiazines

Les résultats que nous venons d'exposer concernant la nitration des thiényldiazines nous ont permis de préciser l'influence des ions diazinium sur la nitration du cycle thiophénique. Les renseignements ainsi obtenus peuvent être utilement complétés par une étude de la réactivité relative de ces systèmes bihétérocycliques opposés dans des réactions de concurrence selon la méthode utilisée par Kauffmann *et al.* pour étudier les réactivités relatives de nombreux composés biaryliques (1).

Nous avons réalisé trois type de réactions de concurrence: (*i*) entre la (thiényl-2)-3 pyridazine (**1**) et la (thiényl-2)-4 pyridazine (**2**) dans lesquelles la pyridazine est assemblée par son sommet 3 ou 4 au cycle thiophénique; (*ii*) entre la (thiényl-2)-4 pyridazine (**2**) et la (thiényl-3)-4 pyridazine (**7**) dans le but d'apprécier l'influence de la pyridazine selon qu'elle est assemblée par le sommet 2 ou 3 du thiophène; (*iii*) entre la (thiényl-2)-4 pyridazine (**2**) d'une part et la (thiényl-2)-4 pyrimidine (**4**) ou la (thienyl-2)pyrazine (**6**) d'autre part dans le but d'apprécier cette fois le rôle de la diazine liée au thiophène.

### 1. Résultats

Le choix de ces réactions de concurrence s'est trouvé imposé par la possibilité de déterminer la composition des mélanges réactionnels par rmn de $^1H$. Il est, en particulier, nécessaire de choisir des isomères dont l'un au moins est facilement repérable en rmn par la présence d'un pic caractéristique dans une région donnée du spectre. La même propriété doit se retrouver pour l'un au moins des dérivés nitrés. Ces considérations nous ont conduit à utiliser la (thiényl-2)-4 pyridazine (**2**) comme partenaire privilégié dans les différentes nitrations compétitives mises en oeuvre.

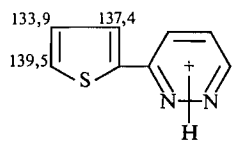
Par ailleurs, pour que le bilan de la réaction de concurrence ait une signification il faut que la nitration des thiényldiazines mises ainsi en compétition se fasse individuellement avec un excellent rendement. C'est le cas de toutes les réactions étudiées (voir Tableau 1) et aussi de la nitration de la (thiényl-3)-4 pyridazine (**7**) qui fournit le dérivé nitré en 5 sur le cycle thiophénique avec un rendement de 89% (3*c*).

Les résultats sont rassemblés dans le Tableau 4.

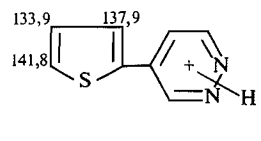
### 2. Discussion

Les résultats des réactions de concurrence permettent de compléter la discussion sur la réactivité des thiényldiazines en utilisant notamment les renseignements fournis par les spectres de rmn de $^{13}C$ dans $H_2SO_4$.

(*a*) Les groupes pyridazinyl-3 ou pyridazinyl-4 protonés exercent des effets identiques sur la réactivité du thiophène. Cela signifie que l'importance de l'effet électroattracteur de l'ion pyridazinium est indépendante de sa position d'assemblage au cycle thiophénique. Les déplacements chimiques, très voisins en rmn de $^{13}C$ des carbones thiophéniques des composés **1** et **2** dans l'acide sulfurique sont en accord avec ce résultat.



1

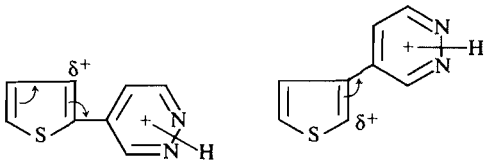


2

(*b*) On note que le groupe pyridazinyl-4 désactive plus le thiophène quand il lui est relié par le sommet 2 plutôt que par le sommet 3. Ce comportement avait déjà été mis en évidence par Gronowitz et Liljefors (2*b*) lors de l'étude de la nitration des (thiényl-2 et -3)-2 pyrimidines. Ce résultat apparaît normal si on examine les facteurs qui influencent

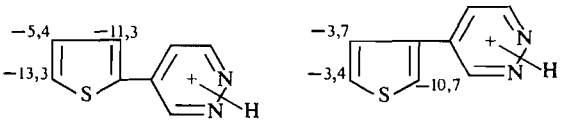
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

les réactivités du sommet 2 de la (thiényl-2)-4 pyridazine et du sommet 5 de la (thiényl-3)-4 pyridazine.



2 7

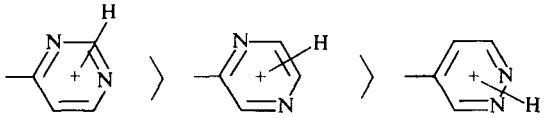
Les formules limites les plus significatives sont celles représentées ci-dessus où apparaissent des charges (ou des fractions de charges) dues au effets -M ou -I exercés par le cycle pyridazinique sur les sommets 3 et 5 du composé **2** et sur le sommet 2 du composé **7**. On constate que le cycle pyridazinique assemblé en 2 au cycle thiophénique entraîne une déficience électronique sur le sommet 5, ce qui diminue bien sûr la réactivité de ce sommet vis-à-vis d'un réactif électrophile. A l'inverse, le groupe pyridazinyle assemblé en 3 au cycle thiophénique appauvrit surtout le sommet 2 en électrons et exerce peu d'effet sur le sommet 5 où a lieu l'attaque. Là encore, l'étude des spectres de $^{13}C$ dans l'acide sulfurique confirme le résultat observé. En effet, si on examine le déblindage subit par un carbone donné des composés **2** et **7** dans l'acide sulfurique par rapport à son déplacement chimique dans $CDCl_3$ on a les valeurs suivantes (tirées des Tableaux 2 et 3).



2 7

On constate que globalement, les carbones thiophéniques du composé **2** sont plus déblindés que ceux du composé **7** ce qui traduit bien une désactivation plus importante exercée par la pyridazine dans le premier composé par rapport au second. On peut ajouter que le déblindage nettement plus faible du carbone 5 du composé **7** par rapport aux carbones 4 et 5 du composé **2** correspond lui aussi à une plus grande réactivité de ce sommet.

(*c*) En ce qui concerne l'influence de la nature de la diazine assemblée au cycle thiophénique, on observe que le groupe pyrimidyl-4 exerce un effet désactivant plus élevé que celui du groupe pyridazinyl-4, cependant que le groupe pyrazinyl-2 possède un effet intermédiaire. Ces résultats peuvent s'expliquer si on considère que l'effet le plus important semble être celui exercé par le nombre et la proximité des liaisons iminium conjuguées avec le thiophène (3*c*).



On peut remarquer qu'il existe une corrélation entre ce classement et celui établi lors de la comparaison des pourcentages de dérivé nitré en 4 obtenus dans la nitration des (thiényl-2)diazines (Tableau 1). Rappelons que ce classement est en accord avec l'examen des spectres de rmn de $^{13}C$ des composés étudiés en milieu acide.

D'une manière générale, on peut noter que les résultats obtenus peuvent s'expliquer en faisant intervenir les effets électroniques. On peut ajouter que les renseignements fournis par les spectres de rmn de $^{13}C$ dans l'acide sulfurique peuvent être corrélés avec les réactivités de ces thiényldiazines. Il faut cependant remarquer qu'il n'existe pas de relation directe entre le déplacement chimique d'un carbone du cycle thiophénique dans $CDCl_3$ et la position de nitration sur ce cycle.

Ces méthodes (étude des produits de la nitration et examen des spectres de $^{13}C$ dans le milieu réactionnel) fournissent une image précise de l'effet désactivant exercé par les ions diazinium et de la réactivité des thiényldiazines.

## Partie expérimentale

*1. Enregistrement des spectres de résonance magnétique nucléaire $^{13}C$*

Les spectres $^{13}C$ dans $CDCl_3$ ont été enregistrés sur un Spectromètre WP 80 à transformée de Fourier à 20,11 MHz à 28°C. La référence interne utilisée est le pic central du deutérochloroforme pris à 76,91 ppm. Les spectres en solution dans l'acide sulfurique ont été obtenus sur un WH 90C multinoyaux à 22,63 MHz et 28°C. Le lock utilisé était un capillaire de benzène à température ordinaire et d'acétone à basse température. La référence a été prise par rapport au pic central du $C_6D_6$ du capillaire (127,96 ppm) ou de l'acétone-$d_6$ (29,22 ppm) sans correction de susceptibilité magnétique.

*Composé 1 dans $H_2SO_4$*: nous avons enregistré le spectre normal cinq minutes après la mise en solution dans $H_2SO_4$ concentré, alors qu'il y a déjà une quantité importante de produit sulfoné. Une heure plus tard on constate que l'échantillon est uniquement constitué de produit sulfoné (en 5 sur le cycle thiophénique). Par différence on peut repérer dans le spectre enregistré après cinq minutes les signaux correspondants au produit **1** dans le milieu réactionnel. Cependant, les valeurs relevées ne sont pas comparables à celles relevées pour les autres composés, car le milieu n'est pas le même (absence de produit sulfoné dans les autres cas). C'est pourquoi nous n'avons pas envisagé le comportement du produit **1** dans la discussion.

*2. Nitration des thiényldiazines*

Les réactifs de départ ont été préparés selon les méthodes

décrites dans le littérature (2*a*, 2*e*, 3*a*, 3*c*). La nitration a été effectuée dans les conditions indiquées précédemment (3*c*).

*3. Réactions de concurrence*

Le réactif utilisé lors des réactions de nitration est préparé de la même manière pour les essais de concurrence (3*c*) Le mode opératoire utilisé pour effectuer les quatre réactions de concurrence est identique et peut se résumer ainsi.

Les deux thiényldiazines mises en compétition sont dissoutes dans l'acide sulfurique concentré à 0°C. Puis sous agitation et en maintenant à 0°C, on ajoute la quantité stoechiométrique du réactif nitrant pour nitrer un seul constituant.

Après une durée de réaction de trois heures, le milieu réactionnel est intégralement versé sur de la glace pilée, puis neutralisé à pH 7 par de l'ammoniaque concentrée. Le précipité obtenu est filtré, lavé soigneusement, séché puis pesé. Ce précipité contient en général des produits nitrés issus de la réaction, le filtrat contenant surtout les thiényldiazines n'ayant pas réagi. Il est extrait au chloroforme. Cet extrait soigneusement lavé est débarrassé du solvant sous pression réduite, puis pesé. Cela permet de faire le bilan global de la réaction qui nous renseigne sur la validité de l'essai effectué.

Le spectre de rmn des diverses fractions récupérées permet de déterminer leur composition. Le rendement global est calculé à partir des rendements en produits nitrés obtenus et en produits de départ récupérés.

# Secondary metabolites from the red alga *Laurencia intricata*: halogenated enynes[1]

JOHN H. CARDELLINA II,[2] STEPHEN B. HORSLEY,[3] JON CLARDY, S. R. LEFTOW, AND JERROLD MEINWALD

*Department of Chemistry, Cornell University, Ithaca, NY 14853, U.S.A.*

Received December 23, 1981

JOHN H. CARDELLINA II, STEPHEN B. HORSLEY, JON CLARDY, S. R. LEFTOW, and JERROLD MEINWALD. Can. J. Chem. **60**, 2675 (1982).

Extracts of the red alga *Laurencia intricata*, collected in Bermuda, have yielded two new halogenated C-15 enynes, bermudenynol and its acetate. Spectroscopic evidence for the assignment of structures **1***a* and **1***b* to these compounds is presented. X-ray analysis verified the proposed structures and established their stereochemistry.

JOHN H. CARDELLINA II, STEPHEN B. HORSLEY, JON CLARDY, S. R. LEFTOW et JERROLD MEINWALD. Can. J. Chem. **60**, 2675 (1982).

Des extraits de l'algue rouge *Laurencia intricata*, recueillis aux Bermudes, ont permis d'isoler deux nouveaux enzymes de type ényne halogénés en position C-15, soit le bermudenynol et son acétate. On présente les preuves spectroscopiques qui appuient les structures **1***a* et **1***b* proposées. L'analyse par rayons X confirme ces structures et établi leur stéréochimie.

[Traduit par le journal]

## Introduction

Red algae of the genus *Laurencia* are prolific sources of an unusual series of halogenated secondary metabolites characterized by a straight chain, fifteen-carbon skeleton which incorporates a terminal, conjugated enyne functionality (1). While it has been apparent for some time that these compounds are sequestered by certain mollusks (*Aplysia* spp.) which graze on *Laurencia*, it was demonstrated only recently that the C-15 enynes can serve as potent feeding deterrents to potential predators of these mollusks (2). In our continuing investigation of compounds which play a role in the chemical ecology of marine organisms, we have isolated two new halogenated C-15 enynes from specimens of *Laurencia intricata* collected in Bermuda.

## Discussion

Successive chromatography of the acetone extracts of the alga on Florisil and Sephadex LH-20 yielded bermudenynol, **1***a*, a crystalline major metabolite (6.9% of the extract). Infrared absorptions at 3265 and 2095 (very weak) $cm^{-1}$ and the ultraviolet absorption spectrum indicated the presence of the terminal conjugated enyne moiety; this assignment was further substantiated by the $^1H$ and $^{13}C$ nmr spectra (see Tables 1 and 2). Mass spectral studies revealed a weak molecular ion cluster at *m/e* 380; both the isotopic abundances and fragment ion masses revealed the presence of one bromine and two chlorine atoms in bermudenynol, leading to a likely molecular formula of $C_{15}H_{19}BrCl_2O_2$. The presence of fifteen carbon and nineteen hydrogen atoms was confirmed by $^{13}C$ nmr analysis. Moreover, the presence of two alkynyl and four alkenyl carbons in the $^{13}C$ nmr spectrum required a monocyclic structure for **1***a*.

Extensive $^1H$ nmr decoupling experiments led us to partial structure **A** (X = heteroatom) for

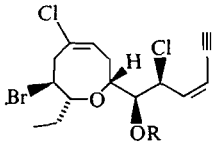
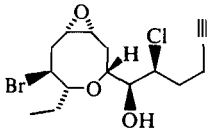
bermudenynol. The mass spectral fragmentation data indicated that one chlorine atom was allylic to the enyne functionality (loss of 99 daltons; $C_5H_4Cl$), and that the other was probably bound to an olefinic carbon atom, since it was retained in most fragment ions and lost only late in the fragmentation scheme.

Acetylation of bermudenynol proved to be facile; a monoacetate was obtained, thereby confirming the presence of an unhindered hydroxyl (3520 $cm^{-1}$) group in **1***a*. The $^1H$ nmr spectrum of this acetate was superimposable on that of a minor constituent of the *L. intricata* extract isolated from a less polar fraction. The semisynthetic and natural acetates also behaved identically ($R_f$ values and $H_2SO_4$ charring characteristics) in two tlc systems. Detailed analysis of $^1H$ nmr decoupling experiments conducted with this compound placed the acetate group at C-6 and allowed assignment of structure **1***b* to the acetate and **1***a* to bermudenynol.



**1** *a* R = H
*b* R = $COCH_3$



**2**

Placement of the bromine substituent at C-12 was supported by the similarity of the chemical shifts observed for the C-12 protons in **1***a* and **1***b* with that of the C-12 methine in poiteol, **2** (3). Since the decoupling experiments had placed the acetate/hydroxyl moieties at C-6, an ether linkage from C-7 to C-13 was required. In fact, comparison of the $^{13}C$ nmr spectra of **1***a* and **2** (see Table 2) revealed excellent correspondence of the carbon resonances, with the exception of those of C-8 through C-11, where the differences in functionality obviously warrant spectral differences. These similarities suggest the same relative stereochemistry of the chiral centers at C-5, C-6, C-7, C-12, and C-13 in **1***a*, **1***b*, and **2**. It is likely that there is a close biosynthetic relationship between bermudenynol and poiteol, since nucleophilic chloride ion attack on the epoxide ring at C-10 in **2**, followed by protonation of the resulting alkoxide ion and dehydration, would give **1***a*.

To verify the proposed stereochemistry, a needle-shaped crystal of bermudenynol of dimensions 0.15 × 0.15 × 0.40 mm was selected for single-crystal X-ray analysis. Preliminary X-ray photographs showed monoclinic symmetry and accurate cell constants, determined from a least-squares fit of fifteen moderate 2$\theta$-values, were $a$ = 10.52(5), $b$ = 5.57(3), and $c$ = 15.80(6) Å and $\beta$ = 108.97°. Systematic extinctions (0$k$0 absent if $k$ = 2 + 1) and the known chirality were uniquely accommodated by the space group $P2_1$ and the density indicated one molecule of $C_{15}H_{19}BrCl_2O_2$ formed the asymmetric unit. All unique diffraction maxima with $2\theta \leq 46°$ were collected on a fully automated four-circle diffractometer using graphite monochromated MoK$\alpha$ (0.710069 Å) radiation and a variable speed $\omega$-scan technique. Of the 1452 reflections surveyed, 1306 (90%) were judged observed [$|F_o| \geq 3\sigma(F_o)$].

The structure was solved by conventional heavy atom techniques. A three-dimensional Patterson synthesis was deconvoluted to determine the bromine and chlorine positions (for major crystallographic programs employed, see ref. 4). The remaining nonhydrogen atoms were located on successive $F_o$-synthesis. Full-matrix least-squares refinement with anisotropic temperature factors for the nonhydrogen atoms, isotropic hydrogens, and anomolous dispersion corrections have converged to a residual of 0.104 for the structure shown and 0.106 for the enantiomer.

Figure 1 shows a computer generated perspective drawing of the final X-ray model of **1***a*. Hydrogen atoms are omitted for clarity. Bond distances and angles agree well with generally accepted values and there were no unusually short intermolecular contacts. The configurations at the five chiral centers are 5($R$*), 6($R$*), 7($R$*), 12($S$*), and 13($R$*) and the double bond of the enyne functionality has a *cis* or *Z* configuration.[4]

[4]Tables of fractional coordinates, thermal parameters, bond distances, bond angles, and observed and calculated structure factors are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

## Experimental

Infrared spectra were recorded on a Perkin–Elmer Model 257 grating infrared spectrophotometer, ultraviolet spectra on a Beckman DB-G spectrophotometer, and optical rotations on a Perkin–Elmer Model 141 polarimeter. Mass spectra were obtained on an Associated Electronic Industries MS-902 mass spectrometer operated at 70 eV. The $^1$H nmr spectra were obtained on a Varian EM-390 spectrometer; $^{13}$C nmr spectra were obtained on a Varian CFT-20 spectrometer; chemical shifts are reported in ppm (δ units) downfield from tetramethylsilane as an internal standard.

*Isolation of bermudenynol*

Specimens of *Laurencia intricata* were collected at depths of one to three feet in Castle Harbour, Bermuda in October 1979, and preserved in acetone prior to analysis. The acetone extracts were decanted and concentrated under reduced pressure. The residual aqueous phase was extracted with $CH_2Cl_2$ to yield a dark green syrup (4.5 g) which was chromatographed on Florisil. Fourteen fractions were collected from the Florisil column (136 g) by elution with mixtures of hexane, ethyl acetate, and methanol of gradually increasing polarity. Sephadex LH-20 gel filtration (2.5 × 191 cm, eluted with $CH_2Cl_2$–MeOH, 1:1) of 407 mg of fraction 4 gave 310 mg of a colorless oil which crystallized on standing. Recrystallization from hexane gave prisms of bermudenynol, 1*a*, mp 80–81°C; $[\alpha]_D^{25}$ +187° (*c* 0.756, $CHCl_3$); uv $\lambda_{max}$ (cyclohexane): 220 nm (ε = 19 600); ir ($CS_2$) $\nu_{max}$: 3520, 3265, 3015, 2940, 2890, 2840, 2095, 1639, 1371, 1238, 1080, 1059, 1023, 970, 935, 888, 851, 815, 750 cm$^{-1}$; CI ms *m/e* (rel. int.): 383(M + 3, 16), 381(M + 1, 13), 347(33), 345(27), 303(41), 301(16), 285(4), 283(13), 281(10), 267(33), 265(M − HBr, HCl, 100), 253(12), 251(10), 229(47), 203(8), 201(7), 197(18), 195(11), 189(10), 187(15), 185(46), 173(25), 171(70), 165(16), 159(9), 157(11), 155(35), 145(13), 143(47), 129(12), 127(13), 107(51), 95(39), 59(22); $^1$H and $^{13}$C nmr data are presented in Tables 1 and 2, respectively.

*Acetylation of 1*a

Acetic anhydride, 0.4 mL, was added to a solution of 25.2 mg of bermudenynol, 1*a*, in pyridine (0.8 mL). The mixture was allowed to stand at room temperature for 8 h, at which time the solvent and excess reagents were removed *in vacuo*, yielding a light brown gum. Gel filtration through Sephadex LH-20 (2 × 100 cm, eluted with $CH_2Cl_2$–MeOH, 1:1) to give 27.6 mg (99%) of a colorless oil, 1*b*; for $^1$H nmr, see Table 1.

*Isolation of bermudenynol acetate*

Fraction 2 from the Florisil chromatography of the crude extract was rechromatographed on silica gel; elution with hexane–$Et_2O$ (9:1) gave 1*b*, 18 mg, a colorless oil, identical by $^1$H nmr (Table 1) and tlc with the acetate prepared from 1*a*.

## Acknowledgments

We thank Mr. Francis Connor for assistance in the field work and Dr. John Schwede for identifying the alga. The field work was supported by H. B. Wilkinson and Continental Corporation Fellowships (to J.H.C.) from the Bermuda Biological Station. Partial support of this work by the U.S.D.A., Forest Service, Northeastern Forest Experiment Station (for S.B.H., Visiting Fellow) and by the Schering Corporation is gratefully acknowledged.

# A convenient entry into the rhoeadan skeleton. Total synthesis of (±)-*cis*-alpinigenine[1]

IJAZ AHMAD AND VICTOR SNIECKUS

*Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1*

Received April 1, 1982

IJAZ AHMAD and VICTOR SNIECKUS. Can. J. Chem. **60**, 2678 (1982).

Condensation of 4-bromoisochroman-3-one (**8***a*) with *N*-methyl-3,4-dimethoxy-β-phenethylamine (**7**) provides the aminolactone **9***a* which by diisobutylaluminum hydride reduction followed by polyphosphoric acid mediated cyclization gives the tetracyclic product **10***a*, thus constituting a convergent, short entry into the rhoeadan alkaloid skeleton. Chromium trioxide oxidation of **10***a* affords a low yield of the corresponding lactone **11***a*. A parallel series of reactions starting from 7,8-dimethoxy-4-bromoisochroman-3-one (**8***b*), prepared either via Baeyer–Villiger oxidation of 4,5-dimethoxy-2-indanone (**14**) or, more conveniently, via benzeneboronic acid assisted condensation of 3-hydroxy-4-methoxyphenylacetic acid (**18**) with formaldehyde, yields 7,8,12,13-tetramethoxy-3-methylrhoeadan (**10***b*). Oxidation of compound **10***b* with chromium trioxide gives the corresponding lactone **11***b* also in low yield. Since **11***b* has been previously converted into (±)-*cis*-alpinigenine (**11***c*) and (±)-*cis*-alpinine (**11***d*), this work constitutes total syntheses of these alkaloids.

IJAZ AHMAD et VICTOR SNIECKUS. Can. J. Chem. **60**, 2678 (1982).

La condensation de la bromo-4 isochromanone-3 (**8***a*) sur la *N*-méthyldiméthoxy-3,4 β-phénéthylamine (**7**) conduit à l'aminolactone (**9***a*) qui, par réduction par l'hydrure de diisobutylaluminium suivie d'une cyclisation en présence d'acide polyphosphorique, donne le produit tétracyclique **10***a*. Ceci constitue une voie d'accès convergente et courte au squelette de l'alcaloide rhoéadane. L'oxydation du composé **10***a* par le trioxyde de chrome conduit, avec un faible rendement, à la lactone correspondante, **11***a*. Une série parallèle de réactions partant de la diméthoxy-7,8 bromo-4 isochromanone-3 (**8***a*), préparée soit par une oxydation de Baeyer–Villiger de la diméthoxy-4,5 indanone-2 (**14**) soit plus facilement par condensation de l'acide hydroxy-3 méthoxy-4 phénylacétique (**18**) sur le formaldéhyde en présence d'acide benzèneboronique, conduit au tétraméthoxy-7,8,12,13 méthyl-3 rhoéadane (**10***b*). L'oxydation du composé **10***b* par le trioxyde de chrome donne la lactone correspondante **11***b* également avec un faible rendement. Depuis que le composé **11***b*, a été transformé antérieurement en (±)-alpinigénine *cis* (**11***c*) et en (±)-alpinine *cis* (**11***d*), ce travail constitue une synthèse totale de ces alcaloides.

[Traduit par le journal]

The Rhoeadine–Papaverrubine class of alkaloids (**1**) (1) is comprised of about 30 bases elaborated almost exclusively within the *Papaver* genus (2, 3). Its major distinguishing structural feature, exhibited only by three other alkaloid types (*Cephalotaxus* group (**2**) (4), stepinonine, a bisbenzylisoquinoline (**3**) (5), and the recently discovered chilenine (**4**) (6)), is the benzazepine skeleton (rings A/B in **1**). This and other inherent structural and stereochemical points of interest as well as the discovery of potentially useful biological activity (1, 7) have provided the predictable stimulus for synthetic effort (1, 2, 8). Most routes (Table 1, refs. 9–13) are initiated from or proceed via intermediates of other classes of benzylisoquinoline alkaloids. The most economic route to rhoeadans reported to date employs phthalideisoquinoline alkaloids as starting materials (10). This route is rendered attractive by the recent availability of improved syntheses of the latter class of alkaloids (2, 14). An attractive synthetic method for the rhoeadan skeleton starting from *N*-benzyl-3,4-dihydroisoquinolinium salts has been developed by Shamma and Töke (12). However, this strategy appears not to have been applied to synthesis of the alkaloids themselves, owing perhaps to the lack of

TABLE 1. Synthesis of rhoeadan alkaloids

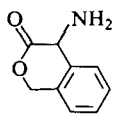
| Precursor alkaloid type | Number of steps | Overall yield | Ref. |
|---|---|---|---|
| Spirobenzylisoquinoline[a] | 8 | ~1% | 9 |
| Phthalideisoquinoline | 5 | 24% | 10 |
| Protoberberine[b] | 5 | 11% | 11 |
| *N*-Benzyl-3,4-dihydroisoquinolinium salt[c] | 6 | 45% | 12 |
| Protoberberine[d] | 8 | 7% | 13 |

[a]Based on a β-phenethylamine starting material.
[b]A synthetic substance was used as starting material.
[c]Synthesis of the rhoeadan ring skeleton only was achieved.
[d]Converted into a relay benz[*d*]indeno[1,2-*b*]azepine system which was also available by total synthesis and had been transformed into a rhoeadan alkaloid.

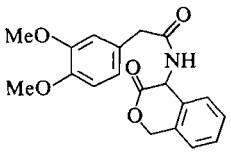
convenient routes to contiguously substituted C/D ring precursors, a situation which has been recently rectified (15). Herein we report a new efficient and convergent entry into the rhoeadan ring system and its application to the synthesis of the (±)-*cis*-alpinigenine (**11***c*) (11, 16).

Several precedents notwithstanding (8), the amide lactone **6**, readily available from the condensation of the aminoisochroman-3-one **5** with 3,4-dimethoxyphenylacetyl chloride, could not be cyclized to a benzazepine derivative under a variety of Friedel–Crafts conditions. The aminolactone **9***a*, prepared in high yield by condensation of the *N*-methyl-β-phenethylamine **7** with 4-bromoisochroman-3-one (**8***a*) (available via Baeyer–Villiger reaction of 2-indanone) (Scheme 1), likewise failed to cyclize or suffered extensive decomposition under Lewis acid catalyzed conditions.[2] In the expectation of increasing reactivity, compound **9***a* was partially reduced with diisobutylaluminum hydride (Dibal) to give the aminolactol **9***b* in high yield. When **9***b* was exposed to neat polyphosphoric acid at 35°C, the desired rhoeadan derivative **10***a* was obtained (13% overall yield from indene).[3] The nmr and ms data of **10***a* were consistent with the tetracyclic structure showing close similarity to those observed for the rhoeadan alkaloids (1). Furthermore, the C-1 and C-2 proton doublets at δ 4.72 and 3.72 respectively showed a coupling constant, $J_{1,2}$ = 2.5 Hz, consistent with a *cis*-B/C ring juncture as expected on the basis of an α-oxo carbonium ion intermediate leading to the thermodynamically more stable stereochemistry (16).

The application of the above model study to the synthesis of the rhoeadan alkaloid, *cis*-alpinigenine (**11***c*), required (a) a search for methods to effect oxidative functionalization at C-14 and (*b*) the



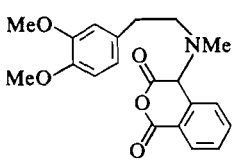
5



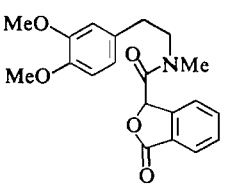
6

development of a route for the dimethoxyisochroman-3-one **8***b*. In order to achieve the first goal, a number of oxidations (e.g., acetoxylation using peroxyesters/$Cu^+$ (17), hydroxylation using $Ce^{+4}$ (18), *t*-BuOK/*t*-BuOH/$O_2$/DMSO (19), Triton B/pyridine/$O_2$ (20))[4] were carried out on the model compound **10***a* with uniformly unsuccessful results. Finally, oxidation using $CrO_3$ in acetic acid (21) gave a mixture of at least six products from which the lactone **11***a* was isolated in ~10% yield by preparative thick-layer chromatography. The conversion of rhoeadan lactones analogous to **11***a* into the corresponding alkaloids (**1**), including *cis*-alpinigenine (**11***c*), is well documented (10, 13*a*). In view of this and in the hope that greater

[2]Attempts to obtain a potentially more attractive intermediate **i** by condensation of **7** with 4-bromoisochroman-1,3-dione gave instead **ii** which formed the basis of a general synthesis of phthalideisoquinoline alkaloids (ref. 14).

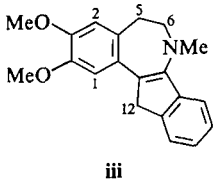


i



ii

[3]A number of other Lewis acid catalysts (e.g. $POCl_3$, $BF_3$·$Et_2O$, HCl) failed to yield **10***a*. Concentrated sulfuric acid furnished the indenobenzazepine **iii** in low yield (see Experimental).



iii

[4]These reactions are described in the Ph.D. thesis of I.A.

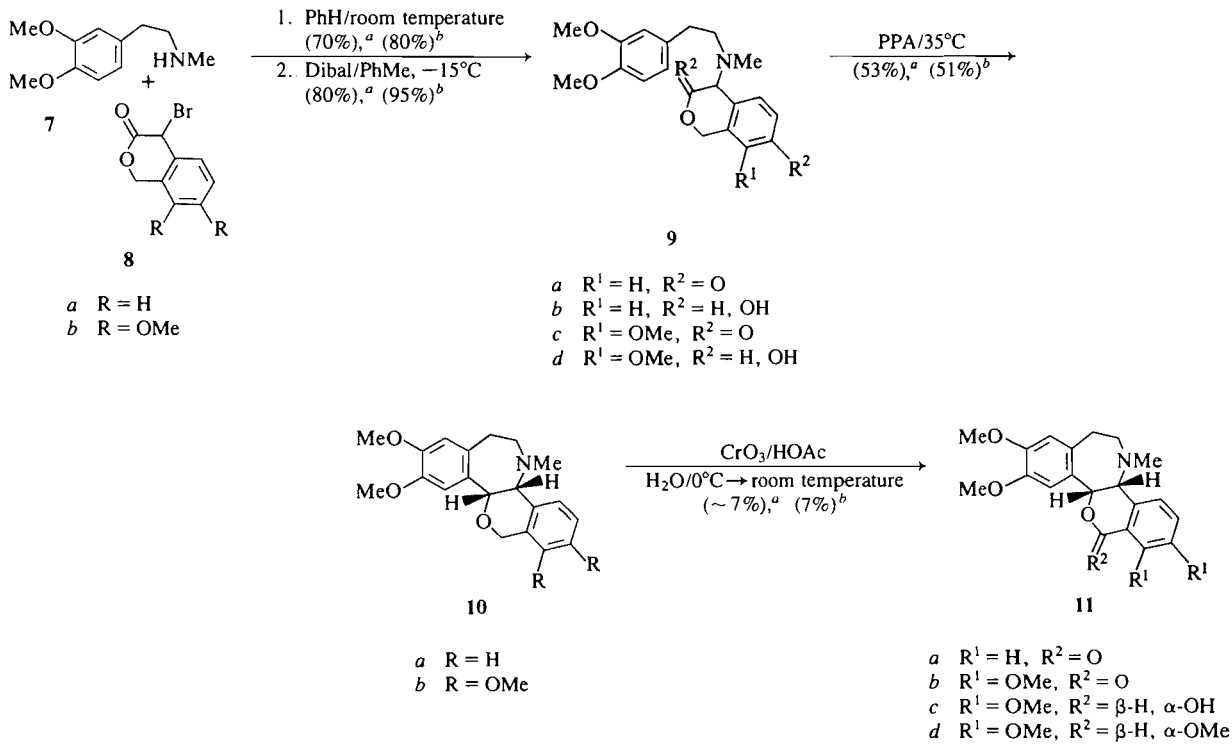

SCHEME 1

[a]Yields for **8***a* series.
[b]Yields for **8***b* series.

C-14 oxidative regioselectivity would be achieved in **10***b* as a result of the presence of activating ring D methoxy groups, the second task, that of synthesizing the isochroman-3-one **8***b* component required for *cis*-alpinigenine, was undertaken.

The construction of 7,8-dimethoxyisochroman-3-one (**8***b*) was achieved by alternative classical and modern methodologies (Scheme 2). In the classical approach, 2,3-dimethoxyphenylpropionic acid (**12**), prepared from 2,3-dimethoxybenzaldehyde by Knoevenagel technology, was subjected to Friedel–Crafts cyclization using polyphosphoric acid to give the 1-indanone **13** in high yield. Ketone transposition to the 2-indanone **14** was effected uneventfully by a four-step sequence. Baeyer–Villiger oxidation with *m*-chloroperbenzoic acid gave a mixture of two isochromanones **15** and **16** which could not be separated by preparative tlc using multiple development and a variety of solvent systems. Examination of the integrated nmr spectrum of this mixture and comparison with authentic **15** synthesized by an alternative route (see Experimental) established that the isomers **15** and **16** were present in a 60:40 ratio in the mixture.[5] The lack of regioselectivity in the formation of **15** and **16** is perhaps expected on the basis of the similar electronic factors and lack of steric constraints operating in the Baeyer–Villiger rearrangement of the intermediate resulting from **14**.[6]

Bromination of the mixture of isochromanones **15**, **16** with one equivalent of bromine gave two major products, **17** and **8***b*, in a 1.3:1 ratio which were easily separated by taking advantage of their solubility differences in ether. Based on the 60:40 ratio of the starting isochromanones **15** and **16**, the

[5]This synthesis of **15** and **16** was first executed in 1972 by C. F. Tahk and K. R. Cuppet at Kent State University in independent synthetic work aimed at the rhoeadan alkaloids which was abruptly terminated. We are grateful to Drs. Tahk and Cuppet for allowing us to develop and use this route and for providing assistance, experimental details, spectra and samples, and for many stimulating discussions.

[6]In contrast, and as expected, Baeyer–Villiger reaction of 5,6-dimethoxy-2-indanone yields 6,7-dimethoxyisochroman-3-one, a useful intermediate for the synthesis of berberine alkaloids (22).

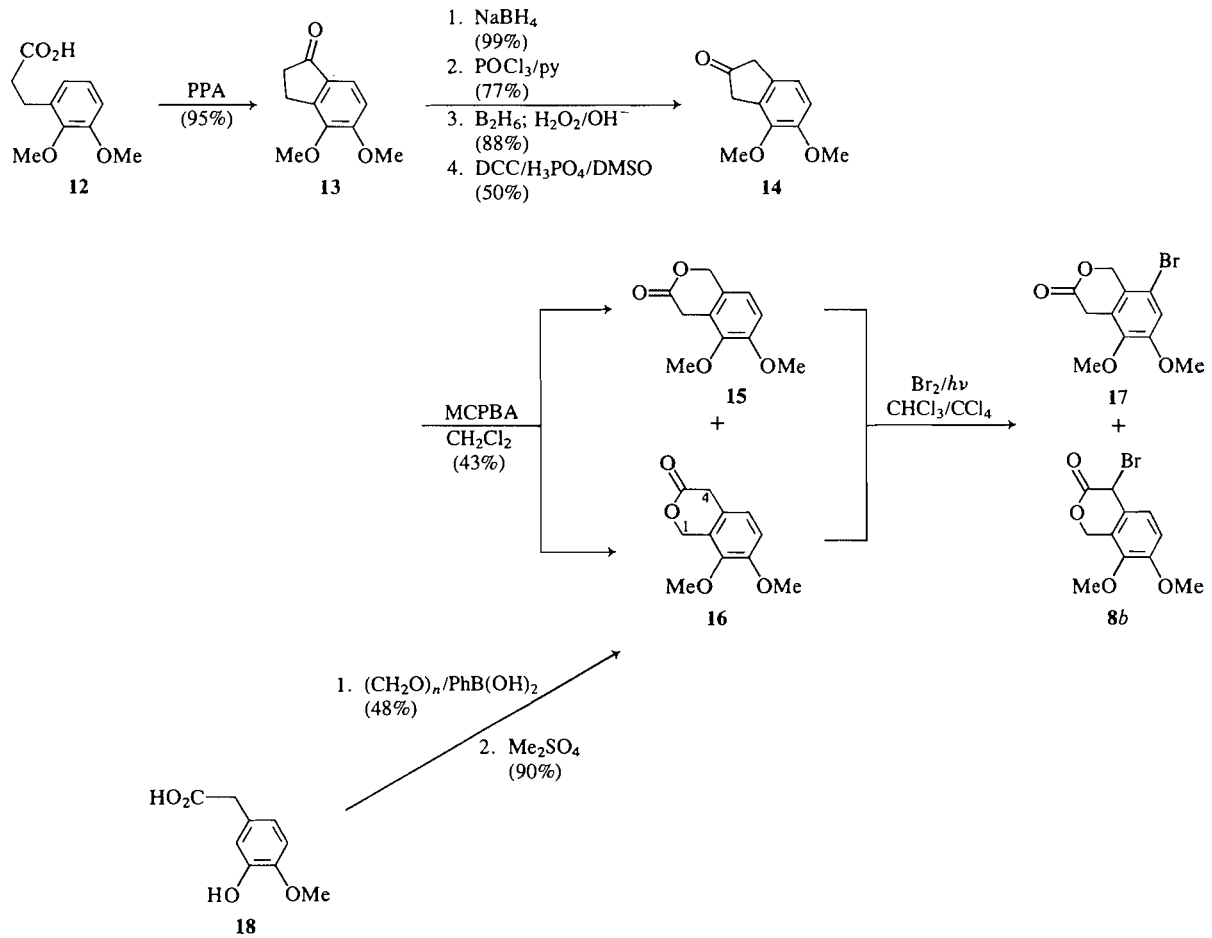

SCHEME 2

calculated yield of **8***b* from **14** is 14%. Their structures were assigned by nmr and ms data, in particular, comparison of such spectra for **8***b* with the model compound **8***a* (see Experimental). The formation of **17** may reflect steric interference to free radical C-4 bromination.

During the course of this work, Nagata and co-workers reported on the direct preparation of the required isochromanone **8***b* in 83% yield by treatment of homoisovanillic acid (**18**) with paraformaldehyde in the presence of benzeneboronic acid followed by conventional methylation (23). This interesting regiospecific introduction of a one-carbon unit, contrasting with normal electrophilic substitution behavior of such systems,[7] most likely involves the intermediacy of a phenoxyboronic acid which coordinates formaldehyde, thereby transferring it into the 2-position of the aromatic ring.[8,9] Unfortunately, in our hands, the reaction of **18** with paraformaldehyde gave 8-hydroxy-7-methoxyisochroman-3-one only in a reproducible 48% yield.[10] Nevertheless, this short route afforded the key intermediate **16** in gram quantities in 25% overall yield (based on commercially available isovanillin), thus showing considerable

[7]For example, the HCl-mediated reaction of 3,4-dimethoxyphenylacetic acid with formaldehyde provides 6,7-dimethoxyisochroman-3-one in 84% yield (24). See also ref. 23*b*.

[8]Intermediate boron heterocycles have been isolated in many cases (23*b*).

[9]Such *ortho*-transfer reactions via prior heteroatom to catalyst coordination have opened new strategies for regiospecific synthesis of polysubstituted aromatics (25).

[10]The yields are critically dependent on the manner of addition of paraformaldehyde and benzeneboronic acid and on the efficiency of water removal from the reaction mixture. Our yields were achieved using a Dean–Stark trap and not the special water separator employed by Nagata *et al.* (23). We are indebted to Drs. W. Nagata and K. Okada for correspondence and a photograph of the water separator and to Dr. M. T. Thomas for carrying out the experiments.

advantage in convenience and efficiency over the Baeyer–Villiger approach described above.[11,12]

The condensation of the bromoisochromanone **8***b* with two equivalents of the β-phenethylamine **7** produced the aminolactone **9***c* in high yield. Dibal reduction led smoothly and in quantitative yield to lactol **9***d* which upon treatment with PPA at steam bath temperatures produced the tetramethoxyrhoeadan **10***b*. Unfortunately, chromium trioxide oxidation of **10***b* gave a complex mixture of products from which 14-oxy-*cis*-alpinigenine (**11***c*) was isolated in low yield by preparative tlc. The identity of **11***b* was established by comparison (mp, mixture mp, tlc, ir, nmr, ms) with an authentic sample prepared by an alternative route also at the University of Waterloo (13*a*).[13] Since **11***b* has been previously converted into *cis*-alpinigenine (**11***c*) and *cis*-alpinine (**11***d*) in high yields (13*a*), our work completes total syntheses of these alkaloids.

The utility of this synthesis for the preparation of rhoeadan alkaloids is undermined by the low yield in the final oxidation step, **10***a*, **10***b* → **11***a*, **11***b*. However, it represents a convenient entry into the rhoeadan ring system (**10***a* in 13%, **10***b* in 7% overall yields) from readily available precursors. The synthesis of **10***b* is made attractive by the efficient preparation of the isochromanone **16** (23, 30).

## Experimental

Microanalyses were performed by A. G. Gygli, Toronto, Ontario. Melting points were measured on a Fisher–Johns apparatus and are uncorrected. Infrared spectra were determined on a Beckmann IR-10 spectrophotometer. The nmr spectra were obtained with a Varian T-60 spectrometer using TMS as internal standard in $CDCl_3$ solution unless otherwise stated. Mass spectra (ms) were recorded on a A.E.I. MS-30 double beam, double-focussing instrument; peaks with *m/e* > 100 and % rel. intensity > 20 only are given. Silica gel 60 (70–230 mesh) and aluminum oxide (neutral, activity 1) from Brinkmann, Canada and Florisil (60–100 mesh) from Fisher Scientific were used for column chromatography; silica gel GF-254 (type 60) and aluminum oxide G (type E) obtained from Brinkmann, Canada were employed for thick-layer chromatography. The phrase standard work-up means extraction with either $CH_2Cl_2$ of $CHCl_3$ followed by drying over $Na_2SO_4$, filtration, and evaporation to dryness *in vacuo*.

*4-Aminoisochroman-3-one (5)*

Indan-2-one (31) was converted into *isochroman-3-one* by a literature method (32), mp 81–83°C (lit. (33) mp 80.6–81°C), ir and nmr identical with those reported (33).

A solution of isochroman-3-one (6.0 g, 40 mmol) and *n*-butyl nitrite (6.2 g, 60 mmol) in a mixture of anhydrous THF (28 mL) and ether (16 mL) was added dropwise to an ice-cold, stirred solution of sodium ethoxide (from sodium metal, 1.04 g, 45 mmol) in a mixture of anhydrous ethanol (15 mL) and ether (20 mL) maintained under nitrogen. The red mixture was stirred at ice-bath temperature for 8 h, treated with water (50 mL), and the resulting solution was washed with ether (80 mL). After acidification (concentrated HCl), the aqueous layer deposited, in 20 h, colourless needles of *4-hydroxyiminoisochroman-3-one* (2.5 g) which were collected by filtration. The filtrate was concentrated *in vacuo* and extracted with chloroform to yield an additional 0.3 g of product (total yield, 39%), mp 191–193°C (EtOH–$CHCl_3$); ir (KBr) $\nu_{max}$: 3460, 1738, 1620 $cm^{-1}$; nmr δ: 5.44 (s, 2H), 7.42–7.65 (m, 4H); ms *m/e* (% rel. intensity): 177 (25, $M^+$), 133 (37), 132 (46), 117 (70), 116 (80), 105 (31), 104 (100), 103 (30), 102 (20). *Anal.* calcd. for $C_9H_7O_3N$: C 61.02, H 3.98, N 7.91; found: C 60.97, H 3.88, N 7.84.

Hydrogenation of 4-hydroxyimino-isochroman-3-one (0.25 g, 1.4 mmol) over platinum oxide in glacial acetic acid (8 mL) at 50 psi and room temperature followed by neutralization ($NH_4OH$) and standard work-up gave a colorless oil which was dissolved in dry ether and subjected to a stream of dry HCl gas. The resulting precipitate was collected and dried under reduced pressure to give 0.26 g (93%) of *4-amino-isochroman-3-one hydrochloride*, mp 154–158°C; ir (KBr) $\nu_{max}$: 3450 (br), 2880 (br), 1762 $cm^{-1}$, which was used without further purification.

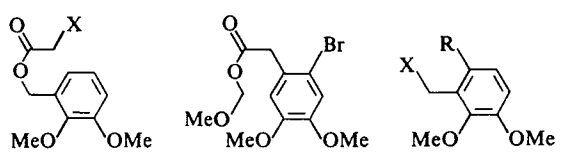
N-*4-(Isochroman-3-one)-2-(3,'4'-dimethoxyphenyl)-acetamide (6)*

A solution of 3,4-dimethoxyphenylacetyl chloride (34) (0.215 g, 1 mmol) in THF (0.8 mL) was added dropwise to a stirred mixture of 4-amino-isochroman-3-one hydrochloride (0.20 g, 1 mmol) and a few drops of a saturated solution of aqueous $NaHCO_3$ in THF (3 mL). The mixture was stirred for 15 min and treated successively with ether (15 mL) and water (10 mL). The resulting colorless precipitate was recrystallized from aqueous EtOH to give 0.28 g (82%) of compound **6**, mp 155–156.5°C; ir (KBr) $\nu_{max}$: 1740, 1642 $cm^{-1}$; nmr δ: 3.80 (s, 2H), 3.93, 3.96 (2 × s, 6H), 5.20–5.83 (m, 3H), 6.4 (br s, 1H, $D_2O$ exch.), 7.0 (br s, 3H), 7.35 (br s, 4H); ms *m/e* (% rel. intensity): 341 (4, $M^+$), 178 (68), 163 (28), 152 (44), 151 (100), 137 (20), 119 (42), 118 (20), 117 (26), 107 (33), 106 (23). *Anal.* calcd. for $C_{19}H_{19}NO_5$: C 66.86, H 5.61, N 4.10; found: C 67.02, H 5.68, N 4.09.

*4-Bromoisochroman-3-one (8a)*

A solution of isochroman-3-one (7.41 g, 50 mmol) in a mixture of spectral grade chloroform (15 mL) and carbon tetrachloride (15 mL) was placed in a two-necked flask fitted with a condenser and a dropping funnel whose lower end was drawn into a

[11]Among the other approaches attempted to achieve the synthesis of **16**, the irradiation of **iv**, X = Br or Cl (26), the acid-catalyzed reaction of **iv** and **v** (27), and the benzylic metalation and carbonation of **vi**, X = $NEt_2$, R = Me (28) resulted either in recovery of starting material, partial degradation, or decomposition. In addition, the selective oxidation of the non-benzylic alcohol function of **vi**, X = OH, R = $CH_2CH_2OH$ (29) could not be achieved (footnote 4 and S. O. de Silva and M. T. Thomas, unpublished results, University of Waterloo).



**iv** **v** **vi**

[12]Recently, **16** has been prepared in high yield via **vi**, X = $NMe_2$, R = $CH_2OH$ obtained by successive metalation (*n*-BuLi) and formaldehyde treatment of **vi**, X = $NMe_2$, R = H (30).

[13]We are grateful to Professor R. Rodrigo and Dr. K. Orito for an authentic sample of **11***b* and pertinent spectral data.

For personal use only.

capillary. The solution was brought to reflux with an unfrosted lamp (200 W, General Electric) positioned 15–20 cm from the flask. Bromine (8 g, 50 mmol) in carbon tetrachloride (10 mL) was slowly introduced. Instant decoloration of bromine was observed. The mixture was further refluxed for 1 h, cooled, diluted with chloroform (30 mL), and washed with successive portions of 5% aqueous sodium bicarbonate solution (20 mL) and water (20 mL). Standard work-up gave 8.4 g of a yellow oil which was purified by column chromatography (Florisil, $CHCl_3$–PhH, 65:35 eluent) to give 7 g (79%) of compound **8***a* as a pale yellow oil, bp 116–117°C/0.3 Torr. Treatment with decolorizing carbon followed by crystallization from ether gave **8***a* as colorless crystals, mp 58.5–59.5°C; ir ($CHCl_3$) $\nu_{max}$: 1740 $cm^{-1}$; nmr δ: 5.25, 5.72 (2 × d, 2H, $J$ = 14 Hz), 5.50 (s, 1H), 7.40 (s, 4H); ms *m/e* (% rel. intensity): 228, 226 (17, $M^+$), 147 (100), 119 (58), 118 (20), 103 (32). *Anal.* calcd. for $C_9H_7BrO_2$: C 47.60, H 3.10; found: C 47.81, H 3.10.

*4-(*N*-Methyl)-β-3′,4′-dimethoxyphenylethylamino)-isochroman-3-one (***9***a)*

A solution of 4-bromoisochroman-3-one (**8***a*) (1.77 g, 10 mmol) in anhydrous benzene (14 mL) was added dropwise under nitrogen to a stirred solution of *N*-methyl-β-3,4-dimethoxyphenethylamine (**7**) (14) (3.91 g, 20 mmol) in dry benzene (20 mL). The mixture was stirred at room temperature for 2 h. The precipitated hydrobromide of **7** was collected by filtration and the filtrate was diluted with benzene (50 mL) and washed with successive portions of 50% aqueous sodium bicarbonate solution (20 mL) and water (20 mL). Standard work-up gave an oil which was purified by column chromatography (silica gel, $CHCl_3$–MeOH, 300:1 eluent) to afford 2.4 g (70%) of compound **9***a* as a colorless thick oil, ir ($CHCl_3$) $\nu_{max}$: 1745 $cm^{-1}$; nmr δ: 2.46 (s, 3H), 2.87 (br s, 4H), 3.78 (s, 6H), 4.31 (s, 1H), 5.03, 5.33 (2 × d, 2H, $J$ = 14 Hz), 6.76 (s, 3H), 7.20–7.50 (m, 4H); ms *m/e* (% rel. intensity); 341 (0.5, $M^+$), 190 (100), 147 (31), 119 (28). *Anal.* calcd. for $C_{20}H_{23}NO_4$: C 70.36, H 6.79, N 4.10; found: C 70.49, H 6.66, N 4.00.

*4-(*N*-Methyl-β-3′,4′-dimethoxyphenylethylamino)-isochroman-3-ol (***9***b)*

A solution of diisobutylaluminum hydride (Alfa Products) (3 mL, 20% *n*-hexane solution) in dry toluene (5 mL) was added dropwise to a stirred solution of compound **9***a* (0.15 g, 0.4 mmol) in toluene (20 mL) at −15°C (ice–salt bath) under nitrogen. The mixture was stirred for 1 h and treated successively with a 2 *M* solution of isopropyl alcohol in toluene (5 mL) and water (0.2 mL). The mixture was stirred at room temperature for 2 h, chloroform (15 mL) and anhydrous sodium sulfate (0.75 g) were added, and the whole was subjected to filtration. The filtrate was concentrated under reduced pressure to give crude material which was purified by column chromatography (silica gel, $CHCl_3$–MeOH, 98:2 eluent) to furnish 120 mg (80%) of compound **9***b* as a colourless oil; ir ($CHCl_3$) $\nu_{max}$: 3270 (br) $cm^{-1}$; nmr δ: 2.31 (s, 3H, $NCH_3$), 2.67–3.15 (m, 4H, $—CH_2CH_2$), 3.60 (d, 1H, $J$ = 3 Hz, C-4 H), 3.82, 3.87 (2 × s, 6H, 2 × $OCH_3$), 4.80 (s, 2H, C-1 H), 4.83 (d, 1H, $J$ = 3 Hz, C-3 H), 5.40 (br s, 1H, OH, $D_2O$ exch.) 6.80 (s, 3H, A ring H), 7.08–7.50 (m, 4H, D ring H); ms *m/e* (% rel. intensity): 343 (< 0.5, $M^+$) 192 (100), 174 (25), 165 (27), 152 (25), 151 (35), 149 (25), 133 (27), 131 (25), 121 (35), 119 (34), 103 (28). *Anal.* calcd. for $C_{20}H_{25}NO_4$: C 69.96, H 7.34, N 4.08; found: C 70.07, H 7.24, N 4.23.

*7,8-Dimethoxy-3-methylrhoeadan (***10***a)*

A mixture of compound **9***b* (1.0 g, 2.9 mmol) and polyphosphoric acid (15 g) (35) was mechanically stirred at 35°C for 24 h. The resulting reddish brown syrup was poured into a stirred ice–water mixture (40 g), basified with ammonium hydroxide, and subjected to standard work-up to give 0.70 g of crude material. Preparative tlc separation (aluminum oxide, activity 1, $CHCl_3$ eluent) followed by recrystallization from chloroform–ethanol afforded 0.5 g (53%) of compound **10***a*, mp 158.5–159°C; nmr δ: 2.38 (s, 3H, $NCH_3$), 2.60–3.50 (m, 4H, $—CH_2CH_2$), 3.72 (d, 1H, $J$ = 2.5 Hz, C-2 H), 3.88, 3.90 (2 × s, 6H, 2 × $OCH_3$), 4.72 (d, 1H, $J$ = 2.5 Hz, C-1 H), 4.97, 5.30 (2 × d, 2H, $J$ = 14 Hz, C-14 H), 6.73, 6.86 (2 × s, 2H, A ring H), 7.10–7.50 (m, 4H, D ring H); ms *m/e* (% rel. intensity): 325 (54, $M^+$), 296 (57), 206 (100), 193 (39), 164 (25), 146 (30). *Anal.* calcd. for $C_{20}H_{23}NO_3$: C 72.82, H 7.12, N 4.30; found: C 72.42, H 7.08, N 4.33.

*7,8-Dimethoxy-3-methylrhoeadan-14-one (***11***a)*

A solution of chromium trioxide (0.8 g) in a mixture of water (1 mL) and glacial acetic acid (4 mL) was added dropwise to an ice-cold, stirred solution of compound **10***a* (1 g, 3.1 mmol) in glacial acetic acid (20 mL). The mixture was stirred at ice-bath temperatures for 15 min, at room temperature for 30 min, treated with an equal volume of water, and extracted with chloroform (6 × 50 mL). The organic extract was washed successively with 5% aqueous sodium bicarbonate solution (30 mL) and water (30 mL) and subjected to standard work-up to give a brown syrup which was resolved into six fractions by preparative tlc (silica gel, $CHCl_3$–MeOH, 100:8). One of the high $R_f$ fractions gave 73 mg (7%) of compound **11***a* as a colourless solid, mp 203–205°C; ir (KBr) $\nu_{max}$: 1718 $cm^{-1}$; nmr δ: 2.21 (s, 3H, $NCH_3$), 2.40–3.40 (m, 4H, $—CH_2CH_2$), 3.51 (d, 1H, $J$ = 2 Hz, C-2 H), 3.82, 3.90 (2 × s, 6H, 2 × $OCH_3$), 5.38 (d, 1H, $J$ = 2 Hz, C-1 H), 6.72, 6.77 (2 × s, 2H, A ring H), 7.40–8.40 (m, 4H, D ring H); ms *m/e* (% rel. intensity): 339 (10, $M^+$), 206 (100), 193 (33) 146 (34). *Anal.* calcd. for $C_{20}H_{21}NO_4$: C 70.37, H 6.24, N 4.13; found: C 70.11, H 6.30, N 4.19.

*5,6,7,12-Tetrahydro-7-methyl-2,3-dimethoxybenz[*d*]indeno-[1,2-*b*]azepine (iii)*

A solution of compound **9***b* (300 mg, 0.8 mmol) in concentrated sulfuric acid (1 mL) was stirred in an ice–water bath for 20 min, treated with ice-water (5 g), and neutralized with ammonium hydroxide solution. Standard work-up gave an oil which was resolved by preparative tlc (silica gel, $CHCl_3$–MeOH, 100:1.5) into three major components one of which ($R_f$ ~0.75) yielded 72 mg (27%) of a colorless oil, nmr δ: 2.90–3.35 (m, 4H, C-5, C-6 H), 3.02 (s, 3H, $NCH_3$), 3.84 (s, 2H, C-12 H), 3.89, 3.95 (2 × s, 6H, 2 × $OCH_3$), 6.74, 7.14 (2 × s, 2H, A ring H), 7.20–7.60 (m, 4H, D ring H); ms *m/e*: 307 ($M^+$). The nmr spectrum was very similar to spectra of analogous more highly substituted benz[*d*]indeno[1,2-*b*]azepine derivatives (9, 13*a*, 36). The instability of compound **iii** precluded its further characterization.

*3-(2,3-Dimethoxyphenyl)propionic acid (***12***)*

Hydrogenation of 2,3-dimethoxycinnamic acid (21.17 g, 102 mmol) (37) over 10% Pd/C (0.164 g) in glacial acetic acid (270 mL) at 65°C and 30 psi gave a solid which upon recrystallization from pentane–cyclohexane afforded 20.15 g (94%) of compound **12**, mp 64–66°C (lit. (38) mp 69–70°C); ir ($CHCl_3$) $\nu_{max}$: 1705 $cm^{-1}$; nmr δ: 2.78 (m, 4H), 3.81 (s, 6H), 6.80 (m, 3H).

*4,5-Dimethoxyindan-1-one (***13***)*

A mixture of compound **12** (11.56 g, 55 mmol) and freshly prepared (35) polyphosphoric acid (100 g) was stirred mechanically at steam bath temperatures for 10 min. The dark red mixture was poured into a stirred ice–water mixture (360 g) and extracted with methylene chloride (4 × 60 mL). The organic extract was washed successively with 10% aqueous sodium bicarbonate (ca. 50 mL) and water (50 mL), and subjected to standard work-up to give 10 g (95%) of compound **13** as a colourless solid, mp 74–76°C (lit. (39) mp 74°C); ir (KBr) $\nu_{max}$:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

1705 $cm^{-1}$; nmr δ: 2.62–3.10 (m, 4H), 3.95 (s, 3H), 3.98 (s, 3H), 7.04 (d, 1H, $J$ = 9 Hz), 7.55 (d, 1H, $J$ = 9 Hz).

This reaction was previously effected in low yield using $P_2O_5$ (38).

*4,5-Dimethoxyindan-1-ol*

Powdered sodium borohydride (2.27 g, 60 mmol) was added in portions to a stirred solution of compound **13** (10 g, 52 mmol) in ethanol (65 mL). The mixture was stirred for 30 min, refluxed for 20 min, diluted with water (300 mL), and extracted with methylene chloride (3 × 100 mL). Standard work-up afforded 10 g (99%) of 6,7-dimethoxyindan-1-ol, mp 91–92°C; ir (KBr) $\nu_{max}$: 3300 $cm^{-1}$; nmr δ: 1.9 (br s, 1H, $D_2O$ exch.), 1.95–3.20 (m, 4H), 5.15 (t, 1H, $J$ = 6.5 Hz), 6.76, 7.06 (2 × d, 2H, $J$ = 9 Hz) which was used in the next reaction without further purification.

*6,7-Dimethoxyindene*

Freshly distilled phosphorus oxychloride (25 g, 163 mmol) was added dropwise to a stirred, ice-cold solution of 4,5-dimethoxyindan-1-ol (10 g, 52 mmol), in anhydrous pyridine (75 mL). The solution was allowed to stand for 45 min, refluxed for 35 min, cooled, and poured slowly into a stirred ice–water mixture (400 mL). 6 *N* Hydrochloric acid (80 mL) was added and the whole was extracted with methylene chloride (5 × 50 mL). Standard work-up followed by steam distillation and extraction of the distillate with methylene chloride gave 7 g (77%) of 6,7-dimethoxyindene as a colourless oil, bp 88–93°C/0.55–0.9 Torr; ir (neat) $\nu_{max}$: 1613 $cm^{-1}$; nmr δ: 3.10–3.50 (m, 2H), 3.85, 3.95 (2 × s, 6H), 6.20–7.30 (m, 4H). *Anal.* calcd. for $C_{11}H_{12}O_2$: C 74.98, H 6.86; found: C 74.89, H 6.83.

*4,5-Dimethoxyindan-2-ol*

Under a dry nitrogen atmosphere, a solution of 6,7-dimethoxyindene (6.86 g, 39 mmol) in anhydrous THF (15 mL) was added dropwise to a magnetically stirred 1 *M* solution of diborane in THF (Aldrich) (19.5 mL, 19.5 mmol) at a rate so as to keep the temperature below 30°C. The resulting solution was stirred 2 h and treated successively with water (0.5 mL), 3 *N* aqueous sodium hydroxide (13.6 mL), and 30% hydrogen peroxide (4.8 mL, 47 mmol) during which time the temperature of the mixture was maintained below 35°C. The reaction mixture was stirred for 16 h, diluted with ether (25 mL), and treated with saturated solid sodium chloride. Standard work-up followed by distillation afforded 6.68 g (88%) of 4,5-dimethoxyindan-2-ol, bp 116–122°C/0.1 Torr; mp 54–56°C; ir (KBr) $\nu_{max}$: 3497 $cm^{-1}$; nmr δ: 2.24 (s, 1H, $D_2O$ exch.), 2.50–3.40 (m, 4H), 3.84 (s, 6H), 4.40–4.80 (m, 1H), 6.73, 6.93 (2 × d, 2H, $J$ = 9 Hz). *Anal.* calcd. for $C_{11}H_{14}O_3$: C 68.02, H 7.27; found: C 68.19, H 7.35.

*4,5-Dimethoxyindan-2-one (14)*

To a stirred solution of 4,5-dimethoxyindan-2-ol (6.6 g, 36 mmol) and dicyclohexylcarbodiimide (22.25 g, 108 mmol) in a mixture of benzene (100 mL) and dry dimethyl sulfoxide (10 mL), was added 0.7 mL of a 5 *M* solution of orthophosphoric acid in dry dimethyl sulfoxide. The mixture was stirred under nitrogen for 20 h and the resulting precipitate was collected by filtration and washed with benzene (75 mL). The combined filtrate was treated with 5% aqueous sodium bicarbonate solution (100 mL) and the mixture was stirred for 1 h. Standard work-up gave a brown oil which was dissolved in absolute ethanol (30 mL) and the resulting solution was cooled to −20°C to deposit 3.7 g of brown crystalline solid. Recrystallization from absolute ethanol gave 3.43 g (50%) of compound **14** as pale yellow needles, mp 91.5–93°C; ir ($CHCl_3$) $\nu_{max}$: 1746 $cm^{-1}$; nmr δ: 3.47 (s, 4H), 3.83 (s, 6H), 6.82, 7.0 (2 × d, 2H, $J$ = 9 Hz). *Anal.* calcd. for $C_{11}H_{12}O_3$: C 68.73, H 6.29; found: C 68.77, H 6.20.

*5,6-Dimethoxyisochroman-3-one (15) and 7,8-dimethoxyisochroman-3-one (16) by Baeyer–Villiger reaction*

A solution of compound **14** (5 g, 26 mmol) and *m*-chloroperbenzoic acid (8.2 g, 40.4 mmol) in chloroform (100 mL) was stirred with the exclusion of air for 2 days. The resulting precipitate was collected by filtration and the filtrate was concentrated *in vacuo* to give 9.0 g of solid which was redissolved in chloroform (150 mL) and shaken with 5% aqueous sodium bicarbonate solution (100 mL) until gas evolution ceased. Standard work-up gave 5.5 g of a light brown solid which upon two recrystallizations from ether–pentane at −20°C provided 2.31 g (43%) of a mixture of the isomeric compounds **15** and **16**, mp 40–45°C; ir (KBr) $\nu_{max}$: 1752 $cm^{-1}$; nmr δ: 3.65 (s, 0.6 H), 3.77 (s, 1.4 H), 3.87, 3.90 (2 × s, 6H), 5.26 (s, 1.4 H), 5.44 (s, 0.6 H), 6.90 (s, 2H); ms *m/e*: 208 ($M^+$). *Anal.* calcd. for $C_{11}H_{12}O_4$: C 63.45, H 5.81; found: C 63.56, H 5.84.

Comparison of the integrated nmr spectrum of the mixture of **15** and **16** with that of pure **15**, synthesized independently as described below, allowed the assignments of the resonances at δ 3.65 (s, —$CH_2CO$), 3.87 (s, $OCH_3$), 5.26 (s, —$CH_2O$) to compound **16**. Therefore the mixture consists of a 60:40 ratio of the isomeric isochroman-3-ones **15** and **16**.

Since attempts to separate this mixture by fractional crystallization and repeated tlc on silica gel and alumina using a variety of solvent systems failed, it was subjected to bromination as described below.

*5,6-Dimethoxyisochroman-3-one (15)*

2,3-Dimethoxybenzaldehyde was converted into 2,3-dimethoxyphenylacetic acid by the following reactions and intermediates: (*1*). $NaBH_4$/EtOH/room temperature/20 h → 2,3-dimethoxybenzyl alcohol (99%), mp 49–51°C (lit. (38) mp 46–48°C); (*2*). $SOCl_2$/PhH/ɲ/1.5 h → 2,3-dimethoxybenzyl chloride (99%), used without purification; (*3*). NaCN/$H_2O$ (40) → 2,3-dimethoxybenzyl cyanide (85%), used without purification; (*4*). 20% aqueous KOH/ɲ/4 h → 2,3-dimethoxyphenylacetic acid (87%), mp 80–82°C (lit. (41) mp 84°C).

A mixture of this compound (1.5 g, 7.6 mmol), concentrated hydrochloric acid (2 mL), glacial acetic acid (3.5 mL), and 30% aqueous formalin solution (0.8 g, 8 mmol) was heated at steam bath temperatures for 2 h. Water (15 mL) was added and the mixture was extracted with chloroform (3 × 40 mL). Standard work-up gave 1.2 g of a thick oil which was resolved by preparative tlc (silica gel, $CHCl_3$–MeOH, 100:1) into the following: *band 1* ($R_f$ = 0.4): 5,6-dimethoxyisochroman-3-one (**15**), 0.12 g (7.5%), mp 153–155°C; ir ($CHCl_3$) $\nu_{max}$: 1740 $cm^{-1}$; nmr δ: 3.78 (s, 2H, —$CH_2$), 3.88, 3.90 (2 × s, 6H, 2 × $OCH_3$), 5.24 (s, 2H, —$CH_2CO$), 6.83, 7.0 (2 × d, 2H, $J$ = 8 Hz, aromatic H); ms *m/e* (% rel. intensity): 208 (7, $M^+$), 193 (71), 164 (100). *Anal.* calcd. for $C_{11}H_{12}O_4$: C 63.45, H 5.81; found: C 63.30, H 5.83; *band 2*: ($R_f$ = 0.1): 5,6-dimethoxy-8-methylenehydroxyisochroman-3-one, 0.6 g (38%), mp 110–112°C; ir ($CHCl_3$) $\nu_{max}$: 3620, 1740 $cm^{-1}$; nmr δ: 2.10 (br s, 1H, OH, $D_2O$ exch.), 3.70 (s, 2H, —$CH_2O$), 3.80, 3.87 (2 × s, 6H, 2 × $OCH_3$), 4.64 (s, 2H, —$CH_2OH$), 5.33 (s, 2H, —$CH_2CO$), 6.87 (s, 1H, aromatic H); ms *m/e* (% rel. intensity): 238 (100, $M^+$), 220 (46), 192 (21), 179 (24), 177 (31), 123 (29). *Anal.* calcd. for $C_{12}H_{14}O_5$: C 60.50, H 5.92; found: C 60.32, H 5.90.

*4-Bromo-7,8-dimethoxyisochroman-3-one (8b) and 5,6-dimethoxy-8-bromoisochroman-3-one (17)*

A mixture of the dimethoxyisochroman-3-ones **15** and **16** (1.04 g, 5 mmol) was brominated according to the procedure used for the preparation of **8***a*. Evaporation to dryness followed by treatment of the residue with ether (5 mL) gave compound **17**, mp 170–172°C; ir (KBr) $\nu_{max}$: 1704 $cm^{-1}$; nmr δ: 3.86, 3.90 (2 × s, 6H), 3.97 (s, 2H), 4.70 (s, 2H), 7.14 (s, 1H). *Anal.* calcd. for $C_{11}H_{11}BrO_4$: C 46.01, H 3.86; found: C 45.80, H 3.90.

The above filtrate was evaporated *in vacuo* at room temperature to give a pale yellow oil which upon column chromatography (silica gel, $CHCl_3$ eluent) yielded 0.55 g (38%) of compound **8***b* as a colourless oil which crystallized upon refrigera-

For personal use only.

tion, mp 122–123°C; ir (KBr) $\nu_{max}$: 1750 $cm^{-1}$; nmr δ: 3.88, 3.98 (2 × s, 6H, 2 × $OCH_3$), 5.15, 5.60 (2 × d, 2H, $J$ = 14 Hz, C-1 H), 5.80 (s, 1H, C-4 H), 6.98 (s, 2H, aromatic H); ms *m/e* (% rel. intensity): 288, 286 (7, $M^+$), 208 (26), 207 (100), 179 (31), 151 (31). *Anal.* calcd. for $C_{11}H_{11}BrO_4$: C 46.01, H 3.86; found: C 45.84, H 4.01.

*7,8-Dimethoxyisochroman-3-one (**16**) from homoisovanillic acid (**18**)*

The Nagata procedure (23) was adapted. A mixture of homoisovanillic acid (**18**) (42) (1.82 g, 10 mmol), benzeneboronic acid (2.0 g), and benzene (100 mL) was stirred and refluxed with azeotropic removal of water (Dean–Stark trap) for 1 h. Paraformaldehyde (1.0 g) was added and the reflux was continued as before for a total of 9 h during which time paraformaldehyde (2 g) was added at 2 h intervals. Next day reflux was resumed using a new condenser after addition of benzeneboronic acid (1 g). Paraformaldehyde was added as before. After 28 h of reaction extending over 4 days, benzene was removed *in vacuo*, water (30 mL) was added to the oily residue, and the mixture was heated at 90–100°C for 1.5 h. The solid which formed was collected by filtration without cooling the mixture and was dissolved in methylene chloride. The organic extract was washed with water, dried ($Na_2SO_4$), and evaporated to dryness to yield 0.939 g (48%) of *8-hydroxy-7-methoxyisochroman-3-one*, mp 180–183°C (lit. (23*a*) mp 183–185°C). Methylation according to Nagata and co-workers (23*a*) gave compound **18** in 90% yield, mp 97–99°C (lit. (23*a*) mp 98–100°C).

*4-(N-Methyl-β-3′,4′-dimethoxyphenylethylamino)-7,8-dimethoxyisochroman-3-one (**9**c)*

The condensation of compound **8***b* (0.29 g, 1 mmol) with *N*-methyl-3,4-dimethoxy-β-phenethylamine (**7**) (0.39 g, 2 mmol), carried out according to the procedure described for the preparation of **9***a*, gave a yellow oil which was chromatographed (silica gel, $CHCl_3$–EtOAc, 2:1 eluent) to give 0.35 g (88%) of compound **9***c* as a colourless oil, ir ($CHCl_3$) $\nu_{max}$: 1740 $cm^{-1}$; nmr δ: 2.33 (s, 3H), 2.72 (br s, 4H), 3.81, 3.83, 3.87 (3 × s, 12H), 4.48 (s, 1H), 4.80, 5.55 (2 × d, 2H, $J$ = 14 Hz), 6.60–6.73 (m, 3H), 6.90 (s, 2H); ms *m/e* (% rel. intensity): 401 (0.5, $M^+$), 250 (80), 207 (100), 179 (20), 151 (21). *Anal.* calcd. for $C_{22}H_{27}NO_6$: C 65.82, H 6.78, N 3.49; found: C 65.64, H 6.71, N 3.45.

*4-(N-Methyl-β-3′,4′-dimethoxyphenylethylamino)-7,8-dimethoxyisochroman-3-ol (**9**d)*

Dibal reduction of compound **9***c* (0.35 g, 0.87 mmol) according to the procedure used to obtain compound **9***b* gave 0.30 g (99%) of oily product which was chromatographed (silica gel, $CHCl_3$–MeOH, 100:2.5 eluent) to give the lactol **9***d* as a colorless oil, ir ($CHCl_3$) $\nu_{max}$: 3300 $cm^{-1}$; nmr δ: 2.33 (s, 3H, $NCH_3$), 2.70–3.10 (m, 4H, $—CH_2CH_2$), 3.71 (d, 1H, $J$ = 3 Hz, C-4 H), 3.81, 3.85, 3.87, 3.90 (4 × s, 12H, 4 × $OCH_3$), 4.70 (d, 1H, $J$ = 3 Hz, C-3 H), 4.76 (s, 2H, C-1 H), 5.60 (br s, 1H, OH, $D_2O$ exch.), 6.60–7.0 (m, 4H, aromatic H), 7.2 (s, 1H, aromatic H); ms *m/e* (% rel. intensity): 403 (< 0.5, $M^+$), 252 (100), 209 (68), 181 (53), 179 (21), 165 (23), 152 (27). *Anal.* calcd. for $C_{22}H_{29}NO_6$: C 65.49, H 7.24, N 3.47; found: C 65.58, H 7.39, N 3.45.

*7,8,12,13-Tetramethoxy-3-methylrhoeadan (**10**b)*

A mixture of the lactol **9***d* (0.35 g, 0.86 mmol) and polyphosphoric acid (10 g) was mechanically stirred and heated at steam bath temperatures for 3.5 h. Standard work-up (see preparation of **10***a*) followed by preparative tlc (alumina, $CHCl_3$ eluent) gave 0.17 g (51%) of compound **10***b* as a colorless oil which crystallized, mp 164–166°C; ir ($CHCl_3$) $\nu_{max}$: 1605 $cm^{-1}$; nmr δ: 2.33 (s, 3H, $NCH_3$), 2.60–3.60 (m, 4H, $—CH_2CH_2$), 3.86 (br s, 12H, 4 × $OCH_3$), 4.04 (d, 1H, $J$ = 2 Hz, C-2 H), 4.50 (d, 1H, $J$ = 2 Hz, C-1 H), 4.87, 5.30 (2 × d, 2H, $J$ = 14 Hz, C-14 H), 6.72, 6.80 and 6.88 (3 × s, 4H, aromatic H); ms *m/e* (% rel. intensity): 385 (47, $M^+$), 370 (25), 357 (31), 356 (98), 354 (41), 343 (28), 342 (100), 326 (20), 207 (22), 206 (100), 204 (22), 194 (22), 193 (56), 192 (59), 191 (31), 190 (22), 179 (28), 178 (47), 177 (22), 176 (28), 165 (37), 164 (44), 163 (36), 162 (25), 161 (25), 151 (34), 150 (34), 149 (34), 148 (34), 147 (22), 135 (28), 134 (31), 133 (22), 121 (31), 119 (22), 118 (25), 107 (25), 103 (22). *Anal.* calcd. for $C_{20}H_{27}NO_5$: C 68.52, H 7.06, N 3.63; found: C 68.31, H 7.20, N 3.52.

*7,8,12,13-Tetramethoxy-3-methylrhoeadan-14-one (14-oxo-cis-alpinigenine) (**11**b)*

The procedure for the oxidation of compound **10***a* to **11***a* was closely followed. From the rhoeadan **10***b* (0.5 g, 1.29 mmol) there was obtained 0.48 g of a crude material which was subjected to preparative tlc (silica gel, $CHCl_3$–MeOH, 100:2 eluent) and was thereby resolved into eight bands, one of which ($R_f$ ~0.6) yielded 35 mg (7%) of compound **11***b*, mp 194–196°C (lit. (13*a*) mp 195–196°C), whose tlc, mixture mp, ir, and ms were shown to be identical with a sample of synthetic material kindly provided by Professor Rodrigo and Dr. Orito (13*a*).

# Troponoid. V.[1] Crystallographic studies on AY-27110 — a dopamine agonist of the troponylpiperazine series[2]

FARID RAMADAN AHMED

*Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

AND

JEHAN BAGLI

*Ayerst Research Laboratories, 1025 Boulevard Laurentien, Saint Laurent (Montréal), Qué., Canada H4R 1J6*

Received May 29, 1982

FARID RAMADAN AHMED and JEHAN BAGLI. Can. J. Chem. **60**, 2687 (1982).

The crystal structure and absolute configuration of a *p*-bromobenzoyl derivative, **2**, of the (−)2-[4-[2-hydroxy-2-(3′,4′-dimethylphenyl)ethyl]-1-piperazinyl]-2,4,6-cycloheptatrien-1-one, **3***a* (AY-27110), which is a dopamine agonist, have been determined by an X-ray analysis. Crystals of $C_{28}H_{29}BrN_2O_5$, fw = 553.47, are monoclinic $P2_1$, $a$ = 12.553(2), $b$ = 6.359(1), $c$ = 17.575(3) Å, β = 108.32(1)°, $V$ = 1331.81 Å$^3$, $Z$ = 2, $\rho_c$ = 1.380, $\rho_o$ = 1.384 g cm$^{-3}$. For 2155 observed reflexions, the final $R$ is 0.036 and $R(w)$ is 0.039. The chirality of this enantiomer is shown to be $S(-)$, based on 18 reflexions with significant differences in the intensities of the corresponding Friedel pairs. The piperazine ring has a distorted chair form that is flattened at the N atom nearest the cycloheptatriene ring as for the psychoactive agents loxapine and amoxapine.

FARID RAMADAN AHMED et JEHAN BAGLI. Can. J. Chem. **60**, 2687 (1982).

On a déterminé par analyse aux rayons X la structure cristalline et la configuration absolue d'un dérivé *p*-bromobenzoyle (**2**) de la (−)[(hydroxy-2(diméthyl-3′,4′ phényl)-2 éthyl)-4 pipérazinyl-1]-2 cycloheptatriène-2,4,6 one-1 (**3***a*) (AY-27110) qui est un antagoniste de la dopamine. Les cristaux de $C_{28}H_{29}BrN_2O_5$, pm = 553,47, sont monocliniques et appartiennent au groupe d'espace $P2_1$ avec $a$ = 12,553(2), $b$ = 6,359(1), $c$ = 17,575(3) Å, β = 108,32(1)°, $V$ = 1331,81 Å$^3$, $Z$ = 2, $\rho_c$ = 1,380, $\rho_o$ = 1,384 g cm$^{-3}$. On a résolu la structure et on l'a ajusté jusqu'à des valeurs conventionnelles de $R$ = 0,036 et de $R(w)$ = 0,039 pour 2155 réflexions observées. On montre que la chiralité de cet énantiomère est $S(-)$ à partir 18 réflexions avec des différences d'intensité significatives des paires de Friedel correspondantes. Le cycle pipérazine a une forme chaise déformée qui est applatie au niveau de l'atome de N le plus près du cycloheptatriène comme dans le cas de la loxapine et l'amoxapine; des agents psychoactifs.

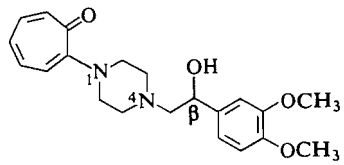
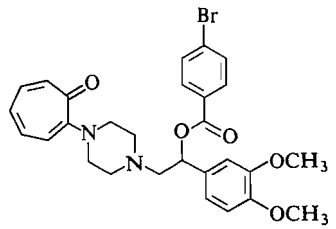
## Introduction

Central dopaminergic mechanisms are known to be impaired in Parkinson's disease (2). Bromocriptine (CB-154), a dopamine agonist, has recently been reported to alleviate these symptoms (3). However, bromocriptine, an ergot derivative, affects not only the dopaminergic system but also other neuronal systems; its effect therefore is not specific. One of the objectives of our synthesis program was to discover a non-ergot dopamine agonist which is more specific than bromocriptine.

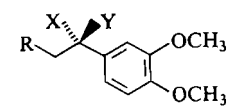
We have recently synthesized a series of troponylpiperazine derivatives (4), some of which demonstrated dopamine agonist activity (5). Compound **1** (2-[4-[2-hydroxy-2-(3′,4′-dimethoxyphenyl)ethyl]-1-piperazinyl]-2,4,6-cycloheptatrien-1-one) emerged as the compound of choice for further biological investigation. It was resolved into its optical enantiomers **3***a* (AY-27,110) and **3***b* using ditoluyl tartaric acids. It was found that the biological activity (5) was associated with the (−) enantiomer **3***a*. It was therefore of interest to establish the absolute configuration of the carbon atom β to the N-4 of the piperazine ring (see formula **1**). For this purpose compound **3***a* was converted to its *p*-



**1**



**2**



R = troponylpiperazine

**3***a*, $S(-)$, X = H, Y = OH

**3***b*, $R(+)$, X = OH, Y = H

bromobenzoyl derivative **2** and subjected to X-ray studies.

## Experimental

*Preparation of 4-bromobenzoic acid, 1-(3,4-dimethoxyphenyl)-2-[4-(7-oxo-1,3,5-cycloheptatrien-1-yl)-1-piperazinyl]ethyl ester (2)*

Triethylamine (0.218 g, or 0.3 mL, 1.8 equiv.) was added to a solution of alcohol **3***a* (0.444 g, 1 equiv.) in methylene chloride (4 mL); then 4-bromobenzoyl chloride (0.473 g, 1.8 equiv.) was added. The mixture was stirred for 3.5 h at room temperature, diluted with chloroform, washed with water, dried, and the solvent was removed. The residue was filtered through silica gel (50 g) and the product eluted with ethyl acetate. The product thus obtained was recrystallized twice from chloroform–ether to yield pure product (0.33 g, 69.8%) mp 129–133°C. *Anal.* calcd. for $C_{28}H_{29}BrN_2O_5$ (553.47): C 60.76, H 5.28, N 5.06; found: C 60.46, H 5.23, N 5.10. Infrared ($CHCl_3$) 1715, 1560 $cm^{-1}$, nmr ($CDCl_3$), δ7.55–7.9 (4H, m, arom.), 6.8 (8H, m, arom.), 6.1 (1H, m, C*H*—O), 3.85–3.8 (6H, 2 × s, C*H*$_3$—O), 3.2 (4H, m, C*H*$_2$—N), 2.75 (6H, m, C*H*$_2$—N), ms: *m/e* 554/552 $(M)^+$,

*X-ray crystallographic analyses*

*(−) 4-Bromobenzoic acid, 1-(3,4-dimethoxyphenyl)-2-[4-(7-oxo-1,3,5-cycloheptatrien-1-yl)-1-piperazinyl]ethyl ester*

$C_{28}H_{29}BrN_2O_5$ fw = 553.47

Monoclinic, $P2_1$, $a$ = 12.553(2), $b$ = 6.359(1), $c$ = 17.575(3) Å, β = 108.32(1)°, $V$ = 1331.81 Å$^3$, $Z$ = 2, $\rho_c$ = 1.380, $\rho_o$ = 1.384 g $cm^{-3}$, $F(000)$ = 572, μ(Cu) = 24.25 $cm^{-1}$.

Measurements were carried out on an Enraf-Nonius CAD-4F diffractometer with Ni-filtered Cu radiation ($\lambda(K\alpha_1)$ = 1.54056, $\lambda(K\alpha_2)$ = 1.54439 Å) on a prismatic crystal, 0.09 × 0.11 × 0.40 mm, mounted with its length along the φ axis. The cell parameters were based on 15 well-centered reflexions, θ = 30–40°, and the indexing was for a right-handed set of unit-cell axes. The intensity data were measured by ω–2θ scans for ω ranges of (0.8 + 0.14 tan θ), extended by 25% at each end for the backgrounds, at scan speeds of 0.64 to 2.51° $min^{-1}$ in ω. A total of 2991 reflexions in the $hkl$ and $\bar{h}kl$ octants with θ = 0–75° were measured, and of these 2153 were considered observed at the 2σ($I$) level. Three standard reflexions, scanned after every hour of exposure time, showed small random variations within ±1.5% of their mean values. The net intensities were corrected for Lorentz and polarization effects, and for absorption by the Gaussian integration method (6) assuming a 4 × 4 × 6 point grid. The range of the absorption corrections to the intensities was 1.20–1.51. Similarly, the Friedel pairs of $hkl$ and $\bar{h}kl$ with θ = 0–20° were scanned and treated in the same way. The discrepancy index for the structure amplitudes of the 50 $h0l$ and $\bar{h}0\bar{l}$ Friedel pairs which have no imaginary components was only 0.014.

Structure determination was by the heavy-atom method. After refinement of the non-hydrogen atomic parameters to $R$ = 0.064 for the observed reflexions, the H atoms were located from a difference map and included in the refinement with isotropic $B$ values. When $R$ was reduced to 0.046, the effect of the anomalous dispersion of Br was tried for the two possible enantiomorphs. The corresponding $R$ indexes, after one cycle of refinement for each, were 0.0434 and 0.0422, indicating a correct determination of the absolute configuration at the 0.5% level (the Hamilton ratio $\mathcal{R}_{1,1726,0.005}$ = 1.0024 while the experimental $R$ ratio = 1.028 and $R_w$ ratio = 1.030). Also, all the 18 Friedel pairs listed in Table 1 which showed the most significant anomalous dispersion effect consistently favoured one enantiomorph. Further refinement of the parameters for the correct enantiomorph produced the values listed in Tables 2 and 3,[3] for which $R$ = 0.036 and $R(w)$ = 0.039.[3] The refinement was by block-diagonal least-squares on $\Sigma w(F_o - F_c)^2$ with $w^{-1} = 1 + [(|F_o| - p_2)/p_1]^2$, $p_1$ = 30 and $p_2$ = 15 in the last three cycles (to make $\Sigma w(F_o - F_c)^2$ independent of $|F_o|$). The unobserved reflexions were excluded, as were (2̄04) and (2̄67) which showed relatively high discrepancies. The scattering factor curves were from ref. 7 and the computer programs were those of ref. 8. In the final cycle, the mean parameter shift was 0.2σ (maximum = 1.2σ) and $[\Sigma w(\Delta F)^2/(m - n)]^{1/2}$ = 0.6. The final difference map contained random electron densities between −0.25 and 0.19 e Å$^{-3}$.

## Results and discussion

A perspective view of the molecular structure showing the absolute configuration as determined from this X-ray analysis is presented in Fig. 1. The chirality at C(15), according to the Cahn–Ingold–Prelog system of notation (9), with the priority sequence HO > $CH_2NH_2$ > $C_6H_5$ > H is *S*(−) as shown in **3***a*. The arbitrarily-selected atomic numbering system and the bond lengths, not corrected for thermal vibration, are presented in Fig. 2. The valence angles and some selected torsion angles are given in Fig. 3 and Table 4, respectively.

The geometry of the piperazinyl ring in this compound is very similar to that of the corresponding rings in the psychoactive agents loxapine and

[3]The structure factor table and anisotropic thermal parameters of the non-hydrogen atoms are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

amoxapine (10). It has a distorted chair form with its four C atoms slightly non-planar ($\chi^2 = 27.3$, deviations from mean plane ±0.013(5) Å). N(8) and N(11) lie on opposite sides at significantly different distances (−0.642(3) and 0.708(4) Å, respectively) from the mean plane of the C atoms. While the endocyclic angles are approximately tetrahedral, 108.0(4)–111.0(4)°, the exocyclic angles are well above tetrahedral values with the angles of 119.3(4) and 119.7(4)° at N(8) considerably larger than those of 112.5(4) and 113.2(4)° at N(11). The flattening of the ring at N(8) was interpreted for loxapine and amoxapine (10) as indicative of some electron delocalization into the bond corresponding to N(8)–C(7), although its length in those structures, as in the present work, was 1.388 Å, i.e. within the range expected for C($sp^2$)—N($sp^3$) bonds (11). The other C—N bonds have a mean length of 1.466(11) Å in the present structure and 1.462(8) Å in the other two structures.

The cycloheptatriene ring is nearly planar, with $\chi^2 = 31.6$ for the seven C atoms. However, excluding C(1), the other six C atoms are coplanar ($\chi^2 = 1.8$) while C(1) is off that plane by −0.036(5) Å, resulting in a slight bend of 2.8(5)° between the plane C(2)—C(1)—C(7) and that of the six atoms. O(1) lies at 0.034(4) Å from the C(2)—C(1)—C(7)

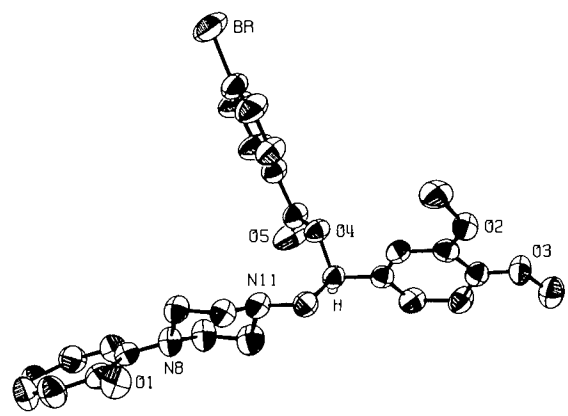

FIG. 1. A perspective view of the molecular structure showing its absolute configuration.

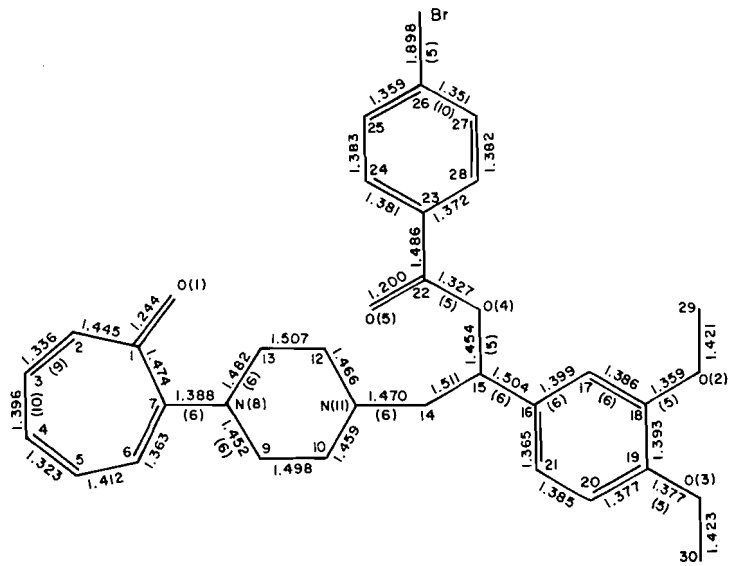

FIG. 2. Bond lengths (Å). The estimated standard deviations are 0.007–0.008 Å except for those given in parentheses.

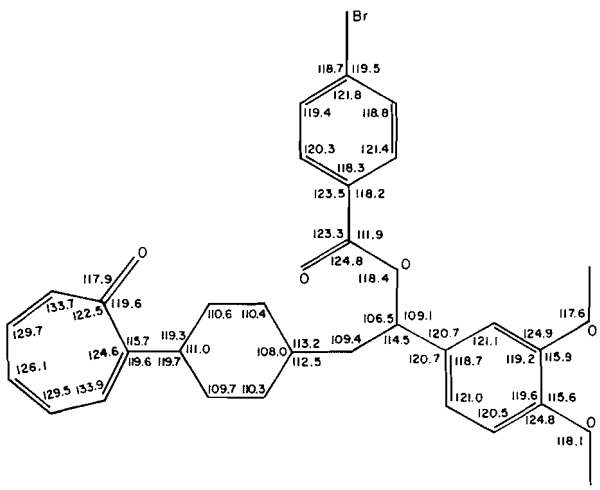

FIG. 3. Valence angles (deg). The estimated standard deviations are 0.4–0.6°.

TABLE 4. Selected torsion angles

| Atoms | Torsion angle (deg) |
|---|---|
| N(11)—C(14)—C(15)—C(16) | −175.1(4) |
| N(11)—C(14)—C(15)—O(4) | 64.1(4) |
| C(15)—O(4)—C(22)—O(5) | −5.9(7) |
| C(15)—O(4)—C(22)—C(23) | 172.1(4) |
| C(17)—C(18)—O(2)—C(29) | −10.9(6) |
| C(19)—C(18)—O(2)—C(29) | 167.7(4) |
| C(20)—C(19)—O(3)—C(30) | 2.5(7) |
| C(18)—C(19)—O(3)—C(30) | −177.5(4) |
| C(14)—C(15)—O(4)—C(22) | −109.4(4) |
| C(16)—C(15)—O(4)—C(22) | 126.5(4) |

plane. The three C=C double bonds have a mean value 1.341 Å which is comparable to the average value (12) of 1.337(6) Å.

The C atoms of the *p*-bromobenzoic group are coplanar ($\chi^2 = 15.3$) with deviations within ±0.013 Å, but the substituents Br and C(22) are at distances 0.059(2) and 0.052(5) Å from the plane of the ring. The Br—C(26) distance of 1.898(5) Å is comparable to the value 1.902(10) Å for *p*-bromobenzoic acid (13).

The remaining aromatic ring C(16) to C(21) is planar ($\chi^2 = 15.2$) with the substituents C(15), O(2), and O(3) in the plane of the ring. The two methyl groups C(29) and C(30) lie on the same side of the ring plane but at unequal distances of 0.260(6) and 0.123(6) Å, respectively. This imbalance is reflected in the corresponding torsion angles in Table 4. The average C—C length in the two aromatic rings is 1.378(14) Å and the average C—H length is 0.97(8) Å. The molecules are separated by normal van der Waals contacts.

In summary, the above assigns the chirality of β-C-atom of **2** as *S*. In turn the chirality of that carbon in AY-27110 follows. The biological activity thus resides with the *S*(−) enantiomer.

# The thermal and photochemical decomposition of *cis*-1,2-cyclobutanedicarboxylic anhydride in the vapour phase[1]

R. A. BACK AND J. M. PARSONS

*Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received May 6, 1982

R. A. BACK and J. M. PARSONS. Can. J. Chem. **60**, 2692 (1982).

The thermal decomposition of *cis*-1,2-cyclobutanedicarboxylic anhydride (CBA) has been studied in a static system in the range 625–725 K. The major process observed was a homogeneous unimolecular decomposition to form ethylene and maleic anhydride, with first-order rate parameters $A = 1.14(\pm 0.1) \times 10^{14}$ s$^{-1}$ and $E = 55.1 \pm 1$ kcal/mol. A very minor decomposition channel yielding butadiene, $CO_2$, and CO was also observed, with $A = 8.4(\pm 0.1) \times 10^{14}$ s$^{-1}$ and $E = 67.5 \pm 1$ kcal/mol.

The decomposition induced by a pulsed $CO_2$ laser was also studied briefly; the same two decomposition channels were observed and their dependence on fluence and pressure examined.

The ultraviolet photolysis of CBA was also investigated between 210 and 365 nm. In addition to the products found in the thermal reaction, cyclobutene was also a major product, and product ratios were measured as a function of wavelength and added $CO_2$. Mechanisms in the three systems are discussed and compared.

R. A. BACK et J. M. PARSONS. Can. J. Chem. **60**, 2692 (1982).

On a étudié la décomposition thermique de l'anhydride cyclobutanedicarboxylique-1,2 *cis* (ACB) dans un système statique avec un intervalle de température allant de 625 à 725 K. Le processus principal observé est une décomposition unimoléculaire homogène qui conduit à l'éthylène et à l'anhydride maléique, avec des paramètres de vitesse d'ordre un de $A = 1{,}14(\pm 0{,}1) \times 10^{14}$ s$^{-1}$ et de $E = 55{,}1 \pm 1$ kcal/mol. On a également observé une voie très secondaire de décomposition qui conduit au butadiène, au $CO_2$ et au CO avec $A = 8{,}4(\pm 0{,}1) \times 10^{14}$ s$^{-1}$ et $E = 67{,}5$ kcal/mol.

On a également étudié brièvement la décomposition induite par un laser à impulsion de $CO_2$. On a observé les deux modes de décomposition et on a examiné l'effet de la fluence et de la pression sur ces voies de décomposition.

On a également étudié la photolyse dans l'ultraviolet du (ACB) entre 210 et 365 nm. En plus des produits trouvés dans la réaction thermique, le cyclobutane est également un produit principal et on mesure les rapports des produits en fonction de la longueur d'onde et du $CO_2$ ajouté. On discute et on compare les mécanismes de ces trois systèmes.

[Traduit par le journal]

## Introduction

There have been few quantitative studies of the thermal decomposition of cyclic anhydrides of dicarboxylic acids, and except for a brief survey of a few mercury-photosensitized reactions (1), their gas-phase photochemistry has also been neglected. In a recent investigation of maleic anhydride in this laboratory (2), it was concluded that both the thermal and photochemical decomposition in the gas phase followed a simple concerted unimolecular path,

[1] Maleic anhydride $\rightarrow C_2H_2 + CO_2 + CO$

with $E = 60.9$ kcal/mol and $A = 2.14 \times 10^{14}$ s$^{-1}$ for the thermal process. With *cis*-1,2-cyclobutanedicarboxylic anhydride (hereafter CBA), the analogous decomposition would yield cyclobutene, but there is also the possibility of a second reaction path, cleavage of the cyclobutane ring. Simple two-channel unimolecular decompositions can be useful probes of energy distributions in thermal and photochemical reactions (3, 4). The present paper describes the thermal decomposition of CBA, a brief study of the decomposition induced by a pulsed $CO_2$ laser, and the photochemical decomposition in the ultraviolet region. Some of the results have been briefly presented elsewhere (3).

[1]NRCC No. 20545.

## Experimental

The pyrolysis and uv photolysis were studied in simple static systems using apparatus and methods employed earlier with maleic anhydride (2). The uv light source was a Hg–Xe 1000 W lamp fitted with a monochromator. The infrared laser experiments were done in a cylindrical Pyrex vessel, 10 cm long and 4 cm in diameter, fitted with NaCl windows at each end. Radiation of 9.20 μm from a Lumonics pulsed $CO_2$ TEA laser (4) was used unfocussed at a fluence of ~ 0.7 J/cm$^2$, or passed through a 2 m f. l. Ge lens placed 1 m from the reaction cell to give a slightly converging beam with a fluence in the reaction cell about 4 times higher. The reaction cell in all experiments was heated to 125°C to permit an adequate vapor pressure of CBA. CBA was obtained from Aldrich with a stated purity of 96% with the parent acid the main impurity; since the latter is much less volatile than the anhydride, the purity of the vapor used in our experiments was probably better than 99%. No other impurities could be detected by gas chromatography.

## Results and discussion

### *The thermal decomposition*

The only important primary product volatile at room temperature was ethylene, presumably formed by cleavage of the cyclobutane ring:

[2] 
Maleic anhydride was not positively identified as a product, but formation of $C_2H_2$, $CO_2$, and CO as secondary products as the reaction progressed was good evidence for its formation (2).

The only other primary hydrocarbon product found in significant amounts was 1,3-butadiene, which varied from about 0.15 to 0.03% of the ethylene. Comparable yields of CO and $CO_2$ were also observed, and there seems little doubt that these products come from cleavage of the anhydride ring:

[3] 
It is not clear whether cyclobutene is an intermediate, as its thermal isomerization to butadiene is fast enough at the reaction temperatures to preclude its detection (5).

Figure 1 shows Arrhenius plots of $k_2$, the first-order rate constant based on $C_2H_4$ formation, and $k_3/k_2$, given by $C_4H_6/C_2H_4$. No significant variation with pressure was observed within the rather narrow range of pressure employed (2–7 Torr), nor when the surface/volume ratio was increased by a factor of 9 in a packed vessel. Reactions [2] and [3] thus appear to be occurring as homogeneous unimolecular reactions, and Arrhenius parameters of $A_2 = 1.14\ (\pm 0.1) \times 10^{14}\ s^{-1}$, $E_2 = 55.1 \pm 1$ kcal/mol, $A_3 = 8.40\ (\pm 0.1) \times 10^{14}\ s^{-1}$, and $E_3 = 67.5 \pm 1$ kcal/mol can be estimated from the plots in Fig. 1.

Reaction [2] is appreciably slower, with a lower $A$ factor and higher $E$ than the analogous decompositions (5) of cyclobutanecarboxaldehyde ($A = 2.7 \times 10^{14}$, $E = 53.3$) and of cyclobutylmethyl ketone ($A = 3.4 \times 10^{14}$, $E = 54.5$), both of which have carbonyl groups adjacent to the cyclobutane ring. This may reflect constraints on the resonance stabilization of the biradical imposed by the presence of the anhydride ring.

The activation energy of reaction [3] is 6.6 kcal/mol higher than that for the analogous decomposition of maleic anhydride; this is somewhat surprising since reaction [3] is only 14.1 kcal/mol endothermic[2] (to yield cyclobutene) compared with

[2]Based on $\Delta H_f^0$ for maleic anhydride of −96.8 kcal/mol and $\Delta H_f^0$ for CBA of −98.6 (based on additivity relations), both in the vapour phase (6, 7).

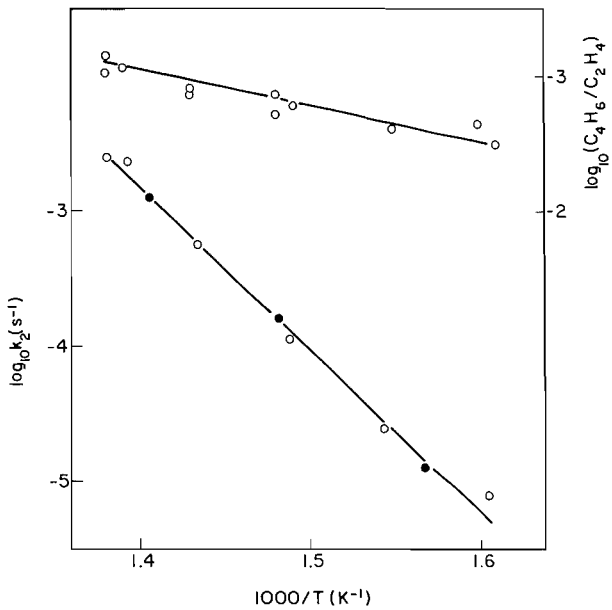

FIG. 1. Arrhenius plots for $k_2$ (bottom) and $k_3/k_2$ (top) for the thermal decomposition of CBA. Solid points are for packed reaction vessel.

an endothermicity of 30.5 for reaction [1]. The higher activation energy is partially compensated by a higher frequency factor, about 4 times larger than for maleic anhydride. The energy required to open the almost strain-free anhydride ring (5) may be estimated as at least 75 kcal/mol, indicating that reaction [3], like reaction [1], probably proceeds by a concerted rather than a biradical mechanism, although the frequency factor is somewhat high. The rather high barrier to reaction may reflect the considerable distortion needed in the transition state for optimum incipient $\pi$ bond formation in the cyclobutene product, which would require the two rings to lie normal to one another and the H atoms in the plane of the cyclobutane ring. Much less distortion would be required in the analogous decomposition of maleic anhydride.

The activation energy of reaction [2], and the $A$-factor, are compatible with a biradical process, but as with other cyclobutane derivatives, in the absence of firm evidence one way or the other, a concerted mechanism cannot be ruled out.

*The infrared multiphoton decomposition*

Products were the same as in the thermal reaction, with relatively more butadiene, between 0.1 and 1% of the ethylene. The extent of decomposition, expressed as a probability of decomposition in a single pulse of a molecule in the laser beam, is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

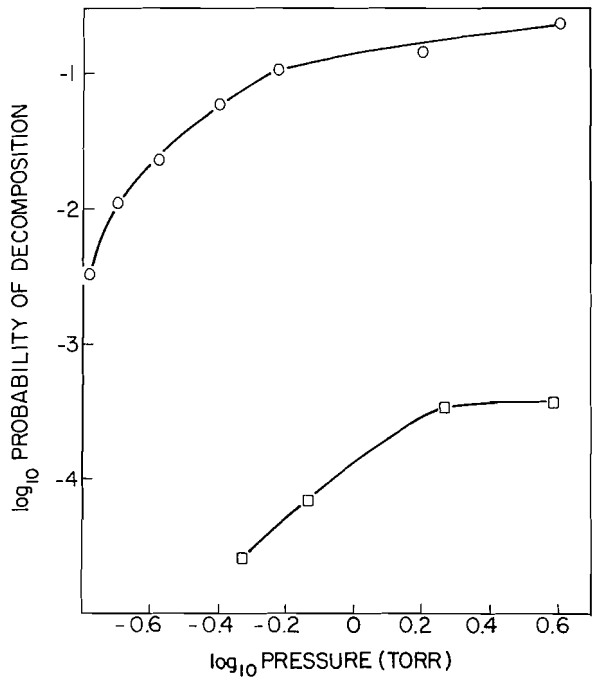

FIG. 2. log–log plot of the probability of decomposition during a single laser pulse vs. the pressure of CBA. □, unfocussed beam; ○, converging beam with fluence increased by a factor of 4.

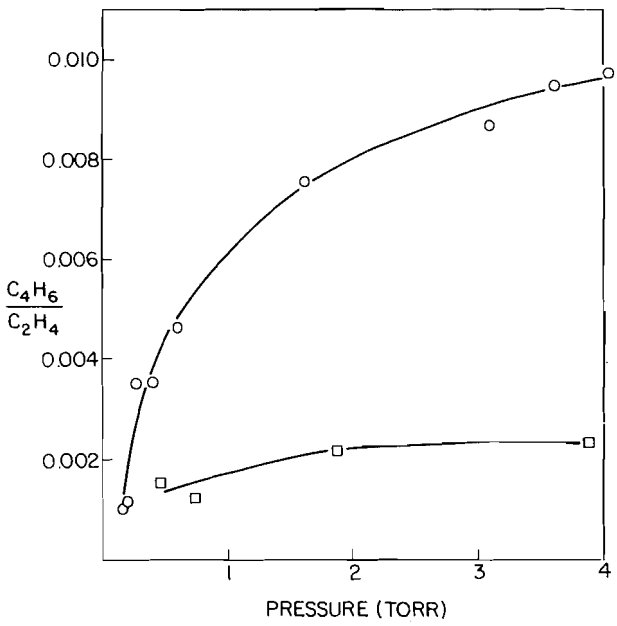

FIG. 3. Product ratio vs. pressure of CBA in the $CO_2$ laser induced decomposition. □, unfocussed beam; ○, converging beam with fluence increased by a factor of 4.

shown in Fig. 2 in a log–log plot as a function of pressure for the two fluences employed. A strong (~ 5th-power) dependence on fluence is evident, and at both fluences the probability of decomposition fell off sharply with decreasing pressure. Figure 3 shows the variation with pressure of the ratio $C_4H_6/C_2H_4$ for the same experiments. The ratio at the highest pressures corresponds to effective "temperatures" of decomposition of 945 and 778 K at the high and low fluences respectively. At both fluences the $C_4H_6/C_2H_4$ ratio falls markedly with decreasing pressure, the decrease being more pronounced at the higher fluence. These trends are similar to those observed recently in the decomposition of cyclobutanone (8) and probably have similar causes; the small yields of $C_4H_6$ make the measurements too inaccurate to extend to the lower fluences and lower pressures required to see whether the similarity in the two systems is significant.

*Photolysis in the ultraviolet*

Figure 4 shows the absorption spectrum of CBA vapor measured at 3.02 Torr at 145°C in a cell 3.7 m long. The observed absorption almost certainly arises from a $\pi^* \leftarrow n$ transition. By analogy with the maleic anhydride spectrum (2) the broad absorption with $\varepsilon_{max} = 60$ at 230 nm and the very weak

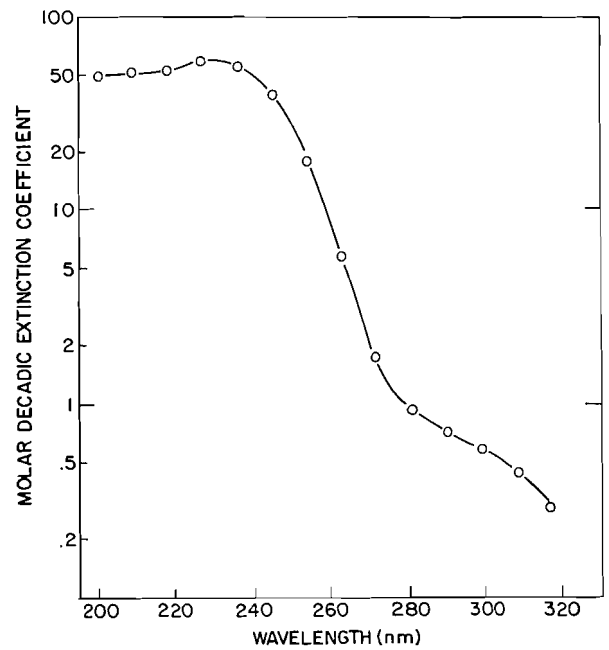

FIG. 4. Ultraviolet absorption spectrum of CBA vapor, measured at 3.02 Torr and 145°C, in units of $cm^{-1}\ M^{-1}$.

shoulder around 300 nm might be assigned to the $\pi^* \leftarrow n^+$ and $\pi^* \leftarrow n^-$ transitions respectively. However, the separation of 1.33 eV is much larger than might be expected from the photoelectric spectrum of succinic anhydride which shows a

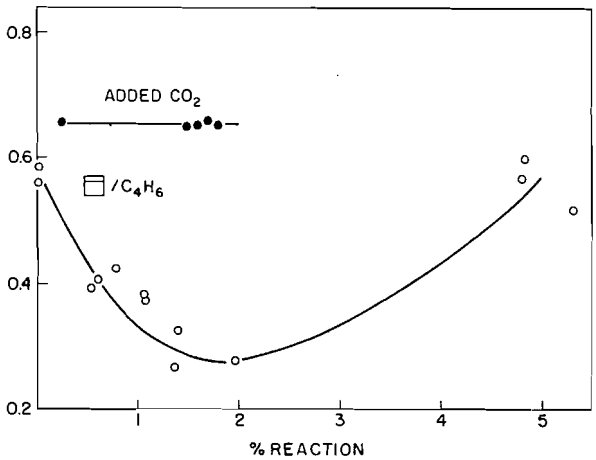

FIG. 5. Variation in product ratio with % reaction in the photolysis of CBA at 240 nm. Solid points are with added $CO_2$ at pressures of 10–100 Torr.

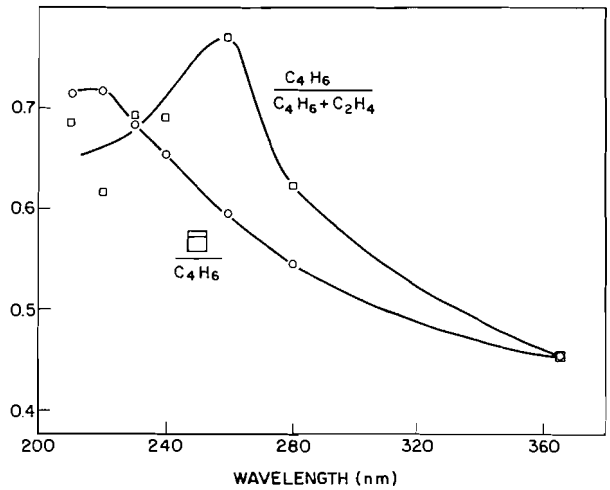

FIG. 6. Product ratios vs. wavelength in the photolysis of CBA with added $CO_2$.

splitting of 0.81 eV, and it is difficult to see why the transition at 300 nm should be so much weaker. No structure was evident anywhere in the spectrum.

Ethylene and butadiene again were products of the photodecomposition, and cyclobutene was also observed. The $C_4$ hydrocarbons were relatively much more important than in the thermal reaction, with the ratio (total $C_4H_6$)/$C_2H_4$ ranging from 0.4 to 3.0, where total $C_4H_6$ = 1,3-butadiene + cyclobutene. The yield of $C_2H_4$ was a linear function of photolysis time up to at least 5% conversion, but cyclobutene and butadiene have an unusual dependence on time (or % reaction) shown in Fig. 5 for the photolysis at 240 nm. The ratio cyclobutene/(total $C_4H_6$) fell sharply from a value of about 0.6 at the shortest photolysis time (7 s), reached a minimum of about 0.3 after 1 or 2% reaction, and finally rose again to about its initial value. The ratio (total $C_4H_6$)/(total $C_4H_6$ + $C_2H_4$) showed a much smaller change; it appeared to rise slightly, then fall again, over the same range of photolysis times. Similar behaviour was observed at other wavelengths. The cause of these effects is obscure;[3] it was discovered, however, that they essentially disappeared on the addition of $CO_2$ at pressures between 10 and 100 Torr.

[3]To explain the observations, there must be a rapid secondary isomerization of cyclobutene to butadiene (which is then reversed at longer photolysis times) and which is eliminated by the addition of $CO_2$. Gas phase thermal isomerization is too slow at 125°C; a surface process might be invoked if it could be inhibited by $CO_2$ adsorption on active sites. An isomerization of cyclobutene photosensitized by the maleic anhydride product building up in the system, which at 240 nm absorbs light much more strongly than CBA, and which could be quenched by $CO_2$, is another possibility. It was not thought useful to pursue these effects further in the present study.

For the photolysis at 240 nm under these conditions, values of cyclobutene/(total $C_4H_6$) = 0.65 and (total $C_4H_6$)/(total $C_4H_6$ + $C_2H_4$) = 0.69 were obtained, independent of $CO_2$ pressure, CBA pressure, and photolysis time. Similar measurements were made at other wavelengths from 210 to 366 nm, and the product ratios obtained are shown in Fig. 6.

The lack of pressure dependence of the product ratios in Fig. 6, and of the yield of decomposition, points to a short-lived excited state that decomposes before much stabilization by collision. Since there is no reason to expect an excited $\pi^* \leftarrow$ n state of a carbonyl compound to be dissociative itself, there must be fast internal conversion to high vibrational levels of the ground state which then rapidly dissociates.

The ratio (total $C_4H_6$)/(total $C_4H_6$ + $C_2H_4$) increases with increasing photon energy (Fig. 6) reaching a maximum of about 0.76 at 260 nm, then declines slightly. The frequency factors for reactions [2] and [3] in the thermal reaction would predict a maximum value of 0.88 for this ratio at infinite temperature. The observed values are probably compatable with a statistical decomposition of a highly excited ground-state molecule, the photon energy at 260 nm of 110 kcal/mol corresponding to excess energies of 55 and 42 kcal/mol for reactions [2] and [3] respectively. The slight decline in the product ratios at shorter wavelengths might suggest a different decomposition mechanism, favoring reaction [2], for photolysis in the $\pi^* \leftarrow \pi$ transition which probably begins to underlie the $\pi^* \leftarrow$ n transition at these wavelengths (Fig. 4).

The ratio cyclobutene/(total $C_4H_6$) does *not* correspond to an equilibrium between cyclobutene and butadiene since at infinite temperature a maximum value of only 0.14 is predicted from the equilibrium constant at infinite temperature (5). It thus appears that cyclobutene is a primary product of a decomposition analogous to that of maleic anhydride. It also appears that butadiene is *not* formed by subsequent decomposition of vibrationally excited cyclobutene, since some pressure dependence would then have been expected, and a decrease in cyclobutene relative to butadiene with decreasing wavelength; it seems more probable that the two hydrocarbons are primary products of parallel unimolecular reactions. These may be the same reactions which occurred in the thermal decomposition, in which a concerted mechanism was favored on energetic grounds, and in which it was impossible to say whether butadiene, or cyclobutene, or both, were primary products, since any cyclobutene formed would have isomerized thermally to butadiene before analysis. The higher energy available in the photolysis, however, would permit biradical formation by opening of the anhydride ring, with subsequent decomposition to CO, $CO_2$, and cyclobutene or butadiene, and such a biradical mechanism may well be operative.

ETELA MILANOVÁ and GENILLE C. B. CAVE. Can. J. Chem. **60**, 2697 (1982).

The activity coefficients of several solutes in dilute binary solutions of nonelectrolytes were determined at 20°C from vapor–liquid equilibria in a novel static equilibration apparatus, by gas-chromatographic analysis of the equilibrium vapor phase. The solutes were nitromethane, nitroethane, 1-nitropropane, 2-nitropropane, acetonitrile, propionitrile, ethyl acetate, and *n*-butyl acetate in *n*-heptane and in benzene as solvents, and also carbon tetrachloride as solute in each of the above-listed polar compounds as the solvent.

The modifications by Weimer and Prausnitz and by Blanks and Prausnitz to the Scatchard–Hildebrand equation in order to accommodate binary mixtures containing a polar component were tested by using the values found in the present work for the limiting activity coefficients of these solutes. In addition, it was found that the ratio of the dipole – induced dipole interaction parameter for polar solutes in the two nonpolar solvents was nearly constant.

Three methods for evaluating the dispersion contribution to the solubility parameter of a polar compound were considered.

ETELA MILANOVÁ et GENILLE C. B. CAVE. Can. J. Chem. **60**, 2697 (1982).

Utilisant un nouvel appareil d'équilibration statique faisant appel à l'analyse par chromatographie en phase gazeuse, des phases vapeur à l'équilibre, on a déterminé les coefficients d'activité de plusieurs solutés dans des solutions binaires diluées de nonélectrolytes à 20°C. Les solutés sont le nitrométhane, le nitroéthane, le nitro-1 propane, le nitro-2 propane, l'acétonitrile, le propionitrile, l'acétate d'éthyle et l'acétate de *n*-butyle dans le *n*-heptane et dans le benzène comme solvants. Le tétrachlorure de carbone a été utilisé également comme soluté dans les composés polaires mentionnés ci-dessus considérés comme solvants.

Utilisant les valeurs trouvées dans ce travail comme coefficients limites d'activité de ces solvants, on a vérifié les modifications de Weimer et Prausnitz ainsi que celles de Blancks et Prausnitz apportées à l'équation de Scatchard–Hildebrand dans le but d'accomoder les mélanges binaires contenant un composant polaire. De plus on a trouvé que le rapport du paramètre d'interaction dipôle – dipôle induit pour les solutés polaires dans les deux solvants non polaires est presque constant. On a considéré trois méthodes d'évaluation de la contribution de la dispersion au paramètre de solubilité d'un composé polaire.

## Introduction

Limiting activity coefficients for liquid nonelectrolyte systems are useful in analytical chemistry and in engineering design and practices. In addition, these values for judiciously chosen binary mixtures permit further testing of already proposed empirical and theoretical concepts or solution models for simple systems, or their extension or modification to accommodate new data.

The present study has two purposes. First, activity coefficients of several solutes in dilute binary solutions of nonelectrolytes were measured from vapor–liquid equilibria at 20°C for several polar–nonpolar systems, and the limiting activity coefficients obtained by extrapolation. For these measurements, a novel apparatus was designed for use with a gas chromatograph having a flame-ionization detector, which made possible the accurate measurement of vapor concentrations down to much more dilute solutions than by conventional methods. As a result, the extrapolation to infinite dilution was short. Second, the values found for the limiting activity coefficients were used to test two correlations involving a dipole – induced dipole interaction parameter ($\psi_{12}$), reported by Prausnitz and co-workers (1, 2). In addition, the ratio of these parameters for each of several polar solutes in two nonpolar solvents is examined.

An extensive literature exists on experimental methods for obtaining the data necessary to calculate activity coefficients for liquid binary systems of nonelectrolytes. The two principal classes of method have been the use of equilibrium stills, and the measurement of the specific retention volume of the solute in a gas-chromatographic column coated with the solvent, which must be relatively nonvolatile. Equilibrium stills include distillation, circulation, dew- and bubble-point, static and flow types. Hála *et al.* (3) have reviewed single-stage devices and list their advantages and disadvantages. Isothermal distillation is the classical method (4), but it may be subject to serious errors (5). Circulation stills may introduce uncertainty as to whether the measured temperature and compositions are for equilibrium conditions. In addition, most data obtained from stills are for liquid concentrations relatively far from infinite

dilution. The pressure (or temperature) vs. composition curves then have curvatures that are too ill-defined to permit calculation, from the slopes, of reliable values for activity coefficients at infinite dilution. The design of a static distillation apparatus is somewhat complex, and sample withdrawal can cause difficulties.

In a simple static apparatus containing the solution, a sample of the equilibrium vapor for analysis is removed either by a syringe (6, 7), or by running mercury into the vessel and collecting the displaced vapor. In all cases it is assumed that equilibrium is not disturbed by the sample withdrawal. Wichterle and Boubliková (8) avoided that uncertainty by fusing an ungreased double-loop stopcock to the neck of the equilibration vessel. One loop comprized part of the vapor space over the solution; the other carried the carrier gas of a gas chromatograph. By a 180° turn of the stopcock the equilibrium vapor was swept into the gas chromatograph for analysis. However, this design has not been widely used, possibly because the fabrication of a greaseless stopcock leakproof at carrier-gas pressures is difficult, and the stopcock is likely to require periodic and time-consuming maintenance.

In view of the difficulties or uncertainties with published apparatus designs, and the need to measure very low concentrations of a vapor component in order to obtain limiting activity coefficients, a new design was conceived and constructed for the present work. It consisted of a static equilibrium cell capped by a rotatable head. This head was fitted with three calibrated vapor-sampling loops that could be sequentially filled with equilibrium vapor over the solution, then switched directly into the carrier-gas stream of a gas chromatograph. This design made possible repetitive measurements of the concentrations of components present in a true sample of the equilibrium vapor over a multicomponent liquid mixture, as does that of Wichterle and Boubliková (8).

Limiting activity coefficients (hereafter abbreviated $\gamma_2^\infty$ for the solute) were found in the present work for nitromethane, nitroethane, 1-nitropropane, 2-nitropropane, acetonitrile, propionitrile, ethyl acetate, and *n*-butyl acetate in *n*-heptane and in benzene as solvents, and also for carbon tetrachloride in each of the above-listed polar compounds as solvents.

## Experimental

*Gas chromatograph*

A Pye gas chromatograph, Series 104 with two exchangeable detector heads, was used. Helium was the carrier gas for the thermal-conductivity detector, and nitrogen for the flame-ionization detector. Packed columns 1/4-in. or 1/8-in. o.d. and lengths 2–5 ft were used in a temperature-controlled oven compartment, with separate temperature control for the sample-injection port. The chromatograms were recorded with a Sargent SR one-millivolt recorder, and the peak areas were measured with an attached disc-area integrator (Model 204, Disc Instruments, Inc.).

*Static liquid–vapor equilibration apparatus*

The liquid–vapor equilibration apparatus was designed to have a gas-chromatographic sampling loop of accurately known volume as an integral part of the vapor space above the liquid. Thus, the apparatus permitted the direct measurement by gas chromatography of the concentrations of minor components in a sample of the equilibrium vapor over a liquid mixture.

The apparatus consisted of a glass cell (Fig. 1) capped by a novel vapor-sampling valve (Fig. 2). Constructional details are reported elsewhere (9*a*). Briefly, the cell and valve could be connected together by a leak-free coupling, the components of which consisted of a threaded brass coupling, a silicone-greased Viton O-ring, and a thin circular Teflon washer. The lower face *F* of the valve (component *A* in Fig. 2*a*) was machined to leave a circular V-projection (*L*) which bit into the Teflon washer to ensure the gas-tight fit between valve and cell.

The valve is shown as sectional drawings in Fig. 2; *a* and *b* are in elevation 60° apart, and *c* is in plan. Components included an inverted cup (*A*) of stainless steel fixed to a disc (*I*) of Rulon, and an upper rotatable disc (*B*) of stainless steel. These components could be tightened to an appropriate tension by disc springs and a locknut on spindle *N*. Of the six 1/4-in. holes drilled vertically from the upper surface of *A* only one diagonal pair was drilled completely through *A*, to provide access to the glass cell. The other four holes were sunk only to corresponding horizontal holes in *A*. Stainless steel tubing welded to each of these horizontal holes, and fitted with a Swagelock nut and ferrule (*H*, Fig. 2*a*), provided for connections to carrier gas and vacuum.

Six holes through Rulon disc *I* and disc *B* were aligned with those in cup *A*. A calibrated sampling loop of carefully cleaned copper tubing was silver-welded into each diagonal pair of holes in *B*.

*Materials*

All chemicals were further purified by conventional methods that are described elsewhere (9*b*). Except for benzene, which was purified by fractional crystallization, the final purification step was fractional distillation under nitrogen, with the middle third being kept. Each product was then stored over molecular sieves 3A in a brown bottle. Care was taken to ensure dry products. The water content of the stored acetone was 0.007%.

Quantitative gas-chromatographic analysis of the final products indicated that the nitro compounds were 99.5 mol% pure with homologs as the major impurities, *n*-hexane was 99.5 mol% and *n*-heptane 99.8 mol% with aliphatic hydrocarbons the major impurities, and the others were 99.9 mol% or better. Densities at 21°C agreed well with literature values (10).

*Procedure*

Procedural details are reported elsewhere (9*c*). Briefly, a 30–50 mL sample of the liquid for study, prepared by weight in the case of mixtures, was placed in the glass cell. An aliquot was reserved for calibration purposes. After attaching the valve, with one of its sampling loops an integral part of the vapor space, the liquid was frozen and the apparatus evacuated. After thawing, the cell was immersed up to nut *A* (Fig. 1) in a water thermostat at 20.00 ± 0.05°C, with the room temperature at 24 ± 1°C. The sample was stirred continuously by a Teflon-coated

*$n = 3$.

magnetic bar. Liquid–vapor equilibrium was established within 30 min.

The equilibrium vapor in the sampling loop *bb'* (Fig. 2*c*) was then swept into the gas chromatograph by rotating disc *B* (Fig. 2) anticlockwise by 60°. Simultaneously, evacuated loop *cc'* became the sampling loop for another vapor sample. In practice, several repetitive samples were taken, with the first one usually being rejected.

Between repetitive vapor samples, calibration standards in the form of measured volumes of the reserved part of the liquid sample were injected into the gas chromatograph via a separate injection port, by a 10-μL Hamilton syringe (No. 710N). This syringe was found to deliver correct to 1%, by a spectrophotometric determination of the benzene it dispensed into *n*-heptane diluted to volume. Further, the measured vapor concentrations over several pure liquids agreed with literature values when the calibration curve used was prepared from liquid samples injected with this syringe.

*Calibration of the three sampling loops*

Prior to the copper loops being welded to the base of disc *B* (Fig. 2*a*) their volumes were measured by weighing them empty, then filled with water. A very small increment in the effective sample volume occurred because the weld was not flush with the face of disc *B*, but it was calculated and added to the loop volume. The corrected volumes are in column 2 of Table 1.

A second, preferred method was to measure the equilibrium vapor concentrations over four pure solvents — benzene, *n*-hexane, carbon tetrachloride, and acetone — by using the above-described equilibration apparatus and procedure, and a thermal conductivity cell as the glc detector. The pure liquids were injected for the calibration graphs. From these data and the known second virial coefficients (11) and reported values (10) of the vapor pressures of the pure liquids at 20°C, the volume of each loop was calculated from the equation of state, with due allowance for the thermal expansion of the equilibrium vapor from 20°C in the cell to the ambient temperature (about 24°C) in the loop. The mean values are in column 3 of Table 1. They agree well with those in column 2, which is evidence of the absence of any significant deficiency in the proposed apparatus and procedure.

*Reliability of the equilibration apparatus and procedure*

The reliability of the apparatus and procedure was confirmed by vapor-concentration measurements of both components of the benzene–*n*-hexane system over the entire concentration range, by using a thermal conductivity detector. From these data the activity coefficients of both liquid components at 20°C were calculated as described below, with the pure liquid component being taken as the standard state. Our results are in Table 2. They are compared in Fig. 3 with those at 25°C of Smith and Robinson (12) and with those at 24.98°C of Jain *et al.* (13). As further proof of agreement of all these data, an

*Each tabulated value of $\gamma$ is the grand mean computed by permitted pooling of the means for the three sample loops. For each loop there were 2–3 replicates of sample and of pure liquid. Variances were computed with higher terms being neglected. Homogeneity of these variances allowed pooling, to give 0.014 as the pooled standard deviation of each grand mean.

area-consistency test was carried out as devised by Redlich and Kister and by Herington and described by Ellis (14).

Further evidence of the method's reliability was our value of 1.15 ± 0.01 for the limiting activity coefficient of carbon tetrachloride in benzene at 20°C; a flame-ionization detector was used for the necessary measurements in very dilute solutions. This value compares favorably with 1.12 found for 40°C when Ellis and Jonah (15) applied an extrapolation procedure to the data of Scatchard *et al.* (16). Only a small temperature dependence of this limiting activity coefficient is expected in view of the low positive enthalpy of mixing.

Vapor concentrations of both components of the acetone–benzene system were also measured over the entire concentration range, and the activity coefficients of both liquid components at 20°C calculated as described below. Our results are in Table 2. They agree well with those of Brown and Smith (17) who used a circulation still under isothermal conditions, but not with those of Campbell *et al.* (18) and Litvinov (19), who obtained decidedly higher results by using bubble saturators. Brown and Smith (20) reported a value of 38 cal mol$^{-1}$ for the enthalpy of mixing of an equimolar mixture of acetone and benzene. Therefore, the temperature differences 20°C, 25°C, 45°C could not account for those higher values.

## Results

Limiting activity coefficients were evaluated from equilibrium vapor concentrations over dilute solutions of the polar solutes in *n*-heptane and in benzene as solvents, and for carbon tetrachloride as solute in each of the polar compounds as solvents. Generally, the range of solute concentrations was 0.001–0.01 mole fraction. The standard state of the solute was the pure liquid at 20°C.

The activity coefficients of the solutes were calculated first without correction for nonideality of the vapor phase, from the usual relationship $\gamma_2 = C_2/x_2C_{02}$. Here $C_2$ is the molar concentration of solute in the equilibrium vapor over the binary solution, obtained from the moles in the known volume of the gas-chromatographic sampling loop; $x_2$ is the known mole fraction of the solute in the equilibrium binary liquid, a correction having been made to the known initial mole fraction, for loss of solute to the vapor phase; and $C_{02}$ is the molar concentration of solute in the equilibrium vapor over the pure liquid solute, obtained also from the gas-chromatographic analysis of the equilibrium vapor of pure solute.

Since replicates both of the binary solution and

*Corrected for vapor imperfections.
†sd means standard deviation, obtained from the "Linfit" computations based on 5 to 7 points in each case.
‡$B_{11}$ for *n*-heptane = −2750, for benzene = −1506 mL mol$^{-1}$. $B_{22}$ for nitromethane, acetonitrile, and ethyl acetate are measured values (11), for the other four solutes they are our estimates.

the calibrating solution were always run, mean values and standard deviations could be computed for each activity coefficient by making use of the well-known relationship for the propagation of errors. Then for each binary mixture the mean activity coefficient and its standard deviation were plotted as a function of mole function $x_2$ of solute. In each case the linearity of the graph was visually evident over the mole fraction range 0.001–0.01 used. Further, over this concentration range the standard deviations were homogeneous. Then for each graph a straight line was fitted by using a subroutine "Linfit" with an unweighted mode. Therefrom, the values of the intercepts $\gamma_2^\infty$ at $x_2 = 0$ and their standard deviations were found. More specific details of the full statistical treatment and also all the basic data are given elsewhere (9).

Each value of $\gamma_2^\infty$ was then corrected for imperfections in the equilibrium vapor phases, as follows. Corrected activity coefficients ($\gamma_2^\infty$) were computed for each binary system by using [1].

$$[1] \quad \ln \gamma_2 = \ln \frac{C_2}{x_2 C_{02}} + 2B_{22}(C_2 - C_{02}) + 2B_{12}C_1$$

where $C_1$ is the solvent concentration in the vapor; $B_{22}$ and $B_{12}$ are the second virial coefficients for pure solute and the mixture respectively. The value of $B_{12}$ was approximated by using the formula $B_{12} = \frac{1}{2}(B_{11} + B_{22})$.

For the calculation, the first term on the right-hand side of [1] was the uncorrected value of $\gamma_2^\infty$, $C_2$ in the $B_{22}$ term was zero, and $C_1$ in the $B_{12}$ term was the vapor concentration above pure solvent. These corrected values of $\gamma_2^\infty$ and their standard deviations are entered in Tables 3 and 4. Most of the corrections amounted to about 1% of the uncorrected values.

The values given by Dymond and Smith (11) were used for $B_{22}$, and are in column 6 of Table 3. For nitroethane, 1-nitropropane, 2-nitropropane, propionitrile, and *n*-butyl acetate literature values were unavailable. They were estimated from an original empirical relationship which was found to apply to some 25 polar and nonpolar liquids tried. Details are reported elsewhere (9*d*). Briefly, when known virial coefficients at 340 K of several homologous series of both polar and nonpolar liquids were plotted against their molar energies of vaporization at their boiling points a family of curves was obtained, one for each homologous series. Values of $B_{22}$ for the above-noted five components were then read from the appropriate curves. To convert them to 298 K, an extrapolation procedure was used based on the general pattern of the known temperature-dependence of several homologous series of polar compounds.

## Discussion of results

The Scatchard–Hildebrand equation for the energy of mixing for a binary nonpolar solution is

$$[2] \quad \Delta E = \phi_1\phi_2 (x_1V_1 + x_2V_2) (c_{11} + c_{22} - 2c_{12})$$

*Subscript 1 denotes solvent.

where $\phi$ is the volume fraction, $x$ the mole fraction, and $V$ the molar volume of each component. The terms $c_{11}$ and $c_{22}$ may be obtained from the solubility parameters $\delta_1$ and $\delta_2$ respectively of the pure components, and $c_{12}$ is equated to $(c_{11}c_{22})^{1/2}$.

In order to accommodate polar–nonpolar binary mixtures, [2] is usually extended as follows: (*i*) $c_{11}$ for the polar component is split into polar and nonpolar contributions

$$[3] \quad c_{11} = {}^{p}\delta_1{}^2 + {}^{d}\delta_1{}^2$$

and, (*ii*) the solute–solvent interaction parameter $c_{12}$ is split into a dispersion contribution and a contribution which represents the dipole – induced dipole interactions between the polar–nonpolar pairs in the mixture. Superscripts d and p denote dispersion and polar interactions or contributions, respectively.

For the solute–solvent interaction parameter $c_{12}$, Prausnitz and co-workers (1, 2) wrote $c_{12} = {}^{d}\delta_1{}^{d}\delta_2 + \psi_{12}$, where ${}^{d}\delta_1{}^{d}\delta_2$ is the geometric-mean term customarily used for the dispersion contribution and $\psi_{12}$ is what they called the apparent induction energy density parameter. These modifications led them to

$$[4] \quad RT \ln \gamma_2{}^{\infty} = V_2[({}^{d}\delta_1 - {}^{d}\delta_2)^2 + {}^{p}\delta_1{}^2 - 2\psi_{12}] + RT\left[\ln \frac{V_2}{V_1} + 1 - \frac{V_2}{V_1}\right]$$

where their last term is the Flory–Huggins entropy term which takes into account the differences in $V_1$ and $V_2$, the molar volumes of the two components.

Weimer and Prausnitz (1) plotted function $L$, namely,

$$RT \ln \gamma_2{}^{\infty} - V_2({}^{d}\delta_1 - {}^{d}\delta_2)^2 - RT\left[\ln \frac{V_2}{V_1} + 1 - \frac{V_2}{V_1}\right] \text{ vs. } V_2{}^{p}\delta_1{}^2$$

separately for seven saturated hydrocarbons, for 1-pentene, and for benzene as the nonpolar solutes (subscript 2) in a variety of polar solvents that spanned a wide range of $V_2{}^{p}\delta_1{}^2$ values, and over a wide temperature range. For each of the three types of solute (i.e. saturated, unsaturated, aromatic) the plot was linear and through the origin, and gave the correlation $\psi_{12} = k\,{}^{p}\delta_1{}^2$. Their values of $k$ depended only on the type of solute, and are in Table 5. The deviations of their values of ln $\gamma_2{}^{\infty}$ were in general within 10%.
