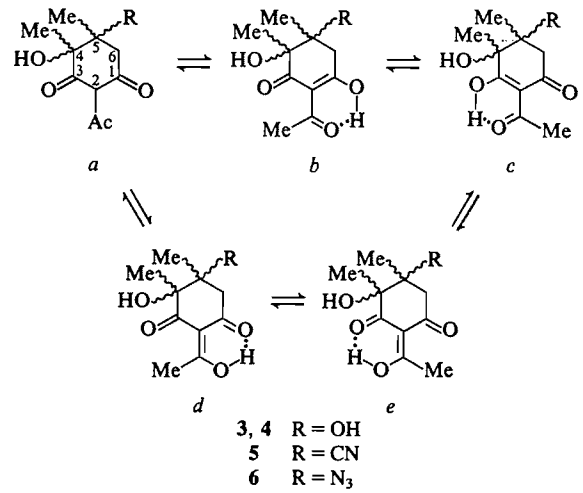
[a]Chemical shifts are reported in ppm downfield from internal $Si(CH_3)_4$ and coupling constants in Hz. Unless otherwise stated, the signals are singlets.
[b]Chelated OH.
[c]The doublets collapsed to singlets by irradiation at δ 5.78 and 5.86, respectively.
[d]The multiplets collapsed to doublets ($J_{2,4}$ 2.6 and 2.0) by irradiation at δ 2.02 and 2.04, respectively.



**3, 4** R = OH
**5** R = CN
**6** R = $N_3$

SCHEME 2

gated chelate OH---CO system (6). An AB system is present in their $^1$H nmr spectra (Table 1) at δ 2.80 for the methylene group together with a singlet at δ 18.0, attributable to hydrogen-bonded enolic protons; the latter shows a remarkable downfield shift characteristic of a six-membered cyclic β-diketone (7). Furthermore, no signal was detectable for CH groups in the $^1$H and $^{13}$C nmr spectra (Tables 1 and 2). These data excluded the dioxo forms **3***a* and **4***a* in the solid state and in chloroform solution.

Attempts to assign the stereochemistry of the epimers based on shifts of the hydroxyl absorption bands in dilute $CCl_4$ solution were not fruitful. Under these conditions, one OH group of compounds **3** and **4** showed an observable shift (from 3460 to 3570 $cm^{-1}$), whereas the other OH group remained substantially unchanged (ca. 3440 $cm^{-1}$). This behavior clearly indicated that, in addition to a strong chelate system (forms *b*–*e*), another intramolecular hydrogen bond was present, but it did not distinguish between the *cis* and *trans* epimers.

The conversion of the cyclopentenone **2** into **3** and **4**, which was carried out both with alkali and acids, could be rationalized on the basis of the reaction scheme illustrated above. The mechanism presumably involves first an attack of the nucleophilic agent ($H_2O$ or $OH^-$) at the position 3 of the starting material, leading either to the cyclopentanones **7** and **8** (route b) or to the corresponding anions (route a), which were formerly regarded as the final products of the reaction (8). However, it is reasonable to assume that these intermediates would react further under the reaction conditions, and would undergo ring expansion into cyclohexane-1,3-diones, through an acyloin rearrangement (9).

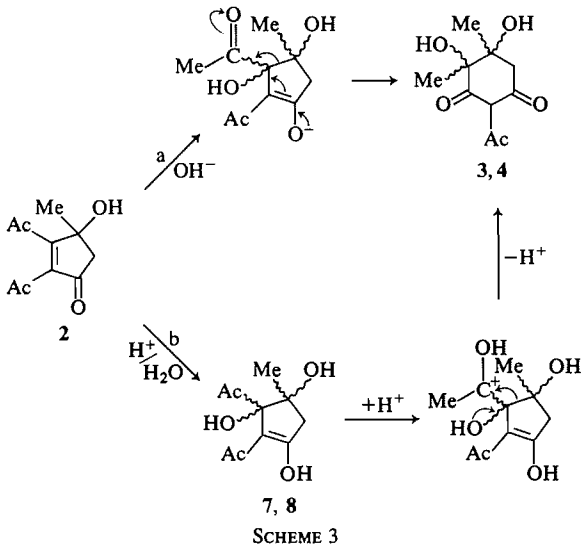
[a]Chemical shifts are reported in ppm downfield from $Si(CH_3)_4$ as secondary reference standard.
[b,c]These numbers can be interchanged within the same row.



SCHEME 3

Heating either of the cyclohexane derivatives **3** and **4** with acids under mild conditions produced the cyclohexene-1,3-dione **9**, which reacted with base at room temperature to give compound **10**; the latter could also be obtained from **3** and **4** in lower yield under similar conditions, and it was converted into a mixture of the methyl derivatives **11** and **12** by treatment with ethereal diazomethane.

Significantly, both isomers **3** and **4**, as well as compound **9**, were converted into 2,6-dihydroxy-3,4-dimethylacetophenone **13** by treatment with zinc in aqueous acetic acid at 60–70°C; this behavior, characterized by a reductive elimination of a tertiary hydroxyl group, closely resembled that of some steroid ketols (10).

Compound **13**, for which conflicting data were previously reported in the literature (11, 12) was unambiguously synthesized together with **14** by Fries rearrangement of 1,3-diacetoxy-4,5-dimethylbenzene **15**.

Conjugate addition of nucleophiles to compound **9** was shown to represent a useful synthetic route for functionalized cyclohexane-1,3-diones. When the former was treated with an excess of KCN or $NaN_3$, the derivatives **5** and **6** respectively were obtained in excellent yields; in both cases the reaction was also highly stereoselective as often reported for the hydrocyanation of conjugated cyclohexenones (13, 14), although the stereochemistry of the products could not readily be determined.

All the structures of the new products reported in Schemes 2 and 4 were consistent with their spectroscopic properties (Experimental, Tables 1 and 2).

The 2,4- and 2,5-dienones **11** and **12** were distinguished on the basis of the uv maxima (230 sh and 308 nm vs. 237 and 283 nm) and by comparison of the $^{13}C$ nmr CO resonances, which exhibit a diagnostic difference for C-1 (204.7 vs. 186.7 ppm) in full agreement with the values reported for similar compounds (192–205 and 178–187 ppm respectively, refs. 15 and 16).

As in the case of the cyclohexane-diones **3–6**, the ir and $^1H$ nmr spectra of **9** were characterized respectively by broad absorptions (3400–2000 and 1570–1490 $cm^{-1}$) and by a signal at very low field ($\delta$ = 17.9 ppm), attributable to a chelate OH---CO system. This behavior, as well as the absence of resonances for saturated CH groups in the $^1H$ and $^{13}C$ nmr spectra ruled out the form **9***a*. On the other hand, the $^{13}C$ nmr values for the CO groups (Table 2) and the uv pattern in $CHCl_3$ ($\lambda_{max}$ = 258 and 310 nm), led us to discard also the 2,5-dienonic structure **9***c* and to prefer the enolized chelate form **9***b* to the external tautomers **9***d* and **9***e*.

As regards the tautomeric behavior of **10**, the uv absorption in $CHCl_3$ ($\lambda_{max}$ < 240 nm) and the presence of resonances for the $CH_2$ group in the $^1H$ and $^{13}C$ nmr spectra (Tables 1 and 2) indicate that it exists almost exclusively in the dioxo form **10***a* in this solvent. In contrast, comparison of the uv spectrum in MeOH with those of compounds **11** and **12** (Experimental) led us to conclude that the product under investigation gives rise to a mixture of the enolic forms **10***b* and **10***c* in methanol solution.

## Experimental

Melting points were determined with a Kofler apparatus and are uncorrected. Unless otherwise stated, the spectroscopic measurements were carried out under the following conditions: ir and uv spectra were determined for dispersions in potassium bromide with a Perkin–Elmer 457 spectrometer and for solutions in methanol with a Cary 14 spectrophotometer respectively; $^1H$ nmr spectra were recorded in $CDCl_3$ with a Perkin–Elmer R32 instrument, whereas $^{13}C$ nmr spectra were obtained in the same solvent by the Fourier-transform technique with a Varian FT-80 A spectrometer. Silica gel plates (Merck $F_{254}$) and silica gel 60 (Merck; 70–230 mesh) were used for analytical and preparative tlc and for column chromatography respectively. Petroleum ether refers to the fraction of bp 30–50°C.

*Tetraacetylethylene (TAE) (1)*

The procedure used for the synthesis of TAE is essentially that already reported (1) but, in order to obtain a good yield, it is necessary to follow strictly the conditions described below.

To a boiling solution of thrice sublimed tetraacetylethane (9 g) in dry toluene (100 mL) was added a solution of thallium(I) ethoxide (Aldrich) (27 g) in the same solvent (80 mL), previously filtered through a sintered disc of porosity 3. The yellow dithallium(I) salt of tetraacetylethane which precipitated was separated by filtration and washed with chloroform to eliminate the unreacted starting material; after a further washing with petroleum ether, it was dried in a desiccator over solid paraffin to give a solid (25.5 g, 93%), which darkened above 145°C; ir $\nu_{max}$: 3500–3050, 1570, 1550, 1450, 1366, 1330 $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{12}O_4Tl_2$: C 19.84, H 1.98; found: C 19.65, H 2.02. A solution of iodine (Merck Suprapur) (4.9 g) in anhydrous ether (80 mL) was added slowly (ca. 3 h), with stirring, at 12–14°C to a suspension of the dithallium salt (12 g) in anhydrous ether (200 mL), and the mixture was stirred for a further 30 min. The solid (TlI and TAE) was filtered and extracted exhaustively with methylene chloride at room temperature; removal of the solvent at the same temperature afforded TAE (1) (3.15 g, 81%), mp 139–140°C (from benzene).

*2,3-Diacetyl-4-hydroxy-4-methylcyclopent-2-en-1-one (2)*

1,5-Diazabicyclo[4.3.0]non-5-ene (0.02 mL) was added to a solution of TAE (0.5 g) in methylene chloride (5 mL) at room temperature and the mixture was stirred for 30 min. Removal of the solvent left a residue which was resolved into two components by column chromatography with ether – petroleum ether (3:1 v/v) as eluent. The faster eluting band afforded a small amount (0.015 g) of a dimer of **2**, mp 219–221°C (from benzene). *Anal.* calcd. for $C_{20}H_{24}O_8$: C 61.22, H 6.16, *Mol. Wt.* 392.4; found: C 60.92, H 6.16, *Mol. Wt.* 390.

The second fraction gave compound **2** as colorless thick oil

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

(0.43 g, 86%), which crystallized on standing, mp 53–55°C (from petroleum ether); uv $\lambda_{max}$ (log ε): 227 (3.87) and 285 sh (2.95) nm; ir $\nu_{max}$: 3450 (OH), 1725 (CO), 1690 (CO), 1610 (C=C) $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{12}O_4$: C 61.22, H 6.16; found: C 60.88, H 6.24.

*2-Acetyl-4,5-dihydroxy-4,5-dimethylcyclohexane-1,3-diones (3) and (4)*

(a) The cyclopentenone **2** (1 g) was added to an aqueous solution of 1 *N* NaOH (10 mL) and stirred until the whole solid was dissolved (ca. 1 h). Acidification with concentrated HCl (pH 1) precipitated the isomer **3** as colorless crystals (0.5 g), mp 108–110°C (from cyclohexane); uv $\lambda_{max}$ (log ε): 233 (3.98) and 274 (4.04) nm; ir $\nu_{max}$: 3460 (OH), 3440 (OH), 3600–2400 (chelated OH), 1660 (CO), 1600–1530 (chelated CO) $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{14}O_5$: C 56.07, H 6.59; found: C 56.37, H 6.71.

The acid solution was exhaustively extracted in a liquid–liquid extractor with ether. Evaporation of the extracts yielded a residue (0.5 g) which was resolved into two components by preparative layer chromatography with benzene–ether (3:2 v/v) as developer. The first band afforded a second crop of compound **3** (0.3 g), whereas the other gave the isomer **4** (0.2 g), mp 124–126°C (from cyclohexane); uv $\lambda_{max}$ (log ε): 234 (3.99) and 274 (4.05) nm; ir $\nu_{max}$: 3450 (OH), 3430 (OH), 3600–2000 (chelated OH), 1665 (CO), 1610–1530 (chelated CO). *Anal.* calcd. for $C_{10}H_{14}O_5$: C 56.07, H 6.59; found: C 55.82, H 6.62.

(b) Reaction of TAE with NaOH, followed by the same work-up as above, gave the same mixture of the isomers **3** and **4** identical (mp, ir and $^1H$ nmr spectra) with the foregoing products.

(c) A solution of compound **2** (0.3 g) in 30% $H_2SO_4$ (4 mL) was stirred for 6 h at room temperature. Filtration of the reaction mixture yielded the isomer **4** (0.02 g). The solution was extracted with ether and the extracts were evaporated to dryness to give a mixture of **3** (0.05 g) and **4** (0.06 g), identical (mp, ir and $^1H$ nmr spectra) with the materials prepared above.

*2-Acetyl-6-hydroxy-5,6-dimethylcyclohex-4-ene-1,3-dione (9)*

A solution of the isomer **3** (or **4**) (1 g) in 60% $H_2SO_4$ (10 mL) was heated at 50°C for 6 h; filtration of the cooled reaction mixture yielded compound **9** (0.65 g), mp 83–84°C (from cyclohexane). The solution was then exhaustively extracted with ether in a liquid–liquid extractor to give another crop (0.22 g) of the same product (total yield 0.87 g, 95%); uv $\lambda_{max}$ (log ε): 233 (4.11), 260 (3.72), and 312 (3.81) nm; $\lambda_{max}$ (log ε) ($CHCl_3$): 258 (3.79) and 310 (3.83) nm; ir $\nu_{max}$: 3460 (OH), 3400–2000 (chelated OH), 1655 (CO), 1570–1490 (chelated CO) $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{12}O_4$: C 61.22, H 6.16; found: C 61.41, H 6.30.

*Acetyl-derivative 16*

Treatment of compound **9** with acetyl chloride at room temperature afforded **16** in 85% yield, mp 75–77°C (from petroleum ether); ir $\nu_{max}$: 3400–2300 (chelated OH), 1740 (OAc), 1670 (CO), 1570–1490 (chelated CO) $cm^{-1}$. *Anal.* calcd. for $C_{12}H_{14}O_5$: C 60.50, H 5.92; found: C 60.55, H 5.98.

*5-Cyano-2-acetyl-4-hydroxy-4,5-dimethylcyclohexane-1,3-dione (5)*

Sodium cyanide (0.16 g) was added portionwise with stirring to a solution of compound **9** (0.6 g) in DMSO (3 mL) and the mixture was heated at 50°C for 30 min. After cooling and neutralization with 25% HCl (ca. 7 mL), the solution was concentrated (4 mL) and acidified with concentrated HCl (pH 1) to give the nitrile **5** which separated as colorless needles (0.5 g), mp 134–135°C (from cyclohexane). Another crop of the same product (0.12 g, total yield 91%) was obtained by extraction of the acid mother liquors with ether; uv $\lambda_{max}$ (log ε): 234 (3.99) and 273 (4.03) nm; ir $\nu_{max}$: 3475 (OH), 3100–2000 (chelated OH), 2240 (CN), 1660 (CO), 1580–1510 (chelated CO) $cm^{-1}$. *Anal.* calcd. for $C_{11}H_{13}NO_4$: C 59.19, H 5.87, N 6.27; found: C 59.54, H 5.78, N 6.12.

*5-Azido-2-acetyl-4-hydroxy-4,5-dimethylcyclohexane-1,3-dione (6)*

Reaction of compound **9** (0.3 g) with sodium azide (0.2 g) in DMSO (2 mL), carried out essentially as above, afforded the derivative **6** (0.29 g, 79%), mp 89–90°C (from ethanol); ir $\nu_{max}$: 3520 (OH), 3200–2000 (chelated OH), 2140 ($N_3$), 1660 (CO), 1580–1520 (chelated CO) $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{13}N_3O_4$: C 50.21, H 5.48, N 17.56; found: C 49.90, H 5.54, N 17.77.

*6-Hydroxy-5,6-dimethylcyclohex-4-ene-1,3-dione (10)*

(a) Piperidine (0.6 mL) was added to a solution of compound **9** (0.5 g) in $CHCl_3$ (10 mL) and the mixture was stirred at room temperature for 3 h. Removal of the solvent left a residue which was dissolved in water (5 mL); the solution was acidified and extracted with ether (3 × 10 mL). Evaporation of the extracts yielded compound **10** (0.31 g, 79%), mp 133–135°C (from toluene); uv $\lambda_{max}$ (log ε): 236 (3.98), 296 (3.60), and 335 sh (3.31) nm; ir $\nu_{max}$: 3485 (OH), 3200–2100 (chelated OH), 1650 (CO), 1580–1490 $cm^{-1}$. *Anal.* calcd. for $C_8H_{10}O_8$: C 62.33, H 6.54; found: C 62.63, H 6.54.

(b) A solution of compound **9** (1 g) in 1 *N* NaOH (15 mL) was heated at 60°C for 24 h; the cooled solution was acidified with concentrated HCl and extracted with ether (3 × 20 mL). Evaporation of the extracts afforded compound **10** (0.4 g, 51%), identical (mp, ir and $^1H$ nmr spectra) with material prepared by method (a).

*Methylation of compound 10 with diazomethane*

A solution of **10** (1 g) in ether (50 mL) was treated with ethereal diazomethane (0.4 g) and set aside overnight. Removal of the solvent left a residue which was resolved into two components by column chromatography using ether as eluent. The first was identified as 3-methoxy-6-hydroxy-5,6-dimethylcyclohexa-2,4-dien-1-one (**11**) which crystallized from petroleum ether as pale yellow needles, mp 64–65°C (0.45 g, 41%); uv $\lambda_{max}$ (log ε): 230 sh (3.57) and 308 (3.70) nm; ir $\nu_{max}$: 3400 (OH), 1665, 1640, 1570 (conjugated CO) $cm^{-1}$. *Anal.* calcd. for $C_9H_{12}O_3$: C 64.27, H 7.19; found: C 64.27, H 7.15.

The second was identified as 3-methoxy-4-hydroxy-4,5-dimethylcyclohexa-2,5-dien-1-one (**12**), which sublimed at 60°C/0.04 Torr as colorless crystals, mp 82–84°C (0.35 g, 32%); uv $\lambda_{max}$ (log ε): 237 (4.15) and 283 (3.69) nm; ir $\nu_{max}$: 3270 (OH), 1665, 1600 (conjugated CO) $cm^{-1}$. *Anal.* calcd. for $C_9H_{12}O_3$: C 64.27, H 7.19; found: C 64.42, H 7.27.

*2,6-Dihydroxy-3,4-dimethylacetophenone (13)*

(a) A mixture of **3** (1 g) and zinc dust (0.6 g) in 50% AcOH (15 mL) was heated at 65°C for 10 h. The yellow needles which separated on cooling were filtered off, washed with water, and dried to give compound **13** (0.55 g), mp 125–127°C (after crystallization from cyclohexane and sublimation at 70°C/0.03 Torr) (lit. (11) mp 82–83°C and (12) mp 122–124°C). Another crop (0.06 g, total yield 71%) precipitated from the mother liquors after dilution with water; uv $\lambda_{max}$ (log ε): 222 (4.03), 276 (4.16), and 350 (3.39) nm; ir $\nu_{max}$: 3270 (OH), 3100–1750 (chelated OH), 1625 b (chelated CO) $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{12}O_3$: C 66.65, H 6.71; found: C 66.61, H 6.63.

(b) Under the same conditions, **9** gave the title compound **13** (82%), identical (ir and $^1H$ nmr spectra) with material prepared with method (a).

*Fries rearrangement of 1,3-diacetoxy-4,5-dimethylbenzene (15)*

Anhydrous aluminium chloride (2 g) was added portionwise to the title compound **15** (17) (1.3 g) in a beaker suspended in an oil bath maintained at 115–120°C. After the initial reaction had begun (3–4 min), the mixture was stirred vigorously with a glass

rod. Heating with periodic stirring was then continued for 30 min, after which time the cooled reaction mixture was ground in a mortar and then added, with stirring, to a mixture of crushed ice (20 mL) and concentrated HCl (1 mL). Decantation of the acid solution left a viscous solid, which was treated with the minimum amount of cold methanol to yield 1,3-diacetyl-2,4-dihydroxy-5,6-dimethylbenzene (**14**) (0.65 g) as pale yellow crystals, mp 78–80°C (from methanol); uv $\lambda_{max}$ (log ε): 257 (4.28), 272 (4.20), and 354 (3.78) nm; ir $\nu_{max}$: 3200–2000 (chelated OH), 1620 b (chelated CO) $cm^{-1}$. *Anal.* calcd. for $C_{12}H_{14}O_4$: C 64.85, H 6.35; found: C 64.88, H 6.27.

A preparative thin layer chromatography of the methanolic solution with ether – petroleum ether (2:1, v/v) as eluent gave in order of mobility another crop of **14** (0.05 g, total yield 54%) and compound **13** (0.1 g), identical (mp, ir and $^1H$ nmr spectra) with material obtained above.

P. MICHAEL BOORMAN, PENELOPE W. CODDING, K. ANN KERR, KELLY J. MOYNIHAN, and VIKRAM D. PATEL. Can. J. Chem. **60**, 1333 (1982).

The complex $(Me_2S)Cl_2W(\mu\text{-}S)(\mu\text{-}SEt)_2WCl_2(Me_2S)$, **1**, has been prepared by reaction of $[WCl_4(Me_2S)_2]$ with 1 mol-equiv. of $SiMe_3(SEt)$ in $CH_2Cl_2$ solution. A single-crystal X-ray diffraction study shows that the molecule has a confacial bioctahedral structure with a W—W bond length of 2.526(2) Å. The structure was solved by heavy atom methods and refined to $R = 0.061$ and $R_w = 0.061$ for 2715 reflections with $I \geq 3\sigma(I)$. Crystals of **1** are triclinic, space group $P\bar{1}$, with $a = 9.661(1)$, $b = 10.695(1)$, $c = 13.253(4)$ Å, $\alpha = 61.84(2)$, $\beta = 66.98(2)$, and $\gamma = 66.44(1)°$, $Z = 2$.

Reaction of **1** with 2 mol-equiv. of $Ph_4PCl$ in $CH_2Cl_2$ solution yields $(Ph_4P)_2[Cl_3W(\mu\text{-}S)(\mu\text{-}SEt)_2WCl_3]$, **2**. Crystals of **2** are triclinic, space group $P\bar{1}$, with $a = 10.153(1)$, $b = 13.043(1)$, $c = 21.876(3)$ Å, $\alpha = 95.16(1)$, $\beta = 96.48(2)$, and $\gamma = 108.90(1)°$, $Z = 2$. The structure was refined to $R = 0.041$, $R_w = 0.048$ for 2384 reflections with $I \geq 3\sigma(I)$; **2** also has a confacial bioctahedral structure with a W—W bond length of 2.522(1) Å.

P. MICHAEL BOORMAN, PENELOPE W. CODDING, K. ANN KERR, KELLY J. MOYNIHAN et VIKRAM D. PATEL. Can. J. Chem. **60**, 1333 (1982).

On a préparé le complexe $(Me_2S)Cl_2W(\mu\text{-}S)(\mu\text{-}SEt)_2WCl_2(Me_2S)$ (**1**) en faisant réagir le $[WCl_4(Me_2S)_2]$ avec un équivalent molaire de $SiMe_3(SEt)$ en solution dans le $CH_2Cl_2$. Une étude par diffraction de rayons X sur un monocristal montre que cette molécule a une structure bioctaédrique concafaciale avec une longueur de liaison de 2,52(2) Å. On a résolu la structure par la méthode des atomes lourds et on l'a affiné jusqu'à des valeurs de $R = 0{,}061$ et de $R_w = 0{,}061$ pour 2715 réflexions avec $I \geq 3\sigma(I)$. Les cristaux du composé de **1** sont tricliniques et appartiennent au groupe d'espace P, avec $a = 9{,}661(1)$, $b = 10{,}695(1)$, $c = 13{,}253(4)$Å, $\alpha = 61{,}84(2)$, $\beta = 66{,}98(2)$ et $\gamma = 66{,}44(1)°$, $Z = 2$.

Le composé **1** réagit avec 2 équivalents molaires de $Ph_4PCl$ en solution dans le $CH_2Cl_2$ pour donner le $(Ph_4P)_2[Cl_3W(\mu S)(\mu\text{-}SEt)_2WCl_3]$, **2**. Les cristaux du composé **2** sont tricliniques et appartiennent au groupe d'espace $P\bar{1}$, avec $a = 10{,}153(1)$, $b = 13{,}043(1)$, $c = 21{,}876(3)$Å, $\alpha = 95{,}16(1)$, $\beta = 96{,}48(2)$ et $\gamma = 108{,}90(1)°$, $Z = 2$. On a affiné la structure jusqu'à des valeurs de $R = 0{,}041$ et de $R_w = 0{,}048$ pour 2384 réflexions avec $I \geq 3\sigma(I)$, le composé **2** a une structure bioctaédrique concafaciale avec une longueur de liaison W—W de 2,522(1) Å.

[Traduit par le journal]

Examples of tungsten(IV) complexes with well-established metal–metal bonded dimeric structures are rare (1, 2). We recently reported the structure of $(C_4H_8S)Cl_2W(\mu\text{-}S)(\mu\text{-}SEt)_2WCl_2(C_4H_8S)$ which possesses a confacial bioctahedral framework with a W—W bond length of 2.524(1) Å. A number of interesting structural features in this molecule prompted us to extend the study to analogous complexes. We report here the X-ray structures of $(Me_2S)Cl_2W(\mu\text{-}S)(\mu\text{-}SEt)_2WCl_2(Me_2S)$, **1**, and of the anionic derivative $(Ph_4P)_2[Cl_3W(\mu\text{-}S)(\mu\text{-}SEt)_2WCl_3]$, **2**.

## Experimental

Synthesis of **1** was carried out by a route analogous to what we reported for the compound $[(C_4H_8S)Cl_2W(\mu\text{-}S)(\mu\text{-}SEt)_2WCl_2(C_4H_8S)]$, **3** (2). The starting material, $WCl_4(Me_2S)_2$, was synthesised as previously described (3). Reaction with 1 mol-equiv. of $SiMe_3(SEt)$ in $CH_2Cl_2$ solution yielded the compound **1** after working up the solution as reported in ref. 2. *Anal.* calcd. for $W_2Cl_4(SEt)_2S(SMe_2)_2$: W 46.70, Cl 18.00, C 12.19, H 2.79; found: W 48.7, Cl 18.9, C 12.6, H 2.85. Crystals suitable for an X-ray study were grown from $CH_2Cl_2$/hexane solutions cooled to ~ −20°C for 5 days.

**2** was prepared by adding $Ph_4PCl$ (0.57 g, 1.54 mmol) to a solution of **1** (0.54 g, 0.69 mmol) in $CH_2Cl_2$ (30 mL). After stirring for 6 h the solution was pumped to dryness. The microcrystalline sample of **2** was recrystallized from MeCN/$Et_2O$ at −10°C. *Anal.* calcd. for $(Ph_4P)_2[W_2Cl_6(SEt)_2S]$: Cl 15.06, C 44.18, H 3.50, S 6.79, P 4.38; found: Cl; 16.1, C 44.7, H 4.20, S 6.80, P 4.60. The spectroscopic properties of these and related compounds will be described elsewhere (4).

### *X-ray structure of $(Me_2S)Cl_2W(\mu\text{-}S)(\mu\text{-}SEt)_2WCl_2(Me_2S)$, 1*

*Collection and reduction of the X-ray data*

A crystal ca. 0.12 × 0.16 × 0.16 mm in size was mounted in epoxy resin on a glass fibre in a general orientation. A coating of the resin was also applied to protect the crystal from aerial degradation and/or loss of $Me_2S$ during the data collection.

Preliminary photographic study of the compound indicated a triclinic space group. The data crystal was then mounted on an Enraf-Nonius CAD4 Automatic Diffractometer. Cell parameters and an orientation matrix were determined from a least-squares fit using 25 accurately centred reflections. Crystal data at 21°C are:

$C_8H_{22}W_2Cl_4S_5$ fw = 787.8
Triclinic, $a$ = 9.661(1), $b$ = 10.695(1), $c$ = 13.253(4) Å, $\alpha$ = 61.84(2), $\beta$ = 66.98(2), $\gamma$ = 66.44(1)°, $V$ = 1071.2 Å; $Z$ = 2, $\rho_{calcd}$ = 2.44; $\rho_{obsd}$ = 2.42 g cm$^{-3}$ (by flotation in $CHBr_3/CCl_4$), $F_{000}$ = 732; $\mu(MoK_\alpha)$ = 121.7 cm$^{-1}$; space group $P\bar{1}$.

The centrosymmetric space group $P\bar{1}$ was confirmed later by use of $E$ statistics and successful refinement in this space group.

Intensities were measured with graphite-monochromatized $MoK_\alpha$ radiation in the $\omega/2\theta$ scan mode, using a scan width of $\Delta\omega = 1.5(0.6 + 0.35 \tan\theta)°$, and a scan speed ranging from (20/3) to (20/40)° min$^{-1}$ in the range $3.0° \leq \theta \leq 27°$. Of the 4660 unique reflections measured, 2715 had $I > 3\sigma(I)$, where $\sigma(I) = (P + 4B)^{1/2}$, $P$ is the sum of the counts accumulated in the central 64 steps of the scan, and $B$ is the sum of the counts in the 16 steps at either end of the scan. Three standard reflections were measured every 3000 s of exposure, and their intensities remained constant to within ±2%. Standard Lorentz and polarization corrections were applied. Data were corrected for absorption using the program CADABS (5).[3] The minimum and maximum values of the correction were 2.805 and 4.655, respectively.

*Solution and refinement*

The structure was solved by the heavy atom technique and refined by a full-matrix least-squares procedure based on $F$. The scattering factors were taken from ref. 6 and anomalous dispersion corrections from ref. 7. All heavy atoms were refined anisotropically. Hydrogen atoms could not be located in the final difference map, and were not included in the model. Secondary extinction was included in the final refinement cycles ($g$ = 0.19(8) × 10$^{-3}$). The maximum shift-to-error in the final cycle was 0.08, with the average value 0.01. The final $R$ values are $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.061$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.061$ for 2715 observed reflections. The weighting scheme used was $w = [\sigma^2(F) + 0.0003F^2]^{-1}$ where $\sigma(F)$ was derived from counting statistics. The standard deviation of an observation of unit weight was 1.08. No peaks of chemical significance could be located in the final difference map which showed maximum fluctuations of ±0.3 e Å$^{-3}$. The final positional and thermal parameters appear in Tables 1 and 2 respectively. The measured and calculated structure factors, and $\sigma(F)$ values have been placed in the Depository of Unpublished Data,[4] as also has Table 2.

*Crystal structure of $(Ph_4P)_2[Cl_3W(\mu\text{-}S)(\mu\text{-}SEt)_2WCl_3]$, 2*

Procedures for data collection followed closely those described for compound **1**. The essential data (21°C) are summarized below:

$C_{52}H_{50}W_2Cl_6S_3P_2$ fw = 1412.2
Triclinic, $a$ = 10.153(1), $b$ = 13.043(1), $c$ = 21.876(3) Å, $\alpha$ = 95.16(1), $\beta$ = 96.48(2), $\gamma$ = 108.90(1)°, $Z$ = 2; $\rho_{calcd}$ = 1.73, $\rho_{obsd}$ = 1.78 g cm$^{-3}$ (flotation in $CHBr_3/CCl_4$), $F_{000}$ = 1380, $\mu(MoK_\alpha)$ = 48.7 cm$^{-1}$, space group $P\bar{1}$.

[3]CADABS: a local modification of a program by Coppens *et al.* to calculate absorption factors by numerical gaussian integration.

Crystal size 0.22 × 0.16 × 0.09 mm; data collected on an Enraf-Nonius CAD4 diffractometer using $MoK_\alpha$ radiation with a graphite monochromator, $\omega$–$2\theta$ scan mode, variable scan speed, scan width $\Delta\omega = 1.5(0.20 + 0.35 \tan\theta)°$, $2° \leq \theta \leq 25°$; three standard reflections checked every 1200 s of exposure with no significant decrease in intensity; 9465 unique reflections of which 2384 have $I > 3\sigma(I)$; minimum and maximum values of absorption corrections are 1.139 and 1.309 respectively.

*Solution and refinement*

The structure was solved by heavy atom methods and refined on $F$. All the atoms were refined anisotropically, except the carbon atoms. The phenyl rings were refined as rigid bodies, while the ethyl carbon atoms were refined isotropically. Phenyl hydrogen atoms were placed in calculated positions but were not refined. Convergence was reached at $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.041$ for 2384 observed reflections and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.048$. The weighting scheme used was $w = [\sigma^2(F) + 0.001F^2]^{-1}$ where $\sigma(F)$ was based on

For personal use only.

counting statistics. The refined value of the secondary extinction parameter is $g = 4.4(4) \times 10^{-3}$. A final electron-density difference map revealed no peaks higher than $\pm 0.2\,e\,Å^{-3}$. The standard deviation of an observation of unit weight was 1.0 and the average shift-to-error in the final cycle was 0.01. Final positions of the non-hydrogen atoms in the $[Cl_3W(\mu\text{-}S)(\mu\text{-}SEt)_2WCl_3]^{2-}$ anion are given in Table 3. The thermal parameters of the anion (Table 4), the positions and thermal parameters for the two $Ph_4P^+$ cations (Tables 5, 6, and 7), and a listing of observed and calculated structure factors and $\sigma(F)$ values have been placed in the Depository of Unpublished Data.

Programs used: the XRAY-76 programs (8) were used for all calculations with the exception of absorption corrections for which CADABS (5) was used.

## Results and discussion

The structures of **1** and the anion of **2** are shown in Figs. 1 and 2, respectively. Bond lengths for the two binuclear tungsten complexes are given in Tables 8 and 9 while pertinent bond angle information for **1** and **2** is presented in Tables 10 and 11. In Table 12 certain comparisons are drawn between these complexes and the related complex **3**.

The three complexes all possess the same bridging groups in a confacial bioctahedral ditungsten species. The W—W bond lengths show a remarkable consistency, all being within experimental error, 2.523 Å. The implication of this observation is that the interaction is indeed due to a direct metal–metal double bond, as was previously suggested (2). The distance is almost identical to that reported by Cotton and co-workers (2.530(2) Å) for the benchmark compound $[W_2S_2(S_2CNEt_2)_4]$ (1). The acute angles subtended at the μ-S atoms are also consistent with a confacial bioctahedral structure severely distorted by a strong metal–metal interaction.

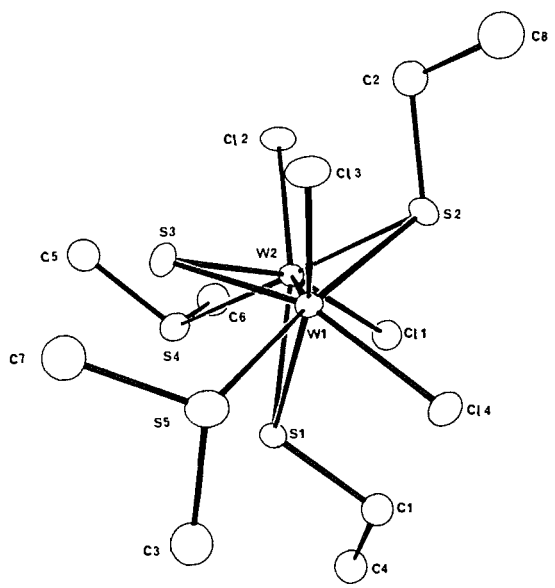

FIG. 1. ORTEP view of the structure of $(Me_2S)Cl_2W(\mu\text{-}S)(\mu\text{-}SEt)_2WCl_2(Me_2S)$, **1**. The envelopes enclose 20% probability thermal ellipsoids.

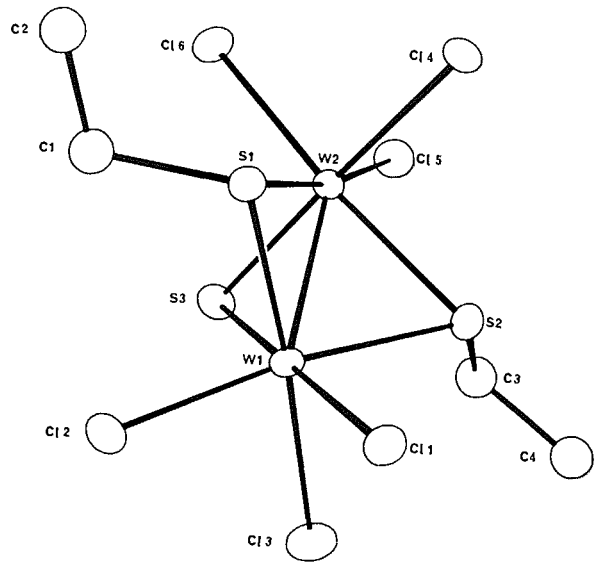

FIG. 2. ORTEP view of the anion $[Cl_3W(\mu\text{-}S)(\mu\text{-}SEt)_2WCl_3]^{2-}$ in complex **2**. (20% probability thermal ellipsoids shown.)

There are two differences, however, in the geometry of the three $W(\mu\text{-}S)(\mu\text{-}SEt)_2W$ moieties. First, the presence of a terminal thioether with a long W—S bond allows the W—S bond *trans* to it to be significantly shorter than the analogous bonds *trans* to chlorine. The surprising feature of the structures of **1** and **3** is that in both cases the thioether is *trans* to a thiolate rather than to the sulfide ligand. This reduces the symmetry of the molecules from the $C_{2v}$ point group potentially available, to $C_s$ in **3**, and $C_1$ in **1**. The relatively short sulfide–tungsten bonds might be expected to be *trans* to the thioether. Since the stereochemistry of the two starting complexes $WCl_4(Me_2S)_2$ and $WCl_4(C_4H_8S)_2$ is believed to be different (9), the products must be thermodynamically stable in their observed geometries, rather than being the result of a kinetically controlled process.

The second feature in which the complexes **1** and **2** differ is in the configurations adopted by the two thiolato sulfur atoms. The anion of **2** possesses the *ee* configuration (following the nomenclature used by Bor and co-workers (10)), but the dimethyl sulfide complex **1** possesses an *ae* configuration. On steric grounds the *ee* isomer would be expected to be the more stable. It may be noted that the —SEt group *trans* to the thioether, which has the shorter W—S bonds, is in the equatorial configuration while the axial configuration is adopted by the

SEt group *trans* to a Cl atom. These observations imply that during the reaction of **1** with $Cl^-$ to produce **2**, inversion occurs at one of the sulfur atoms. The possible interconversion of *ee* to *ae* isomers of complexes of this type in solution has been studied by nmr spectroscopy and will be described elsewhere (4).

The presence of the thioether ligands in terminal positions in complexes **1** and **3** seems to be related to another potentially important aspect of the structure. In both these complexes there is a short S···SEt contact (Table 12) whereas in the chloro-anion of **2** this effect is not pronounced. Similar effects have been observed by other workers, who have advanced a variety of explanations. For example, Stiefel and co-workers (11) suggested that partial bond formation between adjacent sulfurs could arise through a redox process. In another case McCarley and co-workers ascribed a close contact between two bridging Br atoms to the electrostatic repulsion caused by the electrons in a metal–metal bond (12). The phenomenon has also been discussed by Fackler (13), and by Dance, Wedd, and Boyd (14). The simplest explanation in the present case would seem to be a steric repulsion caused by the terminal thioethers. Examination of Fig. 1 does not support this suggestion, since the two sulfur atoms which form the close contact are in fact closest to these ligands, and would more probably be displaced in the opposite direction. There is no systematic trend in the sums of the angles subtended at the sulfur atoms of the μ-SEt groups (Table 12), which might be expected from a steric effect. It may be significant that the closest contact is formed by the sulfur with an axial alkyl group (complex **1**).

We therefore conclude that the most likely

explanation is that there is an attractive interaction between the two sulfurs, which is influenced by the presence of the terminal thioether ligands. We are continuing our study of thiolato-bridged metal clusters to try to shed further light on this problem.

# Studies of confacial bioctahedral tungsten complexes containing metal-to-metal bonds: synthesis, reactions, and nuclear magnetic resonance studies of $W_2Cl_4(\mu\text{-}SR)_2(\mu\text{-}S)L_2$ (R = alkyl; L = monodentate ligand)[1]

VIKRAM D. PATEL AND P. MICHAEL BOORMAN[2]

*Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4*

Received August 27, 1981

VIKRAM D. PATEL and P. MICHAEL BOORMAN. Can. J. Chem. **60**, 1339 (1982).

A series of new binuclear tungsten(IV) complexes, $W_2Cl_4(\mu\text{-}SR)_2(\mu\text{-}S)L_2$ (R = Me, Et, $^i$Bu, $CH_2Ph$; L = $Me_2S$ or THT), is readily synthesized from the metathetical reaction of $WCl_4L_2$ with 1 mol-equiv. of alkylthiotrimethylsilane ($Me_3Si(SR)$). These complexes react with stronger nucleophiles ($Ph_3P$, MeCN, $C_5H_5N$, $Cl^-$) under ambient conditions to yield simple disubstituted products. Reaction of $W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)(SMe_2)_2$ with $PhCH_2X$ (X = Cl, Br) yields $[Me_2SCH_2Ph]_2[W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)X_2]$, whilst with stronger alkylating agents, $MeSO_3F$ or $Et_3OBF_4$, intractable residues result.

The series of homologous complexes has been studied by $^1H$ and $^{13}C$ nmr spectroscopy. When R = Me, two stable configurational isomers are present in solution, whilst only a single isomer exists for more bulky R groups. Trends in the $^1H$ nmr chemical shifts of the methylene and methyl protons of the SEt groups in the complexes $W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)L_2$ allow absolute assignment of the resonances to two magnetically inequivalent thiolato groups.

VIKRAM D. PATEL et P. MICHAEL BOORMAN. Can. J. Chem. **60**, 1339 (1982).

On a préparé facilement une série de nouveaux complexes binucléaires du tungstène (IV), $W_2Cl_4(\mu\text{-}SR)_2(\mu\text{-}S)L_2$ (R = Me, Et, Bu$^i$, $CH_2Ph$; L = $Me_2S$ ou THT) à partir de la réaction de double décomposition du $WCl_4L_2$ avec un équivalent molaire d'alkylthiotriméthylsilane ($Me_3Si(SR)$). Ces complexes réagissent avec des nucléophiles plus forts ($Ph_3P$, MeCN, $C_5H_5N$, $Cl^-$) à la température ambiante pour donner de simples produits bisubstitués. Le composé $W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)(SMe_2)_2$ réagit avec $PhCH_2X$ (X = Cl, Br) pour donner le composé $[Me_2SCH_2Ph]_2[W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)X_2]$ tandis qu'avec des agents alkylants plus forts, du type $MeSO_3F$ ou $Et_3OBF_4$, on obtient des résidus qu'on ne peut isoler.

On a étudié la série des complexes homologues par la spectroscopie de rmn du $^1H$ et du $^{13}C$. En solution, on obtient deux isomères de configurations stables lorsque R = Me tandis qu'il n'existe qu'un seul isomère avec les groupes R plus encombrés. La tendance dans les déplacements chimiques en rmn du $^1H$ des protons du méthylène et du méthyle des groupes SEt des complexes $W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)L_2$ permet une identification absolue des résonances des deux groupes thiolato magnétiquement inéquivalents.

[Traduit par le journal]

## Introduction

We have recently reported (1, 2) the syntheses and crystal structures of two types of tungsten thiolate dimers possessing a confacial bioctahedral framework (Fig. 1). Complexes of type *a* (Fig. 1) (1) have several features of unusual interest. First, it is worthy of note that they possess three types of divalent sulfur ligands ($S^{2-}$, $RS^-$, and $R_2S$), coordinated to a relatively high oxidation state metal centre (W(IV)), and thus should allow assessment of the electrophilic and/or nucleophilic reactivity of these ligands. Second, these complexes are isostructural and isoelectronic with the complexes $M_2Br_6(THT)_3$ (M = Nb, Ta; THT = tetrahydrothiophene) (3). The tantalum complex has been shown to undergo some unusual reactions with nitriles and acetylenes under mild conditions (4). The availability of complexes of type *a* with a variety of R and L substituents has allowed us to study the reactivity of this type of complex, and to compare the chemistry with their niobium and tantalum homologues. Herein we report the reactions of these complexes with electrophiles and nucleophiles, and their solution behaviour as studied by $^1H$ and $^{13}C$ nmr spectroscopy.

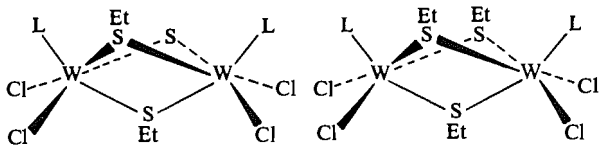

FIG. 1. Structures and solid state geometry of tungsten thiolato complexes.

## Experimental

*General procedures*

All manipulations were carried out in a dry nitrogen-filled glovebox or on a standard double manifold. Analytical grade solvents were dried ($P_2O_5$ or $CaH_2$) and distilled under nitrogen before use. Alkyl sulfides (Aldrich Chemicals) were dried over calcium hydride and distilled under nitrogen prior to use. Tungsten carbonyl was purchased from Alfa Inorganics, as was

tungsten hexachloride. The latter compound was twice resublimed before use. Tungsten tetrachloride was synthesized by the method of McCarley and Schaefer-King (5). Chlorotrimethylsilane was purchased from Aldrich Chemicals as were thiols. (Alkylthio)trimethylsilanes ($Me_3SiSR$; R = Me, Et, $^t$Bu, $CH_2Ph$) were synthesized via the lead salt of RSH by the published procedure (6). The adducts $WCl_4(SMe_2)_2$ and $WCl_4(THT)_2$ were prepared as previously described (5, 7). Tungsten was analyzed by ignition to the oxide ($WO_3$). Other analyses were obtained commercially (Galbraith Laboratories Inc., Knoxville, TN, U.S.A.). Routine ir spectra were recorded as Nujol mulls between CsI plates using a Perkin-Elmer 467 spectrophotometer. Electronic spectra were recorded as solutions in matched quartz cells using a Beckman DB-G spectrophotometer. $^1$H nmr spectra of the complexes were obtained using either a Hitachi Perkin-Elmer R-24B spectrometer (60 MHz), a Bruker WH90 FT spectrometer (90 MHz) or a Varian XL200 FT spectrometer (200 MHz). Proton decoupled $^{13}$C nmr spectra were recorded at room temperature on a Bruker WH90 spectrometer operating at 22.63 MHz.

*Synthesis of $W_2Cl_4(\mu\text{-}SR)_2(\mu\text{-}S)L_2$ (L = THT, $Me_2S$): 1*a, *1*b *(R = Me); 2*a, *2*b *(R = Et); 3 (R = $^t$Bu); 4 ($R = CH_2Ph$)*

The general reaction employed in the syntheses of the above complexes is represented by reactions [1] and [2].

$$[1]\quad [WCl_4L_2] + Me_3SiSR \xrightarrow{CH_2Cl_2} [WCl_3(SR)L_2] + Me_3SiCl$$

L = $Me_2S$ or THT

$$[2]\quad [WCl_3(SR)L_2] \rightarrow \text{products}$$

In a typical reaction, the compound $WCl_4L_2$ (ca. 2.0 g) was dissolved in $CH_2Cl_2$ (35 mL) and to this stirred solution was added the exact, calculated 1 mol-equiv. of $Me_2SiSR$ dissolved in $CH_2Cl_2$. $^1$H nmr studies (8) showed immediate conversion of $Me_3SiSR$ to $Me_3SiCl$ and there was also an instantaneous colour change of the solution from orange–red to a darker red. A light brown precipitate was observed within 2 h, and after stirring overnight at room temperature the solution was filtered to remove this precipitate. Analytical and various spectroscopic data confirmed that this precipitate was a sulfonium salt of the $WCl_6^{2-}$ anion, as shown previously (8, 9). The dark-red-coloured filtrate was diluted to 100 mL with $CH_2Cl_2$, and hexane (40–50 mL) was added to deposit an intractable brown oil. Filtration, followed by slow evaporation of the filtrate solvent *in vacuo*, yielded the desired complex as a red microcrystalline powder, which was collected on a medium frit, washed with hexane, and dried under vacuum (yield ca. 50%). Crystals of the complexes are obtained on allowing the mother liquor (after removal of sulfonium salt and the oily residue) to stand undisturbed at −20°C for 48–72 h. The formulation of these complexes is not evident from the available analytical data (9) (Table S1), but was confirmed by single crystal X-ray analyses of the complexes **2***a* and **2***b* [1]. The difficulty in obtaining reliable analytical data probably results from several causes. The tendency of these complexes to lose thioether ligands upon standing not only leads to erroneous analytical results, but it also precluded recrystallization as a means of purification in many instances. Furthermore, we have found it difficult to obtain reliable commercial analyses for sulfur and chlorine, in particular, on this type of complex. Characterization has therefore been based not only on analytical data, but also on comparisons between the spectroscopic properties of new compounds and those of compounds with crystallographically determined structures. The complexes **2***a* and **2***b* exhibit analogous spectroscopic (ir, uv-visible, and $^1$H and $^{13}$C nmr) properties to the other compounds in this series. Infrared spectra for all the complexes contain an identical broad band centered at 315 cm$^{-1}$, which can be assigned to ν(W—Cl), together with characteristic vibrations due to the hydrocarbon parts of the thiolate and thioether ligands. However, the spectra are devoid of any peak assignable to the bridging W—S—W moiety. The complexes exhibit three strong absorptions in their visible spectra at ~365 (ε = 4000), ~525 (ε ~ 1500), and 780 nm [ε ~ 2000) respectively.

*$(Et_4N)_2[W_2Cl_6(\mu\text{-}SMe)_2(\mu\text{-}S)]$ (1*c*)*

Tetraethylammonium chloride (0.23 g; 1.39 mmol) was added to a solution of **1***a* (0.48 g; 0.57 mmol) in dichloromethane (30 mL). The solution was stirred at ambient temperature for 14 h and to the solution hexane (50 mL) was slowly added. The red microcrystalline precipitate was filtered, washed with hexane, and dried under vacuum. *Anal.* calcd. for $W_2Cl_6S_3C_{18}H_{46}N_2$: C 22.35, H 4.76, S 9.94, N 2.89; found: C 22.40, H 5.0, S 9.70, N 2.80. The same product was obtained from **1***b* under similar reaction conditions.

*$(Et_4N)_2[W_2Cl_6(\mu\text{-}SEt)_2(\mu\text{-}S)]$ (2*f*)*

The complex **2***f* was synthesized from **2***b* and tetraethylammonium chloride by a procedure identical to that used for **1***c*. *Anal.* calcd. for $W_2Cl_6S_3C_{20}H_{50}N_2$: Cl 21.38, C 24.14, H 5.03, S 9.65, N 2.82; found: Cl 21.40, C 24.30, H 4.80, S 9.40, N 2.80.

*$W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)(NCMe)_2$ (2*c*)*

Acetonitrile (0.7 mL; 13.3 mmol) was added to a solution of **2***b* (0.68 g; 0.86 mmol) in dichloromethane (30 mL). The solution was stirred at ambient temperature for 15 h and then the solvent was removed under vacuum. The residue was redissolved in $CH_2Cl_2$ (50 mL) and hexane (30 mL) was slowly added. Reduction in volume of the solution (to ca. 40 mL) afforded **2***c* as a red microcrystalline precipitate which was filtered off, washed with hexanes, and dried under vacuum (yield 0.5 g; 70%). ir: ν(C≡N) at 2310 and 2295 cm$^{-1}$ which are assigned to coordinated acetonitrile (10). Variable amounts of occluded acetonitrile is present in the solid as indicated by its $^1$H nmr spectra (δ 2.02). The displacement of dimethylsulfide by acetonitrile is less facile than in the case of **2***d* and **2***f* as indicated by the recovery of small amounts of **2***b* from the mother liquor.

*$W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)(PPh_3)_2$ (2*d*)*

A solution of **2***b* (0.85 g; 1.08 mmol) and triphenylphosphine (1.41 g; 5.37 mmol) in dichloromethane (50 mL) was gently refluxed for 4 h. After being allowed to cool to room temperature, the mixture was filtered, and hexane (100 mL) was slowly added to the filtrate. Reduction in volume of the solution (to ca. 50 mL) resulted in the precipitation of **2***d* as a red microcrystalline powder. The same complex results (under identical reaction and workup conditions outlined above) from the use of a two molar equivalent of triphenylphosphine.

*$W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)(Py)_2\cdot Py$ (2*e*)*

Excess pyridine (Py) (2.5 mL; 31.2 mmol) was added to a solution of **2***a* (0.50 g; 0.5 mmol) in dichloromethane (20 mL). The resultant dark red solution was stirred at ambient temperature for 2 h before slowly adding hexane (20 mL). Reduction in volume of the solution (to ca. 20 mL) resulted in the precipitation of **2***e*, which was collected by filtration, washed with hexane, and dried under vacuum. *Anal.* calcd. for $W_2Cl_4S_3C_{19}H_{25}N_3$: C 25.71, H 2.82, N 4.73; found: C 25.50, H 3.0, N 4.60.

The ir spectrum of **2***e* contains bands due to both free and coordinated pyridine (Py) as indicated by the presence of the characteristic in-plane ring vibrations at 1578 and 604 cm$^{-1}$ and out-of-plane ring vibration at 405 cm$^{-1}$ of free Py, which are shifted to 1620, 675 cm$^{-1}$ and 445 cm$^{-1}$, respectively, on coordination (11).

*$[Me_2SCH_2Ph]_2[W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)Br_2]$ (2g)*

Benzyl bromide (1.0 mL; 8.4 mmol) was added to a solution of **2***b* (0.65 g; 0.83 mmol) in benzene (25 mL). The solution began to take on a dark-black–green tinge after 3 h, and a greenish precipitate formed. The solution was stirred for a further 12 h and the precipitate collected by filtration, washed with hexane, and dried under vacuum (yield 0.40 g; 43.0%). *Anal.* calcd. for $W_2Cl_4S_5Br_2C_{22}H_{38}$: C 23.33, H 3.40, Cl 12.53; found: C 21.30, H 2.90, Cl 13.40.

*$[Me_2SCH_2Ph]_2[W_2Cl_6(\mu\text{-}SEt)_2(\mu\text{-}S)]$* (2h)

Benzyl chloride (1.0 mL; 8.69 mmol) was added to a solution of **2***b* (0.46 g; 0.58 mmol) in $CH_2Cl_2$ (25 mL). The solution was stirred at ambient temperature for 14 h. The red–black precipitate was collected by filtration, washed with hexane, and dried under vacuum (yield 0.35 g; 55%). $^1$H nmr data ($CD_3CN$) δ: 1.00 (t, 6); 2.75 (s, 12); 3.0 (q, 4); 4.55 (s, 4); 7.3–7.5 (m, 10).

*$[(Ph_4P)_2][W_2Cl_6(\mu\text{-}SEt)_2(\mu\text{-}S)]$* (2i)

Tetraphenylphosphonium chloride (0.57 g; 1.54 mmol) was added to a solution of **2***b* (0.54 g; 0.68 mmol) in $CH_2Cl_2$ (30 mL). The solution was stirred at ambient temperature for 6 h, before removing the solvent under vacuum. The dark red residue was redissolved in $CH_3CN$ (35 mL). Slow addition of anhydrous $Et_2O$ (~60 mL) resulted in the precipitation of the title complex, as dark red needles, which were collected by filtration and washed with hexanes. A further crop of crystals was obtained on allowing the mother liquor to stand undisturbed at −10°C for 48 h. $^1$H nmr data ($CD_2Cl_2$) δ: 1.38 (t, 6); 2.91 (q, 4); 7.5–7.9 (m, 40).

*Attempted reaction of $[Ph_4P]_2[W_2Cl_6(\mu\text{-}SEt)_2(\mu\text{-}S)]$ with EtI and MeI*

Ethyl iodide (0.2 mL; 2.46 mmol) was added to a solution of **2***i* (0.20 g; 0.14 mmol) in $CH_2Cl_2$ (20 mL). The solution was refluxed for 3 h and stirred for an additional 14 h at room temperature. The solvent was removed *in vacuo* and the residue washed with hexanes. The $^1$H nmr spectrum indicated the residue to be unreacted starting materials. Similar results were obtained from the attempted reaction with MeI.

*Attempted reaction of **3** with $PhC{\equiv}CPh$*

A solution of diphenylacetylene (0.035 g; 0.2 mmol) and complex **3** (0.16 g; 0.19 mmol) in $CH_2Cl_2$ (15 mL) was stirred at room temperature for 14 h. No noticeable colour change occurred. The solvent was removed *in vacuo*. The $^1$H nmr spectrum of the residue ($CDCl_3$) showed characteristic resonances attributable to unreacted starting materials.

## Results and discussion

*Synthesis and reactions of $W_2Cl_4(\mu\text{-}SR)_2(\mu\text{-}S)L_2$ ($L = Me_2S$ or THT; R = Me, Et, $^i$Bu, $CH_2Ph$) complexes*

Previously (9, 12), we demonstrated that it was possible to introduce the $SR^-$ ligand into the coordination sphere of tungsten in lieu of $Cl^-$ by utilizing alkyl(aryl)thiotrimethylsilane ($Me_3Si(SR)$) reagents (reaction [1]). The reaction in [1] was found to be sensitive to the stoichiometry of the reactants and the nature of the R groups used (9, 12). Thus, reaction of $WCl_4L_2$ (L = $Me_2S$ or THT) with 2 mol-equiv. of $Me_3SiSEt$ in $CH_2Cl_2$ proceeds smoothly to yield the dimeric mixed oxidation state (W(III, IV)) complex $W_2Cl_4(\mu\text{-}SEt)_3L_2$ (2) (Fig. 1*b*). In contrast to this, under analogous reaction conditions, the use of 1 mol-equiv. of the silyl reagent allows isolation of the red diamagnetic W(IV) complexes, $W_2Cl_4(\mu\text{-}SR)_2(\mu\text{-}S)L_2$ (L = $Me_2S$ or THT) (Fig. 1*a*) in high yields, for R groups possessing protons on the α carbon atom (9). Their formation in the above reaction is the result of a series of complex intermediate reactions (1). Although these W(IV) thiolato complexes are air-, moisture-, and heat-sensitive, they are easily prepared, and well characterized with the structural studies of the complexes for R = Et; L = THT and $Me_2S$ (1). They are also stable and soluble in most common organic solvents ($CH_2Cl_2$, $C_6H_6$, $CHCl_3$, etc.). Hence these complexes are particularly well suited for the exploration of their chemistry.

The chemistry is summarized in Scheme 1. Substitution of the thioether ligands in complexes **2***a*, *b* (and their homologues) by a variety of stronger donor ligands ($Cl^-$, $Ph_3P$, Py, MeCN) proceeds rapidly and cleanly in $CH_2Cl_2$ (Scheme 1). The quaternary salts of the hexachlorotungstate dimers **1***c*, **2***f*, **2***i* are red microcrystalline solids which are air-stable for short periods of time in the solid state but are rapidly air-oxidized in solution. The $Et_4N^+$ salts (**1***c*, **2***f*) are only sparingly soluble in dichloromethane but exhibit increased solubility in acetonitrile. However, the $Ph_4P^+$ salt, **2***i*, is more soluble in $CH_2Cl_2$ as compared to **2***f*. The ir spectra of these hexachloroditungstate anions show a characteristic strong absorption at ~265 $cm^{-1}$ with shoulders at 305 and 250 $cm^{-1}$, which are assigned to ν(W—Cl) and which appear at a frequency ~40 $cm^{-1}$ lower than found in the neutral complexes. In addition to reacting with quaternary salts, the thioether complexes react with acetonitrile, pyridine, and triphenylphosphine in a single type of reaction, namely, simple substitution of the terminal thioether ligands. The complexes, **2***c–e*, are dark red or brown, slightly air-sensitive solids. The facile and quantitative conversion of the neutral thioether dimers to the corresponding substituted products under mild conditions reflects on the relative nucleophilicities and donor strengths of the various ligands at the W(IV) centres.

The most striking feature of the chemistry of these new thioether complexes is their stability towards gross structural disruption. The simple substitution of the thioether by acetonitrile to give **2***c* contrasts directly with the behaviour exhibited by the isostructural and isoelectronic $Ta_2Cl_6(THT)_3$ complex. This latter complex, under analogous reaction conditions, reacts with a variety of nitriles (RCN, R = Me, Et, etc.) to give tantalum complexes possessing reductively coupled nitrile ligands (4*a*).

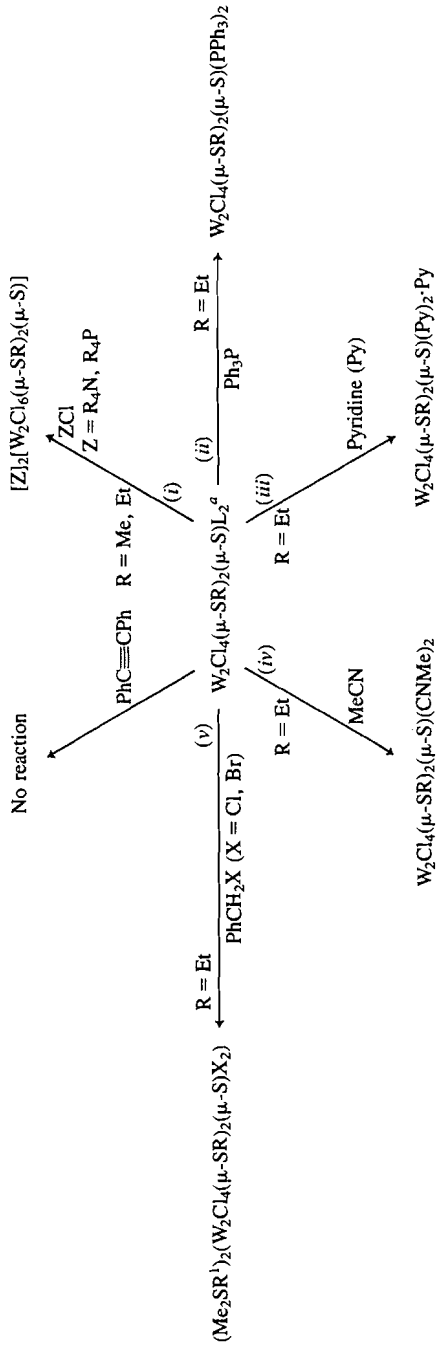

SCHEME 1. Substitution reactions of $W_2Cl_4(\mu\text{-}SR)_2(\mu\text{-}S)L_2$; [a]L = $Me_2S$ or THT (see Experimental for details); all reactions carried out in $CH_2Cl_2$ at 25°C.

In this context it is noteworthy that the complex **2***i* can be crystallized from an acetonitrile solution. Further differences in the behaviour of the two types of complexes becomes evident from the lack of reactivity exhibited by complex **3** towards tolane, PhC≡CPh, whereas the tantalum(III) dimer undergoes facile reactions with a variety of acetylenes (RC≡CR′) to produce mononuclear and binuclear tantalum acetylides (4).

In view of the structural similarities between complexes of type *a* and *b* (Fig. 1), the alkylation of the μ-sulfido ligand in *a* seemed to be an attractive route to the synthesis of compounds of type *b*, which are oxidized by one electron. *S*-Alkylation of sulfur atoms has previously been accomplished by using alkyl halides (12*a*, 13–15), phenylsulfonyl chloride (13), and a variety of other alkylating agents (13–15).

The reaction of excess $PhCH_2X$ (X = Cl, Br) with **2***b* under ambient conditions results in the *S*-alkylation of the thioether ligand to give the corresponding halide-substituted ionic species, **2***g* and **2***h*. These complexes are sparingly soluble in $CH_2Cl_2$, but have increased solubility in acetonitrile. Attempted alkylation of the μ-sulfido ligand by using stronger alkylating agents such as $MeSO_3F$ and $Et_3OBF_4$ resulted only in the formation of intractable residues. The ready *S*-alkylation of the terminal thioether ligand is likely metal-mediated by a mechanism analogous to that proposed for the alkylation of some Ni, Pd, and Pt thiolates by alkyl halides (16). This is further aided by the labile nature of the thioether ligand and the non-coordinating ability of the sulfonium cation at the high oxidation state W(IV) centre.[3] Attempted alkylation of the μ-sulfido ligand of the chloroanions **1***c* and **2***f* with alkyl iodides (MeI or EtI) under ambient and under reflux conditions were unsuccessful and resulted in the recovery of the starting tungsten species.

*Nuclear magnetic resonance studies*

Binuclear complexes possessing two bridging mercaptide ($SR^-$) ligands can exist as configurational isomers, as shown in Fig. 2, depending upon the orientation of the R groups and lone pairs on the bridging sulfur atoms. For cases in which all three terminal ligands are the same (A = B, Fig. 2),

[3]Examples where a sulfonium cation acts as a formal two electron donor have recently been reported, but only for complexes in which the metal is in a low oxidation state; e.g. $[(C_5H_5)Mn(CO)_2(SMe_3)]^+$ (17) and $[Ru(NH_3)_5(SMe_3)]^{2+}$ (18). In these species, the large positive charge on the sulfur can be neutralized by π back-donation to sulfur from the metal centre.

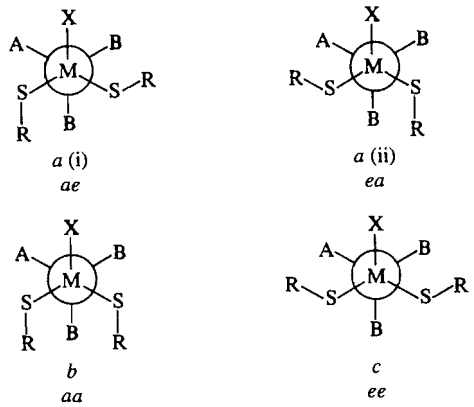

FIG. 2. The possible configurational isomers for the complexes $M_2Cl_4(\mu\text{-}SR)_2(\mu\text{-}S)L_2$, as viewed down the M···M axis.

only three isomers can occur, since the *ae* and *ea* isomers are identical.

In the solid state the molecular configurations of the complexes $W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)(THT)_2$ (**2***a*) (1*a*) and $[Ph_4P]_2[W_2Cl_6(\mu\text{-}SEt)_2(\mu\text{-}S)]$ (**2***i*) (1*b*) correspond to the *ee* type in Fig. 2, whereas $W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)(SMe_2)_2$ (**2***b*) (1*b*) exhibits the *ae* configuration of Fig. 2. Steric considerations in analogous complexes showed that the *aa* isomer (Fig. 2*b*) is energetically the least favourable (19, 20). The observation of the *ae* and *ee* structures in the solid state suggested that the homologous complexes would be capable of existence as mixtures of these two configurational isomers in solution. Conversion of the *ee* isomer to the *ae* or *ea* isomers would require inversion at one sulfur atom. Inversion barriers about coordinated sulfur atoms have been estimated at 50–80 kJ mol$^{-1}$ (19, 21), but this will presumably be dependent upon the stereochemistry and substituent of the sulfur atom (*vide infra*).

In the interpretation of spectra below, it is assumed that the symmetric isomers observed will be *ee*, rather than *aa*, and that the *ae* geometry observed in the crystal structure of **2***b* (1*b*) will be the more likely of the *ae* and *ea* isomers to exist in solution. However, the possible existence of the other isomers cannot be rigorously excluded.

The $^1H$ and $^{13}C$ chemical shift data for $W_2Cl_4(\mu\text{-}SR)_2(\mu\text{-}S)L_2$ complexes, obtained at 25°C, are reported in Tables 1 and 2 respectively. $^1H$ nmr spectra of the complexes show that whereas only one environment occurs for the ligands L in the neutral complexes **2***a–e*, **3**, and **4**, two sets of resonances occur for the SR ligands, when R is other than Me (the SMe complexes **1***a–c* behave differently and are discussed below). The two sets

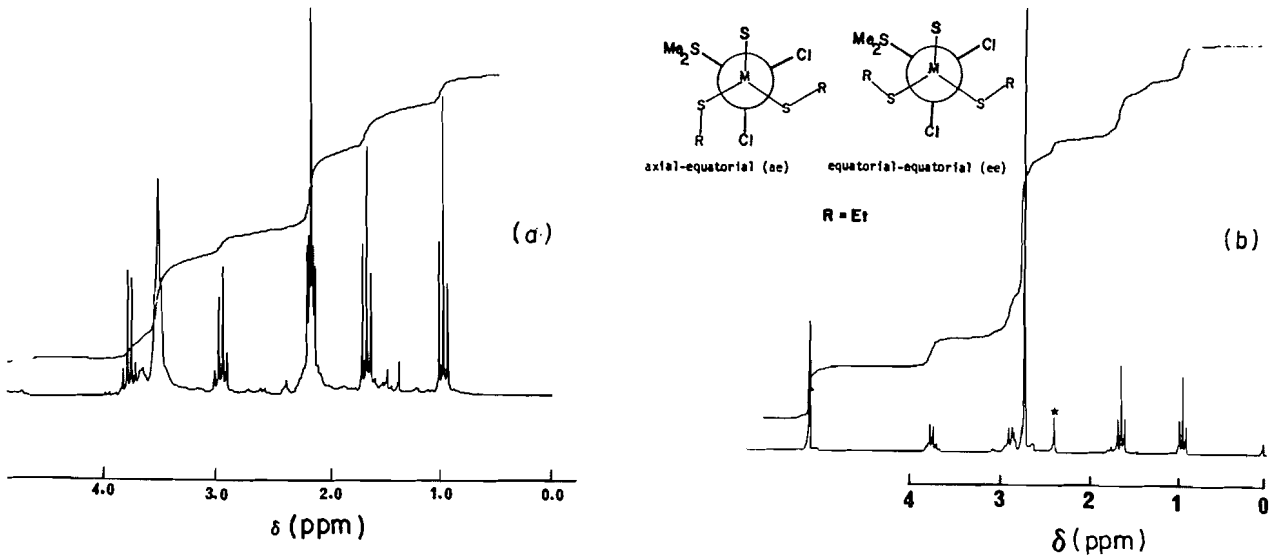

FIG. 3. (*a*) 200-MHz $^1H$ nmr spectrum of complex **2***a* in $CD_2Cl_2$ at 25°C. (*b*) 200-MHz $^1H$ nmr spectrum of complex **2***b* in $CD_2Cl_2$ at 25°C; resonance marked with an asterisk is an impurity in the solvent.

of resonances due to bridging thiolate ligands, which are usually separated by ~1.0 δ for protons on the α-carbon atom, are of equal intensity and, in total, represent a 1:1 intensity ratio with the ligands L (Fig. 3). The two distinct sets of $^1H$ (and $^{13}C$ for complexes **2***a*, **2***b*, and **3**) nmr signals are in accord with the solid state structures of complexes **2***a* (**1***a*) and **2***b* (**1***b*). The low molecular symmetry, in which the two μ-SEt groups are *trans* to different terminal ligands, causes the R groups to be magnetically inequivalent, irrespective of the configuration of the SR groups. The SR groups which are *trans* to thioether ligands have significantly shorter W—S bonds than those *trans* to $Cl^-$ in the structures of **2***a* and **2***b* (**1***a*, **1***b*). A consistent interpretation of the spectra can be made if it is assumed that the more strongly bound SR ligands (*trans* to the weakly bound thioether) are more deshielded than those *trans* to $Cl^-$, and that their $^1H$ and $^{13}C$ resonances therefore occur at lower field. Thus, although for these complexes the existence of a single configurational isomer in solution is evident,[4] the identity of this isomer cannot be established.

The complexes $W_2Cl_4(\mu\text{-}SMe)_2(\mu\text{-}S)L_2$ (**1***a*–*c*) show evidence for the existence of at least two isomers in solution, with the possibility of small quantities of others. $^1H$ nmr spectra (25°C) of complexes **1***a* and **1***b* show three strong resonances of unequal intensity for the SMe groups (Table 1, Fig. 4). Interpretation of these spectra requires the presence of two isomers, for which one pair of resonances at 3.60 δ are accidentally degenerate. It is likely that this low field signal is due to the SMe group *trans* to thioether, and that the configuration

[4]The $^1H$ nmr spectrum of **2***b* shows sharp resonances for the bridging thiolate ligand over the temperature range −90 to +25°C ($CD_2Cl_2$). However, the $Me_2S$ resonance is temperature dependent, being a singlet at 25°C, which splits into two resonances at −60°C. The temperature dependence of the $Me_2S$ signal is attributed to the onset of rapid inversion at sulfur in the high temperature limit, with it being slow on the nmr time scale at −60°C (22, 23).

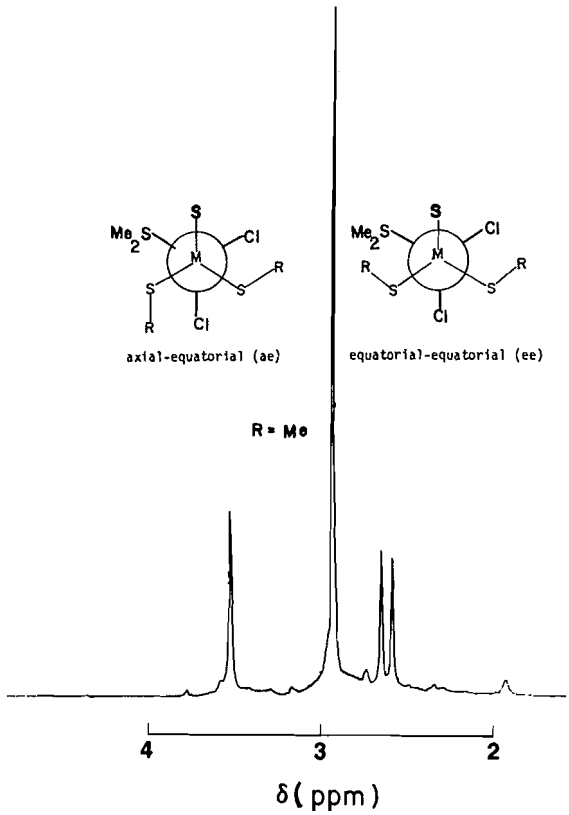

FIG. 4. 200 MHz $^1$H nmr spectrum of **1***b* in $CD_2Cl_2$ at 25°C.

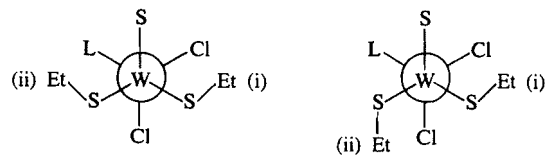
in each case is the same (probably *e*). The assignment is confirmed by the $^{13}$C spectra in which the downfield resonances are resolved (Table 2). It is not possible to assign unequivocally the four SMe $^{13}$C resonances to their respective isomers (i.e., which low field resonance is associated with which high field resonance). If the low field resonances are assigned to the SMe groups *trans* to the thioether ligands in **1***a* and **1***b*, and in the two isomers the configurations are the same, then the other SMe group *trans* to Cl would be the one to exhibit *a* or *e* stereochemistry, thus generating the *ae* and *ee* isomers discussed earlier. The alternative interpretation would necessitate assigning the isomers as *aa* and *ea*. The weak, unassigned resonances found in certain spectra may be associated with these isomers. However, the assumption that the *ae* and *ee* isomers found in the solid state are also the important isomers in solution seems to be most reasonable.

Further information was obtained by the synthesis of the complex $[Et_4N]_2[W_2Cl_6(\mu\text{-}SMe)_2(\mu\text{-}S)]$ (**1***c*) from **1***a* and **1***b*. The higher symmetry of **1***c* allows the SMe groups to be magnetically equivalent in the *ee* isomer. The $^1$H spectrum exhibits three resonances of which the strong resonance at 3.15 δ is due to a symmetric isomer, presumably the *ee* (*vide supra*). The shift to higher field from the **1***a* and **1***b* spectra is consistent with the replacement of thioether by $Cl^-$ *trans* to one bridging SMe group. The two resonances of equal intensity (3.12, 2.90 δ) are assigned to the *ae* isomer (ratio of *ee*:*ae* ≈ 2:1). Attempts to study the interconversion of these isomers of **1***c* in $C_2D_2Cl_4$ at various temperatures were unsuccessful due to overlapping of the $-CH_2$ resonances of the $Et_4N^+$ cation with the methyl resonance of the anion.

The $[W_2Cl_6(\mu\text{-}SEt)_2(\mu\text{-}S)]^{2-}$ anion of the complex **2***f*, derived from either **2***a* or **2***b*, shows only one set of resonances for the SEt groups (Table 1), in the temperature range examined (−90°C to +25°C; $CD_2Cl_2$). We conclude that one of the following conditions exists: (*i*) the barrier to isomerization is very low; (*ii*) the chemical shift differences between the isomers are too small to detect; (*iii*) only one isomer exists in solution.

For **2***f* the acute angles subtended at the bridging thiolate sulfur atoms (~62.5°), which result from the strong metal–metal interaction (1*b*) are likely to increase the inversion barrier[5] about the coordinated sulfur from the normal 50–80 kJ mol$^{-1}$ (19, 21–25). Furthermore, it is unlikely that the chemical shifts will be totally insensitive to stereochemistry (cf. complex **1***c*) and hence we conclude that the solution contains predominantly a single symmetric isomer, namely, the *ee* isomer which was found in the solid state structure (16).



The complex $W_2Cl_4(\mu\text{-}SEt)_2(\mu\text{-}S)(PPh_3)_2$ (**2***d*) appears at first to have an anomalous $^1$H nmr spectrum. However, it can be rationalized in a way which corroborates the above assignments. One of the SEt groups shows a large upfield shift. The methylene resonance at 2.20 δ for **2***d* is ~1 ppm upfield from the corresponding resonances in complexes **2***a*–*c*, **2***e*, and **2***g* (~3.50 δ). Similarly the $CH_3$ resonance is found at −0.2 δ for **2***d* compared with 1.0 δ found for the other complexes. In

[5]Whilst only a single isomer exists for complex **3**, the isostructural anion in the complex $[Ph_4As][W_2O_2Cl_4(\mu\text{-}S^iBu)_2(\mu\text{-}Cl)]$ (angle subtended at $\mu$-S$^i$Bu is ≃ 70.5°) exists as two isomers (*ee* and *ae*) in solution, with a barrier to inversion of ≃ 75 kJ mol$^{-1}$ (27).

contrast, the low field resonances due to the SEt ligand at ~4.0 δ and ~1.75 δ show no marked effect with change of L (Table 1).

Since a *through bond* type of shielding of the ethanethiolate ligand (SEt(i)) *trans* to L is unlikely to cause such a large upfield shift in the case of **2***d*, a *through space* interaction between the hydrogens of the proximal ethanethiolate ligand (SEt(ii)) and an adjacent phenyl ring appears to be the most likely cause of this shift. A similar argument was advanced by Roundhill and co-workers (26) to explain an anomalous chemical shift of the methyl protons in the complex $RuCl_2(\sigma\text{-}MeSC_6H_4PPh_2)_2$. This assignment for **2***d* would necessitate assigning the lower field resonances (1.73, 4.10 δ) in the $^1H$ nmr spectrum to the SEt(i), which is *trans* to the phosphine. This would be consistent with the argument presented earlier.

J. P. HUVENNE, G. VERGOTEN, G. FLEURY, S. ODIOT, and S. FLISZÁR. Can. J. Chem. **60**, 1347 (1982).

Local symmetry force field calculations are presented for the chair and boat forms of cyclohexane and the assignments of frequencies are given. The calculated zero-point and thermal vibrational energies indicate a near invariance of total vibrational energy with respect to chair–boat conformational changes of the cyclohexane ring, thus confirming results of similar nature derived from earlier theoretical thermochemical analyses.

J. P. HUVENNE, G. VERGOTEN, G. FLEURY, S. ODIOT et S. FLISZÁR. Can. J. Chem. **60**, 1347 (1982).

Les calculs en champ de forces de symétrie locale sont présentés pour les formes chaise et bateau du cyclohexane, ainsi que l'attribution des fréquences. Les énergies au point zéro et thermiques indiquent que l'énergie vibrationnelle totale est virtuellement insensible au changement conformationnel du cycle cyclohexanique, en confirmant ainsi des résultats antérieurs de nature similaire, déduits d'analyses thermochimiques théoriques.

[Traduit par le journal]

## Introduction

Molecular energies are determined by a blend of terms referring (*i*) to molecules in their hypothetical vibrationless state at 0 K and (*ii*) of vibrational energies. The latter play an important role in the evaluation of molecular energies at the level of actual experimental conditions, while the energy of atomization

$$\Delta E_a^* = \sum_k \langle \psi_k{}^{at} | H_k{}^{at} | \psi_k{}^{at} \rangle - \langle \psi^{mol} | H^{mol} | \psi^{mol} \rangle$$

only contains the information pertaining to the nuclear-electronic stability of an isolated molecule at equilibrium, which is not an information describing the situation at, say, 25°C. This state of affairs is described by eq. [1]

$$[1] \quad \Delta E_a^* = \sum_i n_i [\Delta H_f^0(A_i) - 5RT/2] - \Delta H_f^0 + \text{ZPE} + H_T - H_0$$

in which $\Delta H_f^0(A_i)$ is the enthalpy of formation of the gaseous atom $A_i$ and $\Delta H_f^0$ that of the molecule consisting of $n_i$ atoms $A_i$ at 298.15 K. ZPE is the zero-point energy, $H_T - H_0 = E_{vibr} + 4RT$ is the change in enthalpy between $T = 0$ and $T = T$ of a nonlinear molecule and $E_{vibr}$ the corresponding increase in vibrational energy.

The atomization energy of the vibrationless molecule at 0 K, $\Delta E_a^*$, can be expressed as a sum of energy terms associated with the individual chemical bonds, plus a very small contribution arising from Coulomb-type interactions between nonbonded atoms, and its calculation is one involving the atomic charges of the individual atoms forming the molecule (1). Theoretical $\Delta E_a^*$ energies deduced along these lines were shown to agree within 0.16 kcal/mol (average deviation) with their experimental counterparts derived from eq. [1], namely, for normal and branched paraffins, cyclohexane, and polycyclic compounds containing chair and/or boat cyclohexane rings (1–3) and for a series of oxygen-containing compounds (4). Conversely, the use of theoretical $\Delta E_a^*$'s in eq. [1], combined with the appropriate enthalpies of formation, leads to rapid and accurate evaluations of ZPE $+ H_T - H_0$ energies (2). This type of calculation is greatly facilitated by the use of carefully established charge–nmr shift correlations for $^{13}C$ and $^{17}O$ nuclei (5), the H charges being determined from charge normalization so that, ultimately, the vibrational results are simply deduced from the appropriate nmr and enthalpy data.

In this manner it was deduced from a study (2, 3) of hydrocarbons containing chair and/or boat cyclohexane rings that the ZPE $+ H_T - H_0$ energy is

virtually invariant upon a chair–boat structural change. Typical examples are offered by bicyclo-[2.2.2]octane, the comparison between the *trans-anti-trans* and *trans-syn-trans* forms of perhydroanthracene and that of twistane with adamantane. The energy difference between the chair and boat forms of cyclohexane itself is traced back to non-vibrational energy contributions, as a consequence of an electron enrichment at the carbon atoms in the chair form, at the expense of the electron populations at the hydrogen atoms, resulting in a destabilization (0.88 kcal/mol) of the CH bonds and a gain in stability of the carbon skeleton (6.27 kcal/mol) for a total difference of 5.39 kcal/mol favoring the chair form (1).

Because of the exceptional importance of the cyclohexane ring in conformational chemistry, we examine here the problem of total vibrational energies in chair and boat cyclohexane. Indeed, although many papers have dealt with the vibrational properties of nonplanar six-membered ring molecules of the cyclohexane type, none has considered specifically this aspect of structure-related energy contributions. Presently, the only available information about total vibrational energies, featuring explicitly the effects related to the chair–boat structural changes, is that derived from thermodynamic energy analyses involving eq. [1] (2). Here we approach the question via detailed calculations of the fundamental vibrational frequencies of both forms, which give access to the respective ZPE + $H_T - H_0$ energies.

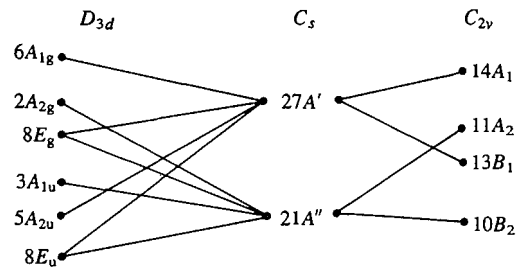
## Outline of calculations

Important studies on cyclohexane were presented by Takahashi *et al.* (6) and by Snyder and Schachtschneider (7). More recently, Wiberg and Shrake (8) have investigated the appropriate selection of an independent subset of valence force constants from a dependent or redundant set when redundant internal coordinates are included. In the earlier studies (6, 7), the cyclohexane geometry was taken in its chair form, in a strictly tetrahedral arrangement, with torsion angles along the CC bonds of 60°. In ref. 6, a Urey–Bradley force field was used and the description of modes was obtained through potential energy distributions. Snyder and Schachtschneider (7), however, used a general valence force field for the study of 17 hydrocarbons, including cyclohexane and adamantane. None of these model force fields was applied for predicting the vibrational frequencies of the boat form of cyclohexane.

On the other hand, it was shown that the "local symmetry force field" (LSFF) (9–11) is the only one based on bond properties which can take advantage of any type of model force field, namely, the general valence or the Urey–Bradley force fields. Here we take full advantage of the LSFF approach which is unique in that it permits the transferability of local symmetry force fields, deduced and refined for the chair form of cyclohexane, to the theoretical study of the boat form. Of course, the main difficulty in the local symmetry approach is to take the local and the cyclic redundancies into proper account.

The normal coordinate treatment was carried out as follows. Firstly, the chair form of cyclohexane was chosen as in ref. 6, with $r_{CC} = 1.54$ and $r_{CH} = 1.09$ Å. Secondly, the symmetry point group being $D_{3d}$, a total of 60 internal coordinates was defined, namely, 18 for the ring part alone (i.e., 6 CC bonds, 6 CCC angle bends, and 6 CCCC torsions) and 42 coordinates involving the hydrogen atoms (i.e., 12 CH bonds, 24 CCH angle bends, and 6 HCH angle bends). This leads to 12 redundant symmetry coordinates of which 6 are the "tree redundant" type (taking coordinates like the bending, scissoring, wagging, rocking, and the twisting of a $CC_2H_2$ group into account), while 6 are cyclic redundant symmetry coordinates determined among the 18 ring internal coordinates (10, 11). In this way, we define a $3n - 6$ dimentional reduced symmetry space.

In order to permit the prediction of the fundamental vibrations of the boat form (symmetry $C_{2v}$) we chose to treat the chair form (symmetry $D_{3d}$) as belonging to the $C_s$ symmetry subgroup of both the $D_{3d}$ and $C_{2v}$ groups. The correlation between these groups is as follows.



With these premises, the local symmetry force field (LSFF) described in local symmetry coordinate space (9) was appropriately expressed in the reduced symmetry space. The original LSFF force constants were obtained from the MVIB library (11, 12). We added some interaction parameters (which are not required for the acyclic hydrocarbons) in order to take the ring structure into proper account (11), i.e., for interaction terms involving neighboring atoms, $CH_2$ sst/$CH_2$ sst = −0.0592, $CH_2$ ast/$CH_2$ ast = −0.0057, $CH_2$ scis/$CH_2$ scis = −0.0081, CC tors/CC tors = 0.0196,

TABLE 1. Observed and calculated wavenumbers ($cm^{-1}$) for the chair form of cyclohexane

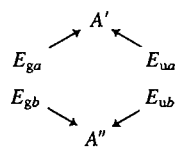
$CH_2$ rock/CC tors = −0.1835, and $CH_2$ scis/$CH_2$ wag = −0.0124. The units are mdyn $Å^{-1}$ for stretching/stretching interactions and mdyn Å for deformation/deformation and deformation–torsion/torsion interactions. We also recorded the far infrared and the classical infrared spectra, as well as the full Raman spectra, of both $C_6H_{12}$ and $C_6D_{12}$ in the liquid phase and completed the normal coordinate analysis of the free molecule using the LSFF parameters adapted to the chair form. The results are as below.

## Results

Table 1 reports the observed and the calculated fundamental frequencies of chair cyclohexane, as well as the potential energy distribution. The abbreviations are: $CH_2$ sst = symmetrical stretching of a $CH_2$ group, $CH_2$ ast = antisymmetrical stretching coordinate of a $CH_2$ group; scis = scissoring deformation coordinate; wag = wagging deformation coordinate; rock = rocking deformation coordinate; twis = twisting deformation coordinate. The following coordinates concern only the ring part: stret = CC stretching; bend = CCC bending, and tors = CCCC torsion coordinate.

These results suggest the following comments. (*i*) The chair form of cyclohexane belongs to the $D_{3d}$ group, in which the $A_{2g}$ and $A_{1u}$ vibrations are inactive, meaning that a total of 5 frequencies cannot be observed. In the correlation $D_{3d} \leftrightarrow C_s$ which allows us to use the same LSFF constants for the chair and the boat forms, this implies that 5 fundamentals of the $A''$ class have no experimental counterparts. Moreover (*ii*), in the same $D_{3d} \leftrightarrow C_s$ correlation, the degenerate vibration $E_g$ and $E_u$ of the chair form split as follows



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

thus preventing us from gaining additional experimental information as regards the $A''$ class. Finally (*iii*), as a direct consequence of (*i*) and (*ii*), it is not possible to obtain any additional experimental evidence for the $A''$ class, which would be useful in refinements of the force field, because the only contributions to this class are the inactive modes (case *i*) or the degenerate components of modes included in class $A'$ (case *ii*).

These observations should be born in mind when comparing to one another the results calculated for the chair and boat forms of cyclohexane (Table 2). Indeed, it appears that the sum of the vibrational frequencies belonging to the $A'$ class is remarkably constant when going from one form to the other (i.e., 42 553 $cm^{-1}$ for the chair form and 42 555 $cm^{-1}$ for the boat cyclohexane), whereas a less good agreement is observed for the $A''$ class (29 781 $cm^{-1}$ for the chair vs. 29 718 $cm^{-1}$ for the boat form). While it is difficult to assess how much of this difference is real, and no additional theoretical argument can be presently invoked in this matter, it remains that the sums of vibrational frequencies appear to be nearly the same, 72 334 $cm^{-1}$ for the chair and 72 273 $cm^{-1}$ for the boat cyclohexane.

The individual zero-point (ZPE) and thermal vibrational energies ($E_{vibr}$) can be estimated in the harmonic oscillator approximation form eqs. [2] and [3], i.e.,

$$[2] \quad \text{ZPE} = N_{av} \sum_i h\nu_i/2$$

$$[3] \quad E_{vibr} = N_{av} \sum_i h\nu_i \exp(-h\nu_i/kT) \div [1 - \exp(-h\nu_i/kT)]$$

Using the calculated frequencies indicated in Table 2, we obtain (in kcal/mol at 298.15 K) ZPE = 103.41 and $E_{vibr}$ = 1.85, giving a total of 105.26 in vibrational energy for the chair form. Similarly, using the experimental results of Table 1 plus the 5 calculated values for the nonobserved vibrations, we find ZPE = 103.40, $E_{vibr}$ = 1.86 and a total of 105.26 kcal/mol. On the other hand, considering now boat cyclohexane (Table 2), the values are ZPE = 103.32 and $E_{vibr}$ = 1.92, for a total of 105.24 kcal/mol in vibrational energy. Finally, using the Snyder and Schachtschneider results (7), we obtain ZPE = 103.30, $E_{vibr}$ = 1.87 and a total of 105.17 kcal/mol. We may conclude from this analysis that the chair and boat cyclohexanes do not differ from one another in their vibrational energy content, at least not to any significant extent.

It is also instructive to consider selected ZPE + $E_{vibr}$ results derived from eq. [1]. These were deduced from $\Delta E_a^*$ energies calculated from charge distributions (1–3), experimental enthalpies of formation, $\Delta H_f^0$(298.15 K, gas), and the appropriate enthalpies $\Delta H_f^0$(C) = 170.89 and $\Delta H_f^0$(H) = 52.09 kcal/mol (13). The results are indicated in Table 3.

We note, to begin with, that the ZPE + $E_{vibr}$ results derived from eq. [1] are in good agreement with their spectroscopic counterparts, namely, for cyclohexane. This sort of agreement is, indeed, verified for a total of ~80 molecules (1–4): their enthalpies of formation were deduced from calculated $\Delta E_a^*$ energies and the appropriate ZPE + $E_{vibr}$ data (eq. [1]), with an average deviation (< 0.2 kcal/mol) which is well within experimental uncertainties. Next, we observe that the *trans-anti-trans* and the *trans-syn-trans* perhydroanthracenes, which differ only because of the center boat in the former compound, have virtually the same ZPE + $E_{vibr}$ energy. Finally the results indicate that adamantane and its (all twist–boat) structural isomer

TABLE 3. Calculation of ZPE + $E_{vibr}$ from eq. [1] (kcal/mol)

| Molecule[a] | $\Delta E_a^{*b}$ | $\Delta H_f^0$ | ZPE + $E_{vibr}$ from Eq. [1] | ZPE + $E_{vibr}$ from Eqs. [2], [3] |
|---|---|---|---|---|
| Cyclohexane | 1760.81 | −29.50 | 105.18 | 105.2 |
| Bicyclo[2.2.2]octane | 2218.53 | −23.75 | 128.61 | 128.46 |
| *trans*-Decalin | 2815.57 | −43.52 | 164.63 | 164.53 |
| *trans-syn-trans*-PHA | 3870.15 | −58.13 | 223.31 | |
| *trans-anti-trans*-PHA | 3865.08 | −52.74 | 223.63 | |
| Adamantane | 2688.01 | −30.65 | 151.16 | 151.17 |
| Twistane | 2979.0 | −21.6 | 151.2 | |

[a]PHA = Perhydroanthracene.
[b]The $\Delta E_a^*$ values are extracted from refs. 1–4. The $\Delta H_f^0$ values are from ref. 14 (cyclohexane, PHA, and *trans*-decalin), ref. 15 (bicyclo[2.2.2]octane and adamantane), and ref. 3 (twistane). The ZPE + $E_{vibr}$ results are taken from refs. 2 and 15 (for bicyclo[2.2.2]octane).

twistane also have the same total vibrational energy. This type of analysis, which was carried further in an earlier work (2), indicates a near invariance of vibrational energies with respect to chair–boat conformational changes of the cyclohexane ring. These results are now supported by the present vibrational analyses of isolated cyclohexane in its chair and boat forms.

# Simulation of edge-effects in electroanalytical experiments by orthogonal collocation. Part 1. Two-dimensional collocation and theory for chronoamperometry

BERND SPEISER AND STANLEY PONS
*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*
Received November 26, 1981

BERND SPEISER and STANLEY PONS. Can. J. Chem. **60**, 1352 (1982).

A two-dimensional model to describe edge-effects at planar circular disc electrodes has been developed. Two-dimensional orthogonal collocation is used to discretize the corresponding partial differential equations. The equations for the simulation of a chronoamperometric experiment are derived.

BERND SPEISER et STANLEY PONS. Can. J. Chem. **60**, 1352 (1982).

On a mis au point une méthode bidimensionnelle pour décrire les effets d'arète au niveau des électrodes à disques circulaires plans. On a utilisé une disposition orthogonale pour les équations différentielles partielles correspondantes. On a dérivé les équations de la simulation d'une expérience de chronoampérométrie.

## Introduction

One common simplification in the theoretical treatment of electrode processes of planar disc electrodes is the assumption of semi-infinite linear diffusion. This results in the reduction of the three-dimensional system to a one-dimensional model, where the distance $x$ from the electrode surface is the only coordinate to be considered. Consequently, the three-dimensional form of Fick's second law

$$[1] \qquad \frac{\partial c}{\partial t} = D\left[\frac{\partial^2 c}{\partial x^2} + \frac{\partial^2 c}{\partial y^2} + \frac{\partial^2 c}{\partial z^2}\right]$$

reduces to the simpler differential equation

$$[2] \qquad \frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2}$$

and the mathematical and computational efforts decrease considerably. The assumption of linear diffusion to a planar electrode might imply an infinite disc without edges. For real systems, however, this of course is not possible.

Thus, measurements at finite disc electrodes should deviate from the simple one-dimensional theory. In fact, it has been shown for different electroanalytical techniques such as chronoamperometry and chronopotentiometry (1) that the diffusion current is higher than expected from the theoretical calculations based on eq. [2], i.e. the Cottrell equation (2) for chronoamperometry. For cyclic voltammograms (3) the peak separation is larger than the theoretical values given by Nicholson and Shain (4). A number of papers have accounted for these deviations as being due to additional diffusion from directions other than perpendicular to the disc electrode (see e.g. refs. 5, 6). In a system with several coupled charge transfer and chemical reactions dramatic changes of the overall voltammogram have been attributed to edge effects (7).

Several attempts have been made to calculate the effects of edge diffusion and to simulate model systems without assuming one-dimensional diffusion (5, 6). Recently, Heinze published a two-dimensional model based on the finite difference method (8, 9), while Oldham (10) and Aoki and Osteryoung (11) developed analytical solutions for the simple reversible mechanism.

These calculations showed, in agreement with experiments, that edge diffusion rates increase with increasing time and decreasing radius of the disc electrode. The deviation from pure Cottrell behavior is claimed to be between 9 and 10% for typical conditions: diffusion coefficient = $10^{-5}$ cm$^2$/s, electrode radius 0.1 cm, electrolysis time 2.65 s (5, 9–11). All methods presented thus far, however, demonstrate results for only the simplest mechanisms (e.g. reversible electron transfer case). Extensions apparently require extensive computational effort.

Orthogonal collocation has been shown to provide a powerful method to simulate responses of several electroanalytical techniques to a variety of mechanisms (12–18). Up to now all these calculations have been performed using one-dimensional diffusion models. We want to report the construction of a two-dimensional model for the diffusion to and from a planar disc electrode and the discretization of the resulting second order partial differential equations to give a set of simultaneous first order ordinary differential equations.

The comparison of the results of this new model with those already presented is the subject of a

separate report now in preparation. Extensions to other mechanisms and electroanalytical experiments will also be considered.

### The two-dimensional model

Consider a planar, circular disc of conducting material imbedded into an insulator (Fig. 1). The radius of the disc is $r_0$. The radius $r_0'$, of the insulator may go to infinity. From the symmetry of the problem, it follows that we may use two coordinates $x$ (perpendicular to the disc) and $r$ (along the radius vector of the disc). We are required to calculate the concentration $c$ of all species as a function of $x$, $r$ and the time $t$, where $c$ is given by second order partial differential equations of the type (9)

$$[3] \qquad \frac{\partial c}{\partial t} = D\left[\frac{\partial^2 c}{\partial x^2} + \frac{1}{r}\frac{\partial c}{\partial r} + \frac{\partial^2 c}{\partial r^2}\right] - f(c)$$

and $f(c)$ is determined by the kinetics of the system investigated. $D$ is the diffusion coefficient.

Let us consider an EC-mechanism (4). There the differential equations describing the concentration of species A, B, and C are given by [5]–[7].

$$[4] \qquad A \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} B \xrightarrow{k} C$$

$$[5] \qquad \frac{\partial c_A}{\partial t} = D_A\left[\frac{\partial c_A}{\partial x^2} + \frac{1}{r}\frac{\partial c_A}{\partial r} + \frac{\partial^2 c_A}{\partial r^2}\right]$$

$$[6] \qquad \frac{\partial c_B}{\partial t} = D_B\left[\frac{\partial^2 c_B}{\partial x^2} + \frac{1}{r}\frac{\partial c_B}{\partial r} + \frac{\partial^2 c_B}{\partial r^2}\right] - kc_B$$

$$[7] \qquad \frac{\partial c_C}{\partial t} = D_C\left[\frac{\partial^2 c_C}{\partial x^2} + \frac{1}{r}\frac{\partial c_C}{\partial r} + \frac{\partial^2 c_C}{\partial r^2}\right] + kc_B$$

For $k = 0$ we deal with a simple reversible electron transfer. The electrode reaction in eq. [4] is drawn as an oxidation but the extension to reductions is immediate. For simplification we may assume that the diffusion coefficients are equal:

$$[8] \qquad D_A = D_B = D_C$$

This, however, is not necessary for orthogonal collocation simulations.

Depending on the electroanalytical method we wish to simulate for the mechanism chosen, certain initial and boundary conditions are imposed upon the solution of eq. [3]. Let us consider a chronoamperometric experiment, where species A, the substrate, is present at a homogeneous concentration $c_A^0$ at the beginning of the experiment. The product species B and C may not be present at $t = 0$ (initial conditions [9], [10]).

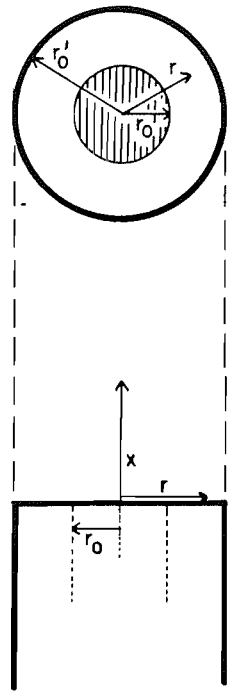

FIG. 1. Geometry of the two-dimensional model.

$t = 0,\ x \geq 0,\ r \geq 0$

$$[9] \qquad c_A(x, r, 0) = c_A^0$$

$$[10] \qquad c_B(x, r, 0) = c_C(x, r, 0) = 0$$

At the boundary $x \to \infty$, i.e. at a distance $x$ far from the electrode where the concentrations are not changed during the experiment:

$t > 0,\ x \to \infty,\ r \geq 0$

$$[11] \qquad c_A(\infty, r, t) = c_A^0$$

$$[12] \qquad c_B(\infty, r, t) = c_C(\infty, r, t) = 0$$

The same condition may hold for a distance $r$ far from the electrode radially:

$t > 0,\ x \geq 0,\ r \to \infty$

$$[13] \qquad c_A(x, \infty, t) = c_A^0$$

$$[14] \qquad c_B(x, \infty, t) = c_C(x, \infty, t) = 0$$

At the electrode surface the Nernst equation has to be fulfilled for $c_A$ and $c_B$ (eq. [14*a*]). If we step to a potential $E$ at least 200 mV past the formal potential $E_{A/B}^0$ the concentration of the substrate A at the electrode is immediately forced to zero and [14*a*] may be replaced by [14*b*]. Additional conditions at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

the electrode surface are given by the flux equations [15] and [16].

$t > 0,\ x = 0,\ 0 \leq r \leq r_0$

$$[14a] \quad \frac{c_A(0, r, t)}{c_B(0, r, t)} = \exp\left[\frac{nF}{RT}(E^0 - E)\right]$$

$$[14b] \quad c_A(0, r, t) = 0$$

$$[15] \quad \left(\frac{\partial c_A}{\partial x}\right)_{x=0} = -\left(\frac{\partial c_B}{\partial x}\right)_{x=0}$$

$$[16] \quad \left(\frac{\partial c_C}{\partial x}\right)_{x=0} = 0$$

At $x = 0$, but outside the electroactive area ($r > r_0$), no species may undergo electron transfer and we have boundary condition [17].

$t > 0,\ x = 0,\ r_0 \leq r \rightarrow \infty$

$$[17] \quad \left(\frac{\partial c_A}{\partial x}\right)_{x=0} = \left(\frac{\partial c_B}{\partial x}\right)_{x=0} = \left(\frac{\partial c_C}{\partial x}\right)_{x=0} = 0$$

Because of the symmetry of the problem there may be no net flux of any species across the $x$-axis at the center of the electrode ($r = 0$).

$t > 0,\ x \geq 0,\ r = 0$

$$[18] \quad \left(\frac{\partial c_A}{\partial r}\right)_{r=0} = \left(\frac{\partial c_B}{\partial r}\right)_{r=0} = \left(\frac{\partial c_C}{\partial r}\right)_{r=0} = 0$$

Equations [4]–[18] describe the two-dimensional model system for an EC-mechanism under chronoamperometric conditions.

Since there are different boundary conditions for $x = 0$ inside ($r \leq r_0$) and outside ($r > r_0$) the electrode, it is convenient to describe the whole system by two concentration functions $c_1$ and $c_2$ which are defined for $0 \leq r \leq r_0$ and $r_0 < r$ respectively. To avoid discontinuities at $r = r_0$ we have to apply some additional "boundary" conditions for all species:

$$[19] \quad c_1(x, r_0, t) = c_2(x, r_0, t)$$

The second derivative of $c$ with respect to $r$ is only defined if the first derivative with respect to $r$ has no discontinuity at $r = r_0$ and this gives the further conditions

$$[20] \quad \left(\frac{\partial c_1}{\partial r}\right)_{r_0} = \left(\frac{\partial c_2}{\partial r}\right)_{r_0}$$

for all species.

It has been pointed out (12) that orthogonal collocation may be applied only to dimensionless systems which have been converted from semi-infinite models to models in the range 0 to 1.

In order to meet these requirements we use the following transformation equations:

$$[21] \quad X = x/L$$

$$[22] \quad c^* = c/c_A^0$$

$$[23a] \quad R = r/r_0$$

$$[23b] \quad R' = (r - r_0)/(M - r_0)$$

$$[24] \quad \alpha = k \cdot r_0^2/D$$

$$[25] \quad T' = Dt/r_0^2$$

where $X$ is the dimensionless distance from the electrode, $L$ is the distance from the electrode in the $x$ direction defined so that at $X = L$ no changes in concentration take place during the time of the experiment, $c^*$ is the dimensionless concentration, $R$ and $R'$ are the dimensionless distances in the $r$ direction inside and outside the electrode disc respectively, $M$ is the distance in the $r$ direction defined in the same manner as $L$, and $T'$ is the dimensionless simulation time.

Application of eqs. [21]–[25] and the subdivision into inner and outer functions $c_1$ and $c_2$ of eqs. [4]–[18] yield the dimensionless model [26]–[33]

$$[26] \quad \frac{\partial c_{A1}^*}{\partial T'} = \beta \frac{\partial^2 c_{A1}^*}{\partial X^2} + \frac{1}{R}\frac{\partial c_{A1}^*}{\partial R} + \frac{\partial^2 c_{A1}^*}{\partial R^2}$$

$$[27] \quad \frac{\partial c_{B1}^*}{\partial T'} = \beta \frac{\partial^2 c_{B1}^*}{\partial X^2} + \frac{1}{R}\frac{\partial c_{B1}^*}{\partial R} + \frac{\partial^2 c_{B1}^*}{\partial R^2} - \alpha c_{B1}^*$$

$$[28] \quad \frac{\partial c_{C1}^*}{\partial T'} = \beta \frac{\partial^2 c_{C1}^*}{\partial X^2} + \frac{1}{R}\frac{\partial c_{C1}^*}{\partial R} + \frac{\partial^2 c_{C1}^*}{\partial R^2} + \alpha c_{B1}^*$$

where

$$[29] \quad \beta = r_0^2/L^2$$

and

$$[30] \quad \frac{\partial c_{A2}^*}{\partial T'} = \beta \frac{\partial^2 c_{A2}^*}{\partial X^2} + \frac{\beta'}{R' + \sqrt{\beta'}}\frac{\partial c_{A2}^*}{\partial R'} + \beta' \frac{\partial^2 c_{A2}^*}{\partial R'^2}$$

$$[31] \quad \frac{\partial c_{B2}^*}{\partial T'} = \beta \frac{\partial^2 c_{B2}^*}{\partial X^2} + \frac{\beta'}{R' + \sqrt{\beta'}}\frac{\partial c_{B2}^*}{\partial R'} + \beta' \frac{\partial^2 c_{B2}^*}{\partial R'^2} - \alpha c_{B2}^*$$

$$[32] \quad \frac{\partial c_{C2}^*}{\partial T'} = \beta \frac{\partial^2 c_{C2}^*}{\partial X^2} + \frac{\beta'}{R' + \sqrt{\beta'}}\frac{\partial c_{C2}^*}{\partial R'} + \beta' \frac{\partial^2 c_{C2}^*}{\partial R'^2} + \alpha c_{B2}^*$$

with the initial conditions

$T' = 0,\ 0 \le X \le 1,\ 0 \le R \le 1,\ 0 \le R' \le 1$

[34] $c^*_{A1}(X, R, 0) = c^*_{A2}(X, R', 0) = 1$

[35] $c^*_{B1}(X, R, 0) = c^*_{C1}(X, R, 0) = c^*_{B2}(X, R', 0) = c^*_{C2}(X, R', 0) = 0$

and boundary conditions

$T' > 0,\ X = 1,\ 0 \le R \le 1$

[36] $c^*_{A1}(1, R, T') = 1$

[37] $c^*_{B1}(1, R, T') = c^*_{C1}(1, R, T') = 0$

$T' > 0,\ X = 1,\ 0 \le R' \le 1$

[38] $c^*_{A2}(1, R', T') = 1$

[39] $c^*_{B2}(1, R', T') = c^*_{C2}(1, R', T') = 0$

$T' > 0,\ 0 \le X \le 1,\ R' = 1$

[40] $c^*_{A2}(X, 1, T') = 1$

[41] $c^*_{B2}(X, 1, T') = c^*_{C2}(X, 1, T') = 0$

$T' > 0,\ X = 0,\ 0 \le R \le 1$

[42a] $\dfrac{c^*_{A1}(0, R, T')}{c^*_{B1}(0, R, T')} = \exp\left[\dfrac{nF}{RT}(E^0 - E)\right]$

[42b] $c^*_{A1}(0, R, T') = 0$

[43] $\left(\dfrac{\partial c^*_{A1}}{\partial X}\right)_{X=0} = -\left(\dfrac{\partial c^*_{B1}}{\partial X}\right)_{X=0}$

[44] $\left(\dfrac{\partial c^*_{C1}}{\partial X}\right)_{X=0} = 0$

$T' > 0,\ X = 0,\ 0 < R' \le 1$

[45] $\left(\dfrac{\partial c^*_{A2}}{\partial X}\right)_{X=0} = \left(\dfrac{\partial c^*_{B2}}{\partial X}\right)_{X=0} = \left(\dfrac{\partial c^*_{C2}}{\partial X}\right)_{X=0} = 0$

$T' > 0,\ 0 \le X \le 1,\ R = 0$

[46] $\left(\dfrac{\partial c^*_{A1}}{\partial R}\right)_{R=0} = \left(\dfrac{\partial c^*_{B1}}{\partial R}\right)_{R=0} = \left(\dfrac{\partial c^*_{C1}}{\partial R}\right)_{R=0} = 0$

$T' > 0,\ 0 \le X \le 1,\ R = 1\ (R' = 0)$

[47] $c^*_{A1}(X, 1, T') = c^*_{A2}(X, 0, T')$

[48] $c^*_{B1}(X, 1, T') = c^*_{B2}(X, 0, T')$

[49] $c^*_{C1}(X, 1, T') = c^*_{C2}(X, 0, T')$

[50] $\left(\dfrac{\partial c^*_{A1}}{\partial R}\right)_{R=1} = \sqrt{\beta'}\left(\dfrac{\partial c^*_{A2}}{\partial R'}\right)_{R'=0}$

[51] $\left(\dfrac{\partial c^*_{B1}}{\partial R}\right)_{R=1} = \sqrt{\beta'}\left(\dfrac{\partial c^*_{B2}}{\partial R'}\right)_{R'=0}$

[52] $\left(\dfrac{\partial c^*_{C1}}{\partial R}\right)_{R=1} = \sqrt{\beta'}\left(\dfrac{\partial c^*_{C2}}{\partial R'}\right)_{R'=0}$

We have to calculate the inner and outer concentrations of species A, B, and C respectively as a function of $X$, $R(R')$, and $T'$.

### Two-dimensional collocation

Orthogonal collocation uses a mathematically suitable trial function to describe the solution of a differential equation at certain points. If one uses a set of weighted orthogonal polynomials as the trial function, the differential equation is satisfied at the zeroes of the polynomial of highest order used (19, 20) for a set of coefficients which depend on time.

To perform orthogonal collocation in two-dimensions, $x$ and $r$, we use a trial function depending on $x$ and $r$

[53] $$c(x, r, t) = \lambda_{1,1}x^0r^0 + \lambda_{2,1}x^1r^0 + \ldots + \lambda_{N_x+2,1}x^{N_x+2-1}r^0 + \lambda_{1,2}x^0r^1 + \lambda_{2,2}x^1r^1 + \ldots + \lambda_{N_x+2,2}x^{N_x+2-1}r^1 + \ldots + \lambda_{1,N_r+2}x^0r^{N_r+2-1} + \lambda_{2,N_r+2}x^1r^{N_r+2-1} + \ldots + \lambda_{N_x+2,N_r+2}x^{N_x+2-1}r^{N_r+2-1}$$

or

[54] $$c(x, r, t) = \sum_{l=1}^{N_r+2}\sum_{j=1}^{N_x+2}\lambda_{j,l}x^{j-1}r^{l-1}$$

i.e. we represent the concentration by a polynomial in $x$ and $r$ whose time-dependent coefficients are the $\lambda_{j,l}$. The polynomial is of order $N_x + 2$ and $N_r + 2$ with respect to $x$ and $r$, respectively. The dummy variables $j$ and $l$ perform the summations over the powers of $x$ and $r$ respectively.

The coefficients are determined thus, that at all collocation points $(x_i, r_k)$, i.e. $N_x + 2$ and $N_r + 2$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

points in the $x$ and $r$ directions, respectively

$$[55] \quad c(x_i, r_k, t) = \sum_{l=1}^{N_r+2} \sum_{j=1}^{N_x+2} \lambda_{j,l} x_i^{j-1} r_k^{l-1}$$

The concentrations at the collocation points may be the elements of a concentration matrix $\Gamma_{i,k}$

$$[56] \quad \Gamma_{i,k} = \mathbf{X}_{i,j} \cdot \Lambda_{j,l} \mathbf{R}^{\mathrm{T}}_{k,l}$$

which is calculated by multiplication of a matrix $\mathbf{X}_{i,j}$, containing the $x_i^{j-1}$ as elements, a matrix $\Lambda_{j,l}$, containing the elements $\lambda_{j,l}$, and a matrix $\mathbf{R}^{\mathrm{T}}_{k,l}$, containing the elements $r_k^{l-1}$. The superscript T denotes a transposed matrix.

Now we can calculate the first and second derivatives of the concentration at the collocation points with respect to $x$ and $r$ respectively:

$$[57] \quad \Gamma^{x}_{i,k} = \mathbf{X}^{x}_{i,j} \cdot \Lambda_{j,l} \cdot \mathbf{R}^{\mathrm{T}}_{k,l}$$

$$[58] \quad \Gamma^{xx}_{i,k} = \mathbf{X}^{xx}_{i,j} \cdot \Lambda_{j,l} \cdot \mathbf{R}^{\mathrm{T}}_{k,l}$$

$$[59] \quad \Gamma^{r}_{i,k} = \mathbf{X}_{i,j} \cdot \Lambda_{j,l} \cdot \mathbf{R}^{r\mathrm{T}}_{k,l}$$

$$[60] \quad \Gamma^{rr}_{i,k} = \mathbf{X}_{i,j} \cdot \Lambda_{j,l} \cdot \mathbf{R}^{rr\mathrm{T}}_{k,l}$$

where the superscript $x(r)$ denotes the first and accordingly $xx(rr)$ characterises the second derivative with respect to $x(r)$.

From eq. [56] it follows that

$$[61] \quad \Lambda_{j,l} = \mathbf{X}^{-1}_{i,j} \cdot \Gamma_{i,k} \cdot (\mathbf{R}^{\mathrm{T}}_{k,l})^{-1}$$

After inserting [61] into [57] we arrive at

$$[62] \quad \Gamma^{x}_{i,k} = \mathbf{X}^{x}_{i,j} \cdot \mathbf{X}^{-1}_{i,j} \cdot \Gamma_{i,k} = \mathbf{A}_{i,j} \cdot \Gamma_{i,k}$$

where the first derivative of the concentration with respect to $x$ is expressed as a function of the concentration itself. In analogy eqs. [61] and [58] give

$$[63] \quad \Gamma^{xx}_{i,k} = \mathbf{X}^{xx}_{i,j} \cdot \mathbf{X}^{-1}_{i,j} \cdot \Gamma_{i,k} = \mathbf{B}_{i,j} \cdot \Gamma_{i,k}$$

From [61] and [59] we get

$$[64] \quad \Gamma^{r}_{i,k} = \Gamma_{i,k} \cdot (\mathbf{R}^{\mathrm{T}}_{k,l})^{-1} \cdot \mathbf{R}^{r\mathrm{T}}_{k,l} = \Gamma_{i,k} \cdot (\mathbf{R}^{-1}_{k,l})^{\mathrm{T}} \cdot \mathbf{R}^{r\mathrm{T}}_{k,l} = \Gamma_{i,k} \cdot (\mathbf{R}^{r}_{l,k} \cdot \mathbf{R}^{-1}_{l,k})^{\mathrm{T}}$$

or

$$[65] \quad \Gamma^{r}_{i,k} = \Gamma_{i,k} \cdot \mathbf{C}_{l,k}$$

Analogous from [61] and [60]

$$[66] \quad \Gamma^{rr}_{i,k} = \Gamma_{i,k} \cdot (\mathbf{R}^{rr}_{l,k} \cdot \mathbf{R}^{-1}_{l,k})^{\mathrm{T}} = \Gamma_{i,k} \cdot \mathbf{D}_{l,k}$$

We may calculate the matrices containing the derivatives of the concentration at the collocation points from the concentration matrix once the matrices $\mathbf{A}_{i,j}$, $\mathbf{B}_{i,j}$, $\mathbf{C}_{l,k}$, and $\mathbf{D}_{l,k}$ have been determined. Returning to summation expressions we can write

$$[67] \quad \left(\frac{\partial c}{\partial x}\right)_{x_i, r_k} = \sum_{j=1}^{N_x+2} A_{i,j} c(x_j, r_k, t)$$

$$[68] \quad \left(\frac{\partial^2 c}{\partial x^2}\right)_{x_i, r_k} = \sum_{j=1}^{N_x+2} B_{i,j} c(x_j, r_k, t)$$

$$[69] \quad \left(\frac{\partial c}{\partial r}\right)_{x_i, r_k} = \sum_{l=1}^{N_r+2} C_{l,k} c(x_i, r_l, t)$$

and

$$[70] \quad \left(\frac{\partial^2 c}{\partial r^2}\right)_{x_i, r_k} = \sum_{l=1}^{N_r+2} D_{l,k} c(x_i, r_l, t)$$

As has been pointed out by Whiting and Carr (12) for the one-dimensional case, the matrices $\mathbf{A}_{i,j}$, $\mathbf{B}_{i,j}$, $\mathbf{C}_{l,k}$, and $\mathbf{D}_{l,k}$ depend solely on the type of polynomial used as trial function and may be calculated from the zeroes of this polynomial. This has to be done only once. Using the values of the elements of those matrices we are able to express the differential quotients of $c$ with respect to $x$ and $r$ at all collocation points.

For linear diffusion problems it has been shown that Legendre polynomials are most suitable (12). Pons (18) used Chebysheff polynomials for diffusion under spherical geometry. It may be noted, however, that the choice of the trial function does not have a large effect on the accuracy of the solutions for higher order approximations. In general, the best trial function is determined by the symmetry of the problem.

In this work, Legendre polynomials have been used for discretization along the $x$-coordinate. The collocation in the direction of the $r$-coordinate has been performed using different types of functions including Legendre, Chebysheff, and polynomials constructed from even powers of $r$, which is suggested by the symmetry of the problem around $r = 0$ (19).

### Discretization of the equations for chronoamperometry

We can substitute the summation expressions [67]–[70] for the partial differential quotients in eqs. [26]–[28] and [30]–[32]. This yields expressions for the time derivative of the concentration of species A, B, and C at all the collocation points as a function of the concentrations at the collocation points. If we substitute the boundary conditions [36]–[41], [42*b*] (i.e. we assume a step to a potential far behind $E^0$) and [47]–[49], we arrive at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

$$[71]\quad \left.\frac{dc^*_{A1}}{dT'}\right|_{X_i,R_k} = \beta\cdot\left\{B_{i,N_x+2} + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{A1}(X_j, R_k, T')\right\} + \left\{E_{1,k}c^*_{A1}(X_i, 0, T') + E_{N_R+2,k}c^*_{A1}(X_i, 1, T') + \sum_{l=2}^{N_R+1} E_{l,k}c^*_{A1}(X_i, R_l, T')\right\}$$

$$[72]\quad \left.\frac{dc^*_{B1}}{dT'}\right|_{X_i,R_k} = \beta\cdot\left\{B_{i,1}c^*_{B1}(0, R_k, T') + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{B1}(X_j, R_k, T')\right\} + \left\{E_{1,k}c^*_{B1}(X_i, 0, T') + E_{N_R+2,k}c^*_{B1}(X_i, 1, T') + \sum_{l=2}^{N_R+1} E_{l,k}c^*_{B1}(X_i, R_l, T')\right\} - \alpha c^*_{B1}$$

$$[73]\quad \left.\frac{dc^*_{C1}}{dT'}\right|_{X_i,R_k} = \beta\left\{B_{i,1}c^*_{C1}(0, R_k, T') + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{C1}(X_j, R_k, T')\right\} + \left\{E_{1,k}c^*_{C1}(X_i, 0, T') + E_{N_R+2,k}c^*_{C1}(X_i, 1, T') + \sum_{l=2}^{N_R+1} E_{l,k}c^*_{C1}(X_i, R_l, T')\right\} + \alpha c^*_{B1}$$

$$[74]\quad \left.\frac{dc^*_{A2}}{dT'}\right|_{X_i,R_{k'}} = \beta\left\{B_{i,1}c^*_{A2}(0, R'_k, T') + B_{i,N_x+2} + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{A2}(X_j, R'_k, T')\right\} + \beta'\left\{F'_{1,k}c^*_{A2}(X_i, 0, T') + F'_{N_{R'}+2,k} + \sum_{l=2}^{N_{R'}+1} F'_{l,k}c^*_{A2}(X_i, R'_l, T')\right\}$$

$$[75]\quad \left.\frac{dc^*_{B2}}{dT'}\right|_{X_i,R_{k'}} = \beta\left\{B_{i,1}c^*_{B2}(0, R'_k, T') + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{B2}(X_j, R'_k, T')\right\} + \beta'\left\{F'_{1,k}c^*_{B2}(X_i, 0, T') + \sum_{l=2}^{N_{R'}+1} F'_{l,k}c^*_{B2}(X_i, R'_l, T')\right\} - \alpha c^*_{B2}$$

$$[76]\quad \left.\frac{dc^*_{C2}}{dT'}\right|_{X_i,R_{k'}} = \beta\left\{B_{i,1}c^*_{C2}(0, R'_k, T') + \sum_{j=2}^{N_x+1} B_{i,j}c^*_{C2}(X_j, R'_k, T')\right\} + \beta'\left\{F'_{1,k}c^*_{C2}(X_i, 0, T') + \sum_{l=2}^{N_{R'}+1} F'_{l,k}c^*_{C2}(X_i, R'_l, T')\right\} + \alpha c^*_{B2}$$

where

$$[77]\quad E_{l,k} = \frac{C_{l,k} + R_k D_{l,k}}{R_k}$$

and

$$[78]\quad F'_{l,k} = \frac{C'_{l,k}}{\sqrt{\beta'} + R'_k} + D'_{l,k}$$

The primed terms, except $T'$ and $\beta'$, correspond to the outer functions. Equations [71]–[76] contain $9N_x + 2N_R + 3N_{R'}$ unknowns, i.e. $c^*_{A1}(X_i, 0, T')$, $c^*_{A1}(X_i, 1, T')$, $c^*_{B1}(X_i, 0, T')$, $c^*_{B1}(X_i, 1, T')$, $c^*_{C1}(X_i, 0, T')$, $c^*_{C1}(X_i, 1, T')$, $c^*_{A2}(X_i, 0, T')$, $c^*_{B2}(X_i, 0, T')$, $c^*_{C2}(X_i, 0, T')$ for all $X_i$; $c^*_{B1}(0, R_k, T')$ and $c^*_{C1}(0, R_k, T')$ for all $R_k$; $c^*_{A2}(0, R'_k, T')$, $c^*_{B2}(0, R'_k, T')$, $c^*_{C2}(0, R'_k, T')$ for all $R'_k$ which may be computed from the boundary conditions as is shown below.

Condition [43] yields

$$[79]\quad \sum_{j=1}^{N_x+2} A_{1,j}c^*_{A1}(X_j, R_k, T') = -\sum_{j=1}^{N_x+2} A_{1,j}c^*_{B1}(X_j, R_k, T')$$

Expanding the sums, introducing [36], [37], and [42*b*], and solving for the concentration of species B at the electrode surface ($X_1 = 0$) gives:

[80] $$c^*_{B1}(0, R_k, T') = -\frac{1}{A_{1,1}}\left\{A_{1,N_x+2} + \sum_{j=2}^{N_x+1} A_{1,j}[c^*_{A1}(X_j, R_k, T') + c^*_{B1}(X_j, R_k, T')]\right\}$$

Condition [44] is changed to

$$\sum_{j=1}^{N_x+2} A_{1,j} c^*_{C1}(X_j, R_k, T') = 0$$

which gives, after introduction of [37],

[81] $$c^*_{C1}(0, R_k, T') = -\frac{1}{A_{1,1}} \sum_{j=2}^{N_x+1} A_{1,j} c^*_{C1}(X_j, R_k, T')$$

In analogy it may be derived from [45] and [40] or [41]

[82] $$c^*_{A2}(0, R'_k, T') = -\frac{1}{A_{1,1}}\left\{A_{1,N_x+2} + \sum_{j=2}^{N_x+1} A_{1,j} c^*_{A2}(X_j, R'_k, T')\right\}$$

[83] $$c^*_{B2}(0, R'_k, T') = -\frac{1}{A_{1,1}} \sum_{j=2}^{N_x+1} A_{1,j} c^*_{B2}(X_j, R'_k, T')$$

and

[84] $$c^*_{C2}(0, R'_k, T') = -\frac{1}{A_{1,1}} \sum_{j=2}^{N_x+1} A_{1,j} c^*_{C2}(X_j, R'_k, T')$$

The condition [46] gives, for species A, B, and C

[85] $$c^*_{A1}(X_i, 0, T') = -\frac{1}{C_{1,1}}\left\{C_{N_R+2,1} c^*_{A1}(X_i, 1, T') + \sum_{l=2}^{N_R+1} C_{l,1} c^*_{A1}(X_i, R_l, T')\right\}$$

[86] $$c^*_{B1}(X_i, 0, T') = -\frac{1}{C_{1,1}}\left\{C_{N_R+2,1} c^*_{B1}(X_i, 1, T') + \sum_{l=2}^{N_R+1} C_{l,1} c^*_{B1}(X_i, R_l, T')\right\}$$

and

[87] $$c^*_{C1}(X_i, 0, T') = -\frac{1}{C_{1,1}}\left\{C_{N_R+2,1} c^*_{C1}(X_i, 1, T') + \sum_{l=2}^{N_R+1} C_{l,1} c^*_{C1}(X_i, R_l, T')\right\}$$

Condition [50] yields

[88] $$\sum_{l=1}^{N_R+2} C_{l,N_R+2} c^*_{A1}(X_i, R_l, T') = \sum_{l=1}^{N_R+2} \sqrt{\beta'}\, C'_{l,1} c^*_{A2}(X_i, R'_l, T')$$

which may be expanded and transformed using [40] and [47]

[89] $$[c_{N_R+2,N_R+2} - \sqrt{\beta'}\, C'_{1,1}] \cdot c^*_{A1}(X_i, 1, T') + C_{1,N_R+2} c^*_{A1}(X_i, 0, T') = -\sum_{l=2}^{N_R+1} C_{l,N_R+2} c^*_{A1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} \sqrt{\beta'}\, C'_{l,1} c^*_{A2}(X_i, R'_l, T') + \sqrt{\beta'}\, C'_{N_{R'}+2,1}$$

From [85] and [89] it follows that

[90] $$c^*_{A1}(X_i, 1, T') = c^*_{A2}(X_i, 0, T') = \frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1} H_l c^*_{A1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} C_{1,1}\sqrt{\beta'}\, C'_{l,1} c^*_{A2}(X_i, R'_l, T') + C_{1,1}\sqrt{\beta'}\, C'_{N_{R'}+2,1}\right\}$$

where

[91] $$G_l = [C_{N_R+2,N_R+2} - \sqrt{\beta'}\, C'_{1,1}] C_{l,1} - C_{l,N_R+2} C_{N_R+2,1}$$

and

[92] $H_l = C_{1,N_R+2}C_{l,1} - C_{1,1}C_{l,N_R+2}$

Conditions [46] and [51] ([46] and [52]) are treated similarly using the corresponding boundary expressions. Thus,

[93] $$c^*_{B1}(X_i, 1, T') = c^*_{B2}(X_i, 0, T') = \frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1} H_l c^*_{B1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} C_{1,1}\sqrt{\beta'}\, C'_{l,1} c^*_{B2}(X_i, R'_l, T')\right\}$$

and

[94] $$c^*_{C1}(X_i, 1, T') = c^*_{C2}(X_i, 0, T') = \frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1} H_l c^*_{C1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} C_{1,1}\sqrt{\beta'}\, C_{l,1} c^*_{C2}(X_i, R'_l, T')\right\}$$

Finally, the concentrations of species A at $R = 0$ and all $X_i$ may be calculated by introducing [90] into [85]:

[95] $$c^*_{A1}(X_i, 0, T') = -\frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1} G_l c^*_{A1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} C_{N_R+2,1}\sqrt{\beta'}\, C'_{l,1} c^*_{A2}(X_i, R'_l, T') + C_{N_R+2,1}\sqrt{\beta'}\, C'_{N_{R'}+2,1}\right\}$$

while it holds from [93] and [86] ([94] and [87]), that

[96] $$c^*_{B1}(X_i, 0, T') = -\frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1} G_l c^*_{B1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} C_{N_R+2,1}\sqrt{\beta'}\, C'_{l,1} c^*_{B2}(X_i, R'_l, T')\right\}$$

and that

[97] $$c^*_{C1}(X_i, 0, T') = -\frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1} G_l c^*_{C1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} C_{N_R+2,1}\sqrt{\beta'}\, C'_{l,1} c^*_{C2}(X_i, R'_l, T')\right\}$$

Now we may substitute the unknown terms in eqs. [71]–[76]. From [71], using [90] and [95] it follows

[98] $$\left.\frac{dc^*_{A1}}{dT'}\right|_{X_i,R_k} = \beta\left\{B_{i,N_x+2} + \sum_{j=2}^{N_x+1} B_{i,j} c^*_{A1}(X_j, R_k, T')\right\} + \frac{1}{G_1}\left\{I_{1,k}\sqrt{\beta'}\, C'_{N_{R'}+2,1} + \sum_{l=2}^{N_R+1}\left[J_{l,k}(\sqrt{\beta'}\, C'_{1,1} - C_{N_R+2,N_R+2}) - I_{1,k}C_{l,N_R+2} + I_{l,k}C_{1,N_R+2}\right]\cdot c^*_{A1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} I_{1,k}\sqrt{\beta'}\, C_{l,1} c^*_{A2}(X_i, R'_l, T')\right\}$$

where

[99] $I_{l,k} = E_{N_R+2,k}C_{l,1} - E_{l,k}C_{N_R+2,1}$

and

[100] $J_{l,k} = E_{1,k}C_{l,1} - E_{l,k}C_{1,1}$

Combination of [72] with [80], [93], and [96] gives

[101] $$\left.\frac{dc^*_{B1}}{dT'}\right|_{X_i,R_k} = \frac{\beta}{A_{1,1}}\left\{\sum_{j=2}^{N_x+1} K_{i,j} c^*_{B1}(X_j, R_k, T') - B_{i,1}\left[A_{1,N_x+2} + \sum_{j=2}^{N_x+1} A_{1,j} c^*_{A1}(X_j, R_k, T')\right]\right\} + \frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1}\left[J_{l,k}(\sqrt{\beta'}\, C'_{1,1} - C_{N_R+2,N_R+2}) - I_{1,k}C_{l,N_R+2} + I_{l,k}C_{1,N_R+2}\right]c^*_{B1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} I_{1,k}\sqrt{\beta'}\, C_{l,1} c^*_{B2}(X_i, R'_l, T')\right\} - \alpha c^*_{B1}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

where

[102] $K_{i,j} = B_{i,j}A_{1,1} - B_{i,1}A_{1,j}$

For the inner function describing the concentration of species C it holds from [73] with [81], [94] and [97]

$$[103]\quad \left.\frac{dc^*_{C1}}{dT'}\right|_{X_i,R_k} = \frac{\beta}{A_{1,1}}\left\{\sum_{j=2}^{N_x+1} K_{i,j}c^*_{C1}(X_j, R_k, T')\right\} + \frac{1}{G_1}\left\{\sum_{l=2}^{N_R+1}[J_{l,k}(\sqrt{\beta'}\,C'_{1,1} - C_{N_R+2,N_R+2}) - I_{1,k}C_{l,N_R+2} + I_{l,k}C_{1,N_R+2}]c^*_{C1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} I_{1,k}\sqrt{\beta'}\,C'_{l,1}c^*_{C2}(X_i, R'_l, T')\right\} + \alpha c^*_{B1}$$

The outer functions for all three species are derived following the same scheme. The time derivative of $c^*_A$ in the outer domain is found from [74], [82], and [90], and in analogy the corresponding equations for species B or C may be calculated from [75], [83], and [93] or [76], [84], and [94].

$$[104]\quad \left.\frac{dc^*_{A2}}{dT'}\right|_{X_i,R_{k'}} = \frac{\beta}{A_{1,1}}\left\{K_{i,N_x+2} + \sum_{j=2}^{N_x+1} K_{i,j}c^*_{A2}(X_j, R'_k, T')\right\} + \frac{\beta'}{G_1}\left\{L'_{N_R+2,k} + \sum_{l=2}^{N_R+1} F'_{1,k}H_l c^*_{A1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} L'_{l,k}c^*_{A2}(X_i, R'_l, T')\right\}$$

with

[105] $L'_{l,k} = F'_{l,k}G_1 + C_{1,1}\sqrt{\beta'}\,C_{l,1}F'_{1,k}$

$$[106]\quad \left.\frac{dc^*_{B2}}{dT'}\right|_{X_i,R_{k'}} = \frac{\beta}{A_{1,1}}\left\{\sum_{j=2}^{N_x+1} K_{i,j}c^*_{B2}(X_j, R'_k, T')\right\} + \frac{\beta'}{G_1}\left\{\sum_{l=2}^{N_R+1} F'_{1,k}H_l c^*_{B1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} L'_{l,k}c^*_{B2}(X_i, R'_l, T')\right\} - \alpha c^*_{B2}$$

$$[107]\quad \left.\frac{dc^*_{C2}}{dT'}\right|_{X_i,R_{k'}} = \frac{\beta}{A_{1,1}}\left\{\sum_{j=2}^{N_x+1} K_{i,j}c^*_{C2}(X_j, R'_k, T')\right\} + \frac{\beta'}{G_1}\left\{\sum_{l=2}^{N_R+1} F'_{1,k}H_l c^*_{C1}(X_i, R_l, T') + \sum_{l=2}^{N_{R'}+1} L'_{l,k}c^*_{C2}(X_i, R'_l, T')\right\} + \alpha c^*_{B2}$$

Now the set of six second order partial differential equations [26]–[28] and [30]–[32] has been transformed into a set of $3N_x(N_R + N_{R'})$ simultaneous ordinary differential equations [98], [101], [103], [104], [106], and [107]. Such systems may be easily integrated by computer programs to give the time dependence of the concentrations of species A, B, and C at the collocation points $(X_i, R_k)$ and $(X_i, R'_k)$. We describe the concentration profiles which develop in front of the electrode by the concentrations at the collocation points.

We note the structural similarity of the formulae describing the time derivatives of the concentrations. This is one of the advantages of the orthogonal collocation method, for if the theory has been derived once it is very easy to express it in a computer language. Furthermore, if more complicated mechanisms are to be simulated, only minor changes in the formulae have to be performed. Also, the extension of the theory to other experimental techniques, i.e. other boundary conditions, is easy. This will be shown in another paper of this series.

We also note that the implementation of the expressions describing species C is not essential to calculate the concentration profiles of A and B, for C is not electroactive and does not react to or with an electroactive intermediate (16). However, if one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

desires, for example, to calculate the spectroelectrochemical response (14) of species C one is interested in the concentration profiles of C as well.

### Calculation of the current

In the one-dimensional diffusion model the current $i$ is simply calculated from the flux of the substrate at the electrode surface:

$$[108] \quad i = nFAD\left(\frac{\partial c_A}{\partial x}\right)_{x=0}$$

where $A$ is the electroactive area of the electrode. This implies that the flux of the substrate is uniform over $A$.

This is clearly not true in the case of a two-dimensional model considering edge effects. Instead, the current is given by

$$[109] \quad i = nFD\int_0^{r_0} 2\pi r\left(\frac{\partial c_A}{\partial x}\right)_{x=0} dr$$

where the $r$-dependent flux through an infinitesimally small part $2\pi r dr$ of the electrode is integrated over the electroactive section $0$–$r_0$ of the $r$-coordinate.

Using the transformation equations [21]–[23], [25], and the definition of β (eq. [29]), eq. [109] yields

$$[110] \quad i = \frac{nFD2\pi r_0^2 c_A^0}{L}\int_0^1 R\left(\frac{\partial c_{A1}^*}{\partial X}\right)_{X=0} dR$$

$$= 2uFAc_A^0\frac{\sqrt{D}}{\sqrt{t}}\sqrt{\beta T'}\int_0^1 R\left(\frac{\partial c_{A1}^*}{\partial X}\right)_{X=0} dR$$

The chronoamperometric "constant" $i\sqrt{t}$ is given by

$$[111] \quad i\sqrt{t} = 2uFAc_A^0\sqrt{D}\sqrt{\beta T'} \times \int_0^1 R\left(\frac{\partial c_{A1}^*}{\partial X}\right)_{X=0} dR$$

Alternatively, we may express this product in terms of the "Cottrell constant" (2)

$$[112] \quad (i\sqrt{t})_C = \frac{uFAc_A^0\sqrt{D}}{\sqrt{\pi}}$$

as

$$[113] \quad \frac{i\sqrt{t}}{(i\sqrt{t})_C} = 2\sqrt{\beta\pi T'}\int_0^1 R\left(\frac{\partial c_{A1}^*}{\partial X}\right)_{X=0} dR$$

Since the differential quotients $(\partial c_A^*/\partial X)$ are given at the collocation points we may calculate the integral exactly by a quadrature formula of the type (ref. 20, p. 134)

$$[114] \quad \int_0^1 y(r)w_k(r)\,dr = \sum_{l=1}^{N_r+2} Q_l y_l$$

where the $Q_l$ are elements of a vector depending on the trial function chosen.

Thus, from [67]

$$[115] \quad \int_0^1 R\left(\frac{\partial c_{A1}^*}{\partial X}\right)_{X=0} dR = \sum_{l=1}^{N_R+2} Q_l\left[R_l\sum_{j=1}^{N_x+2} A_{1,j}c_{A1}^*(X_j, R_l, T')\right]$$

Expanding the sum over $j$ and introducing the boundary conditions [36] and [42$b$], [115] changes to

$$[116] \quad \int_0^1 R\left(\frac{\partial c_{A1}^*}{\partial X}\right)_{X=0} dR = \sum_{l=1}^{N_R+2} Q_l \times\left[R_l A_{1,N_x+2} + R_l\sum_{j=2}^{N_x+1} A_{1,j}c_{A1}^*(X_j, R_l, T')\right]$$

The Gaussian weights $Q_l$ for $l = 1$ and $l = N_R + 2$ are equal to zero, thus [116] reduces to

$$[117] \quad \int_0^1 R\left(\frac{\partial c_{A1}^*}{\partial X}\right)_{X=0} dR = \sum_{l=2}^{N_R+1} Q_l \times\left[R_l A_{1,N_x+2} + R_l\sum_{j=2}^{N_x+1} A_{1,j}c_{A1}^*(X_j, R_l, T')\right]$$

which is a convenient form for computation of the integral.

# Correlation of the hydrogenation catalytic activity of dinuclear complexes of rhodium(I) with the formation of carbonyl-bridged complexes

ALAN R. SANGER

*Alberta Research Council, 11315-87 Avenue, Edmonton, Alta., Canada T6G 2C2*

Received May 8, 1981[1]

ALAN R. SANGER. Can. J. Chem. **60**, 1363 (1982).

Methanolic solutions of the dinuclear cationic complexes of rhodium(I), $[Rh_2(\mu\text{-}X)(CO)_2(Ph_2ECH_2EPh_2)_2]^+$ (X = Cl, Br; E = P, As) and iridium(I), $[Ir_2Cl(CO)_3(Ph_2PCH_2PPh_2)_2]$, are each active catalysts for the hydrogenation of alkynes to alkenes, and alkenes to alkanes. Neutral complexes with pseudohalide ligands have also been investigated but only the cyano-complex $[Rh_2(CN)_2(CO)_2(Ph_2PCH_2PPh_2)_2]$, and the arsine analog, are of significant catalytic activity. Only those complexes which reversibly form bridged complexes with ligands such as CO are also catalytically active.

Similar complexes with dithioether ligands are not efficient catalysts under the conditions tested.

ALAN R. SANGER. Can. J. Chem. **60**, 1363 (1982).

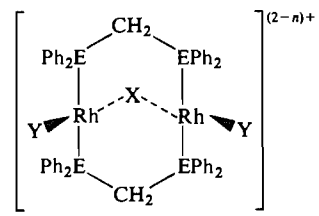
Les complexes cationiques binucléaires de rhodium(I), $[Rh_2(\mu\text{-}X)(CO)_2(Ph_2ECH_2EPh_2)_2]^+$ (X = Cl, Br; E = P, As), et d'iridium(I), $[Ir_2Cl(CO)_3(Ph_2PCH_2PPh_2)_2]^+$, en solutions dans le méthanol, sont des catalyseurs actifs d'hydrogénation des alcynes en alcènes et d'alcènes en alcanes. On a également étudié les complexes neutres ayant des ligands pseudohalogénés, mais seuls les complexes du type cyano $[Rh_2(CN)_2(CO)_2(Ph_2PCH_2PPh_2)_2]$ et leurs analogues du type arsine ont une activité catalytique significative. Seuls les complexes qui forment de manière réversible des complexes liés par un pont avec des ligands, tels le CO, sont également des catalyseurs actifs.

Les complexes semblables avec les ligands dithioéthers ne sont pas des catalyseurs efficaces dans les conditions utilisées.

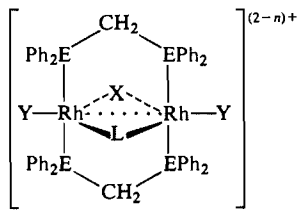
[Traduit par le journal]

## Introduction

The first dinuclear rhodium complex of the geometry designated "A-frame" (**1**) $[Rh_2(\mu\text{-}S)(CO)_2(dpm)_2]$ (dpm is $Ph_2PCH_2PPh_2$ and dam is $Ph_2AsCH_2AsPh_2$) was described in 1977 (1). The synthesis and structure of related complexes of rhodium or iridium has since received much attention (2–16). For complexes of rhodium(I), several instances of co-ordination of two-electron donor ligands (L; e.g. CO, $SO_2$) at the site bridging the metal centers (**2**) have been reported (2, 3, 6, 9, 12–16). The complex cation, $[Rh_2(\mu\text{-}Cl)(CO)_2(dpm)_2]^+$, forms a 1:1 labile, symmetrical (ir, $^{31}P$ nmr) complex with diphenylacetylene (6),[2] and similar neutral complexes have also recently been described (11). Co-ordination of an alkyne at the bridging site (**2**; L = alkyne) is accompanied by lengthening of the carbon–carbon bond such that the product is accurately described as a *cis*-dimetallated alkenyl complex (11). No complex in which an alkene is co-ordinated at either a bridging or terminal site of an A-frame complex has yet been described.



**1** (E = P or As; X is an anionic ligand of formal charge $n-$; Y is a neutral two-electron donor ligand, usually CO)



**2**

The A-frame structure, with the proximity of the two metal centres, has strong potential for dinuclear activation of unsaturated substrates. However, the complex $[Rh_2(\mu\text{-}S)(CO)_2(dpm)_2]$ has been shown to have low activity for the hydrogenation of ethylene (13). Herein I report that those cationic or neutral complexes of rhodium (or iridium) which form carbonyl-bridged complexes (**2**, L = CO) are also effective for the hydrogenation of alkynes and

[1]Revision received February 12, 1982.

[2]This system has been reinvestigated elsewhere (M. Cowie, private communication) and in this laboratory. The differences in spectroscopic parameters between solutions of the cation alone and with diphenylacetylene are now considered to be due to differences in conditions. A cationic complex containing bridging $CH_3OCOCCCO_2CH_3$ has been well characterized (18).

alkenes. One system has also been found to be active for the water–gas shift reaction (12).

## Experimental

Complexes tested for hydrogenation activity were prepared as described in refs. 6 and 15. Catalyst solutions were prepared by stirring (30 min) a solution or suspension (cyanato or thiocyanato complexes) of the complex to be tested (0.02 mmol) in methanol (50 $cm^3$) at 25 ± 1°C under an atmosphere of oxygen-free hydrogen at a total pressure of 1 atm. Subsequently, the substrate (0.100–0.500 $cm^3$) was injected into the catalyst mixture. The stability of successful catalysts was such that injection of successive aliquots of substrate was possible. The composition of the reaction mixture was monitored at frequent intervals (10–30 min), and samples were analyzed by gas chromatography: Hewlett-Packard model 5830A, 10′ × 0.125″ od column packed with Carbowax 20M (25%) on Chromosorb W (60–80 mesh, acid-washed), injection port temperature 250°C. At regular intervals standard solutions were injected to calibrate, and to confirm that no catalysis occurred within the injection port or on the column.

## Results

At low to intermediate concentrations the catalytic activity of a methanol solution of $[Rh_2Cl(CO)_2(dpm)_2]BPh_4$ is similar to that of the $[RhCl_2(CO)_2]^-$ salt, as is appropriate for a fully dissociated complex of which the cation is the catalytically active species. Interactions of the cation with $BPh_4^-$ (17) may therefore be not considered. The structures of complexes in solutions of intermediate concentration have been confirmed by ir and (E = P) $^{31}P$ nmr spectroscopy (6, 15). At higher concentrations the activity of solutions varies in a non-linear manner. The reasons for this phenomenon are not yet known.

The complexes examined were more soluble in acetone than in methanol, but solutions in acetone were less active. Attempts to recover starting materials gave complexes in which acetone was strongly retained (6, 15). These results suggest that acetone is strongly co-ordinated to rhodium, thereby reducing the ability of the complex to co-ordinate and activate an alkene or alkyne.

For the above reasons methanol solutions of intermediate concentration (ca. $0.4 \times 10^{-3}$ *M*) of the various complexes have been tested. The rates of hydrogenation of either phenylacetylene to styrene, or of 1-hexene to hexane, using various complexes as catalysts, are listed in Table 1. Styrene is subsequently hydrogenated to ethylbenzene (Figs. 1, 2), and a variety of other alkynes and alkenes have also been successfully hydrogenated using $[Rh_2Cl(CO)_2(dpm)_2]^+$ or the arsine analogue as catalyst (Table 2). In each case multiple successive aliquots of 1-hexene or phenylacetylene were successfully hydrogenated (see Fig. 1).

Hydrogenation of an alkyne catalyzed by $[Rh_2X(CO)_2(dpm)_2]^+$ (X = Cl or Br) yields successively the corresponding *cis*-alkene and alkane (Fig. 1). This indicates that, while alkyne is present in solution, displacement of the product alkene from the co-ordination sphere of the catalyst by alkyne is more rapid than hydrogenation of the alkene. Hydrogenation of phenylacetylene or 1-phenylpropyne, catalyzed by the arsine complexes, $[Rh_2X(CO)_2(dam)_2]^+$, is also rapid, but subsequent hydrogenation of product styrene or *cis*-1-

TABLE 1. Hydrogenation catalytic activity of A-frame complexes

| Catalyst[a] | Concentration (× $10^{-3}$ *M*) | Rate[b] |
|---|---|---|

[a]Catalyst: $[Rh(\mu\text{-}Cl)(CO)_2(dpm)_2]^+$ ($2.0 \times 10^{-3} M$) in methanol (50 cm³), at 22°C and 1 atm total pressure.
[b]Reference 18.
[c]Catalyst: $[Rh_2(\mu\text{-}Cl)(CO)_2(dam)_2]^+$; for this catalyst hydrogenation of the alkene was very slow, and concurrent *cis* to *trans* isomerization occurred.

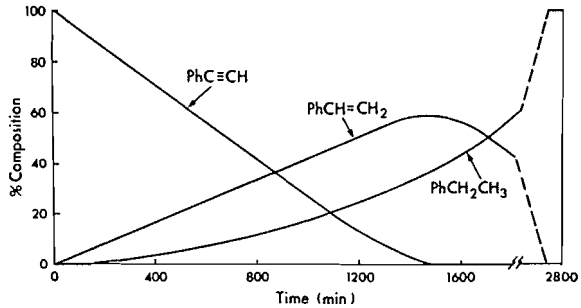

FIG. 2. Hydrogenation of phenylacetylene catalyzed by a solution of $[Ir_2Cl(CO)_4(dpm)_2][IrCl_2(CO)_2]$ ($0.27 \times 10^{-3} M$) in methanol.

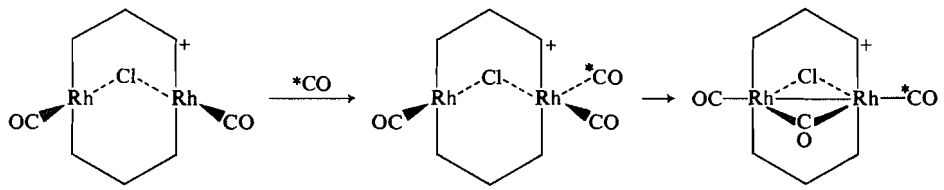
phenylpropene is slow. Hydrogenation of *cis*-1-phenylpropene is so slow that, in this case, isomerization to the *trans* isomer occurs concurrently at a comparable rate (18).

Styrene and ethylbenzene are formed concurrently during hydrogenation of phenylacetylene catalysed by $[Ir_2Cl(CO)_2(dpm)_2]^+$ (6), as shown in Fig. 2. No hydrido-complex of the rhodium complex (1) has been isolated or detected by ir or nmr spectroscopy (6). However, $^{31}P$ nmr spectra of solutions of the iridium complex $[Ir_2Cl(CO)_2(dpm)_2][IrCl_2(CO)_2]$ under an atmosphere of hydrogen indicate formation of a novel, unidentified complex.

## Discussion

The mechanism of addition of CO to the cationic A-frame complex $[Rh_2(\mu\text{-}Cl)(CO)_2(dpm)_2]^+$ (1) has been shown to occur initially by attack at a terminal site, followed by rearrangement to form a carbonyl-bridged A-frame complex, (2) (reaction [1]) (6).

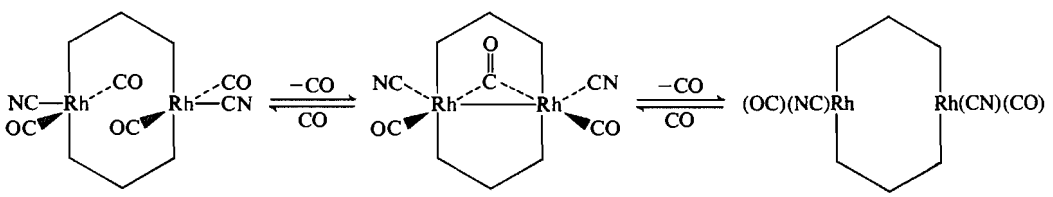
[1]



1 2

The cyano complex, $[Rh_2(CN)_2(CO)_4(dpm)_2]$, reversibly dissociates two carbonyl ligands to form successively a carbonyl-bridged and a dicarbonyl complex (reaction [2]) (15*a*).

[2]



3 4 5

[a]This product is present in low equilibrium amounts in solution; the solid product has not yet been isolated.

A series of reversible reactions of dinuclear complexes with CO is shown in Table 3. Similar bridged complexes are obtained by reaction of $SO_2$ or other two-electron donor ligands (2, 3, 12–16), but it should be noted that attack by $SO_2$ occurs directly at the bridging site (9). Neutral dicarbonyl complexes have structure **5**, and tetracarbonyl complexes have structure **3** (15*a*). It is noteworthy that structure **4** is obtained only when the anionic ligand is cyanide (15*a*).

In solution under an atmosphere of CO the neutral complex $[Rh_2Cl(N_3)(CO)_2(dpm)_2]$ is in equilibrium with lesser amounts of the cationic complex $[Rh_2(\mu\text{-}N_3)(CO)_2(\mu\text{-}CO)(dpm)_2]Cl$ (15*a*). The only complexes which reversibly associate or dissociate CO to form carbonyl-bridged complexes are therefore the chloro-, bromo-, cyano-, and, weakly, azido-complexes (Table 3), and it is precisely these complexes which are highly active for the hydrogenation of alkynes or alkenes (Table 1).

In contrast to these observations, and in a direct parallel to the behaviour of the cyanato or thiocyanato complexes, $[Rh_2(\mu\text{-}S)(CO)_2(dpm)_2]$ does not readily associate CO at the bridging site (1), and is also a poor catalyst for the hydrogenation of ethylene (13). The analogous iridium complex reacts with CO and is also an effective hydrogenation catalyst (14). The correlation of the catalytic activity of A-frame complexes with the ability to form carbonyl-bridged complexes suggests that the catalytic intermediate may also be a carbonyl-bridged complex, formed by attack of the substrate at a terminal site. However, elucidation of the precise mechanism of hydrogenation catalyzed by the above complexes awaits further kinetic studies. Formation of a carbonyl-bridged complex would explain why complexes with dpm or dam ligands are so active, but related diphosphine-bridged complexes of ligands $Ph_2P(CH_2)_nPPh_2$ ($n \geq 3$) (19), which cannot form CO-bridged metal–metal bonded complexes, are less active. The reasons why the systems with terminal $NCO^-$ or $NCS^-$, or bridging sulphide ligands do not readily form carbonyl-bridged complexes are not yet understood.

A similar system to the above is that of the complexes of rhodium(I) with dithioethers $PhS(CH_2)_mSPh$ ($m$ = 1–6), especially $[Rh_2Cl_2(\mu\text{-}CO)(PhSCH_2SPh)_2]$ (20). However, they are not efficient catalysts for the following reasons. The activity of the systems is moderate compared to that of phosphine systems, the complexes are not as air- or water-stable as the phosphine or arsine complexes, and they are readily reduced to rhodium(0) under hydrogenation conditions (20).

Reçu le 2 décembre 1981

ANNA SCHOUTEN et BERNARD CROS. Can. J. Chem. **60**, 1368 (1982).

Des hétéropolyanions mixtes nouveaux de formules $XPb(II)W_{11}O_{39}^{m-}$ (X = Si, Ge, B, Ga), $XPb(II)W_{11}O_{40}^{7-}$ (X = As(V), P(V)) et $X_2'Pb(II)W_{17}O_{61}^{8-}$ (X' = As(V), P(V)) sont préparés. Les résultats des études conductimétriques, polarographiques, spectrophotométriques et cristallographiques sont rapportés. La structure particulière de ces hétéropolyanions mixtes, liée au rayon important du plomb(II) est discutée. La formation de nouveaux types de polyanions de formule symbolique $Pb(XW_{11})_2$ a été observée avec X = Si et Ge.

ANNA SCHOUTEN and BERNARD CROS. Can. J. Chem. **60**, 1368 (1982).

New mixed heteropolyanions with formulae $XPb(II)W_{11}O_{39}^{m-}$ (X = Si, Ge, B, Ga), $XPb(II)W_{11}O_{40}^{7-}$ (X = As(V), P(V)) and $X_2'Pb(II)W_{17}O_{61}^{8-}$ (X' = As(V), P(V)) were prepared. The results of conductimetric, polarographic, spectrophotometric, and crystallographic studies are reported. The peculiar structure of these mixed heteropolyanions due to the large radius of Pb(II) is discussed. The formation of new types of polyanions with the symbolic formula $Pb(XW_{11})_2$ has been noted with X = Si and Ge.

## Introduction

Dans le cadre de l'étude de la complexation des cations d'éléments contenant des électrons *p* dans la couche de valence par les hétéropolyanions[1] tungstiques lacunaires, nous avons décrit (1) la formation d'hpa mixtes de formules $XZW_{11}O_{39}(OH)^{m-}$ (X = Si, Ge, B, As(V), Ga, Co(II), Zn; Z = Ge(IV), Sn(IV)) et $X_2'ZW_{17}O_{61}(OH)^{7-}$ (X' = As(V), P(V); Z = Ge(IV), Sn(IV)). Dans cette étude, le plomb(II) se singularise par son rayon trés important, à priori incompatible avec la dimension du site offert dans la structure lacunaire des hpa $XW_{11}$ ou $X_2'W_{17}$[2] et en tout cas nettement supérieur au rayon du tungstène(VI) occupant les sites homologues. Si le germanium(IV) et l'étain(IV) avaient déjà été utilisés pour la préparation d'hpa mixtes, essentiellement pour permettre de greffer des coordinats organiques (2–4), en revanche l'étude systématique de la complexation du plomb par les hpa lacunaires constitue un travail nouveau.

Nous rapportons ici la préparation d'hpa mixtes $XPbW_{11}$ et $X_2'PbW_{17}$.

## Préparations et analyses

*Produits de départ*

Les hpa lacunaires $XW_{11}$ et $X_2'W_{17}$ sur lesquels Pb(II) est ajouté sont préparés selon les méthodes décrites par Zonnevijlle (5).

*Méthode générale de préparation*

La quantité calculée de nitrate de plomb en solution est ajoutée à une suspension du sel de potassium d'hpa $XW_{11}$ ou $X_2'W_{17}$ (de concentration de l'ordre de 0,1 *M*) préalablement chauffée à 60°C (40°C pour $BW_{11}$). Le sel en suspension se dissout rapidement dès l'addition de la moitié de la solution de plomb. Le pH final dépend du produit préparé: il est de 6,5 à 6,7 pour $GaPbW_{11}$, de 6 à 6,5 pour $SiPbW_{11}$, $GePbW_{11}$, $P_2PbW_{17}$ et $As_2PbW_{17}$, de 5,5 à 6 pour $BPbW_{11}$ et voisin de 5 pour $PPbW_{11}$ et $AsPbW_{11}$. Les hpa mixtes cristallisent à la température ambiante sous forme d'aiguilles incolores. L'addition de nitrate de potassium ou d'une solution d'acétate de potassium dans le méthanol permet d'atteindre un rendement de 90%.

L'hpa d'arsenic $AsPbW_{11}$ est préparé à partir d'une solution sodique de l'hpa lacunaire et le sel de potassium est précipité par addition d'une solution d'acétate de potassium dans le méthanol.

Tous les produits obtenus sont incolores et assez solubles dans l'eau. Comme les autres hpa mixtes contenant un élément Z(II), les hpa contenant le plomb ne sont stables que dans un étroit domaine de pH et les acides correspondants n'existent pas.

La formation du composé de stoechiométrie $Z/XW_{11}$ (ou $Z/X_2'W_{17}$) = 1/1 est mise en évidence par l'évolution de la conductivité de la solution au cours de la réaction d'addition (Fig. 1).

*Analyses chimiques*

Les éléments K, W, Ga sont dosés par les méthodes classiques (gravimétrie à la 8-hydroxyquinoléine pour W et Ga; gravimétrie au tétraphénylborate de sodium pour K). Le pourcentage en eau de cristallisation est déterminé par calcination à 600°C. Le plomb est dosé par volumétrie à l'EDTA en milieu basique (à pH 10, dosage en retour d'un excès d'EDTA par une solution de chlorure de zinc); la présence d'un autre élément métallique (gallium) nécessite la séparation préalable du plomb par fixation sur résine acide fort (Amberlite IR-120).

*Autres méthodes d'analyse*

L'appareillage utilisé pour les mesures spectrophotométriques, potentiométriques, conductimétriques, polarographiques et cristallographiques (sur poudre et sur monocristal) a été décrit par ailleurs (6).

## Résultats

### *Résultats des analyses et formulations*

Les analyses chimiques conduisent aux formules

[1]Par la suite l'abréviation "hpa" est utilisée pour hétéropolyanion.

[2]Dans la rédaction, la formule de composition symbolique simplifiée est souvent utilisée; par exemple $SiW_{11}$ et $P_2W_{17}$ pour $SiW_{11}O_{39}^{8-}$ et $P_2W_{17}O_{61}^{10-}$ respectivement.

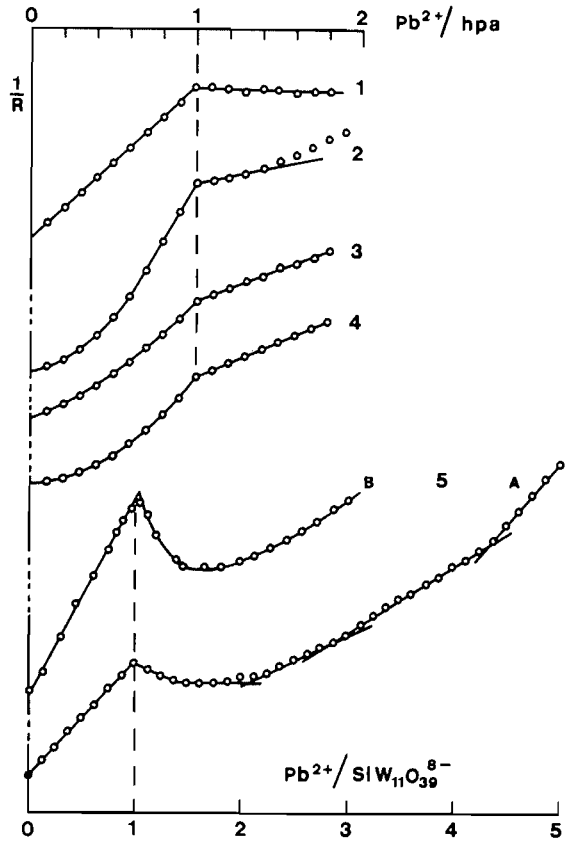

FIG. 1. Evolution de la conductivité des solutions en fonction du rapport des concentrations Pb(II)/$XW_{11}$ (ou Pb(II)/$X_2'W_{17}$): 1, $Pb/GeW_{11}O_{39}^{8-}$; 2, $Pb/P_2W_{17}O_{61}^{10-}$; 3, $Pb/As_2W_{17}O_{61}^{10-}$; 4, $Pb/PW_{11}O_{39}^{7-}$; 5, $Pb/SiW_{11}O_{39}^{8-}$ (A pour $c = 2{,}8 \times 10^{-3}$ *M*; B pour $c = 11{,}7 \times 10^{-3}$ *M*). Les valeurs de $1/R$ sont portées dans une échelle arbitraire.

rassemblées dans le tableau 1. L'hétéroélément n'a été dosé que dans le complexe $GaPbW_{11}$. La formulation proposée pour les sels potassiques des hpa contenant le plomb est différente de celle des sels d'hpa connus contenant d'autres éléments Z(II) pour lesquels la formule fait apparaître une molécule d'eau qui complète la coordination octaédrique de l'élément bivalent substitué. La discussion justifiera ces formules qui excluent une coordination octaèdrique du plomb. Les sels des hpa $AsPbW_{11}$ et $PPbW_{11}$ font exception, la charge déterminée pour les anions conduisant à une formule compatible avec un environnement octaédrique d'atomes d'oxygène pour le plomb.

*Étude conductimétrique*

La réaction en solution du plomb(II) avec les différents hpa lacunaires a été suivie par conductimétrie et les résultats sont reportés sur la figure 1. Dans tous les cas un changement de pente fait apparaître nettement l'existence d'une espèce complexe pour le rapport [Pb(II)]/[hpa] = 1. Les courbes 5A et 5B représentent de façon plus complète les mesures de conductivité pour la réaction d'une solution de nitrate de plomb sur une solution sodique de $SiW_{11}$ à deux concentrations différentes. Dans les deux cas apparaît pour un rapport molaire voisin de 2 un trouble qui se transforme rapidement en précipité. La courbe B se limite à cette région, le précipité formé, très volumineux, gênant les mesures de conductivité. Il semble qu'au delà du rapport 1/1 la formation d'une association soit possible, telle que le nombre et la mobilité des espèces chargées diminue. Au delà du rapport 2, des portions rectilignes de la courbe de conductivité, correspondant à des valeurs croissantes, se coupent pour un rapport 3 et un peu au delà de 4 (courbe A). Si on admet que le complexe 1/1 se forme selon la réaction $SiW_{11}O_{39}^{8-} + Pb^{2+} \rightarrow SiPbW_{11}O_{39}^{6-}$, l'addition des trois autres ions $Pb^{2+}$ pourrait correspondre à la précipitation du sel de plomb de l'hpa $SiPbW_{11}O_{39}^{6-}$. Ces mesures n'excluent cependant pas la formation d'un polyanion contenant plus d'un atome de plomb. Les mesures polarographiques permettent de lever cette incertitude.

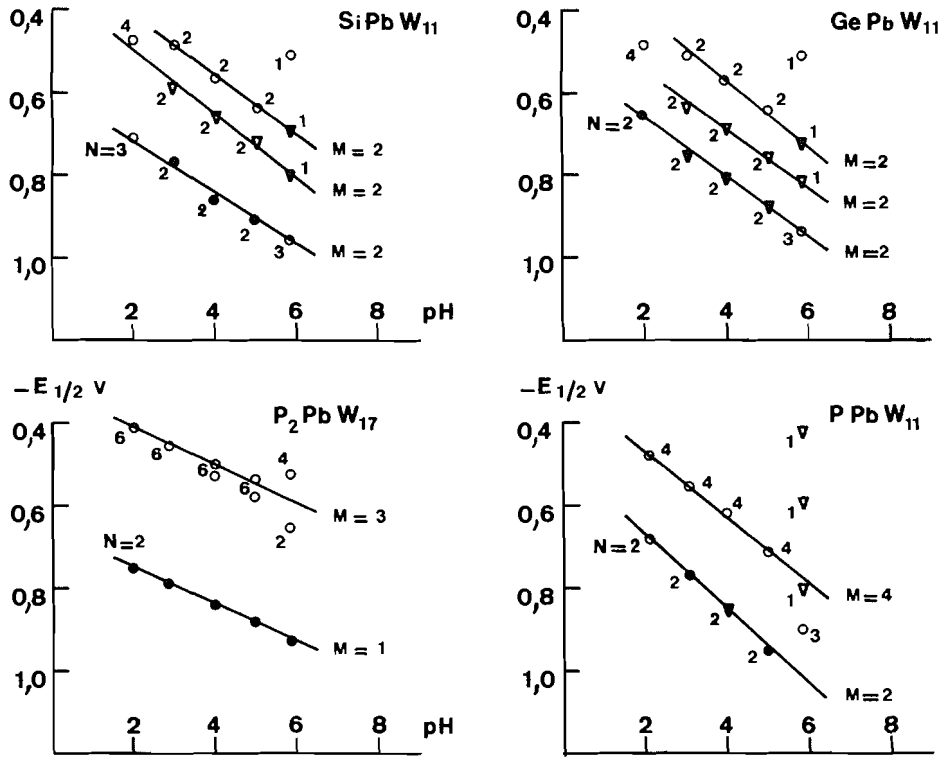

FIG. 2. Potentiel de demi-vague en fonction du pH des solutions d'hpa mixtes contenant le plomb(II). $c_{hpa} = 10^{-3}$ *M*; $c_{tampon} = 0{,}5$ *M*; $c_{NaNO_3} = 0{,}5$ *M*. *N* représente le nombre d'électrons intervenant dans la réaction de réduction; *M* représente le nombre de protons qui participent à la réaction de réduction. Les symboles indiquent: ▽ une réaction réversible; ▼ une réaction assez réversible; ● une réaction peu réversible; ○ une réaction irréversible.

*Étude polarographique*

L'étude est faite par polarographie sur cathode de mercure dans le domaine des potentiels négatifs (Fig. 2). Par rapport aux hpa lacunaires, il apparaît pour tous les polyanions substitués $XPbW_{11}$ et $X_2'PbW_{17}$ une vague de réduction supplémentaire à deux électrons pour un potentiel légèrement moins négatif. On trouve ensuite deux autres vagues, chacune à deux électrons, qui correspondent sensiblement à celles des hpa lacunaires $XW_{11}$ ou $X_2'W_{17}$. Toutes ces vagues sont dépendantes du pH et correspondent à un rapport *M* (nombre de protons fixés)/*N* (nombre d'électrons) égal à 1. Quel que soit le pH, cette première vague supplémentaire, liée à la présence du plomb, est extrêmement voisine de celle qui la suit. Dans certains cas elle est bien détectée à l'aide de la courbe dérivée (ainsi avec $SiPbW_{11}$), mais il est parfois impossible de la distinguer (avec $PPbW_{11}$ ou $P_2PbW_{11}$).

Une étude plus complète est menée avec des solutions de $SiW_{11}$ additionnées de quantités croissantes de Pb(II). La figure 3 présente les résultats obtenus pour des solutions tamponnées à pH 4,12. On a préalablement noté la position de la vague de réduction $Pb^{2+} \rightarrow Pb$ à ce pH ($E_{1/2} = -0{,}42$ V). Pour tous les rapports $[Pb(II)]/[SiW_{11}] < 1$, la vague du plomb cationique libre n'apparaît pas, ce qui confirme la formation de complexes. Par contre, pour un potentiel $E_{1/2} = -0{,}63$ V, apparaît une première vague dont la hauteur est proportionnelle à la quantité de plomb(II) ajouté et dont le potentiel de demi-vague reste inchangé lorsque les rapports varient de 0 à 1. Dès que la valeur de $[Pb(II)]/[SiW_{11}]$ devient supérieure à 1, la vague correspondant au plomb(II) libre ($E_{1/2} = -0{,}42$ V) réapparait, la suite du polarogramme ètant identique à celui de $SiPbW_{11}$. La première vague décelée dans le polarogramme de $SiPbW_{11}$ (vague supplémentaire par rapport aux hpa lacunaires) correspond à la réduction du plomb(II) dans le complexe, soit sa mise en liberté avec protonation de l'anion lacunaire: $SiPbW_{11}O_{39}^{6-} + 2e^- + 2H^+ \rightarrow Pb + H_2SiW_{11}O_{39}^{6-}$. La complexation du plomb entraîne une diminution du potentiel de demi-vague de la réaction de réduction du plomb(II).

*Existence d'autres hpa mixtes*

Les complexes $XPbW_{11}$ et $X_2'PbW_{17}$ correspondant au rapport [Pb(II)]/[hpa] = 1 sont nette-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

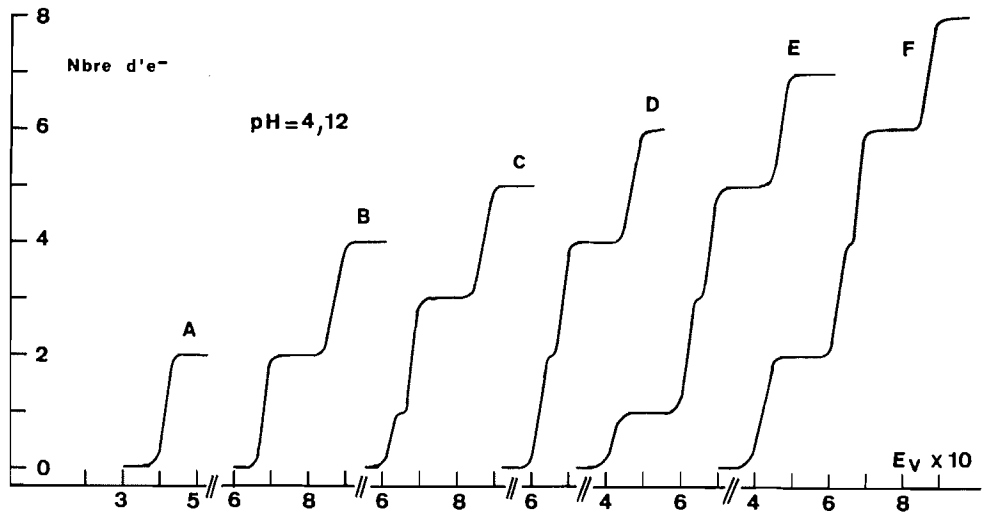

FIG. 3. Mise en évidence de la formation du complexe $SiPbW_{11}$ par étude polarographique de mélanges différents de solutions d'hpa $SiW_{11}$ et de plomb(II) ($c_{hpa} = 10^{-3}$ *M*). A, $Pb^{2+}$; B, $SiW_{11}$; C, $SiW_{11}$ + 0,5 $Pb^{2+}$; D, $SiW_{11}$ + $Pb^{2+}$; E, $SiW_{11}$ + 1,5 $Pb^{2+}$; F, $SiW_{11}$ + 2 $Pb^{2+}$.

ment mis en évidence, mais l'allure particulière des courbes de conductivité des solutions d'hpa lacunaires en présence de proportions différentes de plomb(II) amène à considérer l'éventualité de la formation de complexes pour d'autres rapports.

L'étude par diffraction des rayons X des phases en présence dans les produits de cristallisation de mélanges de différentes concentrations de nitrate de plomb et du sel de potassium de $SiW_{11}$ montre la formation d'une nouvelle phase, isolée pour le rapport [Pb]/[hpa] = 1/2, alors que l'étude conductimétrique ne l'avait pas mise en évidence. L'existence de ce nouveau type de complexe de plomb, observée avec X = Si et Ge, a été confirmée par le passage de sa solution sur résine échangeuse de cations (Amberlite IR-120) sous forme $K^+$. L'analyse de l'éluat montre que le plomb(II) n'est pas retenu sur l'échangeur.

La difficulté de l'étude de cette phase tient à sa très grande solubilité en milieu aqueux et à la fragilité des cristaux mis au contact de l'air. Ce complexe n'est pas mis en évidence par l'étude polarographique en raison de la faible concentration des solutions et du pH relativement bas. Lorsqu'on opère à pH plus élevé, la première vague à 1 $e^-/SiW_{11}$ se détache nettement des vagues tungstiques, ce qui est compatible avec l'existence de $Pb(SiW_{11})_2$.

Au cours de l'étude polarographique (Fig. 3), on n'observe, au delà de la valeur 1 du rapport [Pb(II)]/[$SiW_{11}$], l'apparition d'aucun autre complexe contrairement à ce que l'étude conductimétrique laissait supposer. Le précipité dont l'apparition correspondait à un changement de pente de la courbe enregistrant l'évolution de la conductivité est un sel de plomb (ou mixte de plomb et de potassium) de l'hpa $SiPbW_{11}$. Les cassures successives correspondent à la formation de sels de l'hpa $SiPbW_{11}$ qui diffèrent par le nombre de plombs cationiques par molécule. La faible solubilité des sels de plomb des hpa $XPbW_{11}$ nécessite des précautions pour la cristallisation des complexes mixtes contenant le plomb, habituellement isolés sous forme de sels de potassium. En effet les analyses montrent que, même pour la fraction qui cristallise la première, le sel obtenu est excédentaire en plomb et déficitaire en potassium par rapport à la composition théorique. La recristallisation après passage de la solution sur échangeur d'ions sous forme $K^+$ constitue une méthode de purification. La précipitation des hpa mixtes contenant le plomb sous forme de sels de cations de bases organiques fortes (guanidinium, ammonium tétrasubstitué) évite généralement les anomalies de composition rencontrées avec les sels de cations alcalins.

*Étude spectrophotométrique*

La figure 4 montre les spectres électroniques d'hpa mixtes contenant le plomb. Les bandes d'absorption sont entièrement dans l'uv. Ces spectres diffèrent très peu de ceux des hpa homologues lacunaires. Cette particularité des hpa mixtes contenant le plomb laisse prévoir que cet élément s'incorpore peu à la grappe polytungstique, son addition ne modifiant ainsi pas très sensiblement le système de bandes des hpa lacunaires. Ces résultats sont en accord avec la taille très importante du plomb(II) et la formulation qui attribue un environnement inhabituel à l'élément substitué.

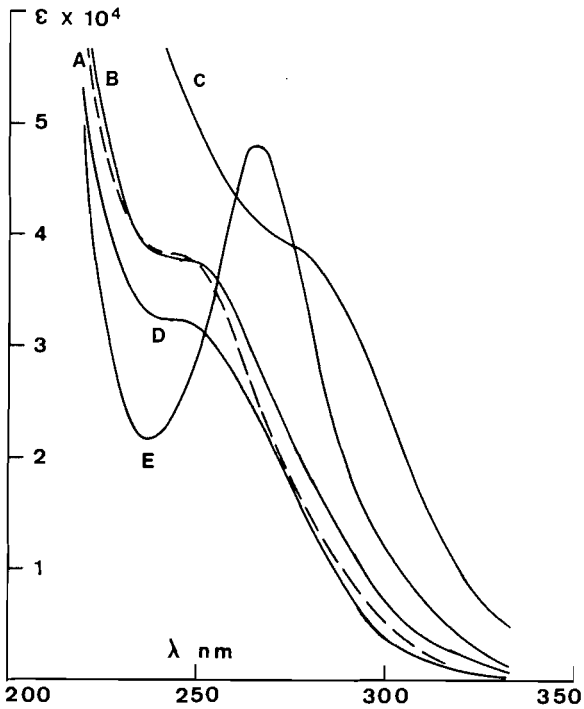

FIG. 4. Spectres d'absorption uv des sels potassiques des hpa mixtes contenant le plomb(II): A, $SiPbW_{11}O_{39}^{6-}$; B, $GePbW_{11}O_{39}^{6-}$; C, $P_2PbW_{17}O_{61}^{8-}$ à comparer à ceux de D, $SiW_{11}O_{39}^{8-}$; E, $SiW_{12}O_{40}^{4-}$.

Ils conduisent à l'étude cristallographique des sels d'hpa mixtes contenant le plomb.

*Étude cristallographique*

Les diagrammes de diffraction X des sels des hpa mixtes contenant le plomb ne correspondent pas aux systèmes cristallins attendus d'après le nombre de cations par polyanion et la nature des cations (7). Ainsi les sels potassiques n'appartiennent à aucun des types structuraux connus des sels alcalins des complexes $XZW_{11}$ et $X_2'ZW_{17}$. Les sels $K_6SiPbW_{11}O_{39},9H_2O$, $K_6GePbW_{11}O_{39},10H_2O$ et $K_7GaPbW_{11}O_{39},16H_2O$ cristallisent dans le système orthorhombique (groupe d'espace $P2_122$ ou $P2_12_12$ pour les deux premiers et *Pnma* pour le troisième). L'étude radiocristallographique d'un monocristal de $K_7GaPbW_{11}O_{39},16H_2O$ a permis de mettre en évidence les particularités structurales des hpa mixtes contenant le plomb. La description de la résolution structurale est reportée par ailleurs (8). Elle confirme l'originalité de l'environnement du plomb et l'absence de coordination octaédrique. L'atome de plomb n'est lié fortement qu'aux quatre atomes d'oxygène du site dans lequel il a été substitué, formant avec ceux-ci un arrangement

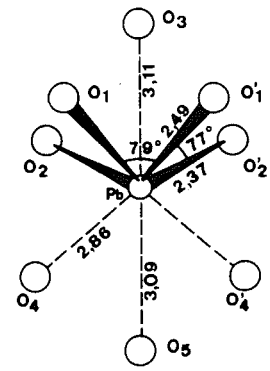

FIG. 5. Proche environnement de l'atome de plomb (les notations $O_n$ et $O_n'$ indiquent des atomes symétriques par rapport au plan dans lequel se situent les atomes Pb, $O_3$ et $O_5$; les atomes $O_4$ et $O_5$ appartiennent à un polyanion voisin).

pyramidal qui le déplace vers l'extérieur de la grappe polytungstique. Cette disposition du proche environnement du plomb est comparable à celle que l'on trouve dans l'oxyde PbO; les distances Pb—O sont du même ordre, 2,37 et 2,49 Å (Fig. 5). Une liaison avec le cinquième oxygène de la lacune parait exclue étant donné la distance de 3,11 Å. En revanche deux atomes d'oxygène d'un anion voisin sont distants de 2,86 Å. Les six atomes d'oxygène formant ainsi le proche environnement de l'atome de plomb constituent un arrangement comparable au polyèdre de coordination de Pb(II) dans $Pb_2O_3$ (9). En solution la coordination du plomb est à quatre atomes d'oxygène et la formulation $XPbW_{11}O_{39}^{p-}$ est justifiée.

## Discussion

Le plomb(II) se distingue dans les réactions de complexation avec les hpa lacunaires par une coordination inhabituelle pour un élément bivalent. Les éléments de taille plus petite (Co(II), Zn, etc.) substitués au tungstène dans les hpa sont entourés octaédriquement par 5 atomes d'oxygène, dont un fait partie de l'environnement tétraédrique de l'hétéroélément central X, et par une molécule d'eau (10). Cette coordination est interdite au plomb par sa taille et par l'effet stérique de la paire électronique libre: il est lié aux 4 atomes d'oxygène qui dans l'hpa lacunaire forment le site vacant, mais reste éloigné de l'oxygène appartenant au tétraèdre central. En phase solide il donne également des liaisons avec 2 atomes d'oxygène d'un hpa voisin, ce type d'hexacoordination se retrouvant dans $Pb_2O_3$. Il est probable qu'en solution des molécules d'eau prennent la place de l'hpa voisin dans le solide.

La phase cristalline trés soluble mise en évidence

pour le rapport $SiW_{11}/Pb = 2$ pourrait correspondre à un composé dans lequel le plomb serait lié à 2 hpa par les atomes d'oxygène formant le site lacunaire. De tels polyanions sont obtenus avec des éléments de grande taille comme les lanthanides et les actinides (11). Dans ces complexes l'hétéroélément substitué a une coordination de 8 par formation de liaisons avec les 4 atomes d'oxygène constituant la lacune des 2 hpa.

Au cours des réactions de complexation par les hpa lacunaires, le plomb joue donc un rôle intermédiaire entre, d'une part les éléments de taille inférieure, et d'autre part les lanthanides et actinides.

COMMUNICATION

# Isolation and structure of combretastatin[1]

GEORGE R. PETTIT[2], GORDON M. CRAGG, DELBERT L. HERALD, JEAN M. SCHMIDT, AND PRASERT LOHAVANIJAYA

*Cancer Research Institute and Department of Chemistry, Arizona State University, Tempe, AZ 85287, U.S.A.*

Received February 15, 1982

GEORGE R. PETTIT, GORDON M. CRAGG, DELBERT L. HERALD, JEAN M. SCHMIDT, and PRASERT LOHAVANIJAYA. Can. J. Chem. **60**, 1374 (1982).

The South African tree *Combretum caffrum* has been shown to contain a constituent capable of significantly reversing astrocyte formation employing the National Cancer Institute's 9ASK system. The constituent responsible for astrocyte reversal was isolated and designated combretastatin (**1**). Structural elucidation was initiated employing spectral methods and completed by X-ray crystallographic analysis. By this means combretastatin was assigned structure **1**. Further biological evaluation and a total synthesis are now in progress.

GEORGE R. PETTIT, GORDON M. CRAGG, DELBERT L. HERALD, JEAN M. SCHMIDT et PRASERT LOHAVANIJAYA. Can. J. Chem. **60**, 1374 (1982).

On montre que l'arbre Sud Africain *Combretum caffrum* contient un constituant capable d'inverser de façon significative la formation de l'astrocyte lorsqu'on l'utilise dans le système 9ASK de l'Institut National du Cancer. On a isolé le constituant responsable de l'inversion de l'astrocyte et on l'a appelé la combrétastatine (**1**). On a entrepris des études structurales en utilisant des méthodes spectrales et l'analyse par cristallographie de rayons X. Sur cette base, on a attribué la structure **1** à la combrétastatine. On travaille actuellement à son évaluation biologique et sa synthèse totale.

[Traduit par le journal]

Malignant gliomas such as anaplastic and malignant astrocytomas and glioblastoma multiforme constitute some 43% of malignant brain tumors. The prognosis for such patients is very grave with a median survival time of six months (2). The need for effective and indeed curative cancer chemotherapeutic drugs for such neoplastic diseases is quite urgent (3). As one approach to this problem, the National Cancer Institute has instituted a biological evaluation system based on the change of immature AC cells (from a rat glioma) to mature differentiated astrocytes (for details of the experimental technique, see ref. 4). We are pleased to report the first isolation of a plant constituent (**1**) based on bioassay techniques using the new astrocyte reversal (9ASK) system. A summary of the isolation and structural elucidation of alcohol **1**, designated combretastatin, now follows.

Root bark of the South African tree *Combretum caffrum* (Eckl. Zeyh.) Kuntze[3] is used as a Zulu charm (5) for harming an enemy and some eight species of this family (Combretaceae) have found application in primitive treatment of cancer (6). We have found *C. caffrum* to afford a methylene chloride – methanol extract that caused astrocyte reversal in the 9ASK system. The methylene chloride – methanol extract obtained from 55 kg of branches, leaves, and fruit was diluted with water and the methylene chloride phase was partitioned employing the sequence 9:1 → 4:1 → 3:2 methanol–water with ligroin → carbon tetrachloride → methylene chloride. The methylene chloride fraction (159 g) was separated by a series of chromatographic steps utilizing Sephadex LH-20 → silica gel. Separation was guided by results of the 9ASK evaluation and led to 0.45 g of combretastatin (**1**) that caused substantial astrocyte reversal[4] and inhibition ($ED_{50}$ 0.011 μg/mL) of the murine P388 lymphocytic leukemia cell line (7).

A pure specimen of combretastatin recrystallized from acetone–hexane as needles melting at 130–131°C: $[\alpha]_D^{26}$ − 8.51°C (*c* 1.41, chloroform); $\lambda_{max}$

[3]Also known as *combretum salicifolium* E., yielded an extract significantly active against the P388 lymphocytic leukemia in the National Cancer Institute's collaborative program with the U.S. Department of Agriculture directed by Drs. John D. Douros, Matthew I. Suffness, and James A. Duke.

[4]The percent astrocyte reversal observed was 71–90% at dose levels of 100 to 1 μg/mL and 51–70% at 0.1 μg/mL with only 0–5% cytotoxicity being exhibited. According to NCI procedure a sample showing 51–90% astrocyte reversal with cytotoxicity not exceeding 50% is considered as active.

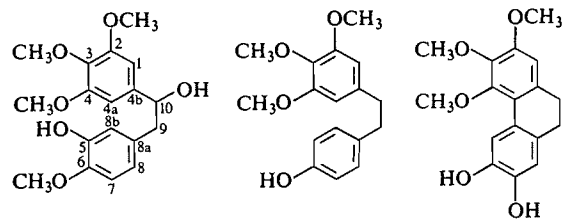
($CH_3OH$) (log ε):212 (4.33), 228 (sh, 4.11), 279 (3.47), and 287 (sh, 3.36) nm; ir (KBr) $\nu_{max}$:3500, 3420, 1600, 1515, 1465, 1423, 1350, 1330, 1282, 1238, 1121, 1053, 1010, 978, 852, 824, 790, 768, 705, and 653 $cm^{-1}$; $^1H$ nmr (100 MHz, $CDCl_3$), δ: 2.12 (1H, br s, C-10—OH), 2.91 (2H, distorted AB system 9-H's), 3.90 (12H, s, 4 × $OCH_3$), 4.83 (1H, dd, $J$ = 9 and 5 Hz, 10-H), 5.72 (1H, br s, C-5—OH), 6.64 (2H, s, 1 and 4a-H's), 6.74–6.93 (3H, 7, 8 and 8b-H's) ppm; and $^{13}C$ nmr (22.63 MHz, $CDCl_3$), δ: 153.28 (2C, C-2, and C-4), 145.77, 145.54 (C-5 and C-6), 139.70, 137.42, 131.28 (C-3, C-4b, and C-8a), 121.04, 115.62, 110.81 (C-7, C-8, and C-8b), 103.01 (2C, C-1, and C-4a), 75.45 (C-10), 60.86 (C-3—$OCH_3$), 56.18 (2C, C-2-, and C-4—$OCH_3$), 56.05 (C-6—$OCH_3$), 45.59 (C-9) ppm; EI mass spectrum *m/e*: 334 ($M^+$ for $C_{18}H_{22}O_6$), 198 (base peak), and 138.

The two prominent peaks at *m/e* 138 and 198 in the mass spectrum of combretastatin were assigned to the products arising from cleavage of the C-9—C-10 bond, namely $(C_8H_9O_2 + H)^+$ and $(C_{10}H_{13}O_4 + H)^+$. Signals in the $^1H$ nmr spectrum that appeared as a three peak multiplet at 2.91 ppm were assigned to a distorted AB pattern typical of a methylene group adjacent to a chiral center whose methinyl proton resonated as a double doublet at 4.83 ppm. The aromatic protons at positions 1 and 4a appeared as a singlet at 6.64 and the three proton multiplet at 6.74–6.93 ppm was assigned to the 7, 8, and 8b protons. An off-resonance decoupled $^{13}C$ nmr spectrum displayed signals at 45.59 (triplet) and 75.45 (doublet) that substantiated the presence of the C-9—C-10 ethyl alcohol system. Assignment of structure **1** to combretastatin and determination of the absolute configuration at C-10 was completed by X-ray crystal structure determination.

A single crystal (from acetone–hexane) of combretastatin was subjected to analysis employing a computer-controlled Enraf Nonius CAD-4 diffractometer and SDP (Structure Determination Package) soft-ware system. Combretastatin (**1**) displayed 222 point group symmetry and accurate lattice constants determined by a least-squares fitting of the orientation matrix components for 25 automatically collected reflections, providing values of $a$ = 5.2046 (0.0029), $b$ = 14.1130 (0.0062), and $c$ = 22.4234 (0.0078) Å. A crystal density of 1.33 g/cc, the known chirality, and systematic extinctions were consistent with the orthorhombic space group $P2_12_12_1$ with one molecule of $C_{18}H_{22}O_6$ per asymmetric unit. By means of graphite-monochromated CuKα radiation (λ 1.54178 Å) and ω/2θ scan technique, one octant comprising a total of 1930 reflections was recorded. After removal of standard reflections and correction for Lorentz polarization and background effects, 1891 reflections were utilized, of which 1787 (94.5%) were greater than 1.0 standard deviation and 1656 (87.5%) greater than 3.0 standard deviations of their intensities. The phasing model was obtained using a multisolution weighted tangent formula (MULTAN 80) (ref. 8) approach coupled with successive difference Fourier analyses. Refinement and visualization was provided with the following major crystallographic programs: ORFFE (9*a*), ORTEP (9*b*), and LSBD (9*c*). The resulting *E*-synthesis and tangent formula recycling procedure revealed all twenty-four non-hydrogen atoms. Hydrogen atoms were located on a difference electron density synthesis following partial refinement. Full matrix least-squares refinements with anisotropic non-H atoms and isotropic hydrogen were carried out to crystallographic unweighted and weighted residuals of 4.36% and 6.12%, respectively, corresponding to structure **1**. Unfortunately, the opposite enantiomorph also refined to $R$ and $wR$ values of 4.38 and 6.12, respectively. The correct enantiomorph will eventually be determined by suitable preparation of a heavy atom derivative.



**1** **2** **3**

Combretaceae species have received very little prior chemical investigation. The principal past effort directed at the genus *Combretum* has uncovered a number of bibenzyl derivatives (e.g. **2** (10)) and a series of related 9,10-dihydrophenanthrenes such as phenol D′ (**3**) (11). Possibly combretastatin is a biosynthetic precursor of such substances and eventually the 9,10-dihydrophenanthrene corresponding to phenol **1** may be located. Presently combretastatin is most interesting from the viewpoint of central nervous system antineoplastic activity and is being evaluated against several of the National Cancer Institute's key evaluation systems. At the same time we are completing assignment of the absolute configuration and a total synthesis of combretastatin.

# Radical reactions in aqueous solution: use of the *aci*-anion of nitromethane as a spin trap

BRUCE C. GILBERT AND RICHARD O. C. NORMAN
*Department of Chemistry, University of York, Heslington, York YO1 5DD, U.K.*

Received July 15, 1981

BRUCE C. GILBERT and RICHARD O. C. NORMAN. Can. J. Chem. **60**, 1379 (1982).

The type of radical detected by esr when first-formed short-lived radicals are generated by photolytic, radiolytic, or flow techniques in the presence of nitromethane is shown to depend upon the nature and structure of the transient radical and on the pH. Thus electron-donating radicals may react with $CH_3NO_2$ itself under certain conditions to give rise to $CH_3NO_2^{-\cdot}$ and the alkoxy nitroxides $CH_3N(OR)O\cdot$. At higher pH, a wide variety of radicals (X) react very readily with the *aci*-anion $CH_2{:}NO_2^-$ to give adducts $XCH_2NO_2^{-\cdot}$ (and, from radicals capable of one-electron transfer, $O_2NCH_2CH_2NO_2^{-\cdot}$). Structural characteristics of adducts $XCH_2NO_2^{-\cdot}$ are described and it is shown how radicals which are normally undetectable in fluid solution can be trapped and recognized in this way. Mechanistic pathways diagnosed with this trap (involving, e.g. alkoxyl radicals, aroyloxyl radicals, aromatic carboxylate cation-radicals) are exemplified.

BRUCE C. GILBERT et RICHARD O. C. NORMAN. Can. J. Chem. **60**, 1379 (1982).

Lorsqu'on produit des radicaux par écoulement, par radiolyse ou par photolyse en présence de nitrométhane, le type de radical détecté par rpe, lorsqu'apparaissent les premiers radicaux de courte vie, dépend de la nature et de la structure du radical intermédiaire et du pH. Ainsi les radicaux électrodonneurs peuvent réagir avec le $CH_3NO_2$ lui-même dans certaines conditions pour donner le $CH_3NO_2$ et les alkoxynitroxydes du type $CH_3N(OR)O$. A des pH plus élevés, une grande variété de radicaux (X) réagit très facilement avec l'anion *aci* $CH_2{:}NO_2^{-\cdot}$ en donnant des adduits $XCH_2NO_2^{-\cdot}$ (et le radical $O_2NCH_2CH_2NO_2^{-\cdot}$ à partir des radicaux pouvant subir un transfert d'un électron). On décrit les caractéristiques structurales des adduits $XCH_2NO_2^{-\cdot}$ et on montre comment les radicaux non détectables normalement en solution fluide peuvent être piégés et identifiés de cette façon. On propose un mécanisme relatif à ce piégeage (qui fait intervenir par exemple les radicaux alkoxy, les radicaux aryloxy et les radicaux cationiques du type carboxylate aromatique) et on l'illustre par des exemples.

[Traduit par le journal]

## Introduction

The increase in our understanding of the radical chemistry of nitro compounds has largely gone hand-in-hand with the development of esr spectroscopy as a physical–organic tool for probing the structures and mechanisms of reaction of free radicals.

Thus both electrochemical techniques, with aromatic (1) and aliphatic (2) substrates, and alkali-metal reduction (3) methods were developed to study relatively stable nitro radical-anions; mechanistic information often resulted, as in the reductive dehalogenation of some aromatic examples (4), electron-transfer reactions involving carbanions and *p*-nitrobenzyl halides (5), and the formation of nitroxides during alkali-metal reduction of nitroalkanes (6). Nitro compounds also provided early examples of the correlation of esr parameters with the results of molecular orbital calculations (1*b*), the occurrence of restricted rotation (for *p*-nitrobenzaldehyde$^{-\cdot}$ (1*a*)), steric inhibition of resonance when bulky substituents are present in the *ortho* positions (1*b*), buttressing effects (7), and many instances of alternating line-width phenomena (8) and solvent effects (2, 9). More recent examples include investigations of substituent effects for $ArNO_2^{-\cdot}$ (10) (and a correlation between angles of twist and rates of electron-transfer from $\cdot CMe_2OH$), $pK_a$ values and hydrogen-bonding effects in aromatic radical-anions (11) and more sophisticated MO calculations (12).

A further important area, to be described here, is the use of esr to study the reactions of nitroalkanes in the presence of short-lived radicals in aqueous solution, and, in particular, the development of "spin-trapping" methods employing both $CH_3NO_2$ and its *aci*-anion $CH_2{:}NO_2^-$.

## Experimental method

Most of the reactions to be described have been studied using an esr spectrometer in conjunction with simple two- or three-way flow systems in which separate solutions are mixed ca. 70 ms before passage of the combined solution through the cavity of the spectrometer; although in the earlier experiments gravity feed was normally employed, it is customary now to maintain the flow with a peristaltic pump. Full experimental details of the flow systems, spectrometers, measurement and calibration of spectra, reagent concentrations, and control and measurement of pH have been given previously (ref. 13 and references therein) and will not be repeated here.

## Results and discussion

### *Radical reactions of nitromethane in aqueous solution*

A variety of redox reactions, normally employing titanium(III) as reductant, have been utilized to generate "primary" radicals (see, e.g. reactions [1]–[4] (13, 14)) whose further reactions have been studied. It should be noted that when a reactive first-formed radical (e.g. $\cdot OH$) is scavenged in the

flow system by reaction solely with an excess of an added substrate (RH), then if the resulting radical R· is short-lived (i.e. $2k_t$ ca. $10^9$ dm$^3$ mol$^{-1}$ s$^{-1}$), a pseudo-steady state condition for the formation and destruction of R· is achieved and kinetic analysis of the reaction system is possible (15); applications will be described later. We shall also describe results, analogous to those obtained using flow systems, from investigations in which ·OH is generated by *in situ* radiolysis (16).

[1] $Ti^{III} + H_2O_2 \rightarrow Ti^{IV} + \cdot OH + OH^-$

[2] $Ti^{III} + S_2O_8^{2-} \rightarrow Ti^{IV} + SO_4^{-\cdot} + SO_4^{2-}$

[3] $Ti^{III} + NH_3OH^+ \rightarrow Ti^{IV} + NH_3^{+\cdot} + OH^-$

[4] $Ti^{III} + RO_2H \rightarrow Ti^{IV} + RO\cdot + OH^-$

*(a) Electron transfer and addition to $CH_3NO_2$.* When ·OH is generated in the presence of ethanol (0.6 mol dm$^{-3}$) and nitromethane (0.03 mol dm$^{-3}$) at pH ca. 8, the strong esr signal detected has $a$(N) 2.57, $a$(3H) 1.20 mT, with $g$ 2.0051 (17); this is assigned to the nitromethane radical-anion $MeNO_2^{-\cdot}$ (1), whose structure will be described later. This radical also results under similar circumstances in the presence of other alcohols with an α-hydrogen atom, and it is concluded that the α-hydroxyalkyl radicals formed by reaction of the electrophilic hydroxyl radical with added alcohols react via an overall one-electron transfer reaction (facilitated by the +M effect of the oxygen substituent). In contrast, a variety of different radicals with parameters somewhat similar to this is detected from the reactions of the same alcohols at low pH (ca. 2) and from the corresponding ether-derived species at both pH 2 and 8. For example, the radical formed from ·CHMeOH and $MeNO_2$ at pH 2 has $a$(N) 2.79, $a$(3H) 1.02 mT, $g$ 2.0052; that from ·CHMeOEt and $MeNO_2$ (at both pH 2 and 8) has $a$(N) 2.74, $a$(3H) 0.86 mT, with $g$ 2.0052. These signals are assigned to the alkoxynitroxide radical-adducts $CH_3N(O\cdot)OCHMeOH$ (**2**) and $CH_3N(O\cdot)OCHMeOEt$ (**3**), formed in reactions which are again facilitated by the +M effect of the oxygen substituents as indicated in Scheme 1 (for an alcohol-derived radical) and Scheme 2 (for an ether-derived example); in the former the base-catalysed route to the radical-anion is also indicated. The reactions of other aliphatic nitrocompounds, the formation of aromatic analogues of the adducts (with splittings from protons in the alkoxy moiety), and the production of nitroxides from $RNO_2H$ (formed in acid solution) have also been described (17). It should be stressed that reactions as shown in Schemes 1 and 2 are typical of radicals with a *reducing* capacity, and are not shown by, for example, Me· (see below).

SCHEME 2

*(b) Reactions of $CH_2$:$NO_2^-$: addition and oxidative electron-transfer.* The attractions of $MeNO_2$ as a spin-probe for radicals in aqueous solution include not only its ready availability and its solubility in water but also the relative stability of its *aci*-anion $CH_2$:$NO_2^-$ ($CH_3NO_2$ has p$K_a$ 10.2 (18)); at pH values ≥ ca. 8.5 (which can be readily achieved in flow system experiments) a significant — and adjustable — concentration of the *aci*-anion can be achieved and its high reactivity exploited.

For example, when ·OH is generated either by the redox reaction [1] in a flow system (19) or by *in situ* γ-irradiation (16) in the presence of $N_2O$ (to convert $e^-$ into ·OH), its resultant reaction with $CH_2$:$NO_2^-$ leads to the detection of the adduct (**4**), with $a$(N) 2.49, $a$(2H) 0.89 mT, $g$ 2.0051 (reaction [5]). Several points are important here; firstly, the very rapid rate of *trapping* of ·OH is notable ($k_5$ has been estimated as $9 \times 10^9$ dm$^3$ mol$^{-1}$ s$^{-1}$ from a pulse radiolysis study (20); in contrast, the electrophilic ·OH radical is relatively unreactive towards $CH_3NO_2$ (21)); secondly, the fact that whereas ·OH itself is undetectable in fluid solution (22),

strong signals from the adduct (**4**) are readily obtained (it has been shown (21) that the related radical-ion $CH_3NO_2^{-\cdot}$, and to a less marked extent $CH_3N(O\cdot)OH$, are significantly longer-lived than simple short-lived organic radicals in solution); and thirdly, that the parameters for the radical detected characterize its structure (see later).

[5] $HO\cdot + CH_2{:}NO_2^- \xrightarrow{k_5} HOCH_2NO_2^{-\cdot}$
**4**

Reaction of ·OH with dimethyl sulphoxide in the presence of $CH_2{:}NO_2^-$ leads to the formation and trapping of Me· (reactions [6] and [7]) to give the easily recognized esr signal of the nitro*ethane* radical-anion (**5**) (Fig. 1) (23, 24); this spectrum (with $a$(N) 2.60, $a$(2H) 0.97, $a$(3H) 0.05 mT, $g$ 2.0050) illustrates the narrow line-widths (and hence good resolution) obtained with this type of trap, which, as in this case, often reveals the presence of a characteristic γ-proton coupling. From the point of view of structural verification it is helpful that independent routes to the spin-adducts are often available (e.g. in this case, the electron-transfer reaction of ·CHMeOH and nitroethane at pH ca. 8; *cf.* Scheme 1). We might also note here that relatively electron-rich radicals, e.g. ·CHMeOH, can also be trapped (24) via addition to $CH_2{:}NO_2^-$ at pH ca. 9 (reaction [8]); the parameters of **6**, and the general usefulness of this spin-trapping reaction, will be discussed subsequently.

[6] $HO\cdot + Me_2S{=}O \rightarrow Me\cdot + MeSO_2H$

[7] $Me\cdot + CH_2{:}NO_2^- \rightarrow MeCH_2NO_2^{-\cdot}$
**5**

[8] $\cdot CHMeOH + CH_2{:}NO_2^- \rightarrow HOCHMeCH_2NO_2^{-\cdot}$
**6**

The spectrum detected (25) during the oxidation of nitromethane in a flow system at pH ca. 9 with $SO_4^{-\cdot}$ is identical to that observed (26) in the one-electron reduction of 1,2-dinitroethane with $\cdot CO_2^-$ and is accordingly assigned to the radical-anion (**7**) (with $a$(N) 2.54, $a$(2H) 1.12, $a$(2H) 0.04 mT, $g$ 2.0050); evidently the sulphate radical-anion effects overall one-electron oxidation of the *aci*-anion to $\cdot CH_2NO_2$, which is subsequently trapped (reactions [9] and [10]). The spectrum of the *adduct* $^-O_3SOCH_2NO_2^{-\cdot}$ is also detected as a minor component in both flow and photolytic experiments. The oxidative reaction sequence illustrated in reactions [9] and [10] is also brought about by the anion-radical $Br_2^{-\cdot}$ (from $Br^-$ and ·OH) and some related species (16).

[9] $CH_2{:}NO_2^- + SO_4^{-\cdot} \rightarrow \cdot CH_2NO_2 + SO_4^{2-}$

[10] $\cdot CH_2NO_2 + CH_2{:}NO_2^- \rightarrow O_2NCH_2CH_2NO_2^{-\cdot}$
**7**

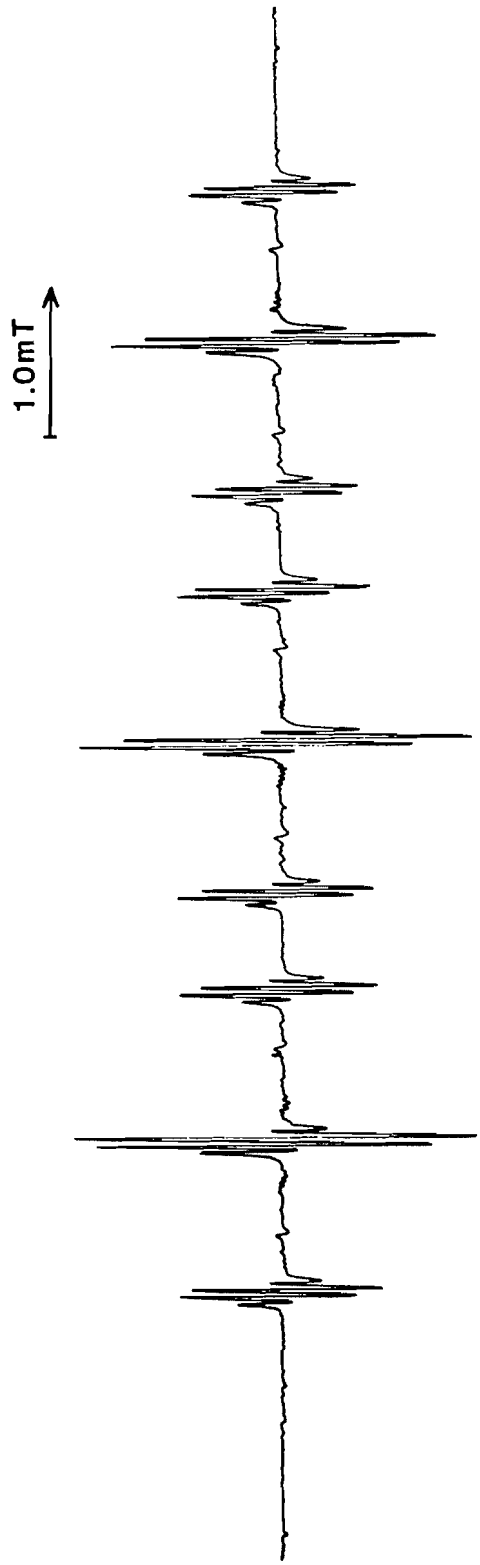

FIG. 1. Electron spin resonance spectrum of $MeCH_2NO_2^{-\cdot}$, formed from the reaction of Me· (from ·OH and $Me_2SO$) and $CH_2NO_2^-$ at pH ca. 9.

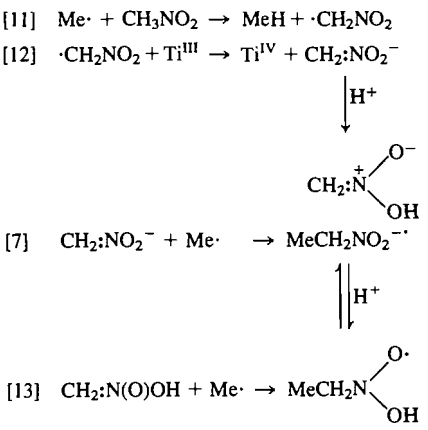
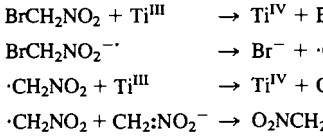
*(c) Hydrogen-atom abstraction from $CH_3NO_2$.* Evidence has been adduced that the radical $\cdot CH_2NO_2$ is also obtained by reaction of the parent nitroalkane with ·Me under appropriate conditions (23). This follows from the detection in the $Ti^{III}$–$H_2O_2$–$Me_2SO$–$MeNO_2$ system of, at pH ca. 6, the radical-anion $EtNO_2^{-\cdot}$ and, at pH ca. 2, the conjugate acid EtN(O·)OH (with $a$(N) 2.81, $a$(2H) 0.91, $a$(1H) 0.32 (23), $g$ 2.0049 (26)): under these conditions the concentration of $CH_2{:}NO_2^-$ formed by ionization of nitromethane is too low (even at pH 6) to serve effectively as a trap and another route to its generation is required. It is proposed that both $CH_2{:}NO_2^-$ and, at lower pH, the conjugate acid $CH_2{:}NO_2H$ are formed by one-electron reduction by $Ti^{III}$ of $\cdot CH_2NO_2$ generated in the initial hydrogen-abstraction reaction (see Scheme 3) and that they can then serve as effective spin



SCHEME 3

traps. It is suggested that $k_{11}$ is ca. $10^3$ dm$^3$ mol$^{-1}$ s$^{-1}$ under these conditions and that both trapping reactions [7] and [13] are very rapid. Electron spin resonance experiments of this sort also enable p$K_a$ to be determined for the nitro radical-anion protonation equilibria (e.g. a value for p$K_a$ of 4.4 was obtained (23) for $Pr^iNO_2H \rightleftharpoons Pr^iNO_2^{-\cdot} + H^+$, these radicals being generated from Me· and CHMe:$NO_2H$ and CHMe:$NO_2^-$ in experiments with nitroethane). A broadly similar mechanism, involving loss of bromide ion from a first-formed radical-anion and subsequent reduction of the α-nitro radical is thought to explain the formation of $O_2NCH_2CH_2NO_2^{-\cdot}$ in the reaction of $Ti^{III}$ with $BrCH_2NO_2$ (see Scheme 4) (28).



SCHEME 4

*Structural properties of $XCH_2NO_2^{-\cdot}$*

In assessing the usefulness of the *aci*-anion $CH_2{:}NO_2^-$ as a spin trap it is helpful to discuss briefly what is known about the structures of the radical-anions $RCH_2NO_2^{-\cdot}$ and to examine the sensitivity of the esr parameters ($a$(N), $a$(β-H), long-range couplings, line-widths, and $g$-values) to variations in the nature of the addend X.

It has been suggested (12*a*) that the enhanced nitrogen splitting of ca. 2.5 mT observed for aliphatic nitro radical-anions and the corresponding alkoxynitroxides, in comparison with typical values of $a$(N) of ca. 1.5 mT for dialkyl nitroxides, is a result of the non-planarity of the bonds at the radical centre; in contrast, most nitroxides are deduced to be essentially planar at the nitrogen atom (29). This conclusion is supported by the results (12*a*) from INDO calculations on $MeNO_2^{-\cdot}$ and $EtNO_2^{-\cdot}$ (for which an angle for out-of-plane bending at the N—O bonds of ca. 6° is suggested) and by the estimate from anisotropic spectra of a $2p{:}2s$ ratio of ca. 11.5 for the orbital of the unpaired electron in nitroalkane radical-anions and related alkoxynitroxides (30). Despite the lack of planarity at the radical centre, it nevertheless appears (12*a*) that the angular dependence of the β-proton splitting in $RNO_2^{-\cdot}$ (R = Me, Et) essentially follows the $B\cos^2\theta$-type expected for hyperconjugative interaction in planar π-radicals (for $MeNO_2^{-\cdot}$ the calculated (INDO) variation of $a$(β-H) with θ is

$$a(\beta\text{-H}) = 0.023 + 0.359\cos\theta + 2.114\cos^2\theta \text{ mT}$$

i.e. with the last term dominant). Variations in $a$(N) and $a(CH_2)$ with structure can generally be interpreted in terms of alterations to the geometry of the radical centre as well as to conformational changes, as will subsequently be explained.

*(a) Carbon-centred radicals.* Table 1 contains details of the esr parameters of some nitro radical-anions formed by trapping carbon-centred radicals (generated in a variety of reactions) with $CH_2{:}NO_2^-$ (24). Although most of these can actually be directly detected under certain circumstances, several others (e.g. Ph·, ·COMe) are generally undetectable by esr under these conditions.

Radicals of the type $RCH_2NO_2^{-\cdot}$ are normally characterized by a nitrogen splitting in the range 2.53–2.60 mT and a β-proton triplet splitting of ca. 1.0 mT; in addition, long-range coupling to γ-$CH_2$ protons and, sometimes, to δ-protons can be observed. This provided crucial diagnostic evidence for the formation of certain radicals, e.g. $\cdot CH_2CHO$ in the base-catalysed rearrangement of $\cdot CH(OH)CH_2OH$ from glycol.

Two other trends are noticeable, and their recognition assists radical diagnosis and hence mech-

TABLE 1. Electron spin resonance parameters for adducts $RCH_2NO_2^{-\cdot}$ formed from carbon-centred radicals[a,b]

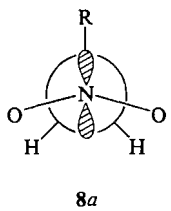
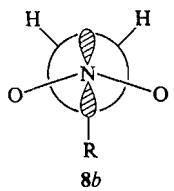
anistic deductions (though mechanistic features will not be elaborated here). The first is the small but significant decrease in $a$(N) associated with bulky β-substituents (cf. in particular, values of $a$(N) of 2.37 and 2.21 mT for adducts with ·$Bu^t$ and ·$CCl_3$ respectively (the enhanced $g$-value for the latter is also notable)); this we attribute to a tendency towards *flattening* of the pyramidal nitro-group induced by the increased size of R. The second is the reduction in $a$(β-H) for such substituents (cf. 0.77 mT for R = $CCl_3$); this we attribute to increased conformational preference for the eclipsed structures **8***a* and **8***b*. The line-width alternation of the 1:2:1 pattern from the β-protons in, e.g. $HOCMe_2CH_2NO_2^{-\cdot}$, and related radicals (25), presumably reflects restricted rotation about either the C—N or the $C_\beta$—$C_\gamma$ bonds or both.



**8***a*



**8***b*

*(b) Spin-adducts from oxygen-centred and nitrogen-centred radicals*. Table 2 contains details of spin-adducts formed from $CH_2{:}NO_2^-$ and some short-lived oxygen- and nitrogen-centred radicals in aqueous solution. The adducts of the oxygen-centred radicals (which themselves are not directly detectable in aqueous solution) are characterized by rather low $a$(N) and $a$(β-H) values (see above) which suggests that the β C—O bond tends to eclipse the orbital of the unpaired electon (and probably lowers $a$(N) by favouring (flattened) structures of type **9**; cf. ·$CH(OH)CH_2OH$ and other radicals with an inductively electron-withdrawing β-substituent and a +M substituent at the radical centre (34)). Further evidence for some assignments derives from changes in the relative concentrations of different adducts with the concentration of the trap; for example, in the oxidation (32) of benzoate with $SO_4^{-\cdot}$ the assignments of adducts **10** (see Table 2) and **11** (see Table 1) are consistent with the increase in concentration of the former, with respect to the latter, as [$CH_2{:}NO_2^-$] is increased so that addition of $PhCO_2$· to trap competes more effectively with fragmentation (see e.g. Fig. 2). Kinetic applications of this type of study will be described later, but it may be noted that simple acyloxy radicals ($RCO_2$·) fragment too rapidly for trapping in this way (35).

The formation of amino radicals and alkylamino radicals in the one-electron reduction (33) of hydroxylamine and *N*-alkylhydroxylamines, respectively, is confirmed by the detection of spin-adducts with $CH_2{:}NO_2^-$ (see Table 2); these possess β-nitrogen couplings as well as long-range splittings from N—H and *N*-alkyl protons. The first-formed radicals in these systems (e.g. ·NHMe) are not detected directly under our conditions, evidently due to the occurrence of very rapid reactions including rearrangement (to α-amino-

alkyl radicals), hydrogen abstraction from parent hydroxylamine, and, possibly, one-electron reduction. Trapping of the azido radical $N_3$· (from azide ion and ·OH, generated radiolytically) leads to the formation of an adduct with long-range coupling from all the nitrogen atoms (see Table 2) (16); a structure with a linear arrangement of the azido nitrogen atoms, $\bar{N}=\overset{+}{N}=NCH_2NO_2^{-\cdot}$ is preferred.

*(c) The trapping of sulphur- and phosphorus-centred radicals*. Table 3 illustrates the potential of this spin-trapping method in characterizing a variety of first-formed radicals, and hence in providing useful mechanistic information, in both radiolysis (16) and flow (36–40) studies. This is nowhere more important than in probing the mechanisms of oxidation of sulphur-containing compounds, especially as most sulphur-centred radicals (e.g. thiyl radicals, RS·) are not directly detectable yet play a key rôle in oxidation pathways. The most notable features of these trapped adducts are the particularly low nitrogen and β-proton splittings, which indicate that there is strong preference for the eclipsed conformation (**12**) (cf. also radicals of the type $\cdot CH_2CH_2SR$ (41)), as well as, in most cases, enhanced $g$-values suggestive of spin-transfer from the radical centre. Recognition of these features leads to the proposal for **13** as the structure of the adduct formed from the reaction of ·OH with $S_2O_3^{2-}$ in the presence of $CH_2{:}NO_2^-$ (16, 36). Further useful information comes from long-range coupling "across sulphur" in the adducts with ·SCN (**14**), $(Pr^iO)_2P(S)S\cdot$ (**15**) (the parent radical's esr spectrum can be detected (42) in fluid media at low temperature but the line-width increases with temperature to render it undetectable under ambient conditions), and in thioalkyl adducts $RCH_2$-$SCH_2NO_2^{-\cdot}$ (**16**) (see Fig. 3). Phosphorus-centred radicals are trapped to give species with large (3–4 mT) β-phosphorus splittings, and, in one case, detectable interaction with a P—H proton (**17**).

*(d) Magnetic inequivalence due to chirality*. A further aid to correct structural identification of adducts is the recognition that for radicals XYZ-$CCH_2NO_2^{-\cdot}$ in which three different groups are

attached to the γ-carbon, the adjacent methylene protons are rendered non-equivalent (diastereotopic) by the chirality at $C_\gamma$, and two non-equivalent splittings result (with consequently a 1:1:1:1 pattern for the β-protons). Examples are given in Table 4 and in Figs. 4 and 5. It should be stressed that this phenomenon occurs *even in the absence of restricted rotation*; where restricted rotation also occurs the inner two lines of the β-protons' 1:1:1:1 pattern are broadened compared with the outer lines (see e.g. the spectrum of $^-O_2CCH_2CH(CO_2^-)CH_2NO_2^{-\cdot}$ in Fig. 4); the crucial observation in this and related examples is that, as the temperature is raised, the inner two lines simply sharpen but do not coalesce, as would have been expected had restricted rotation alone been the cause of inequivalence.

[a]Taken from ref. 24; $g = 2.0050$.

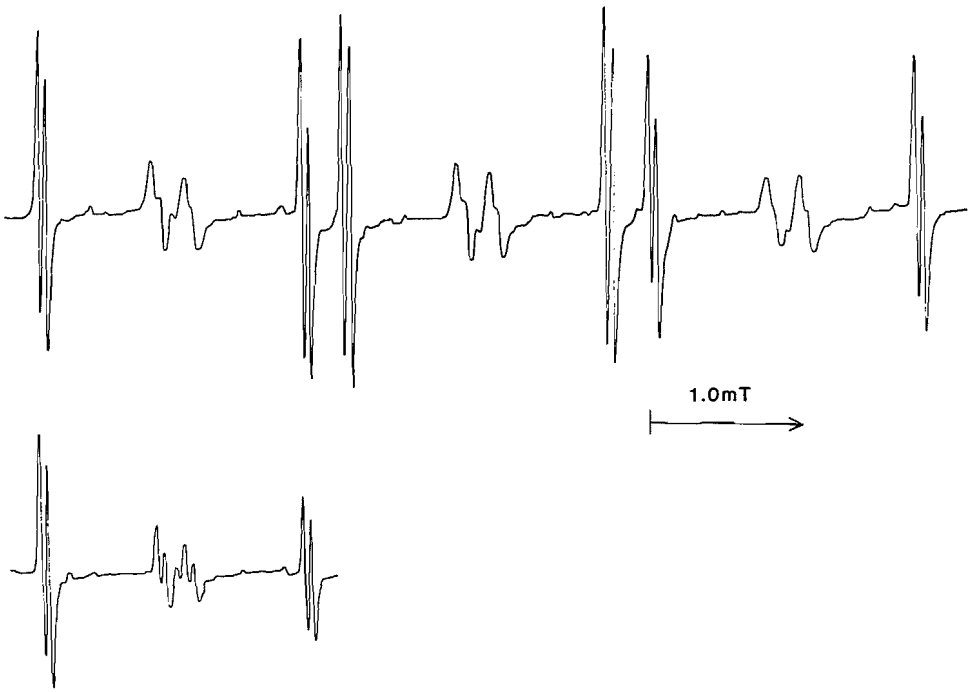

FIG. 4. An example of an adduct $XYZCCH_2NO_2^{-\cdot}$ with non-equivalent splittings from diastereotopic β-protons: $^-O_2CCH_2CH(CO_2^-)CH_2NO_2^{-\cdot}$ (from $SO_4^{-\cdot}$ and succinate) at 20°C, showing the marked line-broadening of the inner lines of the proton hyperfine pattern. The peaks inset are from the low-field components at 40°C.

These phenomena have been discussed in some detail elsewhere (24, 43) and the arguments will not be rehearsed here; however, it might simply be noted now that for these adducts and related nitroxides (43) (e.g. $XYZCCH_2N(Bu^t)O\cdot$) both the differences between the two non-equivalent splittings *and* the extent of differential line-broadening increase with the bulk of the γ-substituents (being particularly marked for carboxylate, chlorine and bromine substituents, see e.g. **18** (24)). This observation can in itself serve a useful diagnostic purpose, as in the characterization of $\cdot CHBrCO_2^-$ (not directly detectable) in the reaction of ·OH with bromoethanoate (see Fig. 5).

*Kinetic and mechanistic studies of radical reactions*

Finally, we illustrate with several examples how the knowledge of the structures of adducts $XCH_2NO_2^{-\cdot}$, as revealed by $a$(N), $a$(H), $g$ etc., can prove helpful in mechanistic and kinetic studies; particular emphasis will be placed upon examples where

the intermediate radicals themselves are not directly detectable in solution by esr (e.g. RO·, $RCO_2$·) or where the radicals show particularly high reactivity, and hence a low, often undetectable, signal-to-noise ratio.

*(a) Decomposition of alkyl hydroperoxides*. It is found (14, 31) that when various alkyl hydroperoxides are reduced by $Ti^{III}$ in a flow system in the presence of $CH_2{:}NO_2^-$, adducts formed from the appropriate alkoxyl radicals (RO·) can be detected (reactions [4] and [14]). Alkoxyl radicals are also formed in the reaction between HO· and dialkyl sulphites (reaction [15]), and they have been characterized similarly (44).[1]

[4] $ROOH + Ti^{III} \rightarrow RO\cdot + OH^- + Ti^{IV}$

[14] $RO\cdot + CH_2NO_2^- \rightarrow ROCH_2NO_2^{-\cdot}$

[15] $HO\cdot + (RO)_2S{=}O \rightarrow RO\cdot + ROSO_2H$

[16] $RO\cdot \xrightarrow{-O-} R'\cdot$

[17] $R'\cdot + CH_2NO_2^- \rightarrow R'CH_2NO_2^{-\cdot}$

In these reactions, the concentration of the spin trap employed is crucial; thus although at high concentrations of spin trap the corresponding alkoxyl radical can in many cases be intercepted, to give $ROCH_2NO_2^{-\cdot}$, other reactions of the alkoxyl radical (fragmentation, rearrangement) can compete effectively with the addition at lower values of $[CH_2NO_2^-]$, and secondary radicals (·R′) can be characterized (reactions [16] and [17]); parameters of the appropriate radicals are given in Table 5.

[1] Confirmation that alkoxy adducts have been correctly identified derives from the independent generation of the radical assigned the structure $EtOCHMeNO_2^{-\cdot}$ (from EtO· and $CHMe{:}NO_2^-$) from the reaction between ·CHMeOEt (from ·OH and diethyl ether) and $NO_2^-$ (45).

For example, in experiments with $Bu^tO_2H$ and $Ti^{III}$, the methyl radical (see reactions [18] and [19]) is directly detectable (45). When the experiment is carried out in the presence of $CH_2{:}NO_2^-$, the spectrum of $MeCH_2NO_2^{-\cdot}$ becomes detectable; at pH 9.5, with $[CH_2{:}NO_2^-]$ ca. $10^{-3}$ mol $dm^{-3}$ the methyl radical is completely scavenged in this way (reaction [7]). Knowledge of the steady-state concentration of Me· in the absence of nitromethane (ca. $10^{-6}$ mol $dm^3$) and the rate constant for self-termination of ·Me (ca. $5 \times 10^9$ $dm^{-3}$ $mol^{-1}$ $s^{-1}$ (46)) leads to the conclusion that to scavenge Me· in this way the rate constant for the addition reaction [7] must be $>10^7$ $dm^3$ $mol^{-1}$ $s^{-1}$. When $[CH_2{:}NO_2^-]$ is raised, the signal from $MeCH_2NO_2^{-\cdot}$ is joined by that attributed to $Bu^tOCH_2NO_2^{-\cdot}$ (with a 1:1 ratio of the Me· and $Bu^tO$· adducts for $[CH_2{:}NO_2^-]$ ca. 0.005 mol $dm^{-3}$): we conclude that addition now competes with fragmentation and also, employing steady-state analysis of the kind described in ref. (14), that $k_{20}/k_{19}$ is ca. $2 \times 10^2$ $dm^3$ $mol^{-1}$.

[18] $Bu^tO_2H + Ti^{III} \rightarrow Ti^{IV} + OH^- + Bu^tO\cdot$

[19] $Bu^tO\cdot \rightarrow Me_2C{=}O + Me\cdot$

[7] $Me\cdot + CH_2{:}NO_2^- \rightarrow MeCH_2NO_2^{-\cdot}$

[20] $Bu^tO\cdot + CH_2{:}NO_2^- \rightarrow Bu^tOCH_2NO_2^{-\cdot}$

Other reactions which can be demonstrated (14) in this way include the 1,2-shift typical of primary alkoxy radicals in aqueous solution (reactions [21] and [22]) and the competing 1,5-shift in [23] (with $k_{22} \simeq k_{23}$); from experiments in which the 1,2-shift is in competition with intermolecular hydrogen-atom abstraction (e.g. the formation of $\cdot CH_2OH$ from PrO· and $CH_3OH$) it is suggested that the pseudo first-order rate constant $k_{21}$ is ca. $10^7$ $s^{-1}$ ($k_{22}$ and $k_{23}$ are presumably also of this magnitude), and the lower limit for addition of propoxyl to $CH_2{:}NO_2^-$ is estimated as $10^8$ $dm^3$ $mol^{-1}$ $s^{-1}$. It is likely that $k_{20}$ is $>10^8$ $dm^3$ $mol^{-1}$ $s^{-1}$ (it may be as high as $10^9$ $dm^3$ $mol^{-1}$ $s^{-1}$) and that $k_{19}$ is in the range $10^6$–$10^7$ $s^{-1}$ (much faster than the fragmentation rate in non-aqueous solution, cf. ref. 47). Particularly rapid reactions ($>10^8$ $s^{-1}$) are the cyclisation (reaction [24]) and the fragmentation and intramolecular abstraction reactions [25] and [26], in which no intermediate alkoxyl radicals could be intercepted.

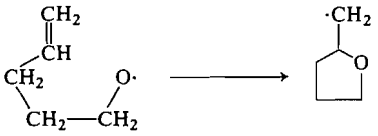
*(b) Generation and reaction of aroyloxyl and acyloxyl radicals.* As mentioned earlier, oxidation of benzoate ion with $SO_4^{-\cdot}$ in the presence of $CH_2{:}NO_2^-$ at pH 9 led to the detection of signals assigned to $PhCO_2CH_2NO_2^{-\cdot}$ and $PhCH_2NO_2^{-\cdot}$ (evidently formed as in reactions [9] and [10]), as

[21] $CH_3CH_2CH_2{-}O\cdot \xrightarrow{(H_2O)} CH_3CH_2\dot{C}HOH$

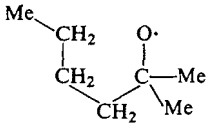
[22] $CH_3CH_2CH_2CH_2{-}O\cdot \rightarrow CH_3CH_2CH_2\dot{C}HOH$

[23] $CH_3CH_2CH_2CH_2{-}O\cdot \rightarrow \cdot CH_2CH_2CH_2CH_2OH$

[24]



[25]



$\rightarrow MeCHCH_2CH_2CMe_2OH$

[26] $\rightarrow MeCH_2CH_2\dot{C}H_2 + Me_2CO$

well as to those of $O_2NCH_2CH_2NO_2^{-\cdot}$ and $^-O_3OSCH_2NO_2^{-\cdot}$ formed by direct reaction between $SO_4^{-\cdot}$ and the trap (32). The assignment $PhCO_2CH_2NO_2^{-\cdot}$ has been challenged (27, 48) on the grounds that an (unassigned) spectrum with these parameters is also detected from the reaction between photolytically generated $SO_4^{-\cdot}$ and $CH_2{:}NO_2^-$ in the absence of benzoate (48). However, important structural evidence (which also provides interesting mechanistic insight) that the assignments to $PhCO_2CH_2NO_2^{-\cdot}$ (**10**) and $PhCH_2NO_2^{-\cdot}$ (**11**) are correct stems from the observation that these same two signals are detected (32) when peroxybenzoic acid is reduced by $Ti^{III}$ under identical conditions. As expected if reactions [27]–[30] are involved, the intensity of the signal assigned to **10** increased at the expense of **11** as $[CH_2{:}NO_2^-]$ was increased (precisely as found for the $PhCO_2^-/SO_4^{-\cdot}$ oxidation). An upper limit for the decarboxylation of benzoyloxyl of ca. $2.5 \times 10^5$ $s^{-1}$ is calculated from the concentration of nitromethane needed to capture $PhCO_2\cdot$ (35).

[27] $PhCO_2OH + Ti^{III} \rightarrow PhCO_2\cdot + OH^- + Ti^{IV}$

[28] $PhCO_2\cdot + CH_2{:}NO_2^- \rightarrow PhC(=O)OCH_2NO_2^{-\cdot}$

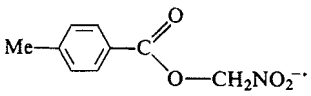
**10**

[29] $PhCO_2\cdot \rightarrow Ph\cdot + CO_2$

[30] $Ph\cdot + CH_2{:}NO_2^- \rightarrow PhCH_2NO_2^{-\cdot}$

**11**

For some substituted aromatic derivatives, however, oxidation of $ArCO_2^-$ by $SO_4^{-\cdot}$ and reduction of the corresponding peroxyacid by $Ti^{III}$ led to contrasting esr observations. For example, *p*-peroxytoluic acid and $Ti^{III}$ gave not only the adducts attributed the structures **19** and **20** but also a weak signal of the adduct **21**; in the oxidation of *p*-toluate with $SO_4^{-\cdot}$, however, only **19** and **21**



**19**

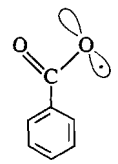
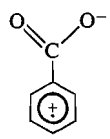
could be detected, with no trace of **20**. Increase of $CH_2{:}NO_2^-$ in the former system led to an increase of [**19**] at the expense of [**20**] and [**21**], whereas in the latter experiment the ratio of [**19**] to [**21**] remained constant.

These results cannot be rationalized on the basis of a scheme in which a common intermediate ($MeC_6H_4CO_2\cdot$) is formed *directly* from both $ArCO_2^-$ and $ArCO_3H$ in the two systems. Our findings can, however, be rationalized by the mechanism outlined in Scheme 5; we envisage that in the peroxyacid reduction, the aroyloxyl radical (**22**), once formed, can undergo competing reactions involving fragmentation (to give the aryl radical, which is then trapped), addition to $CH_2{:}NO_2^-$, and intermolecular hydrogen abstraction from *p*-toluate formed *in situ* to give, ultimately **21** (the benzyl radical itself can be directly detected in the absence of trap; its signal is intensified when *p*-toluate is added to the system). In contrast, in the oxidation of *p*-toluate with $SO_4^{-\cdot}$ the relatively low concentration of aroyloxyl radical trapped and the much stronger signal from **21** — and the invariance of their ratio with $[CH_2NO_2^-]$ — implies that a first-formed intermediate (evidently the radical-cation **23**, *cf.* also ref. 49) is partitioned between loss of a proton, to give the benzyl radical, and conversion into the aroyloxyl radical *before* trapping with $CH_2{:}NO_2^-$. Our finding thus emphasizes the fact that **22** and **23** are not representations (canonical forms) of a single species but that the two are distinct chemical entities; these results are in accord with the suggestion (50) that **22** is a σ-radical (*cf.* **24**), with the unpaired electron in an in-plane σ-orbital, in contrast with the structure of the π-type zwitterion **23** (*cf.* **25**) (examples of this type of radical have been characterized by esr (49)).



**24**



**25**

Similar observations were made for the reactions of *o*-toluate and *o*-peroxytoluic acid with the notable difference that in the reduction of the peracid in the presence of the trap a much greater concentration of the benzyl-type adduct was obtained; this is consistent with the occurrence of very rapid intramolecular hydrogen-atom transfer in the aroyloxyl radical (reaction [31]).

[31] 
Decomposition with $Ti^{III}$ of a variety of peroxoacids (formed in the perhydrolysis of esters and anhydrides with $HO_2^-$ at ca. pH 9) is also thought to proceed via the corresponding aroyloxyl and acyloxyl radicals as precursors of decarboxylated radicals (Ar·, R·) (35). Although the acetoxyl radical was not itself trapped, some aliphatic acyloxy radicals $RCO_2\cdot$ (R = cyclopropyl, $CH_2{=}CH$) live

long enough to be detected via their adducts with the nitromethane *aci*-anion: the rate constants of their decarboxylation are thought to be in the range $10^5$–$10^7$ $s^{-1}$.

Received July 15, 1981

KUNDALIKA M. MORE, GARETH R. EATON, and SANDRA S. EATON. Can. J. Chem. **60**, 1392 (1982).

A series of spin-labeled copper porphyrins has been prepared in which nitroxyl radicals are attached to a porphyrin pyrrole ring by propionamide and propionate ester linkages. The solution epr spectra at room temperature indicate that the values of the electron spin – electron spin coupling constant, $J$, for these compounds are in the range 4 to 18 G, depending on the solvent and the size of the nitroxyl ring. Below −45°C two isomers with different values of $J$ were observed in the epr spectra of two of the compounds. Variable temperature epr spectra were also analyzed for analogous spin-labeled copper porphyrins which have *cis* and *trans* acrylic ester and acrylamide linkages between the porphyrin and the nitroxyl ring. Comparison of the values of $J$ for the complexes with saturated and unsaturated linkages suggests that σ-bonding pathways dominate the copper–nitroxyl interaction in these compounds.

KUNDALIKA M. MORE, GARETH R. EATON et SANDRA S. EATON. Can. J. Chem. **60**, 1392 (1982).

On a préparé une série de phorphyrines de cuivre, contenant un marqueur de spin, dans lesquelles les radicaux nitroxyles sont attachés à la portion porphyrine du cycle pyrrole par des amides et des esters propioniques. Les spectres de rpe, en solution et à la température ambiante, indique que les constantes de couplage spin électron – spin électron dans ces composés varient de 4 à 18 G selon le solvant et la taille du cycle nitroxyle. A des températures inférieures à −45°C, on a observé, dans les spectres de rpe de deux de ces composés, la présence de deux isomères ayant des valeurs différentes de $J$. On a également analysé les spectres de rpe à température variable des porphyrines de cuivre analogues contenant un marqueur de spin dans lesquelles on a intercalé entre le cycle nitroxyle et la portion porphyrine, des amides ou des esters acryliques avec des isomères *cis* et *trans*. La comparaison des valeurs de $J$ de ces complexes avec celles des produits saturés indique que l'interaction cuivre–nitroxyle induite dans ces composés se transmet principalement par les liaisons σ.

[Traduit par le journal]

## Introduction

Interactions between unpaired electrons may be observed via a variety of physical measurements. Of particular interest in biological systems are the interactions observable by electron paramagnetic resonance (epr) among various pairs or clusters of paramagnetic transition metals and/or organic free radicals (1). These paramagnetic centers may be a natural component of the biological system or they may be species purposely added as probes or labels (2). Interactions between these centers may affect the epr spectra enough to invalidate the usual interpretations. For example, a spin-labeled biomolecule may yield an epr spectrum which is not validly interpreted in terms of the motion of the label if a paramagnetic metal is present. If, however, the effect of the metal on the nitroxyl epr spectrum were understood in detail, additional information could be obtained from the epr spectrum. For example, an assessment was made several years ago of the effect of dipolar interactions between a metal and a nitroxyl radical on the epr lineshape of the nitroxyl in a rigid matrix (3). This approach has been used by many investigators to obtain metrical information on spin-labeled biomolecules (1). Others have studied the closely related problem of metal – organic radical interactions in vitamin $B_{12}$-dependent enzyme reactions also seeking metrical information (4, 5).

There is promise of achieving considerable insight into the metric and dynamic features of complicated systems, such as enzymes and membranes, by theoretical analysis and experimental calibration of the impact on their epr spectra and relaxation properties of interaction between unpaired electrons. Substantial confusion can result, however, if proper attention is not given to relevant features of the interaction regime. For example, one must consider relative motion of the two species, whether this motion is correlated or not, the nature of the interaction pathway, environment effects such as specific solvation, and potential nonstatistical effects such as specific ion pair or acid/base interactions. Consideration must also be given to relative values of the various characteristic times of the system, such as tumbling or collisional

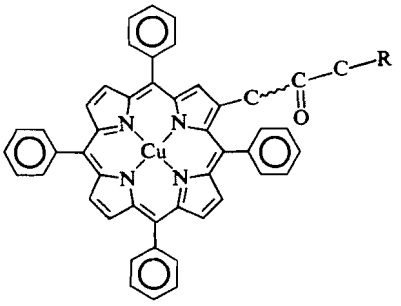
correlation times, electron spin relaxation times, nuclear spin relaxation times, reciprocal of the microwave frequency, and modulation frequency, etc. In some cases the electron–electron interaction can be observed in the lineshape of the normal continuous wave (CW) epr spectrum, and in other cases the interaction is observed only via a non-linear technique (such as CW saturation studies) or time domain (pulsed) epr.

Most work on interacting spin systems has been conducted either in low viscosity fluid solutions or in essentially rigid matrices such as frozen solutions or very slowly tumbling biomolecules. Still to be explored are intermediate tumbling regimes, liquid crystals, phase boundaries (e.g., membrane surfaces), and single crystals.

In this paper we briefly survey the range of phenomena which have been observed in low viscosity fluid solutions of paramagnetic transition metal complexes containing nitroxyl radicals, and mention some preliminary results from work in progress. Detailed description is given of a series of copper(II) porphyrin complexes **I–IX** in which a nitroxyl is observed to exhibit exchange interaction with the copper through a variety of metal–nitroxyl linkages, including a saturated $-CH_2-CH_2-$ chain.



| R | C~C linkage | | |
|---|---|---|---|
| | *cis* C=C | *trans* C=C | saturated $-CH_2-CH_2-$ |
|  | I | IV | VII |
|  | II | V | VIII |
|  | III | VI | IX |

## Experimental section

Infrared spectra were obtained in Nujol mulls on a Perkin-Elmer 337 grating spectrometer. Electronic spectra were obtained in chloroform solution on a Beckman Acta V spectrometer. Data are given below with wavelengths in nm and log ε in parentheses. X-band epr spectra were obtained on a Varian E-9 spectrometer as previously described (6). Electron paramagnetic resonance spectra were run on degassed samples in dried purified solvents with concentrations about $10^{-3}$ *M*. All spectra were obtained with power levels well below saturation. *g*-Values were measured relative to DPPH ($g = 2.0036$). Electron paramagnetic resonance spectra are shown in the figures with the magnetic field increasing to the right. All coupling constants are given in G. High resolution mass spectra were obtained at the Midwest Center for Mass Spectrometry. Elemental analyses were performed by Spang Microanalytical Laboratory.

*Preparation of compounds*

Spin-labeled copper pophyrins **I–VI** were prepared as previously reported (7). *meso*-Tetraphenyl-1-[2-ethoxycarbonylethyl]porphyrin, **X**, was prepared by the method of Momenteau *et al.* (8). The presence of the propionate ester was confirmed by a high resolution mass spectrum. $M^+/e$ observed: 714.3051 ± 0.0126. Calcd. for $C_{49}H_{38}N_4O_2$: 714.2995.

*Copper(II)* meso-*tetraphenyl-1-[2-ethoxycarbonylethyl]-porphyrin,* ***XI***

Cupric chloride (0.2 g, 1.2 mmol) was refluxed with porphyrin **X** (0.72 g, 1 mmol) in DMF (100 mL) until the visible spectra indicated complete conversion to the metalloporphyrin. Water (100 mL) was added to the cooled reaction mixture and the precipitate was collected by filtration. The product was chromatographed on silica gel in $CHCl_3$ solution and the first red band was collected. The product was recrystallized from $CHCl_3$/heptane. Yield: 90%, ir: $\nu_{CO}$ 1720 $cm^{-1}$; vis: 570 (sh, 3.50), 539 (4.29), 416 (5.66).

*Copper(II)* meso-*tetraphenyl-1-[3-propionic acid]porphyrin,* ***XII***

KOH methanol in (7.5 mL, 2 *N*) was added to 100 mg of **XI** in 30 mL of pyridine. The solution was stirred for 24 h at room temperature. The solvent was removed and the residue was neutralized with aqueous HCl. The product was extracted into $CHCl_3$ and the solution was dried over $Na_2SO_4$. The volume of the solution was reduced to 30 mL before putting it on a silica gel column. Unreacted **XI** was eluted with $CHCl_3$. The product was eluted with 2% ethanol in $CHCl_3$ and recrystallized from $CHCl_3$/heptane. The acid appears to decompose when heated for prolonged periods in vacuum. Yield: 67%; ir: $\nu_{CO}$ 1685 $cm^{-1}$; vis: 570 (sh, 3.62), 539 (4.42), 416 (5.81).

*Copper(II)* meso-*tetraphenyl-1-[3-(N-(2,2,6,6-tetramethyl-piperidinyl-1-oxy))propionamido]porphyrin,* ***VII***

Oxalyl chloride (1.1 g, 10 mmol) was added to a solution of **XII** (0.15 g, 0.2 mmol) in 50 mL of dry benzene. The solution was stirred for 2 h at room temperature. The solvent was removed in vacuum and the residue was kept under vacuum for 2 h before dissolving it in 75 mL dry THF and 1 mL dry pyridine. 4-Amino-2,2,6,6-tetramethylpiperidinyl-1-oxy (0.034 g, 0.2 mmol) in 2 mL dry THF was added dropwise under nitrogen. After refluxing the solution for 6 h, the solvent was removed in vacuum and the residue was chromatographed on silica gel in $CHCl_3$ solution. The first red band was collected. The product was recrystallized from $CHCl_3$/heptane. Yield: 61%; ir: $\nu_{CO}$ 1655 $cm^{-1}$, $\nu_{NH}$ 3300 $cm^{-1}$; vis: 570 (sh, 3.65), 539 (4.48), 416 (5.86). *Anal.* calcd. for $C_{56}H_{49}CuN_6O_2$: C 74.60, H 5.48, N 9.32; found: C 74.81, H 5.59; N 9.47.

*Copper(II)* meso-*tetraphenyl-1-[3-(O-(2,2,6,6-tetramethyl-piperidinyl-1-oxy))propionic ester]porphyrin,* ***VIII***

The ester was prepared from copper porphyrin **XII** and 4-hydroxy-2,2,6,6-tetramethyl-piperidinyl-1-oxy by the same procedure as described for **VII**. Yield: 55%. ir: $\nu_{CO}$ 1725 $cm^{-1}$; vis: 570 (sh, 3.64), 539 (4.51), 416 (5.89). *Anal.* calcd. for $C_{56}H_{48}CuN_5O_3$: C 74.52, H 5.36, N 7.76; found: C 74.24, H 5.23, N 7.57.

*Copper(II)* meso-*tetraphenyl-1-[3-(N-(2,2,5,5-tetramethyl-pyrrolidinyl-1-oxy))propionamido]porphyrin,* ***IX***

The amide was prepared from copper porphyrin **XII** and 3-amino-2,2,5,5-tetramethylpyrrolidinyl-1-oxy by the same procedure as described for **VII**. Yield: 67%; ir: $\nu_{C=O}$ 1650 $cm^{-1}$, $\nu_{NH}$ 3320 $cm^{-1}$; vis: 570 (sh, 3.47), 539 (4.28), 416 (5.66). *Anal.* calcd. for $C_{55}H_{47}CuN_6O_2$: C 74.43, H 5.34, N 9.47; found: C 74.27, H 5.21, N 9.28.

## Computer simulations

The interaction between two spins can be expressed in terms of dipolar and exchange components. The main distinguishing feature of dipolar interactions relative to exchange interactions is the angular and distance dependence of the dipolar interactions. It can be shown that expansion of the exchange and dipolar parts of the spin–spin interaction both lead to linear combinations of the same set of nine components of the interaction dyadic (5). The exchange and dipolar components differ only in the scalar coefficients of the dyads (which are bilinear in the spin operators). An epr experiment can yield the values of the coefficients, but their interpretation in terms of exchange and/or dipolar contribution is not unambiguous without additional information such as the geometry of the interaction. The exchange interaction can be written as the sum of three matrices: isotropic exchange, antisymmetric exchange, and symmetric anisotropic exchange. The symmetric anisotropic exchange matrix has precisely the same formal structure as the dipole–dipole interaction matrix, i.e., it is anisotropic but symmetrical about the main diagonal. In rigid media all of these terms have to be considered. However, in rapidly tumbling molecules with the normally encountered $g$-values and distances, it can be estimated that terms other than isotropic exchange average to nearly zero, i.e., less than the linewidths due to other effects. In this case, to which we shall restrict our attention in the rest of the discussion, the isotropic exchange can be treated as a scalar $J$.

It has sometimes been assumed that spin–spin exchange interactions are negligible for distances greater than about 6 Å (9, 10). However, proton–proton spin–spin coupling attributable to exchange interactions has been observed through five bonds in saturated systems and through nine bonds in conjugated hydrocarbons (11). Coupling to distant protons has also been observed in ENDOR spectra (12). Since the electron magnetic moment is much larger than the proton magnetic moment, it is reasonable to expect even longer range spin–spin interactions between two electrons than between two protons or between a proton and an electron. Orbital interactions through six bonds have also been found to be sufficiently large to alter chemical reactivity (13).

A few years ago we reported the first examples of high resolution electron spin – electron spin splitting in epr spectra (14, 15). These spectra can be interpreted in terms of the Hamiltonian [1].

$$[1]\quad \mathcal{H} = g_1\beta H\hat{S}_{1Z} + g_2\beta H\hat{S}_{2Z} + hJ\hat{S}_{1Z}\hat{S}_{2Z} + \frac{hJ}{2}(\hat{S}_{1+}\hat{S}_{2-} + \hat{S}_{1-}\hat{S}_{2+}) + hA_M\hat{S}_{1Z}\hat{I}_{1Z} + hA_N\hat{S}_{1Z}\hat{I}_{2Z} + hA_{N'}\hat{S}_{2Z}\hat{I}_{3Z} + \frac{hA_M}{2} \times (\hat{S}_{1+}\hat{I}_{1-} + \hat{S}_{1-}\hat{I}_{1+}) - g_M\beta_N H\hat{I}_{1Z} - g_N\beta_N H\hat{I}_{2Z} - g_{N'}\beta_N H\hat{I}_{3Z}$$

where $g_1$ and $g_2$ are the $g$ values of the metal and nitroxyl electrons; $\hat{S}_1$ and $\hat{S}_2$ refer to the metal and nitoxyl electron spins, respectively; $J$ is the electron–electron coupling constant in Hertz; $I_1$, $I_2$, and $I_3$ refer to the metal nuclear spin, the nuclear spin of the coordinated nitrogens, and the nuclear spin of the nitroxyl nitrogen, respectively; $A_M$ is the metal electron – metal nuclear coupling constant in Hertz; $A_N$ is the coupling constant in Hertz between the metal electron and the nuclear spins of the coordinated nitrogens; $A_{N'}$ is the coupling constant in Hertz between the nitroxyl electron and the nuclear spin of the nitroxyl nitrogen; and all other symbols are defined as in ref. 16. The first seven terms in the Hamiltonian were treated exactly and the last four were treated as a perturbation to second order for the transition energies and to first order for the transition probabilities. To facilitate visual comparison with the field-swept experimental spectra the values of $J$, $A_M$, $A_N$, and $A_{N'}$ are discussed below in units of G with the conversion between Hertz and Gauss given by eqs. [2]–[4]. The conversion factor for $A_N$ is the same as for $A_M$. Only the absolute value of $J$ can be determined from these calculations.

$$[2]\quad J(\mathrm{G}) = J(\mathrm{Hz}) \cdot \frac{h}{2\beta}\left(\frac{1}{g_1} + \frac{1}{g_2}\right)$$

$$[3]\quad A_M(\mathrm{G}) = A_M(\mathrm{Hz}) \cdot \frac{h}{g_1\beta}$$

$$[4]\quad A_{N'}(\mathrm{G}) = A_{N'}(\mathrm{Hz}) \cdot \frac{h}{g_2\beta}$$

The simulation of epr spectra using Hamiltonian [1] has been reported in detail (16). The computer program CUNO described in ref. 16 has been extended to handle any nuclear spin and to allow more flexibility in simulating linewidths. The essential feature of the calculation can be seen with a simple "stick" diagram (Fig. 1). Each copper transition interacts with each nitroxyl transition producing an "AB quartet" of four lines, analogous to the well-known AB patterns of $^1$H nmr. The

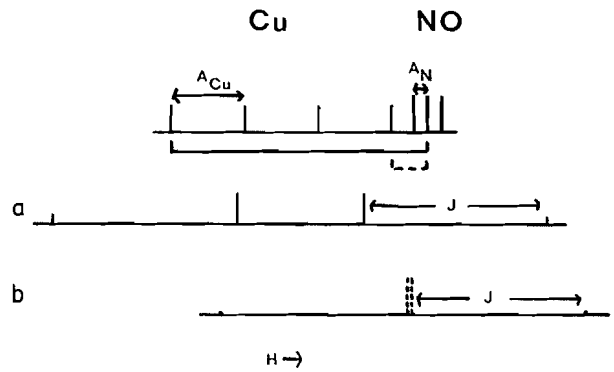

FIG. 1. Schematic representation of two of the AB patterns resulting from interaction of a copper electron ($A_{Cu}$ = 86 G) with a nitroxyl electron ($A_N$ = 15 G) for a value of $J$ of 200 G. The stick spectrum labeled *a* arises from coupling between the $m_I$ = 3/2 copper line (lowest field copper line) and the $m_I$ = 0 nitroxyl line. The stick spectrum labeled *b* arises from coupling between the $m_I$ = −3/2 copper line (highest field copper line) and the $m_I$ = 0 nitroxyl line.

lines in the spectra are referred to as copper or nitroxyl depending on the nature of the transition as $J$ approaches zero. The intensities of the inner and outer lines of the quartet are dependent on the magnetic field separation between the original copper and nitroxyl lines that are interacting and the magnitude of $J$. Figure 1 illustrates this for two different cases. The $m_I$ = +3/2 Cu line and the $m_I$ = 0 line of the nitroxyl are sufficiently far apart that with a $J$ of 200 G, a clear four-line pattern is produced in which the outer lines have significant intensity (Fig. 1, stick spectrum *a*). The Cu −3/2 line and the nitroxyl 0 line are so close together, though, that with a $J$ of 200 G the inner copper and nitroxyl lines are almost superimposed, and the outer lines have little intensity and may in practice not be observable if the linewidths are large (Fig. 1, stick spectrum *b*). Thus, even within a single compound a wide range of ratios of $J$ to the metal-nitroxyl energy separations may occur.

Figure 2 shows observed and calculated room temperature epr spectra for spin-labeled copper porphyrins **VIII**, **XIII** (15, 17), and **XIV** (18). When $J$ is small, as in Fig. 2*A*, the nitroxyl region of the spectrum is an overlapping doublet of triplets and the copper lines only appear to be broadened. In Fig. 2*B* the value of $J$ (78 G) is close to the copper nuclear hyperfine coupling (86 G) so the copper signal is an apparent five-line pattern partially obscured by the sharper nitroxyl lines. The nitroxyl lines are a clearly resolved doublet of triplets. When $J$ is 800 G, as in Fig. 2*C*, the copper and nitroxyl inner lines are nearly coincident, the

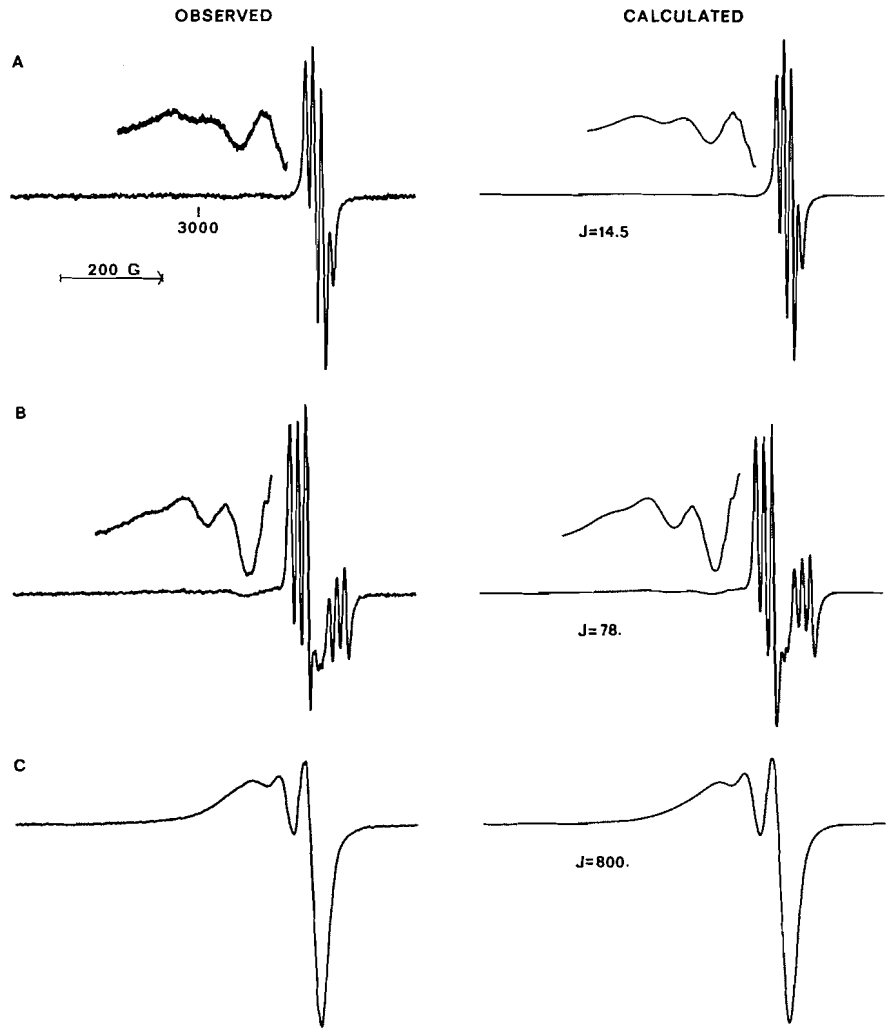

FIG. 2. X-band epr spectra of three spin-labeled copper porphyrins at room temperature and computer simulations to demonstrate the effect of the value of $J$ on the appearance of the spectra. The three spectra are 800 G scans centered at 3025 G. *A*, The spectrum of **VIII** in toluene solution was obtained with 0.63 G modulation amplitude and 4.0 mW power. The computer simulated spectrum was obtained with $J$ = 14.5 G. *B*, The spectrum of **XIII** in $CHCl_3$ solution was obtained with 0.8 G modulation amplitude and 20 mW power. The value of $J$ in the simulated spectrum is 78 G. *C*, The spectrum of **XIV** in toluene solution was obtained with 2 G modulation amplitude and 15 mW power. The value of $J$ in the simulated spectrum is 800 G.

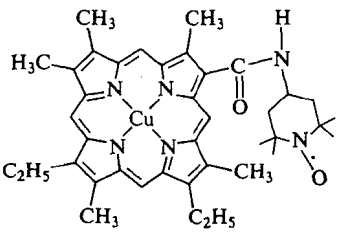
apparent copper hyperfine splitting is one-half $A_{Cu}$ (1/2 × 86 G) and the outer lines of the AB pattern are not observed. Overall there is good agreement between the observed and calculated spectra. There is, however, some discrepancy for the lowest field copper lines due to incomplete motional averaging of $g$- and $A$-anisotropy which is not included in the computer simulations.

## Results and discussion

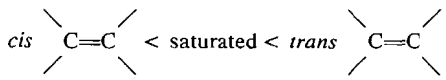
Details are given in the Experimental section for the preparation and characterization of the nitroxyl spin labeled copper porphyrin complexes **VII–IX**. In this section we describe the epr spectra of these compounds and compare them with the spectra of the closely related compounds **I–VI** for which the room temperature epr spectra have previously been reported (7). This series of compounds was designed to compare spin–spin interaction through saturated and unsaturated C—C linkages, keeping everything else as similar as is possible in a series of different compounds.

In a variety of solvents at room temperature the value of $J$ for spin-labeled copper porphyrin **VII**



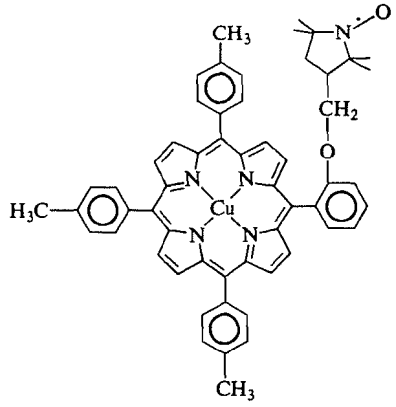
XIII

ranged from 9 to 17 G (cf. Table 1). Similar values of $J$ were observed for **VIII** which contains an ester linkage instead of an amide linkage. The epr spectra of **VIII** in $CHCl_3$ solution (Fig. 2*A*) are typical of the spectra observed for both **VII** and **VIII** at room temperature. The values of $J$ for **VII** and **VIII** are smaller than those previously observed for **IV** and **V** (19–26 G, cf. Table 1) which have a *trans* olefinic linkage between the porphyrin and the nitroxyl (7). For the analogous *cis* isomers **I–III** in noncoordinating solvents the values of $J$ are strongly dependent on solvent and temperature which was attributed to an interaction between the carbonyl oxygen and the porphyrin $\pi$-system or the copper (7). This interaction is blocked by pyridine coordination, so all comparisons in this paper involving the *cis* isomers will be based on spectra taken in the presence of coordinating solvents. Under these conditions the values of $J$ for **I** and **II** are smaller than for **VII** and **VIII**, indicating that exchange interactions through the C—C linkages at room temperature increase in the order



The values of $J$ for **III**, **VI**, and **IX** which contain the pyrrolidine nitroxyl are so small for all three linkages that trends are difficult to ascertain.

We had previously observed that at room temperature in $CHCl_3$ solution two species were observed in the epr spectrum of **V** (7) with values of $J$ of 15.5 and 26.0 G. When the solution is cooled, the lines in the spectrum sharpen and at −40°C the values of $J$ are 13 and 38 G. At room temperature in 2:1 toluene: pyridine solution and in other solvents tested, a single value of $J$ is observed for **V**. However, when a solution of **V** in 2:1 toluene: pyridine is cooled, two species are observed in the epr spectra at 10°C and below (cf. Fig. 3). The values of $J$ for the two isomers at −60°C are 11 and 38 G. We previously reported that nmr studies indicated a specific interaction between halogenated solvents and spin-labeled copper porphyrin **V** (7). It appears that this interaction raises the barrier



XIV

to interconversion of the two isomers such that two species are observable at room temperature in halogenated solvents but reduced temperatures are required to observe separate signals for the two

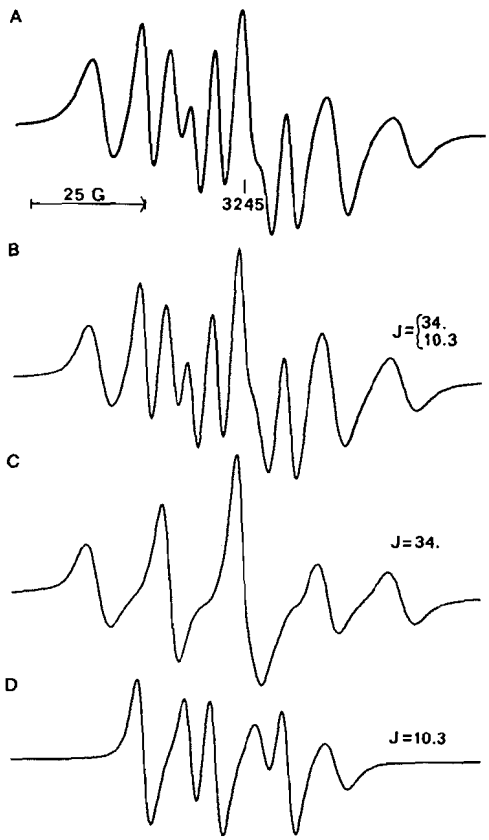


FIG. 3. *A*, 100 G scan of the nitroxyl region of the X-band epr spectrum of **V** at −29°C in 2:1 toluene:pyridine solution obtained with 0.4 G modulation amplitude and 20 mW power. *B*, Computer simulated spectrum with two isomers, $J$ = 34 G (60%) and $J$ = 10.3 (40%). *C*, Contribution to the simulated spectrum from isomer with $J$ = 34 G. *D*, Contribution to the simulated spectrum from isomer with $J$ = 10.3 G.

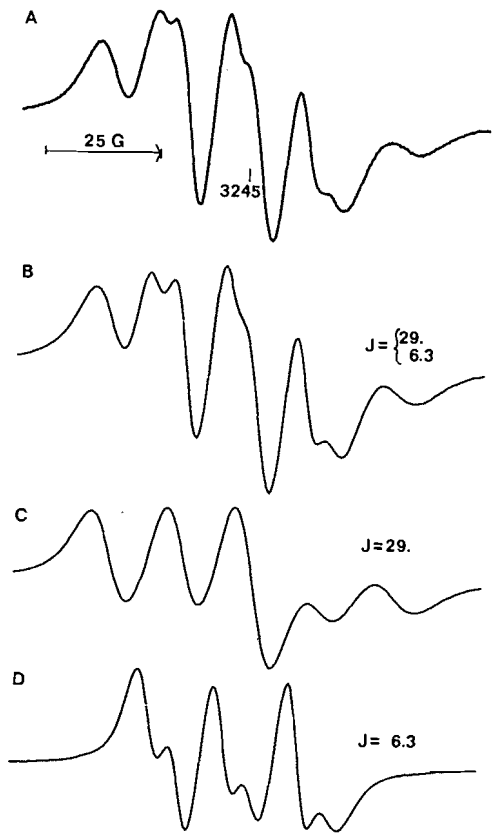

FIG. 4. *A*, 100 G scan of the nitroxyl region of the X-band epr spectrum of **VIII** at −59°C in 1:1 toluene:$CH_2Cl_2$ solution obtained with 0.4 G modulation amplitude and 10 mW power. *B*, Computer simulated spectrum with two isomers $J = 29$ G (65%), and $J = 6.3$ G (35%). *C*, Contribution to the simulated spectrum from isomer with $J = 29$ G. *D*, Contribution to the simulated spectrum from isomer with $J = 6.3$ G.

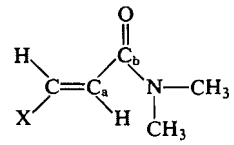
isomers in other solvents. Only a single isomer was observed in the epr spectra of the amides with *trans* olefin linkages, **IV** and **VI**.

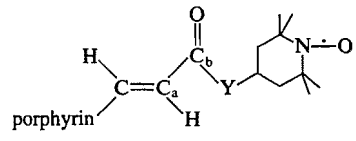
When solutions of **VIII** in 1:1 toluene:$CH_2Cl_2$ or 2:1 toluene:pyridine were cooled, two isomers were observed in the epr spectra at temperatures below −45°C. As shown in Fig. 4 the spectra in 1:1 toluene:$CH_2Cl_2$ at −59°C could be simulated with $J = 6$ and 30 G. Similarly at temperatures below −45°C two isomers were observed in the epr spectra of **VII**. At −60°C in 1:1 toluene:$CH_2Cl_2$ the values of $J$ are 4 and 25 G. Low temperature spectra of **I–III** and **IX** were also examined, but the values of $J$ are sufficiently small and the low temperature linewidths sufficiently broad that it is difficult to determine whether more than one isomer is present.

*Conformational equilibria*

Wojcik and Witanowski have studied halogenated acrylamides and concluded that for the *trans* olefin there is a single conformer **XV** (X = Cl, Br, I) (19) with a *Z* conformation (20) around the $C_a$—$C_b$ bond. The barrier to rotation about the amide C—N bond in acrylamides has been observed to be 12–16 kcal/mol, depending on the substituents on the olefin (21) so the rotation about the C—N bond in **IV** would be expected to be slow on the epr time scale at room temperature. By analogy with polypeptide amide linkages it would be expected that the piperidine ring would be oriented *cis* to the carbonyl group (22). These analogies suggest that **XVI** (Y = NH) is the conformation of **IV**, that other



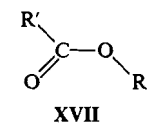
**XV**



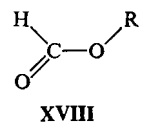
**XVI**

isomers are unlikely, and that the structure is rigid on the epr time scale. The observation of a single isomer of **IV** with relatively narrow lines over a wide temperature range is consistent with the prediction of structural rigidity. Conformation **XVI** (Y = NH) gives a zig-zag or "extended W plan" orientation of the bonds between the porphyrin and nitroxyl ring. This bond geometry has frequently been observed to give rise to large long-range couplings in σ-bonded systems in both nmr and epr studies (11, 23).

For the two isomers of the *trans* ester **V** at low temperature the values of $J$ are 11–13 G and 38 G. The similarity of the larger value of $J$ to that observed for amide **IV** suggests that the isomer with the larger value of $J$ has conformation **XVI** (Y = O). The smaller value of $J$ could then be due to an isomer which does not exhibit a zig-zag conformation. Most carboxylic esters have been observed to adopt conformation **XVII** (24, 25). Oki and Nakashi observed that formate esters exist exclusively in conformation **XVII** (R′ = H)

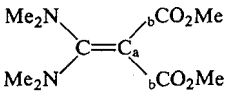


**XVII**



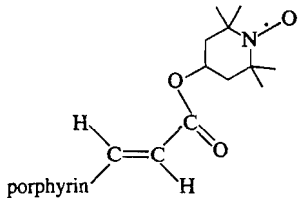
**XVIII**

unless R is sterically demanding (26). When R is *t*-butyl or 3-ethylpentyl 7–9% of the ester exists in conformation **XVIII** at temperatures below −100°C (26). Since the two isomers of **V** have approximately equal populations and the piperidine ring is less sterically demanding than a *t*-butyl group, it appears that rotation around the C—O bond is not the source of the isomerism in **V**. Wennerbeck and



XIX

Sandstrom have observed that the barrier to rotation about the $C_a$—$C_b$ bond in **XIX** is 8.1 kcal/mol (27). In this "push–pull" ethylene the formal C=C bond is weaker than a usual C—C double bond and the $C_a$—$C_b$ bond stronger than in a typical acrylic ester (27). Thus 8.1 kcal/mol should be substantially greater than the barrier to rotation around the analogous bond in **V**. Based on a coalescence temperature of 293 K and an energy separation of 20 G the $\Delta G^{\ddagger}$ for interconversion of the two isomers of **V** is 6.3 kcal/mol (28). This would appear to be a reasonable barrier for rotation about the olefin to carbonyl bond in **V** and suggests that the *Z* and *E* conformers about this bond, **XVI** (Y=O) and **XX**, are the two isomers which are observable below room temperature.



XX

In the spin-labeled complexes with $CH_2$ linkages between the porphyrin and the amide or ester linkage, **VII** and **VIII**, two isomers were observed in the epr spectra at temperatures below −45°C. With a coalescence temperature of about 228 K and an energy separation of 25 G (cf. Table 1) the $\Delta G^{\ddagger}$ for interconversion of the isomers is about 5 kcal/mol. This barrier to rotation is sufficiently low that it is difficult to determine which bonds are involved. However, the larger of the two values of *J* observed for both **VII** and **VIII**, 25 and 30 G, respectively, is sufficiently similar to that observed for conformation **XVI** of **IV** and **V** to suggest that a zig-zag conformation may also occur for **VII** and **VIII**. In the *cis* isomers **I** and **II** the conformation around the olefin linkage precludes a zig-zag conformation consistent with the observation that *J* is small at all temperatures for **I** and **II**. The order *cis* < saturated < *trans* observed at room temperature is consistent with rapid rotation in the complexes with saturated linkages between zig-zag conformers like those of the *trans* isomers in which *J* can be relatively large and conformers like those of the *cis* isomers in which *J* is small. It appears that variations in the values of *J* for **I**, **II**, **IV**, **V**, **VII**, and **VIII** are consistent with explanations in terms of the stereochemistry around the bonds in the linkage between the porphyrin and nitroxyl rings. Although solvent effects shift the equilibria and the observed activation energies the similarity of behavior in a variety of solvents suggests that the differences in *J* are not due primarily to solvation effects. The similarity in the values of *J* for the saturated and unsaturated linkages indicates that in these compounds the metal–nitroxyl interaction is likely dominated by σ-bonding interactions.

*Comparison with other results*

In the perspective of the epr background available at the time these studies were initiated, the observation of high resolution electron spin – electron spin coupling over a distance of about 12 Å, including a saturated carbon pathway, could be considered surprising. However, such an observation is not out of line with nuclear spin coupling data when the differences between nuclear and electron properties are considered. Over the past five years our studies have shown that AB patterns in epr spectra can be observed due to interaction of a nitroxyl unpaired electron with Cu(II), Ag(II) (29), and vanadyl (30) unpaired electrons. Since the electron–electron interaction is so sensitive to the orbital overlaps in the intervening bonds, it is proving to be a useful technique for detection of isomers which cannot readily be studied by other physical methods (17, 30–34). It is also not surprising that in some cases the values of *J* have been found to be strongly dependent on both solvent and temperature (6, 17, 18).

The present study emphasizes the importance of σ-bonding pathways for metal–nitroxyl interactions. In a study of spin-labeled pyridine adducts of $Cu(hfac)_2$, $VO(tfac)_2$, and $VO(hfac)_2$ it was observed that spin-delocalization into the pyridine orbitals was dominated by σ-bonding pathways for Cu(II) but π-bonding pathways were also important for the vanadyl complexes (30). In the same series of compounds it was also observed that interactions through ester, amide, and Schiff base linkages between the pyridine and nitroxyl rings appeared to correlate with the extent of π bonding (27). In a series of spin-labeled metalloporphyrins the magnitude of the metal–nitroxyl exchange interaction increases in the order VO(IV) < Cu(II) < Ag(II), which parallels other indications of the extent of delocalization of the metal unpaired electron into the porphyrin orbitals (29). It can be anticipated that long range exchange interactions through σ as well as π pathways may be a general feature affecting nitroxyl epr spectra. Unless the possibility of exchange interactions affecting the

[a]The designations R and linkage refer to the structural diagram for I–IX. Values of $J$ are in G for solutions at room temperature (20–22°C) unless a different temperature is noted in parentheses after the value of $J$.
[b]Some of the room temperature values in this column were taken from ref. 7.
[c]The large value of $J$ for III in noncoordinating solvents is discussed in ref. 7.

results is somehow excluded, caution should be exercised in applying calculations which assume only dipolar interactions.

The observation of metal–nitroxyl interactions is not limited to lineshape changes of "normal" epr spectra. The interaction also changes the nitroxyl relaxation times. For an accurate measure of this change in relaxation time, time domain (pulsed) epr spectroscopy is needed. However, significant relative measurements can be made using non-linear CW epr, such as a power saturation curve (signal amplitude vs. square root of power) and simulation of saturated spectra. In all of the AB spectra we have obtained, the relaxation times of the nitroxyl signals are substantially altered, such that it is often impossible to saturate the nitroxyl signals at room temperature whereas free nitroxyl spectra generally show effects of saturation above 1–5 mW at the same concentration. In work not yet complete we have also observed nitroxyl relaxation time changes in spin-labeled complexes of Ni(II), Mn(II), Mn(III), and Fe(III). In some cases the unsaturated epr spectrum is almost indistinguishable from a spectrum of the same nitroxyl in the absence of metal, but the power saturation curves clearly reveal the metal–nitroxyl interaction. In these studies it is critically important to distinguish between inter- and intra-molecular interactions.

Beyond the answers these studies are providing to the interpretation of epr in biological systems, and to fundamental magnetic interactions, they also are of importance as measures of the electronic structure and stereochemistry of molecules.

PHILIPPE MAILLARD et CHARLES GIANNOTTI. Can. J. Chem. **60**, 1402 (1982).

En utilisant divers pièges à radicaux comme la diméthyl-5,5′ pyrroline-*N* oxyde (DMPO), le phényl *N-tert*-butylnitrone (PBN), le nitrosodurène (ND) et l'α-pyridyl-4 oxyde-1 *tert*-butyl-2 nitrone (4-POBN) et leur mélange, nous avons pu détecter deux types de radicaux provenant des adduits formés soit avec un atome d'hydrogène, soit avec le radical alkyle libre des alkylcobaloximes, alkylsalen et alkylcobalamines.

En effectuant des deuterations sélectives et en préparant le benzyl bis(diphenylglyoximato)-pyridinato cobaloxime, nous avons montré que l'atome d'hydrogène piégé provient probablement de l'hydrogène chelaté de l'anion diméthylglyoximato du ligand équatorial du complexe du $Co^{III}$. En utilisant un mélange formé de deux pièges à radicaux nous obtenons un spectre rpe contenant, en même temps, les adduits formés par un atome d'hydrogène et un radical alkyle libre.

Pour expliquer l'efficacité du piégeage, alors que les réactions d'homolyse sont en compétition avec des réactions de β-élimination, il faut postuler que la photolyse de ces composés s'effectue dans une cage de solvant. Cette hypothèse explique la forte influence de la nature des solvants utilisés sur la nature des radicaux piégés. Aussi le piège à radicaux peut diffuser dans la cage de solvant et est ainsi capable de piéger, d'une manière très efficace, tout radical libre formé dans la cage de solvant. Le complexe du $Co^{III}$ à l'état excité et le piège à radicaux dans la cage de solvant se comportent comme un exciplex, ce qui pourrait expliquer le piégeage d'atomes d'hydrogène.

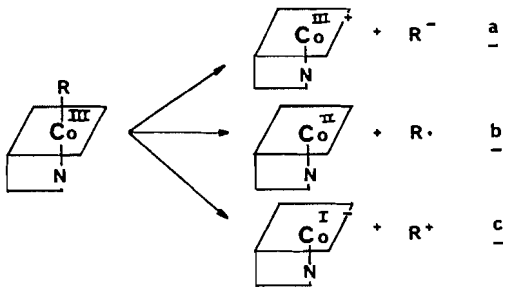
PHILIPPE MAILLARD and CHARLES GIANNOTTI. Can. J. Chem. **60**, 1402 (1982).

Using the spin trapping technique with 5,5′-dimethyl 1-pyrroline *N*-oxide (DMPO), phenyl-*N-tert*-butyl nitrone (PBN), nitrosodurene (ND), and α-4-pyridyl 1-oxide *N-tert*-butyl nitrone (4-POBN), or their mixtures, we have been able to detect two types of radicals, one is a hydrogen atom spin adduct and the other is the corresponding alkyl of the alkylcobaloximes, salens or cobalamines.

By the use of selective deuteration and the preparation of the benzyl bis(diphenylglyoximato)-pyridinato cobaloxime, we have shown that the spin trapped hydrogen atom comes from the chelated hydrogen of the dimethylglyoximato anion of the equatorial ligand of $Co^{III}$ complexes. Using a mixture of two spin traps gives rise to an esr spectrum containing, at the same time, the hydrogen atom and alkyl spin adducts.

To explain such an efficient spin trapping reaction while the homolysis is in competition with a β-elimination process, it should be postulated that the photolysis of such compounds proceeds through a solvent cage environment. This hypothesis explains the strong influence of solvents on the nature of the free radicals trapped. Also the spin trap diffuses in the solvent cage, and is able to trap in a very efficient manner any free radicals occurring in the solvent cage. The excited $Co^{III}$ complexes and the spin trap in the solvent cage behave like an exciplex, which could explain the spin trapping of the hydrogen atom.

Ce travail fait le point, avec l'aide de quelques expériences nouvelles, sur le piègeage d'atome d'hydrogène et de radicaux alkyles, apparaissant au cours de la photolyse d'alkylcobaloximes et de quelques composés voisins.



La rupture de la liaison $Co^{III}$—C dans les complexes du $Co^{III}$ peut s'effectuer de trois manières différentes: une voie radicalaire donne un radical alkyle libre et un complexe du $Co^{II}$ (b); deux voies ioniques possibles qui se décomposent en formation d'un anion alkyle et d'un complexe du $Co^{III}$ (a), ou coupure en un cation alkyle et un complexe du $Co^{I}$ (c).

La photolyse des alkylcobaloximes et des alkyl cobalamines en absence d'oxygène conduit à la rupture plus ou moins rapide de la liaison $Co^{III}$—C et à la formation de produits pratiquement identiques à ceux obtenus par thermolyse anaérobique.

A partir des résultats théoriques (1), un mécanisme expliquant la réaction de photolyse de la liaison $Co^{III}$—C des cobaloximes et des cobalamines a été proposé:

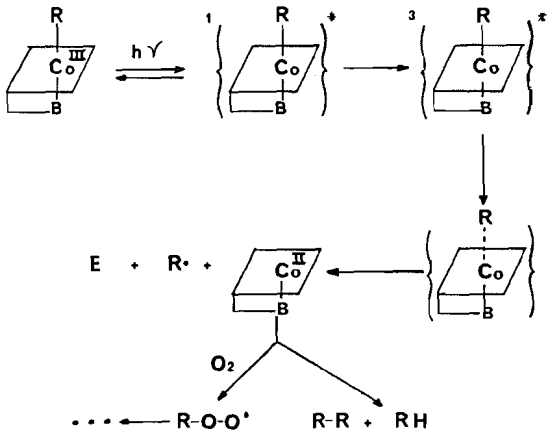
For personal use only.

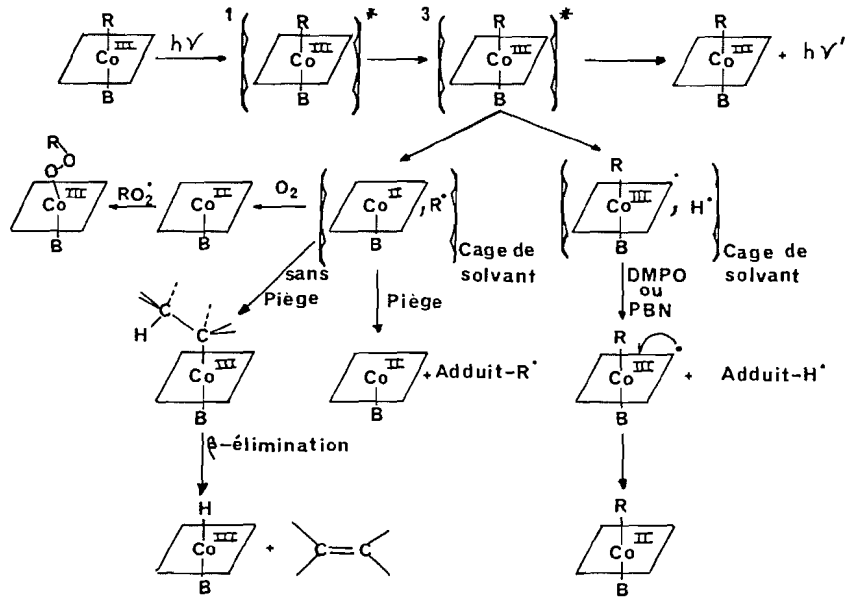


La similitude des produits de dégradation obtenus, soit après photolyse, soit après thermolyse des cobalamines et des cobaloximes à pH = 7, montre que ces deux types de réactions se déroulent selon des mécanismes très proches. La mise en évidence de l'hydrure de cobaloxime (2–4), permet d'envisager un mécanisme concerté de β-élimination.

Par contre la mise en évidence de complexe du $Co^{II}$ et de radicaux alkyles libres au cours de la photolyse des cobalamines (5–8), des cobaloximes (9–12) et des complexes salen du $Co^{III}$ (13, 14) montre que la rupture homolytique de la liaison $Co^{III}$—C est possible. En outre, il a été montré (15–17) qu'il existe un autre mécanisme conduisant à la formation photochimique d'un atome d'hydrogène provenant probablement du ligand équatorial des cobaloximes.

De plus, récemment il a été proposé un mécanisme dans lequel le radical R· formé par thermolyse peut perdre un atome d'hydrogène pour conduire à l'hydrure de cobalt et à l'éthylénique issu de R· (18*a*).

On peut résumer les différents résultats de la littérature en écrivant le mécanisme global suivant:



Dans tous ces mécanismes, les points suivants restent obscurs.

L'hydrogène photolabile des alkylcobaloximes, récemment mis en évidence (15–18*a*), provient-il réellement du méthyle ou de l'hydroxyle du ligand équatorial?

La rupture homolytique de la liaison $Co^{III}$—C des cobaloximes est-elle générale en présence de composés capables de piéger les radicaux?

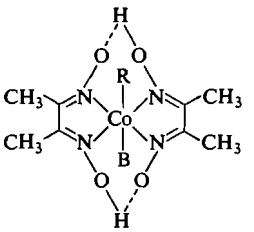
Existe-t-il une influence du solvant en présence de pièges à radicaux?

Nous allons essayer de répondre à certaines de ces questions.

### 1. Photolyse des alkylcobaloximes (1) dans les solvants aprotiques

Au cours de la photolyse anaérobique des alkylcobaloximes en présence de DMPO, il a été observé qu'un atome d'hydrogène est piégé (15–17). Dans le but d'essayer de déterminer l'origine exacte de cet atome d'hydrogène, nous avons synthétisé et étudié la pureté isotopique de la

diméthylglyoxime deutérée et de diverses cobaloximes deutérées.

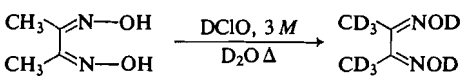


R = alkyle
B = Base aromatique

1

*Synthèse et détermination de la pureté isotopique de la diméthylglyoxime (DMG-$d_8$) et de quelques cobaloximes deutérées*

La diméthylglyoxime (DMG) est deutérée par échange hydrogène, deutérium en milieu acide (11); on obtient la perdeutéro diméthylglyoxime (DMG-$d_8$) ainsi que tous les composés contenant de 1 à 8 atomes de deutérium.



2

La pureté isotopique moyenne en deutérium de la DMG-$d_8$ **2**, calculée à partir des spectres de rmn $^1H$ de deux solutions titrées de DMG et de DMG-$d_8$, dans l'acétone deutérée, est supérieure à 95% pour la fonction N—OD et d'environ 42% pour les groupements méthyles.

Les cobaloximes deutérées sont préparées à partir de la DMG-$d_8$ **2**, selon la méthode décrite par Schrauzer *et al.* (1).

Les différentes cobaloximes marquées au deutérium **3**–**6** sont purifiées par dissolution dans un mélange MeOD/$CDCl_3$ et précipitées par $D_2O$.

La comparaison des spectres rmn $^1H$ du composé **3**, partiellement deutéré, et de son homologue **7**, non deutéré, confirme l'incorporation de deux molécules de DMG-$d_8$ dans le composé **3**. La pureté isotopique des $CD_3$ des ligands équatoriaux de ce dernier, déterminée par rmn $^1H$, est de 40 à 45%. Il n'est pas possible de mesurer la pureté isotopique des fonctions oximes des cobaloximes deutérées par rmn $^1H$, le pic rmn correspondant aux atomes d'hydrogène de ces groupements étant trop large.

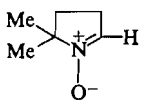
L'analyse du spectre infrarouge d'une solution, dans le chloroforme fraîchement désséché, de perdeutéro isopropylcobaloxime **6**, enregistré à des temps réguliers, *permet de constater que la bande d'absorption de la fonction N—OD (2670 $cm^{-1}$) diminue alors que la bande d'absorption de la fonction N—OH (3660 $cm^{-1}$) augmente. Ce phénomène est la conséquence de l'échange rapide (total en moins d'une heure) du deutérium du groupement hydroxyle des oximes de la cobaloxime* **6** *par un atome d'hydrogène provenant du milieu réactionnel.* Par contre, on ne note aucune modification des bandes comprises entre 2000 et 2500 $cm^{-1}$ correspondant aux diverses liaisons C—D. L'absence des bandes à 3080, 2915 et 2850 $cm^{-1}$ correspondant aux liaisons C—H de la pyridine et du groupement isopropyle hydrogéné, montre que ces derniers sont deutérés à plus de 90%. Ces résultats ont été développés précédemment (17).

L'étude des spectres infrarouge et rmn $^1H$ des cobaloximes deutérés **3** à **6** montre que: (*a*) les ligands axiaux sont deutérés à plus de 80% et ne sont le siège d'aucun échange isotopique; (*b*) les méthyles des deux diméthylglyoximes équatoriales sont deutérés à 40% et n'échangent pas leurs atomes de deutérium avec le milieu réactionnel; (*c*) par contre, les deutériums des groupements hydroxyles des fonctions oximes s'échangent rapidement avec des hydrogènes du milieu extérieur.

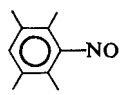
*Étude par rpe de la photolyse des alkylcobaloximes perdeutérées*

Nous avons utilisé les pièges à radicaux suivants:

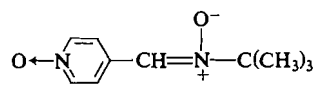
Diméthyl-5,5′ pyrroline-*N*-oxyde (DMPO)



Nitrosodurène

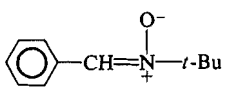


(ND)



α-Pyridyl-4 oxyde-1 *tert*-butyl-2 nitrone (4-POBN)

Phényl *N-tert*-butyl nitrone (PBN)



En étudiant les spectres rpe obtenus après photolyse anaérobique des cobaloximes deutérées **4**, **5** et **6**, dissoutes dans les solvants aprotiques appropriés ($CHCl_3$, $CDCl_3$, $C_6H_6$, $C_6D_6$, $CH_3C_6H_5$ et $CD_3C_6D_5$), contenant un excès de DMPO, nous n'avons mis en évidence que la formation d'un seul adduit correspondant au piègeage d'un atome d'hydrogène (15).

Le fait que le DMPO ne piège aucun atome de deutérium au cours de la photolyse des cobaloximes deutérées **4**, **5** et **6** nous ayant paru surprenant, nous avons vérifié que le DMPO était capable de former un adduit stable avec les atomes de deutérium.

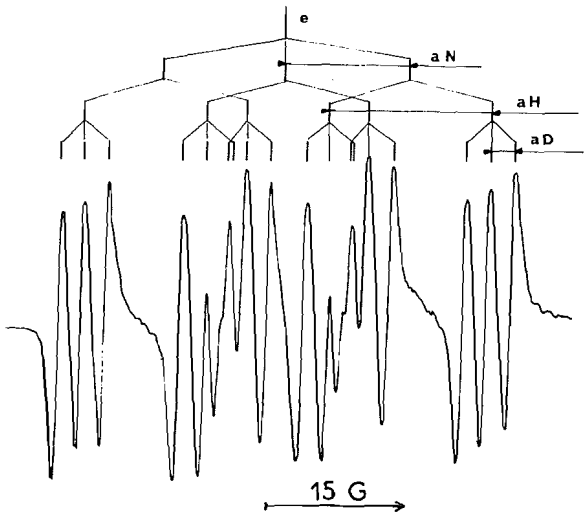

FIG. 1. Spectre rpe obtenu à 100 KHz et à 25°C, de $(C_4H_9)_3SnD$ en solution dans le toluène, en présence de DMPO. Signal gain $6{,}3 \times 10^5$, radiofréquence 9516 MHz, puissance de détection 25 mW.

Pour cela, nous avons irradié, dans le toluène contenant du DMPO, une solution de $(C_4H_9)_3SnD$, ce composé étant connu pour libérer facilement des atomes de deutérium sous l'action de la lumière (18*b*).

Le spectre de l'adduit obtenu (fig. 1) est caractéristique du couplage hyperfin d'un atome d'azote ($a_N$ = 14,33 G), et des couplages hyper-hyperfins d'un atome d'hydrogène ($a_H$ = 18,99 G) et de deutérium ($a_D$ = 2,83 G) avec l'électron célibataire du centre radicalaire. Le rapport $a_H/a_D$ = 6,7, calculé à partir des constantes de couplage mesurées est proche du quotient des rapports gyromagnétiques des atomes H et D $a_H/a_D$ = 6,51 (19).

L'irradiation d'un mélange équimoléculaire de $(C_4H_9)_3SnH$ et $(C_4H_9)_3SnD$ conduit à la mise en évidence par rpe, d'une quantité sensiblement égale d'adduit DMPO–H et DMPO–D (fig. 2). Ceci montre qu'aucun effet isotopique notable ne vient perturber la vitesse de formation de l'adduit DMPO–D, celle-ci étant pratiquement égale à celle de l'adduit DMPO–H.

Bien que capable de piéger des atomes de deutérium, le DMPO ne conduit cependant, lors de la photolyse anaérobique des alkylcobaloximes deutérées **4**, **5** et **6**, qu'à la formation d'un adduit DMPO–H aussi bien après une photolyse courte (18 s à 1 min) qu'après une photolyse longue (plusieurs minutes à 1 h).

Ceci permet d'exclure l'hypothèse d'un effet isotopique ralentissant la libération d'un atome de deutérium par rapport à celle d'atome d'hydrogène.

Afin de confirmer que les groupements méthyles

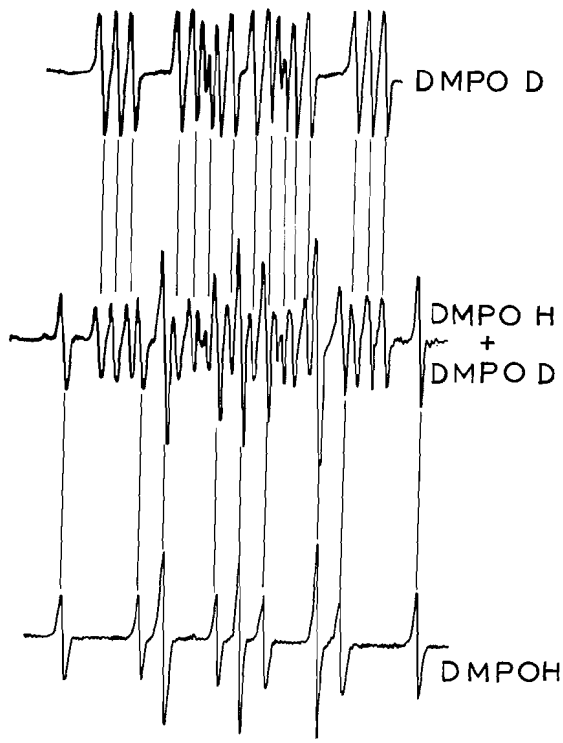

FIG. 2. Spectre rpe obtenu à 100 kHz et à 25°C après photolyse d'un mélange équimoléculaire de $(C_4H_9)_3SnH$ et $(C_4H_9)_3SnD$ dans le toluène en présence de DMPO. Signal gain $5 \times 10^5$, radiofréquence 9517 MHz, puissance de détection 31 mW.

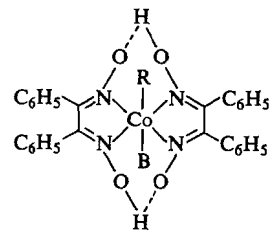
des diméthylglyoximes des cobaloximes ne sont pas la source des atomes d'hydrogène piégé par le DMPO pendant la photolyse (11), nous avons irradié, dans le visible, une solution dégazée de benzyl bis(diphénylglyoximato)-pyridinato cobalt (19) et de DMPO dans le toluène, cette expérience n'a pas été rapportée précédemment.



**9**

R = $CH_2C_6H_5$
B = Py

Sous ces conditions expérimentales, le complexe **9** conduit à la mise en évidence, par rpe, de l'adduit DMPO–H.

Les groupements phényles (étant de mauvais donneurs d'atome d'hydrogène) ne peuvent pas être la source des atomes d'hydrogène photolabiles des alkylcobaloximes.

Ainsi, l'étude de la photolyse des cobaloximes

deutérés **4**, **5** et **6** et du complexe **9** pourrait suggérer qu'une majorité des atomes d'hydrogène photolabile des cobaloximes pourrait provenir des OH des fonctions oximes des ligands équatoriaux de ces composés.

*Étude de la photolyse des cobaloximes non deutérées en présence de DMPO*

Tous les composés deutérés ou non deutérés **3** à **22**, dissous dans des solvants aprotiques dégazés et photolysés dans le visible ($\nu > 420$ nm), donnent un atome d'hydrogène piégé par le DMPO.

Par contre, la photolyse de l'adamantyl-1 cobaloxime **23** (20) dans le toluène, en présence de DMPO, conduit à la formation simultanée de deux adduits dont l'un est caractéristique de l'adduit DMPO–H et l'autre du radical adamantyle-1 libre avec le DMPO (17, 21).

La présence de radical adamantyle-1 et d'atome d'hydrogène, piégés par le DMPO au cours de la photolyse anaérobique du composé **23** dans les solvants aprotiques, montre que la rupture homolytique de la liaison Co—C, et le piégeage d'un atome d'hydrogène du ligand équatorial sont deux réactions en compétition.

Par contre, le fait que, dans des conditions analogues, la photolyse des composés **3**–**22** ne conduise pas à la formation d'adduits DMPO–alkyles, ne permet pas de confirmer la rupture homolytique de la liaison Co—C pour ceux-ci.

Le fait que toutes les cobaloximes étudiées conduisent, sous photolyse anaérobique, à la formation de l'adduit DMPO–H, ne permet pas de préciser si le piègeage des atomes d'hydrogène est la réaction principale prépondérante. Seul le dosage de l'adduit DMPO–H peut permettre de préciser ce point.

TABLEAU 1. Dosage de la concentration de l'adduit DMPO–H effectué entre la 1ère et la 4ème min d'irradiation*

| Composé | $\% = \frac{[\text{DMPO–H}]}{[\text{R(Co)B initiale}]}$ | % Moyen |
|---|---|---|
| Me(Co)Py | 0,75<br>0,20<br>0,57 | 0,5±0,1 |
| $C_6H_5CH_2$(Co)Py | 0,17<br>0,38<br>0,49 | 0,34±0,1 |

*Solvant: toluène; température 300 K; DMPO: $5 \times 10^{-2}$ *M*/L; R(Co)Py: $10^{-3}$ *M*/L. Solution de référence: diphényl-1,1 picryl-hydrazyle $10^{-4}$ *M*/L.

L'adduit DMPO–H n'a une durée de vie que de quelques secondes (15); seul un dosage effectué à l'état stationnaire peut donner un ordre de grandeur de la quantité d'adduit formé. Les résultats obtenus pour la méthyle et la benzylcobaloxime **7** et **8** sont donnés dans le tableau 1. Ces résultats n'ont pas été publiés précédemment.

Ces pourcentages montrent qu'à l'état stationnaire la quantité d'adduit DMPO–H présent dans la solution est très faible, mais ne permettent pas de déduire la quantité totale d'adduit formé.

Une étude complémentaire de la photolyse anaérobique de ces cobaloximes, dans les solvants aprotiques, est nécessaire pour vérifier la rupture homolytique de la liaison $Co^{III}$—C.

Nous avons alors étudié la photolyse des composés **3**–**23** en présence de nouveaux pièges à

radicaux, le nitrosodurène (ND) (22, 23) et le phényl *tert*-butyl nitrone (PBN) (24, 25).

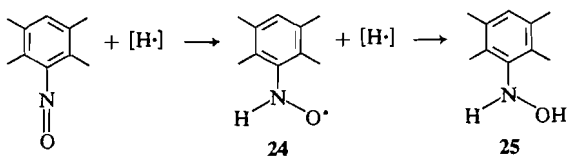
*Photolyse des alkylcobaloximes en présence de nitrosodurène et de PBN*

La photolyse anaérobique, dans le benzène ou le toluène de tous les composés **3** à **23**, en présence de nitrosodurène, conduit à des adduits du type nitrosodurène–alkyle (17).

Le nitrosodurène semble donc incapable de piéger les atomes d'hydrogène mis en évidence par le DMPO, pendant la photolyse des cobaloximes.

Nous avons vérifié, en irradiant une solution de $(C_4H_9)_3SnH$ ou de $(C_4H_9)_3SnD$, dans le toluène contenant un excès de nitrosodurène, que ce dernier était bien incapable de former un adduit stable avec les atomes d'hydrogène ou de deutérium.

On peut supposer que l'adduit **24**, formé entre le nitrosodurène et un atome d'hydrogène ou un atome de deutérium, a une durée de vie très courte et qu'il réagit rapidement avec un second atome d'hydrogène ou de deutérium pour former une hydroxylamine diamagnétique **25**, non détectable par rpe, selon le schéma suivant:



**24** **25**

En effet, après photolyse continue d'un mélange équimoléculaire de nitrosodurène et d'alkylcobaloxime ou de nitrosodurène et de $(C_4H_9)_3SnH$, une hydroxylamine aromatique et des composés minoritaires non identifiés sont détectés et isolés.

Les spectres infrarouge et rmn $^1H$ du produit majoritaire montrent la présence d'une fonction hydroxylamine aromatique dans ce composé (ir ν NOH 3540 $cm^{-1}$, ν NO 1540 $cm^{-1}$ dans $CHCl_3$; rmn $^1H$ multiplet à 5,2 ppm et 5.5 ppm).

Le fait que la formation d'adduit nitrosodurène alkyle soit générale, au cours de la photolyse anaérobique des cobaloximes, ne permet pas de savoir si la rupture homolytique de la liaison cobalt–carbone est la réaction prépondérante.

Les résultats non publiés des dosages de l'adduit nitrosodurène–alkyle effectués par rpe, pendant la photolyse de la méthyl cobaloxime **8** et de la benzylcobaloxime **7** dans le toluène sont rassemblés dans le tableau 2.

Il est impossible par la technique que nous avons employée, de connaître la quantité totale d'adduit nitrosodurène–alkyle qui est formée au cours de la photolyse anaérobique des deux cobaloximes que nous avons étudiées, car l'adduit est photosensible et se détruit lentement au cours de la photolyse.

TABLEAU 2. Dosage de la concentration de l'adduit ND–R effectué entre la 1ère et la 4ème min d'irradiation*

| Composé | $\% = \frac{[ND-R]}{[R(Co)Py\ initiale]}$ | % Moyen |
|---|---|---|
| Me(Co)Py | 3,5<br>3,7 | 3,6±0,1 |
| $C_6H_5CH_2(Co)Py$ | 1,4<br>1,4 | 1,4±0,1 |

*Solvant: toluène: température 300 K; nitrosodurène: 5 × $10^{-3}$ *M*/L; R(Co)Py: $10^{-3}$ *M*/L. Solution de référence: diphényl-1,1 picryl-hydrazyle $10^{-4}$ *M*/L.

Nous ne pouvons atteindre, par cette technique, que la concentration en adduit nitrosodurène-alkyle à l'état stationnaire.

L'étude par rpe, de la photolyse anaérobique des alkylcobaloximes **3**–**23** dans les solvants aprotiques, en présence de DMPO, de nitrosodurène ou de PBN comme pièges à radicaux, suggère aussi le départ d'un atome d'hydrogène du ligand équatorial et montre que la rupture homolytique simultanée de la liaison $Co^{III}$—C a bien lieu.

Dans le but de vérifier ces résultats, nous avons étudié la photolyse anaérobique de deux cobaloximes **7** et **8**, en présence d'un mélange équimoléculaire de DMPO et de nitrosodurène ainsi que de DMPO et de PBN (17). Les différents spectres rpe montrent simultanément des signaux caractéristiques, des adduits DMPO–H, ND–R et DMPO–H, PBN–H et PBN–alkyle (17).

Ces deux expériences confirment la rupture homolytique de la liaison axiale $Co^{III}$—C et le départ simultané par piégeage d'un atome d'hydrogène des alkylcobaloximes.

Bien que le DMPO soit capable de piéger des radicaux alkyles (21, 26), il ne permet pas de les mettre en évidence dans les expériences de photolyse des cobaloximes **3**, **22**. Seule l'irradiation de l'adamantyl-1 cobaloxime **23** donne les deux adduits, DMPO–alkyle et DMPO–H, attendus.

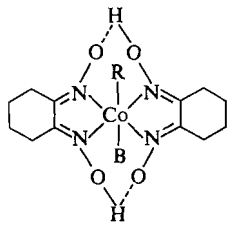
Le piègeage du radical alkyle par le DMPO est en compétition avec la formation très rapide de l'adduit DMPO–H (27) et avec la réaction de recombinaison de la liaison $Co^{III}$—C (6, 11, 12). Ainsi, la concentration de l'adduit DMPO–alkyle dans le milieu réactionnel est trop faible pour permettre l'enregistrement de son spectre rpe. Dans le cas de l'adamantyl-1 cobaloxime **23**, le radical adamantyle-1, suffisamment stable pour être détecté directement par rpe dans certaines conditions (28, 29), ne subit pas facilement de réactions secondaires (recombinaison de la liaison $Co^{III}$—C par exemple).

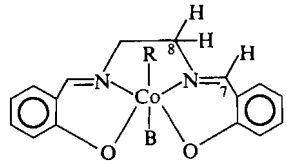
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Il peut donc former avec le DMPO un adduit en quantité suffisante pour être détecté. Par contre, le PBN, réagissant plus lentement que le DMPO avec les atomes d'hydrogène (28), piège suffisamment de radicaux alkyles pour que le spectre rpe de leurs adduits avec le PBN soit enregistrable.

*Étude de la photolyse de complexes du cobalt III proches des alkylcobaloximes: alkylnioxime et alkylsalen*

La structure des différents composés étudiés est donnée ci-dessous:





| R | B | | R | B | |

L'étude de la photolyse des composés **26–31**, dans des conditions analogues à celles des cobaloximes **3–23**, montre que ces types de complexes du $Co^{III}$ se comportent de manière identique.

Par contre, les complexes **32–34** irradiés dans le toluène désoxygéné en présence de DMPO, conduisent à la formation de deux espèces radicalaires: un atome d'hydrogène et un radical méthyle (17).

Il a été montré, par rmn $^1H$, que les hydrogènes situés sur les carbones 7 et 8 des complexes salen du $Co^{III}$ sont labiles (30). Il est donc raisonnable de penser que ces hydrogènes C7 et C8 et plus probablement les hydrogènes C8 pourraient être expulsé facilement par photolyse, bien qu'aucune expérience de marquage isotopique de ces positions n'ait pu être réalisée pour confirmer cette hypothèse.

### 2. Photolyse dans les solvants protiques

Les composés **8** et **11** étant pratiquemment insolubles dans l'eau, nous avons dû synthétiser la cobaloxime **13** rendue soluble dans l'eau grâce à un ligand $CH_2CH_2OH$ axial (31). Aucune trace d'atome d'hydrogène piégé par le PBN n'est détectée lors de la photolyse des composés **8**, **11**, **13** et **33** dans le méthanol. Par contre, la photolyse anaérobique de ces mêmes composés **8**, **11**, **13**, **33**, en présence de DMPO, conduit à la formation unique de l'adduit DMPO–H aussi bien dans $CH_3OH$ que dans $CD_3OD$. La photolyse anaérobique du complexe salen **34**, dans le méthanol ou $CD_3OD$ contenant du DMPO, conduit à la formation de deux radicaux: l'adduit DMPO–méthyle ($a_N$ = 15,35 ± 0,01 G et $g_{iso}$ = 2,0064 ± 0,0003) et l'adduit DMPO–hydrogène ($a_N$:15,58 ± 0,01 G, $a_H$ = 20,66 ± 0,01 G et $g_{iso}$ = 2,0072 ± 0,0003). Ces résultats confirment que l'atome d'hydrogène piégé par le DMPO ne provient ni du solvant ni d'un hydrogène facilement échangeable avec les deutérium du méthanol.

La concentration de l'adduit DMPO–H est environ deux fois supérieure à celle de l'adduit DMPO–méthyle. La photolyse du composé **33** dans le MeOH, en présence de PBN, conduit à la formation immédiate d'un adduit PBN–méthyle. Lorsque la photolyse est arrêtée le spectre rpe de *l'adduit PBN–hydrogène apparaît lentement*. Cet atome d'hydrogène pourrait provenir probablement de la positions 7 ou 8 du complexe salen.

On peut donc dire qu'en présence de pièges à radicaux, la photolyse anaérobique des composés **8**, **11**, **13** et **33**, dans les solvants aprotiques et dans le méthanol, conduit à la formation d'un adduit entre le PBN et un atome d'hydrogène provenant du ligand équatorial et d'un adduit entre le PBN et un radical alkyle provenant de l'homolyse de la liaison $Co^{III}$—C. Ces deux processus photochimiques se produisent sur des molécules différentes et sont en compétition.

*Photolyse des composés 13, 33 dans l'eau*

L'étude rpe de la photolyse anaérobique des complexes **13** et **33**, en milieu aqueux à pH = 7 et en présence de DMPO, ne montre la formation d'aucun adduit.

Par contre, en présence de 4-POBN, on observe la formation instantanée d'adduits formés à partir de radicaux alkyles (fig. 3). Les caractéristiques rpe des deux adduits formés sont les suivantes.

4-POBN – $CH_2CH_2OH$: $g_{iso}$ = 2,0044 ± 0,0003; $a_N$ = 15,75 ± 0,01 G; $a_{\beta H}$ = 2,75 ± 0,01 G.

4-POBN – $CH_3$: $g_{iso}$ = 2,0059 ± 0,0003; $a_N$ = 15,83 ± 0,01 G; $a_{\beta H}$ = 2,16 ± 0,01 G.

Les cobaloximes **8** et **11** sont totalement insolubles dans l'eau et n'ont donc pas pu être étudiées dans ces conditions de photolyse.

Les complexes **13** et **33** photolysés dans l'eau à pH = 7 ne subissent qu'une rupture homolytique de la liaison $Co^{III}$—C.

Golding *et al.* (11) ont montré que, durant la photolyse de solution aqueuse de cobaloximes à pH = 7, la rupture homolytique de la liaison $Co^{III}$—C est un processus très efficace (éq. [1]). Ce résultat est sans doute dû au fait que les molécules

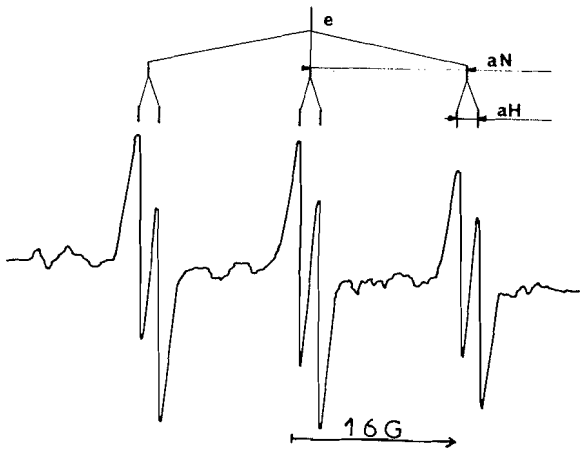

FIG. 3. Spectre rpe obtenu à 100 kHz et à 25°C après photolyse de l'isopropyl pyridinato cobaloxime dans l'eau et en présence de 4-POBN. Signal gain 4 × $10^5$, radiofréquence 9517 MHz, puissance de détection 25 mW.

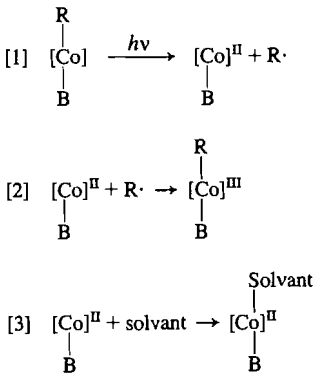
d'eau qui solvatent le complexe $Co^{II}$ (éq. [3]) formé après rupture de la liaison $Co^{III}$—C peuvent bloquer la réaction inverse de recombinaison $Co^{II} + {}^{\cdot}R \rightarrow Co—R$ (éq. [2]) et ainsi favoriser la formation des radicaux alkyles libres plutôt que celle d'atomes d'hydrogène. Le méthanol, solvant moins polaire que l'eau solvate moins le complexe $Co^{II}$ et rend ainsi le départ de l'atome d'hydrogène plus aisé.



### 3. Photolyse de quelques cobalamines en présence de pièges à radicaux

Les trois cobalamines, dont la photochimie nous a plus particulièrement intéressés, sont: le coenzyme $B_{12}$ **35**, la cyanocobalamine **36** et la méthylcobalamine **37**.

L'étude rpe de la photolyse anaérobique de la cyano et de la méthylcobalamine **36** et **37**, dans le méthanol contenant du DMPO ou du PBN, révèle la formation de radicaux $CH_3{}^{\cdot}$ ou $CN^{\cdot}$ (32).

Par contre, la photolyse anaérobique du coenzyme **35** dans le méthanol conduit à la formation des adduits correspondant à l'addition d'un atome d'hydrogène et du radical déoxy-5′-adénosyle libre sur le DMPO et seulement du radical déoxy-5′-adénosyle libre quand on utilise le PBN comme piège (31).

La mise en évidence grâce aux DMPO et PBN de radicaux déoxyadénosyles lors de la photolyse du coenzyme $B_{12}$ **35** dans le méthanol confirme les résultats obtenus par Joblin *et al.* (8). Ces auteurs ont montré que le coenzyme $B_{12}$ ou l'éthylcobalamine subissent sous irradiation anaérobique, une homolyse de la liaison Co–carbone dans l'eau neutre, le DMSO ou un mélange 1:1 de phénol et de chloroforme.

Les traces d'oxygène présentes dans le méthanol modifient de façon notable le cours de la photolyse de la méthylcobalamine **37**. En effet, dans ces conditions, le DMPO piège un radical méthyle et un atome d'hydrogène.

Lorsque la photolyse des cobalamines **35**, **36** et **37** est effectuée dans l'eau ou $D_2O$, à pH = 7, contenant un excès de DMPO, on met en évidence la formation de deux adduits: l'un correspond au radical $R^{\cdot}$ et l'autre au piègeage d'un atome d'hydrogène. Par contre, le 4-POBN ne piège, dans ces conditions, que le radical $R^{\cdot}$.

La structure des radicaux formés au cours de la photolyse des trois cobalamines ne peut être déterminée uniquement grâce aux caractéristiques (structure et couplages hyperfins) des spectres rpe de leur adduit avec le DMPO, le PBN ou le 4-POBN.

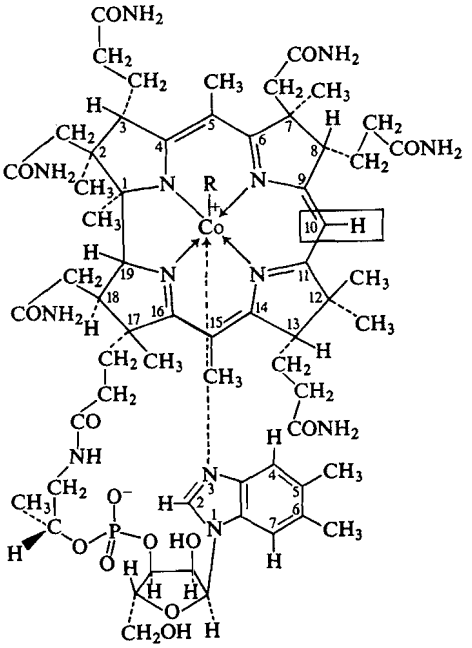
Les structures hyperfines dues à ces adduits ne donnent aucun renseignement sur la nature des atomes des radicaux initiaux, situés sur le centre radicalaire ou en position β. Seule l'utilisation de piège à radicaux du type nitroso permet de connaître la nature de ces atomes. Le nitrosodurène n'étant pas soluble dans l'eau ou le méthanol, nous avons étudié la photolyse des cobalamines **35**, **36** et **37** dans le DMSO (31).

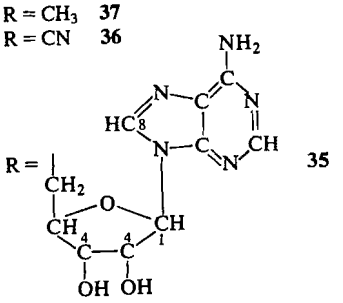
### Discussion et conclusion

L'étude de la photolyse, dans divers solvants, d'alkylcobaloximes, de quelques complexes salen du $Co^{III}$, du coenzyme $B_{12}$ et de deux cobalamines, par résonance paramagnétique électronique (rpe) couplée à la technique des pièges à radicaux, nous a permis de préciser les mécanismes gouvernant la photochimie de ces composés.

Cependant, malgré toutes ces expériences, nous n'avons pas pu obtenir d'évidence directe de la provenance exacte de l'atome d'hydrogène, mais par un processus d'élimination, nous suggérons, jusqu'à preuve du contraire, que l'atome d'hydro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.





gène piégé lors de la photolyse anaérobique des alkylcobaloximes et des complexes salen, en solution dans les solvants pourrait avoir sa source dans le ligand équatorial de ces composés. L'étude de la photolyse de la benzyl bis(diphénylglyoximato)-pyridinato cobaloxime **9** suggère que l'atome d'hydrogène photolabile ne provient pas des méthyles du ligand équatorial. Il pourrait provenir des hydroxyles des fonctions oximes chélatantes, dans le cas des cobaloximes, et probablement de la position C7 ou C8 du ligand équatorial, dans le cas des complexes salen **32–34**.

Une autre possibilité pourrait être la réduction du DMPO en hydroxylamine diamagnétique par les complexes du $Co^{III}$.[1] Mais ces composés ne sont pas réducteur par eux-mêmes la formation d'un hydrure de cobalt, réducteur puissant, sous photolyse n'est possible qu'avec les composés ayant un atome d'hydrogène en position β par rapport à la liaison $Co^{III}$—C et non avec les autres. De plus la photolyse de l'hydroxylamine, n'absorbant pas la lumière, ne peux se faire que dans l'ultraviolet et dans toutes nos expériences nous avons utilisé une lumière visible ($\nu > 420$ nm).

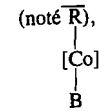
L'emploi de divers pièges à radicaux utilisés pour étudier les réactions de photolyse de trois cobalamines **35–37**, dans différents solvants, a permis de mettre en évidence d'un part, la rupture homolytique de la liaison Co—C et d'autre part, le départ d'un atome d'hydrogène piègeable suivant le solvant.

[1]Suggestion du referee.

L'atome d'hydrogène piègeable au cours de la photolyse pourrait probablement provenir du ligand corrine équatorial dans le cas de la méthyle ou de la cyanocobalamine, et du ligand équatorial ou du groupement déoxy-5′ adénosyle dans le cas du coenzyme.

A partir de ces résultats, nous pouvons postuler le mécanisme suivant lié à la présence de piège à radicaux (schéma 1).

Le complexe de cobalt solvaté, donc en cage de solvant,



en présence d'un grand excès de piège à radicaux, donne une nouvelle espèce en cage où le piège et le complexe de cobalt sont associés à l'état fondamental (A).

Cette espèce (A) irradiée conduit à la formation d'un exciplexe à l'état singulet qui, par conversion intersystème, évolue vers un exciplexe composé du complexe de cobalt à l'état triplet et du piège dans une même cage de solvant (B).

Cet exciplexe (B) à l'état triplet peut évoluer soit vers la formation d'une paire de radicaux: alkyle, complexe du $Co^{II}$ soit vers la formation d'une paire de radicaux: hydrogène, complexe du $Co^{III}$ (D). Ces deux types de paires de radicaux sont dans une cage de solvant contenant toujours le piège à radicaux.

Le fait que le piège soit à l'intérieur de la cage de

SCHÉMA 1

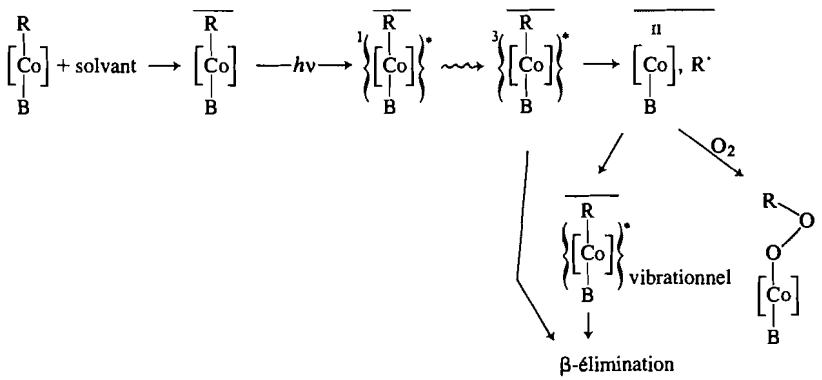

SCHÉMA 2

solvant, donc très proche des radicaux R· ou H·, lui permet de piéger ces espèces avant la recombinaison des paires de radicaux et de diffuser dans la solution.

Il a été montré que la réaction de recombinaison de la liaison $Co^{III}$—C des cobaloximes est fortement ralentie par la présence d'un piège à radicaux (12). Ceci est compatible avec un effet de séparation du radical R· et de l'espèce $Co^{II}$, induit par le piège.

Un effet de cage semblable a été décrit par Ghanekar et Coffman (33) pour expliquer les spectres rpe observés lors de la photolyse de complexes $C_6H_5Co^{III}BAE$. De plus, Endicott et Netzel (7) ont montré que la vitesse de recombinaison $Co^{II}$ + R· → $Co^{III}$ R des cobaloximes est indépendante de la nature du radical R· en absence de pièges à radicaux.

De tels mécanismes en cage de solvant ont déjà été proposés par Roewer *et al.* (13) pour la photolyse des complexes salen du $Co^{II}$ et par Grate et Schrauzer (34) dans le cas d'alkylcobalamines secondaires.

En absence de piège à radicaux, le complexe de cobalt en cage de solvant évolue, sous irradiation, vers son état singulet puis, par conversion intersystème, vers son état triplet. Cette espèce peut subir, soit l'homolyse de la liaison $Co^{III}$—C et par recombinaison de la liaison $Co^{III}$—C évoluer vers une espèce excitée vibrationnelle se désactivant par le processus de β-élimination décrit par différents auteurs (2–4, 13, 34) soit évoluer par le

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

processus de β-élimination, directement à partir de l'espèce dans son état triplet. Ce processus de β-élimination n'est possible que si le groupement axial R contient un hydrogène en position β par rapport à la liaison $Co^{III}$—C.

Ainsi, nous avons montré que le solvant joue un rôle fondamental dans la réactivité photochimique des complexes organométalliques du cobalt. La structure de la cage de solvant liée au complexe du cobalt peut modifier la réactivité de ceux-ci.

De plus, le fait que les pièges à radicaux utilisés pour étudier le mécanisme homolytique de photolyse des complexes du cobalt diffusent à l'intérieur de la cage de solvant contenant le complexe, défavorise le processus de recombinaison et facilite la détection des espèces radicalaires (12). Le processus de β-élimination étant considérablement ralenti, le fait que les pièges à radicaux pénètrent différemment dans les cages de solvant peut expliquer des cinétiques différentes de celles observées (35).

## Partie expérimentale

Les méthodes expérimentales ont été décrites précédemment (9, 10, 15, 16, 31).

Les diverses cobaloximes connues sont synthétisées selon les méthodes décrites par Schrauzer et coll. (1, 36). Les caractéristiques physiques (rmn, infrarouge et uv–visible) sont comparées à celles décrites dans la littérature (1, 36).

*Préparation des pièges à radicaux*

Les différents pièges à radicaux sont préparés suivant les méthodes indiquées dans la littérature: DMPO (37–39), ND (40), PBN (41, 42), 4-POBN (43). Des points de fusion et des microanalyses satisfaisantes ont été obtenus pour l'ensemble des composés.

Tous les pièges à radicaux photolysés, en lumière visible (ν > (ν C—D), 2140 (ν CD$\langle^{CD_3}_{CD_3}$), 2110 (ν CD$\langle^{CD_3}_{CD_3}$). 420 nm) dans les solvants utilisés, ne donnent pas de signaux.

*Synthèse des cobaloximes deutérées*

La diméthylglyoxime perdeutérée a été obtenue en suivant la méthode précédemment décrite (11).

*Isopropyl pyridinato cobaloxime perdeutérée*

Chlorure de cobalt (0,950 g) et 0,950 g de diméthylglyoxime perdeutérée sont dissous dans 5 mL de MeOD déoxygéné, sous azote, contenant 1 $cm^3$ de NaOD 8 *M* et 0,37 mL de pyridine-$d_5$. La solution est agitée, sous azote, 20 min, puis est purgée cinq fois avec du deutérium. On ajoute, sous deutérium, 2 mL de bromure d'isopropyle deutéré. On agite jusqu'à ce que le deutérium ne soit plus absorbé. On purge l'appareil à l'azote, puis on neutralise la solution avec DCl. La solution est diluée dans $D_2O$ et est filtrée. Les cristaux sont lavés avec $D_2O$, à l'éther de pétrole, puis avec l'éther. Les cristaux sont dissous dans un mélange $CDCl_3$/MeOD et précipités par $D_2O$, puis séchés. On récupère 1,4 g de cristaux purs (Rdt 86%); ir ($CHCl_3$) $cm^{-1}$: 2670 (ν OD), 2235 (ν C—D), 2190 (ν C—D), 2160 (ν C—D), 2140 (ν CD$\langle^{CD_3}_{CD_3}$), 2110 (ν CD$\langle^{CD_3}_{CD_3}$).

*Benzyl bis(diphénylglyoximato)-pyridinato cobalt*

Chloro bis(diphénylglyoximato)-pyridinato cobalt (0,554 g), préparé selon la méthode Schrauzer (44), est dégazé sous vide dans un tricol. Quinze millilitres d'un mélange 1:1 d'éthanol et d'eau déoxygénés par barbotage d'argon sont introduits à travers un septum dans le tricol, la suspension obtenue est agitée et refroidie à −10°C, 1,265 g de chlorure de benzyle désoxygéné par barbotage d'argon sont ajoutés à la suspension au travers du septum, puis 180 mg d'acide borique dissous dans le minimum d'eau déoxygénée sont ajoutés à la suspension. Borohydrure de sodium (100 mg), dissous dans le minimum d'eau déoxygénée, est ajouté lentement à l'aide d'une seringue. La solution obtenue est agitée une nuit. L'huile brune surnageante est extraite au chlorure de méthylène et lavée à l'eau. La phase organique est séchée sur sulfate de sodium, et évaporée sous vide. Les cristaux bruns sont dissous dans un minimum de méthanol chaud, puis sont reprécipités par addition d'eau. On obtient 0,230 g de cristaux jaunes (Rdt 38%); ir ($CHCl_3$) $cm^{-1}$: 3050 (ν C—H aromatique), 2975 (ν CH), 1600, 1575 (ν C=C), 1440–1420 (ν CH), 1060–890 (ν CH); rmn ($CDCl_3$), δ: 3,38 (2H, s, $CH_2\phi$), 6.92 (5H, m, $CH_2\phi$), 7,33 (20H, s, *H* DPG), 7,77 (3H, m) et 8,80 (2H, d) (*H* pyridine), 17,33 (2H, s, NO*H*). *Anal.* calc. pour $C_{40}H_{34}N_5O_4Co \cdot 1/2H_2O$ (715,93): C 67,04; H 4,88; N 9,47; tr.: C 66,76; H 4,78; N 9,81.

L'adamantyl-1 pyridinato cobaloxime a été préparée en suivant le processus indiqué précédemment (20). Des analyses centesimales correctes ont été obtenues pour l'ensemble des composés.

# Nitroxides as reaction intermediates

HANS GÜNTER AURICH

*Fachbereich Chemie of the University Marburg, Hans-Meerwein-Straße, D-3350-Marburg, Federal Republic Germany*

Received August 10, 1981

HANS GÜNTER AURICH. Can. J. Chem. **60**, 1414 (1982).

Vinyl nitroxides **4** are obtained by oxidation of the nitrones **3**, as was shown by esr studies and by identification of the reaction products. The formation of **4***d–f* is even observed in oxidation of the hydroxylamines **1***d–f*, nitroxides **2***d–f* and nitrones **3***d–f* being the intermediates. The high reactivity of the vinyl nitroxides **4** at their β-position is illustrated by the reactions of **4***a* with various compounds affording the nitroxides **7–10**, respectively. Compound **4***c* reacts with its precursor **3***c* to give **11**, **12**, or **13**, depending on the reaction conditions. From oxidation of **3***a*, *c*, and *e* the dimerization products **5***a*, *c*, and *e*, respectively, could be isolated. Whereas further oxidation of **5***d* yields **6***d*, the acyl nitroxides **14***a* and *c* are formed in the oxidation of **5***a* and *c*, respectively.

The formation of quinone **23** in the reaction of 2-methyl-2-nitrosopropane with potassium *tert*-butoxide in isopropyl alcohol in the presence of oxygen is discussed. The nitroxide **20** has been detected in the reaction mixture. Imines **24** react with nitrosobenzene giving nitroxides **26**. These are further oxidized by nitrosobenzene to afford nitrones **27**. Whereas **27***a* and *b* could be isolated, **27***c* and *d* undergo further reaction yielding the diimines **30***c* and *d* along with dinitrone **29**.

The formation and reactions of imino nitroxides **31** and of the nitronyl nitroxide **41** are discussed. Electron spin resonance studies revealed the high reactivity of the imidazolyl-1,3-dioxides **46** and the imidazolyl-1-oxides **50**, which easily form radicals **47–49** and **51**, respectively, which are derived from secondary reactions.

---

HANS GÜNTER AURICH. Can. J. Chem. **60**, 1414 (1982).

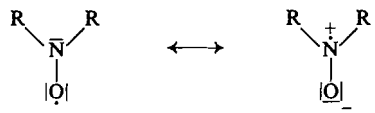
On obtient les vinylnitroxydes **4** par oxydation des nitrones **3** comme le révèlent les études de rpe et l'identification des produits de la réaction. On observe aussi la formation des composés **4***d–f* lors de l'oxydation des hydroxylamines **1***d–f* qui procède par l'intermédiaire des nitroxydes **2***d–f* et des nitrones **3***d–f*. On illustre la grande réactivité de la position β des vinylnitroxydes **4** par les réactions du composé **4***a* avec divers composés qui conduisent respectivement aux nitroxydes des **7–10**. Le composé **4***c* réagit avec son précurseur **3***c* en donnant, en suivant les conditions de la réaction, les composés **11**, **12** ou **13**. L'oxydation des composés **3***a*, *c* et *e*, permet d'isoler respectivement les produits de dimérisation **5***a*, *c* et *e*. Alors qu'une oxydation plus poussée du composé **5***d* conduit au composé **6***d*, l'oxydation des composés **5***a* et *c* conduit respectivment aux acylnitroxydes **14***a* et **14***c*.

On discute de la formation de la quinone **23** lors de la réaction du méthyl-2 nitroso-2 propane avec le *tert*-butoxyde de potassium dans l'alcool isopropylique, en présence d'oxygène. On décelé la présence du nitroxyde **20** dans le mélange réactionnel. Les imines **24** réagissent avec le nitrosobenzène en donnant les nitroxydes **26**. Ces derniers sont de plus oxydés par le nitrosobenzène en donnant les nitrones **27**. Alors qu'on peut isoler les composés **27***a* et *b*, les composés **27***c* et *d* subissent une réaction supplémentaire en donnant les diimines **30***c* et *d* ainsi que la dinitrone **29**.

On discute de la formation et des réactions des iminonitroxydes **31** et du nitronyl nitroxyde **41**. Les études de rpe révèlent la grande réactivité des imidazolyldioxydes-1,3 **46** et des imidazolyloxydes-1 **50** qui forment facilement les radicuax **47–49** et **51** respectivement qui proviennent de réactions secondaires.

[Traduit par le journal]

Nitroxides are stabilized by delocalization of the unpaired electron between oxygen and nitrogen (structures A and B), the delocalization energy being of the order of 30 kcal/mol for dialkyl nitroxides (1). A consequence of this inherent stabilization of the nitroxide group is the easy formation of nitroxides by oxidation of hydroxylamines, as is indicated by the low bond dissociation energy for the OH bond of these compounds (2).



A B

Among the many other reaction routes affording nitroxides, spin trapping by nitrones or nitroso compounds appears to be the most important (3). The facile formation of nitroxides by spin trapping is reflected by the low activation energies for these reactions (4).

Contrary to di-*tert*-alkylnitroxides, which are very persistent radicals, nitroxides with at least one hydrogen atom at the α-carbon atom usually disproportionate to give hydroxylamines and nitrones (5). Because of the facile dehydrogenation of such nitroxides, the oxidation of appropriate hydroxylamines via intermediate nitroxides to give nitrones should be a common reaction. However, complications can arise by reaction of the nitrone with the intermediate nitroxide (6).

Furthermore, oxidation of nitrones with a hydrogen atom at the β-position should afford vinyl nitroxides, which are expected to be additionally stabilized by delocalization of the unpaired electron into the vinyl group (7).

Whereas di-*tert*-alkyl substituted nitroxides are usually extremely persistent, phenyl substituted

nitroxides are not. The reason is that the extended delocalization of the unpaired electron into the phenyl ring makes dimerization by attack at the *para* position possible, thus giving rise to further decomposition (8*a*). This behavior illustrates nicely the difference between stabilization and persistence of radicals (8*b*).

The delocalization of the unpaired electron into the vinyl group of vinyl nitroxides should cause an even more enhanced reactivity of these radicals compared to phenyl nitroxides. Therefore we decided to study the formation of vinyl nitroxides by esr spectroscopy as well as their reaction pathways by product analysis. More generally, we have been interested in the question of how the nitroxide group affects the reactivity at neighbouring positions in cooperation with other functional groups.

## Results and discussion

### A. *Formation and reactions of vinyl nitroxides*

Oxidation of the nitrones **3** (9)[1] or their corresponding tautomers (10) by lead dioxide or nickel peroxide gave the vinyl nitroxides **4**. The lifetime of radicals **4***a*, *b*, *e*, and *f* is sufficient for them to be detected by esr. Their coupling constants are summarized in Table 1. Radicals **4***c* and *d* could not be observed directly, since they react immediately with their precursor nitrones **3***c* and *d*, respectively, to yield derived radicals. However spin trap reactions as well as product formation indicate that they are real intermediates.

In the oxidation of hydroxylamines **1***d*–*f* (10, 11) the esr signals of the nitroxides **2***d*–*f* can be observed initially but after some time they disappear and, instead, that of the radical derived from a secondary reaction of **4***d*, and those of **4***e* and **4***f*, respectively, arise.[1] To the best of our knowledge this is the first time that the formation of a vinyl nitroxide **4** from hydroxylamine via the intermediates **2** and **3** has been observed.

The fate of the vinylnitroxides **4** can be derived from oxidation reactions of **3** on a preparative scale.[1] By performing the oxidation reactions of **3***a*–*e* with lead dioxide or nickel peroxide on a preparative scale we isolated the dimers **5***a*, *c*, and *e* in 81, 85, and 63% yield, respectively; **5***d* could not be isolated but was directly oxidized further to give **6***d*. Only in the case of the oxidation of **3***b* a variety of unidentified products was formed in low yield. Likewise the products **6***d* and **5***e* were isolated in comparable yields by oxidation of the hydroxylamines **1***d* and **1***e*, respectively. These results indicate that *dimerization by formation of a carbon–carbon bond at the β-position of the vinyl group is the major reaction pathway of the intermediate vinyl nitroxides*.

Electron spin resonance studies revealed further that reactions of the vinylnitroxides **4** with other compounds usually also occur at the β-position. The reactions of **4***a* with nitroso compounds,

*N*-benzylidene-aniline-*N*-oxide, 2,4,6-trimethoxybenzonitrile-*N*-oxide, and 2,3-dimethylbuta-1,3-diene, which afford the nitroxides **7–10**, are representative examples (7). Whereas the reactions with the nitroso compounds are simple spin-trapping processes, the formation of **8–10** occurs by cyclizations which are formally 1,3-dipolar cycloadditions. However, it seems more likely that they are

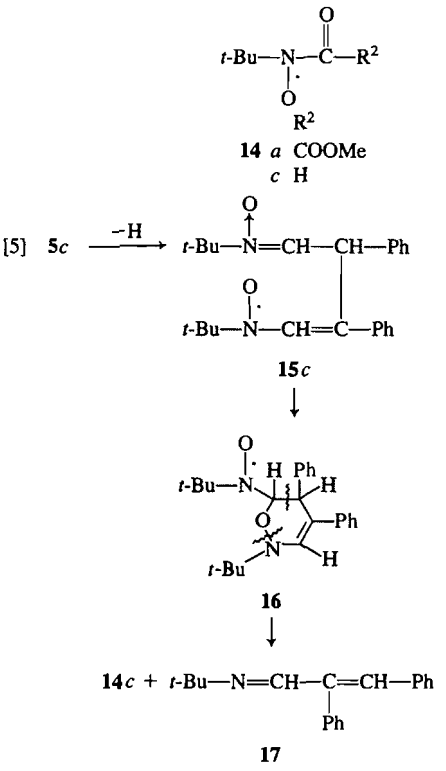
two-step reactions. In this case the formation of **8** and **9** must be considered as a twofold spin-trapping process.

Depending on the reaction conditions, three different radicals, obviously formed by secondary reactions of the rather reactive vinylnitroxide **4***c* with its precursor, have been detected in the oxidation of nitrone **3***c*. The coupling constants of these radicals are: $a^N = 15.45$, $a^H = 2.5$ G (1H) in chloroform; $a^N = 13.5$, $a^H = 5.8$ G (1H) in benzene; and $a^N = 13.9$ G, no proton splitting in benzene.[1] The structures **11**–**13** appear to be most probable for these radicals, but at present unambiguous assignment is not possible.

Whereas the intermediate dinitrone **5***d*, which probably exists in its tautomeric *N*-hydroxyenamine form (10), is easily oxidized to afford product **6***d*, the isolated dinitrones **5***a* and **5***c* surprisingly yield the acylnitroxides **14***a* and **14***c* (12) on oxidation with nickel peroxide. After prolonged oxidation of **5***c*, 2,3-diphenylpropen-2-al was isolated,[2] which is obviously formed by hydrolysis of the corresponding *N*-*tert*-butylimine **17**. Thus it appears that the oxidation of **5***c* initially gives the nitroxide **15***c* which then undergoes an intramolecular spin-trap reaction to yield the nitroxide **16**. The formylnitroxide **14***c* and the imine **17** can then arise by a retro-Diels–Alder reaction of **16**.



B. *Nitroxides as intermediates in other oxidation reactions*

The formation of 2,5-bis-(*tert*-butylamino)-1,4-benzoquinone **23**[3] in 31% yield from the reaction of 2-methyl-2-nitroso propane with potassium *tert*-butoxide in isopropyl alcohol in the presence of oxygen is a rather obscure reaction (14*a*). Electron spin resonance studies indicated that the nitroxide **20** ($a^N = 15.2$ G, $a^H = 10.4$ G (2H), $a^H = 0.65$ G (1H)) is involved. The same radical was obtained by Lagercrantz and Setaka (14*b*) in the reaction of hydroxy radicals with isopropyl alcohol in the presence of 2-methyl-2-nitrosopropane: $a^N = 16.3$ G, $a^H = 13.3$ G (1H), $a^H = 8.9$ G (1H), $a^H = 0.74$ G (1H) in $H_2O$. The larger values for the coupling constants are due to the more polar solvent. In contrast to our findings, Lagercrantz observed two different coupling constants for the methylene protons, but this may be due to the different reaction conditions. Nevertheless, exactly the same ratio $a^N/a^H_{CH_2}$ is obtained in the two cases, if one uses the mean values of the proton couplings.

It must be assumed that the reaction is induced by the formation of the nitroso anion radical **18** on treatment of the nitroso compound with *tert*-butylate (15). Anion radical **18** reacts readily with oxygen and, as is known from reaction in various solvents, hydrogen abstraction from the solvent occurs under these conditions (15). Radical **19** formed from isopropyl alcohol (eq. [6]) is then trapped by the nitroso compound to give the nitroxide **20**. One would expect hydrogen abstraction from isopropyl alcohol to occur exclusively at its central position, as was also pointed out by a referee. But under the very different conditions, applied by Lagercrantz (14*b*) and us, radical **20** could be detected unambiguously, whereas no evidence for the trapping of the radical $CH_3—\dot{C}(OH)CH_3$ was found. Under the oxidative reaction conditions a successive dehydrogenation of **20** to afford the acylnitrone **22** via the intermediate vinyl nitroxide **21** is reasonable. Since it was found that nitrone **22**,[4] which was synthesized independently,

**23**

is converted into the quinone **23** on treatment with various bases, the reaction seems to be rationalized best by the proposed reaction sequence (eq. [7]).

As was found some years ago by Layer (16), imines react in their tautomeric enamine form with nitrosobenzene to give hydroxylamines which are oxidized by further nitrosobenzene to afford the corresponding nitroxides. We performed this reaction with less substituted imines **24** having at least two hydrogen atoms at the β-position (17). The nitroxides **26** could be detected by esr, as expected, but there was no evidence for the existence of the tautomeric β-amino substituted vinylnitroxides **28**. Oxidation of the nitroxides **26** by nitrosobenzene afforded the rather unstable imino nitrones **27** which could be isolated only when substituted as in **27***a* and **27***b*.

In the reactions with imines **24***c* and **24***d*, however, the diimines **30***c* and **30***d* were formed along with the dinitrone **29** (eq. [9]) (18). Since the existence of small amounts of vinylnitroxides **28***c* and **28***d* in equilibrium with **26***c* and **26***d*, respectively, could not be excluded, a dimerization of **28***c* and **28***d* by bond formation at the β-position may be considered to be the first step in a reaction sequence yielding **30***c* and **30***d* along with **29**. But this possibility was refuted by the labelling experiments. The distribution of the carbon-13 label agrees only with a dimerization at the oxidation level of the nitrone **27** in the indicated way.

## C. *Imino and nitronyl nitroxides*

Contrary to the vinyl nitroxides **4**, imino nitroxides **31** do not dimerize, since the gain in energy for the formation of a nitrogen–nitrogen bond does not compensate the loss of delocalization energy for the two nitroxide molecules (ref. 19, see also p. 91).

As in the case of hydroxylamines **1***e* and **1***f*, amino-substituted hydroxylamines such as **33**, which exist in equilibrium with their educts, can be oxidized by lead dioxide to yield imino nitroxides via the corresponding intermediates (20). Starting with nitrone **32** and methylamine, nitroxide **34** was first detected, which was slowly converted to the imino nitroxide **36**. Surprisingly, the oxidation process did not stop at this level. The methyl group was destroyed by further oxidation, the imino nitroxide **37** being the final radical product in the reaction sequence [10]. Compound **35** could be isolated from the reaction mixture as the lead complex in 31% yield.

Similarly, oxidation of **38** (21) proceeds via **39** and **40** to afford the nitronyl nitroxide **41** (eq. [11]). But after some hours the esr signal of **41** disappears, and the imino nitroxide **42** is observed instead. The *N*-hydroxy formhydroxamic acid **43**

was isolated as the lead complex in 5% yield from the reaction mixture (20). The formation of **42** and **43** can be rationalized if one assumes that **41** is trapped by its precursor **40** to give the adduct **44**, which is then split as indicated.

D. *Imidazolyl-1,3-dioxides and imidazolyl-1-oxides*

In imidazolyl-1,3-dioxides the vinyl group and the nitronyl group are both conjugated with the nitroxide moiety. Whereas the 4,5-diaryl substituted imidazolyl-1,3-dioxides (22) as well as the benzimidazolyl-1,3-dioxides (23) are relatively persistent, this is not true for the 4,5-dimethyl substituted radicals **46**. Thus, the radical to which structure **46***a* has been assigned (22) is in fact a radical derived from a secondary reaction.[5]

When we oxidized the 4,5-dimethyl-3-hydroxyimidazole-1-oxides **45***a* (22) and **45***b* to afford **46***a* and **46***b*, we found that the lifetime of these radicals is markedly influenced by the substituent at the 2-position. Although **46***a* was studied at low temperatures its esr spectrum changes so rapidly that it never could be recorded without superposition of the spectrum of the radical derived from a secondary reaction. On the other hand, radical **46***b* has a lifetime of more than five minutes at room temperature. Whereas **46***a* is converted into a cyclic nitronyl nitroxide **47** (24) with slightly different coupling constants for the two nitrogen atoms, indicating an unsymmetric substitution, **46***b* is converted into the oximino nitroxide **48** (eq. [12]). The structure of **48** was assigned by comparison with the coupling constants of related radicals (23*b*). Finally **48** is converted to give the nitronyl nitroxide **49**, which is presumably symmetrically substituted.

Obviously, the easy conversion of **46***a* and **46***b* reveals the particular reactivity of the vinyl group which is conjugated with a nitroxide group. The difference in the reactivity of **46***a* and **46***b* suggests that an attack at the 2-position of **46** or its precursor **45** is involved in the reaction sequence forming the derived radicals.

From this it seems possible that the conversion begins with bond formation between the vinylic carbon atom of **46** and the 2-position of the precursor molecule **45** to afford again a vinyl nitroxide moiety which then undergoes further intramolecular reactions, e.g. spin trapping.

TABLE 3. Coupling constants of the radicals **46**–**51** in Gauss[a]

| Radical | $a_1^N$ | $a_3^N$ | $a_2^H$ | $a_{4,5}^H$ | *g*-value |

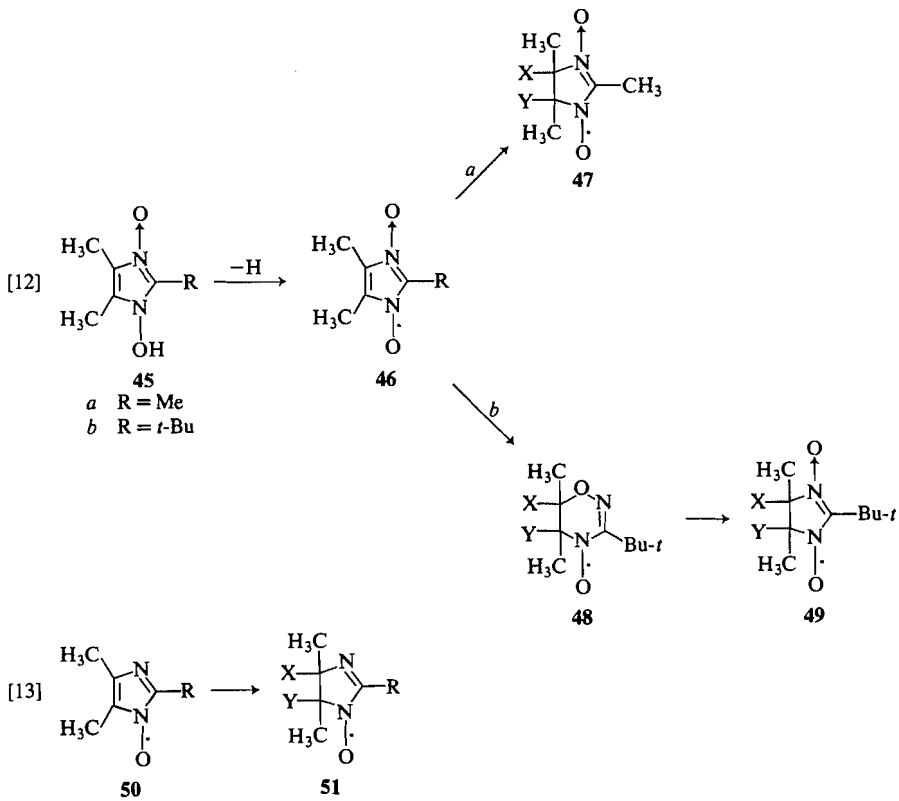
[a]See footnote 5. In $CHCl_3$.

[5]H. G. Aurich and J. Schmock, unpublished results.



The conversion of the imidazolyl-1-oxides **50** into the imidazolinyl-1-oxides **51** is thought to occur in a similar way. Since the esr spectrum of **50***a*, in contrast to that of **50***b*, could never be observed, it must be concluded that this radical is even more reactive than the corresponding radical **46***a*.

# Spin labelling ribosomes: an overview

HERMANN DUGAS AND ANGEL RODRIGUEZ

*Department of Chemistry, Université de Montréal, Montreal (Qué.), Canada H3C 3V1*

Received August 10, 1981

HERMANN DUGAS and ANGEL RODRIGUEZ. Can. J. Chem. **60**, 1421 (1982).

This paper reviews the spin label approach to the problem of structure and function of the bacterial ribosomes from *Escherichia coli*. The work of different research groups towards selective spin labelling of 70S ribosomes is presented and results are compared. Information obtained by binding these derivatized ribosomes with magnesium ions, tRNA, and antibiotics are analyzed. The interaction of selectively spin-labeled $tRNA^{Phe}$ and spin-labeled kanamycin and puromycin with the ribosomes is also discussed.

HERMANN DUGAS et ANGEL RODRIGUEZ. Can. J. Chem. **60**, 1421 (1982).

Cet article fait une revue de l'étude de la structure et de la fonction des ribosomes bactériens de *Escherichia coli* par la méthode du marqueur de spin. Les travaux de différents groupes de chercheurs dans le but de marquer sélectivement les ribosomes 70S sont présentés et comparés. On analyse l'information obtenue lors de la fixation d'ions magnésium, de tRNA et d'antibiotiques sur les ribosomes marqués. On discute aussi les résultats de l'interaction des ribosomes avec du $tRNA^{Phe}$ sélectivement marqué ainsi qu'avec des marqueurs de spin de kanamycine et de puromycine.

## Introduction

In all organisms, the biosynthesis of proteins occurs on a complex "molecular machinery" called the ribosome. The best-characterized ribosome is from the bacterium *Escherichia coli* and consists of three different RNA molecules and 53 to 55 different proteins. The ribosomal particle has a sedimentation value of 70S and is composed of two nonidentical subunits, the 30S and 50S subparticles. The specific nucleic acid protein interactions involved in the assemblage of the ribosome subparticles have interested not only biochemists but also chemists and biophysicists in the last decade, and many aspects of the ribosome's structure and function have been reviewed recently (1–3).

For the ribosome to be active in protein synthesis, many molecules, factors, and ions must interact with its structural components. Of particular interest is the perturbation that can be created by the binding of antibiotics and transfer RNA (tRNA) molecules on the ribosome structure. In this regard, different techniques such as tritium exchange (4) and iodination (5) of ribosomal proteins, fluorescence labelling (6, 7), and the spin-label method (8–14) have been applied to elucidate any structural change taking place on the ribosome. The objective of the present paper is to review the spin-label approach. Contributions from our laboratory (8–11) as well as from others (12–14) will be presented and compared.

## Results and discussion

A simplified representation of the composition of *Escherichia coli* ribosomes is pictured in Fig. 1. How does one go about selectively spin labelling such an organelle? Obviously, an important condition for the application of the spin-label method is the implantation of covalent labels on specific protein groups. In this respect, the reactivity of protein SH groups for alkylating agents such as NEM[1] has been examined in detail. In particular,

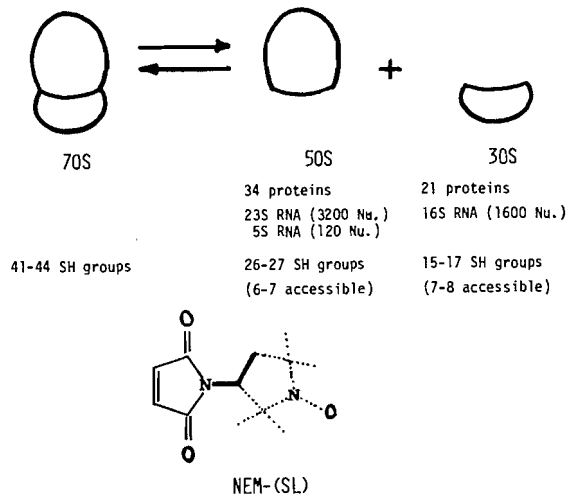

FIG. 1. Representation of the 70S ribosome from *E. coli*. The composition of each subunit and the number of available SH groups are indicated. The structure below emphasizes the similarity between NEM and its spin-label analogue (spin label I).

[1]*Abbreviations*: epr, electron paramagnetic resonance; SL, spin label; ribo, ribosome; NEM, *N*-ethylmaleimide; Cbz, carbobenzyloxy; Sm, streptomycin; Nm, neomycin B; Km, kanamycin A; Pm, puromycin; BSL, 3-(2-bromoacetamido)-2,2,5,5-tetramethyl pyrrolidine-1-oxyl, (bromo-SL); CSL, 1-(*N*-methyl-2-morpholinoethyl)-3-(2,2,6,6-tetramethyl piperidine)-1-oxyl, (carbodiimide-SL); HSL, *N*-hydroxysuccinimide ester of 3-carboxy-2,2,5,5-tetramethyl pyrrolidine-1-oxyl, (hydroxysuccinimide-SL); AMSL, 4-amino-2,2,6,6-tetramethyl piperidine-1-oxyl, (amino-SL); ADPSL, adenosine 5'-diphosphate-4-(2,2,6,6-tetramethyl-piperidine)-1-oxyl; FWR, factors washable from ribosomes.

Bakardjieva and Crichton (15) have done an extensive study on the accessibility of SH groups from ribosomal proteins towards radioactive NEM. Fortunately, spin-labeled analogues of NEM are available. We have thus chosen for our studies the 5-membered ring analogue (spin label I) which bears a close spatial resemblance with NEM as illustrated in Fig. 1 and therefore should not appreciably perturb the ribosome structure beyond the perturbation caused by the presence of NEM itself. Other groups have worked with the nitroxyl 6-membered ring analogue.

*Selective spin labelling of ribosomes*

In the complex structure of the 70S ribosome each SH group of the ribosomal proteins should have a microenvironment unique to itself and the motion of the spin label bound to them should be a characteristic of this environment. Furthermore, the epr signal should also be sensitive to structural modifications of the ribosome during its multiple functions. In order to study a local region of the ribosome without ambiguity, it is essential to label that region as specifically as possible. To achieve a selective spin labelling, the differences in reactivity of the SH groups have been exploited in several laboratories and are summarized in Table 1. Selective spin labelling is indeed possible but only if the labelling is carried out for short periods of time and preferably when the ratio of spin label to ribosome is not too high. It is well established that labelling the 70S ribosome with NEM can perturb some of its functions (16–18) and even affect its conformation (19). Further, dissociation and degradation of the ribosome occur under conditions of intensive labelling (12). For the same reasons, prolonged treatment of the ribosome above room temperature should also be avoided. The utilisation of NEM analogues as probes has thus necessitated a control of the activity and the integrity of the ribosome structure.

It is important to realize that during the assignment of the spin-labeled proteins we have observed that we cannot assume a complete analogy between the reactivity of [$^{14}$C]NEM and the spin-labeled analogues. For instance, L2 and S13 are both reactive proteins towards NEM, but neither is alkylated by the spin label I (9). Furthermore, we have found that proteins L6, L11, and L17 have a reactivity for NEM which is superior to the number of SH groups present on the proteins and suggests that other NEM-sensitive groups (possibly ε-amino groups from lysine residues) are present. Extreme care should thus be exercised during spin-label work if reactivity of analogous probes are compared.

The location on the ribosome of the spin-labeled proteins from our work (9) is depicted in Fig. 2. Cross-linking experiments with bifunctional reagents have suggested physical proximity for these proteins (2). Although some of these proteins (S18, S21) are elongated and can span across the 30S subunit, it is now accepted that proteins S1, S18, S21, and 3′-end of 16S RNA are all localized in the head portion of the 30S subunit and constitute the domain of codon–anticodon interactions (1, 2, 20). It has also been established that the SH groups of proteins S1, S18, and S21 (all one SH per protein) are part of the head portion of the 30S, close to the anticodon region (2, 21). Furthermore, S12 (a neighbor of S21) is implicated in the process of recognition of mRNA and the binding of initiator-tRNA (fMet-tRNA) at the ribosomal P site (20). As for protein L27, it is known to be part of the P site in the 50S subunit in proximity to the 3′-end of tRNA (22). Interestingly, it is the only labeled protein from the 50S subunit and its location is directly facing the other spin-labeled proteins on the 30S subunit when both subunits are associated. This specific region is thus particularly sensitive to alkylating agents. We can thus infer that under our conditions of labelling with spin label I, the labels

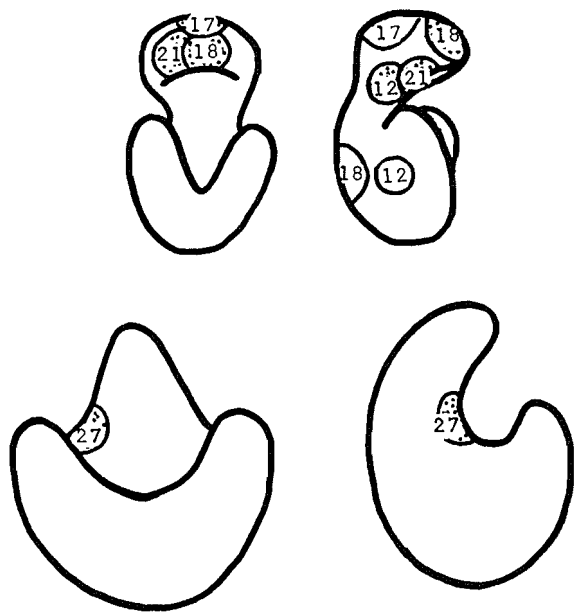

FIG. 2. Location of the spin-labeled proteins on the individual 30S and 50S subunits (9). The two views presented are obtained by rotation through an angle of 90° (2). Spin-labeled regions are represented by dotted zones.

TABLE 1. Summary of the results obtained with spin-labeled ribosomes

| Spin label used | Conditions of labelling | Proteins spin-labeled | Remarks on selectivity | Activity of SL-ribosomes* | Effect of $Mg^{2+}$ ions | Binding of antibiotics | Addition of tRNA |
|---|---|---|---|---|---|---|---|
|  Dugas *et al.* (9) | 2 min 22°C SL/ribo ratio of 40 | S18 > S21, L27 > S17, S12 | 1.5 SL/ribo, 80% on 30S, 48% of S18 labeled | 90% active | SL not affected by changes in $Mg^{2+}$ concentration | Loosening of ribosome structure upon binding Sm (8) | Loosening of ribosome structure on the 30S subunit (11) |
|  Brakier-Gingras *et al.* (12, 13) | 1.5 min 37°C SL/ribo ratio of 125 | S18 > S1 > L 17, L10 | About 1 SL/ribo, 70% on 30S, 57% of S18 labeled | Not determined | | Binding of Sm does not affect reactivity of SH groups. Loosening of ribosome structure upon binding of Sm (Nm had no effect) | |
| | Same conditions but S18 blocked first with NEM | S1, L10 > L17 > S21 | About 1 SL/ribo, 45% on 30S, 30% on S1 | Not determined | | Loosening of ribosome structure upon binding of Nm (Sm had no effect) | |
|  Tritton (14) | 16h, 4°C SL/ribo ratio about 250 | About 20 (not determined) | Not selective but either subunit could be separated and reassociated with non-SL-subunits | Inactive | SL more mobile when SL-subunits associated with non-SL-partners | Loosening of structure upon binding Sm but only when SL are in the 50S subunits | |
|  (14) | Labeled fraction L7/L12 and reconstituted the ribosome | Complex L7/L12 selectively labeled | 0.5 to 1 SL/ribo, only on 50S subunit | Fully active | | | |

*Activity towards poly(U)-directed poly-Phe synthesis.

are in a well-localized domain to allow an adequate monitoring of ribosome–mRNA–tRNA interactions. Furthermore, the head part of the 30S subunit is in the region of binding of the tRNA molecule where local perturbation could be followed (*vide infra*).

Representative epr spectra of the selectively spin-labeled ribosomes are presented in Fig. 3. For spin label I, the spectrum is fairly immobilized and suggests that the environment of the SH groups is rather hydrophobic in nature with an hyperfine splitting ($a_N$) of only 15.9 G. Similar spectra were obtained with the 6-membered ring analogue of NEM (12). Using a series of homologous spin labels, the average depth of the cavity occupied by the spin label has been estimated to around 6 Å (9).

We have performed a series of simulations of the epr spectra[2] of the 70S ribosome, labeled with spin label I (1.5 SL/ribosome). The resemblance between experimental and simulated spectra indicated that 30% of the epr signal corresponds to a $\tau_c$ of 0.5 to 3.0 ns and that the remaining 70% corresponds to a motion of the spin labels characteristic of a $\tau_c$ value between 10 and 80 ns. Free diffusion of 70S ribosome in an aqueous medium corresponds to 2.5 μs (25). Consequently, spectral analysis by simulation showed that a major fraction of the signal corresponds to spin labels strongly immobilized.

Using a different approach, Tritton selectively spin labeled the isolated proteinaceous complex L7/L12 (no SH group present) with an iodoacetamide spin label and reconstituted active ribosomal 70S particles (14). The corresponding epr spectra were indicative of mobile probes, even after reconstitution. This result seems to show that at least a portion of the L7/L12 domain maintains a good deal of flexibility when localized in the ribosome (14). The author suggested that such flexibility in this region of the ribosome structure may be related to its activity. This kind of selective labelling should be very useful for the eventual study of binding of initiation and elongation factors IF-2, EF-Tu, and EF-G (2).

*Selective spin labelling of 16S RNA*

Figure 4 summarized how we have attempted to label specifically the 3′-end of 16S RNA present in the 30S subunits. First, we have used the intact 70S ribosomes and labeled them under conditions similar to those used to label the 3′-end of tRNA molecules (26). The labelling was directed towards the terminal ribose residue by reductive acylation in the presence of amino-SL (AMSL) and $NaBH_4$, using material pretreated with $NaIO_4$. The corresponding epr spectrum has a $\tau_c$ value of 0.09 ns and the incorporation of spin label was 0.28 SL/ribosome. Since AMSL alone could in principle react with certain ribosomal proteins, labelling was also carried out in absence of $NaIO_4$ as a control. Without $NaIO_4$ we obtained an incorporation of 0.11 SL/ribosome ($\tau_c$ = 0.22 ns).

Therefore, the 3′-end of 16S RNA does not seem to be hindered but our labelling is not selective enough; some 23S RNA and some protein residues might also be modified (27). In order to obtain a completely selective labelling, the 16S RNA would have to be isolated from the 30S subunits, labeled, and the 70S ribosomes reconstituted in the presence of spin-labeled 16S RNA.

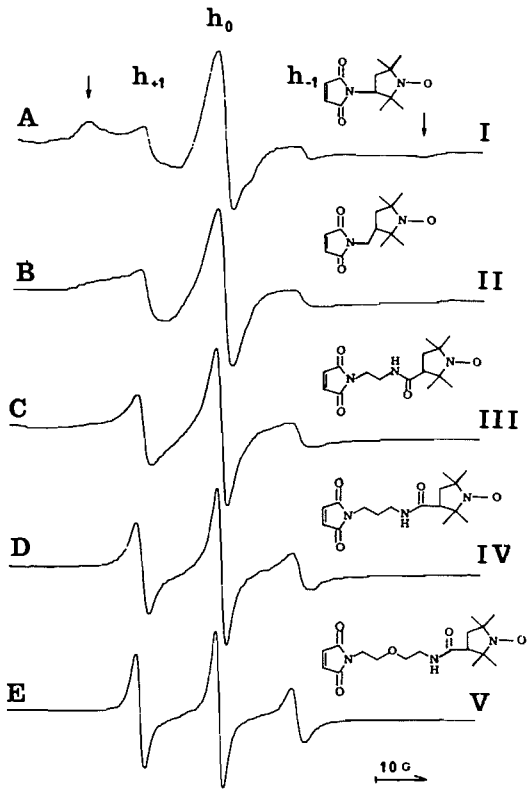

FIG. 3. The epr spectra of selectively spin-labeled 70S ribosomes from *E. coli* at 21°C in 20 m*M* Tris-HCl, 10 m*M* $Mg(OAc)_2$, 0.1 *M* $NH_4Cl$, pH 7.4. The concentration of spin-labeled ribosomes used is $6 \times 10^{-6}$ *M* and the number of spin labels per ribosome was estimated to be 1.5 (9). The distance from the center of each ring for spin labels I to V are, respectively, 4.4, 5.7, 9.3, 10.5, and 12.9 Å. This corresponds to an approximation for the distance between the nitroxide group and the site of attachment on the ribosomal proteins. The spectra were recorded on a Bruker 414S spectrometer.

[2]We have considered an isotropic motion and an axial symmetry of the nitroxide group. The spectra were obtained from a linear combination of four simulated components with the following $\tau_c$ values and relative populations: 0.5 ns (1.5%), 3.0 ns (28%), 10 ns (24.5%), and 80 ns (46%) (23, 24).

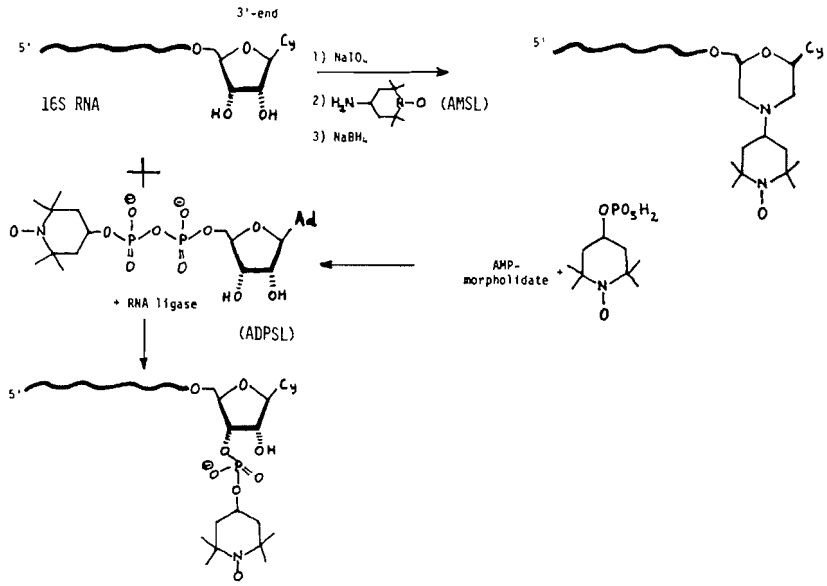

FIG. 4. Approaches to spin labelling the 3'-end of 16S RNA.

In a different approach, we have attempted an enzymatic labelling of the 3'-end of 16S RNA in the presence of RNA ligase (28). As substrate we used a spin-labeled ADP analogue (ADPSL), prepared by the method used by Weiner (29). Unfortunately, using a mixture of 16S and 23S RNA the efficiency of labelling was only 3%. With isolated 30S subunits, the yield of labelling was even lower. Nonetheless, in both cases the spectra showed a very mobile component ($\tau_c = 0.1$ ns), characteristic of a rather exposed 3'-end for the 16S RNA.

*Effect of magnesium ions*

The presence of $Mg^{2+}$ ions is essential for the ribosome to be active and to function normally at 37°C. Since lowering the $Mg^{2+}$ concentration could result in many modifications of the ribosome structural integrity (17), it became interesting to see if such structural perturbations could be detected and followed spectroscopically with spin-labeled ribosomes.

Contrary to previous expectation (17), no epr-detectable changes in the ribosome structure seemed to take place with ribosomes labeled with spin label I, upon dissociation of the 70S particles into subunits by lowering the $Mg^{2+}$ concentration from 20 m*M* to 0.5 m*M* (9). This observation agrees with results obtained by other techniques, especially electron microscopy (30). However, when the ribosomes were spin labeled in their dissociated state, new SH groups became alkylated at the subunit interfaces and the epr spectrum was indicative of more mobile probes. Glick and Brubacher (31) had already shown that, indeed, additional NEM-reactive groups are available upon dissociation of 70S ribosomes.

On the other hand, Tritton (14), using his multi-spin-labeled ribosomes, observed an increase in the motion of the labels when 30S or 50S spin-labeled subunits were associated with non-spin-labeled partners to form 70S particles. The author proposed that such relaxation of structure in both subparticles when they are joined together to form a 70S ribosome may be functionally important for the procession of the organelle through the various steps of protein synthesis (14). In contrast, Favaudon and Pochon (32), with stopped-flow technique using either 30S or 50S subparticles and a fluorescent probe, have observed that only the 30S subunit exhibits a $Mg^{2+}$-dependent conformational change. This divergence thus remains to be clarified by further studies.

*Binding of antibiotics*

Structurally related aminoglycoside antibiotics such as streptomycin (Sm), neomycin B (Nm), and kanamycin A (Km) bind to the ribosomes and interfere with several steps in protein synthesis in bacteria (33). Their structures are shown in Fig. 5. For instance, they can either induce inhibition of protein synthesis by altering the initiation step or, at different degrees, cause misreading of the genetic code. They can also affect the stability of the ribosomal particles. These antibiotics bind to the 30S subunit, on nonidentical but possibly closely related sites (34, 35). Although their mode of action

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

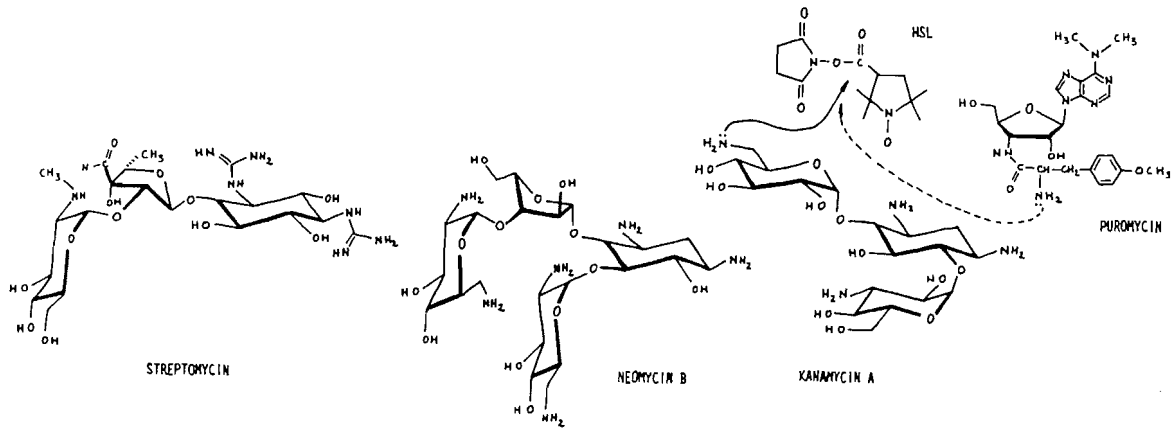

FIG. 5. Structures of the antibiotics discussed in the text. As shown, SL-Km and SL-Pm were prepared by reaction with HSL (see Experimental).

has been studied in some detail, particularly for Sm, the exact location of their binding sites on the ribosome and the extent of perturbation caused on the ribosome structure are still not very well understood. Some workers have argued that the 3′-end of 16S RNA could be involved in the binding of Sm (36), while others have suggested that proteins S1, S12, and S18 are among the proteins implicated in the binding (37). This last hypothesis makes the spin-labeled ribosomes excellent candidates to study the binding of these antibiotics with ribosomes.

Preliminary studies, in which many ribosomal proteins were spin labeled with either spin label I or the 6-membered analogue, suggested already that the binding of Sm seems to loosen the structure of the ribosome (8). A more elaborate work on the interaction of Sm and Nm was carried out by Brakier-Gingras and co-workers (12, 13) using selectively spin-labeled ribosomes (see Table 1). First of all they were able to show that the presence of Sm neither protects the SH groups from reaction with NEM nor induces structural changes so as to expose new SH groups (12). Secondly, they confirmed that indeed the presence of Sm loosens the structure of spin-labeled ribosomes and suggested that this loosening is probably located in a restricted area of the ribosome, since it was observed only when a limited number of ribosomal sites were labeled, especially S1 and S18.

To follow the binding of the antibiotics, they relied on the fluctuation of the relative intensities of the two low field maxima of the spectra. Such exercise must be practiced with much caution because it corresponds to a gross oversimplification of the exact proportion of strongly and weakly immobilized components present in the spectra. Nevertheless, qualitative information can be compared.

More interesting was the finding that Nm had no effect on the epr spectra of ribosomes spin labeled mainly on protein S18. On the other hand, if this protein is first blocked by NEM and then the ribosomes spin labeled, proteins S1 and L10 are the main proteins containing the paramagnetic probe (13). With these new derivatized ribosomes a local loosening was still observed, but only upon binding of Nm; this time Sm had no effect. Proteins S1 and S18 are neighbors and protein L10 is located close to the complex L7/L12 in the 50S subunit (2). These data thus provide evidence that Sm and Nm distort the conformation of the ribosome at different sites, and this could be a consequence of the difference in their mode of action (13). For instance, Nm induces more misreading than Sm.

Tritton (14) has also studied the effect of Sm on reassociated spin-labeled 70S ribosomes. Again a loosening of the ribosome structure was observed but only when the spin labels were in the 50S subunits.

*Spin-labeled antibiotics*

To gain more information on the location of the binding site of antibiotics, spin-labeled kanamycin (SL-Km) and spin-labeled puromycin (SL-Pm) were synthesized by coupling with HSL (see Fig. 5). The objective was to study their interaction with ribosomes and spin-labeled ribosomes. Such an approach could allow the determination of distances between the site of labelling on the ribosome and the site of binding of the spin-labeled antibiotics. Km is an aminoglycoside which binds to the 30S subunit whereas Pm is an antibiotic that binds to the aminoacyl-site (A site) of the ribosome. It can

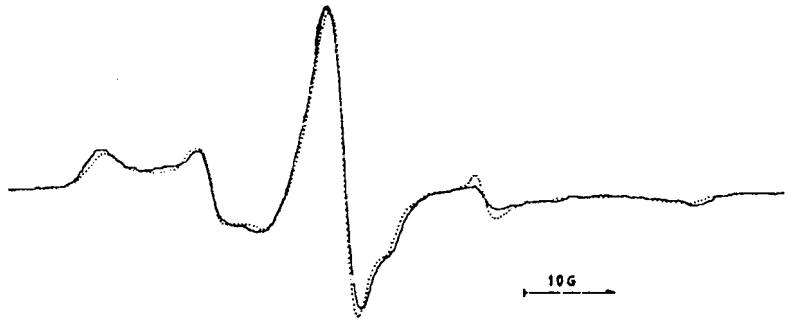

FIG. 6. The epr spectra of spin-labeled 70S ribosomes from *E. coli* in 50 m*M* Tris-HCl, 20 m*M* $Mg(OAc)_2$, 0.14 *M* $NH_4Cl$, pH 7.4 at room temperature. Spectra were normalized in such a way that the central lines have the same amplitude, 6 scans using a Nicolet 1180 computer, total time 20 min; (———), spin-labeled ribosomes containing 1.5 mol of spin label I per mole of ribosome; (---), spin-labeled ribosomes in the presence of poly(U) and $tRNA^{Phe}$ (11).

mimic the 3′-end of aminoacyl-tRNA molecules and its mode of action involves the formation of a peptide bond with the growing peptide chain in the peptidyl-site (P site). This results in a premature termination of polypeptide (protein) synthesis (38).

It should be recalled that the distances from the center of each ring for spin labels III and V are respectively 9.3 and 12.9 Å (see Fig. 3). Unfortunately, upon binding SL-Km or SL-Pm to SL(III)-ribosomes, no sign of nitroxide–nitroxide interactions could be detected. In fact, the only modification detectable in the epr spectra came from a slight increase in the mobility of the epr signal when SL-Pm binds to ribosomes spin labeled with SL(III) or SL(V). On the other hand, binding of SL-Km to ribosomes spin labeled with SL(III) or SL(V) resulted in a slight immobilization of the epr signal. Km binds to the 30S subunit and possibly close enough to protein S18 so as to immobilize the spin-label motion. Therefore, our efforts in this "molecular stick" approach, although preliminary, were rather disappointing. This could result from the fact that the binding capacity ($EC_{50}$) of the spin-labeled antibiotics was found to be much too weak.[3] Since these SL-antibiotics do not bind efficiently with the ribosome, and very large quantities of ribosomes are needed in these experiments, the experiments were not pursued any further.

*Binding of transfer RNA (tRNA)*

As mentioned earlier, some of the spin-labeled proteins, in particular S18 and S21, are believed to be directly implicated in the region of binding of tRNA to the ribosome (21, 39). Our selectively spin-labeled ribosomes (9) are thus properly suited for that type of monitoring. It was found that binding of spin-labeled ribosomes with $tRNA^{Phe}$ or poly(U) alone did not appreciably modify the epr spectra, but when both are present an increase in the mobility of the spin labels was readily detected. This is presented in Fig. 6 and the same effect was observed with an aminoacyl-tRNA molecule, Cbz-Phe-$tRNA^{Phe}$ (11). This spectral change corresponds to a perturbation of the ribosome structure in the environment of the labeled SH groups upon formation of the tertiary complex. Such a subtle fluctuation of the ribosome may be required during the process of protein synthesis. A similar conformational change was previously detected by fluorescence spectroscopy (7) but the spin label contribution indicates that it corresponds to a loosening in the ribosome structure. It is very likely that this perturbation is in the neighborhood of proteins S18 and S21 since the accessibility of their SH groups has been shown to be affected (reduced) by the presence of poly(U) or tRNA molecules (7). However, the technique of iodination of ribosomal proteins has also been used to identify a set of 30S ribosomal proteins involved in the poly(U)-directed nonenzymatic binding of the $tRNA^{Phe}$ (40). The proteins identified were S1, S2, S3, S14, and S19. Since none of these proteins contain a spin label, it is likely that other perturbations away from the site of labelling be involved, yet undetectable by epr spectroscopy.

A comparison of the rate of reduction by ascorbic acid of the nitroxide groups present on spin-labeled ribosomes alone and on spin-labeled ribosomes having tRNA and poly(U) bound to their surface clearly showed that the labels are more accessible in the tertiary complex (11). This finding not only confirms that a structural change has taken

[3]The $EC_{50}$ is the amount of SL-antibiotic necessary to displace 50% of non-spin-labeled antibiotic. It was determined for both SL-antibiotics by N. Moreau, Thiais, France. For SL-Pm a value of $14 \times 10^{-4}$ *M* was obtained and for SL-Km the value was $1.25 \times 10^{-4}$ *M*. Typical values for good binding affinity should be in the $10^{-6}$ *M* range.

place on the ribosome upon binding of the tRNA molecule but also that the labels are more exposed. This is expected if the ribosome structure is more open after binding tRNA and poly(U).

Addition of poly(U) and tRNA to 70S ribosome labeled with SL(V) reduced the motion of the nitroxide group, suggesting that at least the binding of tRNA is at a distance less than 13Å from the labeled SH groups.

In conclusion, the binding of tRNA to spin-labeled ribosomes at the P site (*vide infra*) loosens the ribosomal structure (11) but similar experiments where the tRNA binds predominantly to the A site showed no modification of the epr signal. Therefore, the A site is structurally and conformationally different from the P site with respect to tRNA binding, at least as monitored by epr spectroscopy.

*Binding of spin-labeled tRNA to 70S ribosomes*

An approach complementary to the one described above is to use selectively spin-labeled tRNA molecules and study their interaction with intact ribosomes. This way conformational changes on the tRNA molecules can be monitored. Among the numerous spin-labeled tRNA derivatives known (26, 41), two of them, BSL-Cbz-Phe-tRNA$^{Phe}$, labeled at position $s^4U_8$, and CSL-Cbz-Phe-tRNA$^{Phe}$, labeled at position $U_{33}$ in the anticodon region, were used to study the dynamics of tRNA–ribosome interaction in the presence of poly(U) and factors washable from ribosomes (FWR) (10).[4]

As expected, the spin label CSL in the anticodon loop could follow perturbations in this region. On the other hand, the spin label BSL in the center of the molecule at position $s^4U_8$, because of its unique location in the sequence, could witness structural changes either in the tertiary interactions between dihydrouridine and TψCG loops or in the aminoacceptor arm (3′-CCA arm). Figure 7 shows that indeed the binding of these two selectively spin-labeled aminoacyl-tRNA molecules to the ribosomes could be followed readily by monitoring the variation in the correlation time ($\tau_c$). This was manifested principally by a substantial increase in the amplitude of motion of the spin label BSL at position $s^4U_8$, but it is clear that the environment of both spin labels is affected. The spectroscopic evidence indicates that the tRNA molecules had undergone a conformational change in tertiary structure when bound to the ribosomes.

[4]FWR are obtained during the purification of ribosomes and are rich in initiation factors which bind to tRNA during protein biosynthesis. Experiments in the presence of FWR are referred to as enzymatic binding of tRNA to ribosomes.

Interestingly, BSL-tRNA$^{Phe}$ which was not aminoacylated showed no change in the epr spectra when bound to the ribosome. Therefore, nonspecific binding was unlikely because it should have been observed with uncharged tRNA. As compared to Phe-tRNA$^{Phe}$, the binding capacity of Cbz-Phe-tRNA$^{Phe}$ was, however, reduced to about 68% and the presence of a spin label reduced this value again, but only slightly. Therefore, the presence of the Cbz group seems to be the main factor responsible for lowering the association constant of these tRNA molecules (10).

Experiments in the presence of the antibiotic puromycin, which binds exclusively to the A site, clearly showed that spin-labeled Cbz-Phe-tRNA$^{Phe}$ molecules were bound preferentially to the ribosomal P site (up to 70%) and the effect was more pronounced (83%) in the presence of FWR. It was also found that the presence of poly(U) did not appreciably modify the epr signals of the spin-labeled tRNA's. The main contribution to the variation in the $\tau_c$ values observed then must come from binding to the P site and suggests that specific codon–anticodon recognition cannot be the prime factor responsible for the structural change taking place on the aminoacyl-tRNA molecule upon binding to the ribosome (42). Furthermore, a recent $^1$H nmr study (43) showed that no conformational changes in the $T_{54}$ region of the tRNA could be detected upon formation of the tight complex via complementary anticodon–anticodon interaction between *E. coli* tRNA$^{Glu}$ and yeast tRNA$^{Phe}$. If such a tRNA$^{Phe}$–tRNA$^{Glu}$ duplex can be used as a model of codon–anticodon interaction, it becomes rather unlikely that codon–anticodon recognition may trigger an unfolding of the tertiary structure of tRNA and induce accessibility of the TψCG region. Along the same lines of thought, Vlassov and Mamayev (44) arrived at the conclusion that codon binding does not change the conformation of the tRNA from a chemical modification study of the interaction of tRNA$^{Phe}$ with $(pU)_4$.

By tritium exchange and fluorescence measurement, Farber and Cantor (4) have also found that tRNA$^{Phe}$ interacts with the ribosome similarly in the presence and absence of poly(U). In this direction, Kurland *et al.* (45) have already suggested a "conformational selection mechanism" for tRNA recognition whereby a perturbation away from the anticodon could allow a better codon–anticodon recognition process and at the same time would be responsible for the selection of the right aminoacyl-tRNA. Therefore, the conformational change of tRNA$^{Phe}$ when bound to poly(U)-programmed ribosomes is induced by ribosomes and not by poly(U) or messenger RNA (mRNA) (4, 10).

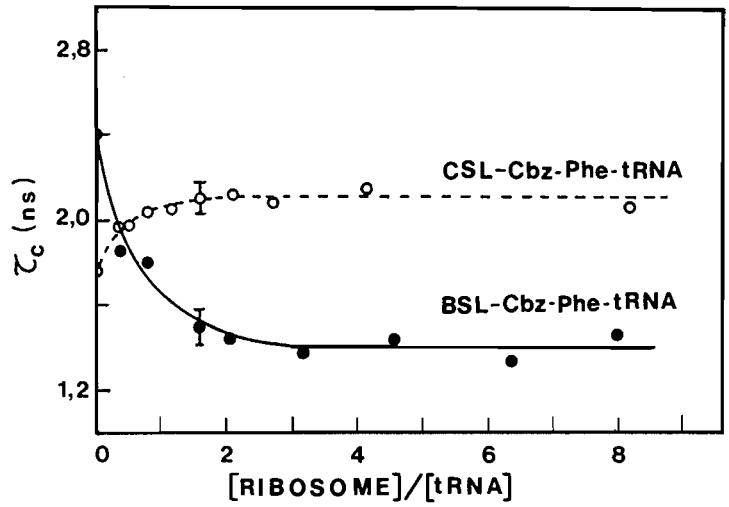

FIG. 7. Variation in the correlation times ($\tau_c$) of spin-labeled Cbz-Phe-tRNA$^{Phe}$ bound to 70S ribosomes in the presence of poly(U), at different ribosome to spin-labeled tRNA ratios. BSL is at position $s^4U_8$ while CSL is in the anticodon region at position $U_{33}$ (10).

In addition, structural changes on the tRNA, at a region remote from the anticodon, could have an important impact on its role in the fidelity of translation of the genetic message.

It is believed that this structural change could be mediated by the binding of tRNA to 5S RNA on the ribosome. For this to happen, some of the intramolecular tertiary hydrogen bonds present between the dihydrouridine and TψCG loops must be broken to allow new intermolecular hydrogen bonds between the TψCG sequence on the tRNA and a complementary Watson–Crick base pair sequence on the 5S RNA. Most of the evidence from the literature suggests that this segment of 5S RNA is located in, or close to, the ribosomal A site (46). This is illustrated in Fig. 8. However, it has been clearly demonstrated that N-blocked aminoacyl-tRNA molecules (spin-labeled derivatives as well) bind primarily to the ribosomal P site (10). Thus the structural loosening in the environment of the $s^4U_8$ residue which has been detected by epr must correspond to a perturbation of the tRNA structure of another kind, different from the one used to bind to 5S RNA.

Different but converging results in this direction came also from the recent work of Farber and Cantor (47). They studied the accessibility of ribosomal 5S RNA within the ribosome by monitoring the slow tritium exchange rates of specific sites with those rates in the free 5S RNA. Most interesting was the finding that the presence of deacylated tRNA$^{Phe}$ bound tightly to the P site of poly(U)-programmed ribosomes did not modify significantly the exchange pattern of 5S RNA.

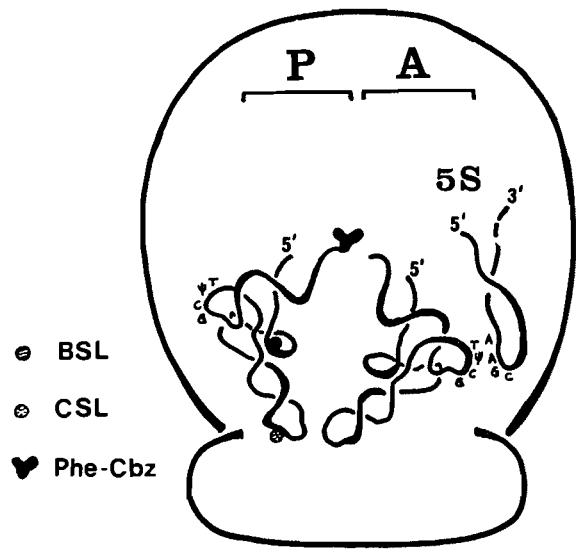

FIG. 8. Hypothetical representation of the binding of two tRNA molecules on the ribosome. Spin-labeled aminoacyl-tRNA$^{Phe}$ is in the peptidyl site (P) and tRNA$^{Phe}$ (or Phe-tRNA$^{Phe}$) is in the aminoacyl site (A). The 3'-end and anticodon regions of each tRNA should be facing each other (22). Part of the ribosomal 5S RNA is also shown in the vicinity of the A site where the fragment CGAA can hydrogen bond to the TψCG loop of the tRNA. The circles on the tRNA structure represent the position of either BSL or CSL.

Consequently, the presence of tRNA in the P site does not seem to induce any ribosomal conformation change to expose the complementary sequence CGAA of 5S RNA in the A site.

Since the epr spectra of uncharged tRNA are not modified by the presence of ribosomes and poly-(U), Rodriguez *et al.* (10) argued that the structural

rearrangement on the tRNA could be mediated by the presence of the amino acid at the 3′-end. In other words, the presence of the amino acid (or the peptidyl group) would facilitate tRNA-ribosome interactions at the P site and such recognition would induce a structural change on the tRNA molecule to maximize these interactions. Earlier findings also converged towards such a rationale where a stereochemically favored disposition of the aminoacyl residue has been shown to increase the affinity of the 3′-end for the ribosome (48, 49). The spin-label method has thus brought another element of proof for this hypothesis.

Probably this modification of the tRNA molecule is due to an interaction between its 3′-end and the 50S subunit since the interaction of BSL-CBz-Phe-tRNA$^{Phe}$ with isolated 30S subunits does not result in an increase in the mobility of the spin label (we have not verified, however, if the 30S subunits were still active).

## Conclusion

Work with spin-labeled ribosomes and spin-labeled tRNA molecules has shown at least one consistency. The binding of tRNA to ribosomes results in a molecular fluctuation in the structure of both molecules. This alteration corresponds, in both cases, to a loosening or opening of their structure. Such a conformational difference in three-dimensional structure between free and bound biological molecules could be a universal consequence of their role, which is molecular adaptation for more efficient function.

## Experimental

The preparation of ribosomes, spin-labeled ribosomes, spin-labeled tRNA, and the binding studies with magnesium ions and antibiotics have been adequately described before (9–14) and will not be repeated here.

*Spin labelling 16S RNA with AMSL*

To 5 μ*M* of 70S ribosomes in 1 mL of buffer C (Tris-HCl 20 m*M*, $Mg(OAc)_2$ 10 m*M*, $NH_4Cl$ 100 m*M*, pH 7.4) was added 1 mL of $NaIO_4$ (2 m*M*) in acetate buffer pH 5.0. After 2 h at 21°C in the dark, the solution was neutralized with sodium acetate 4 *M*, concentrated on a membrane, and washed with carbonate buffer 0.2 *M*, pH 9.5, to eliminate excess $NaIO_4$. Following this, 100 μL of AMSL (120 μ*M*) in carbonate – 10% DMSO buffer was added and the mixture kept at 4°C for 90 min. Then 7.5 μL of $NaBH_4$ (200 m*M*) in carbonate – 10% DMSO buffer was added and after 30 min at 4°C, the reaction mixture was chromatographed on a Sephadex G-25 column (0.6 × 18 cm) equilibrated with buffer C. This chromatography allows the separation of spin-labeled ribosomes from free AMSL.

*Enzymatic spin labelling of 30S subunits*

30S subunits were prepared by differential ultracentrifugation according to Traub *et al.* (50). ADPSL was prepared by the method of Weiner (29) from AMP-morpholidate (Sigma). The labelling via the RNA ligase (P.L. Biochemicals Inc.) was carried out according to England *et al.* (28). The reaction mixture contained 30S subunits (9 μ*M*), ADPSL (136 μ*M*), serumalbumine (10 μg/mL), glycerol 8.3%, $Mg^{2+}$ (20 m*M*), and RNA ligase (200 units/mL). The total volume was 250 μL in Tris-HCl buffer 20 m*M*, pH 7.4, containing $NH_4Cl$ 0.1 *M*, $Mg(OA_c)_2$ 20 m*M*, and β-mercaptoethanol 10 m*M*. After 1 h at 37°C the mixture was chromatographed on a Sephadex G-25 (fine) column (0.7 × 20 cm).

*Preparation of spin-labeled kanamycin*

Kanamycin A sulfate (gift from Bristol Canada) (590 mg) was converted to the free base by chromatography on an anion exchange resin AG 1-X8 ($OH^-$ form) with water and lyophilized. The product was dissolved in $H_2O$–MeOH (1:1), cooled to −5°C, and HSL (35 mg) dissolved in a minimal amount of MeOH was added dropwise. The reaction mixture was kept at 0°C for 6 h, left at room temperature overnight, then lyophilized. The products of the reaction were dissolved in a mixture of $CHCl_3$–MeOH–$NH_4OH$ (2:2:1) containing a few drops of water and chromatographed on a silica gel column (1 × 20 cm). The fractions containing the spin-labeled kanamycin (followed by tlc and detected with Zindzadze reagent) were combined, lyophilized, and passed through a cation exchange resin AG W50-X8 ($NH_4^+$ form) column. After lyophilization 30 mg of crystalline spin-labeled kanamycin was obtained (mp 215°C dec.). A fraction (5 mg) of the product was N,O-permethylated for mass spectrum characterization. The spectral pattern ($M^+$ 848, a *m/e* 169 for the loss of SL and other characteristic *m/e* at 232, 371, 386, 403, 446, 542, 557, 600) is in agreement with the 6′-$NH_2$ position selectively derivatized (51). Spin-labeled kanamycin gave the characteristic 3 lines epr spectrum (Bruker Co.), $a_N$ = 17 G ($H_2O$), $\tau_c$ = 0.29 ns. A spin-concentration determination indicated 0.95 mol of spin label per molecule of kanamycin. The compound was judged adequate for the subsequent binding studies.

*Preparation of spin-labeled puromycin*

A procedure was used similar to that employed for kanamycin. Puromycin $2Cl^-$ (Sigma) was converted to the free base by passage on an anion exchange resin. HSL was dissolved in dioxane and added to a 0.4 *M* $NaHCO_3$–MeOH 20% (pH 8) solution of puromycin. After a few hours at room temperature, the mixture was purified by preparative tlc on silica gel (Merck) using MeOH–$CHCl_3$ (1:9) as eluant to give a crystalline product (mp 230°C); $a_N$ = 17 G ($H_2O$), $\tau_c$ = 0.08 ns. A spin-concentration estimation showed the presence of 0.4 spin label per puromycin molecule. No further purification was needed since only a qualitative epr study with ribosomes was carried out.

## Acknowledgments

The authors would like to express their sincere appreciation to the following diligent co-workers: N. Brisson, G. Tougas, and M. Janssens. We also thank Dr. B. Nayar for the analysis of the mass spectra of the spin-labeled antibiotics. Financial support from the Natural Sciences and Engineering Research Council of Canada and the J. March Foundation (Spain) is acknowledged.

# Methods for preparation of heterobifunctional nitroxides: α,β-unsaturated ketones, β-ketoesters, cyano-nitro-derivatives

H. Olga Hankovszky, Kálmán Hideg, László Lex, Gyula Kulcsár, and H. Anna Halász

*Central Laboratory, Chemistry, University of Pécs, H-7643 Pécs, Hungary*

Received August 10, 1981

H. Olga Hankovszky, Kálmán Hideg, László Lex, Gyula Kulcsár, and H. Anna Halász. Can. J. Chem. **60**, 1432 (1982).

The reactions of 1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-carboxaldehyde (**1**), 1-oxyl-2,2,5,5-tetramethyl-3-cyano-3-pyrroline (**2**), ethyl 1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-carbonyl carbonate (**3**), and *N*-(1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-carbonyl)imidazolide (**4**) are investigated with several nucleophiles (dialkylcadmium, diethyl sodio-malonate, magnesium enolate of ethyl hydrogen malonate, nitromethane-anion) to obtain α,β-unsaturated ketones, β-ketoesters, or conjugated reaction products. Aldehyde **1** is reacted with several methyl ketones (acetylmethylene-triphenylphosphorane, acetophenone, 2-acetylpyridine, 4-phenyl-3-butyn-2-one) to give spin labeled polyenones. The reaction of 4-(1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-yl)-2-buten-2-one (**24***a*) with ethylenediamine gives 7,14-bis-(1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-yl)-5,12-dimethyl-1,4,8,11-tetraazatetradeca-7,14-diene biradical (**25**).

H. Olga Hankovszky, Kálmán Hideg, László Lex, Gyula Kulcsár et H. Anna Halász. Can. J. Chem. **60**, 1432 (1982).

On a étudié les réactions de l'oxyl-1 tétraméthyl-2,2,5,5 pyrroline-3 carboxaldéhyde-3 (**1**), de l'oxyl-1 tétraméthyl-2,2,5,5 cyano-3 pyrroline-3 (**2**), de l'oxyl-1 tétraméthyl-2,2,5,5 pyrroline-3 carbonyl-3 carbonate d'éthyle (**3**) et de la *N*-(oxyl-1 tétraméthyl-2,2,5,5 pyrroline-3 carbonyl-3) imidazolide (**4**) avec plusieurs nucleophiles (dialkylcadmium sodio malonate de diéthyle, énolate magnesien du malonate double d'éthyle et d'hydrogène et anion du nitrométhane) en vue d'obtenir des cétones α,β non saturées, des β-cétoesters ou des produits de réactions conjuguées. L'aldéhyde **1** réagit avec plusieurs méthyl cétones (acétylméthylène-triphénylphosphorane, acétophénone, acétyl-2 pyridine, phényl-4 butyne-3 one-2) pour donner des polyénones avec des spins marqués. La réaction de la (oxyl-1 tétraméthyl-2,2,5,5 pyrroline-3 yl-3)-4 butène-2 one-2 (**24***a*) avec l'éthylènediamine donne le biradical, bis-(oxyl-1 tétraméthyl-2,2,5,5 pyrroline-3 yl-3)-7,14 diméthyl-5,12 tétraaza-1,4,8,11 tétradecadiène-7,14 (**25**).

[Traduit par le journal]

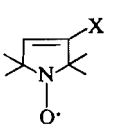
## Introduction

There is a continuing interest in research of novel nitroxide free radicals having reactive functional groups by which they can be coupled to biologically important macromolecules for the study of the internal properties of the spin-labeled biomolecules by esr spectroscopy (1–3). We have published in the previous papers in this series the synthesis and reactions of 1-oxyl-2,2,6,6-tetramethylpiperidine-4-sulfonates with nucleophiles (4), synthesis and reactions of reactive derivatives of 1-oxyl-2,2,5,5-tetramethylpyrroline-3-carboxylic acid (5), nitroxide acylated aminoacids and peptides (6), synthesis of spin-label azidoformate (7), spin-labeled local anesthetics (8), synthesis and reactions with 1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-carboxaldehyde (9), preparation and reaction of a highly reactive allylic sulfonate (or halide) nitroxide (10), and synthesis and reaction of spin-label phosphinimines (11). Very recently as a part of the collaboration between J. F. W. Keana's and our laboratory a joint paper was prepared about the reactions of 3-substituted 1-oxyl-2,2,5,5-tetramethyl-3-pyrroline derivatives, carboxaldehyde, acid, and nitrile, with methyllithium (12). A characteristic of all of these reactions with methyllithium was that the diamagnetic *N*-methoxy derivative was also formed beside the *N*-hydroxy derivative which spontaneously oxidized in air to the corresponding paramagnetic nitroxide derivative.

In the present study we wish to report our attempts to prepare novel spin label nitroxides having two possible reaction centres for biomolecules.

## Results and discussion

For starting compounds the 3-substituted derivatives of 1-oxyl-2,2,5,5-tetramethyl-3-pyrroline were chosen: the aldehyde (**1**), nitrile (**2**), acyl carbonate (**3**), and acyl imidazole (**4**).



**1** X = CHO
**2** X = CN
**3** X = COOCOOEt
**4** X = CO—N

The reactions of aldehyde **1** with alkyllithium to prepare the nitroxide secondary alcohol were accompanied by the formation of *N*-alkoxy alcohol (12). The reaction of aldehyde **1** with methylmagnesium iodide or ethylmagnesium bromide has resulted in essentially the same mixture of secondary alcohols which was oxidized to diamagnetic and paramagnetic ketones (**5**, **6** and **7**, **8**). The reaction

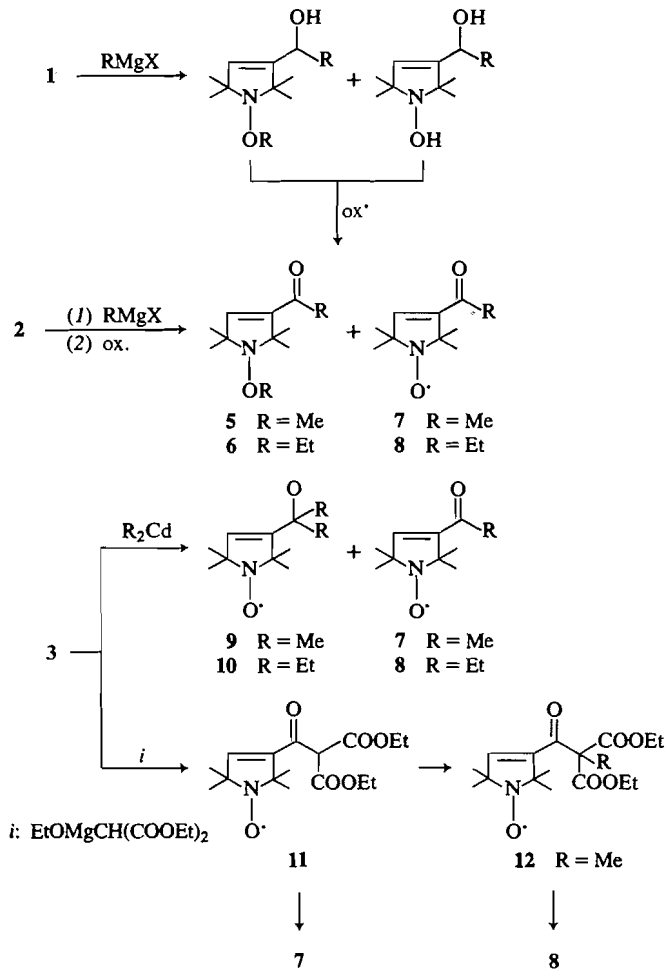

SCHEME 1

of nitrile **2** with ethylmagnesium iodide was even less promising because the dominating product after the oxidations was the diamagnetic ketone (**6**), while the paramagnetic ketone (**8**) was the minor product. Therefore it was necessary to find a reactive derivative of carboxylic acid which exhibits suitable reactivity toward milder organometallic reagents which are inert toward the nitroxide radical. The synthesis of the ketone directly from the reaction of acyl carbonate **3** with methylmagnesium iodide could not be carried out in a reasonable yield. However, the reaction of acyl carbonate **3** with *in situ* formed dialkylcadmium (dimethylcadmium or diethylcadmium) has resulted in a fair yield of the desired ketone (**7** or **8**) without any loss of the radical. In this reaction, as a minor product, the tertiary alcohol (**9** or **10**) was also formed, which could be separated by column chromatography.

Another approach was also successful in obtaining the ketones by an alternative route. The diethyl ethoxymagnesium malonate (13), either with acyl carbonate **3** or acyl imidazole **4**, could be converted in a good yield to the acyl malonate (**11**). The **11** could be alkylated with methyl iodide to **12**. The diethyl acyl malonates (**11** or **12**) could be hydrolysed with dilute acid via the *N*-hydroxy derivative to the corresponding ketone (**7** or **8**).

The reaction of the magnesium enolate of ethyl hydrogen malonate (14) either with acyl carbonate **3** or acyl imidazole **4** with concomitant decarboxylation gave the β-ketoester (**13**) in good yield. Utilization of the well-known reactivity of the β-ketoesters (15) may make this spin-label β-ketoester a very versatile building block in further synthesis starting from β-ketoesters. As an example of this type of reaction **13** was alkylated with dodecyl bromide to α-dodecyl-β-ketoester (**14**). The ester group could be eliminated by hydrolysis

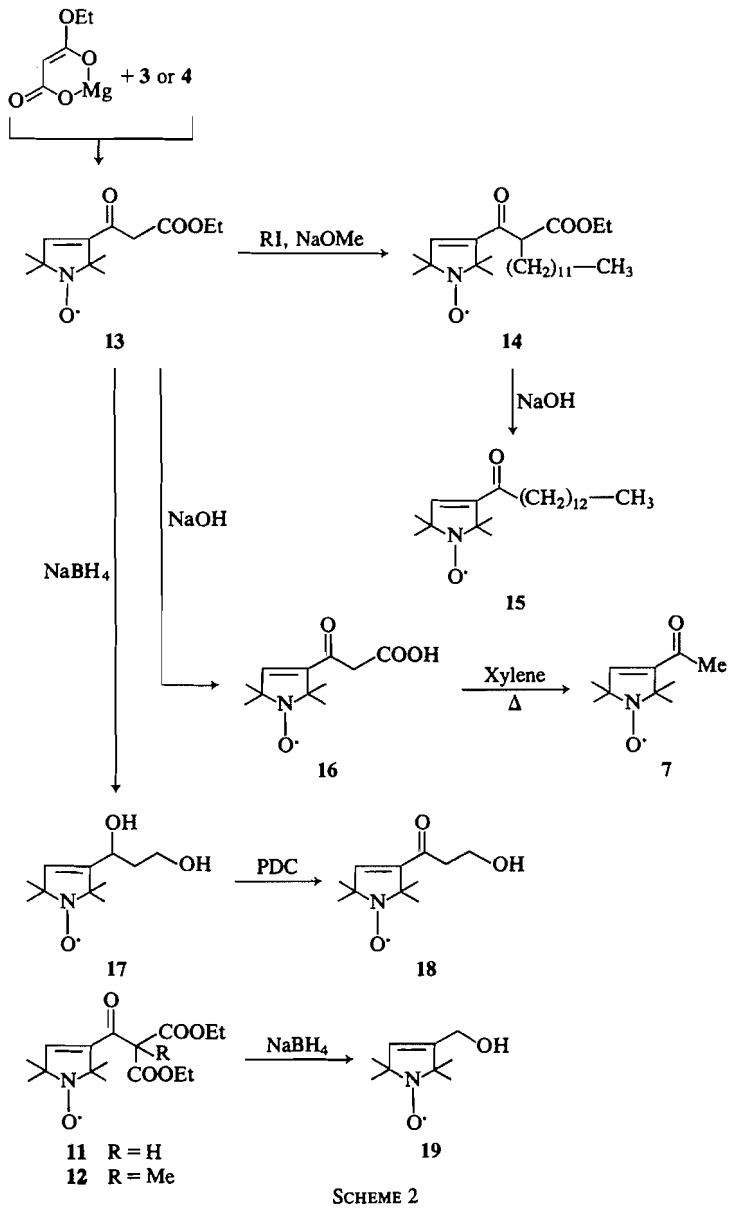

SCHEME 2

with dilute sodium hydroxide to get a long chain alkyl α,β-unsaturated ketone (**15**). However, the preparation of α-unsubstituted β-ketoacid (**16**) was also possible when **13** was hydrolysed with dilute sodium hydroxide. The ketoacid (**16**) could be decarboxylated to **7** when refluxed in xylene. By the reduction of the β-ketoester (**13**) with sodium borohydride the dihydroxy compound **17** could be obtained in a fair yield. Diol **17** could be selectively oxidized at the allylic hydroxy group to a β′-hydroxy-α,β-unsaturated ketone (**18**). It is interesting to note that, in contrast, the reduction of another type of β-ketoester, the diethyl acyl malonates (**11**, **12**), has resulted in the elimination of the malonate and gives the hydroxymethylpyrroline derivative (**19**). By analogy to the recently described reaction of addition of ethyl monomagnesium enolate to the α,β-unsaturated ketones (16), the aldehyde **1** was reacted with ethyl monomagnesium enolate affording the conjugate adduct (**20**) in moderate yield. The 1,2-condensation reaction product diene ester (**21**), which can be separated by column chromatography, was also obtained from the reaction.

A conjugate addition reaction could be carried out on unsaturated nitrile (**2**) with diethyl malonate or with nitromethane (in the presence of base

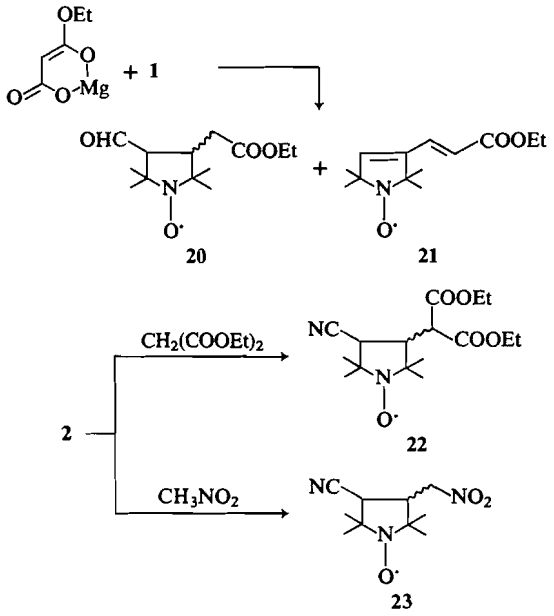
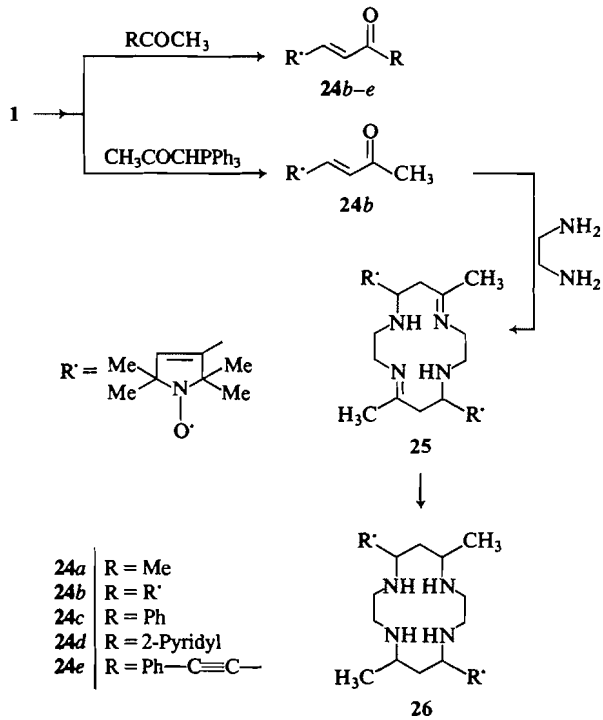


SCHEME 3

catalysts sodium ethoxide or Triton B) to obtain cyanoalkylated diethyl malonate (**22**) and cyanoalkylated nitro spin label (**23**). These molecules may be very versatile synthons in further synthesis.

We also wished to prepare potentially more reactive, novel dienones suitable for nucleophilic addition of thiol or amino groups. While in the aldol type of condensation of unsaturated aldehyde **1** with various methyl ketones (acetophenone, 2-acetylpyridine, or acetylphenylacetylene) polyenones (**24***b–e*) could be obtained in reasonable yield, the methyl dienone (**24***a*) could be obtained only by a Wittig reaction with acetylmethylene-triphenylphosphorane. Utilizing the method for preparation of a 14-membered macrocyclic ligand (17, 18), a 14-membered macrocycle (**25**) can be prepared from **24***a* with ethylenediamine. By the reduction of the azomethine groups with sodium borohydride, the more stable saturated macrocycle (**26**) could be prepared, which may be a useful spin-labeled tetradentate ligand in complex formation reaction.



SCHEME 4

## Experimental

Melting points were measured using a Boetius micro mp-determining instrument and were not corrected. The ir spectra were measured as a neat oil or in Nujol suspensions with a Zeiss Specord 75 type of instrument. The esr spectra were obtained from a $10^{-3}$ *M* solution using a Zeiss ER9 spectrometer. All the monoradicals exhibited three equidistant lines and the biradical showed five equidistant lines with $n_N$ = 14.8–15.0 G. The $^1H$ nmr spectra were recorded on a Perkin–Elmer R12 instrument in $CDCl_3$, using tetramethylsilane as internal standard. The nmr spectra of radicals were taken in a 10% solution of diphenylhydrazine in $CDCl_3$ ($CDCl_3$–DPH). The mass spectra were taken in a Varian-MAT-SM-1 instrument. Solvents were reagent grade and dried prior to use. All organic extracts obtained during the work-up of the reaction mixture were dried over anhydrous magnesium sulfate and distilled off *in vacuo*. For column chromatography silica gel 60, for preparative tlc silica gel F(254 Merck-60 or Whatman PK6F), were used.

*Reactions with organometallic reagents*

(a). *Reaction of aldehyde 1 with alkylmagnesium iodides. Synthesis of 1-oxyl-2,2,5,5-tetramethyl-3-acetyl-3-pyrroline (7) and 1-oxyl-2,2,5,5-tetramethyl-3-ethanoyl-3-pyrroline (8)*

To a stirred solution of the Grignard reagent (prepared from magnesium turnings (0.36 g, 0.15 mol) and methyl iodide (2.1 g, 15 mmol) in dry ether (20 mL)) a solution of unsaturated aldehyde **1** (9) (1.68 g, 10 mmol) in dry ether (20 mL) was added at 0°C under nitrogen and stirred for 3 h. The reaction was quenched with saturated aqueous $NH_4Cl$ (25 mL). The ether phase was separated, dried, and evaporated to dryness. A mixture of manganese(IV) dioxide (15 g) and lead(IV) dioxide (5 g) was added to the stirred solution of remaining pale yellow oil in carbon tetrachloride (50 mL) and refluxed for 6 h. The filtrate was subjected to column chromatography with carbon tetrachloride/ethyl acetate (10:1); two fractions were separated.

The first colorless fraction was the *N*-methoxy derivative **5**: 0.40 g (20%) as a colorless oil. The product was identical with the authentic (12) sample of **5**. The second yellow fraction was the main product **7** (from hexane), 1.01 g (55%), mp 71–72°C (lit. (12) mp 71–72°C).

The ethyl ketone **8** was prepared in the same way from aldehyde **1** (10 mmol) and ethylmagnesium bromide (15 mmol) to give the *N*-ethoxy derivative **6**, 0.70 g (31%) as a colorless oil. Infrared $\nu_{max}$: 1670, 1620 $cm^{-1}$; $^1H$ nmr ($CDCl_3$) δ: 0.9–1.5 (m, 18H), 2.61 (q, 2H), 3.83 (q, 2H), 6.32 (s, 1H). *Anal.* calcd. for $C_{13}H_{23}NO_2$ (mol. wt. 225.3): C 69.30, H 10.29, N 6.22; found: C 69.33, H 10.35, N 6.18.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

The second yellow band was the paramagnetic ethyl ketone **8**, yield 0.82 g (41%), mp 65–66°C; ir $\nu_{max}$: 1670, 1620 $cm^{-1}$. *Anal.* calcd. for $C_{11}H_{18}NO_2$ (mol. wt. 196.3): C 67.32, H 9.24, N 7.14; found: C 67.45, H 8.93, N 7.16.

(b). *Reaction of nitrile (2) with ethylmagnesium bromide*

A solution of nitrile **2** (19) (1.65 g, 10 mmol) in dry ether was added to a freshly prepared solution of ethylmagnesium bromide (20 mmol) in ether under nitrogen at 0°C and stirred for 3 h, then the reaction was quenched with a saturated solution of ammonium chloride (5 mL) and the ether phase separated, dried, and evaporated to dryness. The pale oil was taken up in 5 *M* hydrochloric acid (20 mL) and refluxed for 2 h, then basified (to pH 10) and extracted with ether (3 × 10 mL). The ether solution was stirred with lead(IV) dioxide (3 g) for 3 h, then filtered. The filtrate was evaporated to dryness to give **6**, yield 1.58 g (70%), which was contaminated with only a minimal amount (less than 8%) of paramagnetic ketone **8**.

(c). *Reaction of acyl carbonate with dimethylcadmium: synthesis of 1-oxyl-2,2,5,5-tetramethyl-3-acetyl-3-pyrroline (7) and 2-(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)-propan-2-ol (9)*

The dimethylcadmium (20) was freshly prepared as follows. Anhydrous cadmium chloride (3.6 g, 20 mmol) was added to a freshly prepared solution of Grignard reagent (magnesium turnings (0.96 g, 40 mmol) with methyl iodide (6.25 g, 44 mmol) in dry ether (40 mL)) under nitrogen. A solution of acyl carbonate **3** (5, 21) (5.12 g, 20 mmol) in dry ether (25 mL) was added to the stirred suspension of dimethylcadmium and the mixture was stirred overnight. The reaction was quenched with a saturated solution of $NH_4Cl$, the organic phase was dried and evaporated to dryness. The residual yellow oil was column chromatographed with carbon tetrachloride/ethyl acetate (1:1).

The first yellow band was the ketone (**7**), yield 2.21 g (60%), mp 71–72°C (from hexane). The ketone **7** was identical with an authentic sample of **7** obtained above or as it has been described earlier (12). The second yellow band was the tertiary alcohol **9**, yield 0.32 g, (8%), mp 127–129°C (from chloroform/hexane); ir $\nu_{max}$: 3400–3200 $cm^{-1}$. *Anal.* calcd. for $C_{11}H_{20}NO_2$ (mol. wt. 198.3): C 66.63, H 10.17, N 7.06; found: C 66.79, N 9.98, N 6.96.

(d) *Reaction of acyl carbonate 3 with diethylcadmium: synthesis of 1-oxyl-2,2,5,5-tetramethyl-3-ethanoyl-3-pyrroline (8) and 3-(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)pentan-3-ol (10)*

A solution of acyl carbonate **3** (2.56 g, 10 mmol) in dry ether (10 mL) was added to a solution of diethylcadmium (20) (10 mmol) (prepared from a solution of ethyl magnesium bromide (20 mmol) and dry cadmium chloride (20 mmol) in ether (20 mL)), reacted, and worked up as above for methylketone **7**. The first yellow band obtained from the silica gel column was ethyl ketone **8**, yield 1.00 g (51%), mp 65–66°C (from hexane); it was identical with **8** obtained from the Grignard method above. The second minor yellow band was the tertiary alcohol **10**, yield 0.30 g (13%), mp 117–119°C (from ether/hexane); ir $\nu_{max}$: 3400–3200 $cm^{-1}$. *Anal.* calcd. for $C_{13}N_{24}NO_2$ (mol. wt. 226.3): C 68.98, H 10.69, H 6.19; found: C 69.04, H 10.76, H 6.26.

*Diethyl (1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-carbonyl-malonate (11)*

A solution of acyl carbonate **3** (2.56 g, 10.0 mmol) in dry ether was added slowly to a stirred solution of freshly prepared diethyl ethoxy magnesium malonate (13) (2.28 g, 10.0 mmol) in dry ether (30 mL) under nitrogen. The reaction mixture was kept at room temperature overnight, then saturated $NH_4Cl$ solution (10 mL) was added. The ether phase was separated and washed with dilute (5%) sulphuric acid (20 mL), saturated $NaHCO_3$, water, dried, and evaporated to dryness. The remaining thick yellow oil was practically pure product **11**, yield 2.86 g (87.6%); ir $\nu_{max}$: 1745, 1685, 1620 $cm^{-1}$; $^1H$ nmr ($CDCl_3$–DPH) δ: 1.1–1.5 (m, 18H), 4.2 (q, 4H), 4.90 (s, 1H), 6.36 (s, 1H). *Anal.* calcd. for $C_{16}H_{24}NO_6$ (mol. wt. 326.4): C 58.89, H 7.41, N 4.29; found: C 59.05, H 7.39, N 4.22.

*1-Oxyl-2,2,5,5-tetramethyl-3-acetyl-3-pyrroline (7)*

The acyl malonate (**11**) (3.26 g, 10.0 mmol) was dissolved in a mixture of acetic acid (6 mL), concentrated sulphuric acid (1 mL), and water (4 mL) and refluxed for 4 h. The cooled solution was extracted with ether (3 × 20 mL). The ether phase was worked up as above to give the pure ketone (**7**), yield 1.02 g (55%), mp 71–72°C. The product was identical with an authentic sample of **7**.

*Reaction of 12 to ethyl ketone (8)*

The reaction of alkylated acyl malonate (**12**) with acids under the same condition as above gave **8**, mp 65–66°C, yield 30%.

*Diethyl 2-methyl-2-(1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-carbonyl)malonate (12)*

A solution of sodium ethoxide (1 *M*) (10 mL) in ethanol was added under nitrogen to a stirred solution of acyl malonate **11** (3.26 g, 10.0 mmol) in dry ether (15 mL), followed by a solution of methyl iodide (2.13 g, 15.0 mmol) in dry THF (15 mL), and refluxed for 4 h. To the cooled solution saturated NaCl was added and the organic phase was separated, dried, and evaporated to dryness. The remaining yellow oil was purified on a silica gel column (solvent: hexane/ethyl acetate, 3:1). The first band was the unreacted **11** (0.90 g, 27%), the second band was **12** (1.03 g, 30%), mp 72–73°C (from hexane); ir $\nu_{max}$: 1770, 1730, 1680, 1620 $cm^{-1}$. $^1H$ nmr ($CDCl_3$–DPH) δ: 1.0–1.5 (m, 18H), 1.7 (s, 3H), 4.2 (q, 4H), 6.3 (s, 1H). *Anal.* calcd. for $C_{17}H_{26}NO_6$ (mol. wt. 340.4): C 59.98, H 7.70, N 4.12; found: C 60.05, H 7.72, N 4.22.

*Ethyl 2(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)-2-oxopropionate (13)*

To a freshly prepared and well stirred solution of magnesium monoethyl malonate (14) (2.20 g, 14 mmol) in dry tetrahydrofuran (20 mL) was added dropwise a solution of acyl carbonate **3** (2.56 g, 10.0 mmol) in dry tetrahydrofuran (20 mL) under nitrogen at room temperature and kept overnight. Saturated ammonium chloride solution was added to the reaction mixture and the organic phase separated and washed with dilute (5%) sulphuric acid, saturated sodium chloride, dried, and evaporated to dryness. The residue was a yellow oil contaminated with ethyl 1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-carboxylic acid, therefore it was column chromatographed with carbon tetrachloride. The fast moving band was the contaminating ester (identified by an authentic sample). The second band was the β-ketoester as a thick yellow oil after evaporating from the solvent. Yield 1.28 g (50%); ir $\nu_{max}$: 1720, 1660, 1600 $cm^{-1}$. $^1H$ nmr ($CDCl_3$–DPH) δ: 1.0–1.5 (m, 15H), 3.5 (s, 2H), 4.1 (q, 2H), 6.4 (s, 1H). *Anal.* calcd. for $C_{13}H_{20}NO_4$ (mol. wt. 254.3): C 61.40, H 7.93, N 5.51; found: C 61.35, H 8.02, N 5.62. The ketoester **13** was prepared as above but acylimidazole (**4**) (22, 23), (2.34 g, 10.0 mmol) was used instead of **3**. Yield 1.85 g (73%).

*Ethyl 2-(1-oxyl-2,2,5,5-tetramethyl-3-pyrroline-3-carbonyl)tridecanoic acid (14)*

Sodium methoxide (0.108 g, 2.00 mmol) was added under nitrogen to a solution of **13** (0.508 g, 2.00 mmol) and dodecylbromide (0.498 g, 2.0 mmol) in dry ethanol (10 mL) and refluxed for 8 h. The reaction mixture was diluted with water (20 mL) and extracted with ether (3 × 20 mL). The ether phase was dried and evaporated to dryness. The remaining yellow oil was purified from the unreacted starting compounds on preparative tlc (silica gel Whatman PK6F) with hexane/ethyl acetate (3:1) to give the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

pure **14** as a thick yellow oil, yield 0.690 g (81%); ir $\nu_{max}$: 1735, 1670, 1615 $cm^{-1}$. *Anal.* calcd. for $C_{25}H_{44}NO_4$ (mol. wt. 422.7): C 71.05, H 10.49, N 3.31; found: C 71.12, H 10.53, N 3.36.

*Hydrolysis of **14** to 1-oxyl-2,2,5,5-tetramethyl-3-*n*-tridecyl-3-pyrroline (**15**)*

Sodium hydroxide (10%) (3 mL) was added to a solution of **14** (211.3 mg, 0.5 mmol) in ethanol (3 mL) and allowed to stay at room temperature for two days. The reaction mixture was acidified (to pH 3) with sulfuric acid (5%) and extracted with chloroform (3 × 10 mL). The chloroform phase was evaporated to dryness. The crude oil was purified on preparative tlc with ethyl acetate/hexane (1:1) to give the pure ketone, 132 mg (75%); ir $\nu_{max}$: 1675, 1610 $cm^{-1}$. *Anal.* calcd. for $C_{22}H_{40}NO_2$ (mol. wt. 350.6): C 75.37, H 11.50, N 4.00; found: C 75.31, H 11.43, N 4.12.

*2-(1-Oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)-2-oxopropanoic acid (**16**)*

A solution of **13** (0.254 g, 1.00 mmol) in 2.5 *M* sodium hydroxide (2 mL) was kept at room temperature for 2 h, then extracted with chloroform (3 × 2 mL). The aqueous phase was acidified (pH 3) with dilute sulphuric acid (5%), saturated sodium chloride (10 mL) was added to the solution, and it was extracted again with chloroform (3 × 5 mL). The chloroform solution was dried and evaporated to dryness. The remaining solid was **16**, yield 183 mg (80%). The analytical sample was crystallized from ether/hexane, mp 107–108°C; ir $\nu_{max}$: 1735, 1665, 1615 $cm^{-1}$. *Anal.* calcd. for $C_{11}H_{16}NO_4$ (mol. wt. 226.3): C 58.40, H 7.13, N 6.19; found: C 58.46, H 7.27, N 6.23.

*Decarboxylation of **16** to **7***

A solution of **16** (113 mg, 0.5 mmol) in xylene (5 mL) was boiled for 4 h and evaporated to dryness. The residue was the ketone **7**, yield 47 mg (51%), which was identical with an authentic sample of 7 obtained by an alternative method.

*Reduction of **13** to 1(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)-1,3-dihydroxypropane (**17**)*

Sodium borohydride (756 mg, 20.0 mmol) was added to a solution of **13** (508 mg, 2.0 mmol) in dry ethanol (10 mL) and refluxed for 2 h. The reaction mixture was diluted with saturated sodium chloride solution and extracted with ether (3 × 10 mL). The ether phase was dried and evaporated to dryness. The residue was a thick oil, yield 342 mg (80%), and showed one spot on tlc; ir $\nu_{max}$: 3600–3100 $cm^{-1}$, and no ester bond was present; $^1H$ nmr, δ: 1.0–1.3 (m, 12H) 1.5–2.0 (m, 2H), 3.2–3.6 (m, 2H, 2HO), 3.6–3.9 (m, 2H), 4.0–4.4 (m, 1H, CH); ms, *m/e*: $M^+$ 214 (56), 151 (29), 139 (72), 135 (100).

*Oxidation of diol **17** with pyridinium dichromate (ref. 24) to β-hydroxyketone (**18**)*

The diol (**17**) (428 mg, 2 mmol) was dissolved in methylene chloride (15 mL) and pyridinium dichromate (PDC) (2.78 g, 7.4 mmol) was added to the solution and stirred for 2 h. Then ether (20 mL) was added to the black suspension, which was stirred for one further hour and filtered. The filtrate was evaporated to dryness. The residue was subjected to preparative tlc (Whatman PK6F) with hexane/ethyl acetate (1:3); the intensive yellow band was the β-hydroxy ketone **18**, 300 mg (70%), mp 96–98°C; ir $\nu_{max}$: 3600–3300, 1660, 1610 $cm^{-1}$; ms, *m/e*: $M^+$ 212 (50), 182 (100), 167 (45), 138 (55). *Anal.* calcd. for $C_{11}H_{18}NO_3$ (mol. wt. 212.3): C 62.24, H 8.55, N 6.60; found: C 62.12, H 8.40, N 6.49.

*Reduction of diethyl acyl malonates (**11** or **12**) with sodium borohydride to 1-oxyl-2,2,5,5-tetramethyl-3-hydroxymethyl-3-pyrroline (**19**)*

Sodium borohydride (378.3 mg, 10.0 mmol) was added to a solution of **11** (326.4 mg, 1.0 mmol) in dry ethanol (20 mL) and refluxed for 3 h. The reaction mixture was concentrated *in vacuo*, then the residue was taken up with saturated sodium chloride solution (10 mL) and extracted with chloroform (3 × 10 mL). The chloroform phase was dried and evaporated to dryness. The solid yellow residue was recrystallized from chloroform/hexane to give **19**, yield 140 mg (82%), mp 75–77°C. The **19** was also prepared from **12** (340.4 mg, 1.0 mmol) under the same condition as above, yield 133 mg (78%), mp 75–77°C; ir $\nu_{max}$: 3500–3100 $cm^{-1}$. The above samples of **19** were identical with the authentic sample of **19** (9).

*Ethyl (1-oxyl-4-formyl-2,2,5,5-tetramethylpyrrolidin-3-yl)-acetate (**20**)*

A freshly prepared solution of magnesium monoethyl malonate (14) (2.20 g, 14 mmol) in dry DMF (10 mL) was added under a nitrogen atmosphere to a stirred solution of 1-oxyl-2,2,6,6-tetramethyl-3-pyrroline-3-carboxaldehyde (**1**) (1.68 g, 10 mmol). The reaction mixture was kept at 40°C for three days, then acetic acid (1.6 mL) was added and kept at 80°C for two further days to achieve the decarboxylation. The solution was diluted with water (about 50 mL) and extracted with ether (3 × 20 mL). The ether phase was washed with saturated sodium hydrogen carbonate, saturated sodium chloride, dried, and evaporated to dryness. The remaining yellow oil (1 g) showed 3 spots on tlc (hexane/ethyl acetate (1:1)). The crude oil was subjected to column chromatography with carbon tetrachloride/ether (10:1). The second band proved to be **20**, yield 0.80 g (31%) (yellow oil); ir $\nu_{max}$: 1730, 1680 $cm^{-1}$; ms, *m/e*: $M^+$ 256 (100), $M^+ + 1$ 257(20), 226(27), 211(25), 143(91), 140(28), 111(32), 110(63). *Anal.* calcd. for $C_{13}H_{22}NO_4$ (mol. wt. 256.3): C 60.91, H 8.65, N 5.47; found: C 60.83, H 8.54, N 5.59. The first band was proved to be the unreacted **1** by ir. The third band isolated as yellow crystals was the diene ester, ethyl 3-(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)-2-propenoate (**21**), yield 0.90 g (38%), mp 80–81°C (from hexane), identical with the authentic sample.

*Preparation of authentic **21** by Wittig reaction*

A solution of **1** (168 mg, 1.00 mmol) and (ethoxycarbonyl methylene)triphenylphosphorane (348 mg, 1 mmol) in dry THF was refluxed for 3 h, then evaporated to dryness. The solid residue was dissolved in hot petroleum ether (bp 40–70°C) (3 × 10 mL), then evaporated to a minimal volume and cooled. The yellow crystals were filtered off to give **21**, yield 210 mg (88%), mp 80–81°C (from hexane); ir $\nu_{max}$: 1685, 1620, 1590 $cm^{-1}$. *Anal.* calcd. for $C_{13}H_{20}NO_3$ (mol. wt. 238.3): C 65.52, H 8.46, N 5.88; found: C 65.46, H 8.46, N 5.99.

*Diethyl 2(1-oxyl-4-cyano-2,2,5,5-tetramethylpyrrolidin-3-yl)-malonate (**22**)*

A solution of unsaturated nitrile (**2**) (1.65 g, 10.0 mmol) was added to a solution of diethyl malonate (2.40 g, 15.0 mmol) and sodium ethoxide (1 *M*) (3 mL, 3 mmol) in dry ethanol (10 mL) and refluxed for 16 h. The reaction mixture was diluted with a solution of saturated sodium chloride (20 mL) and extracted with ether (3 × 10 mL). The organic phase was dried and evaporated to dryness. The residual yellow oil (3 g) was subjected to column chromatography on silica gel with chloroform/petroleum ether (bp 40–70°C) (9:11). The first yellow band was the unreacted nitrile (**2**), 0.50 g (30%). The second wide band was a mixture of the two stereoisomers of **22**, yield 1.64 g (50%), mp 86–88°C (from hexane); ir $\nu_{max}$: 2235, 1750, 1710 $cm^{-1}$; $^1H$ nmr δ: 0.5–1.5 (m, 18H), 2.3–2.5 (m, 2H), 3.3–3.5 (m, 1H), 3.9–4.4 (m, 4H). *Anal.* calcd. for $C_{16}H_{25}N_2O_5$ (mol. wt. 325.4): C 59.06, H 7.74, N 8.61; found: C 58.95, H 7.73, N 8.77.

*(1-Oxyl-2,2,5,5-tetramethyl-4-cyanopyrrolidin-3-yl) nitromethane (**23**)*

A solution of unsaturated nitrile (**2**) (1.65 g, 10 mmol) and nitromethane (0.91 g, 15 mmol) in dry THF (20 mL) was refluxed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

in the presence of Triton B catalyst (0.2 mL) for 3 days, then worked up as above for the reaction of **22**. The products were separated on a silica gel column; the first band was unreacted nitrile (**2**) (0.70 g, 42%) and the second one the two nonseparated stereoisomers of **23** (0.70 g, 31%). The stereoisomers were separated on a second column with carbon tetrachloride/ether (6:4); $R_f$ I: 0.50, $R_f$ II: 0.65. Isomer I: 0.50 g (17.6%), mp 69–70°C; ir $\nu_{max}$: 2230, 1550 $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{16}N_3O_3$ (mol. wt. 226.3): C 53.08, H 7.13, N 18.57; found: C 52.98, H 6.96, N 18.43. Isomer II: 0.30 g (13.4%), mp 55–56°C; ir $\nu_{max}$: 2230, 1540 $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{16}N_3O_3$ (mol. wt. 226.3): C 53.08, H 7.13, N 18.57; found: C 53.17, H 7.20, N 18.40.

*4-(1-Oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)-3-buten-2-on (24a)*

A solution of (acetylmethylene)triphenylphosphorane (3.18 g, 10.0 mmol) and unsaturated aldehyde **1** (1.68 g, 10.0 mmol) in dry tetrahydrofuran (30 mL) was refluxed for 16 h, then evaporated to dryness. The remaining semisolid was dissolved in light petroleum ether (bp 40–70°C) (50 mL), then evaporated again. The orange oil was subjected to column chromatography with chloroform/ether (1:1) to give an orange oil, yield 1.31 g (63%); ir $\nu_{max}$: 1670, 1620, 1590 $cm^{-1}$; $^1H$ nmr ($CDCl_3$–DPH) δ: 1.28 (s, 6H), 1.38 (s, 6H) 2.24 (s, 3H), 5.95 (s, 1H), 6.32 (d, 1H, HC=C, $J$ = 16.8 Hz). *Anal.* calcd. for $C_{12}H_{18}NO_2$ (mol. wt. 208.3): C 69.20, H 8.71, N 6.73; found: C 69.19, H 8.69, N 6.71.

*General procedure for Claisen condensation of 1 with methyl ketones*

The equivalent amount (0.5 mmol) of **1** and a methyl ketone were dissolved in aqueous methanol (50%) (5 mL) and sodium hydroxide (3 drops of 10% solution) was added to the reaction mixture and kept at room temperature overnight, then diluted with water (5 × 10 mL) to make the crystallization more complete. The crystals were filtered and the analytical samples were crystallized from ether/hexane.

Compound **24b**: yield 75%, mp 170–171°C; ir $\nu_{max}$: 1650, 1595, 1578 $cm^{-1}$. *Anal.* calcd. for $C_{19}H_{28}N_2O_3$ (mol. wt. 332.4): C 68.65, H 8.49, N 8.43; found: C 68.74, H 8.42, N 8.37.

Compound **24c**: yield 68%, mp 106–107°C; ir $\nu_{max}$: 1660, 1620, 1590 $cm^{-1}$. *Anal.* calcd. for $C_{17}H_{20}NO_2$ (mol. wt. 270.4): C 75.53, H 7.46, N 5.18; found: C 75.44, H 7.36, N 5.10.

Compound **24d**: this derivative was isolated after extraction of the reaction mixture with ether, then chromatographed on preparative tlc with ethyl acetate/hexane (1:1). Yield: 50%, mp 100–101°C; ir $\nu_{max}$: 1660, 1595, 1570 $cm^{-1}$. *Anal.* calcd. for $C_{16}H_{19}N_2O_2$ (mol. wt. 271.3): C 70.83, H 7.06, N 10.32; found: C 70.82, H 6.98, N 10.46.

Compound **24e**: yield 74%, mp 111–112°C; ir $\nu_{max}$: 2205, 1610, 1575 $cm^{-1}$. *Anal.* calcd. for $C_{19}H_{20}NO_2$ (mol. wt. 294.4): C 77.52, H 6.85, N 4.76; found: C 77.44, H 7.00, N 4.96.

*7,14-Bis-(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)-5,12-dimethyl-1,4,8,11-tetraazatetradeca-7,11-diene (25)*

Ethylene diamine (0.72 g, 12.0 mmol) and anhydrous $K_2CO_3$ (1 g) were added to a solution of dienone (**24a**) (2.08 g, 10.0 mmol) in cyclohexane/ether (2:1) (30 mL) and refluxed for 6 h then filtered. The filtrate was evaporated to dryness at 0°C *in vacuo*. The residue was crystallized from ether to give macrocyclic diene **25**, yield 3.75 g (75%), mp 139–140°C; ir $\nu_{max}$: 3270, 1660, 1570 $cm^{-1}$. *Anal.* calcd. for $C_{28}H_{48}N_6O_2$ (mol. wt. 500.7): C 67.16, H 9.67, N 16.78; found: C 67.08, H 9.76, N 16.80.

*7,14-Bis-(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)-5,12-dimethyl-1,4,8,11-tetraazatetradecane (26)*

The diene (**25**) (500 mg, 1 mmol) was added to a suspension of sodium borohydride (76 mg, 2.0 mmol) in dry ethanol (5 mL) and refluxed for 2 h, then diluted with water and extracted with chloroform (3 × 10 mL). The chloroform phase was dried and evaporated to dryness. The solid residue was recrystallized from chloroform/hexane to give **26**, yield 362 mg (72%), mp 200°C; ir $\nu_{max}$: 3240 $cm^{-1}$. *Anal.* calcd. for $C_{28}H_{52}N_6O_2$ (mol. wt. 504.8): C 66.63, H 10.38, N 16.65; found: C 66.70, H 10.22, N 16.55.

JOHN F. W. KEANA, KÁLMÁN HIDEG, G. BRUCE BIRRELL, OLGA H. HANKOVSZKY, GEORGE FERGUSON, and MASOOD PARVEZ. Can. J. Chem. **60**, 1439 (1982).

Several new nitroxide spin labels have been prepared. Nitroxide mesylate **5** and *p*-hydroxyacetophenone gave **6** which was selectively brominated with cupric bromide to give the alkylating agent **7**. The more water soluble phenacyl bromide analogue **17** was prepared either via the route **8** → **11** → **17** or else via the route **15** → **16** → **11** → **17**. Preliminary results indicate that toward aconitase, nitroxide alkylating agent **17** behaves similarly to phenacyl bromide. Several new difunctional nitroxides were prepared with an eye toward application as saturation transfer esr spin labels. Conjugate addition of HCN to **11** gave **18**, condensation of which with *p*-azidobenzaldehyde gave photolabile **19**. Azide **20** could similarly be prepared directly from **11**. Aldehyde **15** underwent condensation with *p*-azidoacetophenone to give azide **21**. This substance was allowed to react with hemoglobin. Upon photolysis the esr spectral mobile component was substantially reduced, suggesting covalent attachment at more than one site. Conjugate addition of HCN to **23** gave a mixture of *cis*, *trans* isomers **24** and **25**; the structure of **25** was established by X-ray crystallographic analysis to be the *trans* isomer. Conjugate addition of ethyl thioglycolate to **15** led to heterocycles **29–34**.

JOHN F. W. KEANA, KÁLMÁN HIDEG, G. BRUCE BIRRELL, OLGA H. HANKOVSZKY, GEORGE FERGUSON et MASOOD PARVEZ. Can. J. Chem. **60**, 1439 (1982).

On a préparé plusieurs nouveaux marqueurs de spin de type nitroxyde. Le mésylate nitroxyde (**5**) et la *p*-hydroxyacétophénone donnent le composé **6** que l'on brome sélectivement avec le bromure cuivrique pour accéder à l'agent alkylant **7**. On prépare le bromure de phénacycle **17** analogue, plus soluble dans l'eau, soit selon la voie **8** → **11** → **17** ou selon la voie **15** → **16** → **11** → **17**. Des études préliminaires indiquent que l'agent alkylant nitroxyde **17** se comporte vis à vis de l'aconitase de façon analogue au bromure de phénacyle. On a préparé plusieurs nouveaux nitroxydes bifonctionnels dans le but de les utiliser comme transfert de saturation dans la rpe des marqueurs de spin. L'addition conjuguée du HCN sur le composé **11** conduit au composé **18** dont la condensation sur le *p*-azidobenzaldéhyde donne le composé photolabile **19**. On peut préparer de la même façon l'acide **20** en partant directement du composé **11**. L'aldéhyde **15**, par condensation sur le *p*-azidoacétophénone, conduit à l'azoture **21**. On a fait réagir ce dernier avec l'hémoglobine. Lors de la photolyse, le spectre rpe du composant mobile est réduit de façon significative, suggérant ainsi une liaison covalente en plusieurs endroits. L'addition conjuguée de HCN sur le composé **23** donne un mélange des isomères *cis* et *trans*, **24** et **25**; on a établi par cristallographie de rayons-X que le composé **25** est l'isomère *trans*. L'addition conjuguée du thioglycolate d'éthyle sur le composé **15** conduit aux hétérocycles **29** à **34**.

[Traduit par le journal]

The nitroxide spin labeling method constitutes a productive approach to the study of biological and other macromolecular systems by electron spin resonance (esr) spectroscopy (1). Central to this method is the availability of an array of functionalized stable nitroxide molecules which may be selectively attached to reactive sites on the molecule to be spin labeled (2). In connection with an ongoing collaborative investigation involving the non-heme iron–sulfur enzyme aconitase (EC 4.2.1.3), we required a series of nitroxide alkylating agents which were similar in reactivity to that of phenacyl bromide (**1**). Phenacyl bromide is known to react stoichiometrically with a single SH group near the active site of aconitase, leading to a loss of enzymatic activity (3). The first objective of this paper is to report the synthesis and some preliminary results with two new nitroxide alkylating agents modeled after phenacyl bromide.

The second objective of this paper is the development of several new hetero- and homodifunctionalized nitroxide spin labels. Difunctional spin

labels have the possibility of becoming rigidly attached to a macromolecule through simultaneous or sequential covalent bonding at more than one site. By essentially confining the motion experienced by such a label to that of the macromolecule itself, molecular motion of the macromolecule in the correlation time range $10^{-7} < \tau < 10^{-3}$ s may be conveniently studied using the relatively new saturation transfer electron paramagnetic resonance (STEPR) method (4, 5). Studies of protein motion in this time range are of considerable current interest owing to its possible functional significance (5, 6). Those relevant difunctional nitroxides already described are relatively few and include nitroxides **2** (7), **3** (8), and **4** (9).

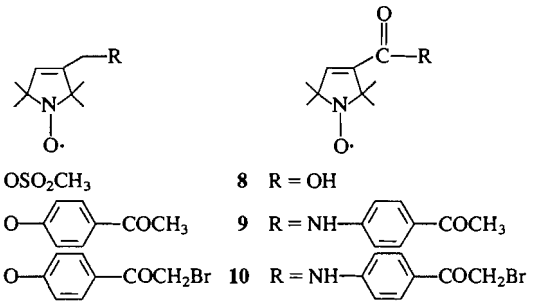
## Results and discussion

Our first objective was to prepare several representative spin labeled phenacyl bromide analogues for subsequent studies with aconitase. Thus, nitroxide mesylate **5** (10) was allowed to react with *p*-hydroxyacetophenone in the presence of sodium hydroxide to give ketone **6** (52%), mp 101–102°C. Selective bromination of **6** was effected with cupric bromide (11), affording nitroxide phenacyl bromide **7** (14%), mp 73–74°C. The low yield of **7** resulted at least partially because of the difficulty in separating (by preparative tlc) the bromo derivative from the starting ketone.

Preliminary experiments with **7** and aconitase[2] were not promising owing to the low aqueous solubility of **7**, even in the presence of tolerable levels of organic cosolvents. For an alternative approach we prepared amide **9** (86%), mp 165–166°C, by reaction of the acid chloride of nitroxide acid **8** with *p*-aminoacetophenone. Unfortunately, initial attempts to prepare bromo derivative **10** led to intractable mixtures of many products.

Success was achieved through the synthesis of nitroxide bromoketone **17**. It was anticipated that the overall shape, solubility, polarity, and chemical reactivity of **17** might better approximate that of phenacyl bromide as compared with **7**. The precursor of **17**, nitroxide ketone **11**, was prepared in two ways. Firstly, nitroxide acid **8** was allowed to react with excess methyllithium (12), affording after air oxidation a readily separable mixture of ketone **11**, mp 71–72°C (18%) and *N*-methoxy derivative **13** (19%) as a colorless oil.

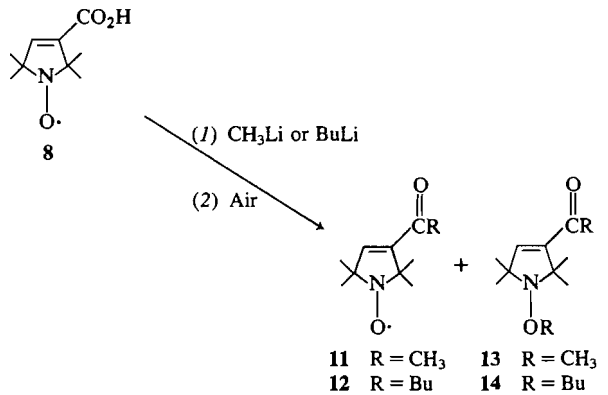


**5** R = $OSO_2CH_3$ **8** R = OH

**6** R = O—$COCH_3$ **9** R = NH—$COCH_3$

**7** R = O—$COCH_2Br$ **10** R = NH—$COCH_2Br$

The successful reaction of a nitroxide carboxylic acid with methyllithium to produce (after reoxidation) a nitroxide methyl ketone is of special interest in view of the known rapid reaction of butyllithium with the nitroxide moiety of 2,2,6,6-tetramethylpiperidine-1-oxyl to give the corresponding N—H, N—OH, and N—OBu derivatives (13). Our results with **8** demonstrate that even though reaction at the nitroxide moiety of **8** does occur with methyllithium, nevertheless through use of excess reagent,



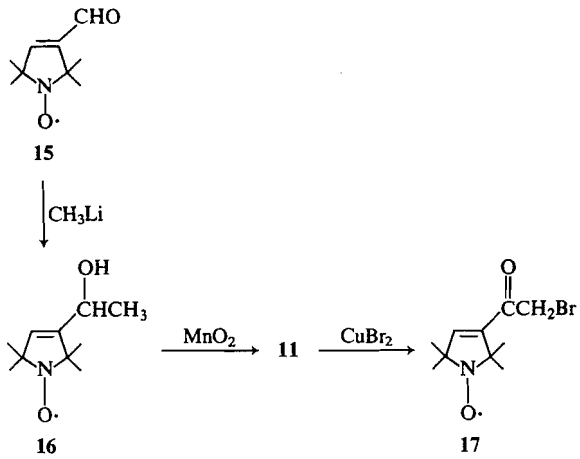
**11** R = $CH_3$ **13** R = $CH_3$

**12** R = Bu **14** R = Bu

the carboxyl group reacts in the expected manner to give the methyl ketone. In order to check the generality of this procedure, acid **8** was allowed to react with excess butyllithium. Useful amounts of the analogous product, nitroxide ketone **12** (oil, 24%), and *N*-butoxy derivative **14** (oil, 23%) were produced after air oxidation of the reaction mixture.

The versatile (see below) intermediate ketone **11** was also prepared by a second method. Reaction of

[2]Prof. H. Beinert, University of Wisconsin, Madison, WI, private communication.

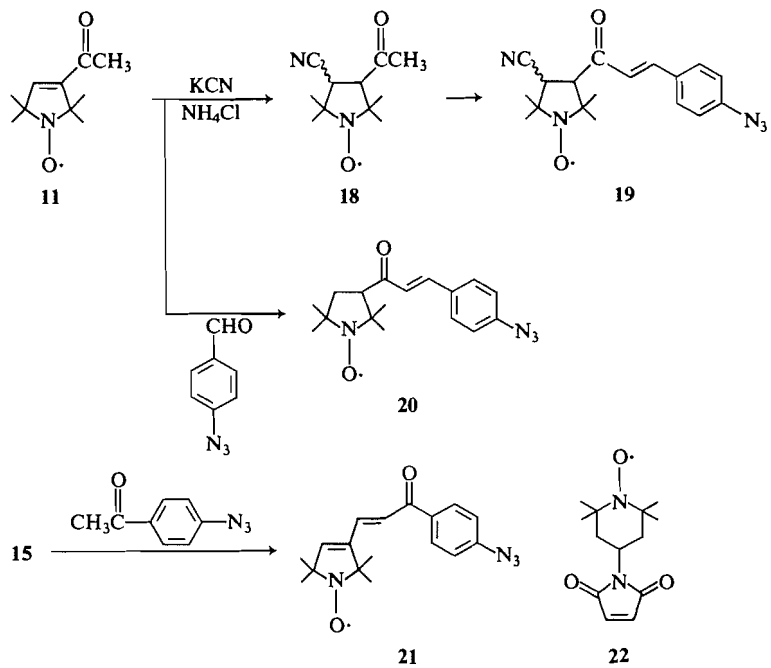


methyllithium with aldehyde **15** (14, 15) gave alcohol **16**, mp 80–81°C (45%). Oxidation of **16** with activated manganese dioxide afforded **11** in 83% yield.

Selective bromination of **11** with cupric bromide proceeded somewhat better than in the case of **6**, affording nitroxide bromoketone **17**, mp 67–69°C, in 25% yield (adjusted for recovered **11**). Preliminary experiments[2] demonstrate that treatment of aconitase with **17** under conditions similar to those employed with phenacyl bromide (3) likewise results in inactivation of the enzyme. These results and associated biophysical studies will be reported in detail later.

We next turned to the synthesis of several difunctional nitroxides while at the same time exploring some of the chemistry of ketone **11**, nitrile **23**, and aldehyde **15** (14, 15). The initial plan was to introduce one of the functions by way of a 1,4-conjugate addition reaction. The reaction of cyanide ion with **11** and **23** was first investigated with the ultimate aim of converting the cyano group into either an activated carbonyl group or else an imidate, for example. Thus, treatment of ketone **11** with potassium cyanide – ammonium chloride – DMF readily afforded the adduct **18** (29%), mp 104–107°C, likely as a mixture of stereoisomers. The adduct smoothly underwent a base-catalyzed condensation reaction with *p*-azidobenzaldehyde, giving phenylazidocyanonitroxide **19**, mp 110–114°C (41%). Alternatively, ketone **11** could be condensed directly with the azidoaldehyde, affording nitroxide **20**, mp 138–141°C (dec.) (47%). Also, aldehyde **15** underwent condensation with *p*-azidoacetophenone to give the α,β,γ,δ-unsaturated ketone **21**, mp 135–136°C (77%).

Nitroxides **19**, **20**, and **21** constitute a potentially versatile series of difunctional spin labels. Each is capable of reacting with a protein SH or $NH_2$ group in a 1,4-conjugate addition reaction analogous to the reaction of maleimide spin label **22** (16) with proteins. While only a single point of covalent attachment to the protein is possible with label **22**, a second point of attachment may be introduced by photolysis of protein adducts of **19**, **20**, and **21**. The reactive phenylnitrene intermediate so generated



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

For personal use only.

should be capable of forming a covalent bond with an adjacent protein residue (or the solvent (17)).

In order to test this approach nitroxide **21** and maleimide label **22** were attached covalently to hemoglobin under identical conditions. The top spectrum in Fig. 1 is a conventional esr spectrum of **21** bound to hemoglobin. The spectrum is dominated by a large bound component, but a small amount of mobile component (indicated by the arrows) is also evident. After photolysis (bottom spectrum of Fig. 1) the mobile component was reduced substantially. The amount of mobile component in the maleimide nitroxide **22**-labeled preparation was comparable to that of **21**-labeled hemoglobin before photolysis. After photolysis, however, the esr spectrum of maleimide **22**-labeled hemoglobin was unchanged.

It is useful to compare the splitting between the low field maximum and the high field minimum ($2A_{max}$) for hemoglobin labeled with the maleimide label **22** and difunctional nitroxide **21** (after photolysis). At 25°C $2A_{max}$ for maleimide-labeled hemoglobin is 66.3 gauss while for hemoglobin labeled with nitroxide **21**, $2A_{max}$ is 69.9 gauss. This difference could result from either polarity differences (a more polar environment would cause $2A_{max}$ to be larger) or from the maleimide label undergoing a small amount of molecular motion independent of that of the protein. By obtaining esr spectra at −196°C where molecular motion is negligible, any differences in $2A_{max}$ should be due to polarity effects alone. The esr spectra recorded at −196°C of hemoglobin labeled with the two spin labels are essentially the same, indicating that differences in polarity are not significant. We conclude, therefore, that differences in $2A_{max}$ in the room temperature esr spectra of these labels covalently bound to hemoglobin are due to nitroxide **21** being more motion-restricted than the maleimide label.

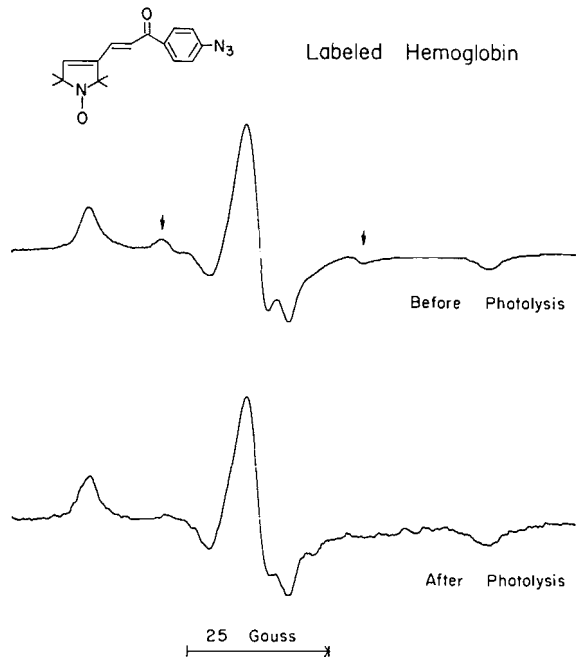

FIG. 1. The 25°C esr spectra of hemoglobin covalently labeled with nitroxide **21** before and after photolysis. The arrows in the top spectrum indicate the mobile component, the relative amount of which is reduced when the preparation is exposed to visible light.

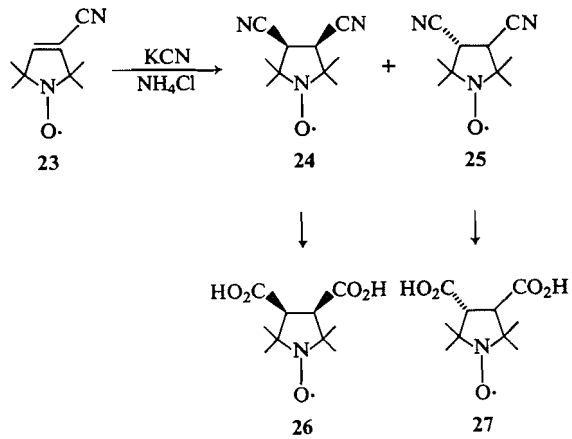
With the 1,4-addition of potassium cyanide to ketone **11** in hand, we next investigated the corresponding reaction with unsaturated nitrile **23**. A separable mixture of *cis* dinitrile **24**, mp 85°C (21%) and *trans* dinitrile **25**, mp 146–147°C (18%) was produced. Vigorous hydrolysis of **24** and **25** with aqueous sodium hydroxide gave acids **26**, mp >250°C, and **27**, mp 220°C, respectively.



Initially, we had planned to establish the stereochemistry of **24** and **25** through formation of the cyclic anhydride from the *cis* acid **26**. Preliminary attempts to form a cyclic anhydride from either isomer using for example, heat, hot acetic anhydride, or dicyclohexylcarbodiimide were not promising. Eventually, we turned to an X-ray crystallographic analysis of the higher melting dinitrile isomer **25** which unambiguously establishes that it has the *trans* configuration (Fig. 2). The crystal structure (Fig. 3) contains discrete molecules separated by normal van der Waals distances. Molecular dimensions are in Table 1. The N—O distance, 1.269(4) Å, is within the usual range for unconjugated radicals (18) and other distances (N—C$sp^3$ 1.476 and 1.484(4), C$sp^3$—C$sp^3$ 1.503–1.555(4), C$sp^3$—C(N) 1.468 and 1.488(5), C≡N 1.104 and 1.109(4) Å) are unexceptional. The five membered ring adopts a slightly distorted envelope conforma-

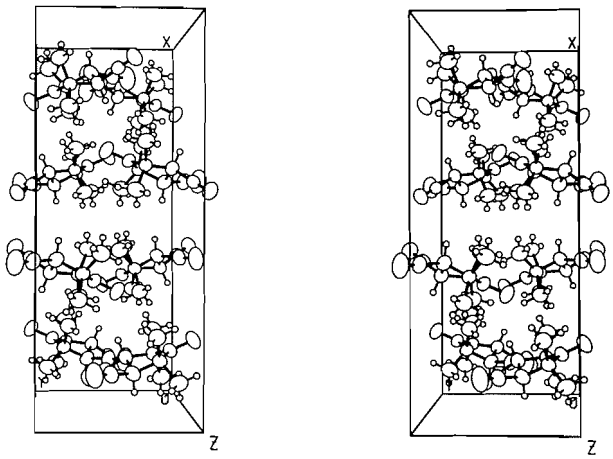

FIG. 3. Stereoview of the crystal structure of **25**.

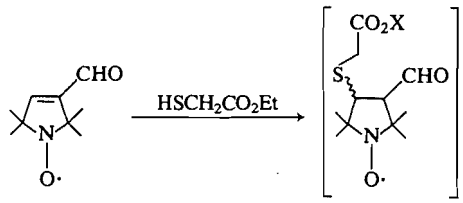
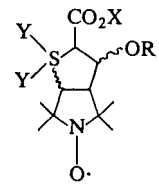
tion with C(3) (see Fig. 2 for crystallographic numbering scheme) at the flap.

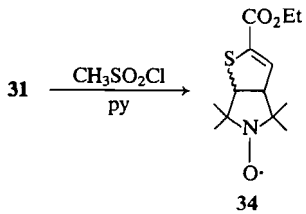
The 1,4-conjugate addition of sulfur reagents to nitroxide acceptors was particularly interesting owing to the generally excellent nucleophilicity of sulfur and also the presence of free reactive sulfhydryl groups on many proteins. Preliminary model experiments involving the addition of sodium phenylsulfinate to aldehyde **15** were not encouraging. Reaction of **15** with ethyl thioglycolate, however, led to the sulfur heterocycle **29**, mp 86–88°C (49%) (mixture of stereoisomers), likely through the intermediacy of adduct **28**. Preparative tlc of **29** followed by two recrystallizations of one of the bands gave a single pure isomer, mp 138–139°C.

Several other heterocycles were prepared from the stereoisomeric mixture **29**. Acetylation of **29** gave acetate **31**, mp 126–127°C (82%), while hydrogen peroxide oxidation of **29** gave sulfone **32**, mp





**29** R = H; X = Et; Y = :
**30** R = H; X = Me; Y = :
**31** R = Ac; X = Et; Y = :
**32** R = H; X = Et; Y = O
**33** R = X = H; Y = :



156–157°C (63%). Reaction of **29** with methanesulfonyl chloride in pyridine gave olefin **34**, mp 113–116°C, (74%) as the major product, confirming the β-hydroxyester formulation for **29**. Reaction of **15** with methyl thioglycolate gave ester **30**, mp 136–137°C (44%), hydrolysis of which led to the acid **33**, mp 212–213°C (81%).

## Experimental

Infrared spectra were recorded with either a Beckman IR-5 or IR-7 spectrometer. The nmr spectra were recorded on a Varian XL-100 high resolution spectrometer in $CDCl_3$ and only the characteristic peaks are reported. Chemical shifts are reported in parts per million (δ) downfield from internal $Me_4Si$; mass spectra (70 eV) (*m/e*) were determined on a CEC 110-2B double-focusing mass spectrometer equipped with a direct inlet. Elemental analyses were performed at the University of Oregon by Dr. R. Wielesek. Ultraviolet spectra were determined on a Cary 15 uv spectrometer. Silica gel column chromatography was done with Baker 60-200 mesh silica gel. Preparative thin layer chromatography (tlc) was done on either Analtech 1000 μ silica gel GF 254 or Whatman PKF6 plates. Melting points were recorded on a Thomas–Hoover apparatus. Solvents were routinely distilled.

*1-Oxyl-2,2,5,5-tetramethyl-3-(4-acetylphenoxymethyl)pyrroline (6)*

To a stirred solution of 4-hydroxyacetophenone (150 mg, 1.10 mmol) and nitroxide mesylate **5** (10) (248 mg, 1.00 mmol) in MeOH (5 mL) was added a solution of $Na_2CO_3$ (100 mg) in water

(3 mL). After a 3 h stir at 25°C, the precipitated product was collected and washed with water, affording 150 mg (52%) of nitroxide **6** as long yellow needles. Recrystallization from MeOH/water afforded the analytical specimen, mp 101–102°C; esr ($CHCl_3$) 3 lines ($a_n$ = 15.0 G); ir (Nujol): 1690 and 1610 $cm^{-1}$. *Anal.* calcd. for $C_{17}H_{22}NO_3$: C 70.80, H 7.69, N 4.86; found: C 70.91, H 7.76, N 4.84.

*1-Oxyl-2,2,5,5-tetramethyl-3-(4-bromoacetylphenoxymethyl)-pyrroline (7)*

To a well stirred solution of ketone **6** (86 mg, 0.30 mmol) in ethyl acetate/$CHCl_3$ (dry) (1:1) (20 mL) was added $CuBr_2$ (134 mg, 0.600 mmol). The mixture was refluxed for 5 h and then filtered. The filtrate was treated briefly with activated charcoal, filtered, and evaporated to dryness. Preparative tlc (Whatman) (ethyl acetate/hexanes (1:1)) gave two major bands which were eluted with ethyl acetate: $R_f$ 0.56 amounted to 45 mg (52%) of unreacted ketone **2**: $R_f$ 0.65 amounted to 15 mg (14%) of desired crystalline **7**. Recrystallization from ether/hexanes gave the analytical specimen, mp 73–74°C; esr ($CHCl_3$) 3 lines ($a_n$ = 15.0 G); ms *m/e*: 368 (8), 366.070 (10) (calcd. for $C_{17}H_{21}NO_3Br$, 366.071), 288 (14), 168 (32), 149 (55), 138 (90), 123 (100), 122 (40), 107 (40).

*1-Oxyl-2,2,5,5-tetramethylpyrroline-3-(N′-p-acetylphenyl)-carboxamide (9)*

To a stirred solution of 1-oxyl-2,2,5,5-tetramethyl-3-carboxypyrroline (**8**) (3.68 g, 20.0 mmol) in benzene (20 mL) and dry pyridine (5 mL) at 0°C was added dropwise a solution of thionyl chloride 3.0 g (0.025 mmol) in benzene (10 mL). After 30 min a solution of 4-aminoacetophenone (2.7 g, 20 mmol) in benzene (50 mL) was added dropwise and the resulting solution was refluxed for 1 h. The cooled reaction mixture was extracted with 1 *N* HCl followed by 10% aqueous $K_2CO_3$ and water. Concentration of the dried ($Na_2SO_4$) benzene layer gave a yellow oil which was triturated in ether. The resulting solid was filtered, affording 5.2 g (86%) of crude **9** suitable for further reactions. Recrystallization of a portion from $CHCl_3$/hexanes afforded the analytical specimen, mp 165–166°C; ir (Nujol): 3125, 1670, and 1590 $cm^{-1}$. *Anal.* calcd. for $C_{17}H_{21}N_2O_3$: C 67.75, H 7.02, N 9.30; found: C 67.54, H 7.27, N 9.28.

*1-Oxyl-2,2,5,5-tetramethyl-3-acetylpyrroline (11) and 1-methoxy-2,2,5,5-tetramethyl-3-acetylpyrroline (13)*

To a stirred suspension ($N_2$) of acid **8** (552 mg, 3.00 mmol) in ether (10 mL) was added dropwise 5.0 mL (7.5 mmol) of a 1.5 *M* solution of MeLi in ether at a rate such that a gentle reflux was maintained. After addition was complete, the mixture was quenched by dropwise addition of saturated aqueous $NH_4Cl$. The mixture was diluted with brine and extracted with ether. The almost colorless ether phase was dried ($Na_2SO_4$) and concentrated, affording a pale yellow oil. In order to facilitate the oxidation of the *N*-hydroxy intermediate, the oil was dissolved in $CHCl_3$ (15 mL) and vigorously stirred under air for 12 h. Evaporation of the solvent gave 310 mg of a viscous yellow oil which was subjected to preparative tlc (Analtech) (ethyl acetate/hexanes (1:1)). The band at $R_f$ 0.93 was *N*-methoxy ketone **13**, obtained as a colorless oil; 110 mg (19%); ir (film): 1675 and 1622 $cm^{-1}$; nmr δ: 1.30 (s, 6), 1.38 (s, 6), 2.30 (s, 3), 3.72 (s, 3), 6.42 (s, 1); ms *m/e*: 197.142 (11) (calcd. for $C_{11}H_{19}NO_2$, 197.142), 196 (19), 182 (72), 136 (100), 105 (20).

The band at $R_f$ 0.75 afforded nitroxide **11** as yellow needles (98 mg, 18%) from hexanes, mp 71–72°C; esr ($CHCl_3$) 3 lines ($a_n$ = 14.8 G); ir (Nujol): 1675 and 1620 $cm^{-1}$; ms *m/e*: 183 (6), 182.118 (28) (calcd. for $C_{10}H_{16}NO_2$, 182.118), 152 (53), 138 (11), 137 (100), 126 (16), 110 (16), 109 (53). *Anal.* calcd. for $C_{10}H_{16}NO_2$: C 65.90, H 8.85, N 7.69; found: C 65.82, H 8.90, N 7.73.

*1-Oxyl-2,2,5,5-tetramethyl-3-butanoylpyrroline (12) and 1-butoxy-2,2,5,5-tetramethyl-3-butanoylpyrroline (14)*

Preparation of **12** and **14** was similar to that of **11** and **13**. From acid **8** (184 mg, 1.00 mmol) and 3.0 mL (4.8 mmol) of 1.6 *M* butyllithium in hexane, there was obtained after preparative tlc 65 mg (23%) of oily *N*-butoxy ketone **14** ($R_f$ 0.95; ir (film): 1675 and 1623 $cm^{-1}$; nmr δ: 2.63 (t, 2), 3.86 (t, 2), 6.20 (s, 1); ms *m/e*: 282 (10), 281.237 (36) (calcd. for $C_{17}H_{31}NO_2$, 281.235), 267 (28), 266 (100), 210 (30), 182 (57), 126 (15), 109 (12)) and 53 mg (24%) of yellow oily nitroxide **12** ($R_f$ 0.73; esr ($CHCl_3$) 3 lines ($a_n$ = 14.8

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

G); ir (film): 1675 and 1620 $cm^{-1}$; ms *m/e*: 226 (25), 225 (29), 224.165 (59) (calcd. for $C_{13}H_{22}NO_2$, 224.165), 210 (61), 194 (59), 179 (25), 137 (100), 126 (32), 110 (33), 109 (79)). The pale yellow aqueous phase from the original work-up of this reaction was acidified (pH 3) and extracted with $CHCl_3$. From the extract there was obtained 25 mg (14%) of the starting acid **8**.

*1-Oxyl-2,2,5,5-tetramethyl-3-(1-hydroxyethyl)pyrroline (16)*

To a stirred solution of nitroxide aldehyde **15** (14, 15) (505 mg, 3.00 mmol) in dry ether (15 mL) at 25°C was added dropwise 4.0 mL (3.9 mmol) of a 1.3 *M* solution of MeLi in ether. After 30 min the reaction was quenched by addition of saturated aqueous $NH_4Cl$ (1 mL) followed by brine (20 mL). The mixture was extracted with ether. The extract was dried ($Na_2SO_4$) and concentrated. The pale yellow residue was dissolved in $CHCl_3$ (20 mL) and stirred under air for 12 h (solution now deep yellow). The solvent was evaporated and the residue was crystallized from ether–hexane (0°C), affording 250 mg (45%) of crystalline **16**, suitable for further reactions. Recrystallization from $CHCl_3$/hexanes afforded the analytical specimen, mp 80–81°C; ir (Nujol): 3400 $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{18}NO_2$: C 65.18, H 9.85, N 7.60; found: C 64.70, H 9.80, N 7.68.

The mother liquors were combined, evaporated, and the residue was dissolved in $CHCl_3$ (30 mL). Active $MnO_2$ (3 g) was added to the stirred solution and the mixture was refluxed for 3 h and then filtered. The filtrate was concentrated and then subjected to preparative tlc (Analtech) (ethyl acetate/hexanes, 1:1). There was obtained 120 mg (20%) of *N*-methoxy ketone **13** and 30 mg (6%) of nitroxide ketone **11**.

Alternatively, pure nitroxide alcohol **16** (46 mg, 0.25 mmol) was dissolved in $CHCl_3$ (10 mL) and treated with active $MnO_2$ (0.5 g). The mixture was stirred under reflux for 3 h (monitored by tlc) and filtered. The filtrate was subjected to preparative tlc, affording 38 mg (83%) of ketone **11**, mp 71–72°C.

*1-Oxyl-2,2,5,5-tetramethyl-3-(bromoacetyl)pyrroline (18)*

To a stirred solution of ketone **11** (91 mg, 0.50 mmol) in ethyl acetate/$CHCl_3$ (20 mL) (1:1) was added powdered $CuBr_2$ (223 mg, 1.00 mmol). The mixture was refluxed for 7 h after which period the black $CuBr_2$ was nearly completely replaced by a white precipitate of CuBr. The green supernatant was treated with activated charcoal and filtered. The filtrate was evaporated to dryness and the residue was subjected to preparative tlc (Whatman), giving two major bands which were eluted with ethyl acetate: $R_f$ 0.43 amounted to 35 mg (38%) of unreacted ketone **11**. $R_f$ 0.55 amounted to 20 mg (15%) of desired bromo ketone **17**, mp 67–69°C; esr ($CHCl_3$) 3 lines, $a_n$ = 14.7 G; ms *m/e*: 262 (32), 260.029 (32) (calcd. for $C_{10}H_{15}BrNO_2$, 260.029), 152 (24), 151 (100), 137 (38), 110 (24), 109 (67).

*1-Oxyl-2,2,5,5-tetramethyl-3-acetyl-4-cyanopyrroline (18)*

A mixture of ketone **11** (91 mg, 0.50 mmol) KCN (65 mg, 1.0 mmol), and $NH_4Cl$ (59 mg, 1.1 mmol) was dissolved in water–ethanol (10 mL, 8:2) and refluxed for 2 days. Brine (20 mL) was added and the mixture was extracted with ether. The extract was dried ($Na_2SO_4$), evaporated, and the residue was subjected to preparative tlc (Analtech) ($CHCl_3$/ether, 1:1). Starting ketone **11** (15 mg, 16%) was recovered from the upper band. The lower band afforded 30 mg (29%) of adduct **18**, likely as a mixture of stereoisomers, mp 104–107°C; ir ($CHCl_3$): 2230 and 1720 $cm^{-1}$; ms *m/e*: 210 (7), 209.128 (26) (calcd. for $C_{11}H_{17}N_2O_2$, 209.129), 195 (16), 179 (45), 135 (22), 110 (100). *Anal.* calcd. for $C_{11}H_{17}N_2O_2$: C 63.13, H 8.19, N 13.39; found: C 62.51, H 8.64, N 13.15.

*1-Oxyl-2,2,5,5-tetramethyl-3-(4-azidocinnamoyl)pyrroline (20)*

To a stirred solution of ketone **11** (109 mg, 0.600 mmol) in MeOH (3 mL) (protected from light) was added aqueous NaOH (0.3 mL, 1 *N*), followed by a solution of 4-azidobenzaldehyde (97 mg, 0.66 mmol) in MeOH (1 mL). During the addition the color became deep orange. Afte 2 h the precipitated yellow crystals were collected, washed with MeOH–water, and dried in the dark, affording 87 mg (47%) of azide **20**, mp 138–141°C (dec.); ir (Nujol): 2100 and 1655 $cm^{-1}$; ms *m/e*: 312 (46), 311.150 (100) (calcd. for $C_{17}H_{19}N_4O_2$, 311.151), 297 (62), 253 (56), 238 (50), 210 (27), 146 (62), 144 (81), 125 (56), 116 (100), 109 (42), 108 (30), 106 (42).

*1-Oxyl-2,2,5,5-tetramethyl-3-(4-azidocinnamoyl)-4-cyanopyrroline (19)*

The above procedure was followed. From cyano ketone **18** (52 mg, 0.25 mmol) and 4-azidobenzaldehyde (37 mg, 0.25 mmol) there was obtained 35 mg (41%) of yellow crystalline **19**, mp 110–114°C (dec.); ir (Nujol): 2245, 2210, 1685, 1655, and 1595 $cm^{-1}$; ms *m/e*: 339 (11), 338.161 (19) (calcd. for $C_{18}H_{20}N_5O_2$, 338.162), 172 (26), 146 (35), 145 (21), 144 (100), 116 (58), 110 (22).

*1-Oxyl-2,2,5,5-tetramethyl-3-(2-(4-azidobenzoyl)ethenyl)-pyrroline (21)*

To a stirred solution of aldehyde **15** (16.8 mg, 0.100 mmol) in MeOH (1.0 mL) (protected from light) was added a solution of 4-azidoacetophenone (16.1 mg, 0.100 mmol) in MeOH (3.0 mL) followed by 1.0 *N* NaOH (0.1 mL). After a 3 h stirring period at 25°C the precipitated yellow crystalline plates were collected and washed with aqueous MeOH, affording 24 mg (77%) of crystalline ketone **21**, mp 125–129°C. Recrystallization from aqueous MeOH afforded the analytical specimen: mp 135–136°C; esr ($CHCl_3$) 3 lines ($a_n$ = 14.7 G); ir (Nujol): 2120, 1665, and 1610 $cm^{-1}$; ms *m/e*: 312 (36), 311.151 (100) (calcd. for $C_{17}H_{19}N_4O_2$, 311.151), 297 (23), 283 (14), 269 (22), 253 (26), 238 (43), 225 (48), 212 (40), 210 (28), 182 (14), 135 (20), 120 (41), 105 (18). *Anal.* calcd. for $C_{17}H_{18}N_4O_2$: C 65.57, H 6.15, N 18.00; found: C 65.62, H 6.23, N 17.98.

*1-Oxyl-2,2,5,5-tetramethyl-3,4-dicyanopyrrolidine* cis, trans *isomers (24 and 25)*

A mixture of nitrile **23** (165 mg, 1.00 mmol), KCN (130 mg, 2.00 mmol), and $NH_4Cl$ (107 mg, 2.00 mmol) was dissolved in DMF (3 mL)/water (30 mL), heated at 70°C for 3 h, and then set aside at 25°C for 48 h. Brine (15 mL) was added and the mixture was extracted with ether. The extract was dried ($Na_2SO_4$) and evaporated to dryness. Preparative tlc (Analtech) of the residue gave three major bands ($CHCl_3$/ether, 1:1): $R_f$ 0.80 amounted to 43 mg (26%) of starting **23**. $R_f$ 0.63 amounted to 35 mg (18%) of yellow crystalline *trans* dinitrile isomer **25**, mp 146–147°C ($CHCl_3$/hexane); ir (Nujol): 2220 $cm^{-1}$; ms *m/e*: 193 (11), 192.113 (59) (calcd. for $C_{10}H_{14}N_3O$, 192.114), 179 (4), 178 (35), 177 (31), 163 (6), 162 (46), 83 (11), 82 (100), 81 (73). *Anal.* calcd. for $C_{10}H_{14}N_3O$: C 62.48, H 7.34, N 21.86; found: C 61.82, H 7.37, N 21.36. $R_f$ 0.37 amounted to 40 mg (21%) of the *cis* isomer **24** which slowly crystallized, mp 85°C; ir (film): 2220 $cm^{-1}$; ms *m/e*: 193 (3), 192.113 (15) (calcd. for $C_{10}H_{14}N_3O$, 192.114), 178 (18), 162 (16), 85 (28), 83 (100), 82 (19). *Anal.* found: C 62.1, H 6.9, N 21.0.

*X-ray analysis of 25*

Crystal data:

$C_{10}H_{14}N_3O$ f.w. = 192.1

Orthorhombic, $a$ = 19.155(2), $b$ = 7.634(1), $c$ = 15.059(3) Å, $U$ = 2202.1 Å$^3$, $Z$ = 8, $D_c$ = 1.16, $F(000)$ = 824, $MoK_\alpha(\lambda = 0.71069$ Å), $\mu$ = 0.5 $cm^{-1}$, space group $Pbcn$ ($D_{2h}^{14}$) from the systematic absences $hk0$, $k = 2n + 1$; $h0l$, $h + l = 2n + 1$.

A small crystal of dimensions 0.40 × 0.33 × 0.13 mm was used in the analysis. Unit cell contstants and intensity data were determined using an Enraf–Nonius computer-controlled CAD-4 diffractometer. For the cell dimension determination, the setting angles of 25 reflexions with θ near 15° were used in a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

least-squares refinement. During data collection three well separated reflections were monitored at regular intervals and showed no reduction in intensity. The intensities of 1930 reflections with $2 < \theta < 25°$ were measured by the $\theta/2\theta$ scan technique. The 1068 reflections with $I > 3\sigma(I)$ were labelled "observed" and used, after correction for Lorentz and polarization factors, in the determination and refinement of the structure.

The structure was determined by direct methods using the SHELX program (19). The first $E$-map calculated with $E$'s > 1.2 revealed all 14 non-hydrogen atoms. Four cycles of full-matrix isotropic refinement reduced $R$ to 0.14 and a subsequent difference map revealed positions for all 14 protons. These were then allowed for in idealized positions (C—H 0.95 Å) and only an overall isotropic temperature factor was refined for protons in subsequent refinement. After six further rounds of full-matrix calculations, with the non-hydrogen atoms allowed anisotropic motion, the refinement was completely converged with $R = 0.058$ and $R' = \Sigma w\Delta^2/\Sigma wF_0^2 = 0.074$. In the refinement cycles, weights were derived from the counting statistics, $w = 1/(\sigma^2 F + 0.005F^2)$, and scattering factors were taken from refs. 20 and 21. A final difference map was free of any significant features. Final atomic coordinates are given in Table 2. The measured and calculated structure factors and thermal parameters have been placed in the Depository of Unpublished Data.[3]

trans-*1-Oxyl-2,2,5,5-tetramethyl-3,4-dicarboxypyrrolidine (27)*

A solution of **25** (10 mg, 0.52 mmol) and 2 *N* aqueous NaOH (0.62 mL, 1.2 mmol) was heated at 90°C until evolution of $NH_3$ (22) ceased (34 h). The solution was cooled, carefully neutralized to pH 4 by addition of 6 *N* HCl, and extracted with ether. Evaporation of the extract afforded 2.8 mg of crude partially hydrolyzed nitroxide which still contained cyano absorption in the ir spectrum. The original aqueous phase was further acidified to pH 2 and again extracted with ether. The extract was dried ($Na_2SO_4$) and evaporated. The residue was recrystallized from ether–hexane, affording 7.3 mg (61%) of **27**, mp 220°C; ms *m/e*: 230.102 (70) (calcd. for $C_{10}H_{16}NO_5$, 230.103), 216 (23), 197 (20), 170 (18), 169 (30), 154 (25), 110 (22), 109 (25), 101 (95), 100 (65), 83 (100), 82 (60).

*cis-1-Oxyl-2,2,5,5-tetramethyl-3,4-dicarboxypyrrolidine (26)*

The *cis* dinitrile isomer **24** (27 mg) was hydrolyzed as in the previous experiment, affording 18 mg (56%) of diacid **26** as a yellow powder, mp >250°C; ms *m/e*: 231 (15), 230.104 (50) (calcd. for $C_{10}H_{16}NO_5$, 230.103), 216 (45), 197 (14), 170 (30), 169 (23), 154 (21), 110 (24), 109 (21), 101 (79), 100 (49), 83 (100), 82 (57).

*2-Carboethoxy-3-hydroxy-4,4,6,6-tetramethyl-2,3,3a,4,6,6a-hexahydrothieno[2,3-c]pyrrole-5-oxyl (29)*

Ethyl thioglycolate (120 mg, 1.00 mmol) was added to a solution of aldehyde **15** (168 mg, 1.00 mmol) in MeOH (5 mL) containing diethylamine (14.6 mg, 0.200 mmol). After a 24 h reflux period, the solution was concentrated and subjected to preparative tlc (Analtech) (ethyl acetate/hexanes, 1:1). The $R_f$ 0.64 band amounted to 35 mg (21%) of starting aldehyde **15**. Two very close lower bands, $R_f$ 0.54, were collected together, affording 140 mg (49%) of the title compound, likely as a mixture of stereoisomers, mp 86–88°C; ir (Nujol): 3550–3250 and 1740 $cm^{-1}$; ms *m/e*: 290 (2), 289 (8), 288.128 (31) (calcd. for $C_{13}H_{22}NO_4S$, 288.127), 215 (16), 174 (59), 143 (4), 142 (13), 141 (100), 110 (75), 101 (52). *Anal.* calcd. for $C_{13}H_{22}NO_4S$: C 54.14, H 7.69, N 4.85; found: C 53.94, H 7.56, N 5.35. Repeated preparative tlc followed by two crystallizations from ether–hexane gave one pure isomer of **29**, mp 138–139°C.[3]

*2-Carbomethoxy-3-hydroxy-4,4,6,6-tetramethyl-2,3,3a,4,6,6a-hexahydrothieno[2,3-c]pyrrole-5-oxyl (30)*

The above procedure was followed. From methyl thioglycolate (106 mg, 1.00 mmol) and aldehyde **15** (168 mg, 1.00 mmol) there was obtained 40 mg (24%) of recovered aldehyde and 120 mg (44%) of ester **30**, mp 136–137°C (ether/hexane); ms *m/e*: 275 (36), 274.111 (91) (calcd. for $C_{12}H_{20}NO_4S$, 274.111), 260 (56), 244 (31), 160 (100), 127 (87), 110 (69), 101 (44), 99 (80).

*2-Carboethoxy-3-acetoxy-4,4,6,6-trimethyl-2,3,3a,4,6,6a-hexahydrothieno[2,3-c]pyrrole-5-oxyl (31)*

Acetic anhydride (20.4 mg, 0.200 mmol) was added to alcohol **29** (28.8 mg, 0.100 mmol) in pyridine (1.0 mL) and the solution was allowed to stand at 25°C for 3 h. The usual work-up afforded a yellow solid which crystallized from ether/hexane to give 27 mg (82%) of acetate **31**, mp 126–127°C; ms *m/e*: 332 (6), 331 (25), 330.136 (69) (calcd. for $C_{15}H_{24}NO_5S$, 330.137), 242 (11), 241 (16), 240 (82), 216 (34), 174 (100), 167 (40), 141 (41), 99 (72).

*2-Carboethoxy-3-hydroxy-4,4,6,6-tetramethyl-2,3,3a,4,6,6a-hexahydrothieno[2,3-c]pyrrole-5-oxyl-1,1-dioxide (32)*

Hydrogen peroxide (30%) (1.0 mL) was added to a solution of alcohol **29** (28.8 mg) in MeOH (2.0 mL). Sodium tungstate (3 mg) was then added and the solution was allowed to stand for 3 h at 25°C. The solution was diluted with brine (10 mL) and extracted with $CHCl_3$. The extract was dried ($Na_2SO_4$) and evaporated to dryness, affording a solid residue which was triturated with ether. Filtration afforded 20 mg (63%) of crystalline sulfone **32**, mp 156–157°C; ms *m/e*: 320.118 (10) (calcd. for $C_{13}H_{22}NO_6S$, 320.117), 164 (20), 139 (3), 111 (35), 110 (100), 109 (13), 95 (29).

*2-Carboxy-3-hydroxy-4,4,6,6-tetramethyl-2,3,3a,4,6,6a-hexahydro[2,3-c]pyrrole-5-oxyl (**33**)*

A solution of methyl ester **30** (144 mg, 0.500 mmol) and 1.0 mL (1.0 mmol) of 1 *N* NaOH in MeOH (3.0 mL) was allowed to stand at 25°C for 3 h. The solution was diluted with brine, acidified, and extracted with ether. Evaporation of the dried ($Na_2SO_4$) extract gave 105 mg (81%) of crystalline acid **33**. Recrystallization from $CHCl_3$/ether/hexenes gave the analytical specimen, mp 212–213°C; ms *m/e*: 260.096 (5) (calcd. for $C_{11}H_{18}NO_4S$, 260.096), 169 (29), 154 (95), 138 (67), 126 (100), 123 (38), 110 (86), 109 (33), 108 (29), 95 (52), 92 (71).

*2-Carboethoxy-4,4,6,6-tetramethyl-3a,4,6,6a-tetrahydrothieno[2,3-c]pyrrole-5-oxyl (**34**)*

Methanesulfonyl chloride (22.9 mg, 0.200 mmol) was added to a solution of alcohol **29** (28.9 mg, 0.100 mmol) in pyridine (1.0 mL) and the solution was allowed to stand at 25°C for 6 h. The mixture was diluted with brine, acidified to pH 4 with 6% hydrochloric acid, and extracted with ether. The dried ($Na_2SO_4$) extract was evaporated and the residue was subjected to preparative tlc (Analtech) (ethyl acetate/hexanes, 1:1). The major band, $R_f$ 0.74, afforded 20 mg (74%) of crystalline **34**. Recrystallization from ether/hexanes gave the analytical specimen, mp 113–116°C; ir (Nujol): 1720 and 1560 $cm^{-1}$; ms *m/e*: 272 (5), 271 (14), 270.116 (54) (calcd. for $C_{13}H_{20}NO_3S$, 270.116), 241 (11), 240 (63), 226 (16), 225 (100), 198 (16), 197 (87), 184 (14), 183 (89), 181 (16), 169 (53), 167 (84), 155 (37), 153 (42), 151 (47), 133 (33), 125 (73), 113 (94), 111 (65).

*Spin labeled hemoglobin*

Stock solutions (5 mg/mL) of 3-maleimido-2,2,5,5-tetramethyl-1-pyrrolidinyloxyl (**22**) (Syva Co.) and nitroxide **21** were prepared in ethanol. Hemoglobin (20 mg, Sigma, Type I, bovine) was dissolved in 30 m*M* Tris pH 8.0 buffer (0.5 mL) in subdued light. The spin label stock solution (6 μL) was added and the resulting solution was stirred 2 h at 25°C. After removal of unreacted spin label by dialysis, the sample was concentrated to 50 μL using a collodion bag apparatus (Schleicher & Schuell, MW cutoff 25 000) before esr spectra were recorded. Samples to be photolyzed were diluted to 0.5 mL with the Tris buffer and then illuminated 5 min at 0°C with filtered (1 *M* $KNO_2$) radiation from a 1000 W quartz–halogen lamp. After the photolysis, the samples were concentrated to 50 μL and esr spectra (Varian E-Line spectrometer) were again recorded.

# Nitroxides. IX.[1] Synthesis of nitroxide free radical α-amino acids

LÁSZLÓ LEX, KÁLMÁN HIDEG,[2] AND H. OLGA HANKOVSZKY
*Central Laboratory, Chemistry, University of Pécs, H-7643 Pécs, Hungary*

Received September 12, 1981

LÁSZLÓ LEX, KÁLMÁN HIDEG, and H. OLGA HANKOVSZKY. Can. J. Chem. **60**, 1448 (1982).

Three methods are described for preparation of a new stable nitroxide free radical amino acid, 2-amino-3-(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl) propionic acid and its derivates. This amino acid may be used as a paramagnetic amino acid synthon in studies of peptides.

LÁSZLÓ LEX, KÁLMÁN HIDEG et H. OLGA HANKOVSZKY. Can. J. Chem. **60**, 1448 (1982).

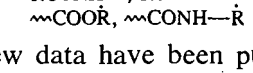
On décrit trois méthodes de préparation d'un nouveau radical libre nitroxyde stable d'un acide aminé: l'acide amino-2 (oxyl-1 tétraméthyl-2,2,5,5 pyrroline-3 yl-3)-3 propionique et ses dérivés. On utilise cet acide aminé comme synthon paramagnétique dans des études de peptides.

[Traduit par le journal]

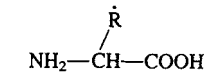
## Introduction

Reactive functional groups containing nitroxides have often been used for acylating or alkylating peptides and proteins at reactive functional groups such as amino, thiol, or carboxyl groups (2–5).

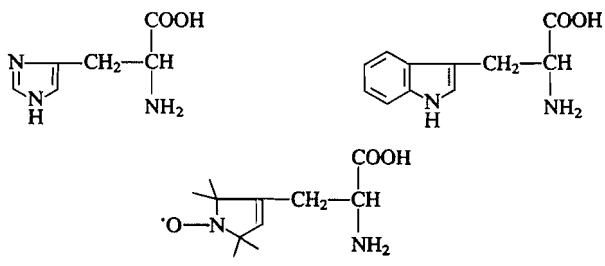
It is essential to carry out the labeling with as minimal perturbance of the biomolecule as possible to fulfill the requirements for an ideal reporter-group. That is of course not possible, because the modification of any essential function (e.g. acylating an amino group, alkylating a thiol group, or acylating a carbonyl group) may result in the loss of biological activity.



Relatively few data have been published on the synthesis of nitroxide free radical analogues of amino acids (6–8):



We wish to report methods generally applicable for synthesis of nitroxide α-amino acids, which can be used as synthons due to their structural resemblance to natural aralkyl amino acids like histidine or tryptophane:



As starting compounds, nitroxide derivatives are needed which are reactive enough and do not have a chiral centre. These requirements are fulfilled excellently by either the 1-oxyl-2,2,5,5-tetramethyl-3-bromomethyl-3-pyrroline (**1***a*) or the 1-oxyl-2,2,5,5-tetramethyl-3-methanesulfonyloxymethyl-3-pyrroline (**1***b*) (9).

## Results and discussion

Three esters of α-functionalized carboxylic acids are acylated on their active methylene or methine group with **1***a* or **1***b* in alkaline media. In the first route (Method A) the dimethyl 2-acetamino malonate (**2**) is alkylated with **1***a* to **3** in the presence of sodium ethoxide. After partial hydrolysis of **3** the monomethyl ester of dicarboxylic acid (**4**) is formed. The acetamino nitroxide amino acid (**6**) can be obtained via decarboxylation of **4** and the hydrolysis of **5**. The compound **6** is suitable for reactions of its free carboxylic group with amino acids or peptides because its amino terminal is protected by an acetyl group.

The second method (Method B) utilizes a synthetic route by which the Schiff's base **7** (formed from benzophenone and glycine ester) can be alkylated with alkyl halides in a two-phase system using tetrabutylammonium hydrogen sulfate as a phase transfer catalyst (10). Following this, **7** can be alkylated with **1***a* to **8**. After acidic hydrolysis of **8** with aqueous citric acid (11) the ethyl ester of the nitroxide amino acid (**9**) is obtained. This route leads to a free α-amino group containing ester which can be acylated on its amino terminal. For longer storage the more stable tosylate salt of **9** is prepared with toluenesulfonic acid in dry acetone. On acetylation of **9** with 1-acetylimidazole, **10** is formed, which can be hydrolyzed to **6** obtained at the end of Method A.

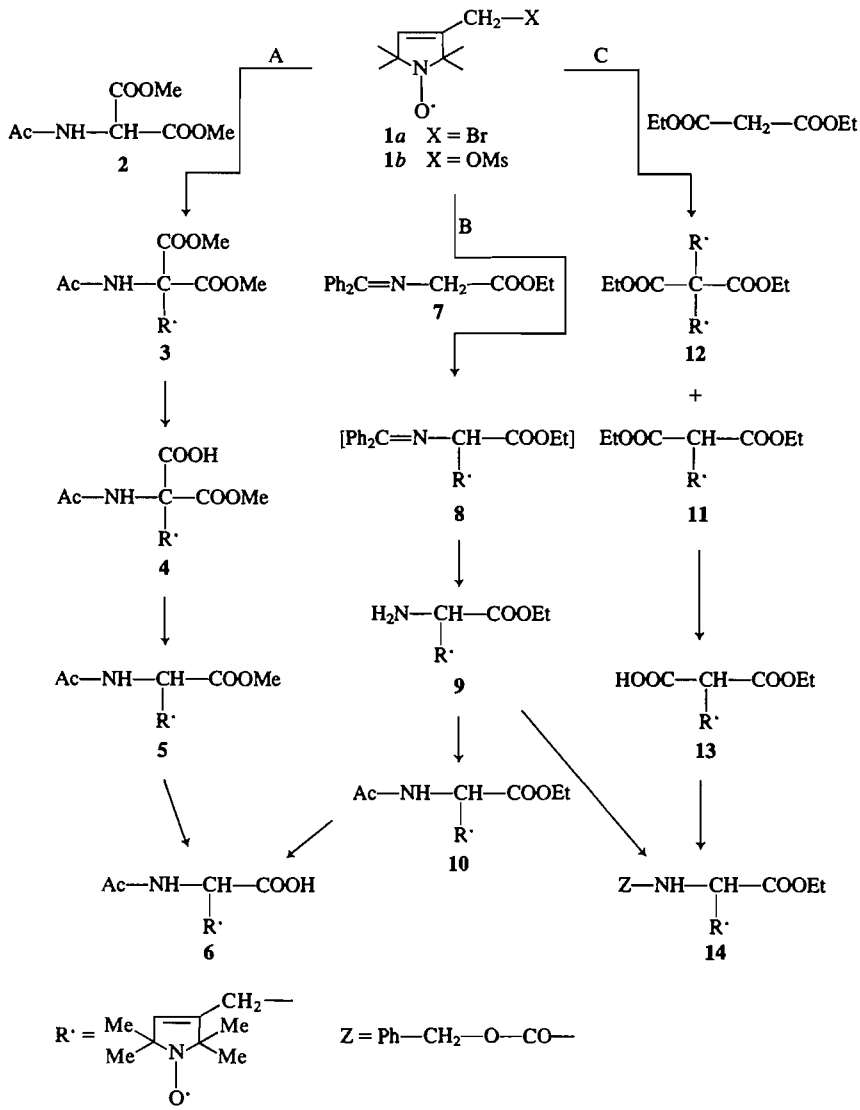

SCHEME 1

In the third route (Method C) the sodium diethyl malonate is alkylated with **1***b* (9) to **11** with formation of some bis-alkylated compound (**12**) as well. The biradical compound exhibits a 5-line esr spectrum characteristic of nitroxide biradicals.

In a partial hydrolysis of diester **11** the acid monoethyl ester (**13**) is formed. Utilizing the carbonyl-azide formation reaction with diphenyl phosphorylazide (DPPA) (12) **13** is allowed to react with DPPA and then with benzyl alcohol to obtain the desired ethylester of nitroxide amino acid (**14**) which is protected on its amino terminal by a carbobenzyloxy group (Z). This derivative can also be obtained when **9** is reacted with benzyl chloroformate in the presence of triethylamine.

These methods are equally useful for preparing derivates of nitroxide amino acids protected either on amino or carboxyl terminal groups. All of these amino acids are racemates; the experiments for resolution are in progress.

## Experimental

Melting points were measured using a Boetius micro mp-determining instrument and are not corrected. The ir spectra were measured as a neat oil or in Nujol suspensions with a Zeiss Specord 75 type of instrument. The esr spectra were obtained

from $10^{-3}$ *M* solution using a Zeiss ER9 spectrometer. All the monoradicals exhibited three equidistant lines and the biradical showed five equidistant lines with $a_N$ = 14.8–15.0 G. The mass spectra were taken using a Varian-MAT-SM-1 instrument. Solvents were reagent grade and dried prior to use. All organic extracts obtained during the work-up of the reaction mixture were dried over anhydrous magnesium sulfate and distilled off *in vacuo*. For column chromatography silica gel 60 was used.

*Dimethyl 2-acetamino-2-[(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)methyl] malonate (3)*

To a stirred solution of **2** (0.95 g, 5.0 mmol) in dry ethanol (15 mL) with sodium ethoxide (1 *M*, 5 mL, 5.0 mmol) a solution of **1***a* (1.17 g, 5.0 mmol) in dry ethanol (10 mL) was added, refluxed for 5 h, and then evaporated *in vacuo* to dryness. The residue was taken up in water (10 mL) and extracted with chloroform (3 × 10 mL). The organic phase was separated, dried, and evaporated. The solid residual was subjected to column chromatography on silica gel with tetrachloromethane/ethyl acetate (2:1). The first yellow band was unreacted **1***a*, 0.3 g (25%); the second one was compound **3**, yield: 0.9 g (53%), mp 97–98°C; ir $\nu_{max}$: 3345 (NH), 1725 (CO), 1665 (CONH) $cm^{-1}$. *Anal.* calcd. for $C_{16}H_{25}N_2O_6$ (Mol. Wt. 341.4): C 56.30, H 7.38, N 8.21; found: C 56.42, H 7.37, N 8.35.

*Monomethyl ester of 2-acetamino-2-[(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)methyl] malonic acid (4)*

Sodium hydroxide solution (1 *M*, 2 mL, 2.0 mmol) was added to a solution of **3** (0.341 g, 1.0 mmol) in methanol (2 mL) and allowed to stay at room temperature overnight, then diluted with water (10 mL), acidified with dilute sulfuric acid (5%), and extracted with chloroform (3 × 10 mL). The organic phase was dried and evaporated to dryness. The solid residue was crystallized from chloroform/hexane to give **4**, yield: 0.27 g (82%), mp 120–121°C; ir $\nu_{max}$: 3500–3200 (OH), 3365 (NH), 1730 (CO), 1640 (CONH) $cm^{-1}$. *Anal.* calcd. for $C_{15}H_{23}N_2O_6$ (Mol. Wt. 327.4): C 55.04, H 7.08, N 8.56; found: C 55.20, H 7.09, N 8.54.

*Methyl 2-acetamino-3-(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)propionate (5)*

A suspension of the monomethyl ester (**4**) (0.327 g, 1.0 mmol) in water (10 mL) was refluxed for 3 h, then extracted with chloroform (3 × 10 mL). The organic phase was dried, evaporated, and crystallized from ether/hexane to give the pure **5**, yield: 0.22 g (78%), mp 87–88°C; ir $\nu_{max}$: 3250 (NH), 1740 (CO), 1635 (CONH) $cm^{-1}$. *Anal.* calcd. for $C_{14}H_{23}N_2O_4$ (Mol. Wt. 283.4): C 59.35, H 8.18, N 9.89; found: C 59.41, H 8.08, N 9.92.

*2-Acetamino-3-(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl) propionic acid (6)*

A solution of sodium hydroxide (2 *N*, 5 mL, 10.0 mmol) was added to a solution of **5** or **10** (5.0 mmol) in ethanol (15 mL) and left at room temperature overnight, then diluted with water (20 mL) and extracted with chloroform (3 × 10 mL). The aqueous phase was acidified with 1 *N* hydrochloric acid to pH 3, saturated with sodium chloride, and extracted with chloroform (3 × 10 mL), dried, evaporated to dryness, and crystallized from chlorform/methanol/ether to give **6**, yield: 0.99 g (74%) from **5**, and 0.96 g (72%) from **10**; mp in both cases 174–176°C; ir $\nu_{max}$: 3330 (NH), 1700 (CO), 1620 (CONH) $cm^{-1}$. *Anal.* calcd. for $C_{13}H_{21}N_2O_4$ (Mol. Wt. 269.3): C 57.98, H 7.86, N 10.40; found: C 57.81, H 7.66, N 10.65.

*Ethyl 2-amino-3-(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)-propionate (9) and its tosylate salt*

A solution of sodium hydroxide (2 *N*, 18 mL, 36.0 mmol) was added to a methylene chloride solution (15 mL) of **7** (4.0 g, 15.0 mmol), tetrabutylammonium hydrogen sulfate (TBAH) (6.1 g, 18.0 mmol), and **1***a* (4.2 g, 18.0 mmol) and stirred at room temperature for 2 days. The organic layer was separated, washed with water, dried, and evaporated to dryness to remove the residue quaternary bromide. The residue was taken up in ether and filtered. The filtrate was evaporated to dryness. The aqueous citric acid (10%, 30 mL) was added to the tetrahydrofuran (20 mL) solution of the Schiff's base **8** and stirred overnight. The reaction mixture was diluted with water (30 mL) and extracted with chloroform (2 × 25 mL) to remove the benzophenone. The aqueous phase was basified with 2 *N* sodium hydroxide solution to pH 8, extracted with chloroform (3 × 20 mL), dried, and evaporated to dryness to give **9** as a red oil, yield: 2.9 g (75%); ir $\nu_{max}$: 3400–3200 ($NH_2$), 1730 (CO) $cm^{-1}$. *Anal.* calcd. for $C_{13}H_{23}N_2O_3$ (Mol. Wt. 255.4): C 61.15, H 9.08, N 10.97; found: C 61.05, H 9.10, N 11.16.

*The tosylate salt of 9*

A solution of *p*-toluenesulfonic acid monohydrate (0.95 g, 5.0 mmol) was added to the solution of **9** (1.27 g, 5.0 mmol) in dry acetone (10 mL) and diluted with ether until the crystallization started. The crude product was recrystallized from chloroform/ether/hexane to give the pure salt of **9**, yield: 1.8 g (84%), mp 145–146°C; ir $\nu_{max}$: 1750 (CO) $cm^{-1}$. *Anal.* calcd. for $C_{20}H_{31}N_2O_6S$ (Mol. Wt. 427.5): C 56.19, H 7.31, N 6.55; found: C 56.07, H 7.02, N 6.44.

*Ethyl 2-acetamino-3-(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)propionate (10)*

To a stirred solution of **9** (1.27 g, 5.0 mmol) in dry tetrahydrofuran (15 mL) a solution of 1-acetylimidazole (0.55 g, 5.0 mmol) was added in dry tetrahydrofuran (10 mL). The reaction mixture was allowed to stay for 2 h, then evaporated to dryness, and taken up in ethyl acetate. The ethyl acetate solution was extracted with 1 *N* hydrochloric acid solution, the organic phase was washed with saturated sodium hydrogen carbonate solution (5%), dried, evaporated to dryness, and the solid residue was crystallized from ether/hexane to give **10**, yield: 1.2 g (80%); mp 87–88°C; ir $\nu_{max}$: 3240 (NH), 1745 (CO), 1640 (CONH) $cm^{-1}$. *Anal.* calcd. for $C_{15}H_{25}N_2O_4$ (Mol. Wt. 297.4): C 60.59, H 8.47, N 9.42; found: C 60.54, H 7.99, N 9.61.

*Diethyl 2-[(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)methyl]-malonate (11) and diethyl bis-2-[(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)methyl]malonate (12)*

A solution of diethyl malonate (1.6 g, 10.0 mmol) in dry ethanol (10 mL) was added to a freshly prepared solution of sodium ethoxide (1 *M*, 10 mL, 10.0 mmol) and stirred for 30 min. Then a solution of **1***b* (2.48 g, 10.0 mmol) in dry ethanol (25 mL) was added to the reaction mixture and heated at 60°C for 2 h. The reaction mixture was diluted with water (30 mL) and extracted with chloroform (3 × 30 mL). The chloroform extract was washed with water, dried, and evaporated to dryness to give a red oil. The oil was suspended in ether (10 mL) and the precipitated crystals were filtered to give as a by-product the bis-alkylated malonate (**12**), yield: 0.9 g (19%), mp 189–190°C; ir $\nu_{max}$: 1720 (CO) $cm^{-1}$; esr ($CHCl_3$): 5 lines, $a_N$ = 14.9 G. *Anal.* calcd. for $C_{25}H_{40}N_2O_6$ (Mol. Wt. 464.6): C 64.63, H 8.68, N 6.03; found: C 64.79, H 8.41, N 6.07.

The filtrate was evaporated and subjected to column chromatography on silica gel with tetrachloromethane/ethyl acetate (10:1) to give the monoalkylated product (**11**) as a red oil, yield: 1.6 g (51%); ir $\nu_{max}$: 1735 (CO) $cm^{-1}$. *Anal.* calcd. for $C_{16}H_{26}NO_5$ (Mol. Wt. 312.4): C 61.52, H 8.39, N 4.48; found: C 61.25, H 8.15, N 4.89.

*Monoethyl ester of 2-[(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)methyl] malonic acid (13)*

A solution of potassium hydroxide (0.56 g, 10.0 mmol) was

added in ethanol (10 mL) to a stirred solution of **11** (3.12 g, 10.0 mmol) in absolute ethanol (20 mL) and refluxed for 2 h. The reaction mixture was evaporated *in vacuo* to dryness and dissolved in water (30 mL). The aqueous solution was extracted with chloroform (2 × 20 mL). The aqueous phase was acidified with 1 *N* hydrochloric acid to pH 3 and extracted again with chloroform (3 × 10 mL), dried, and evaporated to dryness. The solid residue was crystallized from ether/hexane to give the pure **13**, yield: 2.2 g (77%), mp 110–111°C; ir $\nu_{max}$: 3200–2600 (OH), 1730 (CO) $cm^{-1}$. *Anal.* calcd. for $C_{14}H_{22}NO_5$ (Mol. Wt. 284.4): C 59.14, H 7.80, N 4.93; found: C 59.32, H 7.46, N 5.02.

*Ethyl 2-benzyloxycarbonylamino-3-(1-oxyl-2,2,5,5-tetramethyl-3-pyrrolin-3-yl)propionate (**14**)*

Triethylamine (0.5 g, 5.0 mmol) and diphenylphosphoryl azide (1.38 g, 5.0 mmol) were added to a solution of **13** (1.42 g, 5.0 mmol) in dry benzene (30 mL) and refluxed for 1 h, then benzyl alcohol (0.7 g, 7.0 mmol) was added to the reaction mixture and refluxed for 2 days. The reaction mixture was evaporated to dryness *in vacuo* and chromatographed on a silica gel column with benzene/tetrahydrofuran (10:1) to give **14**, yield: 1.0 g (51%), mp 61–62°C; ir $\nu_{max}$: 3310 (NH), 1740 (CO), 1690 (CONH) $cm^{-1}$; ms, *m/e*: $M^+$ 389(31), $M^+ + 1$ 390(8), 316(27), 224(14), 223(20), 135(19), 123(12), 91(100). *Anal.* calcd. for $C_{21}H_{29}N_2O_5$ (Mol. Wt. 389.5): C 64.76, H 7.51, N 7.14; found: C 64.74, H 7.41, N 7.48.

*Preparation of **14** from **9***

Triethylamine (0.1 g, 1.0 mmol) and benzylchloroformate (0.170 g, 1.0 mmol) were added to the solution of **9** (0.255 g, 1.0 mmol) in dry tetrahydrofuran (10 mL) and stirred at room temperature for 1 h. The reaction mixture was diluted with water (20 mL) and extracted with ethyl acetate (3 × 10 mL). The ethyl acetate phase was washed with 1 *N* hydrochloric acid, saturated sodium bicarbonate, saturated sodium chloride, dried, and evaporated to dryness *in vacuo*. The residue was crystallized from chloroform/hexane to give **14**, yield: 0.3 g (77%), mp 61–62°C.

# Nitroxide destruction and flavin-photosensitized damage in inner mitochondrial membranes

ROLF JOACHIM MEHLHORN AND LESTER PACKER

*Membrane Bioenergetics Group, Lawrence Berkeley Laboratory and Department of Physiology–Anatomy, University of California, Berkeley, CA 94720, U.S.A.*

Received August 10, 1981

ROLF JOACHIM MEHLHORN and LESTER PACKER. Can. J. Chem. **60**, 1452 (1982).

Nitroxide free radicals lost their paramagnetic absorption spectrum when they were illuminated with visible light in aged but not freshly isolated inner mitochondrial membranes (SMP's). The action spectrum of spin loss rates coincided with a flavin absorption spectrum. Spin loss consisted of one-electron reduction and "destruction", the latter being defined as spin loss that cannot be reversed by ferricyanide oxidation. By placing SMP's in gas permeable tubing and illuminating alternately under nitrogen and air, it was possible to discriminate qualitatively between spin reduction and destruction. Aerobic spin loss consisted entirely of destruction. When aged SMP's were centrifuged, spin loss was observed in supernatants but not pellets. Flavin fluorescence was observed in the supernatants, suggesting that free flavins catalyzed spin loss. However, addition of exogenous flavins to fresh SMP's did not cause spin loss; hence some other factor was required to cause nitroxide destruction. This factor accumulates during either aerobic or anaerobic aging of SMP's and may be present in mitochondria. Supernatants of aged SMP's, when added to freshly isolated SMP's, induced rapid nitroxide destruction, slightly accelerated photodamage to succinate oxidase, and considerably increased photo-induced lipid peroxidation.

ROLF JOACHIM MEHLHORN et LESTER PACKER. Can. J. Chem. **60**, 1452 (1982).

Les spectres d'absorbtion paramagnétique des radicaux libres du type nitroxyde disparaissent lorsqu'on les illumine avec de la lumière visible dans des membranes mitochondriales internes (SMP) qui ont veilli; ce n'est pas le cas avec des membranes fraîchement isolées. Le taux de disparition des spin concide avec le spectre d'absorption d'une flavine. La perte de spin correspond à une réduction par un électron et une "destruction"; on définit la "destruction" comme une perte de spin qui ne peut être renversée par une oxydation au ferrocyanure. Si on place des SMP dans un tube perméable aux gaz et si on les illumine alternativement sous azote et à l'air, il est possible de distinguer qualitativement entre une réduction de spin et une "destruction". La perte de spin aérobique est uniquement une destruction. Lorsqu'on soumet des SMP qui ont vieilli à la centrifugation, on observe une perte de spin avec le liquide qui surnageant mais pas avec le précipité. Dans le liquide qui surnage, on observe la fluorescence de la flavine, ceci suggère que les flavines libres exogènes à des SMP fraîchement isolées ne provoque aucune perte de spin; on doit donc faire appel à d'autres facteurs pour expliquer la destruction du nitroxyde. Ces facteurs s'accumulent pendant le vieillissement aérobique ou anaérobique des SMP et peuvent être présents dans la mitochondrie. L'addition de liquide surnageant des SMP vieillies, à des SMP fraîchemenet isolées, induit une destruction rapide du nitroxyde, accélère légèrement le dommage photochimique à l'oxydase du succinate et augmente considérablement la peroxydation photo-induite des lipides.

## Introduction

The destructive effect of visible light on tissues, cells, and organelles has been studied extensively (1). Blue light is particularly damaging in many cases, suggesting flavin involvement. Previously, this laboratory reported on visible light effects in mitochondria (2, 3). Progressive functional inactivation was observed, beginning with the loss of ATP synthesis, and followed by inactivation of dehydrogenase flavoenzymes. Functional damage was accompanied by loss of flavins, sulfhydryl groups, and lipid peroxidation. Although light damage was enhanced by exogenous flavins, covalently bound flavins were destroyed at rates comparable to those for dissociable flavins. Furthermore, the inactivation required oxygen but it was unclear whether this requirement was merely to maintain the flavins in their light absorbing oxidized form or whether active oxygen species were directly responsible for damage. Failure to achieve protection with SOD, singlet oxygen scavengers, hydroxyl radical quenchers, and antioxidants, suggested a minor role if any for these potentially destructive species except perhaps at the active sites of flavoenzymes (2).[1]

Two aspects of the damage process interested us particularly because of the possibility of further studies using nitroxide spin probes. These were (*i*) the possibility that damage was mediated by free radicals that might have been generated by the excited flavins and (*ii*) the role of bound vs. free flavins. Nitroxides are potentially useful to study oxygen involvement in free radical reactions because they are themselves free radicals, N—O•, which resemble ground state oxygen, •O—O•, and

which may thus compete with oxygen in free radical addition reactions. However, $O_2$ adducts are reactive peroxy radicals which may participate in chain reactions, whereas nitroxide spin pairing products are expected to be relatively unreactive. A number of stable nitroxide adducts have been described (4, 5). Nitroxides also have the potential to serve as free radical detectors in another sense, since they should readily undergo one-electron or hydrogen transfer reactions with other free radical molecules. One-electron transfer reactions of nitroxides have been demonstrated with reduced flavins (6), and with electron transport components of mitochondria (7). However, since reduction of nitroxides can occur by two-electron reductants like ascorbate, loss of nitroxide paramagnetism as assayed by electron spin resonance is not sufficient to establish free radical involvement in an interaction per se, and additional analyses are required to establish such involvement.

In other detection schemes, nitroxide precursors and derivatives have been used to detect active oxygen species, including superoxide radicals (8, 9) and singlet oxygen (10). These detection schemes exploit oxidation of the nitroxide derivatives to elicit a paramagnetic signal.

Mechanisms and biological effects of photosensitized oxidation were recently reviewed (11). The photooxidation of amino acids by flavins in particular has been studied extensively (e.g., 12, 13). Analysis of the photoinactivation of a flavoenzyme, porcine D-amino acid oxidase, provided evidence of localized destruction of amino acid residues at the flavin binding site (14). The light mediated reduction of many flavoproteins appears to be catalyzed by traces of free flavins, i.e., aqueous photoreductants generally do not appear to have direct access to enzyme-bound flavins (15).

In this report, the effect of illumination on nitroxides in mitochondrial membrane suspensions is described and correlated with photodamage to succinate oxidase of the respiratory chain and with light induced lipid peroxidation.

## Materials and methods

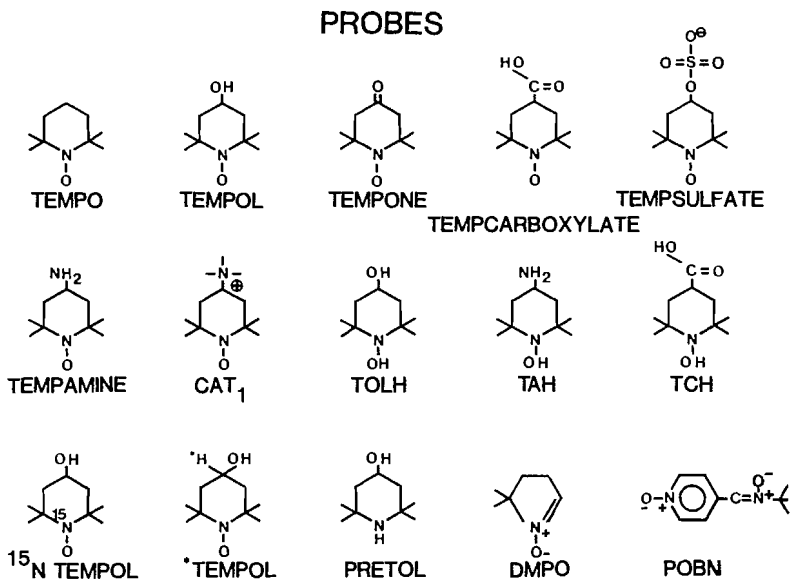
*Preparations*

Rat liver mitochondria were isolated and suspended in 200 m*M* mannitol, 70 m*M* sucrose, and 1 m*M* Tris, pH 7.4. They were washed twice in the same medium and finally resuspended in 30 m*M* potassium phosphate, pH 7.4. Submitochondrial preparations (SMP's) were prepared by intermittent sonication of the mitochondria with a Branson 350 cell disruptor at a power setting of 5 for a cumulative time of 2 minutes. Undisrupted mitochondria were removed by centrifugation at 8,500 × g for 10 min and the SMP's collected by centrifugation at 100 000 × g for 30 min. They were resuspended in 30 m*M* potassium phosphate, pH 7.4, at protein concentrations indicated in the figures.

*Aging procedure*

SMP's were placed in 25 mL Erlenmeyer flasks, and the flasks were sheathed with aluminum foil and closed with a rubber stopper to prevent evaporation. In one experiment, flasks were flushed for 30 min with argon on an ice bath before being stoppered. The flasks were then placed on a shaking water bath at 37°C for the time periods indicated in the figures.

Nitroxides, some reduced derivatives and a precursor are shown below:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

The designation, TEMPR, refers to the structure 4-*R*-2,2,6,6-tetramethyl piperidine-1-oxyl (except for TEMPO).

TEMPOL, TEMPONE, TEMPAMINE, PRETOL, DMPO, and POBN were purchased from Aldrich Chemical Co. TEMPCARBOXYLATE (16) and $CAT_1$ (17) were synthesized. TEMPO, TEMPOL, and $^{15}N$ TEMPONE were generous gifts from A. D. Keith. $^{15}N$ TEMPOL was prepared by reducing $^{15}N$ TEMPONE with sodium borohydride and extracting the product into diethyl ether.

The reduced nitroxides TOLH, TAH, and TCH were prepared by treating TEMPOL, TEMPAMINE, and TEMPCARBOXYLATE, respectively, with ten equivalents of sodium ascorbate at pH 7, adjusting the pH to 7, 11, and 3, respectively, and extracting the products into diethyl ether. The ether extracts were washed once with phosphate buffer solutions at pH 7, 11, and 3 as above, dried over $Na_2SO_4$, and the solvent was removed under reduced pressure.

TEMPSULFATE was prepared as follows: 3 g of TEMPOL and 4.45 g of *N*,*N*-diisopropyl-ethylamine were taken up in 100 mL of acetone. The solution was stirred rapidly on an ice bath and 1.76 g of chlorosulfonic acid were added over a period of 10 min. The reaction mixture was removed from the ice bath, allowed to stand at room temperature for 2 hours, treated with 1.4 g of NaOH in 20 mL of water, and then the amine and unreacted TEMPOL were extracted exhaustively with diethyl ether. The water fraction was dried under an air stream and used without further purification.

*Electron spin resonance experiments*

Stock solutions of the probes in water were adjusted to pH 7.0 with HCl or NaOH. In a 0.6 mL test tube, 35 microliters of SMP's were mixed with 0.35 microliter of probe. Mixing was effected with hand agitation. Except for the action spectrum experiment, labeled samples were transferred to gas-permeable tubing (18) with a 100 microliter syringe, and then the flexible tubing was bent in the middle and inserted in a thin-walled quartz tube open at both ends. The pressure of the tubing on the walls of the quartz housing tube was sufficient to immobilize the sample within the esr cavity even in the presence of a nitrogen stream. The action spectrum was obtained with samples in 50 μL glass capillaries sealed at one end with a propane torch. The esr experiments were conducted in a Varian E109E spectrometer at a power setting of 10 mW and a modulation amplitude of 1.25 gauss at a frequency of 100 kHz. A typical gain setting for a kinetic scan was $3.2 \times 10^4$.

*Illumination*

Samples were illuminated within the microwave cavity of the esr instrument with a 100 W projector and a glass heat filter. The light intensity at the sample was 150 mW/cm². The intensity was determined outside the esr instrument with a Hewlett–Packard 8330A radiant flux meter and a 8334A detector and subsequently determined within the instrument by comparing FMN-mediated oxidation rates of TOLH inside and outside the cavity under nonsaturating conditions. The action spectrum of spin loss rates was determined using Oriel interference filters of 10 nm band width (G-522-11) and normalizing spin loss rates with respect to light intensities transmitted by the filters as measured with the radiant flux meter. Except where white light is indicated in the figure legends, all sample illumination in the esr instrument was conducted with an Oriel broadband interference filter with a peak position at 450 nm and a 50 nm bandwidth. With this filter, FMN-mediated TOLH oxidation occurred at 1/3 the rate observed with white light. For the ferricyanide-reoxidation experiment, SMP's in an Erlenmeyer flask at room temperature were illuminated with the same light source but the light was passed through a Corning glass #3389 400 nm cutoff filter. The photodamage experiment was conducted at 10°C in an apparatus that was described previously (3), providing an intensity of 300 mW/cm² with the Corning #3389 filter.

TBA reactive materials, a measure of lipid peroxidation, were assayed according to published methods, with the inclusion of 0.01% butylated hydroxytoluene (BHT) in the reaction mixture prior to heating (19). Total flavins were identified and quantitated fluorometrically with a Perkin Elmer MPF 44A spectrofluorometer at an excitation wavelength of 375 nm and bandwidth of 5 nm. Emission spectra were recorded from 390 nm to 620 nm and flavins were identified by comparison with fluorescence spectra of defined flavins in buffer. No attempt was made to discriminate between different flavin nucleotides or their hydrolysis products.

Succinate oxidation by the mitochondrial respiratory chain was assayed in a Rank oxygen electrode (Rank Brothers, Bottisham, Cambridge, England). Typically protein concentrations of 3 mg/mL were used in a reaction medium of 30 m*M* potassium phosphate, pH 7.4, with 10 m*M* sodium succinate.

## Results

*Description of the spin loss phenomenon*

A spectrum of TEMPOL in a suspension of SMP's is shown in the inset of Fig. 1. The effect of visible light on this spectrum is to cause a decrease of the intensity of the spectrum, but only if the membranes have been allowed to incubate prior to illumination. As shown in Fig. 1, the onset of spin loss with illumination as well as its cessation in the dark are virtually instantaneous.

*Action spectrum*

Spin loss rates at different wavelengths of light are shown in Fig. 2. Because of the narrow bandwidths of the interference filters used for these experiments, effective light intensities were low and about 15 min of illumination were required to obtain measurable spin loss rates at some wavelengths. An absorption spectrum of flavin mononucleotide (FMN) is shown for comparison.

*Direct interactions between flavins and nitroxides*

The action spectrum of spin loss rates implicated flavins in the spin loss process observed in aged SMP's. Therefore, several flavins, i.e., riboflavin, FMN, and FAD, were tested to study direct interactions of flavins with nitroxides in the light, if any. There was no interaction between flavins and TEMPOL in aerobic solution as assayed by esr. In anaerobic solution, TEMPOL signal loss was observed, but at a considerably slower rate than that observed for aerobic, aged SMP's. There was no effect of TEMPOL on FMN fluorescence at TEMPOL concentrations that were tested (< 1 m*M*). Flavins photooxidize the reduced nitroxides TOLH and TAH. The photooxidation of TCH was also observed, but at a ten-fold lower rate than that of TOLH. To study the interaction between flavin radicals and nitroxides, FMN, 30 μ*M* $^{14}N$ TOLH as an electron donor, and 30 μ*M* $^{15}N$ TEMPOL, as

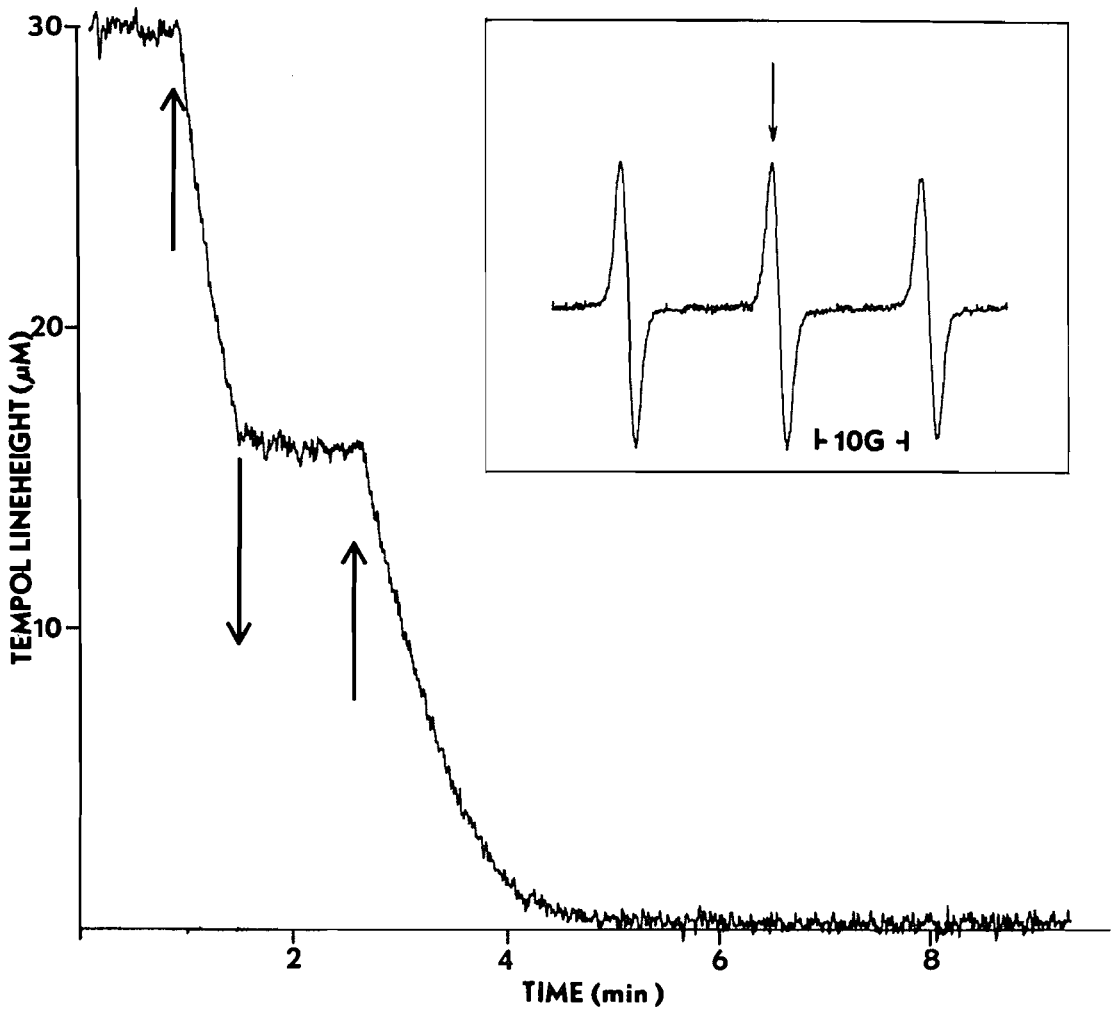


FIG. 1. The line height of TEMPOL expressed in terms of known TEMPOL concentration in buffer as a function of illumination. Inset, esr spectrum of TEMPOL in SMP; arrow points to the field position where the line height was monitored. Upward arrows denote light on, downward light off. Protein concentration 12 mg/mL. SMP incubated for three hours at 36°C prior to white light illumination.

an electron acceptor, were illuminated anaerobically. The nitroxides having $^{14}N$ and $^{15}N$ paramagnetic centers give rise to distinct spectral lines; hence, reduction and oxidation rates can be monitored simultaneously. Upon illumination, there was a decrease in the $^{15}N$ TEMPOL signal and a simultaneous increase in the $^{14}N$ TEMPOL signal at the same rates. Upon admitting air to the sample under continuous illumination, both spectra increased to the original line height seen for 30 μ*M* $^{15}N$ TEMPOL.

*Comparison of TEMPOL reduction and other processes of spin loss*

One-electron reduction of TEMPOL yields the nonparamagnetic hydroxylamine TOLH. Reoxidation of TOLH to TEMPOL is rapidly effected by ferricyanide. Thus, when 30 μmol of TOLH is treated with 2 m*M* potassium ferricyanide at pH 7.4, a spin signal rapidly appears, increasing to a maximum within two minutes at 25°C. The final line height corresponds to 30μmol of a fresh TEMPOL solution in the presence of 2 m*M* ferricyanide. Accordingly, ferricyanide oxidation was used in SMP's after illumination with TEMPOL to determine the fraction of spin loss due to reduction. The remaining fraction of spin loss is operationally defined as nitroxide "destruction." If ferricyanide is added to SMP's during illumination, it effectively inhibits light-driven spin loss, i.e. spin loss rates progressively decrease with increasing ferricyanide concentrations such that in the presence of 7

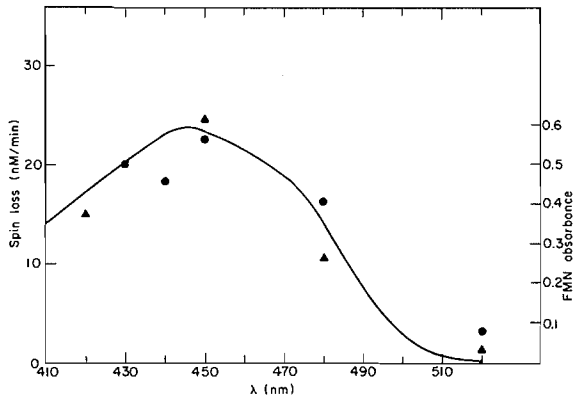

FIG. 2. Action spectrum of spin loss rates. SMP at 29 mg/mL protein, were incubated for 1.5 h at 37°C prior to illumination. Two experiments are denoted by ● and ▲. The solid line shows an absorption spectrum of 40 μ*M* FMN, the absorbance units are arbitrary.

μ*M* ferricyanide, the spin loss rate is half of what is observed in the absence of ferricyanide. Therefore, reoxidation of any TOLH produced during illumination was carried out in post-illumination experiments.

To compare reduction and destruction rates, illumination of 30μ*M* TEMPOL and SMP's containing 10 mg/mL protein was conducted in an aerobic flask. At one-minute time intervals, 70 μL samples were withdrawn for esr analysis of TEMPOL line heights; 35 μL were examined directly and the remaining 35 μL were treated with 2 m*M* ferricyanide. The signal heights were identical for the two sets of samples. A similar experiment was conducted with 100 μmol TOLH and SMP's. In this case, there was a light-driven appearance of TEMPOL line heights in the samples. The ferricyanide treated samples showed that no spin destruction occurred initially. Spin destruction became apparent only after TOLH had been converted to TEMPOL during the illumination. When the TEMPOL concentration had reached 30 μ*M*, the destruction rate was comparable to what was observed for the sample containing only TEMPOL initially.

To study the effect of oxygen on spin loss, experiments were conducted in gas permeable tubing surrounded by air or nitrogen. Figure 3 shows that aerobic illumination of TEMPOL and SMP's causes less rapid spin loss than is observed under nitrogen. Upon admitting air into the anaerobic sample, a partial recovery of the spin signal is seen which gives way to complete signal loss upon prolonged illumination. This result is similar to aerobic illumination of TOLH, where transient and partial oxidation is observed under illumination. No oxidation of TOLH is seen under nitrogen. A comparison of initial rates seen for aerobic TEMPOL destruction and TOLH oxidation shows that destruction occurs at a rate comparable to oxidation.

Iron had a marked effect upon spin loss rates. As indicated earlier, ferricyanide was inhibitory at low concentrations. On the other hand, ferric chloride accelerated spin loss about two-fold at a concentration of 10 μ*M*. Considerable variability was seen in spin loss rates among different membrane preparations that were studied, possibly due to fluctuations in the concentrations and binding states of traces of iron among the different preparations.

*The role of membranes in spin loss*

To define the source of light-induced spin loss, SMP's that had been incubated in the dark for three hours at 37°C were centrifuged and spin destruction rates, i.e., aerobic rates of spin loss, were measured in the pellet, supernatant, and in pellets that had been resuspended in their supernatants. The maximum spin loss rate was observed in the supernatant, the intermediate rate in the resuspended membranes, and the minimum rate in the pellet. Washed pellets had no spin loss activity.

The effect of charged groups on the nitroxides is shown in Table 1. The positively charged nitroxides exhibit significantly lower rates of spin loss and the positively charged hydroxylamine, TAH, a significantly higher photooxidation rate than the other nitroxides. The most hydrophobic nitroxide, TEMPO, exhibits the most rapid spin loss rate. The rates of photooxidation of the reduced nitroxides, i.e., TAH > TOLH > TCH, are the same as observed for the direct interaction between flavins and reduced nitroxides. However, whereas TCH is photooxidized by FMN or riboflavin, only spin loss of a trace of TEMPCARBOXYLATE in the sample is observed with SMP's.

*Flavin fluorescence and spin loss rates*

Figure 4 shows the aerobic spin loss rates and the appearance of flavin fluorescence in the supernatants of centrifuged SMP's as a function of time of incubation of the SMP's at 37°C in the dark. At two temperatures the two parameters increase in parallel with time up to about three hours of incubation. Longer incubation does not substantially increase flavin fluorescence or spin loss rates.

*The effect of exogenous flavins on spin loss rates*

SMP's that had been incubated in the dark at 37°C for various time periods were treated with FMN to study the effect of exogenous flavins on spin loss. As shown in Fig. 5, freshly isolated

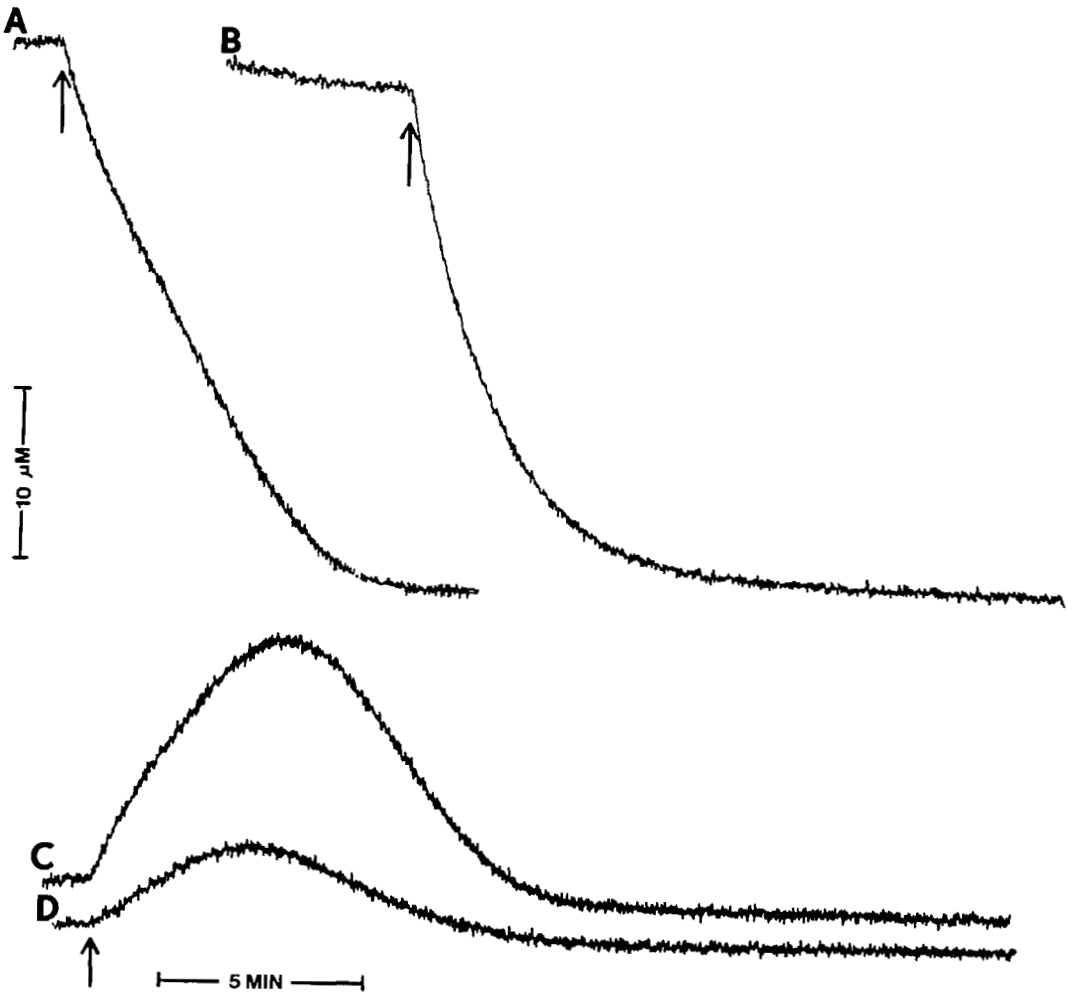

FIG. 3. Aerobic and anaerobic esr line height changes of TEMPOL in illuminated SMP's. Conditions as in Fig. 1. A, 30 μ*M* TEMPOL in air; B, 30 μ*M* TEMPOL under $N_2$; C, 30 μ*M* TOLH in air; D, same sample as B, but now in air.

TABLE 1. Light-dependent aerobic spin loss and oxidation rates for different nitroxides and hydroxylamines*

| Nitroxide | Initial rate of spin loss (μmol/min) | Hydroxylamine | Initial rate of oxidation (μmol/min) |
|---|---|---|---|
| TEMPO | 32 | TOLH | 3.1 |
| TEMPOL | 16 | TAH | 12.7 |
| TEMPAMINE | 5.5 | TCH | −2.8 |
| $CAT_1$ | 3.8 | | |
| TEMPCARBOXYLATE | 11.5 | | |
| TEMPSULFATE | 9.5 | | |

*Protein, 10 mg/mL; SMP's preincubated 2 h at 37°C in the dark.

SMP's do not cause spin loss of nitroxides in the light even in the presence of added FMN. The presentation of data in this figure takes into account flavin release during dark incubation by referring to the results in Fig. 4. It is assumed that the flavins observed in the supernatant of centrifuged SMP's behave photochemically like free FMN and hence can be pooled with exogenous flavins as "free flavins." Figure 5 shows that at a fixed concentration of free flavin, there is an increase in aerobic

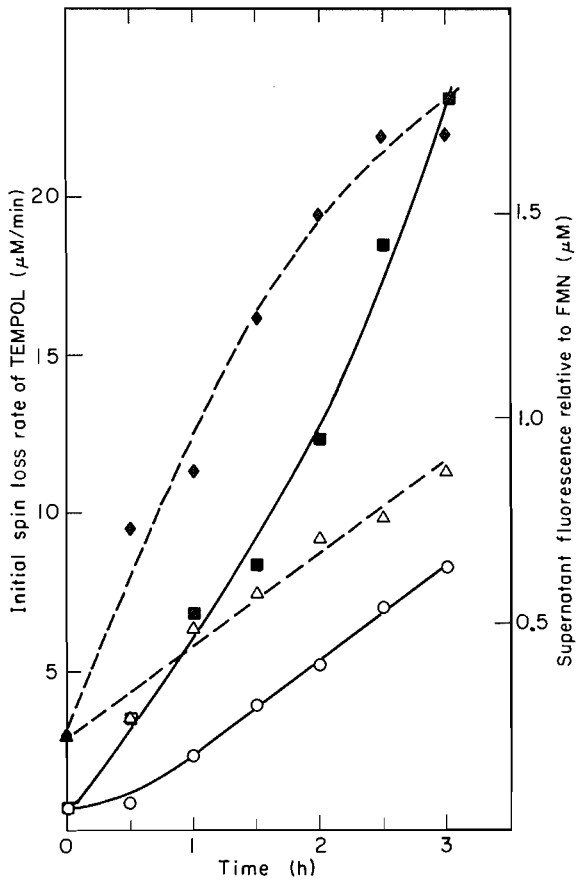

FIG. 4. SMP supernatant flavin fluorescence and aerobic TEMPOL spin loss rates as a function of incubation time in the dark. SMP protein was 7.9 mg/mL. △: supernatant flavin fluorescence at 31°C; ○: spin loss rate at 31°C; ■: supernatant flavin fluorescence at 37°C; ◆: spin loss rate at 37°C. Flavin fluorescence is expressed as FMN equivalents.

spin loss rates with increasing time of dark incubation. Similar data were obtained for SMP's that had been incubated in the dark under argon.

*Partial characterization of "destroyed" TEMPOL*

Radioactively labeled *TEMPOL was illuminated in the presence of SMP's for a sufficient period of time to completely destroy the spin. The suspension was centrifuged and essentially all of the radioactivity was found in the supernatant. Another preparation of destroyed TEMPOL was extracted into ether at alkaline pH and the ether extract was oxidized with the strong oxidant *m*-chloroperoxybenzoic acid. The product of this procedure was concentrated and taken up in phosphate buffer at pH 7.4. An esr spectrum of this sample was observed and was similar to a spectrum obtained when PRETOL was subjected to the same oxidation procedure.

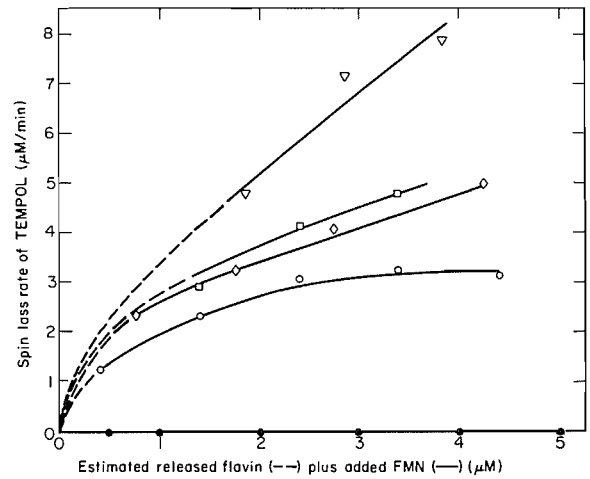

FIG. 5. Effect of dark incubation time and exogenous FMN on aerobic TEMPOL spin loss rates. SMP protein was 10 mg/mL. Dashed lines indicate that the free flavin concentration for that region of the curve was estimated from the flavin supernatant fluorescence data in Fig. 4.

*Spin trapping experiments with nitrones*

In the presence of 100 m*M* DMPO, the rate of light-induced TEMPOL destruction with SMP's decreased by a factor of two, while 100 m*M* POBN completely inhibited TEMPOL destruction. An esr spectrum was observed with DMPO both in the presence and absence of TEMPOL. This spectrum was identical to a spectrum obtained with DMPO and FMN in buffer (Fig. 6). No esr spectrum was observed for POBN and SMP's with the broadband interference filter. With white light a spectrum appeared very slowly, i.e., 30 min of illumination were required to obtain measureable coupling constants ($A_N = 15.8$ G, $A_H = 2.0$ G).

*Relation of spin loss to photodamage*

Since freshly isolated SMP's exhibited little or no spin destruction with or without exogenous flavins and since aging of SMP's caused the appearance of the spin loss phenomenon in the aqueous environment of membranes, these diverse conditions were compared in terms of photodamage to the respiratory chain and to membrane lipids. Figure 7 shows that succinate oxidase activity is progressively lost under illumination and that conditions which induce spin loss, i.e., addition of supernatant from aged SMP's, only slightly acelerate photodamage of these components of the respiratory chain. However, there is a marked correlation between lipid peroxidation and spin destruction. The supernatant treated SMP's yield considerably more TBA-reactive material during illumination than either freshly isolated control

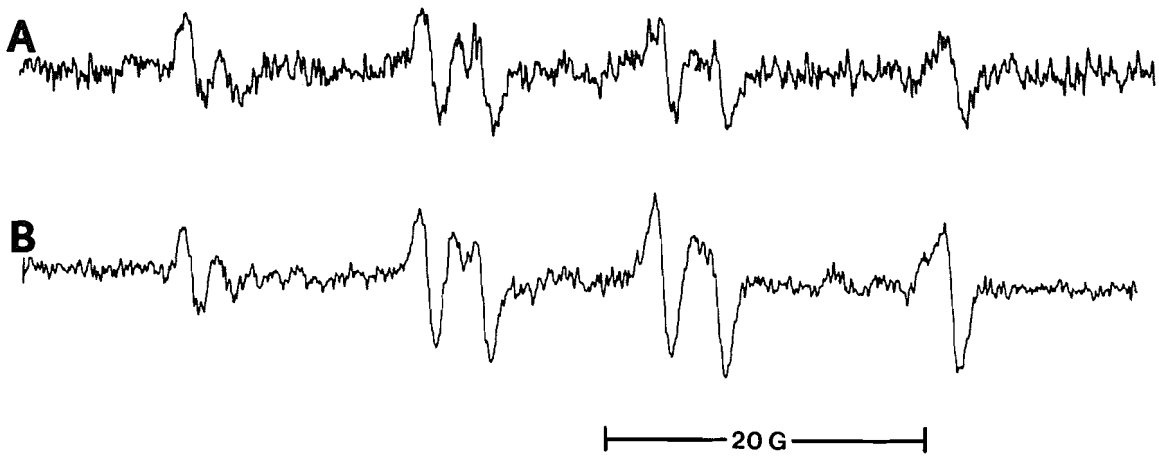

FIG. 6. A, Spectrum of DMPO adducts in SMP's. SMP protein was 10.8 mg/mL. B, Spectrum formed within two minutes of illumination of 100 m*M* DMPO and 10 μ*M* FMN in the cavity of the esr instrument.

SMP's or SMP's containing exogenous FMN at a concentration equal to "released" flavin in the supernatant. Some aging of the freshly isolated SMP's is reflected in the small spin loss rates seen in the two preparations without added supernatant.

*Photochemical model systems*

EDTA is a well-known photoreductant for flavins. Figure 8 shows that a TEMPOL signal was reduced on illuminating a mixture of FMN and EDTA. Spin loss was rapid under nitrogen and could be largely reversed when air was admitted to the sample. A sample that was illuminated aerobically suffered relatively little spin loss.

## Discussion

*Characterization of nitroxide esr signal changes*

We were interested in using nitroxides as spin traps to elucidate photodamage mechanisms in mitochondria. Intact mitochondria were not suitable for study because their electron transport activity causes one-electron reduction of nitroxides in the dark (20). Therefore, our studies were conducted with isolated inner mitochondrial membranes (SMP's) where substrates for electron transport have been removed from the membranes. Since nitroxides are quite stable in the presence of SMP's in the dark, these preparations were deemed suitable for studies of photodamage with nitroxides.

Aerobic aged SMP's illuminated with visible light cause nitroxides to lose their paramagnetism and subsequent treatment of these SMP's with the oxidant ferricyanide does not cause a reappearance of the esr signal; hence the phenomenon is not one-electron photoreduction of the nitroxides. It was also observed that the reduced nitroxides TOLH and TAH are photooxidized by aged SMP's and by flavins. By illuminating anaerobic SMP's and subsequently allowing them to become aerobic, a partial recovery of the nitroxide esr signal was observed. Hence, under anaerobic conditions, some of the nitroxides are photoreduced to hydroxylamines under illumination. The use of gas permeable tubing permits a comparison of the effects of anaerobic and aerobic illumination in the same sample and thus represents a convenient tool for discriminating qualitatively between one-electron photoreduction and other mechanisms of spin loss. When this technique was applied to a simple photochemical system, FMN and EDTA, spin loss was seen to be comprised primarily of one-electron photoreduction. This is to be expected since FMN becomes photoreduced by EDTA anaerobically (21) and since it is known that reduced flavins reduce nitroxides (6).

The action spectrum of spin loss implicated flavins as the sensitizers for nitroxide spin loss. However, studies with simple model systems showed the oxidized flavins had no effect on nitroxide spectra. Reduced flavins, $FlH_2$, and flavin radicals, $FlH^{\bullet}$, reduce nitroxides (6). The experiment with $^{14}N$ TOLH and $^{15}N$ TEMPOL showed that neither the flavin radical $FlH^{\bullet}$, which is necessarily produced during photooxidation of TOLH, nor its oxidation product with molecular oxygen cause spin destruction. Hence it is concluded that flavins are not directly responsible for the observed aerobic spin loss of nitroxides.

The association of spin loss activity with supernatants but not pellets of centrifuged SMP's implies that "released" flavins are necessary for the spin loss. "Released" flavins is an operational term

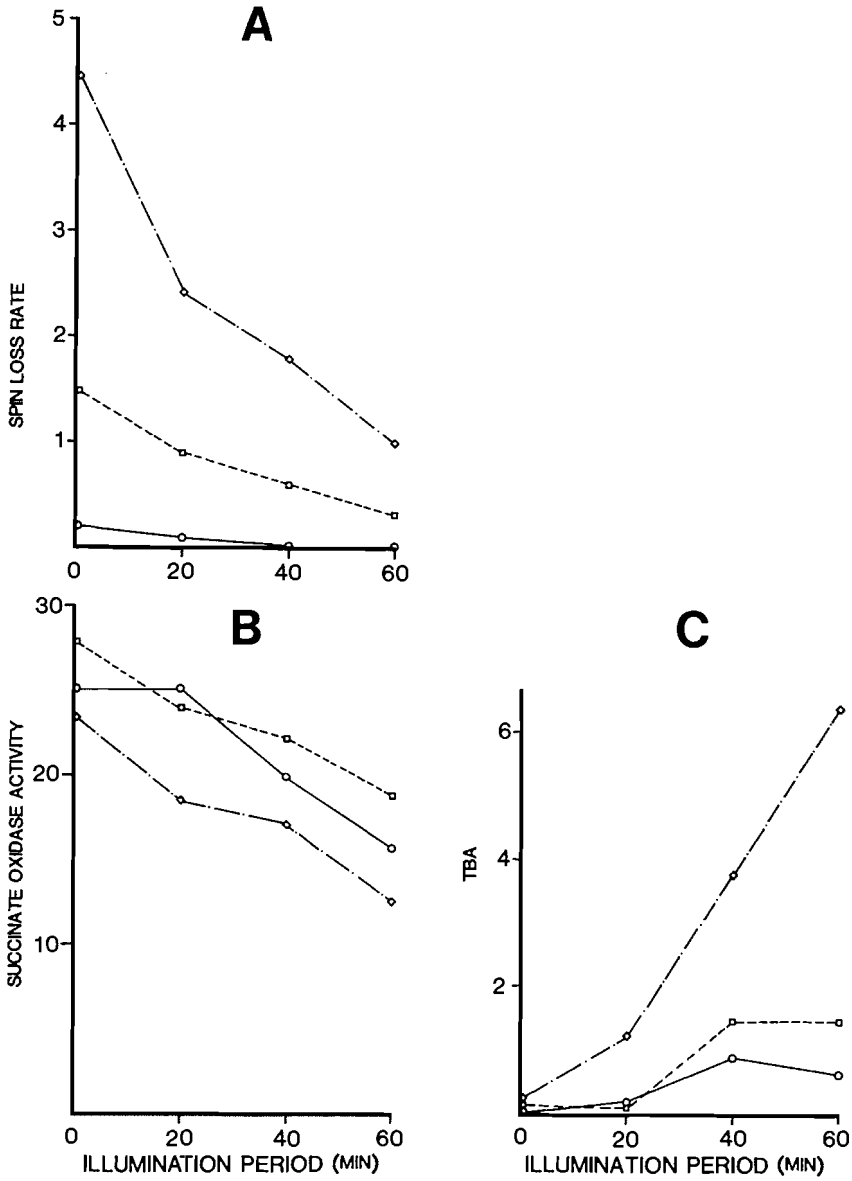

FIG. 7. Effect of addition of FMN or supernatant from aged SMP's on spin loss rates μmol/min, SMP's at 6.32 mg/mL protein (A); light dependent succinate oxidase inactivation μmol $O_2$/min, SMP's at 0.31 mg/mL protein (B); formation of TBA-reactive materials mmol/mg (C). (——) control; (----) 2.7 μ*M* FMN; (-·-·) supernatant containing 2.7 μmol "released" flavin as estimated from fluorescence.

since centrifugation speeds were insufficient to pellet individual proteins or membrane fragments. The most likely source of released flavin is NADH dehydrogenase, which contains noncovalently bound FMN. The steep temperature dependence of flavin release suggests that only low concentrations of free flavins exist in SMP's illuminated at 10°C, where photoinactivation of respiratory activities is nevertheless observed (3).

Since certain amino acids are photoreductants for flavins (12, 13), it seemed possible that anaerobic SMP's would cause nitroxide reduction under illumination. However, freshly isolated anaerobic SMP's exhibit no significant light-dependent spin reduction, even in the presence of 5 μ*M* exogenous FMN or riboflavin (data not shown). Hence, mitochondrial membranes are poor photoreductants and direct oxidation of membranes, e.g., hydrogen abstraction from amino acid residues by free flavins, is not likely to play an important role in photo-

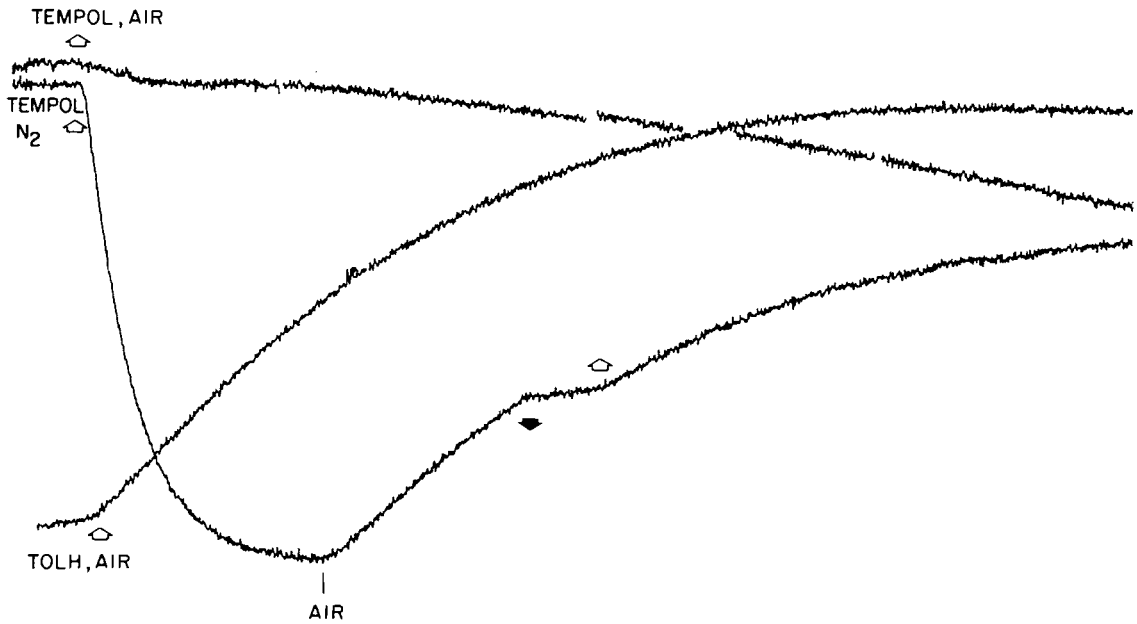

FIG. 8. Aerobic and anaerobic esr line height changes of TEMPOL and TOLH in a photochemical model system. The model system contained 10 μ*M* FMN, 10 m*M* EDTA, and 30 m*M* potassium phosphate, pH 7.4. Aerobic illumination, and alternately anaerobic and aerobic illumination as indicated.

damage. The aerobic experiment with exogenous flavins (Fig. 5) showed that at a given concentration of free flavins there is an acceleration of nitroxide spin loss with aging of the membranes. Hence, some phenomenon other than flavin release occurs during the aging process which together with free flavins causes spin loss. Taken together with the occurrence of spin loss in supernatants of centrifuged SMP's, it is inferred that some other factor(s) in addition to flavins are released from the SMP's into their aqueous environment during dark incubation. These factors react with excited flavins to bring about nitroxide spin loss. Since 30 μmol TEMPOL are destroyed by less than 2 μmol flavin, as estimated from supernatant fluorescence, it is clear the flavins act catalytically in the nitroxide destruction process, strengthening the conclusion that neither flavins nor their degradation products cause spin destruction.

*Inference that free radicals probably cause nitroxide destruction*

Destruction of nitroxides could occur by several mechanisms. One is the direct coupling of nitroxides with other radicals. Known examples of radicals which form stable products with nitroxides include several alkyl radicals (4, 5). Also, it has been shown in pulse radiolysis experiments that nitroxides react with hydroxyl radicals (22). However, the products of the latter reaction seem to decompose rapidly since model systems, e.g., uv photolysis of $H_2O_2$ and Fenton reagents, did not destroy the paramagnetic signal of TEMPOL. Another example of spin pairing is the reaction of nitroxides with thiyl radicals, a process which ultimately leads to the formation of tetramethyl piperidines, e.g., PRETOL (23). Studies of reactions between nitroxides and free radicals derived from ethylbenzene suggest that peroxy radicals, R′OO·, do not react with nitroxides (24). Oxidation of nitroxides with a powerful oxidant would yield ammonium ions which would immediately decompose in aqueous solution to nitroxides and hydroxyl radicals (5). Under strongly reducing conditions, TEMPOL can be reduced to PRETOL. This mechanism is unlikely to explain the spin loss observed in SMP's, however, since over-reduction would probably proceed via the TOLH intermediate (5) and since TEMPOL destruction is much more rapid than TOLH destruction. Thus, the mechanism of spin destruction appears to be radical pairing of nitroxides with other radicals, excluding oxygen-centered radicals, like hydroxyl or peroxy radicals.

Nitrone spin traps like DMPO and POBN have been used extensively to demonstrate the existence of free radicals (25). Since the esr spectrum arising from DMPO with illuminated SMP's is identical to the spectrum seen with only DMPO and FMN,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

there appears to be no correlation between nitroxide spin destruction and DMPO spin formation. It was suggested previously that nitroxides could arise from DMPO and light-excited flavins by a nonradical mechanism (26). The spin adduct seen with POBN with white light is difficult to interpret owing to its rather low rate of appearance and the failure to observe an adduct with the broad-band interference filter. In summary, these nitrone traps do not appear to trap radicals observable by esr in illuminated SMP's even under conditions of rapid TEMPOL destruction. This does not rule out the interpretation that TEMPOL destruction is caused by radicals; rather it suggests that these nitrones with illuminated SMP's do not form radicals sufficiently stable to be observed by esr spectrometry.

*Relationship to membrane damage*

It was of interest to determine whether the species causing nitroxide destruction played a role in the mechanism of flavin-sensitized photodamage. In freshly isolated SMP's without exogenous FMN, there is appreciable photodamage to succinate oxidase even though no TEMPOL destruction was detected under these conditions. Thus, it is inferred that bound flavin exerts its destructive effects in close proximity to its binding site, and that there is no propagation of damage to distant sites as seen in the lack of lipid peroxidation and spin destruction. Exogenous FMN increases photodamage only slightly, suggesting that singlet oxygen generated by free flavin is not a major damaging species in SMP photodamage.

The addition of supernatant from aged SMP's greatly increases lipid peroxidation and slightly increases inactivation of succinate oxidase. Since the supernatant contains factor(s) that interact with light-excited flavins to destroy nitroxides, it is seen that these factors have destructive potential. Once initiated exogenously, damage propagation seems to occur in the SMP membranes since the most hydrophobic nitroxide, TEMPO, is destroyed appreciably more rapidly than the other probes. The relevance of these observations to photodamage in vivo is not clear. The factors we describe in aged SMP's could also be present in vivo. Since they are water soluble, they would be removed from the SMP's during membrane isolation procedures, and hence freshly centrifuged SMP's would not exhibit light-dependent nitroxide destruction. Given the potential of these factors for causing damage to lipids and enzymes, their further characterization is warranted.

# Use of spin traps to elucidate radical mechanisms of oxidations by hydroperoxides catalyzed by hemeproteins

BRENDA WALKER GRIFFIN[1]

*Department of Biochemistry, The University of Texas Health Science Center at Dallas, 5323 Harry Hines Blvd., Dallas, TX 75235, U.S.A.*

Received August 10, 1981

BRENDA WALKER GRIFFIN. Can. J. Chem. **60**, 1463 (1982).

The use of the spin traps nitrosobenzene and 2-methyl-2-nitrosopropane has established that metmyoglobin and liver microsomal cytochrome P-450 initiate a radical decomposition of cumene hydroperoxide. With metmyoglobin and the alkyl nitroso compound, the only radical product of cumene hydroperoxide trapped was the methyl radical formed by β scission of the cumyloxy radical. With both hemeprotein initiators, nitrosobenzene trapped only the cumyl radical, considered to be a decomposition product of the unstable spin adduct phenylcumyloxynitroxide. Support for this proposal includes: (1) previous spin trapping studies of the chemical decomposition of cumene hydroperoxide; and (2) significant inhibition by nitrosobenzene of the one-electron oxidation of aminopyrine and the autoxidation of unsaturated membrane lipids resulting from addition of the hydroperoxide to liver microsomes. Aminopyrine altered the epr signal amplitudes of the spin adducts produced with both nitroso compounds, indicative of oxidation of aminopyrine by the methyl radical and reduction of cumene hydroperoxide by the aminopyrine radical. The participation of hydroperoxide-derived radicals in the low peroxidatic activities of certain hemeproteins is quite distinct from the catalytic function of the true hemeprotein peroxidases, which bring about an efficient two-electron reduction of specific hydroperoxides.

BRENDA WALKER GRIFFIN. Can. J. Chem. **60**, 1463 (1982).

L'utilisation du nitrosobenzène et du méthyl-2 nitroso-2 propane comme capteurs de spin a permis de démontrer que la métmyoglobine et le cytochrome microsomique P-450 provoquent la décomposition radicalaire de l'hydroperoxyde de cumène. Avec la métmyoglobine et le composé nitrosoalkyle, le radical méthyle, formé par la scission β du radical cumylpéroxy, est le seul produit radicalaire piégé de l'hydroperoxyde de cumène. Avec les deux initiateurs du type hèmeprotéine, le nitrosobenzène piège seulement le radical cumyle qui serait un produit de décomposition du phenylcumyloxynitroxyde, un adduit de spin instable. Cette proposition est basée sur: (1) les études antérieures de piégeage de spin lors de la décomposition chimique de l'hydroperoxyde de cumène; (2) le fait que le nitrosobenzène inhibe de façon significative l'oxydation, par un électron, de l'aminopyrine et l'autoxydation des lipides de la membrane insaturées résultant de l'addition de l'hydroperoxyde aux microsomes du foie. L'aminopyrine modifie les amplitudes du signal de rpe des adduits de spin provenant des deux composés nitrosés indiquant ainsi une oxydation de l'aminopyrine par le radical méthyle et une réduction de l'hydroperoxyde de cumène par le radical aminopyrine. La participation des radicaux provenant de l'hydroperoxyde dans des activités peroxydantes faibles de certaines hèmeprotéines est tout à fait distincte de la fonction catalytique des vraies peroxydases de l'hèmeprotéines qui provoquent une réduction efficace par deux électrons d'hydroperoxydes spécifiques.

[Traduit par le journal]

## Introduction

Hemeprotein peroxidases are among the most efficient and best studied protein catalysts. These enzymes utilize $H_2O_2$, and in certain cases, a limited number of organic hydroperoxides and peroxy acids, to oxidize various electron donors (1). A class of peroxidase isozymes isolated from horseradish root exhibits rather low specificity for the reducing substrate, which includes aromatic amines, phenols, and many other compounds (1). However, catalases from mammalian and other sources exhibit their largest activities with $H_2O_2$ as the reducing substrate, thereby effecting a rapid decomposition of $H_2O_2$ to $O_2$ and $H_2O$ (2). It has been clearly established that the mechanism of catalysis by horseradish peroxidase (HRP) involves the following sequence of reactions (1):

[1*a*] HRP ($Fe^{3+}$) + $H_2O_2$ → Compound I

[1*b*] Compound I + AH → Compound II + A·

[1*c*] Compound II + AH → HRP ($Fe^{3+}$) + A·

[1*d*] A· + A· → A–A

Reaction of the ferric hemeprotein with $H_2O_2$ produces the spectroscopically distinct enzyme species designated as Compound I (1); this species retains both oxidizing equivalents of the peroxide, as evidenced by regeneration of the ferric enzyme (via another hemeprotein species compound II), upon the sequential transfer of two electrons from two molecules of the reducing substrate AH (1). Some of the more stable radical species (A·) formed in this catalytic cycle have been detected directly by epr (1); the final oxidation products of AH result from non-enzymatic reactions of the A· radicals; dimerization, disproportionation, or other reactions are possible, depending on the chemical reactivity of the particular radical and the experimental conditions (1).

The catalysis of $H_2O_2$ decomposition by catalase also involves the formation of a species very similar to Compound I of horseradish peroxidase (2); however, reduction of this enzyme species by $H_2O_2$ appears to be a concerted two-electron transfer reaction, without the involvement of a Compound II-like enzyme intermediate (2). The electronic structure of Compound I is considered to be that of a porphyrin $\pi$ cation radical associated with Fe(IV) (3); the single oxidizing equivalent of Compound II of horseradish peroxidase remains as Fe(IV) (3). It is very significant that, although the catalysis of $H_2O_2$-supported oxidations by free and complexed metal ions often produces radical species from the peroxide ($HO_2\cdot$ and $OH\cdot$) (4), these species play no role in the formal catalytic cycle of hemeprotein peroxidases given by reaction [1]. However, low levels of peroxy radicals and superoxide radical anion may be produced during the peroxidase-catalyzed oxidation of certain electron donors; these species arise from non-enzymatic reactions of the substrate radicals $A\cdot$ with molecular $O_2$ present in the reaction system (5).

The studies described herein were initiated after several reports of the "peroxidatic" activities of cytochrome P-450 appeared (6). This hemeprotein is found in many mammalian and non-mammalian organisms, where it catalyzes the oxidation by molecular $O_2$ of compounds, such as hydrocarbons and steroids, having relatively unactivated C—H bonds (7). These reactions are designated as monooxygenations because one atom of the $O_2$ molecule is incorporated into the organic substrate and the other is reduced to $H_2O$ by two electrons originating in reduced pyridine nucleotides (NADH or NADPH), the electron-transfer agents in biological systems (7):

$$[2] \quad NADPH + H^+ + O_2 + BH \rightarrow NADP^+ + H_2O + BOH$$

The mechanism by which cytochrome P-450 "activates" molecular $O_2$ for specific insertion into an organic compound is of considerable interest. The reports that organic hydroperoxides could function as the oxidant in certain cytochrome P-450-catalyzed oxidations led to the proposal that these reactions were altogether similar to those of other hemeprotein peroxidases, involving the formation of a Compound I-like species of cytochrome P-450 (8). This species was presumed to function as the oxygen-transfer agent in both the peroxidatic and monooxygenase reactions catalyzed by this hemeprotein (8). However, several features of the cytochrome P-450-catalyzed reactions with hydroperoxides were inconsistent with the well-known chemistry of peroxidase catalytic function: the catalytic activities were extremely low, yet substantial destruction of the heme group occurred (8); also, $H_2O_2$ was much less effective as the oxidant than were organic hydroperoxides, such as cumene hydroperoxide (6, 8) which is a very poor oxidizing substrate for horseradish peroxidase (1, 8). On the other hand, these properties and others were compatible with cytochrome P-450 initiation of a radical decomposition of cumene hydroperoxide, as occurs with various metal ions (9). We have tested this hypothesis by using epr and other techniques to characterize the decomposition of cumene hydroperoxide by well-defined model systems and by cytochrome P-450.

## Experimental

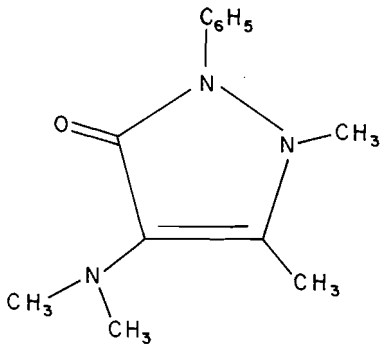
Metmyoglobin was a highly purified preparation isolated from beef heart (10); other purified hemeproteins and hemin were purchased from commercial sources. Microsomal fractions were prepared from the livers of phenobarbital-treated male rats, as described in (11). Aminopyrine, 4-aminoantipyrine, nitrosobenzene, 2-methyl-2-nitrosopropane (MNP), and metyrapone were purchased from Aldrich; acetone-$d_6$ was a product of Merck, Sharp and Dohme.[2] The sodium salt of cumene hydroperoxide was prepared (12) from a technical grade product supplied by Matheson, Coleman, and Bell; the purity of the salt was confirmed by high-performance liquid chromatography and iodometric titration. All other reagents were the highest quality commercially available. The experimental techniques employed for the epr experiments, which made use of a Varian E-4 spectrometer interfaced to a Digital Equipment Corporation PDP 11/05 computer, have been described in detail elsewhere (13, 14). Details of the high-performance liquid chromatographic analysis of the products of decomposition of cumene hydroperoxide have been published (14).

## Results and discussion

### *Model system studies*

Aminopyrine (Fig. 1) has served in this study as a convenient spectroscopic probe for monitoring the formation of one-electron oxidants in enzymatic reactions. The *N*-demethylation of this drug has been commonly used to assay the monooxygenase activity of liver microsomal cytochrome P-450, a membrane-associated hemeprotein (7). The electrochemical oxidation of aminopyrine was reported by Sayo and Masui (15) to produce a relatively stable, violet radical species of this compound. In

[2]The common chemical names and abbreviations used are: aminopyrine, 4-dimethylamino-2,3-dimethyl-1-phenyl-3-pyrazolin-5-one; 4-aminoantipyrine, 4-amino-2,3-dimethyl-1-phenyl-3-pyrazolin-5-one; MNP, 2-methyl-2-nitrosopropane; metyrapone, 2-methyl-1,2-di-3-pyridyl-1-propanone; cumene hydroperoxide, $\alpha,\alpha$-dimethylbenzyl hydroperoxide; Tris, tris-(hydroxymethyl)aminomethane; Hepes, *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid; NAD, NADP, nicotinamide adenine dinucleotide, nicotinamide adenine dinucleotide phosphate; DMPO, 5,5-dimethyl-1-pyrroline-1-oxide.



Aminopyrine

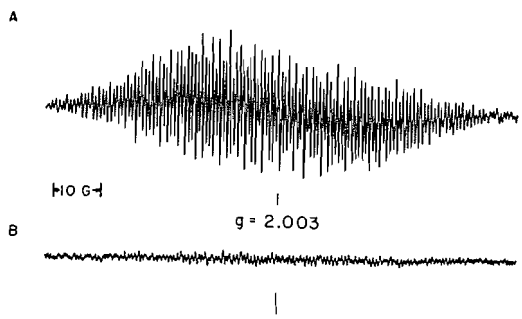

FIG. 2. Electron paramagnetic resonance spectrum of the aminopyrine free radical produced with cumene hydroperoxide and metmyoglobin. (*A*) The reaction mixture contained 20 m*M* aminopyrine, 30 m*M* cumene hydroperoxide, and 40 μ*M* metmyoglobin in 0.1 *M* potassium phosphate buffer, pH 5.0 (*B*) Control experiment: identical to *A*, except for omission of metmyoglobin. Microwave power, 10 mW; modulation amplitude, 0.25 G; temperature, 22°C.

our laboratory, it was shown that the horseradish peroxidase-catalyzed oxidation of aminopyrine with $H_2O_2$ produced the same radical species, which was proposed to be an intermediate in the *N*-demethylation of aminopyrine by this enzymatic system (13):

$$[3]\quad R_2N{-}CH_3 \xrightarrow{-e^-} R_2N{-}CH_3{}^{\cdot+} \xrightarrow{-H\cdot} R_2N^+{=}CH_2 \xrightarrow{H_2O} R_2NH_2^+ + H_2C{=}O$$

This reaction sequence is consistent with: (*1*) the mechanism of peroxidase-catalyzed generation of radical species from many reducing substrates (1); (*2*) non-enzymatic *N*-demethylation reactions effected by various chemical oxidants (16); and (*3*) the chemical structure of aminopyrine, which is closely related to the well-studied violenes, such as *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine (17). The unusual stability of the aminopyrine radical, coupled with its rather intense absorbance in the visible region (with a maximum near 565 nm in aqueous solution (18)), is an obvious advantage for studying oxidizing systems with low catalytic activities, a characteristic property of cytochromes P-450 (6–8).

In model-system studies of the oxidation of aminopyrine by cumene hydroperoxide catalyzed by metmyoglobin, the epr signal of the aminopyrine radical was readily detected in aqueous buffered solutions at room temperature, as shown in Fig. 2. Metmyoglobin was selected for these studies because it not only exhibits peroxidatic activities with cumene hydroperoxide comparable to those reported for cytochrome P-450 (6, 8, 19), but it also has somewhat larger peroxidatic activities with $H_2O_2$ as oxidant (13, 20). Indeed, the reaction of metmyoglobin with a two-fold excess of $H_2O_2$ has been shown to produce an enzyme species with the spectral properties of Compound II of horseradish peroxidase, which also retains a single oxidizing equivalent of the oxidant (20). Both the rate of formation of this so-called higher oxidation state of the heme iron and its subsequent reduction by electron donors are considerably slower than for horseradish peroxidase (13, 20), consistent with large differences in their catalytic activities toward common electron donors. Our efforts to demonstrate that a discrete higher oxidation state of metmyoglobin comparable to Fe(IV) is formed by reaction of the hemeprotein with cumene hydroperoxide were unsuccessful; a large excess of the hydroperoxide was required to perturb appreciably the absorbance spectrum of the hemeprotein, and the observed changes could be correlated with irreversible destruction of the heme group (18).

The chemistry of the induced radical decomposition of cumene hydroperoxide has been shown to be complex (9), and the radical species produced in this reaction (alkoxy, peroxy, and alkyl) are not particularly persistent (21). As expected, no epr signals were detected at room temperature when metmyoglobin was mixed with cumene hydroperoxide in aqueous buffered solutions. However, when 2-methyl-2-nitrosopropane (MNP) was present, the reaction produced an epr signal, Fig. 3, which contained two nitroxide radicals, assigned to spin adducts of MNP with a methyl radical and a butyl radical (14). The latter nitroxide has been shown to arise from light-induced decomposition of the spin trap (22), and was, accordingly, observed in all control experiments. However, the epr signal of the spin adduct of MNP and the methyl radical was detected only when both metmyoglobin and cumene hydroperoxide were present with the spin trap. Among the large number of control experi-

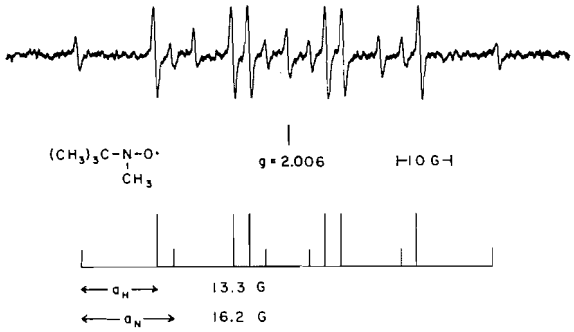

FIG. 3. Electron paramagnetic resonance signals detected in a solution of metmyoglobin, cumene hydroperoxide and MNP. The reaction mixture contained 24 $\mu M$ metmyoglobin, 30 m$M$ cumene hydroperoxide, 50 m$M$ MNP, and 10% acetone-$d_6$ in 0.1 $M$ Tris–HCl buffer, pH 9.0. Microwave power, 20 mW; modulation amplitude, 0.82 G; temperature, 22°C. (Reprinted from ref. 14 with permission.)

ments performed were variation of the pH and the solvent, which was required at low levels to increase the solubility of the spin trap in these aqueous solutions; because alcohols were oxidized to radicals which were trapped by MNP, deuterated acetone proved to be the most suitable solvent. At the level (10%) employed in these epr experiments, acetone did not have any significant effect on the measured aminopyrine $N$-demethylase activity of metmyoglobin with cumene hydroperoxide.

Addition of aminopyrine to the reaction mixture containing metmyoglobin, cumene hydroperoxide, and MNP caused the amplitude of the epr signal of the MNP-trapped methyl radical to decrease dramatically, as shown in Fig. 4. One possible explanation of this effect, namely a direct reaction of aminopyrine with the spin adduct, was eliminated by appropriate control experiments, also shown in Fig. 4. Product assays showed that the metmyoglobin-initiated decomposition of cumene hydroperoxide produced significant amounts of acetophenone, in addition to cumenol (14). Acetophenone formation was clearly incompatible with the usual mechanism of peroxidase catalysis, which would be expected to yield cumenol as the sole product of reduction of cumene hydroperoxide. In the presence of aminopyrine, under experimental conditions comparable to those of the epr experiments, the total yield of both acetophenone and cumenol was increased, but their ratio was not significantly affected, Table 1. These experimental results are consistent with the known chemistry of the radical decomposition of cumene hydroperoxide: formation of the cumyloxy radical, which undergoes a one-electron reduction to cumenol or

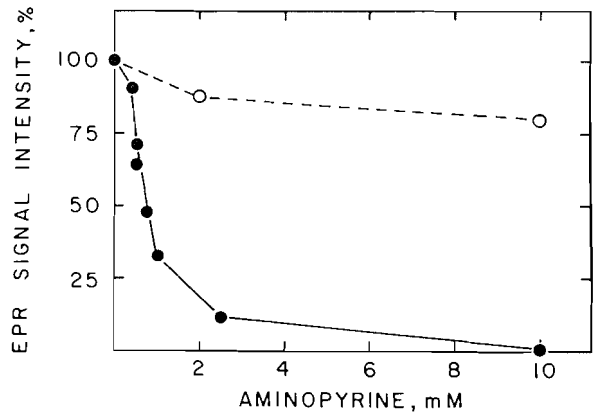

FIG. 4. Effect of aminopyrine on the relative EPR signal amplitude of the MNP-trapped methyl radical produced by the reaction of cumene hydroperoxide with metmyoglobin. The reaction mixture (●) was identical to that described in Fig. 3, except that the cumene hydroperoxide concentration was 20 m$M$ and aminopyrine was present at the indicated concentration. For the control experiment (○), the epr signal amplitude of the spin adduct of MNP and the $t$-butyl radical (decomposition product of MNP) was measured in the presence of cumene hydroperoxide alone, or metmyoglobin and $H_2O_2$, in 0.1 $M$ Tris–HCl buffer, pH 9.0. (Reprinted from ref. 14 with permission.)

β-scission to yield acetophenone and the methyl radical (9).

[4] 

The finding that aminopyrine stimulated acetophenone formation, but inhibited trapping of the methyl radical, formed in equimolar amounts with

acetophenone, suggested that aminopyrine reacted predominantly with the more reactive radical species ($CH_3$·) arising from cumene hydroperoxide. According to the simple scheme above, one-electron reduction of the cumyloxy radical by aminopyrine would be expected to decrease significantly the ratio of acetophenone to cumenol produced. Later experiments suggested that the aminopyrine radical can function as an electron donor to cumene hydroperoxide, thereby promoting the radical chain decomposition of the oxidant.

We next investigated nitrosobenzene as a potential trap of the cumyloxy radical produced in the metmyoglobin – cumene hydroperoxide system (23). In these experiments an unusually stable nitroxide was detected (Fig. 5), which exhibited no hyperfine splitting from nuclei of the trapped moiety. This splitting pattern is that expected for a trapped *tertiary* alkyl or *tertiary* alkoxy radical, and is quite distinct from that previously reported for the methyl radical trapped by nitrosobenzene (24). Indeed, when both nitrosobenzene and MNP were present, the wings of the broader epr signal of the MNP-trapped methyl radical were not detected, and the epr signal of the nitrosobenzene spin adduct was unchanged. These results suggested that $CH_3$· was not formed in the presence of this concentration of nitrosobenzene, consistent with efficient trapping of the cumyloxy radical by the spin trap. The effect of aminopyrine on the epr signal amplitude of the spin adduct was stimulation, as shown in Fig. 6, which was observed only

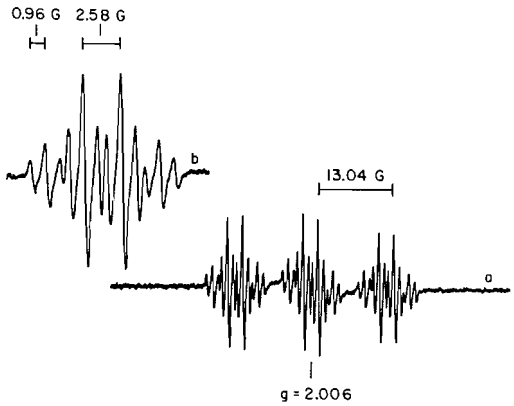

FIG. 5. Electron paramagnetic resonance signal produced in a solution of metmyoglobin, cumene hydroperoxide, and nitrosobenzene. The reaction mixture contained 27.5 μ*M* metmyoglobin, 30 m*M* cumene hydroperoxide, 25 m*M* nitrosobenzene, and 5% acetone-$d_6$ in 0.1 *M* Tris–HCl buffer, pH 9.0. (*a*) Complete signal; (*b*) low-field portion of the signal on an expanded magnetic field scale. Microwave power, 20 mW; modulation amplitude, 0.4 G; temperature, 22°C. (Reprinted from ref. 23 with permission.)

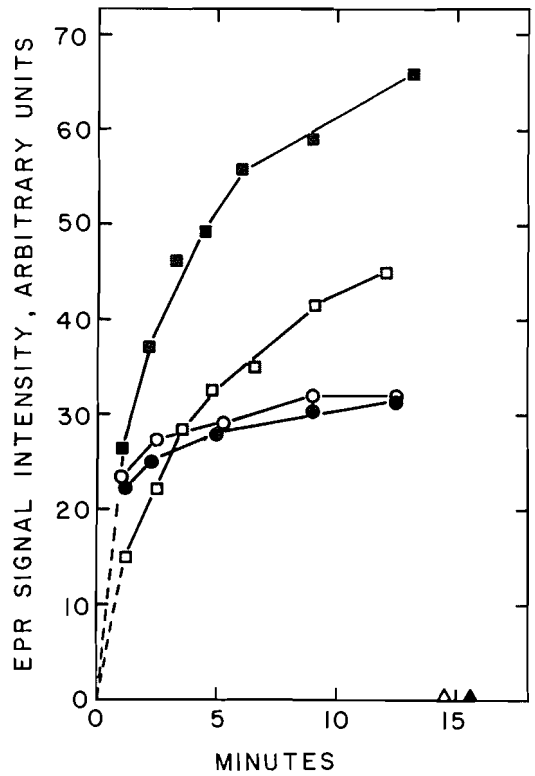

FIG. 6. Effect of aminopyrine on the epr signal amplitude of the nitrosobenzene spin adduct produced by the reaction of cumene hydroperoxide with metmyoglobin. The reaction mixtures contained 27.3 μ*M* metmyoglobin, either no aminopyrine (open symbols) or 40 m*M* aminopyrine (closed symbols), and additional components, as described, in 0.1 *M* Tris–HCl buffer, pH 9.0 with 5% acetone-$d_6$: (□, ■), 7.5 m*M* nitrosobenzene and 10 m*M* cumene hydroperoxide; (○, ●), 25 m*M* nitrosobenzene and 30 m*M* cumene hydroperoxide. Control experiments (△, ▲): metmyoglobin was omitted. Other conditions as given in Fig. 5 legend. For clarity of presentation, the instrument gain was 1.67 times larger for the open and filled square symbols. (Reprinted from ref. 23 with permission.)

when the concentration of aminopyrine was much larger than that of nitrosobenzene. This experiment was possible because the aminopyrine radical (Fig. 2) was not detected at the alkaline pH which was optimal for formation of the spin adduct of nitrosobenzene (23). Also, addition of aminopyrine to the reaction after the epr signal had attained its maximal intensity produced no effect, indicating that aminopyrine does not react directly with the nitroxide.

The reaction scheme shown in Fig. 7 provides a consistent explanation of the experimental results obtained by the use of two nitroso spin traps as probes of the reaction of metmyoglobin with cumene hydroperoxide. With nitrosobenzene, the initially-formed spin adduct is considered to be the unstable

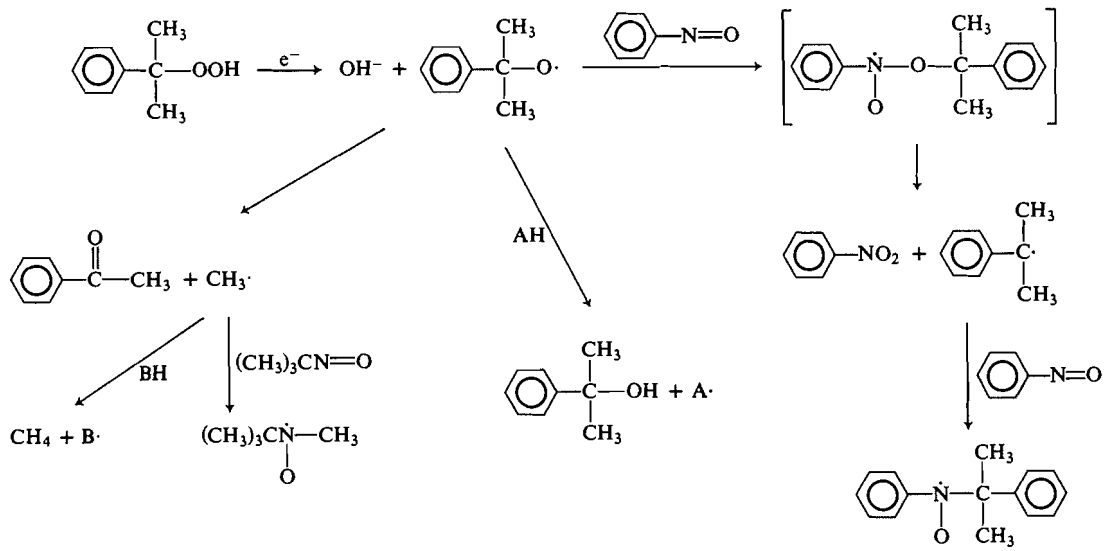

FIG. 7. Proposed mechanism for the metmyoglobin-initiated radical decomposition of cumene hydroperoxide, including the trapping reactions of MNP and nitrosobenzene. AH and BH are electron donors.

phenylcumyloxynitroxide, which decomposes to nitrobenzene and the cumyl radical; subsequent trapping of the cumyl radical by nitrosobenzene produces the stable nitroxide detected by epr. Evidence for the identity of this trapped species as the cumyl radical was previously published by Terabe and Konaka (25), who studied the trapping reactions of a series of aromatic nitroso compounds in purely chemical systems. They reported the hyperfine splitting constants of an epr signal which developed when a solution of cumene hydroperoxide and nitrosobenzene in benzene was heated (25). We observed that benzene extraction of the nitroxide produced in aqueous solutions of metmyoglobin, cumene hydroperoxide, and nitrosobenzene decreased the hyperfine splitting constants to those observed under Terabe and Konaka's experimental conditions (23, 25), Table 2. Those workers based their identification upon a number of control experiments with cumene, which gave identically the same epr signal (25). The same nitroxide has been generated by photochemical means, which established the structure rather conclusively as phenylcumylnitroxide (26). A comparison of the hyperfine splitting constants of this nitroxide with those reported for phenylbutylnitroxide (27) and phenylbutoxynitroxide (28), shown in Table 2, supports the assignment of a trapped cumyl radical. Finally, the failure to detect the methyl radical trapped by nitrosobenzene or by MNP in the presence of nitrosobenzene can be attributed to very efficient trapping of the cumyloxy radical by nitrosobenzene, Fig. 7.

The stimulatory effect of aminopyrine on the nitroxide radical produced in the presence of nitrosobenzene can also be explained by this scheme, Fig. 7: the requirement for a large excess of aminopyrine relative to nitrosobenzene is consistent with efficient trapping of the cumyloxy radical by the nitroso compound. Those cumyloxy radicals which escape trapping at low concentrations of the trap will lead to one-electron oxidation of aminopyrine, either directly or by the methyl radical product of β scission of the cumyloxy radical (9). The additional phenylcumylnitroxide formed in the presence of aminopyrine is attributed to one-electron reduction of cumene hydroperoxide by the aminopyrine radical (cf. reaction [3]), which sustains the radical chain reaction. The stimulation of the $Fe^{2+}$-induced decomposition of cumene hydroperoxide by hydroquinone (9) has been proposed to involve the semiquinone radical in a similar role. Control experiments showed that aminopyrine, even at high concentrations, could not initiate formation of phenylcumylnitroxide in the absence of metmyoglobin. However, aqueous solutions of cumene hydroperoxide and nitrosobenzene, in the absence of the hemeprotein, slowly developed the same epr signal which formed rapidly in the presence of the enzyme (Fig. 6).

Although the experimental observations support the proposed origin of the cumyl radical, i.e., as a decomposition product of phenylcumyloxynitroxide, other possible sources of the cumyl radical were considered and eliminated. Cumene present as a contaminant in the hydroperoxide could be

oxidized to the cumyl radical. However, the hydroperoxide was highly purified, with no detectable cumene. Moreover, addition of low levels of cumene to the metmyoglobin – cumene hydroperoxide system containing nitrosobenzene produced no significant effect on the amplitude of the epr signal. Another potential source of the cumyl radical is reversible dissociation of $O_2$ from the cumylperoxy radical (29). While we obtained no direct evidence for formation of the cumylperoxy radical in these reactions, it should arise by transfer of a hydrogen atom from the hydroperoxide to the cumyloxy and methyl radicals in the absence of any other electron donors (28). However, in the presence of a good electron donor like aminopyrine, the cumylperoxy radical is not expected to be formed; even if it were formed, it should play no significant role in the oxidation of aminopyrine because of the characteristically low reactivity of peroxy radicals in hydrogen atom abstraction (29). This has been clearly demonstrated by the recent publication (30) of absolute rate constants for hydrogen atom abstraction from a carbon α to a nitrogen (quite analogous to the oxidation of aminopyrine, reaction [3]) effected by *t*-butoxy and *t*-butylperoxy radicals; the alkoxy radical was more reactive by a factor of $10^5$ to $10^6$ (30).

Rosen and Rauckman detected in a system containing hematin, cumene hydroperoxide, and DMPO a nitroxide assigned to the cumylperoxy adduct of the nitrone (31). However, this species was detected only weakly at pH 3.0, where nitrones readily undergo acid-promoted hydrolysis. There is other experimental evidence (40) that alkylperoxy spin adducts of nitrones are highly unstable, particularly at temperatures greater than 0°C. We must conclude that the identity of the nitroxide reported by Rosen and Rauckman (31) is uncertain, and that the proposed role of the cumylperoxy radical is not supported by their data. Available data indicate that in aqueous solutions the common nitroso and nitrone spin traps are not suitable for positive identification of oxygen-centered organic radicals. However, the use of nitrones appears to be subject to more oxidation artefacts, i.e., 5,5-dimethylpyrrolidone-(2)-oxyl-(1) (31, 40), than is the use of nitroso spin traps.

*Studies with liver microsomes*

For spin trapping experiments with cumene hydroperoxide and liver microsomal fractions containing the membrane-associated hemeprotein cytochrome P-450, nitrosobenzene was chosen because of the stability of the spin adduct and the greater detection sensitivity for this radical. As shown in Fig. 8, the epr signal detected in this system clearly contained the sharp resonances of phenylcumylnitroxide and another broad component, considered to be the membrane-associated fraction of the same nitroxide (32); the broadening is attributed to slower rotational motion of the nitroxide in the membrane and measurable paramagnetic exchange interaction with $O_2$, present at a higher concentration in the lipid phase of this system. It was observed that: (*1*) this epr signal was considerably less stable in microsomes than in the model system, and (*2*) all control experiments except one were negative: microsomes containing only nitrosobenzene gave a very weak epr signal quite distinct from that detected with both cumene hydroperoxide and nitrosobenzene present. This epr signal was consistent with that reported for the phenylhydronitroxide radical (33), suggesting that it arises from reduction of nitrosobenzene by substances in the microsomes. This epr signal was destroyed by oxidants such as *t*-butyl hydroperoxide, and also was not detected in the presence of cumene hydroperoxide. Significantly, metyrapone, a bipyridyl compound which is a specific inhibitor of cytochrome P-450, produced measurable inhibition (46%) of the epr signal detected with liver microsomes, cumene hydroperoxide, and nitro-

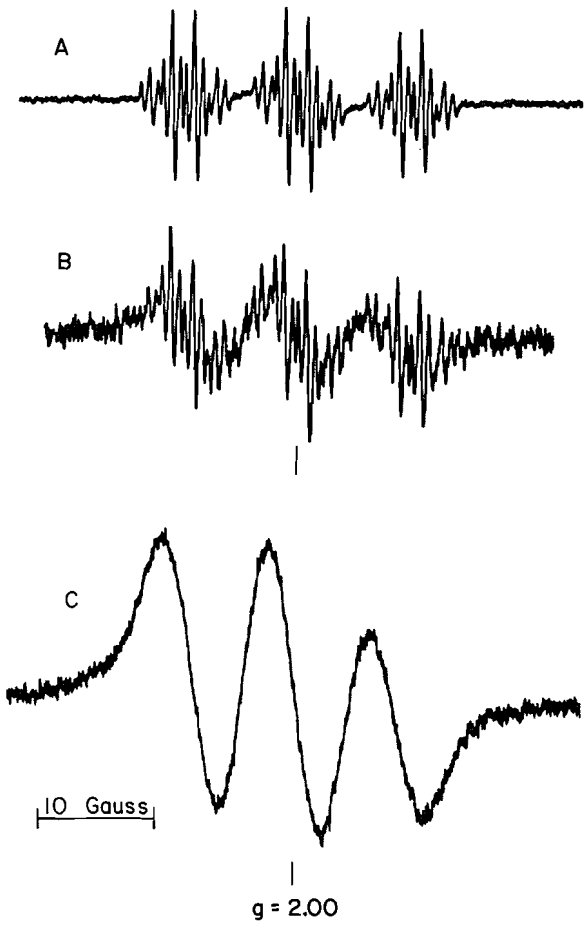

FIG. 8. Comparison of epr signals resulting from addition of metmyoglobin or rat liver microsomes to cumene hydroperoxide in the presence of nitrosobenzene. The reaction with metmyoglobin (*A*) was that described in the Fig. 5 legend. The reaction mixtures for *B* and *C* contained 18.8 μ*M* liver microsomal cytochrome P-450, 30 m*M* cumene hydroperoxide, 12.5 m*M* nitrosobenzene, and 2.5% acetone-$d_6$ in 0.1 *M* Hepes–Tris buffer, pH 6.5. Microwave power, 20 mW; modulation amplitude, 0.4 G (*A*, *B*) or 5.0 G (*C*); gain, $8 \times 10^2$ (*A*); $5 \times 10^3$ (*B*); $1.5 \times 10^3$ (*C*).

sobenzene, but had no effect on metmyoglobin-dependent generation of this nitroxide (32). Also, the metmyoglobin system was much more sensitive to inhibition by cyanide than was the microsomal system (32), consistent with the relative affinities of the two hemeproteins for this ligand. These results strongly implicated cytochrome P-450 as the initiator of cumene hydroperoxide decomposition in these liver microsomal fractions.

The possibility that inorganic iron, a likely contaminant of microsomes, could be responsible for the results obtained with microsomes was eliminated by control experiments. The addition of ferrous (but not ferric) ion to aqueous solutions of cumene hydroperoxide and nitrosobenzene (pH ~ 4.0) produced the phenylcumylnitroxide and also detectable levels of the less stable spin adduct of nitrosobenzene and the methyl radical. The $Fe^{2+}$-dependent reaction was also distinguished from that initiated by the hemeproteins by: (*1*) the requirement for $Fe^{2+}$ concentrations approximately 20-fold larger than the hemeprotein concentrations employed; and (*2*) complete inhibition of the epr signal by 10 m*M* EDTA. Neither hemeprotein–cumene hydroperoxide system displayed any sensitivity to EDTA. Moreover, the addition of 200 μ*M* $Fe^{2+}$ to microsomes had no effect on the epr signal detected in the absence of this metal ion.

The epr experiments indicated that nitrosobenzene trapped efficiently the initial radical arising from cumene hydroperoxide in the presence of hemeproteins or $Fe^{2+}$; but the failure to detect the spin adduct of the cumyloxy radical made independent confirmation of these results important, especially for the microsomal system. Spectral changes observed during the microsomal oxidation of aminopyrine by cumene hydroperoxide demonstrated the rapid formation of the violet aminopyrine radical, Fig. 9; however, the absorbance con-

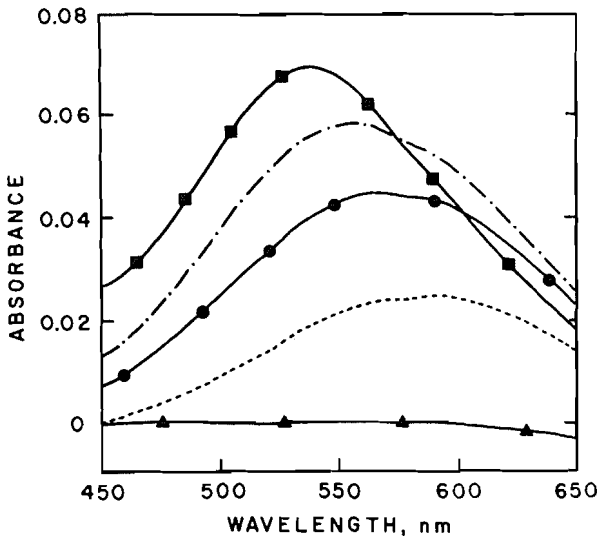

FIG. 9. Spectral changes observed during the microsomal oxidation of aminopyrine by cumene hydroperoxide. A solution containing 1 mg total microsomal protein/mL in 50 m*M* Hepes–Tris buffer, pH 6.5, with 0.15 *M* KCl, 10 m*M* $MgCl_2$, and 30 m*M* aminopyrine was added to both sample and reference cuvets, and the baseline was recorded (▲). The spectrum was scanned at the indicated times after addition of 0.25 m*M* cumene hydroperoxide to the sample cuvet: 15 s (---), 1 min (●), 3 min (—·—·), and 5 min (■), which corresponded to the maximal absorbance increase. The spectrum recorded at 1 min is nearly identical to that of the aminopyrine radical produced in other enzymatic oxidizing systems (18). (Reprinted from ref. 34 with permission.)

tinued to increase with a concomitant shift in the absorbance maximum from 560 nm to 535 nm, followed by a slower decay and a further shift of the absorbance maximum to 527 nm (34). It was shown that oxidation of 4-aminoantipyrine by microsomes and cumene hydroperoxide, or other oxidizing systems, produced a 525 nm-absorbing chromophore; this species had been identified from earlier studies of the chemistry of 4-aminoantipyrine as antipyrine red, a coupling product of two molecules of the parent compound (35). We note that 4-aminoantipyrine is the product of oxidative cleavage of two *N*-methyl groups from the amino group of aminopyrine (cf. Fig. 1) and is oxidized much more easily than aminopyrine (13). Thus, the spectral changes of Fig. 9 are considered to represent initial formation of the aminopyrine radical, followed by rapid loss of two *N*-methyl groups from the radical, and subsequent oxidation of the product, 4-aminoantipyrine, to antipyrine red. This reaction sequence apparently occurs even though the aminopyrine concentration is considerably larger than the concentration of both cumene hydroperoxide and 4-aminoantipyrine which is formed; the localization of these reactions in the microsomal membrane, which has a limited capacity for the very water-soluble aminopyrine, is probably responsible for this phenomenon. The important point for this study, however, is that nitrosobenzene very effectively inhibited the absorbance changes which occurred during the microsomal oxidation of aminopyrine by cumene hydroperoxide (Fig. 10), or the oxidation of 4-aminoantipyrine by this system (34). The sensitivity of spectrophotometric detection of the aminopyrine radical (15, 18) and the adequate solubility of nitrosobenzene in $H_2O$ made the use of organic solvents unnecessary in these experiments.

Nitrosobenzene also inhibited another reaction – the consumption of molecular $O_2$ — which occurs when cumene hydroperoxide is added to liver microsomes (34); the concentrations of nitrosobenzene which produced significant inhibition of this reaction (Fig. 11) and the microsomal oxidation of aminopyrine by cumene hydroperoxide (Fig. 10) were very similar. Both phenomena dependent on cumene hydroperoxide — aminopyrine oxidation and $O_2$ consumption — were similarly inhibited by metyrapone and known substrates of liver microsomal cytochrome P-450. The $O_2$ consumption was attributed to autoxidation (peroxidation) of unsaturated membrane lipids initiated by one or more of the radical species derived from cumene hydroperoxide. This proposal was tested by control experiments with a model system in which metmyoglobin

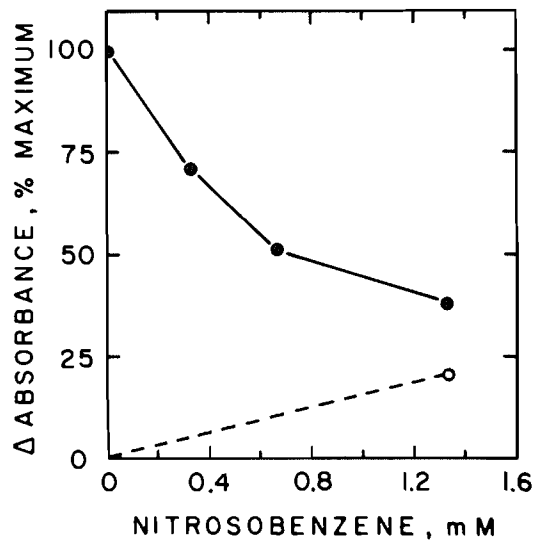

FIG. 10. Effect of nitrosobenzene on the maximal absorbance measured during the microsomal oxidation of aminopyrine by cumene hydroperoxide. Experimental conditions were identical to those described in the Fig. 9 legend, with nitrosobenzene added at the indicated concentrations (●). The maximal absorbance increase which developed near 535 nm was measured. The control experiment (○), in which aminopyrine was omitted, developed a measurable, but featureless, absorbance in the visible region. (Reprinted from ref. 34 with permission).

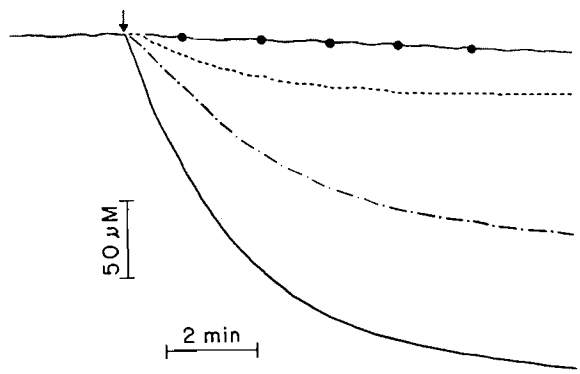

FIG. 11. Effect of nitrosobenzene on $O_2$ consumption resulting from addition of cumene hydroperoxide to rat liver microsomes. Experimental conditions were identical to those described in the Fig. 9 legend, except that aminopyrine was omitted and nitrosobenzene was added at the stated concentrations: —, 0; ----, 0.33 m*M*; ---, 0.67 m*M*; ●, 1.33 m*M*. The reaction was initiated by adding 0.25 m*M* cumene hydroperoxide at the point indicated by the arrow. The $O_2$ concentration was monitored continuously by a Clark-type electrode in stirred solutions within a cell which was closed to the atmosphere and maintained at 25°C. (Reprinted from ref. 34 with permission.)

and arachidonic acid were substituted for cytochrome P-450 and for the unsaturated membrane lipids of the microsomes. In the absence of arachidonic acid, no measurable $O_2$ uptake occurred in aqueous solutions of metmyoglobin and cumene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

hydroperoxide under the experimental conditions of Fig. 11. With 0.3 m*M* arachidonic acid also present, the rate of $O_2$ consumption dependent on cumene hydroperoxide was somewhat lower than the control rate observed for the microsomal system (Fig. 11). At relatively higher concentrations of arachidonic acid, low levels of contaminating hydroperoxides formed by air oxidation of this compound were sufficient to sustain $O_2$ consumption with metmyoglobin without any requirement for cumene hydroperoxide. Significantly, both the cumene hydroperoxide-dependent and -independent $O_2$ uptake in the metmyoglobin/arachidonic acid system were inhibited by levels of nitrosobenzene which were effective in the analogous microsomal reaction (Fig. 11). Finally, it was shown that cyanide, but not metyrapone, could inhibit metmyoglobin-initiated autoxidation of arachidonic acid. The inhibitory effect of nitrosobenzene on hemeprotein-initiated autoxidation of unsaturated lipids is also consistent with the trapping of a carbon-centered radical produced by hydrogen atom abstraction from the lipid molecule. Enzymatic oxygenation reactions of polyunsaturated fatty acids have been probed by 2-methyl-2-nitrosopropanol (36), MNP (37), and nitrosobenzene (38); in each case, a secondary carbon-centered radical adduct of the nitroso compound was identified by its epr spectrum (36–38). However, epr data obtained with the lipid-free model system in our study have provided the best evidence for the point of nitrosobenzene inhibition of the radical decomposition of cumene hydroperoxide initiated by hemeproteins. Based on various kinds of experimental data obtained with two spin traps, as well as numerous similarities between the model system containing metmyoglobin and the microsomal system containing cytochrome P-450, we conclude that the reaction sequence of Fig. 7 accounts for the major reactions that occur in the hemeprotein-initiated decomposition of cumene hydroperoxide, in the absence or presence of nitroso spin traps.

These experimental results indicate that reactive one-electron oxidants produced by the addition of cumene hydroperoxide to liver microsomes are responsible for both aminopyrine oxidation and initiation of autoxidation of unsaturated lipids. The findings that rather low levels of nitrosobenzene significantly inhibited both reactions, taken with the epr spin trapping data, strongly implicate the cumyloxy and/or methyl radicals as the oxidizing species. The reactions initiated by adding cumene hydroperoxide to liver microsomes clearly required cytochrome P-450, since metyrapone, a specific and high-affinity ligand of this hemeprotein, was an excellent inhibitor of these reactions. The results obtained with metmyoglobin and cumene hydroperoxide were analogous, with this system, however, showing sensitivity to inhibition by cyanide, a known ligand of metmyoglobin. The ability of $H_2O_2$ (and certain organic hydroperoxides and peroxy acids) to oxidize ferric hemeprotein peroxidases to species containing Fe(IV) (1–3) suggests that those hemeproteins which react with cumene hydroperoxide may transfer a single electron to this oxidant. The products of this reaction would presumably be the cumyloxy radical and an Fe(IV) heme species of unknown structure. It also seems likely that the heme group in this or other oxidation state of the enzyme is attacked by one or both of the hydroperoxide-derived radicals which are responsible for oxidation of other electron donors. Indeed, we have observed that destruction of the heme group of metmyoglobin by cumene hydroperoxide can be inhibited by aminopyrine or nitrosobenzene. Also, recent evidence was published for the reaction of methyl radicals with ferric, ferrous, and iron-free deuteroporphyrin (39). The low selectivity of the organic free radical oxidants derived from cumene hydroperoxide in the presence of hemeproteins can, thus, account for all of the phenomena which have been observed in these systems.

These experiments are now being extended to other hemeproteins, as well as other organic hydroperoxides. With hemin and catalase, the same cumene hydroperoxide-derived radicals trapped by MNP and nitrosobenzene have been detected; both heme compounds also exhibit low peroxidatic activities with this hydroperoxide. However, horseradish peroxidase shows no reactivity with cumene hydroperoxide by any of the techniques employed in this study. These results suggest that, while the high catalytic activities of hemeprotein peroxidases with $H_2O_2$ and a limited number of other peroxidic agents derive from the characteristic reactivity of iron and its chelated forms with peroxides, evolutionary development of the protein structures of peroxidases has modified this reactivity to prevent the formation of reactive oxidizing radicals from the oxidant. The advantage to these enzymes of such altered reactivity would appear to be self-preservation, so that "the show (efficient catalysis) may go on". Those hemeproteins with biological functions not directly related to efficient catalytic reduction of hydroperoxides have retained to varying degrees the ability to effect one-electron reduction of hydroperoxides, which accounts for their low peroxidatic activities. Finally, it seems appropriate to emphasize what

others (40) have cautioned about spin trapping applications, especially in biological systems: a critical approach is essential. In addition to using several spin traps to investigate a given system, and other experimental techniques in conjunction with epr, it is necessary to perform all possible control experiments. Only then can one draw definitive conclusions about the formation and possible significance of free radicals in the system under study.

# Photochemistry of protein and nucleic acid constituents: electron spin resonance and spin-trapping with 2-methyl-2-nitrosopropane

PETER RIESZ AND IONEL ROSENTHAL[1]

*Laboratory of Pathophysiology, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205, U.S.A.*

Received August 10, 1981

PETER RIESZ and IONEL ROSENTHAL. Can. J. Chem. **60**, 1474 (1982).

Our recent studies of the direct uv-photolysis of aliphatic and aromatic peptides, DNA constituents, and their 5-haloderivatives in aqueous solution and the photo-induced reactions of benzoylperoxide with amino acids, peptides, fatty acids, and pyrimidines in dimethylsulfoxide-containing solutions are reviewed.

2-Methyl-2-nitrosopropane was used for spin-trapping and characterization of free radicals generated photochemically with light in the wavelength range of 220–313 nm in aqueous or aprotic solvents. Direct photolysis of aliphatic dipeptides and of phenylalanine peptides produced mostly decarboxylation radicals, while for tyrosine peptides both decarboxylation and deamination radicals were spin-trapped; for tryptophan di- and tripeptides, deamination radicals were predominantly produced, while for long chain polypeptides, main-chain scission was observed.

When pyrimidine bases were photolysed, radicals consistent with the addition of an H-atom or an OH-radical at the C(5) position of the 5,6-double bond could be detected. The general reaction pattern in the photolyses of 5-chloro, bromo, or iodouracil was the homolytic cleavage of the carbon–halogen bond, while for 5-fluorouracil, the α-fluoro radical was spin-trapped.

Dibenzoylperoxide was found to photoinduce the free radical generation in amino acids, peptides, and fatty acids exposed to ultraviolet light, which is not absorbed by these compounds, that is, $\lambda = 313 \pm 10$ nm. The most predominant reaction is the decarboxylation of the terminal acid moiety. This process is explained by an electron transfer from the acid to the photoexcited peroxide or its fragmentation products. Pyrimidine bases, such as cytosine and thymine, can be oxidized under these conditions to generate C(5) centered radicals.

PETER RIESZ et IONEL ROSENTHAL. Can. J. Chem. **60**, 1474 (1982).

On passe en revue nos récentes études sur la photolyse direct uv des peptides aromatiques et aliphatiques, des constituants de l'ADN et de leurs dérivés halogénés en solution aqueuse ainsi que les réactions photo-induites du peroxyde de benzoyle avec les acides aminés, les peptides, les acides gras et les pyrimidines dans des solutions contenant du diméthylsulfoxyde.

Nous avons utilisé le méthyl-2 nitroso-2 propane comme capteur de spin et pour caractériser les radicaux libres produits photochimiquement avec une lumière dont la longueur d'onde varie de 220 à 313 nm dans des solvants aqueux ou aprotiques. La photolyse directe des dipeptides aliphatiques et des peptides contenant de la phénylalanine produit surtout des radicaux de décarboxylation, tandis que dans les cas des peptides contenant la tyrosine, on a capté des radicaux de décarboxylation et de désamination. Dans le cas des di- et des tripeptides du tryptophane, on obtient surtout des radicaux de désamination tandis que l'on observe une scission de la chaîne principale dans le cas des longues chaînes de polypeptides.

Quant on photolyse les bases du type pyrimidine, on détecte des radicaux qui correspondent à l'addition d'un atome d'hydrogène ou d'un radical OH sur le carbone en position 5 de la double liaison en position 5,6. Le schéma général des photolyses du chloro-5, bromo-5 ou iodo-5 uracile est le clivage homolytique de la liaison carbone–halogène tandis que dans le cas du fluoro-5 uracile il y a piégeage de spin du radical α fluoro.

On a trouvé que le peroxyde de dibenzoyle induit photochimiquement la formaton de radicaux libres dans les acides aminés, dans les peptides et les acides gras exposés à lumière ultraviolette que ces composés n'absorbent pas soit à $\lambda = 313 \pm 10$ nm. La décarboxylation de l'unité acide terminale constitue la réaction la plus courante. On explique cette réaction par un transfert d'électron de l'acide au peroxyde excité photochimiquement ou à ses produits de fragmentation. Les bases du type pyrimidine telles la cytosine et la thymine peuvent être oxydées dans ces conditions en produisant des radicaux centrés en C(5).

## Introduction

The damaging effects of ultraviolet light on biological systems have been extensively described in the literature. Correlations have been made between survival of uv-irradiated cells and the production of certain types of photochemical damage in their DNA. Vital proteins and enzymes are denatured and inactivated due to changes which could be traced to particular amino acid residues. Finally, DNA and protein could be photochemically cross-linked in cells (1, 2).

The understanding of these effects requires basic knowledge of the primary chemical events which followed the light absorption. In this respect, esr provides the experimental tool for detecting the initial transients generated in response to the specific energy input in a certain chromophore moiety of a complex biological polymer.

With the advent of the spin-trapping method (3, 4), it is now possible to gain information about free radicals generated at physiological temperatures without suppressing thermally activated processes

and hydration interaction with the solvent. We have extensively used 2-methyl-2-nitrosopropane (MNP) for trapping and characterization of free radicals generated in protein and nucleic acid constituents over a wide range of wavelengths of (220–313 nm) by direct or sensitized photolyses.

## Experimental

Aqueous solutions of MNP (1.5 mg/mL) were prepared by stirring overnight at room temperature. Dimethylsulfoxide solutions were prepared by stirring MNP (15 mg) and dibenzoylperoxide (50 mg) in 10 mL of solvent for 15 min. The photolyses were performed *in situ* at room temperature in aerated solutions, in a standard aqueous quartz cell placed in the esr cavity, using a Schoeffel 1000 W high pressure Hg–Xe lamp coupled with a grating monochromator. The irradiation times varied between 10 s up to 45 min. A Varian E-9, X-band spectrometer was used for esr measurements. The spectra from spin-trapped radicals were recorded at room temperature as first derivatives. The magnetic field modulation frequency was 100 kHz, and 10 mW of microwave power were used.

In many cases a large di-*tert*-butyl nitroxide (DTBN) signal prevented the identification of the underlying spectrum due to other radical species. Two methods were used to remove the DTBN signal: one was to adjust the pH to about 4 and allow the DTBN signal to decay, since it generally decayed faster than the other spin-adducts; the other was to extract the DTBN formed after irradiation with petroleum ether (boiling range 37–55°C). Except in some instances, where the spin-adduct was also soluble in the organic phase, good results were generally obtained. The procedure was the following: after irradiation of the esr cell outside the cavity, which was often carried out three or four times to expose the entire flat part of the cell to the uv beam, the solution contained in the cell was transferred to a small test tube and extracted three times with an equal volume of petroleum ether. The aqueous phase was then transferred back into the cell and the spectrum recorded. The spectrum before extraction was usually also recorded in order to check for possible loss of signals other than DTBN.

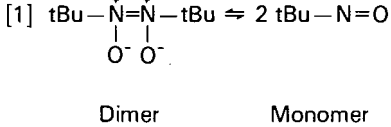
## Results and discussion

### A. *Direct photolyses in aqueous solutions*

#### I. *MNP*

Since MNP became a part of the system investigated, knowledge of its photochemical properties is required.

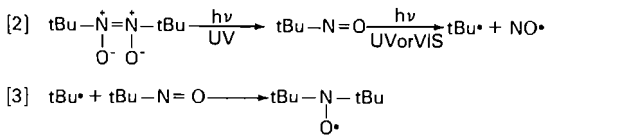
In aqueous solution, MNP exists in a monomer–dimer equilibrium (eq. [1]) (5).



[1] $tBu-\overset{+}{N}(O^-)=\overset{+}{N}(O^-)-tBu \rightleftharpoons 2\ tBu-N=O$

Dimer Monomer

After 12 h at 30°C the monomer concentration reaches its maximum value (ca. 60%). The aqueous MNP exhibits a light absorption at 662 nm due to the monomer, and more intense absorptions at 287 and 224 nm attributed mainly to the dimer. The photochemistry of MNP in water has not been studied, but the following reactions (eqs. [2], [3]) are known to occur in organic solvents (6, 7):



[2] $tBu-\overset{+}{N}(O^-)=\overset{+}{N}(O^-)-tBu \xrightarrow[UV]{h\nu} tBu-N=O \xrightarrow[UVorVIS]{h\nu} tBu^{\bullet} + NO^{\bullet}$

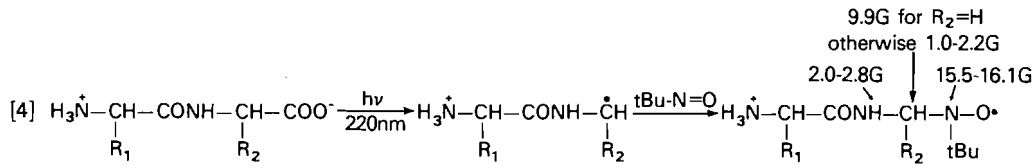
[3] $tBu^{\bullet} + tBu-N=O \longrightarrow tBu-\underset{O^{\bullet}}{N}-tBu$

We assume that the generation of this undesired di-*tert*-butyl nitroxide radical was the reason for the lack of enthusiasm in using MNP for spin-trapping in photochemical reactions (8). However, we found that frequently the formation of di-*tert*-butyl nitroxide can be entirely avoided by choosing the right experimental conditions such as reactant concentration and irradiation time. Even when produced, its very simple and characteristic esr expression (a sharp triplet of hyperfine splitting constant which is solvent dependent) has a minimal interference with the spin-adduct and can be easily subtracted. When, however, the concentration of the spin-adduct of interest is very low compared to di-*tert*-butyl nitroxide, two methods could be used to remove this undesired signal: one is to adjust the pH to about 4 and allow it to decay, since it generally decays faster than the other spin adducts; the second is to extract it with petroleum ether after photolysis. Except in instances when the spin-adduct is also soluble in the organic phase, useful results can be obtained. We note, however, that occasionally the excessive formation of di-*tert*-butyl nitroxide is symptomatic of a different process. Thus, during an attempt to detect free radicals following the photoexcitation ($\lambda_{exc}$ = 365 nm) of psoralens (5-hydroxy psoralen, trioxsalen, and 8-methoxypsoralen) in a dimethylsulfoxide solution, di-*tert*-butyl nitroxide was generated exclusively in amounts much larger than in control experiments performed under identical conditions but in the absence of psoralens. We suggest that psoralens photosensitize the homolytic breakdown of MNP (unpublished results from this laboratory).

#### II. *Protein constituents*

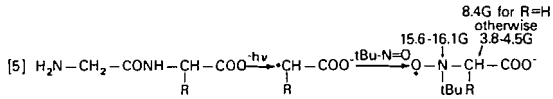
The absorption spectrum for peptide bonds shows a peak in the region of 180–190 nm which decreases essentially to zero by about 240 nm (9). It was found that the direct photolyses of aliphatic dipeptides of the types X-Gly, Gly-X, X-Ala, and Ala-X in aqueous solution with 220 ± 10 nm light, generated free radicals as a result of decarboxylation (eq. [4]) (10).

In these dipeptides no scission between the two amino acids residues was observed. The reaction was found to occur over a wide pH range from 2 to



11.5; however, the yield of decarboxylation radicals rises steeply in acid solution below pH = 3.5, suggesting an increase with the concentration of the nonionized form of the carboxyl group.

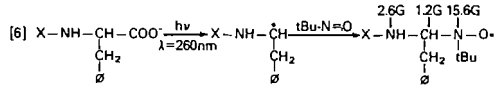
In strongly alkaline solutions (9 *M* NaOH) this reaction does not occur and only secondary deamination radicals were detected (eq. [5]).

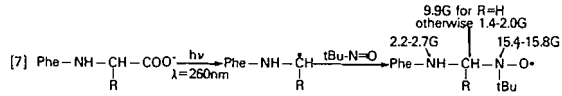


The photolyses of several polypeptides of the type $(Ala)_n$ where $n = 3-90$ was investigated in aqueous solution in order to ascertain whether the decarboxylation radical of the C-terminal residue was the only radical product or whether main-chain scission would occur. The experiments were carried out with solutions containing 10 mg/mL of the polypeptide, and all other conditions of the experiment (spin-trap concentration, pH, duration of photolysis) were kept constant. Under these conditions the concentration of peptide bonds is kept constant while that of the C-terminal carboxyl group decreases with increasing chain length. If the radical products arise only from the C-terminal carboxyl residue, the yield of the decarboxylation radical would be expected to decrease when the number of alanine residues increases from 2 to 90. However, the results indicate that main-chain scission must occur since the radical yield does not decrease appreciably when the average number of alanine residues in the polypeptide is 90.

As a model compound for proteins, poly (Gly-LAla-LPro)$_{12}$ was photolysed. This amino acid sequence frequently occurs in collagen which is the major component of the cornea of the eye. The major radical formed with this compound is the same as the one observed from polyalanine. This indicates that the chain scission occurs predominantly between the alanine and proline residues.

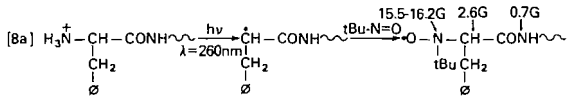
Photodecarboxylation is not limited to aliphatic peptides. It was also found to occur in phenylalanine-containing peptides (11). In this case, the reaction can also be induced by uv light of longer wave-length, that is 260 nm which is absorbed by the aromatic chromophore (eqs. [6], [7]).



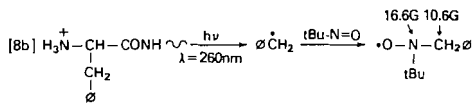


However, when the aromatic chromophore is excited the yield of decarboxylation is not sensitive to pH, and is independent of the state of ionization of the carboxyl group.

In Phe-X type dipeptides the primary deamination radicals were also detected (eq. [8a]).



Occasionally the spectrum of spin-trapped benzyl radical generated by photo-dissociation of the Phe residue overlapped the main signal (eq. [8b]).



When phenylalanine was embedded in a larger peptide such as ribonuclease-*S*-peptide, following photolyses, chain scission occurred to give a small fragment attached to the decarboxylation radical of the phenylalanine.

In tyrosine-containing peptides several reaction patterns could also be detected (12). While the direct excitation of the peptide bond with $\lambda = 220$ nm consistently generated the decarboxylation radicals, excitation of the aromatic chromophore with $\lambda = 265$ nm in neutral solution yielded a spin adduct formed by trapping of the fragment resulting from the scission between the $\alpha$ carbon atom and the methylene group attached to the aromatic ring (eq. [9]).

In addition, deamination radicals could also be detected. The relative yield of deamination adducts was found to be pH dependent, increasing with the increase in pH. As a model for longer proteins, the oxidized insulin A chain was uv-photolysed. This compound was chosen because it is a relatively short polypeptide (21 amino acids) and contains only two tyrosine residues at positions 14 and 19. In this case the only fragment which could be identified was tentatively attributed to the photoscission of the side chain of the tyrosine moiety. In alkaline medium an additional type of deamination spin adduct was observed which could be a deamination radical from any residue of the chain.

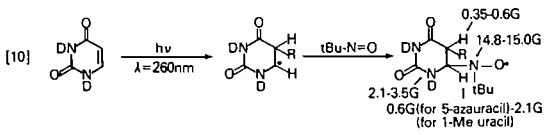
Finally, the photolyses of tryptophan-containing dipeptides ($\lambda = 280 \pm 10$ nm) was investigated (13). Consistently, these compounds generated the deamination radical of the N-terminal amino acid. These results were explained in terms of hydrated electrons photoejected from the tryptophan residue (14) reacting with the carbonyl group followed by deamination of the N-terminus. This mechanism was proved by a sensitization experiment using tryptophan as a sensitizer and glycine as substrate. The ultraviolet irradiation of a mixture of these two amino acids, with light of 280 nm absorbed exclusively by tryptophan, generated the deamination radical spin-adduct of glycine which has very characteristic hyperfine coupling constants (two equivalent β-protons, $a_H^\beta = 9.9$ G).

III. *Nucleic acid constituents*

The photochemical reactions of nucleic acids and their constituents have been the subject of extensive investigations in recent years in attempts to clarify, at the molecular level, the ultraviolet induced damage of living systems. Thus, major photochemical products of pyrimidines such as cyclobutane-type dimers and photohydrates have been correlated to biological effects (15).

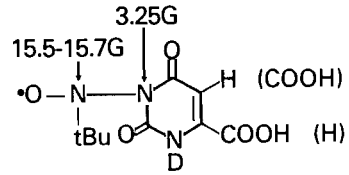
We found that direct photolyses of several pyrimidine bases (uracil and substituted derivatives) in aqueous solution ($D_2O$), at room temperature generated free radicals which could be trapped by MNP and characterized (16).

The general reaction pattern is exemplified for uracil in eq. [10] and is consistent with the addition of an unidentified radical (D or OD) at the C(5) position of the uracil ring.



The added radical was unambiguously identified as H when 5-azauracil was photolysed in $H_2O$.

Orotic and isoorotic acid behaved differently. Both these compounds afforded identical 3 × 3 lines spectra suggestive of a radical localized at N(3).

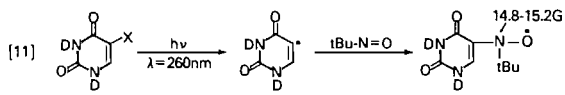


It is, however, noted that in the nucleosides tested, uridine and 2-deoxyuridine, the addition of the D-atom took place at C(6) to yield a paramagnetic center localized at C(5).

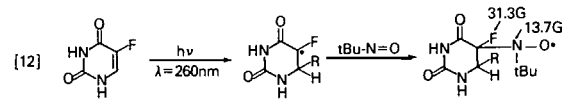
All these results indicate that the photochemical excitation of pyrimidine bases yields free radicals as a general phenomenon. While these species cannot lead to the formation of the major photoproducts in irradiated nucleic acids, such as cyclobutane-type dimers and photohydrates, they may precede the formation of dihydropyrimidines and other pyrimidine bimolecular photoproducts.

It is well known that the incorporation of 5-halogenated derivates of uracil in DNA causes an increased sensitivity to the lethal effect of uv-irradiation (17). In order to obtain information concerning the mechanism of photosensitization, the free radicals produced in 5-halopyrimidines by direct uv photolyses in aqueous solution were studied (18).

The general reaction pattern in photolyses of 5-chloro, bromo, iodo uracil was the homolytic cleavage of the carbon–halogen bond (eq. [11]).



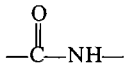
5-Fluorouracil reacted in a different manner; this was the addition of an unidentified radical (H· or OH) to the C(6) position (eq. [12]).



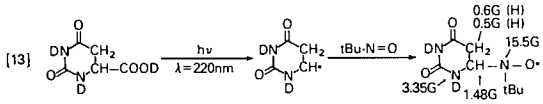
The same basic reactions could be detected when the corresponding nucleosides were photolysed. However, in these cases additional free radicals could be detected, which were tentatively attributed to the abstraction from the C(5′) position of the sugar moiety.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

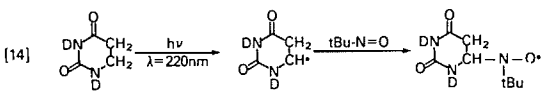
Finally, we investigated the photolyses of 5,6-dihydropyrimidines (19). The chromophoric group in these compounds is the amido moiety



and consequently their photolysis was expected to be induced by light of 220 nm which was required in the photolysis of aliphatic dipeptides. When 5,6-dihydroorotic acid was photolysed under these conditions, decarboxylation occurred at C(6), entirely analogous to the reaction of peptides (eq. [13]).



The same type of C(6) centered radical was detected when several alkyl derivatives of 5,6-dihydrouracils, dihydrothymines, and dihydrocytosines were photolysed. The reaction is exemplified for 5,6-dihydrouracil in eq. [14].



It was noted that the same radicals were trapped when polycrystalline samples of the parent compounds were γ-irradiated and subsequently dissolved in the spin-trap solution.

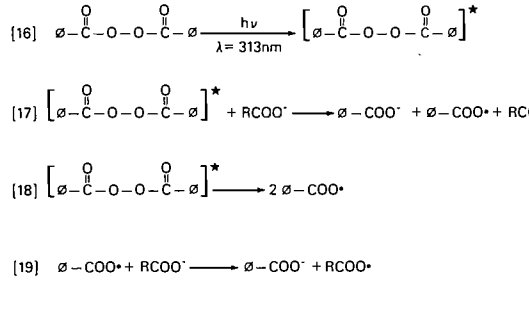
B. *Photolyses in organic solvents*

I. *Dibenzoylperoxide photo-induced reactions*

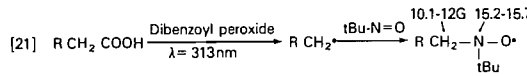
Dibenzoylperoxide can photoinitiate the free radical generation in amino acids and peptides by uv-light which is not absorbed by these compounds, that is $\lambda = 313$ nm. The most predominant reaction is the decarboxylation of the amino acids or of the carboxyl-terminal residue in peptides (eq. [15]) (20).

These reactions were performed in dimethylsulfoxide solutions without any interference from the solvent. Over 50 amino acids and dipeptides were tested and followed this reaction pattern. The hyperfine splittings varied between 14.55–15.00 G for nitroxide nitrogen, 2.5–3.0 G for the peptide nitrogen, and 1.0–1.8 G for the β nitrogen. When the glycine residue was terminal and consequently decarboxylated, the two equivalent β-hydrogens had the characteristic large splitting of 7.3 G.

Two mechanistic schemes could explain these results. Both are initiated by the light absorption by dibenzoylperoxide (eq. [16]). Dibenzoylperoxide has a broad adsorption band at $\lambda_{max} = 275$ nm (21) whose end absorption extends beyond 300 nm under our experimental conditions, thus acting as the exclusive light absorption system in the reaction mixture. Subsequently the nucleophilic attack of the carboxyl group cleaves the excited molecule (eq. [17]). Alternatively, the excited dibenzoylperoxide homolyses to benzoyloxy radicals (eq. [18]) which, by one-electron oxidation of the amino acid carboxyl group, generate the corresponding neutral radical (eq. [19]). This species dissociates spontaneously to $CO_2$ and to the trapped decarboxylation radical (eq. [20]).



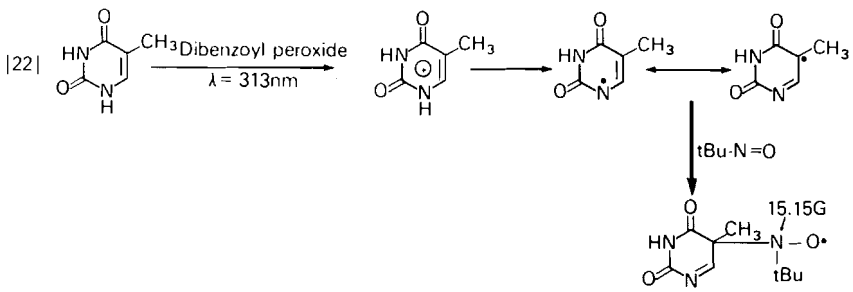
This reaction is not limited to amino acids. Carboxylic acids of different chain-lengths, from formic to linolenic, were tested and found to be decarboxylated by the photoexcited dibenzoylperoxide (22) (eq. [21]).



Even pyrimidine bases such as cytosine and thymine can be oxidized by a one-electron transfer under these reaction conditions to generate C(5) centered radicals (eq. [22]).

These results are of interest since dibenzoyl peroxide is extensively used as a topical medication for the treatment of facial acne (23) and was recently discovered to be a potent promoter of carcinogenesis (24).

The present review indicates that MNP is a useful spin-trap for identifying intermediate radical species in the photochemistry of protein and nucleic acid constituents. Since radicals produced in the photolysis of high molecular weight polypeptides (10–12) can be spin-trapped with MNP, it is reasonable to expect that in the future enzymatic hydrolysis followed by high performance liquid chromatography, which allows the separation of nitroxide radicals, will lead to the identification of



radicals in the photolysis of proteins and nucleic acids.

# Electron spin resonance of spin trapped radicals in γ-irradiated polycrystalline dipeptides. Chromatographic separation of radicals

KEISUKE MAKINO AND PETER RIESZ

*Laboratory of Pathophysiology, National Cancer Institutes, National Institute of Health, Bethesda, MD 20205, U.S.A.*

Received August 13, 1981

KEISUKE MAKINO and PETER RIESZ. Can. J. Chem. **60**, 1480 (1982).

Polycrystalline dipeptides (glycyl-glycine, glycyl-L-valine, glycyl-L-leucine, L-alanyl-glycine, and L-prolyl-L-alanine) were γ-irradiated at room temperature in the absence of air. Subsequently they were dissolved in aqueous solutions containing 2-methyl-2-nitrosopropane as the spin trap. From the esr spectra of the nitroxide radicals separated by high-performance liquid chromatography, structural assignments of the radicals were made. For glycyl peptides, H-abstraction from the α-carbon atoms of the carboxyl terminal residues and from the side-chains were observed. For L-alanyl-glycine, H-abstraction from the glycyl residue and the formation of the deamination radical could be shown to occur. For L-prolyl-L-alanine, the ring opening (deamination) reaction, decarboxylation and H-abstraction from the C-terminal α-carbon were seen.

KEISUKE MAKINO et PETER RIESZ. Can. J. Chem. **60**, 1480 (1982).

On a irradié aux rayons γ, à la température ambiante et en l'absence d'air, les dipeptides polycristallins suivants: (glycyl-glycine, glycyl-L-valine, glycyl-L-leucine, L-alanyl-glycine et L-prolyl-L-alanine). On les a ensuite dissous dans des solutions aqueuses contenant le capteur de spin, méthyl-2 nitroso-2 propane. A partir des spectres de rpe des radicaux nitroxydes, séparés par chromatographie en phase liquide à haute performance, on a pu déterminer les structures des radicaux. On a observé, dans le cas des peptides glycidiques, l'élimination d'un hydrogène à partir des atomes de carbone en α du residue terminal carbxyle et à partir des chaînes latérales. Dans le cas du L-alanyl-glycine, on peut montrer qu'il se produit une élimination d'hydrogène à partir du résidu glycyle et la formation d'un radical de désamination. Dans le cas du L-prolyl-L-alanine, on a observé une réaction d'ouverture de cycle (désamination), de décarboxylation et d'élimination d'un atome d'hydrogène à partir du carbone terminal en position 2.

[Traduit par le journal]

## Introduction

Among spin trapping studies, 2-methyl-2-nitrosopropane (MNP) has been utilized as one of the most informative spin traps (1–5). However, it is known that when the method of spin trapping with MNP is applied to γ-radiolysis in aqueous solutions, esr spectra obtained are often too complicated to be analyzed accurately. Recently this problem has been overcome by the combination of high-performance liquid chromatography and esr spectroscopy (6–12). By this method, each spin adduct present in the sample is separated and shows its individual esr spectrum.

It has been demonstrated previously that spin trapping with MNP can be applied to the study of the effect of ionizing radiation on polycrystalline solids (13–16). The solids are γ-irradiated and subsequently dissolved in aqueous MNP solutions. By this method, free radicals produced by γ-irradiation of polycrystalline amino acids, *N*-acetyl amino acids, and dipeptides have been analyzed (14). However, when the esr spectra overlap, only major components in the spectra obtained by spin trapping have been analyzed. Since single crystal esr studies of room temperature free radicals produced in such compounds are difficult, particularly when several different radicals are present, the spin trapping method appears to be helpful. For γ-irradiated dipeptides, only glycyl-glycine has been studied by single crystal esr (17) and nine dipeptides have recently been studied by ENDOR and ELDOR of the polycrystalline powder X-irradiated at 77 K and subsequently warmed to room temperature (18).

In the present work, the method of chromatographic separation of nitroxide spin adducts was applied to polycrystalline dipeptides irradiated at room temperature in the absence of air. It should be noted that the validity of this method depends on the stability of the nitroxide spin adduct on the column during the separation.

## Experimental

MNP was purchased from Aldrich Chemical Company and kept under $N_2$ at 5°C in the dark. Dipeptides were obtained from Sigma Chemical Company and Vega Fox Biochemicals.

Aqueous MNP solutions (5 mg/mL) were prepared by stirring in the dark for 1.5 h at 45°C (7).

Polycrystalline dipeptides samples were evacuated at $10^{-4}$ Torr for at least 24 h so that oxygen and moisture could not affect the production of free radicals. The evacuated samples were irradiated with $^{60}$Co γ-rays at a dose rate of $6.0 \times 10^5$ rad/h to a total dose of ca. 20 Mrad at room temperature and subsequently dissolved in the aqueous MNP solutions. The range of dipeptide concentrations was 10–100 mg/mL.

The sample solution (2.0 mL) was loaded on an IEX-210SC column (Toyo Soda, 3/8 in. id × 60 cm) which was attached to the chromatograph (Waters, Model 6000A). A Pyrex flow cell, which was fixed in the esr sample cavity, was connected to the exit of the column with ca. 0.25 mm id Teflon tubing. In order to obtain higher resolution, gradient elution was adopted. Eluents

were: 0.3 *M* phosphate buffer (pH 6.8) and 0.3 *M* NaOH–$Na_2HPO_4$ buffer (pH 10.8). Other chromatographic conditions were: pressure, ca. 200 psi; flow rate, 0.3 mL/min; temperature, ca. 25°C. The eluate was collected in a fraction collector after passing through the flow cell. During the separation, the magnetic field was fixed at one position and a high amplitude of 10 G modulation was applied to cover a wide range of signal. The collected fractions which showed the chromatographic radical peaks were measured by esr (Varian, E-9, X-band) in the standard aqueous flat cell.

## Results and discussion

In Figs. 1, 2 and 3, the esr spectra obtained from γ-irradiated polycrystalline glycyl dipeptides (glycyl-glycine (Gly-Gly), glycyl-L-valine (Gly-L-Val), and glycyl-L-leucine (Gly-L-Leu)) are shown. Figure 1 displays the original esr spectrum of γ-irradiated Gly-Gly, which was dissolved in an aqueous MNP solution. When this sample solution was loaded on the column, only one peak appeared in the chromatogram. From the fraction which gave the peak, the same spectrum as the original one was obtained. The spectrum changed with pH in acidic solution as shown in the same figure whereas it was not altered in alkaline solution. This suggests that

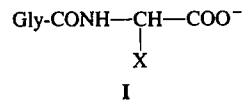
the nitroxide group is close to the carboxyl group. The stick diagram in the same figure shows that the spin adduct has a β-H and a β-N. Consequently the spectrum is assigned to structure **I**



**I**

where X = $^t$Bu—N(O•)— The parent radical of the spin adduct is formed by H-abstraction from the C-terminal carbon. The hyperfine coupling constants (hfcc) measured in the spectrum are listed in Table 1. This spin adduct has been previously identified (12, 17) and the parent radical of **I** has been found in the single crystal studies of Gly-Gly (19).

In Fig. 2(*a*), the original esr spectrum of γ-irradiated Gly-L-Val which was dissolved in the spin trap aqueous solution is shown. Overlapping lines are observed in the spectrum. By chromatographic separation, two different esr spectra were obtained as shown in Fig. 2 (*b*) and (*c*), respectively. The spectrum in Fig. 2 (*b*) consists of triplet split into a further triplet with a 1:1:1 intensity ratio. The

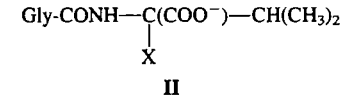
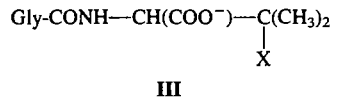
*All the values were obtained in neutral solutions.

primary splitting is due to a N nucleus in the nitroxide group and the secondary splitting is attributed to the β-N in the peptide group. The unusually broad lines imply that the spin adduct might contain γ-nuclei with different characteristics. Consequently the spectrum is assigned to the spin adduct formed by H-abstraction from the C-terminal α-carbon (**II**). The spectrum was unchanged with pH in alkaline solutions. The other spectrum shown in Fig. 2 (*c*) has only three lines, implying that the spin adduct does not have any β-nuclei. The only possible structure is



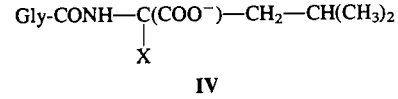
**II**



**III**

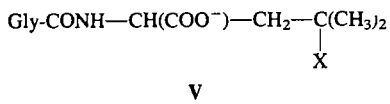
The untrapped free radical of **III** is produced by H-abstraction from the side-chain carbon of the C-terminal carbon. The hfcc of spin adduct **II** and **III** are shown in Table 1. The spin adduct **III** could not be found in a previous work (14).

Similar to the results obtained with Gly-L-Val, in the analogous experiment with Gly-L-Leu, a triple–triplet and a simple triplet were detected as shown in Fig. 3 (*b*) and (*c*), respectively. According to the assignment made for the spectrum in Fig. 2 (*b*), the spectrum in Fig. 3 (*b*) is assigned to structure **IV**. The parent radical of the spin adduct **IV** is formed by H-abstraction from the C-terminal α-carbon. The spectrum was unchanged with pH in alkaline



**IV**

solutions. The triplet in Fig. 3 (*c*) is also consistent with structure **V**. The hfcc of the spin adducts **IV** and **V** are summarized in Table 1.



**V**

Considering the results obtained in the γ-radiolysis and subsequent spin trapping of three glycyl dipeptides, the following facts were revealed: (*1*), The deamination radicals which are usually observed in the analogous experiments with amino acids are not detected. (*2*), The decarboxylation radical is not observed. (*3*), The major products are the spin adducts whose parent radicals are generated by H-abstraction from the C-terminal α-carbon and the carbon of the side-chain on the C-terminal residue. In previous papers (20, 21), it has been demonstrated that the deamination radicals, which are produced by the reaction of the hydrated electron with these three dipeptides and the decarboxylation radicals, which are generated by the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

reaction of $SO_4^{\cdot -}$ can be efficiently spin trapped with MNP.

From γ-irradiated polycrystalline L-Ala-Gly which was dissolved in an aqueous MNP solution, two kinds of esr spectra were detected by the method of chromatographic separation, as shown in Fig. 4 (*b*) and (*c*), respectively. The spin adduct giving the spectrum in Fig. 4 (*b*) was eluted very fast compared to the other one. As exhibited by the expanded spectrum of the $M_I = 0$ component of Fig. 4 (*b*) and by the stick diagram in the same figure, the primary N triplet is split into doublets due to a β-H which are further split into sextets with an intensity ratio of 1:4:7:7:4:1 by three equivalent γ-hydrogens and a γ-N. Consequently the spectrum can be assigned to the spin adduct which is produced by deamination, **VI**.

$$\begin{array}{l} CH_3—CH—CONH\text{-}Gly \\ \quad\quad\ | \\ \quad\quad\ X \end{array}$$

**VI**

The other spectrum shown in Fig. 4 (*c*) consists of a triplet which is further split into four lines due to a β-H and a β-N. The structure of the spin adduct is

$$L\text{-}Ala\text{-}CONH—CH(COO^-)—X$$

**VII**

The hfcc are listed in Table 1. Both the spin adduct **VI** and **VII** have been detected previously (14). In the same paper (14), the spin adduct produced by decarboxylation has been found.

Figure 5 (*a*) shows the original esr spectrum of γ-irradiated polycrystalline L-Pro-L-Ala dissolved in an aqueous MNP solution. The major component in the spectrum consists of a triplet further split into four lines. This has been analyzed previously (14) as the decarboxylation radical, **VIII**.

$$L\text{-}Pro\text{-}CONH—CH(CH_3)—X$$

**VIII**

Using chromatographic separation, two other spectra could be obtained from the same sample solution, as shown in Fig. 5 (*b*) and (*c*), respectively. The triple triplet in Fig. 5 (*b*) is attributed to a N nucleus in the nitroxide group and to a β-N nucleus

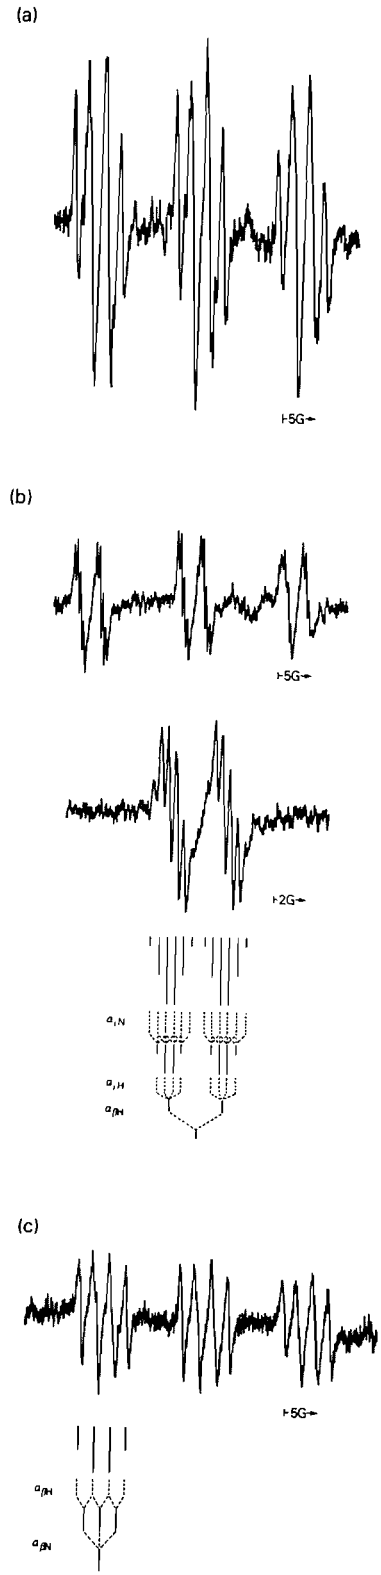


FIG. 4. (*a*), Electron spin resonance spectrum of polycrystalline L-Ala-Gly γ-irradiated at room temperature and subsequently dissolved in aqueous MNP solutions. (*b*) Electron spin resonance spectrum of the separated spin adduct and the expansion of the $M_I = 0$ component with the stick diagram. (*c*) Electron spin resonance spectrum of the separated spin adduct, which was eluted more slowly than that whose esr spectrum is shown in (*b*).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

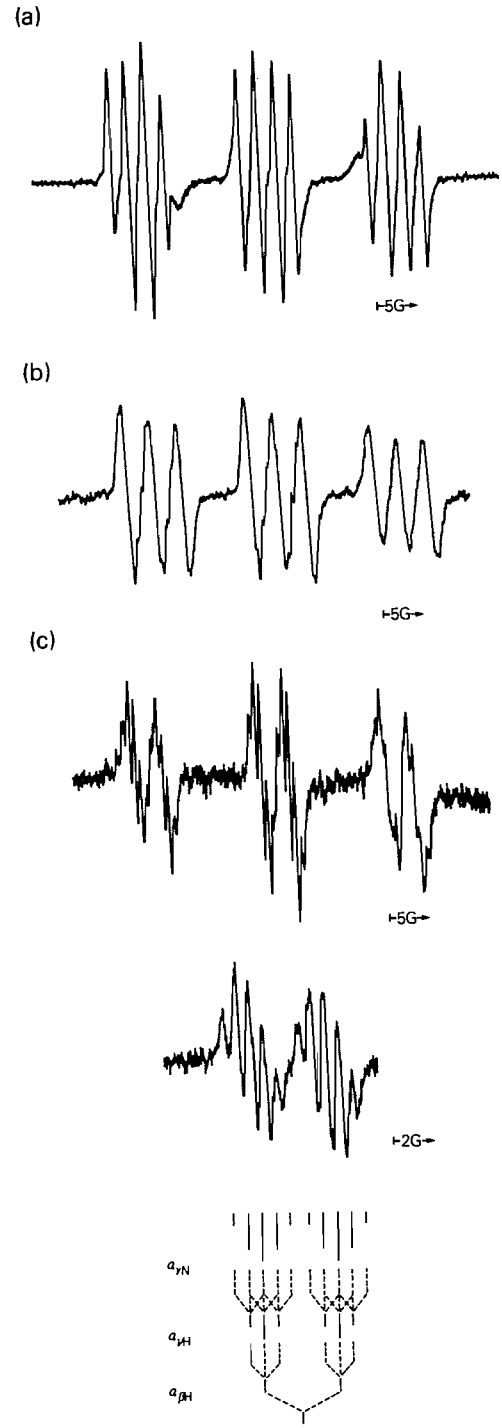

FIG. 5. (*a*) Electron spin resonance spectrum of polycrystalline L-Pro-L-Ala γ-irradiated and subsequently dissolved in aqueous MNP solutions. (*b*) Electron spin resonance spectrum of the separated spin adduct, which was eluted faster than the other. (*c*) Electron spin resonance spectrum of the separated spin adduct and the expansion of the $M_I = 0$ component with the stick diagram.

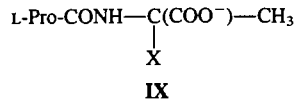
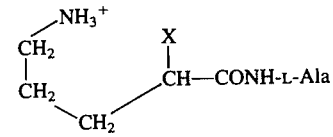
in the peptide group. The structure of the spin adduct is



**IX**

This spin adduct has not been found previously. The fine structure due to γ-hydrogens could not be observed even when a low modulation amplitude was used. In Fig. 5 (*c*), the other spectrum is shown with the expansion of the $M_I = 0$ component and its stick diagram. The triple doublet is split into five lines with an intensity ratio of 1:3:4:3:1. This spectrum is due to the ring opening (deamination) radical which has been identified (14);



**X**

The hfccs of spin adducts **VIII**, **IX**, and **X** are listed in Table 1.

In experiments with γ-irradiated polycrystalline L-Ala-Gly and L-Pro-L-Ala, the deamination radicals and the decarboxylation radical could be detected in addition to the spin adducts produced by H-abstruction. These results are quite different from those obtained in the experiments of γ-irradiated polycrystalline glycyl dipeptides (Gly-Gly, Gly-L-Val, and Gly-L-Leu).

The present work indicates that spin trapping combined with high-performance liquid chromatography is a useful method, apart from single crystal esr, for studying the room-temperature free radicals in γ-irradiated polycrystalline peptides. Further work remains to be done to establish quantitative methods for determining free radical distributions in γ-irradiated solids.

# Spin-trapping with 2-methyl-2-nitrosopropane: photochemistry of carbonyl-containing compounds. Methyl radical formation from dimethyl sulfoxide

IONEL ROSENTHAL,[1] MAGDI M. MOSSOBA, AND PETER RIESZ

*Laboratory of Pathophysiology, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205, U.S.A.*

Received September 1, 1981

IONEL ROSENTHAL, MAGDI M. MOSSOBA, and PETER RIESZ. Can. J. Chem. **60**, 1486 (1982).

The photochemical reactions of several carbonyl-containing compounds investigated by spin-trapping with 2-methyl-2-nitrosopropane revealed different modes of scission depending on the structure of the initial compound. Thus, in photo-Fries rearrangements, the acyl radical was detected. 1,3-Diphenyl-2-propanone decarbonylated to yield the benzyl radical. Finally, valerophenone yielded the radicals expected by γ-hydrogen abstraction. In a dark reaction, dimethyl sulfoxide reacts with NaOH to generate methyl radicals. The latter result suggests the need for caution in the use of dimethyl sulfoxide with 2-methyl-2-nitrosopropane for the detection of hydroxyl radicals.

IONEL ROSENTHAL, MAGDI M. MOSSOBA et PETER RIESZ. Can. J. Chem. **60**, 1486 (1982).

Les réactions photochimiques de plusieurs composés contenant un carbonyle, étudiés par captage de spin avec le méthyl-2 nitroso-2 propane, révèlent des modes différents de scission selon la structure du composé de départ. Ainsi dans les réarrangements photochimiques de Fries, on a décelé le radical acyle. La diphényl-1,3 propanone-2 par décarbonylation conduit au radical benzyle. Finalement, la valérophénone donne les radicaux attendus par élimination γ d'hydrogène. A l'abri de la lumière, le diméthylsulfoxyde réagit avec la NaOH en générant des radicaux méthyles. Ce dernier résultat suggère d'utiliser avec précaution le diméthylsulfoxyde avec le méthyl-2 nitroso-2 propane lors de la détection des radicaux hydroxyles.

## Introduction

The advent of the spin-trapping method in esr spectroscopy (1, 2) has facilitated the identification of the free radicals produced at room temperature in fluid solutions. Consequently, it is feasible to use spin-trapping to provide direct support for conceivable reaction pathways, otherwise indirectly implied, in various chemical processes, or to reveal the basic chemical reactions.

In this note we report the results of studying several chemical reactions by spin-trapping with 2-methyl-2-nitrosopropane (MNP).

## Experimental

Spin-trap solutions were prepared by dissolving about 1–1.5 mg of MNP per mL of organic solvent at room temperature in the dark for 20 min. Aqueous solutions of MNP were prepared by stirring 1.5 mg of MNP per mL of $H_2O$ (or $D_2O$) at room temperature in the dark overnight. MNP, phenyl acetate, phenyl benzoate, acetanilide, 1,3-diphenyl-2-propanone, valerophenone, dibenzoyl peroxide, and hexadecyltrimethylammonium chloride were purchased from Aldrich Chemical Co. 1,8-Diaminooctane was obtained from Sigma Chemical Co. Hydrogen peroxide (30%) was acquired from Fisher Scientific Co. Deuterium oxide (99.8%) was purchased from Bio-Rad Laboratories.

The photolyses were performed *in situ* at room temperature, in aerated solutions, in the standard aqueous quartz cell (60 × 10 × 0.25 mm) placed in the esr cavity, using a Schoeffel 1000 W high pressure Hg–Xe lamp coupled with a grating monochromator. The irradiation time was about 5 minutes.

A Varian E-9, X-band Spectrometer was used for esr measurements. The magnetic field modulation frequency was 100 kHz. The scans were traced with a modulation amplitude equal to, or lower than 0.2 G, and the microwave power level was maintained at 10 mW to avoid saturation. An NMR Gauss Meter was used to calibrate the magnetic field. The hyperfine couplings are accurate to ± 0.05 G. All esr measurements were carried out at room temperature.

[1] On sabbatical leave from Department of Technology, Agricultural Research Organization, Volcani Center, Bet-Dagan, Israel.

## Results and discussion

The short-lived radicals generated by uv photolysis which react with MNP to produce stable nitroxide radicals exhibit a primary triplet hyperfine coupling from the $^{14}N$ of the nitroxyl group. The primary triplet is split into secondary lines which generally arise from the interaction of the free electron with the magnetic nuclei of the trapped radical. The α, β, and γ positions of the nuclei on the spin adduct are defined with respect to the nitroxyl nitrogen as illustrated below:

$$(CH_3)_3CN(\dot{O})C^{\alpha}H_2^{\beta}—C^{\beta}H_2^{\gamma}—$$

TABLE 1. Hyperfine coupling constants $a_{N(nitroxyl)}$ (G) of the spin-trapped radicals in the photo-Fries rearrangement at 260 ± 10 nm

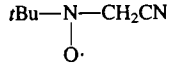
| Substrate | Radical | $a_{N(nitroxyl)}$ | | | |
|---|---|---|---|---|---|
| | | $CH_3OH$ | $CH_3CN$ | $C_6H_6$ | Dioxan |
| Phenyl acetate | $CH_3CO\cdot$ | 7.8 | 7.9 | 7.8 | 8.0 |
| Phenyl benzoate | $C_6H_5CO\cdot$ | 8.1 | 8.1 | 8.0 | 8.0 |
| Acetanilide | $CH_3CO\cdot$ | 7.8 | 7.9 | 7.8 | 8.0 |

bond, as the first step in the rearrangement of aryl esters.

We attempted the direct detection of the free radicals involved in the photo-Fries rearrangements of phenyl acetate, phenyl benzoate, and acetanilide by spin-trapping with MNP. Thus, MNP solutions containing the substrates (50 μL/mL) in different solvents were irradiated with light of λ = 260 ± 10 nm.

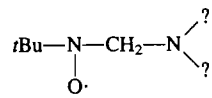
In all cases, a spectrum composed of a sharp triplet was recorded, and it was assigned to acyl radicals in view of the characteristically small hyperfine splittings of the nitrogen of the nitroxyl group (6). The results of these experiments are summarized in Table 1. The aromatic radical counterpart of the acyl radical could not be spin-trapped. Occasionally, di-*tert*-butylnitroxide radical (DTBN) was also detected and the lines due to DTBN are labelled (S) in the figures. The $^{14}N$ hyperfine coupling constants of the nitrogen of the nitroxyl group were 16.03 G (methanol) and 15.15 G (benzene or acetonitrile).

Parenthetically, we noted that an unusual spin adduct was recorded when the photolysis of phenyl acetate in acetonitrile was induced with light of λ = 313 ± 10 nm. This spin adduct (Fig. 1a) could be analyzed in terms of 3 × 3 × 3 lines and was initially attributed tentatively to the hydrogen atom abstraction from acetonitrile (I) ($a_N$ = 15.3 G, $a_H$ = 10.9 G (2H), and $a_N$ = 2.0 G).



I

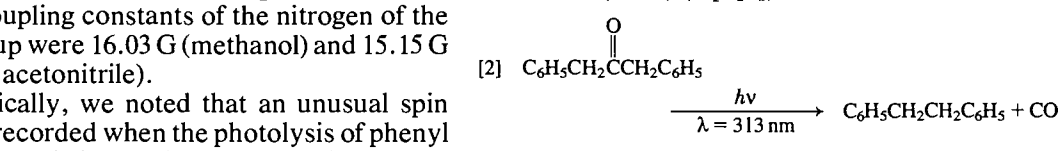
Spin adduct I was not reported previously in the literature, acetonitrile being considered to be fairly inert to radical attack.[2] However, by reaction of acetonitrile with OH· generated photochemically from $H_2O_2$ (100 μL of 30% $H_2O_2$ per mL of $CH_3CN$ containing MNP (1 mg/mL) irradiated with λ = 260 nm for 20 s) we successfully generated I and recorded it as a simple triplet of triplets (Fig. 1b) of $a_{N(nitroxyl)}$ = 15.5 G and $^{\beta}a_H$ = 9.0 G (2H). Furthermore, the 313 nm photolyses of phenyl acetate in solvents other than $CH_3CN$, such as benzene, also generated a similar 3 × 3 × 3 line spectrum ($a_{N(nitroxyl)}$ = 14.8 G, $^{\beta}a_H$ = 10.9 G (2H) and $^{\beta}a_N$ = 2.0 G) which under these circumstances can be attributed only to radical II, whose complete structure could not be ascertained from the present data, in which the nitrogen originates from the spin trap.



II

II. *Photodecarbonylation of 1,3-diphenyl-2-propanone*

1,3-Diphenyl-2-propanone is one of the few non-cyclic ketones which loses carbon monoxide nearly quantitatively and with high quantum yield when irradiated (7–10) (eq. [2]).



[2]

A free radical mechanism which involves decarbonylation and radical recombination was suggested on the basis of the analyses of the chemical products (7–9) and CIDNAP studies (11). The question of whether the mechanism is concerted, or stepwise, involving the formation of phenylacetyl radical and benzyl radical, has been decided in favor of the latter (10) by experiments of radical recombination of these two radicals with the nitroxide 2,2,6,6-tetramethylpiperidine-1-oxyl.

We found that the uv irradiation (λ = 313 nm) of 1,3-diphenyl-2-propanone ($5 \times 10^{-4}$ *M*) in different solvents at room temperature generated benzyl radical which could be detected as its spin adduct with MNP (III) (Fig. 2). DTNB was found in addition to radical III when dilute solutions of 1,3-diphenyl-2-propanone were photolyzed in

aqueous solutions in which this ketone is only slightly soluble. The hyperfine coupling constants of radical III are summarized in Table 2.

Since no acyl radicals could be detected in our reaction conditions, we assume that the rate of decarbonylation of the phenylacetyl radical is much faster than its addition to MNP. The failure to trap the phenyl acetyl radical with MNP has been reported previously in benzene at 40°C (12).

The recombination of benzyl radicals generated

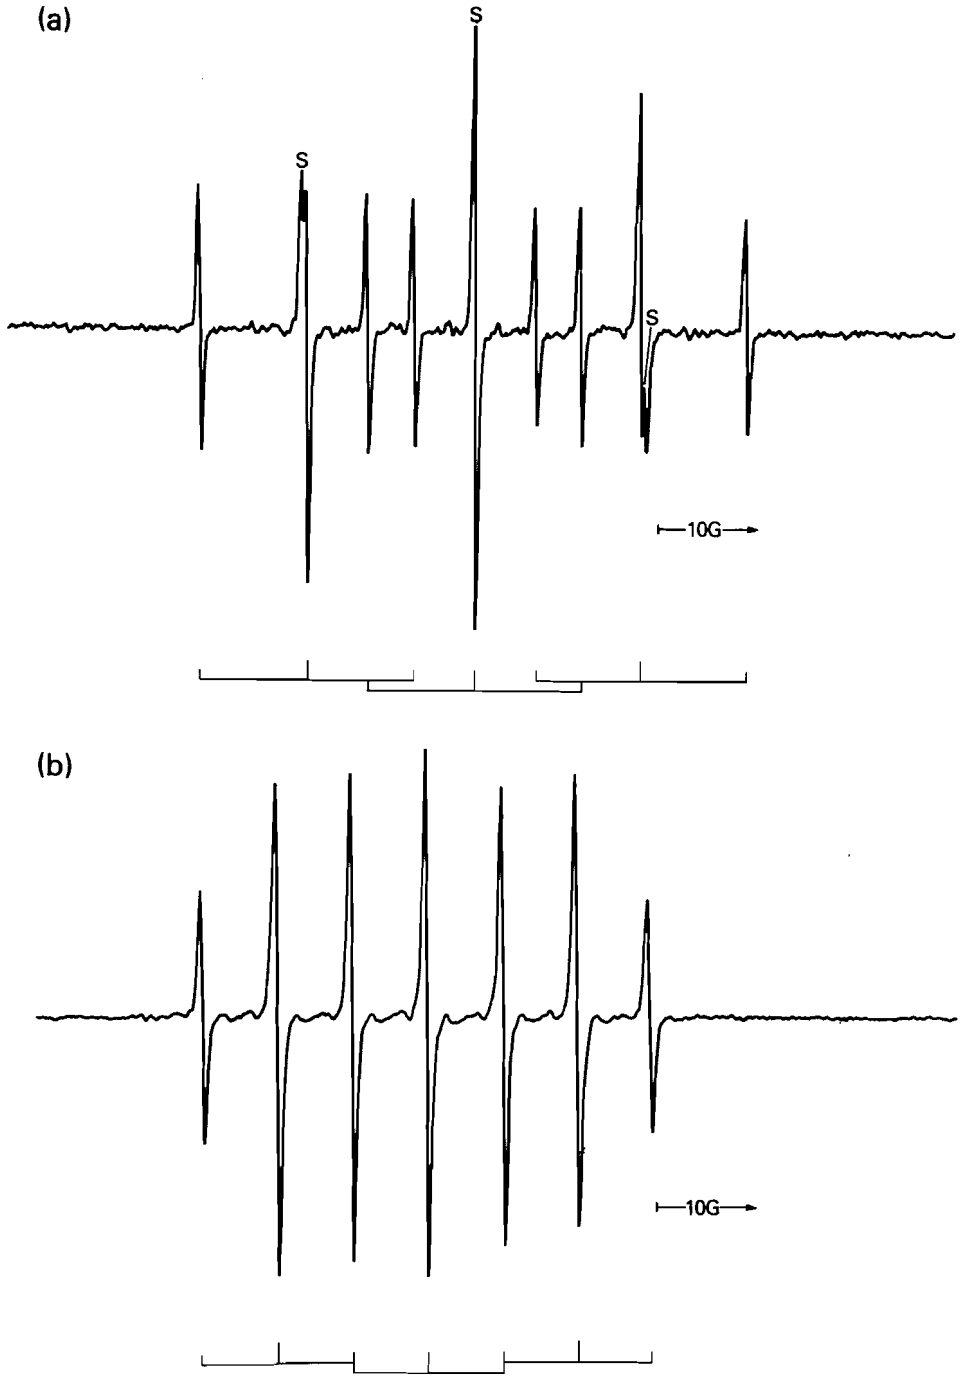

FIG. 2. The esr spectrum of the spin-trapped benzyl radical from 313 nm photolysis of 1,3-diphenyl-2-propanone in the presence of MNP in (a) water and (b) benzene. The lines labelled (S) are due to DTBN.

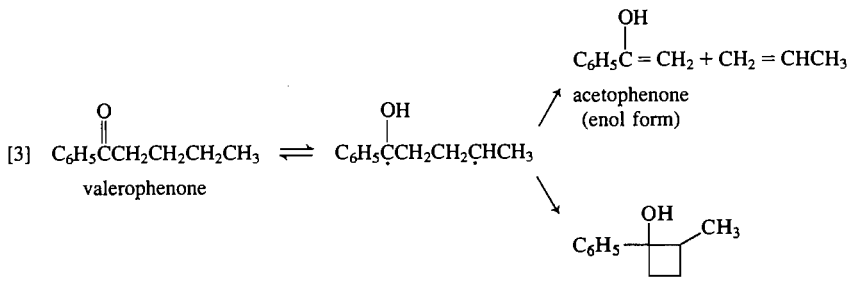
by photodecarbonylation of dibenzyl ketones has been shown to be predetermined in micellar solution (13, 14). We attempted to trap the benzyl radical under these conditions ($5 \times 10^{-2}$ *M* hexadecyltrimethylammonium chloride in water which is above the critical micelle concentration) at concentrations of 1,3-diphenyl-2-propanone ($5 \times 10^{-4}$ *M*) employed for its detection in other solvents. However, the exclusive paramagnetic species detected was di-*tert*-butylnitroxide ($a_N$ = 16.6 G). Since in micellar solution at the concentration ratio employed, the benzyl radical generation is confined to

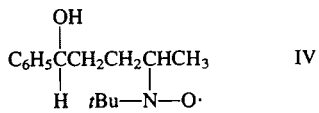


the small hydrophobic portion of the micelle with very little diffusion out (13), radical recombination is highly favored, leaving no chance for competitive trapping by MNP. When, however, the same experiment was repeated at a much higher ketone concentration ($5 \times 10^{-3}$ *M*) so that the ketone is forced into the aqueous phase, the photolysis occurs as in a homogeneous solution and the benzyl spin adduct could be detected.

III. *Photolyses of valerophenone*

The photoinduced intramolecular γ-hydrogen abstraction by the triplet state of phenyl alkyl ketones has been well documented (15–17) (eq. [3]).

The irradiation of valerophenone at 313 ± 10 nm in the presence of MNP generated a mixture of two radicals (Fig. 3). The predominant one, which was stable in the dark after initial photogeneration (radical A), showed a triplet of doublets attributed to intramolecular γ-hydrogen abstraction (IV). The



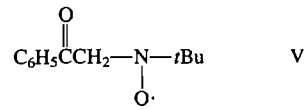
IV

minor signal which could be detected only during uv-irradiation (radical B) could be analyzed in terms of 3 × 3 lines, and it was attributed to radical (V). The H-atom could be abstracted from acetophenone by photoexcited valerophenone or acetophenone, in an intermolecular reaction subsequent to the cleavage of valerophenone (18). Thus, the identity of radical (V) was confirmed by irradiating solutions of acetophenone in benzene and acetonitrile in the presence of MNP. The results are summarized in Table 3.

TABLE 2. Hyperfine coupling constants (G) of benzyl radical spin adducts obtained by uv photolysis of 1,3-diphenyl-3-propanone at 313 ± 10 nm

| Solvent | $a_{N(nitroxyl)}$ | $^{\beta}a_H$ |
|---|---|---|
| $H_2O$ | 16.63 | 10.56 |
| $D_2O$ | 16.63 | 10.56 |
| Benzene | 15.00 | 7.50 |
| Methanol | 15.80 | 8.50 |
| Acetonitrile | 15.23 | 8.53 |

The photolysis of valerophenone was suggested



V

as a device to probe solute location in micelles (19). When valerophenone (0.01 *M*) was irradiated in an aqueous solution of MNP (1.5 mg/mL) containing hexadecyltrimethyl ammonium chloride ($5 \times 10^{-2}$ *M*), two overlapping spectra were recorded. Again, the major and the stable one, composed of a triplet of doublets, is explained by the attachment of a —CH— radical to the spin trap ($a_{N(nitroxyl)}$ = 15.56 G, $^{\beta}a_H$ = 1.9 G). This radical could originate from the intramolecular γ-hydrogen abstraction in valerophenone or intermolecular H-abstraction from the alkyl chain of the surfactant by valerophenone. The less prominent signal of 3 × 2 lines of equal intensity was light-dependent and was attributed to the H-adduct (VI).

FIG. 3. The esr spectrum of the spin-trapped radical from photolysis of valerophenone in the presence of MNP at 313 nm.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

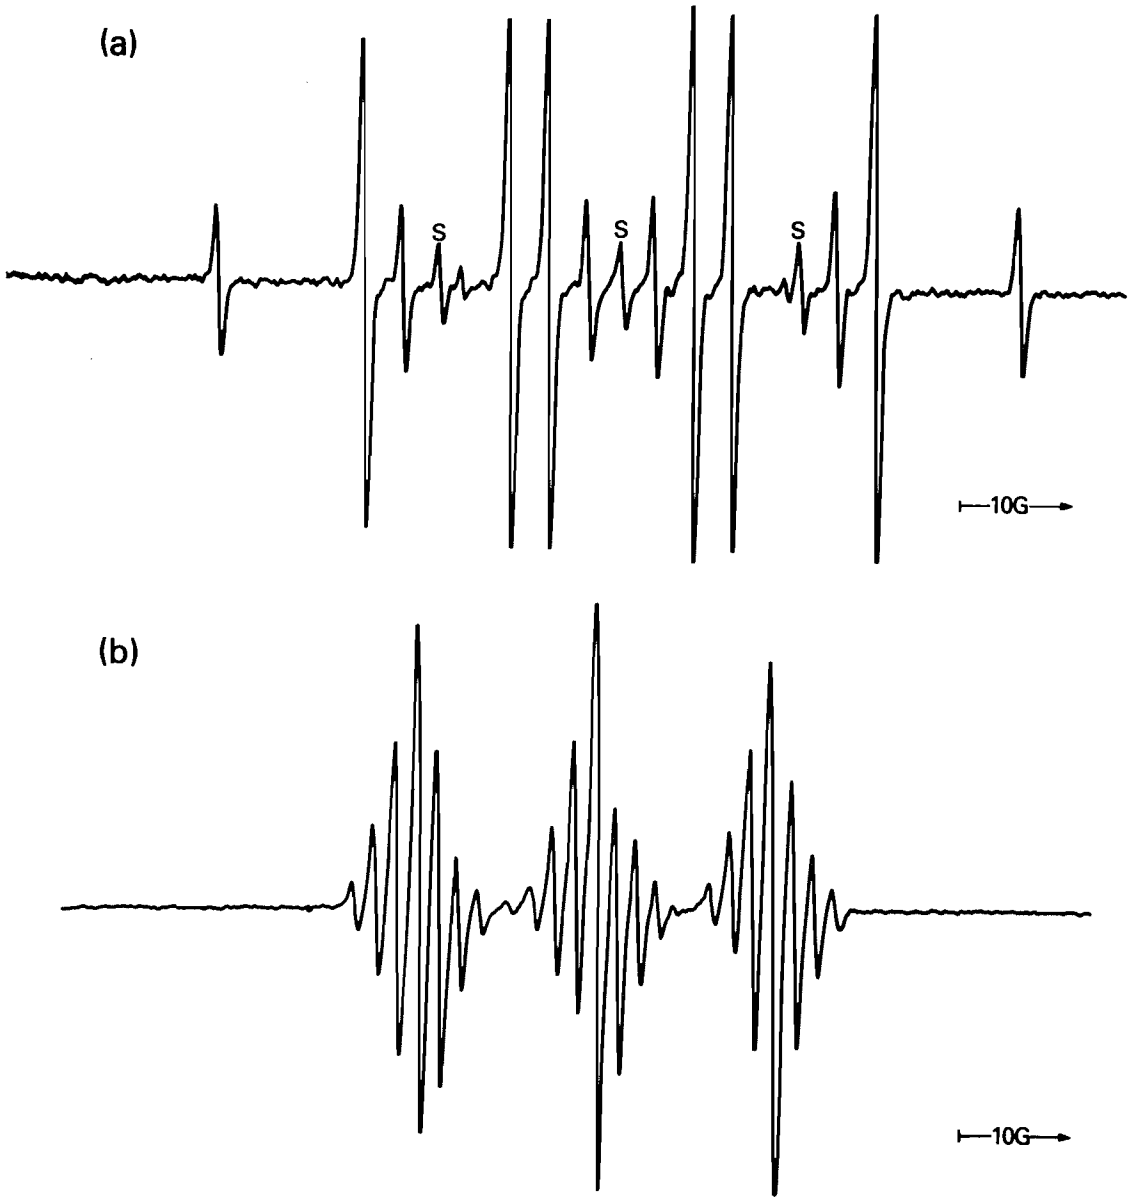

FIG. 4. The esr spectrum of the spin-trapped (a) $CH_3$-radical and (b) $CD_3$-radical, generated in the dark reactions between dimethyl sulfoxide and NaOH in the presence of MNP. The lines labelled (S) are due to DTBN.

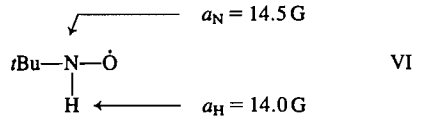

VI

The formation of the H-adduct can be easily explained by the reaction of an unstable phenylbutylhydroxyl radical with MNP (20–23) (eq. [4]).

## IV. *On the generation of methyl radical from dimethyl sulfoxide*

The photochemically generated OH-radicals react with dimethyl sulfoxide to generate methyl radicals which are trapped by MNP to yield a very persistent and characteristic spin adduct (24). This reaction has been used in biological systems to detect OH radicals (25).

We found, however, that dimethyl sulfoxide can

[4] $C_6H_5\dot{C}(OH)(CH_2)_3CH_3 + tBu{-}N{=}O \rightarrow C_6H_5C(=O)(CH_2)_3CH_3 + tBu{-}N(H){-}\dot{O}$

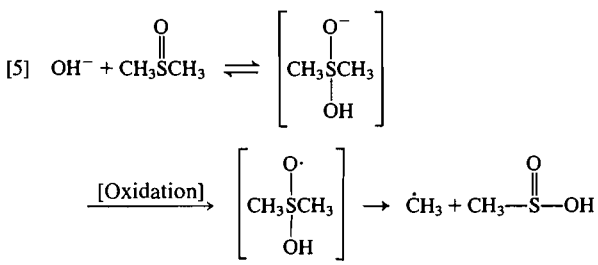
TABLE 3. Hyperfine coupling constants (G) of spin-trapped radicals generated by uv photolysis of valerophenone at 313 ± 10 nm

| Solvent | Radical IV | | Radical V | |
|---|---|---|---|---|
| | $a_{N(nitroxyl)}$ | $^{\beta}a_H$ | $a_{N(nitroxyl)}$ | $^{\beta}a_H$ |
| Neat | 14.63 | 1.75 (H) | | |
| Benzene | 14.75 | 1.65 (H) | 14.25 | 7.75 (2H) |
| Methanol | 15.38 | 1.75 (H) + unidentified radical | | |
| Acetonitrile | 15.00 | 1.73 (H) | 14.50 | 8.06 (2H) |

generate the MNP–methyl spin adduct under reaction conditions which do not involve hydroxyl radical, such as the chemical reaction with a base. Thus, after mixing in the dark, at ambient temperature, a solution of MNP in dimethyl sulfoxide (1.5 mg/mL) with a solution of NaOH in water (2%) in the ratio 1:1, the $CH_3$ spin adduct can be easily detected ($a_{N(nitroxyl)} = 16.4$ G, $^{\beta}a_H = 12.5$ G (3H)). When the reaction is performed in dimethyl sulfoxide-$d_6$, the corresponding $CD_3$-adduct is recorded ($a_{N(nitroxyl)} = 15.9$ G, $^{\beta}a_D = 1.9$ G (3D)) (Fig. 4). Since the reaction proceeds relatively slowly at room temperature, a continuous increase in the intensity of the spin adduct can be observed with time. A possible reaction mechanism is depicted in eq. [5].



This suggested mechanism is supported by the observation that dimethyl sulfoxide undergoes oxygen exchange with NaOH (26).

Accidentally, we also detected the methyl spin adduct in an entirely anhydrous medium. Thus, in the course of an investigation of free radicals derived from polyamines (27) it was found that when a dimethyl sulfoxide solution of MNP (1.5 mg/mL) and dibenzoyl peroxide (5 mg/mL) was saturated with 1,8-diaminooctane in the dark, at room temperature, the methyl spin adduct spectrum was exclusively observed. Control experiments indicated that all of these components were necessary for the formation of the methyl adduct. The mechanism of this particular process is unknown at the present time.

We feel that these observations should serve as a cautionary mark for the nondiscriminatory conclusion that the detection of methyl spin adduct from dimethyl sulfoxide is an indisputable proof for hydroxyl radical generation in complex chemical systems.

# Electron spin resonance of spin-trapped radicals of amines and polyamines. Hydroxyl radical reactions in aqueous solutions and γ-radiolysis in the solid state

MAGDI M. MOSSOBA, IONEL ROSENTHAL,[1] AND PETER RIESZ

*Laboratory of Pathophysiology, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205, U.S.A.*

Received September 4, 1981

MAGDI M. MOSSOBA, IONEL ROSENTHAL, and PETER RIESZ. Can. J. Chem. **60**, 1493 (1982).

The reactions of hydroxyl radicals with methylamine, dimethylamine, trimethylamine, diethylamine, *sec*-butylamine, ethylenediamine, 1,3-diaminopropane, putrescine, cadaverine, 1,7-diaminoheptane, ornithine, spermidine, spermine, agmatine, and arcaine in aqueous solutions have been investigated by spin-trapping and esr. Hydroxyl radicals were generated by the uv photolysis of $H_2O_2$ and 2-methyl-2-nitrosopropane (MNP) was used as the spin-trap. The effects of ionizing radiation on the same polyamines in the polycrystalline state were also investigated. The free radicals produced by γ-radiolysis of these solids at room temperature in the absence of air were identified by dissolution in aqueous solutions of MNP. The predominant reaction of ȮH with amines and polyamines below pH 7 was the abstraction of hydrogen atoms from a carbon that is not adjacent to the protonated amino group. For agmatine and arcaine which contain guanidinium groups abstraction occurred from the α-CH. Dimethylamine was oxidized to the dimethylnitroxyl radical by $H_2O_2$ in the dark. γ-Radiolysis of polyamines in the polycrystalline state generated radicals due to H-abstraction from either the α-CH or from a carbon atom in the middle of the alkyl chain. The deamination radical was obtained from ornithine.

MAGDI M. MOSSOBA, IONEL ROSENTHAL et PETER RIESZ. Can. J. Chem. **60**, 1493 (1982).

Faisant appel à la rpe et à l'utilisation de piegeurs de spin, on a étudié la réaction des radicaux hydroxyles avec des solutions aqueuses des amines suivantes: méthylamine, diméthylamine, triméthylamine, diéthylamine, *sec*-butylamine, éthylènediamine, diamino-1,3 propane, putrescine, cadavérine, diamino-1,7 heptane, ornithine, spermidine, spermine, agmatine et arcaine. Les radicaux hydroxyles furent produits par la photolyse uv de $H_2O_2$ et on a utilisé le méthyl-2 nitroso-2 propane (MNP) comme piégeur de spin. On a également étudié les effets des radiations ionisantes sur les mêmes polyamines à l'état polycristallin. On a identifié les radicaux libres produits par radiolyse-γ de ces solides à la température ordinaire en l'absence de l'air en les dissolvant dans des solutions aqueuses de MNP. L'élimination d'atomes d'hydrogène de l'atome de carbone non adjacent au groupe amino protoné est la réaction principale du radical ȮH avec les amines et les polyamines à un pH inférieur à 7. Dans le cas de l'agmatine et de l'arcaine, qui contiennent des groupes guanidiniums, l'élimination se produit au niveau du CH en α. On a oxydé la diméthylamine en radical diméthylnitroxyde par $H_2O_2$ à l'obscurité. La radiolyse γ des polyamines à l'état polycristallin produit des radicaux par suite de l'élimination d'hydrogène soit du CH en α ou de l'atome de carbone qui se trouve au centre de la chaîne alkylée. À partir de l'ornithine, on a obtenu le radical de désamination.

[Traduit par le journal]

## Introduction

Polyamines, which consist of hydrocarbon chains with multiple amine groups, are intimately involved in the control of normal and malignant growth processes (1, 2). Polyamines are especially useful as biochemical markers of cancer patient response to radiation, surgery, immunotherapy, and chemotherapy (2). They are found in elevated concentrations in physiological fluids of patients and appear to be markers of pathology related to overproliferation and cell death (2).

In this work, we have investigated the effects of γ-radiolysis in the solid state and the reactions of OH radicals in aqueous solutions with a number of biologically significant polyamines such as putrescine (1,4-diaminobutane), cadaverine (1,5-diaminopentane), spermidine ($H_3\overset{+}{N}—(CH_2)_3—\overset{+}{N}H_2—(CH_2)_4—NH_3^+$), spermine ($H_3\overset{+}{N}—(CH_2)_3—\overset{+}{N}H_2—(CH_2)_4—\overset{+}{N}H_2—(CH_2)_3—\overset{+}{N}H_3$), etc., as well as several primary, secondary, and tertiary amines.

Free radical formation from aliphatic amines has been investigated previously by a number of methods. For studies of the solid state, electron spin resonance was used to observe radical species produced by X-rays (3) and γ-radiolysis (4–6) in single crystals or by uv photolysis (7, 8) in frozen glasses. Optical absorption was used to follow the radicals produced by pulse radiolysis (9–12) in aqueous solutions that were saturated with $N_2O$ to convert $e^-_{aq.}$ to ȮH. The radicals generated by ȮH (or Ḣ) attack formed by steady-state radiolysis of aqueous solutions (13, 14) or by the $Ti^{3+}$–$H_2O_2$ flow system (15–17) were detected by direct, *in situ* esr observation. The flow method is limited by the requirement of considerable amounts of substrate to be investigated.

In the single crystal studies, H-abstraction from carbon as in $\cdot CH_2\overset{+}{N}H_3$ (5) and from nitrogen (e.g., $Me_3\dot{N}^+$ (6)) was produced by ionizing radiation.

*N*-centered radicals were also formed by ultraviolet irradiation of glassy samples of mono-, di-, and trialkyl amines at low temperatures (7, 8). However, in the reaction of OH radicals with aliphatic amines in aqueous solution (9–14, 17), H-abstraction from the nitrogen as well as from the carbon adjacent to it occurred in alkaline medium. In acid solution, abstraction was observed to take place only from those carbons which were not adjacent to the $-\overset{+}{N}H_3$ group.

In this work electron spin resonance and spin-trapping (18–21) were used to identify the free radicals. The reactions of $\dot{O}H$ radicals were investigated by uv photolysis of aqueous solutions containing hydrogen peroxide and the amine or polyamine. The direct effects of ionizing radiation on the polyamines in the solid state were investigated by γ-radiolysis of the polycrystalline solids followed by dissolution in a solution containing the spin-trap (22, 23).

In principle, a spin-trap, such as 2-methyl-2-nitrosopropane (MNP), $Me_3CN{=}O$, reacts with short-lived radicals, $R^{\bullet}$, to produce longer-lived spin-adducts, $Me_3CN(R)\dot{O}$, whose structures can conveniently be identified by esr. The α, β, and γ positions are defined with respect to the nitrogen of the nitroxyl group as illustrated for the spin-adduct of methylamine:

[1] $O{=}N{-}CMe_3 + {\cdot}CH_2\overset{+}{N}H_3 \rightarrow O^-{-}\dot{N}^+(CMe_3){-}C^{\alpha}H_2{-}C^{\beta}H_2{-}\overset{+}{N}H_3^{\gamma}$

## Experimental

Polyamines as well as primary, secondary, and tertiary amines were purchased from Sigma Chemical Company. 2-Methyl-2-nitrosopropane (MNP) was obtained from Aldrich Chemical Company and $D_2O$ (99.8%) was acquired from Bio-Rad Laboratories.

Aqueous solutions of the MNP were prepared in water by adding 50 mg of the spin-trap to 10 mL of $D_2O$ and stirring in the dark at 45°C for 2 hours (24).

*In the γ-radiolysis experiments, solid samples of polyamines* were irradiated in a $^{60}Co$ γ-source to a dose of 120 kGy in the absence of air at room temperature. The irradiated samples were subsequently dissolved in the spin-trap solution.

For the study of OH radical reactions in aqueous solution, the amines and polyamines were dissolved in the spin-trap solutions to which 25 μL of 30% $H_2O_2$ per mL were added just prior to uv illumination. The radicals were generated by photolysis *in situ* at room temperature in the standard aqueous quartz cell (60 × 10 × 0.25 mm) placed in the esr cavity, using a Schoeffel 1000 W high-pressure Hg–Xe lamp coupled with a grating monochromator. The excitation light had a maximum centered at 260 ± 10 nm and the irradiation time ranged from 5 to 30 seconds.

The esr measurements were made on a Varian E-9, X-band (9.4 GHz) spectrometer. The esr spectra from spin-trapped radicals were recorded at room temperature as first derivatives. The esr scans were traced with a 100 kHz modulation of 0.05 or 0.1 G amplitude and the microwave power level was maintained at 10 mW to avoid saturation of the esr signals. Thermal decay studies of the spin-adducts were performed at room temperature and proved helpful in analyzing overlapping spectra due to the presence of more than a single radical species. The magnetic field was calibrated with an nmr Gauss Meter.

## Results and discussion

In spin-adducts the free-electron spin density is mostly localized on the nitrogen and oxygen atoms of the nitroxyl group and the interaction of the unpaired electron with $^{14}N$ ($I = 1$) of the nitroxyl group generates a primary triplet. Some of the electron spin is also delocalized on the atoms of the trapped radicals and produces hyperfine structures, referred to as secondary splittings, which are most useful in identifying the structure of the spin-adducts. The primary and secondary hyperfine splitting constants of the spin-trapped radicals of the polyamines and amines investigated are listed in Table 1. The esr spectra of photolyzed aqueous solutions of MNP usually show a 17.2 G triplet from the di-*tert*-butylnitroxyl radical. This spectrum is marked S in the figures.

Initially, the simple amines were studied as models for more complex polyamines. Aqueous solutions of several primary, secondary, and tertiary amines were uv-photolyzed in the presence of MNP and $H_2O_2$ at room temperature. The esr spectrum produced by the spin-trapped radicals of diethylamine showed detailed hyperfine structure. Figure 1(a) displays the observed spectrum which has a primary nitrogen hyperfine coupling constant of 16.2 G and a secondary structure consisting of a 1:2:1 triplet of 13.6 G which is further split into another 1:2:1 triplet of 0.4 G. Only radical **1** is

$${\cdot}CH_2{-}CH_2{-}\overset{+}{N}H_2{-}CH_2{-}CH_3$$
**1**

consistent with this observation and is formed by H-abstraction from a terminal carbon. Radical **1** has been previously detected by esr in the reaction of $\dot{O}H$ with diethylamine using a $Ti^{3+}$–$H_2O_2$ flow method (17).

Figure 1(b) shows the spectrum obtained from the spin-adducts of *sec*-butylamine which is due to the presence of two radial species. Radical **2** is due

$${\cdot}CH_2{-}CH_2{-}CH(\overset{+}{N}H_3){-}CH_3$$
**2**

to H-abstraction, as in diethylamine, from a terminal carbon except that the middle lines of the 11.5 G secondary triplet overlap with the more intense 2.0 G secondary doublet arising from the spin-adduct of radical **3**. This doublet is clearly observed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

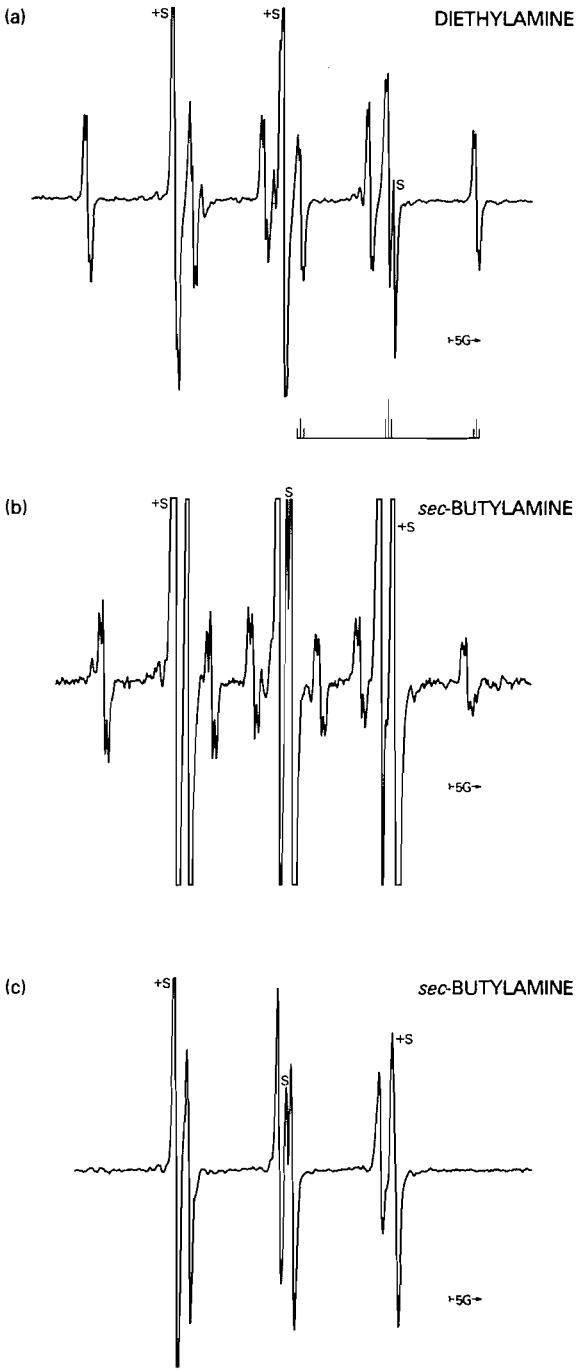

FIG. 1. The esr spectrum from uv-photolyzed aqueous solutions containing MNP, $H_2O_2$, and (a) diethylamine, (b) *sec*-butylamine, (c) *sec*-butylamine after decay.

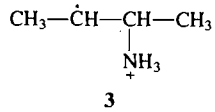
in Fig. 1(c) since the spin-adduct of radical **2** decayed in about 10 min at room temperature.

The spectrum of the spin-trapped radicals of trimethylamine obtained by ȮH attack is shown in



**3**

Fig. 2(a) and arises from the spin-adduct of radical **4** since it consists of a 1:2:1 triplet of 8.3 G, due to two equivalent hydrogen atoms, which is further split into a 1:1:1 triplet of 3.0 G due to the nitrogen atom.

Radical **4** has been previously observed in alka-

**4**

line medium (9, 13). During radiolysis of acid solutions of trimethylamine, a minor product, the aminium radical $Me_3\dot{N}^+$ was detected by esr at pH 1 and 3 (14). This radical has also been observed in γ-irradiated single crystals of tetramethylammonium chloride (6). However, the aminium radical could not be detected by spin-trapping under our experimental conditions.

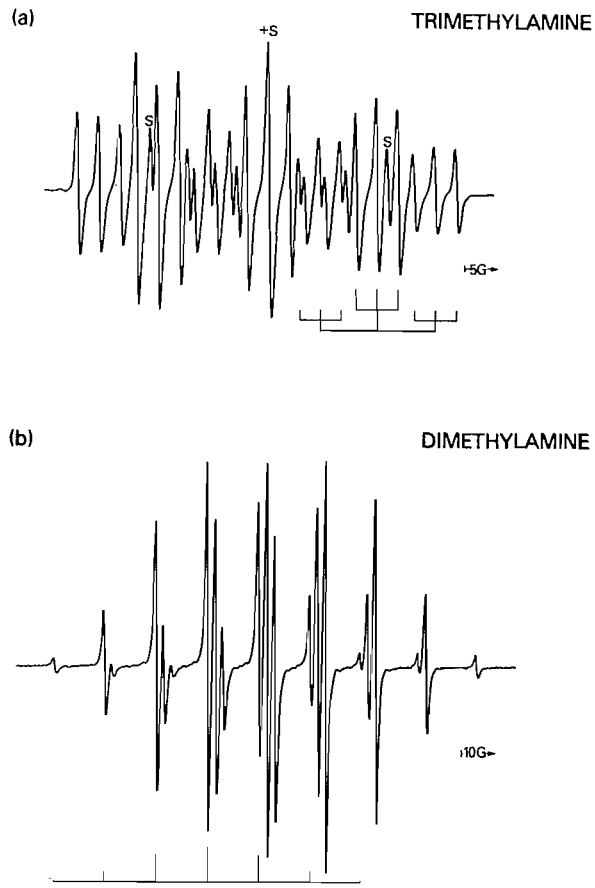


FIG. 2. (a) The esr spectrum from uv-photolyzed aqueous solutions containing MNP, $H_2O_2$, and trimethylamine; (b) esr spectrum from aqueous solutions containing $H_2O_2$ and dimethylamine in the dark.

[a]Accurate to ± 0.1 G.
[b]pD = observed pH + 0.4 (31).

When ȮH radicals reacted with methylamine a spectrum similar to the one obtained for trimethylamine was observed and the untrapped radical from methylamine has structure **5**. The spin-adducts of both radicals **4** and **5** decayed after about 4 min at room temperature.

$$\cdot CH_2\overset{+}{N}H_3$$
**5**

Radical **5** has been previously observed by esr in a single-crystal study of methylammonium alum (5). In acid solutions, **5** was detected by pulse radiolysis (9) but not by esr (13, 17) due to line broadening caused by chemical exchange of the ammonium protons (13). Only in the pH range 7–13.5 the conjugate base of **5**, $\cdot CH_2NH_2$, was observed by esr in γ-irradiated aqueous solution of methylamine (13).

Dimethylamine was found to react with $H_2O_2$ in the dark in the absence of MNP. The observed spectrum (Fig. 2(b)) is characteristic of a 17.0 G 1:1:1 triplet which was further split into a 14.6 G septet with a relative intensity of 1:6:15:20:15:6:1 due to six equivalent hydrogen atoms. This evidence is consistent with the formation of the nitroxyl radical **6**.

**6**

$H_2O_2$-oxidation of dimethylamine has previously been obtained in a 1 *N* NaOH solution (25). The oxidation product **6** has also been produced in a titanous ion – hydrogen peroxide flow system (15, 16).

After ethylenediamine dihydrochloride was γ-irradiated in the solid state to a dose of 120 kGy, it was dissolved in an aqueous solution of MNP. The observed esr spectrum of the spin-adduct consisted of a secondary 1:1:1 triplet (3.0 G) which was further split into a doublet (1.3 G). This observation is consistent with the formation of radical **7**. The

$$H_3\overset{+}{N}—\dot{C}H—CH_2—\overset{+}{N}H_3$$
**7**

same radical species was also found when an aqueous solution of ethylenediamine containing MNP and $H_2O_2$ was photolyzed for 5 seconds at 260 nm as shown in Fig. 3(a).

Solid-state radiolysis of 1,3-diaminopropane dihydrochloride yielded radical **8**. The esr spectrum, shown in Fig. 3(b), indicates the equivalence of the β-nitrogen and the β-hydrogen of the spin-adduct

**8**

of radical **8**. In the $H_2O_2$-photolysis experiment a mixture consisting of radical **8** as well as the one (structure **9**) generated by H-abstraction from the C(2) carbon was obtained.

$H_3\overset{+}{N}—CH_2—\dot{C}H—CH_2—\overset{+}{N}H_3$

**9**

The esr spectrum of the spin-adduct generated from γ-radiolysis of polycrystalline L-ornithine hydrochloride and spin-trapping in aqueous solution exhibited a 4.5 G doublet which was further resolved into a 0.5 G triplet (1:2:1). This spectrum is due to the formation of the deamination radical **10**. This result is similar to that obtained for

$H_3\overset{+}{N}—(CH_2)_3—\dot{C}H—COO^-$

**10**

γ-irradiated polycrystalline α-amino acids (23). The interaction of OH radicals with L-ornithine did not generate radical **10**, but gave rise to an unresolved mixture of H-abstraction radicals.

Similar esr spectra were recorded for 1,4-diaminobutane and 1,5-diaminopentane. Hydrogen abstraction from the middle of the chain was observed by both $H_2O_2$-photolysis and γ-radiolysis. The spin adduct of radical **11** shows an esr spectrum (Fig. 4(a) and (b)) that consists of a 2.0 G secondary doublet. At higher gain, the esr spectrum (Fig. 4(c)) observed in the photolysis experiment also shows two other sets of lines. The lines labelled A arise from radical **12**, while the ones

$H_3\overset{+}{N}—CH_2—\dot{C}H—(CH_2)_2—\overset{+}{N}H_3$

**11**

$H_3\overset{+}{N}—\dot{C}H—(CH_2)_3—\overset{+}{N}H_3$

**12**

labelled with numbers are tentatively attributed to a $\cdot CH_2$-type radical which could be obtained from **12** by a β-scission mechanism (26) giving radical **13**:

[2] $H_3\overset{+}{N}—\dot{C}H—CH_2—CH_2—CH_2—\overset{+}{N}H_3$

**12**

$\xrightarrow{\beta\text{-scission}}$ $H_3\overset{+}{N}—CH{=}CH_2 + \cdot CH_2—CH_2—\overset{+}{N}H_3$

**13**

This type of radical was also observed for spermidine (radical **21** in Table 1). The esr spectrum obtained by $H_2O_2$-photolysis of 1,7-diaminoheptane only showed the radical generated by

H-abstraction from the middle of the hydrocarbon chain.

γ-Radiolysis of the free base 1,8-diaminooctane yielded radical **18**. This type of radical was also

$$H_2N—\dot{C}H—(CH_2)_7—NH_2$$

**18**

found in the γ-irradiation of spermidine and spermine in which the β-nitrogen and β-hydrogen were found to be equivalent since their esr spectra exhibited a secondary 1:2:2:1 pattern. Abstraction of ȮH from a middle carbon was, however, observed for spermidine and spermine. The radicals obtained from agmatine and arcaine, by γ-radiolysis or $H_2O_2$-photolysis, exhibited esr spectra with a 6-line secondary pattern due to the nonequivalence of the β-N and β-H and are due to abstraction from a carbon adjacent to a nitrogen. For agmatine a second radical was also observed during photolysis, due to abstraction from the middle of the carbon chain. Radical **26** was generated from the $H_2O_2$-photolysis of arcaine.

$$H_2N—\underset{\underset{\overset{+}{N}H_2}{\|}}{C}—NH—\dot{C}H—(CH_2)_3—NH—\underset{\underset{\overset{+}{N}H_2}{\|}}{C}—NH_2$$

**26**

Previous work has shown that the nature of the radicals produced from the reaction of ȮH radicals with amines is strongly pH dependent (9–12, 27–29). The rate of reactions of ȮH with amines in their basic form, $RNH_2$, is close to being diffusion controlled and it is one to two orders of magnitude larger than that with $R\overset{+}{N}H_3$ (9, 27). In alkaline solutions, at pH values where the amines are deprotonated, $R—\underset{\underset{H}{|}}{\overset{H}{\overset{|}{C}}}—NH_2$, ȮH radicals abstract H atoms mainly from —$NH_2$ and α-CH (9). On the other hand, the strong inductive effect of a protonated amino group leads to the transmission of negative charge from the H atoms in the α-position through the carbon atom to the —$\overset{+}{N}H_3$ group. Hence an electrophilic attack of ȮH on hydrogen atoms in the position adjacent to the —$\overset{+}{N}H_3$ group becomes less favorable and abstraction is more likely to occur from positions further away from the ammonium group (9).

In the present study, the observed products in the reaction of ȮH radicals with amines and polyamines in their protonated form are consistent with the pathways described above. The predominant site of ȮH attack is not on the carbon attached

to the ammonium group. This is clearly illustrated in the cases of diethylamine, *sec*-butylamine, 1,4-diaminobutane, or spermine. For agmatine and arcaine, which contain one and two guanidinium groups respectively, H-abstraction occurred at a carbon adjacent to a nitrogen, possibly because the proton is shared between the three nitrogen atoms of the guanidinium moiety and the inductive force of $-\overset{+}{N}H_3$ is no longer present.

The observed radicals from polyamines generated by ionizing radiation in the polycrystalline state were not the same as those obtained by ȮH radicals. It can be seen from Table 1 that radicals due to H-abstraction from either the α-CH or from a carbon atom in the middle of the alkyl chain were produced. A deamination radical was only formed in the γ-radiolysis of ornithine. This result is in agreement with the conclusion of previous studies (30) that deamination requires the presence of a carboxyl group separated by one $-CH_2-$ from the amino group.

# Do spin-adducts of 5,5-dimethylpyrroline-*N*-oxide dimerize?[1]

A. L. CASTELHANO,[2] D. GRILLER, AND K. U. INGOLD
*Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received September 1, 1981

A. L. CASTELHANO, D. GRILLER, and K. U. INGOLD. Can. J. Chem. **60**, 1501 (1982).

The conclusion by Bullock *et al.* that aminoxyls formed by radical addition to 5,5-dimethylpyrroline-*N*-oxide are extensively dimerized in aqueous solution is shown to be incorrect. Aminoxyl dimerization is not a serious limitation to the use of this spin trap in quantitative studies of radical production.

A. L. CASTELHANO, D. GRILLER et K. U. INGOLD. Can. J. Chem. **60**, 1501 (1982).

On montre que la conclusion de Bullock et de ses collaborateurs, relative au fait que les aminoxydes formés par additions radicalaires sur le *N*-oxyde de diméthyl-5,5 pyrroline sont très fortement dimérisés en solution aqueuse, est incorrecte. La dimérisation de l'aminoxyle ne constitue par une limitation sérieuse à l'utilisation de ce capteur de spin lors des études quantitatives de production de radicaux.

[Traduit par le journal]

In a recent note entitled "5,5-Dimethylpyrroline-*N*-oxide: a trap for the unwary", Bullock, Gavin, and Ingram (1) claimed that the "nitroxides (**2**) formed by radical addition to the spin trap 5,5-dimethylpyrroline-*N*-oxide (**1**) are extensively dimerized in aqueous solution and this constitutes a serious limitation to the use of the trap in quantitative studies of radical production," viz.

[1] 
**1** **2** (**2***a*, R = H)

[2] 
We wish to present evidence that the so-called "trap for the unwary" has nothing to do with the dimerization of **2**. Instead it appears to have been due to excessive consumption of **1** combined with back-oxidation of the hydroxylamine **3** which was presumably formed mainly by the well-known bimolecular self-reaction of primary and secondary dialkyl aminoxyls (2–4), viz.:

[3] 
**2** **3** (**3***a*, R = H)

[4] 
[1]NRCC No. 20077.
[2]NRCC Research Associate 1980–1981.

Bullock *et al.*'s (1) experimental evidence for the equilibrium [2] was that the strength of epr signal for **2** having R = H (**2***a*) or HO (these radicals having been generated by glow-discharge electrolysis in the presence of **1**) could be increased and decreased in an "almost completely reversible" manner (not more than four heating and cooling cycles) on raising and lowering the temperature in the range 5 to 24°C. A value of 50 ± 7 kJ mol$^{-1}$ was estimated for $\Delta H_2$, though if all the data given had been used to calculate $\Delta H_2$, a value nearer to 65–71 kJ mol$^{-1}$ would have been obtained. However, it should be noted that a plot of log [**2**] vs. $1/T$, using Bullock *et al.*'s data is curved in the *opposite* sense from that to be expected for a radical–dimer equilibrium (5).

It is well known that sterically unhindered dialkylaminoxyls can dimerize reversibly *at low temperatures in non-polar solvents* (3, 4, 6). However, at ambient temperatures the equilibrium very strongly favors the monomeric radical over its dimer (6). For example, for the process

[5] $2(CH_3CD_2)_2NO\cdot \underset{-5}{\overset{5}{\rightleftharpoons}} ((CH_3CD_2)_2NO)_2$

the equilibrium constant, $K = k_{-5}/k_5$, has a value of 0.63 *M* at 25°C in isopentane and $\Delta H_5 = 32$ kJ mol$^{-1}$ (4). Equilibrium constants of comparable magnitude have been found for other sterically unhindered dialkylaminoxyls (6). Equilibrium constants in water are expected to favor the radical even more strongly (7).

In view of the growing importance of **1** in quantitative studies of spin trapping we felt it was essential to check on whether **2** really did behave in the unprecedented manner suggested by Bullock *et al.* (1), i.e., do **2** exist in equilibrium with their dimer in water at the concentrations ($< 10^{-4}$ *M*)

encountered in spin trapping?[3] For study we chose **2***a* since Bullock *et al.* (1) did most of their work with this aminoxyl and we investigated its behavior by epr spectroscopy.

## Results

The "cleanest" method known to us for producing aminoxyl radicals in solution is the direct uv photolysis of the parent hydroxylamine (3).

$$[6] \quad R_1R_2NOH \xrightarrow{h\nu} R_1R_2NO^{\cdot} + H^{\cdot}$$

$$[7] \quad H^{\cdot} + R_1R_2NOH \longrightarrow R_1R_2NO^{\cdot} + H_2$$

Though not a very efficient process it is quite satisfactory for most aminoxyls because of their relative persistence.

Carefully purified **3***a* dissolved ($[\mathbf{3}a] = 0.5–1.0\,M$) in deionized water or in benzene that had been *rigorously* deoxygenated showed, at most, a very weak epr signal due to **2***a* ($[\mathbf{2}a] < 10^{-7}\,M$). A strong signal of **2***a* ($[\mathbf{2}a] = 10^{-4}–10^{-5}\,M$) could be obtained by continuous uv photolysis of the solution. On shuttering the light **2***a* decayed with the expected (3, 4) second order kinetics with $2k_3 = 7.5 \times 10$ and $2.4 \times 10^3\,M^{-1}\,s^{-1}$ in water and benzene, respectively, at 25°C. With such *relatively* slow radical decays it was possible to undertake heating and cooling experiments on the "residual" aminoxyl signal remaining after decay had proceeded for a few half-lives. At $[\mathbf{2}a] = 10^{-5}–10^{-6}\,M$ the increase in the concentration of **2***a* caused by an increase in temperature from 5 to 25°C was negligible, varying from 0% to 20% in different experiments.[4,5] In contrast, Bullock *et al.* (1) observed a nearly 300% increase in $[\mathbf{2}a]$ on raising the temperature from 5 to 24°C with a similar concentration of **2***a* (8).

An alternative procedure that has been used to demonstrate the occurrence of a reversible dimerization of free radicals is to generate the radical in a series of light flashes (9). When there is an equilibrium this step-wise approach leads to higher concentrations of radical (and dimer) after each light flash. When **2***a* was generated from **3***a* in deoxygenated water or benzene using a series of well-spaced light pulses of equal intensity and duration the decay traces were superimposable and there was no net accumulation of aminoxyl. Therefore, **2***a* is not in equilibrium with its dimer at ambient temperatures and the experimental observations reported by Bullock *et al.* must clearly have an alternative explanation.

One possibility is that the samples used by Bullock *et al.* were contaminated by atmospheric oxygen. We have previously shown that diethyl hydroxylamine reacts with atmospheric oxygen to give diethyl nitroxide (3). The reaction has a substantial activation energy so that the steady-state radical concentration observed becomes larger as the temperature increases (3). The concentration of the nitroxide can be repeatedly increased and decreased by raising and lowering the temperature (3). However, the nitroxide is not in reversible equilibrium with the dimer since its epr signal ultimately disappeared when all of the oxygen was consumed (3). These characteristics are essentially the same as those observed by Bullock.

As confirmation of these and similar (10) observations we found that a relatively strong signal of **2***a* was obtained when **3***a* was dissolved in water or benzene which had not been deoxygenated, or if air were let into a carefully degassed sample. Under such conditions the concentration of **2***a* increased by more than 100% on raising the temperature from ca. 5 to 25°C, and decreased again on lowering the temperature. The whole process was almost reversible, except that the radical concentration (at one temperature) decreased with time in systems in which the oxygen could become depleted.

$$[8] \quad \mathbf{3}a + O_2 \rightarrow \mathbf{2}a + HOO^{\cdot} \text{ (or } H^+ + O_2^{-\cdot})$$

A second potential oxidant in Bullock *et al.*'s experiments is hydrogen peroxide, it being well known that both organic hydroperoxides (2) and hydrogen peroxide (11) oxidize hydroxylamines to the corresponding aminoxyls. Addition of a 10% mole equivalent of a 3% $H_2O_2$ solution to a degassed aqueous solution of **3***a* gave a very strong signal of **2***a*. Again the intensity of the signal could be increased by more than 100% on raising the temperature from ca. 5 to 25°C. The effect of temperature was reversible, but only for limited periods of time, the length of time depending on the temperature program and the amount of hydrogen peroxide added. Once all the $H_2O_2$ had been consumed the concentration of **2***a* decreased rapidly.

$$[9] \quad \mathbf{3}a + H_2O_2 \rightarrow \mathbf{2}a + H_2O + (^{\cdot}OH)$$

[3]If **2** did exist in equilibrium with their dimers under spin-trapping conditions the work reported in refs. 10 and 19 would be wrong!

[4]The signal did, however, increase appreciably on further raising the temperature to 65°C, an effect we attribute either to an increased rate of reaction of **3***a* with residual oxygen (*vide infra*), or to the thermal instability of the hydroxylamine.

[5]Similarly, the OH spin adduct of **1**, i.e., **2** (R = OH), prepared at a steady concentration of $2 \times 10^{-5}\,M$ by making up a $1.2\,M$ solution of **1** in 1% $H_2O_2$, showed no change in concentration on changing the temperature between 5 and 25°C, whereas Bullock *et al.* (1) found a change similar to what they found for **2***a*. In this system the spin adduct is probably formed mainly by photolysis of the $H_2O_2$ by the normal laboratory lighting since the signal was barely detectable in the dark, under which conditions it is presumably formed by hydrolysis of the nitrone followed by oxidation (11).

For personal use only.

By analogy with the known formation of mono-alkyl and mono-arylaminoxyls by reaction of their parent hydroxylamine with their parent nitroso compound (12) and of iminoxyl radicals by reaction of oximes with nitrile oxides (13) the possibility that the nitrone **1** might also oxidize **3***a* to **2***a* could not be ignored. However, when prepared under as nearly oxygen-free conditions as possible, a solution 1.0 *M* in **1** and 1.0 *M* in **3***a* in benzene or in water gave an epr signal due to **2***a* which was of virtually the same strength ($< 10^{-7}$ *M*) as a 1.0 *M* solution of **3***a* prepared under the same conditions. This result was obtained at both 25 and at 65°C. Reaction [3] is therefore irreversible at normal temperatures.

## Discussion

Our results prove that the aminoxyl **2***a* is not in equilibrium with a dimer at ambient temperature and at radical concentrations $\leq$ca. $10^{-4}$ *M*. The cause of the observation that led to Bullock *et al.*'s proposed "trap for the unwary" is most probably excessive consumption of **1**, with the consequence that **3** is formed via reaction [3], combined with oxidation of **3** by adventitious oxygen and/or $H_2O_2$ formed by glow-discharge electrolysis (14).[6]

Our present results serve to reemphasize earlier studies (3, 4) which implied that spin-trapping experiments should not be permitted to proceed to the point where hydroxylamine is formed by aminoxyl disproportionation if the reaction medium contains oxygen or some other oxidizing agent. Since the technique of spin trapping is now used extensively in free radical chemistry (15), particularly in biological systems (16), we hope that this work will lead to an increased awareness of the potential problems due to inadvertant hydroxylamine oxidation.

## Experimental

The hydroxylamine **3***a* was synthesized by $LiAlH_4$ reduction of **1** (Aldrich) by the method of Morgan and Beckett (17). In dry conditions under $N_2$, 1.0 g **1** was dissolved in 50 mL dry ether and was then added dropwise to a stirred suspension of 1 g $LiAlH_4$ in 100 mL dry ether. After 3½ h a minimum amount (4 mL) of water was added dropwise to decompose excess hydride. A white residue formed and upon addition of 2 g celite the solution was filtered. The filtrate was dried over $MgSO_4$ and concentrated under reduced pressure (30 Torr) to yield a light yellow oil. Double bulb-to-bulb distillations gave the colorless hydroxylamine in 60% yield. Since this is sensitive to oxygen (*vide supra*) and light it was kept under $N_2$ in the dark. Attempted analytical gas chromatography was frustrated by thermal decomposition. The hydroxylamine readily reduced aqueous alkaline triphenyltetrazolium chloride to the red formazan (18). **1** $^1$H nmr: $\delta(CDCl_3)$, 1.12 (s, 6H, $C_5CH_3$), 1.6 (m, 4H, $C_3$—H, $C_4$—H), 3.0 (m, 2H, $C_2$—H), 8.0–8.5 ppm (broad, 1H, OH); $^{13}$C nmr: $\delta(C_6D_6)$, 19.2 (t, C-3), 23.3 (broad at room temperature; 18.9, 26.6 at −11°C, two quartets, $C_5$—$CH_3$), 35.2 (t, C-4), 54.6 (t, C-2), 64.2 ppm (s, C-5).

[6]The concentration of $H_2O_2$ in the glow discharge electrolysis experiments was $\leq 4 \times 10^{-3}$ *M* (8). Conventional electrolysis, i.e., cathodic reduction of **1**, gave **2***a* and the signal showed the same large variation with temperature as that of **2***a* formed by glow-discharge electrolysis (8). In the conventional electrolysis $H_2O_2$ should be absent (8); the most likely oxidant is therefore $O_2$.

## Acknowledgements

We are extremely grateful to Miss Ann Sneddon and to Mrs. L. Planinic for preliminary studies of the **1** + **3***a* system.

# Some physical and chemical aspects of spin trapping of organometallic radicals by quinones: optically active radical complexes

KATHERINE A. M. CREBER, TONG-ING HO, M. CATHERINE DEPEW, DOUGLAS WEIR, AND JEFFREY K. S. WAN

*Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6*

Received September 1, 1981

KATHERINE A. M. CREBER, TONG-ING HO, M. CATHERINE DEPEW, DOUGLAS WEIR, and JEFFREY K. S. WAN. Can. J. Chem. **60**, 1504 (1982).

A brief account is presented on the use of substituted quinones as spin traps for organometallic radicals and on the applications of CIDEP and esr–HPLC techniques to the study of quinone – organometallic radical complexes. Many of these radical adducts are thermally very stable and can be isolated by the HPLC technique for detailed spectroscopic and chemical studies. This in turn allows us to present a different approach to the "spin trapping" chemistry of unstable organometallic radicals by generating initially a stable quinone – metal carbonyl radical complex, separating the parent radicals by esr–HPLC and using them to react with other organometals via ligand exchange between the CO group(s) and the organometals. It then follows that if the entering organometal ligand is optically active, the substituted radical complex would also be chiral. This simple concept has led to the isolation of the first pure optically active radical complex with well-defined physical properties, including optical rotation.

KATHERINE A. M. CREBER, TONG-ING HO, M. CATHERINE DEPEW, DOUGLAS WEIR et JEFFREY K. S. WAN. Can. J. Chem. **60**, 1504 (1982).

On présente un bref compte rendu sur l'utilisation des quinones substituées comme capteurs de spin pour les radicaux organo-métalliques et sur les applications des techniques de PEDIC et de rpe–CLHP à l'étude des complexes de quinone – radical-organométallique. Plusieurs de ces adduits radicalaires sont très stables thermiquement et peuvent être séparés par la technique de CLHP en vue d'études spectroscopiques et chimiques approfondies. Ceci nous permet ainsi de présenter une approche différente de la chimie de "captage de spin" des radicaux organométalliques instables en générant initialement un complexe de quinone – radical métal carbonyle stable et en séparant les radicaux apparentés par la rpe–CLHP et en les faisant réagir par la suite avec d'autres produits organométalliques par l'intermédiaire d'un échange de ligand entre le groupe CO et l'organométallique. Il s'en suit que si le ligand organométallique de l'ion introduit est optiquement actif, le complexe radicalaire substitué sera également chiral. Ce concept simple a conduit à la séparation du premier complexe radicalaire optiquement actif à l'état pur ayant des propriétés physiques bien définies y compris le pouvoir rotatoire.

[Traduit par le journal]

For many years the popular nitroxide spin trapping technique has provided evidence for numerous transient metal centered radicals (1). The ability of quinones to form radical complexes and spin adducts with a variety of organometals was recently emphasized (2, 3) and added another dimension to the spin trapping chemistry. The quinone – metal radical complexes are interesting generally because both the metal centre and the quinone ligands can be redox active. Since the first major study on quinone–metal complexes was carried out by Eaton (4), many other interesting complexes have been synthesized directly by the reactions of metal carbonyls with quinones (5, 6). The use of quinones in spin trapping photochemistry has yet another advantage. There is a large pool of information available for the photochemical and photophysical properties of carbonyl compounds but the quenching of the excited states of carbonyl compounds by various electron donors, including some of the organometals, has continued to attract attention (7). In this laboratory, the photoreduction of quinones by alcohols and phenols (8, 9) and by vitamins such as C and $K_1$ (10) have been extensively used as model systems for chemically induced magnetic polarization studies. They in turn provide some valuable information about the relative efficiencies of the triplet quenching reaction, the mechanisms of the secondary radical reactions, and the dynamics of the intersystem crossing processes which are responsible for the difference in the spin populations of the triplet sub-levels. The CIDEP technique was further applied to study the quenching of quinone triplets by organometals (11) and the results indicate the nature of electron transfer between the organotin compounds and the triplet quinone in the photochemical primary process. Unequivocal evidence of the electron transfer mechanism was subsequently obtained by the direct esr characterization of the triplet state of the primary radical ion pair formed and trapped during the photolysis of a solid solution containing the quinone and the organotin at 77 K (12).

When the metal – quinone radical complexes exhibit time-resolved CIDEP, their spin–lattice relaxation times $T_1$ can be estimated at low micro-

wave power levels (13). These experimental $T_1$'s provide interesting data for studies of the structural and dynamic properties of these novel radical complexes such as the uranyl–phenanthroquinone radical ion (14). However, we were a little surprised when we found that the $T_1$'s for the quinone – tin radical adducts are essentially the same as the parent semiquinone radicals (11). Subsequently, with the collaboration of Professor D. A. Hutchinson we have successfully interpreted the $T_1$ data by approximate calculations on the odd electron in the $\pi$ system (15), in which the state of the odd electron is described by the Hückel method and the contributions to $T_1$ of **G** tensor modulation and spin rotation coupling are treated. The results show that $T_1$ is just as sensitive to the number of rings as it is to the actual size of the radical. The addition of the organotin moiety does not contribute significantly to the $\pi$ system and thus has little effect on the magnitude of the $T_1$ in the radical adduct.

In recent years we have extended out quinone–metal complex studies to include other metal carbonyls, such as Re, Mn, W, Cr, and Mo. For the series of radical complexes containing rhenium carbonyl and the substituted analogs, the trapping using *ortho*-quinones has produced some extremely stable species. These radical complexes have been successfully isolated by an integral esr–HPLC (high performance liquid chromatography) technique (16). The ability of preparing and isolating these radical complexes in *pure* form has opened up many possibilities for detailed spectroscopic studies, including the emission/fluorecence of these radical complexes (16).

Another interesting aspect of the quinone spin trapping chemistry is the facility of ligand exchange in these radical complexes. We have reported earlier (17) the general exchange reactions between alkali radical ion pairs and triple ions of dicarbonyl compounds and group IVB organometals. Using *ortho*-quinone radical complexes, other exchange reactions observed include the uranyl ion (14), the organomercury (18), the group IVB organometals (19), the group VIB (3, 20) and group VIIB metal carbonyls (21). The application of these ligand exchange techniques provides another approach to the art of spin trapping of some elusive radicals. For example, substituted rhenium carbonyl radicals such as $\dot{R}e(CO)_4PPh_3$ and $\dot{R}e(CO)_3(PPh_3)_2$ have been proposed (22) in chemical reactions but not yet detected or trapped by nitroxides. In our approach (20) we began by preparing the stable quinone – rhenium carbonyl radical complex as the "trap" which is then further allowed to exchange its labile carbonyl ligand with phosphine in a thermal process. In the direct photolysis, the trapping of the elusive rhenium carbonyl – phosphine radicals is also possible by *ortho*-quinones and 1,2-dicarbonyl compounds. Further exploration of the chemistry of these stable quinone – organometal radical complexes has led to the formation of numerous hetero-binuclear and trinuclear metal organic radical complexes as well as the use of other bidentate organic ligands such as bipyridines. Some of these systems will be described here for the first time.

The key development and combination of the esr–HPLC with the radical ligand exchange technique have further excited our imagination. It follows that when the organometal ligand under exchange is optically active, the daughter radical complex would exhibit chirality. Moreover, if these chiral radical complexes can be separated by esr–HPLC, a pure optically active radical would be obtained. Such an extremely simple idea has been made into a fact in our current studies. To the best of our knowledge, *isolation* and direct identification of a pure optically active radical has not been heretofore achieved. A few of the previous studies have involved optically active radical intermediates (23–26) by inferring from product analysis or by observing different optical rotation values for the solution containing both the presumed chiral radical and the parent optically active reactant.

The implications of stable optically active radicals have yet to be fully understood. Our current efforts directed towards both the physical and chemical characterizations, including CIDEP of chiral radicals, hopefully will shed some light on this novel area of optically active radicals. This paper is dedicated to the present and former students of this laboratory and much of the experimental detail can be found in previous publications (11, 16, 17).

We shall now proceed to describe some of the current results.

## I. Spin trapping of rhenium carbonyl fragment by *ortho*-quinones, 1,2-diketones, and some nitrogen donor ligands

Formation of the $\dot{R}e(CO)_5$ fragment is accomplished by irradiation of the $\sigma \rightarrow \sigma^*$ band at 310 nm of $Re_2(CO)_{10}$ (27). In the presence of a spin trap such as *d,l*-camphorquinone (CQ) the reaction proceeds as shown below:

$$[1]\quad Re_2(CO)_{10} \xrightarrow[\text{benzene}]{h\nu,\ 310\,\text{nm}} 2\dot{R}e(CO)_5$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

1

The esr spectrum of the complex **1** is shown in Fig. 1. In an earlier study we have shown, using 3,5-di-*tert*-butyl-0-benzoquinone (DTBQ) as the spin trap in an analogous reaction, that the resulting radical complex displays octahedral symmetry about the Re centre (3). The use of CQ in the current experiments is obvious, since there are asymmetric centres in CQ. However, reaction [2] does not lead to any observable optical resolution, as expected. Partial enantioselective complexation is possible in reaction [2], when the rhenium centered radical contains an optically active ligand.[1]

Table 1 lists the esr parameters of a number of rhenium carbonyl radical complexes with quinones and 1,2-diketones. All radical complexes studied in this series are relatively stable thermally and many of them have been isolated by the esr–HPLC technique using a Partisil-5 or Partisil-10 column. For example, under identical conditions and a flow rate of 1.44 mL/min, the retention times for the series of quinone – rhenium carbonyl radical complexes are 138 s for the DTBQ–$\dot{}$–$Re(CO)_4$, 161 s for the NQ–$\dot{}$–$Re(CO)_4$, and 145 s for the PQ–$\dot{}$–$Re(CO)_4$. Generally, the quinone complexes are more stable than the diketone complexes.

Table 2 shows the esr parameters of the radical complexes between the rhenium carbonyl and the organic spin traps with various nitrogen-donor ligands, instead of quinones. The esr spectra of these complexes were found to be more resolved at room temperatures, in contrast to the quinone-type spin traps. However, these complexes were not nearly as stable as the quinone-type complexes and no attempts were made to isolate any of these complexes by HPLC. For the phenanthroline – rhenium carbonyl radical complex, the well-resolved esr spectrum shown in Fig. 2 clearly identifies the structure of the radical species as a coplanar complex. The resolved hyperfine couplings due to four equivalent nitrogen atoms indicate that two phenanthroline molecules are co-ordinated to the rhenium centre.

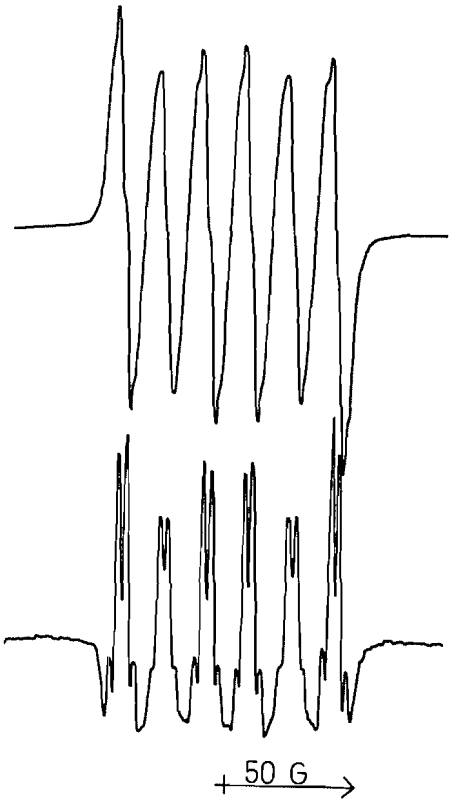

FIG. 1. The first derivative (upper) and second derivative (lower) esr spectra of CQ–$\dot{}$–$Re(CO)_4$ in toluene at 50°C.

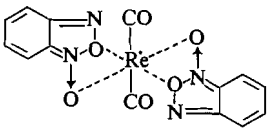
The benzofuroxan – rhenium carbonyl radical complex is very interesting, as the splittings due to two equivalent nitrogen atoms are readily observed in the spectrum. If the rhenium is co-ordinated via the two oxygen atoms in the benzofuroxan molecule, then inequivalent nitrogen splittings would be expected. One possible structure of the radical complex is the following:



The fact that these radical complexes involving donor nitrogen ligands are less stable than the

[1]Preliminary experiments using a shift reagent Eu(III)-tris-[3-(heptafluoropropylhydroxymethylene)d-camphorato] in the pmr analysis of the unreacted camphoroquinone showed a definite excess of one enantiomer but the quantitative separation and yield have not yet been obtained. We wish to thank Professor M. J. Perkins for suggesting the use of the shift reagent.

analogous oxygen donors suggests that in a molecule such as benzofuroxan containing both the nitrogen and the oxygen donors, the more stable structure would be obtained by using the oxygen donors for co-ordination.

## II. Spin trapping of group VIB metal carbonyl fragments by phenanthroquinone

Few systematic studies of spin trapping of group VIB metal carbonyl fragments have been carried out with quinones. Earlier, trapping of Mo(Cp)(CO)$_3$ fragment by nitrosodurene was reported by Hudson and co-workers (28) while the Russian workers have used other nitroso spin traps to co-ordinate Cr(CO)$_4$Cl species (29). We have examined (21) systematically the photochemical reactions of group VIB metal hexacarbonyls (including Mo, W, and Cr hexacarbonyls) in toluene and in the presence of phenanthroquinone as a spin trap. In all three cases stable metal carbonyl – quinone radical complexes were observed by esr during irradiation.

The structure of these metal carbonyl – quinone radical complexes is of great interest, since the diamagnetic group VIB metal–PQ complexes in the form of M(PQ)$_3$ are well known (3). Furthermore, data from the electrochemical redox reactions of the diamagnetic neutral quinone complexes of group VIB metals are available in the literature (30, 31). It is, therefore, noteworthy that the photochemical reactions of these metal hexacarbonyls with PQ lead to the formation of stable radical complexes involving only one quinone ligand.

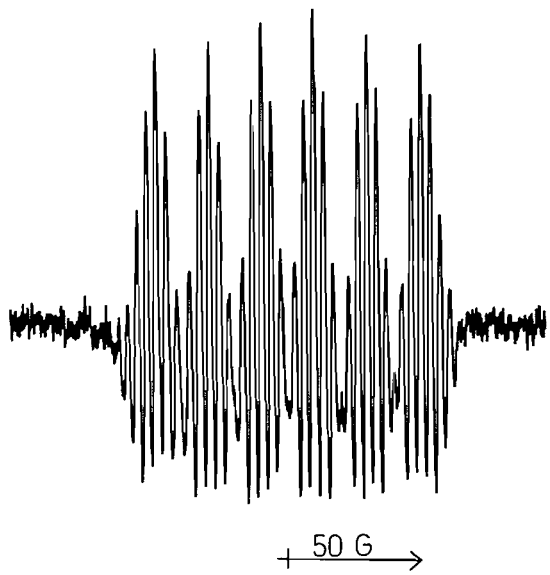

FIG. 2. The second derivative esr spectrum of the [phenanthroline]$_2$–$\dot{}$–Re(CO)$_2$ radical complex in toluene at 25°C.

On the other hand, current studies have further indicated the presence of another series of radical complexes in which *two* PQ molecules are involved in each metal radical complex. The $g$-factors for the $\dot{M}(CO)_2(PQ)_2$ are significantly lower than the corresponding $\dot{M}(CO)_4PQ$ complexes (Table 3). For Mo and W carbonyl systems, $\dot{Mo}(CO)_2(PQ)_2$ and $\dot{W}(CO)_2(PQ)_2$ radical complexes were observed after about 15 min of continuous degassing, without irradiation. The esr intensity of these complexes indicates that they are formed only as a

*PQ = Phenanthroquinone.

minor intermediate. Upon irradiation, they quickly disappeared with the simultaneous formation of the major $\dot{M}(CO)_4PQ$ complexes. In the Cr hexacarbonyl system, the results are different. Here the $\dot{C}r(CO)_2(PQ)_2$ was the major radical complex either in the dark or under irradiation. The minor radical species was the $\dot{C}r(CO)_4PQ$ complex which was produced only by photolysis.

### III. Radical ligand exchange reactions between quinone – metal carbonyl complexes and group VA organometals

It is well known that 17-electron species are very labile towards CO substitution (32). Thus, our series of stable metal carbonyl – quinone radical complexes offered excellent possibilities for ligand exchange study. Normally, the parent metal carbonyl – quinone complexes, $M(CO)_4$–Q, were first prepared and characterized by esr. Appropriate organometal ligands were then added to the solution and the substitution reactions were monitored either by esr or uv/visible spectrophotometry. Table 4 gives the esr parameters of some representative substituted heterobinuclear and trinuclear radical complexes formed via these simple ligand exchange reactions. In the DTBQ–rhenium carbonyl series, substitution by group VA ligands proceeded quite readily, with the ease of reaction under similar concentration range and other experimental conditions decreasing in the order: N > P > As > Sb. In the majority of cases, only one CO could be replaced readily by an organometal ligand. However, when the entering ligand was a phosphite two CO groups could be replaced in a consecutive manner. Preliminary studies also indicate that the ligand substitution is an equilibrium process in which the exchange can be retarded by saturating the solution of added carbon monoxide under high pressure.

[a]Taken from ref. 20.

It is interesting to examine the trends in the esr parameters on going from the parent DTBQ–$Re(CO)_4$ complex to the monosubstituted followed by the disubstituted complex where $P(OCH_3)_3$ is the entering ligand. Heat was necessary for disubstitution. As ligands are added, $a_H$ decreases, $a_{Re}$ increases, $a_P$ increases, and the $g$-factor decreases. These trends indicate that the electron density is being withdrawn from the quinone moiety towards the phosphite ligands. The increase in the $a_{Re}$ and the lower $g$-factor are consistent with the increased participation of the rhenium in the co-ordination through the phosphite ligands. When bidentate phosphorous ligands were used, in no case could both P atoms be forced to co-ordinate the rhenium atom.

Kinetic studies of these radical ligand exchange reactions are underway in an effort to elucidate the mechanism of the substitution, as the current views differ on whether an associative (33) or a dissociate (34) mechanism prevails. Our preliminary results tend to favour the dissociative mechanism, as rates for the substitution by $PPh_3$, $AsPh_3$, and $SbPh_3$ in the DIBQ–$Re(CO)_4$ complex are very close, while addition of CO apparently retards the rate significantly.

It appears rather unusual at first that although nitrogen donor ligands generally reacted faster than other ligands, neither $NPh_3$ nor $NHPh_2$ would replace a CO group on the DTBQ–$Re(CO)_4$. In an effort to explain this, we looked at a number of nitrogen–donor ligands, shown in Table 5. It became clear that the complexes fell into two distinct classes: those with high $g$-factors and low $a_{Re}$, which were very stable and those with much lower $g$-factors and higher $a_{Re}$ values, which were not at all stable. From these observations we concluded that in order to form stable substituted complexes,

TABLE 5. Electron spin resonance parameters of some nitrogen donor ligand substituted DTBQ·—$Re(CO)_3N$ radical complexes in benzene at 25°C

| Ligand | $g$-Factor | $a_{Re}$ (G) |
|---|---|---|
| Aniline | 2.0027 | 22.8 |
| Pyridine | 2.0029 | 20.1 |
| 3,5-Diethoxycarbonyl-1,4-dihydropyridine | 2.0024 | 19.5 |
|  | 2.0032 | 21.8 |
| Pyrrolidine | 2.0013 | 26.4 |
| | 2.0010 | 24.2 |
| Morpholine | 2.0024 | 25.1 |
| 1,1-Carbonyldiimidazole | 2.0028 | 23.3 |
| Quinidine | 2.0029 | 18.7 |
| Methylbenzylamine | 2.0027 | 22.3 |
| Triethylamine | 2.0022 | 24.6 |
| Bicyclohexylamine | 2.0017 | 24.9 |
| Tetrahydropyridine | 2.0013 | 26.4 |

the incoming ligand must not be sterically hindered at the donor atom centre (as were $NPh_3$ and $NHPh_2$). They must also possess some way to delocalize the excess electron density such as aromatic $\pi$ system (as in $PhNH_2$), a heteroatom as in morpholine, or empty $d$-orbitals as in the phosphine ligands.

Other quinone·—$Re(CO)_4$ complexes will also undergo substitution reactions with a variety of ligands. A representative group of different quinones involved is shown in Table 6. Several interesting effects due to the choice of quinone can be seen from the esr parameters. Napthoquinone has an extensive $\pi$ system, hence delocalizes electron density very efficiently, resulting in lower $g$-factors and smaller metal hyperfine coupling constants. Camphorquinone, on the other hand, has no aromatic character and in the case of a substituted phosphite ligand $a_P$ becomes much greater than $a_{Re}$.

Similar ligand substitution reactions also occur with the group VIB metal carbonyl – PQ radical complexes. The noted difference is that for the $Mo(CO)_4$·—PQ complex, both equatorial CO groups can be replaced by two $PPh_3$ ligands (21). On the other hand, substitution reactions involving $Cr(CO)_2$·—$PQ^2$ complex were much more difficult. With $PPh_3$, the reaction took a few hours to complete and only one of the two axial CO groups was replaced. Attempt to replace the CO group with other group VA organometals was not successful.

These results represent a comprehensive and systematic study of the radical ligand exchange reactions in metal carbonyl complexes. The information is extremely valuable as we move further towards the novel radical complex systems which contain exchanged ligands exhibiting optical activity.

## IV. The stable optically active organometallic radical adducts

Many of the substituted metal carbonyl—quinone radical complexes studied above are thermally stable and have been separated by the esr–HPLC method. A simple idea was then developed to prepare the first pure optically active radical complex by combining our experience in esr–HPLC and in radical ligand exchange technique. When the entering ligand is optically active, the stable daughter radical complex will also be chiral. We have recently succeeded in making and *isolating* the first two pure optically active radical complexes by the following reactions:

[3] DTBQ·—$Re(CO)_4$ + 
(+)DIOP

↓

DTBQ·—$Re(CO)_3$—(+)DIOP + CO

**2**

[4] DTBQ·—$Re(CO)_4$ + 
(−)DIOP

↓

DTBQ—$Re(CO)_3$—(−)DIOP + CO

**3**

Electron spin resonance–HPLC was then used to separate the optically active radical complexes **2** and **3** in respective systems from the parent radical as well as the unreacted optically active phosphine. At a typical flow rate of chloroform at 2.0 mL/min through a Partisil-10 column, the retention times were 115 s for the parent radical, 490 s for the optically active radical complexes **2** or **3**, and 150 s for DIOP. Obviously, the different optically active configurations are not separated by HPLC, and therefore pure (+) or pure (−)DIOP ligands must be used to produce the corresponding optically active daughter radicals.

*TTBQ = Tetrabromo-*o*-quinone.

TABLE 7. Optical rotation measurements for (±)DIOP ligands, and for the DTBQ–$\dot{}$–$Re(CO)_3$(±)DIOP radical complexes in benzene at room temperature with light at 436 nm

| System | c, mg/mL | α, deg | $[\alpha]^{22°}_{436\ nm}$, deg |
|---|---|---|---|
| (+)DIOP | 12.2±0.5 | 0.022±0.002 | 18.0±1.0 |
| (−)DIOP | 13.7±0.5 | −0.025±0.002 | −18.0±1.0* |
| DTBQ–$\dot{}$–$Re(CO)_3$(+)DIOP | 1.40±0.10 | 0.010±0.002 | 7.0±1.0 |
| DTBQ–$\dot{}$–$Re(CO)_3$(−)DIOP | 0.86±0.10 | −0.006±0.002 | −7.0±1.0 |

*Compared with the literature value of $[\alpha]^{22°}_{D} = -12.3$ (c, 4.57).

Optical rotation, esr, and uv/visible spectroscopy were used to characterize these two pure optically active radical complexes. The measurement of the optical rotation was carried out at 436 nm, since the radicals absorbed strongly in the 589 nm (sodium line) region. The optical rotation of the pure DIOP ligand was therefore also checked at 436 nm and compared with the value of the daughter radicals (Table 7).

In another exploratory investigation of the photolysis of $Re_2(CO)_{10}$ in the presence of optically pure DIOP ligand and with a racemic mixture of camphorquinone as a spin trap, an optically active radical complex containing the camphorquinone–$\dot{}$–$Re(CO)_3$DIOP was obtained and isolated. The remaining unreacted camphorquinone, however, exhibited optical activity, indicating a partial optical resolution during the spin trapping process. The results also suggest that a $Re(CO)_3$(+)DIOP fragment would selectively complex with the (+) camphorquinone while a $Re(CO)_3$(−)DIOP would similarly select the (−) camphorquinone for complexation. The results are extremely important and have far-reaching implications. To answer a few questions, we have also prepared, using established procedures, the pure optically active camphorquinones and studied their chemical reactions as spin traps in the Re carbonyl reactions. Furthermore, we have looked into the CIDEP of the optically active camphorquinone reactions with organotin compounds. For example, we have established that the reactions of camphorquinone with amines or phenols do not lead to CIDEP observation and concluded that the intersystem

crossing to the camphorquinone triplet sublevels produced no primary electron polarization. However, in the presence of organotin compound, a charge-transfer triplet state involving both the tin and the camphorquinone may result in a different set of spin dynamics leading to CIDEP of the camphorquinone – tin radical adducts, as observed experimentally. A detailed account of the chemistry of optically active organometallic radical complexes and adducts will be published in the near future.

As we progress from the early spin trapping experiments with quinones to the exciting development of optically active spin traps, we have the feeling that this is not the time to reflect or summarize past results; this is the time to expand and search for the new horizons in the world of free radicals and spin traps.

### Acknowledgments

The expert assistance of Susan Allen, a summer undergraduate student, and Mike Bishop, a fourth year chemistry student, was essential in many of the experimental work. Financial support by the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged.

# Synthesis of new radical-cations with 2,2,6,6-tetramethylpiperidine-*N*-oxyl and pyridinium moieties

ILEANA DRAGUTZAN

*Center of Organic Chemistry, 202 B Splaiul Independenţei, 78100 Bucharest, Romania*

AND

ALEXANDRU T. BALABAN

*Department of Organic Chemistry, The Polytechnic, Bucharest, Romania*

Received September 1, 1981

ILEANA DRAGUTZAN and ALEXANDRU T. BALABAN. Can. J. Chem. **60**, 1512 (1982).

Two new radical-cations (as crystalline perchlorates) **1** and **2** were synthesized from the respective amines **3** and **4**, and 2,4,6-trimethylpyrylium perchlorate **5**. The properties and spectra of the new radical-cation perchlorates (which may be recrystallized from ethanol or from water) are described.

ILEANA DRAGUTZAN et ALEXANDRU T. BALABAN. Can. J. Chem. **60**, 1512 (1982).

Deux nouveaux radicaux-cations **1** et **2** ont été synthétisés (sous la forme de perchlorates cristallisés) à partir des amines **3**, respectivement **4**, et du perchlorate de 2,4,6-triméthylpyrylium **5**. On décrit les propriétés et les spectres des perchlorates **1** et **2** qui peuvent être recristallisés en utilisant de l'eau ou de l'éthanol.

Spin labels (1–6) have become widely used in biochemistry (7, 8) or in polymer chemistry (9, 10). So far, cationic nitroxides have only been known as quaternary ammonium salts with 2,2,6,6-tetramethylpiperidine-*N*-oxyl (11, 12) or phosphonium salts with pyrrolidine-*N*-oxyl moieties (13). Since pyridinium rings can be easily formed from pyrylium salts and primary amino groups (14–16), and since both pyrylium salts (17, 18) and nitroxides with primary amino groups are readily available, we now report the preparation of spin labels possessing pyridinium rings, namely **1** and **2**.

The primary amines **3** and **4** were prepared with suitable modifications following the general pathways described in refs. 19–21 and 22–24, respectively.

Unlike the usual spin labels which are lipophilic and water insoluble, the new spin labels **1** and **2** are soluble in ethanol and may be recrystallized from water. The delocalization of the positive charge over the pyridinium ring makes these new cation-radicals **1** and **2** different from ammonium or phosphonium radical-cations described earlier (11–13), because the latter compounds have a more

localized positive charge. The spacing between the nitroxide group and the pyridinium ring is larger in **2** than in **1**, assuming a stretched conformation of the molecule.

The properties of the new spin labels **1** and **2** related to their use in studying biological systems by esr are being checked by R. J. Mehlhorn and L. Packer and they will be reported in a future paper.

## Experimental

*2,4,6-Trimethyl-*N*-(4'-methylene-2',2',6',6'-tetramethyl-piperidine-*N*'-oxyl)-pyridinium perchlorate (1)*

Reaction of **3** (bp 123–124°C/3 Torr, mp 52°C, lit. (19) mp 56.5°C; ir ($CH_2Cl_2$) $\nu_{NH}$: 3385 and 3650 $cm^{-1}$; esr triplet in benzene indicates $a_N = 1.673$ mT, $g = 2.0059$) (0.4 g, 2.16 mmol) in 5 mL dry ethanol with 0.35 g (1.57 mmol) 2,4,6-trimethylpyrylium perchlorate (17) at room temperature for 15 min, followed by addition of 0.1 mL acetic acid and stirring for another 15 min, yielded a red solution. Gaseous ammonia was bubbled to convert any unreacted pyrylium salt into liquid 2,4,6-collidine, then the orange-coloured precipitate was filtered off (0.29 g, mp 212°C). On dilution with ethyl ether the filtrate deposits a second crop of crystals, mp 195°C (0.165 g), total yield 54%. The combined product **1** was purified by recrystallization from ethanol–ether yielding yellow crystals, mp 217–219°C. In the ir spectrum (KBr pellet) the $ClO_4$ anion presents bands at 622 and 1090 $cm^{-1}$ and the pyridinium ring gives rise to a band at 1635 $cm^{-1}$. The esr spectrum (in benzene) presents a triplet indicating $a_N = 1.673$ mT, $g = 2.0059$. *Anal.* calcd. for $C_{18}H_{30}N_2O^+ClO_4^-$: C 55.46, H 7.70, N 7.19%; found: C 55.26, H 7.83, N 7.08%.

*2,4,6-Trimethyl-*N*-(2',2',6',6'-tetramethylpiperidine-*N*'-oxyl-4'-aminoethyl)-pyridinium perchlorate (2)*

2,4,6-Trimethylpyrylium perchlorate (17) (0.7 g, 3.15 mmol) and 0.8 g (3.75 mmol) **4** (ir spectrum ($CCl_4$) has a broad massif with maxima at 3310 and 3400 $cm^{-1}$, and bands at 1470 and 1630 $cm^{-1}$; lit. (24) ir (neat): 3350, 3300, 1590 $cm^{-1}$) were stirred at room temperature in 10 mL dry ethanol. After work-up as in the preceding analogous reaction, 1.1 g orange-coloured product (70% yield) was obtained, with mp 153–155°C (from ethanol–ether). Infrared spectrum (KBr pellet): $ClO_4^-$ anion with bands at 625 and 1095 $cm^{-1}$, 1643 (ring stretch), and 3313 $cm^{-1}$ ($\nu_{NH}$); esr triplet in ethanol indicates $a_N = 1.64$ mT. *Anal.* calcd. for $C_{19}H_{33}N_3O^+ClO_4^-$: C 54.49, H 7.89, N 10.04%; found: C 54.79, H 8.26, N 9.73%.

# Synthesis and spin trapping kinetics of new alkyl substituted cyclic nitrones

D. L. HAIRE AND EDWARD G. JANZEN

*Department of Chemistry, Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1*

Received September 1, 1981

D. L. HAIRE and EDWARD G. JANZEN. Can. J. Chem. **60**, 1514 (1982).

Three new nitrones, 5-*n*-propyl-5-methyl-1-pyrroline-*N*-oxide (PMPO), 5-*n*-hexyl-5-methyl-1-pyrroline-*N*-oxide (HMPO), and 5-*n*-decyl-5-methyl-1-pyrroline-*N*-oxide (DeMPO), amphiphilic versions of the spin trap 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO), have been synthesized. A comparative study of the absolute rate constants for formation and decay of the *tert*-butoxyl spin adducts to these cyclic nitrones as well as 3,3,5,5-tetramethyl-1-pyrroline-*N*-oxide ($M_4PO$) has been undertaken using esr kinetic techniques.

D. L. HAIRE et EDWARD G. JANZEN. Can. J. Chem. **60**, 1514 (1982).

On a synthétisé trois nouvelles nitrones: le *N*-oxyde de *n*-propyl-5 méthyl-5 pyrroline-1 (OPMP), le *N*-oxyde de *n*-hexyl-5 méthyl-5 pyrroline-1 (OHMP) et le *N*-oxyde de *n*-décyl-5 méthyl-5 pyrroline-1 (ODeMP) qui sont des versions amphiphiles du capteur de spin *N*-oxyde de diméthyl-5,5 pyrroline-1 (ODMP). Faisant appel aux techniques cinétique de rpe, on a entrepris des études comparatives des constantes absolues de vitesse de formation et de désintégration des adduits de spin *tert*-butoxyle de ces nitrones cycliques ainsi que du *N*-oxyde de la tétraméthyl-3,3,5,5 pyrroline-1 ($OM_4P$).

## Introduction

Heightened attention has been drawn lately to the intermediacy of free radical species in biological systems. The increased activity has been due in part to the considerable success of spin trapping (see refs. 1 (for biochemical applications) and 2 (for a general review)) with cyclic nitrones (3). The detection and identification of transient bio-radicals includes ·OH (4) and $\cdot O_2^-$ (5) which are difficult to study by other methods. It was realized (6) that effective examination of free radical phenomena in biphasic media such as biological membranes or models thereof required the development of "tailored" spin trapping agents of hydrophilic and/or lipophilic design. A number of these new nitrone (7) and nitroso (8) spin traps have become available. However, 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO) counterparts have not yet been reported. The present research was directed towards the synthesis of spin traps wherein hydrocarbon chains of systematically increasing length (*n*-propyl, *n*-hexyl, *n*-decyl) were connected to C-5 of the pyrroline ring to impart increased lipophilic character to the DMPO nucleus.

The general procedures employed in synthesis of the cyclic nitrone spin traps (I, II, III) are outlined in Scheme 1.

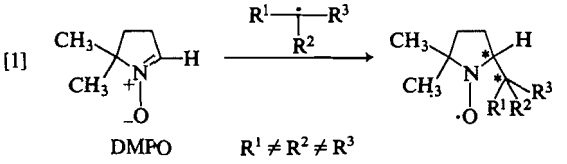
Several years ago (9) it was demonstrated that spin trapping could serve as a quantitative probe for certain free radical reactions in solution. However, only recently has there emerged an increased awareness of the importance of kinetic spin trapping data. Maeda and Ingold (10*a*) have suggested that spin trapping will not fully evolve until rate constants for all ·R's and spin traps become available.

The viability of a given spin trap is dependent to a large extent upon the rates of formation of spin adducts ($k_f$) and their subsequent decay ($k_d$). An objective of the present study was to apply kinetic esr spectroscopic techniques to ascertain the effect, if any, of alkyl chains of differing lengths (*n*-propyl, *n*-hexyl, *n*-decyl) at C-5 of the pyrroline ring on the spin trapping and spin adduct decay rate constants relative to those for DMPO.

## Results and discussion

### *Diastereomeric cyclic aminoxyl radicals*[1]

The capture of a free radical by DMPO creates an enantiomeric mixture of spin adducts with an asymmetric center located at position 2 of the pyrrolidine ring. Only one esr spectrum is anticipated and this indeed is observed (3*c*), see Fig. 1 (a). When the group that was the radical possesses an element of chirality, however, diastereomeric aminoxyls are produced (eq. [1]). Differences in the hyperfine patterns are expected and may be observed (11).



[1]Note, the term "aminoxyl" was introduced during the spin trapping conference and was deemed more appropriate than "nitroxyl".

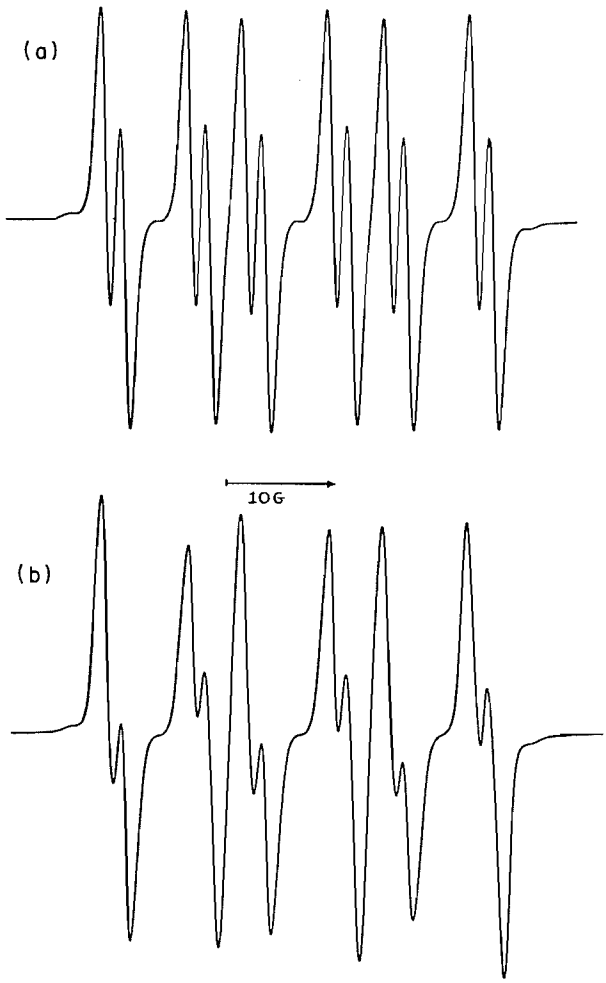

FIG. 1. (*a*) Spectrum from 0.05 *M* DMPO and 0.01 *M* DBPO in benzene (25°C). (*b*) Spectrum from 0.10 *M* HMPO and 0.05 *M* DBPO in benzene (25°C).

The *tert*-butoxyl adduct derived from an RMPO spin trap is diastereomeric. This is due to the presence of the two chiral sites which are incorporated in this case within the pyrrolidine framework at C-2 and C-5 (eq. [2]).

[2] 
RMPO

R = (*n*-propyl, *n*-hexyl, *n*-decyl), $R^1 \neq H$

Linewidths ranging from 0.12 to 0.13 G were observed with all *tert*-butoxyl adducts of DMPO and RMPO. Existence of the relatively wide lines decreases the chances of detecting a distinct esr spectrum for each diastereomer. For this reason the spectra of RMPO BO· adducts might be expected to exhibit dissymmetry when the spectra of diastereomers superimpose, i.e. the typical asymmetric spectral appearance of RMPO *tert*-butoxyl adducts, Fig. 1 (b) may be indicative of diastereomeric cyclic aminoxyls.

The question of asymmetric spectra arising from impurity radicals rather than diastereomeric spin adducts appears unlikely. *tert*-Butoxyl radicals are known (12*a*) to fragment to acetone and methyl radicals. Asymmetry is definitely not due to spin trapping of methyl or other *C*-centered radicals because the spectra of these adducts are character-

[3] 
ized by sharp lines and sizably different in their hfsc's; e.g. for the methyl adduct of DMPO in benzene, $a_N = 14.31$ and $a_\beta^H = 20.52$ G (3*d*). The hfsc's for the cyclic nitrone BO· spin adducts are listed in Table 1.

*Formation kinetics*

The absolute rate constant of *tert*-butoxyl trapping by PBN was determined by correlation with the well established rate constant of hydrogen abstraction from cyclohexane by BO· radicals (12*b*). Rate constants for spin trapping *tert*-butoxyl radicals with cyclic nitrones were obtained by competitive *in situ* scavenging experiments with PBN. *tert*-Butoxyl radicals generated in reaction [4] are trapped by the cyclic nitrone and PBN in reactions [5] and [6] respectively.

[4] 
[5] 
[6] 
Due to marked differences in their hfsc's, Table 1, initial formation rate constants of the two adducts may be quantitated by monitoring as a function of time the peaks indicated in Fig. 2. The formation rate constants of the BO· adducts of the cyclic nitrone and PBN are represented by expressions [7] and [8] respectively.

TABLE 1. Hyperfine splitting constants for *tert*-butoxyl spin adducts[a]

| Nitrone | $a_N$ | $a_\beta^H$ | $a_\gamma^H$ |
|---|---|---|---|
| DMPO | 13.19[b] | 8.16 | 1.82 (1H) |
| | (13.01)[c] | (6.63) | (2.04) |
| PMPO | 13.24 | 8.17 | 1.94 (1H) |
| | (12.92) | (6.91) | (1.98) |
| HMPO | 13.03 | 7.99 | 1.87 (1H) |
| | (12.88) | (6.87) | (1.65) |
| DeMPO | 13.08 | 7.97 | 1.77 (1H) |
| | (12.95) | (6.92) | (2.17) |
| $M_4$PO | 13.39[d] | 5.88 | |
| | (13.16) | (4.90) | |
| PBN | 14.29[e] | 1.84 | |

[a] All spectra were recorded at 25°C in benzene from 0.05 *M* nitrone and 0.01 *M* di-*tert*-butylperoxalate, all hfsc's are in Gauss.
[b] Compare with $a_N$ = 13.11, $a_\beta^H$ = 7.93, $a_\gamma^H$ = 1.97 (1H) G, ref. 3*c*.
[c] Bracketed values indicate spectra recorded in di-*tert*-butylperoxide.
[d] Compare with $a_N$ = 13.31, $a_\beta^H$ = 5.81 G, ref. 3*e*.
[e] Compare with $a_N$ = 14.22, $a_\beta^H$ = 1.95 G, ref. 9*b*.

[7] $$\frac{d[\text{cyclic adduct}]_0}{dt} = k_{fc}[\text{cyclic nitrone}]_0[BO\cdot]_0$$

[8] $$\frac{d[\text{PBN adduct}]_0}{dt} = k_{fp}[\text{PBN}]_0[BO\cdot]_0$$

Since $k_{fp}$, $[PBN]_0$, $[\text{cyclic nitrone}]_0$ are known, $k_{fc}$, the spin trapping rate constant for the cyclic nitrone may be determined by measuring the initial rates of growth of the two spin adducts.

[9] $$\frac{d[\text{cyclic adduct}]_0/dt}{d[\text{PBN adduct}]_0/dt} = \frac{k_{fc}[\text{cyclic nitrone}]_0}{k_{fp}[\text{PBN}]_0}$$

Plots of esr growth for cyclic nitrone and PBN BO·

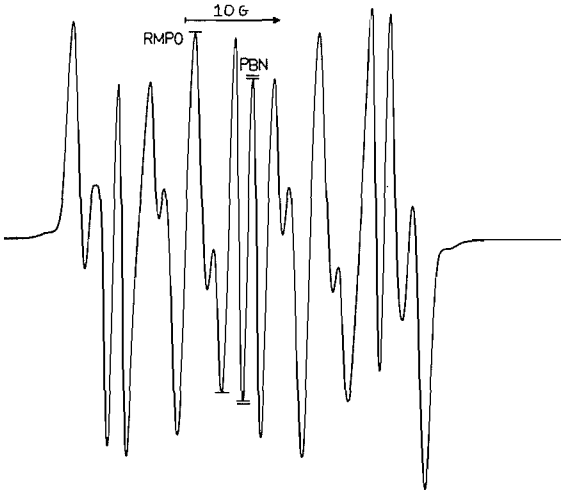

FIG. 2. Spectrum from 0.01 *M* HMPO, 0.30 *M* PBN, and 0.005 *M* DBPO in benzene (25°C).

adducts were characteristically linear (all corr. >0.999) over a 1500 s timescale. A representative plot, i.e. the PMPO adduct, is provided in Fig. 3. Cyclic nitrone adduct growth gradually slowed thereafter causing curvature in the plots due to the onset of spin adduct decay. When the cyclic nitrone concentration was increased from 0.001 to 0.10 *M* nonlinearity effects occurred earlier (~200 s) and were considerably more pronounced. This observation might suggest that spin adduct disappearance was due in some degree to spin adduct reaction with the spin trap. A similar rate constant of *tert*-butoxyl adduct production (within experimental error), $5.2 \times 10^8$ vs. $4.1 \times 10^8$ $M^{-1}$ $s^{-1}$ (Table 2) was, nevertheless, obtained with 0.10 *M* PMPO. This adds further support (9*b*) to the argument that all BO· radicals generated in this system are scavenged by spin trapping.

Spin trapping rate constants for *tert*-butoxyl are reported in Table 2. Reproducibility of the results, as judged by duplicate runs, was ±10%. The rate constant of *tert*-butoxyl trapping by DMPO was $7.3 \times 10^8$ $M^{-1}$ $s^{-1}$. This is slightly greater than the value of $5.0 \times 10^8$ $M^{-1}$ $s^{-1}$ previously reported (9*b*). Rate constants for RMPO (R = *n*-propyl, *n*-hexyl,

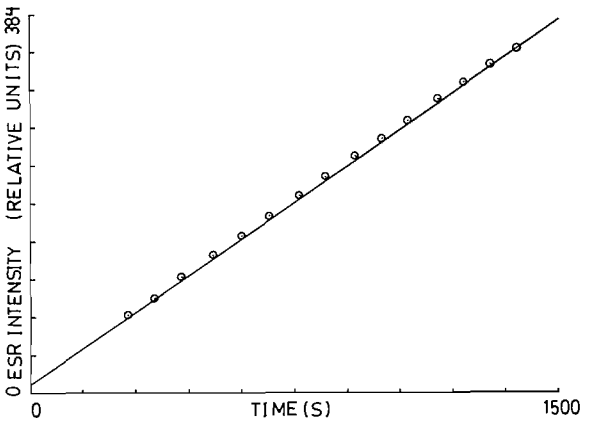

FIG. 3. Plot of the esr signal intensity for the *tert*-butoxyl spin adduct of PMPO versus time in benzene.

TABLE 2. Absolute *tert*-butoxyl spin trapping rate constants of various cyclic nitrones[a]

| Spin trap | Spin trapping rate constant $k_{fc} \times 10^{-8}$, $M^{-1}$ $s^{-1}$ |
|---|---|
| DMPO | 7.3[b] |
| PMPO | 4.1 |
| HMPO | 3.8 |
| DeMPO | 3.3 |
| $M_4$PO | 0.086[c] |

[a] All rate constants were determined at 25°C in benzene.
[b] Compare with $5.0 \times 10^8$ $M^{-1}s^{-1}$, ref. 9*b*.
[c] Compare with $0.16 \times 10^8$ $M^{-1}$ $s^{-1}$, ref. 3*e*.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

*n*-decyl) BO· trapping of 4.1, 3.8, and 3.3 × $10^8\ M^{-1}\ s^{-1}$ respectively are marginally lower than the DMPO value. Examination of molecular models indicates that the rate constant decrease relative to DMPO might rest in a steric effect wherein a propyl or longer alkyl substituent at C-5 of the pyrroline ring is required to interfere with radical addition at C-2. *tert*-Butoxyl addition to $M_4PO$, $0.086\ M^{-1}\ s^{-1}$ (compare $0.16 \times 10^8\ M^{-1}\ s^{-1}$ (3*e*)), was decreased 85× with respect to DMPO obviously due to steric interactions caused by the two additional methyl groups located "β" to the nitrone functionality.

*Decay kinetics*

Rate constants for the decay of the *tert*-butoxyl adducts of the various nitrones are listed in Table 3. Duplicate experiments indicated a reproducibility of ±20%. Ultraviolet photolysis of di-*tert*-butylperoxide (BOOB) over approximately five minutes produced $\sim 1.5 \times 10^{-6}\ M$ steady-state *tert*-butoxyl adduct concentrations according to reactions [5] and [10].

[10] $\text{BOOB} \xrightarrow{\hbar\nu} 2\,\text{BO}\cdot$

Solubilization of each of the cyclic nitrones (except $M_4PO$) at 25°C in di-*tert*-butylperoxide produced an exceedingly weak yet persistent triplet ($a_N$ = 15.29). The anomalous signal situated midway between doublets 1 & 2, 3 & 4, 5 & 6 (Figs. 1 (a) and (b)), presumably of a di-*tert*-alkyl aminoxyl, was completely unaffected by photolysis and remained unchanged even days later. This aminoxyl does not appear to interfere with the spin trapping system chemically or spectrally (i.e. the triplet does not overlap the BO· adduct peaks). Hence the kinetic data reported here should remain valid.

Simple dialkyl aminoxyls bearing at least one β-H substituent, such as diethylaminoxyl, are known to decay via disproportionation to the respective hydroxylamine and nitrone.[2]

[11]  $\xrightarrow{k_d}$ nonradical products

[2]For the mechanism of diethylaminoxyl decay,

$$(CH_3CH_2)_2NO\cdot \xrightarrow{k_d} (CH_3CH_2)_2NOH + CH_3CH{=}\overset{+}{N}(-O)CH_2CH_3$$

see ref. 10*b*. Further examples exhibiting the second order decay of dialkylaminoxyls are presented in ref. 10*c*.

TABLE 3. Absolute rate constants for the second order decay of the various cyclic *tert*-butoxyl adducts[a]

| Spin trap[b] | Initial radical concentration ($M$) | Decay rate constant $k_d \times 10^{-2}$, $M^{-1}\ s^{-1}$ |
|---|---|---|
| DMPO | $1.8 \times 10^{-6}$ | 5.1 |
| PMPO | $1.8 \times 10^{-6}$ | 3.9 |
| HMPO | $1.3 \times 10^{-6}$ | 5.5 |
| DeMPO | $1.2 \times 10^{-6}$ | 4.1 |
| $M_4PO$ | $1.5 \times 10^{-6}$ | 0.65 |

[a]All rate constants were determined at 25°C in di-*tert*-butylperoxide.
[b]All nitrones were 0.20 *M*.

Best fits were obtained with second order plots (all corr. >0.99). The decay of the DeMPO *tert*-butoxyl adduct is representative (Fig. 4). A degree of first order character may also be present because these plots were also reasonably linear (all corr. 0.90–0.95).

The decay rate constants of the RMPO *tert*-butoxyl adducts are effectively equal within experimental error. This suggests that despite the increased number of methylene hydrogens (due to the longer alkyl substituents in the RMPO adducts) their persistence remains essentially the same as DMPO adducts. The rate constant of decay for the BO· adduct of $M_4PO$, $0.65 \times 10^2\ M^{-1}\ s^{-1}$, is 8× slower than that of DMPO. Decay rate constants for all the cyclic nitrone adducts are of comparable magnitude though slightly smaller than that reported for a *C*-radical spin adduct of related structure, i.e. the $\cdot CH_2OH$ adduct of DMPO decayed at $184\ M^{-1}\ s^{-1}$ (4*c*).

*Summary*

In this study the viability of five cyclic nitrone spin traps (DMPO, PMPO, HMPO, DeMPO, and $M_4PO$) as scavengers of BO· radicals has been

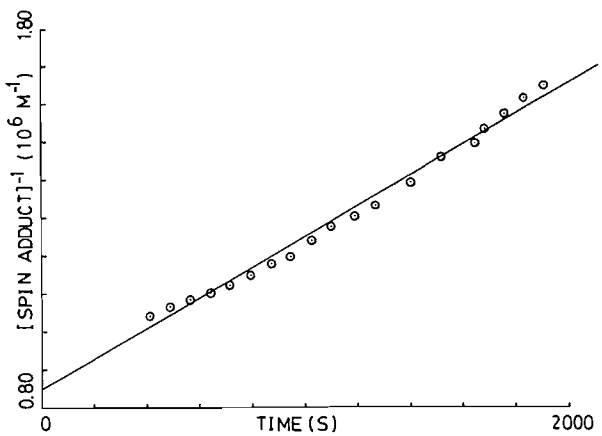

FIG. 4. Plot showing decay of the *tert*-butoxyl adduct of DeMPO is second order at 25°C in di-*tert*-butylperoxide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

evaluated. We find that the RMPO spin traps offer the following advantages in spin trapping.

(a) There is potential for preferentially probing radical reactions in lipid-like regions of mixed phase media.

(b) The spin trapping rate constants for radicals are fast, Table 2, e.g. *tert*-butoxyl ($\sim 3.7 \times 10^8\ M^{-1}\ s^{-1}$).

(c) The spin adducts, e.g. *tert*-butoxyl, are persistent, Table 3, ($\sim 4.5 \times 10^2\ M^{-1}\ s^{-1}$).

(d) Isotropic esr spectra are obtained which are (in addition) sensitive to the nature (polar versus nonpolar) of the radical trapped, Fig. 1 (b) (also refs. 3*c*, 3*d*).

Interpretation of esr spectra of RMPO adducts thus far has not been hampered by the existence of diastereomers because differences in hfsc's have been less than the linewidths. Detailed examination of RMPO adducts by ENDOR spectroscopy is planned. Preliminary experiments with the RMPO spin adducts in model membrane systems are currently in progress.

*Synthetic methodology*

Synthesis involved essentially the conversion of secondary aliphatic nitroalkanes to nitrones via a procedure developed by Todd and co-workers (13). Several variations in experimental conditions for these reactions were required. Details are given in the Experimental.

Three distinct Sequences (1, 2, 3), Scheme 1, to 2-nitroalkanes were examined. A recent Corey modification (14) is evidence that the oxidation of oximes through intermediate halonitroso compounds is still an important route to nitro compounds. The route, however, seems to be limited to the preparation of cyclic and short chain (< 6 carbons) 2-nitroalkanes. Sequence 1 utilized a modified version of the original procedure (15). A major inconvenience inherent in Sequence 2 is the high yield (> 30%) of the side product 2-alcohols. Removal of these impurities from long chain (> 12 carbons) 2-nitroalkanes proved exceedingly difficult. Described in Sequence 3 is the successful extension of a recently developed primary nitroalkane procedure (16) to the synthesis of long chain secondary nitroalkanes.

## Experimental

The nmr spectra were recorded on a Varian (T60 or EM 360L) spectrometer and only the characteristic peaks are reported. Chemical shifts were reported in $CDCl_3$ as a solvent in parts per million (δ) downfield from internal tetramethylsilane. The ir spectra were obtained from a Beckman Acculab 6 spectrophotometer. Elemental analyses were performed by Guelph Chemical Laboratories, Guelph, Ontario. References to the original literature accompany all known compounds.

*Synthesis of nitrones and precursors*

I. *Secondary nitroalkanes*

*Sequence 1*

*2-Bromo-2-nitrosopentane*

Freshly distilled 2-pentoxime (24.0 g; 237.1 mmol) (94% from 2-pentanone (17)) was added gradually to a vigorously stirred suspension of 63.3 g (355.7 mmol) *N*-bromosuccinimide and 39.8 g (474.2 mmol) sodium bicarbonate in 400 mL of 5°C water. After the reaction subsided, the ice/$H_2O$ bath was removed and stirring was continued for 3 h. The thermally labile bromonitrosoalkane was extracted with pentane (3 × 150 mL), dried over sodium sulfate, and filtered. Approximately 80% of the solvent was removed at atmospheric pressure giving a dark blue oil, (not distillable, lit. (15)), which was used directly in the next step.

*2-Bromo-2-nitropentane*

30% Aqueous hydrogen peroxide (120 mL) and 50 mL of concentrated nitric acid were added in succession to the crude bromonitrosoalkane. The mixture was heated at 50°C for 4 h, cooled, extracted with 3 × 200 mL pentane, washed with 2 × 120 mL 2% NaOH, dried over sodium sulfate, filtered, and solvent removed under reduced pressure. 2-Bromo-2-nitropentane (27.9 g; 142.3 mmol) was isolated in 60% yield (from the oxime) as a clear colorless oil, bp 72°C/12 Torr (lit. (15) 3-isomer, 3-bromo-3-nitropentane, bp 70°C/10 Torr); $^1$H nmr ($CDCl_3$) δ: 2.20–2.60 (s, 3H, Br ($NO_2$)—C—$CH_3$), 2.20–2.60 (t, 2H, Br ($NO_2$)—C—$CH_2$).

*2-Nitropentane*

2-Bromo-2-nitropentane (27.9 g; 142.3 mmol) was gradually added to a mechanically stirred solution (0°C) of 20.0 g (528.7 mmol) of sodium borohydride in 270 : 90 (mL) methanol–water. Stirring was continued for 12 h after which the mixture was filtered through sintered glass, methanol was evaporated under reduced pressure, and the resulting aqueous phase acidified by dropwise addition of 15% aqueous hydroxylamine hydrochloride solution. After stirring for 2 h the aqueous mixture was extracted with 3 × 200 mL pentane, dried ($Na_2SO_4$), and filtered. The solvent was evaporated under reduced pressure (25°C) and the residue fractionated to provide 10.0 g (85.4 mmol), 60% yield, of colorless 2-nitropentane, bp 152°C/ 750 Torr (lit. (18) bp 149°C/760 Torr); $^1$H nmr ($CDCl_3$) δ: 1.52 (d, 3H, $NO_2$—C—$CH_3$), 4.62 (sextet, 1H, $NO_2$—C—H).

*Sequence 2*

*2-Bromooctane*

2-Octyl-*p*-toluenesulphonate (19) was obtained as a thermally labile faint yellow oil in 72% yield by reaction of 56.5 g (433.8 mmol) of dried, freshly distilled 2-octanol with 90.9 g (476.8 mmol) of purified *p*-toluenesulphonyl chloride in 350 mL (4.33 mol) of dry pyridine for 4 h at −5°C. 2-Octyl-*p*-toluenesulphonate (88.7 g; 312.3 mmol) and 32.3 g (313.9 mmol) of anhydrous sodium bromide in 500 mL of dry *N*,*N*-dimethylformamide were stirred for 3.5 days at 25°C. To the mixture were added 200 : 200 (mL) pentane–water. The aqueous DMF portion was extracted with 3 × 150 mL pentane. The combined organic layers were washed with 3 × 150 mL of water, dried over sodium sulfate, filtered, and solvent evaporated under reduced pressure. 2-Bromooctane (57.9 g; 299.8 mmol) (96% yield) was collected as a colorless oil, bp 69°C/12 Torr (lit. (19) bp 87°C/20 Torr); $^1$H nmr ($CDCl_3$) δ: 1.70 (d, 3H, Br—C—$CH_3$), 4.01 (m, 1H, Br—C—H).

*2-Nitrooctane*

2-Bromooctane (57.9 g; 299.8 mmol), dry sodium nitrite (36.0 g; 521.7 mmol), dry phloroglucinol (37.8 g; 299.7 mmol), and dry urea (39.9 g; 664.6 mmol) were stirred in the dark for 45 h at 25°C in 600 mL of dry DMF. Pentane (300 mL) and 300 mL of water

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

were added to the mixture. The aqueous DMF layer was extracted with 3 × 150 mL pentane. The combined organic phases were washed with 3 × 150 mL of water, dried over sodium sulfate, filtered, and solvent evaporated under reduced pressure. The crude product was fractionated through a 1 × 20 cm Vigreux column, and 22.9 g (143.9 mmol) of 2-nitrooctane (48% yield) were collected as a colorless oil, bp 70°C/3 Torr (lit. (20) bp 67°C/3 Torr); $^1$H nmr ($CDCl_3$) δ: 1.52 (d, 3H, $NO_2$—C—$CH_3$), 4.60 (sextet, 1H, $NO_2$—C—H).

*Sequence 3*

*3-Hydroxy-2-nitrododecane*

To 58.1 g (371.6 mmol) of freshly distilled decanal and 1.75 g (18.59 mmol) finely ground potassium fluoride dihydrate in 400 mL of 2-propanol at 25°C were added 55.8 g (743.2 mmol) nitroethane. The mixture was stirred for 48 h, dried over magnesium sulfate, filtered, and solvent evaporated under reduced pressure. 3-Hydroxy-2-nitrododecane was obtained in 85% yield as a pale yellow oil; ir (film): 3380–3600 (O—H), 1560, 1390 ($NO_2$) cm$^{-1}$; $^1$H nmr ($CDCl_3$) δ: 1.64 (d, 3H, $NO_2$—C—$CH_3$), 3.58 (s, 1H, C—OH, $D_2O$ exch.), 4.00 (m, 1H, O—C—H), 4.55 (m, 1H, $NO_2$—C—H).

*3-Acetoxy-2-nitrododecane*

3-Hydroxy-2-nitrododecane (73.1 g; 315.9 mmol) was dissolved in 600 mL of anhydrous ether. To this solution was added a mixture of 47.4 g (464.3 mmol) acetic anhydride and 2.27 g (18.59 mmol) 4-dimethylaminopyridine. The mixture was stirred at 25°C for 18 h, dried over magnesium sulfate, and solvent evaporated under reduced pressure at 25°C. Note evaporation under reduced pressure at 45°C caused formation of the highly reactive nitroalkene 2-nitro-2-dodecene identified by ir (film): 1660 (C=C), 1510, 1330 ($NO_2$) cm$^{-1}$ and $^1$H nmr ($CDCl_3$) δ: 1.90–2.32 (s and m, 5H, $NO_2$—C—$CH_3$ and $NO_2$—C=C—$CH_2$), 7.08 (t, 1H, $NO_2$—C=C—H). 3-Acetoxy-2-nitrododecane was obtained in 85% yield as a light yellow oil; ir (film): 1750 (C=O), 1550, 1375 ($NO_2$) cm$^{-1}$; $^1$H nmr ($CDCl_3$) δ: 2.1 (s, 3H, O=C—$CH_3$), 4.71 (m, 1H, $NO_2$—C—H), 5.34 (m, 1H, O=C—O—C—H).

*2-Nitrododecane*

To an ice cooled/mechanically stirred solution of 73.4 g (268.5 mmol) 3-acetoxy-2-nitrododecane in 500 mL of absolute ethanol were added gradually ($T < 30$°C) 28.1 g (742.2 mmol) of sodium borohydride. Stirring was continued for 12 h at 25°C. Acidification was effected by dropwise addition of 10% hydrochloric acid. The mixture was extracted with pentane, dried over sodium sulfate, and solvent evaporated under reduced pressure. The crude product was triply distilled through a 1 × 15 cm Vigreux column affording 34.7 g (161.1 mol) of 2-nitrododecane as a colorless oil, bp 120°C/1.4 Torr (lit. (21) 1-isomer, 1-nitrododecane, bp 128°C/2.0 Torr); ir (film): 1580, 1365 ($NO_2$) cm$^{-1}$; $^1$H nmr ($CDCl_3$) δ: 1.53 (d, 3H, $NO_2$—C—$CH_3$), 4.55 (sextet, 1H, $NO_2$—C—H).

II. *Michael addition (4-nitroaldehydes)*

*4-Methyl-4-nitroheptanal*

2-Nitropentane (10.0 g; 85.4 mmol) and 0.57 mL (1.37 mmol) of Triton B (40% hydroxide in methanol) were dissolved in 75 mL of dry THF. Dropwise addition ($T < 0$°C) of 4.21 g (75.08 mmol) of freshly distilled acrolein in 25 mL of dry THF caused the initially colorless solution to turn brown-green. After stirring for 4 h at 0°C the reaction was quenched with 4.72 mL of 10% aqueous HCl. The mixture was shaken thoroughly with 300 mL of methylene chloride, washed with 3 × 100 mL of saturated NaCl, dried over sodium sulfate, filtered, and solvent evaporated under reduced pressure (25°C). The viscous brown-orange residue was immediately fractionated by distillation; 7.6 g (58% yield) of 4-methyl-4-nitroheptanal were obtained as a faint yellow oil, bp 57°C/ 0.010 Torr; $^1$H nmr ($CDCl_3$) δ: 1.54 (s, 3H, $NO_2$—C—$CH_3$), 9.96 (s, 1H, O=C—H).

*Precaution*! Thermally unstable residues may form. The product must be distilled over quickly, though preferably with an oil bath temperature < 150°C. Distillation must be halted immediately when black residues appear.

*4-Methyl-4-nitrodecanal*

Similarly 22.90 g (143.9 mmol) of 2-nitrooctane and 0.96 mL (2.30 mmol) Triton B in 127 mL THF were reacted with 7.09 g (126.5 mmol) acrolein in 50 mL THF. 4-Methyl-4-nitrodecanal (14.71 g; 68.33 mmol) was collected as a faint yellow oil (54% yield), bp 127°C/0.060 Torr; $^1$H nmr ($CDCl_3$) δ: 1.52 (s, 3H, $NO_2$—C—$CH_3$), 9.98 (s, 1H, O=C—H).

*4-Methyl-4-nitrotetradecanal*

Similarly 34.7 g (161.1 mmol) of 2-nitrododecane and 1.08 mL (2.57 mmol) of Triton B in 150 mL THF were reacted with 7.94 g (141.6 mmol) acrolein in 100 mL THF. 4-Methyl-4-nitrotetradecanal (17.93 g; 66.07 mmol) was isolated as a pale yellow oil (47% yield), bp 145°C/0.050 Torr; $^1$H nmr ($CDCl_3$) δ: 1.53 (s, 3H, $NO_2$—C—$CH_3$), 10.00 (s, 1H, O=C—H).

Note: a heating mantle ($T > 150$°C) was required to distil the product.

III. *4-Nitroacetals*[3]

*4-Methyl-4-nitroheptanal (ethylene acetal)*

4-Methyl-4-nitroheptanal (7.60 g; 43.88 mmol), 3.23 g (52.04 mmol) of ethylene glycol, and 0.0938 g (0.493 mmol) of *p*-toluenesulphonic acid monohydrate were refluxed in 75 mL benzene (25°C) utilizing a Dean–Stark separator. The cooled mixture was added to 200 mL pentane, washed with 3 × 75 mL of 10% aqueous sodium bicarbonate, dried over sodium sulfate, filtered, and solvent evaporated under reduced pressure. The residue was distilled providing 6.86 g of the nitroacetal (72% yield, 31.59 mmol), bp 90°C/0.10 Torr; $^1$H nmr ($CDCl_3$) δ: 1.57 (s, 3H, $NO_2$—C—$CH_3$), 3.90 (m, 4H, $OCH_2CH_2O$), 4.85 (t, 1H, $(CH_2O)_2C$—H).

*4-Methyl-4-nitrodecanal (ethylene acetal)*

4-Methyl-4-nitrodecanal (14.71 g; 68.33 mmol), 5.03 g (80.88 mmol) of ethylene glycol, and 0.1460 g (0.767 mmol) of *p*-toluenesulphonic acid monohydrate were refluxed under similar conditions in 125 mL of benzene to give (70% yield) 12.40 g (47.83 mmol) of nitroacetal, bp 140°C/0.05 Torr; $^1$H nmr ($CDCl_3$) δ: 1.56 (s, 3H, $NO_2$—C—$CH_3$), 3.87 (m, 4H, $OCH_2CH_2O$), 4.83 (t, 1H, $(CH_2O)_2C$—H).

*4-Methyl-4-nitrotetradecanal (ethylene acetal)*

Similarly, 17.93 (66.07 mmol) of 4-methyl-4-nitrotetradecanal, 4.86 g (78.30 mmol) of ethylene glycol, and 0.1412 g (0.742 mmol) *p*-toluenesulphonic acid monohydrate in 125 mL benzene gave 13.88 g (44.00 mmol) nitroacetal in 67% yield; $^1$H nmr ($CDCl_3$) δ: 1.54 (s, 3H, $NO_2$—C—$CH_3$), 3.88 (m, 4H, $OCH_2$—$CH_2O$), 4.85 (t, 1H, $(CH_2O)_2C$—H).

IV. *1-Pyrroline-*N*-oxides and acetal-*N*-hydroxy intermediates*[3]

*5-Propyl-5-methyl-1-pyrroline-*N*-oxide*[4] *(PMPO) (I)*

To a mechanically stirred mixture of 7.10 g (32.67 mmol) of 4-methyl-4-nitroheptanal (ethylene acetal) and 1.86 g (34.77 mmol) ammonium chloride in 12:24 (mL) THF–$H_2O$ were added 8.66 g (119.1 mmol) 90% zinc dust keeping $T < 5$°C. Stirring was continued for approximately 4 h at 25°C. The reduction was monitored by analysis of a 0.25 mL aliquot which was filtered, extracted (pentane), dried ($Na_2SO_4$), filtered, and

[3]The nitroacetals and hydroxylaminoacetals in the text have been named as ethylene acetal derivatives rather than nitrodioxolans and hydroxylaminodioxolans respectively.

[4]5-Methyl-5-propyl-1-pyrroline-*N*-oxide may strictly be the more appropriate nomenclature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

solvent evaporated under reduced pressure. 4-Methyl-4-hydroxylaminoheptanal (ethylene acetal) was detected by $^1$H nmr ($CDCl_3$) δ: 3.87 (m, 4H, $OCH_2CH_2O$), 4.83 (t, 1H, $(CH_2O)_2$—C—H), 5.46 (s, 2H, C—NHOH, $D_2O$ exch.). The mixture was vacuum filtered, the filtercake washed with 3 × 40 mL hot (50°C) THF. The filtrate was evaporated under reduced pressure ($T$ < 30°C); 4.9 : 60 (mL) of concentrated HCl – $H_2O$ were added and the mixture stirred for 2 h (70°C). The mixture was cooled (25°C), neutralized with $NaHCO_3$, stirred for 1 h, filtered through sintered glass, extracted with 3 × 75 mL pentane, washed with 3 × 75 mL saturated NaCl, dried ($Na_2SO_4$), and solvent evaporated under reduced pressure. The residue was distilled, bp 56°C/0.070 Torr. Successive elution on a silica gel column with pentane, benzene, and finally methylene chloride provided 3.0 g (21.24 mmol) of the nitrone (65% yield) as a colorless hygroscopic oil; ir (film): 1560 (C=N), 1242 (N—O) cm$^{-1}$; $^1$H nmr ($CDCl_3$) δ: 1.39 (s, 3H, O—N—C—$CH_3$), 2.15 (m, 2H, $CH_2$), 2.55 (m, 2H, $CH_2$), 6.82 (t, 1H, O—N=C—H). The nitrone afforded a complex (1:1) with 2,4,6-trinitrophenol, mp 82°C (from absolute ethanol). *Anal.* calcd. for $C_{14}H_{18}N_4O_8$: C 45.41, H 4.90, N 15.13; found: C 45.98, H 5.00, N 14.93.

*5-Hexyl-5-methyl-1-pyrroline-*N*-oxide (HMPO) (II)*

Similarly, stirring of 12.40 g (47.83 mmol) of 4-methyl-4-nitrodecanal (ethylene acetal), 2.72 g (50.85 mmol) ammonium chloride, and 12.68 g (174.5 mmol) of 90% zinc dust gave 4-methyl-4-hydroxylaminodecanal (ethylene acetal) identified by $^1$H nmr ($CDCl_3$) δ: 3.85 (m, 4H, $OCH_2CH_2O$), 4.81 (t, 1H, $(CH_2O)_2C$—H), 5.49 (s, 2H, C—NHOH, $D_2O$ exch.). Acidification followed by distillation, bp 110°C/0.30 Torr, and silica gel chromatography (methylene chloride) provided the nitrone (57%), 5.0 g (27.26 mmol) as a pale yellow oil;[5] ir (film): 1567 (C=N), 1241 (N—O) cm$^{-1}$; $^1$H nmr ($CDCl_3$) δ: 1.39 (s, 3H, O—N—C—$CH_3$), 2.16 (m, 2H, $CH_2$), 2.61 (m, 2H, $CH_2$), 6.76 (t, 1H, O—N=C—H).

*5-Decyl-5-methyl-1-pyrroline-*N*-oxide (DeMPO) (III)*

Similarly, reaction of 13.88 g (44.00 mmol) of 4-methyl-4-nitrotetradecanal (ethylene acetal), 2.51 (46.92 mmol) of ammonium chloride, and 11.66 g (160.4 mmol) of 90% zinc dust produced 4-methyl-4-hydroxylaminotetradecanal (ethylene acetal) detected by $^1$H nmr ($CDCl_3$) δ: 3.88 (m, 4H, $OCH_2CH_2O$), 4.82 (t, 1H, $(CH_2O)_2$—C—H), 5.44 (s, 2H, C—NHOH, $D_2O$ exch.). Acidification gave the crude nitrone which decomposed upon attempted distillation (110°C/0.05 Torr). The nitrone was purified instead by filtration through Celite and silica gel chromatography (methylene chloride). The isolated yield (53%) was 5.6 g (23.39 mmol) as a pale yellow oil.[5] ir (film): 1564 (C=N), 1244 (N—O) cm$^{-1}$; $^1$H nmr ($CDCl_3$) δ: 1.38 (s, 3H, O—N—C—$CH_3$), 2.16 (m, 2H, $CH_2$), 2.60 (m, 2H, $CH_2$), 6.72 (t, 1H, O—N=C—H).

*Electron spin resonance (kinetic esr procedure)*

The esr spectra were observed with a Varian E-104 spectrometer and were calibrated by comparison with Fremy's salt (22) ($a_N$ = 13.09 G, $g$ = 2.0055). The quartz esr cell was equipped with two adjoining compartments to house separately the radical source and spin trap(s). This arrangement has been amply described previously (23).

*Thermally generated* tert-*butoxyl radicals*

Di-*tert*-butylperoxalate (DBPO) prepared by Bartlett's method (24) was freshly recrystallized (hexane, −40°C) before kinetic runs. One compartment of the esr cell arrangement was cooled by liquid $N_2$. Into this sidearm was placed approximately 2.5 mg of DBPO. A 2.0 mL benzene solution (25°C) containing both nitrones, typically (0.01 *M*) in RMPO and (0.30 *M*) in PBN, except $M_4$PO which was equimolar (0.05 *M*) with PBN, was placed into the other compartment. Deoxygenation was accomplished by purging the esr cell and sidearms simultaneously with dry $N_2$ gas for 5–10 min. The contents were mixed vigorously and esr spectra recorded immediately thereafter as a function of time. DBPO decomposes at 25°C in benzene according to reaction [4].

Four lines (2 independent doublets) in the middle of the 18-line spectrum due to the cyclic nitrone and PBN adducts were scanned repeatedly at 70 s intervals for 20–25 min. The specific peaks that were evaluated kinetically are depicted in the esr spectrum derived from (PBN/HMPO/DBPO) in benzene, Fig. 2.

*Photochemically generated* tert-*butoxyl radicals*

Di-*tert*-butylperoxide (Lucidol–Penwalt) was routinely eluted through a silica gel column to remove possible traces of hydroperoxide. Photolysis of BOOB, reaction [10], was accomplished by irradiating the quartz cell with a medium pressure Hg arc equipped with a Pyrex filter.

A 0.20 *M* solution of cyclic spin trap in di-*tert*-butylperoxide scavenged the BO· radicals thus formed. The second doublet in the 12-line pattern was scanned repeatedly at 70 s intervals for 25–30 min. It was important that all decay rates be obtained under as similar experimental conditions as possible since these were direct kinetic measurements. This involved utilization of identical reaction temperatures, esr spectrometer settings, esr cells, and uv lamp intensities for every experiment.

*Spin adduct concentrations*

Concentrations (or ratios of concentrations) of spin adducts were determined by double integration of nonoverlapping lines (of known degeneracy) in the esr spectra. Area units were calibrated by the use of the stable aminoxyl spin label, 2,2,5,5-tetramethyl-3-carbamidopyrrolidine-1-oxyl (Aldrich). The general procedure has been described elsewhere (9*c*).

[5]Alicyclic nitrones are typically thermally labile hygroscopic oils. Elemental analysis is thus usually restricted to their solid derivatives (13). Unfortunately, HMPO and DeMPO did not form crystalline 2,4,6-trinitrophenol complexes or methiodides; ir, $^1$H nmr, and tlc (silica gel – acetone, HMPO ($R_f$ 0.6); DeMPO ($R_f$ 0.5)) indicated the nitrones' purity at 99+%.

# The utilization of nitrone spin traps in a study of the photochemistry of pigment dispersions

JOHN R. HARBOUR, MICHAEL L. HAIR, AND SANDRA L. ISSLER
*Xerox Research Centre of Canada, 2480 Dunwin Drive, Mississauga, Ont., Canada L5L 1J9*

Received September 1, 1981

JOHN R. HARBOUR, MICHAEL L. HAIR, and SANDRA L. ISSLER. Can. J. Chem. **60**, 1523 (1982).

Examples of the use of nitrone spin traps for the elucidation of reaction mechanisms during the illumination of pigment dispersions are presented. Detection of superoxide and hydroxyl radicals with CdS, phthalocyanine, and ZnO is discussed. Singlet oxygen is also detectable with spin traps by following the $O_2$ consumption in these dispersions as a function of illumination. These results are discussed in relation to the applications of pigment dispersions in both novel imaging systems and solar energy utilization systems.

JOHN R. HARBOUR, MICHAEL L. HAIR et SANDRA L. ISSLER. Can. J. Chem. **60**, 1523 (1982).

On présente des exemples d'utilisation des capteurs de spin du type nitrone pour établir les mécanismes de réaction lors de l'irradiation des dispersions de pigments. On discute de la détection des radicaux superoxyde par CdS, la phthalocyanine et le ZnO. On peut également détecter l'oxygène singulet avec les capteurs de spin, en suivant la consommation du $O_2$ dans ces dispersions en fonction de l'irradiation. On discute de ces résultats en rapport avec des applications des dispersions de pigments à la fois dans le nouveau système d'image et dans les systèmes qui utilisent l'énergie solaire.

[Traduit par le journal]

## Introduction

Pigments are highly insoluble materials which are usually obtained commercially as fine powders. Particle size can vary significantly but most pigments have an average particle size of less than 1 micron. These pigments can be dispersed in a liquid phase, sometimes with the aid of a surfactant or polymer dispersant creating opaque suspensions. In most applications, pigments are used for their absorbing or reflecting nature as in paints or inks. In these cases, it is desired that the pigments are photostable. This, however, is not always the case, as, for example, in the phenomenon of chalking in the paint industry where the polymer binder is destroyed by a photosensitized reaction involving the pigment (1).

There are, however, applications of pigment photochemistry where the photoactivity of semiconducting pigments is exploited. Two examples of this will be given. They are: (*1*) Photoactive Pigment Electrophotography (PAPE) Imaging systems (2) and (*2*) Solar Energy Utilization (SEU) systems (3).

In PAPE systems (2), the photoactive pigment must be capable of a photoinduced interfacial charge transfer with the surroundings, thereby reversing the polarity of the charged particle. This is shown in Fig. 1, for a system referred to as Photoelectrophoresis (PEP) (4). The particles which (for example) are negatively charged adhere to the top positively biased transparent electrode. The pigment absorbs the incident imaging light and subsequently undergoes electron loss to create a positively charged particle which is electrophoretically driven through the insulating solvent to the negatively charged counterelectrode.

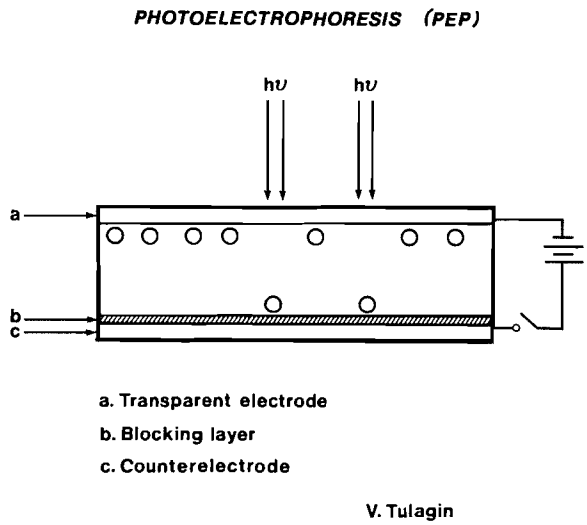

FIG. 1. The general concept of PEP imaging. Particles are electrophoretically driven to the top electrode, *a*, in the dark. Imaging light causes a reversal of particle charge driving the particle to the opposite electrode, *c*, which is covered with a blocking layer, *b*, to prevent additional charge exchange.

A second example is shown in Fig. 2 of a system referred to as PEP Stimulated Imaging (PEPSI) (5). In this system photosensitive particles are mixed with an inert pigment and sandwiched between two electrodes overcoated with a blocking layer. In the exposed region, light induces a charge transfer ultimately from the photosensitive to the inert

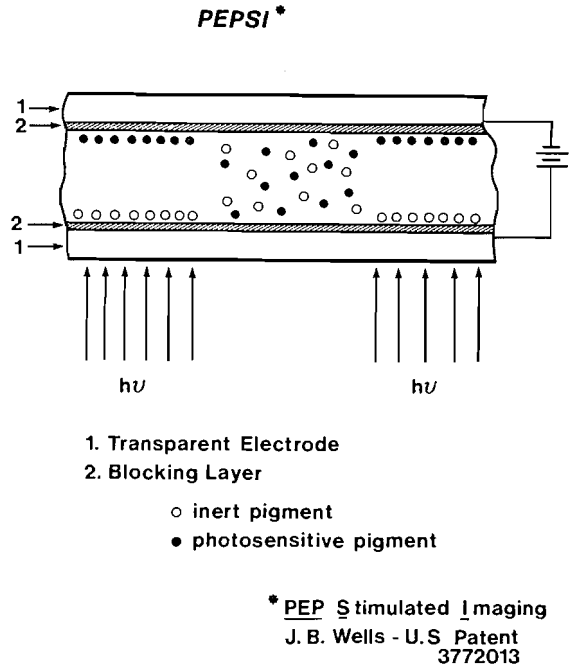

FIG. 2. In this imaging system, called PEPSI, an inert pigment (○) is mixed with a photosensitive pigment (●) in low dielectric solvent. Imaging light causes a charge exchange between the inert and photosensitive pigment and they are driven by the electric field to opposite transparent electrodes (1) which are overcoated with a blocking layer.

pigment. This charges the particles oppositely in the insulating organic fluid and they are again driven electrophoretically to opposite electrodes. In this case, the blocking electrode prevents a direct involvement of the electrode itself and suggests that the charge transfer occurs in dispersion. The molecular mechanism for these processes is not well understood and spin trapping (6) offers an excellent means whereby radical intermediates can be detected and identified in these imaging systems.

The photoactivity of semiconducting pigments can also be used for solar energy utilization (3). Most photoelectrochemical systems use single crystals of materials as electrodes but a recent article has demonstrated that pigments with a polymer binder are also effective as photoelectrodes (7). Pigment dispersions can also be employed as a means of utilizing solar irradiation for photocatalysis or photosynthesis (8). This was first suggested by Rubin *et al.* in 1953 (9) in the photogeneration of $H_2O_2$ in aqueous ZnO dispersions. The present authors have shown that CdS was capable of reducing methyl viologen at the expense of EDTA. It was stated and later proved that $H_2$ evolution was indeed possible from this system. Frank and Bard (11) suggested photocatalysis with $TiO_2$ as a means of removal of $CN^-$ and $SO_2$ in waste streams. Reiche *et al.* (12) extended these ideas to the removal of Cu by photodeposition onto $TiO_2$ or $WO_3$. The metallization of pigments offered new alternatives for production of fuels using these systems and platinization (of $TiO_2$) was particularly useful in this regard (13). We have synthesized platinized CdS (14) which is capable of $H_2$ production upon illumination, using EDTA as a sacrificial donor. This was carried further by Gratzel (15) who codeposited $RuO_2$ and was able to generate both $H_2$ and $O_2$ upon excitation of the CdS.

Many of the reactions which occur in these systems are thought to involve radical intermediates and spin trapping offers a unique way of experimentally determining this. This paper will review several examples of the way in which this has been accomplished. In addition, the ability of nitrone spin traps to react with $^1O_2$ in aqueous medium is discussed. This reaction can be monitored by $O_2$ uptake with an oxygen electrode (16). Therefore, with nitrone spin traps (17) using both esr spectroscopy and $O_2$ uptake, it is possible to detect both radical intermediates and $^1O_2$ produced during the photolysis of pigment dispersions.

## Results and discussion

An electron photochemically promoted to the conduction band has an energy determined by the particular semiconductor being used (18). It is convenient to express this band edge energy in terms of standard redox potentials, $E^{0\prime}$ (vs. $H_2$ electrode, pH = 7) by eq. [1] (19). For ZnO, which has a CB edge energy

$$[1] \quad E^{0\prime} = -4.5 - E_F^{0\prime}\,(\text{eV})$$

of −4.0 eV (20), the standard redox potential would be, $E_{CB}^{0\prime} = -0.5$ V. (Many semiconductors including $TiO_2$ and CdS have $E_{CB}^{0\prime}$ values less than or equal to −0.5 V (20)). Molecular oxygen is a good oxidizer and consequently is easily reduced ($E^{0\prime} = -0.15$ V) (21). Since $O_2$ is present in most technical applications it seems likely that formation of superoxide ($O_2^-$) at the solid/liquid interface will occur to a significant extent. It had in fact been postulated as an intermediate during the photolysis of pigment dispersions (8) but its detection was not accomplished due to its short lifetime. However, in 1974, Harbour *et al.* (22), used the technique of spin trapping with nitrones to successfully detect $O_2^-$ in solution. Thus spin trapping appeared to be an ideal technique for application to the study of short-lived radical intermediates generated during the photolysis of pigment dispersions.

Historically, the first system studied was an aqueous suspension of CdS (10). The sub-micron

For personal use only.

sized CdS particles were dispersed in water using ultrasonic irradiation. The nitrone spin trap, DMPO, was then added and the dispersion transferred to an aqueous esr cell. In situ irradiation with light of wavelength less than 510 nm resulted in the generation of the $O_2^-$ adduct of DMPO ($a^N = 14.1$ G, $a^H = 11.2$ G, $a^H = 1.2$ G, $g = 2.0061$) (22). This adduct only appeared when dissolved $O_2$ was present. The addition of a good electron donor, ethylene diamine tetraacetic acid, significantly enhanced the amount of $O_2^-$ adduct produced. This enhancement is understandable in terms of maintaining electrical neutrality and will be discussed in more detail in the case of ZnO dispersions. In the absence of EDTA, the photogenerated hole can oxidize CdS itself creating $Cd^{2+}$ in solution and elemental sulfur.

Spin trapping gives indirect evidence for the generation of short-lived radicals. It is therefore important to parallel the trapping results with a directly detected radical intermediate. In the CdS case this was accomplished by incorporating methyl viologen ($MV^{2+}$) into a $N_2$-purged dispersion. $MV^{2+}$ has a redox potential of $-0.44$ V and is reduced to a stable cation radical, $MV^+$. Thus, this photoreduction is thermodynamically allowed. Experimentally this is confirmed by the light-induced formation of $MV^+$, which is evidenced by both its readily identifiable esr spectrum as well as its blue optical absorption (23). Addition of EDTA again enhanced this photoreduction exactly paralleling the indirect spin trapping results. Hence the direct detection results give strong support to the interpretation of the spin trapping experiments.

The use of spin trapping techniques has since been extended to non-aqueous dispersions, particularly those of CdS and the organic pigment x-phthalocyanine ($H_2Pc$) (24). A variety of solvents were used and these demonstrated the general mechanism of photoinduced reduction of $O_2$ to superoxide. Clearly, the hyperfine splittings of the DMPO adducts are a function of solvent polarity. These have been determined and application to most solvent systems is now possible.

The understanding of the primary steps which occur when these semiconducting pigments are irradiated, particularly in low dielectric solvents, is of direct consequence to our understanding of the PAPE imaging process mentioned in the introduction. Molecular oxygen is an ever present "impurity" in the imaging fluids and can clearly act as an electron trap for photoproduced electrons. In the absence of electron donors it is clear that the particle must become positively charged and that photoelectrophoretic imaging can then occur.

Up to this point we have mainly been discussing the fate of electrons in the conduction band. The holes which were created during illumination are also reactive intermediates which can oxidize species in solution. The application of spin trapping to the study of the photochemical events occurring in ZnO aqueous dispersions provides perhaps the best example of the use of this technique in elucidating the oxidative reactions of photogenerated holes (25).

It has long been known that $H_2O_2$ is produced when aqueous ZnO dispersions are irradiated (9) and that the formation of $H_2O_2$ is enhanced when a suitable donor is added to the system. When DMPO was added to an aqueous ZnO suspension containing no added donors and irradiated ($\lambda <$ 380 nm), large quantities of $^{\cdot}OH$ radical adducts were produced. It was determined that the number of $^{\cdot}OH$ radicals produced was dependent upon the amount of dissolved $O_2$ in the system. $O_2$ uptake studies revealed that oxygen was consumed during photolysis and that $H_2O_2$ was generated. Yet no superoxide adduct could be detected by spin trapping. When a donor such as formate or oxalate was added to this system significant changes were observed. Hydroxyl adducts were no longer observed but large quantities of the $^{\cdot}CO_2^-$ adduct were detected. The results for the oxidation are summarized below.

*Oxidation*

[2] $OH^- + \oplus \rightarrow {}^{\cdot}OH$

or

[3] $Zn\text{—}OH + \oplus \rightarrow Zn^{2+} + {}^{\cdot}OH$

*With additives*

[4] $HCO_2^- + {}^{\cdot}OH \rightarrow H_2O + {}^{\cdot}CO_2^-$

and

[5] $HCO_2^- + \oplus \rightarrow H^+ + {}^{\cdot}CO_2^-$

The oxidation of $H_2O$ ($OH^-$) is thermodynamically allowed since the redox level of the $\oplus$ approaches $E_{\oplus}^{0\prime} = +2.6$ V (20) while $E^{0\prime}$ for the oxidation of $H_2O$ is $+0.8$ V. However, the oxidation of ZnO ($E^{0\prime} = 0.7$ V) (20) is also allowed and therefore both eqs. [2] and [3] are possible and lead to the same intermediate, the hydroxyl radical. Which of the two reactions will predominate is determined by the kinetics of the reactions. Similarly two reactions can occur in the presence of formate (eqs. [4] and [5]) and both account for $^{\cdot}CO_2^-$ production. In one case (eq. [4]), the formate anion acts as an hydroxyl radical scavenger whereas in (eq. [5]), a direct oxidation of $HCO_2^-$ by the hole is occurring. The rate of $O_2$ uptake is increased when a donor is added reflecting that both the oxidation of $H_2O$ and ZnO itself are sluggish kinetically compared to formate oxida-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

tion. Hence, in the case where formate is excluded, the hole has a greater opportunity to back react with an $e_{CB}^-$ reducing the overall quantum efficiency. This in fact is observed.

The reduction mechanism deduced from both $O_2$ uptake studies and spin trapping is shown in eqs. [6]–[10] where the subscript "s" refers to a surface species.

[6] $(O_2)_s + e^- \rightarrow (O_2^-)_s$

[7] $(O_2^-)_s + H^+ \rightarrow (HO_2^{\cdot})_s$

[8] $(HO_2^{\cdot})_s + e^- \rightarrow (HO_2^-)_s$

[9] $(HO_2^-)_s + H^+ \rightarrow (H_2O_2)_s \leftrightarrows H_2O_2$

or

[10] $2(HO_2^{\cdot})_s \rightarrow H_2O_2 + O_2$

Quantitative studies revealed that the quantum efficiency for the production of spin adducts was 0.04 compared to a value of 0.14 from the $O_2$ uptake measurements for the formate case. Several reasons make the $\Phi = 0.04$ a minimum value for the esr measurement and therefore it was demonstrated that the radical production was reflecting the major photochemical reactions in this system rather than a side reaction. Hence spin trapping allows for a determination of the mechanisms occurring during the photolysis of pigment dispersions.

Recently there has been an evolving interest in the use of metallized semiconductor particles for solar energy conversion and hydrogen production (3). Nitrone spin traps can play an important role in determining the short-lived radical intermediates formed in these systems. Thus, Jaeger and Bard (26) describe a recent application of the spin trapping technique to the photolysis of platinized $TiO_2$ dispersions. One interesting result was that they were unable to observed an $H^{\cdot}$ adduct despite the fact that hydrogen gas is produced in these dispersions. The present authors (14) have used DMPO to study aqueous Pt/CdS dispersions but found no spin adducts upon illumination.

While all previous studies indicate that nitrone spin traps can be exceedingly useful in studying the initial photochemistry in pigment dispersions, the results must be treated with some caution: Nitrone spin traps also react with singlet oxygen in aqueous media (16). The rate constants for the quenching of $^1O_2$ by several nitrone spin traps have been recorded. The rates vary from 14 to $1.8 \times 10^7\ M^{-1}\ s^{-1}$ for PBN and DMPO respectively. It is noted that this is a chemical quenching which results in consumption of oxygen. Clearly, if $^1O_2$ is also being produced when the semiconducting pigment dispersions are irradiated, then an oxygen depletion could occur to the extent that the normal radical reaction may be inhibited. Since the rate constant for quenching by DMPO is approximately one order of magnitude less than with PBN and other nitrones it would be the better choice for spin trapping in systems where the presence of $^1O_2$ is suspected. The rate of quenching of the singlet oxygen by nitrones can be monitored by incorporating an oxygen membrane electrode into the closed photochemical cell. This technique conveniently measures dissolved oxygen concentration and can be applied to both solutions and dispersions. It thus provides a useful method for allowing the kinetics of the oxygen uptake. Thus addition of a nitrone to an illuminated dispersion should cause an observable increase in the rate of oxygen uptake if $^1O_2$ is being photochemically generated.

Pappas and Fischer (1) have presented data using a different experimental technique which suggests that both $TiO_2$ and ZnO can generate singlet oxygen in methanol. Conversely, Spikes (27) has presented data suggesting that singlet oxygen is not generated when aqueous suspensions of CdS are irradiated. By monitoring the rate of oxygen uptake as a function of PBN concentration, we have been able to confirm that indeed CdS does not generate singlet oxygen in aqueous media. However, aqueous ZnO suspensions appear to produce singlet oxygen. With $TiO_2$ only a marginal increase in the rate of oxygen consumption is noted when PBN is added to the system. Clearly the mechanism by which singlet oxygen is generated in these dispersions is an interesting but complex subject and this will be the subject of a separate paper (28).

In this paper we have shown that the short-lived intermediates formed when particulate suspensions of semiconducting pigments are irradiated can be crucial to the understanding of photoelectrophoresis (PAPE). In particular, the use of nitrone spin traps in the detection of superoxide and hydroxyl radicals is emphasized. The chemical interaction of $^1O_2$ with the nitrones is a complication, but the introduction of oxygen uptake measurements adds a new dimension to the studies and enables the observation of both radical and singlet oxygen formation in these photoactive dispersions.

# Free radical production during phenylhydrazine-induced hemolysis

H. A. O. Hill and P. J. Thornalley

*Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, England OX1 3QR*

Received September 1, 1981

H. A. O. Hill and P. J. Thornalley. Can. J. Chem. **60**, 1528 (1982).

The production of phenyl radicals during phenylhydrazine-induced hemolysis has been demonstrated by the use of the spin traps, DMPO, $M_4PO$, and LINPyBN. The phenyl spin adducts of DMPO and $M_4PO$ were produced in moderate yield by an oxygenated 1% erythrocyte suspension. With the lipid soluble spin trap LINPyBN, a dramatic increase (400%) in the yield of phenyl spin adduct was observed despite little increase in the rate of phenyl radical trapping. The production of phenyl spin adducts was decreased when phenylhydrazine-4-sulphonic acid or carbonmonoxyhemoglobin-containing erythrocytes were used. These results suggest that the reaction of phenylhydrazine with oxyhemoglobin leads to the formation of phenyl radicals that are preferentially trapped in the erythrocyte membrane.

H. A. O. Hill et P. J. Thornalley. Can. J. Chem. **60**, 1528 (1982).

Faisant appel aux capteurs de spin du type DMPO, $M_4PO$ et LINPyBN, on a démontré qu'il y a production de radicaux phényles lors de l'hemolyse induite par la phénylhydrazine. A l'aide d'une suspension à 1% d'érythrocytes oxygénés, on a produit avec un rendement modéré les adduits de spin phényle du DMPO et du $M_4PO$. Dans le cas du capteur de spin LINPyBN soluble dans les lipides, on observe une augmentation considérable (400%) du rendement en adduit de spin du type phényle en dépit d'une faible augmentation de la vitesse de piégeage du radical phényle. La production des adduits de spin du type phényle diminue lorsqu'on utilise de l'acide phénylhydrazinesulfonique-4 ou des érythrocytes contenant de la carbonemonoxyhémoglobine. Ces résultats suggèrent que la réaction de la phénylhydrazine avec l'oxyhémoglobine conduit à la formation des radicaux phényles qui sont piégés préférentiellement dans la membrane de l'érythrocyte.

[Traduit par le journal]

## Introduction

The factors that affect the useful life of erythrocytes have been much studied (1). Certain drugs have been demonstrated to show a remarkable specificity to oxidise cellular components and cause lysis in erythrocytes (2). Phenylhydrazine is one such drug (3, 4). It has found clinical use in lowering the red cell count in polycythemia vera (5), and experimentally is used to produce hemolytic anaemias (6). Phenylhydrazine is known to increase the level of hydrogen peroxide in erythrocytes, exceeding the levels with which glutathione peroxidase and catalase can cope. This is a contributory factor to the overall toxicity of phenylhydrazine towards erythrocytes, particularly where inherited defects or aging give diminished activity of glucose-6-phosphate dehydrogenase (7). The reactive intermediates which cause hemoglobin breakdown, membrane oxidation, and cell lysis, have yet to be identified. An explanation of the specificity (8) of phenylhydrazine for erythrocytes is lacking. Hemolysis is (9) commonly intravascular. A method of measuring the active hemolytic agent *in vitro* would be of value in the screening of drugs for possible hemolytic acitivity (9).

The involvement of superoxide (10), hydroxyl (11) and phenyl radicals (12) in phenylhydrazine-induced hemolysis has been proposed. We have used three spin traps (Fig. 1) to study the hemolytic reaction: (*i*) 5,5-dimethyl-1-pyrroline-1-oxide (DMPO) — this was used initially (12) because of its high reactivity and water solubility; (*ii*) 5,5,3,3-tetramethyl-1-pyrroline-1-oxide ($M_4PO$) — this has a similar reactivity to DMPO but forms more stable adducts; (*iii*) α,4-(*N'*-linoleylpyridinium chloride)-*N*-*t*-butyl nitrone (LINPyBN) — a lipid soluble spin trap which we presume is preferentially located in the erythrocyte membrane.

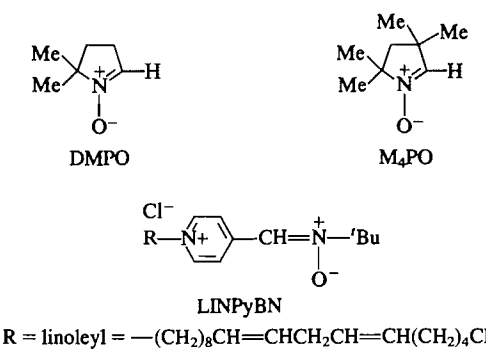

FIG. 1. Spin traps used.

## Experimental

*Preparation of erythrocytes*

Erythrocytes were prepared from blood drawn from normal human subjects by venous puncture, as described in ref. 12. Carbonmonoxyhemoglobin-containing erythrocytes were prepared by the method of Goldberg and Stern (13).

*Spin traps*

The spin traps DMPO and $M_4PO$ were prepared by the

method of Bonnet *et al.* (14). LINPyBN was prepared by the method of Emmons (15) from *t*-butylhydroxylamine and *N*-linoleyl-4-carboxaldehydopyridinium chloride. The latter was prepared from the reaction of the tosylate of linoleyl alcohol (Sigma Chemical Company Ltd, Poole, Dorset, U.K.) with excess pyridine-4-carboxaldehyde (Aldrich Chemical Company Ltd, Gillingham, Dorset, U.K.), followed by ion exchange chromatography of the tosylate for chloride using a Dowex-1 column. The nitrone product was characterised by mass spectral data (molecular ion $m/e = 462.5$), $^1$H nmr (linoleyl residue — methylene protons 0, divinyl methylene protons 11.6, and vinyl protons 14.0 ppm; nitrone residue — *t*-butyl protons 1.6, vinyl proton 8.4, and aromatic protons 8.8–9.1 ppm), CHN analysis (calcd. C 72.6, H 10.2, N 6.1; found: C 71.2, H 10.8, N 7.0). A chloroform solution (0.5 *M*) did not give an esr spectrum.

*Other reagents*

The complexing ligand, diethylenetriaminepentaacetic acid (DETAPAC), was obtained from Aldrich. All other reagents were of standard analytical grade except phenylhydrazine (Fisons laboratory reagent) and phenylhydrazine-4-sulphonic acid (Fluka, Basle, Switzerland) which were both recrystallised twice (mp 20°C and 286°C, respectively) before use and subsequently stored at 0–4°C in the dark.

*Electron spin resonance*

Electron spin resonance spectra were recorded on a Varian E104 ESR spectrometer fitted with an E935 data acquisition system. The reaction time course of spin adduct production was followed by measuring the amplitude of the signal at an appropriate constant value of the applied field. Spin adduct concentrations were determined from a calibrated second integral.

## Results

The initial results (12) from a phenylhydrazine-treated erythrocyte suspension in the presence of DMPO provided evidence for the production of a phenyl radical spin adduct, Fig. 2 (**1***a*). Using phenylhydrazine-4-sulphonate, however, very little phenyl-4-sulphonate spin adduct was observed, despite little change in trapping rates. This effect was ascribed to poor transport of the sulphonate derivative across the erythrocyte membrane.

A similar yield of phenyl spin adduct was obtained using an identical system but with $M_4PO$ at the same concentration as DMPO, Fig. 2 (**2***a* and **2***b*), though the stability of the spin adduct was slightly greater. Using LINPyBN, a dramatic increase in yield of the phenyl spin adduct was observed, Fig. 2 (**3***a* and **3***b*). (The additional discontinuity in the center of the spectrum in Fig. 2 (**3***a*, **3***b*) is probably due to a decomposition product of LINPyBN, viz., di-*t*-butylnitroxide). DMPO, $M_4PO$, and LINPyBN have similar trapping rates for phenyl radicals. The ratio of the phenyl radical trapping rates for DMPO:$M_4PO$ (aq., pH 7):LINPyBN (hexane) is 1:0.6:0.9, as determined by competition experiments using uv photolysis of phenylhydrazine as a source of phenyl radicals. The phenyl radical

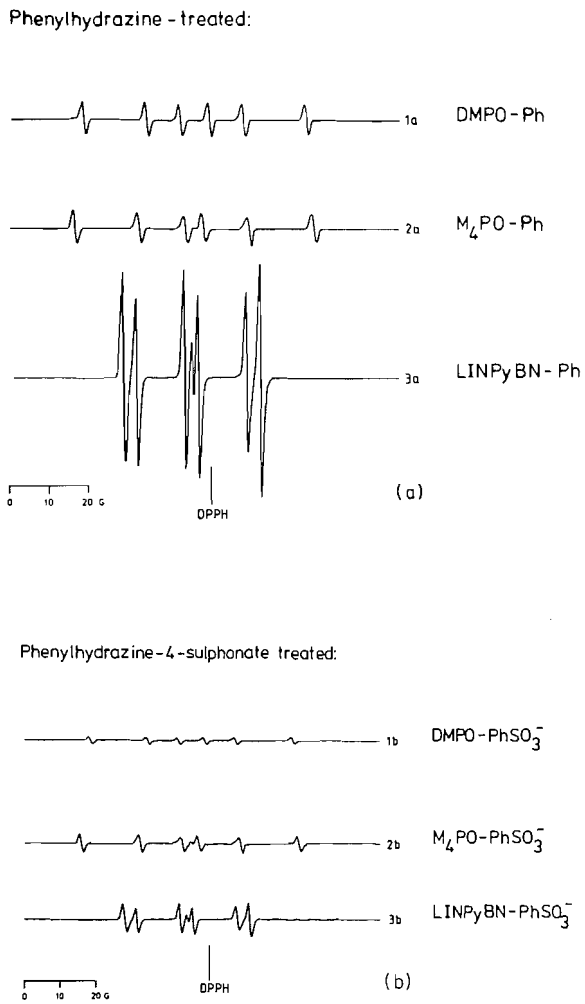

FIG. 2. Phenyl radical spin adducts generated during phenylhydrazine-induced hemolysis. The reaction mixtures contain: 1% suspension of human erythrocytes, 2 m*M* phenylhydrazine (*a*) or 2 m*M* phenylhydrazine-4-sulphonate (*b*), 1 m*M* DETAPAC, 20 m*M* spin trap using (1) DMPO, (2) $M_4PO$, and (3) LINPyBN in isotonic phosphate buffer, pH 7.4. The instrumental details were: field set 3385 G, field scan 100 G, mod. freq. 100 kHz, mod. amp. 1.0 G, receiver gain $2 \times 10^3$, time constant 0.128 s, scan time 120 s, microwave frequency 9.478 GHz, microwave power 10 mW.

LINPyBN spin adduct also has an increased stability as is indicated by Fig. 3, which shows the time course of the reaction for all the spin traps used. It also illustrates in Fig. 3 (**2***c*) the very low yield of $M_4PO$—Ph obtained using erythrocytes in which the hemoglobin was in the carbonmonoxy form. This is consistent with the observation that such erythrocytes are known (13) to be resistant to phenylhydrazine attack.

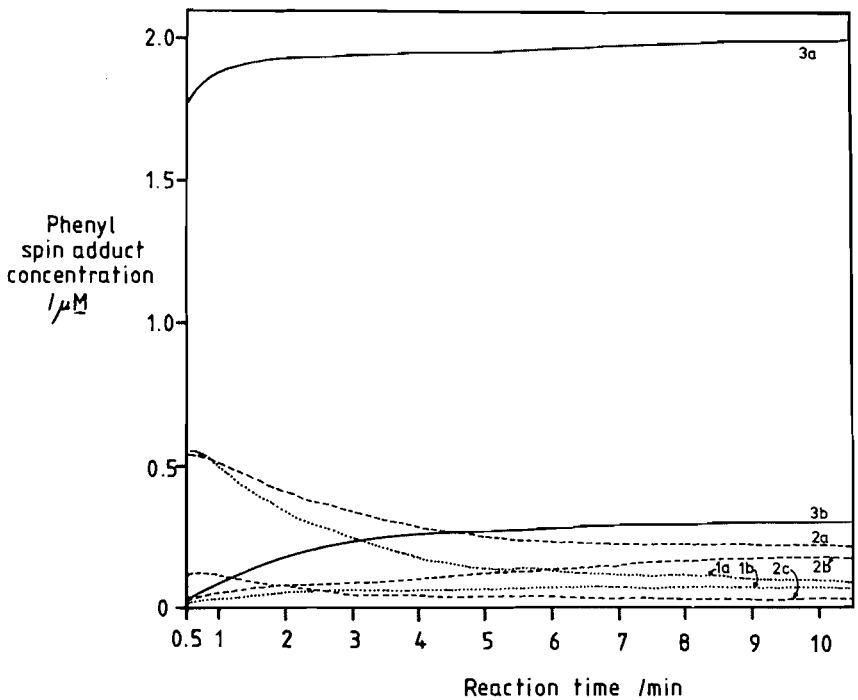

FIG. 3. The reaction time course studied with the field held constant at a value of the lowest field resonance in the esr spectrum; receiver gain $5 \times 10^3$, time constant 4.0 s, remaining settings as for the spectra. The curves are labelled as in Fig. 2 except that (2*c*) is the time course of a reaction carried out using the erythrocytes in the carbonmonoxy form.

## Discussion

*The autoxidation of phenylhydrazine*

Misra and Fridovich (16) showed phenylhydrazine to be stable in acid solutions but autoxidised in neutral and alkaline buffers. The oxidation was catalysed by traces of metal ion complexes, of which oxyhemoglobin was the most effective. The scheme they proposed to account for the observations is shown below. Phenyldiazene rapidly decays (17), giving traces of benzene and biphenyl. A kinetic analysis emphasised (16) the role of superoxide. Following initiation, there are two possible routes to phenyldiazene: (*a*) a superoxide-dependent propagation producing hydrogen peroxide; (*b*) a superoxide-independent autocatalysis via a benzadiazonium cation intermediate. Therefore, after an initial lag phase, the autoxidation of phenylhydrazine to phenyldiazene may not be effectively inhibited by superoxide dismutase (SOD), and may indeed be stimulated by SOD (16).

Initiation:

[*a*] $PhNHNH_2 + \underset{\text{OxyHb}}{HbFe^{3+}—O_2^-} + H^+ \rightarrow PhNH\dot{N}H + \underset{\text{MetHb}}{HbFe^{3+}} + H_2O_2$

Superoxide-dependent propagation:

[*b*] $PhNH\dot{N}H + O_2 \rightarrow H^+ + O_2^- + PhN{=}NH$

[*c*] $O_2^- + H^+ + PhNHNH_2 \rightarrow H_2O_2 + PhNH\dot{N}H$

Superoxide-independent autocatalysis:

[*d*] $PhN{=}NH + (1/2)O_2 \rightarrow PhN{\equiv}N^+ + H_2O$

[*e*] $PhN{\equiv}N^+ + PhNHNH_2 \rightarrow 2PhN{=}NH + H^+$

Phenyldiazene decay:

[*f*] $PhN{=}NH + (1/2)O_2 \rightarrow [PhN{=}\dot{N}] + O_2^- + H^+$

$[PhN{=}\dot{N}] \xrightarrow{\text{v. fast}} Ph^\cdot + N_2$

[*g*] $Ph^\cdot + subH \rightarrow PhH + sub^\cdot$

Termination:

[*h*] $2PhNH\dot{N}H \rightarrow PhNHNH_2 + PhN{=}NH$

[*i*] $2O_2^- + 2H^+ \xrightarrow{SOD} H_2O_2$

SCHEME 1. Mechanism for the autoxidation of phenylhydrazine catalysed by oxyhemoglobin

*Spin trapping of the products of autoxidation of phenylhydrazine*

It has long been suspected (18) that phenyl radicals are produced in the oxidation of phenylhydrazine. Consequently the formation of phenyl spin adducts in the spin trapping of phenylhydrazine-induced hemolysis is not surprising. The lack of other spin adducts, however, is. Why, for example, is superoxide not trapped? It is generated in the oxidation of phenylhydrazine — reactions [*b*] and [*f*], but it is consumed in reactions [*c*] and [*i*]. The spin trap is competing for the superoxide with SOD, which is present in the erythrocyte, phenylhydrazine, and possibly the benzadiazonium cation. Given the low rate (19) of reaction of superoxide with the spin traps at pH 7, it is understandable that no superoxide spin adduct is detected. The decay of phenyldiazene in aerobic media is so rapid that the lifetime of phenyldiazenyl radicals may be too short to form a phenyldiazenyl spin adduct. The phenylhydrazyl radical is generated and consumed in the propagation steps — reactions [*b*] and [*c*]. Phenylhydrazyl may also dismute — reaction [*h*]. The lack of detection of a phenylhydrazyl spin adduct during phenylhydrazine autoxidation may be due to the inability of the spin traps to compete successfully with $O_2$ and dismutation reactions for the phenylhydrazyl radicals.

*A mechanism for phenylhydrazine-induced hemolysis*

The autoxidation of phenylhydrazine is catalysed by oxyhemoglobin within the erythrocytes, producing high levels of hydrogen peroxide (20) and phenyl radicals (12). The use of a membrane-solvated spin trap, LINPyBN, which we assume to be preferentially located in the erythrocyte membrane, suggests that either the phenyl radicals are produced in the membrane or they diffuse to the membrane where they are trapped. We note that the esr spectrum of the LINPyBN phenyl spin adduct is not that of an immobilised nitroxide. It is known (21) that simple lipid soluble nitroxides may orient themselves parallel to the membrane but within the membrane, to give isotropic nitroxide esr spectra. It is possible that the cytotoxic activity (13) of phenylhydrazine is due to the attack of phenyl radicals on the membrane thus initiating the oxidation of unsaturated fatty acid residues in phospholipids (22) and aggregation of membrane proteins (23). Indeed, high levels of lipid peroxidation products and spectrin polymers have been observed in the reticulocyte membranes prepared from phenylhydrazine-treated animals (23). It was suggested that the polymerisation of spectrin may lead to the loss of integrity of the erythrocyte membrane.

Phenylhydrazine-induced hemolysis may be mediated by phenyl radicals through an intravascular route, the hydrogen peroxide-dependent extravascular route playing an increasingly important role as the detoxification mechanisms for reduced oxygen species are overcome. However, it is unlikely that either route occurs in isolation.

# Spin trapping by use of nitrosodurene and its derivatives

RYUSEI KONAKA,[1] SHIGERU TERABE,[2] TAIICHI MIZUTA, AND SHIGERU SAKATA
*Shionogi Research Laboratories, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553, Japan*
Received September 1, 1981

RYUSEI KONAKA, SHIGERU TERABE, TAIICHI MIZUTA, and SHIGERU SAKATA. Can. J. Chem. **60**, 1532 (1982).

In spin trapping the *N*-methyl-*N*-phenylaminomethyl radical with nitrosodurene, an esr spectrum exhibiting line width alternation was observed despite the normal spectral pattern found with the use of nitroso-*tert*-butane.

Nitrosodurene derivatives, *N*-duryl nitrone and methyl *N*-duryl nitrone, have been revealed to be other excellent spin traps for the *N*-, *O*-, and *S*-centered radicals. Spin adducts of these radicals, which can be independently prepared by spin trapping with nitrosodurene, are stable and can be easily discriminated by large differences in β-hydrogen splittings or characteristic patterns.

Methyl *N*-duryl nitrone reacted with *tert*-butyl hydroperoxide to give a spin adduct which could be clearly distinguished in the esr spectra from the *tert*-butoxy adducts prepared independently from other sources. Accordingly, it seems to be the *tert*-butylperoxy adduct. Similarly, hydrogen peroxide gave a different spectrum from the hydroxy adducts.

Alkyl hydroperoxides caused molecule-induced homolysis with the nitroso compounds to produce alkoxy adducts of the respective nitroso compounds. Some phenyl and duryl alkoxy nitroxides undergo decomposition to give alkyl radicals which were trapped by the nitroso compounds.

RYUSEI KONAKA, SHIGERU TERABE, TAIICHI MIZUTA et SHIGERU SAKATA. Can. J. Chem. **60**, 1532 (1982).

Lors du piégeage du radical *N*-méthyl *N*-phénylamino méthyle avec le nitrosodurène, le spectre de rpe présente une alternance de largeur de ligne en dépit de l'allure de spectre normal trouvé lors de l'utilisation du nitroso-*tert*-butane.

Les dérivés du nitrosodurène, la *N*-durylnitrone et la méthyl *N*-durylnitrone, se sont révélés d'excellents capteurs de spin pour les radicaux ayant en leur centre le N, le O ou le S. Les adduits de spin de ces radicaux, qui peuvent être préparés indépendemment par captage de spin avec le nitrosodurène, sont stables et peuvent être facilement différenciés par des grandes différences dans le dédoublement de l'hydrogène en β ou par des traits caractéristiques. La méthyl *N*-duryl nitrone réagit avec l'hydroperoxyde de *tert*-butyle pour donner un adduit de spin que l'on peut clairement distinguer, par la rpe, des adduits *tert*-butoxy préparés indépendemment à partir d'autres sources. En conséquence, il ressemble à un adduit *tert*-butylperoxy. De la même façon, le peroxyde d'hydrogène donne un spectre différent de celui des adduits hydroxy.

Les hydroperoxydes d'alkyles, provoquent une hémolyse induite des composés nitrosés conduisant à la formation d'adduits alkoxy des composés nitroso respectifs. Quelques phényl et duryl alkoxynitroxydes donnent, par décomposition, des radicaux alkyles qui sont captés par les composés nitroso.

## Introduction

In 1968, Konaka and Terabe applied the spin trapping technique using nitrosobenzene (NB) to oxidation reactions with nickel peroxide (NiPO) and were able to identify the free radicals involved as reaction intermediates (1, 2). Although NB is a useful spin trap whose spin adducts show characteristic finger-print spectra, the assignment of esr spectra of the spin adducts is very tedious because of their complexity.

Among alternative spin traps, nitrosodurene (ND) has proved to be a particularly interesting compound because of the following advantages (3).

(*1*) The nitroxides formed have simple esr spectra: In general, no resolvable splitting due to the aromatic ring of the spin adducts of ND is observed. This suggests that the nitroxyl group twists along the ring-carbon–nitrogen bond from the plane of the aromatic ring.

(*2*) ND does not undergo photolysis to produce detectable paramagnetic species: A benzene solution of ND irradiated with light from a 1 kW high-pressure mercury lamp did not show any esr signal. Accordingly, ND can be used as a spin trap in photochemistry.

(*3*) Wide scattering of β-hydrogen splitting constants leads to ready discrimination of the radicals trapped: The most characteristic feature in esr spectra of alkyl duryl nitroxides is the wide variation of the β-hydrogen splitting constants depending on the structure of the radical trapped. As an example, β-hydrogen splitting constants of the secondary alkyl radical adducts produced by trapping with nitroso-*tert*-butane (NtB), NB, or ND can be compared in Table 1. In the case of ND, the steric requirements owing to the *ortho* methyl groups emphasized by the buttressing effects of the *meta* methyl groups of the duryl nitroxide seem to cause significant differences.

(*4*) Highly efficient trapping occurs in spite of the fact that a large portion of the dimeric form exists in solution: Recently, Maeda and Ingold determined

the rate constants for spin trapping alkyl radicals using a variety of spin traps in benzene at 40°C (5), and also Yoshida and Doba measured the trapping rate constants of the *tert*-butyl radical using various spin traps in benzene at 26°C (6). From these results, ND proved to give the largest rate constants among the spin traps examined. Even though ND is mostly in the dimeric form in benzene ($K$ = [dimer]/[monomer]$^2$, $K = 303\,M^{-1}$ at 40°C (5)), it is highly efficient for trapping alkyl radicals.

This paper describes an interesting example of spin trapping carbon-centered radicals with an adjacent nitrogen atom using ND.

Generally, nitrones such as phenyl *tert*-butyl nitrone (PBN) (7), 5,5-dimethylpyrroline-*N*-oxide (DMPO) (8), and 3,3,5,5-tetramethylpyrroline-*N*-oxide ($M_4$PO) (9) have been used extensively as spin traps other than nitroso compounds so far. This paper also reports the usefulness of *N*-duryl nitrone (DN) and methyl *N*-duryl nitrone (MDN), which are related to ND. In addition, esr spectroscopy of the peroxy adducts of MDN or DN, which appears to be an attractive problem in radical chemistry, is described.

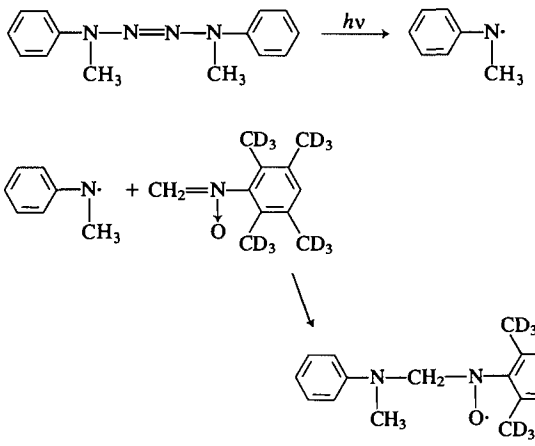
Finally, molecule-induced homolysis of hydroperoxides with *C*-nitroso compounds was investigated by applying the spin trapping technique, and the behavior of the alkoxy nitroxides is discussed.

## Spin trapping carbon-centered radicals with an adjacent nitrogen atom

Although an enormous amount of spectral data is available for nitroxide radicals, not much has appeared on spin trapping of carbon-centered radicals adjacent to the nitrogen atom (10–14). This section compares the trapping of aminoalkyl radicals using ND ($d_{12}$) and NtB.

On mixing *N*,*N*-dimethylaniline with NiPO in benzene or fluorobenzene in the presence of NtB at room temperature, a spectrum consisting of 27 lines was observed. Analysis of this spectrum showed that two equivalent β-hydrogen couplings exist, and this spectrum was assigned to *N*-methyl-*N*-phenylaminomethyl *tert*-butyl nitroxide. Even at −20°C in fluorobenzene, the same spectrum as that at room temperature was obtained. On oxidation of *N*-methyl-*N*-phenylaniline with NiPO in the presence of NtB, almost the same spectrum was observed.

When the radical generated photochemically from *N*,*N*-dimethylaniline in benzene or fluorobenzene was trapped with ND ($d_{12}$) at room temperature, an unusual spectrum was observed. The photolysis of 1,4-dimethyl-1,4-diphenyl-2-tetrazene in benzene in the presence of DN, which is described later, gave the same spectrum.



To discover the reason for this phenomenon, the spectra were followed with variation of tempera-

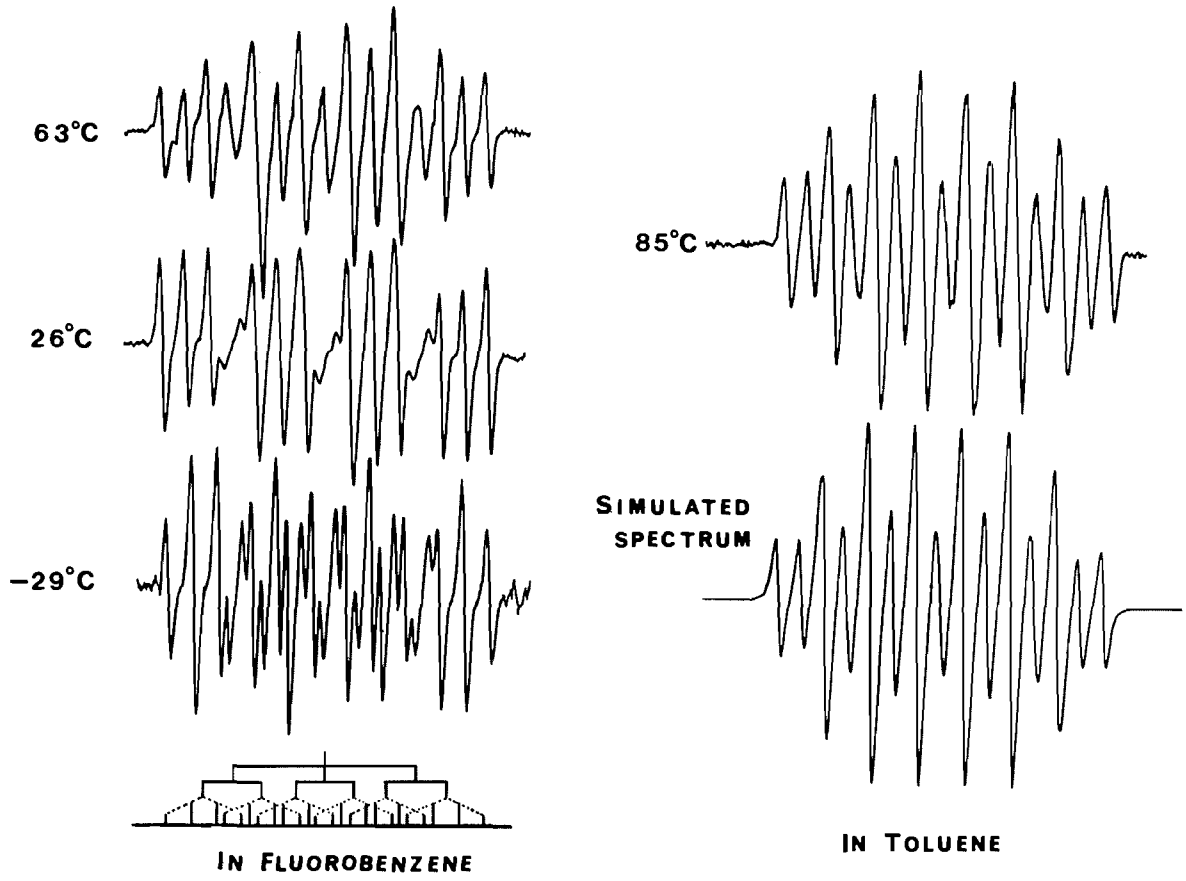


FIG. 1. Electron spin resonance of the *N*-methyl-*N*-phenylaminomethyl spin adduct of nitrosodurene ($d_{12}$) obtained by photolysis of *N*,*N*-dimethylaniline in the presence of di-*tert*-butyl peroxide at various temperatures.

ture (Fig. 1). At −29°C in fluorobenzene, the spectrum showed non-equivalent β-hydrogen splitting constants. Increase in temperature made the spectral lines broader, and at 63°C in fluorobenzene, the shoulder peaks disappeared and other new lines appeared. This behavior is a typical line width alternation (LWA) which takes place for a slow interconversion process between two conformers. The exchange rate constant at about 30°C was calculated to be $3.1 \times 10^7\ s^{-1}$.

However, the spectrum of the duryl nitroxide produced by trapping the radical generated photochemically from *N*-methyl-*N*-phenylaniline using ND ($d_{12}$) at room temperature showed a usual spectrum which is similar to that of the *tert*-butyl nitroxide. Even at −40°C in fluorobenzene, the spectrum, in which two β-hydrogen splittings are equivalent, did not change.

These spectral parameters are summarized in Table 2. Only the case of trapping the *N*-methyl-*N*-phenylaminomethyl radical with ND ($d_{12}$) showed a quite different behavior from the other cases. Other examples of the duryl adducts of the aminomethyl radicals which exhibit LWA are shown in Table 3. Although in LWA in a sterically hindered nitroxide the importance of solvent interaction is emphasized (15), this type of nitroxide seems to be subject to LWA owing to an internal factor based on comparison with the behavior of the *t*-butyl nitroxides under the same circumstances. The reason for this phenomenon arising from the use of ND is not clear, but is probably associated with the bulkiness of the duryl group.

From the esr parameters in Table 2, the conformation of *N*-methyl-*N*-phenylaminomethyl duryl nitroxide was estimated as follows. Assuming planar geometry around the nitroxide nitrogen atom, the approximation eq. [1] of the Heller–McConnell relation (16) was applied.

$$[1] \quad a_{\beta\text{-H}} = B_H \cos^2 \theta_\beta \rho_N$$

where $\rho_N$ is spin density on nitrogen, $B_H$ is a constant, and $\theta_\beta$ is the dihedral angle between the C—$H_\beta$ bond and the $p_z$ orbital containing an odd

| | | 13.13 | 12.55($H_A$ + $H_B$) | 3.57 | +20°C |
| | | 13.02 | 6.35(2H) | 3.52 | +50°C |

electron. In the methyl adduct of ND, the β-hydrogen splitting constant is reported to be 12.17 G (3). Based on the free rotation of the methyl group around the N—C bond, the averaged dihedral angle can be considered to be 45°. Hence eq. [2] was obtained.

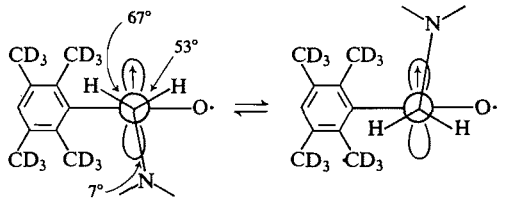
$$[2] \quad B_H = 24.34/\rho_N$$

Using the β-hydrogen splitting constants at −29°C in Table 2 and eq. [2], eqs. [3] and [4] were obtained.

$$[3] \quad 8.49 = \frac{24.34}{\rho_N} \times \cos^2\theta_\beta \times \rho_N'$$

$$[4] \quad 3.52 = \frac{24.34}{\rho_N} \times \cos^2(120 - \theta_\beta) \times \rho_N'$$

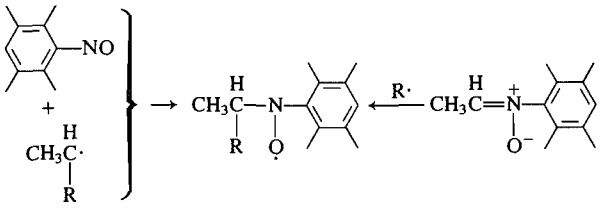
The nitrogen splitting constant of the methyl adduct is approximately equal to that of this nitroxide. Thus, $\rho_N$ approximately equals $\rho_N'$. From eqs. [3] and [4], $\theta_\beta$ = 53.8° and 52.4° were obtained, respectively; the two values agreed well with each other. Using the average value, $\theta_\beta$ = 53°, the dihedral angle of the $C_\alpha$—$N_\beta$ bond was estimated to be 7°, so that this bond seems to be almost eclipsed by the $p_z$ orbital of the nitrogen atom of the nitroxide.



### Spin trapping by use of duryl nitrones

The typical nitrone used as a spin trap, PBN, unfortunately has the property of narrow scattering of the β-hydrogen splitting constants. 5,5-Dimethylpyrroline-*N*-oxide (DMPO) developed by Janzen (8) has the nature of wide scattering of the β-hydrogen splitting constants.

As mentioned previously, the β-hydrogen splitting constants of duryl nitroxides vary markedly with the nature of the radical trapped, and moreover, duryl nitroxides can be obtained in two ways.



Accordingly, duryl nitrones can be expected to be a useful nitrone type spin trap other than PBN and DMPO.

Duryl nitrones were prepared from nitrosodurene by use of diazomethane or diazoethane (17); methyl *N*-duryl nitrone (MDN, mp 87.5–89°C) is more stable than *N*-duryl nitrone (DN, mp 89–91°C). DN was able to trap the hydroxymethyl or α-hydroxyethyl radicals generated photochemically by use of di-*tert*-butyl peroxide in methanol or ethanol solutions, respectively. However, in general it is not so ready to trap the carbon-centered radicals using DN or MDN. The trapping rate is probably very slow. On the other hand, duryl nitrones could readily trap heteroatom-centered radicals. The spectrum of the MDN adduct of the *n*-propylthiyl radical produced by photolysis of the corresponding disulfide in benzene is shown in Fig. 2. The thiyl adducts of MDN are considerably more stable than the thiyl adducts of DN. The spectrum of the carbazolyl adduct of MDN is shown in Fig. 3.

The results obtained in spin trapping the heteroatom-centered radicals using MDN are summarized in Table 4. In the thiyl radical adducts, the variation of the β-hydrogen splittings is not very large, but small splittings probably arising from γ-hydrogen are available for identifying a spectrum. In the amino radical adducts, the β-hydrogen splittings varied remarkably, demonstrating the characteristic feature of duryl nitroxide. Among these radicals, the assignment of ethylthiyl, carbazolyl, and *tert*-butoxy adducts was also confirmed using ND. As shown in Table 4, MDN can be used in photochemistry but is less stable to ultraviolet light than ND.

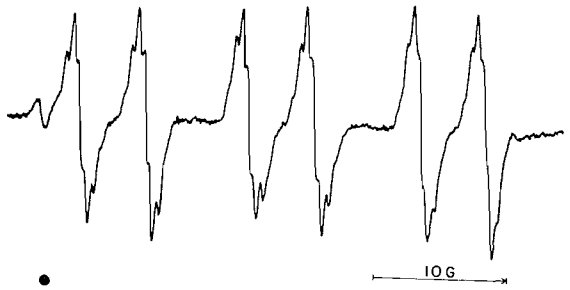


FIG. 2. Electron spin resonance spectrum of the *n*-propylthiyl spin adduct of methyl *N*-duryl ($d_{12}$) nitrone obtained by photolysis of *n*-propyl disulfide in benzene at room temperature.

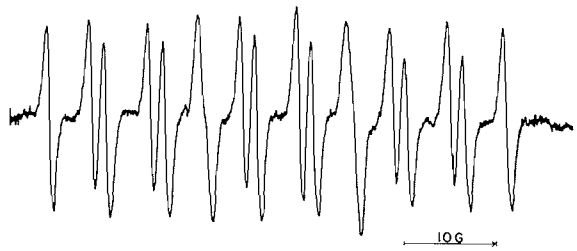

FIG. 3. Electron spin resonance spectrum of the carbazolyl spin adduct of methyl *N*-duryl ($d_{12}$) nitrone obtained by oxidation of carbazole with nickel peroxide in benzene at room temperature.

### Molecule-induced homolysis of hydroperoxides with nitrones

It is well known that a variety of reagents cause 1,3-dipolar addition to nitrones (18). However, there has been no report about the reaction of hydroperoxides and hydrogen peroxide with nitrones.

Mixing *tert*-butyl hydroperoxide with PBN in benzene–*tert*-butanol at room temperature produced an esr spectrum of a nitroxide. In order to identify this radical, the *tert*-butoxy adduct of PBN was prepared in the following two ways: by trapping the *tert*-butoxy radical generated from di-*tert*-butyl peroxyoxalate using PBN and by trapping the radical generated from benzyl *tert*-butyl ether with di-*tert*-butyl peroxyoxalate using NtB. From the results shown in Table 5 and the data summarized from the literatures in Table 6, the radical under consideration was identified as the *tert*-butoxy adduct of PBN. Table 6 shows that the nitrogen and β-hydrogen splittings of the *tert*-butylperoxy adduct are somewhat different from those of the *tert*-butoxy adduct.

The reaction of *tert*-butyl hydroperoxide with nitrones was re-examined using MDN and DN. Similarly, on mixing *tert*-butyl hydroperoxide with

[a] DBPO: di-*t*-butyl peroxyoxalate.

MDN, a nitroxide spectrum was observed. However, this spectrum was quite different from that of the *tert*-butoxy adduct prepared from di-*tert*-butyl peroxyoxalate (Fig. 4). A spectrum similar to the latter was observed in trapping the radical generated from *tert*-butyl ethyl ether in the presence of di-*tert*-butyl peroxyoxalate by use of ND.

In a similar manner, two types of the spin adduct were observed by employing DN instead of MDN. Furthermore, trapping the radical produced from *tert*-butyl methyl peroxide in the presence of di-*tert*-butyl peroxyoxalate with ND gave a spectrum which could be assigned to the *tert*-butylperoxy adduct of DN, although another signal was mixed in the spectrum.

From these spectral data, summarized in Table 7, the nitroxides observed in the reaction of *tert*-butyl hydroperoxide with MDN or DN seem to be α-*tert*-butylperoxyethyl or *tert*-butylperoxymethyl duryl nitroxides, respectively.

[a]I: ND; II: DN; III: MDN (solvent: ϕH—Bu$^t$OH).

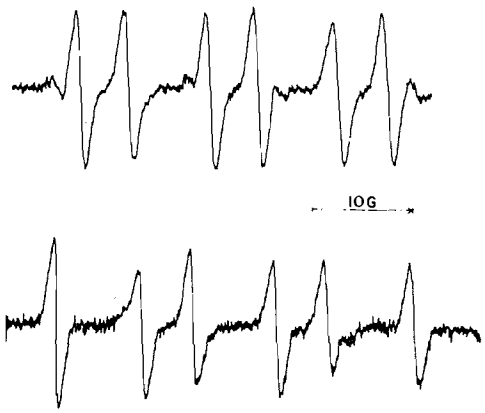

FIG. 4. Top: esr spectrum obtained from the reaction of *tert*-butyl hydroperoxide with methyl *N*-duryl nitrone in benzene/*tert*-butanol (2:1) at room temperature. Bottom: esr spectrum obtained from the reaction of di-*tert*-butyl peroxyoxalate with methyl *N*-duryl nitrone in benzene/*tert*-butanol (2:1) at room temperature.

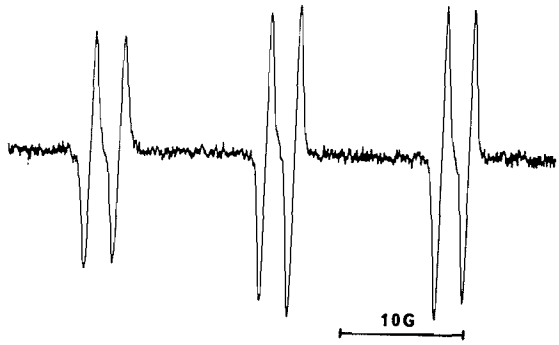

FIG. 5. Electron spin resonance spectrum obtained from the reaction of hydrogen peroxide (90% grade) with phenyl *tert*-butyl nitrone in benzene/*tert*-butanol (2:1) at room temperature.

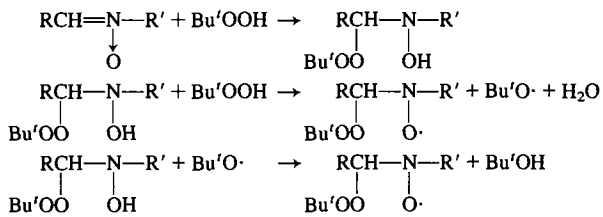
In the experiment of the reaction of MDN with 90% hydrogen peroxide instead of *tert*-butyl hydroperoxide, a spectrum having the esr parameters shown in Table 8 was observed. Since these parameters are different from those of α-hydroxyethyl duryl nitroxide, which was obtained in trapping by use of ND (Table 8), the former appears to be α-hydroperoxyethyl duryl nitroxide. From the results of the experiments using DN instead of MDN and trapping the hydroxymethyl radical by ND (Table 8), it seems that the spectrum of hydroperoxymethyl duryl nitroxide was similarly obtained in the reaction of hydrogen peroxide with ND.

In addition, when 90% hydrogen peroxide was added into the benzene–*tert*-butanol (2:1) solution of PBN, the spectrum shown in Fig. 5 was obtained ($a_N$ = 14.13, $a_{\beta\text{-H}}$ = 2.26 G). According to the plot of the nitrogen and β-hydrogen splitting constants proposed by Janzen *et al.* (23), this nitroxide is presumed to be the hydroperoxy adduct.

Based on the results mentioned above, these phenomena can be explained by the following scheme.



Hydroxylamines are known to react with hydroperoxides to produce radicals by molecule-induced homolysis (24–26). The reaction of *N*-*tert*-butyl-*N*-benzyl hydroxylamine with *tert*-butyl hydroperoxide produced a spectrum of the corresponding nitroxide.

### Molecule-induced homolysis of hydroperoxides with nitroso compounds and the behavior of alkoxy nitroxides

On mixing *tert*-butyl hydroperoxide with *m*-

deuterated nitrosobenzene ($d_2$), an esr spectrum was obtained, which was assigned to *tert*-butoxy phenyl nitroxide ($d_2$) based on the parameters reported by de Boer *et al.* (27). When the solution was allowed to stand for 4 h at room temperature, an additional signal appeared in the spectrum. After 24 h, only the second signal was observed, which was assigned to *tert*-butyl phenyl nitroxide ($d_2$) based on the literature by de Boer *et al.* (28). Figure 6 shows the change of spectra with time. Even in the dark, the same spectrum was obtained. The concentration of the former radical was much higher than that predicted from the spontaneous decomposition rate of *tert*-butyl hydroperoxide reported by Hiatt *et al.* (29). Thus, this reaction is considered to be one of molecule-induced homolysis.

A considerable amount of nitrobenzene was found by gas phase chromatography in this reaction. A further interesting fact is that even when *tert*-butyl peroxyoxalate was used as a peroxide, nitrobenzene was produced.

In addition, spin trapping using ND on the photolysis of dicumyl peroxide at −80°C gave the spectrum shown in Fig. 7 assigned to the cumyloxy adduct. However, at room temperature, two kinds

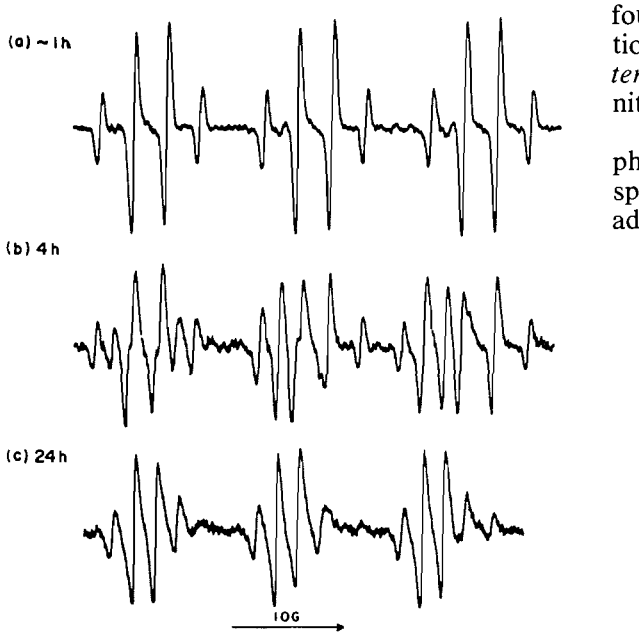

FIG. 6. Electron spin resonance spectra of the spin adducts obtained on mixing *m*-dideuterionitrosobenzene and *tert*-butyl hydroperoxide in benzene at room temperature at various times. Top spectrum: $a_N$ = 14.68 G, $a_{o,p\text{-H}}$ = 2.89 G (*tert*-butoxy adduct). Bottom spectrum: $a_N$ = 12.59 G, $a_{o,p\text{-H}}$ = 1.87 G (*tert*-butyl adduct). Middle spectrum: mixture of the top and bottom spectra.

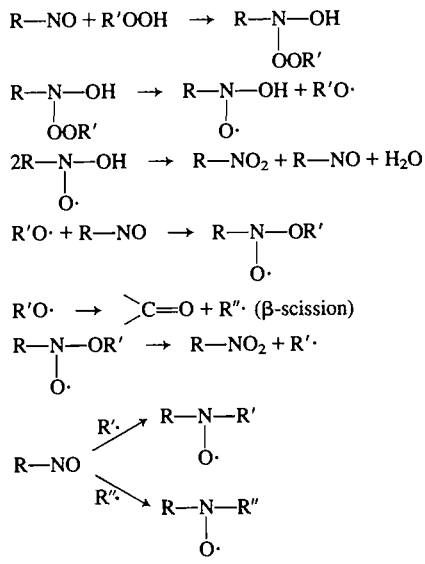

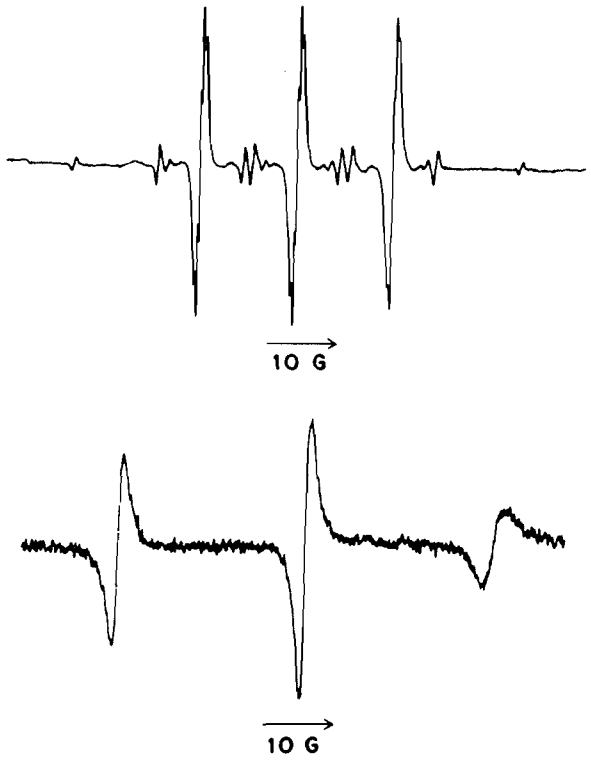

FIG. 7. Electron spin resonance spectra of the spin adducts obtained by photolysis of dicumyl peroxide in the presence of nitrosodurene ($d_{12}$). Top spectrum: in benzene at room temperature; $a_N$ = 13.69 G, $a_{\gamma\text{-H}}$ = 0.41 G (6H) (cumyl adduct); $a_N$ = 13.61 G, $a_{\beta\text{-H}}$ = 12.18 G (3H) (methyl adduct). Bottom spectrum: in dichloromethane at −80°C; $a_N$ = 26.21 G (cumyloxy adduct).

of signals were observed which were assignable to the cumyl and methyl adducts.

Based on these results, the following mechanism of molecule-induced homolysis of hydroperoxides with nitroso compounds is proposed.

In 1978, Pfab attempted to trap peroxy radicals by using *C*-nitroso compounds. However, this method did not permit discrimination between the alkylperoxy and alkoxy radicals, since ready fission of the O—O bond of the alkylperoxy adduct occurs and produces the alkoxy radicals (30).

In general, the formation and decomposition pathways of alkoxy nitroxides can be summarized as follows.

$$\mathrm{RNO + R'O\cdot} \underset{b}{\overset{a}{\rightleftharpoons}} \mathrm{RNOR'} \underset{d}{\overset{c}{\rightleftharpoons}} \mathrm{RNO_2 + R'\cdot}$$

$$\mathrm{RNOR'} \quad (\mathrm{O\cdot}) \qquad e \Updownarrow f$$

$$\mathrm{R\cdot + R'ONO}$$

The process ($d \rightarrow b$) was confirmed by Inamoto and Shimamura (31), Waters *et al.* (32), and Sutcliff *et al.* (33). The pathway ($a \rightarrow e$) was established by de Boer *et al.* (34) and Ingold *et al.* (35). The process ($f \rightarrow b$) is presumed by the papers of Kharasch *et al.* (36), Gray *et al.* (37), and Jest *et al.* (38). In addition to these pathways, the present study confirmed the existence of the process ($a \rightarrow c$). Which process predominates may depend on the stability of the R or R′ radicals.

A similar phenomenon has been reported by Kochi *et al.* (39) in regard to bond fission of phosphoranyl radicals.

# Simulation of isotropic electron spin resonance spectra: a transportable basic program

UWE M. OEHLER AND EDWARD G. JANZEN

*Guelph-Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1*

Received September 1, 1981

UWE M. OEHLER and EDWARD G. JANZEN. Can. J. Chem. **60**, 1542 (1982).

A computer program written in BASIC is presented for the simulation of isotropic esr spectra using a microprocessor. Since BASIC is the most common microprocessor language, this program can easily be adapted to most microprocessors. Through the use of more efficient methods the capabilities of much larger FORTRAN programs, run on mainframe computers, are retained in the more restricted environment of the microprocessor. As a result, most spin trapping results can be dealt with easily. A number of sample simulations illustrate the program's features.

UWE M. OEHLER et EDWARD G. JANZEN. Can. J. Chem. **60**, 1542 (1982).

On présente un programme pour ordinateur écrit dans le langage BASIC pour la simulation des spectres de rpe isotropes à l'aide d'un micropresseur. Puisque le langage BASIC est le plus courant des langages des microprocesseurs, on peut facilement adapter ce programme à la plupart des microprocesseurs. En faisant appel à des méthodes plus efficaces, on a retenu, dans l'environnement plus restreint du microprocesseur, les possibilités qu'offrent les programmes FORTRAN plus étendus utilisés de concert avec des ordinateurs centraux. Par conséquent, la plupart des expériences de captage de spin peuvent être traités facilement. Un certain nombre de simulations d'échantillons illustre les caractéristiques du programme.

[Traduit par le journal]

## Introduction

Electron spin resonance spectra can be very complicated and often it is only through spectral simulation that an analysis can be verified. Comparison of calculated and experimental spectra usually leads to better estimates of the parameters involved.

Simulations have normally been implemented on large, centralized, mainframe computers which offer high speed operation and large memory capacities. These computers can, however, be unavailable or inconvenient at times. Through the use of more efficient programs inexpensive microprocessors can perform these simulations as well, albeit more slowly. A recent review (1) has surveyed the use of computers in esr over the last 10 years. Of the references offering simulation programs to the reader, most deal with simulation of anisotropic spectra. None of the references offer a general, microprocessor compatible simulation program for isotropic esr spectra (2).[1]

When surrounded by abundant memory and fast calculation speeds more emphasis is commonly placed on programming ease than on program efficiency. The resulting code is more straightforward but usually longer and less space efficient. Not surprisingly, these programs seldom translate well directly into the relatively restricted memory of a microprocessor. More efficient algorithms can produce programs which are better suited to these constraints.

A further consideration when using microprocessors is that BASIC is the "universal" language and that to maintain transportability it must be used. Unfortunately, "interpreter" as opposed to "compiled" BASIC is most common and is slow in execution. There is, therefore, an urge to use machine language programs which execute much more rapidly. This restricts programs to computers having a common machine language and similar memory layouts, reducing their applicability. Our own purpose has been to provide a simulation program which can easily be used by anyone with a microprocessor and this has dictated the use of BASIC. This program should prove useful to any spin trappers who want to implement a simulation program on a microprocessor based system. We are currently using a 2 MHz, 6502 based Ohio Scientific Challenger 8P computer with 48K RAM (random access memory) and a Hewlett Packard 7202A graphics plotter. The computer is equipped with Microsoft BASIC.

## Method

There are many different ways in which an isotropic esr spectrum can be simulated. We have used a modified Stone–Maki (3) program successfully on the main university computer. When a microprocessor is used and the Stone–Maki program is translated into BASIC the result is too

[1]In ref. 2 the authors report an esr data aquisition system using an APPLE II PLUS computer. A BASIC simulation program is included but will work only on the specified computer since several features peculiar to the internal architecture of the APPLE were used.

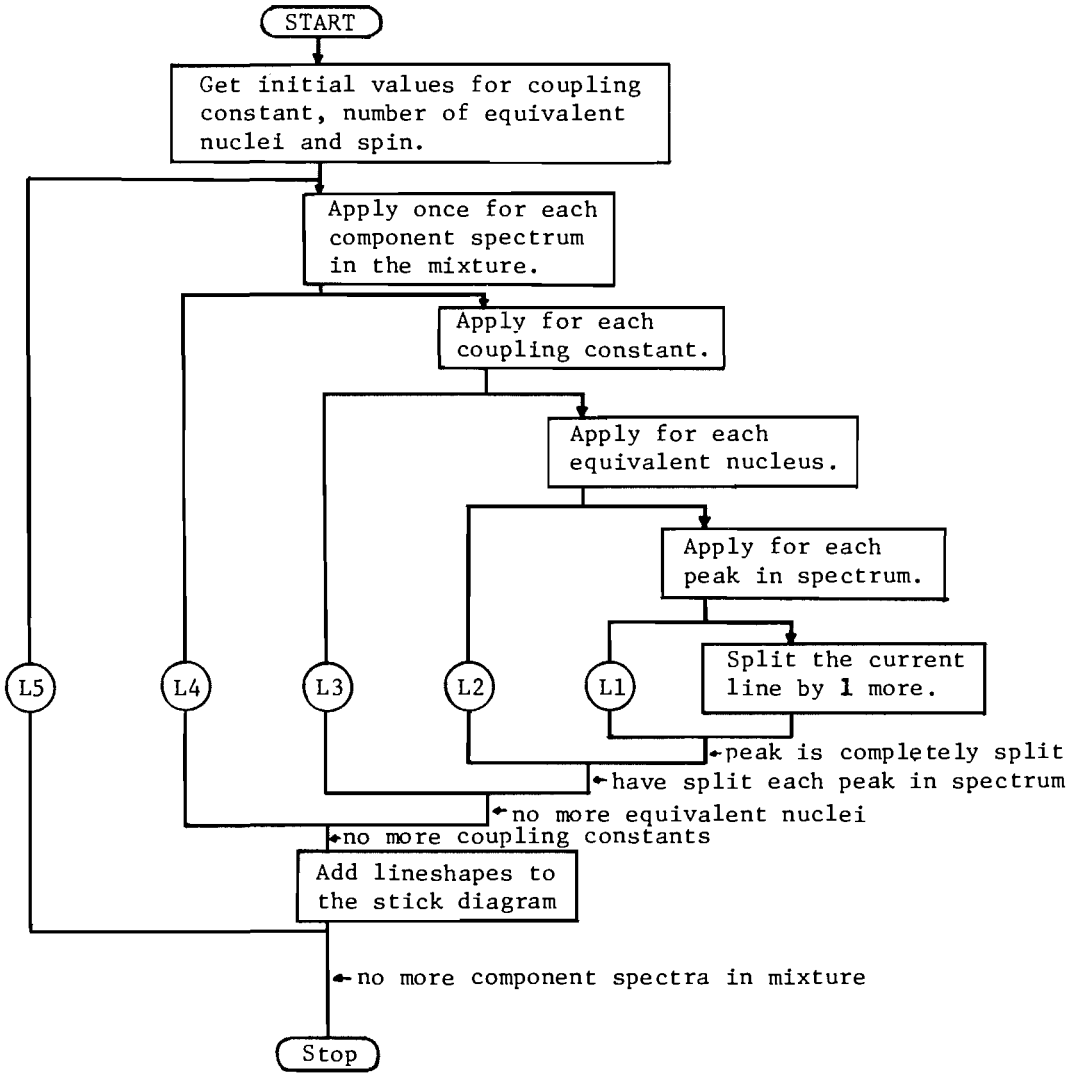

FIG. 1. A simplified flow chart of the program logic.

wasteful of memory space. Very promising programs have been based on fast fourier transforms (FFT) (4, 5) but to use these on a microprocessor requires that the transform routine be written in machine language. This is precluded by our desire for portability. The program presented here represents a compromise which retains the capabilities of larger programs while using less space and retains portability through the use of BASIC.

The spectrum is simulated through the use of two arrays. One is used to generate a stick diagram which represents the location and intensity of each peak. A single lineshape is then calculated and, using the stick diagram as a map, is copied into the second array to build the final spectrum. By clearing the stick diagram and building another in its place it is possible to overlay several spectra into the second array allowing mixtures to be simulated.

The generation of the stick diagram is handled in a highly general manner and as a result any spin or number of equivalent nuclei can be simulated. The algorithm used is highly repetitive and consists of five nested loops as seen in Fig. 1.

The innermost loop, L1, is used to generate the splitting of one peak due to the presence of a single nucleus of spin $S$. The loop is executed $2S$ times and during each repetition, it places one new stick to the right of the parent stick, maintaining spacings of one coupling constant between all the added lines and the parent. The next loop, L2, searches

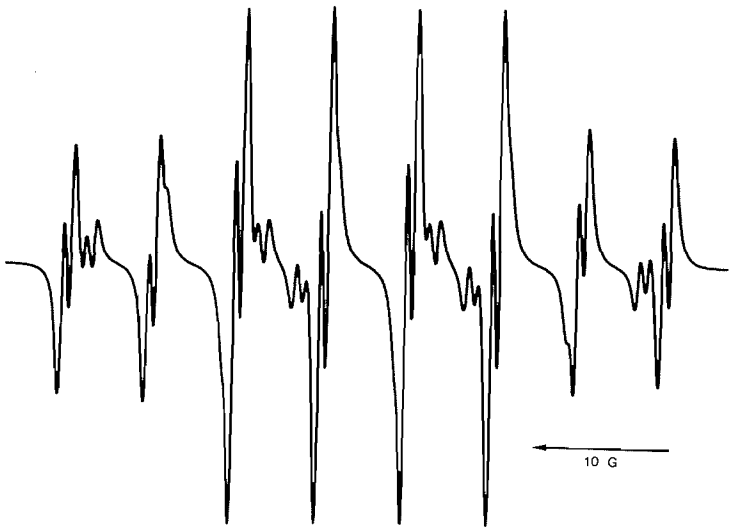

FIG. 2. Simulation of the spectrum due to the chlorine adduct to PBN. $A_N = 12.33$ G, $A_H = 0.70$ G, $A_{^{35}Cl} = 6.15$ G, $A_{^{37}Cl} = 5.04$ G, linewidth = 0.50 G, 3.5 min required to calculate for an $x$ increment of 0.05 G.

the spectrum from right to left and applies L1 to each peak that it locates thereby introducing the splitting, due to one nucleus, into the entire spectrum. Loop 3, L3, applies both L1 and L2 once for each equivalent nucleus and loop 4, L4, applies all of the inner loops once for each different coupling constant generating the final stick diagram. The outermost loop, L5, is used in the case of mixtures and repeats the entire process for each component spectrum. Before this is done, however, the stick diagram must serve as a map to locate the individual first derivative lineshapes in the spectrum.

The calculated lineshape contains contributions from both Lorentzian and Gaussian lineshapes. The ratio used can be varied for the best fit with the experimental lineshape. Since the lineshape is symmetrical about a point of inversion only half is actually calculated. When the lineshape is copied into the final spectrum the missing portion is supplied by reflecting and inverting the calculated half.

Further, since the number of points required to represent one half the lineshape will vary widely with both the line width and the $x$ axis increment it was decided to calculate the lineshape in 100 point portions. This means that the memory required to hold the lineshape at any given time will never exceed the equivalent of 100 points although in its entirety the lineshape might actually require much more. By doing this the amount of space available for the final spectrum remains constant irrespective of the lineshape.

## Results

To illustrate the operation of the program several sample simulations are shown. The calculation times do not include plotting since this is highly dependent on the plotter used.

It is important to realize the potential weaknesses of the method of simulation presented in this paper. When these are kept in mind, few problems occur. Problems can arise from the fact that we are approximating a continuous function, the esr spectrum, as a set of points. The result is that peaks can only be placed at specific locations in the spectrum and these may not correspond perfectly to their actual locations. The error in the peak location can be as large as plus or minus one half the $x$ axis step size. To solve this we must choose an $x$ increment which results in an error smaller than that in the actual measurement from the experimental spectrum. When this is done, however, the number of points calculated increases. For a spectral width of 30 G the $x$ increment cannot be below 0.01 G and still yield less than 3000 points. Further, the time required to calculate 3000 points becomes excessive for routine work. Fortunately a compromise can be struck for many spectra by using an $x$ increment of about 0.05 G and calculating about 1000–1500 points. This is because the pen width itself is often greater than 0.05 G on a 100 G scan and also because typical linewidths of about 0.5 G mask such small positional errors. It is in cases of extremely narrow lines combined with small coupling constants that care must be taken.

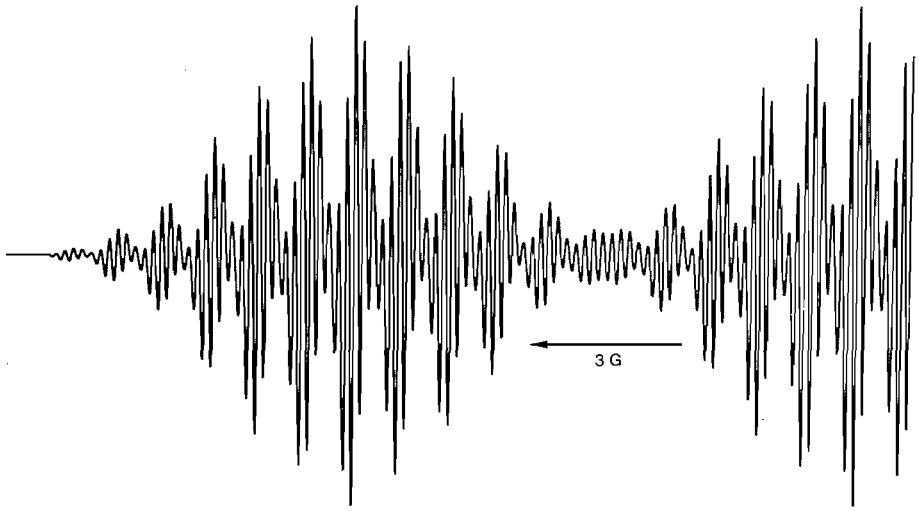

FIG. 3. Simulation of the spectrum due to di-*p*-anisylnitroxide. $A_N = 10\,G, A_{H(ortho)} = 1.92\,G, A_{H(meta)} = 0.90\,G, A_{H(methoxy)} = 0.18\,G$, linewidth = 0.10 G, 27 min required to calculate for an $x$ increment of 0.012 G.

Figure 2 shows a simulation of the spectrum due to the chlorine adduct of PBN (phenyl-*N*-*tert*-butylnitrone) (6). In this case the spectrum is actually a mixture since there are two isotopes of chlorine. The calculation time is the sum of the times required for the individual components. An important point to note is that the same error which can occur in peak placement can occur as well in the location of the center of the spectrum. The result of this is that a small but unintentional $g$ shift can be introduced into a mixture. In the case of the chlorine adduct each isotope of chlorine has a different coupling constant. As a result, the widths of the component spectra are different and the numbers of points required to represent them differ. The components of this simulation contain 877 and 810 points respectively between the two outermost sticks of their stick diagrams. Since one contains an odd number of points and the other an even number their respective centers must be offset by one half the $x$ increment. In this case the offset is only 0.025 G. While the offset is small it must be considered in critical cases. In the simulation shown the shift is not visible.

The simulation in Fig. 3 is that for the spectrum of di-*p*-anisylnitroxide (7). This spectrum is more challenging (525 peaks, 27 min calculation time). However, the 3000 point resolution of this program is sufficient to introduce negligible error. The coupling constants are measured to two decimal places implying a minimum error of +/−0.005 G. by using an $x$ increment of 0.012 G we introduce a maximum error in peak position of 0.006 G which is similar to the experimental accuracy.

In the course of our testing we also simulated the spectrum for the *N*,*N*,*N*′,*N*′-tetramethylbenzenediamine radical cation (Wurster's blue) (8). This spectrum is unusual in that it has a width of about 117 G as compared to 30–40 G for most common spectra in spin trapping. As a result the $x$ increment cannot be much smaller than 0.042 G. This introduces an error which is about 4 times the experimental error of 0.005 G. This spectrum represents a practical limit beyond which another program, capable of finer resolution, would be needed to further refine the coupling constants. These sorts of situations typically arise when sharp lines with widths approaching the $x$ increment in size are combined with small line separations also nearing this increment size.

As shown, this program can perform routine simulations in about 2–5 min when 1000–1500 points are calculated. The small positional errors in peak and center locations introduced by this method have also been shown to be minimal, generally being less than the experimental error. Only in extreme cases is the 3000 point resolution insufficient for the job. Even very complicated spectra can be simulated if attention is payed to the $x$ increment size and patience is practiced.

## Appendix

This program is written in Microsoft BASIC and requires about 33 K of free RAM to operate. The memory requirements can be reduced by lowering the maximum number of points that can be calculated. This is done by changing the numbers 3000 in lines 20 and 170 to the new maximum.

Since not all versions of BASIC are exactly identical, those features which might cause some confusion are explained below.

(*1*) all variables are automatically assigned the value of zero when the program is executed;

(*2*) variable names may consist of one or two letters or a letter followed by a single digit;

(*3*) the symbol ^ means "raised to the power";

(*4*) the symbol : is the end of a line;

(*5*) the symbol $\langle\ \rangle$ means "not equal to";

(*6*) in IF THEN statements, all instructions occurring on the same line after the THEN are executed only if the condition is true.

The input required by the program follows.

(*1*) *number of spectra*: this is the number of components in a mixture;

(*2*) x *increment*: the step size in G, along the $x$ axis, between calculated points;

(*3*) *phase*: if 1, the first derivative lineshape goes positive and then negative. If $-1$, the reverse occurs.

The following information must be supplied for each component spectrum in a mixture:

(*4*) *number of coupling constants*: the number of different coupling constants required to simulate the $n$th component;

(*5*) *line width*: the $x$ axis distance between the positive and negative peaks of the first derivative lineshape;

(*6*) *maximum* Y: relative height of the largest stick in the $n$th component's spectrum as compared to the largest stick in that of component one;

(*7*) *delta* G: the shift, in G, between the center of the $n$th component's spectrum and the first components spectrum. The delta $G$ for the first radical must be 0;

(*8*) *fraction lorentzian*: the fractional contribution to the area of the lineshape by a lorentzian lineshape. The remainder is gaussian.

The following information must be supplied for each different coupling constant:

(*9*) *number of nuclei*: the number of nuclei having the same coupling constant and value of spin;

(*10*) *coupling constant*: the coupling constant in G;

(*11*) *spin*: the spin of the nuclei. May be any integral multiple of 0.5 other than 0.

One important point to note is that when a mixture is being simulated the component spectrum which extends the furthest downfield (to the left) must be entered as the first component. Each spectrum extends eight linewidths past the location of the last peak.

# Lyoluminescence and spin trapping

KAMIL V. ETTINGER, ALEXANDER R. FORRESTER, AND CHARLES H. HUNTER

*Department of Biomedical Physics and Bioengineering, and Department of Chemistry, University of Aberdeen, Aberdeen, Scotland, U.K.*

Received September 12, 1981

KAMIL V. ETTINGER, ALEXANDER R. FORRESTER, and CHARLES H. HUNTER. Can. J. Chem. **60**, 1549 (1982).

The chemical origin of lyoluminescence has been probed using spin trapping techniques. Radicals derived from amino acids and saccharides by γ-irradiation in the solid state have been identified after trapping with aliphatic and aromatic nitroso compounds. Most of the radicals trapped were secondary alkyl radicals. Reaction of peroxyl radicals derived therefrom are thought to produce the emitting species (excited carbonyl compound and/or singlet oxygen). The effect which thermal annealing of the solids after γ-irradiation has on (*a*) the concentration of radicals in the solid, (*b*) the concentration of trapped radicals, and (*c*) the light yield has been investigated. One new water-soluble spin trap has been prepared.

KAMIL V. ETTINGER, ALEXANDER R. FORRESTER et CHARLES H. HUNTER. Can. J. Chem. **60**, 1549 (1982).

On a prouvé l'origine chimique de la lyoluminescence en utilisant les techniques de captage de spin. On a identifié les radicaux provenant des acides aminés et des saccharides en les irradiant aux rayons γ dans l'état solide après les avoir captés avec des composés nitroso aliphatiques et aromatiques. La plupart des radicaux piégés sont des radicaux alkyles secondaires. On pense que la réaction des radicaux peroxydes qui en découlent produit les espèces émétrices (composé carbonylé excité et/ou oxygène singulet). On a étudié l'effet d'annellation thermique des solides après l'irradiation aux rayons γ sur: (*a*) la concentration des radicaux dans le solide, (*b*) la concentration des radicaux piégés et (*c*) le faible rendement. On a préparé un nouveau capteur de spin soluble dans l'eau.

Lyoluminescence is the term used to describe the phenomenon by which light is emitted on dissolution of a previously γ-irradiated solid. Although discovered (1) at the end of the nineteenth century it was not until the pioneering work of Ahnström and Ehrenstein (2) and Westermark and Grapengiesser (3) at about 1960 that interest in the subject was awakened. For several organic compounds, the "light yield" is proportional to dose over a wide range, hence lyoluminescence provides the basis of a dosimetric method (4, 5) suitable for measuring therapeutic doses and, because it is so sensitive, accidental doses of irradiation. The light yield is obtained by integrating the area under the glow curve, a typical example of which is shown in Fig. 1. Lyoluminescence has been observed for virtually all organic compounds but by far the most useful at this stage appear to be amino acids and sugars (Figs. 2 and 3) (4, 5). These are also said to have "tissue equivalence" and hence work on such substrates has relevance to radiation damage in biological systems.

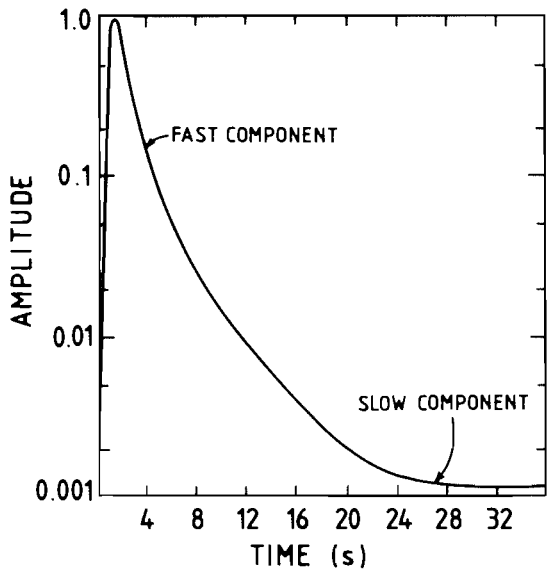

FIG. 1. Glow curve for a saccharide dissolved in water.

The ideal lyoluminescent material (phosphor) would (*a*) give a high light yield; (*b*) have a linear dose – light yield relationship over a wide dose range; (*c*) give reproducible light yields after storage under a variety of conditions (humidity, temperature, aerobic and anaerobic atmospheres). Design of such a phosphor clearly requires an understanding of the fundamental chemical reactions leading to the emission process. There is very strong circumstantial evidence from a variety of sources (2, 4–6) that free radicals are implicated. Of the several reaction sequences which have been postulated to account for the emission, by far the most attractive in our view is that described by the Russell–Vassilev scheme, Scheme 1 (7). In this scheme, primary and/or secondary alkyl radicals generated during γ-irradiation react with oxygen to give the corresponding peroxyl radicals which

2 MNP 3 MNPOB 4 DBNSA

5 6

disproportionate via a tetroxide, **1** (7). The Wigner conservation rule requires that either (*a*) the oxygen is generated in the singlet state with ground state singlet carbonyl or (*b*) the carbonyl is generated in the triplet state with ground state triplet oxygen. The overall reaction is highly exothermic (115–120 K cal $mol^{-1}$) and, according to Kellog (8), the exothermicity is concentrated in the carbonyl function, de-excitation of the carbonyl compound being the origin of the observed chemiluminescence. Excited carbonyls emit (9) in the range 397–510 nm and the spectra observed from amino acids usually show a maximum in this region. For example, glutamine and threonine emit at 460 ± 10 nm and glutamic acid at about 480 nm with a low intensity continuum towards longer wavelengths (Fig. 4). Spectra of saccharides (Fig. 5), unlike those of aminoacids, vary with pH. For many at pH 6, there is a maximum between 600–700 nm tailing off to ca. 400 nm (9). In alkaline solution, pH 11, there is a hypsochromic shift to about 450 nm. However, it must be stressed that there is a much greater variety of shape in the spectra of saccharides.

If singlet oxygen is formed then emission at 1270 nm corresponding to $^1\Delta_g \rightarrow {}^3\Sigma_g^-$ and/or 760 nm corresponding to $^1\Sigma_g^+ \rightarrow {}^3\Sigma_g^-$ should be detectable.

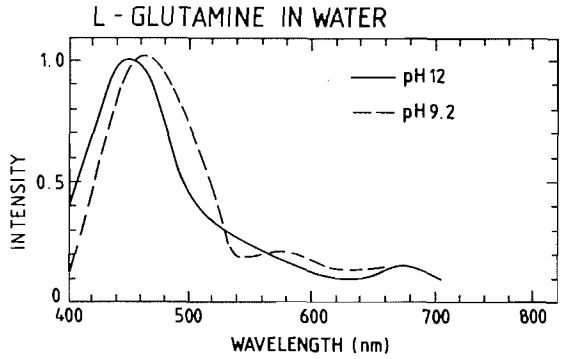

FIG. 4. LL spectra of L-glutamine.

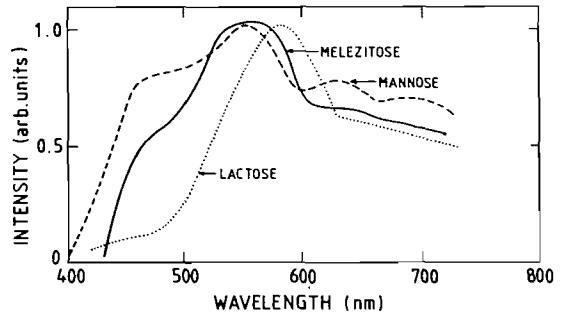

FIG. 5. LL spectra of saccharides.

Emission at 1270 nm has been observed after dissolution of heavily irradiated glutamine and some saccharides (melezitose) (5). Collisional pairs of singlet oxygen molecules could give rise to emission at 380, 480, 520, 635, and 703 nm (10) but with the lifetime of singlet oxygen in water being so short (2 μs for $^1\Delta_g$ and 10 ps for $^1\Sigma_g^+$) these would have to form in gas bubbles (in gas phase $^1\Delta_g$ has a lifetime of 64 min and $^1\Sigma_g^+$ 10 s). Significantly, the singlet oxygen quencher β-carotene reduced the LL emission from mannose by about 20% (11). Further replacement of water by deuterium oxide (in which the lifetime of singlet oxygen is increased about ten-fold) gave only a 13% increase in the LL yield of mannose and no change for glutamine at 635 nm but a significant increase at 1270 nm (5).

We conclude that the LL emissions observed from amino acids and saccharides in alkaline solution are more easily understood if a triplet carbonyl is the main emitter but with saccharides in neutral solution collisional pairs of singlet oxygen are also likely to play a part. Better understanding of the LL process requires more precise knowledge of the concentration, structure, and reactivity of the radicals present in the solid and in the solution at the moment of dissolution. With this aim we undertook a spin-trapping study of γ-irradiated amino acids and saccharides.

## Spin trapping[1]

For our purposes water-soluble spin traps were required. Also, nitroso traps were generally preferred over nitrone traps since the spin adducts from the former usually give more structural information about the radical trapped. It is also important to use more than one trap in view of the wide variation in reactivity of traps to different types of radical. This is a general point about spin trapping which has yet to be fully recognised. The following were the traps used.

*(a) 2-Methyl-2-nitrosopropane (MNP), 2 (13)*

This is not very soluble in water (1 mg/mL) and is light- and heat-sensitive but there is a very large body of data available on the esr parameters of *t*-butyl nitroxides which often helps the interpretation of observed spectra.

*(b) 2-Methyl-2-nitroso-4(4'-pyridyl-1'-oxide)-butane (MNPOB), 3*

This is a new water-soluble trap which was synthesised according to Scheme 2. It exists in the solid state as the colourless dimer. Variable temperature nmr measurements indicate that at room temperature in deuterium oxide it is dissociated to 22% and at 80°C to 79%. However, the dimer ⇌ monomer equilibration rate is relatively slow, hence solutions of the trap were warmed before use. Its trapping reactivity appears to be similar to that of MNP but much higher concentrations of trap can be used and hence stronger spectra are observed. The spin adduct spectra usually have slightly larger linewidths than those from MNP. In other respects (heat and light sensitivity), it resembles MNP.

*(c) 3,5-Dibromo-4-nitrosobenzenesulphonic acid (DBNSA), 4 (14)*

The sodium salt of this acid was recently reported. We shortened its preparation by using *p*-nitroperoxybenzoic acid rather than hydrogen peroxide to oxidise the amine in the final stage. Nuclear magnetic resonance measurements indicated that the dimer was 94% dissociated at room temperature. This trap has the advantage that it is much less sensitive to light than the corresponding alkyl nitroso compounds and it does not give the corresponding diaryl nitroxide on exposure of its aqueous solutions to daylight. Unfortunately, it gives spin adduct spectra with relatively broad lines; in the worst circumstances 2 G wide. When L-glutamine (8 Mrad dose) was added to a series of solutions

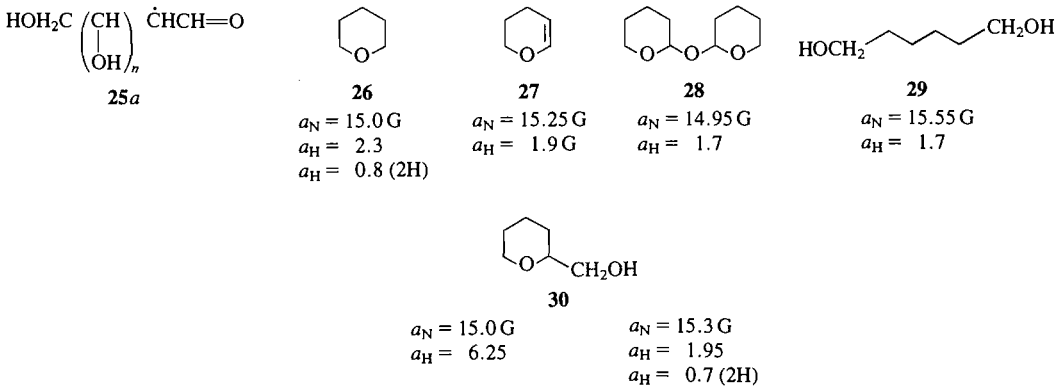

SCHEME 2. (*Concluded*)

0.004–0.2 *M* of this trap, the maximum concentration of spin adduct was achieved with solutions >0.02 *M*.

*(d)* N-t-*Butyl*-C-*(4'-pyridyl-1'-oxide)nitrone (POBN) 5 (15)*

This water-soluble nitrone has approximately the same trapping efficiency as DMPO. When irradiated, L-threonine (8 Mrad) was dissolved in an aqueous solution 0.1 *M* with respect to DMPO and POBN the two spin adduct spectra observed were of approximately equal intensity.

*(e) 5,5-Dimethylpyrrol-1-ine-1-oxide (DMPO), 6 (16)*

On storage, DMPO turns yellow and its solutions then display esr spectra with $a_N = 14.4$ G. To avoid this the trap was distilled before use and stored in the cold. Preliminary trapping experiments with this trap using irradiated amino acids confirmed that the trapped radicals were carbon-centred (Table 1). However, the $a_H$ values were not sufficiently different for these spectra to be used for structural identification of the trapped radicals.

## Relationship between dose, radical concentration, and light yield

For several organic compounds the LL light yield is proportional to (5) (*a*) the dose over a fairly wide range (Fig. 6) and (*b*) the radical concentration in the solid (Fig. 7). Another important relationship to establish is that between the LL light yield and the concentration of radicals in solution since it is these radicals which are thought to be responsible for the emission process. This has now been done (Fig. 8) using both a nitrone (POBN) and nitroso (DBNSA) trap and L-glutamine samples dosed to 100–600 krad. We have also shown that for L-glutamine there is a linear relationship between trapped radical concentration and solid state radical concentration (Fig. 9). Significantly this plot does not pass through the origin, hence not all of the radicals in the solid state are trapped. However, these radicals which are trapped must be responsible for the light emission since there was a sharp

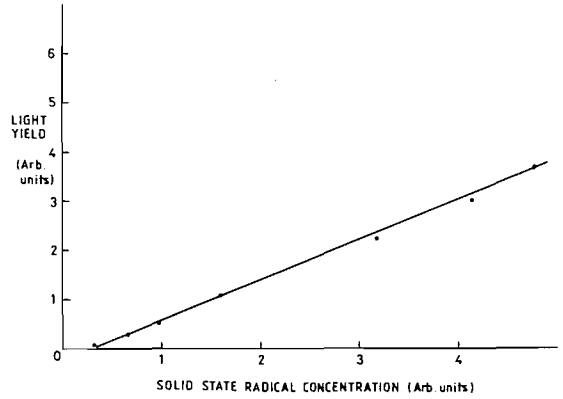

FIG. 7. Radical concentration (solid state) – light yield relationship for L-glutamine.

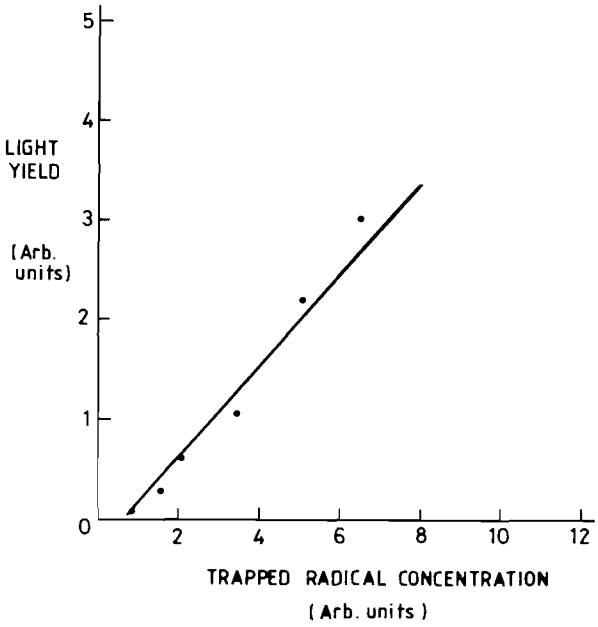

FIG. 8. Light yields – trapped radical concentration (DBNSA) relationship for L-glutamine.

decrease in the light yield when a solution of the trap DBNSA was used instead of water in the LL measurements with L-glutamine (8 Mrad). Further, the minimum concentration of trap (0.01 *M*) required to suppress the LL light emission corresponded almost exactly to the minimum concentration of trap required to give maximum yield of spin adduct.

## Annealing

When a series of irradiated samples of L-glutamine was heated to 110°C for 5 h the average concentration of radicals in the solids decreased by 32%. This was not unexpected. The increased temperature of

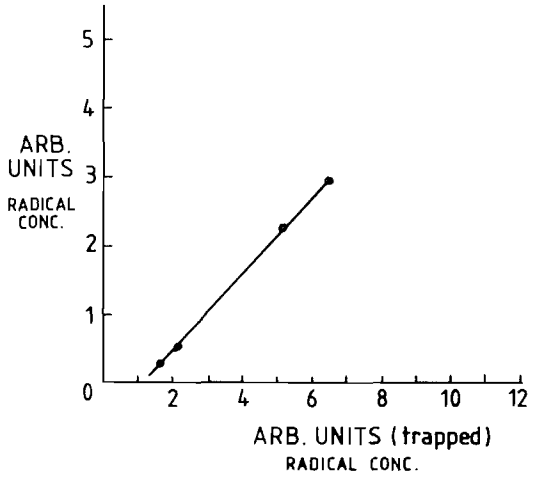

FIG. 9. Radical concentration (solid) – radical concentration (trapped) relationship for L-glutamine.

the crystals presumably allowed greater reaction between proximate radical centres. Surprisingly, however, the average LL light yield from the annealed samples increased by 50% which corresponded approximately to the increased concentration of trapped radicals using DBNSA (42% increase), and POBN (25% increase). We rationalise these observations as follows. Selective destruction of radical sites in the solid by heating increases the probability of reaction of the remaining radicals with oxygen or a trap on dissolution. Increase in the concentration of peroxyl radicals leads to an increase in light yield.

## Structure of radicals trapped

*(a) Amino acids*

γ-Irradiation of α-amino acids **7** leads primarily to oxidised **8** and/or reduced **10** species by electron loss or gain, respectively. These decay by decarboxylation (**8** → **9**) or deamination (**10** → **11**) to radicals which may react further. Most commonly, they abstract hydrogen from the parent amino acid to give what will be referred to hereafter as "hydrogen abstraction" radicals, **12**. Evidence for these reaction sequences has been adduced from direct esr and ENDOR measurements of single crystals, and product studies. The primarily formed species are only detected at low temperatures (4 and 77 K). At room temperature "deaminated" and "hydrogen abstraction" radicals are the most frequently encountered (17).

Thirteen amino acids were investigated using the nitroso traps MNP, MNPOB, and DBNSA. The radicals trapped with the corresponding coupling constants are given in Table 2. In general, the radicals trapped were "deaminated" and "hydro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

For personal use only.

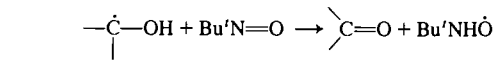
gen abstraction'' radicals in accord with the esr work reported for the solid state. The results are similar to those recently and independently obtained by Riesz and co-workers (18) who used only MNP as trap. However, there are significant differences.

The rate constants for reaction of radicals with spin traps are a function, *inter alia*, of the structure of the radical and of the trap. The relative ease with which primary, secondary, and tertiary alkyl radicals are trapped by several nitrones and nitroso compounds has been quantified (19). Hence, it is important to use more than one trap if all of the radicals in the system are to be detected. Even then the relative concentrations of the spin adducts do not necessarily reflect the concentration of radicals present in the solid. For example, with glycine the ''hydrogen abstraction'' radical was the main radical trapped with MNP but with DBNSA only the ''deaminated'' radical was trapped. Our results with glutamine are of special interest in view of its high light yield and hence potential utility. Computer simulation gives the best fit when there is weak equal coupling (0.6 G) with one nitrogen and *three* protons. This corresponds better to the spin adduct from the ''hydrogen abstraction'' radical **13** rather than that from radical **14** although the latter would seem the more likely on chemical grounds. It is clear from Table 2 that the type of radical most frequently trapped in this work was secondary alkyl, thus providing circumstantial evidence for the Russell–Vassilev mechanism.

*(b) Sugars*

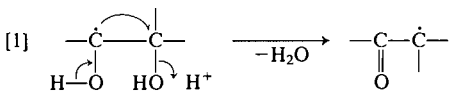
Spectra from the sugars were invariably much weaker than those from the amino acids and best results were obtained when the spectra were accumulated (~30 scans). Spectra obtained after trapping with DBNSA were stronger than those obtained with the alkyl nitroso compounds but the lines were broader. Results are given in Tables 3 and 4. Splittings from β-protons do not usually exceed 1 G in aliphatic nitroxides and hence it is clear from the tables that many of the radicals trapped are secondary alkyl radicals, some with and others without β-hydrogen atoms. The task of assigning these spectra to particular radical structures is not a trivial one with such multifunctional substrates and it is constructive at this stage to consider some of the possibilities.

Carbon–hydrogen bond breaking is one of the most frequently encountered processes in studies of γ-irradiation of solid carbohydrates (33). Of the six possible radicals formed by hydrogen removal from a monosaccharide such as glucose **15**, only one, **16**, is a secondary alkyl radical. What then is the fate of the *t*-oxyalkyl radicals such as **17** and **18** which should be the predominant radical species initially formed? Significantly, it is only with DBNSA that *t*-alkyl spin adducts are usually detected. Hence, the *t*-oxyalkyl radicals must be converted into other radicals before they can be trapped or react with the *t*-alkyl nitroso compounds in some other way. Apparent in all of the spectra of the spin adducts with MNP and MNPOB is the spectrum of

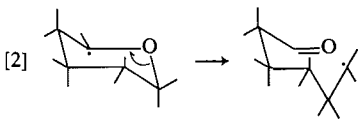


the corresponding monoalkyl nitroxide (*t*-RNHȮ). The intensity of this spectrum increased with increasing concentration of MNPOB. Hence, we believe that the *t*-oxyalkyl radicals reduce the nitroso compound as shown. With the amino acids, significant quantities of monoalkyl nitroxide were only detected with hydroxyproline and threonine, both of which are hydroxy acids.

Consumption of oxyalkyl radicals in this way cannot be total, otherwise no radicals would be trapped. Production of secondary alkyl radicals from tertiary oxyalkyl radicals could occur in a number of ways but a likely route is that described by Norman and Pritchett (34) (reaction [1]). This



reaction is acid- and base-catalysed in solution but there is evidence that it can occur in stored solid samples of γ-irradiated sugars such as trehalose (35). A further possibility is that ring-opening (fragmentation) (reaction [2]) of the initial oxyalkyl



radicals occurs to give a secondary alkyl or other radical (36). Thus, glucose **15** could give initially five tertiary and one secondary oxyalkyl radicals (e.g. **16**, **17**, and **18**), all of which have been detected by esr after reaction of glucose with hydroxyl radicals in a flow system (37). Rearrangement of these according to reaction [1] could lead to six possible cyclic secondary α-acylalkyls (e.g. **19** and **22**), four ring-opened secondary alkyls (e.g. **20** and **21**), and fragmentation to two further radicals.

Support for the rearrangement step at least is provided by spin trapping studies of *meso*-inositol **23**. When a neutral solution of *meso*-inositol, hydrogen peroxide, and MNP or MNPOB in water

is photolysed the spin adduct of a tertiary alkyl radical **24** is detected. At pH 1 only a secondary alkyl spin adduct ($a_N$ = 15.0 and $a_H$ = 1.75 G), presumably that of **25**, is formed. When γ-irradiated *meso*-inositol is dissolved in neutral aqueous solutions of MNP or MNPOB the spectrum of only the spin adduct of the secondary alkyl radical is detected. Similar changes with pH have been reported for radicals generated from *meso*-inositol by reaction with hydroxyl radicals in a flow system and detected directly by esr (38).

To aid the interpretation of the spectra, details of which are given in Tables 3 and 4, and hence identify or at least classify the saccharide-derived radicals, we have adopted the following approaches. (*a*) Examined γ-irradiated model compounds. (*b*) Generated radicals from the saccharides and their models in other ways and tried to characterise their spin adducts. In this respect saccharide-derived radicals whose structures have been confirmed by direct esr measurement are the most attractive. (*c*) Relate the differences in the spectra of the spin adducts to structural differences in the saccharides.

*(a) Model compounds*. Several γ-irradiated polyols including mannitol, sorbitol, ribitol, and dulcitol were first examined. There are lyoluminescent phophors in their own right but results with the three traps were disappointing. The same secondary alkyl radicals were trapped at pH 1 and pH 7 (for MNP and MNPOB, $a_N$ = 15.53, $a_H$ = 1.4–2.3 G) and hence rearrangement must have occurred before dissolution of the trap. Under these circumstances, it is difficult to be certain of the structures of the radicals trapped but they are probably of the general structure **25***a*.

[a] Both radicals trapped have been detected in the solid at room temperature (20): the "hydrogen abstraction" radical has been trapped by MNP after reaction of the hydroxyl radical with glycine and the "deaminated" radical after reaction of glycine with the hydrated electron (21, 22).
[b] "Deaminated radical" detected in the solid state at room temperature (23): "hydrogen abstraction" radical trapped after reaction of L-α-alanine with the hydrated electron (22).
[c] "Hydrogen abstraction" radical detected among others in the solid state (24).
[d] "Hydrogen abstraction" radicals detected in the solid state (25): "deaminated radical" previously trapped by MNP after reaction of amino acid with the hydrated electron (22).
[e] "Deaminated" and "hydrogen abstraction" radical detected in the solid state (26).
[f] "Hydrogen abstraction" radicals trapped with MNP after reaction of glutamine with hydroxyl radicals (21).
[g] "Hydrogen abstraction" radical detected in solid state at room temperature (27): the "deaminated radical" has been trapped after reaction of L-glutamic acid with the hydrated electron and the "hydrogen abstraction" radical after reaction with hydroxyl radicals (21, 22).
[h] "Hydrogen abstraction" radical detected in the solid state and trapped with MNP after reaction of L-arginine with the hydroxyl radical or hydrated electron (28): the "deaminated radical" has also been trapped (21, 22).
[i] "Hydrogen abstraction" and "deaminated" radicals detected in the solid state (29): the deaminated radical has been trapped with MNP after reaction of asparagine with the hydrated electron and with hydroxyl radicals (21, 22).
[j] "Hydrogen abstraction" and "deaminated" radicals previously trapped by MNP (21, 22).
[k] "Deaminated" radical detected in the solid state at low temperature and trapped by MNP after γ-irradiation of aqueous solutions of lysine (22, 30).
[l] "Deaminated" radical detected in the solid state and trapped by MNP after reaction of histidine with the hydrated electron (22, 31).
[m] "Hydrogen abstraction" and "deaminated" radicals detected in the solid state (32): deaminated radical trapped by MNP after reaction with the hydrated electron (22).
[n] In some cases γ-H and/or β-N splittings were not resolved because of the linewidth.

*(b) Model reactions*. Reaction of saccharides with hydroxyl radicals produces all possible C—H abstraction radicals which rearrange with change in pH (37). When MNP and MNPOB were included in these reaction mixtures, complex mixed spectra of spin adducts were detected whose full interpretation has still to be achieved. However, the saccharide models **26–30** with MNP gave spectra with the coupling constants shown. From these we draw the general conclusions: (*a*) Spin adducts of pyran-2-yl radicals with MNP have $a_{\alpha\text{-H}} = 2$ G and $a_{\beta\text{-H}} < 1$ G. (*b*) Spin adducts of aliphatic hydroxyalkyl radicals have $a_{\alpha\text{-H}} = 2$ G. (*c*) Spin adducts of pyran-2-ylhydroxymethyl radicals have a $a_{\alpha\text{-H}} = 6$ G.

With this information it is now possible to make some assignment at least of radical type, of some of the radicals trapped on dissolution of the sugars. With glucose, mannose, and galactose radicals of type **16** ($a_H = 5$–6 G) and of type **19** or **20** are being trapped (39). Because of the similarity in the α-proton splittings the spin adducts of pyran-2-yl and aliphatic secondary hydroxyalkyl radicals (both 1.5 to 2.5 G), it is not possible at this stage to confidently distinguish between the adducts from **19** and **22** and those from **20** and **21**. These and other fine distinctions will only be made after a series of specifically deuterated or substituted saccharides have been examined. Only with gluconolactone and arabinose was there evidence of trapping *t*-oxyalkyl radicals with MNP. However, with DBNSA, *t*-oxyalkyl radicals were often the major type of radical trapped at pH 7. Spin adducts of rearranged radicals predominated at low pH. A continuing aim of the work is to establish better criteria for distinguishing between the spin adducts of saccharide derived radicals. However, even at this stage it is

TABLE 3. Spin trapping of radicals from γ-irradiated (5 Mrad) saccharides with MNP at pH 7

| Saccharide | Coupling constants (G) of trapped radicals (MNP) | |
|---|---|---|
| D-Glucose | $a_N = 15.0, a_H = 6.0$<br>$a_N = 14.5, a_H = 1.9, a_H = 0.75$ | |
| D-Mannose | $a_N = 15.05, a_H = 5.8$<br>$a_N = 14.7, a_H = 2.0, a_H = 0.7$ | |
| D-Galactose | $a_N = 15.0, a_H = 5.0$<br>$a_N = 15.4, a_H = 1.8$<br>$a_N = 15.0$ | |
| 1,5-Gluconolactone | $a_N = 15.0, a_H = 1.5$<br>$a_N = 15.0$ | |
| D-Rhamnose | $a_N = 14.5, a_H = 6.35$<br>$a_N = 14.5, a_H = 2.25, a_H = 0.9$ | |
| D-Glucuronic acid | $a_N = 15.25, a_H = 2.25$ | |
| D-Fructose | $a_N = 14.5, a_H = 1.45$ (br) | |
| D-Arabinose | $a_N = 14.3, a_H = 2.0$<br>$a_N = 14.0$ | |
| D-Ribose | $a_N = 14.25, a_H = 2.0$ (weak) | |
| D-Xylose | $a_N = 14.25, a_H = 2.0$ | |
| Mesoinositol | $a_N = 14.95, a_H = 1.75$<br>$a_N = 15.1, a_H = 1.85$ | pH 7<br>pH 1 |

clear that secondary alkyl radicals are commonly present in solution when γ-irradiated saccharides are dissolved, lending further support to the Russell–Vassilev mechanism.

## Experimental

*2-Methyl-2-nitro-4-(4'-pyridyl-1-oxide)butane*

2-Methyl-2-nitro-4-(4'-pyridyl)butane (40) (5 g, 2.6 mmol) in glacial acetic acid (12 mL) and 30% aqueous hydrogen peroxide (5 mL) was heated under reflux for 6 h and left at room temperature overnight. After removal of solvent *in vacuo* the resulting yellow oil was dissolved in chloroform and the solution was extracted with aqueous bicarbonate solution until evolution of carbon dioxide ceased, washed with water, and finally dried. Removal of solvent gave the *product* (5.14 g, 94%) as a yellow oil, bp 190–240°C/0.15 mm Hg (which was used without further purification. $\nu_{max}$ 1535, 1350, and 1245 $cm^{-1}$; δ 1.66 (6H, s, 2Me), δ 2.20 (2H, m, $CH_2$), 2.59 (2H, m, $CH_2$), 7.12 (2H, d, *J* 5.9 Hz, ArH), and 8.16 (2H, d, *J* 5.9 Hz, ArH).

*2-Hydroxylamino-2-methyl-4-(4'-pyridyl-1-oxide)butane*

The above nitro compound (43.5 g, 0.21 mol) in methanol (435 mL) was treated with a solution of ammonium chloride (6.51 g, 0.12 mol) in water (50 mL) and heated to boiling under reflux. Zinc dust (104 g, 116 mol) was added in small portions with vigorous stirring and the reaction mixture was heated and stirred for a further 2 h. The zinc residues were collected and washed with methanol. The filtrate and washings were evaporated, giving a brown oil which partially solidified on standing. Recrystallisation from chloroform–petrol gave the product (17.5 g, 43%), mp 146–150°C. (*Anal.* calcd. for $C_{10}H_{16}N_2O_2$: C 61.2, H 8.2, N 14.2, *M*, 196.1211; found: C 61.3, H 8.1, N 14.4, $M^+$, 196.1211.) $\nu_{max}$ 3222, 3180, δ 1.14 (6H, s, 2Me), 1.75 (2H, m, $CH_2$), 2.64 (2H, m, $CH_2$), 7.15 (2H, d, *J* 6.4 Hz, ArH), 8.15 (2H, d, *J* 6.4 Hz, ArH).

*2-Methyl-2-nitroso-4-(4'-pyridyl-1'-oxide)butane (MNPOB)*

The above hydroxylamine (2 g, 10 mmol) in water (100 mL) was treated with five portions of a solution of sodium metaperiodate (each 0.4 g, 0.18 mmol) in water (5 mL). After each addition the reaction mixture was extracted with chloroform (25 mL). The combined chloroform extracts were washed with water, dried, and the solvent was removed to give the product (1.19 g, 61%) as a blue oil which slowly solidified to a pale green solid, mp 87–90°C (from chloroform–petrol) (*Anal.* calcd. for $C_{10}H_{14}N_2O_2 \cdot H_2O$: C 61.9, H 7.2, $M^+ - NO$ 164.1073; found: C 60.0, H 7.4. *Anal.* calcd. for $C_{10}H_{14}NO$: *M* 164.1075). $\nu_{max}$ 3200, 1270, 1235, 850 $cm^{-1}$; δ 1.20 and 1.66 (2H, s, 2Me), 2.39 (4H, m, $2CH_2$), 7.12 (2H, d, ArH), and 8.15 (2H, d, ArH).

*3,5-Dibromo-4-nitrosobenzenesulphonic acid (DBNSA)*

4-Amino-3,5-dibromobenzenesulphonic acid (41) (3.31 g, 10 mmol) in water (100 mL) was treated with 4-nitroperoxybenzoic

TABLE 4. Spin trapping of radicals from γ-irradiated (5 Mrad) saccharides with DBNSA at pH 7

| Saccharide | Coupling constants of radicals trapped DBNSA | |
|---|---|---|
| D-Glucose | $a_N = 13.5$<br>$a_N = 12.75, a_H = 4.0$ | |
| D-Mannose | $a_N = 13.5$<br>$a_N = 12.75, a_H = 6.4$ | |
| D-Galactose | $a_N = 13.5$<br>$a_N = 13.25, a_H = 4.0$ | |
| 1,5-Gluconolactone | $a_N = 13.0$<br>$a_N = 13.25, a_H = 4.3$ | not seen at pH 1 |
| D-Rhamnose | — | |
| D-Glucuronic acid | $a_N = 13.0$<br>$a_N = 13.25, a_H = 5.25$ | not seen at pH 1 |
| D-Fructose | — | |
| D-Arabinose | $a_N = 14.35$ | |
| D-Ribose | — | |
| D-Xylose | $a_N = 13.4$ | |

acid (6.46 g, 30 mmol of 85% purity) and stirred at room temperature for 48 h. The reaction mixture was extracted twice with ether (2 × 100 mL) and then the aqueous phase was evaporated to drynes to yield a brown waxy solid. Trituration of the residue with benzene followed by evaporation of the benzene extracts to dryness gave the *product* (3.16 g, 92%), mp 200°C (decomp.) which was used for spin trapping studies without further purification. (*Anal.* calcd. for $C_6H_3Br_2NO_4S$: *M* 342.8149; found:[2] $M^+$ 342.8150.) $\nu_{max}$ 3400, 1555, 1370, 1285, 1215, 1140, and 1040 $cm^{-1}$; $\delta(D_2O)$ 8.22 (2H, s, 2ArH).

*γ-Irradiation*

Amino acids were purchased from BDH or Sigma Chemicals and were used without further purification. The materials were irradiated at the Scottish Universities Research and Reactor Centre, East Kilbride in a Cobalt 60 rig. The dose rate was approximately 0.2 Mrad per hour at room temperature. Doses were calculated using the "Red Perspex" method (42) and are accurate to about 5%.

*Spin trapping with MNP*

An aqueous solution of MNP was prepared by warming a mixture of the trap (5 mg) and water (2 mL) in the dark until the blue colour of the monomer was apparent. The irradiated material (200 mg) was then added with rapid stirring and the resulting solution transferred to a flat esr cell. A similar procedure was used with MNPOB.

*Spin trapping*

To a solution of the trap in water (1–2 mL) the irradiated material (200 mg) was added with stirring or shaking. The pH of the solution was varied when required by addition of sulphuric acid, sodium hydroxide solution, or a buffer powder.

# Substituent effects in the kinetic analysis of free radical reactions with nitrone spin traps[1]

C. L. GREENSTOCK AND R. H. WIEBE

*Medical Biophysics Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Man., Canada R0E 1L0*

Received September 12, 1981

C. L. GREENSTOCK and R. H. WIEBE. Can. J. Chem. **60**, 1560 (1982).

The kinetics of reactions of the water radiolysis species with substituted phenyl-N-*tert*-butyl nitrones (PBN), have been studied directly, *in situ*, using a pulsed Van de Graaff accelerator and kinetic spectrophotometry. The spin trapping of other secondary radiation-induced electrophilic and nucleophilic free radical species was also studied. The mechanistic aspects of these reactions are discussed in terms of the kinetic data. The effect of structure and substituents on the rate of spin trapping was tested for five *para*-substituted PBN's. It was found that electron-withdrawing groups increase the rate of nucleophilic reactions involving hydrated electrons, formyl anions, and α-hydroxyalkyl radicals with substitued PBN. Electron-donating substituents produce the opposite effect.

These studies confirm that nitrones are effective spin traps because of their high reactivity towards radiation-induced free radicals. Caution must be observed, however, in view of their lack of specificity, in interpreting spin-trapping data in complex steady-state systems involving more than one primary or secondary radical species, or where unstable spin-adducts are formed.

C. L. GREENSTOCK et R. H. WIEBE. Can. J. Chem. **60**, 1560 (1982).

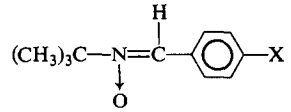
En utilisant un accélérateur de Van de Graaff à impulsions et la spectrophotométrie cinétique, on a étudié directement *in situ* la cinétique des réactions de phényl N-*tert* butyl nitrones (PBN) substituées avec les espèces provenant de la radiolyse de l'eau. On a également étudié le piégeage de spin d'autres espèces secondaires de radicaux libres électrophile et nucléophile induits par radiation. On discute du mécanisme de ces réactions en fonction des données cinétiques. On a vérifié l'effet de la structure et des substituants sur la vitesse de piégeage de spin, dans le cas des PBN substituées en position para. On a trouvé que les groupes électroattracteurs augmentent la vitesse des réactions nucléophiles impliquant des électrons hydratés, des anions du type formyle et des radicaux α-hydroxyalkyles, avec les PBN substituées. Les substituants électrodonneurs produisent l'effet inverse.

Ces études confirment le fait que les nitrones sont des capteurs de spin efficaces par suite de leur grande réactivité vis-à-vis des radicaux libres induits par radiation. En raison de leur manque de spécifité, on doit faire attention en interprétant les données de piégeage de spin dans des systèmes complexes à l'état stationnaire impliquant plus d'une espèce radicalaire primaire ou secondaire ou lorsqu'il se forme des adduits de spin instables.

[*Traduit par le journal*]

## Introduction

Free radicals are implicated in a variety of normal biological processes (1), as well as in certain diseases and pathological or xenobiotic processes (2). The harmful effects of physical and chemical carcinogens may be attributed to free radicals (3–6). It has long been recognized that free radicals, particularly the activated oxygen species, are involved in radiation damage (3, 4, 7, 8). Unfortunately, because of the ubiquitous and transient nature of such free radical species, their indiscriminate reactivity, and their proclivity to take part in interconversion or chain reactions (9), their unambiguous identification and mechanistic characterization in any chemical, biochemical, or biological system are often difficult. This situation was helped by the development of spin traps (10, 11) which react with free radicals to produce relatively stable or persistent paramagnetic spin-adducts with characteristic properties allowing, ideally, identification of the trapped radicals by esr techniques. Recently, a number of nitrones (RNO) have been developed (12) that appear to be well suited to the spectroscopic study of simple free radicals such as those generated by water radiolysis, but there is a dearth of kinetic information on such spin trapping reactions. We have used the radiation chemistry of aqueous solutions in the presence of different free radical scavengers to generate specific free radicals. The technique of pulse radiolysis (13) is used to observe, directly, these simple radiation-induced free radicals including the hydrated electron ($e_{aq}^-$), hydroxyl radical ($^\cdot OH$), superoxide ($O_2^{-\cdot}$), formyl ($CO_2^{-\cdot}$), and hydroxymethyl ($CH_2O^{-\cdot}$) radical anions and α-hydroxyalkyl radicals, and to measure the rates of spin trapping of these radicals with substituted 4-phenyl-N-*tert*-butyl nitrones:



where X = $CH_3$, $CH_3O$, H, CN, $NO_2$.

The effect of *para*-substitution of PBN on the rate constants for electrophilic and nucleophilic free radical reactions is discussed in terms of the

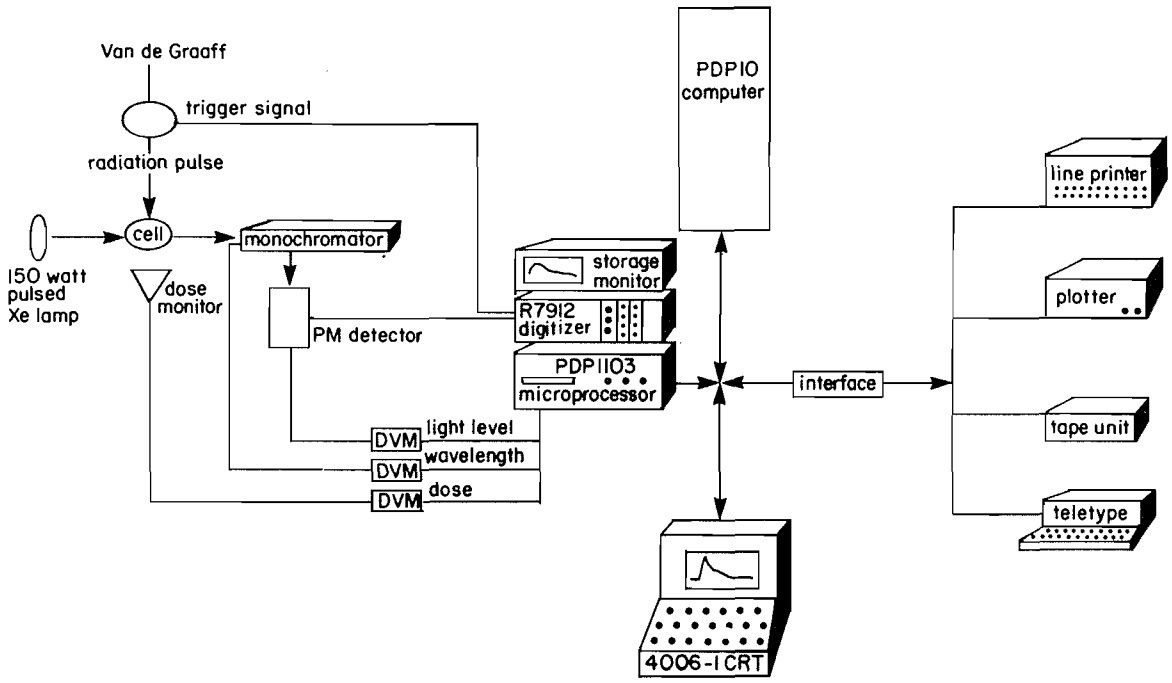

FIG. 1. Schematic diagram of the equipment for automatic data analysis in computerized pulse radiolysis.

kinetic design and interpretation of spin-trapping experiments.

## Experimental

The nanosecond pulse radiolysis system is similar to that described previously (13). The present optical detection system employs a Tektronix R 7912 transient digitizer in place of a conventional oscilloscope to monitor light output from a six-stage RCA C 7912 E or modified IP 28 photomultiplier tube. Automatic analysis of the kinetic spectrophotometric data from the digitizer is achieved on-line, by means of a PDP 10 computer interacting with a PDP 1103 microprocessor via a Tektronix 4006-1 video terminal (Fig. 1). The errors associated with measuring rate constants by directly monitoring the kinetics of the reactive species (i.e. hydrated electrons, see Table 1) are estimated to be ±5%. In the case of competition kinetics the errors associated with measuring the rate data are ±10%. In the special case of competition between a fast and a slow reaction, such as the competing reactions of $O_2^{\cdot-}$ with *p*-benzoquinone and spin traps, the errors are larger.

TABLE 1. Absolute bimolecular rate constants for the reaction of hydrated electrons with nitrone spin traps (RNO)

$$RNO + e_{aq}^- \xrightarrow{H_2O} R(H)NO\cdot + OH^-$$

| Spin trap | $k$ ($10^{10}$ L mol$^{-1}$ s$^{-1}$) |
|---|---|
| $CH_3$–PBN | $1.0_5$ |
| $CH_3O$–PBN | $1.5_5$ |
| PBN | 1.0 |
| CN–PBN | 1.0 |
| $NO_2$–PBN | $1.2_5$ |

A High Voltage Engineering KS-4000 Van de Graaff accelerator delivers single 50 ns pulses of 4 MeV electrons. The dose per pulse is typically 1–2 krad (10–20 Gy), producing 3–6 μmol L$^{-1}$ of radicals. In aqueous aerated solution, pulse radiolysis generates $e_{aq}^-$, H·, ·OH, and $O_2^{\cdot-}$ and their molecular products, $H_2$ and $H_2O_2$. In the presence of scavengers such as nitrous oxide ($N_2O$), formate ($HCO_2^-$), *t*-butanol ($(CH_3)_3COH$) or other additives, a principal reactive species can be generated for individual study (13).

[1] $H_2O \rightsquigarrow e_{aq}^-, H\cdot, \cdot OH, H_2, H_2O_2$

[2] $e_{aq}^- + N_2O \xrightarrow{H_2O} N_2 + OH^- + \cdot OH$

[3] $e_{aq}^- + O_2 \rightarrow O_2^{\cdot-}$

[4] $\cdot OH(H\cdot) + HCO_2^- \rightarrow CO_2^{\cdot-} + H_2O(H_2)$

[5] $CO_2^{\cdot-} + O_2 \rightarrow CO_2 + O_2^{\cdot-}$

[6] $\cdot OH(H\cdot) + (CH_3)_3COH \rightarrow \cdot CH_2(CH_3)_2COH + H_2O(H_2)$

[7] $\cdot OH(H\cdot) + HROH \rightarrow \cdot ROH + H_2O(H_2)$

[8] $\cdot ROH \xrightarrow{OH^-} RO^{\cdot-}$

The *para*-substituted PBN's were a gift from Professor E. G. Janzen. Solutions of spin traps were prepared with triply distilled water.

## Results and discussion

The reactivity of PBN's with $e_{aq}^-$ was studied in neutral deaerated solution containing *t*-butanol, which scavenges ·OH and H· (reaction [6]). The rate constants for these reactions were determined directly by monitoring the rate ($k'$(s$^{-1}$)) of decay of

the $e_{aq}^-$ absorbance at 650 nm as a function of PBN concentration. The pseudo-first order bimolecular rate constants, $k(=k'[\text{PBN}]\,\text{L mol}^{-1}\,\text{s}^{-1})$ for the reaction of $e_{aq}^-$ with the substituted PBN spin traps are given in Table 1. These reactions, which, in neutral or acidic solutions, presumably yield a paramagnetic H-spin adduct capable of being detected by esr spectroscopy, are close to diffusion-controlled, and show little or no effect of *p*-substitution of PBN.

In nitrous oxide saturated aqueous solutions, $e_{aq}^-$ is converted to ·OH (reaction [2]). Since neither ·OH nor the ·OH-spin adduct could be observed directly using our kinetic spectrophotometric detection system, the rate constants for the reaction of ·OH with PBN's were determined by competition kinetics (reactions [9] and [10]) using thiocyanate ion ($CNS^-$) as the competitive solute (14):

[9] $\cdot OH + CNS^- \xrightarrow{CNS^-} (CNS)_2^{-\cdot}$

[10] $\cdot OH$ + spin trap → spin-adduct

Rate constants are obtained from competitive plots showing the change in absorbance of $(CNS)_2^{-\cdot}$ at 490 nm with ($A$) and without ($A_0$) increasing the concentration of the spin trap, in accordance with eq. [11]:

$$[11]\quad k_{10} = 1.1\times 10^{10}(A_0/A - 1)\,[CNS^-]/[\text{spin trap}]$$

This equation assumes that the absorbance of the spin-adduct does not interfere with that of $(CNS)_2^{-\cdot}$, and this has been confirmed experimentally. Rate constants obtained in this manner (15) are listed in Table 2. These rate constants, like those for $e_{aq}^-$, are also very fast, and show no significant effects of PBN substitution. The rate constants obtained by the pulse radiolysis technique (16) agree well with those obtained by other less direct methods (17).

In oxygen-saturated aqueous solutions containing formate or *t*-butanol (reactions [3]–[6]), $O_2^{-\cdot}$ is the principal reactive species. Attempts to observe, directly, a reaction between $O_2^{-\cdot}$ and PBN were unsuccessful. A kinetic competition method using *p*-benzoquinone (*p*-BQ) as the competitive solute (18) provided only an upper limit of $\lesssim 0.6\times 10^7\,\text{L mol}^{-1}\,\text{s}^{-1}$ for the reactions (Table 3):

[12] $O_2^{-\cdot} + p\text{-BQ} \rightarrow O_2 + p\text{-BQ}^{-\cdot}$

[13] $O_2^{-\cdot}$ + spin trap → non-absorbing product

The rate constant, $k_{13}$, is estimated by monitoring the change in the $p\text{-BQ}^{-\cdot}$ absorbance at 420 in the absence ($A_0$) and presence ($A$) of increasing concentrations of the spin trap according to eq. [14]:

$$[14]\quad k_{13} = 1.0\times 10^9\,(A_0/A - 1)\,[p\text{-BQ}]/[\text{spin trap}]$$

Equation [14] assumes that the absorbance of the product of reaction [13] does not interfere with that of $p\text{-BQ}^{-\cdot}$, and this has been confirmed experimentally. This is a much slower reaction than that of $e_{aq}^-$ or ·OH. The results in Table 3 are only upper limits but may indicate the apparently weak nucleophilic nature of the species. Preliminary studies indicate a differential reactivity of $O_2^{-\cdot}$ and its protonated form $HO_2\cdot$ towards PBN, the latter being more reactive. More experiments are necessary to confirm this and to investigate the effects of *para*-substitution. Finkelstein *et al.* (17), using an indirect steady-state method, have reported rate constants $\sim 10\,\text{L mol}^{-1}\,\text{s}^{-1}$ for the reaction of $O_2^{-\cdot}$ with α-4-pyridyl-1-oxide-*N*-*tert*-butylnitrone.

A study of the reactivity of the radical anions $e_{aq}^-$, $CO_2^{-\cdot}$, $CH_2O^{-\cdot}$, and $O_2^{-\cdot}$ with unsubstituted PBN yielded the results shown in Table 4. In these experiments, there is a clear correlation between the rate constant for the reactions and the standard reduction potential $E^0$ (V) of the radiolytic species, indicating a strong nucleophilic reaction with the nitrone group. It appears from these results that the reduction potential of the unsubstituted nitrone moiety is between −1.25 and −2.87 V, i.e. between the reduction potentials of $CO_2^{-\cdot}$ and $e_{aq}^-$.

In a further attempt to clarify the role of *p*-substituents in modifying the free radical reactivity of PBN's, the reactivity of α-hydroxyalkyl radicals

| $O_2^{-\cdot}$ | <0.5 | −0.33 |

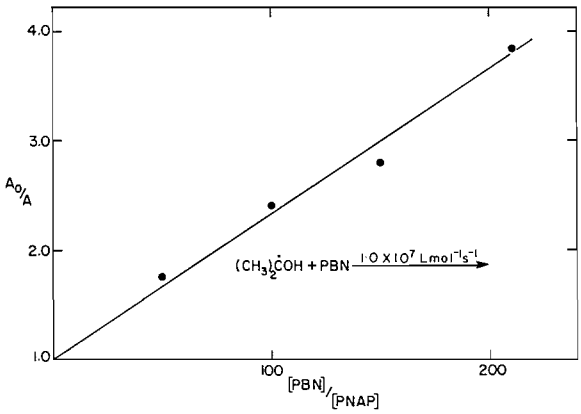

FIG. 2. Kinetic competition between PBN and *p*-nitroacetophenone (PNAP) for isopropyl alcohol radicals. Nitrous oxide saturated solutions containing 10 μmol L$^{-1}$ PNAP and 50 μm mol L$^{-1}$ isopropanol are irradiated with single doses ~1–2 krad (10–20 Gy). The yields of the *p*-nitroacetophenone radical anion in the presence ($A$) and absence ($A_0$) of PBN were determined, 100 μs after the pulse, by kinetic spectrophotometric methods.

(·ROH) derived from the OH-induced hydrogen abstraction of primary and secondary alcohols (reaction [7]) was studied, using *p*-nitroacetophenone (PNAP) as a competitive solute (19):

[15] $\cdot R'OH + PNAP \rightarrow PNAP^- + R'OH^+$

[16] $\cdot R'OH$ + spin trap → non-absorbing product

$$[17] \quad k_{16} = k_{15}(A_0/A - 1)[PNAP]/[\text{spin trap}]$$

A typical competition plot is shown in Fig. 2. Rate constants (eq. [17]) derived from such plots are shown in Table 5 for various *p*-substituted PBN's reacting with α-hydroxyalkyl radicals derived from methanol, ethanol, *n*- and isopropanol. The results clearly show that, in all cases, electron withdrawing substituents on PBN increase the reactivity of α-hydroxyalkyl radicals, as expected on the basis of their nucleophilic nature. In addition, a progressively greater α-hydroxyalkyl radical reactivity is observed in going from long chain to short chain alcohols, reflecting the inductive, ionic, and possible steric influence of the alkyl group.

TABLE 5. Rate constants for the reaction of various α-hydroxyalkyl radicals with nitrone spin traps (RNO)

$$RNO + \cdot R'OH \xrightarrow{H_2O} \begin{cases} \rightarrow R(R'OH)NO\cdot \\ \rightarrow R(H)NO\cdot + R'OH^+ + OH^- \end{cases}$$

| | $k$ ($10^7$ L mol$^{-1}$ s$^{-1}$) | | | |
|---|---|---|---|---|
| Spin trap | ·MeOH | ·EtOH | ·*n*-ProOH | ·*iso*-ProOH |
| $CH_3$–PBN | 2.5 | 0.1 | 0.35 | 0.1 |
| $CH_3O$–PBN | 2.9 | 0.9 | 0.1 | 0.15 |
| PBN | 4.3 | 1.6 | 1.3 | 1.0 |
| CN–PBN | 75 | 2.0 | 1.7 | — |
| $NO_2$–PBN | 120 | 3.5 | 0.65 | — |

Although spin traps are proving to be important spectroscopic probes of transient free radical species, caution must be used in the interpretation of results obtained under steady-state conditions. It must be remembered that the esr spin-trapping technique is only applicable to the study of persistent, paramagnetic spin-adducts. It will not detect redox reactions such as that shown in reaction [16] (see Table 5), or other reactions not yielding a paramagnetic product; neither will it detect many unstable spin-adducts. In complex systems, esr spin-trapping experiments may not detect either unreactive or highly reactive free radicals, and may not necessarily reflect the principal transient species or the main reaction sequence.

It is clear that nitrones react very rapidly with simply reducing ($e_{aq}^-$) and oxidizing (·OH) species, whereas the reaction with other nucleophiles ($O_2^{-\cdot}$, $CO_2^{-\cdot}$), and α-hydroxyalkyl radicals) is much slower. Consequently, care must be taken in studies of free radical interconversion or in complex mixtures of radicals to ensure that the reactions of reactive species do not obscure the more specific or selective spin trapping of a less reactive, but perhaps more important, reactant. The use of appropriate free radical scavengers, selected on the basis of kinetic considerations, may help to clarify future studies of the application of spin traps in free radical chemistry.

# Spin trapping in photochemistry of coordination compounds

DETLEF REHOREK AND HORST HENNIG

*Sektion Chemie, Karl-Marx-Universität Leipzig, DDR-7010 Leipzig, German Democratic Republic*

Received September 12, 1981

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

DETLEF REHOREK and HORST HENNIG. Can. J. Chem. **60**, 1565 (1982).

The application of spin-trapping technique to detect short-lived paramagnetic species formed during photochemical reactions of coordination compounds is reviewed. Interference of radical recombinations by scavenging action of spin traps has been pointed out to be important at high spin-trap concentrations only. Due to only a limited extent of side reactions, nitrosodurene and phenyl N-*tert*-butyl nitrone were found to be excellent spin traps for the study of photoreactions of metal complexes in nonpolar solutions, whereas 5,5-dimethyl pyrroline-1-oxide is recommended for aqueous solutions. Using these spin traps, both organic and inorganic radicals, e.g. H, Cl, $N_3$, CN, OH, $O_2^-$, as well as solvated electrons and metal-centered free radicals have been detected during the photolysis of coordination compounds. The detection of singlet oxygen by reaction with 2,2,6,6-tetramethyl piperidine is briefly discussed.

DETLEF REHOREK et HORST HENNIG. Can. J. Chem. **60**, 1565 (1982).

On examine de nouveau l'application de la technique de captage de spin à la détermination des espèces paramagnétiques de courte vie qui se forment lors de réactions photochimiques de composés de coordination. ON a mis en évidence le fait que l'influence des recombinaisons de radicaux sous l'action protectrice des capteurs de spin, devient importance uniquement pour des fortes concentration en capteurs de spin. En raison de l'existence de très peu de réactions secondaires, on a trouvé que le nitrosodurène et la phènyl N-*tert*-butyle nitrone sont d'excellents capteurs de spin pour l'étude des réactions photochimiques des complexes métalliques dans des solutions non polaires, tandis que la diméthyl-5,5 pyroline-oxyde-1 convient pour les solutions aqueueses. L'utilisation de ces capteurs de spin a permis, lors de la photolyse des composés de coordination, de détecter les radicaux organiques et inorganiques tels que; H, Cl, $N_3$, CN, OH, $O_2^-$ aussi bien que les électrons solvatés et les radicaux libres centrés sur des métaux. On discute brièvement de la détection de l'oxygène singulet par la réaction avec le tétraméthyl-2,2,6,6, pipéridine.

[Traduit par le journal]

## 1. Introduction

The use of radical addition reactions to detect short-lived radicals was first proposed by Janzen (1) in 1965. Since then this technique for which Janzen and Blackburn (2) coined the name "spin trapping" has been extensively developed. Now it has become a powerful method widely used for the detection of short-lived paramagnetic intermediates in thermally, photochemically, and radiation-induced reactions as described in several review articles (3).

Although some early papers by Janzen and Blackburn (2) and Lagercrantz *et al.* (4) have pointed out the possible application of spin trapping in photochemistry of coordination compounds, its wider use has been reported only relatively recently. There are many reasons behind this: some are subjective (as for a long time nitroxyl radical chemistry did not find any interest among inorganic chemists) but the peculiarities of metal complexes complicating the application of the spin-trapping technique may have played a significant role.

In this paper we would first like to discuss some general problems connected with the application of the spin-trapping technique (exclusively based on the nitroxyl method) to the photochemistry of metal complexes, we then turn to some reactions in detail. Other questions will be considered at the end of the paper.

## 2. General modes of interactions of metal complexes with spin traps and spin adducts

Quantum yields for the production of short-lived paramagnetic species from typical photoactive coordination compounds are often less than 0.1. Due to further reactions with either the solvent or the metal complex the stationary concentration of the paramagnetic intermediate is normally extremely low. As a result there is only a very limited number of publications on direct electron spin resonance detection of short-lived paramagnetic species during the photolysis of coordination compounds in liquid solution.

The spin-trapping technique, which normally leads to very persistent radicals exhibiting well-resolved esr spectra, therefore, would be a recommendable method for the detection of these species. One of the conditions to be met by the spin traps is that they do not interfere with the photochemical reaction of the metal complex. However, this condition is seldom fulfilled. Since radicals photogenerated from coordination compounds often undergo secondary reactions with the metal complex, at least the total quantum yield of metal reduction and/or oxidation is influenced by the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

presence of the spin trap. It is, however, by far more important that in many cases the metal complex reacts with the spin trap or with the nitroxides to form other radicals or to lead to the disappearance of radical signals.

From our experience, difficulties in the application of the spin-trapping technique to the photochemistry of coordination compounds do arise from the interaction of the nitroxide spin adducts with the metal complex rather than from the interactions of the spin trap with the complex.

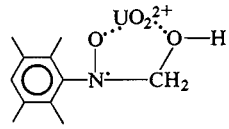
Despite the low complexing ability of nitroso compounds and nitrones, however, there are some known examples of nitroso compounds which react with metal complexes by substitution (6). Due to the low $\pi$-acceptor ability of nitroso compounds such reactions are expected only for electron-rich complexes, i.e. metal complexes in a low oxidation state such as organometallic compounds. Typical Werner-type complexes such as Co(III), Cu(II), and Fe(III) normally do not interact with nitroso compounds and nitrones by substitution. Furthermore, Blount *et al.* (7) have shown that nitrones and also nitroso compounds exhibit a large electroinactive window, i.e. a potential range where they can be neither oxidized nor reduced. In accordance with these investigations we have preference for the spin traps nitrosodurene (ND) and C-phenyl N-*tert*-butyl nitrone (PBN), which are found to be stable even toward oxidation by Ce(IV), at least in neutral solution. However, in acidic or alkaline solutions redox reactions have to be considered. Thus, during the reaction of $UO_2(NO_3)_2 \cdot 6H_2O$ with ND in the presence of $CF_3COOH$ or $CCl_3$-COOH, the spectrum of a radical showing large $^{14}N$-hyperfine splitting ($a_N = 3.36$ mT, $a_H^1 = 0.195$ mT (3H), $a_H^2 = 0.056$ mT (4H)) could be observed (8). It has to be noted that such a signal assigned to the nitrosodurene cation radical ($ND^{+\cdot}$) is detectable only in strongly acidic media. Weaker acids such as acetic acid and propionic acid do not stabilize $ND^{+\cdot}$. On the other hand, nitrosodurene anion radical ($ND^{-\cdot}$) is considerably more stable. It could be detected during many different photoreactions, e.g. $[Cr(CN)_5NO]^{3-}$ in alkaline methanol, $NO_2^-$ and $NO_2$ in alcohols, and $UO_2^{2+}$ in $CH_2Cl_2$/alcohol (9). Surprisingly, $ND^{-\cdot}$ was also observed during the photolysis of Ce(IV) in alcohols (10). However, it could be shown that $ND^{-\cdot}$ stems from secondary photoreaction of $NO_2^-$ which is a byproduct of the photoreduction of $(NH_4)_2[Ce(NO_3)_6]$ with polychromatic light.

The $^{14}N$ hyperfine splitting of $ND^{-\cdot}$ varies from about 1.2 to 1.4 mT depending on the solvent and the metal complex. Obviously, there are coordinative interactions of $ND^{-\cdot}$ with metal ions and metal complexes. However, in those cases where the metal ion has no nuclear spin, it is not easy to make a clear distinction between free nitrosodurene anion radicals and coordinated ones. Probably, the triplets observed by Giannotti *et al.* (11) and Gasanov and Freidlina (12), originally assigned to U(IV) or U(III) and $Cr(CO)_5Cl$ spin adducts, respectively, correspond to the nitrosodurene anion radical.

In comparison with nitroso compounds and nitrones, nitroxides normally interact more strongly with metal complexes. It is well known that nitroxides behave as Lewis bases which may coordinate to metal centers (13).

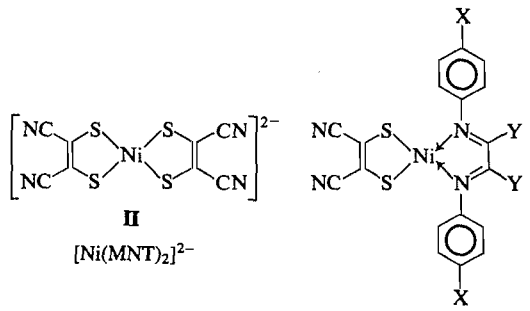
[1] $\dot{N}(+)—\bar{O}|^- + M \rightleftharpoons \dot{N}(+)—\bar{O}|^- \longrightarrow M$

This effect is often indicated only by an increased line-width. However, under certain circumstances drastic changes in hyperfine splitting patterns are observed. Thus, for 1-hydroxyalkyl duryl nitroxides significantly increased $\beta$-hydrogen hyperfine splittings were found in the presence of uranyl ions indicating the formation nitroxide complexes with $UO_2^{2+}$, **I** (14).



**I**

It should be noted that the two $\beta$-protons still remain equivalent, probably due to twisting vibrations of the chelate ring. A more pronounced interference to the spin-trapping method is caused by redox reactions of metal complexes with nitroxides. Since this effect is a kinetically-controlled reaction, the stability of sterically more shielded nitrosodurene spin adducts is greater than the spin adducts of, e.g., 2-methyl-2-nitroso propane (MNP). Therefore, nitrosodurene appears to be a more reliable spin trap for reactions of metal complexes than aliphatic nitroso compounds. However, in most cases the lifetime of spin adducts is so short that they can be detected only *in situ*. In some cases, the spin-trapping technique breaks down completely. For example, we have studied the photoreaction of dithiolato nickel(II) complexes in halocarbon solvents (15). During the photolysis of Ni(II) chelates, **II** and **III**, the esr signal of Ni(III) $(MNT)_2^-$ ($g = 2.063$ (16)) was readily detectable. Furthermore, from scavenging experiments with



II
$[Ni(MNT)_2]^{2-}$

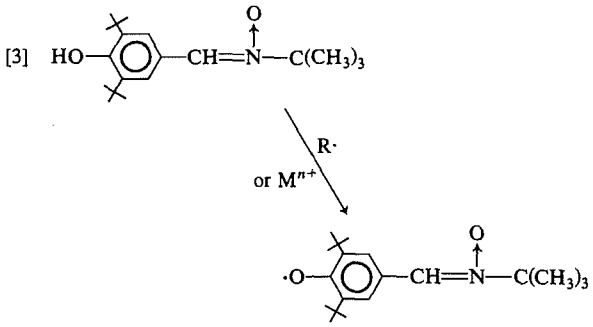
III
X = Cl, $CH_3$, $OCH_3$
Y = H, $CH_3$

acrylamide in $CCl_4$ this process was clearly shown to be radical in nature (reaction [2]).

[2] $Ni(II) + RX \xrightarrow{h\nu} Ni(III) + R^{\cdot} + X^{-}$

However, no spin adducts could be observed in the presence of spin traps such as nitrosodurene, 2-methyl-2-nitroso propane, and phenyl *N-tert*-butyl nitrone. Mixing of independently prepared nitroxides with $Ni(MNT)_2^{2-}$ immediately led to the formation of a Ni(III) complex, indicating that nitroxides are readily reduced by Ni(II).

On the other hand, the oxidizing properties of many coordination compounds exclude the application of spin traps such as that proposed by Pacifici and Browning (17), since aroxyl radicals may be formed thermally, reaction [3].



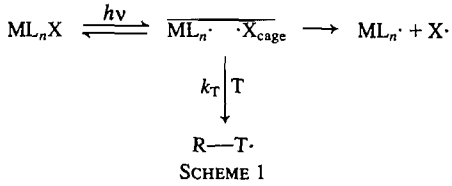
Further problems do arise from the photochemical behaviour of spin traps and spin adducts.

Nitroso compounds exhibit weak absorption bands in the visible spectral region (n,π* transitions of monomeric form) and strong bands in the uv region (π,π*), whereas nitrones have absorptions only in the uv region (18). These absorption bands can act as internal filters, thus leading to complications in quantitative photochemical studies. However, it is by far more important that irradiation into these bands can lead to formation of nitroxide radicals as it was shown for both aliphatic nitroso compounds (19) and nitrones (3*a*, 20). The main advantage of aromatic nitroso compounds is in their greater photochemical stability, albeit a slight photosensitivity has been reported even for the sterically-hindered aromatic nitroso compounds (21).

Furthermore, the resulting nitroxides are known to be very efficient quenchers for both excited singlet and triplet states (22). However, since lifetime of excited states of metal complexes normally is very short ($\ll 10^{-6}$ s), substantial quenching is expected for extremely high concentrations of nitroxides, i.e., after long irradiation time, only.

A further possibility of interference by spin traps is related to radical recombination processes which may be suppressed by spin traps.

If there is a photochemical process with geminate radical pairs formed, which underlies a very efficient recombination process, the quantum yield normally will be close to zero (Scheme 1).



SCHEME 1

The fraction of radicals which escapes the cage in the presence of a scavenger T, but otherwise would undergo secondary recombination, has been derived by Noyes (23) as to be given by eq. [4].

[4] $P = 2a(2\pi k_T c_T)^{1/2}$

where $a = 10^{-6}$ s$^{1/2}$ (23).

It is important to know that spin traps can serve as such scavengers. The photoreactions of alkyl cobaloximes and alkyl cobalamines studied by Giannotti *et al.* (24) and Roewer *et al.* (25), respectively, are well known examples for such a type of interference.

It is quite interesting that neglecting the possibility of such interaction may lead to qualitatively different results as it was shown in the case of copper(II) chelates with sterically-hindered 1,2-diimine ligands such as dmp (dmp = 2,9-dimethyl-1,10-phenanthroline) (26).

From scavenger experiments Sundararajan and Wehry (27) deduced the radical nature of the photoreaction in alcoholic solutions. However, no evidence for free radicals was found by low temperature esr experiments or by spin-trapping studies with low spin trap concentrations. Flash photolysis demonstrates that the reaction may be described by Scheme 2 (26).

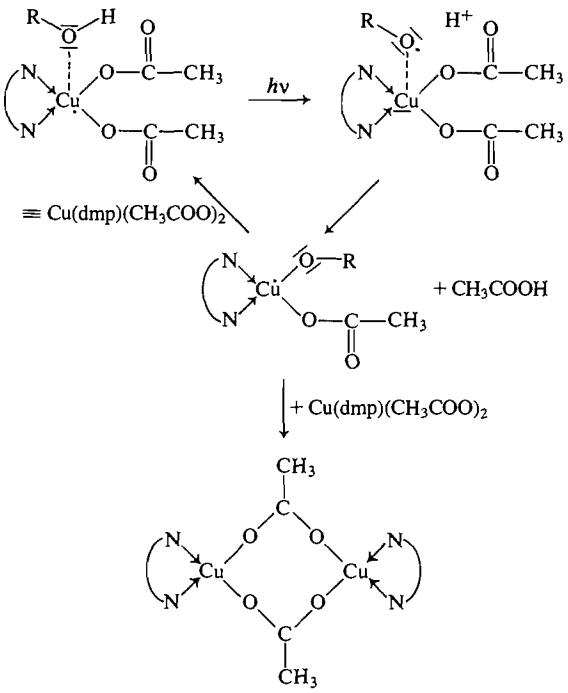

SCHEME 2

Using very high concentrations of spin traps, esr signals of alkoxy spin adduct could be detected in the case of 2-methyl propane-1-ol. The signal intensity was found to be linearly dependent on the square root of spin trap (PBN) concentration as one would expect from Noyes' theory (23).

However, flash experiments show that it is quite understandable for spin traps to interact with the primarily formed Cu(I)–alkoxyl pair and that the reaction in alcohols is, unlike in nonpolar solvents (28), indeed a non-radical one.

The interaction of spin traps with caged radicals seem to be a general problem in photochemistry of metal complexes. In this case the study of concentration dependency does offer an opportunity to distinguish between free and caged radicals.

### 3. Application of the spin-trapping technique to photochemistry of coordination compounds

#### *3.1. Spin trapping of organic free radicals formed in photoreactions of coordination compounds*

Already in the early stages of spin-trapping studies (2, 4, 5), the photolytic scission of organometallic complexes, e.g. $Et_4Pb$, $Bu_4Sn$, $Bu_3SnCl$, $Pb(CH_3COO)_4$, $Tl(CH_3COO)_3$ etc., has been reported. However, the aim of investigations of such compounds was directed to well-defined radical sources rather than to the study of unknown photoreactions. The first interesting results (with respect to photochemistry) came from the investigations by Ledwith *et al.* (29) who showed that uranyl nitrate, which so far was known to react with alcohols exclusively by α-hydrogen abstraction, reaction [5], can also react by electron transfer, reaction [6].

[5] $*UO_2^{2+} + R'RCHOH \rightarrow UO_2H^{2+} + R'\dot{R}COH$

[6] $*UO_2^{2+} + R'RCHOH \searrow UO_2^{+} + R'RCH\dot{O}H^{+}$ $(R'RCHO\cdot + H^{+})$

These investigations have also been extended to other alcohols (9) and other metal ions such as Ce(IV) (10), Cr(VI) (30), Fe(III) (31), and V(V) compounds (32). It should be noted that the alkoxyl radicals, although easily detectable by spin trapping, hitherto have not been detected in photoreactions of coordination compounds by other spectroscopic methods.

Alkoxyl radicals have also been trapped during the aerobic photolysis of alkyl cobalt(III) complexes (24, 25). However, up till now it is not clear whether these radicals are really free radicals produced by the cleavage of cobalt peroxyl complexes, reaction [7], or if they are produced by the decay of the peroxyl spin adducts (33).

[7] $\left[\begin{matrix}OOR\\|\\Co\end{matrix}\right] \xrightarrow[\text{or } kT]{h\nu} \left[\begin{matrix}O\cdot\\|\\Co\end{matrix}\right] + RO\cdot$

Since it is known (34–36) that the alkyl peroxyl spin adducts of PBN are sufficiently stable to be detected at lower temperatures, reexamination of the aerobic photolytic decomposition of alkyl cobalt(III) complexes at low temperature should provide more information concerning the primary photochemical processes.

The high sensitivity of the spin-trapping method does permit the study of the outer-sphere redox reactions which proceed only with low quantum yields. Thus, organic free radicals formed during the photoreaction of Co(III) and Cu(II) ion pairs with tetraphenylborate were readily detected by spin trapping (37, 38). In this context, it is quite interesting that during the photolysis of tetraphenylborates, phenyl radicals are observed exclusively, unlike the photolytic decomposition of tetraphenylborates of aryl diazonium salts (39) and diaryl iodonium salts which lead to both phenyl radicals and diphenyl(phenylcyclohexadienyl)borane radicals. The latter may be trapped by nitrosodurene ($a_N = 1.38$ mT, $a_H = 1.44$ mT).

In contrast to these results, no radicals have been detected with PBN during the electrochemical

For personal use only.

oxidation of $BPh_4^-$ (40). Probably metal ions can catalyze the formation of phenyl radicals from diphenyl(phenylcyclohexadienyl)borane.

*3.2. Trapping of atoms and inorganic radicals*

Upon photolysis many coordination compounds yield short-lived paramagnetic species such as atoms or small reactive radicals, e.g. $\cdot N_3$, $\cdot NO_3$, $\cdot CN$, $\cdot SO_4^-$, $\cdot OH$, $\cdot O_2^-$ etc., which are often named inorganic radicals. The possibility of spin trapping of hydrogen atoms has been known for a long time (see ref. 3*a* and references therein). Its formation during the photolysis of alkyl cobaloximes has been shown by Giannotti and Bolton (24*a*) using PBN and 5,5-dimethyl pyrroline-1-oxide (DMPO) as spin traps, respectively. These authors found that hydrogen atoms stem from the equatorial oxime ligand, whereas the corresponding alkyl cobalamines give hydrogen atoms only when the axial alkyl ligand has active β-hydrogen atoms (25*b*). However, it has been pointed out that the formation of hydrogen spin adduct is very likely due to the thermal reaction of PBN with intermediate Co(III) hydride complex.

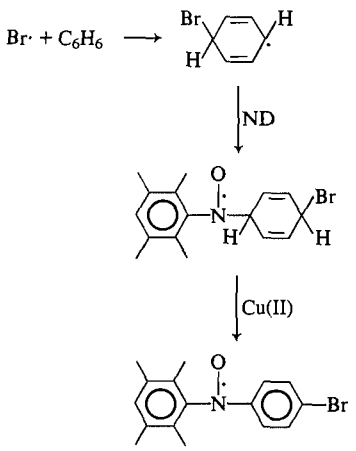
Although fluorine atoms were shown to form stable spin adducts with PBN (3*a*), hitherto no examples are known for the formation of F· atoms from photoexcited coordination compounds.

Very recently we were able to detect chlorine atoms during the photolysis of $(Bu_4N)_3[Co(C_2O_4)_2Cl_2]$ ($C_2O_4^{2-}$ = oxalate anion) in $CH_2Cl_2$ using PBN as a spin trap ($a_N$ = 1.21 mT, $a_H$ = 0.072 mT, $a_{^{35}Cl}$ = 0.61 mT, $a_{^{37}Cl}$ = 0.49 mT). On the other hand, all attempts to detect Cl· atoms during the photolysis of chlorocuprates(II) and $[Cu(dmp)_2Cl]Cl$ hitherto did not succeed.

It has been expected that photolysis of $[Cu(dmp)_2Br]Br$ and $[Co(phen)_2Br_2]Br$ yields bromine atoms. However, only in the presence of PBN could the benzoyl *tert*-butyl nitroxide ($a_N$ = 0.79 mT) be observed. Interestingly, Gasanov and Freidlina (41) have detected a spin adduct ($a_N$ = 1.48 mT, $a_H$ = 0.62 mT) showing no bromine hyperfine splitting which they have assigned to the Br· adduct to PBN.

In benzene we obtained the spin adduct of a 4-substituted phenyl radical ($a_N$ = 0.95 mT, $a_H$ = 0.27 mT (2H)) with nitrosodurene as a spin trap. This spin adduct may be attributed to the 4-bromo phenyl adduct (42). Its formation may be explained by Scheme 3.

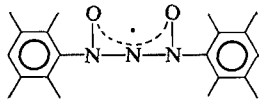
$[Cu(dmp)_2NO_3]NO_3$ was found to react in a similar way. However, since no hyperfine splitting due to substituents in the 4-position has been resolved, these experiments are not of much use as diagnostic probes except in decision-making as to whether or not a reaction proceeds via free radicals.



SCHEME 3

Spin trapping of pseudohalide radicals is possible too. It was shown that azidyl radicals, $\cdot N_3$, produced by the photolysis of $[Co(NH_3)_5N_3]^{2+}$ and $[Co(CN)_5N_3]^{3-}$, respectively, are readily trapped by both PBN and nitrosodurene (43). It is interesting that $\cdot N_3$ radicals normally are not detectable by other methods such as flash photolysis. Recently Janzen *et al.* (44) and Kremers and Singh (45) confirmed the possibility of spin trapping of $\cdot N_3$ radicals by nitrones. Furthermore, the latter could show that DMPO is a very efficient spin trap for both $\cdot N_3$ and $(N_3)_2^{-\cdot}$ radicals.

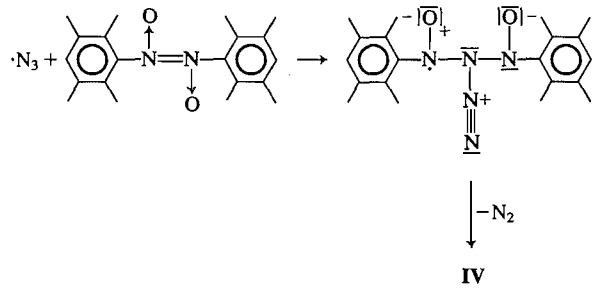
Surprisingly, spin adducts of $\cdot N_3$ radicals with nitrosodurene are very persistent too (43*b*). The esr spectrum exhibits a 1:2:3:2:1 quintet of triplets which has been assigned to structure **IV**.



**IV**

Although it has been proved that this spin adduct really originates from $\cdot N_3$ radicals (or ·N atoms!), the mechanism of its formation remains unclear. Based on the recently published paper by Suehiro *et al.* (46), who showed that nitrosodurene can act as spin trap in its dimeric form, the mechanism in Scheme 4 seems to be very likely.

This suggestion is further supported by the fact that the intensity of the esr signal correlates well with the concentration of dimeric nitrosodurene rather than with the monomer concentration. The possibility of spin trapping of other pseudohalide radicals such as ·CN and ·OCN has been demonstrated by Janzen *et al.* (44). In this context it should be noted that during the photolysis of



IV

SCHEME 4

$Mo(CN)_8^{3-}$ in methanol at −80°C we were able to detect a weak esr signal of a spin adduct to PBN ($a_N^1$ = 1.46 mT, $a_N^2$ = 0.16 mT, $a_H$ = 0.46 mT). Based on the data given by Mao and Kevan (49), this spin adduct was originally attributed to ·CN radical (48). However, it was shown by Janzen *et al.* (44) that this assignment is obviously not correct. Thus the assignment of the spin adduct reported by Mao and Kevan and by ourselves still remains unclear. It is quite interesting that in $CH_2Cl_2$ instead of methanol, the ·CN spin adduct to PBN ($a_N$ = 1.49 mT, $a_H$ = 0.20 mT) can be readily observed during the photolysis of $Mo(CN)_8^{3-}$. In methanol, $\cdot OCH_3$ radicals are the major oxidation product (48). Other important intermediates during the photolysis of metal complexes are known to be hydroxyl, ·OH, and superoxide, $\cdot O_2^-$, radicals, respectively. Both Harbour, Chow, and Bolton (50) and Janzen *et al.* (51) have shown that these radicals add readily to nitrones to give quite persistent spin adducts. However, the stability of superoxide spin adduct was found to be strongly dependent on pH (52).

Recently Giannotti *et al.* (53) and Harbour and Hair (54) have studied the formation of superoxide radicals during the photolysis of porphyrins and phthalocyanines, both in its free and metal-complexed form. The spin-trapping technique was found to be a reliable method for the elucidation of rather complicated photochemical mechanisms.

Hydroxyl radicals were formed during the photolysis of $Mo(CN)_8^{3-}$ and $W(CN)_8^{3-}$ in aqueous solution, whereas irradiation ($\lambda > 320$ nm) of the corresponding Mo(IV) and W(IV) complexes, respectively, did not give rise to any free radicals. In these experiments, DMPO could be used as spin trap without any detectable interference.

With regard to the experiments made with Mo(IV) and W(IV), it was very surprising for us to find signals of ·OH spin adducts to DMPO when solutions containing $Mo(CN)_8^{4-}$ and $Cu^{2+}$ were irradiated with light of $\lambda > 320$ nm. Since neither of these compounds alone cause the formation of hydroxyl radicals, a sequential two-photon process is assumed (55), see Scheme 5.

It has to be stressed that the lifetime of the Cu(I), Mo(V) couple, formed by irradiation into the intervalence charge transfer band, is less than $10^{-6}$ s, as confirmed by flash experiments. The formation of hydroxyl radicals during the irradiation of $Cu^{2+}/Mo(CN)_8^{4-}$ solutions is further confirmed by the bleaching of 4-*N*,*N*-dimethylaminonitrosobenzene which is known to be a very efficient ·OH scavenger (56). In principle, it is also possible to detect solvated electrons by the spin-trapping technique. Since solvated electrons are common intermediates in many photooxidation reactions of low-valent coordination compounds, e.g., $Mo(CN)_8^{4-}$, $W(CN)_8^{4-}$, $Fe(CN)_6^{4-}$, and $Ru(CN)_6^{4-}$ (57), such a simple method for the detection of solvated electrons would be of great importance to inorganic photochemists. Indeed, it was found that nitroso compounds are able to trap solvated electrons forming anion radicals (8*c*, 58), but this reaction is not a very efficient one. On the other hand, if there are additional typical electron scavengers such as carbon halides and thio-compounds, formation of alkyl spin adducts may be used as a diagnostic probe for solvated electrons provided other strongly reducing species are absent.

$$Cu^{2+} + [Mo(CN)_8]^{4-} \rightleftharpoons Cu^{2+}, [Mo(CN)_8]^{4-}$$

$$\downarrow h\nu_1 \ (\lambda = 500\ \text{nm})$$

$$Cu^{+}, [Mo(CN)_8]^{3-}$$

$$\downarrow h\nu_2, H_2O \ (\lambda = 385\ \text{nm})$$

$$Cu^{+} + [Mo(CN)_8]^{4-} + \cdot OH$$

SCHEME 5

### 3.3. *Spin trapping of metal-centered free radicals*

The photolysis of coordination compounds often leads to both free organic or inorganic radicals, ·X, and unstable coordinatively unsaturated metal fragments, $\cdot ML_n$, reaction [8].

$$[8] \quad ML_nX \xrightarrow{h\nu} ML_n\cdot + \cdot X$$

In some cases the metal fragment, which is sometimes named metallo radical, may also be trapped by the usual spin traps. The first examples were reported by Waters *et al.* (59), who demonstrated the trapping of $Co(CN)_5^{3-}$ by both aromatic and aliphatic nitroso compounds. However, first reference to photochemistry was made by Hudson *et al.* (60) who showed that carbonyl complex fragments

of transition metals such as Mn, Re, Mo, Co, and Fe may be trapped by nitrosodurene. Later, the list of possible spin adducts with metallo radicals has been extended to further examples, see Table 1. It should be noted that these spin adducts are often photochemically unstable and decompose as in reaction [9].

$$[9]\quad R{-}\overset{\displaystyle O}{\overset{|}{N}}{\cdot}{-}ML_n \xrightarrow{h\nu} RNO^{-\cdot} + ML_n^{+}$$

Probably for that reason, only nitrosomesitylene anion radicals have been observed during the photolysis of $[Co(CN)_5N_3]^{3-}$. Interestingly, $Mo(CN)_7^{2-}$ forms rather stable spin adducts with both nitrosodurene and nitrosomesitylene even during irradiation (48). As shown by Alberti and Camaggi (61), nitro compounds may serve as efficient spin traps for manganese-centered radicals too.

Metallo radicals formed by photolysis of Group IVB organometallic compounds are not trapped by nitroso compounds (62). Instead, they add to nitro derivatives affording the corresponding relatively stable oxynitroxides (63). (For spin trapping with aromatic and aliphatic ketones, which will not be considered here, see ref. 64 and references therein.)

It is interesting that the same entire spectrum obtained by Davies and Hawari (63*c*) in the reaction of $Bu_3Sn\cdot$ with 2-nitro-2-methyl-propane was found during the photolysis of tributyl stannyl chromate(VI) in the presence of MNP (67). Thus it is assumed that the formation of tributylstannoxyl radicals, $Bu_3SnO\cdot$, is by cleavage of the Cr—O bond.

$$[10]\quad Bu_3Sn{-}O{-}Cr(O)_2OSnBu_3 \xrightarrow{h\nu} Bu_3SnO\cdot + \cdot Cr(O)_2OSnBu_3$$

$$[11]\quad Bu_3SnO\cdot + O{=}N{-}C(CH_3)_3 \rightarrow Bu_3Sn{-}O{-}\overset{\displaystyle O}{\overset{|}{N}}{\cdot}{-}C(CH_3)_3$$

$Bu_3SnO\cdot$ radicals may be trapped by PBN too ($a_N$ = 1.41 mT, $a_H$ = 0.21 mT, Sn hyperfine splitting not clearly resolved). It should also be noted that

germanium-centered radicals may be trapped by PBN (68).

*3.4. Detection of singlet oxygen*

The Detection of singlet oxygen ($^1\Delta_g$) by a spin-trapping-like reaction of 2,2,6,6-tetramethyl piperidine with $^1O_2$ to form stable piperidineoxyl radical was first demonstrated by Lion, Delmelle, and Van de Vorst (69). This is no doubt one of the most remarkable results in application of spin-trapping technique to photochemical problems.

Recently it was shown by several authors (53*a*, 70) that $^1O_2$ may also be detected by this method during photoreactions of metal complexes. However, the possibility of formation of piperidineoxyl radicals by other reactions, e.g. by reaction with peroxyl radicals (71) or with oxidizing metal complexes, has to be taken into account before one turns to wider applications, of this attractive method. No systematic studies of formation of piperidineoxyl radicals by reactions other than $^1O_2$ have been published up till now.

## 4. Concluding remarks

The spin-trapping technique provides a useful method for the detection of short-lived paramagnetic species formed in the photoreaction of coordination compounds. If one considers possible side reactions (redox reactions, substitution), usually there is no special problem in the spin trapping of organic free radicals in the presence of metal complexes. However, spin trapping of typical inorganic radicals is by far less well understood, thus, spin trapping of a series of important inorganic radicals, e.g. $NO_3$, $NH_2$, SCN, Br, I, still remains an open problem. The detection of coordinatively unsaturated paramagnetic metal complexes is limited to organometallic species and to some cyano complexes. The interactions of nitroso compounds with complex fragments, which contain more than one unpaired electron, have not been studied systematically up till now.

Most of the spin-trapping studies concerning the photoreactions of coordination compounds hitherto published were made in non-aqueous solutions. Considerable progress is expected by using water-soluble spin traps such as DMPO (72) and recently described substituted C-aryl nitrones (73). However, till now no soluble nitroso compounds are known to be suitable for the study of photoreactions in aqueous solution.

The main disadvantage of any spin trap based on the formation of stable nitroxides may be attributed to its limitation only to neutral or weakly acidic media. No spin trapping is possible with nitroso compounds and nitrones in strongly acidic solutions.

# An electron paramagnetic resonance study of the reaction of nitrosobenzene with cholesterol

RAJAGOPALAN SRIDHAR AND ROBERT A. FLOYD

*Biomembrane Research Laboratory, Oklahoma Medical Research Foundation, Oklahoma City, OK 73104, U.S.A.*

Received September 12, 1981

RAJAGOPALAN SRIDHAR and ROBERT A. FLOYD. Can. J. Chem. **60**, 1574 (1982).

The reaction of nitrosobenzene with cholesterol ($\Delta^5$-cholesten-3β-ol) produces a fairly stable aminoxyl (nitroxyl) derivative. This steroidal aminoxyl is presumed to be the oxidation product of the hydroxylamine formed by Alder-ene addition of nitrosobenzene to cholesterol. Evidence is presented to show that, in this ene reaction, the double bond in the $\Delta^5$ position of the steroid shifts to the $\Delta^4$ rather than the $\Delta^6$ position.

RAJAGOPALAN SRIDHAR et ROBERT A. FLOYD. Can. J. Chem. **60**, 1574 (1982).

La réaction du nitrosobenzène avec le cholestérol ($\Delta^5$-cholestérol-3β) produit un dérivé aminoxyle (nitroxyle) moyennement stable. On pense que cet aminoxyle stéroïdal est le produit d'oxydation de l'hydroxylamine formée par une addition ène-Alder du nitrosobenzène sur le cholestérol. On prouve que, dans cette réaction du type ène, le double liaison en position $\Delta^5$ du stéroïde glisse en position $\Delta^4$ de préférence à la position $\Delta^6$.

[Traduit par le journal]

## Introduction

Many carcinogens and pharmaceutical agents are derivatives of arylamines and aromatic nitro compounds. The formation of nitroso intermediates during the metabolism of arylamines and nitroaromatics has been known or suspected for some time. In view of the biological activity of these compounds, it would be of interest to study the reactions of nitroso compounds with biologically important molecules. In this paper, we describe the reaction of nitrosobenzene (**1**) with cholesterol (**2**).

## Experimental

*Chemicals*

All solvents were of reagent grade and obtained from commercial suppliers. Nitrosobenzene, nitrobenzene-$d_5$, 99 at.% D, cholesterol, mesityl oxide, and phorone were purchased from Aldrich Chemical Company. Nitrobenzene-$d_5$ was converted into *N*-hydroxylaminobenzene-$d_5$ by reduction with a mixture of zinc dust and ammonium chloride in aqueous ethanol. Oxidation of the hydroxylamine with potassium ferricyanide yielded pentadeuterated nitrosobenzene.

*Electron paramagnetic resonance spectra*

The epr spectra were run at room temperature using a Varian E-9 x-band spectrometer. This instrument operates in the $TE_{104}$ mode and incorporates a 9-inch electromagnet with 100 kc/s in addition to low frequency (29 to 400 cps) field modulation. The instrument is also equipped with a Varian variable temperature control unit which maintains a constant temperature (± 1°C) while the spectrum is recorded.

## Results and discussion

A stable aminoxyl free radical (the terms nitroxyl and nitroxide have been used instead of aminoxyl in earlier literature), detectable by room temperature electron paramagnetic resonance spectroscopy, is produced when cholesterol and nitrosobenzene are mixed together in an organic solvent such as methanol or ethyl acetate at room temperature (Fig. 1). The epr spectral characteristics are unaffected when cholesteryl acetate is substituted for cholesterol in this reaction. This indicates that the 3β-OH group of the steroid is not involved in the reaction leading to the free radical product. Further, the spectral features are preserved irrespective of whether the steroid or the nitroso compound is employed in a molar excess. The reaction mixtures usually contained the free radical product along with unreacted starting materials. The instability of the free radical to long term chromatographic procedures hampered the isolation of the aminoxyl in a pure crystalline form.

Sullivan (1) has shown that nitrosobenzene can participate in an ene reaction with 2,3-dimethylbut-2-ene to yield a hydroxylamine which undergoes subsequent oxidation to yield an aminoxyl derivative. Since other examples of ene reactions involv-

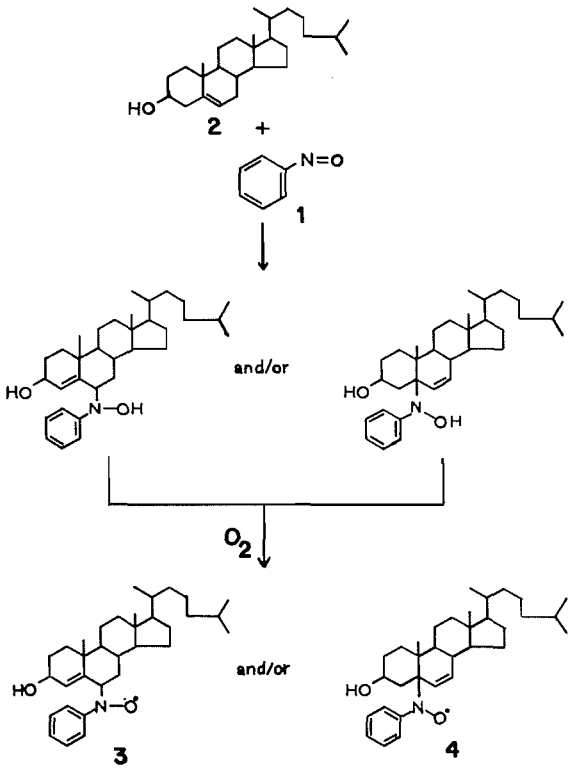

FIG. 2. Reaction scheme illustrating the pathway to aminoxyls via Alder-ene addition of nitrosobenzene to cholesterol.

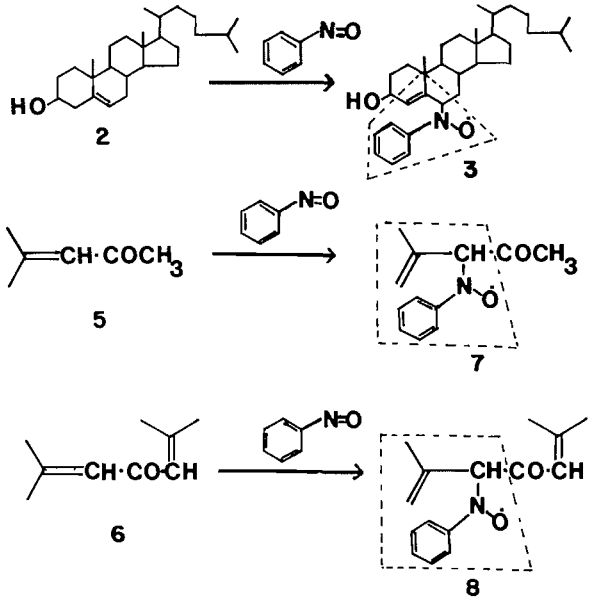

FIG. 3. Reaction of nitrosobenzene with mesityl oxide (5) and phorone (6) respectively, leading to the model aminoxyls (7) and (8) that bear a structural resemblance to the aminoxyl (3) derived from cholesterol.

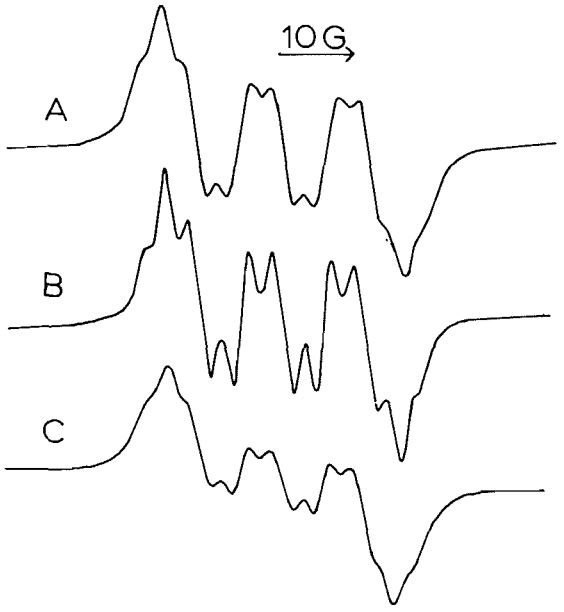

FIG. 4. The epr spectra of the aminoxyls **3**, **7**, and **8**. Spectrum A: the aminoxyl **3** from cholesterol; Spectrum B: the aminoxyl **7** from mesityl oxide; and Spectrum C: the aminoxyl **8** from phorone. The reaction conditions were as follows. Nitrosobenzene (11 mg) was dissolved in ethyl acetate (1 mL) and mixed with (*i*) cholesterol (20 mg) for spectrum A; (*ii*) mesityl oxide (40 μL) for spectrum B; and (*iii*) phorone (40 μL) for spectrum C. The reaction mixtures were contained in glass pasteur pipettes whose narrow end had been sealed off in order to serve as esr sample cells. Spectra were run after the mixtures had stood at room temperature for 15 h.

ing aromatic nitroso compounds and olefins are also known (2–4), we believe that nitrosobenzene adds to the steroid in an Alder-ene manner to yield a hydroxylamine which is easily oxidized to the corresponding aminoxyl (Fig. 2).

The ene reaction of nitrosobenzene (**1**) with cholesterol (**2**) can lead to two different aminoxyls (**3** and **4**) depending on whether the double bond in the $\Delta^5$ position of the steroid shifts to the $\Delta^4$ or the $\Delta^6$ position. The aminoxyl **3**, formed as a result of the shift of the double bond to the $\Delta^4$ position, would be characterized by its epr spectrum which should reflect the presence of a hydrogen β to the aminoxyl. Such a β hydrogen is not present in the aminoxyl **4**.

The experimentally obtained spectrum shown in Fig. 1 seems very similar to a computer simulated spectrum[1] generated by assuming the following

[1]The authors are grateful to Dr. Robert Clarkson and Dr. John Paxton of the Varian Associates for computer simulation of the spectrum.

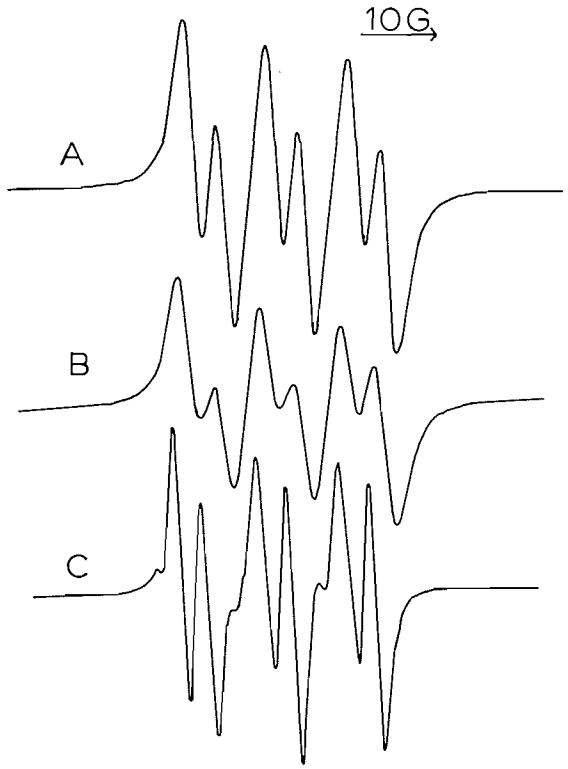

FIG. 5. The epr spectra of the aminoxyls produced by the reaction of nitrosobenzene-$d_5$. Spectrum A: the aminoxyl from cholesterol (**3**-$d_5$); Spectrum B: the aminoxyl from mesityl oxide (**7**-$d_5$); and Spectrum C: the aminoxyl from phorone (**8**-$d_5$). Reaction conditions were similar to those for Fig. 4.

parameters: line width 1.5 G; $a_N = 11.0$ G; $a^H_{ortho} = a^H_{para} = 3.1$ G; $a^H_{meta} = 0.75$ G; and $a^H_\beta = 3.05$ G.

In order to determine whether **3** or **4** was formed in the reaction, model aminoxyl compounds possessing the essential structural features of **3** were prepared so that their epr spectra could be compared with that of the steroidal aminoxyl. The reaction of nitrosobenzene with (*i*) mesityl oxide and (*ii*) an excess of phorone gave the required aminoxyls with defined structures, since ene-type addition could occur in an unambiguous way in these reactions. The structural similarity of the aminoxyl **3** and the model aminoxyl compounds prepared from mesityl oxide and phorone are indicated by the portion enclosed within the dotted boundaries (Fig. 3).

The spectra of these model aminoxyls are quite similar to that of the steroidal aminoxyl, indicating that **3** and not **4** is produced in the reaction of cholesterol with nitrosobenzene (Fig. 4). Substituting pentadeuterated nitrosobenzene for nitrosobenzene in the reactions with mesityl oxide, phorone, and cholesterol simplified the epr spectra and the prominent splitting due to the hydrogen atom β to the aminoxyl was seen in all three cases (Fig. 5). The reaction of pentadeuterated nitrosobenzene with 2,3-dimethylbut-2-ene leads to an aminoxyl which contains no β hydrogens. As expected, the epr spectrum does not show the splitting due to β-H (spectrum not shown).

# Observations on nitroxyl free radicals in arylamine carcinogenesis and on spin-trapping hydroxyl free radicals

ROBERT A. FLOYD

*Biomembrane Research Laboratory, Oklahoma Medical Research Foundation, Oklahoma City, OK 73104, U.S.A.*

Received October 10, 1981

ROBERT A. FLOYD. Can. J. Chem. **60**, 1577 (1982).

The work presented illustrates the valuable ways that spin-trapping and nitoxyl free radical chemistry has helped us in gaining a better view of the nature of certain biological processes and thus, hopefully, will help to disentangle the principles governing the causes of certain diseases.

ROBERT A. FLOYD. Can. J. Chem. **60**, 1577 (1982).

Le présent travail illustre les moyens intéressants qu'offre la chimie des capteurs de spin et des radicaux libres du type nitroxyle en vue de nous aider à mieux comprendre la nature de certains processus biologiques et éventuellement, nous aider, on l'espère, à éclaircir les principes régissant les causes de certaines maladies.

[Traduit par le journal]

## Introduction

The techniques of spin-trapping and spin-labeling, as well as nitroxyl free radical chemistry in general, have contributed significantly to a better understanding of free radical aspects of biologically important reactions and have provided a more comprehensive view of the organization of biological systems. This has resulted in contributions to the solution of certain medically important problems. This report is a summary of the work of my own laboratory over the last several years.

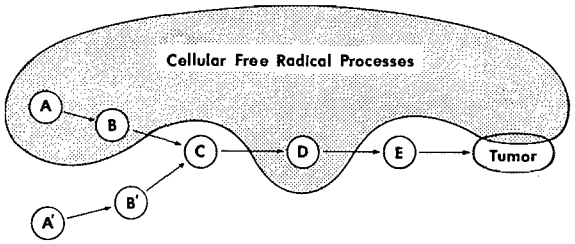

FIG. 1. Schematic representation of sequential development of tumor leading through the domain of cellular free radical processes (3).

## Free radicals in arylamine carcinogenesis

Free radicals have been considered as being closely linked with cancer for a long time. Apparently the notion originated with the demonstration of cancer induction by ionizing irradiation (1). The pace of work in this area has increased rapidly in recent years, apparently spurred on by demonstrations showing that, in general, antioxidants slowed down cancer development (2). It appears likely now that chemical carcinogen induction of tumor in many cases may progress through steps involving free radicals as illustrated in highly schematic form in Fig. 1 (3). If specific free radical steps are rate limiting, then modification of the rate of these steps would be expected to influence the overall rate of cancer development.

### 1. *Activation of 2-acetylaminofluorene*

The arylamine carcinogens consist of a large class of chemicals shown to induce tumors in laboratory animals and considered to be human carcinogens on the basis of epidemiological studies. The most widely studied member of this class of carcinogens is 2-acetylaminofluorene (AAF). It has been known for over 40 years that AAF will induce tumors in rats. In fact, when AAF is fed at about 0.02% in the diet, it induces liver tumor in male and mammary gland tumor in female rats. The single most important advancement in terms of understanding the mechanism of action of this chemical carcinogen occurred in 1960 when Cramer *et al.* (4) demonstrated that *N*-hydroxylation of AAF was a necessary first step in the metabolic activation of this chemical by liver enzymes; that is,

### 2. *Peroxidase activation of* N-*hydroxy-2-acetylaminofluorene*

It should be pointed out that the *N*-hydroxylated product, *N*-hydroxy-2-acetylaminofluorene (N-OH-AAF) itself is not the ultimate reactive chemical species of this carcinogen but must be further activated to yet another chemical species, the identity of which is not resolved at the present time (1).

As far as our approach to this problem, a key observation was made in 1970 by Forrester *et al.* (5) and Bartsch and Hecker (6). Bartsch and Hecker (6) demonstrated that N-OH-AAF was activated to 2-nitrosofluorene (NOF) and *N*-acetoxy-2-acetylaminofluorene (N-OAc-AAF) in a system containing horseradish peroxidase (HRP) and $H_2O_2$. The

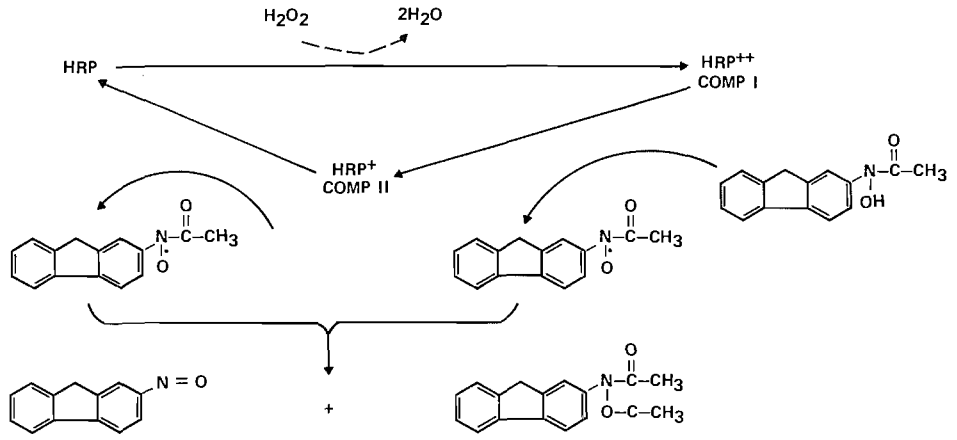

FIG. 2. Schematic representation of the nitroxyl free radical route of the activation of *N*-hydroxy-2-acetylaminofluorene (6). HRP refers to horseradish peroxidase and $HRP^{+++}$ (Comp I) and $HRP^{+}$ (Comp II) refer to compound one and compound two of HRP, respectively.

scheme they proposed to explain their results is shown in Fig. 2. In this scheme, N-OH-AAF acts as a one-electron donor to facilitate HRP cycling through three oxidation states. The nitroxyl free radical of N-OH-AAF is formed in this process, and this free radical dismutates to form NOF and N-OAc-AAF. This system has been investigated much more extensively (7); it has been shown to activate N-OH-AAF readily and, in addition, very interestingly is inhibited by antioxidants such as ascorbate (7).

### 3. *Membrane lipid peroxides as substrate for peroxidase activation of N-OH-AAF*

Membrane lipid peroxidation apparently involves oxygen free radical events and yields lipid hydroperoxides. We therefore reasoned that it was desirable to determine if lipid hydroperoxides act as a substrate to activate N-OH-AAF in a manner similar to the peroxidase route. It was shown that linoleic acid hydroperoxide in the presence of hematin activated N-OH-AAF to NOF and N-OAc-AAF stoichiometrically (8) as shown in Fig. 3. The nitroxyl free radical of N-OH-AAF is shown as an obligatory intermediate in this reaction, but to prove that this was the actual case required much more extensive work including a careful study (9) of two parameters, (A) the rate of oxidation of N-OH-AAF, and (B) the amount of N-OH-AAF nitroxyl free radical as the reaction proceeded. The rate of oxidation of N-OH-AAF and the amount of nitroxyl free radical became zero at the same time after the initiation of the reaction (9). If oxidation of N-OH-AAF is proceeding through a nitroxyl free radical step, then the equations shown below are true (9).

$$(a)\quad \text{N-OH-AAF} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{N-}\dot{\text{O}}\text{-AAF}$$

$$(b)\quad \text{N-}\dot{\text{O}}\text{-AAF} + \text{N-}\dot{\text{O}}\text{-AAF} \xrightarrow{k_2} \text{NOF} + \text{N-OAc-AAF}$$

$$(c)\quad \frac{d(\text{N-OH-AAF})}{dt} + -k_1(\text{N-OH-AAF}) + k_{-1}(\text{N-}\dot{\text{O}}\text{-AAF})$$

$$(d)\quad \frac{d(\text{N-}\dot{\text{O}}\text{-AAF})}{dt} = -k_2(\text{N-}\dot{\text{O}}\text{-AAF})^2 + k_1(\text{N-OH-AAF}) - k_{-1}(\text{N-}\dot{\text{O}}\text{-AAF})$$

$$(e)\quad -\frac{d(\text{N-OH-AAF})}{dt} = \frac{d(\text{N-}\dot{\text{O}}\text{-AAF})}{dt} + k_2(\text{N-}\dot{\text{O}}\text{-AAF})^2$$

The bottom equation states that the rate of N-OH-AAF oxidation can be expressed in terms of the nitroxyl free radical of N-OH-AAF. Therefore, if the reaction is proceeding via an obligatory nitroxyl free radical step, then it should be possible, using the bottom equation, to calculate one parameter, say the rate of N-OH-AAF oxidation utilizing the other parameter, the amount of nitroxyl free radical at any time during the reaction. This indeed was the case (9). In addition, utilizing the bottom equation, it was possible to calculate the N-OH-AAF nitroxyl free radical dismutation constant, $k_2$. This calculated value is $2.7 \times 10^5\ M^{-1}\ s^{-1}$ (9) which indicates that the nitroxyl free radical of N-OH-AAF dismutates in a physiological buffer solution more slowly than, for instance, the ascorbyl free radical (10).

### 4. *$P_{450}$ activation of N-OH-AAF via peroxidase route*

It was necessary to test whether the heme protein $P_{450}$ was capable of activating N-OH-AAF

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

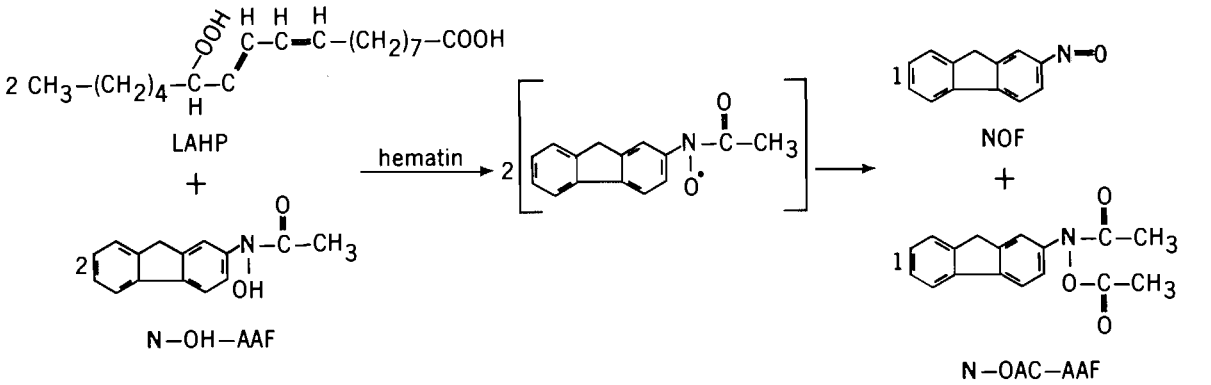

FIG. 3. The stoichiometry of the activation of *N*-hydroxy-2-acetylaminofluorene by hematin with linoleic acid hydroperoxide (LAHP) acting as a substrate (8).

in a peroxidase pathway. Utilizing rat liver "$P_{450}$ particles" which are liver microsomes treated such as to enrich them with respect to $P_{450}$, we showed that $P_{450}$ per se was relatively inactive in the peroxidase type oxidation of N-OH-AAF (11). However, conversion of $P_{450}$ to the high spin $P_{420}$ form caused a significant increase in oxidation of N-OH-AAF whereas the low spin $P_{420}$ form was almost completely inactive in this regard (11). To further substantiate this observation, we utilized purified $P_{450}$ $LM_2$, a gift of Dr. M. Coon (Univ. of Michigan). In this case as well, the high spin $P_{420}$ form was quite active whereas the low spin $P_{420}$ form as well as $P_{450}$ itself was relatively inactive (11). The effectiveness with which the various hydroperoxides act as a substrate in combination with low spin $P_{420}$ to oxidize N-OH-AAF was investigated. Linoleic acid hydroperoxide was found to be much more effective than cumene hydroperoxide or hydrogen peroxide (11). In this regard, we previously have shown that with the hematin – linoleic acid hydroperoxide system, N-OH-AAF-oxidation to the nitroxyl free radical was detected with as little as 1.8 μM of the hydroperoxide [8].

### 5. *Peroxidase activation of N-OH-AAF in mammary gland*

The relevance of the peroxidase route of N-OH-AAF activation to the true mechanism of AAF carcinogenesis remains to be completely elucidated. However, on the basis of our recent findings, it appears that the peroxidase route may be very important in the AAF-induced development of tumor in female rat mammary gland. First evidence to support this came when we showed that rat mammary gland homogenate contained an active peroxidase capable of activating N-OH-AAF to NOF and N-OAc-AAF (12). Linoleic acid hydroperoxide proved to be a very effective substrate for this peroxidase and it was found that N-OH-AAF activation was inhibited by the antioxidants propyl gallate and ascorbate (12).

Much more definitive observations demonstrating the importance of the peroxidase route have come about recently as a result of the use of high pressure liquid chromatography (hplc) to study the metabolism of N-OH-AAF in isolated rat mammary gland parenchymal cells, a target tissue for AAF. Our results (13) can be summarized as follows: (A) Utilizing hplc, we have demonstrated that N-OH-AAF is metabolized in rat mammary gland parenchymal cells to NOF and N-OAc-AAF; (B) The metabolism of N-OH-AAF in these cells is inhibited by the antioxidants ascorbate and *p*-aminophenol, which implicates a peroxidase route, but is not inhibited by paraoxon, an inhibitor of the deacetylase route of NOF formation from N-OH-AAF; (C) exogenously added arachidonic acid enhances N-OH-AAF activation and the inhibitor 5,8,11,14-eicosatetraynoic acid (ETYA) considerably decreased N-OH-AAF activation, whereas indomethacin or aspirin were ineffective as inhibitors; (D) the lipid hydroperoxide 12L-hydroperoxy-5,8,10,14-eicosatetraenoic acid (12-HPETE) is an effective substrate for activation of N-OH-AAF; (E) rat blood platelets which are a rich source of the lipoxygenase pathway activated N-OH-AAF

when exogenous arachidonate was added; and, (F) ram seminal vesicle microsomes, a source rich in the prostaglandin synthetase pathway, activated N-OH-AAF when exogenous arachidonate was added.

6. *Prostaglandin synthetase activation of N-OH-AAF*

The scheme presented in Fig. 4 will help to understand the mechanism of the peroxidative activation of N-OH-AAF by the prostaglandin synthetase system as well as the lipoxygenase system. The reaction which starts the cascade of reactions involves phospholipase $A_2$ cleavage of arachidonic acid from the membrane phospholipid. Arachidonate can then be oxidized by the prostaglandin cyclooxygenase to produce prostaglandin $G_2$ ($PGG_2$). Alternatively, arachidonate can be oxidized by a lipoxygenase to yield several hydroperoxides including 12-HPETE. Ram seminal vesicle microsomes have a high activity of the prostaglandin synthetase system but the lipoxygenase activity is very low or absent. We demonstrated N-OH-AAF activation by ram seminal vesicle microsomes in a peroxidative manner (13). Our postulate as to how this occurs is that the peroxidase, an enzymatic activity intimately associated with (most likely the same enzyme as) the cyclooxygenase (14), activates N-OH-AAF utilizing $PGG_2$ as a substrate. Our postulate is partially based upon demonstrations by Zenser *et al.* (15), Marnett *et al.* [16], Eling and co-workers [17], and Egan *et al.* [18] of similar type cooxidative reactions with other drugs or carcinogens. In the mammary gland, our results lead us to the conclusion that an active lipoxygenase forms a lipid hydroperoxide which acts as a substrate for a peroxidase, which most likely is not the same peroxidase associated with prostaglandin cyclooxygenase, to oxidatively activate N-OH-AAF. These results are exciting since they provide a way of explaining the mechanism as to why AAF induces tumor of the mammary gland, because other than the peroxidase route, other known routes of N-OH-AAF activation such as the sulfotransferase are either absent (19) or the acyltransferase, although apparently present, is lower in activity than liver (20), a somewhat resistant tissue in female rats.

7. *Covalent binding of 2-nitrosofluorene to membrane lipids*

Very surprisingly, I found that when 2-nitrosofluorene (NOF) was added to a solution containing oleic acid, a nitroxyl free radical type esr spectrum was formed (21). In addition, we found that not only oelic acid, but linoleic acid and squalene, as well as several other membrane lipid components, yielded nitroxyl free radicals when NOF was added to the solution in which any one of these compounds was present. Further study demonstrated that the presence of carbon–carbon double bonds in the lipid component was necessary for nitroxyl free radical formation (21). We subsequently demonstrated that when NOF was added to natural membranes, an esr signal resembling a nitroxyl exhibiting hindered rotation was formed quite rapidly (22). The addition of NOF to liposomes formed from the total lipids extracted from rat liver microsomes yielded a similar type esr spectrum as was seen with the natural membranes (22). This result illustrated that the membrane proteins did not contribute to the reaction of NOF with membrane lipids to form the nitroxyl free radical. The nitroxyl free radical which formed upon addition of NOF to rat liver microsomes was subject to reduction–oxidation control. NADPH reduced the nitroxyl; subsequent oxidation could be obtained by ferricyanide addition (22). After much work on this problem, we conclude that NOF adds to natural membranes in a manner as illustrated in Fig. 5. This scheme follows the scheme outlined by Sullivan to explain his observations of nitrosobenzene addition to 2,3-dimethylbutene to form a nitroxyl free radical adduct (23). All the work we have conducted on these systems over the last 5 years can be explained by the scheme presented in Fig. 5. Thus, these results, in effect for the first time, demonstrate that a carcinogen adds covalently to membrane lipids.

8. *Metabolism of* N*-hydroxylated aromatic amine carcinogens to form NOF–Lipid adducts*

Formation of NOF from N-OH-AAF may occur by mechanisms other than via the nitroxyl free radical route. One possible route, shown in the equation below, is by deacetylation of N-OH-AAF to form *N*-hydroxy-2-aminofluorene which undergoes rapid oxidation to NOF which then may covalently bind to membrane lipids. Paroxon, a powerful esterase inhibitor, has been shown to inhibit the deacetylation reaction (24). We have tested microsomes from male rat liver, a target

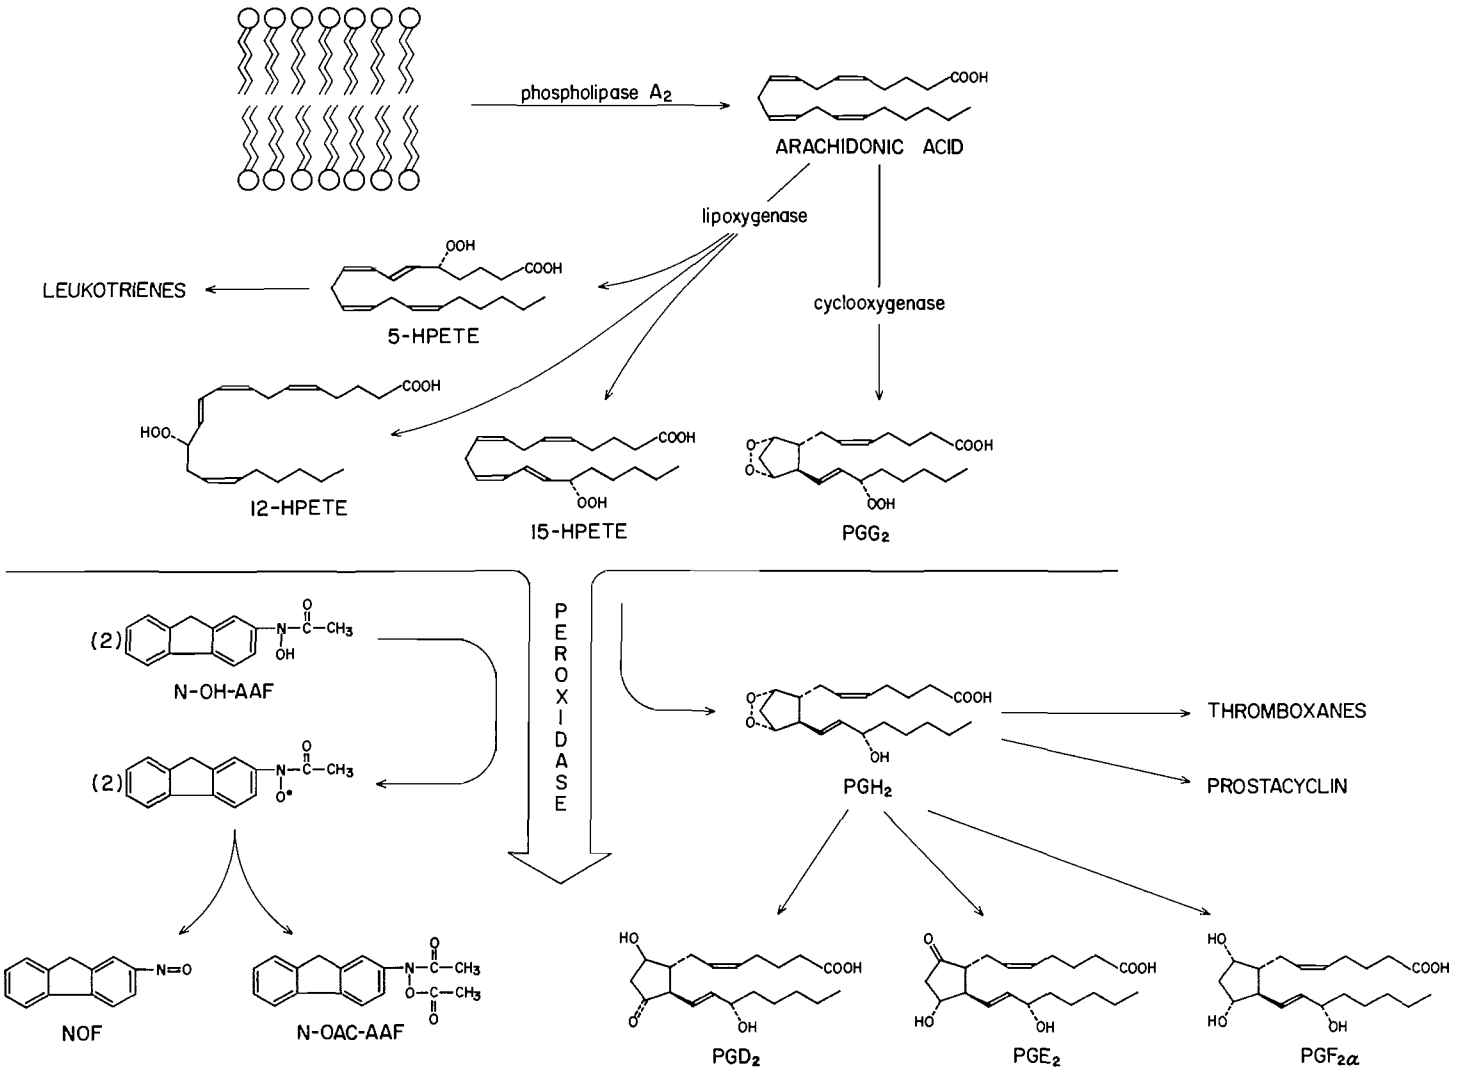

FIG. 4. Schematic representation of the activation of *N*-hydroxy-2-acetylaminofluorene via the prostaglandin synthetase system or via lipoxygenase *plus* peroxidase pathway which appears to be the route of activation of this carcinogen in female rat mammary gland (13).

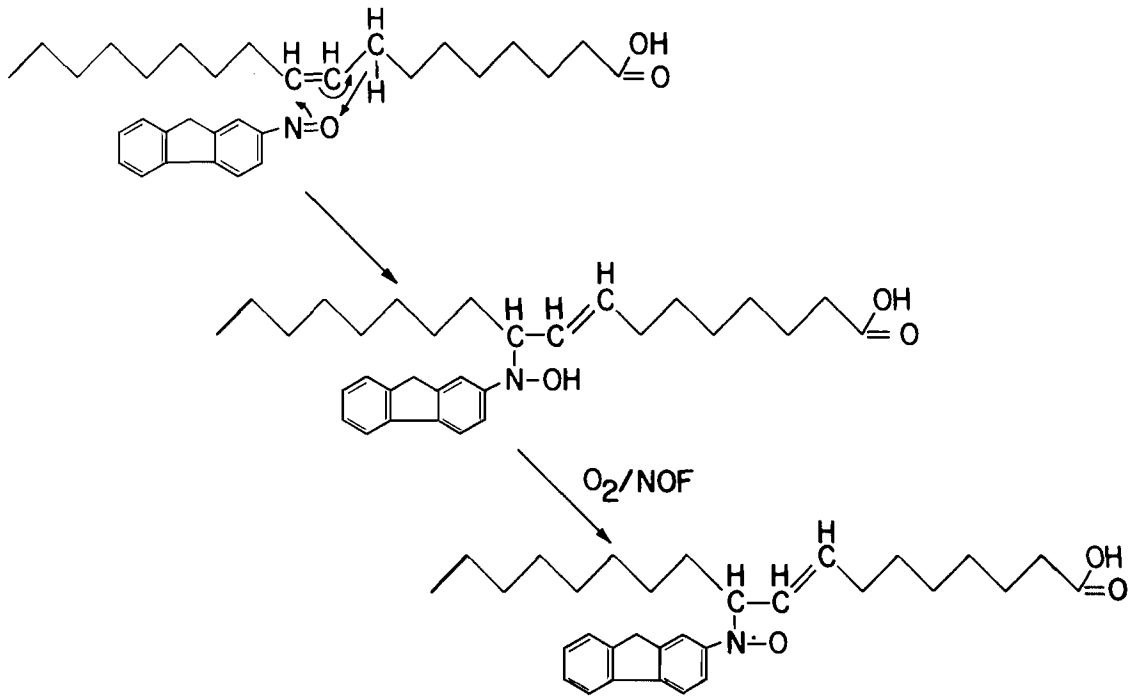

FIG. 5. The Alder-ene addition scheme to explain 2-nitrosofluorene addition to carbon–carbon double bonds in membrane lipids (22).

tissue, to determine if deacetylation of N-OH-AAF occurs. Optical as well as esr experiments demonstrated that this was the case (25). If TME (2,3-dimethylbutene), which acts as a ready substrate for NOF-adduct formation, was added to microsomes then a larger amount of adduct was apparent (1). Heated microsomes were ineffective in carrying out the deacetylation reaction, and paroxon at $5 \times 10^{-6}$ *M* level prevented deacetylation of N-OH-AAF (25).

Deacetylation of other *N*-hydroxylated aromatic amine carcinogens occurs, resulting in formation of the membrane lipid adducts. Thus, *N*-hydroxy-4-acetyl aminobiphenyl is a bladder carcinogen and its deacetylation to eventually form the *C*-nitroso membrane lipid adduct is readily apparent in rat liver microsomes (1).

We have found that the NOF-lipid adduct is formed when N-OH-AAF is given to the whole animal (1). N-OH-AAF dissolved in corn oil was given interperitoneally to a rat. After 1.5 hours, the animals were killed, the liver removed, homogenized, and extracted with ethyl acetate. The esr spectrum of the concentrated ethyl acetate extract from an animal receiving corn oil only illustrated the absence of nitroxyl free radical, whereas in the concentrated ethylacetate extract from an animal receiving N-OH-AAF, the presence of a nitroxyl free radical was obvious (1). The coupling constant of the nitroxyl free radical was similar to that of the NOF-lipid adducts observed previously (21, 22).

9. *Formation of 2-nitrosofluorene – cholesterol adduct*

We have found that NOF adds covalently to cholesterol to form a nitroxyl free radical adduct (1). There are two possible NOF–cholesterol adducts, as is shown in Fig. 6. Work where specific hydrogens on cholesterol are replaced by deuterium, as well as the reaction of NOF with model compounds, has proven that the carbon-5 adduct of cholesterol is the predominant species formed in this reaction.

10. *Relevance of 2-nitrosofluorene – lipid adducts to carcinogens*

It is not possible to know the relevance of the formation of the NOF–lipid adducts to the carcinogenesis of either AAF or NOF at the present time. It is possible, however, to point out some interesting relationships and observations that may have bearing upon this problem. First of all, the attachment of a lipid component to NOF would most likely change the carcinogenic properties of NOF. Possibly a relevant observation is the one made by Bartsch *et al.* (26) who showed that if the acetyl group of N-OH-AAF is replaced by the myristate,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

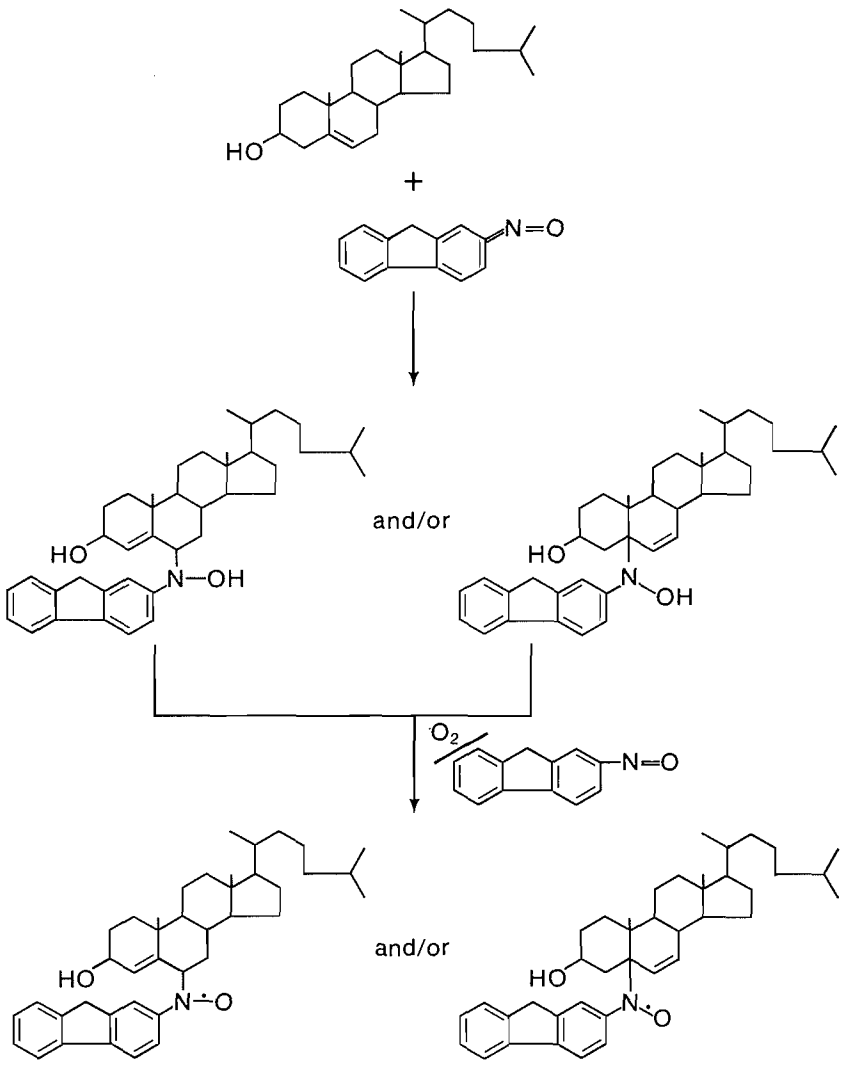

FIG. 6. The Alder-ene addition of 2-nitrosofluorene to cholesterol. Two pathways are possible. The one on the left is the one found to occur.

i.e. becoming N-OH-MyAF, or if the acetoxy group of N-OAc-AAF is replaced by the myristate ester, i.e. becoming N-OMy-AAF, then the compounds possessing the long lipophilic moieties were much more carcinogenic than the compounds having the acetyl or acetoxy groups. They attributed the increased carcinogenicity to enhanced retention of the more lipophilic compounds at the site of injection. Based upon Bartsch's work, it is tempting to speculate that the attachment of NOF to a lipophilic component may enhance its carcinogenicity. This remains to be proven, but we have conducted a study of the carcinogenicity of the NOF – oleic acid methyl ester adduct and the NOF–cholesterol adduct in the newborn mouse model utilized by Miller *et al.* (27). We found in our preliminary study that the NOF–cholesterol adduct was more carcinogenic than NOF per se, but the NOF – oleic acid methyl ester adduct was less carcinogenic than NOF. This study was preliminary and is complicated by the fact that, as we discovered later, more than one product was present in the adducts injected into the animals. This study needs to be repeated with highly purified NOF adducts.

Another observation that may have some relevance concerns our work on the mutagenicity of NOF as influenced by the number of carbon–carbon double bonds in the membrane lipids of the Ames tester strain bacteria TA98. In general, we found that as the membrane unsaturation increased (28) in the 37°C and 27°C grown bacteria which

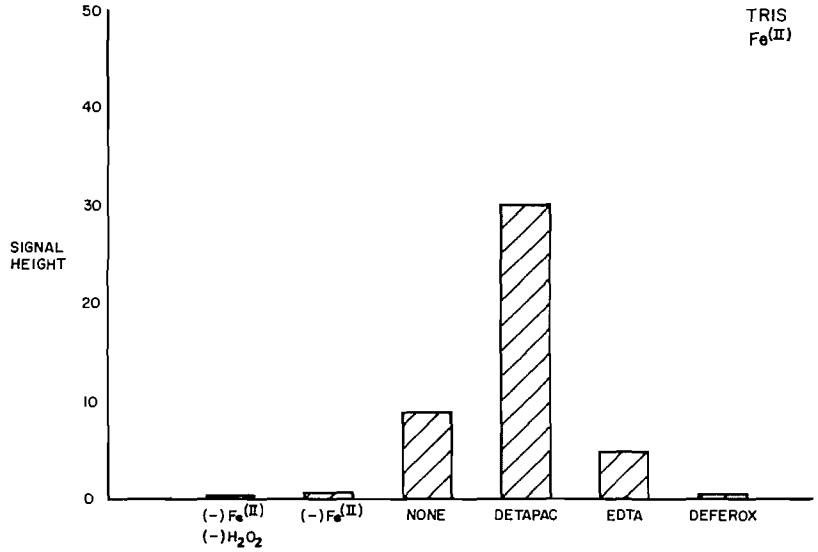

FIG. 8. The amount of ȮH spin-trapped by DMPO in the Fenton system using Tris (trihydroxylaminomethane) buffer, pH 7.4.

were the best comparisons, then mutagenicity of NOF increased (29). It should be noted that the NOF – oleic acid methyl ester is only slightly mutagenic as compared to NOF (30); however, the mutagenicity may not correlate with the carcinogenicity of the compounds (see, for instance, Bartsch *et al.* (26)).

## Oxygen free radicals

Oxygen free radicals is a subject that has been given more and more attention lately. A large amount of this recent interest in oxygen free radicals is due to the discovery of superoxide and the demonstration of its relevance to biological processes largely due to the work of Fridovich and co-workers (31). It is becoming quite apparent that oxygen free radicals have a major role in the etiology of many disease states.

## Spin-trapping hydroxyl free radicals in a Fenton-type reaction

Since oxygen free radicals are implicated in so many damaging biological processes, it appears necessary to know more about their properties and

For personal use only.

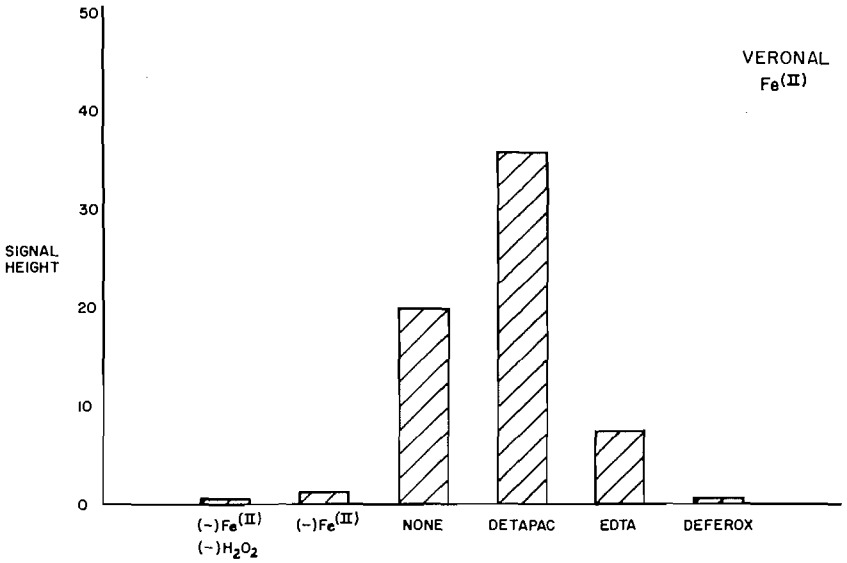

FIG. 9. The amount of ȮH spin-trapped by DMPO in the Fenton system using veronal buffer, pH 7.4.

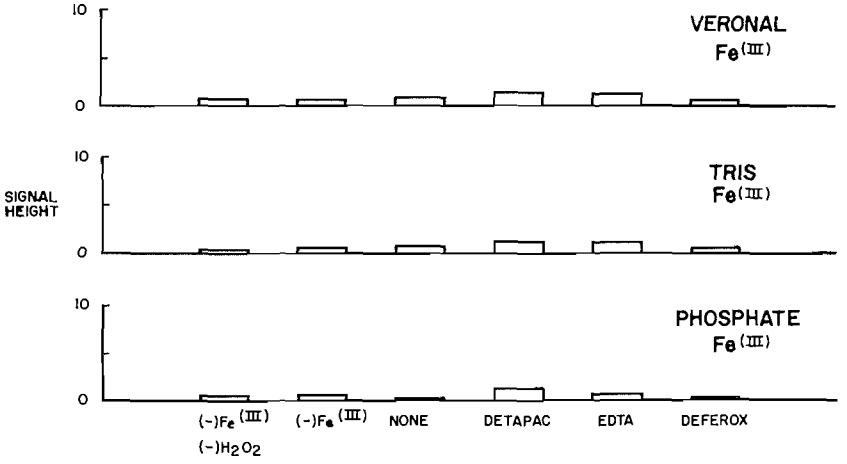

FIG. 10. The amount of ȮH spin-trapped in a Fenton system using Fe(III) with various buffers and various chelators.

the conditions under which they manifest their action. In particular, we have concentrated upon examining the conditions affecting hydroxyl free radical formation from a Fenton-type reaction. We have utilized spin-trapping in this regard because of the difficulty of observing hydroxyl free radicals directly, and also because ȮH reacts with the spin-trap 5,5-dimethylpyrolidine-*N*-oxide (DMPO) at nearly a diffusion limited rate ($3.4 \times 10^9\ M^{-1}\ s^{-1}$) (32). The DMPO–hydroxy free radical spin-adduct formed has a unique esr spectrum with a 1:2:2:1 pattern where $A_N = A_\beta{}^H = 14.9$.

Our first attempts at characterizing the conditions for hydroxyl free radical formation from $H_2O_2$ as catalyzed by chelated iron illustrated the magnitude of our misconception of the complexity of the problem. That is, we found that there was on the order of a 50-fold difference in the amount of hydroxyl free radical spin trapped depending upon the order of addition of reagents. The order of additions between the two experiments are shown below. The top sequence corresponds to a 50-fold increased amount of spin-trapped ȮH versus that for the bottom sequence of reagent addition.

$$\text{Buffer, DMPO, DETAPAC, Fe(II)} \xrightarrow[37°C]{30\ s} + H_2O_2$$

$$\text{Buffer, DMPO, Fe(II), DETAPAC} \xrightarrow[37°C]{30\ s} + H_2O_2$$

Thus, a reversal in the order of addition of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

chelator DETAPAC (diethylene triamine pentaacetic acid) and iron as Fe(II) made the difference between the two results.

The amount of ȮH spin-trapped was sensitive to several other variables including the type of buffer, the type of metal ion chelator, the oxidation state of the metal ion, and the time interval after addition of the metal ion (33). Figure 7 demonstrates that for potassium phosphate buffer pH 7.4, the amount of ȮH spin-trapped was vastly different depending upon the chelator used. The experiments were carried out by the protocol illustrated by the top sequence above, only the chelator was changed. Thus, Fe(II) with DETAPAC, as compared to EDTA (ethylenediaminetetraacetic acid) or deferoxamine, was quite effective in producing ȮH from the added $H_2O_2$. The amount of Fe(II) added was about 25 μmol; the other components DMPO (200 mmol), chelator (100 μmol), and $H_2O_2$ (400 μmol) were in excess. The amount of radical trapped was about 15 μmol in the case of DETAPAC in the phosphate buffer. Therefore, since the following equation describes the reaction

$$Fe(II) + H_2O_2 \rightarrow Fe(III) + OH^- + \dot{O}H$$

and if Fe(II) is limiting and DMPO is in large excess, then it follows, since the rate of the Fenton reaction is slower than the spin-trapping reaction, that Fe(II) is either not at 25 μmol or the reaction as written is wrong. It turns out, based upon the work of Cohen and Sinet (34), that Fe(II) is rapidly becoming oxidized and that the difference between the chelators is due to the effectiveness of each in preventing the rapid oxidation of Fe(II). Therefore, since we are spin-trapping about 15 μmol ȮH with DETAPAC as the chelator, then about 40% of the added Fe(II) has become oxidized in 30 s at 37°C. With buffers other than phosphate, similar but slightly different amounts of ȮH were spin-trapped as is shown in Fig. 8 for Tris (trihydroxylaminomethane) or veronal buffer (Fig. 9).

The importance of the oxidation state of iron is illustrated by the data presented in Fig. 10 demonstrating that irrespective of buffer or chelator, Fe(III) was quite ineffective in catalyzing ȮH formation from $H_2O_2$.

## Acknowledgments

The work presented was supported in part by National Institutes of Health grants CA18591 and CA21542. I thank Ms. E. Miser for typing of the manuscript.

# From early spin-trapping experiments to acyl nitroxide chemistry: synthesis of and spin trapping with a water-soluble nitrosopyrazole derivative

HARPARKASH KAUR AND M. JOHN PERKINS[1]

*Department of Chemistry, Chelsea College, Manresa Road, London SW3 6LX, England*

Received September 19, 1981

HARPARKASH KAUR and M. JOHN PERKINS. Can. J. Chem. **60**, 1587 (1982).

A personal view of early experiments which led to the use of *C*-nitroso-compounds as spin traps is presented, and it is shown how these experiments resulted in the first isolation, and subsequent investigation, of acyl nitroxide radicals: the use of 1-methyl-4-nitroso-3,5-diphenylpyrazole as a spin trap, and the preparation and preliminary investigation of its water-soluble analogue (**1**) are described.

HARPARKASH KAUR et M. JOHN PERKINS. Can. J. Chem. **60**, 1587 (1982).

*On présente une façon personnelle de concenvoir les premières expériences qui ont conduit à l'utilisation des composés C*-nitrosés comme capteurs de spin. On montre comment ces expériences ont conduit à la première séparation et à l'étude des radicaux acylnitroxydes. On décrit l'utilisation du méthyl-1 nitroso-4 diphényl-3,5 pyrazole comme capteur de spin ainsi que la préparation et les études préliminaires de son analogue (**1**) soluble dans l'eau.

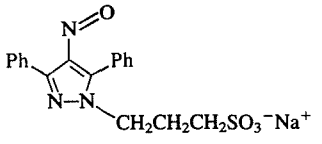
This article is sub-divided into two sections. In the first, we summarise the work which was the basis of the review paper presented at the Guelph symposium; in the second we give a more detailed account of the evolution of the new water-soluble spin trap, **1**.



**1**

## 1. Review section

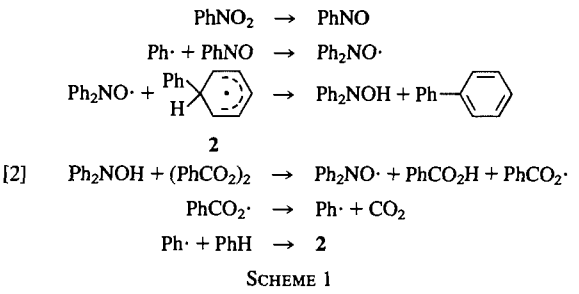
Our interest in nitroxide chemistry began with investigations of free-radical arylation in D. H. Hey's laboratory at King's College in London. It was known at that time (ca. 1960), that whilst thermolyses of benzoyl peroxide in benzene gave poor yields of organic products (ca. 40%, but see ref. 1) according to the simple stoichiometry of reaction [1] (Ar = Ph), similar reactions with

$$[1]\quad (ArCO_2)_2 + PhH \xrightarrow[N_2]{80^\circ C} ArCO_2H + ArPh + CO_2$$

nitrobenzene as solvent (or with equimolar mixtures of benzene and nitrobenzene employed in "competition" experiments) gave surprisingly good yields. It was also known that nitrobenzoyl peroxides, on thermolysis in benzene, gave high yields of the appropriate nitro-substituted products.

The natural extension of these observations was to examine the products of reaction of benzoyl peroxide in benzene containing a "catalytic" quantity (ca. 1%) of added nitrobenzene. The yields of biphenyl and benzoic acid rose dramatically to around 90%.

The explanation (2) of the effect of added nitro-compound was eventually traced to the reduction of a small fraction of the nitrobenzene to nitroso-benzene, and formation from that of diphenyl nitroxide and related species which then take part in a hydrogen transfer redox process wherein the key cyclohexadienyl intermediate **2** is oxidised before it can proceed to products of self-reaction (dimerisation or disproportionation). The essential features of the process are summarised in Scheme 1.



**2**

SCHEME 1

The molecule-induced homolysis of benzoyl peroxide (reaction [2]) by diphenylhydroxylamine was established in separate experiments (3).[2]

The most puzzling aryl precursors had for a long time been the nitrosoacylarylamines (e.g. *N*-

[1]To whom all correspondence should be addressed.

[2]We do not believe that our kinetic data in this work (3) can be reinterpreted in terms of "homosolvolysis" by nitroxide as has been suggested recently. (4).

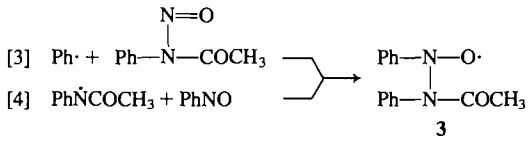
nitrosoacetanilide). It was shown by Rüchardt and co-workers that the apparent anomalies reported for this system could all be accounted for if a relatively persistent radical were to mediate in the reaction (5); one role for this was again the oxidation of cyclohexadienyl intermediates. Rüchardt also succeeded in demonstrating (6) the presence of such an intermediate using esr techniques. However, the species detected did *not* have the diazotate structure (PhN:NO·) originally assigned, although that radical is still believed to play an important role in nitrosoacetanilide decomposition (7). By analogy with our earlier work with nitrocompounds in the benzoyl peroxide reaction, we suggested an alternative structure for the species detected, namely that of the nitroxide (**3**) formed by addition of phenyl radicals to the nitrosoamide (reaction [3]). This formulation was quickly corroborated by a reaction ([4]) (8) which proved for us

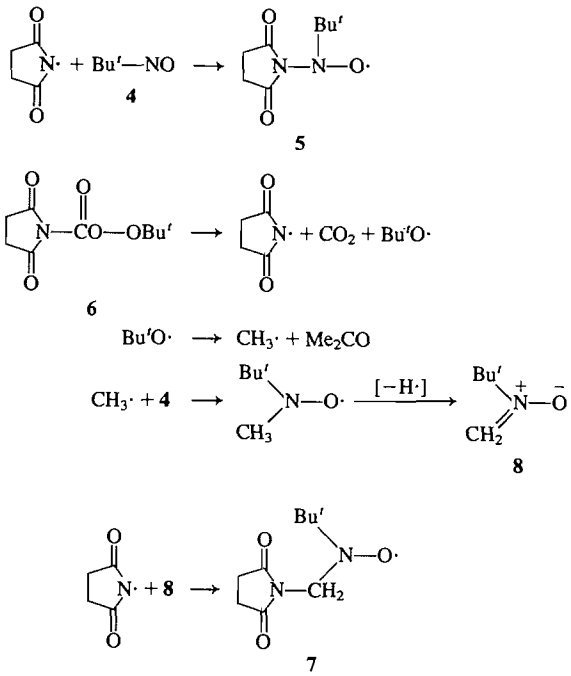


**3**

to be the fore-runner of the technique named "spin trapping" by Professor Janzen (9).

The ready detection of nitroxides in systems containing radical precursors and a trace of *C*-nitroso-compound led to a more general examination of this procedure for the study of free-radical reactions. In view of the interception of amidyl radicals (reaction [4]), it was natural that we should examine the succinimidyl radical problem.[3] However, because of the complexity of spectra of nitroxides derived from nitrosobenzene, we turned our attention to 2-methyl-2-nitrosopropane (MNP, **4**) as a radical trap. This had been shown by De Boer and his colleagues to give nitroxides by radical addition, and most of the adducts displayed exceedingly simple esr spectra which were readily interpreted in terms of the structure of the radical trapped.

In photochemical experiments with *N*-bromosuccinimide, MNP gave the succinimidyl adduct **5** (11), reported also by Lagercrantz and Forshult (12). In contrast, when the succinimidyl source was the perester **6**, the nitroxide **7** was unexpectedly formed. The explanation of this, involving the methylene nitrone intermediate **8**, has been detailed elsewhere (11). The nitrone (**8**) can be synthesised, and was indeed mentioned as an alternative radical trap in our first paper advocating the use of



nitroso-compounds to investigate radical reactions (13). More recently it has found wider application, and is a particularly reactive radical scavenger which can be used in aqueous as well as non-aqueous systems.

Much of the early work from our group was summarised in a short review (14) and will not be re-examined here.[4] One of the more fruitful observations recorded in that early review was the trapping by MNP of trichloromethyl radicals. Under normal experimental conditions, the trichloromethyl nitroxide adduct is converted into the chlorocarbonyl nitroxide **9**, which is readily transformed by alcohols or amines into alkoxycarbonyl or aminocarbonyl nitroxides respectively (Scheme 2) (16). These proved to be exceptionally persistent at very high concentrations, which prompted us to attempt to isolate them.

Initial experiments involving ethoxycarbonyl chloride and *N*-*t*-butylhydroxylamine gave both *N*- and *O*-acylated products, of which the former could be oxidised to the desired ethoxycarbonyl *t*-butyl nitroxide (a blue oil) in good yield by nickel peroxide. Although the product was not particularly stable, a range of acyl *t*-butyl nitroxides, including several biradicals, have now been isolated (17), and crystal structures have been determined for two of these (18).

Equilibration of the hydroxamic acid precursors

[3]For a recent evaluation, see ref. 10.

[4]A more recent review of the spin-trapping technique and its varied applications will be found in ref. 15.

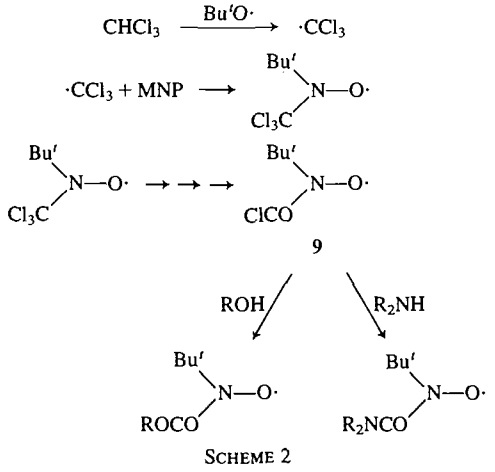
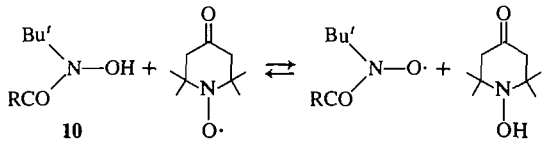
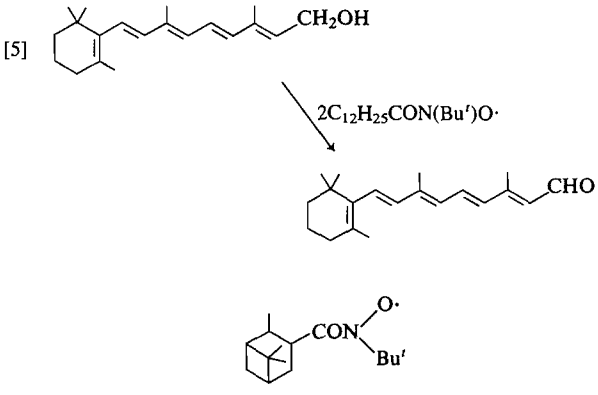


SCHEME 2

**10** for these acyl nitroxides with 2,2,6,6-tetramethylpiperid-4-one-*N*-oxyl, and measurement of the equilibrium constant, allows the strengths of the OH-bonds in the hydroxamic acids to be estimated (19), since the strength of the OH-bond in the hydroxylamine **11** is known. The results indi-



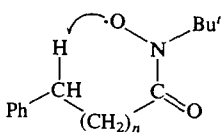
cate that the acyl nitroxides should be appreciably more reactive in radical reactions than are hindered dialkyl nitroxides, and this has been verified in a wide variety of oxidation experiments (20). Two examples are the efficient oxidation of Vitamin A alcohol to retinal by an alkanoyl nitroxide (reaction [5]) (21), and the enantioselective oxidation of benzoin to benzil by the chiral pinane derivative **12** (22).



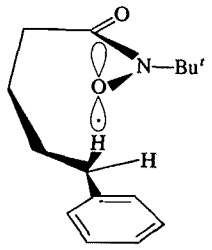
(12)

More recently our attention has been focused on intramolecular reactions, among which is the finding that intramolecular benzylic hydrogen transfer in **13** is faster than that in **14**. This can be accounted for in terms of the relatively planar carbonyl nitroxide "template", the structure of which is supported by the crystallographic results. This relatively rigid $\pi$-electron system is easily spanned by the four-methylene chain in **13** (see structure **13***a*), but much less readily by the two-methylene unit in **14** (23).

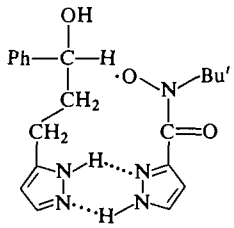
In an unpublished work (24), this type of behaviour is being investigated for intra-complex reactions, and we have obtained preliminary kinetic evidence consistent with intra-complex oxidation of the alcohol **15** by nitroxide **16**. Work is now in hand to further quantify this result, and to overcome the disadvantage of the present system wherein the preferred orientation in the complex is



**13**: $n = 3$
**14**: $n = 1$



**13***a*



**15** **16**

undoubtedly that in which oxidation of the benzylic centre is impossible!

### 2. A water-soluble nitrosopyrazole spin trap

Whilst our primary efforts in nitroxide chemistry have now shifted away from spin trapping to the acyl nitroxides, we have retained an interest in the former topic (15). In the course of their work on nitrone traps, Janzen and his colleagues have synthesised several compounds having water solubility (25), as well as others which are amphiphilic (26). 2-Methyl-2-nitrosopropan-1-ol was the first nitroso spin trap which was studied specifically to take advantage of its water solubility (27). However, this compound shares with MNP the disadvantage of high sensitivity to visible light (in which photo-reactions di-*t*-alkyl nitroxides are produced (28)). The hindered nitrosobenzenes developed by Konaka *et al.*, for example nitrosodurene, have proved to be especially useful spin traps (29). It

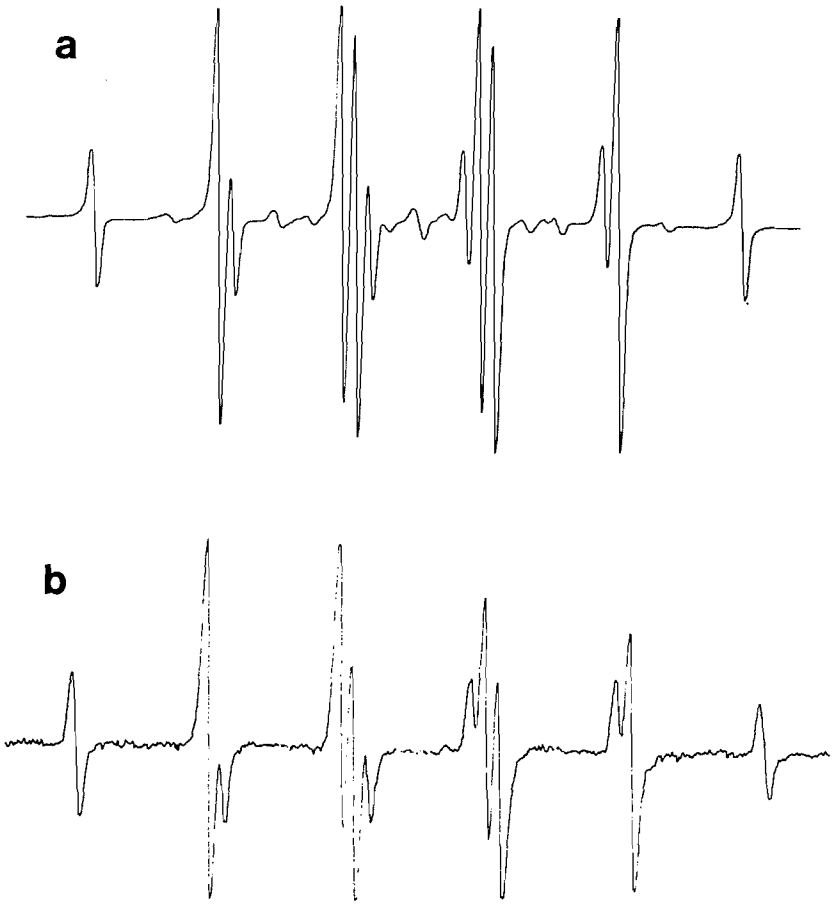

FIG. 1. Electron spin resonance spectra of methyl spin adducts (*a*) from nitrosopyrazole **18** in benzene, and (*b*) from nitrosopyrazole **1** in glacial acetic acid.

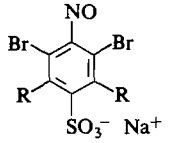
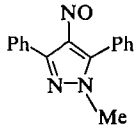
seemed of interest to develop a water-soluble analogue of these compounds, and we recently reported the first examples, namely the nitrosobenzenesulphonate **17***a*, and its dideutero-derivative **17***b* (30). Spectra of spin adducts of **17***b* are uncomplicated by small splittings from the two *meta* protons present in **17***a*.

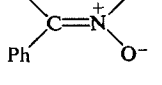
A trap which is closely related to the hindered nitrosobenzenes, and which is introduced for the first time here, is the nitrosopyrazole **18**. In organic solvents this scavenges reactive radicals to give nitroxides whose esr spectra are readily interpreted, since they have no resolvable splittings from magnetic nuclei in the pyrazole unit, and they display quite sharp lines. The spectrum of the methyl adduct is traced in Fig. 1, and splitting constants for a representative range of spin adducts are summarised in Table 1. In addition to the simplicity of spectra of nitroxides derived from **18**, this trap has the advantage of being completely monomeric over a wide range of concentrations in solution, and, as judged by its green colour, is at least partially monomeric as a solid.



**17** a: R = H
b: R = D



**18**



**19**

Simple kinetic experiments have been carried out to compare the reactivity of **18** with that of "phenyl *t*-butyl nitrone" (PBN, **19**) towards primary alkyl radicals produced by thermolysis of lauryl peroxide in benzene at 40°C. Under these conditions, a rate constant of $1.5 (\pm 1) \times 10^7$ L mol$^{-1}$ s$^{-1}$ has been estimated for scavenging of undecyl radicals by **18**, based on a value of $1.3 \times 10^5$ L mol$^{-1}$ s$^{-1}$ for PBN (31). Close scrutiny of the figures in the experimental section of this and the accompanying

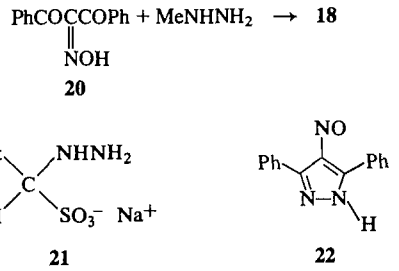
*$(RCO_2)_2$ = appropriate diacyl peroxide; DMSO = dimethyl sulphoxide; AcOH = glacial acetic acid; DTBPO = di-*t*-butyl peroxyoxalate.

paper indicates that the nitrosopyrazole was marginally *more* reactive than the nitrosotriptycene, yet we have preferred values (with large error limits) indicating the opposite to be true. Direct comparison of the two nitrosocompounds towards attack by undecyl radicals showed the nitrosotriptycene to be more reactive than **18** by a factor of 2. We are unable to offer an explanation for this discrepancy. The results, however, are considered valuable in view of the convenience of the traps described and the "factor of two" error limits estimated for other spin-trapping rate constants (15).

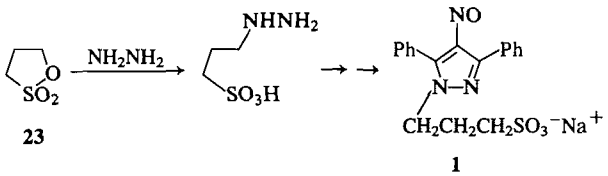
Exposure of solutions of **18** to visible light apparently does not give detectable concentrations of nitroxides under the normal conditions of spin-trapping experiments. In view of this, of the simplicity of the spectra of spin adducts of **18**, and of the fact that, unlike **18**, most of the hindered nitrosobenzene traps (including **17**) are highly associated (as nitroso-dimers) in solution, we have investigated the synthesis of water-soluble analogues of **18**.

The synthesis of **18** is achieved by condensation of the isonitroso-derivative (**20**) of dibenzoylmethane with methylhydrazine (32). Initial attempts to reproduce this chemistry with a hydrazine derivative incorporating a sulphonate salt employed hydrazine analogues of aldehyde bisulphite addition complexes, e.g. **21** (33). These, however, were degraded during attempted condensation, and the only pyrazole which could be isolated was unsubstituted at nitrogen (**22**).

An alternative approach utilised the hydrazine **24**



obtained by hydrazinolysis of the sultone **23** (34). In this case we were successful in isolating **1** as a green solid, readily soluble in water to give green solutions. The spectrum of the methyl spin adduct of **1**, obtained by thermolysis of acetyl peroxide in glacial acetic acid in the presence of **1** is also traced in Fig. 1, and hyperfine splittings of other spin adducts are collected in Table 1. As with **17**, we were unable to characterise either a hydrogen spin adduct or a hydroxyl adduct of **1**.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

A final, and rather curious feature, of importance in connection with foreign-compound metabolism studies, is our failure to detect trichloromethyl adducts to either **1** or **17**, despite the fact that such adducts are easily formed from nitrosodurene or from **18** in organic solvents, and are characterised by well resolved chlorine hyperfine splittings in their esr spectra.

## Experimental

*1-Methyl-4-nitroso-3,5-diphenylpyrazole (18)*

This compound was obtained as a green solid, mp 117–118°C by the method of Boyd and Norris (32). It has been our experience that the product needs careful purification, which may account for the lower melting point (96–97°C) given in the earlier work. We have not, however, encountered any significant differences in behaviour as a spin trap between the initial product and that which has been purified by chromatography and repeated crystallisation. The visible absorbtion of **18** at 738 nm (benzene) had an extinction coefficient of 92, independent of concentration up to at least 0.03 *M*.

*Sodium 3-(4-nitroso-3,5-diphenyl-1-pyrazolyl)propane-1-sulphonate (1)*

An aqueous solution of 3-hydrazinopropane-4-sulphonic acid (2.6 g in 60 mL), prepared from propane sultone by the method of Schindler and Pietrzok (34), was added with stirring to a solution of isonitrosodibenzoylmethane (4.2 g) in methanol (120 mL). The mixture was boiled under reflux for 7 h, after which most of the solvent was removed under reduced pressure. The residual green aqueous solution was washed twice with ether and then dissolved in 3 *M* $H_2SO_4$ (150 mL) and subjected to continuous extraction with ether. Removal of solvent from the dried ether extract gave a brown crystalline solid considered to be the pyrazolylpropanesulphonic acid corresponding to **1**. ($\lambda_{max}$(ethanol) 715 (ε 71)] (2.3 g, 38%, softens 73°C, mp, 100–104°C). This acid (1 g) in water (10 mL) was treated with sodium bicarbonate (0.24 g) at room temperature. After 30 min the green microcrystalline solid which had separated was removed by filtration. Its proton nmr ($D_2O$) showed peaks at δ 2.0–2.45, 2H, broad m; 2.55–2.95, 2H, broad t; 3.95–4.20, 2H, broad t; 7.3–7.8, 10H, m. Found: C 54.2, H 4.0, N 10.1. $C_{18}H_{16}N_3O_4SNa$ requires C 55.0, H 4.1, N 10.7.

*Spin trapping*

Experiments were carried out in solutions deoxygenated by nitrogen bubbling or by vacuum out-gassing. Spectra were recorded using a Varian E4 spectrometer, and were calibrated by comparison with those of di-*t*-butyl nitroxide.

Competition experiments using the nitrosopyrazole **18** and phenyl *t*-butyl nitrone were carried out by preparing solutions of lauryl peroxide and measured quantities of the two traps in benzene at ca. 10°C, and, after degassing, rapidly warming the solutions to 40°C in the cavity of the spectrometer. The initial growth of the two spin adducts was then monitored using spectral lines which showed little or no overlap. Double integration of these permitted relative concentrations to be estimated. The ratios of concentrations remained constant during the initial stages of each reaction, and from these ratios and the known ratios of concentrations of the traps, the relative reactivities of the two traps were deduced. The relative reactivities were found to be independent of the ratios of spin-trap concentrations when these were changed nearly thirty-fold. Results of individual experiments were as follows (in each case the first figure is the ratio [PBN]/[**18**], the second is the estimated reactivity ratio); 193, 0.006; 49.8, 0.009; 24.9, 0.006; 6.7, 0.006. Taking 0.006 as the mean value, and using $1.3 \times 10^5$ L $mol^{-1}$ $s^{-1}$ for the rate of reaction of primary alkyl radicals with PBN in benzene at 40°C (31), we deduce a value of ca. $1.5 (\pm 1) \times 10^7$ L $mol^{-1}$ $s^{-1}$ for the reaction with **18** under these conditions. This conclusion depends on the assumption that trapping of undecyl radicals will occur at a rate similar to that of hexyl and hex-5-enyl radicals used in the earlier work (31).

# Spin trapping with 9-nitrosotriptycene

HARPARKASH KAUR, M. JOHN PERKINS,[1] ANDRÉ SCHEFFER, AND DAVID C. VENNOR-MORRIS
*Department of Chemistry, Chelsea College, Manresa Road, London SW3 6LX, England*

Received September 26, 1981

HARPARKASH KAUR, M. JOHN PERKINS, ANDRÉ SCHEFFER, and DAVID C. VENNOR-MORRIS. Can. J. Chem. **60**, 1594 (1982).

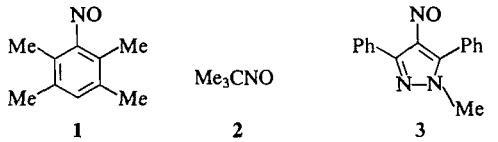
Nitrosotriptycene is found to be a potentially useful spin trap when used in organic solvents; the esr spectra of its spin adducts are simple, but they may show marked temperature dependence due to restricted rotation. Nitrosotriptycene traps primary alkyl radicals with a rate constant of ca. $2 \times 10^7$ L mol$^{-1}$ s$^{-1}$ at 40°C in benzene.

HARPARKASH KAUR, M. JOHN PERKINS, ANDRÉ SCHEFFER et DAVID C. VENNOR-MORRIS. Can. J. Chem. *60*, 1594 (1982).

On a trouvé que le nitrosotriptycène est un capteur de spin potentiel utile lorsqu'on l'utilise dans des solvants organiques. Les spectres de rpe des adduits de spin sont simples mais ils montrent une influence marquée de la température en raison d'une rotation limitée. Le nitrosotriptycène capte les radicaux alkyles primaires avec une constante de vitesse d'environ $2 \times 10^7$ L mol$^{-1}$ s$^{-1}$ dans le benzène à 40°C.

[Traduit par le journal]

For a *C*-nitroso-compound, RNO, to be a good spin trap (1), it should be largely or entirely monomeric in solution, and be reasonably stable to heat, and stable to visible light. Furthermore, in its spin adducts (RR'NO·) there should be minimal interaction between the unpaired electron and magnetic nuclei in the R group derived from the nitroso-compound, so that esr spectra of these adducts are simple and show easily identified hyperfine splittings from nuclei in the radicals that are trapped. Amongst the most commonly used nitroso-traps, nitrosodurene (ND; **1**) is quite strongly associated in solution as the nitroso-dimer (2), and 2-methyl-2-nitrosopropane (MNP; **2**) is well known to be sensitive to red light, rapidly giving di-*t*-butyl nitroxide on photolysis. The spectra of adducts of these two traps also suffer from line-broadening due to unresolved splitting by the protons in the duryl and *t*-butyl groups respectively, though in both cases narrower spectral lines (and improved resolution) have been achieved by deuteration (3, 4).

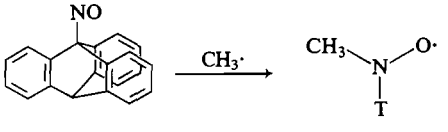


**1**

$Me_3CNO$

**2**

**3**



**4** = TNO **5**

A useful and readily accessible alternative nitroso-trap, the nitrosopyrazole **3**, as well as a water-soluble analogue, has been introduced in the accompanying paper, and we now outline results which suggest that 9-nitrosotriptycene, **4** (TNO), whilst less readily available, may also be a useful spin trap for investigations using organic solvents.

Compound **4** (5) was obtained as a pale blue solid which gives blue solutions in organic solvents. We have detected no evidence for association up to a concentration of 0.1 *M* in benzene at room temperature. Unlike those of MNP, its solutions do not give esr signals on exposure to visible light. Presumably, since the trivalent carbon in the 9-triptycyl radical cannot become planar, and the unpaired electron is in an orbital orthogonal to the $\pi$-electrons of the benzene rings, the triptycyl–nitrogen bond in **4** is much stronger than that in MNP and a quantum of red light absorbed by the molecule carries insufficient energy to cause dissociation. We have made no attempt to study the ultraviolet photochemistry of **4**, except in the esr spectrometer, where signals believed to be due to ditriptycyl nitroxide are observed. This is discussed briefly at the end of this paper.

Figure 1 shows the spectrum of the methyl spin adduct **5** of **4**. Although in this example it is at once clear that there is no resolvable hyperfine structure in the spectrum other than that from nitrogen and from the methyl protons, in some spin-adduct spectra there was evidence for weak interaction with three equivalent protons from the triptycene nucleus (the "*peri*" protons?). Table 1 lists splitting parameters found for spectra of representative nitrosotriptycene spin adducts.

The spectrum of the butoxymethyl spin adduct **7** was first observed in experiments in which substan-

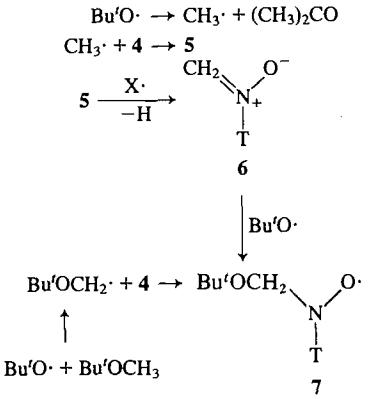
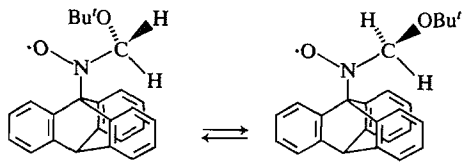
tial quantities of di-*t*-butyl peroxyoxalate had decomposed in benzene solutions of **4**. Its appearance in that system may be attributed to the formation of the methyl spin adduct and its subsequent oxidation *in situ* to the methylene nitrone **6**. Trapping of butoxy radicals by **6** then gives **7**, the identity of which was confirmed by an experiment in which butoxymethyl radicals were generated by



hydrogen abstraction from *t*-butyl methyl ether in the presence of **4**. The temperature dependence of the spectrum of **7** (Fig. 2) is of interest, since it may be interpreted in terms of a rocking of the butoxymethyl group; possibly the methylene hydrogens may be meshing with the triptycene cogwheel (structures *7a* ⇌ *7b*). In any case, it is important to recognise that *free* rotation of the butoxymethyl group is not required for the methylene protons to become equivalent. We estimate a free energy barrier of ca. 6.5 kcal $mol^{-1}$ at 17°C for the conformational change responsible for the observed change in spectrum.



*7a* *7b*

There has been interest recently in the meshing of two triptycene residues attached to a common atom (6). Although we obtained a spectrum attributed to ditriptycyl nitroxide both by photolysis (see above) and by thermolysis of bis-9-triptoyl peroxide in benzene in the presence of **4**, this showed only nitrogen splitting and the question of triptycyl rotation could not be investigated. The nitrogen splitting in this nitroxide is relatively small, but the *g*-value of 2.0062 is in the range expected for a dialkyl nitroxide, so that the alternative alkoxyaminyl structure, TONT, seems unlikely for the radical responsible for this spectrum. It may be noted that $a_N$ for the relatively hindered isopropyl and

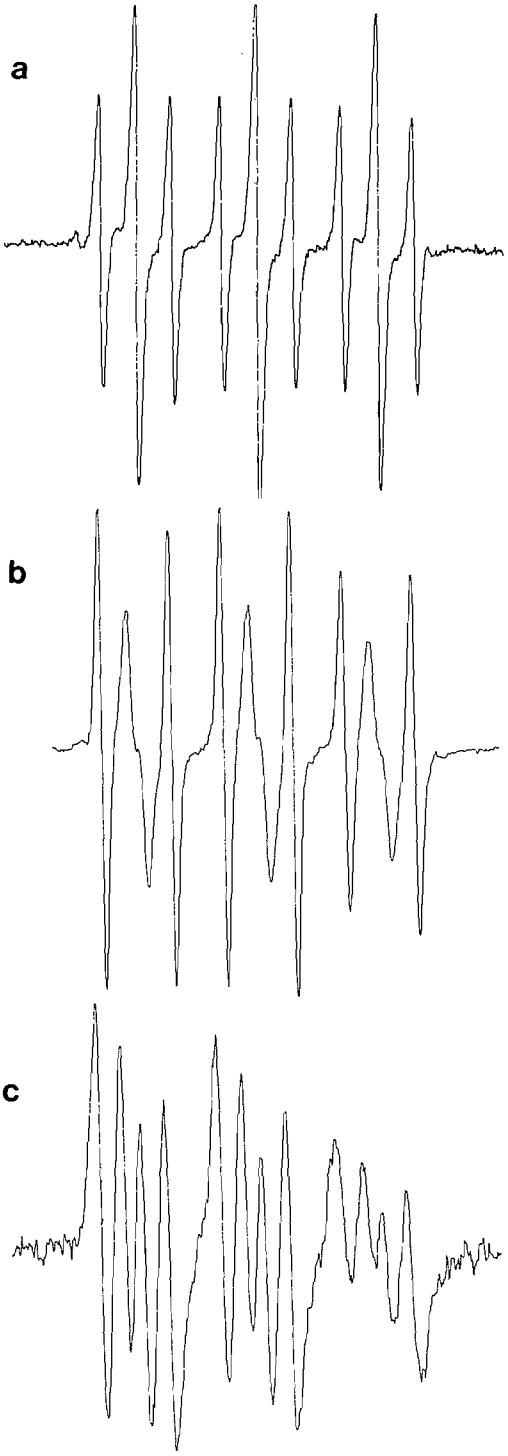

FIG. 2. Electron spin resonance spectra of the $Bu^tOCH_2^{\bullet}$ spin adduct of 9-nitrosotriptycene in *t*-butyl methyl ether (*a*) at 50°C; (*b*) at −18°C; (*c*) at −57°C.

cyclohexyl spin adducts are also small. In view of this, the rather larger value of $a_N$ found for the *t*-butyl adduct, formed by photolysis of MNP in the presence of excess **4**, may seem surprising. However a similar spectrum was obtained in an experiment in which ditriptoyl peroxide was allowed to decompose in the presence of MNP. A further point of interest is that the spectrum of the cyclohexyl adduct of **4** does not show long-range splittings similar to those observed in the spectrum of MNP–cyclohexyl spin adduct.

Finally, the reactivity of **4** towards primary alkyl radicals was estimated by allowing it to compete with PBN for undecyl radicals formed by thermolysis of lauryl peroxide in benzene. At 40°C, a value of $2(\pm 1) \times 10^7$ L mol$^{-1}$ s$^{-1}$ was estimated. The large error limits reflect the current level of precision of these measurements (2).

## Experimental

*Materials*

9-Nitrotriptycene was prepared from 9-nitroanthracene by the method of Bowden *et al.* (7) and converted into 9-nitrosotriptycene by the method of Theilacker and Beyer (5). Di-9-triptoyl peroxide was derived from triptoic acid by the method of Bartlett and Greene (8).

*Spin trapping*

Experiments followed the same general procedure as indicated in the accompanying paper. In the competition study using PBN and nitrosotriptycene in benzene at 40°C, the ratio of concentrations of traps in individual experiments ([PBN]/[**4**]) and calculated relative reactivities were as follows: 273, 0.007; 193, 0.007; 50, 0.006; 25, 0.007. From these, the mean reactivity ratio was taken to be 0.007, whence the rate constant of $2(\pm 1) \times 10^7$ L mol$^{-1}$ s$^{-1}$ is estimated for trapping of undecyl radicals by nitrosotriptycene in benzene at 40°C. This is based on a value of $1.3 \times 10^5$ L mol$^{-1}$ s$^{-1}$ for PBN under these conditions (9) and depends on the assumption that there is negligible difference between the rates of trapping of undecyl and those of hexyl and hexenyl radicals (9).

# Spin trapping of the azide radical with nitroso compounds[1]

WALTER KREMERS, GRANT W. KOROLL, AND AJIT SINGH[2]

*Medical Biophysics Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Research Company, Pinawa, Man., Canada R0E 1L0*

Received September 19, 1981

WALTER KREMERS, GRANT W. KOROLL, and AJIT SINGH. Can. J. Chem. **60**, 1597 (1982).

Azide radicals ($N_3^{\cdot}$) are formed in aqueous solutions by the reaction of hydroxyl radicals ($^{\cdot}OH$) with azide anions ($N_{3aq}^{-}$). Azide radicals have been spin trapped with three nitroso spin traps: nitrosodurene (ND), 2,6-dideutero-3,5-dibromo-4-nitrosobenzene sulfonate (DDNBS), and 2-methyl-2-nitrosopropane (MNP). The electron spin resonance (esr) spectra show the presence of two molecules of the spin traps in the spin-trapped species.

WALTER KREMERS, GRANT W. KOROLL et AJIT SINGH. Can. J. Chem. **60**, 1597 (1982).

On obtient les radicaux azotures ($N_3^{\cdot}$) en solution aqueuses en faisant réagir les radicaux hydroxyles ($^{\cdot}OH$) avec les anions azotures ($N_3^{-}{}_{aq}$). On a capté les radicaux azotures avec trois capteurs de spin du type nitroso: le nitrosodurène (ND), le sulfonate de dideutéro-2,6 dibromo-3,5 nitroso-4 benzène (DDNNB) et le méthyl-2 nitroso-2 propane (MNP). Les spectres de rpe montrent la présence de deux molécules de capteurs de spin dans les espèces piégées.

[Traduit par le journal]

## Introduction

The azide radical ($N_3^{\cdot}$) has been trapped by several spin traps (1–6). The spectra of nitrone adducts are straightforward and show contributions of one nitrogen from the trap and one additional nitrogen from the azide radical (1–6). The nitrosodurene (ND) adduct, however, indicates the presence of two equivalent nitrogens and one nonequivalent one (hfs: $a_N^{1,2} = 0.73$ mT, $a_N^3 = 0.23$ mT) (4, 5). Rehorek and Hennig (5) have suggested that, with ND, the adduct dissociates to produce $N_2$ and the residual radical adds onto another molecule of the spin trap. We have, therefore, undertaken further work with nitroso spin traps to try to resolve the identity of the adduct.

Azide radicals were generated by uv photolysis of a 1% solution of $H_2O_2$ in the presence of $NaN_3$ (1).

$N_3^{\cdot}$ was trapped with 2,6-dideutero-3,5-dibromo-4-nitrosobenzene sulphonate (DDNBS) (hfs: $a_N^{1,2} = 0.71$ mT, $a_N^3 = 0.27$ mT) and the well-known trap methylnitrosopropane (MNP) (hfs: $a_N^{1,2} = 0.11$ mT, $a_N^3 = 1.29$ mT). Both spectra show the presence of two equivalent nitrogens and one nonequivalent one. We further trapped azide radicals generated from 100% $^{15}N$-labelled $NaN_3$ with ND. The quintet of triplets collapsed into a quintet of doublets (hfs: $a_N^{1,2} = 0.77$ mT, $a_N^3 = 0.33$ mT). These results show that the two equivalent nitrogens originate from ND and only one from the azide radical, i.e. the adduct contains two ND molecules and one azide radical.

# Electron spin resonance studies of the reactions of sorbate with nitrite in the presence of a spin trap

AVINASH JOSHI, DENNIS M. HINTON, AND GEORGE C. YANG[1]

*Food and Drug Administration, Washington D.C. 20204, U.S.A.*

Received October 8, 1981

AVINASH JOSHI, DENNIS M. HINTON, and GEORGE C. YANG. Can. J. Chem. **60**, 1598 (1982).

An esr spectrum was generated when a spin trap, *t*-nitroso butane (*t*NB), was added to potassium sorbate solution at pH of 6.4. This spectrum can be explained by the abstraction of allylic hydrogen by $NO_2$, generated by the decomposition of *t*NB, followed by spin trapping of the radical product. With increasing concentration of $NO_2$, which was accomplished by either the addition of sodium nitrite or by lowering the pH to cause rapid decomposition of *t*NB, a different esr spectrum was observed. This spectrum can be accounted for by a radical formed by addition of $NO_2$ to the 4,5 double bond of the sorbate and subsequent trapping by *t*NB.

AVINASH JOSHI, DENNIS M. HINTON et GEORGE C. YANG. Can. J. Chem. **60**, 1598 (1982).

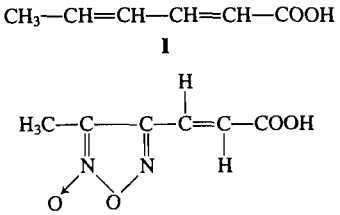
On a enregistré le spectre de rpe du capteur de spin, nitroso *tert*-butane (*t*NB), dans une solution de sorbate de potassium à un pH de 6,4. On peut expliquer le spectre par l'élimination de l'hydrogène allylique par le $NO_2$, provenant de la décomposition du tNB, suivie de la capture du produit radicalaire. On observe un spectre de rpe différent en augmentant la concentration $NO_2$ soit par l'addition de nitrite de sodium soit par une diminution du pH provoquant une décomposition rapide du *t*NB. On peut attribuer ce spectre à un radical provenant de l'addition de $NO_2$ sur la double liaison en positions 4,5 du sorbate suivie du piègeage par le *t*NB.

[Traduit par le journal]

## Introduction

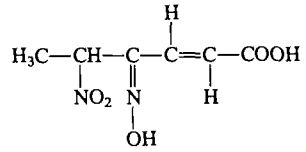
The implication of nitrites as precursors in the formation of certain carcinogenic nitrosamines has led to studies of the use of other food preservatives. Since potassium sorbate exhibits both fungicidal and bacteriostatic activity, reduction of nitrite concentration combined with relatively high concentrations of sorbate has been tested experimentally as a substitute for nitrite alone (1). Several reports have appeared which address the potential toxicity of the combination of sorbate and nitrite (2, 3).

At low pH, 2 to 5, sorbic acid, **I**, has been shown to react with sodium nitrite (4–6). Recently Osawa *et al.* (7) isolated and identified three new compounds, a furoxan derivative, **II**, and its two precursors, **III** and **IV**, in the reaction of sorbate with sodium nitrite. They further proposed that sorbate can be easily transformed to compounds **II** and **III** by the addition of nitro and nitroso groups to its 4,5 double bond. In a previous study, we also investigated the conditions under which sorbate and nitrite react (8). In the present study, we have attempted to spin trap the transient free radicals generated in this reaction in order to gain additional information on the reactive intermediates which led to the formation of the final product.



**I**

**II**



(*syn* and *anti*)

**III, IV**

## Experimental

Potassium sorbate was obtained from Monsanto Chemical Co. Sodium nitrite was Fisher Certified ACS Grade. Tertiary nitrosobutane (*t*NB) was obtained from Aldrich Chemical Co. Inc. All chemicals were used without further purification. Hydrochloric acid was used to attain pH 3.5 to 4.0. To improve solubility, sorbate was dissolved in 50% ethanol in the case of low pH. Electron spin resonance spectra were obtained on a Varian E-9 Spectrometer. Chromatographic separations were done using a Perkin Elmer 601 HPLC in conjunction with a Perkin Elmer LC55 UV detector at 235 nm. A reverse phase PXS 5/25 ODS Whatman column was used at 50°C. The composition of the elution solvent was 60% water, 25% acetonitrile, and 15% methanol.

*pH 6.4*

When 0.0125 *M* *t*NB was present in a solution of 0.5 *M* sorbate, 0.05 *M* phosphate buffer, and 25% methanol at a final pH of 6.4, the esr spectrum shown in Fig. 1 was observed. This spectrum consists of a triplet (N) and its $^{13}C$ satellite lines arising from di-*t*-butyl nitroxide radical, and also contained another triplet with $A_N = 15.3$ G, further split into a triplet of intensity ratio 1:2:1 with $A_H = 5.8$ G. Sargent and Gardy (9) have observed a similar spectrum from the addition of $^{\bullet}CH_2OH$ to

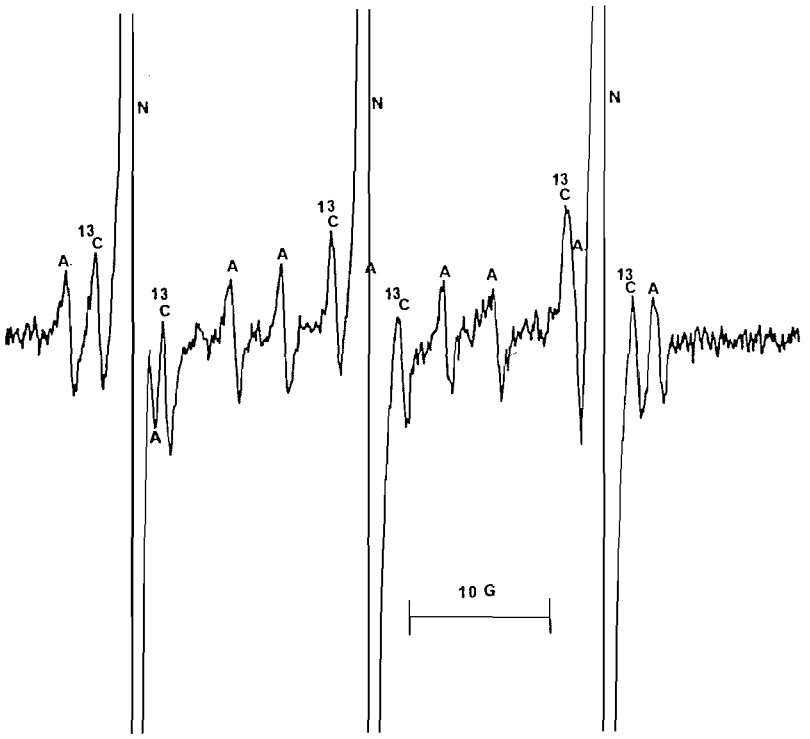

FIG. 1. Electron spin resonance spectrum observed in the mixture of 0.0125 *M* *t*NB, 0.5 *M* potassium sorbate, 0.05 *M* phosphate buffer in 25% MeOH at pH 6.4. N = di-*t*-butyl nitroxide; $^{13}C{=}^{13}C$ lines of the di-*t*-butyl nitroxide; A = reaction product.

*t*NB with $A_N = 14.5$ G and $A_H = 4.5$ G. In our experiments, *t*NB was dissolved in both methanol and methanol-$d_4$ and no spectral differences were observed. This indicated that the reaction of *t*NB with methanol was not responsible for the observed spectrum.

Pryor and Lightsey (10) proposed that at low concentration of nitrogen dioxide, nitrogen dioxide reacts with cyclohexene almost exclusively by abstraction of allylic hydrogen.

$$NO_2 + \text{—CH=CH—CH}_2 \rightarrow HONO + \text{—}\bar{C}\text{H—}\dot{C}\text{H—}\bar{C}\text{H—}$$

Based on this mechanism, as well as the observed esr spectrum, the following is proposed for the reaction between *t*NB spin trap and sorbate.

Radical **V**, which contains one nitrogen and two equivalent protons, is consistent with the observed spectrum.

$$2(CH_3)_3C\text{—}N{=}O \rightarrow (CH_3)_3C\text{—}\underset{\displaystyle C(CH_3)_3}{\underset{|}{N}}\text{—}O\cdot + NO$$

$$NO + O_2 \rightarrow NO_2$$

$$NO_2 + CH_3\text{—}CH{=}CH\text{—}CH{=}CH\text{—}COOH \rightarrow$$

$$HNO_2 + \bar{C}\bar{H}_2\text{—}\dot{C}\bar{H}\text{—}\bar{C}\bar{H}\text{—}CH{=}CH\text{—}COOH \xrightarrow{(CH_3)_3CN{=}O}$$

$$(CH_3)_3C\text{—}\underset{\displaystyle O\cdot}{\underset{|}{N}}\text{—}CH_2\text{—}CH{=}CH\text{—}CH{=}CH\text{—}COOH$$

**V**

When 0.25 *M* sodium nitrite was present in the reaction mixture of sorbate and *t*NB, as described above, and again pH measured to be 6.4, an esr spectrum shown in Fig. 2 was obtained. This spectrum contains a triplet of $A_N = 17.0$ G due to di-*t*-butyl nitroxide and another triplet with $A_N = 15.9$ G, further split into doublets with $A_H = 3.5$ G.

In acidic medium nitrite decomposes into nitric oxide which is easily oxidized to nitrogen dioxide. It has been demonstrated that $NO_2$ adds to the double bonds of the unsaturated fatty acids (11, 12).

$$NO_2 + \text{—C=C—} \rightleftarrows O_2N\text{—}\dot{C}\text{—C—}$$

Pryor and Lightsey (10) also demonstrated this reaction mechanism when the concentration of $NO_2$ is relatively high. Based on this assumption and the esr spectrum, we propose the following reaction in the mixture of sorbate, nitrite, and *t*NB.

$$\text{Sorbate} + NO_2 \rightarrow CH_3\text{—}\underbrace{\dot{C}H\text{—}\dot{C}H}_{NO_2}\text{—}CH{=}CH\text{—}COOH$$

$$\xrightarrow{(CH_3)_3C\text{—}NO} CH_3\text{—}\underbrace{CH\text{—}CH}_{NO_2,\ N\text{—}O\cdot}\text{—}CH{=}CH\text{—}COOH$$

$$\text{(}C(CH_3)_3\text{ on N)}$$

**VI**

Although not considered in this paper, the presence of NO in this mixture and its possible involvement in this reaction should not be ruled out.

*pH 3–4*

When 0.0125 *M* or 0.145 *M* *t*NB was present with 0.5 *M* or

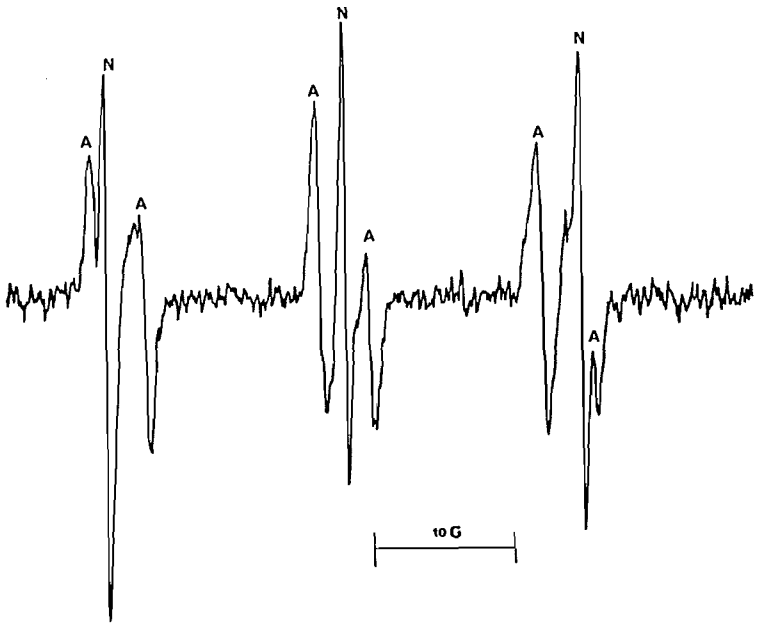

FIG. 2. Electron spin resonance spectrum observed in the mixture as in Fig. 1, with the presence of 0.25 *M* $NaNO_2$. N = di-*t*-butyl nitroxide; A = reaction product.

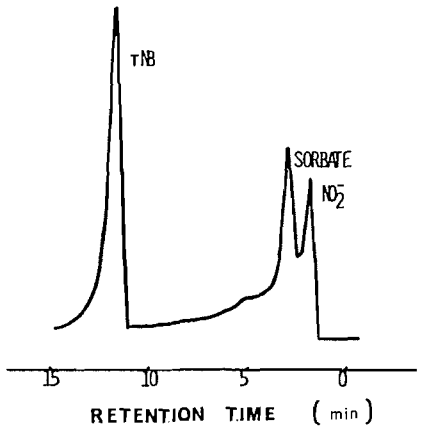

FIG. 3. HPLC chromatograph showing the retention times for $NO_2^-$, *t*NB, and sorbate.

0.225 *M* potassium sorbate respectively, in 50% ethanol and the pH was adjusted to 3.5, using HCl or HBr, an esr spectrum identical to that in Fig. 2, rather than to Fig. 1, was observed. In acidic medium, *t*NB decomposes much more readily, resulting in high $NO_2$ concentration. The addition of $NO_2$ to the 4,5 double bond of sorbate now becomes more favorable as compared to H· abstraction. This mechanism is the same as in the mixture of *t*NB, sorbate, and nitrite at pH 6.4, yielding radical **VI** whose esr spectrum is presented in Fig. 2.

When *t*NB and sorbate were mixed at pH 3.5, an additional peak in the HPLC chromatogram, as shown in Fig. 3, indicated the presence of nitrite, on the basis of the known retention time. Thus, with *t*NB in acidic medium or with nitrites in pH 6.4 solution, nitrite ions are evidently involved in the reaction. This accounts for the observation of identical esr spectra for *t*NB with sorbate in low pH or nitrite plus *t*NB with sorbate at pH 6.4. The same esr spectrum was obtained when nitrite was also present in the reaction mixture at low pH, which favors the formation of $HNO_2$.

## Conclusions

Depending upon the pH range and the presence or absence of nitrite, two distinct esr spectra were observed when nitroso spin trap (tNB) is added to sorbate solution. At pH of 6.4, spectrum whose hyperfine parameters corresponding to that of the addition of $^{\cdot}CH_2$— to *t*NB was observed. We attribute the formation of this radical to the abstraction of the allylic hydrogen of the sorbate by $NO_2$ and the subsequent trapping by *t*NB. Since the source for $NO_2$ primarily depends on the degradation of *t*NB, $NO_2$ concentration remains fairly low. However, if one substantially increases the $NO_2$ concentration by either the addition of nitrite or by lowering the pH to hasten *t*NB degradation, a different esr spectrum appears. The spin trapping of the radical created by the $NO_2$ addition to the 4,5 double bond of sorbate by *t*NB has hyperfine parameters consistent with the observed spectrum.

The reaction mechanisms for nitrogen dioxide are in complete agreement with the recent finding of Pryor and Lightsey (10). At high $NO_2$ concentrations, they demonstrated that $NO_2$ adds to the double bonds of the unsaturated fatty acids while at low concentrations of $NO_2$, abstraction of allylic hydrogen dominates.

We are currently isolating reaction products,

including those formed at the higher pH range, in order to further understand the chemistry of the interactions of sorbate and nitroso compounds.

# Spin-trapping in early and some recent nitroso chemistry

TH. J. DE BOER

*Laboratory for Organic Chemistry, University of Amsterdam, Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands*

Received October 10, 1981

TH. J. DE BOER. Can. J. Chem. **60**, 1602 (1982).

The radical scavenging properties of nitroso compounds were discovered accidentally during investigations of photochemical nitrosation of hydrocarbons with alkyl nitrites. Depending on the nature of substrates and nitrosating agent, various nitroxides can be generated. Identification of these nitroxides by their esr spectra has triggered the development of the spin-trapping technique which has been useful in the elucidation of many organic radical reaction mechanisms. Recent studies have shown that the behavior of nitrosocyclopropanes and α-chloro-nitroso alkanes is unorthodox upon irradiation. Dark reactions of α-chloro-nitroso alkanes with Grignard reagents lead to nitrones by a polar mechanism and to oximes by electron transfer. In the latter case high yields of hydrocarbon dimers are sometimes obtained from the Grignard and other organometallic reagents, despite the presence of nitroso compounds. In the postulated reaction mechanism dimers and higher associates from the organometallic reagent play an essential role.

TH. J. DE BOER. Can. J. Chem. **60**, 1602 (1982).

On a découvert accidentellement les propriétés de pièges à radicaux des composés nitroso en étudiant la nitrosation photochimique des hydrocarbures par les nitrites d'alkyles. En fonction de la nature des substrats et de l'agent nitrosant, on peut produire divers nitroxydes. L'identfication de ces nirtoxydes, d'après leurs spectres de rpe, a permis le développement de la technique de captage de spin qui est très utile pour clarifier plusieurs mécanismes de réactions radicalaires organiques. Des étudés récentes ont montré que le comportement des nitroso-cyclopropanes et des α-chloro-nitroso alcanes est inhabituel lors de l'irradiation. La réaction des α-chloro-nitroso alcanes avec les réactifs de Grignard à l'obscurité conduit aux nitrones selon un mécanisme polaire et aux oximes par transfert d'électron. Dans ce dernier cas, on obtient quelquefois d'excellents rendements d'hydrocarbures dimères à partir du réactif de Grignard ou d'autres réactifs organométalliques, en dépit de la présence des compos és nitroso. Dans le mécanisme de réaction proposé, les molécules dimères et celles possédent un plus haut degré d'association à partir du réactif organométallique jouent un rôle essentiel.

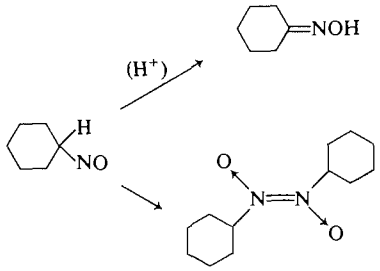
## Introduction

Photochemical nitrosation of hydrocarbons was developed for industrial purposes in the sixties, especially in Japan, and also studied in Germany along closely related routes. In the Toray process (1) the nitrosating agent is nitrosyl chloride while in the so-called Tubingen method (2) it consists of a mixture of NO and $Cl_2$. A quantum yield below 1.0 is in accordance with the following scheme for NOCl.

$$\text{NOCl} \xrightarrow{h\nu} \text{NO}^{\cdot} + \text{Cl}^{\cdot}$$
$$\text{RH} + \text{Cl}^{\cdot} \longrightarrow \text{R}^{\cdot} + \text{HCl}$$
$$\text{R}^{\cdot} + \text{NO}^{\cdot} \longrightarrow \text{RNO}$$

Chlorine atoms are generated photochemically and these abstract hydrogen from the hydrocarbon RH, leaving a radical R· which combines with NO. There is no selectivity problem for hydrogen abstraction from cyclohexane and this is one reason why this abundant petrochemical has found wide application. The product nitrosocyclohexane is easily isomerized to the oxime, which in turn can undergo Beckmann rearrangement to caprolactam, the monomer for the production of nylon-6. In the Japanese as well as in the German process, the presence of acid makes sure that the isomerization of nitrosocyclohexane to the oxime is fast and far more rapid than dimerization, which normally takes place in neutral medium.



*Photochemical nitrosation with* tert-*butylnitrite*

When we tested *tert*-butylnitrite as an alternative less corrosive nonhalogen-containing nitrosating agent for cyclohexane, dimeric nitrosocyclohexane could be isolated in 80% yield (3). Under the reaction conditions there is little oxime formation, because the liberated *tert*-butanol is a much poorer catalyst for the isomerizations of the nitroso compound (at room temperature) than mineral acid and consequently dimerization prevails. At elevated

$$t\text{-BuONO} \xrightarrow{h\nu} t\text{-BuO}^{\cdot} + \text{NO}^{\cdot}$$
$$t\text{-BuO}^{\cdot} + \text{RH} \longrightarrow \text{R}^{\cdot} + t\text{-BuOH}$$
$$\text{R}^{\cdot} + \text{NO}^{\cdot} \longrightarrow \text{RNO} \rightarrow \text{dimer}$$

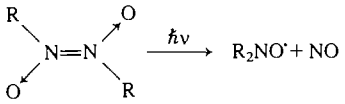
temperatures the dimer dissociates and the monomer isomerizes to oxime, as outlined in the relevant patent (3). Yet it is inadvisable to carry out the photochemical nitrosation above room temperature, because this has a detrimental effect on combined product yields of nitroso-dimer and oxime. It will be shown that a shift in the nitrosoalkane dimer/monomer equilibrium is responsible for this effect.

Poor yields are also obtained at low temperatures. For instance at −60°C the photochemically produced monomer dimerizes so slowly that it becomes subject to side-reactions other than isomerization to the oxime. Electron spin resonance studies are helpful in explaining the nature of side-reactions.

*Mechanism of nitroxide formation*

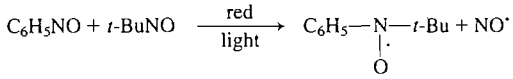
At the time it was known that nitroso compounds can give rise to radical reactions, but in the mid-sixties German and American investigators postulated that nitroso compounds "which exist only as monomers do not give disubstituted nitroxides on irradiation" (4). It was therefore thought that the dimer is an essential precursor for nitroxide formation.



A study of the combined influence of temperature and wavelength of incident light on nitroxide formation provided a more realistic mechanistic picture. Irradiation of solutions of nitrosocyclohexane with red light ($\lambda > 660$ nm) gave no esr signals, but when the temperature was raised above room temperature (40°C) the esr spectrum of dicyclohexylnitroxide appeared (5). The red light cannot be absorbed by the dimer simply because it lacks an absorption band in this spectral region. But at elevated temperatures the dimer dissociates partly and the monomer thus formed can absorb visible light which triggers homolytic rupture of the weak R—NO bond. It should be noted that the dimer can also dissociate under the influence of uv light.

Radicals R generated by R—NO homolysis add to the (monomeric) nitroso compound with nitroxide formation, providing the key step in what later has aptly been described by Janzen and Blackburn as spin-trapping (6). The technique involves capture of a short-living radical by a suitable scavenger (nitroso compound or nitrone) and conversion into a more persistent (nitroxide) radical (7). The nitroso dimer/monomer equilibrium in solution lies far more to the monomer side for tertiary nitroso alkanes than for primary and secondary nitroso compounds. Consequently nitroxide formation at low temperatures (−100°C) is possible by irradiation of *tertiary* nitroso compounds with red light.

As to the behaviour of aromatic nitroso compounds, the main difference from their aliphatic counterpart lies in a stronger C—NO bond and a somewhat longer wavelength absorption ($\lambda_{max}$ = 750 nm). The $n-\pi^*$ excitation energy in (monomeric) nitrosobenzene turns out to be insufficient for C—NO homolysis and therefore nitrosobenzene gives no nitroxide upon irradiation with red light. This property can be exploited for the generation of mixed alkyl-aryl nitroxides from a monomeric aliphatic nitroso compound in the presence of an excess of an aromatic nitroso compound (5).

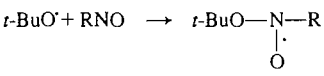


At increasing concentrations of *t*-BuNO the formation of the symmetrical di-*tert*-butylnitroxide becomes more and more important. The symmetrical diphenylnitroxide is only formed with actinic light. It so happens that alkyl nitrites have their absorption maximum round 380 nm which is just in between the absorption maxima of dimeric and monomeric nitroso compounds (approx. 300 and 700 nm respectively). In the photochemical nitrosation of cyclohexane with *tert*-butyl nitrite, optimum yields of (dimeric) nitrosocyclohexane were obtained by irradiation at wavelengths around 400 nm (3).

Mechanistic aspects of nitroxide formation continue to attract attention, and "spontaneous" radical formation can be due to inadvertent homolysis (27).

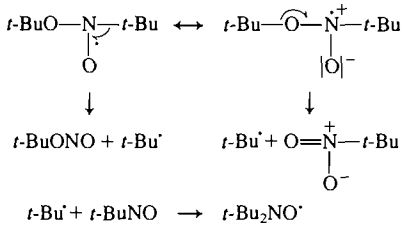
*Photochemical and thermal generation of alkoxynitroxides*

In photochemical nitrosation of toluene, ethylbenzene, and cumene with *tert*-butyl nitrite at −40°C (a temperature where the monomeric nitroso compound is not immediately removed by dimerization), esr studies indicated that beside nitroxides with an $a_N$ value of 15 Gauss, typical for dialkyl nitroxides, there were also signals pointing to the presence of nitroxides with the much higher $a_N$ value of 28 Gauss (8). These were identified as *tert*-butoxy-aralkyl nitroxides, the simplest esr spectrum arising from cumene because of the



absence of β-hydrogens in the nitroxide. Each line in the nitroxide obtained similarly from ethylbenzene (R = $C_6H_5CHCH_3$) appeared as a doublet, and from toluene (R = $C_6H_5CH_2$) as a triplet, in accordance with the increasing number of β-hydrogens responsible for further splitting in the nitroxide.

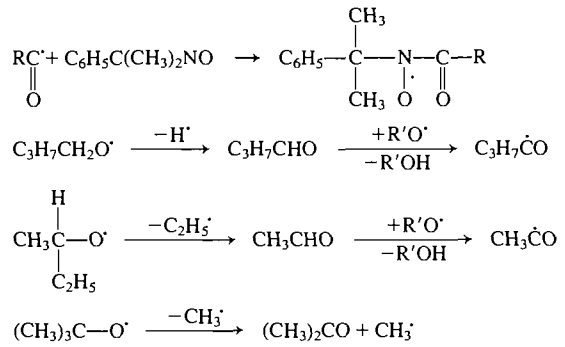
The same type of nitroxides with a similarly high $a_N$ value could be obtained from an unambiguous nonphotochemical source for *tert*-butoxy radicals, i.e. di-*tert*-butyl peroxalate. When this decomposes slowly at 20°C in the presence of *t*-BuNO, the esr spectrum of *tert*-butoxy-*tert*-butyl nitroxide with $a_N$ = 28.3 Gauss appears. It was noticed that the original spectrum of *tert*-butoxy-*tert*-butyl nitroxides ($a_N$ = 28.1) is gradually replaced by that of di-*tert*-butyl nitroxide ($a_N$ = 15.4 Gauss), presumably because the nitroxide can undergo a β-fission in two ways, each producing a *tert*-butyl radical. Some of the latter nitroxide may arise by trivial thermal dissociation of *t*-BuNO.



*Photochemical and thermal generation of acyl-nitroxides*

In all previous experiments on photochemical nitrosation, the nitrosating agent was *tert*-butyl nitrite. When this is replaced by *s*-butyl or by *n*-butyl nitrite in the photochemical nitrosation of cumene, esr spectra of reaction mixtures alter distinctly. The most conspicuous change is the appearance of signals pointing to the presence of a new nitroxide with $a_N$ around 8 Gauss. We have attributed this to an acylnitroxide (9), formed by addition of acyl radicals to the nitrosation product 2-nitroso-2-phenyl-propane ("nitrosocumene"). Acyl radicals arise in turn by β-fission of *s*-butoxy and *n*-butoxy radicals generated in nitrite-photolysis.

The strongest signals are obtained with *n*-butyl-nitrite, presumably because the intermediary *n*-butoxy radical can form an aldehyde easily by β—C—H fission, e.g. by disproportionation. *s*-Butoxy radicals must undergo a more difficult β—C—C fission in order to form an aldehyde, while *tert*-butoxy radicals only produce ketones by β-fission. Aldehydes being the essential precursors for acyl radicals, it is clear that acylnitroxides are



only formed during photolysis of hydrocarbons with *n*-butyl and *s*-butyl nitrites, and never with *tert*-butyl nitrites. In principle methyl radicals can be generated in the latter case but these have never been captured as spin adducts, possibly because rapid disproportionation of methyl *tert*-butyl nitroxide prevents detection. Acylnitroxides can also be formed by photolysis of *t*-BuNO in the presence of aldehydes. The esr signals become stronger by supplying some *tert*-butyl peroxalate as a convenient source of *tert*-butoxy radicals. These abstract aldehydic hydrogen more efficiently than the radical generated by photolysis of *t*-BuNO.

The preceding sections illustrate how monomeric nitroso compounds can function as radical traps. As such, 2-methyl-2-nitrosopropane ("*tert*-nitrosobutane") has found wide application, despite the precautions that must be taken to avoid unwanted photochemical or thermal formation of symmetrical di-*tert*-butylnitroxide.

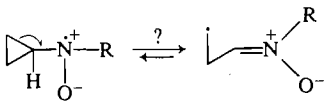
On the other hand, the nitroso compound has the advantage that in its spin adducts the scavenged radical is directly attached to the nitroxide nitrogen and will therefore exert a relatively large influence on $a_N$. Furthermore, the esr spectrum of the spin adduct is likely to reveal splittings from magnetic nuclei in the trapped radical, which will greatly facilitate its identification. For a comparison with alternative spin traps we refer to Perkin's recent review (10).

*Reactivity of nitrosocyclopropanes*

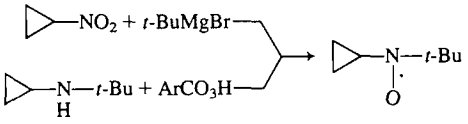
As part of our interest in small ring chemistry we were prompted to investigate the properties of nitroxides with a cyclopropyl group. In their polar structure, nitroxides have an electron deficiency on nitrogen and the question is whether this can induce opening of a neighbouring small ring, as it does for instance in related cyclopropylmethyl (11) and cyclopropyloxy radicals (12).

Applying the preparation of a nitroxide from a nitro compound and a Grignard reagent (13) we found that nitrocyclopropane reacts with *t*-BuMgBr

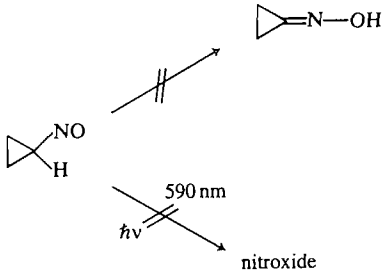
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.



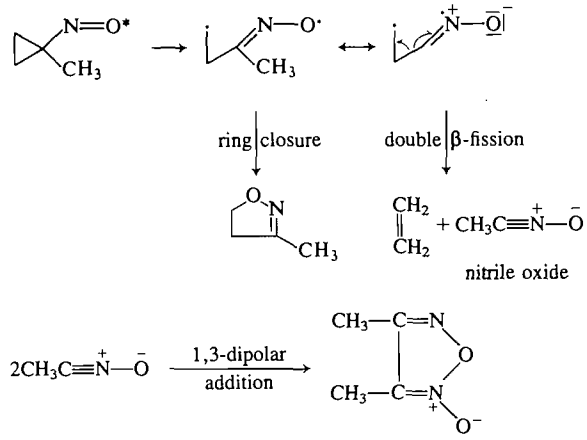
to give a nitroxide with $a_N = 16.0$ Gauss (in $CFCl_3$ at 20°C) and a doublet splitting $a_H = 3.3$ Gauss due to one β-hydrogen, suggesting the presence of a cyclopropyl-*tert*-butylnitroxide. The same nitroxide was obtained by oxidation of *tert*-butylcyclopropylamine with *p*-nitroperbenzoic acid (14). The nitroxide has a persistence comparable with ordinary dialkylnitroxides as judged from its esr spectrum.



The straightforward approach employing nitrosocyclopropane is somewhat hampered because this spin trap is not easily accessible (see ref. 14 and, for an earlier approach with $F_2O$ as the oxidant, ref. 15). Recently we found that nitrosocyclopropane can be prepared in 30% yield from cyclopropylamine by oxidation with sodium tungstate and $H_2O_2$ in a two-phase system ($CFCl_3/H_2O$) (16). Unlike other nitroso compounds possessing α-hydrogen, nitrosocyclopropane has no tendency to isomerize to the corresponding oxime. Apparently the energy barrier for formation of the exocyclic double bond in cyclopropanone oxime is so large, that the reaction simply does not take place.



Nitrosocyclopropane differs also from aliphatic nitroso compounds in that it gives no nitroxide upon irradiation with red light, presumably because of the relatively strong C—N bond due to its high *s*-character. As a spin trap, nitrosocyclopropane functions normally with alkyl and acyl radicals, nitroxides being obtained with $a_N = 15.3$–$16.0$ Gauss and $a_H = 3$–$4$ Gauss. The fact that nitrosocyclopropane forms no nitroxide upon irradiation does not mean that nitrosocyclopropanes are photochemically inert. For instance when α-methylnitrosopropane is irradiated with red light, it undergoes decomposition and the main products are an isoxazoline (40%), a furoxan (10%), and ethylene, first identified by its singlet in nmr at $\delta = 5.3$ (17).



All these products follow logically from ring opening of the excited nitroso compound to a biradical (not observed in esr). This has, on the one hand, the properties of an alkyl radical and, on the other, of an oximino radical. Ring closure to a five-membered ring leads to an oxazoline. When the oximino moiety is written in its polar canonical structure it becomes formally a 1,4-diradical. Such radicals can undergo a double β-fission with greater ease than cyclization to a four-membered ring. The double β-fission produces ethylene and a nitrile oxide, the latter undergoing dimerization to a furoxan.

The striking difference in photochemical behaviour between nitrosocyclopropane and its α-methyl derivative is caused by the totally different properties of acetonitrile oxide and its lower homologue HCNO (fulminic acid), obtainable in an analogous process from unsubstituted nitrosocyclopropane. Because of its labile proton, fulminic acid can tautomerize and form polymeric products with complicated structures (18). The tremendous influence of an α-substituent on the photochemistry of nitrosocyclopropanes is also obvious in α-

phenylcyclopropane. Upon irradiation with red light it gives an "ordinary" nitroxide because C—N homolysis in the excited state is now facilitated by the radical stabilizing effect of the phenyl group in the α-phenylcyclopropyl radical.

For personal use only.

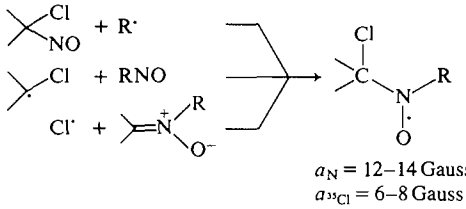
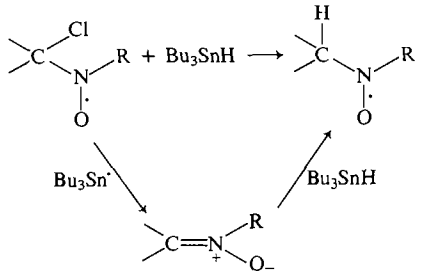
Finally it should be noticed that quantum yields for disappearance of α-methyl-nitrosocyclopropane ($\phi \approx 0.2$) are concentration independent and distinctly lower than the concentration dependent quantum yields for the α-phenyl derivative or for *t*-BuNO ($\phi = 0.9$–$1.3$). In the latter case the nitroso compound is not only removed by photolysis but also in dark reactions (e.g. nitroxide formation) in contrast with α-methyl-nitrosocyclopropane which reacts in an entirely different way as illustrated above.

*α-Chloro-nitrosoalkanes*

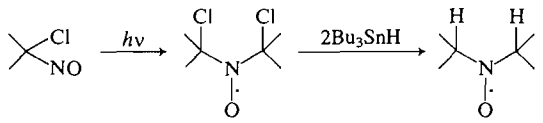
It was noted already in the early days of nitroxide esr spectroscopy, that α-chloro-nitroso compounds, largely present as monomers in solution, do not seem to form nitroxides by photolysis under standard conditions. The apparent resistance to form di(α-haloalkyl) nitroxides is somewhat surprising if one considers that *mono*(α-haloalkyl) nitroxides can be generated without special precautions along various routes, as summarized in the following scheme (19). Although the nitroxides generated in



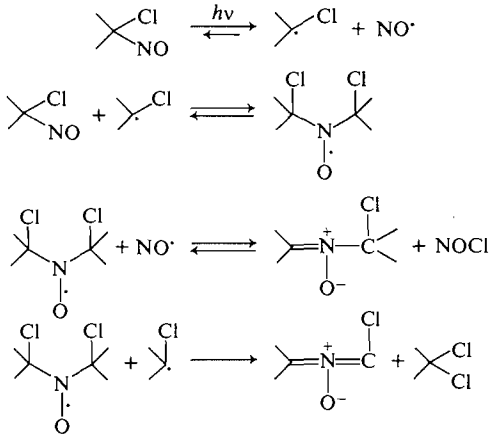
one of these ways are not particularly persistent, their esr spectra can be recorded without difficulty. Spectra are somewhat complicated because of the two chlorine isotopes each with a spin quantum number $I = 3/2$. They can be considerably simplified, when tributyltinhydride is added (20).



As in ordinary aliphatic chlorides, the halogen atom is replaced by hydrogen, and the same happens in our halogenated nitroxides, presumably by a mechanism involving $Bu_3Sn^{\cdot}$ radicals and a nitrone which is known to react with $Bu_3SnH$. When $Bu_3SnH$ is added to solutions of α-chloro-nitroso compounds, replacement of chlorine by hydrogen is slow and only after prolonged reaction times can the reduction product oxime (the tautomer of the halogen-free nitroso compound) be isolated. However, when reaction mixtures are irradiated with red light, rapid nitroxide formation takes place. Judging from esr spectra, these nitroxides do not contain halogen. Presumably a di(α-chloroalkyl)-nitroxide is formed in the early stages of the reaction, but this reacts rapidly with $Bu_3SnH$ much like a nitroxide containing only one α-chloroalkyl group.

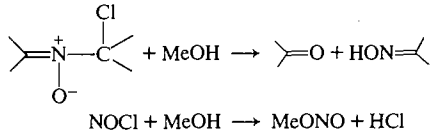


During photolysis of α-chloro-nitroso compounds in the absence of BuSnH, we assume that it is the NO and the α-chloroalkyl radical (instead of $Bu_3Sn^{\cdot}$) which is responsible for removing chlorine from the di(α-alkyl)-nitroxide. In the case of α-chloro-nitrosoadamantane, the *gem* dichloride has been isolated in 44% yield from photolyses in benzene (21). Some of it may also be formed by combination of α-chloroadamantyl radicals with $Cl^{\cdot}$, arising from photolysis of NOCl. Because the nitrone formed in the last two reactions is also a radical scavenger, reaction mixtures become complicated. In alco-



holic solvents the product distribution changes drastically. The main products, ketone, oxime, and nitrite, arise by solvolysis of the nitrone and of NOCl, thus supporting the suggested mechanism (22).

The foregoing illustrates that α-chloroalkyl nitroxides contain labile chlorine which can easily be



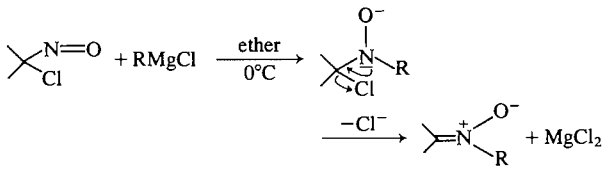
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

removed by a variety of radicals. The lability of chlorine plays also an essential role in the reactions to be described in the final section.

*Reaction of α-chloro-nitroso compounds with Grignard reagents*

Reaction of aliphatic and aromatic nitroso compounds leads in the first instance to hydroxylamines, much as ketones give alcohols. Because hyroxylamines and nitroso compounds can couple, complicated product mixtures are often obtained.

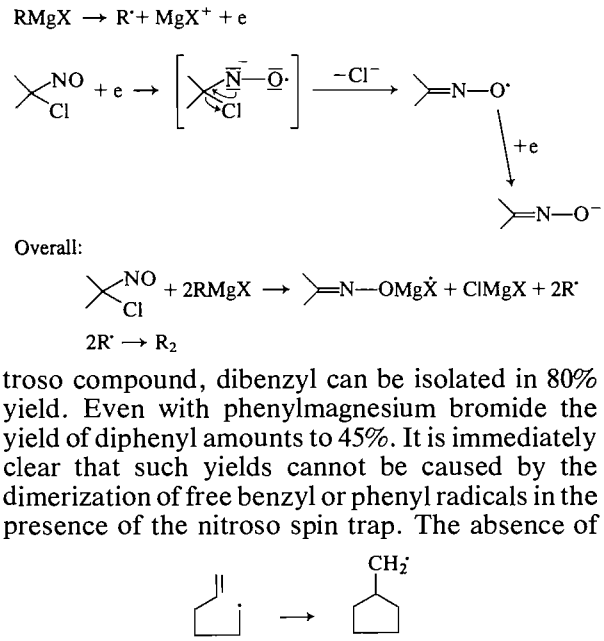
When the (aliphatic) nitroso compound contains an α-chloro substituent the reaction with a Grignard reagent is remarkably simplified, because the substituted hydroxylamine can lose halogen and a nitrone can be isolated in many cases (23). In principle, nitrones can also react with Grignard reagents, and therefore addition of an excess must be avoided. In practice this means that the Grignard reagent must be added slowly to the α-chloro-



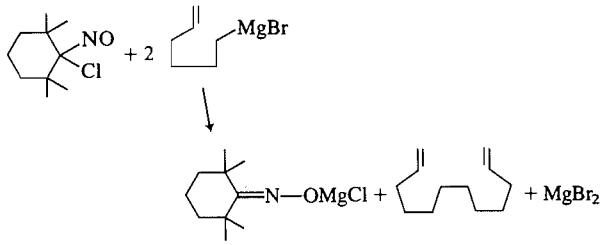
nitroso compound until its blue colour has disappeared. In this way nitrone yields of up to 90% have been reached. The stoichiometry of the nitrone formation is such that discoloration of the nitroso compound requires an equimolar amount of Grignard reagent.

In actual fact we find that in some cases almost twice as much of the Grignard reagent is necessary, particularly when access to the nitroso group is sterically hindered, as for instance in 1-chloro-1-nitroso-2,2,6,6-tetramethylcyclohexane. The high consumption of Grignard reagent is not due to its further attack on an intermediary nitrone. In fact nitrone formation is hardly or not at all involved. Instead of a sterically hindered polar reaction, a more facile electron transfer from the Grignard reagent to the nitroso compound takes preference. The resulting radical anion loses a halide ion and leaves an oximino radical. This radical can pick up another electron from the Grignard reagent to form an oxime anion (24*a*; for a recent review on Grignard reagents as electron donors, see ref. 24*b*). This scheme is not meant to imply free radicals or free (solvated) electrons but merely illustrates that in this stoichiometry, discoloration of the nitroso compound requires two equivalents of Grignard reagent and leaves formally two radicals R·.

In the reaction of benzylmagnesiumchloride with the earlier mentioned sterically hindered chloronitroso compound, dibenzyl can be isolated in 80% yield. Even with phenylmagnesium bromide the yield of diphenyl amounts to 45%. It is immediately clear that such yields cannot be caused by the dimerization of free benzyl or phenyl radicals in the presence of the nitroso spin trap. The absence of

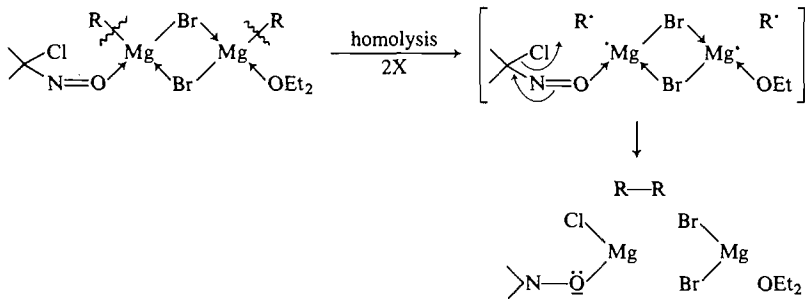


*free* radicals is also obvious from an experiment with 5-hexenylmagnesium bromide. It is known that the hexenyl radical can undergo ring closure very rapidly (25). The cyclization is so fast that it often serves as a sensitive test for radical-type processes. In the reaction of 5-hexenylmagnesium bromide with chloronitroso compounds, the formation of cyclopentyl derivatives is negligible and this again illustrates that free radicals cannot very well be involved.



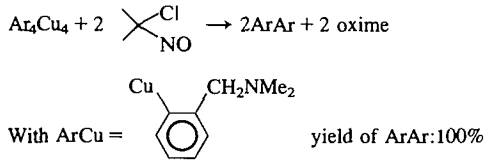
In order to rationalize the efficient production of dimers RR it should be realized that Grignard reagents RMgX are normally present as dimers in ethereal solution. We postulate that, in such a dimeric complex, one of the two ether molecules is displaced by the nitroso compound. Transfer of two electrons, one from each RMgX moiety, to the oxygen of the nitroso compound in rapid succession, combined with coupling of the two R fragments which remain in close proximity within the complex, leads to the dimer RR and the oxime salt.

The presence of the organometallic compound as a complex in solution is essential in this explanation. It is supported by the finding that an aromatic

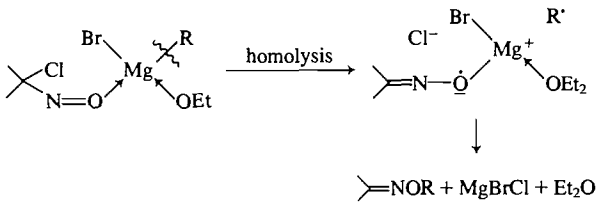


copper complex of known tetrameric structure (26) can react with an α-chloro-nitroso compound to form diaryl quantitatively.

At high dilution the Grignard reagent is (partly) present in solution in its monomeric form, and consequently formation of the dimer RR is made more difficult. For instance when benzylmagnesium bromide reacts in high dilution with a sterically hindered α-chloro-nitroso compound, only one



(not two) electron(s) can be transferred to the nitroso group within the complex. After loss of halide anion, this leaves formally an oximino radical and a benzyl radical. Radical combination leads to the benzyl ether of the oxime, isolated in 10–20% yield. That this by-product is not simply formed by polar attack of the Grignard reagent on the oxygen atom of the sterically hindered nitroso group finds support in the nature of reaction products obtained with other Grignard reagents at high dilution such as methyl- or phenyl-magnesium bromide. Instead of the methyl- or phenyl-ether of the oxime we now find the hydrocarbons methane and benzene while the oximino radical has coupled with a radical derived from the solvent diethylether. Apparently the (formal) methyl and phenyl radicals are in such a position within the complex that it is easier to abstract a hydrogen atom from a



nearby diethylether molecule, than to combine with the oximino radical. Methane was detected mass spectrometrically and $CH_3D$ was analysed unambiguously, when diethylether was replaced by fully deuterated tetrahydrofuran $(CD_2)_4O$ as the solvent. This supports the suggested reaction scheme. It is also in accordance with the observation that in the reaction with phenylmagnesium bromide equimolar amounts of benzene and solvent-derived oxime ether are found.

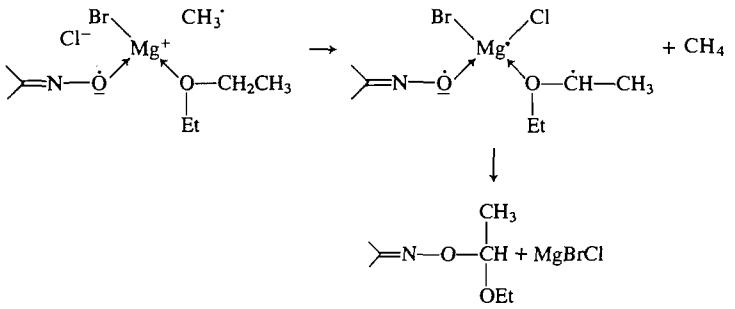
We have seen that with benzyl radicals, direct combination with the oximino radical is the preferred route, presumably because benzyl radicals are incapable of abstracting an α-hydrogen atom from an ether molecule. That α-hydrogen abstraction from the ether by $CH_3$ or phenyl radicals takes place within the complex, is supported by the observation that the addition of cumene or the even better hydrogen donor 1,4-diisopropylbenzene has no influence, i.e. the labile side-chain hydrogen does not take part in the reaction, presumably because these aromatic compounds are not associated with the metalorganic complex.

All the above reactions require that the Grignard reagent is (partly) present in its monomeric form. This prompted us to test organic aluminium compounds such as trimethylaluminium which are known to be present in ethereal solution in their monomeric form (complexed with one molecule of ether). In the absence of steric hindrance we find that the polar nitrone reaction prevails, as illustrated with α-chloro-nitrosoadamantane.

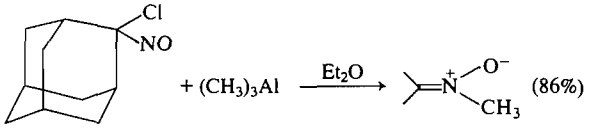
On the other hand, when the chloro-nitroso compound is sterically hindered, solvent participation (up to 85%) is observed, thus clearly illustrating the tremendous influence on the reaction course exerted by association of the organometallic complex (or the lack thereof). This is particularly true when sterically hindered chloro-nitroso compounds are involved and electron transfer becomes easier than polar attack by the organometallic reagent.

In the above reactions it has been shown that the oximino radical can undergo a variety of coupling reactions with other radicals. However, when there is a nearby efficient electron donor (as in higher organometallic complexes) it will rapidly accept an electron. This is in full agreement with the polarographic behaviour of α-chloro-nitroso compounds. After acceptance of the first electron,

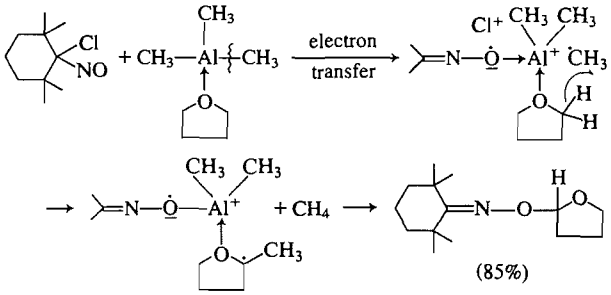
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.



chloride ion is rapidly and irreversibly eliminated. The uptake of a second electron by the resulting



oximino radical is found to be even easier than the first, i.e. α-chloro-nitroso compounds act as two-electron oxidants. Considering that they are prepared from oxime and chlorine, their use as oxidants in the conversion of Grignard reagents RMgX



into dimers RR (with the regeneration of oxime), is therefore essentially an overall oxidation with chlorine.

# Electron spin resonance and electron nuclear double resonance study of diastereomeric nitroxyl radicals produced by spin trapping

YASHIGE KOTAKE AND KEIJI KUWATA

*Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka, 560 Japan*

Received September 1, 1981

YASHIGE KOTAKE and KEIJI KUWATA. Can. J. Chem. **60**, 1610 (1982).

Electron spin resonance and electron nuclear double resonance spectra of nitroxyl radicals having two asymmetric carbons on one side of the nitroxyl function were observed. The radicals were produced by the abstraction of hydrogen by photoexcited benzophenone from amines, ethers, and alcohols followed by spin trapping with phenyl-*N*-*t*-butylnitrone. The difference in esr parameters of diastereomers depends on the functional group attached to the asymmetric carbon. The nature of the intramolecular interaction which brings about this difference is discussed in detail.

YASHIGE KOTAKE et KEIJI KUWATA. Can. J. Chem. **60**, 1610 (1982).

On a observé les spectres de rpe et de résonance nucléaire double de l'électron des radicaux nitroxydes ayant deux carbones asymétriques sur un côté de la fonction nitroxyle. On produit les radicaux par l'élimination d'un hydrogène des amines, des éthers et des alcools par de la benzophénone photoexcitée, suivie du captage de spin par le phényl-*N*-*tert*-butylnitrone. La différence des paramètres des rpe des diastérioisomères dépend de la nature des groupes fonctionnels attachés au carbone asymétrique. On discute en détail de la nature des interactions intramoléculaires qui sont responsables de ces différences.

[Traduit par le journal]

## Introduction

It is evident that the differences in chemical and physical properties of diastereomers arise from the differences in the interactions between substituents. However, detailed investigation into the factors influencing the magnitude of the spectroscopic separation of diastereomers is not always an easy task.

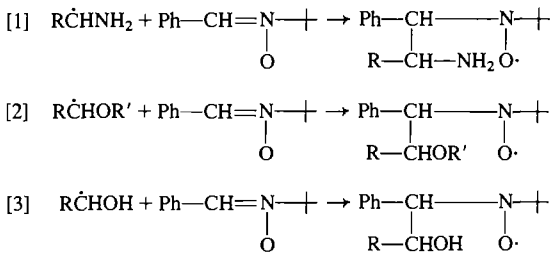
Recently it was reported that the spin trapping technique is capable of systematically producing various diastereomeric nitroxyl radicals (1, 2). The presence of diastereomers has been detected by characteristic esr spectra due to the slight differences in the hyperfine splittings (hfs) of the β-hydrogen and nitroxyl nitrogen, and the *g*-values of the two radicals. The small difference in β-H hfs which was not resolved by esr spectroscopy was also detected by making use of electron nuclear double resonance (ENDOR) spectroscopy.

In the present study the modes of separation of diastereomers in the three different kinds of spin adducts from alkylamines, ethers, and alcohols are compared. Since small differences in the β-H hfs of diastereomers in aminoalkyl adducts were detected by ENDOR experiments, it is possible to discuss the origin of the differing esr parameters.

All of the formed diastereomeric radicals have two asymmetric carbons on one side of the nitroxyl group. The magnitude of the hfs of the β-H reflects the conformation of the side chain. On the other hand, the nitrogen hfs and *g*-value reflect changes in the electronic structure of the nitroxyl group as a result of the differences of the steric configurations assumed by the substituents on the two asymmetric carbon atoms. Therefore the analysis of the separation of the diastereomeric spectra clarifies the intramolecular interaction which gives them different chemical and physical properties.

## Experimental

Nitroxyl radicals having two asymmetric carbons on one side of the nitroxyl group were produced by photosensitized hydrogen abstraction followed by spin trapping with phenyl-*N*-*t*-butylnitrone (PBN) (3, 4). The neat solution of the radical precursor (amines, ethers, and alcohols) which contains $10^{-3}$ mol $dm^{-3}$ PBN and $10^{-3}$ mol $dm^{-3}$ benzophenone was photolyzed by a 1 kw mercury arc for 10 min under vacuum. The reaction schemes of the trapping of the radicals from amines, ethers, and alcohols are shown as follows:



Materials used were purified by the method described elsewhere (1, 2). Electron spin resonance spectra were measured by a home-made spectrometer equipped with 15 kHz field modulation. Electron nuclear double resonance spectra were measured by combining a home-built rf unit with the esr spectrometer. The rf unit operates with a 150 W frequency-modulated radiofrequency. The modulation frequency is 7 to 10 kHz. Field modulation was not applied. The external magnetic field was fixed at one of the central doublet lines of the esr spectrum. The temperature of the sample was controlled by the flow of chilled nitrogen so as to obtain the best ENDOR signal.

## Results

*Aminoalkyl adducts*

Electron spin resonance spectra of aminoalkyl adducts of PBN have been observed with the parent amine as the solvent. The spectrum parameters (hfs and $g$-value) determined by spectral simulation have been listed elsewhere (2). In most aminoalkyl adducts the presence of diastereomers was not confirmed by esr due to the small differences in the spectrum parameters.

The ENDOR spectrum of the adduct from di-*n*-butylamine was observed in di-*n*-butylamine. Figure 1 shows the ENDOR spectrum with its esr spectrum. An important feature of the ENDOR spectrum is the doublet peak at around 17.3 MHz, which is assigned to the β-hydrogens of each diastereomer. Two pairs of peaks around the free proton frequency were assigned to the γ- and δ-protons. The results of the analysis are listed in Table 1. Splitting of the peaks of the γ- and δ-protons was not observed. Although the diastereomeric radicals have slightly different β-H hfs constants, the esr spectrum is symmetrical (Fig. 1*B*). This fact shows that the difference in $g$-values is negligible. Di-*n*-butylamine is the only amine for which ENDOR spectra were obtained. The observation of ENDOR spectra of other adducts was unsuccessful because of the low concentration of the adduct or the lack of suitable solvents.

*Alkoxyalkyl adducts*

Diastereomers of several alkoxyalkyl adducts have been observed by esr. The analysis based upon spectral simulation has been given elsewhere (2). The differences in the hfs constants and $g$-values were large enough for esr identification in most cases.

TABLE 1. Hyperfine-splitting constants of diastereomeric nitroxyl radicals determined by ENDOR

| Parent chemicals of adducts | $A_{\beta\text{-H}}$/mT | $A_{\gamma\text{-H}}$/mT | $A_{\delta\text{-H}}$/mT |
|---|---|---|---|
| Di-*n*-butylamine* | 0.263 | 0.068 | 0.021 |
| | 0.236 | 0.068 | 0.021 |
| Tetrahydrofuran† | 0.268 | 0.054 | 0.020 |
| | 0.171 | 0.054 | 0.020 |

*The structure of the adduct is shown in Fig. 1.
†The structure of the adduct is shown in Fig. 2.

The only ENDOR spectrum observed for an alkoxyalkyl adduct is that of the tetrahydrofuranyl adduct. The ENDOR spectrum is shown in Fig. 2 with its esr spectrum. Toluene was chosen as the solvent for the ENDOR measurement (5). Two separated peaks were detected at 16.2 MHz and 17.6 MHz, and assigned to the β-hydrogens of the diastereomers. Small splittings due to the γ- and δ-protons were also observed. The results of the analysis are given in Table 1. Since the low and high field doublets are not symmetric the diastereomers must have different hfs constants and $g$-values.

In spite of the expectation that the diastereomeric radicals have the same concentration, the inten-

For personal use only.

sities of the two ENDOR peaks were not the same. Because of the slight difference in $g$-value in isomer it is very difficult to choose the fixed position of the external field, where the contribution from both radical to the esr intensities are the same (6, 7). In this work internal field lock was employed to fix the external field at the one of the zero crossing points of the central doublet. The relative ENDOR intensities of the two β-hydrogens were observed to change considerably by changing the fixed position of the field. It is also noted that the esr lines of isomer have different linewidths. This may be attributed either to the different relaxation time or to the difference in the hfs of protons beyond γ-position. This can also be a probable cause of the unequal ENDOR intensity for the isomer.

ENDOR spectra of other alkoxyalkyl adducts were not observed mainly because of the low concentrations of the radicals.

*Hydroxyalkyl adducts*

The presence of diastereomers has been confirmed by changing the solvent from the parent alcohol to an aprotic solvent such as toluene (1). Typical esr spectra in both solvents are shown in Fig. 3 for the hydroxybutyl adduct. Such a drastic solvent effect has been attributed to the formation of an intramolecular hydrogen bond. The spectrum parameters for several hydroxyalkyl adducts have been published elsewhere (1).

Electron nuclear double resonance spectra have not been observed although it is not difficult to get high concentrations of the radical. Perhaps the dynamics of hydrogen bond formation affects the electron and nuclear spin relaxation processes resulting in the inability to find optimum conditions for obtaining an ENDOR signal (8).

## Discussion

It is noted that the diastereomers formed from the hydrogen-abstracted radicals of amines, ethers, and alcohols have different spectral parameters as detected by esr and ENDOR. Judging from the esr spectra each of the pairs of diastereomeric spin adducts show different modes of separation: aminoalkyl adducts only show differences in the hfs of the β-H while alkoxyalkyl adducts show differences in both the hfs and $g$-value. Hydroxyalkyl adducts have different hfs constants and $g$-values only when they are dissolved in aprotic solvents. It is proposed that intramolecular interactions are responsible for such modes of separation.

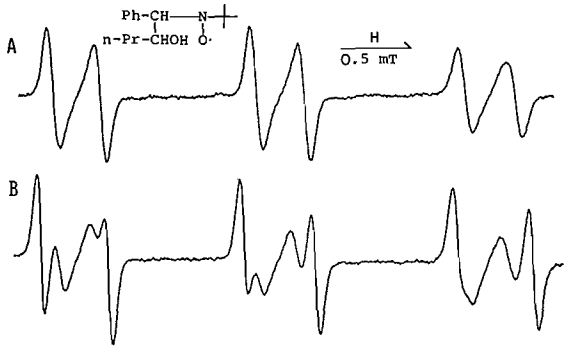

FIG. 3. Electron spin resonance spectra of spin adducts formed from butanol and PBN. *A*: in butanol at room temperature. *B*: in toluene at room temperature.

The reason for the spectroscopic separation of diastereomers may be due to the differences in the interactions of the substituents on the two asymmetric carbons $C_\alpha$ and $C_\beta$. The differences in the hfs and $g$-value are the indirect result of the interactions of substituents on $C_\alpha$ and $C_\beta$. Thus it has been proposed that in the stable conformers for these diastereomers the hydrogens on $C_\alpha$ and $C_\beta$ are *trans* to each other (9). The Newman projections of these isomers are shown in Fig. 4. The functional group X can interact with the nitroxyl group only in structure **A** of Fig. 4.

*Steric repulsion*

If the steric repulsion among bulky groups on the α and β carbons is predominant, the structure shown in Fig. 4 is realistic. When one expresses the interaction between R and R′ as (R, R′) then the dominant interactions are (R, Ph) and (X, NO) for Fig. 4*A* and (X, Ph) and (R, NO) for Fig. 4*B*. This results in differences in the overall conformation of the N—$C_\alpha$—$C_\beta$ chain and thus affects the dihedral angle between the β-H and the orbital containing the unpaired electron (10). This leads to slight differences in the β-H hfs constants for the isomers, which are resolved only by ENDOR. This is the case for the aminoalkyl adducts.

*Intramolecular solvation*

If the functional group X contains an electronegative atom such as oxygen, the nitroxyl radical having the structure **A** of Fig. 4 tends to favor the polar resonance structure.

[4]

The hfs of the nitrogen increases when compared to that in structure **B**. The usual solvent effect shifts

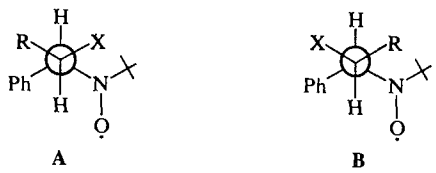

FIG. 4. Stereochemical diagram of diastereomeric nitroxyl radicals.

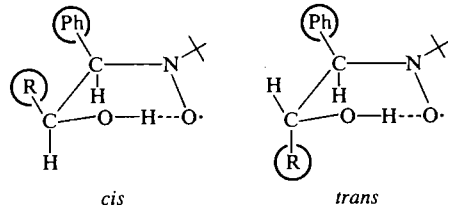

FIG. 5. Stereochemical diagram of hydrogen bonded chelate rings from diastereomers.

the $g$-value to a higher value, as well (11). This proximity effect of the functional group to the nitroxyl group explains the case of the alkoxyalkyl adduct well.

*Intramolecular hydrogen bonding*

If the functional group X in Fig. 4 is a hydroxy group then the intramolecular hydrogen bond between the OH and nitroxyl groups is possibly stronger than the steric repulsion (12). In such a case the radical is forced to take the conformations shown in Fig. 5. The conformation of R and Ph becomes *cis* or *trans* depending on the configuration of substituents on the two asymmetric carbons. The steric repulsion between R and Ph in the *cis* structure causes a distorted chelate ring changing the dihedral angle of the β-H with the unpaired electron orbital. In addition to the change in the hfs of the β-H the hydrogen bond also favors the polarized structure in reaction [4]. Changes in the strength of the hydrogen bond cause small differences in the hfs of the nitrogen and the $g$-value. This occurs in the case of the hydroxyalkyl adduct. The separation of the isomers was seen most clearly in aprotic solvents, which provides additional support for the presence of a hydrogen bond.

# Involvement of nitroxide radicals in cocaine-induced hepatotoxicity

ELMER J. RAUCKMAN, MICHELLE W. KLOSS, AND GERALD M. ROSEN
*Departments of Surgery and Pharmacology, Duke University Medical Center, Durham, NC 27710, U.S.A.*

Received September 12, 1981

ELMER J. RAUCKMAN, MICHELLE W. KLOSS, and GERALD M. ROSEN. Can. J. Chem. **60**, 1614 (1982).

Cocaine administration can produce hepatotoxicity in non-induced mice of at least one strain, DBA/2Ha and hepatotoxicity in induced mice of several strains. Metabolic studies and the administration of metabolites indicate that the minor metabolic pathway, cocaine → norcocaine → *N*-hydroxynorcocaine → norcocaine nitroxide, is responsible for the observed cocaine-induced hepatotoxicity. *In vitro* experiments show that cytochrome P-450 can oxidize *N*-hydroxynorcocaine to norcocaine nitroxide. Norcocaine nitroxide is unreactive towards cellular proteins or glutathione but does react directly with reduced pyridine nucleotides and is rapidly reduced enzymatically by the microsomal flavoproteins, NADPH-cytochrome P-450 reductase and FAD-containing monooxygenase. These reactions constitute a futile cycle in which NADPH is consumed and superoxide and hydrogen peroxide are generated. We postulate that the destruction of hydrogen peroxide by glutathione peroxidase results in the accumulation of excess oxidized glutathione which is actively excreted by the cell, since insufficient NADPH is available for glutathione reductase to maintain the GSH/GSSG ratio at an acceptable level. As reduced glutathione levels diminish, the cell can no longer protect itself against toxic lipid hydroperoxides which accumulate as a result of stimulation of lipid peroxidation (caused by the one electron cycling reaction, *N*-hydroxynorcocaine to norcocaine nitroxide cycle). Finally, as glutathione is depleted below a certain level, the cell loses the ability to maintain the GSH/GSSG ratio in a range consistent with homeostasis resulting in loss of cellular function. Ultimately, necrosis results. This mechanism is consistent with all the information available concerning cocaine-induced hepatotoxicity.

ELMER J. RAUCKMAN, MICHELLE W. KLOSS et GERALD M. ROSEN. Can. J. Chem. **60**, 1614 (1982).

L'administration de cocaine peut produire de l'hépatotoxicité chez les souris non-induites de la souche DBA/ZHA ainsi que de l'hépatotoxicité chez plusieurs souches de souris induites. Des études métaboliques et l'administration des métabolites indiquent que la séquence métabolique mineure: cocaine → norcocaine → *N*-hydroxynorcocaine → nitroxyde de cocaine est responsable de l'hépatotoxicité induite par la cocaine que l'on a observée. Des expériences *in vitro* montrent que le cytochrome P-450 peut oxyder la *N*-hydroxynorcocaine en nitroxyde de cocaine. Le nitroxyde de cocaïne n'a aucun effet sur les protéines cellulaires ou sur le glutathion mais il réagit directement avec la pyridine réduite des nucléotides et elle est rapidement réduite enzymatiquement par les flavoprotéines microsomiques: la réductase du NADPH-cytochrome P-450 et la mono-oxygénase contenant le ADF. Ces réactions constituent un cycle non efficace au cours duquel le NADPH est consommé et où un superoxyde et le peroxyde d'hydrogène se forment. Nous pensons que la destruction du peroxyde d'hydrogène par la peroxydase du glutathion provient de l'accumulation d'un excès de glutathion oxydé qui est activement secrété par la cellule, puisqu'une insuffisance de NADPH est nécessaire à la peroxydase du glutathion pour maintenir le rapport GSH/GSSG à un niveau acceptable. Lorsque le niveau du glutathion réduit baisse, la cellule ne peut plus se protéger contre la toxicité des hydroperoxydes des lipides (provoqué par une réaction cyclique à un électron de la *N*-hydroxynorcocaine en cycle de nitroxyde de norcocaine). Finalement quand le glutathion baisse en dessous d'un certain niveau, la cellule perd sa capacité de maintenir le rapport GSH/GSSG dans un intervalle qui serait favorable à l'homéostasie qui provient d'une perte de fonction cellulaire. En dernier ressort, il se forme des nécroses. Ce mécanisme est en accord avec toute l'information disponible relative à l'hépatotoxicité induite par la cocaine.

## Introduction

The illicit use of cocaine as a recreational drug has steadily increased during the past decade. Although this drug of abuse has been extensively investigated psychopharmacologically, it has only recently been discovered that cocaine administration results in hepatic injury in mice (1). In this review article, we will examine some of the current investigations into the mechanism of cocaine-mediated hepatotoxicity.

## Discussion

### *Chemistry and metabolism of cocaine*

Relatively little is known about the metabolism of cocaine, despite its history of widespread use. Chemically, cocaine is a benzoylmethylecgonine, an ester of benzoic acid and a nitrogen-containing base, methylecgonine. In the body, cocaine rapidly achieves high concentrations in plasma after intravenous and intraperitoneal injections and a major part of cocaine is hydrolyzed by serum and liver esterases to produce benzoylecgonine, ecgonine methyl ester, and ecgonine (2–4). The work of Misra *et al.* (5) provides evidence that cocaine (**I**) is also *N*-demethylated to norcocaine (**II**) via microsomal oxidation in the rat. Additional studies have demonstrated that norcocaine is further metabolized *in vivo* by the liver to *N*-hydroxynorcocaine (**III**) (6–8). The subsequent fate of *N*-hydroxynorcocaine *in vivo* is somewhat controversial; suggestions of the formation of an epoxide derivative and a reactive nitroxide (**IV**) (9–11) both appear in the literature. It is important to note that all hepatic metabolites subsequent to norcocaine have been demonstrated to be pharmacologically inert.

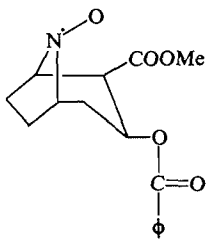
*Animal models and the role of oxidative enzymes in cocaine hepatotoxicity*

The reports of Evans *et al.* (12) and Shuster *et al.* (13) clearly implicate cocaine as a potent hepatotoxin in mice when given by intraperitoneal injection to this species induced with phenobarbital or housed on pine shaving bedding. Recent work by Freeman and Harbison (14) also demonstrated that chronic intraperitoneal injection of cocaine produced hepatotoxicity in non-induced mice but not in rats. This hepatotoxicity is manifested by fatty infiltration, midzonal and periportal necrosis, and marked elevation of serum glutamic-oxaloacetic transaminase (SGOT) levels. Similarly, hepatic dysfunction, as measured by elevated SGOT levels, has also been described in human heroin and cocaine addicts (14).

The work of Evans and Harbison (1) and Evans *et al.* (12) first suggested that a metabolite of cocaine, rather than cocaine itself, was responsible for the observed hepatotoxicity, based on data obtained when known cytochrome P-450 inducing agents were used. These investigations suggested that the active metabolite might be an *N*-oxide intermediate that was formed during the initial dealkylation of cocaine to norcocaine. Subsequent data later indicated, however, that the actual hepatotoxin was a further metabolite of norcocaine oxidation (15).



IV

More recent work by Thompson *et al.* (8) suggests that the bioactivation of cocaine to a more hepatotoxic metabolite is carried out by the cytochrome P-450 monooxygenase system and confirms data implicating a norcocaine metabolite as the reactive species. When tested for their ability to elevate SGOT levels, hydrolytic metabolites of cocaine were found not to be hepatotoxic; both norcocaine and *N*-hydroxynorcocaine, however, were shown to produce marked hepatotoxicity. Furthermore, cytochrome P-450 inhibitors such as SKF-525A blocked this liver damage, while inducing agents greatly enhanced the hepatotoxicity from cocaine, norcocaine, and *N*-hydroxynorcocaine administration. Thus, it was concluded that the cytochrome P-450 system was responsible for all metabolic conversions of the three compounds. Unfortunately, this study chose to measure drug metabolism only in terms of hepatotoxic manifestations, as opposed to the actual isolation of metabolites. It might therefore have been misleading to conclude that only one oxidative enzyme system participates in the bioactivation of cocaine based merely on data derived from the end result of complete metabolism. For example, the FAD-containing monooxygenase system, and not the cytochrome P-450 system, may be operative in the oxidation of norcocaine to *N*-hydroxynorcocaine, since this enzyme is known to catalyze the *N*-oxidation of many secondary amines (16, 17). What may be inferred from the current data is that a further metabolite of *N*-hydroxynorcocaine is responsible for the observed hepatotoxicity and that the cytochrome P-450 system participates in at least one metabolic conversion of the multi-step bioactivation of cocaine.

To date, all published investigations had failed to demonstrate cocaine-induced hepatic injury in mice without induction of cytochrome P-450. We have, however, recently developed an animal model, the DBA/2Ha male mouse, in which a cocaine dose of as little as 30 mg/kg, i.p., produces pronounced hepatic injury without the administration of cytochrome P-450 inducing agents. This hepatic injury was assessed by histopathology, depression of various hepatic enzyme activities, and elevation of

TABLE 1. Effect of single dose of cocaine on SGOT and selected hepatic enzymes in DBA/2Ha mice

| Cocaine dose mg/kg | Cyt P-450 content | FAD-M activity | Isocit. D.H. | SGOT | SOD |
|---|---|---|---|---|---|
| 10 | N/S | N/S | N/S | N/S | N/S |
| 20 | ↓ 26%* | N/S | N/S | ↑ 26%* | N/S |
| 30 | ↓ 48%* | ↓ 21%* | ↓ 21%* | ↑ 447%* | ↓ 24%* |
| 40 | ↓ 45%* | ↓ 34%* | ↓ 19%* | ↑ 718%* | ↓ 29%* |
| 60 | ↓ 60%* | ↓ 41%* | ↓ 24%* | ↑ 826%* | ↓ 30%* |

*$p < 0.05$ or better, FAD-M = FAD-containing monooxygenase; Isocit. D.H. = isocitric dehydrogenase; Cyt P-450 = cytochrome P-450; SOD = superoxide dismutase; SGOT = serum glutamic – oxaloacetic transaminase.

serium glutamic-pyruvic transaminase levels (Table 1). The use of phenobarbital as an inducing agent in this strain of mouse enhances the hepatotoxicity that results from cocaine exposure. Furthermore, a preliminary experiment designed to determine the time course and rate of recovery from cocaine-induced hepatotoxicity (and, hence, the severity of hepatic impairment) was conducted using adult male DBA/2Ha mice (Table 2). These data clearly demonstrate that hepatic cellular damage occurs within the first 24 h after cocaine administration; recovery, however, is not yet complete 3 days after cocaine exposure. Thus, an animal model for cocaine-induced hepatotoxicity which does not require induction of cytochrome P-450 is available in which the hepatotoxic effects of cocaine affect a wide variety of hepatic enzymes.

It is clear from the current literature that microsomal metabolism of cocaine is a prerequisite for the resulting hepatotoxicity; however, the enzymes responsible for the various steps in the bioactivation of cocaine to its nitroxide have not been established. As discussed earlier, it has been inferred that the cytochrome P-450 system is involved in the activation of cocaine based on a series of induction and inhibition studies using cocaine (9, 18), norcocaine (8), or *N*-hydroxynorcocaine (8). In principle, however, only the final step, activation of *N*-hydroxynorcocaine to the toxic intermediate, need be mediated by this hemoprotein to account for all the findings. Evans and Harbison (9) have found evidence of increased *N*-demethylation of cocaine after pretreatment with phenobarbital; even with this reaction, however, cytochrome P-450 could be of secondary importance to FAD-containing monooxygenase, since *N*-demethylation is known to be catalyzed by this enzyme acting in concert with cytochrome P-450 (19, 20).

TABLE 2. Effect of a single dose (60 mg/kg) of cocaine on SGPT and selected hepatic enzymes in DBA/2Ha mice as a function of time

| Post-injection time (h) | Cyt P-450 content | FAD-M activity | SGPT |
|---|---|---|---|
| 24 | ↓ 69%* | ↓ 40%* | ↑ 1676%* |
| 48 | ↓ 64%* | ↓ 30%* | ↑ 171%* |
| 72 | ↓ 42%* | ↓ 19%* | N/S |

*$p < 0.05$ or better; Cyt P-450 = cytochrome P-450; FAD-M = FAD-containing monooxygenase; SGPT = serum glutamic-pyruvic transaminase.

The hydroxylation of basic amines, such as norcocaine, is now generally considered to be mediated by the FAD-containing monooxygenase (21, 22). In fact, it is known that enhancement of FAD-containing monooxygenase activity occurs by castration of male mice (23) and we have observed that castration enhances the hepatotoxicity induced by norcocaine administration (unpublished observations). Furthermore, we have found that purified porcine liver FAD-containing monooxygenase will oxidize norcocaine to *N*-hydroxynorcocaine (unpublished results).

*Role of norcocaine nitroxide in cocaine hepatotoxicity*

Nayak *et al.* (6) first suggested that a nitroxide radical formed subsequent to norcocaine could be the species responsible for cocaine-induced hepatic injury. Later, Thompson *et al.* (8) proposed that this radical might either bind covalently to proteins or serve to initiate lipid peroxidation as a mechanism to account for the hepatotoxicity induced by cocaine. More recently, Evans (10) and Evans and Johnson (11) have presented evidence for the formation of norcocaine nitroxide from *N*-hydroxynorcocaine by phenobarbital-induced mouse microsomes and have attempted to correlate this formation with the covalent binding of radiolabeled cocaine to cellular proteins. To support their argument that norcocaine nitroxide is the ultimate toxic intermediate, these investigators cited their inability to detect the production of this nitroxide in rat and hamster microsomes, both of which are species that do not exhibit cocaine-induced hepatotoxicity *in vivo*. We have, however, found that the addition of *N*-hydroxynorcocaine to microsomes from non-induced mice, rats, or hamsters (in the presence of a NADPH-generating system)

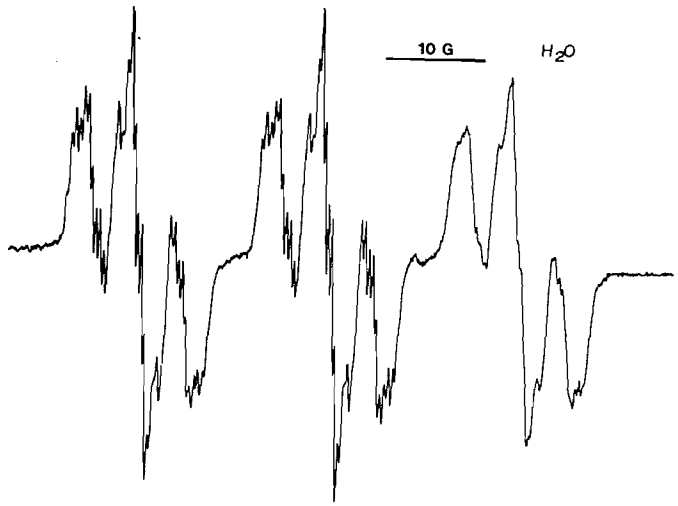

FIG. 1. The electron paramagnetic resonance spectrum of norcocaine nitroxide in water at ambient temperature. This spectrum was recorded on a Varian Associates model E-9 spectrometer, gain = $4 \times 10^3$; microwave power = 10 mW; modulation amplitude = 0.32 G; time constant = 0.3 s; scan time = 12.5 G/min.

results in the formation of norcocaine nitroxide (24). The formation of this nitroxide in the reaction mixture was determined by observation of its electron paramagnetic resonance (epr) spectrum which was identical to that of norcocaine nitroxide synthesized by the oxidation of norcocaine with *m*-chloroperbenzoic acid (Fig. 1). This nitroxide exhibited the characteristic hyperfine splitting pattern for a nitroxide with two β-hydrogens (25), and appeared immediately after the reaction was initiated by the addition of *N*-hydroxynorcocaine to microsomes in the presence of a NADPH generating system. The epr signal intensity reached maximum after 2 to 10 min (depending on the microsomal concentration) after admixture of the reactants, at which point, the signal decreased steadily. Norcocaine nitroxide, itself, however, was found to be relatively stable, decomposing at about 1% per hour in aqueous solution. This observation suggests that norcocaine nitroxide reacts with some constituent of the microsomal mixture and that the level of norcocaine nitroxide observed in the incubation mixture is controlled by its rate of formation and subsequent rate of reaction. Phenobarbital-induced animals (mice, rats, or hamsters) were found to produce maximal levels of norcocaine nitroxide, which were about five times greater than was observed using non-induced animals (24). These observations suggest that a specific subpopulation of cytochrome P-450 preferentially oxidizes *N*-hydroxynorcocaine to its corresponding nitroxide and that the ability of a hepatic microsomal system to convert *N*-hydroxynorcocaine to norcocaine nitroxide is not the only factor to be considered in cocaine-induced hepatotoxicity, since rats and hamsters are not known to exhibit hepatic necrosis after exposure to cocaine (10).

The mechanism of this microsomal one electron oxidation of *N*-hydroxynorcocaine to norcocaine nitroxide appears to be unusual. We have previously reported that the microsomal one electron oxidation of hydroxylamines to nitroxides is a result of microsomal superoxide production rather than a direct enzymatic conversion (26). The oxidation of *N*-hydroxynorcocaine to its corresponding nitroxide, however, appears to be an exception to this generalization. All data compiled to date indicate that cytochrome P-450 directly mediates this oxidation. Phenobarbital induction enhances the microsomal oxidation of *N*-hydroxynorcocaine to norcocaine nitroxide, metyrapone and SKF-525A inhibit the conversion, and a type I binding spectrum for *N*-hydroxynorcocaine is observable. Compounds which produce type I binding spectra are almost invariably substrates for cytochrome P-450 (27). Thus, *N*-hydroxynorcocaine meets at least three of the four criteria commonly used to establish the involvement of cytochrome P-450 in the oxidation of a substrate (28). The reaction of *N*-hydroxynorcocaine with cytochrome P-450 to produce norcocaine nitroxide is not, then, a mixed function oxidation reaction, but rather a form of "substrate activation" by cytochrome P-450. It is possible that in the tertiary cytochrome P-450-substrate – oxygen complex, a hydrogen atom is abstracted from the substrate (29). In this situation, the substrate becomes a donor of the reducing equivalents. It has been suggested that hydrogen

TABLE 3. Reduction of norcocaine nitroxide and TEMPO by non-induced rat hepatic microsomes

| Mixture | Rate of substrate reduction* | |
|---|---|---|
| | TEMPO† | Norcocaine nitroxide |
| NADPH | 0 | 2.2 |
| NADPH + microsomes | 2.9 | 17.0 |
| NADPH + microsomes + metyrapone | 0.99 | 16.8 |
| NADH | 0 | 1.2 |
| NADH + microsomes | 0.7 | 8.9 |
| NADH + microsomes + metyrapone | 0.4 | 8.8 |

*Rates were determined by following the loss of epr signal intensity with time and are expressed in μmol substrate reduced per minute per mg protein. The NADPH and NADH rates have been divided through by the protein values so they are comparable directly to the enzymatic rates.
†TEMPO = 2,2,6,6-tetramethylpiperidinoxyl.

peroxide is formed as a consequence of this "substrate activation" reaction (30). A likely mechanism for this reaction is depicted in Fig. 2.

*Reactivity of norcocaine nitroxide*

Nitroxide radicals are known to be relatively unreactive chemically. In fact, a wide variety of chemical reactions may be performed on other parts of a molecule containing a nitroxide moiety without affecting the nitroxide (31). Purified synthetic norcocaine nitroxide was found to be unreactive with proteins in the form of either washed hepatic microsomes or dialized hepatic cytosol (24). This observation eliminates the possibility that covalent binding of cocaine to microsomal proteins occurs by simple reaction of the nitroxide moiety with proteins.

The direct reaction of nitroxides with sulfhydryl groups is often mentioned in the literature (31); however, we have found that this reaction is generally an artifact produced by heavy metal contamination (unpublished observations). In the case of cocaine-mediated hepatotoxicity, it is tempting to ascribe the observed depletion of hepatic glutathione to direct reaction of reduced glutathione with norcocaine nitroxide. Unfortunately, purified norcocaine nitroxide was determined not to react with either reduced glutathione or cysteine (24). Norcocaine nitroxide was, however, found to react rapidly with dithiothreitol or β-mercaptoethanol (24).

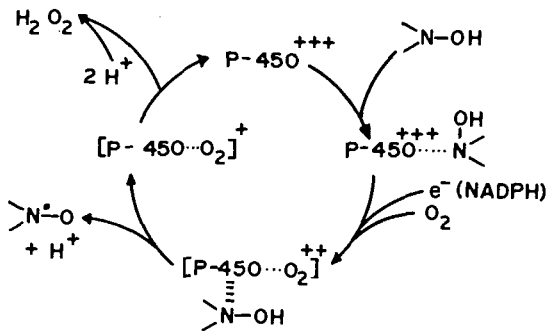

FIG. 2. Proposed mechanism for the oxidation of *N*-hydroxynorcocaine to norcocaine nitroxide by cytochrome P-450.

Norcocaine nitroxide was demonstrated to oxidize directly the pyridine nucleotides NADH and NADPH resulting in the reduction of the nitroxide free radical (Table 3) (24). Furthermore, it was determined that microsomal enzymes rapidly reduce norcocaine nitroxide in the presence of NADPH or NADH (Table 3). It had previously been shown that microsomal reduction of simple nitroxides, such as 2,2,6,6-tetramethylpiperidinoxyl (TEMPO), was mediated by cytochrome P-450 (32). In the case of norcocaine nitroxide, however, free radical reduction was not inhibited by metyrapone (Table 3), suggesting that cytochrome P-450 was not responsible for this reduction. Experiments with purified enzymes indicated that the flavoproteins NADPH-cytochrome P-450 reductase and FAD-containing monooxygenase reduce norcocaine nitroxide (Table 4) (24). The fact that these reductions of norcocaine nitroxide are one electron reactions implies that the reductant (pyridine nucleotide or flavoprotein) is oxidized to a free radical species. In the presence of oxygen, one reaction which is known to occur with these species is an electron transfer producing superoxide and the oxidized pyridine nucleotide (33) or flavoprotein. This was shown to be the case for NADH, NADPH, and FAD-containing monooxygenase, but not for NADPH-cytochrome P-450 reductase as illustrated in Table 4. Norcocaine nitroxide was demonstrated to inhibit the normal superoxide production by purified NADPH-cytochrome P-450 reductase.

*FADM = FAD-containing monooxygenase; RED = cytochrome P-450 reductase; NCN = norcocaine nitroxide.
†Norcocaine nitroxide reduction was measured by loss of epr signal intensity. NCN, 3 μ*M*; NAD(P)H, 55 μ*M*; FADM, 170 n*M*; RED, 44 n*M*; in pH 8.3 tricine buffer containing 1 m*M* DETAPAC.
‡Superoxide production was measured as the superoxide dismutase (SOD) (10 μg/mL) inhibitable cytochrome c reduction (39). The cytochrome P-450 reductase superoxide production was measured using succinylated cytochrome c. Conditions were the same as in † except norcocaine nitroxide used was 30 μ*M*.

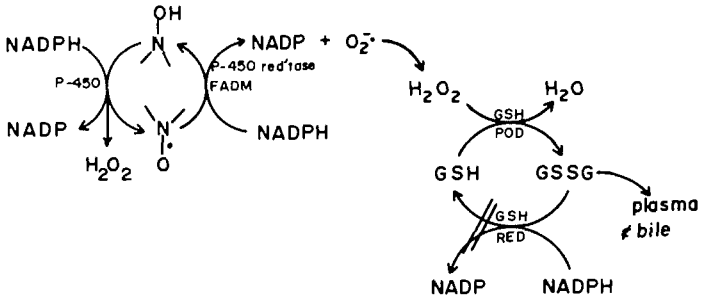

FIG. 3. Proposed mechanism for cocaine induced hepatotoxicity mediated by the cocaine metabolite, norcocaine nitroxide.

produce radical species suggested that lipid peroxidation may be stimulated *in vitro*. It was demonstrated that the addition of the spin trap α-(4-pyridyl-1-oxide)-*N*-*tert*-butylnitrone (4-POBN) to a microsomal-NADPH – norcocaine nitroxide mixture resulted in the spin trapping of higher levels of free radicals than were trapped in the absence of norcocaine nitroxide (24). The spin-trapped radical species were identified as lipid peroxyl radicals (24, 34), indicating that stimulation of lipid peroxidation by norcocaine nitroxide had occurred *in vitro*. The mechanism of this *in vitro* stimulation of lipid peroxidation was not investigated.

*Mechanism of cocaine-induced hepatotoxicity*

The studies demonstrating cytochrome P-450's oxidation of *N*-hydroxynorcocaine to norcocaine nitroxide and the investigation of the reactivity of norcocaine nitroxide with biomolecules allows us to speculate how norcocaine nitroxide participates in cocaine-induced hepatotoxicity.

We favor a complex mechanism where a futile redox cycle is set up between oxidation of *N*-hydroxynorcocaine to norcocaine nitroxide and reduction of norcocaine nitroxide to *N*-hydroxynorcocaine, both at the expense of NADPH. This cycle (note Fig. 3) results in the loss of NADPH and the production of hydrogen peroxide (from the cytochrome P-450 oxidation reaction and from dismutation of superoxide produced as a result of the reductive reaction). The hydrogen peroxide is destroyed by glutathione peroxidase concomitantly converting reduced glutathione to oxidized glutathione. Reduction of oxidized glutathione, we postulate, is partially blocked because levels of NADPH are reduced by the futile redox cycle. This results in the buildup of oxidized glutathione which is actively excreted by the cell in order to maintain its GSH/GSSG ratio in a "normal" range (35, 36). This active excretion of GSSG accounts for the observed cocaine-induced glutathione depletion. Toxic lipid hydroperoxides, produced by norcocaine-induced stimulation of lipid peroxidation, would also accumulate if sufficient glutathione were not available as a co-factor for glutathione peroxidase to reduce organic hydroperoxides to alcohols. As reduced glutathione continues to be oxidized, the cell can no longer excrete oxidized glutathione to maintain a physiologic GSH/GSSG ratio. Because of the resulting imbal-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

ance, various enzymatic activities which depend upon a "normal" GSH/GSSG ratio being maintained are lost (36). With lipid peroxidation damaging cellular membranes and with GSH/GSSG ratios at a level incompatible with homeostatis, cellular death is inevitable.

This hypothetical mechanism is consistent with what is known about cocaine-induced hepatotoxicity and accounts for the observed loss of glutathione (8, 9). The known protection afforded by glutathione against cocaine-induced hepatotoxicity (8) and the known reactivity of norcocaine nitroxide (24) are also supported by this model. This mechanism is also consistent with the established relationship of exogenous hydroperoxide administration to oxidized glutathione efflux. Sies *et al.* (37) have demonstrated that GSSG is released from isolated perfused liver in the presence of exogenous hydroperoxide administration with a concomitant decrease in the NADPH/$NADP^+$ ratio as observed by surface fluorescence. Sies *et al.* (38) have proposed that when levels of NADPH are diminished past a critical level, the cell's ability to reduce GSSG to GSH via glutathione reductase is compromised.

THOMAS H. WALTER, ERIC E. BANCROFT, GREGORY L. MCINTIRE, EDWARD R. DAVIS, LILA M. GIERASCH, HENRY N. BLOUNT, HENRY J. STRONKS, and EDWARD G. JANZEN. Can. J. Chem. **60**, 1621 (1982).

An overview of applications of spin trapping to electrochemical investigations is presented. Cited studies include characterizations of primary electrode reaction products (e.g., electrooxidations of halide and pseudohalide species, electroreduction of *N*-methylpyridinium ion) as well as the identification of transient intermediates arising from homogeneous reactions which are electroinitiated. The validity of spatially resolved spin trapping as a probe in the investigation of interfacial processes is demonstrated with examples drawn both from the previously reported covalent attachment of nitrone derived spin traps to silaceous surfaces and from recent studies of spin trapping in micelle and vesicle systems. Amphiphilic nitrone spin traps have been shown to coassemble with both micelles and vesicles such that the nitrone functionality resides in the interfacial region of the ordered system. The ability of these interfacially localized nitrones to trap transient radicals generated both in the hydrophobic domain of the micelle or vesicle and in the aqueous exterior domain is demonstrated.

THOMAS H. WALTER, ERIC E. BANCROFT, GREGORY L. MCINTIRE, EDWARD R. DAVIS, LILA M. GIERASCH, HENRY N. BLOUNT, HENRY J. STRONKS et EDWARD G. JANZEN. Can. J. Chem. **60**, 1621 (1982).

Une revue des applications des pièges à spins dans les études électrochimiques est presentée. Les travaux décrits comprennent la caractérisation des produits primaires des réactions sur les électrodes (par example, les électrooxydations des halides et des pseudohalides, et l'électroréduction du *N*-méthylpyridinium) ainsi que l'identification des intermédiaires transitoires qui sont produits dans des réactions homogènes électroinitiées. La validité d'une méthode utilisant des pièges à spins situés à un endroit précis pour l'étude des procédés interfaciaux est montrée. Deux exemples sont donnés: les études déjà rapportées des pièges à spins derivés du nitrone liés aux surfaces silacieuses, et les études récentes des pièges à spins dans les micelles et dans les vésicules. Il a été montré que les pièges à spins sont des nitrones amphiphiliques qui se sont rassemblés avec les micelles et les vésicules de sorte que le nitrone se situe dans la région interfaciale du système organisé. La capacité de ces nitrones, situés à l'inferface, de pièger les radicaux transitoires créés dans la région hydrophobique du micelle ou de la vésicule et dans la phase aqueuse extérieure est montrée.

## Introduction

The detection and characterization of transient radical intermediates produced in reactions which are initiated by heterogeneous electron transfer processes are essential to the mechanistic definition of those processes. The necessity of such mechanistic understanding is becoming increasingly pronounced in areas of energy conversion and storage, electrosynthesis, heterogeneous catalysis, and biological electron transfer. Spin trapping (1, 2) with various nitroso and nitrone derived moieties has proven to be a fruitful approach to the detection and characterization of transient radical intermediates ensuing from electrooxidations (3–6), photoassisted oxidations (7–9), and electroreductions (4, 10–12) of various substrates in solution. The viability of spin trapping as an investigative tool in electron transfer processes requires that (*i*) the spin trap reagent be electroinactive at potentials required to discharge the substrate, (*ii*) the rate of reaction of radical intermediates with the spin trap be favorable relative to those of other radical-consuming reactions, and (*iii*) the product of the radical/spin trap reaction (the *spin adduct*) also be electroinactive at potentials which are employed to oxidize or to reduce the substrate. Several studies (3, 4, 6–8, 10, 12, 13) have provided insight into the electroactivities of spin traps and spin adducts. Also, the kinetics of spin trapping reactions have recently been reviewed (14).

In addition to the three general requirements for spin trapping in electron transfer processes, a fourth constraint may have to be met for mechanistic definition of *interfacial* electron transfer reac-

tions of interest. In heterogeneous electron transfer systems, the spin trapping reaction should be spatially resolved, i.e., the spin trap reagent should be localized in the vicinity of the interface where the primary redox process takes place. Recently, strategies have been developed which permit spin traps to be attached to solid surfaces (15, 16). These approaches hold promise for productive spin trapping investigations of mechanisms of electrocatalytic processes (16). In addition, protocols for localization of spin traps at the interfaces between micelles and aqueous solutions, and between vesicles and aqueous solutions, have been developed (17). These findings suggest the use of spin trapping as a viable mechanistic probe for reactions which are initiated by heterogeneous electron transfer reactions which take place at membrane/solution interfaces.

This report provides an overview of spin trapping in electrochemical studies conducted in these laboratories and also details recent developments in spin trapping in micellar and vesicular media.

## Experimental

*Materials*

Sources of and purification procedures for acetonitrile (AN), tetraethylammonium perchlorate (TEAP), tetra-*n*-butylammonium perchlorate (TBAP), and lithium perchlorate have already been reported (18–20). Tetraethylammonium (TEA) and tetra-*n*-butylammonium (TBA) salts of cyanide (TEACN), cyanate (TEAOCN), thiocyanate (TBASCN), chloride (TBACl), azide ($TBAN_3$), and tetra-*n*-butylboride ($TBABBu_4$) were either commercially available or were prepared by standard methods (21). The synthesis and purification of α-(4-dodecyloxyphenyl)-*N*-*tert*-butylnitrone (DOPBN) is described elsewhere (22). The preparations, purification procedures, and characterizations of all other nitrone and nitroso spin trap reagents used in this work have been previously summarized (13). The preparation of *N*-methylpyridinium ($NMP^+$) salts has also been described (12). Sources of controlled pore glass beads (CPG) and cyanuric chloride (CC), and synthetic protocols for the immobilization of HOPBN (Table 1) to CPG have been previously detailed (15). Sodium dodecylsulfate (SDS, Aldrich) was purified as reported elsewhere (23). Dioctadecyldimethylammonium chloride (DODAC) was prepared from the bromide salt (Eastman) by ion exchange after the manner of Lim and Fendler (24). Lecithin was obtained from fresh egg yolks by the method of Singleton *et al.* (25). DODAC/DOPBN vesicles (10:1 mol ratio, 60 mg DODAC/mL) were prepared by ultrasound irradiation (Sonicor ultrasonic cleaner) of an aqueous mixture of the two components for 30 min at 50°C. Lecithin/DOPBN vesicles (20:1 w/w, 10 mg lecithin/mL) were prepared by ultrasonication under nitrogen of a mixture of these two components in 0.10 *M* NaCl for 100 min at 25°C. Phenylazotriphenylmethane (PAT, Eastman) was used as received. Phenyldiazonium tetrafluoroborate (PDT) was synthesized by conventional methods (26). All other materials were reagent grade or equivalent.

*Apparatus*

Electron spin resonance (esr) spectra were recorded at room temperature on Varian E-104 or Varian E-109E spectrometers which were periodically calibrated with Fremy's salt. *In situ* electrolyses were performed at controlled potentials in the esr cavity using a Varian E-256 electrolytic sample cell configured with either a Pt gauze or a Hg pool working electrode. Electrochemical instrumentation and cells have already been described (13). All potentials are reported relative to the aqueous saturated calomel electrode (SCE). Measurements of hyperfine splitting constants (hfsc's) were verified by spectral simulation.

## Results and discussion

The structures, designations, and electrochemical properties of eighteen of the most well-characterized spin traps are summarized in Table 1. The effects of molecular structure on the electrochemical behavior of these spin traps have been described, as have the homogeneous chemical reactions which follow the oxidation and reduction of these species (13). All of the spin traps shown in Table 1 exhibit broad "potential windows" (ranges of electrode potentials over which the entities in question are electroinactive) which render them suitable for use in a wide variety of electrochemical investigations.

*Spin trapping of primary electrode reaction products*

Spin trapping investigations of the oxidative electrochemistry of pseudohalide and halide species provide examples of systems in which the *primary* electrode reaction product can be detected and characterized. The general reaction scheme which describes the oxidative discharge of pseudohalide and halide species ($X^-$) can be represented by

$$[1]\quad X^- \rightleftharpoons X^{\cdot} + e^-$$

$$[2]\quad 2X^{\cdot} \rightarrow X_2$$

$$[3]\quad X_2 + X^- \rightleftharpoons X_3^-$$

where the primary electrode reaction product, $X^{\cdot}$, is most often adsorbed onto the electrode surface. While the perpseudohalide or perhalide is the ultimate reaction product in many pseudohalide and halide electrooxidations, there are exceptions as noted below. Radical dimerization (eq. [2]) is quite fast in these systems and is the process with which the spin trapping reaction must compete.

Cyanide can be selectively oxidized in the presence of PBN (Tables 1 and 2). *In situ* electrooxidation of TEACN in TEAP/AN containing PBN gives rise to the cyanyl spin adduct of PBN which affords the esr spectrum shown in Fig. 1A. That this spin adduct is only observable at PBN/TEACN ratios ≥ 3000 attests to the velocity of the radical dimerization process (eq. [2]). The triplet of doublets seen in Fig. 1A suggests a spin adduct of structure **1** resulting from a carbon-centered cyanyl radical as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

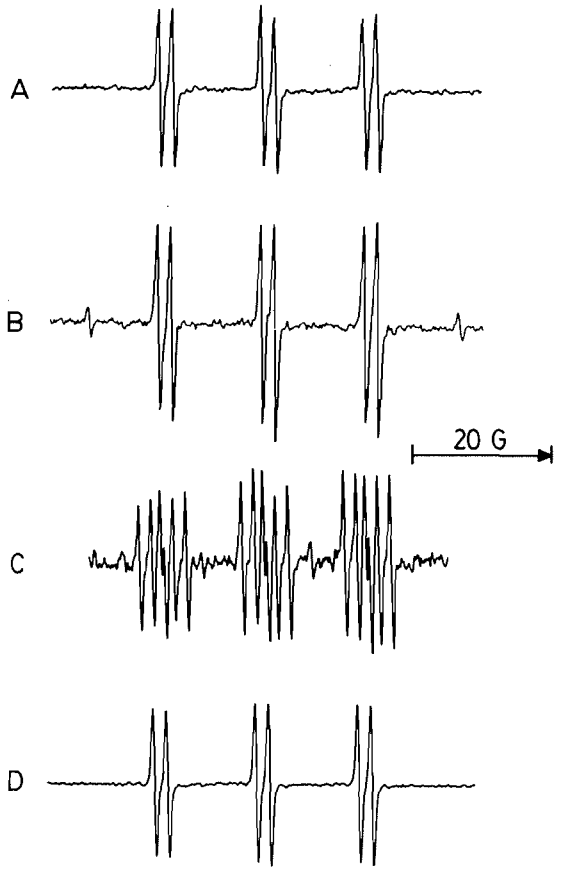

FIG. 1. The esr spectra of spin adducts produced by (A) *in situ* electrooxidation of TEACN in the presence of PBN in TEAP/AN; (B) reaction of *t*-BuO· with benzyl cyanide in the presence of N*t*B; (C) *in situ* electrooxidation of TEAOCN in the presence of PBN in TEAP/AN; (D) *in situ* electrooxidation of TBASCN in the presence of PBN in TEAP/AN.

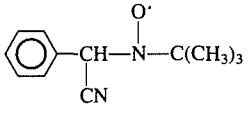
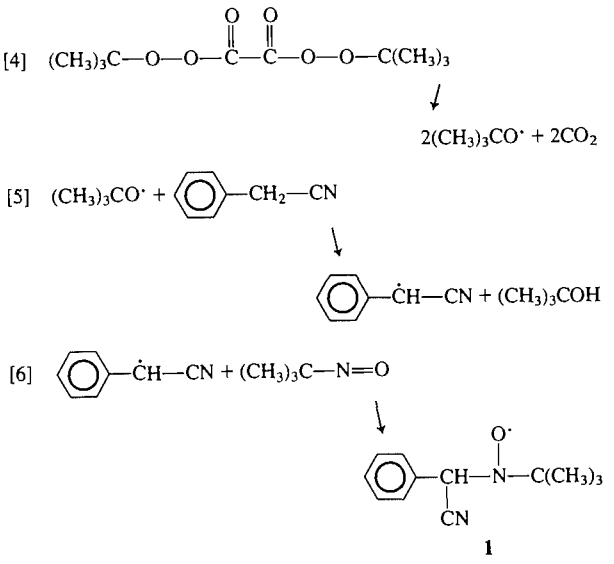
reported by Forrester and Hepburn (27) and Mao and Kevan (28). Verification of the assignment of the spectrum shown in Fig. 1A to **1** has been provided through an alternate preparation and esr characterization of **1**. Thermal decomposition of



**1**

di-*tert*-butylperoxyoxalate (DBPO) produces *t*-BuO· (eq. [4]) which abstracts an α-hydrogen atom from benzyl cyanide (eq. [5]). The resulting α-cyanobenzyl radical is trapped by N*t*B (eq. [6]) and gives rise to the esr spectrum shown in Fig. 1B. The agreement between the hyperfine splitting constants (hfsc's) of this spin adduct ($a_N = 15.04$, $a_\beta^H = 1.98$ G) and those of the spin adduct derived from electrooxidation of TEACN (Table 2) confirms the

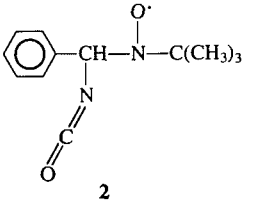


**1**

assignment of the spectrum shown in Fig. 1A to the carbon-centered cyanyl spin adduct of PBN (**1**).

The electrooxidation of cyanate (as TEAOCN) in the presence of PBN in TEAP/AN gives rise to the spin adduct **2** whose esr spectrum is shown in Fig. 1C. This result is consistent with the findings of Cauquis and Pierre (29, 30) that the electrooxidation of cyanate initially gives rise to the cyanatyl radical which dimerizes and subsequently decomposes to cyanogen and oxygen. Like the cyanyl case, the cyanatyl radical adds to PBN via the "softer" atom (31). Additionally, the assignment of the esr spectrum in Fig. 1C to structure **2** is consistent with the spin trapping of cyanatyl radicals produced both by persulfate oxidation of cyanate in the presence of PBN and by the photolysis of aqueous solutions of cyanate containing PBN (6).

On the basis of the spin trapping behavior of cyanyl and cyanatyl radicals which add to PBN



**2**

through the "softer" atom, thiocyanatyl radical could be expected to add to PBN to give the spin adduct **3**. *In situ* electrooxidation of thiocyanate (as TBASCN) in TEAP/AN containing PBN gives rise to a spin adduct whose esr spectrum is shown in Fig. 1D. Whereas **3** is predicted to give rise to such a triplet of doublets, the $a_N$ and $a_\beta^H$ values of the observed spin adduct are identical to those noted

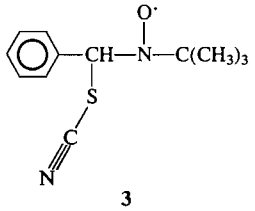
for the cyanyl adduct of PBN (Table 2). Although initially disturbing, the observation that the cyanyl spin adduct of PBN ensues from the electrooxida-



3

tion of thiocyanate is consistent with the conclusions of Pereiro *et al.* (32), that upon electrooxidation, the thiocyanatyl radical is strongly adsorbed onto the platinum electrode:

[7] $SCN^- \underset{}{\overset{\text{Pt electrode}}{\rightleftharpoons}} Pt(SCN)^{\cdot}_{surf} + e^-$

Decomposition of the Pt(SCN)$^{\cdot}$ surface species to the extremely stable PtS (33) with concomitant loss of the cyanyl radical is a tenable mechanism for formation of **1** in this system:

[8] $Pt(SCN)^{\cdot}_{surf} \rightarrow PtS_{surf} + {}^{\cdot}CN$

[9] ${}^{\cdot}CN + PBN \rightarrow \mathbf{1}$

Alternatively, **1** may be formed by the heterogeneous reaction of PBN with the Pt(SCN)$^{\cdot}$ surface species:

[10] $Pt(SCN)^{\cdot}_{surf} + PBN \rightarrow PtS_{surf} + \mathbf{1}$

The spin trapping results do not permit distinction

to be made between these two possible modes of formation of **1**.

The observed solution-resident reaction product, parathiocyanogen (32), may be formed via two suggested mechanisms (34) which do not require ·SCN to be present in solution where it would presumably be trapped. The first of these mechanisms involves dimerization of adsorbed, *mobile* ·SCN species:

[11] $2Pt(SCN)^{\cdot}_{surf} \rightarrow 2Pt + (SCN)_2$

The second mechanism reflects the oxidative dimerization of adsorbed, *nonmobile* ·SCN species:

[12] $Pt(SCN)^{\cdot}_{surf} + SCN^- \rightarrow Pt + (SCN)_2 + e^-$

There are three observations which, in concert, afford evidence for the existence of the Pt(SCN)· surface species and subsequent formation of PtS. Firstly, ·SCN is not detected in solution; secondly, ·CN is trapped by solution-resident PBN; and thirdly, the growth in intensity of the spectrum of the cyanyl spin adduct of PBN (**1**) is seen to cease shortly after onset of *in situ* steady state electrolysis of $SCN^-$. This last observation suggests that the electrode surface is altered during the initial stages of the electrolysis process, probably through formation of PtS (eq. [8] or eq. [10]).

Spin trapping of the product of the electrooxidation of chloride with PBN is another case in which spin adduct formation may proceed via a heterogeneous reaction between PBN and an adsorbed radical species (35, 36). *In situ* electrooxidation of $Cl^-$ (as TBACl in TEAP/AN) in the presence of PBN gives rise to the spin adduct **4** whose esr spectrum is shown in Fig. 2A. This spectrum is characteristic of the two isotopes of chlorine (37) which have different nuclear magnetic moments that result in spin adducts (Table 2) of different

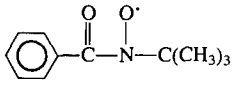
4

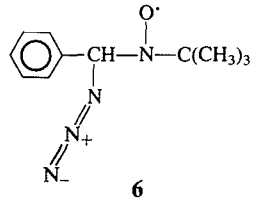
*g*-values. The intense triplet ($a_N \simeq 8$ G) in the center of this spectrum is due to the nitroxone **5** which likely arises from oxidation of PBN by $Cl_2$.



5

When 4MePyBN is used as the trapping reagent in these electrooxidation experiments, the spin adduct spectrum shown in Fig. 2C is obtained. The diminished nitroxone component in this spectrum may reflect the fact that 4MePyBN is more difficult to oxidize than PBN (Table 1). Alternatively, the $Cl^\cdot$ electrode reaction product may undergo far more rapid addition to 4MePyBN than to PBN, in which case the competitive formation of $Cl_2$, the expected oxidant in nitroxone production, is diminished.

Electrooxidation of azide to produce the azidyl radical ($N_3^\cdot$) and subsequent trapping with PBN, 4PyOBN, 2PyOBN, and 2SPBN provides an example of the importance of choice of spin trap reagent on the spin adduct spectrum observed. Electrooxidation of azide (as $TBAN_3$ in TEAP/AN) in the presence of PBN gives rise to the spin adduct **6** whose esr spectrum is shown in Fig. 3A. The assignment of this spectrum to the spin adduct



6

of structure **6** is consistent with PBN spin trapping of $N_3^\cdot$ produced by photolysis of aqueous solutions of sodium azide (6), photolysis of aqueous and methanolic solutions of $K_3[Co(CN)_5N_3]$ and $[Co(NH_3)_5N_3]Cl_2$ (38, 39), oxidation of sodium azide by Fenton's reagent in aqueous solution (6), and persulfate oxidation of aqueous solutions of sodium azide (6). It is noteworthy that far more well resolved spin adduct spectra are obtained from electrooxidations than from these other routes to the spin adduct. The triplet of 1:2:2:1 quartets seen in Fig. 3A arises from equality of β-nitrogen and β-hydrogen hfsc's in **6** (Table 2). Information regarding the radical which has been trapped may be obscured by the linewidth of the spectrum. As seen in Fig. 3C, the equality of β-N and β-H hfsc's

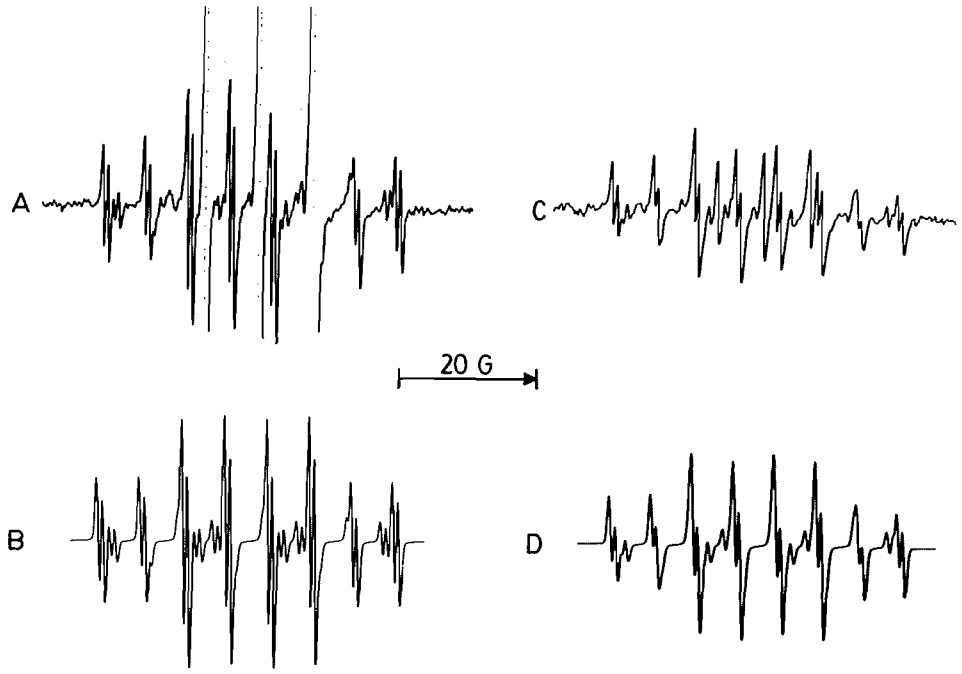

FIG. 2. The esr spectra of spin adducts formed upon *in situ* electrooxidation of TBACl in TEAP/AN in the presence of (A) PBN; (B) computer simulation of A; (C) 4MePyBN; (D) computer simulation of C. Parameters for computer simulations are given in Table 2.

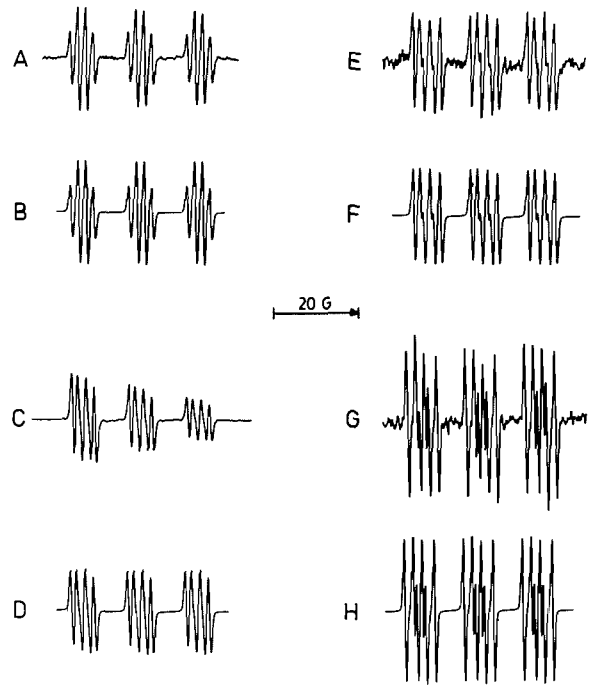

FIG. 3. The esr spectra of spin adducts derived from *in situ* electrooxidation of $TBAN_3$ in TEAP/AN in the presence of (A) PBN; (B) computer simulation of A; (C) 4PyOBN; (D) computer simulation of C; (E) 2PyOBN; (F) computer simulation of E; (G) 2SPBN; (H) computer simulation of G. Parameters for computer simulations are given in Table 2.

is removed when 4PyOBN, rather than PBN, is used as the trapping agent. Here, the 1:2:2:1 pattern observed with PBN (Fig. 3A) has been altered to a 1:1, 1:1, 1:1 pattern. Although a difference in $a_\beta^N$ and $a_\beta^H$ is observed (Table 2), resolution of the two additional lines in each multiplet is incomplete, and they appear as shoulders in Fig. 3C. Further improvement in resolution of the azidyl spin adduct spectrum is achieved when 2PyOBN is employed as the spin trap (Fig. 3E). The increased difference in $a_\beta^N$ and $a_\beta^H$ (Table 2) derives from sterically induced alteration of the time-averaged dihedral angle between the β-hydrogen, α-carbon, nitrone nitrogen plane, and the plane defined by the α-carbon, nitrone nitrogen, and its *p*-orbital (1). In the case of trapping electrogenerated azidyl radical with 2SPBN (Fig. 3G, Table 2), all eighteen lines of the spectrum are well resolved. The spin adduct spectra shown in Fig. 3 clearly demonstrate the impact of spin trap selection on the ease of unambiguous spectral analysis.

Spin trapping of primary electrode reaction products has recently been utilized in an investigation of the mechanism of the electroreduction of *N*-alkylpyridinium ions (12). Reduction of *N*-methylpyridinium ion ($NMP^+$) in aqueous solution has long been believed to be a monoelectronic process resulting in a transient radical which subsequently dimerizes:

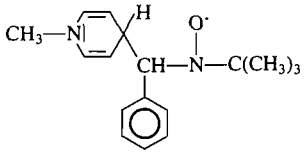
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

[13] $CH_3-N^+(\bigcirc) + e^- \rightleftharpoons CH_3-N(H)(\cdot)$ (7)

[14] $2\,CH_3-N(H)(\cdot) \longrightarrow CH_3-N(H)-C_6H_4-N-CH_3$ (H)

Although the 1-methyl-1,4-dihydro-4-pyridinyl radical (**7**) has been widely proposed (40–43), its existence has not been established.

*In situ* electroreduction of $NMP^+$ at a mercury pool cathode in aqueous media saturated with PBN gives rise to an esr spectrum consisting of a triplet of doublets (Table 3) which has been tentatively assigned to the spin adduct **8** formed by addition of



**8**

**7** to PBN (12). Verification of this assignment by independent preparation of authentic **8** has not been possible as no successful synthetic route has been found. Assignment of the observed esr spectrum to **8** is based on the observations that $a_\beta^H$ is indicative of an adducted radical having steric properties characteristic of a pseudoplanar six-membered ring (48) and that the linewidth reflects unresolved γ-H hyperfine splitting. Considerations of other radicals which might likely form during reduction of $NMP^+$ have discounted $H^\cdot$, $HO^\cdot$, $CH_3^\cdot$, $CH_3O^\cdot$, and $CH_3-N^+(\bigcirc)\cdot$ spin adducts of PBN by comparison of accepted hfsc values for these nitroxyl radicals with those observed for **8** (Table 3).

Alternate spin trapping experiments performed with spin traps which typically afford more informative spin adduct spectra (e.g., N*t*B or DMPO) have not been successful. Whether the absence of detectable spin adducts when these traps are used is a consequence of **7** not being trapped or is due to the electroactivity of the resulting spin adduct is not known.

### *Spin trapping of intermediates in coupled chemical reactions*

The identification of intermediates in reactions which are initiated by heterogeneous electron transfer is essential to an understanding of the mechanisms of those processes (49, 50). A clear illustration of the utility of spin trapping in assessing the influence of solution conditions on the intermediates produced in an electrochemically initiated reaction is provided by the electrooxidation of tetra-*n*-butylboride anion ($BBu_4^-$) at a platinum electrode in AN containing 0.10 *M* TBAP (3). Selective oxidation of $BBu_4^-$ (as $TBABBu_4$) in rigorously deoxygenated TBAP/AN containing PBN affords the spin adduct spectrum shown in Fig. 4A. Electrooxidation without deoxygenation of $BBu_4^-$ in TBAP/AN containing PBN gives rise to a mixture of two spin adducts (Fig. 4B), one of which is spectrally identical to that obtained in the absence of oxygen (Fig. 4A). Electrooxidation of $BBu_4^-$ in oxygen-saturated TBAP/AN containing PBN affords a single spin adduct whose esr spectrum, recorded after removal of oxygen, is shown in Fig. 4C. This spectrum is identical with the

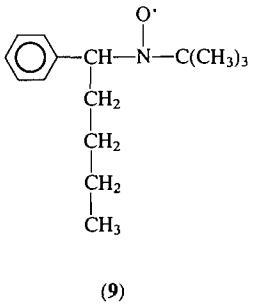
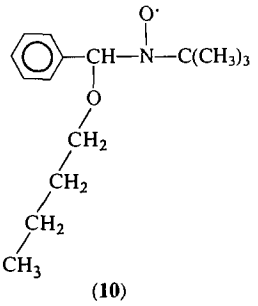
second component of the mixture spectrum shown in Fig. 4B. Using the hfsc's from the spectra in Figs. 4A and 4C (Table 4), the spectrum shown in Fig. 4D was computer simulated for a mixture of 68% 4A and 32% 4C.

The spectrum in Fig. 4A was assigned to **9** in that authentic **9**, produced by the photolysis of tri-*n*-butylplumbyl acetate (*n*-$Bu_3PbOAc$) in TBAP/AN containing PBN gave rise to a spin adduct that



(**9**)



(**10**)

exhibited hfsc's which were identical (Table 4) to those in Fig. 4A (3). The spectrum in Fig. 4C was assigned to **10** (3) on the basis of known reactions of alkyl radicals with $O_2$ (51, 52), the spectral linewidth (1, 48), the *g*-value (1), and the sameness of the hfsc's of this spectrum and those of the *n*-pentyloxy spin adduct of PBN (51). The use of other spin traps was also diagnostic in this study in that the presence of $R—CH_2—CH_2^{\cdot}$ in **9** was established through spin trapping with N*t*B (3).

*Spatially resolved spin trapping in heterogeneous systems*

In cases where spin trapping techniques are to be employed to characterize primary reaction products in heterogeneous electron transfer processes, localization of the spin trap reagent in the interfacial region is desirable. This is true in conventional electrochemical processes involving solid or liquid electrodes, in photoelectrochemical reactions, and in electron transfer processes occurring at membrane/solution interfaces. To this end, methods for localizing spin trap reagents in these interfacial regions have been pursued. Not only must the spin trap be constrained near the interface, but once there, it must retain its facility for trapping radical species and also give rise to well resolved spin adduct spectra.

Progress toward the goal of constraining spin traps at solid/solution interfaces is reflected in the recently reported covalent attachment of HOPBN to silaceous surfaces (15). In that work, cyanuric chloride (CC) was attached to the surface of controlled pore glass beads (eq. [15]):

[15] 
The CC derivatized beads were then reacted with HOPBN to produce the covalently attached nitrone **11**:

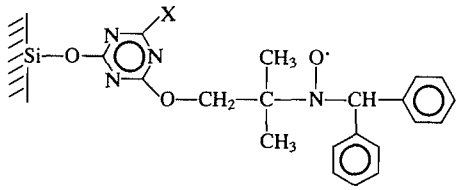
**11**

That **11** functions as a spin trap was demonstrated by its exposure to phenyl radicals arising from the thermal decomposition of phenylazotriphenylmethane (PAT). A dispersion of **11** in deoxygenated benzene containing millimolar PAT afforded the esr spectrum shown in Fig. 5A. This spectrum, recorded after 21 h, increased in intensity over a period of 48 h. Assignment of this spectrum to the spin adduct **12** was made on the basis of agreement



**12**

between the hfsc's measured from Fig. 5A ($a_N$ = 14.56, $a_\beta^H$ = 2.36 G) and those determined from the spectrum of the spin adduct formed by reaction of phenyl radicals (from PAT) with HOPBN in isotropic benzene solution ($a_N$ = 14.54, $a_\beta^H$ = 2.40 G). The absence of a detectable esr signal in the supernatant solution indicated that the spectrum in Fig. 5A was indeed derived from attached nitroxyls only.

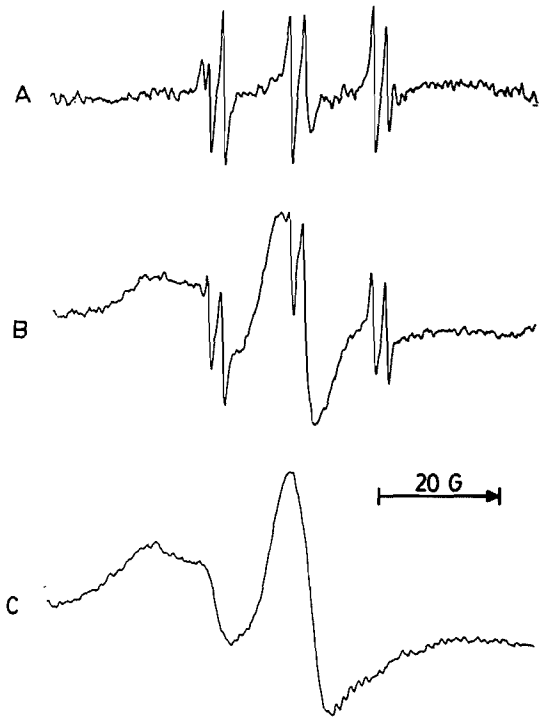


FIG. 5. The esr spectra obtained by contacting benzene solutions of a phenyl radical source (PAT) with HOPBN which had been covalently linked through cyanuric chloride (CC) to glass beads. (A) 5% CC – 5% HOPBN loading exposed to 1 m*M* PAT for 21 h; (B) 5% CC – 5% HOPBN loading exposed to 6 m*M* PAT for 20 h; (C) 30% CC – 30% HOPBN loading exposed to 6 m*M* PAT for 8.5 h. See text for details of glass bead loading. *Reprinted with permission from J. Phys. Chem.* **84**, 557 (1980), copyright 1980 American Chemical Society.

beads to this millimolar solution of phenyl radical source resulted in the observation of an additional weak, broad resonance. This resonance is the dominant spectral feature observed upon exposure of **11** to higher concentrations of phenyl radical precursor (Fig. 5B). In cases of higher surface loading of **11** and higher PAT concentrations, the sharp spectral features seen in Fig. 5A are lost and only a spectrum which is indicative of a "highly immobilized" nitroxyl species (53) is observed (Fig. 5C). It is significant that under conditions of low surface loading of **11**, where dipolar broadening is minimal (54), immobilized spin traps can give rise to relatively sharp-lined spin adduct spectra which indicate freedom of rotation of the nitroxyl radical about an axis perpendicular to a plane containing the nitroxyl $z$-axis (15, 53).

In addition to the development of a protocol for the localization of spin traps at solid/solution interfaces, recent work in these laboratories has been directed toward the design and evaluation of a spin trap system with which the interfacial regions of membranes and membrane models can be probed. The detection and characterization of radical intermediates arising from heterogeneous electron transfer reactions taking place at membrane/solution interfaces is essential to mechanistic delineation of many physiological processes (55). Inasmuch as the well controlled characterization of membrane/solution interfacial processes involving intact, naturally occurring systems is an experimentally complex problem, several membrane-mimetic systems have been devised for such studies. Principal among these are micelles and vesicles (56, 57). The order imparted to the reaction environment by these membrane models can significantly affect the observed redox properties of substrates resident within the respective microstructures. For example, when 10-methylphenothiazine (MPTH), an analogue of several common membrane-active neuroleptic agents (58), is incorporated into anionic sodium dodecylsulfate (SDS) micelles, its oxidation potential is observed to be 80 mV less anodic than that noted in isotropic aqueous media (59). These results indicate that the product of the electrooxidation, the cation radical ($MPTH^{+\cdot}$), is stabilized by the local microenvironment. Electron spin resonance spectroscopy confirms the interactions between $MPTH^{+\cdot}$ and SDS micelles. In the absence of SDS, the esr spectrum of $MPTH^{+\cdot}$ exhibits the 254 lines shown in Fig. 6A. At SDS concentrations above the critical micelle concentration (CMC), the esr spectrum of $MPTH^{+\cdot}$ is strikingly broadened (Fig. 6B), reflecting the slow tumbling of the $MPTH^{+\cdot}$/micelle aggregate.

Recent work in these laboratories has been

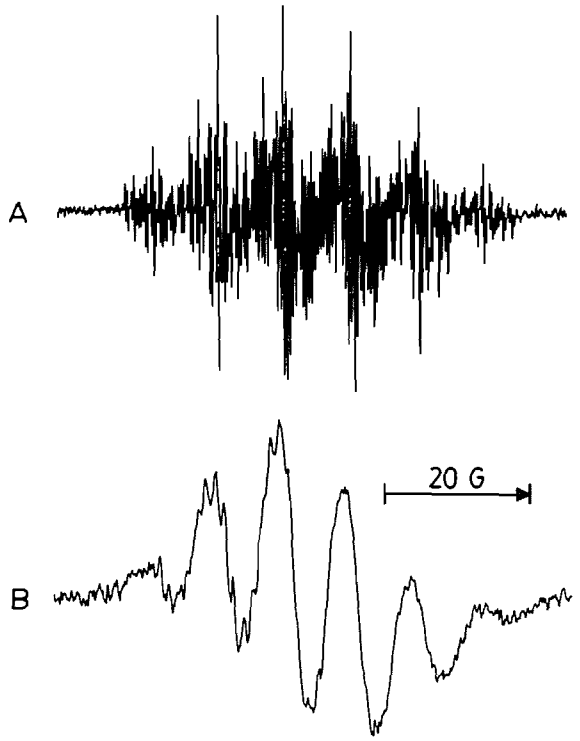

FIG. 6. The esr spectra of $MPTH^{+\cdot}$ in (A) 50 m$M$ $LiClO_4$; (B) 50 m$M$ $LiClO_4$ containing 20 m$M$ SDS.

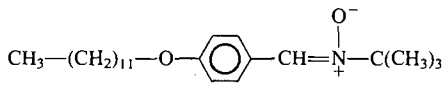
directed toward the design of spin trapping systems with which transient radical species arising from heterogeneous electron transfer processes at membrane/solution interfaces may be perceived. Radical species produced in such reactions may be generated either on the hydrophobic side of the interface or on the hydrophilic (aqueous) side external to the membrane. Consequently, the ability of the spin trapping apparatus to react efficiently with radicals produced on either side of the interface must be evaluated. To address this question, a nitrone derived spin trap has been synthesized (22) and incorporated into micellar and vesicular systems. The ability of these assemblies to trap radical species produced on either side of the interface has been assessed through the use of the same radical (phenyl) derived from precursors which are resident in either the hydrophobic or in the hydrophilic regions of the ordered systems (17).

The nitrone spin trap which has been designed to be intimately associated with the microstructure of micellar and vesicular systems is the water-insoluble 4-dodecyloxy derivative of PBN, DOPBN (**13**). DOPBN has been found to coassemble with SDS up to a maximum mole ratio of 1:5 DOPBN to SDS. At ratios in excess of 2:5, liquid crystalline phases become evident at room temperature. The SDS/



13

DOPBN micelles are quite stable (>1 week) and afford no detectable esr signals. Based on the literature value of the aggregation number of SDS (56), an average micelle consists of approximately 60 SDS and 12 DOPBN entities. The uv absorption maxima of DOPBN indicate that the nitrone functionality resides in a region of the micelle having a micropolarity comparable to that of ethanol ($\lambda_{max}$ (DOPBN/SDS) = 224 nm, $\lambda_{max}$ (DOPBN/pentane) = 210 nm, $\lambda_{max}$ (DOPBN/EtOH) = 223 nm). This is consistent with residence of the nitrone function in the Stern layer (interfacial region) of the micelle (56).

The ability of the interfacially resident nitrone to trap radicals generated within the micelle has been tested by using phenyl radicals produced by the thermal decomposition of PAT. The pronounced hydrophobicity of this molecule together with its micelle-dependent solubilization by SDS in aqueous solution points to its residence in the hydrocarbon region of the SDS/DOPBN aggregate. Phenyl radicals generated from this precursor are indeed trapped by the coassembled DOPBN and give rise to markedly broadened spin adduct spectra typified by that shown in Fig. 7A. Upon addition of an equal volume of AN to this solution, the system order is destroyed and the resulting isotropic solution affords the well resolved spin adduct spectrum shown in Fig. 7B. Generation of the phenyl adduct of DOPBN in an *isotropic* solution of AN/$H_2O$ (50 vol.%) containing SDS, DOPBN, and PAT gives rise to hfsc values (Tables 5) which are equal to those observed in the disrupted micelle solution. Additionally, the authentic phenyl adduct of DOPBN was synthesized by reaction of equimolar amounts of phenyllithium and DOPBN in diethyl ether, followed by air oxidation of the resulting anion to the nitroxyl radical and subsequent solvent exchange (48). Electron spin resonance examination of this radical in AN/$H_2O$ (50% v/v) also affords hfsc values (Table 5) which are in excellent agreement with those noted above. This finding permits assignment of the spectra shown in Fig. 7 to the phenyl adduct of DOPBN.

Addition of a *water-soluble* phenyl radical source to a solution of SDS/DOPBN micelles provides a test for the ability of the interfacially resident nitrone to trap radicals generated external to the micelle. Whereas phenyldiazonium tetrafluoroborate (PDT) is stable in nonaqueous media (60), it has been shown to rapidly decompose in aqueous solution to afford a convenient source of phenyl radicals (12). Addition of PDT to a solution containing SDS/DOPBN micelles gives rise to the esr spectrum shown in Fig. 8A. Again, destruction of the system order through addition of an equal volume of AN affords an isotropic solution whose esr spectrum is shown in Fig. 8B. Identical hfsc values are observed for the spin adduct in this disrupted micelle solution and for the phenyl adduct of DOPBN generated in an *isotropic* solution of PDT, DOPBN, and SDS in 50% aqueous AN (Table 5). These values are also in agreement with those noted for the authentic phenyl adduct of DOPBN prepared by the phenyllithium reaction (*vide supra*). Hence, the spectra shown in Fig. 8 are also assigned to the phenyl adduct of DOPBN.

These results indicate that micelle-resident DOPBN traps phenyl radicals generated both within the micelle and external to that structure. This trapping of radicals produced on either side of the

micelle/solution interface further supports residence of the nitrone functionality at that interface. Recent reports, however, suggest that the micelle structure is relatively "open" (61, 62) and consequently the interior of the micelle may be accessible to water-resident species. Additionally, micelle dynamics are rapid (56, 63) and provide ample opportunity for the micelle solubilized trap to interact with both solution-resident and micelle-resident radical species. Given the dynamic nature of micelle aggregates and the possible penetration of aqueous species into their interiors, micelles may be of limited utility as models for the study of interfacial spin trapping processes.

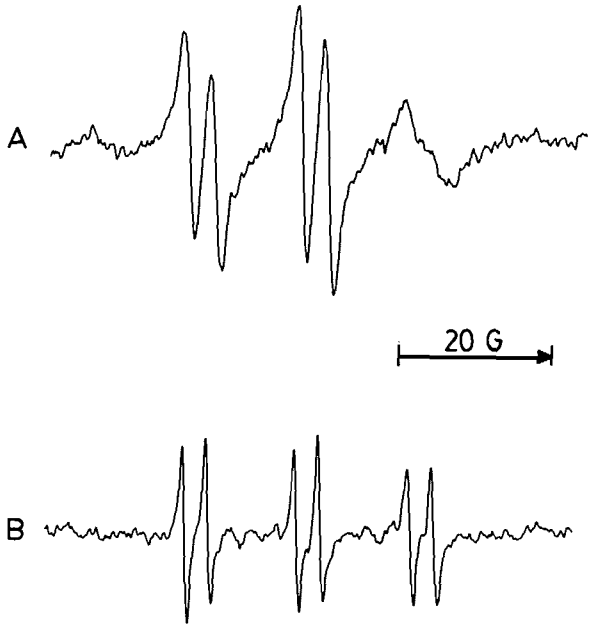

FIG. 8. The esr spectra of phenyl adduct of DOPBN produced by decomposition of PDT in the presence of SDS/DOPBN micelles. (A) spectrum observed in a solution of intact SDS/DOPBN micelles; (B) spectrum observed upon disruption of micelles by the addition of AN.

Vesicles, on the other hand, are ordered systems which are characterized by profoundly longer monomer residence times (hours vs. microseconds) (57) and a more well-defined interface which is less penetrable by aqueous species. DOPBN has been assembled into vesicle structures with dioctadecyldimethylammonium chloride (DODAC) and with lecithin in order to again test the interfacial residency of the nitrone and its bilateral trapping ability in these model membranes.

Water-insoluble PAT is solubilized by DODAC/DOPBN and lecithin/DOPBN vesicles. Thermal decomposition of this phenyl radical precursor in DODAC/DOPBN vesicles gives rise to the extremely broadened esr spectrum shown in Fig. 9A. Addition of an equal volume of $CHCl_3$ results in disruption of the vesicles and extraction of the spin adduct into the $CHCl_3$ phase. Figure 9B shows the esr spectrum of the extracted spin adduct. The authentic phenyl adduct of DOPBN, prepared by the phenyllithium reaction, was examined by esr in $CHCl_3$. The hfsc's of this species, together with those from the spectrum shown in Fig. 9B, are summarized in Table 6. The sameness of these parameters and those derived from the spectrum shown in Fig. 9B permits the assignment of the spin adduct spectra in Fig. 9 to the phenyl adduct of DOPBN. Parallel spin trapping experiments with lecithin/DOPBN vesicles afforded similar results. The hfsc values observed for the $CHCl_3$ extract of the spin adduct formed in lecithin/DOPBN vesicles are given in Table 6. In this case as well, the spin adduct formed from the decomposition of PAT in

Commun. **102**, 1350 (1981), copyright 1981 Academic Press, Inc.

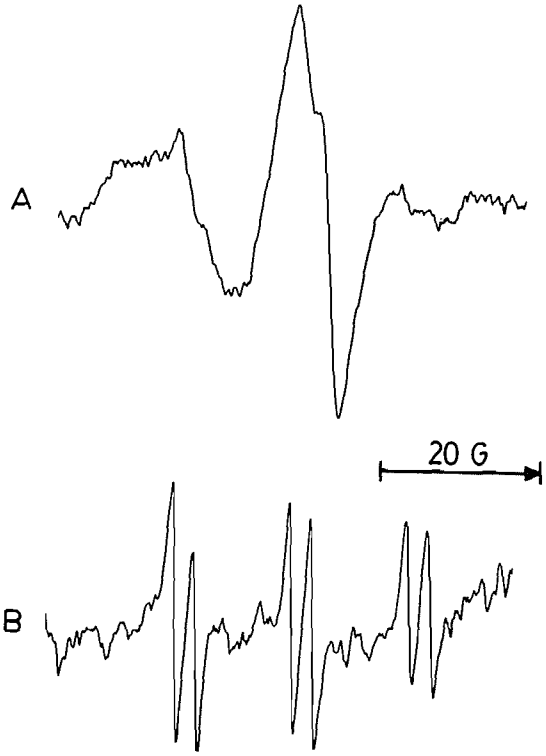

FIG. 10. The esr spectra of phenyl adduct of DOPBN arising from the decomposition of PDT in the presence of DODAC/DOPBN vesicles. (A) spectrum observed in a solution of intact DODAC/DOPBN vesicles; (B) spectrum of $CHCl_3$ extract of A.

the hydrophobic region of the bilayer is the phenyl adduct of DOPBN.

The addition of water-soluble PDT to DODAC/DOPBN vesicle preparations affords broad esr spectra typified by that shown in Fig. 10A. Extraction of the spin adduct/vesicle solution with an equal volume of $CHCl_3$ and subsequent esr examination of the $CHCl_3$ solution gives rise to the spectrum shown in Fig. 10B. The hfsc values derived from this spectrum are identical to those of the authentically prepared phenyl adduct of DOPBN described above (Table 6) and permit assignment of the spectra in Fig. 10 to the phenyl adduct of DOPBN. The same sequence of experiments carried out in lecithin/DOPBN vesicles gives rise to analogous results. Once again, the esr spectrum of the $CHCl_3$ extract of the spin adduct formed from reaction of the lecithin/DOPBN vesicles with phenyl radicals derived from the non-vesicle resident PDT indicates formation of the phenyl adduct of DOPBN.

The results obtained in DODAC/DOPBN and lecithin/DOPBN vesicles show that DOPBN traps phenyl radicals which have been generated on either side of the membrane/solution interface.

This bilateral trapping ability of DOPBN in these systems where monomer exchange rates and interfacial penetration by the aqeuous solution are minimal is consistent with residence of the nitrone functionality at the membrane/solution interface. Moreover, the results obtained in these vesicle systems lend credence to the validity of the interfacial description of the spin trapping processes observed in micelles (*vide supra*). In sum, these experimental findings in micelle and vesicle systems suggest that spatially resolved spin trapping can be profitably employed for the detection and characterization of radical species arising from heterogeneous electron transfer processes at membrane/solution interfaces.

REVIEW/SYNTHÈSE

# Biosynthetic studies using $^{18}O$ isotope shifts in $^{13}C$ nuclear magnetic resonance[1,2]

JOHN C. VEDERAS

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received January 8, 1982

JOHN C. VEDERAS. Can. J. Chem. **60**, 1637 (1982).

Isotopic substitution with oxygen-18 induces an observable upfield shift in the $^{13}C$ nmr positions of directly-attached carbons, and in some cases, β-carbons. The magnitudes of these shifts range from about 0.05 ppm to 0.01 ppm, and are dependent on structure in an empirically predictable fashion. Incorporation of doubly labeled ($^{13}C$, $^{18}O$) precursors into polyketides followed by $^{13}C$ nmr analysis can identify carbon–oxygen bonds remaining intact during microbial biosynthesis. This technique has been applied to studies on antibiotics such as brefeldin A, cytochalasin B, granaticin, and lasalocid A, as well as aflatoxin precursors such as averufin, versicolorin A, and sterigmatocystin.

JOHN C. VEDERAS. Can. J. Chem. **60**, 1637 (1982).

La substitution isotopique par de l'oxygène-18 induit, en rmn du $^{13}C$, un déplacement chimique observable vers les hauts champs des positions des atomes de carbone qui leur sont directement liés et, dans certains cas, des déplacements des atomes de carbone en position β. L'ordre de grandeur de ces déplacements varie de 0,05 ppm à 0,01 ppm et ils dépendent d'une façon empirique de la structure. L'incorporation de précurseurs doublement marqués ($^{13}C$, $^{18}O$) dans les polycétides suivie d'une analyse par rmn du $^{13}C$ permet d'identifier les liaisons carbone–oxygène qui demeurent intactes durant la synthèse microbienne. On a utilisé cette technique pour étudier les antibiotiques tels la brefeldine A, la cytochalasine B, la granaticine et la lasalocide A de même que des précurseurs d'aflatoxine tels que l'avérufine, la versicolorine A et la stérigmatocystine.

[Traduit par le journal]

During the last decade the development of $^{13}C$ nmr techniques in biosynthesis has elucidated the arrangement of precursor units in carbon skeletons of most classes of secondary metabolites (1). However, the mechanisms and sequence by which these units are linked remain largely speculative, partly because of lack of methods to follow changes in intermediate oxidation states. In response there is a growing interest in determination of the biosynthetic fate of precursor hydrogens using $^{2}H$ nmr (2) and of oxygens using mass spectrometry (3, 4). The latter technique can detect both commonly-employed stable isotopes of oxygen, $^{17}O$ and $^{18}O$, but ascertaining the exact structure of the mass spectrometric fragments in partially-labeled polyoxygenated molecules is often difficult. Frequently preliminary specific labeling experiments or chemical degradations are necessary (4). Unlike $^{16}O$ and $^{18}O$, oxygen-17 has a nuclear spin (5/2) and can be observed directly by nmr. Unfortunately its use in biological studies (5, 6) has been limited by low natural abundance (0.037%) and consequent expense, as well as by broadness of nmr signals due to its quadrupole and spin–spin coupling.

Recently, investigations by Boyer and co-workers (7), Risley and Van Etten (8), Darensbourg *et al.* (9), and our group (10) have confirmed the theoretical prediction (11) that the more abundant oxygen-18 (0.204%) can be indirectly detected by changes induced in the $^{13}C$ nmr chemical shifts of directly-attached carbon atoms. For example, propyl cyclohexane carboxylate **1** labelled with $^{18}O$ in the ether oxygen exerts moderate isotope shifts at both adjacent carbons (Fig. 1) and a much smaller one (0.005 ppm) at the β-carbon of the propyl group (10). The magnitudes of these shifts are governed by structure in an empirically predictable way and display almost no solvent dependence except for [$^{18}O$] alcohols (8, 10). Generally, single-bonded oxygens show smaller effects (approx. 0.035 to 0.010 ppm) than doubly bonded oxygens (approx. 0.055 to 0.030 ppm). For carbonyl compounds the shifts decrease in the order: ketones ≥ aldehydes ≥ esters ≥ amides, while for alcohols the order is: tertiary ≥ secondary ≥ primary ≥ phenols (8, 10). Other noticeable trends include direct additivity of shift magnitudes at both α and β carbons upon multiple $^{18}O$ substitution, and reduction of the effect due to conjugation or electron donation through a π system. Since this technique can directly determine the location and extent of $^{18}O$ labeling in organic molecules, it has already seen interesting applications in study of

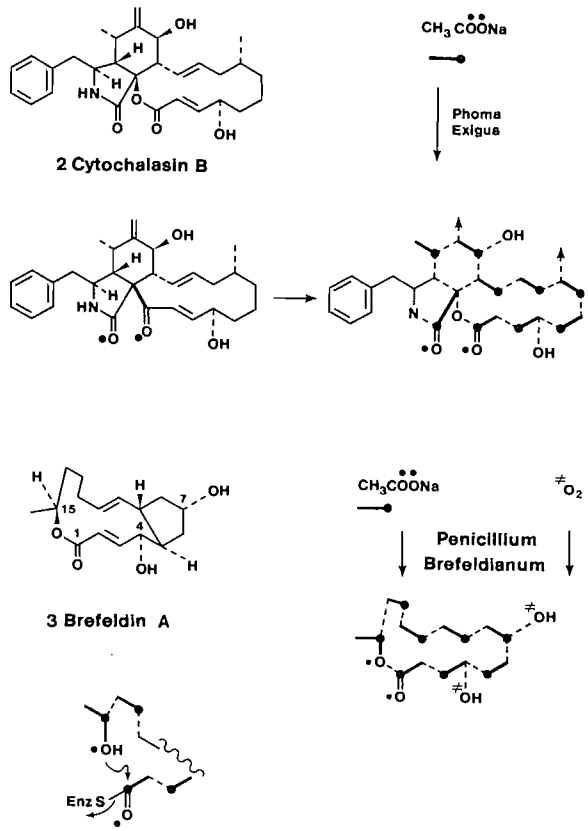

FIG. 2. Incorporation of sodium [1-$^{13}C$, $^{18}O_2$]acetate into cytochalasin B **2** and brefeldin A **3**.

chemical mechanism (9, 12). Obviously the methodology also promises to be a valuable tool for probing a variety of biological mechanisms, including those of polyketide biosynthesis.

Among the fungal secondary metabolites we examined in our early work were cytochalasin B **2**, an important tool in cell biology (13), and the structurally-related antibiotic brefeldin A **3** (14).[3] The highly functionalized macrocyclic rings of both of these compounds originate by head to tail coupling of acetate units (Fig. 2) (13, 15, 16). In considering possible biogenetic intermediates, a key question is whether the functionality is introduced by aerobic oxidation of a saturated precursor resulting from normal fatty acid biosynthesis, or whether it arises from incomplete reduction during assembly of the acetate chain.

Earlier mass spectrometric studies on several metabolites had already demonstrated that $^{18}O$ labeling could provide the answer if the location and extent of isotopic oxygen could be determined (4, 17). However, this type of analysis has often required extensive work to identify the mass spectral fragments. Incorporation[3] of doubly labeled sodium [1-$^{13}C$, $^{18}O_2$]acetate into brefeldin A **3** by *Penicillium brefeldianum* followed by $^{13}C$ nmr analysis confirmed Hutchinson's previous results (4) that only the two lactone oxygens were labeled. The observation of a single $^{18}O$ isotope shift at C-1 for the doubly-bonded oxygen as well as a shift at C-15 due to the bridging oxygen shows that these two carbon–oxygen bonds originate from acetate during biosynthesis, and that lactone formation involves attack by the oxygen at C-15 on the carbonyl (C-1). Since the natural abundance of $^{13}C$ is low (1.1%) and the likelihood that two neighboring acetate units will both be labeled within the same molecule is small in a typical incorporation experiment, doubly-labeled [$^{13}C$, $^{18}O$] precursors allow detection of intact carbon–oxygen bonds. This is true even in cases like brefeldin A **3** where the labeled oxygen bridges via a newly-formed bond to a carbon which is likely to be $^{13}C$-labeled in another molecule. Analogous incorporation of sodium [1-$^{13}C$, $^{18}O_2$]acetate into cytochalasin B **2** and $^{13}C$ nmr spectral examination demonstrated that only the two doubly-bonded oxygens were labelled (18). The lack of label in the singly-bonded lactone

[3]Brefeldin A was studied in collaboration with Prof. C. R. Hutchinson, School of Pharmacy, University of Wisconsin.

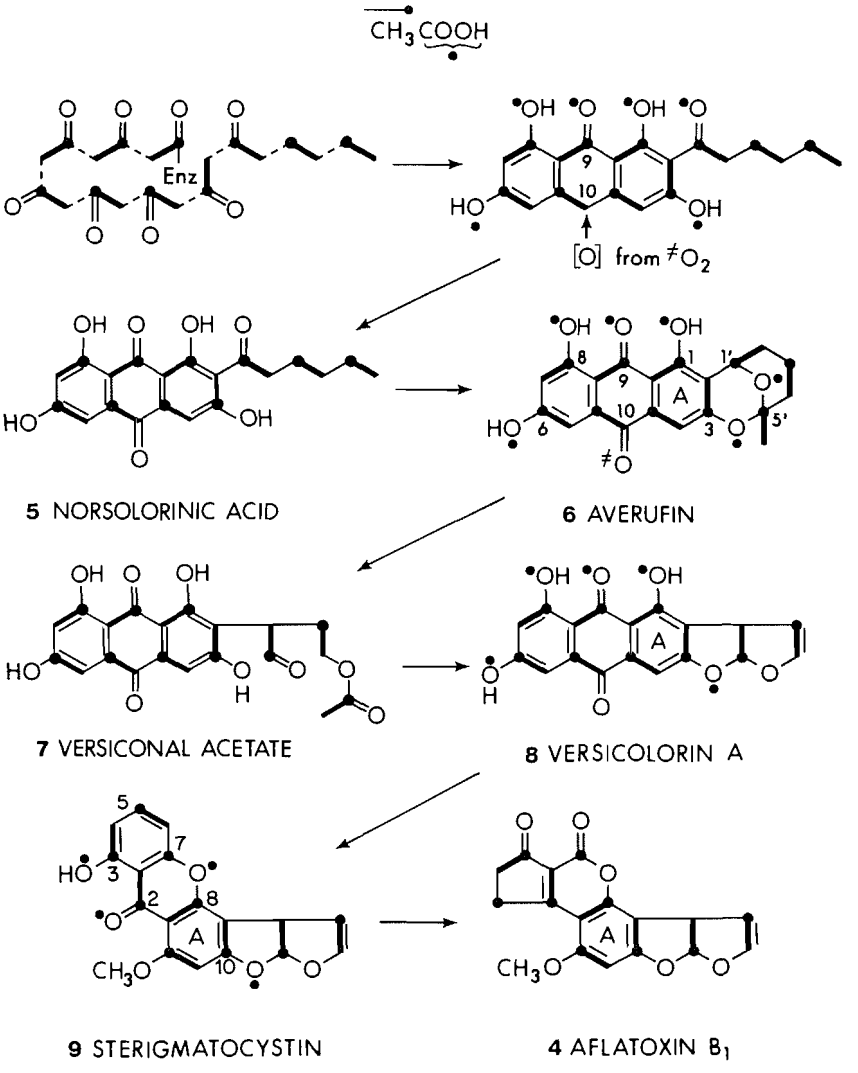

FIG. 3. Biosynthetic sequence to aflatoxin $B_1$ 4.

oxygen agrees with earlier work (19) indicating that, in contrast to brefeldin A **3**, this macrolide ring originates via a biological Baeyer–Villiger oxidation (20) of a ketonic precursor.

Aflatoxin $B_1$ **4** and related compounds which possess a bis-dihydrofuran moiety fused onto an aromatic ring are toxic hepatocarcinogens produced by fungi (usually *Aspergillus*) which frequently contaminate food products (21). Extensive investigation by various research groups has elucidated the arrangement of acetate carbons in most of these compounds and has suggested a fascinating biosynthetic pathway: acetate → norsolorinic acid **5** → averufin **6** → versiconal acetate **7** → versicolorin A **8** → sterigmatocystin **9** → aflatoxin $B_1$ **4** (Fig. 3) (21). Recent pulse labeling experiments indicate that an alternative route to aflatoxin may also be present which does not have sterigmatocystin **9** as an obligatory precursor (22). Since oxygen labeling patterns in such highly oxidized metabolites are not easily analyzed by mass spectrometry, the $^{13}C$ nmr isotope shift method seemed especially useful for obtaining mechanistic insights.

In our first study (23) a mutant of *Aspergillus parasiticus* blocked in aflatoxin formation was used to incorporate sodium [1-$^{13}C$, $^{18}O_2$]acetate into averufin **6**. All of the anthraquinone carbons bearing oxygen showed isotope shifts except the carbonyl at C-10. A separate fermentation with [$^{18}O$] oxygen gas and an unlabeled carbon source produced averufin **6** containing isotopic oxygen only at that carbonyl. Our findings support the hypothesis that intramolecular aldol reactions in the polyketonic chain are followed by enolizatons to gener-

ate an anthrone which is then aerobically oxidized to an anthraquinone. The acetal carbon at C-5′ had a very low intensity isotope-shifted peak in the acetate feeding experiment due to the small proportion of molecules which were intramolecularly dilabeled at C-5′ ($^{13}C$ only) as well as at C-3 or C-1′ ($^{13}C$ and $^{18}O$). Although these experiments cannot determine the source of oxygen presumably present at C-5′ prior to acetal formation, the apparent intermediacy of norsolorinic acid **5** and averantin (22, 24) implies complete reduction of the first two carbonyls during assembly of the polyketide chain and subsequent aerobic oxidation at C-5′ just before averufin **6** formation.

Preliminary results on the relatively insoluble pigment versicolorin A **8** produced by another blocked mutant of *A. parasiticus* indicate that the anthraquinone oxygens are labeled as would be predicted by biosynthesis from averufin **6** (Fig. 3). The oxygen in the terminal dihydrofuran ring probably originates from the aqueous medium since no $^{18}O$ could be detected by $^{13}C$ nmr examination of the adjacent carbon after incorporation of [$^{18}O$] acetate or [$^{18}O$] oxygen gas. This is not unexpected in view of the intermediacy of versiconal acetate 7 (21, 25) which can easily exchange the aldehyde oxygen.

In order to determine the source of oxygens in sterigmatocystin **9**, sodium [1-$^{13}C$, $^{18}O_2$]acetate was fed to *A. versicolor*, a species which produces many of the same aflatoxin precursors as *A. parasiticus* (21, 22). However, the normal proton decoupled $^{13}C$ nmr spectra of this toxin gave signals which were complex patterns due to long range carbon–carbon couplings resulting from multiple intramolecular precursor incorporation. Although these complex patterns initially obscured the small $^{18}O$ isotope shifts, we have recently been able to resolve the uncoupled singlets from the superimposed doublets using spin echo Fourier transform techniques (26).[4] Presence of [$^{18}O$] acetate-derived oxygens could be detected by isotope shifts at C-1, C-3, C-8, and C-10 of sterigmatocystin **9**. Xanthone ring formation must therefore proceed by attack of the oxygen at C-8 on the C-7 position, probably via an addition–elimination process (27) on an unsymmetrical intermediate since the carbon labeling pattern in the phenolic ring is unscrambled (21, 28). Lack of $^{18}O$ label at C-12 is in accord with probable aerobic cleavage of the anthraquinone ring of a versicolorin A type precursor, but the absence of any oxygen functionality at C-5 of sterigmatocystin **9** remains unexpected.

[4]Descriptions of spin echo resolution of $^{18}O$ isotope shifts in $^{13}C$ nmr have been published (36, 37).

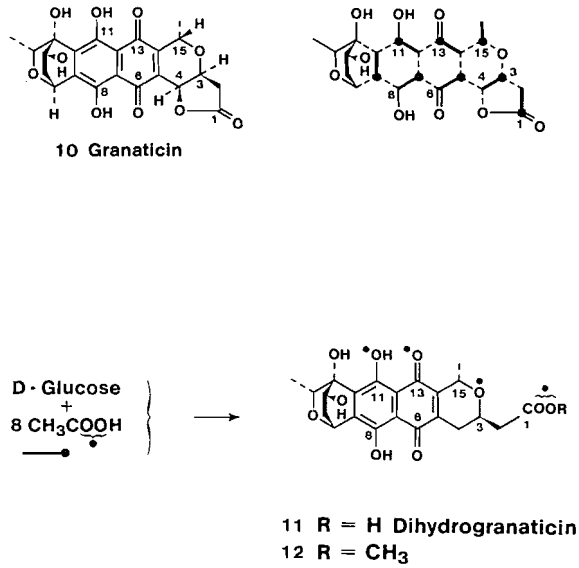

FIG. 4. Biosynthesis of granaticin **10** and dihydrogranaticin **11** from sodium [1-$^{13}C$, $^{18}O_2$]acetate.

A separate study[5] centers on granaticin **10**, an antitumor antibiotic from *Streptomyces violaceoruber*. Its carbon skeleton originates from acetate and glucose, and it often occurs with dihydrogranaticin **11** which can be converted to it by cell free extracts of the producing organism (Fig. 4) (29). Incorporation of sodium [1-$^{13}C$, $^{18}O_2$]acetate into **10** was followed by chemical conversion to dihydrogranaticin methyl ester **12** and $^{13}C$ nmr analysis. Preliminary results indicate that acetate-derived oxygens are retained at C-1, C-3, C-11, and probably C-13. Observation of an isotope shift at C-3 but not at C-15 demonstrates that the C-3 carbon–oxygen bond is preserved during closure of the dihydropyran ring. Additional work is in progress to also determine the mechanism of lactone formation in granaticin **10**.

Since the construction of macrolide and polyether antibiotics is thought to be similar to that of fatty acids and polyaromatics (30), we[6] investigated the biosynthesis of lasalocid A **13** (Fig. 5) (31). Lasalocid A **13** (also known as X537A) is an ionophoric antibiotic (32) from *Streptomyces lasaliensis* which is effective against certain poultry infections (33). The carbon skeleton had already been shown to be assembled from acetate, propionate, and butyrate units (34). Three plausible biosynthetic mechanisms could account for the oxygen substituents and the overall stereochem-

[5]Granaticin is being studied in collaboration with Prof. H. G. Floss, School of Pharmacy, Purdue University.

[6]Lasalocid A was investigated in collaboration with Prof. C. R. Hutchinson, University of Wisconsin.

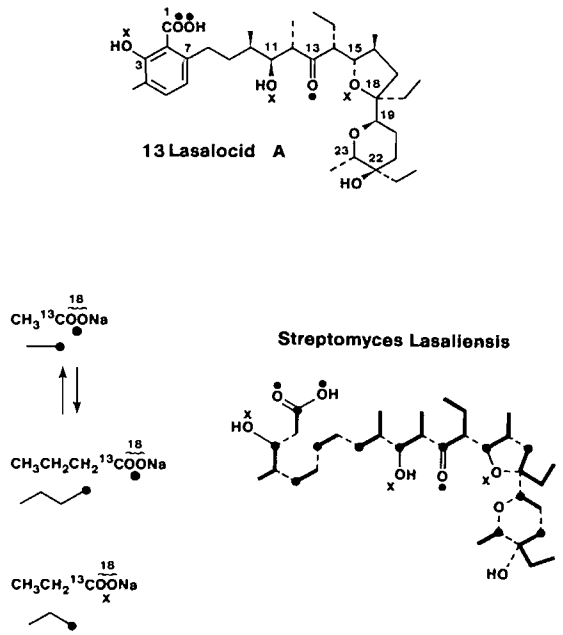

FIG. 5. Incorporation of sodium [1-$^{13}$C, $^{18}O_2$]propionate and [1-$^{13}$C, $^{18}O_2$]butyrate into lasalocid A **13**.

istry: divergent stereospecific fatty-acid type condensations and partial reductions of the growing chain to produce the observed functionality; condensation–reduction followed by dehydration and stereospecific rehydration of the resulting enones; or multistep reduction to a deoxygenated chain followed by stereospecific aerobic oxidation. In principle each of the fatty acid units could be transformed to the appropriate oxidation state and stereochemistry by one of these three sequences. Separate incorporations of sodium [1-$^{13}$C, $^{18}O_2$]-propionate and [1-$^{13}$C, $^{18}O_2$]butyrate (which is biologically also converted to [1-$^{13}$C, $^{18}O_2$]acetate) produced labeled lasalocid A **13** samples. Direct $^{13}$C nmr analysis proved fruitless because of peak broadening, probably due to intramolecular hydrogen bonding (10), but chemical derivatization of the hydroxyls permitted resolution of the isotope shifts. Propionate-derived oxygen was found attached to C-3, C-11, and C-15, while butyrate (and acetate) oxygen was detected at C-1 and C-13. The results clearly exclude the latter two of the three mechanisms proposed for oxygen origin and stereochemistry for the C-1 to C-15 portion of the lasalocid A chain. Absence of oxygen labeling in the rest of the chain supports the biosynthetic proposal by Westley *et al.* (34) shown in Fig. 6.

Elegant biosynthetic applications of the $^{18}$O isotope shift in $^{13}$C nmr have recently been reported by Cane *et al.* on monensin and erythromycins A and B (35) and by Sankawa *et al.* on

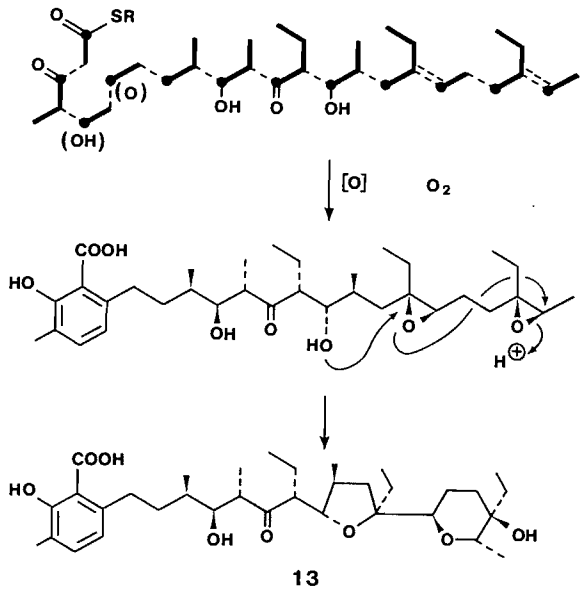

FIG. 6. Proposed biosynthetic sequence to lasalocid A **13** (34).

citrinin (6). It is not unlikely that further uses of this technique with more advanced [$^{18}$O] precursors will aid in understanding the detailed chemistry of complex biological transformations (36).

## Acknowledgements

The author gratefully acknowledges the research of his collaborators and co-workers whose names appear in the footnotes and references. Reference samples and fungal strains for mycotoxin work were donated by Dr. P. S. Steyn (Council for Scientific and Industrial Research, Pretoria, South Africa), Dr. C. A. Townsend (Chemistry Department, Johns Hopkins University), and Dr. D. T. Wicklow (Northern Regional Research Laboratory, U. S. Department of Agriculture). The Stable Isotopes Resource of Los Alamos National Laboratory sent generous gifts of [$^{18}$O] water and oxygen gas, and the Natural Sciences and Engineering Research Council of Canada provided financial support.

# Specific adsorption of sulfamate ions at the mercury/solution interface

ERNESTO R. GONZALEZ[1]

*Instituto de Fisica e Quimica de São Carlos, USP, C.P. 369, 135650 São Carlos, SP, Brazil*

Received April 23, 1981

ERNESTO R. GONZALEZ. Can. J. Chem. **60**, 1643 (1982).

The adsorption of sulfamate ions on mercury electrodes has been studied by measuring the double layer capacity in constant ionic strength solutions of composition $xM$ $NH_4SO_3NH_2$ + $(1 - x)M$ $NH_4F$. It was found that sulfamate ions are weakly adsorbed on mercury, the amount adsorbed being significant only for $x > 0.1$ at positive charges on the electrode. Because of this, the properties of the inner layer were found to be strongly dependent on the adsorbed water molecules and the structure of the diffuse layer. It was determined that the adsorption of sulfamate ions can be described by an isotherm based on the electrostatic model of the double layer. The possible effects of the activity coefficient variation with solution composition are discussed.

ERNESTO R. GONZALEZ. Can. J. Chem. **60**, 1643 (1982).

On a étudié l'adsorption des ions sulfamates sur des électrodes de mercure en mesurant la capacité de la couche double, à force ionique constante, des solutions de composition $xM$ $NH_4SO_3NH_2$ + $(1 - x)M$ $NH_4F$. On a trouvé que les ions sulfamates sont faiblement adsorbés sur le mercure, la quantité adsorbée étant significative seulement pour $x > 0,1$ aux charges positives sur l'électrode. Pour cette raison, on a trouvé que les propriétés de la couche interne dépendent fortement des molécules d'eau adsorbées et de la structure de la couche diffuse. On a déterminé que l'adsorption des ions sulfamates peut être discuté par un isotherme en s'appuyant sur le modèle électrostatique de la couche double. On discute des effets possibles de la variation du coefficient d'activité avec la composition de la solution.

[Traduit par le journal]

## Introduction

The study of the influence of the electrical double layer on the kinetics and mechanisms of electrode processes is of primary importance in electrochemistry. In the absence of specific adsorption of ions of the supporting electrolyte, the well-known Frumkin's theory accounts reasonably well for the observed effect. On the other hand, when specific adsorption is present, the situation is much more complicated, and it is only recently that quantitative treatments have been attempted with some degree of success. Specific adsorption of supporting electrolyte ions is also a complicating factor in the studies of adsorption of neutral molecules on electrodes. Within this context, the importance of having electrolytes that present negligible or low specific adsorption becomes evident.

Capacity–potential curves for the system mercury – aqueous solutions of sulfamic acid, recorded over a restricted concentration range (1), showed that the sulfamate ion may present a low specific adsorption on mercury. This observation prompted the present study aimed to a quantitative determination of the adsorbed charge and to an evaluation of the properties of the double layer. The system was studied by recording capacity–potential curves for mercury electrodes in aqueous solutions of $NH_4SO_3NH_2$ + $NH_4F$ at constant ionic strength. The possible change of activity coefficients with solution composition was not considered in the calculation because of the lack of data on activity coefficients for sulfamate solutions and the difficulties involved in the experimental determination. However, the effect that this change might have on the present results is discussed.

## Experimental

Ammonium sulfamate (Carlo Erba, RPE) and ammonium fluoride (Carlo Erba, RPE) were used without further purification. Water and mercury were purified as described previously (2). The differential capacity ($C$) was measured using equipment, cells, and electrodes already described (2). Potentials of zero charge ($E_z$) were measured using the streaming electrode technique (3). Twelve solutions of composition $xM$ $NH_4SO_3NH_2$ + $(1 - x)M$ $NH_4F$, where $x$ had the values 0, 0.01, 0.015, 0.025, 0.05, 0.075, 0.1, 0.15, 0.25, 0.5, 0.75, and 1.0 were used. In all experiments, the temperature was maintained at 25.0 ± 0.1°C. All potentials were measured against a commercial saturated calomel electrode (Coleman 3-712). Attempts at preparing a $Hg/Hg_2(SO_3NH_2)_2$ electrode to measure activity coefficients in sulfamate solutions were unsuccessful because of the instability of the mercurous salt.

## Results

Figure 1 shows the capacity–potential plots for the system $NH_4SO_3NH_2$ + $NH_4F$. No difference was found between the curve for $1M$ $NH_4F$ and curves for the mixed system for which $x < 0.01$. By comparison with the behavior of most other systems, this fact alone is indicative of the weak adsorption of the sulfamate ion. A maximum in the capacity curves develops at potentials positive of $E_z$. However, this maximum is not very pro-

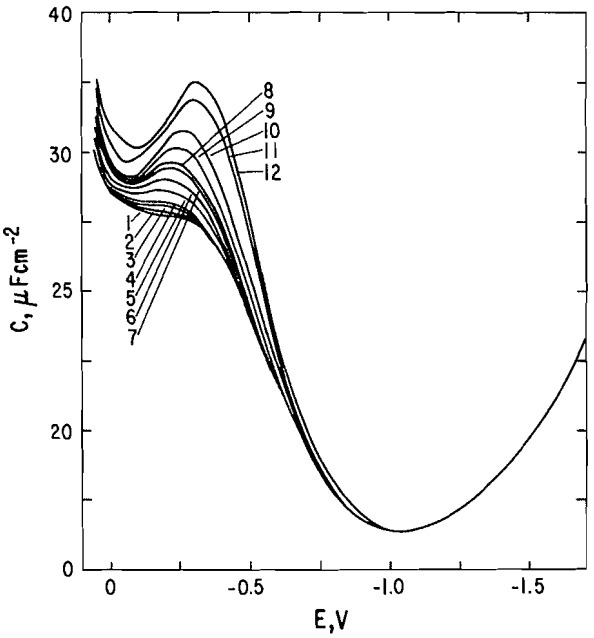

FIG. 1. Differential capacity of the electrical double layer for a mercury electrode in aqueous $xM$ $NH_4SO_3NH_2$ + $(1 - x)M$ $NH_4F$ at 25°C. $x$ = (*1*) 0, (*2*) 0.01, (*3*) 0.015, (*4*) 0.025, (*5*) 0.05, (*6*) 0.075, (*7*) 0.1, (*8*) 0.15, (*9*) 0.25, (*10*) 0.5, (*11*) 0.75, (*12*) 1.0.

nounced. It increases slightly with sulfamate concentration and, at the same time, shifts toward more negative potentials. Another feature of these curves is the fact that they seem to converge at the most positive potentials. However, an extension of the potential range examined would be required to draw more definite conclusions.

Using the experimental values of $E_z$ presented in Table 1, the capacity–potential curves were integrated to obtain the electrode charge density ($q$). A second integration was performed to obtain the surface tension ($\gamma$) as a function of potential. The necessary integration constants (Table 1) were obtained from the value 425.7 mN $m^{-1}$ for $\gamma$ at $E_z$ for the pure fluoride solution (4) and noting that all the capacity curves coincide for potentials more negative than −1.00 V. The magnitudes of $\gamma$ and $q$ were combined to obtain Parsons' function, $\xi_+ = \gamma + qE_+$ (in the present case $E_+$ is taken as being equal to $E$) from which the values of the specifically adsorbed charge density ($q_-'$) due to sulfamate ions were obtained in the usual way (2). The calculation described here was performed using suitable computer programs. Differentiation of the function $\xi$ vs. $\log x$ was done by fitting a quadratic equation to a five-point moving segment using a least-squares procedure. The quadratic was normally differentiated at the central point, although results in both extremes of the concentration range were also

obtained. With this method, and taking into account that five points per decade were used in the concentration range, the error in $q_-'$ is expected to be no greater than 0.5 μC $cm^{-2}$ (5). On the other hand, the values of $q_-'$, particularly for high values of $x$ and $q$, may be affected by an error for not having considered the variation of activity coefficients with solution composition (6). This point is discussed below.

Figure 2 shows the specifically adsorbed charge as a function of ln $x$ for different values of $q$. Considering that values of $q_-' < 5$ μC $cm^{-2}$ are probably without much relevance, it is seen that the adsorption of sulfamate ions on mercury becomes significant only for $x > 0.1$ and at fairly positive values of $q$. From the same figure, it is apparent that for most of the concentration interval $q_-' < q$. On the basis of the electrostatic model of the double layer, this means that the values of $q_-'$ are probably lower than those that would be obtained in solutions of single sulfamate salts, where the compensating effect of the diffuse layer is smaller. However, the difference is not expected to be large.

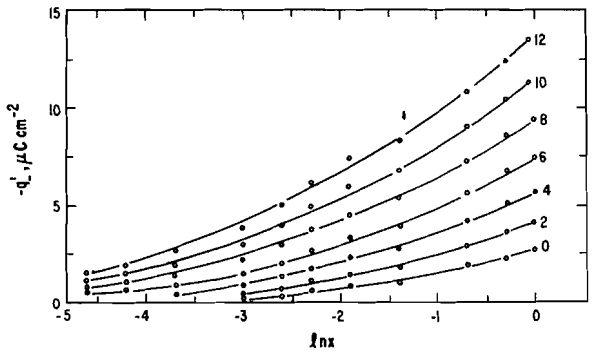

FIG. 2. Adsorbed charge density due to $SO_3NH_2^-$ ions against the logarithm of $SO_3NH_2^-$ concentration in the bulk. Figures on the curves indicate charge density on the electrode in μC $cm^{-2}$.

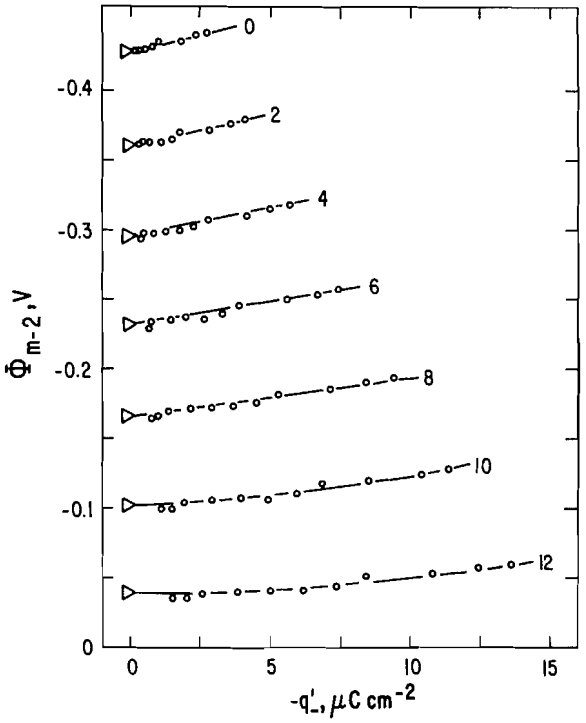

FIG. 3. Potential drop across the inner layer as a function of specifically adsorbed charge at constant charge on the electrode (indicated by the figures on the lines in μC cm$^{-2}$).

Figure 3 shows plots of potential drop across the inner layer, $\phi_{m-2}$, against the adsorbed charge density at constant $q$. $\phi_{m-2}$ was obtained by subtracting the potential $\phi_2$ of the outer Helmholtz plane (o.H.p.), calculated from the diffuse layer theory, from the electrode potential. The figure also includes the values corresponding to the base solution. For $q < 10$ μC cm$^{-2}$, the plots are fairly linear, extrapolating through the base solution points. An important fact to be noted is that the slope of the lines is not constant, decreasing with increasing values of $q$. Furthermore, for the most positive values of $q$, an extrapolation through the points corresponding to the base solution means that a certain degree of curvature has to be admitted.

Adsorption studies in single salt and constant ionic strength solutions have indicated the adequacy of the isotherm based on electrostatic models of the double layer (see, for example, refs. 2 and 7). This isotherm can be derived from detailed electrostatic models of ionic adsorption (8) or from more simple approaches (7, 9, 10). It has even been used as a working hypothesis to discuss the entrance of counter-ions in the inner layer (11). Disregarding the volume differences between the adsorbed ions and the displaced water molecules, and considering that the values of the adsorbed charge are small, the isotherm can be written (8, 12) as follows:

$$[1] \quad \ln(-q_-') = \ln x + \Phi + \frac{F}{RT}\phi_2 + aq_-' + bq$$

where as a first approximation, $\Phi$ can be considered a constant and $a$ and $b$ are functions of the inner layer parameters. Equation [1] was tested by plotting $q_-'$ vs. $(RT/F)\ln(-q_-'/x) - \phi_2$. It was found that the dispersion of the points was too large. According to diffuse layer theory and for the type of solution under consideration

$$[2] \quad \phi_2 = \frac{2RT}{F}\sinh^{-1}\left(\frac{q+q'}{2A}\right)$$

where $A = 5.86I^{1/2}$ in water at 298 K, $I$ being the ionic strength of the solution. As in a previous case (13), the values of $q + q_-'$ are small, so minor errors in $q_-'$ produce large variations in $\phi_2$, which explains the dispersion found in the plot of eq. [1]. On the other hand, small values of $q + q_-'$ mean that eq. [2] can be approximated to

$$[3] \quad \phi_2 \simeq \frac{RT}{F}\frac{(q+q_-')}{A}$$

For most of the experimental range in this work $\phi_2 < 25$ mV, so the difference between eq. [2] and eq. [3] is $< 1$ mV. In extreme cases $\phi_2 \simeq 40$ mV, for which the difference is ~3 mV.

Introducing eq. [3] into eq. [1]

$$[4] \quad \ln(-q_-'/x) = \Phi + \left(a + \frac{1}{A}\right)q_-' + \left(b + \frac{1}{A}\right)q$$

This expression can be tested by plotting $q_-'$ vs. $(RT/F)\ln(-q_-'/x)$, and the results are shown in Fig. 4. In spite of some dispersion, reasonable straight lines are obtained. A least-squares analysis of the lines shows that the slope varies from 106 μC cm$^{-2}$ at $q = 0$ to 170 μC cm$^{-2}$ at $q = 10$ μC m$^{-2}$, indicating that $a$ is dependent on $q$. It may then be concluded that the approximation for $\phi_2$ (eq. [3]) partly solves the problem created by the explicit introduction of $\phi_2$ in the isotherm.

## Discussion

*Effects of activity coefficient variation*

The variation of activity coefficients with solution composition may be one of the sources of error in the determination of the adsorbed charge. The effect is twofold: on the one hand, the assumption that potential variations measured against a fixed

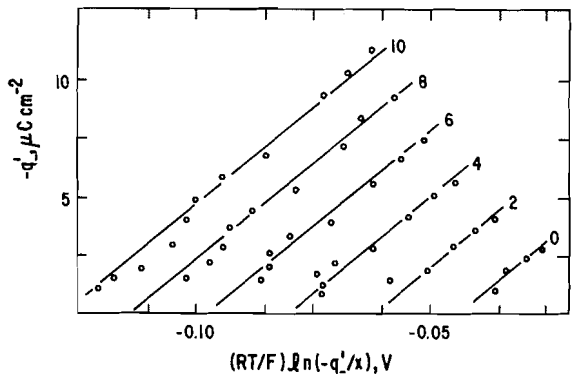

FIG. 4. Plots of adsorption data for $SO_3NH_2^-$ ions according to the isotherm (eq. [4]), at constant charge on the electrode (indicated by the figures on the lines in $\mu C\ cm^{-2}$).

reference electrode are equal to those measured on a thermodynamic scale may not be valid (6). However, this effect is expected to be small and will not be further considered. On the other hand, when activity coefficient variations are introduced in the thermodynamics of the double layer, the relationship between the differential of $\xi$ and $q_-'$ takes the form (6)

$$[5]\quad \frac{F}{RT}\left(\frac{1}{1+\beta x}\right)\left(\frac{\partial \xi}{\partial \ln x}\right)_q = q_-' + \left(\frac{\beta x}{1+\beta x}\right) q_-^{\,d}$$

where $q_-^{\,d}$ is the anionic charge in the diffuse layer. In this case $\beta$ is defined as

$$\beta = (\beta_{NH_4SO_3NH_2} - \beta_{NH_4F})I$$

where $\beta_{MA}$ is the interaction coefficient between the cation M and the anion A. $\beta$ can be determined experimentally (6), evaluated from available data (13), or estimated from the values of the activity coefficients of the pure salts (14). In the present case, $\beta$ could not be determined because, to the author's knowledge, no published data on activity coefficients for sulfamate solutions are available and attempts at an experimental determination of $\beta$ using a $Hg/Hg_2(SO_3NH_2)_2$ electrode were unsuccessful. However, in order to have an indication of the error introduced, eq. [5] was written in the form

$$[6]\quad \frac{F}{RT}\left(\frac{\partial \xi_+}{\partial \ln x}\right)_q = q_-' - \beta x(q + q_+^{\,d})$$

where $q_+^{\,d}$ is the cationic charge in the diffuse layer. If a difference as large as 15% exists between the activity coefficients of $NH_4F$ and $NH_4SO_3NH_2$ at $1\,M$ concentration, $\beta$ can be estimated as being $\sim$0.3. After obtaining $q_+^{\,d}$ from the diffuse layer theory (here the already determined values of $q_-'$ are used so the procedure is not exact), it is easy to estimate that for $x = 1$ and $q > 3\ \mu C\ cm^{-2}$ the error introduced in $q_-'$ is larger than the experimental one. The same situation applies to $x = 0.75$ and $q > 4$ and to $x = 0.5$ and $q > 6$. For lower values of $x$ the correction can be neglected. As a consequence, application of the least-squares procedures to the lines of Figs. 3 and 4 did not consider the points falling in those ranges. However, the same general conclusion would be obtained by taking them into account, which means that in the above considerations the error in $q_-'$ was probably overestimated.

*The inner layer*

According to a simplified electrostatic model (9), the potential drop in the inner layer can be divided into a component dependent on the electrode charge and a component dependent on the adsorbed charge. Thus, $\phi_{m-2}$ can be written in the form:

$$[7]\quad \phi_{m-2} = \frac{q}{{}_qK^i} + \frac{q_-'}{{}_{q'}K^i}$$

where ${}_qK^i$ and ${}_{q'}K^i$ are the integral capacities of the inner layer at constant amount adsorbed and at constant charge on the electrode, respectively.

The integral capacity ${}_qK^i$ is related to the inverse of the vertical separation of the curves presented in Fig. 3. Thus, it is apparent that ${}_qK^i$ decreases with increasing $q_-'$. As in previous studies (2, 13), this can be attributed to changes in the thickness of the double layer. For low values of $q_-'$, the electroneutrality of the interface is brought about by an excess of $F^-$ ions in the diffuse layer. As $q_-'$ increases and $q_-' + q$ becomes negative, $F^-$ ions are replaced by $NH_4^+$ ions in the diffuse layer. So it is reasonable to assume that in this process the thickness of the double layer will increase due to the fact that cations are more strongly solvated than anions.

According to eq. [7], the integral capacity ${}_{q'}K^i$ is related to the inverse of the slopes of the curves in Fig. 3. Up to $q = 8\ \mu C\ cm^{-2}$, the plots may be considered linear, which means that ${}_{q'}K^i$ does not depend on $q_-'$. On the other hand, ${}_{q'}K^i$ increases with $q$, as shown by the decreasing slope of the Christie plots. This is probably because of the fact that the amount of specifically adsorbed sulfamate ions is quite low, the electrode charge influences the adsorbed water molecules so as to make ${}_{q'}K^i$ increase with $q$. This effect will still be more pronounced if the interaction between adsorbed sulfamate ions and water molecules is weak as is observed with the $ClO_4^-$ ions (15).

These arguments could also explain the onset of curvature on the plots for $q > 8\ \mu C\ cm^{-2}$ in Fig. 3. At low values of $q_-'$, the properties of the interface

are dominated by the effect of $q$ on the adsorbed water molecules. As the amount of adsorbed sulfamate ions increases, the effect is less marked and ${}_{q'}K^{i}$ increases. At the same time, this transition is enhanced by the already discussed change from negative to positive diffuse layer charge.

In the region $3 < q < 7\ \mu C\ cm^{-2}$, average values of ${}_{q}K^{i}$ and ${}_{q'}K^{i}$ can be used (9) to give an indication of the relationship between the distances from the metal to the inner Helmholtz plane (i.H.p., $x_1$) and from the metal to the o.H.p. ($x_2$). For the present system $x_1/x_2 \simeq 0.9$, which means that the i.H.p. is very near the o.H.p. This point is further discussed below. Thus, the nature of the ion defining the diffuse layer charge is expected to have a marked influence on the dielectric properties of the i.H.p. Christie plots could also be distorted by the entrance of counter-ions into the inner layer (16) but this phenomenon can be ruled out in the present system due to the low values of the adsorbed charge.

*The adsorption isotherm*

The coefficients $a$ and $b$ in the isotherm (eq. [1]) have been obtained by using the cutoff-disc model of ionic adsorption (8). The expression for $a$ is

$$[8]\quad a = \frac{F}{RTK_2}\left(1 - g\,\frac{K}{K_1}\right)$$

where $K$ is the integral capacity of the inner layer, $K_1$ that between the metal and the i.H.p., and $K_2$ that between the i.H.p. and the o.H.p. The parameter $g$ expresses the self-atmosphere potential of the adsorbed ion. The coefficient $b$ is given by

$$[9]\quad b = \frac{F}{RTK_2}$$

The integral capacity $K$ can be identified with ${}_{q}K^{i}$ in eq. [7]. Also, if the adsorbed ions are confined to the i.H.p. $K_2 = {}_{q'}K^{i}$. From the plots in Fig. 3 it is evident that the parameters of the isotherm depend on both $q$ and $q_-'$ so a quantitative analysis is difficult to make. However, in the range $3 < q < 7\ \mu C\ cm^{-2}$, the slope of the lines in Figs. 3 and 4 have the smallest variation, so it will be assumed that $a$, and also $b$, are constant in that region. From Fig. 3 $K_2 = 286\ \mu F\ cm^{-2}$ and $K = 26.0\ \mu F\ cm^{-2}$, so $K = 28.6\ \mu F\ cm^{-2}$. From Fig. 4, $(RT/F)a = -2.3 \times 10^{-3}$ V cm$^2$ $\mu C^{-1}$, so that from eq. [8], $g = 1.8$.

The parameter $g$ has been evaluated for two different models of dielectric constant variation in the inner layer (17, 18). In both cases, $g$ is strongly dependent on the relative positions of the i.H.p. and the o.H.p., the value obtained here indicating again that the i.H.p. is near the o.H.p. The situation is similar to that found for nitrate (13) in the sense that for contact adsorption and according to the structure of the sulfamate ion (19), the i.H.p. should be at about 2 Å from the metal surface while the o.H.p. would be at more than twice that distance. Thus it is possible that the sulfamate ion is separated from the surface by a layer of water molecules as it was postulated for $ClO_4^-$ (20). The model on which this discussion is based will not hold if the cations enter the inner layer (11) but, as stated before, this is highly improbable due to the low values of the adsorbed charge. In spite of the limited relevancy of this discussion based on the slope of the lines in Fig. 4, the characteristics of those plots do not seem to justify an analysis of the other parameters of the isotherm.

PHOTIS DAIS and ARTHUR S. PERLIN. Can. J. Chem. **60**, 1648 (1982).

Various nmr spectroscopic techniques have been used to determine the orientation of the anomeric hydroxyl group of 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose (**1**) in dimethylsulfoxide solution, as well as other conformational features of the molecule. $^{13}C$ and $^{1}H$ coupling constants indicate that in its most probable orientation the O—H bond is *anti* with respect to carbon-2, and forms an angle of ~40° with the C-1—H-1 bond. Spin-lattice relaxation rates ($R_1$) and nuclear Overhauser enhancements (nOe) have been measured for the pertinent protons and used, in conjunction with $^{13}C$ relaxation times, as additional criteria for characterizing the geometry of the anomeric alcohol group of **1**. These results are in good agreement with the coupling constant data. The conformations of the mannofuranose ring, the 2,3-*O*-isopropylidene ring, and the C-4 to C-6 region of the molecule are also described.

PHOTIS DAIS et ARTHUR S. PERLIN. Can. J. Chem. **60**, 1648 (1982).

On a utilisé diverses techniques de spectroscopie de rmn pour déterminer l'orientation du groupe hydroxyle anomère du di-*O*-isopropylidène-2,3:5,6 α-D-mannofurannose (**1**) dans une solution de diméthylsulfoxyde, ainsi que d'autres caractéristiques conformationnelles de la molécule. Les constantes de couplage du $^{13}C$ et du $^{1}H$ indiquent, que dans son orientation la plus probable, la liaison O—H est *anti* par rapport au carbone en position-2 et forme un angle d'environ 40° avec la liaison C-1—H-1. On a mesuré les vitesses de relaxation spin-réseau ($R_1$) et l'augmentation des effets Overhauser nucléaires (eOn) pour les protons concernés et on les a utilisés, en relation avec les temps de relaxation du $^{13}C$, comme critère additionnel pour caractériser la géométrie du groupe alcool anomère du composé **1**. Ces résultats sont en bon accord avec les données de constante de couplage. On décrit également les conformations du cycle mannofurannose, du cycle *O*-isopropylidène-2,3 et les régions de la molécule allant de C-4 à C-6.

## Introduction

Although a great deal is known (1, 2) from X-ray crystallographic data about the disposition of hydroxyl groups of carbohydrate molecules in the solid state, little is available as to their stereochemistry in solution. An indication of favorable orientations in solution is given (3–6) by the magnitude of spin–spin coupling between a hydroxyl proton and a vicinal $^{1}H$ or $^{13}C$ nucleus. However, a more definitive description of rotamers of hydroxyl groups should be afforded by augmenting coupling data with spatial parameters derived from spin-lattice relaxation rates and nuclear Overhauser effect measurements. This approach is examined in the present study, which deals with a sugar derivative containing a single hydroxyl group, namely 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose (**1**). To ensure slow exchange (7) of the hydroxyl proton, as well as to preserve the compound exclusively in the α-anomeric form (8), dimethyl sulfoxide was used as the solvent.

It was apparent that measurements dealing with the geometry of the anomeric centre of **1** had to take account of a larger segment of the molecule. Indeed, in this particular instance, there was the added incentive of simultaneously examining the conformations of the furanose and *O*-isopropylidene rings by the same overall approach. Consequently, in the discussion to follow, a detailed analysis of nmr spectra of **1** is presented together with the results of relaxation rate and nOe measurements on various protons, so that several structural features of the molecule are treated qualitatively, in addition to a quantitative treatment of the C-1 alcohol moiety.

## Results and discussion

### A. *$^{1}H$ and $^{13}C$ nmr chemical shifts*

At 200 MHz, the $^{1}H$ nmr spectrum of **1** was almost fully resolved and first order (Fig. 1*a*), although the H-4 and H-6 resonances overlapped, even at 400 MHz. The assignments listed for the proton resonances in Table 1 were straightforward, especially with the aid of homo decoupling. Also given in Table 1 are the $^{13}C$ chemical shifts for **1**, the assignments made having been confirmed by off-resonance and selective decoupling. Being diastereotopic, the four *C*-methyl groups produce separate signals in both the $^{1}H$ and $^{13}C$ nmr spectra (Table 1).

### B. *$^{1}H$ and $^{13}C$ coupling constants*

A first approximation for determining the shape of **1** is afforded by various coupling constants (Table 1), which reflect (9) not only the geometries of the coupling pathways, but also the influences of

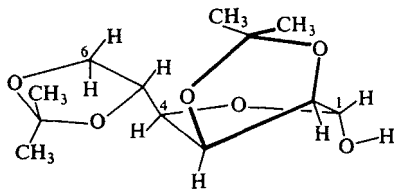

FIG. 2. Representation of the $^2T_3$ conformation of 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose (**1**).

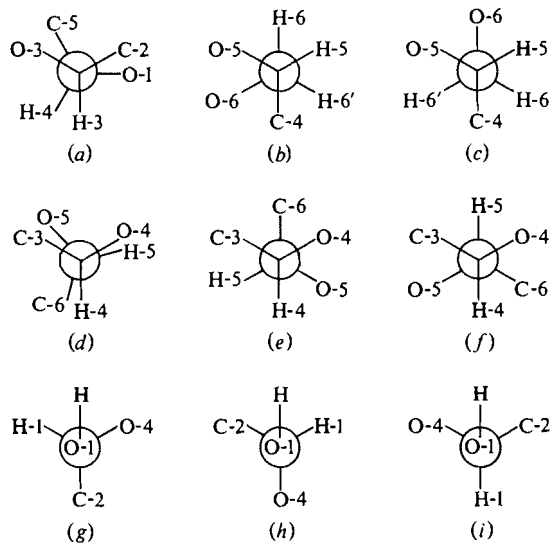
such structural parameters as carbon hybridization, electronegative substituents, etc.

Protons 1 and 2 may be positioned on a molecular frame at an angle of ~ 90° with respect to each other, because they exhibit no coupling, as has been found (10) also with structurally-related compounds, α-D-mannofuranose 2,3-carbonate and 2,3-*O*-isopropylidene-α-L-rhamnofuranose. Similarly, as the vicinal couplings between H-2 and H-3, and H-3 and H-4, are less than that expected (11, 12) for pairs of eclipsed hydrogens, the overall data are consistent with a twist conformation ($^2T_3$) in which C-2 and C-3 lie, respectively, above and below the plane formed by ring atoms C-4, O-4, and C-1 (Fig. 2). Additional support for this proposal comes from the value of 4.3 Hz for coupling between $^{13}$C-5 and H-3, which is commensurate (13) with a dihedral angle of about 140° relating these two nuclei in the depicted projection along the C-3,C-4 bond (*a*). By way of contrast, the furanose ring of methyl-α-D-mannofuranoside appears (14, 15) to favor a $^3T_4$ conformation, illustrating the strongly distorting impact of the fused 2,3-*O*-isopropylidene moiety.

Implicit in the representation of the α-D-mannofuranose ring in Fig. 2, is a nonplanar conformation for the fused 2,3-*O*-isopropylidene ring as well, in accord with earlier findings (12) on various *O*-isopropylidene derivatives. The projected dihedral angle between H-2 and H-3 is ~35°, based on the value of 5.88 Hz for $^3J_{H\text{-}2,H\text{-}3}$.



Projection formulas *b* and *c* represent the extreme limits of puckering by the 5,6-*O*-isopropylidene ring. Because spin–spin coupling of H-5 with H-6 and H-6′ (6.38 and 5.82 Hz, respectively) is intermediate in value, contributions from both *gauche* and *anti* interactions are implied. However, as there was no observable two-bond coupling between $^{13}$C-6 and H-5, an *anti* orientation of O-6 with respect to H-5 (as in *b*) should be a prominent characteristic (13, 16).

Stereochemical models indicate that rotation about the C-4,C-5 bond is restricted by nonbonded interactions, mainly involving the methyl groups, to a librational motion having an angular amplitude of ~ 180°: *d* and *e* represent the two extremes of the rotamer population, and *f* an intermediate array. According to coupling data, both of the energetically more favored rotamers, *e* and *f*, appear to be represented. That is, the value of 6.41 Hz for $^3J_{H\text{-}4,H\text{-}5}$ is intermediate between that expected for the *gauche* relationship of H-4 and H-5 in *e* and the value for their *anti* relationship in *f*, whereas the coupling of 3.3 Hz between $^{13}$C-6 and H-4 is smaller than should be anticipated for *e*, and slightly large for *f*. It is noteworthy that in the absence of analogous substitutions at the 5,6-positions, as in α-D-mannofuranose 2,3-carbonate, the rotamer corresponding to *f* is strongly favored, as shown (10) by the value of 9.0 Hz for $^3J_{H\text{-}4,H\text{-}5}$.

Turning to the anomeric hydroxyl group of **1**, there are two experimentally-determined coupling constants (Table 1) that reflect its orientation, i.e., a value of 4.34 Hz for $^3J_{H\text{-}1,OH}$, and of 7.65 Hz for $^3J_{C\text{-}2,OH}$. By applying eq. [1], derived (4) from a

$$[1] \quad J_{HCOH} = 10.4\cos^2\phi - 1.5\cos\phi + 0.2$$

least-squares fit of various values of $^3J_{H,OH}$, angle φ is estimated to be 39° or 142°. Because of the strong coupling between C-2 and the hydroxyl proton, rotamer *g*, in which these two nuclei are *antiperiplanar*, must be a major contributor as compared with rotamers *h* and *i*. Consequently, the vicinal coupling between H-1 and OH-1 is most prominently represented by the *gauche* orientation of these nuclei in *g* and, hence, the time-average value of φ is much closer to 30° than to 142°. As noted earlier (5), for a solution of **1** in $CDCl_3$ the corresponding values of $^3J_{H\text{-}1,OH}$ and $^3J_{C\text{-}2,OH}$ are 2.6 Hz and 9.2 Hz, respectively, which are both consistent with an even greater preponderance of rotamer *g*, assuming that the magnitude of these $^3J$ values is not appreciably solvent-dependent.

To summarize, conformational characteristics of molecule **1** pertaining to the anomeric hydroxyl group, the furanose ring, the C-4,C-5 bond, and the two *O*-isopropylidene rings have been described in terms of the coupling observed between protons and other protons or $^{13}$C-nuclei. In the sections to follow, these characteristics are assessed independently on the basis of relaxation and nOe measurements.

### C. *$^1$H relaxation rates*

The proton relaxation rates ($R_1$) listed in Table 2 furnish a complementary source of information about the molecular architecture of **1**. This stems from the fact (17–19) that, under normal experimental circumstances, proton relaxation occurs preponderantly by the intramolecular dipole–dipole mechanism,[1] which is strongly distance-dependent. Provided that a molecule undergoes a rapid reorientation, so that the extreme narrowing condition is met, the nonselective relaxation rate ($R_1$) of any proton, or set of equivalent protons, is represented by the specific relaxation contributions between the receptor nucleus and the donor nuclei, and by the molecular correlation time $\tau_c^0$, characterizing the overall molecular motion.[2] Consequently, as the relaxation rate is dependent on the inverse sixth power of the distance separating the nuclei, the value of $R_1$ is determined largely by the proximity of its immediate neighbours, as well as their number. Furthermore, because of its relationship to $\tau_c^0$, the $R_1$ value can provide information about the reorientational motion of a molecule as a whole, and of the internal motion of flexible molecular segments.

Di-*O*-isopropylidene derivative **1** was shown to be characterized by an isotropic overall motion. That is, the $^{13}$C spin-lattice relaxation times of the mannose ring carbons, each of which bears a single proton, were found to be essentially the same.[3] Consequently, the relaxation rates of the various protons (Table 2) should primarily be a reflection of intramolecular contributions from other protons in the immediate vicinity, although they could be influenced significantly by cross-relaxation and cross-correlation effects (19–22). However, this latter possibility was found to be negligible for the protons of **1**. An experimental criterion (23) of contributions by cross-correlation effects *plus* possible nonexponential relaxation, is a difference in $R_1$ values for individual components of a multiplet, whereas the appropriate data for **1** (Fig. 1b) show that differences within multiplets do not exceed 10–15%. Furthermore, as additional means for effectively cancelling out these effects, the sums of the intensities for all components of each proton were taken as the basis for measuring total magnetization recoveries, and the initial-slope method (23–25) was used in determining relaxation rates. Overall, then, circumstances appeared to ensure that direct dipole–dipole interactions were preeminent in the acquisition of these rates (Table 2).

Comparing the $R_1$ values for protons of the mannose ring, it is found that H-3 and H-4 relax faster than the other two, whereas the rate for H-2 is about 15% faster than that of H-1. These differences accord with evidence (23) from studies on monosaccharides indicating that a *gauche* $^1$H–$^1$H orientation is much more effective in promoting relaxation than is a *trans*-diaxial one. Hence H-3, which possesses the highest rate, is *quasi-gauche* to both H-2 and H-4. Presumably, these latter two interact similarly with H-3, and as H-4 has a faster rate than H-2, it is evidently provided with additional relaxation pathways by H-5, and possibly protons at C-6. Of the two staggered rotamers consistent with spin-coupling data, *e* is more favored on the basis of the relaxation measurements because of the *gauche* relationship of H-4 with H-5, in contrast to their *anti* disposition in *f*. Proton 2 can receive no comparable contribution from vicinal proton H-1, because these two protons are *trans* in α-anomer **1**. Analogously, H-1 has the slowest rate

[1]Although intermolecular dipole–dipole mechanisms may contribute significantly to proton-relaxation, the use of a highly dilute solution minimized their importance in the present study.

[2]See eqs. [5*a*] and [5*b*].

[3]The $T_1$ values, measured for a 1.0 *M* solution of **1** in dimethyl sulfoxide-$^2H_6$ at 20°C were: C-1, 0.65; C-2, 0.67; C-3, 0.69; C-4, 0.70 s (±5%). All of these carbons relaxed by dipole–dipole interactions, as evidenced by 100% $^{13}$C-[$^1$H] nuclear Overhauser enhancements.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

among the ring protons, consistent with its relative isolation from the influence of H-2, as well as of H-3,H-4 and the *endo*-$CH_3$ group of the 1,2-*O*-isopropylidene ring; stereomodels indicate that H-1 is 4.25, 4.16, and 4.32 Å, respectively, from these latter protons (the value for $CH_3$ being an average distance). As shown later, the hydroxyl proton furnishes the main relaxation pathway for H-1.

The geminal disposition of the 6,6′-protons ensures a mutually efficient relaxation for them, and characteristically fast relaxation rates (Table 2). Contributions of these two protons towards the relaxation of H-5 through *gauche*,*gauche* interactions in rotamer *b*, as well as the *gauche* orientation of H-5 with respect to H-4 in rotamer *e*, presumably account for the fact that although H-5 is in a relatively mobile environment, its relaxation rate is comparable to those of ring protons 1 and 2.

Values of $R_1$ for the methyl groups of the *O*-isopropylidene rings range from 1.64 to 2.36 $s^{-1}$ (Table 2). Evidently, these variations reflect the sensitivity of relaxation rates to changes in the rates of anisotropic modes of reorientation. Although, overall, the molecular tumbling of **1** appears to be isotropic, additional degrees of freedom expressed as internal methyl rotation, librational and puckering motions of the flexible *O*-isopropylidene rings can affect the motional correlation times ($\tau_c$) of individual interproton vectors, and hence their relaxation efficiencies. These factors, and such questions as potential barriers to methyl rotation, are to be considered in some detail in a forthcoming publication.

D. *Relaxation characteristics of OH-1*

Earlier, it was surmised that OH-1 makes the major contribution to the rate of relaxation of H-1. A direct measure of this contribution may be obtained by comparing the effect of exchanging the hydroxyl proton by deuterium. Equation [2] relates the nonselective relaxation rates for H-1 (A-*i*) in the normal molecule [$R_1^{A\text{-}i}(ns, H\text{-}j)$] and in its deuterated analog [$R_1^{A\text{-}i}(ns, D\text{-}j)$], assuming that the protons relax exclusively by the dipole–dipole mechanism and that molecular tumbling is in the extreme narrowing range:

$$[2] \quad \rho_{A\text{-}i,H\text{-}j} = 0.6959\,[R_1^{A\text{-}i}(ns, H\text{-}j) - R_1^{A\text{-}i}(ns, D\text{-}j)]$$

Equation [2] not only gives the relative importance of atom H-*j* to the relaxation of atom A-*i* but also, in conjunction with eq. [5*b*], can be used to predict their relationship in various models of conformational dynamics, given a value of $\tau_c^0$ and a reasonable estimate of the geometry of the molecule.

| 360 | 2.00 | 3.02 | 4.50 | 4.52 | |

[a] The $^2T_3$ skew conformation was considered.
[b] The H-1—C-1—O—H dihedral angle.
[c] The dihedral angles relating H-2,H-3 and H-3,H-4 were taken to be 30°.

Hence, it is possible to compare the distance of the hydroxyl-proton in various rotamers from the other protons, based on the geometry expected for **1**, with average values of $\langle r_{H_i\text{—}OH} \rangle$ where $i$ = H-1, -2, etc.) obtained from the $^1$H-relaxation data, before and after deuteration of the hydroxyl group. Because of internal motion by the hydroxyl group, vector $r_{H_i\text{—}OH}$ is a time dependent quantity representing an "effective", or average, distance.

Although no crystallographic data were found for **1**, information from X-ray studies (26) on several, related, *O*-isopropylidene aldofuranose derivatives provided an appropriate basis for a quantitative description of its geometry in the $^2T_3$ conformation (Fig. 2). Atomic coordinates and interatomic distances were generated by employing the Z-matrix method of a Gaussian-79 program (27). Interproton distances as a function of the H-1—C-1—O—H dihedral angle ($\phi$) are listed in Table 3.

Relaxation rates for the various protons of **1** following deuteration of the hydroxyl group are presented in Table 2, for comparison with the data for the protio compound.[4] It is evident that the effect of introducing the deuterium atom was confined almost exclusively to H-1.

By utilizing eqs. [2] and [5*b*], and the value of $\tau_c^0 = (69.3 \pm 0.2) \times 10^{-12}$ s obtained from the $^{13}$C relaxation measurements, interatomic distances were calculated for the H-1,OH and H-2,OH pairs of protons. These distances were 2.23 ± 0.03 and

[4] To avoid exchange between the —OD group and traces of water in the solvent, a drop of deuterium oxide was introduced. As $R_1$ values for protons far removed from the hydroxyl group are closely similar in both sets of measurements (Table 2), changes in viscosity and polarity due to deuterium oxide were negligible.

TABLE 4. $^1$H nuclear Overhauser enhancement for 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose

[a] Values in parentheses are standard deviations.

3.32 ± 0.27 Å, respectively, the error in these calculations being based on the errors in the $T_1$ measurements for $^1$H and $^{13}$C. When compared with the interproton distances given in Table 3, these values indicate that in its preferred orientation, the O—H bond forms a dihedral angle (ϕ) of about 60° with the H-1—C-1 bond. Hence, of such rotamers as *g*, *h*, and *i* that may be depicted for the C-1 alcohol moiety, the rotamer that occurs with the greatest frequency must be confined to the first quadrant (60° ± 30°) of the circular motion of the OH group. In agreement with the spin-coupling data already considered, rotamer *g* is representative of this most highly populated region.

E. *$^1$H nOe experiments*

Steady-state nOe data for the hydroxyl proton and ring protons of **1** (Table 4) show that although the hydroxyl proton exhibited a positive nOe upon irradiation of H-1, negative nOe effects were produced when H-2, -3, or -4 was irradiated.[5] In the present instance, the negative nOe's were not spurious but, rather, characteristic of the molecule, and strongly dependent on the orientation of the hydroxyl group. This was first verified qualitatively by an analysis of 3-spin systems according to the method of Noggle and Shirmer (19). As represented by Fig. 3, the geometry of a group of three spins can be specified by angle θ and interproton distances α and λα, parameter α being constant whereas θ and λ are time-dependent variables. Analysis of this system showed that negative enhancements are associated with values of θ greater than 90°. Consequently, in evaluating various orientations of the hydroxyl group with respect to 3-spin systems formed by H-2,H-1,OH, by H-3,H-2,OH, and by H-4,H-1,OH, only those orientations conforming to the condition 90° ≤ θ ≤ 180° were regarded as consistent with the experimental data of Table 4.

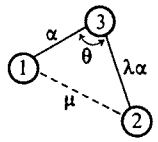

FIG. 3. Representation of the geometry of a group of three spins, according to Noggle and Shirmer (19).

Stereomodels indicate that OH rotamers incorporating angles of that magnitude are confined mainly to the first quadrant of circular motion by the OH group, that is, a finding in accord with the relaxation rate measurements. More satisfactorily, however, a quantitative determination of most probable interproton distances in **1**, and hence of most probable conformations, was effected by combining the results of the nOe measurements with those on $^1$H and $^{13}$C spin-lattice relaxation rates.

For loosely coupled spin 1/2 systems, the fractional nOe of a spin *k* when spin *l* is irradiated, $f_k(l)$, under conditions such that intramolecular dipole–dipole interactions dominate relaxation and cross-correlation effects may be neglected, is expressed as

$$[3] \quad R_k f_k(l) = 0.5\rho_{kl} - 0.5 \sum_{\eta \neq k,l} \rho_{k\eta} f_\eta(l)$$

where

$$[4] \quad f_k(l) = \frac{\langle I_{zk} \rangle - I_{ok}}{I_{ok}}$$

[5] Negative intramolecular nOe effects observed in a number of studies have been accounted for either on conformational grounds (19), or by the contribution of relatively low-frequency components to the motion of large molecular systems (28).

$$[5a] \quad R_i = \sum_{j \neq i} \rho_{ij} + \rho_i^*$$

and

$$[5b] \quad \rho_{ij} = \frac{\gamma_i^2 \cdot \gamma_j^2 \hbar^2}{r_{ij}^6} \tau(ij)$$

$\rho_i^*$ is the relaxation rate of spin $i$ due to other relaxation paths (e.g. intermolecular interactions, spin-rotation, etc.), $\tau(ij)$ is the correlation time of vector $r_{ij}$ between spins $i$ and $j$, $\langle I_{zk} \rangle$ is the magnetization of the observed nucleus $k$ when nucleus $l$ is irradiated, and $I_{ok}$ is the equilibrium magnetization in the absence of irradiation.

For the 5-spin system, x, a, b, c, d (where x = OH, a = H-1, b = H-2, c = H-3, and d = H-4), eq. [3] becomes

$$\begin{aligned}
R_x f_x(a) &= 0.5\rho_{ax} - 0.5\rho_{bx} f_b(a) \\
&\quad - 0.5\rho_{cx} f_c(a) - 0.5\rho_{dx} f_d(a) \\
R_x f_x(b) &= -0.5\rho_{ax} f_a(b) + 0.5\rho_{bx} \\
&\quad - 0.5\rho_{cx} f_c(b) - 0.5\rho_{dx} f_d(b) \\
R_x f_x(c) &= -0.5\rho_{ax} f_a(c) - 0.5\rho_{bx} f_b(c) \\
&\quad + 0.5\rho_{cx} - 0.5\rho_{dx} f_d(c) \\
R_x f_x(d) &= -0.5\rho_{ax} f_x(d) - 0.5\rho_{bx} f_b(d) \\
&\quad - 0.5\rho_{cx} f_c(d) + 0.5\rho_{dx}
\end{aligned} \quad [6a]$$

plus four additional, analogous, expansions of eq. [3] where, according to eq. [5a],

$$\begin{aligned}
[7] \quad R_x &= \rho_{ax} + \rho_{bx} + \rho_{cx} + \rho_{dx} + \rho_x^* \\
R_a &= \rho_{ax} + \rho_{ab} + \rho_{ac} + \rho_{ad} + \rho_a^* \\
&\text{etc.}
\end{aligned}$$

The five expansions of eq. [3] can be solved to determine either the ratio of $\rho_{ij}$'s or the individual $\rho_{ij}$'s, for instance,

$$[8] \quad \rho_{ab} = 2R_b \begin{vmatrix} 1 & f_b(x) & -f_c(x) & -f_d(x) \\ -f_x(a) & f_b(a) & -f_c(a) & -f_d(a) \\ -f_x(c) & f_b(c) & 1 & -f_d(c) \\ -f_x(d) & f_b(d) & -f_c(d) & 1 \end{vmatrix} \Big/ \begin{vmatrix} 1 & -f_a(x) & -f_c(x) & -f_d(x) \\ -f_x(a) & 1 & -f_c(a) & -f_d(a) \\ -f_x(c) & -f_a(c) & 1 & -f_d(c) \\ -f_x(d) & -f_a(d) & -f_c(d) & 1 \end{vmatrix}$$

As mentioned earlier, the relaxation of any given spin is complex. Therefore, the relaxation rates ($R_i$) appearing in the various equations above may contain contributions from cross-relaxation and cross-correlation effects. However, one can always define an initial relaxation rate, $R_i^0$, which will describe the relaxation before cross-relaxation causes significant nonexponential behaviour. To the extent that

$$\rho_i^* \ll \sum_{j \neq i} \rho_{ij}$$

the nonselective relaxation rates for the protio compound listed in Table 2 can be identified with the initial relaxation rates, $R_i^0$, and as they were calculated by the initial-slope method, cross-relaxation effects may be neglected. By substituting values for $R_i$ and nOe into the 16 equations taking the form of eq. [8], all of the corresponding values for $\rho_{ij}$ were obtained (two determinations for $\rho_{ij}$, $ij \neq$ x, one determination for $\rho_{ij}$, $i$ or $j$ = x). The values are listed in Table 5. Using these, and the correlation time ($\tau_c^0$) of (69.3 ± 0.2) × $10^{-12}$ s (for a 0.1 *M* solution of **1** in dimethyl sulfoxide-$^2H_6$), already cited, the set of interproton distances ($r_{ij}$) listed in Table 5 was determined (again, two determinations for $r_{ij}$, $ij \neq$ x, and one for $r_{ij}$, $i$ or $j$ = x). The error limits cited for the values of $\rho_{ij}$ and $r_{ij}$ reflect how accurately the errors in the various experimental quantities are known.

For internuclear distances between the ring protons of **1**, the data of Table 5 and the values expected from the molecular model (Table 3) are in good agreement. This is true especially when the distances are relatively small. Hence, experimentally, $r_{H\text{-}1,H\text{-}2}$ is 2.61 ± 0.14 Å, whereas the expected distance is 2.65 Å, and the comparable data for $r_{H\text{-}3,H\text{-}4}$ are 2.22 ± 0.10 Å and 2.28 Å, respectively. This high level of concurrence suggests that the assumptions involved in the measurements of relaxation and nOe were reasonable. Nevertheless, as there is poorer agreement when internuclear distances are longer (≥3.5 Å) and, accordingly,

TABLE 5. Relaxation rates ($\rho_{ij}$, $s^{-1}$) and interproton distances (Å) for 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose

| (*ij*) | $\rho_{ij} \times 10^2$ | $r_{ij}$ (exptl.) | $r_{ij}$ (calcd.) |

interproton relaxation less effective, the neglect of contributions from such remote sources as the $CH_3$ groups may not be justified. Perhaps, for example, this accounts for the negative $\rho_{ij}$ values in Table 5. The largest errors might be associated with H-4, because its relaxation receives contributions from H-5,H-6 and -6′ in a variety of orientations.

Distances of various protons from the hydroxyl proton, given in Table 5, reflect the most probable orientation attained by the hydroxyl group during its rotation about the C-1—O-1 bond. The close agreement between the experimental values and the calculated values of $r_{H\text{-}1,OH}$ and $r_{H\text{-}2,OH}$ is commensurate with a dihedral angle of 60° ± 30° for the H-1—C-1—O—H array, and hence with a conformation of **1** in which rotamer *g* for the anomeric alcohol group is the most heavily populated. Consequently, these findings are in complete agreement with the 3-spin system analysis already described, as well as with the relaxation rate and spin–spin coupling data presented earlier. Finally, it is worth noting that the conformational angle ($\theta$) for O-4—C-1$^{\theta}$—O—H in favored rotamer *g* is 60°, whereas calculations on methoxymethanol predict (29) that the most favored value of $\theta$ for the hemiacetal moiety of an aldose is ~65°.

## Experimental

All $^1H$ and $^{13}C$ nmr experiments were conducted with a Varian XL-200 spectrometer, operating at 200 and 50.3 MHz for $^1H$ and $^{13}C$ nuclei, respectively. The probe temperature was 20°C. The solutions of 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose (**1**) in dimethyl sulfoxide-$^2H_6$ were 0.1 *M* for all of the $^1H$ and $^{13}C$ nmr measurements. Each sample was carefully degassed by using at least 4 "freeze–pump–thaw" cycles, and then sealed.

*Measurement of* $R_1$

Proton spin-lattice relaxation rates were measured by the $(180°\text{–}\tau\text{–}90°\text{–}t)_x$ inversion recovery sequence (30), with an average of 16 free induction decays (fid). The delay between sequences was at least 5× the estimated value of the longest $T_1$ and, in all, three sets of experiments were performed. The optimal 180° pulse length, determined by producing a null in the amplitude of the fid, was 14 s. Typically, about 25 values of $\tau$ were "arrayed" in each run by utilizing the XL-200 $T_1$ programme, an appropriate range of $\tau$ values having been selected in preliminary experiments. Intensities of the components of each resonance were obtained from the computer printout; for multiplet resonances, they were summed. The total magnetization intensity for each resonance (except those of the overlapping H-4 and H-6 multiplets, only two of the four resonance components of each being summed) was then processed by a two-parameter linear regression analysis, to give an $R_1$ value. In all determinations, the initial-slope method (23–25) was used to ensure that cross-relaxation effects would be negligible. $R_1$ values are listed in Table 2; the error limits given are standard deviations of the fit.

$^{13}C$ spin-lattice relaxation measurements were made under conditions of full $^1H$ noise decoupling, by the two-pulse inversion recovery technique. The pulse duration for a 180° flip angle, checked as mentioned previously, was 24 μs, whereas the acquisition and waiting times were 1.023 and 6 s, respectively. A spectral window of 4000 Hz was used, and 100 scans were accumulated for each spectrum, while arraying 15–20 values of $\tau$. To minimize systematic errors, and factor out time as a variable in long experiments, the interleaving procedure available with the XL-200 spectrometer was used. Values of $T_1$ were determined by a two-parameter linear fit, using an equilibrium magnetization value ($M_0$) that was the average of at least 4 separate determinations.

*Measurement of nOe*

Steady-state proton nOe values were obtained from the intensities of the observed peaks in the "enhanced" spectrum, obtained with the irradiating field on, as compared with the intensities in the normal spectrum. At least 10 experiments were performed for each nOe value. In order to protect the receiver from overload, and to eliminate distortion of the spectrum by spin-decoupling, the irradiating field was gated off during acquisition of the fid. Delays of more than 10× the longest $T_1$ were used between the 90° pulses, and the irradiating power was the minimum required for effective saturation of the irradiated nucleus. The nOe values listed in Table 4, together with standard deviations, were calculated from eq. [8] by using integrated intensities.

Received September 29, 1981

IKBAL A. AKHTAR, JOHN J. MCCULLOUGH, SUSAN VAITEKUNAS, ROMOLO FAGGIANI, and COLIN J. L. LOCK. Can. J. Chem. **60**, 1657 (1982).

Irradiation of 2-cyanobicyclo[2.2.1]hept-2-ene (2-cyanonorbornene, **4**) in hexane, with the full arc of a mercury vapour lamp, gives the rearrangement products 1-cyanobicyclo[4.1.0]hept-2-ene **5** and 7-cyanotricyclo[4.1.0.$0^{3,7}$]heptane **6** in the ratio 20:1. These products were separated by preparative vpc. The structure of the major product **5** was determined by single crystal X-ray analysis. Reduction of **5** with lithium aluminum hydride gave the corresponding primary amine, which was converted to the *p*-bromobenzenesulfonamide **9**, mp 150–151°C, which gave single crystals from ethanol–water. The crystal and molecular structures are described. The minor product **6** was hydrogenated to give 7-cyanobicyclo[2.2.1]heptane. Formation of **5** and **6** may involve concerted $\sigma_{2s} + \pi_{2s}$ and $\sigma_{2a} + \pi_{2a}$ processes respectively, which are photochemically allowed.

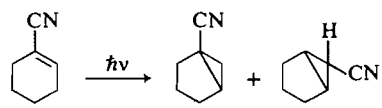
IKBAL A. AKHTAR, JOHN J. MCCULLOUGH, SUSAN VAITEKUNAS, ROMOLO FAGGIANI et COLIN J. L. LOCK. Can. J. Chem. **60**, 1657 (1982).

L'irradiation du cyano-2 bicyclo[2.2.1] heptène-2 (cyano-2 norbornène, **4**) dans l'hexane avec l'arc complet d'une lampe à vapeur de mercure conduit aux produits de transposition suivants: cyano-1 bicyclo[4.1.0] heptène-2 (**5**) et cyano-7 tricyclo [4.1.0.$0^{3,7}$] heptane (**6**) dans un rapport de 20:1. On a isolé ces produits par cpg préparative. On a déterminé la structure du produit majoritaire **5** par analyse aux rayons-X d'un mono-cristal. La réduction du composé *1* par l'alanate de lithium conduit à l'amine primaire correspondante. On transforme cette dernière en *p*-bromobenzènesulfonamide (**9**), pf 150–151°C, qui donne des monocristaux dans l'éthanol–eau. On décrit la structure du cristal et la structure moléculaire. Le produit secondaire **6**, par hydrogénation, conduit au cyano-7 bicyclo [2.2.1] heptane. La formation des composés **5** et **6** peut impliquer respectivement des processus concertés $\alpha_{2s} + \pi_{2s}$ et $\sigma_{2a} + \pi_{2a}$ qui sont permis photochimiquement.

[Traduit par le journal]

## Introduction

We have described (1) the rearrangement of 1-cyanocyclohexene **1**, which on direct irradiation in hexane gives the bicyclohexane derivatives **2** and **3**. Formation of these products must involve rearrangement of the σ-bonded group, and although these kinds of rearrangements are known in the photochemistry of neutral molecules, they are not numerous (some examples are enone "type A" rearrangements (2*a*), methyl migration (2*b*), and Wagner–Meerwein shifts (2*c*)). To determine the generality of the above rearrangement, and to study the effect of structure on the reaction, we have investigated the photochemistry of 2-cyanobicyclo[2.2.1]hept-2-ene **4**. This bicyclic nitrile also rearranges on irradiation, and the structure



**1** **2** **3**

work on the products is described. The bicyclic system might be used later for labelling experiments to determine reaction stereochemistry.

## Results

The required nitrile **4** was prepared by reaction of 2-chloronorbornene with cuprous cyanide in *N*-methylpyrrolidinone (1). The 2-chloronorbornene was prepared via 2,2-dichloronorborane, which was obtained by reaction of norcamphor with phosphorus pentachloride. Details are given in the experimental section.

Irradiation of 2-cyanonorbornene **4** in hexane with unfiltered light from a Hanovia 450 W lamp gave two products, identified as 1-cyanobicyclo[4.1.0]hept-2-ene, **5**, and 7-cyanotricyclo-[4.1.0.$0^{3,7}$]heptane, **6**, in the ratio 20:1. The reaction is shown in Scheme 1.

The products were separated by preparative vpc and the gross structural features determined from their spectra. Product **5** had ir: 2240 $cm^{-1}$ (CN stretch); $^1H$ nmr, δ: 6.02 (1h, doublet, $J$ = 10.0 Hz, vinylic), 5.66 (1H, multiplet, vinylic), 1.1–2.1 (7H,

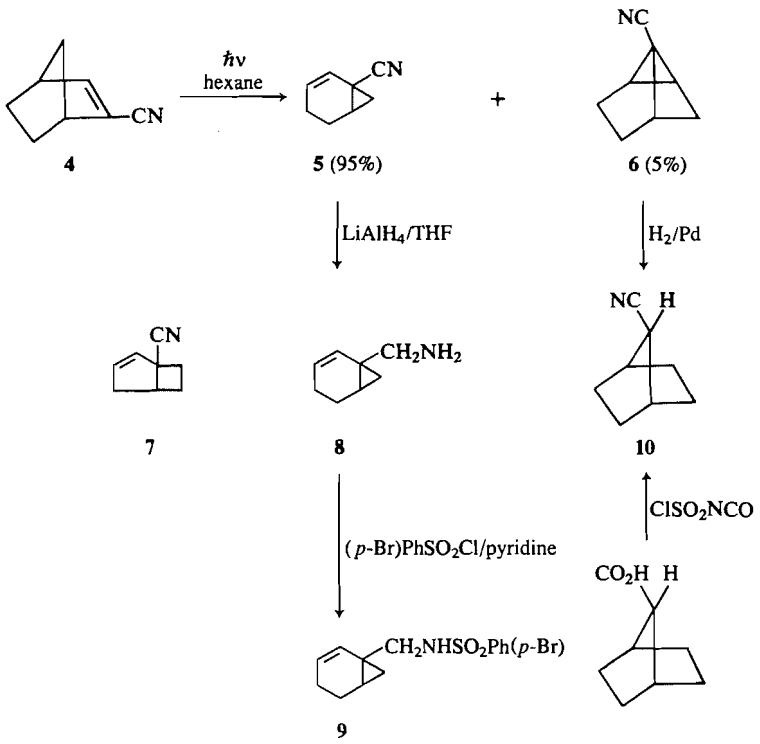

SCHEME 1

envelope of aliphatic protons); mass spectrum, *m/e*: 119 ($M^+$, $C_8H_9N$).

Although $J_{vinyl\text{-}vinyl}$ of 10.0 Hz is in the range for a cyclohexene derivative (3), we attempted to distinguish between structure **5** and the isomer **7** by synthesizing the latter (4).[2] None of the synthetic approaches proved successful, and X-ray crystal structure analysis was used. Reduction of **5** with $LiAlH_4$ gave the amine **8**, which readily formed a *p*-bromobenzenesulphonyl chloride in pyridine (Scheme 1). This gave crystals suitable for X-ray work, which is described below and in the experimental section. The structure **9** is shown[3] in Fig. 1.

The minor product **6** had the following spectral data: infrared, bands at 2215 $cm^{-1}$ (CN) and 3050 $cm^{-1}$ (cyclopropyl CH); $^1H$ nmr, envelope from δ: 1.0–3.0; mass spectrum, *m/e*: 119 ($M^+$). Catalytic hydrogenation gave 7-cyanobicyclo[2.2.1]heptane **10**, and structure 7-cyanotricyclo[4.1.0.$0^{3,7}$] heptane is assigned (Scheme 1).

*Description of crystal and molecular structure*

The molecule is illustrated in Fig. 1 and selected bond lengths and angles are given in Table 1. There is excellent agreement between the bond lengths in

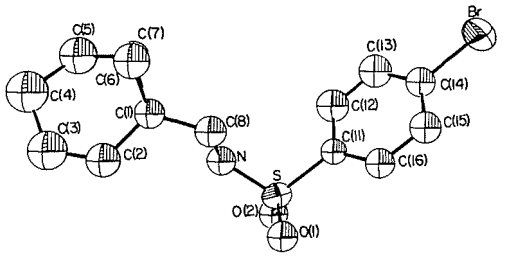

FIG. 1. The molecule bicyclo[4.1.0]hept-2-en-1-ylmethanamine *p*-bromobenzenesulphonamide (**9**), showing the atom numbering. Hydrogen atoms have been omitted for simplicity.

the cyclohexene moiety and values found previously (5–8). Internal angles at the olefin agree well with previous values, but angles adjacent to the cyclopropane ring (C(2)—C(1)—C(6), 115.2(6)°, C(1)—C(6)—C(5), 117.1(8)°) and possibly (C(4)—C(5)—C(6) 114.3(9)°) are larger than normal values of 111°. Presumably this increase is caused by steric requirements of the cyclopropane ring. Further distortions are observed by comparing distances of atoms from the C(1)C(2)C(3)C(4) plane or torsional angles within the cyclohexene ring with previous results (6, 8). Thus C(5) is 0.768(9) Å out of the plane compared with 0.340(7) Å for C(6), both in the same direction, whereas a value of ~0.38 Å on opposite sides of the plane is more normal (5, 7). Alternately the torsional angles differ significantly

[2]While this work was in progress, structure **7** (*cis*-fused) was described (4). The vinyl–vinyl coupling is 5.6 Hz.

[3]The three-membered ring can be seen more clearly in Fig. 2.

from those in $\Delta^{1,11}$-dicyclohexenyl ketone (6). The resulting form is a modified "boat" and corresponds neither to the $C_2$ "half-chair" form, observed in other structures (5–9) or the "1–2 diplanaire", calculated by Bucourt to be the next most stable form (10). Clearly the abnormal structure observed here arises from the interaction (one bond separation) of the constraints of the olefin and the cyclopropane ring, both of which will tend to make torsional angles about their C—C bonds as close to 0° as possible.

Bond lengths and angles within the *p*-bromosulfonamide portion of the molecule agree very well with those observed previously (11). The torsional angles (Table 2) show that the backbone of the molecule is arranged to minimize nonbonded interactions, except that between C(11)—H(16) and O(1) (O(1)SC(11)—C(16) = 14.2°). Apparently the

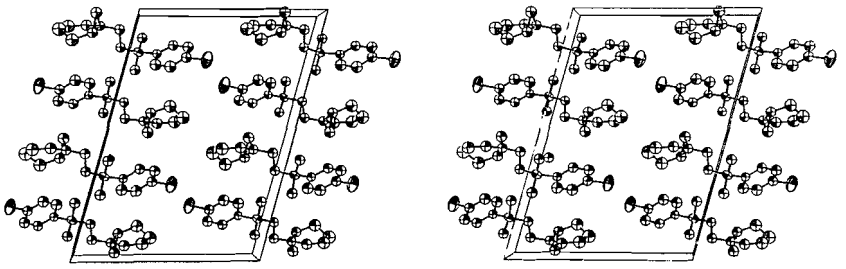

FIG. 2. The packing of *p*-bromobenzenesulphonamide (**9**), within the unit cell; *a* and *c** are parallel to the bottom and sides of the page and the view is down *b* (hydrogen atoms omitted).

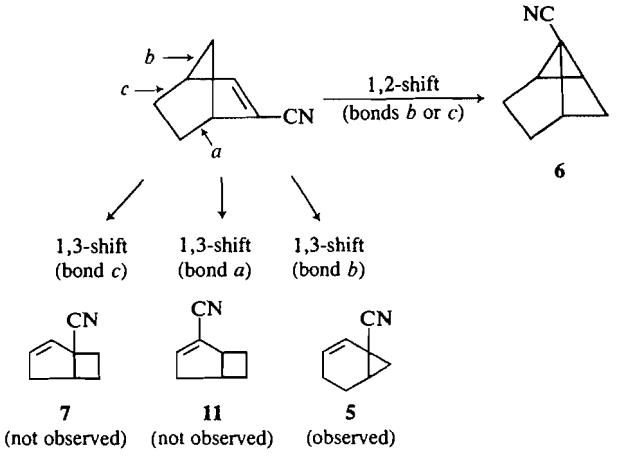
steric requirements of the $-NH_2$ group are more important in determining the orientation of the aromatic ring.

Bond lengths and angles in the cyclopropane unit are normal and the dihedral angle of 108.1(2)° between C(1)C(6)C(7) and C(5)C(6)C(1)C(2) is similar to values observed previously by others (12) (Range 104.2° to 110.1°) and ourselves (105.7(2)°) (13).

The packing of the molecules is shown in Fig. 2. The overall shape of the molecule resembles a shallow V (see Fig. 1) and the molecules are arranged in layers centred on the 100 faces so that the apices of the V's lie roughly in the face. The V is symmetric about the face and the angle of the V is roughly parallel to the 001 face. Within these layers adjacent molecules related by the $2_1$ axes at $x = 0, z = 1/4, 3/4$ are hydrogen bonded together through N···O(2)′ (2.92(1) Å) to form a spiral chain parallel to *b*. Adjacent chains in the layer have the apices of the V's pointing in opposite directions along *b* and contact between the chains involves hydrocarbon fragments and van der Waals interactions. Between layers, in the *a* direction, contacts at $x = 1/2$ are hydrocarbon–hydrocarbon, bromine–bromine, and bromine–hydrocarbon.



SCHEME 2

## Discussion

The tricyclic product **6** is the product of the 1,2-shift of a σ-bond, in the same fashion as reported previously (1). The tricyclo[4.1.0.$0^{3,7}$]-heptane ring system is well-known, and is formed in solvolysis reactions (14, 24), in photochemistry of unsaturated ketones (15), and in the photorearrangement of benzonorbornadiene (16). Note that 1,2-migration of either bond "*b*" or "*c*" (Scheme 2) would give product **6**, and labelling studies will be needed to distinguish which bond is involved.

Formation of the major product **5** involves 1,3-migration of a σ-bond, and although this process is known in photochemical (17) and thermal reactions (18), it was not observed in the photochemistry of 1-cyanocyclohexene (1). Formation of **5** requires 1,3-migration of bond "*b*" (Scheme 2); in contrast, migration of bonds of the ethano-bridge ("*c*" or "*a*") would give the bicyclo[3.2.0]heptane system, e.g. **7** or **11** respectively.

Thus, formation of **6** and **5** involves competing 1,2- and 1,3-sigmatropic shifts. Both processes are

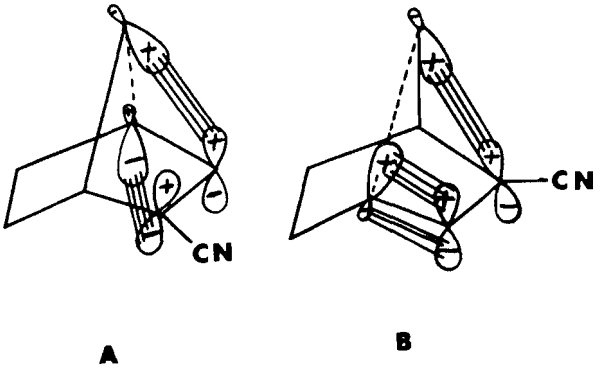


FIG. 3. Possible transition states for the photochemical symmetry allowed 1,2-(A) and 1,3-(B) sigmatropic shifts. A is $\sigma_{2a} + \pi_{2a}$ and B is $\sigma_{2s} + \pi_{2s}$.

symmetry allowed (19, 20) in the excited state ($\sigma_{2a} + \pi_{2a}$ and $\sigma_{2s} + \pi_{2s}$ respectively). The orbitals involved are shown in Fig. 3. We are not sure at present that the reaction is concerted, and plan further work on the mechanism, stereochemistry, and generality of the rearrangement.

## Experimental

*Materials*

The norcamphor, chlorosulphonyl isocyanate, and other organic reagents were obtained from the Aldrich Chemical Company. Hexane for the photolysis was "Spectrograde", or was purified using fuming sulphuric acid (1). Tetrahydrofuran was distilled from LAH immediately before use. Pyridine was distilled and kept over KOH pellets. 2,2-Dichloronorbornane was prepared as described by Bixler and Niemann (21).

*Instruments*

Irradiations were carried out using a Hanovia 450 W lamp and a quartz water-cooled immersion well. The solution was purged with argon. Ultraviolet spectra were run on a Carey 14 spectrometer, infrared spectra on a Perkin–Elmer 283, and nmr spectra on a Varian EM-390 or a Bruker WH-90 spectrometer. Mass spectra were obtained with a VG Micromass 7601 instrument.

Gas chromatography was performed on a Varian Aerograph 202 instrument with thermal conductivity detectors (preparative) or on a Tracor 560 with flame ionization detectors (analytical). Carrier gas was helium, and columns used are given below. Elemental analyses were by Galbraith Laboratories, Knoxville, Tenn., and Guelph Chemical Laboratories, Guelph, Ontario.

*2-Chlorobicyclo[2.2.1]heptene*

This compound was prepared from 2,2-dichlorobicyclo-[2.2.1]heptane (21) by dehydrochlorination using potassium *tert*-butoxide (22*b*). It has bp 29–30°/12 Torr, and infrared and $^1$H nmr spectra in good agreement with the literature (22).

*2-Cyanobicyclo[2.2.1]hept-2-ene*

The above vinyl chloride (8.0 g, 0.062 mol) and $Cu_2(CN)_2$ (11.1 g, 0.062 mol) were heated under reflux in 50 mL of 1-methyl-2-pyrrolidinone for 3 h. After cooling the mixture was poured into 300 mL of water containing 12.9 g of NaCN. Benzene (300 mL) was added, and the mixture was filtered through Celite. The layers were separated, and the aqueous phase was extracted with 2 × 50 mL benzene. The benzene extracts were washed with 200 mL of 10% aqueous NaCN, 200 mL of water, and dried ($Na_2SO_4$). The benzene was evaporated and the residue distilled to yield crude 2-cyanobicyclo[2.2.1]hept-2-ene, bp 67–69°C/12 Torr, 2.35 g (35%). The ir showed that 1-methyl-2-pyrrolidinone was present (band at 1700 cm$^{-1}$). The product was dissolved in 25 mL ether, and washed with 3 × 50 mL water. After distillation, infrared showed the band at 1700 cm$^{-1}$ was absent; ir (neat): 2210, 1570 cm$^{-1}$; $^1$H nmr ($CCl_4$), δ: 6.90 (1H, d, $J$ = 4 Hz, vinylic proton), 3.0–3.2 (2H, m, bridgehead proton), 1.0–1.9 (6H, M, other ring protons). $J_{(vinyl-bridgehead)}$ of 4 Hz is reported (23). *Anal.* calcd. for $C_8H_9N$: C 80.63, H 7.60, N 11.75%; found: C 80.14, H 7.60, N 11.95%.

*Irradiation of 2-cyanobicyclo[2.2.1]*heptene

The unsaturated nitrile **4** (550 mg, 4.5 mmol) in hexane (400 mL) was irradiated under argon for 3 h, using the Hanovia 450 W lamp. Vapor phase chromatographic analysis (6 ft × ¼ in. of 3% OV-1, glass column, at 80°C) showed two products, ratio 20:1 with retention times 350 and 455 s respectively. The solution was filtered through Celite, and the hexane distilled (1 atm) through a column of glass helices. The residue was distilled in a Kugelrohr apparatus (100°C/15 Torr) to yield 320 mg of the mixed photoproducts. These were separated by vpc (5 ft × ¼ in. of 7% QF-1 on Chromosorb W at 125°C, with the flow rate of 30 mL/min). The minor product (retention time 19 min) had $m/e$ = 119 ($M^+$); ir (neat): 3055, 2215 cm$^{-1}$; $^1$H nmr ($CDCl_3$), δ: 1.2–2.9 (envelope); $^{13}$C nmr ($CDCl_3$); 42.6 ppm (d), 37.7 (t), 33.7 (d), 27.2 (d), 25.1 (t), 22.6 (t) ppm. The structure **6** is assigned from the hydrogenation to 7-cyanonorbornane, described below. The major product (retention time 14 min) also had $m/e$ = 119 ($M^+$); ir (neat): 1648, 2240 cm$^{-1}$; $^1$H nmr ($CDCl_3$)δ: 6.02 (1H, d, $J$ = 10.0 Hz) and 5.66 (1H, m, vinylic protons), 1.2–2.2 (7H, m); $^{13}$C nmr ($CDCl_3$): 125.3, 123.7, 24.3, 20.2, 19.4, 17.0 ppm. *Anal.* calcd. for $C_8H_9N$: C 80.63, H 7.61, N 11.76; found: C 80.61, H 7.61, N 11.90%. The structure 1-cyanobicyclo[4.10]hept-2-ene **5** is assigned from the X-ray work described below.

*Hydrogenation of minor product **6** from photolysis*

The tricyclic nitrile **6** (81 mg, 5.6 × 10$^{-3}$ mol) (83% pure by vpc) in ethyl acetate (7.0 mL) was hydrogenated over 10% Pd-on-carbon catalyst at 1 atm. Nine milliliters of $H_2$ were absorbed (4 × 10$^{-3}$ mol), and vpc analysis (6 ft × ¼ in. of 3% OV-1 at 100°C) showed the reaction was essentially complete. The catalyst was filtered, the solvent was evaporated, and the residue distilled (Kugelrohr, 100°/12 Torr) to give 64.3 mg, which was purified by vpc (6 ft. × ¼ in. of 7% QF-1 on WP 80/100, at 90°C). This afforded 7-cyanobicyclo[2.2.1]heptane, mp 61–64°C (lit. (24) mp 65–67°).

*Preparation of 7-cyanobicyclo[2.2.1]heptane from bicyclo-[2.2.1]heptane-7-carboxylic acid*

The method of Lohaus (25) was used. Bicyclo[2.2.1]heptane-7-carboxylic acid[4], mp 75–78°C (5 mg, 3.6 × 10$^{-5}$ mol) in pentane (10 mL) was treated with several drops (~100 mg) of chlorosulphonyl isocyanate at 40°C, under argon. After 4 h the mixture was cooled to 20°C, and dimethylformamide was added until gas evolution ceased. After 30 min crushed ice was added, aqueous and pentane layers were separated, and the aqueous layer was extracted with 2 × 10 mL pentane. The pentane layers were combined, dried, and concentrated; vpc analysis (6 ft × ¼ in. 3% OV-1 at 100°C) showed a product with the same retention time (192 s) as the above hydrogenation product. The structure 7-cyanotricyclo[4.1.0.0$^{3,7}$]heptane **6** is assigned to the minor photoproduct.

*Preparation of derivative of **5** for X-ray work. Reduction of 1-cyanobicyclo[4.1.0]hept-2-ene with lithium aluminum hydride*

The major photoproduct **5** (100 mg, 8.4 mmol) in hexane (~1.0 mL) was added to $LiAlH_4$ in tetrahydrofuran (5.0 mL). The mixture was stirred and heated under reflux for 24 h. Excess $LiAlH_4$ was decomposed with wet THF, and the mixture was filtered through Celite. Water and ether were added, and the ether layer was separated and dried ($Na_2SO_4$). The ether was evaporated and the residue distilled (Kugelrohr) to yield bicyclo[4.1.0]hept-2-en-1-ylmethanamine, 70 mg (68%); ir (neat): 3700–3100 cm$^{-1}$, no CN band.

*Preparation of p-bromobenzensulphonamide of bicyclo[4.1.0]-hept-2-en-1-ylmethanamine **8***

The products from the above reduction (70 mg) and *p*-bromobenzenesulphonyl chloride (118 mg) were dissolved in pyridine and kept in the refrigerator for 24 h. The mixture was poured into ice-cold 6*N* HCl, and extracted with 3 × 25 mL of ether. The extracts were dried and evaporated to afford the crude

derivative, mp 124–140°C. Two cyrstallizations from ethanol–water gave an analytical sample, mp 150–151°C. *Anal.* calcd. for $C_{15}H_{16}NSO_2Br$: C 49.13, H 4.71, N, 4.09; found: C 49.22, H 4.79, N 3.92%. A crystal suitable for the following X-ray work was obtained by slow crystallization from ethanol–water.

*Collection of the X-ray data*

An acicular crystal of the above *p*-bromosulphonamide, selected after examination under a polarizing microscope for homogeneity, was ground to a cylinder and sealed to a glass fibre for X-ray examination. Precession photographs showed the crystal was monoclinic and unit cell parameters were obtained from a least squares fit of χ, φ, and 2θ for 15 reflections in the range 17.7° < 2θ < 25.1° recorded on a Syntex $P2_1$ diffractometer using graphite-monochromated MoKα radiation (λ 0.70926 Å). Crystal data and other numbers related to data collection are summarized in Table 3. The density was obtained by flotation in an aqueous zinc bromide solution to which a few drops of liquid detergent had been added in order to wet the crystal. Intensities were also recorded on the Syntex $P2_1$ diffractometer using a coupled θ(crystal) – 2θ(counter) scan. The methods of selection of scan rates and initial data treatment have been described (26, 27). Corrections were made for Lorentz polarization effects, but not for absorption. This will make a maximum error in $F_o$ of < 1.0%.

*Solution of the structure*

The bromine atom was found from a three dimensional Patterson synthesis, and a series of full-matrix least-squares refinements and electron density difference syntheses revealed all the atoms. At this stage the temperature factors of the bromine and sulphur atoms were made sequentially isotropic.

Received October 9, 1981

A. D. PELTON, J. M. SKEAFF, C. W. BALE, and P. L. LIN. Can. J. Chem. **60**, 1664 (1982).

Phase diagrams and total vapour pressures in the reciprocal ternary systems LiCl–NaCl–$LiAlCl_4$–$NaAlCl_4$, LiCl–KCl–$LiAlCl_4$–$KAlCl_4$, and NaCl–KCl–$NaAlCl_4$–$KAlCl_4$ have been calculated by means of computerized optimization and interpolation techniques based on an analysis of the constituent binary systems.

The system LiCl–NaCl–$LiAlCl_4$–$NaAlCl_4$ exhibits an extensive composition region of one-phase liquid solution whereas the LiCl–KCl–$LiAlCl_4$–$KAlCl_4$ system has a miscibility gap which covers ~ 50% of the composition region. Comparison of the calculated phase diagram with measured data for NaCl–KCl–$NaAlCl_4$–$KAlCl_4$ was made and the agreement between the two was found to be satisfactory.

Temperatures and compositions of chloride electrolytes suitable for the electrowinning of aluminum have been proposed from the isothermal sections of the phase diagrams and total vapour pressure curves. In all of the systems, the total vapour pressure is greater than the minimum for non-volatilization.

A. D. PELTON, J. M. SKEAFF, C. W. BALE et P. L. LIN. Can. J. Chem. **60**, 1664 (1982).

Faisant appel à une maximisation calculée et à des techniques d'interpolation basées sur une analyse de constituants des systèmes binaires, on a calculé les diagrammes de phase et les pressions totales de vapeurs des systèmes linéaires réciproques de LiCl–NaCl–$LiAlCl_4$–$NaAlCl_4$, LiCl–KCl–$LiAlCl_4$– $KAlCl_4$ et de NaCl–KCl–$NALCl_4$–$KAlCl_4$.

Le système LiCl–NaCl–$LiAlCl_4$–$NaAlCl_4$ montre une région de composition extensive d'une solution en phase liquide tandis que le système LiCl–KCl–$LiAlCl_4$–$KAlCl_4$ a une intervalle de miscibilité qui couvre environ 50% de la composition de la région. On a comparé les diagrammes de phase calculés avec les données mesurées dans le cas du système NaCl–KCl–$NaAlCl_4$–$KAlCl_4$ et on a trouvé que les résultats s'accordent bien. A partir des sections isothermes des diagrammes de phase et des courbes de pression totales de vapeur, on a proposé les températures et les composition des électrolytes contenant des chlorures qui conviennent parfaitement à l'électro-gain de l'aluminium. Dans tous les systèmes, la pression totale de vapeur est supérieure au minimum de non volatilisation.

[Traduit par le journal]

## Introduction

The problems of high energy consumption as well as the production of CO, $CO_2$, and fluoride emissions associated with conventional Hall-Heroult process aluminum smelters (1) have prompted investigation into new processes which would reduce or eliminate these difficulties. One such process is the electrowinning of aluminum from fused chloride salts, which has been reviewed elsewhere (1, 2).

Major considerations in the fused salt electrowinning of liquid metals from chloride media are: (*1*) that the electrolyte be a one-phase liquid; (*2*) that the electrolyte losses due to volatilization be minimized; (*3*) that the metal chloride decomposition potential be determined; (*4*) that the difference in density between the electrolyte and the electrowon liquid metal be sufficient to cause their rapid gravity separation; (*5*) that the electrolyte have a low viscosity; and (*6*) that the electrolyte have a high ionic conductivity. It is thus necessary to have data on phase diagrams, vapour pressures, decomposition potentials, densities, viscosities, and electrical conductivities of possible electrolytes in order to determine temperatures and compositions suitable for electrowinning or electrorefining.

While aluminum electrowinning experiments have been conducted to determine current densities, current efficiencies, and energy consumptions, usually with binary fused chloride systems as the electrolyte, the literature indicates that ternary fused chloride systems which have been employed or may be suitable for the electrowinning of alumi-

num have not been thermodynamically well characterized. Most notably, published data are lacking on the phase diagrams and vapour pressures of ternary chloride systems involving aluminum chloride with the alkali chlorides.

In a previous publication (3), the authors presented the results of the calculation of the phase diagrams and vapour pressures of the ternary fused chloride systems LiCl–KCl–$PbCl_2$, LiCl–KCl–$ZnCl_2$, NaCl–KCl–$PbCl_2$, and NaCl–KCl–$ZnCl_2$ from the known properties of the constituent binary systems. Temperatures and compositions in these electrolytes suitable for the electrowinning of lead and zinc were then proposed from isothermal sections of the phase diagrams and from iso-vapour pressure curves of $PbCl_2$ and $ZnCl_2$.

In the present publication, we extend this method of calculating phase diagrams and vapour pressures to the systems LiCl–NaCl–$AlCl_3$, LiCl–KCl–$AlCl_3$, and NaCl–KCl–$AlCl_3$. The method, which has been described in detail previously (3–7), consists of a computer-assisted critical analysis of the available phase diagrams and thermodynamic data for the binary subsystems in order to obtain mathematical expressions for the thermodynamic properties of all known phases. At the same time, this critical analysis serves to help resolve discrepancies in the literature and to help set error limits on all data and calculations. The thermodynamic properties of the ternary systems are estimated from these binary data, and the ternary phase diagrams and vapour pressures are then calculated.

Based on the results of these calculations, we then discuss electrolyte temperatures and compositions for aluminum electrowinning from the view point of (*1*) maintaining a one-phase liquid solution, and (*2*) minimizing the total vapour pressures to reduce volatilization losses.

Because of very high vapour pressures which have been calculated (8) to occur in these systems for $X_{AlCl_3} > 0.5$, and therefore render $AlCl_3$-rich compositions of limited practical interest for electrowinning, in this paper we will be concerned only with compositions for which $X_{AlCl_3} \leq 0.5$.

## One-component chlorides

There are three alkali metal chlorides and one light metal chloride listed in Table 1, which are to be considered in the present study. For the phase diagram calculations, the free energies of fusion of the alkali chlorides are required. Values from the literature (9) are listed in Table 2.

## Binary systems

The binary systems which must be analyzed in order to calculate the ternary phase diagrams are also listed in Table 1. Note that for the $AlCl_3$ – alkali chloride systems we are concerned only with the sub-systems ACl–$AAlCl_4$ (where A = Li, Na, or K). Furthermore, three quasi-binary systems, e.g., $NaAlCl_4$–$KAlCl_4$, etc., have been included. This treatment is discussed later.

A thorough literature search of all available phase diagram and thermodynamic data for these systems was performed by R. J. C. MacDonald, Information Officer of CANMET, Dept. of Energy, Mines and Resources, Canada, using the following computerized data bases: Chemical Abstracts, Engineering Index, Inspec, SSIE, Conference Papers, CDI and NTIS.

The method described and employed previously (3–7) was used to analyse the binary systems listed in Table 1. Briefly, a least-squares optimization technique is used to obtain the coefficients $h_{ij}$ and $s_{ij}$ of polynomial expansions for the molar enthalpies and excess entropies of each solution phase in the following form:

$$[1] \quad \Delta H = \sum_{i,j} h_{ij} X_A^i X_B^j$$

$$[2] \quad S^E = \sum_{i,j} s_{ij} X_A^i X_B^j$$

where $X_A$ and $X_B$ are the mole fractions of the components. The optimization analysis is also used to obtain the Henrian activity coefficients of dilute solid solutions and the free energies of formation of intermediate stoichiometric solid phases.

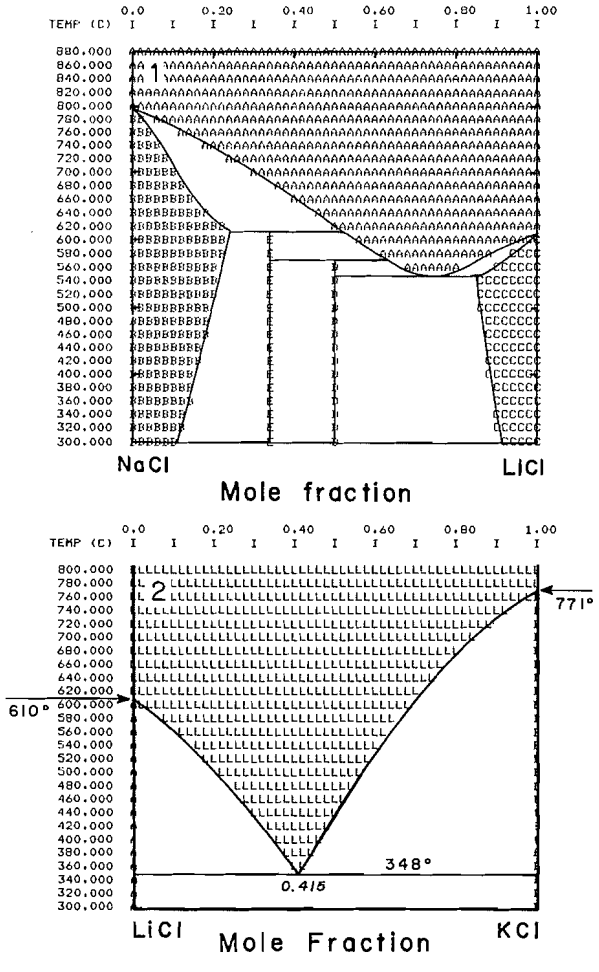
TABLE 2. Free energies of fusion and melting points of pure chlorides (9)
$\Delta G^0_{fusion}$ (cal/mol) = $a + bT + cT^2 + dT \ln T + eT^{-1}$

| Chloride | $T^0_{fusion}$ (K) | $a$ | $b$ | $c \times 10^3$ | $d$ | $e \times 10^{-5}$ |
|---|---|---|---|---|---|---|
| KCl | 1044 | 1136.6 | 51.481 | 3.0435 | −8.026 | 0.436 |
| LiCl | 883 | 1056.5 | 47.16 | 3.928 | −7.64 | |
| NaCl | 1074 | 1848.6 | 48.3 | 2.85 | −7.606 | |

The details of the critical analyses for each binary system are discussed below and error limits are given. The computer-calculated phase diagrams for each binary system are given in Figs. 1–7, and the coefficients $h_{ij}$ and $s_{ij}$ are listed in Table 3.

*LiCl–NaCl (Fig. 1)*

$\Delta H$ for the liquid is as reported by Hersh and Kleppa (10). It is reasonable to suppose that $S^E = 0$ for the liquid. There are several measured phase



FIGS. 1, 2. Computer-generated phase diagram for LiCl–NaCl (*1*) and KCl–LiCl (*2*).

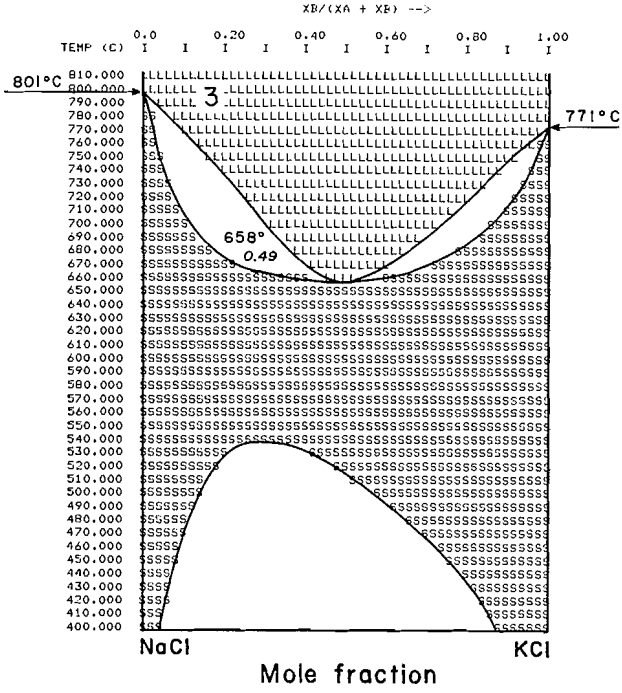


FIG. 3. Computer-generated phase diagram for KCl–NaCl.

diagrams for this system. All are in reasonable agreement as regards the liquidus curves. However, the diagrams of Plyushchev *et al.* (11*a*) and of Smits *et al.* (11*a*) show complete solid solution, while the most recent diagram of Akopov and Bergman (11*b*) shows no solid solubility at all and in addition shows two intermediate compounds. These intermediate compounds also appear in the measured ternary phase diagram of the LiCl–NaCl–KCl system which the present authors have also calculated obtaining good agreement between measured and calculated diagrams. This supports the existence of these two compounds. If no solid solubility is assumed, then the calculated liquidus curves do not agree with the measured. On the other hand, fitting the diagram with the assumption of complete solid solubility requires the thermodynamic functions of the solid solution to be highly asymmetric and rather unlikely functions of composition. As a compromise, it was assumed that limited solid solutions exist and that these are

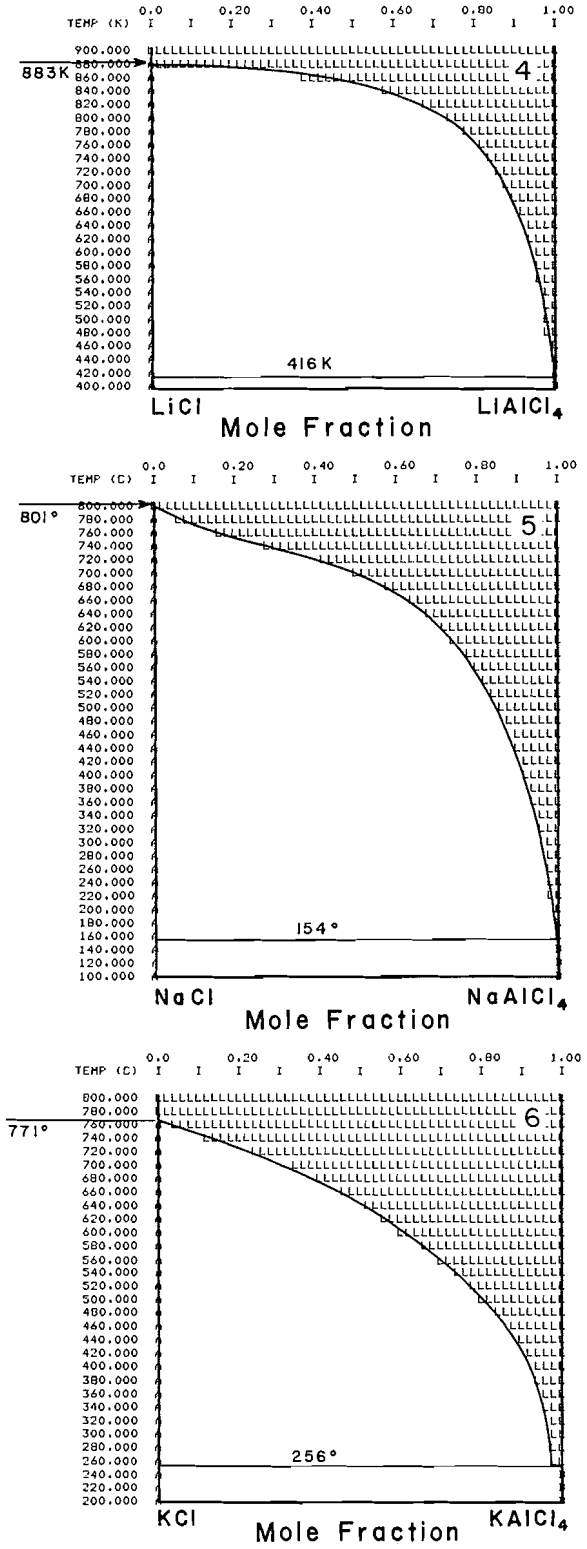
For personal use only.



FIGS. 4–6. Computer-generated phase diagram for LiCl–$LiAlCl_4$ (*4*); NaCl–$NaAlCl_4$ (*5*); and KCl–$KAlCl_4$ (*6*).

Henrian solutions. The calculated and measured liquidus curves are then in agreement to within 2 mol% everywhere except near pure NaCl where the diagram of Akopov and Bergman (11*b*) does not agree with the other diagrams. However, in this region the two other diagrams agree with each other and with the calculated diagram. The Henrian activity coefficients of the solid phases were obtained as:

$$RT \ln \gamma_{LiCl} = 1200 \text{ cal}$$

$$RT \ln \gamma_{NaCl} = 1700 \text{ cal}$$

The free energies of formation from pure liquid LiCl and NaCl of the two intermediate compounds were also obtained by the phase diagram analysis as:

$$\Delta G^0 (LiCl)_{1/2} (NaCl)_{1/2} = -7894 + 7.526T \text{ cal/mol}$$

$$\Delta G^0 (LiCl)_{1/3} (NaCl)_{2/3} = -6701 + 5.86T \text{ cal/mol}$$

Probable maximum error of calculated liquidus: ±10°.

*KCl–LiCl (Fig. 2)*

$\Delta H$ was fitted to the measured values of Hersh and Kleppa (10). $S^E$ was determined by fitting the measured phase diagram. Limiting slopes of liquidus curves indicate negligible solid solubility. The two measured diagrams agree with each other within 5°. The more recent eutectic temperature of 348°C (11*b*) is more consistent with smooth thermodynamic functions for the liquid phase than is the older value of 354°C (11*a*).

Probable maximum error of calculated diagram: ±5°.

*KCl–NaCl (Fig. 3)*

The measured enthalpies of Hersh and Kleppa (10) were used to obtain the expression for $\Delta H_{liquid}$. The most recently measured liquidus (12) and solidus (11*c*) were then analysed in order to obtain the coefficients for $S_{liq}^E$, $\Delta H_{solid}$, and $S_{solid}^E$ given in Table 3. The measured (11*c*, 12) and calculated liquidus and solidus agree within less than 2° and less than 5° respectively. The calculated consolute point agrees with the measured (11*a*) within 50° in temperature, and in composition within the limits of experimental error. All parts of the calculated diagram thus agree with the experimental within the error limits of the latter.

Probable maximum error of calculated diagram: ±2° for liquidus and ±5° for solidus.

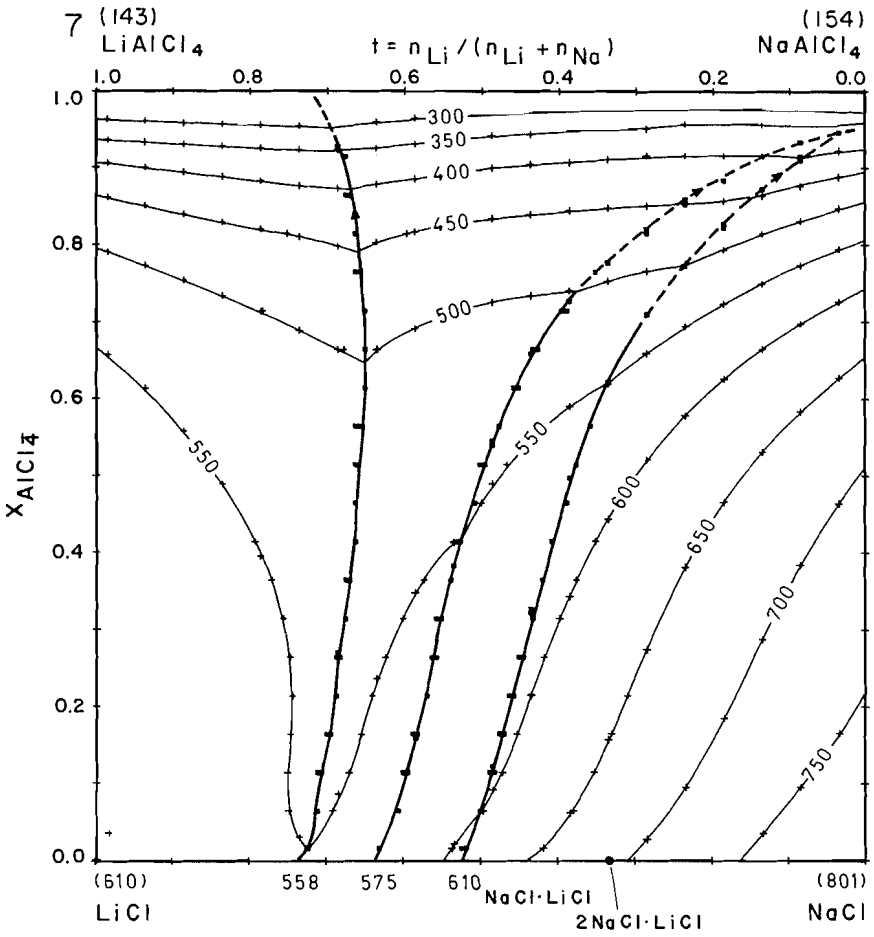

FIG. 7. Calculated phase diagram for LiCl–NaCl–$LiAlCl_4$–$NaAlCl_4$. Temperatures are in °C.

*$LiCl$–$LiAlCl_4$ (Fig. 4)*

The system $AlCl_3$–LiCl has been divided into two sub-systems: LiCl–$LiAlCl_4$, and $LiAlCl_4$–$AlCl_3$. This is consistent with the strong evidence provided by the vapour pressure measurements to be discussed later in this paper that the melts contain very stable $AlCl_4^-$ complex anions. As noted previously, we are concerned only with compositions for which $X_{AlCl_3} \leq 0.5$, i.e., the LiCl–$LiAlCl_4$ sub-system. The measured phase diagram of this sub-system can be fitted by assuming ideal entropy for the sub-system and only small well-behaved deviations from ideality in the enthalpy. That is, the general shape of the measured phase diagram also strongly supports the splitting into two sub-systems.

With $S^E$ taken to be zero in the sub-system, the recent phase diagram of Sato and Ejima (13) was fitted to obtain the expression for $\Delta H$. Agreement between measured and calculated diagrams is of the order of 10°. The entropy of fusion of the compound $LiAlCl_4$ was taken to be 8.0 cal/mol K, which is approximately that of similar compounds. The enthalpy of fusion was then determined from this entropy and the reported melting point. (Most recent evidence indicates that this is a congruently melting compound.) The fit is consistent with the vapour pressure measurements which will be mentioned later in this report.

Probable maximum error in calculated diagram: ±5 to 10°.

*$NaCl$–$NaAlCl_4$ (Fig. 5)*

Exactly the same comments as given above for the LiCl–$LiAlCl_4$ system also apply to this system. Data for the measured phase diagram were taken from ref. 11*a*.

*$KCl$–$KAlCl_4$ (Fig. 6)*

Exactly the same comments as given above for the NaCl–$NaAlCl_4$ system also apply for this system.

TABLE 3. Summary of optimized thermodynamic parameters of eqs. [1], [2] for the enthalpy and excess entropy of binary liquid phases

| Binary system (liquid phase unless otherwise stated) | | | | | |
|---|---|---|---|---|---|
| A | B | $i$ | $j$ | Enthalpy coefficient $h_{ij}$ (cal) | Excess entropy coefficient $s_{ij}$ (cal $K^{-1}$) |
| KCl | LiCl | 1 | 1 | −4290 | −0.6211 |
| | | 2 | 1 | 90 | −0.6047 |
| NaCl | KCl | 1 | 1 | −555 | −0.4 |
| | | 1 | 2 | 65 | |
| NaCl | KCl (solid phase) | 1 | 1 | 6690 | 3.0 |
| | | 1 | 2 | −2880 | |
| | | 1 | 3 | 1900 | |
| LiCl | NaCl | 1 | 1 | −1120 | |
| LiCl | $LiAlCl_4$ | 1 | 1 | 5464 | |
| | | 1 | 2 | −10687 | |
| | | 1 | 3 | 19276 | |
| | | 1 | 4 | −17786 | |
| | | 1 | 5 | 6049 | |

| | | 1 | 2 | −1754 | |
| KCl | $KAlCl_4$ | 1 | 1 | 2936 | |
| | | 1 | 2 | −4083 | |
| | | 1 | 3 | 3213 | |
| $LiAlCl_4$–$NaAlCl_4$ | | | Ideal | | |
| $NaAlCl_4$–$KAlCl_4$ | | | Ideal | | |
| $LiAlCl_4$–$KAlCl_4$ | | | Ideal | | |

*$KAlCl_4$–$NaAlCl_4$*

The entropies of fusion were taken to be 8.0 cal/mol K, which is approximately that of similar compounds. The enthalpies of fusion were then determined from this entropy and the measured melting points. Under the assumption that the liquid is an ideal solution and that there is no solid solubility, the system was calculated to exhibit a simple eutectic at 125 ± 1°C and mole fraction 0.74 ± 0.03 $NaAlCl_4$, which is within the error limits of the diagram measured by Chikanov (11*b*).

Probable maximum error of calculated diagram: ±10°.

*$KAlCl_4$–$LiAlCl_4$ and $LiAlCl_4$–$NaAlCl_4$*

No data are available for these two quasi-binary systems. In light of the above findings for the $KAlCl_4$–$NaAlCl_4$ system, it is assumed that the liquid phases are ideal and that there is no solid solubility.

## Calculation of ternary systems containing $AlCl_3$ from binary systems

Once all the binary systems have been analysed, the thermodynamic properties of the ternary systems can be estimated by means of standard interpolation procedures which have been applied elsewhere (3–7) with success to many other ionic systems.

As discussed previously, the binary systems $ACl$–$AlCl_3$ (A = Li, Na, K) were each divided into two sub-systems, $ACl$–$AAlCl_4$ and $AAlCl_4$–$AlCl_3$. By extension, the composition triangle of each of the three ternary systems $ACl$–$BCl$–$AlCl_3$ (A, B = Li, Na, K) can be considered to be divided into two regions by a line joining the two compounds $AAlCl_4$ and $BAlCl_4$. The upper region becomes the ternary system $ACl_3$–$AAlCl_4$–$BAlCl_4$, and the lower region becomes the "reciprocal ternary system" $ACl$–$BCl$–$AAlCl_4$–$BAlCl_4$. As noted previously, we are concerned only with the reciprocal ternary systems, i.e., those composition regions for which $X_{AlCl_3} \leq 0.5$.

*Reciprocal systems $ACl$–$BCl$–$AAlCl_4$–$BAlCl_4$ (A, B = Li, Na, K)*

*Calculation of phase diagrams*

The calculated phase diagrams for the subsystems LiCl–NaCl–$LiAlCl_4$–$NaAlCl_4$, LiCl–KCl–$LiAlCl_4$–$KAlCl_4$, and NaCl–KCl–$NaAlCl_4$–$KAlCl_4$ are presented in Figs. 7, 8, and 9 respectively. Each of these "reciprocal systems" contains two cations, $A^+$ and $B^+$, and two anions, $Cl^-$ and $AlCl_4^-$. The horizontal axes of these diagrams

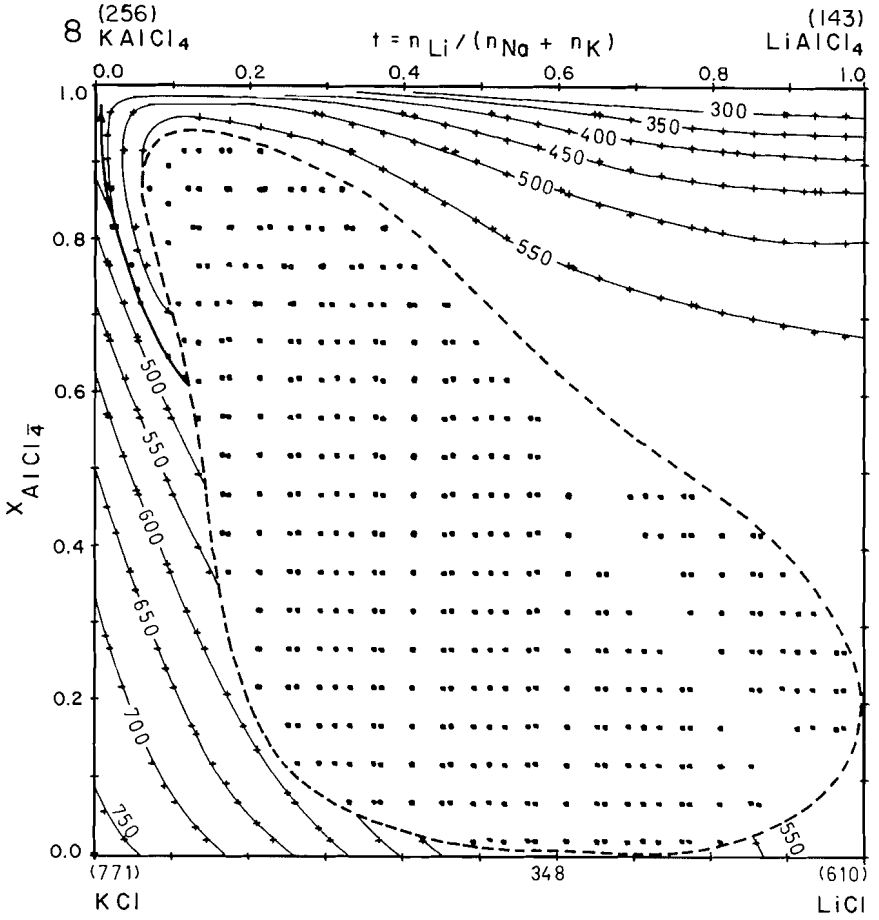

FIG. 8. Calculated phase diagram for LiCl–KCl–$LiAlCl_4$–$KAlCl_4$. Temperatures are in °C.

are the cationic fractions $t = n_{B^+}/(n_{A^+} + n_{B^+})$ and the vertical axes are the anionic fractions $X_{AlCl_4^-} = n_{AlCl_4^-}/(n_{Cl^-} + n_{AlCl_4^-})$[1] (where $n_i$ = moles of ion $i$). The dashed lines on the diagram for the LiCl–KCl–$LiAlCl_4$–$KAlCl_4$ systems are the loci of intersection of a liquid immiscibility gap with the liquidus. These phase diagrams were calculated by interpolation from the four binary systems which form the edges of the composition diagrams. The Conformal Ionic Solution (CIS) theory (14) for reciprocal salts was employed for the calculations. Details of the interpolation formulae are given in ref. 14. It has been shown in several studies (14–19) that good approximations to reciprocal salt phase diagrams can be obtained by this approach.

A factor which is of prime importance in the calculation of a reciprocal salt phase diagram via the CIS theory is $\Delta G^{EX}$, the free energy change of the "exchange reaction":

[A] $ACl + BAlCl_4 \rightleftharpoons BCl + AAlCl_4$

[1] $X_{AlCl_3} = X_{AlCl_4^-}/(1 + X_{AlCl_4^-})$ and $X_{AlCl_4^-} = X_{AlCl_3}/(1 - X_{AlCl_3})$.

$\Delta G^{EX}$ cannot be obtained solely from the four binary sub-systems, but rather, it must be obtained independently. for the three exchange reactions in the present case, $\Delta G^{EX}$ was determined from analysis of vapour pressure and other thermodynamic data (9, 20). Values are given in Table 4.

If $\Delta G^{EX} < 0$ for reaction [A], then BCl and $AAlCl_4$ are called the "stable pair" while ACl and $BAlCl_4$ are the "unstable pair".

If $\Delta G^{EX} < 0$, then it is energetically favorable to have $B^+$ ions next to $Cl^-$ and $A^+$ ions next to $AlCl_4^-$ ions. If we mix pure BCl with pure $AAlCl_4$, we force some $B^+$ ions to be situated next to $AlCl_4^-$ ions and force some $A^+$ ions to be next to $Cl^-$ ions. This is energetically unfavourable. On the other hand, mixing of the pure members of the unstable pair is energetically favourable. The result is that strong positive deviations from ideality (manifested by a flat liquidus with widely spaced isotherms) are observed along the diagonal of the phase diagram which joins the stable pair (the "stable diagonal"), while strong negative deviations from ideality (steep liquidus, closely spaced isotherms) are ob-

For personal use only.

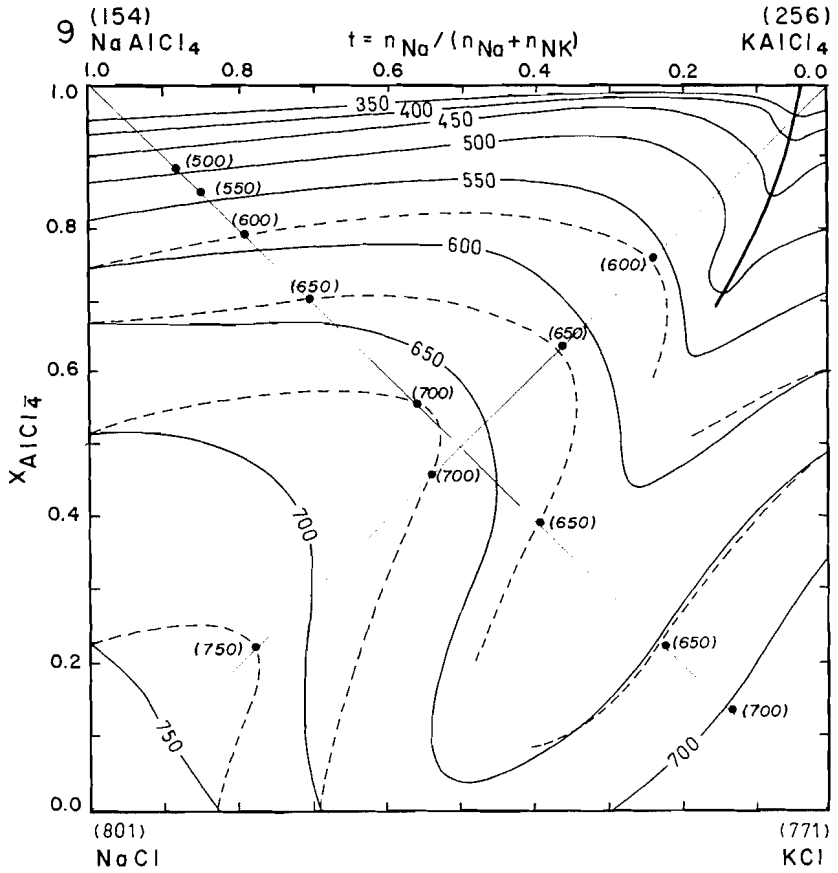

FIG. 9. Calculated phase diagram for NaCl–KCl–$NaAlCl_4$–$KAlCl_4$ plus experimental points (21) and estimated experimental isotherms (---). Temperatures are in °C.

served along the "unstable diagonal". This can clearly be seen in the three calculated phase diagrams. As $\Delta G^{EX}$ becomes more and more negative, these deviations are accentuated until, as in the case of the LiCl–KCl–$LiAlCl_4$–$KAlCl_4$ system, a miscibility gap appears with tie lines lying approximately parallel to the stable diagonal.

The NaCl–KCl–$NaAlCl_4$–$KAlCl_4$ phase diagram has been determined experimentally along the two composition diagonals by Fischer and Simon (21). Points from their experimental phase diagram are also shown in Fig. 9 along with some experimental isotherms estimated from the curves measured by Fischer and Simon (21). These isotherms are shown terminating at points from the calculated binary phase diagrams from the present study because these points agree closely with the most recently measured binary phase diagrams, whereas the binary phase diagrams of Fischer and Simon are not in good agreement with the latter. The difference between the measured and calculated diagrams is greatest in the central portion of the figure. The apparent disagreement between the measured and calculated diagrams is accentuated by the very flat liquidus in this region which causes a small difference in temperature to be accompanied by a large difference in composition. For lower concentrations of $AlCl_3$, which are of most interest in electrowinning, the discrepancy is less. The difference between the measured and calculated diagrams is most likely caused by errors in the literature value of $\Delta G^{EX}$ for this system. Nonetheless, the calculated diagram maintains all the qualitative features of the measured diagram, and the agreement is not unsatisfactory. Clearly the CIS model gives a reasonable estimate of the thermodynamic properties of the ternary liquids.

The isothermal boundaries of the miscibility gap in the system LiCl–KCl–$LiAlCl_4$–$KAlCl_4$ have been measured at several temperatures by Moore (22). In the present work only the intersection of the gap with the liquidus surface was calculated, so

TABLE 4. Thermodynamic data (9, 20) for $AlCl_3$-containing systems

a direct comparison is difficult. However, the overall extent and shape of the calculated and measured miscibility gaps appear to be in good agreement.

*Calculation of vapour pressures*

The total vapour pressures above melts in the binary systems $LiCl–LiAlCl_4$, $NaCl–NaAlCl_4$, and $KCl–KAlCl_4$ have been measured recently by Linga *et al.* (20) at several temperatures. This experimental work appears to be very reliable. Experimental vapour pressure curves for the three binary systems at selected temperatures are shown in Figs. 10–12. By a sophisticated and convincing thermodynamic analysis involving their data as well as literature data, Linga *et al.* (20) managed to separate their measured total vapour pressures into partial vapour pressures of the various gaseous species. As can be seen from Figs. 10–12, the major contribution comes from the partial pressures of the gaseous species $LiAlCl_{4(g)}$, $NaAlCl_{4(g)}$, and $KAlCl_{4(g)}$. $AlCl_{3(g)}$ plays lesser role and $Al_2Cl_{6(g)}$ plays a negligible role except at high concentrations of $AlCl_3$. A summary of the thermodynamic data involving the gaseous species in these systems as obtained from the analysis of Linga *et al.* (20) as well as from the literature (9) is presented in Table 4.

The analysis of Linga *et al.* (20) also yielded values for the excess free energies in the liquid $ACl–AAlCl_4$ systems (A = Li, Na, K). For the sodium and potassium systems these values agree very well with those obtained by the present phase diagram analysis as presented in Table 3. Phase diagrams calculated from the partial excess free energy ($G^E$) values of Linga *et al.* reproduce the measured phase diagrams of $NaCl–NaAlCl_4$ and $KCl–KAlCl_4$ to within about 5°. From the values in Table 4 and from the thermodynamic properties of the liquid phases in Table 3 determined from the phase diagram analyses discussed previously, the partial vapour pressures as well as the total vapour pressures of the binary systems with sodium and potassium were calculated. Agreement with the experimental values of $P_{tot}$ is excellent as can be seen from Figs. 11 and 12. At other temperatures, agreement is just as good.

For the $LiCl–LiAlCl_4$ system, however, the $G^E$ values obtained by Linga *et al.* yield a binary diagram differing by up to 60° from the measured (13). Conversely, if the values in Table 4 are used along with the thermodynamic properties of the liquid phase in Table 3 obtained from the phase diagram analysis discussed previously, then the calculated $P_{tot}$ does not agree with the measured at higher concentrations of $AlCl_3$.

An attempt was made to alter the values for the free energies of vapourization and of dissociation of $LiAlCl_{4(l)}$ in Table 4 within reasonable limits, in

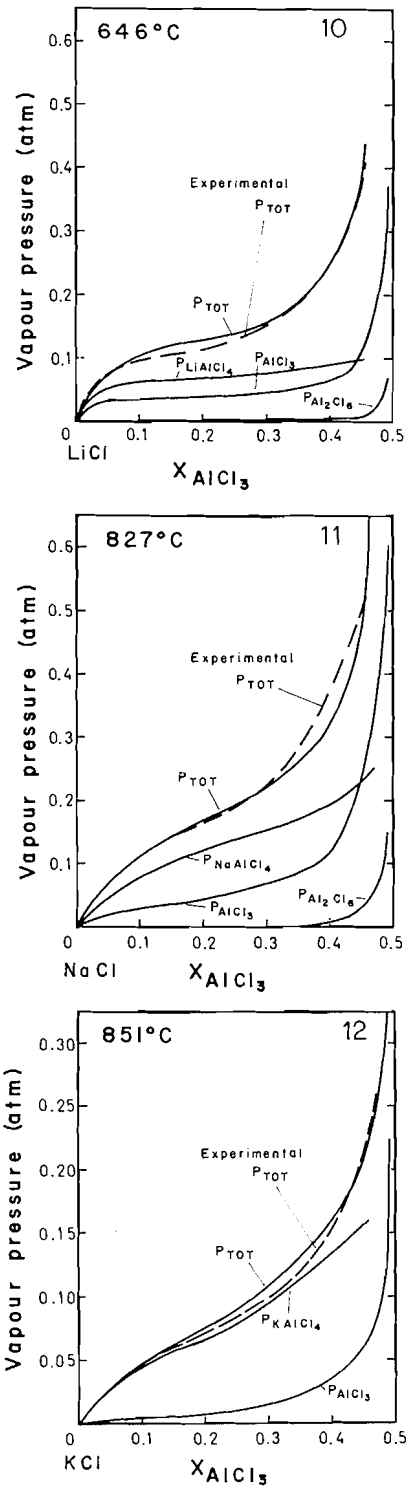

FIGS. 10–12. Calculated partial and total vapour pressures, and experimental (20) total vapour pressures in the system $LiCl–AlCl_3$ at 646°C (*10*); $NaCl–AlCl_3$ at 827°C (*11*); and $KCl–AlCl_3$ at 851°C (*12*).

order to reproduce the measured $P_{tot}$ curves while still retaining $G^E$ for the liquid obtained from the phase diagram analysis. This proved unsuccessful. Hence, it would seem impossible to reconcile all the available data. Fortunately, the problem affects only those reciprocal ternary compositions near the $LiAlCl_4$ composition and this composition region is not of great practical importance due to anticipated high vapour pressures and hydroscopicity.

In order to calculate the vapour pressures in the $LiCl–LiAlCl_4$ system, the values of $G^E$ for the liquid phase obtained by the analysis of Linga *et al.* were fitted to the following power series expansion:

$$[3]\quad G^E = X_{LiCl}X_{LiAlCl_4}(3709 - 5234X_{LiAlCl_4} + 2891X^2_{LiAlCl_4})\ \text{cal/mol}$$

The excess entropy was assumed to be zero by Linga *et al.* From the values of Table 4 and from eq. [3], the partial and total vapour pressures of the binary system were calculated. Agreement with the experimental $P_{tot}$ at 646°C was excellent, as can be seen from Fig. 10. At other temperatures the agreement was as good.

From the data of Table 4 and the reciprocal ternary thermodynamic properties calculated from the CIS theory, partial vapour pressures of all species were calculated at 675, 700, 725, and 775°C for all three reciprocal ternary systems (8) (eq. [3] was used for the $LiCl–LiAlCl_4$ system in these calculations).

## Temperatures and compositions for aluminum electrowinning

The calculated total vapour pressures, $P_{tot}$, in atm for the one-phase liquid solution regions of the three reciprocal ternary systems at 675, 700, and 775°C are given in Figs. 13 to 21. Data for 725°C, although omitted from the figures for the sake of brevity, will be discussed in the text and are available from the authors. In the (*a*) series of these diagrams, isobars of total vapour pressure, in atm, have been combined with isothermal sections of the calculated reciprocal phase diagrams, or in the case of $NaCl–KCl–NaAlCl_4–KAlCl_4$, with isothermal sections derived from the measured reciprocal diagonals and the calculated binaries. Cross-hatched areas of these diagrams indicate compositions where the liquid is in equilibrium with a solid phase. As with the phase diagrams, the dashed lines in the series (*a*) figures for $LiCl–KCl–LiAlCl_4–KAlCl_4$ represent the loci of intersection of a liquid miscibility gap with the liquidus surface.

In order to show on a more enlarged scale the variation of total vapour pressure in composition

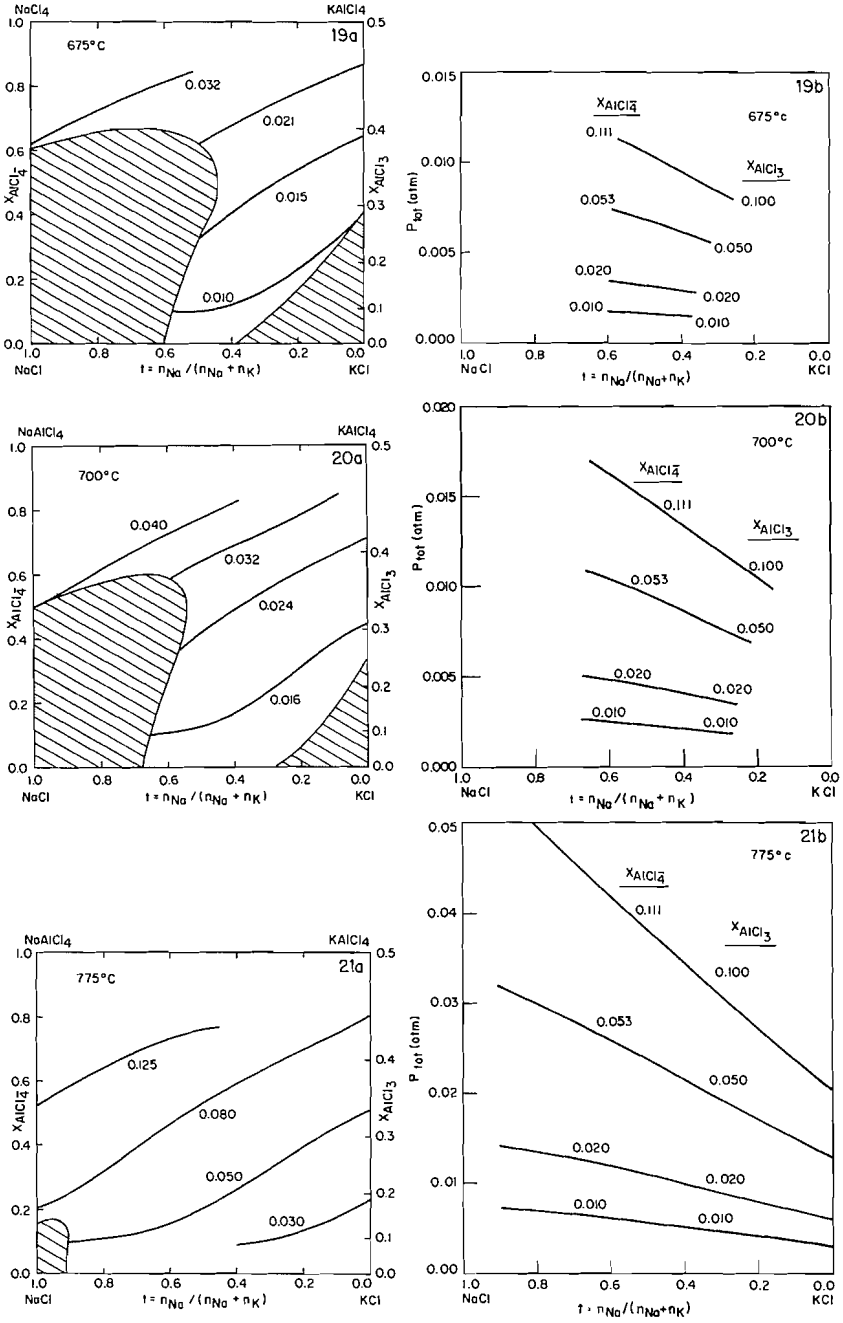

FIGS. 19–21. Calculated total vapour pressure lines in atm for one-phase liquid solution regions of NaCl–KCl–$NaAlCl_4$–$KAlCl_4$ at 675°C (19*a*), 700°C (20*a*), and 775°C (21*a*). Calculated total vapour pressures vs. $t$ for $X_{AlCl_3} < 0.10$ in one-phase liquid solution regions of NaCl–KCl–$NaAlCl_4$–$KAlCl_4$ at 675°C (19*b*), 700°C (20*b*), and 775°C (21*b*). $t = n_{Na}/(n_{Na} + n_K)$.

regions which are of practical interest in aluminum electrowinning, the (*b*) series of Figs. 13–21 gives the total vapour pressures, in atm, for the one-phase liquid solution regions of each system at 675, 700, and 775°C as a function of the cationic fraction, $t$, for values of $X_{AlCl_3} = 0.01$, 0.02, 0.05, and 0.10.

According to Good *et al.* (23), electrowinning of aluminum from a NaCl–KCl 1:1 mole ratio electrolyte containing less than 2 wt% $AlCl_3$ (~1 mol% $AlCl_3$) causes the formation and burning of sodium. Hence, to avoid proposing electrolytes which decompose producing an alkali metal, the minimum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

attainable vapour pressures in each system will be taken as those which occur at $X_{AlCl_3} = 0.02$ (2 mol% $AlCl_3$) and at a value of $t$, $t_{min}$, which is a minimum when the mole fraction of the larger alkali cation is a maximum in a one-phase liquid solution. We seek to minimize $t$ because, for a given value of $X_{AlCl_3}$, introducing more of the larger cation into solution will reduce $P_{tot}$.

Although the vapour loss of a component of a fused salt solution depends on its vapour pressure, the geometry of the enclosure, and the turbulence of the surrounding or imposed atmosphere, volatilization of the fused salt chlorides is not expected to lead to significant electrolyte losses if the total vapour pressure is less than $1.32 \times 10^{-4}$ atm (0.1 Torr).

The compositions suitable for electrowinning at various temperatures have been determined within areas of one-phase liquid solution to ensure that no solid phases precipitate in the electrolytes, and by taking into account the maximum probable errors associated with each calculated system. These compositions are based on thermodynamic considerations only and may in fact be unsuitable with respect to electrolyte viscosity, conductivity (particularly for high concentrations of KCl), stability in the presence of air, kinetic considerations, and electrode stability (e.g., the presence of $K^+$ in the melt may cause swelling of graphite electrodes).

The discussions which follow apply to the systems at constant temperature. Temperature gradients within the molten salts could cause the formation of solid phases and interfere with electrolysis.

*LiCl–NaCl–LiAlCl$_4$–NaAlCl$_4$*

In this system, Figs. 13(*a*) to 15(*a*), there exists a wide range of compositions between 675 and 775°C which exhibit a one-phase liquid solution. Only a minor part of the NaCl-rich corner at the lower temperature has a solid phase in equilibrium with the liquid.

The highest total vapour pressures are to be found, as expected, in the LiCl- and $AlCl_3$-rich composition regions where, as an example, for $X_{AlCl_4^-} = 0.67$ and $t = 0.8$, $P_{tot}$ has values of ~0.26, 0.37, 0.52, and 0.99 atm at 675, 700, 725, and 775°C respectively. These high LiCl and $AlCl_3$ compositions would probably be unsuitable for aluminum electrowinning since their high vapour pressures would lead to significant melt losses by volatilization. The vapour consists of gaseous $LiAlCl_4$, $NaAlCl_4$, $AlCl_3$, and $Al_2Cl_6$, the quantities of which are approximately 56, 3.6, 40, and 1.3 mol% respectively at 725°C (8). These percentages do not change significantly between 675 and 775°C (8).

Of more practical importance, since the vapour pressures are lower, are composition regions containing low concentrations of aluminum chloride, i.e., $X_{AlCl_3} \sim 0.05$. For example, one electrolyte mentioned in the ALCOA process for aluminum electrowinning has a composition in mol% of 47.5 NaCl, 49.4 LiCl, 2.0 $AlCl_3$, 0.5 $CaCl_2$, 0.3 $MgCl_2$, and 0.4 KCl maintained at 700°C (24). Neglecting the small reduction in $P_{tot}$ due to the presence of the alkaline earth chlorides and KCl, we can see from Fig. 14(*b*) that $P_{tot} = 0.021$ atm for $X_{AlCl_3} = 0.02$ and $t = 0.50$. At 700°C, the components of the vapour in equilibrium with this solution are calculated (8) to consist of 33 mol% $LiAlCl_4$, 43 mol% $NaAlCl_4$, and 24 mol% $AlCl_3$. The alkali–aluminum chlorides and $AlCl_3$ are thus calculated to comprise ~81 wt% and ~19 wt% of this vapour respectively. This is in reasonable agreement with the values of 72 wt% and 28 wt% for the alkali–aluminum chlorides and $AlCl_3$ which are obtained by a suitable interpretation of the somewhat ambiguous ALCOA patent on fume recovery (25).

The minimum total vapour pressures in this system are calculated to vary between 0.010 and 0.018 atm for 675 and 775°C; these data are given in Table 5 and are several orders of magnitude greater than the minimum vapour pressure for non-volatilization.

*LiCl–KCl–LiAlCl$_4$–KAlCl$_4$*

Since the shape of the miscibility gap in LiCl–KCl– $LiAlCl_4$–$KAlCl_4$ is not known as a function of temperature, the non-isothermal intersection, which varies in temperature between 450 and 600°C, of the miscibility gap with the liquidus surface is shown in Figs. 16(*a*)–18(*a*) in order to give an indication of compositions in which

For personal use only.

two liquids exist. However, this composition region will diminish in area with increasing temperature so that the composition regions of one-phase liquid solution at 675, 700, 725, and 775°C are likely to be significantly larger than indicated.

On the $AlCl_3$-rich side of the $LiCl–KAlCl_4$ pseudo-binary, one-phase liquid solutions do exist which have total vapour pressures greater than 0.1 atm. For instance, for $X_{AlCl_4^-} = 0.67$ and $t = 0.8$, the total vapour pressures are 0.23, 0.33, 0.46, and 0.87 atm at 675, 700, 725, and 775°C, respectively. As with the corresponding composition in the $LiCl–NaCl–LiAlCl_4–NaAlCl_4$ system, compositions in this region would undoubtedly be unsuitable as electrolytes due to the probability of high volatilization losses. At 725°C and this composition, the vapour consists of gaseous $LiAlCl_4$, $KAlCl_4$, $AlCl_3$, and $Al_2Cl_6$, the quantities of which are 50, 3.1, 38, and 1.1 mol% respectively. As with the previous system, these quantities do not change significantly between 675 and 775°C (8).

For $X_{AlCl_4^-} > 0.1$, relatively lower vapour pressures are calculated to exist for low values of $t$ in the narrow composition band of the one-phase liquid solution occurring between the miscibility gap and either the line of solid–liquid equilibrium or $t = 0.0$. These calculated vapour pressures also have a significant dependence on $t$ and are in the approximate ranges:

| $T$ (°C) | Vapour pressure (atm) |
|---|---|
| 675 | 0.012–0.018 |
| 700 | 0.015–0.025 |
| 725 | 0.020–0.035 |
| 775 | 0.040–0.070 |

Total vapour pressures for $X_{AlCl_3} \leq 0.10$ in this system are given in Figs. 16(*b*) to 18(*b*). While the composition region of one-phase liquid solution is severely restricted, it would likely be possible to employ an electrolyte of composition $t = 0.2$ and $X_{AlCl_3} = 0.02$, for which $P_{tot}$ has values of 0.0048, 0.0064, 0.0086, and 0.015 atm at 675, 700, 725, and 775°C, respectively. An increase in $X_{AlCl_3}$ to 0.05 will double the respective total vapour pressures. The gaseous species in equilibrium with these solutions are calculated (8) to contain approximately 88–92 mol% $KAlCl_4$, 10–6 mol% $AlCl_3$, and 2 mol% $LiAlCl_4$.

The minimum vapour pressures for this system, as given in Table 5, are calculated to be in the order of 0.005 atm, which is somewhat lower than in $LiCl–NaCl–LiAlCl_4–NaAlCl_4$, but not low enough to prevent significant volatilization.

It would be of interest to calculate or experimentally determine the quantities of NaCl to be added to this system to transform the miscibility gap to a one-phase liquid solution.

### *$NaCl–KCl–NaAlCl_4–KAlCl_4$*

For this system, the lines of solid–liquid equilibrium estimated from experimental data as discussed previously have been combined with the calculated total vapour pressures in Figs. 19(*a*) to 21(*a*). At 675°C, sub-liquidus compositions occupy approximately 50% of the isothermal section, and this significantly restricts the composition region suitable for electrowinning, particularly in the sodium-rich corner. However, there is a corridor of one-phase liquid solution in the KCl-rich side for $0.0 < X_{AlCl_4^-} < 0.55$ in which $P_{tot} < 0.015$ atm. Because $T$ vs. $X_{AlCl_3}$ is shallow for $X_{AlCl_4^-} < 0.55$, the region of one-phase liquid solution widens rapidly as the temperature is increased, Figs. 20(*a*) and 21(*a*), until the isothermal section at 775°C exhibits no significant area of sub-liquidus composition.

For $X_{AlCl_4^-} = 0.67$ and $t = 0.8$, the total vapour pressures are 0.029, 0.044, 0.064, and 0.13 atm at 675, 700, 725, and 775°C, respectively. At 725°C, the vapour consists of gaseous $NaAlCl_4$, $KAlCl_4$, and $AlCl_3$, which are calculated (8) to comprise 58, 14, and 27 mol% of the vapour respectively at 725°C. As with the other systems, these mole percentages do not vary significantly with temperature (8).

The total vapour pressures for $X_{AlCl_3} < 0.10$ are given in Figs. 19(*b*) to 21(*b*). For $X_{AlCl_3} = 0.02$ and $t = 0.50$, the total vapour pressures are 0.0032, 0.0045, 0.0061, and 0.011 atm at 675, 700, 725, and 775°C, respectively. Increasing $X_{AlCl_3}$ to 0.05 has the effect of increasing the total vapour pressures by factors between 2.11 and 2.17.

As reviewed elsewhere (2), several investigators (23, 26, 27) have studied the deposition of liquid aluminum from fused $NaCl–KCl–AlCl_3$ electrolytes containing NaCl and KCl in a 1:1 mole ratio and concentrations of $AlCl_3$ between 2.7 wt% and 30 wt% ($0.014 < X_{AlCl_3} < 0.176$) at temperatures between 685 and 750°C. Since the calculated total vapour pressures associated with these compositions are between 0.0025 atm for 2.7 wt% $AlCl_3$ and 0.0364 atm for 30 wt% $AlCl_3$, the electrolytes used by these investigators probably became significantly depleted in $AlCl_3$-bearing species due to volatilization of aluminum-bearing gases.

The minimum total vapour pressures in this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

system, as given in Table 5, are calculated to vary between 0.0028 and 0.0060 atm for 675 to 775°C, i.e. not substantially different from those of the previous system and not low enough to prevent significant volatilization.

## Conclusions

Phase diagrams and total vapour pressure curves at 675, 700, 725, and 775°C in the reciprocal ternary fused salt systems LiCl–NaCl–$LiAlCl_4$–$NaAlCl_4$, LiCl–KCl–$LiAlCl_4$–$KAlCl_4$, and NaCl–KCl–$NaAlCl_4$–$KAlCl_4$ have been calculated via the Conformal Ionic Solution Theory from the known thermodynamic properties of the appropriate binary systems by means of computer-assisted analytical techniques. Among the three ternary systems, only the latter's phase diagram has been reported in any detail in the literature. Agreement in this latter case between the experimental and calculated phase diagrams was acceptable.

A miscibility gap which occupies more than 50% of the composition region was calculated to occur in the system LiCl–KCl–$LiAlCl_4$–$KAlCl_4$.

Compositions suitable for electrowinning of aluminum from the viewpoint of maintaining a one-phase liquid solution were proposed. These are severely restricted in LiCl–KCl–$LiAlCl_4$–$KAlCl_4$ because of the miscibility gap and only somewhat less so at lower temperatures in NaCl–KCl–$NaAlCl_4$–$KAlCl_4$ because of the solid–liquid equilibrium. The system LiCl–NaCl–$LiNaCl_4$–$NaAlCl_4$ exhibits the widest range of one-phase liquid solutions.

Minimum total vapour pressures in systems involving potassium were calculated to be 20–40 times the maximum vapour pressure for non-volatilization. The minimum vapour pressures in LiCl–NaCl–$LiAlCl_4$–$NaAlCl_4$ were calculated to be 75–140 times this value. It can thus be expected that the use of these systems as electrolytes in the electrowinning of aluminum will necessitate extensive fume recovery systems regardless of the compositions employed.

With each region of one-phase liquid solution, extensive variations of density, viscosity, and electrical conductivity can be expected to occur. The experimental measurement of these properties, combined with the thermodynamic properties given in this report, will enable a determination of the optimum temperature and composition for each of the three ternary systems. Hence, future investigation into these systems could involve the measurement of the density, viscosity, and conductivity of their regions of one-phase liquid solution as well as the experimental verification of some of the calculated total vapour pressures and of the two ternary phase diagrams involving lithium.

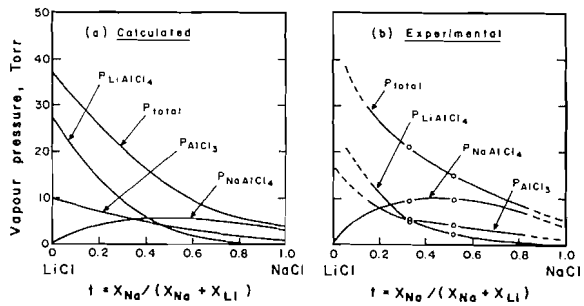

FIG. 22. Calculated and experimental (28) total and partial vapour pressures over LiCl–NaCl–$AlCl_3$ melts versus the molar ratio of NaCl to LiCl at 700°C at 4 wt. % $AlCl_3$.

NOTE ADDED IN PROOF:

In an article which appeared after the present article was submitted, Knapstad *et al.* (28) report vapour pressure measurements over LiCl–NaCl–$AlCl_3$ ternary melts dilute in $AlCl_3$ (over the range 2 to 10 wt. % $AlCl_3$). In addition, they report vapour composition measurements which permit them to calculate partial pressures under the assumption that $LiAlCl_4$, $NaAlCl_4$, and $AlCl_3$ are the major vapour species. Some results showing total and partial pressures versus the NaCl to LiCl ratio at 700°C over melts containing 4 wt. % $AlCl_3$ are compared with calculated values in Fig. 22. Measurements were reported by Knapstad *et al.* at $t = X_{Na}/(X_{Na} + X_{Li}) = 0.33$ and at $t = 0.52$. Dashed lines in Fig. 22 indicate that results for pure LiCl and NaCl were extrapolated by the authors from previous (20) measurements at higher $AlCl_3$ contents.

It can be seen that the calculations reproduce well the observed negative deviations from linearity in the $P_{total}$ curve. In addition, the observation that $NaAlCl_4$ is the major vapour species over most of the composition range even though $P_{total}$ for LiCl–$AlCl_3$ is much higher than $P_{total}$ for NaCl–$AlCl_3$ is reproduced by the calculations. The maximum deviation between measured and calculated values of $P_{total}$ in Fig. 22 is about 20%. Deviations at other reported compositions in the range 2 to 10 wt. % $AlCl_3$ were all less than ±20%.

# Kinetics and mechanism of ion exchange sorption of some detergents on zinc ferrocyanide

SURESH K. SRIVASTAVA, CHAKRESH K. JAIN, CHANDER K. OBEROI, AND ASHOK K. SHARMA

*Department of Chemistry, University of Roorkee, Roorkee-247667, India*

Received October 9, 1981

SURESH K. SRIVASTAVA, CHAKRESH K. JAIN, CHANDER K. OBEROI, and ASHOK K. SHARMA. Can. J. Chem. **60**, 1681 (1982).

Studies have been made on the kinetics and mechanism of exchange sorption of detergents on zinc ferrocyanide using a modified limited bath technique. The effects of concentration, particle size of the sorbent material, and temperature on the sorption rate have been investigated. In the case of cationic detergents (cetyl pyridinium bromide and cetyl trimethylammonium bromide), equilibrium is attained in a period of 2–3 h while 12–16 h are required for anionic detergents, viz., sodium dodecyl sulphate and sodium dodecyl benzene sulphonate. The slowest step governing the sorption rate is found to be the diffusion within the exchanger particles at higher concentrations. The effective diffusion coefficients have been evaluated at four different temperatures and found to be comprised of mainly two components. The energy barriers against the diffusion of exchanging ions have been assessed from the Arrhenius equation. Entropies of activation for various sorption systems have also been calculated. The results are discussed in terms of the size and geometry of the detergents, pore-widths in the sorbent material, and the electric potential gradient along the diffusion path. No change in the internal structure of zinc ferrocyanide is inferred due to the sorption of detergent ions.

SURESH K. SRIVASTAVA, CHAKRESH K. JAIN, CHANDER K. OBEROI et ASHOK K. SHARMA. Can. J. Chem. **60**, 1681 (1982).

Faisant appel à la technique modifiée du bain limité, on a étudié la cinétique et le mécanisme de la sorption d'échange des détergents sur le ferrocyanure de zinc. On a étudié les effets de la concentration, de la dimension de la particule du matériel adsorbant et de la température sur la vitesse de sorption. Dans le cas des détergents cationiques (bromure de cétyl pyridinium et bromure de cétyl triméthylammonium), on atteint l'équilibre sur une période de 2–3 h tandis que dans le cas des détergents anioniques (dodécylsulfate de sodium et dodécylbenzènesulfonate de sodium), il faut 12–16 h. On a trouvé que la vitesse de diffusion, à l'intérieur des particules échangées à des concentrations plus élevées, est l'étape déterminante de la vitesse de sorption. On a évalué les coefficients de diffusion effective à quatre températures différentes et on a trouvé qu'ils sont constitués principalement de deux composantes. On a évalué les barrières d'énergie de la diffusion des ions échangés à partir des équations d'Arrhénius. On a également calculé les entropies d'activation de systèmes de sorption différents. On discute des résultats en fonction de la dimension et de la géométrie des détergents, de la largeur des pores du matériel adsorbant et du gradient de potentiel électrique près de la cellule de diffusion. Aucun changement de la structure interne du ferrocyanure de zinc n'est attribué à sorption des ions du détergent.

[Traduit par le journal]

## Introduction

A survey of the literature shows that inorganic gels exhibiting good sorption properties so far have not been explored for waste treatment. Recently, we have reported the use of chromium ferrocyanide gel for the removal of heavy metal ions (*1*). Preliminary studies with zinc ferrocyanide (ZFC), which is found to possess both cation and anion exchange properties (*2*), reveal the utility of this compound as a good scavenger for detergents (*3*). It is quite well known that detergents, even in low concentrations, pollute water and affect the sorption characteristics of the soil. As the rate factor in sorption processes is of great significance for the exploitation of sorbent materials on an industrial scale, extensive studies have been reported in this article on the kinetics and thermodynamics of ion-exchange sorption of some cationic and anionic detergents on ZFC. Cationic and anionic detergents, cetyl pyridinium bromide (CPB), cetyl trimethylammonium bromide (CTAB), sodium dodecyl sulphate (SDS), and sodium dodecyl benzene sulphonate (SDBS), which are non-biodegradable in nature, have been chosen for these investigations. Some parameters, viz., effective diffusion coefficient, entropy of activation, and energy of activation, have been evaluated and utilized to interpret the mechanism of sorption and interaction between ZFC and detergent ions.

## Experimental

Detergents were obtained from B.D.H. All other chemicals used were of analytical grade. Doubly distilled water was used for preparing solutions.

pH measurements were made with a pH-meter, model pH 821, E.C.I., India. The Bausch and Lomb Spectronic-20 and the Unicam-500 were used for spectrophotometric work. Infrared spectra of the samples were recorded on a Beckmann IR-20 spectrophotometer in a potassium bromide medium.

*Preparation and characterization of zinc ferrocyanide*

Zinc ferrocyanide was prepared according to the method of Kourim *et al.* (*2*) by the reaction of 0.1 *M* sodium ferrocyanide with 0.1 *M* zinc nitrate. The reaction mixture was heated on a boiling water bath (1–2 h). It was then cooled, filtered, and washed with water. After thorough draining, it was heated slowly for 4 h. Maximum temperature after 1 h of drying was ~110°C. A faint green coloured material, obtained after drying, was quite stable in water, concentrated salt solutions, and acids (4 *M*).

Analysis of the product was carried out by first drying the material over $P_2O_5$ under vacuum and then dissolving in a

mixture of aqua regia and sulphuric acid. The estimations of iron and zinc were made by classical methods (4).

Iron and zinc contents in ZFC were found to be 15.0 and 32.9% respectively, corresponding to a molar ratio of Zn/Fe ≈ 2:1. The water content determined by thermogravimetric analysis was about 12%. The content of cyanide group was calculated by subtraction to be 40.1%. The formula assigned (4) to the product is $Zn_2[Fe(CN)_6]2.5H_2O$.

Infrared spectra of the compound showed all the characteristic absorption frequencies reported in the literature for metal ferrocyanides. A broad band at 3700 $cm^{-1}$ was due to interstitial water molecules and OH groups (5), while the characteristic HOH bending (5) appeared at 1600 $cm^{-1}$. The sharp bands, one at 2080 $cm^{-1}$ and other at 580 $cm^{-1}$, were assigned to cyanide stretching and Fe—C stretching frequencies (6). Another sharp band at 500 $cm^{-1}$ was attributed to the Zn—N stretching mode, thus indicating a certain degree of polymerization in the product (7, 8).

Zinc ferrocyanide was treated with 1 *M* HCl to convert it into homoionic form ($H^+$, $Cl^-$) and used as such for subsequent investigations. Cation and anion exchange capacities of ZFC, determined by standard methods (9–11), were found to be 4.65 mequiv. $g^{-1}$ and 0.14 mequiv. $g^{-1}$, respectively.

*Estimation of detergents*

The method of Few and Ottewill (12) was used for the estimation of cationic detergents. The solutions were treated with an anionic dye (Orange II) and the complex formed between the detergent and dye was extracted into chloroform. Estimations of the colour intensity in the organic phase were made spectrophotometrically at 485 nm.

The modified methylene blue method of Wang (13) was used for estimating the concentrations of SDBS and SDS in solutions. The sample to be analysed was treated with an excess of methylene blue reagent at pH 10. The methylene blue – detergent complex thus formed was extracted in the chloroform layer and the concentrations were measured spectrophotometrically at 650 nm.

*Particle size*

Dried ZFC was ground and sieved to collect the fractions of (50–100), (100–170), and (170–200) B.S.S. mesh-size. Average particle radius of each fraction was determined (14) with the help of a projector, Agfa Diamator m (Germany). No significant change in the mean particle radius was observed when the samples were kept in water or detergent solutions for 48 h.

*Kinetic measurements*

For kinetic measurements, the modified limited bath technique (batch technique) was employed (14–16) because of its relative simplicity over the column and shallow-bed arrangement.

Known volumes (10 mL) of the detergent solutions were placed in a number of stoppered Pyrex glass tubes and subjected to continuous mechanical shaking in a thermostat at the desired temperature. Weighed amounts of ZFC (0.1 g for anionic and 0.05 g for cationic detergents) were then introduced into each tube. The tubes were taken out from the thermostat at appropriate time intervals and the sorption process was checked by immediate filtration. To observe the effect of concentration on the rate of sorption, experiments were performed for different concentrations of CPB, CTAB, SDBS, and SDS ($10^{-4}$–$10^{-5}$ *M*). The investigations were also carried out with different particle sizes of ZFC and at four different temperatures (30, 35, 40, 45 ± 0.1°C).

*Rate expression and evaluation of kinetic and thermodynamic parameters*

The fractional attainment of equilibrium $F$ at time $t$ has been determined as:

$$[1]\quad F = \frac{Q_t}{Q_\infty} = \frac{\text{Amount of exchange sorption at time } t}{\text{Amount of exchange sorption at infinite time or at equilibrium}}$$

The equations developed by Boyd *et al.* (17) and later improved by Reichenberg (18) have been applied for particle-diffusion-controlled rate processes. According to these expressions, if the rate of exchange sorption is governed by particle diffusion, i.e. the diffusion of exchanging ions through the exchanger is slowest, $F$ is related to $t$ and the particle radius $r$ as:

$$[2]\quad F = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{\exp(-n^2Bt)}{n^2}$$

where $n$ is the number of exchanger particles and $B$, the time co-ordinate, is expressed as:

$$[3]\quad B = \frac{\pi^2}{r^2}D_i$$

where $D_i$ stands for the effective diffusion coefficient of ingoing ions.

Obviously, plots of $Bt$ vs. $t$ must be straight lines passing through the origin. In the present studies, for every observed value of $F$, the corresponding $Bt$ value has been obtained from Reichenberg's table (18). The experimental conditions were set for the particle-diffusion mechanism to evaluate the thermodynamic parameters of the sorption processes. The energy of activation $E_a$ has been determined by applying the Arrhenius type expression (14, 16):

$$[4]\quad D_i = D_0 \exp(-E_a/RT)$$

The pre-exponential constant $D_0$ gives the entropy of activation $\Delta S^*$ as (14, 16, 19):

$$[5]\quad D_0 = 2.72d^2\frac{kT}{h}\exp\left(\frac{\Delta S^*}{R}\right)$$

where $k$, $h$, and $R$ are the Boltzmann, Planck, and gas constants, respectively, $d$ is the average distance between the successive exchange sites and is taken as 5 Å (14, 16). $T$ (=273 K) is the temperature on the Kelvin scale.

All linear plots have been drawn according to the method of least-squares. The standard deviations on all reported values are less than 5%.

## Results and discussion

The effects of detergent concentration, particle size, and temperature on the rate of exchange sorption are depicted for some typical systems in Figs. 1, 2, and 3, respectively. The representative log $(1 - F)$ vs. $t$ plots (McKay plots (20)) are shown in Fig. 4. Figure 5 indicates the relationship between the logarithm of the effective diffusion coefficient and the reciprocal temperature ($K^{-1}$) for the sorption of cationic and anionic detergents on ZFC. Tables 1 and 2 record the kinetic and

thermodynamic parameters for all the systems reported herein.

The sorption of cationic detergents has been found to be faster than that of anionic detergents. The equilibrium is reached in a period of 2–3 h for $CP^+$ and $CTA^+$, while in the case of $DS^-$ and $DBS^-$ 12–16 h are required. Also, the capacities of $CP^+$ and $CTA^+$ (2.97 and 2.12 mequiv. $g^{-1}$, respectively) are much greater than those of $DS^-$ and $DBS^-$ (0.05 and 0.04 mequiv. $g^{-1}$, respectively) on ZFC. The higher uptake and relatively faster sorption rate of cationic detergents may be attributed to a higher cation exchange, viz., 4.65 mequiv. $g^{-1}$, as compared to anion-exchange value viz., 0.14 mequiv. $g^{-1}$, of the sorbent material.

It is evident from Fig. 1 that plots of $Bt$ vs. $t$ for the sorption of cationic detergents on ZFC are linear and independent of initial solution concentration at and above 7.5 × $10^{-5}$ $M$. However, at 4.0 × $10^{-5}$ $M$, the plots deviate from linear behaviour.

TABLE 1. Effective diffusion coefficients ($D_i$) for ionic detergents at different temperatures

| Detergent | $D_i$ (cm$^2$ s$^{-1}$) 30°C | 35°C | 40°C | 45°C |
|---|---|---|---|---|
| CPB | $5.0 \times 10^{-9}$ | $5.4 \times 10^{-9}$ | $6.7 \times 10^{-9}$ | $7.6 \times 10^{-9}$ |
| CTAB | $4.0 \times 10^{-9}$ | $4.8 \times 10^{-9}$ | $5.8 \times 10^{-9}$ | $6.9 \times 10^{-9}$ |
| SDS | $62.9 \times 10^{-12}$ | $90.9 \times 10^{-12}$ | $121.0 \times 10^{-12}$ | $142.4 \times 10^{-12}$ |
| SDBS | $49.0 \times 10^{-12}$ | $69.6 \times 10^{-12}$ | $94.8 \times 10^{-12}$ | $117.9 \times 10^{-12}$ |

TABLE 2. $D_0$ values and thermodynamic parameters for the exchange sorption of ionic detergents

| Detergent | $D_0$ (cm$^2$ s$^{-1}$) | $E_a$ (kcal mol$^{-1}$) | $\Delta S^*$ (cal deg$^{-1}$ mol$^{-1}$) |
|---|---|---|---|
| CPB | $2.6 \times 10^{-4}$ | 6.6 | −10.0 |
| CTAB | $8.0 \times 10^{-4}$ | 7.4 | −7.7 |
| SDS | $2.5 \times 10^{-3}$ | 10.5 | −5.5 |
| SDBS | $3.2 \times 10^{-2}$ | 12.2 | −0.40 |

This shows that the sorption rate of $CTA^+$ and $CP^+$ is particle-diffusion controlled at and above $7.5 \times 10^{-5}$ $M$, while at lower solution concentration ($4.0 \times 10^{-5}$ $M$), film-diffusion also affects the process (14–18). Similar behaviour has also been observed for the exchange sorption of $DS^-$ and $DBS^-$ on ZFC, where plots of $Bt$ vs. $t$ are concentration independent and linear at and above $4.0 \times 10^{-6}$ $M$. The increases in sorption rate with decrease in particle size of sorbent material (Fig. 2) and also with increase in temperature (Fig. 3) further support a particle-diffusion mechanism as the rate-controlling process (14–18). The non-linear behaviour of plots of log $(1 - F)$ vs. $t$ (Fig. 4) drawn for only one system, $CP^+/H^+$, is also evidence in favour of a particle-diffusion mechanism as the rate-controlling step in the sorption of detergent ions on zinc ferrocyanide (15, 16).

It is interesting to note that the concentrations of anionic detergents required for the particle-diffusion mechanism are lower compared to those of cationic detergents for the exchange on the same sorbent material ZFC. Such behaviour may be due to the relatively more rapid uptake for cationic than for anionic detergents (16, 17). Obviously, in systems with fast sorption rates, a significant concentration gradient exists in the liquid film surrounding the sorbent particles, and if mechanical agitation is kept unchanged, a higher concentration of sorbate is required to level out the concentration gradient so that film-diffusion does not remain dominant (17).

The observed concentrations of detergents for the particle-diffusion mechanism are considerably less than those reported for the exchange sorption of some simple as well as complex cations on various sorbents (14–16, 21–28). It is well known that the rate of uptake and mobility of ions in solution effectively determine the characteristics of the liquid film surrounding the sorbent particle. In the present case, the bigger size of $CTA^+$, $CP^+$, $DS^-$, and $DBS^-$ ions and their relatively slow rate of sorption, as compared to simple metal ions, reduce the possibility of the existence of a concentration gradient at the solid–liquid interface (14, 17), and hence even at such lower concentrations ($10^{-5}$–$10^{-6}$ $M$), the rate is governed by the particle-diffusion mechanism.

The shapes of the McKay plots (Fig. 4) for the sorption of $CP^+$ on ZFC are similar to those obtained for independently decaying radioactivities (29). Also for other systems under study (McKay plots not shown here), the same behaviour has been observed. The resolution (29) of these plots has been depicted for one temperature only. It can be inferred that in the sorption of detergent ions two interdiffusion processes contribute to the overall rate of exchange. As the system tends towards equilibrium, the faster of these becomes less significant and the slower one dominates. This behaviour is also evident from the shape of $F$ vs. $t$ plots (Figs. 1–3) where the rate of uptake is initially rapid and decreases with time.

The values of $D_i$, $D_0$, $E_a$, and $\Delta S^*$ have been calculated using eqs. [3], [4], and [5] for all the sorption systems. It is clear from Table 1 that the values of effective diffusion coefficients are higher for $CP^+$ and $DS^-$ as compared to those for $CTA^+$ and $DBS^-$, respectively. This may be due to the larger sizes of $CTA^+$ and $DBS^-$ compared to those of $CP^+$ and $DS^-$, thus are hindered in their mobility within the pores of the sorbent material. It may further be argued that effective diffusion coefficients ($D_i$) are mainly comprised of two components, which are due to the diffusion of the ingoing detergent ions through pores of different widths, and different electric fields along the diffusion path. The diffusion within the wider pores and weaker electrostatic retarding forces (particularly at the surface of the sorbent) accounts for the faster, and that within the narrower pores and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

stronger retarding forces accounts for the slower, component of $D_i$. With increase of temperature the contribution of the faster component to $D_i$ also increases, due to the increasing mobility of the ions and this to some extent overcomes the influence of retarding forces. Helfferich *et al.* (30–33) have observed a similar behaviour and explained the variable interdiffusion coefficients on the basis of electric field gradient along the diffusion path.

It is worthwhile to note (Tables 1, 2) that the order in the values of pre-exponential constants ($D_0$), viz., $DBS^- > DS^- > CTA^+ > CP^+$, is the reverse of that of $D_i$ values. This may be attributed to the higher activation energy values associated with higher values of $D_0$ (Table 2, eq. [4]). These observations are analogous to those observed in this laboratory for the exchange sorption of complex cations on chromium ferrocyanide gel (14) and for ion-exchange in felspathoids by Barrer *et al.* (34).

It is found (Table 2) that the energies of activation for the sorption systems under study are in the order: $CP^+ > CTA^+ > DS^- > DBS^-$. This sequence in $E_a$ values can also be understood on the basis of higher affinity of ZFC towards cations as compared to anions, and the fact that $CTA^+$ and $DBS^-$ are larger than $CP^+$ and $DS^-$, respectively.

The entropies of activation are negative for all the sorption systems. Negative values of $\Delta S^*$ have also been observed for the exchange sorption of heavy alkali metal ions on chromium ferrocyanide gel (16), and other workers have reported analogous results for various sorption systems (24–28, 35, 36). In the case of diffusion of alkaline earth metal ions in zeolites, the negative values of $\Delta S^*$ have been taken as indicative of a comparatively higher degree of mobility and the lack of an orientational effect which the ingoing ion influences upon its water environment (37). It can also be inferred from the negative values of entropies of activation that there is no significant change in the internal structure of the sorbent material (16, 26, 27) as a result of sorption of cationic and anionic detergents.

# Electrochemical oxidation of trifluoroacetic acid anion. V. Formation of bis(trifluoromethyl) alicyclic compounds from activated dienes[1]

ROGER N. RENAUD,[2] CAMPBELL J. STEPHENS, AND DENIS BÉRUBÉ
*Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received November 16, 1981

ROGER N. RENAUD, CAMPBELL J. STEPHENS, and DENIS BÉRUBÉ. Can. J. Chem. **60**, 1687 (1982).

The electrochemical oxidation of trifluoroacetate anion in the presence of activated dienes, ROOCCH=CH(CH$_2$)$_n$CH=CHCOOR, gave bis(trifluoromethyl) alicyclic products. The ring size of the products was determined by comparing the fluorine nuclear magnetic resonance spectra of the protonated with the corresponding α,α′-dideuterated compounds. The results can be explained by an intramolecular radical addition and by an intramolecular coupling of a biradical intermediate.

ROGER N. RENAUD, CAMPBELL J. STEPHENS et DENIS BÉRUBÉ. Can. J. Chem. **60**, 1687 (1982).

L'oxydation électrochimique de l'anion trifluoroacétate en présence de dioléfines activées, ROOCCH=CH(CH$_2$)$_n$CH=CHCOOR, donne des produits cycliques bis(trifluorométhylés). La dimension des cycles fut déterminée en comparant les spectres de la résonance magnétique nucléaire du fluor du composé protoné avec celui du composé α,α′-dideutérié correspondant. Les résultats peuvent être expliqués par une addition radicalaire intramoléculaire et par un couplage intramoléculaire d'un biradical.

The addition of electrochemically generated trifluoromethyl radicals to olefinic double bonds has been the subject of previous studies (1–3).

$$CF_3COO^- \xrightarrow[-CO_2]{-e^-} CF_3\cdot \xrightarrow{>C=C<} \text{Products}$$

It has been shown that, in the case of an activated olefin **1** (Scheme 1), the first $CF_3$ radical always adds to the β-carbon of the electron-withdrawing substituent to give **2**. This was based on the observation that only the head-to-head dimeric product **3** was obtained and never the head-to-tail or the tail-to-tail analogues. Under a low concentration of the olefin **1** acceptable yields of the monomer **4** were obtained with only small amounts of dimer **3**. When the concentration of the olefin **1** was increased, the yield of dimer **3** increased accordingly.[3] Chkir and Lelandais (4) similarly observed the formation of the head-to-head dimer (as **3**) in high yields by the electrochemical oxidation of acetate anion in the presence of activated olefins.

To our knowledge, dimer **6** was never detected but telomer **7** has been isolated (3). Assuming that **6** and **7** are formed through the common radical **5**, it is difficult to explain the formation of **7** without the formation of **6**.

The objective of the present investigation was to study the formation of cyclic molecules by a radical alkylation of a series of substrates having two activated double bonds. Therefore the trifluoromethylation of activated diethylenic compounds **8** (Scheme 2) was done under experimental conditions favouring the formation of monomeric ring products (high current density and low olefin concentration). This should also permit us to observe the formation of an intramolecular analogue of **6**.

## Results and discussion

Trifluoromethylation of diolefinic dicarboxylate esters via the electrolysis of trifluoroacetate anion gives bis(trifluoromethyl) alicyclic compounds in acceptable yields (Scheme 2 and Table 1). The actual proof for the formation of a cyclic system is based on the observation that infrared and proton nuclear magnetic resonance spectra show no CH=CH group and the elemental and the mass spectrometric analyses agree for monomeric bis(trifluoromethyl) alicyclic products. The ring size of the products obtained was determined by the comparison of the fluorine nuclear magnetic resonance spectra of the protonated with the corresponding α,α′-dideuterated products (Scheme 2). The number of doublets[4] is the same for **10** and **10**-*d* while the doublets due to the $CF_3$ group on the α-carbon in **9** become singlets[5] for **9**-$d_2$ (Table 1). The results show that both rings **9** and **10** are formed in a ratio depending on the number of carbons *n* involved in the process.

The analytical glc of the volatile fraction ob-

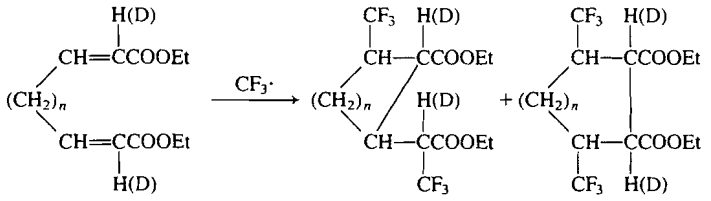
SCHEME 1

tained from $n = 0$, 1, and 2, when distilled under reduced pressure at 20°C, showed two major peaks and a number of minor peaks. The two major peaks obtained from the protonated and the dideuterated analogues analyzed as either structural isomers ($n = 0$) or stereoisomers[6] ($n = 1$ and 2) by elemental analysis, mass spectrometry, and $^{19}F$ nmr spectroscopy. The reaction is more complex with $n = 3$. The high vapor pressure fraction gave three important peaks in the analytical glc. The elemental analysis of the mixture of the three peaks and the gc–ms analysis showed only monomeric bis-(trifluoromethylated) products. However, the $^{19}F$ nmr spectrum of the mixture gave twelve doublets while the corresponding dideuterated mixture showed two doublets and ten singlets. Two of the three peaks were separated by preparative glc and analyzed as six-membered ring stereoisomers (**9***d*).[6] The remaining peak was shown by glc analysis to be a mixture of at least two compounds. The $^{19}F$ nmr spectrum gave only doublets while the corresponding $\alpha,\alpha'$-dideuterated products showed only singlets with $\delta < 70$ ppm. Unfortunately, these compounds could not be obtained pure enough for identification. Nevertheless, they do not analyze for the seven-membered ring **10***d*.

Different pathways describing the formation of

[6]The stereochemistry of the products could not be determined because the 60 Mz $^1H$ nmr spectra were far too complex. A systematic spectroscopic study is necessary before any conclusion can be given on the stereochemistry of this new class of compounds.



*a*, $n = 0$; *b*, $n = 1$; *c*, $n = 2$; *d*, $n = 3$

SCHEME 2

the products **9** and **10** are presented in Scheme 3. The postulation that the attack of the first $CF_3$ radical on **8** gives the radical **11** is well founded since never as yet, from similar reactions (1–3), was a product obtained from the attack of the first $CF_3$ radical on the carbon adjacent to the carbethoxy group. Therefore, the radical **11** was considered to be the first intermediate in the reaction.

In order to explain the formation of **9** and **10** from the radical **11**, four important factors have to be considered. (*i*) Baldwin's rules and Beckwith's guidelines: Baldwin (5*a*) has demonstrated that, in an intramolecular radical addition to a double bond, the 3 to 7-*exo*-trig ring closures are all favoured processes while the 3 to 5-*endo*-trig are disfavoured and the 6 to 7-*endo*-trig are favoured. However, according to Beckwith *et al.* (5*b*), the 3 to 7-*exo*-trig processes are all favoured while the 3 to 7-*endo*-trig processes are all disfavoured. (*ii*) The stability of the radical intermediates. (*iii*) The strain of the ring system involved. (*iv*) The rate of addition of a second $CF_3$ radical compared with the rate of an intramolecular radical addition.

The formation of the intermediate **12** can be explained by the favoured *exo*-trig ring closure according to Baldwin's rules (*i*). Moreover, the carbethoxy group should exert a stabilizing effect on the adjacent radical center (*ii*). Thus, considering these two factors, the involvement of the intermediate **13** (*endo*-trig closure) can be ruled out. The exclusive formation of **9***c* and **9***d*, corresponding to a 5 and 6-*exo*-trig ring closure respectively, is in accord with these factors. The product **9***a* (3-*exo*-trig process) was also observed but in a very small amount. In fact, it is known that cyclopropylmethyl radicals have very short lifetimes and the reversed reaction to the open chain radicals is very fast (6). The small quantity of **9***a* detected may be attributed to a trapping of the radical **12***a* by a $CF_3$ radical. Note that the concen-

SCHEME 3

tration of $CF_3$ radicals at the electrode surface would be large since a high current density was used in our study. Thus it seems that, in the case of the three-membered ring **12***a*, the reversed process to **11***a* is preferred, probably because the release in strain (*iii*) becomes the predominant factor. This process should allow the radical **11***a* to proceed to other possible reaction products. The same type of argument can be applied to the four-membered ring intermediate **12***b* and explains, at least in part, the lack of **9***b*.

The exact mechanism for the formation of **10***a* and **10***b* is not straightforward because at least two pathways are possible: pathway B to form **13** and pathway C to give **14**. The radical intermediate **13** from **11** is somewhat disfavoured as outlined before by Baldwin's rules (*i*) and the loss of some energy of stabilization (*ii*). This is particularly true in the case of **10***a* for which the intermediate **13***a* corresponds to a 4-*endo*-trig closure. This type of closure appears to be disfavoured kinetically and thermodynamically. Moreover, the product **9***b* resulting from the more favoured 4-*exo*-trig closure was not observed. Thus it appears that the intramolecular addition is much slower than the addition of a second $CF_3$ radical to form the biradicals **14***a* and **14***b* respectively. Such a biradical intermediate is also involved in the formation of cyclic acyloins from esters of aliphatic dibasic acids (7). So the formation of the biradical **14** (pathway C) by the fast addition of two $CF_3$ radicals before cyclization seems to be the most plausible mechanism whenever the intramolecular addition gives a strain ring.

## Experimental

The starting diolefinic compounds **8** and **8**-*d* were prepared according to methods described in the literature (8, 9). The acetonitrile (from Aldrich) was used without further purification. The cell used in this study was described before (10). Gas–liquid chromatographic analyses and separations were performed respectively on a Fisher/Victoreen Series 4400 and an Aerograph Autoprep model A-700 using a 20 ft × 3/8 in. column, 30% SE30 on 45/60 Chromosorb P. The $^1H$ nmr spectra were taken in $CDCl_3$ on a Varian Associates spectrometer model EM 360 and the chemical shifts are reported on the δ scale. The $^{19}F$ nmr spectra were obtained in $CHCl_3$ on a Varian Associates XL100A FT accessory and are reported in ppm using $CFCl_3$ as reference. The mass spectra were obtained from a Finnigan 400 gc–ms spectrometer.

*Electrolysis of sodium trifluoroacetate in the presence of the diolefinic substrate 8*

Trifluoroacetic acid (45 mL) was added to a cold solution of

sodium hydroxide (6 g) in water (60 mL). This solution was added to the anodic compartment containing acetonitrile (150 mL). The cathodic compartment was charged with a 1.0 *M* solution of NaOH in water. A current of 1.8 A was passed through the solution for a period of 15 min. The temperature of the solution was maintained at 22°C using a cold ethanol bath. Then the substrate **8** (5 mmol; 0.02 *M*) was added and the electrolysis was continued for 7 h at a current of 1.8 A (0.15 A/cm$^2$).

The organic solution was concentrated on a rotary evaporator and the residue was poured into water (400 mL). The resulting mixture was extracted with four 75 mL portions of $CH_2Cl_2$. The organic solution was successively washed with an aqueous solution of $NaHCO_3$, dried over $MgSO_4$, and concentrated on a rotary evaporator to leave an oil. The high vapor pressure fraction was separated by a bulb-to-bulb distillation under a pressure of $10^{-2}$ Torr.

*Purification and physical properties of the products*

A. *From diethyl 2,4-hexadienedioate (8a)*

The oil obtained from the bulb-to-bulb distillation at 45°C amounted to 0.62 g (37%); ir and $^1$H nmr: no CH=CH. Analytical glc: two important peaks in a ratio of 9:1 and a few very small peaks. Mass spectrum *m/e*: (major peak) 336 $(M)^+$, 291 $(M - OC_2H_5)^+$, 263 $(M - CO_2C_2H_5)^+$; (minor peak) 291 $(M - OC_2H_5)^+$, 263 $(M - CO_2C_2H_5)^+$. *Anal.* calcd. for $C_{12}H_{14}F_6O_4$: C 42.86, H 4.17; found (mixture of the two important peaks purified by preparative glc): C 42.86, H 4.10. The two peaks were fractionated by preparative glc. Major peak: ir (film): 2960, 1745, 1230, 1125; $^1$H nmr:[7] 1.30 (6H, t), 1.82–2.90 (2H, m), 3.50–4.00 (2H, m), 4.20 (4H, q); $^{19}$F nmr: the spectrum corresponded to the four-membered ring **10***a* (Table 1). The minor peak was overlapping with the major peak and could not be obtained pure. However, the $^{19}$F nmr of the enriched protonated and $\alpha,\alpha'$-dideuterated products agreed with the three-membered ring **9***a* (Table 1). Unfortunately, the $^1$H nmr data were not conclusive.

B. *From diethyl 2,5-heptadienedioate (8b)*

The anodic solution gave, after a bulb-to-bulb distillation at 65°C, 0.65 g (37%) of a slightly yellow oil; ir and $^1$H nmr: no CH=CH. The analytical glc of this oil showed two important peaks in a ratio of 5:1 and a few other small peaks. Mass spectrum *m/e*: (major peak) 350 $(M)^+$, 330 $(M - HF)^+$, 310 $(M - 2HF)^+$, 305 $(M - OC_2H_5)^+$; (minor peak) 350 $(M)^+$, 305 $(M - OC_2H_5)^+$. *Anal.* calcd. for $C_{13}H_{16}F_6O_4$: C 44.57, H 4.57; found (the mixture of the two main peaks purified by preparative glc): C 44.41, H 4.61. The two peaks were separated by preparative glc. Major peak: ir (film): 2996, 1752, 1260, 1175, 1125; $^1$H nmr:[7] 1.28 (6H, 2t), 2.35–4.00 (6H, complex m), 4.17 (4H, 2q); $^{19}$F nmr: Table 1. Minor peak: $^1$H nmr: 1.27 (6H, t), 1.8–3.5 (complex m), 4.18 (4H, 2q); $^{19}$F nmr: Table 1. The $^{19}$F nmr data suggested two stereoisomers of the five-membered ring **10***b*.

C. *From diethyl 2,6-octadienedioate (8c)*

The diolefinic compound **8***c* gave 0.75 g (42%) of a yellow oil from the bulb-to-bulb fractionation at 65°C; ir and $^1$H nmr: no CH=CH. Analytical glc: two important peaks in a ratio of 2:1 and other small peaks. Mass spectrum *m/e*: (major and minor peaks) 364 $(M)^+$, 319 $(M - OC_2H_5)^+$, 291 $(M - CO_2C_2H_5)^+$. *Anal.* calcd. for $C_{14}H_{18}F_6O_4$: C 46.15, H 4.95; found (the mixture of the two main peaks purified by preparative glc): C 46.08, H 4.74. The two peaks were separated by preparative glc. Major peak: ir (film): 2998, 1752, 1745; $^1$H nmr: 1.28 (6H, 2t), 1.50–2.35 (4H, m), 2.55–3.40 (4H, m), 4.20 (4H, 2q); $^{19}$F nmr: Table 1. Minor peak: ir (film): 2996, 1750; $^1$H nmr: 1.30 (6H, 2t), 1.50–2.20 (4H, m), 2.55–3.90 (4H, m), 4.20 (4H, 2q); $^{19}$F nmr: Table 1. The $^{19}$F nmr data showed that the two products were stereoisomers of **9***c*.

D. *From diethyl 2,7-nonadienedioate (8d)*

The bulb-to-bulb distillation at 65°C gave 0.80 g (42%) of distillate; ir and $^1$H nmr: no CH=CH. Analytical glc: three important equivalent peaks and a number of less important peaks. Mass spectrum: all the peaks have a *m/e* 378 $(M)^+$, 333 $(M - OC_2H_5)^+$, 291 $(M - CO_2C_2H_5)^+$. *Anal.* calcd. for $C_{15}H_{20}F_6O_4$: C 47.62, H 5.29; found (the mixture of the three peaks after purification by preparative glc): C 47.90, H 5.39. The three peaks were separated by preparative glc. The first peak analyzed as a mixture of two compounds by analytical glc. These compounds could not be separated by conventional methods of purification. Second and third peaks: ir (film): 2995, 1735, 1265, 1190; $^1$H nmr: 1.28 (6H, t) 1.40–3.70 (10H, m), 4.21 (4H, q). The $^{19}$F nmr data showed the presence of two stereoisomers (**9***d*) (Table 1).

[7] A small multiplet was always appearing at δ 5.82–6.08. It may be due to an impurity or to the presence of a minor isomer.

# The kinetics of proton and deuteron transfer from 1-(4-nitrophenyl)-1-nitroethane to 1,8-diazabicyclo[5.4.0]undec-7-ene in aprotic solvents

KENNETH T. LEFFEK AND PRZEMYSLAW PRUSZYNSKI[1]

*Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4H6*

Received December 14, 1981

KENNETH T. LEFFEK and PRZEMYSLAW PRUSZYNSKI. Can. J. Chem. **60**, 1692 (1982).

1-(4-Nitrophenyl)-1-nitroethane reacts with the base 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in both acetonitrile and toluene solvents in a normal second-order proton-transfer reaction, in contrast to its behaviour with the base 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene in acetonitrile.

The primary isotope effect, $k_H/k_D$ = 12.0 at 25° in toluene is very similar to that observed by other workers for the reaction of 4-nitrophenylnitromethane with DBU under the same conditions. In acetonitrile solvent a $k_H/k_D$ ratio of 7.8 was found at 25°C. The isotope effects on the activation parameters for the reaction in both solvents indicate that tunnelling of the proton through the potential energy barrier makes a significant contribution to the reaction rate.

KENNETH T. LEFFEK et PRZEMYSLAW PRUSZYNSKI. Can. J. Chem. **60**, 1692 (1982).

Contrairement à son comportement vis-à-vis de la base diméthoxy-2,7 bis(diméthylamino)-1,8 naphtalène dans l'acétonitrile, le (nitro-4 phényl)-1 nitro-1 éthane réagit avec la base diaza-1,8 bicyclo[5.4.0] undécène-7 (DBU) dans l'acétonitrile et le toluène selon une réaction normale de transfert de proton d'ordre deux.

L'effet isotopique primaire $k_H/k_D$ = 12,0 à 25°C dans le toluène est très voisin de celui observé par d'autres chercheurs dans le cas de la réaction du nitro-4 phényl nitrométhane avec le DBU dans les mêmes conditions. On a trouvé un rapport de $k_H/k_D$ = 7,8 dans l'acétonitrile à 25°C. L'effet isotopique, sur les paramètres d'activation dans les deux solvants, indique que l'effet tunnel du proton à travers la barrière d'énergie potentielle apporte une contribution significative à la vitesse de réaction.

[Traduit par le journal]

## Introduction

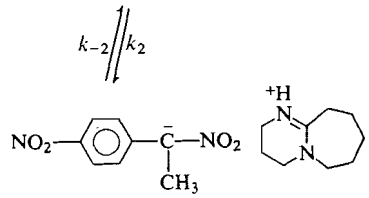
In a recent study of the proton transfer reaction from 1-(4-nitrophenyl)-1-nitroethane **1** to 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene in acetonitrile solvent (1), the reaction was found to follow first-order kinetics with respect to the substrate with no dependence on the base concentration. This behaviour was in marked contrast to the reaction of the same base with 4-nitrophenylnitromethane **2**, which showed the normal second-order kinetics. It is of interest, therefore, to investigate the generality of the phenomenon by studying the reaction of the ethane **1** with other bases.

Caldin and Rogne (2) reported the kinetic isotope effects for the proton transfer reaction of the methane **2** with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in toluene solvent. This reaction gave very good first-order kinetics, with the base concentration in large excess over that of the acid, both with the normal and deuterated acid, and gave a primary deuterium isotope effect $k_H/k_D = 13.3 \pm 1.2$ at 25°C.

The study of the reaction [1] of the ethane **1** with DBU in acetonitrile solvent allows a comparison of the kinetics with those of the reaction of the 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene, and in toluene solvent allows a comparison of the isotope effect with that determined by Caldin and Rogne (2). The ethane **1**, having only one acid hydrogen, gives a primary isotope effect undistorted by a secondary effect, as in the case of the methane **2**.

[1] 

**1** DBU



## Results and discussion

The reaction [1] gives a coloured product consisting of a single absorption peak, $\lambda_{max}$ = 445 nm in toluene and 505 nm in acetonitrile solvent. The optical density variation with base concentration was fitted to eq. [2] which is derived from eq. [1] assuming that the product is an ion-pair; [A] and [B] are the initial concentrations

[2] $[A]/OD = 1/K\varepsilon[B] + 1/\varepsilon$

of **1** and DBU respectively, OD is the optical density, $\varepsilon$ the molar absorptivity, and $K$ the equilib-

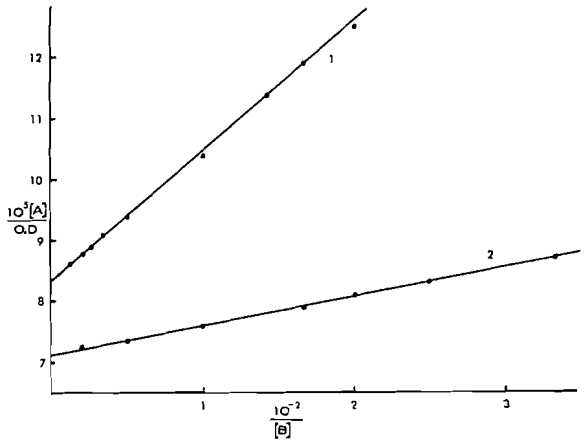

FIG. 1. Plots of [A]/OD vs. 1/[B] for the reaction of 1-(4)-nitrophenyl)-1-nitroethane with 1,8-diazabicyclo[5.4.0]undec-7-ene at 20°C in (1) toluene and (2) acetonitrile.

rium constant. The plots of [A]/OD vs. 1/[B] are shown in Fig. 1 and yield $K = 390\,dm^3\ mol^{-1}$ (20°C), $\varepsilon = 12\,000\,dm^3\ mol^{-1}\ cm^{-1}$ in toluene, and $K = 1400\,dm^3\ mol^{-1}$ (20°C), $\varepsilon = 14\,000$ in acetonitrile.

The positions of the absorption maxima are very similar to those previously reported; for the methane **2** and DBU Caldin and Rogne (2) found $\lambda_{max} = 440$ nm in toluene and for **1** and 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene in acetonitrile $\lambda_{max} = 520$ nm (1). It is clear that the product is the ion-pair containing the anion of **1**.

The equilibrium constant in toluene is much smaller than that of $2.9 \times 10^4\ dm^3\ mol^{-1}$ observed (2) for the methane **2**, as expected, since **1** is a weaker acid. Thus, the reaction is more symmetrical for the ethane substrate than for the methane, so at least as much proton tunnelling should occur in this reaction as in the methane reaction provided that the barrier dimensions are the same.

For the reaction of **1** and deuterated **1** pseudo-first-order rate constants were determined at a number of different base concentrations with the base always in large excess, for a series of temperatures. The second-order rate constants are the calculated slopes of plots of $k_1$ vs. [DBU]. All of these rate constants are shown in Table 1. The isotope effects are given in Table 2 and the activation parameters are collated in Table 3. The errors quoted in these tables are the standard deviations.

The first-order rate constants are directly proportional to the base concentration, indicating a second-order proton transfer similar to that observed by Caldin and Rogne (2), in contrast to the first-order reaction found with the base 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene(2,7-DMDAN) in acetonitrile solvent (1). The first-order rate constant with DBU at 25°C is about 150 times greater than that with 2,7-DMDAN. Thus, it appears that the absence of steric hindrance in the DBU reaction, compared to that in the 2,7-DMDAN reaction, allows the direct bimolecular proton transfer to take place, whereas the 2,7-DMDAN is sufficiently hindered that a two-step reaction is observed involving an initial slow ionization of the carbon acid (1).

The second-order rate constant for the reaction of ethane **1** with DBU in toluene is about 1000 times smaller at 25°C than the corresponding constant for methane **2** determined by Caldin and Rogne (2), as would be expected, since the ethane is a much weaker acid than the methane. This rate difference is entirely due to a difference in enthalpy of activation, which at 6.2 kcal $mol^{-1}$ for the ethane is 4.2 kcal $mol^{-1}$ greater than that for the methane. This is consistent with the idea that the difference in reactivity of the two acids is due to electronic and steric effects.

The isotopic rate ratio at 25°C for ethane **1** and DBU in toluene is 12.0, very similar to the 13.3 reported by Caldin and Rogne (2) for methane **2**. If the secondary isotope effect contained in the latter result is assumed to be 15% (3–5), the primary effect for the methane is a ratio of 11.6. The ethane might be expected to have a larger isotope effect because of the greater steric hindrance to the reaction and because of the more symmetrical transition state, but the two measurements are the same within experimental error. Similarly, the differences between the isotope effects on $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for ethane **2** and methane **1** are the same within the reliability of the experiments.

The enthalpy of activation isotopic differences of 2.0 and 1.7 kcal $mol^{-1}$ for toluene and acetonitrile solvent, respectively, indicate that tunnelling of the proton through the potential energy barrier probably makes a significant contribution to this reaction, as proposed by Caldin and Rogne for the

| $E_{H\ obs}/E_{H\ calc}$ | 0.87 | 0.92 |
| $E_{D\ obs}/E_{D\ calc}$ | 1.0 | 1.0 |

methane **2** reaction (2). The actual barrier heights in the absence of tunnelling and the barrier width, assuming a parabolic barrier, may be computed using Bell's equation (6–8) and the trial and error technique of Caldin and Mateo (9). The results, shown in Table 4, give tunnelling corrections to the activation energy of 1.0 kcal mol$^{-1}$ and 0.6 kcal mol$^{-1}$ for the reaction in toluene and acetonitrile solvent, respectively. These values and the calculated barrier widths, $2b$, are in general agreement with those of Caldin and Mateo (9) for other proton transfer reactions. Thus, the kinetic measurements are consistent with some contribution from proton tunnelling.

Thus, we have found that, although the ethane **1** is more sterically hindered than the methane **2**, the effect is not large enough to interfere with the normal bimolecular proton transfer to the base DBU. The similarity of the isotope effects for the reaction of the two acids with DBU in toluene serves to confirm the work of Caldin and Rogne (2) and leads to the conclusion that the width of the energy barrier is very similar for the two reactions.

## Experimental

*Materials*

1-(*p*-Nitrophenyl)-1-nitroethane and its α-deuterated analogue were prepared as described previously (1). The deuterated material showed no nmr peak for the α-hydrogen and was, therefore, at least 98% deuterated.

1,8-Diazabicyclo[5.4.0]undec-7-ene (Aldrich) was dried with potassium hydroxide and fractionally distilled under reduced pressure.

Toluene was dried with sodium and fractionally distilled. Acetonitrile was purified by the method of O'Donnell *et al.* (10) and fractionally distilled from $P_2O_5$.

*Equilibrium constant measurements*

The absorbance at equilibrium was measured for a series of reactions with acid concentration of $5 \times 10^{-5}$ *M* and nine different base concentrations ranging between $1 \times 10^{-3}$ and $8 \times 10^{-2}$ *M*. The values of the equilibrium constants obtained from the slopes of the graphs in Fig. 1 agreed with those derived from the kinetic measurements to within 10%, well within the precision of the two methods.

*Kinetic measurements*

The reaction rates were measured with a Durrum stopped-flow spectrophotometer using the standard technique previously described (11). Acid concentrations of $1 \times 10^{-5}$ to $4 \times 10^{-5}$ *M* were used with the base concentrations shown in Table 1, which gave an excess of base over acid never less than 250. The reaction traces fitted the first-order kinetic equation very well.

# The reinvestigation of the kinetics of the reactions of fluorodi(4-nitrophenyl)ethanes with sodium methoxide in methanol

KENNETH T. LEFFEK AND GRZEGORZ SCHROEDER[1]

*Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4H6*

Received December 14, 1981

KENNETH T. LEFFEK and GRZEGORZ SCHROEDER. Can. J. Chem. **60**, 1696 (1982).

The procedure previously described for the preparation of 1-fluoro-2,2,-di(4-nitrophenyl)ethane actually yields 1,1,2-tri-(4-nitrophenyl)ethane. 1-Fluoro-2,2-di(4-nitrophenyl)ethane has been prepared and rate constants, isotope effects, and activation parameters for the β-elimination reaction with methoxide ion in methanol are reported. These parameters indicate a concerted E2 mechanism, with a fairly symmetrical transition state. The subsequent dimerization reaction of the olefin product to yield 1,1,3,3-tetra(4-nitrophenyl)butene-1 is described.

The reaction of 1,1,1-trifluoro-2,2-di(4-nitrophenyl)ethane with methoxide ion in methanol has been reinvestigated and the reaction of the first product 1,1-difluoro-2,2-di(4-nitrophenyl)ethylene with excess methoxide, to give di(4-nitrophenyl)ketene dimethylacetal in a multistep reaction, is reported.

KENNETH T. LEFFEK et GRZEGORZ SCHROEDER. Can. J. Chem. **60**, 1696 (1982).

La méthode proposée antérieurement pour la préparation du fluoru-1 bis(nitro-4 phényl)-2,2 éthane donne en fait du tris(nitro-4 phényl)-1,1,2 éthane. On a préparé le fluoro-1 bis(nitro-4 phényl)-2,2 éthane et on rapporte les constantes de la réaction d'élimination β avec l'ion méthanolate dans le méthanol. Ces paramètres indiquent un mécanisme concerté E2 impliquant un état de transition moyennement symétrique. On décrit la réaction ultérieure de dimérisation du produit oléfinique qui conduit au tétra kis(nitro-4 phényl)-1,1,3,3 butène-1.

On a de nouveau étudié la réaction du trifluoro-1,1,1 bis(nitro-4 phényl)-2,2 éthane avec l'ion méthanolate dans le méthanol et on rapporte la réaction du premier produit, le difluoro-1,1 bis(nitrophényl-4)-2,2 éthane, avec un excès de méthanolate qui en plusieurs étapes conduit au diméthylacétal du bis(nitro-4 phényl) cétène.

[Traduit par le journal]

## Introduction

In an earlier study (1), it was reported that 1-fluoro-2,2-di(4-nitrophenyl)ethane underwent a β-elimination reaction with sodium methoxide in methanol to give the olefin product, di(4-nitrophenyl)ethylene, which had an absorption maximum at 380 nm. Rates of reaction, activation parameters, and primary deuterium isotope effects were also reported.

Subsequently, attempts to prepare this substrate again, by the methods of Kaluszyner *et al.* (2) and Bergmann and Kalmus (3) which we had used in the earlier study, were unsuccessful. The first step of the preparation, the conversion of ethyl monofluoroacetate to the fluorodiphenylcarbinol by reaction with phenylmagnesium bromide was reported (4–6) to give, at low temperature, ω-fluoroacetophenone as the main product and 1-fluoro-2,2-diphenylethanol as the minor product. Under the reaction conditions the ω-fluoroacetophenone could react further with phenylmagnesium bromide to form ω-phenylacetophenone (7), which would then yield 1,1,2-triphenylethane. This led to the suspicion that our earlier work was not based on an authentic sample of the fluoroethane, so a reinvestigation has been carried out.

[1]Postdoctoral Fellow 1980–1981.

## Results and discussion

When ethyl monofluoroacetate was reacted with phenylmagnesium bromide and the product reduced with red phosphorus in hydriodic and glacial acetic acids according to the conditions used in our earlier work (1), the nmr and ir spectra of the purified product matched almost exactly with the standard literature spectra (8, 9) of 1,1,2-triphenylethane. Thus, the product of this reaction was not, as we previously reported, 1-fluoro-2,2-diphenylethane, but 1,1,2-triphenylethane.

The rate constants and isotope effects published as those for the reaction of 1-fluoro-2,2-di-(4-nitrophenyl)ethane and sodium methoxide in methanol (1) actually refer to the reaction of 1,1,2-tri(4-nitrophenyl)ethane with sodium methoxide in methanol. A sample of the latter substrate was prepared by nitration of 1,1,2-triphenylethane with a mixture of nitric and sulfuric acids and the purified product was reacted with sodium methoxide in methanol at 30.0°C. The second-order rate constant for the appearance of the absorption peak at 380 nm was determined by the same technique used in the earlier study (1) and found to be 0.070 L $mol^{-1}$ $s^{-1}$, in good agreement with the value of 0.073 L $mol^{-1}$ $s^{-1}$ reported previously (1).

Thus, the absorption peak at 380 nm is due, since the reaction shows a significant primary deuterium isotope effect (1), to the product of a proton

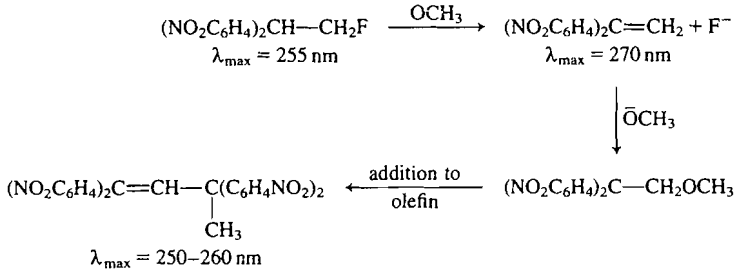

SCHEME 1

abstraction from the substrate. This product must be the carbanion of 1,1,2-tri(4-nitrophenyl)ethane. This absorption peak is at rather short wavelength compared to the carbanion of di(4-nitrophenyl)methane at over 500 nm, which caused it to be mistaken for an olefin absorption in our earlier work (1). This might indicate some double bond character between the two aliphatic carbon atoms, resulting from a 4-nitrophenyl bridged structure in the carbanion.

*The 1-fluoro-2,2-di(4-nitrophenyl)ethane reaction*

The material was prepared from sodium monofluoroacetate via fluoroacetyl chloride, ω-fluoroacetophenone, 1-fluoro-2-phenylethanol, and 1-fluoro-2,2-diphenylethane. The substrate was characterized by its nmr spectrum and fluorine analysis.

The reaction of 1-fluoro-2,2-di(4-nitrophenyl)ethane with sodium methoxide is complex. The substrate has a uv absorption maximum at 255 nm, which disappears after about 15 minutes and is replaced by a broad absorption at higher wavelength. When isolated, the product of this reaction gives a uv absorption at 270 nm. Comparison of the uv and nmr spectra with an authentic sample of 1,1-di(4-nitrophenyl)ethylene established this as the first product of the reaction.

When the reaction is allowed to proceed to completion the product is 1,1,3,3-tetra(4-nitrophenyl)butene-1 with a broad absorption peak at $\lambda_{max}$ 250–260 nm, characterized by its nmr spectrum. The reaction sequence is shown in Scheme 1. The butene-1 is formed by a nucleophilic addition of methoxide ion to the ethylene to give the carbanion shown. When the reaction was stopped by addition of HCl before completion, the mass spectrum of the product showed a molecular ion of 302 corresponding to the ether derived from the carbanion. The final product is formed by nucleophilic addition of the carbanion to the ethylene. This reaction probably proceeds via a cyclodimerization reaction (10). The preparation of 1,1,3,3-tetraphenylbutene-1 from 1,1-diphenylethylene by this mechanism has been described (11).

The kinetics of the reaction were measured spectrophotometrically by recording the increase in absorbance with time at 330 nm, using two different time scales. At this wavelength the consecutive reactions to yield first the ethylene and then the butene-1 did not interfere with each other, since the rates of the two reactions were sufficiently different to allow their separate measurement.

The first-order rate constants were measured, using varying methoxide ion concentrations always in large excess, at a series of different temperatures. The second-order rate constant at each temperature was calculated from the slope of the plot of $k_1$ vs. $[\bar{O}CH_3]$. The measurements were repeated for the deuterated substrate, but no isotope effect was found ($k_H/k_D$ was unity within experimental error at all temperatures) for the appearance of the butene-1. The results are shown in Tables 1 and 2.

The primary isotope effect of $k_H/k_D = 4.7$ at 30°C for the appearance of the ethylene indicates a concerted E2 mechanism for this reaction. Although the second-order rate constant of 0.64 L mol$^{-1}$ s$^{-1}$ at 30°C is about the same as that for the trifluoro compound (1), this rate constant is 64 times greater than the value of 0.01 L mol$^{-1}$ s$^{-1}$ predicted by the results of McLennan and Wong (12) for the irreversible ElcB mechanism (1). Therefore, the monofluoro compound reacts 64 times faster than it is predicted to form carbanions. Thus, the monofluoro compound reacts by the E2 mechanism and, from the magnitude of the isotope effect, the transition state must be fairly symmetrical with respect to the breaking of the C—H bond.

The activation parameters, calculated from Table 1, are $\Delta H_H^{\ddagger} = 9.9 \pm 0.7$ kcal mol$^{-1}$, $\Delta S_H^{\ddagger} = -26.6 \pm 3.3$ cal mol$^{-1}$ deg$^{-1}$, $\Delta H_D^{\ddagger} = 10.6 \pm 0.8$ kcal mol$^{-1}$, $\Delta S_D^{\ddagger} = -27.6 \pm 2.7$ cal mol$^{-1}$ deg$^{-1}$. The enthalpies of activation are considerably lower than those for the β-elimination reactions of the trifluoro and trichloro compounds and the entro-

pies of activation are much more negative (1). This is in accord with the assignment of the E2 mechanism for the monofluoro compound and the $(ElcB)_R$ mechanism for the trifluoro compound (1). It has been noted (13) that E2 dehydrohalogenations have more negative entropies of activation by 20–30 cal $mol^{-1}$ $deg^{-1}$ than ElcB dehydrohalogenations by alkoxide ions in alcohols (14–16).

The second-order rate constants for the dimerization reaction of the ethylene, given in Table 2, are about 13 times slower than those for the β-elimination reaction (Table 1) and give $\Delta H^{\ddagger} = 15.9 \pm 0.8$ kcal $mol^{-1}$ and $\Delta S^{\ddagger} = -11.92 \pm 2.5$ cal $mol^{-1}$ $deg^{-1}$. This dimerization reaction is multistage, consisting of two nucleophilic additions to the ethylene double bond and possibly the formation of a cyclic addition product (10, 11). However, if the latter is formed it would rapidly decompose to give the butene-1 product. Thus, the rate-determining step of the reaction is either the addition of $\bar{O}CH_3$ to the ethylene or the addition of the carbanion thus formed, shown in Scheme 1, to the ethylene. Since the ether derived from the latter carbanion could be detected by mass spectroscopy of the reaction product when the reaction was stopped before completion, it is concluded that the nucleophilic addition of the carbanion to the ethylene must be at least partly rate determining. However, the kinetics follow a first-order rate law with respect to the ethylene when the base is in large excess, as shown in Table 2. For a consecutive reaction scheme of this type, eqs. [1] and [2], in

which the ethylene (E) reacts with base (B) to form the carbanion (C) which then reacts with

$$[1]\quad E + B \xrightarrow{k_1} C$$

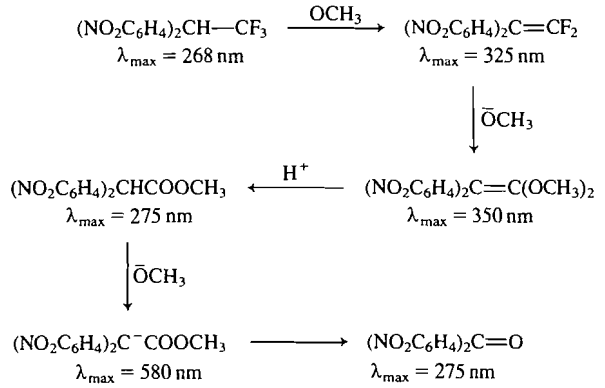
$$[2]\quad C + E \xrightarrow{k_2} P$$

another molecule of ethylene to yield the product (P), the rate of appearance of the carbanion and of the product are given by eqs. [3] and [4].

$$[3]\quad \frac{d[C]}{dt} = k_1[E][B] - k_2[E][C]$$

$$[4]\quad \frac{d[P]}{dt} = k_2[E][C] = k_1[E][B] - \frac{d[C]}{dt}$$

Although it is not valid to assume the steady state approximation with respect to the carbanion, under the conditions used to follow the rate of appearance of the product, $d[C]/dt$ may be small compared to $k_1[E][B]$ giving rise to the observed kinetics. The rate constants and activation parameters are, therefore, approximately identified with the addition of methoxide to the ethylene.



SCHEME 2

*The 1,1,1-trifluoro-2,2-di(4-nitrophenyl)ethane reaction*

In the previous study (1), the kinetics of the olefin-forming β-elimination reaction, initiated by methoxide ion, were reported and the mechanism deduced. A subsequent study (17) of the same substrate with *tert*-butoxide ion in *tert*-butyl alcohol showed that the olefin product reacts further with the excess *tert*-butoxide. The changes in the uv spectrum of the substrate with methoxide in methanol clearly indicate a set of consecutive reactions (Scheme 2). The first product of the reaction is 1,1-difluoro-2,2-di(4-nitrophenyl)ethylene with an absorption peak at 325 nm, for which the kinetics and primary isotope effects have been reported (1).

The reaction of the olefin to the second product is slow. This has an absorption maximum at 350 nm and is stable only in a water-free solvent. The substance contains no fluorine and was shown to be di(4-nitrophenyl)ketene dimethylacetal by ms and nmr analysis. When treated with HCl in methanol, conversion to methyl di(4-nitrophenyl)acetate took place. The acetate, with an excess of methoxide in methanol, gave a product with an absorption at 580 nm and this product decomposed to the final product 4,4′-dinitrobenzophenone. The complete reaction is shown in Scheme 2. A similar reaction to that of the last two steps was found for ethyl di(4-nitrophenyl)acetate with tetramethylguanidine in a mixture of methanol and tetrahydrofuran solvents (18).

The conversion of the difluoroethylene to the dimethylacetal must proceed via two steps of nucleophilic addition of methoxide ion to the double bond and two steps of elimination of fluoride ion. A similar reaction has been described by Mechoulam *et al.* (19).

Fluoro olefins are well known for their susceptibility to nucleophilic addition (20). The adducts

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

decompose to give products, either by addition of $H^+$ or, as in the present case, by the elimination of $F^-$ to yield another olefin. Evidence exists (20) that the rate determining step is the addition of the nucleophile rather than the elimination of $F^-$. In the present reaction, however, there are two nucleophilic additions, the first to a difluoro olefin and the second to a monofluoro olefin. The fluorine atoms strongly stabilize the carbanion formed by the nucleophilic addition and are assumed to lower the activation energy of the reaction (20). Of the two nucleophilic additions, therefore, the second addition to the monofluoro olefin would be expected to be slower, with a higher activation energy than the first. This second nucleophilic addition would, therefore, be the rate-determining step for that part of Scheme 2 in which the difluoroethylene is converted to di(4-nitrophenyl)ketene dimethylacetal.

Rate constants for the appearance of ketene product are given in Table 3 from which the second-order constants yield activation parameters, $\Delta H^{\ddagger} = 9.0 \pm 0.9$ kcal mol$^{-1}$ and $\Delta S^{\ddagger} = -35.0 \pm 3.0$ cal mol$^{-1}$ deg$^{-1}$.

If the theory of Chambers (20), quoted above, is correct, the activation energy of the nucleophilic addition in the reaction of the trifluoroethane should be lower than that measured in the monofluoroethane reaction, since in the latter the addition is to an olefin containing no fluorine. This is indeed the case, the difference in enthalpies of activation being almost 7 kcal mol$^{-1}$. However, the difference in the entropies of activation cancels a large proportion of this so that the second-order rate constant for the ketene product step is about the same as that for the dimerization step in the reaction of the monofluoroethane.

## Experimental

*Preparation of 1,1,2-tri(4-nitrophenyl)ethane*

Ethyl fluoroacetate (0.1 mol) was added dropwise to phenylmagnesium bromide (0.3 mol) in ether at 0°C during 15 min. The reaction mixture was hydrolyzed immediately by the slow addition of ammonium chloride in ice-water. The carbinol product was recovered by extraction with ether, dried, and distilled under vacuum. The carbinol was reduced with red phosphorus in a mixture of hydriodic and glacial acetic acids by refluxing for 10 days. The product was purified by recrystallization from methanol. The nmr spectrum ($CDCl_3$) δ: 3.30 (2H,d,$J$ = 8.0 Hz), 4.20 (1H,t,$J$ = 7.5 Hz), 6.9–7.5 (15H) agrees very closely with the literature spectrum (8). The peaks in the ir spectrum (Nujol) also matched very closely with the literature melt spectrum (9). The ethane was nitrated by a mixture of nitric and sulfuric acids and the product was crystallized several times from methanol.

*Preparation of 1-fluoro-2-2-di(4-nitrophenyl)ethane*

Sodium monofluoroacetate (0.23 mol) was mixed with $PCl_5$ (0.25 mol) and crude fluoroacetyl chloride was distilled off. This was fractionally distilled, 0.16 mol dissolved in methylene chloride (30 mL), and added to aluminum chloride (0.19 mol) in methylene chloride (100 mL) (3). The reaction mixture was stirred for 30 min, then the solution was decanted from the solid residue and cooled to 0°C. Benzene (0.1 mol) in methylene chloride (16 mL) was added dropwise during 15 min with stirring and the stirring was continued for a further 20 min. The mixture was poured onto ice and HCl, and the product ω-fluoroacetophenone was separated, dried, and distilled under vacuum (3).

The ω-fluoroacetophenone was reduced by $AlLiH_4$ ($AlLiD_4$ for the deuterium analogue) on a 0.015 mol scale by the procedure of Bergmann and Kalmus (3) to yield the carbinol, which was dissolved in a 4-fold molar excess of benzene, then cooled to 0°C. A 5:1 mixture of concentrated $H_2SO_4$/oleum was added dropwise with constant stirring and 1-fluoro-2,2-diphenylethane was isolated, nmr spectrum ($CDCl_3$) δ: 4.76(2H,d, $J$ = 48 Hz), 4.25(1H,t,$J$ = 4.0 Hz), 7.15(10H).

Finally, the fluoroethane was nitrated with a mixture of nitric and sulfuric acids. The product was crystallized several times from methanol, mp 87–92°C (dec.); nmr ($CDCl_3$) δ: 5.12 (2H,d,$J$ = 48 Hz), 5.45(1H,t,$J$ = 4.0 Hz), 7.50–8.50 (8H). Fluorine, found: 6% (neutron activation); calcd.: 6.5%.

The tertiary hydrogen nmr signals were completely absent in the deuterated compound, indicating at least 98% deuteration in that position.

*Reaction of 1-fluoro-2,2,di(4-nitrophenyl)ethane with methoxide ion*

The first product was isolated by neutralizing the reaction mixture with HCl after about 15 min. Removal of the solvent and repeated extraction with diethyl ether, then with chloroform, gave the product in about 60% yield with an nmr spectrum ($CDCl_3$) δ: 5.65(2H,s), 7.40–8.40 (8H). A sample of di(4-nitrophenyl)ethylene, prepared from acetophenone by standard methods, confirmed the above nmr spectrum.

When the reaction was allowed to proceed for four hours before the work-up of the products, the nmr spectrum was

Guggenheim analysis yields $k_H = 2.69 \times 10^{-4}$ s$^{-1}$

δ: 1.15(3H,s), 7.15(1H,s), 7.40–8.40(16H). The same material was obtained when the synthetic di(4-nitrophenyl)ethylene was treated with sodium methoxide in methanol. The spectrum is characteristic of 1,1,3,3-tetra(4-nitrophenyl)butene-1.

*Preparation of 1,1,1-trifluoro-2,2-di(4-nitrophenyl)ethane*

This material was prepared as previously described (1).

*Reaction of 1,1,1-trifluoro-2,2-di(4-nitrophenyl)ethane with methoxide ion*

The first olefin product ($\lambda_{max}$ 325 nm) of this reaction was isolated as reported earlier (1).

When the reaction was allowed to proceed for two hours the peak at 325 nm was replaced by one at 350 nm. This second product was isolated by evaporation of the solvent under reduced pressure and repeated extraction with anhydrous ether. The material contained no fluorine (neutron activation analysis) and decolourized bromine solution. The ms showed a molecular ion of 330 awu and the nmr spectrum ($CDCl_3$) showed δ: 5.2 (6H,s), 7.2–8.4 (8H). This product is, therefore, di(4-nitrophenyl)ketene dimethylacetal.

The acetal is stable only in the absence of water and decomposes slowly with adventitious water. The addition of HCl (0.02 mol) to the acetal (0.002 mol) in methanol solution yielded a product, mp 138°C, after recrystallization from methanol. The ms gave a molecular ion of 316 awu and the nmr ($CDCl_3$) δ: 4.4(3H,s), 5.4 (1H,s), 7.6–8.6 (8H), indicating that the product is methyl di(4-nitrophenyl)acetate. A corresponding reaction was also described by Mechoulam *et al.*(16).

A mixture of methyl di(4-nitrophenyl)acetate and sodium methoxide in methanol gave a coloured solution ($\lambda_{max}$ 580 nm), which slowly decomposed during 10 h to a product with $\lambda_{max}$ 275 nm, identified as 4,4′-dinitrobenzophenone, mp 186–188°C (lit. (21) mp 188–189°C).

*Kinetic measurements*

The reaction rates were measured spectrophotometrically using a technique previously described (1). Two sample runs are given in Table 4.

# $^1$H nuclear magnetic resonance study of tunnelling in molecules with multiple methyl groups trapped in hydrates[1]

J. A. RIPMEESTER

*Division of Chemistry, National Research Council, Ottawa, Ont., Canada K1A 0R9*

Received June 11, 1981[2]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

J. A. RIPMEESTER. Can. J. Chem. **60**, 1702 (1982).

Methyl group tunnelling frequencies were derived from low-temperature $^1$H lineshapes for isobutane-$d_1$, *tert*-butyl fluoride, and trimethylamine trapped in heavy water hydrates and for *tert*-butyl chloride, *tert*-butyl alcohol, and neopentane enclathrated in the heavy water double hydrates with $D_2S$. Methyl group rotational barriers derived from the tunnelling frequencies are generally not very different from values found for the pure solids and gases and are much larger than barriers to overall reorientation of the guest molecules in the hydrate cages. Disorder in the orientation of the water molecules which make up the hydrate cages led to a distribution in barrier heights.

---

J. A. RIPMEESTER. Can. J. Chem. **60**, 1702 (1982).

A partir des formes des raies en rmn du $^1$H, on a déduit les fréquences de l'effet tunnel des groupes méthyles de l'isobutane-$d_1$, du fluorure de *tert*-butyle et de la triméthylamine piégés avec des hydrates d'eau lourde ainsi que celles des groupes méthyles du chlorure de *tert*-butyle, de l'alcool *tert*-butylique et du néopentane sous formes de clathrate dans des hydrates doubles d'eau lourde et de $D_2S$. Les barrières à la rotation du groupe méthyle, déduites des fréquences de l'effet tunnel, ne sont pas généralement très différentes des valeurs trouvées dans le cas des solides purs et des gaz et elles sont beaucoup plus élevées que les barrières de la réorientation globale des molécules hôtes dans les cages de l'hydrate. Le désordre dans l'orientation des molécules d'eau qui façonne les cages de l'hydrate conduit à une distribution des hauteurs de la barrière.

[Traduit par le journal]

In a previous publication (1) we have illustrated the use of methyl group tunnelling frequencies to derive information on methyl group rotational barriers of molecules bearing a single methyl group enclathrated in heavy water clathrates. There was found to be a contribution to methyl group barriers from guest–host interactions, the magnitude of which depended on the relative size of the guest molecule and the free diameter of the hydrate cage. In addition, it was found that the guest–host barrier contribution was distributed about a mean value presumably because of disorder in the orientation of the water molecules and the possibility of off-centre sites of the guest molecules in the hydrate cages.

In this contribution $^1$H nmr lineshapes for molecules containing 3 or 4 methyl groups are examined and tunnelling frequencies and barrier heights are derived.

## Experimental

Heavy water clathrates of ideal composition $M.17D_2O$ of isobutane-$d_1$ (Merck, Sharp and Dohme) and *tert*-butyl fluoride (PCR Inc.) were prepared as described in ref. 2, method B. The preparation of heavy water double hydrates of $D_2S$ with *tert*-butyl chloride, *tert*-butyl alcohol-OD, and neopentane of ideal composition $M.2D_2S.17D_2O$ has also been described (1). The hydrate of trimethylamine resulted on freezing an aqueous solution of composition $NMe_3.10\ 1/4D_2O$ (4).

Other experimental details have been given previously (1).

## Results and discussion

The $^1$H nmr lineshape derivatives of the enclathrated molecules were essentially independent of temperature below ~10 K, and are shown in Figs. 1–6. The lineshapes differ considerably from those expected for either rigidly held or rapidly rotating methyl groups (3). Hence the dipolar split Zeeman levels for the methyl groups must be perturbed by

methyl group tunnelling at frequencies of some tens of kHz (5).

At the low temperatures employed, the methyl groups should be in their torsional ground states so that the equations of Apaydin and Clough (6) are applicable to the lineshape calculation. It must also be assumed that there is no coupling between methyl groups and that all intermethyl group dipolar interactions can be included in the isotropic Gaussian broadening parameter.

However, as found previously (1), a good fit of calculated lineshapes with experimental results could not be obtained unless a distribution in methyl group tunnelling frequencies was assumed.

For convenience a log-Gaussian distribution in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

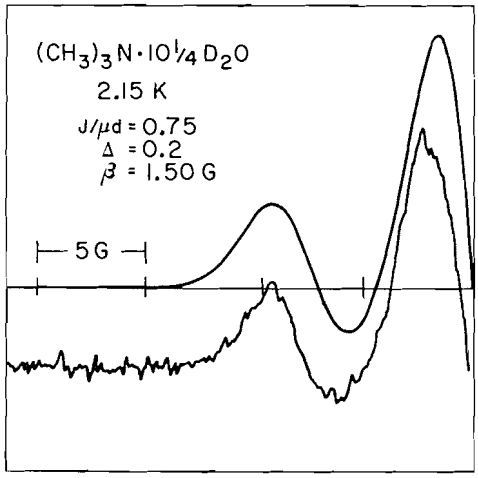

FIG. 6. Experimental and calculated $^1$H nmr lineshape derivative for $NMe_3$.10 1/4$D_2O$.

tunnelling frequencies, which leads approximately to a Gaussian distribution in barrier heights, was assumed. The parameters in the lineshape calculation then are: $J_0/\mu d$ where $3J_0/h$ is the mean tunnelling frequency, $\mu d/h$ the dipolar coupling frequency with $\mu = \gamma h/2$, $d = 3/2\ \mu/R^3$, $\gamma$ the proton gyromagnetic ratio, $R$ the methyl group interproton distance; $\beta$ is the Gaussian broadening parameter, $\Delta$ is the width parameter of the distribution in tunnelling frequencies, and $\delta V$ is the corresponding width of the barrier height distribution.

The lineshape intensity at $\omega_i$ for any tunnelling frequency $J_j$, $f(\omega_i,J_j)$, can be calculated using the equations of Apaydin and Clough. The total lineshape intensity at $\omega_i$ is then given by

$$F(\omega_i) \propto \sum_j f(\omega_i,J_j)\, g(Z_j)$$

where

$$g(Z_j) = \frac{1}{\Delta\sqrt{2\pi}} \exp(-Z_j^2/2\Delta^2)$$

and

$$Z_j = \ln J_j/J_0$$

Typically $j$ was equal to 30–50 for adequate definition of the lineshape. The splitting of the tunnelling side band away from the centre is governed by the mean tunnelling frequency, $J$, the amplitude of the tunnelling side band by distribution width $\Delta$, and the broadening parameter $\beta$. The uncertainty estimates, given in Table 1 along with the parameters, reflect the points at which the fit deteriorates noticeably. Calculated lineshape derivatives are given in Figs. 1–6. It should be emphasized that the exact nature of the distribution function is not critical, only that a distribution exists.

TABLE 1. Lineshape parameters and tunnelling frequencies

| Guest molecule | Mean $J/\mu d$ | $\Delta$ | $\beta$(gauss) | $3J_0/h$ (kHz) |
|---|---|---|---|---|
| $(CH_3)_3CD$ | 1.0±0.1 | 0.2±0.1 | 1.5±0.1 | 23.5 |
| $(CH_3)_3CF$ | 2.1±0.2 | 0.4±0.2 | 1.6±0.1 | 49.3 |
| $(CH_3)_3CCl$ | 0.4±0.1 | 0.2±0.1 | 1.3±0.1 | 9.4 |
| $(CH_3)_3COD$ | 0.8±0.2 | 0.8±0.2 | 1.5±0.1 | 18.8 |
| $(CH_3)_4C$ | 0.6±0.1 | 0.8±0.2 | 1.8±0.1 | 14.1 |
| $(CH_3)_3N$ | 0.75±0.05 | 0.2±0.1 | 1.5±0.1 | 17.6 |

The relationship derived by Hecht and Dennison (7) was used to obtain mean barrier heights, as well as barrier height distributions (Table 2). Also shown are barrier heights derived by other techniques both for the solid and gaseous materials.

Barriers to overall molecular reorientation of the guest molecules in the hydrate cages may be estimated from the second moment vs. temperature behaviour. The relationship used in a modified form (8) of the Waugh and Fedin estimate (9) and is expressed as

$$V = 32.4\, T_{1/2}$$

where $T_{1/2}$ is the temperature at which the second moment has fallen to half the rigid lattice value.

The barriers to overall reorientation of the guest molecules can be seen to be much lower than the methyl internal rotation barriers. This is consistent with the weak nature of guest–host interactions in clathrate hydrates.

The low barrier to overall reorientation of neopentane, 0.78 kcal/mol as opposed to 1.2–1.7 kcal/mol for the other molecules of similar shape and size, points to a fundamental difference in the motional averaging process for octahedral or tetrahedral molecules on the one hand, and molecules of lower symmetry on the other (14). For a molecule of tetrahedral symmetry with a rotational symmetry number of 12, any motion which causes exchange between the 12 indistinguishable sites at sufficiently rapid rate is enough to cause complete averaging of all intramolecular nuclear dipolar fields. For molecules of lower symmetry, however, complete averaging of the dipolar fields can take place only if the molecule can occupy distinguishable and hence potentially inequivalent sites in the hydrate cage.

For the partially deuterated ethyl halides enclathrated in the hydrate cages, the methyl group barrier height could be written as $V = V_{gas} + V_{cage}$, where $V_{gas}$ is the barrier for a molecule in the gas phase, and $V_{cage}$ is a contribution to the methyl group barrier from interactions with the hydrate cage. There was a clear trend of $V_{cage}$ with molecu-

TABLE 2. Summary of barrier height data

| Guest molecule | Mean barrier to guest reorientation (kcal/mol) | Mean methyl tunnelling barrier (kcal/mol) | Width of barrier distribution $\delta V$ (kcal/mol) | Barriers of solid(s) and gas (g) phases (kcal/mol) |
|---|---|---|---|---|
| $(CH_3)_3CD$ | 1.20 | 4.06 | 0.09 | 4.36(s)[a] 3.94(s)[b] 3.39(g)[b] |
| $(CH_3)_3CF$ | — | 3.74 | 0.22 | 4.41(s)[a] 4.34(g) |
| $(CH_3)_3CCl$ | 1.68 | 4.42 | 0.10 | 4.98(s)[a] 4.51(s)[b] |
| $(CH_3)_3COD$ | 1.39 | 4.15 | 0.38 | 4.13(s)[d] |
| $(CH_3)_4C$ | 0.78 | 4.26 | 0.38 | 4.40(s)[a] 4.34(s)[c] |
| $(CH_3)_3N$ | — | 4.17 | 0.10 | 4.35(s)[b] 3.63(g)[a] |

lar size with $V_{cage} = 0$, 0.5, 1.0 kcal/lmol for $CH_3CD_2X$, X = Cl, Br, I.

For the structure II hydrates considered here, such a clear trend is not evident. The guest molecules are all relatively large compared to the structure II large cage, the $(CH_3)_3CCl$, $(CH_3)_3COD$, and $(CH_3)_4C$ requiring the presence of a help gas in the small structure II cage for hydrate stability. The methyl group rotational barriers for the enclathrated molecules considered here are generally slightly smaller than the barrier found for these molecules in the solid phase, and somewhat larger than those found for the gas phase. This is in keeping with the barrier being largely intramolecular in origin.

An interesting trend evident in Table 2 concerns the methyl group rotation barriers $V_X$ for $(CH_3)_3CX$, X = D, F, Cl. Clearly for the enclathrated molecules $V_F < V_D < V_{Cl}$. For the pure solids $V_F \sim V_D < V_{Cl} < V_{Br}$ (10), and for other solids of the type $CH_3CX_3$, $(CH_3)_2CX_2$, $V_F < V_H < V_{Cl} < V_{Br}$ (10). Evidently a simple argument involving steric repulsion and van der Waal's radii is inadequate in explaining such trends.

# Étude des bases de Schiff derivées de la salicylaldehyde et de la 2-aminopyridine. Propriétés et capacité de complexation

L. F. CAPITÁN-VALLVEY, F. SALINAS, C. JIMÉNEZ ET L. CUADROS

*Département de Chimie Analytique de la Faculté des Sciences de l'Université de Granada et Département de Recherches Chimiques du C.S.I.C., Granada, Espagne*

Reçu le 25 septembre 1981

L. F. CAPITÁN-VALLVEY, F. SALINAS, C. JIMÉNEZ et L. CUADROS. Can. J. Chem. **60**, 1706 (1982).

Les propriétés spectroscopiques (ir, uv, rmn et spectre de masse) et thermiques des azométhines (*N*-(4-méthyl-2-pyridyl)benzaldimine, *N*-(6-méthyl-2-pyridyl)benzaldimine, *N*-(4-méthyl-2-pyridyl)salicylaldimine, et *N*-(6-méthyl-2-pyridyl)salicylaldimine) ont été étudiées. La valeur de leurs constantes d'acidité est discutée en fonction de la stéréochimie de ces molécules. Enfin la réaction avec des sels métalliques a été étudiée qualitativement.

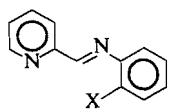
L. F. CAPITÁN-VALLVEY, F. SALINAS, C. JIMÉNEZ, and L. CUADROS. Can. J. Chem. **60**, 1706 (1982).

The spectroscopic (ir, uv, nmr, and ms) and thermal properties of *N*-(4-methyl-2-pyridyl)benzaldimine, *N*-(6-methyl-2-pyridyl)benzaldimine, *N*-(4-methyl-2-pyridyl)salicylaldimine and *N*-(6-methyl-2-pyridyl)salicylaldimine have been studied. Their acidity constants are discussed in relationship to their stereochemistry. Finally, reaction of these compounds with metal salts has been studied in a qualitative manner.

[Journal translation]

## Introduction

Dans des travaux précédents (1–4) nous avons fait connaître les résultats obtenus sur l'étude des propriétés, de la capacité complexante et des applications analytiques des bases de Schiff hétérocycliques, et plus spécialement l'influence qu'exerce l'introduction de différents groupes fonctionnels en position *ortho* par rapport au groupe azométhinique sur la molécule (formules **1–4**).

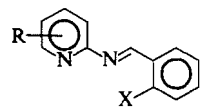


**1** X = H
**2** X = OH
**3** X = SH
**4** X = COOH

En suivant toujours la même ligne de travail, nous avons étudié la capacité de complexation de ces bases de Schiff. D'une part, nous avons inverti la position du groupe azométhinique dans la molécule par rapport aux précédents, et d'autre part, nous avons introduit des groupes méthyles dans diverses positions de l'anneau pyridinique.

L'objectif est double: d'un côté, augmenter la sélectivité de ces composés dans leurs réactions en presence d'ions inorganiques et d'un autre côté, diminuer la solubilité des complexes qui ont pu se former.

Les azométhines que nous avons étudiés sont: *N*-(4-méthyl-2-pyridyl)benzaldimine (4-MPBI) (**5**), *N*-(6-méthyl-2-pyridyl)benzaldimine (6-MPBI) (**6**), *N*-(4-méthyl-2-pyridyl)salicylaldimine (4-MPSI) (**7**)



**5** R = 4-$CH_3$; X = H (4-MPBI)
**6** R = 6-$CH_3$; X = H (6-MPBI)
**7** R = 4-$CH_3$; X = OH (4-MPSI)
**8** R = 6-$CH_3$; X = OH (6-MPSI)

et *N*-(6-méthyl-2-pyridyl)salicylaldimine (6-MPSI) (**8**).

Malgré une intense recherche bibliographique, nous n'avons réussi à trouver aucun travail traitant des bases de Schiff 4-MPBI et 6-MPBI. Au sujet de 4-MPSI et 6-MPSI nous avons trouvé une référence dans un travail de Császár et Balog (5) dans lequel ils étudient l'influence qu'exerce, sur la capacité complexante, l'introduction de groupes méthyles dans des positions différentes de l'anneau pyridinique et le type de liaisons de ces potentiels ligands tridentés.

Bien qu'on ne trouve plus d'information au sujet de nos azométhines, il y en a cependant quelques-unes qui se rapportent fondamentalement au *N*-(2-pyridyl)salicylaldimine dans les travaux de Pitea *et al.* (6), Geary *et al.* (7), Garnovskii *et al.* (8) et Holzbecher et Van Trung (9).

## Expérimental

*Produits*

Les produits employés sont de qualité réactive (Merck ou BDH) ou purifiés par nous.

*Synthèse—4-MPBI et 6-MPBI*

On condense des quantités équimoléculaires d'aldéhyde et d'amine dans l'éthanol. L'huile jaunâtre résultant de l'élimination du solvant à vide est insolubilisée avec du cyclohexane, on

*4-MPSI et 6-MPSI*

On condense des quantités équimoléculaires d'aldéhyde et d'amine dans l'éthanol. Le solvant et l'excès d'aldéhyde s'éliminent à vide. L'huile obtenue est dissoute dans l'éthanol chaud qui permet la cristallisation. On recristallise dans l'éthanol. 4-MPSI: cristaux jaunes; 90% de rendement; pf 98°C (litt. (5) pf 99,4°C). *Anal.* calc. pour $C_{13}H_{12}N_2O$: C 73,57; H 5,71; N 13,20; trouvée: C 73,20; H 5,67; N 13,06. 6-MPSI: cristaux aciculaires jaunes; 85% de rendement; pf 68°C (litt. (5) pf 65,8°C). *Anal.* trouvée: C 73,77; H 5,73; N 13,49.

*Appareil et mesures*

Spectrophotomètre ir Beckman 4240; thermoanalyseur Setaram GDTD-10, muni d'une électrobalance B-70 avec thermopaires Pt/Pt-Rh; spectrographe de masses Hewlett Packard 5930 A (70 eV) à 110°C de température de sonde; potentiomètre Methrom Herisau E-536 muni d'une burette automatique et d'électrodes en verre et calomel; spectrophotomètre uv–vis Beckman ACTA III; spectrofluorimètre Aminco–Bowman SPF.

Pour l'analyse thermique on a employé 10 mg d'échantillon dans un creuset en Pt de 5 mm de diamètre, en opérant dans une atmosphère statique d'air à la vitesse de 5°C/min. On a employé de l'alumine calcinée comme matériel de référence pour ATD, avec une particule du même ordre que celle de l'échantillon (> 63 nm).

On a étudié la stabilité des dissolutions spectrophotomètriquement, en régistrant la variation d'absorption avec le temps à la longueur d'onde du maximum de la bande K dans des dissolutions préparées récemment d'azométhine en milieu dioxane–eau 50% v/v; on a étudié également spectrofluorimétriquement en éthanol–eau 5% v/v en régistrant le spectre d'émission à des temps différents en excitant à 290 nm. Le maximum d'émission se trouve à 367 nm.

On a calculé les constantes de dissociation acide par l'application de la méthode directe, vu que des expériences précédentes ont démontré qu'entre $pK_1$ et $pK_2$ il existe une différence suffisante pour considérer les deux équilibres séparément. De cette façon on a calculé $pK_2$ de 4-MPBI et 6-MPBI et $pK_1$ de 4-MPSI et 6-MPSI, à partir des courbes de neutralisation obtenues en valorant l'acide conjugué de la base de Schiff présente. La valeur de $pK_2$ et $pK_3$ de ces dernières a été calculée par l'application de la méthode de Irving et Rossotti (10). On a opéré dans du dioxane–eau au 50% v/v de force ionique 0,1 *M* ($KNO_3$) et à 25, 0 ± 0,1°C.

L'étude de la réactivité qualitative en présence d'ions inorganiques a été effectuée dans des concentrations de 1 g/L. L'observation a été réalisée au moyen d'illumination avec lumière visible et uv (de 360 et 245 nm). Les réactions ont été étudiées dans toute la gamme de pH.

## Résultats et discussion

*Étude des propriétes des réactifs*

Les bandes ir assignées (comprimé de KBr) ont été réunies au tableau 1, où les fréquences caractéristiques des azométhines apparaissent. Nous remarquons la large bande entre 2500 et 3500 $cm^{-1}$ pour 4-MPSI et 6-MPSI, ce qui nous indique l'existence de forte association par liaison d'hydrogène. Les données obtenues ne concordent pas totalement avec les données bibliographiques (5), ainsi pour la ν (C=N) azométhinique que nous assignons à 1614 $cm^{-1}$ pour 4-MPSI et 1608 $cm^{-1}$ pour 6-MPSI, dans la bibliographie on l'indique à 1603 et 1619 $cm^{-1}$ respectivement.

Les principaux caractéristiques du spectre de rmn ($Cl_3CD$) sont enregistrées au tableau 2. Les données trouvées dans la bibliographie sont relativement en concordance (5) avec celles que nous avons trouvées excepté pour le signal du proton phénolique qu'ils assignent entre 12,16 et 13,69 ppm et nous entre les signaux aromatiques.

Seulement nous remarquons le fait que le proton azométhinique de la 4-MPSI et la 6-MPSI apparaît dans un champ plus bas que celui de deux autres. Phénomène qui appuie l'existence des liaisons d'hydrogène entre l'OH phénolique et le N iminique, le H azométhinique restant moins blindagé pour cette même raison. L'intégration nous donne dans tous les cas la relation 1:8:3 qui est correcte.

L'ensemble des données qu'offre le spectre de masses des quatre composés obéit au schéma fondamental de fragmentation de bases de Schiff

TABLEAU 2. Signaux fondamentaux du spectre de rmn des réactifs dans $Cl_3CD$

*Dans la parenthèse % abondance.

hétérocycliques étudié par Barnes *et al.* (11) (Schéma 1).

Les ions les plus grands que nous avons trouvés sont réunis au tableau 3. Les bases de Schiff que nous étudions nous montrent un spectre de masses en accord avec le spectre de la *N*-(2-pyridyl)benzaldimine (11). Le pic base est le *m/e* 93 qui correspond à la picoline protonée, lequel se trouve à *m/e* 93 et non à 92 dû à ce que l'hydrogène du carbone azométhinique se transfère a l'anneau pyridinique, la charge restant positive sur l'azote.

Le spectre ultraviolet réalisé à partir de dissolutions éthanoliques montre les bandes recueillies au tableau 4. De cette façon la bande $E_1$ a des longueurs d'onde inférieures à 220 nm et que l'on attribue à des transitions localisées dans le noyau pyridinique. La bande $E_2$ entre 260–270 nm que l'on assigne à la transition d'électrons que comprennent l'anneau benzolique et la double liaison azométhinique et enfin la bande K, bande de conjugaison. Dans 4-MPSI et 6-MPSI apparaît en plus une bande sur 350 nm qui appartient aux bandes de conjugaison (29).

L'analyse thermique des composés (Fig. 1) montre un comportement différent de 4-MPBI et 6-MPBI par rapport à ses hydroxy derivés (4-MPSI et 6-MPSI). Dans les deux premières on aperçoit un processus de volatilisation totale sur les 200°C (de manière analogue à ce que nous avons trouvé pour la 2-pyrilidenaniline (1)), tandis que dans la 4-MPSI et 6-MPSI, nous voyons un processus pyrolitique qui a deux étapes, dans la première une perte de l'anneau pyridinique (perte de poids expérimental: 4-MPSI 43,0%, 6-MPSI 43,3%; calculée 43,8%) et après une combustion du reste.

Les constantes de dissociation des réactifs que nous étudions ont été déterminées potentiométri-

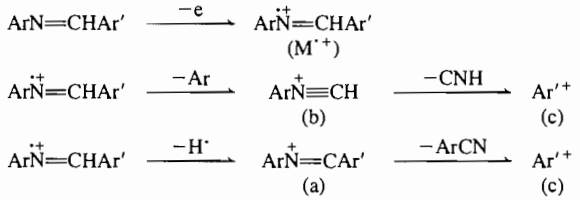

SCHÉMA I

TABLEAU 4. Bandes uv des réactifs en éthanol

| Base de Schiff | Bande $E_1$ | Bande $E_2$ | Bande K | |
|---|---|---|---|---|
| 4-MPBI | 213(4,53)* | 262(4,13) | 290(4,20) | — |
| 6-MPBI | 219(4,16) | 260(4,11) | 295(4,16) | — |
| 4-MPSI | 213(4,13) | 267(4,17) | 301(4,22) | 348(4,17) |
| 6-MPSI | 218(4,23) | 270(4,09) | 310(4,14) | 350(4,14) |

*Dans la parenthèse log ε.

quement, en milieu dioxane–eau au 50% v/v dans lequel ils sont solubles et relativement stables. Les temps de semidécomposition déterminés spectrophotométriquement, dans ces conditions, sont presque de deux heures pour 4-MPSI et 6-MPSI (d'accord avec ceux obtenus par Geary *et al.* (7)) et d'une heure pour 4-MPBI et 6-MPBI, et ils sont relativement élevés par rapport aux cinq minutes employées pour la valoration.

Etant donné le faible caractère basique des azotes, on a déterminé les constantes de dissociation des acides conjugués de ces bases. Les valeurs de p*K* obtenues sont indiquées au tableau 5. Le $pK_1$ de 4-MPBI et 6-MPBI n'est pas indiqué puisque quand on opère en milieu aussi acide, l'hydrolyse de ces deux composés est exaltée sans obtenir des valeurs reproductibles malgré que son ordre de grandeur soit près de 2.

Les constantes obtenues correspondent aux équilibres indiqués ensuite (7, 9, 12) (Schéma 2).

Les valeurs de $pK_2$ et $pK_3$ concordent avec celles des composés avec des fonctions semblables. Ainsi pour le salicylaldéhyde, Jones *et al.* trouvent une valeur de $pK_{OH}$ de 9,50 (13) tandis que nous trouvons pour 4-MPSI et 6-MPSI les valeurs de 9,18 et de 9,15 respectivement. On pourrait attribuer ces petites variations à ce que dans le premier cas est la liaison d'hydrogène avec un oxygène et dans notre cas avec l'azote azométhinique, le premier étant un peu plus fort que le second.

TABLEAU 5. Valeurs de p*K* des bases de Schiff

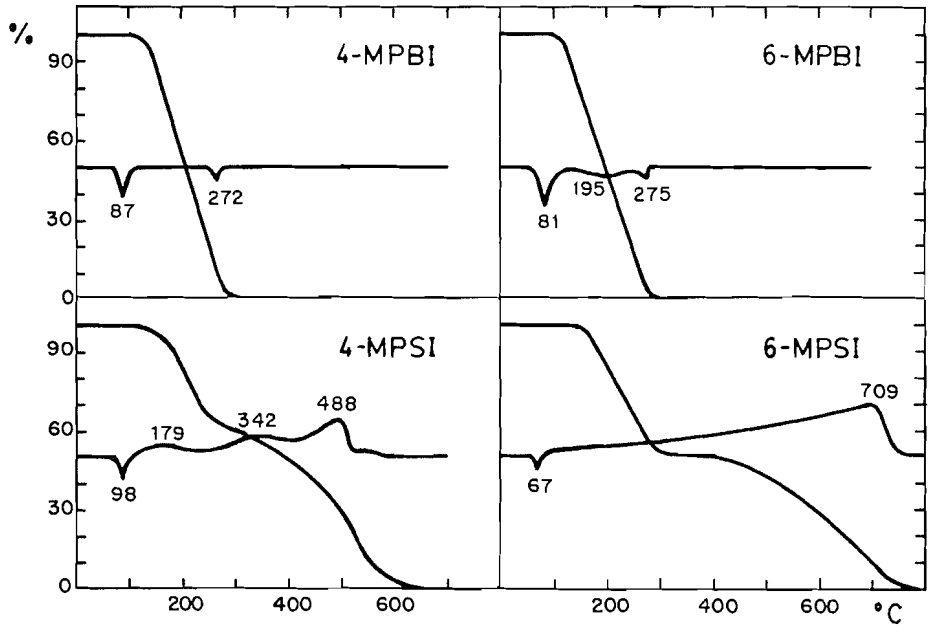

FIG. 1. Analyse thermique des azométhines.

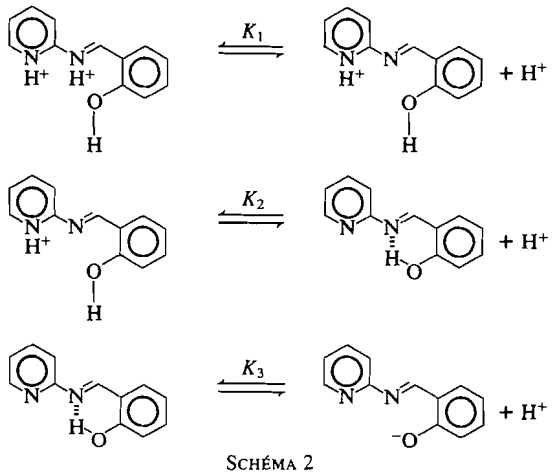

SCHÉMA 2

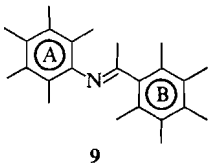
Pour la constante de dissociation de l'acide conjugué de l'aminopyridine, Maley et Mellor (14) ont donné la valeur 6,71. Les valeurs de $pK_2$ que nous avons trouvées pour les quatre bases de Schiff étudiées oscillent entre 6,6 et 6,82.

Par contre pour $pK_1$ de 4-MPSI et 6-MPSI nous trouvons des valeurs très basses malgré qu'en principe les azotes pyridiniques et azométhiniques montrent assez de similitude structurale.

Ce dernier fait a été observé dans les données bibliographiques et aussi dans les valeurs déterminées par nous pour d'autres bases de Schiff *N*-aromatiques. Cependant la valeur de p*K* azométhinique est du même ordre que le pyridinique quand il s'agit de bases de Schiff *N*-alkyldérivées. Dans le tableau 6 nous avons recueilli les valeurs de constantes qui démontrent l'affirmation précédente.

À notre avis, il faut chercher la raison de ce comportement, qui suppose que la paire électronique du nitrogène azométhinique n'est pas aussi capable que le pyridinique de former la liaison avec le proton, dans des considérations structurelles des bases de Schiff en général. On pourrait penser à priori que les bases de Schiff aromatiques (type bencylidenaniline) présentent une structure plane. Cependant il existe une série de faits expérimentaux, résumés par Pitea *et al.* (6), qui sont en contradiction avec la même. Cela est dû à l'existence d'une interaction estérique entre l'hydrogène azométhinique et l'hydrogène du carbone en *ortho* par rapport à l'azote iminique (**9**).



**9**

Dans le but de justifier les données expérimentaux en contradiction avec la structure plane on a proposé différentes hypothèses structurelles. La première indique que le nitrogène azométhinique passe d'un état d'hybridation $sp^2$ à un état $sp$, de cette façon l'angle Ar—N=C est de 180° et non de 120° et la molécule reste plane (23). Une deuxième hypothèse suppose que l'anneau B tourne par rapport au reste de la molécule d'un angle de 90° et

TABLEAU 6. Donnés bibliographiques de $pK_a$ de bases de Schiff aliphatiques et aromatiques

| Base de Schiff | $pK_1$* | $pK_2$ | $pK_3$ | Milieu | Méthode | Référence |

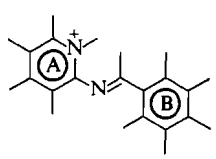
*$pK_1$: correspond au N azométhinique; $pK_2$ au N pyridinique; $pK_3$ au OH phénolique excepté pour 14 et 19. a: eau; b: eau–méthanol; c: eau–éthanol 5%; d: eau–éthanol 10%; e: dioxane–eau 50%. S: spectrophotométrie. P: potentiométrie.

pour cela tous les deux résultent orthogonaux, et de cette façon l'hybridation du nitrogène azométhinique est $sp^2$ (24). De cette façon il y a une conjugaison compétitive de la paire électronique du nitrogène entre la conjugaison qui rend la molécule plane et la conjugaison de la paire d'électrons avec les électrons de l'anneau B. Pour la troisième hypothèse il faut qu'il y ait rotation d'un anneau par rapport à l'autre, ainsi qu'un changement dans l'hybridation du nitrogène de $sp^2$ à $sp$, avec cela la paire libre du nitrogène azométhinique reste dans l'orbitale atomique $p$ et vient faire partie de la conjugaison de l'anneau B. Cela suppose l'existence de deux systèmes conjugués orthogonaux à l'intérieur de la molécule (25).

L'acceptation de la deuxième comme de la troisième hypothèse justifierait la basse basicité du nitrogène azométhinique par rapport au pyridinique, puisque cela suppose une dislocalisation effective de la paire électronique du nitrogène azométhinique. Cependant il faut tenir compte qu'étant donné que la plus grande interaction estérique est celle qui a lieu entre l'hydrogène azométhinique et l'hydrogène en *ortho* par rapport au pont iminique, il y aura une diminution de l'empêchement estérique par azosubstitution du carbone en *ortho* par rapport au nitrogène azométhinique, comme cela se produit précisément dans les bases de Schiff dérivées de la 2-aminopyridine. Sa conformation sera d'autant plus proche à la plane comme le démontrent Pitea *et al.* (6). Pour les bases de Schiff étudiées par nous, dérivées de la 2-amino-X-méthylpyridine, on peut penser à une structure conformationnelle analogue, c'est-à-dire proche de la plane. Cependant nous avons trouvé très peu de basicité, ce qui n'est pas en accord avec une structure proche à la plane pour des bases de Schiff dérivées de la 2-aminopyridine.

On pourrait justifier ceci si nous tenons compte du schéma de protonation, que nous avons déjà proposé, dans lequel le premier nitrogène qui se protone est le pyridinique, de cette façon nous arrivons à une structure similaire à celle de la benzylidénaniline, en obligeant à un changement de conformation vers une autre forme plus tournée et donc a une plus grande conjugaison de la paire du nitrogène avec l'anneau pyridinique et de cette façon la basicité diminuera beaucoup (**10**).

Un dernier fait à commenter, c'est que les valeurs de $pK_1$ trouvées par nous sont plus petites que celles que nous avons trouvées pour des azométhines analogues, tandis que les valeurs de $pK_2$ sont notamment plus grandes. On pourrait justifier ceci en considérant que la 2-aminopyridine



**10**

présente une structure de résonance entre les deux nitrogènes, comme cela a été démontré par Angyal et Angyal (26), et à la suite de quoi le proton s'unira de préférence au N pyridinique et ce sera une base plus forte que la pyridine ($pK_a$ pyridine: 5,23 (27);

*Dans la parenthèse on indique la sensibilité comme cologarithme de la concentration limite (p$D$).
†p = précipité.

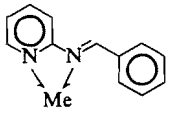
p$K_a$ 2-aminopyridine 6,71 (14); 2-amino-6-méthylpyridine: 7,41 (28)). On peut suggérer une résonance similaire pour les bases de Schiff étudiées, ce qui justifierait les valeurs basses de p$K_1$ du N azométhinique et les hautes valeurs de p$K_2$ du N pyridinique de la même façon que Geary *et al.* (7), qui a justifié le fait que la *N*-(2-pyridyl)salicylaldimine ajoute un proton comme base à cette hypothèse. Cependant en opérant dans les conditions adéquates on peut déterminer le p$K_1$ qui, comme on peut s'y attendre, est exceptionnellement bas.

*Réaction avec des ions métalliques*

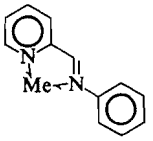
Les résultats dans la réactivité qualitative en présence d'ions inorganiques sont montrés au tableau 7, où nous pouvons apprécier qu'elle est peu abondante pour les quatre azométhines, bien qu'elle soit plus grande pour les *o*-hydroxydérivées.

Dans la comparaison des résultats obtenus quand nous étudions la réactivité de la 4-MPBI et de la 6-MPBI avec celle qui correspond à la 2-pyrilideneaniline (**1**) nous pouvons voir que les deux premières ont une réactivité plus petite, les réactions de cette dernière étant plus sensibles. Ainsi, par exemple, pour la réaction avec Fe(II), la sensibilité pour les deux premières est du p$D$ = 4,8, tandis que pour le 2-pyrilideneaniline elle est de 6,3.

On peut attribuer cette différente réactivité au fait que la 4-MPBI, comme la 6-MPBI, à la groupe azométhinique inverti par rapport à la 2-pyrilideneaniline et de cette façon les complexes de deux premières formeraient des anneaux de cinq membres (**11** et **12**).



**11**



**12**

La comparaison de réactivité entre la 4-MPSI et la 6-MPSI avec la 2-pyrilidene-*o*-hydroxyaniline, nous amène à une conclusion similaire. La 6-MPSI réagit avec 8 ions et la 4-MPSI avec 9 parmi tous ceux que nous avons essayés, tandis que la 2-pyrilidene-*o*-hydroxyaniline réagit avec 45 ions. La plus grande sensibilité trouvée pour les trois réactifs correspond à la réaction avec le Ni(II) dont les p$D$ sont 5,5 (6-MPSI), 5,7 (4-MPSI) et 7,2 (2-pyrilidene-*o*-hydroxyaniline). Ce comportement différent dans les composés qui possèdent les mêmes groupes chelants est dû, comme dans le cas précédent, à la différente position que ceux-ci occupent dans la molécule.

La 2-pyrilidene-*o*-hydroxyaniline agit comme tridenté en formant deux métallocycles de cinq membres, tandis que les deux autres le font comme tridentés en formant un métallocycle de six et un autre de quatre, ou comme bidenté en formant un métallocycle de six membres.

Quelques-uns des complexes formés, ceux de Fe(II), Ni(II), $UO_2$(II), Co(II) et Cu(II), sont partiellement extractibles en $CHCl_3$ et donnent une couleur jaune à la couche organique, excepté avec celui de Fe(II) qui donne une couleur rouge. La sensibilité trouvée est basse dans tous les cas (p$D$ = 5,7).

Quand nous étudions la réactivité de ces composés avec Al(III), Be(II) et Zn(II) on obtient des produits fluorescents, fluorescence engendrée par hydrolyse des bases de Schiff, catalysée par ces ions métalliques. Dans le cas du Be(II) la fluorescence est particulièrement intense (p$D$ = 7,2) et selon Holzbecher et Van Trung (9) elle est due à la formation d'un composé avec salicylaldéhyde.

Les dissolutions de 6-MPSI et 4-MPSI présentent une fluorescence jaune en milieu basique en l'absence d'ions métalliques. Dans ce milieu apparaît lentement et dans le milieu acide plus rapidement une fluorescence violette qui est due, selon ce que nous avons prouvé, aux amines obtenues par hydrolyse des réactifs. On observe que, quand nous diminuons le pH, la vitesse d'hydrolyse augmente en accord avec les résultats de Cordes et

Jencks (16) et Koehler *et al.* (15) dans l'étude des bases de Schiff aromatiques, qui indique qu'il existe une catalyse acide–base du processus d'hydrolyse.

# Complexes de Cu(II), Co(II), Ni(II) et $UO_2$(II) avec les bases de Schiff *N*-(4-méthyl-2-pyridyl)salicylaldimine et *N*-(6-méthyl-2-pyridyl)salicylaldimine

L. F. Capitán-Vallvey, C. Jiménez et L. Cuadros

*Département de Chimie Analytique de la Faculté des Sciences de l'Université de Granada et Département de Recherches Chimiques du C.S.I.C., Granada, Espagne*

Reçu le 25 septembre 1981

L. F. Capitán-Vallvey, C. Jiménez et L. Cuadros. Can. J. Chem. **60**, 1713 (1982).

On isole les complexes des bases de Schiff *N*-(4-méthyl-2-pyridyl)salicylaldimine et *N*-(6-méthyl-2-pyridyl)salicylaldimine avec Co(II), Ni(II), Cu(II) et $UO_2$(II) aussi bien en milieu hydroalcoolique qu'en milieu éthanolique absolu. On remarque une forme différente d'agir en tant que ligands de ces bases de Schiff suivant le milieu. D'ailleurs, les complexes déjà nommés en milieu hydroalcoolique ont une capacité remarquable de réaction face à des substances présentes en solution. On propose deux nouvelles méthodes gravimétriques pour le dosage du Ni(II) et $UO_2$(II).

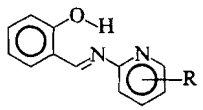
L. F. Capitán-Vallvey, C. Jiménez, and L. Cuadros. Can. J. Chem. **60**, 1713 (1982).

We have isolated the complexes of the Schiff bases *N*-(4-methyl-2-pyridyl)salicylaldimine and *N*-(6-methyl-2-pyridyl)salicylaldimine with Co(II), Ni(II), Cu(II), and $UO_2$(II) in both aqueous alcoholic and absolute alcoholic solutions. We note different modes of action of these Schiff bases according to the medium used. However, in aqueous alcoholic solution the complexes mentioned have a remarkable capacity for reaction with the substances in solution. We propose two new gravimetric methods for Ni(II) and $UO_2$(II).

[Journal translation]

## Introduction

Dans une publication précédente (1), nous avons commencé l'étude des bases de Schiff *N*-(4-méthyl-2-pyridyl)benzaldimine (4-MPBI) et *N*-(6-méthyl-2-pyridyl)benzaldimine (6-MPBI), de même que celle de leurs *o*-hydroxydérivés: *N*-(4-méthyl-2-pyridyl)salicylaldimine et *N*-(6-méthyl-2-pyridyl)salicylaldimine (4-MPSI et 6-MPSI respectivement). Après avoir synthétisé ces composés, nous en étudions diverses propriétés et, parmi d'autres, leur réactivité en face d'ions inorganiques. Dans ce travail nous essayons d'élargir la connaissance des chélates métalliques qui forment les composés 4-MPSI et 6-MPSI en étudiant les complexes de Co(II), Ni(II), Cu(II) et $UO_2$(II).



**1** R = H
4-MPSI R = 4-$CH_3$
6-MPSI R = 6-$CH_3$

Dans la bibliographie consultée il existe un nombre réduit de données sur la capacité complexante des bases de Schiff dérivées de la 2-aminopyridine. Les seules données existantes sur 4-MPSI et 6-MPSI sont dues à Császár et Balog (2) qui étudient les complexes de Ni(II) en milieu chloroformique et acétonique et leur attribuent les formules $(4\text{-MPSI})_2Ni\cdot 2H_2O$ et $(6\text{-MPSI})_2Ni$, en agissant 4-MPSI comme ligand bidenté et 6-MPSI comme tridenté.

Au sujet de la *N*-(2-pyridyl)salicylaldimine (**1**) composé très lié aux ligands à l'étude, et qui doit se conduire de façon similaire à ceux-ci, Geary *et al.* (3) remarquent que celui-là agit comme ligand bidenté en dissolution (dioxane–eau 50%), où ils ont établi potentiométriquement l'existence d'un complexe de Cu(II) 2:1 (L:Cu) et la libération pendant la complexation d'un proton par molécule de ligand. Ils indiquent de même la possibilité pour le ligand d'agir comme tridenté, en se basant sur le fait qu'ils ont isolé le complexe **1**-CuCl en milieu éthanolique.

Garnovskii *et al.* (4), de leur côté, informent sur l'obtention du complexe $TiCl_4$-**1** en benzène, et ils supposent que la complexation a lieu à travers des nitrogènes azométhinique et pyridinique, sans l'intervention du groupe OH dans la chélation. Verkhovodova et coll. (5) obtiennent, d'après eux, dans du méthanol le complexe $Cu(\mathbf{1})_2$, où les atomes coordonnants sont le N azométhinique et le O phénolique avec la perte du proton correspondant.

Holzbecher et Van Trung (6), de leur côté, étudient les complexes de **1** avec Zn(II) et Be(II), et remarquent la formation de composés de stoechiométrie 1:1 et 2:1 respectivement, bien qu'ils ne les isolent pas en tant que solides.

Enfin Mahmoud et El-Haty (7) isolent les complexes solides de **1** avec Co(II), Ni(II), Cu(II), $UO_2$(II) et Th(IV), en opérant en éthanol absolu, et ce sont les bases de Schiff non déprotonnées qui agissent comme des ligands bidentés. L'enchaîne-

ment a lieu à travers du N azométhinique et du groupe OH phénolique.

## Partie expérimentale

*Produits employés*

*N*-(4-méthyl-2-pyridyl)salicylaldimine et *N*-(6-méthyl-2-pyridyl)salicylaldimine synthétisés par le procédé indiqué dans une publication précédente (1). Dissolutions de Co(II), Ni(II) et Cu(II) (à partir de nitrates et de chlorures) et de $UO_2$(II) (à partir de nitrates et d'acétates) $10^{-2}$ *M* en éthanol absolu et éthanol–eau 1:1. Cela a été étalonné comme d'habitude. Ces mêmes sels sont employés pour la synthèse de complexes solides.

*Synthèse des complexes métalliques*

1. *Synthèse en milieu hydroalcoolique*

Les complexes ont été obtenus en ajoutant à la solution aqueuse du sel métallique une solution éthanolique de la correspondante base de Schiff en proportion molaire 1:2. Les produits obtenus, comme nous commenterons plus tard, sont différents selon le milieu – neutre, ammoniacal ou basique fort – où ils sont obtenus. De même leur constitution diffère également si après avoir été précipité le complexe est filtré immédiatement ou par contre est soumis à digestion. Le temps de digestion a été, dans ce cas, de deux heures à 60°C. Les produits obtenus, après avoir été filtrés, ont été lavés avec de l'éthanol chaud et désséchés à vide sur $CaCl_2$ et $H_2SO_4$.

2. *Synthèse en milieu éthanolique absolu*

Au sel métallique dissous en éthanol absolu on ajoute dissolution éthanolique des bases de Schiff en relation molaire 1:2 et l'on maintient à reflux pendant une heure. Et on continue l'obtention dans la forme ci-dessus indiquée. Au tableau 1 on indique les complexes obtenus à partir de 4-MPSI, 6-MPSI, salicylaldéhyde et salicylaldimine, leur couleur, le milieu utilisé et les résultats de l'analyse de nitrogène et métal déterminés par des méthodes conventionnelles.

*Mesures physiques*

On a utilisé un spectrophotomètre uv–vis Beckman ACTA III muni de cuvettes de quartz d'un centimètre et un spectrophotomètre ir Beckman mod. 4240. Les mesures de conductivité sur des dissolutions éthanoliques $10^{-4}$ – $10^{-5}$ *M* en complexe, ainsi que les données précises pour la détermination du produit de solubilité ont été obtenues avec un conductimètre Radiometer mod. CDM2e. La diffraction de rayons X a été réalisée dans un appareil Philips PW 1060, le TG-ATD dans un équipement SETARAM GDTD-10, muni d'une électrobalance B-70 dans les conditions spécifiées dans une publication précédente (1). Pour les titrages conductimétriques on a utilisé un équipement Metrohm–Herisau comportant un conductoscope E 365B, une burette automatique E 536 et une cellule de conductivité EAG08. Toutes les courbes de titrage obtenues, en ajoutant à la dissolution éthanolique du cation celle du réactif au même milieu, ont été corrigées compte tenu de la dilution. De celles qui ont été réalisées en milieu hydroalcoolique on a tenu compte de l'effet de la dilution et de la variation de la constante diélectrique du milieu lorsqu'on ajoute du réactif dans l'éthanol.

## Résultats et discussions

L'étude a été réalisée en essayant d'obtenir les chélates en milieu éthanol–eau ou en éthanol absolu et en changeant le pH des dissolutions.

1. *Milieu hydroalcoolique (1:1)*

En ce milieu on n'a observé qu'un réaction en solution neutre et basique, et l'on a vérifié que les produits de réaction dépendent aussi bien de la base utilisée que des conditions opératoires.

(a) En milieu neutre, Co(II), Ni(II) et Cu(II) provoquent avec 6-MPSI et 4-MPSI l'apparition de précipités dont la couleur évolue par digestion. Après avoir isolé les différentes phases solides et les avoir étudié dans la forme que l'on indique ensuite, on arrive à la conclusion que bien que les deux bases de Schiff forment d'abord des complexes de stoechiométrie 2:1 (L:Me), après, pendant le processus de digestion à 60°C, elles se transforment en bissalicylaldéhydo-complexes, d'après l'équation [1].

En effet, les solides isolés immédiatement après leur formation sont des complexes des bases de

[1] 
Schiff avec Co(II), Ni(II) et Cu(II) tel que le démontre l'analyse élémentaire (Tableau 1). Les données de conductivité (Tableau 2) indiquent qu'ils ne sont pas des electrolytes, ce qui suppose, en principe, que le groupe phénolique des réactifs se déprotonne préalablement à la formation du complexe. Le spectre ir (Tableau 3) corrobore ces extrêmes car il n'apparaît dans les complexes ni la vibration ν (OH) (ca. 3400 $cm^{-1}$), ni la δ (OH) (ca. 1280 $cm^{-1}$) qui apparaissent dans les réactifs. D'autre part, les vibrations de ν (C=N) azométhinique et pyridinique apparaissent dans des fréquences légèrement inférieures dans les complexes plutôt que dans les réactifs (sur 10 $cm^{-1}$ pour les complexes de 4-MPSI et de 2 $cm^{-1}$ pour ceux de 6-MPSI dans la vibration ν (C=N) azométhinique). Ce fait pourrait être en rapport avec un accroissement dans l'ordre de liaison du groupe azométhinique, tel que Teyssie et Charette (8) l'indiquent, dû à l'existence d'une conjugaison croisée du métallocycle formé par rapport au reste de la molécule.

Les donnés du spectre uv–vis de ces complexes sont montrées au tableau 2. Dans les deux réactifs apparaissent deux bandes, la première d'une plus grande longueur d'onde (350 nm) (9, 10) et qui par complexation se déplace vers de plus grandes longueurs d'onde (400–440 nm) grâce au fait que la présence de l'atome métallique facilite le transfert de charge; la deuxième d'une moindre longueur d'onde (300 nm), née de transitions $\pi \rightarrow \pi^*$ qui embrassent toute la molécule et qui se modifie légèrement par complexation (305–325 nm).

Comme nous avons déjà indiqué, la digestion de ces complexes provoque la formation de salicylaldéhydo-complexes, lesquels ont été identifiés au moyen d'une analyse élémentaire (Tableau 1) et du spectre ir (Tableau 3). La donnée plus expressive du spectre est l'apparition de la ν (C=O) à 1645 $cm^{-1}$. Il y a lieu d'attribuer le processus de transformation en premier lieu à la tendance hydrolytique de ces bases de Schiff, déjà mise en évidence dans une publication précedente (1) et remarquée par Geary *et al.* (3), et en deuxième lieu, peut-être, à la plus grande stabilité des salicylaldéhydo-complexes.

TABLEAU 2. Bandes des spectres uv–vis des complexes et coefficient d'extinction molaire dans éthanol. Valeurs de conductance des complexes dans DMF

(b) En milieu ammoniacal se forment des composés solides. Nous avons vérifié que ces phases solides sont, sauf celle de Co(II), salicylaldimine-complexes formées par réaction de l'ammoniac sur les complexes des bases de Schiff. Ces complexes ont été caractérisés par analyse élémentaire (Tableau 1) et spectroscopie ir (Tableau 3) où apparaît la bande caractéristique ν (NH) environ 3300 $cm^{-1}$.

Bien que nous n'ayons pas étudié le mécanisme de cette réaction de substitution d'amine il y aurait lieu de penser, suivant Nuñez et Eichhorn (11) que la réaction passe à travers d'une attaque nucléophilique de l'ammoniac sur le carbone azométhinique de la base de Schiff complexée avec l'ion métallique, alors la réaction a lieu grâce, d'une part, au fait que le $NH_3$ possède un caractère basique très supérieur à celui des 2-aminométhylpyridines (12, 13), et, d'autre part, à l'insolubilité des salicylaldimine complexes formés (équation [2]).

[2] 
Dans le cas du cobalt la transformation ne se produit pas due, nous croyons, à la facile oxydation de celui-ci à cobaltiammines stables dont la présence a été détectée en essayant de synthétiser le complexe. Seul dans le cas où l'on ajoute une très petite quantité de $NH_3$ on obtient les complexes de Co(II) avec les bases de Schiff ci-dessus commentées, des complexes qui se dissolvent à nouveau dans un excès de $NH_3$.

(c) En milieu basique de NaOH on a obtenu des complexes avec les bases de Schiff à l'étude, avec des propriétés et stoechiométrie identiques aux isolés en milieu neutre. Ces complexes des bases de Schiff doivent être isolés très rapidement, car si on les laisse en digestion à 60°C, ils se transforment dans les correspondants oxydes métalliques comme il a été démontré en enregistrant le spectre ir qui a montré toute une absence de bandes dues au ligand, ainsi que la présence des bandes correspondantes aux oxydes. Pour NiO: 651m et 460m (litt. (14) 650m et 465s); CuO: 611m, 490s et 412m (litt.

[a]Celle-lá est comprise dans la bande large ν (C=N)$_{az}$.

610m, 500s et 410m); CoO: 650m, 570s, 465b (litt. 655s, 562s et 460b). En outre, l'analyse élémentaire a été réalissée; calculée: CuO 79,88, NiO 78,58, CoO 78,65; trouvée: CuO 79,41, NiO 78,06, CoO 78,47.

On n'obtient pas dans ce cas les salicylaldéhydocomplexes qui proviendraient de l'attaque nucléophilique du $OH^-$ au carbone azométhinique, puisqu'on a vérifié que ces complexes sont instables en dit milieu basique en se dissolvant et en précipitant les cations métalliques tels des oxydes (équation [3]).

[3] 

Il faut remarquer d'une manière spéciale (cela a été déjà fait dans la publication précédente (1)) la réaction avec $UO_2$(II) car elle revêt des caractéristiques spéciales. Elle provoque avec les deux réactifs en milieu neutre des phases solides couleur orange. Nous avons montré que tels solides sont les complexes (4-MPSI)$_2UO_2$ et (6-MPSI)$_2UO_2$, lesquels diffèrent remarquablement dans leur solubilité, car tandis que le dérivé de la 4-MPSI est insoluble, celui de la 6-MPSI est relativement soluble. On a déterminé la constante du produit de solubilité de (4-MPSI)$_2UO_2$, par des mesures conductimétriques dans l'eau (conductance molaire à dilution infinie de l'anion de 4-MPSI 80,4 $ohm^{-1}$ $cm^2$ $mol^{-1}$) qui résulte de $1,3 \pm 0,1 \times 10^{-15}$. Si l'on tient compte du fait que la solubilité molaire du complexe est insignifiante, la solubilité ionique présente une valeur de $7 \times 10^{-6}$ mol $L^{-1}$.

D'ailleurs, le spectre ir des uranylcomplexes, de même que les autres complexes, ne montre pas les bandes ν (OH) et δ (OH). D'autre part, les ν (C=N) pyridinique et azométhinique se déplacent, dans ce cas, en sens inverse, bien qu'avec une magnitude pareille à celle des autres complexes étudiés, où ν (C=N) azométhinique varie davantage que la ν (C=N) pyridinique. Tel qu'il a été indiqué par quelques auteurs (15, 16) ce fait peut se rapporter à une diminution de l'ordre de liaison du groupe C=N, dû à la haute électronégativité des oxygènes du $UO_2$(II). Il y a lieu de penser aussi que cette diminution de l'ordre de liaison est compensée par une stabilisation des cycles formés par le $UO_2$(II) avec la base de Schiff, ce qui est d'accord avec les données fournies par Geary *et al.* (3), lesquelles prouvent que la constante de stabilité du complexe $UO_2$(II) – 2-pyridylsalicylaldimine est plus grande que celle des complexes de Cu(II), Co(II), et Ni(II) ($\log K_1 = 8,1$ face à 7,3, 5,3 et 4,9 respectivement).

Il est à remarquer, par ailleurs, que tandis que le composé (4-MPSI)$_2UO_2$ ne s'altère pas par digestion, le dérivé de la 6-MPSI se transforme en un autre solide jaune qui, d'après les données suivantes, est $UO_3 \cdot 2H_2O$ (% U calculé: 73,91; trouvé: 73,52). L'analyse thermique indique la présence de

deux molécules d'éau (% $H_2O$ calculé: 11,19; trouvé: 10,97). Le spectre ir ne présente pas les bandes correspondants au ligand organique, tandis qu'il présente les bandes correspondantes à $UO_3$ ($\nu_1 = 840\,cm^{-1}$ et $\nu_3 = 935\,cm^{-1}$ (14)). La diffraction de rayons X montre un diagramme dont les lignes fondamentales apparaissent à 7,25 (*I/I* 100), 3,21 (50) et 3,35 (40), ce qui s'accorde avec ce qui a été indiqué par Debets et Loopstra (17) pour le $UO_3 \cdot 2H_2O$ dans sa forme β (orthorhombique).

Cette réaction de démolition du complexe pourrait être représentée par la équation [4].

[4] 2 

2. *Milieu éthanolique*

En ce milieu on a obtenu le complexe (6-MPSI)-$CuCl_2$, composé non électrolyte et dont le spectre ir montre, en outre des bandes déjà commentées, une à 3460 $cm^{-1}$ due à ν (OH) et une autre à 1318 $cm^{-1}$ de δ (OH), ce qui indique que le groupe phénolique se coordonne, dans ce cas, sans perdre son proton.

On a synthétisé les complexes de $UO_2$(II) à partir de $UO_2(NO_3)_2$, et prouvé qu'ils ne sont pas des électrolytes avec stoechiométrie 2:1 et spectre ir identiques à ceux obtenus en milieu hydroalcoolique. Le complexe de $UO_2$(II) obtenu à partir du $UO_2(CH_3—COO)_2$ répond à la formule (6-MPSI)-$UO_2(CH_3—COO)$, il n'est pas un électrolyte et ne présente pas la bande ν (OH) ni δ (OH).

## Discussion

En milieu hydroalcoolique il y a lieu de déduire que 4-MPSI et 6-MPSI agissent comme des ligands bidentés s'enchaînant à travers du nitrogène azométhinique et l'oxygène phénolique, après avoir fait une déprotonnation des réactifs. Cela prouve, à notre avis, la disparition des fréquences ν (OH) et δ (OH) du réactif dans le spectre ir des complexes, ainsi que la légère variation de la ν (C=N) pyridinique par complexation, excepté les complexes de $UO_2$(II) où l'on observe une plus grande variation, laquelle est du même ordre que celle que l'on remarque pour la ν (C=N) azométhinique. Cependant nous ne pensons pas que le ligand agisse comme tridenté face au $UO_2$(II), puisque la variation de la ν (C=N) pyridinique malgré tout est petite (12 $cm^{-1}$) en comparaison avec les 50 $cm^{-1}$ de variation trouvés par Garnovsky *et al.* (4) pour le complexe Ti(2-pyridylsalicylaldimine)$Cl_4$.

Les résultats obtenus des titrages conductométriques en ce milieu s'accordent avec les stoechiométries attribuées aux complexes solides (2:1) et l'on trouve en plus ceux de stoechiométrie 1:1 (Fig. 1).

Dans de l'éthanol absolu le groupe OH agit comme coordonnant, c'est-à-dire sans se déprotoner préalablement. Voilà ce qui est déduit des données citées avant et qui s'accorde avec les données trouvées par Mahmoud et El-Haty (7) dans leur étude des complexes de la 2-pyridylsalicylaldimine avec plusieurs ions métalliques. Les complexes de $UO_2$(II) obtenus en ce milieu, où l'on remarque que la groupe phénolique subit toujours une déprotonation, sont un cas à part.

Il y a une influence du sel de $UO_2$(II) dès le debut sur le complexe obtenu. Si l'on part de $UO_2(NO_3)_2$ le complexe est de stoechiométrie 2:1. Par contre l'emploi de $UO_2(CH_3—COO)_2$ en provoque un de stoechiométrie 1:1. Ces stoechiométries ont été

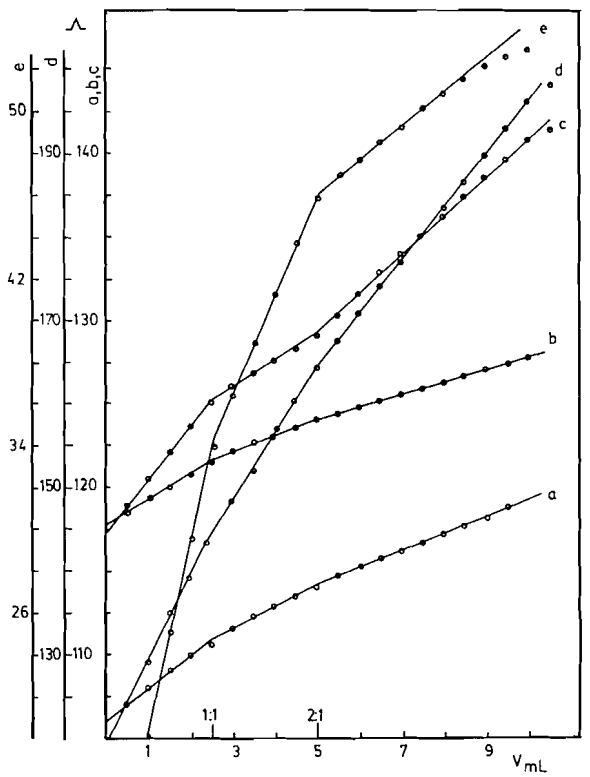

FIG. 1. Titrages conductimétriques en milieu hydroalcoolique 50%. [Me] = $10^{-3}$ *M*; [L] = $10^{-2}$ *M*; T = 25°C ± 0,1. a: Ni(II), b: Co(II), c: $UO_2$(II) ($NO_3^-$), d: Cu(II), e: $UO_2$(II) ($CH_3—COO^-$).

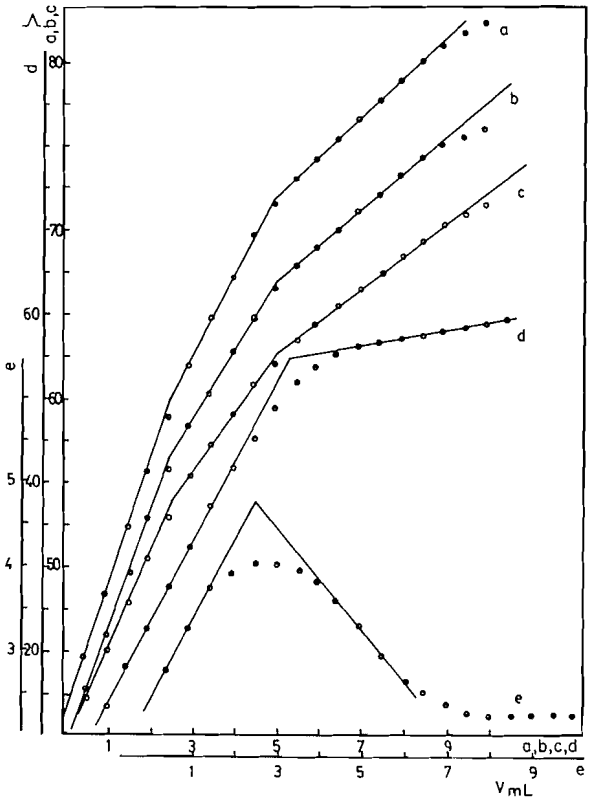

FIG. 2. Titrages conductimétriques en milieu éthanolique. [Me] = $10^{-3}M$; [L] = $10^{-2}M$; T = 25°C ± 0,1. a: Cu(II), b: Ni(II), c: Co(II), d: $UO_2$(II) ($NO_3^-$), e: $UO_2$(II) ($CH_3$—$COO^-$).

conformées au moyen d'une titration conductimétrique (Fig. 2). La structure de ce dernier complexe ne peut s'expliquer qu'en acceptant que le ligand agisse comme tridenté, hypothèse peu vraisemblable car cela supposerait une structure octaédrique avec une tension remarquable ou bien que l'acétate agisse comme ligand bidenté. À l'appui de cette dernière hypothèse nous trouvons que la ν (C═O) de la groupe acétate apparaît à 1527 $cm^{-1}$ et la ν (C—O) à 1436 $cm^{-1}$, c'est un déplacement à des fréquences plus petites que la première (1560 $cm^{-1}$ en acétate libre) et à des fréquences plus grandes que la deuxième (1416 $cm^{-1}$), ce qui suppose une différence entre les deux fréquences dans le complexe de 91 $cm^{-1}$, ce qui s'accorde avec les données présentées par Itoh et Berstein (18), qui trouvent une différence entre les deux fréquences de l'ordre de 80 $cm^{-1}$ dans la façon d'agir comme ligand bidenté de l'acétate et de l'ordre de 250 $cm^{-1}$ lorsqu'il agit comme monodenté.

Ces données contredisent les résultats obtenus par Mahmoud et El-Haty (7) pour le complexe de $UO_2$(II) avec 2-pyridylsalicylaldimine, puisqu'ils indiquent que la groupe se coordonne sans le perte de $H^+$.

On n'a observé qu'une influence de la différente position de la groupe méthyl avec la solubilité des complexes, les complexes de 4-MPSI étant dans tous les cas plus insolubles. Ces différences de solubilité ont été également observées dans les bases de Schiff et amines dès le commencement.

*Applications analytiques*

On propose l'emploi de ces réactifs pour l'analyse gravimétrique de $UO_2$(II) et Ni(II).

1. La détermination de $UO_2$(II) se réalise moyennant 4-MPSI (entre 0,07 et 0,2 g de U) en agissant à pH 3–5 ajusté avec $HNO_3$ et précipitant et pesant comme $(4\text{-MPSI})_2UO_2$ après avoir séché à 105–110°C (facteur gravimétrique 0,3437). L'erreur relative de la détermination est 0,1% et le nombre d'interférences petit, et celle de Fe(III) et Pd(II) se remarquent.

2. La détermination de Ni(II) (entre 0,015 et 0,075 g de Ni) se réalise moyennant 6-MPSI en milieu ammoniacal, ce qui suppose une précipitation homogène (par synthèse *in situ* de la salicylaldimine qui est le réactif de précipitation), en pesant à l'état de bissalicylaldiminate de Ni(II) (facteur gravimétrique 0,1905). L'erreur relative de la détermination est 0,14% et réduit le nombre d'interférents dont nous remarquons Co(II), Cu(II) et $UO_2$(II).

## Conclusions

1. On observe une influence remarquable du milieu dans la façon d'agir des bases de Schiff 4-MPSI et 6-MPSI. En milieu hydroalcoolique les ligands se coordonnent comme des anions avec les ions métalliques étudiés à travers du N azométhinique et le O phénolique après avoir perdu le proton. En milieu éthanolique ils s'enchaînent à travers du N azométhinique et le OH phénolique sans déprotonation préalable, excepté dans le cas du $UO_2$(II) où la coordination a lieu comme en milieu hydroalcoolique.

2. Les complexes tendent à réagir avec des substances présentes au milieu hydroalcoolique en provoquant des composés plus stables.

3. Le complexe de 4-MPSI avec $UO_2$(II) et le produit de réaction de Ni(II) avec 6-MPSI peuvent être utilisés comme des méthodes analytiques pour la détermination gravimétrique de ces ions.

# An infrared study of the photoisomerization of *N*-benzylideneaniline

J. W. LEWIS AND C. SANDORFY

*Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1*

Received August 25, 1981

J. W. LEWIS and C. SANDORFY. Can. J. Chem. **60**, 1720 (1982).

The infrared spectra of Nujol solutions and thin polycrystalline films of *N*-benzylideneaniline have been investigated. The 313 nm irradiation of ambient temperature samples produces no observable changes in the infrared spectra, however, similar irradiation of samples maintained at 77 K results in spectral changes that are thermally and photochemically reversible. The infrared spectra of low temperature irradiated samples are interpreted in terms of *trans* → *cis* photoisomerization.

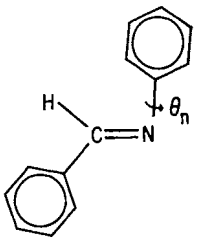
J. W. LEWIS et C. SANDORFY. Can. J. Chem. **60**, 1720 (1982).

Les spectres infrarouges de l'*N*-benzylideneaniline en solution dans le Nujol ont été examinés. L'irradiation à 313 nm à la température ambiante ne produit aucun changement observable dans le spectre ir; cependant à 77 K cette irradiation provoque des changements qui sont réversibles thermiquent aussi bien que photochimiquement. Ce dernier spectre est interprété en termes d'une photoisomérisation *trans* → *cis*.

## Introduction

Despite some early doubts (1) as to the existence of more than one stable geometric form of anils or of other compounds that contain the carbon–nitrogen double bond, the experimental evidence is now overwhelmingly supportive of at least two stable geometric isomers. Kuhn and Weitz (2) proposed that a *syn* ⇌ *anti* photoisomerization about a carbon–nitrogen double bond was reponsible for reversible color changes which result from the irradiation of triphenylformazan. Fisher and Frei (3) have demonstrated beyond any doubt that reversible ultraviolet spectral changes result from the irrradition of low temperature solutions of *N*-benzylideneaniline and *N*-(1-naphthylidene)-1-naphthylamine. These authors proposed that the observed, reversible spectral changes were due to a *trans* → *cis* photoisomerization with respect to the C=N bond. Following this pioneering work, there have been several studies (4–7) of the phenomenon by means of ultraviolet absorption and nuclear magnetic resonance techniques. Other groups (8, 9) have studied the thermal *trans–cis* isomerization and have reported activation energies of 61.0 to 78.6 kilojoules per mole.

In addition to the above studies of the *trans–cis* isomerization, there have been others (10–17, and references therein), both theoretical and experi the structure and conformation of Schiff bases. the structure and confrontation of Schiff bases. There has been some controversy regarding the planarity of *N*-benzylideneaniline, but it now appears certain that the aniline nucleus is twisted with respect to the plane of the remainder of the molecule. X-ray analysis (18) indicates that the angle of twist, $\theta_n$, is near 55.1° for *N*-benzylideneaniline. By



means of photoelectron spectroscopy, Bally *et al.* (19) estimate $\theta_n$ as 36° and, by means of gas phase electron diffraction, Traetteburg *et al.* (20) have determined that $\theta_n$ equals 52°. Akaba *et al.* (12, 13) estimate a solution phase $\theta_n$ of 30–35° and a gas phase $\theta_n$ of 48–55°.

The thermally stable form of *N*-benzylideneaniline is reported to be the *trans* form (18–21). As outlined above, a wealth of ultraviolet spectral changes regarding the *trans* → *cis* photoisomerization is available in the literature. More recently, Maeda *et al.* (5) have observed nuclear magnetic resonance spectral changes following the irradiation of suitably cooled solutions of substituted *N*-benzylideneanilines. These authors reported that the *cis*-isomer of the parent compound was unstable at the temperature of the experiments, −70°C. It was, however, found to be stable at −100°C in agreement with the results of Fischer and Frei (3).

In the present work, the vibrational spectral changes which result from the photoisomerization of *N*-benzylideneaniline will be considered. The interpretation of the new infrared spectrum provides additional insight towards the actual geometric changes that result from photoisomerization and complements that provided by other physical

methods. In addition, spectral evidence that *N*-benzylideneaniline crystallizes from melts in both the *trans*- and *cis*-conformations is presented. The *trans* is the dominant isomer in melt derived crystals and is even more dominant in low temperature Nujol solutions.

## Experimental

*N*-Benzylideneaniline was prepared by mixing anhydrous ethanol solutions containing equimolar quantities of benzaldehyde and aniline. The anil was then purified by recrystallization in anhydrous ethanol and by careful fractional sublimation.

The source used for the irradiation of the anils was an Oriel Model 7340 equipped with a 200 W medium pressure mercury arc. The irradiation wavelengths were isolated by means of an Oriel Model 7240 monochromator. The bandwidths of the excitation lines were approximately 20 nm, according to the manufacturer's specifications.

The low temperature infrared cell was constructed after the pattern described by Wagner and Hornig (22). The infrared spectra were recorded by means of a Perkin Elmer 621 Spectrometer. The spectra were recorded from samples in the form of thin polycrystalline films and of Nujol solutions. In both cases the samples were held between sodium chloride plates. The frequency scales of the spectra are calibrated to that of a thin polystyrene film.

It should also be pointed out that the reported Nujol solutions are true solutions, not mulls. Despite the polar nature of this compound, a solution, 0.35 molar in *N*-benzylideneaniline, in Nujol was easily attained at room temperature. A thin film of this solution, when cooled to 77 K, showed no signs of crystallization.

## Results and discussion

The 1750 to 1550 $cm^{-1}$ region of the infrared spectrum of a Nujol solution of *N*-benzylideneaniline is reproduced in Fig. 1 (for reference purposes, a listing of previously assigned vibrational bands in the infrared spectra of *N*-benzylideneaniline and related compounds is provided in Table 1). Quite clearly, irradiation of the low temperature solution produces substantial changes in this region of the spectrum. The spectral changes produced by irradiation at 313 nm are reversible by re-irradiation at longer wavelengths. The amount of the second form present at the photostationary state depends on the wavelength of irradiation and a definite photostationary state is reached at each wavelength (3). Maeda *et al.* (5) indicate that 85% of the *cis*-isomer of *N*-benzylideneaniline is present at the photostationary state (methylcyclohexane solution, −100°C and irradiation at 313 nm). Therefore, if the sample temperature is maintained at or below −100°C and if irradiation is begun, then a certain percentage of each isomer is always present. The amount of each isomer present at the photostationary state is dependent solely on the ratio of the molar absorptivities of the *trans*- and *cis*-isomers at the wavelength of excitation, provided, of course, that other experimental conditions are equal. Apparently there is not a wavelength at which one isomer absorbs exclusively. The phenomena are illustrated by the curves reproduced in Fig. 1. The shoulder at the high frequency side of the C=N stretching band of the nonirradiated sample indicates that some of the *cis*-isomer may be present in Nujol solutions at liquid nitrogen temperature.

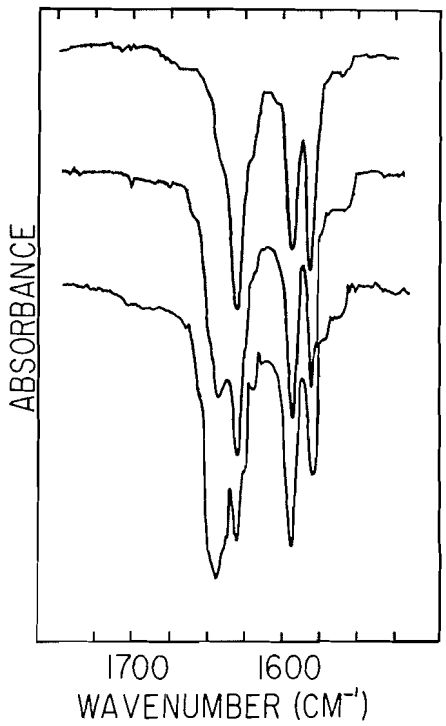

FIG. 1. The 1700–1500 $cm^{-1}$ region of the infrared spectra of a 0.35 *M* solution of *N*-benzylideneaniline in Nujol maintained at 77 K. Upper, nonirradiated solution; middle, after an intermediate period of irradiation (2–3 hours); and lower, after a long period of irradiation (5 hours).

The new infrared band at 1642 $cm^{-1}$ which appears upon irradiation of the sample is assigned as the C=N stretching of the *cis*-isomer of *N*-benzylideneaniline. The fact that the C=N stretching of the *cis*-isomer occurs at higher frequency than does the *trans*-isomer is perhaps surprising. For the central C=C stretching of stilbene and other substituted ethylenes, the opposite effect is found. Freeman (28) lists frequencies of 1629 $cm^{-1}$ for *cis*-stilbene and 1648 $cm^{-1}$ for *trans*-stilbene. On the contrary, the carbonyl stretching of 3-penten-2-one shows an effect similar to that of *N*-benzylideneaniline. The *trans*-isomer has the lower fre-

TABLE 1. Assigned vibrations of *N*-benzylideneanilines

| Vibration | Frequency ($cm^{-1}$) | Reference |
|---|---|---|
| νC=N | 1631 | 23 |
| νC=N | 1631 | 24 |
| νC—H (azomethine) | 2890 (2865 sh) | 24 |
| δC—H (out-of-plane, azomethine) | 872 | 24 |
| ν ring* | 1612–1605 | 24 |
| νAr—N | 1191 | 25 |
| δC—N (in-plane, azomethine) | 976 | 25 |
| C—H (out-of-plane, azomethine) | 873 | 25 |
| νC=N | 1625 | 26 |
| ν ring | 1591 | 26 |
| ν ring + C=N | 1578 | 26 |
| ν C=N † | 1625–1576 | 27 |
| νAr—N† | Two bands in 1375–1475 $cm^{-1}$ range | 27 |
| C=N—C† | Two bands (891–919) and (830–877 $cm^{-}$) | 27 |

*This band was found to increase in relative intensity with increasing basicity of the nitrogen, whereas the C=N band at 1631 $cm^{-1}$ was found to decrease in intensity with increasing basicity.
†These assignments are for a related compound, *N*-(2-hydroxybenzylidene)-4′-toluidine and the assignments are based on the results of $^{15}N$-labelling experiments.

quency, 1674 $cm^{-1}$, as compared to 1693 $cm^{-1}$ for the *cis*-isomer (29, 30).

In Fig. 1 it should also be noted that the lower frequency "aromatic" band at 1579 $cm^{-1}$ is the more intense of the two bands in the nonirradiated, low temperature solution spectrum. This band dramatically decreases in intensity as the intensity of the 1642 $cm^{-1}$ band increases. In some of our experiments this band has been observed to decrease to less than one-seventh its original intensity, indicating that there is perhaps greater than 80% conversion to the *cis*-isomer.

Percy and Thornton (27), in their $^{15}N$-labelling study, have associated the lower frequency of the two "aromatic" bands with the C=N stretching of *N*-(2-hydroxybenzylidene)aniline since it appeared to be more vibrationally pure than did a band at 1625$cm^{-1}$, ($\Delta\nu = -8\,cm^{-1}$ compared to $\Delta\nu = -5\,cm^{-1}$). In the present work, the 1579 $cm^{-1}$ band of *N*-benzylideneaniline is to be associated with the 1576 $cm^{-1}$ of *N*-(2-hydroxybenzylidene)aniline discussed by Percy and Thornton. This seems reasonable since the two molecules are structurally very similar.

The relative intensities and positions of the three bands in the 1700–1500 $cm^{-1}$ region need some elaboration. For the *trans* form the bands are at 1628, 1595, and 1579 $cm^{-1}$. The first one is naturally assigned to the C=N stretching vibration, the two others to the well-known phenyl ring vibrations. Under the given conditions these vibrations cannot be "pure" group frequencies. Indeed in previous studies (26, 27) of anils, as well as in the present study, there is substantial evidence for coupling of the C=N and a phenyl group vibration. A consequence of this coupling is likely to be a shift to higher frequency of the C=N band. Furthermore, since the C=N group is a part of an extended conjugated system its force constant is lowered by interaction with the π systems of the two phenyl rings. Conjugation would perhaps put the C=N stretching frequency as low as 1615 $cm^{-1}$ but mechanical coupling makes it appear at 1628 $cm^{-1}$. After *trans* → *cis* photoisomerization the aniline ring will tilt out of the plane of the benzaldehyde moiety (see below). This must greatly diminish the extent of conjugation as well as mechanical coupling. The first effect should raise the C=N frequency while the second one would lower it. The result, 1642 $cm^{-1}$, observed for the *cis*-isomer is surprisingly high and makes one think that mechanical coupling is less important than has been presumed. (In examples of mechanical coupling it is usually assumed that one of the vibrations is raised to higher frequency and the other is lowered; so the higher frequency must come down if coupling is suppressed.)

In this respect it should be remembered that the phenyl bands near 1600 $cm^{-1}$ constitute a well-known case of Fermi resonance (see Herzberg (31), p. 364). In benzene itself, in the vapor state, the Raman active $\nu_{16}$ fundamental ($e_{2g}$) is at 1584.8 $cm^{-1}$ while the $\nu_2 + \nu_{18}$ ($E_{2g}$) combination band is 1606.4$cm^{-1}$ ($\nu_2$: 991.6 $cm^{-1}$ ($a_{1g}$); $\nu_{18}$: 605.6 $cm^{-1}$ ($e_{2g}$)). The anharmonic (Fermi) resonance of the fundamental and the combination, both of $e_{2g}$ symmetry, is inherited by most benzene derivatives. In *N*-benzylideneaniline the relative intensities of the bands at 1595 and 1579 $cm^{-1}$ are probably greatly influenced by this Fermi resonance. (One might try to assign one of these bands to the aniline ring and the other to the benzaldehyde ring but in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

view of the above this would be probably naive. The degree of contribution of the two rings to the intensities of the bands is probably different, however.) Furthermore, in view of the mechanical (harmonic) coupling of the C=N and phenyl motions there is likely to be a significant amount of anharmonic coupling between the C=N and phenyl fundamentals in this part of the spectrum giving rise to Fermi resonance involving the three bands. Finally, the relative intensities of the three bands will depend on (a) the extent of conjugation and coplanarity; (b) mechanical coupling; and (c) Fermi resonance.

Now, it is hard to see how the spectacular decrease in the intensity of the 1579 $cm^{-1}$ band upon *trans* → *cis* photoisomerization together with the 1628 → 1642 $cm^{-1}$ increase can be explained on the basis of mechanical coupling only. In itself it would *lower* the C=N frequency; the loss of coplanarity and conjugation might go some way in raising the frequency of the 1628 $cm^{-1}$ band and decreasing the intensity of the 1579 $cm^{-1}$ band; the raising of the frequency to 1642 $cm^{-1}$ could spoil conditions for Fermi resonance making the 1579 $cm^{-1}$ band lose much of its intensity borrowed from the C=N band.

In Fig. 2 the partial spectra (1250–650 $cm^{-1}$) of irradiated and nonirradiated low temperture Nujol solutions of *N*-benzylideneaniline are reproduced. The spectral changes observed here parallel those shown in Fig. 1. They are also reversible in that they may be erased by re-irradiating the sample at longer wavelengths. In both regions the spectral changes may then safely be identified with the *trans* → *cis* photoisomerization product and not with one or more photochemical degradation products. Samples that have been cycled as many as twenty times show no spectral evidence of irreversible photochemical decomposition. These observed spectral changes may also be erased by allowing the sample temperature to rise to the neighbourhood of −78°C.

In Fig. 2, it is interesting to note that the Ar—N stretching band of *trans*-*N*-benzylideneaniline at 1191 $cm^{-1}$ moves to higher frequency in the spectrum of the *cis*-isomer (1206 $cm^{-1}$). The +15 $cm^{-1}$ shift is very similar to that observed for the C=N vibration. On the other hand, the C—H deformation bands of the azomethine group are shifted to lower frequency in the spectra of the *cis*-isomer. The in-plane deformation band shifts from 976 to 956 $cm^{-1}$ and the out-of-plane deformation band shifts from 873 to 845 $cm^{-1}$. The latter assignment is somewhat tentative since there is also a band that develops at slightly higher frequency than that of

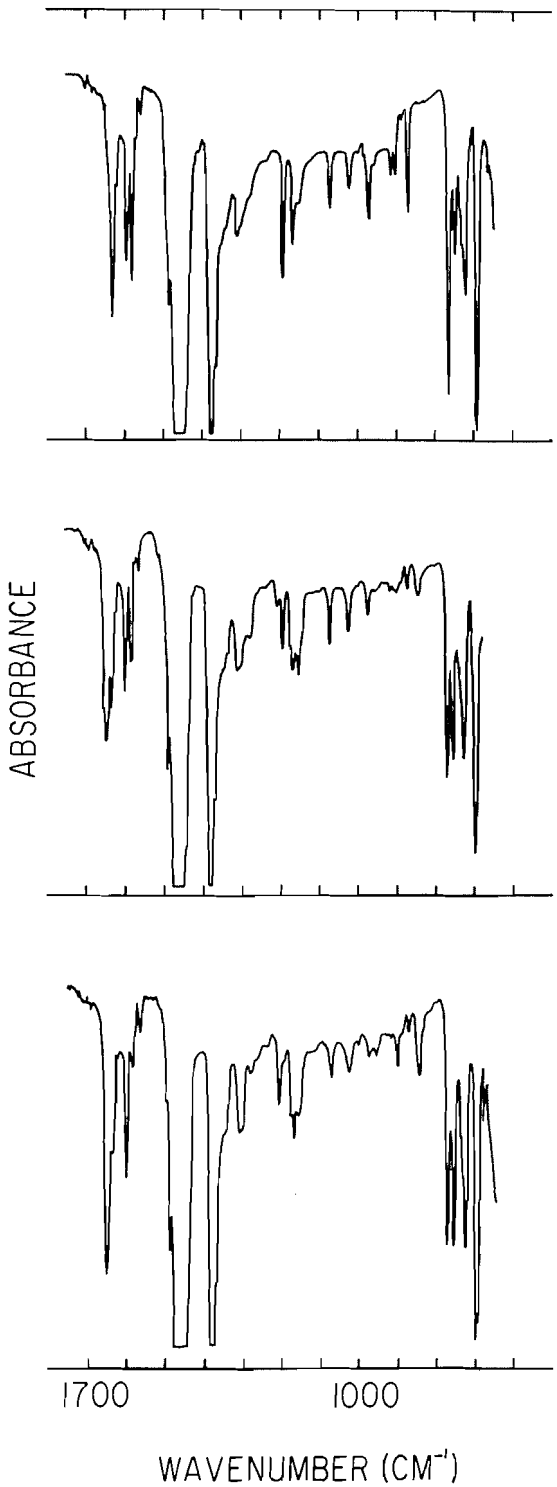

FIG. 2. The 1700–650 $cm^{-1}$ region of the infrared spectra of a 0.35 *M* solution of *N*-benzylideneaniline in Nujol maintained at 77 K. Upper, nonirradiated solution; middle, after a long period of irradiation (5 hours); and lower, photostationary state.

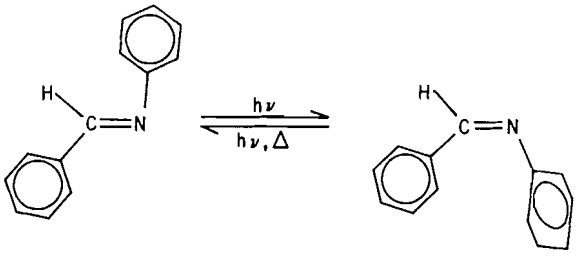
the out-of-plane deformation band of the *trans*-isomer.

The spectral changes that are observed in Fig. 2 are also explicable in terms of a *trans* → *cis* isomerization. It has been argued that when the *N*-benzylideneaniline molecule assumes the *cis*-conformation the aniline ring is further out of the plane of the remainder of the molecule. As the angle of twist increases, the conjugation of the aniline ring and the C=N group is lost. This results in a shortening of the C=N bond. The stretching frequency of the C=N is thereby increased to the point that Fermi resonance is no longer possible. (The arguments regarding the angle of twist, θ, are not meant to imply that the increase in non-coplanarity is achieved by means of a rotation about the C=N single bond. Various authors (7, 9) have successfully demonstrated that the *cis*-isomer is produced by means of an inversion at the nitrogen.)

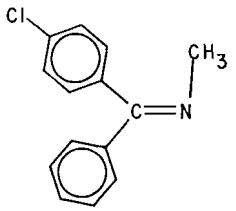
The increase in non-coplanarity of the aniline ring also provides for more effective participation of the nitrogen lone pair (9). This participation increases the Ar—N bond order, as is indicated by the shift of the infrared absorption band to higher frequency. The increased participation of the nitrogen lone pair of the *cis*-isomer should result in decreased basicity, as has been proposed (9). It



also results in a change in the direction and magnitude of the dipole moment (8, 9, 32).

It has been noted that the azomethine C—H deformation frequencies are lower for the *cis*-isomer. The C—H stretching frequency is not affected by *trans* → *cis* isomerization; hence it seems reasonable that the lowering of the deformation frequencies of the azomethine C—H is due to the removal of steric repulsions (5) between the azomethine hydrogen and the *ortho* hydrogen of the aniline ring. This further substantiates the argument that the aniline ring of the *cis*-isomer is further out of the molecular plane than it is in the *trans*-isomer.

In a study of a related compound, *p*-chlorobenzophenone methylimine, Curtin and Hausser



(33) have found some interesting results. This compound crystallizes as the *cis*-isomer (*cis* refers to the relative positions of the methyl group and the *p*-chlorophenyl group). If the crystals are held at 125°C for 15 min or if cyclohexane solutions of the compound are allowed to stand at room temperature for two weeks, the corresponding infrared spectra indicate a mixture of the *cis*- and *trans*-isomers. The C=N stretching band at 1620 $cm^{-1}$ did not change upon isomerization but two other infrared bands showed a definite shift. A sharp band at 693 $cm^{-1}$, which is assigned as a vibration of a monosubstituted phenyl group (34), decreased in intensity upon standing of the solution and another band developed at 701 $cm^{-1}$. A second sharp band located at 827 $cm^{-1}$, which is assigned as the C—H deformation of the *p*-chlorophenyl ring (34), decreased in intensity upon standing of the solution and another band developed at at 837 $cm^{-1}$.

Although the vibrational assignments in the 800–650 $cm^{-1}$ region of the spectrum of *N*-benzylideneaniline have not been made, it is of interest to compare the results of the present experiments to those of Curtin and Hausser. In Fig. 2 it is noted that a very strong band is located at 695 $cm^{-1}$. There is some indication that the intensity of this band varies with 313 nm irradiation of these solutions, but the changes are within the limits of error of these experiments. At somewhat higher frequencies two bands are apparent. In the spectrum of nonirradiated Nujol solutions the higher frequency band at 768 $cm^{-1}$ is the most intense. This 768 $cm^{-1}$ band decreases in intensity and the band at 749 $cm^{-1}$ increases with the irradiation of the samples. In keeping with previous assignments in this study, the higher frequency band is assigned as an absorption of the *trans*-isomer and the lower frequency band is assigned as a vibration of the *cis*-isomer.

Changes in the aromatic C—H deformation frequency of the aniline portion of the molecule are entirely expected. It has been argued that the conformation of the *cis*-isomer leads to favorable interaction of the nitrogen lone pair with the aniline ring and to a lessening of steric repulsions. It is

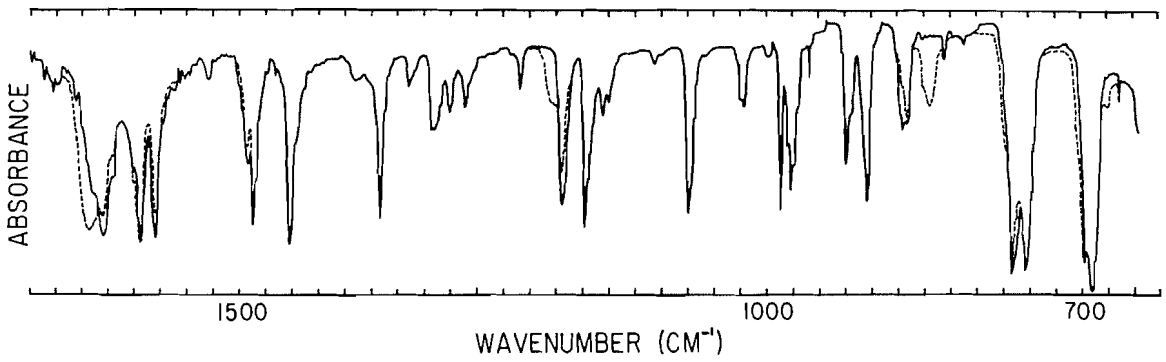


FIG. 3. The 1700–650 $cm^{-1}$ region of the infrared spectra of a thin polycrystalline film of *N*-benzylideneaniline maintained at 77 K. The solid line indicates absorption prior to irradiation and the broken line indicates changes in absorption after 5 hours of irradiation at 313 nm.

believed that these interactions result in a net lowering of the aniline C—H deformation frequency. In this respect the present interpretation is in line with that of Curtin and Hausser. These authors expected to observe a lower frequency for the *cis*-isomer of *p*-chlorobenzophenone methylimine but, when the opposite effect was observed, they concluded that there were no favorable lone pair – ring interactions.

All the effects of *trans* → *cis* photoisomerization on the infrared spectrum of Nujol solutions of *N*-benzylideneaniline are also observed in the spectrum of thin polycrystalline films maintained at low temperature. These spectra are reproduced in Fig. 3. As might be expected, these changes are less well defined than are those in the solution spectra. This depends, among others, on *cis–trans* ratios. Apparently the quantum yield of photoisomerization is lower in the solid state so that prolonged irradiation times would be necessary in order to achieve the same *cis–trans* ratio that is observed in the solution spectra.

In Fig. 3 it is evident that some spectral changes occur in the 1550–1350 $cm^{-1}$ region that is obscured in the Nujol solution spectra. The greatest changes occur in a pair of bands which appear at 1490 and 1485 $cm^{-1}$. This region is expected to be dominated by vibrations of a phenyl group, so it might be that these changes reflect electron redistributions in the aniline nucleus.

## Conclusions

It has been shown that major infrared spectral changes result from the 313 nm iradiation of low temperture Nujol solutions and polycrystalline films of *N*-benzylideneaniline. These changes reflect those which are expected to result from a *trans* → *cis* photoisomerization. The changes also indicate that as a result of isomerization there is an increase of the non-coplanarity of the aniline ring with the remainder of the molecule.

In order to interpret frequency and intensity variations in the 1628 and 1579 bands, changes in coplanarity and Fermi resonance had to be invoked.

# A spectroscopic study of the solvent dependent processes of the anils of benzaldehyde and salicylaldehyde

JERRY W. LEWIS AND CAMILLE SANDORFY
*Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1*
Received August 25, 1981

JERRY W. LEWIS and CAMILLE SANDORFY. Can. J. Chem. **60**, 1727 (1982).

The ultraviolet–visible, infrared, and Raman spectral characteristics of some anils of benzaldehyde and salicylaldehyde in several solvents have been investigated. The ultraviolet–visible absorption data indicate that in solvents with a proton donating ability less than or equal to trifluoroethanol a single equilibrium exists in solutions of *N*-(2-hydroxybenzylidene)aniline, whereas in solvents with a proton donating ability equal to or greater than hexafluoroisopropanol more than one equilibrium occurs. The infrared spectra of this compound dissolved in trifluoroethanol do not show new absorption bands in the 1700–1500 $cm^{-1}$ region; however, new absorption bands in this region do appear when hexafluoroisopropanol is employed as solvent. From these data it is inferred that the first equilibrium involves the breaking of the chelate hydrogen bond and the second equilibrium involves actual protonation of *N*-(2-hydroxybenzylidene)aniline in the electronic ground state. A comparison of the infrared and Raman spectra of the title compounds is also made and alternate assignments for several observed bands in the 1700–1500 $cm^{-1}$ region are proposed.

JERRY W. LEWIS et CAMILLE SANDORFY. Can. J. Chem. **60**, 1727 (1982).

Les spectres ultraviolet–visible, infrarouge et Raman d'un certain nombre d'anils de la benzaldéhyde et de l'aldéhyde salicylique ont été déterminés. Les spectres d'absorption électroniques montrent qu'il y a un équilibre entre deux espèces dans les solutions de la *N*-(2-hydroxybenzylidene)aniline dans des solvants qui sont des donneurs de protons moins bons ou aussi bons que le trifluoroethanol. Par contre dans les solvants ayant un pouvoir de donneur de proton égal ou supérieur à celui de l'hexafluoroisopropanol un équilibre entre un plus grand nombre d'espèces existe. Les spectres infrarouges de ce composé dissout dans l'trifluoroethanol ne présentent aucune bande nouvelle entre 1700 et 1500 $cm^{-1}$. Par contre des bandes nouvelles apparaissent dans hexafluoroisopropanol. On peut déduire de ces spectres que le premier équilibre implique la rupture de la liaison hydrogène du chélate alors que le second implique la protonation de *N*-(2-hydroxybenzylidene)aniline dans son état fondamental. La comparaison entre les spectres ir et Raman de ces composés conduit à des attributions nouvelles pour certaines bandes dans la région spectrale de 1700 à 1500 $cm^{-1}$.

## Introduction

The ultraviolet–visible absorption spectra of aromatic anils of salicylaldehyde have long been observed to undergo dramatic changes when the solvent is changed from a nonpolar to a polar hydrogen-bonding one. In the polar hydrogen-bonding solvents, a new absorption band develops in the spectral region near 440 nm. Charette *et al.* (1), in a study of a series of *N*-salicylidene alkylimines, attributed a long wavelength absorption band to an enol form which had the intramolecular hydrogen bond replaced by an intermolecular hydrogen bond to the solvent molecules. It was suggested that there was stronger solvent stabilization of the excited state than of the ground state; hence the absorption band shifted to longer wavelengths.

Cohen and Flavian (2) have criticized the Charette explanation on several grounds, including the fact that the expected variation of band position with solvents of varying polarity was not observed. These authors concluded that the absorption band was due to a transition of the *cis-ortho*-quinone form. This conclusion was reached in apparent contradiction to a preceding paper (3) in which Cohen and Flavian described the behavior of anils according to Scheme 1. In this particular case, the authors based their conclusions on the very large Stokes shift of the observed fluorescence from the normal absorption, the reasonable overlap between the observed fluorescence and the long wavelength band, and the identity of the fluorescences excited by irradiation into the normal and the long wavelength absorption bands.

Richey and Becker (4) and Barbara *et al.* (5) state that there are subtle but real differences in the fluorescence spectra, depending upon whether the excitation wavelength lies within the normal absorption band or within the long wavelength absorption band.

To date, no conclusive vibrational data which support the existence of the *ortho*-quinone or the "ion-pair" have been presented. Despite this lack of data, the ground state equilibrium proposed by Charette *et al.* (1) and excited state acid–base reactions of the type first discussed by Förster (6) and greatly expanded by Weller (7), and modifications thereof, have now been abandoned in favor of the enol → keto equilibrium and the *ortho*-quinone form (2, 4, 5, 8, 9, 15, and 16).

In the present study a comparison of the ultraviolet–visible, infrared, and Raman spectra of *N*-

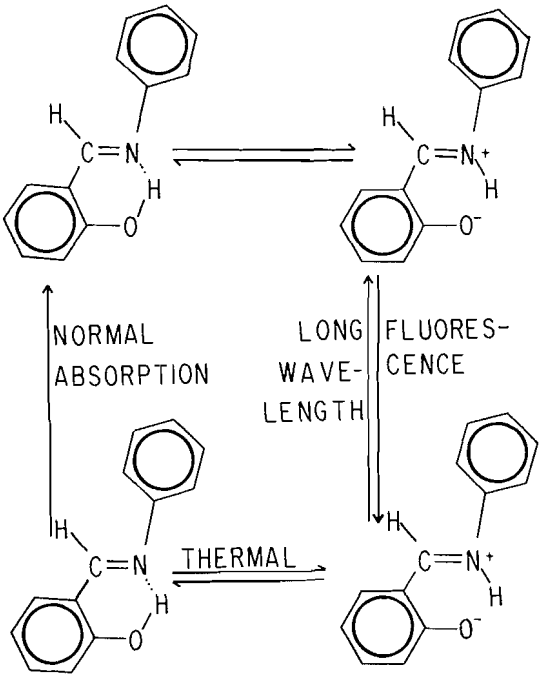

SCHEME 1

benzylideneaniline (BA), *N*-(2-hydroxybenzylidene)aniline (HBA), and other aromatic anils will be made. It is found that there is indeed a significant shift of the long wavelength visible absorption band of HBA as the solvent becomes increasingly acidic. The shift is, however, in the opposite direction to that expected purely on the basis of solvent stabilization of the excited state. It is further noted that there are no changes in the carbon–nitrogen double bond stretching frequency when this compound is dissolved in a solvent of sufficient acidity to cause the ultraviolet–visible absorption spectrum to be dominated by the long wavelength band. These results lead to the conclusion that neither the enol–keto nor the enol – "ion-pair" ground state equilibrium is supported by these vibrational spectroscopic experiments. These results are such that no single equilibrium mechanism is capable of explaining them.

## Experimental

The anils used in this study were prepared and purified by means of the methods described for the preparation and purification of BA in the preceding paper.

The Raman spectra were recorded by means of a Spex Ramalog 6 spectrometer. This instrument was equipped with a Coherent Radiation CR 6 argon-ion laser or a Coherent Radiation Model 590 dye laser. The reported Raman frequencies were calibrated to known frequencies of carbon tetrachloride.

It should be noted that solutions of the hydrochlorides of the anils are particularly unstable in the presence of moisture. The hydrochlorides are also relatively insoluble in dry, ethanol-free chloroform. Suitable spectra, free of contributions by hydrolysis products, were obtained from anhydrous chloroform solutions which contained 0.1 to 0.2% by volume of anhydrous ethanol.

## Results and discussion

### A. *Ultraviolet–visible absorption studies*

In order to demonstrate the anomalous ultraviolet–visible absorption characteristics of aromatic anils, several of these spectra are presented in Figs. 1 and 2. Several observations can be made from these spectra.

1. In the polar hydrogen-bonding solvents a new band develops in the absorption spectrum of HBA.

2. The normal absorption bands of HBA and BA undergo hypsochromic shifts when the solvent is changed from a nonpolar to a polar hydrogen-bonding one.

3. The new band in the spectrum of HBA intensifies and undergoes a hypsochromic shift as the solvent becomes more acidic. On the other hand, in a mixed solvent system, an increase in the concentration of the acidic component causes an intensification of the band but does not greatly affect the band position.

4. The longest wavelength absorption bands of the fully protonated forms of HBA and BA are bathochromically shifted with respect to the corresponding normal absorptions of the neutral species. The new solvent-dependent absorption band in the spectrum of HBA appears to converge to the lowest energy absorption band of the hydrochloride.

Clearly these observations are consistent with the idea of a ground state equilibrium or equilibria. As was noted in the introduction, three different equilibria have been proposed in the literature in order to account for the presence of the long wavelength absorption band of anils. However, it has not been clearly demonstrated whether or not more than one equilibrium is involved in a particular solvent or whether or not the same equilibrium is implicated in the different solvents. For example, for any monomolecular reaction, $A \rightleftharpoons B$, where A and B are characterized by at least one noncommon absorption band, it is a well-known fact that the absorption spectra of solutions containing varying concentrations of A and B will exhibit well-defined isosbestic points. Deviation from this strict requirement normally indicates that more than one reaction is involved (a deviation from this requirement could also mean that one of the components does not follow the Beer–Lambert law in its absorption spectral characteristics). Thus, while many have described the solvent-dependent absorption spectra of HBA and its derivatives in

terms of a single monomolecular reaction, only a single author (8) actually provides spectra of something other than the new long wavelength absorption band. In order to explore this variable, a study was made and the results are summarized in Figs. 3 and 4. It is found that in solutions containing a simple alcohol such as ethanol or a more acidic alcohol such as 1,1,1-trifluoroethanol (TFE), the strict requirement of an A → B reaction is met. However, in a more acidic solvent such as that containing hexafluoroisopropanol (HFIPr), the requirement is not met. In solutions containing difluoroacetic acid, it is observed that the A → B reaction requirement is not met and that the long wavelength absorption band shifts over a wide range of wavelength, depending on the concentration of difluoroacetic acid. Therefore, it must be concluded that once a certain solvent acidity, namely that of HFIPr, is by-passed, a single monomolecular reaction is incapable of explaining the experimental facts.

The principal argument in favour of the enol ⇌ keto tautomerization of HBA seems to reside in the fact that a new absorption band does not appear in the spectrum of BA when the solvent is changed from a nonpolar to a polar hydrogen-bonding one. For example, compare the spectra of HBA and BA shown in Fig. 2. It is noted that no new band appears in the spectrum of BA even in strongly hydrogen-bonding solvents and that the new band is clearly observable in the spectrum of HBA in methanol solution.

Ottolenghi and McClure (9) have also discussed the possibility of an intra ⇌ intermolecular hydro-

gen bond equilibrium. To account for the long wavelength band of HBA, these authors proposed that it could be rationalized on the grounds that the transition probabilities of the hydrogen bridged species are different in the case of the unbridged species. Since BA does not contain the intramolecular chelate ring, there is no a priori reason to suspect that its absorption spectrum would be greatly affected by solvent.

As noted earlier, the normal absorption bands of HBA and BA undergo blue shifts when the solvent is changed from a nonpolar to a polar one. As expected, the shift of the HBA absorption bands in methanol solution is much smaller than the shift of the BA absorption bands in TFE solution (it is not possible to compare the shift of the normal absorption bands of HBA in TFE since in this solvent the spectrum is dominated by the long wavelength band). It might be argued that this observation is proof that the excited state of HBA cannot be stabilized more than is the ground state, contrary to what was argued by Charette *et al.* It must be recalled, however, that in these solutions an equilibrium exists. For example, in methanol solution the majority of HBA molecules remain intramolecularly hydrogen bonded and the weaker bond with the solution is an additional stabilizing force on their ground state.

The blue shift of the normal absorption band of HBA and its derivatives has been observed previously (9). Allen and Roberts (10) have examined in detail the effects of hydrogen bonding and protonation on the nitrogen-15 chemical shifts of

several compounds that contain the C=N group. They concluded that in TFE solution BA and several of its derivatives are hydrogen bonded to the solvent, whereas in a more acidic solvent, trifluoroacetic acid (TFAA), the same derivatives are fully protonated. (Unfortunately, this study did not include any 2-hydroxy derivatives wherein a combination of hydrogen bonds could exist.) If, in Fig. 2, the wavelengths of 315 and 297 nm are chosen as the reference maxima of the BA absorption bands in carbon tetrachloride and TFE solution, respectively, then the observed shift represents an energy difference of about 23 kilojoules per mole. This value for the energy of the H-bond is quite normal. Furthermore, this is the energy shift expected for an $\pi^* \leftarrow n$ transition (11). Jaffé *et al.* (12) have proposed that the $\pi^* \leftarrow$ n is the lowest energy transition of BA, but this has not been confirmed experimentally and even if the $\pi^* \leftarrow n$ were the lowest energy transition this would not explain the large blue shift of both absorption bands of BA.

In terms of the normal explanation, the effect of hydrogen bonding on an $\pi^* \leftarrow n$ transition is to stabilize the *n* orbital by an amount approximately equal to the energy of the hydrogen bond (13). During the process of excitation an *n* electron is promoted to a $\pi^*$ orbital and the remaining *n* electron is unable to maintain the hydrogen bond. The hydrogen bond is thus broken in the excited state and the polar hydrogen-bonding solvent should not significantly affect the energy of the excited state (14). It should be pointed out, however, that the examples used to arrive at these conclusions involve molecules with well defined $\pi^* \leftarrow n$ transitions. This is the equivalent of not allowing for any $n$–$\pi$ mixing in the ground and/or excited states. For the examples of BA, HBA, and related compounds, $\pi^* \leftarrow n$ transitions have not been located in the absorption spectra. On the other hand, both the absorption bands of BA and, perhaps to a lesser extent, three bands of HBA behave as though they contained *n*-character, since the observed solvent shift is in the opposite direction and is much larger than any solvent shift expected for a $\pi^* \leftarrow \pi$ transition.

It has been noted that the long wavelength absorption band of HBA intensifies and undergoes a blue shift as one acidic solvent is exchanged for another and that this band appears to converge to that of the protonated species. It is believed that these data and those presented in Figs. 3 and 4 imply the existence of more than one equilibrium. It is difficult to imagine how the *ortho*-quinone structure could fit into such a scheme. The apparent smooth convergence of the long wavelength band with the absorption band of the protonated species implies that, at some point, solvent-dependent ionic species are involved. In order to retain the *ortho*-quinone idea, it is necessary to assume that such a structure is solvent favored up to a point, and that beyond this point the enol and protonated enol are once again favored.

Some supporting evidence for the existence of more than one equilibrium is found in the literature. Smith *et al.* (15), in an optical rotatory dispersion (ord) study of optically active amines, examined the absorption spectra and ord curve of (*S*)-(+)-*N*-salicylidene-α-phenylethyl amine in hexane, dioxane, and 95% ethanol solutions. Two positive

For personal use only.

Cotton effects centered near 410 and 315 nm were observed in the 95% ethanol solution (the corresponding absorption maxima occur at 403 and 315 nm). In hexane and dioxane solution only one Cotton effect, that at 315 nm, was observed. In spite of this fact, the 410 nm absorption band is of significant intensity in the dioxane solution spectrum, but is absent in the hexane solution spectrum. These authors concluded that a simple shift in a tautomeric equilibrium did not adequately explain the presence of the 410 nm band in the dioxane solution spectrum.

B. *Infrared and Raman studies*

In order to study the effects of solvents on the carbon–nitrogen double bond stretching frequency and thus better identify the implicated equilibrium or equilibria, the infrared and Raman spectra of HBA and BA in several solvents were obtained. If the proposed ground state enol–keto or enol – "ion pair" equilibrium occurs in hydrogen-bonding solvents, substantial changes in the infrared and Raman spectra are expected, barring an identity of the spectra of the enol and the *ortho*-quinone or of the enol and the ion-pair. If either of these equilibria occurred, then infrared and/or Raman spectral changes which could be correlated with the 440 nm visible absorption band would be expected. A number of spectra are presented in Figs. 5–9.

Particular attention should be paid to the infrared spectra of BA in chloroform solution and in the 50% chloroform – 50% TFE solution. It will be noted in Fig. 5 that the C=N stretching band of BA at 1625 $cm^{-1}$ is unchanged with respect to position in the solvent of greater acidity. Since, according to general experience as well as Allen and Roberts' (10) observation of the $^{15}N$ nmr spectrum, a hydrogen bond must be formed between BA and TFE, this is somewhat surprising. The insensitivity of the C=N stretching frequency can perhaps be connected with the relative weakness of the hydrogen bond; also, since the proton acceptor is likely to be the nitrogen lone pair its participation in the H-bond may not affect significantly the C=N force constant. Freedman (17) has noted that, while the strength of the intramolecular H-bond of *N*-salicylidene-anilines is comparable to that of carboxylic acid dimers or enolized β-diketones, the chelate ring has little effect on the carbon–nitrogen double bond stretching frequency; this can be taken for another sign of the insensitivity of C=N to H-bonding. Furthermore, since, as it has been suggested, the C=N frequency is influenced by Fermi resonance, the downward H-bond shift could be compensated for by slightly increased

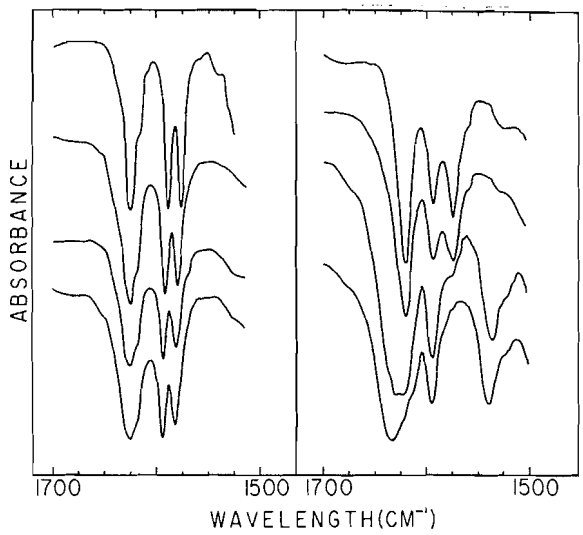

FIG. 5. Infrared absorption spectra of *N*-(2-hydroxybenzylidene)aniline and *N*-benzylideneaniline. Right side, HBA, top to bottom: 0.28 *M* in $CHCl_3$, 0.30 *M* in $CHCl_3$ · TFE, 0.36 *M* in $CHCl_3$ · HFIPr, 0.34 *M* in HFIPr. Left side, BA,top to bottom: 0.20 *M* in $CHCl_3$, 0.29 *M* in $CHCl_3$ · TFE, 0.39 *M* in $CHCl_3$ · HFIPr, 0.34 *M* in HFIPr.

Fermi resonance. The lack of a frequency shift cannot be taken for a proof of the absence of H-bonding.

A similar situation is encountered when the infrared spectra of HBA in chloroform and in a one-to-one mixture of chloroform and TFE are compared (Fig. 5). The three bands in the 1700–1500 $cm^{-1}$ region are slightly broadened in the mixed solvent spectrum, as are those of BA, but there is essentially no shift in position. (The broadening in itself may be considered as an indication of H-bonding.) More importantly, no new bands which might be attributed to the stretching motions of $C{=}NH^+$ or C=O have appeared. These findings are in complete agreement with the results of Ledbetter's study (16). He also obtained the infrared spectrum of HBA in pure TFE and found no new absorption bands in the 1700–1500 $cm^{-1}$ region. Since no new bands are observed in this region of the infrared spectra of HBA dissolved in TFE or in a mixture of TFE and chloroform, it is concluded that neither the enol–keto tautomerization nor ion-pair formation occurs in the ground state. The similarity of the infrared spectra of HBA and BA in this region strongly suggests that in TFE-chloroform solution both compounds undergo the same transformation; namely, both compounds are H-bonded to the solvent. It could be argued that the expected "new" C=O or $C{=}NH^+$ bands are simply too weak to appear in the infrared

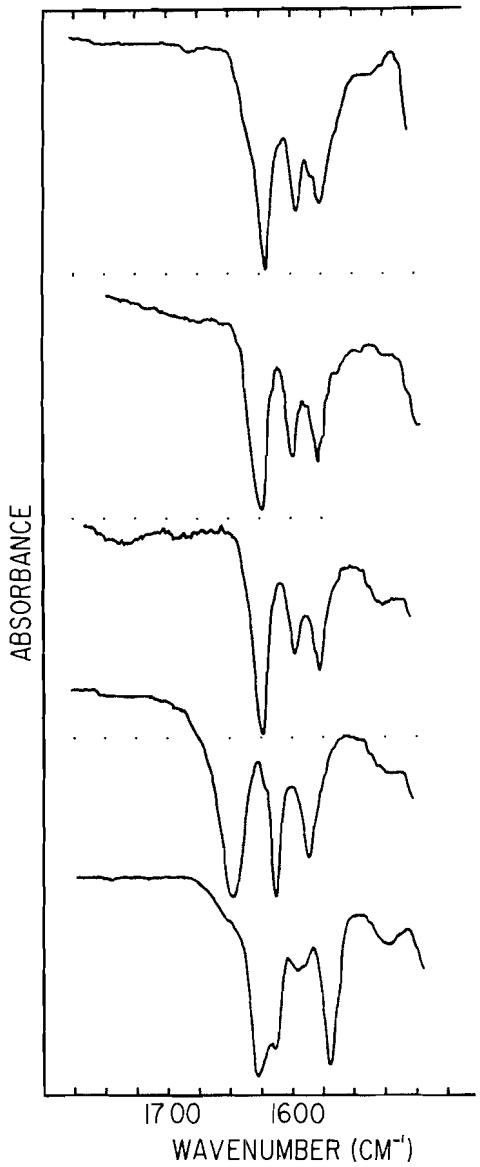

FIG. 6. Infrared absorption spectra of *N*-(2-hydroxybenzylidene)aniline. Top to bottom: solid film, 0.21 *M* in Nujol, 0.18 *M* in $CHCl_3$, 0.18 *M* in $CHCl_3$ saturated with HCl, 0.18 *M* in $CHCl_3$ saturated with DCl.

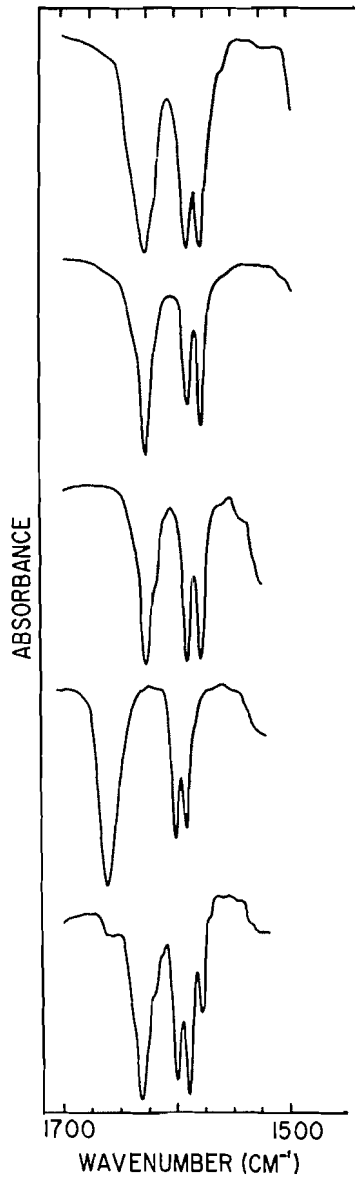

FIG. 7. Infrared absorption spectra of *N*-benzylideneaniline. Top to bottom: solid film, 0.35 *M* in Nujol, 0.20 *M* in $CHCl_3$, 0.26 *M* in $CHCl_3$ saturated with HCl, 0.26 *M* in $CHCl_3$ saturated with DCl.

spectrum. This could be so if only a slight amount of the keto tautomer or ion-pair was present, perhaps up to 2 or 3%, but this is not the issue. The amounts that have been claimed are much larger, and, since the C=O or $C{=}NH^+$ bands are by no means weaker than a C=N band they would be seen if the related species was present in the solutions.

The surprising fact is that a relatively weak H-bond is capable of causing the appearance of the 440 nm band in the visible. No other alternative seems to be possible, however.

We now have to describe the spectra of HBA and BA in the more acidic solvents: in a one-to-one mixture of chloroform and HFIPr and in neat HFIPr (Fig. 5). Ledbetter (16) previously obtained the spectra of HBA and BA in pure HFIPr. In the present study no new bands are found in the spectrum of BA in either the mixed solvent or in pure HFIPr. The C=N stretching is not affected

by these solvents, except for a slight broadening of the bands. For HBA, the situation is somewhat different. In the mixed solvent spectrum the high frequency band is still broader and appears to be composed of two overlapping bands at 1630 and 1622 $cm^{-1}$ and a shoulder at perhaps 1635 $cm^{-1}$. This is likely to correspond to conditions in which a fraction of HBA remains nonprotonated and is simply H-bonded to the solvent and another fraction is protonated and probably also H-bonded to the solvent in various ways. The higher frequency constituent of the broad band would then correspond the $C{=}NH^+$ absorption. In pure HFIPr the fraction of the protonated species is larger, but complete protonation apparently does not occur. Favrot *et al.* (18) have reported that other simpler imines are H-bonded in TFE and are fully protonated in perfluoro-*tert*-butanol, whereas in HFIPr these simpler imines exist as a mixture of hydrogen bonded and protonated species. Whether protonation is due to the proton transfer in the original intramolecular H-bond or if the latter opens in favor of direct protonation by a solvent molecule cannot be ascertained at this stage. It should be pointed out that if any significant amount of the quinoid form were present, a much more intense (carbonyl) band would be present at the high frequency side but this is not the case.

In the spectrum of HBA in HFIPr and in the mixed solvent it will be noticed that the band near 1574 $cm^{-1}$, in the chloroform solution spectrum, decreases in intensity and that a new band appears near 1540 $cm^{-1}$. It is at 1536 $cm^{-1}$ in the mixed solvent spectrum. The disappearance of the band at 1574 $cm^{-1}$ and the appearance of another band in the 1550–1500 $cm^{-1}$ region has first been pointed out by Ledbetter (16). The 1550–1500 $cm^{-1}$ band in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

the spectrum of HBA in HFIPr solution was assigned by this author as due to a stretching vibration of the vinyl C=C bond of the quinoid form. He asserted that for the quinoid structure the band occurs near 1545 $cm^{-1}$, that for the protonated imine the band occurs near 1525 $cm^{-1}$, and that in both cases the band might shift to slightly higher or lower frequency depending on the amount of double-bond character in the bond. The appearance of such a band in the spectrum of the proposed quinoid might easily be rationalized in these terms. However, if it is supposed that the external C=C bond acquires more "double-bond" character, then it must also be granted that the C=N bond has less "double-bond" character. This is not substantiated by experiment. As to the protonated imine which has no external double bond the assignment is even more difficult to accept. The $C{=}NH^+$ frequency of HBA (for the hydrochloride) occurs at 1643 $cm^{-1}$ while the C=N frequency occurs at 1619 $cm^{-1}$.

Thus, in order to properly evaluate the solution equilibrium or equilibria of *ortho*-hydroxy Schiff bases, it is critical to firmly establish the identity of the infrared and Raman bands that are found in the 1700–1500 $cm^{-1}$ region. The difficulties in making such assignments have previously been discussed (18).

As pointed out by Aton *et al.* (19) it seems reasonable to expect that the $C{=}NH^+$ stretching should occur at lower frequency than that of C=N (i.e., protonation should lower the C=N force constant and increase the effective mass of the nitrogen, and both these effects should tend to lower the stretching frequency). Experience, on the other hand, often dictates that this is not the case. To explain this apparent anomaly, Aton *et al.* propose that upon protonation the $C{=}NH^+$ stretching and the $C{=}N^+{-}H$ deformation are coupled. Therefore the observed $C{=}NH^+$ stretching occurs much higher in frequency than would otherwise be expected.

For the examples of the aromatic anils under consideration here, this is an especially interesting observation. Several infrared spectra of HBA are presented in Fig. 6. Note that there are some relative intensity changes in the three 1700–1500 $cm^{-1}$ bands as the spectra of the solid, the Nujol solution, and the chloroform solution are compared. It appears that protonation causes an upward shift of 24 $cm^{-1}$ in the C=N stretching frequency and that a subsequent deuterium exchange lowers the $C{=}NH^+$ stretching frequency by 16 $cm^{-1}$.

An identical series of infrared spectra of BA is presented in Fig. 7. It should be observed that, with one notable exception, these spectra reflect changes identical to those seen in the spectra of HBA. The infrared spectrum of the deuterochloride of BA exhibits four principal bands, whereas all the other spectra of BA and of HBA exhibit only three principal bands.

Identical series of Raman spectra of HBA and BA are presented in Figs. 8 and 9, and the vibrational data are summarized in Tables 1 and 2. The Raman spectra of the solid, the Nujol solution, and the chloroform solution of each compound are essentially identical to the corresponding infrared spectra except that the relative intensity changes are more pronounced. For example, the lowest frequency band in the spectrum of HBA is the weakest band in the infrared and Raman spectra of the solid sample; but in the chloroform solution spectra this band is the strongest band in the Raman and it has also gained considerable intensity in the infrared spectrum.

The Raman spectra of the hydrochlorides and deuterochlorides of HBA and BA are, however, different from the corresponding infrared spectra. Each of these Raman spectra consist of one fewer bands than the infrared spectra. The lowest frequency infrared bands, located at 1574 and 1579 $cm^{-1}$, respectively, in the chloroform solution spectra of HBA and BA, are absent in the Raman spectra of the hydrochlorides. It may further be observed that all the Raman spectra of HBA and

BA exhibit a phenyl band in the 1595–1589 $cm^{-1}$ region. A similar band is found in all the infrared spectra of BA and in all the infrared spectra of HBA except those of the hydrochloride and the deuterochloride. (A weak band in the 1590–1585 $cm^{-1}$ region of the infrared spectrum of the deuterochloride of HBA is observed; however, its origin is questionable. It could be the result of incomplete deuteration.)

Now, since the $N^+$—H deformation is expected to be very weak in the Raman, the lowest frequency band at 1583 $cm^{-1}$ in the infrared spectrum of the hydrochloride of HBA is most probably the $N^+$—H deformation which is coupled with the C=$NH^+$ stretching motion. Note that the band is absent in the Raman spectrum. The reappearance of a low frequency band in the Raman spectrum of the deuterochloride would, at first, appear to refute this assignment; but, this Raman band at 1569 $cm^{-1}$ is likely to be of different origin than that of the infrared band at 1583 $cm^{-1}$. Note that upon deuterium substitution the C=$ND^+$ stretching occurs very near the frequency of the neutral C=N group. Since protonation of the imine nitrogen is not expected to greatly perturb the combinations and overtones of the aromatic nuclei, Fermi resonance of the C=$ND^+$ stretching mode may occur once again. Thus the lowest frequency band in the Raman spectrum of the deuterochloride of HBA is of the same origin as the lowest frequency bands in the Raman spectra of the neutral molecule.

The ultimate location of the infrared spectral band which might be attributed to the $N^+$—H deformation is dependent on the extent of coupling of the C=$NH^+$ stretching mode and the $N^+$—H deformation, and on the strength of the $N^+$—H bond (or N...H in the case of hydrogen bonding). Therefore, it is clear that this vibration might be found to occur over a relatively wide frequency range. For example, the band in the spectrum of a hexafluoroisopropanol solution of HBA is located at 1540 $cm^{-1}$, and at 1537 $cm^{-1}$ in the spectrum recorded from a one-to-one mixture of hexafluoroisopropanol and chloroform. The band occurs at 1583 $cm^{-1}$ in the spectrum of the fully protonated hydrochloride. In the case of the deuterochloride the coupling is much less extensive since the frequencies of the two vibrations are widely separated. The $N^+$—D deformation occurs outside the spectral region shown in the present spectra.

The next major difference between the infrared and Raman spectra of the hydrochloride of HBA is that observed in the 1595 and 1610 $cm^{-1}$ regions. All the Raman spectra exhibit a strong band in the 1595–1592 $cm^{-1}$ region but do not exhibit a band of significant intensity near 1610 $cm^{-1}$. On the other hand, the infrared spectra of the neutral forms of HBA exhibit a band in the 1593–1590 $cm^{-1}$ region that is not present (or is very weak) in the spectra of the hydrochloride and the deuterochloride. These latter spectra do, however, contain a strong band near 1610 $cm^{-1}$. There is general agreement that the band near 1595 $cm^{-1}$ may be attributed to an aromatic C=C stretching motion. Since there exists the possibility of two quadrant stretching vibrations in the 1620–1585 and 1590–1565 $cm^{-1}$ region (20), it is felt that both these bands may be assigned as vibrations of the aromatic nuclei. The reasons for widely different intensities of the 1595 $cm^{-1}$ band in the infrared and of the 1610 $cm^{-1}$ band in the Raman spectra of the hydrochloride and deuterochloride are not clear.

The infrared and Raman spectra of BA may be explained in the same terms as were the spectra of HBA. The spectra of the neutral molecule are almost identical to the corresponding spectra of HBA and thus deserve no further comment than to add that these Raman spectra exhibit a fairly intense band or shoulder in the 1605–1600 $cm^{-1}$ region. The spectra of the hydrochloride and deuterochloride do, however, require more explanation. It is observed that all the spectra of BA contain a strong band in the 1594–1589 $cm^{-1}$ region, whereas the similar band in the infrared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

spectra of the hydrochloride and deuterochloride of HBA was missing. It can also be seen that the infrared spectra of the hydrochloride and deuterochloride of BA exhibit a strong band at 1600 $cm^{-1}$. It seems reasonable to believe that this band is of similar origin as the 1610 $cm^{-1}$ band in the corresponding spectra of HBA, and is of the same origin as the 1605–1600 $cm^{-1}$ band in the Raman spectra of BA.

It is also observed that a band which might be attributed to the $N^+$—H deformation mode of the hydrochloride of BA is not to be found in the spectrum. Since there are relative intensity differences in the 1600 $cm^{-1}$ band of the hydrochloride and deuterochloride it is probable that the $N^+$—H deformation is located in this region.

A comparison of the infrared and Raman spectra of protonated and neutral forms of HBA and BA thus leads to alternate assignments for several observed bands. It is believed that these assignments, which are summarized in Tables 1 and 2, provide a consistent set for the 1700–1500 $cm^{-1}$ region of the spectra of these compounds. The key point seems to be the recognition of the role played by mixing with the $N^+$—H bending mode in determining the frequencies of the C=N stretching and phenyl ring vibrations. These assignments also provide an alternate explanation of the "1550–1500" infrared band described by Ledbetter and, this, together with the absence of a carbonyl stretching band, suggests that substantial amounts of an *ortho*-quinone tautomer do not exist in solution.

## Conclusion

The ultraviolet–visible, infrared, and Raman data presented herein offer no proof for the presence of substantial amounts of enol–keto or enol–"ion-pair" tautomers in the ground state. New infrared bands which might be correlated with the "440 nm" optical absorption band of HBA are not found. As a result of this evidence, it is proposed that in solvents less acidic than hexafluoroisopropanol the C=N bond of HBA is intact and thus no tautomerization or ionization has occurred. This evidence also indicates that in solvents with acidities somewhat greater than or equal to that of hexafluoroisopropanol more than one equilibrium must be taken into account in order to explain the spectral characteristics. The apparent convergence of the "440 nm" absorption band to that of the protonated species strongly suggests that the second equilibrium involves ionic species. It appears therefore that the origin of the 440 nm visible absorption band is still open for future research.

# A spectroscopic study of proton transfer and photochromism in *N*-(2-hydroxybenzylidene)aniline

J. W. LEWIS AND C. SANDORFY

*Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1*

Received 25 August 1981[1]

J. W. LEWIS and C. SANDORFY. Can. J. Chem. **60**, 1738 (1982).

The infrared spectral characteristics of *N*-(2-hydroxybenzylidene)aniline, its deuterium substituted analogue, *N*-(2-hydroxybenzylidene)-*m*-toluidine, and their photoproducts have been investigated. The infrared spectrum of a low temperature polycrystalline film of *N*-(2-hydroxybenzylidene)aniline exhibits new absorption bands at 3380, 1646, 1537, 1502, 1319, and 1310 $cm^{-1}$ upon irradiation at 365 nm. Likewise, the spectrum of the *m*-toluidine derivative exhibits new absorption bands at 3320, 1650, 1535, 1503, 1321, 1310, and 995 $cm^{-1}$ upon irradiation at 365 nm. These new data, in conjunction with the newly acquired data on the hydrochloride and deuterochloride of the title compound, indicate that the photoproduct is a zwitterion, not an *ortho*-quinone. It is also inferrred that the photoproduct exists in a conformation which is *cis* about the central carbon–nitrogen double bond.

J. W. LEWIS et C. SANDORFY. Can. J. Chem. **60**, 1738 (1982).

Les spectres infrarouges de l'*N*-(2-hydroxybenzylidène)aniline (HBA), de son analogue deutérié, de l'*N*-(2-hydroxybenzylidène)-*m*-toluidine et ceux de leurs produits obtenus par irradiation ont été examinés. Dans le spectre infrarouge de l'HBA de nouvelles bandes apparaissent à 3380, 1646, 1537, 1502, 1319 et 1310 $cm^{-1}$ après irradiation à 365 nm. D'une manière analogue le spectre du dérivé *m*-toluidinique présente des bandes nouvelles à 3320, 1650, 1535, 1503, 1321, 1310 et 995 $cm^{-1}$ après irradiation à 365 nm. Ces données nouvelles ajoutées à celles obtenues pour l'hydrochlorure et le deutérochlorure du HBA indiquent que le produit de l'irradiation est un zwitterion et non pas une *ortho*-quinone. En outre, on peut conclure que le produit d'irradiation a une configuration *cis* par rapport à la liaison centrale C=N.

## Introduction

In recent years, there has been much interest in the thermochromic and photochromic activities of salicylaldehyde anils. Many publications on various aspects of these phenomena have appeared. For example, Cohen *et al.* (1–10) have reported that some crystalline anils are photochromic while others are thermochromic, but none of the anils was found to exhibit both properties. Insofar as different crystalline modifications of an anil are concerned, however, one modification might be thermochromic while another is photochromic. These studies also provided proof that the 2-hydroxy group of the salicylaldehyde portion of the anil is a necessary, but insufficient, condition for the observation of the photochromic or the thermochromic phenomenon in the solid state. The sufficient condition was established to be related to the molecular packing in the crystal. A "loose" packing which permits movement of parts of the molecule upon absorption of ultraviolet light was found to be necessary for the observation of photochromism. In a similar manner, a "tight" packing in the crystal was related to the thermochromic behavior of some solid anils. These investigators also demonstrated that in rigid glassy matrices all anils derived from salicylaldehyde and substituted salicylaldehydes are photochromic, independently of whether or not they are so in crystalline form.

In 1962, Cohen and Schmidt (3) proposed mechanisms for the two phenomena. These mechanisms involve the existence of the three tautomers shown in Scheme 1.

In these formulae the labels *cis* and *trans* refer only to the relative positions of the oxygen atom and the hydrogen atom that is covalently bound to the nitrogen atom, and not to any specific conformation of the molecule. The thermochromic process thus involves a simple proton transfer that is made possible by means of certain unspecified intermolecular interactions. The photochromic process involves a proton transfer and a geometric rearrangement (an isomerization about the ring carbon – azomethine carbon bond).

A number of publications on the subject of photochromic anils have appeared since 1962 (4–10, 11–26). With few exceptions, these papers

would appear to confirm the basic proposals of Cohen and Schmidt. That is, the *cis*-quinoid should be identified with the species produced in the thermochromic process as well as the second species found in solutions of anils in hydrogen-bonding solvents, and the *trans*-quinoid should be identified with the species produced photochemically. The exceptions include those of Cohen and Flavian (7, 8), Richey and Becker (14), Rosenfeld *et al.* (18), Wettermark and Dogliotti (15), and Anderson and Wettermark (16).

In their investigation of the luminescence properties of the anils, Cohen and Flavian proposed that ionic species are involved in the long wavelength absorption and emission. Richey and Becker suggested that the final photocolored product is a nonequilibrium form of the true *cis*-quinoid tautomer. Rosenfeld and co-workers, on the basis of theoretical calculations and experimental results, suggested that more than one photocolored species is produced in the forward photochemical reaction. Wettermark and Dogliotti, as well as Anderson and Wettermark, proposed that there are two equilibria in the photochemical reaction. One equilibrium involves proton transfer and tautomerization and the other involves a *trans* → *cis* isomerization about the central carbon–nitrogen double bond. Other authors (5, 6, 22) have also suggested that more than three molecular species may be involved in these processes.

Hadjoudis *et al.* (26) have studied the thermochromic and photochromic properties of a series of Schiff bases derived from 2-hydroxybenzaldehydes and 2-aminopyridines. It was found that none of these compounds, in the form of crystalline films, was photochromic. The crystalline films did show thermochromic effects and, in solution, the compounds were photochromic. These authors concluded that in the crystalline state the compounds are essentially planar and thermochromic, whereas in solution the molecules are able to assume various geometries and are photochromic.

Despite this apparent wealth of spectroscopic data, very little direct structural information concerning the forward (photochemical) and the reverse (photochemical or thermochemical) reaction products of the anils is to be found in the literature. The lack of infrared spectral changes, upon the irradiation of these compounds with ultraviolet light, has been attributed to the unfavorably small quantity of the photoproduct that is attainable by means of ordinary laboratory techniques.

Due to the structural and electronic similarity of these compounds to *N*-benzylideneaniline, it is convincing to argue that the photochemistry should also be somewhat similar. The spectral properties are, however, further complicated by internal hydrogen bonding and by proton transfer in the excited state. In this paper, the nature of the stable photoproduct of *N*-(2-hydroxybenzylidene)aniline will be discussed. On the basis of this investigation it is concluded that it is not necessary to invoke the presence of *ortho*-quinone tautomers to explain the spectral changes that are observed to occur.

## Experimental

*N*-(2-Hydroxybenzylidene)aniline (HBA) and *N*-(2-hydroxybenzylidene)-*m*-toluidine were prepared and purified by the methods described in the preceding papers. The deuterium substituted anil was prepared by refluxing the parent anil in a one-to-three mixture of $D_2O$ and methanol-$d_1$. The process was repeated twice and the final product contained > 90%—OD. The thin polycrystalline films of the anils were produced from a melt between either quartz or sodium chloride plates. Ultra thin films were produced by means of the technique described by Cohen *et al.* (9).

The light source used for the irradiation of the compounds was an Oriel Model 7340 equipped with a 200 W medium pressure mercury arc. The excitation wavelengths were isolated by means of an Oriel Model 7240 monochromator. The bandwidths of the excitation lines were approximately 20 nm, according to the manufacturer's specifications.

The low temperature infrared cell was constructed after the pattern described by Wagner and Hornig (27). The ultraviolet–visible absorption spectra were recorded by means of a Cary 17 spectrometer and the infrared spectra were recorded by means of a Perkin–Elmer 621 spectrometer. The reported infrared frequencies were calibrated to the known bands of polystyrene.

## Results and discussion

### A. *Ultraviolet–visible measurements*

Several absorption spectra of thin polycrystalline films of *N*-(2-hydroxybenzylidene)aniline (HBA) are reproduced in Fig. 1. The visible absorption spectra of the irradiated films exhibit a broad new absorption band with maximum absorbance near 480 nm. In contrast to the featureless absorption band near 440 nm that is observed in the spectra of anils in hydrogen-bonding solvents, the photochemically produced band of this anil has some structure. The spectrum shows shoulders at about 550, 510, and 460 nm in addition to the maximum at 478 nm. The absorption band observed in these spectra has been assigned to a $\pi^* \leftarrow \pi$ transition of the *trans*-quinoid tautomer (3).

The new absorption band reproduced in Fig. 1 is observable only after the irradiation of the anil. (In this work the irradiation was normally carried out at 365 nm since this is the most intense line in the ultraviolet portion of the medium pressure mercury arc spectrum.) The new absorption band is erased or bleached by irradiation at any wavelength which

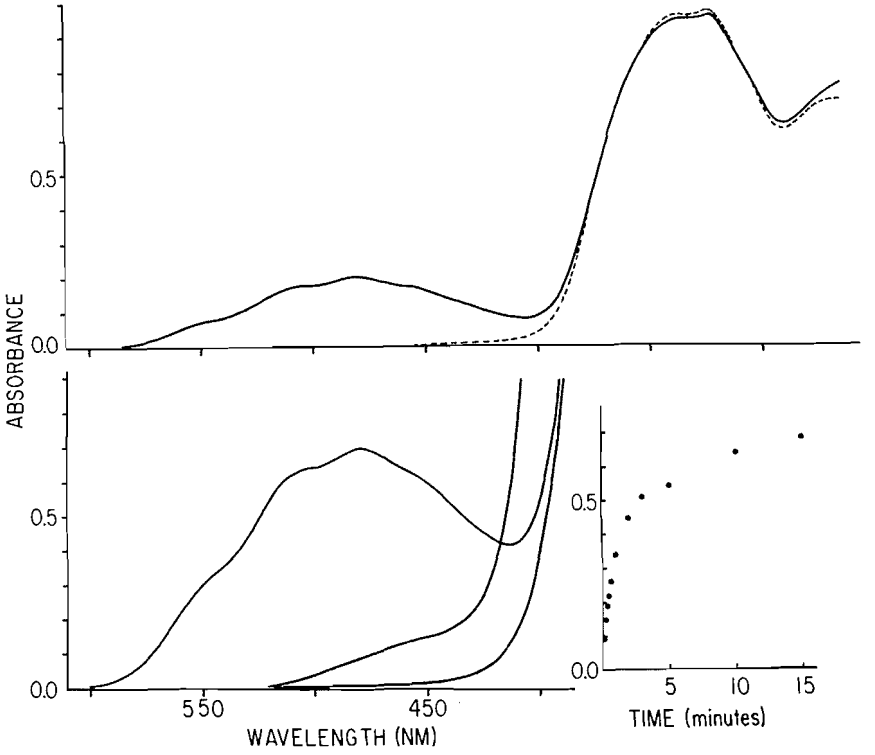

FIG. 1. Absorption spectra of *N*-(2-hydroxybenzylidene)aniline; upper curves: ultra-thin polycrystalline film, ----- before irradiation, — after irradiation at 365 nm; lower curves: thin polycrystalline film; lower right: absorbance at 478 nm as a function of time of irradiation.

lies within this band. It is then obvious that once a sufficient, and small, quantity of the photoproduct has accumulated, the photoproduct begins to absorb the 365 nm radiation and the bleaching commences. In this manner, a limiting concentration of the photoproduct is quickly attained. The development of absorbance at 478 nm as a function of time of irradiation is shown in the bottom right of Fig. 1. In addition to the screening effect or inner filter effect, thermal bleaching is also a contributor to the observed nonlinearity. In these room temperature experiments there is considerable deviation from linearity even after only two minutes of irradiation, although there continues to be an increase in 478 nm absorbance throughout at least fifteen minutes of irradiation.

The thermal bleaching is effectively eliminated by lowering the sample temperature to 77 K, where the photocolor is stable for long periods of time. The inner filter effect is not eliminated, however, by lowering the temperature. Both the forward and the reverse photochemical transformations of crystalline HBA occur at 77 K, but the quantum yields of both are greatly reduced as compared with the room temperature yields. Therefore, some advantage in the form of slightly higher concentration of photoproduct and the elimination of thermal bleaching is gained by lowering the sample temperature to 77 K, but only at the expense of greatly lengthened irradiation times.

It should also be mentioned that the recorded absorption spectra are not corrected for thermal bleaching nor for the photochemical bleaching caused by the measurement process. It is estimated that these errors amount to less than about 8%. (This estimate was made by scanning the entire spectrum, then rapidly returning to various wavelengths within the absorption band and measuring the decrease in absorbance.) The overall shape of the absorption spectra should not, therefore, be greatly affected.

In an attempt to reduce the inner filter effect, irradiation of low temperature thin films of polycrystalline HBA was carried out at 340, 330, 313, and 303 nm. In each case there was no significant change in the amount of photoproduct attained. This could mean that the photoproduct also absorbs at these wavelengths or simply that, due to the diminished intensity of the source at these wavelengths, a much longer period of irradiation is necessary.

At this point, it is perhaps of interest to make

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

For personal use only.

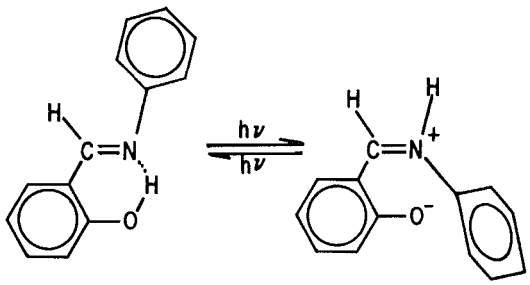
some comments relative to the apparent molar absorption coefficient of the photoproduct. The spectra of an irradiated and a nonirradiated ultra thin film are also shown in Fig. 1. Clearly the increase in absorbance at 478 nm is at least ten times greater than the decrease in absorbance at 340 nm. If it is assumed that absorbance at 340 nm is linear with concentration of the enol, then it must be concluded that the coefficient of the photoproduct is ten times that at the solid enol. It is, of course, a distinct possibility that enol absorbance at 340 nm is not linear with concentration despite the fact that the total absorbance is less than 1.0. Cohen *et al.* (5, 6) report the spectra of irradiated and nonirradiated low temperature solutions of several *N*-salicylideneanilines and in all cases it appears that the increase in absorbance at the visible wavelength is greater than the decrease in absorbance at the near ultraviolet wavelength. In no case, however, is the ratio so large as in the case of the ultrathin polycrystalline film reported here. Some of the photoproduct spectra reported by Cohen and coworkers may also indicate an additional new absorption band in the region of the lowest energy band of the enol. The spectra reported in this present work do not give such an indication. While no conclusions may be made, it appears that the absorption coefficient of the photoproduct exceeds that of the enol. In any case, it is a matter which requires further investigation.

On the basis of similar electronic structure, it might be assumed that the photochemistry of HBA and *N*-benzylideneaniline (BA) are also closely related. The scheme shown (Scheme 2) might be proposed for overall photoproduct formation. Like BA, the initial enol of HBA exists in a conformation which is *trans* about the C=N bond and the aniline ring is somewhat twisted out of the molecular plane. (Note that *trans* and *cis*, as used here, describe the conformation about the C=N bond and not the relative positions of the hydrogen and oxygen atoms as was the case in Scheme 1.) The absorption of a photon causes an ultrafast proton transfer (24) which might be followed by a slower inversion at the nitrogen. The inversion results in a conformation which is *cis* about the C=N bond. This model differs considerably from that proposed by other investigators. It has been argued that the *trans*-quinoid (see Scheme 1) is produced by means of a rotation about the ring carbon – imine carbon bond (13), but there is no valid reason to suspect that the photochemistry of HBA and BA should be so different.

It is well known that protonation of the imine nitrogen actually stabilizes the *cis*-conformation of



SCHEME 2

BA (28). For example, the irradiation of room temperature solutions of BA produces no stable photoisomers, although the *cis*-conformer may be observed by means of flash techniques (29). The irradiation of room temperature solutions of BA in 96% sulfuric acid, on the other hand, results in the formation of the thermally stable *cis*-*N*-benzylideneanilinium cation (28). In this solvent system BA is protonated in the ground state, hence the protonated imine nitrogen inhibits the return to the *trans*-conformation. It would be of interest to know whether a similar phenomenon occurs in solvent systems wherein BA is not protonated in the electronic ground state but in which protonation could occur in the excited state.

The ultraviolet–visible absorption spectrum of irradiated solutions of thin polycrystalline films of HBA may then contain contributions from three species. These are the original intramolecularly hydrogen bonded enol, an enol that is not internally hydrogen bonded, and the *cis* "ion-pair". The spectrum is dominated by the absorption of the original hydrogen bonded enol because inner filter effects (reverse, *cis* → *trans* photoisomerization) limit the concentration of the *cis* "ion-pair".

B. *Infrared measurements*

According to the arguments presented in the previous sections, the infrared spectrum of an irradiated thin polycrystalline film of HBA should reflect changes similar to those of an irradiated film of BA. In addition to the spectral changes that result from the *trans* → *cis* isomerization, changes indicating the transferred proton and changes involving the phenolate anion are to be expected. It should be added that perhaps very little change in the Ar—N stretching frequency is expected since there can be little favorable nitrogen lone pair – aniline ring interactions (see Scheme 2).

The 3500–2500 and 1700–1500 $cm^{-1}$ regions of the spectra of irradiated and nonirradiated thin films of HBA are shown in Fig. 2. As was expected, the new photoproduct bands are weak but assignments are entirely possible. The three new bands at

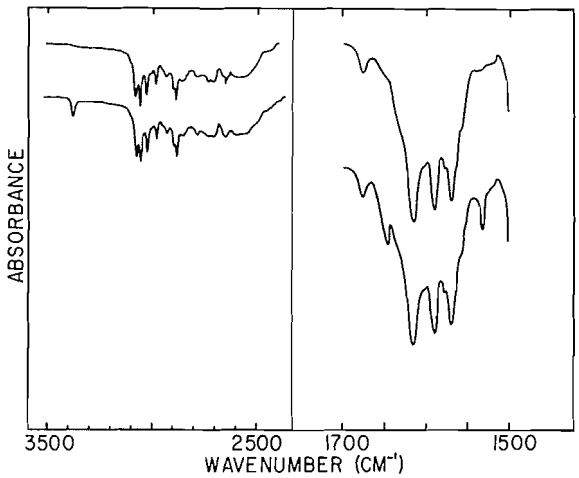


FIG. 2. Infrared absorption spectra of *N*-(2-hydroxybenzylidene)aniline; upper curve: thin polycrystalline film before irradiation, 77 K; lower curve: thin polycrystalline film after irradiation at 365 nm, 77 K.

3380, 1646, and 1537 $cm^{-1}$ are directly associated with the development of the 478 nm optical absorption band. These bands may be bleached by re-irradiating the sample at 547 nm, for example, or by allowing the sample to warm. The irradiation and re-irradiation of the sample may be repeated at will without any sign of fatigue or photodecomposition. The new bands in the spectrum of the irradiated sample shown in Fig. 2 result from six hours of continuous irradiation at 365 nm of a film maintained at 77 K. A similar intensity of the 1646 $cm^{-1}$ band may be developed by only 30 min of irradiation at 365 nm of a room temperature sample; however, in the infrared beam of the spectrometer, the photocolor fades very rapidly as attempts to record a spectrum are made. For example, during the time required for the normal recording of the spectrum from 1700 to 1500 $cm^{-1}$, the 1537 $cm^{-1}$ band will have decreased in intensity by more than one-half. It is thus not surprising that ordinary infrared spectra of the photoproduct have not previously been published.

Nakagaki *et al.* (23) have obtained a difference spectrum, by means of Fourier transform infrared techniques (FTIR), of *N*-(2-hydroxybenzylidene)-*m*-toluidine. These authors' results are summarized in Table 1. In view of our observations, it seems to be necessary to modify some of these assignments.

(a) It is rather unusual that the C=N stretching frequency of a deuterium substituted Schiff base should be higher than that of the hydrogen derivative. It is true that intramolecular hydrogen bonding does not produce the magnitude of spectral

TABLE 1. Infrared bands of *N*-(2-hydroxybenzylidene)-*m*-toluidine after Nakagaki *et al.* (23)[a]

| Assignment | Frequency ($cm^{-1}$)(—OH) | Frequency ($cm^{-1}$)(—OD) |
|---|---|---|
| C=N | 1616 | 1620 |
| Ring skeletal stretching | 1597 | 1597 |
| | 1570 | 1570 |
| C=O | 1651 | 1644 |
| Amide vinylog and ring skeletal stretching | 1539 | 1529 |
| | 1510 | 1505 |
| | 1487 | 1487 |
| C—N | 1319 | 1319 |

[a]The recorded data were obtained from an FTIR difference spectrum of a KBr disc at room temperature.

shifts that might be expected on reasonable theoretical grounds and intermolecular hydrogen bonding has essentially no effect at all, but the shifts, when observed, are generally in the proper direction.

(b) The band assigned by Nakagaki and co-workers as due to a C=O stretching and two of the three bands assigned to modes of a "quinoid ring and the amide vinylog, HN—C=C—C=O", of the photoproduct exhibit deuterium isotope shifts of 7, 10, and 5 $cm^{-1}$, respectively. On the other hand, the C—N (single bond) stretching mode, which is subject to a greater isotope effect since this bond is nearer to the site of deuterium exchange, shows no isotope effect at all. The proposed structure of the photoproduct, a *trans*-quinoid (see Scheme 1), is not capable of exhibiting hydrogen (deuterium) bonding, hence the reported isotope shifts must be due to a mass effect. The mass effect must be transmitted along the DN—C=C—C=O chain and, as a result, the lack of an effect on the adjacent C—N bond is hard to understand.

(c) One of the 1579, 1510, and 1487 $cm^{-1}$ bands must be the so-called amide II band. Amide II bands are normally ascribed to an interaction between the N—H bending and the C—N stretching modes (30–32). The resultant two bands, amide II and amide III, are sensitive to isotope effects. Deuterium shifts are smaller than expected but still amount to about 6% (32) or approximately 100 $cm^{-1}$ in the case of the amide II band. The small deuterium frequency shifts observed by Nakagaki and co-workers are then not easily reconcilable with an amide II band assignment.

In the present work, experiments have also been carried out with HBA-$d_1$, and the spectra are reproduced in Fig. 3. Before further discussion of the photoproduct spectral bands, it is of interest and indeed necessary to examine the spectrum of a polycrystalline film of nonirradiated HBA-$d_1$. It is observed that this spectrum exhibits bands at 1614,

FIG. 3. Infrared absorption spectra of *N*-(2-hydroxybenzylidene)aniline-$d_1$; upper curve: thin polycrystalline film before irradiation; lower curve: thin polycrystalline film after irradiation at 365 nm.

1589, 1578 (shoulder), and 1558 $cm^{-1}$. The corresponding spectrum of HBA shows bands at 1615, 1590, 1578 (shoulder), and 1571 $cm^{-1}$. It is quite obvious that the shift of the 1571 $cm^{-1}$ band to 1558 $cm^{-1}$, upon deuterium exchange, cannot be explained if its assignment as a pure ring skeletal vibration is retained. In the preceding article it was shown that the band at 1571 $cm^{-1}$ in the spectrum of polycrystalline HBA is influenced by Fermi resonance with the 1615 $cm^{-1}$ C=N stretching mode. For HBA-$d_1$ the same arguments are applicable if the changed conditions for Fermi resonance are taken into account. The expected downward deuterium shift of the C=N stretching band is not accurately represented by the negligible 1 $cm^{-1}$ shift of the 1615 $cm^{-1}$ component. Deuterium substitution leads to increased repulsion between the two states and leads to the apparent lack of a shift of the 1615 $cm^{-1}$ band and the observed shift of the 1571 $cm^{-1}$ band to 1558 $cm^{-1}$. The extent of the deuterium shift on the C=N stretching frequency is, therefore, not known since the true position of the C=N stretching frequency is in question.

Percy and Thornton (33), in a study of 28 *N*-(2-hydroxybenzylidene)anilines, assign a pair of bands in each infrared spectrum as due to the C=N stretching mode. In these examples the high frequency band occurs in the range from 1629 to 1613 $cm^{-1}$ and the low frequency band occurs in the range from 1582 to 1568 $cm^{-1}$. Further, these authors discuss the infrared spectra of 38 Co(II), Ni(II), Cu(II), and Zn(II) chelates derived from these Schiff bases. A pair of bands attributable to the C=N stretching mode were found in 37 of the 38 infrared spectra. In these examples the high frequency bands were found in the 1618 to 1602 $cm^{-1}$ range and the low frequency bands were found in the 1597 to 1574 $cm^{-1}$ range. They also invoked Fermi resonance in order to interpret their spectra.

A comparison of Figs. 2 and 3 reveals that the photoproduct bands of HBA at 1646 and 1537 $cm^{-1}$ are apparently shifted to 1642 and 1529 $cm^{-1}$, respectively, in the spectrum of the deuterium substituted photoproduct, HBA-$d_1$. It will also be noted that the ordinary infrared spectra of the HBA and HBA-$d_1$ photoproducts exhibit only one band in the 1550–1510 $cm^{-1}$ range, whereas Nakagaki and co-workers report two bands in this region of the FTIR difference spectra of the *N*-(2-hydroxybenzylidene)-*m*-toluidine photoproduct and its deuterium substituted photoproduct. Obviously, the comments made earlier with respect to the assignments of Nakagaki and co-workers are also applicable here in the case of HBA and HBA-$d_1$. The small apparent isotope effects that are observed are not consistent with the assignment of these bands to the C=O stretching and the C=C or H—N (D—N) + C—N (amide II) stretching modes. On the one hand, a large (100 $cm^{-1}$) deuterium shift is expected for an amide II band and the observed shift is only 8 $cm^{-1}$, and, on the other hand, only a negligible deuterium shift is expected for a C=O stretching vibration and a 4 $cm^{-1}$ shift is observed. It is quite possible, however, that the 1537 $cm^{-1}$ band observed in the spectrum of the HBA photoproduct is of different origin than the 1529 $cm^{-1}$ band of the HBA-$d_1$ photoproduct.

The band at 3380 $cm^{-1}$ in the spectrum of the HBA photoproduct is attributed to the $N^+$—H stretching vibration. This spectrum provides the first recorded experimental evidence related to the disposition of the phototransferred proton. Clearly the sharpness of this band and its relatively high frequency (34, 35) eliminate the possibility of hydrogen bonding to the phenolate oxygen or to neighboring molecules. Unfortunately, an $N^+$—D stretching band was not located in the spectrum of the HBA-$d_1$ photoproduct. It is likely, however, that the $N^+$—D stretching band is much weaker than the already weak $N^+$—H stretching band.

It is proposed, therefore, that the 1646 and 1537 $cm^{-1}$ bands in the spectrum of the HBA photoproduct are attributable to the C=$NH^+$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

stretching and the N—H deformation modes. These modes are not completely independent. It was shown previously that these modes of the HBA hydrochloride are strongly coupled, so there is every reason to suspect that they would also be coupled in this case. The differences between the frequencies of the photoproduct bands and those of the hydrochloride may be rationalized in terms of changes in the degree of coupling. For example, the photoproduct is necessarily a zwitterion, which is probably in a *cis*-conformation about the C=N bond, while the hydrochloride is a true salt. In addition, the spectrum of the hydrochloride was obtained from a solution while that of the photoproduct was obtained from a polycrystalline film. These environmental perturbations could exaggerate the frequency differences.

The stretching frequency of a $C{=}NH^+$ group is expected to decrease some 25–35 $cm^{-1}$ (36) when the hydrogen is replaced by a deuterium atom. The observed frequency shift in the spectrum of the HBD-$d_1$ photoproduct is only 4 $cm^{-1}$. Meanwhile the HBA photoproduct band at 1537 $cm^{-1}$ apparently shifts to 1529 $cm^{-1}$ in the spectrum of the HBA-$d_1$ photoproduct. These small isotope shifts would appear to invalidate the above assignments for the photoproduct of HBA, but it must be recalled that the lower frequency infrared bands in the spectra of the hydrochloride and deuterochloride of HBA were interpretable only (paper II) when different degrees of Fermi resonance, by which the bands are affected, are considered. There are small differences between the corresponding band positions of the photoproduct and the deuterochloride, but these may be satisfactorily accounted for by differences in the structure of the two species and by changes in the amount of resonance.

The infrared spectra of a polycrystalline film of *N*-(2-hydroxybenzylidene)-*m*-toluidine, recorded before and after irradiation at 365 nm, are presented in Fig. 4. These spectra are severely distorted in the range from 1650 to 1550 $cm^{-1}$, as may be ascertained by a comparison with the accompanying spectrum which was obtained from a chloroform solution of the compound. Numerous attempts to obtain a better quality film were not successful and KBr discs, even after repeated grindings, failed to yield a quality spectrum in the 1650–1550 $cm^{-1}$ region. In order not to complicate the spectra only those regions wherein major spectral changes occur are reproduced in Fig. 4. Despite the quality of the spectra, new photoproduct bands are observable at near 3320, (1650), 1535, 1503, 1321, 1310, and 995 $cm^{-1}$. Note that the band

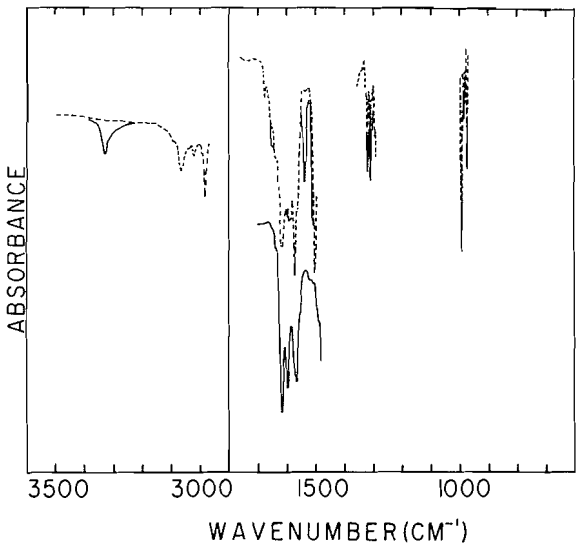

FIG. 4. Infrared absorption spectra of *N*-(2-hydroxybenzylidene)-*m*-toluidine; upper curves: ----- thin polycrystalline film before irradiation, — thin polycrystalline film after irradiation at 365 nm, 77 K; lower curve: chloroform solution.

located near 1650 $cm^{-1}$ appears only as a slight broadening.

For the reasons outlined earlier the 3320 $cm^{-1}$ band is attributable to the $N^+$—H stretching mode and the pair of bands at (1650) and 1535 $cm^{-1}$ are attributable to the coupled $C{=}NH^+$ stretching and $N^+$—H deformation modes. It is probable that the band located near 1503 $cm^{-1}$ reflects a slight shift of an aromatic skeletal stretching motion, which is produced by the geometric rearrangement. This assignment is made since a similar band is observed in the spectrum of irradiated *N*-benzylideneaniline, which is not capable of undergoing any structural change except *trans* → *cis* isomerization. The two bands at 1321 and 1310 $cm^{-1}$ may be related to the phenolate anion; however, it should be mentioned that a pair of bands occurs at these frequencies in the spectrum of the nonirradiated compound. It is likely therefore that these spectral changes represent intensifications of existing bands and do not represent new vibrational modes such as the C—N stretching as proposed by Nakagaki *et al.* (23). The weak band located near 995 $cm^{-1}$ is of undetermined origin but may reflect a vibration of the aromatic phenolate nucleus.

The 1500–700 $cm^{-1}$ region of the infrared spectra of nonirradiated and irradiated films of HBA is not presented since these spectra are very similar to those of *N*-(2-hydroxybenzylidene)-*m*-toluidine. New but weaker photoproduct bands are observed near 1502, 1319, and 1310 $cm^{-1}$ and these bands

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

show no deuterium isotope effects. No new photoproduct band was observed near 1000 $cm^{-1}$, but an intensification of a band near 863 $cm^{-1}$ is noted.

The infrared study of the photochromic properties of other Schiff bases was also attempted. Films of Schiff bases derived from salicylaldehyde and *p*-methoxy-, *p*-bromo-, *p*-chloro, *p*-iodo-, and 2,5-dimethylaniline and *p*-aminoacetophenone were formed and tested. Only the film formed from *N*-(2-hydroxybenzylidene)-*p*-aminoacetophenone proved to be slightly photochromic, although no useful infrared bands of the photoproduct could be found in the spectrum. This latter compound proved, however, to be most interesting. The solid compound, as obtained by crystallization from ordinary solvents, is highly photochromic, perhaps even more so than any of the compounds studied. Crystals that are derived from a melt, on the other hand, were very weakly photochromic. The 3500–3000 and 1800–1500 $cm^{-1}$ regions of the infrared spectra of a perchloroethylene solution and a crystalline film (derived from a melt) are shown in Fig. 5. The solid state spectrum is greatly distorted in the 1800–1500 $cm^{-1}$ region and the carbonyl C=O stretching is split into two bands. Apparently this is due to intermolecular hydrogen bonding between the phenolic O—H and the C=O of the acetyl group. There is also evidence (the sharp band at 3400 $cm^{-1}$) that at least some of the molecules exhibit free phenolic O—H groups. Thus several different species exist in the melt-derived crystals. The solution spectrum shows no evidence of free O—H groups nor of intermolecular hydrogen bonding. It is therefore highly probable that for this particular compound the photochromic character is strictly dependent on the internal chelate ring involving the O—H...N hydrogen bond. Apparently intermolecularly hydrogen bonded and non-hydrogen bonded molecules do not exhibit photochromism.

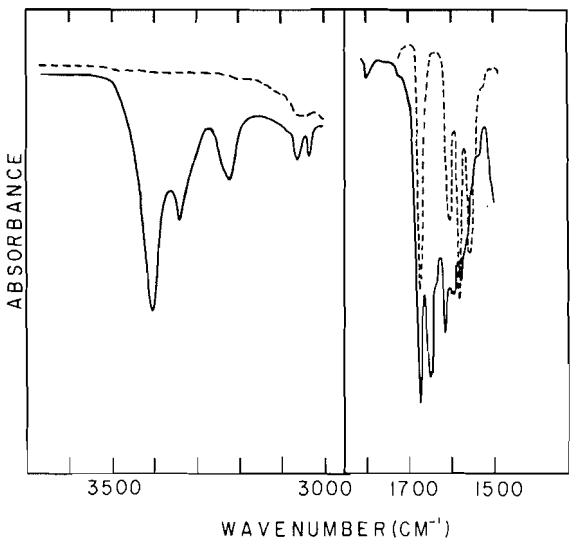

FIG. 5. Infrared absorption spectra of *N*-(2-hydroxybenzylidene)-*p*-aminoacetophenone, ----- perchloroethylene solution, — thin polycrystalline film.

## Conclusion

The infrared spectra of *N*-(2-hydroxybenzylidene)aniline, its deuterium substituted counterpart, *N*-(2-hydroxybenzylidene)-*m*-toluidine, and their photoproducts have been presented. These new data, in conjunction with the information gained in the studies of *N*-benzylideneaniline and its photoproduct and of the solvent dependent processes of these compounds, permit well founded assignments of the observed bands in the infrared spectra of the photoproducts. The photoproduct is thus determined to be a zwitterion, not an *ortho*-quinone. It is further noted that the *cis*-conformation about the C=N bond is required since hydrogen bonding between the $C—O^-$ and $N^+—H$ groups does not exist.

J. P. WIGNACOURT, G. MAIRESSE, P. BARBIER, A. LORRIAUX-RUBBENS, and F. WALLART. Can. J. Chem. **60**, 1747 (1982).

The degree of hydration of stable hydrates is discussed on the basis of early literature results and our determination of the phase diagrams for the systems $InCl_3$–KCl–$H_2O$ and $InBr_3$–KBr–$H_2O$ at 21°C. The existing double salts are formulated: $3KCl \cdot InCl_3 \cdot H_2O$ and $2KCl \cdot InCl_3 \cdot H_2O$ in the chloride system, and $3KBr \cdot InBr_3 \cdot 1.5H_2O$, $2KBr \cdot InBr_3 \cdot H_2O$, $KBr \cdot InBr_3 \cdot 2H_2O$, and $3KBr \cdot 2InBr_3$ in the bromide system. All of them are incongruently saturating at 21°C. A summary of their crystallographic and Raman spectroscopic data is given.

J. P. WIGNACOURT, G. MAIRESSE, P. BARBIER, A. LORRIAUX-RUBBENS et F. WALLART. Can. J. Chem. **60**, 1747 (1982).

A partir de la détermination des diagrammes de phase à 21°C: $InCl_3$–KCl–$H_2O$ et $InBr_3$–KBr–$H_2O$, la composition exacte des hydrates stables à cette température est discutée par rapport aux données bibliographiques antérieures. Les sels doubles existants sont formulés: $3KCl \cdot InCl_3 \cdot H_2O$ et $2KCl \cdot InCl_3 \cdot H_2O$ dans le système des chlorures; $3KBr \cdot InBr_3 \cdot 1.5H_2O$, $2KBr \cdot InBr_3 \cdot H_2O$, $KBr \cdot InBr_3 \cdot 2H_2O$ et $3KBr \cdot 2InBr_3$ dans le système des bromures. Ceux-ci sont tous à solubilité non congruente à 21°C. Un résumé de leurs caractéristiques cristallographiques et spectroscopiques (Diffusion Raman) est donné.

## Introduction

Although the hydrated double salts between indium trihalides and potassium halides (general formula $K_3InX_6 \cdot nH_2O$) were reported in early literature, their degree of hydration is still a much debated question. The $K_3InCl_6 \cdot 1.5H_2O$ complex was first proposed by Meyer (1) in 1869. Early in the present century, Wallace (2) identified compounds with the $K_3InX_6 \cdot 2H_2O$ (X = Cl, Br) formulation. In 1974, we established the $InCl_3$–KCl–$H_2O$ solubility diagram at 21°C (3) which characterises the existence of the $K_3InCl_6 \cdot H_2O$ and $K_2InCl_5 \cdot H_2O$ incongruently saturating compounds, as well as the salt $InCl_3 \cdot 4H_2O$. The formulation $K_3InCl_6 \cdot 2H_2O$ was given more recently in a study by Kartzmark of the same system at 25°C (4).

Arguing from the results of X-ray and Raman structural investigations, we discuss the formulation of the existing double salts at 21°C in the $InCl_3$–KCl–$H_2O$ system, as well as in the corresponding one $InBr_3$–KBr–$H_2O$.

## Experimental

The starting materials were $InCl_3$ and $InBr_3$ synthesised in this laboratory and reagent grade potassium halides. The systems studied were stirred at 21°C in a water bath thermostated at 20 ± 0.2°C.

The solubility diagrams were established using the "global point" and the "wet residue" methods. We chose the starting mixture composition (global point) so that the whole diagram is covered with a minimum set of experiments. Indium trihalide is introduced in the solubility reactor and weighed in a dry box, and the corresponding quantities of potassium halide and water are then calculated and added (the total mass being about 5 g). Equilibrium is considered to be reached when the solution density, measured by means of a double capillary (Cornec-Cottet) pipette, remains constant. About 2 or 3 days are required for equilibrium in the bromide system and most of the chloride one. For the highly viscous indium halide-rich solutions, crystallisation of the solid phase requires thermal treatment (5) to transform the vitreous metastable state into a thermodynamic equilibrium between the solid phase and its saturated solution.

In all cases, the solution is sampled by means of the densimetric pipette and submitted to chemical analysis. Then, the solid phase is separated from the remaining solution through sintered glass, and identified by X-ray diffraction, Raman scattering, and chemical analysis.

Chloride and bromide are analysed by mercurimetry, the reactive indicator being nitroprusside. Indium is determined by precipitation of the $In(C_9H_6NO)_3$ oxinate, and the potassium ion is determined with a Perkin-Elmer atomic absorption apparatus. Both are reproducible to within 1%.

The results of the analyses, plotted on the diagrams of Figs. 1 and 3, are consistent when a straight line joins the solution, the global and the solid points, respectively. The composition of the stable compounds and the invariant solutions are obtained from the intersection points of sets of these lines. As numerous double salts have been identified in both systems, the right-triangle representation (6) was adopted, resulting in better separation of existence areas than is obtained with the usual equilateral triangle.

X-ray diffraction patterns are obtained from dried polycrys-

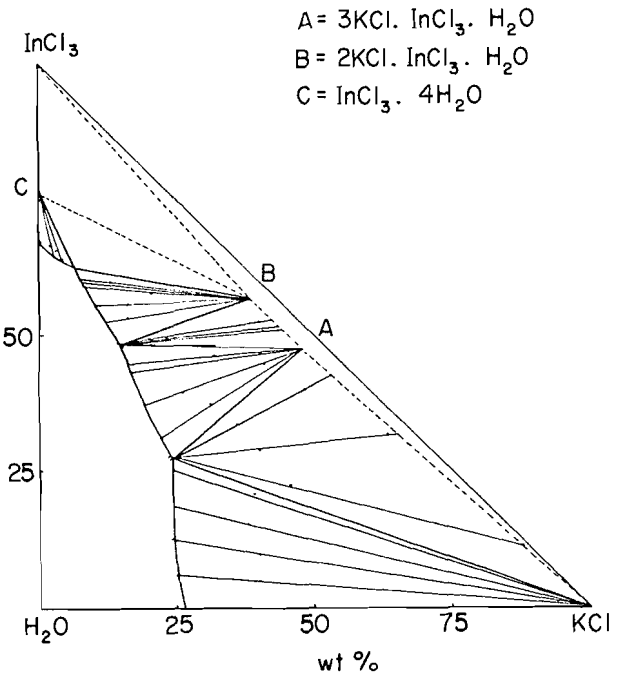

FIG. 1. $InCl_3$–KCl–$H_2O$ system at 21°C.

talline samples. The unit cell dimensions have been determined from single crystals studied on the Philips PW 1100 four circle automated diffractometer of the University of Lille.

The Raman spectra were obtained with a triple monochromator spectrometer using the 514.5 nm exciting line of a Spectra Physics $Ar^+$ laser. Polycrystalline samples were studied directly in the reactor, whereas single crystals were sealed in glass tubes.

## Results and discussion

### *$InCl_3$–KCl–$H_2O$ system*

The experimental data are plotted in Fig. 1 and the compositions of the invariant solutions given in Table 1. The identification of the compounds was made using Raman spectroscopy and X-ray diffraction. The low-frequency Raman spectra, which are shown in Fig. 2, are very specific; thus identification is possible from the analysis of the spectra in the 270–300 $cm^{-1}$ frequency range, which includes the $\nu_s$(In—Cl) stretching vibration (Fig. 2). The band shapes are quite different, as well as their frequencies: 274 and 288 $cm^{-1}$ for $K_3InCl_6 \cdot H_2O$ (7); 286 $cm^{-1}$ for $K_2InCl_5(H_2O)$ (8), and 296 $cm^{-1}$ in $InCl_3 \cdot 4H_2O$ (9).

The $K_3InCl_6 \cdot nH_2O$ molar masses, with $n = 1$, 1.5, or 2 are not very different, being 463.1, 472.1, and 481.1 respectively. Thus the precise determination of $n$ is difficult.

From this study we propose three arguments in favour of the monohydrate $K_3InCl_6 \cdot H_2O$: (*1*) The determination of $n$ from the diagram is unambiguous, as the composition results from the convergence of a set of lines displayed on such a wide area of concentration, that the value obtained is sufficiently precise. (*2*) The chemical analyses of large crystals (5 × 4 × 4 mm), carefully dried from the mother liquor, lead to a value of $n = 1$ (Table 2). (*3*) The thermal dehydration beginning at 50°C shows a mass loss corresponding to one water molecule per salt molecule.

Furthermore a recent crystal structure determination (10) confirms the $K_3InCl_6 \cdot H_2O$ formulation.

The room-temperature stable hydrate of indium trichloride was given as the tetrahydrate $InCl_3 \cdot 4H_2O$ by Ensslin *et al.* (11) in 1942. We have proven its existence at 21°C by the controlled hydrolysis of $InCl_3$ (3): when submitted to a constant vapor

pressure, the sample mass first goes up, and then stabilizes at a level corresponding to a $4H_2O/1InCl_3$ mass ratio. Furthermore, the resulting compound shows an X-ray pattern and a Raman spectrum identical to those obtained on the basis of the solubility diagram.

In several recent papers (12, 13) concerning the diagrams of the systems $InCl_3$–pyridine–$H_2O$, $InCl_3$–NaCl–$H_2O$, $InCl_3$–$CaCl_2$–$H_2O$, and $InCl_3$–dioxane–$H_2O$ at 25°C, Kartzmark indicated the existence of $InCl_3 \cdot 3H_2O$. The author proposed this formulation as the one given on the label from the commercial supplier. The knowledge of our results (3) made her reexamine her formulation, and in a recent paper (4) the tetrahydrate was reported as the stable salt at 25°C in the systems $InCl_3$–$In_2(SO_4)_3$–$H_2O$ and $InCl_3$–$M^ICl$–$H_2O$ ($M^I$ = Li, K, Rb, Cs, $NH_4$).

The selective preparation of the incongruently saturating double salts $K_2InCl_5 \cdot H_2O$ and $K_3InCl_6 \cdot H_2O$ on the basis of the ternary diagram has enabled their complete structural investigation by X-ray and Raman scattering (7, 8, 10), the results being widely discussed and compared with the literature. The crystallographic data are summarized in Table 3.

*$InBr_3$–KBr–$H_2O$*

Data which were obtained from the analyses of 36 solubility tubes are plotted on Fig. 3. They indicate the existence at 21°C of the dihydrate $InBr_3$–$2H_2O$, and of four incongruently saturating double salts: $K_3InBr_6 \cdot 1.5H_2O$; $K_2(InBr_5,H_2O)$; $KInBr_4(H_2O)_2$ and $K_3In_2Br_9$. The composition of invariant solutions are given in Table 4.

The two salts $K_3InBr_6 \cdot 1.5H_2O$ and $K_2(InBr_5, H_2O)$ are isomorphous with the corresponding chlorinated compounds, as shown by the crystallographic data (9) given in Table 3.

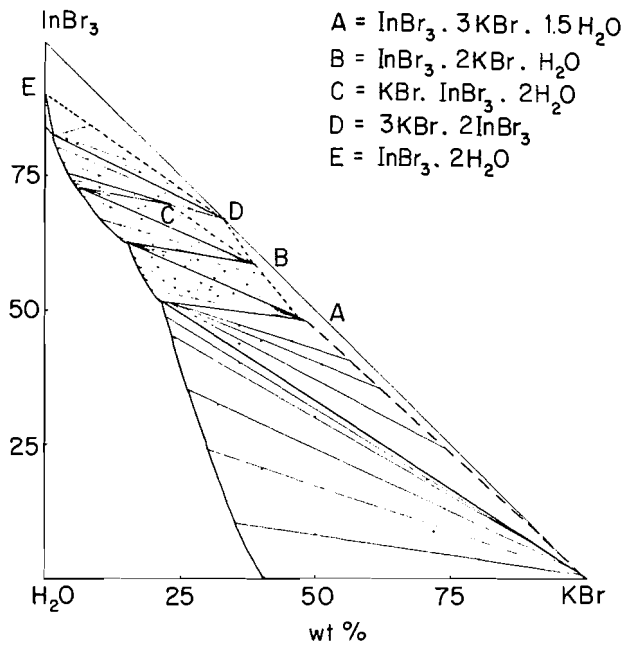

FIG. 3. $InBr_3$–KBr–$H_2O$ system at 21°C.

At 21°C, the area of existence of $KInBr_4(H_2O)_2$ is narrow; experiments at higher temperatures (25–30°C) show enlargement to the detriment of the area for $K_2InBr_5 \cdot H_2O$. In this part of the diagram, we used Raman identification of the solid phases, as X-ray diffraction is less reliable on highly hygroscopic polycrystalline samples. Nevertheless, a single crystal X-ray study led to a characterisa-

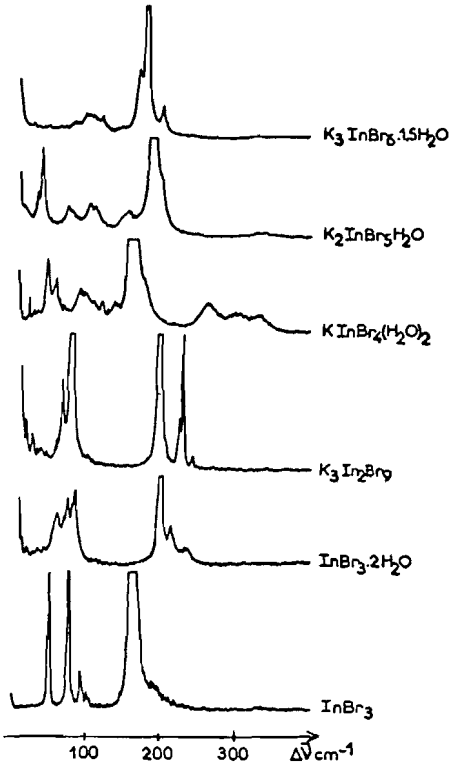

FIG. 4. Raman spectra of the stable solid phases in the bromide system.

tion of the $(InBr_4(H_2O)_2)^-$ centrosymmetric ion, in which the water molecules are *trans*-located (14).

The fact that $K_3In_2Br_9$ was obtained from an aqueous bromide mixture is rather surprising because the $InBr_3$–KBr binary system (15) does not show the existence of such a double salt. An analogous phenomenon has been observed in the $TlCl_3$–CsCl–$H_2O$ system (16) with the formation of $Cs_3Tl_2Cl_9$.

In the $InBr_3$–$H_2O$ binary system, Ensslin *et al.* (11) have shown the existence of $InBr_3 \cdot 2H_2O$ over the temperature range 21 to 33°C. The hydrate existing under 21°C was $InBr_3 \cdot 5H_2O$ and the anhydrous salt was obtained above 33°C. In this work, we found that the hydrate stable at 21°C is $InBr_3 \cdot 2H_2O$. It should be pointed out, however, that some experiments carried out at 20.7°C have yielded $InBr_3 \cdot 5H_2O$. Curiously, in a study of the $InBr_3$–NaBr–$H_2O$ system (17) at 25°C, Kartzmark found $InBr_3$ as the stable solid phase.

The different compounds are identified by their low-frequency Raman spectra (Fig. 4), in which the 150–250 $cm^{-1}$ region is characteristic. The $\nu_s$(In—Br) band shape and position are different for each compound, the frequency values being: 169 $cm^{-1}$ in $InBr_3$; 195 $cm^{-1}$ for $InBr_3 \cdot 2H_2O$; 197 $cm^{-1}$ for $K_3In_2Br_9$; 162 $cm^{-1}$ in $KInBr_4(H_2O)_2$; 185 $cm^{-1}$ for $K_2(InBr_5, H_2O)$ and 175 $cm^{-1}$ in $K_3InBr_6 \cdot 1.5H_2O$.

## Conclusion

The preparation of incongruently saturating double salts from aqueous solution can only be reliably carried out with a knowledge of the appropriate ternary phase diagram. In this work the double salts between $InX_3$ and KX (X = Cl, Br) were prepared at 21°C by this method. In such an investigation Raman spectroscopy serves as a powerful solid phase identification tool.

A summary gives the crystallographic data and the frequencies $\nu_s$(In—X) of the indium–halogen symmetric stretching vibration for each stable solid phase.

# Observation de la résonance paramagnétique électronique dans les composés organométalliques de l'uranium (III)

E. J. SOULIÉ, G. FOLCHER ET H. MARQUET-ELLIS

*Département de Physico-Chimie, Centre d'Etudes Nucléaires de Saclay, 91191 Gif-sur-Yvette Cedex, France*

Reçu le 25 septembre 1981[1]

E. J. SOULIÉ, G. FOLCHER et H. MARQUET-ELLIS. Can. J. Chem. **60**, 1751 (1982).

L'état de valence III de l'uranium peut être facilement mis en évidence en solution gelée par RPE. Un signal de résonance large, observé à température très basse (7 K) à $g = 3.5$ est caractéristique de l'état trivalent de l'uranium dans $UZrF_7$(poudre), $U(C_5H_5)_3$·tétrahydrofurane et $U(C_5H_5)_3{\cdot}CH_3^-$ (solution gelées).

E. J. SOULIÉ, G. FOLCHER, and H. MARQUET-ELLIS. Can. J. Chem. **60**, 1751 (1982).

The trivalency of uranium can be easily established in frozen solution by epr. The broad resonance signal observed at low temperature (7 K) with $g = 3.5$ appears as characteristic of the trivalent state in $UZrF_7$(powder), $U(C_5H_5)_3$· tétrahydrofuran, and $U(C_5H_5)_3{\cdot}CH_3^-$ (frozen solutions).

Le degré d'oxydation III de l'uranium est relativement instable en solution aqueuse où le potentiel du couple $U^{III}/U^{IV}$ est de −0,620 V/ENH. Par contre il apparaît que l'$U^{III}$ est stabilisé par les ligands de type $C_5H_5$ (noté Cp). C'est ainsi que l'adduit $UCp_3$·THF où THF désigne le tétrahydrofurane est obtenu facilement par plusieurs méthodes à partir de $UCp_3Cl$ ou $UCp_3$-alkyl (1–4). De même un trimère $[(Me_5C_5)_2U\text{-}Cl]_3$ a été isolé par Marks et coll. (5).

Mais alors que dans le cas des métaux de transition et des lanthanides le degré d'oxydation de l'ion métallique est clairement caractérisé par son spectre électronique, la situation, en ce qui concerne les dérivés organométalliques de l'uranium, est plus confuse. D'une part les transitions de transfert de charge oblitèrent assez largement la région des bandes $f$–$f$; d'autre part la champ cristallin loin d'être une perturbation de la répulsion coulombienne et du couplage spin-orbite mélange les multiplets et rend le spectre des transitions $f$–$f$ trop compliqué, et de ce fait insuffisamment caractéristique du degré d'oxydation pour nous renseigner de manière définitive à son sujet.

L'identification de composés d'uranium III devra donc se faire par d'autres méthodes. L'analyse chimique du composé, s'il peut être isolé et purifié, ne laisse en général aucun doute mais la purification est toujours délicate. Une technique indirecte consiste à utiliser le pouvoir réducteur de l'uranium III.

L'électrochimie ne peut généralement pas être employée sur des composés non isolés.

Il nous a semblé intéressant d'utiliser la résonance paramagnétique électronique (RPE): l'uranium III de structure électronique $5f^3$ est un ion à nombre impair d'électrons dont le niveau fondamental est dégénéré d'après le théorème de Kramers en l'absence de champ magnétique appliqué; contrairement au cas de l'uranium (IV) (6), il doit donc avoir un spectre RPE, sauf cas particulier. (La probabilité de transition entre les deux états issus du doublet de Kramers du niveau fondamental est nulle lorsque ces états n'ont pas de composante $Jz = \pm \frac{1}{2}$. C'est par exemple le cas en symétrie $C_{3v}$ pour un niveau fondamental de représentation irréductible $\Gamma_{5T} + \Gamma_{6T}$.)

Une telle méthode présente l'avantage de pouvoir être mise en oeuvre sur des solutions gelées, elle devrait être sensible si le signal n'est pas trop élargi et surtout sélective dans la mesure ou $U^{IV}$ ne donne aucun signal (6) et $U^V$ apparaît avec un facteur $g$ nettement inférieur à 2 (7) tandis que les radicaux organiques résonnent en donnant des raies fines, parfois nombreuses, s'écartant très peu de $g = 2$. Nous allons voir comment cette méthode a pu être appliquée à l'identification du degré d'oxydation d'un composé d'uranium en solution.

## Résultats et discussion

Aucun spectre d'$U^{III}$ dans un composé pur n'a jamais été rapporté mais l'on connaît le spectre de cristaux où $U^{III}$ intervient comme dopant $LaCl_3$ (8) et $CaF_2$ (9).

Nous disposons d'un composé d'$U^{III}$ parfaitement stable à savoir $UZrF_7$ (10). Ce composé sous forme de poudre a le spectre RPE présenté dans la figure 1. L'allure du spectre résulte de l'élargissement consécutif aux interactions qui sont absentes des composés en matrice.

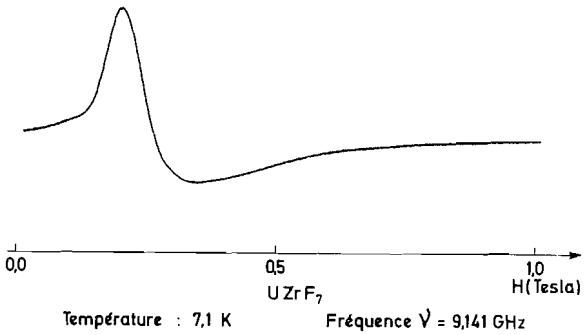

FIG. 1. Spectre RPE de $UZrF_7$ en bande X.

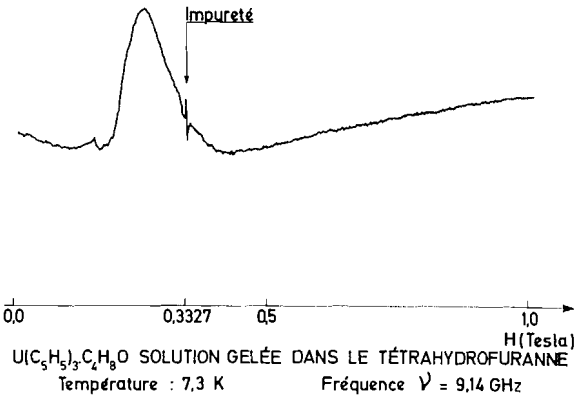

FIG. 2. Spectre RPE de l'adduit de $U(C_5H_5)_3$ et des tétrahydrofurane.

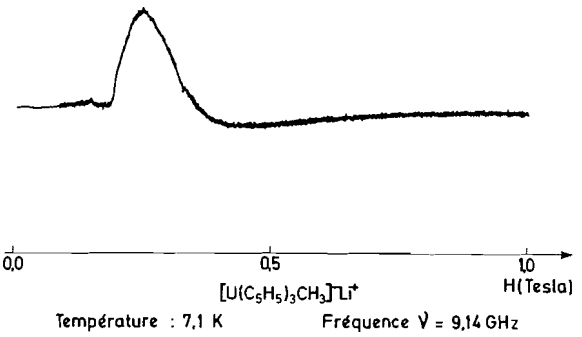

FIG. 3. Spectre RPE de $[U(C_5H_5)_3CH_3]^-Li^+$ en solution gelée dans le tétrahydrofurane en bande.

La forme du signal observé est caractéristique d'un tenseur $g$ axial et présentant une très forte anisotropie.[2] L'intersection de la courbe dérivée d'absorption avec la ligne de base donne approximativement la valeur du facteur $g$ perpendiculaire $g_\perp \sim 2{,}56$ (à 0,1 près). Aucun autre signal n'apparaissant sur le spectre, on en déduit que le champ de résonance correspondant à $g$ parallèle est supérieur au champ maximum atteint soit 1 Tesla; par conséquent $g$ parallèle est inférieur à la valeur de $g$ correspondant à ce champ: $g_{\|} < 0{,}65$. On ne pouvait guère attendre que la structure hyperfine due à l'uranium 235 (8) fût observable dans un composé en poudre où cet isotope est en abondance naturelle (0,7%).

La figure 2 présente le spectre de $UCp_3 \cdot THF$. Ce spectre est très voisin du précédent du point de vue de la dissymétrie et des valeurs de $g$. Ce composé préparé par photolyse de $Cp_3UMe$ ou par réduction de $Cp_3UCl$ par LiH (11) ou $LiAlH_4$ (2) est facilement identifié par son spectre RMN (2) et son spectre électronique publié par Kanellakopulos *et al.* (1).

L'intensité du signal observé d'une part, l'analogie morphologique avec celui de $UZrF_7$, et les arguments exposés plus haut en ce qui concerne les degrés d'oxydation (IV) et (V) de l'uranium permettent d'attribuer ce signal à l'uranium (III).

Cette conclusion s'est trouvée confirmée par l'expérience suivante. Dans un "bitube" scellé, on a mis d'un côté $LiAlH_4 \cdot THF$ et de l'autre $UCl_4 \cdot THF$. Les deux tubes ont été successivement placés dans la cavité de résonance paramagnétique en étant refroidis à 5 K environ. Aucun spectre n'a été observé dans le cas de $LiAlH_4 \cdot THF$, mais on a observé pour $UCl_4 \cdot THF$ un sextuplet caractéristique d'une impureté de manganèse.

Puis après réchauffement des deux branches du bitube, on fait passer $LiAlH_4 \cdot THF$ d'une branche vers l'autre. On refroidit alors le tube où se trouve le mélange vers 5 K. Un spectre entièrement nouveau apparaît, qui ressemble à ceux des figures 1 et 2, et est beaucoup plus intense que celui de l'impureté de manganèse. Ces observations ne peuvent s'interpréter que par la réduction de l'uranium (IV) en uranium (III) lors du mélange, et démontrent que le signal de résonance électronique de l'uranium (III) est observable à basse température dans la solution gelée.

Nous considérons maintenant le produit préparé en réduisant $Cp_3UCH_3$ par $LiCH_3$. Les détails de la préparation seront publiés par ailleurs (12).

La RMN permettait de proposer une formule de la forme $UCp_3 \cdot CH_3^- \cdot Li^+$ mais il n'était pas possible d'isoler le composé. Le degré d'oxydation de l'uranium ne peut pas être déduit du spectre optique qui comporte de multiples transitions dans les régions du spectre occupées par les transitions $f$–$f$.

L'analogie de ce signal RPE (Fig. 3) dont la bande de résonance est à $g = 2{,}56$ avec ceux des deux composés présentes (Figs. 1 et 2) confirme le degré d'oxydation III de l'uranium dans ce nouveau composé.

Cet exemple montre l'intérêt et la simplicité de la méthode. Il faut cependant signaler que l'hélium liquide est indispensable, les spectres disparaissant entre 10 et 20 K.

En conclusion, ce travail a permis de montrer qu'un signal de résonance paramagnétique de l'uranium (III) est effectivement observable à basse température dans des composé organométalliques. Et la RPE a été utilisée pour mettre en évidence la valance III de l'uranium dans un composé organométallique difficile à caractériser par ailleurs.

# Osmotic and activity coefficients of sodium sulphate in water from 150 to 250°C

OM N. BHATNAGAR AND A. N. CAMPBELL

*Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2*

Received October 22, 1981

OM N. BHATNAGAR and A. N. CAMPBELL. Can. J. Chem. **60**, 1754 (1982).

Osmotic and activity coefficients of sodium sulphate in aqueous solution have been determined at temperatures up to 250°C, at solute concentration from 0.3 *m* to saturation, by measurements of vapour pressure using a newly designed high pressure cell. A precision pressure transducer is used in this cell for pressure measurement. Certain thermodynamic quantities have been calculated from the activity coefficients.

OM N. BHATNAGAR et A. N. CAMPBELL. Can. J. Chem. **60**, 1754 (1982).

Opérant à des températures allant jusqu'à 250°C et à des concentrations allant de 0,3 *m* à la saturation, on a déterminé les coefficients de pression osmétique et d'activité du sulfate de sodium en solution aqueuse, en mesurant la pression de vapeur à l'aide d'une nouvelle cellule à haute pression de conception récente. On a utilisé un transducteur de pression de précision dans cette cellule pour mesurer la pression. On a calculé certaines quantités thermodynamiques à partir des coefficients d'activité.

[Traduit par le journal]

## Introduction

The problems of corrosion and scale formation in steam generators are widespread and are of great concern to industry (1, 2). Knowledge and understanding of thermodynamic properties of aqueous electrolyte solutions at elevated temperatures are helpful in attempts to solve these problems. Moreover, the thermodynamic data are of interest to the oil industry for understanding the problem of secondary recovery in oil wells. Some work on the thermodynamic properties of electrolyte solutions at elevated temperatures has been reported in the last few years (3–13, 22). In a previous paper (4) we reported the osmotic and activity coefficients of sodium sulphate from 50 to 150°C. Recently, Rogers and Pitzer (23) have reported heat capacities of aqueous sodium sulphate solutions from 30 to 200°C. They have used their data to calculate a number of thermodynamic properties, such as osmotic and activity coefficients. In this paper, we report the osmotic and activity coefficients of sodium sulphate in water from 150 to 250°C, and at concentrations from 0.3 *m* to saturation using a newly designed vapour pressure cell.

## Experimental

Our method consists in the determination of vapour pressure. In order to extend our work beyond 150°C it was necessary to design a vapour pressure cell that could withstand high pressure and in which the pressure could be measured without visual observation.

The design of the cell is shown in Fig. 1. The cell is made from 316 stainless steel, machined from a solid 9 cm diameter rod. The inside of the cell, which is a cavity of 2.5 cm diameter and 10 cm deep, was plated with gold to protect it from corrosion. The pressure is measured using a pressure transducer, specially made for high temperature work by Kaman Science Corporation (P.O. Box 7463, Colorado Springs, CO 80933, U.S.A.).

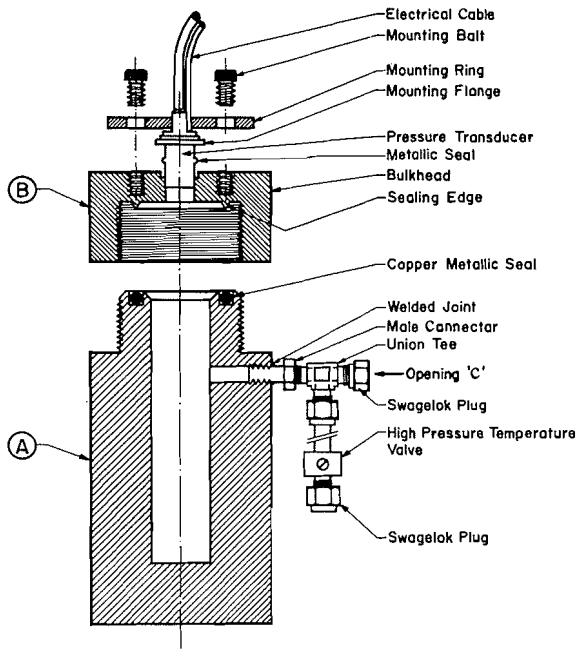

FIG. 1. High temperature vapour pressure cell.

The pressure transducer is mounted on the Cap (B) as shown in Fig. 1. A pressure-tight seal is made by using a silver metallic seal between transducer and the cap. The cap is screwed on to the lower part of the cell (A). The sealing edge inside the cap presses on to the copper metallic seal, providing a pressure-tight seal. The Swagelok connections and high-temperature high-pressure valve serve to introduce and degas the solutions. Before performing an experiment, the cell is assembled as shown in Fig. 1. It is attached to a helium leak detector through the high-pressure high-temperature valve, and the system is checked for any leaks. A sample of liquid is then introduced into the cell through the opening "C", and the end is sealed with a

Swagelok plug. The sample is degassed several times after freezing in an acetone and solid $CO_2$ mixture, through the high-temperature high-pressure valve. After degassing, the cell is placed in the constant temperature oil bath. The pressure readings are measured as millivolt output from the transducer. By using a calibration curve provided by the manufacturer, the pressure at each temperature can be obtained readily. The system was tested using triply distilled water and 1 *m* NaCl solution; our values of osmotic coefficients of NaCl were within 1% of the literature values (8). By knowing the vapour pressures of water and those of the solutions, the values of $\Delta P$, the vapour pressure lowerings, were evaluated for each concentration, in the temperature range of 150 to 250°C. Analytical grade sodium sulphate was used to make the solutions. The concentrations of solutions were determined after each experiment by gravimetric analysis of the sample as barium sulphate (14). The temperature of the bath was measured by a platinum resistance thermometer. The saturation concentration values were taken from the literature (20).

## Results and discussion

The osmotic coefficients were calculated using the following equation (8):

$$[1]\quad \phi = \frac{1000}{\nu m M_1 RT}\left[RT\ln(P^0/P) - \int_P^{P^0}\xi\,dP - \bar{V}_1{}^0(l)\Delta P\right]$$

where $\phi$ is the osmotic coefficient, $R$ the gas constant, $T$ the absolute temperature, $\nu$ the number of ions resulting from the ionization of one molecule, $m$ the molality, $M_1$ the molecular weight of water, and $P^0$ and $P$ the vapour pressures of pure water and solution respectively. The first term in the brackets gives the osmotic coefficient at low pressures, the second term gives the correction for deviations of the vapour from the perfect gas law, while the third term is a reasonable approximation for the isothermal compression of the solution from its own vapour pressure to that of liquid water. The term $\xi$ was calculated from the equations of Smith, Keyes and Gerry (15). The molar volume of pure water, $V_1{}^0(l)$ and $P^0$ were calculated using the equations in ref. 15. In our calculations $\bar{V}_1{}^0(l)$ is used instead of $\bar{V}_1(l)$ for the partial molal volume of water because under these conditions the difference is negligible. The osmotic coefficients calculated from eq. [1] were fitted to the recently developed equations of Pitzer (16). These equations are semiempirical but they are quite successful in predicting the thermodynamic properties of electrolyte solutions up to 6 *M* (17–19) and can be applied to any valence type compounds. Pitzer's equations for osmotic and activity coefficients are given below:

$$[2]\quad \phi - 1 = -|Z_M Z_X| A\phi\,\frac{I^{1/2}}{1+bI^{1/2}} + \frac{m 2\nu_M\nu_X}{\nu}\left[\beta_{MX}{}^{(0)} + \beta_{MX}{}^{(1)}\exp(-\alpha I^{1/2})\right] + \frac{m^2 2(\nu_M\nu_X)^{3/2}}{\nu}\,C_{MX}{}^{\phi}$$

$$[3]\quad \ln\gamma_{\pm} = -|Z_M Z_X| A\phi\left[\frac{I^{1/2}}{1+bI^{1/2}} + \frac{2}{b}\ln(1+bI^{1/2})\right] + \frac{2m\nu_M\nu_X}{\nu} \times \left[2\beta_{MX}{}^{(0)} + \frac{2\beta_{MX}{}^{(1)}}{\alpha^2 I}\left\{1-\left(1+\alpha I^{1/2}-\frac{\alpha^2 I}{2}\right)\exp(-\alpha I^{1/2})\right\}\right] + \frac{3m^2 2(\nu_M\nu_X)^{3/2} C_{MX}{}^{\phi}}{2\nu}$$

where $Z_M$ and $Z_X$ are the positive and negative ionic charges in electronic units. $I$ is the ionic strength, $A\phi$ is the Debye–Hückel coefficient for osmotic functions, $\nu_M$ and $\nu_X$ are the numbers of ions of each type in the formulae, and $\nu = \nu_M + \nu_X$. $\beta_{MX}{}^{(0)}$ and $\beta_{MX}{}^{(1)}$ account for various short range interactions between M and X and for cosphere overlap effect, $C_{MX}{}^{\phi}$ accounts for triple ion interaction and is of importance at high concentration. The parameters $\alpha$ and $b$ are given values of 2 and 1.2 respectively for the present calculations and are treated as temperature independent (17). The Debye–Hückel coefficient $A\phi$ is given by

$$[4]\quad A\phi = 1/3\left(\frac{2\pi N_0\rho_\omega}{1000}\right)^{1/2}\left(\frac{e^2}{DkT}\right)^{3/2}$$

where $N_0$ is the Avogadro number, $\rho_\omega$ is the density of water at temperature $T$, $D$ is the static dielectric constant of water, $k$ is the Boltzmann's constant, and $e$ is the electronic charge. The experimental values of $\phi$ and $m$ were used to evaluate $\beta_{MX}{}^{(0)}$, $\beta_{MX}{}^{(1)}$, and $C_{MX}{}^{\phi}$ which, in turn, were used to calculate mean ionic activity coefficients, $\gamma_{\pm}$, using eq. [3]. As reported earlier (4) the possibility of $HSO_4^-$ ion formation was considered but it was

free energy change, $\Delta G^0$, can be calculated from the following equations:

[5] $$\Delta G^0 = -RT \ln K$$

for $Na_2SO_4$

[6] $$\Delta G^0 = -RT \ln K_{sp} = -RT \ln [2m_+\gamma_\pm]^2[m_-\gamma_\pm]$$

where $K_{sp}$ is the solubility product constant and $m_+$ and $m_-$ refer to analytical molalities of $Na^+$ and $SO_4^{2-}$ respectively.

The values of $\log K_{sp}$ calculated from eq. [6] were fitted to a polynomial equation of the following form

[7] $$\log K_{sp} = A + A_1\left(\frac{1}{T}\right) + A_2\left(\frac{1}{T}\right)^2$$

Using a least-squares programme for polynomial

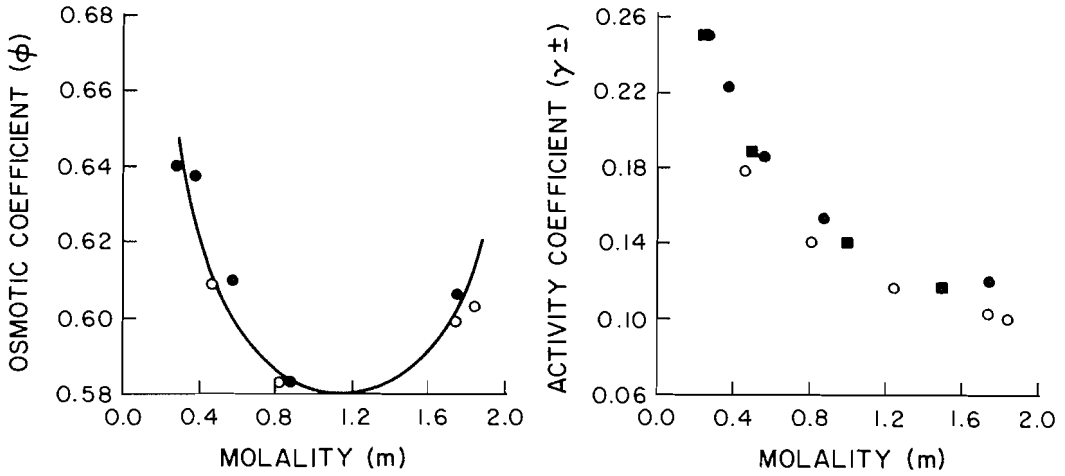

FIG. 2. Osmotic and activity coefficients of sodium sulphate in water at 150°C. ○ data from ref. 4; ■ data from ref. 23; ● data from present work.

TABLE 4. Parameters for eq. [7]

| Parameter | Value |
|---|---|
| $A$ | $4.4110 \times 10$ |
| $A_1$ | $-4.7513 \times 10^4$ |
| $A_2$ | $1.2068 \times 10^7$ |

curve fitting, values of $A$, $A_1$, and $A_2$ were evaluated and these are given in Table 4. The Van't Hoff equation can be written as

$$[8] \quad \left(\frac{\partial \log K_{sp}}{\partial\left(\frac{1}{T}\right)}\right)_p = -\frac{\Delta H^0}{2.303R}$$

Differentiations of eq. [7] with respect to $1/T$ and subsequent substitution in eq. [8] give the values of $\Delta H^0$, the standard change in enthalpy at a given temperature. From the values of $\Delta G^0$ and $\Delta H^0$ the values of $\Delta S^0$ were evaluated. The values of $K_{sp}$, $\Delta G^0$, $\Delta H^0$, and $\Delta S^0$ are given in Table 5. The values of $\gamma_\pm$ can also be used to calculate relative partial molal heat capacity, $\bar{J}_2$.

The osmotic and activity coefficients decrease with increasing temperature and reach a minimum at approximately 225°C; beyond this temperature they increase again. For each temperature, the osmotic coefficients decrease with increasing concentration and pass through a minimum at about 1 molal. Marshall (21) has reported the thermodynamic data on the $Na_2SO_4$–$H_2O$ system from 300 to 350°C, but our results cannot be compared with those of Marshall because anhydrous sodium sulphate undergoes an allotropic change, from rhombic to monoclinic, at 241°C. Marshall's work throughout is in a temperature range where sodium sulphate is in the monoclinic form.

Our $\beta_{MX}^{(0)}$ values are in good agreement with those reported by Rogers and Pitzer (23), considering that their values refer to a different concentration range from ours. Our $C_{MX}^{\phi}$ values show a similar trend, with respect to change in temperature, to those of Rogers and Pitzer (23) but the numerical values are different. The variation with temperature of the $\beta_{MX}^{(1)}$ values reported by us show a minimum at 200°C, but Rogers and Pitzer (23) report no such minimum and we find this quite puzzling. Recently, Homes and Mesmer (24) have reported $\beta_{MX}^{(0)}$, $\beta_{MX}^{(1)}$, and $C_{MX}^{\phi}$, for $SrCl_2$ and

# Calculated uranium solubility in groundwater: implications for nuclear fuel waste disposal[1]

BRUCE GOODWIN

*Environmental and Safety Assessment Branch, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0*

Received October 22, 1981

BRUCE GOODWIN. Can. J. Chem. **60**, 1759 (1982).

Uranium solubilities of the order of $10^{-10}$ *M* have been calculated for a range of conditions which are considered to be representative of those expected in a Canadian nuclear fuel waste disposal vault. Factors taken into consideration include the pH and Eh range expected for deep groundwaters, the projected temperature range near a nuclear fuel waste disposal vault, the effect of the composition of two representative groundwaters, the effect of non-ideality, and the effect of the stability of several uranium solids.

The model used in these calculations is based on the assumption of chemical equilibrium. Calculations show that the most important factors influencing uranium solubility under the postulated conditions are pH and Eh.

These results applied to an assessment of the nuclear fuel waste disposal program suggest that uranium concentrations will be very low in the disposal vault, and that the irradiated $UO_2$ fuel matrix will remain relatively intact for long periods of time.

BRUCE GOODWIN. Can. J. Chem. **60**, 1759 (1982).

On a calculé des solubilités de l'uranium de l'ordre de $10^{-10}$ *M* dans un intervalle de conditions que l'on considère représentatif de celles attendues dans une voute d'entreposage de déchets de combustibles nucléaires canadiens. Les facteurs considérés comprennent les domaines de pH et de Eh auxquels on peut s'attendre pour les eaux souterraines profondes, le domaine de température prévue près d'une voute de déchets de combustibles nucléaires, l'effet de la composition de deux eaux souterraines représentatives, l'effet de non-idéalité et l'effet de stabilité de plusieurs solides contenant de l'uranium.

Le modèle utilisé dans ces calculs repose sur l'hypothèse d'un équilibre chimique. Les calculs révèlent que la plupart des facteurs importants qui influencent la solubilité de l'uranium dans les conditions choisies sont le pH et le Eh.

Ces calculs, appliqués à une évaluation du programme d'entreposage des déchets de combustible nucléaire, suggèrent que les concentrations en uranium seront très faibles dans les voutes d'entreposage et que la matrice de combustible $UO_2$ irradié restera relativement intacte pendant un temps assez long.

## Introduction

The solubility of uranium in natural groundwater is of interest from two viewpoints. For some time, this subject has been studied in relation to the formation and dissolution of uranium ores (1), often in oxidizing environments. More recently the subject has become of interest in relation to the nuclear fuel waste disposal program. This report is oriented towards the latter aspect.

Nuclear fuel waste disposal is the final stage of the nuclear energy cycle, and is intended to safeguard man and the environment for the hazardous lifetime of the wastes. The proposed Canadian approach to this problem involves isolating the irradiated fuel or reprocessing waste in a deep underground vault in a crystalline pluton in the Precambrian Shield, and includes "engineered barriers" such as metal containers and a low-permeability backfill material (2–4). The isolation of the wastes and the integrity of the vault are expected to be such that the only feasible mechanism for escape of radioactive material would be transport in groundwater. This scenario requires that groundwater penetrates the vault, corrodes the metal container, and eventually leaches the contained radioactive waste for transport to the surface.

One of the parameters critical to these studies is the degree to which radioactive waste dissolves in natural groundwater. In particular, the solubility of uranium oxide is very important since the irradiated fuel from a CANDU[2] reactor consists of approximately 98% by weight $UO_2$, and less than 2% by weight of the more hazardous fission product and actinide isotopes (5). Knowledge of uranium solubilities can lead to estimates of (*i*), the time required to dissolve the uranium in irradiated fuel, and (*ii*), the rate of release of radionuclides which are trapped in the $UO_2$ fuel matrix, and which are released as uranium dissolves. Other information required for these estimates includes the availability of groundwater and the mechanism of fuel dissolution.

In addition, knowledge of the parameters affecting uranium solubility can be used in a feedback process to influence the criteria used in the design of engineered barriers and in the selection of a suitable vault site. By way of example, data presented in this report indicate that the environment

of an ideal vault would include a groundwater which is slightly acid to neutral and which is buffered at a reducing Eh.

Details of the calculated results are presented, as is a brief description of the chemical model used to produce these results.

### Description of the chemical model

The model used in these calculations is based on the assumption of chemical equilibrium, using relationships which derive from the laws of thermodynamics. One approach to calculation of an equilibrium assemblage is based on solution of the non-linear equations deriving from the law of mass action (6–8).

A non-linear equation may be written for each of the possible chemical reactions, and an auxiliary set of (linear) mass balance equations is also required so that the number of equations equals the number of unknowns.

This system of linear and non-linear equations is easily solved only for simple chemical systems. Many problems of interest involve large numbers of competing reactions, and the requirement to analyze such systems has led to the development of a variety of computer programs (6–8). The results reported here were computed using a modified version of the program SOLMNEQ — a geochemical solution–mineral equilibrium program (9).

Modifications to SOLMNEQ included the introduction of the uranium aqueous species and solids listed in Table 1. Calculation of uranium speciation parallels existing logic in SOLMNEQ; for example, starting from the mass balance equation for uranium:

$$[1] \quad [U]_{total} = [U^{3+}] + [U^{4+}] + [UO_2^{+}] + [UO_2^{2+}] + [U(SO_4)_2^{0}] + \ldots.$$

one develops a single non-linear equation in $[U^{4+}]$ and the anionic species by substituting for all uranium species from their corresponding mass action equation. Typical substitutions might be

$$[2a] \quad [U(SO_4)_2^{0}] = [U^{4+}]\,[SO_4^{2-}]^2/K$$

where $K$ is the equilibrium constant for the reaction

$$[2b] \quad U(SO_4)_2^{0} \rightleftarrows U^{4+} + 2SO_4^{2-}$$

Other substitutions invoke the Nersnt equation to account for redox reactions between U(IV) and U(III), U(V), or U(VI) species. It was also necessary to modify the logic of SOLMNEQ to evaluate these equations in log units, because of the wide range in speciation constants that are encountered for uranium species.

TABLE 1. Aqueous and solid uranium species included in the calculations*

| | Aqueous species | Solids |
|---|---|---|
| U(III): | $U^{3+}$ | — |
| U(IV): | $U^{4+}$ | $UO_2$ |
| | $U(OH)^{3+}$ to $U(OH)_5^{-}$ | $UF_4$ |
| | $UCl^{3+}$ | $UF_4 \cdot \frac{5}{2}H_2O$ |
| | $UF^{3+}$ to $UF_6^{2-}$ | |
| | $U(HPO_4)^{2+}$ to $U(HPO_4)_4^{4-}$ | |
| | $U(SO_4)^{2+}$ to $U(SO_4)_2^{0}$ | |
| U(V): | $UO_2^{+}$ | $NaUO_3$ |
| U(VI): | $UO_2^{2+}$ | $\gamma$-$UO_3$ |
| | $UO_2(OH)^{+}$ to $UO_2(OH)_2^{0}$ | $UO_2CO_3$ |
| | $(UO_2)_3(OH)_5^{+}$ | $(UO_2)_3(PO_4)_2$ |
| | $(UO_2)_3(OH)_7^{-}$ | $(UO_2)_2(HPO_4)_2$ |
| | $UO_2(CO_3)^{0}$ to $UO_2(CO_3)_3^{4-}$ | $\beta$-$UO_2(OH)_2$ |

*The corresponding thermodynamic data were taken from ref. 13.

Equation [1] may now be solved iteratively, taking an initial guess for the free ionic species and $[U]_{total}$ from the reported chemical analysis. When all feasible competing reactions are taken into account (for example $Ca^{2+}$ will compete with $U^{4+}$ for $SO_4^{2-}$, etc.), a new guess of the free ionic species is computed, and the entire process is repeated until the calculated sums of *free* anionic species (e.g., $SO_4^{2-}$) and *complexed* ionic species (e.g., $U(SO_4)^{2+}$, $U(SO_4)_2^{0}$, $CaSO_4^{0}$) converge to the reported anion concentration. Convergence tests are performed for carbon, chlorine, sulphur, phosphorous, and fluorine aqueous anionic species.

These computations result in the calculated concentration of various charged and neutral species in solution. SOLMNEQ also computes activity products and compares them with solubility products to indicate the state of saturation of various minerals and solids. For uranium solids, a new option added to SOLMNEQ searches for the maximum uranium in solution which is in equilibrium with the most stable (least soluble) uranium solid under specified conditions of Eh, pH, groundwater composition, and temperature. This is achieved by backward substitution of a new estimate for $[U]_{total}$ based on the uranium solid which is most supersaturated (or nearest saturation). In most cases convergence is obtained within three iterations.

Other features of SOLMNEQ are described in

TABLE 2. Groundwater compositions (molar) at 25°C assumed for the nuclear fuel waste vault

| Components | Granite groundwater | Brine groundwater* |
|---|---|---|
| Ca | $3.24\times10^{-4}$ | 0.396 |

| Ionic strength | 0.00184 | 1.43 |

*SOLMNEQ predicts that this brine is supersaturated at 25°C in several minerals, including tremolite, talc, gypsum, anhydrite, and quartz. Tremolite and talc are considerably supersaturated, but since they have not been detected experimentally (16), we conclude that their formation must be kinetically hindered. Gypsum, anhydrite, and quartz are also not observed, but these minerals are only slightly supersaturated, and the disparity is more likely due to the inaccuracy in calculation of activity coefficients at the very high ionic strength of the brine.

detail elsewhere (9) and include: (*i*), provision to handle over 230 inorganic aqueous species (including over 70 uranium and plutonium species added to the modifications described above); (*ii*), calculation of aqueous speciation in the temperature range 0–350°C; (*iii*) calculation of non-ideality effects on the activity coefficients by means of a modified Debye–Hückel equation for charged species and by analogy with the activity coefficient of $CO_2$ for neutral species (10); and (*iv*) calculation of changes in pH as a function of temperature, using an extra mass balance constraint for species containing $H^+$ and $OH^-$ and taking into account the variation with temperature of the equilibrium constants for the ionization of water and other reactions (11). This latter calculation assumes pH is known at some reference temperature.

The database required by SOLMNEQ and used in these calculations is largely from the original SOLMNEQ database (9), with a few minor corrections. Equilibrium constants for uranium species were generated by the program COTDET (12) using the free energy and heat capacity data contained in a recent review by Lemire and Tremaine (13). Parameters required for the Debye–Hückel equation for uranium species were chosen using guidelines in the report by Kielland (14).

Copies of this version of SOLMNEQ and its database are available on request from the author.

## Results and discussion

In order to estimate uranium solubilities in the proposed nuclear fuel waste disposal vault, we have chosen a range of environments which are expected to be representative of the geochemical conditions in a crystalline pluton. The environments are characterized by several important parameters which describe the chemistry of the groundwater permeating the vault, including the groundwater composition, the electrochemical potential (Eh), pH, and temperature. We have not taken into consideration the effect of the vault backfill, which may contain additives to reinforce the expected conditions for pH and Eh.

### *Groundwater composition*

Two extremes of groundwater types have been chosen for this study. These are a synthetic granite groundwater used for experimental studies of sorption (15), and a synthetic brine groundwater used for experimental leaching studies (16). The latter has been included since saline waters have been found in the Canadian Precambrian Shield (17).

Analytical compositions of both groundwaters are presented in Table 2. Although there are obvious differences between real and synthetic groundwaters, results given below, and in other compositional sensitivity studies, suggest that water composition does not constitute an important variable for maximum uranium solubilities near the Eh and pH regimes of interest, and hence the differences are not expected to be important. In particular, neither groundwater includes the presence of phosphate anions, but results presented

TABLE 3. Calculated reference groundwater pH and Eh (V) at elevated temperatures

| Temperature (°C) | Granite groundwater | | | Brine groundwater | | |
|---|---|---|---|---|---|---|
| | pH* | Eh-low† | Eh-high‡ | pH* | Eh-low† | Eh-high‡ |
| 25 | 7.00 | −0.200 | −0.011 | 7.00 | −0.200 | −0.011 |
| 50 | 6.93 | −0.239 | −0.080 | 6.70 | −0.225 | −0.066 |
| 75 | 6.94 | −0.269 | −0.137 | 6.42 | −0.233 | −0.101 |
| 100 | 6.97 | −0.314 | −0.218 | 6.14 | −0.253 | −0.157 |
| 125 | 7.02 | −0.355 | −0.283 | 5.85 | −0.263 | −0.190 |
| 150 | 7.06 | −0.396 | −0.347 | 5.58 | −0.271 | −0.222 |
| 175 | 7.11 | −0.437 | −0.425 | 5.34 | −0.280 | −0.267 |

*pH is assumed to be 7.00 at 25°C, and is calculated by SOLMNEQ for the other temperatures.
†Calculated assuming the Eh is buffered by the equilibrium between magnetite and hematite, and using eq. [4] with $\Delta G^0$ from ref. 21 ($\Delta G_{175}^0$ was interpolated).
‡As above, but assuming the Eh buffer is the siderite–goethite reaction with $p_{CO_2}$ fixed at $10^{-3.5}$ atm.

elsewhere (18) suggest that uranium–phosphate complexes are not important for the particular cases described in this report.

*pH*

Both groundwaters have an assumed pH of 7.00 at 25°C, which is within the expected range of 6–10 for natural groundwaters (19). In some plots reproduced below, calculated curves are over a wider pH range to show the effect of its variation.

For temperatures other than 25°C, the pH of the groundwaters can be expected to vary due to temperature-dependent change in the dissociation constants for water and aqueous species, and due to temperature-dependent water–mineral reactions. If the latter reactions are not important for water near the $UO_2$ fuel, SOLMNEQ can be used to estimate a "reference" vault pH at elevated temperatures for both groundwaters. Some results are shown in Table 3, and it may be noted that, relative to neutral water, the pH of the brine groundwater remains near neutral at 150°C, whereas the granite groundwater is somewhat more basic. These differences in calculated pH can be attributed to the complex temperature-dependent behaviour of a variety of complexes, such as $Ca(HCO_3)^+$, $Mg(OH)^+$, etc.

*Eh*

There is little experimental data for the electrochemical potential or Eh of deep groundwaters, although it has been postulated that the Eh of these waters tends to approach the relatively reducing potential of the magnetite–hematite pair (19, 20). Since these minerals are common in the Precambrian Shield, a reasonable assumption is that the magnetite–hematite reaction:

$$[3a] \quad \underset{\text{magnetite}}{Fe_3O_4(c)} + \tfrac{1}{2}H_2O \rightleftarrows \tfrac{3}{2}\underset{\text{hematite}}{Fe_2O_3(c)} + H^+ + e^-$$

is *representative* of the lower Eh limit which can be expected near the proposed waste disposal vault. We have also assumed that the siderite–goethite reaction:

$$[3b] \quad \underset{\text{siderite}}{FeCO_3(c)} + 2H_2O \rightleftarrows \underset{\text{goethite}}{Fe(OH)_3(c)} + H^+ + CO_2 + e^-$$

can be taken to be *representative* of an upper limit of the Eh near the vault (20). For both reactions, Eh is a function of pH given by the Nernst equation:

$$[4] \quad Eh = -\frac{\Delta G^0}{nF} - \frac{2.3RT}{nF}\,pH$$

where $\Delta G^0$ is the Gibbs energy for the reaction, $n$ is the number of electrons involved in the reaction, $F$ is the Faraday constant (the activity of water is set to unity), $R$ is the gas constant, and $T$ is the temperature in Kelvin. For reaction [3*b*], we have included in $\Delta G^0$ a term which involves the partial pressure of $CO_2$ ($p_{CO_2}$). For our calculations $p_{CO_2}$ was fixed at $10^{-3.5}$ atm, which is $p_{CO_2}$ in the atmosphere and which is a reasonable value for groundwaters near the water table (20). Higher values of $p_{CO_2}$ might be expected for deep groundwaters, resulting in higher carbonate concentrations and a more oxidizing Eh, but these changes do not have a large effect on the results presented here.

Equation [4] was used with data from ref. 21 to evaluate the low and high Eh values listed in Table 3. At temperatures other than 25°C, pH was chosen to be that calculated by SOLMNEQ, so that the upper and lower Eh limits effectively correspond to the equilibrium Eh–pH boundaries between magnetite–hematite and siderite–goethite, respectively.

*Temperature*

The last parameter used to define vault geochemistry is the temperature. The ambient temperature of a pluton in the Precambrian Shield at 1000 m is approximately 20 to 25°C, and heat transport

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

studies have suggested that the vault temperature will rise to approximately 100°C due to the imposed heat loading of the radioactive wastes (22). Results reproduced here are at 25 and 100°C.

*Calculated solubilities*

Figures 1 and 2 display the calculated uranium solubilities in the synthetic granite and brine groundwaters as a function of pH. Note that although the abscissa is labelled pH, the Eh is also varied according to eq. [4] for both Eh buffers at the two temperatures. Except for some exceptions noted below, the stable uranium solid was predicted to be $UO_2$. Other uranium solids, such as coffinite, etc. (23), were not included in these calculations due to a lack of high-temperature data, but some scoping calculations suggest that these other minerals are not likely to be more stable than $UO_2$ under the reference conditions of pH, Eh, and groundwater compositions considered here.

These results show that expected uranium solubilities in the waste vault are very low — of the order of $10^{-10}$ *M* or 0.02 parts per billion. This value is in agreement with uranium concentrations found in naturally occurring groundwaters in reducing environments (23–25), and with recent experimental results under similar conditions (26).

A comparison of Figs. 1 and 2, and other sensitivity studies, reveal that uranium solubility is not greatly affected by groundwater composition over the pH range 6–9 at the low Eh boundary. This

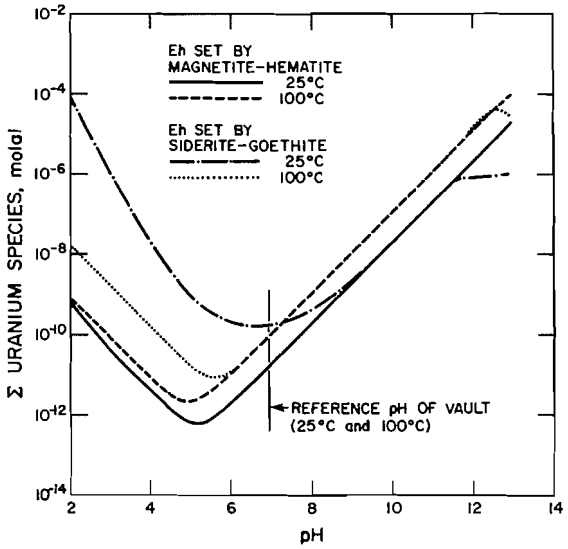

FIG. 1. Calculated uranium solubilities in granite groundwater. The Eh also varies with pH, and was calculated from eq. [4] for the equilibrium reactions [3*a*] for magnetite–hematite and [3*b*] for siderite–goethite (see text). The "reference" vault pH at each temperature is denoted by the arrows.

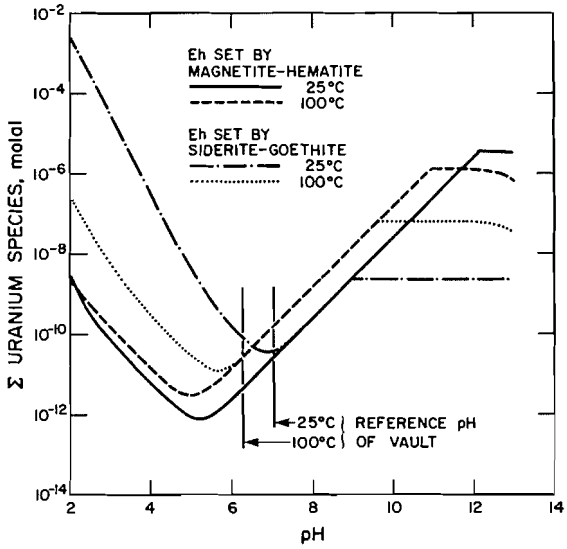

FIG. 2. Calculated uranium solubilities in brine groundwater. Other details as in Fig. 1.

is because the major uranium species is $U(OH)_5^-$, whose abundance is largely determined by pH. At the high Eh boundary of siderite–goethite, similar conclusions follow, except that the 25°C curves vary up to about pH 8 due to varying abundances of other species such as $UO_2(CO_3)_2^{2-}$.

These features are clearer in Figs. 3 and 4, which are distribution of species diagrams along the Eh–pH boundary of the magnetite–hematite and siderite–goethite reactions, respectively. Figure 3 shows that the species $U(OH)_5^-$ accounts for almost all the uranium in solution above pH 6 in granite groundwater. A similar diagram may be obtained for brine groundwater. Figure 4 shows a much more complicated pattern, with uranium carbonate species being important up to about pH 8. A similar diagram results for brine groundwater at the siderite–goethite boundary.

On the high pH side of Figs. 1 and 2, the abrupt changes in slope are due to the change in type of uranium solid which is in equilibrium with the aqueous solution. Below about pH 10, the most stable solid is $UO_2$, whereas $Na_2U_2O_7$ or $NaUO_3$ become more stable above pH 10. The slope change is most obvious in the brine groundwater, largely because of its much higher $Na^+$ concentration. Also shown at high pH for brine groundwater is the unusual result that uranium is less soluble at the higher oxidizing siderite–goethite boundary than at the magnetite–hematite boundary. This is due to the shape of the stability field for $NaUO_3$ (18). Along the siderite–goethite boundary, the stability field of $NaUO_3$ is reached near pH 9.5 and

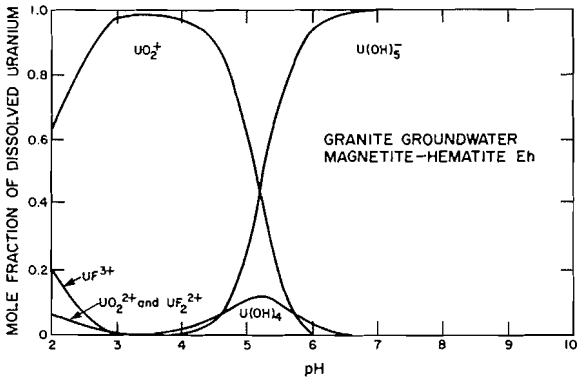

FIG. 3. Calculated distribution of uranium species in granite groundwater at 25°C. The Eh used corresponds to the equilibrium boundary for the magnetite–hematite reaction. Species with ionic fractions less than 0.01 are not shown.

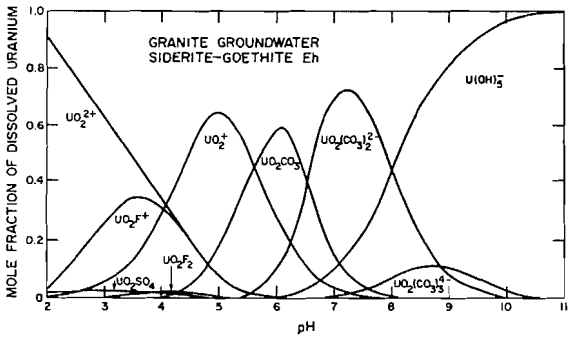

FIG. 4. Calculated distribution of uranium species in granite groundwater at 25°C along the siderite–goethite equilibrium boundary (with $p_{CO_2}$ fixed at $10^{-3.5}$ atm). Other details are as described in Fig. 3.

$[U]_{total} \simeq 10^{-8} M$, whereas along the lower magnetite–hematite boundary the stability field of $NaUO_3$ is not reached until pH ~ 12 and $[U]_{total} \sim 10^{-5} M$.

Figures 1 and 2 also reveal that the effect of temperature on uranium solubility is small. In fact, uranium solubility shows a "reverse" or weak temperature dependence, as indicated in Fig. 5, which was computed using Eh and pH data of Table 3. Although the exact shape of these curves may be questionable due to the uncertainty in the thermodynamic data (13), it is more certain that uranium solubility is only slightly dependent on temperature at reducing and near neutral conditions.

The above discussion and other data not reproduced here can also be used to study the sensitivity of uranium solubility under conditions expected in deep groundwaters. It follows that uranium solubilities are mostly dependent on pH, with decreasing dependence on the parameters Eh, temperature,

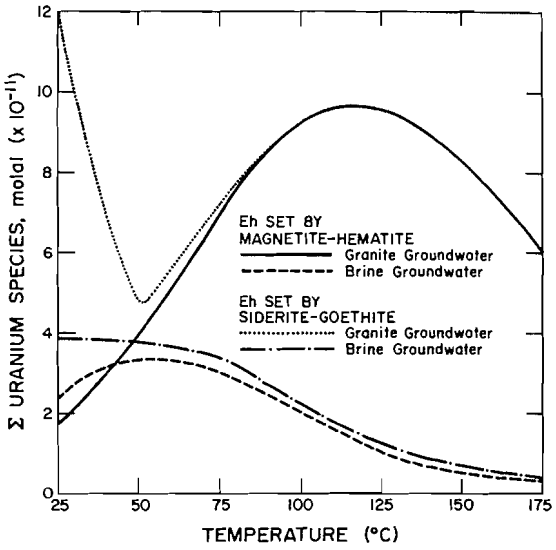

FIG. 5. Calculated uranium solubilities as a function of temperature. The four curves are for granite and brine groundwater along the siderite–goethite and magnetite–hematite equilibrium boundaries (see text).

and groundwater composition. This conclusion is also reflected in the following reaction, which describes most of the uranium "chemistry" expected to occur in deep groundwaters:

[5] $UO_2 + 3H_2O \rightleftarrows U(OH)_5^- + H^+$

For the siderite–goethite Eh boundary, other uranium reactions (involving uranium(VI) carbonates) are also important at lower pH. In all cases, however, it appears that uranium solubilities are very low, ranging from approximately $10^{-8}$ to $10^{-12} M$ in the pH range 6–10, and with a value near $10^{-10}$ under the conditions expected in a nuclear fuel waste vault. It also appears that the most stable uranium solid is likely to be $UO_2$, except in the brine groundwaters at high pH (other uranium minerals, such as coffinite (23), may also be important in groundwaters containing higher concentrations of dissolved silica than were considered here).

### Limitations of the model

Due to the complex nature of these calculations, it is probably as important to be aware of the inherent qualifications and limitations as it is to be knowledgeable of the final results. Some limitations are mentioned below, and although it is not possible to provide a quantitative estimate of their effects, it is expected that they will not influence the results by more than one or perhaps two orders of magnitude.

A major limitation of equilibrium models is that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

they cannot describe non-equilibrium effects such as chemical kinetics or the formation of colloids. By way of example, it has already been mentioned in the footnote to Table 2 that the brine groundwater does not correspond to a stable system since it is supersaturated with respect to some minerals. These objections may be unimportant, however, if we take into account the extremely low water velocity expected for deep groundwaters (of the order of 0.3 m/year (22)), which increases the time allowed for the system to equilibrate. Another important non-equilibrium process not considered here is the effect of radiolysis, which might give rise to local variations in Eh and pH near the irradiated fuel containers.

Other important limitations follow from uncertainties in the database, or missing data. In the calculations described here, for example, a number of uranium minerals, such as coffinite and tyuyamunite (23), are missing, as are data (possibly) for aqueous U(IV) carbonates. Missing solids result in an over-estimation of uranium solubilities, if they are more stable than $UO_2$, whereas the reverse is true of missing aqueous species.

Other simplifications in the equilibrium model used here will also affect the results; for example, pressure effects were not studied, and it is well known that the modified semi-empirical Debye–Hückel equation is inaccurate at the high ionic strength of the brine groundwater under consideration. The effect of solid solutions such as $UO_{2+x}$, $0 \leq x \leq 0.6$ (27) were also not considered. These effects and the others mentioned above suggest areas requiring further experimental research.

## Implications and conclusions

Maximum uranium concentrations of the order of $10^{-10}$ *M* have been calculated for a range of conditions which bracket the conditions expected in a deep underground nuclear fuel waste vault in crystalline rock. Parameters studied included pH, Eh, temperature, and groundwater composition.

Given the low solubility of $UO_2$, and because irradiated CANDU fuel is largely $UO_2$, we can expect that the irradiated fuel matrix will also be characterized by a very low solubility. We can also expect that the original fuel matrix will persist for a long time in the postulated vault environment, since $UO_2$ is likely the stable thermodynamic solid and since groundwater flows are expected to be very small. Recent analysis (28, 29) of the leaching behaviour of irradiated fuel also suggests that the fission products (except iodine and cesium, which apparently are preferentially leached during the initial stages) and the actinides will be released in very low concentrations, because they appear to be released congruently as the $UO_2$ fuel matrix dissolves. We can also find geological evidence supporting these conclusions; in particular, observations made on the natural reactor discovered at Oklo suggest that irradiated uraninite grains have remained intact for over a billion years (30).

The calculated results also suggest that the environment of the ideal nuclear fuel waste vault would include a groundwater which is buffered at a slightly acid to near neutral pH and at a moderately reducing Eh. This environment may be reinforced by the addition of suitable materials to the low permeability backfill surrounding the irradiated fuel containers.

# Quenching of the singlet and triplet state of benzene by halogenated alkanes in the vapor phase

H. A. KHWAJA, G. P. SEMELUK, AND I. UNGER

*Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3*

Received September 16, 1981

H. A. KHWAJA, G. P. SEMELUK, and I. UNGER. Can. J. Chem. **60**, 1767 (1982).

The second order rate constants ($k_q$) for the quenching of the singlet state of benzene by several halogenated alkanes (viz. $CH_2Br_2$, $CCl_4$, $CH_3CCl_3$, $CHCl_3$, $CHF_3$, $CH_3Cl$, $CH_3F$, $CH_2F_2$, $CH_2Cl_2$, $CFCl_3$, $CF_2Cl_2$, $CF_3Cl$, $CF_4$) in the vapor phase have been measured. For $CCl_4$, $CHCl_3$, $CH_2Cl_2$, and $CH_3Cl$, which were previously studied by Das Gupta and Phillips, there is satisfactory agreement between the $k_q$ values obtained in the separate investigations. The linear dependence of the electron affinity of quencher with the corresponding quenching rate constants supports an exciplex mechanism in accordance with Klein's model. Charge transfer occurs from benzene to halogenated alkane and is greater for the chloro alkanes than for mixed fluoro–chloro alkanes. In the case of the triplet state of benzene, whose behaviour was monitored using the sensitized emission of biacetyl technique, quenching effects were at best one order of magnitude smaller and probably involve more than one bimolecular process.

H. A. KHWAJA, G. P. SEMELUK et I. UNGER. Can. J. Chem. **60**, 1767 (1982).

On a mesuré les constantes de vitesse de second ordre ($k_q$) du piégeage en phase vapeur de l'état singulet du benzène par divers alcanes halogénés (tels: $CH_2Br_2$, $CCl_4$, $CH_3CCl_3$, $CHCl_3$, $CHF_3$, $CH_3Cl$, $CH_3F$, $CH_2F_2$, $CH_2Cl_2$, $CFCl_3$, $CF_2Cl_2$, $CF_3Cl$, $CF_4$). Dans le cas des alcanes suivants, $CCl_4$, $CHCl_3$, $CH_2Cl_2$ et $CH_3Cl$ que Das Gupta et Phillips ont étudié antérieurement, il y a un accord satisfaisant entre les valeurs de $k_q$ obtenues par études différentes. Le fait que l'affinité électronique du piège dépende linéairement des constantes de vitesse de piégeage correspondant, constitue une preuve de mécanisme par exciplex prévu par le modèle de Klein. Le transfert de charge a lieu du benzène vers l'alcane halogéné et il est plus grand dans le cas des chloroalcanes que dans celui des fluoro–chloroalcanes mixtes. Dans le cas de l'état triplet du benzène dont on a enregistré le comportement en utilisant la technique d'émission sensibilisée de biacétyle, les effets de piégeage sont au plus d'un ordre de grandeur plus faible et impliquent probablement plus qu'un processus bimoléculaire.

[Traduit par le journal]

## Introduction

The quenching of electronically excited states of aromatics can occur by at least four mechanisms: (*1*) electronic energy transfer, which requires acceptors possessing energy states lower than those of the aromatic donor molecules, (*2*) enhancement of non-radiative decay, (*3*) chemical reaction, and (*4*) exciplex formation.

Exciplexes are excited state complexes between donor and acceptor having definite stoichiometry but which are dissociative in the ground state. These may be formed by charge transfer from the excited aromatic to the additive or vice versa depending upon the relative ionization potentials and electron affinities of the aromatic molecule and the quencher. Considerable evidence supporting the intermediacy of exciplex formation in the quenching of aromatic singlet excited states by a variety of additives has been provided in recent years (1–5). Most of these investigations have been carried out in dilute solutions (1, 2, 4, 5). Only a limited amount of work in the vapor phase has been reported so far (3).

The quenching of the excited singlet states of aromatic hydrocarbons and their derivatives by halogenated alkanes (1–4), dienes (6), and amines (7) is generally believed to proceed via an intermediate contact exciplex of charge-transfer character. The rate of formation of these exciplexes is considered to be the rate determining step in these quenching processes. According to Klein's model (1), which is based on the absolute rate theory of Eyring, the charge-transfer nature of such exciplexes can be expressed as a linear correlation between the overall second order quenching rate constant ($k_q$) and the exponential of some measure of the free energy change associated with the excited state complex formation:

$$[1] \quad k_q \propto \exp[-(IP_D - EA_A - C - P - h\nu_s)]/kT$$

In eq. [1] $IP_D$ represents the ionization potential of the donor; $EA_A$, the electron affinity of the acceptor; $C$, the coulomb stabilization energy of the complex; $P$, the polarization energy of the separated charges; and $h\nu_s$ the excitation energy of the first excited state.

The purpose of this study of the quenching of singlet and triplet states of a common aromatic donor molecule (benzene) by a variety of electron-deficient quenchers (halogenated alkanes) was: (*a*) to establish whether or not an exciplex is formed in the vapor phase and to test the validity of Klein's

model (1) for these systems; (*b*) to determine the mechanism which is operative in benzene – halogenated alkanes system; and (*c*) to examine the possibility of any increase in quenching efficiency due to a heavy-atom effect.

Because the surrounding matrix in solutions plays an important role in determining the stability of these excited complexes and other factors such as media polarity and/or polarizability also may contribute to excited-state complexation, our study was undertaken in the vapor phase, where such complications would be reduced.

## Experimental

*Chemicals*

Benzene was obtained from Fisher Scientific Company as a Spectrograde product having a stated purity of 99.9%. It was used without further purification.

The biacetyl used was from Aldrich Chemical Company and was purified by bulb-to-bulb distillation "in vacuo" and stored in a blackened bulb on a vacuum line. All the halogenated alkanes were purified by gas–liquid chromatography using an HP Model 7620A chromatograph attached to a 5797A collecting unit, with He as the carrier gas; detection was by flame ionization. This chromatographic procedure gave a purity of >99.9% for each of the materials.

*Apparatus and measurements*

Most details of the apparatus and data collection and processing used in this study have been provided elsewhere (9). The apparatus consisted of a steel vacuum line equipped with Hoke packless diaphragm valves, a flow system incorporating a quartz cuvette and U-tube in series with an all-glass circulating pump, and a modified Aminco-Bowman spectrophotofluorometer (SPF). The principal modification is an optical-electronic system for obtaining spectra corrected for photomultiplier and phototube spectral response, which also compensates for variations in lamp intensity, and an accurate transmittance measuring-recording circuit. For 20 Torr benzene in a 1 cm path, more than 300 determinations over a five-month period yielded a transmittance value of 0.9355, with a standard deviation of 0.0041 (0.43%). The accuracy of the compensating analog electronics was ~0.2%, while the stability over a 12-h period, as determined with the help of precision test equipment, was ~0.02%. For a 1-h period, typical of the time to do a "run", the stability was better than 0.01%. The intensity of the lamp, whose "flicker" (period ≥0.008 s) was minimized by a magnetic arc stabilizer, typically decreased during a 12-h period by less than 1%. The compensating electronic system was able to maintain an output constant to <0.1% for a variation of 30% in lamp intensity in the form of either a 120 Hz sine or square wave (actual fluctuations seldom exceed 1%). The 935 phototubes used to monitor lamp intensity and transmitted intensity were both operated at photocurrents less than 33 nA in order to avoid the fatigue effects noted by Yip and Dickinson (10).

The vacuum line was evacuated to better than $5 \times 10^{-6}$ Torr. Pressures of samples were measured with an MKS Baratron type 170 M capacitance gauge. Inside dimensions of the quartz cuvette were 1 cm × 1 cm × 4.5 cm. Samples were admitted to the working manifold from sample reservoirs attached to the vacuum line and were degassed prior to use by three to four freeze–pump–thaw cycles to remove dissolved gases. All experiments were carried out at room temperature (297.6 ± 0.5 K).

A relative method was adopted to convert measured photocurrents and emission intensities into quantum yields. The standard compound for this purpose was benzene with a known vapor phase fluorescence quantum yield of 0.183 (11). In the singlet-state quenching experiments, 20 Torr of benzene was introduced into the cell and frozen down in the U-tube. A known pressure (5 to 80 Torr) of halogenated alkane was then admitted into the U-tube containing the frozen material. Mixing was accomplished in the U-tube by several flash vaporizations, followed by circulating the vapors with the help of a glass circulating pump. The gaseous mixture was excited using a wavelength of 254 nm (see below) and the benzene fluorescence was recorded. Using the standard fluorescence yield value for benzene alone, a separate calibration constant was calculated for each individual additive pressure, and the quantum yield in the presence of the additive could then be determined by using this constant (12).

The sensitized emission of biacetyl technique (13) was used to investigate the quenching of the triplet state of benzene by halogenated alkanes. The quantum yield of the triplet state of benzene (20 Torr) and biacetyl (0.1 to 0.3 Torr) mixture excited at 253.7 nm has been reported to be 0.63 (14). Varying amounts (5 to 80 Torr) of halogenated alkanes were added to a mixture of benzene (20 Torr) and biacetyl (0.1 to 0.2 Torr). Mixing was carried out in a way similar to that of the singlet-state experiments. The mixture was irradiated to 254 nm and the sensitized emission of biacetyl was recorded from 200–650 nm. In order to eliminate the "pump effect" (15), the pump was turned off immediately prior to recording the emission spectrum. Triplet yields could then be calculated using a calibration constant obtained from the experiment involving benzene and biacetyl alone, for each individual pressure of additive.

Emission intensities were in all cases determined by measuring the areas recorded in the spectral scan. This area measurement was carried out by a computer program using input from a Summagraphics tablet digitizer having a resolution of 0.1 mm, interfaced to a PDP-11/10 computer. Calibration against known areas indicated a precision of ~0.5% for the areas involved in the singlet quenching experiments, and ~1% for the areas involved in the triplet quenching experiments.

The slit arrangements used in the excitation monochromator produced a band width at half intensity of 3 nm at the mercury resonance line. The monochromator output actually observed at a setting of 254 nm (using a Xenon-Mercury Compact Arc lamp) was asymmetric, with the low wave length side dominant and the maximum at 253 nm.

## Results and discussion

### *A. Singlet-state quenching*

The quenching of the excited singlet state of benzene by $CH_2Br_2$, $CCl_4$, $CH_3CCl_3$, $CHCl_3$, $CHF_3$, $CH_3Cl$, $CH_3F$, $CH_2F_2$, $CH_2Cl_2$, $CFCl_3$, $CH_2Cl_2$, $CF_3Cl$, and $CF_4$ has been measured. In all the systems examined, the fluorescence quantum yield of benzene ($\phi_f$) in the presence of halogenated alkanes shows a steady decrease with increasing pressure of quencher. The most effective quencher was $CH_2Br_2$ while the least effective was $CF_4$, whose quenching effect was smaller by four orders of magnitude. In general, quenching efficiency increased with increasing number of chlorine atoms; the mixed fluoro–chloro alkanes were far less effective in quenching than the corresponding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

hydro–chloro alkanes. For fluorescent yields >0.10 the uncertainty in $\phi_f$ is calculated to be no larger than 10%, while for lower values it is ~15%. The absorption spectra of benzene in vapor phase in the presence of the highest pressures of quenchers employed in the emission experiments did not show any sign of ground-state complex formation.

Figures 1 and 2 depict the Stern–Volmer plots of $\phi_f^0/\phi_f$ (the fluorescence yield of benzene in the absence of quencher divided by the fluorescence yield at a given amount of quencher) against the pressure of quencher. Each calculated ratio involves recording and measuring two areas at constant incident intensity, and is therefore calculated to have a precision of better than 4%. The least-squares fit of the data to a straight line were obtained in all cases by omitting the co-ordinate (0,1) from the calculation as a more stringent test of how closely the best fit line extrapolates to an intercept of 1. It is evident that these data fit the Stern–Volmer relation satisfactorily, with the possible exception of $CH_2Br_2$, whose intercept is somewhat greater than 1 (see Table 1). Non-linear Stern–Volmer plots may be due to a variety of reasons (16) and for benzene may show upward or downward curvature (17). It should also be noted that $CH_2Br_2$ has a continuous unstructured absorption spectrum in the spectral region of this investigation, and that the extinction coefficient is of the same order as that of benzene. The absorbance of the mixture of benzene and $CH_2Br_2$ was the sum of the individual absorbances at the applicable partial pressures, and no reaction was detectable during the time of a complete measurement, as evidenced by the constant transmittance of the mixture (if photolysis of $CH_2Br_2$ was significant the expected

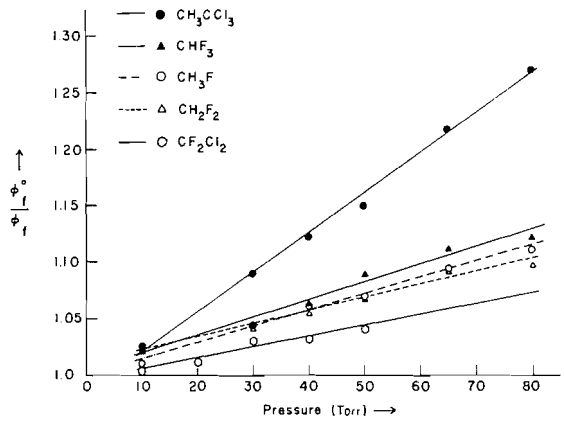

FIG. 1. Plot of $\phi_f^0/\phi_f$ for the benzene (20 Torr) singlet-state quenching by varying amounts of halogenated alkanes ($CH_3CCl_3$, $CHF_3$, $CH_3F$, $CH_2F_2$, $CF_2Cl_2$). $\lambda_{ex} = 254$ nm, $T = 297.6 \pm 0.5$ K.

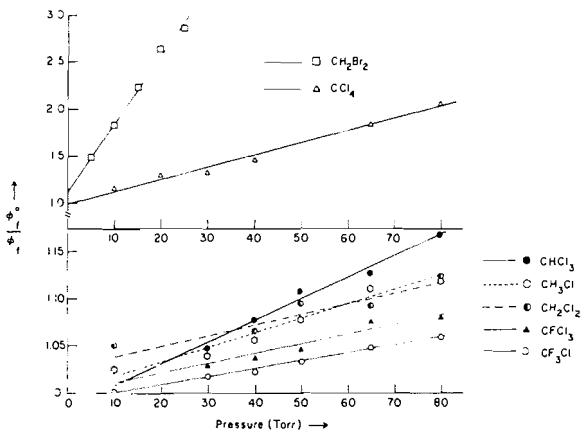

FIG. 2. Plot of $\phi_f^0/\phi_f$ for the benzene (20 Torr) singlet-state quenching by varying amounts of halogenated alkanes ($CH_2Br_2$, $CCl_4$, $CHCl_3$, $CH_3Cl$, $CH_2Cl_2$, $CFCl_3$, $CF_3Cl$). $\lambda_{ex} = 254$ nm, $T = 297.6 \pm 0.5$ K.

products would include bromobenzene which has an $\varepsilon$ approximately ten times that for benzene and $CH_2Br_2$).

The slopes of the least-square fits of the data give the product $k_q\tau$, where $k_q$ is the observed second order quenching rate constant and $\tau$ is the observed lifetime of benzene in the absence of quencher. Several workers (18–22), using three different techniques, have determined the fluorescence lifetime ($\tau$) of benzene vapor to be 75 ± 10 ns for conditions similar to those used in this experiment. A comparable value has been obtained recently for solid benzene (23). Using this value of $\tau$, $k_q$ values were then evaluated. Table 1 provides a summary of the data obtained from our experiments, additional information from other sources, and a summary of the data obtained by Das Gupta and Phillips for the compounds common to the two investigations. Because the latter workers used a different value of $\tau$ in their calculations, we have recalculated and listed their observed slopes for a more appropriate comparison of the derived data. Also given in Table 1 are the standard deviations for the intercepts and slopes obtained from the least-squares analysis.

The agreement between the two investigations on the molecules in common is satisfactory considering the differences in such experimental details as lamps, bandwidths, cells, and method of emission measurement. A major source of uncertainty is the low absorbance of benzene. Our choice of individual pair experiments, i.e., benzene alone followed immediately by introduction of a known pressure of quencher with discarding of this mixture as soon as measurements were complete, was designed to

avoid the problem of product accumulation which manifests itself as a change in transmittance if the alternate procedure of adding increments of quencher to a single charge of benzene is adopted. An experimental check of the influence of refractive index changes caused by changing gas pressures on a nonparallel beam showed this to be negligible at the transmittances of our experiments.

The competitive process following benzene excitation to its first singlet state in the presence of halogenated alkanes may be initially represented by a general scheme which includes reactions previously established or postulated between benzene and other additives. A reasonable set of such reactions to which reference can be made, and with which our results are consistent, is

where D and A refer to ground-state benzene and ground-state halogenated alkane, respectively. An asterisk denotes an electronically excited state while the prefixes give the multiplicity of the electronic states. $I_a$ represents the rate of absorption of light by the benzene molecule.

Janda *et al.* (24) have shown in the benzene–acetone system that vibrational relaxation can influence the quenching efficiency of the added molecule. At the pressures and excitation wavelength of our experiments, it is reasonable to assume that benzene vibrational deactivation is complete prior to the occurrence of both unimolecular and bimolecular processes.

Some of the processes given above may be neglected for various reasons: (*i*) The extent of isomer formation process [6] is not appreciable under the experimental conditions used here and may be neglected in comparison to the much more rapid processes of intersystem crossover and fluorescence (13). (*ii*) None of the benzene – halogenated alkane systems examined exhibited any emission other than the fluorescence of benzene molecule. Moreover, the fluorescence spectra of benzene does not reveal any basic structural change upon the addition of the quenchers used in this study. On the basis of the above, the complex emission process [10] is excluded from the scheme. (*iii*) It has been shown that the extent of overlap of the fluorescence emission spectrum of the donor with that of the absorption spectrum of the acceptor provides a measure of the probability for radiationless intermolecular energy transfer. There is no overlap between the absorption spectrum of the halogenated alkanes used in this study and the fluorescence spectrum of benzene. Therefore, the possibility of singlet-state quenching by energy transfer, step [11], may be omitted.

Application of the steady state approximation to the above mechanism yields:

$$[13]\quad \frac{\phi_f^0}{\phi_f} = 1 + \frac{(k_{ic}' + k_{isc}')k_a[A]}{(k_f + k_\Delta + k_{isc})(k_d' + k_{ic}' + k_{isc}')} = 1 + k_q\tau[A]$$

where

$$\tau = (k_f + k_\Delta + k_{isc})^{-1}$$

expresses the fluorescence lifetime of benzene in the absence of quencher, and

$$[14] \quad k_q = \frac{(k_{ic}' + k_{isc}')k_a}{(k_d' + k_{ic}' + k_{isc}')}$$

is the expected second order rate constant for singlet-state quenching. According to eq. [13], plots of $\phi_f^0/\phi_f$ as a function of halogenated alkane pressure should be linear. This is found to be the case in all systems examined (see Figs. 1 and 2).

According to eq. [14] $k_q$ should be dependent upon several factors including the binding energy of the complex and it may be influenced by heavy-atom quenchers. A detailed quantitative discussion of the quenching mechanism can be made only if each component rate constant for a particular aromatic/quencher pair is available. $k_q$, other than for $CH_2Br_2$, was determined to be some two orders of magnitude smaller than what would be expected on the basis of ground-state collision cross sections (Table 1). Thus, either benzene and the halogenated alkane must approach each other closely before interaction occurs, or both $k_a$, the association constant, and $k_d'$ the dissociation constant of the complex, must be large.

The ionization potentials of the halogenated alkanes are much higher than that of $C_6H_6$. This, coupled with the fact that quenching efficiency increases with increasing electron affinity of the quencher, suggests that quenching is due to a charge transfer complex, of the type described by Klein *et al.* (1), and that the charge transfer is from $C_6H_6$ to chlorinated alkane.

The electron affinities (EA) of seven of the compounds are known and these were plotted against ln $k_q$ as a check of eq. [1] (see Fig. 3). Inspection of Fig. 3 shows that the model proposed by Klein *et al.* (1) is indeed appropriate for the halogenated alkanes; further, two distinct apparently linear relationships exist, one for the chlorinated alkanes and another for the mixed fluoro–chloro alkanes. Since the slope of the line in plots of ln $k_q$ vs. EA is considered a measure of the amount of charge transfer, it is obvious that benzene transfers a greater amount of charge to hydro–chloro (8%) than to fluoro–chloro alkanes (0.3%). It must be noted that the Klein equation does not take into account heavy atom effect. Thus departure from linearity is to be expected as $\xi$ values of quencher increase.

*B. Triplet-state quenching*

The triplet state of benzene does not exhibit emission in the vapor phase, although a considerable body of evidence demonstrates its existence in various phases (13, 25) including the gas phase. An indirect technique is therefore necessary to monitor this species. The sensitized emission of biacetyl technique (13) was employed to determine the rate constants for the quenching of the triplet state of benzene by the same molecules described in part A. The following additional steps describe the behavior of the triplet state of benzene in the presence of biacetyl.

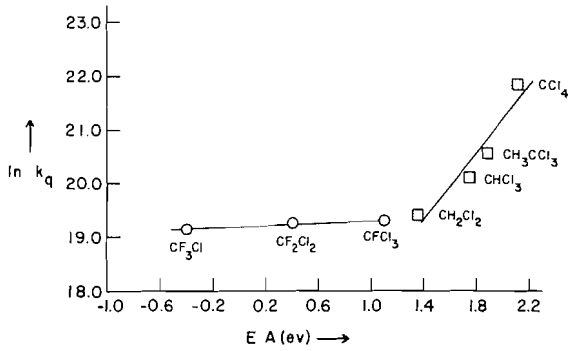

FIG. 3. Dependence of the observed quenching rate constant ($k_q$) of benzene fluorescence on the electron affinity of the halogenated alkane quenchers.

$$[15] \quad {}^3D^* \xrightarrow{k_{isc}'} D$$

$$[16] \quad {}^3D^* + A \xrightarrow{k_d'} \text{Quenching}$$

$$[17] \quad {}^3D^* + BiA \xrightarrow{k_{et}'} D + {}^3BiA^*$$

$$[18] \quad {}^3BiA^* \xrightarrow{k_p'} BiA + h\nu_p$$

$$[19] \quad {}^3BiA^* \xrightarrow{k_{isc}''} BiA$$

BiA refers to a ground-state biacetyl molecule and all the other symbols have the same meaning as above. Under the experimental conditions employed, reaction [16] is much less important than reaction [18]. Thus the above mechanism leads to expression [20] for quantum yield of phosphorescence of biacetyl sensitized by the benzene in the presence of quenchers ($\phi_t$):

$$[20] \quad \phi_t = \frac{k_{isc}}{(k_f + k_\Delta + k_{isc} + k_q[A])} \times \frac{k_{et}'[BiA]}{(k_q'[A] + k_{et}'[BiA]} \times \frac{k_p'}{(k_p' + k_{isc}'')}$$

The expression for fluorescence efficiency of benzene in the presence of quencher is:

$$[21] \quad \phi_f = \frac{k_f}{k_f + k_\Delta + k_{isc} + k_q[A]}$$

Combination of eqs. [20] and [21] gives:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

$$[22] \quad \frac{\phi_f}{\phi_t} = \frac{k_f}{k_{isc}} \times \frac{(k_p' + k_{isc}'')}{k_p'} \times \frac{k_{et}'[BiA] + k_q'[A]}{k_{et}'[BiA]}$$

A ratio form of this equation which is particularly convenient for test purposes in our case is obtained by dividing eq. [22] for the general case of any quencher concentration [A] by the reference value obtained when [22] is evaluated for zero quencher concentration. This results in:

$$[23] \quad \frac{R_q}{R_0} \equiv \frac{(\phi_f/\phi_t)_q}{(\phi_f/\phi_t)_0} = 1 + \frac{k_q'[A]}{k_{et}'[BiA]}$$

Since [BiA] is constant and known, and $k_{et}' = 3.43 \times 10^{10}$ L mol$^{-1}$ s$^{-1}$ (27), then assuming [23] holds, a plot of $R_q/R_0$ vs. quencher concentration will yield a straight line whose slope (L mol$^{-1}$ s$^{-1}$) = ($k_q'/2.80 \times 10^5$). The determination of this ratio involves recording and measuring four areas at constant incident intensity. Under these relatively favourable conditions the calculated uncertainty is a maximum of 5% and is almost entirely due to uncertainty in the areas. The results for five of the compounds are summarized in Table 2.

Values of $k_q'$ calculated from [23] (see Table 2), except for $CH_3F$, show a large relative standard deviation (0.18, 0.3, 0.3, for $CH_3Cl$, $CCl_4$, and $CF_3Cl$ respectively, and 0.07 for $CH_3F$) suggesting that the linear relationship [23] may not be applicable. This is illustrated best by $CH_2Br_2$ (Fig. 4), for which $k_q'$ calculated from [23] is negative. The quenchers $CHCl_3$ and $CH_3CCl_3$ also show small negative values, $\sim -10^5$ to $-10^6$, for $k_q'$. For the remaining molecules the calculated $k_q'$ values are $< 5 \times 10^6$ L mol$^{-1}$ s$^{-1}$, and have very large relative standard deviations. The experimental observations indicate that three of the molecules, $CF_3Cl$, $CH_3Cl$, and $CCl_4$, exhibit a small but significant increase in $\phi_f/\phi_t$ with increasing quencher pressure

indicating the occurrence of some quenching of the triplet state of benzene by these molecules. This phenomenon has been shown to occur (27) with molecules having high $\zeta$ values. $CH_2Br_2$, on the other hand, exhibits an overall decrease in $\phi_f/\phi_t$ with increasing quencher pressure, i.e., the singlet is depleted much more rapidly than the triplet state. This suggests that quenching of the benzene singlet by $CH_2Br_2$ probably occurs via two steps, reaction [7] discussed earlier and in addition

$$[24] \quad {}^1D^* + CH_2Br_2 \rightarrow {}^3D^* + CH_2Br_2$$

This is to be expected since $CH_2Br_2$ should exhibit a much greater heavy atom effect than any other of the molecules studied. For the remaining molecules $\phi_f/\phi_t$ is much less sensitive to quencher pressure.

Received August 28, 1981

JUANA BELLANATO, ENRIQUE GALVEZ, ROSARIO ESCOBAR and JOSE MANUEL CANO-PAVON. Can. J. Chem. **60**, 1775 (1982).

Treating 8-aminoquinoline with di-2-pyridyl ketone, pyridine-2-carboxaldehyde, or 6-methylpyridine-2-carboxaldehyde leads to the formation of the corresponding aminal instead of the expected Schiff base. The ir, $^1$H nmr, and mass spectra of these compounds are described and discussed.

Infrared and $^1$H nmr analyses indicate that these aminals enjoy intramolecular hydrogen bonding. This effect is considered to contribute significantly to their unusual stability.

JUANA BELLANATO, ENRIQUE GALVEZ, ROSARIO ESCOBAR et JOSE MANUEL CANO-PAVON. Can. J. Chem. **60**, 1775 (1982).

L'amino-8 quinoléine réagit avec la di-pyridyl-2 cétone, la pyridinecarboxaldéhyde-2 ou la méthyl-6 pyridinecarboxaldéhyde-2 en donnant les composés aminés correspondants au lieu des bases de Schiff attendues. On décrit les spectres de rmn, les spectres de masse et les spectres ir de ces composés et on en discute. L'analyse des spectres ir et de rmn indique que ces composés aminés possèdent des liaisons hydrogènes intramoléculaires. On pense que cet effet contribue grandement à leur stabilité inusitée.

[Traduit par le journal]

## Introduction

There are few data in the literature concerning formation of aminals from the reaction of primary amines with aldehydes (1–4). Lions *et al.* reported that 8-aminoquinoline (**1**) reacts readily with pyridine-2-carboxaldehyde (5, 6) and 6-methylpyridine-2-carboxaldehyde (7) to give the Schiff bases. However, under the working conditions described in the present paper, the corresponding aminals were obtained instead of the Schiff bases.

In a previous paper (8) we described the synthesis and some analytical properties of the compound di(2-pyridyl)-*N*,*N*-di((8-quinolyl)amino)methane (DPQAM, **2**), which was obtained by reaction of **1** with di-2-pyridyl ketone. We describe here the preparation and spectroscopic features of the aminals formed by condensation of **1** with pyridine-2-carboxaldehyde (PQAM, **3**) and 6-methylpyridine-2-carboxaldehyde (6M-PQAM, **4**). The structures of **2**–**4** are also discussed.

3, $R_1 = H$, $R_2 =$ 
4, $R_1 = H$, $R_2 =$ 
## Experimental

*Synthesis*

*DPQAM (2)*

Compound **2** was prepared as previously described (8).

*PQAM (3)*

Pyridine-2-carboxaldehyde (0.56 g) was added to a solution of 8-aminoquinoline (1.5 g) in absolute ethanol (1.2 mL) and the mixture was warmed at 40°C for 5 min. After cooling to room temperature, ether (50 mL) was added, and the collected product (yellow needles) was recrystallized from ethanol (mp 109–112°C, yield 25%). A change in the reactant ratio did not affect the yield. *Anal.* calcd. for $C_{24}H_{19}N_5$: C 76.37, H 5.07, N 18.56; found: C 76.70, H 4.79, N 18.90.

*6M-PQAM (4)*

6-Methylpyridine-2-carboxaldehyde (0.66 g) was added to a solution of 8-aminoquinoline (1.5 g) in absolute ethanol (1.5 mL) and the mixture was heated at 60°C for 10 min and then cooled to room temperature. After addition of ether, the yellow-brownish needles were collected and recrystallized from ethanol (mp 119–121°C, yield 30%). As in the case of **2** and **3**, modification of the reactant ratio did not affect the yield. *Anal.* calcd. for $C_{25}H_{21}N_5$: C 76.70, H 5.40, N 17.88; found: C 76.69, H 5.33, N 17.65.

*Methods*

Infrared spectra were recorded on a Perkin-Elmer 457 spectrophotometer. Indene and polystyrene were used for instrument calibration. All compounds were compressed into KBr pellets. Spectra in deuterated chloroform and carbon tetrachloride solutions at different dilutions were also recorded.

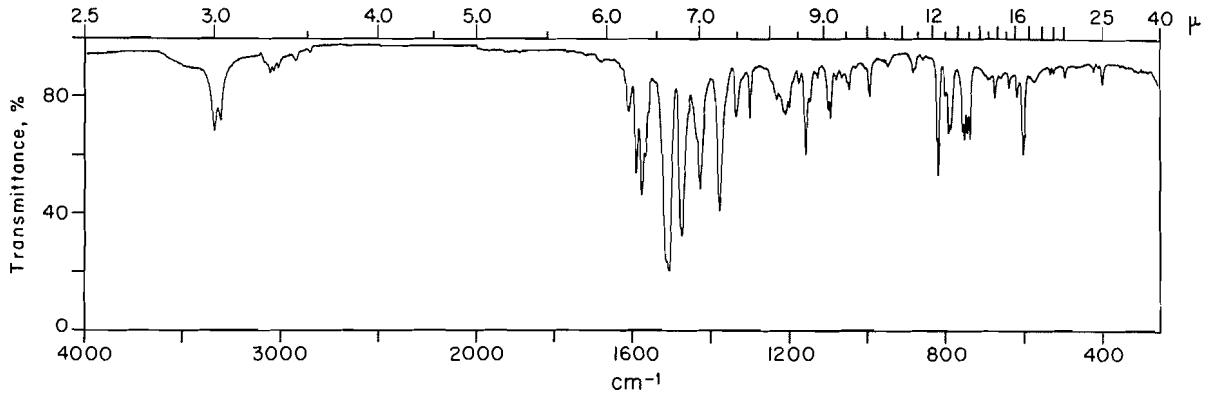

FIG. 1. Infrared spectrum of **2** in the solid state (KBr).

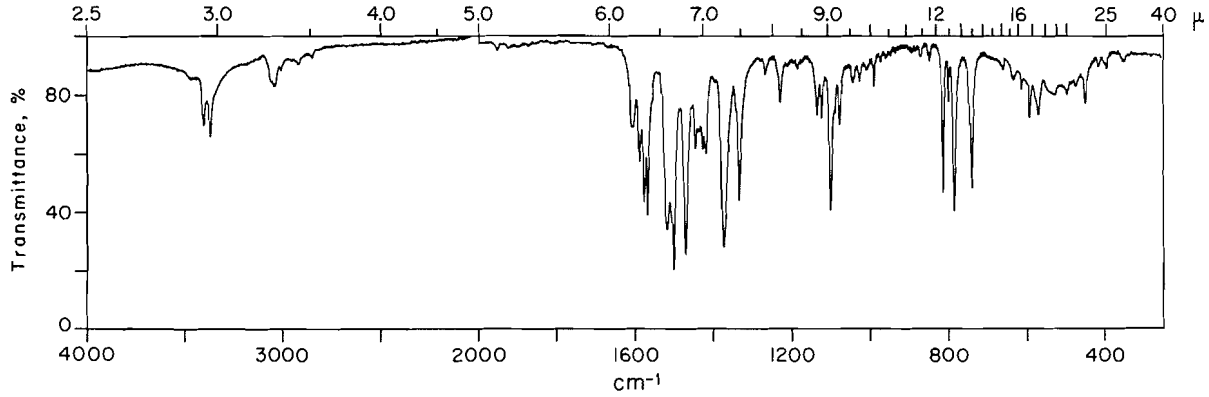

FIG. 2. Infrared spectrum of **3** in the solid state (KBr).

$^1$H nmr spectra were obtained in DMSO-$d_6$ or deuterated chloroform at 90 MHz with a Varian EM 390 spectrometer using tetramethylsilane as internal reference.

The $^{13}$C nmr spectrum of **2** was recorded at 20 MHz with a Varian FT-80A spectrometer in the Fourier transform mode; the spectrum was obtained under moderate heating; DMSO-$d_6$ (39.6 downfield relative to tetramethylsilane) was used as reference.

The mass spectra were measured at 70 eV on an AEI Model MS-30 instrument. Spectra of solid samples were obtained by direct injection into the source at 250°C with the probe at a temperature 20°C below the melting points.

## Results and discussion

*Infrared spectra*

The KBr-infrared spectra of compounds **2–4** are given in Figs. 1–3, and the N—H stretching frequencies determined from their solid and solution spectra, including data for **1** in Table 1.

Some infrared characteristics of 8-aminoquinoline have been discussed by Jensen and Nielsen (9).

It can be expected that in the molecule of 8-aminoquinoline one of the hydrogen atoms of the amino group takes part in intramolecular hydrogen bonding with the heterocyclic nitrogen, and consequently the two infrared bands at 3450 and 3350 cm$^{-1}$ in the spectrum of the solid are assigned to the "free" and bonded N—H, respectively. In $CDCl_3$ solution these bands shift towards 3500 and 3390 cm$^{-1}$ respectively. On deuteration both bands disappear and four bands are observed in the 2650–2450 cm$^{-1}$ region corresponding to mono- and di-deuterated species. As remarked by Jensen and Nielsen, the bands at 1617 and 1598 cm$^{-1}$ are sensitive to deuteration which is implicative of a contribution of the δ(N—H) mode to both bands.

The infrared spectrum of **2** in KBr shows a band at 3340 cm$^{-1}$ which is commensurate with the presence of secondary NH group ruling out a Schiff base structure for this compound. In some solid samples another band or shoulder at 3305 cm$^{-1}$ appeared in the spectrum indicating differences in the surroundings of both N—H groups in the crystal. Characteristic bands of the 8-quinolyl group appear at 1592, 1579, 1508, 1477, 1429, 1377, 1337, 1098, 820, and 795 cm$^{-1}$. The bands due to the

[c] Abbreviations: s, strong; m, medium; w, weak; sh, shoulder; v, very.

di-2-pyridyl group are obscured in the spectrum probably due to overlapping by the predominant quinoline bands. The band at 1616 $cm^{-1}$ of 8-aminoquinoline (partly $\delta NH_2$) is shifted towards 1611 $cm^{-1}$ and its intensity decreases. This new band is not sensitive to deuteration. The spectra in $CCl_4$ and $CDCl_3$ showed only minor changes. The ν(N—H) band appears nearly at the same frequency in KBr as it does in solution (Table 1) and is consistent with the chelate structure. However, a new band at 3500 $cm^{-1}$ indicates the coexistence of free NH groups and a shoulder at 3385 $cm^{-1}$ can be attributed to the existence of other chelated species. All these bands disappear on deuteration, confirming the presence of N—H character.

In the case of **3** several crystalline forms were obtained giving slightly different spectra. Changes were observed in the N—H stretching region which revealed different types of hydrogen bonding. The spectrum given in Fig. 2 shows two ν(N—H) bands at 3405 and 3370 $cm^{-1}$, suggesting that one NH group is single bonded whilst the other takes part in a bifurcated hydrogen bond. In this spectrum the quinoline characteristic bands are observed at 1592, 1579, 1569, 1502, 1470, 1420, 1375, 1337, 1104, 816, 787, and 743 $cm^{-1}$. In very dilute $CCl_4$ solutions two bands at 3495 and 3390 $cm^{-1}$ are observed and support the existence of free NH groups as in compound **2**. The $CDCl_3$ solution spectra are similar and also reveal the presence of chelated species. In both solvents results are best interpretated if only single bonded NH groups exist.

Contrary to the case of compound **3**, only a crystalline form was obtained for **4**. Its KBr-spectrum (Fig. 3) shows a sharp ν(N—H) band at 3395 $cm^{-1}$ and bands due to the quinoline rings at 1591, 1580, 1571, 1517, 1508, 1473, 1423, 1380, 1337, 1131, 820, 797, 791, 758, and 750 $cm^{-1}$. Results in $CCl_4$ and $CDCl_3$ are comparable to those obtained for **3** and are interpreted in the same way.

*Nuclear magnetic resonance spectra*

The most significant features of the $^1H$ nmr spectra of **2–4** are listed in Table 2.

The spectrum of **3** shows a triplet at δ6.30 which converts into a singlet on deuteration. This signal is assigned to the methine proton coupled to the

[b]Abbreviations: s, singlet; t, triplet.
[c]In DMSO-$d_6$.
[d]Not identified. See text.

amine protons. The existence of this coupling suggests that the amine hydrogens are bonded. Moreover, the triplet shape indicates that the amine signal appears at lower field than the signal of the methine proton and therefore must be overlapped by the heterocyclic proton signals. The data for compound **4** are similar to those found for **3** (see Table 2).

In the case of compound **2**, the signal at δ9.90 which disappears on deuteration is attributed to the amine protons. The high δ-value of this signal is attributed to the strong chelated hydrogen bonds in this compound.

Finally, the proton noise-decoupled $^{13}$C nmr spectrum of **2** which shows a signal at δ73.95 corresponding to a tetrahedral carbon unequivocally proves the aminal structure for compound **2**.

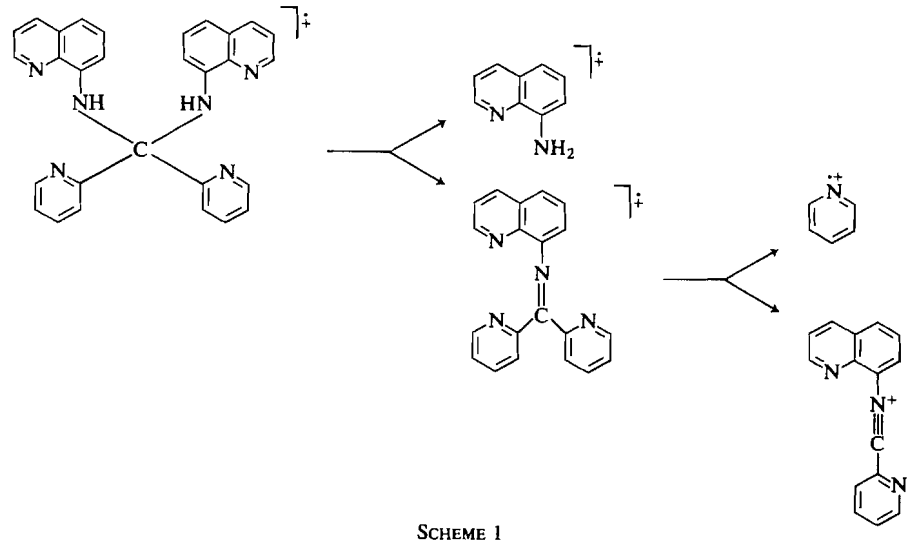
*Mass spectra*

The mean features of the mass spectrum of **2** are: a very weak $M^+$ peak at *m/e* 454, an intense peak at *m/e* 144, and a weak peak at *m/e* 310 which are originated from $M^+$ through a C—N cleavage with a simultaneous hydrogen rearrangement. The loss of a pyridinium radical ion (*m/e* 78) from the ion *m/e* 310 explains the base peak at *m/e* 232. Moreover, a metastable peak at *m/e* 173.3 confirms the transition 310→232. This fragmentation is in agreement with literature data (10). The peak at *m/e* 144 is attributed to an aminoquinolinium radical ion which originates the peaks at *m/e* 117, 116, 90, 89, 63, and 39 in accordance with the literature (11). The above data suggest the fragmentation pattern depicted by Scheme 1.

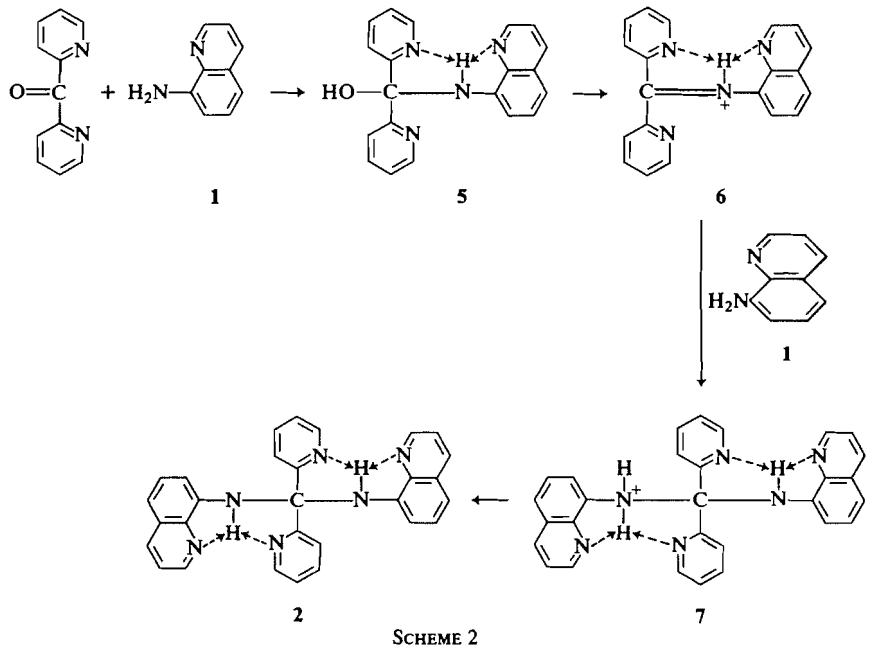
The mass spectra of compounds **3** and **4** presented similar features to those of compound **2**. In addition, an intense peak at *m/e* 129 and less abundant peaks at *m/e* 102, 76, 75, 51, and 50 were also observed. The ion of *m/e* 129 is due to quinolinium ion-radical $C_9H_7N^+$ which is originated from the molecular ion and/or from the amine ion through a cleavage with hydrogen rearrangement (see Scheme 1). Furthermore, in the mass spectra of **3** and **4** weak peaks at *m/e* 249 and 263 were respectively observed and are attributed to $(M - C_9H_6N)$.

Summarizing, the obtained results show that from the reaction of 8-aminoquinoline with pyridine-2-carboxaldehyde, 6-methyl-pyridine-2-carboxaldehyde, and di-2-pyridyl ketone aminals are obtained. The stability of these aminals is due to the occurrence of intramolecular hydrogen bonding which is also present even in polar solvents as was deduced from spectroscopic data. In this context it may be noted that when l-naphtylamine reacts with benzaldehyde the Schiff base is formed very easily (8).

The mechanism proposed for the formation of



SCHEME 1



SCHEME 2

the aminals studied is given in Scheme 2 for compound **2**. The immonium cation **6** is stabilized by intramolecular hydrogen bonding; thus the nucleophilic addition of a second molecule of 8-aminoquinoline to **6** leads to **7** and finally to the aminal **2** by the loss of a proton.

The aminals **2–4** are good analytical reagents for transition metals, specially Fe(II), originating stable chelates (8). They can also be applied for the indirect determination of voluminous anions such as perchlorate, iodide, and others which form ionic pairs with the chelates allowing the extraction of these chelates.

Throughout the present work the complexes of the reagents with Fe(II), Ni(II), Co(II), and Cu(I) in the form of perchlorates or iodides have been isolated. The study of the relation between spectroscopic properties and structures of these complexes will be the subject of a future paper.

ROSS ELMORE ROBERTSON, KALVELIL MATTHEW KOSHY, ADRIANNE ANNESSA, JAN N. ONG, JOHN MARSHALL WILLIAM SCOTT, and MICHAEL JESSE BLANDAMER. Can. J. Chem. **60**, 1780 (1982).

Kinetic data are reported for the solvolysis in water of propane-2-nitrate, butane-2-nitrate, cyclopentyl nitrate, and cyclohexyl nitrate. In each case, the dependence of rate constant on temperature is analysed in terms of two mechanisms for the solvolytic reaction. First it is assumed that the rate constant describes a single step reaction, the analysis leading to estimates of the heat capacity of activation $\Delta C_p^{\neq}$. Three different analytical methods are discussed in this regard. Second it is assumed that the rate constant describes a two stage mechanism, the first stage being reversible. In this case the explanation of the $\Delta C_p^{\neq}$ term calculated according to the first mechanism is quite different. We comment on the alternative explanations of trends in activation parameters.

ROSS ELMORE ROBERTSON, KALVELIL MATTHEW KOSHY, ADRIANNE ANNESSA, JAN N. ONG, JOHN MARSHALL WILLIAM SCOTT et MICHAEL JESSE BLANDAMER. Can. J. Chem. **60**, 1780 (1982).

On rapporte des données cinétiques pour la solvolyse des nitrates de propyle-2, de butyle-2, de cyclopentyle et de cyclohexyle dans l'eau. Dans chaque cas, on analyse l'effet de la température sur la constante de vitesse en fonction de deux mécanismes pouvant régir la réaction de solvolyse. On admet premièrement que la constante de vitesse décrit une réaction en une seule étape, l'analyse conduisant à une évaluation de la capacité calorifique d'activation, $\Delta C_p^{\neq}$. De ce point de vue, on discute trois méthodes analytiques différentes. Deuxièmement, on admet que la constante de vitesse décrit un mécanisme en deux étapes, la première étant réversible. Dans ce cas, l'explication du terme $\Delta C_p^{\neq}$ calculé selon le premier mécanisme est tout à fait différente. Nous commentons d'autres explications relatives aux tendances des paramètres d'activation.

For personal use only.

An extensive body of information describes the kinetics of solvolysis of simple organic esters in water (1). For the most part, the dependence of rate constant, $k$, on temperature has been analysed using the Valentiner equation (2, 3) thereby leading to estimates of the thermodynamic activation parameters including the enthalpy of activation $\Delta H^{\neq}$ and the heat capacity of activation $\Delta C_p^{\neq}$. The latter quantity attracted considerable interest because, it was argued (1), a major contribution to the sign and magnitude of $\Delta C_p^{\neq}$ stems from reorganisation of solvent around the substrate on activation. However, certain features (4), previously unrecognised (1), of the Valentiner equation (2) prompted a reconsideration (5) of the methods of analysing the dependence of rate constant on temperature. We draw attention to these and other features of the Valentiner equation in this paper. A consequence of this reconsideration has been an investigation of other methods of data analysis with reference to the kinetics of solvolysis in water (5–7) and in mixed solvents (8) and to kinetic solvent isotope effects (9). For the most part this exercise has involved reexamining previously published data (1). In this communication, we report kinetic data for the solvolysis of four secondary nitrates in water. Originally, the experimental investigation was prompted by the need for a comparison between the activation parameters for these nitrates and those reported (10) for 2-adamantyl nitrate. However, as indicated above, the developments on the analytical side have overtaken events.

## Results

The rate constants were determined by the conductance method (1). First order rate constants at several temperatures are summarized in Tables 1–4. We report the averaged rate constants at each temperature but in the analysis we used the individual rate constants obtained from 3 or more determinations at each temperature.

### *Analysis*

In common with almost all solvolytic reactions of simple organic esters in water (1), plots of ln $k$ against $T^{-1}$ for the data given in Tables 1–4 are nonlinear. This observation can be accounted for in one of two ways; (A) the mechanism of reaction is a simple single-stage process but $\Delta C_p^{\neq}$ is nonzero (1), or (B) the mechanism of reaction is complex but

the individual enthalpies of activation are independent of temperature (6, 7).

The mathematical analysis has been carried out using (*i*) computer programs (FORTRAN and GLIM (11) routines) for the CDC Cyber 73 at the University of Leicester and (*ii*) computer programs for a Hewlett–Packard 9825A desk-top computer.

A. *Single stage mechanism*

The underlying assumption is that the rate constant $k$ describes a single stage process;

[1] $\mathrm{R{-}NO_3} \xrightarrow{k}$ products

With this starting hypothesis, several methods can be used to fit the dependence of $k$ on $T$. We consider here three approaches to the evaluation of the activation parameters.

In the Valentiner equation (2), the dependence of $\ln k$ on $T$ is expressed as shown in eq. [2].

[2] $\ln k = a_1 + (a_2/T) + a_3 \ln T$

The outcome of the analysis for the four nitrates is summarized in Table 5. An estimate of the goodness of fit is provided by the quantity $\Omega$ defined by eq. [3] where $f$ is the number of degrees of freedom.

[3] $\Omega^2 = (\ln k(\mathrm{obs}) - \ln k(\mathrm{calc}))^2/f$

In all four cases $\Delta C_p^{\ddagger}$ is negative. A common feature of the data for 17 alkyl nitrates is shown in Fig. 1 which shows plots of $a_2$ against $a_3$ and $a_1$ against $a_3$. We have commented elsewhere (4) on this phenomenon and examined the statistical significance underlying the linear dependences (12).

We have applied the polynomial suggested by Eyring and co-workers (13) to the analysis of kinetic data (7), eq. [4]:

$$[4] \quad \ln k = \sum_{i=1}^{i=m} a_i (T - \theta)^{i-1}$$

For the systems described here it was only significant to include all terms up to $m = 5$. The derived parameters are summarized in Table 6, together with the corresponding standard errors and estimates of $\Delta H^{\ddagger}(\theta)$, $\Delta C_p^{\ddagger}(\theta)$, $d\Delta C_p^{\ddagger}/dT$, and $d^2\Delta C_p^{\ddagger}/dT^2$.

The Clarke–Glew equation (14) uses a reference temperature but is based on a Taylor expansion of the enthalpy term about this reference temperature;

$$[5] \quad \ln\left(\frac{k}{T}\right) = \ln(k(\theta)/\theta) + \frac{\Delta H^{\ddagger}(\theta)}{R}\left[\frac{1}{\theta} - \frac{1}{T}\right] + \frac{\Delta C_p^{\ddagger}(\theta)}{R}\left[\frac{\theta}{T} - 1 + \ln\left(\frac{T}{\theta}\right)\right] + \frac{d\Delta C_p^{\ddagger}(\theta)/dT}{R} \times \left[\frac{T}{\theta} - \frac{\theta}{T} - 2\ln\left(\frac{T}{\theta}\right)\right]$$

The outcome of the analysis is summarized in Table 7.

B. *Two stage mechanism*

The assumption is that the mechanism of solvolysis follows the scheme (15) shown in eq. [6].

$$[6] \quad RX \underset{k_2}{\overset{k_1}{\rightleftharpoons}} (int) \xrightarrow{k_2} products$$

The measured first order rate constant $k$ is related to $k_1$ and $\alpha$ ($= k_2/k_3$) where $k = k_1/(1 + \alpha)$. The simplification introduced here is that $\ln k_1$ and $\ln \alpha$ are linear functions of $T^{-1}$. Hence

$$[7] \quad \ln k = (g_1/T) + g_2 - \ln[1 + \exp(g_3/T + g_4)]$$

The temperature at which $\alpha = 1$ is given by $-g_3/g_4$.

We have discussed elsewhere (12) the technique of fitting the data to eq. [7] using the Wentworth method (16). The results are summarized in Table 8. For each set of kinetic data there are two sets of solutions (17). Included in Table 8 are the calculated activation parameters, $\Delta H_1^{\ddagger}$ and $\Delta\Delta H^{\ddagger}$ ($= \Delta H_3^{\ddagger} - \Delta H_2^{\ddagger}$).

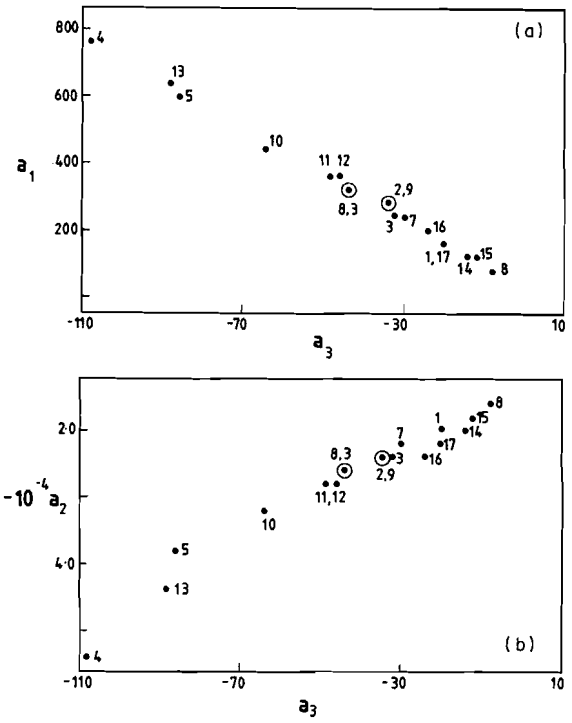

FIG. 1. Parameters obtained using the Valentiner equation; (a) dependence of $a_1$ on $a_3$, and (b) dependence of $a_2$ on $a_3$; the substrates are 1. Methyl nitrate (21); 2. allyl nitrate;[1] 3. benzyl nitrate ($D_2O$);[2] 4. 1-adamantyl nitrate (10); 5. 2-adamantyl nitrate (10); 6. *p*-trifluoromethylbenzyl nitrate (22); 7. *p*-nitrobenzyl nitrate (22); 8. *p*-methylbenzyl nitrate (22); 9. *p*-chlorobenzyl nitrate (22); 10. 2,6-dimethylbenzyl nitrate (23); 11. *m*-methylbenzyl nitrate (23); 12. *o*-methylbenzyl nitrate (23); 13. *m*-trifluoromethylbenzyl nitrate (22); 14. propane-2-nitrate; 15. butane-2-nitrate; 16. cyclohexyl nitrate; 17. cyclopentyl nitrate.

## Discussion

Details of the analysis in terms of the Valentiner equation are presented for comparison with the results obtained for other substrates (1). Our reservations over this approach stem from the plots shown in Fig. 1. We attribute these patterns to the fact that both $T^{-1}$ and ln $T$ are close to linear functions of $T$ (11). For this reason the Clarke–Glew equation has merit in that the equation contains different functions of $T$, ln $T$, and θ. Both sets of derived parameters (Tables 7 and 8) are in reasonable agreement. The value for $\Delta C_p^{\neq}$ (θ) provides an important clue here in that the estimates and their standard errors overlap for each substrate. However, the polynomial equation leads to estimates of $\Delta C_p^{\neq}$ (θ), together with the corresponding first and second temperature derivatives. Indeed, in all four systems, the analysis suggests that $\Delta C_p^{\neq}$ decreases with increase in temperature.

Granted that method A is a satisfactory explanation of the kinetic data, it is noteworthy that the calculated heat capacities of activation are significantly smaller than those previously reported for systems where the solvolysis involves a unimolecular process with extensive charge development in the transition state (10). The activation parameters are consistent with direct solvent participation in the activation process. In one extreme the data, here and in ref. 10, can be understood in terms of relatively little charge separation in the substrate but considerable nucleophilic involvement by solvent. At the same time it is possible that, in contrast to halides, there are special steric and related factors involved with the solvation of the leaving group in the case of alkyl nitrates. Hence it is possible to evolve numerous schemes such that the calculated activation parameters are composite quantities. Here is the link with mechanism B which breaks down the solvolytic reaction into component parts. Analysis in these terms raises new problems as indicated in Table 8. Thus for each nitrate there are two almost statistically equivalent solutions. For butane-2-nitrate and cyclopentyl nitrate results, solution (b) offers an intuitively reasonable set of parameters where the ratio

*Favoured solution, see text.

$\alpha$ is $< 1.0$ over the experimental range of temperatures. More importantly, $\Delta\Delta H^{\neq}$ is positive and because we anticipate no marked difference between the four substrates, we favour solution (a) for propane-2-nitrate and solution (a) for cyclohexyl nitrate. However, for this latter system the two solutions are not wildly different because the temperature $T(\alpha = 1)$ falls within the experimental range. Indeed this system, cyclohexyl nitrate provides an important clue to a major problem in this work.

According to Model A, the heat capacity of activation is a true heat capacity term. Because the partial molar heat capacities of apolar solutes in water are positive, it is not altogether surprising that $\Delta C_p^{\neq}$ is negative. According to Model B, the $\Delta C_p^{\neq}$ term is an apparent quantity and no allowance is made for a contribution arising from the changes in real heat capacity of the substrate. Clearly this approximation is too sweeping and some compromise is sought. A line of argument would proceed as follows. Where the calculated $|\Delta C_p^{\neq}|$ quantity is large, a major part of that calculated heat capacity of activation stems from kinetic complexity. We anticipate that in these circumstances, the temperature T ($\alpha = 1$) is close to or within the experimental range (of cyclohexyl nitrate). Where the calculated $|\Delta C_p^{\neq}|$ is small (cf. propane-2-nitrate), the mechanism of solvolysis is controlled by one step. Moreover, $T$ ($\alpha = 1$) where calculated according to method B lies some way removed from the experimental range. This compromise view has much to commend it.

## Experimental

The alkylnitrates were prepared using methods based on published procedures (18–20) combined with nmr measurements as a confirmation of purity.

*Products*

In each study a separate experiment with the nitrate in water in the ratio 1:4–1:6 was sealed in a glass ampoule and reacted in a constant temperature bath in the experimental range for about 10 half-lives. The product was extracted with ether and identified by vpc on a FFAP column. In each case the only significant product was the corresponding alcohol. In the case of cyclohexyl nitrate, traces of cyclohexene in the original sample also appeared in the product.

Received September 18, 1981

Z. BORKOWSKA and W. R. FAWCETT. Can. J. Chem. **60**, 1787 (1982).

The entropy of formation of the mercury/methanol interface has been calculated from double layer capacity and interfacial tension measurements. In contrast to results for aqueous and propylene carbonate solutions, the plot of entropy against electrode charge density passes through a minimum at negative charge densities and a maximum at positive charge densities in the same regions where a minimum and maximum are found on the capacity curve. The excess surface entropy of methanol is negative for all charge densities, indicating that the solvent is more structured at the mercury surface than in the bulk. The results have been discussed in terms of the three state model in which the charge dependence of the entropy is attributed to reorientation of solvent dipoles at the interface.

Z. BORKOWSKA et W. R. FAWCETT. Can. J. Chem. **60**, 1787 (1982).

On a calculé l'entropie de formation de l'interface mercure–méthanol à partir de mesures de la capacité de la couche double et de la tension interfaciale. Contrairement aux résultats obtenus pour des solutions aqueuses et dans le carbonate de propylène, la courbe d'entropie en fonction de la densité de charge passe par un minimum pour des densités de charge négative et par un maximum pour des densités de charge positive dans la région où l'on trouve un minimum et un maximum pour la courbe de capacité. L'excès d'entropie de surface du méthanol est négatif pour toutes les densités de charge indiquant ainsi que le solvant est plus structuré à la surface du mercure que dans l'ensemble de la solution. On discute des résultats en fonction d'une modèle à trois états dans lequel on attribue l'effet de la charge sur l'entropie à une réorientation des dipoles du solvant à l'interface.

[Traduit par le journal]

## Introduction

In a previous paper (1), the dielectric properties of the Hg/methanol (MeOH) interface in the presence of KF, $NaClO_4$, and $LiBF_4$ were discussed. Ionic specific adsorption could not be detected at charge densities in the range $-0.11 \leq \sigma \leq 0.04$ C m$^{-2}$ but the interfacial capacity was a function of the counter ion nature at higher charge densities. The main shape of the capacity curve, that is, the appearance of a maximum at positive charge densities and minimum at negative charge densities, was the same for all investigated solutions. Moreover, the coordinates of the minimum were independent of counter ion nature. These results suggested that, at least in the limited range of charge densities around the minimum ($\sigma = -0.05$ C m$^{-2}$), the dielectric properties of the Hg/solution interface are determined by the solvent.

The inner layer capacity curves for the electrolytes studied at various temperatures in methanol (1) and the temperature dependence of the surface potential (2) have been satisfactorily described by a three state model for unassociated solvents (3), although it is well known that methanol is to some extent hydrogen-bonded in the bulk (4).

In this paper, an attempt is made to answer the question of the extent of MeOH association in the surface layer as compared with the bulk solution and to test in more detail the applicability of the three state model. In this regard the entropy of formation of the Hg/MeOH interface has been evaluated on the basis of the measured temperature dependence of the surface tension at the point of zero charge (pzc), and the previously published temperature dependence of the inner layer capacity (1) and the surface potential (2) for a 0.1 *M* $NaClO_4$ solution in MeOH. The results have been compared with the entropy of formation of the free surface calculated from data in the literature (4) and with that calculated according to the three state model.

The Gibbs surface excess entropy and the entropy of formation have been reported for the mercury/aqueous solution interface (5–8). The only other data available for a mercury/nonaqueous interface are those for the mercury/propylene carbonate (PC) interface in the presence of $KPF_6$ (9).

## Experimental

MeOH and $NaClO_4$ were purified as described previously (1). Solutions were prepared in a dry box and transferred to the cell under an argon atmosphere. The water content in 0.1 *M* $NaClO_4$

solutions in MeOH was about 0.02% as determined by Karl Fischer titration. The solutions were deaerated with argon which had been presaturated with the vapour of the solution under study.

Surface tension was measured in 0.1 *M* $NaClO_4$ solutions in the temperature range −5 to 50°C using the maximum bubble pressure method (10). The cell and the mercury column were kept at the same temperature by pumping ethylene glycol from a thermostated bath through external jackets. The temperature was measured directly in the cell, the difference between the solution and the top of the mercury column being less than 0.5°C. The electrometer was calibrated by measurements in an aqueous solution of 0.05 *M* $Na_2SO_4$ assuming $\gamma = 426.2 \pm 0.2$ mN $m^{-1}$ at 25°C for the interfacial tension at the pzc (11). The performance of the capillary in the investigated solution was checked by comparing the results with literature data for 0.1 *M* $NaClO_4$ in MeOH at 25°C ($\gamma = 392.7 \pm 0.2$ mN $m^{-1}$) (12). The check was repeated after each measurement at a temperature different than 25°C. The temperature dependence of the surface tension at the electrocapillary maximum was calculated taking into account the change in the density of mercury (13). The electrocapillary measurements were carried out with the position of the interface being kept constant in the capillary and with constant solution volume. The electrode potential was measured with respect to a saturated KCl calomel electrode in MeOH (1).

## Data analysis and results

The entropy of formation of the interface, $\Delta S^{m-s}$, was calculated following the method of Harrison *et al.* (7) on the basis of the system

[1] Hg/$NaClO_4$ in MeOH/Na(Hg)

The appropriate isobaric electrocapillary equation is

$$[2] \quad -d\gamma = \Gamma_s dT + \Gamma_- d\mu_{salt} + \sigma d\varepsilon_+$$

or

$$[3] \quad -d\xi_+ = \Gamma_s dT + \Gamma_- d\mu_{salt} - \varepsilon_+ d\sigma$$

where $\xi_+ = \gamma + \sigma\varepsilon_+$ and $\varepsilon_+ = E_+ - \mu_{Na(Hg)}/F$. $\Gamma_s$ is the surface excess of entropy, $\Gamma_-$, that of the anions and $E_+$, the potential of the Hg electrode measured against the Na amalgam reference electrode. It follows that

$$[4] \quad \Gamma_s = -\left(\frac{\partial\gamma}{\partial T}\right)_{E_+,\mu_{salt}} = -\left(\frac{\partial\xi_+}{\partial T}\right)_{\sigma,\mu_{salt}}$$

The entropy of formation of the interface may be calculated by comparing the entropy of the components in the surface phase $\alpha$ with the values they would have if they were in the bulk of their respective phases, $\beta$, metal and solution. Accordingly,

$$[5] \quad \Delta S^{m-s} = \sum_i m_i^{\alpha}\tilde{s}_i^{\alpha} - \sum_i m_i^{\alpha}\tilde{s}_i^{\beta}$$

where $m_i^{\alpha}$ is the concentration of component $i$ in the surface phase, $\tilde{s}_i^{\alpha}$, its molar entropy in the surface phase, and $\tilde{s}_i^{\beta}$, its value in the bulk phase.

On the other hand, the surface excess of entropy is given by (14)

$$[6] \quad \Gamma_s = \sum_i m_i^{\alpha}\tilde{s}_i^{\alpha} - m_{Hg}^{\alpha}\tilde{s}_{Hg}^{\beta} - m_{MeOH}^{\alpha}(\tilde{s}_{MeOH}^{\beta} + \tilde{s}_{salt}^{\beta} m_{salt}^{\beta}/m_{MeOH}^{\beta})$$

Keeping in mind the definition of the relative ionic surface excess $\Gamma_{\pm}$, namely,

$$[7] \quad \Gamma_{\pm} = m_{\pm}^{\alpha} - m_{MeOH}^{\alpha} m_{\pm}^{\beta}/m_{MeOH}^{\beta}$$

it is easily shown that

$$[8] \quad \Delta S^{m-s} = \Gamma_s - \Gamma_+\tilde{s}_+^{\beta} - \Gamma_-\tilde{s}_-^{\beta} = \Gamma_s - \Gamma_-\tilde{s}_{salt}^{\beta} + \sigma\tilde{s}_+^{\beta}/F$$

Since $d\mu_{salt} = -\tilde{s}_{salt}^{\beta} dT$ at constant electrolyte concentration, on combining eqs. [3] and [8], one obtains

$$[9] \quad -d\xi_+ = (\Delta S^{m-s} - \sigma\tilde{s}_+^{\beta}/F)dT - (E_+ - \mu_{Na(Hg)}/F)d\sigma$$

By cross-differentiation

$$[10] \quad \left(\frac{\partial\Delta S^{m-s}}{\partial\sigma}\right)_{m,P,T} = -\left(\frac{\partial E_+}{\partial T}\right)_{m,P,\sigma} + \frac{\tilde{s}_+^{\beta} - \tilde{s}_{Na(Hg)}}{F}$$

The potential drop across the Hg/solution interface is given by (2)

$$[11] \quad \Delta\phi^{m-s} = E_+ + (\mu_+ - \mu_{Na(hg)})/F$$

Differentiating this expression with respect to temperature, one finds the simple relationship

$$[12] \quad \left(\frac{\partial\Delta S^{m-s}}{\partial\sigma}\right)_{m,P,T} = -\left(\frac{\partial\Delta\phi^{m-s}}{\partial T}\right)_{m,P,\sigma}$$

$\Delta\phi^{m-s}$ is simply related to the differential capacity of the interface which may be measured experimentally:

$$[13] \quad \Delta\phi^{m-s} = \int_0^{\sigma}(1/C)d\sigma$$

where $C$ is the differential capacity. The temperature derivative of $\Delta\phi^{m-s}$ is given by

$$[14] \quad \left(\frac{\partial\Delta\phi^{m-s}}{\partial T}\right)_{m,P,\sigma} = \left(\frac{\partial\Delta\phi_0{}^{m-s}}{\partial T}\right)_{m,P} + \int_0^{\sigma}\left(\frac{\partial(1/C)}{\partial T}\right)_{m,P,\sigma} d\sigma$$

where $\Delta\phi_0{}^{m-s}$ is the potential drop at the pzc. It is convenient to consider separately the contributions to these quantities from the inner and diffuse

parts of the double layer, for example,

$$[15]\quad \left(\frac{\partial \Delta\phi^{m-s}}{\partial T}\right)_{m,P,\sigma} = \left(\frac{\partial \Delta\phi^{m-d}}{\partial T}\right)_{m,P,\sigma} + \left(\frac{\partial \Delta\phi^{d-s}}{\partial T}\right)_{m,P,\sigma}$$

where $m - d$ designates the inner layer and $d - s$ the diffuse layer. The entropy of formation of the inner layer is then

$$[16]\quad \Delta S^{m-d} = \Delta S_0^{m-d} - \int_0^{\sigma}\left(\frac{\partial \Delta\phi^{m-d}}{\partial T}\right)_{m,P,\sigma} d\sigma$$
$$= \Delta S_0^{m-d} - \int_0^{\sigma}\left(\frac{\partial \Delta\phi_0^{m-d}}{\partial T}\right)_{m,P,\sigma} d\sigma - \int_0^{\sigma}\int_0^{\sigma}\left(\frac{\partial (1/C_i)}{\partial T}\right)_{m,P,\sigma} (d\sigma)^2$$

where $\Delta S_0^{m-d}$ is the entropy of formation of the inner layer at the pzc and $C_i$, the capacity of the inner layer. A similar equation can be written for the entropy of formation of the diffuse layer, $\Delta S^{d-s}$. The separation of the experimental capacity into inner layer and diffuse layer contributions is based on Gouy–Chapman theory with the assumption that ionic specific adsorption is absent.

Values of the temperature coefficient of the inner layer capacity for the Hg/MeOH interface as a function of electrode charge density were reported earlier (1). The coefficient $\partial(1/C_i)/\partial T$ was found to have a minimum value at $\sigma = -0.05$ C m$^{-2}$, coincident with the minimum on the capacity against charge density curve. The corresponding values of the coefficient $\partial \Delta S^{m-d}/\partial\sigma$ calculated on the basis of eqs. [12]–[14], and using the previously determined values of $\partial(1/C_i)/\partial T$ (1) and the temperature coefficient of the surface potential, $\partial \Delta\phi_0^{m-s}/\partial T$ (2) are shown in Fig. 1. As expected, this coefficient has a maximum at the charge density where $\partial(1/C_i)/\partial T$ is zero (−0.019 C m$^{-2}$).

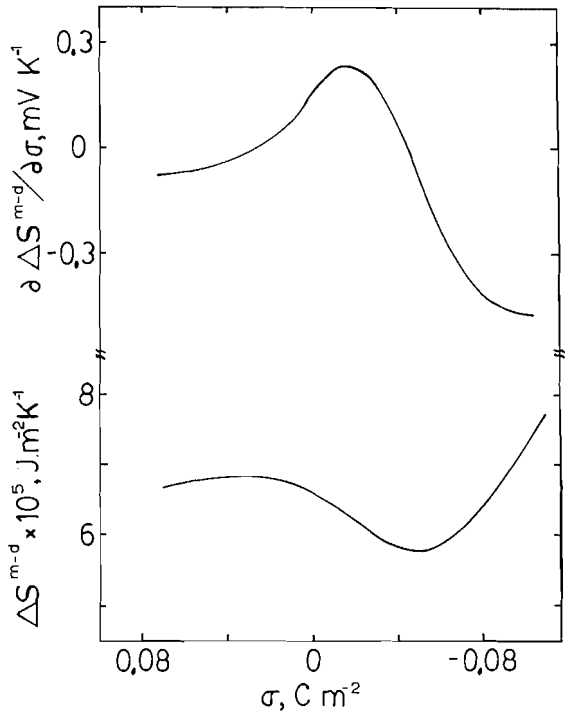

FIG. 1. Thermodynamic properties of the mercury/methanol interface as a function of electrode charge density σ with 0.1 $M$ $NaClO_4$ as electrolyte: (*a*) the coefficient $\partial \Delta S^{m-d}/\partial\sigma$ where $\partial \Delta S^{m-d}/\partial\sigma = -\partial \Delta\phi^{m-d}/\partial T$ and the superscript $(m-d)$ refers to the inner layer; and (*b*) the entropy of formation of the inner layer, $\Delta S^{m-d}$.

The data obtained for the interfacial tension in the temperature range −5 to 40°C and calculated values of $\Delta S^{m-s}$ at the pzc are recorded in Table 1. In the absence of specific adsorption, $\Gamma_+$ and $\Gamma_-$ are zero at the pzc and the temperature derivative of the surface tension gives directly the entropy of formation of the interface, $\Delta S^{m-s}$. Furthermore, since the entropy of formation of the diffuse layer is zero at the pzc, $\Delta S^{m-s}$ is identical with $\Delta S^{m-d}$, the entropy of formation of the inner layer. It was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

noted that $\Delta S^{m-s}$ is a function of temperature. On the basis of eq. [16], the entropy of formation of the inner layer was calculated as a function of electrode charge density. The results presented in Fig. 1 show that there is a minimum in $\Delta S^{m-d}$ at $-0.05\,C\,m^{-2}$, the same charge density as the minimum on the inner layer capacity curve and the curve of $\partial(1/C_i)/\partial T$ against $\sigma$. A shallow maximum is also found at $\sigma = 0.028\,C\,m^{-2}$. The extrema on the entropy curve appear at charge densities where $\partial \Delta S^{m-d}/\partial\sigma$ is zero as one would expect (15).

The present results can be compared with those obtained earlier for the mercury/aqueous (5–8) and mercury/PC solution interfaces (9). In both cases, $\Delta S^{m-d}$ passes through a maximum at negative charge densities. It is interesting to note that MeOH is the only known solvent for which the temperature dependence of surface potential is negative (2) and also for which the predominant extremum on the curve of $\partial(1/C_i)/\partial T$ against $\sigma$ is a minimum (16).

Finally, one would expect $\Delta S^{m-d}$ to depend on the nature of the counter ion at charge densities outside of the range $-0.03 \leq \sigma \leq 0.03\,C\,m^{-2}$, that is, in the region where the diffuse layer contribution is negligible. However, it seems unlikely that the main features of the entropy curve would change. Therefore, the results presented here are considered to be typical for the Hg/MeOH interface.

## Discussion

According to the present data, the most ordered structure of the Hg/MeOH interface occurs at a negative charge density ($\sigma = -0.05\,C\,m^{-2}$) where a minimum is observed on the capacity curve. Maximum disorder exists at a positive charge density ($\sigma = 0.028\,C\,m^{-2}$). The position of the entropy minimum follows the predictions of the three state model according to which $\partial \Delta\phi^{m-d}/\partial T$ is zero at the extrema on the capacity curve. The entropy maximum occurs at a less positive charge density than the capacity maximum observed in the $NaClO_4$ system at $\sigma = 0.05\,C\,m^{-2}$. The difference could be due to weak specific adsorption of the perchlorate anion and suggests that the capacity hump is due partly to solvent reorientation and partly to ionic adsorption. However, the capacity minimum is due entirely to the orientation of solvent dipoles.

According to the three state model (1, 3), the solvent dipoles in a monolayer at the interface can take up three orientations, namely, with the positive end of the dipole towards the metal ("up"), the negative end towards the metal ("down"), and the dipole vector parallel to the electrode ("parallel"); the fractions in each of these orientations are $f_1$ ("up"), $f_2$("down"), and $f_3$ ("parallel"). The average orientation of dipoles surrounding a given dipole and the field due to the charge on the metal, $E$, define the reaction field $X$. Thus, the fraction of solvent molecules in a given orientation is determined by the local field $\mathscr{E} = E + X$ and a non-electrostatic residual energy $U_{ri}$ accounting for chemical interactions between the dipole in a given orientation and the metal. From the equations defining $f_1, f_2$, and $f_3$ given previously (1, 3), one may derive a set of simultaneous equations for calculating the temperature coefficients $\partial f_i/\partial T$ at constant field $E$:

$$[17]\quad \frac{\partial f_1}{\partial T} + \frac{\partial f_2}{\partial T} + \frac{\partial f_3}{\partial T} = 0$$

$$[18]\quad \frac{kT}{f_1}\left(\frac{\partial f_1}{\partial T}\right) - \frac{kT}{f_2}\left(\frac{\partial f_2}{\partial T}\right) = -k\ln\left(\frac{f_1}{f_2}\right) - 2p\frac{\partial X}{\partial T}$$

and

$$[19]\quad \frac{kT}{f_1}\left(\frac{\partial f_1}{\partial T}\right) - \frac{kT}{f_3}\left(\frac{\partial f_3}{\partial T}\right) = -k\ln\left(\frac{f_1}{f_3}\right) - p\frac{\partial X}{\partial T}$$

The temperature coefficient of the reaction field is given by

$$[20]\quad \frac{\partial X}{\partial T} = \frac{c_e}{Ad^3}\left[p\left(\frac{\partial f_1}{\partial T} - \frac{\partial f_2}{\partial T}\right)\right]$$

where $p$ is the magnitude of the dipole moment, $c_e$ the effective coordination number, $d$ the molecular diameter of the solvent molecule represented as a sphere, $\alpha$ its polarizability, and $A = 1 + c_e\alpha/d^3$. According to this model the free energy of the monolayer is given by (3)

$$[21]\quad F_i = \frac{N_T d^3 A \mathscr{E}^2}{2c_e} - \frac{N_T d^3 E^2}{2c_e} + \sum_i N_T f_i U_{ri} + \sum_i kTN_T f_i \ln f_i$$

where $N_T = 2/(\sqrt{3}d^2)$ is the number of solvent dipoles in hexagonal close packing per unit area. The expression for the entropy is then

$$[22]\quad S_i = \frac{-N_T d^3 A \mathscr{E}}{c_e}\frac{\partial X}{\partial T} - \sum_i N_T\left(\frac{\partial f_i}{\partial T}\right)U_{ri} - \sum_i kN_T f_i \ln f_i - \sum_i kTN_T\left(\frac{\partial f_i}{\partial T}\right)\ln f_i - \sum_i kTN_T\left(\frac{\partial f_i}{\partial T}\right)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

and that for the temperature coefficient of the potential drop across the monolayer,

$$[23]\quad \frac{\partial \Delta\phi}{\partial T} = \frac{4\pi N_T d^3}{c_e}\left(\frac{\partial X}{\partial T}\right)$$

where $\partial\Delta\phi/\partial T = -\partial S_i/\partial\sigma$.

Curves of $S_i$ and $\partial S_i/\partial\sigma$ against electrode charge density were calculated on the basis of parameters found previously to describe representative capacity curves (1).[1] The molecular diameter was set equal to 0.335 nm and the effective coordination number $c_e$ to 13.95. The dipole moment ($5.54 \times 10^{-30}$ C m) and polarizability ($3.26 \times 10^{-3}$ nm$^3$) were taken from the literature. The results of these calculations are illustrated in Fig. 2. Comparison of the experimental data (Fig. 1) and theoretical curves (Fig. 2) reveals that the theory gives a reasonable qualitative description of the temperature coefficients concerned. However, just as was found with $\partial(1/C_i)/dT$ (1), the magnitude of the calculated values of $\partial S_i/\partial T$ is greater than that obtained experimentally. It is also apparent that the theory is only capable of predicting curves which are symmetrical with respect to the principal extremum on the capacity curve. The nonsymmetrical nature of the experimental curves is attributed to effects due to the specific counter ions which are not considered in either the three state model of the inner layer or the Gouy–Chapman model of the diffuse layer.

The contribution of the solvent to the entropy of formation of the electrode/solution interface was calculated on the basis of two assumptions (7–9): (*1*) the entropy of formation of an isolated Hg surface is not affected by being brought into contact with the solution and is not altered by the electrical field across the interface; on the basis of the temperature coefficient of the surface tension of the Hg/air interface, $m^{\alpha}_{Hg}(\tilde{s}^{\alpha}_{Hg} - \tilde{s}^{\beta}_{Hg})$ is equal to $2.1 \times 10^{-4}$ J m$^{-2}$ K$^{-1}$ (9); (*2*) the charge dependence of $\Delta S^{m-d}$ is due chiefly to reorientation of the solvent dipoles; the change in the surface concentration of MeOH is assumed to be quite small. On the basis of eq. [5], one may define the surface excess entropy of MeOH as follows:

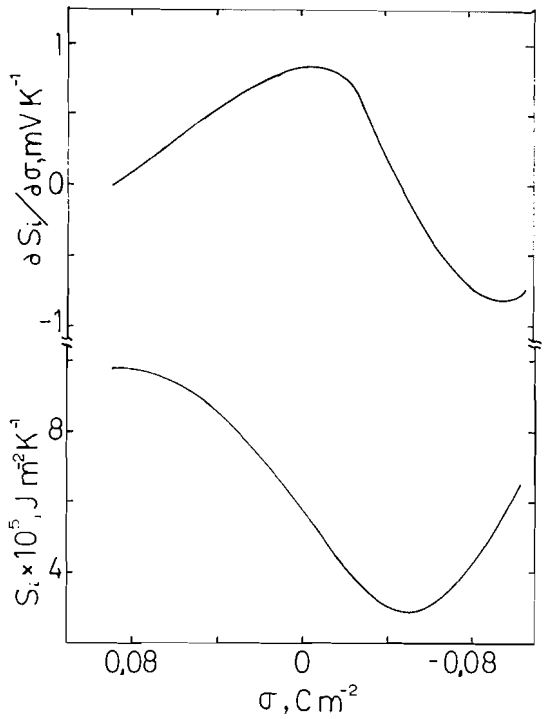

FIG. 2. Thermodynamic properties of the inner layer according to the three state model: (*a*) the coefficient $\partial S_i/\partial\sigma = -\partial\Delta\phi/\partial T$ where $S_i$ is the entropy of the dipole monolayer and $\Delta\phi$, the potential drop across it, and (*b*) $S_i$ as functions of electrode charge density $\sigma$. The parameters assumed are $d = 0.335$ nm, $c_e = 13.95$, $p = 1.66$ D, $\alpha = 3.26 \times 10^{-3}$ nm$^3$, $U_{r1} - U_{r3} = 18.05$ kJ mol$^{-1}$ and $U_{r2} - U_{r3} = 0.97$ kJ mol$^{-1}$. $U_{r1}$, $U_{r2}$, and $U_{r3}$ correspond to the residual energies for dipoles in the "up", "down", and "parallel" orientations, respectively. See the text for definition of the remaining symbols.

$$[24]\quad \Delta S^{m-d}_{MeOH} = m^{\alpha}_{MeOH}(\tilde{s}^{\alpha}_{MeOH} - \tilde{s}^{\beta}_{MeOH}) = \Delta S^{m-d} - m^{\alpha}_{Hg}(\tilde{s}^{\alpha}_{Hg} - \tilde{s}^{\beta}_{Hg})$$

According to the present results, $\Delta S^{m-d}_{MeOH}$ is equal to $-14.4 \times 10^{-5}$ J m$^{-2}$ K$^{-1}$ at the pzc and, to $-15.4 \times 10^{-5}$ J m$^{-2}$ K$^{-1}$ at the minimum on the entropy curve. These values cannot be compared directly with the results from the three state model which assumes that the solvent monolayer is in vacuum with the exception that the imaging roles of the contiguous metal and solution phases are considered (3). However, the difference in the values of $S_i$ between the pzc and minimum on the entropy curve is $3 \times 10^{-5}$ J m$^{-2}$ K$^{-1}$, a result which compares favorably with experiment.

Assuming the surface monolayer of solvent consists of a hexagonally closepacked layer of spheres of diameter equal to 0.335 nm (1), the surface concentration is $1.7 \times 10^{-5}$ mol m$^{-2}$. Accordingly, the molar surface excess entropy of MeOH, $\tilde{s}^{\alpha}_{MeOH} - \tilde{s}^{\beta}_{MeOH}$ at the pzc is $-8.5$ J mol$^{-1}$ K$^{-1}$. The negative result suggests that MeOH is more structured at the

[1]It should be noted that plots of $S_i$, $\partial\Delta\phi/\partial T$, and $\partial(1/C_i)/\partial T$ against $\sigma$ were presented earlier (1). These quantities were calculated by estimating the free energy, $\Delta\phi$ and $1/C_i$, respectively at three different temperatures. The temperature coefficient was estimated by assuming the latter quantities are linear functions of temperature, the temperature coefficient being calculated by linear regression. This procedure for obtaining the temperature coefficients is clearly not as precise as that based on the analytical expressions used here. It should also be noted that the quantity plotted in Fig. 7 of ref. 1 is $-S_i$ not $S_i$ as stated in the figure legend.

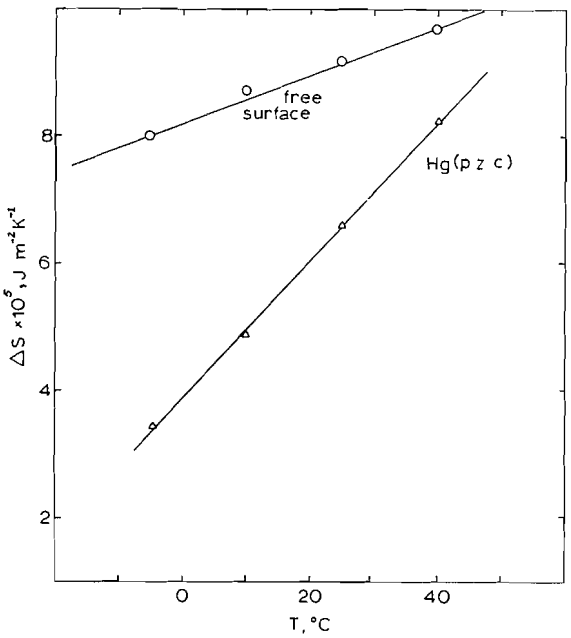

FIG. 3. Entropies of formation of the free methanol surface and of the uncharged mercury/methanol interface (0.1 *M* $NaClO_4$ in methanol) as a function of temperature.

electrode surface than in the bulk. The corresponding results for aqueous systems is $\tilde{s}^{\alpha}_{H_2O} - \tilde{s}^{\beta}_{H_2O} = -6.3\,J\,K^{-1}\,mol^{-1}$.

One possible explanation of the charge dependence of $\Delta S^{m-d}_{MeOH}$ is that the surface concentration of MeOH is also changing. On the basis of the observed change in $\Delta S^{m-d}_{MeOH}$ in the region $-0.05 \leq \sigma \leq -0.085\,C\,m^{-2}$, the change in solvent concentration in the monolayer should be $\sim 7 \times 10^{-7}$ mol $m^{-2}$. Although change in solvent concentration may affect $\Delta S^{m-d}_{MeOH}$ in some ranges of the polarizability of the electrode (17), it does not seem probable that it could account for all the features of the entropy against charge density curve.

On the basis of the above analysis, it is concluded that the charge dependence of the surface entropy is due to reorientation of MeOH molecules. According to the three state model, most solvent molecules are in the "parallel" orientation at the pzc, with a small excess of negatively oriented dipoles over positively oriented ones. The minimum on the entropy curve at $-0.05\,C\,m^{-2}$ corresponds to maximum coverage by the "parallel" species. As the charge is changed in either direction from this value, the entropy increases, the stability of the "parallel" species decreases and that of the "up" or "down" species increases. At the charge density where the probability of the "up" or "down" orientation is equal to that of the "parallel" one, maxima are observed on the entropy curve. The entropy decreases at the extremes of polarization due to the tendency for the dipoles in the surface monolayer to orient totally in either the "up" or "down" direction.

Finally, it is interesting to compare the entropy of formation of the uncharged Hg/MeOH interface, $\Delta S^{m-d}_0$ with the entropy of formation of the free methanol surface $\Delta S_0$. These data are presented in Fig. 3, the results for the free surface having been presented in the literature earlier (18). The entropy values obtained are remarkably similar in spite of the fact that $\Delta S^{m-d}_0$ includes a contribution from the entropy of formation of the mercury surface. A similar observation was made for aqueous solutions (8). If the entropy of formation of the mercury surface is independent of the nature of the solvent, then the entropies of surface formation for both MeOH and water are negative at all charge densities at the Hg/solution interface and positive at the free surface. This implies that both solvents are more structured at the mercury interface.

# Asymmetric homogeneous hydrogenation of olefins catalyzed by alkylphosphine complexes of rhodium(I)

WILLIAM R. CULLEN AND J. DEREK WOOLLINS

*Chemistry Department, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6*

Received December 9, 1981

WILLIAM R. CULLEN and J. DEREK WOOLLINS. Can. J. Chem. **60**, 1793 (1982).

The cationic rhodium(I) complexes of the optically active ferrocenes, $C_5H_5FeC_5H_3[CH(CH_3)N(CH_3)_2][ER_2]$-1,2, catalyze the asymmetric hydrogenation of acetamidoacrylic acid derivatives, itaconic acid and styrene, when $ER_2$ is $P(C_6H_5)_2$ or $P(C(CH_3)_3)_2$. The configuration of the product is reversed on substituting $C_6H_5$ for $C(CH_3)_3$ groups. The catalyst with the *tert*-butyl groups can afford higher optical yields and is faster overall. The rhodium(I) complexes of the arsenic derivatives $ER_2 = As(C_6H_5)_2$ or $As(CH_3)_2$ do not catalyze the hydrogenation reactions. The nmr spectrum of the arsenic complex ($ER_2 = As(C_6H_5)_2$) is temperature dependent which seems to be due to a process involving the making and breaking of the Rh—N bond. The unsuccessful use of the MEM group (β-methoxyethoxymethyl) to protect an alcohol function α to a ferrocene ring is described. The hydrogenation results are discussed in the light of models which are currently used to predict the results of rhodium(I) catalyzed reactions but which are inapplicable to this work.

WILLIAM R. CULLEN et J. DEREK WOOLLINS. Can. J. Chem. **60**, 1793 (1982).

Les complexes cationiques du rhodium(I) avec des ferrocènes optiquement actifs du type $C_5H_5FeC_5H_3[CH(CH_3)N(CH_3)_2][ER_2]$-1,2, catalysent l'hydrogénation asymétrique des dérivés de l'acide acétamidoacrylique, de l'acide itaconique et du styrène lorsque le groupe $ER_2 = P(C_6H_5)_2$ ou $P(C(CH_3)_3)_2$. On observe une inversion de la configuration du produit lorsqu'on remplace le groupe $C(CH_3)_3$ par le groupe $C_6H_5$. Le catalyseur portant un groupe *tert*-butyle conduit à des rendements optiques plus élevés et agit d'une façon plus rapide. Les complexes du rhodium(I) des dérivés de l'arsenic $ER_2 = As(C_6H_5)_2$ ou $As(CH_3)_2$ ne catalysent pas les réactions d'hydrogénation. Le spectre de rmn du complexe de l'arsenic ($ER_2 = As(C_6H_5)_2$) dépend de la température et ceci semble être dû à un processus impliquant la formation et la rupture d'une liaison Rh—N. On décrit un essai qui n'a pas porté fruit d'utiliser le groupe MEM (β-méthoxyéthoxyméthyle) pour protéger la fonction alcool en α du cycle du ferrocène. On discute des résultats de l'hydrogénation en se basant sur les modèles couramment utilisés pour prédire les résultats de la catalyse par le rhodium(I) mais qui ne peuvent pas s'appliquer à ce travail.

## Introduction

The spectacular success in achieving nearly 100% enantiomeric excess in the homogeneous hydrogenation of α-acetamidoacrylic acids, using cationic rhodium(I) complexes of chelating ligands as catalysts, eq. [1], has generated considerable interest (1–15). One mechanism of the reaction, based on studies of the commonly used substrates and catalysts, appears to be as depicted in eqs. [2]–[5] (3). However, as discussed below, this need not apply to all systems.

The source of the stereospecificity in these reactions is of particular importance. On the basis of the crystal structures of several catalyst precursors, all of which have ditertiary phosphines as ligands, Knowles and co-workers (6, 7) have suggested that the absolute configuration of the amino acid product can be predicted in terms of a model which requires the square planar intermediate **1** to have the structure shown in **4**. Here the COOH group (R′ = H) is located above the *face* of a phenyl group on the ligand.[1]

[1] 
[2] $[Rh(L\text{-}L')(solvent)_2]^+ + substrate \leftrightarrows [Rh(L\text{-}L')substrate]^+$ **1** + 2 solvent

[3] $[Rh(L\text{-}L')(substrate)]^+ + H_2 \rightarrow [Rh(H)_2(L\text{-}L')(substrate)]^+$ **2**

[4] $[Rh(H)_2(L\text{-}L')(substrate)]^+ \rightarrow (Rh(H)(L\text{-}L')(Hsubstrate)]^+$ **3**

[5] $Rh(H)(L\text{-}L')(Hsubstrate) \rightarrow [Rh(L\text{-}L')(solvent)_2]^+ + (H)_2substrate$

Halpern and co-workers (3, 4) have recently determined the structure of two square planar intermediates **4** (L-L′ = $Ph_2P(CH_2)_2PPh_2$, $Ph_2P\overset{*}{C}HMeCH_2PPh_2$, R′ = Me, R = Ph). The olefin is bound as indicated but in both solids the COOR group lies over an *edge* of a phenyl ring. This, in the case of the optically active complex, hydrogenation would give the amino acid product of opposite configuration to that actually observed. These and other results led to the suggestion that the discrimination arises because of differences in the rates of reaction of the diasterotopic complexes **1** (or **4**) (eq.

[1]The four aromatic groups bound to phosphorus on the ditertiary phosphine, (L-L′), in **1** (or **4**) are "seen" by the incoming substrate as an alternating set of edge-on or face-on rings.

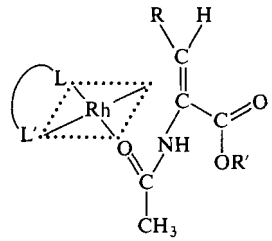
[c]$CH_2Cl_2$ solvate.

[3]). It should be noted that these rate differences could arise because of steric effects in the 6-coordinate *cis* hydride intermediate (13). In this connection Knowles *et al.* (7) have implied that the rate of subsequent reactions of **1** is a function of the flexibility of the ligand.



**4**

This paper describes some further studies with complexes of some ferrocenylphosphines **6–9**. The results indicate that some of the currently accepted models are not applicable to these systems. In particular, unexpectedly high optical yields are achieved using complexes of the bulky phosphine **9**.

## Experimental

Air sensitive reagents and products were manipulated in a nitrogen or argon atmosphere. Optical rotations were monitored on a Perkin Elmer 141 polarimeter. A cell length of 10 cm was used and the light source was the sodium D line (589 nm). *N,N*-dimethyl-α-ferrocenylethylamine **5** was prepared and resolved using (*R*)-(+)-tartaric acid as previously described (16). Microanalyses were done by Mr. Peter Borda, Chemistry Department, University of British Columbia. Data are given in Table 1.

*Preparation of the Group V derivatives* ***7–9***

The procedure for the preparation of **7–9** from **5** is essentially the same as that described for the preparation of **6** (13) (eq. [6]).

The resolved amine (or the racemic mixture) (0.01 mol) was placed in a Schlenck tube together with 15 mL of dry diethyl ether. The solution was treated with *n*-butyllithium (0.01 mol) and stirred for 1.5 h. The reaction is exothermic. The appropriate halide $XER_2$ ($ClAs(C_6H_2)_2$, $IAs(CH_3)_2$, $ClP(C(CH_3)_3)_2$) (0.01 mol) was added slowly and the solution stirred a further 3 h. An aqueous slurry of sodium bicarbonate (5 g in 10 mL) was added and the mixture was stirred for a further 1 h before it was filtered. The precipitate was washed with ether and the filtrate and washings were washed with water (2 × 30 mL). The organic layer, dried over $K_2CO_3$, was evaporated to leave an oily residue which was purified by recrystallization from absolute ethanol (**7**, 56% yield) or chromatography on an alumina column. Both **8** (40% yield) and **9** (40% yield) were eluted with 40:60 petroleum ether/diethyl ether; the first band was the desired product.

*Preparation of the rhodium(I) perchlorate complexes (**13–15**)*

The perchlorate salts of the ligands **7–9** were prepared essentially using the procedure of Schrock and Osborn (17) as described by Cullen *et al.* (13). Recrystallization required very little solvent. Thus at the ~1 m*M* scale the first formed cationic perchlorate salt was dissolved in ~1.5 mL of dichloromethane and treated with 5 mL of ethanol and 0.1 mL of diethyl ether to give crystals.

*Preparation of the acetate, **10***

The amine, **5**, (0.0125 mol) was sealed in a Carius tube with acetic anhydride (0.025 mol). The tube was heated to 100°C for 12 h. The reaction mixture was treated with $K_2CO_3$ (15 g in 50 mL of water) and extracted with diethyl ether. The ether extract was washed with dilute HCl (5%), $K_2CO_3$ (5%), and water, and dried over $K_2CO_3$. Evaporation of the solvent gave a 93% yield of **10**.

*Preparation of the alcohol, **11***

The acetate **10** in diethyl ether was treated with a slight excess of butyllithium and the mixture was stirred for 1 h. Water was added and the ether layer separated, washed with water, and dried over $K_2CO_3$. Removal of the solvent gave a 100% yield of **11**. The product can be recrystallized from heptane.

*Preparation of the MEM derivative of ferrocenylethanol, **12***

Ferrocenylethanol (11.7 g, 0.05 mol) was dissolved in dry dichloromethane (50 mL). To this solution was added diisopropylethylamine (9.7 g, 0.075 mol) and MEM chloride (9.35 g, 0.075 mol) was slowly added to the cooled stirred mixture (0°C). The temperature was slowly raised to 20°C (4 h). The resulting reaction mixture was washed with 5% HCl (2 × 50 mL), water (50 mL), and dried over $K_2CO_3$. Removal of solvent gave a brown liquid, **12**, in 88% yield. The liquid decomposed on distillation.

*Hydrogenation reactions*

A standard gas uptake apparatus was used for all hydrogenation reactions (13). The appropriate conditions are given in Table 3.

TABLE 2. The $^1H$ nmr spectra of new compounds[a]

| Compound | $CH(CH_3)(J(H,CH_3))$ | $N(CH_3)_2$ | $C_5H_5$ | Other |
|---|---|---|---|---|
| **7** | 1.21 (7) | 1.78 | 3.97 | — |
| **8** | 1.28 (6) | 2.11 | 4.10 | 1.22 (s), 1.03 (s), $(As(CH_3)_2)$ |
| **9** | [b] | 2.14 | 4.14 | 1.45(d), 0.88(d), $J(P,H) = 11$, $(P(C(CH_3)_3)_2)$ |

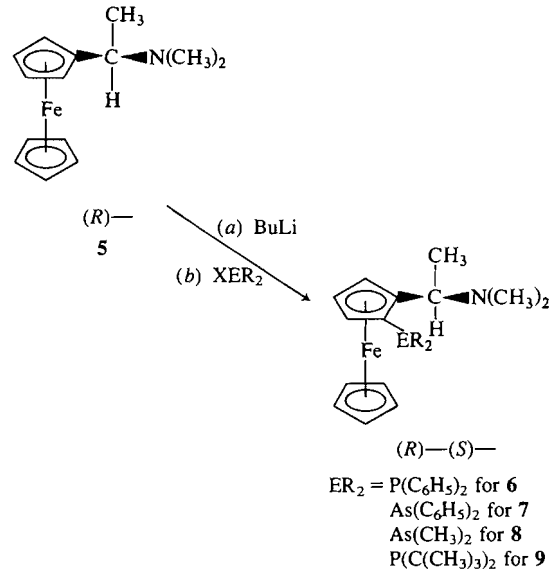
## Results and discussion

The lithiation of optically pure **5** is almost stereospecific (18), which allows the preparation of disubstituted derivatives **6–9** in reasonable yield. The products have the (*R,S*)-configurations as shown in eq. [6]. The (*S*)-isomer of **5** affords (*S,R*)-products. The phosphine **6** has been described previously (13, 15, 19) but the other derivatives **7–9** are new. The analytical results, Table 1, and the nmr spectra, Table 2, confirm their formulation. In particular, all show the singlet at about 4 ppm characteristic of an unsubstituted $C_5H_5$ ring. The most interesting feature of these spectra is the appearance of two signals for the alkyl groups in the $—P(C(CH_3)_3)_2$ and $—As(CH_3)_2$ derivatives. This could be due to inter- or intramolecular complex formation with the amine acting as a donor, however, since the $—N(CH_3)_2$ signal is a singlet this explanation seems unlikely. Probably the doubling arises because the groups are diastereotopic. The spectrum of the corresponding $—P(CH_3)_2$ derivative is reported to show inequivalent methyl groups (doublets at 1.08 and 1.31 ppm) (19).

[6]

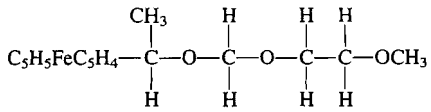


$ER_2$ = $P(C_6H_5)_2$ for **6**
$As(C_6H_5)_2$ for **7**
$As(CH_3)_2$ for **8**
$P(C(CH_3)_3)_2$ for **9**

The action of acetic anhydride in the amine **6** affords the acetate **10**. This compound has been prepared by others, also in high yield, using essentially the same conditions (19) and the spectroscopic data are in good agreement. The acetate **10** is readily converted to the alcohol **11** by reaction with butyllithium, a procedure which has been used to prepare this and related derivatives (19). The nmr spectrum of **11** is different from that previously described. The OH absorption is actually a doublet due to coupling with the C—H proton which itself is shifted downfield to 5.6 ppm and, because of the approximate equality of the couplings $J(CH_3,H)$ and $J(HO,H)$, it is seen as a sextet (a quartet of doublets).

In order to extend the chemistry of the phosphine **11** it was desirable to be able to protect the alcohol function. The β-methoxyethoxymethyl (MEM) group described by Corey *et al.* (20) seemed to offer many advantages, so preliminary experiments were carried out on α-ferrocenylethanol.

The MEM derivative, **12**, is formed easily from MEM chloride and the alcohol in the presence of diisopropylethylamine as described in the literature (20) (other suggested procedures involving, for example, butyl lithium are less desirable).



**12**

A number of unsuccessful experiments were attempted to establish if the MEM group would direct lithiation in ferrocene derivatives. Typically when **12** is treated with 1 equivalent of TMEDA and 1 equivalent of butyllithium a dark solution is obtained. Nuclear magnetic resonance investigation of the product following hydrolysis of this solution with $D_2O$ shows no lithiation reaction

takes place. Seemingly the MEM derivative complexes with the butyllithium. If excess butyllithium is used (three equivalents), cleavage occurs and an 80% yield of $C_5H_5FeC_5H_4C(CH_3)HOD$ can be isolated following treatment of the reaction mixture with $D_2O$.

Thus it seems that the MEM group is not as useful in ferrocene chemistry as could be hoped and no attempts were made to investigate the MEM derivative of **11**.

*Cationic rhodium(I) complexes*

The phosphines and arsines **6–9** all form derivatives $[(L\text{-}L')RhNBD]^+CO_4^-$ (L-L′ = bidentate ligand, and NBD=norbornadiene). The analytical results in Table 1 confirm the formulation of the new derivatives of **7–9**, however, the nmr spectra of the complexes are not straightforward. Some spectra of the perchlorate derivative of the arsine **7** are shown in Fig. 1. At ambient temperature, the phenyl region of the spectrum is more spread out than usual indicating that the two rings are in different environments and are, perhaps, held in a fixed orientation relative to each other. This difference in orientation is obvious in the crystal structure of the similar cation obtained from the $—P(C_6H_5)_2$ analogue **6** (13). The spectrum (Fig. 1) also shows a broad signal for the $N(CH_3)_2$ group which collapses and becomes the expected two singlets on cooling. The separation between the two signals is 72 Hz at −30°C. At this temperature the specturm is very similar to that of the analogous complex of **6** measured at ambient temperature.

It is difficult to account for this temperature effect by any simple exchange process such as conformational averaging because the methyl groups will always be inequivalent if the ring structure is preserved. The steps which seem to be necessary are as follows. (*i*) The Rh—N bond breaks. (*ii*) Rotation about the $C—N(CH_3)_2$ bond and inversion at nitrogen occurs. (*iii*) The Rh—N bond reforms.

A number of investigators have been attracted to work with ligands containing both hard and soft donor atoms in the hope that their metal complexes might show bond lability. This result could be the first clear demonstration of this expectation.

Work is now in progress to establish the validity of these proposals and hopefully the results will also enable an interpretation of the nmr spectra of complexes **15** and **16** which show similar features.

*Hydrogenation studies*

The results of a number of catalyzed hydrogenation reactions are given in Table 3.

The two phosphine derivatives **6** and **9** form rhodium complexes which are catalyst precursors but the arsine analogues **7** and **8** do not. Furthermore, the arsines **7** and **8** do not give catalytically active solutions when mixed with $[Rh(1,5\text{-}COD)Cl]_2$ (COD = cyclooctadiene).

The failure of the arsines to afford catalytic systems is yet a further example of the unpredictability of experiments of this type and no good rationalization is available. Thus, in related work, the rhodium(I) complexes (produced *in situ*) of the

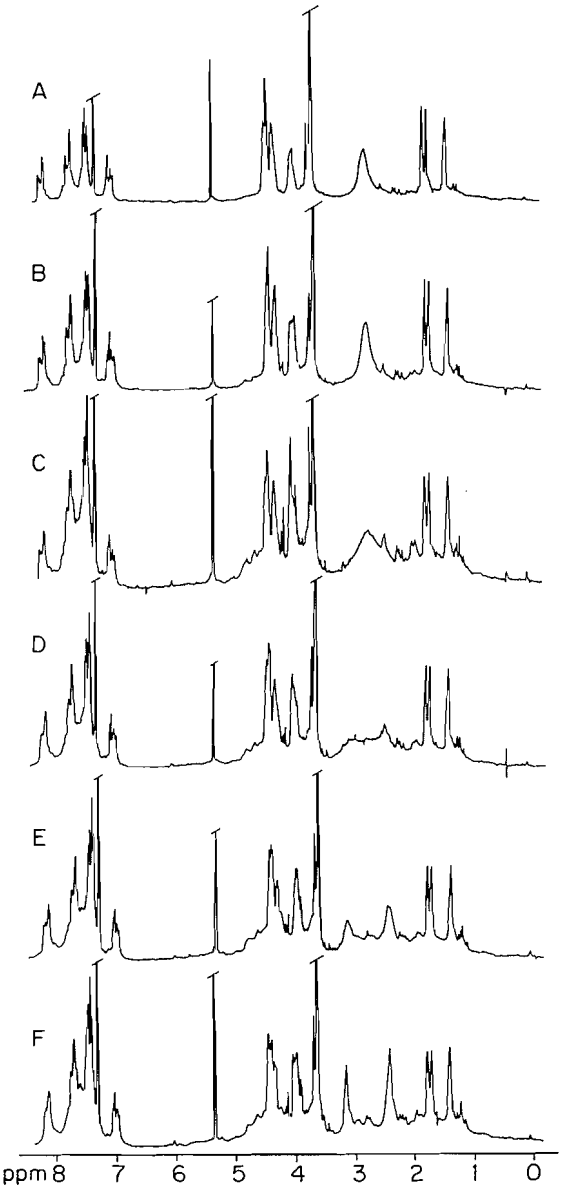


FIG. 1. The $^1H$ nmr spectrum of the arsine complex **13** (100 MHz). A, at ambient temperature; B, 10°C; C, 0°C; D, −10°C; E, −20°C; F, −30°C.

TABLE 3. Homogeneous hydrogenation of some olefins catalyzed by $[Rh(L\text{-}L')(NBD)]^+ ClO_4^-$[a]

| L-L′ of the catalyst precursor | Substrate | Time (h) | Optical yield (%) | Configuration |
|---|---|---|---|---|
| **9** | Acetamidocinnamic acid | 16 | 84 | *S* |
| | Acetamidoacrylic acid | 12 | 24 | *S* |
| | Itaconic acid | 16 | 43 | *R* |
| | Styrene | 6 | — | — |
| **6** | Acetamidocinnamic acid | 24 | 76 | *R* |
| | Acetamidoacrylic acid | 18 | 49 | *R* |
| | Itaconic acid[b] | 72 | 33 | *S* |
| | Styrene | 12 | — | — |

[a] Reactions were carried out at 1 atm $H_2$ and 30°C. The concentration of the catalyst was $5 \times 10^{-4}$ *M* and the substrate $5 \times 10^{-2}$ *M*. Optical yields are based on the rotation of the isolated products. All reductions were quantitative (by nmr or gas chromatography) except [b] which was only 21% completed after 72 h.

arsenic analogue of DIOP (**16**, $ER_2 = As(C_6H_5)_2$) catalyze reductions such as shown in eq. [1]. The rates are slower than with phosphine based catalysts (21, 22) and the optical yields are low. The products also have the opposite configuration. The same *in situ* catalyst can also be used for the reduction of ketones via hydrosilylation. The yields, chemical and optical, are similar to those obtained from DIOP based catalysts but this time no reversal of product configuration is found.

In the case of the unsymmetrical ligands **17** ($ER_2 = P(C_6H_5)_2$ or $As(C_6H_5)_2$, $R' = CH_3$), *in situ* rhodium(I) catalysts prepared from the phosphine give high chemical and optical yields for the hydrosilylation of ketones, with the optical yields being higher than those obtained from DIOP (**16**) based catalysts in some cases. However, even though the arsine **17** ($ER_2 = As(C_6H_5)_2$, $R' = CH_3$) affords an *in situ* catalyst for the hydrosilylation reaction the optical yields are very low or zero in spite of very similar chemical yields.[2]

The catalyst precursor based on **6** has a known crystal structure and, using this as model, it is apparent that in an intermediate like **1** the two, and only two, phenyl rings would have an edge-on face-on arrangement with respect to the bound substrate (13). The face-on ring is adjacent to the cyclopentadiene rings and from models its motion appears to be restricted.

As mentioned in the Introduction, Knowles and co-workers (6, 7) have pointed out that the absolute configuration of the products from reactions of this type can be predicted by requiring the intermediate **1** to have a structure with the COOR group lying above the face of an aromatic ring attached to phosphorus. If this model is applied to the present results (L-L′ = **6**) then the opposite configuration to that actually obtained is predicted.

[2] N. C. Payne and D. W. Stephan. Personal communication.

It is worth noting that using ligands like **6** with P and N donor atoms the Knowles requirement would ensure that the olefin C=C bond would have to be *trans* to the nitrogen in **4** ($L' = N(CH_3)_3$). This apparently is a favourable situation for binding since the crystal structure of (P-N)Ir(CO)Cl, when P-N is the closely related ligand *o*-diphenylphosphino-*N*,*N*-dimethylaniline, (**17**, $ER_2 = P(C_6H_5)_2$, $R' = H$) shows that the CO group is *trans* to N and that the Ir—(CO) and Ir—P bonds are unusually short and presumably strong (23).

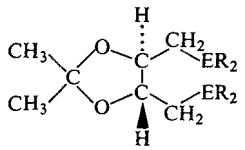
A further striking feature of these new results (Table 3) is that changing the $-P(C_6H_5)_2$ group to $-P(C(CH_3)_3)_2$ results in an effective hydrogenation catalyst which gives products of the opposite absolute configuration. Furthermore, the reactions go to completion in a shorter time and, in one case, a higher optical yield is obtained. Clearly, aromatic rings on the ligand donor atom are not needed to achieve good optical yields and fast rates can be obtained in spite of the bulk of the *tert*-butyl groups. (The noteworthy reversal of product configuration should be considered with the same effect caused by changing the $ER_2$ group in **16** from $P(C_6H_5)_2$ to $P(C_6H_4OCH_3\text{-}o)_2$ (24).)

There are only a few reports of asymmetric catalysis by metal complexes of aliphatic phosphines. Thus, Kumada and co-workers (25) showed that a closely related ferrocene derivative to **6–9** in which the $ER_2$ group is $P(CH_3)_2$ can be used to prepare an *in situ* rhodium(I) catalyst for the hydrosilylation of ketones. The optical yields are moderate (~50%). This same reaction and reactions such as [1] are reported (26) to be catalyzed by rhodium(I) complexes of ditertiary phosphines related to DIOP (**16**, $ER_2 = P(alkyl)_2$). It should also be mentioned that alkyl sulfoxides with the DIOP skeleton (**16**, $ER_2 = S(O)CH_3$) form ruthenium complexes which catalyze hydrogenations like [1]. However, the optical yields are low (27).

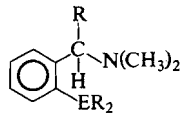
The hydrogenations reported by Otsuka (26) appear to proceed via a hydride intermediate $[(L\text{-}L)Rh(H)_2\ (solvent)_x]^+$ rather than the simple solvate **1** described in eq. [2]. Brown *et al.* (28) also described cationic rhodium hydrides which have phosphines such as $(C_6H_5)_2P(CH_2)_5P(C_6H_5)_2$ as ligands. Thus it is certainly possible that the pathway of some of the reactions described in Table 3 also involves the formation of a stable hydride. This will be checked by kinetic and spectroscopic measurements.

When itaconic acid is the substrate (Table 3) the hydrogen uptake is slower than observed for the other substrates. The optical yields are in the same range reported for similar catalyzed hydrogenations. It seems that the hydrogen bonding in the acid needs to be disrupted in some way before high optical yields are achieved (29).

Kumada and co-workers have found that rhodium(I) complexes of the amine and alcohol **18** (R =



**16**



**17**

DIOP $ER_2 = P(C_6H_5)_2$

OH or $N(CH_3)_2$) are excellent hydrogenation catalysts (15, 19, 30, 31). In view of the result that the closely related **6** gives complexes which are as effective, it was of interest to establish if the same would hold for the alcohol **11**. The results of a number of experiments can be summarized as follows. For olefin reductions (eq. [1]) reaction is slow and optical yields are low. Thus acetamidocinnamic acid is 25% reduced after 3 days at 30°C (1 atm $H_2$). The optical yield is 17%. Ketones are not reduced under the same conditions.

These results could well be due to lack of chelate formation by **11**. Both P and N are bound in complexes of **6** (13) and both P atoms are bound in complexes of **18** ($R' = N(CH_3)_2$).[3]

# The mass spectra of pyrimidines: 2(1H)-pyrimidinone and some N(1)-substituted derivatives

EVA M. KAZDAN, ROBIN T. B. RYE,[1] AND OSWALD S. TEE

*Department of Chemistry, Concordia University, 1455 de Maisonneuve Blvd., W., Montreal, P.Q., Canada H3G 1M8*

Received December 16, 1981

EVA M. KAZDAN, ROBIN T. B. RYE, and OSWALD S. TEE. Can. J. Chem. **60**, 1800 (1982).

The EI induced fragmentation of 2-pyrimidinone (**1**) and several N(1)-substituted derivatives has been studied. Principal fragmentation pathways have been identified using $^2H$ labelling, metastable defocussing, and exact mass measurements.

The fragmentation of **1** parallels that of cytosine. The hydrogen atom at C(4), and not the tautomeric hydrogen, is involved in the formation of the prominent $[M - H]^+$ peak in the spectrum of **1**; subsequent fragmentations of the $[M - H]^+$ moiety contribute significantly to the spectrum.

Side chain eliminations predominate in the mass spectra of the N(1)-substituted derivatives, but peaks characteristic of the pyrimidinone nucleus are observable in every case. Alternative structures for the $[M - H]^+$ entity formed by $H^\cdot$ loss from the substituent are proposed for the *N*-phenyl and *N*-benzyl compounds.

EVA M. KAZDAN, ROBIN T. B. RYE et OSWALD S. TEE. Can. J. Chem. **60**, 1800 (1982).

On a étudié la fragmentation IE de la pyrimidinone-2 (**1**) et de plusieurs dérivés substitués sur le N(1). On a identifié le mécanisme principal de fragmentation en faisant appel au marquage au $^2H$, à l'étude des ions métastables et à des mesures de masses exactes.

La fragmentation du composé **1** ressemble à celle de la cytosine. C'est l'atome d'hydrogène sur le carbone en position 4 et non l'hydrogène tautomère qui est impliqué dans la formation du pic intense $[M - H]^+$ du spectre de ce composé **1**; des fragmentations ultérieures de l'unité $[M - H]^+$ apportent une contribution appréciable au spectre.

Des éliminations dans la chaîne latérale prédominent dans le spectre de masse des dérivés substitués sur le N(1) mais on observe dans chaque cas les pics caractéristiques du noyau pyrimidinone. Dans le cas des composés *N*-phényle et *N*-benzyle, on propose une autre structure pour l'unité $[M - H]^+$ qui se forme par élimination d'un $H^\cdot$ du substituant.

[Traduit par le journal]

## Introduction

Interest in the mass spectrometry of pyrimidines and related compounds has focussed primarily on the naturally occurring nucleosides and nucleotides. Mass spectra of nucleosides containing the pyrimidine moiety were first reported by Biemann and McClosky (1); the utility of mass spectrometry as a probe of nucleoside structure has since been firmly established. The electron impact induced fragmentation of the biologically imortant pyrimidines uracil, thymine, and cytosine has been well documented (2).

Derivatives of 2-pyrimidinone (**1**), while not naturally occurring, are receiving increased attention because of their wide-ranging biological activity. Oyen (3) and Holy and co-workers (4) showed that 1-(β-D-ribofuranosyl)-2-pyrimidinone is an efficient inhibitor of DNA synthesis in *E. coli*, and the latter group subsequently studied a number of other synthetic nucleosides derived from **1** (5). McCormack *et al.* (6) have recently reported that 2-pyrimidinone riboside and related compounds are inhibitors of the enzyme cytidine deaminase, and 5-halo derivatives of **1** are reported (7) to have potential value as metaphase inhibitors. Aspects of the chemistry of **1** in aqueous solution have been studied in our laboratory (8). Our ongoing interest in pyrimidinones and pyrimidine nucleosides has prompted us to examine the mass spectra of **1** and a number of N-substituted derivatives; the compounds studied are listed in Table 1.

## Experimental

*Synthesis*[2]

The majority of the compounds employed in this study were synthesized by literature procedures (9), with appropriate variations to make the N(1)-substituted compounds bearing deuterium in the substituent. Synthesis of 5-deuterio-2-pyrimidinones is possible by direct exchange in deuterated aqueous acid at elevated temperatures (10), but this route is time consuming and sometimes suffers from poor yields due to product decomposition. Furthermore, such a procedure would not be applicable to the synthesis of the 5-deuterio-2-thio analogues, compounds in which we are also interested. To avoid these problems we developed the modified cyclization route shown in Scheme 1. In this the unlabelled *bis*-acetal (1,1,3,3-tetramethoxypropane) is hydrolysed in *deuterated* aqueous acid so that the resulting malondialdehyde undergoes facile exchange of the methylene hydrogens. After 5 minutes, to allow for completion of these two processes, the appropriate urea (or thiourea) is added and condensation is achieved in the normal way. This procedure gives, after work-up, the desired labelled pyrimidinone (or pyrimidinthione) in acceptable yields (40–50%). We note that a similar approach has been used by Beak and Bonham (11) to prepare deuterium labelled 4-pyridones.

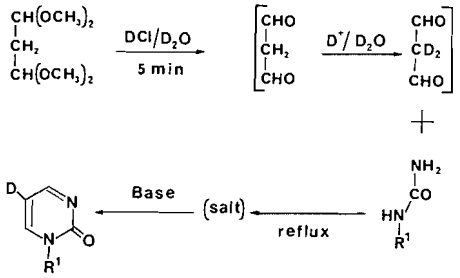
*Spectra*

The mass spectra were taken on a Hitachi–Perkin–Elmer RMU-7 instrument using 70 V ionizing electrons and the lowest practicable source temperature. First field free region metastables were observed by the accelerating voltage scan method, using an instrument modification described by McGillivray and co-workers (12). Exact mass measurements at high resolution were made on a Kratos-AEI MS-902S instrument.



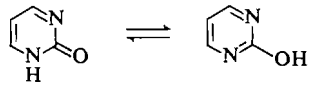
SCHEME 1. Synthetic route to 5-deuterio-2-pyrimidinones.

## Results and discussion

The 70 eV mass spectra of the compounds studied are reported in Table 2. Fragmentation pathways leading to the principal daughter ions have been deduced from exact mass measurements and from observed first field free region (FFFR) metastable decompositions.

(a) *2(1H)-Pyrimidinone* (**1**)

The partial mass spectrum of **1** has been reported by Undheim and co-workers (13) in connection with vapour phase tautomer analysis. In aqueous or ethanolic solution, **1** exists predominantly in the keto form **1***a*, whereas at equilibrium in the gas phase the enol form, **1***b*, is favoured by a factor of at least 10:1 (14). On the basis of ionization energy measurements it was concluded that **1***b* is the predominant tautomer even under the nonequilibrium conditions prevailing in the ion source. Since **1***a* is present to a significant extent in the solid state



**1***a* **1***b*

(15), it has been suggested that the enol form evaporates preferentially in the inlet system of the mass spectrometer. Little information as to the tautomeric form of **1** could be obtained from the electron impact induced fragmentation pattern.

An intense molecular ion peak is characteristic of all the compounds studied, and in the mass spectrum of **1** it gives the base peak at *m/z* 96. Other major peaks of interest are found at *m/z* 95, 69–67, and 51–53. Loss of a hydrogen atom from the molecular ion to give the peak at *m/z* 95 can be rationalized in terms of either tautomer. If the enol form **1***b* is indeed predominant, it would be anticipated that loss of deuterium from **2** would be minimal and that loss of H• would be comparable to that observed from **1**. The spectrum of **2** is consistent with this view, but a comparison of the two spectra indicates that a quantitative measurement of the [H• loss]/[D• loss] ratio for **2** is not possible because of significant back exchange in the inlet system and ion source and an isotope effect of unknown magnitude. Calculations based on the relative intensity ratio for $[M^{+\bullet}]/[M - H]^+$ in the spectrum of **1** do show, however, that the relative intensity of the *m/z* 95 peak in the spectrum of **2** is entirely consistent with the presence of unlabelled and/or back exchanged material and the noninvolvement of the tautomeric hydrogen. On this basis we propose that the tautomeric hydrogen is not lost in the fragmentation leading to the [M − H] ion and infer that the enolic form of the molecular ion is involved. The absence of significant D• loss from **3** confirms C(4) and/or C(6) as the principal site(s) of H• loss from **1**, **2**, and **3**. Metastable peaks for these H•(D•) losses were not observed.

The peaks at *m/z* 69, 68, and 67 in the spectrum of **1** shift to *m/z* 70, 69, and 68, respectively, in **2** and **3**, confirming that the tautomeric hydrogen and the hydrogen at C(5) are retained in these fragment ions. Exact mass measurements show that the peak at *m/z* 69 in the spectrum of **1** is due solely to $[C_3H_3NO]^{+\bullet}$ (found: 69.0212, calcd.: 69.0215), corresponding to loss of HCN from the molecular ion. By analogy with the fragmentation of 2-pyridone (16, 17) and cytosine (2), the intense peak at *m/z* 68 was assumed to arise by loss of CO from $M^{+\bullet}$; high resolution measurements confirmed this assignment. Maquestiau *et al.* (17) have shown that CO loss from the molecular ion of 2-pyridone is from

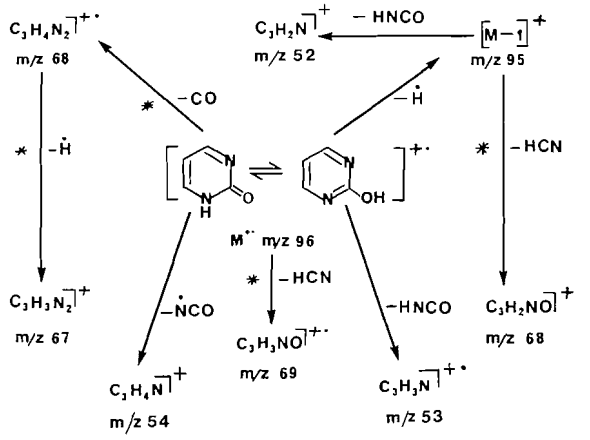
the enolic tautomer, with a prior rate determining migration of the hydroxylic hydrogen to C(3). Because of molecular symmetry the equivalent process in **1** is indistinguishable from keto–enol tautomerism. A second route to *m/z* 68 in the spectrum of **1** involves loss of HCN from the $[M - H]^+$ ion; the analogous process is observed for cytosine but not for 2-pyridine.

The relative intensities of the $[C_3H_4N_2]^{+\cdot}$ and $[C_3H_2NO]^+$ peaks are in a ratio of 6:1, and the appropriate metastable peak was observed in each case. The peak at *m/z* 67 was also shown to be doublet under high resolution. Loss of H$^\cdot$ from $[M - CO]^{+\cdot}$ to give $[C_3H_3N_2]^+$ (found: 67.0298, calcd.: 67.0296) generates the major component of the peak; the fragmentation path leading to the minor component, $[C_3HNO]^\cdot$ (found: 62.0057, calcd.: 67.0058), has not been identified. The peaks at *m/z* 54–52 can be rationalized in terms of the retro-Diels–Alder mechanism proposed for cytosine, i.e. loss of NCO from $M^{+\cdot}$ (*m/z* 54), loss of HNCO from $M^{+\cdot}$ (*m/z* 53), and elimination of HNCO from $[M - H]^+$ (*m/z* 52). After correction for back exchange the spectrum of **2** gives very similar relative abundances for these peaks, indicating that N(1) is lost along with the tautomeric hydrogen in the elimination of HNCO. An alternative to the retro-Diels–Alder mechanism, involving ring opening prior to loss of HCO or HNCO, cannot be ruled out; the spectrum of **3** shows that the deuterium at C(5) is involved to some extent in these fragmentations, although we are unable to formulate an adequate mechanism at the present time. Owing to limitations in the range over which it was possible to scan the accelerating voltage, the fragmentations leading to the *m/z* 54–52 peaks are not confirmed by observed FFFR metastable peaks.

The principal fragmentation pathways for **1** are summarized in Scheme 2.



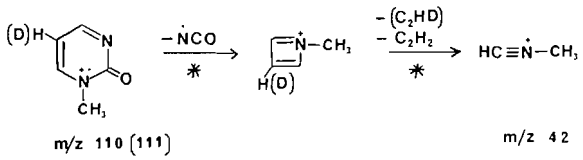
SCHEME 2. Principal fragmentation pathways for the molecular ion of **1**.

(b) N-*R*$^1$-*2-Pyrimidinones*

In common with the fragmentation of **1**, **4** ($R^1 = CH_3$) has the molecular ion as the base peak in the spectrum and an intense $[M - H]^+$ peak. The spectrum of **5** ($R^1 = CD_3$) indicates that there is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

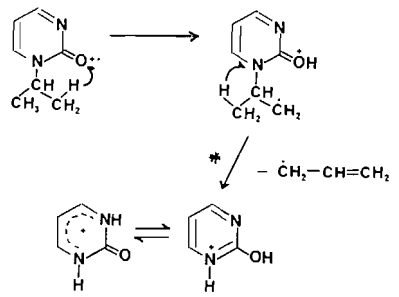
only minor involvement of the methyl group hydrogens in formation of the $[M - H]^+$ ion, with the relative intensities of $[M - H]^+$ and $[M - D]^+$ being in the ratio of approximately 30:1. The spectrum of the 5-$d_1$ analogue, **6**, indicates that some loss of the hydrogen at C(5) does occur. Loss of CO from $M^{+\cdot}$ and loss of HCN from $[M - H]^+$ give rise to the peak at *m/z* 82, parallelling the formation of *m/z* 68 from **1**. The peak at *m/z* 68 in the spectrum of **4** results from the loss of NCO from $M^{+\cdot}$; the analogous processes in **5** and **6** give peaks at *m/z* 71 and *m/z* 69, respectively. Observation of the appropriate metastable peak confirms that, at least in part, the abundant peak at *m/z* 42 in the spectrum of **4** arises by loss of 26 daltons, possibly as $C_2H_2$, from $[M - NCO]^+$. In the spectrum of **5** the corresponding fragmentation generates *m/z* 45, confirming the absence of significant mixing of ring and methyl hydrogens, whereas for **6** the analogous fragment ion occurs at *m/z* 42, corresponding to loss of $C_2HD$ from $[M - NCO]^+$. Plausible ion structures consistent with these results are given in Scheme 3.



SCHEME 3. Origin and plausible structure of *m/z* 42 in the spectrum of **4**.

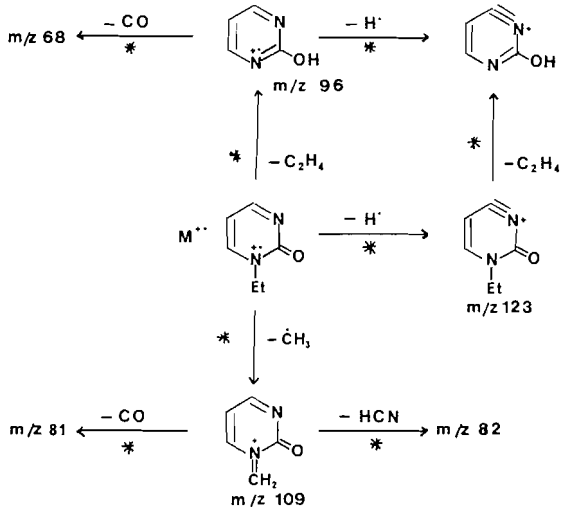
Fragmentations involving the *N*-alkyl substituent dominate the spectra of **7** ($R^1 = C_2H_5$) and **9** ($R^1 = CH(CH_3)_2$). Loss of ethylene from **7** via a McLafferty rearrangement is the main route to the intense *m/z* 96 peak, with loss of CO from $M^{+\cdot}$ making now only a minor (<10%) contribution. The $[M - C_2H_4]^{+\cdot}$ daughter ion, assumed to have the 2-pyrimidinone structure, fragments by loss of CO and H$^\cdot$ to generate the peaks at *m/z* 68 and *m/z* 95, respectively. Facile loss of $CH_3^\cdot$ from $M^{+\cdot}$ is followed by fragmentation of the *m/z* 109 ion to give peaks at *m/z* 81 (—CO) and *m/z* 82 (—HCN). Loss of H$^\cdot$ from the molecular ion is a relatively minor process but, in contrast with the fragmentation of **4**, there is significant involvement of the *N*-alkyl hydrogens; for **8** ($R^1 = C_2D_5$) the relative intensity ratio for $[M - H]^+/[M - D]^+$ is 2:1. The fragment ion resulting from loss of a ring hydrogen subsequently eliminates ethylene, but fragmentation of the ion formed by loss of H$^\cdot$ from the *N*-ethyl group has not been confirmed (Scheme 4).

The fragmentation of **9** parallels that of **7** but with the base peak at *m/z* 97 generated by a double



SCHEME 4. Principal fragmentation pathways for the molecular ion of **7**.

rearrangement and elimination of $C_3H_5$ from the molecular ion (Scheme 5). Consistent with this mechanism, the peak shifts to *m/z* 99 for **11** ($R^1 = CH(CD_3)_2$), but is unchanged in the spectrum of **10** ($R^1 = CD(CH_3)_2$). Loss of $C_3H_6$ from **9** via the McLafferty rearrangement and loss of $CH_3^\cdot$ from **9** give rise to peaks at *m/z* 68 and *m/z* 123, respectively; subsequent decomposition of these fragment ions parallels the corresponding processes observed for **7**. The $[M - H]^+$ peak is of minor intensity, and arises by loss of both ring and alkyl group hydrogen atoms as was the case for **7**. The spectra of **10** and **11** confirm that only methyl hydrogens are lost from the alkyl substituent, with a relative intensity ratio for $[M - H]^+/[M - D]^+$ of 1:1 in the spectrum of **11**.



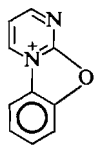
SCHEME 5. Origin of base peak in the spectrum of **9**.

The mass spectra of **12** ($R^1$ = phenyl) and **14** ($R^1$ = benzyl) are characterized by base peak molecular ions and intense peaks at *m/z* 77 and *m/z* 91, respectively, the latter peaks corresponding to N—C bond cleavage with the formation of the stable 2-oxypyrimidine radical and the appropriate

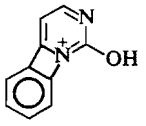
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

aryl cation. Other major peaks in the spectrum of **12** originate by cleavage of the substituent-bearing pyrimidine ring, with loss of CO from $M^{+\cdot}$ and HCN loss from $[M - H]^+$ generating the doublet at *m/z* 144; subsequent elimination of a 27 dalton fragment presumably involves HCN loss from the $[M - CO]^{+\cdot}$ moiety to give *m/z* 117. The trend towards decreasing H· loss from the molecular ion with increasing size of the N-substituent is markedly reversed in **12**, with a relative intensity of 41.7% for $[M - H]^+$. Interpretation of the spectrum of **13** ($R^1$ = 2,4,6-$d_3$-phenyl) is complicated by incomplete labelling (ca. 70% $d_3$) but the relative abundances of the FFFR metastable peaks for H· and D· loss indicate that involvement of phenyl ring hydrogens is of minor importance (see below). Some departure from the usual pattern is seen in the spectrum of **14**, with CO and HCNCO being lost from $[M - H]^+$ and elimination of NCO from the molecular ion. Formation of $[M - H]^+$ involves the benzylic hydrogens as well as those on the phenyl and pyrimidine rings, with the relative abundance ratio for $[M - H]^+/[M - D]^+$ being 1:1 for the α,α-$d_2$-benzyl pyrimidinone, **15**.

Intense FFFR metastable peaks are observed for H· loss from **12** and **13**. Since hydrogen atom elimination from C(4) of the pyrimidine ring is, typically, a fast simple cleavage process for which a metastable peak is not observed, we associate the observed metastable decompositions with a slow rearrangement process involving either the phenyl ring hydrogens or the C(6) hydrogen in the heterocycle. By analogy with 1-phenyl pyridone (16), loss of H· from the *ortho* position of the phenyl ring combined with new bond formation to the carbonyl oxygen would generate a $[M - H]^+$ ion with the stable oxazolium structure **16**. Aryl-oxygen bond formation in odd-electron ions with H· elimination has been postulated in the fragmentation of β-diketones and α,β-unsaturated esters and acids (18), and an analogous process has been proposed in the mass spectra of pyridinium oxides (19). However, the absence of metastable peaks of significant intensity for D· loss from **13** leads us to suggest that formation of **16** is, at best, a minor process in the fragmentation of **12** in the metastable time frame. An alternative structure, **17**, can be formulated in terms of an *ortho*-hydrogen transfer to oxygen followed by H· loss and new bond formation at C(6) of the pyrimidine ring. It is of interest to note that a very intense metastable peak is observed for D· loss from the molecular ion of 1-(2,4,6-$d_3$-phenyl)-pyrimidinthione (20).



**16**



**17**

In the absence of further labelling studies, interpretation of H· loss from **14** ($R^1$ = benzyl) is speculative. Although the conventional spectrum of **15** indicated that the benzylic hydrogens are involved in formation of $[M - H]^+$, the corresponding metastable peaks were not observed. Thus the FFFR metastable peaks for H· loss observed for **14** and **15** can be associated with H· loss from the phenyl ring; by analogy with the phenyl derivative, structures corresponding to new bond formation to oxygen or to C(6), **18** and **19**, respectively, are plausible. Given the importance of $[M - H]^+$ ion fragmentations in the mass spectra of the 2-pyrimidinones, the characterization of the structure of these ions would be of considerable interest.

# Formation of unusual side-products from succinimidyl esters of fatty acids during the acylation of amino acids[1]

ALENKA PAQUET AND MICHEL BERGERON

*Food Research Institute, Canada Department of Agriculture, Ottawa, Ont., Canada K1A 0C6*

Received December 7, 1981

ALENKA PAQUET and MICHEL BERGERON. Can. J. Chem. **60**, 1806 (1982).

A new side-product, succinohydroxamic decanoic anhydride, was isolated from the reaction mixture during the acylation of lysine by succinimidyl decanoate in the presence of aqueous sodium hydroxide. Lauric and palmitic acid derivatives were also obtained. It is shown that these compounds can be used for acylation of amino acids. The hydroxamic acid derivatives were also detected when the acylations by succinimidyl esters of fatty acids were carried out under anhydrous conditions. Preparation of *N*-lauroyl-L-tyrosine methyl ester from tyrosine methyl ester and succinimidyl laurate is also described.

ALENKA PAQUET et MICHEL BERGERON. Can. J. Chem. **60**, 1806 (1982).

On a isolé un nouveau produit secondaire, l'anhydride succino-hydroxamique décanoique, du mélange réactionnel obtenu lors de l'acylation de la lysine par le décanoate de succinimidyle en présence d'hydroxyde de sodium aqueux. On a également obtenu des dérivés des acides laurique et palmitique. On montre que l'on peut utiliser ces composés pour acyler des acides aminés. On a également décelé des dérivés de l'acide hydroxamique lorsqu'on réalise les acylations des acides gras par les esters succinimidyles en milieu anhydre. On décrit également la préparation de l'ester méthylique de la *N*-lauroyl-L tyrosine à partir du tyrosinate de méthyle et du laurate de succinimidyle.

[Traduit par le journal]

There have been several reports in the literature on formation of various side-products arising during the peptide synthesis where the activation of the carboxyl group is promoted by *N*-hydroxysuccinimide. Thus, the presence of succinimidoxycarbonyl-β-alanine-*N*-hydroxysuccinimide ester arising from *N*-hydroxysuccinimide in the presence of dicyclohexylcarbodiimide was observed in some dicyclohexylcarbodiimide/*N*-hydroxysuccinimide mediated couplings (1, 2). Another type of side-product is *O*,*N*-diacylhydroxylamine derivative formed from Boc-proline-*N*-hydroxysuccinimide ester and proline during the coupling of these two amino acids under anhydrous conditions (3).

This paper deals with the side-products arising from succinimidyl esters of fatty acids during the acylation of lysine in the presence of aqueous sodium hydroxide. In the previous communication (4) we have shown that good yields (72–84%) of $N^6$-substituted lysine derivatives can be obtained by acylation of lysine by succinimidyl esters of fatty acids in water – organic solvent in the presence of triethylamine. The use of aqueous sodium hydroxide as an alternative possibility was described for the work with decanoic acid ester. In such a procedure a large excess of reagent had to be used but the yield was lower (69%). Here we show that the presence of aqueous sodium hydroxide gives rise to mixed succinohydroxamic anhydrides from succinimidyl esters of fatty acids.

The hydrolysis of cyclic *N*-hydroxyimides in the form of their salts to hydroxamic acids has been reported in the literature (5). To our knowledge, this type of hydrolysis has not yet been observed with O-acylated *N*-hydroxyimides. It would be expected that the ester group would undergo saponification under such conditions faster than hydrolysis of the cyclic imide structure. The long chain of fatty acid hinders the ester group and gives rise to a hydroxamic acid derivative instead. In the previously reported syntheses, where excess of triethylamine was used (4), hydroxamic acid derivatives were also formed in all cases. They were separated from the products by extraction with organic solvent and characterized by infrared spectroscopy. Their isolation in pure form could not be achieved. We suggest that precautions should be taken in peptide synthesis when the excess of base is used during work with succinimidyl esters.

Thus, when lysine was acylated by succinimidyl decanoate in 2 *N* sodium hydroxide in dioxane (4), the by-product was isolated in 30% yield by extracting the crude $N^6$-decanoyl-L-lysine with ethanol. It was crystallized from chloroform–ether and identified as *O*-succinohydroxamic decanoic anhydride (**1**) on the basis of its elemental analysis, infrared and nmr spectra. By treating succinimidyl decanoate with 2 *N* sodium hydroxide in dioxane in the absence of lysine, 56% of the identical com-

**1** R = $C_9H_{19}$
**2** R = $C_{11}H_{23}$
**3** R = $C_{15}H_{31}$

pound was obtained, besides decanoic acid, which was easily separated by extraction with chloroform–hexane. This serves as a further proof that the amino acid was not implicated in the formation of this compound.

When lysine was acylated by an excess of succinimidyl palmitate, succinohydroxamic palmitic anhydride (**3**) was isolated in 60% yield, besides the desired $N^6$-palmitoyl-L-lysine (57%). An identical hydroxamic acid derivative was obtained in 40% yield from succinimidyl palmitate in the absence of lysine. An additional amount of triethylamine was added to the reaction mixture during the work with this reagent. The same conditions served for the conversion of succinimidyl laurate into succinohydroxamic lauric anhydride (**2**) (absence of substrate).

Because hydroxamic acid derivatives have been known as acylating agents useful in peptide synthesis (6–8), it was of interest to explore the possibility of using these side-products for acylation of amino acids. Succinohydroxamic lauric anhydride and β-alanine in water–acetone mixture in the presence of three equivalents of triethylamine gave 76% of *N*-lauroyl-β-alanine. When 1 equivalent of triethylamine or sodium bicarbonate was used, the reaction was slow and impractical. No product was obtained when the acylation was carried out in the presence of 2 *N* sodium hydroxide. This fact explains the reason why these side-products accumulate in the reaction mixture during the acylation of lysine and do not react further with the substrate to give the desired product.

In selective acylations by succinimidyl esters of fatty acids carried out under the anhydrous conditions, namely acylation of the amino group in tyrosine methyl ester in chloroform–triethylamine mixture, only small amounts of hydroxamic acid derivatives could be detected (infrared spectra showed 1800 $cm^{-1}$, indicating the *O*-acylhydroxylamine bond) even in experiments where excess of reagent was used. The isolation of the side-products in the pure state from these reactions could not be achieved. However, we report in this paper the isolation and structure determination of the main product of the reaction, *N*-lauroyl-L-tyrosine methyl ester, as this structure was unexpected in the light of the results published by other authors. Recently Girin and Shvachkin reported the synthesis of *O*-(Boc-glycyl)-L-tyrosine ethyl ester from L-tyrosine ethyl ester and Boc-glycine-*p*-nitrophenyl ester in chloroform in the presence of an excess of triethylamine (9–11). Upon treating L-tyrosine methyl ester with succinimidyl laurate under such conditions we have obtained *N*-lauroyl-L-tyrosine methyl ester, identified on the basis of its elemental analysis, ir and nmr spectra, and its identity with the compound obtained from the reaction between tyrosine methyl ester and succinimidyl laurate in the absence of base. Its hydrolysis furnished *N*-lauroyltyrosine in 89% yield.

## Experimental

Melting points were taken by the capillary method. The nmr spectra were recorded on a Varian T-60 spectrometer. The ir spectra were recorded on a Beckman IR-20 instrument.

Succinimidyl esters of fatty acids were prepared as described previously (4). Amino acids were purchased from Sigma Chemical Company (Saint Louis, Missouri, U.S.A.).

*Succinohydroxamic decanoic anhydride (1)*

A. *From the acylation of lysine by succinimidyl decanoate*

To a stirred solution of L-lysine hydrochloride (456 mg, 2.5 mmol) in 2 *N* sodium hydroxide (7 mL) was added succinimidyl decanoate (2.01 g, 7.5 mmol) in dioxane (10 mL). A further amount of 2 *N* sodium hydroxide was added to keep the pH at 11–11.5. After 0.5 hour the mixture was acidified with concentrated hydrochloric acid to pH 3 and evaporated to a smaller volume. Then pH was brought up to 6 and the mixture was chilled; the precipitated $N^6$-substituted lysine derivative was filtered off and washed with water, chloroform–ether (to remove decanoic acid), and with ethanol. The ethanolic extract was evaporated to dryness and the residue crystallized from chloroform–ether to give 735 mg (25%, related to starting succinimidyl ester) of the title compound, mp 153–155°C; ir (Nujol): 1680, 1710–1720, 1795 $cm^{-1}$; nmr (DMSO) δ: 0.96 (m, 3H, $CH_3$-decanoic acid), 1.26 (s, 14H, $CH_2$-decanoic acid), 2.53 (m, 6H, $CH_2$-succinic acid, α-$CH_2$-decanoic acid). *Anal.* calcd. for $C_{14}H_{25}NO_5$: C 58.51, H 8.77, N 4.87; found: C 59.32, H 8.49, N 4.80.

B. *From succinimidyl decanoate and aqueous sodium hydroxide*

A solution of succinimidyl decanoate (808 mg, 3 mmol) in 2 *N* sodium hydroxide (3 mL) and dioxane (2 mL) was stirred for 2 hours. The mixture was chilled and acidified to pH 4 and concentrated to a small volume. The solid was separated by filtration, washed with ice-cold water, chloroform–ether mixture (1:4), and recrystallized from chloroform–ether to give 483 mg (56%) of the title compound, mp 155°C. The ir spectrum of this compound was identical with the product obtained from the acylation of lysine.

*Succinohydroxamic palmitic anhydride (3)*

This compound was obtained from succinimidyl palmitate using procedures A and B described for the preparation of the decanoyl derivative in 60 and 40% yields respectively, mp 153–155°C; ir (Nujol): 1680, 1715–1720, 1795–1800 $cm^{-1}$; nmr (DMSO) δ: 0.95 (m, 3H, $CH_3$-palmitic acid), 1.26 (s, 26H, $CH_2$-palmitic acid), 2.50 (m, 6H, $2CH_2$-succinic and α-$CH_2$-palmitic acid). *Anal.* calcd. for $C_{20}H_{37}NO_5$: C 64.65, H 10.03, N 3.76; found: C 64.75, H 10.00, N 3.83.

*Succinohydroxamic lauric anhydride (2)*

This compound was prepared from succinimidyl laurate in 1 mmol scale as described for decanoic derivative (procedure B) to give 162 mg (54%) of the product, mp 152–155°C; ir: 1680, 1710, and 1790 $cm^{-1}$. *Anal.* calcd. for $C_{16}H_{29}NO_5$: C 60.93, H 9.27, N 4.44; found: C 60.92, H 9.03, N 4.76.

N-*lauroyl-β-alanine*
