To a stirred solution of β-alanine (89 mg, 1 mmol) and triethylamine (0.42 mL, 3 mmol) in acetone (1 mL) and water (1 mL) was added 315 mg (1 mmol) succinohydroxamic lauric anhydride. The mixture was stirred overnight, water was added, and concentrated hydrochloric acid to pH 2. The mixture was chilled, the solid separated, washed with water, and recrystallized from ethanol yielding 329 mg (76%) of the title compound. The ir spectrum in Nujol was identical with the spectrum of an authentic sample (1530–1550, 1660–1680 (amide), 1715 (carboxyl)).

N-*lauroyl-L-tyrosine methyl ester in an excess of base*

A solution of 195 mg (1 mmol) of L-tyrosine methyl ester, 297 mg (1 mmol) of succinimidyl laurate, and 1.4 mL (10 mmol) of triethylamine in chloroform (3 mL) was stirred at room temperature overnight (the analysis did not show any laurate present). The mixture was evaporated *in vacuo* till dryness, dissolved in chloroform (5 mL), and washed with 5% hydrochloric acid (2 times, 2 mL), water, and dried over sodium sulfate. The solvent was removed *in vacuo* and the residue was recrystallized from methanol–water and then from chloroform–ether mixture giving 304 mg (80%) of the title compound, mp 82–83°C; $[\alpha]_D^{25}$ +34.5° (*c* 1.0, ethyl acetate); ir ($CHCl_3$): 1510, 1665, 1740 $cm^{-1}$; nmr ($CHCl_3$) δ: 1.3 (s, 18H), 2.23 (m, 2H), 3.06 (m, 2H), 3.73 (s, 3H), 4.9 (m, 1H), 6.16 (broad s, 1H), 6.9 (m, 4H). *Anal.* calcd. for $C_{22}H_{35}NO_4$: C 69.99, H 9.34, N 3.70; found: C 69.91, H 9.11, N 3.47.

N-*lauroyl-L-tyrosine methyl ester in absence of base*

88% of the product was obtained from this reaction which was carried out as described for the acylation in an excess of base, with the exception that no triethylamine was added and the reaction time was extended to 3 days; mp 83°C; $[\alpha]_D^{25}$ +34.4° (*c* 1.16, ethyl acetate). Infrared and nmr spectra were identical with the product obtained in an excess of base.

N-*lauroyltyrosine*

To a solution of 19.8 mg of *N*-lauroyl-L-tyrosine methyl ester (obtained in the presence of an excess of triethylamine) in methanol (0.2 mL) was added 3% aqueous solution of sodium hydroxide (0.2 mL). The mixture was kept overnight at 0°C, diluted with water, and acidified with concentrated hydrochloric acid to pH 2 and kept at 0°C for two hours. The crystalline solid was collected by filtration, washed with water, and dried, giving 16.8 mg (88%) of the title compound, mp 134–135°C (Koffler block); ir: 1715 (carboxyl), 1660, and 1530 $cm^{-1}$ (amide). *Anal.* calcd. for $C_{21}H_{33}NO_4$: C 69.39, H 9.15; found: C 69.37, H 9.22.

# Effect of alkylation of ammonia on the optical band shape of solvated electrons[1]

FANG-YUAN JOU AND GORDON R. FREEMAN
*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received November 24, 1981

FANG-YUAN JOU and GORDON R. FREEMAN. Can. J. Chem. **60**, 1809 (1982).

At 200 K the width at half height, $W_{1/2}$, of the $e^-_{solv}$ optical absorption band in *n*-propyl amine is 2.1-fold greater than that in ammonia. Three quarters of the broadening occurs on the high energy side of the band. The energy $E_r$ at half height on the low energy side of the band is nearly the same in the amine as in ammonia, while $E_b$, the energy at half height on the high energy side, is 42% greater in the amine. The temperature coefficient $dE_{Amax}/dT$ is 1.8-fold greater in the amine than in ammonia. The larger width is consistent with there being a less uniform distribution of localization sites in the system, and the larger temperature coefficient implies that the sites are more easily disturbed by thermal agitation. A quantum statistical mechanical model, such as the one begun by Simons, is needed to extend the theoretical treatment of $e^-_{solv}$ spectra. The correlation between optical absorption energies of $e^-_{solv}$ and the structure of the solvent, as partially reflected in the Kirkwood correlation factor, is re-emphasized.

FANG-YUAN JOU et GORDON R. FREEMAN. Can. J. Chem. **60**, 1809 (1982).

A 200 K, la largeur à la mi-hauter, $W_{1/2}$, de la bande d'absorption optique de l'$e^-_{solv}$ dans la *n*-propyl amine est 2,1 fois plus grande que dans l'ammoniac. Les trois quarts de l'élargissement se produisent du côté de haute énergie de la bande. L'énergie $E_r$ à mi-hauteur du côté de faible énergie de la bande est presque la même dans l'amine et dans l'ammoniac, tandis que $E_b$, l'énergie à mi-hauteur du côté de haute énergie, est 42% plus élevée dans l'amine. Le coefficient de température $dE_{Amax}/dT$ est 1,8 fois plus élevé dans l'amine que dans l'ammoniac. La plus grande largeur est en accord avec le fait que la distribution des sites de localisation est moins uniforme dans le système; le coefficient de température plus élevé implique que les sites sont plus facilement perturbés par l'agitation thermique. Un modèle de mécanique statistique quantique tel que celui commencé par Simons est nécessaire pour développer l'étude théorique des spectres de $e^-_{solv}$. On a de nouveau mis l'accent sur la corrélation entre les énergies d'absorption optique de $e^-_{solv}$ et la structure du co-solvant, telle que reflétée partiellement dans le facteur de corrélation de Kirkwood.

[Traduit par le journal]

## Introduction

The optical absorption spectrum of solvated electrons in a primary alcohol (1–5) is about twice as wide as, and more asymmetric than, that in water (3–7). At a given temperature and pressure the hydroxy group determines the approximate energy of the absorption maximum $E_{Amax}$, while the alkyl group increases the band width. The shift of the band with temperature is also larger in alcohols than in water (7).

The situation is similar for electrons in ammonia (8–12) and primary amines (13–15), the optical bands being broader in the amines. The absorption energies are 2–3 times lower in the nitrogen compounds than in their oxygen analogs. The lower absorption energies are attributed to shallower potential wells, which are rationalized in terms of the lower polarity and less orderly structure of the former liquids (16). The degree of structure in the liquids is reflected in the Kirkwood molecular correlation factor $g_K$ (17), which can be calculated from physical properties of the liquid (18–21). The values of $g_K$ at 298 K are 2.7–3.3 in water and methyl to *n*-propyl alcohol, while they are 1.3–1.6 in ammonia and methyl to *n*-propyl amine (Table 1).

Oster and Kirkwood suggested that as a basis for classification of liquids according to their thermodynamic behavior, the correlation parameter $g_K$ is more significant than the molecular dipole moment (17). The value of $g_K$ reflects the degree of orderliness or intermolecular structure in the liquid. The correlation of $E_{Amax}$ with $g_K$, and the lack of correlation with dielectric constant $\varepsilon_s$ or dipole moment $\mu$ (Table 1), indicate that the details of liquid structure have a dominating influence on the energy levels of solvated electrons as well. In the estimation of $g_K$ values the spacial and optical anisotropies of the molecules were neglected. Refinements would be difficult to make and may not be worthwhile for our purposes. The present stage of development is sufficient to indicate that calculations of solvated electron spectra require a quantum statistical mechanical model that includes the liquid structure. An excellent beginning has been made (22, 23). Fluctuations in solvent properties were introduced in an early stage of the model, rather than being added on at the end of the calculation in the usual manner. However, multibody interactions were still handled as sums of pair interactions, and it was not possible to include the orientational disorder and the optical and electrical anisotropies of the molecules in a real calculation. Much work remains to be done to overcome these

serious shortcomings, but the Simons approach (22), or something similar, seems to be the most promising for the next several years.

Calculations based upon the continuum, semicontinuum, and *ab initio* models of the past will yield little more information than they already have. Continuum models ignore the dominating short range interactions and the solvent structure. Semicontinuum models ignore the solvent structure and the extremely important structural connection between the first solvation layer and the rest of the solvent. The *ab initio* approach is the most basic, but current quantum mechanical methods are inadequate for the resolution of solvated electron structures. The optical and transport properties of solvated electrons would follow readily from the solution of the structure problem. The *ab initio* method cannot succeed with solvated electrons until it has been successful in describing the structures of the pure solvents.

To prepare for the arrival of a practical qsm model we are trying to obtain as complete as possible an empirical description of the behavior of electrons in liquids. The description includes both optical and transport properties. Reported below are details of the band shape and temperature dependence of the optical spectrum of electrons in *n*-propyl amine.

The temperature coefficients of $E_{Amax}$ in water (7) and ammonia (9, 12) are the same, −2.4 meV/K, and smaller than those in alcohols (2, 24) and amines (14). The reason for picking *n*-propyl to be the amine to be examined in more detail was through analogy with the alcohols. In *n*-alcohols the band width at half height, $W_{1/2}$, increases with alkyl length until *n*-propyl (5); longer alkyl groups do not increase $W_{1/2}$. Propyl amine may therefore provide an optimum band shape for contrast with that in ammonia.

## Experimental

The 2 MeV electron source and the optical system were described elsewhere (4, 25). The sizes of the radiation pulses used were 1 μs ($2 \times 10^{17}$ eV/g) for spectrum measurement, and 0.1 μs ($2 \times 10^{16}$ eV/g) for yield determination. The dosimeter was triple distilled water (distilled successively from acidic dichromate, basic permanganate, and no reagent, each time refluxing through a 50 cm column packed with glass beads) at 295 K, using $G\varepsilon_{715} = 50{,}000$ $e^-_s$/100 eV $M$ cm at 715 nm (26). A 15 mm Spectrosil cell was used at wavelengths $280 < \lambda < 1050$ nm, and a 3 mm Vitreosil cell at $800 < \lambda < 2200$ nm. The band pass of the monochromator in the present work was slightly larger than that for ammonia, and corresponded to an energy uncertainty of 10 meV throughout the band.

One half liter of *n*-propyl amine (Eastman) and 0.5 g of lithium aluminum hydride were refluxed under ultra high purity nitrogen (Linde) for 2 h. The middle 0.3 L was collected in a flask connected to a vacuum rack. When preparing a sample for irradiation, about 30 mL was vacuum distilled into a reservoir containing a mirror of triple distilled potassium, cooled by liquid nitrogen. The amine was melted and stirred for an hour at room temperature. The solubility of potassium in *n*-propyl amine is much less than in ammonia, but the solution was sky blue. The liquid was then distilled into a degassing trap cooled by liquid nitrogen, while pumping. When enough sample was collected, the reservoir was closed and pumping continued on the trap until pressure reached 0.3 mPa. The sample was then vacuum distilled into a cell reservoir.

## Results

The optical absorption spectra of electrons solvated in *n*-propyl amine at 190–295 K are shown in Fig. 1. The uncertainty in the reported temperatures is ±0.4 K. The variation of optical absorbance at the same wavelength per unit dose for consecutive pulses was <2%; the first and last points in a run were taken at the same wavelength and the variation in absorbance per unit dose was < 4%, after making a first order correction for the

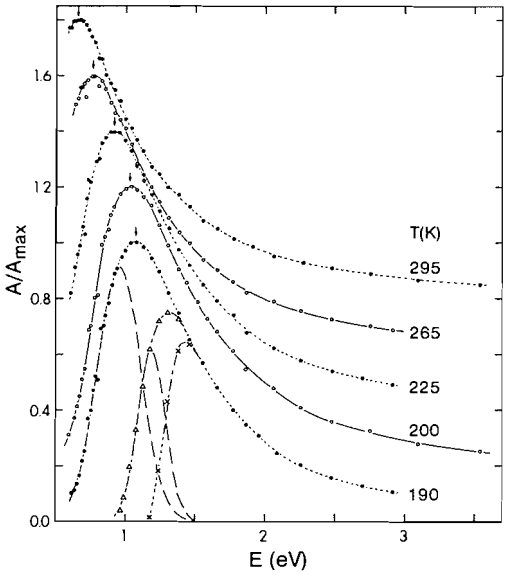

FIG. 1. Optical absorption spectra of solvated electrons in *n*-propyl amine at different temperatures. The points are experimental. The lines are empirical, except for 190 K (see text. $\Delta$, remainder after subtracting first Gaussian; $\times$, remainder after second Gaussian removed.). The arrows mark $E_{Amax}$. Successive spectra are displaced vertically by 0.2 units for clarity.

decay during the 1.0 μs pulse. The correction was only approximate, because at $T < 265$ K the geminate reaction was not complete at 1 μs and the total reaction was not first order.

At $\lambda < 650$ nm the first half life was longer than that at $\lambda > 650$, and it increases with decreasing wavelength. The longer lived species were presumably free radicals. A simple correction (25) was made to extract the absorbance due to solvated electrons.

The absorption band does not have a combined Gaussian–Lorenzian shape. The band can be well resolved into two Gaussians and a continuum remainder (5). For example, at 190 K one obtains $A_1 = 0.913$, $E_1 = 0.955$ eV, $g_1 = 0.185$ eV, and $A_2 = 0.612$, $E_2 = 1.19$ eV, $g_2 = 0.118$ eV (Fig. 1). However, the small temperature range does not warrant further analysis, because reliable temperature coefficients of these resolved parameters could not be obtained. The spectrum parameters listed in Table 2 were determined empirically. In a graph of $A/A_{max}$ against λ a smooth line was drawn through (near) the experimental points. At $A/A_{max} = 0.9$, 0.8, 0.7, and so on, the center point between the two sides of the band was marked. These points were then joined by a straight line, which was extrapolated to the band maximum to determine $\lambda_{Amax}$ and hence $E_{Amax}$. An example is shown in Fig. 2. This method was not applicable at 265 and 295 K, so $E_{Amax}$ was picked visually from the graphs for these temperatures.

The energies at half height on the red ($E_r$) and blue ($E_b$) sides of the band were used to calculate

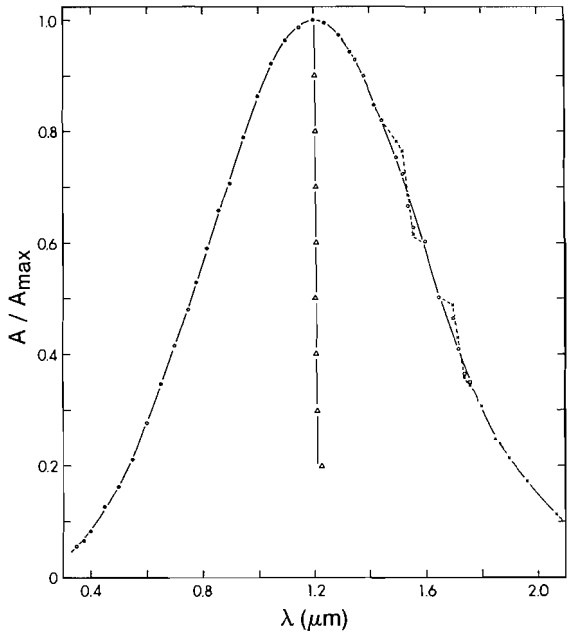

FIG. 2. Empirical location of $\lambda_{Amax}$ by extrapolation of middle points $\Delta$. Temperature = 200 K. Abnormal points near 1.45–1.60 μm and 1.65–1.77 μm were caused by increasing the optical slit width when light was absorbed by N—H and C—H stretching overtones, respectively, of the solvent. Band pass: ○, ≤ 26 nm; ×, 46 nm.

$W_{1/2} = E_b - E_r$, $W_r = E_{Amax} - E_r$, and $W_b = E_b - E_{Amax}$ (Table 2).

The zig–zags shown by dashed lines around 1.52 and 1.72 μm in Fig. 2 are artifacts caused by changing the optical slit width to compensate for absorption by solvent. The overtone of the N—H stretching band occurs at ~1.47–1.56 μm and that of the C—H stretching band is at 1.69–1.75 μm (27). When a measurement is made at wavelengths that are on a steep slope of a solvent absorption band, the transmitted light is not uniform across the monochromator band pass, but is distorted towards the less absorbed wavelengths. The effect is larger when the band pass is wider. The zig–zags occur on the long wavelength side of the $e^-_{solv}$ band in Fig. 2. The crest of each of these zig–zags corresponds to a measurement taken on the short wavelength slope of a solvent band, and the trough corresponds to a measurement on the long wavelength slope of a solvent band. Zig–zags were observed at the same wavelengths at all temperatures in the present work. They had also been observed but not mentioned in earlier studies with ammonia (12) and ethers (25), due to absorption by N—H and C—H stretching overtones, respectively.

The temperature effect on the spectrum parameters is shown in Fig. 3. All the characteristic energies, with the possible exception of $W_r$, decrease with increasing temperature.

The shift with temperature of the band at a given value of $A/A_{max}$ is approximately constant at −4.2 meV/K on the low energy side of $A_{max}$ (Fig. 4). The coefficient is somewhat more negative, −4.6 meV/K, on the high energy side at $A/A_{max} = 0.5$. The shift appears to be smaller in the high energy tail (Fig. 4), although the experimental uncertainty is greater at $A/A_{max} \leq 0.1$.

## Discussion

*Comparison of band parameters*

Alkylation of ammonia has the same general effect upon the solvated electron optical spectrum as does alkylation of water, namely, to broaden the band (see ratio $W_{1/2}/E_{Amax}$ in Table 1) and increase the temperature dependence. The spectrum parameters in $n$-propyl amine and $n$-propyl alcohol are compared with those in ammonia and water in Table 3.

At 200 K, on going from ammonia to $n$-propyl amine $W_{1/2}$ broadens 2.1-fold and $dE_{Amax}/dT$ increases 1.8-fold. The broadening occurs mainly (3/4) on the high energy side of the band; the energy $E_r$ half way up the low energy side of the band is nearly the same in the two liquids, while $E_b$ is 42% greater in the amine than in ammonia (Table 3).

By comparison, at 298 K, on going from water to $n$-propyl alcohol $W_{1/2}$ broadens 1.9-fold and $dE_{Amax}/dT$ increases 1.4-fold. Three quarters of the broadening occurs on the high energy side of the band; the value of $E_r$ is nearly unshifted, while $E_b$ increases by 35% (Table 3).

The values of the above ratios are somewhat temperature dependent (Table 3). There is no single temperature at which the values of all the parameters are available for all four systems, so we picked temperatures that would give similar values of $T/T_c$ for each liquid while having the same temperature for the two liquids in a pair. The critical temperatures $T_c$ are 497 K for the amine, 406 K for ammonia, 537 K for the alcohol, and 647 K for water. The ratios $T/T_c$ are in the vicinity of 0.5 (Table 3). The reason for not picking a fixed $T/T_c$, say 0.50, for all liquids is that $T$ itself is important in determining the spectral parameter values, and $T_c$ of water is greatly different (1.6-fold) from that of ammonia.

The spectral parameter ratio that is most different for the two pairs of systems is $G_{fi}\varepsilon_{max}$ (Table 3). The value 0.28 for alcohol/water is due mainly to the higher dielectric constant of water (Table 1) and

[e] $G_{fi}$ = free ion yield, $\varepsilon_{max}$ = maximum molar absorptivity.
[f] Reference 40.

its effect on $G_{fi}$ (28). The value 0.06 for amine/ammonia is due mainly to the low encounter efficiency of the $e^-_{solv} + NH^+_{4,solv}$ reaction in ammonia and the consequent high free ion yield in that liquid (11).

The values of $G_{fi}\varepsilon_{max}$ are independent of temperature in *n*-propyl amine (Fig. 5), ammonia (12), water (7), and alcohols (29, 30). However, the spur reactions are greatly slowed at low temperatures, so the total observed yield at the end of a 100 ns pulse increases at low temperatures. The behavior in *n*-propyl amine (Fig. 5) is similar to that recorded earlier for alcohols (29, 30) and ethers (25).

*Asymmetry of the band*

The asymmetry factor $W_b/W_r$ for an F center is $1.2 \pm 0.1$ (31, 32). The factor is larger for solvated electrons, being 1.35 for electrons in water (7) and ammonia (12), 1.6 in tetrahydrofuran (5), and 1.8–2.4 in a variety of alcohols and diols (5) and propyl amine (Table 2). The greater asymmetry is consistent with the suggestion that both bound–bound and bound–continuum transitions make significant contributions to the optical band of solvated electrons. The large increase in asymmetry factor on going from water or ammonia to an alcohol or amine (Table 3) might indicate an extra bound–bound transition for electrons in the latter liquids. Photoconductivity measurements on trapped electrons in glassy MTHF (33), alcohol/water (34), and amines (35) also indicate that both bound–bound and bound–continuum transitions occur in these systems. Moment analysis of the spectra in water, ammonia, and MTHF (36) substantiates a substantial contribution from bound–continuum transitions.

*Oscillator strength*

The oscillator strength $f$ was estimated from eq. [1].

[1] $f = 3.5 \times 10^{-5}\ \varepsilon_{max} W_{1/2} I$

where

$$I = (1/W_{1/2}) \int_0^\infty (\varepsilon_E/\varepsilon_{max}) dE$$

The value of the integral was measured from the spectra shown in Fig. 1, and is ~1.45 (Table 2). Values of $I = 1.3$–$1.5$ have also been found in ammonia (12), water (7), and many alcohols (5).

Taking a typical value of $f = 0.7$ (5) one obtains $\varepsilon_{max} \approx \sim 1.7 \times 10^3$ m²/mol ($1.7 \times 10^4 M^{-1}$ cm$^{-1}$). The earlier reported value of $4.5 \times 10^3$ m²/mol in *n*-propyl amine at 293 K (15) is too high because it would give $f = 2.0$.

*Band shape stability*

The temperature coefficient $(\partial E/\partial T)_{A/A_{max}}$ for solvated electrons in *n*-propyl amine increases gently from the low energy side up to $E_b$, then decreases (Fig. 4). This shows a slight band shape instability. Using Golden and Tuttle's method (37, 38), the band at 190 K was chosen as a reference and that at another temperature was shifted to it by adding a fixed amount of energy which resulted in a minimum deviation between the reference and the shifted band. The root-mean-square (rms) deviation for the shifted bands was 0.04 eV/100 K. Similar values had been obtained for water, methanol, tetrahydrofuran, methyl amine, and ammonia (37, 38). This method of band analysis seems to be less sensitive than one which treats the high and low energy sides separately.

JAMES H. CLARK, JAMES D. PILE, JACK M. MILLER, SERGIO PAONE, and SHWE Y. TAN. Can. J. Chem. **60**, 1815 (1982).

Two useful but quite different manifestations of strong hydrogen bonding in systems containing NH groups are reported and discussed. The $pK_a$ limit for observation of proton–proton HNCH spin–spin coupling in *N*-methylanilines is shown to be related to the strength of added H-bond electron donors so that $Ph_3PO$, $Ph_3AsO$, and $F^-$ in particular are useful reagents for resolving this type of coupling. The mechanism of hydrogen exchange between anilines and water and the role of the added electron donors are discussed. Strong H-bonding between anilines or benzylamines and $F^-$ causes pronounced changes in the chemical reactivity of the amine. Results of experiments on the alkylation of these amines using potassium and tetra-*n*-butylammonium fluorides demonstrate the synthetic utility of this effect.

JAMES H. CLARK, JAMES D. PILE, JACK M. MILLER, SERGIO PAONE et SHWE Y. TAN. Can. J. Chem. **60**, 1815 (1982).

On rapporte, tout en les discutant, deux manifestations utiles mais très différentes de fortes liaisons hydrogènes dans des systèmes contenant des groupes NH. On montre que la limite du $pK_a$ pour observer le couplage spin proton–proton du HNCH dans les *N*-méthylaniline est reliée à la force des liaisons hydrogènes des électrodonneurs ajoutés de sorte que $Ph_3PO$, $Ph_3AsO$ et $F^-$ en particulier sont des réactifs utiles pour résoudre ce type de couplage. On discute du mécanisme de l'échange d'hydrogène entre les anilines et l'eau et du rôle des électrodonneurs ajoutés. De fortes liaisons hydrogènes entre les anilines ou les benzylamines et $F^-$ provoquent des changements importants de la réactivité chimique de l'amine. Les résultats des expériences sur l'alkylation de ces amines utilisant les fluorures de potassium et de tétra-*n*-butylammonium démontrent l'utilité de cet effet en synthèse.
[Traduit par le journal]

## Introduction

The concept of strong or very strong hydrogen bonding is not a new one, but it is only in the last few years that enough evidence has been accumulated to support its classification as a type of bonding quite distinct from normal or weak hydrogen bonding (1, 2). The identification of strong H-bonds in a large number of systems has enabled investigators to associate a number of interesting properties with this type of bonding. Ionic fluorides for example, are capable of forming strong H-bonds to a variety of H-bond electron acceptors and are known for their base-like reaction properties, but it is only through complementary spectroscopic and chemical reactivity studies that these properties are beginning to be linked (3, 4).

We report here what we believe to be two interesting and potentially useful examples of strong H-bonding in systems containing amines: changes in the exchange rate of the NH hydrogen in *N*-methylanilines facilitating the observation of proton–proton HNCH spin–spin coupling, and enhanced reactivities of some anilines and benzylamines.

## Experimental

The $^1H$ nmr spectra were recorded on a JEOL MH-100 (100 MHz), Bruker WP-60 (60 MHz), or Varian A60 (60 MHz) spectrometer. The $^1H$ nmr spectra of products from the alkylation reactions were recorded in $CDCl_3$ solution, while those of the solutions used to study proton–proton coupling were recorded in various solvents (see text). Reported coupling constants were recorded on at least two of the spectrometers. The $^{19}F$ nmr spectra were recorded on the Bruker spectrometer at 56.4 MHz. Mass spectra were determined with an AEI MS-30 double beam mass spectrometer interfaced via a Bieman separator to a 3% SE30 Chrom W (80–200 mesh) column in a Pye 104 gas chromatograph. Infrared spectra were recorded on Perkin Elmer 237B and 735 spectrophotometers.

Triphenylarsine oxide was prepared by treatment of an acetone solution of the parent arsine with aqueous permanganate. A solution of tetra-*n*-butylammonium fluoride (TBAF) was prepared by neutralization of 20% tetra-*n*-butylammonium hydroxide with hydrofluoride acid. The resulting solution was concentrated before use. Potassium fluoride was dried at 100°C under reduced pressure for several hours prior to use. All solvents were commercial grade dried over 5 Å molecular sieves before use. Other reagents were commercial grade samples used without further purification except as detailed below.

For the study of nmr coupling in the *N*-methylanilines, it was usually sufficient to dry the metal fluoride as described above, and to use fresh samples of 18-crown-6, analytical grade solvent, and the amine. Generally, however, and specifically for studies of the tolerance of the KF (18-crown-6) – *N*-methylaniline system to water content, we used 18-crown-6 that had been dried by the following method. The crown and freshly distilled nitromethane were mixed in equimolar proportions. The result-

ing mixture was cooled to ca. −20°C and then evaporated on a rotary evaporator until all of the nitromethane had escaped. This process was repeated, and the final white solid pumped under high vacuum overnight. All subsequent manipulations were then carried out in a glove box operating under a dry nitrogen atmosphere.

*Reactions*

All reactions were carried out in ordinary glassware using efficient stirring techniques. All products are known compounds and gave satisfactory elemental analyses and $^1$H nmr, ir, and mass spectra consistent with their structure and, where reported data are available, consistent with those reported in the literature. Details of a representative reaction are given below.

*Preparation of* N-n-*butylaniline using KF–DMF*

1-Chlorobutane (0.01 mol) was added to a stirred mixture of KF (0.02 mol) and aniline (0.01 mol) in DMF (10 g) and the resulting mixture was stirred at 120°C for 12 h, after which time $^1$H nmr analysis showed no starting material remaining. Extraction of the cooled mixture with diethyl ether, aqueous washing (to remove the DMF), drying ($MgSO_4$), and evaporation under reduced pressure gave a brown viscous product. The product was purified by reduced pressure distillation giving *N-n*-butylaniline (0.0055 mol, 55%) bp 75–78°C/1 Torr (lit. (20) bp 118–120°C/20 Torr); $^1$H nmr δ: 7.3–6.5 (5H, m, ring CH), 3.45 (1H, s, N—H), 3.15 (2H, tr, $CH_2N$), 1.7–1.2 (4H, m, $(CH_2)_2$), 0.8 (3H, tr, $CH_3$) ppm; ms *m/e*: 149 ($M^+$). *Anal.* calcd. for $C_{10}H_{15}N$: C 80.54, H 10.07, N 9.40; found: C 79.78, H 10.03, N 10.00.

The above reaction may also be accomplished in a similar reaction time and with a slightly higher yield of product in the absence of DMF and using an excess of the aniline to make the mixture workable. Replacing KF by TBAF (the aqueous solution of which should be concentrated by evaporation at reduced pressure in the presence of the amine before use) produces similar results although reactions may now be accomplished at lower temperatures (> 80°C).

## Results and discussion

### *Proton–proton H—N—C—H spin–spin coupling in* N-*methylanilines*

The NH hydrogens of many secondary amines are labile on the nmr time scale, so that under normal conditions, proton–proton H—N—C—H spin–spin coupling will not be observed for such compounds. This problem is not limited to the nmr of secondary amines; alcohols, amides, and other compounds containing a fairly acidic hydrogen may not show short range coupling to that hydrogen (5).

In the case of *N*-methylanilines, a correlation between the lack of or presence of HNCH coupling, and the $pK_a$ of that amine has been established (6). Under normal conditions, coupling is observed only for those amines with $pK_a < 3.5$. Attempts to overcome the problems of fast hydrogen exchange in amines have been numerous (6–12) but have usually met with limited success. The most successful techniques that have been developed rely on the total removal of water from the amine–solvent systems (11, 12), although these methods inevitably demand very careful and often tedious experimentation and severe and highly reactive desiccants such as NaK alloy (11) or dimethylzinc (12). Of more interest here is the observation of Rae that use of pyridine as the nmr solvent allows the $pK_a$ limit to be extended by about 1 unit (6). This observation has been explained in terms of the ability of pyridine to effectively scavenge protons, but this does not seem to us to be the whole story as very weak bases such as DMSO have been used to extend the limit for observation of HNCH coupling in similar systems (13).

On the basis of the evidence available, the most probable mechanism for proton exchange in these systems would involve initial H-bonding of water to the amine NH nitrogen (eq. [1]). If this mecha-

[1] 
nism is correct, then it would seem that the best approach to solving the problem of fast exchange would be to attempt to control the H-bonding in the systems rather than introduce proton scavengers or powerful chemical desiccants. With this consideration in mind, we have studied the effects of a range of compounds of different H-bond electron donor abilities on the $^1$H nmr of solutions containing representative *N*-methylanilines. The amines we selected cover a $pK_a$ range up to 5.36 and the two higher $pK_a$ amines at least would normally require rigorous drying precautions for HNCH coupling to be observed at ambient temperatures. The results of our experiments are summarized in Table 1.

The results reported here reveal a definite correlation between the presence or absence of HNCH coupling and known H-bond electron donor abilities (1, 3, 14, 15) but not with aqueous basicities. Solutions containing the three powerful H-bond electron donors, $F^-$, $Ph_3PO$, and $Ph_3AsO$ show well-defined coupling for at least one of the amines. The medium strength donors DMSO, pyridine, and DMF do not produce defined coupling in any of the amines under the conditions used, but do reveal a broadening of the N—$CH_3$ proton resonance for the lowest $pK_a$ amine (*N*-methyl-*o*-toluidine). It has been reported that coupling in *N*-methyl-*o*-toluidine can be observed in pure pyridine (6) but we have generally used an electron donor to amine mole ratio of 2:1. Chloroform, a very weak donor, is totally ineffective. All $J_{HNCH}$ values observed here are consistent with those reported in the literature (12).

TABLE 1. H—N—C—H proton–proton coupling constants and chemical shifts for H-bond electron donor *N*-methylaniline systems[a]

Solutions containing fluoride ions are particularly effective at revealing HNCH coupling in all three amines checked here. In all cases, coupling was very well-defined. No change was observed on replacing KF by RbF or CsF, but coupling was not observed when potassium acetate, KCl, or KI were used. These observations clearly point to the importance of the fluoride anion and are consistent with the concept of strong hydrogen bonding playing the major role in these systems. Changing the bulk solvent from benzene to bromobenzene, chlorobenzene, acetonitrile, or carbon tetrachloride also has no effect on the coupling. However, a single N—$CH_3$ proton resonance is observed in methanol suggesting that the fluoride anion is effectively masked by $CH_3OH\cdots F^-$ H-bonding in this solvent.

Normally, we did not take any special precautions before running the nmr's of the solutions (see Experimental) so as to determine the potential of the method as a routine analytical technique; but we did carry out a series of relative concentration and water tolerance studies using predried KF, 18-crown-6, benzene, and *N*-methylaniline. These studies showed that HNCH coupling is still clearly seen at amine to fluoride mole ratios of greater than 50 to 1, and water to fluoride mole ratios of about 10 to 1. These results strongly suggest that the function of the fluoride anion is to scavenge the water molecules rather than in some way block the amine NH sites. This is not unreasonable since OH groups are normally better H-bond electron acceptor sites than NH groups, and it is not immediately obvious how H-bonding to the NH hydrogen would inhibit hydrogen exchange with water molecules. It is not reasonable to suggest that fluoride, $Ph_3PO$, and $Ph_3AsO$ are acting as conventional desiccants and we believe that our observations confirm our suggested mechanism and, in particular, show that our H-bonding approach to the solution of the problem of observing coupling in rapidly exchanging systems of this type is a viable one. Our method would seem to compare very favourably in terms of ease, convenience, and efficiency with those methods employing rigorous drying techniques and highly reactive drying agents.

Results of raising the temperature in representative fluoride solutions are given in Table 1. Dried reagent systems withstand appreciable increases in temperature before the N—$CH_3$ proton doublet collapses. The coalescence temperatures for *N*-methylaniline systems are sensitive to fluoride concentration and to the identity of the cation so that $T_{coal}(CsF) > T_{coal}(RbF) > T_{coal}(KF)$.

It is not advisable to place too much emphasis on the absolute values for the N—$CH_3$ proton chemical shifts reported, as these values are rather sensitive to factors such as amine concentration and water content. But it is apparent that the maximum chemical shifts are observed in the very weakly associating solvents $CCl_4$ and $CHCl_3$, while the minimum values are observed in methanol and the aromatic solvents. Presumably, the high field chemical shift values observed in aromatic media are derived from an intermolecular interaction between the methyl group and the aromatic group of the solvent (12), while in methanol the effect is caused by actual molecular association.

The final column in Table 1 gives positions of the single resonances observed in almost all solutions containing salt – crown ether combinations (which we assume to be due to salt – crown ether complexes) relative to the position of uncomplexed crown. All of these solutions were made up with a large excess of crown (16) and relative intensities of the complex and free crown resonances suggest 1:1 or 2:1 crown/salt complexes. Too much emphasis should not be placed on the actual values quoted here for reasons similar to those given above, but it is interesting to note their solvent dependence and in particular the observation that in acetonitrile or benzene the complex resonances consistently occur upfield of that of the free crown, whereas in all other solvents the opposite effect is observed. This is obviously a subject of interest but a more detailed investigation is beyond the scope of this work and will be reported in a subsequent article.

The diffuse nature of the NH resonances of amine solutions which showed N—CH proton doublets made conventional decoupling experiments difficult and did not provide us with consistent results. We therefore decided to look at the $^{19}F$ nmr spectra of the fluoride-containing solutions in an attempt to rule out the possibility of coupling to the fluorine and to hopefully provide more information on these systems in general. In all of the solutions we investigated, $^{19}F$ nmr revealed an extremely broad resonance ($\omega_{1/2}$ = ca. 4 kHz) which was insensitive to the presence or absence of the amine and disappeared only on removal of the crown ether. A sample of KF (18-crown-6) in water showed a sharp signal characteristic of aqueous fluoride superimposed on the broad signal. The broad signal was centred at ca. 30 ppm downfield from $C_6F_6$, that is in the strong H-bonding to fluoride region of the spectrum, although it is extremely doubtful that such a wide band may be attributed to a simple H-bonding interaction. No

TABLE 2. Hydrogen bond assisted *N*-alkylation of anilines and benzylamines

| Amine | Alkylating agent | Solvent | Fluoride | Temperature (°C) | Time (h) | Alkylated product yield (%)[a] | Benzyl fluoride yield (%)[a] |
|---|---|---|---|---|---|---|---|

effect was observed on applying proton decoupling power. We are carrying out further investigations on this phenomenon.

*Hydrogen bond assisted alkylations*

In the last section, we reported one spectroscopic manifestation of strong H-bonding in amine systems. On introducing powerful H-bond electron donors into solutions containing amines and water, the donor apparently preferentially H-bonded to water molecules although it seems certain that any excess donor molecules would H-bond to amine molecules. Here we turn our attention to possible chemical reactivity manifestations of strong H-bonding in amine systems. By using an excess of the electron donor (ionic fluorides have been chosen to exaggerate the effect), the effect of strong H-bonding to the amine should be readily observable.

There are relatively few examples in the literature of chemical reactivity manifestations of H-bonding at NH sites, although the biochemical as well as chemical importance of such reactions is clear. Since we reported our preliminary results on KF-promoted amine alkylations (3), related work elsewhere has confirmed the promise of the method (17). We here report a more comprehensive set of results for the reactions of anilines and benzylamines with alkylating agents in the presence of KF and, for comparison purposes, we have carried out the same reactions in the presence of TBAF which has become one of the more popular alternatives to its potassium counterpart (Table 2) (4).

The *N*-alkylation of the amino function to give a secondary or tertiary amine is an important, but often problematic, reaction. Conventional methods of *N*-alkylation require rather drastic conditions using powerful bases such as sodium hydride or potassium *tert*-butoxide, and are apt to produce complex mixtures containing unalkylated, partially alkylated, and quaternary products, as well as the required product. Our results would seem to confirm that ionic fluorides are a practicable alternative to conventional reagents for this type of reaction. It is also clear that the strong H-bond between the amine NH and the fluoride anion, established by us in our earlier article (3), provides a significant localization of charge at the NH nitrogen resulting in a synthetically useful increase in the amine nucleophilicity.

It should be noted from the results in the table that the use of DMF rather than an excess of the amine as the reaction solvent generally results in a smaller isolated yield. This is probably due to increased difficulties in separation and isolation of the pure products rather than any significant reduction in reactivity. The use of DMF as solvent does offer the advantages of easier working of the reaction systems, and allows for use of solid or highly viscous reagents.

Replacing KF by TBAF provided a homogeneous reaction system, but did not usually result in higher product yields although the temperature necessary for reaction was appreciably lower than before. As with all fluoride ion promoted reactions (4), the systems were found to be very sensitive to the amount of water present. This is likely to have a

For personal use only.

much greater effect with those systems containing the extremely hygroscopic TBAF than with those using KF, which can be effectively dried before use and manipulated relatively easily. We did attempt to reduce the water present in the TBAF systems by coevaporation of the reactant amine with the aqueous TBAF (4) but it seems certain that our TBAF reaction systems contained significantly more water than those employing KF.

Reactions involving benzyl halides as the alkylating agents were the only reactions that we studied which produced significant quantities of side-products. Benzyl fluoride was isolated and identified in all such reactions (see Table 2). The competition between highly electrophilic carbons and H-bond electron acceptor sites for the fluoride anion is often a problem in fluoride-promoted reactions. Indeed recognition of this competition in attempted fluorination reactions led to the upsurge in interest in H-bond assisted reactions (4). While we were not able to overcome this problem, we did observe that the amount of fluorination that occurred could be kept to a minimum by using excess amine rather than DMF as solvent and by using KF rather than TBAF.

Tetraalkylammonium fluorides have been shown to be capable of promoting many reactions more efficiently than their alkali metal counterparts (4) but it does seem that, where fairly high reaction temperatures are required, the advantages of the former are less obvious. We believe that for *N*-alkylations, the advantages of using TBAF do not outweigh such disadvantages as higher cost, greater hygroscopicity, and increased yields of fluorine-containing side-products. We prefer the use of KF and suggest that useful improvements in reaction efficiency would be gained by achieving a better understanding of the importance of the physical characteristics of KF, as has been suggested by the recent work of Ishikawa, Ando and co-workers (18).

Received December 2, 1981

M. GAMAL EL DIN, EDWARD E. KNAUS, and CHOO-SENG GIAM. Can. J. Chem. **60**, 1821 (1982).

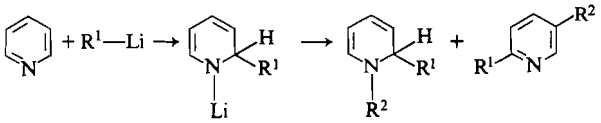
The reaction of 3-cyano **5***a*, 3-diethylaminocarbonyl **5***b*, and 3-methoxycarbonylpyridine **5***c* with alkyllithiums **6** has been investigated as a method of preparing stable dihydropyridines. Reaction of **5***a* with **6** affords a mixture of 1,2- and 1,6-dihydropyridines **10** and **11**, whereas reaction of **5***b* and **5***c* with **6** yields a mixture of 1,4- and 1,6-dihydropyridines **11** and **12**. The cyano and diethylaminocarbonyl substituents of **5***a* and **5***b* are relatively resistant toward attack by the alkyllithium whereas reaction of the methoxycarbonyl substituent of **5***c* is competitive with addition to the ring. The stabilities of the dihydropyridines prepared are described.

M. GAMAL EL DIN, EDWARD E. KNAUS et CHOO-SENG GIAM. Can. J. Chem. **60**, 1821 (1982).

On a examiné la possibilité d'utiliser la réaction des cyano-3 (**5***a*), diéthylaminocarbonyl-3 (**5***b*) et méthoxycarbonyl-3 pyridine (**5***e*) avec les alkyllithiums (**6**) pour préparer des dihydropyridines stables. La réaction du composé **5***a* avec le composé **6** conduit à un mélange de dihydro-1,2 et de dihydro-1,6 pyridines (**10** et **11**) tandis que les composés **5***b* et **5***c* dans les mêmes conditions fournissent un mélange des dihydro-1,4 et dihydro-1,6 pyridines (**11** et **12**). Les subsituants cyano et diéthylaminocarbonyle des composés **5***a* et **5***b* ne sont pas attaqués par l'alkyllithium tandis que le substituant méthoxycarbonyle réagit de façon compétitive avec l'addition sur le cycle. On décrit la stabilité des dihydropyridines ainsi préparées.

[Traduit par le journal]

Organolithium reagents add readily to the 2-position of pyridine to afford isolable *N*-lithio-2-alkyl(aryl)-1,2-dihydropyridines **1** (1). Reaction of **1** with acyl(aroyl) chlorides or esters gives predominately the *N*-substituted product **2** along with a low yield of **3** (2), whereas reaction with alkyl



**1** **2** **3**

$R^1$ = *n*-Bu, *t*-Bu, Ph

halides yields only the β-substituted pyridines **3** (3). The 1,2-dihydropyridines **2** ($R^2$ = H), obtained by treatment of **1** with water (4), are very susceptible to oxidation, are thermally unstable, and undergo rapid conversion with acid catalysis to 1,2,3,6-tetrahydro-2,3[1]-dipyridyls **4** (4).

It is well documented that electron-attracting substituents capable of resonance interaction such as COOH, COMe, $CO_2Me$, $CONH_2$, $NO_2$, and CN in the C-3 and C-5 positions stabilize dihydropyridines by extending the conjugation (5). The reactions of 3,5-dicyano(dimethoxycarbonyl)pyridine with methyl(ethyl)lithium or methyl magnesium bromide yield a mixture of 1,2- and 1,4-dihydropyridines as well as products resulting from reaction of the nucleophilic reagent with the cyano or methoxycarbonyl substituent(s). Sodium borohydride reduction of these dinitriles (diesters) also affords 1,2- and 1,4-dihydropyridines even in protic solvents (5). On the other hand, sodium borohydride reduction of 3-cyanopyridine in aprotic solvents yields 3-cyano-1,4-dihydropyridine and 3-cyano-1,4,5,6-tetrahydropyridine in protic solvents (6). The regioselective nucleophilic addition of organolithium compounds to 3-(4,4-dimethyloxazolin-2-yl)pyridine was recently shown to yield stable crystalline 1,4-dihydropyridines in excellent yield (7). It is therefore of interest to develop preparatively useful procedures for the synthesis of 1,2-, 1,4-, and/or 1,6-dihydropyridines stabilized by a single electron-attracting substituent. These dihydropyridines could be used directly as the *N*-lithio-1,2-(1,4-, 1,6-)dihydropyridines to prepare stable *N*-substituted 1,2-(1,4-, 1,6-)dihydropyridines required in other studies or hydrolyzed with

water to provide stable *N*-unsubstituted 1,2-(1,4-, 1,6-)dihydropyridines. The reaction of 3-cyano, 3-diethylaminocarbonyl, and 3-methoxycarbonylpyridines with alkyl lithiums now provides a useful reaction for the preparation of stabilized dihydropyridines.

Addition of 3-cyanopyridine (**5***a*) to an ethereal solution of *tert*-butyllithium (**6***a*) at −65°C results in the precipitation of a yellow solid, which is likely a mixture of **7** and **8**, since hydrolysis with water afforded a mixture which was separated by preparative hplc to give 1,2-dihydropyridine **10***a* (32.3%) and 1,6-dihydropyridine **11***a* (55.8%). No product **12***a* resulting from attack at the C-4 position was obtained. A similar reaction which involved addition of *n*-butyllithium (**6***b*) to **5***a* gave **10***b* (18.7%), **11***b* (51.4%), and 2-*n*-butyl-5-cyanopyridine **13***a* (6.9%). The aromatic product **13***a* arises from **11***b* during the hplc separation since it was not detected by $^1H$ nmr in the reaction product. A $^1H$ nmr study showed that a solution of **11***b* in $CDCl_3$ at 25°C oxidized slowly to **13***a* on standing with a **11***b*/**13***a* ratio of 15:100, 45:100, 55:100, and 77:100 after 2, 12, 18, and 25 days respectively. No product resulting from self condensation of **11***b* was observed.

The reaction of **7** and **8** with other electrophilic reagents was also investigated. Reaction of **7** and **8** ($R^1 = CN, R^2 = t\text{-Bu}$) with methyl chloroformate at −65°C gave a mixture of **10***c* and **11***c* (81.6%) in a ratio of 2:5 as determined from integration of the H-4 hydrogens at 7.24 and 6.58 δ for the respective compounds. A similar reaction of **7** and **8** ($R^1 = CN$, $R^2 = n\text{-Bu}$) afforded **10***d* (18.7%), **11***d* (48.1%), and **14***a* (14.1%) arising from reaction of *n*-butyl lithium with the 3-cyano substituent. The difficulty in separating **10***c* and **11***c* could be avoided by separating **10***a* and **11***a* by preparative hplc and regenerating the individual *N*-lithio derivatives prior to treatment with methylchloroformate.

The reaction of 3-diethylaminocarbonylpyridine **5***b* with *tert*-butyllithium was also studied with the

[d]Arises from the oxidation of **11***e* during preparative hplc.

view of determining the influence of the 3-substituent upon the position of attack by the organolithium reagent and the stabilizing effect it imparts to the dihydropyridines produced. Reaction of *tert*-butyllithium with **5***b* followed by treatment with water afforded 1,6-dihydropyridine **11***e* (11.5%), 1,4-dihydropyridine **12***e* (14.1%), 3-diethylaminocarbonyl-6-*tert*-butylpyridine **13***b* (27%), and 3-diethylaminocarbonylpyridine **5***b* (44.15%). The $^1H$ nmr spectrum of the initial reaction mixture did not display aromatic pyridyl resonances and **5***b* could not be detected by tlc. Dihydropyridines usually undergo aromatization via a dehydrogenation reaction rather than loss of a substituent. However, dealkylative oxidation is particularly favoured when the substituent eliminated is capable of forming a stable carbonium ion and is assisted by relief of steric strain (8). For example, thermal or chemical oxidation of 3-(4, 4-dimethyloxazolin-2-yl)-4-*tert*-butyl-1,4-dihydropyridine was often accompanied by loss of the *tert*-butyl substituent (7). It is therefore expected that 3-dimethylaminocarbonylpyridine **5***b* arises due to dealkylative oxidation of **12***e* during preparative hplc, whereas **13***b* arises due to dehydrogenation of **11***e*. On the other hand, treatment of the *N*-lithio-1,2 and 1,6-dihydropyridyl intermediates **8** and **9** ($R^1 = CONEt_2$, $R^2 = t$-Bu) with methyl chloroformate gave only **11***f* (26.3%) and **12***f* (39.8%), whereas treatment with methyl iodide yielded **11***g* (44.5%) and **12***g* (39.5%). No product resulting from dealkylative oxidation was detected in these two latter reactions.

The reactions of 3-methoxycarbonylpyridine **5***c* with alkyllithiums **6***a* and **6***b* were more complex since products resulting from reaction with the methoxycarbonyl substituent were also produced. Thus reaction of *tert*-butyllithium with **5***c* and then treatment with water gave **11***h* (27%), **12***i* (29.3%), **13***c* (13.43%), **14***b* (2.5%), and a trace of **13***d*. It is not known whether **14***b* arises from reaction of *tert*-butyllithium with the methoxycarbonyl group of **5***c* and/or dealkylative oxidation of **12***i*. *n*-Butyllithium also reacted extensively with the methoxycarbonyl substituent of **5***c* to afford **11***j* (10.6%), **12***j* (2.3%), **13***e* (2.2%), **14***a* (11%), and **14***c* (35.5%) which arises from further reaction of **14***a* with *n*-butyllithium. A similar reaction of **5***c* with *n*-butyllithium and then with methyl chloroformate gave **11***k* (16.9%), **12***l* (3.2%), **14***c* (18.2%), and methyl nicotinate (33% recovery).

The 3-substituent of **5** influences the position of attack by alkyllithium reagents since 3-cyanopyridine undergoes attack at the C-2 and C-6 positions whereas 3-diethylaminocarbonylpyridine and 3-methoxycarbonylpyridine undergo addition to the C-4 and C-6 positions. The 3-cyano and 3-diethylaminocarbonyl substituents of **5** are quite stable toward alkyllithiums **6**, whereas a 3-methoxycarbonyl substituent competes readily with addition to the ring system. It is possible that reaction with the methoxycarbonyl substituent of **5***c* could be prevented by replacing the methyl by a bulky group such as *tert*-butyl, since it has been reported that Grignard reagents do not react with the carbonyl group of 3-mesityl(duryl)carbonylpyridine (9, 10).

The 3-cyano group appears to have a greater stabilizing effect than a 3-methoxycarbonyl or 3-diethylaminocarbonyl substituent for 1,6-dihydropyridines since 3-cyano-6-*tert*-butyl-1,6-dihydropyridine **11***a* was more stable toward oxygen and heat than the 3-methoxycarbonyl and 3-diethylaminocarbonyl analogs **11***h* and **11***e*. 3-Cyano-6-*tert*-butyl-1,6-dihydropyridine **11***a* was more stable than 3-cyano-6-*n*-butyl-1,6-dihydropyridine

**11***b*. On the other hand, 4-*n*-butyl-1,4-dihydropyridines appear to be more stable than the corresponding 4-*tert*-butyl-1,4-dihydropyridine analogs since the latter undergo dealkylative oxidation quite readily. The *N*-methoxycarbonyl and *N*-methyl 1,2-, 1,4-, and 1,6-dihydropyridines are more stable than the corresponding *N*-unsubstituted analogs.

## Experimental

Melting points were determined with a Büchi capillary apparatus and are uncorrected. Nuclear magnetic resonance spectra were determined for solutions in deuterochloroform with TMS as internal standard with a Varian EM-360A or Bruker WH-200 spectrometer. Infrared spectra (sodium chloride films unless otherwise noted) were taken on a Unicam SP-1000 or Perkin–Elmer-267 spectrometer. Preparative high pressure liquid chromatography was performed using a Water's Prep LC/System 500A using Prep Pak-500 silica cartridges. Mass spectra were measured with an AEI-MS-50 mass spectrometer and these exact mass measurements are used in lieu of elemental analysis. All of the products described gave rise to a single spot on tlc using a solvent system of low, medium, and high polarity. No residue remained after combustion of the products.

*2-*tert*-Butyl-3-cyano-1,2-dihydropyridine (**10**a) and 3-cyano-6-*tert*-butyl-1,6-dihydropyridine (**11**a)*

A solution of 3-cyanopyridine (1.04 g, 10 mmol) in 20 mL dry ether was added dropwise during 30 min to a solution of *tert*-butyllithium (0.768 g, 12 mmol) in 8 mL hexane under a nitrogen atmosphere, at −65°C with stirring. The resulting solution, in which a pale yellow precipitate forms, was allowed to stir for 30 min at −65°C prior to warming slowly to 25°C. Water (20 mL) was added and stirring was continued for 15 min. Extraction with ether (4 × 50 mL), drying ($Na_2SO_4$), and removal of the solvent *in vacuo* gave a pale yellow oil which was separated by preparative hplc using petroleum ether (bp 30–60°C) – ether (7:3 v/v) at a flow rate of 250 mL/min. Removal of the solvent from the peak having a retention time of 4.6–7.2 min gave **10***a* as a pale yellow oil (0.523 g, 32.3%); ir: 3380 (m, NH) and 2210 (s, C≡N) $cm^{-1}$; $^1H$ nmr δ: 0.96 (s, 9H, —C—$Me_3$), 3.92 (d, $J_{NH,2}$ = 4.8 Hz, 1H, H-2), 4.75 (br s, 1H, NH, exchanges with deuterium oxide), 4.75 (d, $J_{4,5}$ = 7.2 Hz of d, $J_{5,6}$ = 7.2 Hz of d, $J_{5,NH}$ = 1.8 Hz, 1H, H-5), 6.62 (d, $J_{5,6}$ = 7.2 Hz of d, $J_{NH,6}$ = 7.2 Hz of d, $J_{4,6}$ = 1.2 Hz, 1H, H-6), 6.84 (d, $J_{4,5}$ = 7.2 Hz of d, $J_{4,6}$ = 1.2 Hz, 1H, H-4). *Exact Mass* calcd. for $C_{10}H_{14}N_2$: 162.1155; found (high resolution ms): 162.1149. Collection of the peak with retention time of 12.4–16.4 min and removal of the solvent *in vacuo* gave **11***a* (0.91 g, 55.8%) as a pale yellow oil; ir: 3370 (m, NH) and 2205 (s, C≡N) $cm^{-1}$; $^1H$ nmr δ: 0.9 (s, 9H, C—$Me_3$), 3.95 (d, $J_{5,6}$ = 4.5 Hz of d, $J_{NH,6}$ = 2 Hz, 1H, H-6), 5.1 (d, $J_{4,5}$ = 9.75 Hz of d, $J_{5,6}$ = 4.5 Hz of d, $J_{NH,5}$ = 1.5 Hz, 1H, H-5), 5.8 (br s, 1H, NH, exchanges with deuterium oxide), 5.95 (d, $J_{4,5}$ = 9.75 Hz, 1H, H-4), 7.05 (d, $J_{NH,2}$ = 7 Hz, 1H, H-2, collapses to a singlet after exchange with deuterium oxide). *Exact Mass* calcd. for $C_{10}H_{14}N_2$: 162.1155; found (high resolution ms): 162.1156.

*2-n-Butyl-3-cyano-1,2-dihydropyridine (**10**b), 3-cyano-6-n-butyl-1,6-dihydropyridine (**11**b), and 2-n-butyl-5-cyanopyridine (**13**a)*

A solution of *n*-butyllithium (1.28 g, 20 mmol) in 9.2 mL hexane was added dropwise to a solution of 3-cyanopyridine (2.08 g, 20 mmol) in 75 mL dry tetrahydrofuran, under a nitrogen atmosphere, at −65°C with stirring. The resulting solution, in which a pale yellow precipitate forms, was allowed to stir for 1 h at −65°C prior to warming slowly to 25°C. Water (25 mL) was added. Extraction with ether (4 × 50 mL), drying ($Na_2SO_4$), and removal of the solvent *in vacuo* at 30–35°C afforded a pale yellow oil which was separated by preparative hplc using petroleum ether (bp 30–60°C) – ethyl acetate (9:1 v/v) at a flow rate of 250 mL/min. The eluant was collected in 100 mL fractions which were analyzed using $^1H$ nmr. Removal of the solvent from the 1200–1700 mL fractions gave **10***b* as a yellow oil (0.60 g, 18.7%); ir: 3360 (m, NH) and 2242 (s, C≡N) $cm^{-1}$; $^1H$ nmr δ: 0.95 (t, $J$ = 7 Hz, 3H, $CH_2CH_3$), 1.1–1.9 (m, 6H, $CH_2CH_2CH_2CH_3$), 4.2 (m, 1H, H-2), 4.8 (d, $J_{4,5}$ = 7 Hz of d, $J_{5,6}$ = 6 Hz of d, $J_{NH,5}$ = 1.5 Hz, 1H, H-5), 5.1 (br s, 1H, NH, exchanges with deuterium oxide), 6.4–6.85 (m, 2H, H-4, H-6). *Exact Mass* calcd. for $C_{10}H_{14}N_2$: 162.1155; found (high resolution ms): 162.1152. Collection of the 2000–3500 mL eluant gave a mixture of **11***b* as a yellow oil (1.566 g, 48.6%); ir: 3345 (s, NH) and 2210 (s, C≡N) $cm^{-1}$; $^1H$ nmr δ: 1.0 (t, $J$ = 7 Hz, 3H, $CH_2CH_3$), 1.15–1.9 (m, 6H, $CH_2CH_2CH_2CH_3$), 4.25 (m, 1H, H-6), 5.03 (d, $J_{4,5}$ = 9.75 Hz of d, $J_{5,6}$ = 4 Hz of d, $J_{5,NH}$ = 1.5 Hz, 1H, H-5), 5.55 (br s, 1H, NH, exchanges with deuterium oxide), 5.85 (d, $J_{4,5}$ = 9.75 Hz, 1H, H-4), 6.96 (d, $J_{2,NH}$ = 6.5 Hz, 1H, H-2, collapses to a singlet after addition of deuterium oxide). *Exact Mass* calcd. for $C_{10}H_{14}N_2$: 162.1155; found (high resolution ms): 162.1155; and **13***a* as a yellow oil (0.111 g, 3.45%); ir: 2240 (s, C≡N) $cm^{-1}$; $^1H$ nmr δ: 1.0 (t, $J$ = 7 Hz, 3H, $CH_2CH_3$), 1.15–2.1 (m, 4H, $CH_2CH_2CH_2CH_3$), 3.0 (t, $J$ = 7 Hz, $CH_2CH_2CH_2CH_3$), 7.38 (d, $J_{4,5}$ = 8 Hz, 1H, H-5), 8.0 (d, $J_{4,5}$ = 8 Hz of d, $J_{4,6}$ = 2 Hz, 1H, H-4), 8.9 (d, $J_{4,6}$ = 2Hz, 1H, H-6). *Exact Mass* calcd. for $C_{10}H_{12}N_2$: 160.0999; found (high resolution ms): 160.0998. The ratio of **11***b* and **13***a* was calculated from the integrals of the respective H-2 absorptions. Removal of the solvent from the 3600–3900 mL fractions also afforded a mixture of **11***b* (0.088 g, 2.8%) and **13***a* (0.111 g, 3.47%).

*1-Methoxycarbonyl-2-*tert*-butyl-3-cyano-1,2-dihydropyridine (**10**c) and 1-methoxycarbonyl-3-cyano-6-*tert*-butyl-1,6-dihydropyridine (**11**c)*

A solution of 3-cyanopyridine (1.04 g, 10 mmol) in 20 mL dry ether was added dropwise during 15 min to a solution of *tert*-butyllithium (0.768 g, 12 mmol) in 8 mL hexane, under a nitrogen atmosphere, at −65°C with stirring. The resulting solution, in which a pale yellow precipitate forms, was stirred for 30 min at −65°C after which methyl chloroformate (1.034 g, 11 mmol) was added. After an additional 30 min at −65°C, the reaction mixture was allowed to return to 25°C prior to addition of 20 mL water. Extraction with ether (4 × 50 mL), drying ($Na_2SO_4$), and removal of the solvent *in vacuo* gave a pale yellow oil (2.2 g). An aliquot of this product (0.512 g) was purified on ten 8 in. × 8 in. silica gel G plates, 1.0 mm in thickness, using petroleum ether – ether (5:5 v/v) as development solvent. Extraction of the band having $R_f$ 0.7 using warm absolute ethanol gave a mixture of **10***c* and **11***c* (1.79 g, 81.6%) in a ratio of 2:5 as determined by integration of the H-4 hydrogens at 7.24 and 6.58 δ for the respective compounds; ir: 2235 (s, C≡N), 1750 (s, CO), and 1730 (s, CO) $cm^{-1}$. The $^1H$ nmr spectrum of **10***c* showed the following absorptions, δ: 0.88 (s, 9H, C—$Me_3$), 3.9 (s, 3H, OMe), 4.84 (s, 1H, H-2), 5.6 (m, 1H, H-5), 6.92 (d, $J_{5,6}$ = 6 Hz, 1H, H-6), 7.24 (d, $J_{4,5}$ = 9.75 Hz, 1H, H-4), while **11***c* exhibited δ: 0.88 (s, 9H, C—$Me_3$), 3.9 (s, 3H, OMe), 4.74 (d, $J_{5,6}$ = 5.5 Hz, 1H, H-6), 5.6 (m, 1H, H-5), 6.15 (d, $J_{4,5}$ = 9.5 Hz, 1H, H-4), 7.68 (s, 1H, H-2). *Exact Mass* calcd. for $C_{12}H_{16}N_2O_2$: 220.1209; found (high resolution ms): 220.1207. Repeated attempts to separate **10***c* and **11***c* by hplc and glc were unsuccessful.

*1-Methoxycarbonyl-2-n-butyl-3-cyano-1,2-dihydropyridine (**10**d), 1-methoxycarbonyl-3-cyano-6-n-butyl-1,6-dihydropyridine (**11**d), and 3-pentanoylpyridine (**14**a)*

A solution of *n*-butyllithium (0.672 g, 10.5 mmol) in 4.3 mL

hexane was added dropwise to a solution of 3-cyanopyridine (1.04 g, 10 mmol) in 60 mL dry tetrahydrofuran, under an atmosphere of nitrogen, at −65°C with stirring. The mixture was allowed to stir for 30 min after which methyl chloroformate (0.87 g, 9.3 mmol) was added. The reaction was allowed to proceed for 30 min at −65°C with stirring prior to warming to 25°C. Water (20 mL) was added. Extraction with ether (4 × 50 mL), drying ($Na_2SO_4$), and removal of the solvent *in vacuo* gave a yellow oil which was purified by preparative hplc using hexane – ethyl acetate (9:1 v/v) at a flow rate of 250 mL/min. Removal of the solvent from the eluant having a retention time of 8.6–14 min gave a mixture of **10***d* and **11***d* as a pale yellow oil (1.47 g, 67.1%) in a ratio of 1:2.6 as determined by integration of the H-4 hydrogens at 7.08 and 5.96 δ for the respective compounds. Preparative glc of this hplc purified fraction, using a 6 ft × 1/4 in. column packed with 5% OV-101 on Chrom W (80–100 mesh) with a helium flow rate of 60 mL/min and a column temperature of 180°C, afforded a mixture of **10***d* and **11***d* in a ratio of 2:1 with a retention time of 9 min; ir: 2218 (s, C≡N) and 1735 (s, CO) $cm^{-1}$. The $^1H$ nmr spectrum of this mixture displayed the following absorptions for **10***d*: δ: 0.9 (t, $J$ = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.2–1.8 (m, 6H, $CH_2CH_2CH_2CH_3$), 3.88 (s, 3H, OMe), 5.02 (m, 1H, H-2), 5.42 (m, 1H, H-5), 6.72 (d, $J_{5,6}$ = 6 Hz, 1H, H-6), 7.1 (d, $J_{4,5}$ = 9.75 Hz, 1H, H-4). *Exact Mass* calcd. for $C_{12}H_{16}N_2O_2$: 220.1210; found (high resolution ms): 220.1209. Collection of the peak with a retention time of 16 min gave a pure sample of **11***d*; ir: 2230 (s, C≡N) and 1745 (s, CO) $cm^{-1}$. $^1H$ nmr δ: 0.9 (t, $J$ = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.2–1.8 (m, 6H, $CH_2CH_2CH_2$-$CH_3$), 3.88 (s, 3H, OMe), 4.84 (m, 1H, H-6), 5.66 (d, $J_{4,5}$ = 9.75 Hz of d, $J_{5,6}$ = 6 Hz, 1H, H-5), 5.96 (d, $J_{4,5}$ = 9.75 Hz, 1H, H-4), 7.52 (s, 1H, H-2). *Exact Mass* calcd. for $C_{12}H_{16}N_2O_2$: 220.1210; found (high resolution ms): 220.1211.

Removal of the solvent from the preparative hplc fraction having a retention time of 20.8–27.6 min gave a semi-solid product which was purified further using six 8 in. × 8 in. silica gel G plates, 1.0 mm in thickness, using chloroform – ethyl acetate (1:1 v/v) as development solvent. Extraction of the band having $R_f$ 0.4 using warm absolute ethanol afforded **14***a* (0.23 g, 14.1%); ir: 1690 (CO) $cm^{-1}$; $^1H$ nmr δ: 0.95 (t, $J$ = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–2.1 (m, 4H, $CH_2CH_2CH_2CH_3$), 3.0 (t, $J$ = 7 Hz, CO—$CH_2$), 7.42 (d, $J_{4,5}$ = 8 Hz of d, $J_{5,6}$ = 5 Hz, 1H, H-5), 8.25 (d, $J_{4,5}$ = 8 Hz of d, $J_{2,4}$ = 2 Hz of d, $J_{4,6}$ = 2 Hz, 1H, H-4), 8.8 (d, $J_{5,6}$ = 5 Hz of d, $J_{4,6}$ = 2 Hz, 1H, H-6), 9.2 (d, $J_{2,4}$ = 2 Hz, 1H, H-2). *Exact Mass* calcd. for $C_{10}H_{13}NO$: 163.0995; found (high resolution ms): 163.0993.

*3-Diethylaminocarbonyl-6-*tert*-butyl-1,6-dihydropyridine (**11**e), 3-diethylaminocarbonyl-4-*tert*-butyl-1,4-dihydropyridine (**12**e), 3-diethylaminocarbonyl-6-*tert*-butylpyridine (**13**b), and 3-diethylaminocarbonylpyridine (**5**b)*

A solution of 3-diethylaminocarbonylpyridine (2.55 g, 15 mmol) in 60 mL dry tetrahydrofuran was added dropwise during 30 min to a solution of *tert*-butyllithium (0.43 g, 18 mmol) in 12 mL hexane, under a nitrogen atmosphere, at −65°C with stirring. The reaction mixture was stirred at −65°C for a further 30 min before warming to room temperature. Water (30 mL) was added. Extraction with ether (4 × 50 mL), drying ($Na_2SO_4$), and removal of the solvent *in vacuo* gave 3.40 g of a yellow viscous oil. The $^1H$ nmr spectrum of this oil did not exhibit any aromatic pyridine absorptions. Trituration of the above product with 3 mL ether resulted in the precipitation of **12***e* as a white solid (0.15 g, 4.24%); mp 111°C; ir (KBr): 1672 (s, $CONEt_2$) and 3290 (s, NH) $cm^{-1}$; $^1H$ nmr δ: 0.75 (s, 9H, *t*-Bu), 1.15 (t, $J$ = 7 Hz, 6H, $CH_2CH_3$), 3.1–3.9 (m, 5H, $CH_2CH_3$, H-4), 4.64 (d, $J_{5,6}$ = 8 Hz of d, $J_{4,5}$ = 6 Hz of d, $J_{5,NH}$ = 2 Hz, 1H, H-5), 5.86 (broad s, 1H, NH, exchanges with deuterium oxide), 6.16 (d, $J_{5,6}$ = 8 Hz of d, $J_{NH,6}$ = 4.5 Hz, 1H, H-6), 6.48 (d, $J_{NH,2}$ = 5.5 Hz, 1H, H-2, collapses to a singlet after deuterium oxide exchange). *Exact Mass* calcd. for $C_{14}H_{24}N_2O$: 236.1892; found (high resolution ms): 236.1888. The remainder of the product was separated by preparative hplc using petroleum ether (bp 30–60°C) – ethyl acetate (8.5:1.5 v/v) at a flow rate of 250 mL/min. One hundred mL fractions were collected. Fractions 7–17 contained **13***b* (0.153 g, 4.32%) which arises from aromatization of **11***e* on the column; ir: 1640 (s, $CONEt_2$) $cm^{-1}$; $^1H$ nmr δ: 1.22 (t, $J$ = 7 Hz, 6H, $CH_2CH_3$), 1.38 (s, 9H, *t*-Bu), 3.48 (m, 4H, $CH_2CH_3$), 7.42 (d, $J_{4,5}$ = 8 Hz, 1H, H-5), 7.7 (d, $J_{4,5}$ = 8 Hz of d, $J_{2,4}$ = 2.5 Hz, 1H, H-4), 8.66 (d, $J_{2,4}$ = 2.5 Hz, 1H, H-2). *Exact Mass* calcd. for $C_{14}H_{22}N_2O$: 234.1728; found (high resolution ms): 234.1726. Removal of the solvent from fractions 18–26 gave a mixture of **12***e* (0.349 g, 9.86%) and **5***b* (0.931 g, 34.9%) as determined by integration of H-5 for **12***e* at 4.64 δ and H-2 and H-6 for **5***b* at 8.56 δ. The $^1H$ nmr spectrum of this mixture was identical to an authentic mixture of the two pure products. Fractions 27–30 contained **5***b* (0.247 g, 9.25%), identical (ir, $^1H$ nmr) with an authentic sample. Removal of the solvent from fractions 31–46 gave additional **13***b* (0.197 g, 5.62%), whereas fractions 47–57 were composed of a mixture of **13***b* (0.305 g, 8.67%) and **11***e* (0.407 g, 11.5%) as shown by $^1H$ nmr integration of H-2 for **13***b* at 8.66 δ and of H-4 for **11***e* at 6.13 δ. The 1,6-dihydropyridine **11***e* exhibited the following spectral data; ir: 3350 (m, NH) $cm^{-1}$; $^1H$ nmr δ: 0.88 (s, 9H, *t*-Bu), 1.12 (t, $J$ = 7, 6H, $CH_2CH_3$), 3.1–3.62 (m, 4H, $CH_2CH_3$), 3.82 (d, $J_{5,6}$ = 4.5 Hz of d, $J_{NH,6}$ = 2 Hz, 1H, H-6), 4.93 (d, $J_{4,5}$ = 9.5 Hz of d, $J_{5,6}$ = 4.5 Hz of d, $J_{NH,5}$ = 1.5 Hz, 1H, H-5), 5.42 (broad s, 1H, NH, exchanges with deuterium oxide), 6.13 (d, $J_{4,5}$ = 9.5 Hz, 1H, H-4), 7.06 (d, $J_{2,NH}$ = 6 Hz, 1H, H-2, collapses to a singlet after exchange with deuterium oxide). Removal of the solvent from fractions 58–68 gave additional **13***b* (0.304 g, 8.64%).

*1-Methoxycarbonyl-3-diethylaminocarbonyl-6-*tert*-butyl-1,6-dihydropyridine (**11**f) and 1-methoxycarbonyl-3-diethylaminocarbonyl-4-*tert*-butyl-1,4-dihydropyridine (**12**f)*

A solution of 3-diethylaminocarbonylpyridine (2.55 g, 15 mmol) in 60 mL dry tetrahydrofuran was added dropwise during 30 min to a solution of *tert*-butyllithium (0.43 g, 18 mmol) in 12 mL hexane, under a nitrogen atmosphere, at −65°C with stirring. Stirring was continued at −65°C for 30 min after which methyl chloroformate (1.41 g, 15 mmol) was added. The reaction mixture was allowed to return to 25°C, after stirring at −65°C for 30 min, and 30 mL water was added. Extraction with ether (4 × 50 mL), drying ($Na_2SO_4$), and removal of the solvent *in vacuo* gave an oil (3.52 g) which was subjected to preparative hplc using petroleum ether (bp 30–60°C) – chloroform (7:3 v/v) with a flow rate of 250 mL/min. One hundred mL fractions were collected. Removal of the solvent from fraction 27 gave a mixture of two dihydropyridines **11***f* and **12***f* (3.105 g). An aliquot (0.528 g) of this mixture was separated by preparative tlc on eight 8 in. × 8 in. plates, 1.0 mm in thickness, using petroleum ether – ethyl acetate (7:3 v/v) as development solvent. Extraction of the band having $R_f$ 0.6 gave **12***f* (0.298 g, 39.8%) as a yellow oil; ir: 1730 (s, $CO_2Me$) $cm^{-1}$; $^1H$ nmr δ: 0.88 (s, 9H, *t*-Bu), 1.25 (t, $J$ = 7 Hz, 6H, $CH_2CH_3$), 3.24–3.83 (m, 5H, $CH_2CH_3$, H-4), 5.18 (d, $J_{5,6}$ = 8 Hz of d, $J_{4,5}$ = 5 Hz, 1H, H-5), 6.95 (d, $J_{4,5}$ = 8 Hz, 1H, H-4), 7.22 (s, 1H, H-2). *Exact Mass* calcd. for $C_{16}H_{26}N_2O_3$: 294.1928; found (high resolution ms): 294.1921. Extraction of the band having $R_f$ 0.4 afforded **11***f* (0.1982 g, 26.3%) as an oil; ir: 1730 (s, $CO_2Me$) $cm^{-1}$; $^1H$ nmr δ: 0.9 (s, 9H, *t*-Bu), 1.15 (t, $J$ = 7 Hz, 6H, $CH_2CH_3$), 3.42 (q, $J$ = 7 Hz, 4H, $CH_2CH_3$), 6.7 (d, $J_{5,6}$ = 5.5 Hz, 1H, H-6), 5.64 (d, $J_{4,5}$ = 9.75 Hz of d, $J_{5,6}$ = 5.5 Hz, 1H, H-5), 6.26 (d, $J_{4,5}$ = 9.75 Hz, 1H, H-4), 7.22 (s, 1H, H-2). *Exact Mass* calcd. for $C_{16}H_{26}N_2O_3$: 294.1928; found (high resolution ms): 294.1921.

*1-Methyl-3-diethylaminocarbonyl-6-*tert*-butyl-1,6-dihydropyridine (**11**g) and 1-methyl-3-diethylaminocarbonyl-4-*tert*-butyl-1,4-dihydropyridine (**12**g)*

A solution of 3-diethylaminocarbonylpyridine (2.55 g, 15

For personal use only.

mmol) in 60 mL dry tetrahydrofuran was added dropwise during 30 min to a solution of *tert*-butyllithium (0.43 g, 18 mmol) in 12 mL hexane, under a nitrogen atmosphere, at −65°C with stirring. Stirring was continued at −65°C for 30 min after which methyl iodide (2.13 g, 15 mmol) was added. The reaction mixture was allowed to return to 25°C, after stirring at −65°C for 30 min, and then 30 mL water was added. Extraction with ether (4 × 50 mL), drying ($Na_2SO_4$), and removal of the solvent *in vacuo* gave 3.375 g of a yellow oil. An aliquot of this product (0.721 g) was purified by preparative tlc using ten 8 in. × 8 in. silica gel G plates, 1.0 mm in thickness, using petroleum ether (bp 30–60°C) – ethyl acetate (2:7 v/v) as development solvent. Extraction of the band having $R_f$ 0.7 using warm absolute ethanol gave **12***g* (0.316 g, 39.5%) as a yellow oil; ir: 1680 (s, $CONEt_2$) $cm^{-1}$; $^1H$ nmr δ: 0.78 (s, 9H, *t*-Bu), 1.18 (t, $J$ = 7 Hz, 6H, $CH_2CH_3$), 2.96 (s, 3H, N—Me), 3.1–3.9 (m, 5H, $CH_2CH_3$, H-4), 4.62 (d, $J_{5,6}$ = 8 Hz of d, $J_{4,5}$ = 5.5 Hz, 1H, H-5), 5.96 (d, $J_{5,6}$ = 8 Hz of d, $J_{4,6}$ = 1.5 Hz, 1H, H-6), 6.35 (d, $J_{2,4}$ = 1.5 Hz, 1H, H-2). *Exact Mass* calcd. for $C_{15}H_{26}N_2O$: 250.2043; found (high resolution ms): 250.2042. Extraction of the band having $R_f$ 0.5 yielded **11***g* (0.356 g, 44.5%) as a yellow oil; ir: 1650 (s, $CONEt_2$) $cm^{-1}$; $^1H$ nmr δ: 0.90 (s, 9H, *t*-Bu), 1.18 (t, $J$ = 7 Hz, 6H, $CH_2CH_3$), 3.12 (s, 3H, N—Me), 3.44 (q, $J$ = 7 Hz, 4H, $CH_2CH_3$), 3.70 (d, $J_{5,6}$ = 5.5 Hz of d, $J_{4,6}$ = 1.5 Hz, 1H, H-6), 4.94 (d, $J_{4,5}$ = 9.75 Hz of d, $J_{5,6}$ = 5.5 Hz, 1H, H-5), 6.33 (d, $J_{4,5}$ = 9.75 Hz of d, $J_{4,6}$ = 1.5 Hz, 1H, H-4), 7.02 (s, 1H, H-2). *Exact Mass* calcd. for $C_{15}H_{26}N_2O$: 250.2043; found (high resolution ms): 250.2031.

*3-Methoxycarbonyl-6-*tert*-butyl-1,6-dihydropyridine (**11**h), 3-*tert*-butylcarbonyl-4-*tert*-butyl-1,4-dihydropyridine (**12**i), 3-*tert*-butylcarbonyl-6-*tert*-butylpyridine (**13**c), 3-methoxycarbonyl-6-*tert*-butylpyridine (**13**d), and 3-*tert*-butylcarbonylpyridine (**14**b)*

A solution of 3-methoxycarbonylpyridine (2.74 g, 20 mmol) in 60 mL dry tetrahydrofuran was added dropwise during 30 min to a solution of *tert*-butyllithium (1.536 g, 24 mmol) in 16 mL hexane, under an atmosphere of nitrogen, at −65°C with stirring. The resulting solution was allowed to stir for 30 min at −65°C prior to warming slowly to 25°C. Water (30 mL) was added. Extraction with ether (4 × 50 mL), drying ($Na_2SO_4$), and removal of the solvent *in vacuo* gave a pale yellow oil which was separated by preparative hplc using methylene chloride – ethyl acetate (30:1 v/v) at a flow rate of 250 mL/min. One hundred mL fractions were collected. Fractions 4–7 contained **12***i* (1.3 g, 29.3%) which contained a trace of **14***b* arising from aromatization of **12***i*; ir: 3320 (m, NH) and 1665 (s, CO) $cm^{-1}$; $^1H$ nmr δ: 0.72 (s, 9H, $C_4$—*t*-Bu), 1.36 (s, 9H, CO—*t*-Bu), 3.5 (d, $J_{4,5}$ = 6 Hz, 1H, H-4), 4.9 (d, $J_{5,6}$ = 8 Hz of d, $J_{4,5}$ = 6 Hz of d, $J_{NH,5}$ = 2 Hz, 1H, H-5), 6.25 (d, $J_{5,6}$ = 8 Hz of d, $J_{NH,6}$ = 4.5 Hz, 1H, H-6), 6.8 (broad s, 1H, NH, exchanges with deuterium oxide), 7.5 (d, $J_{NH,2}$ = 5.5 Hz, 1H, H-2, collapses to a singlet after deuterium oxide exchange). The mass spectrum did not exhibit a molecular ion for $C_{14}H_{23}NO$ at *m/e* 221 but it did show a $M-2$ peak due to facile loss of $H_2$ and a $M-C_4H_9$ peak due to loss of a *tert*-butyl ion. *Exact Mass* calcd. for $C_{14}H_{21}NO$: 219.1602; found (high resolution ms): 219.1586. *Exact Mass* calcd. for $C_{10}H_{13}NO$: 164.1076; found (high resolution ms): 164.1075. The CI ms showed a $M+1$ ion at *m/e* 222 for the parent compound. Removal of the solvent from fraction 8 gave **14***b* (0.081 g, 2.5%); ir: 1690 (s, CO) $cm^{-1}$; $^1H$ nmr δ: 1.3 (s, 9H, *t*-Bu), 7.35 (d, $J_{4,5}$ = 8 Hz of d, $J_{5,6}$ = 6 Hz, 1H, H-5), 8.02 (d, $J_{4,5}$ = 8 Hz of d, $J_{4,6}$ = 2 Hz of d, $J_{2,4}$ = 2 Hz, 1H, H-4), 8.72 (d, $J_{5,6}$ = 6 Hz of d, $J_{4,6}$ = 2 Hz, 1H, H-6), 9.0 (d, $J_{2,4}$ = 2 Hz, 1H, H-2). *Exact Mass* calcd. for $C_{10}H_{13}NO$: 163.0993; found (high resolution ms): 163.0988. Fractions 12–24 were composed primarily of **11***h* along with a trace of **13***d* which arises from aromatization of **11***h* (1.05 g, 27.0%). The 1,6-dihydropyridine **11***h* exhibited ir: 3340 (m, NH) and 1735 (s, $CO_2$) $cm^{-1}$; $^1H$ nmr δ: 0.88 (s, 9H, *t*-Bu), 3.65 (s, 3H, OMe), 3.8 (m, 1H, H-6), 5.05 (d, $J_{4,5}$ = 9.75 Hz of d, $J_{5,6}$ = 4 Hz of d, $J_{NH,5}$ = 2 Hz, 1H, H-5), 5.35 (br s, 1H, NH, exchanges with deuterium oxide), 6.48 (d, $J_{4,5}$ = 9.75 Hz of d, $J_{2,4}$ = 2 Hz, 1H, H-4), 7.5 (d, $J_{NH,2}$ = 6 Hz of d, $J_{2,4}$ = 2 Hz, 1H, H-2, collapses to a d, $J_{2,4}$ = 2 Hz after exchange with deuterium oxide). The mass spectrum did not show a $M^+$ at *m/e* 195 for $C_{11}H_{17}NO_2$ but it did exhibit a $M-2$ peak due to the facile loss of $H_2$. *Exact Mass* calcd. for $C_{11}H_{15}NO_2$: 193.1099; found (high resolution ms): 193.1096. Compond **13***d* showed: $^1H$ nmr δ: 1.36 (s, 9H, *t*-Bu), 3.95 (s, 3H, OMe), 7.46 (d, $J_{4,5}$ = 8 Hz, 1H, H-5), 8.26 (d, $J_{4,5}$ = 8 Hz of d, $J_{2,4}$ = 2 Hz, 1H, H-4), 9.2 (d, $J_{2,4}$ = 2 Hz, 1H, H-2). *Exact Mass* calcd. for $C_{11}H_{15}NO_2$: 193.1099; found (high resolution ms): 193.1096. Fractions 24–30 contained **13***c* (0.588 g, 13.43%); ir: 1690 (s, CO) $cm^{-1}$; $^1H$ nmr δ: 1.36 (s, 18H, *t*-Bu), 7.42 (d, $J_{4,5}$ = 8 Hz, 1H, H-5), 8.08 (d, $J_{4,5}$ = 8.5 Hz of d, $J_{2,4}$ = 2 Hz, 1H, H-4), 9.08 (d, $J_{2,4}$ = 2 Hz, 1H, H-2). *Exact Mass* calcd. for $C_{14}H_{21}NO$: 219.1622; found (high resolution ms): 219.1621.

*3-Methoxycarbonyl-6-*n*-butyl-1,6-dihydropyridine (**11**j), 3-methoxycarbonyl-4-*n*-butyl-1,4-dihydropyridine (**12**j), 3-methoxycarbonyl-6-*n*-butylpyridine (**13**e), 3-pentanoylpyridine (**14**a), and 3-[1-(1-hydroxy-1-*n*-butyl pentyl)]pyridine (**14**c)*

A solution of *n*-butyllithium (1.34 g, 20.1 mmol) in 8.6 mL hexane was added dropwise to a solution of methyl nicotinate (2.74 g, 20 mmol) in 60 mL dry tetrahydrofuran, under an atmosphere of nitrogen, at −65°C with stirring. The reaction was allowed to proceed for 60 min at −65°C prior to warming to 25°C. Water (30 mL) was added. Extraction with ether (4 × 50 mL), drying ($Na_2SO_4$), and removal of the solvent *in vacuo* gave an oil which was separated by preparative hplc using ether–chloroform (1:1 v/v) at a flow rate of 250 mL/min. One hundred mL fractions were collected. Removal of the solvent from the 700–775 mL fraction gave a mixture of **12***j* (0.09 g, 2.3%) and **13***e* (0.03 g, 0.8%) in a ratio of 3:1 as determined by integration of H-6 of **12***j* and H-2 of **13***e* at 6.1 and 9.18 δ respectively. The 1,4-dihydropyridine **12***j*; exhibited the following spectra; ir: 3350 (m, NH) and 1732 (s, $CO_2$) $cm^{-1}$; $^1H$ nmr δ: 0.7–1.9 (m, 9H, *n*-Bu), 3.55 (m, 1H, H-4), 3.72 (s, 3H, OMe), 4.9 (d, $J_{5,6}$ = 8 Hz of d, $J_{4,5}$ = 5 Hz of d, $J_{NH,5}$ = 2 Hz, 1H, H-5), 6.1 (d, $J_{5,6}$ = 8 Hz of d, $J_{NH,6}$ = 4.5 Hz, 1H, H-6), 7.35 (br s, 1H, NH, exchanges with deuterium oxide), 7.35 (d, $J_{NH,2}$ = 5.5 Hz, 1H, H-2, collapses to a singlet after exchange with deuterium oxide). The mass spectrum did not exhibit a molecular ion for $C_{11}H_{17}NO_2$ at *m/e* 195; it did show a $M-2$ peak due to the facile loss of $H_2$. *Exact Mass* calcd. for $C_{11}H_{15}NO_2$: 193.1100; found (high resolution ms): 193.1098. Collection of the 800–1100 mL fractions gave **11***j* (0.41 g, 10.6%); ir: 3350 (m, NH) and 1732 (s, $CO_2Me$) $cm^{-1}$; $^1H$ nmr δ: 0.88 (t, $J$ = 7 Hz, 3H, —$CH_2CH_2CH_2CH_3$), 1.1–1.8 (m, 6H, $CH_2CH_2CH_2CH_3$), 3.7 (s, 3H, OMe), 4.25 (m, 1H, H-6), 5.0 (d, $J_{4,5}$ = 9.75 Hz of d, $J_{5,6}$ = 4 Hz of d, $J_{NH,5}$ = 2 Hz, 1H, H-5), 6.0 (br s, 1H, NH, exchanges with deuterium oxide), 6.35 (d, $J_{4,5}$ = 9.75 Hz of d, $J_{2,4}$ = 2 Hz, 1H, H-4), 7.42 (d, $J_{NH,2}$ = 6 Hz, 1H, H-2, collapses to a singlet after exchange with deuterium oxide). *Exact Mass* calcd. for $C_{11}H_{17}NO_2$: 195.1258; found (high resolution ms): 195.1256; and **13***e* (0.057 g, 1.4%), which likely arises during hplc chromatography; ir: 1735 ($CO_2Me$) $cm^{-1}$; $^1H$ nmr δ: 0.75–1.9 (m, 7H, $CH_2CH_2CH_2CH_3$), 2.9 (t, $J$ = 7 Hz, $CH_2CH_2CH_2CH_3$), 3.95 (s, 3H, OMe), 7.3 (d, $J_{4,5}$ = 8 Hz, 1H, H-5), 8.25 (d, $J_{4,5}$ = 8 Hz of d, $J_{2,4}$ = 2 Hz, 1H, H-4), 9.15 (d, $J_{2,4}$ = 2 Hz, 1H, H-2). *Exact Mass* calcd. for $C_{11}H_{15}NO_2$: 193.1102; found (high resolution ms): 193.1100. The yields of **11***j* and **13***e* were calculated from the integrals for the respective H-4 and H-2 protons at 6.35 and 9.15 δ. A pure sample of **13***e* was obtained by tlc separation of the above mixture. Collection of the 1200–1400 mL fraction gave **14***a* (0.36 g, 11%) which exhibited a $^1H$ nmr spectra identical to that previously described. Removal of the solvent from the

1500–2000 mL fraction gave **14***c* (1.57 g, 35.5%) as a pale yellow oil; ir: 3250 (br m, OH) $cm^{-1}$; $^1H$ nmr δ: 0.6–2.1 (m, 18H, *n*-Bu), 4.05 (br s, 1H, OH, exchanges with deuterium oxide), 7.28 (d, $J_{4,5}$ = 8 Hz of d, $J_{5,6}$ = 5 Hz, 1H, H-5), 7.86 (d, $J_{4,5}$ = 8 Hz of d, $J_{4,6}$ = 2 Hz of d, $J_{2,4}$ = 2 Hz, 1H, H-4), 8.46 (d, $J_{5,6}$ = 5 Hz, 1H, H-6), 8.7 (d, $J_{2,4}$ = 2 Hz, 1H, H-2). *Anal.* calcd. for $C_{14}H_{23}NO$·picrate: C 53.28, H 5.82, N 12.44; found: C 53.36, H 5.84, N 12.43.

*1,3-Dimethoxycarbonyl-6-*n*-butyl-1,6-dihydropyridine (**11**k), 1-methoxycarbonyl-3-pentanoyl-4-*n*-butyl-1,4-dihydropyridine (**12**l), and 3-[1-(1-hydroxy-1-*n*-butylpentyl)]pyridine (14*c*)*

A solution of *n*-butyllithium (1.28 g, 20 mmol) in 9.2 mL hexane was added dropwise to a solution of methyl nicotinate (2.74 g, 20 mmol) in 60 mL dry tetrahydrofuran, under an atmosphere of nitrogen, at −65°C with stirring. The reaction was allowed to proceed at −65°C for 30 min after which methylchloroformate (1.27 g, 20 mmol) was added dropwise. The mixture was stirred at −65°C for a further 30 min prior to warming to 25°C. Water (30 mL) was added and the reaction mixture was extracted with ether (4 × 50 mL), the extract dried ($Na_2SO_4$), and the solvent removed *in vacuo* to give an oil which was separated by preparative hplc using methylene chloride – chloroform (4:1 v/v) at a flow rate of 250 mL/min. Collection of the 900–1000 mL fraction afforded **12***l* (0.067 g, 1.2%) as a pale yellow oil; ir: 1735 (s, $CO_2$), 1680 (s, C=O), and 1620 (s, C=C) $cm^{-1}$; $^1H$ nmr δ: 0.7–2.0 (m, 16H, $C_4$-Bu, $COCH_2CH_2CH_2CH_3$), 2.68 (t, $J$ = 7 Hz, 2H, $COCH_2CH_2CH_2CH_3$), 3.48 (m, 1H, H-4), 3.92 (s, 3H, OMe), 5.2 (d, $J_{5,6}$ = 8 Hz of d, $J_{4,5}$ = 5 Hz, 1H, H-5), 6.85 (d, $J_{5,6}$ = 8 Hz, 1H, H-6), 7.95 (s, 1H, H-2). *Exact Mass* calcd. for $C_{16}H_{25}NO_3$: 279.1823; found (high resolution ms): 279.1817. The 1000–1100 mL fraction contained a mixture of **12***l* (0.11 g, 2.0%) and **11***k* (0.068 g, 1.34%). Removal of the solvent from the 1200–1600 mL fraction gave **11***k* as a viscous oil (0.767 g, 15.6%); ir: 1712 and 1734 (CO) $cm^{-1}$; $^1H$ nmr δ: 0.65–1.7 (m, 9H, Bu), 3.78 (s, 3H, OMe), 3.86 (s, 3H, OMe), 4.8 (m, 1H, H-6), 5.6 (d, $J_{4,5}$ = 9.75 Hz of d, $J_{5,6}$ = 5.5 Hz, 1H, H-5), 6.4 (d, $J_{4,5}$ = 9.75 Hz, 1H, H-4), 7.9 (s, 1H, H-2); *Exact Mass* calcd. for $C_{13}H_{19}NO_4$: 253.1314; found (high resolution ms): 253.1306. Elution with 1000 mL ethyl acetate gave a viscous oil which was purified using 1.0 mm silica gel G with chloroform–methanol (19:1 v/v) as development solvent. Extraction of the band having $R_f$ 0.4 using warm absolute ethanol gave **14***c* (0.84 g, 18.2%) identical ($^1H$ nmr) with the sample described previously. Extraction of the band having $R_f$ 0.7 afforded methyl nicotinate (0.90 g) identical ($^1H$ nmr) with an authentic sample.

# Solute–solvent interactions in the association of hexacyanoferrate(III) with group II A cations. A calorimetric study

ROBERTO ARUGA

*Institute of Analytical Chemistry, University of Turin, via Giuria 5, 10125 Turin, Italy*

Received October 6, 1981

ROBERTO ARUGA. Can. J. Chem. **60**, 1828 (1982).

Enthalpy of association of hexacyanoferrate(III) ion with Mg(II), Ca(II), Sr(II), and Ba(II) cations has been determined by direct calorimetry. Using the equilibrium constants, Gibbs function and entropy were also obtained. Measurements were carried out in aqueous medium at 25°C and ionic strength $I = 0.1$ mol $L^{-1}$. Examination of the thermodynamic quantities obtained and calculation of the distance of closest approach between cation and anion show the presence of different desolvation processes for the metals studied. More particularly, solvent-separated ion pairs in the case of magnesium and contact pairs in the case of barium seem to be present. The presence of desolvation processes is uncertain for calcium and strontium. The $\Delta H^0$ and $\Delta S^0$ values show also an important influence from solvent-destructuring processes on ion pair formation.

ROBERTO ARUGA. Can. J. Chem. **60**, 1828 (1982).

On a déterminé, par calorimétrie directe, l'enthalpie d'association de l'ion hexacyanoferrate(III) avec les cations Mg(II), Ca(II), Sr(II) et Ba(II). On a également obtenu la fonction de Gibbs et l'entropie au moyen de la constante d'équilibre. On a effectué les mesures en milieu aqueux à 25°C et à une force ionique de $I = 0{,}1$ mol. $L^{-1}$. L'étude des quantités thermodynamiques obtenues et le calcul de la distance d'approche la plus faible entre le cation et l'anion révèle la présence d'un processus différent de désolvatation pour les métaux étudiés. Plus particulièrement, les paires d'ions séparés par le solvant dans le cas du magnésium et les paires de contact dans le cas du baryum semblent être présents. La présence du processus de dé solvatation est incertaine dans le cas du calcium et du strontium. Les valeurs de $\Delta H^0$ et de $\Delta S^0$ montrent également une influence marquée des processus de déstructuration par le solvant lors de la formation d'une paire d'ions.

[Traduit par le journal]

## Introduction

Desolvation processes of cation in complex formation and the factors which determine different orders of stability constants (1) are among the main points of interest in the study of associations of alkaline-earth metals with anions in aqueous solution.

More particularly, the problem of desolvation appears not sufficiently explained in the case of associations of these metals with hexacyanoferrate(II) and (III) anions. Jackman and Lister (2), by considering the thermodynamics of association, came to the conclusion that in the case of magnesium–hexacyanoferrate(II) pairs, the cation and anion are separated by solvent molecules, while for barium contact pairs are formed. On the contrary, in a previous paper (3), for associations of the same type, it was concluded that all pairs formed (those of barium included) are of outer-sphere type.[1] Other papers on the subject (4–6) do not seem to clarify this point.

By taking into account that enthalpy and entropy data are unavailable for the whole series from magnesium to barium with hexacyanoferrate(III) (7), it was thought interesting, in the present work, to determine these quantities by calorimetry, and to complete previous thermodynamic results for hexacyanoferrate(II) (2).

The data obtained refer to ionic strength $I = 0.1$ mol $L^{-1}$ and 25°C.

## Experimental

### *Reagents*

Mg(II), Ca(II), Sr(II), and Ba(II) nitrates were used (C. Erba RPE). The metal concentration was determined by complexometric titration with EDTA (0.1 *M* solution, C. Erba RPE). The ligand was used in the form of potassium salt (Fluka puriss. and C. Erba RPE ≥ 99%) without further purification. Its purity was checked iodometrically by Mohr's method (8). Hexacyanoferrate(III) solutions were prepared before each measurement and sheltered from light. Under these conditions they could be kept for some days without showing any evidence of decomposition. The background electrolyte was lithium nitrate for the measurement of the heat of dilution (C. Erba RPE).

### *Equipment*

Calorimetric measurements were performed at 25.00°C by an LKB 8700-2 Precision Calorimetry System and an LKB 8726-1 100 mL titration vessel, provided with a standard resistor (50 Ω) and a thermistor (2000 Ω). The accuracy of the instrument was checked by measuring the molar enthalpy of the reaction between tris(hydroxymethyl)methylamine and HCl in aqueous solution. The temperature of the titrant was kept at the temperature of the calorimeter by immersing (at least 12 h before the measure) the teflon reservoir of the titrant in the same thermostatic bath containing the calorimetric cell. The calorimeter was also equipped with a Radiometer ABU 12b autoburet for the titrant addition. The calorimetric experiments were

[1]The expression outer- or inner-sphere refers to the metal ion. With regard to the present anion all pairs, of course, are of outer-sphere type.

*Initial concentration of metal in the cell: 0.033 mol $L^{-1}$; concentration of hexacyanoferrate(III) in the titrant solution: 0.300 mol $L^{-1}$.
†Concentration of $KA^{2-}$ after the corresponding dilution experiment: $1.18 \times 10^{-3}$ mol $L^{-1}$.

performed in a room with temperature kept constant within ±0.3°C.

*Procedure*

For each metal–ligand system a set of measurements was carried out. Each measurement was performed by adding 2.507 ± 0.002 mL of potassium hexacyanoferrate(III) solution to 88.00 mL of metal nitrate solution contained in the calorimetric cell, and by measuring the corresponding heat (for the metal and ligand concentrations, see Table 1). The pH of all solutions had been previously brought to 6.0 ± 0.3. Under these conditions the following results were obtained: (*a*) the absence of hydrolysis processes of the metals; (*b*) no interaction of hexacyanoferrate(III) with proton (ferricyanic acid is completely dissociated above pH 1 (9)); (*c*) a negligible heat of neutralization between $H^+$ and $OH^-$; (*d*) an ionic strength constant at 0.1 mol $L^{-1}$ (the ionic strength variation during the addition of titrant was calculated, and was found to be lower than 0.02 mol $L^{-1}$); (*e*) the absence of triple ions of the type $M_2A^+$ ($A^{3-}$ = hexacyanoferrate(III) anion). Even with a strong excess of metal (up to 1.5 mol $L^{-1}$), the absence of these triple ions was previously demonstrated (6). Therefore, considering the weaker associating properties of $K^+$ ion with hexacyanoferrate(III) (10), species of the type KMA were also thought to be absent. For the $KA^{2-}$ pairs shown to be present, see below (Treatment of the experimental data).

The heat of dilution was measured by adding the same amount of titrant solution to 88.00 mL of lithium nitrate about 0.1 mol $L^{-1}$, at pH = 6. This salt was already used as background electrolyte in the study of associations of hexacyanoferrate(III) with several cations up to $I$ = 3 mol $L^{-1}$ (11). Tetraalkylammonium nitrate was not used, as it seems to associate more strongly with hexacyanoferrate(III) than alkaline metals (12).

*Treatment of the experimental data*

Hexacyanoferrate(III) associates to a certain extent with $K^+$. By knowing the concentration of $KA^{2-}$ after dilution and reaction (see Table 1), the heat of dissociation of these pairs was calculated, and found not negligible. So the experimental heats were corrected for both dilution and dissociation of the ligand. In these calculations the following values were used for the association between $K^+$ and $[Fe(CN)_6]^{3-}$: log $K$ = 0.85 at 25°C and $I$ = 0.1 mol $L^{-1}$ (10); $\Delta H^0$ = 0.5 kcal $mol^{-1}$. The latter value was obtained calorimetrically by Eaton *et al.* (13). Table 1 collects, as an example, the following experimental data for some measurements: concentration of species in the cell after the titrant addition ($C(MA^-)$, $C(KA^{2-})$, $C(A^{3-})$); dissociation heat of $KA^{2-}$ ($Q_{diss}$); heat corrected for dilution ($Q_c$), and for dilution and dissociation ($Q_{cc}$).

The molar enthalpies of association were obtained from the experimental heats ($Q_{cc}$) and from the concentration of the species $MA^-$, calculated using the stability constants in literature (4). These constants were obtained by conductance measurements at 25°C and $I$ = 0 mol $L^{-1}$. They were corrected to $I$ = 0.1 mol $L^{-1}$ by Davies' equation:

$$-\log f = Az^2[\sqrt{I}/(1+\sqrt{I}) - 0.2I]$$

where $A$ for water at 25°C is equal to 0.509. The $\Delta H^0$ values were calculated by the numerical method reported previously (14). The entropy variation was obtained from: $\Delta G^0 = \Delta H^0 - T\Delta S^0$.

## Results and discussion

The thermodynamics of complex formation of the present metals with hexacyanoferrate(III) and other quantities relating to the products of association are listed in Table 2.

Very few enthalpy and entropy data are available for the present associations. The following $\Delta H^0$ and $\Delta S^0$ were previously found for magnesium: −3.4 kcal $mol^{-1}$ and −16 cal $K^{-1}$ $mol^{-1}$; for barium: −3.7 and −15, respectively (5, 7). They refer to $T$ = 25°C and $I$ = 3 mol $L^{-1}$. The high ionic strength used in that work probably has a strong influence on the results, and may justify their large disagree-

*The $\bar{S}^0$($MA^-$, aq) values refer to $I$ = 0 mol $L^{-1}$.
†The results are expressed in terms of the thermochemical calorie, equal to 4.1840 J.
‡The uncertainty in each case is given as the estimated standard deviation.

ment (even in the sign) with the present ones. For calcium with hexacyanoferrate(III), Hanania and Israelian (15) obtained, by direct calorimetry, $\Delta H^0$ = 1.6 ± 0.2 kcal $mol^{-1}$ and $\Delta S^0$ = 17 ± 1 cal $K^{-1}$ $mol^{-1}$ at 25°C and $I$ = 0.07 mol $L^{-1}$. The agreement of these results with the present ones is only partial, since rather different values of log $K$ were used to calculate $\Delta H^0$ and $\Delta S^0$ in ref. 15 and in the present work.

Examination of the data in Table 2 shows that the stability of the species $M[Fe(CN)_6]^-$ is determined by the entropy factor, while enthalpy opposes association. This fact generally indicates the presence of electrostatic rather than covalent bonds. Furthermore, it indicates the prevalence of bond-breaking rather than bond-forming processes. In other words, solvent-destructuring external processes should prevail in the formation of these pairs. For both $\Delta H^0$ and $\Delta S^0$ the same sequence is followed: Mg > Ca > Sr < Ba. The same was previously observed in hexacyanoferrate(II) (2). Although it is difficult to draw certain conclusions from these data, the unexpectedly high values for barium could be due to desolvation processes of the cation (2).

For a more detailed investigation of desolvation processes of cations, the equations previously reported by Davies (16) may be useful. They allow one to correlate the association constant, $K$, with the distance of closest approach, $a$, of two ions in ion pair:

$$[1] \quad K = \frac{4\pi N}{1000}\left(\frac{|z_1z_2|e^2}{\varepsilon kT}\right)^3 Q(b)$$

$$[2] \quad Q(b) = \int_2^b x^{-4}\exp x \, dx$$

where: $x = |z_1z_2|e^2/(r\varepsilon kT)$, $b = |z_1z_2|e^2/(a\varepsilon kT)$, $N$ represents Avogadro's number, $z_1$ and $z_2$ the charge of cation and anion, $e$ the charge of electron, $k$ Boltzmann's constant, $r$ the distance between two ions in ion pair, $T$ the absolute temperature. By using the values of the thermodynamic constants of ref. 4 ($K$ = 613, 680, 709, 758 for Mg, Ca, Sr, and Ba respectively), and taking as reference $T$ = 298 K, the values of $a$ in Table 2 were obtained. The quantities $a - (r_1 + r_2)$ were determined by considering the crystal radii of cations, $r_1$, given by Pauling, and the value of 4.5 Å reported in literature (17) for the radius of hexacyanoferrate(III) ($r_2$). Then by taking into account ($a$), the water molecule has a tetrahedral structure with a center–vertex distance of about 1 Å (the O—H internuclear distance is 0.97 Å (18)); ($b$) Powell and Latimer (19) considered a thickness of 2 Å for the first hydration sphere of cations, the values of $a - (r_1 + r_2)$ in Table 2 are in accord with the presence of one water molecule between magnesium and hexacyanoferrate(III) in the corresponding pair, while they seem to indicate the presence of inner-sphere pairs for barium. The results for calcium and strontium appear more uncertain. Similar conclusions were drawn previously for the corresponding associations of hexacyanoferrate(II) (2).

Tanaka *et al.* (3), by considering the association constants of Mg, Ca, and Ba with hexacyanoferrate(III), and the corresponding interionic distances, suggested the presence of solvent separated pairs for all the metals studied. It must be noted, however, that instead of the radius of hexacyanoferrate(III), these authors considered the simple sum of Fe—C and C—N interatomic distances. In this manner, the contribution of the radius of the nitrogen atom of —C≡N group (about 1.5 Å (17)) was not taken into account.

The $\Delta S^0$ data in Table 2 provide another way of verifying these conclusions. More precisely, in order to calculate the water molecules displaced from a cation, the following empirical equation of Cobble may be used (20):

$$[3] \quad \bar{S}^0 = 49 - 99z[f/(r_1 + r_2)] + n\bar{S}(H_2O)$$

where $\bar{S}^0$ is the standard partial molal entropy of complex species; in the present case: $\bar{S}^0(MA^-, aq) = \Delta S_0{}^0 + \bar{S}^0(M^{2+}, aq) + \bar{S}^0(A^{3-}, aq)$; $z$ is the anion charge; $n$ is the number of water molecules re-

moved from the cationic sphere in complex formation; $\bar{S}(H_2O)$ is the partial molal entropy of water; $f$ is a structural constant; and $r_1$ and $r_2$ are the crystal radii of cation and anion. The expression $f/(r_1 + r_2)$ may be substituted by $1/r_{12}$, where $r_{12}$ is the actual interatomic crystal distance between cation and anion. The values of $\Delta S_0^0$ (the entropy variation referred to $I = 0$ mol $L^{-1}$) were obtained[2] from $\Delta S^0$ in Table 2. The results were as follows: 18.8, 18.4, 17.3, 18.0 cal $K^{-1}$ $mol^{-1}$ for Mg, Ca, Sr, and Ba, respectively. For $\overline{S^0}(M^{2+}, aq)$ the literature data were considered (21), while for $\overline{S^0}(A^{3-}, aq)$, from the absolute quantity previously reported (22), the value of 64.6 cal $K^{-1}$ $mol^{-1}$ was obtained. The resulting $\overline{S^0}(MA^-, aq)$ values are listed in Table 2. For the actual interatomic crystal distance ($r_{12}$) the $a$ values in Table 2 may be used.[3] Two observations must be made about the use of eq. [3]. (*a*) The $\overline{S^0}$ or $n$ values calculated by this equation are not always in agreement with the experimental results (20). (*b*) An uncertainty range exists for the calculated values of $\Delta S_0^0$. In order to eliminate the above causes of error, it seems more reasonable to calculate $n$ for the different metals by taking as reference a reaction of the same type, for which $n$ is known. Taking into account the results of the initial part in the discussion, we may assume that in the case of magnesium: $n_{Mg} = 0$, and write eq. [3] as follows:

$$[4] \quad (n_M - n_{Mg})\bar{S}(H_2O) = \overline{S^0}(MA^-, aq) - \overline{S^0}(MgA^-, aq) + 99z(1/a_{MA^-} - 1/a_{MgA^-})$$

Remembering that $\bar{S}(H_2O)$ is equal to 16.7 cal $K^{-1}$ $mol^{-1}$ (23), the values of $n_M\bar{S}(H_2O)$ and $n_M$ of Table 2 are obtained by eq. [4]. In accordance with the preceding conclusions, these values seem to suggest a contact-pair formation for barium, with the displacement of two water molecules. Desolvation processes could also take place for calcium and strontium, even though in a more limited form than for barium.

[2] $\Delta S_0^0$ was calculated by means of the equation:

$$\Delta S_0^0 = \Delta S^0 + R[T\Sigma\nu_i\partial(\ln\gamma_i)/\partial T - \Sigma\nu_i \ln\gamma_i]$$

reported by Austin, Matheson, and Parton (ref. 20, p. 370). For the values used in these calculations see also ref. 24.

[3] The present demonstration can be considered independent of the preceding one, even if the values of $a$ obtained by [1] and [2] are used. In fact, different values of $r_{12}$ ($r_{12} = a$, or $r_{12} = r_1 + r_2$) were found to have no substantial influence on the final conclusions.

# Thermochemistry of conjugation of simple cyclopropane derivatives

RICHARD FUCHS, JOHN H. HALLMAN, AND MICHAEL O. PERLMAN
*Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.*

Received January 6, 1982

RICHARD FUCHS, JOHN H. HALLMAN, and MICHAEL O. PERLMAN. Can. J. Chem. **60**, 1832 (1982).

Heats of vaporization of cyclopropyl cyanide and cyclopropylbenzene have been measured by vaporization calorimetry, and combined with liquid state heats of formation to give gaseous state heats of formation. When these compounds, cyclopropane, 1,1-dimethylcyclopropane, and cyclopropylamine are involved in (hypothetical) isodesmic reactions with ethane to give the isopropyl derivative and propane, the enthalpies of reaction are $-116.0 \pm 1.3$ kJ mol$^{-1}$, except for cyclopropylbenzene ($-103.7$ kJ mol$^{-1}$). The latter is less exothermic, in part, because of slight steric destabilization of the product, isopropylbenzene, but mainly due to 8 kJ mol$^{-1}$ stabilization of cyclopropylbenzene, which is the only of these cyclopropyl derivatives showing appreciable thermochemical stabilization.

RICHARD FUCHS, JOHN H. HALLMAN et MICHAEL O. PERLMAN. Can. J. Chem. **60**, 1832 (1982).

Faisant appel à la calorimétrie de vaporisation, on a mesuré les chaleurs de vaporisation du cyanure de cyclopropyle et du cyclopropylbenzène et on les a combinées aux chaleurs de formation à l'état liquide pour obtenir les chaleurs de formation à l'état gazeux. Quand ces composés: le cyclopropane, le diméthyl-1,1 cyclopropane et la cyclopropylamine sont impliqués dans des réactions isodesmiques (hypothétiques) avec l'éthane pour conduire au dérivé isopropylique et au propane, les enthalpies de réaction sont de $-116{,}0 \pm 0{,}3$ kJ mol$^{-1}$, sauf pour le cyclopropylbenzène ($-103{,}7$ kJ mol$^{-1}$). Ce dernier est moins exothermique, en partie à cause de la légère déstabilisation stérique du produit, l'isopropylbenzène, mais principalement à cause de la stabilisation de 8 kJ mol$^{-1}$ cyclopropylbenzène, qui est le seul de ces dérivés cyclopropyles à montrer une stabilisation thermochimique appréciable.

There is a growing feeling among theorists that molecular parameters can be more accurately calculated than measured. The results of a calculation may indeed be closer to the "truth" than the corresponding experimental measurement, but the significance of the calculation may be limited by our inability to establish error limits accurately by experiment. It is therefore of the utmost importance that the best possible experimental measurements be performed. The alternative is devolution of chemistry from an experimentally verifiable science to the status of a religion, based on articles of nondemonstrable faith.

When a group, X, is substituted into a molecule, Y—H, we may consider the interactions between Y and X in the resulting molecule, Y—X, which lead to alteration in spectra, bond lengths, etc. But the most significant question is whether special interactions between X and Y lead to a *thermochemically demonstrable decrease in the energy of Y—X* relative to reasonable models.

For many years data have been presented suggestive of "double bond character" of the cyclopropane ring (1), but evidence for significant conjugation is strongest for cationic reaction intermediates (2) and excited states, rather than for the ground states of neutral cyclopropane derivatives. We have recently completed a decade of substantial theoretical interest in conjugative interactions of the cyclopropane ring. Variation in ring bond lengths with the nature of the attached group have been examined (3–8), and often indicate substantial substituent-ring conjugation (3–7). Hoffmann (9) attributed the stabilization of norcaradienes by cyano and phenyl substituents (relative to the isomeric cycloheptatrienes) to π-type cyclopropane-substituent conjugation. *Ab initio* calculations by Hehre (10) predicted a 13.4–14.6 kJ mol$^{-1}$ stabilization of vinylcyclopropane. Dill, Greenberg, and Liebman (11) recently made extensive calculations on small ring and bicyclic systems with a variety of substituents. They predict the following stabilizations of cyclopropane by substituents: $CH_3$, 10.0 kJ mol$^{-1}$; CN, 24.3 kJ mol$^{-1}$; and $NH_2$, 12.1 kJ mol$^{-1}$; but note that STO-3G calculations appear to overestimate stabilizations. It has been suggested (11) that stabilization or destabilization results not only from the ring-substituent bond character, but also from an increase or decrease in ring strain. It is the sum of these factors which is calculated, and is experimentally measurable.

What of the experimental thermochemical data previously available? We note several problems. (*a*) The data are few. (*b*) Some "experimental" values of gaseous state heats of formation ($\Delta H_f^0$(g)) are based on estimated heats of vaporization (11) (methylcyclopropane). (*c*) Some $\Delta H_g^0$(g) values are based on defective values of $\Delta H_v^0$ (12) (cyclopropyl cyanide).

It is the objective of the present study to provide $\Delta H_f^0$(g) data of sufficient accuracy that a critical assessment of cyclopropane-substituent thermo-

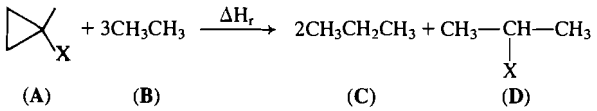
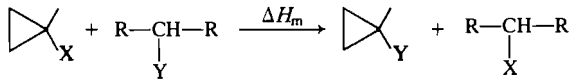
chemical stabilization can be made. We will examine the results by two methods. The first involves the (hypothetical) isodesmic reaction (13), or group separation method, as recently modified (11, 14):



(A) (B) (C) (D)

where $\Delta H_r = 2\Delta H_f^0(g)$ (C) + $\Delta H_f^0(g)$ (D) − $\Delta H_f^0(g)$ (A) − $3\Delta H_f^0(g)$ (B). The reaction is exothermic due to the ring strain in (A), and $-\Delta H_r$ is the strain energy. $\Delta H_r$ will be the same where X = H and all other nonconjugating substituents, but $\Delta H_r$ will be less exothermic when a stabilizing interaction of X and the ring occurs, or more exothermic if (A) is destabilized.

The second method we term the metathetical relationship. Here substituents are exchanged by conjugating and equivalent, but nonconjugating systems:



conjugated nonconjugated nonconjugated nonconjugated
(A) (B) (C) (D)

(B) can be the 2-propyl, cyclopentyl, or cyclohexyl derivative, with Y = H or other nonconjugating substituent, and $\Delta H_m = \Delta H_f^0(g)$ (C) + $\Delta H_f^0(g)$ (D) − $\Delta H_f^0(g)$ (A) − $\Delta H_f^0(g)$ (B). The reaction is thermoneutral if (A) is unstabilized, endothermic if (A) is stabilized, and exothermic if (A) is destabilized.

## Experimental

The technique and apparatus for measurement of calorimetric heats of vaporization (15) have been considerably changed in the present study, but the results with test substances are in excellent agreement with our earlier work, and with the best literature values (16). The vaporization calorimeter is again a coiled tube embedded in a copper disc heat sink fitted with a thermistor and heater, and enclosed in a vacuum jacketed solution calorimeter. The coiled tube is 0.476 cm (3/16 in.) od nickel tubing rather than copper, and the inlet and outlet stopcocks are Hamilton valves made of Teflon and Kel-F. Nitrogen flow is established by a low range digital mass flow controller (0–10 cc/min, Porter Instrument Co.). Vacuum below 1.3 kPa (10 Torr) is furnished by a vacuum pump, and by an aspirator with a drying column at higher pressures. Well dried 100 μL samples are introduced volumetrically (microliter syringe, constant stroke adapter), and the mass of separate samples is determined with a semimicro balance, using air buoyancy corrections. A major change from our earlier procedure (15) is introduction of the sample into the (25.00°C) calorimeter at a temperature at which no net heating or cooling effect occurs in the absence of vaporization. Surprisingly, these conditions are met with the sample and syringe jacket at 22.00 ± 0.01°C, and the 30 cm Teflon needle (air) temperature at 23.00 ± 0.05°C. We presume that the delivered sample is warmed by frictional heating and by handling of the needle. The previously used heat capacity correction for the sample is, therefore, no longer required. The validity of this procedure is verified not only by the excellent agreement of measured $\Delta H_v^0$ values of test substances with literature values, but also by the observation that nonvolatile samples (hexadecane introduced under conditions suitable for the evaporation of hexane) produce random temperature changes no greater than $1–2 \times 10^{-4}$ K. We have also observed that the overall cycle of closing the exit stopcock to the vacuum system, refilling the calorimeter with dried nitrogen or air to atmospheric pressure, opening the entrance stopcock to the atmosphere for 30 s (the time required for sample introduction) and reestablishment of the original nitrogen flow and vacuum produces negligible change ($< 1 \times 10^{-4}$ K) in the calorimeter temperature.

Sample evaporation occurs over a 14–20 min period, and the cooling effect is periodically compensated by short (8 or 10 s) heating periods (total 75–175 s), such that temperature excursions of 0.06–0.08 K occur symmetrically about the equilibrium temperature of the calorimeter. When no further evaporation cooling occurs, the block is brought to the original temperature ($\pm 1 \times 10^{-4}$ K). The calorimeter temperature is monitored for an additional 4 min to establish that the final and initial equilibrium temperatures are identical. The temperature measurement system consists of a thermistor (2000 Ω) imbedded in the copper heat sink, as the unknown resistance of a Wheatstone bridge, the output of which is displayed on a digital multimeter (Keithley 177, 19.999 mV full scale). The multimeter analog output is plotted on a potentiometer recorder. The heating system consists of a Type RN55C metal film resistor (822.8 Ω), a timed constant current source (17) with an output of 19.85 mA, and monitored by a digital milliammeter, and an adjustable interval timer based on the 555 integrated circuit. Operation of the vaporization calorimeter was verified by measurements of compounds with well established values of $\Delta H_v^0$ (16, 18): pentane, 26.61 ± 0.09 kJ mol$^{-1}$ (reported, 26.74 ± 0.21); hexane, 31.54 ± 0.18 (31.55 ± 0.04); octane, 41.44 ± 0.07 (41.51 ± 0.04); butanenitrile, 39.22 ± 0.11 (39.29 ± 0.08); butyl acetate, 43.66 ± 0.09 (43.60 ± 0.21); and isopropylbenzene, 45.12 ± 0.02 (45.15 ± 0.04).

Cyclopropyl cyanide (Fluka) and cyclopropylbenzene (Aldrich) were fractionally distilled. Purity was established by gas chromatography (99.90% and 99.70%, respectively), using a Shimadzu Mini 2 gc with a glass lined system, a 30 m × 0.25 mm id SE-30 silica capillary column, and a Hewlett-Packard 3390A integrator.

## Results and discussion

### *Heats of vaporization and gaseous heats of formation*

The standard heat of vaporization at 25°C of cyclopropyl cyanide (the mean of six determinations) is 41.94 ± 0.11 kJ mol$^{-1}$. A previously reported value based on vapor pressure measurements (12) is 39.8 ± 0.4 kJ mol$^{-1}$. However, a number of $\Delta H_v^0$ values published in this article appear to be considerably too low (by 12 kJ mol$^{-1}$ for ethyl benzoate, 8.3 kJ mol$^{-1}$ for cyclohexyl cyanide, etc.).

We are unaware of any previous $\Delta H_v^0$ measurements on cyclopropylbenzene. The mean of our

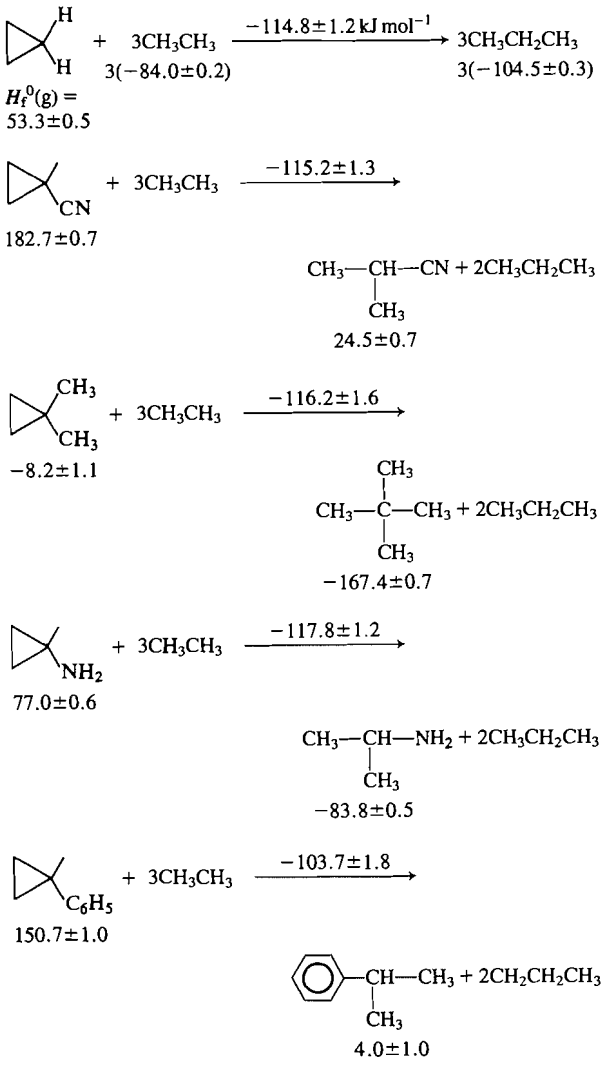
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

four determinations is 50.22 ± 0.10 kJ mol$^{-1}$ where the indicated uncertainty is twice the standard deviation.

Based on the liquid state heats of formation (16) of cyclopropyl cyanide (140.8 ± 0.7 kJ mol$^{-1}$), and of cyclopropylbenzene (100.5 ± 1.0 kJ mol$^{-1}$) one may derive gaseous state heats of formation of 182.7 ± 0.7 kJ mol$^{-1}$ and 150.7 ± 1.0 kJ mol$^{-1}$, respectively, where $\Delta H_f^0(g) = \Delta H_f^0(l) + \Delta H_v^0$. Other values of $\Delta H_f^0(g)$ below are taken from the Pedley–Rylance Tables (16).

*Enthalpies of isodesmic reactions*

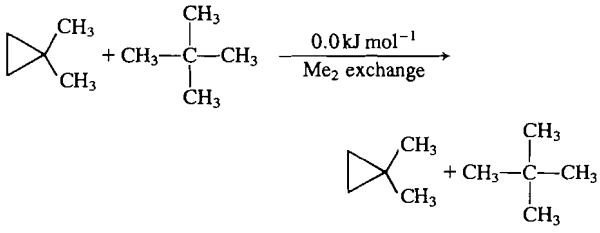
The following are isodesmic reactions of cyclopropane and the four simply substituted cyclopropane derivatives for which *experimental* values of $\Delta H_f^0(g)$ are now known. The values are in kJ mol$^{-1}$.



The mean of the first four heats of reaction is −116.0 ± 1.3 kJ mol$^{-1}$ (−27.7 ± 0.4 kcal/mol). Only the reaction of cyclopropylamine differs from the mean value by more than the experimental uncertainty; the difference is only 0.6 kJ mol$^{-1}$ (0.1 kcal/mol) larger than the uncertainty, and is of doubtful significance. By contrast, the reaction of cyclopropylbenzene is 12.3 kJ mol$^{-1}$ less exothermic than the mean of the other four reactions. Of this, 4.4 kJ mol$^{-1}$ results from steric strain in the product isopropylbenzene (the isodesmic reaction of isopropylbenzene with ethane to give isobutane and neopentane is more exothermic by this amount than the corresponding reactions of benzene, toluene, and ethylbenzene). The remaining 7.9 kJ mol$^{-1}$ results from conjugative stabilization in cyclopropylbenzene.

*Enthalpies of metathetical reactions*

An alternative but related method of detecting thermochemically significant interactions involves metathetical reactions. Exchange of substituents between two nonconjugated systems should be thermally neutral ($\Delta H = 0$), but destruction of a conjugated molecule leads to an endothermic reaction.



The other four cyclopropane derivatives can be similarly involved in metathetical reactions: cyclopropyl cyanide (CN, H exchanged for $Me_2$), $\Delta H$ = 1.0 ± 1.6; cyclopropane, 1.4 ± 1.4; cyclopropylamine, −1.6 ± 1.5; and cyclopropylbenzene, 12.5 ± 1.9 kJ mol$^{-1}$. The first four reactions have enthalpies which, essentially within the uncertainty limits, are zero. This again demonstrates that no stabilizing interactions occur in cyclopropyl cyanide, 1,1-dimethylcyclopropane, and cyclopropylamine, which are not also present in (unconjugated) cyclopropane. Similar conclusions would be drawn if cyclopropane substituents were exchanged with cyclopentane. Data for cyclopentane derivatives are less available and have larger uncertainties than the data for propane derivatives used above. The enthalpy of reaction of cyclopropylbenzene (12.5 kJ mol$^{-1}$) is in excellent agreement with the results of the isodesmic reaction, and indicates 8.1 kJ mol$^{-1}$ stabilization of cyclopropylbenzene.

## Conclusions

Studies of cyclopropane derivatives (3–7, 9–11) experimentally and by calculations have generally indicated appreciable ring-substituent interactions, and substantial stabilization has been predicted for many of the substituted compounds relative to unsubstituted cyclopropane. An exception is 1,1-dibromo-*trans*-2,3-diphenylcyclopropane (8), where the phenyl–cyclopropane interaction is apparently not strong enough to require a conjugating conformation in the crystal structure. However, *trans*-2-(*p*-nitrophenyl)cyclopropyl methyl ketone (19), the only unhindered cyclopropylbenzene derivative of known crystal structure, has the rings very close to the bisected (conjugated) conformation.

Many of the conclusions of previous studies regarding the stabilization of cyclopropane derivatives cannot be confirmed by the present experimental thermochemical measurements. Perhaps compounds such as cyclopropyl cyanide have a substituent-ring stabilizing $\pi$ interaction of 5–10 kJ $mol^{-1}$, together with destabilization of other orbitals and increased ring strain amounting to 4–9 kJ $mol^{-1}$. If this were the case, the very small net stabilization might not be observed thermochemically. We feel it is presently unwise to use calculations, structural data, and other nonthermochemical information to draw quantitative thermochemical conclusions about small effects.

# Polymer supported enantioselective reactions. II. α-Methylation of cyclohexanone[1]

COLIN R. MCARTHUR,[2] PAUL M. WORSTER, JI-LONG JIANG, AND CLIFFORD C. LEZNOFF[2]

*Department of Chemistry, York University, Toronto, Ont., Canada M3J 1P3*

Received January 4, 1982

COLIN R. MCARTHUR, PAUL M. WORSTER, JI-LONG JIANG, and CLIFFORD C. LEZNOFF. Can. J. Chem. **60**, 1836 (1982).

Insoluble cross-linked copolymers of styrene and 1% divinylbenzene with covalently bonded (*S*)-2-aminoalkoxy groups were used in the enantioselective α-methylation of cyclohexanone through the corresponding imines. Enantiomeric excesses of 94% of (*S*)-2-methylcyclohexanone were observed on methylation at 20°C. An analogous optically active 2-aminoalkyl benzyl ether, under otherwise identical conditions, resulted in a lower enantiomeric excess (49%) with selectivity approaching that of the polymer only at −78°C.

COLIN R. MCARTHUR, PAUL M. WORSTER, JI-LONG JIANG et CLIFFORD C. LEZNOFF. Can. J. Chem. **60**, 1836 (1982).

On a utilisé des copolymères de styrène et divinylbenzène réticulés à 1% et portant des groupes (*S*)-amino-2 alkoxy liés par des liaisons covalentes lors pour l'α méthylation énantiosélective de la cyclohexanone par l'intermédiaire des imines correspondantes. On a observé un excès énantiomérique de 94% de (*S*)-méthyl-2 cyclohexanone lors de la méthylation à 20°C. Un éther amino-2 alkyl benzylique analogue optiquement actif conduit dans des conditions identiques, à un excès énantiomérique de seulement 49%, la sélectivité ne se rapproche de celle du polymère qu'à −78°C.

## Introduction

A number of advantages over the use of the solution phase have been identified in the use of solid, insoluble polymers as media for certain operations in synthesis. Considerable documentation exists on the usefulness of the property of insolubility of such media for facilitating separations and allowing for automated processes. In addition, other properties of these systems such as the decreased interaction between reactant moieties, a phenomenon which simulates high dilution, have been recognized (for reviews see ref. 1).

Speculation that a decrease in translational and conformational mobilities of moieties covalently bonded to cross-linked polymers, relative to their solution analogues, might enhance stereoselectivities of certain types of reactions led us to investigate the applicability of this type of medium to asymmetric syntheses (2). The situation might bear some general resemblance to that at the reactive sites of some enzymes. In the only research of which we are aware, prior to our work, into an example of an asymmetric synthesis on a polymer support, it was suggested that enhancement of the enantioselectivity observed relative to an analogous reaction in solution may result from conformational rigidity in the cross-linked polymer (3).

Enantioselectivities in solution may be considerably influenced by temperature (4). In particular, in the α-methylation of the metaloenamine formed by reaction of isopropylmagnesium bromide with the imine derived from cyclohexanone and (*R*)-1-butoxy-2-aminobutane, the enantiomeric excess of (*R*)-2-methylcyclohexanone formed after hydrolysis was 81% at −78°C, but only 20% at 65°C (5). In similar examples of the enantioselective alkylation of cyclohexanone imines, alkylation conditions routinely include temperatures of −98 and −78°C (6). Additional examples have been cited (7).

It seemed conceivable that the use of polymeric media might allow highly enantioselective reactions to occur at ambient temperatures, perhaps with concomitant increases in reaction rates relative to those observed in solution at low temperatures. Further, the separation of the optically active product after cleavage from the asymmetric induction sites on the polymer would be accomplished completely and easily by a simple filtration. At the same time, the insoluble polymer would be easily recovered and would be expected to be reusable.

In a preliminary article (2), we reported the use of a Merrifield polymer (**1**) bonded through ether linkages to (*S*)-2-amino-1-propyl groups. Condensation with cyclohexanone to give the corresponding polymer-bound ketimine followed by metalation, alkylation, and hydrolysis afforded optically active 2-alkylcyclohexanones in high enantiomeric excesses as well as high chemical yields and purities. In this paper we present the details of these and related studies on the enantioselective α-methylation of cyclohexanone using polymer-bound chiral amines.

## Results and discussion

*Bonding* (S)-*2-aminoalkoxy groups to polystyrene*

(*S*)-2-Aminopropanol (**2**), (*S*)-2-aminobutanol (**3**), and (*S*)-2-amino-3-phenylpropanol (**4**) were converted, to prevent *N*-substitution by the polymer, to their corresponding *N*-phthaloyl derivatives (**5***a*, **5***b*, and **5***c* respectively) by reaction with *N*-(ethoxycarbonyl)phthalimide (8). The corresponding potassium alkoxides reacted with **1** to give the corresponding (*S*)-2-phthalimidoalkoxymethylated chloromethylated polystyrenes (**6***a*, **6***b*, and **6***c* respectively) as outlined in Scheme 1. The loadings of unreacted chloromethyl groups in **6** were determined quantitatively by reaction with pyridine, followed by analysis of the solution phase for chloride (9). These chloromethyl groups would be expected to become involved in subsequent steps in the reaction sequence to cause decreases in enantioselectivities. Such expectations were borne out experimentally as will be described.

Accordingly, the chloromethyl groups of **6** were converted to unreactive methyl groups by treatment with sodium iodide and then with tributyltin hydride. The resulting polymers (**7**) upon hydrazinolysis afforded polystyrene derivatives functionalized only with (*S*)-2-aminoalkoxy groups (**8**).

*Enantioselective methylation of cyclohexanone using polymers 8*

Condensation of polymers **8** with cyclohexanone gave the corresponding ketimines (**9**) (Scheme 2). The loadings of the ketimine functions on the polymers were in the range of 0.5 to 0.6 mmol/g as determined by hydrolysis to regenerate cyclohexanone and quantitative analysis of the solution phase by gas chromatography.[3]

Methylation of polymers **9** by reaction of the corresponding lithioenamines with iodomethane afforded the corresponding 2-(2-methylcyclohexyl-

SCHEME 2

[3]Commercially available Merrifield polymer, used in numerous other reported syntheses, affords loadings in this range. Such loadings would be expected to minimize the potential complication of site to site interactions in interpreting results, a factor which we wished to avoid at this stage of our studies.

TABLE 1. Enantioselective α-methylations of polymeric imines, **9**, of cyclohexanone at 20°C

| Polymer | Loading of imine (mmol/g) | Yield of 2-methylcyclohexanones (%) | Enantiomeric excess* of (*S*)-2-methylcyclohexanone (%) |
|---|---|---|---|
| **9***a* | 0.57 | 32.5 | 92 |
| **9***b* | 0.56 | 86 | 94 |
| **9***c* | 0.54 | 87 | 94 |

*Based on optical rotation of pure (*R*)-2-methylcyclohexanone at −16.4°C (5).

TABLE 2. Comparison of **6***c* and **7***c* in subsequent enantioselectivities

| Parameter | Starting polymer **6***c* | Starting polymer **7***c* |
|---|---|---|
| $ClCH_2$ loading (mmol/g) | 0.4 | 0 |
| Imine loading (mmol/g) | 0.84 | 0.54 |
| Yield of 2-methylcyclohexanones (%) | 46 | 87 |
| Enantiomeric excess of (*S*)-2-methylcyclohexanone (%) | 32 | 94 |

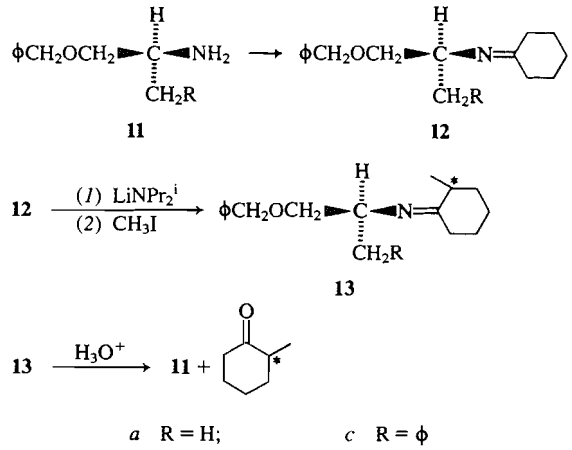
idene)aminoalkoxymethylated polymers (**10**) which, on hydrolysis released (*R*)- and (*S*)-2-methylcyclohexanone to the solution phase. The predominant product under all of the variations in conditions studied (temperature, and the structure of R) was (*S*)-2-methylcyclohexanone[4] in enantiomeric excesses of >90%.

Results of methylation at ambient temperature (20°C) are shown in Table 1. In the methylation of **9***a* and subsequent hydrolysis, the chemical yield was much lower than was the case with **9***b* and **9***c* although, in all three systems, enantioselectivities appear in the same range (>90%).

The polymeric derivative **6***c* with chloro groups remaining after reaction of **1** with **5***c* was treated in the same sequence as that described above for polymers **7**. The 2-methylcyclohexanones were produced with the (*S*)-enantiomer in only 32% enantiomeric excess. The results are tabulated in Table 2. It would appear that the chloromethyl groups in **6***c* reacted in the hydrazinolysis step, and that the resulting hydrazyl groups formed polymer-bound cyclohexanone hydrazone functions which could methylate only non-enantioselectively.

*Comparison of polymer-bound systems with analogous systems in solution*

For quantitative comparison of asymmetric induction in the polymeric systems with analogous systems in solution, (*S*)-2-aminopropyl benzyl ether (**11***a*) and (*S*)-2-amino-3-phenylpropyl benzyl ether (**11***c*) were prepared. Conversion to the corresponding cyclohexanone imines (**12**) and then to their 2-methyl derivatives (**13**), followed by hydrolysis, afforded product mixtures from which the 2-methylcyclohexanones could be separated (Scheme 3). The separation, of course, was not as conveniently affected as was the case using the polymeric system.



SCHEME 3

Much lower enantioselectivities (~50%) were observed from the methylations at 20°C using the systems in solution (Scheme 3) than were observed (>90%) using the analogous polymeric systems (Scheme 2). As might be expected, the enantioselectivities in solution increased as the temperature of the methylation reaction was decreased. Thus, for example, the enantiomeric excess of (*S*)-2-methylcyclohexanone from methylation of **11***c* in solution at −78°C was 85% compared with 49% at 20°C. In the polymeric systems, the enantioselectivities appeared to increase slightly (being of course already ~94% at ambient temperature) as the temperature was decreased. The chemical yields in solution at the temperatures required for enantioselectivities that approach those obtained using the polymer are much lower (compare 58%

[4]In all experiments, the identity of the 2-methylcyclohexanone produced was confirmed by comparison with an authentic sample through the use of ir, nmr, and vpc mass spectroscopy. The absence of polymethylated derivatives such as 2,6-dimethyl- and 2,2,6-trimethylcyclohexanone was confirmed by comparison of the vpc using authentic samples.

| 1 | 0.53 | 80 | 96 |

from **11***c* at −78°C with 87% from **9***c* at 20°C). The results are summarized in Table 3.

*Recycling the regenerated polymer* **8**c

The facile separation of the polymer used for the optical induction reaction is an obvious technical advantage over the homogeneous system in solution. The polymer may also be recycled. Preliminary experiments using recycled **8***c* indicated no decrease in the enantioselectivity of the methylation reaction (Table 4). There may be some decrease in chemical yield (87% to 80%) although this variation may be within experimental error. Additional experiments are required to examine more thoroughly this practical aspect of the use of polymeric systems in asymmetric syntheses.

## Conclusions

High enantioselectivities have been observed in the α-methylation, at 20°C, of cyclohexanone imines formed from cross-linked polystyrene functionalized with optically active 2-aminoalkoxy groups. Advantages over analogous systems in solution include facility in handling, separating, and recycling regenerated polymer, as well as higher enantioselectivities.

## Experimental

Optical rotations were determined using a Carl Zeiss polarimeter, no. 372140. All other instrumentation and general procedures are the same as described previously in a publication from these laboratories (10).

(S)-*2-Phthalimido-1-propanol (*5a)

A solution of (*S*)-2-amino-1-propanol (**2**) (4.625 g, 62.5 mmol) in tetrahydrofuran (10 mL) was added to a stirred slurry of *N*-(ethoxycarbonyl)phthalimide (**8**) (13.94 g, 62.74 mmol) in tetrahydrofuran (50 mL) at 0°C (ice–water bath). After 5 min, the bath was removed and the mixture stirred overnight at ambient temperature. After removal of the solvent under reduced pressure (boiling water bath), distillation (bulb-to-bulb, 0.1 Torr) gave ethyl carbamate (3.98 g, 71% yield). The residue was crystallized from a solution of toluene (25 mL) and hexane (10 mL) to give **5***a* (10.46 g, 74% yield); mp, 79–81°C; nmr, δ: 7.80 (d, 4H arom.), 4.30–4.66 (m, 1H), 3.80–4.10 (m, 2H), 3.10 (m, OH), and 1.40 (d, 2H) ppm. *Anal.* calcd. for $C_{11}H_{11}NO_3$: C 64.38, H 5.37, N 6.82; found: C 64.22, H 5.48, N 6.89.

(S)-*2-Phthalimido-1-butanol (*5b)

In a manner similar to that described above for **5***a*, (*S*)-2-amino-1-butanol (**3**) was converted to **5***b* (74% yield); oil; nmr, δ: 7.80 (d, 4H), 4.0–4.33 (m, 3H), 3.10 (m, OH), 1.70–2.10 (m, 2H), and 1.00 (t, 3H) ppm. *Anal.* calcd. for $C_{12}H_{13}NO_3$: C 65.75, H 5.94, N 6.39; found: C 65.69, H 6.31, N 6.43.

(S)-*2-Phthalimido-3-phenyl-1-propanol (*5c)

In a manner similar to that described for **5***a*, (*S*)-2-amino-3-phenyl-1-propanol (**4**) was converted to **5***c* (82% yield); mp 105–106°C; nmr, δ: 7.80 (d, 4H), 7.33 (s, 5H), 4.50–4.90 (m, 1H), 4.0–4.33 (m, 2H), 3.30 (d, 2H), and 2.90 (m, OH) ppm. *Anal.* calcd. for $C_{17}H_{15}NO_3$: C 72.59, H 5.34, N 4.98; found: C 72.64, H 5.57, N 4.94.

(S)-*2-Phthalimido-1-propoxymethylated chloromethylated polystyrene (*6a)

To a slurry of 1.006 g (25.02 mmol) of potassium hydride (washed with hexane) and tetrahydrofuran (100 mL) was added, with stirring, a solution of (*S*)-2-phlthalimido-1-propanol (**5***a*) (3.746 g, 18.27 mmol), dibenzo-18-crown-6 (200 mg, 0.56 mmol), and hexamethylphosphoric triamide (10 mL). After 1 h at ambient temperature, a slurry of chloromethylated polystyrene (**1**) (22.92 g, 23.30 mequiv. Cl) in tetrahydrofuran (50 mL) was added. The reaction mixture was stirred and heated under reflux for 48 h. The polymer was separated by filtration and washed successively with solutions of tetrahydrofuran and ethanol (1:1), tetrahydrofuran and methanol (1:1), and then with ether. The polymer was dried to constant weight under reduced pressure to give **6***a* (22.393 g); ir, ν(C=O): 1710 $cm^{-1}$; Cl(9), 0.5 mequiv./g.

(S)-*2-Phthalimido-1-butoxymethylated chloromethylated polystyrene (*6b)

In a manner similar to that described for **6***a*, chloromethylated polystyrene, using (*S*)-2-phthalimido-1-butanol (**5***b*), was converted to **6***b*; ir, ν(C=O): 1710 $cm^{-1}$; Cl(9), 0.45 mequiv./g.

(S)-*2-Phthalimido-3-phenylpropoxymethylated chloromethylated polystyrene (*6c)

In a manner similar to that described for **6***a*, chloromethylated polystyrene, using (*S*)-2-phthalimido-3-phenyl-1-propanol (**5***c*), was converted to **6***c*; ir, ν(C=O): 1710 $cm^{-1}$; Cl(9), 0.4 mequiv./g.

(S)-*2-Phthalimido-1-propoxymethylated methylated polystyrene (7*a)

To a solution of sodium iodide (13.182 g, 87.88 mmol) in acetone (150 mL) was added **6***a* prepared as described above (21.093 g, 10.55 mequiv. Cl). The mixture was stirred under reflux for 48 h and then allowed to cool to ambient temperature. The polymer was separated by filtration and washed successively with acetone, tetrahydrofuran, ethanol, methanol, aqueous methanol, methanol, and finally ether and then dried under reduced pressure to constant weight to give a polymer (22.018 g). To a stirred slurry of this polymer in tetrahydrofuran (150 mL) was added tributyltin hydride (6 mL, 22.74 mmol). The reaction mixture was heated under reflux for 48 h. The polymer was then removed by filtration and washed successively with the solvents described above and dried to constant weight to give **7***a* (21.903 g); ir, ν(C=O): 1710 $cm^{-1}$; Cl(9) not detected.

(S)-*2-Phthalimido-1-butoxymethylated methylated polystrene (7*b) *and (S)-2-phthalimido-3-phenyl-1-propoxymethylated methylated polystyrene (7*c)

Procedures similar to that described above for **7***a* were used to prepare **7***b* and **7***c* from **6***b* and **6***c*, respectively.

(S)-*2-Amino-1-propoxymethylated polystyrene (8*a), (S)-*2-amino-1-butoxymethylated polystyrene (8*b), *and* (S)-*2-amino-3-phenylpropoxymethylated polystyrene (8*c)

To a slurry of either polymer **7***a*, **7***b*, or **7***c* prepared as described above (ca. 20 g) in a solution of tetrahydrofuran (100 mL) and ethanol (100 mL) was added, with stirring, aqueous 95% hydrazine (10 mL). The reaction mixture was stirred for 16 h at ambient temperature. The insoluble polymer was then removed by filtration and washed successively with tetrahydrofuran, acetone, ethanol, methanol, aqueous methanol, and then ether to give, after drying under reduced pressure to constant weight (ca. 20 g), polymers **8***a*, **8***b*, or **8***c* respectively. Each exhibited an ir spectrum with absorptions at 3300 $cm^{-1}$ assignable to amino groups.

(S)-*2-Cyclohexylideneamino-2-propoxymethylated polystyrene (9a)*

A slurry of **8***a* prepared as described above (20 g, 10 mequiv. $NH_2$) in a solution of cyclohexanone (8.64 g, 88 mmol) in benzene (200 mL) was heated under reflux in a Soxhlet extractor in which the thimble contained 3 Å molecular sieves. The polymer was removed by filtration and washed successively with tetrahydrofuran, methanol, and then ether to give, after drying under reduced pressure to constant weight (20 g), **9***a*.

(S)-*2-Cyclohexylideneamino-1-butoxymethylated polystyrene (9*b) *and* (S)-*2-cyclohexylideneamino-3-phenyl-1-propoxymethylated polystyrene (9*c)

In a similar manner to that described above for the preparation of **9***a*, the polymers **8***b* and **8***c* were converted respectively to **9***b* and **9***c*.

*Determination of loadings of* **9**a, **9**b, *and* **9**c

A slurry of polymer **9***a* (2.983 g) in a buffer solution (14 mL) prepared from acetic acid (25 mL), sodium acetate (10.8 g), and water (25 mL), and methylene chloride (15 mL) was stirred at ambient temperature for 0.5 h. The methylene chloride layer was washed with water, then saturated sodium bicarbonate solution, and dried over magnesium sulfate. Removal of methylene chloride by distillation afforded a liquid residue (0.1667 g); gc, one sharp peak (tr, 2.5) assignable to cyclohexanone (>99% purity), and representing 0.57 mmol per g of **9***a*.

By the same method, cyclohexanone was obtained from polymers **9***b*, and **9***c* in amounts representing loadings of 0.56 mmol and 0.54 mmol/g of **9***b* and **9***c* respectively.

*2-(2-Methylcyclohexylideneamino)-1-propoxymethylated polystyrene (10a), 2-(2-methylcyclohexylideneamino)-1-butoxymethylated polystyrene (10*b), *and 2-(2-methylcyclohexylideneamino)-3-phenyl-1-propoxymethylated polystyrene (10*c)

To a stirred slurry of either **9***a*, **9***b*, or **9***c* (ca. 10 g, ca. 5.4 mequiv.) in tetrahydrofuran was added, *at 0°C* (ice–water bath), with stirring, diisopropylamine (2.0 mL, 14 mmol) followed by a solution of butyllithium (1.55 *M* in hexane, 10 mL, 15.5 mmol). The reaction mixture was stirred at either ambient temperature (*20°C*) or *0°C* (ice bath) for 20 h, or at *−78°C* (Dry-Ice bath) for 40 h. Then, iodomethane (2.0 mL, 40 mmol) was added, dropwise, and the reaction mixture stirred for 8 h while the same temperature was maintained. The polymer was removed by filtration and washed successively with tetrahydrofuran, methanol, and finally ether, and then dried under reduced pressure to constant weight (ca. 10 g) to give **10***a*, **10***b*, or **10***c* respectively.

*Formation of* (R)- *and* (S)-*2-methylcyclohexanone with regeneration of polymers 8*a, *8*b, *and 8*c

A slurry of polymer **10***a* prepared *at 20°C* as described above (5.231 g 2.98 mequiv.) in a buffer solution (15 mL) prepared from acetic acid (25 mL), sodium acetate (10.8 g), and water (25 mL), and methylene chloride (15 mL) was stirred at ambient temperature for 0.5 h. The methylene chloride layer was separated and washed successively with water (15 mL), saturated sodium bicarbonate solution (15 mL), 5% aqueous sodium chloride solution, and dried over magnesium sulfate. Removal of methylene chloride by distillation afforded a liquid residue (109 mg); gc, one sharp peak (>99%) assignable to (*R*)- and (*S*)-2-methylcyclohexanone (33% yield); polarimetric analysis $[\alpha]_D$ 15.2° (*c* 0.694, MeOH) (lit. (5) $[\alpha]_D$ 16.4°), 92% enantiomeric excess of (*S*)-2-methylcyclohexanone.

In a similar manner, polymer **10***a* prepared *at 0°C* as described above gave (*R*)- and (*S*)-2-methylcyclohexanone in 50% yield and 94% enantiomeric excess of the (*S*)-enantiomer.

In a similar manner, the polymer **10***b* prepared *at 20°C* as described above gave a liquid product; gc, one sharp peak (tr, 2.9) assignable to (*R*)- and (*S*)-2-methylcyclohexanones (86% yield calculated from the loading of **9***b*); polarimetric analysis, $[\alpha]_D$ 15.33° (lit. (5) $[\alpha]_D$ 16.4°), 93.5% enantiomeric excess of (*S*)-2-methylcyclohexanone.

Similarly, polymer **10***c* prepared *at 20°C* as described above gave essentially pure (*R*)- and (*S*)-2-methylcyclohexanone (87% yield calculated from loading of **9***c*); polarimetric analysis, $[\alpha]_D$ 15.40°, 93.8% enantiomeric excess of (*S*)-2-methylcyclohexanone.

In a similar manner, polymer **10***c* prepared *at 0°C* and −78°C as described above gave essentially pure (*R*)- and (*S*)-2-methylcyclohexanone in 97% and 72% yields respectively, and in 96 and 98% enantiomeric excesses of (*S*)-2-methylcyclohexanone respectively.

(S)-*2-Phthalimidopropyl benzyl ether*

To a slurry of potassium hydride (1.72 g, 43 mmol, washed with hexane) in tetrahydrofuran (100 mL) containing dibenzo-18-crown-6 (200 mg, 0.56 mmol) was added (*S*)-2-phthalimido-1-propanol (**5***a*) prepared as described above (8.27 g, 40.33 mmol). The reaction mixture was stirred at ambient temperature for 1 h and then cooled to, and maintained at, 0°C (ice–water bath) while benzyl bromide (10.07 g, 58.9 mmol) was added. After 0.5 h, the reaction mixture was allowed to warm to ambient temperature and stirred for 48 h. After addition of methanol (10 mL), the reaction mixture was concentrated under reduced pressure. To the residue was added ether (100 mL) and water (100 mL). The ether layer was washed with water, dried over magnesium sulfate, filtered, and concentrated. The residue was fractionated by column chromatography (Kieselgel 60,

For personal use only.

Korngrösse 0.040–0.063 mm, 230–400 mesh ASTM). An eluent of 3% methanol in ether–hexane (1:1) gave, after evaporation of solvent, crystalline **11***a*, (6.71 g, 56.4% yield), mp 39–41°C; $[\alpha]_D$ +44.6° (*c* 1.0, MeOH); nmr, δ: 7.70 (d, 4H), 7.30 (s, 5H), 4.65–5.05 (m, 1H), 4.55 (s, 2H), 3.50–4.20 (m, 2H), and 1.40 (d, 3H) ppm. *Anal.* calcd. for $C_{18}H_{17}NO_3$: C 73.22, H 5.76, N 4.74; found: C 73.30, H 5.82, N 4.51.

(S)-*2-Phthalimido-3-phenylpropyl benzyl ether*

In a similar manner, *N*-2-phthaloyl-3-phenylpropanol was converted to **11***c*, 33% yield; mp 62–64°C; $[\alpha]_D$ −78.1° (*c* 0.267, MeOH); nmr, δ: 7.70 (d, 4H), 7.30 (d, 10H), 4.66–5.05 (m, 1H), 4.55 (s, 2H), 3.45–4.30 (m, 2H), and 3.20–3.35 (m, 2H) ppm. *Anal.* calcd. for $C_{24}H_{21}NO_3$: C 77.63, H 5.66, N 3.77; found: C 77.63, H 6.18, N 3.46.

(S)-*2-Aminopropyl benzyl ether (11*a)

A solution of (*S*)-2-phthalimidopropyl benzyl ether prepared as described above (2.155 g, 7.30 mmol) in ethanol (15 mL) was added to an excess of 95% aqueous hydrazine solution (1.5 g). The mixture was stirred at 30°C for 2 h and then treated with an excess of dilute hydrochloric acid. The insoluble phthalhydrazide was removed by filtration. The fitrate was concentrated, cooled, and filtered to remove additional phthalhydrazide. The filtrate was treated with dilute potassium hydroxide solution (to pH 14) and the mixture extracted with ether. The ether extract was dried over magnesium sulfate and concentrated. The residue was distilled (bulb-to-bulb, 0.5 Torr, 85–90°C) to give **11***a* (1.110 g, 92.3% yield); oil; $[\alpha]_D$ +16.35° (*c* 0.847, MeOH); nmr, δ: 7.50 (s, 5H), 4.65 (s, 2H); 4.50–4.90 (m, 1H), 3.10–3.45 (m, 2H), 2.10 (m, $NH_2$), 1.15 (d, 3H) ppm. Formation of the hydrochloride of **11***a* by reaction of a solution of **11***a* in ether with dry hydrogen chloride gave an analytical sample. *Anal.* calcd. for $C_{10}H_{16}ClNO$: C 59.6, H 7.94, N 6.94; found: C 60.06, H 8.16, N 6.84.

(S)-*2-Amino-3-phenylpropyl benzyl ether (11*c)

In a manner similar to that described above for **11***a*, (*S*)-2-phthalimido-3-phenylpropyl benzyl ether was converted to **11***c* (96.4% yield); oil; $[\alpha]_D$ + 5.59° (*c* 0.626, MeOH); nmr, δ: 7.30 (d, 10H), 4.55 (s, 2H), 3.00–3.55 (m, 3H), 2.55–2.80 (m, 2H), and 1.60 (m, $NH_2$) ppm. *Anal.* of the hydrochloride, calcd. for $C_{16}H_{20}ClNO$: C 69.18, H 7.21, N 5.04; found: C 69.11, H 7.36, N 4.93.

(S)-*2-Cyclohexylideneaminopropyl benzyl ether (12*a)

A solution of **11***a* (1.044 g, 6.33 mmol), and cyclohexanone (806.8 mg, 8.23 mmol) in benzene (100 mL) was heated under reflux for 8 h using a Dean–Stark trap for collection of water. Benzene was removed under reduced pressure and the residue distilled (bulb-to-bulb, 0.5 Torr, 165–170°C) to give crude **12***a* (1.488 g, 95% yield) which was redistilled to give a clear viscous oil; $[\alpha]_D$ +7.29° (*c* 1.007, MeOH); nmr, δ: 7.50 (s, 5H aromatic), 4.55 (s, 2H), 3.00–3.80 (m, 3H), 1.65–2.25 (m, 10H), and 1.20 (d, 3H) ppm.

(S)-*2-Cyclohexylideneamino-3-phenylpropyl benzyl ether (12*c)

In a manner similar to that described for **12***a*, **11***c* was converted to **12***c* (91% yield; bulb-to-bulb, 0.5 Torr, 190–195°C); $[\alpha]_D$ −15.9° (*c* 0.464, MeOH); nmr, δ: 7.20–7.50 (m, 10H aromatic), 4.55 (s, 2H), 3.80–4.20 (m, 1H), 3.30–3.60 (m, 2H), 2.65–3.00 (m, 2H), and 1.40–2.30 (m, 10H) ppm.

(R)- *and* (S)-*2-Methylcyclohexanones from 12*a *at −78°C*

To a solution of diisopropylamine (0.8 mL, 5.71 mmol) in tetrahydrofuran (15 mL) was added, with stirring at 0°C, a solution of butyllithium in hexane (1.6 *M*, 3.60 mL, 5.76 mmol). After 15 min, the reaction mixture was cooled to −30°C (Dry-Ice in acetone bath) and **12***a* (1.225 g, 5.0 mmol) was added. After 1.5 h, the solution was cooled to −78°C and a solution of iodomethane (0.4 mL, 6.42 mmol) in tetrahydrofuran (5 mL) was added dropwise over 0.5 h. The reaction mixture was stirred at −78°C for 2 h, and then poured into a saturated solution of sodium chloride (50 mL) and extracted with ether. The extract was washed with aqueous sodium chloride solution, dried over magnesium sulfate, and concentrated.

A solution of the residue in pentane (25 mL) was shaken for 0.5 h with a solution of sodium acetate (1.65 g) and acetic acid (3.75 mL) in water (17.5 mL). The aqueous layer was separated and washed with pentane. The combined pentane solutions were washed successively with hydrochloric acid (1 *N*), water, 5% aqueous sodium bicarbonate solution, water, and aqueous sodium chloride solution. Concentration of the pentane solution and distillation of the residue (bulb-to-bulb) gave a liquid product (241 mg); gc, one sharp peak assignable to (*R*)- and (*S*)-2-methylcyclohexanones (43% yield); polarimetric analysis, $[\alpha]_D$ 11.70° (*c* 0.573, MeOH) indicating an enantiomeric excess of (*S*)-2-methylcyclohexanone of 71.3%.

(R)- *and* (S)-*2-Methylcyclohexanones from 12*c *at −78°C*

In a manner similar to that described above for **12***a*, **12***c* produced (*R*)- and (*S*)-2-methylcyclohexanone in 58% yield and 85.3% enantiomeric excess of (*S*)-2-methylcyclohexanone.

(R)- *and* (S)-*2-Methylcyclohexanones from 12*c *at 20°C*

In a manner similar to that described above for **12***c* *at* −78°C, **12***c* was treated with lithium diisopropylamide at 20°C and iodomethane at 20°C to give 2-methylcyclohexanones in 62% yield, and 49% enantiomeric excess of (*S*)-2-methylcyclohexanone.

# The chemistry of thujone. V.[1] Thujone as a chiral synthon for the preparation of sesquiterpenes. Synthesis of (+)-carissone

JAMES P. KUTNEY AND ASHOK K. SINGH

*Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6*

Received February 2, 1982

JAMES P. KUTNEY and ASHOK K. SINGH. Can. J. Chem. **60**, 1842 (1982).

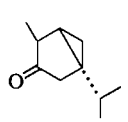
An efficient synthesis of (+)-carissone (**4**) from (+)-β-cyperone (**2**) is described. The latter sesquiterpene is readily available from thujone (**1**), via a previously described synthesis.

JAMES P. KUTNEY et ASHOK K. SINGH. Can. J. Chem. **60**, 1842 (1982).

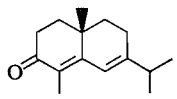
On décrit une synthèse éfficace de la (+)-carissone (**4**) à partir de la (+)-β-cyperone. Ce dernier sesquiterpène est obtenu convenablement de la thujone (**1**) par une méthode de synthèse décrit antérieurement.

[Traduit par le journal]

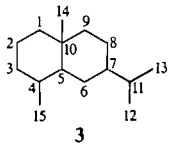
Previous research in these laboratories has shown the uses of thujone (**1**)[2] in the preparation of acyclic insect juvenile hormone analogues(1,2), bicyclic natural products (e.g. (+)-β-cyperone **2**) (3), and of several pyrethroid analogues (4). In the synthesis of **2**, we have shown that thujone is an extremely efficient chiral synthon for the preparation of optically active sesquiterpenes possessing the eudesmane carbon skeleton (**3**) and (+)-β-cyperone with an optical purity of >98.8% was obtained. Here we wish to report the results of further chemical investigations to elaborate the isopropyl side chain in the basic skeleton. Of particular interest was the development of synthetic routes to eudesmane intermediates with hyroxyl groups at C7 and C11 (see **3**) and olefinic linkages at the C7—C11 or C11—C12 positions. Such studies have led to an effective synthesis of the bicyclic sesquiterpene (+)-carissone (**4**) from (+)-β-cyperone (**2**).



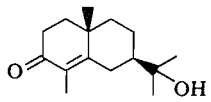
**1**



**2**

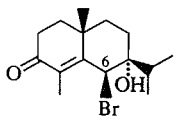


**3**

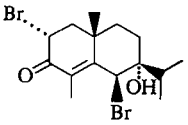


**4**

Treatment of **2** with *N*-bromosuccinimide in a tetrahydrofuran (THF)–water (1:1) mixture resulted in the formation of bromohydrin **5** in 76% yield. The ratio of THF to water was found to have an effect on the product composition. If a THF–water ratio of 7:3 was used, in addition to **5**, a dibromo product **6** was also obtained.



**5**



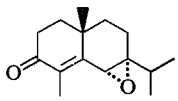
**6**

The stereochemistry of the bromohydrin was assigned on the basis of spectral data and consideration of the established mechanism of bromohydrin formation with $NBS/H_2O$ (5). In the $^1$Hmr spectrum of **5** the C6 proton which resonated at δ 4.87 appeared clearly as a doublet with a coupling constant of 2 Hz. This is consistent with a 1,3 di-equatorial coupling between the C6α-proton and the C8α-(equatorial) proton (6). Thus the *trans* configuration of the bromohydrin **5** is as depicted.

Attempts to introduce the C7—C11 double bond by conversion of the C7-hydroxyl group to the mesylate led to the exclusive formation of the epoxide **7**. Indeed the bromohydrin is quite labile under basic conditions and is readily converted to **7**. Reaction of **5** with thionyl chloride also failed to give the desired exocyclic double bond with (+)-β-cyperone being the final isolated product.

Debromination of **5** with triphenyl *or* tri-*n*-butyl tin hydride was ineffective for selective removal of the 6β-bromo group.

Treatment of **5** with "super hydride" resulted in



**7**

For personal use only.

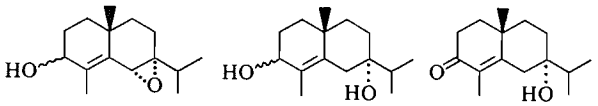
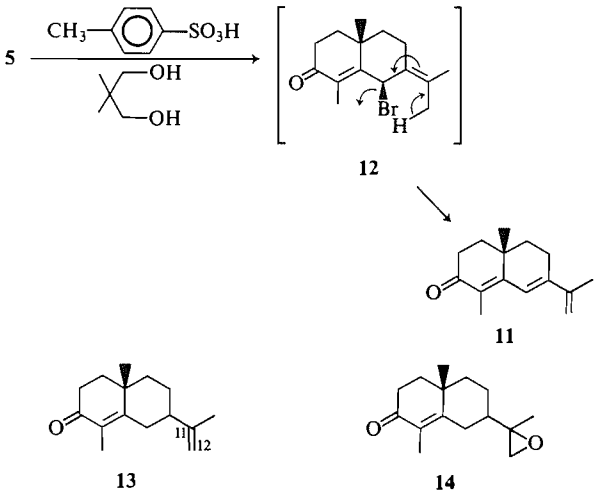
the initial conversion of the bromohydrin function to an epoxide with concomitant reduction of the C3-ketone to give **8**. Further reduction of the epoxide **8** by "super hydride" afforded the diol **9** while oxidation of **8** with $CrO_3$–pyridine complex provided an epoxyenone identical to **7** as obtained above. Oxidation of **9** under similar conditions gave the keto alcohol **10**. This compound was found to be very acid sensitive and hence attempts to dehydrate the tertiary hydroxyl group (or its derivatives) in a regiospecific manner, so as to furnish the exocyclic double bond, could not be realized.



**8** **9** **10**

Reaction of **10** with thionyl chloride or methanesulfonyl chloride resulted only in the formation of (+)-β-cyperone (**2**). Further attempts to functionalize the isopropyl side chain employing intermediate **10** were abandoned when a convenient procedure to the trienone **11** directly from the bromohydrin **5** was discovered (Scheme 1).



SCHEME 1

Treatment of **5** with a mixture of *p*-toluenesulfonic acid and 2,2-dimethyl-1,3-propanediol in anhydrous benzene at 75°C for 10 min afforded a high yield of **11**. Presumably the reaction proceeded by an initial dehydration to **12** which then underwent a facile dehydrobromination to form the trienone **11**. The fully conjugated trienone system was evident from the uv absorption chromophore with $\lambda_{max}$ at 320 nm and from ir spectrum with $\nu_{max}$ at 1636 and 1584 $cm^{-1}$. The $^1$Hmr spectrum is also in full agreement with the structure assigned (δ 1.88, C4 vinyl methyl; 2.02, C11 vinyl methyl; 6.60, C6H; 5.31, 5.15, C12(methylene)).

In their synthesis of (+)-carissone (**4**) from (+)-α-cyperone (**13**) Pinder and Williams (7) selectively converted the C11—C12 double bond into an epoxide **14** by means of perbenzoic acid.

Our attempts to carry out specific epoxidation of the same side chain double bond employing compound **11** were unsuccessful. However, this double bond can be selectively oxidized by osmium tetroxide or alkaline potassium permanganate to give a diastereomeric mixture of diols **15** (Scheme 2). Considerable efforts were expended in attempting to separate this mixture by various chromatographic methods. For example, preparative layer chromatography involving numerous (thirteen) developing solvents did afford several milligrams of the pure isomers but this separation was accompanied by large losses of materials and was therefore abandoned. The subsequent steps of the sequence (**15** ↠ **19**) were therefore performed on a mixture since **16**, **18**, and **19** were similarly difficult to separate and the eventual objective, the synthesis of **4**, was not restricted by this situation.

Hydrogenation of **15** with palladium on charcoal as catalyst under basic conditions afforded the partially reduced product **16** as the major component. The β-configuration of the side chain, as shown, became evident in subsequent studies when (+)-carissone (**4**) was obtained.

A minor product, the fully reduced intermediate **17**, was also isolated from the hydrogenation mixture. The characterization data for this compound, which is of no further use in the present synthetic work, are given in the Experimental section.

As expected, tosylation of the dihydroxy ketone **16** with tosyl chloride afforded only the monotosylate **18**. Lithium aluminium hydride reduction of the primary tosylate was accompanied by reduction of the C3 carbonyl function to give the diol **19**.

Finally oxidation (chromium trioxide, pyridine) converted **19** to a single product possessing all the physical properties of (+)-carissone (**4**) (see Experimental).

The above described route represents the most efficient synthesis of this natural product and represents an overall yield of **4** of 17% from β-cyperone (**2**).

Other syntheses of **4** (7–9) generally involve less readily available starting materials and proceed in lower yields.

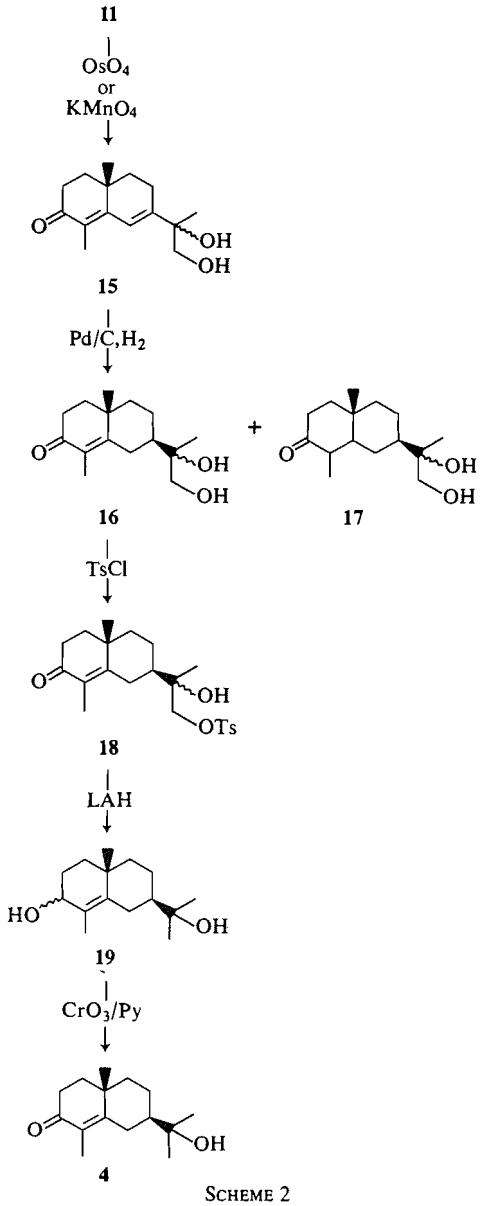

SCHEME 2

## Experimental

Ultraviolet spectra were recorded on a Cary 15 spectrophotometer using methanol as solvent. Infrared spectra were recorded on a Perkin–Elmer 710 spectrophtometer using chloroform as solvent. The $^1$Hmr spectra were recorded on either a Varian XL-100 or Nicolet Oxford H-270 or a 400 MHz instrument. Chemical shifts are reported as ppm from TMS, used as internal standard. Low resolution mass spectra were recorded on either an Atlas CH-4B or an AEI MS-902 spectrometer. High resolution mass measurements were made on an AEI MS-50 spectrometer. Optical rotations were recorded on a Perkin–Elmer 141 polarimeter. Rotations were obtained using a cell with a path length of 10 cm. Microanalyses were carried out by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. Column chromatography utilized Merck silica gel 60 (70–230 mesh). Preparative and thin layer chromatography utilized Merck silica gel $GF_{254}$. Petroleum ether refers to the fraction with boiling range 30–60°C.

*Bromohydrin* **5**

To a solution of **2** (500 mg) in THF and water (50 mL, 1:1 v/v) was added NBS (2 g) at room temperature and the mixture stirred for 22 h. The reaction mixture was diluted with water (50 mL), extracted with ether (2 × 100 mL), and the organic layer washed with water (3 × 50 mL), dried ($MgSO_4$), and concentrated. Crystallization of the residue from ether–petroleum ether gave colourless crystals **5** (550 mg, 76%); mp 114–115°C; $[\alpha]_D$ −118.5° (*c* 0.615, $CHCl_3$); ir $\nu_{max}$: 3486, 1666 cm$^{-1}$; uv $\lambda_{max}$: 249 (ε 12 372) nm; $^1$Hmr δ: 0.97 (3H, d, *J* = 7 Hz), 1.02 (3H, d, *J* = 7 Hz), 1.53 (3H, s), 1.59 (1H, s, $D_2O$ exchangeable), 1.72 (1H, ddd, *J* = 12, 5, 2 Hz), 1.81 (1H, ddd, *J* = 12, 5, 2 Hz), 1.87 (3H, s), 1.92 (1H, dt, *J* = 14, 4 Hz), 2.05 (1H, dt, *J* = 16, 4 Hz), 2.27 (1H, septet, *J* = 7 Hz), 2.49 (1H, ddd, *J* = 14, 6, 2 Hz), 2.66 (1H, ddd, *J* = 16, 14, 2 Hz), 4.87 (1H, d, *J* = 2 Hz); ms *m/e*: 316 ($M^+$), 314 ($M^+$), 298, 296, 273, 271, 234. High resolution molecular weight determination, calcd. for $C_{15}H_{23}O_2Br^{79}$: 314.0881; found: 314.0893; calcd. for $C_{15}H_{23}O_2Br^{81}$: 316.0861; found: 316.0866. *Anal.* calcd. for $C_{15}H_{23}O_2Br$: C 57.14, H 7.30, Br 25.39; found: C 56.94, H 7.41, Br 25.17.

A mixture of **2** and NBS stirred in THF and $H_2O$ (7:3 v/v) under the above condition gave **5** and **6** in the ratio 1:1 which were separated by silica gel column chromatography. The compound **6** was obtained as colourless crystals; mp 142–143°C; $[\alpha]_D$ −12.99° (*c* 0.231, $CHCl_3$); ir $\nu_{max}$: 3525, 1676 cm$^{-1}$; uv $\lambda_{max}$: 260 (ε 11 471) nm; $^1$Hmr δ: 0.97 (3H, d, *J* = 7 Hz), 1.02 (3H, d, *J* = 7 Hz), 1.60 (3H, s), 1.94 (3H, s), 4.81 (1H, d, *J* = 2 Hz), 5.00 (1H, dd, *J* = 12, 8 Hz); ms *m/e*: 396 ($M^+$), 392 ($M^+$), 315, 313. High resolution molecular weight determination, calcd. for $C_{15}H_{22}O_2Br_2^{79}$: 391.9986; found 391.9999; calcd. for $C_{15}H_{22}O_2Br_2^{81}$: 395.9946; found: 395.9940. *Anal.* calcd. for $C_{15}H_{22}O_2Br_2$: C 45.68, H 5.58, Br 40.60; found: C 45.49, H 5.42, Br 40.46.

*Epoxyenone* **7**

The bromohydrin **5** (50 mg) was dissolved in previously cooled pyridine (3 mL) to which methane sulfonyl chloride (0.02 mL) was added and stirred at 0°C for 3 h. It was poured into crushed ice, taken up in ether, and the organic layer washed successively with 10% HCl, 10% $NaHCO_3$ solution, and finally with water and dried ($MgSO_4$). After the removal of the solvent, the solid epoxyenone **7** (35 mg, 94%) was crystallized from petroleum ether as colourless crystals; mp 84–85°C; $[\alpha]_D$ +262.27° (*c* 0.6619, $CHCl_3$); ir $\nu_{max}$: 1666 cm$^{-1}$; uv $\lambda_{max}$: 249 (ε 14 549) nm; $^1$Hmr δ: 1.05 (3H, d, *J* = 7 Hz), 1.07 (3H, s), 1.08 (3H, d, *J* = 7 Hz), 1.28 (1H, ddd, *J* = 13.5, 5, 2 Hz), 1.46 (1H, dt, *J* = 13.5, 6 Hz), 1.6–1.72 (2H, m), 1.80 (1H, dt, *J* = 13.5, 5 Hz), 1.86–2.02 (5H, m, including 1.93 (3H, s)), 2.46 (1H, ddd, *J* = 17, 5, 2 Hz), 2.63 (1H, ddd, *J* = 17, 14.5, 5 Hz), 3.30 (1H, s); ms *m/e*: 234 ($M^+$), 219, 206, 136. High resolution molecular weight determination, calcd. for $C_{15}H_{22}O_2$: 234.1620; found: 234.1619. *Anal.* calcd. for $C_{15}H_{22}O_2$: C 76.92, H 9.40; found: C 77.09, H 9.43.

*Hydroxyenone* ***10***

To a reaction flask equipped with reflux condenser, magnetic stir bar, and rubber septum, was introduced super hydride ($LiEt_3BH$) (9.5 mL, 1 *M* in THF) by syringe under nitrogen. Bromohydrin **5** (448 mg) in THF (3 mL) was added in one portion by syringe. The resulting reaction mixture was stirred at ambient temperature for 24 h. The reaction mixture was diluted with ice water, extracted with ether, and dried ($MgSO_4$). Evaporation of solvent gave a solid which was chromatographed on silica gel (10 g). Elution with ether–petroleum ether (1:1 v/v) gave the hydroxyepoxide **8** (32 mg, 10%) as a viscous

For personal use only.

oil; $[\alpha]_D$ +75.35 (*c* 0.215, $CHCl_3$); ir $\nu_{max}$: 3462 $cm^{-1}$; $^1$Hmr δ: 0.97 (3H, s), 1.03 (3H, d, *J* = 7 Hz), 1.05 (3H, d, *J* = 7 Hz), 1.08–1.85 (9H, m, including 1.80 (1H, s, $D_2O$ exchangeable)), 1.91 (3H, s), 2.06 (1H, m), 3.34 (1H, s), 4.13 (1H, dd, *J* = 10, 6 Hz); ms *m/e*: 236 ($M^+$), 218, 203, 193. High resolution molecular weight determination, calcd. for $C_{15}H_{24}O_2$: 236.1776; found: 236.1761. *Anal.* calcd. for $C_{15}H_{24}O_2$: C 76.27, H 10.17; found: C 76.34, H 10.28. Further elution with the same solvent furnished dihydroxy **9** (232 mg, 69%) as a colourless solid; mp 106–108°C; $[\alpha]_D$ −17.28° (*c* 0.162, $CHCl_3$); ir $\nu_{max}$: 3460 $cm^{-1}$; $^1$Hmr δ: 0.99 (6H, d, *J* = 7 Hz), 1.08 (3H, s), 1.30–1.73 (10H, m, including 1.54 (2H, s, $D_2O$ exchangeable)), 1.78 (3H, s), 1.94 (1H, m), 2.09 (1H, d, *J* = 14 Hz), 2.46 (1H, dd, *J* = 14, 3 Hz), 4.13 (1H, t, *J* = 8 Hz); ms *m/e*: 238 ($M^+$), 220, 205, 195, 167. High resolution molecular weight determination, calcd. for $C_{15}H_{26}O_2$: 238.1933; found: 238.1939. *Anal.* calcd. for $C_{15}H_{26}O_2$: C 75.63, H 10.92; found: C 75.42, H 10.86.

To the chromium–pyridine complex from chromium trioxide (310 mg) and pyridine (3 mL) was added a solution of dihydroxy **9** (153 mg) in pyridine (5 mL). The mixture was stirred at room temperature for 20 min and then diluted with cold water and extracted with benzene–ether (100 mL, 1:1 v/v), dried ($MgSO_4$), and evaporated to give a solid. Recrystallization from ether afforded hydroxyenone **10** (30 mg, 86%) as a colourless solid; mp 147–148°C; $[\alpha]_D$ +102.18° (*c* 0.321, $CHCl_3$); ir $\nu_{max}$: 3450, 1656, 1616 $cm^{-1}$; uv $\lambda_{max}$: 252 (ε 15 385) nm; $^1$Hmr δ: 0.98 (6H, d, *J* = 6.7 Hz), 1.20 (3H, s), 1.45–1.95 (11H, m, including 1.63 (1H, s, $D_2O$ exchangeable) and 1.80 (3H, s)), 2.20 (1H, d, *J* = 14 Hz), 2.36–2.60 (2H, m), 2.70 (1H, dd, *J* = 14, 2.7 Hz); ms *m/e*:236 ($M^+$), 218, 193, 138. High resolution molecular weight determination, calcd. for $C_{15}H_{24}O_2$: 236.1776; found: 236.1763. *Anal.* calcd. for $C_{15}H_{24}O_2$: C 76.27, H 10.16; found: C 76.15, H 10.26.

The compound **8** on $CrO_3$–pyridine oxidation afforded epoxyenone **7**, the same as described earlier.

*Trienone 11*

A mixture of bromohydrin **5** (1.5 g), 2,2-dimethyl-1,3-propanediol (7 g), and *p*-toluenesulfonic acid (20 mg) in dry benzene (60 mL) was heated at 74–79°C under argon for 10 min. It was then cooled, diluted with water (50 mL), and extracted with ether (3 × 50 mL). The combined extract was washed with water (2 × 50 mL), dried ($MgSO_4$), and concentrated *in vacuo*. Crude material was chromatographed on silica gel (100 g) eluted with 5% ether in petroleum ether to furnish a yellow oil (0.729 g, 71%) which solidified on standing; mp 35–36°C; $[\alpha]_D$ +622.74° (*c* 0.63975, $CHCl_3$); ir $\nu_{max}$: 1636, 1584 cm$^1$; uv $\lambda_{max}$: 320 (ε 33 469) nm; $^1$Hmr δ: 1.11 (3H, s), 1.48–1.88 (7H, m, including 1.88 (3H, s)), 2.02 (3H, s), 2.41–2.53 (3H, m), 2.67 (1H, ddd, *J* = 18, 14, 6 Hz), 5.15 (1H, s), 5.31 (1H, s), 6.60 (1H, s); ms *m/e*: 216 ($M^+$), 201, 188, 173. High resolution molecular weight, calcd. for $C_{15}H_{20}O$: 216.1514; found: 216.1517. *Anal.* calcd. for $C_{15}H_{20}O$: C 83.33, H 9.26; found: C 83.05, H 9.42.

*Hydroxydienone 15*

The trienone **11** (50 mg) in dioxane (3 mL) was treated with osmium tetroxide (64 mg) in dioxane (2 mL). The mixture was stirred for 18 h at ambient temperature under an atmosphere of nitrogen. The solution was saturated with $H_2S$, then filtered. After removal of the solvent it yielded solid which was recrystallized with ether–petroleum ether to afford a mixture of diols **15** (38 mg, 66%); mp 92–94°C. The diols were separated by preparative tlc plate developed several times in the same solvent, ether–petroleum ether–methanol (70:28:2). The less polar isomer gave: mp 114–115°C; $[\alpha]_D$ +392.48° (*c* 0.0665, $CHCl_3$); ir $\nu_{max}$: 3450, 1644, 1615 $cm^{-1}$; uv $\lambda_{max}$: 297 (ε 25 595) nm; $^1$Hmr δ: 1.10 (3H, s), 1.36 (3H, s), 1.51–1.81 (4H, m), 1.86 (3H, s), 2.18–2.76 (6H, m), 3.54 (1H, d, *J* = 10 Hz), 3.76 (1H, d, *J* = 10 Hz), 6.76 (1H, d, *J* = 2 Hz); ms *m/e*: 250 ($M^+$), 232, 219. High resolution molecular weight determination, calcd. for $C_{15}H_{22}O_3$: 250.1569; found: 250.1567. *Anal.* calcd. for $C_{15}H_{22}O_3$: C 72.00, H 8.80; found: C 71.86, H 8.96. The more polar isomer gave: mp 99–100°C; $[\alpha]_D$ +233.88° (*c* 0.0885, $CHCl_3$); ir $\nu_{max}$: 3450, 1645, 1616 $cm^{-1}$; uv $\lambda_{max}$: 297 (ε 25 000) nm; $^1$Hmr δ: 1.10 (3H, s), 1.36 (3H, s), 1.51–1.81 (4H, m), 1.86 (3H, s), 2.10–2.75 (6H, m), 3.57 (1H, d, *J* = 12 Hz), 3.75 (1H, d, *J* = 12 Hz), 6.74 (1H, d, *J* = 2 Hz); ms *m/e*: 250 ($M^+$), 232, 219. High resolution molecular weight determination, calcd. for $C_{15}H_{22}O_3$: 250.1569; found: 250.1569. *Anal.* calcd. for $C_{15}H_{22}O_3$: C 72.00, H 8.80; found: C 71.84, H 8.92.

A mixture of trienone **11** (28 mg), sodium hydroxide (20 mg), and potassium permanganate (55 mg) in aqueous *tert*-butanol (6 mL, 1:1 v/v) was stirred at 0°C for 1.5 h. Solid sodiumbisulfite was added until the solution became clear. This was concentrated and extracted with methylene chloride, washed with water, dried ($MgSO_4$), and evaporated to give **15** (16 mg, 50%), identical with that obtained above.

*Diols 16 and 17*

A solution of diols **15** (117 mg) and potassium hydroxide (18 mg) in ethanol (20 mL) containing 10% palladium/charcoal (32 mg) was stirred under an atmosphere of hydrogen at ambient temperature for 30 min. The solution was filtered and then evaporated. The residue was acidified with 10% HCl and extracted with ether (2 × 50 mL). The combined extract was washed with water, brine, and dried ($MgSO_4$), and concentrated to leave 118 mg of colourless oil. Preparative scale tlc gave pure diols **16** (85 mg, 72%) and **17** (28 mg, 24%) as viscous oils. The physical properties of **16** are as follows: $[\alpha]_D$ +147.92° (*c* 0.528, $CHCl_3$); ir $\nu_{max}$: 3464, 1652, 1617 $cm^{-1}$; uv $\lambda_{max}$: 249 (ε 14 560) nm; $^1$Hmr δ: 1.19, 1.21 (3H, s, two sets), 1.22 (3H, s), 1.40–1.77 (6H, m), 1.78, 1.80 (3H, s, two sets), 1.87–2.02 (3H, m, including 1.97 (2H, s, $D_2O$ exchangeable)), 2.41 (1H, dt, *J* = 16, 4 Hz), 2.53 (1H, ddd, *J* = 16, 14, 7 Hz), 2.76, 2.94 (1H, dt, *J* = 16, 4 Hz, two sets), 3.46–3.54 (2H, m), 3.66, 3.67 (1H, d, *J* = 11 Hz, two sets); ms *m/e*: 234 ($M^+-H_2O$), 221, 219, 203, 177. High resolution molecular weight determination, calcd. for $C_{15}H_{24}O_3-H_2O$ ($M^+-H_2O$): 234.1619; found 234.1618. *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.43, H 9.52; found: C 71.14, H 9.54. And for **17**, $[\alpha]_D$ −3.22° (*c* 0.4955, $CHCl_3$); ir $\nu_{max}$: 3450, 1706 $cm^{-1}$; uv $\lambda_{max}$: 284 (ε 60.27) nm; $^1$Hmr δ: 0.99, 1.02 (3H, d, *J* = 7 Hz, two sets), 1.08 (3H, s), 1.14, 1.16 (3H, s, two sets), 1.22–1.77 (10H, m), 1.85 (1H, ddd, *J* = 15, 5, 3 Hz), 1.96 (1H, b, $D_2O$, exchangeable), 2.22 (1H, m), 2.35 (1H, ddd, *J* = 15, 5, 3 Hz), 2.53 (1H, dt, *J* = 20, 6 Hz), 3.45, 3.46 (1H, d, *J* = 11 Hz, two sets); 3.60, 3.61 (1H, d, *J* = 11 Hz, two sets); ms *m/e*: 254 ($M^+$), 236, 223. High resolution molecular weight determination, calcd. for $C_{15}H_{26}O_3$: 254.1882; found: 254.1875. *Anal.* calcd. for $C_{15}H_{26}O_3$: C 70.87, H 10.24; found: C 71.06, H 10.19.

*Tosylates 18*

The diols **16** (85 mg) were dissolved in pyridine (5 mL) to which was added *p*-toluene sulfonyl chloride (192 mg) and the mixture stirred for 16 h. The solution was poured into ice water, extracted with ether, washed with water, dried ($MgSO_4$), evaporated to leave tosylates **18** (117 mg, 86%), mp 90–92°C; $[\alpha]_D$ +84.23° (*c* 0.6945, $CHCl_3$); ir $\nu_{max}$: 1656, 1616, 1380, 1190 $cm^{-1}$; uv $\lambda_{max}$: 227 (ε 17 585), 249 (15 678) nm; $^1$Hmr δ: 1.17, 1.20 (3H, s, two sets), 1.18 (3H, s), 1.35–1.70 (8H, m, including 1.67 (1H, s, $D_2O$ exchangeable)), 1.72, 1.75 (3H, s, two sets), 1.86, 1.94 (1H, d, *J* = 16 Hz, two sets), 2.39 (1H, dt, *J* = 16, 4 Hz), 2.47–2.56 (4H, m, including 2.47 (3H, s)), 2.68, 2.85 (1H, dt, *J* = 16, 4 Hz, two sets), 3.92, 3.93 (1H, d, *J* = 10 Hz, two sets), 4.00, 4.03 (1H, d, *J* = 10 Hz, two sets), 7.36 (2H, d, *J* = 8 Hz), 7.80 (2H, d, *J* = 8 Hz); ms *m/e*: 406 ($M^+$), 388, 234, 216, 190. High resolution molecular weight determination, calcd. for

$C_{22}H_{30}O_5S$: 406.1814; found: 406.1794. *Anal.* calcd. for $C_{22}H_{30}O_5S$: C 65.02, H 7.39; found: C 65.04, H 7.43.

*Diols* ***19***

A solution of tosylates **18** (58 mg) in anhydrous ether (25 mL) was added to LAH (100 mg) and the mixture refluxed for 4 h. It was cooled, poured onto ice, extracted with ether, and dried ($MgSO_4$). Removal of ether yielded crystalline diols **19** (30 mg, 88%); mp 31–33°C; $[\alpha]_D$ +50.51° (*c* 0.291, $CHCl_3$); ir $\nu_{max}$: 3442 $cm^{-1}$; $^1$Hmr δ: 1.19 (3H, s), 1.22 (6H, s), 1.25–1.70 (11H, m), 1.74 (3H, s), 1.92 (1H, m), 2.61 (1H, dt, $J$ = 14, 4 Hz), 4.04 (1H, t, $J$ = 6 Hz); ms *m/e*: 238 ($M^+$), 220, 205. High resolution molecular weight determination, calcd. for $C_{15}H_{26}O_2$: 238.1933; found: 238.1943. *Anal.* calcd. for $C_{15}H_{26}O_2$: C 75.63, H 10.92; found: C 75.61, H 10.89.

*(+)-Carissone* ***4***

Oxidation of diols **19** (30 mg) in pyridine (1 mL) with $CrO_3$ (70 mg) in pyridine (0.8 mL) gave **4** (26 mg, 86%); mp 78–79°C (lit. 7,10) mp 78–79°C); $[\alpha]_D$ +136.6° (*c* 0.1625, $CHCl_3$) (lit. (10) +136.6° ±2° (in chloroform); ir $\nu_{max}$: 3472, 1556, 1615 $cm^{-1}$; uv $\lambda_{max}$: 249 (ε 15652) nm; $^1$Hmr δ: 1.21 (3H, s), 1.25 (3H, s), 1.26 (3H, s), 1.36–1.60 (6H, m, including 1.56 (1H, s, $D_2O$ exchangeable)), 1.79 (3H, s), 1.67–1.77 (2H, m), 1.91 (1H, t, $J$ = 14 Hz), 2.40 (1H, dt, $J$ = 15, 3 Hz), 2.52 (1H, ddd, $J$ = 18, 12, 6 Hz), 2.87 (1H, dt, $J$ = 15, 3 Hz); ms *m/e*: 236 ($M^+$), 218, 203. # Synthesis and characterization of some oxidized derivatives of citronellal ethylene acetal

WESLEY G. TAYLOR

*Agriculture Canada Research Station, Lethbridge, Alta., Canada T1J 4B1*

Received October 26, 1981

WESLEY G. TAYLOR. Can. J. Chem. **60**, 1847 (1982).

Three pairs of geometrical isomers corresponding to allylic monooxidation products of the trisubstituted olefin, citronellal ethylene acetal (**3**), were synthesized. These compounds were the *E* and *Z* isomers of 7-(1,3-dioxolan-2-yl)-2,6-dimethyl-2-hepten-1-ol, -1-al, and -1-oic acid (methyl ester), precursors for identifying the biodegradation products from citronellal and some of its derivatives. The *E* aldehyde (**4**) was obtained from **3** by the Sharpless procedure with catalytic quantities of selenium dioxide. The *E* ester (**5**) and *E* alcohol (**6**) were prepared in high isomeric purity (97–99%) from **4** with activated manganese dioxide and sodium borohydride, respectively. Selective ozonolysis of the isobutenyl group in **3** gave 5-(1,3-dioxolan-2-yl)-4-methyl-1-pentanal (**7**). Under the conditions used, ozone did not react with the ethylene acetal group. Acetal aldehyde (**7**) was stereoselectively converted to the *Z* alcohol (**8**) by a Wittig reaction. Manganese dioxide oxidation of **8** (98–99% *Z* isomer) to the *Z* aldehyde (**9**) and of **9** to the *Z* ester (**10**) was accompanied by partial *Z* to *E* isomerization. The distribution of *E* and *Z* isomers in crude reaction mixtures was determined by gas chromatography with a glass capillary column or by proton magnetic resonance spectroscopy.

---

WESLEY G. TAYLOR. Can. J. Chem. **60**, 1847 (1982).

On a synthétisé trois paires d'isomères géométriques qui proviennent de la mono-oxydation allylique de l'oléfine trisubstitué, l'acétal éthylènique du citronellal (**3**). Ces composés sont les isomères *E* et *Z* du (dioxolanne-1,3 yl-2)-7 diméthyl-2,6 heptène-2 ol-1, de l'aldéhyde (al-1) et de l'acide (oique-1 sous forme d'ester méthylique) correspondants qui sont les précurseurs dans l'identification des produits de biodégradation du citronellal et de quelques-uns de ses dérivés. On a obtenu l'aldéhyde *E* (**4**) à partir du composé (**3**) en faisant appel au procédé de Sharpless avec des quantités catalytiques de bioxyde de sélénium. On a préparé l'ester *E*-(**5**) et l'alcool *E*-(**6**) avec une grande pureté isomérique (97–99%) en soumettant respectivement le composé **4** à une oxydation par le bioxyde manganèse activé et à une réduction au borohydrure de sodium. L'ozonolyse sélective du groupe isobuténylé du composé **3** donne le (dioxolanne-1,3 yl-2)-5 méthyl-4 pentanal-1 (**7**). Dans les conditions utilisées, l'ozone ne réagit pas avec l'acétal éthylènique. On a transformé d'une façon stéréosélective l'acétal-aldéhyde **7** en alcool *Z* (**8**) par une réaction de Wittig. L'oxydation du composé **8** (isomère *Z* à 98–99%) en aldéhyde *Z* (**9**) et du composé **9** en l'ester *Z* (**10**) par le bioxyde de manganèse s'accompagne d'une isomèrisation partielle de *Z* en *E*. On a déterminé la distribution des isomères *E* et *Z* des mélanges réactionnels bruts par chromatographie en phase vapeur avec un colonne capillaire en verre ou par la spectroscopie de rmn du proton.

[Traduit par le journal]

Several investigators have demonstrated that xenobiotics with the isobutenyl group are capable of undergoing metabolic oxidation in mammals according to eq. [1] (1–5). To explore such meta-

[1] $(CH_3)_2C{=}CHR \longrightarrow HOCH_2(CH_3)C{=}CHR + HC(=O)(CH_3)C{=}CHR + HOC(=O)(CH_3)C{=}CHR$

bolic transformations, authentic reference samples of the *E* (*trans*) and *Z* (*cis*) alcohols, aldehydes, and acids are required. In principle, these isomeric products are accessible from the substrate. Thus, it is known that *E* trisubstituted olefinic alcohols or aldehydes can usually be obtained by use of selenium dioxide chemistry (6–8) and that the cyanohydrins of conjugated *E* aldehydes have been converted to methyl esters of *E* trisubstituted olefinic acids with activated manganese dioxide in methanol (9). *Z* Trisubstituted alcohols of this particular type have been accessible with a special type of Wittig reaction (8), as demonstrated initially by Corey *et al.* (10, 11) and by Schlosser *et al.* (12–14). A new synthesis of *Z* trisubstituted olefinic alcohols by the Wittig reaction has also been reported (15).

The problem of obtaining reference oxidation products arose during investigations (unpublished) on the elucidation of metabolic pathways for citronellal (**1**) and stereoisomeric mixtures of its *N*-acetyloxazolidine derivative (**2**), two insect repellents with the isobutenyl group (16). However, it was evident that neither of these unsaturated monoterpenoids would withstand the reaction conditions necessary for stereoselective synthesis of both series of isomers, so a potentially versatile intermediate to **1** and **2** was selected instead. This paper describes the chemistry that has been explored during the synthesis of *E* and *Z* alcohols, aldehydes, and acids (as methyl esters) of citronellal ethylene acetal (**3**). It is planned to use these derivatives of **3** for identifying the biodegradation products from metabolic experiments with **1** and **2**.

## Results and discussion

### trans-*Oxidized derivatives of* 3

Clark *et al.* (17) had already prepared **4** by the regioselective oxidation of **3** with selenium dioxide in ethanol. In this work, a new procedure from Sharpless and co-workers (7, 18) was used in which **3** was oxidized in methylene chloride solution with

10 $R^1 = CH_3, R^2 = CO_2CH_3$

a mixture of selenium dioxide and *tert*-butylhydroperoxide. The main product was **4**, as determined by spectral analysis of a sample from column chromatography. The *E* stereochemistry for **4** was indicated from the nmr spectrum because a signal for the unsaturated aldehyde proton was seen at 9.4 ppm. A signal for the aldehyde proton of the *Z* isomer would appear downfield near 10 ppm if it was present in detectable amounts (6, 19). The nmr analysis of the crude reaction product mixture gave no evidence for the presence of the *Z* aldehyde, so it was concluded that this reaction had proceeded with high (> 95%) stereoselectivity.

By employing a method from Crombie *et al.* (20) for converting related *E* trisubstituted olefinic aldehydes to *E* methyl esters, **4** gave the desired *E* acetal ester (**5**). The structure of **5** was confirmed by elemental and spectral analysis on a purified sample. Analysis of crude samples by glass capillary gas chromatography (capillary gc) showed **5** as a major component. A minor component, comprising 1–2% of the mixture, was also seen with a shorter retention time. It was apparent that the oxidation of **4** proceeded with little, if any, *E* to *Z* isomerization. In fact, only one olefinic proton was seen in the nmr spectrum of **5** and it resonated at the expected position (6.8 ppm) for an *E* trisubstituted olefinic ester of this type (6).

Alcohol (6) had previously been prepared by the incomplete oxidation of **3** with selenium dioxide in ethanol and pyridine (21). In the present investigation, **6** was obtained by reduction of **4** with sodium borohydride. The product from this reaction showed a major component and a minor component with a peak area ratio of 97:3 by capillary gc. Under conditions for electron impact mass spectrometry (ei-ms) combined with capillary gc, these two components gave nearly identical mass spectra, thus indicating that the *Z* isomer of **6** was probably present. Both components gave small $M - 1$ ions, which are characteristic ions in related ethylene acetals (22), and the base peak at *m/z* 73 was seen for the oxonium ($C_3H_5O_2$) ion (23). The latter ion was the base peak in the ei-ms of all of the compounds examined.

Confirmatory evidence for the presence of the *Z* isomer of **6** in samples from the reduction of **4** with sodium borohydride came from the independent synthesis of this isomer (discussed later). Additional evidence was also obtained by reducing the methyl ester function in **5** with lithium borohydride. The same isomeric alcohols, in approximately the same ratio (98:2), were found by capillary gc. This experiment also confirmed that **5** was formed from **3** with approximately 98% stereoselectivity.

Quasimolecular ions usually dominated the chemical ionization mass spectra (ci-ms) of these compounds and aided in confirming their structures. In the case of **3**, the loss of 60 amu from both the quasimolecular ion ($(M + 1) - 60$) and from the $M - 1$ ion ($(M - 1) - 60$) accounted for the major fragmentation pathways. With **4** and **6**, $(M - 1) - 60$ was more favorable. The most intense ion in **6** corresponded to $(M + 1) - 18$, a process observed in the ci-ms of saturated alcohols (24). Other prominent ions in **6** occurred at *m/z* 137 and *m/z* 135, which can be rationalized by $(M + 1) - 18 - 60$ and $(M - 1) - 18 - 60$ pathways. The most prominent fragment ion in **5** was seen at *m/z* 211, corresponding to $(M + 1) - CH_3OH$ (25).

*Ozonolysis of 3*

Synthetic approaches to the *Z* isomers of **4**, **5**, and **6** required that the olefinic bond in **3** first be cleaved and the product acetal aldehyde (**7**) subjected to a Wittig reaction. By employing a modification of the Wittig reaction for *Z* selectivity, where electrophilic substitution of intermediate β-oxido ylides with formaldehyde gave *Z* trisubstituted allylic alcohols directly (10–14), **7** should give the *Z* acetal alcohol (**8**).

A potential problem arose during the attempted synthesis of **7** by the ozonolysis of **3** (eq. [2]). This

[2] 
3 7

was because a number of acetals, including ethylene acetals, were known to react with ozone in ethyl acetate solution to give β-hydroxy esters (26–29). However, treatment of **3** with ozone at −78°C in methylene chloride solution gave one main product as detected by capillary gc. The nmr spectrum clearly indicated the formation of **7** since

an aldehyde signal (at 9.8 ppm), an acetal signal (at 4.9 ppm), and a four proton multiplet (at 3.6–4.1 ppm) for the methylene groups of the 1,3-dioxolane ring were present. The crude ozonolysis product was also examined by capillary gc in combination with ei-ms and ci-ms. By selected ion monitoring techniques, no evidence for the presence of β-hydroxy esters of **3** or **7** was obtained. The main component gave a weak molecular ion for **7** under ei conditions and the base peak (at *m/z* 73) suggested that the 1,3-dioxolane ring was present. Under ci-ms conditions, the most prominent ion of the main component occurred at *m/z* 173, which represented the quasimolecular ion for **7**. Ions were also seen at *m/z* 155 [(*M* + 1) − 18] and *m/z* 111 [(*M* − 1) − 60].

The crude material from ozonolysis experiments was purified by chromatography with silica gel and **7** was isolated in reasonable yields (40–80%). The use of high pressure liquid chromatography for purification of **7** was preferred. It was also important to stop the reaction as soon as **3** had disappeared and to use dimethylsulfide (30) as a reducing agent. The structure of **7** was confirmed by the synthesis of this aldehyde by reaction of **3** with osmium tetroxide and sodium periodate (Experimental section).

cis-*Oxidized derivatives of* **3**

The preparation of *Z* alcohol (**8**), and the subsequent conversion of **8** with manganese dioxide to *Z* aldehyde (**9**) and, via the cyanohydrin of **9**, to *Z* ester (**10**) depended on the functionalization of **7** with the hydroxyisopropenyl group. Since *Z* trisubstituted olefinic alcohols have been obtained from ketal aldehydes in this laboratory by a Wittig reaction (8), it was anticipated that acetal aldehyde (**7**) would behave analogously. In fact, the Wittig reaction on **7**, performed by adding **7** to a cold solution of ethylidenetriphenylphosphorane in THF, followed by the addition of *n*-butyllithium, formaldehyde, and water gave the desired **8**, in yields ranging from 0–50%. In comparison to dry paraformaldehyde or *s*-trioxane, gaseous formaldehyde, generated according to the procedure of Benkeser *et al.* (31), gave the best yield of **8**. The identity of **8** was confirmed from elemental analysis and from spectral comparisons to samples of the *E* alcohol (**6**). Noteworthy differences in nmr chemical shift values were apparent for the methyl, methylene, and vinyl protons of the isobutenyl group (Experimental section) and were in agreement with published values on isomers related to **6** and **8** (6, 8, 11). Capillary gc on samples of **8** showed that **6** was also present but only to the extent of 1–2%. Possible reasons for the remarkable stereoselectivity in this type of Wittig reaction have already been discussed (32).

For the preparation of **9**, pure samples of **8** were oxidized with activated manganese dioxide in hexane (9). Despite the high *Z* isomer content of **8** (98–99%), the nmr spectrum showed that the product was a mixture of isomeric aldehydes consisting predominantly of **9**. Thus, a main signal for the aldehyde proton in **9** resonated at 10.1 ppm and a minor signal was seen at 9.4 ppm which had the same chemical shift as the aldehyde proton for the *E* isomer (**4**). This *Z* to *E* isomerization, estimated at 25–30% in an experiment with a large excess of manganese dioxide, was reduced to 5–10% by the gradual addition of a minimum quantity of the reagent. Attempts to further suppress this isomerization were unsuccessful (Experimental section).

The **9** isolated from these experiments was an unstable compound and freshly isolated samples were used without purification for the synthesis of **10**. Cyanohydrin formation, followed by oxidation with manganese dioxide in methanol (as described for **5**), gave a mixture of **5** and **10**. This was confirmed by mass spectrometry. Capillary gc showed that there was from 15% to 32% of **5** in all samples of **10**. This amount was discernible in the nmr spectrum, particularly by comparison of chemical shifts for the vinylic proton. In **10**, this signal occurred at 5.9 ppm whereas the same signal for **5** was seen at 6.8 ppm.

The mass spectra of the isomeric pairs of esters and alcohols were very similar, especially under ei-ms conditions. A noteworthy difference in the ci-ms of **6** and **8** was apparent in the intensities of ions at *m/z* 153 [(*M* − 1) − 60] and *m/z* 197 [(*M* + 1) − 18]. Comparisons between the isomeric aldehydes were impractical because **9** was not amenable to capillary gc analyses.

The methodology described here illustrates a possible solution to the problem of obtaining authentic samples of the metabolites formed by eq. [1].

## Experimental

Proton nuclear magnetic resonance (nmr) spectra were obtained on a Varian EM-360 A spectrometer using tetramethylsilane as the internal standard. Infrared spectra were taken as liquid films on a Perkin–Elmer Model 137 Infracord spectrophotometer. For capillary gc, a Hewlett–Packard 5838A instrument equipped with a model 18835B capillary inlet system was used. The glass column (22 m × 0.31 mm id) was wall coated with Carbowax 20M-terephthalic acid according to the method of Grob and Grob (33). Helium at a velocity of 30 cm/s served as the carrier gas and nitrogen at a flow rate of 30 mL/min was used as a make-up gas for the flame ionization detector. Samples were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 178.218.224.3 on 09/06/12
For personal use only.

injected by the split technique. The injector and detector temperatures were 225°C and 250°C, respectively. For mass spectrometry, a Hewlett–Packard 5985B gc–ms computer system was used with a glass capillary column (55 m × 0.31 mm id) coated with Carbowax 20M-terephthalic acid. Electron-impact mass spectra were recorded at 70 eV whereas positive chemical ionization mass spectra were recorded using isobutane as the reagent gas at a source pressure of 0.5 Torr. High pressure liquid chromatography was performed with a Waters Prep LC/System 500 A instrument equipped with a Prep PAK Silica cartridge (Waters Associates, Inc.). Mallinckrodt cc-7 silica gel was used for column chromatography. Elemental analyses were obtained from Dr. C. Daessle, Montreal, Quebec. Melting points and boiling points are uncorrected.

Citronellal (Eastman P312), *tert*-butylhydroperoxide (Aldrich 18,471-3), selenium dioxide (K and K, 17660), activated manganese dioxide (K and K, 28107), and ethyl triphenylphosphonium bromide (Aldrich E5, 060-4) were used as received. *n*-Butyllithium (Aldrich 18,617-1) was standardized by titration (34) before use. Tetrahydrofuran (THF) was distilled from lithium aluminum hydride and then redistilled immediately before use from sodium and benzophenone. Evaporations were performed with a Büchi rotary evaporator at water aspirator vacuum and a bath temperature of 25–35°C.

*2-(2,6-Dimethyl-5-heptenyl)-1,3-dioxolane (3)*

This acetal was prepared from **1** (77 g, 0.5 mol), ethylene glycol (44.5 g, 0.72 mol), *p*-toluenesulfonic acid (0.1 g), and benzene as described in the literature (17). A center portion of the distillate gave **3** (57 g, 57.5% yield) as a colorless oil. Capillary gc (temperature programmed from 100°C to 130°C at 3°C/min) showed 78% of **3** with a retention time of 9.9 min. Pure samples of **3** were obtained in 48–52% overall yield by preparative hplc with 2% ethyl acetate in methylene chloride: bp 76–78°C (0.3 Torr) (lit (17) bp 125–130°C (18 Torr)); nmr ($CDCl_3$) δ: 5.17 (m, C=C*H*), 4.90 (t, $J$ = 4 Hz, acetal *H*), 4.10–3.53 (m, $OCH_2CH_2O$), 2.43–1.13 (m, 13 *H*), 0.96 (d, $J$ = 5 Hz, $CHCH_3$); ei-ms *m/z* (% relative abundance): 198 ($M^+$, 4), 197 (2), 121 (61), 113 (78), 73 (100); ci-ms: 199 ($MH^+$, 45), 197 (4), 139 (100), 137 (54).

*5-(1,3-Dioxolan-2-yl)-4-methyl-1-pentanal (7)*

Using an ozone-generating apparatus previously described in detail (8), **3** (14 g, 70 mmol) in methylene chloride solution (Caledon glass distilled, 300 mL) at −78°C was allowed to react with ozone until the starting material had just been consumed (gc evidence). With dual ozonizers and an oxygen flow rate of 12 L/h, the time of reaction was 7 h (± 30 min). The cold mixture was swept with nitrogen for 30 min and dimethylsulfide (10 mL) was added. The mixture was gradually allowed to approach room temperature with continuous stirring during 16–18 h. A crude oil (~ 18 g) was obtained by removing the volatiles on a rotary evaporator. Capillary gc (as described for **3**) showed a major component (> 70% of the mixture) with a retention time of 15.8 min. Samples of **7** (80–90% purity) were isolated in 40–60% yields by column chromatography with silicAR cc-7 and eluting with hexane–ether mixtures. Alternatively, **7** (75–95% purity) was obtained in 50–80% yields by preparative hplc using a solvent system of 4% ethyl acetate in methylene chloride: bp 72–76°C (0.3 Torr); ir: 1725 $cm^{-1}$ (C=O); nmr ($CDCl_3$) δ: 9.78 (m, aldehyde *H*), 4.90 (t, $J$ = 4 Hz, acetal *H*), 4.10–3.60 (m, $OCH_2CH_2O$), 2.70–2.10 (m, 2*H*), 2.06–1.20 (m, 5*H*), 0.98 (d, $J$ = 5.5 Hz, $CHCH_3$); ei-ms *m/z* (% relative abundance): 172 ($M^+$, 0.2), 171 (2), 73 (100); ci-ms: 173 ($MH^+$, 100), 171 (5), 155 (48), 111 (13), 93 (19). During ci-ms analyses, ions at *m/z* 215 and 189 were monitored but these ions, which correspond to quasi-molecular ions for β-hydroxy esters of **3** and **7**, were absent.

Aldehyde **7** (a colorless liquid) gave a crystalline, deep red 2,4-dinitrophenylhydrazone derivative, which was recrystallized from THF–water: mp 214–218°C. *Anal.* calcd. for $C_{15}H_{20}N_4O_6$: C 51.13, H 5.72, N 15.90; found: C 51.41, H 5.49, N 15.74.

Alternatively, **7** was prepared by stirring a mixture of **3** (9.915 g, 50 mmol), osmium tetroxide (0.051 g dissolved in ether, 0.2 mmol), dioxane, and water for 30 min at room temperature. Sodium periodate (20 g, 94 mmol) was added during 1 h and the mixture was heated at 50°C for 24 h (35). The mixture was filtered and the white precipitate was washed with ether. The aqueous layer was extracted with ether and the combined organic extracts were washed with 5% aqueous sodium carbonate and with water. The organic extract was dried ($Na_2SO_4$) and concentrated on a rotary evaporator to give 7.38 g of a crude product. Column chromatography with silicAR cc-7 and hexane–ether mixtures gave 1.9 g (22% yield) of **7** which had a purity of 70% by gc.

(E)*(4) and* (Z)*(9) isomers of 7-(1,3-dioxolan-2-yl)-2,6-dimethyl-2-hepten-1-al*

*By oxidation of 3 with selenium dioxide*

Following the literature method (7), **3** (11.9 g, 60 mmol) was allowed to react with a mixture of selenium dioxide (3.32 g, 30 mmol), *tert*-butylhydroperoxide (15.4 mL of a 70% aqueous solution, 120 mmol), and methylene chloride (60 mL) for 60 h. The reaction mixture was worked up as described (18) to give 8.78 g of a faint yellow oil. Capillary gc (160–180°C at 2°C/min) showed a major component (~ 60%) with a retention time of 10.75 min. A pure sample of **4** (2.3 g, 18% yield) was obtained by column chromatography with silicAR cc-7 and eluting with hexane–ether mixtures: ir: 1670 $cm^{-1}$ (C=O); nmr ($CDCl_3$) δ: 9.40 (s, aldehyde *H*), 6.48 (ragged t, $J$ = 7 Hz, C=C*H*), 4.88 (t, $J$ = 4 Hz, acetal *H*), 4.07–3.63 (m, $OCH_2CH_2O$), 2.63–2.10 (m, 2*H*), 1.93–1.20 (m, 8*H*), 0.98 (d, $J$ = 5.5 Hz, $CHCH_3$); ei-ms *m/z* (% relative abundance): 212 ($M^+$, O), 211 (1), 73 (100); ci-ms: 213 ($MH^+$, 100), 195 (3), 151 (35).

*By oxidation of 8 with activated manganese dioxide*

A mixture of **8** (2.143 g, 10 mmol), manganese dioxide (8.69 g, 100 mmol, added in portions during five days), and hexane (250 mL) was stirred at 20°C for 6 days and then filtered. A yellow oil (1.94 g) was obtained by removal of the solvent on a rotary evaporator. Capillary gc with Carbowax 20M-TPA and with SP 2300 (20 m × 0.29 mm id) showed a complex mixture of products, including a small peak with the same retention time as **4**. The mixture showed **9** and **4** by nmr ($CDCl_3$): δ: 10.15 (s, ~ 0.9 *H*, aldehyde *H* for *Z* isomer), 9.40 (s, ~ 0.1 *H*, aldehyde *H* for *E* isomer). This experiment was repeated at 0°C, by adding a total of 200 mmol of manganese dioxide in portions during two days to a suspension of **8** (4.2 g, 20 mmol) in hexane (400 mL). The product (3.30 g) contained **9** and **4** in an approximate ratio of 90:10 (nmr evidence). The same isomeric ratio was found on repeating this experiment with the Attenburrow grade of manganese dioxide (12.5-fold mole excess added during 2 days), which was prepared here by the literature method (36). When manganese dioxide (20-fold mole excess) was added in one portion to a mixture of **8** at 0°C, the reaction was completed in 4 h and the ratio of **9**/**4** was 70:30 (nmr evidence). Storage of neat samples resulted in a gradual decomposition of **9** to unidentified products. The aldehyde nmr signal for **9** had completely disappeared after storage of samples at 0°C for six months.

(E)*(5) and* (Z)*(10) isomers of the methyl ester of 7-(1,3-dioxolan-2-yl)-2,6-dimethyl-2-hepten-1-oic acid*

*By manganese dioxide oxidation of the cyanohydrin of 4*

A solution of **4** (2.16 g, 10.2 mmol) in methanol (150 mL) was stirred with sodium cyanide (2.5 g, 51 mmol) and glacial acetic acid (1.0 mL) for 1 h. Activated manganese dioxide (17.73 g, 204

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 178.218.224.3 on 09/06/12
For personal use only.

mmol) was then added and the mixture was stirred at room temperature for 90 h. The mixture was filtered, the filtrate evaporated on a rotary evaporator, and the residue dissolved in chloroform. Washing with water and evaporating the dried ($MgSO_4$) organic phase gave 2.06 g (83% yield) of a yellow oil. The residue gave a main peak (98%) at 13.37 min and a minor peak (2%) at 10.05 min when analyzed by capillary gc (as described for **4**). The sample was purified by column chromatography (silicAR cc-7) with hexane–ether mixtures to give **5** as a colorless oil: bp 80–85°C (0.05 Torr); ir: 1720 $cm^{-1}$ (C=O); nmr ($CDCl_3$) δ: 6.77 (ragged t, $J$ = 7 Hz, C=C*H*), 4.92 (t, $J$ = 4 Hz, acetal *H*), 4.10–3.80 (m, $OCH_2CH_2O$), 3.75 (s, $OCH_3$), 2.47–2.00 (m, 2*H*), 1.93–1.13 (m, 8*H*), 0.99 (d, $J$ = 5.5 Hz, $CHCH_3$); ei-ms *m/z* (% relative abundance): 242 ($M^+$, O), 241 (1), 73 (100); ci-ms: 243 ($MH^+$, 100), 211 (25), 183 (4), 181 (7). *Anal.* calcd. for $C_{13}H_{22}O_4$: C 64.43, H 9.15; found: C 64.67, H 9.43.

*By manganese dioxide oxidation of the cyanohydrin of* **9**

A crude sample of **9** (1.9 g, ~ 9 mmol) in methanol (150 mL) was allowed to react with sodium cyanide (2.45 g, 50 mmol) and glacial acetic acid (1.0 mL), then with activated manganese dioxide (17.39 g, 200 mmol) for 160 h at 20°C as described for the preparation of **5**. A yellow oil (2.05 g, 90% yield) was isolated. Capillary gc (as described for **4**) showed **10** at 10.05 min and **5** at 13.37 min in a ratio of 82:18. Column chromatography (silicAR cc-7) with hexane–ether mixtures gave predominantly **10** as a colorless oil: bp 96–100°C (0.05 Torr); ir: 1720 $cm^{-1}$ (C=O); nmr ($CDCl_3$) δ: 5.93 (ragged t, $J$ = 7 Hz, C=C*H*), 4.93 (t, $J$ = 4 Hz, acetal *H*), 4.10–3.80 (m, $OCH_2CH_2O$), 3.76 (s, $OCH_3$), 2.73–2.10 (m, 2*H*), 2.00–1.00 (m, 8*H*), 0.98 (d, $J$ = 5.5 Hz, $CHCH_3$); ei-ms *m/z* (% relative abundance): 242 ($M^+$, 0.1), 241 (1), 73 (100); ci-ms: 243 ($MH^+$, 100), 211 (44), 183 (5), 181 (16). *Anal.* calcd. for $C_{13}H_{22}O_4$: C 64.43, H 9.15; found: C 64.17, H 9.16.

In three additional experiments on this oxidation (as described), crude samples of **10** contained from 15–25% of the *E* isomer (**5**) (capillary gc and nmr evidence). The ratio of **10/5** was 68:32 in another experiment with manganese dioxide prepared by the method of Attenburrow *et al.* (36).

(E)*(6) and* (Z)*(8) isomers of 7-(1,3-dioxolan-2-yl)-2,6-dimethyl-2-hepten-1-ol*

*By reduction of* **4** *with sodium borohydride*

A crude sample of **4** (1.83 g, 8.6 mmol) in 95% ethanol (30 mL) at 6°C was treated dropwise with a solution of sodium borohydride (1.085 g, 29.0 mmol) in 95% ethanol (30 mL; pH adjusted to 8 with NaOH) during 45 min. The mixture was stirred at room temperature for 18 h. Acetone (15 mL) was added and the solvents were evaporated on a rotary evaporator. The residue was dissolved in saturated brine and extracted with ether. The ether extract was dried ($MgSO_4$) and evaporated. There was obtained 1.636 g (88.6%) of **6** which eluted at 18.02 min under conditions of capillary gc analysis (as described for **4**). An analytically pure sample, as a colorless oil, was obtained by column chromatography (silicAR cc-7), eluting with hexane–ether mixtures: bp 82–84°C (0.1 Torr); ir: 3490 $cm^{-1}$ (OH); nmr ($CDCl_3$) δ: 5.40 (ragged t, $J$ = 7 Hz, C=C*H*), 4.90 (t, $J$ = 4 Hz, acetal *H*), 4.10–3.63 (m, $OCH_2CH_2O$ and $CH_2OH$), 1.93 (broad s, $CH_2OH$, exchanged with $D_2O$), 1.67 (s, $C=CCH_3$), 2.30–1.10 (m, 7*H*), 0.95 (d, $J$ = 5.5 Hz, $CHCH_3$); ei-ms *m/z* (% relative abundance): 214 ($M^+$, O), 213 (0.5), 113 (59), 73 (100); ci-ms: 215 ($MH^+$, 13), 213 (11), 197 (100), 155 (5), 153 (93), 137 (25), 135 (62). *Anal.* calcd. for $C_{12}H_{22}O_3$: C 67.25, H 10.35; found: C 67.34, H 10.46.

*By reduction of* **5** *with lithium borohydride*

To a mechanically stirred suspension of lithium borohydride (0.022 g, 1.0 mmol) in THF (5 mL) was added dropwise a solution of **5** (0.1 g, 0.41 mmol) in THF (3 mL). The mixture was stirred under an argon atmosphere for 16 h at 20°C, then heated under reflux for 21 h. Water was added and the pH was adjusted to 1 with 0.1 *N* hydrochloric acid. The product was isolated by extraction with ethyl acetate. The organic extracts were washed with water and saturated brine, then dried ($MgSO_4$) and concentrated on a rotary evaporator. The colorless oil (51 mg) when subjected to capillary gc (as described for **4**) and gc–ms showed the *E* alcohol (**6**, ~ 56% of the mixture) and the *Z* alcohol (**8**, ~ 1%). A component at 14.13 min (~ 27%) was identified by capillary gc–ms as the saturated alcohol, 7-(1,3-dioxolan-2-yl)-2,6-dimethyl-1-heptanol: ei-ms *m/z* (% relative abundance): 216 ($M^+$, O), 215 (1), 73 (100); ci-ms: 217 ($MH^+$, 100), 215 (5), 199 (8), 155 (44), 137 (11).

*By reaction of* **7** *in the Wittig reaction*

The preparation of ethylidenetriphenylphosphorane from ethyltriphenylphosphonium bromide (19.45 g, 52.4 mmol) and *n*-butyllithium (52.4 mmol) in THF (125 mL) was performed at 0°C as previously described (8). Aldehyde **7** (9.0 g from hplc, 52.4 mmol) was added by syringe at −78°C and, after 20 min of mechanical stirring, another 52.4 mmol of *n*-butyllithium was added. After 45 min, the Dry Ice bath was replaced by crushed ice. When the temperature was −5°C, formaldehyde gas (~ 3 g, freshly generated from 11.1 g of dried paraformaldehyde (31)) was delivered above the reaction mixture during 10 min. The color changed from deep red to creamy white during the delivery of formaldehyde. After stirring at 20°C for 12 h, the product was isolated as described (8). Distillation of the crude product *in vacuo* gave a volatile fraction (1.5 g, bp 57–98°C at 0.1 Torr) and another fraction (bp 98–120°C at 0.1 Torr) which was identified as **8** (4.86 g, 43.4%). Capillary gc (as described for **4**) on the first fraction showed several components. Two major components were seen with retention times of 2.8 and 2.9 min. These were tentatively identified by capillary gc–ms as 3-methyl-6-octen-1-al ethylene acetal (a 1:1 mixture of *E* and *Z* isomers); ei-ms *m/z* (% relative abundance); 184 ($M^+$, O), 183 (1), 73 (100) for both isomers; ci-ms showed prominent ions at 185, 125, and 123. Capillary gc on the second fraction from distillation showed a main peak (75–85% of the mixture) with a retention time of 15.85 min. This fraction was purified by column chromatography (silicAR cc-7) with hexane–ether mixtures, followed by redistillation. A pure sample of **8** was obtained as a colorless oil: bp 107°C (0.1 Torr); ir: 3490 $cm^{-1}$ (OH); nmr ($CDCl_3$) δ: 5.26 (ragged t, $J$ = 7 Hz, C=C*H*), 4.90 (t, $J$ = 4 Hz, acetal *H*), 4.11–3.63 (m, $OCH_2CH_2O$ and $CH_2OH$), 2.05 (broad s, $CH_2OH$, exchanged with $D_2O$), 1.80 (s, $C=CH_3$), 2.33–1.13 (m, 7*H*), 0.95 (d, $J$ = 5.5 Hz, $CHCH_3$), ei-ms *m/z* (% relative abundance): 214 ($M^+$ O), 213 (0.5), 113 (60), 73 (100); ci-ms: 215 ($MH^+$, 16), 213 (5), 197 (50), 153 (100), 137 (17), 135 (35). *Anal.* calcd. for $C_{12}H_{22}O_3$: C 67.25, H 10.35; found: C 67.05, H 10.60.

This reaction was repeated as described except gaseous formaldehyde (generated by heating paraformaldehyde in a vessel connected to the reaction flask by means of glass tubing) was used. Delivery of formaldehyde above the surface of the reaction, which was at −15°C, ultimately gave **8** in 43% yield. Delivery of formaldehyde below the surface of the reaction (at −78°C) resulted in the formation of a thick solid from which **8** was isolated in 25% yield. Addition of paraformaldehyde directly to the reaction mixture (at 0°C, −5°C, or −78°C) gave **8** in yields ranging from 11–29%. None of the desired **8** was isolated when excess *s*-trioxane (added at −5°C) was used as the source of formaldehyde. Volatile side products accounted for the majority of material in these experiments.

# Specific heats of polymer powders by differential scanning calorimetry

EVA I. VARGHA-BUTLER AND A. WILHELM NEUMANN
*Department of Mechanical Engineering, University of Toronto, 5 King's College Road, Toronto, Ont., Canada M5S 1A4*
AND
HASSAN A. HAMZA
*Western Research Laboratory, Department of Energy, Mines and Resources, CANMET, Edmonton, Alta., Canada T6G 2C2*
Received November 12, 1981

EVA I. VARGHA-BUTLER, A. WILHELM NEUMANN, and HASSAN A. HAMZA. Can. J. Chem. **60**, 1853 (1982).

The specific heats of five polymers were determined by differential scanning calorimetry (DSC) in the temperature range of 300 to 360 K. The measurements were performed with polymers in the form of films, powders, and granules to clarify whether or not DSC specific heat values are dependent on the diminution of the sample. It was found that the specific heats for the bulk and powdered form of the polymer samples are indistinguishable within the error limits, justifying the determination of specific heats of powders by means of DSC.

EVA I. VARGHA-BUTLER, A. WILHELM NEUMANN et HASSAN A. HAMZA. Can. J. Chem. **60**, 1853 (1982).

On a déterminé les chaleurs spécifiques de cinq polymères par calorimétrie à balayage différentiel (CBD) dans l'intervalle de température allant de 300 à 360 K. On effectué les mesures sur des polymères sous forme de film, de poudre ou de granules pour vérifier si les valeurs de chaleur spécifique déterminées par CBD dépendent de la diminution de l'échantillon. On a trouvé que les chaleurs spécifiques des échantillons sous forme encombrée et sous forme de poudre ne se distinguent pas à l'intérieur des limites d'erreurs, justifiant ainsi la détermination des chaleurs spécifiques des poudres par la CBD.

[Traduit par le journal]

## Introduction

Our studies of the specific heat of polymers were motivated by work on the wettability of coal and of other solid particles by means of a freezing front technique (1–3). Specific heat data are a prerequisite for the quantitative determination of contact angles on solid particles using the above technique. As such data were not available for coal in powdered form, it was decided to generate them by differential scanning calorimetry (DSC) (4). Since data for comparison were not available, it was also decided to measure the specific heats of several polymeric materials. The main concern in this connection is the question whether or not differential scanning calorimetry can be used to measure the specific heat of powders. The literature is not explicit on this point. Barrall and Johnson (5) state that "for very precise work, it is desirable to form the sample in the same shape as the sapphire standard". From this statement, as well as the rest of their review article, it seems that the possibility of studying the specific heat of a powder by DSC was not even considered as a possibility. These doubts are reinforced by McNaughton and Mortimer (6) in their discussion of the theory of DSC. They divide the total thermal resistance $R$ into two additive parts, $R_0$ and $R_s$, where $R_0$ represents the thermal resistance between pan and holder and $R_s$ between pan and sample. They base their further arguments on the assumption that for a close contact between sample and pan, $R_s$ will be very small compared to $R_0$. This assumption might well be incorrect in the case of powders where each particle in the bottom layer will normally be in contact with the pan only at a few points. In view of the fact that "the method is a dynamic method" (5), it thus is not *a priori* clear that DSC may be used to determine the specific heat independent of the degree of diminution of the sample. Therefore measurements were performed with several polymers in the form of films, powders, and granules. The results appear to be of sufficient interest to be reported here.

## Experimental

*Materials*

The specific heats of the following polymer samples were determined: (*1*) Poly(propylene), PP, powder (Polysciences Inc.). (*2*) Poly(styrene), PS, in both powder and film forms with a molecular weight of 20 400 and PS powder with a molecular weight of 200 000; $M_w/M_n$ less than 1.06 (Pressure Chemical Co., Pittsburgh, Mellon Institute, special PS standard). (*3*) Poly(hexamethylene adipamide), Nylon 66, PA 66, powder and film (Polysciences Inc.). (*4*) Poly(tetrafluoroethylene), Teflon, PTFE, granules and powder (Polysciences Inc.). (*5*) Tetrafluoroethylene–hexafluoropropylene copolymer, FEP, film (Commercial Plastics, Toronto).

The polymer films were prepared from the polymer powder either by heat pressing or by means of solvent casting (7). PTFE and FEP films were prepared by heat pressing, while the films of PP, PS, and PA were prepared by solvent casting.

*Method*

The specific heat measurements were performed in the temperature range from 300 to 360 K using a Perkin-Elmer Model DSC-2 calorimeter. The heating and cooling rate was

selected as 10 K/min, the chart range as 5 mV, the range control as 5 mcal/s, and the chart speed as 20 mm/min. These settings were chosen on the recommendation of Perkin-Elmer for $C_p$ measurements. Lower rates give poor sensitivity, higher rates provide greater sensitivity but poorer temperature accuracy. Nitrogen gas of 99.99% minimum purity was used for purging the sample holders. A detailed discussion of the DSC-2 and the specific heat measurements are given in refs. 8–10.

An 8.21 mg synthetic sapphire ($\alpha$-$Al_2O_3$) standard was used for calibration; the specific heat values of sapphire were obtained from the work of Ginnings and Furukawa (11). The difference in the weights ($\Delta W$) of the aluminum sample–pans (in which the samples were encapsulated and weighed) were taken into account. The $\Delta W$ value defines an additional ordinate displacement ($\Delta D$ in mm) which has to be added to the displacement ($D$ in mm) caused by the material in the lighter pan. The $\Delta W$ values vary from 0.01 to 2.00 mg which, if not corrected, could cause errors in $C_p$ values up to 25%.

The specific heat of the polymer samples, $C_p$(sample), can be calculated after the calibration with the sapphire disc (ratio method (10)) using the formula

$$[1] \quad C_p(\text{sample}) = \frac{W(\text{sapphire})}{W(\text{sample})} \times \frac{D(\text{sample})}{D(\text{sapphire})} \times C_p(\text{sapphire})$$

where $C_p$(sapphire) is the specific heat of the sapphire standard in cal/g K, $W$(sapphire) and $W$(sample) are the weights of the standard and of the sample, respectively, in mg, $D$(sapphire) and $D$(sample) are the corrected ordinate displacements of the sapphire and that of the sample in mm. Finally, the specific heats were expressed in kJ/kg K.

The specific heat data presented here are the arithmetic mean values of at least three measurements. The standard deviation and the population mean were calculated from the sample mean assuming a $t$ distribution. The errors given in Tables 1–3 are 95% confidence limits.

The samples were reweighed after the experiments but no significant (less than 0.1 mg) change in weight was observed.

## Results and discussion

In Figs. 1 and 2 the specific heats of the various polymer samples are plotted as a function of temperature. For all of the polymers the specific heat increases linearly with temperature over the whole range investigated as expected for materials not undergoing conformational changes. However, Nylon 66 (PA 66) has a glass transition (12) around 323 K. Conceivably the slight deviation of our points at 330 K may be due to this conformational change, but this is of no concern for our present purposes.

As the plots in Figs. 1 and 2 are not adequate for recovering actual data, the results are summarized in Table 1, together with information on the accuracy.

A comparison of our results with literature data is shown in Tables 2 and 3. The data of the present work are given as the arithmetic mean of the specific heats obtained for the bulk and powdered forms of polymers. The $C_p$ values from the literature were selected for well defined systems only.

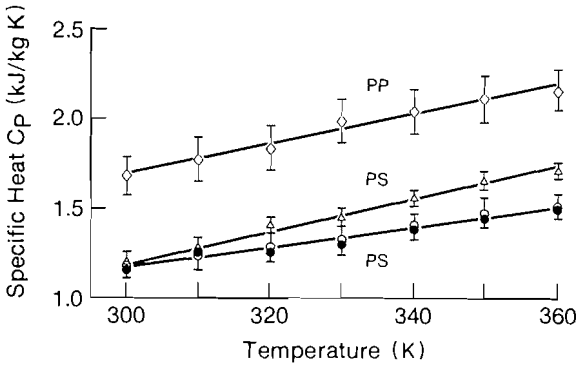

FIG. 1. Temperature dependence of specific heats of polypropylene and polystyrene: ◇ PP powder, ○ PS powder, MW 20 400, ● PS film, MW 20 400, △ PS powder, MW 200 000.

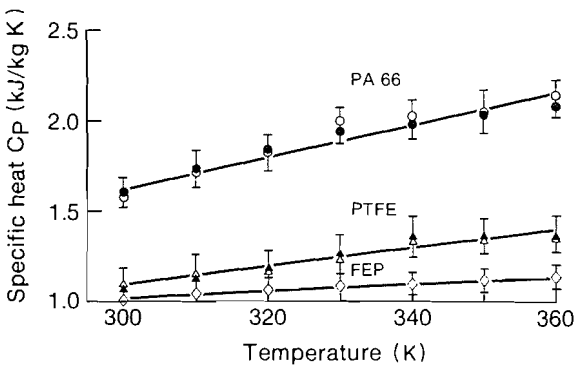

FIG. 2. Temperature dependence of specific heat of PA 66, PTFE, and FEP: ○ PA 66 powder, ● PA 66 film, △ PTFE powder, ▲ PTFE granules, ◇ FEP film.

In general, the agreement is satisfactory considering that the polymers used for the various specific heat measurements had different molecular weight, crystallinity, or pretreatment (annealing, molding, etc.). The specific heat of nylon 66 was found to be higher than that of the data given by Wilhoit and Dole (14), but their experimental results also showed some irregularity between 315 and 536 K. In Table 3, the temperature dependence of the specific heat of an atactic poly(propylene) and the average value of several sets of measurements averaged by Wunderlich (17) are compared with

our results. The data of the present work agree with the average $C_p$ given for poly(propylene) (17); however, both are lower than the specific heat of the atactic poly(propylene) measured by Wilkinson and Dole (16). The specific heats of poly(styrene) agree with both the average data given for PS (17) and with the results from measurements of Chang *et al.* (18) and Karasz *et al.* (19). These authors used a commercial preparation and an N.B.S. standard sample of atactic poly(styrene) of a rather broad molecular weight distribution, respectively; the specific heat was determined by means of adiabatic calorimetry.

## Conclusions

From these measurements no differences were found between the results obtained for powdered and bulk polymers. On the other hand, relatively small differences in chemical structure (PTFE vs. FEP) as well as differences in molecular weight (PS powders with an MW of 20 400 vs. 200 000) show considerable differences in the specific heat.

The results found here agree well with literature values or at least fall within the spread typically found by different investigators, using different samples. This finding reinforces our main point, i.e. that DSC is an appropriate technique for determining the temperature dependence of polymer powders, and by implication, of powdered materials in general.

# Structure–sweetness relationships for fructose analogs. Part I. Synthesis and evaluation of sweetness of 5-deoxy-D-*threo*-hexulose

OLIVIER R. MARTIN, SIRKKA-LIISA KORPPI-TOMMOLA, AND WALTER A. SZAREK

*Carbohydrate Research Institute and Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6*

Received December 28, 1981

OLIVIER R. MARTIN, SIRKKA-LIISA KORPPI-TOMMOLA, and WALTER A. SZAREK. Can. J. Chem. **60**, 1857 (1982).

5-Deoxy-D-*threo*-hexulose ("5-deoxyfructose", "5-deoxysorbose") has been prepared in six steps from D-fructose. The reaction of 2,3-*O*-isopropylidene-β-D-fructopyranose with sulfuryl chloride afforded exclusively 5-chloro-5-deoxy-2,3-*O*-isopropylidene-α-L-sorbopyranose in the key step. "5-Deoxyfructose" exists only in the $^2C_5$(D) pyranoid form in solution, and was found to be much sweeter than L-sorbose and nearly as sweet as D-fructose. Comments on this unexpected sweetness result are given.

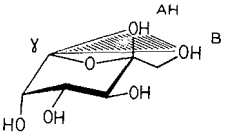
OLIVIER R. MARTIN, SIRKKA-LIISA KORPPI-TOMMOLA et WALTER A. SZAREK. Can. J. Chem. **60**, 1857 (1982).

Le désoxy-5-D-*thréo*-hexulose ("désoxy-5-fructose", "désoxy-5-sorbose") a été préparé en six étapes à partir du D-fructose. La chloration de l'*O*-isopropylidène-2,3-β-D-fructopyrannose par le chlorure de sulfuryle conduit exclusivement au chloro-5-désoxy-5-*O*-isopropylidène-2,3-α-L-sorbopyrannose et constitue l'étape clé de la synthèse. Le "désoxy-5-fructose" adopte uniquement la forme pyrannique $^2C_5$(D) en solution, et se révéla beaucoup plus doux que le L-sorbose et presque aussi doux que le D-fructose. Le résultat inattendu des tests de douceur est commenté.

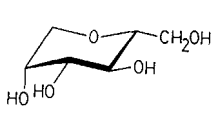
## Introduction

D-Fructose, the well-known fruit sugar, is the sweetest of the naturally occurring sugars;[1] however, the structural features responsible for its high sweetness have not yet been established with accuracy. Since the sweetness diminishes with the appearance of the furanose forms during mutarotation, the taste of D-fructose is thought to arise only from the β-D-fructopyranose form (1), the common form in the solid state. According to Shallenberger's theory of sweet taste based on intermolecular hydrogen bonding with the taste receptor of the tongue (2), the anomeric 2-OH and the $CH_2OH$ groups should correspond, respectively, to the H-donor, AH, and the H-acceptor, B, of the principal saporous unit of D-fructose (I); the stereochemical requirements between the AH and B groups are secured by the Lemieux effect (3). Since the physico-chemical interaction leading to sweet taste seems to need a lipophilic function (4), a third, hydrophobic component (γ) has been added to the AH,B system to form a tripartite site (see I).

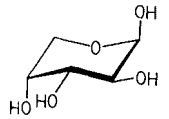
Studies on modified forms by Birch and coworkers (5) seem to confirm Shallenberger's intuitive proposal for the sweetness of D-fructose; thus, "2-deoxyfructose" (II, 2,6-anhydro-D-mannitol) and β-D-arabinose (III) are indeed less sweet than D-fructose. However, L-sorbose, which adopts almost exclusively the α-L-pyranose form (IV) in solution (6), is far less sweet than D-fructose, although both of the ketoses are simply epimeric at C-5.



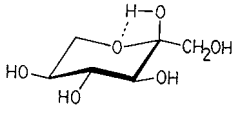
I



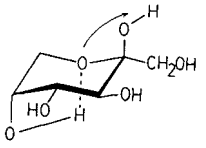
II



III



IV



V

According to Birch (5), hydrogen bonding between HO-5 and the ring oxygen atom of β-D-fructopyranose (V) would release the anomeric hydroxyl group to participate in the AH,B system, whereas the HO-2 group of the C-5 epimer (IV) would be inhibited by an intramolecular H-bond. Further investigation proved to be necessary to explain this sweetness difference and to obtain more information about the origin of the high sweet taste of D-fructose.

Suppression of the 5-hydroxyl group of these ketoses would constitute a very interesting modification to examine the role played by this function. The corresponding 5-deoxyketose (5-

[1]Sweetness comparisons are normally made on a weight basis.

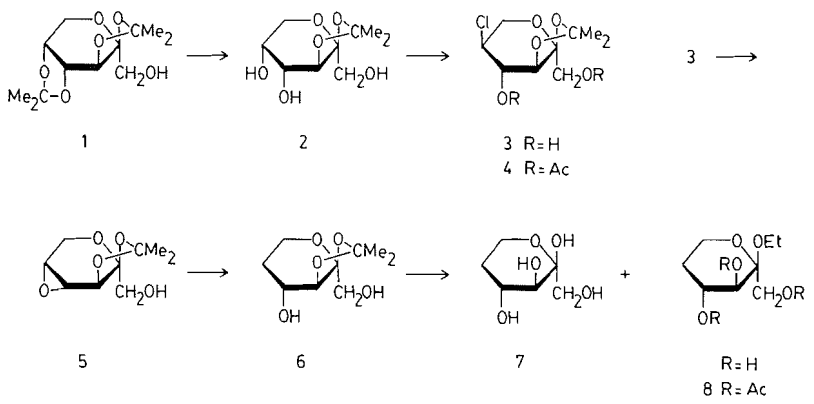

SCHEME 1

deoxy-D-*threo*-hexulose) was obtained 35 years ago as a by-product in the large scale biochemical oxidation of sorbitol to L-sorbose (7). Our synthesis involves six steps starting from D-fructose. The reaction of 2,3-*O*-isopropylidene-β-D-fructopyranose with sulfuryl chloride was anticipated (8) to give mainly the 5-chloro-5-deoxy derivative and constitutes the key step of the synthetic scheme.

## Results and discussion

In contrast to the facile selective hydrolysis of 1,2:4,5-di-*O*-isopropylidene-β-D-fructopyranose (9), partial hydrolysis of the 2,3:4,5-isomer **1** is known (10) to give a poor yield of 2,3-*O*-isopropylidene-β-D-fructopyranose (**2**), the desired starting material (Scheme 1). Treatment of **1** with a strongly acidic ion-exchange resin in 95% ethanol gave, after interruption of the reaction at the optimal time (tlc), **2** (11%), **1** (61%), and D-fructose. An overall yield of 27% of **2** could be obtained by repetition of the hydrolysis on the recovered **1** (four runs).

The reaction of **2** with sulfuryl chloride at low temperature afforded a two-component mixture ($R_f$ 0.67 and 0.76, solvent *B*). Displacement of the chlorosulfonyloxy group at C-5 by chloride ion is slow and the complete transformation of 2,3-*O*-isopropylidene-β-D-fructopyranose 1,4,5-tri(chlorosulfate) (A, $R_f$ 0.67) (Scheme 2) into 5-chloro-5-deoxy-2,3-*O*-isopropylidene-α-L-sorbopyranose 1,4-di(chlorosulfate) (B, $R_f$ 0.76) was achieved after 3 days at room temperature. Dechlorosulfation of B with methanolic sodium hydrogen carbonate gave **3** in 70% yield whereas dechlorosulfation after only 2 hours at 20°C afforded mainly the cyclic sulfate **9** (58%) and some chlorodeoxy derivative **3** (9%) (Scheme 2). The regiospecificity of the reaction arises from the fact that nucleophilic attack by chloride ion at C-4 of A would be highly unfavorable because of dipolar repulsion and steric interaction with the vicinal, axial OR substituent at C-3 of A (8), which adopts mainly (see below) the $^5C_2$(D) conformation.

Alkaline treatment of **3** gave readily 4,5-anhydro-2,3-*O*-isopropylidene-β-D-fructopyranose (**5**) which was specifically reduced at the less hindered site by lithium aluminum hydride to give the 2,3-acetonated form of "5-deoxyfructose" (**6**) in 94% yield. Deacetalation of **6** with $H^+$-resin in

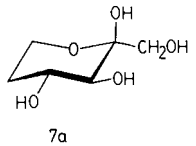
| **8** | 10 | 10 | 5 | 8 | 11 | ~2 | ~2 |
| **9** | 2.4 | 7.8 | — | 0.9 | 1.7 | — | — |

[a]A,B assignments made on basis of chemical shifts ($\delta_A < \delta_B$); for **6** and **7**: H-5A = H-$5_{axial}$, H-5B = H-$5_{equatorial}$; H-6A = H-$6_{equatorial}$, H-6B = H-$6_{axial}$.

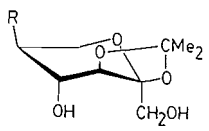
aqueous ethanol gave "5-deoxyfructose" (**7**) in 78% yield together with some ethyl glycoside of **7** (6%) which was characterized as its acetylated derivative **8**.

Owing to the lack of a 5-OH group, **7** cannot exist in a furanose form and its constitutional equilibrium is much simpler than in the case of D-fructose. As in the case of L-sorbose, **7** does not show any mutarotation and was found on the basis of its nmr parameters to adopt exclusively the $^2C_5$(D) β-D-pyranoid form (*7a*) in solution. If the ethyl glycoside **8** has the same conformation, then the 2,3-*O*-acetonated precursors exhibit completely different types of conformations, as shown by the vicinal *J* values (see Table 1). Thus, the small $J_{3,4}$ coupling constants observed for the chlorodeoxy derivative **4** and the protected "5-deoxyfructose" indicate that these compounds adopt the unusual $^5C_2$ conformation (see *3a* and *6a*); however, according to the other coupling-constant values, the true conformation probably deviates from the ideal chair to a flattened chair, as in the case of 2,3-*O*-isopropylidene-β-D-fructopyranose (11).

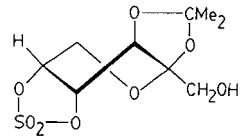
Interestingly, the Lambert *R*-value (12), which accounts for the chair distortion of (hetero)cyclohexanes, can be calculated for the ethylene fragments of **6** and **7**. As expected, **7** exhibits an *R*-value (1.93) close to that of the *R*-parameter of an undistorted chair (2.16), whereas the *R*-value for **6** (1.14) is an indication of a considerable flattening of the pyranoid ring.



7a



3a R = Cl
6a R = H



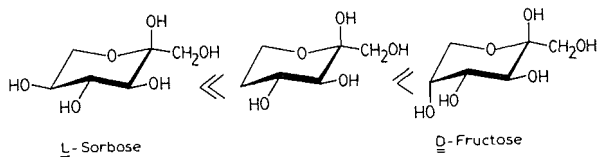
9a

The presence of the epoxide ring in **5** changes dramatically the conformation of the sugar ring which adopts an $^0H_2$- or $^2H_0$-type conformation (13). Furthermore, the cyclic sulfate **9** appears to exist in the same non-chair conformation as do 2,3:4,5-di-*O*-isopropylidene-β-D-fructopyranose (11) and di-*O*-isopropylidene-D-arabinose or di-*O*-isopropylidene-D-galactose derivatives (14), namely close to the $^6S_4$ skew conformation (see *9a*).

*Sweetness of "5-deoxyfructose"*

The sweetness of a 3% solution of **7** has been evaluated by four trained panelists and compared in several sessions to the tastes of 3% solutions of D-fructose and L-sorbose, and of water. All of the individual results showed clearly that "5-deoxyfructose" (**7**) is *much sweeter than* L-*sorbose and nearly as sweet as* D-*fructose*. In fact, the sweetness of D-fructose and of its 5-deoxy analog are very difficult to differentiate as two panelists found the latter sweeter than the common ketose. However, owing to the presence of other, non-sweet forms in D-fructose solutions, β-D-fructopyranose can still be considered as being slightly sweeter than the corresponding 5-deoxy-ketopyranose.

According to the existing theory (5), 5-deoxyfructose was expected to exhibit a sweetness close to that of L-sorbose. Our results show now that the axial, 5-hydroxyl group is not an indispensable component of the saporous unit of D-fructose and that the proposed mechanism of a "proton-releasing" effect on the HO-2 group by a competitive hydrogen bonding of HO-5 with the ring oxygen is not tenable. The large difference in



L-Sorbose D-Fructose

sweetness between the two ketoses epimeric at C-5 cannot arise only from a different degree of hydrogen bonding between HO-2 and the ring oxygen. It now appears that the equatorial 5-OH group exerts some detrimental influence on the saporous unit, possibly of a steric nature, which could preclude a correct alignment of the sugar on the taste receptor.

Further work is currently in progress to prepare new model compounds to gain more information about the intriguing problem of the sweetness of D-fructose.

## Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 automatic polarimeter at 23 ± 3°C. Infrared spectra were recorded with a Perkin–Elmer 598 spectrophotometer. The $^1$Hmr spectra were recorded with a Bruker HX-60 (60 MHz) or a Bruker CXP-200 (200 MHz) spectrometer in chloroform-*d* with tetramethylsilane (TMS) as the internal standard, unless otherwise stated. The $^{13}$Cmr spectrum was obtained at 15.09 MHz on a Bruker HX-60 spectrometer equipped with an FT60M Fourier transform accessory; chemical shifts are given in parts per million downfield from TMS. Some of the coupling constants are given in Table 1. Thin-layer chromatography (tlc) was performed using silica gel G as the adsorbent in the following solvent systems (v/v): (*A*) ethyl acetate; (*B*) toluene – ethyl acetate, 2:1; (*C*) toluene – ethyl acetate, 1:1; (*D*) ethyl acetate – toluene, 3:1; (*E*) ethyl acetate – methanol–water, 7:1:0.2. The developed plates were dried and compounds located by spraying with 10% aqueous sulfuric acid containing 1% cerium sulfate and 1.5% molybdic acid, and heating at 150°C. Column chromatography was performed on silica gel 60 (70–230 mesh, Merck). The term "petroleum ether" refers to the fraction of bp 30–60°C.

*2,3;4,5-Di-*O*-isopropylidene-β-*D*-fructopyranose (1)*

This compound was prepared from D-fructose (72 g, 0.4 mol) by the method of Brady (15). The crude product (91.2 g, 87.7%) was recrystallized from ether–pentane to afford white needles (57 g, 55%), mp 97°C (lit. (15) mp 97°C), $[\alpha]_D^{23}$ −24.2° (*c* 0.6, $CHCl_3$) (lit. (15) $[\alpha]_D^{25}$ −24.7° (*c* 1.1, $CHCl_3$)). The $^1$Hmr spectrum is in agreement with the published spectrum (11).

*2,3-*O*-Isopropylidene-β-*D*-fructopyranose (2)*

This compound was prepared by a modification of the procedure of Wolfrom *et al.* (10). Compound **1** (45 g, 0.17 mol) was treated with Dowex 50W-X8 ($H^+$) resin (20 g) in 95% ethanol (160 mL) at room temperature. Thin-layer chromatographic analysis (solvent *A*) showed a slow formation of **2** ($R_f$ 0.40) together with D-fructose ($R_f$ 0, main product); after ~6 days the proportion of **2** was the greater. The resin was removed by filtration and the solvent evaporated. The residue was taken up in water and the resulting mixture extracted with methylene chloride (2 × 70 mL, 1 × 50 mL); the combined extracts were washed with water (3 × 25 mL), dried ($MgSO_4$), and concentrated to afford pure **1** (27.6 g, 61%).

The combined aqueous phases were concentrated to a yellowish syrup, which was chromatographed on a silica gel column using solvent *A* as eluent to give pure **2** as a syrup (4.1 g, 11%). The hydrolysis was repeated on the recovered **1** to yield finally 10.2 g (27%) of **2** from 45 g of **1** in four runs. The separation of **2** from D-fructose could also be achieved by continuous extraction of the aqueous solution with chloroform for three days, drying the organic phase ($MgSO_4$), evaporating the solvent, and treating the crude **2** with Darco, activated decolorizing charcoal in water. Compound **2** exhibited $[\alpha]_D^{23}$ +13.0° (*c* 1.5, water) (lit. (10) $[\alpha]_D$ +17.5° (*c* 2.3, water) after purification through the crystalline triacetate). The $^1$Hmr spectrum of 1,4,5-tri-*O*-acetyl-2,3-*O*-isopropylidene β-D-fructopyranose, prepared according to the procedure of Wolfrom *et al.* (10), was in agreement with the published spectrum (11).

*5-Chloro-5-deoxy-2,3-*O*-isopropylidene-α-L-sorbopyranose (3)*

This compound was prepared by a modification of the general procedure (16) for reactions with sulfuryl chloride. A solution of **2** (5.3 g, 24.1 mmol) in dry chloroform (100 mL) and pyridine (11.7 mL, 145 mmol, 2 equiv/OH) was cooled at −78°C (Dry Ice – acetone). Sulfuryl chloride (9.75 mL, 120.5 mmol) was added dropwise (1 h) to the viscous reaction mixture with vigorous stirring. The mixture was stirred at ~ −65°C for a further 5 h, then allowed to warm slowly to room temperature; stirring was continued at 20°C for 72 h after which time tlc revealed that all of the 2,3-*O*-isopropylidene-β-D-fructopyranose 1,4,5-tri(chlorosulfate) ($R_f$ 0.67, solvent *B*) had been converted into 5-chloro-5-deoxy-2,3-*O*-isopropylidene-α-L-sorbopyranose 1,4-di(chlorosulfate) ($R_f$ 0.76). The reaction mixture was poured into ice–water (150 mL) and the chloroform layer separated. The aqueous phase was extracted with chloroform (3 × 50 mL); the combined organic phases were washed with saturated aqueous sodium hydrogen carbonate (50 mL), then with water (50 mL), dried ($MgSO_4$), and concentrated. The residue was treated with sodium hydrogen carbonate (13 g) in methanol (150 mL) for 12 h at room temperature to achieve dechlorosulfation. The mixture was filtered and the filtrate was evaporated; the residue was dissolved in chloroform (100 mL) and water (10 mL). The aqueous layer was extracted with chloroform (3 × 10 mL) and the combined organic phases were dried ($MgSO_4$) and concentrated. The crude product was combined before purification with the product obtained from the same reaction using 2.1 g (9.6 mmol) of **2**; column chromatography (solvent *C*) afforded 38 mg (< 1%) of the cyclic sulfate derivative **9** and 5.59 g (69.7%) of **3** which was recrystallized from chloroform–ether – petroleum ether to give white crystals, mp 88–90°C; $R_f$ 0.14 (solvent *B*); $[\alpha]_D^{23}$ +24.0° (*c* 0.8, $CHCl_3$); $\nu_{max}$ (KBr): 3360, 3480 (OH) and 1373, 1384 $cm^{-1}$ ($CMe_2$); $^1$Hmr δ: 1.40 and 1.64 (2s, 2 × 3H, $CMe_2$), 3.34 (t, 1H, $J_{1A,OH}$ = 6.5 Hz, $J_{1B,OH}$ = 5.7 Hz, exchanged in $D_2O$, HO-1), 3.61 (dd, d after $D_2O$ exchange, 1H, $J_{1A,1B}$ = 11.5 Hz, H-1A), 3.85 (dd, d after $D_2O$ exchange, 1H, H-1B), 3.92–4.16 (m, 3H, H-6A, H-6B, H-3 or H-5), 4.24–4.37 (m, 3H, 2H after $D_2O$ exchange, H-4, HO-4, H-5 or H-3). *Anal.* calcd. for $C_9H_{15}ClO_5$: C 45.35, H 6.33, Cl 14.85; found: C 45.35, H 6.42, Cl 14.42.

*1,4-Di-*O*-acetyl-5-chloro-5-deoxy-2,3-*O*-isopropylidene-α-L-sorbopyranose (4)*

Acetylation of **3** (200 mg, 0.84 mmol) by the standard procedure afforded 250 mg (92%) of homogeneous **4** which was recrystallized from ether – petroleum ether, mp 47–49°C, $R_f$ 0.58 (solvent *B*), $[\alpha]_D^{23}$ +27.5° (*c* 1.16, $CHCl_3$); $\nu_{max}$ (KBr): 1745 (C=O), 1382 and 1390 $cm^{-1}$ ($CMe_2$); $^1$Hmr δ: 1.43 and 1.67 (2s, 2 × 3H, $CMe_2$), 2.15 and 2.16 (2s, 2 × 3H, 2 OAc), 3.98–4.10 (m, 3H, H-5, H-6's), 4.17 (d, 1H, $J_{3,4}$ = 2.9 Hz, H-3), 4.21 (d, 1H, $J_{1A,1B}$ = 12.2 Hz, H-1A), 4.32 (d, 1H, H-1B), 5.48 (narrow m, 1H, H-4). *Anal.* calcd. for $C_{13}H_{19}ClO_7$: C 48.38, H 5.93, Cl 10.99; found: C 48.54, H 6.14, Cl 11.09.

*2,3-*O*-Isopropylidene-β-*D*-fructopyranose 4,5-cyclic sulfate (9)*

A solution of compound **2** (2.0 g, 9.1 mmol) in chloroform

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

(60 mL) containing pyridine (4.4 mL, 55 mmol) was treated with sulfuryl chloride (3.7 mL, 45.6 mmol) at low temperature as described for the preparation of **3**, and the reaction was stopped after having been stirred for 2 h at room temperature. The reaction mixture was treated with sodium hydrogen carbonate in methanol for 70 h and processed; column chromatography afforded 1.5 g (58%) of syrupy **9** and 0.19 g (9%) of **3**. Compound **9** crystallized from ether – petroleum ether, mp 82.5–84°C, $R_f$ 0.46 (solvent *B*), $[\alpha]_D^{23}$ −23.8° (*c* 2.1, $CHCl_3$); $\nu_{max}$ (KBr): 3370 (OH), 1400 and 1205 $cm^{-1}$ ($SO_2$); $^1$Hmr δ: 1.46 and 1.60 (2s, 2 × 3H, $CMe_2$), 2.16 (t, 1H, $J_{1,OH}$ = 7 Hz, exchanged in $D_2O$, HO-1), 3.77 (d, s after $D_2O$ exchange, 2H, H-1's), 4.05 (dd, 1H, $J_{5,6A}$ = 0.9 Hz, $J_{6A,6B}$ = 14.7 Hz, H-6A), 4.15 (dd, 1H, $J_{5,6B}$ = 1.7 Hz, H-6B), 4.58 (d, 1H, $J_{3,4}$ = 2.4 Hz, H-3), 5.04 (ddd, 1H, $J_{4,5}$ = 7.8 Hz, H-5), 5.33 (dd, 1H, H-4). *Anal.* calcd. for $C_9H_{14}SO_8$: C 38.29. H 5.00; found: C 38.04, H 5.07.

*4,5-Anhydro-2,3-*O*-isopropylidene-*β*-*D*-fructopyranose (5)*

Compound **3** (4.95 g, 20.7 mmol) was treated with potassium hydroxide (1.4 g, 25 mmol) in ethanol (120 mL) at room temperature for 6 h. The mixture was neutralized with 1 *N* hydrochloric acid and concentrated. The residue was dissolved in methylene chloride (100 mL) and water (10 mL) the separated aqueous layer washed with methylene chloride (3 × 5 mL) and the combined organic phases dried over magnesium sulfate. Concentration of the solution afforded 4.1 g (98%) of crystalline **5**. An analytical sample was obtained from ether – petroleum ether, mp 114–116.5°C, $R_f$ 0.12 (solvent *B*); $[\alpha]_D^{23}$ −11.1° (*c* 0.8, $CHCl_3$); $\nu_{max}$ (KBr): 3460 (OH), 1377 and 1387 $cm^{-1}$ ($CMe_2$); $^1$Hmr δ: 1.45 and 1.55 (2s, 2 × 3H, $CMe_2$), 2.37 (broad s, 1H, exchanged in $D_2O$, HO-1), 3.28 (broad d, 1H, $J_{4,5}$ = 4.1 Hz, $J_{5,6A}$ = 1.1 Hz, $J_{5,6B}$ < 0.5 Hz, H-5), 3.39 (dd, 1H, $J_{3,4}$ = 0.9 Hz, H-4), 3.50 (broad dd, d after $D_2O$ exchange, 1H, $J_{1A,1B}$ = 11.7 Hz, $J_{1A,OH}$ ~ 7 Hz, H-1A), 3.64 (d, 1H, H-1B), 4.10 (d, 1H, H-6A), 4.21 (d, 1H, H-6B), 4.41 (s, 1H, H-3). *Anal.* calcd. for $C_9H_{14}O_5$: C 53.46, H 6.98: found: C 53.77, H 7.15.

*5-Deoxy-2,3-*O*-isopropylidene-*β*-*D*-threo-hexulopyranose (6)*

A solution of **5** (4.0 g, 19.8 mmol) in dry tetrahydrofuran (40 mL) was added, dropwise over a period of 45 min, under nitrogen to a suspension of lithium aluminum hydride (2.3 g, 61 mmol) in tetrahydrofuran (80 mL) at room temperature. Stirring was continued for 3.5 h at 20°C and 2 h at reflux temperature. Ice-water (20 mL) was then added carefully; the mixture was filtered, the filtrate neutralized with 0.5 *N* hydrochloric acid and concentrated. The residue was dissolved in chloroform (50 mL) and water (5 mL), the separated aqueous layer concentrated, and the crystalline residue triturated with chloroform (5 mL) and then with acetone (5 mL). The combined organic phases were dried ($MgSO_4$) and concentrated to afford 3.8 g (94%) of homogeneous (tlc) **6**. Pure **6** (3.1 g, 77%) was obtained by crystallization from chloroform–ether – petroleum ether followed by column chromatography (solvent *D*) and crystallization as before; mp 95–97°C, $R_f$ 0.22 (solvent *D*), $[\alpha]_D^{23}$ +28.6° (*c* 1.0, $CHCl_3$); $\nu_{max}$ (KBr): 3410 (OH), 1375 and 1384 $cm^{-1}$ ($CMe_2$); $^1$Hmr δ: 1.40 and 1.58 (2s, 2 × 3H, $CMe_2$), 1.72 (tdd, 1H, $J_{4,5A}$ = 2.6 Hz, $J_{5A,5B}$ = 14.3 Hz, $J_{5A,6A}$ = 5.6 Hz, $J_{5A,6B}$ = 5.6 Hz, H-5A), 2.12 (tdd, 1H, $J_{4,5B}$ = 5.6 Hz, $J_{5B,6A}$ = 5.6 Hz, $J_{5B,6B}$ = 7.2 Hz, H-5B), 3.47 (dd, 1H, $J_{1A,OH}$ = 5.0 Hz, $J_{1B,OH}$ = 7.5 Hz, exchanged in $D_2O$, HO-1), 3.67 (dd, d after $D_2O$ exchange, 1H, $J_{1A,1B}$ = 11.5 Hz, H-1A), 3.77 (d, 1H, $J_{4,OH}$ = 6.0 Hz, exchanged in $D_2O$, HO-4), 3.87 (obscured td, 1H, $J_{6A,6B}$ = 11.9 Hz, H-6A), 3.88 (dd, d after $D_2O$ exchange, 1H, H-1B), 3.97 (ddd, 1H, H-6B), 4.12 (d, 1H, $J_{3,4}$ = 2.7 Hz, H-3), 4.30 (tt, td after $D_2O$ exchange, 1H, H-4). *Anal.* calcd. for $C_9H_{16}O_5$: C 52.93, H 7.90; found: C 52.88, H 8.10.

*5-Deoxy-β-D-threo-hexulopyranose (7) ("5-deoxy-D-fructose" or "5-deoxy-L-sorbose")*

Compound **6** (2.7 g, 13.2 mmol) was treated with Dowex 50W-X8 ($H^+$) resin (75 g) in an ethanol (200 mL) – water (50 mL) mixture at room temperature for 7 days. The resin was removed by filtration and the filtrate concentrated. Resolution of the reaction mixture by column chromatography (solvent *E*) afforded 140 mg (5%) of **6**, 150 mg (6%) of the ethyl glycoside of **7** ($R_f$ 0.42), 200 mg of a mixture of the latter and **7**, and 1.69 g (78%) of homogeneous (tlc) **7**, which was recrystallized from methanol – acetate; mp 117.5–118.5°C, (lit. (7) mp 110°C); $R_f$ 0.23 (solvent *E*), $[\alpha]_D^{23}$ −65.8° (*c* 1.1, $H_2O$) (lit. (7) $[\alpha]_D$ −67.0° (*c* 1.0, $H_2O$)); $\nu_{max}$ (KBr): 3350 (very broad, OH), 1050, 1095, and 1150 $cm^{-1}$; $^1$Hmr ($CD_3OD$; a = axial,, e = equatorial) δ: 1.62 (tdd, 1H, $J_{5a,5e}$ = 12.8 Hz, $J_{5a,6a}$ = 12.8 Hz, $J_{4,5a}$ = 11.4 Hz, $J_{5a,6e}$ = 5.2 Hz, H-5a), 1.89 (dddd, 1H, $J_{4,5e}$ = 5.1 Hz, $J_{5e,6a}$ = 2.2 Hz, $J_{5e,6e}$ = 1.5 Hz, H-5e), 3.39 (d, 1H, $J_{3,4}$ = 9.5 Hz, H-3), 3.45 (d, 1H, $J_{1A,1B}$ = 11.1 Hz, H-1A), 3.63 (ddd, 1H, $J_{6a,6e}$ = 11.5 Hz, H-6e), 3.66 (d, 1H, H-1B), 3.87 (ddd, 1H, H-4), 3.95 (ddd, 1H, H-6a); ($D_2O$) δ: 1.71 (~qd, 1H, $J_{5a,5e}$ = 12 Hz, $J_{5a,6a}$ = 12 Hz, $J_{4,5a}$ = 12 Hz, $J_{5a,6e}$ = 5.5 Hz, H-5a), 2.05 (dm, 1H, $J_{4,5e}$ = 5 Hz, $J_{5e,6a}$ = 2 Hz, $J_{5e,6e}$ = 2 Hz, H-5e), 3.51 (d, 1H, $J_{3,4}$ = 9.5 Hz, H-3), 3.54 (d, 1H, $J_{1A,1B}$ = 11.7 Hz, H-1A), 3.79 (d, 1H, H-1B), 3.72–4.05 (m, 3H, H-4, H-6a, H-6e); $^{13}$Cmr ($D_2O$) δ: 33.9 (C-5), 59.8 (C-6), 64.8 (C-1), 69.4, 73.3 (C-3, C-4), 99.3 (C-2). *Anal.* calcd. for $C_6H_{12}O_5$: C 43.90, H 7.37; found: C 43.50, H 7.00.

*Ethyl 1,3,4-tri-*O*-acetyl-5-deoxy-*β*-*D*-threo-hexulopyranoside (8)*

The syrupy ethyl glycoside of **7** (150 mg) obtained as described above was acetylated by the standard procedure to afford 220 mg (89%) of **8**. An analytical sample of syrupy **8** was obtained by column chromatography (hexane – ethyl acetate, 2:1 (v/v)), $R_f$ 0.43 (solvent *B*); $[\alpha]_D^{23}$ −75.6° (*c* 1.11, $CHCl_3$); $\nu_{max}$ (film): 1750 $cm^{-1}$ (C=O); $^1$Hmr ($CD_3OD$; a = axial, e = equatorial) δ: 1.26 (t, 3H, $OCH_2CH_3$), 1.84 (m, 1H, $J_{4,5a}$ = 10 Hz, $J_{5a,5e}$ = 13 Hz, $J_{5a,6e}$ ~ 8 Hz, $J_{5a,6a}$ ~ 11 Hz, H-5a), 2.03, 2.09, and 2.12 (3s, 3 × 3H, 3 OAc), 2.18 (m, 1H, $J_{4,5e}$ = 5 Hz, $J_{5e,6a}$ ~ 2 Hz, $J_{5e,6e}$ ~ 2 Hz, H-5e), 3.51 (qd, 1H, $J_{H_A,CH_3}$ = 6.8 Hz, $J_{H_A,H_B}$ = 9.2 Hz, $OCH_AH_BCH_3$), 3.67 (qd, 1H, $J_{H_B,CH_3}$ = 7.2 Hz, $OCH_AH_BCH_3$), 3.8 (m, 2H, H-6a, H-6e), 4.04 (d, 1H, $J$ = 11.7 Hz, H-1A), 4.29 (d, 1H, H-1B), 5.19 (d, 1H, $J_{3,4}$ = 10 Hz, H-3), 5.28 (td, 1H, H-4). *Anal.* calcd. for $C_{14}H_{22}O_8$: C 52.83, H 6.97; found: C 52.78; H 7.35.

# The biosynthesis of *myo*-inositol and its isomers[1,2]

OTTO HOFFMANN-OSTENHOF[3] AND F. PITTNER

*Institut für Allgemeine Biochemie der Universität Wien and Ludwig-Boltzmann-Forschungsstelle für Biochemie, Vienna, Austria*

Received January 8, 1982

OTTO HOFFMANN-OSTENHOF and F. PITTNER. Can. J. Chem. **60**, 1863 (1982).

The present state of our knowledge about the biosynthetic processes leading to the inositols is reviewed. On the basis of experimental data obtained in the laboratory of the authors and by other groups working on the problem, a new mechanism of action for the mammalian *myo*-inositol-1-phosphate synthase is suggested. The central position of *myo*-inositol in the synthesis of the other inositols is described.

OTTO HOFFMANN-OSTENHOF et F. PITTNER. Can. J. Chem. **60**, 1863 (1982).

On passe en revue l'état actuel de nos connaissances sur les processus biosynthétiques conduisant aux inositols. En se basant sur des données expérimentales obtenues dans le laboratoire des auteurs et par d'autres groupes de chercheurs, on suggère un nouveau mécanisme d'action de la synthase du *myo*-inositol-phosphate-1 des mammifères. On décrit la position centrale du *myo*-inositol dans la synthèse des autres inositols.

[Traduit par le journal]

## Introduction

*myo*-Inositol is a natural compound with several important biological functions. It was first isolated by Scherer, a student of Wöhler, as a sugar-like compound from meat juice in 1850 (1). More than 30 years later Maquenne (2) found the compound to be a cyclohexanehexol. Its configuration was finally established almost simultaneously by Dangschat and Fischer (3) and by Posternak (4) in 1942.

Maquenne (2), as early as 1900, suggested that *myo*-inositol was the product of an intramolecular head-to-tail C—C cyclization of a hexose molecule, but more than half a century passed until this hypothesis could be confirmed. Fischer (5), realizing the analogy of four asymmetric centres in D-glucose and *myo*-inositol, considered D-glucose to be the most probable candidate for such a cyclization reaction and also supported his view by model experiments. However, the final establishment of this pathway was achieved much later with the use of radioactively labelled precursor substrates.

Employing selectively $^{14}$C-labelled D-glucose and a method of partial biological degradation of the product, Loewus and Kelly (6) showed it most probable that indeed a condensation between the carbon atoms 1 and 6 of D-glucose is the pathway to *myo*-inositol. Their conclusion was based on the assumption that *myo*-inositol incorporated into pectin producing plants yields D-galacturonyl residues via D-glucuronate without any fragmentation of the carbon chain during this transformation. A completely chemical degradation pathway for *myo*-inositol obtained from selectively labelled D-glucose in living organisms was developed in our laboratory (7); this method permitted the localization of radioactivity in all the carbon atoms of the molecule. The results also supported the correctness of the mechanisms suggested by Maquenne and Fischer.

Almost simultaneously with the establishment of the precursor function of D-glucose in the biosynthesis of *myo*-inositol, the first reports on cell-free homogenates capable of transforming D-glucose to *myo*-inositol appeared (8, 9). It soon was found that the overall reaction involves at least three stages (Scheme 1). Initially D-glucose is converted to D-glucose 6-phosphate by the well-known hexokinase. D-Glucose 6-phosphate is then transformed to 1 L-*myo*-inositol 1-phosphate which is finally dephosphorylated to *myo*-inositol by a rather specific phosphatase. It is probable that similar enzyme systems exist in all eucaryotes. On the other hand, this is not always the case in procaryotes since e.g. *E. coli* is not capable of producing or utilizing *myo*-inositol (10). On the other hand, *Streptomyces griseus*, which uses *myo*-inositol as a precursor of the antibiotic streptomycin, does synthesize it by an apparently analogous enzyme system (11).

## *myo*-Inositol-1-phosphate synthase, the key enzyme of inositol biosynthesis

Of the three steps concerned in the transforma-

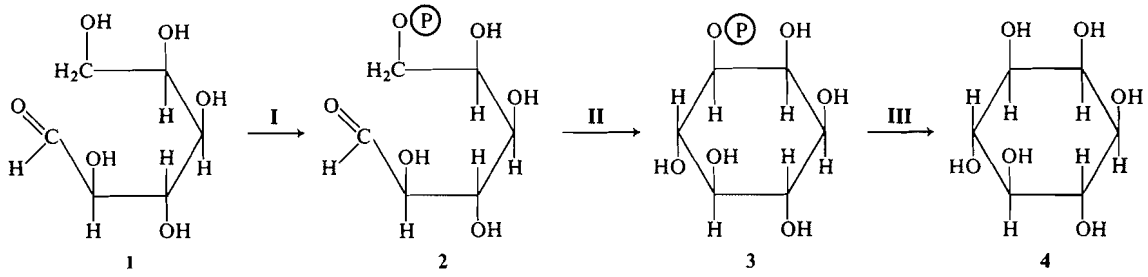


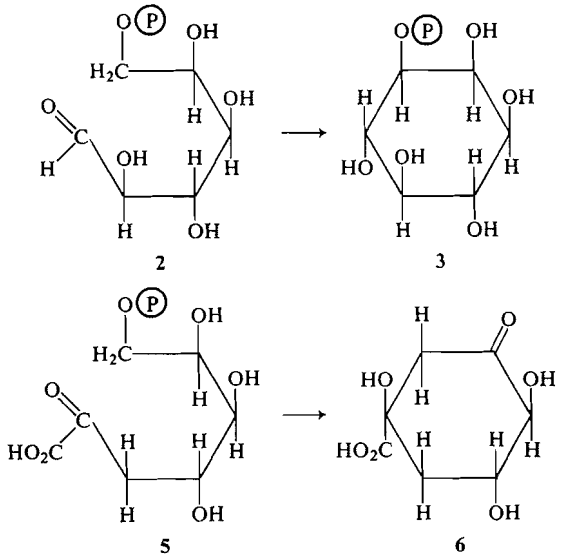
SCHEME 1. The pathway from D-glucose to *myo*-inositol. Enzyme I is hexokinase, enzyme II is *myo*-inositol-1-phosphate synthase, and enzyme III is a phosphatase.

tion of D-glucose to *myo*-inositol, the second one involving the cyclization of D-glucose 6-phosphate (**2**) to 1 L-*myo*-inositol 1-phosphate (**3**), attracted considerable interest among enzymologists. It was soon found that one enzyme only is responsible for this key reaction in *myo*-inositol synthesis, although apparently several intermediate steps are involved. The enzyme, originally called cyclase or cycloaldolase, now has the name *myo*-inositol-1-phosphate synthase (EC 5.5.1.4). The reaction is rather unusual, although it shows a certain analogy to the transformation of 3-deoxy-D-*arabino*-heptulosonate 7-phosphate (**5**) to 3-dehydroxyquinate (**6**), a reaction catalyzed by dehydroquinate synthase (EC 4.6.1.3). This enzyme requires $NAD^+$ for its action and plays a role in the biosynthesis of aromatic compounds (12). However, dehydroquinate synthase eliminates the phosphate moiety concomitantly with cyclization, whereas with *myo*-inositol-1-phosphate synthase the phosphate group is preserved in the product (Scheme 2).

*myo*-Inositol-1-phosphate synthase has been isolated from various animals, higher plants, yeasts, and some procaryotes. The enzyme proteins from these different sources vary considerably in their chemical and physical properties, such as metal content, molecular mass, and specific acitivity. They all, however, either contain more or less strongly bound $NAD^+$ or at least require this coenzyme for their action. Generally it seems to be established that the enzyme preparations from all sources catalyze a sequence of at least three reactions (Scheme 3). (1) The oxidation with $NAD^+$, as hydrogen acceptor, of the 5-hydroxyl group of D-glucose 6-phosphate to form L-*xylo*-hexosulose 1-phosphate, which remains bound to the enzyme. (2) This compound then undergoes an intramolecular aldol condensation to the cyclic product 2 L-2-phospho-2,4,6/3,5-pentahydroxycyclohexanone, which also remains bound to the enzyme. Concomitantly with the cyclization, one hydrogen atom, originally bound to the 6-position of the substrate, is set free as a proton. (3) Eventually, the last mentioned product is reduced to 1 L-*myo*-inositol 1-phosphate with the previously formed NADH acting as hydrogen donor.

There is good reason to assume that either the substrate itself or its oxidation product must exist in the open chain form to make the cyclization reaction possible. It is known that the spontaneous anomerization of α-glucose 6-phosphate within the physiological pH range is more than two orders of magnitude faster than that of α-glucose (13). It is debatable whether this anomerization that necessarily proceeds via the open chain form is sufficiently rapid in order not to be the limiting factor of the *myo*-inositol-1-phosphate synthase reaction, or whether we have to postulate an additional anomerizing activity for the enzyme.

Originally two possible mechanisms for the cyclization reactions catalyzed by *myo*-inositol-1-phosphate synthase were proposed, namely an aldol condensation corresponding to the reaction



SCHEME 2. *myo*-Inositol-1-phosphate synthase and dehydroquinate synthase.

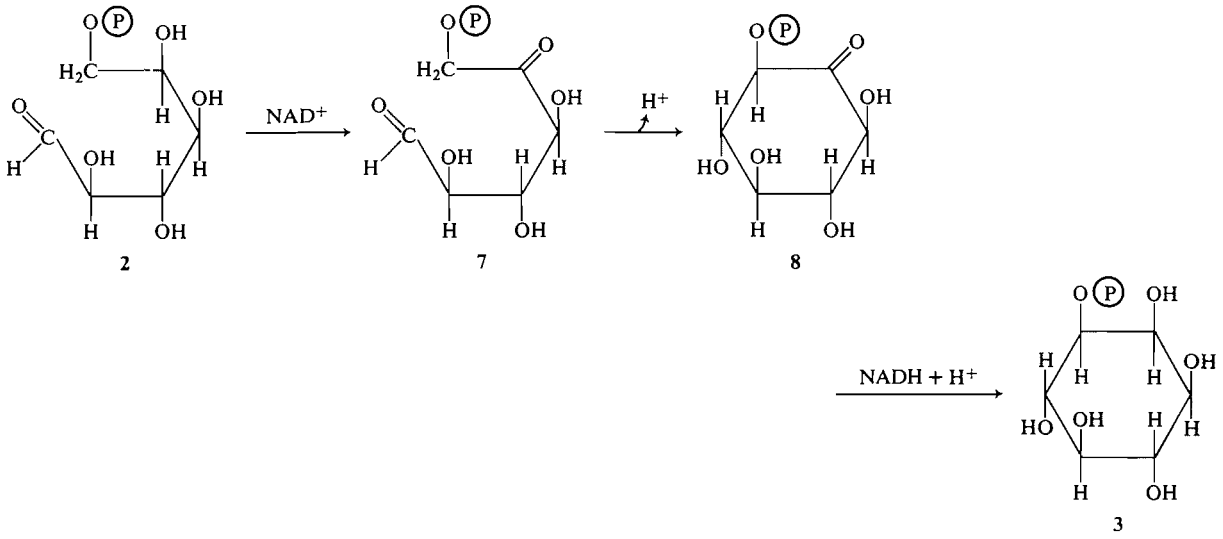

SCHEME 3. The general mechanism of action of *myo*-inositol-1-phosphate synthase; the intermediary compounds are bound to the enzyme.

scheme given in Scheme 3, and an acyloin condensation, where the carbon atom 6 of the substrate would be primarily hydroxylated by $NAD^+$ (14). However, especially through the work of Barnett and Corina (15), it seems to be established that it is indeed the aldol condensation mechanism that is responsible for the cyclization reaction. Although the two postulated intermediates have never been obtained in free form from the reaction mixture, there is ample evidence for their function as intermediates (16, 17).

The action of *myo*-inositol-1-phosphate synthase also poses some stereochemical problems. Quite recently it could be shown that, in contrast to an earlier report (18), it is the pro-*R* atom of C-6 of D-glucose 6-phosphate that is set free during the cyclization reaction (19). Another very recent paper (20) shows that in the first step of the reaction sequence the hydrogen from the 5-position of the substrate is transferred to $NAD^+$ to become the pro-*S* hydrogen at position 4 of the nicotinamide moiety of the reduced coenzyme. This pro-*S* hydrogen of NADH is also transferred to the keto group of 2 L-2-phospho-2,4,6/3,5-pentahydroxycyclohexanone in the third step of the sequence.

Whereas many enzymes of this specificity from plants or microorganisms are inhibited by EDTA and seem to contain bivalent ions or at least require them for their action, the animal enzymes so far investigated are metal-free and cannot be inhibited by EDTA. There is here a certain similarity to the situation encountered in the group of aldolases, where we can distinguish two types, namely the aldolases class I and the aldolases class II. The aldolases class I do not contain any bivalent metal ion and are characterized by the intermediate formation of a Schiff's base between the ε-amino group of a lysyl residue of the enzyme and a carbonyl group of the substrate. Aldolases class II require metal ions for their action. There is a marked similarity of the reactions catalyzed by *myo*-inositol-1-phosphate synthase to those by the aldolases.

In earlier papers by Naccarato *et al.* (21) and from our laboratory (22), experiments were reported that seemed to indicate that the *myo*-inositol-1-phosphate synthase from the rat (mammae, testes) is a Schiff's base forming enzyme. The main arguments for such a mechanism were that typical inhibitors of Schiff's base formation like pyridoxal phosphate or trinitrobenzenesulphonate acted as competitive inhibitors of the enzyme, furthermore $NaBH_4$ when added to the reaction mixture also had an inhibiting action. When radioactive substrate was used, reduction of the reaction mixture with $NaBH_4$ resulted in incorporation of radioactivity from the substrate into the enzyme protein; an analogous result was also obtained with cold substrate and tritiated $NaBH_4$. The affinity-labelled protein thus obtained was degraded by proteolytic enzymes and the resulting mixture was analyzed by paper chromatography. One single radioactive spot was found and the product was isolated.

According to the general reaction mechanism described above, this product can have two structures (Scheme 4). Two carbonyl groups can react with the ε-amino group of a lysyl residue, namely

SCHEME 4

SCHEME 4. The two alternative possibilities for the structure of the reduced Schiff base between lysine and D-glucose 6-phosphate isolated after enzymic hydrolysis of the enzyme protein obtained from the incubation mixture treated with $NaBH_4$.

(a) the aldehyde group of the open chain of the substrate or of the first intermediate, L-*xylo*-hexosulose 1-phosphate, leading to product **9**, and (b) the oxo group on C-5 in this intermediate, which derives from the C-5 hydroxyl of the substrate by the dehydrogenation with $NAD^+$ as hydrogen acceptor. In this case **10** is produced.

For reasons of analogy to fructose-bisphosphate aldolase (EC 4.1.2.13), class I (Schiff's base forming), we originally considered mechanism (b) more probable, but in order to clarify this question, the product described above was analyzed for its structure by mass spectroscopy and by nmr. By comparison with a synthetically obtained sample it could be established that the compound is $N^{\varepsilon}$-1-D-glucityl-L-lysin, i.e. the product **10**, which means that mechanism (a) is operating (23). Thus, we have here no parallel to the aldolases class I.

Considering the bond formed between the lysyl residue of the enzyme and the substrate, we made some further interesting observations (23). Firstly the enzyme does not form the bond if $NAD^+$ is removed from the enzyme with the help of Norite; when $NAD^+$ is then added back, the ability of binding the substrate and with it the full activity of the enzyme is regained. From this result it can be concluded that in the absence of $NAD^+$ the enzyme shows very little affinity to the substrate; this may be due to a reversible change of conformation of the enzyme protein caused by the removal of $NAD^+$. Another set of experiments dealt with the incorporation of radioactivity into the enzyme from tritiated $NaBH_4$ when reduction of the reaction mixture took place at pH 6.0, the optimal conditions for the reduction of an —N=C— bond, and afterwards at pH 8.0, a condition favouring the reduction of a carbonyl bond. After isolation of the enzyme protein and preparation of the mentioned lysyl derivative from an aliquot reduced at pH 6.0 only and a second aliquot reduced at both pH 6.0 and 8.0, it was shown that the product from the second aliquot contained about twice as much activity as the product from pH 6.0 reduction. However, when the latter product was oxidatively degraded by means of periodate, about half of its activity was lost. This means that the activity lost was located in that part of the molecule which is split off by periodate oxidation, in our opinion most probably in the C-5 position of the substrate, which carries a keto group after the first oxidoreduction step of the reaction sequence.

It is not easy to explain these results. Firstly, it seems that the binding takes place before the first oxidoreduction step of the reaction sequence. Secondly, the binding may have the effect of fixing the enzyme to the substrate in such an orientation that the dehydrogenation step with $NAD^+$ as acceptor is made possible. A third possibility involves the mechanism of ring closure, as will be described further below.

Until quite recently, we thought that, in spite of some differences, the analogy with aldolases, class I, would hold at least as far as the nature of the bond between the enzyme protein and the substrate is concerned, namely that it should be a Schiff's base. Inhibition by typical inhibitors of Schiff's base formation, inhibition of the reaction by addition of $NaBH_4$ to the reaction mixture, the isolation of a reduction product that apparently derived from the reduction of Schiff's base, were all strong arguments for the involvement of this type of bond. However, it was Sherman and his group (24) who claimed that a Schiff's base could not participate in the reaction sequence. When the reaction takes place in a medium enriched with $H_2{}^{18}O$, an increased incorporation of $^{18}O$ into the product must be expected, because if a Schiff's base bond is intermediarily formed, a hydrolysis of this bond has to take place in order to make the ring closure possible, and this hydrolysis would cause an increased uptake of the isotope. Since Sherman *et al.* could not find such an effect, they suggest that an acid–base catalysis without any Schiff's base intermediate is operating.

Quite recently, Floss and co-workers (19) proposed some new ideas concerning the mechanism of our enzyme, partly based on their elucidation of the stereochemistry of the hydrogen removal from C-6 of the substrate during the reaction sequence. They suggest that a single base group of the enzyme acts alternately in the base form, abstracting the proton from C-6, and in the conjugate acid form,

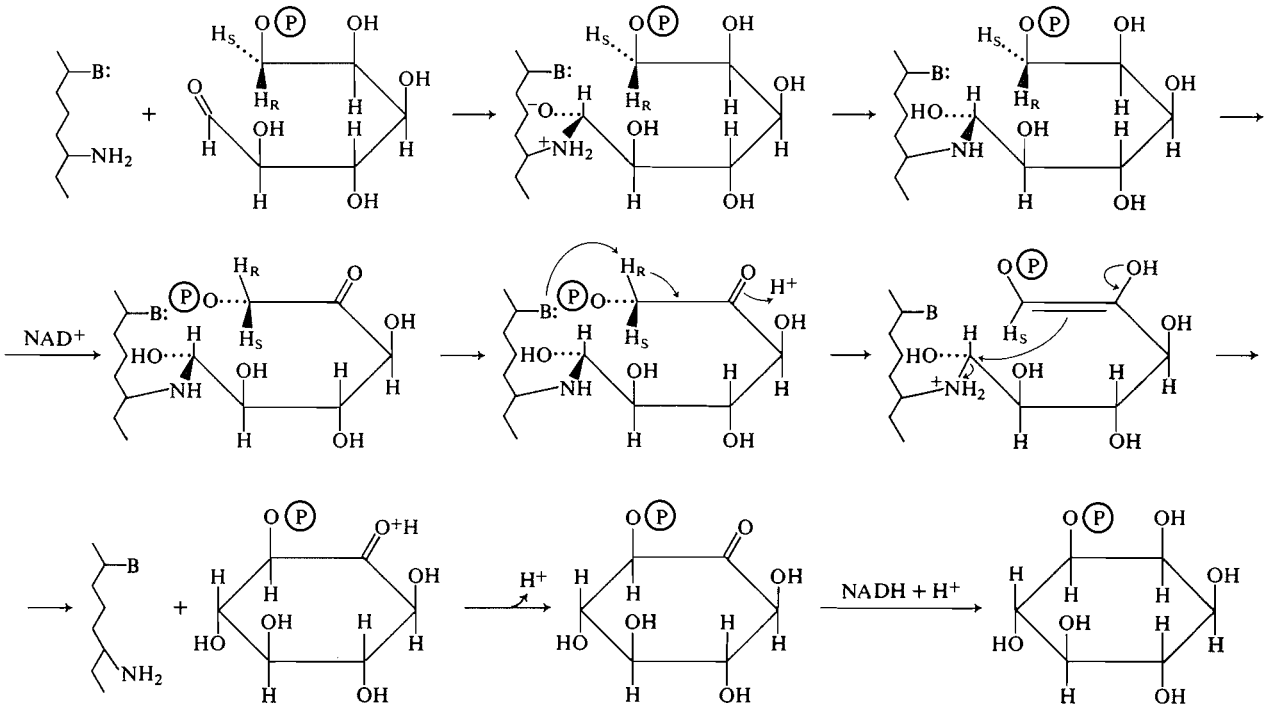

SCHEME 5. Suggested reaction scheme for *myo*-inositol-1-phosphate synthase from rat testes.

protonating the oxygen at C-1. This proposal is supported by the fact that the nucleophilic attack at C-1 occurs on the *Re* face of the carbonyl group, as evidenced by the configuration of the product.

In this context the same authors speculate that the base group may be the same lysine amino group that appears in the lysyl derivative isolated in our laboratory, and that the formation of a Schiff's base at C-1 may be a side reaction rather than an essential part of the reaction mechanism. Due to mutarotation such a side reaction would not bring about a measurable incorporation of $^{18}O$ from $H_2{}^{18}O$ into the product.

There is no doubt that the mechanism of Floss and co-workers represents a useful working hypothesis for the complex mechanisms of the reaction sequence of our enzyme. However, as enzymologists, we have considerable reservations concerning the existence of side reactions in enzyme-catalyzed processes; furthermore, some of our results are not easily brought to agree with the suggestions of the named authors.

We have now worked out a new mechanism that somewhat differs from that suggested by Floss and his group, but which seems to be in agreement with the data reported by them as well as with those of Sherman *et al.* (24).

As mentioned before, the data obtained by mass spectrometry by Sherman make a Schiff's base mechanism rather improbable, but on the other hand our reduction experiments and also the action of so-called Schiff's base inhibitors strongly support the idea that a binding between the ε-amino group of a lysyl residue of the enzyme with the aldehyde group of the substrate takes place. Such binding does not necessarily involve a Schiff's base. Another possibility is the formation of a carbinolamine, which on reduction would give the same products as a Schiff's base. Formation of a carbinolamine ought also to be inhibited by compounds inhibiting Schiff's base formation.

Some details of the proposed mechanism are represented in Scheme 5.

As shown there, a carbinolamine is formed as the aldehyde group of D-glucose 6-phosphate combines with the ε-amino group of a lysyl residue of the enzyme and a proton is transferred from N to O. The hydroxyl group at C-5 of the sugar is then oxidized by a $NAD^+$-mediated step to a keto group and a concomitant shift in the position of the substituents on C-6 takes place.

This is followed by a protonation of the keto oxygen and by an attack of a basic group of the enzyme to remove the pro-*R* hydrogen from C-6. This hydrogen is relatively acidic, as it is in an α-position to the carbonyl group. Due to steric

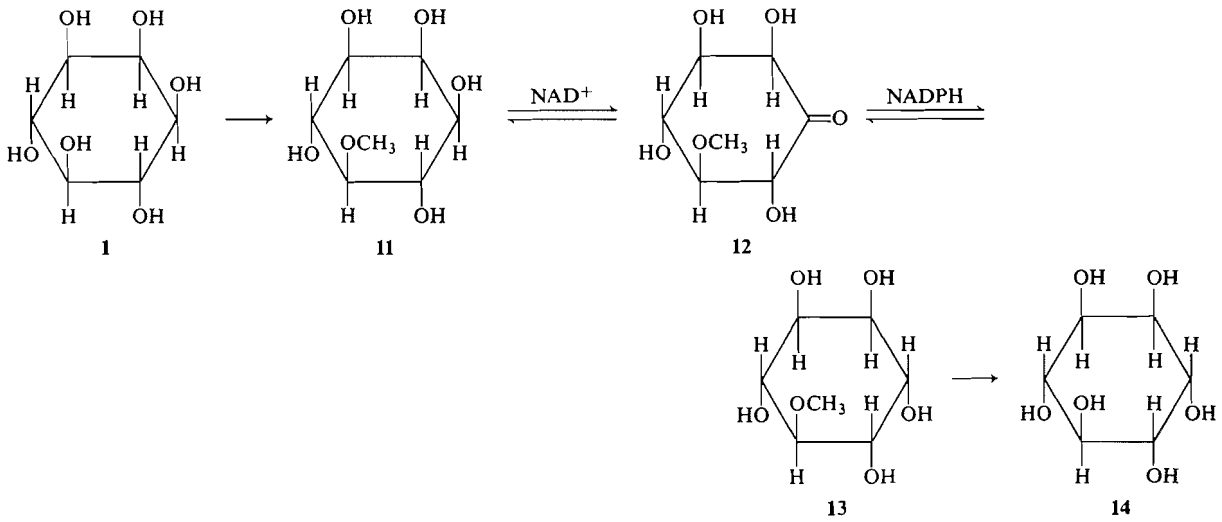

SCHEME 6. The pathway from *myo*-inositol to D-pinitol and D-*chiro*-inositol.

hindrance, the pro-*S* hydrogen could not react so easily. Following enol bond formation between C-5 and C-6, ring closure takes place as the resulting enol bond attacks C-1. As a consequence of this, the ammonium group of the enzyme is substituted by the carbanion, i.e. the electron pair of the enol bond, and consequently no hydrolysis is involved in the removal of the enzyme from the reactant.

The keto group in the product of the ring closure is finally reduced with NADH as hydrogen donor.

It has to be admitted that it will be difficult to find experimental ways to distinguish between the reaction mechanism suggested by Floss and co-workers and the one just reported. In any case, it must be stated here that the mechanism of action of the animal enzyme does not correspond to that of the aldolases, class I (cf. also Sherman *et al.* (25)).

The mechanism suggested here for the action of *myo*-inositol-1-phosphate synthase was elaborated for the mammalian enzyme only; it is probably not applicable to enzymes of the same specificity from higher plants, fungi, algae, or procaryotes. As mentioned before, some of these enzymes are metalloenzymes, which can be inhibited by EDTA. However, in a recent report (26) it is stated that the enzyme of pollen of *Lilium longiflorum* and possibly also that of *Neurospora crassa* are not metalloenzymes, although the latter enzyme is inhibited by EDTA. Anyhow, we have to agree with these authors (26) that, in the case of *myo*-inositol-1-phosphate synthase, a classification into two classes, analogous to that used for the aldolases, is not possible.

In our laboratory, three metalloenzymes with synthase activity, namely those from *Lemna gibba* (27), *Candida utilis* (unpublished), and *Streptomyces griseus* (11), have been studied. They all are strongly inhibited by EDTA and can be reactivated by either $Mn^{++}$ or $Mg^{++}$. It is to be noted that these metal-requiring *myo*-inositol-1-phosphate synthases exhibit a much stronger specific activity than the animal enzymes of the same specificity. Thus the enzyme from *Lemna gibba* is about 500 times more active than the enzyme from rat testes (27). This is the more surprising as usually plant enzymes are considerably less active than those from animal sources.

Investigations on the function of the metal in these enzymes have so far not led to a plausible picture of the reaction mechanism.

**Biosynthesis of the inositols other than *myo*-inositol**

Six of the nine inositol isomers occur in nature either as such or in the form of their methyl ethers. Most of them are found in higher plants. It was speculated that mechanisms similar to that of *myo*-inositol biosynthesis are responsible for their formation, in which case monosaccharides other than D-glucose would have to act as precursors for each of these inositols. For example, an intramolecular head-to-tail condensation of D-galactose would yield D-*chiro*-inositol (**14**).

It was soon found that such biosynthetic mechanisms for the inositols other than *myo*-inositol do not exist. With one minor exception, which may be without any biological significance, it could be established that all these compounds derive from *myo*-inositol via epimerization reactions. The one exception is also closely related to *myo*-inositol biosynthesis. It has been shown that *myo*-inositol-

For personal use only.

1-phosphate synthase acts on D-mannose 6-phosphate to yield *neo*-inositol 1-phosphate (**18**). This reaction, however, is several orders of magnitude slower than the reaction with D-glucose 6-phosphate (28). On the other hand, *neo*-inositol can also be the product of an enzymic epimerization of *myo*-inositol (29).

In some cases such epimerizations of *myo*-inositol do not take place directly but require a previous methylation of the substrate. Thus in many higher plants, e.g. the *Trifolium* species, D-*chiro*-inositol (**14**) is found in relatively small quantities. The plant also contains *myo*-inositol, sequoyitol (*myo*-inositol 5-methylether, **11**), and, in large quantities, D-pinitol (D-*chiro*-inositol 5-methylether, **13**). It could be shown that the reaction sequence leading to D-*chiro*-inositol (Scheme 6) starts with a methylation of *myo*-inositol to form sequoyitol, which in turn is epimerized to D-pinitol. Eventually, a small amount of D-pinitol is demethylated to D-*chiro*-inositol which, at least in higher plants, cannot be formed from *myo*-inositol by direct epimerization (30). Algae, however, can epimerize *myo*-inositol to D-*chiro*-inositol without intermediary formation of methyl ethers (31). The enzymes catalyzing the epimerization reaction in *Trifolium incarnatum* have been isolated and characterized (32); they are an NAD-specific sequoyitol dehydrogenase (EC 1.1.1.143) and an NADP-specific D-pinitol dehydrogenase (EC 1.1.1.142). The first enzyme oxidizes the equatorial hydroxyl group on C-3 of sequoyitol to a keto group, which then is reduced by the second enzyme to an axial hydroxyl group. It is interesting to note that these two enzymes show a different stereospecificity toward the nicotinamide part of their respective coenzymes.

Many epimerization reactions of this kind, acting on methylated and on nonmethylated inositols, are known, but not all of them have been thoroughly investigated with regard to their mechanism of action. It seems that two coenzymes are not always involved; animal systems of such epimerizations have been reported to act with $NAD^+$ or $NADP^+$ only (29, 33, 34).

Scheme 7 illustrates the central position of *myo*-inositol in the synthesis of the other inositols as well as the inositol methyl ethers, the formation of which is frequently required for the epimerization reaction to take place. The reactions shown in the scheme occur in different organisms, mostly in higher plants. Horizontal or perpendicular arrows represent epimerizations, whereas oblique arrows indicate methylations with *S*-adenosyl-L-methionine as methyl donor (cf. e.g. ref. 35). Thus whereas biogenetically all inositols seem to be closely interrelated, it should be noted that naturally occurring cyclitols, which do not belong to the inositol series, such as cyclohexanepentols (e.g. quercitol and viburnitol), the cyclohexenetetrols (conduritol, leucanthemitol), and the *C*-methylinositols (mytilitol, laminitol), are in general not synthesized via *myo*-inositol. The biosynthesis of these cyclitols seems to follow several independent pathways, some of them known to start also from monosaccharides (cf. ref. 36).

**Acknowledgements**

The authors are very grateful to Dr. I. D. Spenser (McMaster University, Hamilton) for the critical discussion of the results reported here and of the mechanism of action of the animal *myo*-inositol-1-phosphate synthase suggested. The experimental work of the authors reported here has been generously supported by the "Fonds zur Förderung der wissenschaftlichen Forschung in Österreich" (projects 2639, 3389, and 4067).

Received December 23, 1981

JOSÉ A. BARBERO, KEITH G. MCCURDY, and PETER R. TREMAINE. Can. J. Chem. **60**, 1872 (1982).

A flow microcalorimeter and vibrating tube densimeter were used to obtain apparent molal heat capacities and volumes of aqueous NaHS and $Na_2S$ from 0.1 to 1.0 mol $kg^{-1}$ and of aqueous $H_2S$ from 0.03 to 0.08 mol $kg^{-1}$ at 10, 25, and 40°C. Standard state heat capacities and volumes for $H_2S$ and $HS^-$ were obtained by extrapolation to infinite dilution. Combining these results with 25°C enthalpy data yields an expression for the temperature dependence of the equilibrium constant for $H_2S$ neutralization at pressures near those of steam saturation, $H_2S + OH^- = HS^- + H_2O$, $\log K_1^b = 19.84 + 930.8/T - 2.800 \ln T$, with an estimated uncertainty of ±0.47 at 300°C. The heat capacity data for bulk aqueous $Na_2S$ suggest that the relative concentration of $S^{2-}$ at these molalities is small.

JOSÉ A. BARBERO, KEITH G. MCCURDY et PETER R. TREMAINE. Can. J. Chem. **60**, 1872 (1982).

On a utilisé un microcalorimètre à écoulement et un densimètre à tube vibrant pour obtenir les capacités calorifiques et les volumes molales apparents du NaHS et du $Na_2S$ aqueux à des concentrations allant de 0,1 à 1,0 mol $kg^{-1}$ et du $H_2S$ aqueux à des concentrations de 0,03 à 0.08 mol $kg^{-1}$ à −10, 25 et 40°C. On a obtenu les capacités calorifiques et les volumes de l'état standard du $H_2S$ et du $HS^-$ en extrapolant à dilution infinie. La combinaison de ces résultats avec les données d'enthalpie à 25°C donne une expression pour l'effet de la température sur la constante d'équilibre de la neutralisation du $H_2S$ à des pressions voisines de celles de la vapeur saturée, $H_2S + OH^- = HS^- + H_2O$, $\log K_1^b = 19{,}84 + 930{,}8/T^- 2{,}800 \ln T$ avec une incertitude évaluée à ±0.47 à 300°C. Les données de capacité calorifique pour la masse aqueuse de $Na_2S$ suggèrent que la concentration relative de $S^{2-}$ est petite à ces molalités.

## Introduction

Accurate values for the temperature dependence of the first ionization constant of aqueous $H_2S$, $K_1$, are required to model steam-based methods for the in-situ extraction of bitumen and heavy oil, mass transport in Girdler-Sulfide heavy water plants, and hydrometallurgical procedures for treating sulfide ores. Low temperature measurements have been made by many workers using a variety of techniques (1) and the values for $K_1$ near 25°C are well established. Experiments above 100°C are difficult, largely because aqueous sulfide poisons the platinum electrodes commonly used to determine ionization constants in high temperature water. Ellis and co-workers (2) obtained data for $K_1$, up to 276°C using a spectrophotometric method, but noted that the results might be in error since their technique did not permit *in situ* pH measurements. Values to 150°C, reported by Tsonopoulos *et al.* (3), were also obtained by a spectrophotometric method and deviate from Ellis' results above 75°C. No other values for $K_1$ above 100°C have been reported.

The enthalpy of the ionization reaction at 25°C is known (4, 5) and has been used in the van't Hoff equation to extrapolate $K_1$ to high temperatures (1). The standard volume and heat capacity of ionization are required in such an extrapolation to account for the effects of pressure and, more important, changes in the enthalpy of reaction with temperature, respectively. As yet, no accurate values for these properties have been reported. We have now measured apparent molal heat capacities and volumes for aqueous NaHS and $H_2S$ at temperatures of 10°C, 25°C, and 40°C. The results yield both infinite dilution and excess partial molal heat capacities and volumes for these important species which can then be combined with existing low temperature enthalpy data to extrapolate $K_1$ to

elevated pressures and temperatures. The results from such an extrapolation are also presented here, along with a detailed evaluation of uncertainties.

The many attempts to measure the equilibrium constant and other thermodynamic properties of the second ionization step have produced ambiguous results (1), possibly because of oxidation products or other impurities (6). Heat capacity measurements on $Na_2S$ solutions are included in our study and the experimental difficulties discussed.

## Experimental

The heat capacity and density of each solution were measured relative to water using a commerical Picker flow microcalorimeter and vibrating tube densimeter, both of which have been described previously (7, 8). Density determinations were made at the mean temperature of the calorimetric measurements. Kell's values (9) for the specific heat capacity and density of pure water were used in the calculation:

$$C_{p1}{}^0/\text{J g}^{-1}\text{ K}^{-1} = 4.1919,\ 4.1793,\text{ and } 4.1783,$$

$$d_1{}^0/\text{g cm}^{-3} = 0.999700,\ 0.997045,\text{ and } 0.992215$$

at 10°C, 25°C, and 40°C, respectively. The procedure of Desnoyers *et al.* (10) was used to correct for a small systematic difference in NaCl heat capacities obtained from our calorimeter and the values in ref. 10. Following this method, the average apparent molal heat capacity from calorimeter cells 1 and 2, $C_{p\phi}$, was multiplied by the mean heat leak correction factor $f = 1.009 \pm 0.003$, which we obtained from the calibration.

Water for these experiments was singly distilled, passed through a Milli-Q reagent grade mixed bed ion exchange and activated carbon system, then vigorously purged with He gas immediately before use. The conductivity of the final product was less than 1 $\mu$S cm$^{-1}$. Orion 0.1000 *M* $Pb(ClO_4)_2$ solutions, standardized by the manufacturer against standards traceable to NBS, were used for the sulfide determinations. Fisher "Full Range" glass electrodes standardized with commercial pH 7 and pH 10 buffers were used to measure pH.

Commercial purity $H_2S$ (Fisher) was bubbled through a saturated $Ba(OH)_2$ solution in a sealed glass system, which had been thoroughly purged with helium, then on into a sealed flask containing water or a 1 *m* NaOH solution to prepare stock solutions of $H_2S$ and NaHS, respectively. In the latter case, a sealed pH electrode allowed us to stop the gas flow when the pH fell to a value between 10 and 8, indicating that the composition was stoichiometric to within 0.01% in molality. Solutions of NaHS were also prepared from well defined crystals, synthesized in ethanol by reacting $H_2S$ with sodium ethoxide using the method of Stephens and Cobble (11). The crystals were then washed thoroughly in diethyl ether under a nitrogen atmosphere and stored in a vacuum desiccator (0.01 Pa). Well-formed crystals of analytical reagent grade $Na_2S$ (Mallinckrodt) were recrystallized twice from filtered hot aqueous solutions immediately before use. To minimize oxidation, the solutions were prepared by quickly removing large well-formed crystals from the recrystallization flask, washing in deoxygenated water, then dissolving them in a second flask of water, all in a nitrogen glove bag. The final clear colourless solutions had a pH of about 13.5 and the approximate concentration of $Na_2S$ in each was easily obtained by measuring the density. The NaHS solutions, which are less alkaline and hence less susceptible to oxidation, were prepared by weight using a $N_2$ glove bag for all transfers. During the calorimetric runs, the solutions of NaHS and $Na_2S$ were contained in closed 50 mL polythene bottles, which had been filled under nitrogen, and were siphoned into the calorimeter or densimeter via a short length of 0.8 mm i.d. Teflon tubing which passed through a small hole in the bottle cap. Immediately after each set of measurements, aliquots from each bottle were quickly pipetted into a flask containing the sulfide antioxidant buffer SAOB II (12) so that the sulfide concentration could be determined by titration with standardized $Pb(ClO_4)_2$ solution using an Orion model 94-16 sulfide ion electrode to detect the end point.

The $H_2S$ solutions, prepared by bubbling in a closed system at 1 atm, were handled and standardized in the same way except that the solutions were contained in closed Pyrex flasks to avoid $H_2S$ evaporation. Both the $H_2S$ solutions and the water reference solution were connected to the same cylinder of ultra high purity nitrogen so that manipulating a three-way stopcock allowed either to be pressurized. A second three-way stopcock allowed the $H_2S$ solution or the water to be forced into the calorimeter or densimeter by the overpressure of nitrogen. A needle valve downstream of the instruments controlled the flow rate. Before and after each run, the solutions were standardized by diverting the tubing so that the solution flowed directly under the surface of a weighed aliquot of SAOB II. The amount of solution which passed into the SAOB II was measured by noting the weight gain and the amount of sulfide determined by titration, as above.

Several preparations of the $H_2S$, NaHS, and $Na_2S$ solutions were made by each of the methods described above, to ensure that small changes in technique did not affect the heat capacity and density values.

## Results: Apparent molal heat capacities and volumes

Apparent molal heat capacities, $C_{p\phi}$, and volumes, $V_\phi$, are defined by the expression

$$[1] \qquad Y_\phi = (Y - n_1 Y_1{}^0)/n_2$$

where $Y$ is the extensive property of the aqueous solution, $n_1$ and $n_2$ are the number of moles of water and solute respectively (if $n_1 = 55.509$, $n_2 =$ molality, $m$), and $Y_1{}^0$ is the property of 1 mol of pure solvent.

Following Roux *et al.* (13), we used the least-squares method to fit expressions of the form

$$[2] \qquad Y_\phi = Y_\phi{}^\infty + A_Y(d_1{}^0 m)^{1/2} + B_Y m$$

to our $C_{p\phi}$ and $V_\phi$ data for aqueous NaHS. Here, $Y_\phi{}^\infty$ is the value of $Y_\phi$ at infinite dilution, $A_Y(d_1{}^0)^{1/2}$ is the Debye–Hückel limiting slope at the temperature in question on the molality scale and $B_Y$ is an adjustable parameter. We note that no significant concentrations of either $H_2S$ or $S^{2-}$ exist (1) in the pH range of 8 to 11, which was observed for all our NaHS solutions. The experimental data at 25°C from aqueous NaHS prepared both from synthesized crystals and by bubbling $H_2S$ through NaOH are plotted in Figs. 1 and 2. At 25°C, the results from solutions made using the synthesized NaHS

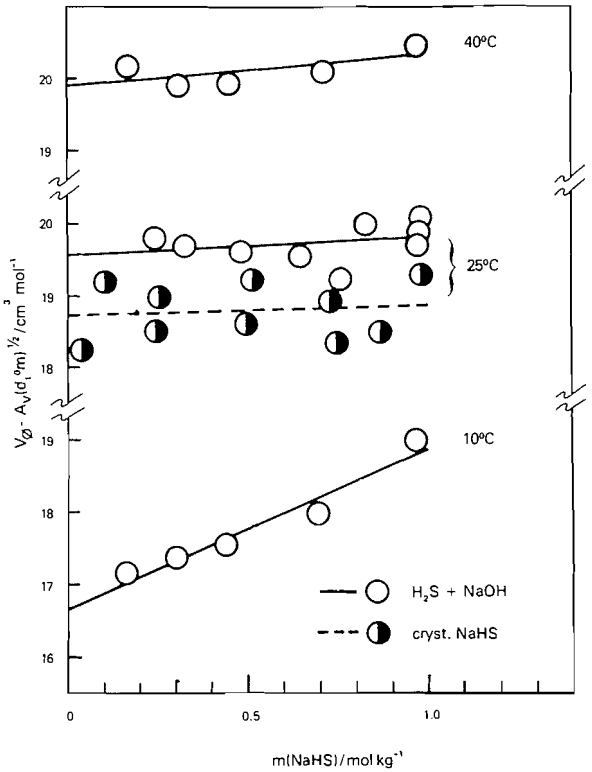

FIG. 1. Apparent molal volumes of aqueous NaHS from two preparation routes after subtracting the Debye–Hückel limiting slope. The lines are least squares fits.

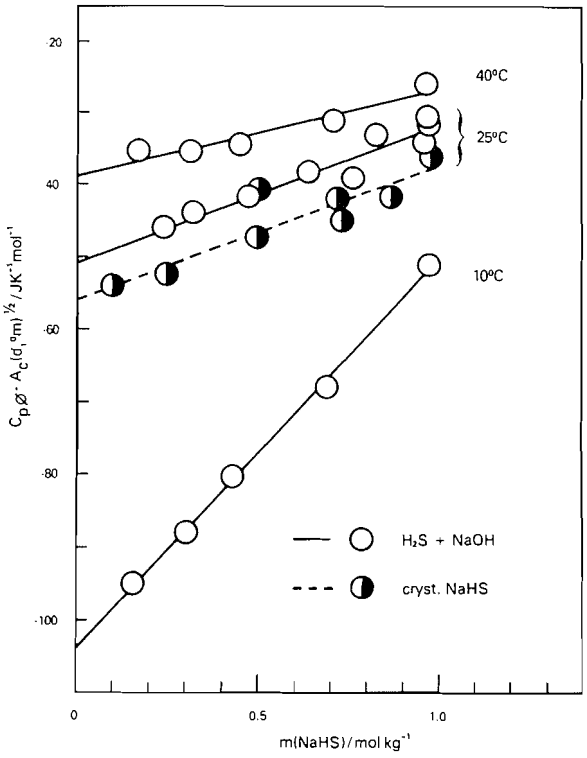

FIG. 2. Apparent molal heat capacities of aqueous NaHS from two preparation routes after subtracting the Debye–Hückel limiting slope. The lines are least squares fits.

crystals were more negative than those prepared from $H_2S$ and aqueous NaOH, by about 5 J $K^{-1}$ $mol^{-1}$ in $C_{p\phi}$ and smaller by about 1 $cm^3$ $mol^{-1}$ in $V_\phi$. Synthesized crystals which had been stored under a pumping vacuum for several days and washed commercial crystals produced solutions which yielded even more negative values. Thus, while the very similar values which were obtained from the two preparation routes confirm that no major impurities are present, we believe that the solutions prepared by bubbling $H_2S$ through aqueous NaOH yield superior results. The crystalline NaHS is probably slightly contaminated with sulfate or thiosulfate, which are known to have very negative aqueous heat capacities and volumes (14) or possibly by polysulfides.

Values of $C_{p\phi}^\infty$, $B_C$, $V_\phi^\infty$, and $B_V$ from NaHS solutions prepared from aqueous NaOH are listed in Table 1, along with the Debye–Hückel terms from Perron *et al.* (15), which were used in the fit.[2] Allred and Woolley's values for NaOH (16) are included for use in the ionization constant calculations presented below, as are Kell's data for water (9). The $V_\phi^\infty$ and $B_V$ values for NaHS are very similar to those for NaCl reported by Allred and Woolley, as might be expected since $Cl^-$ and $HS^-$ are isoelectronic ions. The $C_{p\phi}^\infty$ results are more positive than those for NaCl (16) by 24, 33, and 26 J $K^{-1}$ $mol^{-1}$ at 10, 25, and 40°C respectively. The substantial increase in $B_C$ with decreasing temperature is much like that reported for NaCl and NaOH (16).

The apparent molal properties of $H_2S$, also listed in Table 1, were obtained at the very low molalities, 0.03 to 0.08 mol $kg^{-1}$, which can be achieved by small overpressures of the gas. Solute–solute interactions are negligible at these concentrations, where $H_2S$ is known to obey Henry's law (17). Our measured values were therefore assumed to be equal to those at infinite dilution, $C_{p\phi}^\infty$ and $V_\phi^\infty$. Median values are reported in the table, along with the standard deviations of the median. Data obtained at 25°C were significantly more precise than those at 10°C and 40°C, because of temperature control problems and the nucleation of $H_2S$ bubbles in the instruments, respectively. The large

†From Allred and Woolley (16).
‡From Kell (9).

positive values of $C_{p\phi}$ are typical of neutral solutes in water.

Experimental values for the apparent molal properties of bulk aqueous $Na_2S$ are listed in Table 2. A functional representation, such as eq. [2], cannot be fitted easily to the data because both $HS^-$ and $S^{2-}$ may be present and their relative concentration is very uncertain (1). Since alkaline sulfide solutions are very easily contaminated (6), we tested two aliquots of solution for impurities by acidifying them to pH 9 with aqueous HCl to form mixed solutions (≈ 0.5 $m$ in both $Na_2S$ and HCl), then measuring the heat capacity of each. At this pH, hydrolysis of $S^{2-}$ to $HS^-$ is complete (1) so that the solutions contained only aqueous NaHS and NaCl. By analogy with Young's rule for enthalpies (18), $C_{p\phi}$ for this mixture can be calculated from the values for the pure components using the expression

$$[3]\quad C_{p\phi}(\text{NaHS} + \text{NaCl}) = \frac{1}{m(\text{NaCl}) + m(\text{NaHS})} \times [m(\text{NaHS})C_{p\phi}(\text{NaHS}) + m(\text{NaCl})\,C_{p\phi}(\text{NaCl})]$$

Here, each $C_{p\phi}$ is calculated from eq. [1] using $n_2 = n(\text{NaHS}) + n(\text{NaCl})$ and $\Delta C_{p\phi}$ of mixing at constant ionic strength is assumed to be zero. Our experimental values were more negative than those calculated using data from Table 1 and ref. 16 in eq. [3], by 11 and 21 J K$^{-1}$ mol$^{-1}$. As a result, the apparent molal heat capacities in Table 2 have been adjusted by 16 J K$^{-1}$ mol, on the assumption that the discrepancy was caused by impurities, present in concentrations proportional to the original $Na_2S$ molality. The uncertainty in this correction is estimated to be ±12 J K$^{-1}$ mol$^{-1}$. Bubbling air through the $Na_2S$ solutions for an hour did not affect the heat capacities so the effect was apparently not due to air oxidation.

## Discussion

*$H_2S$ vaporization below 50°C*

By definition, $C_{p\phi}^{\infty}$ is equal to $C_p^0$, the heat capacity of a solute in its hypothetical one molal standard state. McBride and Gordon (19) have calculated detailed ideal gas thermodynamic functions for $H_2S$, which are now accepted by several critical tabulations (20–24). Combining their results for $C_p^0(H_2S,g)$ with our $C_{p\phi}^{\infty}(H_2S)$ data yields the values for the heat capacity of vaporization, $\Delta C_{pR}^0$(vap), which are tabulated in Table 3. Values for $\Delta C_{pR}^0$(vap) can also be obtained by twice differentiating very accurate vapour pressure data with respect to temperature. Clark and Glew (17) have summarized the many

$H_2S$ pressure measurements in the literature. Heat capacity data from their own very precise measurements are also tabulated in Table 3. The values from the calorimetric and vapour pressure measurements differ by no more than 5 J K$^{-1}$ mol$^{-1}$, well within the combined experimental uncertainty.

*$H_2S$ ionization versus temperature*

The thermodynamic expressions describing the temperature and pressure dependence of acid base ionization have been reviewed by Hepler and Hopkins (25). The key relationships are:

$$[4a] \quad (\partial \ln K/\partial T)_p = \Delta H_R^0/RT^2$$

$$[4b] \quad (\partial \Delta H_R^0/\partial T)_p = \Delta C_{pR}^0$$

$$[4c] \quad (\partial \ln K/\partial P)_T = -\Delta V_R^0/RT$$

where $T$ is the absolute temperature. Because $\Delta C_{pR}^0$ is related to the *second* derivative of $\ln K$ with respect to temperature and because compressibility effects are generally small, even a poor estimate of the temperature dependence of $\Delta C_{pR}^0$ and $\Delta V_R^0$ can yield quite accurate values of $K$ to rather high temperatures along the steam saturation curve of water providing that $\ln K$ and $\Delta H_R^0$ are known accurately at 25°C.

Rao and Hepler (1), and most other compilers (21–23) accept the value $\log K_1 = -6.99 \pm 0.10$ at 25°C for the acid dissociation reaction,

$$[5] \quad H_2S(aq) = H^+ + HS^-$$

This is slightly more positive than recent measurements by Tsonopoulos *et al.* (3) and by Ellis' group (2) but their values lie within the error limits, as do most of the many other measurements (1). Combining $\log K_1$ with $\log K_w$ (26) yields the value $\log K_1^b = 7.01 \pm 0.10$ for the neutralization reaction

$$[6] \quad H_2S + OH^- = H_2O + HS^-$$

Kury, Zielen, and Latimer (4) measured the value $\Delta H_R^0 = -33.7 \pm 0.3$ kJ mol$^{-1}$ for reaction [6] at 25°C by titration of $H_2S$ with a large excess of NaOH. Their result is based on Konopik and Leberl's value (27) for the second acid dissociation constant of $H_2S$, $\log K_2 = -12.7$. Recalculating their results in the region of the first end-point using Ellis and Giggenbach's much more negative value, $\log K_2 = -17$ (2), only slightly changes the result, $\Delta H_R^0 = -33.8$ kJ mol$^{-1}$. Using the same method, Zeumer and Roth obtained $\Delta H_R^0 = -34.2 \pm 0.2$ kJ mol$^{-1}$ at 20°C. The $\Delta C_{pR}^0$ values presented below can be used to correct this to 25°C with the result $\Delta H_R^0 = -33.9 \pm 0.2$ kJ mol$^{-1}$. We choose the median, $-33.8 \pm 0.3$ kJ mol$^{-1}$, as being consistent with both sets of results. We note that similar enthalpy of neutralization experiments with LiOH (28) yield a slightly more positive result, possibly because of the difficulty in purifying LiOH. Values of $\Delta C_{pR}^0$ and $\Delta V_R^0$ and their excess property terms can be calculated directly from the data in Table 1 since, by definition, $Y^0 = Y_\phi^\infty$. These are tabulated in Table 4, along with the other thermodynamic constants for $H_2S$ neutralization presented above.

Heat capacities and volumes of simple electrolytes are known (29–31) to increase with temperature to a maximum near 100°C, then to decrease as the temperature is raised further. Above 200°C, this decrease becomes dramatic, largely because of changes in the electrostatic properties of water along the steam saturation line (32, 33). The simple electrostatic effects tend to cancel when reactions are written symmetrically, so that the charge on each reactant species is equal to that on one of the product species, as in reaction [6]. Hence, for symmetric, or "isocoulombic" (31), reactions, $\Delta C_{pR}^0$ and $\Delta V_R^0$ might be expected to pass through only a shallow maximum or minimum depending on the relative magnitude of the electrostatic effect for each ion. This behavior has been observed for several systems (29, 31), and is well illustrated by the very accurate data recently reported for the neutralization of phosphoric acid and carbonic acid (34) at elevated temperatures. Below 250°C, values for $\Delta C_{pR}^0(T)$ for both systems vary by less than 50 J K$^{-1}$ mol$^{-1}$ from $\Delta C_{pR}^0$(25°C). Since the low temperature heat capacities in Table 4 decrease with temperature, $\Delta C_{pR}^0$ for reaction [6] probably passes through a minimum, shown schematically by curve $A$ in Fig. 3.

For the reasons outlined above, we believe the most appropriate extrapolation procedure for symmetric reactions is to assume that $\Delta C_{pR}^0$ and $\Delta V_R^0$ do not change substantially from their values at 25°C (curve $B$ in Fig. 3), and to assign error limits based on plausible estimates of the maximum and minimum values for $d\Delta C_{pR}^0/dT$ and $d\Delta V_R^0/dT$ which might be expected, averaged over the whole temperature range.

*Reference 1.
†Recalculated data from refs. 4 and 5.

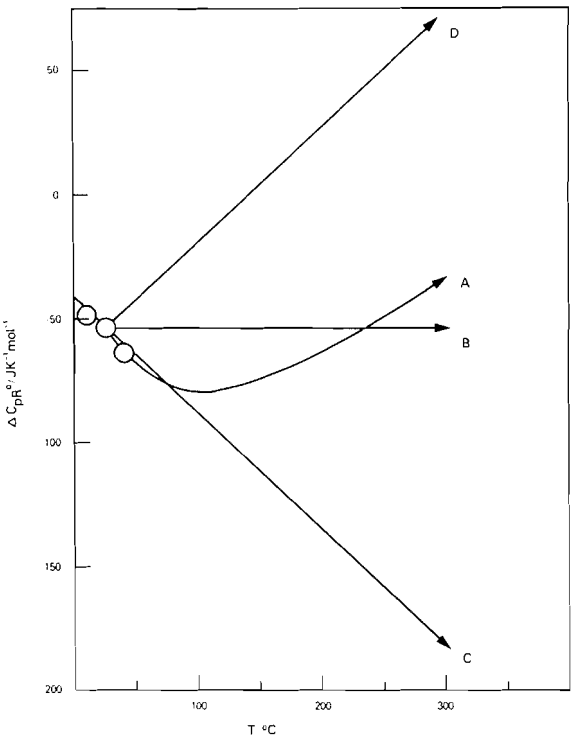

FIG. 3. A schematic drawing of the temperature dependence of $\Delta C_{pR}{}^0$ for reaction [6]: *A* is a plausible locus showing a shallow minimum; *B* is the locus if $\Delta C_{pR}{}^0$ is assumed constant; *C* and *D* are the values used to calculate the error limits in Table 5. Experimental data are shown.

Integrating eqs. [4*a*] and [4*b*] at constant pressure yields the result

$$[7]\quad \ln K_1{}^b(T) \approx \ln K_1{}^b(25°C) - [\Delta H_R{}^0(25°C)/R - 298.15\Delta C_{pR}{}^0(25°C)/R]\left[\frac{1}{T} - \frac{1}{298.15}\right] + \Delta C_{pR}{}^0(25°C)/R]\ln(T/298.15)$$

if $\Delta C_{pR}{}^0$ is temperature independent. Substituting the thermodynamic constants from Table 4 reduces this to the following equation,

$$[8]\quad \log K_1{}^b(T) = 19.840 + 930.8/T - 2.800\ln T$$

which was used to calculate the equilibrium constants tabulated in Table 5. The rather conservative error limits include the uncertainties in $\ln K_1{}^b$(25°C) and $\Delta H_R{}^0$(25°C), and also our estimate of the systematic error due to the unknown variation in $\Delta C_{pR}{}^0$ with temperature. This systematic error was calculated using a more general form of eq. [7] (35) in which $\Delta C_{pR}{}^0(T)$ varies with temperature, and by assuming that the value, $d\Delta C_{pR}{}^0/dT = 0.46$ J K$^{-2}$ mol$^{-1}$, observed between 10°C and 40°C, is the maximum positive or negative deviation from $\Delta C_{pR}{}^0$(25°C) which might be expected over the entire temperature range of 0 to 300°C (curves *C* and *D* in Fig. 3). Even if $\Delta V_R{}^0$ differs from the 25°C value by as much as ±50 cm$^3$ mol$^{-1}$, the effect of the vapour pressure of water (36) on $\log K_1{}^b$ is less than 0.05 at 300°C and so is negligible by comparison with the uncertainty in the extrapolation.

Results for the acid dissociation constant, $K_1$, were calculated from $K_1{}^b$ using Olofsson and Hepler's values for the dissociation constant of water (26). These are included in Table 5 and are also plotted in Fig. 4 for comparison with the

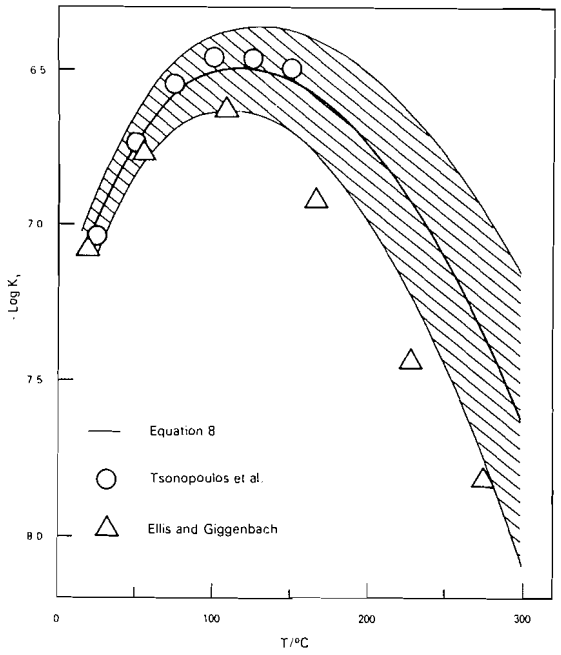

FIG. 4. The temperature dependence of the first ionization constant of $H_2S$, $H_2S \rightleftharpoons HS^- + H^+$. The shaded area represents the combined uncertainty from Table 5.

experimental data from refs. 2 and 3. Both sets of experimental values of $K_1$ (2, 3) may contain systematic errors, since neither apparatus provided a mechanism for measuring the equilibrium pH. Our results for log $K_1$ below 150°C deviate from those of Tsonopoulos *et al.* by no more than 0.05 at any temperature and therefore do not support the more negative values reported by Ellis and Giggenbach (2). Consequently, at higher temperatures, the extrapolated data in Table 5 are quite possibly more accurate than the direct measurements described in ref. 2.

The limiting law Debye–Hückel terms for $OH^-$ and $HS^-$ cancel out in reaction [6] so that $K_1{}^b$ can be expected to be independent of ionic strength up to about $0.1\,m$. The small but finite values for $\Delta B_C$ in Table 4 suggest that variations may occur at higher ionic strengths, at least at low temperatures. No excess free energies or enthalpies data for reaction [6] have been reported but when these become available, the $\Delta B_C$ and $\Delta B_V$ data can be used to extrapolate ionic strength effects to elevated temperatures and pressures (37). Variations in the acid dissociation constant, $K_1$, can readily be calculated from $K_1{}^b$ and values for the ionic strength dependence of $K_W$, which are well established over a wide range of temperatures and molalities (26, 38).

*$HS^-$ ionization*

Values ranging from log $K_2 = -12.5$ to $-17$ have been reported for the equilibrium constant of the second ionization reaction of $H_2S$ (1)

[9] $HS^- = H^+ + S^{2-}$

If little or no $S^{2-}$ is present and mixing effects are small (18), the apparent molal properties of $Na_2S$ are simply the sum of the values for NaHS and NaOH at ionic strength $I \approx 2\,m$ minus the value for the mole of water lost by the hydrolysis of $S^{2-}$, so that

[10] $$Y_\phi(Na_2S, m) = Y_\phi(NaOH, 2\,m) + Y_\phi(NaHS, 2\,m) - Y^0\,(H_2O)$$

The $C_{p\phi}(Na_2S)$ results from Table 2 are plotted in Fig. 5 along with the curve calculated by inserting the data from Table 1 into eq. [10]. The calculated and experimental results agree within the combined error limits below $0.5\,m$ (ionic strength $1.0\,m$), the highest ionic strength at which the NaHS and NaOH data were measured, and therefore provide no indication that the relative concentration of $S^{2-}$ is significant at these molalities. The

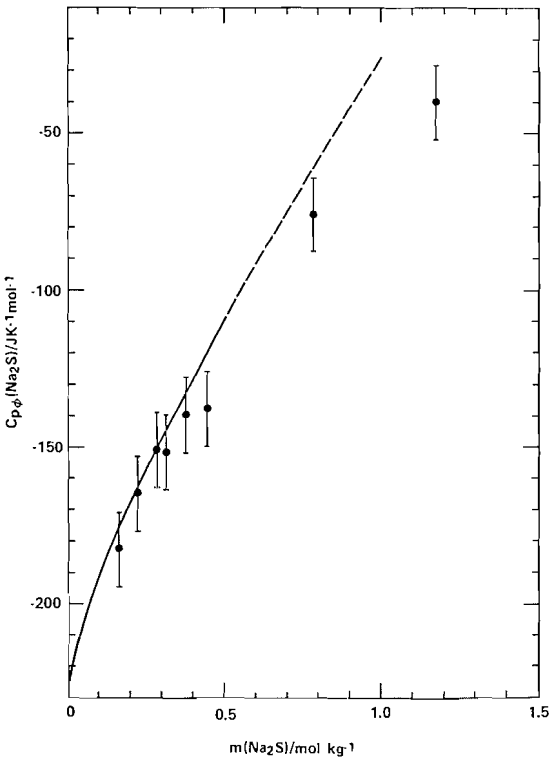

FIG. 5. Apparent molal heat capacities of bulk aqueous $Na_2S$. The solid curve corresponds to a solution containing only $Na^+$, $HS^-$, and $OH^-$ using data in Table 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

extrapolation of eq. [10] to above 1.0 $m$ $Na_2S$ deviates significantly from the one experimental value, suggesting that some further ionization of $HS^-$ may have occurred above about 0.7 $m$. These observations are consistent with recent work (2, 3, 6, 11) which found log $K_2$ to be more negative than −13.5.

## Conclusions

The apparent molal volume and heat capacity results reported here yield standard state values for $HS^-$ and $H_2S$ and permit the extrapolation of low temperature equilibrium constants, as presented above. Equally important, the $H_2S$ heat capacities and high temperature values of $K_1$ calculated from $C_{p\phi}{}^0(H_2S)$ and $C_p{}^0(HS^-)$ provide a sensitive test of the results reported by Clark and Glew (17) and Tsonopoulos *et al.* (3), respectively. The agreement between data obtained using such very different techniques increases confidence in the accuracy of all these results and also of the other constants (3, 4, 19) used in the calculations, so that self-consistent thermodynamic functions for hydrogen sulfide and the hydrogen sulfide ion can easily be calculated (see Appendix). Finally, the $Na_2S$ heat capacities reinforce other evidence that, despite much uncertainty in its stability constant, the sulfide ion, $S^{2-}$, is at most a minor species in solutions less alkaline than pOH ≈ 0.5.

## Acknowledgements

We wish to express our appreciation to Drs. L. G. Hepler, J. Gulens, and D. W. Shoesmith for many helpful comments and suggestions, and to Dr. D. Smith-Magowan, Mr. M.-A. Simard, and Mr. L. Holloway for their assistance in setting up and calibrating the calorimeter. We are particularly grateful to Dr. Hepler and the University of Lethbridge for their long-term loan of the calorimetry system and to the Comisión Nacional de Energía Atómica of Argentina for awarding a CNEA Fellowship to A. Barbero. Funds for the project were provided jointly by the Alberta Research Council and the Alberta Oil Sands Technology and Research Authority.

## Appendix

Table 6 is a tabulation of thermodynamic constants for $H_2S(g)$, $H_2S(aq)$, and $HS^-(aq)$ at 25°C based on the work presented above and consistent literature data. The values for $\Delta H_f^0$ (39), $S^0$ (19), and $C_p^0$ (19) for $H_2S(g)$ are identical to those in recent compilations (20–24) and lead to the value for $\Delta G_f^0(H_2S,g)$. Combining these with Clark and Glews' vapour pressure measurements (17) yields the values for $H_2S(aq)$, except for $V^0$ and $C_p^0$ which are from this work. Standard ionic heat capacities and volumes ($C_p^0(H^+) = 0$, $V^0(H^+) = 0$) were calculated for $HS^-$ using Allred and Woolley's data (16) and our results. Combining the data for $H_2S(aq)$ with log $K_1$[b] (7) and $\Delta H_R^0$ for reaction [6] (3, 4) yields $\Delta G_f^0(HS^-)$, $\Delta H_f^0(HS^-)$ and, hence, $S^0(HS^-)$. As in refs. 19–22, the standard state gas reference pressure is 101.325 kPa.

TABLE 6. Thermodynamic constants for hydrogen sulfide and the hydrogen sulfide ion at 25°C

| Parameter | Value | | |
|---|---|---|---|

Received September 10, 1981

ANDRÉ D. BANDRAUK, K. D. TRUONG, and S. JANDL. Can. J. Chem. **60**, 1881 (1982).

Raman spectra are reported for single crystals of the organic salt KTCNQ (potassium tetracyanoquinodimethane) and its deuterated analogue. Intensities of intramolecular and intermolecular (phonons) vibrations exhibit strong variations at the phase transition temperature associated with a dimer–monomer transition. A simple model is presented to interpret and correlate these results with previously observed ir intensity anomalies in this and other organic semiconductors.

ANDRÉ D. BANDRAUK, K. D. TRUONG et S. JANDL. Can. J. Chem. **60**, 1881 (1982).

On rapporte les spectres Raman d'un monocristal du sel organique KTCNQ (tétracyanoquinodiméthane potassium) et de son analogue deutéré. Les intensités des vibrations intra et intermoléculaires (phonons) montrent de fortes variations à la température de transition de phase, associé à une transition dimère–monomère. On présente un modèle simple pour interpréter et faire correspondre ces résultats aux anomalies d'intensités observées en ir dans ce semi-conducteur organique ainsi que dans d'autres.

[Traduit par le journal]

## 1. Introduction

The charge transfer complexes of TCNQ (tetracyanoquinodimethane), besides providing us with new semiconducting materials, are important since their detailed study enables us to formulate general principles to correlate the high conductivity of such systems with their structural parameters (1–2). Torrance has recently pointed out the strong relationship that exists between various degrees of ionic bonding and conductivity (1). Thus, ionic complexes with complete charge transfer as in KTCNQ ($\rho = 1$) (3), and neutral covalent complexes ($\rho = 0$) such as perylene TCNQ (4–5) are highly insulating, whereas mixed valence complexes ($\rho < 1$, partial charge transfer) such as TTF—TCNQ are excellent conductors (6). The metallic nature of the highly conducting complexes is easily associated to their extreme optical anisotropy as a strong absorption band polarized parallel to the conduction axis, the molecular stacking axis, always appears in these systems. TTF—TCNQ, with the highest conductivity, has a very low electronic absorption band at $\sim 3000\ cm^{-1}$, which is displaced to $\sim 8000\ cm^{-1}$ in the less conductive salt such as RbTCNQ and others (1, 7). These bands are usually attributed to electron transfer between neighboring TCNQ anions along the stacking axis, i.e., perpendicular to the molecular axis, which therefore explains their polarization.

In single particle interpretations of the unusually high or low anisotropic conductivity of these systems, different scattering and interaction mechanisms have been proposed: electron–electron (8), electron–phonon (6, 9), electron–vibration (10, 11), and electron–libration (12, 13). In particular, the electron–vibration coupling effects show up dramatically at phase transitions, which are usually accompanied by large resistivity and magnetic susceptibility changes. These changes in physical properties are parallelled by *anomalous temperature* dependent absorptions in the *infrared region*. This anomalous infrared (ir) activity has been extensively studied by Pecile and co-workers in chloranil (14), TCNQ (15), and TTF salts (16, 17). A similar phenomenon has been recently observed in metal–dithiolene complexes (18) and in polyacetylene polymers (19). These infrared frequencies are usually attributed to symmetric $a_g$ molecular vibrations which become infrared active via a vibronic mechanism induced by the electron charge transfer (20, 21). These observations are consistent with a dimerization of the anionic columns with decreasing temperature (11). Furthermore, these $a_g$ infrared active modes shift to lower frequencies in the low temperature semiconducting or insulating phases when compared to the corresponding Raman frequencies which are unaffected by this mechanism. Such a behaviour has been predicted by Rice (10, 11, 22) with a theory based on a linear electron molecular vibration (emv) coupling mechanism in the dimer. Infrared studies have therefore been instrumental in identifying the

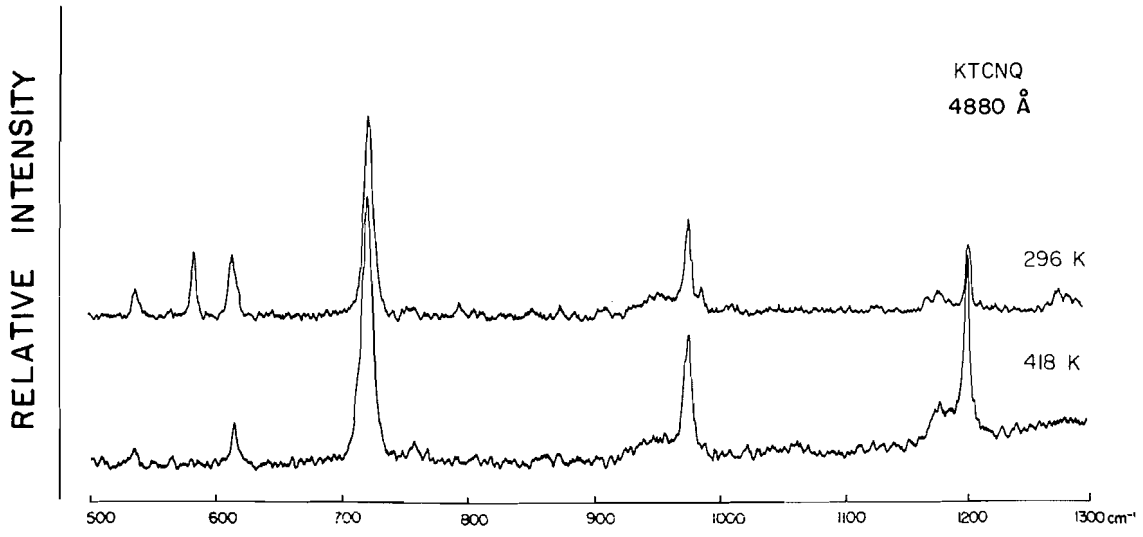

FIG. 1. Raman spectra of KTCNQ single crystal: intramolecular modes.

intramolecular modes which are coupled to the conduction electrons. Recently some attempt has been made to identify by ir spectroscopy the external modes which are activated by conduction electrons in the conductor TTF—TCNQ (23).

Since no previous Raman work exists on single crystals of TCNQ salts, we have undertaken a detailed study of the temperature dependence of the Raman spectra of intramolecular and intermolecular vibrations of single crystals of KTCNQ (24). This work is therefore motivated by the ir intensity anomalies observed in organic conducting and semiconducting salts by Pecile and others, as mentioned above (the ir measurements are usually done in KBr or mulls, and not on single crystals). We have found that such intensity anomalies indeed appear also in the Raman spectra and we propose a single dimer model to interpret these results in terms of the dimerization phase transition thought to occur in KTCNQ at 396 K (25, 26).

## 2. Experimental

The preparation of the crystals, the laser apparatus and spectrometer have been described in our previous Raman studies of this system at 25°C (27). The data in the present work were obtained from free standing single needles (in vacuum) of typical dimension 1 mm × 15 mm with the crystal axis (stacking axis) along the needle axis (26). Excitation of the Raman spectra was obtained with an argon-ion laser with typical power levels below 15 mW. Such low powers were necessary as crystals were found to rapidly deteriorate above this power level. Low frequencies were verified in the anti-Stokes region to confirm the assignments and eliminate errors due to plasma lines. All spectra were recorded, at 90° scattering geometry, on a strip recorder and simultaneously stored in a multichannel analyser. Normal speed of scanning was 1 $cm^{-1}$/min with 30S/channel being used particularly for low frequency modes and for comparison of line intensities. Slit width was maintained at 2 $cm^{-1}$ for simultaneous optimum power and resolution conditions.

## 3. Spectral results and assignments

Previous Raman work on KTCNQ and other alkali salts was done in KBr pellets (27, 28) and in solution (29, 30), to examine the resonance enhancement expected when one enters into an electronic absorption band (30, 31). In this work, we present results obtained on single crystals of KTCNQ and its deuterated analogue $KTCNQ_{d4}$. Partial Raman data were also obtained for the ammonium salt ($NH_4TCNQ$), the results being less complete for the latter due to its instability to laser irradiation (24).

### *(a) High frequency modes*

In Figs. 1 and 2 we present the Raman-active vibrations in the frequency range of 300 to 1300 $cm^{-1}$ for KTCNQ and $KTCNQ_{d4}$, taken at a laser wavelength of 488 nm, which gives intense lines for most modes (24). These spectra are reported at two temperatures, i.e., room temperature and one temperature above $T_c$, the phase transition temperature at 396 K as determined by X-ray diffraction (26). Clearly evident in these figures is the strong temperature dependence of the intensities of the lines at 585(568), 725, and 1204(875) $cm^{-1}$ for the $TCNQ^-$ ion (deuterated lines in parentheses). A more detailed study of the temperature dependence of the intensities of the close doublet at 585(568) and 618(612) $cm^{-1}$ is illustrated in Figs. 3 and 4. For both compounds, deuterated and undeuterated, the lower frequency component disappears progressively as the phase transition temperature is ap-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

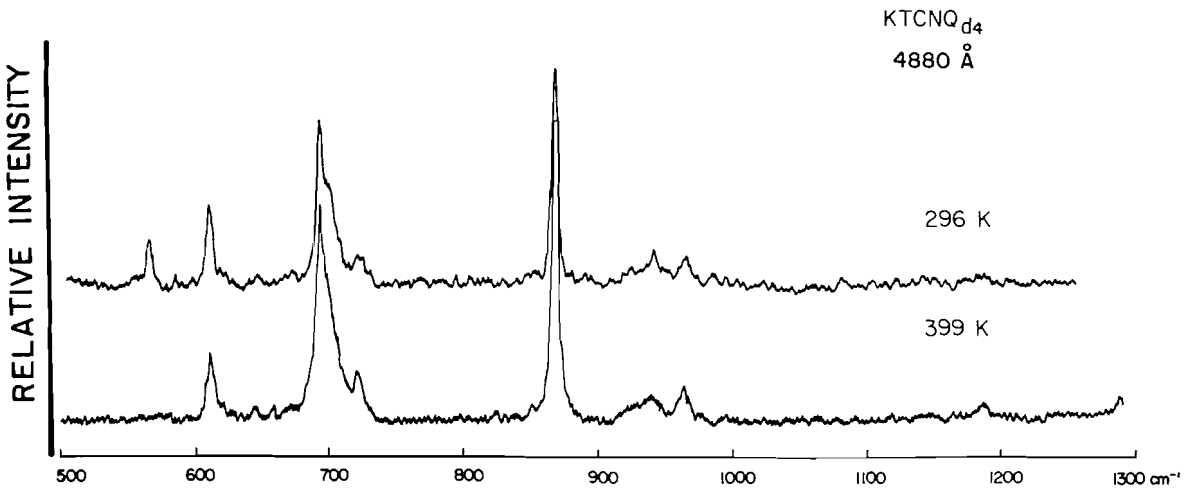

FIG. 2. Raman spectra of deuterated KTCNQ single crystal: intramolecular modes.

proached. In Figs. 5 and 6, for comparison, we illustrate the temperature-dependent intensities of the 725 and 1204(875) $cm^{-1}$ modes. The 699 $cm^{-1}$ line of $TCNQ_{d4}^-$ (Fig. 2), the equivalent of the undeuterated 725 $cm^{-1}$ line in $TCNQ^-$ (Fig. 1), also shows some intensity variation, but due to the presence of a sideband no quantitative measurements were possible. Of note is that the 585(568) $cm^{-1}$ mode vanishes at $T_c$ whereas the 725 and 1204(875) $cm^{-1}$ modes peak in intensity at $T_c$; the 618(612) $cm^{-1}$ vibration is relatively insensitive to the phase change. (The same results were found by exciting at different laser wavelengths (24).) This behaviour is related to the symmetries of these vibrations, as will be shown in detail in the next section. Thus, following Bozio *et al.*'s assignments (32), the 585(568) $cm^{-1}$ mode is an *out-of-plane* $\nu_{29}(b_{2g})$ mode whereas all the other modes are $a_g$, i.e., the strongest Raman-active modes.

*(b) Low frequency modes*

Low frequency modes, usually lattice modes such as translations and librations, are sensitive to changes in crystal structure and hence are a useful probe for phase transitions. With this view in mind, Raman spectra were taken in the region below 300 $cm^{-1}$ for single crystals with the incident light polarized perpendicular or parallel to the needle axis, *a*, which from X-ray work is known to be the stacking axis of the $TCNQ^-$ molecular planes (26). Thus in Figs. 7 and 8, with the incident light polarized perpendicular to the needle axis (i.e., in the plane of the TCNQ's) we observe the same low frequency mode distribution in $TCNQ^-$ and $TCNQ_{d4}^-$, the only noticeable isotope shift occurring for the 98(91) $cm^{-1}$ line which consequently is attributed as the in-plane $\nu_{49}(b_{3g})$ vibration following the normal mode analysis of Girlando and Pecile (33).

More detailed information is presented in Figs. 9 to 11 for the polarization dependence of the scattering of the low frequency modes. Thus Fig. 9 shows an exceptional resolution of the *bc–bc* scattering, i.e., in the plane of the TCNQ anions. In the high temperature phase, where from Konno's X-ray work (26), all TCNQ's are equivalent, only three main peaks remain in Fig. 9, at 98, 168, and 232 $cm^{-1}$. The 98 $cm^{-1}$ line is, as mentioned above, the in-plane $\nu_{49}(b_{3g})$ mode; the line at 168 $cm^{-1}$ is attributed to the out-of-plane $\nu_{17}(b_{1g})$ mode and the weak 300 $cm^{-1}$ line is assigned to $\nu_{31}(b_{2g})$, in agreement with the normal coordinate analysis of Girlando and Pecile (33). Recent high resolution infrared vibrational crystal spectra of TTF—TCNQ show the appearance of 95 and 165 $cm^{-1}$ modes only *below* the metal–semiconductor phase transition at 60 K for this compound (23). These have been assigned to $TCNQ^-$ Raman modes vibronically activated by the conduction electrons. Our results confirm these modes as being indeed $b_g$ modes. The vibration at 232 $cm^{-1}$ observed many times in $TCNQ^-$ powder salts can be now attributed as an $a_g$ out-of-plane mode (Fig. 11). Its temperature-dependent intensity suggests it is a fundamental strongly coupled to phonons (possibly a symmetric ring bending vibration).

Since no previous measurements of low frequency single crystal Raman modes of TCNQ salts exist, we therefore report in Table 1 these modes as observed by us in the dimerized low temperature phases for the two potassium salts as well as, for comparison, modes of $NH_4TCNQ$ which has a

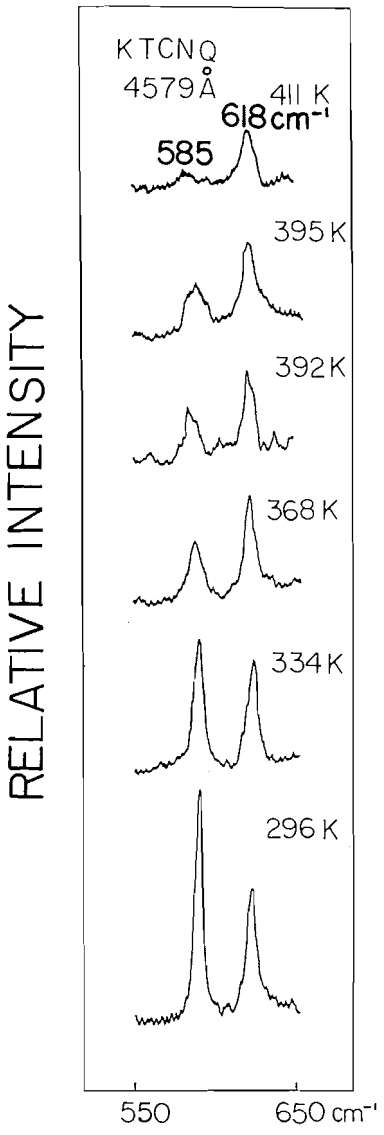

FIG. 3. Temperature dependent intensity of the out-of-plane $\nu_{29}(b_{2g})$ mode at 585 $cm^{-1}$ (618 $cm^{-1}$, $a_g$).

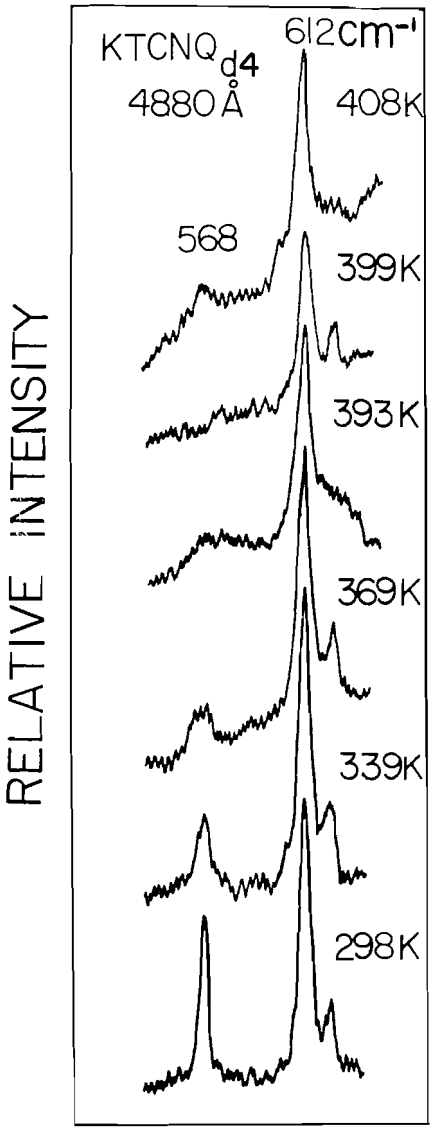

FIG. 4. Temperature dependent intensity of the deuterated out-of-plane $\nu_{29}(b_{2g})$ mode at 568 $cm^{-1}$ (612 $cm^{-1}$, $a_g$).

phase transition at 300 K (16, 25). For the latter salt, high temperature spectra were unobtainable due to crystal deterioration at laser powers even as low as 5 mW. One observes in Table 1 generally good correlation for the frequencies of the three different salts, even though the crystal structure of $NH_4$-TCNQ (orthorhombic) is slightly different from the potassium salt (monoclinic). This correlation permits us tentatively to conclude that vibrations of $K^+$ are absent in view of the disparity in mass of the two cations. In any case, as a result of the low temperature crystal structure of KTCNQ (space group $P2_1/n$, $Z = 8$ (26)), $K^+$ has approximate $C_i$ site symmetry as compared to $C_s$ for the dimerized $TCNQ^-$ ions; the $K^+$ translational modes therefore should be very weak.

In the high temperature phase (space group $P2_1/c$, $Z = 2$ (26)), all site symmetries now are $C_i$, so that in addition to the $C_{2h}$ crystal symmetry, one should observe above $T_c$ only librations of $a_g$ and $b_g$ symmetry for the $TCNQ^-$ anions. In the dimerized low temperature phase, translations of these anions ($C_s$ site) may now be Raman active. In Figs. 10 and 11 we notice from the polarization measurements

three broad bands in the low regions 45–50 $cm^{-1}$, 64–80 $cm^{-1}$, and the higher region 100–110 $cm^{-1}$. Since the moments of inertia of the TCNQ's are respectively 0.8 ($I_x$), 2.6 ($I_y$), 3.3 ($I_z$) $\times$ $10^{-37}$ g $cm^2$ where $x$ and $y$ are the long and short molecular axis, and $z$ is perpendicular to the molecular plane (9° off the stacking axis (26)), we readily obtain for the ratios of the reciprocals of the square roots of these moments — 2.1:1.2:1. The frequencies of librations should roughly follow (for equal force constants) this ratio so that we can expect three groups of frequencies as observed in Figs. 10 and 11. These three groups of frequencies broaden very

rapidly as one approaches the transition temperature but are still identifiable. We therefore attribute these frequencies to the librations of the individual $TCNQ^-$ anions. In particular, the libration at 110 $cm^{-1}$ is strongly temperature dependent, appearing at 125 $cm^{-1}$ at low temperatures in all salts (Table 1), and seemingly converging to 100 $cm^{-1}$ at high temperatures as clearly seen in Fig. 8. Since it is polarized along the stack axis, Fig. 11, it is therefore easily influenced by the progressive elongation along that axis known to occur as the temperature increases (26).

## 4. Discussion

### *A. Theory*

The generally assumed simple model to explain spectral changes for the TCNQ salts consists of a dimerized unit which because of electron transfer parallel to the stacking axis activates $a_g$ modes in the infrared (11, 14). In order to apply this model to the discussion of our Raman spectra, we will rely on the theory developed by one of us for multiphoton vibrational processes in molecules (31).

Thus, for the dimer one can form linear combinations of molecular vibrations into symmetric, $Q_g$, and antisymmetric, $Q_u$, pairs, with respect to the inversion center of the dimer, i.e.,

$$[1] \quad Q_{g,u} = \frac{1}{\sqrt{2}} [Q_1 \pm Q_2]$$

where the +(−) sign is associated to the g(u) mode, and $Q_1$ and $Q_2$ are vibrations of the same symmetry on molecules 1 and 2. The total electronic Hamiltonian $H$ will be a function of $Q_g$, $Q_u$, and $d$, the distance between the monomer units. The dimer electronic molecular orbitals will also separate into

symmetric, $\psi_g$, and antisymmetric, $\psi_u$, combinations of the monomer orbitals $\psi_1$ and $\psi_2$, i.e.,

$$[2] \quad \psi_{g,u}(Q_g,Q_u,d) = \frac{1}{\sqrt{2}}[\psi_1(Q_1) \pm \psi_2(Q_2)]$$

Vibrations induce changes in the orbitals via the *Herzberg–Teller* effect, which for our two-state model is given exactly by (31)

$$[3] \quad \frac{\partial\psi_u}{\partial Q} = \frac{\langle g|\partial H/\partial Q|u\rangle}{E_u - E_g}$$

where $E$ is the dimer orbital energy. Thus for the antisymmetric mode $Q_u$, the electronic matrix element $\langle g|\partial H/\partial Q_u|u\rangle$ between the dimer orbitals $\psi_g$ and $\psi_u$ is, from eqs. [1] to [3], given by

$$[4] \quad \langle g|\partial H/\partial Q_u|u\rangle = \frac{1}{2\sqrt{2}}[\langle\psi_1|\partial H/\partial Q_1|\psi_1\rangle + \langle\psi_2|\partial H/\partial Q_2|\psi_2\rangle]$$

where we have used the relation $\partial H/\partial Q_u = +\partial H/\partial Q_1 - \partial H/\partial Q_2$ and cross terms have cancelled. By the Hellmann–Feynman theorem (31, 34), the energy derivative is the average force, i.e.,

$$[5] \quad \partial\varepsilon/\partial Q = \langle\psi|\partial H/\partial Q|\psi\rangle$$

so that eq. [4] becomes

$$[6] \quad \langle g|\partial H/\partial Q_u|u\rangle = \frac{1}{\sqrt{2}}(\partial\varepsilon/\partial Q)$$

where $\varepsilon$ is the *energy* of the *monomer* orbitals $\psi_1(Q_1)$ or $\psi_2(Q_2)$ and $Q$ is now $Q_1$ or $Q_2$ and must be of $a_g$ symmetry.

The infrared absorption amplitude can now be calculated by assuming an electronic virtual absorption into the state $|u\rangle$ from the ground state $|g\rangle$, followed by emission of a vibration (phonon) through the term $\partial\psi_u/\partial Q_u$, which corresponds to either nondiagonal electron–phonon coupling (35), or variation of the electronic transition moment (31). Thus,

$$[7] \quad T(\text{ir}) = \frac{\langle g|\boldsymbol{\mu}\cdot\boldsymbol{e}|u\rangle\langle u|\partial H/\partial Q_u|g\rangle}{(E_g + \hbar\omega - E_u)(E_u - E_g)}$$

where $\hbar\omega$ is the energy of the absorbed photon of polarization $\boldsymbol{e}$ and $\boldsymbol{\mu}$ is the electronic dipole operator (31). In view of relation [6], we now have the ir absorption intensity proportional to the square of the transition amplitude

$$[8] \quad T(\text{ir}) = \frac{1}{\sqrt{2}}\frac{\langle g|\boldsymbol{\mu}\cdot\boldsymbol{e}|u\rangle}{(E_g+\hbar\omega-E_u)(E_u-E_g)}\left(\frac{\partial\varepsilon}{\partial Q}\right)$$

To calculate the corresponding Raman intensities (31), we calculate the amplitude for absorption (emission), of a photon of energy $\hbar\omega_1$ ($\omega_2$) and polarization $e_1$ ($e_2$) with emission of vibrations, i.e., keeping account of symmetries we get,

$$[9] \quad T(\text{R}) = \frac{\langle g|\boldsymbol{\mu}\cdot\boldsymbol{e}_1|u\rangle\langle u|\partial H/\partial Q_g|u\rangle\langle u|\boldsymbol{\mu}\cdot\boldsymbol{e}_2|g\rangle}{(E_g+\hbar\omega_1 - E_u)(E_g+\hbar\omega_2 - E_u)}$$

By similar arguments which gave eq. [6] we can also show that

$$[10] \quad \langle u|\partial H/\partial Q_g|u\rangle \simeq \frac{1}{\sqrt{2}}(\partial\varepsilon/\partial Q)$$

Equations [8] and [9] illustrate that upon dimerization, both the ir and the Raman spectra are governed by a *common antisymmetric* dimer electronic state (orbital $\psi_u$). Since the absorption must be polarized along the stacking axis because of the inversion symmetry of the orbitals $\psi_g$ and $\psi_u$, we see that the monomer $Q(a_g)$ modes appear both in the ir and Raman by electronic excitations *perpendicular* to the monomer axis. This follows since $\partial\varepsilon/\partial Q$ is

nonvanishing only for symmetric modes, eq. [5], as it is a measure of the force on the nuclei giving rise to a displacement of their equilibria and therefore, to Franck–Condon excitation (31). Therefore this explains the appearance of the $a_g$ modes as seen by Pecile *et al.* (14–17). We note, however, that the ir and Raman bands can be made more intense by entering into near-resonance with the state $|u\rangle$, which corresponds to the electronic absorptions seen between 3000–8000 $cm^{-1}$ from TTF—TCNQ to KTCNQ (3). This therefore indicates the importance of infrared lasers to probe these states. In that case one would see, both by ir and Raman spectroscopy, the *same* $a_g$ modes.

*B. Correlation of intramolecular vibrations*

With the above theoretical model, we can now correlate our Raman results with the infrared studies of Pecile *et al.* of simple TCNQ salts. (We reiterate that our Raman spectra are for single crystals as opposed to the ir spectra.) In particular, these authors have found that the intensity of the 725 $cm^{-1}$ mode diminishes abruptly around $T_c$ (15) and have interpreted this effect as due to the dimer–monomer phase transition inferred from X-ray diffraction (25, 26). In the case of our Raman results, we first point out that the temperature dependence of the electronic absorption spectra may be ruled out as a mechanism for intensity variations, since the absorption has been observed to decrease with increasing temperature in KTCNQ (36) contrary to what we observe in the Raman intensities. These, we reiterate, peak at $T_c$ for the $a_g$ modes at 725 and 1204 $cm^{-1}$, Fig. 5, whereas the $b_{2g}$ mode at 585 $cm^{-1}$ disappears at the transition temperature, Figs. 3 and 4.

Previous resonance Raman experiments in KBr and solution (28, 29) show that the 725 $cm^{-1}$ mode is insensitive to the absorption to the localised electronic charge transfer band at 645 nm but responds rather to the higher energy band at 400 nm. The 1204 $cm^{-1}$ vibration is known to be enhanced when excited in the red so that contrary to the 725 $cm^{-1}$ vibration, it is coupled to the low wavelength absorption bands of $TCNQ^-$. *Ab initio* calculations (37) indicate that the 400 nm absorption corresponds to transfer out of the last occupied molecular orbital $b_{2g}$ to a highly delocalized $a_u$ orbital, whereas the 645 nm absorption increases the occupation of the $b_{2g}$ orbital by transferring electrons out of the C—H region from a $b_{1u}$ orbital. The large contribution of the C—H bond to the 1204 $cm^{-1}$ mode (shifted to 875 $cm^{-1}$ by deuteration) helps explain the strong coupling of this vibration to the $b_{2g}$ electron observed in conductivity measurements (22). Rice *et al.* have deduced from these measurements that the electron–vibration coupling is larger for the 1204 $cm^{-1}$ than the 725 $cm^{-1}$ vibration in KTCNQ. Our Raman studies, Fig. 5, correlate well with the conductivity experiments. We observe the 1204 $cm^{-1}$ vibration is much more sensitive to the phase transition than the 725 $cm^{-1}$ mode. In addition, the intensities of both vibrations peak at the phase transition temperature $T_c$, thus indicating a change in the nature of the excited electronic states and consequently a decrease in the electron–vibration interactions above $T_c$. We can explain this as due to the uniform spacing of the TCNQ's above $T_c$ which favors electron delocalization along the chain. This delocalization, by reducing the electron densities of the molecules, reduces the force $\partial H/\partial Q$, eq. [5], which is responsible for bond elongations and Franck–Condon excitations (31). We can conclude that as one approaches $T_c$ from below, electrons are returning to the molecular planes from the dimer overlap region, increasing $\partial\varepsilon/\partial Q$ and consequently the intensity. Above $T_c$, delocalization reduces these couplings and therefore the intensities. This interpretation does not take into account the variation of the energy $E_u$, of the dimer orbital $\psi_u$, on the dimer spacing $d$, eq. [3]. This presumably is negligible, since we did not observe translational modes in the low frequency region.

Contrary to the in-plane $a_g$ modes, the *out-of-plane* $\nu_{29}(b_{2g})$ mode at 585 $cm^{-1}$ disappears at and beyond $T_c$.[1] This mode has not been considered in previous ir (14–17) and conductivity measurements (22). The Raman intensity variations of this mode as a function of temperature, Figs. 1–4, clearly reflect the physical change along the stacking axis of the crystal. Since this mode contains a strong C—H component (568 $cm^{-1}$ in $TCNQ_{d4}$) and it is an out-of-plane bending mode, it must probe the overlap region between the TCNQ's. Furthermore, molecular orbital calculations (37) indicate an increase in electron distribution in the C—H region of $TCNQ^-$ as compared to $TCNQ^0$. We can therefore understand the sensitivity of this predominant out-of-plane C—H vibration to the phase transition. Thus, the return to a more symmetric electronic environment in approaching $T_c$ will decrease the force $\partial H/\partial Q_{b_{2g}}$ to zero at $T_c$, with the same effect on the intensity of that mode. We conclude therefore that these Raman spectroscopic results on single crystals confirm the model of a dimer–monomer phase transition proposed from

[1]It is not present in solution (24), thus confirming its presence only upon association (dimerization).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

other physical measurements, and that at least one out-of-plane bending mode is strongly coupled to the conduction electrons. This has not been considered before.

*C. Temperature dependence of low frequency modes*

Temperature effects are much more pronounced for the modes below 100 $cm^{-1}$, a region normally attributed to the phonon region (translations + librations). Thus above $T_c$ (396 K), the modes at 64, 70, 85, 98, and 110 $cm^{-1}$ still remain in evidence although much broadened (Figs. 5–11). Measurements were done for the intensity of three lines 64, 85, and 98 $cm^{-1}$ as a function of temperature, since only for these, meaningful measurements were still feasible, i.e., they were still identifiable (Figs. 7, 10, 11). The results are illustrated in Fig. 12, where the 64 $cm^{-1}$ line, assigned as a libration, the 98 $cm^{-1}$ line (intramolecular $\nu_{49}(b_{3g})$), and the 85 $cm^{-1}$ (unassigned) decrease rapidly in intensity as one approaches $T_c$, the phase transition temperature. The similarity in temperature behaviour suggests the 85 $cm^{-1}$ line is probably a libration and that the 98 $cm^{-1}$ line must be strongly mixed with librations, a suggestion also made for TTF—TCNQ (23). (We have scaled down the 64 $cm^{-1}$ intensity by a half for convenience.) The temperature behaviour of these lines correlates rather well with the temperature dependence of the deviation from uniform spacing of the TCNQ's along their stacked column as determined from X-ray and magnetic susceptibility temperature data (26). Morawitz and Gutfreund *et al.* have indicated that librations (i.e., rotational displacements) should couple effectively to the electronic band motion in metal–insulator transitions which are a result of dimerization (12, 13). The strong temperature dependence observed in Figs. 10 to 12 is seen to be a reflection of this mechanism. The large linewidths, unfortunately, exclude any quantitative measurements, so that for these low frequency modes, a direct correlation of intensities and linewidths with electron–vibration couplings was not possible as for the intramolecular modes discussed previously.

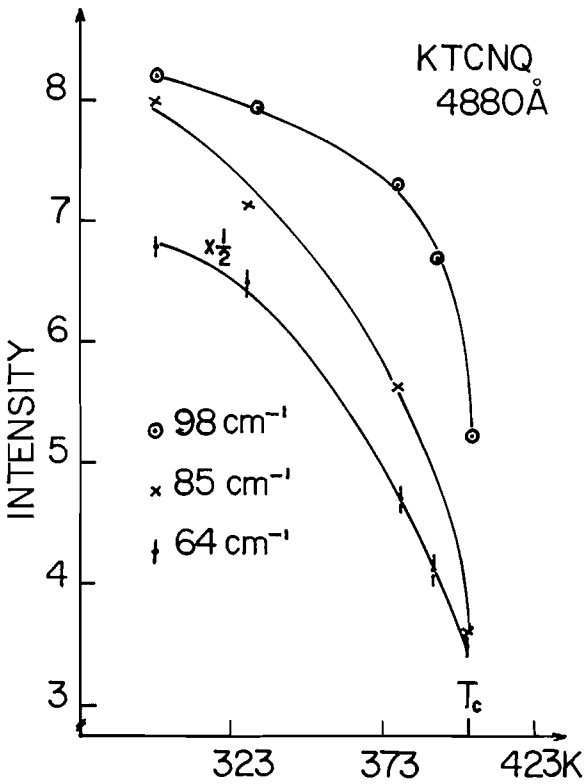

FIG. 12. Temperature dependent intensities of low frequency modes (arbitrary scale).

## Conclusion

The present work was motivated by the need to complement the important findings of Pecile *et al.* (14–17) on the infrared activation of the symmetric modes of TCNQ and TTF salts. We have found that the intensities of our Raman spectra correlate rather well with the dimerization phase transitions proposed for these salts (25, 26). Thus, we have found out-of-plane intramolecular modes which vanish at the phase transitions and sharp variations exist in the intensities of the in-plane symmetric modes at the transition temperature. We suggest that librations are important in describing the physical properties of these systems, a suggestion which has been made more than once (12, 13). We base our conclusions on the temperature effects observed in both the phonon and intramolecular regime of the spectrum. A simple theory, previous section, indicates that infrared lasers would be very useful in establishing the dominant electron–vibration (phonon) interactions. Since most of these organic salts have low electronic absorption bands (3000 ~ 8000 $cm^{-1}$ (6)), vibronic effects will be enhanced by near resonant optical excitations of these bands. The true nature of these electronic states is at the present not well known. Suffice it to mention that similar low energy charge transfer states are thought to be important in biological molecules (38), and organic radicals (39), so that similar electron–vibration effects should be anticipated in these systems.

# Solid state decomposition studies on fluoroperoxo species of transition metals. Part XI. Kinetics of isothermal and photochemical decomposition of $K_2TaO_2F_5.H_2O$

GOPAL V. JERE,[1] LATHA SURENDRA, SURENDER M. KAUSHIK, AND MAHINDER K. GUPTA

*Department of Chemistry, Indian Institute of Technology Delhi, Hauz Khas, New Delhi 110 016, India*

Received September 24, 1981

GOPAL V. JERE, LATHA SURENDRA, SURENDER M. KAUSHIK, and MAHINDER K. GUPTA. Can. J. Chem. **60**, 1891 (1982).

The kinetics of the solid state isothermal and photochemical decompositions of $K_2TaO_2F_5.H_2O$ have been studied by measuring the pressure of oxygen evolved in a constant volume apparatus. Isothermal decomposition of the sample was carried out in the temperature range 528 to 553 K. The reaction is predominantly deceleratory. The initial stage of the decomposition can be described by the unimolecular decay law whereas the later stage obeys the contracting volume equation. The activation energy values of the two processes are 120 and 90 kJ $mol^{-1}$, respectively. The photolysis of the compound at different intensities yields a pressure–time curve which can be described by the rate equation $p = kt^{1/2}$. The rate of photolysis was found to be linearly dependent on intensity, indicating a monoexcitation process for peroxide decomposition.

GOPAL V. JERE, LATHA SURENDRA, SURENDER M. KAUSHIK et MAHINDER K. GUPTA. Can. J. Chem. **60**, 1891 (1982).

On a étudié la cinétique des décompositions photochimiques et isothermes du $K_2TaO_2F_5.H_2O$ à l'état solide en mesurant la pression d'oxygène dégagé dans un appareil à volume constant. On a réalisé la décomposition isotherme d'un échantillon dans un intervalle de température allant de 528 à 533 K. La réaction diminue de vitesse de façon prédominante. On peut décrire l'étape initiale de la décomposition selon la loi de désintégration unimoléculaire; la dernière étape obéit à l'équation de contraction de volume. Les valeurs des énergies d'activation des deux modes de réaction sont respectivement de 120 kJ $mol^{-1}$ et de 90 kJ $mol^{-1}$. La photolyse du composé à des intensités différentes conduit à une courbe de la pression en fonction du temps que l'on peut décrire par l'équation de vitesse $p = kt^{1/2}$. On a trouvé que la vitesse de photolyse dépend linéairement de l'intensité indiquant un processus de mono-excitation pour la décomposition du peroxyde.

[Traduit par le journal]

## Introduction

Peroxo compounds of transition metals have a wide range of utility because of their ability to release oxygen in active form either chemically, on heating, or on irradiation. These serve as reagents for the oxidation of various substrates (1, 2), epoxidation of olefins (1–5), and also serve as synthetic oxygen carriers in biological systems (6). However, due to the lack of solid state kinetic investigations on these compounds, as yet, no well-founded mechanism is established for the evolution of oxygen on decomposition. A kinetic study is a first important step in this direction. These factors prompted the authors to carry out the solid state thermal and photochemical decomposition of transition metal peroxo compounds on an elemental basis (7–12) to determine the generalities, trends, or differences in the mode of decomposition by changing the cation, anion, or the nature of peroxide linkages etc. This paper is a part of this series and reports the isothermal and photochemical decomposition of $K_2TaO_2F_5.H_2O$.

## Experimental

The title compound, potassium pentafluoroperoxotantalate(V) monohydrate, $K_2TaO_2F_5.H_2O$ (13), was prepared by heating 1 g of tantalum pentoxide in 25 mL of 40% hydrogen fluoride for a period of 10–12 h over a waterbath in a covered polythene beaker. To the clear solution, 20 mL of 30% hydrogen peroxide was added; the resulting solution was cooled. This was followed by the addition of potassium hydroxide solution in the stoichiometric amount. The compound was crystallized by adding alcohol to the above solution and was filtered, washed with alcohol and ether, and dried over phosphorus pentoxide. The dried solid was analysed for active oxygen, fluoride, and potassium contents. The analytical values are $O_A((1/2)O_2^{2-})$, 4.0%; F, 25.6%; K, 21.7%. The loss in weight in TGA run was 8% which is attributable to peroxy oxygen and water. Infrared and laser Raman spectra (530.9 nm laser irradiation) were recorded ($\nu_{O-O}$, at 875 $cm^{-1}$ (s)). The unground sample was used for decomposition studies.

The constant volume equipment and experimental procedures for thermal and photochemical decomposition remained the same as reported earlier (7–12). The kinetics were studied by measuring the pressure of oxygen evolved on decomposition; 4–5 mg (weighed on a Mettler H-54 balance) of compound was heated in a furnace electronically maintained at the desired temperature. Photolysis of the sample was carried out with a high pressure mercury arc lamp emitting principal lines at 365.5, 313.0, 265.3, and 253.7 nm along with a strong background of radiation in the near uv and visible region. Actinometry of the lamp was carried out with potassium trisoxalatoferrate(III) trihydrate and different intensities were obtained by changing the distance between the lamp and the sample. A liquid air trap was used in the system to condense the volatile vapour and water, if produced, during the decomposition reaction.

## Results

### *(a) Thermal decomposition*

Isothermal decomposition of the compound $K_2TaO_2F_5.H_2O$ was carried out in the temperature range of 528 K to 553 K. The values of fractional

decomposition, $\alpha$, ranged from 0.45 to 0.60. The $\alpha$–time plots are presented in Fig. 1. This shows that the decomposition reaction is predominantly deceleratory. The initial stage of the reaction can be described by the unimolecular decay law, $-\log(1-\alpha) = k_1 t$, at all temperatures (Fig. 2). The activation energy, deduced from an Arrhenius plot (Fig. 3), is 120 kJ mol$^{-1}$. The subsequent decomposition at various temperatures obeys the contracting sphere equation, $1-(1-\alpha)^{1/3} = k_2 t$ (Fig. 4). The activation energy of this process is 90 kJ mol$^{-1}$ (Fig. 5).

*(b) Photochemical decomposition*

Photochemical decomposition studies, wherever feasible, are often complementary to thermal decomposition studies in understanding the mechanism of decomposition reactions. The diffuse reflectance spectrum of $K_2TaO_2F_5.H_2O$ shows a broad absorption band in the range 230–350 nm, similar to other fluoroperoxo species reported by us earlier (8, 10). It undergoes appreciable photochemical decomposition and is amenable for the study of photolysis kinetics. Unlike the thermal decomposition, water is not evolved during photolysis.

The pressure–time curves for the photodecomposition at different intensities and constant temperature (25°C) are parabolic in nature (Fig. 6) and $p$–$t$ data can be fitted to the equation, $p = kt^{1/2}$ (Fig. 7). To determine the effect of intensity on photodecomposition, the rate of photolysis $k$ was plotted against intensity, $I$ (Fig. 8). It was observed that temperature does not have a significant effect on

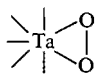
## Discussion

The solid, potassium pentafluoroperoxotantalate(V) monohydrate, $K_2TaO_2F_5.H_2O$, is a typical coordination compound. In the anion, $[TaO_2F_5]^{2-}$, tantalum is surrounded by a pentagonal bipyramidal arrangement of ligands, the peroxo group and three fluorine atoms forming the equatorial plane and the two remaining fluorine atoms at the apices (14). The peroxo group is bidentate chelating in nature, forming a strained triangularly linked configuration



Water is lattice held.

The thermal decomposition of the solid is represented as below:

$$K_2TaO_2F_5.H_2O\ (s) \rightarrow K_2TaOF_5\ (s) + \tfrac{1}{2}O_2\ (g) + H_2O\ (g)$$

Potassium pentafluoroperoxotantalate(V) monohydrate — Potassium oxopentafluorotantalate(V) — Condensed in a cold trap

The weight loss calculated on the above basis agrees well with TGA data. Further, it is also seen that most of the lattice water is lost prior to peroxide decomposition. The reaction is irreversible and peroxide decomposition is exothermic. No melting of the solid is observed. It is also interesting to note that tantalum fluorine bonds are very stable and the only moiety undergoing decomposition in the anion, $[TaO_2F_5]^{2-}$, i.e. inside the coordination sphere, is the triangularly linked bidentate peroxo group.

Brown, Dollimore, and Galwey observe that, as with ionic solids, the reactivity and kinetic behaviour of coordination compounds can successfully be dealt with by invoking the rate equations and other ideas developed in dealing with model systems of simple inorganic ionic solids (15). Hence, the unimolecular decay law and contracting sphere equation have been used to describe the isothermal decomposition of the compound. The deceleratory nature of the reaction and kinetic obedience to a unimolecular decay law indicate instantaneous nucleation or facile nucleation followed by rapid surface growth of the product. As stated earlier the only moieties undergoing thermal decomposition in the title solid are the lattice water and peroxy oxygen from the coordination sphere. Hence the important factors leading to the instantaneous nucleation are probably the dehydration step, which occurs prior to the onset of peroxide decomposition and the inherent defects in this compound. Also, the decomposition reaction itself may initiate or generate large defects in the solid leading to instantaneous nucleation.

The later stage obeys the contracting volume equation (Fig. 4). This implies that the surface is completely transformed into the product and the interface progresses towards the centre of the crystal. The reaction is deceleratory since the interface progressively decreases.

The activation energies computed from the Arrhenius plots, 120 and 90 kJ $mol^{-1}$, are in agreement with the general finding that the $E_a$ value for the processes occurring on the surface of a crystal is higher than that of the reaction occurring at the interface (16).

The deceleratory nature of the photodecomposition can be explained in terms of "special sites" which assist photolysis and are present in the solid. These "special sites" are slowly consumed during photolysis leading to the decline of the rate of decomposition. This view point has been discussed by several workers (16–18). The rate equation, $p = kt^{1/2}$, describes a parabolic relationship between the pressure of oxygen evolved from peroxide decomposition and the duration of irradiation. Similar equations have been used in the photolysis of inorganic systems by Prout and Lownds (19), Morantz *et al.* (20), Yoganarasimhan and Sood (21), and Jere and Kaushik (10). It is seen from Fig. 8 that the photodecomposition is linearly dependent upon light intensity in the range studied, which shows that the peroxide photolysis probably involves a monoexcitation process (8, 10). However, a larger range of variation is desirable, if linear dependance of the rate on light intensity is to be demonstrated unequivocally. The absence of a dark rate indicates that entities induced by photolysis are either relatively stable or decay extremely rapidly resulting in a thermally stable product.

It is reasonable to assume that in the case of the title solid and other related fluoroperoxo species, the mechanism of the thermal and photochemical reactions appear the same except for the method of excitation. Probably the metal–peroxide ring system and peroxide–peroxide interaction at special sites play important roles in the evolution of oxygen in the decomposition of these solids. This has already been reported (8, 10) and can be visualized as below:

$$O_2^{2-} \xrightarrow{\text{Thermal or } h\nu} O_2^{2-*}$$

$$O_2^{2-} + O_2^{2-*} \rightarrow O_2 + 2O^{2-}$$

In coordination compounds the complexity of the ligands present in the anion increases the number of types of bond redistribution processes which are possible within and between the coordination spheres. This situation puts a severe restriction on kinetic studies of coordination compounds. The situation, however, is much more simple in the case of fluoroperoxo species of transition elements, like the title solid, wherein the only moiety undergoing either thermal or photochemical decomposition inside the coordination sphere of the anion $[TaO_2F_5]^{2-}$ is the peroxo group. The authors feel that these solids may serve as near ideal systems for examining the solid state reactivity and kinetic behaviour of coordination compounds. They also provide an easy route for the synthesis of oxofluorometallates (22) which are finding interesting applications as solid state materials (23).

# Scaled particle theory of gas solubility — inclusion of the temperature dependent hard sphere term

BRUCE A. COSGROVE[1] AND JOHN WALKLEY[2]

*Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6*

Received October 6, 1981

BRUCE A. COSGROVE and JOHN WALKLEY. Can. J. Chem. **60**, 1896 (1982).

The limiting behaviour of the scaled particle theory (spt) of gas solubility has been examined for the inert gases in a range of solvents. The hard sphere limit is shown to exhibit thermodynamic self-consistency only with the inclusion of an effective hard sphere diameter temperature dependence whereas the original spt (exclusion of a temperature dependence) fails to extrapolate to the correct hard sphere limit. Furthermore, inclusion of the temperature dependence yields correct thermodynamic properties for gases of small atomic diameter (and well depth potential) as would be expected from a hard sphere based theory.

BRUCE A. COSGROVE et JOHN WALKLEY. Can. J. Chem. **60**, 1896 (1982).

On a étudié le comportement limitant de la théorie de la particule graduée relative à la solubilité des gaz pour les gaz inertes dans divers solvants. On montre que la limite de sphère dure possède des propriétés thermodynamiques qui sont en accord entre elles uniquement lorsqu'on inclut l'effet de la température sur le diamètre effectif de la sphère dure, alors que la théorie originale (excluant l'effet de la température) ne peut être extrapolée vers la bonne limite de la sphère dure. De plus, l'introduction de l'effet de la température donne les bonnes propriétés thermodynamiques des gaz de faible diamètre atomique (et le potentiel de puit) tel qu'attendu à partir d'une théorie fondée sur la sphère dure.

[Traduit par le journal]

## Introduction

Recent work on the development of a theory of gas solubility based upon a hard sphere perturbation approach (1, 2) suggests that it is useful to take a further look at approaches based upon the use of scaled particle theory (spt) (3, 4). Like the perturbation approach, the leading terms (coming from spt) are rigorous for systems of hard spheres (5). With the future development of the perturbation approach, which will necessarily involve approximations for the application to systems even as complex as argon in benzene or water solvent, a comparison of the two theories should be mutually beneficial.

The scaled particle theory of gas solubility (6–8) has been used extensively over the past two decades and has been shown to give excellent agreement with experiment (9). The most surprising aspect of the theory is that it appears to predict the thermodynamic properties (Henry's law coefficient $K_H$, enthalpies of solution $\Delta H_S$, entropies of solution $\Delta S$) of gases dissolved in water as successfully as it does for less complex organic solvents. Despite some criticisms of the early theory (10–13), the formulation as put forward by Pierotti is still used. Basic to the theory is the use of terms derived by Reiss *et al.* (3, 4) for the calculation of the reversible work of making a cavity in a hard sphere solvent. The prescription used for the gas dissolution process is a very simple one. The gas solute is discharged to a hard sphere. As a hard sphere it makes a cavity in the real (undischarged) solvent. Finally, the solute is recharged and allowed to interact with the solvent molecules. This simple prescription has two important features. First is the recognition that when the (discharged) hard sphere solute makes a cavity in the real solvent the solute molecule interacts only with the effective hard sphere diameter of the solvent molecules. The second is that the retention of the solvent as an undischarged system has the not-negligible advantage of allowing the use of experimental solvent properties; for instance, the coefficient of thermal expansion, in the evaluation of the thermodynamic solubility terms.

In this paper we examine the criticism that the Pierotti theory neglects the temperature dependence of the "effective hard sphere diameter" of the solvent molecules (10, 12). Such a dependence is now well recognized and we shall show that without its inclusion the theory fails to extrapolate to the expected hard sphere limit.

## Theory

The spt of gas solubility is so well known and has been "rederived" so many times that we consider it necessary to quote only the required equations. We shall retain the notation as used by Pierotti (6) for all thermodynamic terms, using subscript 1 for solvent and subscript 2 for solute. For this theory the Henry's law coefficient for the dissolved gas

may be written:

[1] $$\ln K_H = \bar{G}_i/RT + \bar{G}_c/RT + \ln (RT/V_1)$$

where $\bar{G}_c$ is the reversible work required to make a cavity in a hard sphere solvent sufficient to accommodate a hard sphere solute molecule, and $\bar{G}_i$ is the free energy associated with the recharging step in the prescribed dissolution process. The assumption is made that this term is equivalent to the enthalpy of recharging, thus neglecting any entropy contribution from this step. Since the pressure of the system remains 1 atm (solvent is *not* discharged to an equivalent hard sphere system), the enthalpy of recharging $\bar{H}_i$ may be equated to the energy of interaction $\bar{E}_i$. This latter term may be written in terms of an appropriate potential of interaction and the radial distribution function of the solvent (a van der Waal's approximation is usually made (14)).

The enthalpy of solution may be written:

[2] $$\Delta H_S = \left(\frac{\partial \ln K_H}{\partial(1/RT)}\right)_P = \bar{H}_i + \bar{H}_c - RT + \alpha_p RT^2$$

(where $\alpha_p$ is the thermal expansion coefficient of the real solvent) and the entropy of solution, since $\bar{G}_i \equiv \bar{H}_i$, becomes

[3] $$T\Delta S = \bar{H}_c - RT + \alpha_p RT^2 - \bar{G}_c - RT \ln (RT/V_1)$$

In this paper we are interested primarily in those thermodynamic terms associated with the dissolution of a hard sphere solute into the real solvent. A hard sphere solute is one having a zero value for its molecular polarizability ($\alpha$) so for the dissolution of such a solute all terms arising from the recharging process must become zero. Thus, we may write:

[4] $$\lim_{\alpha \to 0} \ln K_H = \ln K_H{}^0 = \bar{G}_c/RT + \ln (RT/V_1)$$

[5] $$\lim_{\alpha \to 0} \Delta H_S = \Delta H_S{}^0 = \bar{H}_c - RT + \alpha_p RT^2$$

and, hence,

[6] $$\lim_{\alpha \to 0} T\Delta S^0 = \Delta H_S{}^0 - RT \ln k_H{}^0$$

Since spt gives us an expression for $\bar{G}_c$, we are concerned with the formulation of $\bar{H}_c$ from $\bar{G}_c$. That is, in obtaining the derivative

[7] $$\bar{H}_c = -RT^2[\partial(\bar{G}_c/RT)/\partial T]_p$$

where (3),

[8] $$\bar{G}_c/RT = A^2\{\tfrac{9}{2}[y/(1-y)]^2 + 3y/(1-Y)\} + 3yA/(1-y) - \ln(1-y) + n\pi Pa_2{}^3/6RT$$

If we recognise the effective hard sphere diameters ($a_i$) to be temperature dependent and define $l_i = 1/a_i(da_i/dT)_p$, then, since $y = \pi a_1{}^3 N/6V_1$,

[9] $$\bar{H}_c = yRT^2(\alpha_p - 3l_1)(1-y)^{-3}\{3(1+2y)A^2 + 3(1-y)A + (1-y)^2\} - N\pi Pa_2{}^3(3Tl_2 - 1)/6$$

We note that $A = a_2/a_1$ and, thus, $(\partial A/\partial T)_p$ is of negligible magnitude. For any real solvent the last term in eq. [9] is small and will henceforth be ignored. It is seen that eq. [9] differs from the expression for $\bar{H}_c$ given by Pierotti by the inclusion of the $3l_1$ term.

## Discussion

Pierotti (15) recognized that for the inert gas atoms a plot of the effective hard sphere diameter (that value of the inter-atomic separation at which the interaction potential is zero) against the atomic polarizability of the gas gave a smooth curve. The extrapolation of this curve to zero polarizability thus gives the hard sphere diameter ($a_2{}^0$) of a hard sphere (inert gas) atom ($a_2{}^0 = 2.55$ Å). If a similar plot is constructed for $\ln k_H$ (for the inert gases in a given solvent), then the extrapolation of this curve to zero polarizability will give the $\ln k_H{}^0$ value for the hard sphere solute in that solvent. It is easily seen from eqs. [4] and [8] that knowing $\ln k_H{}^0$ and $a_2{}^0$ allows $a_1$ to be determined.

Wilhelm later extended this technique and by examining $\ln k_H$ data over a range of temperatures, and hence obtaining $\ln k_H{}^0$ values at different temperatures, was able to show that the $a_1$ values so obtained did exhibit a sensible temperature dependence (16, 17). This approach to determining an $l_1$ value relies heavily upon the availability of accurate $k_H$ values over a wide temperature range. It is obvious, however, that if we obtain $\Delta H_S{}^0$ values from the extrapolation of a $\Delta H_S$ vs. atomic polarizability plot, then from eqs. [5] and [9] we may determine $l_1$ directly.

In Table 1 we present the extrapolated $\Delta H^0$ values (for the inert gases dissolved in a range of solvents). We compare these $\Delta H_S{}^0$ values to those calculated from eq. [5] when the Pierotti assumption of no hard sphere temperature dependence ($l_1 = 0$) is made (in eq. [9]). The agreement between these two sets of values is seen to be very poor, and certainly outside the $\pm 100$ cal mol$^{-1}$ error possible in the extrapolated $\Delta H_S{}^0$ values. A comparison is also made between the $l_1$ values calculated from these extrapolated $\Delta H_S{}^0$ values and those deter-

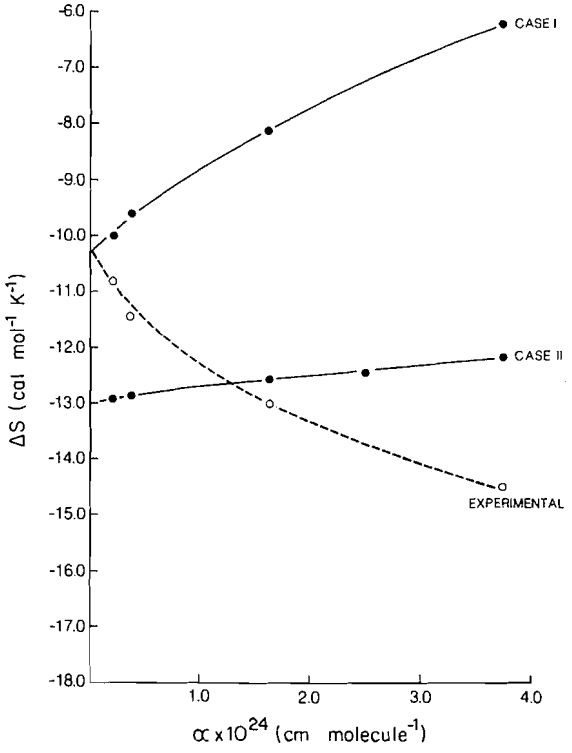

FIG. 1. Entropy of solution $\Delta S$ of inert gases in $C_6H_6$ vs. inert gases polarizability: case I, spt with $l_1 = -0.15 \times 10^{-3}$ K$^{-1}$; case II, original spt with $l_1 = 0$.

mined from the ln $K_H^0$ values (16). Here, the agreement is seen to be excellent.

It is of interest to examine the hard sphere limit of the entropy of solution term, eq. [6], since with the assumption that $\bar{G}_i \equiv \bar{H}_i \equiv \bar{E}_i$ the theoretical expression for $\Delta S$ (eq. [3]) itself contains no "interaction" term. In Fig. 1 we plot the entropy of solution as a function of the polarizability of the inert gas solutes in benzene. Only that theoretical curve calculated with the enthalpy term including the appropriate $l_1$ value agrees with the hard sphere extrapolation value of the experimental data. Using the Pierotti assumption, that $l_1 = 0$, the entropy plot again fails to give the correct limiting case value and though this data appears to give better agreement with experiment this is obviously the dominance of the $RT \ln (RT/V_1)$ term in the entropy expression ($\approx 12$ cal K$^{-1}$ mol$^{-1}$).

Ben-Naim and Friedman (10) suggested that a hard sphere temperature dependence should have been incorporated into the Pierotti theory. Pierotti examined the experimental gas solubility data then available and was unable to find any variation of $a_1$ with temperature for either water or benzene solvent (15). Wilhelm (16), using later data, showed a strong temperature dependence to exist. The fact that this term is not included in the Pierotti formulation for the enthalpy term seems to be based on the argument that although the solvent $a_1$ value is obtained from the ln $k_H^0$ and $a_2^0$ values at a given temperature the enthalpy term is that for the process of making a cavity in a system of hard spheres of *defined hard sphere radius* (at that temperature). That is to say $\Delta H$ is calculated using a different $a_1$ value at each temperature but not, however, incorporating an implicit temperature dependence for $a_1$ in the formulation of eq. [9]. Since the theory should work equally well for the dissolution of totally hard sphere solutes (i.e., of zero molecular polarizability) we can examine eqs. [1] and [2] for thermodynamic self-consistency for the dissolution of such a hypothetical solute molecule (i.e., for that case where $\bar{H}_i = \bar{G}_i = 0$). We chose hard sphere molecules of diameters corresponding to the $a_2$ values of the inert gases. We examine the enthalpy of solution term at 298 K calculated according to eq. [2] and an enthalpy calculated numerically from ln $k_H$ values (eq. [1]) at two temperatures spanning (±5 K) the 298 K value. Computer calculations show ln $k_H$ (298 K) to be the arithmetic mean of ln $k_H$ (293 K) and ln $k_H$ (303 K). We will define

$$[10] \quad \Delta H_S (\ln k_H) = -RT^2 \times \left( \frac{\ln k_H (303) - \ln k_H (293)}{10} \right)$$

and $\Delta H_S^p$(calcd) as that value calculated at 298 K using the Pierotti assumption that $l_1 = 0$ and $\Delta H_S^l$(calcd) as that value calculated using the "correct" $l_1$ value for that particular solvent. In Table 2 we present these enthalpy values for a

TABLE 2. Enthalpies of solution (cal $mol^{-1}$) inert gas type hard sphere solutes ($\bar{H}_1 = \bar{G}_1 = 0$)

| System | $\Delta H_S^p$ | $\Delta H_S$ (ln $k_H$) | $\Delta H_S^l$ (calcd) |
|---|---|---|---|
| $He/H_2O$ | −86.08 | $3.43\times10^2$ | $3.44\times10^2$ |
| $Ne/H_2O$ | −42.35 | $4.27\times10^2$ | $4.28\times10^2$ |
| $Kr/H_2O$ | $2.33\times10^2$ | $9.59\times10^2$ | $9.61\times10^2$ |
| $Xe/H_2O$ | $4.14\times10^2$ | $13.07\times10^2$ | $13.11\times10^2$ |
| $He/C_6H_6$ | $2.04\times10^3$ | $2.84\times10^3$ | $2.91\times10^3$ |
| $Ne/C_6H_6$ | $2.25\times10^3$ | $3.12\times10^3$ | $3.21\times10^3$ |
| $Kr/C_6H_6$ | $3.59\times10^3$ | $4.91\times10^3$ | $5.03\times10^3$ |
| $Xe/C_6H_6$ | $4.46\times10^3$ | $6.07\times10^3$ | $6.22\times10^3$ |
| $Ar/H_2O$ | $1.60\times10^2$ | $8.18\times10^2$ | $8.20\times10^2$ |
| $Ar/C_6H_6$ | $3.24\times10^3$ | $4.44\times10^3$ | $4.55\times10^3$ |
| $Ar/C_7H_{16}$ | $2.60\times10^3$ | $3.52\times10^3$ | $3.53\times10^3$ |
| $Ar/CCl_4$ | $2.83\times10^3$ | $3.89\times10^3$ | $3.93\times10^3$ |

range of hypothetical rare gas hard sphere solutes in water, in benzene and for hard sphere argon in a range of other solvents (18). It is seen that the necessary self-consistency is found only between the $\Delta H_S$ (ln $k_H$) and the $\Delta H_S^l$(calcd) values.

The interaction term in eqs. [1] and [2], representing the recharging step in the dissolution process, is necessarily approximate. It would not be expected that this term should represent the structural characteristics of the solvent surrounding the solute molecule as might terms beyond the hard sphere basis term of a perturbation approach. This term does, however, add a useful empirical element to the theory. In Figs. 2 and 3 we examine the predictive success of the theory in a plot of the difference term ($\Delta H_S$(calcd) − $\Delta H_S$(expt)) for the

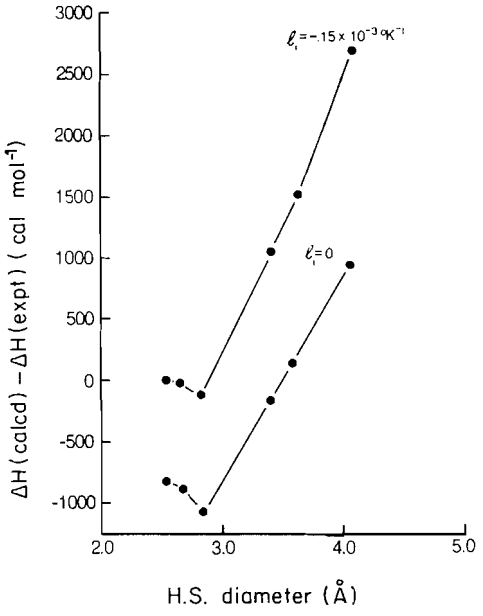

FIG. 2. $\Delta H_S$(calcd) − $\Delta H_S$(expt) for the inert gases in $C_6H_6$ vs. inert gases hard sphere diameters.

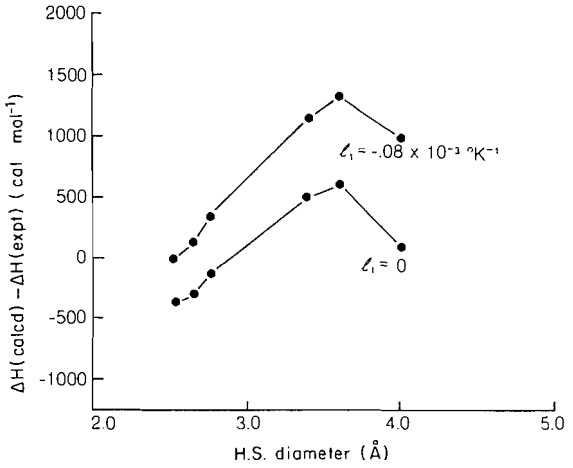

FIG. 3. $\Delta H_S$(calcd) − $\Delta H_S$(expt) for the inert gases in $H_2O$ vs. inert gases hard sphere diameters.

rare gases in benzene and water solvent, respectively. The pattern exhibited by those calculations made with the inclusion of the $l_1$ term again emphasises the correct limiting behaviour (as the molecular polarizability approaches zero) of this version of the theory, whereas calculations made with the assumption that $l_1 = 0$ appear only to give good agreement "around argon and krypton". To emphasise this we present in Table 3 ln $k_H$ and $\Delta H_S$ data for helium and neon in a range of solvents and it is seen that only those values calculated with the inclusion of the $l_1$ term give acceptable agreement with experiment.

We can summarise by noting that the original theory (with $l_1 = 0$) fails to give the expected hard sphere enthalpy value, fails to give thermodynamic self-consistency for the temperature variation of ln $k_H$ (for hard sphere solutes), and agrees with experiment only for gases of size and interaction well depth similar to argon and krypton. This is observed for all solvents (18). With the inclusion of the $l_1$ term the theory is observed to give excellent agreement with the hard sphere limiting enthalpy value, exhibits the correct thermodynamic self-

consistency, and gives agreement with the experimental data for gases of small interaction well depth. Thus, this latter version of the theory behaves in a manner expected of a theory based upon terms which are exact for hard sphere systems.

In Table 4 we give the values of the various physical parameters used in the above calculations. For experimental data values see refs. 9, 19.

S. B. SINGH and K. N. MEHROTRA. Can. J. Chem. **60**, 1901 (1982).

The reaction of 2-diazo-1,2-diphenylethanone (**1**) with 2-imino-1,2-diphenylethanones **2***a–e* gave new N-substituted 3,3,4-triphenyl-4-benzoylazetidin-2-ones **3***a–e*, together with 1,1′,2,2′-tetraphenyl-2,2′-azinodiethanone (**4**). Similar reaction of **1** with 2-iminoacenaphthenones **6***a*, *b* yielded N-substituted 3′,3′-diphenyl spiro(acenaphthen-1-one-2,4′-azetidin-2′-ones) **7***a*, *b* and ketazine **4**. Lithium aluminium hydride reduction of azetidinones **3***a*, *b* gave **4**-α-hydroxybenzylazetidin-2-ones **5***a*, *b*. The spiro azetidinones **7***a*, *b* on reduction with sodium borohydride yielded spiro(1-hydroxyacenaphthene-2,4′-azetidin-2-ones) **8***a*, *b*. The azetidinones **3***a–e* and **7***a*, *b* were found to be unaffected by either acid or base hydrolysis. The marked selective reactivity of the imino group as compared to the carbonyl group towards diphenylketene has been observed in the present studies. The comparative reactivity of carbonyl groups present in azetidinones **3***a*, *b* and **7***a*, *b* has been presented.

S. B. SINGH et K. N. MEHROTRA. Can. J. Chem. **60**, 1901 (1982).

La diazo-2 diphényl-1,2 éthanone (**1**) réagit avec les imino-2 diphényl-1,2 éthanones (**2***a–e*) en donnant les nouvelles triphényl-3,3,4 benzoyl-4 azétidinones-2 (**3***a–e*) substituées sur l'azote ainsi que la tétraphényl-1,1′,2,2′ azino-2,2 diéthanone (**4**). D'une manière analogue, le composé **1** réagit avec les imino-2 acénaphténones (**6***a*,*b*) en donnant les diphényl-3′,3′ spiro(acénaphténones-1 azétidine-2,4′ ones-2′) (**7***a*,*b*) substituées sur l'azote ainsi que la cétazine (**4**). La réduction des azétidinones (**3***a*,*b*) par $LiAlH_4$ conduit aux α-hydroxy benzyl-4 azétidinones-2 (**5***a*,*b*). La réduction des spiro(azétidinones) (**7***a*,*b*) par le borohydrure de sodium conduit aux spiro(hydroxy-1 acénaphthène-azétidine-2,4′ ones-2′) (**8***a*,*b*). On a trouvé que les azétidinones (**3***a–e* et **7***a*,*b*) ne s'hydrolysent pas en milieu acide ou en milieu basique. Dans cette étude, on a observé une réactivité sélective marquée du groupe imino, par comparaison au groupe carbonyle, envers le diphénylcétène. On présente une comparaison de la réactivité des groupes carbonyles présents dans les azétidinones **3***a*,*b* et **7***a*,*b*.

[Traduit par le journal]

The cycloaddition of diphenylketene with imines (1), diimines (2), azines (3), conjugated imines (4), and 1,3-diazabutadienes (5) is known to form β-lactams. Addition of dimethylketene to 2-*p*-tolyl-imino-1,2-diphenylethanone, having a ketoimine group, has been observed to give 4,4-dimethyl-1,5-diphenyl-2-*p*-tolyl-6-oxa-2-azabicyclo[3.1.0]-hexan-3-one (6). A few spiro(2-azetidinones) have been obtained from the reaction of isocyanates with olefins (7) or allenes (8), carbodiimides with 4,4-dicarboxy-2-azetidinones (9), and acid chlorides with anils (10). We now report the cycloaddition of diphenylketene, generated *in situ* by thermal decomposition of 2-diazo-1,2-diphenylethanone (**1**), with 2-imino-1,2-diphenylethanones **2***a–e* and 2-imino-acenaphthenones **6***a*, *b* leading to new azetidinones **3***a–e* and spiro azetidinones **7***a*, *b* in fair yields. This study has also revealed the marked selective reactivity of the imino group as compared to the carbonyl group in ketoimines **2***a–e* and **6***a*, *b* towards diphenylketene. The carbonyl group in the azetidinone ring in the products **3***a–e* and **7***a*, *b* is found to be unaffected either by hydrolysis or treatment with lithium aluminium hydride and sodium borohydride. The carbonyl group, not present in the azetidinone ring of the products **3***a*, *b*, is found to be less reactive than the corresponding carbonyl group in spiro azetidinones **7***a*, *b* as the former is reduced by lithium aluminium hydride while the latter is reduced even by sodium borohydride. Moreover, azetidinones **3***a–e* and **7***a*, *b* obtained in the present work could be used as precursors and their synthetic utility could be tapped as the carbonyl group left unattacked by diphenylketene could be developed to other desired functionalities.

## Results and discussion

The product mixture obtained by the reaction of 2-diazo-1,2-diphenylethanone (**1**) with 2-isopropyl-imino-1,2-diphenylethanone (**2***a*) was separated by fractional crystallization from *n*-hexane – ethanol (1:1) mixture and ethanol; it consisted of 1,1′,2,2′-tetraphenyl-2,2′-azinodiethanone (**4**, 4%) and 1-isopropyl-3,3,4-triphenyl-4-benzoyl-2-azetidinone (**3***a*, 44%). The structural assignment of **3***a* was made on the basis of analytical and spectral data given in Tables 1 and 2. The ir spectrum of **3***a* shows strong bands at 1740 (C=O, azetidinone) (11) and 1680 (C=O, benzoyl) $cm^{-1}$. The nmr

spectrum of **3***a* displays the aromatic protons as multiplets at δ 7.33 (15H) and 6.97 (5H), the methine proton as a septet at δ 3.48 ($J$ = 7 Hz) and the methyl protons as a pair of doublets (11) at δ 1.70 and 1.23 (6H, $J$ = 7 Hz). The mass spectrum shows the molecular ion peak at $m/e$ 445. The authentic sample of **4** was prepared according to the reported method (12) for comparison (ir, nmr, and also mmp).

Similar treatment of ketoimines **2***b*–*e* with **1** gave azetidinones **3***b*–*e* (11–45%), identified on the basis of their analytical and spectral (uv, ir, and nmr) data (Tables 1 and 2), and ketazine **4** (5–10%).

The reduction of **3***a* with lithium aluminium hydride in dry ether gave 1-isopropyl-3,3,4-triphenyl-4-(α-hydroxybenzyl)-azetidin-2-one (**5***a*, 86%), characterized on the basis of analytical and spectral data. Its ir spectrum exhibits a medium intensity band at 3440 $cm^{-1}$, characteristic of the O—H group, and a strong band at 1735 $cm^{-1}$, characteristic of C=O (azetidinone) (11). The nmr spectrum displays the aromatic protons as multiplets at δ 7.93 (2H), 7.53 (4H), and 7.05 (14H), the benzylic proton as a doublet (collapses to a singlet on deuteration) at δ 4.89 ($J$ = 4 Hz), the methine proton as a septet at δ 2.69 ($J$ = 7 Hz), the hydroxy proton as a broad singlet at δ 2.00 (exchangeable on deuteration), and the methyl protons as a pair of

doublets (11) at δ 1.54 and 1.20 (6H, $J$ = 7 Hz). When the product **3***b* was treated with LAH in a similar way, the reduced product **5***b* was obtained. The formation of products **3***a–e*, **4**, and **5***a*, *b* is shown in Scheme 1.

2-Imino-acenaphthenones **6***a*, *b* were prepared by the condensation of appropriate amines with acenaphthenequinone in dry toluene; ir (Nujol): 1730 (C=O, quinone) (13) and 1650 (C=N) $cm^{-1}$; uv (ethanol): 228, 305, 365, and 440 nm. The nmr spectra are in agreement with the proposed structures.[2]

The reaction between **1** and 2-phenylimino-acenaphthenone (**6***a*) gave ketazine **4** and 1′,3′,3′-triphenyl spiro(acenaphthen-1-one-2,4′-azetidin-2′-one) (**7***a*). The product **7***a* shows absorption maxima at 250, 318, and 345 nm in the uv spectrum. The ir spectrum exhibits strong bands at 1750 and 1730 $cm^{-1}$, characteristic of a spiro azetidinone (10) and a quinone (13), respectively. The sodium borohydride reduction of **7***a* afforded 1′,3′,3′-triphenyl spiro(1-hydroxyacenaphthene-2,4′-azetidin-2′-one)(**8***a*); ir (neat): 3580 (O—H), 1750 (C=O, spiro azetidinone) $cm^{-1}$ and absence of a band at 1730 $cm^{-1}$, characteristic of a quinone (13), revealing that the reduction of the carbonyl group at the 1-position of **7***a* has occurred. Similar treatment of **1** and **6***b* gave spiro azetidinone **7***b*, which on reduction with sodium borohydride gave **8***b* and ketazine **4**. The products **7***a*, *b* have been characterized by analytical and spectral (uv, ir, and nmr) data given in Tables 3 and 4. The formation of products **7***a*, *b* and **8***a*, *b* is depicted in Scheme 2.

The azetidinones **3***a–e* and spiro azetidinones **7***a*, *b* were found to be resistant to ordinary alkaline or acid hydrolysis supporting the above assigned structures. The bicyclic product, obtained earlier (6) by reaction of dimethylketene and 2-*p*-tolyl imino-1,2-diphenylethanone, undergoes hydrolysis quite readily (6).

Thermal decomposition of 2-diazo-1,2-diphenylethanone (**1**) may lead to benzoylphenylcarbene which may combine with **1** to form ketazine **4**. Benzoylphenylcarbene has been known to undergo Wolff rearrangement to give rise to diphenylketene (14) which may interact either with the C=N bond (15) or with the C=O (16) of ketoimines **2** and **6** leading to either azetidinones or β-lactones. The β-lactones, on decarboxylation, would have readily given rise to the corresponding olefins (16). The formation of azetidinones and not β-lactones has been supported on the basis of the analytical,

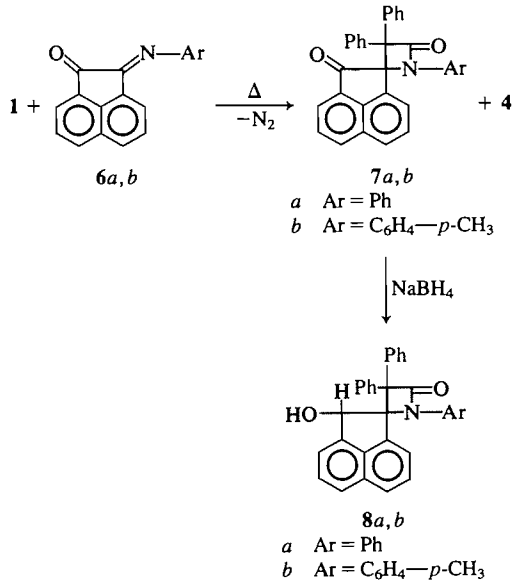


SCHEME 2

spectral, and chemical behaviour of the products. This reaction shows the high reactivity of the C=N in comparison with the C=O group towards diphenylketene. Since azetidinones **3***a*–*e* show their inertness towards sodium borohydride while the spiro azetidinones **7***a*, *b* undergo reduction with sodium borohydride, the carbonyl group present in the benzoyl moiety of azetidinones **3***a*–*e* is less reactive than the quinone carbonyl group of spiro azetidinones **7***a*, *b*. The azetidinone ring in **3***a*–*e* and **7***a*, *b* is unaffected on reduction ($NaBH_4$ or $LiAlH_4$) and thus appears to be quite stable. The formation of azetidinones takes place through the collapse of a possible zwitterionic intermediate (Scheme 3). A similar intermediate has been proposed in the reaction of diphenylketene and benzylideneaniline giving *N*-phenylimidate (15).

## Experimental

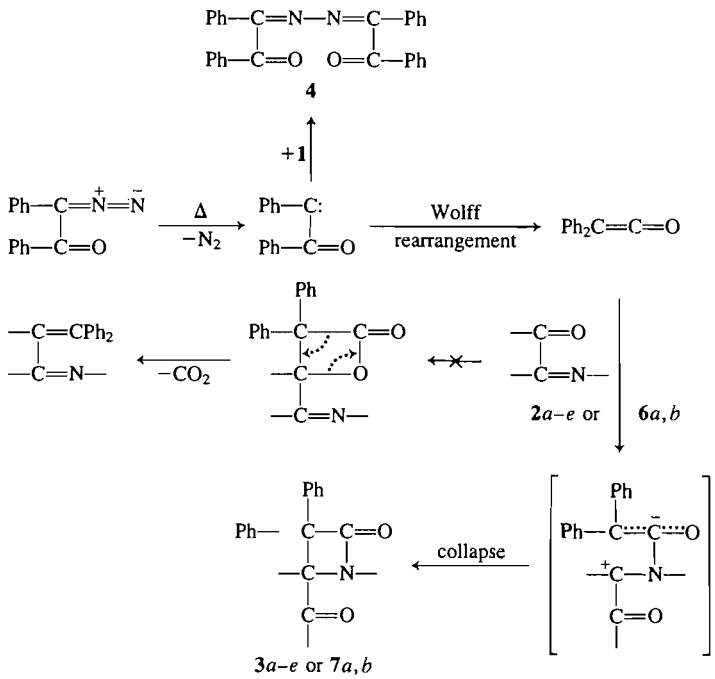
Melting points were determined on a Büchi apparatus (capillary method) and have been uncorrected. Ultraviolet spectra were obtained in 95% ethanol on a Cary-14 spectrophotometer. Infrared spectra were recorded in Nujol mull on a Perkin–Elmer 720 spectrophotometer. Proton nuclear magnetic resonance data were obtained on a Varian A-60D spectrometer in $CCl_4$ or $CDCl_3$ using TMS as internal standard.

*Materials*

Benzil, lithium aluminium hydride, and sodium borohydride were obtained from EGA chemicals, West Germany and 2-diazo-1,2-diphenylethanone (17), α-phenylethylamine (18), α-*p*-tolylethylamine (18), benzhydrylamine (19), and acenaphthenequinone (20) were prepared according to the reported methods.

*General procedure for preparation of ketoimines* **2**a–e *and* **6**a, b

The ketoimines **2***a*–*d* were prepared by dissolving a mixture containing 10 mmol of benzil and 10 mmol of corresponding freshly distilled amine in 30–40 mL of absolute ethanol at room temperature and keeping it for a week. The ketoimines **6***a*, *b* were obtained by refluxing a solution of 10 mmol of acenaphthenequinone and 10 mmol of corresponding amine in 60–80 mL of dry toluene for 2 h using a Dean–Stark separator to remove the water formed. The ketoimine **2***e* was obtained by heating a mixture of equimolecular amounts of benzil and aniline at 150°C for 2 h. The solvent in all cases was removed on a rotary evaporator and residual matter was triturated with ethanol. The



SCHEME 3

solid obtained was crystallized from ethanol to afford the product.

*General procedure for preparation of azetidinones* 3a–e *and spiro azetidinones* 7a, b

A mixture containing 10 mmol of 2-diazo-1,2-diphenylethanone (1) and 10 mmol of ketoimines 2*a–e* or 6*a*, *b* in 80 mL of dry benzene (thiophene free) was heated to reflux for 8 h under a nitrogen atmosphere. The reaction mixture was kept overnight at room temperature. The solvent was evaporated on a rotary evaporator and the residual matter was triturated with ethanol. The solid obtained was crystallized from ethanol to afford the products. The analytical and spectral data of the products 3*a–e* and 7*a*, *b* have been given in Tables 1–4. Evaporation of solvent from the mother liquor and crystallization from a *n*-hexane – ethanol (1:1) mixture gave a yellow crystalline solid identified as 1,1',2,2'-tetraphenyl-2,2'-azinodiethanone (4) on the basis of comparison (undepressed mixture melting point and identical ir spectrum) with an authentic sample prepared according to the reported method (12).

*Attempted hydrolysis of azetidinones* 3a–e *and spiro azetidinones* 7a, b

A mixture containing 0.02 g of 3*a*, 15 mL of 85% ethanol, and 1 mL of concentrated hydrochloric acid was heated to reflux for 30 h. After the usual work-up, 0.18 g (90%) of starting material was recovered. Similar treatment of 3*b–e* with concentrated HCl and 3*a–e* and 7*a*, *b* with either 40% aqueous alkali (potassium hydroxide or sodium hydroxide) or saturated ethanolic potassium hydroxide solution resulted in the recovery of starting material almost quantitatively.

*Preparation of 1-isopropyl-4-(α-hydroxybenzyl)-3,3,4-triphenyl-2-azetidinone (*5a)

To a suspension of 0.10 g of lithium aluminium hydride in 10 mL of dry ether was added slowly a solution of 0.23 g of 3*a* in 20 mL of dry ether. The reaction mixture was stirred for 3 h and kept overnight at room temperature. After the usual work-up, an oily material was obtained which on crystallization from ethanol gave 0.20 g (89%) of 5*a*; mp 177–178°C; ir (Nujol): 3440 (O—H) and 1735 (C=O, azetidinone) $cm^{-1}$; $uv_{max}$ (ethanol): 255 nm; nmr ($CCl_4$) δ: 7.93 (m, 2H, arom.), 7.53 (m, 4H, arom.), 7.05 (m, 14H, arom.), 4.89 (d, 1H, benzylic, $J$ = 4 Hz, collapses to a singlet on deuteration), 2.69 (septet, 1H, isopropyl, $J$ = 7 Hz), 2.00 (b, 1H, OH, $D_2O$ exchangeable), 1.54 and 1.20 (a pair of doublets, 6H, isopropyl, $J$ = 7 Hz). *Anal.* calcd. for $C_{31}H_{29}NO_2$: C 83.22, H 6.49, N 3.13; found: C 83.40, H 6.55, N 3.25.

*Preparation of 1-(α-p-tolylethyl)-3,3,4-triphenyl-4-(α-hydroxybenzyl)-azetidin-2-one (*5b)

Treatment of 0.26 g of 3*b* and 0.10 g of lithium aluminium hydride in a similar manner as described above gave 0.22 g (85%) of 5*b*, mp 75–76°C; ir (Nujol): 3400 (O—H) and 1730 (C=O, azetidinone) $cm^{-1}$; $uv_{max}$ (ethanol): 258 nm; nmr ($CDCl_3$) δ: 8.12 (m, 2H, arom.), 7.23 (m, 22H, arom.), 5.03 (s, 1H, benzylic), 3.33 (q, 1H, methine, $J$ = 7 Hz), 2.33 (s, 3H, $CH_3$—*p*-$C_6H_4$—), 2.33 (s, 1H, OH, $D_2O$ exchangeable), and 1.72 (d, 3H, methyl, $J$ = 7 Hz). *Anal.* calcd. for $C_{37}H_{33}NO_2$: C 84.89, H 6.31, N 2.67; found: C 84.65, H 6.21, N 2.71.

*Preparation of 1',3',3'-triphenyl spiro(1-hydroxyacenaphthene-2,4'-azetidin-2'-one) (*8a)

To a solution of 0.20 g of 7*a* in 20 mL of absolute ethanol (acetaldehyde free), 0.10 g of sodium borohydride was added. The reaction mixture was stirred for 30 min and kept overnight. After the usual work-up, 0.18 g (90%) of a white oily product 8*a* (which could not be further purified) was obtained; ir (neat): 3580 (O—H) and 1750 (C=O, azetidinone) $cm^{-1}$; the ir spectrum does not show a band at 1730 $cm^{-1}$, characteristic of quinone (13).

*Preparation of 1'-(*p*-tolyl)-3',3'-diphenyl spiro(1-hydroxyacenaphthene-2,4'-azetidin-2'-one) (*8b)

Treatment of 0.20 g of 7*b* with 0.10 g of sodium borohydride in a similar manner as described above gave 0.18 g (90%) of a white oily product 8*b* (which could not be further purified); ir (neat):

## ADDITIONS AND CORRECTIONS/AJOUTS ET CORRECTIONS

Vol. 59, 1981

**John T. Edward.** Conformational effects on the enthalpy of formation of straight and branched-chain alkanes.

Page 3192. Professor P. v. R. Schleyer has brought to my attention that the essential arguments of the paper are to be found in the paper by P. v. R. Schleyer, J. E. Williams, and K. R. Blanchard, "The evaluation of the strain in hydrocarbons. The strain in adamantane and its origin" (J. Am. Chem. Soc. **92**, 2377 (1970)). The group increments for "skew-free conformations" calculated by Schleyer *et al.*, in kcal/mol, are as follows (corresponding values of Edward follow in parentheses): $CH_3$, −10.05 (−10.06); $CH_2$, −5.13 (−5.13); CH, −2.16 (−2.14); C, −0.30 (−0.11). I regret overlooking Professor Schleyer's paper.

**J. M. Stadlbauer, B. W. Ng, D. C. Walker, Y. C. Jean, and Y. Ito.** Muonium addition to vinyl monomers.

Page 3261. (*i*) The value of $k_H$ in Table 2 should be $4 \times 10^9$ not $4 \times 10^{10} M^{-1}$ $s^{-1}$; and (*ii*) $a_\mu$ should have been used for the hyperfine coupling constant on line 13 of p. 3263, rather than $A_\mu$ which is the muon asymmetry in eq. [1].

# Hydrogen bonding of O—H and C—H hydrogen donors to $Cl^-$. Results from mass spectrometric measurements of the ion–molecule equilibria $RH + Cl^- = RHCl^-$

M. A. FRENCH, S. IKUTA,[1] AND P. KEBARLE

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received November 20, 1981

M. A. FRENCH, S. IKUTA, and P. KEBARLE. Can. J. Chem. **60**, 1907 (1982).

Equilibrium constants $K_1$ for reaction [1] $RH + Cl^- = RHCl^-$ in the gas phase were measured with a high pressure mass spectrometer under chemical ionization conditions. Data for some 40 compounds RH are presented. It is found that the binding free energies ($-\Delta G_1^0 = RT \ln K_1$) for RH = oxygen acids increase with the gas phase acidity of RH. The strongest bonds are formed with strong acids like $HCO_2H$, $CH_3CO_2H$, and phenol. Water and alkyl alcohols give much weaker interactions. A simple relationship between gas phase acidity and binding free energy does not occur for RH = carbon acids. Carbon acids like cyclopentadiene, whose high gas phase acidity is largely due to charge delocalization by conjugation in the completed anion, do not give $Cl^-$ adducts with stability commensurate with the acidity. A relationship between gas phase acidity and binding energy is found for carbon acids with carbonyl groups and for the substituted toluenes. Molecular orbital calculations with the STO-3G basis set provide insights to the bonding occurring in $RHCl^-$. For all cases investigated, hydrogen bonding to $Cl^-$ provides the most stable structure. Generally the hydrogen bond occurs through the hydrogen which has the highest net positive charge. The hydrogen bond strength is found approximately proportional to this positive charge. Another proportionality is found between the charge transferred from $Cl^-$ to RH, on formation of $RHCl^-$, and the strength of the hydrogen bond.

M. A. FRENCH, S. IKUTA et P. KEBARLE. Can. J. Chem. **60**, 1907 (1982).

On a mesuré la constante d'équilibre $K_1$ de la réaction [1] $RH + Cl^- = RHCl^-$ en phase gazeuse à l'aide d'un spectromètre de masse à haute pression et à ionisation chimique. On présente les données relatives à 40 composés du type RH. On a trouvé que les énergies libres de liaison, ($-\Delta G_1^0 = RT \ln K_1$), dans les cas où RH = acides oxygénés, augmentent avec l'acidité de la phase gazeuse de RH. Les liaisons hydrogènes les plus fortes s'établissent avec les acides forts, tels le $HCO_2H$, le $CH_3CO_2H$ et le phénol. L'eau et les alcools alkylés donnent lieu à des interactions beaucoup plus faibles. On n'obtient pas de relation simple entre l'acidité de la phase gazeuse et l'énergie libre de liaison dans les cas où RH = acides carbonés. Les acides carbonés du type cyclopentadiène, dont la forte acidité en phase gazeuse est due à une grande délocalisation de la charge par conjugaison de l'anion complété, ne donnent pas d'adduits avec $Cl^-$ qui auraient une stabilité proportionnelle à l'acidité. On a trouvé une relation entre l'acidité de la phase gazeuse et l'énergie de liaison dans le cas des acides carbonés ayant des groupes carbonylés et dans le cas des toluènes substitués. Les calculs d'orbitales moléculaires avec l'ensemble de base STO-3G fournissent des informations sur la liaison qui s'établit dans $RHCl^-$. Dans tous les cas étudiés, la liaison hydrogène avec $Cl^-$ conduit à la structure la plus stable. En général, la liaison hydrogène s'établit par l'intermédiaire de l'hydrogène qui a la plus forte charge positive totale. On a trouvé que la force de la liaison hydrogène est presque proportionnelle à sa charge positive. On a trouvé une autre proportionnalité entre la charge transferrée du $Cl^-$ au RH lors de la formation de $RHCl^-$ et la force de la liaison hydrogène.

## Introduction

The association of molecules with negative ions is of interest in several disciplines. Strongly held adducts involving negative ions and acids like $HNO_2$, $HNO_3$, HCl, and HBr occur in the earth's atmosphere (1). The adducts of various molecular species of $Cl^-$ can be used for analytical purposes in negative ion chemical ionization mass spectrometry (2). Hydrogen bonded complexes between neutral hydrogen donors and negative ions have been observed and studied in aprotic solvents (3, 4). In a more general sense, information on the bonding of various neutral compounds to negative ions like $Cl^-$, etc. belongs to the large area of hydrogen bonding, since the interactions turn out to be predominantly hydrogen bonding ones. Improved understanding of the nature of bonding is of significance also to ion solvation and ion stabilization in different environments. For example, complexing positive ions with suitably designed compounds like crown ethers or cryptates (5) facilitates their passage into hydrophobic media, biological membranes, or liquid membranes in ion selective electrodes (6). Less developed is the design and synthesis of similar compounds which are to complex selectively with negative ions.

The present work provides information on the binding free energies of some 38 compounds with $Cl^-$. The information is obtained from the measurement of the ion–molecule equilibria [1] with a pulsed electron beam high pressure mass spectrometer. Measurement of the equilibrium con-

stants $K_1$ at a given constant temperature $T$ leads to the free energy change $\Delta G_1^0 = -RT \ln K_1$. Measurement of the temperature dependence of $K_1$ leads also, via van't Hoff plots, to $\Delta H_1^0$ and $\Delta S_1^0$.

[1] $Cl^- + RH = RHCl^-$

[2] $R_0^- + RH = R_0H + R^-$

Several determinations of equilibria [1] have been published in previous reports from this laboratory. Measurements involving RH (HCOOH, $CH_3COOH$, $C_6H_5OH$, $HCCl_3$, $(CH_3)_3COH$, $CH_3OH$, $H_2O$) showed (7, 8) that the strong hydrogen bond $Cl^-\cdot\cdot HR$ (i.e. the chloride affinity of HR) increases approximately linearly with increase of the phase acidity of HR. A good linear relation is obtained for the case where the acids are more closely related, i.e. substituted phenols (9).

The early (1, 2) comparisons of chloride affinity and gas phase acidity were made on the basis of very incomplete and somewhat questionable data for the gas phase acidities of the RH compounds involved. Fortunately, since then, abundant data on gas phase acidities have become available from measurements in this (10) and other laboratories (11) of proton transfer equilibria [2] which provide accurate relative gas phase acidities. In the present work comparisons between the chloride affinities and gas phase acidities of the oxyacids are based on these newer and more accurate acidity data. The gas phase acidities of many nitrogen and carbon acids were part of the recent acidity determinations (10, 11). While only a few determinations of the chloride affinities of nitrogen acids have been made, it is to be expected that the relationships observed for oxygen acids will approximately hold also for nitrogen acids. The case of the carbon acids is quite different. Taking the term carbon acids in the broadest sense, carbon acids involve C—H hydrogens of all possible bonding environments, i.e. aromatic C—H hydrogens, allylic hydrogens, etc. Evidently, for some of the compounds involved, bonding to $Cl^-$ may not be occurring via a hydrogen bond, but by an electrostatic interaction with a whole group of atoms or by an interaction with a particular carbon atom, i.e. by the formation of a $\sigma$ complex. Even when the most stable adduct is hydrogen bonded, the parameters determining the strength of the bond are not so easily deduced. It is likely that a simple relationship with the gas phase acidity cannot be expected. For example, cyclopentadiene is a rather strong gas phase acid, its gas phase acidity is comparable to that of $p$-$NH_2$,phenol (10), yet this compound cannot be expected to have a high chloride affinity. The high acidity of the cyclopentadiene is largely due to the charge delocalization in the anion $C_5H_5^-$ in which the charge is evenly distributed on all five CH groups. Evidently, a compound whose gas phase acidity is achieved largely through delocalization of an electron pair from a former C—H bond cannot compete in hydrogen bonding with a compound whose acidity is largely due to a charge separation induced by an electronegative atom like oxygen.

In order to explore the chloride affinities of carbon acids, a number of determinations of equilibria [1] with RH = carbon acids were made in the present work. The measurements provide very useful thermochemical data, but of course no direct structural information. Considerable help in the bonding analysis can be obtained from molecular orbital calculations (STO-3G) of the energies of possible structures of the complexes $RHCl^-$.

## Experimental

The measurements of the equilibrium constants $K_1$ were made with a pulsed electron beam high ion source pressure mass spectrometer. The apparatus was the same as that used in earlier work on $Cl^-$ and phenols (9). It differed from that used in the earliest work (7) where pulsing of the electron beam was not employed. In the earliest work (7) neat gas RH was used in the ion source at pressures of 0.6 to 2 Torr. The use of the neat gas, in some cases, may lead to incorrect measurements due to unimolecular or collision-induced decomposition of the ion–molecule adduct in the mass analysis system (12). Therefore the present measurements were executed with methane as major gas. Generally, the methane contained 0.1 to 5% RH. The total ion source pressure was in the range 1–4 Torr.

The measurements with formic acid and phenol made in the earlier work (7) were repeated. The equilibrium constants for phenol at different temperatures as a function of phenol partial pressure are shown in Fig. 1. The equilibrium constants observed are seen to be quite independent of the phenol partial pressure. The phenol pressure is varied by a factor of 4. At low temperatures, where $K_1$ is large, low phenol partial pressures are used in order not to let the ion ratio $RHCl^-/Cl^-$ become much larger than unity.

van't Hoff plots for three determinations (HCOOH, PhOH, acetone) are shown in Fig. 2. The agreement with the earlier results for HCOOH is fairly good. The data points for the two determinations are very close; however, a deviation of the older data points (7) (see Fig. 2) at high temperature (low $K_1$) leads to a larger slope, i.e. a larger $-\Delta H_1$, for the earlier work. The present data, obtained with improved experimental conditions and extending over a wider temperature range, are believed to be the more reliable set. A considerably larger deviation between present and earlier data is observed for phenol (see Fig. 2). This disagreement must be due to some specific problem connected with the use of neat phenol in the earlier work. The very high molecular weight of phenol and its strong adsorption on metal surfaces may have led to an unusually high residual gas pressure in the acceleration and mass analysis system. Recent work (12, 13) has shown that under such conditions significant collision-induced decomposition (or $RHCl^-$ in the present case) can reduce the observed ion ratio $RHCl^-/Cl^-$. A recent redetermination[2] of the equilibrium $Cl^- + H_2O = Cl^-H_2O$, with methane as major gas, led to results in agreement with the earlier work (8*b*) which was undertaken with neat water. This observa-

[2]T. F. Magnera and P. Kebarle. Kinetics of the hydration of the $Cl^-$ ion. To be published.

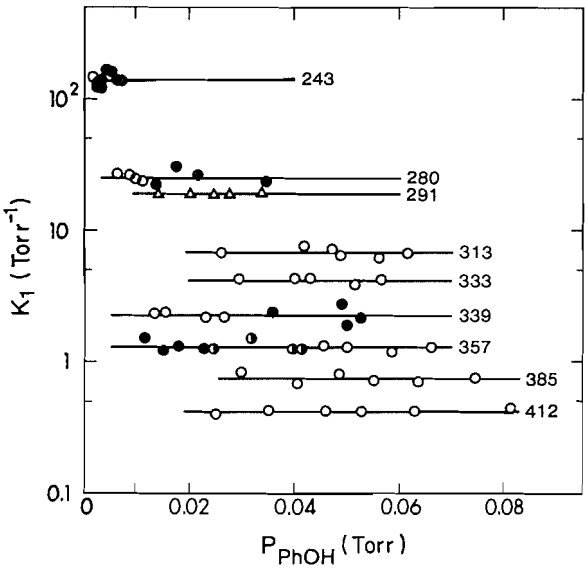

FIG. 1. Measured equilibrium constants for reaction: $Cl^-$ + PhOH = $PhOHCl^-$ at different constant temperatures given in degrees C. Equilibrium constant is found independent of phenol pressure. Experiments performed in the presence of a third gas methane at 1 to 5 Torr pressure. Different symbols for same temperature correspond to different ratios of phenol to methane.

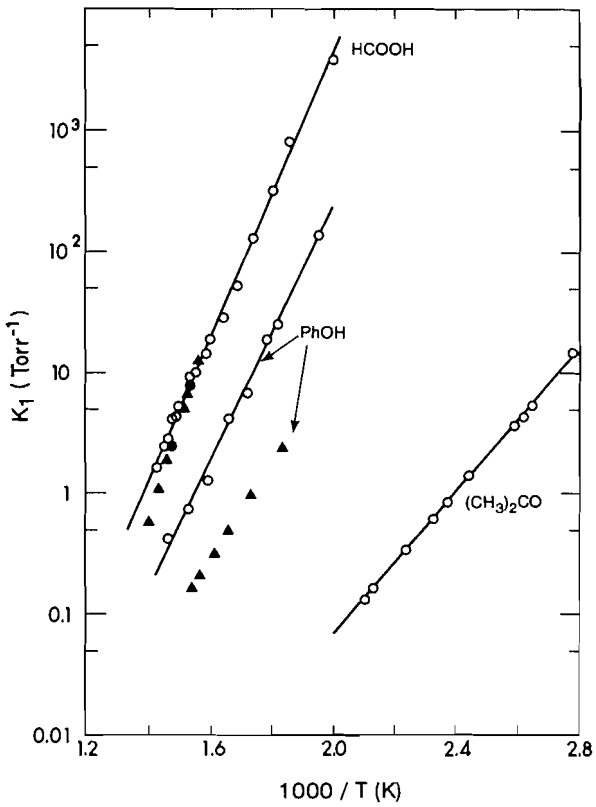

FIG. 2. van't Hoff plots for equilibria: RH + $Cl^-$ = $RHCl^-$. ○, present results with $CH_4$ as major gas. ▲, Yamdagni and Kebarle (7) with use of neat RH. ●, present results with neat formic acid.

tion also suggests that phenol represented a special problem in the earlier measurements. As will be shown in the next section, the present result for phenol is in better accord with theoretical predictions.

In order to cover a large number of compounds RH, determinations of the equilibrium constant $K_1$ were made only at one temperature. These data, shown in Figs. 3 and 4, will be discussed in the next section.

## Calculations

The $\Delta E$(STO-3G) data used in this work were obtained by calculating the total energies of the reactants in reaction [1] and obtaining $\Delta E$ from : $E(RHCl^-) - E(Cl^-) - E(RH)$. The STO-3G calculations of the total energies $E$ were performed with the Gaussian 70 and Hondo 5 programmes based on Pople's (14) STO-3G minimal basis set. The geometries used were standard geometries from Pople and Gordon (14) except: methanol, Harmony *et al.* (15*a*); acetone, J. E. Bel Bene (15*b*); pyrrole, Clementi *et al.* (16*a*); formic acid, Clementi *et al.* (16*b*). In the structures $RHCl^-$ shown in Fig. 6, only a few of the bond distances were optimized. These are shown in Table 3. In general, first the $Cl^-$ distance to the rigid R—H was optimized. Then for a fixed $Cl^-$ distance the O—H distance or C—H distance for oxygen or carbon acids was optimized.

## Results and discussion

*General description of results*

The present results consist of determinations of the equilibrium constants $K_1$ for the reaction [1], $Cl^- + RH = RHCl^-$. The experimental data are summarized in Figs. 2, 3, and 4. Shown in Fig. 2 are the few cases (formic acid, phenol, acetone) for which the temperature dependence of the equilibrium constants was measured. The resulting van't Hoff plots permit the determination of $\Delta H_1^0$ and $\Delta S_1^0$. In order to cover a large number of compounds, the remaining equilibrium constant determinations were made at a single temperature. Figure 3 summarizes the determinations at room temperature. This group consists of 18 compounds and covers equilibrium constants from $K_1 \approx 0.5$ to $K_1 = 1000$ (Torr$^{-1}$). Equilibrium constants much larger than 1000 are difficult to determine with the present apparatus. Therefore several equilibria of interest, involving more strongly bonding compounds, were measured at a temperature of 148°C. These are shown in Fig. 4.

Tables 1 and 2 summarize the available data. Table 1 contains the compounds for which van't Hoff plots are available. Present and previous determinations involving $Cl^-$ (7–9, 17) are included. Table 2 gives the free energy change $\Delta G_1^0 = -RT \ln K_1$ at 300 K of all the compounds for which

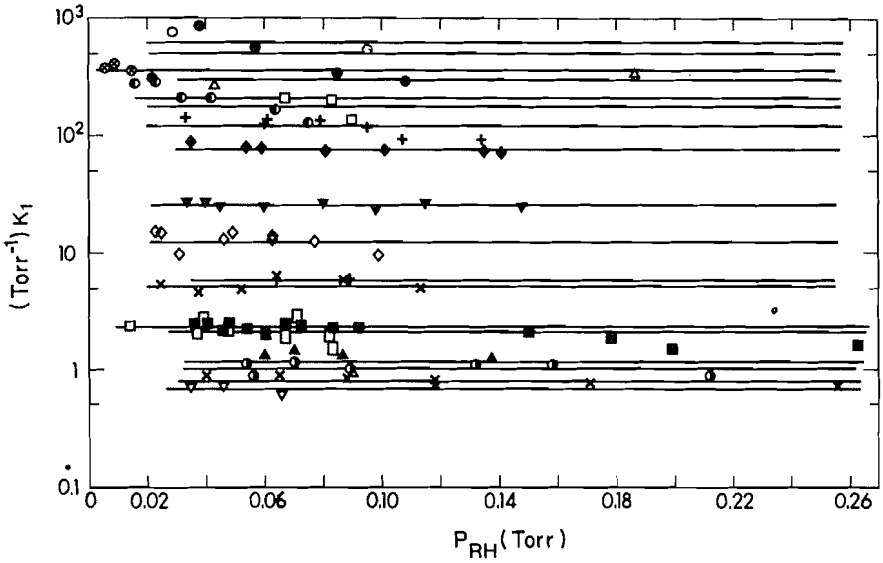

FIG. 3. Measured equilibrium constants for reaction [1]: $Cl^-$ + RH = $Cl^-$· RH at 26°C where RH is ○, acetone; ●, *m*-difluorobenzene; ⊗, *p*-nitrotoluene; △, diphenylmethane; ◐, iodobenzene; □, nitrobenzene; +, bromobenzene; ◆, chlorobenzene; ▼, fluorobenzene; ◇, cumene; +, *n*-propylbenzene; +, ethylbenzene; ⊡, mesitylene; [], *m*-xylene; ▲, toluene; ◑, *p*-xylene; ×, benzene; ▽, 1,4-pentadiene.

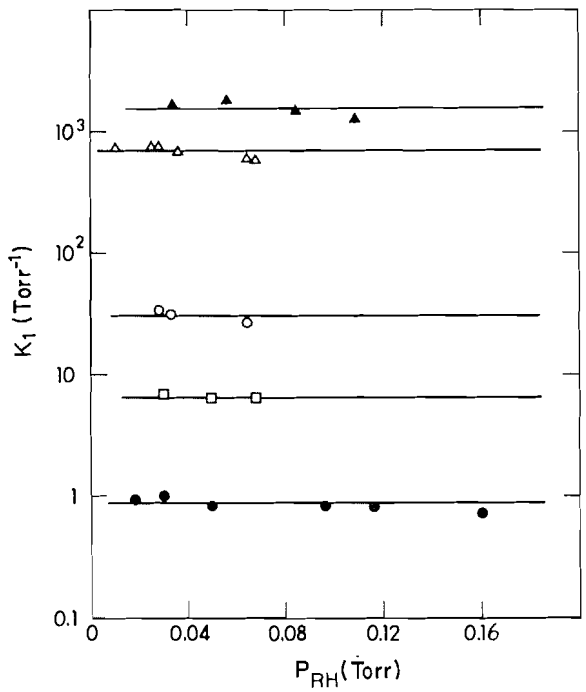

FIG. 4. Measured equilibrium constants for reaction [1]: RH + $Cl^-$ = $RHCl^-$ at 148°C, where RH is: pyrrole ▲; acetylacetone △; phenylacetone ○; acetopheonone □; and acetone ●.

determinations are available from the present and previous work. For the compounds shown in Fig. 4, determinations of the equilibrium constant $K_1$ are available only at 148°C. In order to obtain the free energy change $\Delta G_1^0$, at room temperature, one requires the entropy change $\Delta S_1^0$. We made a rough estimate of $\Delta S_1^0$ on the basis of the results in Table 1. These indicate that $-\Delta S_1^0$ decreases approximately with decreasing $-\Delta H_1^0$. The compounds in Fig. 1 include acetone, whose $\Delta S_1^0 = -19.6$ cal $K^{-1}$ was measured. The compounds in Fig. 4, which include acetone, fall in a not too broad bond strength range. Therefore a constant value of $\Delta S_1^0 = -20$ cal $K^{-1}$ was assumed for all of them. The $\Delta G_1^0$ data in Table 2 for these compounds are obviously only estimates.

*Hydrogen bonding of $Cl^-$ to oxygen acids*

As was mentioned in the introduction, earlier work (6–9, 17) showed that the hydrogen bond strength RH··$Cl^-$ increases as the gas phase acidity of RH increases. Most of the compounds involved in that relationship were oxygen acids.

The correlation was suggested before accurate and plentiful data for gas phase acidities were available. Fortunately, the present data can be examined with the help of recent comprehensive determinations of gas phase acidities (10, 11). The hydrogen bonds to $Cl^-$ ($-\Delta G_1^0$) of oxygen acids are shown in Fig. 5 plotted versus the corresponding gas phase acidities. The data fit quite well into a smooth curve which shows that the hydrogen bond free energies decrease with decrease of acidity of RH. It is interesting to note that the (negative) slope decreases gradually, i.e. the changes of hydrogen bonding with acidity are largest for the strongest

acids for which, one could assume, the largest degree of proton transfer to $Cl^-$ occurs. This behavior is closely analogous to that observed in an earlier series (18) where the acids were oxonium and ammonium ions ($H_3O^+$, $EtOH_2^+$, $MeCO_2H_2^+$, $NH_4^+$, pyrridine $H^+$, etc.) and the proton acceptor was $H_2O$. In that case also, the slope was largest for the strongest acids ($H_3O^+$, $EtOH_2^+$) and decreased as the acids became weaker (pyridinium ions).

When the compounds were closely related, as is the case for the substituted pyridinium ions, the relationship between hydrogen bond energy (to $H_2O$) and acidity of the hydrogen donor was close to linear (18). It was also found that the hydrogen bond energies were proportional to the net positive charge on the acidic hydrogen of the pyridinium ions. The net positive charge was obtained from Mulliken electron population analysis with STO-3G basis sets by Reynolds *et al.* (19). These authors had shown that the acidity of the pyridinium ions is linearly related to the net atomic charge in the acidic hydrogen. Thus the relationship between hydrogen bond and net atomic charge could have been anticipated, once it was shown that the hydrogen bond energy increases with acidity.

It is interesting to note that the situation is exactly analogous for substituted phenols and $Cl^-$.

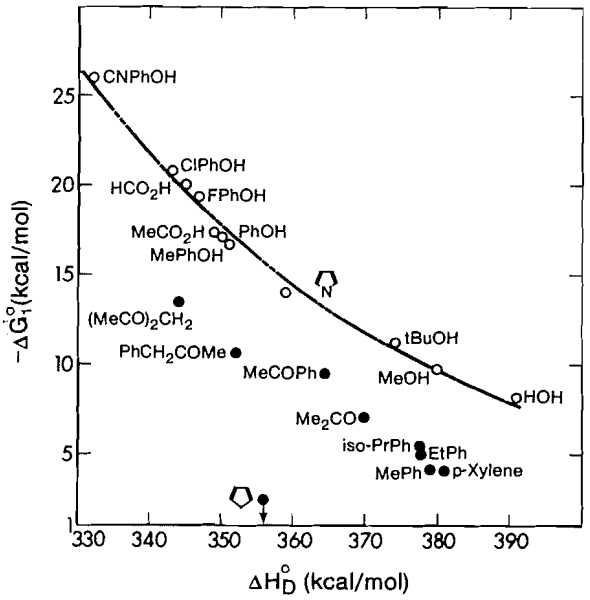

FIG. 5. Plot $\Delta G_1^0$ for gas phase reaction ($RH + Cl^- = RHCl^-$) versus gas phase acidity of RH. ○ RH are oxygen acids (and pyrrole); ● RH are carbon acids. The gas phase acidity is expressed as $\Delta H_D^0$, the deprotonation energy corresponding to enthalpy change for reaction $RH = R^- + H^+$. The gas phase acidity increases as $\Delta H_D^0$ decreases. The RH—$Cl^-$ binding free energies ($-\Delta G_1^0$) of the oxygen acids fit on a common curve. The binding energy increases as the acidity of RH increases. The carbon acids (except cyclopentadiene) also seem to fit on a common curve. Data in Fig. 5 are also given in Table 2.

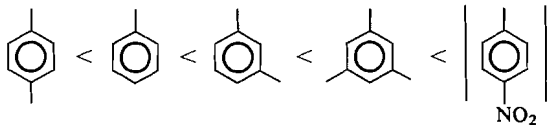
There is a close to linear relationship between the hydrogen bond in $RHCl^-$ and the acidity of the phenols (see Fig. 5 and Fig. 3, ref. 9). The acidities and net atomic charges on the acidic hydrogen of substituted phenols have been calculated by Hehre *et al.* (20). These data, when plotted, demonstrate that a good linear dependence exists between the calculated acidity of the phenols and the net atomic charge on the acidic hydrogen. There is quite good agreement between the STO-3G calculated (20) and the experimental (21, 22) acidities of the substituted phenols. Since there is a near linear relationship between acidity and hydrogen bonding with $Cl^-$, it follows that the hydrogen bond energy in the phenol $Cl^-$ adducts is linearly related to the net atomic positive charge on the acidic hydrogen of the phenols.

*Hydrogen bonding of $Cl^-$ to carbon acids*

The bonding free energies $-\Delta G_1^0$ for $Cl^-$ association to carbon acids RH are shown in Fig. 5. None of these compounds falls on the correlation curve of the oxygen acids. All carbon acids have bonding free energies which are considerably lower than those for oxygen acids of the same gas phase acidity. The lowest chloride affinity is observed for cyclopentadiene (Fig. 3). The gas phase acidity for this compound is close to that of phenol and thus rather high. As already mentioned in the Introduction, the reason for the complete lack of correlation between acidity and chloride affinity in cyclopentadiene is easy to understand. The high acidity of cyclopentadiene is mostly due to the large stabilization by charge delocalization in the fully developed anion, in which each CH group carries one fifth of the negative charge. This stabilization is not available in the cyclo-$C_5H_6Cl^-$ adduct.

The remaining carbon acids (Fig. 5) seem to fall on a common curve which indicates a correlation between gas phase acidity and chloride affinity. For example, the chloride affinity order of the alkyl substituted toluenes: *p*-xylene, toluene, ethylbenzene, isopropylbenzene follows exactly the order of the gas phase acidities. For some of the toluenes, whose chloride affinities were measured in the present work, gas phase acidities are not available. However the acidity order can be inferred. For the series:



data from Table 2 show that the chloride affinities increase in the given orer. The gas phase acidities probably change also in the same order. The acidity order *para*-xylyl < toluene is experimentally observed. Methyl substitution on the aromatic ring, in *para* and *meta* position of phenols, leads to a decrease of acidity; however, the decrease is lower for the *meta* substituent (4, 12). This difference is expected because the π-like electron donation, from *para* methyl in the anion, brings destabilizing negative charge closer to the oxi group than is the case for the *meta* substituent. In the methyl substituted toluenes, *meta* substitution might in fact be slightly acidifying, since the favorable increase of the polarizability may be the overriding effect. This would lead to an acidity order which is the same as that shown above for the chloride affinities. The higher acidity for *p*-nitrotoluene is of course also expected.

The correlation of the chloride affinity with the gas phase acidity for the substituted toluenes and the carbonyl carbon acids (see Fig. 5) suggests that the chloride adducts of these compounds involve hydrogen bonding of the chloride to the most acidic hydrogen, i.e. the hydrogen that would be involved in the acid dissociation. In the next section, STO-

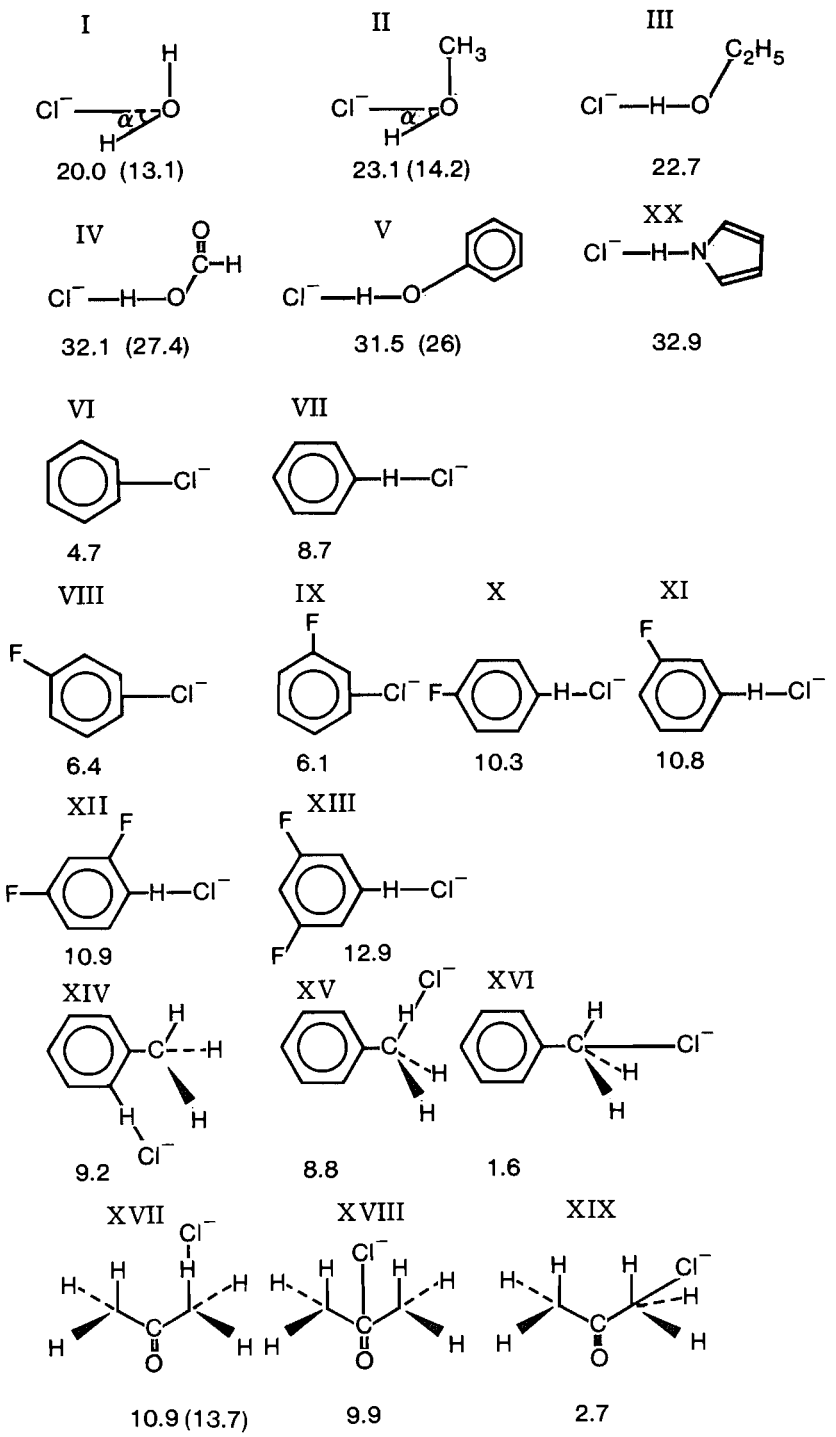


FIG. 6. Results from STO-3G calculations. The $-\Delta E$(STO-3G) calculated for the reaction [1]: RH + $Cl^-$ = $RHCl^-$ is given under the specific structure of $RHCl^-$. Whenever available, the $\Delta H_1^0$ measured experimentally are also given, these values are shown in brackets. Both results are in kcal/mol. In all structures shown, $Cl^-$ and the major bond frame of RH are in the same plane. For example, in the substituted benzenes $Cl^-$ and the benzene ring are in the same plane; in acetone, the $Cl^-$ is in the plane of the C—CO—C bonds. Other details of the calculations are given in Table 3.

[c] Net atomic charge on Cl in $RHCl^-$. Charge on separated $Cl^-$ is −1.0.

3G calculations are used to explore further the nature of the bonding that occurs in the adducts $RHCl^-$.

*Comparison of chloride affinities with results from STO-3G calculations*

The results of the STO-3G calculations are summarized in Fig. 6 and Table 3. Some details concerning the calculations are given in the section Calculations.

The first five structures in Fig. 6 deal with the bonding of $Cl^-$ to the oxygen acids (HOH, $HOCH_3$, $HOC_2H_5$, HOPh, and HOCOH). Given in the figure are the STO-3G calculated binding energies and the experimentally determined $\Delta H$ values. Comparison between these two sets of results shows that the $-\Delta E$(STO-3G) are considerably larger than the experimental $-\Delta H$ values. The difference is most pronounced for the weak acids, HOH and $HOCH_3$. The calculated $\Delta E$ are closer to the experimental $\Delta H$ for the strong acids, phenol and formic acid.

It is well known that the basis set of STO-3G is too small and does not provide reliable stabilization energies even in the absence of electron correlation. Much closer agreement with the experimental result for $Cl^-HOH$, $\Delta H_1 = -13.1$ kcal/mol, has been obtained by Clementi and co-workers (23) who, using a large basis set, complete geometry optimization, correlation binding, and zero point difference correction, calculated $\Delta H_1 = -11.4$ kcal/mol. Kollman and Kunz (24), using the 431-G basis set, have obtained $\Delta E_1 = -19.9$ kcal/mol for the same comound, a value not significantly better than the $\Delta E_1 = -20$ kcal/mol obtained in the present work with the smaller STO-3G basis set. While the STO-3G basis set does not provide reliable absolute binding energies, the relative ordering of the binding energies is generally reliable. For example, the right order is predicted for the series HOH, $CH_3OH$, PhOH, and $HCO_2H$ (see Fig. 6). However, when the differences are very small, the predicted order cannot be trusted. Thus the slightly weaker binding predicted for ethanol relative to methanol is probably wrong, since a slightly stronger bonding for ethanol can be expected on the basis of the higher gas phase acidity of ethanol. The STO-3G energies for the isodesmic reactions are found to be fairly close to the observed enthalpy changes. Three examples are given below, where the energy changes quoted are in kcal/mol. It is probably safe to assume that STO-3G also gives approximately the correct chloride affinity ordering the approximate chloride affinity differences for the other structures given in Fig. 6.

| Reaction | $\Delta E$(STO-3G) | $\Delta H^0$ | $\Delta G^0(300)$ |
|---|---|---|---|
| $Cl^-HOH + CH_3OH = Cl^-CH_3OH + HOH$ | −3 | −1.1 | −1.6 |
| $Cl^-CH_3OH + HCO_2H = Cl^-HCO_2H + CH_3OH$ | −9 | −13.2 | −10.3 |
| $Cl^-PhOH + HCO_2H = Cl^-HCO_2H + PhOH$ | −0.6 | −1.4 | −2.9 |

The results for structures VI and VII show that stronger bonding with benzene is obtained in the hydrogen bonding position VII. The experimental $\Delta G^0_1$, for benzene is −3.8 kcal/mol (Table 2). Assuming the $\Delta S^0_1$ is in the neighbourhood of $-15$ cal $K^{-1}$ $mol^{-1}$ one obtains, from $\Delta G = \Delta H -$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

$T\Delta S$, an estimate of $\Delta H_1^0 \approx -8$ kcal/mol. This value is close to the STO-3G result of 8.7 kcal mol$^{-1}$

Recently, we studied the equilibria of the potassium ion $K^+$ with benzene (25). The result given below shows that the bonding to potassium is much stronger than than to $Cl^-$. Calculations indicated that the most stable $K^+(C_6H_6)$ complex has an axial structure in which the $K^+$ lies on the symmetry axis of the benzene molecule. Benzene has a quadrupole moment of negative sign which is located on the symmetry axis in the centre of the molecule. The positive ion, when in the axial position, maximizes the attraction with the quadrupole and also achieves a substantial energy lowering due to the polarizability of the $\pi$ electron rings. For $Cl^-$, the axial position leads to a repulsive interaction with the quadrupole moment, and bonding that is considerably weaker than that calculated for structure VI.

$$K^+ + C_6H_6 = K^+(C_6H_6) \qquad -\Delta H^0 \approx 18 \text{ kcal mol}^{-1}$$

Structures VIII–XIII (Fig. 6) illustrate the bonding of fluorobenzenes to $Cl^{-1}$. The hydrogen atom *meta* to the fluorine substituent has the largest net atomic positive charge (based on Mullikan population analysis, STO-3G basis set). The strongest hydrogen bond with $Cl^-$ is obtained with that hydrogen. The stronger hydrogen bonding in the *meta* rather than *para* position to the fluorine substituent must be due to $\pi$ donation from the fluorine. While $\sigma$ withdrawal from the fluorine strengthens the hydrogen bond to $Cl^-$, $\pi$ donation weakens it. The effect of $\pi$ donation is smallest for the *meta* position. Increased fluorine substitution in the *meta* position in the series benzene, fluorobenzene, and 1,3-difluorobenzene can be expected to lead to increases of the chloride affinities. This in fact is observed experimentally (Table 2) and is also predicted by the calculations. The composite Fig. 7 shows that there is a linear relationship between the calculated and measured chloride binding energies and between the binding energies and the net atomic charge on the most positive hydrogen.

The chloride affinities of monosubstituted halobenzenes (see Table 2) increase in the order F, Cl, Br, I. The same order was found for the gas phase acidities of halosubstituted acetic acids (26). To explain the acidities of the acetic acids, the increased polarizability in the order F → I was invoked (26). In the present situation also, the increased polarizability should be the major effect, decreased $\pi$ donation in the F → I order may be another contributing factor.

The first report of hydrogen bonding involving an aromatic C—H as hydrogen donor was made by

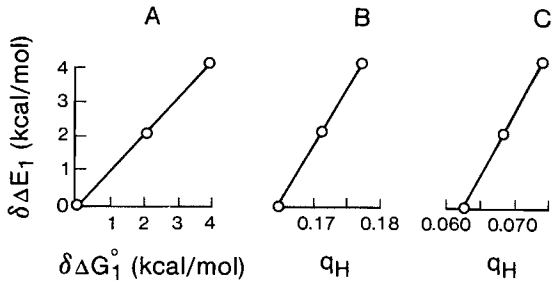

FIG. 7. Results for benzene, fluorobenzene, and difluorobenzene. Figure A shows STO-3G calculated ($\delta\Delta E_1$) versus measured ($\delta\Delta G_1^0$) energy of reaction: $FC_6H_5Cl^- + C_6H_6 = FC_6H_5 + C_6H_6{\cdot}Cl^-$. Figure B gives $\delta\Delta E$ versus net atomic positive charge on interacting hydrogen in complex $RHCl^-$. Figure C shows the same but for net positive charge on RH before formation of complex $RHCl^-$.

Allerhand and Schleyer (27). It was based on observation of an infrared association band for 1,3,5-trichlorobenzene and pyridine in carbon tetrachloride solvent. A hydrogen bonded complex with 1,3-dichlorobenzene was not observed under the same conditions (27). Unfortunately we did not make measurements with 1,3,5-trifluorobenzene or 1,3,5-trichlorobenzene. However, from the trends observed for the halobenzenes that were measured and calculated above, one may conclude that the chloride affinities of 1,3,5-trifluoro- and 1,3,5-trichlorobenzene should be higher than those for the 1,3 disubstituted compounds. Therefore our results are in line with the findings of Allerhand and Schleyer. The fact that they did not observe the more weakly bonded dichloro complex must be attributed to solvent effects. More recently Benoit and co-workers (4) reported that they did not observe a complex between 1,3,5-trichlorobenzene and $Cl^-$ in sulfolane solvent. Again this is obviously a solvent effect, the polar and abundant solvent displacing completely the trichlorobenzene from the $Cl^-$ complex.

Structures XIV, XV, and XVI provide an insight into the bonding of $Cl^-$ to toluene and by inference also for the substituted toluenes. In the lowest energy structure XIV, $Cl^-$ hydrogen bonds to one of the aromatic hydrogens. However, the structure XV, in which $Cl^-$ hydrogen bonds to one of the benzyl hydrogens, is less stable by only 0.4 kcal/mol. This suggests that, for the substituted toluenes with higher acidity than toluene, attachment of the $Cl^-$ will occur to the most acidic hydrogen, i.e. to a benzylic hydrogen. To this extent, one can say that the present STO-3G calculations are supportive of the findings based on the experimental chloride affinities, where the correlation of the affinities with the gas phase acidities of the toluene was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

taken to imply that hydrogen bonding to the benzylic hydrogen occurs.

The results for structures XVII–XIX, dealing with $Cl^-$ and acetone, throw some light on the bonding of $Cl^-$ to carbon acids with carbonyl groups. The most stable structure is XVII where the $Cl^-$ is hydrogen bonded to one of the acidic hydrogens of the methyl group. The bond in XVIII, where $Cl^-$ is in line with the CO dipole is predicted to be of comparable but somewhat weaker strength. The correlation with the gas phase acidity observed for the carbonyl carbon acids in Fig. 5, i.e. progressively higher chloride affinities in the series $Me_2CO$, MeCOPh. $PhCH_2COMe$ and $(MeCO)_2CH_2$, taken together with the STO-3G prediction that the hydrogen bonded structure XVII is the most stable chloride, leads one to expect that, for the stronger acids also, the $Cl^-$ hydrogen bonds to the most acidic hydrogen. For example for $(CH_3CO)_2CH_2$ the $Cl^-$ attachment should be to one of the methylene hydrogens.

Acetone is another solvent molecule for which the bonding to the negative ion ($Cl^-$) $-\Delta H$ = 13.7 kcal $mol^{-1}$, is considerably weaker than that to the positive ion ($K^+$) of similar radius. Measurements from this laboratory (25) give a $-\Delta H$ = 24.4 kcal $mol^{-1}$ for the potassium ion. The reason for this difference is easily understood. The bonding is largely of an electrostatic nature. Most of the permanent dipole is in the CO bond. The positive ion can approach the CO dipole closely. On the other hand, the negative ion is kept from close approach by the presence of the methyl groups.

A comparison between the calculated $\Delta E_1$ (STO-3G) for the most stable structures and the measured $\Delta G^\circ_1$ is shown in Fig. 8. One may expect that the $\Delta S^\circ_1$ differences for the different RH are not very large. In such a case an approximately linear relationship between $\Delta E_1$ and $\Delta G^\circ_1$ should be observed. Such a relationship is indicated in Fig. 8, however, the data are quite scattered. This is probably due to the considerable difference in the nature of the compounds RH included in the figure.

In the preceding discussion it was noted that for related compounds there is a near linear relationship between the net atomic charge of the hydrogen in the RH and the hydrogen bond in the complex $RHCl^-$. This relationship is further explored in the data shown in Fig. 9, which contains the results for the substituted benzenes, the hydroxylic compounds, HOH, MeOH, EtOH, and phenol, and formic acid. It can be seen that the relationship does not hold up as well when strongly differing groups of compounds are included. Still, an approximate proportionality is observed, which suggests that the net atomic charges in the hydrogens of RH are a rough guide to the strength of the hydrogen bond with the negative ion. A much better relationship is observed when the hydrogen

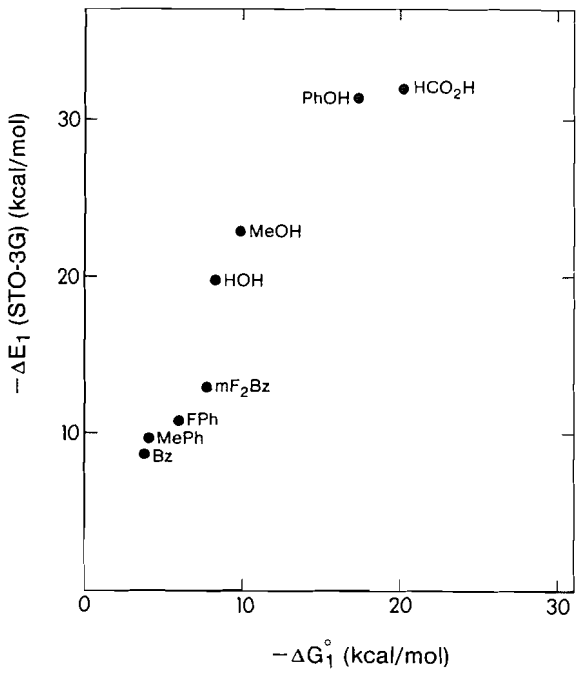

FIG. 8. Plot of calculated $\Delta E$(STO-3G) for reaction [1] (RH + $Cl^-$ = $RHCl^-$) versus measured $\Delta G^\circ_1$ for same reaction. $\Delta G^\circ_1$ values from Table 2.

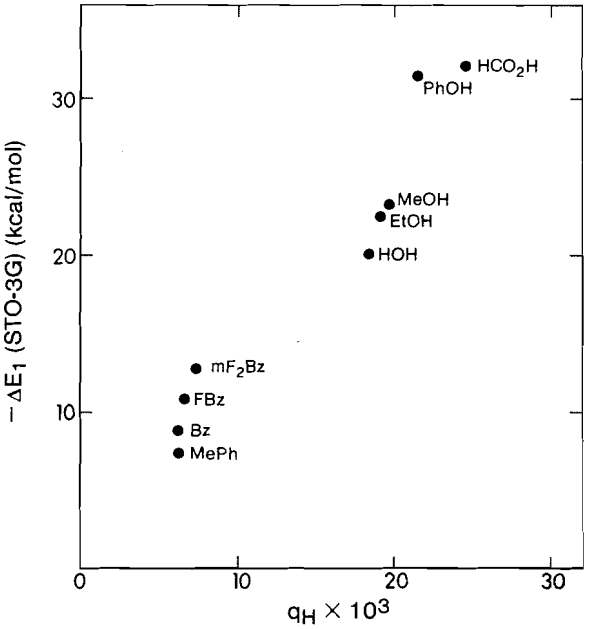

FIG. 9. Plot of $\Delta E$(STO-3G) for reaction [1] versus net positive charge on acidic hydrogen of RH before the reaction.

For personal use only.

bond energies are plotted versus the charge on the chlorine in the complex $RHCl^-$. This is shown in Fig. 10. Since the charge in the separated $Cl^-$ is $-1$, the figure shows that the strength of the hydrogen bond in $RHCl^-$ increases in proportion with the negative charge transferred from $Cl^-$ to the molecule RH, on formation of the complex $RHCl^-$.

Benoit and co-workers (4) have determined the enthalpy change $\Delta H_{1(sl)}$ for reaction [1] occurring in sulfolane solution. These results are given in Table 1. Comparing the $\Delta H_1$ for gas phase and solution, we notice that the exothermicity is much attenuated in solution. The attenuation factor is not constant but is in the range 7 for the stronger acids $HCO_2H$ and phenol and 5 for the weaker HOH and $CH_3OH$. Benoit (4) has also determined the enthalpy of solvation of RH from gas phase to sulfolane (see Table 1) so that the cycle [2] can be set up, which leads to eqs. [3] and [4]. Equation [4] is of

[2]
$$\begin{array}{ccc} RH_{(g)} + Cl^-_{(g)} & \xrightarrow{\Delta H_{1(g)}} & RHCl^-_{(g)} \\ \uparrow\ -\Delta H_{sl}(RH) & & \downarrow\ \Delta H_{sl}(RHCl^-) \\ \uparrow\ -\Delta H_{sl}(Cl^-) & & \downarrow \\ RH_{(sl)} + Cl^-_{(sl)} & \xrightarrow{\Delta H_{1(sl)}} & RHCl^-_{(sl)} \end{array}$$

[3] $$\Delta H_{1(sl)} = -\Delta H_{sl}(RH) - \Delta H_{sl}(Cl^-) + \Delta H_{1(g)} + \Delta H_{sl}(RHCl^-)$$

[4] $$\Delta H_4 = \Delta H_{sl}(RHCl^-) - \Delta H_{sl}(Cl^-) = \Delta H_{1(sl)} - \Delta H_{1(g)} + \Delta H_{sl}(RH)$$

interest since it provides $\Delta H_4$, the solvation energy difference between the complex $RHCl^-$ and $Cl^-$. These results are given in Table 1. $\Delta H_4$ is always positive, as is to be expected. One might have also expected that $\Delta H_4$ will increase with the size of the RH molecule, i.e. $\Delta H_4$ should be larger for phenol than for formic acid. However this trend is not observed, $\Delta H_4$ (phenol) = 7.7 kcal/mol while $\Delta H_4(HCO_2H)$ = 12.4 kcal/mol. The clear trend observed is that $\Delta H_4$ increases with the acidity of RH. On reflection, the reason for this trend becomes clear. The solvation of $RHCl^-$ will decrease with the radius of RH only if substantial negative charge is delocalized onto RH. This delocalization depends on the extent of proton transfer from RH to $Cl^-$, i.e. on the acidity of RH. An even more direct measure is the STO-3G calculated charge transfer from $Cl^-$ to RH. Figures 5 and 9 demonstrate the proportionality between the charge transfer from $Cl^-$, the chloride affinity of RH, and the acidity of RH. Evidently, $\Delta H_4$ will depend on the extent of charge transfer from $Cl^-$ to RH, the sites on RH to which the charge is transferred, i.e. extent of delocalization within RH and the size of RH. The operation of some of these combined effects should be reflected in the available $\Delta H_4$.

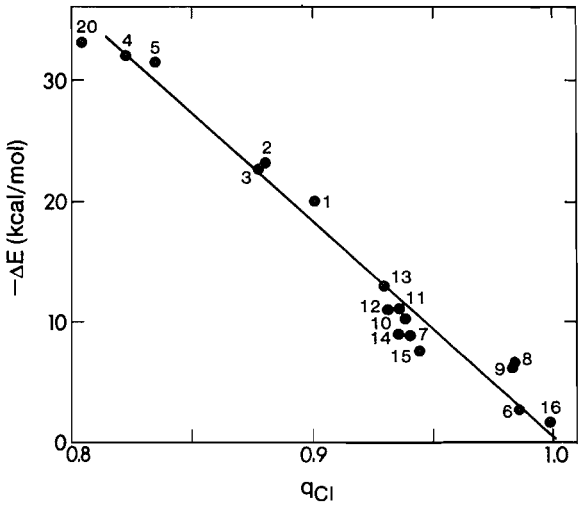

FIG. 10. Plot of $\Delta E$(STO-3G) from reaction [1] versus net negative charge on $Cl^-$ in $RHCl^-$. Numbers on data points correspond to structures (in roman numerals) in Fig. 7. Plot shows good correlation between the bonding in the complex $RHCl^-$ and the charge transferred from $Cl^-$ to RH on formation of the complex $RHCl^-$.

Unfortunately, these are very few and not of high accuracy. One case fits the expected trend. The extent of charge transfer in $ClHCl^-$ should be by far the largest, i.e. 0.5 electrons, since the two Cl atoms become equivalent, (for the other $\delta q Cl^-$, see Table 3). The observed $\Delta H_4$ for HCl is large but not by far the largest. This must be due to the small size of HCl, i.e. even though the charge transfer is large, the overall size of the ion $ClHCl^-$ is small, and this reduces the adverse effect on the solvation energy of the ion.

The attenuation of the observed hydrogen bonding in solution relative to the gas phase is closely analogous to the attenuation of substituent effects on acidity or basicity in the gas phase and solution. For example, a substituent which increases the gas phase acidity of benzoic acid delocalizes the charge in the benzoate anion and reduces the solvation energy of the substituted anion. This leads to an attenuation of the substituent effect in solution (21). In the hydrogen bonding complexes the role of the substituent is played by HR. An HR that forms a strong hydrogen bond, i.e. stabilizes $Cl^-$ strongly, decreases the solvation energy of $RHCl^-$ strongly and this leads to an attenuation of the hydrogen bonding in solution.

The gas phase hydrogen bonding energies could be useful in the design of multiligand complexing agents, i.e. crypts (5) for negative ions. Data from solutions often do not express the true available complexing power of a complexing group in a crypt. For example, the enthalpy changes $\Delta H_{1(l)}$ for

$CH_3OH$ and $CH_3CO_2H$ in sulfolane are equal, $\Delta H_{1(l)} = -3.2$ kcal/mol (4). Yet it is clear from the gas phase data that a carboxylic acid or a phenolic hydroxide group is vastly superior to the OH group from an aliphatic alcohol. Since the radius of the crypt as a whole is dictated largely by other considerations, it is clear that a great advantage in complexing is to be gained by selecting the most acidic hydroxide groups as ligands on the inside of the crypt.

The data in Table 2 give the order of stabilities of $RHCl^-$ gas phase complexes. Thus they have direct application to negative ion chemical ionization mass spectrometry of $Cl^-$ adducts (2). It is clear that adducts of a wide variety of compounds can be formed and that considerable selectivity can be obtained if the ion source temperature is varied from room temperature to 300°C. At room temperature, or below, adducts with all compounds in Table 2 will be formed. At the highest temperatures only adducts with the strongest acids will be observable.

# Peroxide oxidation of $\Delta^4$-3-ketosteroids

HERBERT L. HOLLAND,[1] ELLY RIEMLAND, AND ULRICH DAUM
*Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1*

Received December 15, 1981

HERBERT L. HOLLAND, ELLY RIEMLAND, and ULRICH DAUM. Can. J. Chem. **60**, 1919 (1982).

Treatment of $\Delta^4$-3-ketosteroids with *tert*-butyl hydroperoxide in the presence of lithium hydroxide leads to the formation of the corresponding 4β,5β epoxides stereospecifically and in good yield. The stereospecificity of this reaction is explicable in terms of the accepted mechanism for the hydrogen peroxide epoxidation of $\Delta^4$-3-ketosteroids.

The use of aqueous sodium peroxide as oxidant leads to the production of the corresponding $\Delta^4$-3,6-diones. A mechanism for this reaction is proposed in which the key step is autoxidation of the corresponding deconjugated $\Delta^5$-3-ketone, produced from the starting material *in situ* by the action of the reagents. Lithium peroxide does not oxidize androst-4-ene-3,17-dione at C-6, but produces the 4,5 epoxides in low yield together with an *A*-nor-3,5-secoacid.

HERBERT L. HOLLAND, ELLY RIEMLAND et ULRICH DAUM. Can. J. Chem. **60**, 1919 (1982).

Les $\Delta^4$ céto-3 stéroïdes réagissent avec l'hydroperoxyde de *tert*-butyle en présence d'hydroxyde de lithium en donnant stéréospécifiquement les époxydes 4β,5β correspondants avec un bon rendement. On peut expliquer la stéréospécifité de cette réaction en fonction du mécanisme accepté pour l'époxydation des $\Delta^4$ céto-3 stéroïdes par le peroxyde d'hydrogène.

L'utilisation du peroxyde de sodium en solution aqueuse comme oxydant conduit à la formation des $\Delta^4$ diones-3,6 correspondantes. On propose, pour cette réaction, un mécanisme dans lequel l'étape fondamentale est l'auto-oxydation de la $\Delta^5$-cétone-3 déconjuguée correspondante, obtenue *in situ* à partir du produit de départ sous l'action des réactifs. Le peroxyde de lithium n'oxyde pas l'androstène-4 dione-3,17 en position C-6, mais il conduit à l'époxyde-4,5 avec un faible rendement en même temps qu'à un acide *A*-norseco-3,5.

[Traduit par le journal]

The epoxidation of α,β unsaturated ketones by basic hydrogen peroxide is a reaction which is tolerably well understood. Its mechanistic (1, 2) and stereoelectronic (3) requirements have been formulated, and, in the case of $\Delta^4$-3-ketosteroids (**1**) the details of the reaction leading to both β (**2**) and α (**3**) substituted products have been discussed (4–6). The predominance of the β isomer in the latter case is consistent within the known preference for attack from the β face at C-5 (*4b*) and intermediates for the formation of α and β products as shown in Fig. 1, in which formation of the α epoxide involves unfavourable 1,3 diaxial interactions between the hydroperoxide at C-5 and hydrogens at C-7 and C-9 (*4a*). The influence of long range electrostatic effects caused by a variation in substitution at C-17 on the α/β ratio obtained from reactions of $\Delta^4$-3-ketosteroids with hydrogen peroxide in the presence of sodium hydroxide has been examined by Henbest and Jackson (5, 6).

*tert*-Butyl hydroperoxide is known to epoxidize certain α,β unsaturated ketones in the presence of base (7, 8), but under the conditions employed (Triton B in benzene), was not reactive towards $\Delta^4$-3-ketosteroids (7). In the present study, we have obtained good yields of only β epoxide (**2**) from treatment of $\Delta^4$-3-ketosteroids (**1**) with *tert*-butyl hydroperoxide and lithium hydroxide in ethanol solution. These experiments are summarized in Table 1. Control experiments (Table 1) indicate that the substitution of lithium hydroxide for sodium hydroxide when using hydrogen peroxide as oxidizing agent has little effect on the ratio of α/β

R = H, hydrogen peroxide oxidation
R = $C(CH_3)_3$, *tert*-butyl hydroperoxide oxidation

FIG. 1. The formation of α and β epoxides from $\Delta^4$-3-ketosteroids.

epoxides produced. The production of only the β epoxides (**2**) by *tert*-butyl hydroperoxide is entirely consistent with the accepted mechanism of hydrogen peroxide oxidation (1–6) shown in Fig. 1; for R = $C(CH_3)_3$, the 1,3 diaxial interactions leading to α epoxide are highly unfavourable.

We have also examined the reactions of lithium and sodium peroxides with α,β unsaturated ketosteroids. These are also summarized in the table. The use of aqueous sodium peroxide gave rise to products different from those obtained by treatment with sodium hydroxide/hydrogen peroxide mixtures. In only one case (**5** → **6**) was the expected product obtained (in low yield); the $\Delta^4$-3-ketosteroids **1** gave good yields of the corresponding $\Delta^4$-3,6-diones (**4**) as the sole isolable product. Variation of time and amount of reactants produced no evidence for the formation of any other product in significant amount. Lower yields were obtained with the $\Delta^5$-3-ketosteroid (**12**) and isophorone (**16***a*), whereas the simpler analogue 3-methylcyclohex-2-enone (**14**) gave only a trace of the corresponding oxidation product **15**.

The aqueous decomposition of commercial sodium peroxide, yielding oxygen and sodium hydroxide (9) appears to be a key feature in this reaction. The oxidation of **1***d* to **4***d* proceeded in good yield under a nitrogen atmosphere, but did not

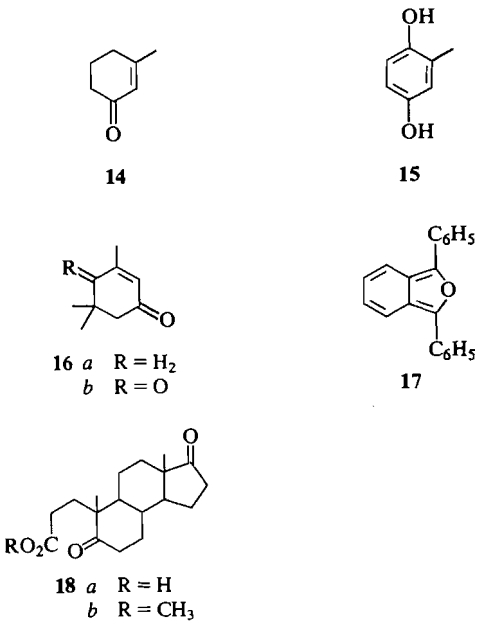
7 8 9 10 11 12

proceed appreciably under anhydrous conditions. The observed conversion of **12** into **4***a*, the known formation of the hydroperoxides **13** from **12** under autoxidative conditions (10, 11), and the established production of **4***a* from **13** under basic conditions (11) suggest the route for the conversion of **1** to **4** presented in Fig 2.

The simple base catalysed autoxidation of conjugated ketones **1** is known to proceed in poor yield, and give the 4-ol-$\Delta^{4,6}$-diene-3-ketones as the major product. However, the conditions reported herein differ appreciably from those described in the literature (12, 13). It has been proposed that the rapid autoxidation of **12** involves the formation of an enolate ion pair rather than the free enolate (11), and a similar mechanism may be operative in the present case (Fig. 2). If this is so, the structure of this intermediate presumably resembles **12** rather than **1**, for the following reasons. Firstly, the related ketosteroid **9**, inert to sodium peroxide oxidation, is only deconjugated under vigorous enolizing conditions (14), and the deconjugated compounds corresponding to **8** and **10** do not autoxidize rapidly at room temperature[2] under conditions where the autoxidation of **12** is fast. (11, 15, 16). The base catalyzed autoxidation of saturated 3-ketosteroids (e.g. **11**) requires 18–50 hours at room temperature before appreciable conversions are achieved (17). The low yields obtained from **14** and **16***a* are attributed to a low rate of autoxidation under basic conditions (18, 19).

The production of epoxide **6** (in low yield) from **5** by sodium peroxide suggested the possibility that the conversion of **1** to **4** may proceed via the 4,5 epoxide (**2** or **3**). However, treatment of **2***b* or **3***b* with aqueous sodium peroxide led only to a complex mixture of material more polar than starting material, of which **4***b* was not a component.

The possibility that singlet oxygen may be released in the decompositions of hydrogen peroxide (20) and potassium superoxide (21) led us to consider that this species may be involved in the oxidation of **12** to **13**. However, several factors militate against this: reaction of **12** with singlet oxygen gives, in addition to **4***a*, products derived from cholest-6-ene-3-one-5α-hydroperoxide (10), which were not produced in the present case; there is no precedent for the generation of singlet oxygen from sodium peroxide (22); and treatment of the singlet oxygen specific reagents cholesterol (**7**) (23) and 1,3-diphenylisobenzofuran (**17**) (24) with aqueous sodium peroxide did not result in the formation of oxidized products.



**14** **15**

**16** *a* R = $H_2$
*b* R = O

**17**

**18** *a* R = H
*b* R = $CH_3$

Treatment of lithium peroxide with water does not result in appreciable production of oxygen (9), and the $\Delta^4$-3,6-dione was not obtained on treatment of **1***d* with these reagents. Instead, the epoxides **2***d* and **3***d* were obtained, together with the *A*-nor-3,5-seco acid **18***a*, a classical oxidative degradation product of $\Delta^4$-3-ketones (25). The latter functionality has also been obtained by treatment of a 5β-3-ketone with potassium superoxide (26). The acid **18***a* may be produced via a mechanism similar to that proposed (26), but the details of its production have not been examined in the present study.

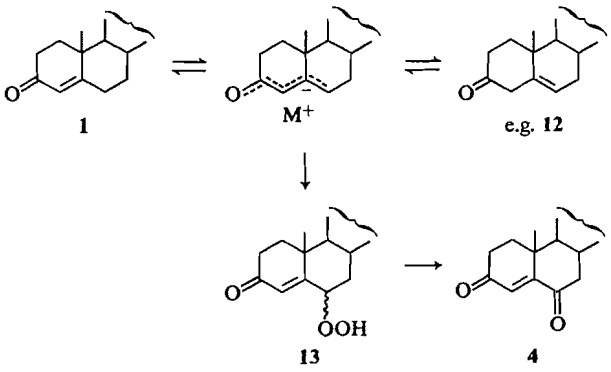

FIG. 2. Proposed routes for the conversions of $\Delta^4$- and $\Delta^5$-3-keto-steroids to $\Delta^4$-3,6-diketosteroids by sodium peroxide.

## Experimental

*Apparatus, materials, and methods*

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with a Perkin–Elmer 237B spectrometer. Proton nmr spectra were obtained with a Varian A-60 or Bruker WP-60 at 60 MHz and $^{13}C$ nmr spectra with a Bruker WP-60 at 15.18 MHz, using $CDCl_3$ as solvent and TMS as internal standard. Mass spectra were obtained with an AEI MS30 spectrometer. Column chromatography was performed on silica gel (60–200 mesh) using a benzene/ether gradient as eluting solvent, and thin layer chromatography on Merck silica gel 60 F-254 (0.25 mm).

*Oxidations with hydrogen peroxide*

These were carried out by the literature procedure (6). The residue was examined by $^1H$ nmr to determine the ratio of α/β epoxides, using the C-4 hydrogen signal intensity (α 3.03; β 2.96 ppm) for a quantitative estimate, and then subjected to column chromatography. The isolated steroids so produced were identified by mp and spectral comparisons with literature values. Hitherto unreported spectral data and literature references are presented below.

*Oxidations with* tert-*butyl hydroperoxide*

*tert*-Butyl hydroperoxide (5 mL, 90%) was added dropwise over 15 min to a stirred solution of steroid (1 g) in ethanol (35 mL, 95%), and lithium hydroxide (4 mL, 4 *N*). The resulting solution was allowed to stand at room temperature for 48 h, and then worked up as described above.

*Oxidations with sodium peroxide*

Water (10 mL) was added dropwise over a 2 h period to a stirred mixture of starting material (1 g) and sodium peroxide (4 g) in ethanol (50 mL). The mixture was then acidified (dilute HCl) and extracted with chloroform. The extract was washed and evaporated. The product was isolated by chromatography and characterized by mp and spectral comparison with literature values. Hitherto unreported spectral data and literature references are presented below. Compounds **2***b*, **7**–**11**, and **17** were not affected by the treatment described above; starting material was recovered unchanged in these cases. The epoxide **2***b* was converted into a complex mixture of polar products of which **4***b* was not a component (tlc).

*Oxidations with lithium peroxide*

Treatment of **1***d* with lithium peroxide by the procedure described above for sodium peroxide, and workup as indicated, followed by chromatography, gave the epoxides **2***d* and **3***d* (1:1, total 23%) and a 33% yield of a compound identified as A-nor-3,5-seco-5,17-diketo-androstan-3-oic acid (**18***a*), mp 106–109°C (lit. (29) mp 108–110°C); ir $\nu_{max}$: 1705, 1730, 2500–3500 $cm^{-1}$; $^1H$ nmr included signals at δ 0.92 (3H, s, C-18H), 1.15 (3H, s, C-19H), 6.5–7.3 (br s, 1H, exchanges $D_2O$, –COOH); $^{13}C$ nmr, δ: 13.7 (C-18), 20.3 (C-19 or C-11), 20.7 (C-11 or C-19), 21.8 (C-15), 29.2 (C-1 or C-7), 29.9 (C-7 or C-1), 31.0 (C-12), 34.4 (C-8), 35.7 (C-16), 37.7 (C-2), 47.6 (C-10 and C-13 or C-6), 48.0 (C-10 and C-13 or C-6), 50.5 (C-9 or C-14), 50.7 (C-14 or C-9), 178.9 (C-3), 214.1 (C-5), and 220.1 (C-17) ppm; ms *m/z* (%): 306 (2), 288 (22), 273 (8), 260 (13), 234 (68), 219 (29) relative to *m/z* 55 (100); methyl ester (**18***b*) *m/z* (%): 320 (3), 305 (12), 302 (9), 289 (10), 273 (15), 261 (14), 247 (10), 234 (100). Compounds **2***b*, **8**, and **11** gave no detectable products (tlc) when treated by the above procedure.

*Physical and spectral data*

Only hitherto unreported data are listed. Other data obtained correspond to those given in the references listed.

*(4β,5)-Epoxy-5β-cholestan-3-one* (**2***a*) (30–32)

$^{13}C$ nmr, δ: 12.0 (C-18), 18.6 (C-21), 19.0 (C-19), 21.5 (C-11), 22.6 (C-26), 22.8 (C-27), 23.9 (C-23), 24.2 (C-15), 26.2 (C-7), 28.1 (C-16 and C-25), 29.9 (C-6), 30.5 (C-1), 32.6 (C-2), 35.1 (C-8), 35.8 (C-20), 36.2 (C-22), 37.2 (C-10), 39.6 (C-12 and C-24), 42.7 (C-13), 46.5 (C-9), 55.9 (C-14), 56.2 (C-17), 62.7 (C-4), 70.4 (C-5), and 206.9 (C-3) ppm.

*(4β,5)-Epoxy-5β-pregnan-3,20-dione* (**2***b*) (6)

$^{13}C$ nmr, δ: 13.3 (C-18), 18.9 (C-19), 21.5 (C-11), 22.8 (C-16), 24.4 (C-15), 26.2 (C-7), 29.8 (C-6), 30.3 (C-1), 31.4 (C-21), 32.6 (C-2), 35.1 (C-8), 37.2 (C-10), 38.5 (C-12), 44.1 (C-13), 46.4 (C-9), 56.0 (C-14), 62.7 (C-4), 63.5 (C-17), 70.2 (C-5), 206.6 (C-3), and 209.1 (C-20) ppm.

*(4β,5)-Epoxy-5β-androstan-17β-ol-3-one* (**2***c*) (6)

*(4β,5)-Epoxy-5β-androstan-3,17-dione* (**2***d*) (6)

*(4α,5)-Epoxy-5α-cholestan-3-one* (**3***a*) (30, 31, 33, 34)

*(4α,5)-Epoxy-5α-pregnan-3,20-dione* (**3***b*) (6)

*(4α,5)-Epoxy-5α-androstan-17β-ol-3-one* (**3***c*) (6)

*(4α,5)-Epoxy-5α-androstan-3,17-dione* (**3***d*) (6)

*Cholest-4-ene-3,6-dione* (**4***a*) (23, 35)

$^1H$ nmr included signals at δ 0.75 (3H, s, C-18H), 0.82 and 0.92 (9H, C-21, -26, -27 H's), 1.18 (3H, s, C-19H), and 6.20 (1H, s, C-4H) ppm.

*Pregn-4-ene-3,6,20-trione* (**4***b*) (35, 36)

$^1H$ nmr included signals at δ 0.70 (3H, s, C-18H), 1.18 (3H, s, C-19H), 2.06 (3H, s, C-21H), and 6.22 (1H, s, C-4H) ppm.

*Androst-4-ene-3,6-dione-17β-ol* (**4***c*) (35, 36)

$^1H$ nmr included signals at δ 0.81 (3H, s, C-18H), 1.18 (3H, s, C-19H), 3.5–3.8 (1H, m, C-17αH), and 6.20 (1H, s, C-4H) ppm.

*Androst-4-ene-3,6,17-trione* (**4***d*) (35–37)

$^1H$ nmr included signals at δ 0.92 (3H, s, C-18H), 1.19 (3H, s, C-19H), and 6.21 (1H, s, C-4H) ppm.

*(16α,17)-Epoxypregn-5-ene-3β-ol-20-one* (**6**) (27)

$^1H$ nmr included signals at δ 1.05 (6H, br s, C-18 and -19 H's), 2.05 (3H, s, C-21H), 3.25–3.7 (1H, m, C-3H), 3.73 (1H, s, C-16H), 5.37 (1H, m, C-6H) ppm.

*2,6,6,-Trimethylcyclohex-2-ene-1,4-dione* (**16***b*) (18, 38).

# The rotational angle dependence of $^5J_m{}^{H,SH}$ in benzenethiol

TED SCHAEFER, TIMOTHY A. WILDMAN, AND RUDY SEBASTIAN
*Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2*

Received February 11, 1982

TED SCHAEFER, TIMOTHY A. WILDMAN, and RUDY SEBASTIAN. Can. J. Chem. **60**, 1924 (1982).

It is suggested that the five-bond spin–spin coupling constant between the sulfhydryl proton and the ring proton in the *meta* position is given by $^5J = {}^5J^{\pi}_{90}\langle\sin^2\theta\rangle + {}^5J^{\sigma}_{180}\langle\sin^2(\theta/2)\rangle$. Here θ is the angle by which the S—H bond twists out of the benzene plane and angular brackets indicate expectation or average values, determined by the twofold barrier to internal rotation about the C—S bond. $^5J^{\pi}_{90}$ is the π electron contribution and has a maximum at θ = 90° and $^5J^{\sigma}_{180}$ is the σ electron contribution with a maximum at θ = 180° (zig-zag orientation). For eight *para* substituted derivatives of benzenethiol, the $^5J$ numbers can be reproduced by this equation, which also agrees with the observed couplings in 2-hydroxybenzenethiol. In this compound θ lies near 90°. It appears that this approach will allow an extension of the *J* method to the evaluation of two-term potential functions in, for example, *ortho* substituted benzene derivatives.

TED SCHAEFER, TIMOTHY A. WILDMAN et RUDY SEBASTIAN. Can. J. Chem. **60**, 1924 (1982).

On suggère que la constante de couplage spin–spin à travers cinq liaisons entre le proton du groupe sulfhydryle et le proton du cycle en position *méta* est donnée par la relation $^5J = {}^5J^{\pi}_{90}\langle\sin^2\theta\rangle + {}^5J^{\sigma}_{180}\langle\sin^2(\theta/2)\rangle$. Dans l'équation, θ est l'angle de torsion de la liaison S—H par rapport au plan du benzène et les parenthèse angulaires indiquent les valeurs prévues ou les valeurs moyennes déterminées par la barrière binaire à la rotation interne autour de la liaison C—S. $^5J^{\pi}_{90}$ est la contribution des électrons π et est maximum à θ = 90° et $^5J^{\sigma}_{180}$ est la contribution des électrons σ avec un maximum à θ = 180° (orientation en zig zag). Pour 8 dérivés du benzènethiol substitués en position *para*, on peut reproduire les valeurs de $^5J$ par cette équation qui est également en accord avec les couplages observés pour l'hydroxy-2 benzènethiol. Dans ce composé, θ se situe près de 90°. Il semble que cette approche permettra une extension de la méthode *J* à l'évaluation des fonctions de potentiel à deux termes dans, par exemple, des dérivés du benzène substitués en *ortho*.

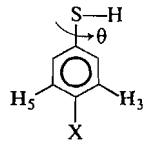
[Traduit par le journal]

## Introduction

The *J* method (1) for the determination of small twofold internal rotational barriers in benzene derivatives depends on the $\sin^2\theta$ dependence of the spin–spin coupling over six bonds between *alpha* and *para* nuclei. When these nuclei are protons, one may write

$$[1] \quad {}^6J_p{}^{H,H} = {}^6J_{90}\langle\sin^2\theta\rangle$$

where $^6J_{90}$ is the value of $^6J_p$ when the bond of the sidechain lies in a plane perpendicular to the benzene plane. In particular, for benzenethiol, **1** (X



**1**

= H), a $^6J_{90}$ of −0.97 Hz and an observed $^6J_p{}^{H,H}$ of − 0.33 Hz (2) yields an expectation value for $\sin^2\theta$ of 0.345 and, via a hindered rotor model, a $V_2$ of 3.4 kJ/mol (3), in good agreement with microwave and far infrared results (4). In fact, the latter can be taken as a calibration of $^6J_{90}$.

Further, it has been shown (3) for *para* substituted derivatives of benzenethiol that $^4J_o{}^{H,H}$ can be used in an equation similar to [1] in order to derive $V_2$ numbers and that a value for $^4J_{90}{}^{H,H}$ of −1.10 Hz yields sensible barriers. In fact, this approach predicts that in *para* amino and *para* methoxybenzenethiols the perpendicular conformation (θ = 90°) becomes the stable form, allowing a rationalization of the contrasting conformation of 4-dimethylaminophenyl sulfide and 4-nitrophenyl sulfide observed in their crystals.

A present limitation of the *J* method is its restriction to twofold barriers, simply because there is only one observable, $^6J_p{}^{H,H}$. Therefore an *ortho* substituted benzenethiol cannot, in general, have the internal rotational potential of its S—H group characterized by $^6J_p$ alone. The internal potential must have at least two terms, $V_1$ and $V_2$ (5). In order to derive $V_1$ and $V_2$, an additional coupling parameter *and* its θ dependence are required.

$^5J_m{}^{H,H}$ may well be such a parameter. If its θ dependence were known, then $^5J$ should be relatable to $V_1$ and probably to $V_2$. It is known that $^5J_m{}^{XH,H_5}$ (θ = 0°) is essentially zero for a variety of X (C=O, O, $CR_2$, etc.) and that $^5J^{XH,H_3}$ (θ = 180°) is large (6). This knowledge has been used extensively in the deduction of conformational preferences for OH, CHO, $CHR_2$, and other sidechain moieties (7–10). However, if the internal barrier to rotation about the C($sp^2$)—X bond is comparable to $kT$ in magnitude (considerable out-of-plane mo-

tion), then in principle the complete θ dependence of $^5J$ is required for a reliable conformational analysis. That is, just as in [1] the expectation value of $\sin^2\theta$ determines $^6J$ via $V_2$, so in the desired equation for $^5J$ the average value of the θ dependence of $^5J$ will determine the observed coupling. In other words, if the planar forms are not preferred by an energy large compared to $kT$, then $^5J^{XH,H_3}$ "borrows" some of $^5J^{XH,H_5}$ and vice versa, leading to an unknown error in conformational deductions.[1]

An indication of the θ dependence of $^5J_m$ comes from INDO MO FPT computations on toluene (14). The computed $^5J_m{}^{H,CH}$ can be written as a sum of two components: a π electron contribution varying as $\sin^2\theta$ (just as for $^6J^{H,CH}$) and a σ electron contribution varying as $\sin^2(\theta/2)$. Unpublished calculations for other sidechains in this laboratory, including the S—H groups, imply a similar θ dependence. Separation of the two components is facilitated by a substituent-induced change in one component only.

In *para* derivatives of benzenethiol the substituent perturbs $V_2$ and $\langle\sin^2\theta\rangle$ and therefore the π component of $^5J$ (3). It follows that $^5J$ in these compounds may allow a test of an assumed θ dependence and, by implication, suggest an eventual extension of $^5J$ to the derivation of two-term potential functions for asymmetrical benzene derivatives.

## Experimental

Most of the $^1$H nmr spectra of the compounds under discussion below have been analyzed previously (15). The spectrum of 4-*tert*-butylbenzenethiol could not be analyzed; the chemical shift dispersion was too small in any of the solvents utilized. However, the $^1$H nmr spectrum of 4-chlorobenzenethiol (Aldrich) in $C_6D_6$ solution, but not in $CCl_4$, displayed an analyzable pattern. A 3.0 mol% solution was degassed by a number of freeze–pump–thaw cycles. Its $^1$H nmr spectrum was recorded on an HA100 spectrometer. The calibration and analysis procedure followed that recently described in great detail (16). Figure 1 displays the observed and calculated spectrum of the sulfhydryl proton. Table 1 presents the spectral parameters.

## Discussion

### 1. *The θ dependence of* $^5J^{H,SH}$

The assumption, indicated theoretically and in agreement with observation at θ = 0° and 180°, is that $^5J_m{}^{H,SH}$ follows eq. [2].

$$[2]\quad {}^5J_m{}^{H,SH} = {}^5J^{\pi}_{90}\langle\sin^2\theta\rangle + {}^5J^{\sigma}_{180}\langle\sin^2(\theta/2)\rangle$$

In [2], $^5J^{\pi}_{90}$ is the π electron contribution to $^5J$ when the S—H bond lies in a plane perpendicular to that of the benzene ring, $^5J^{\sigma}_{180}$ is the maximum σ electron contribution to $^5J$ (zig-zag conformation, $^5J \equiv {}^5J^{SH,H_5}$ in the *planar* form **1**). Angular brackets indicate expectation or average values of the θ functions.

Now, $\langle\sin^2\theta\rangle$ is known from previous work (3) and $\langle\sin^2(\theta/2)\rangle$ is 0.5, independent of $V_2$ in these symmetrical compounds (see Appendix). Accordingly, a plot of $^5J_m{}^{H,SH}$ versus $\langle\sin^2\theta\rangle$ should yield a straight line, whose slope is $^5J^{\pi}_{90}$ and whose intercept is $^5J^{\sigma}_{180}/2$. In Table 2 the relevant data for a series of 4-X-benzenethiols are presented. These data give eq. [3]

$$[3]\quad {}^5J_m{}^{H,SH} = 0.196\langle\sin^2\theta\rangle + 0.360\,(0.5)\text{ Hz}$$

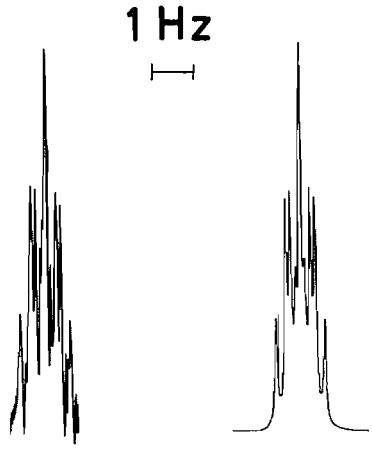

FIG. 1. The observed and calculated sulfhydryl proton $^1$H nmr spectrum at 100 MHz and 305 K for a 3 mol% solution of 4-chlorobenzenethiol in benzene-$d_6$ solution. The linewidth at half height in the calculated spectrum is 0.07 Hz (lorentzian), suggesting a similar linewidth for the observed spectrum.

TABLE 1. The $^1$H nmr spectral parameters for 4-chlorobenzenethiol as a 3.0 mol% solution in benzene-$d_6$ at 305 K

| Parameter | Value | Parameter | Value |
|---|---|---|---|
| $\nu_{SH}$ | 287.325(2)[a,b] | $^4J_o{}^{H,SH}$ | −0.370(3) |
| $\nu_2$ | 663.679(2) | $^5J_o{}^{H,SH}$ | 0.264(3) |
| $\nu_3$ | 681.917(2) | Transitions | 64[c] |
| $^3J_{23}$ | 8.358(4) | Assigned | 50 |
| $^4J_{26}$ | 2.433(4) | Peaks | 38 |
| $^4J_{35}$ | 2.430(4) | rms deviation | 0.008 Hz |
| $^5J_{36}$ | 0.406(3) | Largest deviation | 0.019 Hz |

[a] In Hz at 100.001$_2$ MHz to low field of internal tetramethylsilane.
[b] Numbers in parentheses are the standard deviations in the last significant figure.
[c] Those with a relative intensity greater than 0.05.

[1] The treatment of conformational preferences in terms of an equilibrium between or among rigid conformations has a long history because of its easy application. It has been emphasized recently (11–13) that such an approach, e.g. in the analysis of vicinal coupling constants by the Karplus curve or of temperature dependent band intensities, can lead to substantial errors in the derived equilibria.

TABLE 2. Relevant spin–spin coupling constants and internal barrier data for some *para* substituted benzenethiols[a]

| 4-X | $^4J_o^{H,SH}$ (Hz) | $^5J_m^{H,SH}$ | $\langle\sin^2\theta\rangle$ | $V_2$ (kJ) | $^5J_m^{H,SH}$ |
|---|---|---|---|---|---|
| $NO_2$ | −0.203 | 0.203 | 0.185 | 9.0±0.8 | 0.216[c] |
| Br | −0.333 | 0.231 | 0.303 | 4.8 | 0.240 |
| Cl | −0.370 | 0.264 | 0.335 | 3.7±0.4 | 0.246 |
| H | −0.380 | 0.250 | 0.345 | 3.4 | 0.248 |
| $CH_3$ | −0.439 | 0.271 | 0.399 | 2.2 | 0.258 |
| F | −0.531 | 0.270 | 0.483 | 0.4 | 0.275 |
| $OCH_3$ | −0.649 | 0.298 | 0.590 | −1.9[b] | 0.296 |
| $NH_2$ | −0.697 | 0.294 | 0.634 | −2.9±0.4 | 0.304 |

[a] For 5 mol% solutions in $CCl_4$ at 305 K, except for $NO_2$ (2 mol% in $CDCl_3$) and Cl (3 mol% in $C_6D_6$).
[b] A negative $V_2$ means that the perpendicular conformation is more stable than the planar form.
[c] These are calculated from eq. [3] of the text.

with a correlation coefficient of 0.935, significant at least at the 99% confidence level (17).[2] The standard deviations of the $^5J$ values in the spectral analysis were all considerably smaller than 0.01 Hz, so that at the 95% confidence limit an accuracy of about 0.01 Hz is probably a reasonable estimate (16). Such an error represents 10% of the variation in $^5J$ in Table 2. A $^5J^{\pi}_{90}$ of +0.195 Hz represents about 20% of the magnitude of $-^6J^{\pi}_{90}$ in benzenethiol, understandable in that, to zero order, the mobile bond order vanishes between *meta* carbons in benzene, while in a valence bond formulation the spin correlation function for atoms belonging to different classes is negative (18). In toluene it is estimated that $^5J^{\pi}_{90}$ amounts to about 30% of $-^6J^{\pi}_{90}$ (19, 20).

A test of [3] is available in 2-hydroxybenzenethiol (21), known to exist in a conformation in which stereospecific hydrogen bonding to a lone-pair on sulfur causes the S—H bond to lie in a plane *roughly* perpendicular to the benzene plane ($\theta \simeq 90°$). Therefore $\langle\sin^2\theta\rangle \simeq 1.0$ and $\langle\sin^2(\theta/2)\rangle \simeq 0.5$. Consequently $^5J_m^{H,SH} \simeq 0.195 + 0.180 = 0.376$ Hz from [3]. The observed values are 0.360 and 0.393 Hz, or a mean of 0.376 Hz. In this compound the perturbing hydroxy group lies roughly perpendicular to the C—S—H plane and intuition suggests that intrinsic substituent perturbations at the *ortho* position may not be negligible for other compounds.

In Fig. 2 the θ dependence of $^5J_m^{H,SH}$ in benzenethiol is plotted according to values deduced from eq. [3]. For comparison, the adjusted INDO MO FPT values of $^5J_m^{H,CH_3}$ for toluene (14) are shown. The INDO values of $^5J_m^{H,CH_3}$ are overestimates. To reach agreement with the experimental value of 0.36 Hz, i.e., when $\langle\sin^2\theta\rangle = \langle\sin^2(\theta/2)\rangle = 0.5$, the plotted numbers for $^5J_m^{H,CH_3}$ must be multiplied by 0.78.

[2] Omission of the data for X = Cl changes the slope and intercept by ca. 0.01 Hz and gives $r = 0.965$.

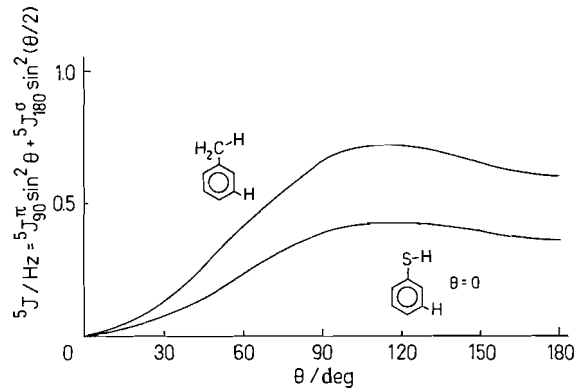

FIG. 2. A plot of $^5J_m^{H,SH}$ in benzenethiol and of $^5J_m^{H,CH_3}$ in toluene as a function of the conformational angle θ. The plot for $^5J_m^{H,SH}$ is inferred from the experimental numbers summarized in eq. [3] of the text. That for $^5J_m^{H,CH_3}$ comes from the MO calculations in ref. 14. The points for $^5J_m^{H,CH_3}$ must be reduced by a factor of 0.78 if the experimental value is to be reproduced.

2. *The internal barrier in 4-chlorobenzenethiol*

Following the procedure in ref. 3, a $V_2$ of 3.7 ± 0.4 kJ/mol is derived, compared to 3.4 ± 0.3 kJ/mol for benzenethiol. A recent dielectric relaxation study at 4 K or 77 K in paraffin solution gave the barrier in 4-chlorobenzenethiol as 0.4 kJ/mol lower than in benzenethiol (22). The dielectric data agreed with the *J* method for the 4-methyl but not for the 4-bromo derivative. Part of these disagreements may arise from solvent effects. According to coupling data for 4-aminobenzenethiol (15) $V_2$ varies by perhaps as much as 0.4 kJ/mol in going from $CCl_4$ to $C_6D_6$ or $CDCl_3$ as solvents.

## Appendix

The classical expectation value of $\sin^2(\theta/2)$ for a twofold barrier is given by:

$$\langle \sin^2(\theta/2)\rangle = \int_0^{\pi} \sin^2(\theta/2)\exp(-\beta V_2 \sin^2\theta)d\theta \times 1\Big/\int_0^{\pi}\exp(-\beta V_2\sin^2\theta)d\theta = I_1/I_2$$

where $\beta = 1/kT$. Let $a = \beta V_2/4$, $z = \exp(i\theta/2)$. Then

$$I_1 = -\exp(-2a)/8i \oint_{|z|=1} dz(z - 2/z + 1/z^3) \times (1 + az^4 + a^2z^8/2! + \ldots) \times (1 + a/z^4 + a^2/2!z^8 + \ldots)$$

Use of the residue theorem and the realization that only the term $-2/z$ of the first factor in the integral will contribute yields

$$I_1 = (-\exp(-2a)/8i)(2\pi i)(-2) \times (1 + a^2 + a^4/(2!)^2 + a^6/(3!)^2 + \ldots) = (\pi/2)\exp(-2a)\sum_{n=0}^{\infty}(a^n/n!)^2$$

Similarly,

$$I_2 = \pi\exp(-2a)\sum_{n=0}^{\infty}(a^n/n!)^2$$

The sums are absolutely convergent. Finally, $\langle \sin^2(\theta/2)\rangle = I_1/I_2 = 1/2$. This result is intuitively correct, of course. Suppose, for example, that $V_2 = \infty$. Then the two values of $\theta$ are 0 and $\pi$. If $V_2 = 0$, then the average value of $\theta$ is $\pi/2$.

# Kinetics and mechanism of the oxidation of 1-propane thiol by 2,6-dichlorophenolindophenol in acidic medium

M. KASHYAP, K. K. MISHRA,[1] AND N. K. PANDEY

*Department of Postgraduate Studies and Research in Chemistry, University of Jabalpur, Jabalpur 482001, (M.P.) India*

Received June 22, 1981[2]

M. KASHYAP, K. K. MISHRA, and N. K. PANDEY. Can. J. Chem. **60**, 1928 (1982).

The kinetics of oxidation of 1-propanethiol by 2,6-dichlorophenolindophenol have been studied in acetone–water medium and in the presence of phosphate buffer. The principal reactants interact in a molar ratio of 2:1 forming disulphide and dihydroindophenol. The reaction follows second order kinetics in indophenol while the order is unity in thiol. The rate increases linearly on increasing $[H^+]$. The rate of oxidation increases on increasing the ionic strength as well as the dielectric constant of the reaction system. The addition of reaction products has no effect on the rate. Activation parameters have been evaluated and a suitable mechanism consistent with kinetic data is suggested.

M. KASHYAP, K. K. MISHRA et N. K. PANDEY. Can. J. Chem. **60**, 1928 (1982).

On a étudié les cinétiques de l'oxydation du propanethiol-1 par le dichloro-2,6 phénolindophénol dans un milieu acétone–eau et en présence d'un tampon au phosphate. Les réactifs principaux dans un rapport molaire de 2:1 conduisent au disulfure et au dihydroindophénol. La réaction suit une cinétique d'ordre deux par rapport à l'indophénol et une cinétique d'ordre un par rapport au thiol. La vitesse augmente linéairement lorsqu'on augmente la concentration en ions $[H^+]$. La vitesse d'oxydation augmente avec la force ionique aussi bien qu'avec la constante diélectrique du système. L'addition des produits de réaction n'a aucun effet sur la vitesse. On a évalué les paramètres d'activation et on suggère un mécanisme convenable qui est en accord avec les données cinétiques.

## Introduction

2,6-Dichlorophenolindophenol (2,6-dichloro *N*-(*p*-hydroxyphenyl) *p*-benzoquinone imine), a well known titrant for vitamin C in biochemical studies, has been used in a host of reactions of pharmaceutical and analytical importance (1, 2). Its reaction with thiols was first reported by Basford and Huennekens (3) and later by Hadler *et al.* (4). These investigations were exploited in biochemical researches to determine the membrane SH group (5). The importance of this reaction attracted our attention and, perhaps for the first time, mechanistic studies on such reactions were undertaken in this laboratory (6–15). In this paper, we now report the results obtained for the oxidation of 1-propanethiol by 2,6-dichlorophenolindophenol in acetone–water medium and in the presence of phosphate buffer.

## Experimental

The solution of 2,6-dichlorophenolindophenol (referred to later as indophenol, In) was prepared by dissolving an exactly weighed quantity of a BDH grade sample in double distilled water. The strength of the solution was checked by titrating it against ascorbic acid (16). The solution was stored in a cool, dark place since both light and temperature affect its stability (17). The solution of 1-propanethiol (symbolized later as 1-PT) was prepared by diluting the sample (obtained from Fluka A.G., Chemische Fabrick, Buchs S.G. Switzerland) in E. Merck's G.R. grade acetone. The thiol solution was standardized by employing a back iodimetric titration procedure (18). Freshly prepared thiol solutions were employed for each run to avoid the possibility of oxidation in air. As a precautionary measure, however, stock solutions were always kept under a nitrogen atmosphere. The corresponding disulphide was prepared by oxidizing thiol with iodine (19), while dihydroindophenol (leucodye) was prepared by passing pure $SO_2$ gas into the known solution of indophenol (6). The pH of the reaction system was maintained by adding phosphate buffer. The kinetics were studied in 50% (v/v) acetone–water medium because at this composition the runs give reproducible results. Other ingredients used in these investigations were either of BDH, AnalaR, or E. Merck's G.R. grade. Double distilled water was used throughout.

*Kinetic measurements*

The progress of the reaction was followed colorimetrically using a Klett–Summerson photoelectric colorimeter fitted with light filter No. 59 (spectral range 565–630 nm) because indophenol shows maximum absorbance at 610 nm ($\varepsilon_{max} = 8 \times 10^3\ cm^2\ mol^{-1}$) while the reaction products, viz. leucodye and the corresponding disulphide, absorb strongly at 282 (4) and 222 nm respectively. The products were characterized by recording the absorption spectra of the reaction mixture (marked with an asterisk in Table 1) after completion of the reaction. All the spectra were recorded by a Pye Unicam SP 8-100 spectrophotometer. The reaction flask made of Corning glass was coated with Black Japan from outside to minimize the photochemical effect. The flasks containing reaction mixture and indophenol were thermostated for a sufficiently long time (variation ± 0.1°C). The runs were made under a nitrogen atmosphere.

## Results and discussion

The stoichiometry of the reaction was determined by computing the residual concentration of

indophenol in the reaction mixtures containing a known excess of oxidant (ca. $4.5 \times 10^{-5}$ $M$) over thiol. In the spectrophotometric method (20) the absorption spectra of the reaction mixture was recorded after completion of the reaction. Both the methods gave a stoichiometry of 2:1. Thus,

$$2RSH + In \rightarrow RSSR + H_2In$$

Here In and $H_2In$ denote indophenol and leucodye, respectively.

The quantitative formation of disulphide and the leucodye ($\varepsilon_{max} = 8.52 \times 10^4$ and 13 760 $cm^2$ $mol^{-1}$, respectively) was confirmed by using the relation $A = \varepsilon Cl$. The reaction follows second order kinetics in indophenol (Fig. 1). The order in indophenol was determined by Ostwald's isolation and van't Hoff's differential methods (21). Table 1 gives the values of the second order rate constant obtained at different [RSH].

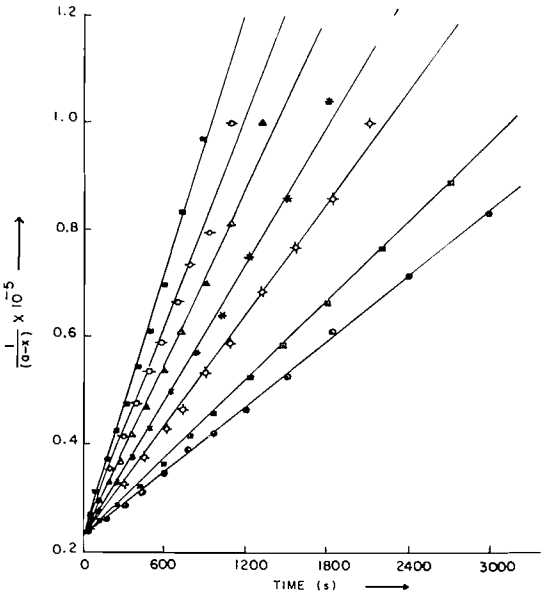

FIG. 1. [1-PT] ⊙ = $4.5 \times 10^{-4}$ $M$; ⊡ = $5.5 \times 10^{-4}$ $M$; ⊹ = $7.5 \times 10^{-4}$ $M$; ∗ = $9.5 \times 10^{-4}$ $M$; △ = $11.5 \times 10^{-4}$ $M$; ○ = $13.5 \times 10^{-4}$ $M$; ■ = $16.5 \times 10^{-4}$ $M$; [In] = $4.5 \times 10^{-5}$ $M$; acetone = 50% (v/v); pH = 6.8; I = 0.132 $M$; temp. = 30°C.

It is apparent from Table 1 that the reaction follows a first order kinetics in the substrate because the relation $k_2$/[RSH] gives nearly constant values. This was further confirmed by the initial rate measurement method. The rate of oxidation of 1-PT is not influenced by variation in [In] (Table 1).

The pH of the system was varied by adding different amounts of potassium dihydrogen phosphate and disodium hydrogen phosphate to the reaction mixtures. It may, however, be added that these variations could be done in a limited range only because, below pH 5.7 (equal to $pK_a$), the blue variety of indophenol changes into the red variety (22). The latter shows $\lambda_{max}$ at 514 nm ($\varepsilon_{max}$ = 6475 $cm^2$ $mol^{-1}$), which shows that there is a substantial change in the chromophoric character of the indophenol molecule with decrease in pH. Moreover, at lower pH (< 5.0), a substantial fading of indophenol is noticed during the course of the reaction and thus kinetic pursuit in this region was not possible. The rate increases on decreasing the pH of the system. The plots of log $k_2$ against log [$H^+$] give a straight line with a slope of unity (Fig. 2).

The ionic strength of the system was maintained constant (ca. 0.15 $M$) by adding the requisite amount of sodium perchlorate in these variations. The rate increases with increasing ionic strength (Table 2). Here only uni-univalent electrolytes could be added because higher valent cations are precipitated in the phosphate buffer as well as in 50% (v/v) acetone–water medium. These studies indicate that the rate-determining step involves the participation of similarly charged species (23).

In order to study the effect of dielectric constant,

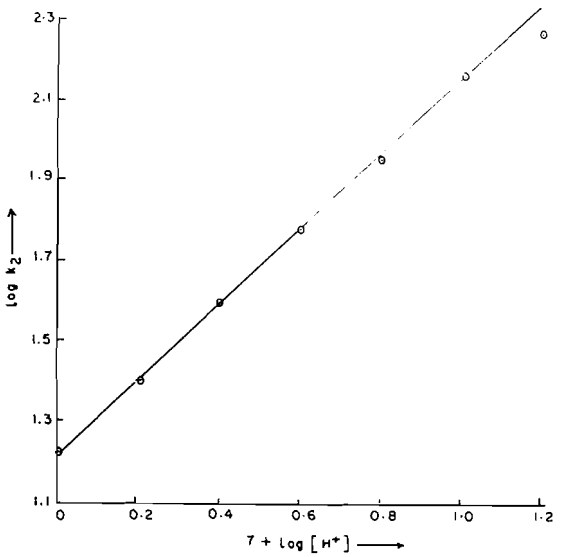

FIG. 2. [1-PT] = $4.5 \times 10^{-4}$ *M*; [In] = $4.5 \times 10^{-6}$ *M*; acetone = 50% (v/v); I = 0.15 *M*; temp. = 30°C.

the composition of the medium was changed by adding varying amounts of acetone. The latter could not be varied above 50% (v/v), because the phosphates are precipitated beyond this level. Table 3 gives a consolidated account of the rate constants obtained at different compositions of acetone along with the values of dielectric constant. The *D* values given here were obtained from the calibration plot using the value given by Kolthoff and co-workers (24).

The rate of oxidation was unaffected on addition of the reaction products, viz. dihydroindophenol and 1,1′-dipropyldisulphide (the disulphide), in the reaction system. The concentration, in both cases, was varied from $2.0 \times 10^{-5}$ *M* to $10.0 \times 10^{-5}$ *M*. This concludes that the end products are not involved in mass law terms. The activation parameters were determined by making the runs at different temperatures keeping other variables unchanged. The plots were drawn between log $k_2$ against $1/T$ and the slopes were measured. The heat of activation was calculated employing the

relation

$$\Delta H^* = -2.303 \times R \times \text{slope}$$

The entropy of activation was calculated from Eyring's equation

$$k_s = \frac{kT}{h} \cdot \exp(-\Delta H^*/RT) \cdot \exp(\Delta S^*/R)$$

(The notations have their usual meaning and $kT/h$ was assumed to be $10^{13}$ s$^{-1}$.) The free energy of activation was determined using the thermodynamic relation

$$\Delta F^* = \Delta H^* - T\Delta S^*$$

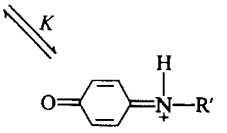
The second order rate constants obtained at different temperatures, along with the activation parameters, are given in Table 4.

*Mechanism*

As described previously, the reactions were investigated in acidic medium and thus the indophenol molecule (the sodium salt) may be presumed to be protonated, probably at nitrogen. The actual site of attack is, however, largely obscured owing to a complex geometry of the molecule.

[1] 

(I, In)



(II, $HIn^+$)

The protonated form of indophenol may combine with another indophenol molecule as shown in the proposed mechanism.

[2] $HIn^+ + In \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} D$

[3] $D + RSH \xrightarrow{k_2} C^* + H^+$

| 313 | 22.48 | | | |
| 318 | 23.02 | | | |

[a] $4.50 \times 10^{-5}$ *M* Indophenol; $4.50 \times 10^{-4}$ *M* 1-PT; acetone 50% (v/v); pH 6.8; ionic strength 0.132 *M*.

Species D given in step [2] represents the indophenol dimer, while C* symbolizes the reactive intermediates (9, 10, 15). These intermediates may include free radicals such as RSIn· (25) and HIn· (26) which may combine with thiol molecules in a series of fast steps as given below:

[4] $$D + RSH \xrightarrow{k_2} RSIn^{\cdot} + HIn^{\cdot} + H^+$$

[5] $$RSIn^{\cdot} + RSH \xrightarrow{fast} RSSR + HIn^{\cdot}$$

[6] $$HIn^{\cdot} + RSH \xrightarrow{fast} H_2In + RS^{\cdot}$$

[7] $$2RS^{\cdot} \xrightarrow{fast} RSSR$$

Incidentally, the association of dye molecules in the presence of various electrolytes and in non-aqueous media has been widely reported in the literature (27). The participation of free radicals in the present case was qualitatively confirmed by the method of Kolthoff and Meehan (28).

The rate of reaction for the above scheme would be given by

[8] $$-d[In]/dt = k_1[HIn^+][In] - k_{-1}[D]$$

On applying steady state treatment for D

[9] $$[D] = \frac{k_1[HIn^+][In]}{k_{-1} + k_2[RSH]}$$

On substituting the value of [D] and $[HIn^+] = K[In][H^+]$, the rate of reaction would be given by the expression

[10] $$-\frac{d[In]}{dt} = \frac{k_1 k_2 K[In]^2[RSH][H^+]}{k_{-1} + k_2[RSH]}$$

If $k_{-1} \gg k_2[RSH]$;

[11] $$-\frac{d[In]}{dt} = \frac{k_1 k_2 K[In]^2[RSH][H^+]}{k_{-1}}$$

Equation [11] explains the second order kinetics in indophenol and first order with respect to thiol. Again, the proposed mechanism successfully explains the direct proportionality of the rate with $[H^+]$.

From eq. [11]

[12] $$k_{obs} = \frac{k_1 k_2 K[RSH][H^+]}{k_{-1}}$$

or

[13] $$\frac{1}{k_{obs}} = \frac{k_{-1}}{k_1 k_2 K[RSH][H^+]}$$

Thus, a plot of $1/k_{obs}$ against 1/[RSH] should give a straight line passing through the origin in conformity with eq. [13], which has actually been observed (Fig. 3). These plots were further exploited to calculate the pseudo-second order rate con-

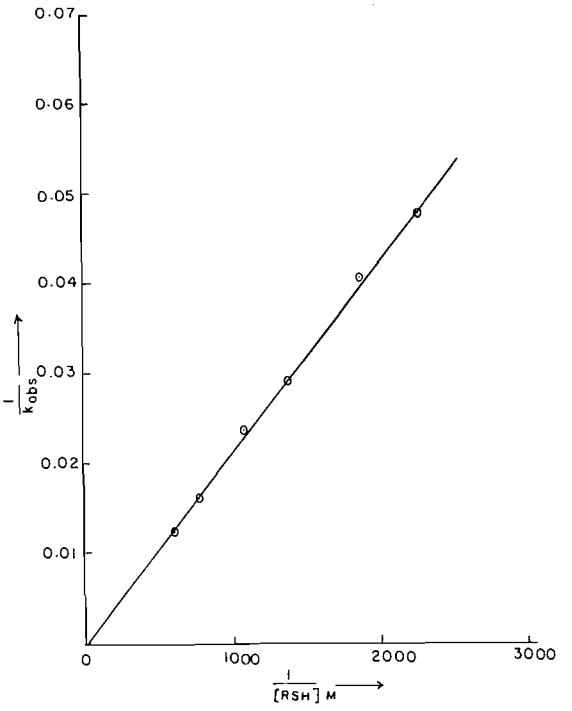

FIG. 3. $[In] = 4.5 \times 10^{-5}$ *M*; acetone = 50% (v/v); I = 0.132 *M*; temp. = 30°C.

TABLE 5. Calculated second order rate constants for the oxidation of 1-PT

stant ($k_{obs}$). From eq. [13]:

$$[14] \quad \text{slope} = \frac{k_{-1}}{k_1 k_2 K[H^+]}$$

Thus,

$$[15] \quad k_{obs} = 1/\text{slope} \times [RSH]$$

The values of the pseudo-second order rate constant calculated from eq. [15] are given in Table 5 (the slope from Fig. 3 is equal to $2.15 \times 10^{-5}$).

These values agree fairly well (except the last value) with those recorded in Table 1 for the corresponding concentrations of thiol and lend credence to the mechanistic approach to be advanced presently.

Reçu le 3 septembre 1981

ROGER BARLET, RAYMOND LE GOALLER et CLAUDE GEY. Can. J. Chem. **60**, 1933 (1982).

Les éthoxy-alcènes s'avèrent d'excellents accepteurs de carbènes dans la réaction de *méthylmonohalogénocyclopropanation* au moyen du dichloro-1,1 éthane et du méthyllithium exempt d'ion iodure. A côté des adduits chlorés, on obtient une forte proportion d'adduits bromés grâce à un échange d'halogène au niveau du complexe carbène–sel intermédiaire. La stéréochimie des adduits est déterminée par rmn $^1H$ et $^{13}C$. La *syn*-stéréosélectivité de la réaction est discutée en termes électroniques et stériques.

ROGER BARLET, RAYMOND LE GOALLER, and CLAUDE GEY. Can. J. Chem. **60**, 1933 (1982).

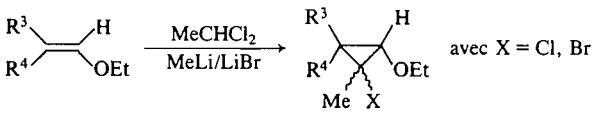
Ethoxy-alkenes act as excellent carbene acceptors in the *methylmonohalogenocyclopropanation* reaction mediated by 1,1-dichloroethane and iodide-ion free methyl iodide. As well as chlorinated adducts, a large proportion of brominated products are obtained by means of halogen exchange at the carbene complex – salt intermediate stage. Adduct stereochemistry is determined by $^1H$ and $^{13}C$ nmr spectroscopy. The *syn*-stereoselectivity of the reaction is discussed in electronic and steric terms.

[Journal translation]

## Introduction

Nous avons récemment rendu compte de la formation, avec de hauts rendements et une nette stéréosélectivité, des éthoxy-1 halogéno-2 cyclopropanes (1). Cette réaction d'*halogénocyclopropanation* des éthoxy-alcènes s'inscrivait dans le cadre général de l'étude, menée par l'un d'entre nous, de la cycloaddition carbénique sur les oléfines désactivées par un groupement électroattracteur (2–4).

Nous présentons ici les résultats, dans la même perspective, de la *méthylhalogénocyclopropanation* des mêmes éthoxy-alcènes faiblement nucléophiles.



La détermination de la configuration *cis* ou *trans* des adduits,[1] rendue ici délicate en rmn par l'absence de couplages caractéristiques $^3J_{H-H}$ et l'absence d'effet nOe significatif, a cependant été obtenue de façon incontestable par la convergence de méthodes spectrographiques (rmn $^1H$, $^{13}C$) et chimiques (facilité d'ouverture disrotatoire). Une telle identification stéréochimique est également justifiée par la mise en évidence des effets d'anisotropie des méthyles, des éthoxy et des halogènes dans de telles structures. Elle permet en outre de mener une étude comparée de la stéréosélectivité de la méthylhalogénocyclopropanation présentée ici et de l'halogénocyclopropanation précédemment décrite.

Notons que nos résultats complètent ceux obtenus, à peu près simultanément, par Conia et coll. concernant l'addition du chlorométhyl carbène sur les siloxyalcènes et appliqués à la formation de systèmes cétoniques α-éthyléniques méthylés en α (5) et éventuellement inclus dans des produits naturels (6).

## Résultats expérimentaux

La réaction de cyclopropanation est obtenue avec un haut rendement (80 à 85%) pour les quatre éthers, d'énols **5–8** ci-dessous.[2] On observe la formation préférentielle des adduits chlorés et méthylés en position 2, de configuration *cis* et *trans*, accompagnés minoritairement des adduits bromés correspondants (Tableau 1).

[1]Comme dans le travail antérieur rendant compte des résultats d'halogénocyclopropanation des mêmes substrats (1), les termes *syn* et *anti* (ou *cis* et *trans*) précisent la position relative du groupement éthoxy et de l'halogène.

[2]Les substrats **5–8** sont identiques aux substrats **1–4** présentés dans notre travail antérieur (1). La numérotation différente est destinée à permettre la distinction des adduits **5***t*, **5***c*, etc ... résultant de la méthylhalogénocyclopropanation par rapport aux adduits homologues **1***t*, **1***c*, etc ... résultant de l'halogénocyclopropanation.

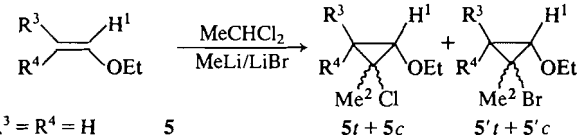
TABLEAU 1. Méthylhalogénocyclopropanation des ethers α-éthyléniques au moyen de $CH_3CHCl_2$ et MeLi/LiBr (température ordinaire)

| Substrats[a] | % Adduits chlorés[b] | % Adduits bromés[b] | Répartition adduits chlorés: No ident. *trans* (*anti*) % | Répartition adduits chlorés: No ident. *cis* (*syn*) % | Répartition adduits bromés: No ident. *trans* (*anti*) % | Répartition adduits bromés: No ident. *cis* (*syn*) % |
|---|---|---|---|---|---|---|
| 5 | 60 (77) | 40 (23) | **5***t* *43* | **5***c* *57* | **5′***t* *49* | **5′***c* *51* |
| 6  | 73 (85) | 27 (15) | **6***t* *34* | **6***c* *66* | **6′***t* *5* | **6′***c* *95* |
| 7 | 75 (89) | 25 (11) | **7***t* *65* | **7***c* *35* | **7′***t* *43* | **7′***c* *57* |
| 8  | 64 (90) | 36 (10) | **8***t* *56* | **8***c* *44* | **8′***t* *48* | **8′***c* *52* |

[a]Les substrats **5**, **6**, **7**, **8** sont les mêmes que les substrats **1**, **2**, **3**, **4** mentionnés dans notre travail précédent (1) mais les adduits correspondants **5***t*, **5***c*, etc ... diffèrent des adduits **1***t*, **1***c*, etc ... par le méthyle géminé avec l'halogène.
[b]Les % indiqués entre parenthèses sont ceux des réactions de cycloaddition menés à −15°C. L'abaissement de température pratiquement sans effet sur la répartition des isomères *syn* et *anti* limite la formation des isomères bromés.

Par rapport à la réaction d'halogénocyclopropanation (1) conduisant aux adduits non méthylés en position 2 ($Me^2$ remplacé par H), nous avons observé un léger affaiblissement du rendement réactionnel, une moins bonne reproductibilité probablement due à une plus grande fragilité des adduits cyclopropaniques, la formation de sous-produits légers non identifiés et une augmentation sensible de la proportion d'adduits bromés.



| | | | |
|---|---|---|---|
| $R^3 = R^4 = H$ | **5** | **5***t* + **5***c* | **5′***t* + **5′***c* |
| $R^3 = H$, $R^4 = Me$ | **6** | **6***t* + **6***c* | **6′***t* + **6′***c* |
| $R^3 = Me$, $R^4 = H$ | **7** | **7***t* + **7***c* | **7′***t* + **7′***c* |
| $R^3 = R^4 = Me$ | **8** | **8***t* + **8***c* | **8′***t* + **8′***c* |

L'addition de méthyllithium associé à un équivalent de bromure de lithium (lithien préparé par action de MeBr sur Li) et exempt d'ions iodures, est menée à faible reflux d'éther sur le mélange: accepteur de carbénoïde – générateur de carbénoïde. La formation des adduits bromés, produits primaires de réaction,[3] s'interprète comme dans la référence 1 par échange chlore–brome au niveau du complexe carbène–sel. Cet échange est bloqué à −80°C et seuls sont alors formés les adduits chlorés. L'existence de ce complexe carbène–sel expliquerait que seule soit mise en jeu la réactivité électrophile de tels carbènes sur la double liaison de cétones éthyléniques (7) alors que les carbénoïdes correspondants, stables à basse température (8), sont connus pour leur facile addition nucléophile sur les esters (9) et les composés carbonyls (10).

L'addition de $Bu_4N^+Br^-$, légèrement soluble, n'augmente pas la quantité de produits bromés ce qui indique, là encore, que la vitesse de formation des adduits est supérieure à celle de l'incorporation des bromures extérieurs au carbène–sel.

### Identification stéréochimique des adduits

Nous ne disposons pas, pour ces composés, de critères directs permettant de déterminer en rmn $^1H$ la stéréochimie *cis* ou *trans* des adduits: en effet, la position relative de $H^1$ et $Me^2$ ne donne pas lieu à un couplage $^4J$ spécifique de chacun des stéréoisomères puisque, même à 250 MHz, nous n'avons pas observé de couplage $^4J_{H^1H^2}$.

Nous nous sommes initialement tournés vers le "nuclear Overhauser effect", à priori la méthode de choix pour une telle détermination. En fait l'examen du signal de $H^1$, suffisamment distinct de tous les autres, avant et après irradiation de $Me^2$,

[3]Nous avons vérifié que la formation de composés bromés n'est pas due à une réaction de substitution nucléophile des adduits chlorés par les ions bromures présents dans le milieu. En effet, les adduits chlorés remis dans ces conditions de la réaction, mais en l'absence d'éthoxy-alcène accepteur, ne conduisent pas aux analogues bromés.

[a]$\nu$ = 60 MHz, $CCl_4$, $\delta$ $10^6$, $J$(Hz).
[b]La mise en évidence de ces couplages $^4J$ a été obtenue à 250 MHz.
[c]Toutes les valeurs nulles figurant dans ce tableau signifient que ces $^4J$ n'ont jamais été observés même à 250 MHz.

ne permet pas de conclure. En effet les mesures multiples faites au spectrographe à onde continue Cameca 250 MHz ou Varian HA 100 donnent des évolutions du signal de $H^1$ quelque peu surprenantes: (a) l'effet nOe est négligeable sur le couple **8***c*/**8***t* dans tous les cas; (b) l'effet est minime sur les couples **5***t*/**5***c* (de 2 à 5% d'exaltation pour **5***t*, de 1 à 6% de diminution pour **5***c*) et **8***t*/**8***c* (de 1 à 4% d'exaltation pour **8***t*, de 1 à 6% de diminution pour **8***c*); (c) l'effet est relativement important dans le cas du couple **7***t*/**7***c*. De façon inattendue l'exaltation se manifeste aussi bien pour **7***t* (10% au minimum) que pour **7***c* (de l'ordre de 5%).

Dans tous les cas, l'effet nOe lorsqu'il se manifeste est faible mais va à l'encontre des hypothèses d'attributions faites par analogie avec les adduits non méthylés (1). Ce résultat nous a contraints par un travail spécifique sur cette série, à accumuler les observations expérimentales propres à étayer la détermination de ces structures.

L'identification stéréochimique des adduits a finalement pris appui sur un certain nombre de critères spectrographiques en rmn $^1H$: effets LIS, analyse des effets de blindage des alkyles et des halogènes; et en rmn $^{13}C$: examen du couplage $^{13}C—H$ entre le carbone de $Me^2$ et le proton $H^1$. Ces critères spectrographiques se sont révélés être convergents avec le critère chimique d'ouverture disrotatoire plus rapide des composés *trans* (11). En outre, nous avons pu ajouter à ces critères de configuration d'autres éléments de preuve cohérents dans toute la série et cohérents avec la série non méthylée ($H^2$ à la place de $Me^2$) (1).

1. *Effet LIS*

L'étude de l'effet LIS menée à partir du chélate de l'Europium $Eu(dpm)_3$ a eu un double objet: (*i*) *l'attribution directe des déplacements chimiques* $\delta R^3$ *et* $\delta R^4$ dans les adduits dérivés de **5** ($R^3 = R^4 =$ H) et de **8** ($R^3 = R^4$ Me), structures dans lesquelles, des deux substituants géminés identiques, le plus déplacé par le chélate est celui qui est en position *cis* par rapport à l'éthoxy complexant. L'ensemble de ces attributions est cohérent avec les attributions de déplacements chimiques des mêmes substituants $R^3$ et $R^4$ dans les adduits dérivés de **6** et de **7** (Tableau 2). (*ii*) *L'attribution des configurations par étude comparée de l'effet LIS sur ces couples* **5**t–**5**c *et* **8**t–**8**c. Dans ce dernier cas, on observe que $Me^4$ est nettement plus déplacé que $Me^2$ et $Me^3$ pour l'un des stéréoisomères. On en conclut alors que $Me^4$ se trouve du côté du OEt tandis que $Me^2$ et $Me^3$ sont du côté opposé. Cet isomère est donc **8***c* (Fig. 1). Dans l'autre isomère **8***t* $Me^2$ et $Me^4$, déplacés de façon voisine et trois à quatre fois plus que $Me^3$, sont donc l'un et l'autre du côté du OEt.

Pour le couple **5***t*–**5***c*, les rapports des pentes $a$ des droites $\Delta\delta = a(C_{Eu}/C_0)$ ($C_0$ concentration en adduit, $C_{Eu}$ concentration en chélate), permettent d'attribuer de façon nette les configurations (Tableau 3). Les rapports $a\,Me^2/a\,H^3$, $a\,Me^2/a\,H^4$, $a\,Me^2/a\,H^1$, $a\,Me^2/a\,OCH_2$ sont toujours supérieurs dans

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

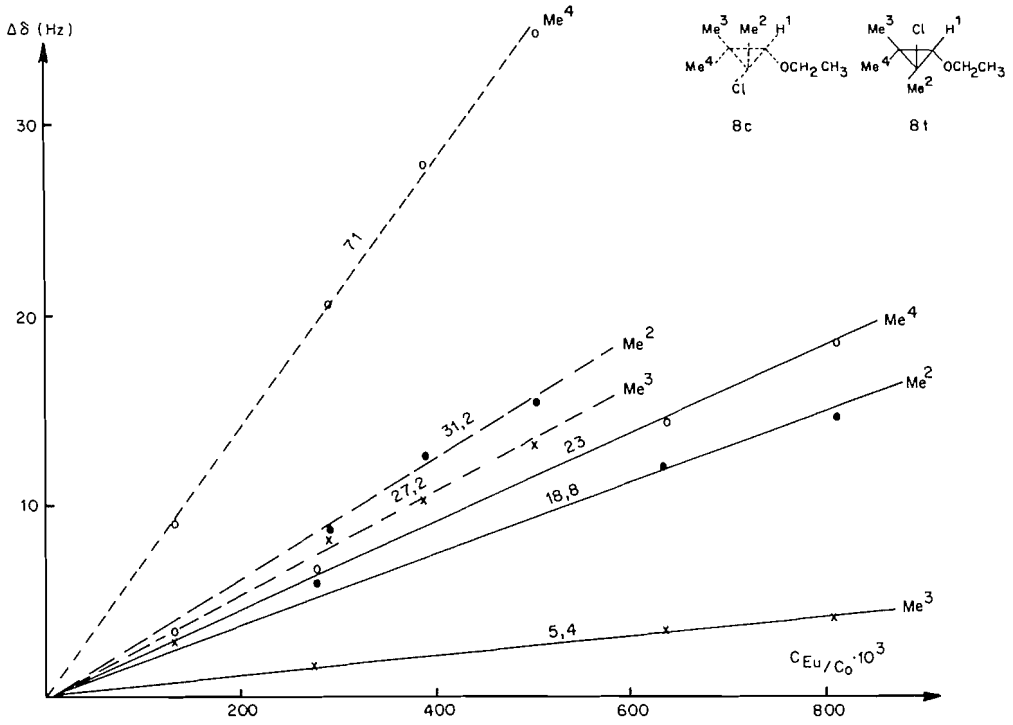

FIG. 1. Valeurs de Δδ et *a* pour les adduits **8***t* et **8***c*.

le cas ou $Me^2$ est plus proche du complexant, c'est-à-dire pour le stéréoisomère **5***t* où ces rapports sont respectivement de 1,14; 0,56; 0,38; 0,45 à opposer à 0,68; 0,31; 0,27 et 0,31 pour l'isomère **5***c*.

Ces attributions de configuration permettent de préciser, sans ambiguïté, les déplacements chimiques de $H^1$ pour chacun des stéréoisomères et par conséquent de prévoir les configurations des adduits dérivés de **6** et **7** (Tableau 2). Comme pour les adduits issus de **5** et **8**, il est en effet cohérent de penser que $\delta H^1$ est sensiblement plus élevé dans le cas du stéréoisomère *trans* (Δδ de l'ordre de 0,5 ppm) que dans celui du *cis*.

2. *Effets de blindage des méthyles et de déblindage des halogènes sur les protons cyclopropaniques*

L'étude des déplacements chimiques des protons $H^1$ (sur le carbone porteur de l'oxygène) et $H^2$ (sur le carbone porteur de l'halogène) dans les adduits de monohalogénation (1) montre que le groupe méthyle exerce sur $H^1$ un effet de blindage de 0,35 à 0,37 ppm pour les composés de la série *t* et 0,20 à 0,33 ppm pour ceux de la série *c*. Cet effet est encore plus grand pour $H^2$: 0,43 à 0,46 ppm pour les composés *t*, 0,35 à 0,36 ppm pour les adduits *c*. Ces valeurs moyennes recoupent sur un nombre de cas plus important celles obtenues antérieurement par Closs et coll. (12).

Ces observations transférées aux produits de méthyl monohalogénation étudiés ici confirment les attributions de configuration obtenues par effet LIS. Le tableau 2 met en évidence *les effets de déblindage attendus de* $Me^3$ *sur le proton* $H^1$ (0,45 ppm entre **5***t* et **7***t*, 0,36 entre **5***c* et **7***c*, 0,41 entre **6***t* et **8***t*, 0,27 entre **6***c* et **8***c*).

De plus, la comparaison des adduits *cis* et *trans*, de même structure alkylée, montre que $\delta H^1$ augmente de 0,39 à 0,53 ppm lorsqu'on passe du stéréoisomère *trans* au *cis* (0,49 de **5***t* à **5***c*, 0,53 de **6***t* à **6***c*, 0,40 de **7***t* à **7***c*, 0,39 de **8***t* à **8***c*). Ce Δδ est la somme en valeur absolue des effets de blindage de $Me^2$ et de déblindage de Cl, ce dernier chiffré comme dans les adduits non méthylés (1) à 0,1 ppm. *L'effet de blindage de* $Me^2$ *sur* $H^1$ *ressort donc dans la fourchette 0,29–0,43 ppm valeur tout-à-fait comparable à l'effet de* $Me^3$ *sur* $H^1$.

La cohérence de ces effets de blindage des méthyles dans l'ensemble des adduits, méthylés ou non, constitue un nouvel argument pour notre attribution de configuration. Une attribution inversée pour les adduits **5***t*–**5***c* .... **8***t*–**8***c* conduirait à des effets très atténués ou même des effets de déblindage des méthyles en opposition aux résul-

tats précédemment observés dans notre série non méthylée (1) ou dans la littérature.

3. *Couplage $^{13}C—H$ entre $Me^2$ et $H^1$*

Il est admis que la valeur du couplage $^3J_{^{13}C—H}$ varie à peu près comme le couplage $^3J_{H—H}$ (13). Il a été montré récemment que dans une série de composés du type oxiranes, thiiranes, sulfones et cyclopropanes, le couplage du carbone substituant le $C^2$ du cycle et du proton porté par le carbone l'était toujours plus grand dans le cas d'une relation *cis* de ce carbone et ce proton que dans le cas d'une relation *trans*. La généralité d'une telle observation a d'ailleurs permis aux auteurs de faire de cette observation comparée de tels $^3J_{^{13}C—H}$ un critère d'attribution de configuration (14).

L'étude des spectres rmn $^{13}C$ des composés **8***t* et **8***c*, permet effectivement de distinguer un couplage $Me^2—H^1$ de 3,7 Hz pour **8***c* et de moins de 1,5 Hz pour **8***t*. Cette détermination comparée des couplages $^3J_{Me^2—H^1}$ constitue un élément de preuve supplémentaire pour notre attribution.

4. *Autres éléments de détermination des configurations*

Indépendamment des critères précédents de détermination des configurations, nous avons pu mettre en évidence d'autres caractères distinctifs entre les isomères *cis* et *trans*, parallèles à ceux que nous avions observés pour les adduits de monohalogénocyclopropanation.

(*i*) Les protons méthyléniques du groupe éthoxy présentent, ici encore, une légère inéquivalence, de l'ordre de 4 Hz, pour les isomères *cis* avec apparition d'un doublet de quadruplets. L'isomère *trans* ne présente, par contre, aucun dédoublement de son quadruplet. Nous interprétons, à nouveau, cette équivalence comme un effet de champ de l'halogène sur les deux hydrogènes voisins $OC\underline{H}_2—CH_3$. La généralisation de cette observation peut constituer un nouveau critère d'attribution de configuration pour les éthoxy-1 halogène-2 cyclopropanes, quel que soit, par ailleurs, leur degré d'alkylation.

(*ii*) Les temps de rétention en chromatographie en phase vapeur sont toujours supérieurs pour les isomères *cis* quelle que soit la nature de la colonne.

(*iii*) Les isomères *trans*, chauffés à reflux de toluène, disparaissent beaucoup plus rapidement que les isomères *cis* sauf dans le cas des adduits **7***t* et **7***c* où les vitesses d'ouverture sont voisines aussi bien dans $CCl_4$ que dans le toluène. Cette aptitude supérieure des isomères *trans* à l'ouverture disrotatoire, avec formation d'éthoxydiènes, est conforme aux règles de l'ouverture thermique de Woodward–Hoffman en série cyclopropanique (11).

(*iv*) Il faut noter un fait expérimental supplémentaire qui, sans être à priori un critère stéréochimique absolu, permet de fait une différenciation entre les isomères de la série *c* et ceux de la série *t*: la réalisation de spectres rmn H à 250 MHz nous a permis de mettre en évidence un léger mais net couplage $^4J$ entre $Me^2$ et $H^3$ ou $H^4$ selon la stéréochimie. Ce couplage à longue distance de 0,5 Hz (cf. Tableau 2) n'apparaît que lorsque le méthyle et l'hydrogène sont en position *trans*. On observe ainsi de tels couplages $^4J_{Me^2—H^3}$ dans les composés **5***t* et **6***t* et $^4J_{Me^2—H^4}$ dans les composés **5***c* et **7***c*. Par contre, à la limite de résolution de l'appareil à 250 MHz, on n'observe pas de coupla-

TABLEAU 4. Comparaison de la stéréosélection dans les reactions d'halogénocyclopropanation et de méthylhalogénocyclopropanation des ethers α-éthyléniques

| Substrats | Adduits | Halogenocyclopropanation | | Méthylhalogenocyclopropanation | |
|---|---|---|---|---|---|
| | | % Adduits chlorés | % Adduits bromés | % Adduits chlorés | % Adduits bromés |
| | *t* + *c* | 76 | 24 | 60 | 40 |
| | *t* | 33 | 28 | 43 | 49 |
| **1** ou **5** | *c* | 66 | 72 | 57 | 51 |
| | *t* + *c* | 77 | 23 | 73 | 27 |
| | *t* | 20 | 5 | 34 | 5 |
| **2** ou **6** | *c* | 80 | 95 | 66 | 95 |
| | *t* + *c* | 84 | 16 | 75 | 25 |
| | *t* | 47 | 45 | 65 | 43 |
| **3** ou **7** | *c* | 53 | 55 | 35 | 57 |
| | *t* + *c* | 93 | 7 | 64 | 36 |
| | *t* | 42 | 8 | 56 | 48 |
| **4** ou **8** | *c* | 58 | 92 | 44 | 52 |

ges analogues $^4J_{H^1—Me^3}$ ou $^4J_{H^1—Me^2}$. Dans ce dernier cas la raison en est sans doute que la présence d'atomes électronégatifs, géminés à la fois avec $H^1$ et $Me^2$, entraîne un abaissement, et en fait ici une disparition, du $^4J$ correspondant de la même façon que nous avions observé un abaissement des couplages $^3J_{H^1—H^2}$ dans les adduits de monohalogénocyclopropanation.

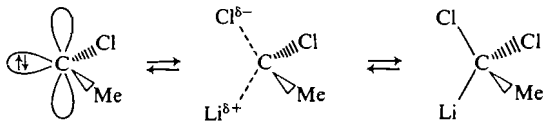
En conclusion, si les résultats obtenus par nOe nous ont fait douter du parallélisme entre la série méthylée et la série non méthylée, toutes les autres observations montrent au contraire une grande cohérence entre les deux. Dans le cas présent, l'effet nOe ne constitue pas un critère de distinction stéréochimique clair. Deux explications peuvent être retenues à ce sujet: d'une part la fréquence de découpleur, calée sur la résonance du $Me^2$, crée une fréquence harmonique très proche de la fréquence de résonance de $H^1$, d'autre part, le quadrupôle du chlore accélère la relaxation et rend l'effet nOe inobservable ou même quelques fois inversé (15). L'effet est dans cette série assez faible mais la tendance à l'inversion est nette.

## Discussion

*Effet* syn-*directeur des groupes méthylés. Absence d'effet stéréodirecteur sensible du groupe éthoxy*

En extension à l'utilisation de $CH_2Cl_2$ comme générateur de carbénoïde, l'*utilisation du générateur méthylé* $MeCHCl_2$, en présence de MeLi/LiBr et dans des conditions expérimentales proches de la température ordinaire, *autorise sur les éthoxyalcènes une réaction de méthylhalogénocyclopropanation facile à mettre en oeuvre et à haut rendement*.

Ce générateur de carbénoïde conduira à un intermédiaire très réactif, à mi-chemin entre le carbène libre singulet à carbone central $sp_2$ et le vrai carbénoïde tétraédrique à carbone central $sp_3$. Cet intermédiaire s'avère apte à ponter des structures désactivées par des groupements inductifs attracteurs comme le groupement éthoxy. L'interprétation de cette anomalie (l'assistance de l'agent de pontage par l'oxygène du substrat accepteur) déjà mise en avant antérieurement (1), nous paraît garder toute sa validité ici. La distance lithium–oxygène est d'ailleurs, dans le cas des éthers d'énols, particulièrement faible par rapport à d'autres substrats tels que cétones ou dioxolannes α-éthyléniques (4) puisque l'oxygène est alors directement lié au système éthylénique. Le pouvoir désactivant de l'éthoxy vis-à-vis d'un réactif électrophile pourrait ainsi être compensé par cette assistance.



Carbène singulet électrophile — Complexe carbène–sel intermédiaire — Carbénoïde nucléophile

Une telle mise en oeuvre d'un carbène–sel de type carbénoïde est justifiée par la méthode de génération carbénique et l'observation de l'échange chlore–brome. Cela nous paraît exclure toute possibilité de formation primaire d'un ylure (où le carbène libre se serait associé au doublet de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

l'oxygène) telle qu'elle a pu être invoquée ou discutée par Vogel et coll. (16) ou Moss (17).

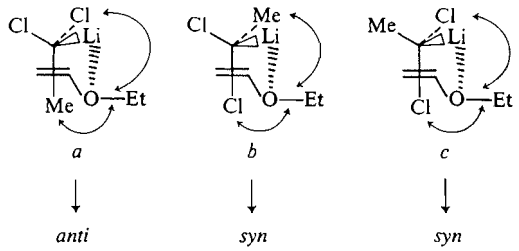
Par rapport à la monohalogénocyclopropanation des mêmes substrats par $CH_2Cl_2$/MeLi, on observe ici le *maintien d'un net effet* syn-*directeur des méthyles de l'accepteur* et une *atténuation sensible de l'effet* syn-*directeur de l'éthoxy* (Tableau 4).

La cycloaddition sur **5** et **8**, permet d'isoler l'effet de l'éthoxy puisque **5** ne présente pas de méthyles et que **8** voit l'action des deux méthyles, de part et d'autre de la double liaison, se neutraliser. La présence d'une légère prépondérance de **5***c* avec renversement en faveur de **8***t* et la quasi disparition de cette prédominance au niveau des isomères bromés montrent que l'*effet de l'éthoxy est sensiblement nul*.

Par contre, l'obtention à partir de **6** et **7** d'environ 2/3 d'isomères **6***c* et **7***t*, stéréoisomères dans lesquels le méthyle est *cis* de l'halogène, montre *la persistance d'un net effet* syn-*directeur d'alkyle*. Par rapport aux adduits d'halogénocyclopropanation, nous observons une diminution globale de la stéréosélection lorsque le méthyle et l'éthoxy sont du même côté (**2***t*/**2***c* = 20:80, **6***t*/**6***c* = 34:66) et une augmentation lorsqu'ils sont de part et d'autre (**3***t*/**3***c* = 47:53, **7***t*/**7***c* = 65:35). Cette évolution est cohérente avec une forte atténuation de l'effet stéréodirecteur de l'éthoxy et un maintien de l'effet de l'alkyle.

Notons que la répartition des isomères bromés **6**′*t*/**6**′*c* et surtout **7**′*t*/**7**′*c* ne paraît pas compatible avec l'explication précédente. Nous pensons que ceci est dû à la forte sensibilité thermique de **6**′*t* et surtout **7**′*t*, qui entraine ainsi un abaissement de la proportion des isomères *trans* déterminée par chromatographie en phase vapeur.

Dans tous les cas la méthylhalogénocyclopropanation conduit à une plus grande quantité de stéréoisomère *trans* et une plus faible quantité d'isomère *cis* que l'halogénocyclopropanation. Ce fait montre que la distribution des isomères ne dépend pas prioritairement de l'interaction stérique attractive Me ... Me dans l'état de transition, tel que le décrivent Hofmann *et al.* (18). Si tel était le cas, le *trans* éthoxy propène devrait donner un accroissement de la quantité de l'isomère *cis*, au détriment du *trans*. Cette interaction secondaire joue donc un rôle mineur par rapport à l'interaction électronique alkyle–halogène habituellement invoquée dans ce type de réaction: *dans l'état de transition la position* cis *de l'halogène sera favorisée par interaction électrostatique entre l'halogène négatif et les alkyles légèrement positifs* lors du transfert d'électrons de la double liaison vers le



carbénoïde (19). A condition que l'effet stérique demeure, comme ici, modeste on obtiendra ainsi, de façon majoritaire, les adduits les plus encombrés.

L'interprétation de la disparition de l'effet *syn*-directeur de l'éthoxy est plus délicate. En conservant le même formalisme que pour les réactions de monohalogénocyclopropanation, les trois états de transition, *a*, *b* et *c* doivent conduire à un rapport *a*/*b* + *c* voisin de 1 et non plus inférieur à 1.

Ce résultat peut s'interpréter si l'on met en jeu, à nouveau, une forte intéraction Li ... O avec torsion dans l'état de transition et net rapprochement du lithium et de l'éthoxy et si l'on considère que Me est stériquement plus encombrant que Cl. Le remplacement de H par Me, sans effet au niveau de *c*, entrainera alors une déstabilisation de *b* (par augmentation de l'intéraction Me *anti* – OEt) supérieure à celle de *a* (intéraction Me *syn* – OEt supérieure à intéraction H *syn* – OEt mais minimisée par l'éloignement imposé par le rapprochement Li ... O).

Par rapport à la monohalogénocyclopropanation, à côté de la modification des éffets *syn*-directeurs, on peut noter une sensible augmentation de la proportion des adduits bromés (voir Tableau 4). Nous proposons l'explication suivante: la vitesse d'incorporation de l'ion bromure au complexe carbène–sel reste du même ordre tandis que les durées de vie de ce complexe sont accrues par l'effet donneur du méthyle. Cet accroissement laisse au brome un temps accru pour se substituer au chlore.

## Conclusion

Ce travail nous a permis d'obtenir des halogéno-2 méthyl-2 éthoxy-1 cyclopropanes, diversement alkylés en 3, par action du générateur de carbénoïde $MeCHCl_2$/MeLi/LiBr sur les éthoxy-alcènes correspondants. La réaction fournit, à côté des composés chlorés attendus, des analogues bromés d'accès réputé difficile (20).

La stéréochimie des adduits a été déterminée, en l'absence de critères absolus, à la fois par voie chimique et par convergence de divers arguments

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

spectrographiques: effet LIS, effet d'anisotropie des alkyles et des halogènes, couplages à longue distance en rmn $^1H$, couplage $^{13}C$—H en rmn $^{13}C$.

Par rapport à l'halogénocyclopropanation antérieurement rapportée (1), la méthylhalogénocyclopropanation des mêmes éthoxy-alcènes s'opère avec maintien d'un net effet *syn*-directeur des méthyles et disparition quasi-totale de l'effet *syn*-directeur de l'éthoxy. Cette différence est interprétée sur la base d'une grande sensibilité stérique de l'état de transition.

## Partie expérimentale

Les spectres de rmn $^1H$ ont été enregistrés dans $CCl_4$ sur appareils fonctionnant, dans la grande généralité des cas, à 60 MHz (Hitachi–Perkin–Elmer R 24) mais également à 100 voire 250 MHz (Varian HA 100, Caméca 250). L'étude de l'effet nOe a été menée à 100 HA 100, et 250 MHz (Caméca). Les spectres de rmn $^{13}C$ ont été enregistrés dans $CDCl_3$ sur un spectromètre à impulsion Brücker WP100 travaillant à 25,182 MHz. Les spectres infrarouge ont été réalisés sur Perkin–Elmer 397.

La cpv analytique a été effectuée sur Aérograph 600 D à ionisation de flamme, le plus souvent avec des colonnes Ucon Oil. La cpv préparative a été effectuée sur Autroprep A 700 et A 705 avec des colonnes Ucon Oil ou SE 30 de 90 cm à 2 m (1/8 po ou 3/8 po).

Les analyses élémentaires ont été réalisées par le Service Central de Microanalyses du C.N.R.S., Echangeur de Solaize, B.P. 22, 69390 Vernaison, France.

*Mode opératoire général*

La préparation du méthyllithium associé au bromure de lithium[4] de même que la mise en oeuvre de la réaction elle-même de *méthylhalogénocyclopropanation* sont entièrement conformes au mode opératoire décrit antérieurement (1) à ceci près que $MeCHCl_2$ remplace ici $CH_2Cl_2$ comme générateur de carbénoïde.

Les substrats soumis à la cycloaddition carbénique sont soit commerciaux (cas de **5**≡**1** et du mélange **6** + **7**≡**2** + **3**, produits Fluka) soit préparé, dans le cas de **8**≡**4** selon la méthode de Claisen (21). Le mélange **6**/**7** (environ 70:30) est séparé en cpv sur SE 30 20 pieds chargée à 30% ($t°$ de colonne = 40°C). Le mélange **6** + **7** soumis directement à la cycloaddition carbénique permet de mettre en évidence que le produit *cis* **6** réagit plus facilement que le produit *trans* **7** puisqu'au rapport de substrats **6**/**7** ≃ 2,5 correspond un rapport d'adduits ≃ 4,5.

*Caractérisation et identification des adduits*

*Caractérisation*

Les adduits de méthylhalogénocyclopropanation sont dans l'ensemble des composés plus fragiles que les adduits homologues non méthylés décrits dans notre travail antérieur (1). Tous ces composés sont des composés nouveaux. Les composés *trans*, aussi bien bromés que chlorés (sauf **5***t*), se décomposent plus ou moins rapidement même en solution (sensibilité plus grande à l'ouverture disrotatoire que les composés *cis*). Les composés *cis* sont relativement stables dans le cas des composés chlorés (sauf **7***c*). Par contre, seul parmi les composés *cis* bromés, **7**′*c* est séparable en chromatographie sans décomposition.

Par conséquent les composés fragiles ne donnent pas d'analyses élémentaires satisfaisantes et reproductibles car la libération d'halogène altère les compositions centésimales même si les spectres rmn restent pratiquement inchangés. Les seules analyses acceptables que nous avons pu obtenir (Cl ± 0,3%, Br ± 0,5%), à condition qu'elles soient faites rapidement après les séparations chromatographiques, sont les suivantes:

| Composé | | Analyse % |
|---|---|---|
| **5***t* | calculée pour $C_6H_{11}OCl$ | C% 53,55; H% 8,18; O% 11,90; Cl% 26,37 |
| | trouvée | C% 53,38; H% 8,25; O% 11,88; Cl% 26,29 |
| **5***c* | calculée pour $C_6H_{11}OCl$ | C% 53,55; H% 8,18; O% 11,90; Cl% 26,37 |
| | trouvée | C% 53,37; H% 8,26; O% 11,94; Cl% 26,24 |
| **6***c* | calculée pour $C_7H_{13}OCl$ | C% 56,58; H% 8,75; O% 10,78; Cl% 23,88 |
| | trouvée | C% 56,33; H% 8,83; O% 10,91; Cl% 23,62 |
| **7**′*c* | calculée pour $C_7H_{13}OBr$ | C% 43,54; H% 6,74; O% 8,29; Br% 41,42 |
| | trouvée | C% 43,37; H% 6,89; O% 8,37; Br% 41,07 |
| **8***c* | calculée pour $C_8H_{15}OCl$ | C% 59,09; H% 9,23; O% 9,85; Cl% 21,82 |
| | trouvée | C% 58,91; H% 9,34; O% 9,98; Cl% 21,56 |

Cependant, même pour les composés fragiles, l'ensemble des données spectrographiques ne laisse aucun doute sur la nature cyclopropanique de ces composés (valeurs des δ en rmn, présence de $\nu_{C-H}$ entre 3025 et 3040 $cm^{-1}$ en ir) et sur leur structure (Tableau 2 et Fig. 1 en rmn relatifs aux adduits chlorés). Les adduits bromés présentent des spectres très proches de ceux des adduits chlorés: les couplages restent inchangés, les déplacements chimiques voisins. Les seules modifications sensibles affectent $\delta H^1$ et $\delta Me^2$. Ainsi par rapport aux homologues chlorés $\delta H^1$ est abaissé de 0,1 à 0,2 ppm pour les bromés *cis* (2,75; 2,31; 2,67; 2,44 respectivement pour **5**′*c*, **6**′*c*, **7**′*c*, **8**′*c*) et de moins de 0,1 ppm pour les bromés *trans* (3,45; 2.98; 3,35; 2,99 respectivement pour **5**′*t*, **6**′*t*, **7**′*t*, **8**′*t*) tandis que $\delta Me^2$ est exalté dans tous les cas de plus de 0,1 ppm (1,74; 1,61; 1,70; 1,61; 1,55; 1,64; 1,63; 1,73 respectivement pour **5**′*t*, **5**′*c*, **6**′*t*, **6**′*c*, **7**′*t*, **7**′*c*, **8**′*t*, **8**′*c*).

*Séparation et détermination des pourcentages*

Les divers produits n'ont pas été séparés par distillation mais par cpv vu les faibles quantités sur lesquelles nous avons opéré (de 0,01 à 0,05 mole de substrat) et la complexité des mélanges obtenus. Les stéréoisomères *trans* sont moins retenus en cpv que les stéréoisomères *cis* aussi bien dans le cas des adduits bromés que des adduits chlorés et quelle que soit la colonne utilisée. Les adduits chlorés *cis* et *trans* sortent habituellement tous les deux avant les adduits bromés correspondants. La seule exception est constituée par les composés **8***t* et **8**′*t* qui sortent sous forme d'un pic unique sur Ucon Oil 30% LB 550 X de 200 cm tandis que, sur Ucon Polar 50 HB 2000 à 20% de 120 cm **8**′*t* est à nouveau bien distingué en 3è position. Sur ces deux colonnes **8**′*c* est totalement décomposé. Le composé **6***t* complètement décomposé sur SE 30 n'est pas affecté sur Ucon Oil tandis que **6***c* est séparé sans décomposition sur SE 30 de même que **7**′*c*.

La détermination des pourcentages d'adduits par cpv analytique n'est pleinement valable que si les températures de colonne sont suffisamment modérées pour empêcher toute décomposition liée à la fragilité de ces composés. La température de colonne pour de telles déterminations n'a jamais été supérieure à 60°C tandis que celle de l'injecteur était de l'ordre de 150°C. Il apparaît clairement qu'une température d'injecteur de 185°C suffit à modifier sensiblement les pourcentages.

[4]Les meilleurs résultats et la diminution des produits légers sont là encore obtenus avec un méthyllithium suffisamment concentré (solution dans l'éther de 0,7 à 1,0 *M*).

*Effet LIS*

L'effet LIS a été étudié sur les couples **5***t*/**5***c* et **8***t*/**8***c*. Le chélate Eu(dpm)$_3$ est additionné peu à peu sur le substrat dont la concentration est déterminée une fois pour toutes au départ. On mesure les déplacements chimiques induits $\Delta\delta$ et on représente les courbes $\Delta\delta = a(C_{Eu}/C_0)$ (Fig. 1) où $C_{Eu}$ et $C_0$ sont les concentrations en chélate et en substrat. Les valeurs de $\Delta\delta$ sont données dans le tableau 4.

*Spectres rmn $^{13}C$ de* **8***t et* **8***c*

Les spectres ont été enregistrés sur un spectromètre à impulsion Brücker WP 100. Les expériences ont été conduites en utilisant une fenêtre spectrale de 4500 Hz avec un temps d'acquisition de 0,9 s pour 8K points mémoire, une largeur d'impulsion de 5 μs (angle de 45°) avec un découplage par bruit de 3 W (mode BB, atténuateur 0,6 dB sur l'échelle 20 W). Les expériences de découplage sélectif ont été réalisées dans les mêmes conditions excepté le découpleur (mode CW, atténuation 20 dB sur l'échelle 20 W) à la fréquence exacte définie sur le spectre proton obtenu grâce à la bobine d'irradiation de la sonde $^{13}C$ (100, 132 MHz) avec taille mémoire de 8K, fenêtre spectrale de 1000 Hz, temps d'acquisition de 4,1 s, largeur d'impulsion de 2 μs). La détermination des constantes de couplage $^3J_{^{13}C-H}$ a été obtenue grâce à des expériences de "gated decoupling". Les conditions expérimentales restent identiques sauf pour le découpleur pulsé, en mode BB, pour lequel on a introduit un délai de 3 s. Les concentrations des solutions étudiées étaient les suivantes: **8***t* = 0,192 mol/l, **8***c* = 0,320 mol/l.

L'étude des spectres $^1H$ montre que $H^1$ et $Me^2$ sont bien isolés dans les deux composés. Les spectres rmn $^{13}C$ réalisés en découplage des protons par bruits montrent deux signaux très faibles correspondant aux carbones quaternaires $C^2$ et $C^3$. Les carbones porteurs de l'oxygène $C^1$ et $OCH_2$ apparaissent nettement plus déblindés, le méthyle de $OCH_2CH_3$ à champ le plus fort. Le découplage sélectif de $H^1$ permet de confirmer l'attribution du $C^1$ tandis que celui du $Me^2$ permet celle du $C^2$. Les carbones de $Me^3$ et $Me^4$ n'ont pas été attribués avec certitude mais il apparaît que le plus déblindé des deux est également le plus couplé. Les expériences de "gated decoupling" permettent ensuite d'analyser le signal du carbone du $Me^2$ et par conséquent d'observer les couplages $^3J_{^{13}C-H}$ entre $Me^2$ et $H^1$.

Résultats: δ de **8***t* (en ppm/TMS): $C^1$ (69,83), $C^2$ (49,97), $C^3$ (25,90), $Me^2$ (18,08), $Me^3$ et/ou $Me^4$ (23,08) et/ou (15,023), $OC\underline{H}_2$ (66,51), $OCH_2—C\underline{H}_3$ (14,63); $^3J_{^{13}C-H}$ ($Me^2—H^1$) ≤ 1.5 Hz. δ de **8***c*: $C^1$ (67,43), $C^2$ (50,35), $C^3$ (24,90), $Me^2$ (23,47), $Me^3$ et/ou $Me^4$ (21,07) et/ou (16,95), $OC\underline{H}_2$ (66,48), $OCH_2—C\underline{H}_3$ (14,98); $^3J_{^{13}C-H}$ ($Me^2—H^1$) = 3.7 Hz.

# Substituent effects in arosemibullvalene photochemistry: the methylcyclopropane rearrangement of 1,8-dimethylbenzosemibullvalene

CHRISTOPHER OWEN BENDER, DONALD LAVERNE BENGTSON, DOUGLAS DOLMAN, CAROLYN ELAINE L. HERLE, AND SEAMUS FRANCIS O'SHEA

*Department of Chemistry, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4*

Received January 11, 1982

CHRISTOPHER OWEN BENDER, DONALD LAVERNE BENGTSON, DOUGLAS DOLMAN, CAROLYN ELAINE L. HERLE, and SEAMUS FRANCIS O'SHEA. Can. J. Chem. **60**, 1942 (1982).

1,6- and 1,8-Dimethylbenzotricyclo[3.3.0.0$^{2,8}$]octa-3,6-diene (**16** and **14**) are the major semibullvalene products formed from acetophenone sensitized irradiations of the barrelenes 2,6- and 2,3-dimethyl-1,4-dihydro-1,4-ethenonaphthalene (**37** and **22**), respectively ($\Phi_{37\rightarrow16} = 0.65$; $\Phi_{22\rightarrow14} = 0.57$). The direct ($\Phi_{14} = 0.017$) or chlorobenzene sensitized ($\Phi_{14} = 0.12$) irradiation of **14** yields 2,3-benzo-5-methyl-6-methylenebicyclo[3.3.0]octa-2,7-diene (**17**), a transformation typical of methylcyclopropanes. Gas phase thermolysis (420°C/6 Torr) of **14** gives 6,7-dimethylbenzocyclooctatetraene (**15**). The direct irradiation ($\Phi_{39} = 0.003$) or the gas phase thermolysis (395°C/6 Torr) of **16** gives 6,9-dimethylbenzocyclooctatetraene (**39**). The rearrangement **14** → **17** is in accord with predictions based upon CNDO-CI calculations of changes in atom–atom interaction energies on excitation to the $S_1$ or $T_1$ excited states of **14**.

CHRISTOPHER OWEN BENDER, DONALD LAVERNE BENGTSON, DOUGLAS DOLMAN, CAROLYN ELAINE L. HERLE et SEAMUS FRANCIS O'SHEA. Can. J. Chem. **60**, 1942 (1982).

Diméthyl-1,6 et -1,8 benzotricyclo[3.3.0.0$^{2,8}$]octa-3,6-diène (**16** et **14**) sont les semibullvalènes principaux qui proviennent des irradiations sensibilisées par l'acétophénone des barrelènes dimethyl-2,6 et -2,3 dihydro-1,4 éthèno-1,4 naphtalène (**37** and **22**), respectivement ($\Phi_{37\rightarrow16} = 0.65$; $\Phi_{22\rightarrow14} = 0.57$). La photolyse directe ($\Phi_{17} = 0.017$) ou sensibilisée par le chlorobenzène ($\Phi_{17} = 0.12$) du **14** conduit au benzo-2,3 méthyl-5 méthylène-6 bicyclo[3.3.0]octa-2,7-diène (**17**), une transformation caractèristique des méthylcyclopropanes. La thermolyse en phase gazeuse (420°C/6 Torr) du **14** conduit au diméthyl-6,7 benzocyclooctatetraène (**15**). L'irradiation directe ($\Phi_{39} = 0.003$) ou la thermolyse en phase gazeuse du **16** (395°C/6 Torr) conduit au diméthyl-6,9 benzocyclooctatetraène (**39**). Le réarrangement **14** → **17** est en accord avec les prédictions qui proviennent de calculs des changements d'énergies d'interactions atome–atome de l'état excité singulet ou triplet de **14**.

## Introduction

Photoisomerizations of arosemibullvalenes (aro-SB's) have not been widely reported. Some rearrange efficiently to give cyclooctatetraene (COT) product (e.g. **1** → **2**, $\Phi = 0.4$ (1), **3** → **5**, $\Phi = 0.1$ (2); Scheme 1) while others show remarkable photostability (e.g. **7**, **8** (3), and **9** (4)), a property of current interest in connection with model organic photoisomer light energy storage devices (4).

In a previous paper we noted that the benzo-SB system was capable of undergoing an additional rearrangement, of the vinylcyclopropane type, to give isomeric SB, namely **10** → **12** (5), and more recently a further example has been found with the related derivative **11** (→ **13**).[1]

Since the photo-vinylcyclopropane rearrangement has thus far been observed only with benzo-SB's containing electron-withdrawing substituents at both C1 and C8, information on the effect of electron-donors at those positions was desired. Herein we report on the photochemistry of 3,4-benzo-1,8-dimethyltricyclo[3.3.0.0$^{2,8}$]octa-3,6-diene (**14**, i.e., 1,8-dimethylbenzo-SB). The selection of methyl as the donor group is additionally intriguing since it presents the opportunity for

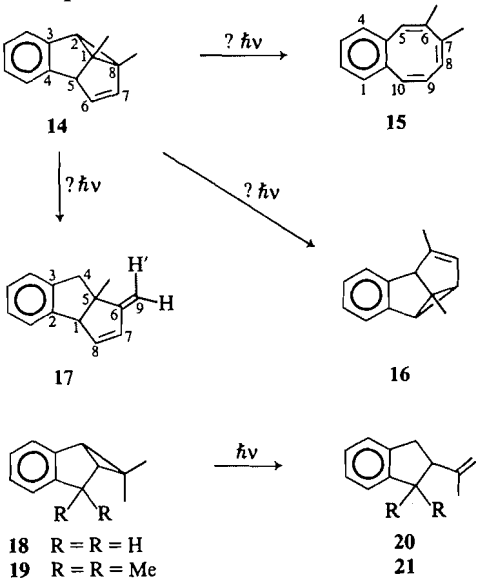
competition between three literature precedented photoisomerizations, each of which would lead to a different product. Transformation to COT **15** and/or SB **16** might be anticipated by analogy with the two known types of conversion discussed above (eqs. [2] and [3]; Scheme 1), and the third possibility is a methylcyclopropane 1,4-hydrogen migration to give conjugated diene **17** (Scheme 2). Although this latter type of isomerization has not been reported in an SB there are numerous examples of its occurrence in alkylphenylcyclopropanes (6), and of particular relevance are compounds **18** and **19** (7, 8) which are structurally similar to **14**.

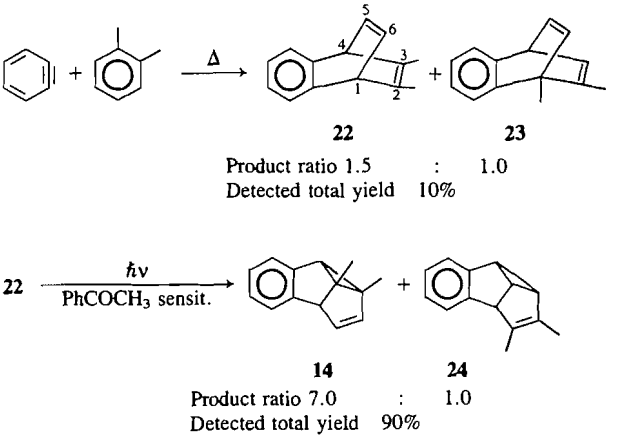
## Results

Compound **14** was obtained as the major product from the acetophenone sensitized photolysis of 2,3-dimethylbenzobarrelene (**22**), the latter being the major of the two possible barrelene products from benzyne addition to *o*-xylene (Scheme 3). The structures assigned to the benzo-SB's **14** and **24** follow from analytical data and comparison of $^1$Hmr spectra with parent benzo-SB (**4**) (9) (see Table 1).

On direct and on chlorobenzene sensitized irradiations, **14** gave, at low conversions, the methylcyclopropane 1,4-hydrogen migrated product **17** as the only detectable product. Glass capillary gas chromatography (GC-2) analyses during the progress of photolyses indicated that possible photoproducts **15** and **16** were absent; **15** and **16** were independently prepared (*vide infra*) and used for GC-2 comparison.



SCHEME 2



SCHEME 3

Attempts at sensitization with acetone led to the slow disappearance of **14** to give nonisomeric material. Both benzo-SB (**4**) (9) and 1-cyanobenzo-SB (**3**) (2) have been noted to behave similarly on attempted sensitization with acetone.

The structure of **17** was deduced from spectral data and from hydrogenation results. Mass spectral analysis indicated that the colourless oil **17** was isomeric with starting material **14**. The ir spectrum contains a moderately strong band at 1635 cm$^{-1}$ (cf. 1630 cm$^{-1}$ for the *exo*-conjugated model compound **25** (10)) and at 880 cm$^{-1}$, the latter band being characteristic for a 1,1-disubstituted vinyl. The uv spectrum shows strong absorption at $\lambda_{max}$ 237 nm (ε 11 700) which is attributed to the conjugated diene moiety (note $\lambda_{max}$ 234 nm (ε 17 900) for **25** (11)); this band is absent in uv spectra of the reduced compounds **29** and **30** (*vide infra*). The 400 MHz $^1$Hmr spectrum of **17** contains signals due to a methyl (s, δ1.39), two benzylic protons (AB q, δ3.13 and 3.01, $J_{AB}$ = 16.5 Hz), an allylic-benzylic proton (br s, δ3.98), and four olefinic protons centered at δ4.87, 4.97, 6.14, and 6.19. These olefinic chemical shift values compare well with those at lower resolution reported for the olefinic protons in **25** (11), i.e. δ4.79 (m, 2H) and δ6.12 (m, 2H). The $^1$Hmr data also provide additional support for the presence of a conjugated *s-trans* diene in **17**. Thus the large 1.4 Hz coupling between H-8 and H-9′ over a five bond conjugated zigzag pathway is close to the reported 1.3 Hz value between the corresponding protons in *s-trans*-butadiene (12).

It is to be noted that structures such as **26–28**, which are *a priori* alternatives for methylcyclopropane 1,4-hydrogen migration products from **14**, are not well accommodated by the uv and $^1$Hmr information. For example, **26** and **27** should show a

[c]Irradiation of H-6 collapsed H-5 and H-7 to singlets.
[d]Irradiation of H-1 collapsed H-5 to an s, and H-2 and H-8 to d's, $J_{2,8} = 6.5$. Irradiation of H-8 collapsed H-1 to a t, $J_{1,2} = J_{1,5} = 6.5$, and H-2 to a d, $J_{1,2} = 6.5$.
[e]Irradiation of H-7 collapsed H-8 to a d, $J_{2,8} = 6.5$, and changed the C6-methyl to a sharp s. Irradiation of the C6-methyl collapsed H-7 to a d, $J_{7,8} = 2.0$.

methyl doublet in the $^1$Hmr spectrum; **27** and **28** contain nonconjugated dienes.

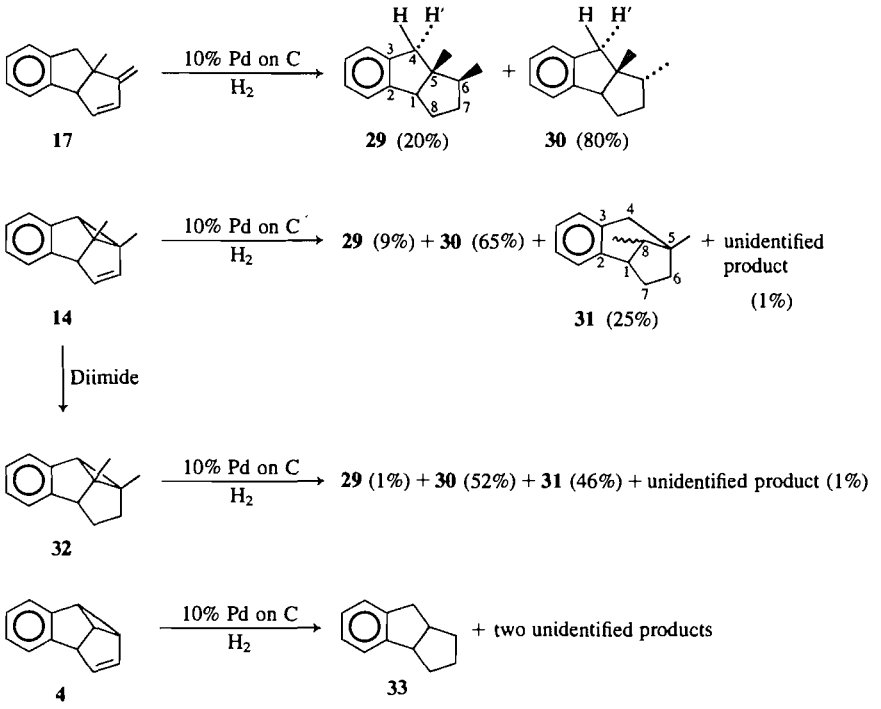
**25** **26**

**27** **28**

Further evidence for structure **17** was obtained from its catalytic hydrogenation at room temperature and pressure. The stereoisomers *syn*- and *anti*-2,3-benzo-5,6-dimethylbicyclo[3.3.0]oct-2-ene (**29** and **30**), containing four more hydrogens than **17**, were the only detectable products (Scheme 4). They were readily separated via preparative gc and were shown to be identical with two of the four components isolated from the atmospheric hydrogenation of **14**. In an additional experiment the alkene double bond in **14** was first reduced with diimide and the resulting product **32** was then catalytically hydrogenated. This procedure was employed in order to preclude the possibility that **14** undergoes rearrangement on the catalytic surface prior to reduction. Either reduction methodology, however, led to the same major components, but product ratios were modified somewhat. For the purposes of comparison it is noted that Zimmerman *et al.* (9) obtained the indane **33** as the major reduction product of benzo-SB (**4**), together with two unidentified components.

The uv spectrum of **33** ($\lambda_{max}$ 273 nm ($\varepsilon$ 925), 266 (857), and 260sh (699)) is similar to those of both **29** ($\lambda_{max}$ 273 nm ($\varepsilon$ 1900), 267 (1500), 265sh (1100), and 261 (870)) and **30** ($\lambda_{max}$ 273 nm ($\varepsilon$1720), 267 (1360), 265sh (1050), and 261 (810)). The 400 MHz $^1$Hmr spectra of **29** and **30** closely resemble each other. For the minor product (**29**) the aliphatic ring protons occur as eight separate one proton resonances, although H-7 (? H-7′) is partially obscured by the C-5 methyl singlet peak. The benzylic methylene protons, H-4 and H-4′, occur as an AB quartet ($J_{AB}$ = 16.5 Hz), while the C-6 methyl is a doublet ($J$ = 7 Hz). Spin decoupling of the C-6 methyl readily enabled identification of H-6 which was then shown to be further coupled only to H-7 and H-7′ ($J$ = 6 and 11 Hz). H-1 occurs as a quartet and it too is coupled to only two protons (H-8 and H-8′, $J$ = 10.5 and 2.3 Hz). Further double irradiations revealed that H-7, -7′, -8, and -8′ are all intercoupled. Thus strong evidence is afford for the presence of isolated partial structure **34** in compound **29**.

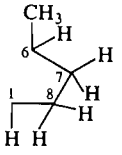
Interpretation of the 400 MHz $^1$Hmr spectrum of the major reduction product **30** was made in



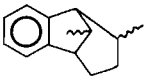
SCHEME 4

essentially the same manner as that used in the case of **29** (see Experimental), except that difficulties due to overlap of the H-7 and H-8′ signals in $CDCl_3$ solvent and of the H-6 and the H-8′ signals in $C_6D_6$ solvent did not permit definitive demonstration of coupling between H-7 and H-8′. Otherwise the double irradiation experiments are consistent with the presence of isolated partial structure **34** in **30**.

The major product **30** from the reduction of **17** is tentatively assigned the *anti* configuration of the



**34**



**35**

C-5 and C-6 methyls, and the minor product **29** the *syn* configuration, on the basis of the greater downfield shift of the H-4′ signal, due to *Van der Waals* deshielding by the C-6 methyl in the $^1$Hmr spectrum of **30** relative to that of H-4′ in **29**; the distance of closest approach of the C-6 methyl hydrogens to H-4′ is 0.9 Å in **30**, and 3.6 Å in **29** (Drieding Models).

The second major product from the reductions of SB **14** appears to be 2,3-benzo-5,8-dimethylbicyclo[3.2.1]oct-2-ene (**31**), arising from cleavage of the cyclopropyl C1—C2 bond. It cannot be **35**, which might result from C1—C8 cleavage, since the $^1$Hmr spectrum contains a methyl singlet and a methyl doublet.

In order to rule out the possible involvement of COT **15** and SB **16** (Scheme 2) in the direct and sensitized irradiations of **14**, their preparation and irradiation was undertaken.

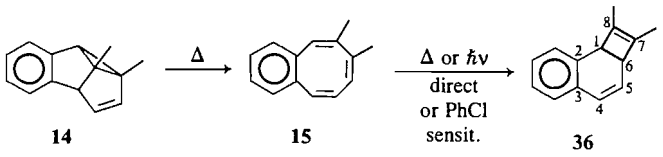
*Preparation and photolyses of COT 15*

COT **15** was conveniently prepared in ca. 80% yield via flash gas phase thermolysis of **14** (ca. 420°C, nitrogen carrier gas at 6 Torr); minor (< 20%) amounts of cyclobutene **36** were also obtained, depending upon the precise conditions (Scheme 5). Note that Paquette *et al.* (13) have investigated the benzo-COT/benzobicyclo[4.2.0]-octatriene thermal interconvertibility and additionally have reported an alternative preparation of COT **15**. However, **15** was not obtained pure by their route (14).

The structure of COT **15** was assigned from $^1$Hmr data. Besides resonances for two methyls, the $^1$Hmr spectrum showed absorptions only in the aromatic-olefinic region; H-5 occurs as a broad singlet, being allylically coupled to the C-6 methyl, and strong coupling is found between H-8, -9, and -10. H-8 is additionally complexed due to allylic coupling to the C-7 methyl.

Both the direct and chlorobenzene sensitized photolysis of **15** gave cyclobutene **36** as the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.



SCHEME 5

unique isomeric photoproduct at low conversions (Scheme 5).

*Preparation and photolyses of SB 16*

The preparation of **16** followed essentially the same procedure used above to obtain SB **14**, *o*-xylene being replaced by *m*-xylene in the benzyne addition stage (Scheme 6). The $^1$Hmr (Table 1) and analytical data are in full accord with structure **16**. The direct irradiation of **16** gave a single isomeric photoproduct, whose structure is assigned as **39** (see Experimental). Compound **39** was also obtained from the flash gas phase thermolysis of **16**.

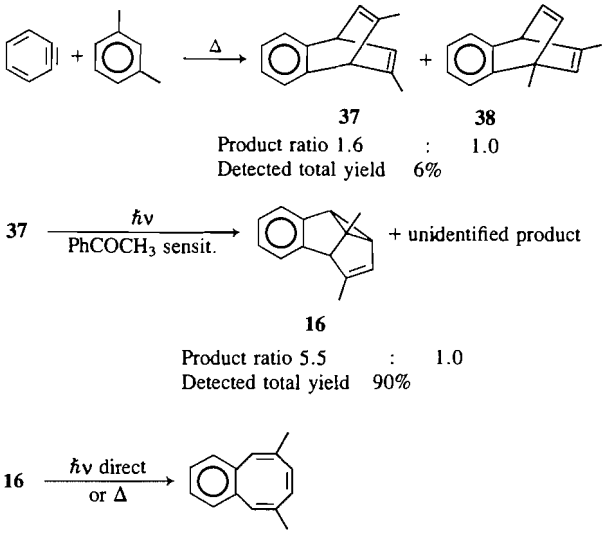
The results of chlorobenzene sensitized photolysis of **16** are quite different to those obtained upon direct irradiation. No COT **39** was detected, but a single and presently unidentified photoproduct appeared as a shoulder on the GC-2 peak of starting material **16**. On the preparative scale, the photoproduct was not separable from **16**. However, the 400 MHz $^1$Hmr spectrum of the photolysate revealed no **17** to be present, nor any other $C_{14}H_{14}$ isomer (except **16**) identified in this study.

*Singlet and triplet energies of 14 and quantum yields*

Since neither fluorescence (room temperature, cyclohexane) nor phosphorescence (77 K, ethanol–ether 4:1 glass) were detected for **14**, $E_{S_1}$ and $E_{T_1}$ could not be obtained by emission techniques. However, inspection of the uv spectrum of **14** indicates that $94 \leq E_{S_1} \leq 101$ kcal/mol, the onset of absorption being ca. 305 nm and $\lambda_{max}$ for the lowest energy peak 283 nm.

For $E_{T_1}$, an "effective" triplet energy at room temperature of $78 \leq E_{T_1} \leq 82$ kcal/mol is suggested by triplet sensitization experiments; the conversion of **14** to **17** can be sensitized efficiently ($\Phi$ = 0.12) by chlorobenzene ($E_{T_1}$ = 82 kcal/mol), but not by acetone ($E_{T_1}$ = 78 kcal/mol) nor by acetophenone ($E_{T_1}$ = 74 kcal/mol). Interestingly, theoretical calculations (CNDO/2-CI, *vide infra*) for the lowest excited states of **14** give the relative energy ratio 1.000 ($S_1$) : 0.840 ($T_1$), and if the uv data range of $94 \leq E_{S_1} \leq 101$ kcal/mol is used as the scaling factor, then one obtains $79 \leq E_{T_1} \leq 85$ kcal/mol, i.e., the triplet energy of **14** is predicted to be above that of acetone.

Quantum yields for all transformations observed in this study were determined on an optical bench arranged for beam splitting into ferrioxalate actinometer (15). The $\Phi$'s for substrate disappearance and for product appearance are given in Table 2. Oxygen at $[O_2] \simeq 10^{-2}$ *M* was found to quench the rearrangement of **14** to **17** at room temperature by ca. 5 ± 3%, whereas 2,5-dimethyl-2,4-hexadiene at concentrations up to $0.5 \times 10^{-2}$ *M* showed no measurable quenching.



SCHEME 6

## Discussion

The observation that neither COT **15** nor SB **16** nor any of their respective photoproducts was detected in the direct and chlorobenzene sensitized irradiations of **14** rules out significant participation of the known benzo-SB photoisomerizations described by eqs. [2] and [3] (Scheme 1). Photochemically then, **14** behaves as a typical methylphenylcyclopropane.

The excited state of **14** yielding **17** upon irradiation in neat chlorobenzene[2] ($E_{T_1}$ = 82 kcal/mol) is assumed to be the triplet (probably $T_1$) since the photoisomer is formed seven times more efficiently than when generated from direct irradiation in

[2]The use of chlorobenzene as a high energy sensitizer–solvent has been discussed by Zimmerman and Samuelson (16).

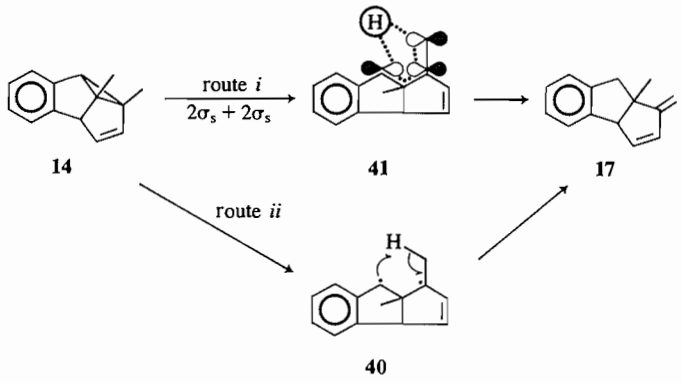
[a]Ferrioxalate actinometry; cyclohexane solvent. Φ's given are extrapolated to zero conversion; product analyses by GC-2 (internal hydrocarbon standard) at several conversions of ≤ 8%. Experimental error for Φ(disappearance) is ± 10%, and for Φ(product appearance) is ± 5%. For sensitized runs, sensitizers absorb > 95% of the incident light.
[b]Quantum yield calculated on the assumption that unidentified product is isomeric with starting material.



SCHEME 7

cyclohexane. If the quantum yield of intersystem crossing for chlorobenzene is taken to be 0.3 (17),[3] then the formation of **17** from $T_1$ of **14** appears to be a highly efficient process, i.e., $\Phi\, T_1\,(\mathbf{14}) \rightarrow \mathbf{17} = 0.4$.

In direct irradiations of **14**, the nature of the excited state species leading to **17** is not certain. Oxygen at $[O_2] \simeq 10^{-2}\,M$ showed only slight (≤5%) quenching of the reaction, suggesting a singlet excited state process. However, a short-lived $T_1$ state of lifetime ≃10 ns (at room temperature, with an assumed $k_q = 10^9\,M^{-1}\,s^{-1}$) cannot be ruled out.

With respect to mechanistic considerations, the formation of **17** from **14** can be accounted for in terms of a photo-allowed, concerted process involving a 4-electron (Möbius) cyclic array with zero nontrivial sign inversions (19), i.e., a $2\sigma_s + 2\sigma_s$ process (20), as shown in Scheme 7 (route *i*), or a two-step process beginning with homolysis of the C2—C8 bond of the cyclopropane ring, giving the benzylic and tertiary-allylic diradical intermediate (**40**), followed by intramolecular hydrogen atom transfer from the C-8 methyl to C-2 (route *ii*, Scheme 7). Note that mechanisms involving initial cleavage of the cyclopropane C1—C8 or C1—C2 bonds do not readily lead to the observed product **17**. Interestingly, CNDO/2-CI calculations of changes in atom–atom interaction energies for the lowest singlet and triplet excited states of **14** concur with the nonconcerted mechanistic analysis depicted by route *ii* (Scheme 7), i.e., the calculations indicate that the cyclopropane bond most weakened relative to the ground state is that between C2 and C8 (cf. cases 1, 3, and 5, Table 3; see Experimental for calculation details).

[3]Note that Bunce *et al.* (18) have recently obtained the value of $\Phi_{ISC} = 0.64$ for chlorobenzene, so that $\Phi T_1\,(\mathbf{14}) \rightarrow \mathbf{17}$ may be as low as 0.2.

## Experimental

The $^1$Hmr spectra were recorded on Bruker 200 or 400 MHz instruments or on a Varian (EM-360) 60 MHz instrument, with TMS as internal standard. The chemical shifts are in δ units and the coupling constants ($J$) in Hz. The abbreviations s, d, t, q, and m refer to singlet, doublet, triplet, quartet, and multiplet, respectively. The ir spectra were recorded on a Perkin–Elmer 337 spectrometer and are given in $cm^{-1}$. The uv spectra (run in cyclohexane solvent) were measured on a Cary 15 spectrometer; maxima are given in nm, with $\varepsilon_{max}$ values in parentheses; sh

TABLE 3. Changes[a,b] in atom–atom interaction energies (eV), between bound atoms, resulting from electronic excitation to the lowest singlet ($S_1$) and triplet ($T_1$) states of SB **14**

| Case | Atom–atom | $S_1$ | $T_1$ |
|---|---|---|---|
| 1 | 1–2 | 0.42 | −0.45 |
| 2 | 1–5 | 0.65 | 0.52 |
| 3 | 1–8 | 0.78 | 1.15 |
| 4 | 2–3 | −0.86 | 0.65 |
| 5 | 2–8 | 1.25 | 1.35 |
| 6 | 3–4 | 1.45 | 0.07 |
| 7 | 4–5 | 0.15 | 1.26 |
| 8 | 5–6 | −0.52 | −1.77 |
| 9 | 6–7 | 3.61 | 10.50 |
| 10 | 7–8 | −1.35 | −2.28 |

[a]Calculated by the CNDO/2-CI method using the theoretical parametization (21). Negative values are interpreted as "forces" tending to bring atoms together, while positive values cause the atoms to move further apart. Calculations on the full molecule **14** were performed; only values for the semibullvalene portion are given here. The underlined values are the most repulsive interactions (bond weakening) between the cyclopropane ring carbons.

[b]Relative theoretical energy ratios of the lower excited states of **14** are: $1.000(S_1):0.840(T_1):1.049(S_2):0.891(T_2)$.

= shoulder. Mass spectra were recorded on an MS 9 (A.E.I.) instrument at 70 eV. All melting points are uncorrected. Elemental analyses were performed by Galbraith Labs. Inc., Knoxville, TN. Fluorescence and phosphorescence studies were carried out on an Aminco–Bowman spectrometer. GC-2 analyses were made on a Varian 3700 instrument (FID) coupled to a Varian CDS 111 computing integrator, and fitted with an OV-101 glass capillary column, 50 m, with helium as carrier gas. Preparative gc separations were carried out on a Varian 2700 instrument (FID) on either a 20 ft × 0.375 in. 20% Carbowax 20M on 45–60 mesh Chromosorb W column or on a 20 ft × 0.375 in. 7.5% OV-101 on 45–60 mesh Chromosorb G column. Column chromatography was performed with Silicar CC-7 (100–200 mesh; Mallinckrodt), Silica Gel 60 (230–400 mesh; Merck), or Silica Gel H (100–200 mesh; Grace). Cyclohexane for photolyses was prepared by scrubbing with 10% of its volume of 30% fuming sulfuric acid, followed by washing with 10% aqueous sodium hydroxide, drying ($MgSO_4$), and finally distilling from calcium hydride. Chlorobenzene and acetophenone sensitizers and 2,5-dimethyl-2,4-hexadiene quencher were distilled prior to use.

*1,2- and 2,3-Dimethyl-1,4-dihydro-1,4-ethenonaphthalene (**23** and **22**)*

A 6 mL portion of isoamyl nitrite was added to a stirred, ice-cooled mixture of 3.5 g (25.5 mmol) of anthranilic acid and a catalytic quantity (70 mg) of trifluoroacetic acid in 35 mL of THF. The stirred mixture was allowed to warm to room temperature during 2 h. The resulting diazonium carboxylate salt was filtered under vacuum through a cotton plug fitted into a polypropylene funnel, washed with THF until the washings were colourless, and then with 1,2-dichloroethane (3 × 10 mL). The salt (WARNING! the dry solid is explosive), slurried in *o*-xylene (30 mL), was transferred to a 1 L round bottom flask and was diluted with 500 mL of *o*-xylene. The mixture was stirred at 50°C overnight under a dry nitrogen atmosphere, and then concentrated. The residue was dissolved in acetone (50 mL) and diluted with cyclohexane (500 mL). The resulting mixture was filtered, and the filtrate was concentrated. The residue was dissolved in benzene (20 mL) and column chromatographed on Silica Gel H (70 × 2 cm); elution was with 2.5% ether–cyclohexane. The first yellow band eluted was concentrated to give an oil which was analysed by GC-2; the ratio of the first and second major peaks eluted was 1.5 (**22**) : 1.0 (**23**), and corresponded to a total barrelene content of 449 mg (10%), as determined by calibration against standardized tridecane. Preparative gc (OV-101, 180°C) separation of the oil afforded 145.0 mg of **22**, mp 63–65°C and 70.3 mg of **23**, mp 36–38°C, after recrystallization of each from ethanol.

The spectral data for **22** were: ir (melt): 745 *o*-substituted benzenoid; uv: 247 sh (850), 257 (760), 264 (950), 271 (1 350), and 278 (1 470); $^1$Hmr (60 MHz, $CCl_4$): 6.58–7.08 (m, 6H, aromatic and vinyl), 4.24–4.48 (sym. m, 2H, H-1 and H-4), and 1.74 (s, 6H, methyls); spin decoupling experiments: irradiation of H-1(4) modified the 6.58–7.08 m, implanted in which was an s at 6.68 (H-5 and H-6); irradiation at 6.68 collapsed the H-1(4) m to an s. Mass spectrum showed molecular ion at *m/e* 182.1096 (92%); $C_{14}H_{14}$ requires 182.1096. *Anal.* calcd. for $C_{14}H_{14}$: C 92.26, H 7.74; found: C 92.43, H 7.78.

For **23**: ir (melt): 745 *o*-substituted benzenoid, 820 trisubstituted alkene; uv: 233 sh (1 070), 255 sh (630), 263 (660), 270 (890), and 277 (940); $^1$Hmr (400 MHz, $CDCl_3$): 7.14–7.19 (m, 2H, aromatics), 6.93–6.96 (m, 2H, aromatics), 6.93 (t, 1H, H-5, $J_{5,4}$ = 6.0, $J_{5,6}$ = 6.5), 6.50 (d × d, 1H, H-6, $J_{6,5}$ = 6.5, $J_{6,4}$ = 1.5), 6.48 (m, 1H, H-3), 4.74 (d × t, 1H, H-4, $J_{4,5} = J_{4,3}$ = 6.0, $J_{4,6}$ = 1.5), 1.94 (s, 3H, C1-methyl), and 1.83 (d, 3H, C2-methyl, $J_{3,Me}$ = 1.5); spin decoupling experiments: irradiation of the C2-methyl collapsed H-3 to a d ($J_{3,4}$ = 6.0); irradiation of H-4 collapsed H-3 to a broad s, and H-5 and H-6 to d's ($J_{5,6}$ = 6.5). Mass spectrum showed molecular ion at *m/e* 182.1096 (84%). *Anal.* found: C 92.25, H 7.83.

*1,3- and 2,6-Dimethyl-1,4-dihydro-1,4-ethenonaphthalene (**38** and **37**)*

Barrelenes **37** and **38** were prepared according to the procedure described above for the preparation of **22** and **23**, except that *o*-xylene was replaced by *m*-xylene. The crude mixture of barrelenes obtained from column chromatography was analysed by GC-2 which revealed the barrelenes to be eluted in the order and ratio of 1.6 (**37**) : 1.0 (**38**). Calibration via addition of standardized tridecane indicated 280 mg (6%) total barrelene production from 3.50 g of anthranilic acid. The barrelenes were difficult to separate from each other. On the preparative gc (OV-101, 180°C) the barrelene peaks coalesced, giving a broad envelope; the barrelenes were collected as one fraction (an oil, 244 mg). The oil was placed in a Craig tube (no solvent) and kept at −12°C for 7 days after which time 47.0 mg of **37**, mp 58–60°C (twice recrystallized from ethanol), were obtained upon centrifuging. The residual oil was resubmitted to preparative gc (Carbowax, 190°C) and **38** was obtained in small quantity from the tail of the barrelene envelope; short-path distillation (60°C/0.1 Torr) gave a colourless oil (GC-2 purity > 97%).

The spectral data of **37** were: ir (melt): 755 *o*-substituted benzenoid, 815 trisubstituted alkene; uv: 236 (1 190), 256 (740), 264 (810), 271 (1 130), and 278 (1 270); $^1$Hmr (60 MHz, $CCl_4$): 6.60–7.10 (m, 4H, aromatics), 6.10–6.35 (m, 2H, H-3 and H-5), 4.47 (t, 1H, H-4, $J_{3,4} = J_{5,4}$ = 5.5), 4.00–4.13 (m, 1H, H-1), and 1.87 (d, 6H, methyls, $J_{3(5),Me}$ = 1.5); spin decoupling experiment: irradiation of H-3(5) collapsed H-1, H-4 and the methyl signals to singlets. *Anal.* found: C 92.02, H 7.88.

For **38**: ir (film): 740 *o*-substituted benzenoid, 835 trisubstituted alkene; uv: 235 sh (1 120), 255 sh (660), 263 (690), 270 (920), and 277.5 (968); $^1$Hmr (400 MHz, $CDCl_3$): 7.14–7.18 (m, 2H, aromatics), 6.86–6.98 and 6.92 (m and t, 3H, remaining aromatics and H-5, $J_{5,4} = J_{5,6}$ = 6.5), 6.53 (d × d, 1H, H-6, $J_{6,4}$ = 1.5, $J_{6,5}$ = 6.5), 6.00–6.04 (m, 1H, H-2, $J_{2,4}$ = 2.0, $J_{2,C3\text{-}Me}$ = 1.7), 4.48–4.52 (m, 1H, H-4, $J_{4,5}$ = 6.5, $J_{4,2}$ = 2.0, $J_{4,6}$ = 1.5), 1.96 (s, 3H, C1-methyl), and 1.91 (d, 3H, C3-methyl, $J_{Me,2}$ = 1.7);

For personal use only.

spin decoupling experiments: irradiation of H-2 collapsed the C3-methyl to an s and H-4 to a d × d ($J_{4,5}$ = 6.5, $J_{4,6}$ = 1.5); irradiation of H-4 collapsed both H-5 and H-6 to d's ($J_{5,6}$ = 6.5); irradiation of H-6 collapsed H-5 to a d ($J_{4,5}$ = 6.5) and H-4 to a d × d ($J_{4,5}$ = 6.5, $J_{2,4}$ = 2.0); irradiation of the C3-methyl collapsed H-2 to a d ($J_{2,4}$ = 2.0). *Anal.* found: C 92.39, H 7.67.

*Preparative photolysis apparatus*

*Apparatus I*

The apparatus consisted of a 450 W Hanovia medium pressure mercury arc surrounded by a water-cooled quartz immersion well. For direct and chlorobenzene sensitized irradiations the light was filtered through a Corex sleeve. For acetophenone sensitized irradiations a Pyrex sleeve was used. Sample solutions were deoxygenated by flushing with argon, before and during irradiations.

*Apparatus II*

On an optical bench arrangement, the arc from an Osram HBO 100W/2 lamp, located at the focus of an elliptical reflector contained in a water-cooled ALH-215 Arc Lamp Housing (P.R.A.), was focussed (image size ≃ 2 mm) onto the inlet slit of a high radiance monochromator (A 200, P.R.A.). The monochromator exit light was passed directly into a cylindrical quartz cell containing the sample solution. Prior to irradiations, the solutions were deoxygenated by flushing with argon. A positive pressure of argon was maintained over the stirred solutions throughout the course of the irradiations.

*Sensitized photolysis of barrelene* ***22***

A stirred solution of 397.7 mg (2.19 mmol) of **22** and 2.0 g of acetophenone in 250 mL of cyclohexane was irradiated for 30 min in apparatus I. The photolysate was concentrated and the residue chromatographed on Silicar (50 × 2.5 cm) with cyclohexane solvent. The first band contained 356.2 mg (90%) of a mixture of 1,8- and 6,7-dimethylbenzotricyclo[3.3.0.$0^{2,8}$]octa-3,6-diene (**14** and **24**) in the ratio of 7.0 : 1.0, respectively (GC-2 analysis). The SB's were separated by preparative gc (OV-101, 180°C), **14** being eluted before **24**. Compound **14** (219.3 mg) was obtained as a colourless oil after short-path distillation at 55°C/0.1 Torr (GC-2 purity > 98%); uv:269 sh (900), 275 (1060), and 282.5 (890); $^1$Hmr, see Table 1. Mass spectrum showed molecular ion at *m/e* = 182.1095 (24%). *Anal.* found: C 92.12, H 7.88.

Compound **24** (20.6 mg) was also obtained as a colourless oil after short-path distillation at 60°C/0.1 Torr (GC-2 purity > 98%); uv:266 sh (1160), 273 (1070), and 282 (860); $^1$Hmr, see Table 1. Mass spectrum showed molecular ion at *m/e* = 182.1093 (95%).

*Direct irradiation of SB* ***14***

A stirred solution of 121.2 mg (0.67 mmol) of **14** in 250 mL of cyclohexane was irradiated in apparatus I for 30 min. The photolysate was concentrated and the residue chromatographed on Silicar (100 × 2 cm) with cyclohexane solvent. The first 200 mL of eluent was discarded, and thereafter 5 mL fractions were collected: fractions 10–20 contained 26.5 mg (22%) of an oily mixture of 2,3-benzo-5-methyl-6-methylenebicyclo[3.3.0]-octa-2,7-diene (**17**) and **14**, in the ratio of 11 : 1, respectively (GC-2 analysis); fractions 21–53 contained 76.7 mg (63%) of a mixture of **14** and **17** in the ratio of 8 : 1, respectively. The contents of fractions 10–20 were separated by preparative gc (OV-101, 180°C) and short-path distilled at 60°C/0.1 Torr to give 15.2 mg of **17** as a colourless oil (GC-2 purity > 98%), **17** being eluted after **14**.

For **17**: ir (film): 1635 conj. C=C, and 880 C=$CH_2$; uv: 237 (11200), 265 sh (1200), 267 (1440), and 273 (1600); $^1$Hmr (400 MHz, $CDCl_3$): 7.14–7.25 (m, 4H, aromatics), 6.17–6.21 (m, 1H, H-8), 6.12–6.15 (broad d × d, 1H, H-7, $J_{7,1}$ = 1.8, $J_{7,8}$ = 5.5), 4.97 (broad s, 1H, H-9), 4.87 (broad s, 1H, H-9'), 3.98 (broad s, 1H, H-1), 3.13 (d, 1H, H-4, $J_{4,4'}$ = 16.5), 3.01 (d, 1H, H-4', $J_{4',4}$ = 16.5), and 1.39 (s, 3H, methyl); spin decoupling experiments: irradiation of H-1 modified H-8 (d of m, $J_{7,8}$ = 5.5), H-7 (broad d, $J_{7,8}$ = 5.5), H-9, and H-9'; irradiation of H-9 modified H-8 (d × q, $J_{7,8}$ = 5.5, $J_{1,8}$ = 2.7, and $J_{8,9'}$ = 1.4), H-7 (d × q, $J_{7,8}$ = 5.5, $J_{1,7}$ = 1.8, $J_{7,9'}$ = 0.7), H-9' and H-1; irradiation of H-9' modified H-8 (d × q, $J_{1,8}$ = 2.7, $J_{7,8}$ = 5.5, $J_{8,9}$ ≃ 0.5), H-7 (d × d, $J_{1,7}$ = 1.8, $J_{7,8}$ = 5.5, $J_{7,9}$ < 0.5), H-9 and H-1. Mass spectrum showed molecular ion at *m/e* = 182.1093 (95%). *Anal.* found: C 92.41, H 7.79.

*Sensitized irradiation of SB* ***14***

A stirred solution of 134.3 mg (0.74 mmol) of **14** in 250 mL of chlorobenzene was irradiated in apparatus I for 10 min. The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (90 × 2 cm) with cyclohexane; the first 700 mL of eluent was discarded and thereafter 10 mL fractions were collected. Fractions 11–18 contained 9.7 mg (7%; GC-2 purity 98%) of colourless oil identical (GC-2, nmr, ir) to **17**; fractions 19–35 contained 104.8 mg (78%) of recovered **14** (GC-2 purity 97%).

*Catalytic reduction of SB* ***14***

A stirred mixture of 57.6 mg (0.32 mmol) of **14** and 28.4 mg of 10% Pd on C in 6 mL of methanol was hydrogenated at room temperature and pressure during 24 h. The catalyst was removed (centrifuge) and the resulting solution concentrated to give 56.9 mg of oil, gc (Carbowax, 160°C) analysis of which showed four peaks, eluted in the order: unidentified product (1%), **29** (9%), **30** (65%), and **31** (25%). The three major components of the oil were separated by preparative gc (Carbowax) giving 2.2 mg (4%) of **29**, 16.9 mg (29%) of **30**, and 7.7 mg (13%) of **31**, each being a colourless oil of GC-2 purity > 98%.

For **29**: uv: 212 (9250), 217 (8050), 247 sh (275), 254 sh (465), 261 (870), 265 sh (1100), 267 (1500), and 273 (1900); $^1$Hmr (400 MHz, $CDCl_3$): 7.07–7.18 (m, 4H, aromatics), 3.14 (q, 1H, H-1, *J* = 10.5 and 2.3), 2.98 (d, 1H, H-4, $J_{4,4'}$ = 16.5), 2.38 (d, 1H, H-4', $J_{4',4}$ = 16.5), 1.95–2.05 (m, 1H, H-8), 1.70–1.78 (m, 1H, H-6), 1.62–1.70 (m, 1H, H-7), 1.54–1.60 (m, 1H, H-8'), 1.14–1.26 and 1.17 (m and s, 4H, H-7' and C5-methyl), and 0.99 (d, 1H, C6-methyl, $J_{Me,6}$ = 7.0); spin decoupling experiments: irradiation of H-1 modified H-8 and H-8'; irradiation of H-4 collapsed H-4' to an s; irradiation of H-8 collapsed H-1 to a broad s and modified H-8', H-7, and H-7'; irradiation of H-6 collapsed the C6-methyl to an s and modified H-7 and H-7'; irradiation of H-7 modified H-6, -7', -8, and -8'; irradiation of H-8' collapsed H-1 to a d (*J* = 10.5), and modified H-7, -7', and -8; irradiation of H-7' modified H-6, -7, -8, and -8'; irradiation of C6-methyl collapsed H-6 to a q (*J* = 6 and 11). Mass spectrum showed molecular ion at *m/e* = 186.1412 (100%), $C_{14}H_{18}$ requires 186.1409.

For **30**: uv: 212 (8750), 216 (7550), 248 sh (220), 254 sh (440), 261 (810), 265 sh (1050), 267 (1360), and 273 (1720); $^1$Hmr (400 MHz, $CDCl_3$): 7.09–7.18 (m, 4H, aromatics), 3.21 (q, 1H, H-1, *J* = 10.0 and 4.0), 2.85 (d, 1H, H-4, $J_{4,4'}$ = 16.5), 2.73 (d, 1H, H-4', $J_{4',4}$ = 16.5), 2.21–2.31 (m, 1H, H-8), 1.70–1.79 (m, 1H, H-7), 1.60–1.70 (m, 2H, H-8' and H-8), 1.41–1.50 (m, 1H, H-7'), 1.07 (s, 3H, C5-methyl), and 0.95 (d, 3H, C6-methyl, $J_{Me,6}$ = 7.0); spin decoupling experiments: irradiation of H-1 modified H-8 and the overlapping H-6 and H-8' m's; irradiation of H-8 collapsed H-1 to a broad s, and modified H-7, H-7', and the overlapping H-6 and H-8' m's; irradiation of H-7' modified H-7, H-8, and the overlapping H-6 and H-8' m's; irradiation of the C6-methyl modified the overlapping H-6 and H-8' m's; $^1$Hmr (400 MHz, $C_6D_6$): 7.04–7.18 (m, 4H, aromatics), 3.07 (q, 1H, H-1, *J* = 10.0 and 3.5), 2.72 (d, 1H, H-4, $J_{4,4'}$ = 16.5), 2.57

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

(d, 1H, H-4', $J_{4',4}$ = 16.5), 2.07–2.16 (m, 1H, H-8), 1.56–1.66 (m, 2H, H-7 and H-8'), 1.47–1.56 (m, 1H, H-6), 1.27–1.37 (m, 1H, H-7'), 0.90 (s, 3H, C5-methyl), and 0.82 (d, 3H, C6-methyl, $J_{Me,6}$ = 7.0); spin decoupling experiments: irradiation of H-1 modified H-8 and the overlapping H-7 and H-8' m's; irradiation of H-8 collapsed H-1 to a broad s, and modified the overlapping H-7 and H-8' m's and H-7'; irradiation of H-7' modified H-6, H-8, and the overlapping H-7 and H-8' m's; irradiation of the C6-methyl collapsed H-6 to a q ($J$ = 11.0 and 6.0). Mass spectrum showed molecular ion at $m/e$ = 186.1410 (100%). *Anal.* calcd. for $C_{14}H_{18}$: C 90.26, H 9.74; found: C 90.08, H 9.93.

For **31**: uv: 213 (8700), 216 sh (7800), 249 sh (150), 254 sh (270), 259 (470), 262 (470), 266 (730), and 273 (900); $^1$Hmr (400 MHz, $CDCl_3$): 6.94–7.10 (m, 4H, aromatics), 2.90 (d, 1H, H-4, $J_{4,4'}$ = 16.5), 2.72 (d, 1H, H-1, $J_{1,7}$ = 6.5), 2.67 (d, 1H, H-4', $J_{4',4}$ = 16.5), 2.12–2.22 (m, 1H, H-7), 1.86 (q, 1H, H-8, $J_{8,Me}$ = 7.0), 1.52–1.68 (m, 3H, H-6, H-6' and H-7'), 1.12 (s, 3H, C5-methyl), and 0.98 (d, 3H, C8-methyl, $J_{Me,8}$ = 7.0); spin decoupling experiments: irradiation of the C8-methyl collapsed H-8 to an s; irradiation of H-7 collapsed H-1 to an s and modified the overlapping H-6, H-6', and H-7' m's; irradiation of H-4 collapsed H-4' to an s. Mass spectrum showed molecular ion at $m/e$ = 186.1407 (100%).

*Catalytic reduction of diene* ***17***

A stirred mixture of 13.0 mg (0.07 mmol) of **17** and 11.7 mg of 10% Pd on C in 5 mL of methanol was hydrogenated at room temperature and pressure during 4 h. The catalyst was removed (centrifuge) and the resulting solution concentrated to give 12.3 mg of an oil, gc (Carbowax, 160°C) analysis of which showed two peaks of relative area 1 (**29**) : 4 (**30**). Preparative gc separation gave 1.6 mg (12%) of colourless oil identical (gc, $^1$Hmr, ir) to **29**, and 6.2 mg (47%) of colourless oil identical (gc, $^1$Hmr, ir) to **30**.

*Diimide reduction of SB* ***14***

To a stirred mixture of 97.6 mg (0.54 mmol) of **14** and 1.0 g (5.16 mmol) of potassium azodicarboxylate in 20 mL of methanol at −30°C, 2 mL of acetic acid was added in one portion. The reaction mixture was allowed to warm to room temperature during 1.25 h after which time the solution was added to 200 mL of cyclohexane and was washed with 5% aqueous sodium hydroxide (200 mL) followed by water (2 × 200 mL). The cyclohexane solution was dried ($MgSO_4$), concentrated, and the residue column chromatographed on Silicar (35 × 2 cm) with cyclohexane solvent. The contents of the first band were short-path distilled (80°C/0.1 Torr) to give 72.4 mg (73%) of 3,4-benzo-1,8-dimethyltricyclo[3.3.0.$0^{2,8}$]oct-3-ene (**32**) as a colourless oil (GC-2 purity > 97%); uv: 229 (4350), 261 sh (470), 268 sh (790), 273 (1070), and 281.5 (1100); $^1$Hmr (400 MHz, $CDCl_3$): 6.95–7.18 (m, 4H, aromatics), 3.28 (broad d, 1H, H-5, $J_{5,6}$ = 5.5), 2.10–2.19 (m, 1H, H-6), 1.86 (s, 1H, H-2), 1.57 (d × q, 1H, H-6', $J_{6',5}$ = 1.5, $J_{6',6}$ = 12.0, $J_{6',7}$ = 8.5, $J_{6',7'} \simeq 0$), 1.37–1.50 and 1.39 (m and s, 5H, H-7, H-7', and methyl), and 1.24 (s, 3H, methyl); spin decoupling experiments: irradiation of H-5 collapsed H-6 to six lines (1;1;2;2;1;1; $J$ = 12.0, $J$ = 11.0, $J$ = 9.0) and H-6' to a q ($J$ = 12 and 8.5); irradiation of H-6 collapsed H-5 to a d ($J_{5,6'}$ = 1.5) and modified the overlapping H-7 and H-7' m's, and H-6' (incomplete decoupling). Mass spectrum showed molecular ion at $m/e$ = 184.1248 (26%), $C_{14}H_{16}$ requires 184.1253. *Anal.* calcd. for $C_{14}H_{16}$: C 91.25, H 8.75; found: C 91.49, H 8.51.

*Catalytic reduction of* ***32***

A stirred mixture of 47.3 mg (0.26 mmol) of **32** and 28.8 mg of 10% Pd on C in 8 mL of methanol was hydrogenated at room temperature and pressure during 24 h. The catalyst was removed (centrifuge) and the solution concentrated to give 42.3 mg of an oil, gc (Carbowax, 160°C) analysis of which showed the same four peaks as in the case of the catalytic reduction of **14**, the relative areas being 1 (unknown) : 1 (**29**) : 52 (**30**) : 46 (**31**). Preparative gc separation of the two major components followed by short-path distillation gave 15.7 mg (33%) of an oil identical (gc, $^1$Hmr, ir) to **30**, and 10.2 mg (22%) of an oil identical (gc, $^1$Hmr, ir) to **31**.

*Gas phase thermolysis of* ***14***

Over a 1 h period 94.4 mg (0.52 mmol) of **14** was sublimed into a Pyrex tube (30 × 2 cm) packed with glass beads (0.5 cm diameter) maintained at 420°C. The pressure in the system was kept at 6 Torr by the passage of nitrogen. The thermolysis product was collected in a cooled U-trap (Dry Ice – acetone) to give 92.6 mg of an oil, GC-2 analysis of which showed three major peaks, eluted in the order and ratio of 1 (**14**) : 8 (**15**) : 2 (**36**). The oil was chromatographed on Silica Gel 60 (90 × 2 cm) with cyclohexane solvent. The first 300 mL of eluent was discarded, and thereafter 10 mL fractions were collected: fractions 3–8 gave 12.4 mg (13%) of 2,3-benzo-7,8-dimethylbicyclo[4.2.0]-octa-2,4,7-triene (**36**) as a colourless oil after short-path distillation at 55°C/0.1 Torr (GC-2 purity 100%); uv: 273 (5650), 283 (5200), 290 sh (3250), 295 sh (2400), and 303 (1400); $^1$Hmr (400 MHz, $CDCl_3$): 6.95–7.13 (m, 4H, aromatics), 6.22 (d, 1H, H-4, $J_{4,5}$ = 10), 5.94 (q, 1H, H-5, $J_{5,4}$ = 10, $J_{5,6}$ = 4.5), 3.76 (broad s, 1H, H-1, $J_{1,6}$ = 4.5, $J_{1,C8\text{-}Me} \simeq$ 1.0), 3.43 (broad s, 1H, H-6, $J_{6,5}$ = $J_{6,1}$ = 4.5, $J_{6,C7\text{-}Me} \simeq$ 1.0), 1.65 (broad s, 3H, C8-methyl), and 1.55 (broad s, 3H, C7-methyl); spin decoupling experiments: irradiation of H-5 collapsed H-4 to an s; irradiation of H-1 modified both methyls; irradiation of H-6 collapsed H-5 to a d ($J_{4,5}$ = 10) and both methyl signals were modified; irradiation of the C8-methyl collapsed H-1 to a d ($J_{1,6}$ = 4.5) and modified the C7-methyl; irradiation of the C7-methyl collapsed H-6 to a t ($J_{1,6}$ = $J_{5,6}$ = 4.5) and modified the C8-methyl. Mass spectrum showed molecular ion at $m/e$ = 182.1093 (100%); fragmentation peak at 128 (76%) corresponding to the loss of dimethylacetylene from molecular ion.

Fractions 10–19 gave, after short-path distillation (55°C/0.1 Torr), 56.2 mg (60%) of 6,7-dimethylbenzocyclooctatetraene (**15**) as a colourless oil (GC-2 purity 98%); uv: 228 (19000), 268 sh (1550), and 280 sh (1350); $^1$Hmr (200 MHz, $CDCl_3$): 6.95–7.22 (m, 4H, aromatics), 6.52 (broad d, 1H, H-10, $J_{10,9}$ = 11.5, $J_{10,8}$ = 0.6), 6.28 (broad q, 1H, H-5, $J_{5,C6\text{-}Me}$ = 1.5), 6.03 (d × m, 1H, H-9, $J_{9,10}$ = 11.5, $J_{9,8}$ = 3.6, $J_{9,C7\text{-}Me}$ = 1.5), 5.53–5.59 (m, 1H, H-8, $J_{8,9}$ = 3.6, $J_{8,C7\text{-}Me}$ = 1.5, $J_{8,10}$ = 0.6), 1.94 (d, 3H, C6-methyl, $J_{C6\text{-}Me,5}$ = 1.5), and 1.78 (t, 3H, C7-methyl, $J_{C7\text{-}Me,8}$ = $J_{C7\text{-}Me,9}$ = 1.5); spin decoupling experiments: irradiation of H-9 collapsed H-10 to a broad s, the C7-methyl to a d ($J_{8,C7\text{-}Me}$ = 1.5), and modified H-8; irradiation of H-10 collapsed H-9 to a single m and modified H-8; irradiation of H-5 collapsed the C6-methyl to an s; irradiation of H-8 collapsed the C7-methyl to a d ($J_{9,C7\text{-}Me}$ = 1.5) and modified H-10 to a sharp d ($J_{9,10}$ = 11.5) and H-9 to a d × q ($J_{9,10}$ = 11.5, $J_{9,C7\text{-}Me}$ = 1.5); irradiation of the C6-methyl collapsed H-5 to an s; irradiation of the C7-methyl collapsed both H-9 to a d × d ($J_{9,10}$ = 11.5, $J_{8,9}$ = 3.6) and H-8 to a d × d ($J_{8,9}$ = 3.6, $J_{8,10}$ = 0.6). Mass spectrum showed molecular ion at $m/e$ = 182.1093 (98%).

*Direct irradiation of COT* ***15***

A stirred solution of 72.3 mg (0.40 mmol) of **15** in 250 mL of cyclohexane was irradiated in apparatus I for 12 min. The photolysate which contained two components in the ratio of 1 (**36**) : 8.5 (**15**) (GC-2 analysis) was concentrated *in vacuo* and the residue chromatographed on Silica Gel 60 (90 × 2 cm) with cyclohexane solvent. The first band off the column gave, after short-path distillation (55°C/0.1 Torr), 4.7 mg (6.5%) of an oil, identical to **36**. The second band gave 57.2 mg (79%) of recovered **15**.

For personal use only.

*Sensitized irradiation of COT 15*

Because of extensive direct light absorption by **15** at wavelengths greater than 300 nm when neat chlorobenzene was used as sensitizer, the monochromator preparative apparatus II was used.

A solution of 47.1 mg (0.26 mmol) of **15** in 15 mL of chlorobenzene was photolysed for a total of 48 h with the monochromator settings of $\lambda$ = 275 nm, input slit = 2.5 mm, and bandwidth = 10 nm. The photolysate was concentrated and the residue was worked up as in the case of the direct irradiation of COT **15** to give 3.1 mg (7%) of an oil identical to **36** and 30.9 mg (66%) of recovered **15**.

*Sensitized photolysis of barrelene 37*

A stirred solution of 137.0 mg (0.75 mmol) of **37** and 2.5 g of acetophenone in 250 mL of cyclohexane was irradiated in apparatus I for 30 min. The photolysate was concentrated and the residue chromatographed on Silicar (50 × 2.5 cm) with cyclohexane. The first band contained 123.4 mg (90%) of an oily mixture of 1,6-dimethylbenzotricyclo[3.3.0.$0^{2,8}$]octa-3,6-diene (**16**) and an unidentified compound in the ratio of 5.5 : 1.0, respectively (GC-2 analysis). The first major band eluted from preparative gc (OV-101, 170°C) of the oil gave, after short-path distillation at 60°C/0.1 Torr, 82.7 mg of **16** as a colourless oil (GC-2 purity > 98%); ir (film): 815 trisubstituted alkene; uv: 268 sh (910), 274.5 (1 030), and 282 (860); $^1$Hmr, see Table 1. Mass spectrum showed molecular ion at $m/e$ = 182.1098 (77%).

*Gas phase thermolsis of 16*

Over a 1.5 h period, 85.0 mg (0.47 mmol) of **16** was thermolysed at 395°C and at 6 Torr of nitrogen in the apparatus described above for the gas phase thermolysis of **14**. An oil (82.3 mg) was obtained, GC-2 analysis of which showed two major components, eluted in the order and ratio of 1.5 (**16**) : 1.0 (**39**). The oil was separated by preparative gc (OV-101, 180°C) to give 32.9 mg (39%) of recovered **16**, and, after short-path distillation at 70°C/0.1 Torr, 19.6 mg (23%) of 6,9-dimethylbenzocyclooctatetraene (**39**) of GC-2 purity 100%; uv: 234.5 (19 000), 273 sh (1 300), and 283 sh (1 000); $^1$Hmr (60 MHz, $CCl_4$): 6.62–7.12 (m, 4H, aromatics), 6.21 (broad s, 2H, H-5(10)), 5.62 (s, 2H, H-7(8)), and 1.82 (d, 6H, methyls, $J_{5(10),Me}$ = 1.5); spin decoupling experiments: irradiation of the methyl doublet modified H-5(10) to a sharp s. Mass spectrum showed molecular ion at $m/e$ = 182.1094 (93%).

*Direct irradiation of SB 16*

A stirred solution of 78.3 mg (0.43 mmol) of **16** in 250 mL of cyclohexane was irradiated in apparatus I for 1.5 h. The photolysate, which contained two components in the ratio of 1 (**39**) : 6 (**16**) (GC-2 analysis) was concentrated *in vacuo*, passed down a short column of Silicar with cyclohexane solvent to remove polymeric material, and then separated by preparative gc (OV-101, 180°C). The first component gave 29.7 mg (38%) of recovered **16**, while the second gave 3.9 mg (5%) of an oil identical to **39**.

*Sensitized irradiation of SB 16*

A solution of 61.3 mg (0.34 mmol) of **16** in 15 mL of chlorobenzene was photolysed for a total of 72 h in apparatus II, with monochromator settings of $\lambda$ = 275 nm, input slit = 2.5 mm, and bandwidth = 10 nm. The progress of photolysis was followed by GC-2 analysis which revealed the buildup of a product eluting from the column as an after shoulder on the starting material (**16**) peak. The photolysis was stopped when the ratio of **16** to unknown product was 5 : 1. The photolysate was then concentrated *in vacuo* and the residue chromatographed on Silicar (75 × 1.5 cm) with cyclohexane solvent; no separation of the unknown photoproduct from **16** was apparent from GC-2 analysis of eluent fractions. Those fractions containing **16** and the unknown were combined and short-path distilled (65°C/0.1 Torr) to give 24 mg of colourless oil. The $^1$Hmr (400 MHz) spectrum of the oil contained no peaks characteristic of **17**. Preparative gc on Carbowax or on OV-101 columns provided no separation of the oil into its components.

*Quantum yield determinations*

Quantum yields were performed on an optical bench using the light source and monochromator system described for the preparative photolysis apparatus II. Attached to the exit slit of the monochromator was a black aluminum housing within which a portion of the radiation was reflected by a thin quartz beam splitter onto a 4 mL cylindrical quartz cell containing ferrioxalate actinometer (15), while the main radiation beam entered a 4 mL cylindrical cell containing the sample solution. Beam splitter ratios at 275 nm and at 313 nm were determined by placing actinometer solutions in both cells. Sample solutions at concentrations of ca. $2 \times 10^{-3} M$ were deoxygenated prior to irradiation by flushing with argon. A positive pressure of argon was maintained over the stirred solutions throughout the course of the irradiations. For further experimental details see Table 2.

*Quenching experiments*

Sample solutions of $5 \times 10^{-3} M$ **14** in cyclohexane in the presence of 0 to $0.5 \times 10^{-2} M$ 2,5-dimethyl-2,4-hexadiene (with argon flushing of solutions) or oxygen at ca. $10^{-2} M$ concentration were irradiated in a turntable reactor with Corex-filtered light provided by a 450 W Hanovia medium pressure mercury arc. The product formation (**17**) was determined by GC-2 analysis with *n*-pentadecane as internal standard. Quenching was discernible only in the case when oxygen was the quencher, to the extent of ca. 5 ± 3%.

*Calculations*

Although the calculations were performed as previously described (2, 23), two points require comment. Attempts to optimize the geometry of SB **14** led to unsatisfactory results, because the bridgehead angle, C4—C5—C6, closed to unreasonably small values. This is due to a well-known deficiency in the CNDO (and INDO) method, and results from the use of a single coulomb integral to represent the interaction between electrons on different atoms; by making the interaction between electrons in *p* orbitals the same as the interactions between electrons in *s* orbitals, the balance between $\sigma$ and $\pi$ type interactions is lost. In the present case the interaction between the unsaturated centres at C4 and C6 is overstabilized, causing the angle to be reduced at the bridgehead. To overcome this problem, the C4—C5—C6 angle was fixed at 101.3°, the value determined by X-ray techniques for 1-cyanosemibullvalene (22), and the remainder of the structure optimized. The other aspect requiring discussion is the conformation of the methyl groups in **14**. Because of their positions on the cyclopropyl ring, there is some possibility that they might influence the position at which the ring opens. However, a series of calculations for varying conformations shows clearly that the methyl groups influence neither the pattern of changes in the atom–atom energies nor the excitation energies. The data in Table 3 refer to a near optimum conformation of the methyl groups.

# Enthalpies of interaction of polar and nonpolar molecules with aromatic solvents

RICHARD FUCHS, L. ALAN PEACOCK, AND W. KIRK STEPHENSON
*Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.*

Received February 9, 1982

RICHARD FUCHS, L. ALAN PEACOCK, and W. KIRK STEPHENSON. Can. J. Chem. **60**, 1953 (1982).

Enthalpies of solution of representative ketones, phenols, alcohols, and ethers have been determined in α,α,α-trifluorotoluene, benzene, toluene, and mesitylene, and combined with heats of vaporization to give enthalpies of transfer from vapor to the aromatic solvents [$\Delta H(v \rightarrow S)$]. Comparison of these values with $\Delta H(v \rightarrow S)$ of nonpolar model compounds provides an estimate of the special interactions (dipole – induced dipole or charge transfer, and hydrogen bonding) of the polar solutes with each aromatic solvent. Unless the model compound is perfectly matched, an alternative procedure, the pure base method, is superior for evaluating hydrogen bonding.

The special interactions of ketones and ethers with aromatic solvents increase with decreasing π electron density of the solvent. By contrast, *m*-cresol shows the strongest special interaction with the most electron-rich solvent (mesitylene > toluene > benzene > trifluorotoluene). These results demonstrate that —OH and —OR groups undergo quite different interactions, and that a distinctive interaction occurs between the hydroxyl group and the aromatic ring.

Calorimetric heats of vaporization have been measured for the solutes *n*-butyl ether (10.68 ± 0.02 kcal/mol), 2,2,4,4-tetramethylpentane (9.20 ± 0.03), *n*-pentane (6.36 ± 0.02), 1-butanol (12.46 ± 0.00), and 2-methyl-2-butanol (11.94 ± 0.02).

RICHARD FUCHS, L. ALAN PEACOCK et W. KIRK STEPHENSON. Can. J. Chem. **60**, 1953 (1982).

On a déterminé les enthalpies de solutions de cétones, de phénols, d'alcools et d'éthers représentatifs dans le α,α,α-trifluorotoluène, le benzène, le toluène et le mésytilène et on les a combinées aux chaleurs de vaporisation pour obtenir les enthalpies de transfert de la phase vapeur aux solvants aromatiques [$\Delta H(v \rightarrow S)$]. La comparaison de ces valeurs avec le $\Delta H(v \rightarrow S)$ de composés modèles non polaires fournit une évaluation des interactions spéciales (dipôle-dipôle induit ou transfert de charge, et liaison hydrogène) des solutés polaires avec chaque solvant aromatique. A moins que le composé modèle corresponde parfaitement, une méthode alternative, la méthode de base pure, est de loin la meilleure pour évaluer la liaison hydrogène. Les interactions spéciales des cétones et des éthers avec les solvants aromatiques augmentent lorsque diminue la densité des électrons π du solvant. Au contraire, le *m*-crésol montre les interactions spéciales les plus fortes avec les solvants les plus riches en électrons (mésitylène > toluène > benzène > trifluorotoluène). Ces résultats démontrent que les groupes OH et OR subissent des interactions très différentes et qu'une interaction distincte se produit entre le groupe hydroxyle et le cycle aromatique.

On a mesuré par calorimétrie les chaleurs de vaporisation des solutés: éther *n*-butylique (10,68 ± 0,02 kcal/mol), tétraméthyl-2,2,4,4 pentane (9,20 ± 0,03), *n*-pentane (6,36 ± 0,02), butanol-1 (12,46 ± 0,00) et méthyl-2 butanol-2 (11,94 ± 0,02).

[Traduit par le journal]

Hydrogen bonding of phenols to aromatic hydrocarbons is a phenomenon which has been examined by infrared spectroscopy and by the calorimetric pure base method (1). Calorimetric measurements of these weak interactions at *high dilution* in an inert solvent are essentially useless because the H-bond donor and acceptor are incompletely complexed, but this is not a problem in the pure base method (1, 2). Ordinarily, hydrogen bonding occurs to a nonbonding (n) electron pair of an electronegative element, but with benzene the π electron system is involved (3). Electron-releasing substituents should increase the ring π electron density, and make the substituted benzene a stronger H-bond acceptor. Conversely, electron attracting substituents should decrease the strength of H-bond formation, provided that the substituent itself lacks n electrons which are strongly H-bond accepting.

In studies by the pure base method, Arnett *et al.* (1) found the enthalpy of H-bond formation ($\Delta H_f$) of phenol and *p*-fluorophenol with aromatic hydrocarbons becomes more exothermic (favorable) in the order benzene < toluene < mesitylene. Here $\Delta H_f$ represents the interactions of phenol with the aromatic base, less the interactions of the non-hydrogen-bonding model compound, anisole, with the same base. It appeared possible to us that the trend in $\Delta H_f$ might reflect increasing steric hindrance to the approach of the model compound, rather than a true trend in H-bond acceptor strength. Furthermore, there is almost no variation of $\Delta H_f$ for 1-butanol (vs. 1-chlorobutane) with the same aromatic solvents, and this also seemed worthy of additional investigation.

We have chosen to examine the bases benzene, toluene, mesitylene, and α,α,α-trifluorotoluene (benzotrifluoride). The latter is nearly ideal for several reasons. (*a*) The $CF_3$ group is substantially electron attracting, but is not appreciably basic nor H-bond accepting. (*b*) Although benzotrifluoride has a dipole moment of about 2.6 D (4), there is little evidence from the boiling point (102°C), heat of vaporization (8.98 kcal/mol (5)) (1 kcal = 4.184 kJ), or cohesive energy density (68.3 cal/cm$^3$) that ap-

preciable dipole–dipole association occurs in the liquid. (The corresponding values for toluene are 110.6°C, 9.08 kcal/mol, and 79.9 cal/cm$^3$.) (*c*) The $CF_3$ group is larger than methyl, but the benzotrifluoride ring is more electron-deficient than that of benzene. This will permit us to distinguish between steric and electronic effects on H-bonding.

The interactions of ketones with cyclohexane, benzene, methanol, and *N*,*N*-dimethylformamide have previously been examined calorimetrically (6), and the acetone–benzene system has been studied by nmr (7). The interactions of polar ketones and ethers with the essentially nonpolar aromatic solvents may be charge-transfer complexation or dipole – induced dipole forces.

Our previous approach has been somewhat different from the pure base method. We have calculated enthalpies of transfer from vapor to solvent for each solute:

$$[1] \quad \Delta H(v \rightarrow S) = \Delta H_s - \Delta H_v$$

where $\Delta H_s$ is the enthalpy of solution of a dilute ($10^{-3}$–$10^{-2}$ *M*) liquid sample in the solvent at 25°C, and $\Delta H_v$ is the solute heat of vaporization at 25°C. The assumption is made that the more exothermic value of $\Delta H(v \rightarrow S)$ for a hydrogen bond donor, relative to the value for a comparably polar nondonor model compound, can be attributed entirely to the enthalpy of hydrogen bond formation. Similarly, the enthalpy of polar interaction ($\Delta H_p$) of a polar solute incapable of H-bond donation (ketones, ethers) is taken as the difference in $\Delta H(v \rightarrow S)$ vs. that of a nonpolar model compound (hydrocarbon) ($\Delta\Delta H(v \rightarrow S)$ method).

In the pure base method (1) hydrogen bonding enthalpy is evaluated in a basic solvent with reference to a nonpolar solvent incapable of H-bonding ($CCl_4$):

$$[2] \quad \Delta H_f = (\Delta H_s^A - \Delta H_s^M)_B - (\Delta H_s^A - \Delta H_s^M)_{ref}$$

where A is the H-bond donating solute, M is the model compound, B is a basic (H-bond acceptor) solvent, and ref is the reference solvent. Using eq. [1] the above equation can be equated to:

$$[3] \quad \Delta H_f = (\Delta H^A(v \rightarrow B) - \Delta H^M(v \rightarrow B)) - (\Delta H^A(v \rightarrow ref) - \Delta H^M(v \rightarrow ref))$$

The two methods of evaluating $\Delta H_f$ will be equivalent *only* when $\Delta H^A(v \rightarrow ref) - \Delta H^M(v \rightarrow ref) = 0$. We will compare results by the two methods, and attempt to evaluate the characteristics of appropriate model compounds.

The required values of $\Delta H_v$ for calculation of $\Delta H(v \rightarrow S)$ are available (5, 8), except for di-*n*-butyl ether. This was measured using a recently developed vaporization calorimetry technique (9). Values for 2,2,4,4-tetramethylpentane, *n*-pentane, 1-butanol, and 2-methyl-2-butanol (for which only an estimate was available) were redetermined.

## Experimental

Solutes and solvents were commercial samples in excess of 99% purity, and dried over 4A molecular sieve. Heat of vaporization samples were di-*n*-butyl ether (99.85%), 2,2,4,4-tetramethylpentane (99.98%), *n*-pentane (99.9%), 1-butanol (99.92%), and 2-methyl-2-butanol (99.75%). Purities were established by gas chromatography using a Shimadzu Mini 2 gc with a glass lined system, a 30 m × 0.25 mm id SE-30 silica capillary column, and a Hewlett-Packard 3390A integrator.

The calorimetric procedure and apparatus have previously been described (10). The calorimeters were immersed in water baths at 25.0°C, with regulation to ±0.002°C. Liquid samples were introduced into the calorimeters from 10-, 20-, or 50-μL syringes with immersed tips. Heats of solution were corrected (0.01–0.03 kcal/mol less endothermic) to allow for the heat capacity of the sample which was introduced at 21–23°C. The uncertainties in $\Delta H_s$ (twice the standard deviation of three or more determinations) are 0.04–0.25 kcal/mol.

Heats of vaporization were determined by evaporating 100 μL samples into a slow stream of nitrogen (0.2–2.0 mL/min) under partial vacuum in a vacuum jacketed calorimeter at 25°C (9). The samples were injected under conditions producing no temperature change ($< 2 \times 10^{-4}$ K) in the absence of evaporation; no sample heat capacity corrections are therefore required. The evaporative cooling was compensated by an electrical heater powered by a timed constant current source (11). Determinations were made on 4–6 samples. The uncertainties listed in Table 1 are twice the standard deviations.

## Results and discussion

Enthalpies of solution of the polar and nonpolar solutes in α,α,α-trifluorotoluene, benzene, toluene, and mesitylene (in kcal/mol) are listed in Table 1, together with the molar volume and enthalpy of vaporization of each. In Table 2 the derived values of $\Delta H(v \rightarrow S)$ are presented, and enthalpies of hydrogen bond formation or other polar interactions are evaluated. The compound used as the non-hydrogen-bonding or nonplar model is identified by number. Table 3 lists polar interactions calculated by the pure base method. Values in Tables 2 and 3 based on two heats of solution and two heats of vaporization, or on four heats of solution, have estimated uncertainties of 0.1–0.3 kcal/mol.

The enthalpies of hydrogen bond formation of *m*-cresol with benzene, toluene, and mesitylene are quite similar to the values of Arnett *et al.* for phenol and *p*-fluorophenol (1), whether the cresol values are calculated from $\Delta H(v \rightarrow S)$ of cresol vs. anisole or by the pure base method. The difference calculated by the two methods (0.11 kcal/mol), is equal to the difference in $\Delta H(v \rightarrow CCl_4)$ between cresol and anisole. Arnett found $\Delta H_f = -1.18$ kcal/mol for the phenol–benzene system, using anisole as a model, by the pure base method.

[g] Reference 1 values are 0.00, −0.06, and 0.12 kcal/mol, respectively, in benzene, toluene, and mesitylene.
[h] Estimated by extrapolation.

The acetone–benzene interaction of 4.0 kcal/mol (Table 2) or 3.1 kcal/mol (Table 3) are both within the uncertainty limits of a value (3.6 ± 0.7 kcal/mol) determined from the temperature dependence of the association constant measured by nmr (7).

The $\Delta H(v \rightarrow S)$ method requires the availability or measurement of appropriate heats of vaporization or sublimation, which for highly associated high boiling substances such as phenols, may not be of high accuracy. The pure base method requires a nonpolar reference solvent in which the polar solutes are unassociated. Carbon tetrachloride serves well as the reference solvent for phenols (1), but $\Delta H_f$ for *m*-cresol in benzene (−1.1 kcal/mol) is appreciably affected if the reference solvent is heptane (−1.3 kcal/mol) or cyclohexane (−1.8 kcal/mol). ($\Delta H_s$ of *m*-cresol and anisole are 5.21 and 1.34 kcal/mol in heptane, and 6.02 and 1.72 kcal/mol in cyclohexane.) On the other hand, if one examines the ketone–benzene system for polar interactions ($\Delta H_p$), there is *no* reference solvent available totally devoid of polar interactions with the ketone dipole. Based on Spencer's estimates (2) of dipole – induced dipole interaction with the methylene group, one calculates an interaction of acetone ($\mu$ = 2.86 D) with cyclohexane at an assumed distance of 4 Å to be 0.7 kcal/mol. This could account for much of the difference in $\Delta H_p$ calculated for the

[f] Estimated by extrapolation of alkane series.
[g] Loss in $\Delta H(v\rightarrow S)$ vs. *n*-isomer per quaternary carbon atom.

acetone–benzene interaction by the pure base method vs. the $\Delta H(v \rightarrow S)$ method, but for ethers, where the calculated differences are as large, the dipole – induced dipole interactions with cyclohexane are only 0.1–0.2 kcal/mol. One evaluates a quantity by the pure base method for non-hydrogen-bonding polar solutes, which is not the *total* polar interaction, but the *difference* in the polar interactions with the "basic" and reference solvents. This problem is avoided in the $\Delta\Delta H(v \rightarrow S)$ method, but the ambiguity here is whether $\Delta H(v \rightarrow S)^P - \Delta H(v \rightarrow S)^M$ results entirely from polar interactions of the polar solute, or whether substances P and M differ in other respects.

The choice of a model compound is a critical part of the $\Delta\Delta H(v \rightarrow S)$ procedure. An ideal model would probably have the same molar volume and dipole moment as the H-bond donor. We note from

[d] Difference between pure base method results and results of Table 2.
[e] Reference 1.
[f] A value of 3.6 ± 0.7 kcal/mol was reported in ref. 7.

Tables 2 and 3 the similarity of $\Delta H_f$ from the $\Delta\Delta H(v \rightarrow S)$ and pure base methods for the cresol vs. anisole comparison (MV 104.6 vs. 108.6 mL; dipole moments (4) 1.5 vs. 1.3 D). In the Arnett comparison of phenol (MV 89.0 mL) vs. anisole (1) $\Delta H_f$ differs by 0.6 kcal/mol by the two methods, resulting from the difference in $\Delta H(v \rightarrow CCl_4)$ of phenol (−10.14 kcal/mol) and anisole (−10.78 kcal/mol). If calculations (2) correspond at least roughly with reality, then the solvent cavity formation term in $CCl_4$ is 1.3 kcal/mol per $CH_2$, and the dispersion interactions are −2.1 kcal/mol per $CH_2$. A methylene group typically contributes 16.1 mL to the molar volume. Relative to anisole, phenol "saves" (19.6/16.1) × 1.3 = 1.6 kcal/mol in cavity formation energy, but loses the dispersion interactions of one methylene group, for an overall loss of 0.5 kcal/mol. The agreement with the experimental may be better than can be counted on, but this suggests the importance of the molar volume match.

We note that 1-butanol (MV 91.5 mL, μ = 1.8 D, $\Delta H(v \rightarrow CCl_4)$ = −7.90 kcal/mol) is better served by 1-chlorobutane as a model (1) (104.5 mL, 2.0 D, −7.93 kcal/mol) than by ethyl ether (103.8 mL, 1.3 D, −6.91 kcal/mol). Both models have larger molar volumes than 1-butanol, but this endothermic cavity contribution may be compensated in 1-chlorobutane by the larger dipole moment and polarizability, resulting in exothermic contributions from increased dipole – induced dipole and dispersion interactions. The ketones (Table 2) are appreciably smaller in molar volume than the hydrocarbon models, while the ethers are slightly larger.

While the factors which determine model compound suitability may be identified, we do not feel that perfect predictions can be made at this time. For this reason hydrogen bond formation enthalpies may be better determined by the pure base method. Estimates of other polar interaction enthalpies by the $\Delta\Delta H(v \rightarrow S)$ procedure should be regarded as only rough approximations.

Regardless of the method of estimation, certain trends in $\Delta H_f$ and $\Delta H_p$ as a function of solvent are evident from Tables 2 and 3. The enthalpy of hydrogen bond formation of *m*-cresol with aromatic solvents becomes more exothermic in the order benzotrifluoride < benzene < toluene < mesitylene, the order of increasing π electron density. Alcohols, by the pure base method are surprisingly comparable in $\Delta H_f$ with cresol. Our values in benzene, toluene, and mesitylene are all more exothermic than those previously reported (1) for 1-butanol. This may reflect our use of the isomeric ethers, rather than the chloroalkane, as model. It is somewhat disappointing to find that the results of the pure base method are so dependent on the choice of models. The general trend in alcohol $\Delta H_f$ with solvent variation resembles that of cresol, except for the unexpectedly strong interaction with benzene.

With both ketones and ethers the trend shows strongest interactions with benzotrifluoride and weakest with mesitylene. Since benzotrifluoride is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

more hindered, less polarizable, and of lower electron density than toluene, the observed order probably results predominantly from charge transfer, rather than from steric factors or simple dipole – induced dipole interactions. The ketones in all cases interact more strongly than the ethers.

$\Delta\Delta H(v \rightarrow S)$ for 1-butanol, 1-pentanol, and 1-octanol vs. alkane models give crude estimates of the total $\Delta H_f + \Delta H_p$. In a given aromatic solvent these values are much more uniform than $\Delta H_f$ (or even $\Delta H_f$ derived from the pure base method). This suggests that ethyl ether, *n*-butyl methyl ether, and butyl ether are not equally well matched to the respective alcohols.

Aniline shows a trend in interaction enthalpies with aromatic solvents similar to the alcohols, suggesting that the principal interaction is hydrogen bond donation. Pyridine and nitrobenzene show almost no variation or trends.

The methylene increment in $\Delta H(v \rightarrow S)$ for alkane solutes in benzotrifluoride, benzene, toluene, and mesitylene are $-1.07$, $-1.04$, $-1.10$, and $-1.17$ kcal/mol, respectively. The latter is the largest we have observed except for *n*-heptane ($-1.18$ kcal/mol).

YOSHIAKI MOTOZATO, TSUKASA NISHIHARA, CHUICHI HIRAYAMA, YOSHIAKI FURUYA, and YOSHIO KOSUGI. Can. J. Chem. **60**, 1959 (1982).

Competitive inclusion in β-cyclodextrin between 4-hydroxy-2,2,6,6-tetramethylpiperidinyl-1-oxy and chloro-substituted acetic acids has been monitored by esr spectroscopy. The temperature dependence of the rotational correlation frequencies calculated by Kivelson's equation, using esr spectra of the radical, suggests that a structural change of β-cyclodextrin occurs at about 30°C and that trichloroacetic acid is included extensively at 20–35°C, but significant inclusion of acetic acid is not observed. The degree of competitive inclusion is in the order of trichloro, dichloro, and monochloroacetic acids over the range of 20–80°C. Carbon-13 nmr studies also prove the inclusion of trichloroacetic acid showing an inclusion shift of the trichloromethyl carbon by 1.4 ppm.

YOSHIAKI MOTOZATO, TSUKASA NISHIHARA, CHUICHI HIRAYAMA, YOSHIAKI FURUYA et YOSHIO KOSUGI. Can. J. Chem. **60**, 1959 (1982).

Utilisant la spectroscopie de rpe, on a enregistré l'introduction compétitive de la β-cyclodextrine entre l'hydroxy-4 tétra méthyl-2,2,6,6 pipérideryloxy-1 et des acides acétiques chlorés. L'influence de la température sur les fréquences de corrélation vibrationnelle, calculées à l'aide des équations de Kivelson, suggère qu'un changement de structure de la β-cyclodextrine se produit à environ 30°C et que l'acide trichloroacétique est inclus de façon extensive à 20–35°C; on n'observe toutefois pas d'inclusion importante d'acide acétique. Le degré d'inclusion compétitive est dans l'ordre des acides trichloro, dichloro et monochloro acétiques dans l'intervalle de 20–80°C. Les études en rmn du $^{13}C$ prouvent également qu'il se produit une inclusion de l'acide trichloroacétique qui provoque un déplacement, dû à l'inclusion, du carbone portant le groupe trichlorométhyle de 1,4 ppm.

[Traduit par le journal]

Cycloheptaamylose or β-cyclodextrin (β-CD) has been used in various ways such as to accelerate or retard organic reactions or as simple models of enzymatic reactions. A number of physical methods to investigate the inclusion behavior have been proposed as β-CD has been applied to numerous reactions related to hydrolysis and decarboxylation. Electron spin resonance (esr) spectroscopy is one of those methods, but examples are few (1–4). Kaiser and co-workers (1–3) used nitroxyl radicals as spin-labels on acyl compounds and exemplified, using esr spectrometry, the deacylation reaction assisted by β-CD.

The mechanism of base catalyzed decarboxylation of trichloroacetic acid in the presence of β-CD has been discussed on the basis of kinetic data in our previous report (5). In the present studies, as a new method without labelling, competitive inclusion of a nitroxyl radical and chloro-substituted acetic acids into β-CD was examined, and rotational correlation frequencies of the spin probe were monitored by means of esr. In this way the high propensity for inclusion of trichloroacetic acid could be demonstrated.

## Results and discussion

Electron spin resonance spectra of an aqueous solution of 4-hydroxy-2,2,6,6-tetramethyl piperidinyl-1-oxy, **1**, consisted of triplet peaks whose hyperfine splitting constant ($a^N$) was 17 G (Fig. 1*a*).

Upon addition of a molar equivalent of β-CD to the solution, the triplet signal of intensity ratio 1:1:1 lost symmetry with a marked broadening (with decrease of the ratio of peak height to width) of the highest field peak ($m = -1$) (see Fig. 1*b*). Such a line broadening is ascribed to slow rotation in β-CD cavity or slow exchange in the equilibrium given by reaction [1].

[1] $\quad \mathbf{1} + \beta\text{-CD} \rightleftarrows [\mathbf{1}\cdots\ \beta\text{-CD}]_{complex}$

As a result of either or both factors, the observed rotational correlation time of the spin is prolonged. Slow rotation is illustrated using the present spin, **1**, by increasing solvent viscosities (6). When di-*tert*-butyl nitroxide is used as a spin in β-CD, free spin and complexed spin give independent peaks (7). Among three typical approximations to calculate rotational correlation time ($\tau_c$), Kivelson's equation (eq. [2]) (8) was employed for the

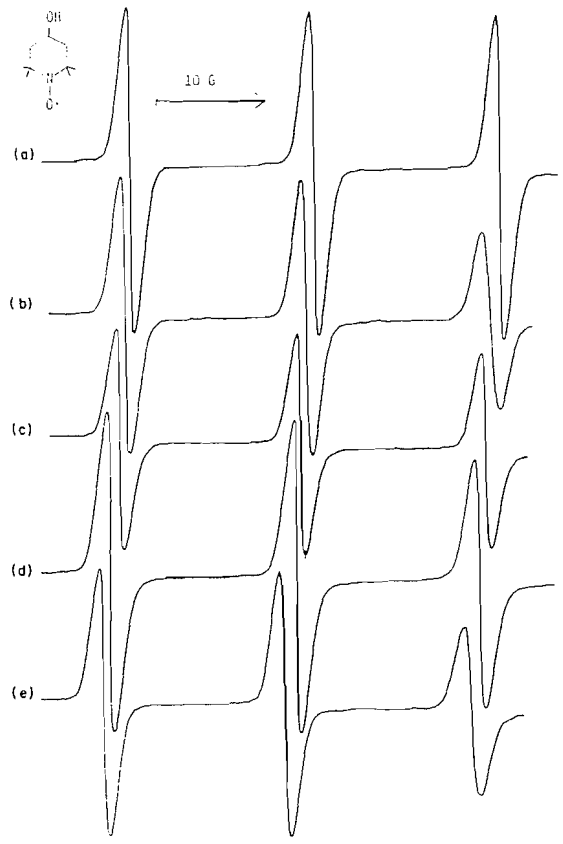

FIG. 1. Electron spin resonance spectra of nitroxy radical **1** in aqueous solutions. (*a*) **1** $3 \times 10^{-4}$ mol/L at 30°C, (*b*) **1** with β-CD at 30°C, (*c*) **1** with β-CD at 80°C, (*d*) **1**, β-CD, and TCAA at 30°C, (*e*) **1**, β-CD, and acetic acid (AA) at 30°C.

nitrogen triplets,

$$[2] \quad \tau_c = \{(h_0/h_{+1})^{1/2} + (h_0/h_{-1})^{1/2} - 2\}(4\pi\sqrt{3}/b^2)W_0$$

where $h$ and $W$ are peak height and peak width, subscripts $+1$, 0, and $-1$ correspond to magnetic spin quantum number $m = +1$, 0, and $-1$, respectively, and the term $(4\pi\sqrt{3}/b^2)$ equals $5.96626 \times 10^{-10}$.

Spectra of the triplet were examined at various temperatures in the presence or absence of β-CD. The line broadening decreased with increase of temperature (e.g. Fig. 1*c*) and a slight inflexion at about 30°C was observed in the temperature dependence of the log $(1/\tau_c)$ when **1** was complexed with β-CD (Fig. 2*b*).

The inflexion is suggestive of a structural change in the β-CD cavity at this temperature. Over the range of lower temperatures (20–35°C) it is known that water molecules of large enthalpy are retained in the cavity (9). At this stage, the hydrophobic radical, **1**, would tend to be more out of the cavity.

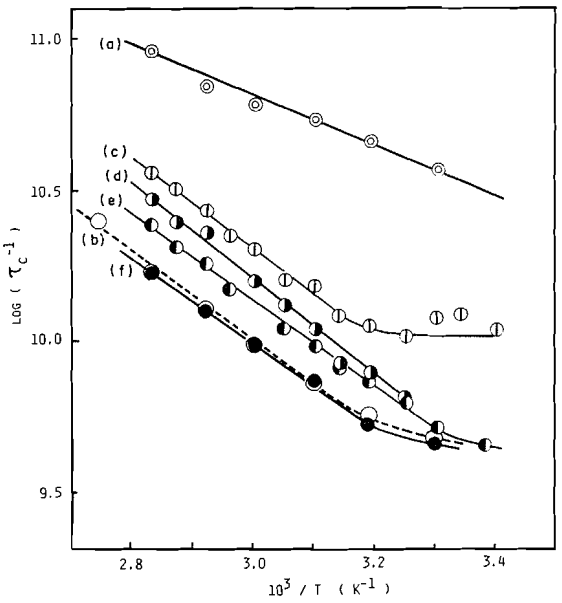

FIG. 2. Relationship between rotational correlation frequency ($\tau_c$) of nitroxy radical **1** and temperature ($T$). (*a*) **1** only, (*b*) **1** and β-CD, (*c*) **1**, β-CD, and TCAA, (*d*) **1**, β-CD, and DCAA, (*e*) **1**, β-CD, and MCAA, (*f*) **1**, β-CD, and AA.

In fact at the lower temperatures, the correlation line of log $(1/\tau_c)$ vs. $1/T$ of **1** with β-CD was almost parallel with that of **1** without β-CD (Fig. 2*a*). The increment of the slope, relative to that at higher temperature, is assigned to the energy of complex formation, calculated to be 2.7 kcal/mol.

The tendency was more evident when hydrophilic trichloroacetic acid (TCAA) was added (Fig. 2*c*). Competitive inclusion between **1** and TCAA according to reactions [1] and [3], respectively, is apparent.

$$[3] \quad \text{TCAA} + \beta\text{-CD} \rightleftarrows [\text{TCAA} \cdots \beta\text{-CD}]_{\text{complex}}$$

The relationship of Fig. 2*a* at six different temperatures did not change with addition of TCAA in the absence of β-CD. The spectrum of **1** (Fig. 1*d*) approached that of free **1** (Fig. 1*a*) and the inclusion of TCAA was much favored at the lower temperatures.

By increasing the amount of TCAA up to 10 times more than **1**, a similar correlation line with scattered points of maximum ±0.1 unit to that of **1** without β-CD was obtained. The scatter of log $(1/\tau_c)$ values from the line was probably caused by either too high concentrations ($3 \times 10^{-3}$ mol/L) of the solution or by partial hydrolysis of β-CD, which might have occurred in the strong acidic medium.

By contrast, acetic acid (AA) instead of TCAA did not alter significantly the correlation line of Fig. 2*b*. Although the spectrum (Fig. 1*e*) is like that of **1**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

with β-CD only, the effect of α-CD on the $pK_a$ value of AA reported by Connors and Lipari (10) using a titration method suggests a slight inclusion is still taking place. Monochloroacetic acid (MCAA) (Fig. 2*e*) or dichloroacetic acid (DCAA) (Fig. 2*d*) decreased the correlation frequencies of **1**, not as much as TCAA, but more than AA did. Therefore the order of feasibility of inclusion is TCAA > DCAA > MCAA > AA. The order can be understood in terms of the order of van der Waals interactions and/or London dispersion forces between acetic acids and β-CD. In no cases at any temperatures investigated were interactions recognized without β-CD and the relationship of log $(1/\tau_c)$ vs. $1/T$ in the presence of acetic acids, but not β-CD, was the same as that of Fig. 2*a*.

Carbon-13 nmr spectra of TCAA in a mixed solvent of $H_2O$ and dimethyl sulfoxide-$d_6$ (DMSO-$d_6$) in the ratio of 1 to 1 showed at ambient temperature (27°C) two peaks at 164.4 and 94.0 ppm of carboxyl carbon ($\delta_{CO}$) and trichloromethyl carbon ($\delta_{CCl_3}$), respectively. Upon addition of β-CD in 1 to 1 ratio, $\delta_{CCl_3}$ moved to 95.4 ppm, while $\delta_{CO}$ remained at 164.4 ppm. The chemical shift change caused by β-CD was examined in cases of DCAA, MCAA, and AA in the same manner as was done for TCAA. No substantial shift changes were observed in all cases under the condition studied.

Thus the results of the nmr method also support the conclusion that the complex formation of TCAA with β-CD is the most favorable among chloro-substituted acetic acids. The inclusion shift of 1.4 ppm for the trichloromethyl carbon suggests that the trichloromethyl group is in or near the hydrophobic cavity of β-CD. The inclusion shift became smaller by 20% when α-CD, of smaller size cavity, was employed. The result is comparable with the fact that rate constants of the decarboxylation reaction (11) decrease, probably because of less stable complex formation with α-CD than β-CD.

## Experimental

All chemicals were of guaranteed grade and were used as purchased. Electron spin resonance sample solutions were made up with 3 mL of **1** ($3 \times 10^{-4}$ mol/L aqueous solution), acetic acids, and 100 mg of β-CD. A capillary tube of 1 mm inner diameter was filled with the sample solution and fixed in an esr sample tube of 3 mm inner diameter.

Electron spin resonance spectra were recorded on a JES-FAEX (JEOL) equipped with a JES-VT-3A2 for variable temperatures. Carbon-13 nmr spectra were taken on a Varian XL-100 spectrometer. Pulse conditions have been described elsewhere (12). Sample concentrations were $3 \times 10^{-4}$ mol/L in a solvent mixture of $H_2O$ and DMSO-$d_6$ in the ratio of 1 to 1 which increased solubilities and stabilized the magnetic field at the same time.

# Analyse conformationnelle d'acyl-5 dioxannes-1,3. Étude en rmn du proton de dioxannes-1,3 substitués en position 5 par un groupement acyle aliphatique ou aromatique

ALAIN DENIS, MICHEL DELMAS, ANTOINE GASET ET JEAN-PIERRE GORRICHON[1]

*Laboratoire du Chimie Organique et d'Agrochimie, École Nationale Supérieure de Chimie (INPT), 118, route de Narbonne, 31077 Toulouse Cedex, France*

Reçu le 1 mars 1982

ALAIN DENIS, MICHEL DELMAS, ANTOINE GASET et JEAN-PIERRE GORRICHON. Can. J. Chem. **60**, 1962 (1982).

L'étude en rmn du proton (basse température, sels de lanthanide) permet d'établir la conformation privilégiée des dioxannes-1,3 substitués en position 5 par un groupement acyle. Dans les acyl-5 alkyl-5 dioxannes-1,3 le groupe acyle est préférentiellement axial tandis que pour l'acétyl-5 dioxanne-1,3 ce substituant est équatorial. Un groupement acyle aromatique adopte préférentiellement la position équatoriale.

ALAIN DENIS, MICHEL DELMAS, ANTOINE GASET, and JEAN-PIERRE GORRICHON. Can. J. Chem. **60**, 1962 (1982).

This $^1$H nmr study (temperature-dependent nmr, lanthanide shift reagent) establishes the preferred conformations of 1,3-dioxans substituted at the five position by an acyl group. For 5-acyl-5-alkyl-1,3-dioxans, this group is preferentially axial whereas in 5-acetyl-1,3-dioxans this substituent is equatorial. An aromatic acyl group is preferentially equatorial.

## Introduction

Les composés cycliques à six chainons ont fait l'objet de travaux d'analyse conformationnelle importants et variés et, notamment, en rmn du proton (1 à 8). Néanmoins, les acyl-5 dioxannes-1,3, dont nous avons par ailleurs rapporté les méthodes de synthèse (9, 10), n'ont fait l'objet d'aucune étude structurale approfondie. Ces composés, du fait de la présence d'un groupement carbonyle en α du cycle dioxannique, sont des intermédiaires de synthèse pour des dérivés dont l'activité biologique dépend de la structure (11). On conçoit, donc, l'intérêt d'une analyse conformationnelle permettant de préciser l'orientation axiale ou équatoriale du groupement acyle sur de telles molécules.

## Résultats et discussion

Les valeurs de déplacements chimiques et des constantes de couplage des protons figurant dans les tableaux 1 et 2 sont en accord avec la structure dioxannique par comparaison avec les valeurs relevées dans la littérature (1 à 8).

Les valeurs des constantes de couplage ne permettent pas de déterminer l'orientation axiale ou équatoriale du substituant acyle. En effet, dans le composé **3***a*, par exemple, on relève des constantes de 7,8 et 4,1 Hz respectivement pour $^3J_{4a\text{-}5}$ et $^3J_{4e\text{-}5}$. Or, les valeurs généralement admises pour ce type de composés, en conformation chaise bloquée, sont de 10–12 Hz ($^3J_{4a-5a}$), 4–6 Hz ($^3J_{4e-5a}$), 4 Hz ($^3J_{4a-5e}$) et 1–2, 5 Hz ($^3J_{4e-5e}$) (2). Il semble donc logique de considérer qu'à température ambiante tous ces composés existent sous la forme d'un équilibre conformationnel entre les deux conformères représentés dans la figure 1.

Afin de mettre en évidence cet équilibre conformationnel, nous avons réalisé une étude à basse température de quelques uns de ces dioxannes. Nous avons appliqué la méthode décrite par Anteunis et coll. (6, 12).

### 1. *Étude en rmn à basse température de l'acétyl-5 méthyl-5 dioxanne-1,3, 3b*

L'allure générale des spectres de rmn correspondant à un abaissement de la température confirme l'existence d'un équilibre conformationnel et à −90°C, les spectres de deux conformères se différencient nettement.

Les valeurs des déplacements chimiques des protons du composé **3***b* à température ambiante et celles des deux formes à −90°C sont rassemblées dans le tableau 3.

Il a été démontré (13, 14) que, pour des dioxannes-1,3 disubstitués en position 5 ou l'un de ces substituants est un méthyle, ce groupement lorsqu'il est équatorial résonne à champ plus fort

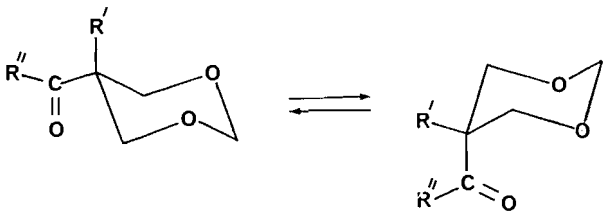

FIG. 1. Représentation des deux conformères des acyl-5 dioxannes-1,3 aliphatiques (R″ aliphatique, R′ aliphatique ou aromatique).

que son homologue axial. On peut déjà en conclure que le conformère majoritaire comporte un groupement méthyle équatorial.

Nous avons confirmé ce résultat en utilisant l'étude en rmn de l'acétyl-5 diméthyl-2,5 dioxanne-1,3 réalisée par Crabb et Newton (15).

En tenant compte de l'effet du méthyle en position 2 équatoriale (7) il est possible de se ramener aux valeurs des déplacements chimiques de l'acétyl-5 méthyl-5 dioxanne-1,3, c'est à dire aux deux formes du composé **3***b*. (cf. Tableau 4).

On note une bonne concordance pour les groupements méthyle et acétyle qui nous permet d'attribuer leur position équatoriale ou axiale sans ambiguité. Les écarts enregistrés pour les déplacements chimiques des protons du cycle dioxannique ne sont pas en désaccord avec cette attribution, car l'ordre de ces derniers est conservé et les différences observées sont probablement dues à un effet de solvant ($CCl_4$ à $CS_2$).

*La conformation privilégiée (A) du composé* **3**b *est donc celle qui comporte le groupement acétyle en position axiale et le groupement méthyle en position équatoriale.*

Un autre argument en faveur de cette attribution est apporté par une étude en rmn en double irradiation à 250 MHz. Il a été montré que pour des dioxannes-1,3 comportant un méthyle en position 5 axiale, il existe un couplage à longue distance entre ce méthyle et les protons en 4a ou 6a allant de 0,8 à 3,2 Hz (15 à 18). Or, même à 250 MHz, à température ambiante dans $CDCl_3$, nous n'observons pas de couplage entre le groupement méthyle et les protons. De plus, sur le spectre à −90°C enregistré à 100 MHz, on note pour la forme minoritaire (B) un couplage de l'order de 0,6 Hz sur le groupement méthyle et un élargissement des raies du massif des protons 4a et 6a. Le groupement méthyle de cette forme est donc bien en position axiale.

Signalons enfin, que le résultat ainsi obtenu apparait contradictoire avec celui rapporté par Anteunis et coll. (19). Ces auteurs indiquent l'existence d'un équilibre conformationnel mais précisent que les deux conformères ont des spectres identiques à −90°C dans $CS_2$. En fait, cette interprétation est certainement liée à un phénomène de cristallisation que nous avons observé. En dessous de la température de coalescence, la cristallisation du conformère B minoritaire est plus rapide que celle du conformère A et de ce fait, il disparait de la

TABLEAU 3. Effet de l'abaissement de la température sur les déplacements chimiques des protons du composé **3***b*.

| | Conformère[a] | | |
|---|---|---|---|
| Paramètre | A + B[c] | A | B |
| Température (°C) | +33 | −90 | −90 |
| $\delta_{2e}$ | 4,71 | 4,79 | — |
| $\delta_{2a}$ | 4,56 | 4,43 | — |
| $\delta_{4,6e}$ | 4,08 | 4,28 | 3,70 |
| $\delta_{4,6a}$ | 3,38 | 3,24 | 3,52 |
| $\delta_{CH_3-C(=O)}$ | 2,12 | 2,20 | 1,98 |
| $\delta_{CH_3}$ | 0,89 | 0,75 | 1,34 |
| Pourcentage des deux formes A/B[b] | 74/26 | 89 | 11 |

[a] Spectre enregistré à 100 MHz dans $CS_2$.
[b] Les pourcentages des deux formes sont calculés à partir des courbes $\Delta\nu$, $\Delta I$, $\Delta\Pi = f(T)$ et $\delta CH_3— = f(T)$ (6, 12). Ils sont en bon accord avec le calcul obtenu par intégration des signaux méthyle et acétyle enregistrés à −90°C.
[c] Les notations A et B *correspondent respectivement aux conformères majoritaire et minoritaire. L'attribution des ces deux formes pour chacun des composés étudiés sera précisée au cours de la discussion.*

phase liquide ne permettant pas l'enregistrement de son spectre dans un laps de temps relativement court à −90°C.

2. *Étude en rmn à basse température des composés* **3**a, **3**e, **3**i

Les données spectrales de ces composés, obtenues de manière identique à celle du produit **3***b*, sont regroupées dans le tableau 5.

En ce qui concerne les composés **3***e* et **3***i*, la comparaison des valeurs obtenues avec celle du tableau 3 montre que leur conformation privilégiée A est également celle pour laquelle le groupement acyle est en position axiale et le groupement alkyle en position équatoriale. D'autre part, d'après les pourcentages obtenus pour ces composés à température ambiante et à −90°C, l'allongement de la chaine alkyle (**3***e*) ne semble pas influencer l'équilibre conformationnel, alors que l'allongement de la chaine du groupement acyle (**3***i*) semble favoriser la conformation A déjà privilégiée.

Dans le cas du composé **3***a*, en se référant aux

TABLEAU 4. Comparaison des valeurs observées et calculées des déplacements chimiques des deux conformères A et B de l'acétyl-5 méthyl-5 dioxanne-1,3 **3***b*

| Conformère | | | Déplacement chimique $\delta_{2e}$ | $\delta_{2a}$ | $\delta_{4,6e}$ | $\delta_{4,6a}$ | $\delta_{CH_3-C(=O)-}$ | $\delta_{CH_3}$ |
|---|---|---|---|---|---|---|---|---|
| $CH_3-C(=O)-$ | ax. | Calculé[a] | — | 4,53 | 4,35 | 3,35 | 2,25 | 0,76 |

posé **3***a*, en présence de sel lanthanide dans le chloroforme, confirme que le conformère majoritaire a le groupement acétyle en position équatoriale. En utilisant le sel d'europium $Eu(fod)_3$ en quantités croissantes, les déplacements chimiques des divers protons varient linéairement pour un rapport ρ entre la concentration de ce sel et celle du composé **3***a* allant jusqu'à 0,45. Par ailleurs, on observe que les constantes de couplage vicinales $^3J_{4a-5}$ et $^3J_{4e-5}$ diminuent lorsque ρ augmente ce ceci d'une façon plus marquée quand ce rapport est supérieur à 0,45.

$$\rho = 0 \begin{cases} J_{4a-5} = 7{,}8\ \text{Hz} \\ J_{4e-5} = 4{,}1\ \text{Hz} \end{cases} \qquad \rho = 0{,}6 \begin{cases} {}^3J_{4a-5} = 6{,}4\ \text{Hz} \\ {}^3J_{4e-5} = 3{,}5\ \text{Hz} \end{cases}$$

La variation de ces constantes de couplage en fonction de la quantité de sel traduit une évolution de l'équilibre entre les deux conformations (20, 21). Cette évolution se fait dans le sens de la formation du complexe le plus stable, c'est-à-dire, dans ce cas, vers le complexe où le groupement acétyle du composé dioxannique est en position axiale. Ceci permettant ainsi (Fig. 2) une complexation tridentate, en général plus stable.

Ceci confirme que le conformère ayant les constantes de couplage vicinales les plus faibles est celui où le groupement acétyle est en position axiale, c'est-à-dire la forme **3***a* A.

3. *Étude des composés* **3**j *à* **3**v

Mis à part, les cas où R' est différent de H (**3***k–m*, Tableau 2) les spectres obtenus sont difficilement

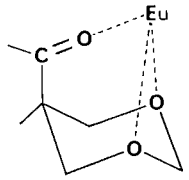

FIG. 2. Complexation tridentate de l'acétyl-5 dioxanne-1,3.

interprétables en ce qui concerne les protons 5, 4e, 4a, 6e, 6a car ils résonnent sous forme d'un massif complexe en raison de l'effet déblindant du groupe acyle aromatique sur le proton 5. Contrairement aux cas des dioxannes comportant un groupement acyle aliphatique, une étude à basse température ne nous a pas permis de déterminer la conformation privilégiée de ces dérivés. Leur température de coalescence, de l'ordre de −90°C, ne nous permet pas d'obtenir un spectre interprétable, compte tenu des limites de l'appareil utilisé (−100°C). Toutefois, en dessous de la température de coalescence (−95°C), nous n'observons pas l'apparition d'un deuxième conformère, ce qui semble indiquer que l'un des conformères est majoritaire à un pourcentage supérieur ou égal à 90%.

*Simulation des spectres (250 MHz) et utilisation d'un sel d'europium ($Eu(fod)_3$)*

En utilisant ces deux techniques, nous avons pu déterminer les déplacements chimiques (cf. Tableau 2) et les constantes de couplage pour les protons des dioxannes **3***j*, **3***n* et **3***o*. Le fait que les constantes $^3J_{4a-5}$ et $^3J_{4e-5}$ aient, pour ces trois composés, des valeurs de 8,8 et 3,6 Hz respec-

tivement, permet de conclure que le groupement acyle aromatique est vraisemblablement en position équatoriale.

## Conclusion

D'après les résultats obtenus au cours de ce travail, nous pouvons conclure que pour un groupement acyle aliphatique (*i*) la conformation privilégiée des acyl-5 alkyl-5 dioxanne-1,3 a le groupement acyle en position axiale, et (*ii*) la conformation privilégiée de l'acétyl-5 dioxanne-1,3 a ce même groupement en position équatoriale.

Il est raisonnable de penser que cette inversion de conformation constatée pour l'acétyl-5 dioxanne-1,3 est liée au fait que, vu la faible polarité du carbonyle, la stabilisation de l'hétérocycle apportée par les interactions électroniques des trois oxygènes, lorsque ce groupement est en position axiale, n'est pas suffisante en l'absence d'un deuxième substituant en position 5 sur le cycle.

Pour un groupement acyle aromatique, la conformation ou ce groupement est équatorial est très fortement privilégiée. Par ailleurs, l'analyse cristallographique de quelques uns de ces composés (22) a montré, sans ambiguité, qu'à l'état solide, le groupement aroyle est équatorial.

## Partie expérimentale

Les spectres de rmn du proton ont été enregistrés sur un appareil Varian T60 travaillant à 60 MHz pour des solutions environ *M*/20 dans le chloroforme deutérié (sauf indication contraire) avec le TMS comme référence interne.

Les études particulières ont été effectuées dans les conditions suivantes.

*Les spectres de rmn à basse température*

Les spectres ont été enregistrés sur un appareil Varian HA100 travaillant à 100 MHz. Les solvants (sulfure de carbone ou acétone deutérié) ont été choisis en fonction de la solubilité respective à basse température des composés étudiés.

*Les spectres de rmn à 250 MHz*

Les spectres ont été obtenus sur un appareil Cameca 250 travaillant à 250 MHz pour des solutions *M*/40 dans le chloroforme deutérié.

*Les spectres de rmn en présence d'Eu (fod)*$_3$

Les spectres ont été enregistrés sur un appareil Bruker WH90 travaillant à 90 MHz en transformé de Fourier pour des solutions dans le chloroforme deutérié.

*Les spectres de rmn du carbone-treize*

Les spectres ont été enregistrés sur un appareil Bruker WP60 travaillant à 15,08 MHz pour des solutions environ *M* dans le chloroforme deutérié avec le TMS comme référence interne.

Les déplacements chimiques ainsi déterminés sont rassemblés dans les tableaux 6 et 7 ci-dessous.

# Gas-phase infrared laser spectroscopy of bound hydrogen-bonded systems

FA-MEI WANG, KHALID IQBAL, HANS-GEORG KRAFT, MARK LUCKSTEAD, WILLIAM C. EUE, AND JOHN W. BEVAN

*Chemistry Department, Texas A&M University, College Station, TX 77843, U.S.A.*

Received February 1, 1982

FA-MEI WANG, KHALID IQBAL, HANS-GEORG KRAFT, MARK LUCKSTEAD, WILLIAM C. EUE, and JOHN W. BEVAN. Can. J. Chem. **60**, 1969 (1982).

Application of tunable infrared lasers to the spectroscopic investigation of equilibrium, gaseous hydrogen-bonded systems is demonstrated. Broadband spectra of the $n\nu_6 + \nu_1 - n\nu_6$ vibrations in HCN---HF and $CH_3CN$---HF have been recorded with a computer-controlled multimode color center laser using both conventional absorption and infrared-acoustic detection methods.

FA-MEI WANG, KHALID IQBAL, HANS-GEORG KRAFT, MARK LUCKSTEAD, WILLIAM C. EUE et JOHN W. BEVAN. Can. J. Chem. **60**, 1969 (1982).

On démontre l'application des lasers à infrarouge réglables à l'étude spectroscopique de l'équilibre des systèmes gazeux ayant des liaisons hydrogènes. On a enregistré les larges bandes des spectres des vibration $n\nu_6 + \nu_1 - n\nu_6$ des systèmes HCN---HF et $CH_3CN$---HF à l'aide d'un laser multimode à centre coloré contrôlé par ordinateur et utilisant comme méthodes de détection tant l'absorption conventionnelle que l'acoustique infrarouge.

[Traduit par le journal]

## Introduction

Infrared spectroscopy has long been recognized as a physico-chemical technique capable of providing fundamental information concerning the nature of bound chemically important hydrogen-bonded systems (1, 2). The majority of these studies have been conducted in the condensed phase where these weakly bound species are sensitive to environmental perturbations which have limited the extent of information which can be determined from this data. Spectroscopic investigations of gaseous equilibrium mixtures (3–5), molecular beam (6), or supersonic jet (7) hydrogen-bonded species offer the opportunity of studying these species in an isolated situation. Infrared spectroscopic studies have been limited to investigations involving classical instrumentation on gas-phase mixtures. However, sensitive high resolution spectroscopic techniques are necessary to resolve the fine structure of vibrational bands associated with these hydrogen-bonded species.

The recent availability of tunable infrared lasers provides the opportunity to observe Doppler-limited and sub-Doppler spectra for such systems. The latter being fundamental to a detailed analysis of the nature of proton dynamics in hydrogen-bonded systems. Broadband laser spectra of these vibrations are an important preliminary to such high resolution Doppler-limited or sub-Doppler analysis and subsequent investigation of proton dynamics in these systems.

## Experimental

Spectra were obtained using a Burleigh Instruments FCL-20 color center laser operating multimode pumped by a Spectra Physics 171-01 Krypton ion laser (Fig. 1). The KCl:Li color center laser crystal used in this research has a maximum output power of 70 mW per watt at 2.69 μm when pumped single line with the 6471 Å output of the pump laser. The multimode infrared laser output has a linewidth of approximately 0.2 $cm^{-1}$ and is tunable from 3448 to 4167 $cm^{-1}$.

The optical cavity of a color center laser is an astigmatically compensated folded mirror system. The end and folding mirrors are enclosed in an evacuated crystal chamber and the output coupler, a precision diffraction grating, served also as a tuning element. The linewidth of the color center laser is homogeneously broadened at liquid nitrogen temperature, oscillation consisting of a fundamental and one or more spatial hole burning modes with a frequency separation of 6.0 GHz

$$\Delta\nu_M = \frac{nc}{4z} \text{ where } n = 1,3,5,\cdots$$

and $z$ is the separation between the crystal and the closest cavity end mirror and $c$ the speed of light.

A North-American Philips K82430 Stepper Motor was connected to the grating drive of the color center laser to scan it. A Micromation Z-64 microcomputer was chosen to control the laser system. An interface board was designed using 4N33 optical isolators to prevent voltage spikes from entering the computer and an SAA-1027 driver for bi-directional control.

The photovoltaic detector in conventional absorption studies utilized an Infrared Industries 2304 PbS detector and LM004 precision operational amplifiers. The infrared-acoustic detector employed was a small-volume non-resonant detector utilizing a BT-1834 Knowles miniature microphone (8). The microphone was carefully prepared to be resistant to the highly corrosive hydrogen-fluoride gas. Output signals of these detectors were applied to a PARC HR-8 lock-in amplifier. The outputs produced from the latter were either applied directly to the recorder or collected by the computer, processed, and then presented.

The hydrogen fluoride was obtained from Matheson and used with purification while spectrograde $CH_3CN$ was used following drying and distillation over calcium hydride. HCN was prepared under vacuum from the action of 50% $H_2SO_4$:$H_2O$ mixtures on KCN. It was collected and dried over $P_2O_5$ following trap-to-trap distillation to remove $CO_2$.

Vacuum lines, cells, and valves were constructed of stainless steel or Teflon with Viton "O" rings to prevent corrosive action

by HF. Conventional absorption studies were carried out with a 1.5 m cell with $CaF_2$ windows.

## Results and discussion

A tunable-laser conventional absorption scan from 3700 to 3800 $cm^{-1}$ is shown in Fig. 2 for an equilibrium gaseous mixture of HCN (50 Torr) and HF (50 Torr) at 300 K. The frequencies of the major features have been measured previously and interpreted as P bandheads associated with the $n\nu_6 + \nu_1 - n\nu_6$ vibration of the HCN---HF hydrogen-bonded complex (5). A better resolved spectrum of the first seven members of this series is shown in Fig. 3. The frequencies of the most prominent of these features at peak maximum have been measured and included in Table 1 with an estimated absolute accuracy of 0.05 $cm^{-1}$. Certain P bandheads are sufficiently resolved from each other to permit rotational–vibrational parameters to be fitted to their experimentally observed spectral profiles. Lorentzian intensity-profiles chosen to represent individual unresolved rotational–vibrational transitions are integrated in these model calculations and molecular parameters varied to simulate the data. Neglecting centrifugal distortion and utilizing (9):

$$\nu = \nu_0 + (B_1 + B_0)m + (B_1 - B_0)m^2 \quad (2)$$

with $B_0 = 0.1197\ cm^{-1}$ (determined from microwave spectroscopy (10)); $B_1$ can be estimated as $0.1219 \pm 0.0003\ cm^{-1}$ for the first P bandhead within the limits of this approximation. The fit also permits a corrected $\nu_0$ frequency to be evaluated as $3714.2 \pm 0.5\ cm^{-1}$ at the band origin.

Other resolved features are apparent (Table 1, Column 2) in the spectrum and are under current investigation.

The infrared-acoustic spectrum (11) of an equilibrium gas mixture of $CH_3CN$ and HF (10 Torr of each, $T = 300$ K) is shown in Fig. 4. The P bandheads are numbered for the first eight members although an extensive number of additional members can be discerned (Table 1). Substructure is also evident in this spectrum for the initial members of the series. The effective interaction pathlength used to record this spectrum is less than 1 cm, indicating that infrared-acoustic laser spec-

troscopy has considerable potential in the investigation of gas-phase hydrogen-bonded species.

## Conclusion

The $n\nu_6 + \nu_1 - n\nu_6$ bandheads in the hydrogen-bonded complexes HCN---HF and $CH_3CN$---HF have been recorded using conventional absorption and infrared-acoustic spectroscopy with a tunable infrared laser respectively. In both cases there is significant improvement in resolution in these pressure-broadened spectra relative to those recorded previously using classical spectroscopic techniques. The reported results form an important preliminary to spectroscopic investigations at much higher resolution using the laser system. Introduction of an intracavity etalon into the color center laser enables its output linewidth to be reduced to $\leq 7$ MHz, permitting application of Doppler-limited and sub-Doppler techniques. Such experiments are in progress.

# Infrared spectra of the ammonium ion in crystals. Part XII. Low-temperature transitions in ammonium dichromate, $(NH_4)_2Cr_2O_7$[1,2]

GÁBOR KERESZTURY[3] AND OSVALD KNOP

*Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3*

AND

MICHAEL FALK

*Atlantic Research Laboratory, National Research Council of Canada, Halifax, N.S., Canada B3H 3Z1*

Received December 11, 1981

GÁBOR KERESZTURY, OSVALD KNOP, and MICHAEL FALK. Can. J. Chem. **60**, 1972 (1982).

Examination of the infrared spectra of the probe ions $NH_3D^+$ and $NHD_3^+$ in ammonium dichromate confirms the existence of the lowest ($T_{tr} \sim 125$ K) of the three transitions that are known, from nonspectroscopic evidence, to occur in this crystal below room temperature. Below $T_{tr}$ the ammonium ions are of two types, in an abundance ratio of 1:1 and both of symmetry $C_1$. Above $T_{tr}$ the probe ion spectra are difficult to interpret in detail. The strength of the hydrogen-bonding interactions covers a wide range, as indicated by the difference between the highest and the lowest values of the isotopically isolated ND stretching frequencies at 10 K, 2392 and 2234 $cm^{-1}$.

GÁBOR KERESZTURY, OSVALD KNOP et MICHAEL FALK. Can. J. Chem. **60**, 1972 (1982).

L'examen des spectres infrarouges des ions $NH_3D^+$ et $NHD_3^+$, étudiés dans le dichromate d'ammonium, confirme l'existence de la plus basse ($T_{tr} \approx 125$ K) des trois transitions qui, d'après des preuves non spectroscopiques, se produisent dans ce cristal à basse température. En dessous de $T_{tr}$, les ions ammonium sont de deux types, avec un rapport d'abondance de 1:1 et les deux ont une symétrie $C_1$. En dessus de $T_{tr}$, il est difficile d'interpréter en détail les spectres de l'ion étudié. La force des interactions des liaisons hydrogènes s'étend sur un large domaine, telle que l'indique la différence entre les plus grandes et les plus faibles valeurs des fréquences de vibration ND isolé d'une façon isotopique à 10 K, 2392 et 2234 $cm^{-1}$.

[Traduit par le journal]

At room temperature the $(NH_4)_2Cr_2O_7$ crystal ($C2/c$, $Z = 4$) contains a single type of ammonium ion, at sites of symmetry $C_1$ (2, 3). The positions of the H atoms have not been determined, but the ammonium ion must be regarded as hydrogen-bonded: each N atom is surrounded irregularly by eight oxygens at distances ranging from ca. 2.83 to ca. 3.17 Å, all of them different, and there is another oxygen at ca. 3.50 Å. On cooling, three transitions have been detected (4) by DTA, calorimetry, and dilatometry, at 268(3), 155(5), and 128(5) K. The total volume of a $(NH_4)_2Cr_2O_7$ crystal varied smoothly on passage through the three transition temperatures, but at 128 K there was an anisotropic discontinuity in the individual dimensions of the crystal; the energy changes associated with the transitions were judged to be small, and the transitions at 155 and 268 K were described as second-degree.

The transition at 268 K appears to correspond to a change of slope in the spin–lattice relaxation time vs. temperature plot for the dichromate (5). Evidence from ir (6–8) and $^2H$ nmr (9) spectra in support of the existence of low-temperature transitions in $(NH_4)_2Cr_2O_7$ and $(ND_4)_2Cr_2O_7$ has also been presented, but no information on the symmetry of any of the low-temperature phases. In the following we report on such observations and conclusions as are obtainable from the temperature variation of the ir spectra of the $NH_3D^+$ and $NHD_3^+$ probe ions in $(NH_4)_2Cr_2O_7$ and $(ND_4)_2Cr_2O_7$, respectively, between 10 and 293 K.

*Spectrum of $NH_3D^+$ in $(NH_4)_2Cr_2O_7$*

For a single type of ammonium ion of symmetry $C_1$ the ir spectrum of the $NH_3D^+$ probe ion, if fully resolved, should contain four $\nu_1(NH_3D^+)$ absorptions in the ND stretching region and eight $\nu_{4bc}(NH_3D^+)$ absorptions in the ND bending region (cf. refs. 10–12), and this would be the situation if the room-temperature crystal structure of the dichromate remained unchanged on cooling. However, at 10 K the ND stretching region of $(NH_4)_2Cr_2O_7$ (4% D) was found to consist of eight clearly resolved $\nu_1$ component bands (Fig. 1), indicative of *two* types of ammonium ion of symmetry $C_1$ in a 1:1 abundance ratio. The octet persisted up to 80 K, at which temperature it began to broaden and collapse to a quartet. This collapse was complete at 120(15) K (Fig. 2*A*), coincident with the transition at 128(5) K detected by calorimetry (4).

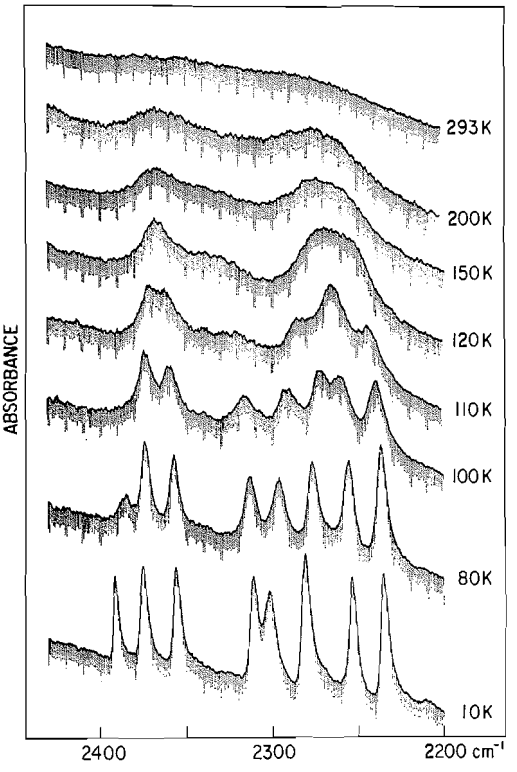

FIG. 1. Spectra of $(NH_4)_2Cr_2O_7$ (4% D) in the region of the ND stretching fundamental $\nu_1(NH_3D^+)$ of the $NH_3D^+$ probe ion at different temperatures.

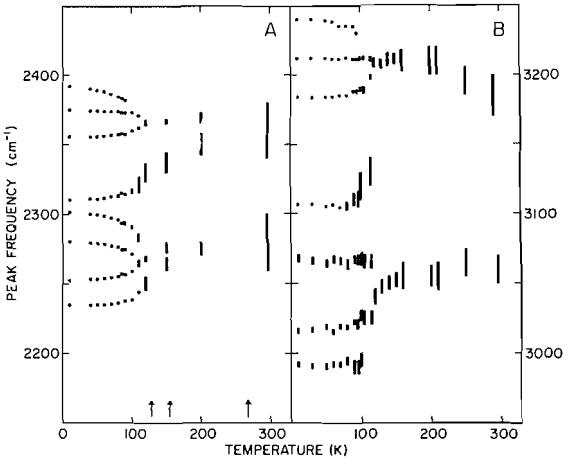

FIG. 2. Temperature variation of peak frequencies of (*A*) the ND stretching fundamental (from Fig. 1) and (*B*) the NH stretching fundamental (from Fig. 5). The arrows correspond to the calorimetrically etc. detected transitions in $(NH_4)_2Cr_2O_7$ (4).

The four bands remained resolved up to 150 K, but on further heating they gradually merged until only two very broad bands were observed at room temperature. The spectra above 120 K were consistent with the expectation from the room-temperature crystal structure; the large halfwidths and the increasingly poor quality of the spectra precluded any conclusions regarding the transitions at 155 and 168 K.

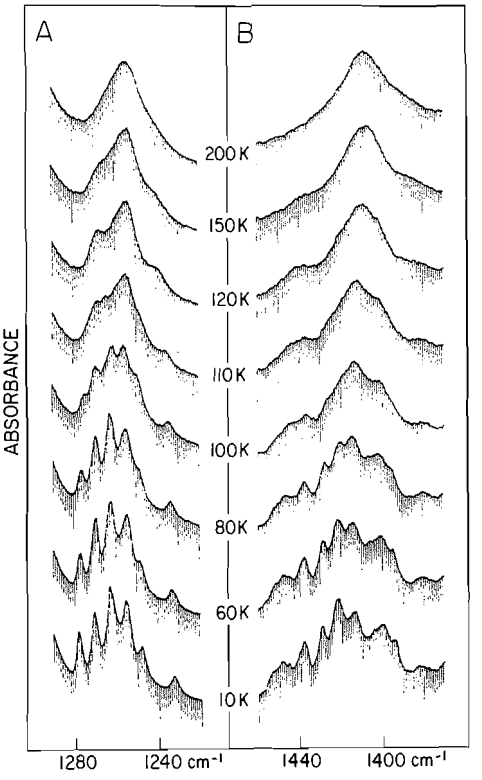

FIG. 3. Spectra in the region of (*A*) the ND bending fundamental $\nu_{4bc}(NH_3D^+)$ of $NH_3D^+$ in $(NH_4)_2Cr_2O_7$ (4% D) and (*B*) the NH bending fundamental $\nu_2(NHD_3^+)$ of $NHD_3^+$ in $(NH_4)_2Cr_2O_7$ (95% D).

The $\nu_{4bc}(NH_3D^+)$ absorption in the ND deformation region (Fig. 3*A*) consisted of six resolved components up to 100 K; these broadened with increasing temperature until only one broad band remained above about 200 K. The resolution of this composite absorption was inadequate for a specific conclusion but not incompatible with the better resolved $\nu_1$ absorption from which one would expect 16 $\nu_{4bc}$ components at low temperatures and 8 $\nu_{4bc}$ components at the higher temperatures. As shown in the plot of the resolved frequencies vs. temperature (Fig. 4), the six-band system collapsed at first, fairly sharply, to a triplet at 120(10) K and then, more gradually, to a singlet at 175(25) K. These spectral changes appear to correspond to the transitions at 128 and 155 K. No conclusion can be made regarding the transition at 268 K.

For personal use only.

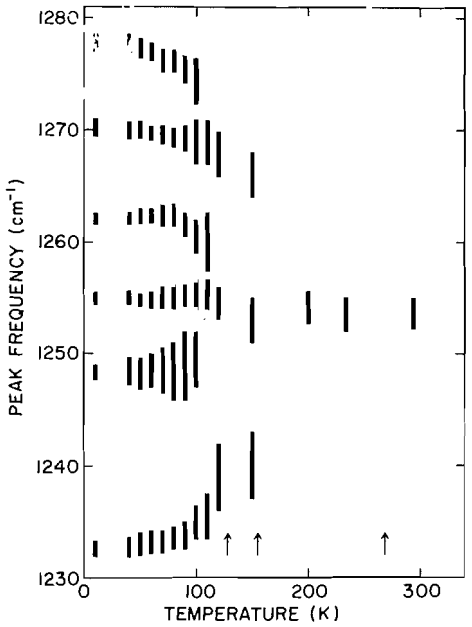

FIG. 4. Temperature variation of the peak frequencies of the ND bending fundamental $\nu_{4bc}(NH_3D^+)$ (from Fig. 3*A*).

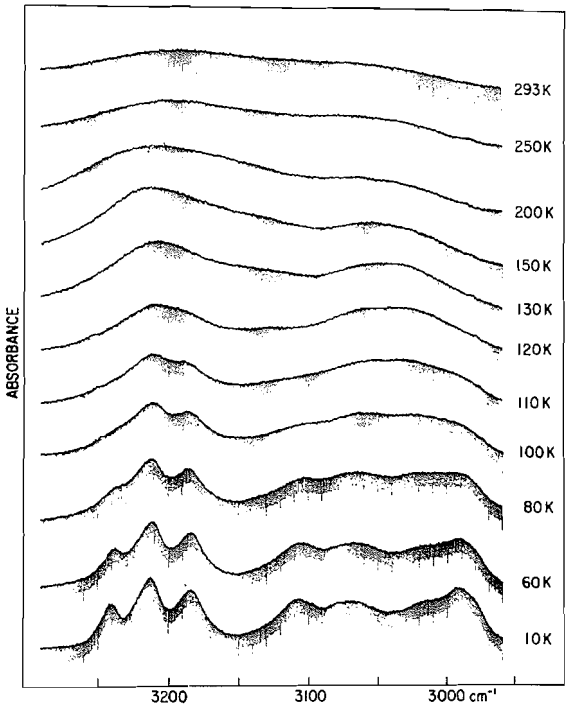

FIG. 5. Spectra in the region of the NH stretching fundamental $\nu_1(NHD_3^+)$ of the $NHD_3^+$ probe ion in $(NH_4)_2Cr_2O_7$ (95% D).

*Spectrum of $NHD_3^+$ in $(ND_4)_2Cr_2O_7$*

The spectra of the $NHD_3^+$ probe ion in $(ND_4)_2Cr_2O_7$ in the NH stretching and deformation regions corresponded closely to the ND stretching and deformation bands of $NH_3D^+$ in $(NH_4)_2Cr_2O_7$. In the NH stretching region at 10 K the $\nu_1(NHD_3^+)$ multiplet consisted of seven resolved peaks (Fig. 5) which clearly correspond to the $\nu_1(NH_3D^+)$ components in $(NH_4)_2Cr_2O_7$ (Table 1). The plot of the $\nu_1(NHD_3^+)$ component frequencies vs. temperature (Fig. 2*B*) parallels the corresponding $\nu_1(NH_3D^+)$ vs. *T* plot of Fig. 2*A*. The collapse of the low-temperature multiplet, which occurred at about 125 K, indicates that the temperature of the lowest transition in the undeuterated and the deuterated dichromate cannot differ by any substantial amount.

The counterpart, in the NH bending region, of $\nu_{4bc}(NH_3D^+)$ is $\nu_2(NHD_3^+)$ (cf. ref. 13). At 10 K at least 12 partially resolved components were discernible in the $\nu_2(NHD_3^+)$ absorption of $(NH_4)_2Cr_2O_7$ (95% D) (Fig. 3*B*). These broadened and collapsed with increasing temperature to a single broad band at room temperature. The collapse occurred in the same temperature region, 130(10) K, as the collapse of the low-temperature $\nu_1(NHD_3^+)$ multiplet.

*Comparison of the NH and ND features*

The NH/ND frequency ratio for the $\nu_1(NH_3D^+)$ and $\nu_1(NHD_3^+)$ absorptions decreased significantly and regularly with frequency (Table 1). This decrease is attributed to the gradually increasing anharmonicity of the NH stretching frequency with the increasing strength of the hydrogen bonding. A similar behaviour has been found for the OH/OD vibrational frequencies of HDO in a number of crystals (14) and solvents (M. Falk, unpublished results).

TABLE 1. Frequencies ($cm^{-1}$) of the $NH_3D^+$ and $NHD_3^+$ probe ions in $(NH_4)_2Cr_2O_7$ and $(ND_4)_2Cr_2O_7$, respectively, at 10 K

The NH stretching bands had much larger halfwidths than the corresponding ND stretching bands, 16 $cm^{-1}$ for the narrowest $\nu_1(NHD_3^+)$ component at 10 K compared with 3 $cm^{-1}$ for the narrowest $\nu_1(NH_3D^+)$ component at the same temperature. We are currently investigating to what

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

extent this difference is due to an intrinsically larger bandwidth of the NH absorptions (over and above that arising from the difference in the relative frequency scale for NH and ND) and hope to discuss our findings elsewhere.

*Temperature dependence of $\nu_4(NH_4^+)$ and $\nu_4(ND_4^+)$*

Although our concern was with the probe ion spectra, we used the opportunity to record the spectra of $(NH_4)_2Cr_2O_7$ in the region of $\nu_4(NH_4^+)$ and those of $(ND_4)_2Cr_2O_7$ in the region of $\nu_4(ND_4^+)$ (Fig. 6), i.e. the absorptions described in refs. 6–8. The $\nu_4(ND_4^+)$ spectra were found to resemble closely those of Fig. 1 of ref. 7 and Fig. 9 of ref. 8, allowing for an improved instrumental resolution. At 10 K five well-resolved peaks and a shoulder[4] were present, their frequencies agreeing within 0.5 $cm^{-1}$ with the frequencies at 17 K reported in Table 3 of ref. 8. The $\nu_4(NH_4^+)$ spectra, however, differed from those reported in refs. 6 and 8. Unlike the latter, they were very similar to the $\nu_4(ND_4^+)$ spectra. At 10 to 70 K, six resolved peaks and two shoulders are seen in our spectra (Fig. 6*A*), in contrast to Fig. 7 of ref. 8, which shows two peaks and some poorly resolved shoulders at 17 K and a different intensity distribution across the composite band. The origin of these differences is not likely to be in the lower instrumental resolution. A possible explanation of this discrepancy might be sought in an incomplete transformation on cooling of the higher phase (i.e. residual supercooling of the 128 K transition) in the sample studied in refs. 6 and 8.

Temperature increase produced broadening and collapse of both the $\nu_4(NH_4^+)$ and $\nu_4(ND_4^+)$ multiplets until at room temperature only one broad absorption was observed. The spectral changes occurred most rapidly around 130 K (Fig. 7), and there was no substantial difference between $(NH_4)_2Cr_2O_7$ and $(ND_4)_2Cr_2O_7$. The gradual changes observed in our $\nu_4(ND_4^+)$ spectra between 50 and 100 K do not support the existence of a transition around 80 K in $(ND_4)_2Cr_2O_7$, tentatively proposed in refs. 7 and 8.

*Thermal collapse of isotopically isolated NH and ND absorptions*

The gradual broadening and eventual collapse of multiplets with increasing temperature were seen particularly clearly in the case of the NH and ND stretching absorptions (Fig. 2). Examples of this

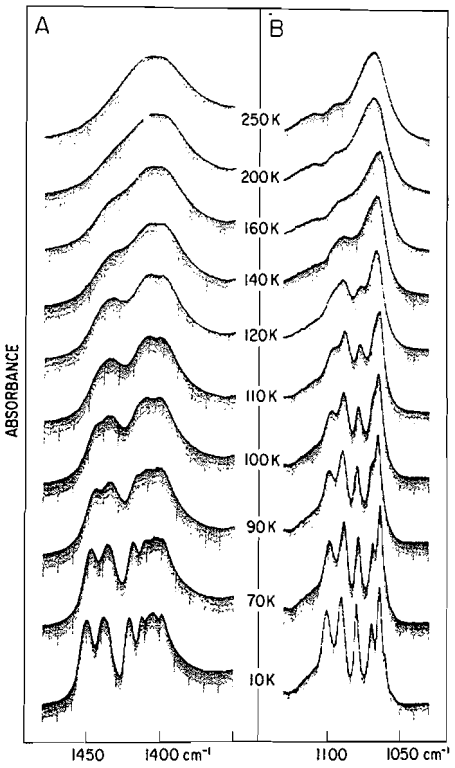

FIG. 6. Spectra in the region of (*A*) the $\nu_4(NH_4^+)$ fundamental of $NH_4^+$ in $(NH_4)_2Cr_2O_7$ (0% D) and (*B*) the $\nu_4(ND_4^+)$ fundamental of $ND_4^+$ in $(NH_4)_2Cr_2O_7$ (95% D). The small bands near 1095 and 1110 $cm^{-1}$ visible at the higher temperatures are probably due to $NHD_3^+$.

behaviour have been reported previously (for $\nu_1(NH_3D^+)$ in $NH_4SnF_3$ and $NH_4CuSO_3$, ref. 15), and several more instances have been noted since (1, 12, 16), including a particularly striking one in the ND stretching region of the spectrum of $NH_4ClO_4$ (results to be published).

It has been suggested (15) that the most important mechanism of such gradual collapse of NH and ND stretching multiplets involves the rapidly increasing thermal amplitude of certain low-frequency motions (mainly librations) of the ammonium ion. This mechanism is characteristic of potential energy functions with very flat, possibly multiple minima; it was invoked earlier (17, 18) to account for a similar thermal collapse of multiplets observed in the spectra of HDO in crystalline hydrates. A quantitative treatment of the phenomenon has recently been proposed by Corn and Strauss (ref. 19 and personal communication).

*Strength of hydrogen bonding*

The frequencies of the $\nu_1(NH_3D^+)$ components at 10 K (Table 1) span a range of 2234–2392 $cm^{-1}$, i.e. almost as wide as the ranges observed in

[4]This shoulder (at 1060 $cm^{-1}$) is not included in Fig. 7, as its frequency cannot be determined with any certainty even at 50 K.

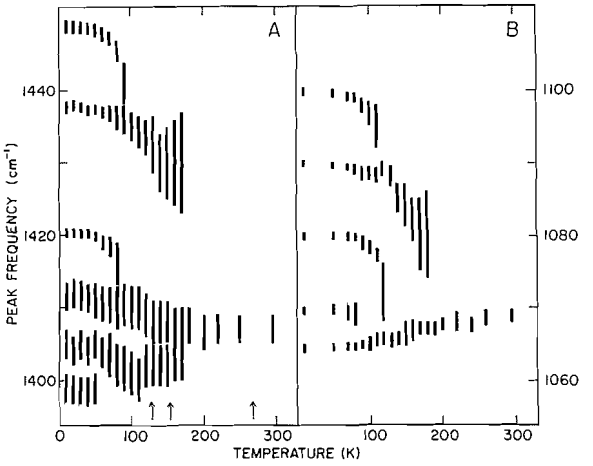

FIG. 7. Temperature variation of the frequencies from Fig. 6.

$NH_4CuSO_3$ (15), $NH_4SnF_3$ (15), and $(NH_4)_2SO_4$ (G. Keresztury, O. Knop, and M. Falk, to be published), which are the widest (~2230 – ~2430 $cm^{-1}$) noted for an ammonium salt to date. This frequency spread indicates a considerable difference in the strength of the individual N—H···O bonds in the lowest-temperature form of the dichromate. The statement (20) that the hydrogen bonding in ammonium dichromate is weak is thus inaccurate, for while the frequency of the highest $\nu_1(NH_3D^+)$ component corresponds clearly to a very weak hydrogen bond, the frequency of the lowest $\nu_1(NH_3D^+)$ component approaches that observed for this fundamental in the strongly hydrogen-bonded $NH_4F$, ~2181 $cm^{-1}$ at 10 K (11). Judging by the clearly discernible anomalous temperature dependence of the frequencies of the 2392, 2374, 2301, and 2280 $cm^{-1}$ absorptions the corresponding hydrogen bonds must be strongly bent and to more than one oxygen acceptor each (cf. ref. 16). This is not surprising if one considers the room-temperature crystal structure; the environments of the ammonium ions in the lowest phase are not likely to be less complicated.

Although the diffuseness of the $\nu_1$ spectra above 130 K makes a precise statement difficult, the evolution of the $\nu_1$ component frequencies with temperature (Fig. 2) does appear to support a general improvement of the hydrogen bonding on cooling through the lowest $T_{tr}$, with some bonds being weakened but others appreciably strengthened. The $\nu_1$ frequency vs. $T$ plots are also suggestive of a specific hydrogen-bonding scheme: at room temperature two of the N—H bonds of the ammonium ion engage in a weaker and the other two in a stronger hydrogen bonding. On cooling through the lowest transition temperature the single set of ammonium ions splits into two nonequivalent sets, but in both sets an ion again contains a pair of weakly and a pair of more strongly engaged N—H bonds.

It is not clear how such a hydrogen-bonding scheme can be reconciled with a mechanism of reorientation of the ammonium ion between 130 K and room temperature that operates with an activation energy of only 4.5 kJ/mol (ref. 5; cf. also refs. 20–22), i.e. about one-third that in simple cubic $NH_4I$, and in particular with the reorientation taking place about "random" axes, as proposed in ref. 20.

## Conclusions

Infrared spectra of the $NH_3D^+$ and $NHD_3^+$ probe ions recorded between 10 and 293 K confirm the existence, in $(NH_4)_2Cr_2O_7$, of a transition the temperature of which had been previously (4) determined as 128(5) K by nonspectroscopic methods. The corresponding transition in $(ND_4)_2Cr_2O_7$ occurs at a similar temperature. The number of components of the $\nu_1(NH_3D^+)$ and $\nu_1(NHD_3^+)$ absorptions between 10 K and this transition temperature indicates the existence of two nonequivalent sets of ammonium ions of $C_1$ symmetry in the low-temperature phase, in a 1:1 abundance ratio. The temperature coefficients of the $\nu_1$ component frequencies suggest that some of the N—H···O bonds are strongly bent and to more than one oxygen acceptor each. The strength of the hydrogen bonding has a wide range.

Above 130 K the well-defined absorptions in the probe-ion spectra of the low-temperature phase merge and the spectra become diffuse. The spectral features persisting above 130 K are compatible with a single set of ammonium ions of $C_1$ symmetry, as required by the room-temperature crystal structure, but they do not permit conclusions as to the nature of the other two transitions detected by nonspectroscopic methods, at 155(5) and 268(3) K.

## Experimental

Reagent-grade $(NH_4)_2Cr_2O_7$ was deuterated by recrystallization from solutions in $H_2O$–$D_2O$ mixtures of the appropriate composition. Nujol or fluorocarbon mulls were sandwiched between $CaF_2$, AgCl, or Irtran-2 windows. The ir spectra were recorded with a Perkin-Elmer model 180 spectrophotometer fitted with a closed-cycle He refrigerator (Displex model 202, Air Products and Chemicals Co.).

The error bars in Figs. 2, 4, and 7 correspond to standard errors calculated from several duplicate sets of spectra in some cases and estimated from the noise level and peak sharpness in others.

# The least-squares intersection of a family of lines and its application to phase equilibria

JOHN W. LORIMER

*Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7*

Received January 19, 1982

JOHN W. LORIMER. Can. J. Chem. **60**, 1978 (1982).

A generalized least-squares method is described for finding the point of intersection of a family of straight lines, each of which is defined by two experimental points. It is shown that the method of the least-squares triangle (Can. J. Chem. **59**, 3076 (1981)) is a good first approximation to the general method. An example demonstrates the method of iteration of both parameters and observations for a problem involving evaluation of solid phase compositions from solubility measurements.

JOHN W. LORIMER. Can. J. Chem. **60**, 1978 (1982).

On décrit une méthode des moindres carrés généralisés qui permet de calculer les coordonnées d'intersection d'une famille de lignes droites, dont chacune est définie par deux points expérimentaux. On démontre que la méthode des triangles moindres carrés (Can. J. Chem. **59**, 3076 (1981)) est une assez bonne approximation initiale de la méthode générale. Un exemple numérique démontre la méthode d'itération à la fois des observations et des paramètres dans un calcul pour évaluer les compositions de phases solides à partir de données de solubilité.

## Introduction

In a previous paper (1) (referred to hereafter as **I**), a least-squares method was developed for finding the coordinates of the common point of intersection of a family of straight lines, each member of which is defined by two points only. An example is provided by tie-lines which pass through experimental solubility and wet residue composition points in a multicomponent system. The method fixed the point of intersection by minimizing the sum of squares of the areas of all triangles formed by the point of intersection and pairs of solubility and wet residue points. In this paper, another method (referred to briefly in **I**) is investigated. It is based on standard non-linear least-squares procedures (2, 3) that are used widely in surveying and photogrammetry, but do not appear to be well known in other fields. Although the basic equations seem at first glance to differ from those for the least-squares triangle, it will be shown that the least-squares triangle, as described in **I**, is a first (and reasonably good) approximation to the more general method. For simplicity, only lines in two-dimensional space will be considered. Generalization to multi-dimensional space is straightforward, but as pointed out in **I**, is usually not necessary for practical calculations involving solubility equilibria.

## Theory

### *(a) The generalized least-squares equations*

The equation of the straight line through the points $x_{k1}'$, $x_{k2}'$ (representing the solubility), $x_{k1}''$, $x_{k2}''$ (representing the wet residue or initial composition), and $x_1$, $x_2$ is

$$[1]\quad f_k = (x_{k2}' - x_{k2}'')(x_{k1}' - x_1) - (x_{k1}' - x_{k1}'')(x_{k2}' - x_2) = 0 \qquad k = 1, \ldots, p$$

If $x_1, x_2$ are the coordinates of the common point of intersection of $p$ such lines, then there are $p - 2$ degrees of freedom. In practice, each point has an associated error, so that eq. [1] is written as

$$[2]\quad f_k = (x_{k2}'^{0} + \delta x_{k2}' - x_{k2}''^{0} - \delta x_{k2}'')(x_{k1}'^{0} + \delta x_{k1}' - x_1^{0} - \delta x_1) - (x_{k1}'^{0} + \delta x_{k1}' - x_{k1}''^{0} - \delta x_{k1}'')(x_{k2}'^{0} + \delta x_{k2}' - x_2^{0} - \delta x_2) = 0 \qquad k = 1, \ldots, p$$

where the superscript zero signifies an approximate value. To the first order in small quantities, this equation can be written as

$$[3]\quad f_k^{0} + \mathbf{E}_k \delta \mathbf{l}_k + \mathbf{G}_k \delta = 0 \qquad k = 1, \ldots, p$$

where the matrices (with their orders) are

$$[4]\quad \mathbf{E}_k = [x_2^{0} - x_{k2}''^{0}\; x_{k1}''^{0} - x_1^{0}\; x_{k2}'^{0} - x_2^{0}\; x_1^{0} - x_{k1}'^{0}] \qquad (1 \times 4)$$

$$[5]\quad \delta \mathbf{l}_k = [\delta x_{k1}'\quad \delta x_{k2}'\quad \delta x_{k1}''\quad \delta x_{k2}'']^{t} \qquad (4 \times 1)$$

$$[6]\quad \mathbf{G}_k = [x_{k2}''^{0} - x_{k2}'^{0}\quad x_{k1}'^{0} - x_{k1}''^{0}] \qquad (1 \times 2)$$

$$[7]\quad \delta = [\delta x_1\quad \delta x_2]^{t} \qquad (2 \times 1)$$

In these equations, superscript t indicates the transpose. The equations can also be obtained by the more general method (2, 3) of expanding $f_k$ in a Taylor series about $f_k^{0}$ and computing the derivatives. Matrix $\mathbf{E}_k$ is the Jacobian matrix of $f_k$ with respect to $\mathbf{l}_k$. If $\hat{\mathbf{l}}_k$, $\mathbf{l}_k$ are the matrices of least-square estimates of the observations and the observations

0008-4042/82/151978-04$01.00/0

For personal use only.

themselves, their difference defines the deviation matrix $\mathbf{v}_k$. Similarly, the difference between $\hat{\mathbf{l}}_k$ and $\mathbf{l}_k{}^o$ defines matrix $\delta\mathbf{l}_k$. Thus,

[8] $\hat{\mathbf{l}}_k = \mathbf{l}_k + \mathbf{v}_k = \mathbf{l}_k{}^o + \delta\mathbf{l}_k$

and eq. [3] can be rewritten in terms of $\mathbf{v}_k$ as

[9] $\mathbf{E}_k\mathbf{v}_k + \mathbf{G}_k\delta = -f_k{}^o - \mathbf{E}_k(\mathbf{l}_k - \mathbf{l}_k{}^o) \equiv F_k{}^o$

For all $p$ equations of this type,

[10] $$\begin{bmatrix} \mathbf{E}_1 & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{E}_2 & \cdots & \mathbf{0} \\ \vdots & \vdots & & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{E}_p \end{bmatrix} \begin{bmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \\ \vdots \\ \mathbf{v}_p \end{bmatrix} + \begin{bmatrix} \mathbf{G}_1 \\ \mathbf{G}_2 \\ \vdots \\ \mathbf{G}_p \end{bmatrix} \delta = \begin{bmatrix} F_1{}^o \\ F_2{}^o \\ \vdots \\ F_p{}^o \end{bmatrix}$$

or

[11] $$\underset{p\times 4p}{\mathbf{E}} \quad \underset{4p\times 1}{\mathbf{v}} + \underset{p\times 2}{\mathbf{G}} \quad \underset{2\times 1}{\delta} = \underset{p\times 1}{\mathbf{F}^o}$$

To obtain least-squares estimates of the correction matrices $\mathbf{v}$ and $\delta$, the function

[12] $\phi = \mathbf{v}^t\mathbf{W}\mathbf{v} - 2\mathbf{k}^t(\mathbf{E}\mathbf{v} + \mathbf{G}\delta - \mathbf{F}^o)$

is minimized with respect to $\mathbf{v}$ and $\delta$. In eq. [12], $\mathbf{W}$ is the $4p \times 4p$ weight matrix of the observations $\mathbf{l}$, and $\mathbf{k}$ is a $p \times 1$ matrix of Lagrange multipliers, so that $\phi$ is the weighted sum of squares of deviations modified by the constraints given by eq. [11]. Equation [12] is now in standard form, and the minimization results are as deduced in ref. 3:

[13] $\delta = \mathbf{N}^{-1}\mathbf{T}$ $(2 \times 1)$

where

[14] $\mathbf{N} = \mathbf{G}^t(\mathbf{E}\mathbf{W}^{-1}\mathbf{E}^t)^{-1}\mathbf{G}$ $(2 \times 2)$

[15] $\mathbf{T} = \mathbf{G}^t(\mathbf{E}\mathbf{W}^{-1}\mathbf{E}^t)^{-1}\mathbf{F}^o$ $(2 \times 1)$

The deviation matrix is

[16] $\mathbf{v} = \mathbf{W}^{-1}\mathbf{E}^t(\mathbf{E}\mathbf{W}^{-1}\mathbf{E}^t)^{-1}(\mathbf{F}^o - \mathbf{G}\delta)$

and an unbiased estimate of the variance is

[17] $\hat{\sigma}^2 = \mathbf{v}^t\mathbf{W}\mathbf{v}/(p - 2)$
$= \{\mathbf{F}^{ot}(\mathbf{E}\mathbf{W}^{-1}\mathbf{E}^t)^{-1}\mathbf{F}^o - \delta^t\mathbf{T}\}/(p - 2)$

The estimated covariance matrix is the same for the corrections $\delta$ and the parameters $\mathbf{x}$:

[18] $\hat{\mathbf{M}}_\delta = \hat{\mathbf{M}}_x = \hat{\sigma}^2\mathbf{N}^{-1}$

The covariance matrix of the functions $\mathbf{F}^o$ follows from the facts that (as noted above) $\mathbf{E}$ is the Jacobian matrix $\partial\mathbf{F}^o/\partial\mathbf{l}$ and that the covariance matrix of the l-values is $\langle\mathbf{v}\mathbf{v}^t\rangle = \sigma^2\mathbf{W}^{-1}$, where $\sigma^2$ is the variance of an observation of unit weight and $\mathbf{W}_F$ is the weight matrix of $\mathbf{F}^o$:

[19] $\mathbf{M}_{F^o} = \langle\mathbf{F}^o\mathbf{F}^{ot}\rangle = \sigma^2\mathbf{E}\mathbf{W}^{-1}\mathbf{E}^t = \sigma^2\mathbf{W}_F{}^{-1}$

This matrix will be diagonal with $p$ scalar elements $\sigma^2(\mathbf{E}\mathbf{W}^{-1}\mathbf{E}^t)_k$ if $\mathbf{W}$ is diagonal (i.e., the observations are uncorrelated) (3). Matrixes $\mathbf{N}$ and $\mathbf{T}$ can be shown easily to be the sums

[20] $\mathbf{N} = \sum_{k=1}^{p} \{\mathbf{G}^t(\mathbf{E}\mathbf{W}^{-1}\mathbf{E}^t)^{-1}\mathbf{G}\}_k$

[21] $\mathbf{T} = \sum_{k=1}^{p} \{\mathbf{G}^t(\mathbf{E}\mathbf{W}^{-1}\mathbf{E}^t)^{-1}\mathbf{F}^o\}_k$

*(b) Practical equations for computations*

Although the above equations can be used as given, it is more useful to calculate the various matrices explicitly. Equation [4] gives

[22] $(\mathbf{W}_F{}^{-1})_k \equiv (\mathbf{E}\mathbf{W}^{-1}\mathbf{E}^t)_k = (x_2{}^o - x_{k2}{}''{}^o)^2 W_{x_{k1}'}{}^{-1} + (x_1{}^o - x_{k1}{}''{}^o)^2 W_{x_{k2}'}{}^{-1} + (x_2{}^o - x_{k2}{}'{}^o)^2 W_{x_{k1}''}{}^{-1} + (x_1{}^o - x_{k1}{}'{}^o)^2 W_{x_{k2}''}{}^{-1}$

while matrices $\mathbf{N}$ and $\mathbf{T}$ are found to be identical to matrices $\mathbf{B}$ and $\mathbf{C} - \mathbf{B}\mathbf{x}^o$, respectively, as defined in eqs. [12] and [14] of **I**, provided that $\sigma_{Ak}{}^2$ in **I** is interpreted as $\sigma^2(\mathbf{W}_F{}^{-1})_k$ in eq. [22] (see below for justification), the matrix $\mathbf{l}$ is taken as the matrix $\mathbf{l}^o$, and $y_{ki} = x_{ki}{}'{}^o - x_{ki}{}''{}^o$. Thus, eq. [13] gives

[23] $\delta = \mathbf{B}^{-1}\mathbf{C} - \mathbf{x}^o$

so that the matrix product $\mathbf{B}^{-1}\mathbf{C}$ gives a direct least-squares estimate of the parameters $\mathbf{x}$, just as in **I**.

In most problems in phase equilibria, $\mathbf{W}^{-1} = \mathbf{I}$ is a reasonable assumption. As a first approximation, it is assumed that $\mathbf{l} = \mathbf{l}^o$ (i.e., $\mathbf{v} = \Delta\mathbf{l}$), $(\mathbf{W}_F{}^{-1})_k = 1$. Next, $\mathbf{x}^o = \mathbf{B}^{-1}\mathbf{C}$ is calculated, this value is used in eq. [22] to compute the weights, and a further iteration gives the corrections $\delta$ and $\mathbf{v}$. Updated approximations

[24] $\mathbf{x}^o = \mathbf{x}^o + \delta$, $\hat{\mathbf{l}} = \mathbf{l} + \mathbf{v}$

are then found, and the equations are iterated until convergence is reached. Note that the corrections $\delta$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

are applied to the previous values of $\mathbf{x}^o$, but that the corrections $\mathbf{v}$ are applied to the initial values $\mathbf{l}$. For problems in phase equilibria, a satisfactory criterion of convergence is $\delta_{max} < \varepsilon$, where $\varepsilon$ is the maximum incremental correction to any parameter; a reasonable value is often 0.005 mass%. The computation is completed by finding the final values of $\hat{\sigma}^2$ and $\hat{\mathbf{M}}_x$, noting that the second term in eq. [17] should be negligible compared to the first when convergence is reached.

In **I**, the effect of the distance between the points $\mathbf{x}_k'$ and $\mathbf{x}_k''$ was investigated by taking

$$[25] \quad \mathbf{y}_k = \mathbf{x}_k' - \mathbf{x}_k'' = L(\mathbf{x}_k' - \mathbf{x}) + \delta\mathbf{y}_k$$

where $L$ is the distance between these points divided by the distance between points $\mathbf{x}_k'$ and $\mathbf{x}$, and $\delta\mathbf{y}_k$ is a random error. If $\delta\mathbf{y}_k \ll L(\mathbf{x}_k' - \mathbf{x})$, substitution of eq. [25] into eq. [22] shows that (for $\mathbf{W} = \mathbf{I}$) the weights $(\mathbf{W}_F^{-1})_k$ each contain the factor $L^2 - 2L + 2$. Matrices $\mathbf{N}$ and $\mathbf{T}$ each contain the factor $L^2/(L^2 - 2L + 2)$, so that $\delta$ is independent of $L$, $\hat{\sigma}^2$ (eq. [17]) is independent of $L$, but $\hat{\mathbf{M}}_x$ (eq. [18]) varies as $1 - 2/L + 2/L^2$. This latter variation is roughly the same as $1/L^2$, so that the standard deviations of the parameters are roughly inversely proportional to $L$, just as in **I**.

*(c) Relation to the least-squares triangle*

Equation [11] can be written as

$$[26] \quad \mathbf{Ev} = \mathbf{F}$$

where

$$[27] \quad \mathbf{F} = \mathbf{F}^o - \mathbf{G}\delta$$

is the matrix with elements

$$[28] \quad F_k = -\mathbf{E}_k(\mathbf{l}_k - \mathbf{l}_k^o) - y_{k2}^o(x_{k1}'^o - x_1) + y_{k1}^o(x_{k2}'^o - x_2)$$

Using the fact that $\mathbf{M}_{F^o}$ is diagonal, it is found from eqs. [16] and [27] that

$$[29] \quad \mathbf{v}^t\mathbf{W}\mathbf{v} = \sigma^2\mathbf{F}^t\mathbf{M}_F^{-1}\mathbf{F} = \mathbf{F}^t\mathbf{W}_F\mathbf{F}$$

where, from eq. [26],

$$[30] \quad \mathbf{M}_F \simeq \sigma^2\mathbf{E}\mathbf{W}^{-1}\mathbf{E}^t = \mathbf{M}_{F^o}$$

is the variance matrix for $\mathbf{F}$. Equations [29] and [30] complete the demonstration that minimizing the weighted sum of squares of the deviations $\mathbf{v}$ is equivalent to minimizing the weighted sum of squares of the functions $\mathbf{F}$. Furthermore, if $\mathbf{l}_k = \mathbf{l}_k^o$, the functions $\mathbf{F}_k$ are each equal to twice the area of the triangle formed by points $\mathbf{x}_k'$, $\mathbf{x}_k''$, and $\mathbf{x}$, so that eq. [29] is also four times the weighted sum of squares of these areas. In **I**, it should be noted that the variance matrix of area $\alpha$ (or $\pm\mathbf{F}/2$ in the present notation) was given as $\langle\alpha\alpha^t\rangle$, while the correct value is eq. [30], which can also be calculated directly as

$$[31] \quad \mathbf{M}_F = \sigma^2\mathbf{J}_l\mathbf{W}^{-1}\mathbf{J}_l^t \simeq \sigma^2\mathbf{E}\mathbf{W}^{-1}\mathbf{E}^t$$

where $\mathbf{J}_l$ is the Jacobian matrix with elements $\partial\alpha/\partial\mathbf{l}$.

When $\mathbf{l}$ and $\mathbf{l}^o$ are not equal, the function $\mathbf{F}^t\mathbf{W}_F\mathbf{F}$ in eq. [29] has to be minimized with respect to both $\mathbf{x}$ and $\mathbf{v}$, subject to the constraint of eq. [26]. This procedure is relatively complicated, because matrices $\mathbf{F}$ and $\mathbf{E}$ are both functions of $\mathbf{x}$. Therefore, the practical theory for iterations on both parameters and observations is that based on eq. [12]. If iterations on the parameters only are to be carried out, eq. [26] is no longer a constraint, and the minimization problem is that solved in **I**, using the weights of eq. [31]. The generalized least-squares procedure gives identical results in this case.

## A numerical example

In **I**, selected solubility and wet residue data (4) were used to illustrate use of the least-squares triangle. These same data can be used to illustrate calculations with iterations on: (*a*) the parameters only; (*b*) both parameters and observations. The procedures are those described in section (*b*) of the Theory, and the results are given in Table 1, where the original data and the first approximation to the parameters are exactly as in **I**. When iterations are performed on the parameters only, convergence is obtained after two iterations to $1 \times 10^{-4}$ mass% for the coordinates $\mathbf{x}$ and for their estimated standard deviations. In this case, the final values of $\mathbf{x}$ do not differ significantly from the initial values. Identical results are obtained using the least-squares triangle with weights given by eq. [22] or [31]. When iterations are performed on both parameters and observations, three iterations are sufficient to obtain convergence to $1 \times 10^{-4}$ mass% for $\mathbf{x}$. The largest corrections to the observations are for the wet residue data points, all of which lie close to the point of intersection. Again, the values of $\mathbf{x}$ do not differ significantly from the values found by the least-squares with $\mathbf{W}_F = \mathbf{I}$, and this is likely to be the case in most problems in phase equilibria. In general, iterations on both parameters and observations should be carried out, because the equations for $\mathbf{F}^o$ are non-linear in the observations $\mathbf{l}$. The least-squares triangle method provides a convenient starting point for these iterations.

TABLE 1. Generalized least-squares analysis of solubility data*

# Stereochemistry of the conventional and modified Bucherer–Bergs reactions of 2-substituted cyclohexanones

GUERINO SACRIPANTE AND JOHN T. EDWARD

*Department of Chemistry, McGill University, 801 Sherbrooke St. West, Montreal, P.Q., Canada H3A 2K6*

Received January 18, 1982

GUERINO SACRIPANTE and JOHN T. EDWARD. Can. J. Chem. **60**, 1982 (1982).

The configurations of the spiro-hydantoins produced from 2-methyl- and 2-phenylcyclohexanone, 2,6-dimethylcyclohexanone, and *dl*-menthone by either the conventional Bucherer–Bergs (B.–B.) reaction, or a variant employing COS or $CS_2$ in place of $CO_2$, have been established by $^{13}C$ nmr. In all cases the conventional B.–B. reaction gave the hydantoin having the 4′-carbonyl group equatorial, and the COS or $CS_2$ variant, the mono- or dithiohydantoin having the 4′-thiocarbonyl group, axial.

GUERINO SACRIPANTE et JOHN T. EDWARD. Can. J. Chem. **60**, 1982 (1982).

Faisant appel à la rmn du $^{13}C$, on a établi les configurations des spiro-hydantoines provenant soit de la réaction conventionnelle de Bucherer–Bergs (B.–B.) des méthyl-2, phényl-2 et diméthyl-2,6 cyclohexanones avec la *dl*-menthone, soit en utilisant une variante de cette réaction faisant intervenir le COS ou le $CS_2$ au lieu du $CO_2$. Dans tous les cas, la réaction conventionnelle de B.–B. conduit à l'hydantoine ayant le groupe carbonyle-4′ en position équatoriale, tandis que l'utilisation du COS ou du $CS_2$ conduit au mono ou au dithiohydantoine ayant le groupe thiocarbonyle-4′ en position axiale.

[Traduit par le journal]

Munday (1) obtained two isomeric amino-acids from 2-methylcyclohexanone (**3**; R = Me): the first, to which he assigned the structure **1** (R = Me), by hydrolysis of the aminonitrile **2** (R = Me) given by the Strecker reaction; the second, to which he assigned the structure **8** (R = Me), by hydrolysis of the hydantoin **4** (R = Me) given by the Bucherer–Bergs reaction (Scheme 1).

Munday's configurational assignments in these and other cases were based on the resistance of the nitrile groups to hydrolysis (indicating axial configurations as in **2** (R = Me)); infrared spectra; and dissociation constants. However, the evidence could not be considered unequivocal, and indeed Cremlyn and Chisholm (2) argued for a reversal of Munday's assignments on the basis of the effect of changing solvent on the two dissociation constants of the various isomeric amino-acids. However, Edward and Jitsrangsri (3), using $^{13}C$ nmr, showed that Munday's assignments of structures for the isomeric amino-acids obtained from 4-*tert*-butylcyclohexanone were correct. Furthermore, they showed that the results in this and other cases in which configurational assignments were based on unequivocal evidence (X-ray crystallography (4, 5), chemical transformations (6)) all accorded with the assignments to be expected from a detailed consideration of steric effects on either a thermodynamically-determined product (the Strecker product) or a kinetically-determined product (the Bucherer–Bergs product). These considerations showed that the amino-acid derived by the Strecker route (e.g. **1**) should have its carboxyl group in the axial orientation, and that the amino-acid derived by the conventional Bucherer–Bergs route (e.g. **8**) should have this group in the equatorial orientation (the EJ rule). Mechanistic considerations also explained why two modifications of the Bucherer–Bergs reaction introduced by Carrington (one using carbon disulfide in place of carbon dioxide, and affording 2,4-dithiohydantoins (7); a second using carbonyl sulphide and affording 4-thiohydantoins (8)) gave products (β-series (9)) having the "Strecker" rather than the conventional Bucherer–Bergs (α-series (9)) configurations.

In view of the success of the EJ rule, it was curious to find that it ran counter to the configurational assignments of Ansell *et al.* (10) for the amino-acids obtained by the Strecker and Bucherer–Bergs routes from 2-phenylcyclohexanone (**3**; R = Ph). These assignments were based on variations in the chemical shift of the benzylic proton nmr band when the amino-acids were converted to *O*-methyl or *N*-acetyl derivatives. Previously Ansell *et al.* had shown that the shifts of the benzylic proton of 2-phenylcyclohexane carboxylic acids when they underwent *O*-methylation, and of 2-phenylcyclohexylamines when they underwent *N*-acetylation, depended on whether the compounds were *cis* or *trans*, and hence proceeded to use the shifts to determine configurations of the amino-acids **1** and **8** (R = Ph).

Because of this apparent failure of the EJ rule, we have investigated by $^{13}C$ nmr the configurations of the α- and β-products obtained from

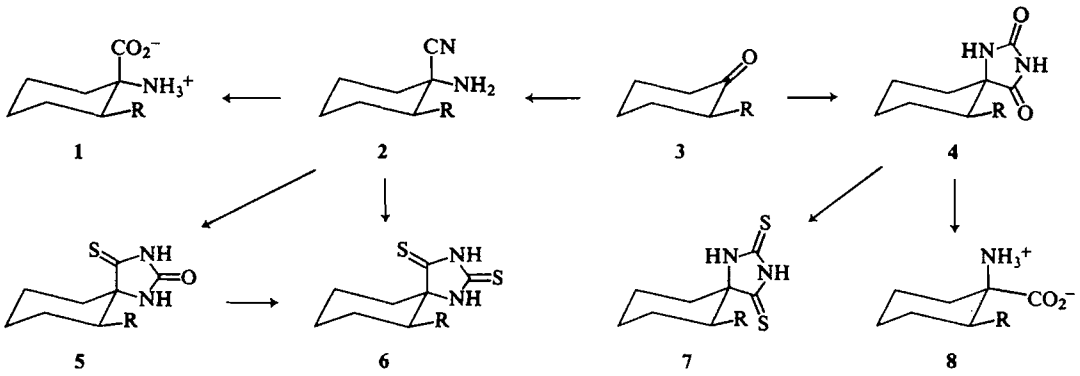

SCHEME I

2-methylcyclohexanone, 2-phenylcyclohexanone, 2,6-dimethylcyclohexanone, and 2-isopropyl-5-methylcyclohexanone (*dl*-menthone) by using either the conventional Bucherer–Bergs reaction (α-series) or its modification employing carbonyl sulfide or carbon disulfide (β-series).

## Experimental

All melting points are in degrees Celsius and are not corrected. The $^{13}C$ nmr spectra were determined on a Varian XL-200 spectrometer. Infrared spectra were measured on a Perkin–Elmer 297 spectrophotometer, and ultraviolet spectra on a Unicam SP800 spectrophotometer. Analyses were by G. Sinclair at Guelph Chemical Laboratories.

*1-Amino-2-phenylcyclohexanenitrile (2; R = Ph)*

A solution of 2-phenylcyclohexanone (5.2 g), ammonion chloride (1.6 g), sodium cyanide (1.5 g), ethanol (28 mL), and water (12 mL) was heated for 9 h at 45–50°C in a pressure bottle. The crude product was removed by filtration and recrystallized from methanol: pale yellow-orange crystals (3.0 g, 47%), mp 110°C; ir (Nujol): 3480, 3415 (NH), 2180 (C≡N) $cm^{-1}$. *Anal.* calcd. for $C_{13}H_{16}N_2$: C 77.96, H 8.03; found; C 78.01, H 8.13.

*2-Phenylcyclohexane-1-spiro-5'-hydantoin (α isomer; 4; R = Ph)*

A solution of 2-phenylcyclohexanone (8.3 g), sodium cyanide (4.6 g), ammonium carbonate (17.0 g), ethanol (37 mL), and water (37 mL) was stirred in a pressure bottle for 6 h at 50–55°C, acidified, and left overnight. The crude product was removed by filtration, washed with water, and crystallized from methanol to yield several crops: 1.65 g, mp 246°C; 1.2 g, mp 240–242°C; and 2.85 g (total yield 49%). Recrystallization from methanol raised the mp of all crops to 246°C; ir (Nujol): 3430, 3280 (NH), 1720 (C=O) $cm^{-1}$. *Anal.* calcd. for $C_{14}H_{16}N_2O_2$: C 68.83, H 6.60; found: C 68.50, H 6.87.

*2-Phenylcyclohexane-1-spiro-5'-(2',4'-dithiohydantoin) (α isomer; 7; R = Ph)*

2-Phenylcyclohexane-1-spiro-5'-hydantoin (α isomer) (1.0 g), phosphorous pentasulfide (1.0 g), and tetralin (20.0 mL) were stirred under reflux for 4 h at 210°C. The hot solution was decanted from some tar and cooled. The solid product was removed by filtration, washed with cold benzene, and found from its uv spectrum (11) to be a mixture of its monothio and dithio derivatives (approx. 80% and 20% respectively). The crude mixture (0.7 g) was therefore allowed to react with *p*-methoxyphenylthionophosphine (12) (1.0 g) in tetralin (20 mL) under reflux for 2 h. The hot solution was decanted from some tar and cooled down, and the product was removed by filtration, washed with cold benzene, and recrystallized from methanol: colorless crystals (0.5 g, 44%), mp 270°C; ir (Nujol): 3240 (NH), 1565, 1545 (thioamide) $cm^{-1}$. *Anal.* calcd. for $C_{14}H_{16}N_2S_2$: C 60.86, H 5.84; found: C 60.66, H 5.89.

*2-Phenylcyclohexane-1-spiro-5'-(4'thiohydantoin) (β isomer; 5; R = Ph)*

A solution of 2-phenylcyclohexanone (2.9 g), sodium cyanide (0.95 g), ammonia (6.3 mL), ethanol (17.3 mL), and water (1.5 mL) was stirred in a three-necked flask immersed in an icebath. Carbon oxysulfide was bubbled into the solution until 3.2 g had been absorbed. The solution was then transferred into a pressure bottle and heated to 50–55°C for 4.4 h. The mixture was cooled, and the crude product was removed by filtration and recrystallized from methanol: 2.5 g, mp 260–265°C, and a second crop, 0.5 g, mp 260–262°C (total yield 69%); ir (Nujol): 3400, 3220 (N—H), 1730 (C=O). *Anal.* calcd. for $C_{14}H_{16}N_2OS$: C 64.60; H 6.20; found: C 64.40, H 6.30.

*2-Phenylcyclohexane-1-spiro-5'-(2',4'-dithiohydantoin) (β isomer; 6; R = Ph)*

(a) *Carbon disulfide modification of the Bucherer–Bergs hydantoin synthesis*

A solution of 2-phenylcyclohexanone (5.2 g), sodium cyanide (1.5 g), ammonion chloride (1.6 g), carbon disulfide (3.0 g), ethanol (28 mL), and water (12 mL) was stirred in a pressure bottle at 50°C for 24 h. The solution was acidified, and the crude product removed by filtration and crystallized from methanol: yellow crystals (0.1 g), mp 242°C; ir (Nujol): 3160 (NH), 1570, 1540 (thioamide) $cm^{-1}$. *Anal.* calcd. for $C_{14}H_{16}N_2S_2$: C 60.86, H 5.84; found: C 60.52, H 5.95.

(b) *Replacement of oxygen in 2-phenylcyclohexane-1-spiro-5'-(4'-thiohydantoin) (β isomer) by sulfur*

2-Phenylcyclohexane-1-spiro-5'-(4'-thiohydantoin) (1.0 g), and phosphorus pentasulfide (1.0 g) in tetralin (20 mL) were heated under reflux for 5 h. The hot solution was decanted from some tar, cooled, and the yellow solid removed by filtration and washed with cold benzene. Crystallization from methanol gave yellow crystals, yield 0.8 g (85%), mp 242°C; identical (mp, uv spectrum) with the compound above.

*2,6-Dimethylcyclohexane-1-spiro-5'-hydantoin (α isomer; 9; X = Y = O)*

A solution of 2,6-dimethylcyclohexanone (4.0 g), potassium cyanide (2.3 g), and ammonium carbonate (15.0 g) in ethanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

(50 mL) and water (40 mL) was heated in a pressure bottle at 50–60°C for 24 h. The mixture was worked up in the usual way, and the hydantoin crystallized from ethanol as colourless needles (3.2 g, 51%), mp 254°C; ir (KBr): 3170, 3100 (NH) 1760, 1710 (C=O) $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{16}N_2O_2$: C 61.20, H 8.22; found: C 61.10, H 8.64.

*2,6-Dimethylcyclohexane-1-spiro-5'-(2',4'-dithiohydantoin) (α isomer; **9**; X = Y = S)*

2,6-Dimethylcyclohexane-1-spiro-5-hydantoin (α isomer) (1.0 g) was heated with phosphorus pentasulfide (1.0 g) in boiling tetralin (20 mL) for 7 h, and the reaction mixture then worked up as usual to give, after crystallization from methanol, yellow crystals (0.5 g, 43%), mp 274°C; ir (KBr): 3240, 3100 (NH), 1525 (thioamide) $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{16}N_2S_2$: C 52.60, H 7.06; found: C 52.84, H 7.40.

*2,6-Dimethylcyclohexane-1-spiro-5'-(4'-thiohydantoin) (β isomer; **10**; X = O, Y = S)*

A solution of 2,6-dimethylcyclohexanone (6.0 mL), potassium cyanide (2.3 g), and concentrated ammonium hydroxide (15.6 mL) in ethanol (50 mL)–water (4 mL) was cooled in an ice-bath. Carbonyl sulfide was passed into the solution until 8.0 g had been absorbed. The solution was transferred to a pressure bottle and heated to 45°C with stirring for 4.2 h. The product, obtained after the usual work-up, was crystallized from methanol and obtained as yellow crystals (2.0 g, 20%), mp 159°C; ir (KBr): 3220, 3130 (N—H), 1735 (C=O) $cm^{-1}$. *Anal.* calcd. for $C_{10}H_{16}N_2OS$: C 56.57, H 7.80, N 13.20; found: C 56.42, H 7.80, N 13.47.

*2,6-Dimethylcyclohexane-1-spiro-5'-(2',4'-dithiohydantoin) (β isomer; **10**; X = Y = S)*

2,6-Dimethylcyclohexane-1-spiro-5'-(4'-thiohydantoin) (β isomer) (1.0 g) was heated with phosphorus pentasulfide (1.0 g) in tetralin (20 mL) to 180–200°C for 7 h, and then worked up as usual. The product crystallization from ethanol as pale yellow crystals (0.5 g, 46%), mp 234–236°C; ir (KBr): 3130 (NH), 1550, 1520 (thioamide) $cm^{-1}$; *Anal.* calcd. for $C_{10}H_{16}N_2S_2$: C 52.60, H 7.10; found: C 52.64, H 7.40.

dl-*Menthane-1-spiro-5'-hydantoin (α isomer; **11**; X = Y = O)*

A solution of *dl*-menthone (5.0 g), potassium cyanide (2.3 g), and ammonium carbonate (15.0 g) in ethanol (50 mL)–water (50 mL) was heated in a pressure bottle to 50–60°C for 9 h. The reaction mixture was worked up in the usual way, and the product crystallized from ethanol: colourless crystals (3.9 g, 54%), mp 233°C; ir (KBr): 3280, 3170 (NH), 1720 (C=O) $cm^{-1}$. *Anal.* calcd. for $C_{12}H_{20}N_2O_2$: C 64.25, H 8.99; found: C 64.00, H 9.20.

dl-*Menthane-1-spiro-5'-(2',4'-dithiohydantoin) (α isomer; **11**; X = Y = S)*

*dl*-Menthane-1-spiro-5'-hydantoin (α isomer) (1.0 g) was heated with phosphorus pentasulfide (1.0 g) in boiling tetralin (40 mL) for 5 h. The product, after the usual work-up, was crystallized from ethanol: pale yellow crystals (0.5 g, 33%), mp 261°C; ir (KBr): 3120 (NH), 1525 (thioamide) $cm^{-1}$. *Anal.* calcd. for $C_{12}H_{20}N_2S_2$: C 56.18, H 7.80; found: 56.10, H 8.14.

dl-*Menthane-1-spiro-5'-(4'-thiohydantoin) (β isomer; **12**; X = O, Y = S)*

A solution of *dl*-menthone (7.1 g), potassium cyanide (2.3 g), and concentrated ammonium hydroxide (15.6 mL) in ethanol (43 mL)–water (3 mL) was cooled in an ice-bath. Carbon oxysulfide was passed into the solution until 8.0 g had been absorbed. The solution was transferred to a pressure bottle, and heated to 50–60°C with stirring for 4.2 h. The product, after the usual work-up, was crystallized from methanol: yellow crystals (7.4 g, 70%), mp 203°C, ir (Nujol): 3240 (NH). *Anal.* calcd. for $C_{12}H_{20}N_2OS \cdot 0.5H_2O$: C 57.78, H 8.48, N 11.27; found: C 58.07, H 7.97, N 11.00.

dl-*Menthane-1-spiro-5'-(2',4'dithiohydantoin) (β isomer; **12**; X = Y = S)*

*dl*-Menthane-1-spiro-5'-(4'-thiohydantoin) (β isomer) (1.0 g) was heated with phosphorus pentasulfide (1.0 g) in boiling tetralin (30 mL) for 5 h. The product crystallized from ethanol in yellow crystals (1.0 g, 94%), mp 150°C[1]; ir (KBr): 3130 (NH), 1550 (thioamide) $cm^{-1}$. *Anal.* calcd. for $C_{12}H_{20}N_2S_2$: C 56.23, H 7.87, N 10.93; found: C 56.32, H 7.70, N 10.91.

## Results and discussion

### *Preparation of 2,4-dithiohydantoins of the α and β series*

Ansell *et al.* (10), in studying the stereochemistry of the Strecker and Bucherer–Bergs reactions of 2-phenylcyclohexanone (**3**, R = Ph), converted the reaction products to the epimeric amino-acids **1** and **8** (R = Ph). We found the amino-nitrile **2** (R = Ph) unusually resistant to acid hydrolysis, perhaps because of the presence of the large phenyl group *gauche* to the axial nitrile, and so for convenience chose as our "Strecker" product the 2,4-dithiohydantoin **6** (R = Ph), produced by the modified reaction using $CS_2$. This reaction went in very poor yield (another indication of hindrance), and the dithiohydantoin **6** (R = Ph) was more readily available by preparing first the monothiohydantoin **5** (R = Ph) by the COS modification of the Bucherer–Bergs reaction (8) (a reaction known to go well with hindered ketones such as adamantanone (13)), followed by sulfuration of the monothiohydantoin to the dithiohydantoin by phosphorus pentasulfide (14). The corresponding 2,4-dithiohydantoin **7** (R = Ph) of the α-series was prepared by sulfuration of the normal Bucherer–Bergs product **4** (R = Ph). This reaction also proved difficult, sulfuration by phosphorus pentasulfide being incomplete after six hours. Sulfuration was accordingly completed by using the more reactive *p*-methoxyphenylthionophosphine (12).

The configurations of the products from 2-phenylcyclohexanone shown in Scheme 1, and assumed in the account above, are those predicted by the EJ rule, and up to this point are only tentative. The same is true for the configurations of the epimeric 2,4-dithiohydantoins **6** and **7** (R = Me) obtained from 2-methylcyclohexanone (**3**; R = Me); the preparation of these products has already been described in the literature (9).

Similar routes were used to prepare the epimeric

[1]Carrington (7) reported obtaining this compound, mp 209°C, in 5% yield by the $CS_2$-modification of the Bucherer–Bergs reaction, but his product had a poor analysis and may have been impure. The purity of our own product follows from its $^{13}C$ nmr spectrum (see below).

TABLE 1. $^{13}C$ chemical shifts (ppm, downfield from TMS) of carbon atoms of epimeric hydantoins and 2,4-dithiohydantoins in DMSO-$d_6$

| Compound | Isomer | Structure | Cyclohexane ring carbons C-1 | C-2 | C-3 | C-4 | C-5 | C-6 | Other carbons $CH_3$ | C-2′ | C-4′ | Σ[a] |

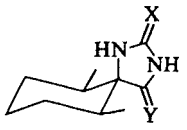
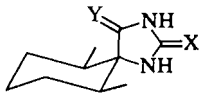
2,4-dithiohydantoins **9** and **10** (X = Y = S) from 2,6-dimethylcyclohexanone and **11** and **12** (X = Y = S) (only one enantiomer shown in each case) from *dl*-menthone. The preparation of the latter compounds encountered no difficulty, the steric hindrance of the isopropyl group (conformational free energy difference of 2.1 kcal mol$^{-1}$ (15) for equatorial–axial change) evidently being much less than that of the phenyl group (conformational free energy difference 2.87 ± 0.09 kcal mol$^{-1}$ (16)).

### $^{13}C$ *nuclear magnetic resonance of* α *and* β *isomers*

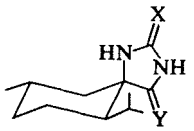
Carbon-13 nmr spectroscopy has proved a powerful tool for revealing the presence of minor isomeric impurities in supposedly pure compounds (5). In the present instance it shows that compounds of Table 1 are free from any appreciable quantity of isomeric impurity, which would be revealed by additional peaks in the spectra. It had been considered possible that the reaction products **9–12** might be contaminated by small quantities of epimers having an axial methyl group, because of epimerization of the starting ketones under the alkaline reaction conditions, but such compounds, if formed, were evidently removed by the isolation and purification procedures followed.



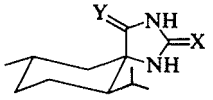
**9**



**10**



**11**



**12**

The nmr peaks of the carbon atoms of the various epimeric hydantoins and 2,4-dithiohydantoins are shown in Table 1. As before (3) the peaks at lowest field can be assigned to C-4′ carbon atoms, and at next lowest field to C-2′ carbons. Peaks at higher field due to cyclohexyl, methyl, phenyl, and isopropyl carbons can be assigned on the basis of splitting patterns in the coupled spectra, although not always unambiguously.

As before (3, 5) the strongest evidence for a particular configuration came from the half-widths of the coupled C-4′ peaks. When C-4′ is axial, as in **6**, **10**, and **12**, it will be coupled with *anti* hydrogen atoms at C-2 and C-6 of the cyclohexane ring, and the vicinal coupling constants, $^3J_{(^{13}C-^1H)}$, should be large. When C-4′ is equatorial, as in the epimers **7**, **9**, and **11**, it will be coupled with *gauche* hydrogens

| Compound | Series | $\lambda_{max}$(nm) | $\varepsilon_{max}$ | $\lambda_{max}$(nm) | $\varepsilon_{max}$ | $\lambda_{max}$(nm) | $\varepsilon_{max}$ |
| **5**, R = Me | β | 389 | 18 | 282 | 12 600 | 233 | 6 150 |
| **6**, R = Me | β | 407 | 39 | 301 | 23 300 | 225 | 6 240 |
| **7**, R = Me | α | 386 | 47 | 300 | 25 400 | 226 | 6 280 |
| **6**, R = Ph | β | 406 | 45 | 304 | 56 200 | 226 | 27 400 |
| **7**, R = Ph | α | 387 | 50 | 302 | 85 300 | 228 | 28 000 |
| **9**, X = Y = S | α | 390 | 45 | 300 | 24 500 | 226 | 7 240 |
| **10**, X = Y = S | β | 410 | 43 | 302 | 26 300 | 226 | 7 140 |
| **11**, X = Y = S | α | 388 | 37 | 300 | 19 500 | 225 | 6 020 |
| **12**, X = Y = S | β | 411 | 44 | 304 | 26 000 | 226 | 8 010 |

at C-2 and C-6, and the vicinal coupling constants should be small. Because of the complexity of the coupled C-4′ peaks, the width at half-height, $W_{1/2}$, was used as an indication of $^3J_{(^{13}C-^1H)}$. The half-widths (in Hz) for the various compounds were as follows:

| β-Series | $W_{1/2}$ | α-Series | $W_{1/2}$ |
|---|---|---|---|
| **6**, R = Me | 20.0 | **7**, R = Me | 10.0 |
| **6**, R = Ph | 26.0 | **7**, R = Ph | 13.5 |
| **10**, X = Y = S | 28.0 | **9**, X = Y = S | 13.6 |
| **12**, X = Y = S | 21.0 | **11**, X = Y = S | 11.3 |

In all cases, the half-widths of the coupled C-4′ peaks of the β epimers were about twice as great as the half-widths for the α epimers. This shows that the β compounds have C-4′ predominantly in the axial position, and the α compounds C-4′ predominantly in the equatorial position, and justifies the various structural assignments in Table 1, and the tentative assignments in Scheme 1. These are all in conformity with the EJ rule.

Further support for these configurational assignments comes from the fact, evident in Table 1, that for **4/5** (O in place of S), **6/7** (R = Me and Ph), and **11/12** the summed values Σ of the $^{13}C$ chemical shifts of the β compounds are smaller than the summed values of the shifts of the α compounds (i.e. the average chemical shift of a β compound is at higher field than the average shift of its corresponding α epimer). That indicates the β compounds to be more strained than the α compounds (17), which is expected from the assignments above. In the β compounds a bulky oxygen or sulfur atom attached to C′-4′ is pushing inward towards the axial hydrogen atoms of the cyclohexane ring, while in the α compounds a smaller hydrogen atom attached to N′-1′ is pushing inwards.

*Ultraviolet absorption spectra of α and β isomers*

The ultraviolet absorption characteristics in ethanol solution of the mono- and dithiohydantoins prepared in this investigation are given in Table 2, the absorption bands being classified according to Janssen's scheme (18). The results for the most part are unexceptional, although the high intensities of Band II and Band IV for **6** and **7** (R = Ph) are noteworthy in indicating the effect of proximate phenyl on what are probably $\pi \rightarrow \pi^*$ transitions (18). However, for our present purposes we need consider only Band I at longest wavelength, which is due to the $n \rightarrow \pi^*$ transition of the 4-thiocarbonyl group. In any epimeric pair the band of the β compound was at longer wavelength (see Table 2), which supports the configurational assignments given above (see ref. 3 for detailed argument).

## Conclusion

We are compelled by the nmr and uv evidence marshalled above to conclude that the stereochemistry of the products obtained from 2-substituted cyclohexanones by the conventional Bucherer–Bergs reaction, on the one hand, and by the Strecker or modified Bucherer–Bergs reactions, on the other hand, are in conformity with the EJ rule. It might seem reassuring to find that Nature is not capricious, and that 2-substituted cyclohexanones behave like other ketones. But the change in the chemical shift of the benzylic proton of the amino-acids **1** and **8** (R = Ph) on formation of *N*-acetyl or *O*-methyl derivatives (10) *is* decidedly capricious and misleading, if the changes in the chemical shifts of this proton in the monofunctional cyclohexylamines and cyclohexane carboxylic acids on formation of the same derivatives are considered normal. The same remarks apply to the very reasonable generalizations of Cremlyn and Chisholm, which were based on the effect of changing solvent composition on the dissociation constants of cyclohexylamines and cyclohexane carboxylic acids of known configuration, and which fail for geminal amino carboxylic acids (19). Evidently the

proximity of amino and carboxylic groups causes simple additive schemes to break down.

J. C. HALLE, M. J. POUET, M. P. SIMONNIN, F. DEBLEDS, and F. TERRIER. Can. J. Chem. **60**, 1988 (1982).

Reaction of 1,3,5-trinitrobenzene (TNB) with pyrrole, 2,5-dimethyl pyrrole, and 2,4-dimethyl-3-ethyl pyrrole in the presence of a strong base ($CH_3O^-$) yields nitrogen- and/or carbon-bonded 1:1 σ-complexes in dimethylsulphoxide (DMSO). Depending on the stoichiometry of the reagents, 1:2 and 2:1 pyrrole–TNB diadducts are also formed. Identification of all complexes was effected by nmr. The reactive species are shown to be the pyrrolide ions and the results emphasize the ambident character of these anions towards an aromatic electrophile. Some of the complexes have been isolated as crystalline potassium salts when experiments are performed in acetonitrile. Among the isolable complexes, the *kinetically but not thermodynamically favored* nitrogen adduct of pyrrole (**5***a*) is remarkably unreactive. The second-order rate constant $k^{H^+}$ for is $H^+$-catalyzed decomposition in aqueous solution is only 1 L mol$^{-1}$ s$^{-1}$ ($t$ = 25°C).

J. C. HALLE, M. J. POUET, M. P. SIMONNIN, F. DEBLEDS et F. TERRIER. Can. J. Chem. **60**, 1988 (1982).

Dans le diméthylsulfoxyde (DMSO) et en présence d'une base forte ($CH_3O^-$), le trinitro-1,3,5-benzène (TNB) réagit avec le pyrrole, le diméthyl-2,5 pyrrole et le diméthyl-2,4 éthyl-3 pyrrole pour donner des complexes-σ azotés et/ou carbonés 1:1. En fonction de la stoechiométrie des réactifs, des diadduits pyrrole–TNB 1:2 et 2:1 sont également formés. L'identification des complexes a été faite par rmn. Les résultats montrent que les espèces réactives sont les ions pyrrolate et mettent en évidence le caractère ambident de ces anions vis-à-vis d'un électrophile aromatique. Quelques complexes ont pu être isolés à l'état solide sous forme de sels de potassium. Parmi ces complexes, et bien qu'il se forme seulement sous contrôle cinétique, l'adduit azoté **5***a* du pyrrole présente une "stabilité" remarquable. La constante $k^{H^+}$ relative à sa dissociation catalysée par les ions $H^+$ est seulement de 1 L mol$^{-1}$ s$^{-1}$ en solution aqueuse ($t$ = 25°C).

## Introduction

Much interest has been devoted to the reactions of aliphatic, alicyclic, and aromatic amines with electron-deficient aromatics like 1,3,5-trinitrobenzene (TNB) to give the nitrogen bonded σ-complexes of general structure **1** (2–7). Equation [1] describes the interaction which proceeds through the initial formation of the zwitterionic complexes **1**, $H^+$. In contrast, but in accord with their much lower basicity, heteroaromatic amines like pyrrole derivatives are not known to react with TNB. In this regard, one can wonder that the reactivity of the corresponding anions, e.g. pyrrolide anions, towards electron-deficient aromatics has received no attention so far. In fact, the behaviour of such anions is of interest for two reasons: (*1*) they are known to react as ambident nucleophiles with most common electrophiles (acyl and alkyl halides), yielding usually N-1 and/or C-2 or C-3 substituted products (8–10); (*2*) they can offer the possibility of forming nitrogen-bonded σ-adducts of type **1** by another route than that depicted in eq. [1], i.e. by direct attack of the anion on the aromatic. We report our observation that N-bonded adducts, C-bonded adducts, and various 1:2 and 2:1 diadducts form in the reactions of TNB with different pyrrolide anions. The results, which are very dependent on the substituents bonded to the pyrrole ring, emphasize the ambident character of pyrrolide anions.

## Results

While no reaction occurs in adding pyrrole (**2***a*), 2,5-dimethyl pyrrole (**2***b*), or 2,4-dimethyl-3-ethyl pyrrole (**2***c*, kryptopyrrole) to a DMSO or acetonitrile solution of TNB, strong colors typical of σ-complexes develop immediately in the presence of methoxide ion. Similar adducts form when the amines are added to a DMSO solution of the TNB–methoxide complex **4**. As will be discussed below, the reactive species are the pyrrolide ions **3***a*, **3***b*, and **3***c*. The structures of the various adducts have been determined by $^1$H nmr.

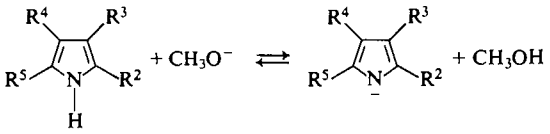
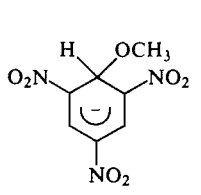
*Pyrrole 2a*

Addition of an equimolar mixture of pyrrole and methoxide ion (1 equiv.) in DMSO to a DMSO solution of TNB (1 equiv.) results in the formation

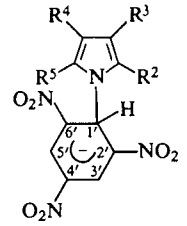


**2a** $R^2 = R^3 = R^4 = R^5 = H$ **3a**
**2b** $R^2 = R^5 = Me$; $R^3 = R^4 = H$ **3b**
**2c** $R^2 = R^4 = Me$; $R^3 = Et$; $R^5 = H$ **3c**

of the N-adduct **5a**. The symmetrical structure of the pyrrole moiety was confirmed by the presence of an AA'BB' system in the $^1H$ nmr spectrum of **5a** which also shows the $AX_2$ system ($\delta H_{1'} = 6.89$; $\delta H_{3',5'} = 8.51$; $^4J = 0.8$) characteristic of the cyclohexadienylide ring (Table 1). The chemical shifts of the $H_{1'}$ and $H_{3',5'}$ protons are consistent with those previously reported for other N-bonded complexes (1). No NH signal is observed. Further confirmation of the structure of **5a** comes from its $^{13}C$ nmr spectrum which consists of six signals, only two of them belonging to fully substituted carbons ($C_{4'}$ and $C_{2',6'}$): $\delta C_{1'} = 52.5$ (d); $\delta C_{2',6'} = 131.6$ (s); $\delta C_{3',5'} = 125.8$ (d); $\delta C_{4'} = 120.6$ (s); $\delta C_{2,5} = 120.2$ (d); $\delta C_{3,4} = 107.6$ (d).



**4**

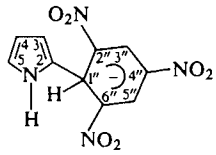


**5a**: $R^2 = R^3 = R^4 = R^5 = H$
**5b**: $R^2 = R^5 = Me$; $R^3 = R^4 = H$
**5c**: $R^2 = R^4 = Me$; $R^3 = Et$; $R^5 = H$

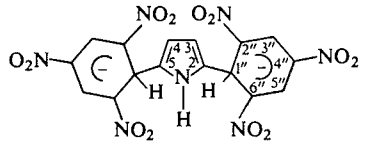
Compound **5a** is very stable and was isolated as a crystalline potassium salt by carrying out similar experiments in acetonitrile and evaporating the solvent (see experimental section). Dissolution of this salt in DMSO-$d_6$ gives a spectrum similar to that observed from the *in situ* generation of **5a** (Fig. 1).

Despite the high stability of **5a**, a slow evolution of the spectra occurs over an extended period of time, i.e. several months. One thus observes the progressive disappearance of the signals of **5a** and the concomitant appearance of pyrrole, the C-2 adduct **6**, the C-2, C-5 1:2 diadduct **7**, and a small amount of the C-2, C-4 1:2 diadduct **8**. Figure 2 shows the spectrum obtained after seven months when the N-adduct **5a** is no longer observed.

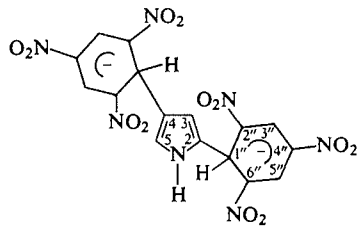
The structure of the C-2 adduct **6** has been established from the following observations: (*1*) the presence of a low-field NH signal ($\delta = 10.51$); (*2*) an



**6**



**7**



**8**

$AX_2$ system ($\delta H_{1''} = 5.73$, $\delta H_{3'',5''} = 8.31$); (*3*) three pyrrolic protons forming an AMX system. In agreement with the lower electronegativity of a carbon atom relative to a nitrogen atom, the chemical shifts of the cyclohexadienylic $H_{1''}$ and $H_{3'',5''}$ protons are at higher field than those of the analogous $H_{1'}$ and $H_{3',5'}$ protons of the N-adduct **5a**. They are also consistent with those previously reported for other TNB C-bonded complexes (1, 4). Double resonance experiments indicate that the three protons of the AMX system are coupled with the amino proton. The various coupling constants of the pyrrolic protons are of the same order of magnitude as those observed for pyrrole itself, allowing an unambiguous assignment of these protons (11, 12) (Table 1).

The nmr spectrum of the symmetrical C-2, C-5

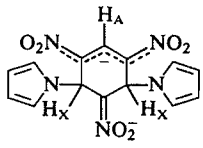
[a]Chemical shifts in ppm relative to TMS as internal standard, $J$ in Hertz.

diadduct **7** exhibits a single cyclohexadienylic $AX_2$ system at δ 8.29 and 5.69, a broad NH signal at δ 9.72, and a high-field doublet at δ 5.44 which coalesces to a *singlet* when irradiating the NH signal. Integration shows that these two latter resonances are in a 1:2 ratio. The chemical shift of the two equivalent protons indicates that they are located in the positions β to the nitrogen. The symmetrical structure of **7** is further supported by the absence of a vicinal coupling constant.

The minor product is the dissymmetrical C-2, C-4 diadduct **8** since its spectrum shows two $AX_2$ cyclohexadienylic systems very close to those observed for **6** and **7** and that the NH proton (δ = 10.20) is coupled with two pyrrolic protons ($\delta H_3$ = 5.52; $\delta H_5$ = 6.18). The large chemical shift difference between these two latter protons confirms that they are located in the positions β and α to the nitrogen atom, respectively.

Another type of diadduct, i.e. **9**, may be obtained in using a 2:1 stoichiometry of the reagents (2 equiv. of pyrrole and $CH_3O^-$ ion, 1 equiv. TNB) or adding a second equivalent of the basic mixture to a solution of the N-adduct **5***a*. In agreement with the structure **9**, the $^1H$ nmr spectrum shows four different resonances in a 1:2:4:4 ratio when going from low to high-field. That both pyrrole moieties in **9** are bonded by their nitrogen atom is evidenced by the presence of a single AA'BB' system. Whether **9** has a *cis* or *trans* configuration (13–15) cannot be deduced from nmr data recorded between 22 and 37°C. The $^4J_{AX}$ coupling constant in **9** is unresolved and has been determined, using Sardella's method, by double resonance experiments (16).



**9**

*2,5-Dimethyl pyrrole (***2**b**) and 2,4-dimethyl-3-ethyl pyrrole (***2**c**)*

Addition of an equimolar mixture of methoxide ion and **2***b* or **2***c* (1 equiv.) to a DMSO solution of TNB (1 equiv.) results in the initial formation of the oxygen adduct **4** which is subsequently converted into a C-adduct. Various attempts to detect the N-bonded complexes **5***b* and **5***c*, even as transient species, have failed. The results in Tables 2 and 3 are consistent with the formation of the C-3 and C-5 complexes **10** and **12** respectively.[4] The nmr spec-

[4]For simplicity, the numbering of the pyrrolic ring of **12** is the same as that of its parent, **2***c*.

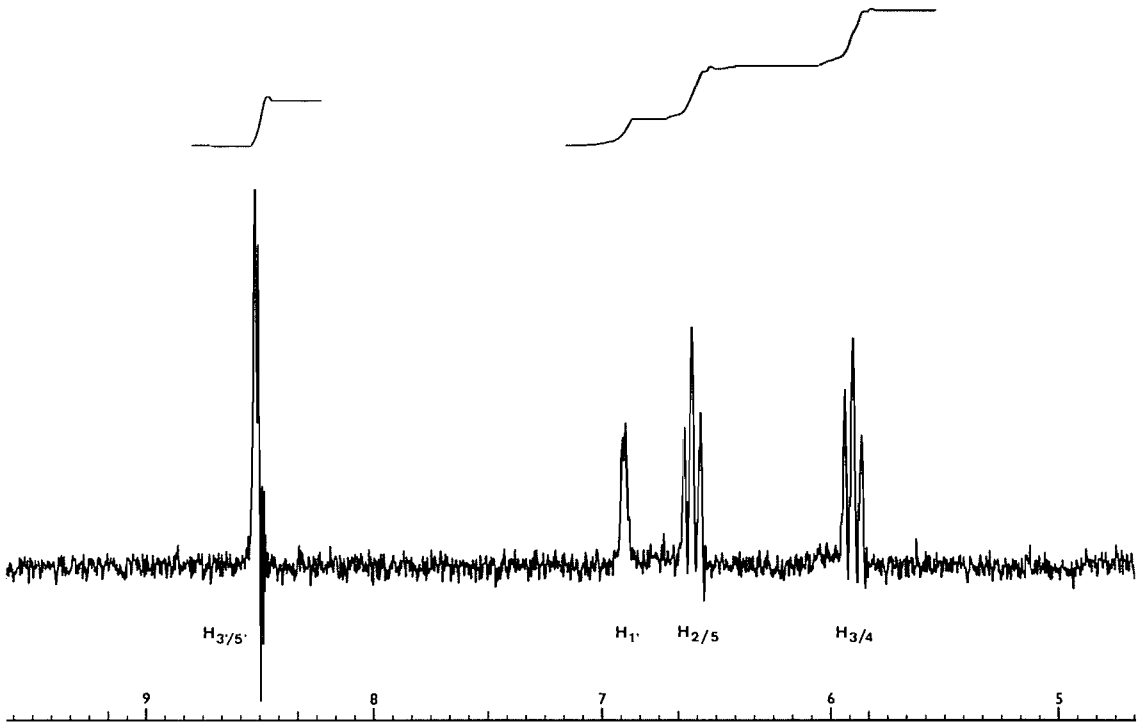

FIG. 1. The $^1H$ nmr spectrum of the potassium salt of the N-adduct **5***a* of pyrrole in DMSO-$d_6$.

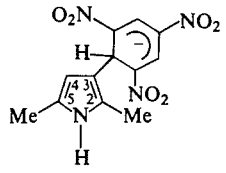
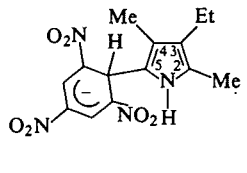
trum of **10** shows in particular that the resonance of the 2-methyl group is a singlet while that of the 5-methyl group is a doublet, due to the allylic coupling constant $^4J_{H_4Me_5}$. In the case of **12**, both 2- and 4-methyl groups give a singlet, thus confirming the absence of the H-5 proton.

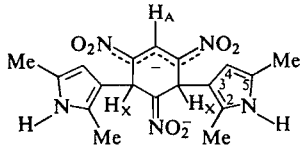


**10**

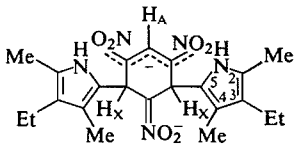


**12**

The use of a 2:1 2,5-dimethyl pyrrole (or kryptopyrrole)/$CH_3O^-$–TNB stoichiometry leads to the formation of the C-bonded diadduct **11** (or **13**). Both nmr spectra exhibit a low-field $AX_2$ system. In addition, the spectrum of **11** shows the presence of one pyrrolic β proton ($\delta H_4$ = 5.21) and two different methyl groups, the most shielded being coupled with $H_4$. On the other hand, and in agreement with a tetrasubstituted pyrrole ring, the spectrum of **13** exhibits no $H_\alpha$ resonance but shows two singlets corresponding to the 2- and 4-methyl groups and the multiplets expected for the ethyl group.



**11**



**13**

## Discussion

*Mechanism of complex formation*

It is well-known that addition of primary and secondary aliphatic and alicyclic amines to TNB and related derivatives in DMSO and acetonitrile obeys eq. [1], the overall interaction requiring two equivalents of amine (B = RR'NH) to form the anionic σ-complex **1** (5, 7, 17–21). Equation [1] also holds for less basic aromatic amines like aniline (7, 22, 23). However, the formation of the anilide zwitterion is thermodynamically so unfavorable that, despite a large $K_p$ value for its deprotonation by aniline, no reaction occurs in only the presence of aniline itself. In this case, addition of a stronger base like $MeO^-$ or diazabicyclo[2,2,2]octane (DABCO) is necessary for the reaction to proceed. The effect of this stronger base is to increase the equilibrium constant $K_p$ for deprotonation of **1**, $H^+$ to the extent that the overall interaction becomes feasible (7, 22, 23).

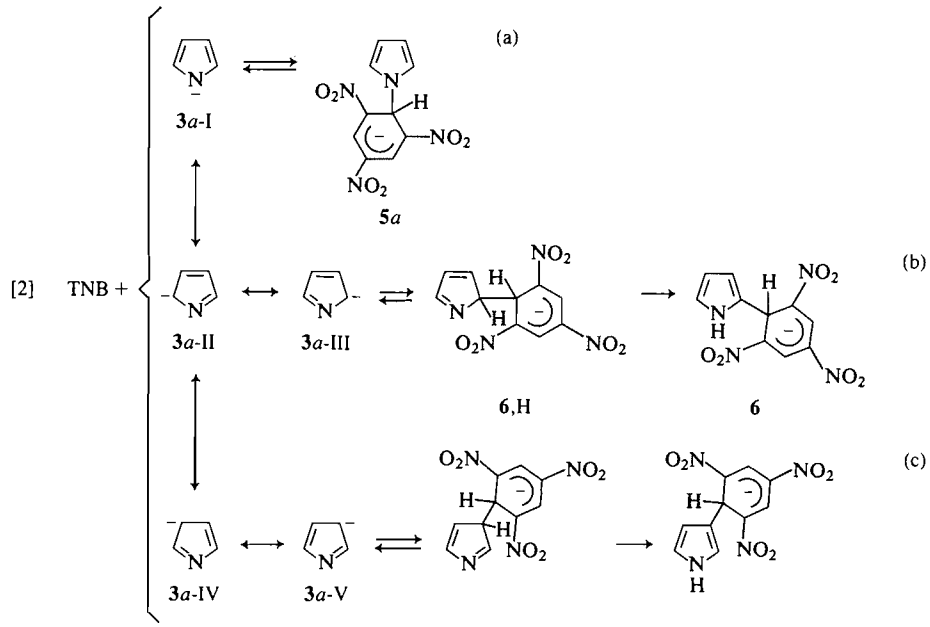
In the case of pyrrole derivatives, the basicity of the nitrogen atom is very low because the lone pair is part of the aromatic sextet: a $pK_a^{H_2O}$ of $\sim -10$ has been estimated for unsubstituted pyrrole (24). Consequently, protonation and other electrophilic reactions occur preferentially at the α carbon atoms (pyrrole: $pK_a^{H_2O}$ ($C_\alpha$) = −3.8) or, if these positions are blocked, at the β carbon atoms (10, 25). In such conditions, direct nucleophilic attack of neutral pyrroles on TNB to give a zwitterion of

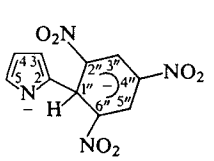
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.



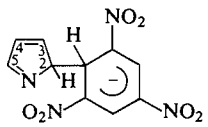
the **1**, $H^+$ type is totally unrealistic. In contrast, substitution on nitrogen is known to normally occur in basic media via the anions **3** and is often followed by isomerization to a C-substituted product, due to the contribution of the mesomeric forms **3***a*-I ·· **3***a*-V (see eq. [2]) (8–10). In accord with these results, there is no doubt that the formation of the N-bonded complex **5***a* reflects the attack of the highly nucleophilic pyrrolide ions, as shown in path (a) of eq. [2]. Support for this mechanism is provided by potentiometric hydrogen electrode measurements which show that ionization of unsubstituted pyrrole occurs to a notable extent in basic MeOH–DMSO and $H_2O$–DMSO mixtures with more than 95% DMSO by volume.[5] With time, and in agreement with a greater contribution of the resonance form **3***a*-II/III over **3***a*-IV/V, **5***a* is converted into the thermodynamically more stable C-2 complex **6**, according to paths (a) and (b) of eq. [2].

Due to the presence of electron-donating alkyl groups, 2,5-dimethyl and 2,4-dimethyl-3-ethyl pyrroles are much less acidic than pyrrole itself (10, 25). Potentiometric hydrogen electrode measurements show that they don't ionize to a great extent in our mixtures, preventing reliable $pK_a$ determinations. In this case, the equilibrium concentrations of the pyrrolide ions **3***b* and **3***c* are small and the methoxy complex **4** is first generated as a result of the highly favorable kinetic and thermodynamic factors associated with the formation of **4** from TNB and $CH_3O^-$ (7, 27). Then, the C-complexes **10** and **12** are formed from **4** according to eq. [3] (shown for 2,5-dimethyl pyrrole). The N-adducts **5***b* and **5***c*, which one would expect to form under kinetic control relative to **10** and **12**, cannot be detected.

The formation of the 1:2 diadducts **7** and **8** may be explained by the fact that the C-2 complex **6** behaves as a 2-substituted pyrrole and should ionize to some extent to give the corresponding pyrrolide ion **14**. In principle, such an anion may



**14**

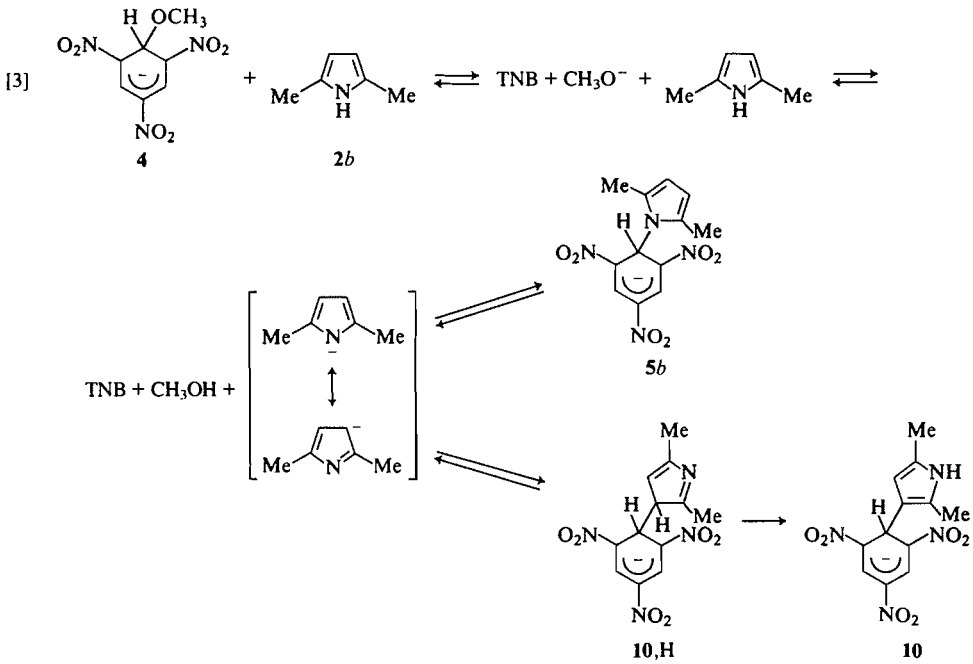


**12**,H

react with TNB at N-1, C-3, or C-4 and C-5. As for alkyl pyrroles **2***b* and **2***c*, attack at N-1 is not favored so that only the C,C-diadducts **7** and **8** are observed. The largely favored formation of **7** over **8** again reflects the preferential occurrence of electrophilic attack at the α-position in pyrroles (8–10).

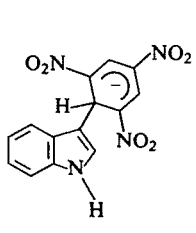
It should be noted that the formation of the various C-adducts (**6**, **10**, and **12**) must be preceded by that of the corresponding C—H pyrrolenine adducts such as **6**, *H* (see eq. [2]), **10**, *H* (see eq. [3]), and **12**, *H*. A similar remark holds for diadducts **7** and **8**. That pyrrolenine adducts are not observed suggests they are not stable and rearrange very fast to **6**, **10**, and **12** or **7** and **8**. Indeed this behaviour is similar to that encountered in the

[5]For example, the $pK_a$ for formation of pyrrolide ion **3***a* is 21.9 in 5% $H_2O$ – 95% DMSO (J. C. Halle, unpublished results) while a 0.01 *M* tetramethylammonion hydroxide solution in this mixture has a pH of 22 (26).

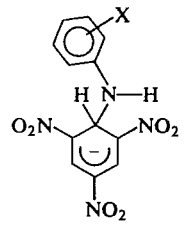


reactions of TNB with indoles to give the C-3 complexes **15** (1).

Although it is not a thermodynamically stable product, the N-adduct **5***a* may be isolated as a crystalline potassium salt. This is because its decomposition is remarkably slow. Thus, no appreciable dissociation of **5***a* into TNB and pyrrole occurs at pH 7 in aqueous solution. However, in dilute hydrochloric acid solutions, the decomposition occurs at measurable rates. The $H^+$-catalyzed second-order rate constant $k^{H^+}$ associated with eq. [4] is equal to $1\,L\,mol^{-1}\,s^{-1}$ ($t$ = 25°C, $I$ = 0.2 *M* KCl). It is one of the slowest rates ever measured for such a process (7). For comparison, the C-adducts **10** and **12** decompose faster: $k^{H^+}$ is equal to 3.09 and $70\,L\,mol^{-1}\,s^{-1}$ for **10** and **12**,



15



16

respectively. However, such $k^{H^+}$ values are in the range of those typically measured for very stable carbon-bonded complexes (7, 28). The exact mechanism of these $H^+$-catalyzed decompositions is currently under investigation.

[4] **5***a* + $H^+$ $\xrightarrow{k^{H^+}}$ TNB + pyrrole

*Nuclear magnetic resonance chemical shifts*

Tables 1, 2, and 3 show that all the protons of the pyrrole moieties move upfield on going from pyrroles **2***a*, *b*, *c* to the monoadducts **5***a*, **6**, **10**, and **12**. These protons undergo an additional high-field shift when substituting an α or β position by a second cyclohexadienyl ring to form the diadducts **7** and **8**. Thus, the NH and H-3 protons in pyrrole and its various adducts have chemical shifts decreasing in the order **2***a* > **5***a* (H-3) > **6** > **8** > **7**. An explanation of this phenomenon on only the basis of anisotropy effects due to either the cyclohexadienyl ring or the nitro groups is not satisfactory since similar upfield shifts are observed for the α and β protons in **5***a*. Also, such behaviour is apparently not consistent with the fact that the trinitrocyclohexadienyl moiety is known to be electron-withdrawing relative to a proton (29–33). It has thus been observed that all the protons of the aniline moiety in the various anilide complexes **16** resonate at lower field than their analogs in the parent anilines (30). In this instance, the electron-demanding cyclohexadienyl ring reduces the electron-releasing capability of the nitrogen in **16** as compared with that in the anilines. Another evidence of the electron-withdrawing effect of the cyclohexadienyl ring is that the zwitterions **1**, $H^+$ are, regardless of the amine, 100 to 400 times more acidic than the parent $RR'NH_2^+$ alkyl or aryl ammonium ions (31–33). In the pyrrole derivatives, the nitrogen lone pair is part of an aromatic sextet, so that the observed upfield shifts suggest that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

cyclohexadienyl moiety diminishes the electron density of the pyrrolic ring, thereby decreasing the ring current. It should be noted that the only case where a downfield shift is observed is the 2-Me group in the C-complex **10**. This is probably because this group is spatially located close to the cyclohexadienyl ring and suggests that the preferred conformation of **10** is different from that of **12**.

## Experimental

*Nuclear magnetic resonance experiments*

The $^1$H nmr spectra were recorded at 60 (Varian A-60; $T$ = +37°C) and 100 MHz (Varian XL-100; $T$ = +31°C) using TMS as an internal standard. The $^{13}$C spectra were collected at 25.17 MHz, using the Fourier transform technique (Varian XL-100) and the solvent $^2$H signal (DMSO-$d_6$) for internal field-frequency lock.

*Isolable complexes*

Potassium salts of **5***a*, **10**, and **12** were prepared by the addition of an equimolar mixture of pyrrole (**2***a*, **2***b*, or **2***c*) and potassium methoxide ion in 1 mL acetonitrile to an acetonitrile solution of TNB (100 mg in 1 mL). The reaction mixtures turned immediately dark red or purple and were allowed to stand at room temperature for one hour (**5***a*) or two days (**10** and **12**). Then some anhydrous ether $Et_2O$ was added to the solutions. The crystals which formed were filtered, ground to a fine powder, washed with copious amounts of ether, and dried *in vacuo* to eliminate any associated solvent. The three complexes decompose from 180 to 200°C. The $^1$H nmr spectra of the salts in DMSO-$d_6$ are similar to those observed in the *in situ* generation of **5***a*, **10**, and **12**.

*Rate measurements*

The kinetics of the decomposition of the complexes **5***a*, **10**, and **12** was followed spectrophotometrically at 480 nm on a Beckman Acta 3 spectrophotometer, the cell compartment of which was thermostated to 25 ± 0.5°C. All kinetic runs were carried out under pseudo first-order conditions with an acid (HCl) or buffer ($HCOO^-$/HCOOH, $CH_3COO^-$/$CH_3COOH$) concentration in large excess over the complex concentration ($2 \times 10^{-5}$ *M*). The reported rate constants represent average values obtained from two or three independent determinations.

# Xanthocyclines: 5-oxaanthracyclines (7,8,9,10-tetrahydrobenzo[*b*]xanthen-12-one)

JAMES L. CHARLTON, VILAYAT A. SAYEED, AND GERALD N. LYPKA
*Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2*

Received February 2, 1982

JAMES L. CHARLTON, VILAYAT A. SAYEED, and GERALD N. LYPKA. Can. J. Chem. **60**, 1996 (1982).

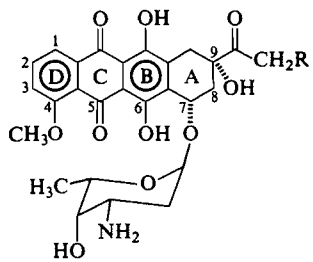
The anthracycline antibiotics daunorubicin and adriamycin are potent antitumor agents. It has recently been suggested that 5-oxaanthracycline analogs of these compounds might show reduced cardiotoxicity, a property that limits the clinical use of the anthracyclines. In this paper we describe the condensation–cyclization reactions of 2-methylchromone-3-carboxylate with cyclohexanones, a reaction that leads ultimately to the xanthocycline skeleton.

JAMES L. CHARLTON, VILAYAT A. SAYEED et GERALD N. LYPKA. Can. J. Chem. **60**, 1996 (1982).

Les antibiotiques du type anthracycline tels la daunorubicine et l'andriamicyne sont des agents puissants contre les tumeurs. On a suggéré récemment que les oxa-5 anthracycline analogues de ces composés, peut exhiber une cardiotoxicité réduite; cette propriété limite l'utilisation clinique des anthracyclines. Dans cette publication, nous décrivons les réactions de condensation–cyclisation du méthyl-2 chromone carboxylate-3 avec les cyclohexanones qui conduisent éventuellement au squelette de la xanthocycline.
[Traduit par le journal]

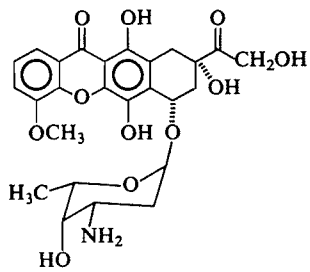
## Introduction

The anthracycline antibiotics daunorubicin, **1**, and adriamycin, **2**, have been the subject of extensive synthetic effort due to their use in the treatment of several human cancers (ref. 1, and for reviews of synthetic methods, see ref. 2). Unfortunately, these drugs also exhibit a cardiotoxicity which limits their clinical use (3). Although some analogs show a reduced cardiotoxicity (4), the search continues for drugs with a higher therapeutic index. It has been suggested that the cardiotoxicity of the anthracycline antibiotics may be related to the electron transport properties of the quinone function within these molecules (5). This in turn led to the suggestion by Wong *et al.* that modification of the C ring might reduce the cardiotoxicity (6).



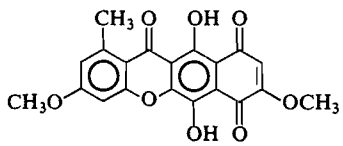
**1** R = H
**2** R = OH

Wong suggested replacing the 5-carbonyl group with an oxygen in order to alter the reduction potential of the C ring. He referred to the 5-oxa-adriamycin analog **3** as xanthoadriamycin (6). We propose the more general name xanthocycline for this class of compounds, that is, compounds having the 7,8,9,10-tetrahydrobenzo[*b*]xanthen-12-one skeleton.



**3**

Xanthones, and especially hydroxyxanthones, have long been known to produce pharmacological and biological effects (7), although few examples of compounds having the general tetracyclic carbon skeleton of compound **3** are known. The one exception is bikaverin **4**, which has been the subject of three independent synthetic studies (8).



**4**

Although bikaverin is reported to show only antiprotozoal activity, we were intrigued to find that other derivatives of 1-hydroxyxanthone were active against Sarcoma 180 tumor cells (9). This further encouraged us to seek a synthetic route to the xanthocyclines, since they contain both the 1-hydroxyxanthone functionality and the major structural features of the anthracycline antibiotics.

In this paper we report the synthesis of the tetracyclic compound **5**

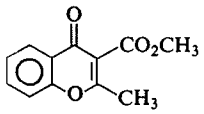
5

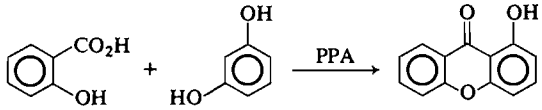
beginning from methyl 2-methylchromone-3-carboxylate **6**.



6

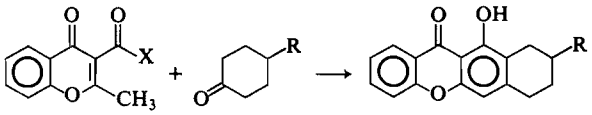
## Results and discussion

Several methods for the synthesis of xanthones have been described in the literature (7, 8). Most of these involve condensation between two aromatic precursors as illustrated in the example below (10). The latest two papers on the synthesis of bikaverin incorporate similar aromatic condensation methods involving two steps, a photo-Fries followed by cyclization (8*a*, *b*). Although these routes are

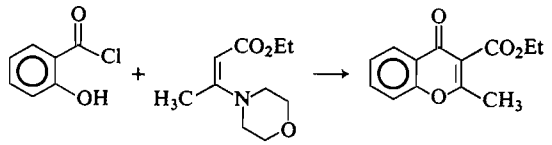


convenient for simple derivatives of xanthones, the possible lack of specificity in coupling, and the difficulty in obtaining the proper aromatic precursors makes this approach less attractive as a general method. The method used by Barton *et al.* in the first successful synthesis of bikaverin (8*c*) requires the A ring to be aromatic and is not suitable for the tetrahydrosubstitution pattern of **5**.

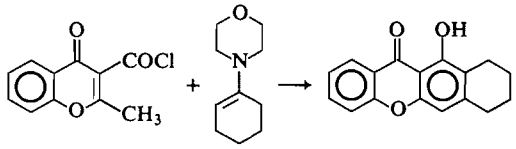
As an alternate to the existing methods for tetracyclic xanthone synthesis, we have attempted to condense 2-methylchromone-3-carboxylic acid derivatives with cyclohexanones in order to form the B ring of the tetracyclic compound from the preformed DC and A ring precursors.



Ethyl 2-methylchromone-3-carboxylate was prepared by the condensation of salicyloyl chloride and the enamine of ethyl acetoacetate (11). Hydrolysis (11) and reesterification with methanol gave the methyl ester **6**. An alternate high yield synthesis of the chromone esters from *o*-fluorobenzoyl chloride has also been recently reported (12).



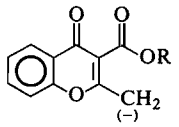
We anticipated that the condensation of the chromone acid chloride **7** with the enamine of cyclohexanone **8** would yield the acylated cyclohexanone which could be easily cyclized to the tetracyclic skeleton **9**. The acid chloride **7** was therefore reacted with cyclohexanone morpholine enamine in methylene chloride using triethylamine as an acid scavenger at several different temperatures. Despite considerable effort the major prod-



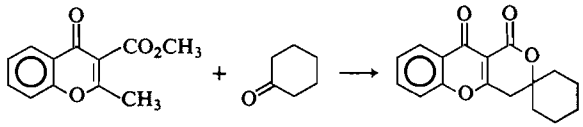
7 8 9 3%

ucts were always the chromone acid and/or its morpholine amide. Under optimum conditions a 3% yield of tetracyclic compound **9** was obtained from chromatography of the reaction mixture on silica gel. Whereas aromatic acid chlorides normally acylate enamines readily at carbon, it appears that the chromone acid chloride reacts primarily at the nitrogen center.

Since it appeared difficult to form a bond to the acyl group of the chromone acid, we investigated the possibility of condensation at the 2-methyl group of the chromone. The anion at this center should be stabilized by delocalization of the charge onto the two carbonyls and a reactivity similar to that of the malonate anion might be expected.



Several attempts to condense the chromone methyl ester **5** with cyclohexanone under conditions suitable for malonic ester condensations (Knoevenagel conditions) led to no appreciable reaction. The use of potassium *tert*-butoxide in *tert*-butyl alcohol/dimethoxyethane, did, however, lead to the spirolactone **10** in high yield as illustrated below.



6 10 ~90%

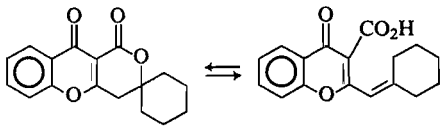
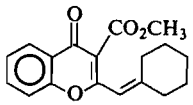
The use of the stronger base apparently allowed the intermediate oxy anion to be trapped intramolecularly. The reaction time had to be kept very short as the product was not stable to the reaction conditions.

The spirolactone had a very low mobility on thin layer chromatography (tlc) and we suspected that, in polar media, it existed in equilibrium with the acid form **11**. Indeed, treating the lactone with diazomethane in diethyl ether led to the cyclohexylidene ester **12**.

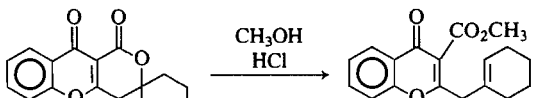


**10** **11**

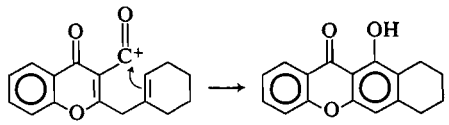


**12**

This same alkene ester could be obtained from treatment of the lactone with methyl iodide and potassium carbonate in acetone. Rather surprisingly though, treatment of the lactone with dry HCl in methanol appeared to give the unconjugated ester **13**. Apparently the double bond is thermodynamically more stable in the unconjugated position. Although the unconjugated ester **13** was not characterized fully, it could also be prepared by treating the ester **12** with *p*-toluenesulfonic acid in benzene, substantiating the structural assignment. The isomerization of the conjugated ester **12** to the unconjugated ester **13** under acidic conditions led to the proposal that the tetracyclic skeleton might be obtained by intramolecular acylation of the double bond. Treatment of the ester **12** with polyphosphoric acid converted it to the tetracyclic compound **9**. In view of this success, the spirolactone itself was treated with various acid catalysts to convert it directly to the tetracyclic xanthone. It was found that both phosphorus pentoxide and trifluoromethane sulfonic acid could convert the lactone directly to the xanthone **9** in approximately 40% yield. The latter reagent is preferred, as the phosphorus pentoxide complexes the product strongly and work-up must include extensive hydrolysis in aqueous acid.

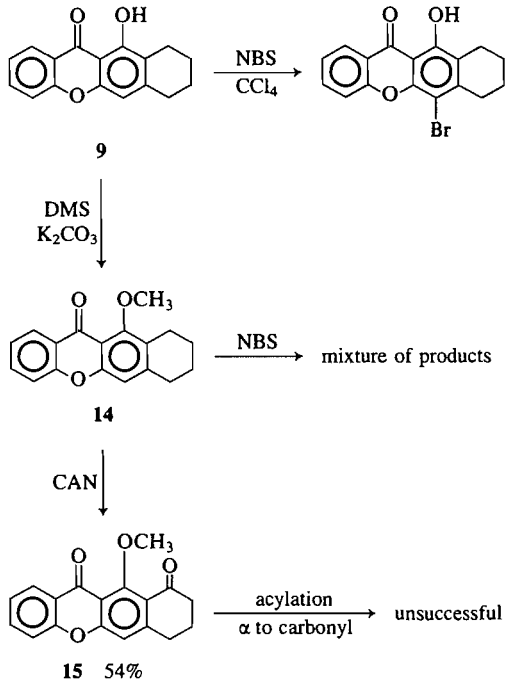


**10** **13**



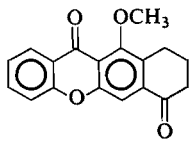
**9**

Since we were interested in the preparation of xanthocyclines with substituents in the A ring, we attempted to modify the cyclohexano ring in **9**. NBS bromination of **9** led primarily to substitution *para* to the hydroxyl and NBS bromination of the *O*-methyl ether of **9** gave a mixture of products with apparent aromatization of the cyclohexano ring.



**9** **14** **15** 54%

Treatment of the ether **14** with ceric ammonium nitrate (CAN) led to the methoxy ketone **15** in 54% yield. The structure **15** was assigned on the basis of our expectation that position 10 will be activated towards oxidation by the methoxyl group and the ring oxygen, whereas position 7 would be deactivated by the xanthone carbonyl. The spectral and analytical data alone were not sufficient to distinguish **15** from the isomeric ketone **16**.



**16**

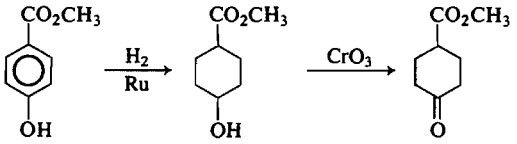
For personal use only.

Unfortunately, we were unable to find conditions which would allow the introduction of an acetyl group α to the carbonyl in compound **15** and this approach to further substitution in the cyclohexano ring was abandoned.

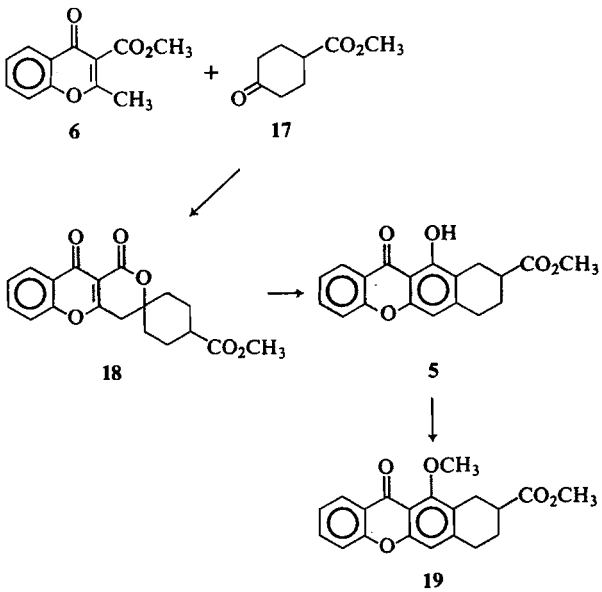
An alternate method of introducing substituents into the cyclohexano ring of **9** begins with the substituent in place, prior to the condensation with the chromone ester **6**. We therefore attempted the condensation of methyl 4-oxocyclohexane carboxylate **17** with the chromone ester **6**. The cyclohexanone was prepared from methyl *p*-hydroxybenzoate (13).



**17**

The synthesis of the final product **5** was analogous to the procedure already described for **9** except that the final step could not be catalysed by trifluoromethane sulfonic acid. Phosphorus pentoxide was successful, and gave the carbomethoxyxanthocycline **5** in 25% yield. Compound **5** was difficult to purify by recrystallization although the mass spectrum and nuclear magnetic resonance spectrum were consistent with the proposed structure. Conversion to the methyl ether **19** and recrystallization to a constant melting point gave a material which gave a satisfactory elemental analysis and the expected spectra for the ether.

The condensation–cyclization reactions of 2-methylchromone-3-carboxylic acid esters with cyclohexanones provide a convenient two step synthesis to the tetracyclic xanthones. The further elaboration of these precursors to daunorubicin analogs will be the object of future work.



## Experimental

Melting points were determined on a Kofler hot stage and are uncorrected. Infrared spectra were obtained with a Beckman IR-10 instrument and nuclear magnetic resonance spectra were recorded on a Varian EM-360 or a Bruker WH90-DS instrument. Chemical shifts are reported in ppm downfield from tetramethylsilane. Mass spectra were recorded on a Finnigan 1015 mass spectrometer. Silica gel column chromatography was carried out on Merck silica gel 60 (230–400 mesh).

*2-Methyl-4-oxo-4H-1-benzopyran-3-carboxylic acid (2-methylchromone-3-carboxylic acid)*

The chromone was synthesized from salicyloyl chloride and the morpholine enamine of ethyl acetoacetate according to the published procedure (11).

*2-Methylchromone-3-carboxylic acid chloride, 7*

The acid chloride was prepared by refluxing the acid (16.0 g) in an excess of thionyl chloride (400 mL) and chlorform (200 mL) for 15 h, followed by evaporation to dryness to leave yellow-brown crystalline material which was used without further purification; nmr ($CDCl_3$) δ: 2.56 (s, 3H), 7.53 (m, 3H), 8.18 (d, 1H); ms *m/e*: 222/224, 187.

*Methyl 2-methylchromone-3-carboxylate, 6*

The acid (33.1 g) was stirred at room temperature overnight in an excess of 3% HCl in methanol (prepared from 10 mL of acetyl chloride and 200 mL of anhydrous methanol). The solvent was removed *in vacuo*, the residue dissolved in chloroform, washed with dilute aqueous bicarbonate, dried ($MgSO_4$), and evaporated *in vacuo* to leave the crystalline ester (31.4 g); nmr ($CDCl_3$) δ: 2.50 (s, 3H), 3.92 (s, 3H), 7.42 (m, 3H), 8.08 (d, 1H).

*Spirolactone, 10*

To a solution of methyl 2-methylchromone-3-carboxylate **6** (0.887 g, 0.004 mol) and cyclohexanone (1.995 g, 0.020 mol) in dimethoxyethane (5 mL) was added a solution of potassium *tert*-butoxide in *tert*-butyl alcohol (35 g of 0.11 *M*). The solution was stirred for one minute at room temperature, poured into 300 mL of 2 *N* HCl, and extracted into chlorform. The extracts were dried ($MgSO_4$) and evaporated *in vacuo* to yield an orange solid (1.187 g). Nuclear magnetic resonance of the crude material indicated that it was greater than 90% lactone. Recrystallization from acetone gave white crystals, mp 164–166.5°C (dec.); ir ($CHCl_3$): 1740, 1655 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.1–2.2 (m, 10H), 3.08 (s, 2H), 7.25–7.85 (m, 3H), 8.10–8.45 (m, 1H); ms *m/e* (relative intensity): 284(20), 261(28), 228(57), 213(23), 200(48), 186(100). *Anal.* calcd. for $C_{17}H_{16}O_4$: C 71.81, H 5.67; found: C 72.14, H 5.89.

*Cyclohexylidenechromone ester, 12*

*Method A*

To a solution of the lactone **10** (0.348 g, 0.0012 mol) in methanol (10 mL) was added an excess of diazomethane in ether (50 mL). The reaction mixture was stirred for 48 h, washed with dilute HCl, dried ($MgSO_4$), and evaporated to give a yellow oil (0.425 g). Chromatography on silica gel (eluent, benzene–ether, 60:40) gave pale yellow crystals (0.190 g, 52%). Recrystallization from isopropanol gave white crystals, mp 154.5–156.5°C; ir ($CHCl_3$): 1640, 1735 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.45–1.95 (m, 6H), 2.1–2.55 (m, 2H), 2.55–2.9 (m, 2H), 3.93 (s, 3H), 6.13 (s, 1H),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

7.2–7.22 (m, 3H), 8.1–8.32 (q, 1H); ms *m/e* (relative intensity): 298(45), 266(71), 255(45), 251(49), 238(57), 225(67), 121(100). *Anal.* calcd. for $C_{18}H_{18}O_4$: C 72.47, H 6.08; found: C 72.28, H 6.22.

*Method B*

A mixture of the lactone **10** (0.124 g), anhydrous potassium carbonate (0.1 g), and methyl iodide (0.226 g) in acetone (10 mL) was stirred at room temperature for 72 h. The reaction mixture was poured into dilute HCl, extracted with chloroform, and the extracts dried ($MgSO_4$) and evaporated *in vacuo* to yield yellow crystals of the ester.

*11-Hydroxy-7,8,9,10-tetrahydrobenzo*[b]*xanthene-12-one, **9***

*Method A*

A solution of the chromone acid chloride 7 (1.52 g, 0.007 mol) in chloroform (20 mL) was slowly added to a stirred, cooled (0°C) solution of 1-morpholinocyclohex-1-ene (5.85 g, 0.035 mol) in chloroform (30 mL). The mixture was refluxed 45 h, cooled, washed with 1 *N* HCl, dried ($MgSO_4$), and evaporated *in vacuo* to leave an oil. Chromatography on silica gel (eluent, benzene/ether, 95:5) gave an early crystalline fraction (45 mg) (for properties see below).

*Method B*

To a solution of the spirolactone **10** in toluene (1.48 g in 100 mL) was added $P_2O_5$ (20 g) and the mixture refluxed, with stirring, for three hours. The toluene was decanted off and a slurry of 2 *N* HCl in crushed ice added to the residue. The toluene was returned to the flask and the mixture heated to distill off the toluene. Extraction of the remaining aqueous solution with chloroform, drying ($MgSO_4$), evaporation, and chromatography on silica gel (eluent, benzene) gave yellow crystals (0.533 g, 38%). Recrystallization from ethanol gave yellow crystals (for properties see below).

*Method C*

The spirolactone **10** (80 mg) was heated in trifluoromethanesulfonic acid (4 mL) in an oil bath at 100–110°C for 42 h. After cooling, addition of water (40 mL), and extraction with chloroform, the extracts were dried and evaporated to give a crystalline residue. Chromatography as above gave pale yellow crystals (32 mg, 43%), mp (ethanol) 199.5–201.5°C; ir ($CHCl_3$): 1616, 1652 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.55–2.04 (m, 4H), 2.50–3.00 (m, 4H), 6.65 (s, 1H), 7.15–7.90 (m, 3H), 8.12–8.35 (q, 1H), 12.63 (s, 1H); ms *m/e* (relative intensity): 266 (100), 265 (38), 251 (55), 238 (37). *Anal.* calcd. for $C_{17}H_{14}O_3$: C 76.67, H 5.30; found: C 76.73, H 5.45.

*11-Methoxy-7,8,9,10-tetrahydrobenzo*[b]*xanthene-12-one, **14***

A mixture of the hydroxycyclohexanoxanthone **9** (0.335 g, 0.00125 mol), anhydrous potassium carbonate (0.35 g), dimethyl sulfate (3 mL), and acetone (20 mL) was refluxed for 18 h. Filtration and evaporation *in vacuo* yielded the methoxyanthone, mp (isopropyl alcohol) 148–149°C; ir ($CHCl_3$): 1625, 1663 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.65–1.95 (m, 4H), 2.65–3.0 (m, 4H), 3.93 (s, 3H), 6.95 (s, 1H), 7.05–8.0 (m, 3H), 8.15–8.40 (m, 1H); ms *m/e* (relative intensity): 294 (100), 276 (57), 265 (71), 236 (71), 139 (90). *Anal.* calcd. for $C_{18}H_{16}O_3$: C 77.12, H 5.75; found: C 76.88, H 5.75.

*11-Methoxy-7,8,9,10-tetrahydrobenzo*[b]*xanthene-10,12-dione, **15***

The methoxyketoxanthocycline **15** was prepared using a modification of the procedure of Trahanovsky and Young (14).

Six equivalents (4.76 g) of ceric ammonium nitrate were added to the methoxyxanthone **14** (0.405 g, 0.0015 mol) dissolved in a mixture of acetic acid, water, and ether (1:1:1, 100 mL). The mixture was heated on a steam bath until it turned a pale yellow (5–10 min) and then poured into water. The product was extracted into chloroform, dried ($MgSO_4$), and the solvent removed *in vacuo* to yield a yellow oil (0.438 g). Chromatography on silica gel (eluent, benzene/ether, 50:50) gave 0.240 g of product which crystallized from isopropyl alcohol in pale yellow needles, mp 186.5–188°C; ir ($CHCl_3$): 1605, 1672, 1698 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.9–2.4 (m, 2H), 2.5–3.2 (m, 4H), 4.07 (s, 3H), 7.05 (s, 1H), 7.18–7.88 (m, 3H), 8.15–8.37 (m, 1H); ms *m/e* (relative intensity): 294(100), 276(97), 265(72), 236(87). *Anal.* calcd. for $C_{18}H_{14}O_4$: C 73.46, H 4.79; found: C 73.52, H 4.98.

*Methyl 4-oxocyclohexane carboxylate, **17***

The procedure of Finnegan and Bachman (13) was used. Methyl *p*-hydroxybenzoate (20 g) and 5% rhodium on alumina (400 mg) were mixed in 95% ethanol (150 mL) and hydrogenated at 45 psi for 96 h. Work-up gave the saturated alcohol in quantitative yield. The alcohol (36 g) was oxidized in ether (200 mL) with aqueous chromic acid (20 g $CrO_3$ in 200 mL of 25% $H_2SO_4$, v/v) at 10°C (cooling), adding the chromic acid over 40 min, followed by stirring at room temperature (4 h). Work-up yielded the ketone **17** (16.5 g, 46%); ir ($CHCl_3$): 1683, 1730 $cm^{-1}$; nmr ($CDCl_3$) δ: 2.0–3.0 (m, 9H), 3.72 (s, 3H); ms *m/e* (relative intensity): 156(22), 128(17), 125(21), 100(100).

*Carbomethoxy spirolactone, **18***

To a solution of methyl 2-methylchromone-3-carboxylate (1.09 g, 0.005 mol) and methyl 4-oxocyclohexane carboxylate (3.44 g, 0.02 mol) in dimethoxyethane (7 mL), was added 0.1 *M* potassium *tert*-butoxide in *tert*-butyl alcohol (55 g). The mixture was stirred one minute at room temperature, poured into 2 *N* HCl (300 mL), and extracted into chloroform. The extracts were dried ($MgSO_4$) and evaporated at high vacuum to remove the excess cyclohexanone ester. The residue was crystallized from $CCl_4$/isopropyl alcohol/hexane to yield brown crystals (0.81 g, 47%). Recrystallization from isopropyl alcohol gave white crystals, mp 153.5–154.5°C; ir ($CHCl_3$) 1662, 1742 $cm^{-1}$; nmr ($CDCl_3$) δ: 1.82–2.42 (m, 8H), 3.01 (s, 2H), 3.69 (s, 3H), 7.33–7.82 (m, 3H), 8.25–8.36 (m, 1H); ms *m/e* (relative intensity): 342(15), 311(7), 265(32), 241(100), 186(62). *Anal.* calcd. for $C_{19}H_{18}O_6$: C 66.66, H 5.30; found: C 66.44, H 5.57.

*9-Carbomethoxy-11-hydroxy-7,8,9,10-tetrahydrobenzo*[b]*xanthene-12-one, **5***

$P_2O_5$ (10 g) was added to a solution of the carbomethoxy lactone **18** (1.17 g, 0.0034 mol) in toluene (100 mL) and the mixture heated, with stirring, in an 130°C oil bath for two hours. The toluene was decanted from the residue, a slurry of 2 *N* HCl in crushed ice added (200 mL), and the toluene returned to the flask and heated until the toluene had distilled off. The aqueous solution was extracted with chloroform, the extracts washed with dilute bicarbonate, dried ($MgSO_4$), and evaporated *in vacuo* to yield 0.565 g. Chromatography on silica gel (eluent, benzene/ether, 60:40) gave 0.277 g of yellow crystals (25%). Recrystallization from ethanol was accomplished with difficulty, mp 160–164°C; ir ($CHCl_3$): 1618, 1650, 1735 $cm^{-1}$; nmr ($CDCl_3$) δ: 2.67–3.29 (m, 7H), 3.75 (s, 3H), 6.69 (s, 1H), 7.33–7.87 (m, 3H), 8.21–8.34 (m, 1H), 12.97 (s, 1H); ms *m/e* (relative intensity): 324(55), 265(100), 249(14), 238(24).

*9-Carbomethoxy-11-methoxy-7,8,9,10-tetrahydrobenzo*[b]*xanthene-12-one, **19***

The carbomethoxy hydroxyxanthocycline **19** (100 mg, $3.09 \times 10^{-4}$ mol), methyl iodide (2 mL), potassium carbonate (400 mg), and dry acetone (25 mL) were refluxed together for 36 h. After cooling and filtering the acetone was evaporated *in vacuo*. The residue was dissolved in chloroform, washed with 1 *N* HCl, dried ($MgSO_4$), and evaporated to give 90 mg (86%) yellow crystals. Recrystallization from 2-propanol cyclohexane gave mp 155–157°C; ir ($CHCl_3$): 1670, 1740 $cm^{-1}$; nmr ($CDCl_3$) δ:

3.10–1.50 (m, 7H), 3.77 (s, H), 3.96 (s, 3H), 7.05 (s, 1H), 7.14–8.00 (m, 3H), 8.15–8.53 (d, 1H); ms *m/e* (relative intensity): 388(88), 323(100), 309(70), 279(82). *Anal.* calcd. for $C_{20}H_{18}O_5$: C 71.01, H 5.32; found: C 70.84, H 5.64.

Received January 14, 1982

JOHN W. APSIMON, ALFRED S. CHAU, ROBIN SAMPSON, HUNG TZE, and ALAIN FRUCHIER. Can. J. Chem. **60**, 2002 (1982).

Solid phase-matrix catalysed ($H_2SO_4$ on alumina) substitution of heptachlor (**1**) by a variety of aromatic species has been studied and the structures of the compound obtained using benzene, toluene, phenol, *o*-dichlorobenzene, and nitrobenzene have been determined by extensive use of 250 MHz proton nmr spectroscopy and mass spectrometry.

Preliminary comments are made concerning the variety of orientation modes noted.

JOHN W. APSIMON, ALFRED S. CHAU, ROBIN SAMPSON, HUNG TZE et ALAIN FRUCHIER. Can. J. Chem. **60**, 2002 (1982).

On a étudié la substitution, catalysée par une matrice en phase solide ($H_2SO_4$ sur alumine), de l'heptachlore (**1**) par une série de produits aromatiques et on a déterminé les structures des composés obtenus, par réaction avec le benzène, le toluène, le phénol, l'*o*-dichlorobenzène et le nitrobenzène, en faisant appel à la spectroscopie de rmn du proton à 250 MHz et à la spectrométrie de masse.

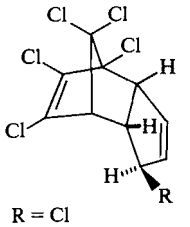
On fait des commentaires préliminaires au sujet de la diversité des modes d'orientation observés.

[Traduit par le journal]

We have recently reported in preliminary form (1) the formation of 1-aryl-chlordene **2** by the reaction of heptachlor **1** with aromatic species on an alumina/sulfuric acid solid matrix. In this article we present our evidence for the structures of compounds arising from the above reaction of heptachlor in the presence of benzene, toluene, phenol, *ortho*-dichlorobenzene, and nitrobenzene as being **2**, **3**, **4**, **5**, and **6** respectively.

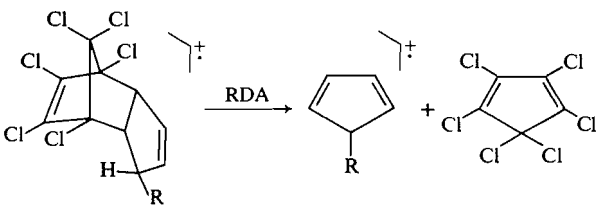
The impetus for this work arises from one of the procedures reported for the confirmation of heptachlor identity in trace amounts using the technique of solid matrix derivatization (2) and the need to isolate the derivatives formed as analytical standards together with the search for more sensitive analytical methods.

All of the products obtained have been examined thoroughly using spectral methods, in particular by the use of proton and carbon-13 nuclear magnetic resonance (nmr). Tables 1 and 2 present the data obtained and analysed with attribution of signals to particular nuclei and include data for chlordene **7** and heptachlor **1** for comparison purposes. Table 3 presents substituent effects on the $^{13}C$ chemical shifts of the compounds studied.



**1** R = Cl
**2** R = ϕ
**3** R = *p*-tolyl
**4** R = *o*-hydroxyphenyl
**5** R = 2′,3′-dichlorophenyl
**6** R = —O-3-*exo*-chlordene
**7** R = H

The nmr spectra and the mass spectra of all compounds studied indicate that no skeletal rearrangements have occurred during the solid matrix reaction but rather that allylic substitution has taken place. Thus all of the mass spectra in this series show, as the base peak, a fragment resulting from the reverse Diels–Alder process as shown



[1]Part XII in the CCIW series, Confirmation of Pesticide Residue Identities. For Part XI see ref. 1.

[a], [b], [c]Assignments can be reversed.

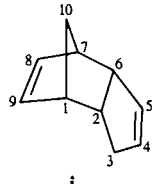
below. A rapid detection of the carbon skeleton present is therefore available.

Two structural questions have to be answered for the isolated compounds: (a) the site and stereochemistry of substitution on the chlordane nucleus, and (b) the substitution site on the aromatic moiety, if this is not phenyl.

The first point is readily answered in part by the mass spectral information described above (i.e. at C-3 or C-5, both sites are identical after allylic substitution occurs) and the stereochemical fate of substitution is evident from the nmr studies where $J_{2,3}$ indicates that no change in geometry at C-3[3] takes place. Thus substitution occurs in all cases with retention of configuration at C-3, not a surprising observation when the geometry of heptachlor and access to any derived allylic carbonium ions at C-10 is considered.[4]

The site of substitution on the benzene ring in compounds **2–5** was solved by an analysis of the 250 MHz $^1H$ nmr spectra of these compounds using LAOCN 3 (3) and summarized in Table 1 in footnotes *b–e*. These assignments are unequivocal and

[3]The numbering system for the chlordene skeleton that we use here is based on the *endo*-tricyclo[5,2,1,$0^{2,6}$]deca-4,8-diene skeleton **i** following the IUPAC nomenclature system.



**i**

Thus, heptachlor is named as 1-*exo*-3,7,8,9,10,10-heptachloro-*endo*-tricyclo[5,2,1,$0^{2,6}$]deca-4,8-diene.

[4]Of course $S_N2'$ reactions with retention of configuration are also possible.

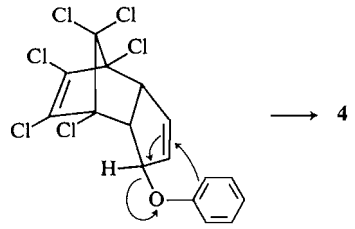
lead to the derivation of the structures depicted herein.

The power of this method is exemplified by Fig. 1 where portions of the experimental and calculated spectra for 1-*exo*-phenylchlordene (**2**) are compared. In the experimental spectrum the signal for H-5 centred at 3.926 ppm is broadened compared to the simulated spectrum because of small long-range benzylic couplings that we did not include in the simulation but are present as indicated by double irradiation.

Compound **6**, prepared by the use of nitrobenzene in this reaction, does not fall into the category of substituted chlordenes. Inspection of its nmr spectra indicates no aromatic substitution has occurred, rather only chlordene type protons (see Table 1) and carbon atoms (see Table 2) appear to be present. For some time this compound presented a problem, until we were able to obtain a satisfactory mass spectrum under conditions of low electron impact energy, showing a molecular ion at 686 together with chlorine isotope peaks, indicating a molecular formula of $C_{20}H_{10}OCl_{12}$. In addition, a major fragment of *m/e* 335 corresponding to $C_{10}H_5Cl_6^+$ was observed. The mass spectral and nmr data are best reconciled by dimeric structure **6**; in particular, the C-3—O—C′-3 moiety accounts for the chemical shift of 81.2 ppm for the two C-3 positions in this compound, a substituent shift of 48.8 ppm. At this stage we have not pursued the mode of formation of this material.

The formation of compounds **2–5** appears to be a Friedel–Crafts type process with the alumina supported acid acting as a catalyst (4), the precedent for this process appearing once in the patent literature (5) using the standard Friedel–Crafts conditions. In our hands this latter process proved less convenient for the preparation of substituted chlordenes, from the point of view of yield, product homogeneity, and isolation, although it must be stressed that we have only pursued a limited number of examples.[5]

There remain some intriguing questions to be answered concerning the mode of formation of compounds **3**, **4**, and **5**. Thus formation of **3** results from exclusive *para* attack of toluene, whereas **4** arises from exclusive *ortho* attack of phenol.[6] If a steric argument is involved it is difficult to reconcile formation of **4**. It therefore appears reasonable to us to suggest that **3** arises via a normal electrophilic substitution of toluene in the *para*-position, the bulk of the chlordene allylic cationic species precluding *ortho* attack, whereas **4** arises via prior O-alkylation to **8** followed by a rapid thermal



**8**

oxy-Cope rearrangement to **4** as shown. This possibility is being presently explored using *ortho*-substituted phenols.

The formation of **5** is a direct alkylation, *ortho* to one of the chlorine atoms of *o*-dichlorobenzene. Here the previously used steric argument for the formation of **3** falls down.

Our continuing work includes an investigation of the questions raised by the formation of the above compounds and attempts to include, in the aromatic substituents, groups that are photochemically active that could lead to ready degradation of the chlordene skeleton. The agricultural implications of such a course are tantalizing.

## Experimental

Proton nmr spectra were determined in the C.W. mode at 250 MHz on a Camera spectrometer at la Faculté de Pharmacie, Marseille, and analysed with the help of the LAOCN 3 program (3) or with a Varian XL-100 spectrometer at C.C.I.W. Carbon-13 spectra were determined in the FT mode on JEOL PS-100-FT and Bruker WP-80-DS spectrometers working at 25.03 and 20.11 MHz respectively in the Laboratoire de Mesures Physiques at U.S.T.L. The nmr data for the compounds described are presented in Tables 1 and 2. The ir spectra were recorded on a Unicon SP 110 spectrophotometer. Mass spectra were obtained

[5]Benzene, toluene, and phenol have been reacted with heptachlor under the usual Friedel–Crafts conditions ($AlCl_3$) yielding **2**, **3**, and **4** in low yield (< 20%) in each case.

[6]We have been unable to detect minor amounts of materials resulting from alternate modes of attack.

on a JEOL JMS-D100 at U.S.T.L. or at C.C.I.W. The chlorine isotope patterns confirm the molecular formula for all fragments. Mass spectral molecular weights are calculated using the $^{35}Cl$ isotope.

Heptachlor was kindly provided by the Velsicol Chemical Corporation. Microanalyses were carried out by the Guelph Chemical Laboratories.

*Alumina/sulfuric acid matrix*

Precooled concentrated sulfuric acid (10 mL) and alumina (50 g) (Woelm neutral grade 1) were mixed rapidly in a mortar and pestle at 0°C in a dry nitrogen atmosphere. The mixture was then transferred to a tightly capped bottle and stored in a desiccator until used.

exo-*3-Phenylchlordene (2)*

Pure heptachlor (2 g) in benzene (200 mL) was shaken with alumina/sulfuric acid solid matrix (50 g) (2) to ensure uniform mixing. Enough benzene was removed under vacuum on a rotary evaporator to ensure that the alumina remained moist. The mixture was heated under reflux on a steam bath overnight when, after cooling to room temperature, the moist mass was extracted with warm acetone (3 × 80 mL). The combined acetone extracts were evaporated to dryness and the solid residue was recrystallized from hexane/benzene (5:1) to yield colorless prisms (1.9 g), mp 76–77°C (lit. (5) mp 77–78°C); ir ($CHCl_3$): 3080, 2020 (C—H), 1610 (Cl—C=C—Cl), 1495, and 1415 ($C_6H_5$) $cm^{-1}$. Mass spectra: $M^+$ 412 (5%) ($C_{16}H_{10}Cl_6$), 270 (10%) ($M - C_5Cl_6$, retro Diels–Alder), 142 (100%) ($C_{11}H_{10}$ retro Diels–Alder). *Anal.* calcd. for $C_{16}H_{10}Cl_6$: C 46.60, H 2.43, Cl 50.97; found: C 46.79, H 2.1, Cl 50.5.

*3-Aryl-chlordenes*

The above procedure was followed using, in separate experiments, toluene (200 mL), *o*-dichlorbenzene (200 mL), nitrobenzene (200 mL), or phenol (4 g) dissolved in isooctane/ether (8:2) (300 mL).

The following materials were obtained. (1) 3-(*p*-Tolyl)-chlordene (**3**), 70% yield, mp 127–128°C; ir (KBr): 1610 (Cl—C=C—Cl), 1512 (aromatic) $cm^{-1}$. Mass spectra: $M^+$ 426 (3%) ($C_{17}H_{12}Cl_6$); *m/e* 156 (100%) ($M - C_5Cl_6$, retro Diels–Alder). *Anal.* calcd. for $C_{17}H_{12}C_6$: C 47.89, H 2.81, Cl 49.30; found: C 47.65, H 2.62, Cl 48.88. (2) 3-(*o*-Hydroxyphenyl)-chlordene (**4**), 50% yield, mp 105°C; ir (KBr): 3300 (O—H), 1605 (Cl—C=C—Cl), 1500 (aromatic) $cm^{-1}$. Mass spectra: $M^+$ 428 (4%) ($C_{16}H_{10}Cl_6O$); *m/e* 158 (100%) ($M - C_5Cl_6$, retro Diels–Alder). *Anal.* calcd. for $C_{16}H_{10}Cl_6O$: C 44.85, H 2.33, Cl 49.07; found: C 44.73, H 2.08, Cl 48.76. (3) 3-(2′,3′-Dichlorophenyl)-chlordene (**5**), 25% yield, mp 153°C; ir (KBr): 1600 (Cl—C=C—Cl) $cm^{-1}$. Mass spectra: $M^+$ 480 (2%) ($C_{16}H_8Cl_8$); *m/e* 210 (100%) ($M - C_5Cl_6$, retro Diels–Alder). *Anal.* calcd. for $C_{16}H_8Cl_8$: C 40.00; H 1.66, Cl 58.33; found: C 39.82, H 1.30, Cl 57.97. (4) Dichlordene ether **6**, 8% yield, mp 258°C; ir (KBr): 1605 (Cl—C=C—Cl) $cm^{-1}$. Mass spectrum: $M^+$ 686 (5%) ($C_{20}H_{10}OCl_{12}$), 335 (100%) ($C_{10}H_5Cl_6$), 65 (95%) ($C_{10}H_5Cl_6$-$C_5Cl_6$, reverse Diels–Alder). *Anal.* calcd. for $C_{20}H_{10}Cl_{12}O$: C 34.98, H 1.46, Cl 61.22; found: C 34.62, H 1.13, Cl 61.54.

## Acknowledgements

We thank the National Research Council of Canada and Le Centre National de la Recherche Scientifique de France for support of this work under the auspices of a joint research program (J.W.A., A.F.). We thank the Velsicol Corporation for a generous gift of pure heptachlor. One of us (J.W.A.) acknowledges the continued generous support of the Natural Sciences and Engineering Research Council of Canada in the form of a Grant-in-Aid of Research.

# Enzymes in organic synthesis. 26.[1] Synthesis of enantiomerically pure grandisol from an enzyme-generated chiral synthon

J. Bryan Jones, Mark A. W. Finch, and Ignac J. Jakovac

*Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1*

Received February 16, 1982

J. Bryan Jones, Mark A. W. Finch, and Ignac J. Jakovac. Can. J. Chem. **60**, 2007 (1982).

The synthesis of enantiomerically pure (+)-grandisol has been achieved from an enzymically generated chiral synthon. The synthesis is an efficient one, the yield of optically pure material being 12% up to the penultimate step and 3% overall.

J. Bryan Jones, Mark A. W. Finch et Ignac J. Jakovac. Can. J. Chem. **60**, 2007 (1982).

On a réalisé la synthèse du (+)-grandisol énatiomèrement pur à partir d'un synthon chiral produit enzymatiquement. C'est une synthèse efficace dont le rendement en produit optiquement pur est de 12% jusqu'à l'avant dernière étape et de 3% pour l'ensemble.

Grandisol (**1**), the major component of the four synergistic compounds of the male boll weevil sex pheromone (**2**), has attracted considerable attention and several successful syntheses have been reported (3). Of these, two have led to optically active grandisol (4) but neither approach afforded enantiomerically pure material. The elegant synthesis of Hobbs and Magnus (*4a*) was limited in this regard by the 90% ee of the (−)-β-pinene starting material available at that time, while a difficult resolution step in the route followed by Mori (*4b*) restricted the optical purity of his product to 80%.

The ready availability of the cyclobutyl lactone **3** of 100% purity, obtained via horse liver alcohol dehydrogenase-catalyzed oxidation of the *meso*-diol **2** (*5a*), prompted us to convert it into natural (+)-(1*R*,2*S*)-grandisol (**1**) in order to provide a further demonstration of the asymmetric synthetic value of enzymically produced chiral synthons (*5b*). As the paper shows, the use of lactone **3** as starting material enables grandisol to be prepared enantiomerically pure for the first time.

The route followed is summarized in Scheme 1. The initial target was the δ-lactone **10**, which in its racemic form had previously been converted to (±)-grandisol by Gueldner and co-workers (6). The lactone ring of the starting material **3** was opened with potassium hydroxide, and the resulting potassium carboxylate solution was acidified carefully to pH 3 at 0°C in order to prevent reformation of the lactone. The hydroxyacid obtained was immediately esterified with diazomethane and then treated with *tert*-butyldimethyl silyl chloride to give the protected ester **4** in 83% yield. No epimerization at the ring junction of **3** occurred during the

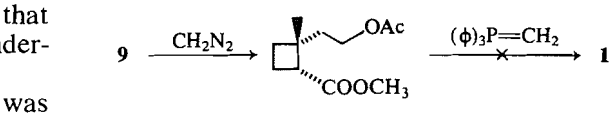
Scheme 1. base-mediated lactone opening step.[2] This was established by glc analysis. Introduction of the angular methyl group into **4** was readily accomplished by treatment with lithium diisopropylamide followed by methyl iodide (7). The methylated ester **5** was isolated in 89% yield. The methylation reaction was stereospecific. No trace of the (1*R*, 2*R*)-diastereomer of **5** could be detected spectroscopically or by glc or tlc analysis. The controlled insertion of the methyl group to give **5** possessing only the desired 1*S*-chirality is attributed to the steric effect of the large *tert*-butyldimethylsilyloxy group in the region of the 2*R*-centre of **4** that precludes approach of methyl iodide to the hindered (*Re*,*Si*)-face of the intermediate enolate.[3]

Conversion of the ester **5** to the aldehyde **6** was achieved in 68% yield and the subsequent Wittig reaction proceeded smoothly to give the alkene **7** in 63% yield. Hydroboration of **7** gave the expected alcohol, which was converted directly to its acetate **8** (60% yield).

The silyl protecting group of **8** was removed with hydrofluoric acid and the exposed alcohol function oxidized with Jones reagent. The carboxyl acetate **9** so obtained (83% yield) was then hydrolyzed in dilute sulfuric acid to give an excellent (90%) yield of the δ-lactone **10**.

Having achieved the preparation of our initial target **10**, known (6) to be transformable into grandisol, we examined the possibility of converting the intermediate **9** into the pheromone more directly via Wittig reaction (9) of the methyl ester **13**. Esterification of **9** with diazomethane yielded **13** quantitatively. Unfortunately, however, all attempts to convert the carbomethoxy group to the desired isopropylidene function using a salt-free (to avoid epimerization) methylene triphenylphosphorane (10) were not fruitful. Accordingly, attention was refocussed on the Scheme 1 route.

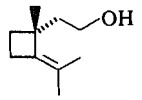
Lactone **10** was converted into the diol **11** in 87% yield using the procedure of Gueldner *et al.* (6). The spectral characteristics of the diol were identical with those of the racemic material prepared previously (6). In fact, the intermediacy of this compound in the penultimate stage of the synthesis had a significant influence on our formulation of the Scheme 1 approach, since it was known that the diol functionalities of **11** would permit its enantiomeric purity to be readily determined (11). The $^1$H nmr examination of the diastereotopic methyl groups of **11** in the presence of Eu(tfc)$_3$ showed the diol to be optically pure. The racemic sample of **11** required for the reference spectra was obtained by treatment of (±)-**13** with methyl lithium.



**13**

In the final step, dehydration of **11** was accomplished with acetic anhydride followed by lithium aluminum hydride reduction of the resulting acetate. The product consisted of a 2:1 mixture of grandisol and its isopropylidene isomer **14**. After purification by preparative glc, (+)-(1*R*,2*S*)-grandisol (**1**) was obtained in 25% yield. Its spectral properties were identical with those reported by Gueldner *et al.* (6) and those of its *p*-nitrobenzoate with those recorded by Hobbs and Magnus (4*a*). No enantiomeric contamination could be detected from $^1$H nmr examination of its MTPA ester (12) in the presence of Eu(fod)$_3$.

The preparation of optically pure grandisol was achieved in 3.1% overall yield from the enzymically generated starting lactone **3**. This compares very favourably with the 3.5% overall yield of Magnus and Hobbs' (4*a*) route. In fact, the overall yield of the Scheme 1 route could undoubtedly be markedly improved by optimization of the conditions in the final step, since the cumulative yield up to the penultimate intermediate **11** is a remarkably high 12.3%. Furthermore, the synthetic approach is a versatile one in that its modification to provide the other enantiomer of grandisol can be readily envisaged. All that is required is the conversion of the starting lactone (1*S*,5*R*)-**3** to its enantiomer (1*R*, 5*S*)-**3** by straightforward chemical transposition of the CO and $CH_2$ functionalities of the lactone ring.



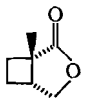
**14**

## Experimental

All compounds were purified at least until pure by glc. The glc analyses were performed on a Varian 2700 instrument using 5% Carbowax or QF-1 on Chromosorb GHP columns. Preparative

[2]In order to effect such epimerization, lactone **2** requires heating with sodium hydroxide in a sealed stainless-steel tube for several days (5*a*).

[3]In an initial approach to grandisol, direct alkylation of **3** to the methylated lactone **12** by the LDA–MeI method was explored. However, all attempts to effect the desired methylation were unsuccessful, presumably as a result of the reluctance of such cyclobutyl systems to form the carbanion intermediate required (8). Lactone **12** can be obtained by treatment of **5** with hydrochloric acid.



**12**

glc separations were effected on a Varian 920 chromatograph with a 5% Carbowax on Chromosorb GHP column. The ir spectra were determined on liquid films with a Unicam SP 1025 spectrometer. The $^1$H nmr spectra were measured on chloroform solutions (TMS internal standard) on a Varian T 60 machine and enantiomeric purity determinations were made with a Bruker WP 80 instrument. Optical rotations were obtained with a Perkin–Elmer 141 polarimeter. Low resolution and high resolution mass spectra were determined on Dupont 21-490 and AEI MS-30 spectrometers respectively.

*(−)-(1*S,2R)-cis-2-tert-*Butyldimethylsilyloxymethyl-1-carboxymethylcyclobutane (4)*

(+)-(1*S*,5*R*)-3-Oxabicyclo[3.2.0]heptan-2-one (**3**, 5.0 g, 44.6 mmol, $[\alpha]_D^{25}$ +118.7° (*c* 10, $CHCl_3$), 100% ee, obtained by horse liver alcohol dehydrogenase-catalyzed oxidation (5*a*) of *cis*-1,2-bis(hydroxymethyl)cyclobutane (**2**)) in methanol (20 mL) was added to KOH (4.5 g, 0.8 mol) in methanol (50 mL). The mixture was refluxed for 1 h, then cooled (20°C) and the methanol removed by rotoevaporation. The resulting white solid was dissolved in ethyl acetate (30 mL) and the cooled (0°C) solution acidified to pH 3 with 2 *N* hydrochloric acid. The aqueous layer was separated and extracted with ethyl acetate (3 × 25 mL). Ethereal diazomethane was then added to the combined ethyl acetate solutions until a yellow color just persisted. The reaction solution was then dried ($K_2CO_3$) and evaporated to yield an orange oil (5 g). This was immediately dissolved in dry dimethylformamide (20 mL) and imidazole (7.5 g, 0.11 mol) and *tert*-butyldimethylsilyl chloride (8.0 g, 53 mmol) added. The mixture was stirred for 12 h at 20°C and then diluted with water (50 mL) and extracted with hexane (2 × 50 mL). The hexane solution was washed with water (50 mL), dried ($MgSO_4$), and evaporated. The crude product obtained was Kugelrohr-distilled to give (−)-(1*S*,2*R*)-*cis-tert*-butyldimethylsilyloxymethyl-1-carboxymethylcyclobutane (**4**) as a colorless oil (10.0 g), bp 70°C (0.7 Torr); $[\alpha]_D^{25}$ −10.7° (*c* 1, $CHCl_3$); ir: 1740 cm$^{-1}$; $^1$H nmr δ: 0.10 (6H, s), 0.93 (9H, s), 1.6–3.3 (6H, m), 3.63 (3H, s), and 3.75 (2H, d, *J* = 5 Hz) ppm; high resolution mass spectrum,[4] *Exact Mass* calcd. for $C_{12}H_{23}O_3Si$ ($M^+ - CH_3$): 243.1416; found: 243.1428; *Exact Mass* calcd. for $C_9H_{17}O_3Si$ ($M^+ - C(CH_3)_3$): 201.0947; found: 201.0970.

*(−)-(1*S,2R)-2-tert-*Butyldimethylsilyloxymethyl-1-carboxymethyl-1-methylcyclobutane (5)*

*n*-Butyllithium (3.3 g, 52 mmol, 1.5 *M* solution in hexane) was added slowly under $N_2$ with stirring to diisopropylamine (6 g, 60 mmol) in dry tetrahydrofuran (50 mL) at −78°C. After stirring the mixture for a further 30 min at −78°C, (−)-(1*S*,2*R*)-*cis*-2-*tert*-butyldimethylsilyloxymethyl-1-carboxymethylcyclobutane (**4**, 10.0 g, 39 mmol) in dry tetrahydrofuran (20 mL) was added and the mixture stirred for 15 min. Methyl iodide (9.4 g, 67 mmol) was added and stirring at −78°C continued for 2 h more. The reaction was then quenched with water (50 mL) and the mixture warmed to 20°C. The aqueous solution was extracted with ether (3 × 50 mL) and the ether solution washed with 2 *N* hydrochloric acid (100 mL), then with 10% aqueous sodium thiosulphate, followed by water (100 mL). The dried ($MgSO_4$) ether layer was rotoevaporated and the residue Kugelrohr-distilled to give (−)-(1*S*,2*R*)-2-*tert*-butyldimethylsilyloxymethyl-1-carboxymethyl-1-methylcyclobutane (**5**) as a colorless oil (9.3 g), bp 80°C (0.6 Torr); $[\alpha]_D^{25}$ −40.4° (*c* 1, $CHCl_3$); ir: 1740 cm$^{-1}$; $^1$H nmr δ: 0.05 (6H, s), 0.95 (9H, s), 1.22 (3H, s), 1.6–2.8 (5H, m), and 3.60–3.70 (3H, s, and 2H, d, *J* = 5 Hz) ppm; high resolution mass spectrum,[4] *Exact Mass* calcd. for $C_{13}H_{25}O_3Si$ ($M^+ - CH_3$): 257.1573; found: 257.1570; *Exact Mass* calcd. for $C_{10}H_{19}O_3Si$ ($M^+ - C(CH_3)_3$): 215.1103; found: 215.1099.

*(−)-(1*S,2R)-2-tert-*Butyldimethylsilyloxymethyl-1-formyl-1-methylcyclobutane (6)*

Diisobutylaluminum hydride (8.6 g, 60.6 mmol, 20% solution in hexane) was added at −78°C under $N_2$ to the above ester **5** (5.5 g, 20.2 mmol) in dry hexane (100 mL). The reaction mixture was stirred for 2 h at −78°C, then quenched with water (50 mL) and warmed to 20°C. The solution was acidified with 2 *N* hydrochloric acid and then extracted with ether (3 × 75 mL). The ether extract was washed with water (100 mL), dried ($MgSO_4$), and evaporated to give (1*S*,2*R*)-2-*tert*-butyldimethylsilyloxymethyl-1-hydroxymethyl-1-methylcyclobutane (5 g, 20 mmol), ir: 3450 cm$^{-1}$; $^1$H nmr δ: 0.05 (6H, s), 0.95 (9H, s), 1.22 (3H, s), 1.3–2.4 (5H, m), and 3.0–3.8 (5H, m) ppm. This material in dry $CH_2Cl_2$ (50 mL) was oxidized at 20°C for 30 min with a solution of chromium trioxide (12.4 g, 124 mmol) and pyridine (9.5 g, 124 mmol) in dry $CH_2Cl_2$ (200 mL). The solvent was then evaporated and the residual black tar dissolved in ether, filtered through Celite, and washed with 2 *N* hydrochloric acid (100 mL), then with water (100 mL) and dried ($MgSO_4$). Evaporation of the solvent yielded, after Kugelrohr distillation, (−)-(1*S*,2*R*)-2-*tert*-butyldimethylsilyloxymethyl-1-formyl-1-methylcyclobutane (**6**) as a colorless oil (3.3 g), bp 70°C (0.5 Torr); $[\alpha]_D^{25}$ −38.0° (*c* 0.6, $CHCl_3$); ir: 2720 and 1720 cm$^{-1}$; $^1$H nmr δ: 0.07 (6H, s), 0.97 (9H, s), 1.38 (3H, s), 1.4–2.7 (5H, m), 3.66 (2H, d, *J* = 5 Hz), and 9.82 (1H, s) ppm; high resolution mass spectrum,[4] *Exact Mass* calcd. for $C_8H_{15}O_2Si$ ($M^+ - CH_3 - C(CH_3)_3$): 171.0841; found: 171.0842.

*(−)-(1*R,2R-2-tert-*Butyldimethylsilyloxymethyl-1-methyl-1-vinylcyclobutane (7)*

The aldehyde (**6**, 3.0 g, 12.5 mmol) in dry tetrahydrofuran (30 mL) was added at −78°C under $N_2$ to the methylene Wittig reagent obtained from methyltriphenylphosphonium bromide (8.9 g, 25 mmol) and *n*-butyllithium (1.44 g, 22.5 mmol, 1.5 *M* solution in hexane) in dry tetrahydrofuran (50 mL). After stirring for 2 h at −78°C, the reaction was quenched with water (100 mL) and extracted with ether (3 × 50 mL). The combined ether extracts were washed with water (50 mL), dried ($MgSO_4$), and evaporated. The residue was distilled to give (−)-(1*R*,2*R*)-2-*tert*-butyldimethylsilyloxymethyl-1-methyl-1-vinylcyclobutane (**7**) as a colorless oil (1.9 g), bp 105°C (25 Torr); $[\alpha]_D^{25}$ −23.6° (*c* 1.2, $CHCl_3$); ir: 3070 and 1640 cm$^{-1}$; $^1$H nmr δ: 0.05 (6H, s), 0.95 (9H, s), 1.26 (3H, s), 1.4–2.5 (5H, m), 3.45–3.75 (2H, m), and 4.7–6.3 (1H, m) ppm; high resolution mass spectrum,[4] *Exact Mass* calcd. for $C_{10}H_{19}OSi$ ($M^+ - C(CH_3)_3$): 183.1205; found: 183.1202.

*(+)-(1*R,2R)-1-(2′-Acetoxyethyl)-2-tert-*butyldimethylsilyloxymethyl-1-methylcyclobutane (8)*

Diborane (7.8 mmol, 7.8 mL of 1 *M* solution in tetrahydrofuran) was added at 0°C with stirring under $N_2$ to the above vinylcyclobutane 7 (2.8 g, 11.7 mmol) in dry tetrahydrofuran (60 mL). The mixture was then allowed to warm to 20°C and stirred for 1 h. Water (5 mL) was added and the mixture cooled to 0°C. 15% Aqueous NaOH (3.5 mL) and 30% hydrogen peroxide (3.0 mL) were added and the mixture warmed to 55°C for 1 h. The mixture was saturated with NaCl at 20°C and extracted with ether (3 × 50 mL). The ether solution was washed with water (50 mL), dried ($MgSO_4$), and evaporated to yield (1*R*,2*R*)-*tert*-butyldimethylsilyloxymethyl-1-(2′-hydroxyethyl)-1-methylcyclobutane (2.5 g), ir: 3350 cm$^{-1}$; $^1$H nmr δ: 0.05 (6H, s), 0.95 (9H, s), 1.20 (3H, s), 1.3–2.4 (7H, m), and 3.5–3.8 (4H, two t, *J* = 7 Hz) ppm. This alcohol was dissolved in dry pyridine (20 mL) and excess acetic anhydride (5 mL) added at 0°C. After keeping

[4]The molecular ions of the silyl derivatives **4–8** were unstable and the fragmentation patterns observed were those of ions resulting from loss of methyl or *tert*-butyl groups. Combustion analyses were not performed for these intermediates since the subsequent compounds, and grandisol itself, had been fully characterized previously.

for 12 h at 20°C, the mixture was diluted with water (25 mL) and extracted with ether (2 × 50 mL). The ether solution was washed with 2 *N* hydrochloric acid (50 mL), then with water (50 mL) and dried ($MgSO_4$). Evaporation gave (+)-(1*R*,2*R*)-1-(2′-acetoxyethyl)-2-*tert*-butyldimethylsilyloxymethyl-1-methylcyclohexane (**8**) which was Kugelrohr-distilled to give a colorless oil (2.1 g), bp 80°C (0.2 Torr); $[\alpha]_D^{25}$ +10.2° (*c* 0.32, $CHCl_3$); ir: 1740 $cm^{-1}$; $^1H$ nmr δ: 0.05 (6H, s), 0.95 (9H, s), 1.10 (3H, s), 1.5–2.2 (7H, m), 2.08 (3H, s), 3.54–3.75 (2H, m), and 4.12 (2H, t, *J* = 7 Hz) ppm; high resolution mass spectrum,[4] *Exact Mass* calcd. for $C_{12}H_{23}O_3Si$ ($M^+ - C(CH_3)_3$): 243.1417; found: 243.1418.

*(−)-(1*R*,2*R*)-6-Methyl-3-oxabicyclo[4.2.0]octan-2-one (**10**)*

10% Hydrofluoric acid (20 mL, prepared by dissolving 40% aqueous hydrofluoric acid in acetonitrile) was added to the above silyl acetate **8** (0.9 g, 3 mmol) and the solution stirred for 1 h at 20°C. Water (20 mL) was then added and the mixture extracted with chloroform (3 × 50 mL). The chloroform solution was washed with water (50 mL), dried ($MgSO_4$), and evaporated to give (1*R*,2*R*)-1-(2′-acetoxyethyl)-2-hydroxymethyl-1-methylcyclobutane (0.6 g), ir: 3400 and 1740 $cm^{-1}$; $^1H$ nmr δ: 1.98 (3H, s), 1.4–2.3 (7H, m), 2.05 (3H, s), 3.2–3.75 (3H, m including O*H*), and 4.15 (2H, t, *J* = 6 Hz) ppm. This material was dissolved in acetone (30 mL) and Jones reagent (13) (5 mL) added. The mixture was stirred for 1 h at 20°C and water (30 mL) then added. The mixture was extracted with ether (3 × 50 mL), and the ether solution then extracted with saturated aqueous sodium bicarbonate (2 × 50 mL). The bicarbonate solution was acidified with 6 *N* hydrochloric acid and then extracted with ether (3 × 50 mL). The combined ethereal layers were washed with water (50 mL), dried ($MgSO_4$), and evaporated to yield (−)-(1*R*,2*R*)-2-(2′-acetoxyethyl)-1-carboxy-2-methylcyclobutane (**9**) as a colorless oil (0.5 g), $[\alpha]_D^{25}$ −2.5° (*c* 0.4, $CHCl_3$); ir: 3750–3100, 1740, and 1715 $cm^{-1}$; $^1H$ nmr δ: 1.27 (3H, s), 1.6–2.2 (6H, m), 2.05 (3H, s), 2.65–3.1 (1H, m), 4.10 (2H, t, *J* = 6 Hz), and 10.9 (1H, s) ppm.

The acid **9** (0.6 g, 3 mmol) was dissolved directly in 5% aqueous sulfuric acid (20 mL) and the solution refluxed for 1 h and then cooled to 20°C, diluted with water (20 mL), and extracted with ethyl acetate (3 × 50 mL). The ethyl acetate solution was washed with water (50 mL), dried ($MgSO_4$), and evaporated to give an oil which was chromatographed on silica gel (ethyl acetate/hexane (20:1) elution) to give (−)-(1*R*,2*R*)-6-methyl-3-oxabicyclo[4.2.0]octan-2-one (**10**) (6*a*) as a colorless oil (0.38 g), $[\alpha]_D^{25}$ −43.1° (*c* 0.4, $CHCl_3$); ir: 1730 $cm^{-1}$; $^1H$ nmr δ: 1.27 (3H, s), 1.6–3.05 (7H, m), and 4.1–4.6 (2H, m) ppm; high resolution mass spectrum, *Exact Mass* calcd. for $C_8H_{12}O_2$ ($M^+$): 140.0837; found: 140.0842.

*(+)-(1*R*,2*R*)-1-(2′-Hydroxyethyl)-2-(1′-hydroxy-1′-methylethyl)-1-methylcyclobutane (**11**)*

The lactone **10** (0.35 g, 2.5 mmol) in dry ether (10 mL) was added with stirring to methyl lithium (0.25 g, 11 mmol) in dry ether (20 mL) at 0°C. The mixture was stirred at 0°C for 2 h and saturated aqueous ammonium chloride (20 mL) then added. The mixture was extracted with chloroform (3 × 30 mL) and the organic solution dried ($MgSO_4$) and evaporated. The crude diol product was purified by thick layer chromatography on silica gel (chloroform development) to give (+)-(1*R*,2*R*)-1-(2′-hydroxyethyl)-2-(1′-hydroxy-1′-methylethyl)-1-methylcyclobutane (**11**, 0.4 g), mp (after recrystallization from cyclohexane) 87°C (lit. (6*b*) (±) mp 87–87.5°C); $[\alpha]_D^{25}$ +17.3° (*c* 0.3, $CHCl_3$); ir: 3300 (broad) $cm^{-1}$; $^1H$ nmr δ: 1.06 (3H, s), 1.12 (3H, s), 1.20 (3H, s), 1.4–2.2 (9H, m), and 3.68 (2H, t, *J* = 7 Hz) ppm.

The 100 ± 3% ee of the diol **11** was established by its $^1H$ nmr examination in $CCl_4$ in the presence of 0.3 equiv. $Eu(tfc)_3$ shift reagent (11). No splitting of the diastereotopic methyl groups of the 2-(1′-hydroxy-1′-methylethyl) side chain was observed, while under the same conditions the corresponding signals in the spectrum of the (±)-diol were clearly separated into doublets (ΔΔδ 0.14 ppm).

*(+)-(1*R*,2*S*)-1-(2′-Hydroxyethyl)-1-methyl-2-isopropenylcyclobutane (**1**, grandisol)*

The diol **11** (0.4 g, 2.3 mmol) was treated with acetic anhydride (3 mL), and the acetate so obtained reduced with lithium aluminum hydride (1.5 g, 39 mmol) as described by Gueldner *et al.* (6*a*). The mixture of grandisol and its isopropylidene isomer isolated was separated by preparative glc to give (+)-(1*R*,2*S*)-1-(2′-hydroxyethyl)-1-methyl-1-isopropenylcyclobutane (**1**, 85 mg), $[\alpha]_D^{25}$ +14.8° (*c* 1, *n*-hexane) (lit. (4*a*) $[\alpha]_D^{21.5}$ +15.9° (*c* 1, *n*-hexane, highly purified +18.4°; lit. (4*b*) $[\alpha]_D^{20}$ +19.6° (*c* 0.23, *n*-hexane)); ir: 3320, 3060, 1650, 1450, 1375, 1260, 1050, 1000, and 885 $cm^{-1}$; $^1H$ nmr ($CCl_4$) δ: 1.18 (3H, s), 1.66 (3H, s), 1.3–2.3 (4H, m), 2.40 (1H, s, OH), 2.52 (1H, t, *J* = 8 Hz), 3.53 (1H, t, *J* = 7.5 Hz), 4.60 (1H, s), and 4.78 (1H, s) ppm. The spectra matched those of grandisol provided by Drs. R. C. Gueldner (6) and P. D. Magnus (4*a*). The *p*-nitrobenzoate (4*a*) had mp 64–65°C; ir: 1725, 1605, 1535, 1350, 1272, 1117, 1100, 1070, 837, 785, and 718 $cm^{-1}$; $^1H$ nmr ($CCl_4$) δ: 1.26 (3H, s), 1.4–2.8 (7H, m), 4.36 (2H, t, *J* = 7.5 Hz), 4.66 (1H, s), 4.82 (1H, s), and 8.18 (4H, s) ppm, also identical with an authentic spectrum provided by Dr. P. D. Magnus (4*a*).

Both (±)- and (+)-(1*R*,2*S*)-**1** were reacted with (+)-(2*R*)-α-methoxy-α-trifluoromethylphenylacetyl chloride and the MeO-groups of the MTPA-esters subjected to 100 MHz $^1H$ nmr examination in the presence of up to 2 equiv. of $Eu(fod)_3$ (12). No enantiomeric contamination could be detected in the MTPA-ester from (+)-**1**. (For the MTPA ester of (±)-**1**, ΔΔδ for the MeO-doublet was 0.05 ppm with 2 equiv. of shift reagent.)

## Acknowledgements

We thank the National Sciences and Engineering Research Council of Canada for generous financial support. We are also grateful to Drs. R. C. Gueldner and P. D. Magnus for their invaluable assistance in providing comparison spectra of (±)-grandisol, and of the natural enantiomer and its *p*-nitrobenzoate.

# Temperature profiles for reactions with self-heating

AVYGDOR MOISE AND HUW O. PRITCHARD
*Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3*

Received August 14, 1981

AVYGDOR MOISE and HUW O. PRITCHARD. Can. J. Chem. **60**, 2012 (1982).

It is shown that the steady temperature distribution for an exothermic reaction taking place in a sphere can be approximated by a simple function for values of the dimensionless heat production rate $\delta \leq 2$. Further, for $2 < \delta \leq 3$, a simple iterative correction to this function yields temperature profiles, $\theta$, which are nowhere in error by more than 1%, the error increasing to 5% at $\delta = 3.3$.

AVYGDOR MOISE et HUW O. PRITCHARD. Can. J. Chem. **60**, 2012 (1982).

On montre que la distribution de température stationnaire pour une réaction exothermique se produisant dans une sphère, peut-être évaluée à l'aide d'une fonction simple pour des valeurs de vitesse de production de chaleur qui sont sans dimensions de $\delta \leq 2$. De plus, pour $2 < \delta \leq 3$, une correction itérative simple de cette fonction fournit les profils de température, $\theta$, avec une erreur maximale de 1%; l'erreur augmente à 5% pour $\delta = 3{,}3$.

[Traduit par le journal]

## Introduction

A long-established method for estimating the steady-state temperature rise at the centre of a sphere for an exothermic reaction is an interpolation based upon the tables of Chandrasekhar and Wares (1), as suggested by Chambre (2); however, this method is cumbersome when it is required to calculate the temperature rise for points other than at the centre of the sphere. In this paper we establish a very simple function which gives accurate estimates for the complete temperature profile at low values of the temperature rise, and which can easily be corrected with a hand-held programmable calculator for temperature profiles right up to the critical one.

In an Appendix, we describe briefly an alternative power-series expansion solution to this problem, since it illuminates the nature of the mathematical difficulty in defining the critical point, a matter which is discussed elsewhere in some detail (3).

The Frank-Kamenetskii heat equation for an exothermic reaction taking place in a sphere may be written as (4–6)

$$[1] \quad \frac{\partial^2\theta}{\partial x^2} + \frac{2}{x}\frac{\partial\theta}{\partial x} = -\delta\, e^{\theta}$$

where $\theta$ (the dimensionless temperature excess) and $\delta$ (the dimensionless heat production rate) have their usual definitions (4–6), and $x$ is the (dimensionless) distance from the centre of the vessel, i.e. $0 \leq x \leq 1$. A solution for $\theta$ will have the properties that $\partial\theta/\partial x|_{x=0} = 0$ and $\theta|_{x=1} = 0$.

Let $\psi = x\theta$, whence it follows that $x^{-1}\partial^2\psi/\partial x^2$ is equal to the left-hand side of [1]; consequently

$$[2] \quad \frac{\partial^2\psi}{\partial x^2} = -\delta x \exp(\psi/x)$$

Expanding the exponential, and retaining only the first term in $x$, we find that

$$\frac{\partial^2\psi}{\partial x^2} \approx \frac{\partial^2\psi^0}{\partial x^2} = -\delta(x + \psi^0)$$

This equation, together with the appropriate boundary conditions $\psi^0|_{x=0} = \psi^0|_{x=1} = 0$, has the solution

$$[3] \quad \psi^0 = \frac{\sin(x\sqrt{\delta})}{\sin\sqrt{\delta}} - x$$

which is, therefore, an approximate solution to the original Frank-Kamenetskii heat equation.

We now write

$$[4] \quad \psi = \psi^0 + \sum_{n=1}^{\infty} b_n \sin.(n\pi x)$$

where $b_n \equiv b_n(\delta)$ is a function of the parameter $\delta$. Substitution of [4] into [2] leads, after some manipulation, to

$$[5] \quad \sum_{n=1}^{\infty} b_n[(n\pi)^2 - \delta]\sin(n\pi x) = \delta x[e^{\theta} - 1 - \theta]$$

Differentiating [5] with respect to $x$ gives

$$[6] \quad \sum_{n=1}^{\infty} b_n[(n\pi)^2 - \delta]n\pi\cos(n\pi x) = \delta[e^{\theta} - 1 - \theta] + \delta x[e^{\theta} - 1]\frac{\partial\theta}{\partial x}$$

and from [4] we get

$$[7] \quad \theta = \frac{1}{x}\left[\frac{\sin(x\sqrt{\delta})}{\sin\sqrt{\delta}} - x + \sum_{n=1}^{\infty} b_n \sin(n\pi x)\right]$$

$$[8]\quad \frac{\partial\theta}{\partial x}=\frac{1}{x}\left[\frac{\sqrt{\delta}\cos(x\sqrt{\delta})}{\sin\sqrt{\delta}}-1-\theta+\sum_{n=1}^{\infty}b_n n\pi\cos(n\pi x)\right]$$

Equations [5]–[8] hold for all $x$, so for convenience we choose to examine the solution $\theta_{1/2}$ at $x = 1/2$, whence $n\pi x$ becomes $n\pi/2$; replacing $n$ by $2n + 1$ in [5] and by $2n$ in [6], they may now be rewritten, respectively, as

$$[9]\quad \sum_{n=1}^{\infty}b_{2n+1}(-1)^n\{[(2n+1)\pi]^2-\delta\}=\frac{\delta}{2}[e^{\theta_{1/2}}-1-\theta_{1/2}]$$

$$[10]\quad \sum_{n=1}^{\infty}b_{2n}(-1)^n(2n\pi)[(2n\pi)^2-\delta]=\delta\left[(e^{\theta_{1/2}}-1)\left(1+\frac{1}{2}\left.\frac{\partial\theta}{\partial x}\right|_{x=1/2}\right)-\theta_{1/2}\right]$$

$$[11]\quad \theta_{1/2}=2\left[\frac{\sin((1/2)\sqrt{\delta})}{\sin\sqrt{\delta}}-\frac{1}{2}+\sum_{n=0}^{\infty}b_{2n+1}(-1)^n\right]$$

$$[12]\quad \left.\frac{\partial\theta}{\partial x}\right|_{x=1/2}=2\left[\frac{\sqrt{\delta}\cos((1/2)\sqrt{\delta})}{\sin\sqrt{\delta}}-1-\theta_{1/2}+\sum_{n=1}^{\infty}b_{2n}(2n\pi)(-1)^n\right]$$

These equations are all exact.

## An approximate solution

Comparison with the exact numerical solution shows that equation [3] *alone* gives a good approximation for the temperature excess $\theta = \psi/x$ provided that $\delta \leq 2$; this is shown in the first five columns of Table 1, and arises because the $b_n$ of eq. [4] are small for all $n$ in this range. We set ourselves the target of trying to find a simple formula for $\theta$ which would be accurate to within 5% right up to the critical point; we felt that this was realistic in view of our experience in a slightly different case, where it was possible to find a subcritical profile to within this accuracy simply by scaling the critical temperature profile by an appropriate factor (7).

We show in the Appendix that the $b_n$ of eq. [4] form a decreasing series, and we assume for the present purposes that we can truncate the series at two terms, whence

$$[13]\quad \psi\approx\psi^0+\sum_{n=1}^{2}b_n\sin(n\pi x)$$

$$\text{i.e.}\quad \psi=\theta x\approx\frac{\sin(x\sqrt{\delta})}{\sin\sqrt{\delta}}-x+b_1\sin\pi x+b_2\sin 2\pi x$$

With this truncation, we have four eqs. [9]–[12] with four unknowns and can solve them without resorting to any integration: the solution is

$$[14]\quad b_1=\frac{\delta}{2(\pi^2-\delta)}(e^{\theta_{1/2}}-1-\theta_{1/2})+O(b_3)=\tfrac{1}{2}(\theta_{1/2}+1)-\frac{\sin((1/2)\sqrt{\delta})}{\sin\sqrt{\delta}}+O(b_3)$$

$$[15]\quad b_2=\frac{\beta\left[(e^{\theta_{1/2}}-1)\left(\frac{\sqrt{\delta}\cos((1/2)\sqrt{\delta})}{\sin\sqrt{\delta}}-\theta_{1/2}\right)-\theta_{1/2}\right]}{1+2\pi\beta(e^{\theta_{1/2}}-1)}+O(b_4)$$

where

$$\beta=\delta/[2\pi(\delta-4\pi^2)]$$

Equations [11]–[15] now constitute a complete solution: substitution of [14] into [11] gives an implicit equation in $\theta_{1/2}$ which can be solved easily by iteration. Once $\theta_{1/2}$ is known, the complete solution is available in this approximation for the given value of $\delta$.

## Properties of the approximate solution

We begin by comparing the formal behaviour of the present solution with the known properties of other solutions. Most illuminating from the point of view of illustrating the general difficulty in solving eq. [1] is a plot of $\partial\theta/\partial x|_{x=1}$ as a function of $\delta$. For the polynomial expansion method described in the Appendix, Fig. 1 shows this behaviour for expansion lengths of 10, 14, 16, and 20: clearly this plot would become a step function at $\partial\theta/\partial x|_{x=1} = -2$ and $\delta = \delta_c$ if a sufficient expansion length could be

[a]In column 3, $\theta_0$* is the iterated solution found by using eqs. [11]–[15]; $\theta_0$ is the exact numerical solution found by the method described in ref. 7. The $b_n$ are the exact values of the expansion coefficients found from eq. [16] and the $b_n$* are the approximate values found by iteration, eqs. [14] and [15].

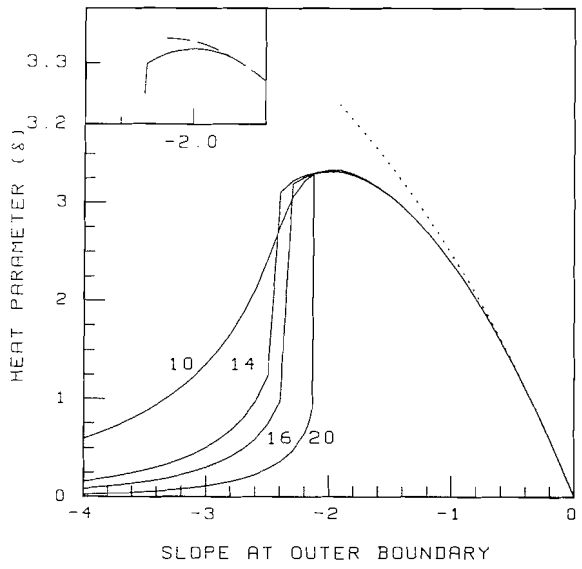

FIG. 1. Plots of $\partial\theta/\partial y|_{y=0}$ vs. $\delta$ for polynomial expansion lengths of $n$ = 10, 14, 16, and 20 for an exothermic reaction taking place in a sphere. Dotted line is eq. [3]. Dashed line (in inset) compares to present approximate solution (eq. [13]) with the 20-term polynomial expansion (eq. [A4]).

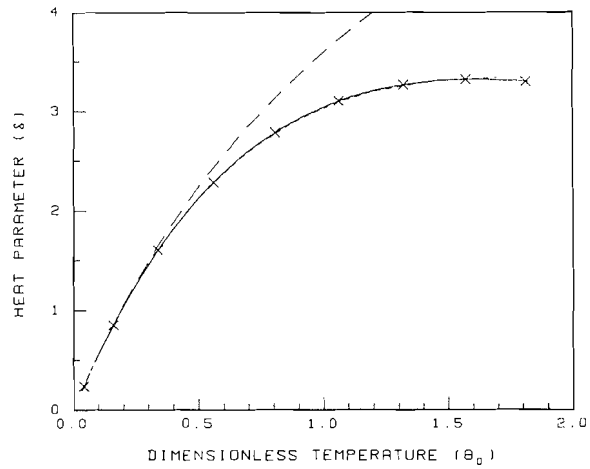

FIG. 2. Plots of $\theta_0$ vs. $\delta$ for the 20-term polynomial expansion and for the present approximate solution: solid line from equation [A4], dashed line from eq. [3], dotted line from eq. [13]; crosses are points from the tabulation of Chandrasekhar and Wares (1).

used. Since a common approach to the determination of $\delta_c$ is to find the maximum of such a curve (3, 4), the observed variability of $\delta_c$ around 3.32 in various solutions is not surprising.

The results of our approximate iterative method are also shown as the dashed line in Fig. 1; the agreement is very close up until about $\delta = 3.2$, and no solutions could be found beyond critical values of $\delta_c^* = 3.341$, $\partial\theta_c^*/\partial x|_{x=1} = -2.074$ (where the asterisk is used to denote the approximate solution by the present method). These approximate critical values may be accounted for easily by making an alternative plot, that of $\delta$ against $\theta_0$; this is shown in Fig. 2. By putting $\partial\delta/\partial\theta_{1/2} = 0$, we obtain for the critical condition $\delta_c^* = \pi^2/e^{\theta_{1/2,c}}$; substitution of this back into [11] leads to the critical solution $\theta_{1/2,c}^* = 1.08325$, from which then follow $\delta_c^* = 3.340_8$, $\theta_{0,c}^* = 1.697$, and $\partial\theta_c^*/\partial x|_{x=1} = -2.074$. Considering the simplicity of eq. [13], these are excellent approximations to the true critical parameters.

Figure 2 makes a comparison of the various methods showing the extent of the agreement between them. The solid line is derived from the 20-term polynomial expansion described in the Appendix; it is extended beyond the critical value of $\theta_0$ for the purposes of evaluating the stationary point in the curve, although there is no physical meaning to this solution beyond $\theta_{0,c}$. Our numerical solution (7) is indistinguishable from the solid line up as far as the critical point. The crosses denote a selection of points (approximately every fifth point) calculated from the tables of Chandrasekhar and Wares (1); our numerical solution (7) confirms the numerical values given in these tables to nine

decimal places up as far as the critical point. The dashed line is the simple function $\psi^0/x$, eq. [3], and the dotted line is the iterated function $\psi/x$, eq. [13].

In conclusion, we give in Table 1 a selection of values of $b_1$* and $b_2$* obtained by this method, and the true values of $b_1$ and $b_2$ (also $b_3$) obtained from the 20-term polynomial solution by evaluating the integral

$$[16] \quad b_n = 2\int_0^1 (\psi - \psi^0)\sin(n\pi x)\,dx$$

Notice the magnitude of $b_3$ is always significantly smaller than that of $b_1$ or $b_2$, justifying our original assumption, and in fact it passes through zero near $\delta = 3.3$; $b_4$ onwards become progressively smaller (see Table 2(*b*) in the Appendix for more details), and generally alternate in sign. Moreover, it is only at the critical point itself that we fail to achieve a calculation of $\theta_0$* within 1% of the correct value, $\theta_0$.

We present this method of calculating approximate temperature profiles for an exothermic reaction taking place in a sphere as an alternative to the method of Chambre, via the tables of Chandrasekhar and Wares (1, 2). Our formula is much simpler for low values of $\delta$; on the other hand, the older method is somewhat easier to use for larger values of $\delta$ if the central temperature *only* is required, but when the complete profile is needed, the present method is much quicker, although not quite as accurate. In the unlikely event that more accurate profiles are required near the critical point, we may use our earlier observation (7) that temperature profiles can be scaled by the ratio of $\theta_{0,\text{exact}}/\theta_{0,\text{approx}}$ with considerable confidence; alternatively, the poor performance of $\theta$* at values of $\delta > 3.3$ can be improved empirically by multiplying the right-hand side of [11] by an arbitrary correction factor of 1.0043, which improves $\theta_{0,c}$* to 1.596 without destroying the agreement at lower values of $\delta$.

## Appendix

We present here an outline of a general power series solution to eq. [1], which was used in generating Fig. 1. The function $\theta(x)$ is almost linear in the region near $x = 1$; consequently, we express $\theta(x)$ as a Taylor expansion about the point $x = 1$, viz.

$$[A1] \quad \theta(x) = \sum_{n=0}^{\infty} a_n (x-1)^n$$

Let $y = x - 1$ so that the limits $x = 0$, 1 become $y = -1$, 0, whence

$$[A2] \quad a_n = \frac{1}{n!}\frac{\partial^n\theta}{\partial x^n}\bigg|_{x=1} = \frac{1}{n!}\frac{\partial^n y}{\partial y^n}\bigg|_{y=0}$$

and

$$\theta(y) = \sum_{n=0}^{\infty}\frac{1}{n!}\frac{\partial^n\theta}{\partial y^n}\bigg|_{y=0} y^n$$

$$\frac{\partial\theta}{\partial y} = \sum_{n=1}^{\infty}\frac{1}{(n-1)!}\frac{\partial^n\theta}{\partial y^n}\bigg|_{y=0} y^{n-1}$$

The boundary conditions are $\theta_{y=0} = 0$ and $\partial\theta/\partial y|_{y=-1} = 0$ giving

$$[A3] \quad 0 = \sum_{n=1}^{\infty} n a_n (-1)^{n-1} = \sum_{n=1}^{\infty}\frac{1}{(n-1)!}\frac{\partial^n\theta}{\partial y^n}\bigg|_{y=0}(-1)^{n-1}$$

with $a_0 = 0$ and $a_1 = \partial\theta/\partial y|_{y=0}$. We may now construct a recursive relation for the expansion coefficients in terms of the $a_1$, viz.

$$[A4] \quad \theta(y) = \sum_{n=1}^{\infty} a_n y^n = \sum_{n=1}^{\infty} f_n(\delta, a_1) y^n$$

The first few members of this series are

$$f_1(\delta, a_1) = \partial\theta/\partial y|_{y=0} = a_1$$

$$f_2(\delta, a_1) = \frac{1}{2!}\partial^2\theta/\partial y^2|_{y=0} = -\frac{1}{2!}(2a_1 + \delta)$$

$$f_3(\delta, a_1) = \frac{1}{3!}\partial^3\theta/\partial y^3|_{y=0} = \frac{1}{3!}[6a_1 + (2 - a_1)\delta] \text{ etc.}$$

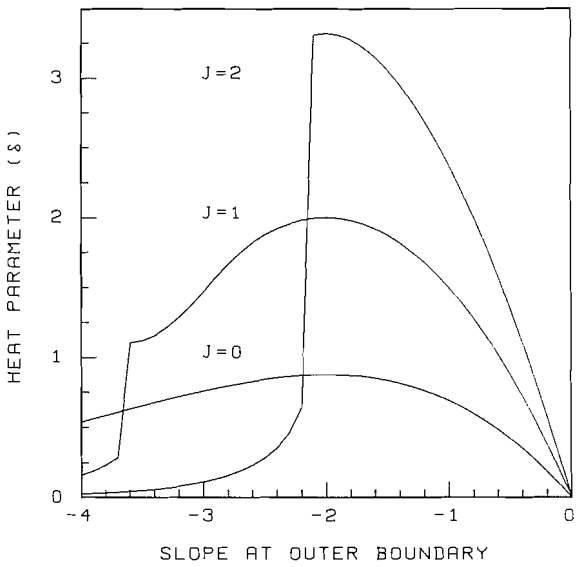

FIG. 3. Plots of $\partial\theta/\partial y|_{y=0} = a_1$ vs. $\delta$ for the 20-term expansion (eq. [A4]) for the sphere ($j = 2$), the infinite cylinder ($j = 1$), and the infinite slab ($j = 0$) (see ref. 6 for the definition of $j$).

This method was used to generate plots of $a_1 = \partial\theta/\partial y|_{y=0}$ vs. $\delta$ and of $\theta_0$ vs. $\delta$ as shown in Figs. 1 and 2, for expansion lengths up to $n = 20$. For $n = 20$, the maximum in the curve of $a_1$ vs. $\delta$ occurred at $a_1 = -2.000 \pm 0.001$ and $\delta_c = 3.322640$ for the case of a sphere, with a corresponding value of $\theta_{0,c} = 1.60569_5$. For the infinite cyclinder and for the infinite slab respectively, our $\theta_{0,c}$ values for a 20-term expansion are 1.38630 and 1.1868, in good agreement with the accepted ones (6, 8); notice that the degree of convergence of this method is poorest for the slab and best for the sphere, as evidenced by the behaviour of these plots, shown in Fig. 3.

In Table 2*a*, we list the first 20 values of $f_n(\delta, a_1)$ required for the expansion [A4] at $\delta = \delta_c = 3.322640$ and $a_1 = -2$ exactly (2); it is a very slowly converging series. This is in contrast with the

TABLE 2[a]

(*a*) Coefficients $f_n(\delta, a_1)$ in the Taylor expansion [A4] for the critical temperature profile in a sphere

| Coefficient | Value | Coefficient | Value |
|---|---|---|---|
| $f_1$ | $-2$ | $f_{11}$ | $-9.412533 \times 10^{-3}$ |
| $f_2$ | $3.386800 \times 10^{-1}$ | $f_{12}$ | $-4.387559 \times 10^{-3}$ |
| $f_3$ | $2.150933 \times 10^{-1}$ | $f_{13}$ | $9.811017 \times 10^{-3}$ |
| $f_4$ | $-3.088693 \times 10^{-1}$ | $f_{14}$ | $-8.819543 \times 10^{-3}$ |
| $f_5$ | $2.186463 \times 10^{-1}$ | $f_{15}$ | $4.871653 \times 10^{-3}$ |
| $f_6$ | $-9.313060 \times 10^{-2}$ | $f_{16}$ | $-9.033602 \times 10^{-4}$ |
| $f_7$ | $6.664293 \times 10^{-4}$ | $f_{17}$ | $-1.529783 \times 10^{-3}$ |
| $f_8$ | $4.204102 \times 10^{-2}$ | $f_{18}$ | $2.191259 \times 10^{-3}$ |
| $f_9$ | $-4.557776 \times 10^{-2}$ | $f_{19}$ | $-1.637864 \times 10^{-3}$ |
| $f_{10}$ | $2.918359 \times 10^{-2}$ | $f_{20}$ | $6.401175 \times 10^{-4}$ |

(*b*) Coefficients $b_n$ in the Fourier expansion [4] for the same temperature profile

| Coefficient | Value | Coefficient | Value |
|---|---|---|---|
| $b_1$ | $1.933 \times 10^{-1}$ | $b_6$ | $6.097 \times 10^{-6}$ |
| $b_2$ | $1.510 \times 10^{-2}$ | $b_7$ | $-8.808 \times 10^{-6}$ |
| $b_3$ | $1.938 \times 10^{-4}$ | $b_8$ | $4.801 \times 10^{-7}$ |
| $b_4$ | $1.103 \times 10^{-4}$ | $b_9$ | $-3.014 \times 10^{-6}$ |
| $b_5$ | $-3.560 \times 10^{-5}$ | $b_{10}$ | $-1.155 \times 10^{-7}$ |

[a]The critical parameters for these functions are $\delta_c = 3.322640$; $\partial\theta/\partial x|_{x=1} = \partial\theta/\partial y|_{y=0} = -2$; $\theta_{0,c} = 1.60569_5$.

Fourier series expansion [4]: Table 2*b* gives the first 10 $b_n$ coefficients, calculated by [16] from the critical profile described in Table 2*a*. In fact, if the last 8 coefficients $b_3 - b_{10}$ are ignored altogether, it makes very little difference, changing the calculated value of $\theta_{0,c}$ from 1.6058 to 1.6033, whereas the correct value is 1.6057.

Finally, we note that our Taylor expansion method also works for the case we have already treated numerically (7), that of variable thermal conductivity; however, we have insufficient computer storage space in which to calculate the required analytic forms for the derivatives beyond the 10th, and at this point, the expansion [A4] is only converged to about $\pm 10\%$.

# Synthesis, structure, and properties of poly-bis(μ-diethylphosphinato)copper(II)

KATHERINE W. OLIVER, STEVEN J. RETTIG, ROBERT C. THOMPSON, AND JAMES TROTTER
*Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6*
Received November 25, 1981

KATHERINE W. OLIVER, STEVEN J. RETTIG, ROBERT C. THOMPSON, and JAMES TROTTER. Can. J. Chem. **60**, 2017 (1982).

The preparation, magnetic properties, electronic and infrared spectra, and molecular structure of poly-bis(μ-diethylphosphinato)copper(II) are described. Crystals of poly-bis(μ-diethylphosphinato)copper(II) are triclinic, $a = 7.700(1)$, $b = 9.807(1)$, $c = 10.101(1)$ Å, $\alpha = 90.48(1)$, $\beta = 104.77(1)$, $\gamma = 112.21(1)°$, $Z = 2$, space group $P\bar{1}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.025$ and $R_w = 0.032$ for 3491 reflections with $I \geq 3\sigma(I)$. The polymeric structure consists of Cu atoms with flattened tetrahedral coordination geometry linked by double phosphinate bridges. Mean bond lengths (corrected for libration) are: Cu—O, 1.924(3), P—O, 1.526(4), and P—C, 1.807(4) Å. Assignment of the electronic spectrum using a crystal field model gives $Dq = 1665$ cm$^{-1}$ and $Cp = 1800$ cm$^{-1}$. Magnetic susceptibility studies give no evidence for magnetic concentration over the temperature range 80 to 300 K.

KATHERINE W. OLIVER, STEVEN J. RETTIG, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **60**, 2017 (1982).

On décrit la préparation les propriétés magnétiques, les spectres électronique et infrarouge et la structure moléculaire de poly-bis (μ-diéthyle phosphinato) cuivre (II). Les cristaux sont tricliniques $a = 7.700(1)$, $b = 9.807(1)$, $c = 10.101(1)$ Å, $\alpha = 90.48(1)$, $\beta = 104.77(1)$, $\gamma = 112.21(1)°$, $Z = 2$, groupe d'espace $P\bar{1}$. La structure a été résolve à l'aide des méthodes directes et affinée par la méthode des moindres carrés (matrices entières) jusqu'à des valeurs de $R = 0.0025$ et $R_w = 0.032$ pour 3491 réflexions avec $I \geq 3\sigma(I)$. La structure polymérique consiste en atomes de cuivre avec une géométrie de coordination tétraédrique aphatie et liés de ponts phosphinates doubles. Des longueurs moyennes de liaison (corrigées pour la libration) sont: Cu—O, 1.924(3), P—O, 1.526(4), et P—C, 1.807(4) Å. On a analysé le spectre électronique en faisant appel à un modèle de champs de cristal et on a obtenu $Dq = 1665$ cm$^{-1}$ et $Cp = 1800$ cm$^{-1}$. Des études de la susceptibilité magnétique ne donnant aucune indication d'une concentration magnétique dans l'intervale de température de 80 à 300 K.

[Traduit par le journal]

## Introduction

Because of their potential industrial use, metal phosphinates have attracted attention over the last few years (1). Although these materials are generally thought to be highly polymeric, with metal atoms joined by O—P—O bridges, the structures of relatively few have been established with certainty by X-ray diffraction methods (2–5). We report here the synthesis and crystal structure determination of poly-bis(μ-diethylphosphinato)copper(II). The vibrational and electronic spectra have been recorded and assigned and magnetic susceptibilities have been measured over the temperature range 80 to 300 K. The magnetic properties of this material are of particular interest because of the possibility of the propagation of magnetic exchange via the bridging phosphinate groups (5–7).

## Experimental

*Synthesis*

Poly-bis(μ-diethylphosphinato)copper(II), $Cu[(C_2H_5)_2PO_2]_2$, was prepared by a route which involved the synthesis of silver(I) diethylphosphinate followed by the reaction of the silver salt with copper(II) chloride in aqueous solution. The silver salt was prepared by Kosolapoff's procedure (8) with the minor change of using reagent grade acetone rather than aqueous ethanol in the final precipitation. An aqueous solution of copper(II) chloride dihydrate (27 mmol) was added to an excess of silver(I) diethylphosphinate (71 mmol) dissolved in water. Silver(I) chloride was removed by filtration, then dilute aqueous HCl was added until no further precipitation of AgCl occurred. The solution was filtered then evaporated under vacuum to yield a gummy solid consisting of the product contaminated with diethylphosphinic acid (an oil at room temperature). This material was washed with acetone. Most of the copper salt remained on the filter while some dissolved in the acetone together with the diethylphosphinic acid. Slow evaporation in air of the acetone washings yielded a deep blue oil in which blue crystals developed over about a week. The crystals used in the X-ray study were separated from the bulk of the oil and residual oil on the crystals was removed by washing with cold acetone. The crude product which remained after washing with acetone was dissolved in methanol; this solution was filtered and then evaporated to dryness. The resulting light blue powder (40% yield) was the desired poly-bis(μ-diethylphosphinato)copper(II) (melting point, 227–228.5°C). *Anal.* calcd. for $CuC_8H_{20}P_2O_4$: Cu 20.78, C 31.43, H 6.59; found: Cu 20.92, C 31.19, H 6.16. Carbon and hydrogen were determined by P. Borda of the Department of Chemistry, The University of British Columbia. Copper was determined by EDTA titration.

*Solubility*

Qualitative solubility tests showed the compound to be quite soluble (in excess of 0.1 g in 100 mL) in water, methanol, chloroform, and carbon tetrachloride; and only slightly soluble in ethanol, acetone, and benzene.

*Infrared spectrum*

Data for the range 1400 to 300 $cm^{-1}$: 1279 sh, 1270 m br, 1245 w br, 1237 sh, 1188 m, 1110 vs, 1049 vs, 997 w sh, 976 w sh, 780 s, 771 s, 757 sh, 728 m, 655 vw, 673 vw, 508 m sh, 487 m, 422 m, 375 w, 335 m (w = weak, m = medium, s = strong, v = very, br = broad, sh = shoulder). Infrared spectra were obtained on Nujol mulls as described previously (9).

*Electronic spectrum*

The electronic spectrum of a Nujol mull obtained using a Cary 14 spectrophotometer (range 3800 to 30000 $cm^{-1}$) showed a broad band centered at 12000 $cm^{-1}$ with a broad shoulder at 14300 $cm^{-1}$.

*Magnetic susceptibilities*

These were obtained using equipment described previously (9). The magnetic susceptibility was corrected for the diamagnetism of all atoms ($155 \times 10^{-6}$ $cm^3$ $mol^{-1}$). A total of twenty measurements made over the temperature range 80 to 300 K gave magnetic moments which were independent of temperature, lying within the narrow range of 1.89 to 1.91 BM.

*X-ray crystallographic analysis of poly-bis(μ-diethylphosphinato)copper(II)*

A crystal ca. $0.12 \times 0.30 \times 0.40$ mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on $2\sin\theta/\lambda$ values for 25 reflections measured on a diffractometer with Mo Kα Radiation ($\lambda = 0.71073$ Å). Crystal data at 22°C are:

$C_8H_{20}CuO_4P_2$ fw = 305.74

Triclinic, $a = 7.700(1)$, $b = 9.807(1)$, $c = 10.101(1)$ Å, $\alpha = 90.48(1)$, $\beta = 104.77(1)$, $\gamma = 112.21(1)°$, $V = 678.2(2)$ Å$^3$, $Z = 2$, $\rho_c = 1.497$ g $cm^{-3}$, $F(000) = 316$, $\mu$(Mo Kα) = 18.4 $cm^{-1}$. Absent reflections: none, space group $P\bar{1}$ ($C_i^1$, No. 2, reduced cell) from structure analysis.

Intensities were measured with graphite-monochromatized Mo Kα Radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.12–10.06° $min^{-1}$ over a range of $(0.72 + 0.35\tan\theta)$ degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to $2\theta = 65°$. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, decreased uniformly by 5% during the data collection. An isotropic decay correction was applied. After data reduction, an absorption correction was applied using the Gaussian integration method (10, 11). Transmission factors ranged from 0.598 to 0.811 for 188 sampling points. Of the 4891 independent reflections measured, 3491 (71.4%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.025(S-B))^2$ with $S$ = scan count and $B$ = background count.

The centrosymmetric space group $P\bar{1}$ was indicated by the $E$-statistics. The structure was solved by direct methods, the coordinates of the Cu, P, and O atoms being determined from an $E$-map and those of the carbon atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.037$, a difference map revealed the positions of all 20 hydrogen atoms which were refined with isotropic thermal parameters in subsequent least-squares cycles. The scattering factors of ref. 12 were used for non-hydrogen atoms and those of ref. 13 for hydrogen atoms. Anomalous scattering factors from ref. 14 were used for the Cu and P atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o|-|F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. Convergence was reached at $R = 0.025$ and $R_w = 0.032$ for 3491 reflections with $I \geq 3\sigma(I)$. For all 4891 reflections $R = 0.048$ and $R_w = 0.033$. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

*$U_{eq}$ = (1/3) trace ($U_{diag}$).

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.16 and 0.98σ respectively. The mean error in an observation of unit weight was 1.985. A final difference map showed no unusual features. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (15). The rms standard error in the temperature factors $\sigma U_{ij}$ (derived from the least-squares analysis) is 0.0009 Å$^2$. Analysis of all unique atoms of the asymmetric unit indicated significant independent motion of the two bridging phosphinate groups which were then analysed separately (rms $\Delta U_{ij}$ = 0.0006, 0.0007, 0.0016, and 0.0023 Å$^2$ for first five-atom and then seven-atom rigid-groups containing P(1) and P(2) respectively). Since derived parameters were very similar for the five- and seven-atom groups, corrections were based on the better-

fitting five-atom groups. The appropriate bond distances have been corrected for libration (15, 16), using shape parameters $q^2$ of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of the eight-membered rings are listed in Table 5. Distances and angles involving hydrogen atoms and a complete list of torsion angles (Tables 6–8) are included as supplementary material.[1]

## Results and discussion

### *The crystal structure of $Cu[(C_2H_5)_2PO_2]_2$*

The crystal structure of $Cu[(C_2H_5)_2PO_2]_2$ consists of well-separated infinite chains of centrosymmetric spiro-fused eight-membered rings extending along the crystallographic [110] direction (see Fig. 2). Each of the eight-membered rings consists of two copper atoms bridged by two phosphinate groups. The two crystallographically independent rings have qualitatively similar conformations which are best described as distorted chairs (torsion angles are given in Table 5). The structure is very similar to that of $Cu[(n\text{-}C_4H_9)_2PO_2]_2$ (5) and analogous to that of $Pb[(C_6H_5)_2PO_2]_2$ (4) which also contains double phosphinate bridges. The other metal phosphinate structures (2, 3) contain tetrahedrally coordinated metal atoms linked alternately by single and triple phosphinate bridges.

The Cu atoms have the same $D_{2d}$ flattened tetrahedral coordination geometry observed pre-

viously for $Cu[(n\text{-}C_4H_9)_2PO_2]_2$ (5). The mean[2] libration-corrected Cu—O, P—O, and P—C distances of 1.924(3), 1.526(4), and 1.807(4) Å as well as bond angles at Cu, P, and O atoms (Table 4) are in excellent agreement with corresponding values found for $Cu[(n\text{-}C_4H_9)_2PO_2]_2$ (5). The Cu···Cu separation of 4.9555(8) Å is slightly longer than the value of 4.938(2) Å in the *n*-butyl analog (5).

*Infrared spectrum*

A detailed assignment of all bands was not attempted; however, by comparison of the observed spectrum with published data for tetra(ethyl)diphosphine disulfide (17) and related phosphinate derivatives (18, 19) it was possible to assign the principal modes associated with the $C_2PO_2$ part of the compound. Two very strong bands at 1110 and 1049 $cm^{-1}$ may be readily assigned as the antisymmetric and symmetric $PO_2$ stretching frequencies (18, 19). A medium intensity absorption at 728 $cm^{-1}$ is assigned to the symmetric $PC_2$ stretching mode with a shoulder at 757 $cm^{-1}$ assigned to the corresponding antisymmetric stretch. For comparison, these vibrations occur at 700 and 738 $cm^{-1}$ in the spectrum of $(CH_3)_2PO_2Na$ (18). Bands at 472 and 440 $cm^{-1}$ in the infrared spectrum of $(CH_3)_2PO_2Na$ were suggested by Nyquist to result from fundamental modes associated with angle bending of both the $PC_2$ and $PO_2$ groups (18). The medium intensity bands observed at 487 and 422 $cm^{-1}$ in the spectrum of $Cu[(C_2H_5)_2PO_2]_2$ are tentatively assigned to these vibrations. The remaining bands in the spectrum, with the possible exception of the absorption at 335 $cm^{-1}$, doubtless arise primarily from internal vibrations of the $C_2H_5$ moieties. The medium intensity band at 335 $cm^{-1}$ may arise from Cu—O stretching. For comparison, bands at 336 $cm^{-1}$ in anhydrous copper(II) nitrate and 345 $cm^{-1}$ in anhydrous copper(II) sulfate have been previously assigned to ν(Cu—O) (20, 21).

It is interesting to note that although the crystal structure of the title compound shows the presence of two structurally distinct phosphinate groups, the difference is not sufficient to result in band duplication or splitting in the infrared spectrum. This clearly illustrates the limitations of infrared spectroscopy as a tool for detailed structure assessment. In spite of such limitations, attempts have been made, for example, to correlate features such as the separation between $\nu_{as}(PO_2)$ and $\nu_{sym}(PO_2)$ with the nature of the bridging groups in phosphinate polymers (22, 23). This may be a useful criterion since we note that the separation of 61 $cm^{-1}$ observed here is of a magnitude expected for symmetrical phosphinate bridging, a result consistent with the X-ray study.

*Electronic spectrum*

To assign this spectrum we considered the crystal field model as described by Gerloch and Slade (24). The copper in the title compound is in a

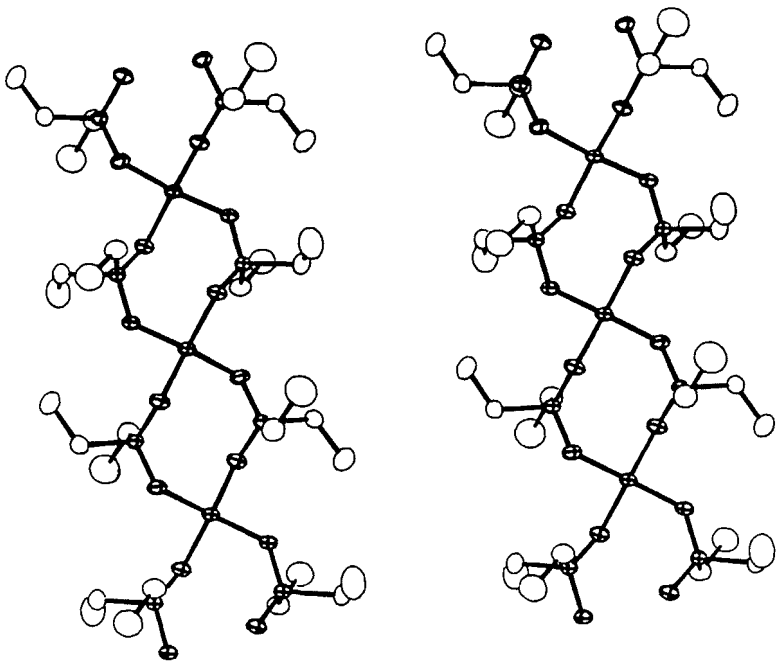

FIG. 2. Stereoview of the structure of poly-bis(μ-diethylphosphinato)copper(II).

compressed tetrahedral environment of four oxygens (approximate $D_{2d}$ symmetry) with the two larger angles 149.85 and 147.24°. The ground electronic state in such a case is $^2B_2$ with $^2E$, $^2B_1$, and $^2A_1$ excited states. Point charge crystal field calculations give the energies of these levels in terms of two crystal field parameters, *Dq* and *Cp* (the fourth-and second-order radial parameters respectively), and a distortion parameter, α (half of the largest O—Cu—O bond angle) (24).

Setting α at 74.3° (as obtained from the structure data) we were able to obtain two fits to the observed spectral data. Setting the crystal field parameters *Dq* and *Cp* at 700 and 3800 $cm^{-1}$ respectively gives $^2B_2 \rightarrow {}^2B_1, \rightarrow {}^2E, \rightarrow {}^2A_1$ transition energies of 6000, 12400, and 14400 $cm^{-1}$. Since the $^2B_2 \rightarrow {}^2B_1$ transition is formally symmetry forbidden, this might account for the fact that we observe no band at 6000 $cm^{-1}$. A major difficulty with this assignment is, however, that the value of *Dq* is unreasonably small (note the definition of *Dq* which is given in ref. 24; these *Dq* values should be regarded as $(9/4)\Delta_{tet}$), smaller even than the *Dq* value for $CuCl_4^{2-}$ (24). *Dq* values for oxygen bonding ligands are usually significantly greater than those for $Cl^-$ (25).

The second and more favored fit involves setting *Dq* and *Cp* at 1665 and 1800 $cm^{-1}$ respectively. This gives $^2B_2 \rightarrow {}^2A_1, \rightarrow {}^2E$, and $\rightarrow {}^2B_1$ transition energies of 11600, 12500, and 14300 $cm^{-1}$. The observed band at 12000 $cm^{-1}$, according to this fit, is reasonably assigned to the unresolved $^2B_2 \rightarrow {}^2A_1, {}^2E$ transition with the shoulder observed at 14300 $cm^{-1}$ assigned to the $^2B_2 \rightarrow {}^2B_1$ transition. The value of *Dq* obtained from this fit is quite reasonable, being of the order of 30–40% greater than the *Dq* for $CuCl_4^{2-}$ (24). For comparison we note that the ligand field "*f*-value" for water is 25% greater than the value for $Cl^-$ (25). To our knowledge this is the first estimate of crystal field *Dq* and *Cp* parameters in phosphinate compounds.

*Magnetic susceptibilities*

We were interested in examining the bulk magnetic properties of $Cu[(C_2H_5)_2PO_2]_2$ because of the possibility of magnetic concentration resulting from exchange interactions propagated by the bridging phosphinate groups. Antiferromagnetic exchange of this type has been observed in some chromium phosphinates (6, 7) and in a related phosphate-bridged copper(II) dimer (26). One interesting feature of this earlier work discussed by Lambert *et al.* (26) is that, although the (approximately) tetrahedral geometries of the bridging groups lead to a hybridization at the central atom that could result in a net ferromagnetic exchange, the observed exchange is, in fact, antiferromagnetic.

Our measurements on poly-bis(μ-diethylphosphinato)copper(II) give no evidence for mag-

netic exchange over the temperature range 80 to 300 K. The temperature independent moment of $1.90 \pm 0.01$ BM is comparable to the temperature independent value of 1.97 BM calculated from the Curie constant reported for the di-*n*-butylphosphinato derivative over the same temperature range (5). The magnetic moment is also similar to that observed for the structurally related $Ca[Cu(CH_3CO_2)_4]\cdot 6H_2O$, although in the latter case the moment varies slightly from 1.93 BM at room temperature to 1.88 BM at 80 K (27). If there is magnetic exchange in the copper(II) phosphinate compounds under discussion here, magnetic susceptibility evidence for it will have to come from measurements at lower temperatures.

# A kinetic study of the interaction of hydrous aluminum oxide colloids with a well-characterized soil fulvic acid[1]

MARK K. S. MAK AND COOPER H. LANGFORD[2]

*Departments of Chemistry, Concordia University, 1455 de Maisonneuve Blvd., West, Montreal, P.Q., Canada H3G 1M8 and Carleton University, Ottawa, Ont., Canada K1S 5B6*

Received January 11, 1982

MARK K. S. MAK and COOPER H. LANGFORD. Can. J. Chem. **60**, 2023 (1982).

Models of the species arising from the interaction of hydrous aluminum oxide colloids with humic substances have been prepared by neutralizing Al(III) stock solutions in the presence of a well-characterized fulvic acid and aging for 24 h. These samples have been examined kinetically using the fluorimetric Al(III) reagent calcein blue. The rates of formation of Al(III) calcein blue complexes allows recognition of five kinetically distinguishable components in the mixtures. Some are similar in lability to simple organic chelates of Al(III). Others are much less labile. Evidence for non-labile colloidal "ternary" complexes of Al(III) ion species complexed to fulvic acid, and bound to hydrous aluminum oxide colloid is presented. The polydisperse mixture character of fulvic acid is seen in patterns of complex lability much as it is seen in patterns of complex stability.

MARK K. S. MAK et COOPER H. LANGFORD. Can. J. Chem. **60**, 2023 (1982).

On a préparé des modèles de l'espèce provenant de l'interaction de colloides d'oxyde d'aluminium hydraté avec des substances humiques en neutralisant des solutions de réserve de Al(III) en présence de l'acide fulvique bien caractérisé et vielli pendant 24 h. On a examiné cinétiquement ces échantillons en utilisant le réactif fluorimétrique de Al(III), le bleu de calcéine. Les vitesses de formation des complexes du bleu de calcéine de Al(III) permettent de reconnaître les cinq composantes du mélange que l'on peut distinguer cinétiquement. Certains de ces composants sont semblables, du point de vue labilité, aux chélates organiques du Al(III). D'autres sont beaucoup moins labiles. On présente la preuve de l'existence des complexes colloidaux "ternaires" de Al(III) non labiles complexés avec l'acide pulvique et liés à des colloides d'oxyde d'aluminium hyraté. On se rend compte du caractère polydipersif du mélange d'acide fulvique dans les processus de labilité des complexes beaucoup plus que dans les processus de stabilité des complexes.

[Traduite par le journal]

## Introduction

The hydrolytic precipitation of Al(III) is unquestionably influenced by the organic acids present in the soil solution and other natural waters (1). This may be important to phenomenon as diverse as aluminum toxicity in plants and fish kills in lakes undergoing acidification. Central among the relevant organic acids are the "soluble" natural soil organic acid mixtures called fulvic acids. (These are the humic substances not precipitated by neutralization of the NaOH extract from a soil.) An especially well-characterized fulvic acid sample is the one obtained by Schnitzer and colleagues at Agriculture Canada (2) from a poorly drained $B_h$ horizon Podsol near Charlottetown, P.E.I., Canada. This sample has been studied extensively and a variety of reports comment on its functional group content, molecular weight, degradation products, and titration functions. (Note especially that we speak of titration functions since the mixture is *not* correctly described by discrete equilibrium constants (3).) The properties are summarized in refs. 2 and 3. The purpose of the present paper is to explore interactions of this fulvic acid with hydrous aluminum oxide colloids. The point of view is kinetic.

Hydrolytic precipitation of Al(III) is a complex subject even without attention to organic ligands (4). Laboratory studies designed to inform studies of natural systems must be carried out at sufficiently *low* total Al(III) concentrations. Turbidity curves reported by Matijevic *et al.* (5, 6) show that a maximum occurs at $10^{-5}$ *M* Al(III). At low Al(III) concentrations, the sol stability was attributed to adsorption of polyhydroxo cations of Al(III). At higher concentration, anion adsorption is taken to stabilize the colloid. This determines a central aspect of our experimental approach. We use a fluorescent reagent, calcein blue, to determine aluminum accurately at concentrations below $10^{-6}$ *M*. We shall see that our studies reflect phenomena related to the turbidity maxima reported by Matijevic *et al.*

The kinetic method of analysis employed has been used successfully to study distinguishable components of colloidal mixtures of Fe(III) hydrous oxides and the corresponding fulvic acid – iron colloids (7, 8). The technique involves the addition of an excess concentration of the metal detection reagent and sufficient buffer to impose

pseudo first order kinetics and to follow the *first order* grow-in of the detection complex, in this case the Al – calcein blue. The number of distinguishable components in the kinetics provides a means of identifying a distinguishable set of components of the colloids. It must be emphasized, however, that the kinetic components are not necessarily (at all!) structurally homogeneous chemical species.

The kinetic data are treated by the expression

$$[1] \quad P = A_0 [1 - \exp(-k_A t)] + B_0 [1 - \exp(-k_B t)] + \ldots + X$$

where $P$ is the product parameter (fluorescence intensity in this case), $A_0$, $B_0$ ... are appropriately scaled (to the same dimension) measures of the initial concentrations of the kinetically distinguishable components of the analytic mixture. The parameters $k_A$, $k_B$ ... are the pseudo first order rate constants. The term $X$ is a time-independent term including blank and any fast reacting components. A standard library nonlinear regression package based on the Marquardt algorithm is used (9, 10). However, we do exploit one unconventional technique. A limit on simple application of nonlinear regression is that one needs to know how many components it is reasonable to try to resolve from the data and one needs physically reasonable *initial* values of total concentrations and rate constants to put into the iterative process. One could assume a *continuum* of rate constants for the mixture called fulvic acid and examine the form of the distribution. Instead, we look for a *minimum* number of parameters needed to *accurately* fit the data. We recognize that the resulting parameters will most probably be averages over parts of the distribution. We have used Guggenheim plots (which should be linear for a single component) to identify the minimum number of resolvable components (the number of linearizable segments in the plots) and to supply initial approximations of parameters for the nonlinear regression. This approach has been evaluated elsewhere in a kinetic study of the complexation of Al(III) by citrate (11, 12).

## Experimental

*Materials*

Stock solutions of Al(III) in 0.1 *M* $HClO_4$ were prepared from $AlCl_3 \cdot 6H_2O$ (B.D.H. Reagent grade) twice recrystallized. The formula of the precipitate was verified gravimetrically by precipitation of Al(III) with 8-hydroxyquinoline. Solutions at various Al(III) concentrations were obtained by diluting a 0.2 *M* stock with $HClO_4$. Calcein blue was obtained from G.F. Smith Chemical Company and used as received. Fulvic acid was a gift of Dr. D.S. Gamble, Agriculture Canada, Ottawa (2). It is metal-free so that Al is the only metal in these experiments. The sample is assumed here to have a molecular weight of (wt. avg.) ~900 (2, 3). This value is subject to significant error and it should be noted that for many purposes it may be wise to convert results to a mg FA per mL basis in preference to molar. Molar units are used here because they allow clearer discussion of some chemically interesting matters. Sodium hydrogen carbonate was obtained from Nichols Chemical company and reagent grade sodium acetate from Fisher Scientific. Water was redistilled in an all glass apparatus from alkaline $KMnO_4$.

*Sample preparations*

Stock solutions of aluminum fulvates were initially prepared at pH = 3.00 from Al(III) stocks and *fresh* fulvic acid solutions. The Al/fulvate ratio and Al concentration ($2 \times 10^{-6} - 2 \times 10^{-5}$) were adjusted at this pH. Then solutions were slowly neutralized with $NaHCO_3$. The pH change was monitored with an Orion Research (701A) digital four place pH meter. After titration, the samples were adjusted to volume with small additions and allowed to "equilibrate" for 24 h. The final pH of the solutions after equilibration was rechecked and found to be within less than ±0.15 pH units of the initial (and nominal) levels.

*Kinetic analysis*

The fluorescence reagent, calcein blue, solution was prepared at pH = 5.00 in a 0.2 *M* acetic acid – sodium acetate buffer. Calcein blue was always chosen to be in excess over Al(III) by a factor of $10^2$. Since equal volumes of this solution and the equilibrated Al(III) sample were mixed, the ionic strength and pH are *determined* during the kinetic run by the components of this reagent. The conditions render component steps pseudo first order.

Kinetic runs were carried out manually on a Perkin-Elmer Model 204S spectrofluorimeter equipped with a strip chart recorder. Samples were contained in 1.00 cm square cross section cuvettes. Excitation was at 377 nm and emission from the Al–CB complex was monitored at 450 nm. Theoretical infinity time values were obtained by reacting Al(III) solutions prepared at pH = 3.00 with calcein blue. This is because recoveries of Al(III) were frequently below 100% and appropriate experimental infinities were not available — some Al(III) reacts extremely slowly if at all! A kinetic experiment was initiated by mixing the Al(III) sample from a syringe into the thermostatted (19.5°C) spectrofluorimeter cell containing an equal volume of reagent solution. Reactions were initially followed for periods up to 2 weeks. However, it was found that no significant changes could be analyzed beyond 24 h. (Perhaps some reaction is occurring on a longer time scale but the instability of the instrument does not permit acquisition of meaningful data. In any event, reaction in the period between 24 h and 2 weeks is not large.) Consequently, all reactions were followed for 24 h.

*Data treatment*

Records from the chart recorder were manually digitized and entered as a data file in the Carleton University computer system. First the data were analyzed and plotted according to the Guggenheim method (11, 12) (where no experimental infinity is required and each well-resolved component may be recognized by a linear segment in a plot). Figures 1 and 2 illustrate the results of this step for a first case where at least two kinetically distinguishable components are clearly recognizable and a second case where only one component is evident.

From slopes and intercepts of the Guggenheim plots preliminary estimates of the rate constants and initial concentrations of the kinetically distinguishable components were obtained. These values were used as *initial* estimates for the nonlinear regression library program which obtained best fit of the data to the model expressed by eq. [1] using the Marquardt algorithm (11, 12). No more than two components were considered

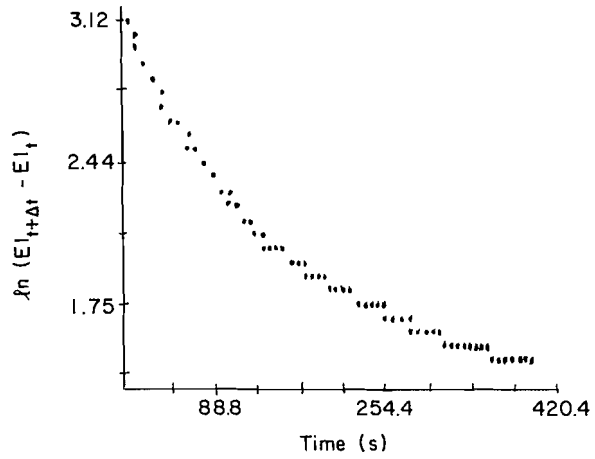

FIG. 1. Guggenheim plot of a typical 2-component system in an aluminum/fulvic acid mixture. System under observation is: $\{2 \times 10^{-5}$ $M$ $[Al^{3+}]/2 \times 10^{-5}$ $M$ [FA]$\}$ mixture at pH = 6.0 + $2 \times 10^{-3}$ $M$ [CB]; in 0.1 $M$ acetate buffer at pH = 5.0. EI designates emission intensity.

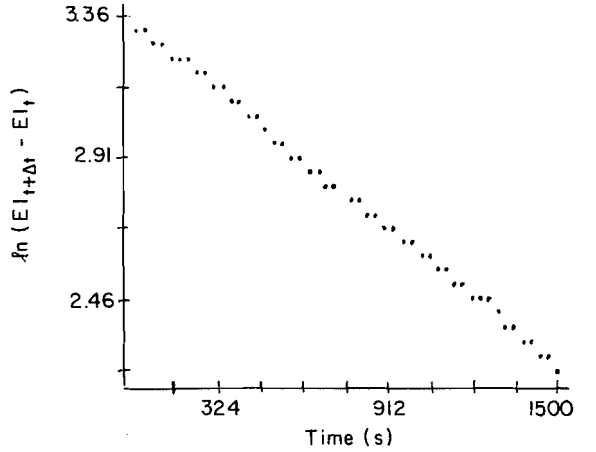

FIG. 2. Guggenheim plot of a typical 1-component system in an aluminum/fulvic acid mixture. System under observation is: $\{2 \times 10^{-6}$ $M$ $[Al^{3+}]/5 \times 10^{-5}$ $M$ [FA]$\}$ mixture at pH = 5.0 + $2 \times 10^{-4}$ $M$ [CB]; in 0.1 $M$ acetate buffer at pH = 5.0. EI designates emission intensity.

because the data for cases like those shown in Fig. 1 were fit within experimental error by two components. The addition of more would not be subject to objective test. Nevertheless, since FA is a mixture, the parameters are probably averages over a relatively narrow segment of the distribution.

## Results

All values reported in the results section are averages of at least five runs. Standard deviation on rate constants is less than 10%. The sums of component concentrations are reproducible to less than 5% of the total. A grand summary of kinetically distinguishable components characterized by their rate constants is shown in Table 1. No single run had more than two objectively demonstrable components but "kinetic" aluminum recovery was generally less than "equilibrium" recovery. That is, the sum of parameters $A_0$ and $B_0$ extracted from the good nonlinear regression fits of data to eq. [1] using components recognizable from Guggenheim plots did not account for all of the Al(III) found from the emission after 24 h. It seems quite plausible and almost necessary to postulate an additional slowly reacting component which is not represented by rate constants in Table 1. This was confirmed by examination of fluorescence after 2 h to that after 24 h. Note that the half-times associated with recognizable components vary from about 5 s to a little over 20 min. The slowest of these is "complete" in less than 2.5 h. The postulated relatively small additional slower component need not react too slowly.

On the basis of three distinguishable relatively

labile forms of Al(III) fulvates plus a slow but reactive component and with the addition of an entirely unreactive and unrecoverable fraction of Al(III), we can summarize Al(III) distribution in five classes. Parameters for these classes, it should be emphasized, are probably averages. The shares to each of the five classes are summarized in Table 2. The coding of samples in Table 2 follows Table 1. The patterns indicated by Tables 1 and 2 are very complex. The individual entries in Table 2 corresponding to fractions smaller than 20% also must be recognized as being associated with quite large uncertainties. It is worth remarking the non-recoverable fractions are large in all cases. These fractions could not be rendered accessible to the calcein blue reagent by boiling with added $HClO_4$. Precipitated hydrous oxides of aluminum are very difficult to redissolve.

## Discussion

We can begin by commenting on samples (a) and (f) of Table 1. These samples, our controls, contained *only* Al(III) and no fulvic acid at pH = 5.00. The second order rate constants obtained are to be compared to values of $2.5 \times 10^2 M^{-1}\ s^{-1}$ reported for unhydrolyzed (pH = 3) Al(III) samples mixed with the present reagent (11, 12). That these values are significantly smaller for the lower Al(III) concentration here suggests that this sample is more extensively hydrolyzed. Such a result, though a bit surprising, is in agreement with the equilibrium recoveries where more Al(III) has disappeared into non-reactive hydrous oxide precipitate at the lower concentration. It is also in agreement with the turbidity maximum result of Matijevic *et al.* It may be appropriate to cautiously suggest an implication. Perhaps labile Al(III) in these studies has some relation to biochemically available metal. If so, availability will be a complex, non-monotonic, function of concentration and pH.

Turning to the aluminum fulvates, two initial comments are important. First, the range studied spans 0.9–45 mg/L, a range appropriate to modeling DOC of natural fresh waters. Second, a $6.67 \times 10^{-6} M$ fulvic acid solution has, according to Gamble and Schnitzer (2), about $2 \times 10^{-5}$ equiv. /L of phenol carboxylate sites and at least $3.3 \times 10^{-5}$ equiv./L of total bidentate chelating sites providing a 1:1 binding capacity for at least $2 \times 10^{-5} M$ Al(III). All experiments use excess fulvic acid as is appropriate to a majority of waters.

Turning next to rate constants associated with objectively distinguishable fractions of the FA mixture, one sees two well-defined sets in the pH range 5–6. These are designated Al—FA(I) with an average $k$ of $2.2 \pm 0.5 \times 10^{-2}\ s^{-1}$ and Al—FA(II) with an average $k$ of $2.6 \pm 0.9 \times 10^{-3}\ s^{-1}$. These values are probably representative of the distribution of components of the fulvic acid mixture which behave most nearly like simple complexes of Al(III). (It is important to remember here that the thrust of a number of recent studies has been to underline the mixture character of fulvic acid and to demonstrate that its complexing behaviour cannot be modeled by a single small molecule ligand (3, 13).)

Given the functional groups identified on fulvic acid samples (2), chelating sites analogous to salicylate (phenol carboxylate) and phthalate (aromatic dicarboxylate) are very probably present in the fulvic acid sample. Secco and Venturini (14) have reported a dissociation rate constant of $7.9 \times$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

$10^{-3}$ $s^{-1}$ for aluminum salicylate at 25°C (higher than our $T = 19.5$°C). This value is actually similar to that we determined for dissociation of aluminum citrate, namely $4.8 \times 10^{-3}$ $s^{-1}$ (11, 12). It is reasonable to associate Al—FA(II) with reasonably strong simple chelating sites such as salicylate or carbohydrate-derived types in the fulvic acid mixture. Dissociation of the chelate is rate determining as was the case in the aluminum citrate study.

The phthalate-like sites on fulvic acid might be expected to be more labile. If formation rate constants for Al(III) complexes are similar for salicylate, oxalate, and phthalate, as is common for the largely dissociative substitution mechanism, the order of stability constants (15) suggests that dissociation rates would decrease in the order phthalates > oxalates > salicylates. However, we cannot overlook the probability that an increase of a factor of 10 in rate constant to about $2.2 \times 10^{-2}$ $s^{-1}$ merely reflects similar chelating groups to those of Al—FA(II) but with neighboring electron-withdrawing groups. Nevertheless, it may be useful to think of Al—FA(I) sites as analogous to simple phthalate chelates of aluminum.

It might be noted here that a comparison with an ion of similar lability to Al(III), namely $Fe(OH_2)_6^{3+}$, and the same fulvic acid in acid media where only one single kinetic component was observed supports the above ideas. The acid dissociation rate constant of Fe(III)—FA was found to be $7 \times 10^{-3}$ $s^{-1}$ at 25°C (16). This is intermediate between the two Al(III) values.

The above analysis is not contradicted by the observation of less labile Al(III) in the cases (k and l) where the FA/Al(III) ratio is largest. The binding constants of metals to fulvic acid mixtures decrease with increasing coverage of sites by the metal (3, 13). At low coverage some especially strong binding sites are resolved. We assign the quantities labelled Al—FA(III) to these sites. The distribution of labilities of sites is similar to that described recently for copper fulvates by Shuman (17). Shuman's work reveals copper fulvates of very widely varying lability. If the slow reacting component which is not represented by rate constants in Table 1 but is represented by the difference between "kinetic" and "equilibrium" (24 hr) recovery in Table 2 is considered, the distribution of labilities of aluminum fulvate sites probably covers as many orders of magnitude as copper fulvate sites.

The complicated pattern of distribution of amounts of material associated with the various lability categories as summarized in Table 2 must now be considered. In most cases, a substantial fraction of the total Al(III) is not recoverable. This is true in the absence of fulvic acid and is attributed to precipitation of hydrous aluminum oxides. Samples a and f already show that the quantity of non-labile Al(III) is a complex function of concentration and pH. This can be understood only in conjunction with the results on a turbidity maximum at Al(III) = $1 \times 10^{-5}$ $M$ already discussed (5, 6).

The presence of fulvic acid introduces additional complexity. Recently, in the context of a study of adsorption on alumina, Bourg (18) has obtained unequivocal evidence for ternary surfaces complexes involving: (*i*) groups from the alumina surface, (*ii*) humic substances, and (*iii*) metal ions from the solution. In the present case, Al(III) can play both the first and third role with the fulvic acid in the second. Such ternary complexes are most probably responsible for the elaborate pattern of variation in the distribution of Al(III) between kinetically recoverable and non-recoverable form found in Table 2. Compare the pairs b, c; d, e; j, k; and even m, n in Table 2. In each of these cases, we see an increase of fulvic acid leading to an increase of unrecoverable Al(III). The simplest explanation is ternary complexes with the hydrous oxide although formation of complexes at the least labile sites may also be significant.

## Conclusions

The distribution of labilities found for aluminum fulvates is qualitatively similar to that found with copper fulvates, and less spectacularly, for iron fulvates. They reinforce the mixture model of fulvic acid and emphasize the variety of sites involved in metal binding. If, as has long been suspected, labilities have a determining influence on bioavailability of Al(III), the complexities hydrous oxide precipitation presents to interpretation are not reduced but instead increased by complexation in binary and ternary forms involving humic organic matter.

# Metal carbonyl complexes of some aromatic *ortho* bis(methylthio)ethers

MICHAEL E. PEACH[1] AND CHRISTIAN BURSCHKA

*Institut für Anorganische Chemie der Universität Würzburg, Am Hubland, 8700 Würzburg, West Germany*

Received January 7, 1982

MICHAEL E. PEACH and CHRISTIAN BURSCHKA. Can. J. Chem. **60**, 2029 (1982).

Various complexes of the type $M(CO)_4L$ and $[M(CO)_4]_2L$, M = Cr, Mo, W, have been prepared and characterized. A series of aromatic *ortho* bis(methylthio)ethers were used as the ligand L. The crystal structures of the free ligand $C_6(SCH_3)_6$ and of the complex $Cr(CO)_4C_6(SCH_3)_6$ are reported.

MICHAEL E. PEACH et CHRISTIAN BURSCHKA. Can. J. Chem. **60**, 2029 (1982).

On a préparé divers complexes du type $M(CO)_4L$ et $[M(CO)_4]_2L$, où M = Cr, Mo, W, et on les a identifiés. On a utilisé une série d'*ortho* bis (méthylthio) éthers aromatiques comme ligand L. On rapporte la structure cristalline du ligand libre $C_6(SCH_3)_6$ et celle du complexe $Cr(CO)_4C_6(SCH_3)_6$.

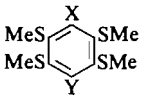
The ligating properties of several chelating sulfur ligands, particularly with various metal carbonyls and the platinum group metals, are the subject of continuing study (1–13). It has been shown that aromatic *ortho* bisthioethers form complexes with a number of metal ions (1). All of the complexes with simple metal ions were polymeric and could not be purified by recrystallization.

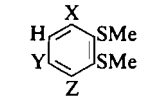
Various chromium, molybdenum, and tungsten carbonyl complexes can be formed by potentially chelating sulfur ligands. The aliphatic bisthioethers, $RS(CH_2)_xSR(L)$, give the complexes $M(CO)_5L$, $[M(CO)_5]_2L$, and $M(CO)_4L$ (2–6). However, the latter complex, $M(CO)_4L$, is only obtained when $x = 2$, and the complex contains a five-membered ring. Similar complexes have been prepared with some *ortho* bisthioethers (L1, L3, L9, L10) (1, 7, 8) and tetrakis(alkylthio)ethenes (9). The tetrakis(alkylthio)ethenes could form two five-membered chelate rings in complexes such as $[M(CO)_4]_2L$, although these were not reported (9). The crystal structure of $W(CO)_4L$, L = *o*-$(MeS)_2C_6H_4$, has been noted (7).

Molybdenum and tungsten hexacarbonyls react with the macrocyclic ligand 2,6,15,19-tetrathia-[7.7]paracyclophane (TTPH) to form the complexes $TTPH[M(CO)_4]_2.2C_6H_6$ (M = Mo, W) and $TTPH[W(CO)_5]_2$ (10). The former two involve the coordination of the $M(CO)_4$ unit to two sulfur atoms and the formation of a six-membered ring, basically $M(CO)_4RS(CH_2)_3SR'$. However, with chromium hexacarbonyl several products are formed, the main one being the $\pi$ complex ($\eta^6$TTPH) chromium tricarbonyl (11). Other products characterized include elimination of the 1,3-propanedithia unit, and coordination of $Cr(CO)_4$ or $Cr(CO)_5$ units to sulfur atoms.

A further series of potential sulfur containing ligands of formula $C_6(SMe)_xH_{6-x}$ has been prepared (14). This paper is an extension of previous studies of the ligand properties of aromatic *ortho* bis(methylthio)ethers (1), with particular reference to the chromium, molybdenum, and tungsten carbonyl complexes. The ligands studied (L1, L2, L3, L4, L5, L6, L7, and L8) are shown below.

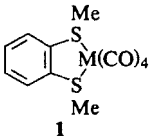


L1, X = Y = SMe
L2, X = SMe, Y = H
L3, X = Y = F
L4, X = Y = Cl
L5, X = Y = H

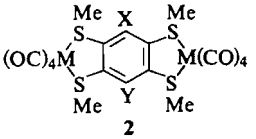


L6, X = Z = SMe, Y = H
L7, X = Y = SMe, Z = H
L8, Y = Z = H, Y = SMe
L9, X = Z = F, Y = SMe
L10, X = Z = F, Y = H

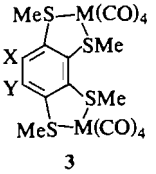
Various carbonyl complexes can be postulated, depending on the specific ligand. All the ligands should form the simple complexes $M(CO)_4L$ (1),



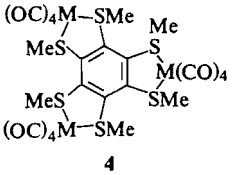
1



2



3



4

whereas the ligands L1, L2, L3, L4, L5, and L6 have two potentially chelating functions and the

‡Based on amount of ligand taken.

complexes $[M(CO)_4]_2L$, structure **2** or **3**, can be postulated. Similarly, it might be possible to prepare the complexes $[M(CO)_4]_3L$ (**4**) from L1.

The complexes $M(CO)_4L$ were readily prepared. Several attempts, mostly unsuccessful, were made to prepare the complexes $[M(CO)_4]_2L$ using an excess of the carbonyl reactant. Although analogous complexes with one polyfunctional sulfur ligand bonded to two metals are not known, some similar complexes with two metals and two ligands have been prepared, such as $Rh_2Cl_2(\mu\text{-CO})(PhSCH_2SPh)_2$ (13) and the group V ligand complexes, $(OC)_4M(EMe_2{-}{-}EMe_2)_2M(CO)_4$, M = Cr, W, Mo; E = P, As, with six-membered rings (15).

The complexes were obtained from *cis* metal tetracarbonyls, $M(CO)_4X_2$, specifically norbornadiene chromium and molybdenum tetracarbonyls and bis(acetonitrile)tungsten tetracarbonyl and the desired ligand in hexane, toluene, or THF solution (tungsten complexes). Some complexes were also prepared by irradiation of chromium hexacarbonyl to form $Cr(CO)_5$.THF, which then reacted with the ligand or from $Et_4N[Cr(CO)_5Cl]$ in ethanol. The yields were very low when tungsten hexacarbonyl was irradiated. The tungsten complexes could not be prepared from *cis*-bis(piperidine)molybdenum tetracarbonyl (16) as the free piperidine generated in the reaction reacted with the sulfur-containing ligand, presumably nucleophilically displacing a methylthio group.

The complexes isolated were mainly of the type $M(CO)_4L$, see Table 1, and did not usually depend on the reactant stoichiometry. Although the chromium complex $Cr(CO)_4L$ was readily prepared the complex $[Cr(CO)_4]_2L$ was not obtained from an excess of $C_7H_8Cr(CO)_4$ or $Cr(CO)_5$THF with L. The complexes $[Cr(CO)_4]_2L$ (L = L1, L3) were precipitated from ethanol solutions of $Et_4N[Cr(CO)_5Cl]$ and L, in stoichiometry 2:1; under the same conditions with L2, L5, and L6 the complex $Cr(CO)_4L$ precipitated. Even with reactant stoichiometry 3:1 $W(CO)_4(MeCN)_2$:L in THF solution

For personal use only.

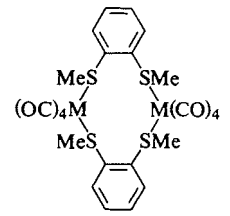
it was generally only possible to isolate or detect in solution the complexes $[W(CO)_4L]$. However, depending on the stoichiometry, the complexes $W(CO)_4C_6(SMe)_6$ and $[W(CO)_4]_2C_6(SMe)_6$ could be prepared. The reactions of $C_7H_8Mo(CO)_4$ with the various ligands were usually studied in toluene solution where precipitation of $Mo(CO)_4L$ sometimes occurred. The reactions with molar ratios $C_7H_8Mo(CO)_4$:L, 2:1, were studied in either toluene or methylene chloride, depending on the solubility of $Mo(CO)_4L$. The nmr spectra of the initial products indicated that although small amounts of $[Mo(CO)_4]_2L$ may have been formed in several reactions, it was only possible to isolate this product when L = L1 or L3. The molybdenum complexes were often formed with incorporation of some solvent in the crystal lattice. This was detected in the nmr spectra and thermal analysis showed a loss of weight (less than 5%) accompanied by an endothermic change before decomposition. Incorporation of solvent benzene in some molybdenum complexes $Mo(CO)_4L$ with sulfur-containing ligands has been noted previously (10).

The formation of the complexes $Cr(CO)_4L$ clearly depends on the bulk of the methyl group. When $p$-$F_2C_6(SBu^t)_4$ was used as a potential ligand no reaction occurred in four days at 45°C with $C_7H_8Cr(CO)_4$, although $C_7H_8Cr(CO)_4$ reacted within 2 days with other ligands containing the methyl group at 45°C. It can be inferred that the large tertiary butyl group blocks the coordination of the metal to the sulfur.

The number of *ortho* methylthio groups in a ligand also determines the ease of the reaction. In a reaction of 1 mmol of $C_7H_8Cr(CO)_4$ with 1 mmol of each of L1 and L5 in toluene at 45°C, the $C_7H_8Cr(CO)_4$ had all reacted within one day. The nmr spectrum of the product, after removal of the solvent, showed that approximately 75% of L1 had formed the complex $Cr(CO)_4L1$. The ligand L1 with six possible *ortho* bis(methylthio) sites for coordination clearly forms the complex $Cr(CO)_4L$ more readily than L5 which has only two *ortho* bis(methylthio) sites.

The structures of the products in solution were determined from their infrared and nmr (H-1) spectra. The spectroscopic data cannot, however, distinguish between the simple monomeric complex, $M(CO)_4L$, and a dimer, such as **5**. However, as the solutions used in the preparations were relatively concentrated ($0.05\,M \sim 0.02\,M$), the possibility of the formation of **5** can be excluded. The crystal structure of $Cr(CO)_4L1$ shows that it is monomeric in the solid state.

The carbonyl vibrations, tabulated in Table 2,

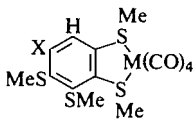


**5**

are all consistent with the established values for *cis*-tetracarbonyl complexes, *cis*-$M(CO)_4X_2$ (1, 9). The proton nmr spectra were normally recorded in benzene or methylene chloride solutions (see Table 2). The complexes decomposed readily in solvents such as deuterochloroform in which they are readily soluble. The structure **1** is clearly indicated for the complexes $M(CO)_4L1$ as three distinct methyl groups are observed in the proton nmr spectra with intensity ratio 1:1:1. Similarly, with the ligands L3, L4, L5, L7, and L8 where only one isomeric product is possible, the structure **1** is clearly indicated by the nmr spectra. The possibility of a $\pi$ complex, as occurs in bis(methylthio-$\eta$-benzene) chromium (18) and the $\eta^6$ arene compound $Cr(CO)_3C_6H_5$—$SC_6H_5$ (19) can be excluded.

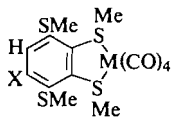
Comparison of the nmr spectra of the complexes and the free ligand in $CH_2Cl_2$ or $CDCl_3$ solution shows that the protons of the methyl group bonded to the ligand sulfur in the complexes $M(CO)_4L$ are deshielded by approximately 0.30 ppm (Cr), 0.38 ppm (Mo), and 0.57 ppm (W) and that there is somewhat greater deshielding in the complexes $[M(CO)_4]_2L$. Similar deshielding has been observed in the complexes $M(CO)_5SRR^1$ (M = Cr, Mo, W), with the magnitude of the deshielding Cr < Mo < W (19, 20). The chemical shifts of the other methyl protons are relatively unchanged in comparison with the free ligand. This deshielding effect is not as clearly observed in benzene solution, with respect to the free ligand, but the magnitude of the deshielding is still Cr < Mo < W.

With the ligands L2 and L6, two isomeric products $M(CO)_4L$ can be postulated, **6** and **7**.



**6**

L2, X = SMe
L6, X = H



**7**

The nmr spectra of both the $M(CO)_4L$ (L = L2, L6) complexes indicate that only one isomeric product is formed. The structure **7** is clearly shown in the spectrum of the L6 complexes as only two methyl proton signals are observed. Similarly, it can be postulated from the observed spectrum of L2 and

the magnitude of the deshielding found in the other complexes that the probable structure of the $M(CO)_4L2$ complexes is also **7**, rather than **6**.

In the free ligand L3, the methyl protons are coupled to the fluorine, and appear as a triplet (17). This can be attributed to steric through space coupling, with free rotation about both the aromatic carbon–sulfur and the methyl carbon–sulfur bonds. In the complexes there is increasing rigidity of the aromatic carbon–sulfur bond, so that no coupling to fluorine is observed in $[M(CO)_4]_2L3$. However, in the complexes $M(CO)_4L3$, two distinct methyl groups are observed. The methyl group bonded to the coordinated sulfur is a singlet, whereas the methyl group bonded to non-coordinated sulfur still appears as a triplet.

While the structures of the complexes $[M(CO)_4]_2L3$ must be unambiguously assigned as **2**, it is not clear from the nmr spectra whether the complexes $[M(CO)_4]_2L1$ have structure **2** or **3**. Two distinct methyl groups are observed in the proton nmr spectrum, with intensity ratio 2:1.

Similarly, any complexes of the type $[M(CO)_4]_2L$ could have structure **2**, when L = L2, L5, and structure **3**, when L = L2 or L6. There was no indication of any complexes $[M(CO)_4]_2L$ being formed with L2, L5, or L6. If the complexes were formed with L6, some rearrangement must have occurred in the solution as the complexes $M(CO)_4L6$ all have structure **7**. The different abilities of the somewhat analogous ligands L3 and L5 to form the $[M(CO)_4]_2L$ complexes may be due to the differences in size of hydrogen and fluorine.

The crystal structures of the free ligand $C_6(SCH_3)_6$, L1, and the chromium complex $Cr(CO)_4L1$ have been examined and compared.

They are shown in Figs. 1, 2, and 3 and some bond lengths and angles are tabulated in Tables 3 and 4.

In the crystal all $C_6(SCH_3)_6$ molecules are found to have a crystallographic centre of symmetry in their middle. The $C_6S_6$ fragment is only roughly planar. With the carbon atoms deviating from a best plane through the origin by ±0.03 Å (signs alternating) the benzene ring is slightly puckered. Deviations of the sulfur atoms from this plane are considerably higher (S1: 0.22 Å, S2: 0.25 Å; S3: 0.24 Å), probably caused by short non-bonding S...S-contacts (Table 3).

While the low temperature nmr spectrum of $C_6(SCH_3)_6$ (−75°C in $CS_2$) indicates that all the methyl groups are equivalent, in the solid state three adjacent methyl groups are situated above the plane, the other three below. The aromatic C—S bond length and S—$CH_3$ bond lengths are as expected, but the aromatic C—S bond length, average 1.78 Å, is approximately 0.05 Å lower than the anticipated sum of the covalent radii (21); however, values of 1.74 and 1.76 Å are reported in di-*p*-toly sulfide (22).

The structure of $Cr(CO)_4C_6(SCH_3)_6$ does not show fundamental changes within the ligand. Still some changes in the SCCS torsion angles can be observed, possibly due to complexation, though it cannot be excluded that intermolecular packing gives rise to similar effects. Bonding to the chromium atom apparently reduces the angle S1C1C2S2 from the range of 11.7°–13.6° in the free ligand to 5.4° in the complex, thus enabling the chelate ring to be more planar. Contrary to that, the carbon–sulfur bonds to S4 and S5 opposite the bonded part of the ligand enclose a torsion angle of 19.8° which is unusual for adjacent $sp^2$-centres normally being coplanar. As for the aromatic carbon-bridging sulfur bond lengths, however, there is virtually no change from those observed in the free ligand.

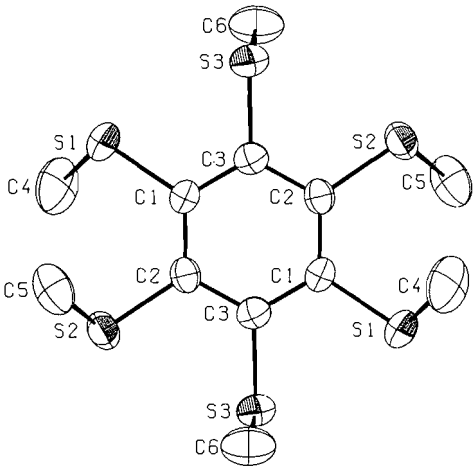

FIG. 1. ORTEP-plot (50% probability) of the molecule $C_6(SCH_3)_6$ direction of view perpendicular to the $C_6$-plane.

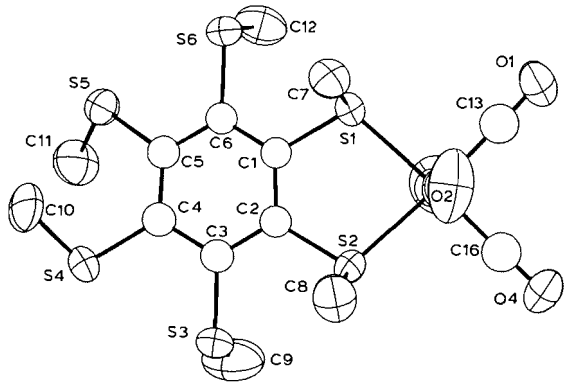

FIG. 2. ORTEP-plot (50% probability) of the complex $Cr(CO)_4L1$ showing the atomic numbering scheme. Direction of view perpendicular to the plane CrS1S2 (C14 and C15 axial: C14 above, C14 and O3 below the projection plane).

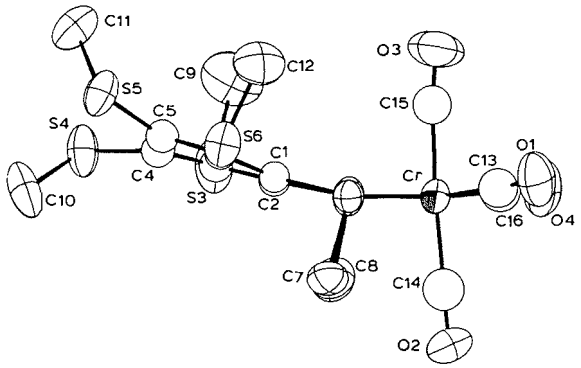

FIG. 3. ORTEP-plot (50% probability) of the complex $Cr(CO)_4L1$ direction of view from atom S1 to atom S2.

In the crystal three of the methyl groups bonded to non-coordinated sulfur are on one side of the ligand plane and only one on the other. This may be due to packing as the room temperature nmr spectrum ($CH_2Cl_2$) shows that there are three distinct methyl groups of equal intensity. On cooling the peaks broaden somewhat and below −25°C the peaks due to the methyl attached to non-coordinated sulfur coalesce and a single broad peak is observed.

The methyl groups bonded to the coordinated sulfur are on the same side of the ligand plane. This was also observed in $W(CO)_4L$ where L = *o*-$(MeS)_2C_6H_4$ (7) and in the complex $Cr(CO)_4L$, where L is tetrakis(methylthio)ethene (9). However, in the complexes $Cr(CO)_4L$ where L is $RS(CH_2)_nSR$ ($n = 2, 3$) and the bridging $(CH_2)_n$ unit is saturated the groups R are *anti* (5, 6).

| C1—C2 | 1.402(3) | C3—C1—S1 | 116.4(2) |
| C1—C3 | 1.403(3) | C1—C3—S3 | 119.4(2) |
| C2—C3 | 1.405(3) | C2—C3—S3 | 119.7(2) |

| Non-bonding S...S-contacts | Distance | Atoms | Dihedral angle (deg) |
|---|---|---|---|
| S1...S3 | 3.083(1) | S1C1C2S2 | 13.2 |
| S2...S3 | 3.119(1) | S2C2C3S3 | 13.4 |
| S1...S2 | 3.401(1) | S3C3C1S1 | 12.3 |

As there is an angle of 13.3° between the plane S1CrS2 and a best plane S1C1C2S2 the chelate ring is envelope shaped. Although it would be tempting to attribute this angle to the space requirements of the methyl groups at C7 and C8, this is apparently not justified, since the chelate ring in $Cr(CO)_4L$, L = bis(*t*-butylthio)ethene, with far more bulky groups in the same positions is reported to be planar.[2] The structure with L = tetrakis(methylthio)ethene (9), however, exhibits an angle of 7.03° between corresponding planes in the ring.

The coordination around chromium in the present structure is octahedral with relatively little distortion. The S—Cr—S angle of 84.5° is in good agreement with that reported in $Cr(CO)_4L$, when L = tetrakis(methylthio)ethene (83.8°) (9) or L = 3,6-dithiaoctane (85.1°) (5).

Influence of the substituents at the sulfur atom on the environment of the metal may be detected from the S—Cr—C angles, which are greater when C = C14 and smaller when C = C15 (see Table 3). A corresponding observation has been made in similar compounds (9).[2] The carbonyl group closest to sulfur is bent to an angle O3—C15—Cr of 173.3(6)° and thus distorted most from 180° with respect to the other three. It was suggested that repulsion from lone pairs of the sulfur atom might be responsible for such a distortion (5). The angle C14—Cr—C15 (176.6°) is significantly larger than that in some other $Cr(CO)_4L$ complexes, when L = bis(*t*-butylthio)ethane (169.8°) (6), L = 3,6-dithiaoctane (174.7°) (5), or L = bis(*t*-butylthio)ethene (173.5°).[2]

Much discussion has been presented about Cr—S and Cr—C(O) distances in similar compounds. Values found in the present structure fit quite well with those already reported. A shortening of the average Cr—S bond (2.39 Å) (2.38 Å when L = tetrakis(methylthio)ethene, 2.42 Å when L = 2,6-dithiaoctane, and 2.44 Å when L = 2,2,7,7-tetramethyl-3,6-dithiaoctane) compared to the sum of the assumed covalent radii (1.48 Å for $Cr^0$ (23) and 1.04 Å for sulfur (21)) has been attributed to multiple bonding between Cr and S (5, 9). Differences in the bond lengths Cr—C(O) of carbonyl groups mutually *trans* and those *trans* to sulfur have been taken as an indicator for the lack of π-interaction in the Cr—S bond compared to the Cr—C(O) bond (5). Similar differences are observed in the present complex, Cr—C(O) mutually *trans* being slightly longer (1.878 Å ave) than Cr—C(O) *trans* to sulfur (1.842 Å ave). Corresponding, though less significant, variations of the C—O bond lengths are found as expected.

## Experimental

All reactions are studied in dry solvents, under $N_2$. The ligands were prepared by literature methods (14, 24). The carbonyl complexes were available commercially or were prepared by slightly modified known procedures, $C_7H_8M(CO)_4$ (M = Cr, Mo), $Et_4N[Cr(CO)_5Cl]$ from $Et_4NCl$ and $Cr(CO)_6$, and $(MeCN)_2W(CO)_4$ from MeCN and $W(CO)_6$.[3]

Infrared spectra were recorded in solution on a Perkin Elmer Infrared Spectrophotometer Model 283 and nmr spectra were recorded on a Varian T-60 (H-1) or XL-90 (F-19). Thermal analyses were studied on a DuPont Thermal Analyser 990.

Details of the reaction conditions, yields, analyses of products, and ir and nmr spectra are shown in Tables 1 and 2, respectively. Microanalyses were performed either by the Mikroanalytical Laboratory, University of Würzburg, or Mikroanalytisches Laboratorium Beller, Göttingen, W. Germany.

*Structure investigation by X-ray methods*

The crystals examined were grown from methanol (L1) and toluene/hexane (1:2 volume ratio) $(Cr(CO)_4L1)$, respectively. Some of the crystal data are given in Table 5. The lattice constants and estimated standard deviations are derived from least-squares calculations based on 19 (20) centered reflections in a 2$\theta$ range of 23°–28° (23°–26°) in the case of the free ligand L1 (the complex $Cr(CO)_4L1$). Systematic extinction was observed for reflections $h0l$ with $h + l = 2n + 1$ and $0k0$ with $k = 2n + 1$ leading to the space group $P2_1/n$ (non standard setting of $P2_1/c$, No. 19 of the International Tables) with the equivalent positions $x, y, z; -x, -y, -z; x + 1/2, 1/2 - y, z + 1/2; 1/2 - x, y + 1/2, 1/2 - z$. X-ray intensity data were measured on a Syntex P $2_1$-diffractometer. They were corrected for Lorentz and polarisation factors but not for absorption. The structure L1 was solved by direct methods (program MULTAN (25)). After refining positional parameters and anisotropic temperature factors[4] for the non-hydrogen atoms by full-matrix least-squares the following $R$-values were obtained: $R_1 = 0.047$, $R_2 = 0.074$ (observed reflections only). The quantity minimized was $\Sigma(|F_{obs}| - |F_{calc}|)^2 \cdot W$ with $W = 1/\sigma^2$ and $\sigma$ derived from counting statistics. Those reflections with $I/\sigma(I) < 3.0$ were classified as unobserved and not included in the refinement.

At this stage all of the 9 hydrogen atoms could be localized among the 12 highest peaks of a difference electron density map at reasonable positions. Including these in the structure factor calculations yielded $R_1 = 0.038$. Further refinement, with hydrogens kept tied to a common isotropic temperature factor, converged at $R_1 = 0.028$ and $R_2 = 0.035$. Positional parameters are listed in Table 6.

During the last cycle change/esd was less than 0.1 for all parameters.

Concerning the complex $(CO)_4CrL1$ the position of the Cr

atom in the unit cell could be found from a Patterson synthesis. Successive structure factor, Fourier and difference Fourier calculations revealed the positions of the lighter atoms except hydrogen. All atoms except C1, ..., C6 and C13, ..., C16 were made anisotropic. Positional parameters as resulting from full-matrix least-squares refinement are given in Table 7. The maximum change/esd during the last cycle was 0.01 and there were no values above 0.5 e/Å$^3$ in the final difference electron density map. *R*-values are given in Table 5.

All calculations were carried out by means of the XTL-programme (26) package on a NOVA 1200 minicomputer with structure factors for uncharged atoms as given in ref. 27. Effects of anomalous dispersion were not taken into account.

*Methods*

*Reactions with $C_7H_8M(CO)_4$, M = Cr, Mo (Method A)*

Equimolecular amounts (1 mmol) of $C_7H_8M(CO)_4$ and ligand were dissolved in ~20 mL toluene and heated to approximately 45°C. The reaction was monitored by observing changes in the ir spectrum in the 2100–1750 cm$^{-1}$ region. When the reaction was approximately 90% complete, any precipitate was filtered off, and further product precipitated by addition of an equal volume of hexane. The products were recrystallized from toluene/hexane.

The nmr spectra and thermal analysis of the Mo products, $Mo(CO)_4L$, showed that they contained some solvent which was lost before the product decomposed. The excess solvent was removed by carefully heating in vacuum.

Reactions with stoichiometry 2:1 $C_7H_8Mo(CO)_4$:L were studied in either toluene at 45°C, or methylene chloride (~35°C) when precipitation had occurred in toluene. The reaction was monitored by ir or nmr spectra. In the reactions with L2, L5, and L6 in $CH_2Cl_2$, the infrared spectrum showed that approximately 50% of the $C_7H_8Mo(CO)_4$ had reacted within 20 h, and that any subsequent reaction was very slow, probably a decomposition generating increasing amounts of $Mo(CO)_6$. After 4 or 5 days, the nmr spectrum showed that the main product formed was $Mo(CO)_4L$ and only traces of possible $[Mo(CO)_4]_2L$ could be detected.

*Reactions with $M(CO)_6$, M = Cr, W (Method B)*

The experimental details have been described previously (1).

*Reactions with $W(CO)_4(MeCN)_2$ (Method C)*

A solution of approximately 1.7 mmol $W(CO)_4(MeCN)_2$ in 20 mL THF was filtered into a solution of the ligand (1.0 mmol) in 10 mL THF. The infrared spectrum showed that the reaction was complete at room temperature within less than 2 h, i.e. specifically the band at 1853 cm$^{-1}$ attributed to $W(CO)_4(MeCN)_2$ (28) had disappeared. Any $W(CO)_5MeCN$ did not react, as no change was observed in the band at 1840 cm$^{-1}$ (28). The solvent was removed and the product extracted with 20 ~ 30 mL toluene. The product was precipitated on addition of an equal volume of hexane. It was recrystallized from a mixture of hexane and toluene.

In the reactions with approximately 3 mmol $W(CO)_4(MeCN)_2$ and 1 mmol ligand, the residue after the toluene extraction to remove $W(CO)_4L$ was further extracted with $CH_2Cl_2$. The product $[W(CO)_4]_2L$ was precipitated on slow addition of toluene. In reactions with L3 and L5, $W(CO)_4L$ was the only complex detected in the nmr spectra of the products.

*Reactions with $Et_4N[Cr(CO)_5Cl]$ (Method D)*

Approximately 1 mmol of $Et_4N[Cr(CO)_5Cl]$ was added to a solution of 0.5 mmol of ligand in 60 mL EtOH at room temperature. The solution was stirred. If precipitation had not occurred within 1 day, approximately 5 mL of $H_2O$ was added. The volume of the solution was reduced until a precipitate had formed. The precipitate was extracted with toluene to remove $Cr(CO)_4L$ and the residue with $CH_2Cl_2$. The product $[Cr(CO)_4]_2L$ reprecipitated on addition of toluene.

# Discreteness-of-charge effects in electrode kinetics. I. The electroreduction of tetrathionate anion in the presence of specifically adsorbed iodide anions

W. Ronald Fawcett and Kveta Markušová[1]

*Guelph-Waterloo Centre for Graduate Work in Chemistry (Guelph Campus), Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1*

Received September 28, 1981

W. Ronald Fawcett and Kveta Markušová. Can. J. Chem. **60**, 2038 (1982).

The kinetics of electroreduction of tetrathionate anion have been studied at a Hg electrode in aqueous solutions of NaI + NaF and KI + KF with an ionic strength of 0.25 *M*. The rate of reaction was observed to decrease as the iodide ion concentration was increased, and when the cation was changed from $K^+$ to $Na^+$ at constant electrode potential. Analysis of the double layer effects on the basis of the Frumkin model results in an overestimation of the repulsive effect of the adsorbed iodide anions. This result is interpreted on the basis of the discreteness-of-charge effect and the possible non-coincidence of the reaction plane and outer Helmholtz plane.

W. Ronald Fawcett et Kveta Markušová. Can. J. Chem. **60**, 2038 (1982).

On a étudié la cinétique de l'électroréduction de l'anion tétrathionate au niveau d'une électrode au Hg dans des solutions aqueuses de NaI + NaF et de KI + KF avec une force ionique de 0,25 *M*. On a observé que la vitesse de réduction décroît lorsqu'on augmente la concentration en ion iodure et lorsqu'on passe du cation $K^+$ au cation $Na^+$ à potentiel d'électrode constant. L'analyse des effets de la couche double en fonction du modèle de Frumkin conduit à une surévaluation très marquée de l'effet répulsif des anions iodures absorbés. On interprète ce résultat en fonction du caractère discret de l'effet de charge et de la non-coincidence possible du plan de la réaction et du plan extérieur de Helmholtz.

[Traduit par le journal]

## Introduction

Discreteness-of-charge effects in electrode kinetics have been discussed in detail in recent literature (1–14). One essential feature of the theory for these effects is that the rate of a simple redox process at an inert electrode is changed less than one would predict on the basis of the classical Frumkin theory of double layer effects (15, 24) in the presence of specifically adsorbed non-reacting ions. For example, the rate of electroreduction of an anion such as tetrathionate at a mercury electrode is slower in the presence of specifically adsorbed iodide anions than in their absence (16, 17), but the extent of deceleration is less than that estimated on the basis of the corresponding shift in the potential drop across the diffuse layer in the negative direction.

The electroreduction of tetrathionate was first studied by Žežula (18–20) who showed that a minimum occurs on the current–potential curve at potentials negative of the point of zero charge (pzc) similar to that found in the electroreduction of other anions (21). The presence of a large double layer effect over a wide potential range for this system makes it a good candidate for more detailed examination. Foresti and Guidelli (16) studied the effects of adsorbed ions on the electroreduction of tetrathionate; however, these experiments were not carried out at constant ionic strength so that detailed interpretation of the results on the basis of the theory of discreteness-of-charge effects is not possible (14). Žežula *et al.* (17) reported similar data at constant ionic strength; their analysis could not be completed because of the lack of double layer data at all the ionic strengths considered. Double layer data for the adsorption of iodide ion at an ionic strength of 0.25 *M* have been obtained for the NaI + NaF and KI + KF systems (22). These electrolytes are particularly convenient for investigating the above phenomena in that the double layer effect is reasonably large at this ionic strength, and the effects of the cations $Na^+$ and $K^+$ can be compared. The results of these experiments are reported in the present paper.

## Experimental

The kinetic data were obtained by dc polarography with a dropping mercury electrode as the working electrode. The counter electrode was a Pt cylinder of large area, and the reference electrode, a saturated calomel electrode. The current–voltage curves were recorded with a PAR model 174A polarographic analyzer. The drop time of the mercury electrode was controlled at 2 s and the mercury flow rate was 0.39 mg $s^{-1}$. The temperature of the cell was maintained at 25°C via an external jacket through which water at controlled temperature was pumped. The fluoride and iodide salts were purified as described previously (22). Reagent grade potassium tetrathionate (K and K Laboratories) was recrystallized twice from triply distilled water before use.

The rate constant was calculated from the ratio of the

observed current to its diffusion limited value according to the theory of Koutecký for an irreversible electrode process with inclusion of the correction of electrode sphericity (23).

## Results

Kinetic data were obtained in twenty different electrolyte solutions of composition $xM$ NaI + $(0.25 - x)M$ NaF or $xM$ KI + $(0.25 - x)M$ KF where $x = 0, 0.0063, 0.01, 0.016, 0.025, 0.04, 0.063, 0.1, 0.16$, and $0.25\,M$. Representative data for the $Na^+$ and $K^+$ systems at potentials negative of the pzc in the pure fluoride electrolyte are shown in Figs. 1 and 2, respectively. As one would expect, the rate constant decreases at constant potential with increase in bulk iodide concentration, that is, with increase in the extent that iodide is adsorbed on the electrode. As the electrode potential is made more negative, the surface excess of iodide decreases and the rate constants in a given system become independent of bulk solution composition. In any system of given bulk iodide and fluoride concentration, the rate constant in the potassium system is higher than that in the sodium system. The latter result agrees with similar observations with a variety of anionic reactants at negatively charged electrodes (21).

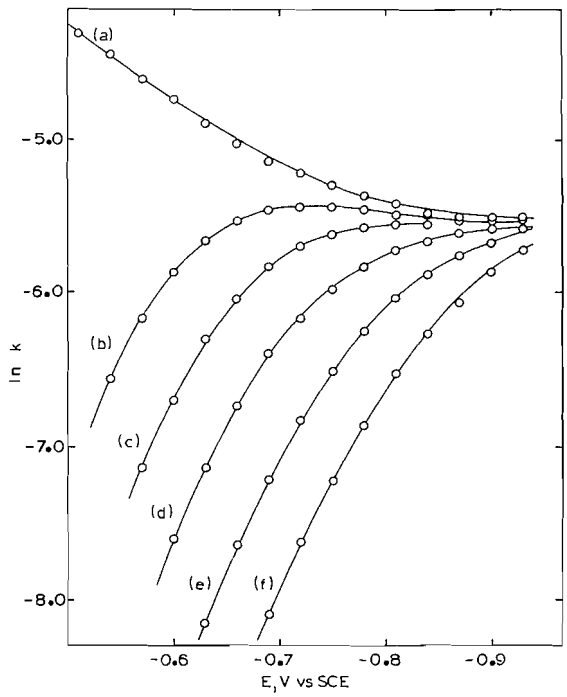

FIG. 1. Logarithm of the rate constant for electroreduction of tetrathionate anion ($S_4O_6^{2-} + 2e \rightarrow 2S_2O_3^{2-}$) at Hg against electrode potential with respect to a saturated calomel electrode. The electrolyte solution contained $x$ mol dm$^{-3}$ KI + $(0.25 - x)$ mol dm$^{-3}$ KF with the following values of $x$: (*a*) 0, (*b*) 0.0063, (*c*) 0.016, (*d*) 0.04, (*e*) 0.10, and (*f*) 0.25 mol dm$^{-3}$.

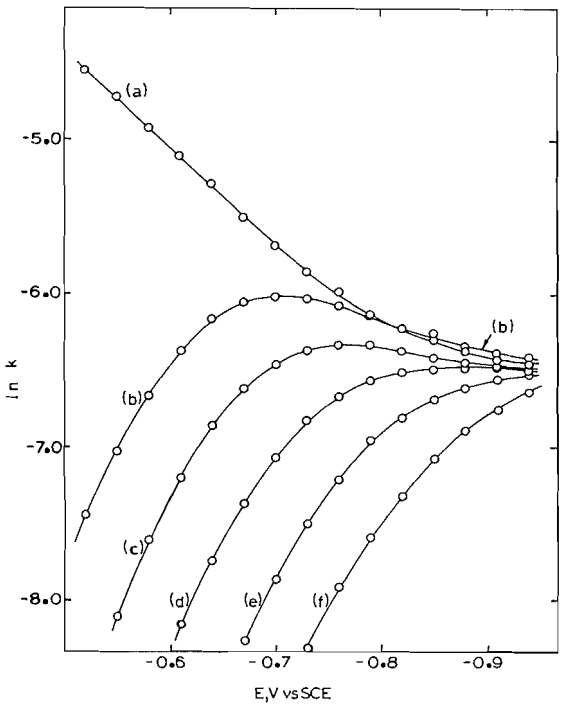

FIG. 2. Kinetic data for the electroreduction of tetrathionate anion as in Fig. 1 except that the electrolyte solution contained $x$ mol dm$^{-3}$ NaI + $(0.25 - x)$ mol dm$^{-3}$ NaF with the following values of $x$: (*a*) 0, (*b*) 0.0063, (*c*) 0.016, (*d*) 0.04, (*e*) 0.10, and (*f*) 0.25 mol dm$^{-3}$.

According to Frumkin's theory for double layer effects in electrode kinetics (15), the reaction site in the double layer is the outer Helmholtz plane (oHp), the potential at the reaction site being the average potential on that plane, $\phi^d$. The kinetic parameters are obtained from corrected Tafel plots (cTp) (24) on the basis of the relationship

$$[1] \quad \ln k + zf\phi^d = \ln k_0 - \alpha_a f(\phi^m - \phi^d)$$

where $k$ is the rate constant for reduction, $z$, the charge on the reacting species, $\phi^m$, the electrode potential on the rational scale, $k_0$, the value of the rate constant at a potential where both $\phi^m$ and $\phi^d$ are zero, $\alpha_a$, the apparent transfer coefficient, and $f = F/RT$. The oHp potential is calculated from Gouy–Chapman theory according to the equation

$$[2] \quad \phi^d = \frac{2}{f}\sinh^{-1}\left(\frac{\sigma_m + \sigma_a}{2A}\right)$$

where $\sigma_m$ is the charge density on the electrode and $\sigma_a$, that due to adsorbed ions, in the present case, iodide anions. The constant $A$ is equal to $(2RT\varepsilon\varepsilon_0 c_s)^{1/2}$ where $\varepsilon$ is the dielectric constant of the solvent, $\varepsilon_0$, the permittivity of free space, and $c_s$, the concentration of electrolyte (ionic strength

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

in the case of 1–1 electrolytes). On the basis of eq. [1], $y = \ln k + zf\phi^d$ should be independent of solution composition provided that $\phi^m - \phi^d$ is held constant.

The kinetic results obtained here were corrected for the double layer effect on the basis of the data for the adsorption of iodide obtained earlier (22). Values of $y$ were estimated as a function of electrode potential and solution composition. These data are plotted in Fig. 3 for the system with $K^+$ as a function of $\sigma_a$ for constant $\phi^m - \phi^d$. It is readily apparent that $y$ does depend on solution composition, its value increasing with $\sigma_a$ for low adsorbed charge densities and then decreasing. Similar results were obtained with $Na^+$ as the cation. It should be noted that the corresponding change in $\ln k$ at constant $\phi^m - \phi^d$ is of the same order of magnitude. For instance, at $\phi^m - \phi^d = 0.25$ V for the $K^+$ system, $\ln k$ decreases by 1.5 units when the iodide concentration is changed from 0 to 0.25 $M$; at the same time, $y = \ln k + zf\phi^d$ increases by 0.9 units. Thus, correction of the double layer effect on the basis of the Frumkin model results in an overestimation of the electrostatic effect of the adsorbed anions by approximately 50% of the observed decrease in the logarithm of the rate constant.

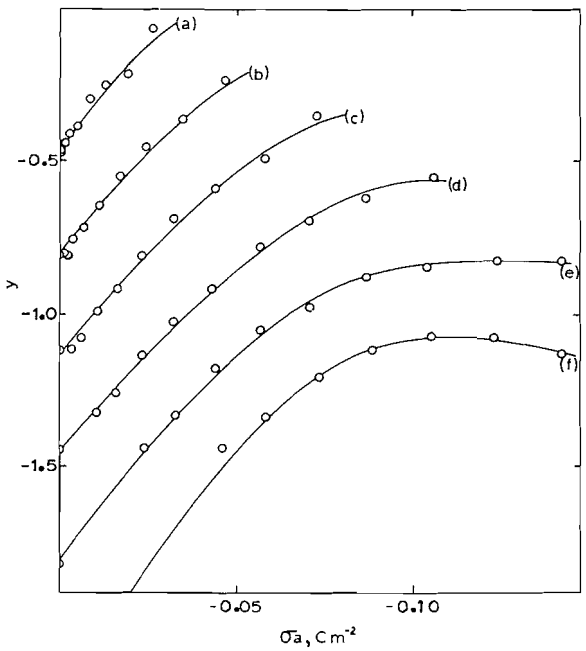

FIG. 3. Corrected logarithm of the rate constant for electroreduction of tetrathionate anion, $y = \ln k - 2f\phi^d$ against adsorbed charge density due to $I^-$ anions, $\sigma_a$ in an electrolyte solution containing KI + KF (ionic strength = 0.25 mol dm$^{-3}$) for constant potential drop across the inner layer, $\phi^m - \phi^d$. The values of $\phi^m - \phi^d$ for each of the curves are (*a*) −0.40, (*b*) −0.35, (*c*) −0.30, (*d*) −0.25, (*e*) −0.20, and (*f*) −0.15 V.

The double layer effect observed in the presence of strongly adsorbed ions is rather complex because of the fact that the reactant has both cations and anions in its immediate environment. In the present case, a negatively charged anion is reduced at a negatively charged electrode in an atmosphere composed predominantly of cations at the oHp with anions on the inner Helmholtz plane (iHp). It follows that one expects some interaction between the reacting species and its atmosphere in the diffuse layer (4, 5, 14, 15, 21). According to the theory of discreteness-of-charge effects (14), the change in the corrected logarithm of the rate constant, $y$ with respect to its value in the absence of adsorbed anions at constant $\phi^m - \phi^d$ is given by

$$[3] \quad y - y_0 = \frac{(\alpha - z)f(1-\lambda)(1-g)\sigma_a}{K_2} + \frac{(a_{\neq}\sigma_d)_0}{RT} - \frac{a_{\neq}\sigma_d}{RT} + p_{\neq}\ln(1 - \sigma_a/\sigma_{am})$$

The parameter $\lambda$ is equal to $K_i/K_{rd}$ where $K_i$ is the integral capacity of the inner layer and $K_{rd}$, that of the region between the reaction plane and the oHp, the reaction site being assumed to be located within the inner layer. $g$ is a dimensionless factor related to the degree that repulsive interactions between adsorbed anions are screened; it is given by (25)

$$[4] \quad g = \frac{C_d + K_2}{C_d + K_i}$$

where $C_d$ is the differential capacity of the diffuse layer and $K_2$, the integral capacity of the region between the iHp and the oHp. $\sigma_d$ is the charge density of cations in the diffuse layer whose distance from the reactant is such that attractive interaction is possible and $a_{\neq}$, the interaction parameter in the activated state (14). $\sigma_d$ and $a_{\neq}$ both vary with electrode potential, $\sigma_d$ being strongly dependent on the value of $\phi^d$. $\sigma_{am}$ is the maximum possible coverage by adsorbed iodide ions and $p_{\neq}$, the number of solvent molecules displaced by the reactant at the surface in the transition state. Since there is no evidence for surface coverage being significant in the analysis of data for iodide adsorption (22, 26, 27), the last term in eq. [3] may be disregarded, especially considering the extent of iodide adsorption under the present experimental conditions. It should also be noted that $\alpha$ is the true transfer coefficient which is obtained after correction for double layer effects, not the apparent value. This follows from the fact

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

that eq. [3] is based on the assumption that the reaction plane is not necessarily coincident with the oHp and that the local potential rather than the average value on the reaction plane is considered (14).

On the basis of the above discussion, the expression for $y - y_0$ becomes

$$[5] \quad y - y_0 = \frac{(\alpha - z)f(1-\lambda)(1-g)\sigma_a}{K_2} + \frac{(a_{\mp}\sigma_d)_0}{RT} - \frac{a_{\mp}\sigma_d}{RT}$$

Since $z$ is negative, the first term increases with increase in $|\sigma_a|$ provided that $g$ is less than unity. This term accounts for the fact that the repulsive effect of the adsorbed anions is overestimated on the basis of the average potential on the reaction plane. The interaction term $(a_{\mp}\sigma_d)_0 - (a_{\mp}\sigma_d)$ also depends on $\sigma_a$ as a result of the corresponding change in inner layer properties. According to Grahame's model of the inner layer (26), one may write that

$$[6] \quad \phi^m - \phi^d = \frac{\sigma_m}{K_i} + \frac{\sigma_a}{K_2}$$

Thus, as the amount of adsorbed iodide increases at constant $\phi^m - \phi^d$, $\sigma_m$ becomes more positive. At the same time, $K_i$ and $K_2$ increase so that ion–ion interactions become less strong because of the increase in average dielectric constant between interacting species (4). Since the anionic reactant is stabilized by the cationic atmosphere at the electrode, $a_{\mp}$ is negative; it depends in a complex way on the local dielectric properties at the reaction site and imaging conditions in the electrode and diffuse layer (4). On the other hand, $\sigma_d$ increases with increase in $|\sigma_a|$ due to the concomitant change in $\sigma_a + \sigma_m$, and thus, $\phi^d$ in the negative direction. However, if the concentration of cations in the vicinity of a reacting anion is sufficiently high, further increase in $\sigma_d$ is not expected to result in reaction acceleration in the case that there is a fixed number of cations associated with one anion (4). On the basis of the experimental results (Fig. 3), it is apparent that $(a_{\mp}\sigma_d)_0 - (a_{\mp}\sigma_d)$ decreases with increase in $|\sigma_a|$ indicating that attractive ion–ion interactions are becoming less important at high adsorbed charge densities.

The two influences on $y - y_0$ may be separated if the variation in this function at constant potential drop across the diffuse layer, $\phi^d$, is considered; under these circumstances, one expects $a_{\mp}\sigma_d$ to be approximately constant since the ionic atmosphere in the diffuse layer is not changing. Plots of $\Delta = (y - y_0)_{\phi^m - \phi^d}$ against $\sigma_a$ at constant $\sigma_a + \sigma_d$ (constant $\phi^d$) are shown in Figs. 4 and 5 for the $Na^+$ and $K^+$ systems, respectively. From these results, it is apparent that $\Delta$ is approximately a linear function of $\sigma_a$ at constant $\phi^d$. The slopes of the plots which are equal to $(\alpha - z)f(1-\lambda)(1-g)/K_2$ decrease with increase in $|\sigma_m + \sigma_a|$, and also, with change in the nature of the counter ion from $K^+$ to $Na^+$. Values of $(\alpha - z)(1-\lambda)(1-g)/K_2$ vary from $9.6 \times 10^{-4}$ to $2.5 \times 10^{-3}$ cm$^2$ $\mu$F$^{-1}$ for variation in $\sigma_m + \sigma_a$ from $-11.5$ to $-9.0$ $\mu$C cm$^{-2}$ in the $Na^+$ system; the corresponding data for the $K^+$ system vary from $2.6 \times 10^{-3}$ to $3.8 \times 10^{-3}$ cm$^2$ $\mu$F$^{-1}$. The larger values of this parameter in the $K^+$ system reflect chiefly a lower value of $\lambda$. This trend has been interpreted as being the result of differences in the distance of closest approach to the electrode of the reacting system, and the predominant non-reacting counter ion, the more weakly solvated $K^+$ ion approaching more closely than the $Na^+$ ion (28). Similar results have been observed previously in the case of electroreduction of other anions (29, 30), neutral molecules (28), and cations (31).

The slopes of the plots in Figs. 4 and 5 may be interpreted further on the basis of the adsorption isotherm for the iodide anions. Neglecting the coverage term, the adsorption isotherm may be written

$$[7] \quad \ln(|\sigma_a|) = \Phi + \ln c_a + f(\phi^a + \zeta_d{}^a)$$

where $\Phi$ is the isotherm constant, $c_a$, the concen-

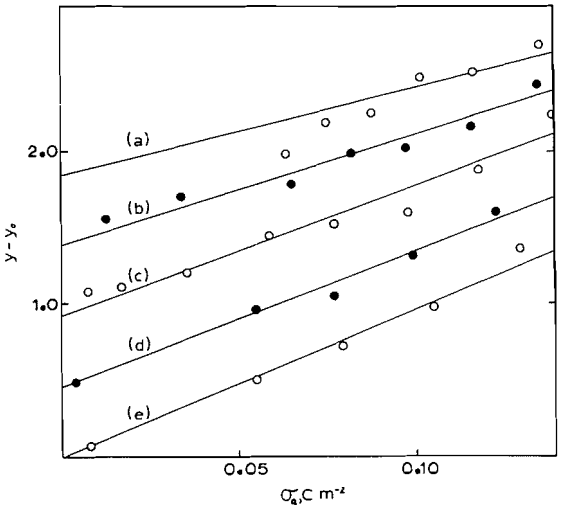

FIG. 4. Corrected logarithm of the rate constant for electroreduction of tetrathionate anion in a solution of NaI + NaF with respect to that in pure NaF at constant $\phi^m - \phi^d$, $y - y_0$ plotted against the adsorbed charge density due to $I^-$ anion, $\sigma_a$ for constant charge density in the diffuse layer, $-(\sigma_m + \sigma_a)$. The values of $\sigma_m + \sigma_a$ are (*a*) $-0.11$, (*b*) $-0.105$, (*c*) $-0.10$, (*d*) $-0.095$, and (*e*) $-0.09$ C m$^{-2}$. The ordinate scale is correct for curve (e); for the others it has been shifted up by (*a*) 2.0, (*b*) 1.5, (*c*) 1.0, and (*d*) 0.5 units.

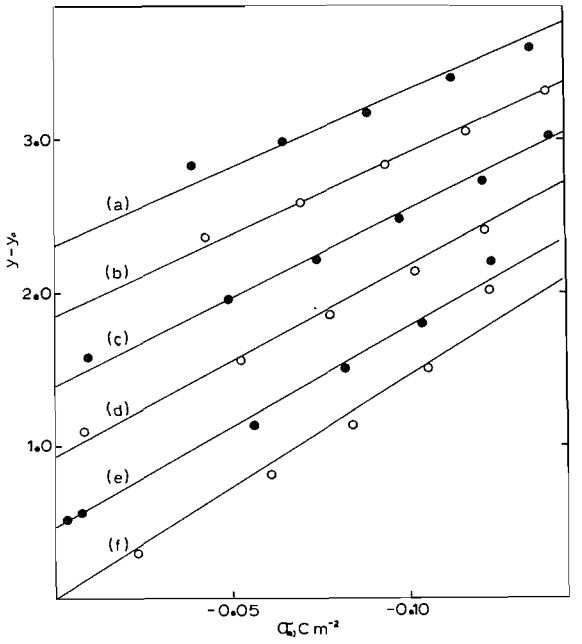

FIG. 5. Kinetic data for the electroreduction of tetrathionate anion as in Fig. 4 except that the electrolyte solution contained KI + KF. The values of $\sigma_m + \sigma_a$ are (*a*) −0.115, (*b*) −0.11, (*c*) −0.105, (*d*) −0.10, (*e*) −0.095, and (*f*) −0.09 C m$^{-2}$. The ordinate scale is correct for curve (f); for the others it has been shifted up by (*a*) 2.5, (*b*) 2.0, (*c*) 1.5, (*d*) 1.0, and (*e*) 0.5 units.

tration of adsorbing anions in the bulk, $\phi^a$, the average potential on the adsorption pt plane, and $\zeta_d{}^a$, the exclusion disc potential on the same plane (25). The average potential $\phi^a$ is given by

$$[8] \quad \phi^a = \phi^d + \frac{\sigma_m + \sigma_a}{K_2}$$

It is easily shown (14) that it can also be expressed as follows

$$[9] \quad \phi^a = \phi^d + \lambda'(\phi^m - \phi^d) + \frac{(1-\lambda')\sigma_a}{K_2}$$

where $\lambda' = K_i/K_2$. The exclusion disc potential is given by (25)

$$[10] \quad \zeta_d{}^a = \frac{-K_i g \sigma_a}{K_1 K_2} = \frac{(1-\lambda')g\sigma_a}{K_2}$$

where $K_1$ is the integral capacity of the region between the electrode surface and the adsorption plane. Combining eqs. [7], [9], and [10] one may write

$$[11] \quad \ln(|\sigma_a|/c_a) - f\phi^d = \Phi + f\lambda'(\phi^m - \phi^d) + \frac{f(1-\lambda')(1-g)\sigma_a}{K_2}$$

The parameters $\lambda'$, $g$, and $K_2$ all vary with electrode charge density (22, 25). However, an approximate value of the parameter $(1-\lambda')(1-g)/K_2$ can be obtained from plots of the function $\ln(|\sigma_a|/c_a) - f\phi^d$ against $\sigma_a$ at constant $\phi^m - \phi^d$.

Plots of data obtained earlier for the $K^+$ system (22) according to eq. [11] are shown in Fig. 6. The average slopes of the plots were determined by least squares and yielded values of $(1-\lambda')(1-g)/K_2$ varying from $6.7 \times 10^{-4}$ cm$^2$ μF$^{-1}$ at $\phi^m - \phi^d = -0.3$ V to $2.2 \times 10^{-3}$ cm$^2$ μF$^{-1}$ at $\phi^m - \phi^d = -0.1$ V. Assuming $\alpha - z$ is equal to 2.5, the corresponding values of $(\alpha - z)(1-\lambda')(1-g)/K_2$ are in the range $1.7 \times 10^{-3}$ to $5.5 \times 10^{-3}$ cm$^2$ μF$^{-1}$. These results are comparable to the values of $(\alpha - z)(1-\lambda')(1-g)/K_2$ obtained from the kinetic data. Thus we conclude that the discreteness-of-charge effect observed in the kinetic data is of the same order of magnitude as that observed for the equilibrium adsorption of the iodide ions. It also follows that the reaction site is in the inner layer but it is not possible to make any estimate of where it is with respect to the iHp on the basis of the present results.

The above analysis ignores the possible change in $(a_{\mp}\sigma_d)_0$ associated with change in Δ at constant $\sigma_m + \sigma_a$. On the basis of eq. [6], and recognizing that $1/K_i = 1/K_1 + 1/K_2$, one may write

$$[12] \quad \phi^m - \phi^d = \frac{\sigma_m + \sigma_a}{K_i} - \frac{\sigma_a}{K_1}$$

Thus, at constant $\sigma_m + \sigma_a$, as $\sigma_a$ increases in the negative direction, $\phi^m - \phi^d$ becomes more positive. The extent that $a_{\mp}\sigma_d$ changes with $\phi^m - \phi^d$ in the absence of specific adsorption is unknown; however, considering the fact that the corrected Tafel plots of kinetic data for tetrathionate anion reduction in NaF and KF media are linear, any change in $(a_{\mp}\sigma_d)_0$ is a linear function of $\phi^m - \phi^d$. The extent that this effect changes the present analysis is probably small but impossible to assess on the basis of the data obtained.

## Discussion

It is interesting to compare the double layer effects obtained in the present study with those reported earlier (16, 17, 19, 20, 33). Foresti and Guidelli analyzed data obtained in NaF and KF using the graphical procedure devised by Gierst (34). They concluded that the charge on the reacting species is −1.5. The apparent transfer coefficients were 0.07 and 0.17 in the presence of NaF and KF, respectively. Fedorovich *et al.* (33) studied the kinetics of electroreduction of $S_4O_6{}^{2-}$ at Bi, Sn, Pb, and Cd electrodes in aqueous solutions of

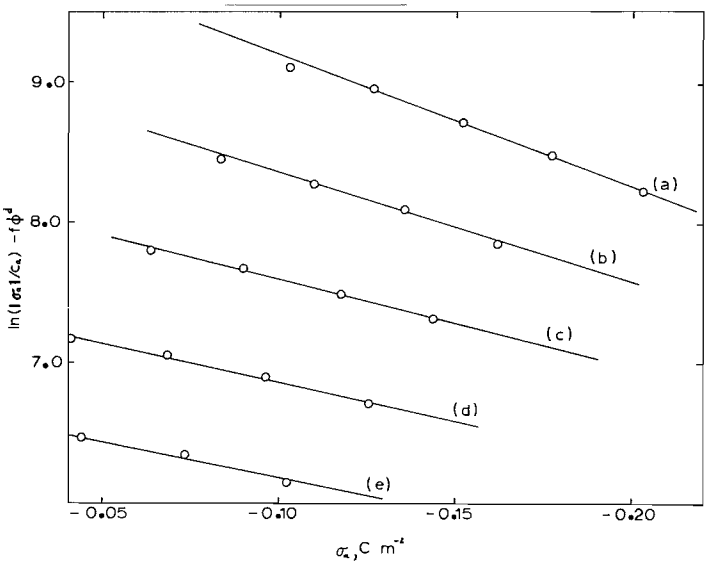

FIG. 6. Isotherms for the adsorption of $I^-$ anion at Hg from solutions of $x$ mol dm$^{-3}$ KI + (0.25 − $x$) mol dm$^{-3}$ KF plotted as ln $(|\sigma_a|/c_a) - f\phi^d$ against $\sigma_a$ at constant $\phi^m - \phi^d$. The values of $\phi^m - \phi^d$ are (*a*) −0.10, (*b*) −0.15, (*c*) −0.20, (*d*) −0.25, and (*e*) −0.30 V.

NaF. On the basis of an analysis of the dependence of ln $k$ on base electrolyte concentration, they determined the charge on the reacting species to be −1.9; furthermore, the apparent transfer coefficient, $\alpha_a$ was independent of the nature of the electrode and equal to 0.24. The great discrepancy between these results can be understood by examining corrected Tafel plots (cTp) in non-adsorbing electrolytes over a wide potential range. These plots for the present data obtained in 0.25 *M* NaF and KF and assuming $z = -2$ are shown in Fig. 7. At negative potentials the slopes of the cTp are linear in the region $-0.1 \geq \phi^m - \phi^d \geq -0.6$ V and yield values of $\alpha_a$ equal to 0.13 and 0.18 for the NaF and KF systems, respectively. However, at more positive potentials, the corrected logarithm of the rate constant is independent of the nature of the base electrolyte cation and the slope of the cTp increases, becoming approximately constant at the most positive values of $\phi^m - \phi^d$. The kinetic parameters at potentials positive of the pzc are probably influenced by specific adsorption of the reactant (35). If a graphical procedure is used to determine $z$ and $\alpha_a$ and data obtained near the pzc are involved, then some error in the analysis will result from the potential dependence of $\alpha_a$ in this potential region. For this reason, the values of $\alpha_a$ reported by Foresti and Guidelli are somewhat low. On the other hand, it is difficult to understand why the value of $\alpha_a$ reported by Fedorovich *et al.* (33) at other polarizable electrodes is so much higher than that reported here at Hg.

According to the analysis of double layer effects

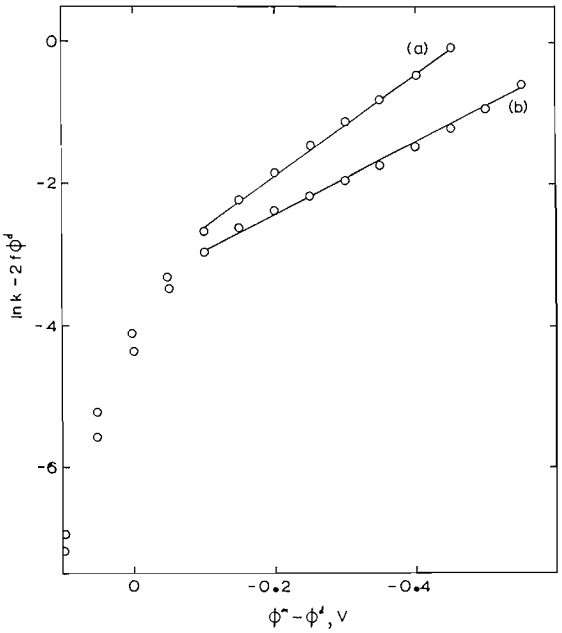

FIG. 7. Corrected Tafel plots of kinetic data for the electroreduction of tetrathionate anion in (*a*) 0.25 mol dm$^{-3}$ KF and (*b*) 0.25 mol dm$^{-3}$ NaF.

given earlier (14), the apparent transfer coefficient for a process involving the reduction of an anion at a negatively charged electrode in the absence of ionic specific adsorption may be written

$$[13] \quad \alpha_a = \alpha + \lambda(z - \alpha) + \frac{\partial(a_{\neq}\sigma_d)}{F\partial(\phi^d - \phi^m)}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

On the basis of previous discussion (29), the parameter $\lambda$ is expected to depend on the solvated size of the counter ion at the electrode, being greater for $Na^+$ than for $K^+$. Since $z - \alpha$ is negative, $\alpha_a$ is less than $\alpha$ by an amount which depends on the counter ion nature. However, $a_{\pm}\sigma_d$ is also negative and may decrease with increase in $|\phi^m - \phi^d|$. Thus, the term $\partial(a_{\pm}\sigma_d)/\partial(\phi^d - \phi^m)$ may also result in a decrease in $\alpha_a$ with respect to $\alpha$; in addition, if $K^+$ interacts more strongly with the reactant than $Na^+$, the effect may be dependent on the nature of the counter ion. The change in the nature of the counter ion from cation to anion and on the onset of specific adsorption of $S_4O_6^{2-}$ results in potential dependence of $\alpha_a$ in the vicinity of the pzc.

The analysis of the effects of specifically adsorbed anions on the electrode kinetics used by Foresti and Guidelli (16) is somewhat different than that presented here. For the present system, $\ln k$ is given by (14)

$$[14] \quad \ln k = \ln(\gamma_A^s k_c) + \frac{(\alpha - z)f(1-\lambda)(1-g)\sigma_a}{K_2} - a_{\pm}\sigma_d/RT - zf\phi^d - \alpha' f(\phi^m - \phi^d)$$

where $k_c$ is the potential independent part of the rate constant, $\gamma_A^s$, the activity coefficient of the reactant in the bulk of the solution, and $\alpha' = \alpha - \lambda(\alpha - z)$. Foresti and Guidelli (16) defined the logarithm of the rate constant corrected for all explicit effects due to the potential drop across the diffuse layer, $\phi^d$, as follows:

$$[15] \quad y' = \ln k + (z - \alpha')f\phi^d = \ln(\gamma_A^s k_c) + \frac{(\alpha - z)f(1-\lambda)(1-g)\sigma_a}{K_2} - a_{\pm}\sigma_d/RT - \alpha' f\phi^m$$

Considering the fact that $\alpha_a$ and, thus, $\alpha'$ are rather low for the present system, the difference between $y'$ and $y$, the corrected value of the logarithm of the rate constant discussed above, is not expected to be great. However, these authors observed that $y'$ decreased at constant $\phi^m$ with increase in $|\sigma_a|$ in the range $-3 \geq \sigma_a \geq -12\ \mu C\ cm^{-2}$. This observation is very different from that reported here, namely, that $y$ increases at constant $\phi^m - \phi^d$ and then decreases with increase in $|\sigma_a|$. The difference can be attributed to the fact that the data of Foresti and Guidelli (16) were obtained in solutions of varying ionic strength. Under these circumstances, one expects to find a concomitant change in the extent of interaction of the reactant with cations in its environment, that is, in the term $a_{\pm}\sigma_d$. As the ionic strength increases, $|\sigma_a|$ increases and $|\phi^d|$ decreases; at the same time, there is a decrease in $\sigma_d$ (14). Thus, the difference between the present results and those obtained at varying ionic strength (16) is attributed to the fact that the latter data were obtained under conditions in which ion–ion interactions vary greatly with adsorbed charge density, $\sigma_a$.

An analysis of the effect of adsorbed $I^-$ anions on the kinetics of electroreduction of $S_4O_6^{2-}$ was carried out by Žežula *et al.* (17) in solutions of constant ionic strength containing NaI and NaF. In this case, the analysis involved plotting $y' - y_0'$ against $\sigma_a$ where $y_0'$ is the value of $y'$ in a solution of pure NaF (eq. [15]). For values of $\sigma_a$ up to $-6\ \mu C\ cm^{-2}$, the slopes of these plots were negative, indicating a net increase in $y'$ with increase in $|\sigma_a|$.[2] The values of the slope, which is approximately equal to $(\alpha - z)f(1-\lambda)(1-g)/K_2$ if one ignores the contribution of the term in $a_{\pm}\sigma_d$, vary between $-0.33$ and $-0.21\ cm^2\ \mu C^{-1}$ for ionic strengths in the range 0.05 to 0.50 *M*. Considering the fact that their analysis differs from that given above, the agreement with the present data is satisfactory.

In conclusion, the present results show clearly that discreteness-of-charge effects must be considered in analyzing the effects of specifically adsorbed ions on electron transfer reactions. Assessment of these effects should be based on data obtained at constant ionic strength; otherwise it becomes exceedingly difficult to separate the various contributions, specifically, the exclusion disc effect and the effects of attractive ion–ion interactions. Finally, it should be recognized that the above analysis is based on the Gouy–Chapman theory of the diffuse layer. On the basis of recent theoretical work (32), it is clear that $|\phi^d|$ is overestimated by the Gouy–Chapman model but to an extent of less than 10% for the range of charge densities and ionic strength involved here. This model is used in the analysis of both the equilibrium adsorption data and the kinetic data. Thus, the error introduced in these analyses is not estimated to be large so that the magnitude of the discreteness-of-charge effect is not expected to change significantly if an improved model of the diffuse layer were used.

AND

THOMAS T. NAKASHIMA

*Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2*

Received April 6, 1982

JOHN A. FINDLAY, JIA-SEN LIU, D. JEAN BURNELL, and THOMAS T. NAKASHIMA. Can. J. Chem. **60**, 2046 (1982).

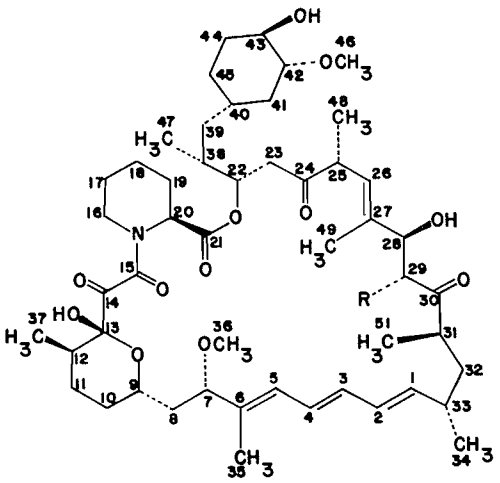
The structure **2**, 29-demethoxyrapamycin, is proposed for a new antibiotic from *Streptomyces hygroscopicus* and has been deduced by comparison of high field $^1H$ and $^{13}C$ nmr spectra, ir, uv, and mass spectra, and ORD/CD curves with those of the known antifungal antibiotic rapamycin **1**.

JOHN A. FINDLAY, JIA-SEN LIU, D. JEAN BURNELL et THOMAS T. NAKASHIMA. Can. J. Chem. **60**, 2046 (1982).

On propose la structure **2**, déméthoxy-29 rapamycine, pour le nouvel antibiotique obtenu à partir du *Streptomyces hygroscopicus*. On a déduit cette structure en comparant les spectres de rmn à haut champ du $^1H$ et du $^{13}C$, les spectres ir, uv, les spectres de masse et les courbes de ORD/DC du produit à ceux de l'antibiotique antifongique connu: la rapamycine **1**.

We reported (1, 2) recently on the structure, absolute configuration, chemistry, and high field nmr spectroscopy of the macrolide antifungal antibiotic rapamycin **1**, $C_{51}H_{79}NO_{13}$, isolated from cultures of *Streptomyces hygroscopicus*. In this paper we propose structure **2**, 29-demethoxyrapamycin, for a new crystalline (mp 107–108°C) antibiotic isolated (3) from the same source.

The uv spectrum ($CH_3OH$) of the latter ($\lambda_{max}$: 288, 276, 266; $E^{1\%}_{1cm}$: 423, 549, 421) is virtually identical with that of the triene rapamycin while the ir ($CHCl_3$) showing 3500 (OH), 1730, 1712 (ester, ketones), and 1640 (broad, amide/triene) $cm^{-1}$ is very similar to that of **1** (4). Elemental analysis, while not definitive, is reasonably consistent with $C_{50}H_{77}NO_{12}$ (calcd.: C 67.95, H 8.72, N 1.58, O 21.74; found: C 67.86, H 8.94, N 1.68, O 21.52). Attempts to obtain supportive mass spectral data for the molecular formula of demethoxyrapamycin have met with limited success. High resolution EI spectra of **1** and **2** are similar in that neither shows a molecular ion but both feature the base peak *m/e* 175.112 ($C_{12}H_{15}O$) and a prominent higher mass ion at *m/e* 304.2035 (28, $C_{19}H_{28}O_3$), both ions originating from the fragmentation and aromatization of a moiety derived by cleavage of the C20—C21 and C28—C29 bonds of rapamycin as proposed (2) by us earlier. The highest ion observed in the EI spectrum of rapamycin **1** at *m/e* 541.3051 (7.4, $C_{31}H_{43}NO_7$) corresponds to the larger fragment ($C_{20,19,\ldots} \rightarrow C_{29}$ incl.) derived by the same two bond cleavages accompanied by the net loss of 4H. The EI spectrum of demethoxyrapamycin **2** shows a highest and isolated ion at *m/e* 511.2944 (1.8, $C_{30}H_{41}NO_6$), readily explained via cleavages at the same C20—C21 and C28—C29 bonds and clearly supporting the contention that rapamycin and demethoxyrapamycin have the



**1** R = $^{50}CH_3O$

**2** R = H

0008-4042/82/152046-02$01.00/0

©1982 National Research Council of Canada/Conseil national de recherches du Canada

TABLE 1. ORD/CD data

| Compound | ORD maxima ($CH_3OH$) | CD maxima ($CH_3OH$) |
|---|---|---|
| **1** | $[\theta]_{315} = -90\,000$<br>$[\theta]_{260} = +77\,000$ | $[\theta]_{296} = -143\,000$<br>$[\theta]_{215} = +90\,000$ ($c = 0.0005$) |
| **2** | $[\theta]_{305} = -80\,000$<br>$[\theta]_{260} = +34\,000$ | $[\theta]_{290} = -112\,000$<br>$[\theta]_{210} = +87\,000$ ($c = 0.00043$) |

identical structural features at all sites except C29 and that they differ in elemental composition by the increment of $CH_2O$.

Corroborative evidence for the elemental composition of rapamycin **1** is available from its CI ($NH_3$) spectrum which displays an ion at *m/e* 931 ($913 + \overset{+}{N}H_4$). The comparable spectrum of demethoxyrapamycin shows its highest mass ion cluster around *m/e* 901 ($883 + \overset{+}{N}H_4$); however, this peak is less intense than the accompanying *m/e* 900 and 902 ions in some scans.

The FD mass spectrum of demethoxyrapamycin shows an ion at *m/e* 883 (69, $C_{50}H_{77}NO_{12}$) but this is complicated by the appearance of a base peak *m/e* 888 as well as an ion at *m/e* 1234 (62.5). In several FD scans rapamycin displays the correct molecular ion *m/e* 913 (100) while in others it shows *m/e* 913 (75) and 882 (100), the latter corresponding to $M^+ - OCH_3$.

The 100.6 MHz $^{13}C$ nmr spectrum ($C_6D_6$) of the new metabolite **2** contains fifty signals all of which have their counterparts in the $^{13}C$ nmr of rapamycin (2). The notable differences are the absence of a signal corresponding to the rapamycin C50 methoxyl and the chemical shift of the signal corresponding to C29, which in the new compound is found at higher field (δ 47.49) than in rapamycin (δ 84.87). These differences are in complete agreement with formulation **2**.

The 400 MHz $^1H$ nmr spectra ($CDCl_3$) of **2** and **1** (2) are remarkably similar except for the absence in the former of a signal corresponding to H-50 and the concomitant presence of signals for two H-29 protons, δ 2.64 ppm ($J_{28,29A} = 9.2$ Hz, $J_{29A,20B} = 17.4$ Hz) and 2.52 ppm ($J_{28,29B} = 2.8$, $J_{29A,29B} = 17.4$ Hz), whose assignments were confirmed by $^1H$–$^1H$ decoupling experiments.

The ORD and CD curves of **1** and **2** (Table 1) are not superimposable but very similar, consistent with the proposal that these molecules, originating from the same organism, are most probably configurationally identical at all common chiral centres but differ in some conformational aspects.

As in the case of rapamycin **1**, the $^{13}C$ and $^1H$ nmr spectra of **2** are complicated by the presence in solution of a minor (~ 20%) isomer component. Additional experiments are in progress to determine the nature of this isomerism and to complete the analysis of nmr spectral data.

We thus conclude that the new metabolite is 29-demethoxyrapamycin, **2**, that it exists in two isomeric forms in solution, and that the absolute configuration is as portrayed in **2** by analogy with rapamycin.

**Acknowledgements**

The authors are grateful to Ayerst Laboratories, Montreal, for providing material (AY-24,668), some spectral data (ir, uv), and financial assistance. The cooperation of Gordon Wood, University of Windsor, in obtaining FD mass spectra and Alan Hogg, Spectral Services Laboratory, Department of Chemistry, University of Alberta, in furnishing CI and EI spectra is much appreciated. The ORD/CD curves were obtained from the Spectral Services Laboratory, University of Alberta. This work was supported, in part, by a grant from the Natural Sciences and Engineering Research Council of Canada.

# Dipole moments and conformation energies for substituted ethanes

VICTOR M. S. GIL
*Department of Chemistry, University of Aveiro, 3800 Aveiro, Portugal*
AND
ANTÓNIO J. C. VARANDAS
*Department of Chemistry, University of Coimbra, 3000 Coimbra, Portugal*

Received September 25, 1981[1]

VICTOR M. S. GIL and ANTÓNIO J. C. VARANDAS. Can. J. Chem. **60**, 2049 (1982).

By using simple model potential energy functions for internal rotation of ethane derivatives ($CH_2X$–$CH_2X$ and $CHX_2$–$CHX_2$), a comparison was made between the continuum and the rotational isomeric state models for obtaining conformation information (especially energy differences for the staggered conformers) from electric dipole moments. It is found that the results obtained by the two procedures may be appreciably different, depending on the features of the conformational energy function and on the temperature considered.

VICTOR M. S. GIL et ANTÓNIO J. C. VARANDAS. Can. J. Chem. **60**, 2049 (1982).

Faisant appel à un modèle simple de fonctions d'énergie potentielle pour la rotation interne des dérivés de l'éthane ($CH_2X$–$CH_2X$ et $CHX_2$–$CHX_2$), on a établi une comparaison entre le modèle continium et le modèle d'état de l'isomère de rotation pour obtenir des informations sur les conformations (spécialement les différences d'énergie entre les conformères décalés) à partir des moments dipolaires électriques. On a trouvé que les résultats obtenus par les deux méthodes peuvent différer de façon appréciable en fonction des caractéristiques de la fonction d'énergie conformationnelle et de la température considérée.

[Traduit par le journal]

## Introduction

The use of electric dipole moments to obtain conformational information on molecules possessing rapid internal rotation, especially substituted ethanes, is well known (1, 2). The most widely used method assumes, namely, that (a) bond and group dipole moments (or atomic charges) are invariant to internal rotation, and (b) the mean-square dipole moment $\overline{\mu^2}$, which is an average for all possible

$$[1] \quad \overline{\mu^2} = \int_0^{2\pi} \mu^2(\theta) \exp[-E(\theta)/RT]d\theta \Big/ \int_0^{2\pi} \exp[-E(\theta)/RT]d\theta$$

conformations of rotation angle $\theta$ (in a classical view of an internally rotating molecule, $E(\theta)$ being the corresponding potential energy function) can be treated as a weighted (populations $p_i$) average of the discrete $\mu_i^2$ values which correspond to the three most stable conformers (the so-called rotational isomeric state approximation):

$$[2] \quad \overline{\mu^2} = \sum_{i=1,2,3} \mu_i^2 p_i$$

In a theoretical work essentially aiming at determining the main features of the conformational energy functions for chloroethanes, Mark and Sutton (3) have found that (for those chloroethanes where dipole moments are a function of the rotation angle, and for temperatures ranging from 298 K to 400 K) assumption (b) is a valid one as far as the calculated root-mean-square dipole moment $(\overline{\mu^2})^{1/2}$ is concerned, providing the discrete rotational isomeric states are taken at the actual minima in the conformation potential energy function, instead of the classical staggered conformers corresponding to $\theta = 60°$, 180°, and 300°, as in ethane. A different result was later found by Vaughan (4) using a slightly different potential function. He also discussed the limits on the application of the rotational isomeric state method to the study of dynamic properties.

In order to establish how the agreement between the continuum and the rotational isomeric state models depends on the features of the conformation energy function and to investigate the validity of this approximation as far as calculated $\Delta E$ values for the most stable conformers are concerned, we have initiated a series of simple calculations using model potential energy functions of increasing complexity. We have previously found that, when vicinal H—H nuclear spin coupling constants are used as the conformational dependent property, the continuum and the discrete approaches (ignoring entropy differences) give significantly different results, the differences being temperature dependent (5). Assumption (a), which is also questionable, is not, however, dealt with in the present study.

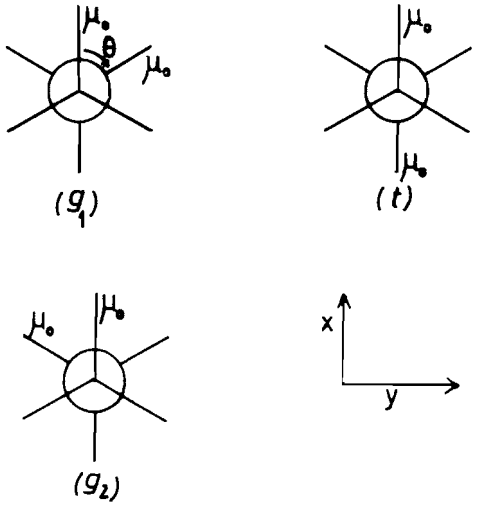
We start by considering the most symmetrical systems $CH_2X$–$CH_2X$ and $CHX_2$–$CHX_2$ where only two different conformational energy minima occur; we further consider the dipole moment vector to be given as a sum of two local dipoles of equal magnitude $\mu_0$. Accordingly, for the staggered conformations of $CH_2X$–$CH_2X$



(and similarly for the $CHX_2$–$CHX_2$ system) we have

[3] $\Delta E = E_g - E_t$

the dependence of $\mu^2$ on $\theta$ being given by

[4] $\mu^2 = \mu_x^2 + \mu_y^2 = m_0^2 (1 + \cos\theta)^2 + m_0^2 \times \sin^2\theta = 2m_0^2 (1 + \cos\theta)$

where $m_0$ is the magnitude of the projected local dipoles on the plane perpendicular to the CC bond ($z$ axis). We will, in particular, compare the "true" $\Delta E$ values obtained directly from the minima of the potential energy curves with the corresponding apparent $\Delta E'$ values which are obtained using the discrete average approach, ignoring entropy differences. We will also compare $\overline{\mu^2}$ and $\overline{\mu'^2}$ values obtained by the continuum and the discrete procedures.

The simplest type of energy functions we have used are given by curves *a* and *b* in Fig. 1, that is, we assume that all eclipsed conformations have the same energy (a condition that is relaxed later, curve *c*) and that the conformational energy minima correspond exactly to $\theta = 60$, 180, and 300°. The form of the $E(\theta)$ function in the interval 0–120° has been taken as $E(60°) \times (1\text{-}\cos 3\theta)/2$ and similarly for the intervals 120–240° and 240–360°; this is the

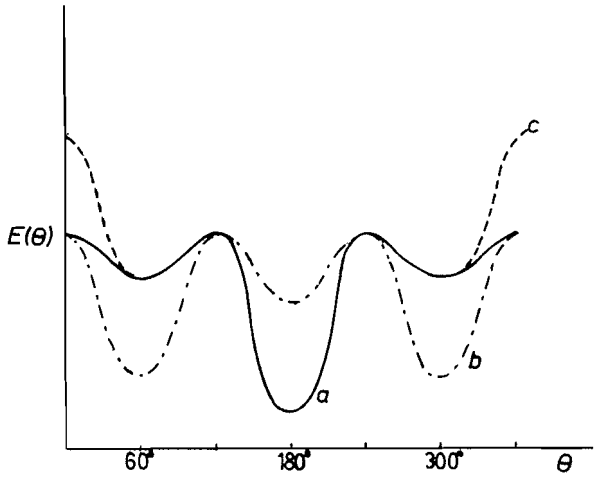


FIG. 1. Types of potential energy functions used.

form of the leading term in the potential energy function for ethane (6).

In a second set of calculations we have taken curves of type *c* in Fig. 1. This is derived from *a* by increasing the energy of the *cis* conformation (the case, for instance, of 1,2-dichloroethane (3)) and keeping the same type of function in the intervals 0–60° and 300–360°. For simplicity the minima have been supposed to occur at the same $\theta$ values. We note that the estimated deviation in such minima is only of the order of 10° in 1,2-dichloroethane where the energy of the *cis* conformation is well above that for the other eclipsed conformations (3).

Using [4] and [1], we simulate "observed" $\overline{\mu^2}$ values (by direct numerical integration of [1]) for various well depths and temperatures. These values are then used to calculate the effective populations, $t$, $g_1 = g_2$, of the three rotational isomers, by applying [2]:

[5] $\overline{\mu^2} \equiv 2m_0^2 \quad \overline{(1 + \cos\theta)} = \mu_t^2 . t + 2\mu_{g_1}^2 . g_1 = 2\mu_{g_1}^2 . g_1 = 6m_0^2 g_1$

(where $\mu_t^2 = 0$ and $\mu_{g_1}^2 = 3m_0^2$ for $\theta = 60°$) in conjunction with the relationship

[6] $t + 2g_1 = 1$

The calculated $\Delta E'$ value is

[7] $\Delta E' = E'_{g_1} - E'_t = RT \ln t/g_1$

which is to be compared with the original $\Delta E$ value.

We also compare the "observed" $\overline{\mu^2}$ values with the corresponding $\overline{\mu'^2}$ quantities which would be obtained if only the staggered conformations, with

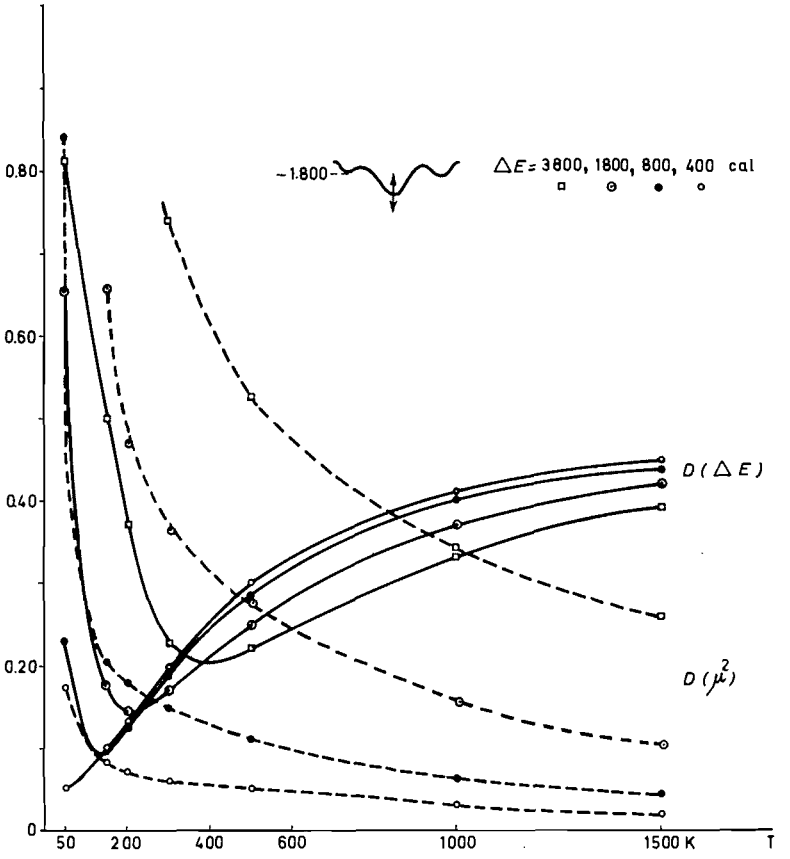

FIG. 2. The deviations $D(\Delta E)$ and $D(\mu^2)$ as a function of $T$ and $\Delta E$, for various $E(\theta)$ functions of type (a) differing in $E_t$ from each other.

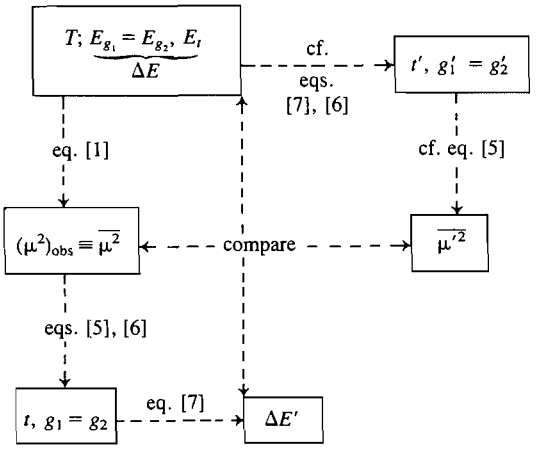
energies given by the potential energy functions used, were populated (populations $t'$, $g_1' = g_2'$). The general scheme is illustrated below.



The differences between $\Delta E$ and $\Delta E'$ and between $\overline{\mu^2}$ and $\overline{\mu'^2}$ stem, in a related manner, from the difference between populations $t$ and $t'$ (or $g$ and $g'$).

## Results and discussion

### (a) *Simple* E(θ) *functions*

Figures 2 and 3 show the deviations $D(\Delta E) = (\Delta E - \Delta E')/\Delta E$ and $D(\mu^2) = |\overline{\mu^2} - \overline{\mu'^2}|/\overline{\mu^2}$ as a function of $T$, obtained with energy functions of type (a) (see Fig. 1) and keeping $E(60°) = E(300°)$ constant while varying $E(180°)$, or vice versa. The corresponding $D(\Delta E)$ and $D(\mu^2)$ curves for functions of type (b) are shown in Figs. 4 and 5.

Whereas these figures essentially show the effect of $\Delta E$ on $D(\Delta E)$ and $D(\mu^2)$ as a function of $T$, Fig. 6 illustrates the effect of the depth of the potential wells, while keeping $\Delta E$ the same. We note that the addition of a constant to $E(\theta)$ does not lead to any changes, as can be directly seen from eq. [1]. Multiplication of a given $E(\theta)$ by a constant $\lambda$, thus changing simultaneously $\Delta E$ and the depth of the energy wells, leads to $D(\Delta E)$ and $D(\mu^2)$ curves that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

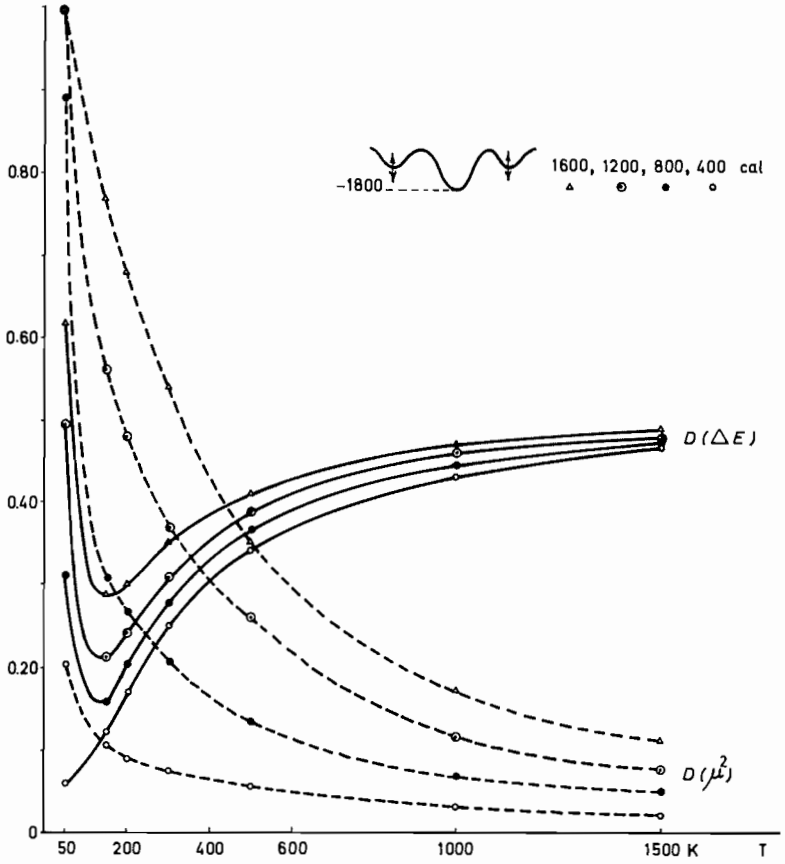


FIG. 3. The deviations $D(\Delta E)$ and $D(\mu^2)$ as a function of $T$ and $\Delta E$, for various $E(\theta)$ functions of type (a) differing in $E_g$ from each other.

can be easily related to the original curves using eq. [1] (5):

[8] $D(\Delta E)\ [E(\theta), T] = D(\Delta E)\ [\lambda E(\theta), \lambda T]$

[9] $D(\mu^2)\ [E(\theta), T] = D(\mu^2)\ [\lambda E(\theta), \lambda T]$

The crossing observed in the $D(\Delta E)$ curves of Figs. 2 and 5 but not in Figs. 3 and 4 can be rationalized as was done in ref. 5. As a matter of fact, the $D(\Delta E)$ curves now obtained are very similar to those constructed on the basis of H—H nuclear spin coupling constants $J$ (5).

As in the work with $J_{HH}$ (5), $|\Delta E'|$ is always smaller than $|\Delta E|$ for a given temperature. The same explanation can be given. Going from a continuum procedure to the rotational isomeric state approximation corresponds to a "transfer" of part of the population from the intermediate conformations into the three minimal energy rotamers; as a result, a bigger increase in the effective population is produced in the case of the upper minima ($g_1$ and $g_2$ for curves $a$) which then appear to be stabilized with respect to the lower minima ($g_1 > g_1'$, $t < t'$ for energy functions $a$). In parallel with these results, one finds $\overline{\mu'^2} < \overline{\mu^2}$ for situations of type $a$ (Figs. 2, 3) and the opposite for curves of type $b$ (Figs. 4, 5).

The discriminating effect of such a "transfer" of population is, of course, expected to decrease as the potential wells become deeper or the $|\Delta E|$ value becomes smaller. This is observed for the $D(\Delta E)$ values in Figs. 3 and 4, and for lower temperatures in the cases of Figs. 2 and 5. It is noted that, in the latter, a decrease of $|\Delta E|$ is accompanied by a raising of the lower minima (um), giving rise to two opposite effects whose relative importance depends on the temperature.

Now, $D(\Delta E)$ and $D(\mu^2)$ can be written as follows:

[10] $D(\Delta E) = 1 - (\ln t/g_1)/(\ln t'/g_1')$

[11] $D(\mu^2) = 1 - g_1'/g_1$

For energy functions of type $a$ (Figs. 2 and 3) the following rationalization of the shapes of $D(\Delta E)$ and $D(\mu^2)$ as a function of $T$ can be offered. When $T \to \infty$, $t$, $g_1$, $t'$, and $g_1'$ all tend to a common value:

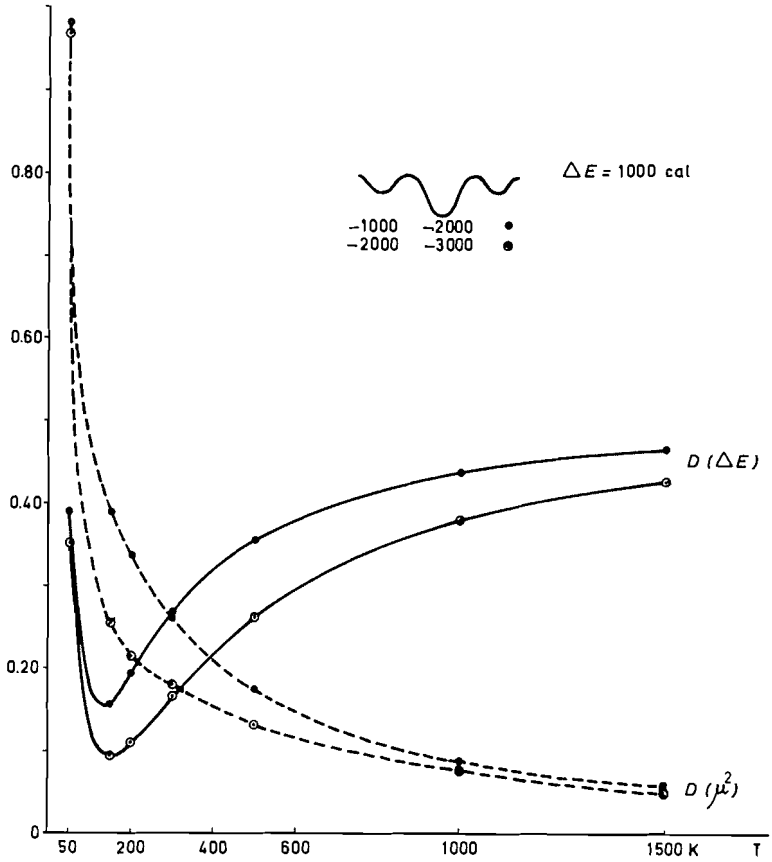

FIG. 6. The effect on $D(\Delta E)$ and $D(\mu^2)$ of the depth of the potential wells (energy functions of type (a)).

1/3; as a result, $D(\Delta E)$ goes to a constant and $D(\mu^2)$ goes to zero. When $T \rightarrow 0$, only the *trans* conformation becomes populated, that is $g_1$ and $g_1'$ go to zero; since $g_1' < g_1$ ($t' > t$), $D(\Delta E)$ and $D(\mu^2)$ both go to 1. For curves of type *b*, a similar reasoning applies; now, when $T \rightarrow 0$, $g_1', g_1 \rightarrow 1$ and $D(\mu^2) \rightarrow 0$ (Figs. 4 and 5).

At this stage we can already conclude that the $\Delta E'$ values calculated from observed dipole moments, using the rotational isomeric state approximation, may be affected by appreciable (temperature-dependent) errors. The same is true of the averaged dipole moments calculated from local dipoles (or atomic charges) and $\Delta E$ values, especially in the cases when the *trans* conformation is more stable than the *gauche* ones; it should be noted, however, that the discrepancy is not as dramatic as Figs. 2 and 3 might suggest, because when the large percentual errors occur the dipole moments are small.

(b) *More realistic* E(θ) *functions*

The conclusion above regarding the deviations of calculated dipole moments is at variance with the calculations of Mark and Sutton (3), namely for 1,2-dichloroethane. Taking a given $E(\theta)$ function, the values they have obtained for the dipole moment are practically the same when using the continuum model and the rotational isomeric state model for $T = 298$ K; the same can be said of the temperature coefficients of the dipole moment in the vicinity of 298 K.

An important difference with respect to the calculations we have done above is that the $E(\theta)$ function they have used is of type *c* in Fig. 1, and not of type *a*. We anticipate that the decrease of population for the *cis* conformation (and for those of $300° < \theta < 60°$) has the effect of reducing the apparent stabilization of the *gauche* conformations with respect to *trans*, on going from a continuum procedure to a discrete one. That is, $\Delta E'$ will become closer to $\Delta E$ and so will the calculated dipole moments, up to the point $\Delta E = \Delta E'$ and $\overline{\mu^2} = \overline{\mu'^2}$. Continuing to increase the energy of the *cis* conformation, the *trans* conformation will become stabilized, $\Delta E' > \Delta E$ and $\overline{\mu^2} < \overline{\mu'^2}$.

These conclusions are corroborated by the calculations using *c* energy functions of variable $E(0°)$

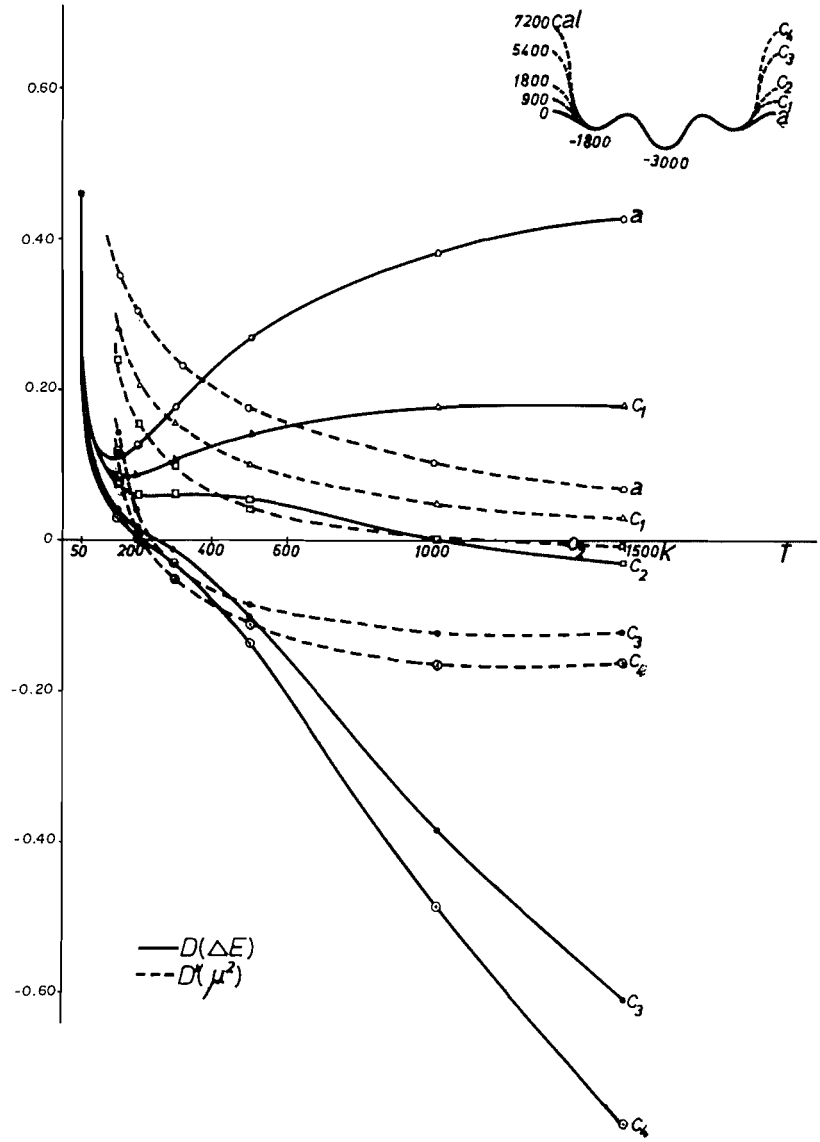

FIG. 7. The effect on $D(\Delta E)$ and $D'(\mu^2)$ of increasing the energy of conformation *cis* with respect to an energy function of type (a). $D'(\mu^2)$ is defined as $(\mu^2 - \overline{\mu'^2})/\mu^2$.

values, as shown in Fig. 7. The $E(\theta)$ function $c_4$ is close to that calculated by Mark and Sutton (3) for 1,2-dichloroethane; in this case, in fact, the deviations $D(\Delta E)$ and $D'(\mu^2)$ for $T = 298$ K are very small ($D'(\mu^2)$ is defined as $(\mu^2 - \mu'^2)/\mu^2$). Further insight is obtained by comparing the ratio of populations $t'/g'$ and $\mu'^2$ for 298 K, for example, calculated from a $\Delta E$ value of 1200 cal,

[12] $\Delta E = 1200 = RT \ln t'/g'$

[13] $t'/g' = 7.59$

[14] $\overline{\mu'^2} = 0.625\, m_0^2$

with the ratios of the total populations (at 298 K) corresponding to the intervals 120°–240° and 0–120°, respectively $t^*$ and $g^*$, for the various $E(\theta)$ functions of Fig. 7:

$$t^*(a)/g^*(a) = 5.58$$
$$t^*(c_1)/g^*(c_1) = 6.26$$
$$t^*(c_2)/g^*(c_2) = 6.71$$
$$t^*(c_3)/g^*(c_3) = 7.67$$
$$t^*(c_4)/g^*(c_4) = 7.95$$

The corresponding $\Delta E^*$ and $\overline{\mu^{*2}}$ values obtained using the discrete average approach are as follows (the $\Delta E'$ and $\mu^2$ values are given in brackets):

| | | | |
|---|---|---|---|
| $\Delta E^*(a)$ = 1018 cal | (989) | $\overline{\mu^{*2}}(a)$ = 0.792 $m_0^2$ | (0.821) |
| $\Delta E^*(c_1)$ = 1086 | (1074) | $\overline{\mu^{*2}}(c_1)$ = 0.726 | (0.737) |
| $\Delta E^*(c_2)$ = 1127 | (1126) | $\overline{\mu^{*2}}(c_2)$ = 0.689 | (0.690) |
| $\Delta E^*(c_3)$ = 1206 | (1220) | $\overline{\mu^{*2}}(c_3)$ = 0.620 | (0.609) |
| $\Delta E^*(c_4)$ = 1228 | (1245) | $\overline{\mu^{*2}}(c_4)$ = 0.603 | (0.584) |

## Conclusion

We can thus conclude that, apart from other sources of error, the use of the rotational isomeric state approximation in conformational studies of internally rotating molecules, based on molecular dipole moments, may lead to appreciable errors, especially as far as the computation of $\Delta E$ values is concerned, depending on the features of the conformational energy function and on the temperature considered. Those cases referred to in the literature (3), where the continuum and the discrete average methods lead to very similar results, are accidental.

After this work was completed, Honegger and Heilbronner (7) published a similar criticism of the rotational isomeric state model when used in conjunction with photoelectron spectral bands.

Further work is in progress regarding other molecular systems. In addition, a general study of the rotational isomeric state method is being carried out, aiming at the identification of the main sources of error affecting enthalpy and entropy values according to the θ-variation of the conformation-dependent property, the form of the potential function, and the temperature.

# Preparation, properties, and X-ray crystal structure of a 1:1 complex of tetrathiafulvalene and *p*-dinitrobenzene

MARTIN R. BRYCE, ANTHONY S. SECCO, JAMES TROTTER,[1] AND LARRY WEILER[1]

*Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6*

Received February 22, 1982

MARTIN R. BRYCE, ANTHONY S. SECCO, JAMES TROTTER, and LARRY WEILER. Can. J. Chem. **60**, 2057 (1982).

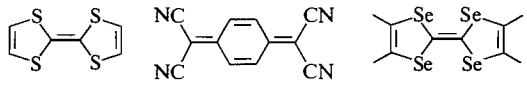
A crystalline complex of tetrathiafulvalene and *p*-dinitrobenzene has been prepared and characterised by esr and ir spectroscopy, bulk magnetic susceptibility, dc conductivity, and an X-ray diffraction analysis. It is a neutral 1:1 complex which is an insulator at room temperature, $\sigma_{RT} = 2.5 \times 10^{-7}$ ohm$^{-1}$ cm$^{-1}$. The complex crystallizes in the triclinic system, space group $P\bar{1}$ with cell constants $a = 6.915(1)$, $b = 7.615(1)$, $c = 8.149(1)$ Å, $\alpha = 79.39(1)$, $\beta = 69.55(1)$, $\gamma = 70.81(1)°$, $Z = 1$. Data were collected on an Enraf-Nonius CAD-4 diffractometer. The structure was solved by direct methods and refined to an *R*-value of 0.028 for 1222 observed reflections. The structure consists of molecules stacked in an alternating donor–acceptor fashion along the *c*-axis. Mixed sheets parallel to $(01\bar{2})$ are comprised of tetrathiafulvalene and *p*-dinitrobenzene molecules arranged end-on in the [021] direction.

MARTIN R. BRYCE, ANTHONY S. SECCO, JAMES TROTTER et LARRY WEILER. Can. J. Chem. **60**, 2057 (1982).

On a préparé un complexe cristallin du tétrathiafulvalène et du *p*-dinitrobenzène et on l'a caractérisé par la rpe, la spectroscopie ir, la susceptibilité magnétique de groupe, la conductivité cd, et par l'analyse de diffraction de rayons X. C'est un complexe neutre 1:1 qui est un isolant à la température ambiante, $\sigma_{RT} = 2{,}5 \times 10^{-7}$ ohm$^{-1}$ cm$^{-1}$. Le complexe cristallise dans le système triclinique et appartient au groupe d'espace $P\bar{1}$ avec $a = 6{,}915(1)$, $b = 7{,}615(1)$, $c = 8{,}149(1)$ Å, $\alpha = 79{,}39(1)$, $\beta = 69{,}55(1)$, $\gamma = 70{,}81(1)°$, $Z = 1$. On a recueilli les données à l'aide d'un diffractomètre Enraf-Nonuis CAD-4. On a résolu la structure par des méthodes directes et on l'a affiné jusqu'à une valeur de *R* de 0,028 pour 1222 réflexions observées. La structure comporte alternativement des molécules de donneur et de receveur qui sont entassées suivant l'axe *c*. Les couches mixtes paralèlles à $(01\bar{2})$ comprennent des molécules de tétrathiafulvalène et de *p*-dinitrobenzène arrangées en positions tête-queue dans la direction [021].

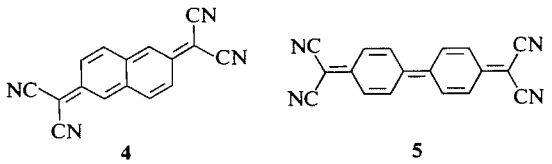
[Traduit par le journal]

Since the discovery of metallic conductivity in the complex of tetrathiafulvalene (**1**) and tetracyanoquinodimethane (**2**) (TTF–TCNQ), great interest has been focussed on the synthesis and properties of related organic charge transfer complexes (1). Many new donors have been prepared; the majority are sulphur and selenium heterocycles, and their complexes with TCNQ have certainly contributed to our understanding of this field (2). Recently, certain salts of tetramethyltetraselenofulvalene (**3**) have exhibited superconductivity at low temperature (3).

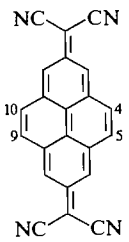


**1** **2** **3**

It is noticeable that there has been considerably less work reported on new electron acceptors. Substitution on the basic TCNQ skeleton has been shown generally to lower the conductivity of charge-transfer complexes formed (4). An alternative approach has been to vary the TCNQ skeleton by extending the conjugated $\pi$ system while retaining the high degree of symmetry and the dicyanomethylene groups of the TCNQ. Accordingly, the acceptors TNAP (**4**) (5), TCNDQ (**5**) (6), and the pyrene analogues **6** (6*c*, 7) and **7** (8) have been synthesized and their charge-transfer complexes studied, but none has room temperature conductivity substantially above that of TTF–TNCQ.



**4** **5**



**6**

**7** 4,5,9,10-tetrahydro

It has become apparent that the range of electron acceptors should be extended and Torrance *et al.* have recently reported that the tetrahalo-*p*-benzoquinones form both metallic and semi-conducting complexes with TTF and its derivatives (9). These complexes were the first, that do not contain TCNQ or a TCNQ-like molecule, to display the

two essential prerequisites for high conductivity; namely, segregated stacks of donors and acceptors, and incomplete charge transfer. They also exhibit several striking new phenomena that have increased our knowledge of intermolecular interactions in the solid state (*9b*).

We now report the preparation, properties, and an X-ray diffraction analysis of a complex of TTF with the electron acceptor *p*-dinitrobenzene (DNB). DNB was chosen as an acceptor because it resembles TCNQ in two important ways. Both molecules are of similar size; it is possible that the failure of some of the larger acceptors to form complexes with TTF may be due to their incompatible molecular dimensions. DNB has the same high symmetry as TCNQ ($D_{2h}$); the key role of the symmetry of the TCNQ radical anion in dictating stacking arrangements in TTF–TCNQ has been shown (10). Electron spin resonance studies of the radical anions of aromatic compounds show that the electronegativity of the nitro group is similar to that of the dicyanomethylene group (11). Thus the two acceptors, TCNQ and DNB, should have similar spin and charge distributions in their radical ions.

A 1:1 complex was obtained quantitatively by evaporation of a toluene solution of TTF and DNB. All the data obtained suggest that TTF–DNB is a neutral, insulating complex. The solid state esr signal has a *g*-value at 2.0018 consistent with a free electron of a π-radical, but the signal is very weak. The esr signal was about 7 G wide and no proton hyperfine splitting could be detected in this signal. The ir spectrum of TTF–DNB consists of sharp peaks typical of insulating complexes; organic metals are characterised by very broad bands in the infrared region (12). The magnetic susceptibility of the complex between 78 and 295 K is constant, again suggesting a diamagnetic complex with no unpaired electrons. The single crystal conductivity is that of an insulator, $\sigma = 2.5 \times 10^{-7}$ ohm$^{-1}$ cm$^{-1}$ at 300 K.

The crystal structure of TTF–DNB consists of stacks along the *c*-axis of alternating TTF and DNB molecules (Fig. 1). It is further characterised by mixed sheets of TTF and DNB molecules which are parallel to $(01\bar{2})$. Peculiar to this structure is the end-on packing arrangement (... TTF ... DNB ... TTF ...) in the [021] direction within the sheets. The intrastack interplanar spacing between TTF and DNB averages 3.64 Å, where the averaging is between the plane of the benzene ring and the two (S(1), C(2), C(3), S(2)) planes in the "chair-like" TTF molecule (*vide infra*); furthermore, the planes of the DNB ring and S(1), C(2), C(3), S(2) moieties are not parallel but subtend angles of 2.6(2)°. Generally, the above structural features are common in donor–acceptor charge-transfer complexes, although the interplanar spacing of 3.64 Å is larger than in even the weak CT-complexes TTF–X, where X is chloranil, fluoranil (13), or bromanil (14).

In view of the apparent lack of charge-transfer properties in the present structure, it is interesting to compare the overlap of TTF and DNB within the stacks. Figure 2 shows the projection of the TTF molecule onto the plane of the DNB ring. All intermolecular contacts are at least the sum of the van der Waals radii for any two atoms, indicating a minimum energy crystal packing. The angle between the long molecular axes of TTF and DNB is 126°. This is in contrast to the suggestion, based on crystal packing arguments in TTF–bromanil and TTF–chloranil by Mayerle, Torrance, and Crowley (13), that in donor–acceptor complexes, if both donor and acceptor molecules have a long molecular axis, they tend to line up. In light of the present study of the TTF–DNB complex, where crystal packing forces appear to be the controlling factor affecting the relative orientations of molecules, the above suggestion by Mayerle *et al.* should perhaps stress an increased role of orbital overlap in determining relative molecular orientations in D–A complexes.

Both the interplanar separation and relative molecular orientation in the present complex seem to prohibit any experimentally observable charge transfer interactions (i.e. conductivity and spectroscopic measurements). However, it is interesting to note the differences between the internal angles (122.5° at C(5) and averaging 118.8° at C(4) and C(6)) in the DNB ring in TTF–DNB (Fig. 3) and the corresponding angles (123.4° and 118.3°) in the neutral *p*-DNB structure (15). The fact that these angles are slightly closer to 120° in the current structure implies an increased electron density in the benzene ring relative to neutral *p*-DNB. The short C—N bond of 1.467(2) Å in the present complex compared to 1.478(2) Å in neutral *p*-DNB is consistent with this implication. Increased electron density in the DNB ring is not explicable on the basis of the electron-withdrawing $NO_2$ substituents and therefore, some interaction between DNB and TTF is inferred. However, the extent of this interaction must be small when considering the other physical properties of the complex.

The C—C bond lengths in the present DNB molecule are not significantly different from those in the neutral *p*-DNB structure. The geometry of the $NO_2$ group is essentially the same in both compounds. Noteworthy is the slightly skewed

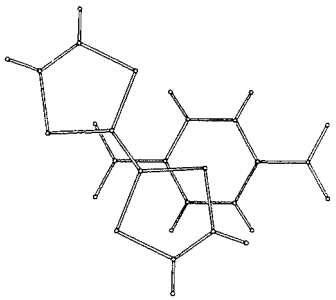

FIG. 2. Projection of the TTF molecule onto the plane of the DNB ring.

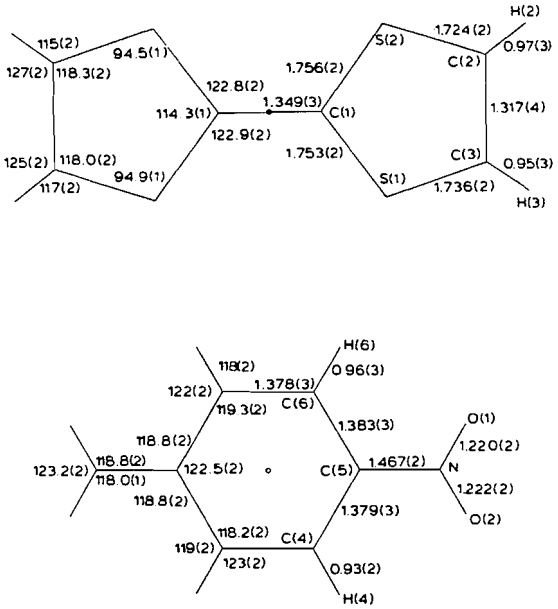

FIG. 3. Bond lengths (Å) and angles (deg) in TTF (top) and *p*-DNB (bottom).

orientation of the $NO_2$ plane with respect to the benzene ring plane; the two planes are twisted about the C—N bond by 1.1° (Table 1), considerably less than the 10° twist in neutral *p*-DNB.

The TTF molecule can be described by three planes (Table 1) forming a "chair-like" structure. In liquid crystals TTF was also found to adopt a non-planar conformation (16). Bond lengths and angles compare favorably with neutral TTF (17) and are generally not significantly different from those in TTF–chloranil and TTF–bromanil (13).

## Experimental

Infrared spectra were run on a Perkin-Elmer model 710 spectrometer; solid spectra were run as KBr discs. Electron spin resonance spectra were obtained on a Varian E-3 spectrometer operating at 9.1 GHz. Bulk magnetic susceptibility data were obtained using a Gouy magnetic balance (18).

Tetrathiafulvalene was purified by gradient sublimation. *p*-Dinitrobenzene was recrystallized from ethanol. Toluene was freshly distilled from sodium under nitrogen.

*TTF–DNB complex*

A solution of TTF (204 mg, 1.0 mmol) in 5 mL of hot toluene was added to a solution of DNB (168 mg, 1.0 mmol) in 5 mL of hot toluene. The resulting dark solution was allowed to cool to room temperature and evaporated to dryness under a stream of nitrogen to give 372 mg (100%) of the complex as long black needles, mp 134°C. *Anal.* calcd. for $C_{12}H_8N_2O_4S_4$: C 38.70, H 2.15, N 7.53; found: C 38.89, H 2.15, N 7.62. Ir (KBr) $\nu_{max}$: 1529, 1324, 1260, 1129, 1050, 1001, 836, 795, 782, 720, 658 $cm^{-1}$; esr (powder) very weak singlet, $g = 2.0018$ (7 G wide).

A crystal with well-defined faces along the *c*-axis and measuring 0.22 × 0.07 × 0.42 $mm^3$ was employed in the crystallographic study. Preliminary Weissenberg and precession photographs indicated a triclinic structure. The crystal data (at 22°C) are:

$C_6H_4S_4.C_6H_4N_2O_4$ fw = 372.5

Triclinic, $a = 6.915(1)$, $b = 7.615(1)$, $c = 8.149(1)$ Å, $\alpha = 79.39(1)$, $\beta = 69.55(1)$, $\gamma = 70.81(1)°$, $V = 378.5(2)$ $Å^3$, $Z = 1$, $\rho_c = 1.634$ g $cm^{-3}$, $\mu(MoK_\alpha; \lambda = 0.71073$ Å) = 5.75 $cm^{-1}$, space group $P\bar{1}$ from structure analysis.

Intensities were measured on an Enraf-Nonius CAD-4 dif-

fractometer in the θ range 1.0–27.0° with an ω–2θ scan and graphite monochromatized $MoK_\alpha$ radiation; scan speeds ranged from 1.01 and 10.06 deg min$^{-1}$. The ω scan angle, (1.00 + 0.35 tan θ)°, was extended 25% on both sides for background measurement. A variable horizontal aperture (2.00 + 0.50 tan θ) mm was employed and the vertical aperture remained constant at 4 mm. Crystal orientation and intensity controls were monitored periodically throughout data collection.

Data processing included the application of Lorentz and polarization corrections in the usual manner. An additional correction was made to account for the slight variation (±3%) in the intensities over the duration of data collection. Of the 1640 accessible data, 1222 (74.5%) had $I \geq 3\sigma(I)$, where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$, $S$ = scan count and $B$ = time-averaged background.

On the basis of the *E*-statistics, the centrosymmetric space group $P\bar{1}$ was chosen and later confirmed to be correct by the subsequent structure refinement. MULTAN (19) yielded the positions of all non-hydrogens in the asymmetric unit which consisted of half a TTF molecule and half a DNB molecule. Following several cycles of full-matrix least-squares refinement, a difference-Fourier synthesis provided the hydrogen positions. The remainder of the refinement included 11 non-hydrogen atoms with anisotropic thermal parameters and 4 hydrogen atoms with isotropic temperature factors yielding a total of 116 variables. Anomalous scattering factors, from ref. 20*a*, were used for S atoms; all other scattering factors were taken from ref. 20*b*. On the final cycle of refinement the mean and maximum parameter shifts were 0.017 and 0.141 σ, respectively; the standard error in an observation of unit weight was 1.207. *R*-values, defined as $R = \Sigma||F_o| - k|F_c||/\Sigma|F_o|$ and $R_w = [\Sigma w(|F_o| - k|F_c|)^2/\Sigma w|F_o|^2]^{1/2}$, were 0.028 and 0.037, respectively, for the 1222 observed data with $I > 3\sigma(I)$ employed in the refinement, whereas for the complete data set $R = 0.047$ and $R_w = 0.037$. The quantity $\Sigma w(|F_o| - k|F_c|)^2$ was minimized in the refinement where $w = 1/\sigma^2(F_o)$, $\sigma^2(F_o)$ being derived from the previously defined $\sigma^2(I)$. The suitability of the chosen weights was confirmed by a weighting analysis program. A difference-map, calculated after convergence, showed random fluctuations in electron density up to 0.25 e/Å$^3$. Final atomic positional parameters and temperature factors are presented in Table 2.[2]

# On the synthesis of cryptosporiopsin: stereochemistry of early intermediates

GEORGE M. STRUNZ

*Canadian Forestry Service, P.O. Box 4000, Fredericton, N.B., Canada E3B 5P7*

AND

PETER S. WHITE

*Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2*

Received March 15, 1982

GEORGE M. STRUNZ and PETER S. WHITE. Can. J. Chem. **60**, 2062 (1982).

The relative configurations of two intermediates in the synthetic route to cryptosporiopsin are clarified through the structure of 3,5-dichloro-1,4-dihydroxy-2-methylcyclopent-2-ene-1-carboxylic acid methyl ester, which was determined by single crystal X-ray techniques. The crystal was monoclinic, space group $P2_1/c$, $a = 7.352(1)$, $b = 8.868(3)$, $c = 16.300(7)$ Å; $\beta = 96.49(2)°$. The structure was solved by direct methods and refined to a final $R$ of 0.057.

GEORGE M. STRUNZ et PETER S. WHITE. Can. J. Chem. **60**, 2062 (1982).

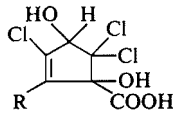
Les configurations rélatives de deux intermédiaires dans la synthèse de cryptosporiopsin sont clarifiées par la structure de l'ester méthylique de l'acide dichloro-3,5 dihydroxy-1,4 méthylcyclopent-2 ene-2 carboxylique-1, qu'on a déterminé par diffraction de rayons-X sur un monocristal. Le cristal était monoclinique et appartenait au groupe d'espace $P2_1/c$, $a = 7.352(1)$, $b = 8.868(3)$, $c = 16.300(7)$ Å; $\beta = 96.49(2)°$. On a résolu la structure au moyen de méthodes directes, et on l'a affinée jusqu'à $R = 0.057$.

The reaction of phenol or 2,4,6-trichlorophenol with alkaline hypochlorite gives rise to a complex mixture of products, from which 3,5,5-trichloro-1,4-dihydroxycyclopent-2-ene-1-carboxylic acid, **1** (R = H), may be isolated in yields up to 50 or 60% (1–3). This compound and the homologue **1** (R = *n*-propyl) derived from 3-*n*-propylphenol have provided useful synthetic entries to some natural products (3, 4), including the fungal metabolite cryptosporiopsin **2** (5).

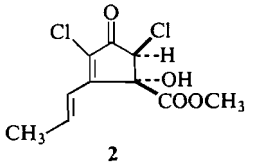
In the course of the latter synthesis, **1** (R = *n*-propyl) was reduced with sodium amalgam (1–3) to the dichloro product **3** (R = *n*-propyl) (5). The newly introduced hydrogen at C-5 was considered to be *cis* with respect to the hydrogen at C-4 on the basis, *inter alia*, of the magnitude of the coupling between them ($J = 6.5$ Hz) (2, 3, 5). Assuming then the *trans* relationship of the hydroxyl groups of **1** (R = H) tentatively favored by earlier authors (3), it seemed likely that the C-1 hydroxyl group and the C-5 hydrogen of **3** (R = *n*-propyl) were *cis*. The stage thus appeared to be set stereochemically for completion of the synthesis of (±) cryptosporiopsin, and this was duly accomplished (5).

Subsequently, X-ray studies by Rickards and co-workers (6) on the lactone **4**, obtained in low yield from 2,4,6-trichlorophenol or from **1** (R = H) by reaction with alkaline hypochlorite, established that the stereochemistry of **1** (R = H) is as depicted in **5** (R = H), i.e., with *cis* rather than *trans* hydroxyl groups.

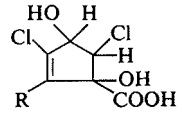
The present study was undertaken in order to clarify the stereochemical ramifications bearing on the successful synthesis of cryptosporiopsin.



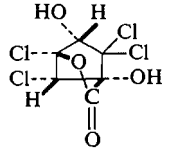
**1**



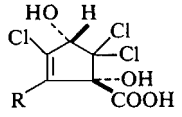
**2**



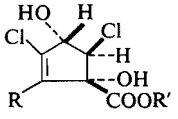
**3**



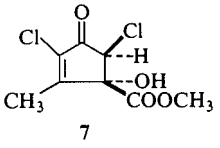
**4**



**5**



**6**



**7**

If sodium amalgam reduction of a precursor **5** (R = *n*-propyl), with *cis* hydroxyl groups, indeed introduces a hydrogen at C-5 *cis* to the C-4 hydrogen, then the (desired) *cis* configuration of C-1 hydroxyl and C-5 hydrogen observed in later intermediates in the synthesis must result from epimerization at C-5 after oxidation of the C-4 hydroxyl group. (The possibility of epimerization of a C-5 epimer of cryptosporiopsin was demon-

strated during other studies after completion of the synthetic work (7).)

Alternatively, the correct stereochemistry would be established at C-1 and C-5 if sodium amalgam reduction of **5** (R = *n*-propyl) yielded **6** (R = *n*-propyl, R′ = H), with C-4 and C-5 hydrogens *trans*.

To distinguish between these possibilities, an X-ray crystal structure analysis of 3,5-dichloro-1,4-dihydroxy-2-methylcyclopent-2-ene-1-carboxylic acid methyl ester[1] was undertaken. This compound, derived from *m*-cresol via the corresponding "Hantzsch acid", has been converted to the cryptosporiopsin analogue **7** in model studies (8).

The structure established by X-ray analysis, **6** (R, R′ = $CH_3$) (*vide infra*), confirms that the 2-alkyl Hantzsch acid **5** (R = $CH_3$) possesses the same relative configuration at C-1 and C-4 as its 2-desalkyl analogue (6), and indicates that the hydrogen introduced at C-5 in the sodium amalgam product is *trans* with respect to the C-4 hydrogen, contrary to the earlier assignment based on interpretation of nmr data (*vide supra*).

Accordingly, by analogy, early intermediates in the cryptosporiopsin synthetic route (5) possess

[1]Selected for study because it afforded crystals suitable for X-ray analysis more readily than its 2-*n*-propyl homologue, the actual synthetic intermediate.

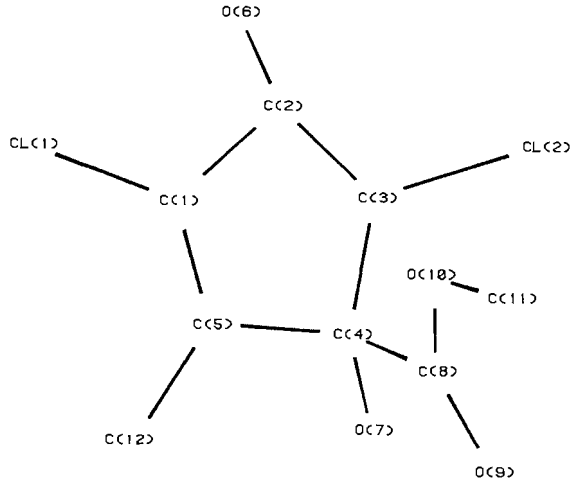

FIG. 2. Labelling scheme for **6** used in the X-ray investigation.

the relative stereochemistry depicted as **5** (R = *n*-propyl) and **6** (R = *n*-propyl, R′ = H or $CH_3$).

A stereo view of **6** (R, R′ = $CH_3$) is presented in Fig. 1. Tables 2 and 3 give the relevant bond lengths and angles and Fig. 2 shows the labelling scheme used in the X-ray determination.

### X-ray structure determination

A preliminary photographic investigation of a suitable crystal showed it to be monoclinic, space group $P2_1/c$. The crystal was mounted onto a Picker FACS-I diffractometer and graphite monochromated Mo $K_\alpha$ radiation was used. After preliminary alignment the cell parameters and an orientation matrix were determined from a least squares fit to the centered coordinates of 12 Friedel pairs of reflections in the range $35° < 2\theta < 50°$. Intensity data were collected, using an $\omega - 2\theta$ scan with a scan rate of 2 deg ($2\theta$) $min^{-1}$, for $2\theta \leq 50°$. The background intensity was estimated by standing counts of 1/10 of the scantime at each end of the scan; if the reflection was considered significant ($I > 2\sigma(I)$) an analysis of the scan profile was performed in order to provide a better estimate of the background. The relevant crystallographic data are:

$C_8H_{10}O_4Cl_2$ fw = 241.07

Monoclinic, space group $P2_1/c$, $a = 7.352(1)$, $b = 8.868(3)$, $c = 16.300(7)$ Å, $\beta = 96.49(2)°$, $V = 1056$ Å$^3$, $Z = 4$, $D_{calc} = 1.52$ Mg m$^{-3}$, crystal size = 0.30 × 0.35 × 0.12 mm, $\mu = 0.60$ mm$^{-1}$.

Two independent sets of data were collected and averaged, the agreement between sets ($\Sigma|\Delta I|\Sigma|I|$) was 0.026. This resulted in 1866 unique reflections of which 1706 were considered observed ($I \geq 3\sigma(I)$) and included in the subsequent refinement.

The structure was solved by multiple solution direct methods using a version of the program MULTAN (9) modified for use on the PDP 8/A computer. The resulting *E*-map revealed the positions of all non-hydrogen atoms. The structure was refined by least squares methods minimizing the function $\Sigma\omega(|F_o| - |F_c|)^2$. The weighting scheme was of the form $\omega = 1/(\sigma^2(F) + pF^2)$ where $\sigma(F)$ was derived from counter statistics and a value of $p = 0.005$ was determined from the statistics of the standard reflections. Scattering factors were taken from the International Tables for Crystallography (10) and were corrected for anomalous dispersion. After the initial cycles of refinement the hydrogen positions were located from a difference synthesis. In the final refinement non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogens were varied with isotropic thermal parameters. The final agreement indices were $R = 0.057$, $R_w = 0.117$ (0.060 and 0.125 respectively for the complete data set). The final coordinates for the non-hydrogen atoms are given in Table 1.[2] The computer programs used were those of Larson and Gabe for the PDP 8/A computer (11).

# The molecular structure of 1-(2′-triphenylphosphonio-3′,3′,4′,4′-tetrafluorocyclobutenyl)(3,3-difluorocyclobutene-2,4-dionate)·chloroform solvate

F. W. B. EINSTEIN AND T. JONES

*Department of Chemistry, Simon Fraser University, Burnaby, B. C., Canada V5A 1S6*

Received January 26, 1982

F. W. B. EINSTEIN and T. JONES. Can. J. Chem. **60**, 2065 (1982).

The title compound, $C_{26}F_{15}O_2F_6P(0.5CHCl_3)$ (**A**), crystallizes as pale yellow crystals in the monoclinic system $C2/c$ with $a$ = 29.624(6), $b$ = 10.224(3), $c$ = 18.576(4) Å; $\beta$ = 116.26(2)°, $Z$ = 8. On the basis of 1652 observed reflections ($I \geq 2.3\sigma(I)$) in the range 3° ≤ 2θ ≤ 42° the structure was solved and refined by least-squares methods to $R$ = 0.042 and shown to be a zwitterion consisting of a phosphonium cation and a delocalised anion. The bond parameters of the cation are normal; P—C distances range from 1.773(5)–1.786(5) Å and C—P—C angles range from 106.4(2)–111.7(2)°. Within the delocalised anionic fragment of the molecule C—C distances range from 1.388(7)–1.440(8) Å and C—O distances are 1.216(7) and 1.208(7) Å.

F. W. B. EINSTEIN et T. JONES. Can. J. Chem. **60**, 2065 (1982).

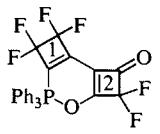
Les cristaux du composé (**A**) mentionné dans le titre, $C_{26}F_{15}O_2F_6P(0,5CHCl_3)$ sont monocliniques de couleur jaune pâle et appartiennenet au groupe d'espace $C2/c$ avec $a$ = 29,624(6), $b$ = 10,224(3), $c$ = 18,576(4) Å; $\beta$ = 116,26(2)°, $Z$ = 8. A partir de 1652 réflexions observées ($I \geq 2{,}3\sigma(I)$) dans l'intervalle 3° ≤ 2θ ≤ 42°, on a résolu la structure par la méthode des moindres carrés et on l'a ajusté jusqu'à une valeur de $R$ = 0,042. Cette structure indique qu'il s'agit d'un Zwitterion constitué d'un cation phosphonium et d'un anion délocalisé. Les paramètres de liaison du cation sont normaux; les distances P—C se situent entre 1,773(5) et 1,786(5) Å et les angles C—P—C varient de 106,4(2) à 111,7(2)°. A l'intérieur de plus fragment anionique délocalisé de la molécule, les distances C—C se situent entre 1,388(7) et 1,440(8) Å et les distances C—O sont 1,216(7) et 1,208(7) Å.

[Traduit par le journal]

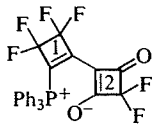
## Introduction

The title compound, formulated as $C_{26}F_{15}O_2F_6P(0.5CHCl_3)$, was believed to exist as one of two possible structures; either (*a*), as a cyclic structure (**i**) involving a five-coordinate phosphorus atom, an oxygen atom, and four carbon atoms in a novel, potentially aromatic, heterocyclic ring system or (*b*), as a zwitterion (**ii**), containing a phosphonium cation and an oxyanion, derived from one of the carbonyl groups attached to ring 2 of the fluorocarbon ligand.

To determine which of these two structures does, in fact, prevail, full crystallographic analysis was carried out.



i



ii

## Experimental

Crystal data:

$C_{26}F_{15}O_2F_6P(0.5CHCl_3)$ fw = 564.06

Monoclinic, $a$ = 29.624(6), $b$ = 10.224(3), $c$ = 18.576(4) Å, $\beta$ = 116.26(2)°, $V$ = 5045.57 Å$^3$, $\rho_c$ = 1.485 Mg/m$^3$, $Z$ = 8, $\mu$ = 33.1 mm$^{-1}$, $\lambda(MoK_{\alpha_1})$ = 0.70926 Å. $F(000)$ = 2279.8.

Bright yellow crystals (10) of **A** were crystallized from $CHCl_3$. A single crystal suitable for data collection (0.45 × 0.25 × 0.28 mm) was mounted in a Lindemann glass tube. Precession and Weissenberg methods were used to determine approximate cell dimensions and the space group as being $Cc$ or $C2/c$ (subsequent structure solution showed $C2/c$ to be the correct space group). Accurate cell dimensions were determined by least-squares refinement of 16 accurately centred reflections (2θ = 16–23°, $\lambda(Mo\text{-}K_\alpha)$ = 0.71069 Å). Data were collected at 298 K, using a Picker FACS-I automatic four-circle diffractometer with a graphite monochromator and a scintillation counter with pulse height discrimination. Symmetrical θ–2θ scans (2° in 2θ min$^{-1}$) were taken for (1.6 + tanθ)°, whilst stationary-crystal, stationary-counter background counts were taken for 10% of the scan time at each scan limit. The background-corrected intensity and associated error of each reflection was determined by the peak profile method of Gabe and Grant (1). Intensity measurement of two standards every 70 reflections showed no evidence of crystal deterioration during data collection. Intensities (3.0–42.0° in 2θ) were measured for 2720 independent reflections, of which 1652 were classed observed ($I \geq 2.3\sigma(I)$).

The structure was solved using MULTAN. The tangent refinement solution with best agreement factors was used to phase an $E$-map which revealed most of the atoms, remaining atoms being located in subsequent difference-Fourier syntheses. After location of what were thought to be all the atoms of the unit cell, the preceding difference map revealed a chloroform molecule of crystallization which lay across the two-fold axis along $b$ alternately in one of the two symmetry-related orientations. This arrangement results in a 50% occupancy for the molecule. A mass spectrum later confirmed the presence of chloroform in the crystals.

The final difference map was very clean apart from the solvent region, where a number of residual peaks and troughs appeared (approximately five times the error associated with the map). In order to account for these peaks, our simple model of alternate two-fold related chloroform molecules was substituted by other more complex models. Despite considerable effort, no chemically reasonable alternative was found. The model which gave best agreement was achieved by allowing the three chlorines

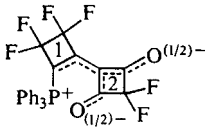
and one carbon to refine anisotropically. It is clear that this description is not totally satisfactory. Phenyl hydrogen atoms were included as fixed contributions in their calculated positions and given isotropic temperature factors related to the carbon atoms to which they are attached. Gausse-Seidel block-diagonal least-squares refinement (3) of all non-hydrogen atoms with anisotropic temperature factors gave final agreement values of $R = 0.042$ and $R_w = 0.039$.

Lorentz and polarisation corrections have been applied, but no absorption correction has been made ($\mu = 33.1\ mm^{-1}$). Unit weights were used. The agreement factors quoted are of the form: $R = \Sigma\ ||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$. Scattering factors were taken from International tables for X-ray crystallography (2). The computer programs used were those belonging to "The NRC pdp-8e crystal structure system" (3).

Final positional and thermal parameters are listed in Table 1. Anisotropic thermal parameters and structure factor listings have been deposited.[1]

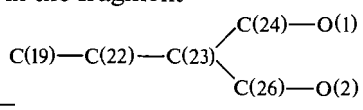
## Discussion

The true structure of **A** was found to be a modification of **ii**; viz., a zwitterion, in which the cationic species is a phosphonium ion, and the negative counter ion is delocalised over both carbonyl oxygen atoms, and a portion of the fluorocarbon ligand (**iii**).



**iii**

The molecular structure of **A** is shown in Fig. 1, whilst the bond parameters are given in Table 2. The P—C distances, which range from 1.773(5)–1.786(5) Å, and C—P—C angles, which range from 106.4(2)–111.7(2)°, are very similar to the values found in other phosphonium ions; e.g., triphenylmethylphosphonium bis((3)-1,2-dicarbollyl)cuprate(III) (4) (P—C = 1.79(2)–1.80(2) and C—P—C angles = 105–112°). The geometries of the phenyl rings also appear to be normal. The bond distances within the cyclobutanone ring in the present compound are compared with those of the analogous rings found in perfluoro-1,2-3,4-5,6-triethanobenzene (**B**) (5) and perfluorotetracyclooctatetraene (**C**) (6) (Table 3). It can be seen that C(19)—C(22) in ring 1 is not a formal double bond, suggesting that it is part of a delocalised system as is the case in **B**, as opposed to the cyclobutene type system found in **C**. Consideration of the bond distances in the fragment



suggests that it is partially if not completely delocalised. The C—C distances in the fragment range from 1.388(7)–1.440(8) Å and are intermediate between the double (1.342(2) Å) and single (1.508(1) Å) bonds formed between $sp^2$ hybridized carbon atoms in this type of compound (7); the C—O distances[2] of 1.216(7) and 1.208(7) Å, which within error are equivalent to one another, are intermediate between the value of 1.259(7) Å found by the crystallographic study of the completely delocalised squarate ion in $K_2[C_4O_4]\cdot H_2O$ (8) and the value of 1.204(6) Å determined by a microwave study of cyclobutanone (9).

The angles within the fragment P(1)—

C(19)—C(22)—C(23)—C(24)—O(1) which range from 135.9(5)–137.4(4)° reflect the angular distortion caused by the adjacent four-membered rings and are similar to the equivalent angles observed in the cyclooctenyl ring in **C** (6).

The C—F distances in both fluorocarbon rings 1 and 2 (1.329(8)–1.355(6) Å) are similar to those found in other fluorocarbon systems; e.g., 1.33(1)–1.36(1) in **C** (6) and 1.336(2) in perfluorocyclobutene (7).

The six-membered rings and the four-membered rings in this compound are all planar as one might expect. The largest deviation of any atom out of its least-squares plane is 0.008(6) Å (information concerning least-squares planes has been deposited). The two four-membered rings are virtually coplanar (interplanar angle = 0.8°) which is consistent with a delocalised system. There is no significant solvent/zwitterion interaction, the shortest distance between the two species is 2.98 Å for C(SOL)—F(3).

TABLE 3. Comparison of the bond distances of some perfluorocyclobutenyl rings

| Bond | Distance | | |

# A rapid semiquantitative approach to the calculation of net group charge (q)

WARREN KENNETH JARDINE, RICHARD FRANCIS LANGLER,[1] AND JOHN ATLEE MACGREGOR

*Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0*

Received January 20, 1982

WARREN KENNETH JARDINE, RICHARD FRANCIS LANGLER, and JOHN ATLEE MACGREGOR. Can. J. Chem. **60**, 2069 (1982).

Huheey's approach to the calculation of partial charges on groups is extended and some group electronegativity parameters modified. The modified form of Huheey's method is shown to provide rapid access to net group charges (population numbers) in cations, radicals, anions, and sulfur trigonal bipyramids. Results obtained by substituent electronegativity calculations are shown to be comparable to those obtained by *ab initio* calculations.

WARREN KENNETH JARDINE, RICHARD FRANCIS LANGLER et JOHN ATLEE MACGREGOR. Can. J. Chem. **60**, 2069 (1982).

On a élargi l'approche de Huheey relative au calcul des charges partielles des groupes et on a modifié quelques paramètres d'électronégativité de groupe. On montre que la forme modifiée de la méthode de Huheey permet d'accéder rapidement aux charges globales des groupes (indice de population) des cations, des radicaux, des anions et des bipyramides trigonales du soufre. On montre que dans le cas des calculs d'électronégativité du substituant, les résultats obtenus sont comparables à ceux obtenus par les calculs *ab initio*.

[Traduit par le journal]

## Introduction

Organic chemists commonly utilize information about partial charges in a given species to speculate on the course of a particular ionic reaction. Such information may be obtained, these days, from molecular orbital calculations which can be both expensive and time consuming. Traditionally, qualitative analyses have employed valence bond theory (1, 2).

We wish to propose an extended form of Huheey's method for calculating partial charges by way of substituent electronegativities (3, 4) to the problem of obtaining rapid, inexpensive, and semiquantitative net group charge information about ions, radicals, and ground state molecules. Such calculations may be supplemented by traditional resonance analyses or a variant which has been discussed in detail elsewhere (5, 6).

## Atomic electronegativity parameters

According to Huheey (3, 4), the Mulliken electronegativity[2] of an atom can be defined as shown in eq. [2]:

$$[2] \quad X_M = a + b\delta$$

where $a$ corresponds (approximately) to the old invariant Pauling electronegativity in Mulliken units, $b$ is the charge coefficient and $\delta$ is the partial charge on the atom. Huheey (3) has reported $a$ and $b$ values for some 19 elements. By plotting Huheey's $a$ values against % orbital $p$ character, it has been possible to obtain some useful $a$ values which have not been previously reported. A similar procedure affords the corresponding $b$ values. These new $a$ and $b$ values are presented as entries 1–6 in Table 1.

## Group electronegativity parameters

In 1945, Sanderson (7) proposed that the electronegativity of two atoms is equalized upon covalent bond formation. Sanderson's assumption, in conjunction with eq. [2], permits one to formulate simultaneous eqs. [3] and [4] for the hypothetical covalent molecule AB.

$$[3] \quad \delta_A + \delta_B = \text{total charge on AB}$$

$$[4] \quad a_A + b_A\delta_A = a_B + b_B\delta_B$$

Provided the $a$ and $b$ values are known for the atoms A and B, the partial charges ($\delta_A$,$\delta_B$) are

TABLE 1. Atomic electronegativity parameters

| | Element | Hybridization | $a$ | $b$ |
|---|---|---|---|---|
| 1. | C | $sp^{2.5}$ | 8.38 | 13.47 |
| 2. | N | $sp$ | 13.94 | 15.91 |
| 3. | N | $sp^2$ | 13.46 | 15.58 |
| 4. | N | $sp^{2.5}$ | 12.50 | 15.18 |
| 5. | O | $sp^2$ | 15.65 | 18.94 |
| 6. | O | $sp^{2.5}$ | 15.45 | 18.61 |
| 7. | S | *$sp^2$ } $sp^3d$ | −1.01 | 10.73 |
| | | $pd$ } $sp^3d$ | −16.93 | 10.73 |
| 8. | S | Average $sp^3d$ | −20.665 | 10.73 |

*These parameters cannot be used for a sulfur atom which is simply $sp^2$ hybridized.

readily found. AB constitutes a new group which may be combined with another atom Q. The $a$ and $b$ values for AB are obtained as follows:

$$[5] \quad a_{AB} = \frac{a_A b_B + a_B b_A}{b_A + b_B}$$

$$[6] \quad b_{AB} = \frac{b_A \cdot b_B}{b_A + b_B}$$

Huheey (3, 4) has tabulated electronegativity parameters for 196 groups. Both SH and $PH_2$ have incorrect $a$ values in Huheey's table (3) and are corrected in Table 2. Two commonly occurring groups require modified electronegativity parameters.

Since carbene is a neutral species ($\delta_{CH_2} = 0$), its Mulliken electronegativity is 7.43 (cf. Table 2 and eq. [2]). However, the Mulliken electronegativity of the methyl cation is 10.80 (cf. Table 2 and eq. [2]). These numbers do not appear to be self consistent for species which are isoelectronic. While Huheey's $a$ value for $CH_2$ is quite satisfactory for the calculation of electronegativity parameters for a host of substituted methyl groups, it is much too small for carbene itself.

The importance of the $CH_2$ group arises from a consideration of the hypothetical reaction between carbene and an anion to give a carbanion. When the resultant carbanionic centre bears an inductive stabilizer, the very low partial charge on $CH_2$ (obtained with Huheey's $a$ value) implicates virtually complete loss of σ bonding to the substituent. Thus the resistance of carbon to the loss of an octet (in inductively stabilized carbanions) provides a second route to the conclusion that the $a$ value for carbene is too small.

Reformulating eq. [2], the electronegativity of carbene can be expressed as shown in eq. [7].

$$[7] \quad X_M{}^{CH_2} = (a_{CH_2} + n b_{CH_2}) + b_{CH_2}\delta_{CH_2}$$

A comparison of calculated partial charges on $CH_2$ in a variety of inductively stabilized carbanions and ylides with results obtained from *ab initio* calculations (presented later), indicate that the value of $n$ should be 0.64. The resultant $a$ and $b$ values are shown in Table 2 for $\cdot\ddot{C}H_2^-$. *These parameters only apply to carbanions and ylides where conventional resonance interactions involving* p *orbitals are not possible*. The application of eq. [7] to alkyl substituted carbanions $CH_3\ddot{C}H^-$—, $CH_3CH_2\text{-}\ddot{C}H^-$—, etc. (with $n = 0.64$) will permit the calculation of partial charges in more complex carbanionic species which lack π bonding interactions.

TABLE 2. Group electronegativity parameters

| Group | Element/Hybridization | $a$ | $b$ |
|---|---|---|---|
| SH | S/unhybridized | 7.29 | 5.62 |
| $PH_2$ | P/unhybridized | 6.72 | 3.80 |
| $CH_2$ | C/$sp^3$ | 7.43 | 4.32 |
| $\underline{C}H_3$ | C/$sp^2$ | 7.55 | 3.25 |
| $\cdot\ddot{C}H_2$* | C/$sp^3$ | 10.19 | 4.32 |
| Ph | — | 7.81 | 26.67 |

*These parameters should only be used for carbanions and ylides in which the atom attached to $\cdot\ddot{C}H_2$ does not have a $p$ orbital available for a conventional resonance interaction.

The second group for which the parameters need modification is the phenyl group. The parameters Huheey has reported (4) for the phenyl group can be obtained by iterative use of eqs. [5] and [6]. No consideration was given to the special nature of aromatic groups in general or the phenyl group in particular. As we have pointed out previously (5), the phenyl group is particularly resistant to resonance interactions which necessarily disrupt the aromatic sextet. Not surprisingly, calculated partial charges on phenyl for such neutral aromatics as toluene and phenol, using Huheey's parameters, are approximately an order of magnitude larger than those obtained with *ab initio* calculations by Hehre *et al.* (8). The general formula for partial charge on phenyl in the generalized molecule PhZ is:

$$[8] \quad \delta_{Ph} = \frac{a_Z - a_{Ph}}{b_{Ph} + b_Z}$$

It is clear from inspection of eq. [8] that phenyl will only acquire small partial charges if $b_{Ph}$ is relatively large. By setting up simultaneous linear equations for toluene and phenol (*vide* eq. [4]), using Huheey's parameters for methyl and hydroxyl and the partial charges obtained by Hehre *et al.* (8), one can obtain the phenyl parameters shown in Table 2. These parameters represent a small decrease for $a_{Ph}$ and a very large increase for $b_{Ph}$.

## Results and discussion

This approach requires the calculation of partial charges using Huheey's method which affords net group charges due to *both* inductive and resonance effects and may be supplemented by the elaboration of a set of resonance contributors which permits an assessment of resonance effects. Since isomeric groups will have the same electronegativity parameters regardless of the arrangement of the atoms within them, *it is prudent to simplify the species as much as possible before carrying out partial charge calculations*.

### (i) *Carbocations*

The simplest carbocation is the methyl cation. A

comparison of the present approach with *ab initio* and INDO results is presented in Table 3. These results appear to indicate what we find in practice, namely, that results obtained by this method match *ab initio* results better than they match semi-empirical results.

Table 4 presents results for calculations on a variety of carbocations obtained by Huheey's method, INDO calculations, and *ab initio* calculations. Provided that one can select the hybridizations appropriate to the atoms in a given structure,

*Heteroatom hybridization: O-$sp^{2.5}$; S-unhybridized.

phenyl ring is somewhat unusual in that its aromaticity precludes substantial interactions with substituents, despite the ease with which one can draw conventional resonance contributors. Application of our revised parameters for the phenyl group (see Table 2) affords the results for monosubstituted benzenes shown in Table 7.

Calculations on a pair of vinyl substituted heteroatomics are presented in Table 8.

(iv) *Carbanions and ylides*

Since resonance stabilized carbanions may have relatively low partial charge on carbon without the implication of loss of σ bonding, such systems can be treated routinely using the *a* and *b* values given for $CH_2$ in Table 2, as shown in Table 9.

Inductively stabilized carbanions and ylides are readily treated using the *a* and *b* values given in Table 2 for $\cdot\ddot{C}H_2^-$. No attempt[4] has been made to resolve $d_\pi$–$p_\pi$ back-bonding and inductive transfer of electrons in anions or ylides stabilized by third row heteroatoms (Si, S, P, and Cl). Results obtained from the present approach are presented, along with those from *ab initio* calculations, in Table 10.

*$CH_2$ carbon hybridized $sp^{2.5}$.

(v) *Beyond tetrahedra*

As Huheey (3) has pointed out, isomeric groups have the same electronegativity parameters, provided all of the corresponding atoms are hybridized the same way in all isomers. For species containing only second row elements, one can often circumvent the ensuing difficulties. For example, a series

containing 1-chloropropyl, 2-chloropropyl, and 3-chloropropyl groups can be examined in an approximate way by utilizing a chloromethyl, a 2-chloroethyl, and a 3-chloropropyl group.

However, third row elements can form species which involve more complex geometries such as rectangular pyramidal and trigonal bipyramidal. Huheey (3) has not provided parameters for atoms which are $sp^3d$ hybridized. Recent semi-empirical calculations[5] (18) provided net charge data for fluorine and sulfur in $SF_4$. By resolving $SF_4$ into two hypothetical components, $SF_2$ ($pd$ hybridized) and $SF_2$ ($sp^2$ hybridized), and reversing the usual substituent electronegativity calculations using the partial charges given elsewhere (18), one can obtain the sulfur parameters listed in Table 1. The problem with using these parameters for sulfur trigonal bipyramids is that they preclude interactions between the apical and equatorial substituents. By reversing the usual substituent electronegativity calculations, utilizing the average net charge on fluorine in $SF_4$ (18), one can obtain electronegativity parameters for sulfur which represent five identical $sp^3d$ orbitals (see Table 1). Utilizing these parameters will permit the calculation of net charge on a substituent which represents the average of what it would bear in an equatorial position and what it would bear in an apical position.

One can now utilize the $pd$ and $sp^2$ parameters given in Table 1 to obtain the following expression for the partial charges of apical and equatorial groups in $SX_4$.

$$[9] \quad \frac{\delta_x^{equ.}}{\delta_x^{ap}} = \frac{-1.01 - a_x}{-16.93 - a_x}$$

[5]Semi-empirical calculations furnish quite different partial charges than do *ab initio* calculations (*vide* Table 6).

Assuming that the ratio of partial charges a given group will bear in an equatorial position to that which it will bear in an apical position is roughly constant from sulfur trigonal bipyramid to sulfur trigonal bipyramid, one can utilize the ratio in eq. [9] to modify the average partial charge $\bar{\delta}_x$ obtained by employing the sulfur $sp^3d$ parameters. The complete expressions for partial charge on X in any SWXYZ (sulfur-$sp^3d$) are given below:

$$[10] \quad \delta_x^{equ.} = \bar{\delta}_x \left[\frac{1.01 + a_x}{8.97 + a_x}\right]$$

$$[11] \quad \delta_x^{ap} = \bar{\delta}_x \left[\frac{16.93 + a_x}{8.97 + a_x}\right]$$

Thus it is now possible to calculate partial charges on substituents in sulfur trigonal bipyramids, which permit interactions between the substituents as well as allowing for the impact consequent upon equatorial or apical disposition.

Table 11 depicts the results of calculations carried out on a variety of sulfur trigonal bipyramids. While these results should be in reasonable agreement with those obtained by the methods used in ref. 18, other methods may give quite different results. For instance Cowley *et al.* (18) obtain a partial charge of +2.18 on the sulfur atom in $SF_4$, while Jolly *et al.* (19) obtain +0.79. Although the sulfur parameters in Table 1 can be modified to yield greater or smaller charges on the substituents, the trends tabulated (Table 11) are a function of the parameters of the substituents and will not be altered significantly by modifying the sulfur parameters.

## Conclusions

The application of Huheey's approach to the

For personal use only.

calculation of partial charges using variable electronegativities for atoms and groups has been shown to afford reasonable semiquantitative net group charges. It has also been shown that Huheey's method can be extended to treat more complex geometries such as the trigonal bipyramid.

PETER H. BIRD, UPALI SIRIWARDANE, RABIN D. LAI, and ALAN SHAVER. Can. J. Chem. **60**, 2075 (1982).

Fusion *in vacuo* of complexes of the type $P_2Pt(SR)_2$ is a facile route to dimers of the type $[PPt(SR)(\mu\text{-}SR)]_2$; thus, the compounds *cis*-$P_2Pt(SR)_2$, where P = $PPh_3$, $PMePh_2$, R = $CH_2Ph$ and *trans*-$P_2Pt(SR)_2$, where P = $PPh_3$, $PMePh_2$, $PMe_2Ph$, R = 4-$C_6H_4CH_3$ gave the appropriate dimers **1–5**. A three-dimensional X-ray structure analysis of the complex $[(PMePh_2)Pt(SCH_2Ph)(\mu\text{-}SCH_2Ph)]_2$, **2**, has shown that it has *cis* geometry with the benzyl groups of the bridging thiolato ligands oriented *anti* with respect to each other. The dihedral angle between the two square planes is 138.8°. Crystals of **2** are triclinic, space group $P\bar{1}$, with two molecules in a cell of dimensions $a$ = 10.856(3) Å, $b$ = 19.935(5) Å, $c$ = 12.202(4) Å, $\alpha$ = 82.52(2)°, $\beta$ = 105.18(2)°, and $\gamma$ = 92.35(2)°. Full-matrix least-squares refinement converged at $R$ = 0.052.

PETER H. BIRD, UPALI SIRIWARDANE, RABIN D. LAI et ALAN SHAVER. Can. J. Chem. **60**, 2075 (1982).

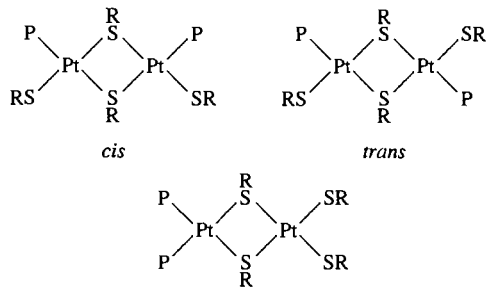
La fusion sous vide des complexes du type $P_2Pt(SR_2)$ conduit facilement aux dimères du type $[PPt(SR)(\mu\text{-}SR)]_2$; ainsi les composés $P_2Pt(SR)_2$-*cis* où P = $PPh_3$, $PMePh_2$, R = $CH_2Ph$ et $P_2Pt(SR)_2$-*trans*, où P = $PPh_3$, $PMePh_2$, R = $C_6H_4CH_3$-4 donnent les dimères appropriés **1–5**. Une analyse de structure en trois dimensions aux rayons X du complexe $[(PMePh_2)Pt(SCH_2Ph)(\mu\text{-}SCH_2Ph)]_2$, **2**, a montré que ce composé a une géométrie *cis*, avec les groupes benzyles des ligands thiolato du pont orientés en *anti* l'un par rapport à l'autre. L'angle dièdre entre les deux plans carrés est de 138,8°. Les cristaux sont tricliniques, groupe d'espace $P\bar{1}$ avec deux molécules par maille et les dimensions de la maille seul: $a$ = 10,856(3) Å, $b$ = 19,935(5) Å, $c$ = 12,202(4) Å, $\alpha$ = 82,52(2)°, $\beta$ = 105,18(2)° et $\gamma$ = 92,35(2)°. On a affiné la structure par la méthode des moindres carrés (matrice complète) jusqu'à une valeur de $R$ de 0,052.

[Traduit par le journal]

## Introduction

Recently we reported the effect of oxygen on the reaction of the dichlorides $P_2PtCl_2$ with thiols in the presence of triethylamine, where P is a phosphine ligand (1). The *cis* isomers of the dithiolato complexes $P_2Pt(SR)_2$ are isolated cleanly and in high yield if oxygen is absent and when R is an alkyl group. However, the presence of oxygen leads to a mixture of products which often included the *trans* isomer plus dimers of the type $[PPt(SR)(\mu\text{-}SR)]_2$ in addition to the *cis* isomer. When R is an aryl group the *trans* isomer is isolated regardless of the presence or absence of oxygen. While studying the stability of the new *cis* complexes the effect of heating them came to our attention. During melting point determinations crystals or clear liquids (phosphines) condensed in the top of the capillary tube. Scaled up to preparative amounts, the fusion *in vacuo* of both *cis* and *trans* monomers is a facile route to a series of the dimers $[PPt(SR)(\mu\text{-}SR)]_2$, some of which were also observed in the solution decomposition of the monomers.

Dimeric platinum complexes with bridging thiolato ligands have been known for many years (2). Previously reported routes to these complexes involve multi-step procedures (3). The fusion method represents a significant simplification in obtaining these dimers. These complexes may occur as *cis* and *trans* isomers or even as the asymmetrical isomer $P_2Pt(\mu\text{-}SR)_2Pt(SR)_2$. It was



not possible from routine spectroscopic characterization to determine which geometry was obtained. An X-ray structural determination found the *cis*

geometry for the complex $[(PMePh_2)Pt(SCH_2Ph)(\mu\text{-}SCH_2Ph)]_2$. Our earlier $^{31}P$ nmr study of the *cis* and *trans* monomers (1) indicated that the nmr *trans*-influences (4) of the phosphine and thiolato ligands were similar. Therefore, it was of interest to compare the structural *trans*-influences of these ligands.

## Experimental

The fusion reactions were performed *in vacuo* ($\leq 10^{-1}$ Torr) and subsequent isolation and characterization was conducted in air. All solvents were of spectrograde quality. Melting points were determined in air on a Thomas-Hoover Uni-melt apparatus and are uncorrected. Proton nmr spectra were obtained on a Varian T-60 spectrometer, using $CDCl_3$ (Merck, Sharpe and Dohme of Montreal) as solvent and TMS as internal standard. Phosphorus nmr spectra were recorded by Mrs. Elva Heyge of McGill University using a Bruker WH-90 instrument operating in the pulsed Fourier Transform mode. The $^{31}P$ chemical shifts of the samples in $CDCl_3$ solution are reported in ppm downfield (positive) from 85% $H_3PO_4$ as external standard, using $D_2O$ as the lock signal. Elemental analyses were performed by Midwest Microlab Ltd., Indianapolis, IN. The midrange infrared spectra (Perkin Elmer 297) of the dimers were almost superimposable on those of the corresponding monomers (1) and were uninformative. The monomers were prepared by reported methods (1, 5).

*A.* *μμ′-Bis(phenylmethanethiolato)bis(phenylmethanethiolatotriphenylphosphineplatinum(II)), [(PPh$_3$)Pt(SCH$_2$Ph)(μ-SCH$_2$Ph)]$_2$*, **1**

The monomor *cis*-$(PPh_3)_2Pt(SCH_2Ph)_2$ (0.24 g, 0.25 mmol) was placed in a 50 mL flask connected to a trap-to-trap vacuum distillation apparatus. The flask was heated to 200°C with a wax bath and the yellow crystals melted (~150°C), effervesced briefly, and resolidified. The upper regions of the apparatus were warmed by pouring the hot wax over it by means of a small pipette or were warmed with a hot-air gun. The phosphine was distilled into the liquid nitrogen cooled collecting flask. The complex was kept at 200°C for 15 min, cooled to room temperature, and extracted in $CH_2Cl_2$. The solution was filtered and evaporated to dryness and the residue recrystallized from $Ch_2Cl_2$/ether to give yellow crystals (0.12 g, 69%).

In a similar experiment, *trans*-$(PPh_3)_2Pt(SCH_2Ph)_2$ (0.48 g, 0.50 mmol) was heated to 230°C *in vacuo*. Recrystallization of the residue from $CH_2Cl_2$/ether gave yellow crystals (0.25 g, 86%).

This dimer was also obtained from the decomposition of the monomer *cis*-$(PPh_3)_2Pt(SCH_2Ph)_2$ in toluene. This complex was formed *in situ* by treating the dichloride *cis*-$(PPh_3)_2PtCl_2$ (6) (3.0 g, 3.8 mmol), suspended in 200 mL toluene, with phenylmethanethiol (0.9 mL, 7.7 mmol) and triethylamine (3 mL, 21.6 mmol) in 100 mL $CH_2Cl_2$ added dropwise. The mixture was stirred at room temperature in air for 22 h and the solvents evaporated on a rotary evaporator. The residue was dissolved in $CH_2Cl_2$ and the solution was washed with 4 × 100 mL portions of distilled water and dried over $MgSO_4$. Recrystallization from hot $CH_2Cl_2$/ether gave yellow crystals of the *trans*-monomer. The mother liquors were evaporated to dryness, the residue boiled in hexane for 1 h and filtered. The insoluble yellow powder was recrystallized as above to give yellow crystals (0.73 g, 33%) of the dimer.

*B.* cis-*μμ′-Bis(phenylmethanethiolato)bis(phenylmethanethiolatomethyldiphenylphosphineplatinum(II))*, cis-*[(PMePh$_2$)Pt(SCH$_2$Ph)(μ-SCH$_2$Ph)]$_2$*, **2**

The complex *cis*-$(PMePh_2)_2Pt(SCH_2Ph)_2$ (0.82 g, 0.97 mmol) was placed in a vacuum microdistillation apparatus and heated for 0.5 h at 210°C with a wax bath as in A. After cooling, the light orange glassy solid was recrystallized from $CH_2Cl_2$/ hexane to give yellow crystals (0.43 g, 70%).

*C.* *μμ′-Bis(4-methylphenylthiolato)bis(4-methylphenylthiolatotriphenylphosphineplatinum(II)), [(PPh$_3$)Pt(4-SC$_6$H$_4$Me)(μ-4-SC$_6$H$_4$Me)]$_2$*, **3**

The monomer *trans*-$(PPh_3)_2Pt(4\text{-}SC_6H_4Me)_2$ (0.81 g, 0.84 mmol) was heated *in vacuo* as in A at 255°C for 0.5 h. After cooling, the clear red glassy residue was extracted with 150 mL of hot $CH_2Cl_2$ and filtered. The filtrate was reduced in volume and excess hexane was added. The resulting yellow powder was filtered, washed with hexane, and pumped on (0.27 g). The product was contaminated by the monomer. Chromatography on alumina failed to separate the two.

*D.* *μμ′-Bis(4)methylphenylthiolato)bis(4-methylphenylthiolatomethyldiphenylphosphineplatinum(II)), [(PMePh$_2$)Pt(4-SC$_6$H$_4$Me)(μ-4-SC$_6$H$_4$Me)]$_2$*, **4**

As in B, *trans*-$(PMePh_2)_2Pt(4\text{-}SC_6H_4Me)_2$ (0.40 g, 0.48 mmol) was heated to 235°C for 5 min. The cooled orange solid was dissolved in toluene and chromatographed on activated alumina. The column was eluted with toluene first, followed by $CH_2Cl_2$ after removal of the first band (*trans*-monomer). The second yellow band was collected, evaporated to dryness, and recrystallized from $CH_2Cl_2$/hexane (0.076 g, 25%).

*E.* *μμ′-Bis(4)methylphenylthiolato)bis(4)methylphenylthiolatodimethylphenylphosphineplatinum(II)), [(PMe$_2$Ph)Pt(4-SC$_6$H$_4$Me)(μ-4-SC$_6$H$_4$Me)]$_2$*, **5**

Again, as in B, *trans*-$(PMe_2Ph)_2Pt(4\text{-}SC_6H_4Me)_2$ (0.51 g, 0.71 mmol) was heated at 250°C for 10 min. The cooled orange glass which contains both the monomer and the dimer in equal proportions was extracted with 10 mL of toluene and filtered. The yellow filtrate was evapoarted to dryness and the residue recrystallized from $Ch_2Cl_2$/ether to give the dimer (0.23 g, 57%).

*X-ray structure determination*

*Crystal data*

$C_{54}H_{54}P_2Pt_2S_4$ fw = 1283.67

Triclinic, $a$ = 10.856(3), $b$ = 19.935(5), $c$ = 12.202(4) Å, $\alpha$ = 82.52(2), $\beta$ = 105.18(2), $\gamma$ = 92.35(2)°, $V$ = 2526.8, $Z$ = 2, $\rho_0$ = 1.69(3), $\rho_c$ = 1.687 g/cm$^3$ (Mo K$\alpha$ $\lambda$ = 0.71069 Å, 20°C, $\mu$ = 60.79 cm$^{-1}$).

The crystal used in the structure determination was grown from methylene chloride. It was approximately a parallelepiped with dimensions 0.30 × 0.25 × 0.20 mm. Preliminary Weissenberg and precession photographs led to the assignment of space groups $P1$ (No. 1) or $P\bar{1}$ (No. 2). The latter choice yielded a successful structure solution. Accurate cell dimensions were obtained by least-squares refinements from the setting angles of 12 reflections on a fully automated Picker FACS-1 diffractometer. Each reflection was centred at both positive and negative 2θ values, and the 2θ, $w$, $\chi$, and $\phi$ values were appropriately averaged before the least-square calculation.

Intensity measurements were made using the θ–2θ scan method. The scanning speed was 2° per min with a scan length of (2.5 + 0.692 tan θ)°. Backgrounds were measured for 20 s on either side of the peak. A hemisphere of data defined by $3.5° < 2\theta < 40°$ and $\pm h$, $\pm k$, $+l$ was collected yielding 6078 intensities. Every 50 cycles, 3 standard reflections were remeasured to check instrumental and crystal stability. These varied randomly by less than 4%.

*Data collection*

Data reduction using locally written programs computed the net intensity $I$ and its estimated standard deviation $\sigma(I)$ as:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

$$I = [N - B \cdot t_s/t_b]$$
$$\sigma(I) = [N + B(t_s/t_b)^2 + (0.02N)^2]^{1/2}$$

where $N$ is the total count accumulated during the scan time $t_s$ and $B$ is the total background count accumulated in time $t_b$.

The reflections having $I > 3\sigma(I)$ (4444 intensities) were considered "observed": the remainder were discarded. The observed data were corrected for Lorentz and polarization effects:

$$(Lp)^{-1} = \sin 2\theta_s(\cos^2 2\theta_n + 1)/(\cos^2 2\theta_m + \cos^2 2\theta_s)$$

where $2\theta_m$ and $2\theta_s$ are the diffraction angles at the graphite monochromator and sample crystal respectively. An absorption correction was applied using the program GNABS by Burnham (7) (transmission factors ranged between 0.30 and 0.55).

*Structure determination*

A three-dimensional Patterson synthesis yielded the positions of the two platinum atoms. The remaining non-hydrogen atoms were found from successive structure factor calculations and Fourier synthesis (FORDAP by A. Zalkin). Structure factor and least-squares calculations were performed using NUCLS in its rigid body version by J. A. Ibers. The scattering factors were taken from the compilation of Cromer and Waber (8). Full-matrix least-squares refinement of the fractional atomic coordinates, anisotropic thermal parameters for the Pt, S, and P atoms and isotropic thermal parameters for the remaining non-hydrogen atoms with the eight phenyl rings refined as rigid groups (C—C = 1.39 Å), resulted in convergence after 7 cycles with $R = 0.052$ and $R_w = 0.066$ ($R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$; $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$, where $w = [\sigma(F_o)]^{-2}$ and $\sigma(F_o) = \sigma(I)/2Lp F_o$). A final difference Fourier showed no significant residual electron density.

The final atomic parameters are listed in the Table 1.[3]

## Results

Fusion *in vacuo* of complexes of the type $P_2Pt(SR)_2$, where P is a phosphine, is a facile route to dimers of the type $[PPt(SR)(\mu\text{-}SR)]_2$. Thus the compounds *cis*-$P_2Pt(SR)_2$, where P = $PPh_3$, $PMePh_2$, R = $CH_2Ph$, and *trans*-$P_2Pt(SR)_2$ where P = $PPh_3$, $PMePh_2$, $PMe_2Ph$, R = 4-$C_6H_4Me$ gave the appropriate dimers **1–5**. Repeated attempts to dimerize the complex *cis*-$(PMe_2Ph)_2Pt(SCH_2Ph)_2$ (containing about 15% of the *trans* isomer) led to decomposition while fusion of *trans*-$(PMe_2Ph)_2Pt(4\text{-}SC_6H_4Me)_2$ gave its dimer. The *trans*-monomers are very stable to decomposition in solution; *trans*-$(PMePh_2)_2Pt(4\text{-}SC_6H_4Me)_2$ was refluxed in decahydronaphthalene for 15 h without any appreciable dimerization or degradation. On the other hand, the *cis*-monomers dimerize slowly in solution in air (1). Since $[(PMe_2Ph)Pt(SCH_2Ph)(\mu\text{-}SCH_2Ph)]_2$ was not obtained by fusion, the appropriate *cis*-monomer was refluxed in decalin. However, extensive decomposition resulted and the dimer was not isolated. Thus, the combination of the $PMe_2Ph$ and $PhCH_2S^-$ ligands appears to be unsuitable for some

[a] In $CDCl_3$ solvent, all $J$ values in Hz, s = singlet, d = doublet, t = triplet, tt = triplet of triplets.
[b] Phenyl resonances in the range 2–3 τ, R = $CH_2Ph$ or 4-$C_6H_4CH_3$ where appropriate.
[c] All $^{31}P$ chemical shifts in ppm upfield (negative) from 85% $H_3PO_4$.
[d] The relative ratio of the three signals is 1:2:1.
[e] The separation of the lines of the small apparent triplet is 5 Hz.
[f] Broad singlet centered at ~7.9–7.85 τ.
[g] Too insoluble to be detected.

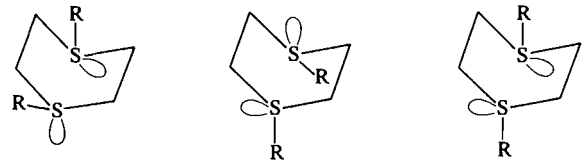
reason with respect to the preparation of the dimer by this method. The *trans*-monomers were also much more resistant to dimerization via fusion than the *cis*-monomers. The dimer was always contaminated by starting *trans*-monomer which made isolation of the former difficult and reduced yields. Prolonging the fusion time or elevating the temperature reduced overall yields. The greater stability of the *trans*-monomer compared to the *cis* during fusion is consistent with the relative stability of the two complexes in solution. The dimers also undergo facile cleavage by phosphines to give the monomers. Thus, nmr tube scale reactions of $[(PMe_2Ph)Pt(4\text{-}SC_6H_4Me)(\mu\text{-}4\text{-}SC_6H_4Me)]_2$ and $[(PMePh_2)Pt(SCH_2Ph)(\mu\text{-}SCH_2Ph)]_2$ with the appropriate phosphine in $CDCl_3$ gave the *trans*- and *cis*-monomers, respectively, identified by their nmr spectra.

The five dimers produced by fusion of the monomeric complexes were obtained as stable yellow–orange materials. Their melting ponts and analytical data are given in Table 2. The solubility of the complexes varied: the benzylthiolato dimers are quite soluble in $CH_2Cl_2$ while $[(PPh_3)Pt(4\text{-}SC_6H_4Me)_2]_2$ is not. The $^1H$ and $^{31}P$ nmr data for the dimers are given in Table 3. The $J$(P—H) coupling patterns for the appropriate monomers permitted the assignment of their geometry with respect to being *cis* or *trans*. However, the phosphine ligands in the dimers are well removed from each other and virtual coupling (9) is not observed. The peaks due to the methyl groups of the 4-methylphenylthiolato ligands were simple singlets and were not helpful for assigning the structures of the dimers containing this ligand. The peaks for the methylene protons in the dimers containing the phenylmethane thiolato ligand should in principle be indicative of the geometry of the complex. In the *cis* geometry there are three different environments for these methylene protons in the ratio 1:1:2, while the in *trans* there are two different types in the ratio 1:1. Three signals in the proper ratio were observed for the methylene protons of both complexes consistent with *cis* geometry. The resonance with double the intensity of the other two is assigned to the terminal thiolato ligands. It is interesting to note the large difference in the chemical shifts of the methylene protons of the two bridging ligands (2 ppm) and that while the high field signal is a slightly broadened singlet with satellites due to $^{195}$platinum coupling, the low field signal is an apparent triplet with a spacing of 5 Hz

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

accompanied by platinum satellites. This triplet of triplets thus observed occurs at much lower field than has been previously observed for the methylene protons of terminal phenylmethane thiolato ligands in the monomeric complexes (1). Irradiation of the triplet in the spectrum of the $PMePh_2$ complex did not decouple any other peaks; however, a slight sharpening of some of the peaks in the phenyl region was observed. Irradiation of these did not decouple the triplet. The value of the coupling (5 Hz) is close to that observed for the monomer *cis*-$(PMePh)_2Pt(SCH_2Ph)_2$ (6 Hz) (1) whereas no coupling could be detected for the latter's *trans* isomer. Thus, it seems reasonable to assign the low field triplet to the bridging thiolato ligand *trans* to the two phosphine ligands. The peaks are broad and difficult to detect at room temperature. The spectrum of the complex containing the $PMePh_2$ ligand undergoes a series of very complicated changes when the sample is cooled wherein the signals due to the phosphine methyl groups, the methylene protons and even some of the phenyl rings are involved. Explanations of the origins of: (*1*) the low field shift of one of the methylene groups and (*2*) the temperature dependence of the spectrum of the $PMePh_2$ derivative are not readily apparent and may require more intensive study.

Such explanations are likely to be related to the possibility of geometrical isomerism in addition to the *cis–trans* type already mentioned. The bridging sulfur atoms are tetrahedral and can generate *syn* and *anti* type geometries depending on the relative arrangement of the organic groups. Since the dimers are bent along the axis joining the bridging sulfur atoms this generates *syn–exo* and *syn–endo*



isomers. Such isomers have been observed for other dimers and their interconversion via inversion at sulfur has been studied (2*a*). It seems possible that at least some of the properties of the nmr spectra of the dimers reported here are due to the interconversion of these types of conformers in solution (10).

There is only one type of environment for the two phosphine ligands in either the *cis*- or *trans*-isomer. The $^{31}P$ nmr spectra reflect this with the chemical shifts and $J$(Pt—P) values being similar for all the complexes and not helpful in the structural assignments. This is consistent with the observation (1) that the $^{31}P$ nmr spectra of the monomers were not very sensitive to the geometry of those complexes either. The spectra of the dimers show additional long range P—P and Pt—P coupling which are being examined (11) to determine if these would be useful structural probes of this type of molecule.

Earlier studies concluded that alkylthiolato bridged dimers have *cis*-geometry while arylthiolato bridged dimers were *trans* (3, 12). X-Ray data has tended to confirm this with the complexes $[(P(C_3H_7)_3)PtCl(\mu\text{-}SC_2H_5)]_2$ (13) and $[(PPh_3)Pd(SC_6F_5)(\mu\text{-}SC_6F_5)]_2$ (14) having *cis* and *trans* geometries, respectively. The crystal and molecular structure of $[(PMePH_2)Pt(SCH_2PH)(\mu\text{-}SCH_2PH)]_2$ has been determined and shows that this alkylthiolato bridged platinum dimer also has the *cis* geometry in agreement with the assignment based on its nmr spectrum.

The molecular configuration and numbering scheme for **2** is shown in Fig. 1. The principal molecular distances and angles are listed in Table 4. A packing diagram of the triclinic unit cell containing two molecules of **2** is shown in Fig. 2. The complex is dimeric with two square planar platinum units joined by two mercaptide bridges, as expected (Fig. 3). The dihedral angle between the two square planes is 138.8°. This compares to a value of 130° for the same angle in the similar complex *cis*-$[(PPr_3)PtCl(\mu\text{-}SEt)]_2$ (13). The angles Pl—Pt1—SB2, S1—Pt1—SB1, P2—Pt2—SB2, and S2—Pt2—SB2 are 91°, 94°, 92°, and 96°,

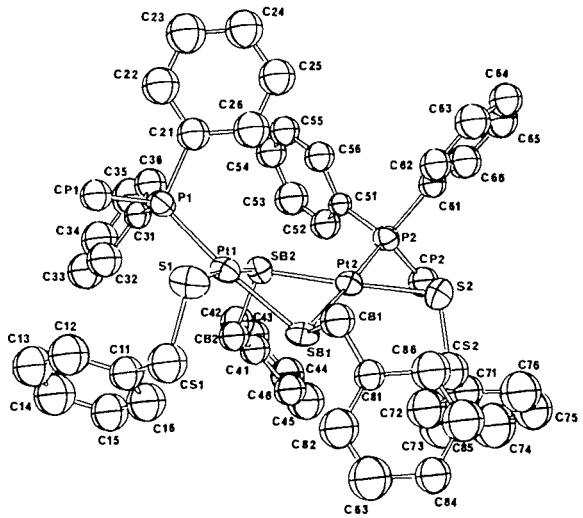


FIG. 1. The molecular configuration and the numbering scheme for **2**.

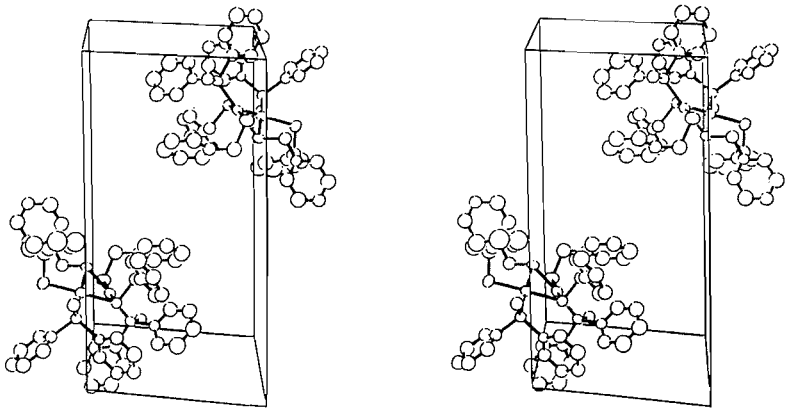

FIG. 2. An illustration of the unit cell packing diagram containing two molecules of **2** as viewed down the *b* axis.

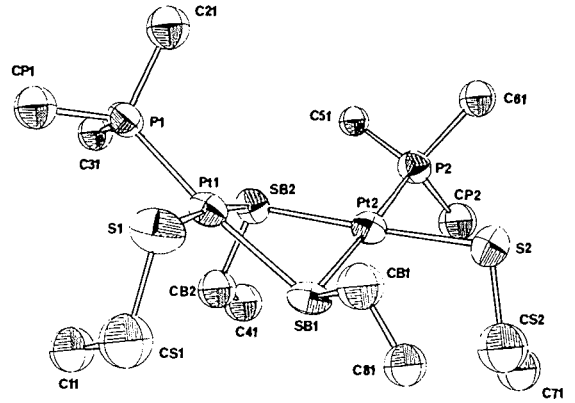

FIG. 3. The configuration of **2** excluding phenyl rings for clarity.

respectively. The adoption of the *anti*-configuration for the benzyl groups of the bridging thiolato ligands with the one *trans* to the two phosphines in the *endo* position (Fig. 3) tends to minimize crowding. The angles at the bridging sulfur atoms Pt1—SB1—Pt2 and Pt1—SB2—Pt2 are 89° and 92°, respectively; expanded slightly from the values of 85° and 89° for the same angles in $[(PPr_3)PtCl(\mu\text{-}SEt)]_2$ (13).

The platinum-to-bridging-sulfur distances *trans* to the terminal thiolato ligands (Pt1—SB2, 2.322(4) Å and Pt2—SB2, 2.323(4) Å) are shorter than those *trans* to the phosphine ligands (Pt1—SB1, 2.380(4) Å and Pt2—SB1, 2.380(4) Å). This would tend to indicate that the structural *trans*-influence of the terminal $PhCH_2S^-$ ligand was less than that of $PMePh_2$ as has been noted (4). This, however, is not reflected in the relative nmr *trans*-influences of the two ligands which have been shown to be very similar (1).

## Discussion

The bridging abilities of thiolato ligands are well known. Early reports of monomeric thiolato platinum complexes (2) are now thought to describe thiolato bridged dimers or polymers (15). Analytical methods for determining the concentration of platinum in aqueous solution (16) very likely pro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

duced $RS^-$ bridged polymers. Relatively recently Chatt and co-workers carried out extensive studies on the preparation of such complexes (3, 12, 17). Their preparations involved the step-wise replacement of terminal and bridging chloride ligands (3). The method has remained popular (11, 15, 17, 18), although sulfide (19) or hydride bridges (20) have also been displaced. A conceptually simpler route to preparing thiolato bridged dimers is the condensation of monomeric thiolato complexes. Examples include the monomers $(Me_2S)_2WCl_3(SEt)$, $[(MeC_5H_4)Mn(SEt)(CO)_2]^-$, $CpFe(SR)(CO)_2$, *trans*-$(PPh_3)_2Pd(SC_6F_5)_2$, and *cis*-$(PPh_3)_2Pt(SCF_3)Cl$ which dimerized to $[(Me_2S)WCl_2(\mu\text{-}SEt)]_2$ (21), $[(MeC_5H_4)Mn(CO)_2]_2(\mu\text{-}SEt)^-$ (22), $[CpFe(\mu\text{-}SR)(CO)]_2$ (23), *trans*-$[(PPh_3)Pd(SC_6F_5)(\mu\text{-}SC_6F_5)]_2$ (14), and $[(PPh_3)_2Pt(\mu\text{-}SCF_3)]_2^{2+}$ (18*d*), respectively. Eighteen-electron complexes such as $CpFe(SR)(CO)_2$ probably dimerize via a dissociative pathway. More relevant to our work is the dimerization of *trans*-$(PPh_3)_2Pd(SC_6F_5)_2$ by warming in ethanol (24). It is reasonable to assume that this reaction and the fusions reported here proceed via an associative pathway (25). Such a route might involve bridged five-coordinate complexes such as are observed for dithiolene dimers (26); however, the details of the mechanism require further study.

## Acknowledgements

This research was supported by grants from the Natural Sciences and Engineering Research Council of Canada and the Quebec Department of Education. We thank the Imperial Oil Co. of Canada for the award of a research grant to A. S. Predoctoral fellowships awarded to R.D.L. by McGill University are gratefully acknowledged. We thank Mrs. Elva Heyge of McGill University for the $^{31}P$ nmr spectra. The authors acknowledge Dr. Gordon Hamer of Xerox Canada for very helpful discussions concerning the nmr spectra of the dimers and for performing the preliminary variable temperature nmr experiments.

# Fast, mild, and convenient procedures for iodination and bromination of carbohydrates: reactions of organoboranes with iodine monochloride, sodium iodide, bromine, and bromine chloride

LAURANCE D. HALL AND JEAN-RICHARD NEESER

*Chemistry Department, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6*

Received February 2, 1982

LAURANCE D. HALL and JEAN-RICHARD NEESER. Can. J. Chem. **60**, 2082 (1982).

5,6-Dideoxy-1,2-*O*-isopropylidene-3-*O*-methanesulfonyl-α-D-*xylo*-hexofuranosene-5 (**1**), reacts with $BH_3$–THF to form the tris(glycosyl)borane (**2**) and with dicyclohexylborane to form the dicyclohexylglycosylborane (**3**). The iodination and bromination of **2** and **3** has been investigated using a variety of electrophiles. Iodination of either **2** or **3** with NaI–Chloramine-T/NaOAc is complete within one minute with high percentage uptake of iodine (70–90%) and recovery of the iodinated sugar (**4**). Bromination of **2** in 15 minutes with NaBr–Chloramine-T permits a high percentage uptake of bromine (75%), and bromination of **3** in 15 minutes with $Br_2$/NaOAc gives the brominated sugar (**5**) with a reasonably good yield (60%) with respect to the starting material (**1**).

LAURANCE D. HALL et JEAN-RICHARD NEESER. Can. J. Chem. **60**, 2082 (1982).

Le didéoxy-5,6 *O*-isopropylidène-1,2 *O*-méthanesulfonyl-3 α-D-*xylo*-hexofurannosène-5 (**1**) réagit avec le complexe $BH_3$ –THF pour donner accès au tris(glycosyl)borane (**2**), tandis que face au dicyclohexylborane, il conduit au dicyclohexylglycosylborane (**3**). L'iodation et la bromation des composés **2** et **3** ont été étudiées en utilisant divers agents électrophiles. En présence de NaI–Chloramine-T/NaOAc, l'iodation des composés **2** ou **3** est complète au bout d'une minute, le fort pourcentage d'incorporation d'iode (70–90%) conduisant sucre iodé (**4**). La bromation du composé **2** par NaBr–Chloramine-T requiert 15 minutes et donne lieu à un fort pourcentage d'incorporation de brome par le sucre (75%); la bromation du composé **3** par $Br_2$/NaOAc s'effectue en 15 minutes et permet d'obtenir le sucre bromé (**5**) avec un rendement acceptable (60%) par rapport au produit de départ (**1**).

## Introduction

In recent years, a very wide variety of radiohalogen-containing radiopharmaceuticals have been developed (1) for use in diagnostic nuclear medicine and positron emission tomography (PET). Much interest has been aroused in the search for rapid methods of halogenation, compatible with the use of very short half-life radiohalogens. Very recently a new, mild, and rapid method for fluorination of aromatic compounds by treatment of aryl-tin derivatives with $^{18}F$-$F_2$ (2) was developed and similar reactions of other aryl-metal derivatives have been evaluated. Continuing in this general field, we have now adapted new, fast, and mild methods for the iodination and bromination of carbon–boron bonds to the area of carbohydrate chemistry. Recently, Kabalka and co-workers have developed two methods for the iodination (3, 4) and two for the bromination (5) of organoboranes, which work under conditions so mild that they are compatible with a wide range of functional groups.

Kabalka and co-workers have observed that when trialkylboranes, derived from the hydroboration of terminal alkenes, are activated in an electron-rich organoborane–acetate complex, two of the three groups on boron react instantaneously when treated with iodine monochloride (3), or with iodide ion in the presence of an oxidizing agent such as Chloramine-T (4). This latter reaction permits the selective cleavage of a primary alkylboron bond when mixed organoboranes, prepared with dicyclohexylborane, react with iodonium ion (4). Without activation of the trialkylborane, one of the three primary alkyl groups on boron reacts instantaneously when treated with bromine in the presence of water, or with bromine chloride prepared *in situ* (5). This latter reaction permits the preferential cleavage (70%) of a primary alkyl–boron bond, when dicyclohexylborane is used as the hydroborating agent (5). All these reactions are postulated to proceed in an ionic fashion, via an $S_E2$ mechanism.

Prior to this study, organoborane technology had been successfully used in carbohydrate chemistry in hydroboration–oxidation sequences (6). The success generally observed in these applications of organoborane technology in carbohydrate chemistry, and the recent interest in research for very fast methods for the synthesis of halogenosugar derivatives, has prompted us to adapt the new "Kabalka" procedures to an unsaturated carbohydrate model, namely 5,6-dideoxy-1,2-*O*-isopropylidene-3-*O*-methanesulfonyl-α-D-*xylo*-hexosene-5 (7) (**1**).

## Results and discussion

The triglycosylborane (**2**), obtained by reaction

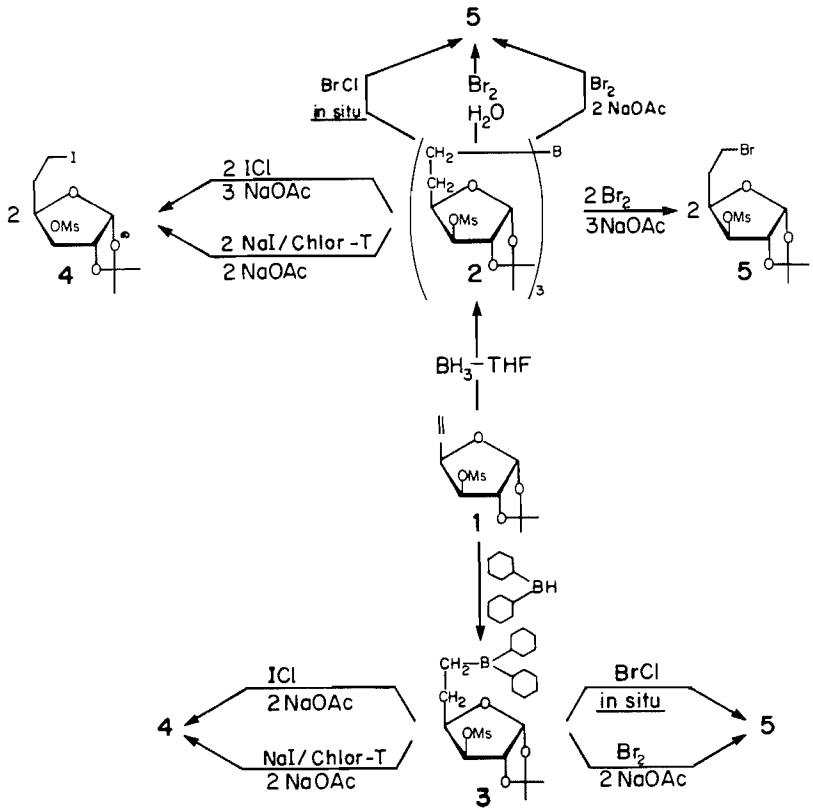

SCHEME 1

of the starting unsaturated carbohydrate (**1**) with $BH_3$–THF, readily reacts in the presence of sodium acetate with two equivalents of ICl, or with two equivalents of sodium iodide and Chloramine-T; under these conditions 74 and 72%, respectively, of the added iodine is consumed. It seems reasonable to speculate that the first carbohydrate moiety attached on the boron atom reacts quantitatively, whereas the reaction of the second group is incomplete. It was possible to confirm this hypothesis by using dicyclohexylborane as the hydroborating agent. It was found that the dicyclohexylglycosylborane (**3**) reacts quantitatively with one equivalent either of the iodide/Chloramine-T reagent or the ICl reagent, the carbohydrate-containing primary alkyl group being selectively iodinated within one minute by the former reagent to produce the iodo derivative (**4**) in excellent yield (ca. 90%). The results for the iodination reactions are summarized in Table 1.

The triglycosylborane (**2**) reacts readily with one equivalent of BrCl prepared *in situ* from bromide/Chloramine-T, and permits the isolation of the bromo derivative (**5**), in 75% yield with respect to the bromide reagent. However, the fact that, in this reaction, only one of the three carbohydrate groups attached to the boron atom is able to react reduces the yield with respect to the unsaturated starting carbohydrate to 25%. Unfortunately the above reaction conditions appear not to discriminate efficiently between bromination of a glycosyl–boron bond and that of a cyclohexyl–boron bond. Thus it was found that the organoboron derivative (**3**) reacted with one equivalent of BrCl *in situ* to give only 36% of the bromo-sugar (**5**) (mixed with an unidentified carbohydrate-containing by-product) and an equivalent yield of bromocyclohexane. Under the same reaction conditions, Kabalka *et al.* (5) report that tricyclohexylborane utilized 67% of the added halogen.

With one equivalent of $Br_2$ in aqueous medium, **2** is converted to **5**, utilizing less than half of the bromine in the reaction. In addition, an unresolved mixture of by-products was isolated by lcc (liquid column chromatography); these contain no carbohydrate and probably come from the tetrahydrofuran present in the reaction medium. Consequently, it seems necessary to activate the

[a]Isolated yields based on the halogenating agent. The numbers in parentheses refer to isolated yields based on starting unsaturated carbohydrate (**1**).
[b]The product (**5**) isolated from this procedure is mixed with an unidentified carbohydrate-containing by-product.

organoboron intermediate (**2**) to obtain a specific reaction with molecular bromine. By analogy with our iodination experiments, **2** was activated with methanolic sodium acetate, and under these conditions one equivalent of $Br_2$ reacts quantitatively with one sugar moiety to give **5**. However, we observe that under the same conditions, two equivalents of $Br_2$ are utilized with a 62% yield of **5**, showing that this reaction permits fast cleavage of two of the three primary alkyl groups attached to the boron atom, but with an incomplete migration of the second group in this case. Fortunately, when treated with one equivalent of $Br_2$, the activated dicyclohexylglycosylborane (**3**) utilizes 60% of the halogen for bromination of the glycosyl group. Thus this latter procedure is more selective for the preferential cleavage of the primary alkyl carbohydrate-containing group than is the BrCl *in situ*. Our results are summarized in Table 1.

In principle, three different products could arise from the hydroboration of **1**: the two, C-5 epimeric 5-bora-5,6-dideoxy-1,2-*O*-isopropylidene-3-*O*-methanesulfonyl-α-D-glucofuranose and β-L-iodofuranose, and the 6-bora-5,6-dideoxy-1,2-*O*-isopropylidene-3-*O*-methanesulfonyl-α-D-*xylo*-hexose (**2** or **3**). The latter is the expected product arising from the normal, anti-Markovnikov hydroboration. Although the fact that only the 6-iodo and 6-bromo derivatives were obtained from the halogenation reactions provides supportive evidence for C-6 boronation, this is not conclusive since it is known that these halogenation methods *preferentially* cleave primary alkyl groups; thus, if small amounts of 5-bora derivatives had been produced by the hydroboration reactions, these products might not be halogenated. The structures of **4** and **5** were unambiguously assigned on the basis of their nmr spectra.

## Conclusion

By the standards of conventional organic syntheses the reactions described here are reasonably efficient, but probably not sufficiently so to warrant their selection in preference to other methods for introducing halogen at a primary centre. However, their merit is somewhat more obvious in the context of the constraints of radiolabelling chemistry, where yields are based on the uptake of halogen rather than consumption of the organic substrate, and where time limitations

For personal use only.

require that the halogenation reaction plus work-up be completed within the equivalent of 2–3 half-lives; this latter limit requires that the halogen be used in essentially the same atomic form in which it is generated in the cyclotron.

Given such constraints and considering the known ease of generating $^{120}$I-iodide, the synthesis of **4** from **1** via dicyclohexylboronation and NaI–Chloramine-T/NaOAc, with essentially quantitative uptake of iodine and quantitative yield of **4**, is very encouraging; that the reaction is completed within 1 minute which amounts to ca. 1% of one radioactive half-life for $^{120}$I (81 min) is exemplary. The synthesis of the bromo-derivative (**5**) is somewhat less satisfactory, but the yields based on the bromine uptake (75%) in the $BH_3$–THF/NaBr–Chloramine-T procedure is again encouraging ($^{75}$Br-bromide being easily generated), as is the time of the reaction, 15 min, 15% of one half life for $^{75}$Br (97 min).

## Experimental

The nmr spectra were run at 270 MHz using a home-built, pulse Fourier transform nmr spectrometer. All chemical shifts are reported in parts per million downfield from $Me_4Si$. The mass spectra were recorded at low resolution, on a Varian MAT Atlas CH4-B mass spectrometer. The specific optical rotation $[\alpha]_D$ values were obtained with a Perkin–Elmer 241 MC polarimeter.

*5,6-Dideoxy-1,2-*O*-isopropylidene-3-*O*-methanesulfonyl-α-*D*-xylo-hexosene-5* (**1**) was prepared according to a published procedure (7), modified as follows: 1,2-*O*-isopropylidene-3,5,6-tri-*O*-methanesulfonyl-α-D-glucose (10 g) and NaI (26 g) were dissolved in 500 mL of 2-butanone and heated under reflux (3.5 h). After work-up using the published procedure (7), the crude product was crystallized from methanol to yield pure **1** (5.35 g, 92%).

*Hydroborations*

Commercially available (Alfa) $BH_3$–THF (1 *M* solution) was used. Reagent Grade THF was deoxygenated according to a published procedure (8*a*) and kept under $N_2$ in a bottle stoppered with a septum. Syringes were purged before each use with $N_2$, according to a published technique (8*b*).

*$BH_3$–THF procedure (synthesis of 1 mmol of 2)*

Compound **1** (792 mg, 3 mmol) was introduced under a blanket of $N_2$ in a round-bottomed flask equipped with magnetic stirrer and septum inlet, which had been flushed hot with $N_2$. THF (1.5 mL) was added via a syringe, the resultant solution cooled to 0°C and $BH_3$–THF (1.05 mL of a 1 *M* solution) added via a syringe. The mixture was stirred for 1.5 h at 25°C.

*Dicyclohexylborane procedure (synthesis of 2 mmol of 3)*

A suspension of dicyclohexylborane in THF at 0°C (4.2 mL of 0.5 *M*) was prepared according to the published procedure (8*c*). During the same time period a solution of **1** (528 mg, 2 mmol) in THF (1 mL) was prepared as above. This solution was added via a syringe to the dicyclohexylborane suspension at 0°C and the mixture was stirred at 25°C for 2 h.

*Iodinations:*

*Iodinations of two groups on boron from 1 mmol of 2 {or one group on boron from 2 mmol of 3}*

The published procedures of Kabalka and Gooch (3, 4) were followed. After quenching, the mixtures were poured into water (20 mL) and extracted with 4 × 10 mL of ether. The combined ether extracts were dried ($MgSO_4$) and ether was removed under reduced pressure. Column chromatography on silica with ether/hexane (2:1) as eluant yielded 580 mg (74%) {or 690 mg (88%)} of pure **4** from the *iodine monochloride procedure*, and 565 mg (72%) {or 715 mg (91%)} of pure **4** from the *iodide/Chloramine-T procedure*.

*Brominations:*

*Brominations of 1 group on boron from 1 mmol of 2 {or 2 mmol of 3}*

The published procedures of Kabalka *et al.* (5) were followed. After reacting, the mixtures were extracted with 15 mL of ether; the ether solutions were washed with two 7.5 mL portions of water, dried over $MgSO_4$, and concentrated. Column chromatography on silica with ether/hexane (2:1) as eluant yielded 260 mg (75%) of pure **5** {or 250 mg (36%) of **5** mixed with an unidentified carbohydrate-containing by-product} from the *BrCl* in situ *procedure*, and 165 mg (48%) of pure **5** from the *molecular bromine/water procedure*.

*Molecular bromine/methanolic sodium acetate procedure*

Methanol (1 mL {or 2 mL}), followed by 2 mL {or 4 mL} of 1 *M* methanolic sodium acetate were added to the organoborane solution in THF. The mixture was cooled to 0°C and shielded from light. Bromine (1 mmol {or 2 mmol}) was added and the mixture stirred 15 min at 0°C; 2 mL of saturated $K_2CO_3$ solution were added and the mixture poured into 15 mL of water. The mixture was extracted with 4 × 10 mL of ether, the combined ether layers were washed with 2 × 7.5 mL of water and 2 × 7.5 mL of saturated NaCl solution, and dried over anhydrous $MgSO_4$. The product was isolated as described before and 320 mg {or 415 mg} of pure **5** was obtained. The yield was 93% {or 60%}.

*Bromination of two groups on boron from 1 mmol of 2*

*Molecular bromine/methanolic sodium acetate procedure*

Three milliliters of 1 *M* methanolic sodium acetate were added to the organoborane solution in THF. The mixture was treated as described previously using 2 mmol of bromine. This method permitted isolation of 430 mg (62%) of pure **5**.

*Characterization of 4 and 5*

*5,6-Dideoxy-6-iodo-1,2-*O*-isopropylidene-3-*O*-methanesulfonyl-α-*D*-xylo-hexose* (**4**) was recrystallized from methanol; mp 70–71°C; $[\alpha]_D^{22}$ +4.06° (*c* 1, $CHCl_3$); $^1$H nmr δ ($CDCl_3$): 1.33 and 1.54 (2s, 2 × 3H, $CMe_2$), 2.12 and 2.22 (2m, 2 × 1H, $H_A$- and $H_B$-C5), 3.08 (s, 3H, $SO_2Me$), 3.30 (m, 2H, H-C6), 4.43 (ddd, 1H, H-C4, $J_{4,5}$ = 8.1 and 4.0 Hz, $J_{4,3}$ = 3 Hz), 4.77 (d, 1H, H-C2, $J_{2,1}$ = 3.8 Hz), 4.98 (d, 1H, H-C3), 5.92 (d, 1H, H-C1); *m/e*: 377(25) ($M^+$ − Me), 239(33), 83(16), 79(18), 59(46), 57(16), 55(20), 43(100), 41(26), 32(23), 28(97). *Anal.* calcd. for $C_{10}H_{17}IO_6S$: C 30.62, H 4.37, I 32.36; found: C 30.51, H 4.35, I 32.30.

*6-Bromo-5,6-dideoxy-1,2-*O*-isopropylidene-3-*O*-methanesulfonyl-α-*D*-xylo-hexose* (**5**) was recrystallized from methanol; mp 74–75°C; $[\alpha]_D^{22}$ +6.50° (*c* 1, $CHCl_3$); $^1$H nmr, δ ($CDCl_3$): 1.34 and 1.54 (2s, 2 × 3H, $CMe_2$), 2.14 and 2.29 (2m, 2 × 1H, $H_A$- and $H_B$- C5), 3.11 (s, 3H, $SO_2Me$), 3.54 (m, 2H, H-C6), 4.52 (ddd, 1H, H-C4, $J_{4,5}$ = 8.2 Hz and 3.8 Hz, $J_{4,3}$ = 2.9 Hz), 4.78 (d, 1H, H-C2, $J_{2,1}$ = 3.8 Hz), 4.99 (d, 1H, H-C3), 5.94 (d, 1H, H-C1); *m/e*: 331–329 (18-18) ($M^+$ − Me), 193–191 (23-23), 79(17), 59(53), 55(14), 43(100), 41(22), 28(20). *Anal.* calcd. for $C_{10}H_{17}BrO_6S$: C 34.79, H 4.96, Br 23.15; found: C 34.95, H 5.02, Br 22.95.

# Préparation stéréosélective de méthyle cétones α-bromées: stéréochimie de l'addition d'anions en α d'un groupe sulfone sur des cyclohexanones monocycliques et stéroïdiques

JEAN-PIERRE BÉGUÉ,[1] DANIÈLE BONNET-DELPON, MICHELINE CHARPENTIER-MORIZE ET JEAN SANSOULET

*GR 12, Centre National de la Recherche Scientifique, 2–8, rue Henri Dunant, B.P. 28, 94320 Thiais, France*

Reçu le 16 décembre 1981

JEAN-PIERRE BÉGUÉ, DANIÈLE BONNET-DELPON, MICHELINE CHARPENTIER-MORIZE et JEAN SANSOULET. Can. J. Chem. **60**, 2087 (1982).

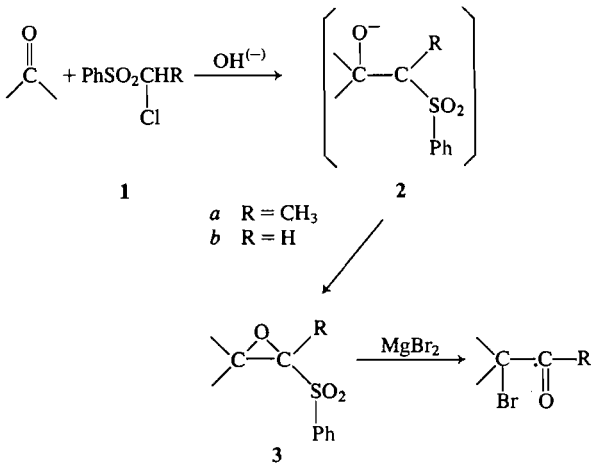
La méthode décrite par Durst et coll. pour la préparation de méthyle cétones α-bromées ou d'aldéhydes α-bromés a été appliquée en série cyclohexane, notamment en série stéroïde à l'obtention de composés *gem*-bromocarbonylés. Le bilan stéréochimique du processus réactionnel a été précisé: dans tous les cas étudiés, le composé carbonylé à brome équatorial se forme très sélectivement. Toutefois, en série monocyclique, cette méthode se trouve limitée par l'existence d'une réaction compétitive d'élimination.

JEAN-PIERRE BÉGUÉ, DANIÈLE BONNET-DELPON, MICHELINE CHARPENTIER-MORIZE, and JEAN SANSOULET. Can. J. Chem. **60**, 2087 (1982).

This work describes stereochemical results obtained for the preparation of α-bromomethyl ketones or α-bromoaldehydes starting from monocyclic and steroid cyclohexanones, using the Durst method. In all the cases studied here, the bromine is introduced selectively in the equatorial position. However, for monocyclic compounds, the yields of α-bromocarbonyl compounds are limited by the competitive formation of α-ethylenic carbonyl compounds.

Lors d'études de déshalogénations de composés carbonylés α-bromés effectuées dans notre laboratoire (2), la préparation de méthyle cétones α-bromées a souvent été source de difficultés. Parmi les méthodes susceptibles d'être utilisées (notamment refs. 3 et 4), celle récemment publiée par Durst *et al.* (1) a attiré notre attention par sa facilité de mise en œuvre.

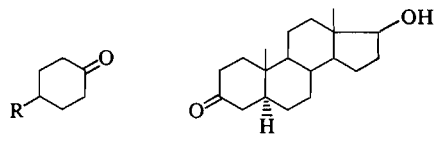
La méthode décrite par Durst *et al.* (1) consiste à additionner, dans les conditions de transfert de phase liquide–liquide, les chlorosulfones **1** sur des cétones ou des aldéhydes: la cyclisation *in situ* de l'anion intermédiairement formé **2** mène à l'époxysulfone **3**. Celle-ci isolée, puis traitée par $MgBr_2$ conduit aux méthyle cétones α-bromées (R = $CH_3$) ou aux aldéhydes α-bromés (R = H).



**1** **2**

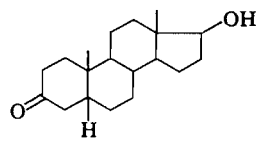
*a* R = $CH_3$
*b* R = H

**3**



**4** R = H
**5** R = $CH_3$
**6** R = *t*Bu

**7** (Androstanolone-5α)



**8** (Androstanolone-5β)

Toutefois, les modèles étudiés par Durst *et al.* n'avaient pas permis de préciser le bilan stéréochimique de la réaction.

## Résultats

Le présent travail décrit l'addition de l'α-chloroéthylsulfone **1***a* sur les cétones **4**, **5**, **6**, **7** et **8** (Tableau 1) et celle de l'α-chlorométhylsulfone **1***b* sur les cétones **4** et **6** (Tableau 2).

A priori toutes ces cétones (sauf **4**) peuvent conduire à un mélange de cétones bromées stéréoisomères (Tableaux 1 et 2).

Dans le cas des expériences **b**, **c** et **d**, effectuées

TABLEAU 1. Préparation de méthyle cétones α-bromées (Addition de **1***a*)

| Cétones | N° expérience | Cétones α-bromées (Rendement)[a] | | Stéréosélectivité[b] | Cétones α-éthylénique (Rendement)[a] |
|---|---|---|---|---|---|
| **4** | **a** |  | (≥90%) | — |  (~10%) |
| **5** | **b** |  **12** + **13** | (38%) | **12/13** = 85:15 |  (61%) |
| **6** | **c** |  **14** + **15** | (39%) | **14/15** = 90:10 |  (42%) |
| **7** | **d** |  **16** + **17** | (38%) | **16/17** = 99:1 |  **18** (8%) |
| **8** | **e** |  **19** + **20** | (51%) | **19/20** = 96:4 |  **21** (6%) |

[a]Les rendements en produits isolés sont calculés par rapport aux cétones de départ et sont la moyenne de plusieurs expériences.
[b]Les pourcentages relatifs des stéréoisomères sont la moyenne de plusieurs expériences et varient d'environ ±5%.

TABLEAU 2. Préparation d'aldéhydes α-bromées (Addition de **1***b*)

| Cétones | N° expérience | Aldéhyde α-bromée (Rendement)[a] | | Stéréosélectivité[b] | Aldéhyde α-éthylénique (Rendement)[a] |
|---|---|---|---|---|---|
| **4** | **f** |  **23** | (23%) | — |  **24** (28%) |
| **6** | **g** |  **25** + **26** | (28%) | **25/26** = 70:30 |  **27** (41%) |

[a]Les rendements en produits isolés sont calculés par rapport aux cétones de départ et sont la moyenne de plusieurs expériences.
[b]Le pourcentage relatif des stéréoisomères est la moyenne de plusieurs expériences et varie d'environ ±5%.

respectivement à partir des cétones **5**, **6** et **7**, l'examen des spectres rmn $^{13}C$ des époxysulfones **3** (produits bruts de réaction), montre que dans les trois cas, un stéréoisomère est très majoritaire (≥90%). Sur la base de cette seule donnée, il n'a toutefois pas été possible de déterminer la configuration de cet isomère majoritaire. Par contre, l'attribution de configuration des cétones bromées a pu être faite par corrélation des spectres de rmn $^{13}C$ et par voie chimique[2] (voir partie expérimentale). L'isomère à brome équatorial est toujours obtenu très majoritairement. (Le pourcentage relatif des stéréoisomères correspond soit à une analyse par cpg (expériences **b**, **c** et **g**), soit aux proportions de produits isolés (expériences **d** et **e**).)

Dans toutes les expériences, à côté des cétones ou aldéhydes α-bromés se forment les composés α-éthyléniques correspondants. La proportion de ces derniers varie de 6% (expérience **e**) à 52% (expérience **b**).

Nous avons repris les conditions décrites par Durst (1) uniquement dans le cas de l'époxysulfone dérivée de la cyclohexanone (3 h, −30°C) pour le traitement par $MgBr_2$ de l'époxysulfone dérivant de la méthyl-4 cyclohexanone. Dans ces conditions, cette époxysulfone est récupérée inchangée; lorsqu'on remonte la température (−15°C) on

[2]Dans le cas des expériences **c** et **g** la configuration des composés bromés était déjà connue (5). Par ailleurs, au laboratoire, il a été montré, à partir d'une importante série de composés cyclohexaniques *gem*-bromocarbonylés que le carbone porteur du brome axial résonne à champ plus faible que celui porteur du brome équatorial, la différence étant toujours de l'ordre de 5 ppm (14).

For personal use only.

observe la formation d'éthylénique et de cétones bromées. Pour avoir une réaction complète dans un temps assez bref, nous avons effectué la réaction à 0°C.

Evidemment, pour voir si la température avait un effet sur la compétition entre la formation de cétone bromée et l'élimination, nous avons répété l'expérience décrite par Durst avec la cyclohexanone mais en effectuant la réaction à 0°C (c'est l'expérience qui est décrite en partie expérimentale). Nous avons obtenu le même rendement (90%) que Durst *et al.* en acétyl bromocyclohexane.[3]

À notre sens, la compétition entre la réaction d'élimination et la formation de cétones bromées est liée essentiellement à la structure de l'époxysulfone et non pas à un effet de température.

## Discussion

L'obtention stéréosélective de cétones (ou aldéhydes) α-bromés et la formation compétitive dans cette réaction de cétones (ou aldéhydes) α-éthyléniques sont les deux faits marquants rapportés dans ce travail. Ils sont la conséquence et de la stéréosélectivité de formation des époxysulfones **3** et du mécanisme d'ouverture de ces dernières sous l'action de $MgBr_2$.

(a) *Stéréosélectivité de formation des époxysulfones 3*

Les époxysulfones **3** se forment par cyclisation *in situ* des anions **2** résultant eux-mêmes de l'addition sur les cyclohexanones du carbanion correspondant à la sulfone **1**. Dans les conditions de transfert de phase utilisées, cette addition est vraisemblablement irréversible.[4] La configuration des époxysulfones **3** serait donc déterminée par le sens de l'attaque du carbanion $Ph—SO_2—C^-(Cl)R$ sur les cyclohexanones (face α ou face β).[5]

Dans le cas des cétones **5** et **6**, il a été montré (7) que les carbanions $ClC^-(CH_3)COR$ et $ClC^-(CH_3)CN$ attaquent très préférentiellement le carbonyle par la face β. Dans le cas de la cétone **7**, les carbanions $C^-(Cl_2)—CO_2$ isoprop. (8)[6] et

$(CH_3)_2—S—CH_2^-$ (9) attaquent exclusivement la face β. Il est donc raisonnable d'admettre que le carbanion $Ph—SO_2—C^-(Cl)R$ de structure et de taille assez voisines attaque les trois cétones **5**, **6** et **7** par la même face β et conduise aux époxysulfones **9** et **10** de configuration α (Schéma 1).

En ce qui concerne la cétone **8**, il n'existe dans la littérature que peu de données concernant la stéréochimie de l'attaque nucléophile du carbonyle en 3 d'un stéroïde en série A/B *cis* 5β. Toutefois, en comparant les résultats obtenus lors de la réduction par les hydrures et lors de l'addition de réactifs de Grignard (10), il semble raisonnable de conclure que, plus le réactif est volumineux, plus l'attaque α est favorisée. Selon cette séquence le carbanion $Ph—SO_2—C^-(Cl)CH_3$ devrait attaquer **8** par la face α et conduire à l'époxysulfone **11** de configuration β.

(b) *Ouverture des époxysulfones 3 sous l'action de $MgBr_2$*

Le mécanisme d'ouverture d'un époxyde sous l'action d'un acide de Lewis est généralement considéré comme un mécanisme limite: dans l'intermédiaire (ou dans l'état de transition) le carbone de la liaison C—O qui se rompt, possède un caractère carbocationique plus ou moins prononcé. Toutefois les réactions de substitution observées s'effectuent très sélectivement avec inversion (11). Selon ce mécanisme, l'attaque par $Br^-$ des époxysulfones **9**, **10** et **11** a donc lieu avec inversion de configuration et conduit aux cétones α-bromées comportant un brome équatorial (Schéma 1).

En ce qui concerne la formation parallèle des composés α-éthyléniques, il est intéressant de rapporter des observations antérieures rapportées par Durst *et al.* (1) puis par Taber et Gunn (12). Ces auteurs ont constaté que les époxysulfones **3** sous l'action de $BF_3$ dans l'éther, conduisent exclusivement aux composés carbonylés α-éthyléniques correspondants. L'observation de la même réaction, lorsque $MgBr_2$ est utilisé à la place de $BF_3$ n'est donc pas surprenante. Toutefois, la proportion substitution–élimination en fonction de la structure des époxysulfones **3** est, avec les données dont nous disposons, difficilement interprétable. Cependant à notre sens, il est bien clair que les deux époxysulfones isomères ont un com-

[3] En fait, dans leur texte, Durst *et al.* (1) ne précisent pas s'il y a ou non élimination compétitive à −30°C. En effet la nature des 10% manquant au bilan de la réaction n'est pas précisée. Nous avons montré que dans notre cas, il s'agit de 10% d'acétylcyclohexène.

[4] Seyden et coll. (6, 7*b*) ont montré sur un exemple analogue que, dans ces conditions réactionnelles, la cyclisation en époxyde de l'oxyanion intermédiaire est beaucoup plus rapide que sa transformation en produits de départ.

[5] Pour faciliter la discussion, nous avons étendu à la série cyclohexane monocyclique, la nomenclature α et β utilisée en série stéroïde (voir Schéma 1).

[6] L'attribution de l'halohydrine (2) doit être inversée (B. Castro, communication personnelle à J. Seyden; voir réf. 7*b*).

For personal use only.

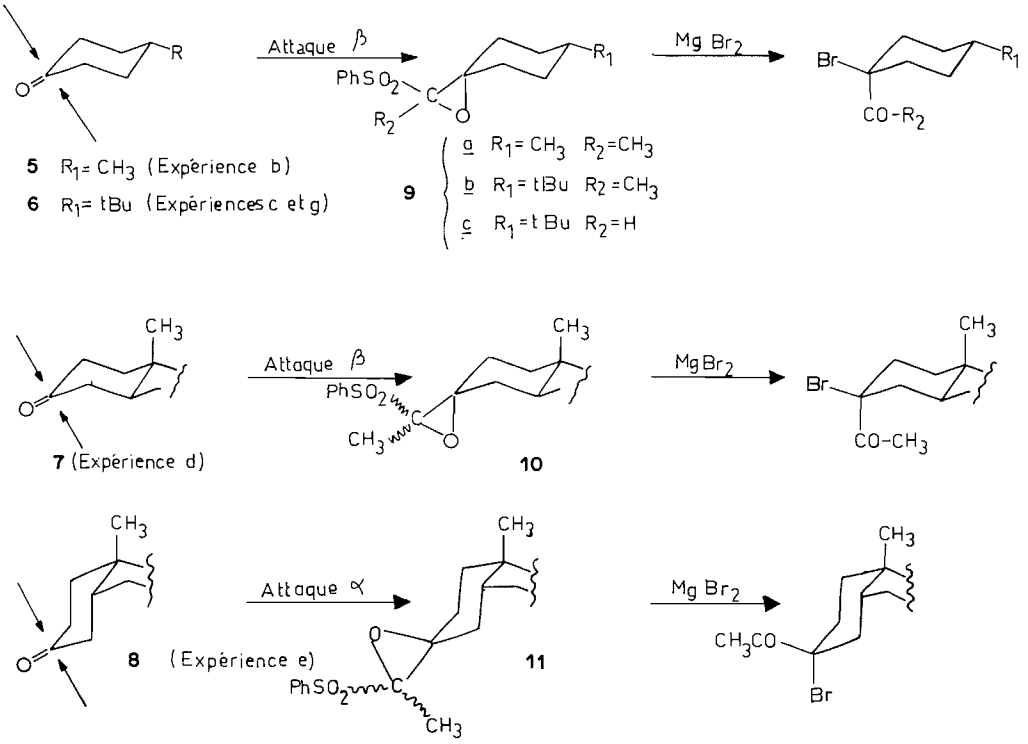

SCHÉMA 1

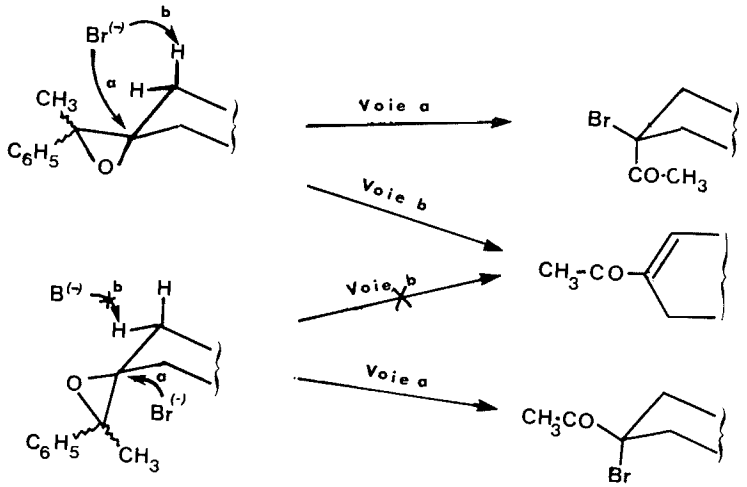

SCHÉMA 2

portement différent vis à vis de la réaction d'élimination (les deux cétones bromées sont stables dans les conditions de la réaction). L'époxysulfone majoritaire (provenant de l'attaque équatoriale) possède un hydrogène axial *trans* antipériplanaire à la liaison C—O, elle est donc susceptible de conduire à la cétone éthylénique (et à la cétone bromée à brome équatorial). Par contre, l'autre époxysulfone minoritaire (provenant de l'attaque axiale) doit conduire uniquement à la cétone bromée à brome axial.

Ceci est bien en accord avec le fait que le rapport entre les deux époxysulfones (> 90:10 dans le cas de **5** ou **6**) soit plus grand que celui entre les deux cétones bromées correspondantes (~ 85:15).

Cela veut donc dire que le degré de stéréosélectivité au niveau de la stéréochimie de l'attaque de la cétone par l'anion de la sulfone est supérieur ou

égal à la valeur des rapports des deux cétones bromées.

Le contraste frappant entre la série cyclohexane monocyclique et la série stéroïde ne conduisant, elle, qu'à une très faible proportion de composés éthyléniques, a récemment été confirmé par d'autres auteurs (13).

## Conclusion

Ce travail montre que la méthode de préparation de méthyle cétones α-bromées par ouverture d'époxysulfones sous l'action de $MgBr_2$ peut constituer pour ces composés une voie d'accès privilégiée et fortement stéréosélective, notamment en série stéroïde où la réaction secondaire d'élimination est très minoritaire.

## Partie expérimentale

*Commentaires généraux*

Les analyses par cpg ont été effectuées sur un appareil Girdel "75 FS" (colonne 1,60 m, Chromosorb 5% SE 30).

Les spectres rmn $^1H$ ont été enregistrés sur un spectromètre Varian T-60 ou A-60 D; les déplacements chimiques sont exprimés en ppm avec comme référence interne le TMS.

Les spectres rmn $^{13}C$ ont été enregistrés à 20 MHz sur un spectromètre Varian CFT-20, avec une largeur spectrale de 5000 Hz.

Les spectres ir (solvant $CCl_4$) ont été enregistrés sur un appareil Perkin–Elmer 157. Les pouvoirs rotatoires ont été mesurés avec un polarimètre Perkin–Elmer 141.

*Modes opératoires généraux*

1. *Époxysulfones*

Une quantité (0,024 mol) d'α-cholorophénylsulfone **1** (1) et 0,029 mol de cyclohexanone sont maintenues pendant 20 h sous agitation à température ambiante en présence de 20 mL de soude à 50% et 200 mg de sulfate acide de tetrabutylammonium. Après dilution dans l'eau, le mélange réactionnel est extrait avec $CH_2Cl_2$. La solution organique est lavée à l'eau, séchée sur $Na_2SO_4$, filtrée sur Florisil et évaporée sous pression réduite.

2. *Ouverture des époxysulfones par $MgBr_2$*

On prépare une solution de $MgBr_2$ et faisant réagir 5,50 g (0,23 mol) de Mg sur 37,6 g (0,2 mol) de dibromoéthane en solution dans 80 mL d'éther anhydre. On ajoute à cette solution refroidie à 0°C, 0,024 mol d'époxysulfone en solution dans 30 mL d'éther anhydre. Après 1 h sous agitation, la solution est hydrolysée ($H_2O$ + glace) puis décantée, séchée et évaporée.

*Description des expériences*

*Expérience **a***

L'expérience décrite par Durst *et al.* (1) a été répétée: il a été montré que le complément à 100% de cette réaction est la cyclohexényl-1 méthyle cétone (comparaison avec un échantillon authentique).

*Expérience **b***

*Époxysulfone* **9**a: 3,3 g (0,029 mol) de méthyl-4 cyclohexanone et 5 g (0,024 mol) de **1***a* conduisent à 6,5 g d'époxysulfone brute (85%); rmn $^1H$ ($CCl_4$) δ ppm: 1,0 (s, 3H, $CH_3$), 1,33 (m, 3H, $CH_3$), 7,6 (m, 3H) et 7,93 (m, 2H) ($C_6H_5$); rmn $^{13}C$, isomère très majoritaire, δ ppm: 15,3 (q, $CH_3$), 21,7 (q, $CH_3$-4), 69,9 (s, C-1), 79,4 (C—$SO_2$); isomère très minoritaire, δ ppm: 74,1 (s, C-1).

*Cétones bromées **12** et **13***: 6,5 g de **5***b* conduisent après traitement habituel et chromatographie sur une colonne de Florisil (pentane) à 1,74 g (38%) de **12** + **13** (**12/13** = 85:15, analyse cpg) et à 1,8 g (61%) de méthyl-4 cyclohexényl-1 méthyle cétone identifiée par rapport à un échantillon authentique. Composé **12**: ir ($CCl_4$): ν C=O: 1695 $cm^{-1}$; rmn $^1H$ ($CCl_4$) δ ppm: 0,88 (d, 3H, $CH_3$), 2,39 (s, 3H, $COCH_3$); rmn $^{13}C$ ($CDCl_3$) δ ppm: 206,4 (C=O), 68,5 (s, C-1), 37,4 (t, C-2), 33,4 (t, C-3), 30,8 (d, C-4), 23,9 ($COCH_3$), 21,3 (q, $CH_3$-4); *m/e*: 219 ($M^+$); sm (ion. chim., $C_4H_{10}$) *m/e*: 219 et 221 $(MH)^+$, 139 $(M - Br)^+$. Composé **13**: rmn $^1H$ ($CCl_4$) δ ppm: 1,0 (d, 3H, $CH_3$), 2,42 (s, 3H, $COCH_3$); rmn $^{13}C$ ($CDCl_3$) δ ppm: 72,5 (s, C-1), 35,5 (t, C-2), 31,5 (t, C-3), 30,5 (d, C-4), 24,4 ($COCH_3$), 21,9 (q, $CH_3$-4), C=O non visible; sm (ion. chim., $C_4H_{10}$) *m/e*: 219 et 221 $(MH)^+$, 139 $(M-Br)^+$.

*Expérience **c***

*Époxysulfone* **9**b: 3,6 g (0,023 mol) de 4-*t*Bu-cyclohexanone et 4 g (0,019 mol) de **1***a* conduisent à 4,6 g d'époxysulfone cristallisée (77%); rmn $^1H$ ($CCl_4$) δ ppm: 0,9 (s, 9H, *t*Bu), 1,43 (s, 3H, $CH_3$), 7,7 et 8,06 (m, 5H, $C_6H_5$); rmn $^{13}C$ ($CDCl_3$) δ ppm: 15,3 (q, $CH_3$), 25,1 (q, *t*Bu), 31,7 (d, C-2), 32,4 (s, $C(CH_3)_3$), 47,0 (d, C-4), 70,1 (s, C-1), 79,5 (*C*—$SO_2Ph$). Dans les eaux mères on isole un isomère minoritaire; rmn $^{13}C$: 15,3 (q, $CH_3$), 25,2 (t, C-3), 27,6 (q, *t*Bu), 30,9 (t, C-2), 32,4 (s, *C*—$CH_3)_3$), 46,7 (d, C-4), 72,0 (s, C-1), 79,4 (*C*—$SO_2$).

*Cétones bromées **14** et **15***: 4 g d'époxysulfone **9***b* brute, sous l'action de $MgBr_2$ conduisent après chromatographie sur Florisil (pentane) à 1,3 g (39%) de **4** + **15** (**14/15** = 90:10, analyse cpg) et à 0,99 g (42%) de 4*t*Bu-cyclohexenyl méthyle cétone. Les produits ont été identifiés par rapport à des échantillons authentiques (5, 14).

*Expérience **d***

*Époxysulfone **10***

Préparée à partir de 8,7 g d'androstan-5α-ol-17β-one-3 et de 6,2 g de **1***a*. Après traitement habituel, la solution finale $CH_2Cl_2$) est concentrée jusqu'à un volume d'environ 50 mL.

*Cétones bromées **16**, **17** et cétone α-éthylénique **18***

La solution précédente est ajoutée dans les conditions habituelles à $MgBr_2$. Après traitement, le produit est filtré sur Florisil (hexane–ether 80:20), concentré puis acétylé par 100 mL de pyridine et 20 mL d'anhydride acétique pendant 20 h. La mélange réactionnel est versé dans l'eau, le précipité est essoré et sèché. Le produit est chromatographié sur Florisil (hexane–$Et_2O$ 90:10); 5 g de **16** sont isolés (38%); on élue ensuite 0,9 g (8%) d'acétate de Δ-2 acétyl-3 androsténol-17β **18** (la cétone bromée **17**, très minoritaire, a pu être mise en évidence à l'état de traces). Composé **16**: pf = 171–172,5°C (EtOH); $R_f$ = 0,72 ($Et_2O$–hexane 40:60); $[\alpha]_{540}^{19}$ +24,8° ($CH_2Cl_2$); ir ($CCl_4$) ν(C=O): 1705 et 1730 $cm^{-1}$; rmn $^1H$ ($CDCl_3$) δ ppm: 0,73 (s, 3H, ME-18), 0,86 (s, 3H, Me-19), 1,99 (s, 3H, $OCOCH_3$), 2,35 (s, 3H, $COCH_3$), 4,53 (t, 1H, H-17); $^{13}C$ ($CDCl_3$) δ ppm: 67,9 (s, C-3), 170,9 ($OCOCH_3$), 201,6 ($COCH_3$). Composé **17**: $R_f$ = 0,56 ($Et_2O$–hexane 40:60); rmn $^{13}C$ ($CDCl_3$) δ ppm: 73,3 (s, C-3), 203,2 ($COCH_3$). Composé **18**: pf: 138–145°C (ether de pétrole); $R_f$ = 0,50 ($Et_2O$–hexane 40:60); $[\alpha]_{546}^{21}$ +3,86° ($CH_2Cl_2$); ir ν(C=O): 1735 et 1670 $cm^{-1}$; ν(C=C): 1640 $cm^{-1}$; rmn $^1H$ ($CDCl_3$) δ ppm: 0,70 (s, 3H, Me-18), 0,78 (s, 3H, Me-19), 2,02 (s, 3H, $OCOCH_3$), 2,26 (s, 3H, $COCH_3$), 4,57 (t, 1H, H-17), 6,8 (m, 1H, H-2); rmn $^{13}C$ ($CDCl_3$) δ ppm: 82,7 (d, C-17), 139,5 (d, C-2), 138,7 (d, C-3), 170,9 ($OCOCH_3$), 199,0 (*C*O—$CH_3$). *Anal.* calc. pour $C_{23}H_{35}O_3Br$: C 62,80, H 7,96, Br 18,18; trouvé: C 63,02, H 8,27, Br 52,52.

*Expérience **e***

*Époxysulfone **11***

Préparée à partir de 10 g d'acétate d'androstan-5β-ol-17β-one-3 et de 6,2 g de **1***a*. Comme dans l'expérience précédente **d**, l'époxysulfone n'a pas été isolée.

Reçu le 2 février 1982

PHIEO TA KIM, ROGER GUILARD et PATRICE RENAUT. Can. J. Chem. **60**, 2093 (1982).

La réaction de l'azidoacétate d'éthyle avec les formyl-6 chromannes, suivie par la cyclisation des azides obtenus conduit aux tetrahydro-1,7,8,9 pyranno[2,3-*g*]indoles et tetrahydro-2,3,4,8 pyranno[3,2-*f*]indoles. Quelques aspects de la réactivité chimique de ces nouveaux systèmes tricycliques sont décrits. Les structures de tous les composés synthétisés sont établies sur la base des données de rmn protonique.

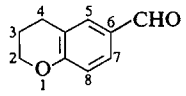
PHIEO TA KIM, ROGER GUILARD, and PATRICE RENAUT. Can. J. Chem. **60**, 2093 (1982).

Reaction of ethyl azidoacetate with 6-formylchromans, followed by cyclisation of the azides obtained, leads to 1,7,8,9-tetrahydropyrano[2,3-*g*]indoles and 2,3,4,8-tetrahydropyrano[3,2-*f*]indoles. Some aspects of the chemical reactivity of these new tricyclic systems are described. The structures of all products synthesized are established on the basis of $^1$H nmr data.

## Introduction

Les systèmes pyrannoindoliques ont été relativement peu étudiés et si un certain nombre de pyranno[*e*]indoles ont été décrits (1–4) depuis environ une décennie, ce n'est que très récemment que les pyranno[*b*]indoles ont été synthétisés (5, 6). Les méthodes préconisées pour l'accès aux pyranno[*e*] et [*b*] indoles ne pouvaient être utilisées pour la synthèse des pyranno[*f*] et [*g*] indoles que nous désirions préparer, ces produits pouvant servir de synthons pour l'obtention de composés à intérêt pharmacologique.[1]

Nous avons pensé que la réaction de Hemetsberger, utilisée avec succès pour la synthèse de nouveaux dérivés indoliques (7), pouvait au départ de formyl chromannes conduire à des pyrannoindoles. Nous nous sommes exclusivement intéressés aux produits porteurs d'un groupe aldéhyde en position 6:



Ces composés étaient *a priori* susceptibles de donner naissance soit à des pyranno[*f*]indoles soit à des pyranno[*g*]indoles.

Nous examinerons tout d'abord les modalités mises en œuvre pour l'accès aux pyrannoindoles recherchés et nous indiquerons ensuite quelques aspects de la réactivité chimique des produits obtenus.

[1]Les dérivés décrits dans ce mémoire font l'objet du brevet français no 80-14246 déposé en juin 1980.

## Synthèses

La série de transformations réalisée au départ des formyl-6 chromannes peut être ainsi schématisée (voir Schéma 1).

La condensation de l'azidoacétate d'éthyle sur les aldéhydes **1** s'effectue de façon classique en présence de méthanolate de sodium; le rendement de la réaction est de l'ordre de 50% et les azides obtenus se cyclisent partiellement au cours de la purification. La cyclisation est totale lorsqu'on traite à ébullition une solution xylénique (ou trichlorobenzénique) d'azide; cette réaction conduit toujours aux pyranno[*g*]indoles substitués **3**, cependant lors de la cyclisation de **2***b* ($R^1$ = Cl) on observe également la formation conjointe du pyranno[*f*]indole **4***b* ($R^1$ = Cl). L'hydrolyse des esters **3** et **4***b* donne naissance (rendement de 90%) aux acides correspondants **5** et **6***b* ($R^1$ = Cl). Leur décarboxylation effectuée selon des conditions classiques (chromite de cuivre activé au baryum comme catalyseur et quinoléine comme solvant) conduit aux pyrannoindoles **7** ou **8** avec des rendements de l'ordre de 60 à 80%. Toutefois au cours du traitement de l'acide **5***a* ($R^1$ = H) apparaît, conjointement au pyranno[*g*]indole attendu **7***a*, le pyranno[*f*]indole **8***a*. Les pourcentages respectifs en produits **7***a* et **8***a* sont de 90 et 10%. Toujours dans le cas où $R^1$ = H, les diverses méthodes d'analyse (rmn, ir ...) utilisées ne nous ont pas permis de mettre en évidence la formation d'un ester correspondant à un arrangement pyranno[*f*]indolique. L'apparition du dérivé **8***a* doit donc résulter soit d'une ouverture du cycle pyrrolique,

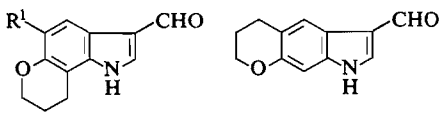
SCHÉMA 1

qui n'a jamais été observée lors des réactions de décarboxylation, soit plus vraisemblablement d'un réarrangement du cycle pyrannique.

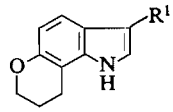
*Quelques aspects de la réactivité des hydropyranno[f ou g]indoles obtenus*

Les tétrahydropyranno[3,2-*f* ou 2,3-*g*]indoles éventuellement substitués en 9 ou 5, **7** et **8** ont été traités selon Vilsmeier; quel que soit le substrat pyrannoindolique de départ, un seul dérivé formylé est obtenu (dérivé **9** pour la série *g* et **10** pour la série *f*) avec un rendement de l'ordre de 40% et le groupe formyle se fixe sur le sommet β pyrrolique.



**9** $R^1 = H, Cl, OCH_3$ **10***a*

L'action du chlorure d'oxalyle sur **7***a* suivie de celle de la diméthylamine conduit au dérivé **11***a* avec un rendement global de 70%. La réaction de Mannich appliquée au même produit **7***a* permet d'obtenir **11***b* (rendement de 58%). Dans les deux cas l'on observe la substitution de l'hydrogène en β de l'atome d'azote.



**11***a*: $R^1 = COCON(CH_3)_2$
**11***b*: $R^1 = CH_2N(CH_3)_2$

## Établissement des structures

La structure de chacun des produits obtenus a pu être établie par analyse des spectres de rmn protonique. Les caractéristiques relevées pour les produits [*g*] et [*f*] ont été regroupées respectivement sur les tableaux 1 et 2.

Avant d'aborder l'analyse des spectres obtenus, rappelons les valeurs moyennes des glissements des protons pyranniques des chromannes situés en position α, β et γ de l'atome d'oxygène (8, 9): $\delta(CH_2)_\alpha \simeq 4{,}3$ ppm; $\delta(CH_2)_\beta \simeq 2{,}0$ ppm et $\delta(CH_2)_\gamma \simeq 2{,}8$ ppm. Les protons méthyléniques en α et γ de l'atome d'oxygène apparaissent sous la forme d'un triplet, ceux du méthylène en β sous celle d'un multiplet. Par ailleurs, les protons du noyau benzé-

For personal use only.

nique ne se différencient pas, tant pour les valeurs de leur déplacement chimique que pour celles de leurs constantes de couplage, de celles observées normalement en série benzénique; cependant on peut noter que de façon générale le proton H8 proche de l'atome d'oxygène est plus blindé que le proton H7.

L'interprétation des données de rmn des pyrannoindoles obtenus découle d'un examen comparatif des spectres des dérivés [*f*] et [*g*] et les pyrannoindoles non substitués **7***a* et **8***a* présentent des spectres caractéristiques de ces deux séries. Pour les deux composés étudiés les protons pyranniques apparaissent aux valeurs attendues soit $\delta(CH_2)_\alpha \simeq 4{,}2$, $\delta(CH_2)_\beta \simeq 2{,}0$ et $\delta(CH_2)_\gamma \simeq 2{,}8$ ppm. De plus et à moyenne résolution les signaux des protons méthyléniques en position α et γ par rapport à l'atome d'oxygène donnent bien un triplet, ceux de $(CH_2)_\beta$ un multiplet. En fait, à plus haute résolution on note, logiquement, que par suite de l'inéquivalence des protons des groupes méthyléniques chaque signal présente la morphologie d'un multiplet. Les protons α et β pyrroliques sont couplés entre eux, la constante de couplage observée correspond à celle signalée en série indolique ($J_{\alpha\beta} \simeq 3{,}2$ Hz) (*7d*, *7e*) et couplés avec l'hydrogène iminique avec des constantes de couplage de l'ordre de 2 Hz.

Les protons benzéniques des deux isomères se manifestent respectivement vers 7,3 et 6,7 ppm et quel que soit le composé envisagé, les protons benzéniques sont couplés entre eux: pour **7***a*, la constante de couplage est 8,6 Hz, c'est-à-dire celle d'un couplage "*ortho*", le produit est donc de type [*g*]; pour **8***a* la constante vaut 0,9 Hz soit celle de protons en "*para*" et le composé **8***a* est [*f*].

Les spectres obtenus au départ de l'un ou l'autre de ces pyrranoindoles présentent les caractéristiques indiquées précédemment, la position en 3 du substituant découlant du fait que le signal du proton pyrrolique restant est celui d'un proton α ($7{,}4 < \delta < 7{,}9$ ppm).

En ce qui concerne les pyrannoindoles obtenus au départ des formyl-6 chromannes substitués, le cycle benzénique ne porte plus qu'un atome d'hydrogène. La position du signal relatif à ce proton implique que l'hydrogène est en 5 pour un composé [*f*] et en 4 pour un produit [*g*]. Pour des composés [*g*] ne différant que par l'absence du proton 5 les déplacements chimiques observés pour H4 sont conformes à l'effet inductif de chacun des substituants et ne s'interprétent raisonnablement que si l'atome de chlore et le groupe méthoxy sont voisins du proton considéré. Cette déduction est confirmée par l'existence, pour les produits méthoxylés ($R^1 = OCH_3$), d'un faible couplage entre proton benzénique et protons méthyliques ($J \simeq 0{,}24$ Hz). En effet, ce couplage ($^5J$ classique ou interaction dans l'espace) apparaît sur les spectres des produits méthoxylés (**3***c*, **5***c*, **7***c*) et il ne peut logiquement se manifester que si l'atome d'hydrogène et le groupe méthoxy sont relativement proches, ce qui n'est réalisé que dans un arrangement [*g*].

La morphologie des spectres des composés **4***b*, **6***b* et **8***b* se rapproche de celle du composé [*f*] que nous avons analysé.

## Partie expérimentale

Les analyses élémentaires ont été effectuées par le Laboratoire Central de Microanalyse du C.N.R.S. Les spectres rmn ont été relevés sur un appareil JEOL FX 100 en utilisant le TMS comme référence interne et, sauf indication contraire, le DMSO-$d_6$ comme solvant. Le couplage des protons avec l'hydrogène iminique a été supprimé par ajout d'eau lourde. Les points de fusion ont été pris sur banc Kofler.

Certains produits de départ ont été préparés par les méthodes citées en référence: bromo-6 dihydro-3,4 2*H*-benzopyranne-1, (10), $Eb_{16}$ 141°C; cyano-6 dihydro-3,4 2*H*-benzopyranne-1, (11); formyl-6 dihydro-3,4 2*H*-benzopyranne-1, **1***a*, (réf. 12, et selon la méthode décrite dans réf. 13), $Eb_{20}$ 160–163°C; bromo-6 chloro-8 dihydro-2,3 4*H*-benzopyranne-1 one-4 (14), pf 109°C; bromo-6 méthoxy-8 dihydro-2,3 4*H*-benzopyranne-1 one-4 (14), pf 137°C.

*Bromo-6 chloro-8 dihydro-3,4 2*H*-benzopyranne-1*

À l'amalgame de zinc (préparé à partir de 1280 g (19,7 at. g.) de zinc, 128 g (0,54 mol) de chlorure mercureux, 64 cm³ d'acide chlorhydrique concentré et 1900 cm³ d'eau) on ajoute dans l'ordre 1000 cm³ d'eau, 1500 cm³ d'acide chlorhydrique concentré, 3500 cm³ de toluène et 640 g (2,45 mol) de bromo-6 chloro-8 chromannone-4. Le mélange est porté à reflux durant 1 h et après refroidissement et décantation il est extrait à l'éther et lavé à l'eau jusqu'à neutralité. On isole ainsi 305 g (50%) de bromo chloro chromanne, $Eb_{0,01}$ 128°C. *Anal.* calc. pour $C_9H_8OBrCl$: C 43,68, H 3,23, Br 32,29; trouvé: C 43,51, H 3,20, Br 31,98.

*Bromo-6 méthoxy-8 dihydro-3,4 2*H*-benzopyranne-1*

Selon le mode de préparation décrit pour le dérivé précédent, au départ de l'amalgame de zinc préparé à partir de 915 g (14 at. g.) de zinc, 91 g (0,38 mol) de chlorure mercureux dans 46 cm³ d'acide chlorhydrique concentré et 1350 cm³ d'eau, après ajout de 700 cm³ d'eau, 1100 cm³ d'acide chlorhydrique concentré, 2500 cm³ de toluène et 450 g (1,8 mol) de bromo méthoxy chromannone, on obtient 200 g (47%) de bromo méthoxy chromanne, pf 67°C. *Anal.* calc. pour $C_{10}H_{11}O_2Br$: C 49,42, H 4,52, O 13,16, Br 32,88; trouvé: C 49,41, H 4,42, O 13,96, Br 31,68.

*Chloro-8 dihydro-3,4 2*H*-benzopyranne-1 carbaldéhyde-6 **1**b*

À 72 g (0,29 mol) de bromo-6 chloro-8 chromanne dissous dans 250 cm³ d'éther anhydre sont ajoutés lentement et sous agitation à 0,29 mol de *n*-butyllithium dans 320 cm³ d'éther anhydre. La température est maintenue à −70°C durant 6 h puis on additionne goutte à goutte 31 g (0,38 mol) de *N*,*N*-diméthylformamide dissous dans 150 cm³ d'éther anhydre. Le mélange réactionnel est encore maintenu sous agitation à la même température durant 12 h puis, après retour à la température ambiante, il est versé sur de l'eau glacée. Après acidification avec l'acide chlorhydrique 5 *N*, extraction à l'éther et évapora-

For personal use only.

tion, on isole 54 g (95%) de **1***b*, pf 51°C. *Anal.* calc. pour $C_{10}H_9O_2Cl$: C 61,11, H 4,57, O 16,27, Cl 18,03; trouvé: C 61,20, H 4,60, O 16,37, Cl 17,99.

*Méthoxy-8 dihydro-3,4 2*H*-benzopyranne-1 carbaldéhyde-6* **1***c*

On procède selon la méthode décrite précédemment mais en maintenant la température à −50°C. Au départ de 186 g (0,77 mol) de bromo-6 méthoxy-8 chromanne dans 500 cm³ d'éther anhydre et de 0,77 mol de *n*-butyllithium dans 650 cm³ d'éther anhydre on isole après ajout de 78 g (1,1 mol) de *N*,*N*-diméthylformamide dans 200 cm³ d'éther anhydre et recristallisation dans l'éther isopropylique, 75 g (51%) de composé **1***c*, pf 81°C. *Anal.* calc. pour $C_{11}H_{12}O_3$: C 68,77, H 6,24, O 24,97; trouvé: C 69,00, H 6,37, O 25,15.

*Synthèses*

*Tétrahydro-1,7,8,9 pyranno[2,3-g]indolecarboxylate-2 de méthyle* **3**a

À une solution méthanolique de méthylate de sodium (1,4 g de Na (0,06 at. g.) dans 30 cm³ de méthanol absolu), on ajoute, à 0°C, 4,5 g (0,028 mol) de formyl-6 chromanne **1***a*, dissous dans 10 cm³ de méthanol absolu. On verse alors, goutte à goutte, à 0°C et sous agitation 7,2 g (0,056 mol) d'azidoacétate d'éthyle dans 10 cm³ de méthanol absolu. Après avoir maintenu la température durant 6 h à 0°C on verse le mélange réactionnel sur l'eau glacée et retient par filtration l'azide **2***a*. À 30 cm³ de xylène porté à ébullition, on ajoute sous agitation l'azide dissous dans 150 cm³ de xylène. L'addition terminée, agitation et reflux sont maintenus durant 5 h. Après élimination du xylène, le résidu solide obtenu est recristallisé dans un mélange éther isopropylique – benzène et on obtient 2,7 g (42%) du pyrannoindole **3***a*, pf 163°C. *Anal.* calc. pour $C_{13}H_{13}O_3N$: C 67,55, H 5,62, O 20,75, N 6,05; trouvé: C 67,60, H 5,74, O 20,75, N 6,05.

*Chloro-5 tétrahydro-1,7,8,9 pyranno[2,3-g]indolecarboxylate-2 de méthyle* **3**b *et chloro-9 tétrahydro,2,3,4,8 pyranno [3,2-f]indolecarboxylate-7 de méthyle* **4**b

Selon la méthode décrite pour l'obtention du composé précédent et au départ de 16 g (0,69 at. g.) de Na dissous dans 600 cm³ de méthanol absolu, 59 g (0,3 mol) du chloroformyl chromanne **1***b* dans 250 cm³ de méthanol absolu et 77 g (0,6 mol) d'azidoacétate d'éthyle dans 100 cm³ de méthanol absolu, on isole 44 g d'azide **2***b*. Une fraction du composé précédent (5 g (0,017 mol)) est dissoute dans 100 cm³ de trichloro-1,2,4 benzène et ajouté à 150 cm³ de trichloro-1,2,4 benzène portés à 110°C. Le mélange est agité et maintenu à 110°C durant 20 min. Après élimination du solvant, on ajoute quelques cm³ d'éthanol et un solide jaune apparaît (2,28 g). Les eaux mères sont évaporées et le résidu chromatographié sur acide silicique (éluant: toluène – acétate d'éthyle 4:1). Or, après recristallisation dans l'alcool éthylique, on isole 2,27 g d'ester méthylique **3***b*, fraction identique au solide jaune précédent (55,5% globalement), pf 238°C et 0,99 g (22%) d'ester méthylique **4***b*, pf 130°C. *Anal.* calc. pour $C_{13}H_{12}O_3NCl$: C 58,79, O 18,06, N 5,27, Cl 13,34; trouvé pour **3***b*: C 58,73, O 18,35, N 5,39, Cl 13,46; trouvé pour **4***b*: C 59,39, N 5,28, Cl 13,42.

*Méthoxy-5 tétrahydro-1,7,8,9 pyranno[2,3-g]indolecarboxylate-2 de méthyle* **3**c

Selon le mode de préparation décrit pour **3***a* et à partir de 19 g (0,8 at. g.) de Na dissous dans 1250 cm³ de méthanol absolu, 73 g (0,38 mol) de méthoxy formyl chromanne **1***c* dans 50 cm³ de méthanol et 98 g (0,76 mol) d'azidoacétate d'éthyle dans 100 cm³ de méthanol, on isole l'azide **2***c*. Après cyclisation de l'azide dans le xylène, on obtient 38 g (38%) d'ester **3***c*, pf 231°C. *Anal.* calc. pour $C_{14}H_{15}O_4N$: C 64,39, H 5,74, O 24,49, N 5,36; trouvé: C 64,35, H 5,85, O 24,27, N 5,17.

*Acide tétrahydro-1,7,8,9 pyranno[2,3-g]indolecarboxylique-2* **5**a

On porte à reflux durant 3 h 30 une solution de 17 g (0,074 mol) d'ester **3***a* et 8,3 g (0,15 mol) de KOH dans 300 cm³ d'eau. Après retour à la température ambiante, acidification à 0°C par l'acide chlorhydrique 5 *N*, le précipité obtenu est filtré, lavé à l'eau jusqu'à neutralité et recristallisé dans un mélange éthanol–eau. On isole 13,2 g (83%) d'acide **5***a*, pf 228°C. *Anal.* calc. pour $C_{12}H_{11}O_3N$: C 66,38, H 5,06, O 22,09, N 6,44; trouvé: C 66,50, H 5,20, O 22,12, N 6,43.

*Acide chloro-5 tétrahydro-1,7,8,9 pyranno[2,3-g]indolecarboxylique-2* **5**b

On procède selon la méthode précédente; au départ de 22,6 g (0,085 mol) d'ester **3***b*, 14 g (0,26 mol) de potasse dans 300 cm³ d'eau, on obtient 20 g (93%) d'acide **5***b*, pf 308°C. *Anal.* calc. pour $C_{12}H_{10}O_3NCl$: C 57,29, H 3,97, O 19,07, N 5,56, Cl 14,09; trouvé: C 57,11, H 4,07, O 19,20, N 5,67, Cl 13,71.

*Acide chloro-9 tétrahydro-2,3,4,8 pyranno[3,2-f]indolecarboxylique-7* **6**b

Selon la même méthode et à partir de 5 g (0,019 mol) d'ester **4***b* dans 15 cm³ de méthanol et 3,2 g (0,055 mol) de soude dans 30 cm³ d'eau, on obtient 4,52 g (95%) d'acide **6***b*, pf (déc.) 270°C.

*Acide méthoxy-5 tétrahydro-1,7,8,9 pyranno[2,3-g]indolecarboxylique-2* **5**c

Selon la même méthode et à partir de 10 g (0,038 mol) d'ester **3***c* dans 150 cm³ de méthanol et 6,4 g (0,11 mol) de potasse dans 15 cm³ d'eau portés à ébullition durant 1 h 30, on isole 9,3 g (98%) d'acide **5***c*, pf 268°C. *Anal.* calc. pour $C_{13}H_{13}O_4N$: C 63,18, H 5,26, O 25,88, N 5,66; trouvé: C 63,12, H 5,33, O 26,00, N 5,82.

*Tétrahydro-1,7,8,9 pyranno[2,3-g]indole* **7**a *et tétrahydro-2,3,4,8 pyranno[3,2-f]indole* **8**a

On chauffe à 190–195°C durant 7 h 30 120 cm³ de quinoléine distillée, 5 g (0,023 mol) d'acide **5***a* et 0,08 g de chromite de cuivre. Après retour à la température ambiante, on retient le catalyseur par filtration, étend par le chloroforme et élimine la quinoléine par lavage à l'acide chlorohydrique 5 *N*. La phase chloroformique est ensuite lavée à l'eau jusqu'à neutralité, évaporée et le résidu obtenu est chromatographié sur acide silicique (éluant: chloroforme–hexane 2:1). On isole après évaporation des fractions d'élution convenables et recristallisation dans l'éther isopropylique 3,3 g (83%) du pyranno[*g*]indole **7***a*, pf 115°C et 0,3 g (7%) du pyranno[*f*]indole isomère **8***a*, pf 97°C. *Anal.* calc. pour $C_{11}H_{11}ON$: C 76,32, H 6,35, O 9,23, N 8,08; trouvé pour **7***a*: C 76,87, H 6,54, O 9,36, N 8,00; trouvé pour **8***a*: C 75,67, H 6,51, O 9,16, N 8,03.

*Chloro-5 tétrahydro-1,7,8,9 pyranno[2,3-g]indole* **7**b

Selon la même méthode et au départ de 9 g (0,036 mol) d'acide **5***b*, 0,18 g de chromite de cuivre dans 240 cm³ de quinoléine, après chromatographie sur acide silicique (éluant: chloroforme) et recristallisation dans un mélange éther isopropylique – hexane, on isole 5,5 g (74%) du pyranno[2,3-*g*]indole **7***b*, pf 108°C. *Anal.* calc. pour $C_{11}H_{10}ONCl$: C 63,65, H 4,81, O 7,70, N 6,74, Cl 17,08; trouvé: C 63,82, H 4,93, O 7,98, N 6.80, Cl 17,18.

*Chloro-9 tétrahydro-2,3,4,8 pyranno[3,2-f]indole* **8**b

Selon la même méthode et au départ de 1,2 g (0,0048 mol) d'acide **6***b*, 0,18 g de chromite de cuivre dans 6 cm³ de quinoléine, après chromatographie sur acide silicique (éluant: hexane–acétone 7:4) et recristallisation dans l'alcool éthylique, on isole 0,45 g (45%) du pyranno[3,2-*f*]indole **8***b*, pf 117°C. *Anal.* calc. pour $C_{11}H_{10}ONCl$: C 63,65, H 4,81, N 6,74; trouvé: C 63,74, H 4,83, N 6,73.

*Méthoxy-5 tétrahydro-1,7,8,9 pyranno[2,3-g]indole* **7**c

De même, mais avec une durée de décarboxylation réduite (4 h), à partir de 12 g (0,049 mol) d'acide **5***c*, 0,24 g de chromite de cuivre et 240 cm³ de quinoléine, après chromatographie sur acide silicique (éluant: chloroforme) et recristallisation dans le benzène, on isole 6 g (60%) du produit **7***c*, pf 138°C. *Anal.* calc. pour $C_{12}H_{13}O_2N$: C 70,96, H 6,40, O 15,74, N 6,89; trouvé: C 71,03, H 6,42, O 15,89, N 6,79.

*Tétrahydro-1,7,8,9 pyranno[2,3-g]indolecarbaldéhyde-3* **9**a

À 0,3 g (0,002 mol) d'oxytrichlorure de phosphore dans 0,12 g (0,0016 mol) de *N,N*-diméthylformamide, on verse à 5°C 10 cm³ de dichloro-1,2 éthane puis 0,27 g (0,0015 mol) du pyranno[*g*]indole **7***a* dissous dans 10 cm³ de dichloro-1,2 éthane. Le mélange est maintenu à 5°C durant 2 h 30 puis porté à reflux pendant 30 min. Après refroidissement on ajoute 1,2 g (0,009 mol) d'acétate de sodium trihydraté dissous dans 10 cm³ d'eau et on porte à ébullition 15 min. Après retour à la température ambiante, neutralisation, lavage à l'eau, on obtient, après recristallisation dans l'éthanol, 0,2 g (64%) de l'aldéhyde **9***a*, pf 232°C; rmn (DMSO-$d_6$, $D_2O$) δ: 8,50 (m, $J_{12}$ = 2,93 et $J_{14}$ = 0,73, H1), 7,72 (d, $J_{12}$ = 2,93 Hz, H2), 9,99 (s, $H_a$), 7,88 (m, $J_{14}$ = 0,73, $J_{45}$ = 8,61 et $J_{49}$ = 0,73 Hz, H4), 6,83 (d, $J_{45}$ = 8,61 Hz, H5), 4,23 (m, $(CH_2)_7$), 2,13 (m, $(CH_2)_8$), 2,87 (m, $(CH_2)_9$). *Anal.* calc. pour $C_{12}H_{11}O_2N$: C 71,66, H 5,46, O 15,90, N 6,96; trouvé: C 71,55, H 5,41, O 15,87, N 7,01.

*Tétrahydro-2,3,4,8 pyranno[3,2-f]indolecarbaldéhyde-6* **10**a

En mettant en œuvre les modalités opératoires précédentes, à partir de 0,2 g (0,0013 mol) d'oxytrichlorure de phosphore, 0,09 g (0,0012 mol) de *N,N*-diméthylformamide, 0,2 g (0,0011 mol) de l'isomère [*f*] **8***a* et 1 g (0,007 mol) d'acétate de sodium trihydraté, on isole, après recristallisation dans le benzène, 0,075 g (31%) de l'aldéhyde **10***a*, pf 195°C; rmn (DMSO-$d_6$, $D_2O$) δ: 8,77 (m, $J_{12}$ = 3,11 et $J_{14}$ = 0,73, H1) 7,70 (d, $J_{12}$ = 3,11 Hz, H2), 9,94 (s, $H_a$), 7,96 (m, $J_{14}$ = 0,73 et $J_{49}$ = 0,92 Hz, H4), 6,82 (2d, $J_{49}$ = 0,92 Hz, H9), 2,96 (m, $(CH_2)_5$), 2,03 (m, $(CH_2)_6$), 4,21 (m, $(CH_2)_7$). *Anal.* calc. pour $C_{12}H_{11}O_2N$: C 71,66, H 5,46, O 15,90, N 6,96; trouvé: C 71,85, H 5,53, O 15,94, N 7,03.

*Chloro-5 tétrahydro-1,7,8,9 pyranno[2,3-g]indole-carbaldéhyde-3* **9**b

À partir de 0,3 g (0,002 mol) d'oxytrichlorure de phosphore, 0,12 g (0,0016 mol) de *N,N*-diméthylformamide dans 10 cm³ de dichloro-1,2 éthane et 0,3 g (0,00145 mol) de pyranno[*g*]indole chloré **7***b*, on obtient après chromatographie sur acide silicique (éluant: chloroforme–acétone 3:1) et recristallisation dans un mélange benzène–hexane 0,1 g (29%) de l'aldéhyde **9***b*, pf 214°C; rmn (DMSO-$d_6$, $D_2O$) δ: 7,73 (d, $J_{23}$ = 2,93 Hz, H2), 9,98 (s, $H_a$), 8,16 (m, H4), 4,36 (m, $(CH_2)_7$), 2,18 (m, $(CH_2)_8$), 2,98 (m, $(CH_2)_9$). *Anal.* calc. pour $C_{12}H_{10}O_2NCl$: C 61,18, H 4,24, N 5,94, Cl 15,04; trouvé: C 59,81, H 4,34, N 5,91, Cl 14,68.

*Méthoxy-5 tétrahydro-1,7,8,9 pyranno[2,3-g]indole-carbaldéhyde-3* **9**c

On opère de même au départ de 0,3 g (0,00147 mol) de pyranno[*g*]indole méthoxylé **7***c*, on isole après chromatographie sur acide silicique (éluant: chloroforme–acétone 3:1) et recristallisation dans le benzène 0,11 g (31%) de l'aldéhyde **9***c*, pf 107°C; rmn (DMSO-$d_6$, $D_2O$) δ: 8,91 (m, $J_{12}$ = 3,22 et $J_{14}$ = 0,73 Hz, H1), 7,69 (d, $J_{12}$ = 3,22 Hz, H2), 9,96 (s, $H_a$), 7,62 (m, $J_{14}$ = 0,73 et $J_{4\text{-}OCH_3}$ = 0,29 Hz, H4), 3,94 (d, $J_{4\text{-}OCH_3}$ = 0,29 Hz, $OCH_3$), 4,32 (m, $(CH_2)_7$), 2,14 (m, $(CH_2)_8$), 2,88 (m, $(CH_2)_9$). *Anal.* calc. pour $C_{13}H_{13}O_3N$: C 67,55, H 5,62, O 20,75, N 6,05; trouvé: C 67,08, H 5,57, O 20,84, N 6,00.

*Tétrahydro-1,7,8,9 pyranno[2,3-g]indolyl-3* N,N-*diméthylglyoxamide* **11**a

À 1 g (0,0057 mol) de pyranno[*g*]indole **7***a* dans 25 cm³ d'éther anhydre, on verse, sous courant d'azote et à 0°C, une solution de 1 cm³ de chlorure d'oxalyle dans 5 cm³ d'éther anhydre. On maintient 30 min à 0°C puis porte 15 min à reflux; après refroidissement à 0°C on ajoute rapidement une solution de diméthylamine jusqu'à ce que le milieu réactionnel soit basique. On abandonne 12 h à température ambiante, filtre le précipité apparu et le recristallise dans le méthanol. On isole 1,1 g (70 %) du dérivé oxamoylé **11***a*, pf 290°C; rmn (DMSO-$d_6$, $D_2O$) δ: 11,91 (m, H1), 7,91 (s, H2), 2,88 et 2,98 (s, $N(CH_3)_2$), 7,78 (d, $J_{45}$ = 8,61 Hz, H4), 6,69 (d, $J_{45}$ = 8,61 Hz, H5), 4,15 (m, $(CH_2)_7$), 2,00 (m, $(CH_2)_8$), 2,92 (m, $CH_2)_9$). *Anal.* calc. pour $C_{15}H_{16}O_3N_2$: C 66,20, H 5,87, N 10,28; trouvé: C 65,33, H 6,06, N 10,06.

*Tétrahydro-1,7,8,9 pyranno[2,3-g]indolyl-3* N,N-*diméthylamine* **11**b

On porte à ébullition durant 3 jours un mélange de 0,46 g (0,0057 mol) de formaldéhyde à 37%, 0,65 g (0,0057 mol) de diméthylamine à 40% et 1 g (0,0057 mol) de pyrannoindole **7***a* dans 30 cm³ de méthanol. Après évaporation du solvant, dissolution du produit huileux obtenu dans l'acétate d'éthyle, on traite par l'acide chlorhydrique 5 *N*, lave au chloroforme et rend la phase aqueuse alcaline par ajout de soude à 20%. On extrait alors par l'éther et isole 0,77 g (58%) d'une huile **11***b*; rmn (DMSO-$d_6$, $D_2O$) δ: 11,21 (m, H1), 7,38 (d, $J_{23}$ = 2,38 Hz, H2), 2,71 (s, $N(CH_3)_2$), 4,36 (s, $CH_2N$), 7,43 (d, $J_{45}$ = 8,61 Hz, H4), 6,58 (d, $J_{45}$ = 8,61 Hz, H5), 4,12 (m, $(CH_2)_7$), 2,46 (m, $(CH_2)_8$), 2,82 (m, $(CH_2)_9$). On ajoute 0,8 g (0,0034 mol) d'acide picrique dissous dans 15 cm³ d'éthanol à température ambiante, agite durant 12 h le mélange réactionnel, filtre le précipité formé, le lave à l'éthanol et obtient ainsi 1,4 g (93%) de picrate, pf 160°C. *Anal.* calc. pour $C_{20}H_{21}O_8N_5$: C 52,31, H 4,57, O 27,86, N 15,24; trouvé: C 52,33, H 4,53, O 27,99, N 15,28.

# Synthèse d'oxopyranno[*g*]indoles

PHIEO TA KIM, PANAYOTIS COCOLIOS ET ROGER GUILARD

*Laboratoire de Synthèse et d'Electrosynthèse organométallique associé au C.N.R.S., Faculté des Sciences "Gabriel", 21100 Dijon, France*

Reçu le 2 février 1982

PHIEO TA KIM, PANAYOTIS COCOLIOS et ROGER GUILARD. Can. J. Chem. **60**, 2099 (1982).

La réaction de l'azidoacétate d'éthyle avec les formyl-6 chromannones, suivie par la cyclisaton des azides obtenus conduit aux dihydro-7,8 pyranno[2,3-*g*] 1*H*-indolone-9. Un aspect de la réactivité de ces nouveaux systèmes tricycliques est décrit. La structure des composés isolés au cours des diverses synthèses réalisées est précisée par spectroscopie rmn protonique.

PHIEO TA KIM, PANAYOTIS COCOLIOS, and ROGER GUILARD. Can. J. Chem. **60**, 2099 (1982).

Reaction of ethyl azidoacetate with 6-formyl-4 chromanones, followed by cyclization of the azides obtained leads to 7,8-dihydropyrano[2,3-*g*]indol-9 (1*H*)-one. One aspect of the chemical reactivity of these new tricyclic systems is described. The structure of the compounds isolated from various syntheses is established by proton nmr data.

Si les pyranno[*f* et *g*]indoles (1) apparaissaient aptes à conduire à des composés susceptibles de présenter une activité pharmacologique intéressante, il en était de même des oxopyranno[*f* ou *g*]indoles et nous avons cherché à synthétiser ces composés au départ des chromannones-6 via la réaction de Hemetsberger. La plupart des synthons nécessaires à la réalisation de ce travail étaient inconnus, notre premier objectif a été de les préparer.

## Synthèses

Nous décrivons ici la préparation des synthons indispensables à notre étude; le Schéma 1 ci-dessous rend compte du mode de synthèse utilisé pour accéder aux formyl-6 chromannones. La bromation des phénols orthosubstitués **1** conduit exclusivement aux dérivés trisubstitués **2**; ces composés soumis à l'action de la β-propiolactone en milieu alcalin permettent d'accéder aux acides **3**. La cyclisation de ces acides en chromannones est totale lorsqu'on traite à ébullition la solution benzénique des acides **3** en présence du mélange $P_2O_5$–$H_3PO_4$. Le groupe carbonyle des chromannones **4** est alors bloqué à l'etat de dioxolanne, l'action ultérieure du *n*-butyllithium suivie de celle du diméthylformamide conduit aux aldéhydes dioxolannes **6**. La fonction carbonyle de ces derniers composés est libérée par traitement acide et l'on isole les chromannones formylées en 6, **7**, le rendement de chacune des transformations étant compris entre 80 et 90%.

En présence de méthanol, l'azidoacétate d'éthyle ne se condense pas sur les aldéhydes **7**, il se forme les hémiacétals **8**. Aussi, avons-nous mis en oeuvre les aldéhydes dioxolanes **6**, les trans-

formations alors effectuées pouvant être ainsi traduites:

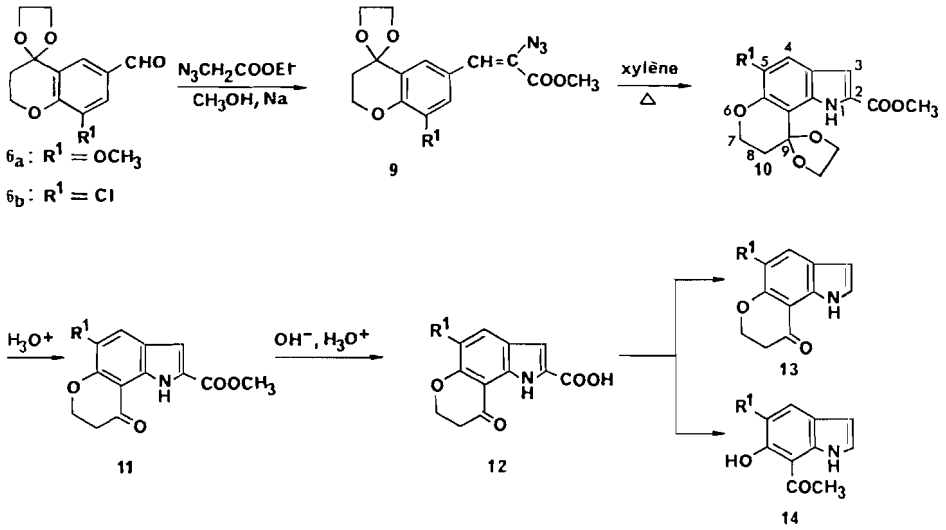

SCHÉMA 2

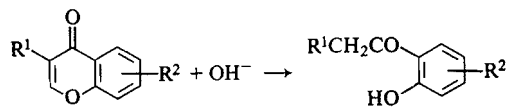
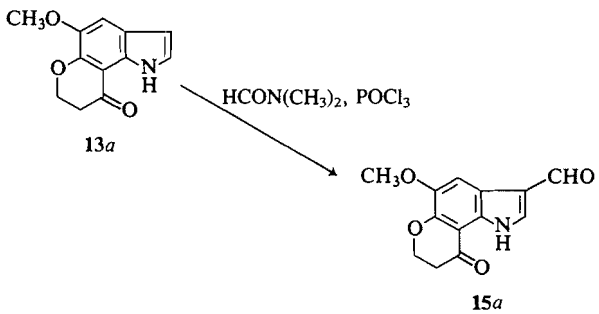
Les composés **6** se condensent aisément sur l'azidoacétate d'éthyle et les azides obtenus **9** se cyclisent totalement en les composés **10**. Après avoir libéré la fonction carbonyle, l'hydrolyse des esters **11** conduit avec un rendement voisin de 90% aux acides **12**. Lorsque le cycle benzénique porte un groupe méthoxy, la décarboxylation de l'acide **12***a* s'effectue dans de bonnes conditions (60%) et donne naissance à l'oxopyrannoindole attendu **13***a*, mais il se forme également le dérivé indolique trisubstitué en 5, 6, 7, **14***a*; les proportions relatives des produits **13***a* et **14***a* sont respectivement de 92 et 8%. Si le substituant en 5 est un atome de chlore, apparaît exclusivement l'indole trisubstitué **14***b*. Par élévation de température le cycle pyrannique des acides **12** a donc tendance à s'ouvrir et ce résultat est à rapprocher de celui observé lors de l'hydrolyse alcaline des chromones (2) selon:



La mise en évidence de la formation d'une cétone benzénique orthohydroxylée après hydrolyse est d'ailleurs considérée comme un test de caractérisation des chromones.

Nous avons examiné un des aspects de la réactivité chimique des oxopyranno[*g*]indoles. Traité selon Vilsmeier, le méthoxy-5 dihydro-7,8 pyranno[2,3-*g*] 1*H*-indolone-9 **13***a* conduit à l'aldéhyde **15***a* selon:



Le groupe formyle se fixe exclusivement sur le sommet β pyrrolique et, comme dans le cas des trihydropyrannoindoles (1), la réactivité du squelette indolique ne semble pratiquement pas affectée par la présence du cycle hydropyrannique orthocondensé au cycle benzénique.

### Établissement des structures

La structure des divers produits préparés a été établie sur la base des données de l'analyse élémentaire et des résultats de rmn protonique. L'ensemble des caractéristiques de rmn observées est regroupé sur le Tableau 1.

Les spectres de rmn des oxopyrannoindoles ont été interprétés sur la base des données de rmn de la chromannone-4 et de ses dérivés de substitution (3–6). Les protons méthyléniques en 2 résonnent vers 4,5 ppm et ceux en 3 vers 2,8 ppm (solvant $CDCl_3$) et l'ensemble donne un système $A_2X_2$. Les signaux des protons benzéniques s'observent à 8,0 ppm pour $H_5$, à 7,6 ppm pour $H_6$ et vers 7,2 pour $H_7$ et $H_8$, le déblindage de $H_5$ étant raisonnablement

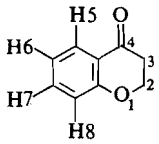
*s, singulet; d, doublet; m, multiplet.
†Spectres relevés en utilisant le DMSO-$d_6$ comme solvant.



attribuable à l'effet électroaccepteur du carbonyle en *péri*. Les protons pyranniques des produits que nous avons préparés présentent bien ces caractéristiques (voir Tableau 1) et les protons pyrroliques sont couplés entre eux ($J_{23} \simeq 3{,}22$ Hz) et avec $H_1$ ($J_{12} \simeq 2{,}3$ et $J_{13} \simeq 2{,}1$ Hz).

## Partie expérimentale

Les analyses élémentaires ont été effectuées par le Laboratoire Central de Microanalyse du C.N.R.S. Les spectres rmn ont été relevés sur un appareil JEOL FX 100 en utilisant le TMS comme référence interne et, sauf indication contraire, le $CDCl_3$ comme solvant. Le couplage des protons pyrroliques avec l'hydrogène iminique a été supprimé par ajout d'eau lourde. Les points de fusion ont été pris sur banc Kofler.

*Matières premières*

Les produits de départ ont été préparés par les méthodes citées en référence: bromo-4 méthoxy-2 phénol **2***a* (7, 8), $Eb_{16}$ 133°C, pf 36–37°C; bromo-4 chloro-2 phénol **2***b* (8), pf 48–49°C.

*Préparation des synthons*

*Acide (bromo-4 méthoxy-2 phénoxy-1)-3 propionique* **3**a

On porte à ébullition un mélange de 203 g (1 mol) de bromo-4 méthoxy-2 phénol **2***a* et 40 g (1 mol) de soude dans 400 cm³ d'eau. Après 15 min d'ébullition on ajoute lentement 72 g (1 mol) de β-propiolactone et maintient l'ébullition durant 50 min. Après refroidissement on acidifie le mélange réactionnel par 100 cm³ d'acide chlorhydrique concentré, extrait le produit à l'éther et lave la phase organique jusqu'à neutralité. On isole, après évaporation du solvant 216 g (79%) de l'acide **3***a*, pf 98°C. *Anal.* calc. pour $C_{10}H_{11}O_4Br$: C 43,67, H 4,00, O 23,26; trouvé: C 43,54, H 3,94, O 22,67.

*Acide (bromo-4 chloro-2 phénoxy-1)-3 propionique* **3**b

Selon la même méthode 311 g (1,5 mol) de bromo-4 chloro-2 phénol **2***b* et 60 g (1,5 mol) de soude dans 600 cm³ d'eau permettent d'obtenir 126 g (30%) de l'acide **3***b*, pf 125°C. *Anal.* calc. pour $C_9H_8O_3BrCl$: C 38,68, H 2,86, O 17,16; trouvé: C 38,72, H 2,83, O 17,25.

*Bromo-6 méthoxy-8 dihydro-2,3 4H-benzopyranne-1 one-4* **4**a

On ajoute, à 0°C, 34 g (0,35 mol) d'acide phosphorique dans un mélange contenant 475 cm³ de benzène anhydre et 56 g (0,4 mol) d'anhydride phosphorique. Après avoir porté 4 h à ébullition on additionne, lentement, 83 g (0,3 mol) d'acide **3***a*. Le mélange est maintenu à ébullition durant 12 h puis, après refroidissement, versé sur l'eau glacée, traité par l'acide chlorhydrique 5 *N* et extrait à l'éther. Après traitement habituel et recristallisation du solide obtenu dans l'éthanol, on isole 67 g (86%) de la chromannone **4***a*, pf 137°C. *Anal.* calc. pour $C_{10}H_9O_3Br$: C 46,73, H 3,50, O 18,66, Br 31,09; trouvé: C 46,74, H 3,53, O 18,76, Br 31,30.

*Bromo-6 chloro-8 dihydro-2,3 4H-benzopyranne-1 one-4* **4**b

On porte durant 2 h à 70–80°C, un mélange de 279 g (1 mol) de l'acide **3***b* et 127 g (1,3 mol) d'acide sulfurique concentré. Le mélange réactionnel est ensuite versé sur l'eau glacée, extrait à l'éther, lavé avec une solution diluée d'ammoniaque puis à l'eau. On obtient finalement 183 g (70%) de chromannone-4 **4***b*, pf 109°C. *Anal.* calc. pour $C_9H_6O_2BrCl$: C 41,34, H 2,29, O 12,23; trouvé: C 41,32, H 2,41, O 12,14.

*Dioxolanne de la bromo-6 méthoxy-8 dihydro-2,3 4H-benzopyranne-1 one-4* **5**a

Un mélange de 10 g (0,039 mol) de chromannone-4 **4***a*, 24 g (0,39 mol) d'éthylène glycol et 0,3 g (0,0017 mol) d'acide paratoluènesulfonique dans 200 cm³ de toluène anhydre est porté à ébullition durant 7 h dans un appareil Dean et Stark. Le mélange réactionnel est ensuite versé sur l'eau glacée, extrait à l'éther et le solide obtenu est recristallisé dans un mélange alcool éthylique–éther. On obtient 9,6 g (82%) du dioxolanne **5***a*, pf 104°C. *Anal.* calc. pour $C_{12}H_{13}O_4Br$: C 47,88, H 4,31, O 21,25, Br 26,54; trouvé: C 47,87, H 4,53, O 21,39, Br 26,44.

*Dioxolanne de la bromo-6 chloro-8 dihydro-2,3 4H-benzopyranne-1 one-4* **5**b

De même 30 g (0,11 mol) de chromannone-4 **4***b*, 71 g (1,1 mol) d'éthylène glycol et 0,2 g (0,0011 mol) d'acide paratoluènesulfonique dans 200 cm³ de toluène conduisent après recristallisation dans un mélange benzène–éther isopropylique à 34 g (97%) du dioxolanne **5***b*, pf 94°C. *Anal.* calc. pour $C_{11}H_{10}O_3BrCl$: C 43,25, H 3,27, O 15,75; trouvé: C 43,20, H 3,21, O 15,60.

*Dioxolanno-4 méthoxy-8 dihydro-2,3 4H-benzopyranne-1 carbaldéhyde-6* **6**a[1]

À 177 g (0,59 mol) de dioxolanne **5***a* (177 g, 0,59 mol) dissous dans 500 cm³ d'éther anhydre est ajouté lentement à −70°C 0,59 mol de *n*-butyllithium dans 570 cm³ d'éther anhydre. Après addition, on maintient le milieu durant 6 h à −70°C et ajoute goutte à goutte 56 g (0,77 mol) de *N,N*-diméthylformamide dissous dans 300 cm³ d'éther anhydre. Le mélange réactionnel est maintenu durant 12 h à −70°C puis après retour à la température ambiante versé sur l'eau glacée. Après extraction au chloroforme, recristallisation du solide obtenu dans l'éthanol, on isole 133 g (90%) de l'aldéhyde dioxolanne **6***a*, pf 167°C.

*Chloro-8 dioxolanno-4 dihydro-2,3 4H-benzopyranne-1 carbaldéhyde-6* **6**b[1]

En opérant de même à partir de 45 g (0,15 mol) du dioxolanne **5***b*, on obtient après recristallisation dans le benzène 31 g (84%) de l'aldéhyde dioxolanne **6***b*, pf 133°C.

*Méthoxy-8 oxo-4 dihydro-2,3 4H-benzopyranne-1 carbaldéhyde-6* **7**a

À 34 g (0,14 mol) du dioxolanne **6***a* dans 700 cm³ d'alcool éthylique on ajoute, lentement et à température ambiante, 90 cm³ d'acide chlorhydrique concentré. Le mélange est maintenu sous agitation durant 1 h, puis versé sur l'eau glacée et extrait à l'éther. Après recristallisation du solide obtenu dans l'alcool éthylique on obtient 26 g (91%) de l'aldéhyde méthoxylé **7***a*, pf 139°C. *Anal.* calc. pour $C_{11}H_{10}O_4$: C 64,10, H 4,85, O 31,03; trouvé: C 64,48, H 4,91, O 30,06.

*Hémiacétal du méthoxy-8 oxo-4 dihydro-2,3 4H-benzopyranne-1 carbaldéhyde-6* **8**a

À une solution méthanolique de méthylate de sodium (3 g de Na (0,13 at. g.) dans 200 cm³ de méthanol absolu), on ajoute, à 0°C, 8,7 g (0,042 mol) de l'aldehyde **7***a* puis, goutte à goutte, 16 g (0,12 mol) d'azidoacétate d'éthyle dans 30 cm³ de méthanol absolu. Le mélange réactionnel est maintenu durant 6 h à 0°C puis versé sur l'eau froide et acidifié par l'acide chlorhydrique 5 *N*. Après extraction par le chloroforme, chromatographie sur colonne d'acide silicique (éluant: chloroforme) et recristallisation dans un mélange benzène–hexane, on obtient 4,8 g (41%) d'hémiacétal **8***a*, pf 110°C. *Anal.* calc. pour $C_{12}H_{14}O_5$: C 60,53, H 5,88, O 33,58; trouvé: C 60,47, H 6,13, O 33,37.

[1]Les dérivés **6***a* et **6***b* ont pu être isolés à l'état de pureté analytique (points de fusion, rmn ...); cependant par suite de leur instabilité due à l'hydrolyse de la fonction dioxolanne, les résultats des analyses élémentaires ne sont pas corrects.

*Méthoxy-5 oxo-9 dihydro-7,8 pyranno[2,3-g]indolecarboxylate-2 de méthyle* ***11****a*

À 0,7 g (0,03 at. g.) de Na dans 30 cm³ de méthanol absolu on ajoute 3 g (0,012 mol) d'aldéhyde dioxolanne **6***a* et 3,7 g (0,029 mol) d'azidoacétate d'éthyle dans 10 cm³ de méthanol absolu. On maintient 7 jours à 0°C et extrait à l'éther. L'azide obtenu **9***a* est ensuite dissous dans 70 cm³ de xylène portés à ébullition durant 3 h et le produit cyclisé ainsi obtenu **10***a* est traité après dissolution dans 50 cm³ d'éthanol par 5 cm³ d'acide chlorhydrique concentré. On abandonne durant 18 h et isole après recristallisation dans le benzène 0,52 g (16%) de l'ester **11***a*, pf 188°C. *Anal.* calc. pour $C_{14}H_{13}O_5N$: C 61,12, H 4,72, O 29,06, N 5,08; trouvé: C 60,87, H 4,63, O 29,29, N 5,10.

*Chloro-5 oxo-9 dihydro-7,8 pyranno[2,3-g]indolecarboxylate-2 de méthyle* ***11****b*

À partir de 26 g de l'aldéhyde dioxolanne **6***b* et selon le protocole expérimental décrit pour la préparation du produit précédent, on obtient après cyclisation de l'azide **9***b* (temps de reflux 8 h) et hydrolyse du dioxolanne ester **10***b* 15 g (54%) de l'ester **11***b*, pf 194°C (recristallisation dans le benzène). *Anal.* calc. pour $C_{13}H_{10}O_4NCl$: C 55,85, H 3,57, O 22,88, N 5,00, Cl 12,68; trouvé: C 55,92, H 3,76, O 22,86, N 5,04, Cl 12,84.

*Acide méthoxy-5 oxo-9 dihydro-7,8 pyranno[2,3-g]indolecarboxylique-2* ***12****a*

En utilisant une méthode de saponification classique à partir de 34 g (0,12 mol) d'ester **11***a* et 14 g (0,25 mol) de potasse dans 700 cm³ d'eau, on isole 30 g (93%) d'acide **12***a*, pf 312°C. *Anal.* calc. pour $C_{13}H_{11}O_5N$: C 59,80, H 4,21, O 30,62, N 5,36; trouvé: C 58,93, H 4,29, O 30,87, N 5,31.

*Acide chloro-5 oxo-9 dihydro-7,8 pyranno[2,3-g]indolecarboxylique-2* ***12****b*

De même 26 g (0,093 mol) d'ester **11***b* permettent l'obtention de 27 g (90%) d'acide **12***b*, pf 227–230°C. *Anal.* calc. pour $C_{12}H_8O_4NCl$: C 54,27, H 3,01, O 24,08, N 5,27; trouvé: C 54,24, H 3,67, O 24,75, N 4,95.

*Méthoxy-5 dihydro-7,8 pyranno[2,3-g] 1H-indolone-9* ***13****a et acétyl-7 hydroxy-6 méthoxy-5 indole* ***14****a*

À partir de 31 g (0,12 mol) d'acide **12***a* et 0,77 g de chromite de cuivre dans 500 cm³ de quinoléine, on isole après 13 h de réaction, chromatographie sur acide silicique (éluant: chloroforme) et recristallisation dans le benzène, 14 g (54%) de pyrannoindole **13***a*, pf 123°C. *Anal.* calc. pour $C_{12}H_{11}O_3N$: C 66,38, H 5,06, O 22,09, N 6,44; trouvé: C 66,39, H 5,08, O 22,27, N 6,32.

On obtient conjointement, après recristallisation dans un mélange benzène–hexane, 1,1 g (4,3%) de dérivé indolique **14***a*, pf 130°C; rmn (DMSO-$d_6$, $D_2O$) δ: 10,02 (m, $J_{12}$ = 2,38, $J_{13}$ = 2,19 et $J_{15}$ = 0,73 Hz, H1), 7,11 (2d, $J_{12}$ = 2,38 et $J_{23}$ = 3,22 Hz, H2), 6,33 (2d, $J_{23}$ = 3,22 et $J_{13}$ = 2,19 Hz, H3), 7,40 (d, $J_{15}$ = 0,73 Hz, H5), 10,88 (m, OH), 3,84 (s, $OCH_3$), 2,69 (s, $COCH_3$). *Anal.* calc. pour $C_{11}H_{11}O_3N$: C 64,41, H 5,36, O 23,39, N 6,82; trouvé: C 64,45, H 5,42, O 23,50, N 6,73.

*Acétyl-7 chloro-5 hydroxy-6 indole* ***14****b*

La décarboxylation de 2,7 g (0,01 mol) de l'acide **12***b* conduit, après chromatographie sur acide silicique (éluant: hexane–chloroforme 1:2) puis recristallisation dans un mélange benzène–hexane–éther isopropylique à 0,11 g (5%) du dérivé indolique **14***b*, pf 150°C; rmn (DMSO-$d_6$, $D_2O$) δ: 11,04 (m, $J_{12}$ = 2,38, $J_{13}$ = 2,19 et $J_{15}$ = 0,73 Hz, H1), 7,26 (2d, $J_{12}$ = 2,38 et $J_{23}$ = 3,22 Hz, H2), 6,45 (2d, $J_{13}$ = 2,19 et $J_{23}$ = 3,22 Hz, H3), 7,92 (d, $J_{15}$ = 0,73 Hz, H5), 11,86 (m, OH), 2,78 (s, $COCH_3$). *Anal.* calc. pour $C_{10}H_8O_2NCl$: C 57,31, H 3,81, O 15,26, N 6,68, Cl 16,91; trouvé: C 57,71, H 4,16, O 15,16, N 6,68, Cl 16,91.

*Méthoxy-5 oxo-9 dihydro-7,8 pyranno[2,3-g]indolecarbaldèhyde-3* ***15****a*

Selon les modalités opératoires de la réaction de Vilsmeier et au départ de 0,4 g (0,0018 mol) du produit **13***a* on obtient, après chromatographie sur acide silicique (éluant chloroforme–acétone 3:1) puis recristallisation dans un mélange éthanol–benzène–hexane 0,19 g (42%) d'aldéhyde **15***a*, pf 236°C. *Anal.* calc. pour $C_{13}H_{11}O_4N$: C 63,70, H 4,48, O 26,09, N 5,71; trouvé: C 63,42, H 4,61, O 25,81, N 5,70.

# Apparent octanol/water partition coefficients of pentachlorophenol as a function of pH

KLAUS L. E. KAISER AND ILZE VALDMANIS

*Environmental Contaminants Division, National Water Research Institute, Burlington, Ont., Canada L7R 4A6*

Received October 6, 1981

KLAUS L. E. KAISER and ILZE VALDMANIS. Can. J. Chem. **60**, 2104 (1982).

The apparent 1-octanol/water partition coefficient (log $P_{App}$) of pentachlorophenol (PCP) varies in non-linear function with pH of the aqueous solution. In the range of pH 1.2 to 13.5 extreme values of log $P_{App}$ 4.84 at pH 1.2 and log $P_{App}$ 1.3 at pH 10.5 were observed. In the alkaline regime, log $P_{App}$ increases strongly with the ionic strength. The ion-corrected partition coefficient of PCP was found to be log $P$ 5.05 in good agreement with literature values.

KLAUS L. E. KAISER et ILZE VALDMANIS. Can. J. Chem. **60**, 2104 (1982).

Le coefficient de partage apparent entre octanol-1/eau, log $P_{app}$, du pentachlorophénol (PCP) varie d'une façon non-linéaire avec le pH de la solution aqueuse. Dans l'intervalle de pH de 1,2 à 13,5, les valeurs extrêmes sont log $P_{app}$ = 4,84 à un pH de 1,2 et de log $P_{app}$ = 1,3 à un pH de 10,5. En régime alcalin, le log $P_{app}$ augmente fortement avec la force ionique. Pour le PCP, on a trouvé que le coefficient de partage corrigé pour les ions est le log $P$ 5,05 qui est en bon accord avec les valeurs publiées dans le littérature.

Partition coefficients (log $P$) of organic solutes in the 1-octanol/water system are very useful physicochemical parameters for the correlation and prediction of the solutes' biological activities (1). The fungicidal properties of pentachlorophenol (PCP) and its resistance to degradation make it an important wood preservative (2). Consequently, it is frequently found to be present in industrial waste water effluents and has been observed as contaminant of water, sediment, and biota of many lakes and rivers (2, 3).

The rates of biological magnification of contaminants correlate with their effective partition coefficients (4). For ionizing compounds, such as PCP, the effective or apparent partition coefficient (log $P_{App}$)[1] is pH dependent. Therefore, it is of interest to determine log $P_{App}$ for the wide range of pH as found in the waste effluents and receiving waters. This paper reports on such measurements for PCP in 1-octanol/water over a range of pH 1.2 to 13.5.

## Experimental

*Materials*

Pentachlorophenol (Aldrich, Gold Label, lot #081587 KC) was twice recrystallized from ethanol/water. 1-Octanol (MCB, Reagent Grade) was fractionated over a 0.6 m glass column; the distillate of bp 194 to 195°C was collected and found free of impurities by gas chromatography – flame ionization detector. Double distilled water was passed through a mixed bed of Amberlite XAD-4 and XAD-8 resins to remove trace organic impurities. Purity was checked by extraction with hexane and gas chromatography on a 3% Dexsil-300 column at 175°C with an electron capture detector. Other solvents were of pesticide grade, acetic anhydride (ANALAR, double distilled), sulfuric acid (ARISTAR).

*Standards and procedure*

Octanol-saturated water and water-saturated octanol were prepared by stirring mixtures of 200 mL octanol with 10 mL water and of 200 mL water with 2 mL octanol, respectively, for 1 h at high speed, centrifugating each mixture for 1.5 h at 2300 rpm and removing the excess octanol, respectively water, with a Pasteur pipette.

A 250 mL stock solution of pentachlorophenol (PCP) in water-saturated octanol was prepared with a PCP concentration of 1.0 mg/mL. This stock solution was diluted with water-saturated 1-octanol to give stock solutions of 0.100 mg/mL PCP (*A*) and 0.010 mg/mL PCP (*B*) in octanol. As standards for the recovery tests, 10 mL volumes of 20.0 mg/mL PCP (*C*) and 0.2 mg/mL PCP (*D*) were also prepared.

The pH of 2 L of octanol-saturated water was determined with a pH meter and adjusted to the desired value with $H_2SO_4$ or NaOH solution. To each four of eight 200 mL aliquots in 250 mL centrifuge flasks, 2.0 mL stock solution *A*, or 10.0 mL stock solution *B* were added. The flasks were covered with acetone-washed aluminum foil, stirred at high speed for 1 h, centrifugated at 2300 rpm for 1.5 h, and allowed to stand for 12 h. After removal of octanol layers with glass pipettes, the aqueous phases were transferred to 250 mL Erlenmeyer flasks and approximately 1.0 g solid NaOH added to each. After dissolution, 1.5 mL acetic anhydride and 5.0 mL toluene were added to each. The flasks were covered with aluminum foil, sealed with screw top caps, stirred gently for 1 h, then at high speed for 0.2 h. The toluene layers were separated with glass pipettes and analyzed directly.

*Analysis*

The toluene phases were analyzed for PCP-acetate by gas chromatography of 1.0 μL volumes, in some cases after dilution with toluene, using a Tracor Microtek 220 with a 1.8 m × 3.1 mm (i.d.) glass column packed with 3% Dexsil-300 on Gas Chrom O and $^{63}Ni$ electron capture detector. The operating conditions were: carrier gas, prepurified $N_2$ at 66 mL/min flow; detector purge gas, 5% $CH_4$ in Ar at 10 mL/min flow; temperatures: injector, 240°C; column, 175°C isothermal; detector, 295°C. The

[1]Normally, the partition coefficients (log $P$), also for ionizing compounds are determined for the non-ionized solute species only. The apparent partition coefficients (log $P_{App}$), as reported here, represent the distribution of the sums of both ionized and non-ionized solute molecules between the two phases of the test system.

chromatograms were recorded with both a Hewlett-Packard strip chart recorder and a Spectra-Physics SP-4000 data system.

In separate tests, the recovery of PCP as PCP-acetate was determined for several PCP concentrations in the aqueous phase. The recovery was found to be 35.5% with a standard deviation of 1.9%. All test data were corrected for this recovery rate and the concentrations of PCP in the octanol phases were determined by difference. As the determination of $P_{App}$ at each pH value, each octanol/water ratio, and each PCP concentration was made in duplicate, the mean of those data pairs were calculated for each test condition. The means and standard deviations reported in Table 1 are those of the four duplicate means at each pH level. The mean of the relative standard deviations of all 136 tests was found to be 10.7%.

## Results and discussion

The apparent octanol/water partition coefficients of PCP were determined at 16 selected pH values between pH 1.2 and 13.5. At each pH value, the four concentrations of 0.02, 0.1, 0.2, and 1.0 mg PCP per test system of 200 mL water and 2 or 10 mL octanol were tested in duplicate. In general, the duplicate measurements were within 5% of each other. Over the entire pH range, the apparent partition coefficient varies by more than three orders of magnitude between log $P_{App}$ 4.84 and 1.30. The means of the duplicate determinations for each pH value and test system are given in Table 1. Except possibly in the range of pH 1.2 to 4.7, no significant differences are found between the test systems with the lower (*A*, *B*) and those with the higher (*C*, *D*) PCP concentrations. This indicates

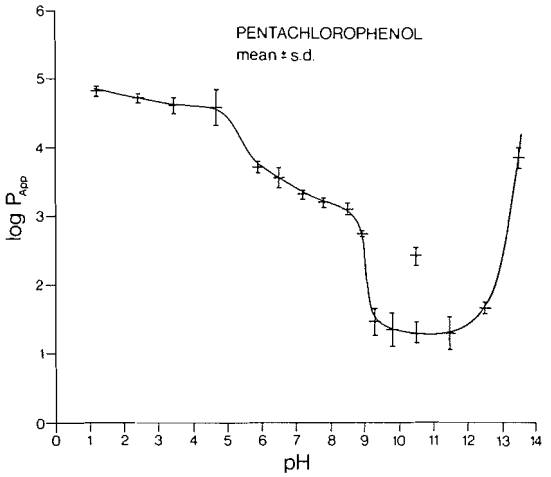

FIG. 1. Apparent octanol/water partition coefficient of pentachlorophenol vs. pH of the aqueous phase. Means and standard deviations of eight determinations in four test systems at each pH value given. The single, high value at pH 10.5 observed at high ionic strength ($\mu = 1.0$).

the absence of any appreciable association of the solute molecules in the organic phase as generally known to occur at higher concentrations. Therefore, the results for the four test systems were combined to the means ± s.d. at each of the pH values and are also given in Table 1.

As is to be expected, the apparent partition coefficient of PCP varies strongly with the pH of its aqueous solution. Figure 1 shows the means and standard deviations of log *P* vs. pH, using the data of Table 1. In the range of pH 1 to 5, the apparent partition coefficient declines slightly from log $P_{App}$ 4.84 to ≈4.5. At increasing values above pH 5, the apparent partition coefficient of PCP is declining more steeply, presumably this is caused by the ionization of this weak acid ($pK_a$ 4.8). At pH ≈9, another strong decrease of log $P_{App}$ is found for a relatively small increase in the pH. The cause of this drop, approximately 1.5 log *P* units, is not clear at this time. According to the general relation between ionization, $pK_a$ and pH (5), at pH 9, PCP is ionized in excess of 99.99% compared with 99.94% of pH 8. This minor change in ionization cannot account for the observed change in log $P_{App}$. Hypotheses which may explain the phenomenon include a change in the specific PCP–octanol solvation complex (6) or the formation of PCP–sodium complexes. The apparent partition coefficient of PCP reaches a minimum of log $P_{App}$ ≈ 1.3 at approximately pH 10.5. Further increase of pH results in a steeply increasing coefficient. At the highest pH investigated, pH 13.5, the partition

coefficient rose to log $P_{App}$ 3.9. This strong rise appears to result from the increase in ionic strength of the aqueous solution with pH. This interpretation is supported by a separate determination of the partition coefficient at pH 10.5 at the higher ionic strength of $\mu$ 1.0 which results in log $P_{App} \approx 2.4$ compared to log $P_{App}$ 1.3 at $\mu \approx 0.01$.

In literature, several values are reported for the ion-corrected partition coefficient of PCP. Values for the 1-octanol/water system are log $P$ 5.01 and log $P$ 5.12 (1), log $P$ 5.86 (7), and log $P$ 3.81 (4). We observed the highest log $P_{App}$ values in the range of pH 3.4 to 1.2. In this pH range, results of the test system $D$ (Table 1) are likely to be more accurate than those of $A$ to $C$ due to the analytical constraints as the PCP concentration in the aqueous phase approached $10^{-10}$ $M$ (0.2 $\mu$g $L^{-1}$). As it has been suggested to measure log $P$ at least 4 pH units away from the p$K$ values (1), it may be reasonable to calculate the partition coefficient for the non-ionized PCP for pH 0.8 from the data for the test system $D$ at the three lowest pH values measured (Table 1). This extrapolation results in log $P$ 5.05 which appears in good agreement with the data presently considered to be most reliable (1).

Our results demonstrate the strong dependence of the apparent partition coefficient of PCP on the pH and, in basic medium, on the ionic strength. As pH and ionic strengths of effluents containing PCP as well as those of the receiving waters vary widely, the environmental effects and pathways of ionizing compounds such as PCP may vary accordingly. In particular, it would appear that the bioconcentration factors, which generally correlate well with the partition coefficients (4, 8), could vary between different aquatic systems by several orders of magnitude. Specifically, the observed variation of log $P_{App}$ of PCP will affect fugacity calculations (9) and may also explain the disagreement between the experimental bioconcentration factor and that calculated from the partition coefficient of the un-ionized PCP moiety (8, 10).

# Fragmentations des cétones aliphatiques métastables. II.[1] Compétition entre éliminations de radicaux hydrocarbonés et d'alcanes.

GUY BOUCHOUX ET YANNIK HOPPILLIARD

*Laboratoire de Synthèse Organique, École Polytechnique, 91128, Palaiseau Cedex, France.*

Reçu le 18 décembre 1981

GUY BOUCHOUX et YANNIK HOPPILLIARD. Can. J. Chem. **60**, 2107 (1982).

Les fragmentations des ions moléculaires métastables de six cétones aliphatiques sont étudiées. Les ions $[M - R^{\bullet}]$ et [M–RH] ($R^{\bullet}$ étant une chaîne latérale à la fonction carbonyle) sont formés par des mécanismes pour lesquels l'énergie d'activation de la réaction retour ($\Delta H_R^0$) est nulle. Seuls les ions moléculaires de la méthyléthylcétone et de la méthylisopropylcétone n'évoluent pas conformément aux prédictions thermodynamiques: les ions fragments détectés $[M–CH_3^{\bullet}]$ ne correspondent pas à l'état final le plus stable. Ce résultat est expliqué ici en terme de durée de vie de l'ion moléculaire.

GUY BOUCHOUX and YANNIK HOPPILLIARD. Can. J. Chem. **60**, 2107 (1982).

The fragmentation of the metastable molecular ions of six aliphatic ketones is studied. The ion fragment abundances $[M - R^{\bullet}]$ and [M–RH] ($R^{\bullet}$ being a lateral radical) can be predicted from the thermochemical stability of the corresponding final states. Exceptions to this behavior are found for metastable molecular ions of methylethylketone and methylisopropylketone where it is demonstrated that the lifetime of these ions is too short to permit significant decompositions via the low energy channel after $10^{-5}$ s.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

Les fragmentations des cétones aliphatiques métastables peuvent conduire aussi bien à des ions à nombre pair d'électrons $[M - R^{\bullet}]$ qu'aux ions radicaux $[M - C_nH_{2n}]^{\bullet+}$ et $[M - C_nH_{2n+2}]^{\bullet+}$. Le radical hydrocarboné $R^{\bullet}$ éliminé n'est pas nécessairement une des chaînes adjacentes à la fonction carbonyle. Ainsi la pentanone-2 (1), l'hexanone-2 (2, 3) et les méthyl cétones isomères (3) éliminent un radical méthyle dont l'origine n'est pas exclusivement la position 1.

Les ions $[M - C_nH_{2n}]^{\bullet+}$ sont généralement issus d'un réarrangement de McLafferty, tandis que l'alcane éliminé pour conduire à l'ion $[M - C_nH_{2n+2}]^{\bullet+}$ contient une des chaînes latérales complétée par un atome d'hydrogène.

Les résultats présentés ici concernent six cétones (**1–6**, schéma 1) qui possèdent la particularité d'être inaptes à engendrer des ions $[M - C_nH_{2n}]^{\bullet+}$.

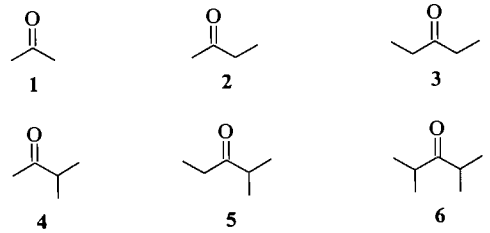

SCHÉMA 1

En effet, seules les réactions d'élimination des chaînes latérales sont observées sur les spectres des ions **1–6** métastables (Tableau 1). Elles se produisent, soit par simple rupture d'une liaison carbone–carbone ($M^{\bullet+} \rightarrow [M - R^{\bullet}]^+$), soit simultanément au transfert d'un atome d'hydrogène ($M^{\bullet+} \rightarrow [M - RH]^{\bullet+}$); cette dernière réaction étant généralement plus facile que l'élimination du radical R correspondant.

Les caractéristiques énergétiques de ces deux réactions compétitives sont présentées dans les deux premiers paragraphes de cette étude. Il est ainsi établi que les ions **1–6** métastables produisent les fragments possédant la meilleure stabilité thermodynamique. Deux ions moléculaires (**2** et **4**) semblent néanmoins faire exception à cette règle, l'examen de leur situation sera complété par une étude particulière.

## *I. Fragmentation $M^{\bullet+} \rightarrow [M - R^{\bullet}]^+$*

De nombreux résultats expérimentaux (4–6) démontrent que l'état de transition de la fragmentation $M^{\bullet+} \rightarrow [M - R^{\bullet}]^+$ possède une enthalpie de formation voisine de celle de l'état final $[M - R]^+ + R^{\bullet}$. Ces résultats sont en faveur d'une élimination du radical $R^{\bullet}$ des cétones ionisées **1–4** par simple rupture d'une liaison carbone–carbone.

Le premier type d'argument est apporté par la valeur de l'énergie cinétique $T$ de séparation des fragments. Pour l'acétone **1** la distribution expérimentale de $T$ est reproduite par un calcul statistique dans lequel il est implicitement admis que le $\Delta H_f^0$ de l'état de transition est égal à celui de l'état final $[CH_3CO]^+ + CH_3^{\bullet}$ (4, 5).

La valeur de $T$ n'a donc pour origine que l'excès d'énergie vibrationnelle de l'ion métastable, au-dessus de l'état de transition. La largeur à

[a] Technique MIKE, spectrométrie VG.ZAB.2F.
[b] L'erreur relative sur les valeurs de $T_{0,5}$ est de l'ordre de 5%.
[c] Un ion $m/z$ 58 est également détecté (≈ 20%), son origine est attribuée à une fragmentation de McLafferty après isomérisation de **4** en pentanone-2 (réf. 1). Notons que le réarrangement de la chaîne isopropyle en *n*-propyle ne peut pas être suspecté pour **5** et **6** puisqu'aucune élimination de 28 unités de masse n'est observée à partir de ces cétones.
[d] Référence 7.
[e] Référence 8.

mihauteur $T_{0,5}$ de la fonction de distribution de $T$, est une valeur de comparaison commode. Dans le cas de l'acétone $T_{0,5} \leq 15$ meV (5), des valeurs de $T_{0,5}$ similaires sont associées aux éliminations des radicaux $CH_3$, $C_2H_5$ et même $iC_3H_7$ des cétones **2**, **3** et **4** (Tableau 1).

Le second élément en faveur de la formation directe des ions acylium $[RCO]^+$ est leur grande stabilité. Les valeurs expérimentales des $\Delta H_f^0$ montrent que les ions $[CH_3CO]^+$ et $[C_2H_5CO]^+$ sont plus stables que leurs isomères (9, 10), leur apparition est donc privilégiée. En ce qui concerne les ions $[C_4H_7O]^+$, le $\Delta H_f^0$(exp) de $[(CH_3)_2CHCO]^+$ (556 kJ mol$^{-1}$) est peu éloigné de celui de $[CH_2CHC(OH)CH_3]^+$ (569 kJ mol$^{-1}$, réf. 11).

L'élimination d'un $CH_3^{\bullet}$ à partir du groupement isopropyle de l'ion **4** est exclue, un calcul MINDO/3 situe l'ion$[CH_3CHCOCH_3]^+$ 201 kJ mol$^{-1}$ au-dessus de l'ion $[(CH_3)_2CHCO]^+$.

Le troisième apport expérimentale est la détermination des énergies d'apparition des ions $[RCO]^+$. La récente investigation de Maccol (6) démontre clairement que les méthylcétones ionisées, de faible énergie interne, produisent directement les ions acylium.

Notons enfin la caractérisation de la structure $[CH_3CO]^+$ par son spectre de décomposition induite par collision (12). Il est ainsi démontré que l'ion fragment $C_2H_3O$ est le même qu'il soit issu de **1** ou de **2**.

Cet ensemble de résultats démontre donc que les cétones **1**–**4** conduisent par un mécanisme simple à l'état final $[M-R^{\bullet}]^+ + R^{\bullet}$.

Aucune élimination de radical n'est observée sur le spectre des composés **5** et **6**. La fragmentation correspondante est éclipsée par la réaction $M^{\bullet+} \rightarrow [M-RH]^{\bullet+}$.

*II. Fragmentation* $M^{\bullet+} \rightarrow [M-RH]^{\bullet+}$

La substitution isotopique des hydrogènes occupant les positions α (schéma 2) met en

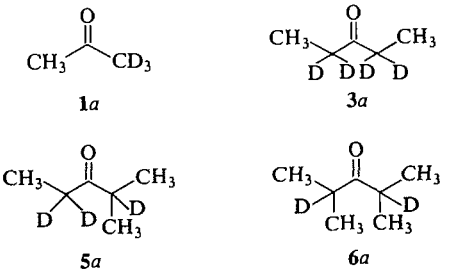

SCHÉMA 2

évidence la grande spécificité de cette réaction ainsi que l'absence à peu près complète d'échanges d'hydrogène avant la fragmentation. Lifshitz et Tzidony (6) observant des éliminations de $CH_3$, $CH_3D$, $CD_3$ et $CD_3H$ à partir de **1***a* dans les proportions 16:1, 1:5:77. Un effet isotopique notable est donc associé à l'élimination de méthane mais aussi à celle du radical méthyle. Une étude de Cooks *et al.* (13) mentionne que **3***a* élimine $CD_3CH_3$ avec une spécificité de l'ordre de 95%. Enfin le Tableau 2 rassemble les résultats obtenus ici pour les composés **5***a* et **6***a*. Il s'avère là encore que seuls les hydrogènes des positions α sont impliqués dans le mécanisme de fragmentation, les échanges d'hydrogène entre les positions α et β sont inférieurs à 1% dans le cas de **5** et à 6% pour **6**.

TABLEAU 2. Spectres de masse des cétones deutériées **5***a* et **6***a* métastables[a]

For personal use only.

La spécificité de cette réaction suggère un mécanisme concerté dont une représentation est donnée sur le schéma 3:

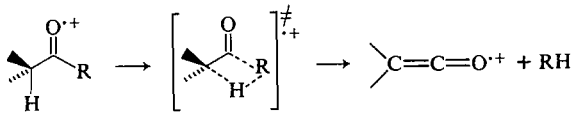

SCHÉMA 3

L'évolution vers un état final constitué d'un céténe ionisé et d'un alcane est également la plus favorable au sens thermodynamique. Les enthalpies standards de formation de quelques ions $[C_nH_{2n-2}O]^{\bullet+}$ sont présentées sur le Tableau 3. Les valeurs de $\Delta H_f^0$ expérimentales résultent pour la plupart de l'addition: $\Delta H_f^0$ $(C_nH_{2n-2}O^{\bullet+})$ = $\Delta H_f^0$ $(C_nH_{2n-2}O)$ + $I$ $(C_nH_{2n-2}O)$. Seule l'énergie d'ionisation est d'origine expérimentale (spectroscopie de photoélectrons), l'enthalpie standard de formation des molécules a été estimée (Tableau 3) par la méthode des incréments de Benson (17); il en résulte nécessairement une incertitude de plusieurs kJ mol$^{-1}$. La comparaison avec des valeurs de $\Delta H_f^0$ calculées par une toute autre méthode (MNDO) permet de contrôler la validité de ces estimations. Les valeurs obtenues par la méthode MNDO (19) ont été calculées après optimisation complète de la géométrie des ions.

Les résultats des calculs sont en bon accord avec l'expérience dans une marge d'erreur inférieure à 20 kJ mol$^{-1}$. La méthode permet donc, en cas de nécessité, de combler certaines lacunes expérimentales. L'ensemble des résultats prouve sans ambiguïté que les ions de formule brute $[C_nH_{2n-2}O]^{\bullet+}$ les plus stables sont des cétènes ionisés. Cette stabilisation représente un gain de plus de 100 kJ mol$^{-1}$ par rapport aux structures de type $[RC{\equiv}COH]^{\bullet+}$. L'acroléine et ses homologues supérieurs sont encore plus défavorisés.

TABLEAU 3. Enthalpies standards de formation (kJ mol$^{-1}$) des ions $[C_nH_{2n-2}O]^{\bullet+}$

| $n$ | Structure | MNDO | Valeurs expérimentales | |
|---|---|---|---|---|
| 2 | $CH_2{=}C{=}O$ | 827 | 879[a] | |
| | H—C≡C—OH | 977 | — | |
| 3 | $CH_3$—CH=C=O | 763 | — | 770[c,e] |

| | $CH_2$=CH—CHO | 900 | 900[b] | |
| 4 | $(CH_3)_2C{=}C{=}O$ | 713 | — | 686[d,e] |
| | $CH_3$—CH—C—C—OH | 859 | — | |
| | $CH_2$=CH—CO—$CH_3$ | 868 | 816[b] | |
| | $CH_3$—CH=CH—CHO | 833 | 833[b] | |
| | $CH_2{=}C(CH_3)$—CHO | 846 | 849[b] | |

[a] Valeur calculée à partir de $\Delta H_f^0$ $[CH_2CO]$ = −48 kJ mol$^{-1}$ (14) et de l'énergie d'ionisation du cétène 9,607 eV (15).
[b] Référence 16.
[c] $\Delta H_f^0$neutre = $\Delta H_f^0$ $[CH_2CO]$ + [Cd − (H) (C) − Cd − $(H)_2$] + [C − $(H)_3$ (C)] = −48 + 10 − 42 = −80 kJ mol$^{-1}$ (14 et 17).
[d] $\Delta H_f^0$neutre = −48 + 17 − 42 − 42 = −115 kJ mol$^{-1}$ (14 et 17).
[e] Référence 18.

La présence ou l'absence d'un $\Delta H_R^0$ pour la fragmentation $M^{\bullet+} \rightarrow [M-RH]^{\bullet+}$ peuvent être démontrées. En effet, la thermochimie comparée des deux éliminations concurrentes de R$^{\bullet}$ et de RH permet d'évaluer les chances d'existence d'un $\Delta H_R^0$ pour la seconde réaction.

La Figure 1 résume l'ensemble des données thermodynamiques concernant ces deux fragmentations. Les valeurs des $\Delta H_f^0$ nécessaires à cette discussion sont rassemblées dans les Tableaux 3 et 4.

On constate par exemple (Fig. 1) que l'acétone élimine $CH_3^{\bullet}$ et $CH_4$, cette dernière réaction étant dix fois plus aisée (Tableau 1). Le pic métastable le plus intense correspondant à la réaction de plus faible énergie critique, l'état de transition conduisant à $[C_2H_2O]^{\bullet+}$ + $CH_4$ possède nécessairement une enthalpie inférieure à celle de $[CH_3CO]^+$ + $CH_3$. En conséquence le $\Delta H_R^0$ associé à l'élimination de méthane s'il existe, est inférieur à 17 kJ mol$^{-1}$. Un raisonnement analogue s'applique aux réactions compétitives: **3** → $[C_3H_4O]^{\bullet+}$ et $C_2H_6$ et **3** → $[C_3H_5O]^+$ + $C_2H_5$. La valeur limite du $\Delta H_R^0$ éventuel correspondant à l'élimination d'éthane est, ici encore, très faible ($\Delta H_R^0 \leq 20$ kJ mol$^{-1}$).

Si les énergies critiques des deux réactions en compétition sont très différentes, un seul type d'ion fragment est détecté. C'est ainsi que, pour les cétones **5** et **6**, les éliminations des radicaux $C_2H_5^{\bullet}$ et i-$C_3H_7^{\bullet}$ ne sont pas observées. La compétition favorise nettement la formation des méthylcétènes:

$$\mathbf{5} \rightarrow [CH_3CHCO]^{\bullet+} + C_3H_8$$
$$\mathbf{5} \rightarrow [(CH_3)_2CCO]^{\bullet+} + C_2H_6$$
$$\mathbf{6} \rightarrow [(CH_3)_2CCO]^{\bullet+} + C_3H_8$$

les $\Delta H_R^0$ étant respectivement inférieurs à 0, 9 et 6 kcal mol$^{-1}$. De la même manière la perte de $C_2H_6$ à partir de **2** et celle de $C_3H_8$ à partir de **3** ne sont pas observées, les états finals sont en effet trop énergétiques.

Il ressort clairement de ces comparaisons que l'élimination d'alcane se déroule sans $\Delta H_R^0$ appréciable. Un argument complémentaire vient étayer cette conclusion: les valeurs de $T_{0,5}$ associées à la formation des ions $[M-RH]^{\bullet+}$ sont

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

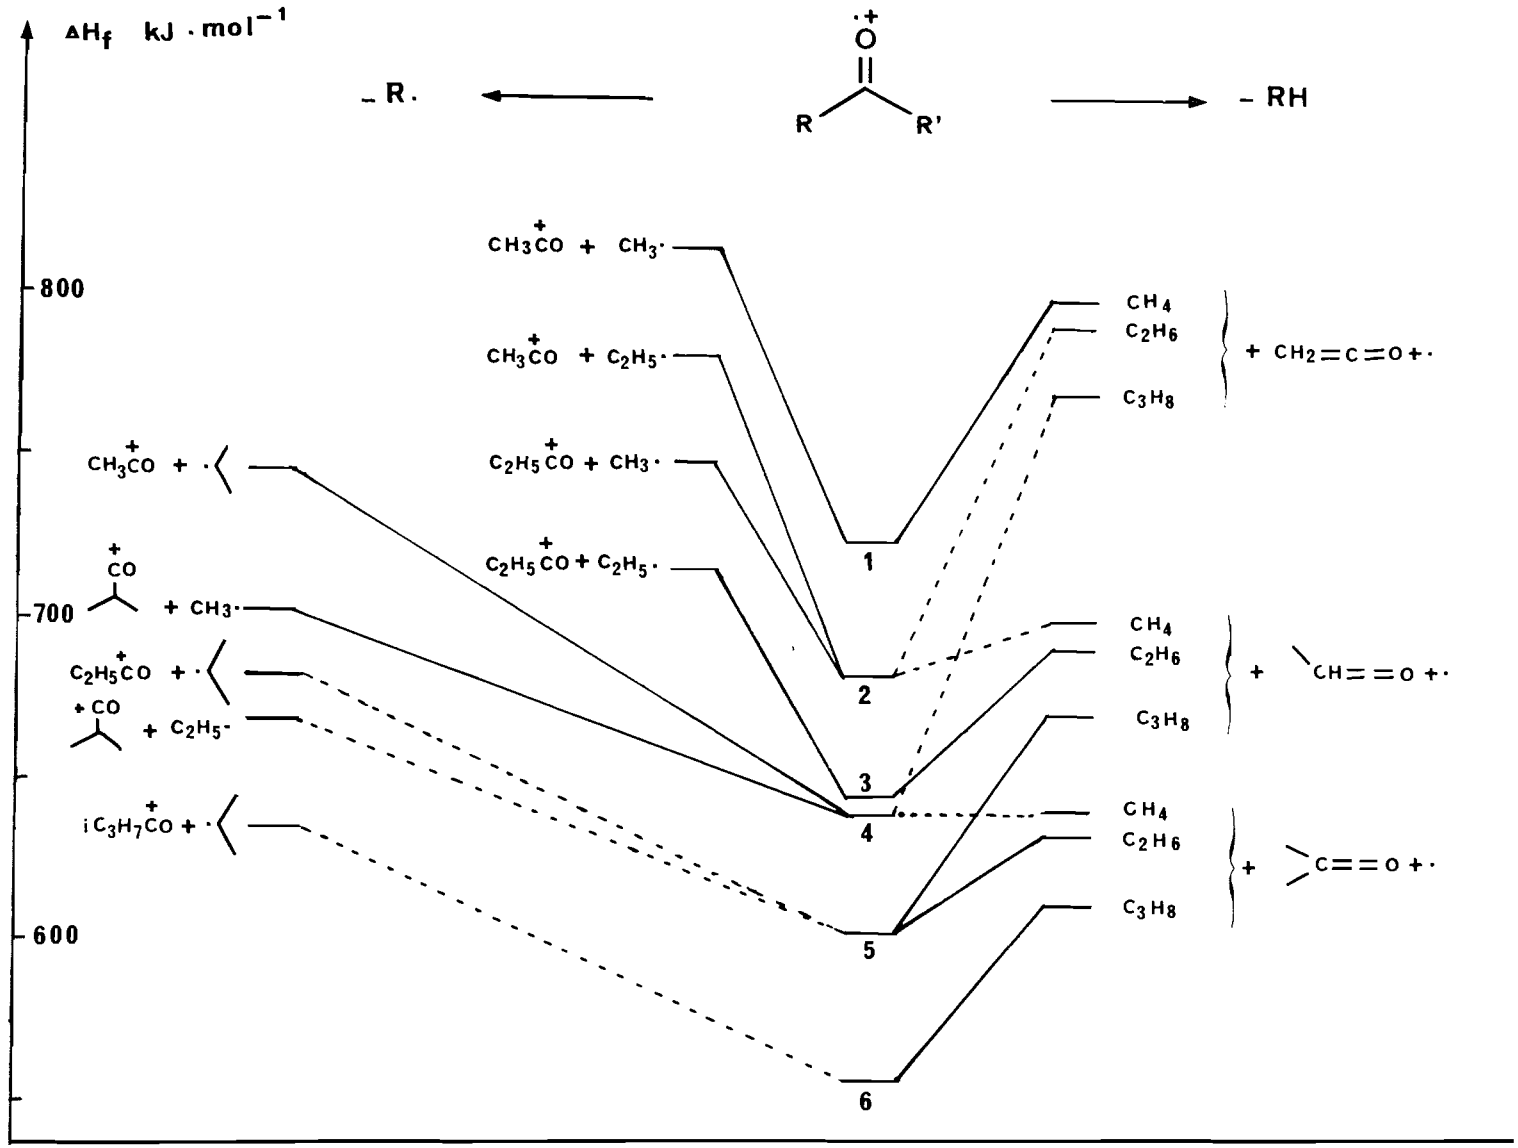

FIG. 1. Diagramme d'énergie associé aux éliminations de R et RH à partir des cétones ionisées métastables. Les états finals correspondant à un pic observé sont connectés à l'ion moléculaire par un trait plein, les lignes pointillées sont associées aux filiations non observées.

TABLEAU 4. Enthalpies standards de formation ($kJ\,mol^{-1}$) utilisées lors de l'établissement de la Figure 1[a]

| $R^1$ | $R^2$ | $\Delta H_f^0(R^1COR^2)^{\bullet+}$ | $\Delta H_f^0(R^1CO)^+$ | $\Delta H_f^0(R^{1\bullet})$ | $\Delta H_f^0(R^1H)$ |
|---|---|---|---|---|---|
| $CH_3$ | $CH_3$ | 720 | 669 | 142 | −75 |
| $CH_3$ | $C_2H_5$ | 678 | — | — | — |
| $C_2H_5$ | $C_2H_5$ | 640 | 602 | 109 | −84 |
| $CH_3$ | i-$C_3H_7$ | 636 | — | — | — |
| $C_2H_5$ | i-$C_3H_7$ | 598 | — | — | — |
| i-$C_3H_7$ | i-$C_3H_7$ | 552 | 556 | 75 | −105 |

[a]Référence 12.

très faibles, de l'ordre d'une dizaine de meV. Ce chiffre est cohérent avec une absence de $\Delta H_R^0$.

L'état de transition de l'élimination de RH est peu éloigné de l'état final, en énergie et par conséquent en structure (20). Cette similitude structurale revient à considérer l'état de transition comme étant une association ion– molécule ([cétène]$^{\bullet+}$–alcane). A cet égard, il convient de noter le rôle important tenu par l'hydrogène transféré dans le complexe intermédiaire. Un fort effet isotopique est observé pour **1** → $[CH_2CO]^{\bullet+}$ + $CH_4$ par Lifshitz et Tzidony (5), une constatation semblable peut être mentionnée ici pour **5**. La comparaison entre **5** et ***5a*** (Tableaux 1 et 2) montre que le rapport $[M-C_2H_6]^{\bullet+}/[M-C_3H_8]$ est égal à 6,7 tandis que $[M-C_2H_3D_3]^{\bullet+}/[M-C_3H_6C_2]^{\bullet+}$ n'atteint plus que 0,2.

En conclusion de cette première partie les deux réactions étudiées $[M]^{\bullet+} \rightarrow [M-R^{\bullet}]^+ + R^{\bullet}$ et $[M]^{\bullet+} \rightarrow [M-RH]^{\bullet+} + RH$ obéissant strictement aux critères de stabilité thermodynamique. Dans les deux cas, aucune énergie d'activation apprèciable ne semble associée aux réactions de recombinaison des fragments.

Deux fragmentations semblent échapper à ces critères: l'élimination de méthane à partir de la méthyléthylcétone et de la méthylisopropylcétone.

*Durée de vie maximum des ions moléculaires*

Bien que les deux réactions:

$$\mathbf{2} \rightarrow [CH_3CHCO]^{\bullet+} + CH_4$$

et

$$\mathbf{4} \rightarrow [(CH_3)_2CCO]^{\bullet+} + CH_4$$

n'aient besoin que d'une très faible énergie d'activation (respectivement 0 et 4 kcal $mol^{-1}$) les pics correspondants au méthylcétène ($C_3H_4O^{\bullet+}$) et au diméthylcétène ($C_4H_6O^{\bullet+}$) n'apparaissent pas. Si la fragmentation est extrêmement rapide, elle devient indétectable à partir d'ions ayant quitté la chambre d'ionisation depuis plusieurs μs.

La durée de vie τ d'une entité se décomposant de façon unimoléculaire avec une constante de vitesse $k$ est donnée simplement par $\tau = 1/k$. La durée de vie maximum d'un ion moléculaire sera donc:

$$\tau_{max} = 1/k(E_0)$$

Si l'énergie d'activation $E_0$ est très basse, $\tau_{max}$ peut devenir inférieur à $10^{-6}$ s. Les évaluations de $\tau_{max}$ portées sur le Tableau 5 montrent que pour un ensemble de 24 oscillateurs (comme l'acétone **1**), $E_0$ doit atteindre environ 1 eV pour que la fragmentation de l'ion métastable soit détectée. Par contre, dans le cas de 42 oscillateurs (**3** et **4**) la valeur de $E_0$ limite est abaissée à 0,6 eV environ. Les deux éliminations de $CH_4$ à partir de **2** et **4** possèdent des valeurs de $\tau_{max}$ nettement inférieures à $10^{-6}$ s. Ce phénomène est donc vraisemblablement responsable du comportement "anormal" des ions **2** et **4**.

Il faut ajouter que le peuplement initial des niveaux d'énergie de l'ion moléculaire proches de l'état fondamental est généralement pauvre. Dans l'hypothèse d'une très faible énergie d'activation, un très petit nombre d'ions fragments est formé au seuil thermodynamique.

TABLEAU 5. Durée de vie maximum $\tau_{max}$ (s) d'ions comportant $s$ oscillateurs[a]

| | $E_0$ (eV) | | |
|---|---|---|---|
| $s$ | 0,2 | 0,5 | 1,0 |
| 24[b] | $3,6\times10^{-11}$ | $8,5\times10^{-9}$ | $4,1\times10^{-6}$ |
| 42[b] | $2,2\times10^{-10}$ | $3,2\times10^{-7}$ | $1,6\times10^{-3}$ |

[a]$\tau_{max}$ est calculé à l'aide de l'approximation proposée par Whitten et Rabinovitch (21) pour un ensemble de $s$ oscillateurs, soit:

$$\tau_{max} = \frac{h(E_0 + a\,E_z)^{s-1}}{(s-1)!\,\frac{s}{\pi}\,h\nu_1}$$

[b]Les fréquences utilisées sont réparties en six groupes de $n$ valeurs: $n\times3000\,cm^{-1}$; $n\times1500\,cm^{-1}$; $n\times1100\,cm^{-1}$; $n\times900\,cm^{-1}$; $n\times600\,cm^{-1}$ et $n\times300\,cm^{-1}$. ($n = 4$ pour $s = 24$ et $n = 7$ pour $s = 42$.)

## Conclusion

Les décompositions des cétones ionisées étudiées obéissent à des critères thermodynamiques. Deux sortes de réaction ont été étudiées, l'élimination de radicaux et l'élimination d'alcanes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

Dans les deux cas, l'énergie de l'état de transition est quasiment égale à l'énergie de l'état final. Les fragmentations qui apparaissent sont celles qui conduisent aux états finals les plus stables.

Il existe deux situations où la fragmentation de plus basse énergie critique n'est pas observée après un laps de temps de plusieurs μs.

Dans le premier cas, présenté ici, les ions précurseurs sélectionnés après plusieurs μs ne sont plus susceptibles de se decomposer par la voie de plus basse énergie. Seule la fragmentation de haut facteur de fréquence sera observée.

Le second exemple correspond à une isomérisation préalable conduisant à un ion précurseur riche en énergie. Si la réaction de plus basse énergie d'activation possède également le plus bas facteur de fréquence, la compétition la défavorise à haute énergie. Ainsi la fragmentation **1** → $[CH_2CO]^{\cdot+}$ + $CH_4$ n'est pas observée si **1** provient de la réaction d'isomérisation de l'énol $[CH_2{=}C(OH)CH_3]^{\cdot+}$ (6).

## Partie expérimentale

La méthyl-2 trideutéro-2,4,4 pentanone **5***a* et la diméthyl-2,4 bideutéro-2,4 pentanone **6***a* ont été préparées à partir des cétones non marquées correspondantes par échange dans $D_2O$ en présence de $K_2CO_3$ (10%). Après 3 heures de chauffage à reflux, les produits organiques sont isolés par décantation. Le composé **5** conduit ainsi à 67% de composé trideutérié, 24% de deutérié, 5% de monodeutérié et 4% de produit non marqué tandis que les pourcentages de 28, 27 et 45 sont obtenus respectivement pour les molécules **6** di, mono et non deutériées.

Les spectres MIKE ont été enregistrés sur le spectromètre VG-ZAB 2F de l'École Polytechnique de Palaiseau. Les conditions d'utilisation de la source à impact électronique sont: courant d'émission = 100 μA, tension d'accélération des électrons = 70 eV, température = 200°c.

Les valeurs des énergies cinétiques $T_{0,5}$ sont calculées à partir des largeurs de pics mesurées à mi-hauteur, la résolution en énergie est de l'ordre de 1500.

Les intensités portées dans les Tableaux 1 et 2 sont déterminées à partir des hauteurs des pics des spectres de masse.

Received March 12, 1982

RODERICK E. WASYLISHEN, ROBERT E. LENKINSKI, and CHARLES RODGER. Can. J. Chem. **60**, 2113 (1982).

Mercury-199 spin-lattice relaxation times are reported for several mercury(II) compounds at 5.875 and 9.40 T. From the field dependence of $T_1$ in $Hg(CN)_2$, $Hg(CH_3)_2$, and $Hg(C_6H_5)_2$, $^{199}Hg$ chemical shielding anisotropies of 3800, 5820, and 5800 ppm are calculated. The errors in these of estimates of $\Delta\sigma$ are at least 10%. Some implications of the large $\Delta\sigma(^{199}Hg)$ values in high field nmr studies are discussed.

RODERICK E. WASYLISHEN, ROBERT E. LENKINSKI et CHARLES RODGER. Can. J. Chem. **60**, 2113 (1982).

On rapporte les temps de relaxation spin-réseau du mercure-199 dans plusieurs composés du mercure(II) à 5,875 et 9,40 T. A partir de l'influence du champ sur $T_1$ dans les composés $Hg(CN)_2$, $Hg(CH_3)_2$ et $Hg(C_6H_5)_2$, on a calculé les anisotropies de blindage chimique du $^{199}Hg$ qui sont respectivement de 3800, 5820 et 5800 ppm. Les erreurs dans ces évaluations sont au moins de 10%. On discute des quelques implications des grandes valeurs $\Delta\sigma(^{199}Hg)$ dans les études de rmn à haut champ.

[Traduit par le journal]

## Introduction

While investigating the high field ($B_0$ = 9.40 T) $^{13}C$ nmr spectra of several organomercury(II) compounds, we observed $^{199}Hg$ satellites due to $^{199}Hg$—$^{13}C$ scalar coupling which were significantly broader than the central uncoupled $^{13}C$ resonance. Of the naturally occurring mercury isotopes, only $^{199}Hg$ (natural abundance 16.84%) has a spin $I$ = 1/2. Although $^{201}Hg$ has $I$ = 3/2, its large quadrupole moment generally leads to extremely efficient quadrupole relaxation for this nucleus, resulting in "self-decoupling" from any spin 1/2 nucleus such as $^{13}C$. In this paper we show that chemical shielding anisotropy relaxation is very efficient for $^{199}Hg$ at applied fields of 9.40 T and that this mechanism can lead to significant $^{199}Hg$ line broadening, thus broadening $^{199}Hg$ satellites in spectra of spin 1/2 nuclei which are scalar coupled to $^{199}Hg$. Values of the $^{199}Hg$ chemical shielding anisotropy, CSA, are estimated from $^{199}Hg$ $T_1$ values measured at applied fields of 5.875 T and 9.40 T and the implications of these values are discussed.

Previously, $^{199}Hg$ $T_1$ values have been reported for neat dimethylmercury (1, 2), divinylmercury (1), and $HgCl_2$ (1.4 $M$ in ethanol) (3). These measurements were carried out in electromagnets where $B_0 \leq 2.35$ T. Both spin rotation and CSA relaxation mechanisms were found to contribute to $^{199}Hg$ relaxation in dimethylmercury (1, 2) and divinylmercury (1) at these applied fields. The mechanism for $^{199}Hg$ relaxation in $HgCl_2$ was not investigated. While this study was being completed, Gillies *et al.* (4) reported the results of a $^{199}Hg$ $T_1$ study on diphenylmercury. At $B_0$ = 7.05 T the $^{199}Hg$ $T_1$ is completely dominated by CSA relaxation. The CSA mechanism is also extremely efficient for several other heavy metal nuclides (5), including $^{195}Pt$ (6), $^{205}Tl$ (7), and $^{207}Pb$ (8).

## Theory

The rate of spin-lattice relaxation observed for a particular spin 1/2 nucleus can generally be expressed as a sum of rates (eq. [1]) due to four distinct mechanisms: dipole–dipole, $T_1(DD)^{-1}$; spin rotation, $T_1(SR)^{-1}$; chemical shielding anisotropy, $T_1(CSA)^{-1}$; and scalar coupling, $T_1(SC)^{-1}$ (9). Of the mechanisms in eq. [1], only the CSA

$$[1]\quad \frac{1}{T_1}(\text{obs.}) = \frac{1}{T_1}(\text{DD}) + \frac{1}{T_1}(\text{SR}) + \frac{1}{T_1}(\text{CSA}) + \frac{1}{T_1}(\text{SC})$$

mechanism becomes more efficient with increasing applied magnetic field, $B_0$. This mechanism is

expected to be most important for isotopes which have a large chemical shift range and for nuclei in an environment with less than tetrahedral symmetry. For a nucleus with axial symmetry, the efficiency of the CSA mechanism depends on the square of the applied magnetic field, $B_0$, as shown in eq. [2]:

$$[2a]\quad \frac{1}{T_1}(\mathrm{CSA}) = \frac{1}{15}(\gamma_I B_0)^2(\Delta\sigma)^2\left(\frac{2\tau_2}{1+\omega_I^2\tau_2^2}\right)$$

$$[2b]\quad \frac{1}{T_2}(\mathrm{CSA}) = \frac{1}{90}(\gamma_I B_0)^2(\Delta\sigma)^2 \times \left(\frac{6\tau_2}{1+\omega_I^2\tau_2^2} + 8\tau_2\right)$$

where $\gamma_I$ is the gyromagnetic ratio, $\omega_I = \gamma_I B_0$, $\tau_2$ is the rotational correlation time, $\Delta\sigma$ is the shielding anisotropy, $\sigma_{||} - \sigma_\perp$, $\sigma_{||}$ is the component of the shielding tensor parallel to the symmetry axis, and $\sigma_\perp$ is the component perpendicular to the symmetry axis (10, 11). For linear mercury(II) compounds $\Delta\sigma$ varies between 3500–8000 ppm (see Results and discussion, which follows). For $\Delta\sigma$ = 6000 ppm in eqs. [2*a*] and [2*b*], Fig. 1 shows the dependence of $\log_{10} T_1$(CSA) and $\log_{10} T_2$(CSA) on the rotational correlation time ($\log_{10}\tau_2$) with $\nu_I$ = 71.67 MHz ($B_0$ = 9.40 T) and $\nu_I$ = 44.80 MHz ($B_0$ = 5.875 T). Under conditions of extreme narrowing, $\omega_I^2\tau_2^2 \ll 1$, $T_1/T_2$ = 7/6 at constant $B_0$ and $T_1(B_0 = 5.875\ \mathrm{T})/T_1(B_0 = 9.40\ \mathrm{T})$ = 2.56 (10, 11). At $B_0$ = 9.40 T, the $T_1$ is a minimum, 0.93 ms, for $\tau_2 = 2.2 \times 10^{-9}$ s. Also at the $T_1$ minimum, $T_2$ = 0.55 ms; hence the line-width at half height, $\nu_{1/2} \geq [\pi T_2(\mathrm{CSA})]^{-1}$ = 580 Hz. Figure 2 shows the dependence of $\log_{10} T_1$(CSA) and $\log_{10} T_2$(CSA) on $\log_{10}\tau_2$ for $\Delta\sigma$ = 5000 ppm and 7000 ppm assuming $B_0$ = 9.40 T. For any value of $\tau_2$, relaxation of a nucleus with $\Delta\sigma$ = 7000 ppm is almost twice as effective as it is for one where $\Delta\sigma$ = 5000 ppm.

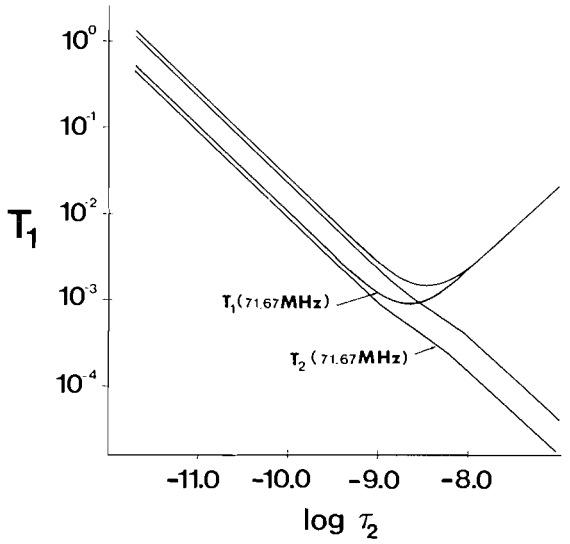

FIG. 1. Plot of $\log_{10} T_1$(CSA) and $\log_{10} T_2$(CSA) vs. $\log_{10}\tau_2$ for $\Delta\sigma$ = 6000 ppm at $\nu_I$ = 71.67 MHz and 44.80 MHz.

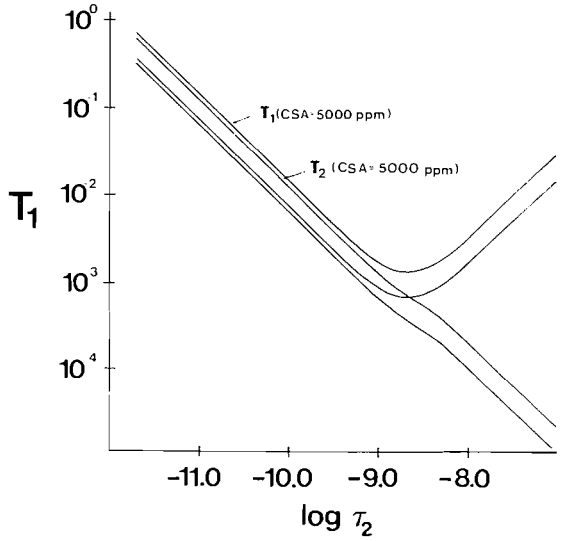

FIG. 2. Plot of $\log_{10} T_1$(CSA) and $\log_{10} T_2$(CSA) vs. $\log_{10}\tau_2$ for $\Delta\sigma$ = 5000 ppm and 7000 ppm. $\nu_I$ = 71.67 MHz.

## Experimental

All mercury compounds were commercially available from Aldrich and Alfa. Mercury cyanide was recrystallized from methanol and dried under vacuum. All other compounds were used as received. Deuterated solvents were obtained from Merck, Sharp and Dohme (Canada). All solutions with the exception of $HgCl_2$, $HgCl_4^{2-}$, and $Hg(CN)_4^{2-}$ were degassed by the freeze–pump–thaw technique. A 0.5 *M* aqueous solution of $HgCl_4^{2-}$ was prepared by mixing equal volumes of 1 *M* $HgCl_2$ and 4 *M* LiCl (12). Similarly a 0.5 *M* $Hg(CN)_4^{2-}$ (aqueous) solution was prepared from equal volumes of 1 *M* $Hg(CN)_2$ and 2.3 *M* KCN (13).

Mercury-199 nmr spectra were recorded at 9.40 T (71.67 MHz) and at 5.875 T (44.80 MHz) on Bruker WH-400 and WM-250 spectrometers respectively. Nitrogen-14 and carbon-13 nmr spectra were obtained at 28.9 MHz and 100.6 MHz respectively (9.40 T). All spin-lattice relaxation times were measured using the inversion–recovery technique (10) and calculated using a 3-parameter fitting procedure (14). All measurements were carried out at 297 ± 2 K.

## Results and discussion

### (a) $^{199}Hg$ Spin-lattice relaxation; $\Delta\sigma(^{199}Hg)$

Measured relaxation times are given in Table 1. The errors in all $T_1$ values are estimated to be less than 15% unless otherwise indicated. For the $^{199}$Hg spin-lattice relaxation times, the ratio $T_1(B_0 = 5.875\ \mathrm{T})/T_1(B_0 = 9.40\ \mathrm{T})$ is given in Table 2.

| $HgCl_4^{2-}$ in $D_2O$ | 5.875 | 6.50±0.50 | |

[a] Measured from the $^{14}$N line-width assuming $T_2^* = T_1$, estimated error of 15%.
[b] Reference 2.
[c] Measured for a 1.4 *M* solution in EtOH (ref. 3).

(i) *Hg(CN)*$_2$

For a spin 1/2 nucleus, the $^{199}$Hg $T_1$'s measured for $Hg(CN)_2$ are exceedingly short. The $T_1$'s are field dependent; at applied fields of 9.40 T, spin-lattice relaxation is more efficient than relaxation at 5.875 T by a factor of 2.9 ± 0.4. This strong dependence on the applied field indicates that the chemical shielding anisotropy mechanism completely dominates. If relaxation mechanisms other than CSA make significant contributions to the observed $T_1$'s, then the ratio of the $T_1$'s at 5.875 and 9.40 T would be less than 2.56; and in the limit where CSA relaxation is unimportant the ratio is 1.0. With the exception of scalar coupling of the second kind (10, 11), all other spin-lattice relaxation mechanisms are field independent under conditions of extreme narrowing. Substitution into standard expressions (10, 11) indicates that the scalar coupling mechanism is unimportant because $T_1$ increases with increasing $B_0$ if this mechanism dominates.

The effective rotational correlation time, $\tau_2$, for mercury(II) cyanide can be estimated from the $^{14}$N line-width at half height, $\nu_{1/2} = 3.0 \pm 0.5$ kHz. Assuming $T_1^{-1} = (T_2^*)^{-1} = \pi\nu_{1/2}$ and that nuclear quadrupolar relaxation is the major relaxation mechanism operative (10, 11),

$$[3] \quad \frac{1}{T_1} = \frac{3}{2}\pi^2\left(\frac{e^2qQ}{h}\right)^2\tau_2$$

TABLE 2. Ratio of observed $^{199}$Hg spin-lattice relaxation times at $B_0$ = 5.875 and 9.40 T

| Compound | $\frac{T_1(5.875\text{ T})}{T_1(9.40\text{ T})}$ |
|---|---|
| $Hg(CN)_2$ | 2.9±0.3 |
| $K_2Hg(CN)_4$ | 1.1±0.1 |
| $Hg(CH_3)_2$ | 2.1±0.2 |
| $Hg(C_6H_5)_2$ | 2.4±0.2 |
| $Hg(CH_2C_6H_5)_2$ | 2.8±0.3 |
| $HgCl_2$ | 2.5±0.2 |

where $(e^2qQ/h) = 3.9513$ MHz (15) is the $^{14}$N nuclear quadrupole coupling constant. Substitution into eq. [3] leads to a value of 40.8 ps for $\tau_2$. Using this value of $\tau_2$ in eq. [2] and the $^{199}$Hg $T_1$ measured at 9.40 T, we calculated $\Delta\sigma = 3800$ ppm. The value of $\Delta\sigma$ obtained by the procedure outlined here may be dependent on the solvent. The mercury atom of $Hg(CN)_2$ is known to interact strongly with nitrogen containing ligands such as ammonia (16) and pyridine (17). Strong mercury–solvent interactions are expected to decrease $\Delta\sigma$ relative to the value one would measure for an isolated molecule in the gas phase.

(ii) *Hg(CN)*$_4^{2-}$

At $B_0 = 9.40$ T, $^{199}$Hg spin-lattice relaxation is less efficient in $Hg(CN)_4^{2-}$ than it is in $Hg(CN)_2$ by a factor of at least 100. The tetracyanomercury(II) ion is known to be tetrahedral (18); thus the chemical shielding anisotropy, $\Delta\sigma$, is expected to be approximately zero. This is supported by the observation that the $^{199}$Hg $T_1$ is independent of $B_0$. Spin-rotation and/or intermolecular dipole–dipole relaxation with protons or unpaired electrons (e.g. dissolved $O_2$ or paramagnetic transition metal impurities) are the most likely relaxation mechanisms for $^{199}$Hg in $Hg(CN)_4^{2-}$.

(iii) *Hg(CH*$_3$*)*$_2$

Nuclear magnetic resonance relaxation in dimethylmercury has been studied in detail by Lassigne and Wells (2) and by Sens *et al.* (1). Over the temperature range studied by Lassigne and Wells (2), 234 to 333 K, the $^{199}$Hg $T_1$'s at 1.41 T decreased with increasing temperature ($E_a = -1.1 \pm 0.2$ kcal/mol), indicating that the spin-rotation mechanism is the most important relaxation mechanism at this applied field. Assuming that the CSA mechanism makes a small contribution to the $^{199}$Hg $T_1$ at 297 K and $B_0 = 1.41$ T, one can calculate lower limits for $T_1(\text{CSA})^{-1}$ at 5.875 and 9.40 T using eq. [4]

$$[4] \quad \frac{1}{T_1}(\text{CSA}) \geq \frac{1}{T_1}(\text{obs.}) - \frac{1}{T_1}(1.41\text{ T})$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

For $B_0$ values of 5.875 and 9.40 T, $T_1(\text{CSA}) \leq 0.417$ and 0.169 s respectively. On the basis of $^1H$ and $^2H$ $T_1$'s, Lassigne and Wells (2) estimate $\tau_2 = 6.7$ ps at 300 K. Substitution of the above values of $T_1(\text{CSA})$ and $\tau_2$ into eq. [2] leads to $\Delta\sigma$ values of 5720 ppm and 5820 ppm. Assuming CSA is the only mechanism at 9.40 T leads to a value of 6100 ppm for $\Delta\sigma$. These values for $\Delta\sigma$ are significantly lower than those of 7475 ± 80 ppm (19) and 7325 ± 55 ppm (20) obtained from liquid crystal data. The main source of error in our calculated value of $\Delta\sigma$ probably results from inaccuracy in $\tau_2$ (2). $\tau_2$ must be less than 4.7 ps in order for the $T_1$ data to be compatible with the liquid crystal data (19, 20).

(iv) *$Hg(C_6H_5)_2$*

The field dependent $^{199}Hg$ $T_1$ data (Table 2) indicate that the chemical shielding anisotropy mechanism must completely dominate at $B_0$ = 9.40 T. The appropriate correlation time for $^{199}Hg$ spin-lattice relaxation in diphenylmercury can be obtained from the $^{13}C$ $T_1$ of the carbon *para* (C4) to mercury (21). This carbon is relaxed entirely by the dipole–dipole mechanism with directly attached protons. Assuming $r_{CH}$ = 108 pm, substitution into eq. [5] yields $\tau_2$ (C2) = 30.8 ps.

$$[5]\quad \frac{1}{T_1} = \frac{\gamma_C^2 \gamma_H^2 \hbar^2}{r_{CH}^6}\ \tau_2$$

Use of this correlation time and $T_1(^{199}Hg) = 0.0356$ s at 9.40 T in eq. [2] gives $\Delta\sigma$ 5800 ± 600 ppm, in fair agreement with the value 6800 ± 680 ppm reported by Gillies *et al.* (4).

Using the rotational diffusion model of Woessner and Snowden (21*a*) and the carbon-13 relaxation data in Table 1, we calculated $D_{\|}/D_{\perp} = 6.8$, where $D_{\|}$ and $D_{\perp}$ are the rotational diffusion constants parallel and perpendicular to the major symmetry axis which passes through the Hg, directly bonded carbons (C1), and the carbon atoms *para* (C4) to the Hg.

(v) *$Hg(CH_2C_6H_5)_2$*

The $^{199}Hg$ $T_1$ data for dibenzylmercury indicate that the CSA mechanism completely dominates at high field. In this case, the absence of axial symmetry precludes calculation of $\Delta\sigma$ using eq. [2].

(vi) *$HgCl_2$ and $HgCl_4^{2-}$*

The decrease in $T_1(^{199}Hg)$ with increasing $B_0$ observed for the linear dichloride indicates that the CSA mechanism completely dominates at high field. We were unable to observe the $^{35}Cl$ or $^{37}Cl$ resonance of $HgCl_2$; thus an estimate of $\tau_2$ and $\Delta\sigma$ is not possible at this time. The relatively long $T_1$ value for the tetrahedral $HgCl_4^{2-}$ ion indicates that the CSA mechanism is not efficient in this species.

(b) *Implications of efficient $^{199}Hg$ CSA relaxation*

There are two main implications of the extremely efficient CSA $^{199}Hg$ relaxation observed for two-coordinate Hg(II) compounds at 9.40 T. Firstly, if mercury is essentially two-coordinate in a macromolecule (for example, see refs. 22–26) which has a rotational correlation time greater than $10^{-9}$ s, it may be difficult to observe the $^{199}Hg$ resonance because of its large line-width ($\nu_{1/2}$ = 335 Hz for $\Delta\sigma$ = 6000 ppm). Secondly, the scalar coupled $^{199}Hg$ satellites (doublet) generally observed in the nmr spectrum of a slowly relaxing nucleus, X, will be significantly broadened. The minimum line-width of the satellites will be $1/\pi T_2(^{199}Hg)$ (27). Figure 3 shows the $^{13}C$ nmr spectrum of $Hg(CN)_2$ at 9.40 T. Whereas the central resonance has a line-width of 15 ± 4 Hz, the satellites are characterized by $^1J(^{199}Hg, ^{13}C)$ = 3158 ± 15 Hz and line-widths of 55 ± 15 Hz. The contributions of CSA relaxation to the $^{199}Hg$ and hence $^{13}C$ line-widths of the compounds studied here are given in Table 3. The large $^{13}C$ line-width of the $^{199}Hg$ satellites in $Hg(CN)_2$ arises at least in part from both CSA relaxation and scalar relaxation of the second kind ($^{199}Hg$—$^{14}N$ scalar coupling). From eq. [2] it is

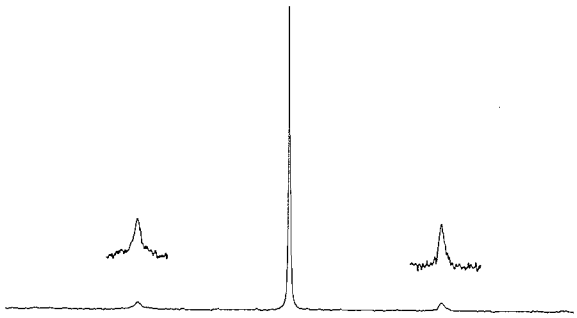

FIG. 3. Carbon-13 nmr spectrum of $Hg(CN)_2$ at $B_0$ = 9.40 T.

TABLE 3. Contribution of CSA relaxation to $^{199}Hg$ line-widths at half-height ($\nu_{1/2}$) at $B_0$ = 9.40 and 5.875 T[a]

| Compound | $B_0$ (T) | $\nu_{1/2}$ (Hz) |
|---|---|---|
| $Hg(CN)_2$ | 9.40 | 5.9 |
| | 5.875 | 2.0 |
| $Hg(CH_3)_2$ | 9.40 | 2.5 |
| | 5.875 | 1.2 |
| $Hg(C_6H_5)_2$ | 9.40 | 10.4 |
| | 5.875 | 4.3 |
| $Hg(CH_2C_6H_5)_2$ | 9.40 | 13.9 |
| | 5.875 | 5.0 |
| $HgCl_2$ | 9.40 | 3.3 |
| | 5.875 | 1.3 |

[a]Minimum $^{199}Hg$ nmr line-widths. Calculated assuming extreme narrowing and CSA relaxation, $T_2 = 6/7\,T_1$.

apparent that for molecules with rotational correlation times greater than $5 \times 10^{-9}$s, the $^{199}$Hg will be essentially "self-decoupled" from nucleus X at applied fields of 9.40 T.

## Acknowledgements

The nmr spectra recorded at 9.40 T were obtained at the Southwestern Ontario NMR Center funded by a Major Installation Grant from the Natural Sciences and Engineering Research Council of Canada. # Formation of acid–water hydrogen bonds with large proton polarizability and molecular processes with dissociation of acids in the p$K_a$ range 0–4

MARTIN LEUCHS AND GEORG ZUNDEL

*Physikalisch-Chemisches Institut der Universität München, Theresienstr. 41, D-8000 München 2, West Germany*

Received September 25, 1981

MARTIN LEUCHS and GEORG ZUNDEL. Can. J. Chem. **60**, 2118 (1982).

Aqueous solutions of fourteen acids in the p$K_a$ region 0–4 were studied by ir spectroscopy as a function of concentration. All data are summarized in a table. The degree of dissociation was determined from bands of the anions. The removal of the protons from the anions decreases in the following series of the acids $CF_3COOH$, $H_2CrO_4$, $(HIO_3)$, $CF_2HCOOH$, $HPO(OH)_2$, $HSO_4^-$, $(HSeO_4^-)$, $H_2POOH$, $PO(OH)_3$, $AsO(OH)_3$ (Table 1, columns 3 and 4). Continua indicate the formation of hydrogen bonds with large proton polarizabilities. In the case of $H_3PO_3$, $H_3PO_4$, and $H_3AsO_4$, the acid–acid hydrogen bonds are still polarizable although they have relatively asymmetrical proton potentials. The acid–water hydrogen bonds (**I**) $AH\cdots OH_2 \rightleftharpoons A^-\cdots H^+OH_2$ (**II**) may show considerable proton polarizability, as indicated by strong continuous absorptions. The proton potential, and thus the proton polarizability of the acid–water hydrogen bonds, are discussed taking into consideration the intensity and the wave number range of the continuum (column 7), as well as the line width of the vibration with δ OH character (column 9). With increasing asymmetry of the hydrogen bonds, the continuum changes to the bands observed with asymmetrical hydrogen bonds. The sequence of acids in the series arranged according to the degree of dissociation is not the same as the sequence according to the intensity of the continuum and proton polarizability. This is explained by the fact that the proton polarizability is mainly determined by the shape of the proton potential, whereas the dissociation equilibrium is also influenced by entropy effects associated with hydrate structure formation.

It is shown that the following molecular processes are of significance for the dissociation of the acids: the formation of acid–water hydrogen bonds with proton polarizability, whereby the weight of the polar proton-limiting structure $A^-\cdots H^+OH_2$ increases with increasing addition of water molecules. Besides the shape of the proton potential, the entropy effects mentioned influence the degree of dissociation, too. Finally, the positive charge transfers from the acid–water into water–water hydrogen bonds, i.e., $H_5O_2^+$ is formed.

---

MARTIN LEUCHS et GEORG ZUNDEL. Can. J. Chem. **60**, 2118 (1982).

Utilisant la spectroscopie ir, on a étudié, en fonction de la concentration, solutions aqueuses de quatorze acides dans le domaine de p$K_a$ allant de 0 à 4. On résume toutes les données dans un tableau. On a déterminé le degré de dissociation à partir des bandes des anions. L'élimination des protons des anions diminue dans la série suivante d'acides: $CF_3COOH$, $H_2CrO_4$, $(HIO_3)$, $CF_2HCOOH$, $HPO(OH)_2$, $HSO_4^-$, $(HSeO_4^-)$, $H_2POOH$, $PO(OH)_3$, $ASO(OH)_3$ (col. 3 et 4 du tableau). Les continua indiquent la formation de liaisons hydrogènes avec de grandes polarisabilités protonique. Dans les cas des acides suivants: $H_3PO_3$, $H_3PO_4$ et $H_3AsO_4$, les liaisons hydrogènes acide–acide sont encore polarisables bien qu'elles aient des potentiels de proton relativement asymétriques. Les liaisons hydrogènes acide–eau (**I**) $AH\cdots OH_2 \rightleftharpoons A^-\cdots H^+OH_2$ (**II**) peuvent montrer une polarisabilité considérable protonique comme l'indiquent les fortes absorptions continues. On discute du potentiel du proton et, par conséquent, de la polarisabilité du proton des liaisons hydrogènes acide–eau, en considérant l'intensité et l'intervalle du nombre d'onde du continuum (col. 7), ainsi que la largeur des bandes de vibration ayant un caractère de δ OH (col. 9). En augmentant l'asymétrie des liaisons hydrogènes, le continuum change pour donner les bandes observées avec les liaisons hydrogènes asymétriques. L'ordre des acides, établi suivant le degré de dissociation, n'est pas le même que celui établi selon l'intensité du continuum et selon la polarisabilité protonique. On explique ceci par le fait que la polarisabilité protonique est principalement déterminée par la forme du potentiel protonique alors que l'équilibre de dissociation est de plus influencé par les effets d'entropie associés à la formation d'une structure d'hydratée.

On montre que les processus moléculaires suivants sont significatifs pour la dissociation des acides: la formation des liaisons hydrogènes acide–eau avec polarisabilité protonique, alors que le poids de la structure limite du proton polaire $A^-\cdots H^+OH_2$ augmente avec l'addition de molécules d'eau. En plus de la forme du potentiel du proton, les effets d'entropie mentionnés influencent également le degré de dissociation. Finalement charge positive des liaisons hydrogène acide–eau transfert en liaisons hydrogènes eau–eau c'est-à-dire $H_5O_2^+$.

[Traduit par le journal]

## I. Introduction

In the case of aqueous solutions of acids with p$K_a < 1$, acid–water hydrogen bonds of the type

$$\underset{\textbf{(I)}}{AH\cdots OH_2} \rightleftharpoons \underset{\textbf{(II)}}{A^-\cdots H^+OH_2}$$

with large proton polarizabilities are observed if these acids can be studied at very high concentrations. The large proton polarizability of these hydrogen bonds is indicated by strong ir continua. In these hydrogen bonds, double minimum proton potentials are present, whereby with the very strong acids the deeper well occurs preferentially at the water molecule (proton-limiting structure **II** has larger weight), and with the less strong acids it occurs preferentially at the anion (proton-limiting structure **I** has larger weight). With increasing $n$ (number of water molecules per acid molecule), i.e., increasing amount of water in the solutions, the weight of proton-limiting structure **II** increases, and more and more protons transfer into the water–water hydrogen bonds, i.e., $H_5O_2^+$ is

formed. The hydrogen bond in this grouping also shows large proton polarizability and causes strong continuous absorption. All these results were obtained from the ir data (for details see ref. 1). The proton polarizability of hydrogen bonds, interactions of these bonds with their environment, and the occurrence of ir continua are discussed in detail in refs. 1–10.

One should expect that with aqueous solutions of acids with $pK_a > 0$, such acid–water hydrogen bonds with large proton polarizabilities should also be found at higher dilution. In the study presented here, ir spectra of aqueous solutions of fourteen acids (Table 1) with $pK_a$ in the region 0–4 are studied and discussed with regard to the degree of asymmetry of the acid–acid and acid–water hydrogen bonds.

## II. Materials and methods

The acids were purchased from Merck in Darmstadt, Germany, Riedl-de-Haen in Seelze, Germany, and Fluka in Buchs, Switzerland. The purity was analytical grade except difluoroacetic acid, iodoacetic acid, and monochloroacetic acid which were for synthesis.

The solutions were studied in a cell with Si windows. Because of the high reflectivity of these windows, considerable interferences would superimpose the spectra when the windows were parallel. Therefore, a wedge-shaped layer with a mean thickness of 9.5 μm was used. This layer is obtained by milling a wedge-shaped groove into one of the windows. With this equipment the reproducibility of the layer is better than 0.2 μm.

This mean layer thickness was calibrated from benzene bands at 1950 and 1815 $cm^{-1}$. However, in the case of a wedge-shaped layer, Lambert–Beer's law is no longer valid. The necessary calibration curve was obtained from the spectra of solutions of cyclohexane in $CCl_4$.

The spectra were taken with a spectrophotometer model 325, Bodenseewerk Perkin-Elmer, Überlingen (slit program 6.5, time response 2, gain 2.5).

The absorbance of the continuum was evaluated at 1900 $cm^{-1}$. It is referred to the same absorbance at 4500 $cm^{-1}$. The quantitative determination of the absorbance of the continuum is described in ref. 11.

The degrees of dissociation were obtained from the characteristic bands of the non-dissociated acids. The intensity of these bands in the spectrum of the water-free acids yields the molar absorbance of these bands. With this molar absorbance, the concentration of the non-dissociated acid molecules in each solution could be determined, and thus the degree of dissociation.

## III. Results and discussion

Figure 1 shows selected spectra. The data are summarized in Table 1. For $H_3PO_2$, $H_3PO_3$, $H_3PO_4$, and $H_3AsO_4$ these data are taken from detailed discussions in ref. 11,[1] and for $CF_3COOH$, $CF_2HCOOH$, and HCOOH from detailed discussions in ref. 13. The acids not studied in detail up to now will be discussed in section III.2.

### *III.1 Fundamentals of discussion*

Information is obtained from the following spectral features:

(*1*) The degree of dissociation can be determined, as in ref. 1 and in many other ir and Raman studies performed by various authors (12–27), from the bands of the acid molecules (Table 1, col. 3). The molarities and $n$ values ($n$ = number of water per acid molecule) at which, with increasing dilution, anion bands begin to appear, i.e. proton-limiting structure **II** becomes noticeable (Table 1, col. 4), in weakly dissociating acids will be discussed.

The presence of acid bands (Table 1, col. 5) indicates that a still non-dissociated species is present, it is also present in dilute solutions.

(*2*) The continua indicate the presence of hydrogen bonds with large proton polarizability, i.e., hydrogen bonds with double minimum proton potential wells. (*a*) If continua are observed, even at $n = 0$, or do not decrease if $n$ becomes $< 1$, then the acid–acid hydrogen bonds are also polarizable (Table 1, col. 6). (*b*) If the intensity of the continuum is zero in the pure acid, and increases on dilution from $n = 0$ to $n = 1$, or if the continuum is observed in the pure acid, and remains with addition of the first water molecules per acid molecule, then the continuum indicates the formation of acid–water hydrogen bonds with large proton polarizability. (*c*) If the intensity of the continuum continues to increase with increasing $n$ for $n > 1$, it indicates that either the degree of asymmetry of the proton potential of the acid–water hydrogen bonds decreases or that positive charge has already transferred into water–water hydrogen bonds, i.e., $H_5O_2^+$ groupings are formed. (*d*) From theoretical calculations, as well as from experimental results, it is known that with increasing degree of asymmetry of the proton potentials in the hydrogen bonds, the continua change as follows: With increasing degree of asymmetry the intensity of the continua should decrease, and they should decrease more strongly at smaller wave numbers (see, for instance, Fig. 6 in ref. 28), i.e., the continua should recede from smaller wave numbers (see Table 1, col. 7). The continuum is still observed in the region of larger wave numbers, however, when the residence time of the protons at one side of the hydrogen bonds is much greater than at the other one, as has been shown theoretically (29, 30) as well as experimentally (25*a*, 26). From theory it is

[1]Some of the data given in ref. 12 are improved due to more exact measurements.

*Band pair caused by νC—O and δ OH (see ref. 27).

known that with increasing degree of asymmetry of the double minimum proton potential, the residence time in the higher well decreases much more strongly than the fluctuation frequency of the protons. Even when the residence time of the proton in the higher well is very short, the polarizability is smaller but still appreciable. This theoretical result was confirmed experimentally with carboxylic acid – *N* base (25*a*) and with phenol–amine (26) systems. It was shown that even when the proton is largely located at one side of the hydrogen bond the absorbance of the continuum in the region of higher wave numbers is weaker, but a less intense continuum can still be observed.

Furthermore, in the region 3000–1500 $cm^{-1}$, band-like structures of the continua are sometimes observed (Table 1, col. 8). These band-like structures become more pronounced with increasing degree of asymmetry of the proton potentials, and the continua finally vanish, and the spectral features change to the bands observed with asymmetrical hydrogen bonds in this region. In considering such band-like structures of continua, one has to take into account that they occur not only with increasing degree of asymmetry of the proton potentials, but also with increasing length of the polarizable hydrogen bonds (25*a*). It was shown theoretically that long hydrogen bonds with large proton polarizabilities show a broad band-like structure in the region 2500–2000 $cm^{-1}$ (see Fig. 5 in ref. 8).

Hadži and co-workers (31, 32) explained band splitting in this region (A, B, C bands) on the basis of Fermi resonance of the fundamental transition of the hydrogen bonds with the overtones of the bending vibrations. With long $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bonds, band splitting and band-like structures of the continua were explained by various authors (28, 32–35) as being caused by Fermi resonance of the fundamental transitions of the hydrogen bonds with combinational vibrations. Finally, Wolff and co-workers (36, 37) explained the fine structure of bands observed with carboxylic acids on the same basis. Thus, splitting of the band-like structures of the continua and splitting of bands, given in Table 1, col. 8, must be explained by such resonance effects.

(*3*) If bands of vibrations with δ OH character caused by the acid–water hydrogen bonds are observed in the spectra (Table 1, col. 9), one can conclude that the residence time of the proton at the anion is long enough for these vibrations to occur, whereby the half width gives additional information.

(*4*) Finally, in more dilute solutions, the hydrogen bond with large proton polarizability in $H_5O_2^+$ groupings may also contribute to the continuum.

From the plots in Fig. 3*a*, *b*, and *d*, it can be decided whether, in addition to these hydrogen bonds, acid–water hydrogen bonds with large proton polarizability are still present, and whether they are also present in the more dilute solutions. As discussed in detail in ref. 27, p. 10, this can be concluded from these figures as follows: the dashed lines shown in Fig. 3 give the absorbance of the continuum which would be expected if all protons removed from the anions were present in $H_5O_2^+$ groupings. The observed intensities of the continuum (solid lines) are, however, greater, thus an additional type of hydrogen bond with large proton polarizability must contribute to the continuum.

(*5*) Finally, the following viewpoint must be mentioned: the proton polarizability is determined by the proton potential, i.e., the potential energy dependent on the proton position. The $AH\cdots OH_2 \rightleftharpoons A^-\cdots H^+OH_2$ equilibrium is, however, determined by free energy and hence also influenced by the entropy term of the Gibbs–Helmholtz equation. It is known from other systems (38–41) that entropy effects are highly significant with proton transfer equilibria in solutions. This viewpoint must be taken into account when considering the molecular processes involving dissociation, as described in sections III.6 and III.7.

### *III.2 Discussion of various acids*

#### *$H_2CrO_4$ (spectra Fig. 1b)*

In the spectrum of the 10.3 *M* solution ($n = 2.6$), only bands of non-dissociated acid molecules are observed. With increasing dilution, beginning with the 6.5 *M* solution, the presence of $HOCrO_3^-$ anions is indicated by $\nu_s CrO_3^-$ at 880 $cm^{-1}$ (42) (see spectrum of the $KHCrO_4$ solution). Hence, the degree of dissociation (first step) can be determined from the absorbance of this band (the band of $\nu_{as} CrO_3^-$ at 950 $cm^{-1}$ cannot be used since it overlaps with a band of the non-dissociated molecules). The degree of dissociation (first step) is plotted in Fig. 2*b* as a function of the molarity, *M*, and of *n*. Also in the spectrum of the most dilute solution (1.0 *M*) studied, no bands of $CrO_4^-$ are observed.

Figures 1*b* and 3*b* show that a continuum arises with increasing molarity of the acid. It is most intense in the saturated solution ($M = 10.3$, $n = 2.6$, at 293 K). This continuum cannot be caused by $H_5O_2^+$ groupings, since under these conditions no dissociated species is present (see also Fig. 2*b*).

Thus, the continuum must be caused by an acid–water hydrogen bond, and it indicates that these bonds

$$\underset{\textbf{(I)}}{CrOH\cdots OH_2} \rightleftharpoons \underset{\textbf{(II)}}{CrO^-\cdots H^+OH_2}$$

show large proton polarizability. At *n* = 2.6, almost all protons are present at the anions (Fig. 2*b*). Thus, the weight of proton-limiting structure **I** is much larger than that of proton-limiting structure **II**, and hence the deeper well of the double mini-

mum proton potential is preferentially present at the anion. Figure 1*b* shows that the continuum also extends towards smaller wave numbers, indicating that these acid–water hydrogen bonds are still considerably polarizable. The residence time of the protons at the anions is sufficiently long that the δ OH vibration is found with maximum at 1170 $cm^{-1}$, whereby the broadening of this band, however, is extremely strong (Fig. 1*b*).

With increasing dilution, more and more protons are removed from the anions (Fig. 2*b*). The weight of proton-limiting structure **II** increases, and excess protons transfer into the network of hydrogen-bonded water molecules, i.e., $H_5O_2^+$ is formed. The comparison (solid and dashed lines in Fig. 3*b*) of the observed continuum with the continuum which one would expect, if all protons were removed from the anions, and present in $H_5O_2^+$, shows that even in solutions with molarities < 1, protons are still present in polarizable acid–water hydrogen bonds, contributing to the continuum.

*$HIO_3$ (spectra Fig. 1c)*

Two intense bands caused by $IO_2OH$ are observed in the spectrum of concentrated solutions, one at 800 $cm^{-1}$ and one at 650 $cm^{-1}$. $IO_3^-$ is indicated by a band at 790 $cm^{-1}$, as shown by the spectrum of the salt solution. The degree of dissociation, however, cannot be determined from these bands, since the bands of the non-dissociated and dissociated species overlap too strongly.

The spectra in Fig. 1*c* and Fig. 3*c* show that with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

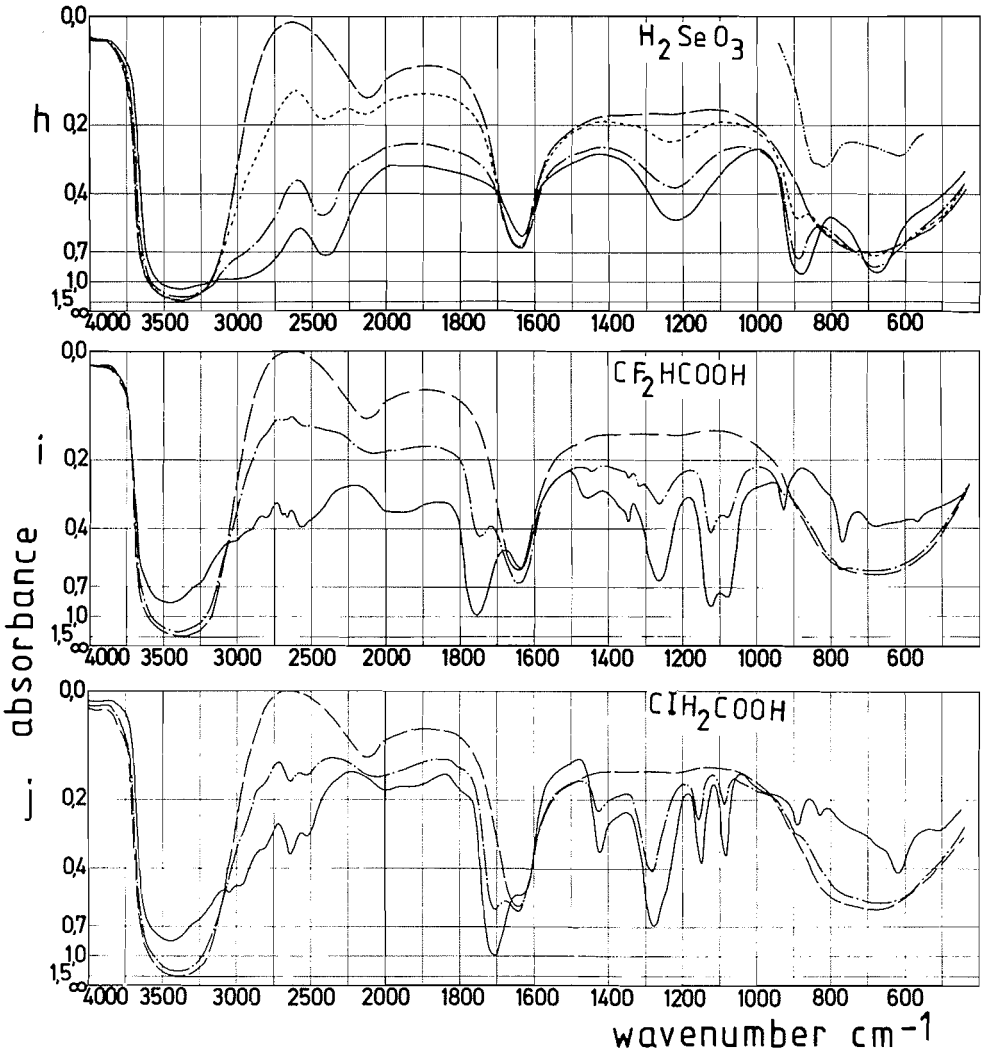

FIG. 1. (*Concluded*). (*h*) $H_2SeO_3$: — 12.3 *M* (*n* = 2.1); ····· 5.6 *M* (*n* = 7.6); --- 1.8 *M* (*n* = 29.2); – – – $H_2O$; ····· $NaHSeO_3$ solution. (*i*) $CF_2HCOOH$: — 9.3 *M* (*n* = 2.6); ····· 2.4 *M* (*n* = 19); – – – $H_2O$. (*j*) $ClH_2COOH$: — 7.9 *M* (*n* = 2.8); ····· 2.8 *M* (*n* = 1.3); – – – $H_2O$.

increasing molarity, a continuum arises which also extends toward the smaller wave numbers. The criteria considered above show that the proton potential in the acid–water hydrogen bonds is similar to that with chromic acid. The $pK_a$ value of $HIO_3$ is 0.77 (43), and hence it is also similar to the $pK_a$ value of the first dissociation step of $H_2CrO_4$, 0.74 (43). Thus, the continuum observed with iodic acid is also mainly caused by acid–water hydrogen bonds with large proton polarizabilities.

*$NaHSO_4$ (spectra Fig. 1*d)

Three bands of the non-dissociated $HOSO_3^-$ molecules are observed, the degenerated $\nu_{as}SO_3$ vibration at 1200 $cm^{-1}$, $\nu_sSO_3$ at 1050 $cm^{-1}$, and νS—O at 990 $cm^{-1}$. With increasing dilution, the band of the triply degenerated antisymmetrical stretching vibration of the $SO_4^{2-}$ anions (42) at 1100 $cm^{-1}$ arises. This band was separated by a computer program. From the absorbance of this band, the degree of dissociation is determined and plotted in Fig. 2*c* as a function of molarity and of *n*. These data do not agree with the Raman data from refs. 21 or 44, however the results in refs. 21 and 44 are also not in agreement with each other.

Figures 1*d* and 3*d* (solid line) show that a continuum arises with increasing molarity of the acid. For comparison, in Fig. 3*d* (dashed line) the absorbance of the continuum is plotted which would be observed if all protons removed from the anions were present in $H_5O_2^+$ groupings. Comparison of the solid and dashed curves in Fig. 3*d*

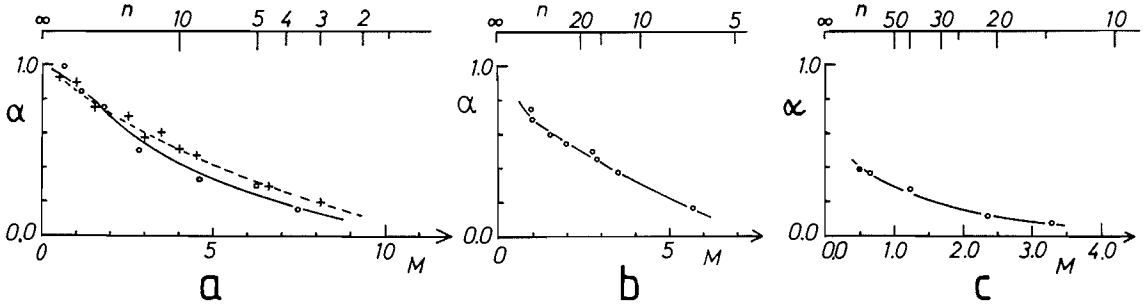

FIG. 2. Degree of dissociation, determined from the ir spectra: (*a*) $CF_3COOH$ (+ values from ref. 20); (*b*) $H_2CrO_4$; (*c*) $NaHSO_4$.

demonstrates that the continuum is not preferentially caused by $H_5O_2^+$ groupings, but by another type of hydrogen bond with large proton polarizability. The only type of hydrogen bond which would be sufficiently symmetrical are acid–water hydrogen bonds.

$$\underset{\text{(I)}}{O_3SO^-H\cdots OH_2} \rightleftharpoons \underset{\text{(II)}}{O_3SO^{2-}\cdots H^+OH_2}$$

Thus, these hydrogen bonds show large proton polarizabilities.

With increasing dilution, more and more protons are removed from the anions (Fig. 2*c*). Thus, the weight of proton-limiting structure **II** increases, and excess protons transfer into the network of hydrogen-bonded water molecules, i.e., $H_5O_2^+$ is formed. But also in solutions less concentrated than 0.5 *M*, acid–water hydrogen bonds with large proton polarizabilities are still present. This is demonstrated by the results presented in Fig. 2*c* and Fig. 3*d*.

*$NaHSeO_4$ (spectra Fig. 1e)*

Three bands of the non-dissociated $HOSeO_3^-$ molecules are observed in the spectra, the degenerated $\nu_{as}SeO_3$ vibration at 920 $cm^{-1}$, $\nu_sSeO_3$ at 865 $cm^{-1}$, and νSe—O at 730 $cm^{-1}$. The triply degenerated antisymmetric stretching vibration of the $SeO_4^{2-}$ anions occurs at 870 $cm^{-1}$ (45), as shown by the spectrum of the salt solution. With decreasing concentration, the intensity of the band at 920 $cm^{-1}$ decreases much faster than that of the band at 865 $cm^{-1}$. The larger intensity at 865 $cm^{-1}$ is caused by $\nu_{as}SeO_4^-$, arising at this position with increasing dilution, indicating dissociation. A quantitative evaluation is not possible, due to the strong overlapping of these bands. The proton acceptor strength of the $SeO_4^-$ ions, however, should be greater than that of the $SO_4^-$ ions (45). Hence, the degree of dissociation of $HOSeO_3^-$ should be a little less than that of $HOSO_3^-$.

Figures 1*e* and 3*e* show that with increasing molarity of this acid, a continuum arises which is only a little weaker than that observed with hydrogen sulfate solutions (cf. Figs. 3*d* and *e*). Paetzold (45) has shown that the affinity of $SeO_4^{2-}$ ions for protons is greater than that of $SO_4^{2-}$ ions. Thus the weight of proton-limiting structure **I** of the acid–water hydrogen bonds is a little greater and, therefore, the well of the double minimum in the average a little deeper at the anion, than with $HSO_4^-$. This larger degree of asymmetry explains the smaller intensity of the continuum. Nevertheless, the continuum also extends toward smaller wave numbers (Fig. 1*e*). The very broad band, with maximum at about 1270 $cm^{-1}$, superimposed on the continuum, is the OH bending vibration in the acid–water groupings. The appearance of this band demonstrates that the residence time of the proton at the anion is sufficiently long for the occurrence of this OH bending vibration.

*$H_2SeO_3$ (spectra Fig. 1h)*

Simon and Paetzold (46) demonstrated that this acid is present in the form $O{=}Se(OH)_2$. At 890 $cm^{-1}$, νSe=O is found, and at 680 $cm^{-1}$ the stretching vibration of the $Se(OH)_2$ groups is observed (46). No bands of dissociated groupings can be found even in the spectrum of the 1 *M* ($n = 55$) solution. This is shown by comparison with the spectrum of the aqueous $NaHSeO_3$ solution.

The intensity of the continuum is much weaker than with arsenic acid (cf. Fig. 1 *h* and *g*). It no longer extends toward smaller wave numbers. Very pronounced bands, however, with maxima at about 2900 $cm^{-1}$ and 2420 $cm^{-1}$, caused by the OH stretching vibration and the overtone of the OH bending vibration of the acid–water hydrogen bonds are observed. The latter is intensified by Fermi resonance with the stretching vibration (31, 32). The bending vibration itself is observed as a broad intense band with maximum at 1225 $cm^{-1}$. With increasing dilution, no bands of $HSeO_3^-$ are found. All these observations together demonstrate that the degree of asymmetry of the acid–water hydrogen bonds is already so large that the continuum has vanished to a large degree, and only

the usual bands observed with asymmetrical hydrogen bonds are found. Thus, the polarizability of the acid–water bonds with selenous acid is very weak.

*$CClH_2COOH$, $ClH_2COOH$ (spectra Fig. 1j), $CHOOH$ (Fig. 1e and f in ref. 13)*

Even in 0.95 *M* solution of $CClH_2COOH$, and in 1.7 *M* aqueous solutions of $ClH_2COOH$, no shoulders of bands of dissociated molecules can be observed, as shown by comparison with the spectra of the sodium salt solutions (with $ClH_2COO^-$, $\nu_{as}CO_2^-$ at 1595 $cm^{-1}$ and $\nu_sCO_2^-$ at 1370 $cm^{-1}$).

With these acids, various bands are observed in the region 3200–1750 $cm^{-1}$ which raise the background slightly. These bands are caused by the OH stretching vibration of the acid–water hydrogen bonds and by overtones and combinational vibrations which are intensified by Fermi resonance with the OH stretching vibration, as discussed by Wolff and co-workers (36, 37). No rise of background is observed below 1600 $cm^{-1}$. Also in the diluted solution, no bands of dissociated acid molecules are observed. Thus, the proton potentials in the acid–water hydrogen bonds with these carboxylic acids are single minima with the well at the anions. These hydrogen bonds are asymmetrical and show no anomalous proton polarizabilities due to proton motion.

*III.3 Degree of dissociation*

In the case of acids **7–15**, bands of the dissociated species (Table 1, col. 3) appear with increasing dilution (Table 1, col. 4). This demonstrates that the proton-limiting structure **II** of the acid–water hydrogen bonds (see section III.5)

$$\underset{\textbf{(I)}}{AH\cdots OH_2} \rightleftharpoons \underset{\textbf{(II)}}{A^-\cdots H^+OH_2}$$

acquire noticeable weight. Thus, addition of water molecules, i.e., a more polar environment, increases the weight of the polar proton-limiting structure $A^-\cdots H^+OH$. This result is in very good agreement with the findings obtained from other systems (25, 26, 50–52).

The spectroscopically-observed removal of the protons from the anions decreases in the following series of acids (Table 1, col. 4): $CF_3COOH$ **7**, $H_2CrO_4$ **8**, ($HIO_3$ **9**), $CF_2HCOOH$ **15**, $HPO(OH)_2$ **12**, $HSO_4^-$ **10**, ($HSeO_4^-$ **11**), $H_2POOH$ **13**, $PO(OH)_3$ **14**, $AsO(OH)_3$ **16**. With $AsO(OH)_3$, no bands of the dissociated species are observed, even in the 0.8 *M* ($n = 57$) solution.

With these spectroscopically-determined degrees of dissociation, one must always keep in mind that the acid molecules observed as dissociated are not only those from which the protons have been removed from the anions and are present in $H_5O_2^+$ groupings, but also those with which the proton is present in the proton-limiting structure **II** in the acid–water hydrogen bonds.

*III.4 Polarizable acid–acid hydrogen bonds*

In the case of strong acids, such as $HClO_4$ (1, 27) or $HNO_3$ (1, 47), no continua are observed with the pure acids. In contrast to this finding, $H_3PO_2$, $H_3PO_3$, $H_3PO_4$, and $H_3AsO_4$ show intense continuous absorption, even for $n < 1$, and if they could be studied pure, also in the pure liquid acid (see Fig. 1*f* and figures in ref. 12). This result demonstrates that with these acids, the acid–acid hydrogen bonds

$$\underset{\textbf{(I)}}{POH\cdots OP} \rightleftharpoons \underset{\textbf{(II)}}{PO^-\cdots H^+OP}$$

$$\underset{\textbf{(I)}}{AsOH\cdots OAs} \rightleftharpoons \underset{\textbf{(II)}}{AsO^-\cdots H^+OAs}$$

show still noticeable proton polarizabilities. No bands of anionic groupings, i.e. bands caused by proton-limiting structure **II**, can be observed in the spectra (cf., for instance, in Fig. 1*f* the spectrum drawn with solid line with the spectrum of the sodium salt solution ·····). Thus, the weight of proton-limiting structure **II** is very small, and the double minimum proton potential present in these hydrogen bonds largely asymmetrical, with the deeper well preferentially at the anion. As already mentioned in section III.1, when the proton is largely located at one side of the hydrogen bond its proton polarizability is much weaker and the continuum is less intense, but it can still be observed in the region of larger wave numbers. Thus, as already discussed in detail in ref. 12, the proton polarizabilities of these acid–acid hydrogen bonds are much smaller than those of structurally symmetrical hydrogen bonds with a double minimum, but still much larger than the proton polarizabilities of asymmetrical hydrogen bonds with single minimum.

Some acids in this $pK_a$ region, as, for instance, $CF_3COOH$ and $CF_2HCOOH$, which can also be studied pure, show no continuum when no water molecules are present. This fact is understandable, since these acids form dimers via two hydrogen bonds. With these dimers, a symmetrical total proton potential is present when both protons transfer simultaneously in the hydrogen bonds. The barrier for such a cooperative proton transfer is, however, high, since both protons repel each other. Furthermore, with the transfer of both protons, no considerable change of the dipole

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

moments occurs. Therefore, no continua are observed.

The question arises then, why, in this $pK_a$ region, do the hydrogen bonds between the acid molecules become so symmetrical that they show noticeable proton polarizability? The degree of asymmetry of the acid–acid bonds should decrease, if the proton is less easily removed from the anions, and if the hydrogen bond acceptor strength of the acceptor sites at the acid molecules increases. Hence, with increasing $pK_a$ of the acids, a $pK_a$ region should occur in which the degree of asymmetry of the acid–acid hydrogen bonds is low. The prevailing results show that this is the case with the above-mentioned acids in the $pK_a$ region 1–2.5.

*III.5 Acid–water hydrogen bonds with large proton polarizability*

With $CF_3COOH$ **7**, $H_2CrO_4$ **8**, $HIO_3$ **9**, $NaHSO_4$ **10**, and $NaHSeO_4$ **11**, intense continua are observed even in the concentrated solutions in which, as shown by the results presented in Fig. 3*a*, *b*, and *d*, the concentration of $H_5O_2^+$ can be neglected. Thus, these continua are caused by acid–water hydrogen bonds, and indicate that these hydrogen bonds are of the type

$$\underset{\textbf{(I)}}{AH\cdots OH_2} \rightleftharpoons \underset{\textbf{(II)}}{A^-\cdots H^+OH_2}$$

and show large proton polarizabilities. At high concentrations, no bands of the dissociated species are found (Fig. 1*a*–*e*, data given in Table 1, col. 3 and col. 4). Thus, the weights of proton-limiting structure **II** are still very low. The result that the continua also extend toward smaller wave numbers (Table 1, col. 7), however, indicates that these acid–water hydrogen bonds still show considerable proton polarizability. Thus, a relatively asymmetrical double minimum proton potential, with the deeper well preferentially at the anion, is present in these acid–water hydrogen bonds. The band with δ OH bending character of the OH groups in these hydrogen bonds is found in the region 1350–1150 $cm^{-1}$, indicating that the residence time of the protons at the anions is long enough for this vibration to occur (Table 1, col. 9). With the exception of $CF_3COOH$, however, this band is extremely or at least very strongly broadened, indicating that the residence time of the protons at the anions is comparable to that necessary for the occurrence of this vibration.

It is known from studies of acids with $pK_a < 0$ (1) that increasing weight of the polar proton-limiting structure in the acid–water hydrogen bonds favors the transfer of the positive charge into water–water hydrogen bonds, i.e., the $H_5O_2^+$ formation. Therefore, in more dilute solutions of stronger acids of the above series, for instance, $CF_3COOH$, $H_2CrO_4$, and $NaHSO_4$, the hydrogen bond in the $H_5O_2^+$ groupings with large proton polarizability contribute to the continuous absorption. The question arises, whether, even in the most dilute solutions of these acids, acid–water hydrogen bonds are still present. Comparison of the solid with the dashed curve in Fig. 3*a*, *b*, and *d* shows (see section III.1, point 4) that with these acids, even in relatively dilute solutions, acid–water hydrogen bonds with large proton polarizability occur. This result is confirmed by the observation that even in relatively dilute solutions of these acids, bands of nondissociated acid molecules are still found (see Table 1, col. 5).

The series of acids, $H_3PO_4$ **14**, $H_3AsO_4$ **16**, $OSe(OH)_2$ **17**, $ClH_2COOH$ **18**, $ClH_2COOH$ **19**, CHOOH **20** (Fig. 1*f*–*h* and *j* and Table 1, col. 8), shows that with increasing degree of asymmetry of the acid–water hydrogen bonds, the continuum vanishes and the usual bands of strong hydrogen bonds occur in the region 3000–1600 $cm^{-1}$. With $H_3PO_4$, a relatively intense continuum is still observed in the region 3000–1500 $cm^{-1}$, showing a band-like structure with maxima at 2900 $cm^{-1}$, 2350 $cm^{-1}$ and 1700 $cm^{-1}$. With $H_3AsO_4$, the intensity of the continuum in this region is already weaker, but the bands with maxima at 2850 $cm^{-1}$ and 2350 $cm^{-1}$ are much more pronounced, and the continuum is no longer observed below 1600 $cm^{-1}$. With $OSe(OH)_2$, the intensity of the continuum vanishes almost completely, also in the region above 1600 $cm^{-1}$, and two pronounced bands are observed with maxima at 2900 $cm^{-1}$ and 2420 $cm^{-1}$, whereby the band at the higher wave number is the stretching vibration of the OH groups in the acid–water hydrogen bonds, and the band at lower one, the overtone of the OH bending vibration, which is intensified by Fermi resonance with the former vibration (32). Thus, in the series of acids, **14**, **16** to **20**, the double minimum proton potential in the acid–water hydrogen bonds changes to an asymmetrical single minimum with the well at the anion.

In summary we can state: with increasing asymmetry of the double minimum proton potential in the acid–water hydrogen bonds, as expected (see section III.1, point 2), the absorbance of the continuum per acid–water hydrogen bond decreases, vanishing first at smaller wave numbers.

The sequence of the acids in the series arranged according to the degree of dissociation discussed in sec III.3 is not the same as the sequence of the acids arranged according to the intensity of the continuum which they cause. The most striking

example is $CF_2HCOOH$. The polar proton-limiting structure $O^-\cdots H^+OH_2$ begins to be observed when only $n = 5.8$ water molecules per acid molecule are present, whereas almost no continuum is observed with this acid at smaller wave numbers (cf. the spectra in Fig. 1*i* with the spectra in Fig. 1*b–f*). This different behavior regarding degree of dissociation and continuum will be explained in the next section.

*III.6 Polarizable acid–water hydrogen bonds as a function of $pK_a$ and intensity of the continua*

In Fig. 4, the absorbance of the continuum at 1900 $cm^{-1}$ is plotted as a function of the $pK_a$ of the respective acids. For comparison, results with acids having $pK_a < 0$, taken from ref. 1, are also given in this figure.

As previously discussed in ref. 1, the absorbance of the continuum with the 1 *M* solutions is the same with all acids having $pK_a < 0$, since it is always the same hydrogen bond, the easily polarizable hydrogen bond in $H_5O_2^+$ groupings, which causes the continuum. With the acids having $pK_a > 0$, the absorbance of the continuum decreases with increasing $pK_a$. This decrease of the continuum has two causes: (*1*) With increasing $pK_a$, fewer protons transfer in the network of hydrogen bonds formed between water molecules, i.e., the concentration of the hydrogen bond with large proton polarizability in $H_5O_2^+$ groupings decreases. (*2*) The degree of asymmetry of the proton potentials in the acid–water hydrogen bonds increases, and hence the proton polarizability of these bonds and thus the intensity of the continuous absorbance caused by these hydrogen bonds decreases.

Figure 4 shows that two different types of acids with regard to the absorbance of the continuum as a function of $pK_a$ are observed. The absorbance of the continuum decreases at lower $pK_a$ values with the following acids (type **I**): $CF_3COOH$ **7**, $IO_2OH$ **9**, $H_2POOH$ **12**, $CF_2HCOOH$ **15**, $CClH_2COOH$ **18**, $ClH_2COOH$ **19**, $HCOOH$ **20**. In contrast to this result, it decreases at higher $pK_a$ values with the following acids (type **II**): $CrO_2(OH)_2$ **8**, $(SO_3OH)^-$ **10**, $(SeO_3OH)^-$ **11**, $HPO(OH)_2$ **13**, $PO(OH)_3$ **14**, $AsO(OH)_3$ **16**, $SeO(OH)_2$ **17**. The first type of acid has only one OH group, and these acids are not charged when non-dissociated. The second type of acid has either more than one OH group as hydrogen bond donor (**8**, **13**, **14**, **16**, **17**), or the acid is charged, i.e. the acid has strong hydrogen bond acceptor groupings (**10**, **11**). These different properties of the two types of acids may explain their different behavior.

As already mentioned in sec. III.1 point 5, the

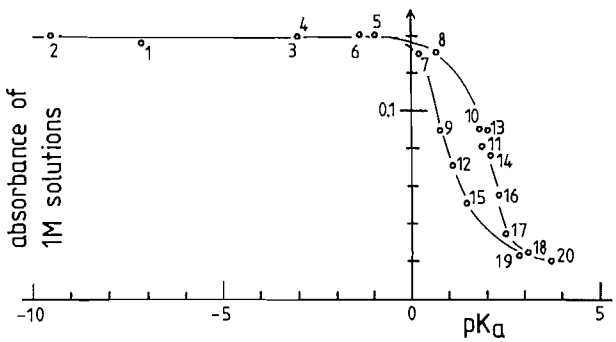

FIG. 4. Absorbance of the continuum of 1 *M* solutions at 1900 $cm^{-1}$ as a function of $pK_a$: **1** $HClO_4$; **2** HI; **3** $H_2SO_4$; **4** $H_2SeO_4$; **5** HCl; **6**, $HNO_3$; **7** $CF_3COOH$; **8** $H_2CrO_4$; **9** $HIO_3$; **10** $HSO_4^-$; **11** $HSeO_4^-$; **12** $H_2POOH$; **13** $HPO(OH)_2$; **14** $PO(OH)_3$; **15** $CF_2HCOOH$; **16** $AsO(OH)_3$; **17** $SeO(OH)_2$; **18** $CClH_2COOH$; **19** $ClH_2COOH$; **20** $HCOOH$.

proton potential is mainly determined by enthalpy effects, whereas the dissociation equilibrium is also determined by entropy effects. These are highly significant with proton transfer processes (38–41). Thus, the $AH\cdots OH_2 \rightleftharpoons A^-\cdots HOH_2$ equilibrium is also significantly determined by entropy effects caused by interaction effects of these hydrogen bonds with their environments. With regard to the fact that the continuum and the position of the $AH\cdots OH_2 \rightleftharpoons A^-\cdots H^+OH_2$ equilibria are determined by two different thermodynamic quantities, it is not surprising that, with systems showing the same intensity of the continuum (determined by the proton potential), another position of the dissociation equilibrium (determined by the free energy) is observed. Furthermore, it is not surprising that types with similar interaction properties show a similar relation between intensity of the continuum and of the position of the equilibrium

$$AH\cdots OH_2 \rightleftharpoons A^-\cdots H^+OH_2$$

*III.7 Molecular processes on dissociation of acids*

The following molecular processes are decisive on the dissociation of an acid (16):

(*a*) The formation of acid–water hydrogen bonds

$$AH\cdots OH_2 \rightleftharpoons A^-\cdots H^+OH_2$$

with large proton polarizability. The position of this equilibrium is determined by the hydrogen bond donor strength of the acid and by the hydrogen bond acceptor strength of the lone pairs at the water molecules as well as by the polarity of the environment, i.e., on the polarity of non-dissociated acid molecules and anions as well as on the presence of water molecules.

(*b*) With the addition of more than one water molecule per acid molecule, this equilibrium is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

shifted to the right hand side, since polar environments favor the polar proton-limiting structure. The reason for this is that an additional negative enthalpy contribution occurs, caused by the stronger dipole–dipole interaction of structure **II** with the more polar environment, i.e., the interaction of the dipole of the $A^-\cdots H^+OH_2$ structure with the reaction field induced by this dipole in its environment.

(*c*) Entropy effects associated with the hydrate structure formation, however, shift this proton transfer equilibrium in the opposite direction, i.e., to the left hand side.

(*d*) Increasing weight of structure **II** favors the transfer of the positive charge from the acid–water into water–water hydrogen bonds, i.e., the $H_5O_2^+$ formation.

(*e*) If the free energy of solvation of the separated species $A^-$ and $H^+OH_2$ due to non-dissociated acid molecules is high enough, then the $A^-\cdots H^+OH_2$ groupings may dissociate, even in very concentrated solutions, before the processes *b*–*d* occur. Of course, also in this case, with the addition of more water molecules, $H_5O_2^+$, and more-extended hydrogen-bonded networks around this structure, are formed.

Thus, for the acids discussed in this paper, the formation of acid–water hydrogen bonds with large proton polarizability, and the interaction of these hydrogen bonds with their environments are highly important for the molecular processes on dissociation with these acids.

## Acknowledgements

We thank Professor G. S. Denisov, Dr. V. M. Schreiber, and Dr. N. S. Golubev of the University of Leningrad for very valuable discussion regarding proton transfer and entropy effects. Furthermore, our thanks are due to the Deutsche Forschungsgemeinschaft and the Fonds der Deutschen Chemischen Industrie for providing facilities for this work.

# Thermochemical study of adducts of methylurea with zinc, cadmium, and mercury halides

CLAUDIO AIROLDI,[1] AÉCIO P. CHAGAS, AND FRANCISCO P. ASSUNÇÃO[2]

*Instituto de Química, Universidade Estadual de Campinas, Caixa Postal 6154–13.100–Campinas, São Paulo, Brasil*

Received January 14, 1982

CLAUDIO AIROLDI, AÉCIO P. CHAGAS, and FRANCISCO P. ASSUNÇÃO. Can. J. Chem. **60**, 2132 (1982).

The adducts $Zn(mu)_2X_2$ (X = Cl, Br), $M(mu)X_2$ (M = Cd, Hg and X = Cl, Br) have been characterized. The CO and NH stretching frequencies indicate that methylurea (mu) is bound to metals through oxygen. Enthalpies of dissolution of the adducts in ethanol or methanol have been measured calorimetrically. Combination with the enthalpies of solution of metal halides and ligand in the same solvents at 298.15 K yielded the standard enthalpy ($\Delta H_R^\ominus$/kJ mol$^{-1}$) for the reaction: $MX_2(s) + n\,mu(s) \rightarrow M(mu)_nX_2$ (s): $Zn(mu)_2Cl_2$, (−36.27±0.51); $Zn(mu)_2Br_2$, (−37.52±0.97); $Cd(mu)Cl_2$, (−22.78±0.26); $Cd(mu)Br_2$, (−9.58±0.26); $Hg(mu)Cl_2$, (−13.91±0.41); and $Hg(mu)Br_2$, (−13.29±0.48). The standard enthalpies of formation of the adducts in the same sequence as above, $\Delta H_f^\ominus$ (s, 298.15 K): −1024, −938, −701, −612, −524, and −470 kJ mol$^{-1}$, were determined from these values, the standard enthalpy of the ligand (−285±15 kJ mol$^{-1}$) being obtained via combustion calorimetry, and literature values of the standard enthalpies of metal halides being used. With the determination of the standard enthalpy of sublimation of the ligand (78.2 kJ mol$^{-1}$) it was possible to determine the standard enthalpies of the reactions $MX_2(g) + n\,mu(g) \rightarrow M(mu)X_2$ (s) and $M(mu)_nX_2$ (s) → $MX_2$ (s) + $n$mu(g). The enthalpies of metal–oxygen bonds were also estimated.

CLAUDIO AIROLDI, AÉCIO P. CHAGAS et FRANCISCO P. ASSUNÇÃO. Can. J. Chem. **60**, 2132 (1982).

On a caractérisé les adduits $Zn(mu)_2X_2$ (X = Cl, Br), $M(mu)X_2$ (M = Cd, Hg et X = Cl, Br). Les fréquences de vibration du CO et du NH indiquent que la méthylurée (mu) est liée au métal par l'intermédiaire de l'oxygène. On a mesuré par calorimétrie les enthalpies de dissolution des adduits dans l'éthanol ou le méthanol. La combinaison avec des enthalpies de solution des halogénures métalliques et du ligand dans les mêmes solvants à 298,15 K donne l'enthalpie standard ($\Delta H_R^\ominus$/kJ mol$^{-1}$) de la réaction: $MX_2(s) + n\,mu(s) \rightarrow M(mu)_nX_2$ (s): $Zn(mu)_2Cl_2$, (−36,27±0,51); $Zn(mu)_2Br_2$, (−37,52±0,97); $Cd(mu)Cl_2$, (−22,78±0,26); $Cd(mu)Br_2$, (−9,58±0,26); $Hg(mu)Cl_2$, (−13,91±0,41) et $Hg(mu)Br_2$, (−13,29±0,48). En se basant sur ces valeurs, sur l'enthalpie standard du ligand (−285±15 kJ) obtenue par calorimétrie de combustion et sur des valeurs d'enthalpie standard des halogénures métalliques tirées de la littérature, on a déterminé l'enthalpie de formation des adduits $\Delta H_F^\ominus$ (s, 298,15 K) dans la même ordre que ci-dessus: −1024, −938, −701, −612, −524 et −470 kJ mol$^{-1}$. La détermination de l'enthalpie standard de sublimation du ligand (78,2 kJ mol$^{-1}$) rend possible la détermination des enthalpies standards des réactions: $MX_2(g) + n\,mu(g) \rightarrow M(mu)X_2$ (s) et $M(mu)_nX_2$ (s) → $MX_2$ (s) + $n$mu(g). On a également évalué les enthalpies des liaisons métal–oxygène.

[Traduit par le journal]

## Introduction

Our interest in the thermochemistry of adducts of halides of the zinc family with urea derivatives as ligand is now focused on methylurea (mu). The determinations of crystallographic parameters for $Cd(mu)_nX_2$ (X = Cl, Br, I and $n$ = 1, 2) and $Zn(mu)_6Br_2$ were the pioneer studies involving methylurea as a ligand (1, 2). Moreover, a complete X-ray diffraction pattern for $Cd(mu)Cl_2$ illustrates an interesting structure (3) where the metal is octahedrally coordinated, with the participation of methylurea as a monodentate ligand. This polymer structure shows one site of coordination occupied by oxygen of the ligand carbonyl with the other positions being occupied by chloride bridges.

The coordination characteristic of methylurea is expected to be the same as that of *N*,*N*′-dimethylurea (dmu) where both molecules resemble the urea molecule (4, 5) in structure. From infrared studies methylurea has a nearly planar configuration of the N—C(O)—N moiety with the C—N bonds possessing appreciable double bond character and a tendency to form hydrogen bonds (4). It can act as a ligand utilizing either nitrogen or oxygen as the donor atom.

From the results on thermal decomposition of $CdLCl_2$ (L = urea, methylurea, and *N*,*N*′-dimethylurea) adducts by thermogravimetric analysis in air and vacuum, the following order of stability was established: urea > methylurea > *N*,*N*′-dimethylurea (6). This sequence clearly indicates an influence of ligand substituents on stability. This is the only thermochemical datum dealing with the methylurea ligand.

In our study, the $Zn(mu)_2X_2$ (X = Cl, Br) and $M(mu)X_2$ (M = Cd, Hg and X = Cl, Br) adducts were synthesized and characterized, with special concern being devoted to obtaining thermochemical data of these adducts and ligand. Nevertheless, bearing in mind the systematic behavior observed for the urea derivatives, a comparison of the present results will be made with tetramethylurea

(7) and *N*,*N'*-dimethylurea (8), mainly in relation to the thermochemical data.

Broadly speaking, in any kind of systematic study, attention is always pointed toward well- or badly-behaved systems and correlations are used to illustrate the adjustment of the experimental data. To exemplify our very well-behaved systems, considering the enthalpies of combustion of urea (9), methylurea, *N*,*N'*-dimethylurea (dmu) (8), trimethylurea (10), and tetramethylurea (tmu) (11), a correlation $\Delta U_C^{\ominus}$(ureas)/kJ mol$^{-1}$ = $-49.14\,M + 2305.15$ is observed with less than 1% of error, $M$ being the molar mass of the urea and its derivatives. Moreover, the basicity order, tmu > dmu > mu, could be established from our experimental results. These results indicate that the sequence of basicity follows the inductive effect of the methyl groups, in agreement with the successive replacement of the hydrogen on the nitrogen of urea. Other thermochemical results involving mu and adducts will be reported here.

## Experimental

*Materials*

Only reagent grade materials were used throughout. Methylurea (Aldrich) was recrystallized twice in anhydrous ethanol at −5°C (12). After crystallization the amide was filtered in a dry nitrogen atmosphere, washed with a cold ethanol–ether (1:5) mixture, and dried *in vacuo* for 6 h. Nitromethane, acetone, and ethanol for conductance measurements as well as methanol and ethanol for calorimetric measurements were rigorously dried. Anhydrous chlorides and bromides of zinc and cadmium were prepared as before (7). The commercial mercury chloride (E. Merck) and bromide (Baker) were dried *in vacuo* for 3 h before use.

*Preparation of $Zn(mu)_2Cl_2$*

7.2 mmol of $ZnCl_2$ were dissolved in 10 mL of acetone. This was poured into a solution of 14.2 mmol of methylurea dissolved in 5 mL of acetone. This mixture was stirred at room temperature and a viscous product resulted after evaporation of the solvent *in vacuo*. The prolonged vacuum for 6 h produced crystals which were washed with a cold mixture of ethanol–ether (1:5) and dried *in vacuo* for 6 h.

*Preparation of $Zn(mu)_2Br_2$*

A solid mixture of 8.9 mmol of $ZnBr_2$ and 17.8 mmol of ligand was ground in a mortar with 0.3 mL of ethanol. The resulting paste was dissolved in ethylacetate and after evaporation of this solvent, the adduct crystallized, and was dried *in vacuo*.

*Preparations of $M(mu)X_2$ (M = Cd, Hg and X = Cl, Br)*

A solution of methylurea in 15 mL of ethanol was added dropwise to a solution of $MX_2$ dissolved in 50 mL of ethanol in a stoichiometric ratio 4:1. After evaporation of half of the solvent, the adduct started to settle, and was then filtered, washed, and dried as before.

*Analysis*

Weighed samples of the product were analysed for halide, metal, and nitrogen. The metals were spectrophotometrically titrated by EDTA. Halides were determined by potentiometric titration. Nitrogen was determined by the micro-Kjeldahl method (8).

*Calorimetry*

A LKB 8700 precision calorimetric system was used for all measurements of the enthalpies of the process of dissolution at (298.15±0.02) K, and operation and calibration have been described previously (7, 8). The measurements were carried out using 90 mL of solvent and the ampoules varied from 6 to 65 mg. Each enthalpy value was obtained from at least five independent runs.

The enthalpy of combustion of methylurea was determined from a conventional static bomb – calorimeter system (Veb Apparatenbau Babelsberg of the type Berthelot-Thomsen), for which the calibration and procedure have been described previously (13). The sample of ligand was ignited in an oxygen atmosphere of ~3 MPa in a calorimetric bomb of 250 mL internal capacity containing 1 mL of distilled water. The energy equivalent of the calorimeter, $E = -(10\,211 \pm 12)$ J K$^{-1}$, was determined from the combustion of benzoic acid on $\Delta U = -(26\,435.1 \pm 2.9)$ J g$^{-1}$. The auxiliary data used are $\Delta H_f^{\ominus}(HNO_3,l) = 59.7$; $\Delta H_f^{\ominus}(H_2O,l) = -(285.83 \pm 0.04)$; and $\Delta H_f^{\ominus}(CO_2,g) = -(393.51 \pm 0.31)$ kJ mol$^{-1}$ (14, 15).

The enthalpy of fusion, heat capacity of solid and liquid forms of methylurea were determined in a Perkin-Elmer DSC-2 differential scanning calorimeter. For the first determination seven measurements were made and the range of masses varied between 1 to 4 mg. The heat capacities of solid and liquid were determined from three and four runs, respectively, and in this case the masses varied in the 9–15 mg range. The calibration constant of the instrument, $k = 0.0394$ cm$^{-1}$ s$^{-1}$, was obtained from seven measurements of the fusion of indium (16, 17).

*Other measurements*

Melting point, infrared, conductance, mass spectra, and thermogravimetry of the ligand and adducts were performed as before (7, 8).

## Results

The new compounds are listed in Table 1, together with analytical data, melting point, and conductivities. The melting points are not reproducible due to decomposition of the adducts during the heating. The $Cd(mu)X_2$ (X = Cl, Br) adducts did not show a liquid phase when heated up to 210°C. However, the thermograms demonstrate the loss of ligand below this temperature, which characterizes a real interval of decomposition. The $Cd(mu)X_2$ (X = Cl, Br) adducts presented a low solubility in nitromethane and acetone; for this reason their conductance values were obtained in ethanol. In comparing adducts of the same stoichiometry, the conductance data in nitromethane revealed a higher conductance of the chloride adducts, which is opposite to that found in acetone.

In observing the thermograms of the zinc and cadmium adducts, two distinct steps can be seen. First of all, the adducts lose the ligands followed by the sublimation of the halides, leaving no residue, except in the case of the zinc chloride adduct which leaves an unidentified 10% of residue. Similar

[b]Conductance in ethanol.

thermograms are displayed for the adducts of mercury, in which the total mass loss is observed in only one step. All thermograms showed a loss of mass very well correlated with the stoichiometry of the adducts.

The mass spectrum of the ligand (18) showed the peak of the parent ion at $m/e$ 74 and the fragments: 58 $CH_3NHCO$ and 44 $HN(CH_3)_2$. These same peaks appeared in the spectra of the zinc and cadmium adducts, while in the mercury adducts the peaks of the mercury halides and metal were also observed.

The standard enthalpy of the reaction in the condensed phase, $MX_2(s) + n\,mu(s) = M(mu)_n X_2(s)$; $\Delta H_R^\ominus$, was obtained in ethanol or methanol. $\Delta H_R^\ominus$ values are derived from the individual enthalpies of solution of reactions 1, 2, and 3 of Table 2.

The standard enthalpy of formation of the adducts ($\Delta H_f^\ominus$) can be determined from the enthalpy of formation of metal halides (19), the enthalpy of formation of the ligand, and the enthalpy of the reaction in condensed phase, $\Delta H_R^\ominus$. The enthalpy of formation of mu was obtained by six measurements of the enthalpy of combustion: $C_2H_6N_2O(s) + 3O_2(g) = 2CO_2(g) + 3H_2O(l) + N_2(g)$; $\Delta H_c^\ominus = -(1358.3\pm7.6)$ kJ mol$^{-1}$ which gave the standard enthalpy of formation $\Delta H_f^\ominus(mu,s) = -(286\pm15)$ kJ mol$^{-1}$. In all those determinations the error quoted is twice the standard deviation of the mean and included all the uncertainty of the auxiliary data used.

A sharp peak at 373 K which corresponds to fusion and yields the value $\Delta H_{fus}^\ominus = (14.9\pm0.2)$ kJ mol$^{-1}$ was observed from the dsc thermograms of methylurea. The heat capacities of the solid and liquid forms of the ligand were also obtained and gave 0.093 and 0.184 kJ mol$^{-1}$ K$^{-1}$, respectively. Attempts were made to measure the enthalpy of vaporization ($\Delta H_v^\ominus$) of the ligand, but it decomposes at its temperature of normal ebulition. Thus, $\Delta H_v^\ominus$ was calculated by means of Riedel–Plack–Miller equations (20) and the obtained value was 58.8 kJ mol$^{-1}$. The heat capacity in the gas phase of mu was estimated by the method of generalized vibrational assignment (21) by means of the expression:

$$Cp(g) = -10 \times 10^{-3} + 2.96 \times 10^{-4}T - 11.9 \times 10^{-8}T^2$$

Now the standard enthalpy of sublimation of the ligand can be obtained from

$$\Delta H_{sub}^\ominus(298\ K) = \int_{298}^{373} Cp(s)dT + \Delta H_{fus}^\ominus(373\ K) + \int_{373}^{453} Cp(l)dT + \Delta H_{vap}^\ominus(453\ K) - \int_{298}^{453} Cp(g)dT$$

giving the value, $\Delta H_{sub}^\ominus = 78.2$ kJ mol$^{-1}$.

From thermodynamic cycles, the standard enthalpies of reactions $M(mu)_nX_2(s) = MX_2(s) + n\,mu(g)$; $\Delta H_D^\ominus$ and $MX_2(g) + n\,mu(g) = M(mu)_nX_2(s)$; $\Delta H_M^\ominus$ could also be calculated and these values are summarized in Table 3. In this table only the infrared bands which indicate the coordination of the ligand to the metal, i.e., the CO and NH stretching vibrations, are listed.

## Discussion

The infrared spectrum of methylurea (4) exhibits a large splitting of the NH stretching frequency due to the presence of hydrogen bonding, whose presence is also revealed in the adducts, but at higher frequencies, see Table 3. The very strong bands at 1650 and 1570 cm$^{-1}$ in the free ligand are assigned to CO stretching frequency and CN stretching vibration or amide II, respectively. After coordination both bands remain with their same intensities; however, their frequencies shift in opposite directions (22). The decrease of νCO and the increase of νCN and νNH frequencies are evidence that the carbonyl group of the ligand is coordinated to the metal. It is worthwhile to mention that the CO out-of-plane deformation, which appeared at 655 cm$^{-1}$ in the free ligand, did not change its position in the adducts.

The molar conductivities of the new adducts are typical for non-electrolytes. The conductance for a 1:1 electrolyte type in nitromethane, acetone, and ethanol should be in the intervals 75–95, 100–140, and 35–45 Ohm$^{-1}$ cm$^2$ mol$^{-1}$, respectively (23). The low values listed in Table 1 suggest that the halides are coordinated to the metal and their conductivities are probably due to a small degree of solvolysis of the adduct in this solvent (24).

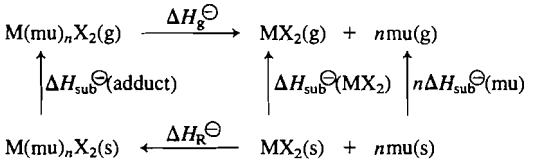
The heats of formation of the adducts in the condensed phase ($\Delta H_R^\ominus$) have been used to compare the acidity of metals and the basicity of ligands for adducts of the same structure (13, 25). In our results it is difficult to establish an order of acidity for all elements of the family because of the variation of the stoichiometry of the adducts. Nevertheless, the acidity order, $CdCl_2 > HgCl_2$, is observed, but the inverse order appeared with the bromides (Table 3), assuming that these adducts have the same crystal structures. The apparent anomaly observed for Cd and Hg can be explained through the effects of lattice energy. This fact is demonstrated by the enthalpy of dissolution of the adduct of mercury (31.16±0.48) which is somewhat higher than that of the cadmium adduct (18.97±0.20), see Table 2.

In connection with other urea derivatives it is worthwhile to consider the $\Delta H_R^\ominus$ values for adducts of tetramethylurea (7), dimethylurea (8), and methylurea. For example, $ZnL_2Br_2$ showed $\Delta H_R^\ominus$/kJ mol$^{-1}$: −88.68±1.32; −55.87±0.97, and −37.52±0.97, for L = tmu, dmu, and mu, respectively. These results enable us to establish the basicity order, tmu > dmu > mu. This sequence reflects that the donor ability of the ligand is associated with the electronic density of the oxygen, which is derived from the inductive effect of the methyl groups linked to the nitrogen atoms. Bearing in mind that these ligands involve a gradual decrease in $\Delta H_R^\ominus$ from tmu to mu, the great difference between tmu and dmu (compare 33 kJ mol$^{-1}$ from tmu to dmu and 18 kJ mol$^{-1}$ dmu to mu) can be attributed to the absence of trimethylurea results.

The adduct lattice enthalpy ($\Delta H_M^\ominus$) and $\Delta H_D^\ominus$, which is the enthalpy of the inverse of the decomposition reaction (Table 3), decrease from zinc to mercury. Both thermochemical parameters have been used to compare and systematize adducts which do not sublime without decomposition (7, 8, 26, 27). The enthalpy of formation of the adducts also presents the same trend in variation.

Under the conditions of the physical measurements such as melting point, thermogravimetry, and mass spectrometry one knows that the adducts decompose during the heating and the enthalpy of sublimation of the adduct is not accessible experimentally (26). In this case, the enthalpy of metal–ligand bond can be estimated (7, 8, 26). For that evaluation the enthalpy of reaction in the gas phase: $MX_2(g) + n\,mu(g) = M(mu)_nX_2(g)$; $\Delta H_g^\ominus$, was considered and this enthalpy was calculated by means of an appropriate thermochemical cycle. In

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.



such a way, it was assumed that the enthalpy of 1 mol of ligand is equal to the enthalpy of sublimation of the adduct (26). It is clearly known from infrared spectra that the metal is bound to oxygen, so $\Delta H_g^\ominus/n = \Delta H_{(M-O)}^\ominus$ and its value is higher for monoadducts, as was observed previously. For adducts of the same stoichiometry, $\Delta H_{(M-O)}^\ominus$ presents high values for Cd. The small $\Delta H_{(M-O)}^\ominus$ value for mercury should reflect its different bonding characteristics in relation to the other elements within the family, also it does not correlate with the shift in frequency of CO stretching frequency upon coordination. Of course, it must be remembered that this vibration is probably subject to extensive coupling. Of further interest, the large shift of νCO is observed with adducts of mercury, which have small $\Delta H_{(M-O)}^\ominus$.

# A low-temperature structural phase transition in aqueous dimyristoyl phosphatidylcholine bilayers observed by Raman scattering[1]

PATRICK T. T. WONG AND HENRY H. MANTSCH

*Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6*

Received April 15, 1982

PATRICK T. T. WONG and HENRY H. MANTSCH. Can. J. Chem. **60**, 2137 (1982).

A new structural phase change at −60°C and atmospheric pressure was observed in the gel phase of aqueous DMPC dispersions. This gel–gel phase transition exhibits first-order characteristics and is equivalent to the phase transition observed at 2.6 kbar and 30°C. The decrease in temperature has analogous effects on the ordering of the acyl chains in DMPC as has the increase in pressure. The rigid interchain reorientational fluctuations in the gel phase are gradually damped with decreasing temperature and below −60°C the interchain orientation becomes highly ordered.

PATRICK T. T. WONG et HENRY H. MANTSCH. Can. J. Chem. **60**, 2137 (1982).

On a observé un nouveau changement structural de phase à 60°C et à la pression atmosphérique dans la phase gel des dispersions aqueuses du CDMP. Cette transition de phase gel–gel a des caractéristiques d'ordre un et équivaut à la transition de phase observée à 2,6 kbar et à 30°C. La diminution de température a des effets analogues sur l'agencement des chaînes acyles du CDMP lorsque la pression augmente. Les fluctuations dans la réorientation entre chaînes rigides de la phase gel sont amorties graduellement lorsque la température diminue; et en-dessous de −60°C, l'orientation entre les interchaines devient fortement ordonnée.

## Introduction

Temperature-induced phase transitions in dimyristoyl phosphatidylcholine (DMPC) – water dispersions have been extensively studied (1–5). Two first-order phase transitions have been found at 24°C and 14°C and are generally referred to as the main transition and the pretransition, respectively. In a recent study (6) we have shown that the temperature of the main transition ($T_m$) and that of the pretransition ($T_p$) can be raised to 30°C by increasing the hydrostatic pressure to 0.15 and 1 kbar, respectively. In addition, a third first-order gel–gel phase transition was found at 2.6 kbar and 30°C. According to the thermodynamic Clausius–Clapeyron relationship, one may predict that this latter gel–gel phase transition should also occur at low temperature and atmospheric pressure. Yellin and Levin (7) have studied the temperature dependence of the Raman spectrum of DMPC–water dispersions from temperatures slightly below that of the pretransition to about −180°C. No cooperative phase transition was found in this temperature region; however, an inflection point at −40°C in the plot of the peak height ratio between the antisymmetric and the symmetric $CH_2$ stretching bands was observed in their study and was attributed to the onset of the *gauche–trans* isomerization in the acyl chains.

In the present work we have performed a detailed study of the temperature dependence of the frequencies and widths of various Raman bands of DMPC–water dispersions in the gel phase with the hope to detect a phase transition at low-temperature and atmospheric pressure, which would correspond to that observed at high pressure (6). We were aided considerably by instrumental and computational improvements with our Raman system, which enabled us to detect discontinuities in frequency of less than 1 $cm^{-1}$ (6).

## Experimental

DMPC–water dispersions containing 33.5 wt% water was prepared as previously described (6). The DMPC sample was placed in a quartz capillary which was mounted in a low-temperature system cooled by boiling liquid nitrogen. A chromel–alumel thermocouple was taped on the capillary tube as close as possible to the laser beam transit. Temperature control was maintained within ±1°C.

The Raman spectra were excited by using the 5145 nm argon line with a power of 200 mW at the sample from a CRL model 12 argon ion laser. The temperature increase due to the local heating by the 200 mW laser beam was estimated to be 2°C (6). The Raman spectra with a resolution of 2 $cm^{-1}$ were recorded with a Spex Model 14018 double monochromator having 1800 lines/mm holographic gratings and a cooled RCA C31034 photomultiplier. The data acquisition system and the data treatment have been described previously (6).

## Results

Raman spectra of DMPC–water dispersions in the gel phase were measured in the C—H stretching (2770–3100 $cm^{-1}$), the $CH_2$ bending (1350–1520 $cm^{-1}$), the $CH_2$ twisting (1270–1350 $cm^{-1}$), and the C—C skeletal stretching (960–1270 $cm^{-1}$) regions, at various temperatures between 9 and −120°C. Representative spectra are shown in Fig. 1.

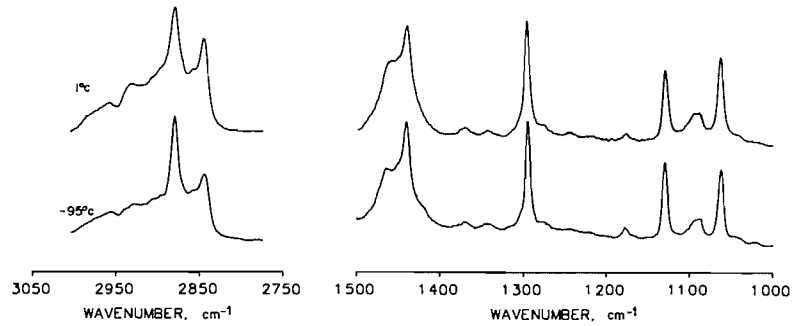

FIG. 1. Representative Raman spectra above (1°C) and below (−95°C) the GII to GIII phase transition.

The temperature dependencies of the frequencies and band-widths of these Raman bands are shown in Fig. 2. Discontinuities near −60°C are observed in the temperature–frequency plots for all these modes. The widths of most of the Raman bands decrease considerably with decreasing temperature between 9 and −60°C. Below −60°C the band-widths are constant or decrease only slightly with decreasing temperature. An exception is the symmetric $CH_2$ stretching vibration, the width of which increases with decreasing temperature, reaches a maximum at −60°C, and decreases thereafter.

The ratio of peak heights between the antisymmetric and the symmetric $CH_2$ stretching bands, H2885/H2845, is plotted against temperature in Fig. 3. This ratio first increases with decreasing temperature but becomes almost constant below −60°C.

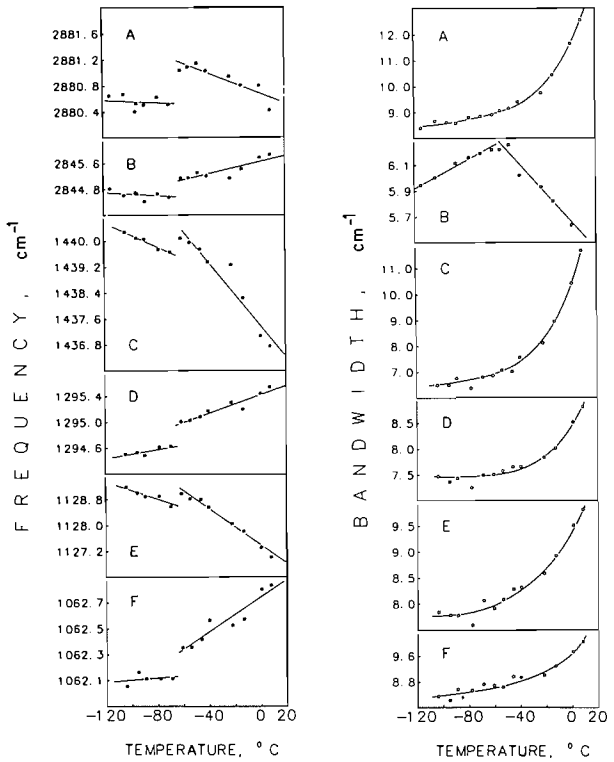

FIG. 2. Frequencies (closed symbols) and band-widths (open symbols) of selected Raman bands of DMPC as a function of temperature. *A*: antisymmetric $CH_2$ stretch; *B*: symmetric $CH_2$ stretch; *C*: $CH_2$ bend; *D*: $CH_2$ twist; *E*: asymmetric C—C stretch; *F*: symmetric C—C stretch. Band-widths were measured at different peak-heights: *A* (0.75), *B* (0.9), *C* (0.8), and *D*, *E*, *F* (0.5).

## Discussion

The changes near −60°C in the temperature dependencies of the band-frequencies, band-widths, and the peak height ratio, H2880/H2845, shown in Figs. 2 and 3 clearly indicate that a structural phase transition takes place at this temperature. The Raman spectra at temperatures between 9 and −60°C are similar to those observed at pressures between 1 and 2.6 kbar (6); the spectra in the C—H stretching region resemble those observed in *n*-alkanes with hexagonal interchain packing (8). Below −60°C, the Raman spectra are similar to those observed at pressures above 2.6 kbar and the spectra in the C—H stretching region resemble those of *n*-alkanes with orthorhombic or monoclinic interchain packing (8). Furthermore,

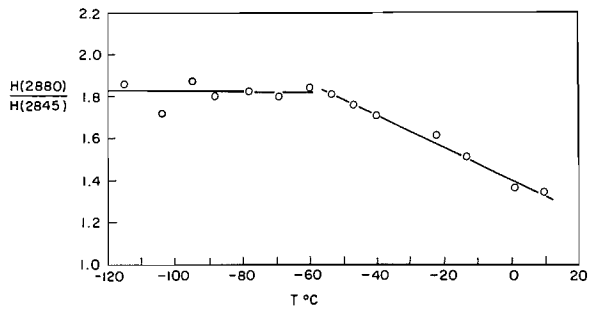

FIG. 3. Temperature dependence of the peak height ratio H2880/H2845.

the correlation field component of the $CH_2$ bending mode near 1410 $cm^{-1}$, which is a characteristic band for *n*-alkanes and polyethylene with the orthorhombic subcell structure, appears in the spectra immediately below −60°C. As the spectral features observed at temperatures below and above −60°C are similar to those observed at pressures above and below 2.6 kbar, respectively, the gel phases above and below −60°C can be identified with the gel phases below and above 2.6 kbar, designated in ref. 6 as GII and GIII phases, respectively. Thus, the phase transition at −60°C can be associated with a structural change from the GII gel phase at temperatures above −60°C to the GIII gel phase at temperatures below −60°C. From X-ray studies the GII phase has been correlated with distorted hexagonal (9) or quasi-orthorhombic (10) chain packing. However, diffraction studies of the GIII phase are required to determine the exact nature of the structural change at this phase transition. Although the phase behaviour of DMPC–water has not been explored at temperatures below −10°C, the changes observed at −60°C could possibly be correlated with a transition between the two lamellar gel phases $L_{\beta'}$ and L (9).

The change in band-width observed in the depolarized and weakly polarized bands when the temperature was decreased from 9 to −60°C is comparable with that observed at constant temperature when the pressure was increased from 1 to 2.6 kbar. For instance, the half-width of the 1295 $cm^{-1}$ band decreases in the GII phase from 8.8 $cm^{-1}$ at 9°C to 7.5 $cm^{-1}$ at −60°C while it decreases from 8.5 $cm^{-1}$ at ~ 1 kbar to 7.4 $cm^{-1}$ at ~ 2.6 kbar (6). This decrease in band-width is largely due to the damping of the large angle reorientational fluctuation about the long axis of the acyl chains. At temperatures near $T_p$ (9, 11) or at pressures near 1 kbar (6) there are rapid reorientational fluctuations about the long axis of the acyl chains. It is well documented (12, 13) that the narrowing of the depolarized and weakly polarized Raman bands mainly arises from the decrease in the rate of such reorientational fluctuations. Below −60°C the widths of the depolarized and weakly polarized bands are much less sensitive to temperature, a situation similar to that observed in the high pressure GIII phase (6), indicating that the acyl chains are highly orientationally ordered in this phase. On the other hand, the width of the highly polarized 2845 $cm^{-1}$ band (symmetric $CH_2$ stretch), which is not affected by the reorientational fluctuation but is strongly affected by intermolecular interactions and vibrational relaxation (14–16), increases in the GII phase with decreasing temperature (Fig. 2*B*). The same effect was observed when the pressure was increased throughout the GII phase (6). However, below −60°C the width of this polarized band decreases slightly with decreasing temperature. This indicates that in the GIII phase the contribution of the intramolecular anharmonicity, which would narrow the width of this polarized band (16) as the temperature decreases, dominates that of the interchain interaction.

Isotopic dilution studies at constant temperature (8, 17, 18) have shown that the peak height ratio H2880/H2845 represents a measure of the magnitude of interchain interactions. We found earlier (6) that at constant temperature the H2880/H2845 ratio, and thus the interchain interaction, increased in the GII phase with increasing pressure due to the pressure damping of the reorientational fluctuation. In the present study we found that at constant pressure the H2880/H2845 ratio increases linearly with decreasing temperature in the GII phase. The total change observed in this ratio in the temperature range of the GII phase is comparable with that observed in the pressure range of the GII phase (6). We therefore conclude that the increase in the H2880/H2845 ratio observed in the present work is largely due to the increased interchain interaction rather than the decrease in the number of the *gauche* conformers in the acyl chains (7). The increase in interchain interaction with decreasing temperature is undoubtedly the result of the damping of the reorientational fluctuation as demonstrated by the temperature dependence of the widths of the depolarized and weakly polarized Raman bands. The increase in interchain coupling with decreasing temperature is also evident from the increase in the width of the highly polarized 2845 $cm^{-1}$ Raman band with decreasing temperature. In the GIII phase the H2880/H2845 ratio is almost independent of temperature, which implies that due to the highly ordered structure of the acyl chains in this phase, the interchain coupling does not increase by further lowering the temperature. Thus, the changes observed in DMPC–water dispersions at −60°C have all the characteristics of the GII to GIII phase transition previously found to occur at 2.6 kbar and 30°C.

# Heat capacities and volumes of dissociation of phosphoric acid (1st, 2nd, and 3rd), bicarbonate ion, and bisulfate ion in aqueous solution

JOHN W. LARSON,[1] KEVIN G. ZEEB, AND LOREN G. HEPLER

*Department of Chemistry and Oil Sands Research Laboratory, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4*

Received January 18, 1982

JOHN W. LARSON, KEVIN G. ZEEB, and LOREN G. HEPLER. Can. J. Chem. **60**, 2141 (1982).

Measurements at 25°C with a flow calorimeter and a flow densimeter have led to heat capacities and densities of aqueous solutions of $H_3PO_4$, $NaH_2PO_4$, $Na_2HPO_4$, $Na_3PO_4$, $NaHCO_3$, $Na_2CO_3$, $H_2SO_4$, and various buffer solutions. Results are presented in terms of apparent molar heat capacities ($\phi_C$) and apparent molar volumes ($\phi_V$). Analysis of the experimental $\phi_V$ values to obtain the desired standard state $\phi_V^0$ values for single electrolytes requires that allowance be made for hydrolysis and dissociation reactions of certain solutes, along with extrapolation to zero concentration. Analysis of $\phi_C$ values requires similar considerations of hydrolysis and dissociation reactions, allowance for enthalpy and equilibrium changes ("relaxation") during calorimetric measurements, and extrapolation to zero concentration. Procedures for these calculations are presented. The $\phi_C^0$ and $\phi_V^0$ values that result from all of these measurements and calculations are used to obtain $\Delta C_p^0$ and $\Delta V^0$ values for acid dissociation reactions, which are then related to effects of temperature and pressure on other thermodynamic properties.

JOHN W. LARSON, KEVIN G. ZEEB et LOREN G. HEPLER. Can. J. Chem. **60**, 2141 (1982).

Des mesures à 25°C, à l'aide d'un calorimètre à écoulement et d'un densimètre à écoulement, ont conduit aux capacités calorifiques et aux densités des solutions aqueuses de $H_3PO_4$, $NaH_2PO_4$, $Na_2HPO_4$, $Na_3PO_4$, $NaHCO_3$, $H_2SO_4$ et de plusieurs solutions tampons. On présente les résultats en termes de capacités calorifiques molaires apparentes, ($\phi_C$), et de volumes molaires apparents, ($\phi_V$). Lorsqu'on effectue une analyse des valeurs expérimentales de $\phi_V$, en vue d'obtenir les valeurs $\phi_V^0$ de l'état standard d'électrolytes spécifiques, on doit tenir compte des réactions d'hydrolyse et de dissociation de certains solutés en plus de faire une extrapolation à dilution infinie. Pour faire une analyse des valeurs $\phi_C$, on doit aussi prendre en considération les réactions d'hydrolyse et de dissociation, on doit tenir compte des variations d'enthalpie et d'équilibre ("relaxation") pendant les mesures calorimétriques et faire une extrapolation à concentration zéro. On présente les marches à suivre pour ces calculs. On a utilisé les valeurs de $\phi_C^0$ et de $\phi_V^0$ qui résultent de toutes ces mesures et de tous ces calculs, pour obtenir les valeurs de $\Delta C_p^0$ et de $\Delta V^0$ pour les réactions de dissociation des acides que l'on peut alors relier aux effets de température et de pression sur d'autres propriétés thermodynamiques.

[Traduit par le journal]

## Introduction

The thermodynamic properties of the aqueous acids listed in the title are important in such fields as boiler water chemistry, interaction of aqueous solutions with minerals, biochemistry, marine science, and analytical chemistry. The research to be described in this paper was undertaken to provide information about changes in heat capacity ($\Delta C_p^0$) and volume ($\Delta V^0$) accompanying dissociation of these acids and then to use these values in calculations of the thermodynamics of dissociation over ranges of temperature and pressure. Obtaining the desired standard state changes in volume from measured densities of solutions requires appropriate extrapolations to zero concentration and also "corrections" for such chemical reactions as hydrolysis and dissociation, for which we have developed convenient methods. Evaluation of standard state changes in heat capacities involves similar "corrections" and extrapolations and also requires that allowance be made for "relaxation" effects that are associated with the changes in equilibrium states that occur with changing temperature during the course of calorimetric measurements of heat capacities.

## Experimental

Our heat capacity measurements have been made with a Picker flow calorimeter of the type previously described (1). A *small* systematic error in measurements with this calorimeter has been detected and corrected on the basis of measurements (2–4) on NaCl (aq) solutions. Densities of solutions were measured with a flow densimeter (5). Results of all of these measurements refer to (25.0 ± 0.1)°C.

BDH AnalaR grade $Na_2CO_3$ was dried at 270°C. BDH reagent grade $NaH_2PO_4$ and $Na_3PO_4$ were recrystallized from water–ethanol and dried at 150°C. Fisher certified $Na_2HPO_4 \cdot 7H_2O$ and Baker reagent grade $NaHCO_3$ were used as received. The $Na_2HPO_4 \cdot 7H_2O$ was analyzed for water by heating to constant weight at 150°C.

All compounds mentioned above were titrated with standardized HCl or NaOH and found to contain no appreciable acid–base impurities and had overall purities of not less than 99.7%.

Stock solutions of sulfuric acid and phosphoric acid were prepared from ACS reagent grade concentrated acids and distilled water, and were then analyzed by titration with standardized NaOH solutions.

Buffer solutions of $NaHCO_3/Na_2CO_3$ and $NaH_2PO_4/Na_2H$-

$PO_4$ were prepared from known masses of the solids and distilled water. These buffer solutions were made with mole ratios equal to 9/1, 1/1, and 1/9. Solutions of $Na_3PO_4$ were prepared from known masses of solid and distilled water. Further solutions were prepared by quantitative dilutions of several of these solutions.

## Experimental results and analyses of data

Results of measurements with the Picker flow calorimeter are heat capacities per unit volume of solution. Combination of these heat capacities with the densities that we have also measured leads to heat capacities per unit mass of solution. Further combination of these latter heat capacities with the already known (6) heat capacity of water (4.1793 J K$^{-1}$ g$^{-1}$) leads to apparent molar heat capacities. Similarly, densities of solutions in combination with the already known density of water (0.997044 g cm$^{-3}$) lead to apparent molar volumes. These apparent molar properties are defined according to

$$[1] \quad \phi_Y = Y(\text{sol'n}) - n_1 Y_1^0 / \sum_{i>1} n_i$$

in which $Y$ is the extensive property (heat capacity or volume) of a specified quantity of solution, $n_1$ is the number of moles of water in the specified quantity of solution, $Y_1^0$ is the molar property of pure water, and $n_i$ for $i > 1$ represents the numbers of moles of solutes. Results of our measurements of heat capacities and densities, expressed in terms of apparent molar heat capacities and volumes, are listed in Tables 1, 2, and 3. Treatment of these experimental results is described in the following paragraphs.

Our principal interest in this investigation has been to obtain the $\phi_C^0$ and $\phi_V^0$ values for zero concentration that are identical to the corresponding partial molar quantities that then lead to $\Delta C_p^0$ and $\Delta V^0$ values for various dissociation reactions. Analysis of our apparent molar volumes for this purpose requires that appropriate allowance be made for hydrolysis and dissociation reactions of certain solutes along with extrapolation to zero concentration. Analysis of our apparent molar heat capacities requires similar considerations of hydrolysis and dissociation reactions, allowance for enthalpy and equilibrium changes during calorimetric measurements, along with extrapolations to zero concentration. Because of their relative simplicity, we consider volumes first.

Apparent molar volumes of reasonably dilute solutions of electrolytes are accurately represented by equations of the form

$$[2] \quad \phi_V = \phi_V^0 + A_V (d_1^0)^{1/2} (\omega)^{3/2} (m)^{1/2} + B_V \omega m$$

in which $A_V$ and $\omega$ come from the Debye–Hückel theory and $B_V$ is an adjustable parameter for each solute. We have used

$$A_V (d_1^0)^{1/2} = 1.865 \text{ cm}^3 \text{ mol}^{-3/2} \text{ kg}^{1/2}$$

from Millero (7) and the "valence factor" $\omega$ as commonly defined (8) is

$$[3] \quad \omega = I/m = (0.5\,\Sigma\nu_i z_i^2 m_i)/m$$

in which $I$ is the molal ionic strength, $m_i$ is the molality of a particular solute, and $m$ is the total molality. For non-electrolytes and undissociated weak electrolytes such as $H_3PO_4$(aq) we have [2′] instead of [2]:

$$[2'] \quad \phi_V = \phi_V^0 + B_V m$$

Many of our measurements have been made on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

buffer solutions that are described as containing component solutes in ratios equal to 9/1, 1/1, and 1/9. We now define solute mole fractions $F_2$ and $F_3$ according to

[4] $$F_2 = n_2/(n_2 + n_3)$$

and

[5] $$F_3 = n_3/(n_2 + n_3)$$

in which subscript 2 refers to a 1:1 electrolyte and subscript 3 refers to a 2:1 electrolyte. For $F_2$ values of 0.9, 0.5, and 0.1 we have ω values equal to 1.2, 2.0, and 2.8, respectively. As shown in Tables 1 and 2, we have made measurements on solutions having three different $F_2$ values at several different total molalities.

For our $NaH_2PO_4/Na_2HPO_4$ and $NaHCO_3/Na_2CO_3$ buffer solutions we find that hydrolysis and dissociation corrections are negligible. We have therefore obtained values of $\phi_V^0$ and $B_V$ by least-squares fitting of $\phi_V - A_V(d_1^0)^{1/2}(\omega)^{3/2}(m)^{1/2}$ against $\omega m$, as suggested by eq. [2], with results that are given in Table 4. Further linear least-squares fits of $\phi_V^0$ values for buffers against corresponding $F_2$ values lead to $\phi_{V,2}^0$ and $\phi_{V,3}^0$ values for single electrolyte components of the buffers, as reported in Table 5. Using

$$\phi_V^0(Na^+) = -1.2\,cm^3\,mol^{-1}$$

from Millero (7), based on the useful convention that

$$\phi_V^0(H^+) \equiv 0$$

we then obtain the conventional ionic volumes for $H_2PO_4^-(aq)$, $HPO_4^{2-}(aq)$, $HCO_3^-(aq)$, and $CO_3^{2-}(aq)$ that are listed in Table 6.

For solutions of phosphoric acid we need consider only the first dissociation as in

[6] $$H_3PO_4(aq) = H^+(aq) + H_2PO_4^-(aq)$$

for which we have the equilibrium constant $K_6$ from a recent review (9). We calculate the fraction dissociated (α) from $K_6$ and the Davies equation for activity coefficients (γ):

[7] $$\log \gamma = (-Az^2I^{1/2})/(1 + I^{1/2}) + 0.1z^2I$$

The apparent molar volumes of solutions of phosphoric acid are expressed as

[8] $$\phi_V = (1-\alpha)\phi_V(H_3PO_4) + \alpha\phi_V(H^+ + H_2PO_4^-)$$

Substitution of the appropriate version of eq. [2] and [2′] in [8] leads us to obtain the desired apparent molar volume of undissociated phosphoric acid, $\phi_V^0(H_3PO_4)$, by extrapolating

$$\frac{\phi_V - \alpha\phi_V^0(H^+ + H_2PO_4^-) - (\alpha)^{3/2}A_V(d_1^0)^{1/2}(m)^{1/2}}{(1-\alpha)}$$

to zero concentration. Our value for $\phi_V^0(H_3PO_4)$ is listed in Table 6.

The hydrolysis of solutions of sodium phosphate is represented by

[9] $$PO_4^{3-}(aq) + H_2O(liq) = HPO_4^{2-}(aq) + OH^-(aq)$$

We have calculated α (fraction hydrolyzed) values from the equilibrium constant (9) and activity coefficients (10). The apparent molar volumes of solutions of sodium phosphate are then expressed as

[10] $$\phi_V = (1-\alpha)\phi_V(3Na^+ + PO_4^{3-}) + \alpha\phi_V(2Na^+ + HPO_4^{2-}) + \alpha\phi_V(Na^+ + OH^-) - \alpha V^0(H_2O)$$

Substitution of appropriate versions of eq. [2] in [10] and rearrangement of the resulting complicated expression has led us to extrapolate

$$[\phi_V - \alpha\phi_V^0(2Na^+ + HPO_4^{2-}) - \alpha\phi_V^0(Na^+ + OH^-) + \alpha V^0(H_2O) - (6-2\alpha)A_V(d_1^0)^{1/2}(I)^{1/2}]/(1-\alpha)$$

to zero ionic strength to obtain the desired $\phi_V^0(3Na^+ + PO_4^{3-})$ that is listed in Table 5 and thence the conventional $\phi_V^0(PO_4^{3-})$ that is listed in Table 6.

| $HSO_4^-$(aq) | 22 | 35.2 |
| $SO_4^{2-}$(aq) | −278[a] | 14.0[b] |

[a] From ref. 19.
[b] From ref. 7.

Sulfuric acid in our solutions is completely dissociated into $H^+$(aq) and $HSO_4^-$(aq) and some of the bisulfate ions are further dissociated as in

[11] $HSO_4^-(aq) = H^+(aq) + SO_4^{2-}(aq)$

We have calculated α (fraction of $HSO_4^-$ dissociated) values from the equilibrium constant (9) and the Davies equation (10). The apparent molar volumes of sulfuric acid solutions are expressed as

[12] $\phi_V = (1 - \alpha)\phi_V(H^+ + HSO_4^-) + \alpha\phi_V(2H^+ + SO_4^{2-})$

Substitution of the appropriate forms of eq. [2] in [12] and rearrangement lead us to obtain $\phi_V^0(H^+ + HSO_4^-)$ by extrapolation of

$$\phi_V - \alpha\phi_V^0(2H^+ + SO_4^{2-}) - (1 + 2\alpha)A_V(d_1^0)^{1/2}I^{1/2}/(1 - \alpha)$$

to zero ionic strength to obtain the $\phi_V^0(H^+ + HSO_4^-)$ that is listed in Table 5. The conventional $\phi_V^0(HSO_4^-)$ is listed in Table 6.

Analysis of experimental apparent molar heat capacities for reactive systems to obtain the desired $\phi_C^0$ values of specified solute species requires that we allow for the temperature dependent state of equilibrium and related thermal effects. These "relaxation" effects have been considered previously for other systems by Woolley and Hepler (11) and by Jolicoeur, Lemelin, and Lapalme (12). As these earlier investigations have shown, experimental apparent molar heat capacities ($\phi_C$) can be regarded as a sum of two kinds of contributions. One contribution is from the solute species present in the solution of interest and is designated $\phi_C^{sp}$; it is this contribution that we will relate to the desired standard state heat capacities of various solute species. The other contribution to the total experimental apparent molar heat capacity is from the thermal effects associated with changes in chemical equilibrium ("relaxation") and is designated $\phi_C^{rel}$. We therefore have

[13] $\phi_C = \phi_C^{sp} + \phi_C^{rel}$

The contribution of "relaxation" to the apparent molar heat capacity is given (11, 12) by

[14] $\phi_C^{rel} = \Delta H(d\alpha/dT)$

Thus the desired contributions due to the aqueous solute species can be obtained as

[15] $\phi_C^{sp} = \phi_C - \Delta H(d\alpha/dT)$

Procedures for calculating $(d\alpha/dT)$ from equilibrium constants, enthalpies, and activity coefficients for systems of various charge types follow those previously described (11, 12) and recently extended (13). The required equilibrium constants and enthalpies have been taken from a recent review (9).

The "relaxation" effects on heat capacities of the $NaH_2PO_4/Na_2HPO_4$ buffer systems are very small compared with the experimental uncertainties. We have therefore taken $\phi_C = \phi_C^{sp}$ for these solutions and used the $\phi_C$ values in Table 1 for our subsequent calculations for this system. For all other systems we have calculated $\phi_C^{sp}$ values by way of experimental $\phi_C$ values and eq. [15], which has involved calculation of $\Delta H(d\alpha/dT)$ as described in detail elsewhere (11–13), with results presented in parentheses in Tables 2 and 3.

The next step has been to analyse the $\phi_C^{sp}$ values in Tables 2 and 3 and the $\phi_C$ ($= \phi_C^{sp}$) values in Table 1 on the basis of the equation

[16] $\phi_C^{sp} = \phi_C^0 + A_C(d_1^0)^{1/2}(\omega)^{3/2}(m)^{1/2} + B_C\omega m$

in which $A_C$ is derived from the Debye–Hückel theory and $B_C$ is an adjustable parameter. We have used

$$A_C(d_1^0)^{1/2} = 28.95\,\text{J K}^{-1}\,\text{mol}^{-3/2}\,\text{kg}^{1/2}$$

from Desnoyers (14, 15). In this connection we note that there is recent evidence (16, 17) for a slightly larger value of $A_C(d_1^0)^{1/2}$, but the difference is not enough to be significant for our present purposes.

We have used our $\phi_C^{sp}$ results with eq. [16] in carrying out calculations and extrapolations to zero concentration in ways that are equivalent to those already described in detail for our $\phi_V$ values. The resulting $\phi_C^0$ values are listed in Tables 4 and 5. These $\phi_C^0$ values have been combined with the conventional $\phi_C^0(H^+) \equiv 0$ and $\phi_C^0(Na^+) = 43\,\text{J K}^{-1}\,\text{mol}^{-1}$ and $\phi_C^0(SO_4^{2-}) = -278\,\text{J K}^{-1}\,\text{mol}^{-1}$ from earlier work (18, 19) to obtain the conventional $\phi_C^0$ values listed in Table 6.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

TABLE 7. Standard state changes in heat capacity and volume for acid dissociation reactions at 25.0°C, from $\phi_C^0$ and $\phi_V^0$ values in Table 6

| Reaction | $\Delta C_p^0$ / J K$^{-1}$ mol$^{-1}$ | $\Delta V^0$ / cm$^3$ mol$^{-1}$ |
|---|---|---|
| $H_3PO_4 = H^+ + H_2PO_4^-$ | −128 | −16.8 |
| $H_2PO_4^- = H^+ + HPO_4^{2-}$ | −220 | −26.1 |
| $HPO_4^{2-} = H^+ + PO_4^{3-}$ | −242 | −24.0 |
| $HCO_3^- = H^+ + CO_3^{2-}$ | −247 | −29.2 |
| $HSO_4^- = H^+ + SO_4^{2-}$ | −300 | −21.2 |

We have used the conventional standard state heat capacities and volumes listed in Table 6 for calculation of $\Delta C_p^0$ and $\Delta V^0$ for the acid dissociation reactions listed in Table 7. It should be emphasized that the arbitrariness in setting $\phi_Y^0(H^+) \equiv 0$ to obtain the conventional values in Table 6 cancels out of the calculations leading to Table 7 so that the reported $\Delta C_p^0$ and $\Delta V^0$ values are independent of the conventional values chosen for $\phi_Y^0(H^+)$.

We estimate that uncertainties in most of our $\phi_V^0$ and $\phi_C^0$ values are about $\pm 0.6$ cm$^3$ mol$^{-1}$ and about $\pm 4$ J K$^{-1}$ mol$^{-1}$, respectively; exceptions are $Na_3PO_4$(aq), $PO_4^{3-}$(aq), and $HSO_4^-$(aq) for which uncertainties are larger than for the other solutes. Our further estimates for uncertainties in $\phi_V^0$ are about $\pm 3$ cm$^3$ mol$^{-1}$ for $Na_3PO_4$(aq) and $PO_4^{3-}$(aq) and about $\pm 0.8$ cm$^3$ mol$^{-1}$ for $HSO_4^-$(aq). We also estimate that uncertainties in $\phi_C^0$ are about $\pm 20$ J K$^{-1}$ mol$^{-1}$ for $Na_3PO_4$(aq) and $PO_4^{3-}$(aq) and about $\pm 8$ J K$^{-1}$ mol$^{-1}$ for $HSO_4^-$(aq). As shown in the next section, results of several earlier investigations provide evidence that most of our $\phi_V^0$ values (Tables 5 and 6) and related $\Delta V^0$ values (Table 7) are reliable to within the estimated uncertainties; the only exceptions are $Na_3PO_4$(aq) and $PO_4^{3-}$(aq) and the related $\Delta V^0$ for dissociation of $HPO_4^{2-}$(aq), for which the true uncertainties may be larger than our estimates above. Uncertainties in most earlier $\Delta C_p^0$ values are so large that they provide little evidence for or against our $\Delta C_p^0$ values and our estimates of their uncertainties.

## Comparisons of results

There have been many investigations of partial molar volumes and also dissociation constants at various pressures that have yielded volumes to be compared with our values in Tables 6 and 7. Nearly all such results obtained before 1973 have been cited and summarized in Hamann's excellent review (20). Now we also have some useful results from more recent investigations.

Hamann (20) has listed $\Delta V^0 = -16.6$ and $-16.2$ cm$^3$ mol$^{-1}$ for the first dissociation of phosphoric acid. More recently, Lo Surdo, Bernstrom, Jonsson, and Millero (21) have reported $\Delta V^0 = -16.26$ cm$^3$ mol$^{-1}$ for this dissociation. All of these results are in good agreement with our $\Delta V^0 = -16.8$ cm$^3$ mol$^{-1}$.

Hamann (20) has listed $\Delta V^0 = -24.0$ and $-24.1$ cm$^3$ mol$^{-1}$ for the second dissociation of phosphoric acid, for which Lo Surdo *et al.* (21) have recently reported $\Delta V^0 = -25.85$ cm$^3$ mol$^{-1}$. Our $\Delta V^0 = -26.1$ cm$^3$ mol$^{-1}$ for this dissociation provides support for the value from Lo Surdo *et al.* (21) in preference to the earlier values.

Lo Surdo *et al.* (21) have also reported $\Delta V^0 = -35.96$ cm$^3$ mol$^{-1}$ for the third dissociation of phosphoric acid, for which we found $\Delta V^0 = -24.0$ cm$^3$ mol$^{-1}$. There is no obvious explanation for the difference in these values.

We also note that the $\phi_V^0$ values reported by Lo Surdo *et al.* (21) for $H_3PO_4$(aq), $NaH_2PO_4$(aq), and $Na_2HPO_4$(aq) are all in good agreement with our corresponding values in Table 5. On the other hand, their $\phi_V^0$ for $Na_3PO_4$(aq) is in poor agreement with our value.

Previous reviews by Millero (7) and by Hamann (20) have led to a choice of $\Delta V^0 = -27.7$ cm$^3$ mol$^{-1}$ for dissociation of $HCO_3^-$(aq). The more recently reported partial molar volumes of Perron, Desnoyers, and Millero (8) lead to $\Delta V^0 = -28.4$ cm$^3$ mol$^{-1}$. As shown in Table 7, our measurements lead to $\Delta V^0 = -29.2$ cm$^3$ mol$^{-1}$ for this dissociation. We suggest that both of the latter two values are more accurate than the first value quoted above.

Both Millero (7) and Hamann (20) chose $\Delta V^0 = -21.7$ cm$^3$ mol$^{-1}$ for dissociation of $HSO_4^-$(aq). More recent volumetric measurements by Rohwer, Brink, and Cruywagen (22) lead to $\Delta V^0 = -20.0 \pm 1.0$ cm$^3$ mol$^{-1}$. These earlier values are in good agreement with our $\Delta V^0 = -21.2$ cm$^3$ mol$^{-1}$ for this dissociation.

We now turn to some comparisons of our heat capacities with earlier results.

Bates (23) has evaluated the first dissociation constant of $H_3PO_4$(aq) at 5° intervals from 0 to 60°C. An equation of type $\log K = f(T)$ has been fitted to the results; two differentiations with respect to $T$ have led to a reported $\Delta C_p^0 = -154 \pm 5$ J K$^{-1}$ mol$^{-1}$ at 25°C. More recently, Mesmer and Baes (24) have investigated the first dissociation of $H_3PO_4$(aq) at 25° intervals from 0 to 300°C. Their results have led to $\Delta C_p^0 = 34 \pm 29$ J K$^{-1}$ mol$^{-1}$ for the neutralization reaction

[17] $H_3PO_4(aq) + OH^-(aq) = H_2PO_4^-(aq) + H_2O(liq)$

Combination of this result with $\Delta C_p^0 = -215\,J\,K^{-1}\,mol^{-1}$ for dissociation of water from a recent review (9) leads to $\Delta C_p^0 = -186 \pm 30\,J\,K^{-1}\,mol^{-1}$ for the first dissociation of $H_3PO_4(aq)$. Because of the well-known magnification of uncertainties and errors associated with double differentiation and also because of the difficulties in evaluating accurately the relatively small $pK$ of $H_3PO_4(aq)$ as reviewed recently by Pitzer and Silvester (25), we believe that our $\Delta C_p^0 = -128\,J\,K^{-1}\,mol^{-1}$ is the best available for the first dissociation of $H_3PO_4(aq)$.

For the second dissociation of phosphoric acid we have four separate values of $\Delta C_p^0$ to compare with our value. Bates and Acree (26) have determined this dissociation constant at 5° intervals from 0 to 60°C; two differentiations of the derived $\log K = f(T)$ have led to $\Delta C_p^0 = -226\,J\,K^{-1}\,mol^{-1}$. Bates and Acree (26) also calculated $\Delta C_p^0 = -189\,J\,K^{-1}\,mol^{-1}$ from the earlier dissociation constants of Nims (27), determined over the temperature range 20 to 50°C. Grzybowski (28) has determined dissociation constants at 5°C intervals from 5 to 50°C and has similarly calculated $\Delta C_p^0 = -200 \pm 9.5\,J\,K^{-1}\,mol^{-1}$ for the second dissociation. Finally, Mesmer and Baes (23) have determined equilibrium constants for

[18] $H_2PO_4^-(aq) + OH^-(aq) = HPO_4^{2-}(aq) + H_2O(liq)$

at 25° intervals from 0 to 300°C and have calculated $\Delta C_p^0 = 32 \pm 25\,J\,K^{-1}\,mol^{-1}$ for this neutralization reaction. Combination of this result with $\Delta C_p^0$ for dissociation of water (9) leads to $\Delta C_p^0 = -183 \pm 26\,J\,K^{-1}\,mol^{-1}$ for the second dissociation of phosphoric acid. We suggest that our $\Delta C_p^0 = -220\,J\,K^{-1}\,mol^{-1}$ is the best available value. Although we are generally skeptical of $\Delta C_p^0$ values based on double differentiation of $\log K = f(T)$, we note that the equilibrium constants of Bates and Acree (26) and Grzybowski (28) appear to have been determined with considerable skill and accuracy; it is therefore gratifying to note that their (26, 28) $\Delta C_p^0$ values are in good agreement with our value.

We do not know of any earlier results that permit calculation of the heat capacity change for the third dissociation of phosphoric acid to compare with our $\Delta C_p^0 = -242\,J\,K^{-1}\,mol^{-1}$.

For the dissociation of $HCO_3^-(aq)$ we have several $\Delta C_p^0$ values to compare with our value. Harned and Scholes (29) have determined the equilibrium constant at 5° intervals from 0 to 50°C and by double differentiation of the resulting equation of type $\log K = f(T)$ have obtained $\Delta C_p^0 = -276\,J\,K^{-1}\,mol^{-1}$. Nakayama (30) has treated the experimental results of Harned and Scholes (29) slightly differently to obtain $\Delta C_p^0 = -282\,J\,K^{-1}\,mol^{-1}$ for this dissociation. More recently, Plummer and Busenberg (31) have analyzed equilibrium data over a wider range of temperature; double differentiation of their $\log K = f(T)$ now leads us to $\Delta C_p^0 = -291\,J\,K^{-1}\,mol^{-1}$ at 298.15 K. Plummer (31) has also found that different selection and treatment of the equilibrium constants leads to less negative $\Delta C_p^0$ values. Perron, Desnoyers, and Millero (8) have measured heat capacities of aqueous solutions of $NaHCO_3$ and $Na_2CO_3$. We have used their *reported* $\phi_C^0$ values in calculating $\Delta C_p^0 = -214\,J\,K^{-1}\,mol^{-1}$ for the dissociation of $HCO_3^-(aq)$. We know, however, that their *reported* $\phi_C^0$ values for these salts and this calculated $\Delta C_p^0$ value are incorrect because of neglect of the chemical relaxation effect (11–13), which had not yet been recognized (11) at the time Perron, Desnoyers, and Millero (8) wrote their paper. We have therefore made use of eqs. [13]–[15] with their experimental results to obtain a corrected $\Delta C_p^0 = -249\,J\,K^{-1}\,mol^{-1}$ for the dissociation of $HCO_3^-(aq)$. We also note that Peiper and Pitzer (32) have independently and by a slightly different procedure (also using slightly different auxiliary data) made "relaxation corrections" to the results of Perron, Desnoyers, and Millero (8) to obtain $\Delta C_p^0 = -260\,J\,K^{-1}\,mol^{-1}$ for the dissociation of $HCO_3^-(aq)$. These "corrected" $\Delta C_p^0$ values from the measurements of Perron, Desnoyers, and Millero (8) are in good agreement with our $\Delta C_p^0 = -247\,J\,K^{-1}\,mol^{-1}$ for this dissociation.

For dissociation of $HSO_4^-(aq)$ we have several values for $\Delta C_p^0$ as follows. Lietzke, Stoughton, and Young (33) have determined equilibrium constants at temperatures from 25 to 225°C and have obtained an equation of type $\ln K = f(T)$ from which we now calculate $\Delta C_p^0 = -209\,J\,K^{-1}\,mol^{-1}$ for the dissociation of $HSO_4^-(aq)$ at 298.15 K. Marshall and Jones (34) have determined equilibrium constants from 25 to 350°C and have calculated $\Delta C_p^0 = -238\,J\,K^{-1}\,mol^{-1}$. Young, Singleterry, and Klotz (35) have reported results of their determinations of equilibrium constants at 10° intervals from 5 to 55°C and have calculated two values for the heat capacity change associated with dissociation of $HSO_4^-(aq)$: $\Delta C_p^0 = -192$ and $-238\,J\,K^{-1}\,mol^{-1}$. Readnour and Cobble (36) have measured enthalpies of solution of $Na_2SO_4(c)$ in water and in dilute hydrochloric acid at several temperatures and have calculated $\Delta C_p^0 = -356\,J\,K^{-1}\,mol^{-1}$ for dissociation of $HSO_4^-(aq)$ at 25°C. More recently, Criss (37) has used the experimental results of Readnour and Cobble (36) in some improved calculations and has

TABLE 8. Selected standard state thermodynamic properties for acid dissociation reactions in aqueous solution at 298.15 K and 1 atm

| Reaction | $K^a$ | $\Delta H^0$ / J mol$^{-1}$ | $\Delta S^0$ / J K$^{-1}$ mol$^{-1}$ | $\Delta C_p{}^0$ / J K$^{-1}$ mol$^{-1}$ | $\Delta V^0$ / cm$^3$ mol$^{-1}$ |
|---|---|---|---|---|---|
| $H_3PO_4 = H^+ + H_2PO_4^-$ | $7.13 \times 10^{-3}$ | $-7.74 \times 10^3$ | $-67.06$ | $-128$ | $-16.3$ |
| $H_2PO_4^- = H^+ + HPO_4^{2-}$ | $6.31 \times 10^{-8}$ | $3.60 \times 10^3$ | $-126.82$ | $-220$ | $-25.9$ |
| $HPO_4^{2-} = H^+ + PO_4^{3-}$ | $4.22 \times 10^{-13}$ | $17.2 \times 10^3$ | $-179.2$ | $-242$ | |
| $HCO_3^- = H^+ + CO_3^{2-}$ | $4.69 \times 10^{-11}$ | $14.70 \times 10^3$ | $-148.45$ | $-250$ | $-28.7$ |
| $HSO_4^- = H^+ + SO_4^{2-}$ | $1.05 \times 10^{-2}$ | $-22.6 \times 10^3$ | $-113.7$ | $-300$ | $-21.0$ |

[a] All $K$ values here are based on compositions of solutions expressed in terms of molalities (mol kg$^{-1}$) of solutes and the hypothetical one molal standard state so that activity coefficients approach unity as $m$ approaches zero.

obtained $\Delta C_p{}^0 = -280$ J K$^{-1}$ mol$^{-1}$ for dissociation of $HSO_4^-$(aq) at 25°C. We believe that our $\Delta C_p{}^0 = -300$ J K$^{-1}$ mol$^{-1}$, supported by the value from Criss (37), is the best value available for the dissociation of $HSO_4^-$(aq) at 25°C.

## Thermodynamic calculations

A principal purpose of this research has been to obtain $\Delta V^0$ and especially $\Delta C_p{}^0$ values for acid dissociation reactions with a view toward using these values in calculating the dependences of other thermodynamic properties on pressure and temperature. For these calculations we want the "best" available values for the equilibrium constant $K$, $\Delta H^0$, $\Delta S^0$, $\Delta C_p{}^0$, and $\Delta V^0$ for dissociation reactions at 298.15 K and 1 atm. Our selected values for these quantities are given in Table 8; sources of these values are as follows.

Equilibrium constants for the first and second dissociations of phosphoric acid have already been cited (23–28). For the third dissociation we select the $K$ value from Quist and Vanderzee (38). Enthalpies for these dissociations have been selected from values calculated with $d \ln K/dT = \Delta H^0/RT^2$ (23, 24, 26–28) and from results of calorimetric measurements (39–43). The selected $\Delta C_p{}^0$ values are all based on our calorimetric results as reported in this paper. Selected $\Delta V^0$ values are based on our results and on other values already cited (20, 21).

We take the equilibrium constant at 298.15 K for dissociation of $HCO_3^-$(aq) from Harned and Scholes (29) and the enthalpy of dissociation from Berg and Vanderzee (44). Our selected $\Delta C_p{}^0$ is based on the present calorimetric results and the "corrected" results from Perron, Desnoyers, and Millero (8). The selected $\Delta V^0$ is a weighted average of the values cited earlier in this paper.

For the dissociation of $HSO_4^-$(aq) we have equilibrium constants from investigations already cited (33–35) and many others, especially including Covington, Dobson, and Srinivasan (45) and Pitzer, Roy, and Silvester (46). We select the $K_{298.15}$ value in Table 8 from this last investigation (46). Pitzer, Roy, and Silvester (46) have also calculated a $\Delta H_{298.15}{}^0$ value for dissociation of $HSO_4^-$(aq), which we have considered along with values derived from investigations already cited (33–35) and from several calorimetric investigations (47). Our selected value is given in Table 8. We have also selected $\Delta C_p{}^0$ from our results, in good agreement with the recalculated $\Delta C_p{}^0$ from Criss, Readnour, and Cobble (36, 37). The selected $\Delta V^0$ is based on our results and those cited earlier (7, 20, 22).

A first approximation to the effect of temperature on thermodynamic properties associated with chemical reactions is to take $\Delta C_p{}^0 = 0$. In this approximation both $\Delta H^0$ and $\Delta S^0$ are independent of temperature and the effect of temperature on the equilibrium constant is expressed as follows:

$$[19] \quad \ln K_T = -(\Delta H^0/RT) + (\Delta S^0/R)$$

$$[20] \quad \ln K_T = \ln K_{298.15} + (\Delta H^0/298.15RT)(T - 298.15)$$

$$[21] \quad \ln K_T = (298.15/T) \ln K_{298.15} + (\Delta S^0/RT)(T - 298.15)$$

The $\Delta C_p{}^0$ values in Table 8 show that $\Delta C_p{}^0 = 0$ is a poor approximation for the reactions of interest in this paper; hence eqs. [19]–[21] can be regarded as useful only when $T$ is very close to 298.15 K. We therefore go on to the next approximation, a non-zero $\Delta C_p{}^0$ that is considered to be independent of temperature.

Integration of $(d\Delta H^0/dT) = \Delta C_p{}^0$ with $\Delta C_p{}^0$ taken to be independent of temperature leads to

$$[22] \quad \Delta H_T{}^0 = \Delta H_{298.15}{}^0 + \Delta C_p{}^0(T - 298.15)$$

and similar integration of $(d\Delta S^0/dT) = \Delta C_p{}^0/T$ leads to

$$[23] \quad \Delta S_T{}^0 = \Delta S_{298.15}{}^0 + \Delta C_p{}^0 \ln(T/298.15)$$

Combinations of eqs. [22] and [23] with

$$\Delta G_T{}^0 = \Delta H_T{}^0 - T\Delta S_T{}^0 = -RT \ln K_T$$

or integration of

$$d\ln K/dT = \Delta H^0/RT^2$$

with [22] leads to the following:

[24] $$\ln K_T = \ln K_{298.15} + (\Delta H_{298.15}{}^0/298.15RT) \times (T - 298.15) - (\Delta C_p{}^0/RT)(T - 298.15) + (\Delta C_p{}^0/R)\ln(T/298.15)$$

[25] $$\ln K_T = (298.15/T)\ln K_{298.15} + (\Delta S_{298.15}{}^0/RT) \times (T - 298.15) - (\Delta C_p{}^0/RT)(T - 298.15) + \Delta C_p{}^0/R)\ln(T/298.15)$$

[26] $$\ln K_T = -(\Delta H_{298.15}{}^0/RT) + (\Delta S_{298.15}{}^0/R) - (\Delta C_p{}^0/RT)(T - 298.15) + (\Delta C_p{}^0/R)\ln(T/298.15)$$

Calculations with eqs. [24]–[26] and comparisons with experimental $K$ values for several reactions show (48) that these equations yield very accurate $K$ values over the temperature range 0-100°C (273–373 K) and yield moderately accurate $K$ values at temperatures to 200°C (473 K) or even higher.

According to eqs. [19]–[21], $\ln K$ should be a linear function of $1/T$, with no minimum or maximum. It is, however, known that $\ln K$ is *not* generally a linear function of $1/T$ and that $\ln K$ versus $1/T$ or $T$ often passes through a minimum or maximum. Equations [24]–[26] are substantial improvements over eqs. [19]–[21] in that the equations containing $\Delta C_p{}^0$ allow for non-linearity of plots of $\ln K$ versus $1/T$ and also permit a minimum or maximum. Consideration of

$$d\ln K/dT = \Delta H^0/RT^2$$

shows that $\ln K$ will go through a minimum or maximum at the temperature where $\Delta H^0 = 0$. We therefore set $\Delta H_T{}^0 = 0$ in eq. [22] and solve to obtain

[27] $$T_m = 298.15 - (\Delta H_{298.15}{}^0/\Delta C_p{}^0)$$

in which we have used $T_m$ to represent the temperature corresponding to a minimum or maximum in $\ln K$ (or $K$). No minima nor maxima have been observed for $\ln K$ values for dissociation of $H_3PO_4$(aq) and $HSO_4^-$(aq), in accord with the $T_m < 273$ K values that we calculate using $\Delta H_{298.15}{}^0$ and $\Delta C_p{}^0$ values from Table 8. For dissociation of $H_2PO_4^-$(aq) and $HCO_3^-$(aq) we calculate $T_m$ = 314 K and 357 K, respectively. Both these values are in satisfactory accord with experimental results (24, 26–28, 31). For dissociation of $HPO_4^-$(aq) we calculate $T_m$ = 369 K, but have no high temperature experimental results to compare with this value.

Effects of pressure on enthalpies and entropies of reaction can be calculated with

[28] $$(d\Delta H^0/dP)_T = \Delta V_T{}^0 - T(d\Delta V^0/dT)_P$$

and

[29] $$(d\Delta S^0/dP)_T = -(d\Delta V^0/dT)_P$$

Of more immediate use to us in relation to the data that we have available ($\Delta V^0$, but not usually $d\Delta V^0/dT$) is

[30] $$(d\ln K/dP)_T = -\Delta V^0/RT$$

Integration of eq. [30] taking $\Delta V^0$ to be independent of pressure leads to

[31] $$\ln K_P = \ln K_1 - (\Delta V^0/RT)(P - 1)$$

in which $K_1$ represents the equilibrium constant at 1 atm and $P$ is the pressure of interest expressed in atm. Use of $K$ and $\Delta V^0$ values from Table 8 in eq. [31] leads to calculated $K_P$ values that are in good agreement with experimental results (20) over moderate ranges of pressure. Better accuracy over wide ranges of pressure can be obtained by considering $\Delta V^0$ to be dependent on pressure (non-zero partial molar compressibility changes) as summarized elsewhere (7, 20, 21).

## Acknowledgments

We are grateful to the Alberta Oil Sands Technology and Research Authority and the Natural Sciences and Engineering Research Council of Canada for support of this research. We also thank Dr. Gregory Allred for his helpful advice. Finally, we thank Dr. K. S. Pitzer and Dr. L. N. Plummer for sending us manuscript copies of their papers (31, 32) and Dr. C. M. Criss for sending us the results of his recent calculations.

# Les équations cinétiques pour les systèmes réactifs. Initiation photochimique et thermique. Les coefficients de vitesse

JUAN VEGUILLAS, MIGUEL ANGEL DIAZ ARMENTIA ET ANGEL MARIA GUTIERREZ TERRON

*Departamento de Química-Física, Facultad de Ciencias, Universidad del Pais Vasco, Apdo. 644 Bilbao, Espagne*

Reçue le 10 avril 1981[1]

JUAN VEGUILLAS, MIGUEL ANGEL DIAZ ARMENTIA et ANGEL MARIA GUTIERREZ TERRON. Can. J. Chem. **60**, 2151 (1982).

Dans une publication antérieure, on a mis au point une méthode permettant d'obtenir des équations cinétiques pour un système en réaction. Dans la présente publication, on applique cette méthode au système $Br_2 + H_2 \rightleftharpoons 2HBr$ pour lequel l'initiation est une photodissociation. On a trouvé l'Hamiltonien du réactif par l'intermédiaire d'une transformation généralisée de Tani. On a utilisé l'équation cinétique généralisée. On a développé le superopérateur de collision "en cluster" à l'aide du développement du superopérateur résolvant en faisant l'hypothèse que les collisions sont instantanées. On a obtenu les équations généralisées de Boltzman. À l'aide des équations cinétiques, nous avons obtenu l'équation maîtresse et, grâce à elle, on a identifié les coefficients de vitesse. [Traduit par le journal]

JUAN VEGUILLAS, MIGUEL ANGEL DIAZ ARMENTIA, and ANGEL MARIA GUTIERREZ TERRON. Can. J. Chem. **60**, 2151 (1982).

In a previous publication a method was developed for obtaining kinetic equations for a reacting system. In this publication that method is applied to a system $Br_2 + H_2 \rightleftharpoons 2\,HBr$ whose initiation is a photodissociation. The reactive Hamiltonian has been found through Tani's generalized transformation. The generalized kinetic equation has been used. The cluster expansion of the collision superoperator has been obtained from the cluster expansion of the resolvent superoperator, by assuming that collisions are instantaneous. The generalized Boltzmann equations have been obtained. From the kinetic equations we have found the master equations and from them the rate coefficients have been identified.

## I. Introduction

L'un des principaux questions que l'on pose par rapport aux systèmes chimiques réactifs consiste à exprimer les coefficients de vitesse des différentes réactions en fonction des propriétés microscopiques des particules.

Pour les réactions chimiques à l'initiation thermique des gaz dilués, on a déjà résolu cette question (1–4). Pourtant, l'étude des réactions à l'initiation non thermique est encore sans réponse, bien que l'on a proposé des équations cinétiques à l'initiation photochimique (5, 6).

Dans cet article, on obtient les équations cinétiques, valables pour des systèmes homogènes, qui rapportent l'évolution statistique des particules d'un système réactif constitué par les atomes Br et H, les molécules $Br_2$, $H_2$ et BrH, et le champ électromagnétique. Les interactions réactives que l'on prend en considération sont:

[1.1] $Br_2 + \hbar\nu \xrightarrow{k_{i1}} Br + Br$

[1.2] $Br_2 + Br_2 \xrightarrow{k_{i2}} Br + Br + Br_2$

[1.3] $Br + H_2 \xrightarrow{k_1} HBr + H$

[1.4] $H + Br_2 \xrightarrow{k_2} HBr + Br$

[1.5] $HBr + H \xrightarrow{k_{-1}} Br + H_2$

[1.6] $Br + HBr \xrightarrow{k_{-2}} H + Br_2$

[1.7] $Br + Br \xrightarrow{k_{t1}} Br_2 + \hbar\nu$

[1.8] $Br + Br + Br_2 \xrightarrow{k_{t2}} Br_2 + Br_2$

qui composent le schéma cinétique d'une réaction en chaîne. Dans ce mécanisme, on tient compte de deux façons d'initiation, c'est-à-dire, l'ouverture de la molécule de $Br_2$ est realisée à l'aide du rayonnement d'un champ électromagnétique convenable ou d'une forme thermique. De la même façon, la rupture a

[1]Revision reçue le 15 mars 1982.

For personal use only.

aussi ces deux possibilités. L'ouverture et la rupture thermique sont réalisées en présence d'une troisième particule qui peut être une molécule de $Br_2$ comme dans le présent schéma cinétique.

Le but final de cet étude est exprimer les coefficients de vitesse, rattachés aux differéntes interactions élémentaires prises en considération dans le schéma cinétique, en fonction des propriétés microscopiques (3).

L'article a été organisé de la forme suivante.

Dans la section II, on commence avec un Hamiltonien, dans la quantification secondaire, exprimé en fonction des constituants élémentaires (noyaux de H, noyaux de Br, électrons et photons). Les forces d'interactions entre les noyaux de H, noyaux de Br et électrons sont de Coulomb. A l'aide de la transformation généralisée de Tani (7–10), on obtient un Hamiltonien où les termes rattachés aux atomes, molécules, interactions non réactives et réactives apparaissent explicitement. Les termes d'interaction sont considerés sous deux formes: les interactions entre atomes ou/et molécules qui seront appelées interactions matière–matière et les interactions entre atomes ou molécules et le champ électromagnétique qui seront appelées interactions lumière–matière.

Dans la Section III, on commence avec l'équation cinétique sous la forme proposée par le Groupe de Bruxelles (11, 12). La superopérateur de collision du système est dévéloppé en "cluster" à l'aide du dévéloppement en "cluster" du superopérateur résolvante (13, 14) où l'on suppose la statistique de Boltzmann pour les atomes et les molécules. Ce dévéloppement en "cluster" du superopérateur résolvante nous permet de faire une séparation du superopérateur de collision de telle sorte qu'il apparaît le superopérateur de transition rattaché aux collisions matière–matière celui-ci satisfaisant à l'équation de Lippmann–Schwinger du "scattering" formel, et un superopérateur de collision rattaché aux collisions lumière–matière à l'approximation du faible couplage.

En définant les matrices densité réduite, on obtient les équations cinétiques reliées à l'évolution statistique des particules du système. Ensuite, on exprime les superopérateurs de transition en fonction des matrices de transition au cas des interactions matière–matière (3, 4, 15, 16) et le superopérateur de collision lumière–matière à l'approximation du faible couplage en fonction de la matrice du Hamiltonien de l'interaction lumière–matière.

Dans la section IV, on obtient les équations "master" en appliquant la trace convenable aux équations cinétiques. De cette façon, on identifie les coefficients de vitesse.

La section V est consacrée aux discussions.

## II. Hamiltonien réactif

Le système considéré est constitué par les atomes H, Br, les molécules $Br_2$, $H_2$, HBr et le champ électromagnétique.

Pour commencer l'étude de ce système, on va faire usage d'un représentation où seulement les noyaux de brome ($Z$), les noyaux d'hydrogène ($Y$), les électrons ($X$) et les photons apparaissent.

Telles variables ont vraiment la forme suivante $Z \equiv (R_z, \sigma_z)$, $Y \equiv (R_y, \sigma_y)$ et $X \equiv (r, \sigma_x)$ où $R_z$, $R_y$ et $r$ sont les rayons vecteurs et $\sigma_z$, $\sigma_y$, $\sigma_x$ sont les variables de "spin".

Dans cette représentation, le Hamiltonien dans la quantification secondaire est:

$$[2.1] \quad H = T_z + T_y + T_x + V_{zy} + V_{zx} + V_{yx} + V_{zz} + V_{yy} + V_{xx} + H_1 + H_{l-m}$$

où $T$ est l'opérateur énergie cinétique, $V$ est l'opérateur énergie potentielle d'interaction qui a une nature coulombienne, $H_1$ est le Hamiltonien de la lumière non perturbé et $H_{1-m}$ est le Hamiltonien relié à l'interaction entre la lumière et les constituants élémentaires.

Dans cette représentation, les propriétés des atomes et molécules n'apparaissent pas explicitement et elles doivent être inclues dans les conditions de contour des vecteurs état.

Pourtant, on peut trouver une transformation unitaire $\mathbf{U}$ (7–10) telle que $\mathbf{U}^{-1}\mathbf{H}\,\mathbf{U}$, qui a d'abord la même information que $\mathbf{U}$, contienne les variables dynamiques atomiques et moléculaires.

Le résultat d'appliquer la transformation unitaire généralisée de Tani est un Hamiltonien transformé que l'on approxime de telle sorte qu'il doit contenir les termes réactifs proposés au schéma cinétique. De cette façon, on écrit:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

$$[2.2]\quad \mathbf{U}^{-1}\mathbf{H}\mathbf{U} = H_{H} + H_{Br} + H_{H_2} + H_{Br_2} + H_{I} + H_{H_2-H_2} + H_{Br_2-Br_2} + H_{HBr-HBr} + H_{H-H} + H_{Br-Br} + H_{H-Br} + H_{H-H_2} + H_{H-Br_2} + H_{H-HBr} + H_{Br-H_2} + H_{Br-Br_2} + H_{Br-HBr} + H_{H_2-Br_2} + H_{H_2-HBr} + H_{Br_2-Br_2} + H(HBr + H \leftarrow H_2 + Br) + H(H_2 + Br \leftarrow HBr + H) + H(HBr + Br \leftarrow Br_2 + H) + H(Br_2 + H \leftarrow HBr + Br) + V(Br + Br \leftarrow Br_2 + \hbar\nu) + V(Br_2 + \hbar\nu \leftarrow Br + Br) + H(Br + Br + Br \leftarrow Br_2 + Br_2) + H(Br_2 + Br_2 \leftarrow Br + Br + Br)$$

où, par exemple:

$$[2.3]\quad H_{Br} = \sum_i E_{Br_i} a^+_{Br_i} a_{Br_i}$$

$$H_I = \sum_i \bar{h}\omega_i b^+_i b_i$$

$$H_{H-Br} = \sum_{iklm} \langle br_i h_k | V | h_l br_m \rangle a^+_{Br_i} a^+_{H_k} a_{H_l} a_{Br_m}$$

$$H(HBr + H \leftarrow H_2 + Br) = \sum_{iklm} \langle hbr_i h_k | V | h_{2_l} br_m \rangle a^+_{HBr_i} a^+_{H_k} a_{H_{2_l}} a_{Br_m}$$

$$V(Br + Br \leftarrow Br_2 + \hbar\nu) = \frac{1}{2} \sum_{ijkl} V_{ikjl} a^+_{Br_i} a^+_{Br_i} b_j a_{Br_{2_l}}$$

$$H(Br + Br + Br_2 \leftarrow Br_2 + Br_2) = \frac{1}{4} \sum_{iklmn} \langle br_i br_k br_{2_l} | V | br_{2_m} br_{2_n} \rangle a^+_{Br_i} a^+_{Br_k} a^+_{Br_{2_l}} a_{Br_{2_m}} a_{Br_{2_n}}$$

où par exemple $a^+_{Br_i}$, $a_{Br_i}$, $b^+_j$ et $b_j$ sont les opérateurs idéals de création de annihilation du brome et des photons respectivement. L'indice $i$ représente l'état quantique et l'indice $j$ représente le vecteur d'onde et la polarisation simultanément.

Ces opérateurs satisfont aux conditions de commutation de Bose. Il faut remarquer que les éléments matriciels de la première et la troisième relation de [2.3] sont coulombiens et que $V_{ikjl}$ est l'élément matriciel rattaché à l'interaction réactive entre la molécule de $Br_2$ et la lumière. Les expressions de ces éléments matriciels ont été déjà calculés (17, 18).

## III. Équations cinétiques

L'équation cinétique proposée par le Groupe de Bruxelles est:

$$[3.1]\quad i\partial_t P\rho(t) = \Omega\Psi(+i0)P\rho(t)$$

où $P$ est le superopérateur projettant les éléments diagonaux, $\Psi(+i0)$ est le limite lorsque $z \rightarrow +i0$ du superopérateur de collision irréductible $\Psi(z)$ dont l'expression formelle est:

$$[3.2]\quad \Psi(z) = PLQ \frac{1}{z - QLQ} QLP$$

où $L$ est le superopérateur de Liouville et $Q = I - P$.

Le superopérateur $\Omega$ prend en considération la durée finite des collisions et il peut être exprimé sous la forme:

$$[3.3]\quad \Omega = 1 + \Psi'(+i0) + \ldots$$

Les collisions peuvent être considerées instantanées au limite du faible couplage pour l'interaction lumière–matière (19) et puis pour les systèmes dilués les collisions matière–matière peuvent aussi être considerées instantanées (11).

Si l'on considère les conditions ci-dessous on peut écrire $\Omega = 1$ et l'équation [3.1] devient:

$$[3.4]\quad i\partial_t P\rho(t) = \Psi(+i0)P\rho(t)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

Pour les systèmes homogènes, on peut écrire les suivantes relations:

[3.5] $L_0P = 0 \quad PL'P = 0$

où $L_0$ et $L'$ sont les parties non perturbée et perturbée de superopérateur de Liouville $L$, respectivement.

On peut trouver une rélation très simple, pour les systèmes dilués et homogènes, entre le superopérateur de collision, $\Psi(z)$, et le superopérateur de transition, $W(z)$, rattaché aux collisions matière–matière celui-ci satisfaisant à l'équation de Lippman–Schwinger:

[3.6] $W(z) = L' + L'R(z)L'$

où $R(z)$ est le superopérateur résolvante dont l'expression formelle est:

[3.7] $R(z) = 1/(z - L)$

Cette rélation est:

[3.8] $PW(z)P = \Psi(z)$

On a pris en considération les rélations [3.5] valables pour les systèmes homogènes.

Ensuite, on fait le dévéloppement du superopérateur de collision (13, 14), $\Psi(z)$, en négligeant tous les termes réactifs non inclus dans le schéma cinétique.

Le vecteur état dans la quantification secondaire est:

[3.9] $|h_1..h_{N_H}br_1..br_{N_{Br}}h_{2_1}..h_{2_{N_{H_2}}}..br_{2_1}..hbr_1..hbr_{N_{HBr}}n_{f_1}..n_{f_m})$

où l'on a supposé la statistique de Boltzmann pour les atomes et molécules ce qui veut dire que les nombres de remplissage peuvent prendre deux valeurs, $n_i = 0,1$. Les symboles de $N_H, N_{Br}, N_{H_2}, N_{Br_2}, N_{HBr}$ représentent le nombre d'atomes de H, atomes de Br, molécules de $H_2$, $Br_2$ et HBr. Le nombre de photons est $\Sigma_m n_{f_m}$.

Le vecteur état [3.9] peut être exprimée d'une forme symbolique:

[3.10] $|h, br, h_2, br_2, hbr, n_f)$

Le superopérateur résolvante peut être développé en "cluster".

$$
\begin{aligned}
[3.11]\quad (h,br,h_2,br_2,hbr,n_f;h,br,h_2,br_2,hbr,n_f|R(z)|h',br',h_2',br_2',hbr',n_f';h',br',h_2',br_2',hbr',n_f') \\
= (h,br,h_2,br_2hbr,n_f;h,br,h_2,br_2hbr,n_f|R_0(z)|h',br',h_2',br_2',hbr',n_f';h',br',h_2',br_2',hbr',n_f') \\
+ (h,br,h_2,br_2,hbr;h,br,h_2,br_2,hbr|R_0(z)WR_0(z)|h',br',h_2',br_2',hbr;h',br',h_2',br_2',hbr') \\
+ \sum_{i<j;k,l} (br_ibr_j;br_ibr_j|R_0(z)\Psi^{(2)}_{l-m}(z)R_0(z)|f_k'br_{2_l}';f_k'br_{2_l})\delta \\
+ \sum_{i,j;k<l} (f_ibr_{2_j};f_ibr_{2_j}|R_0(z)\Psi^{(2)}_{l-m}(z)R_0(z)|br_k'br_l';br_k'br_l')\delta
\end{aligned}
$$

où $W$ est le superopérateur de transition pour les collisions matière–matière, $\Psi^{(2)}_{l-m}(z)$ est le superopérateur de collision pour l'interaction lumière–matière à l'approximation du faible couplage, et $\delta$ est la delta de Kronecker pour les états qui n'apparaissent pas dans les vecteurs ci-dessus.

L'expression formelle de $\Psi^{(2)}_{l-m}(z)$ est:

[3.12] $$\Psi^{(2)}_{l-m}(z) = PL'Q \frac{1}{z - L_0} QL'P$$

où $L'$ est le superopérateur de Liouville pour l'interaction réactive entre la lumière et la molécule de $Br_2$.

Ensuite, on exprime les éléments diagonaux du superopérateur résolvante en fonction du superopérateur irréductible de collision.

[3.13] $$PR(z)P = \frac{1}{z - \Psi(z)} P$$

On peut exprimer l'équation [3.13] à l'aide d'une série formelle de $1/z$:

[3.14] $$PR(z)P = \sum_{n=0}^{\infty} \frac{1}{z^{n+1}} |\Psi(z)|^n$$

Pour les collisions instantanées (11), il est suffisant d'écrire seulement les deux premiers termes de [3.14]:

[3.15] $$PR(z)P = \frac{1}{z} + \frac{1}{z} \Psi(z) \frac{1}{z}$$

Le dévéloppement global du superopérateur de collision est obtenu en prenant en considération les rélations [3.11] et [3.15], et en tenant compte du dévéloppement en "cluster" du superopérateur de transition pour les collisions matière–matière.

Un terme de ce dévéloppement du superopérateur de collision rattaché aux collisions matière–matière a la forme:

[3.16] $$\sum_{i,j} (br_i hbr_j; br_i hbr_j | W | h_i' br_j'; h_i' br_j') \delta$$

et l'un autre rattaché aux collisions lumière–matière a la forme:

[3.17] $$\sum_{i<j;kl} (br_i br_j; br_i br_j | \Psi^{(2)}_{l-m} | f_k' br_{2_l}'; f_k' br_{2_l}') \delta$$

Dans ce dévéloppement, il faut introduire le terme:

[3.18] $$\sum_{i<j;k} (br_i br_j br_{2_k}; br_i br_j br_{2_k} | W' | br_i' br_j' br_{2_k}'; br_i' br_j' br_{2_k}') \delta$$

rattaché à une collision non réactive de trois particules afin d'obtenir le terme de perte dans l'équation cinétique qui se rapporte à l'interaction réactive de trois particules pour en donner deux, en étant $W'$ la partie connectée du superopérateur de transition des collisions de trois particules, qui peut être exprimée sous la forme:

[3.19] $$W_{ijk}' = W_{ijk} - W_{ij} - W_{ik} - W_{jk}$$

Les autres termes non réactives considerées dans le dévéloppement en "cluster" appartiennent à l'approximation binaire puisque seulement les collisions binaires ont importance à cause des conditions diluées du système.

La matrice densité est normalisée de la forme suivante:

[3.20] $$\mathrm{Tr}\, \rho^{(N)} = N_{\mathrm{H}}! N_{\mathrm{Br}}! N_{\mathrm{H_2}}! N_{\mathrm{Br_2}}! N_{\mathrm{HBr}}! N_{\mathrm{F}}!$$

on définit les matrices densité réduite:

[3.21] $$\rho_\alpha^{(n)} = \left\{ (N_\alpha - n)! \prod_{\beta \neq \alpha; a} N_\beta! N_a! \right\}^{-1} \mathrm{Tr}'_{1..n\varepsilon\alpha} \rho^{(N)}$$

[3.22] $$\rho_a^{(2n)} = \left\{ (N_a - n)! \prod_{\alpha; b \neq a} N_\alpha! N_a! \right\}^{-1} \mathrm{Tr}'_{1..2n\varepsilon a} \rho^{(N)}$$

[3.23] $$\rho_{\alpha a}^{(2n+m)} = \left\{ (N_\alpha - m)!(N_a - n)! \prod_{\substack{\beta \neq \alpha \\ b \neq a}} N_\beta! N_b! \right\}^{-1} \mathrm{Tr}'_{\substack{1..m\varepsilon\alpha \\ m+1..2n\varepsilon a}} \rho^{(N)}$$

où "$\alpha$" représente les atomes H, Br et les photons, et "$a$" représente les molécules $H_2$, $Br_2$ et HBr. La trace Tr′ est appliquée sur toutes les particules sauf celles qui sont indiquées par les indices.

Les superopérateurs de transition peuvent être reliés avec les matrices de transition à l'aide des suivantes rélations (3, 4, 15, 16).

[3.24] $$(a_i b_j; a_i b_j | W | a_i' b_j'; a_i' b_j') = 2\pi i \delta(E_{a_i} + E_{b_j} - E_{a_{i'}} - E_{b_{j'}}) |\langle a_i b_j | T | a_i' b_j' \rangle|^2$$

$$(a\alpha; a\alpha | W | b\beta; b\beta) = 2\pi i \delta(E_a + E_\alpha - E_b - E_\beta) |\langle a\alpha | T | b\beta \rangle|^2$$

où $T$ est l'opérateur de transition.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

Par rapport à l'interaction de la lumière avec les particules composées, le formalisme de la matrice de transition $T$ ne peut pas être appliqué (21), et c'est pourquoi la méthode à employer n'est pas le même. Pour le superopérateur de collision lumière–matière, à l'approximation du faible couplage, on a:

$$[3.25]\quad (br_i br_j; br_i br_j|\Psi^{(2)}_{l-m}|f_i' br_{2_j}; f_i' br_{2_j}) = 2\pi i\delta(E_{br_i} + E_{br_j} - \bar{h}\omega_{f_i'} - E_{br_{2_j}'})|\langle br_i br_j|V|f_i' br_{2_j}'\rangle|^2$$

En tenant compte des considérations ci-dessus, on peut écrire les équations cinétiques de chacun des composants du système. On écrit seulement l'équation cinétique de l'atome de brome, puisque cette équation nous rapporte tous les coefficients de vitesse des processus élémentaires considerés dans le schéma cinétique.

$$\begin{aligned}[3.26]\quad i\partial_t(br_i|\rho^{(1)}_{Br}|br_i) = &\sum_{br_i' br_{j'}} \sum_{br_j} 2\pi i\delta(E_{br_i} + E_{br_j} - E_{br_{i'}} - E_{br_{j'}})|\langle br_i br_j|T|br_i' br_j'\rangle|^2 \\
&\{(br_i'|\rho^{(1)}_{Br}|br_i')(br_j'|\rho^{(1)}_{Br}|br_j') - (br_i|\rho^{(1)}_{Br}|br_i)(br_j|\rho^{(1)}_{Br}|br_j)\} \\
&+ \sum_{br_i' h_{j'}} \sum_{h_j} 2\pi i\delta(E_{Br_i} + E_{h_j} - E_{Br_{i'}} - E_{h_{j'}})|\langle br_i h_j|T|br_i h_j\rangle|^2 \\
&\times \{(br_i'|\rho^{(1)}_{Br}|br_i')(h_j'|\rho^{(1)}_{H}|h_j') - (br_i|\rho^{(1)}_{Br}|br_i)(h_j|\rho^{(1)}_{H}|h_j)\} \\
&+ \sum_{br_i' h_{2'}} \sum_{h_2} 2\pi i\delta(E_{br_i} + E_{h_{2_j}} - E_{br_{i'}} - E_{h_{2_j}'})|\langle br_i h_{2_j}|T|br_i' h_{2_j}'\rangle|^2 \\
&\times \{(br_i'|\rho^{(1)}_{Br}|br_i')(h_{2_j}'|\rho^{(2)}_{H_2}|h_{2_j}') - (br_i|\rho^{(1)}_{Br}|br_i)(h_{2_j}|\rho^{(2)}_{H_2}|h_{2_j})\} \\
&+ \sum_{br_i' br_{2_{j'}}} \sum_{br_{2_j}} 2\pi i\delta(E_{br_i} + E_{br_{2_j}} - E_{br_{i'}} - E_{br_{2_{j'}}})|\langle br_i br_{2_j}|T|br_i' br_{2_j}'\rangle|^2 \\
&\times \{(br_i'|\rho^{(1)}_{Br}|br_i')(br_{2_j}'|\rho^{(2)}_{Br_2}|br_{2_j}') - (br_i|\rho^{(1)}_{Br}|br_i)(br_{2_j}'|\rho^{(2)}_{Br_2}|br_{2_j}')\} \\
&+ \sum_{br_i' hbr_{j'}} \sum_{hbr_j} 2\pi i\delta(E_{br_i} + E_{hbr_j} - E_{br'} - E_{hbr_{j'}})|\langle br_i hbr_j|T|br_i' hbr_j'\rangle|^2 \\
&\times \{(br_i'|\rho^{(1)}_{Br}|br_i')(hbr_j'|\rho^{(2)}_{HBr}|hbr_j') - (br_i|\rho^{(2)}_{Br}|br_i)(hbr_j|\rho^{(2)}_{HBr}|hbr_j)\} \\
&+ \sum_{hbr_i' h_{j'}} \sum_{h_{2_j}} 2\pi i\delta(E_{br_i} + E_{h_{2_j}} - E_{hbr_{i'}} - E_{h_{j'}})|\langle br_i h_{2_j}|T|hbr_i' h_{j'}\rangle|^2 \\
&\times \{(hbr_i'|\rho^{(2)}_{HBr}|hbr_i')(h_j'|\rho^{(1)}_{H}|h_j') - (br_i|\rho^{(1)}_{Br}|br_i)(h_{2_j}|\rho^{(2)}_{H_2}|h_{2_j})\} \\
&+ \sum_{h_i' br_{2_{j'}}} \sum_{hbr_j} 2\pi i\delta(E_{br_i} + E_{hbr_j} - E_{h_{i'}} - E_{br_{2_{j'}}})|\langle br_i hbr_j|T|h_i' br_{2_j}'\rangle|^2 \\
&\times \{(h_i'|\rho^{(1)}_{H}|h_i')(br_{2_j}'|\rho^{(2)}_{Br_2}|br_{2_j}') - (br_i|\rho^{(1)}_{Br}|br_i)(hbr_j|\rho^{(2)}_{HBr}|hbr_j)\} \\
&+ \sum_{f_i' br_{2_{j'}}} \sum_{br_j} 2\pi i\delta(E_{br_i} + E_{br_j} - \hbar\omega_{f_i'} - E_{br_{2_{j'}}})|\langle br_i br_j|V|f_i' br_{2_{j'}}\rangle|^2 \\
&\times \{(f_i'|\rho^{(1)}_{F}|f_i')(br_{2_j}'|\rho^{(2)}_{Br_2}|br_{2_j}') - (br_i|\rho^{(1)}_{Br}|br_i)(br_j|\rho^{(1)}_{Br}|br_j)\} \\
&+ \sum_{br_{2_i}' br_{2_{j'}}} \sum_{br_j br_{2_k}} 2\pi i\delta(E_{br_i} + E_{br_j} + E_{br_{2_k}} - E_{br_{2_{i'}}} - E_{br_{2_{j'}}})|\langle br_i br_j br_{2_k}|T|br_{2_{i'}} br_{2_{j'}}\rangle|^2 \\
&\qquad \times \{(br_{2_i}'|\rho^{(2)}_{Br_2}|br_{2_i}')(br_{2_j}'|\rho^{(2)}_{Br_2}|br_{2_j}') - (br_i|\rho^{(1)}_{Br}|br_i)(br_j|\rho^{(1)}_{Br}|br_j)(br_{2_k}|\rho^{(3)}_{Br_2}|br_{2_k})\}\end{aligned}$$

En obtenant l'équation [3.26], on a fait usage de l'expression [3.8], et de la suivante rélation (22)

$$[3.27]\quad \sum_{n_1', n_2'} (n_1 n_2..; n_1 n_2..|\Psi(+10)|n_1' n_2'..; n_1' n_2'..) = 0$$

et on a utilisé l'approximation du chaos moléculaire.

## IV. Équation master. Coefficients de vitesse

L'équation "master" est obtenue en appliquant la trace sur l'expression [3.26], sur les états $br_i$ de l'atome de Br.

A l'aide des définitions des matrices densité réduite, la trace de telles matrices devient le nombre du particules:

[4.1] $\mathrm{Tr}\,\rho_{\mathrm{Br}}^{(1)} = N_{\mathrm{Br}}$

En tenant compte de la réversibilité microscopique, les termes non réactifs deviennent nuls lorsqu'on applique les traces; on a, par exemple:

$$[4.2]\quad \sum_{br_i'br_j'}\sum_{br_ibr_j} 2\pi i\delta(E_{br_i}+E_{br_j}-E_{br_i'}-E_{br_j'})|\langle br_ibr_j|T|br_i'br_j'\rangle|^2 \times\{(br_i'|\rho_{\mathrm{Br}}^{(1)}|br_i')(br_j'|\rho_{\mathrm{Br}}^{(1)}|br_j')-(br_i|\rho_{\mathrm{Br}}^{(1)}|br_i)(br_j|\rho_{\mathrm{Br}}^{(1)}|br_j)\}=0$$

L'équation "master" est:

$$[4.3]\quad \partial_t N_{\mathrm{Br}} = k_{i,1}(h\omega,\mathrm{Br}_2;\mathrm{Br},\mathrm{Br})N_{\mathrm{Br}_2} - k_{t,1}(\mathrm{Br},\mathrm{Br};\mathrm{Br}_2,h\omega)|N_{\mathrm{Br}}|^2 + k_{i,2}(\mathrm{Br}_2,\mathrm{Br}_2;\mathrm{Br},\mathrm{Br},\mathrm{Br})|N_{\mathrm{Br}_2}|^2 - k_{t,2}(\mathrm{Br},\mathrm{Br},\mathrm{Br}_2;\mathrm{Br}_2,\mathrm{Br}_2)N_{\mathrm{Br}_2}|N_{\mathrm{Br}}|^2 + k_1(\mathrm{HBr},\mathrm{H};\mathrm{Br},\mathrm{H}_2)N_{\mathrm{HBr}}N_{\mathrm{H}} - k_{-1}(\mathrm{Br},\mathrm{H}_2;\mathrm{HBr},\mathrm{H}) \times N_{\mathrm{Br}}N_{\mathrm{H}_2} + k_2(\mathrm{H},\mathrm{Br}_2;\mathrm{HBr},\mathrm{Br})N_{\mathrm{H}}N_{\mathrm{Br}_2} - k_{-2}(\mathrm{HBr},\mathrm{Br};\mathrm{H},\mathrm{Br}_2)N_{\mathrm{HBr}}N_{\mathrm{Br}}$$

A l'intérieur des parenthèses des coefficients de vitesse on montre le réaction qui a lieu, en apparaissant d'abord les réactifs et après les produits.

En vertu de l'équation [4.3], on obtient pour les coefficients de vitesse les suivantes expressions:

$$[4.4]\quad k_{i,1}(\hbar\nu,\mathrm{Br}_2;\mathrm{Br},\mathrm{Br}) = \sum_{f_i'br_{2_j}'}\sum_{br_ibr_j} 2\pi\delta(E_{br_i}+E_{br_j}-h\omega_{f_i'}-E_{br_{2_j}'})|\langle br_ibr_j|V|f_i'br_{2_j}'\rangle|^2 \times (f_i'|\rho_{\mathrm{F}}^{(1)}|f_i')(br_{2_j}'|\rho_{\mathrm{Br}_2}^{(2)}|br_j')|N_{\mathrm{Br}_2}|^{-1}$$

$$[4.5]\quad k_1(\mathrm{Br},\mathrm{H}_2;\mathrm{HBr},\mathrm{H}) = \sum_{hbr_i'h_j'}\sum_{br_ih_{2_j}} 2\pi\delta(E_{br_i}+E_{h_{2_j}}-E_{h_j'}-E_{hbr_i'})|\langle br_ih_{2_j}|T|hbr_i'h_j'\rangle|^2 \times (br_i|\rho_{\mathrm{Br}}^{(1)}|br_i)(h_{2_j}|\rho_{\mathrm{H}_2}^{(2)}|h_{2_j})|N_{\mathrm{Br}}|^{-1}|N_{\mathrm{H}_2}|^{-1}$$

$$[4.6]\quad k_{t,2}(\mathrm{Br},\mathrm{Br},\mathrm{Br}_2;\mathrm{Br}_2,\mathrm{Br}_2) = \sum_{br_{2_i}'br_{2_j}'}\sum_{br_ibr_jbr_{2_k}} 2\pi\delta(E_{br_i}+E_{br_j}+E_{br_{2_k}}-E_{br_{2_i}'}-E_{br_{2_j}'}) \times|\langle br_ibr_jbr_{2_k}|T|br_{2_i}'br_{2_j}'\rangle|^2(br_i|\rho_{\mathrm{Br}}^{(1)}|br_i)(br_j|\rho_{\mathrm{Br}}^{(1)}|br_j)(br_{2_k}|\rho_{\mathrm{Br}_2}^{(2)}|br_{2_k})|N_{\mathrm{Br}}|^{-2}|N_{\mathrm{Br}_2}|^{-1}$$

Pour les autres coefficients que l'on obtient, les expressions sont pareilles.

## V. Discussion

Dans cet article, on obtient les équations cinétiques d'un système gazeux homogène dilué réactif, qui interactionne avec un champ électromagnétique.

Les différents processus réactifs, considérés dans cet étude, sont exposés dans le schéma cinétique, où on fait inclusion de deux formes d'initiation et de rupture; de cette façon, l'ouverture de la molécule de $Br_2$ a deux possibilités: l'initiation photochimique et l'initiation thermique.

Par analogie, la rupture a aussi deux possibilités. On peut penser que, dans les conditions du milieu ambiant et en présence de lumière convenable, l'initiation sera préférablement photochimique et la rupture sera thermique.

Le Hamiltonien réactif permet d'obtenir, explicitement, tous les termes réactifs proposés dans le schéma cinétique, et on y inclut les interactions réactives de deux particules pour donner trois particules et de trois particules pour en donner deux.

Le dévéloppement du superopérateur de collision est realisé à l'aide d'un dévéloppement en "cluster" du superopérateur résolvante. C'est ici qu'il apparaît le superopérateur de collision rélié à l'interaction lumière–matière à l'approximation du faible couplage.

L'obtention d'une seule équation cinétique, rattachée à l'atome de brome, nous permet de trouver tous les coefficients de vitesse. Pourtant, la méthode employée permet d'obtenir, de la même façon, les équations cinétiques des autres composants du système.

Enfin, il faut remarquer que l'on a choisi la réaction de $Br_2$ avec $H_2$ dans cet étude, du fait qu'elle a la possibilité de trois formes d'initiation: l'initiation thermique, photochimique et hétérogène. Pourtant, la méthode employé n'est pas exclusive de ce système mais elle est complètement générale et elle nous permet d'écrire les équations cinétiques aux cas d'autres systèmes gazeux homogènes et dilués. De la même façon, on veut indiquer que des prochaines articles, se rapportant a l'initiation hétérogène, seront publiés.

# Topochemical photodimerization of 7-acetoxycoumarin: the acetoxy group as a steering agent

N. RAMASUBBU, K. GNANAGURU, K. VENKATESAN, AND V. RAMAMURTHY[1]

*Department of Organic Chemistry, Indian Institute of Science, Bangalore 560012, India*

Received March 19, 1982

N. RAMASUBBU, K. GNANAGURU, K. VENKATESAN, and V. RAMAMURTHY. Can. J. Chem. **60**, 2159 (1982).

Among the various substituted coumarins investigated only 7-acetoxycoumarin is observed to photodimerize topochemically in the crystalline state and this observation may be of importance in the context of "crystal engineering".

N. RAMASUBBU, K. GNANAGURU, K. VENKATESAN et V. RAMAMURTHY. Can. J. Chem. **60**, 2159 (1982).

Des diverses coumarines substituées étudiées, seule l'acétoxy-7 coumarine se photodimérise topochimiquement à l'état cristallin; cette observation peut avoir de l'importance dans le contexte de "l'ingénierie des cristaux".

[Traduit par le journal]

The photochemical and photophysical processes of many organic compounds are a function of the environment in which they are present. In this connection, we have chosen to investigate the environmental perturbations on the photodimerization of coumarins and the results of our study in the crystalline state are presented here. Coumarins have been chosen for our investigation as their fascinating photochemical behaviour has been fairly well understood (1) and therefore the environmental influence, which is the subject of our concern, would more easily be understandable. The type of bimolecular photochemical process which has been investigated extensively in the solid state is $[\pi_{2s} + \pi_{2s}]$ cycloaddition (2). It has been established that the success of this process in the solid state requires a packing arrangement in which the reacting double bonds are parallel to one another with mean interplanar distances < ca. 4.1 Å. The utility of such photoreactions as a synthetic tool is limited by the difficulty of achieving the desired type of crystal structure in any given case, for the factors that control the crystal packing are not fully understood. However, attempts to design molecules wherein the potentially reactive chromophores are brought into favourable orientation have been reported. So far as dimerization of olefins is concerned, the utilization of dichlorophenyl substituents has been of great value (3). A similar strategy, involving the strong tendency for oxygen atoms of ester groups to pack over the centre of the benzene ring of a neighbouring molecule, has been utilized to "engineer" crystals (4). Scope undoubtedly exists for "engineering" many other crystals and the results presented below are important in this context.

Coumarin is known to be photostable in the solid state (5) although it readily dimerizes in solution (1).[2] Therefore, this appeared to be a good molecular framework to study the role of substituents in bringing about the preferred molecular packing for photodimerization. Of the several coumarins examined by us only a few underwent photodimerization in the solid state upon uv irradiation (450 W medium pressure mercury lamp) as illustrated in Table 1. X-ray crystallographic studies of the monomers of 7-methoxy, 8-methoxy, and 4-chlorocoumarins completed in our laboratory reveal that packing arrangements in these crystals do not allow favorable orientation of the potentially reactive double bonds for dimerization to occur. These appear to be defect-initiated dimerizations (6). In this communication, we present our results on the solid state photodimerization of 7-acetoxycoumarin which is interesting in the context of crystal engineering. The mechanism of dimerization and the nature of the dimer are yet to be characterized in the case of other coumarins listed in Table 1.

The dimer (mp 215–217°C) formed in quantitative yield upon irradiation of 7-acetoxycoumarin

[a]Irradiated using 450 W medium pressure mercury lamp; yields were measured by nmr integration.
[b]Nature of the dimer is yet to be characterized.

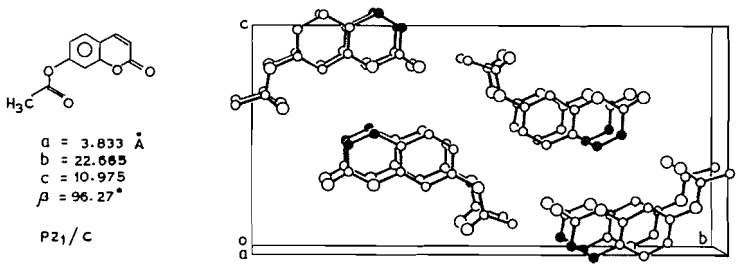
was shown to have the *syn* head–head configuration based on its spectral properties: ir (Nujol): 1750 $cm^{-1}$; $^1$Hmr (DMSO-$d_6$) δ: 2.21 (3H, s), 4.22 (2H, m, AA′BB′ pattern), 6.66 (1H, d, $J$ = 2 cps), 6.73 (1H, d × d, $J$ = 2 and 8.5 cps) and 6.92 (1H, d, $J$ = 8.5 cps); ms (CI, $NH_3$): 426 (M + $NH_4^+$). Comparison of the above nmr spectral data with those published for the *anti* head–head dimer of 7-acetoxycoumarin and the *syn* head–head dimers of polymethylene-dicarboxylic acid (7-coumarinyl) diesters (7) revealed that the above dimer is *syn* head–head.

In order to elucidate the nature of the intermolecular packing which leads to the formation of the observed dimer, a crystal structure analysis of 7-acetoxycoumarin was carried out.[3] The packing thus obtained is displayed in Fig. 1.

[3]7-Acetoxycoumarin crystallizes from chloroform solution in the space group $P2_1/c$ with $a$ = 3.833(2), $b$ = 22.665(4), $c$ = 10.975(3) Å, β = 96.27(2)°, and $Z$ = 4. A total of 1789 reflections were collected on an Enraf Nonius CAD-4 diffractometer (λ = 1.5418 Å, ω/2θ scan) out of which 1016 were unique and significant [$|F_o| > 3\sigma(|F_o|)$]. The direct methods programme package MULTAN-80 was used for the structure solution (9). Full matrix least-squares refinement of positional and anisotropic thermal parameters of non-hydrogen atoms (treating hydrogen atoms isotropically) led to an $R$ value of 0.056. The computer data on which this calculation is based are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The 7-acetoxycoumarin possesses so-called β-type packing which is characterized by the close packing of parallel and nearly planar reactive double bonds (8) with a separation distance of 3.833 Å along the $a$-axis. Thus the *syn* head–head dimer obtained is the direct consequence of this packing arrangement. It is noteworthy that coumarin which does not undergo dimerization in its stable modification (5) in the solid state undergoes a clean topochemical photoreaction when substituted by an acetoxy group. Thus it is evident that the acetyl group plays a strategic role in steering coumarin rings to pack themselves into a β stacked structure. Earlier, interaction involving overlap of an ester group of one molecule with a benzene ring of another had been utilized to steer diacrylic acids into structures suited for solid state polymerization (4). However, perusal of the figure reveals no such interaction in our case.

Photostability of some of the coumarins (Table 1) in the solid state is not due to any inherent electronic or steric properties of these molecules as they all dimerize readily in solution. It must be attributed to unfavourable packing of these molecules in the crystal lattices. The results of our study on 7-acetoxycoumarin reveal that electronic and steric aspects play, if any, only a minor role in the solid state reactions. It is significant that 7-acetoxycoumarin does not dimerize in solution (7), probably owing to the deactivation of the active



β-TYPE PACKING OF 7-ACETOXYCOUMARIN DOWN a AXIS

FIG. 1.

double bond by the electron withdrawing acetoxy group. Therefore, it appears that adoption of a crystal packing arrangement favourable for bimolecular reaction can overcome the disadvantageous inherent electronic factors. Attempts are underway to explore the generality of acetoxy group effects in "crystal engineering".

present Communication we wish to disclose a high yield preparation of bufalin from digitoxigenin using still another such transformation. The direct synthesis of bufalin from testosterone, which is in progress, will be the subject of a separate paper. A lengthy transformation of digitoxigenin to bufalin was reported some time ago by Pettit *et al.* (5).

The starting material was the dibenzyl aldehyde **II** easily prepared from digitoxigenin **I** (3). Acetalization by the standard method with benzene and *p*-toluenesulfonic acid yielded 92% of the oily Δ-14,15 acetal **1**;[1] $^1$H nmr ($CDCl_3$) δ: 7.18 (br s, 1H, C21-H), 6.33 (br s, 1H, C22-H), 5.83 (s, 1H, C24-H), 5.23 (m, 1H, C15-H), 3.88–4.20 (m, 4H, O—$CH_2$—$CH_2$—O).

[1]All compounds gave correct molecular ions in mass spectrometry and all spectral data consistent with the structures assigned to them. All crystalline compounds gave acceptable C/H analyses.

The acetal **1** was irradiated with a 100 W high pressure mercury lamp at −70°C in $CH_2Cl_2$ in the presence of mesotetraphenylporphine (6) (0.4%) while oxygen was bubbled through the solution. The resulting endoperoxide solution was treated with a large excess of dimethylsulfide and the solvent was evaporated to dryness. the residue was taken up in aqueous tetrahydrofuran (THF) and 2 *N* NaOH and reduced with an excess of $NaBH_4$. Purification by preparative thin layer chromatography (tlc) yielded 82% of the pure oily acetal **2**; $^1$H nmr ($CDCl_3$) δ: 5.52, 5.56 (2 sets, d, $J$ = 8 Hz, 1H, C22-H), 4.90 (d, $J$ = 4 Hz, 1H, C24-H), 4.12 (br s, 2H, C21-H), 3.93 (br s, 4H, —O—$CH_2$—$CH_2$—O—).

Compound **2** was heated under reflux for 5 h in a mixture of THF and 3 *N* HCl. The crude hemiacetal **3** was obtained in a yield of 95% and it was used without further purification. Compound **3**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

was heated under reflux with silver carbonate on Celite in benzene for 30 min (7). Purification by preparative tlc yielded 75% of the hydroxy lactone **4** which crystallized from ether–hexane (mp 117–119°C); ir ($CHCl_3$) $\nu_{max}$: 3550 (OH), 1735 (C=O) $cm^{-1}$; $^1H$ nmr ($CDCl_3$) δ: 5.88 (m, 1H, C22-H), 4.60–4.87 (m, 3H, C21-H + C23-H).

The hydroxy lactone **4** was dissolved in $CH_2Cl_2$ and stirred on the ice-bath with mesyl chloride and triethylamine. The crude mesylate was isolated in the usual manner and it was heated under reflux with DBN in benzene. The α-pyrone **5** was isolated by preparative tlc and crystallization from ether–hexane in a yield of 85% (mp 115–116°C).

The introduction of the C14-β hydroxy group was performed as described previously (cf. ref. 1). The benzyl derivative **6** was isolated in a yield of 70% and recrystallized from ether–$CHCl_3$ (mp 198–200°C). Debenzylation with palladium hydroxide on carbon as described previously (ref. 8, see also ref. 3) finally yielded 70% of semi-synthetic bufalin **7**. It was recrystallized from $CHCl_3$–hexane and melted at 235–237°C; ir ($CHCl_3$) $\nu_{max}$: 3600, 3450 (OH), 1710, 1635 (pyrone) $cm^{-1}$; uv (EtOH) $\lambda_{max}$ nm (log ε): 298 (3.77); $^1H$ nmr ($CDCl_3$) δ: 7.83 (dd, $J$ = 10, 2 Hz, 1H, C22-H), 7.23 (d, $J$ = 2 Hz, 1H, C21-H), 6.25 (d, $J$ = 10 Hz, 1H, C23-H).

The semi-synthetic compound **7** was identical with natural bufalin by melting point, mixture melting point, uv, ir, $^1H$ nmr, and mass spectrometry and by tlc in several systems.

# Thermochemical parameters for organic radicals and radical ions. Part 1. The estimation of the p$K_a$ of radical cations based on thermochemical calculations

A. MARTIN DE P. NICHOLAS AND DONALD R. ARNOLD[1]

*Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3*

Received November 30, 1981

A. MARTIN DE P. NICHOLAS and DONALD R. ARNOLD. Can. J. Chem. **60**, 2165 (1982).

Three methods for estimating the p$K_a$ of a radical cation using thermochemical cycles are discussed. These methods enable the calculations of the p$K_a$ of radical cations which have not been determined experimentally. Radical cation acids are classified according to the nature of their respective conjugate bases. The application of these methods is illustrated for a σ-acid (the benzene radical cation) and π-acid (the toluene radical cation). The potential of these methods to estimate relative and absolute solvation energies is also discussed. The use of thermochemical cycles in estimating standard oxidation potentials of organic compounds is outlined.

Calculations show that the toluene radical cation is an extremely strong acid and the benzene radical cation a moderately strong acid in acetonitrile solution. Difficulties in directly determining the p$K_a$ value of aromatic hydrocarbon radical cations are also discussed.

A. MARTIN DE P. NICHOLAS et DONALD R. ARNOLD. Can. J. Chem. **60**, 2165 (1982).

On discute de trois méthodes d'évaluation du p$K_a$ d'un cation radicalaire en utilisant les cycles thermochimiques. Ces méthodes permettent de calculer le p$K_a$ des cations radicalaires que l'on ne peut pas déterminer expérimentalement. Les cations radicalaires acides sont classés selon la nature de leurs bases conjuguées respectives. On illustre l'application de ces méthodes dans le cas d'un acide σ (le cation radicalaire du benzène) et dans le cas d'un acide π (le cation radicalaire du toluène). On discute également du potentiel de ces méthodes en ce qui a trait à l'évaluation des énergies de solvatation relatives et absolues. On souligne l'utilisation des cycles thermochimiques dans l'évaluation des potentiels standard d'oxydation des composés organiques.

Les calculs indiquent que le cation radicalaire du toluène est un acide extrêmement fort et que le cation radicalaire du benzène est un acide moyennement fort en solution dans l'acétonitrile. On discute également des difficultés rencontrées lors de la détermination directe de la valeur du p$K_a$ des cations radicalaires des hydrocarbures aromatiques.

[Traduit par le journal]

## Introduction

A radical cation can be described as the species obtained upon removal of an electron from a neutral molecule (1, 2). These oxidations have been achieved by chemical oxidants (e.g., concentrated sulphuric acid (3), $SO_4^{-\cdot}$ (4), the metal ion oxidants (5), Mn(III) (5*a*), Co(III) (5*b*, *c*), Ce(IV) (5*d*, *e*), and Ag(II) (5*f*), and Lewis acids $AlCl_3$ and $SbCl_5$ (6)), physical methods (e.g., photoionization, pulse radiolysis, and electron impact) (7), anodic oxidation (2, 8), and photosensitization (electron transfer) (9).

The deprotonation of radical cations has been found to be an important reactive pathway, for example, in the oxidation of alkyl aromatics (5, 10, 11). The Co(III) ion catalysed oxidation of toluene (5*b*) is believed to involve the sequence shown in reactions [1] and [2].

$$[1] \quad C_6H_5CH_3 \xrightarrow{\text{Co(III)}} (C_6H_5CH_3)^{+\cdot} \xrightarrow{(a)} \text{Products}$$

$$[2] \quad (C_6H_5CH_3)^{+\cdot} \xrightarrow{\text{base}} C_6H_5CH_2^{\cdot} \xrightarrow{(b)} \text{Products}$$

One of the factors that determines the ratio of products obtained from paths (*a*) and (*b*) will obviously be the acidity of the radical cation of toluene. This makes the study of the acidities of these reactive radical ions in general, of interest, and it is surprising that so little is, in fact, known.

The p$K_a$ of neutral hydrocarbons has been expressed in terms of standard oxidation potentials and bond dissociation energies (12*a*, *b*). The p$K_a$ of a radical cation can be related to several important thermochemical parameters (13) via simple thermochemical cycles which will be discussed below. Conversely, such relationships make possible the estimation of a related thermochemical parameter if the p$K_a$ of the radical cation can be obtained by an independent method.

Differences in solvation energies of ions cause deviations in the linear correlation observed between gas phase ionization potential data and solution phase standard oxidation potentials (14, 15). The relationship between acidities of radical ions in the gas phase and in solution should make possible the estimation of the solvation energies of organic radical ions.

Various types of radical cations have been recognised and described in the literature (1*a*). For the purposes of this discussion of the acidity of radical cations it is convenient to subclassify these

species according to the nature of their conjugate bases. Thus, the benzene radical cation can be considered a σ-acid since the deprotonation yields a phenyl σ-radical. The toluene radical cation yielding the benzyl radical would be a π-acid, whereas the radical cation of phenol would be classed as a hetero-π-acid, since the radical of the conjugate base (the phenoxyl radical) is delocalised. If the unpaired electron was localised on oxygen it would be a hetero-σ-acid. The aminylium radical cations of the type $RNH_2^{+\cdot}$ (R = alkyl) will thus be considered as hetero-σ-acids.

Recent studies (16) of the behaviour of the tertiary aminylium radicals, $R_3N^{+\cdot}$, seem to indicate that these species can undergo fast proton exchange with other protic species in solution as a result of the following resonance structures of their conjugate bases (reaction [3]).

[3] $$\rangle N^{+\cdot}-CH_2- \underset{H^+}{\overset{-H^+}{\rightleftharpoons}} \rangle \overset{+}{N}-\overset{-}{C}H- \leftrightarrow \rangle \dot{N}-\dot{C}H-$$
$$(a) \qquad (b)$$

These radical cations can be considered as *p*-acids, albeit profoundly stabilized by the nitrogen substituent which allows 3-electron bonding ((*a*) ↔ (*b*)).

So few studies of the $pK_a$ of radical cations have been reported that in the next few paragraphs we can provide a complete review of this area. In fact all of the radical cations whose $pK_a$'s have been determined are of the hetero-σ or π-acid type. The $pK_a$ of the radical cation of durohydroquinone was estimated to be −1 by Bridge, Land, and Porter (17*a*, *b*). They also estimated a $pK_a$ of −5 for the radical cation of 2,4,6-triphenylphenol (7*c*, 17*c*). The phenoxyl radicals were generated by flash photolysis, chemical oxidation, and photolysis of rigid solutions. The $pK_a$'s were estimated by observing the absorption spectrum of the phenoxyl radicals as a function of pH. Dixon and Murphy (13, 18) generated phenoxyl radicals in aqueous solution using cerium(IV) oxidation in a flow esr system, and, followed the equilibrium shown in reaction [4] as a function of $H_0$.

[4] $$ArO^{\cdot} \underset{-H^+}{\overset{H^+}{\rightleftharpoons}} (ArOH)^{+\cdot}$$

The $pK_a$'s of a number of phenol radical cations were determined in this manner ($pK_a(PhOH)^{+\cdot}$ = −2.0).

The acidities of a few hetero-σ-acids have been determined (19). For example, a study of the intermediates produced in the one-electron oxidation and reduction of hydroxylamines enabled the determination of the $pK_a$ of $NH_3^{+\cdot}$ (6.7 ± 0.2), $HONH_2^{+\cdot}$ (4.2 ± 0.1), and $CH_3ONH_2^{+\cdot}$ (2.9 ± 0.2) (19*a*). Pulse radiolysis was used to generate the radical cations and their conjugate bases. The $pK_a$ of the radical cations was determined by observing the pH dependence of the optical absorption spectra of the intermediates formed.

The determination of the $pK_a$ of radical cations of aromatic hydrocarbons in solution has not been reported. An equilibrium constant for the acid–base equilibrium of the radical cation of hexamethylbenzene (HMB) and its conjugate base, a benzylic radical, in the solvent system dichloromethane – trifluoroacetic acid was estimated from kinetic data obtained in an anodic oxidation of HMB (20) (see reaction [5]).

[5] $$ArCH_3^{+\cdot} + B \rightleftarrows ArCH_2^{\cdot} + BH^+$$

However, a $pK_a$ value for $(HMB)^{+\cdot}$ could not be obtained from the deduced $K_5$ value because the nature of the base (B) in reaction [5] was unknown. Further work by this group seems to indicate that the assumptions made are in error. Hence the equilibrium constant value they deduced is not reliable (21*a*, *b*). In a study by Sehested and Holcman, radical ions of polyalkylbenzenes were generated in solution by pulse radiolysis. They then attempted to correlate relative rates of deprotonation of the radical cations with the ionization potentials of the corresponding neutral compounds (10*d*, 22). These kinetic indications of acidity are informative with regard to the reactivity of radical cations; however, it is clearly desirable to know the thermodynamic acidities of these and other π- and σ-acids.

For the sake of completeness it should be mentioned that an electrochemical (potentiometric) determination of the $pK_a$ of radical cations is possible in principle (23). However, such a potentiometric determination requires that $RH^{+\cdot}/(R^{\cdot} + \frac{1}{2}H_2)$ be a reversible redox couple. In general, the high reactivity of these species precludes the establishment of an equilibrium. Refinements in current methods of studying equilibrium systems and/or new experimental techniques are needed to directly determine the $pK_a$ of aromatic hydrocarbon radical cations. With presently available methods and techniques even attaining measurable steady state concentrations of acid–base forms is not easy. Thus, we feel that an empirical approach to estimate the $pK_a$'s of radical cations is useful in that it enables the prediction of the fate of these radical ions in solution.

In the following section, three empirical methods to estimate the $pK_a$ of radical cations will be discussed. These methods have been applied to the radical cations of benzene and toluene.

## Results and discussion

*Method I (eq. [19]), based upon the standard oxidation potential of RH ($E^0_{RH}$) and the free energy of bond dissociation of RH ($\Delta G_{BDE}$)*

The p$K_a$ of the radical cation $RH^{+\bullet}$ in solution is related to the standard oxidation potential of RH ($E^0_{RH}$) and the free energy change associated with the homolytic cleavage of the R—H bond ($\Delta G_{BDE(RH)}$) in the gas phase. This relationship can be defined using the thermochemical cycle summarised in Fig. 1, which shows that the p$K_a$ of the radical cation is dependent upon the free energy change $\Delta G_6$ (eq. [6]) and is given by eq. [7].

[6] $RH^{+\bullet}_{sol} \rightarrow R^{\bullet}_{sol} + H^{+}_{sol}$

[7] $pK_a(RH^{+\bullet})_{sol} = \Delta G_6/2.303RT$

$G$, the Gibbs free energy, is a thermodynamic property:

[8] $\oint \Delta G = 0$

Application of eq. [8] to the thermochemical cycle in Fig. 1 gives eq. [9].

[9] $$\Delta G_6 = -\Delta G_{10} + \Delta G_{14} + \Delta G_{16} + \Delta G_{13} - \Delta G_{17} - \Delta G_{11} + \Delta G_{18}$$

The quantity, $\Delta G_{10} + \Delta G_{11}$, can be expressed in terms of the standard oxidation potential of RH referred to the standard hydrogen electrode (S.H.E.) (eq. [12]).

[10] $RH_{sol} \rightarrow RH^{+\bullet}_{sol} + e^-$

[11] $e^- + H^+_{aq} \rightarrow \frac{1}{2}H_{2(g)}$

[12] $\Delta G_{10} + \Delta G_{11} = FE^0_{RH(sol)}$

The free energies of solvation of gaseous neutral compounds and radicals are known to be small compared with the solvation energies of ions. It has also been shown that the difference in the free energy of solvation of a neutral compound RH and its corresponding radical, R$^\bullet$, is likely to be very small (24).[2] This energy difference has been neglected in previous studies (2*a*, *b*). Thus, by considering the following reactions ([13] and [14]) it is reasonable to assume that eq. [15] is valid.

[13] $R^{\bullet}_g \rightarrow R^{\bullet}_{sol}$

[14] $RH_{sol} \rightarrow RH_g$

[15] $$\Delta G_{13} + \Delta G_{14} = \Delta G_{solvation(R^\bullet)} - \Delta G_{solvation(RH)} \approx 0$$

$\Delta G_{16}$ is the standard free energy associated with the homolytic cleavage of the R—H bond in the gas phase ($\Delta G^0_{BDE(RH)}$), where the H atom removed is the acidic H of its radical cation. In reaction [16] all species are in their standard state of 1 atm pressure.

[16] $RH_g \rightarrow R^{\bullet}_g + H^{\bullet}_g$

The other free energy terms required to complete the cycle in Fig. 1 are given by reactions [17] and [18].

[17] $\frac{1}{2}H_{2(g)} \rightarrow H^{\bullet}_g$

[18] $H^+_{aq} \rightarrow H^+_{sol}$

$\Delta G_{17}$ is the standard free energy of formation of the hydrogen atom ($\Delta G^0_{f(H)g}$) using the convention that the standard free energy of formation of the gaseous hydrogen molecule is zero. $\Delta G_{18}$ is the standard free energy associated with the transfer of a proton from water to the solution of interest ($\Delta G^0_{tr(H^+)}$)$_{sol}$. Substitution of eqs. [7], [12], and [15] in eq. [9] and rearranging terms gives eq. [19].

[19] $$pK_{a(RH^{+\bullet})sol} = \frac{1}{2.303RT}(-FE^0_{RH} + \Delta G^0_{tr(H^+)sol} + \Delta G^0_{BDE(RH)g} - \Delta G^0_{f(H)g})$$

The standard free energy of formation of the hydrogen atom, $\Delta G^0_{f(H)g}$, can be calculated (25). The free energy of transfer of a proton from water to other solvents has been estimated (26). Thus if the standard oxidation potential ($E^0_{RH}$) and the free energy associated with the homolytic cleavage of the R—H bond ($\Delta G_{BDE(RH)}$) (27) are known, the p$K_a$ of the radical cation $RH^{+\bullet}$ can be estimated.

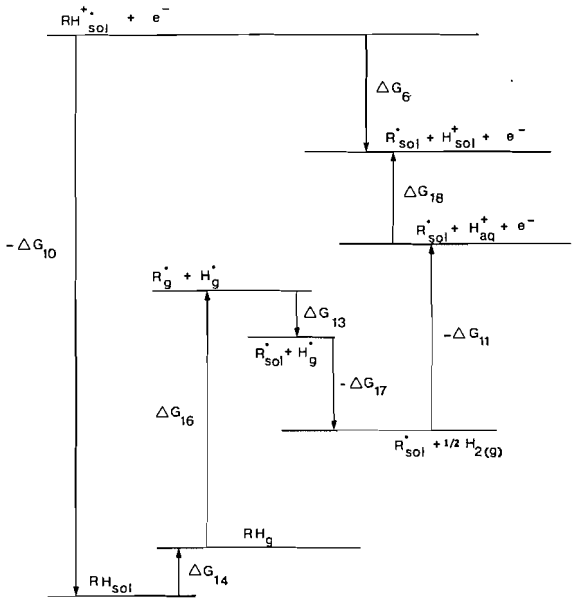

FIG. 1. The relationship between the p$K_a$ of a radical cation ($RH^{+\bullet}$), the standard oxidation potential ($E^0_{RH}$), and the standard free energy of bond dissociation ($\Delta G^0_{BDE(RH)}$).

[2]This approximation may not be valid for hetero acids of low molecular weight (e.g. $NH_3$ and $NH_2^\bullet$) and/or where strong hydrogen bonding is possible.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

*Method II (eq. [27]), based upon the standard oxidation potential and free energy of bond dissociation of R—H ($\Delta G_{BDE(RH)}$) in comparison with the standard oxidation potential of $B^-$ and free energy of bond dissociation of the B—H bond ($\Delta G_{BDE(BH)}$)*

Protolytic or proton transfer reactions can be used to determine the $pK_a$ of an acid relative to a standard. Similarly the $pK_a$ of a radical cation can be obtained by considering the proton transfer reaction from radical cation to the conjugate base of an acid, BH, with a known $pK_a$ (eq. [20]).[3] It is useful to define this relationship:

[20] $RH^{+\cdot}_{sol} + B^-_{sol} \rightleftarrows R^{\cdot}_{sol} + BH_{sol}$

in terms of the thermochemical cycle summarised in Fig. 2 where $pK_{a(RH^{+\cdot})}$ is expressed by eq. [21]

[21] $$pK_{a(RH^{+\cdot})} = \frac{\Delta G_{20}}{2.303RT} + pK_{a(BH)}$$

$\Delta G_{20}$ is related to the standard oxidation potentials of RH and $B^-$ and the free energies associated with homolytic cleavage of the R—H and B—H bonds (eqs. [22]–[27]).

The oxidation of anion $B^-$ will result in the formation of $B^{\cdot}_{sol}$:

[22*a*] $B^-_{sol} - e^- \rightarrow B^{\cdot}_{sol}$

Combining eq. [22*a*] with the reduction of $H^+$ ions to hydrogen gas, eq. [11]:

[22*b*] $$\Delta G_{22a} + \Delta G_{11} = FE^0_{B^-/B^{\cdot}(sol)}$$

where $E^0_{B^-/B^{\cdot}(sol)}$ is the standard oxidation potential of the anion $B^-$. Combining eqs. [12] and [22*b*] we obtain an expression for the free energy associated with the indirect electron transfer from anion $B^-_{sol}$ to radical cation $RH^{+\cdot}_{sol}$ (eq. [23]).[4]

[23] $RH^{+\cdot}_{sol} + B^-_{sol} \rightarrow RH_{sol} + B^{\cdot}_{sol}$

$\Delta G_{23}$ can be given in terms of standard oxidation potentials of $B^-$ and RH as shown in eq. [24].

[24] $$\Delta G_{23} = \Delta G_{22a} - \Delta G_{10} = F[E^0_{B^-/B^{\cdot}(sol)} - E^0_{RH(sol)}]$$

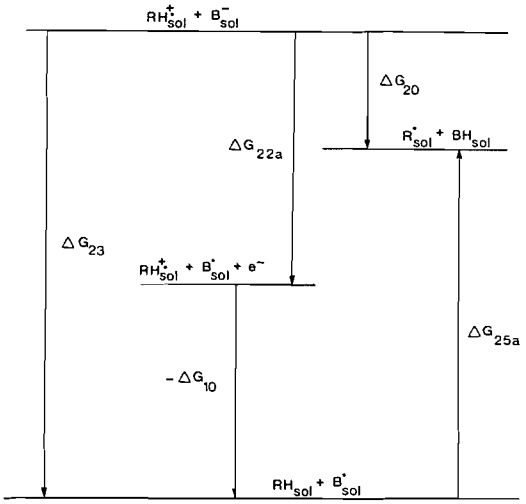

FIG. 2. The relationship between the $pK_a$ of a radical cation ($RH^{+\cdot}$), relative to a standard acid (BH), and the comparison of the standard oxidation potential ($E^0_{RH}$) and the standard free energy of bond dissociation ($\Delta G^0_{BDE(RH)}$) with the standard oxidation potential of $B^-$ ($E^0_{B^-}$) and the standard free energy of bond dissociation of the B—H bond ($\Delta G^0_{BDE(BH)}$).

If $\Delta G_{23}$ can be determined by independent measurements of $E^0_{B^-/B^{\cdot}(sol)}$ and $E^0_{RH(sol)}$, the only term required for obtaining $\Delta G_{20}$ is the free energy associated with the indirect hydrogen atom transfer between $RH_{sol}$ and $B^{\cdot}_{sol}$ to form $R^{\cdot}_{sol}$ (the conjugate base of the radical cation $RH^{+\cdot}$) and $BH_{sol}$ (reaction [25*a*]).

[25*a*] $RH_{sol} + B^{\cdot}_{sol} \rightarrow R^{\cdot}_{sol} + BH_{sol}$

$\Delta G_{25a}$ can be expressed in terms of the free energies associated with the homolytic cleavage of the R—H bond (reaction [25*b*]) and B—H bond (reaction [25*c*]), where the H atom removed is the acidic H of the radical cation $RH^{+\cdot}$

[25*b*] $RH_{sol} \rightarrow R^{\cdot}_{sol} + H^{\cdot}_{sol}$

[25*c*] $BH_{sol} \rightarrow B^{\cdot}_{sol} + H^{\cdot}_{sol}$

[25*d*] $$\Delta G_{25a} = \Delta G_{25b} - \Delta G_{25c} = \Delta G^0_{BDE(RH)sol} - \Delta G^0_{BDE(BH)sol}$$

As before, it is assumed that the difference in the free energy of solvation will be the same for the pairs RH/R$^{\cdot}$ and BH/B$^{\cdot}$ without the introduction of any serious error (eq. [25*e*]).

[25*e*] $$\Delta G^0_{solvation(RH)} - \Delta G^0_{solvation(R^{\cdot})} = \Delta G^0_{solvation(BH)} - \Delta G^0_{solvation(B^{\cdot})}$$

Substituting the equality expressed in eq. [25*e*] into eq. [25*d*] we get eq. [25*f*].

[25*f*] $$\Delta G_{25a} = \Delta G^0_{BDE(RH)g} - \Delta G^0_{BDE(BH)g}$$

[3]It is assumed that the only interaction between the radical cation and base is proton transfer. Thus effects of counter ions on the stability of ions in solution are ignored. It is also assumed that all ions are solvated but remain as discrete species in solution. The above assumptions are reasonable, as Method II is not based on results of a single experiment involving equilibrium [20] but on data related by a thermochemical cycle.

[4]$\Delta G_{23}$ is not the free energy associated with direct homogeneous electron transfer between $RH^{+\cdot}_{sol}$ and $B^-_{sol}$. Thus the free energy associated with bringing ions to encounter distance is not considered.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

From Fig. 2 we see that

[26] $$\Delta G_{20} = \Delta G_{22a} - \Delta G_{10} + \Delta G_{25a} = F(E^0_{B^-/B^{\cdot}(sol)} - E^0_{RH}) + \Delta G^0_{BDE(RH)g} - \Delta G^0_{BDE(BH)g}$$

By substituting the result obtained in eq. [26] into eq. [21], eq. [27] which gives $pK_a(RH^{+\cdot})$ is obtained.

[27] $$pK_{a(RH^{+\cdot})sol} = \frac{F\delta E^0 + \delta\Delta G^0_{BDE}}{2.303RT} + pK_{a(BH)sol}$$

where

$$\delta E^0 = E^0_{B^-/B^{\cdot}(sol)} - E^0_{RH}$$

and

$$\delta\Delta G^0_{BDE} = \Delta G^0_{BDE(RH)g} - \Delta G^0_{BDE(BH)g}$$

If all the terms of the right hand side of eq. [27] can be estimated, $pK_{a(RH^{+\cdot})}$ can be obtained. However, if $pK_{a(BH)sol}$ is unknown, BH can be chosen as a standard and the acidity of a radical cation can be expressed relative to this standard.

An approximate $pK_a$ value can be obtained in the absence of $\Delta G$ data if $\Delta H$ data are available using eq. [29].[5]

Equation [27] allows derivation of two other useful relationships from Fig. 2.

*Case (i)*

If BH ≡ RH and the acidic hydrogen of RH and its radical cation $RH^{+\cdot}$ are the same, from eq. [25*f*]

[30] $$\delta\Delta G^0_{BDE} = \Delta G_{25a} = 0$$

eq. [30] is obtained. Substitution of eq. [30] into eq. [27] gives eq. [31]

[31*a*] $$pK_{a(RH^{+\cdot})sol} = \frac{F\delta' E^0}{2.303RT} + pK_{a(RH)sol}$$

or

[31*b*] $$\delta' pK_a = \frac{F\delta' E^0}{2.303RT}$$

where

$$\delta' pK_a = pK_{a(RH^{+\cdot})sol} - pK_{a(RH)sol}$$

and

$$\delta' E^0 = (E^0_{R^-/R^{\cdot}} - E^0_{RH})$$

*Case (ii)*

If BH ≡ $RH_2^+$, $B^-$ ≡ RH, and $B^{\cdot}$ ≡ $RH^{+\cdot}$ from eq. [24] we obtain eq. [32].

[32] $$\delta E^0 = E^0_{B^-/B^{\cdot}(sol)} - E^0_{RH} = 0$$

Substitution of eq. [32] in eq. [27] gives eq. [33],

[33*a*] $$pK_{a(RH^{+\cdot})sol} = \frac{\delta''\Delta G^0_{BDE}}{2.303RT} + pK_{a(RH_2^+)sol}$$

or

[33*b*] $$\delta'' pK_a = pK_{a(RH^{+\cdot})sol} - pK_{a(RH_2^+)sol} = \frac{\delta''\Delta G^0_{BDE}}{2.303RT}$$

where

$$\delta''\Delta G^0_{BDE} = \Delta G^0_{BDE(RH)g} - \Delta G^0_{BDE(RH_2^+)g}$$

The free energy of bond dissociation considered in $RH_2^+$ is associated with the bond that when cleaved gives the same radical cation $RH^{+\cdot}$ as obtained on oxidizing RH in solution.

From eq. [31] it is evident that a knowledge of the standard oxidation potentials of an organic compound RH and its anion $R^-$ along with the $pK_a$ of RH in the solvent of interest provides a direct estimate of the $pK_a$ of its radical cation $RH^{+\cdot}$. Similarly, eq. [33] shows that if the bond dissociation free energies of $RH_2^+$ and RH are known along with the $pK_a$ of $RH_2^+$, the $pK_a$ of $RH^{+\cdot}$ can be estimated.

*Method III (eq. [39]), based upon the gas phase acidity and free energies of solvation of the species involved in the acid–base equilibrium (i.e. $RH^{+\cdot}$, $R^{\cdot}$, and $H^+$)*

Solvation factors have a profound influence on the acid–base properties of any species in solution. Recently considerable effort has been applied to the determination of gas phase acidities of organic molecules (28), where intrinsic molecular properties free of solvation effects will be reflected. Determinations of gas phase acidities of radical cations are, however, of additional interest because they constitute further means of estimating $pK_a$'s in solution.

The $pK_a$ of a radical cation $RH^{+\cdot}$ in solution is related to its gas phase acidity and the free energy of solvation of the species $RH^{+\cdot}_g$, $R^{\cdot}_g$, and $H^+_g$. It is useful to define this relationship in terms of Figs. 3 and 4.

The gas phase acidity of a radical cation can be

---

[5]An approximate value of the $pK_a$ can be obtained if we assume [28].

[28] $$S^0_{RH(g)} - S^0_{R^{\cdot}(g)} \approx S^0_{BH(g)} - S^0_{B^{\cdot}(g)}$$

Substitution of [28] in [27] gives [29]

[29] $$pK_{a(RH^{+\cdot})sol} \approx \frac{F\delta E^0 + \delta\Delta H^0_{BDE}}{2.303RT} + pK_{a(BH)sol}$$

where $\delta\Delta H^0_{BDE} = \Delta H^0_{BDE(RH)} - \Delta H^0_{BDE(BH)}$.

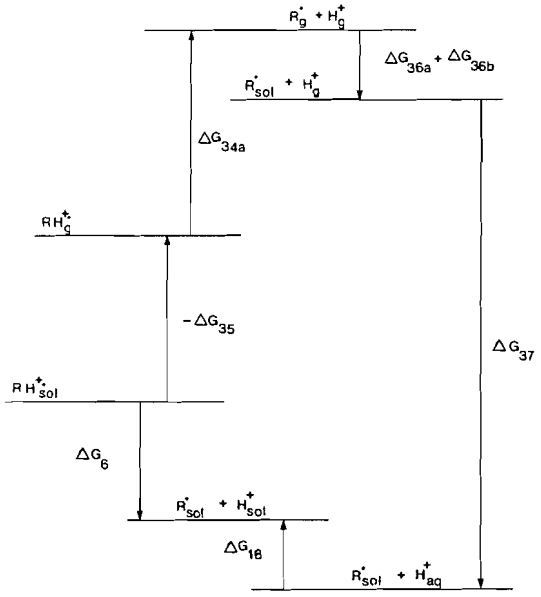

FIG. 3. The $pK_a$ of a radical cation ($RH^{+\cdot}$) in solution in relation to its gas phase acidity and the standard free energy of solvation of the species $RH^{+\cdot}_g$, $R^{\cdot}_g$, and $H^+_g$.

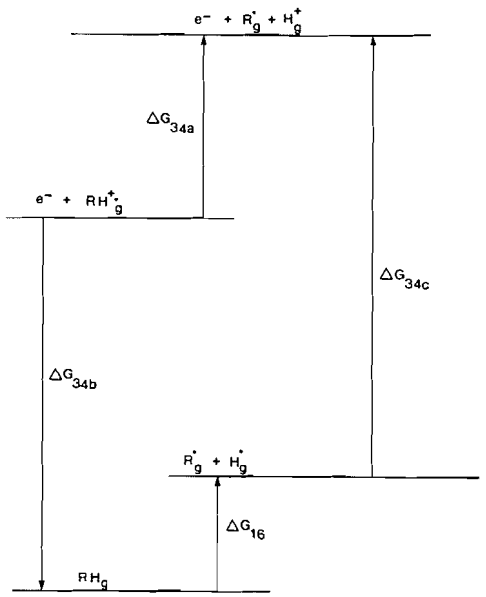

FIG. 4. The relationship between the $pK_a$ of a radical cation ($RH^{+\cdot}$) in the gas phase, the adiabatic ionization potential ($IP_{adiabatic(RH)}$), and the standard free energy of bond dissociation ($\Delta G^0_{BDE(RH)}$).

expressed in terms of the free energy change $\Delta G_{34a}$ for its deprotonation in the gas phase by eq. [34*a*]. This quantity, $\Delta G_{34a}$, can be calculated for many species

[34*a*] $RH^{+\cdot}_g \rightarrow R^{\cdot}_g + H^+_g$

using existing data from the relationship summarised in Fig. 4 and expressed by eqs. [34*a*] to [34*f*] and eq. [16].

[34*b*] $e^- + RH^{+\cdot}_g \rightarrow RH_g$

[16] $RH_g \rightarrow R^{\cdot}_g + H^{\cdot}_g$

[34*c*] $R^{\cdot}_g + H^{\cdot}_g \rightarrow R^{\cdot}_g + H^+_g + e^-$

[34*d*] $\Delta G_{34a} = \Delta G_{34b} + \Delta G_{16} + \Delta G_{34c}$

$\Delta G_{34b}$ is assumed to be equal to $\Delta H_{34b}$ because $\Delta S_{34b}$ has been shown to be negligible (29, 30).[6] $\Delta H_{34b}$ is given by eq. [34*e*].

[34*e*] $\Delta H_{34b} = -\text{IP(adiabatic)}_{RH} - \Delta\int C_p\,dT$

where IP(adiabatic), the adiabatic ionization potential, is the energy difference between the ground vibrational and rotational level of the lowest electronic state of the radical cation and the ground vibrational and rotational level of the lowest electronic state of the molecule. This is rigorously equal to the difference in the enthalpies of formation of $RH^{+\cdot}$ and RH at 0 K. For most aromatic compounds the heat capacities of the molecule and the corresponding radical cation are effectively the same, so that $\Delta\int C_p\,dT$ is negligible and $\Delta H_{34b} \approx -\text{IP(adiabatic)}_{RH}$ (30).

Assuming $\Delta S_{34b}$ and $\Delta\int C_p\,dT$ are both negligible we can write eq. [34*f*].

[34*f*] $\Delta G_{34b} \approx -\text{IP(adiabatic)}_{RH}$

$\Delta G_{16}$ can be calculated from the existing thermochemical data (27) (see Table 3). $\Delta G_{34c}$ is calculable because $\Delta H^0_{f(H^+)g}$, $\Delta H^0_{f(H)g}$, $S^0_{H^+(g)}$, and $S^0_{H\cdot(g)}$ are well known (25, 31); $\Delta G_{34a}$ can therefore be calculated using eq. [34*d*].

The solvation of the species in eq. [34*a*] can be expressed by the following reactions [35]–[37] and [18].

[35] $RH^{+\cdot}_g \rightarrow RH^{+\cdot}_{sol}$

[36*a*] $R^{\cdot}_g \rightarrow R^{\cdot}_{aq}$

[36*b*] $R^{\cdot}_{aq} \rightarrow R^{\cdot}_{sol}$

[37] $H^+_g \rightarrow H^+_{aq}$

[18] $H^+_{aq} \rightarrow H^+_{sol}$

From Fig. 3 we get eq. [38].

[38] $\Delta G_6 = -\Delta G_{35} + \Delta G_{34a} + \Delta G_{36a} + \Delta G_{37} + \Delta G_{36b} + \Delta G_{18}$

[6]The benzene radical cation undergoes a Jahn–Teller distortion and shows a difference in symmetry compared to benzene. Thus there will be a change in rotational entropy on forming the radical cation. However, this change has been neglected because it will introduce only a small error compared to the uncertainty in the estimated value of $pK_a$.

For personal use only.

Substitution of the result of eq. [38] in eq. [7] gives eq. [39].

$$[39] \quad pK_{a(RH^{+\cdot})sol} = pK_{a(RH^{+\cdot})g} + \frac{\Sigma\Delta G^0_{solvation}}{2.303RT}$$

where

$$pK_{a(RH^{+\cdot})g} = \frac{\Delta G_{34a}}{2.303RT}$$

and

$$\Sigma\Delta G^0_{solvation} = \Delta G^0_{solvation(H^+)g} + \Delta G^0_{solvation(R\cdot)g} - \Delta G^0_{solvation(RH^{+\cdot})g}$$

Application of eq. [39] to estimate $pK_a$ is limited because the free energies of solvation of most organic radical cations have not been determined. However, the free energies of solvation of radical cations of a series of alternant aromatic hydrocarbons have been estimated (15*a*, *b*), permitting the estimation of $pK_a$ values for these radical ions (eq. [39]).

*In addition, since an experimental $pK_a$ value has been determined for the phenol radical cation it is possible to estimate acidities of radical cations relative to the phenol radical cation (eq. [41]).*

The acidity of the phenol radical cation has been determined in aqueous solution (13). A measure of the acidity of a radical cation relative to the phenol radical cation enables an estimate of its $pK_a$ to be made.

Using eq. [39] the $pK_a$ of the phenol radical cation in aqueous solution can be expressed by eq. [40].

$$[40] \quad pK_{a(C_6H_5OH)^{+\cdot}{}_{aq}} = pK_{a(C_6H_5OH)^{+\cdot}{}_g} + \Sigma\Delta G^0_{solvation(RH\equiv C_6H_5O-H)}$$

where

$$pK_{a(C_6H_5OH)^{+\cdot}{}_g} = \Delta G_{34a(RH^{+\cdot}\equiv(C_6H_5OH)^{+\cdot})}/2.303RT$$

and

$$\Sigma\Delta G^0_{solvation} = \Delta G^0_{solvation(H^+)} + \Delta G^0_{solvation(C_6H_5O\cdot)} - \Delta G^0_{solvation(C_6H_5OH)^{+\cdot}}$$

Subtraction of eq. [40] from eq. [39] gives, on rearrangement, eq. [41].

$$[41] \quad pK_{a(RH^{+\cdot})aq} = [pK_{a(RH^{+\cdot})g} - pK_{a(C_6H_5OH)^{+\cdot}{}_g}] + \frac{\delta\Delta G^0_{solvation}}{2.303RT} + pK_{a(C_6H_5OH)^{+\cdot}{}_{aq}}$$

It is convenient to summarise the relationship in eq. [41] in terms of Fig. 5 using the following reactions [42]–[44].

$$[42] \quad C_6H_5O^{\cdot}{}_g + RH^{+\cdot}{}_g \rightarrow (C_6H_5OH)^{+\cdot}{}_g + R^{\cdot}{}_g$$

$$[43a] \quad (C_6H_5OH)^{+\cdot}{}_g \rightarrow (C_6H_5OH)^{+\cdot}{}_{aq}$$

$$[43b] \quad C_6H_5O^{\cdot}{}_g \rightarrow C_6H_5O^{\cdot}{}_{aq}$$

$$[36a] \quad R^{\cdot}{}_g \rightarrow R^{\cdot}{}_{aq}$$

$$[43c] \quad RH^{+\cdot}{}_g \rightarrow RH^{+\cdot}{}_{aq}$$

$$[44] \quad C_6H_5O^{\cdot}{}_{aq} + RH^{+\cdot}{}_{aq} \rightarrow (C_6H_5OH)^{+\cdot}{}_{aq} + R^{\cdot}{}_{aq}$$

The difference in the acidities of the radical cations of phenol and RH in the gas phase can be expressed by eq. [45],

$$[45] \quad pK_{a(RH^{+\cdot})g} - pK_{a(C_6H_5OH)^{+\cdot}g} = \frac{\Delta G_{42}}{2.303RT}$$

and the other term of interest in eq. [41], $\delta\Delta G^0_{solvation}$, can be expressed by eq. [46].

$$[46] \quad \delta\Delta G^0_{solvation} = \Delta G_{43a} + \Delta G_{36a} - \Delta G_{43b} - \Delta G_{43c}$$

The free energy of solvation of neutral radicals is known to be small (24) and the approximation [47] may be made.

$$[47] \quad \Delta G_{43b} \approx \Delta G_{36a}$$

If RH is an aromatic hydrocarbon, its radical cation $RH^{+\cdot}$ will be less extensively hydrated in solution as compared to the phenol radical cation (14*b*). This can be expressed by the inequality [48].

$$[48] \quad (-\Delta G_{43a}) > (-\Delta G_{43c})$$

Substitution of eqs. [47] and [48] into eq. [41] gives the inequality [49]

$$[49] \quad pK_{a(RH^{+\cdot})aq} < (pK_{a(RH^{+\cdot})g} - pK_{a(C_6H_5OH)^{+\cdot}g} + pK_{a(C_6H_5OH)^{+\cdot}aq}$$

Thus, the inequality [49] can be used to estimate an upper value for the $pK_a$ of an aromatic hydrocarbon radical cation in aqueous solution. However, if the difference in solvation energies of the radical cations of phenol and the aromatic hydrocarbon can be estimated the $pK_a$ can be obtained using eq. [41].

### *An empirical approach to the estimation of standard oxidation potentials*

The estimation of the $pK_a$ of radical cations by methods I and II require standard oxidation potentials of RH. ($E_{1/2}$ values do not have the same thermodynamic significance.) In addition, method II requires the standard oxidation potential of the $B^-$ anion. We have also shown that a knowledge of the standard oxidation potential ($E^0$) of $R^-$ can give an independent route to the estimation of radical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

cation acidities. Furthermore, standard redox potentials are of general interest as they have been used extensively in calculating other thermochemical parameters (32). The estimation of the $pK_a$ values of weakly acidic hydrocarbons (12*a*, *b*, 33*a*) and the solvation energies of aromatic hydrocarbon radical ions (15*b*) are recent examples. Other applications of redox potentials are determining the energetics and establishing the mechanism of electrode reactions (24*b*, 33*b*, *c*). Unfortunately, with the present methods and techniques $E^0$ values cannot be experimentally determined for most compounds.

The direct measurement of standard redox potentials using a conventional electroanalytical technique such as cyclic voltammetry will give accurate results only where both the substrate and intermediates formed at the electrode are relatively stable (34). Recent studies have shown that second harmonic AC voltammetry at high frequencies is capable of providing standard redox potentials even when very reactive intermediates are formed at the electrode (35). This method too has inherent limitations in its use, since theoretical calculations show that reversible potentials are measurable only as long as $k < 3\omega$, where $k$ is the first order or pseudo first order rate constant for the reaction of the intermediate and $\omega$ is the angular frequency of the applied AC signal (35*a*). Use of thermochemical cycles to estimate standard redox potentials constitutes a useful method of obtaining these thermodynamically significant parameters when they cannot be measured directly (24*b*, *c*). The basis for the use of redox potentials in thermochemical calculations is their direct relationship to equilibrium constants eq. [51]. The $E^0$ of the redox couple Ox/Red can be related to the free energy change (hence equilibrium constant) of reaction [50] by eq. [51].

[50] $\quad Ox + \frac{1}{2}H_{2(g)} \rightarrow Red + H^+_{aq}$

$$[51] \quad E^0_{Red/Ox} = \frac{-\Delta G_{50}}{F} = \frac{RT \ln K_{50}}{F}$$

In the section that follows two empirical methods to estimate the standard oxidation potential of organic compounds are discussed. This approach has been applied to benzene and toluene to compare the estimated values with the experimental values obtained recently (2*a*, *b*, 15*b*).

*Method A (eq. [67]), based upon the $pK_a$ of RH (or $RH_2^+$) and the free energy of dissociation of the R—H bond in RH, $\Delta G_{BDE(RH)}$ (or $RH_2^+$, $\Delta G_{BDE(RH_2^+)}$)*

The following thermochemical cycle summarised by eqs. [52]–[57] is similar to that used by Berdinikov and Bazhin (24*a*) to estimate the standard redox potentials of the inorganic radicals $^{\bullet}OH$, $HO_2^{\bullet}$, $O_2$, and $NO_3$, in an aqueous solution. It is extended here to be applicable in any solvent (reaction [56]).

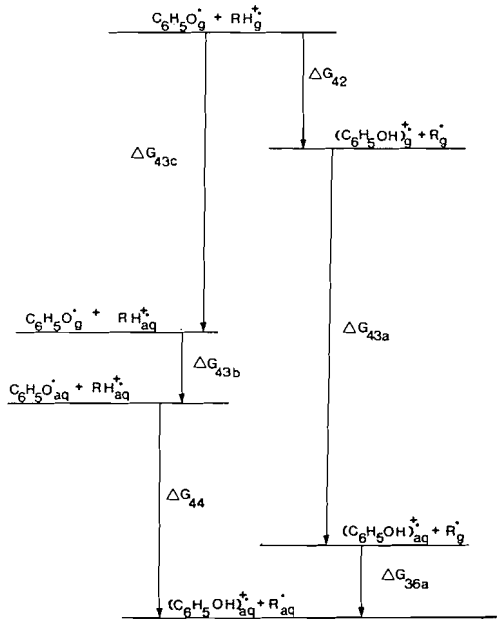

FIG. 5. The relationship between the $pK_a$ of a radical cation ($RH^{+\bullet}$) relative to the $pK_a$ of the phenol radical cation in the gas phase and in solution.

[52] $\quad R^{\bullet}_{sol} \rightarrow R^{\bullet}_g$

[53] $\quad \frac{1}{2}H_{2(g)} + R^{\bullet}_g \rightarrow RH_g$

[54] $\quad RH_g \rightarrow RH_{sol}$

[55] $\quad RH_{sol} \rightarrow R^-_{sol} + H^+_{sol}$

[56] $\quad H^+_{sol} \rightarrow H^+_{aq}$

[57] $\quad R^{\bullet}_{sol} + \frac{1}{2}H_{2(g)} \rightarrow R^-_{sol} + H^+_{aq}$

Application of the result expressed in eq. [51] to eq. [57] gives eq. [58].

$$[58] \quad E^0_{R^{\bullet}/R^-} = -\Delta G_{57}/F$$

where $\Delta G_{57}$ can be expressed by eq. [59].

$$[59] \quad \Delta G_{57} = \Delta G_{52} + \Delta G_{53} + \Delta G_{54} + \Delta G_{55} + \Delta G_{56}$$

Substitution of the value of $\Delta G_{57}$ in eq. [59] gives eq. [60].

$$[60] \quad E^0_{R^{\bullet}/R^-} = -(\Delta G_{52} + \Delta G_{53} + \Delta G_{54} + \Delta G_{55} + \Delta G_{56})/F$$

In the absence of accurate data for the solvation energies of organic radicals in solution, the assumption is made that for neutral species $R^{\bullet}$ and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

RH, which are of similar size, the free energies of solvation are equal (24) as in eq. [61]. This approximation has been shown to be reasonable by comparing physical characteristics of the radicals (R) and corresponding molecules (RH) (2*a*, *b*, 24).

[61*a*] $\Delta G^0_{\text{solvation}(R^{\cdot}_g)} = \Delta G^0_{\text{solvation}(RH)g}$

or expressed as [61*b*]

[61*b*] $\Delta G_{52} + \Delta G_{54} = 0$

Values for $\Delta G_{53}$ and $\Delta G_{55}$ are available in the literature. However, $\Delta G_{55}$ values have been reported mostly in aqueous solution. $\Delta G_{56}$ values have been estimated for a few solvents (26); but if the $E^0$ value in aqueous solution is required $\Delta G_{56}$ will be zero. Substitution of eq. [61*b*] in eq. [60] gives eq. [62].

[62*a*] $E^0_{R^{\cdot}/R^-} = -(\Delta G_{53} + \Delta G_{55} + \Delta G_{56})/F$

and in aqueous solution

[62*b*] $E^0_{R^{\cdot}/R^-} = -(\Delta G_{53} + \Delta G_{55})/F$

From eq. [62] the standard oxidation potential of $R^-$ in solution is estimated.

To estimate the standard oxidation potential of RH, $RH^{+\cdot}$ and $RH_2^+$ are substituted for $R^{\cdot}$ and RH respectively in eqs. [52] to [57].[7] This gives eqs. [63*a*–*d*], [64] which are summarised in Fig. 6.

[63*a*] $RH^{+\cdot}_{sol} \rightarrow RH^{+\cdot}_g$

[63*b*] $\frac{1}{2}H_{2(g)} + RH^{+\cdot}_g \rightarrow RH_2^+{}_g$

[63*c*] $RH_2^+{}_g \rightarrow RH_2^+{}_{sol}$

[63*d*] $RH_2^+{}_{sol} \rightarrow RH_{sol} + H^+_{sol}$

[56] $H^+_{sol} \rightarrow H^+_{aq}$

[64] $RH^{+\cdot}_{sol} + \frac{1}{2}H_{2(g)} \rightarrow RH_{sol} + H^+_{aq}$

The standard redox potential $E^0$ for the redox couple $RH^{+\cdot}/RH$ is obtained by application of eq. [51] to eq. [64] and is expressed by eq. [65].

[65] $$E^0_{RH^{+\cdot}/RH} = -(\Delta G_{63a} + \Delta G_{63b} + \Delta G_{63c} + \Delta G_{63d} + \Delta G_{56})/F = -\Delta G_{64}/F$$

If we assume that the free energies of solvation for organic ions of equal charge and similar size are equal and express it by eq. [66], substitution of eq. [66] into eq. [65] gives eq. [67].

[66*a*] $\Delta G^0_{\text{solvation}(RH^{+\cdot})g} = \Delta G^0_{\text{solvation}(RH_2^+)g}$

or

[7]This method is applicable only if the protonation of RH in the gas phase and in solution yield the same $RH_2^+$ species.

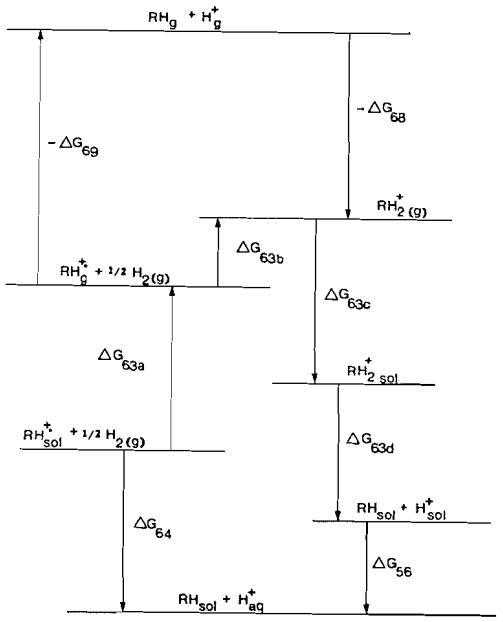

FIG. 6. The standard oxidation potential of RH ($E^0_{RH}$) in relation to the standard free energy of bond dissociation ($\Delta G^0_{BDE(RH_2^+)}$) and the $pK_a$ of its conjugate acid $RH_2^+$.

[66*b*] $\Delta G_{63a} + \Delta G_{63c} = 0$

[67] $$E^0_{RH^{+\cdot}/RH} = -(\Delta G_{63b} + \Delta G_{63d} + \Delta G_{56})/F = (\Delta G^0_{BDE(RH_2^+)g} - \Delta G^0_{f(H)g} - 2.303RTpK_{a(RH_2^+)sol} + \Delta G^0_{tr(H^+)sol})/F$$

Values for $\Delta G_{63b}$ are not available in the literature. But reasonable estimates can be made using the following reactions [68]–[70].

[68] $RH_2^+{}_{(g)} \rightarrow RH_g + H^+_g$

[69] $RH_g + H^+_g \rightarrow RH^{+\cdot}_g + \frac{1}{2}H_{2(g)}$

[70] $RH_2^+{}_{(g)} \rightarrow RH^{+\cdot}_g + \frac{1}{2}H_{2(g)}$

Thus, if the free energy values $\Delta G_{63d}$ and $\Delta G_{56}$ are available the standard oxidation potential of RH in solution can be estimated using eq. [67].

*Method B (eq. [77]), based on ionization potentials and free energies of solvation*

The free energies of solvation for a series of radical cations of alternant aromatic hydrocarbons (including benzene) have been estimated (15*b*). This makes possible the use of the thermochemical cycle summarised in Fig. 7 (eqs. [71]–[74], [54], [37]) to estimate redox potentials of alternant aromatic hydrocarbons.

[71] $RH^{+\cdot}_{sol} + \frac{1}{2}H_{2(g)} \rightarrow RH^{+\cdot}_g + \frac{1}{2}H_{2(g)}$

[72] $RH^{+\cdot}_g + \frac{1}{2}H_{2(g)} \rightarrow RH^{+\cdot}_g + H^{\cdot}_g$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

[73] $RH^{+\cdot}{}_g + H^{\cdot}{}_g \rightarrow RH_g + H^+{}_g$

[54] $RH_g \rightarrow RH_{sol}$

[37] $H^+{}_g \rightarrow H^+{}_{aq}$

---

[74] $RH^{+\cdot}{}_{sol} + \frac{1}{2}H_{2(g)} \rightarrow RH_{sol} + H^+{}_{aq}$

and $E^0$ for the redox couple $RH^{+\cdot}/RH$ is given by eq. [75].

[75] $$E^0{}_{RH^{+\cdot}/RH} = \frac{-(\Delta G_{71} + \Delta G_{72} + \Delta G_{73} + \Delta G_{54} + \Delta G_{37})}{F} = \frac{-\Delta G_{74}}{F}$$

Thus, if the $\Delta G$ terms in eq. [75] are known the standard oxidation potential of an alternant aromatic hydrocarbon can be estimated.

The free energy change ($\Delta G_{72} + \Delta G_{73}$) can be expressed as:

$$\Delta G_{72} + \Delta G_{73} = \Delta G^0{}_{f(RH)g} + \Delta G^0{}_{f(H^+)g} - \Delta G^0{}_{f(RH^{+\cdot})g}$$

$\Delta G^0{}_{f(H^+)g}$ can be calculated (25, 31). In the absence of changes in entropy and heat capacity of RH on ionization eq. [76] can be assumed (29, 30).

[76] $$\Delta G^0{}_{f(RH^{+\cdot})g} - \Delta G^0{}_{f(RH)g} = IP(adiabatic)_{RH}$$

Substitution of eq. [76] in eq. [75] gives eq. [77].

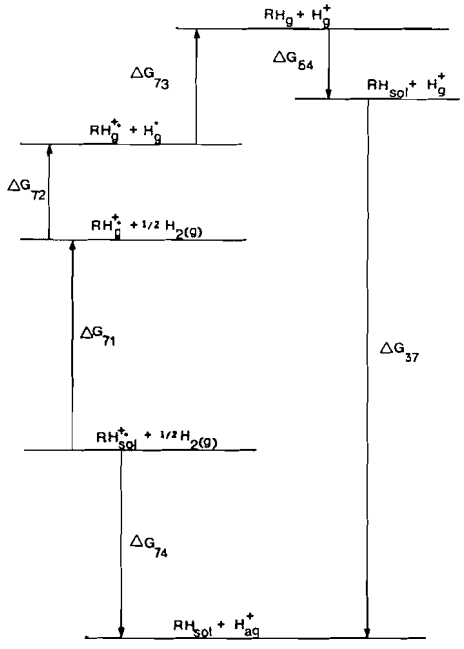

FIG. 7. The standard oxidation potential of RH ($E^0{}_{RH}$) in relation to its adiabatic ionization potential ($IP_{adiabatic(RH)}$) and the standard free energies of solvation of $RH^{+\cdot}{}_g$, $RH_g$, and $H^+{}_g$.

[77] $$E^0{}_{RH^{+\cdot}/RH} = IP(adiabatic)_{RH} + (\Delta G^0{}_{solvation(RH^{+\cdot})g} - \Delta G^0{}_{hydration(H^+)g} - \Delta G^0{}_{solvation(RH)g} - \Delta G^0{}_{f(H^+)g})/F$$

where $E^0$ and IP are expressed in eV.

It has been shown recently that $\Delta G^0{}_{solvation(RH^{+\cdot})g}$ is approximately constant over a series of alternant aromatic hydrocarbons (15*b*). Similarly if $\Delta G^0{}_{solvation(RH)g}$ is assumed to be constant, eq. [77] will simplify to eq. [78].

[78] $$E^0 = IP + \text{constant}$$

Equation [78] is applicable to a series of compounds where the free energies of solvation of the radical cations and the parent compounds are both constants.

## Applications and conclusions

We now apply methods I, II, and III to estimate the $pK_a$ of the radical cations of benzene and toluene. The results are tabulated in Table 1. Whenever possible, experimentally determined thermochemical quantities have been used.[8] In the

---

[8]The data required to estimate the $pK_a$ values are given in Tables 2 to 4. In addition, the following data at 300 K have been used. The stationary electron convention has been used in this work (31*a*).

$\Delta G^0{}_{f(H)g} = 203.2\ kJ\ mol^{-1}$ (25)

$\Delta G^0{}_{f(H_2)g} = 0$ (25)

$\Delta G^0{}_{tr(H^+)CH_3CN} = 46.0\ kJ\ mol^{-1}$ (26)

$\Delta G^0{}_{tr(Cl^-)CH_3CN} = 42.3\ kJ\ mol^{-1}$ (26)

$\Delta G^0{}_{tr(Br^-)CH_3CN} = 32\ kJ\ mol^{-1}$ (26)

$\Delta G^0{}_{hydration(H^+)g} = -1090 \pm 4\ kJ\ mol^{-1}$ (36)

$\Delta G^0{}_{solvation(C_6H_6)^{+\cdot}{}_g} = -186\ kJ\ mol^{-1}$ (15*b*)

$\Delta G^0{}_{solvation(C_6H_6)g} = \Delta G^0{}_{hydration(C_6H_6)g} + \Delta G^0{}_{tr(C_6H_6)CH_3CN} = 0.2\ kJ\ mol^{-1}$

$\Delta G^0{}_{hydration(benzene)}$ was calculated from ref. 24*b* and $\Delta G^0{}_{tr(benzene)}$ was calculated as suggested in ref. 37*a* using the Raoult's Law activity coefficients, $\gamma_x$: 2.7 (in MeCN (37*b*)) and $2.4 \times 10^3$ (in $H_2O$ (37*c*)). $\Delta G^0{}_{solvation}$ of the benzyl and phenyl radicals were assumed to be equal to that of benzene.

$pK_{a(HCl)}$ in $CH_3CN = 8.9$ (38)

$pK_{a(HBr)}$ in $CH_3CN = 5.5$ (38)

$pK_a$ of cyclohexadienyl cation (protonated benzene) in aqueous solution $= -23.0 \pm 1$ (39)

$pK_{a(C_6H_5OH)^{+\cdot}{}_{aq}} = -2.0$ (13)

$\Delta H^0{}_{f(H^+)g} - \Delta H^0{}_{f(H)g} = 1312\ kJ\ mol^{-1}$ (31*a*)

$\Delta G^0{}_{f(H^+)g} = 1517\ kJ\ mol^{-1}$ (31)

The free energy of bond dissociation of protonated benzene

[g] Estimated using method A.

absence of oxidation potentials for benzene and toluene in aqueous solution, values estimated in this work were used in the calculation of the p$K_a$ of the radical cations.

From Table 1, we see that there is general agreement in the estimated p$K_a$ values by the three methods, within the limits of error.

These estimates indicate that the radical cations of benzene and toluene should deprotonate even in moderately acidic media if alternative pathways for decay do not exist.

Application of Methods I–III indicates that the radical cation of benzene is a strong acid in acetonitrile solution,[9] with p$K_a$ between −1 and −4. This is indeed a surprising result, for there are no known examples where unambiguous evidence for the deprotonation of the benzene radical cation in acidic media have been reported (41). The Co(III) oxidation of benzene in trifluoroacetic acid (TFA) is believed to occur via the radical cation. Proton incorporation was not observed during the Co(III) oxidation of perdeutero-benzene ($C_6D_6$) in TFA where the only trifluoroacetate ester formed was $C_6D_5O_2CCF_3$; conversely, $C_6H_6$ in TFA-$d_1$ produced only $C_6H_5O_2CCF_3$ (5*c*). Under these conditions, there was no evidence for an acid–base equilibrium between the benzene radical cation and the phenyl radical. Even evidence for the phenyl radical formed by deprotonation of the radical cation was absent. When stoichiometric amounts of the reagents were used biphenyl and other oxidative condensation products, which would result if phenyl radicals were formed, were not detected. However, the deprotonation of the benzene radical cation and subsequent biphenyl formation in acetonitrile solution has been

($\Delta G^0_{BDE(RH_2)^+}$) was estimated from free energies associated with eqs. [68], [69], and [70] where RH = benzene.

The free energy change for eq. [68] was obtained from $\Delta G^0_{300}$ for the proton transfer reaction $C_6H_{6(g)} + NH_4^+{}_{(g)} \rightarrow C_6H_7^+{}_{(g)} + NH_{3(g)}$ (40*a*) and $\Delta G^0_{300}$ for $NH_4^+{}_g \rightarrow NH_{3(g)} + H^+{}_g$. The free energy change for the latter reaction was obtained by adjusting the $\Delta G^0$ value in ref. 40*b* and using the $\Delta H^0$ value in ref. 40*c*.

$$C_6H_{6(g)} + NH_4^+{}_{(g)} \rightarrow C_6H_7^+{}_{(g)} + NH_{3(g)} \qquad \Delta G^0{}_{300} = 79.5\ \text{kJ mol}^{-1}$$

$$NH_4^+{}_{(g)} \rightarrow NH_{3(g)} + H^+{}_{(g)} \qquad \Delta G^0{}_{300} = 812 \pm 8\ \text{kJ mol}^{-1}$$

From the above equations

$$\Delta G^0_{BDE(C_6H_7^+)g} = 305 \pm 8\ \text{kJ mol}^{-1}$$

where $C_6H_7^+$ is the cyclohexadienyl cation.

[9] Whether acetonitrile would be appreciably protonated by the benzene radical cation cannot be predicted because the p$K_a$ of protonated acetonitrile in acetonitrile is not known.

[a] Reference 31*a*.
[b] $\Delta G_{34b} \approx IP_{adiabatic}$ (see text).
[c] $\Delta G_{34a} = \Delta G_{34b} + \Delta G_{16} + \Delta G_{34c}$; $\Delta G_{16}$ values were taken from Table 3 and $\Delta G_{34c} = \Delta G^0_{f(H^+)g} - \Delta G^0_{f(H)g} = 1314$ kJ mol$^{-1}$ (see text).
[d] p$K_{a(RH^{+\cdot})g} = 0.174\Delta G_{34a}$ at 300 K where $\Delta G$ is in kJ mol$^{-1}$.

suggested (41*a*). Recent studies of the oxidation of benzene by $SO_4^{-\cdot}$ demonstrate the reactivity of the benzene radical cation in aqueous solution (41*d*). Product analysis shows the formation of phenol in greater yield than biphenyl. This indicates that the formation of the hydroxycyclohexadienyl radical is preferred to the formation of the phenyl radical. However, the formation of biphenyl does not prove that deprotonation of the radical cation has occurred; for example, it can arise from the attack of the benzene radical cation on benzene. In fact, such a reaction of benzene with its radical cation has been suggested to explain the increase in yield of biphenyl with an increasing initial benzene concentration (5*c*).

The apparent reluctance of the benzene radical cation to deprotonate may be due to competition from even more rapid reactions, reaction with nucleophile, for example. However, there may be an activation barrier in forming the σ-radical from a π-delocalised radical cation. Also, rapid deprotonation generally requires a pre-formed hydrogen bond.

The toluene radical cation is an extremely strong acid in acetonitrile solution with a p$K_a$ between −9 and −13. When we compare this value to the reported p$K_a$ value of toluene in acetonitrile (12*a*), *a difference of over 60 p$K_a$ units is indicated.* Although this may appear surprising at first, it can easily be understood in terms of eq. [31]. The standard oxidation potential of the benzyl anion is between −1.1 V and −1.6 V vs. S.H.E.; ($E_{1/2}$ = −1.1 V (12*b*) and $E^0 > -1.6$ (12*a*, *b*)); this difference of about 3.5 to 4 V in the standard oxidation potentials of toluene and the benzyl anion corresponds to a difference of 60–70 units in the acidities of toluene and its radical cation.

In the case of phenol the corresponding difference is only 12 p$K_a$ units since the difference between the standard oxidation potentials of phenol and the phenoxide anion will not be as great as it is for toluene. Phenol will be expected to have a considerably lower oxidation potential than toluene and the phenoxide anion should have a considerably higher oxidation potential than that of the benzyl anion.

From Methods I and II it is evident that the extremely low p$K_a$ value estimated for the toluene radical cation is the result of both the relatively low bond dissociation free energy of toluene and its high oxidation potential. A comparison of standard oxidation potentials shows that the toluene radical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

cation is somewhat more stable than the benzene radical cation relative to their respective parent compounds. However, the conjugate base of the toluene radical cation, the benzyl radical, a $\pi$-radical, is resonance stabilized. This is shown by the large difference in the bond dissociation free energy of toluene and benzene ($\delta\Delta G_{BDE} \approx 88\,kJ\,mol^{-1}$). This difference far outweighs the lower oxidation potential of toluene as compared to that of benzene ($\delta E^0 \approx 40\,kJ\,mol^{-1}$).

In general, for compounds with very similar standard oxidation potentials a difference in their respective bond dissociation free energies of $\approx 10\,kJ\,mol^{-1}$ corresponds to a difference of $\approx 2\,pK_a$ units in the acidities of their respective radical cations. Conversely, for compounds with very similar bond dissociation free energies a difference in their respective standard oxidation potentials of $\approx 0.1$ V corresponds to a difference of $\approx 2\,pK_a$ units in the acidities of their radical cations.

The comparison between gas phase and solution phase acidities of radical cations provides a means of obtaining free energies of solvation of radical cations. We have shown how the gas phase acidity of a radical cation of an aromatic hydrocarbon, relative to that of the phenol radical cation, can give an upper estimate for its $pK_a$ in solution. The difference in the gas phase acidities of the radical cations of aniline and phenol ($\delta pK_a \approx 9$; see Table 4) is very similar to their difference in aqueous solution ($\delta pK_a \approx 9$; see refs. 7*c* and 13). This indicates that the solvation energies of the radical cations of phenol and aniline are very similar in aqueous solution.

A comparison of the difference in the $pK_a$'s of $NH_4^+$ and $NH_3^{+\cdot}$ in the gas phase ($\delta pK_a \approx 10$) with that in aqueous solution ($\delta pK_a \approx 2.5$; see ref. 19*e*) indicates a significant difference in solvation energies of these ions. Extensive studies of the solvation of aliphatic amines have shown that the extent of solvation decreases in the series $NH_4^+ > RNH_3^+ > R_1R_2NH_2^+ > R_1R_2R_3NH^+$ (40*b* and 42). Further work is required before the difference in the solvation energies of $NH_4^+$ and $NH_3^{+\cdot}$ is completely understood.

From eq. [19], it is possible to obtain the standard oxidation potentials of phenol ($E^0 \approx 1.4 \pm 0.1$), aniline ($E^0 \approx 0.6 \pm 0.2$), and $NH_3$ ($E^0 \approx 1.9$) in aqueous solution. However, the effects of hydrogen bonding in the solvation of phenol and aniline can introduce an error in the estimated $E^0$ values using eq. [19]; this error may be considerable for ammonia.

The present article is an attempt to illustrate the usefulness of thermochemical cycles to obtain thermodynamically significant parameters not directly determinable by experiment. Wherever possible, experimentally determined quantities have been used in the calculations. We note that there may be a greater uncertainty than has been reported in some of the thermochemical data used. Thus the derived results may have a larger uncertainty than is shown in Table 1. We hope the above applications will encourage more accurate determinations of some of these useful thermochemical parameters in future.

# Solution carbocation stabilities measured by internal competition for a hydride ion

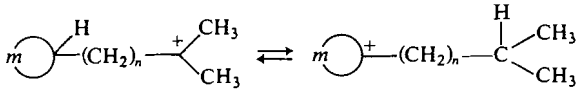
NANCY E. OKAZAWA AND TED S. SORENSEN[1]

*Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4*

Received November 20, 1981

NANCY E. OKAZAWA and TED S. SORENSEN. Can. J. Chem. **60**, 2180 (1982).

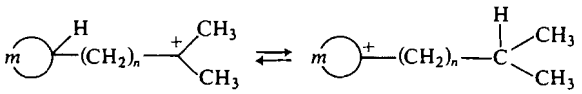
Although many techniques are known which allow one to compare the stabilities of solution carbocations, that involving the intermolecular competition for a hydride ion is conceptually (but not experimentally) the simplest procedure. This paper describes a variant of this which is experimentally more reliable and which uses intramolecular equilibria where the two competing systems are held together by a $-(CH_2)_n-$ chain, e.g.



By systematically varying "$n$" in this example ($n$ = 0, 1, 2, or 3), it has been found that a methylene chain of two or more carbons is necessary in order to minimize steric interactions between the end "systems". It has also been found that all cycloalkyl rings studied (except cyclohexyl) stabilize a cation centre much better than an aliphatic equivalent, i.e. $-\overset{+}{C}(CH_3)_2$, in agreement with solvolysis rate studies. The same situation was found when comparing this aliphatic "system" against the 2-norbornyl cation (bicyclic) or against the tricyclic 2-adamantyl cation. In fact, in these cases the equilibria are too lop-sided to obtain numerical values for the equilibrium constants concerned. Finally, three carbocations were looked at where the 2-norbornyl cation structure was pitted against the structurally very related cyclopentyl, bicyclo[2.1.1]hexyl, and bicyclo[3.2.1]octyl cations. In all cases, the 2-norbornyl cation is the more stable. $^{13}C$ nmr spectroscopy was used as the analytical tool to measure (or attempt to measure) the equilibrium constants. Depending on the *rate* of the equilibration process, three different techniques are involved and the relative merits of these are discussed in the latter part of the paper.

NANCY E. OKAZAWA et TED S. SORENSEN. Can. J. Chem. **60**, 2180 (1982).

Parmi toutes les techniques connues qui permettent de comparer les stabilités des carbocations en solution, celle qui implique la compétition intramoléculaire de l'ion hydrure est conceptuellement (mais non expérimentalement) la plus simple. Ce travail décrit une variante de cette technique qui est plus fiable expérimentalement et qui utilise les équilibres intramoléculaires lorsque les deux systèmes en compétition sont maintenus ensembles par une chaîne de $-(CH_2)_n-$, comme dans



En faisant varier "$n$" d'une façon systématique dans cet exemple ($n$ = 0, 1, 2 ou 3) on a trouvé qu'une chaîne contenant au moins deux unités méthylènes est nécessaire afin de minimiser les interactions stériques entre les systèmes terminaux. On a également trouvé que tous les cycloalkyles étudiés (à l'exception du cyclohexyle) stabilisent mieux le centre cationique que les équivalents aliphatiques c'est-à-dire $-\overset{+}{C}(CH_3)_2$; ceci est en accord avec les études de vitesse de solvolyse. On a trouvé la même situation en comparant ce "système" aliphatique avec le cation norbornyle-2 (bicyclique) ou avec le cation tricyclique adamantyle-2. En fait, dans ces cas les équilibres sont trop dissymétriques pour obtenir les valeurs numériques des constantes d'équilibres concernées. Finalement, on a étudié trois carbocations où la structure du cation norbornyle-2 est opposée aux cations cyclopentyle, bicyclo[2.1.1]hexyle et bicyclo[3.2.1]octyle qui sont structurellement très reliés. Dans tous les cas, le cation norbornyle-2 est le plus stable. On a utilisé la spectroscopie de rmn du $^{13}C$ pour mesurer (ou pour essayer de mesurer) les constantes d'équilibre. Dépendant de la vitesse du processus d'équilibration, on utilise trois techniques différentes et on discute de leurs mérites relatifs dans la dernière partie de cette publication.

[Traduit par le journal]

## Introduction

The comparative base strengths of anions in general, and carbanions in particular, can be measured by setting up solution equilibria in which two anions compete for a proton, e.g.

$$[1]\quad R_1{-}H + R_2^- \underset{}{\overset{K}{\rightleftharpoons}} R_1^- + R_2H$$

This classic procedure (1) has an opposite charge analogy, in which solution cations formally compete for a hydride ion, e.g.

$$[2]\quad R_1{-}H + R_2^+ \overset{K}{\rightleftharpoons} R_1^+ + R_2H$$

Where $R^+$ is a carbocation, one can in principle use this procedure to study the relative stabilities of carbocations. However, it should be noted that while the proton transfer process (reaction [1]) can be defined in terms of $pK_a$'s, this is not true of reaction [2]. Furthermore, much information relating to relative carbocation stabilities is available from a host of other techniques, such as solvolysis rate comparisons, calorimetry of ionization processes (2), mass spectrometry and ion cyclotron resonance (3) (reaction [2]-type *gas-phase* equilibria are now accurately known for a large number of systems), $pK_a$-type equilibria (4), kinetics of various acid-catalyzed reactions, ionization equilibria (5), etc. Nevertheless, reaction [2] solution equilibria, if the measurements could be made general for a wide variety of cation structures, would be unsurpassed as a "true" measure of solution cation stability since the hydrogen being competed for is the smallest transfer "group" possible, minimizing as much as one can steric contributions. This can be contrasted, for example, with the simplest traditional $pK_a$ equilibrium (reaction [3])

[3] $\text{>C=C<} + (H^+) \rightleftarrows \text{>C(H)—C}^+\text{<}$

Not only are these equilibria very hard to measure (6) (because of polymerization) but we believe that one must take account of more steric factors in this case.

Although many studies involving [2]-type reactions have appeared in the past, they have focussed primarily on kinetics (7) or synthetic applications, the numerical equilibrium constant being of secondary concern. However, Kramer and co-workers have reported some studies devoted entirely to measuring [2]-type equilibria (8).

A serious drawback to intermolecular equilibria involves experimental difficulties associated with an oxidation of the hydrocarbon component (9) of these equilibria by the excess strong acid solvent system used in generating the cation component, leading to "messy" nmr spectra. Furthermore, in choosing solvent systems where both cation and hydrocarbon are soluble, one is reduced to solvents such as dichloromethane, where extensive ion-pairing may result, coincidentally, also a problem with some carbanion equilibria. For example, in the study by Kramer *et al.* (8), the results quoted are markedly influenced by the choice of both the solvent and the Lewis acid.

Our approach to the above problems is to link the $R_1$ and $R_2$ fragments, modifying reaction [2] as follows:

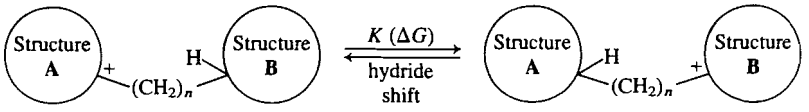
[4] $R_1—H + R_2^+ \overset{K}{\rightleftharpoons} R_1^+ + R_2H$

Each species is now a cation so that solubility problems no longer exist and oxidation is certainly a less serious problem.

Other studies have in the past used the position of a suitable *intramolecularly-generated* carbocation equilibrium in order to probe various phenomena related to carbocation stabilities, e.g. the hyperconjugative order (10). However, the recent availability of routine $^{13}C$ nmr spectroscopy now makes it potentially possible to study a wider variety of such equilibria.

We were therefore interested in looking at intramolecular equilibria related to the above intermolecular processes and as a consequence of this in: (*a*) the design of suitable carbocation systems for such equilibrium measurements and (*b*) an examination of the relative practical merits of various $^{13}C$ nmr techniques needed to obtain the equilibrium constant numerical data.

The design of the desired organic systems can be schematically represented as follows:



I II

The major uncertainty initially was in knowing how large to make "*n*" so that structures **A** and **B** would not directly interfere with each other, the aim being of course to mimic intermolecular equilibria as closely as possible. We therefore prepared a number of systems in which only "*n*" was allowed to vary.

A consequence of changing "*n*" is that the *rate* for the equilibration will also change (based on the known behavior of simple model systems) (11, 12).

Depending on how fast this equilibration rate is, there are three separate $^{13}C$ nmr techniques which could be used to measure the equilibrium constant $K$: (A) for very fast rates, only averaged nmr peaks will be observed and $K$ can be calculated if reasonable estimates can be made for the chemical shifts of the individual components. Also, these averaged peaks will be measureably temperature-dependent if $K$ is not too large or too small. (B) for intermediate exchange rates, an nmr line-broadening technique could be used, in particular the application of techniques designed to detect potentially very lop-sided equilibria (13), and (C) for moderately slow rates, one could expect to quantitatively detect peaks characteristic of both ions **I** and **II**.

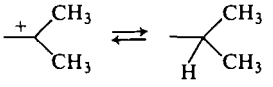
In evaluating these three techniques, we will be concerned with two factors: (*a*) the potential ability of the technique to detect very large and very small $K$ values and (*b*) a confidence factor which ultimately comes into play when pushing these techniques to their practical limits.

## Results

All of the carbocations were prepared *in situ* from the corresponding alcohol using previously described techniques (14). The alcohols were prepared by standard Grignard or alkyl lithium reactions. Nuclear magnetic resonance procedures for determining $K$'s will be discussed later. Each specific cation is given an arabic number, but when we wish to discuss the series in a general way we use the Roman numerals **I** ⇄ **II**.

*Effect of varying "*n*" in* ***I*** ⇄ ***II***

A series of cations were prepared in which one end was simply



and this "structure" we equate as being equivalent to a normal acyclic tertiary carbocation, e.g. *t*-butyl. In this study, the other "structure" was a cycloalkyl group (ring size = 4–8) (monocyclic), or 2-norbornyl (bicyclic) or 2-adamantyl (tricyclic). For the purposes of investigating the effect of $n$, only the cyclohexyl system **1** ⇄ **2** (structures in Table 1) was suitable, all other systems involving at least some equilibria which were too lop-sided to quantitatively measure. The data are summarized in Table 1.

There is an increase in $K$ as $n$ is increased, but the change from $n = 2$ to $n = 3$ is minimal and we conclude that direct proximity effects between the two "structures" have become insignificant for $n = 2$ and 3.

*Effect of ring size*

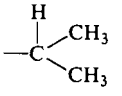
A series of cations were prepared, where $n = 0$, 1, and 2 and the ring size $m + 1 = 5$, 7, and 8 (general structures **3** and **4**, see Table 2). The alcohols for the $m + 1 = 4$ series were also prepared but the corresponding cations could not be prepared, a ring expansion to a cyclopentyl or a cyclohexyl ring occurring too fast. The data are summarized in Table 2.

For the $n = 0$ series, equilibrium constants could be measured for $m + 1 = 5$ and 7, but not 8. However, for $n = 1$ or 2, only minimum estimates were obtained. This situation is not unexpected if one looks at the Table 1 data.

The 2-norbornyl comparisons (cations **5** and **6** in Table 3) were also made for the $n = 0$, 1, and 2 series and are summarized in Table 3. These equilibria are even more lop-sided than those in Table 2 and even the $n = 0$ equilibrium constant cannot be obtained.

Finally the tricyclic 2-adamantyl comparisons (cations **7** and **8** in Table 4) were made. In this case only the $n = 1$ equilibrium constant could be measured.

As it turns out, most of the presently chosen equilibria are too lop-sided to obtain numerical $K$ values, i.e. the combination of the $sp^2$ $C^+$ centre in the cyclic, bicyclic, or tricyclic ring and the CH $sp^3$ centre in



is much better than the alternative. In principle, it would probably be possible to devise a series of overlapping equilibria which would permit one to evaluate all of the $K$'s looked at here, but this would require more study. However, since the tertiary 2-norbornyl cation "structure" has been the subject of numerous studies, it seemed worthwhile to look at cation equilibria in which the 2-norbornyl cation was pitted against the structurally-related cyclopentyl cation, and also against related tertiary bicyclic frameworks, in the hope that this closer similarity of the two "structures" would yield measurable $K$'s. The comparisons are shown below with dark lines emphasizing the similarities in the two "structures". An $n = 2$ connection was used to minimize direct interactions.

For **9** ⇄ **10**, the equilibrium constant was 15 at −90°C, while for **11** ⇄ **12**, only ion **12** was observed at equilibrium, $K \geq 30$ at −90°C. Similarly, it can be

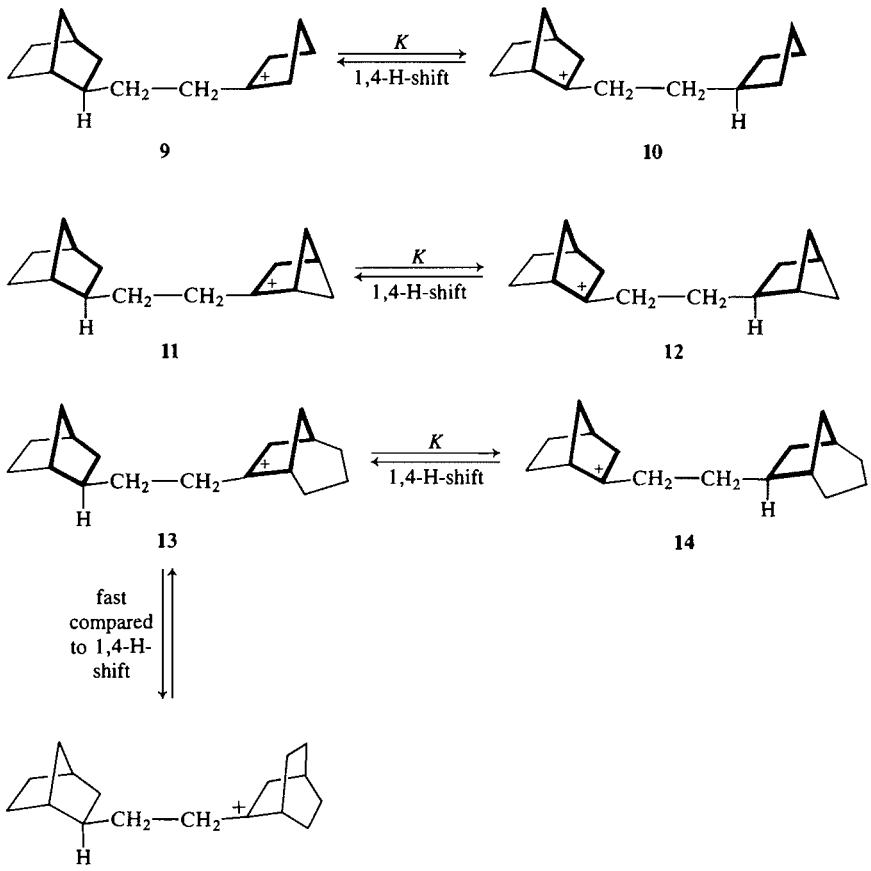
deduced that the **13** ⇄ **14** equilibrium lies completely on the side of **14**, $K \geq 400$ at −90°C. This case is somewhat complicated by another equilibrium involving cation **15** and this is discussed later.

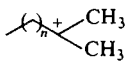
## Discussion

As with carbanion equilibria, the equilibrium constant for **I** ⇄ **II** is *not* necessarily a direct measure of the stability of the two cation "structures" in **I** and **II**. One must also consider the two $sp^3$ CH centres and their relative stabilities, although these will not normally be expected to be the dominant factors involved.

The situation in kinetic solvolysis work is also related, although this involves a variety of larger leaving groups and transition-state developed "cations". Nevertheless, the rather incomplete equilibrium constant data (or limits) for the cycloalkyl vs. acyclic carbocation "structures" is completely in accord with previous solvolysis rate comparisons. These are shown in Table 5.



The equating of the *t*-Bu solvolysis data in Table 5 with our



"structure" can be justified by noting the similarity of the solvolysis data for *t*-BuCl, 2-methyl-2-chlorobutane, and 2-methyl-2-chloropentane (less than a factor of two difference among these) (15).

The $K$ equilibrium constant data for $n = 2$ in Table 5 employs the nmr method C and, as will be discussed subsequently, this is not very sensitive. It is entirely possible, based on the more sensitive (nmr method B) $n = 1$ data, that these $K$ values are indeed much larger than the lower limits quoted in Table 5. It is entirely reasonable, of course, that the present $K$ equilibrium constant data would be larger than $k_{cyclic}/k_{t\text{-Bu}}$ because the temperature of the $K$ measurements is quite low (favoring larger $K$'s) and in addition, fully developed cations are involved. The "I-strain" concept (16) generally accounts for both the internal solvolysis comparisons and the equilibrium constant data; however, other factors like C—H hyperconjugation are probably involved as well.

The 2-norbornyl results in ions **5** ⇄ **6**, **9** ⇄ **10**, **11** ⇄ **12**, and **13** ⇄ **14** are also interesting in the context of comparisons to solvolysis data. Both *exo*- and *endo*-2-methyl-2-norbornyl esters or halides lead, of course, to the same carbocation intermediate. They typically differ greatly in solvolysis rate, however, and it is not immediately obvious which comparisons, if any, one should make. The data in Table 6 are illustrative.

The first column shows that tertiary cyclopentyl solvolysis rates typically fall between tertiary *exo*- and *endo*-2-norbornyl. Column two shows that the $k_{exo}/k_{endo}$ difference also applies to a chloride-leaving group and column three shows the solvolysis comparison of acyclic, monocyclic, and *exo*-bicyclic chlorides.

In view of the 1:355 solvolysis ratio, the complete dominance of ion **6** in the **5** ⇄ **6** equilibrium is to be expected. Ion **5**, although not present in detectable amounts, would be expected

to have the *exo* stereochemistry on steric grounds and this can actually be verified for the **9** ⇄ **10** equilibrium.

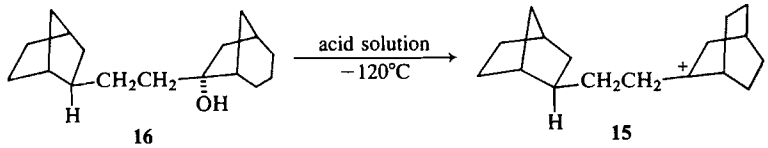
The comparisons in **9** ⇄ **10**, **11** ⇄ **12**, and **13** ⇄ **14** are more relevant since one is comparing rather similar structures. The stability of **10** over **9** seems to clearly involve an "extra" stability associated with the tertiary 2-norbornyl cation. For example, having the $sp^3$ centre (as in **10**) should preferentially disfavor the simple cyclopentyl ring (more eclipsing interactions), but this is obviously more than made up for by some favorable effect, presumably associated with the 2-norbornyl cation "structure".

An even closer comparison comes from the rather exotic **11** ⇄ **12** equilibrium and this serves to

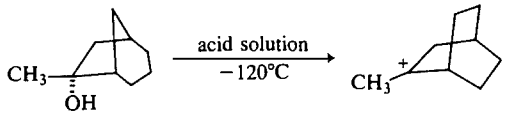
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

show that ring strain *per se* is not involved in stabilizing the 2-norbornyl cation, the 2-bicyclo-[2.1.1]hexyl "structure" being much more strained and also clearly disfavored as a cation site in the **11** ⇄ **12** comparison.

A three-carbon "backside" bridge is also much less favorable than the two-carbon one in 2-norbornyl, as shown by the **13** ⇄ **14** equilibrium. This equilibrium is somewhat more complicated than the others since we do not actually see cation **13**. Even carrying out the addition of the alcohol **16** to the acid solution at −120°C, the initially expected **13** has rearranged to **15** ($K \geq 20$). Model system experiments starting with alcohol **17** confirm this observation, i.e. ionization of **17** at −120°C gives "immediately" >90% of the known (14) 2-methylbicyclo[2.2.2]octyl cation **18**.



**16** **15**

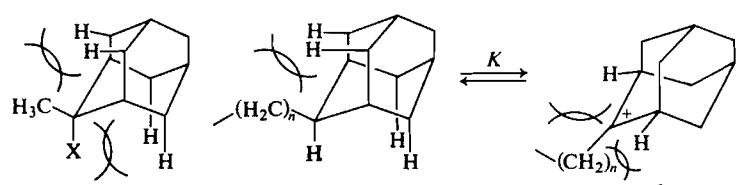


**17** **18**

At about −90 to −100°C, cation **15** rearranges to **14** (via **13** and a 1,4-H-shift) since a *neutral* bicyclo[3.2.1]octane skeleton is more stable than the [2.2.2] skeleton (17). The **15** ⇄ **14** equilibrium lies completely to the right ($K \geq 20$), but since one already knows that **13** is less stable than **15**, one has a combined result giving a minimum $K$ of 400 for the **13** ⇄ **14** equilibrium.

Overall, the $K$'s for the 2-norbornyl "structures" correlate much better with *exo*-leaving-group solvolyses, the implication being that these are "normal" and that factors *other* than the intrinsic cation stability are involved in the transition-state for *endo*-solvolyses. This has been a point of contention for a number of years and our results are consistent with the arguments of Brown (18). These "interpretation problems" also point out the advantages of using equilibria as a measure of cation stability.

The 2-adamantyl equilibria also correlate with solvolysis data, i.e. *t*-BuBr/2-methyl-2-adamantyl bromide rates are about 1:10 (19). These enhanced rates are usually attributed to the removal of 1,3-diaxial interactions in going to the $sp^2$ carbocation intermediate and are also found in dehydration studies (20). However, in the ion equilibria where the 2-position of adamantane is $sp^3$-hybridized, i.e. ion **7**, only one 1,3-diaxial interaction is important (hydrogen occupying the other position) and this is balanced in the $sp^2$-hybridized case, structure **8**, by eclipsing interactions of the 2-alkyl group with hydrogens on the 1- and 3-carbons of the adamantyl ring, as shown below:



solvolysis starting material **7** **8**

However, interactions in **7** may be the dominant factor and it is significant in this regard that in the one case where a $K$ could be measured (Table 4, $n = 1$, the isobutyl group), molecular mechanics calculations (20) suggest the least steric gain in going from the $sp^3$-hybridized adamantane to the corresponding $sp^2$-hybridized cation. The calculated relief in the isopropyl case ($n = 0$) is

considerably larger and would account for the fact that $K$ is larger here than in the $n = 1$ case.

It is somewhat surprising that one sees no 1-adamantyl cations in the equilibria. Although a 1,2-hydride shift in **8** is probably proscribed (21), there is ample opportunity to form a 1-adamantyl cation by a 1,3-hydride shift from **7***a*, a 1,4-shift from **7***b*, or a 1,5-shift from **7***c*.

*Overall conclusions on the equilibrium results*

Solvolysis rate comparisons, when used to probe cation stabilities, are obviously capable of a much greater range than the equilibria looked at in this study. However, as previously noted, solvolysis data are more complex and, besides cation stability and steric effects associated with $sp^3 \rightarrow sp^2$ hybridization changes, are also concerned with internal return (ion-pairing), stereoelectronic participation, solvent effects, leaving group effects, etc., as witnessed by comparing *exo*- and *endo*-2-norbornyl solvolysis rates (which lead to the same cation). The equilibrium method described in this work is restricted at present to subtle comparisons such as cyclopentyl vs. 2-norbornyl in cations **9** $\rightleftarrows$ **10**. Eventually, of course, one could probably devise overlapping equilibria which would allow one to compare quantitatively all of the "systems" looked at in this study, as well as a host of others.

An even better approach is suggested by the elegant work of Arnett and co-workers (2), who have developed calorimetric techniques to measure cation stabilities, including methods for measuring the heat of isomerization of cations, e.g. 4-methyl-2-norbornyl → 2-methyl-2-norbornyl (22). The cations described in this work which are related by 1,4-H shifts rearrange slowly enough to be potential candidates for such calorimetry. Direct $K$ ($\Delta G$) measurements and $\Delta H_{\text{isom.}}$ measurements tend to be complementary techniques, since the latter are best applied where energy differences are relatively large, the former where they are small.

With regard to comparisons to gas-phase ion work, we do not feel that we have enough data yet to make very many meaningful comparisons, i.e. the effect of solvation on cation stabilities.

**Discussion of the nmr methods used to determine $K$**

As mentioned in the Introduction, three $^{13}C$ nmr methods were used in determining $K$ (methods A, B, and C).

*Method A*

For the 1,2-hydride shift equilibria ($n = 0$ case), the associated rate constant is very fast over the temperature range of our measurements. One sees only averaged spectra for ions **I** and **II**. In those cases where there is no temperature dependence of the chemical shift and where the spectrum "fits" a single isomer, we obviously cannot measure any $K$ value and only a lower limit has been estimated. It does not matter which alcohol one starts with to prepare the cation (both were used for **1***a* $\rightleftarrows$ **2***a* and for **3***a* $\rightleftarrows$ **4***a*) and one has to determine the presence of **I** or **II** from the detailed analysis of the actual $^{13}C$ shifts (easily done by looking at the methyl signals in ions **1–8**).

A detectable equilibrium for the $n = 0$ case is signalled by noting a temperature dependence for the "averaged" $C^+$—CH and CH—$C^+$ carbon peaks in **I–II**, the higher field combination moving downfield on increasing the temperature and the other moving upfield. Other peaks will possibly shift as well but to a much smaller extent. There are four unknowns here: (*1*) the chemical shift separation $\Delta_1$ for the $C^+$ carbon in **I** and the CH carbon in **II**; (*2*) $\Delta_2$ for the $C^+$ of **II** and the CH of **I**; (*3*) $\Delta H$ (assumed independent of temperature); and (*4*) $\Delta S$. Normally, one assumes that $\Delta_1 = \Delta_2 = \Delta$, and then adjusts $\Delta$ to give a good ln $K$ vs. $1/T$ van't Hoff plot, $K = \Delta - \delta/\Delta + \delta$, where $\delta$ = the observed separation of the $C^+$—CH and CH—$C^+$ peaks at a given temperature.

In the cyclohexyl vs. dimethyl case, ions **1***a* $\rightleftarrows$ **2***a*, there is no question but that an observable equilibrium exists. The data for these ions are shown in Table 7.

The best fit van't Hoff plot gives $K = 0.045$ at $-105°C$, $\Delta H = 1.2$ kcal/mol, and $\Delta = 254$ ppm (Fig. 1). Since the peaks being averaged in Table 7 are ca. 5700 Hz apart, the temperature dependence is large. For the remaining peaks in **1***a*–**2***a*, only small changes are observed (nevertheless providing enough information to assign **1***a* as the major species).

The data for the cyclopentyl vs. dimethyl case, ions **3***a* $\rightleftarrows$ **4***a*, are shown in Table 8. A van't Hoff plot gives $\Delta = 285$ ppm, $K = 25$ at $-105°C$, and $\Delta H = -1.9$ kcal/mol. One has uncertainties in $K$ because this number is very dependent on the $\Delta$ value used.

As expected, there are situations, for example **3***d* $\rightleftarrows$ **4***d*, where one sees even smaller changes and in the right directions. One knows that $K$ cannot be smaller than a certain value but one cannot be very certain that the actual value calculated is correct. In general, one should be able to detect $K$'s between 200 and 0.005 by this procedure but the confidence factor will be lower as one approaches these extremes.

TABLE 7. Chemical shift values for the averaged $C^+$—CH and CH—$C^+$ peaks in $1a \rightleftarrows 2a$[a]

| Temperature (°C) | $^{13}C$ shift (ppm) | | δ separation (ppm) |
|---|---|---|---|
| | $C^+$ (1*a*)—CH (2*a*) | $C^+$ (2*a*)—CH (1*a*) | |
| −133 | 320.9 | 77.3 | 243.6 |
| −126 | 319.5 | 78.2 | 241.3 |
| −116 | 317.7 | 80.0 | 237.7 |
| −105 | 314.9 | 82.8 | 232.1 |
| −96 | 313.3 | 84.7 | 228.6 |
| −84 | 310.2 | 87.5 | 222.7 |

[a]Saunders and Lloyd have also looked at this equilibrium and the one shown in Table 8; their results are similar to ours (ref. 45, ref. 46, footnote 31).

TABLE 8. Chemical shift values for the averaged $C^+$—CH and CH—$C^+$ peaks in $3a \rightleftarrows 4a$

| Temperature (°C) | $^{13}C$ shift (ppm) | | δ separation (ppm) |
|---|---|---|---|
| | $C^+$ (4*a*)—CH (3*a*) | $C^+$ (3*a*)—CH (4*a*) | |
| −128 | 336.2 | 60.5 | 275.7 |
| −116 | 333.1 | 63.5 | 269.6 |
| −105 | 329.1 | 66.8 | 262.3 |

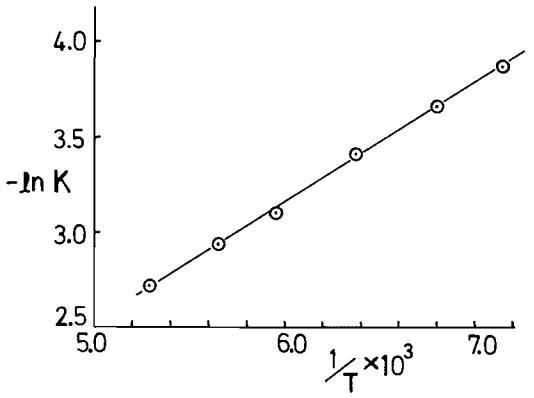

FIG. 1. Van't Hoff plot for the equilibrium 1*a*–2*a*, using the data in Table 7.

For the single $n = 3$ case studied, ions $1d \rightleftarrows 2d$, a 1,5-hydride shift is involved. Over a large temperature range from about −80 to −120°C, intermediate exchange kinetics made the averaged $C^+$—CH and CH—$C^+$ signals too broad to detect. Eventually, at about −70°C, they sharpen sufficiently to detect and using nmr method A, an equilibrium constant was calculated.

Standard deviation type errors for method A are very small.

*Method B*

Equilibrium in the $n = 1$ cases involves a 1,3-hydride shift. From previous work by Brouwer and Saunders (11, 12), it was expected that these shifts would be moderately fast on the nmr time scale (very fast on a conventional kinetic time scale). Consequently, either of the alcohols related, for example, to cations 1*b* and 2*b* can be used to prepare the equilibrium mixture. To determine the equilibrium constant, one could in principle use methods A, B, or C (see subsequent discussion). However, the temperature where averaged spectra would be obtained (method A) is too high for the survival of any of the cations studied in this work. Method C will apply at low temperatures under "frozen-out" exchange conditions. This procedure is the method of choice where both isomers can in fact be detected, but only in the cyclohexyl vs. dimethyl case (1*b*–2*b*) was this situation found. In all other cases, we have applied (or tried) method B.

Method B involves cases where one sees only one isomer at low temperatures (frozen-out conditions). As one warms the solution, one looks for line-broadening due to exchange with the "hidden" equilibrium partner. This method has been discussed in detail elsewhere (13). Cations **I** ⇄ **II** are particularly suitable for such a treatment if one focuses on the $C^+$ and CH carbons of the major isomer. The corresponding minor exchange partners (CH and $C^+$ respectively) are separated by about 6000 Hz in each case (there is very little uncertainty involved in estimating this separation using model systems). Since the potential line-broadening is a linear function of this separation, one should see *selective* broadening of these two peaks and much smaller changes, if any, in the others. In addition, these peaks should resharpen at still higher temperatures. This method is capable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

of detecting much larger or smaller $K$'s than either A or C, and this is nicely shown in the 2-adamantyl vs. dimethyl case, ions **7***b* ⇄ **8***b*. In this system, the peaks for the $C^+$ and CH (in isobutyl) carbons each reach a maximum broadness, in excess of the natural line-width, of ca. 20 Hz at −79°C, corresponding to a $K$ of ca. 330. The rate constant for **8***b* → **7***b* is ca. 120 $s^{-1}$, $\Delta G^{\ddagger}$ = 9.3 kcal/mol at −79°C. No other peaks are significantly broadened and a subsequent resharpening of the $C^+$ and CH carbon peaks was also observed. Selected spectra are shown in Fig. 2.

This method is quite capable of detecting $K$'s between 1000 and 0.001 using a 22.63 MHz instrument (and even wider ranges with higher fields). In those cases where we still have detected no line-broadening, e.g. 2-norbornyl vs. dimethyl, **5***b* ⇄ **6***b*, one can place a lower limit on $K$ *providing one is willing to accept that we have passed through a temperature where the equilibrium rate would have maximized the line-broadening if it had been detectable*. In the two cases where detectable changes were observed, $\Delta G^{\ddagger}$ for the 1,3-hydride shift was 8.9 and 9.3 kcal/mol (cf. 8.5 for the 2,4-dimethylpentyl cation) (11). It therefore appears reasonable to expect a similar $\Delta G^{\ddagger}$ (and temperature of maximum broadness) for all of these ions, particularly since the 1,3-hydride shift is not constrained by unfavorable geometries.

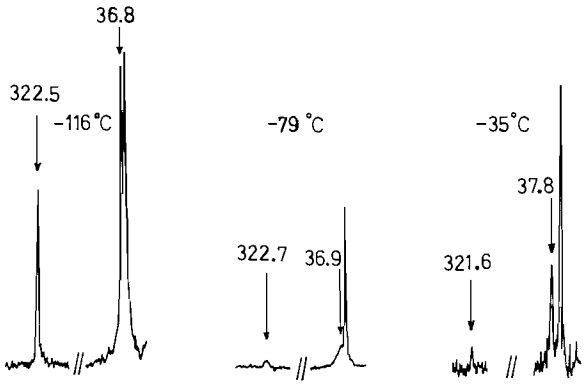

FIG. 2. Three (partial) $^{13}C$ nmr spectra of cation **8***b* taken at three temperatures (others are not shown). The spectrum at the left is the "frozen out" spectrum of **8***b* showing the $C^+$ and isobutyl CH peaks. The spectrum at −79°C (maximum broadness) shows the *specific* line-broadening caused by the dynamic exchange with cation **7***b* (which is "hidden" in the spectrum at −116°C because its concentration is very small). The peak to the right of the one at 36.9 ($C_6$) is included in the diagram to illustrate that the other peaks in **8***b* are *not* broadened. At −35°C, the peaks are "resharpened" and are from the averaged **7***b*–**8***b* situation. However, they have remained at almost the same chemical shift because of the very small concentration of **7***b* involved here.

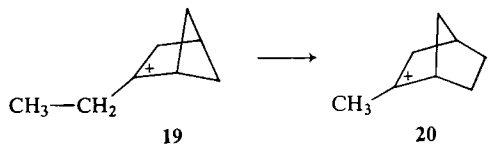
In the case of the cycloheptyl vs. dimethyl cation, we were unable to reach −80°C (ring-contraction), so this can place a restriction on the use of method B.

Method B requires some faith that one understands the rearrangement under consideration since, as mentioned, one often does not directly "see" the minor equilibrium partner. However, the selectivity involved in the line-broadening would be very difficult to interpret in any alternative way and we believe that this method has a good confidence factor over the $K$ range that we quote. The error limits are probably within ±20% of the quoted $K$ values.

*Method C*

Equilibrium via a 1,4-hydride shift (either direct or a combination of 1,2-shifts) was already known from model systems to be a slow process on an nmr time scale (11). Therefore, this nmr method is simply involved in trying to "see" peaks from both isomers. Ultimately for large or small $K$'s the limitation is determined by signal/noise considerations. In order to verify that a 1,4-shift is reasonably fast on a conventional kinetic time scale, we prepared both alcohols related to cations **1***c* and **2***c* and to **3***c* and **4***c* and found the same $^{13}C$ nmr spectrum for the ions at −100°C, i.e. equilibration has occurred. The equilibration reaction was directly observed in the case of **9** ⇄ **10** and **11** ⇄ **12**, where the less stable cations **9** and **11** were first prepared at −120°C and the isomerization to **10** and **12**, respectively, could be followed at ca. −90 to −100°C. That **10** and **12** are the species formed is clear from a detailed analysis of the $^{13}C$ peak positions and comparisons to the $^{13}C$ shifts and reactivity of model systems, for example, the ring expansion of **11** was shown to be slow by preparing the 2-ethyl-2-bicyclo[2.1.1]hexyl cation **19** and noting that the quantitative expansion to the 2-methyl-2-norbornyl cation **20** occurred only at much higher temperatures than that involved in a 1,4-hydride shift.



**19** **20**

In the case of cations **3***f*–**4***f*, **3***i*–**4***i*, **5***c*–**6***c*, and **7***c*–**8***c*, only one species was observed, but one can confidently presume equilibration conditions were present based on the near constancy of the 1,4-hydride shift rate in the four cases where this was checked.

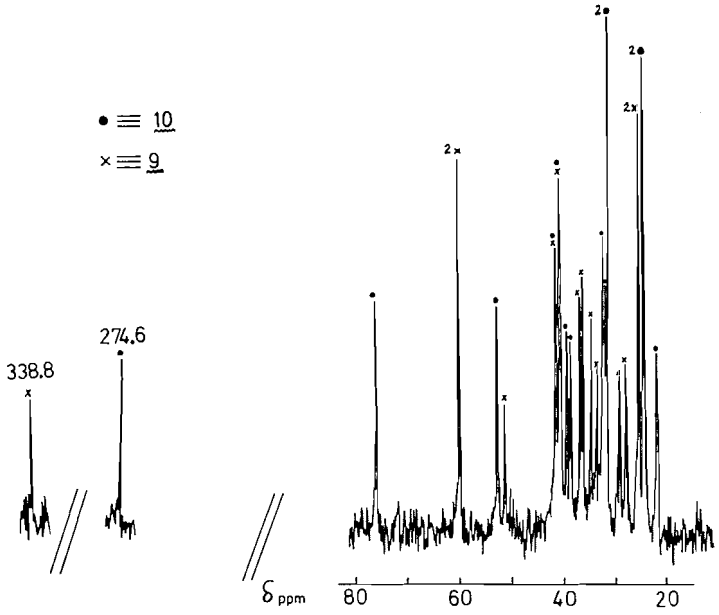


FIG. 3. Illustration of the "Method C" procedure for determining $K$ values. This spectrum (1000 scans at −90°C) was recorded at an intermediate point in the rearrangement of **9** to **10** to show the "fingerprinting" capabilities of the $^{13}C$ nmr spectra (only two lines are overlapped in the two ions). With longer times, the **9** ⇄ **10** equilibrium is reached.

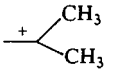
The S/N limits for the *absence* of detectable amounts of the minor partners in the above cases employed a search for the characteristic methyl signals from



which occur (or would occur) at about 45 ppm, a region fairly free of other $^{13}C$ peaks. In most cases, spectra were obtained after about 4000 accumulations, which has sufficient S/N to place an upper limit of about 3% on the maximum possible minor isomer. Thus, this method is not as sensitive as A or B, depending of course on how many accumulations one is able or willing to obtain.

Where equilibrium constants can be measured, one has a high confidence rating. For example, in ions **9** and **10**, there are fourteen peaks possible for each ion and in mixtures, twenty-two of these are completely resolved, i.e. "fingerprinting" comparisons have numerous peaks to use. This is shown in Fig. 3. The error limits are probably within ±10% of the reported $K$ values.

*Carbocation structures*

All of the ions prepared in this work are new, but in all cases, the corresponding methyl-substituted species has been reported. In the ions prepared in this work, only in the case of cation **4***g* are any anomalies noted in the expected (based on the methyl-substituted species) $^{13}C$ peak positions and this case has been discussed elsewhere (23). The $^{13}C$ shifts which are relevant to determining $K$'s or for structure assignment are given in Table 9.

Like the methyl analog, the cyclohexyl cations show evidence of a chair – twist boat conformational equilibrium and the cyclooctyl cations show a conformational line-broadening for some of the $^{13}C$ peaks.

*Carbocation rearrangements*

All of the cations eventually irreversibly rearrange. In the monocyclic cations, ring expansions or contractions readily occur, leading to cyclohexyl cations. Thus, none of the cyclobutyl ions could even be prepared, the cyclopentyl cations ring expand at ca. −80°C, a rate rather similar to the simple 1-ethyl analog (24), the cycloheptyl cations readily contract at about −90°C to −100°C, again similar to the 1-methyl analog (24), and the cyclooctyl cations also ring contract. In most cases, the products of these reactions were the same 1-isoalkylcyclohexyl cations which had already been characterized.

The 2-norbornyl cations are stable to about −30°C and the initial ring-expanded product is likely a 2-bicyclo[2.2.2.]octyl cation system. The 2-adamantyl cations are also stable to about −30°C. In the one case where rearrangement peaks were recorded, peaks characteristic of 1-adamantyl

| **19** | 329.1 ($C^+$), 78.8 (C-1), 57.1 (C-5, C-6), 55.7 ($CH_2$ of Et), 48.3 (C-3), 36.2 (C-4), 9.1 ($CH_3$ of Et) | −90 | |

[a]Dynamic line-broadening occurs at higher temperatures due to the **1***b* ⇄ **2***b* rate process becoming fast on the nmr time-scale.
[b]At other temperatures one sees changes in the ratio of **1***c* and **2***c*.
[c]The methyl carbons move to lower field at lower temperatures, indicating that while enthalpy favors **1***d*, entropy favors **2***d*.
[d]The $C^+$ and CH peaks did not broaden up to −85°C.
[e]Total chemical shift vs. temperature changes were only about 2 ppm over a 25°C span.
[f]Rearranges before the temperature needed for the 1,3-H-shift to show dynamic nmr line-broadening.
[g]See ref. 23 for a full description of this system.
[h]A dynamic chair–twist boat ⇄ twist boat–chair conformational interchange broadens some of the peaks. See ref. 14 for an analysis of the 1-methyl analog.
[i]Line-broadening, due to the well-known (25) 6,2-H-WM-6,2-H rearrangement, begins to show up at the higher temperatures.
[j]See Fig. 2, showing the line-broadening due to the exchange with the "hidden" **7***b*.
[k]See Fig. 3, showing an intermediate spectrum in the rearrangement of **11** to **12**.
[l]The peak at δ 20.1 is not compatible with a bicyclo[2.2.2]octane ring (26).
[m]In all cases, the spectra were also run at a number of other temperatures.

cations were observed, although the rearrangement appears to be "deep-seated".

## Experimental

*General procedures*

Mass spectra were obtained on a Varian CH-5 mass spectrometer. $^1H$ nmr spectra of neutral precursors were obtained on a Varian HA-100, Varian A-60, or Hitachi Perkin-Elmer R24B spectrometer. $^{13}C$ nmr spectra were obtained using a Bruker WH-90 or Varian XL-200 spectrometer, in $CDCl_3$ unless otherwise stated. Boiling points and melting points are uncorrected.

*Preparation of alcohol precursors*

Alkyl lithium reagents were prepared by standard procedures. The appropriate ketone, dissolved in ether, was added dropwise under argon at 0°C and then the mixture was refluxed for several hours. After work-up, the alcohols were isolated by fractional distillation. Yields using isopropyl lithium were generally poor (enolization) but purity of product was the main concern. $^{13}C$ and/or $^1H$ nmr spectroscopy and mass spectrometry were used to characterize the liquid products and to check the alcohol purity.

*1-(1-Methylethyl)-1-cyclobutanol*, bp 51°C/12 mm, *m/e* = 114.

*1-(1-Methylethyl)-1-cyclopentanol*, bp 63–66°C/11 mm, lit. (27), 53°C/6 mm, $^{13}C$ nmr ($CFCl_3$): δ 84.9, 38.8, 37.8, 24.4, and 18.0.

*1-(1-Methylethyl)-1-cyclohexanol*, bp 70–77°C/11 mm, lit. (27), 77°C/13 mm, $^{13}C$ nmr ($CFCl_3$): δ 72.8, 38.3, 34.7, 26.5, 22.3, and 17.0.

*1-(1-Methylethyl)-1-cycloheptanol*, bp 42°C/0.09 mm, lit. (28), 96°C/12 mm, $^{13}C$ nmr ($CFCl_3$): δ 76.9, 39.7, 38.8, 30.2, 23.3, and 17.7.

*1-(1-Methylethyl)-1-cyclooctanol*, bp 133–135°C/26 mm, reported in patent literature (29), $^{13}C$ nmr ($CFCl_3$): δ 75.5, 36.2, 34.7, 28.5, 25.5, 22.5, and 17.0.

*2-(1-Methylethyl)-2-bicyclo[2.2.1]heptanol*, bp 85–89°C/13 mm, *m/e* = 154, reported with no details (30), $^{13}C$ nmr ($CFCl_3$): δ 81.3, 45.8, 44.9, 39.0, 38.0, 36.7, 28.6, 23.3, 17.7, and 16.3.

*2-(1-Methylethyl)-2-tricyclo[3.3.0.0$^{3,7}$]decanol*, mp 59°C, lit. (31), 72.8–73.8°C, $^{13}C$ nmr ($CFCl_3$): δ 75.4, 39.0, 35.2, 34.4, 33.8, 30.0, 27.8, and 15.5.

Isobutyl lithium reactions also gave generally poor yields

because of the facile reduction of ketones by this particular reagent.

*1-(2-Methylpropyl)-1-cyclobutanol*, bp 58°C/10 mm, *m/e* = 128.

*1-(2-Methylpropyl)-1-cyclopentanol*, bp 69–71°C/10 mm, lit. (32), 120°C/22 mm, $^{13}C$ nmr ($CFCl_3$): δ 82.6, 50.9, 40.8, 25.3, 24.8, and 23.9.

*1-(2-Methylpropyl)-1-cyclohexanol*, bp 80–83°C/10 mm, lit. (32), 95°C/15 mm, $^{13}C$ nmr ($CFCl_3$): δ 71.7, 52.3, 38.5, 26.3, 25.1, 23.8, and 22.6.

*1-(2-Methylpropyl)-1-cycloheptanol*, bp 98–102°C/10.5 mm, lit. (32), 120°C/16 mm.

*1-(2-Methylpropyl)-1-cyclooctanol*, bp 116–118°C/9 mm, *m/e* = 184.

*2-(2-Methylpropyl)-2-bicyclo[2.2.1]heptanol*, bp 91–93°C/10 mm, *m/e* = 168.

*2-(2-Methylpropyl)-2-tricyclo[3.3.0.0$^{3,7}$]decanol*, mp 51°C, lit. (33), 57°C.

Isopentyl alcohols were prepared using the Grignard reagent or where noted, the lithium reagent, and yields were good in most cases.

*1-(3-Methylbutyl)-1-cyclobutanol*, isolated on a small scale by molecular distillation, bath temperature 50–75°C at 10 mm, *m/e* = 142, $^{13}C$ nmr: δ 75.8, 37.5, 36.0, 32.5, 28.5, 22.7, and 12.3.

*1-(3-Methylbutyl)-1-cyclopentanol*, bp 88–89°C/11 mm, *m/e* = 156, $^{13}C$ nmr: δ 82.5, 39.7, 39.3, 33.8, 28.6, 23.9, and 22.7.

*1-(3-Methylbutyl)-1-cyclohexanol*, bp 60–62°C/0.025 mm, reported in patent literature (34), $^{13}C$ nmr: δ 71.4, 40.2, 37.5, 32.0, 28.6, 26.0, 22.7, and 22.4.

*1-(3-Methylbutyl)-1-cycloheptanol*, using Li reagent, bp 115–121°C/10 mm, reported in patent literature (29).

*1-(3-Methylbutyl)-1-cyclooctanol*, using Li reagent, bp 86–92°C/0.25 mm, *m/e* = 198.

*2-(3-Methylbutyl)-2-bicyclo[2.2.1]heptanol*, bp 58–60°C/0.05 mm, *m/e* = 182, $^{13}C$ nmr: δ 79.5, 46.8, 45.8, 40.2, 38.7, 37.2, 32.3, 28.6, 22.7, and 22.2.

*2-(3-Methylbutyl)-2-tricyclo[3.3.0.0$^{3,7}$]decanol*, using Li reagent, mp 65°C, *m/e* = 204 (M − 18).

Cation solutions **1***a*–**2***a*, **1***c*–**2***c*, **3***a*–**4***a*, and **3***c*–**4***c* were also prepared from the corresponding sidechain alcohols.

*2-Cyclohexyl-2-propanol*, bp 76–78°C/9 mm, lit. (27), 85°C/15 mm, $^{13}C$ nmr ($CFCl_3$): δ 72.5, 50.0, 28.1, 27.3, and 27.2.

*4-Cyclohexyl-2-methyl-2-butanol* was prepared from 3-cyclohexylpropanoic acid by reaction of the acid chloride with 2 mol of methyl lithium, bp 108–110°C/11 mm, lit. (35), 96–97°C/7 mm.

*2-Cyclopentyl-2-propanol*, bp 35–36°C/0.35 mm, lit. (27), 50°C/3 mm, $^{13}C$ nmr ($CFCl_3$): δ 71.9, 51.8, 28.4, 27.7, and 26.6.

*4-Cyclopentyl-2-methyl-2-butanol*, prepared like the cyclohexyl analog, bp 90–93°C/11 mm, *m/e* = 138 (M − 18).

Cation **1***d*–**2***d* solutions were prepared from *5-Cyclohexyl-2-methyl-2-pentanol*, bp 70–76°C/0.09 mm, $^{13}C$ nmr ($CFCl_3$): δ 70.5, 44.7, 38.5, 38.1, 33.9, 29.4, 27.0, 26.8, and 22.0. This alcohol was prepared from the known (36) 3-cyclohexyl-1-bromopropane and acetone via the lithium reagent of the former.

Cations **9** and **10** both originated from the alcohol related to **9**.

*1-[2-(*exo*-2-bicyclo[2.2.1]heptyl)ethyl]-1-cyclopentanol*, bp 125–130°C/0.5 mm, solidifying at 25°C. *Anal.* calcd. for $C_{14}H_{24}O$: C 80.7, H 11.6; found: C 80.9, H 12.0. This alcohol was prepared by adding cyclopentanone at 0°C to the Grignard reagent from 1-bromo-2-(*exo*-2-bicyclo[2.2.1]heptyl)ethane and was formed in near quantitative yield.

*1-Bromo-2-(*exo*-2-bicyclo[2.2.1]heptyl)ethane*, bp 45–46°C/0.6 mm, was prepared from the known (37) alcohol ($Br_2$, triphenylphosphine, in acetonitrile) (38). In our case, the alcohol was prepared by esterification and $LiAlH_4$ reduction of the commercially-available carboxylic acid. The bromide had $^{13}C$ nmr: δ 62.4 ($CH_2$—Br), 40.8 (CH), 40.0 ($CH_2$), 37.6 ($CH_2$), 36.5 (CH), 35.5 (CH), 32.0 ($CH_2$), 30.0 ($CH_2$), and 28.7 ($CH_2$).

*2-[2-(*exo*-2-Bicyclo[2.2.1]heptyl)ethyl]-2-bicyclo[2.1.1]hexanol* was prepared like the cyclopentyl analog and was used to prepare both cations **11** and **12**, bp 103–106°C/0.3 mm, solidifies to a slightly oily solid at 25°C. *Anal.* calcd. for $C_{15}H_{24}O$: C 81.8, H 11.0; found: C 82.0, H 11.6. The alcohol is expected to be a mixture of two diastereomers and the $^{13}C$ nmr spectrum indicates this. The 2-bicyclo[2.1.1]hexanone was prepared by the method of Bond (39).

*6-[2-(*exo*-2-Bicyclo[2.2.1]heptyl)ethyl]-6-bicyclo[3.2.1]octanol* was prepared like the cyclopentyl analog using 6-bicyclo-[3.2.1]octanone (40) as the ketone, bp 128–140°C/0.6 mm, solidifies at room temperature. *Anal.* calcd. for $C_{17}H_{28}O$: C 82.2, H 11.5; found: C 82.0, H 11.7. This alcohol is likewise a mixture of diastereomers, but is expected to have the *endo*-alcohol configuration at C-6 (40).

*Preparation of the cations*

All of the cations were prepared by adding the weighed alcohol (80–200 mg dissolved in 200–500 μL of $CFCl_3$) to 2 mL of a 1:4 mixture of Magic acid (1:1 $SbF_5$–$FSO_3H$) and $SO_2ClF$. The acid solution was cooled to ca. −130°C in a liquid $N_2$ slush bath prior to the alcohol addition. In all cases, except the cyclobutanols, carbocations were obtained with unrearranged alcohol carbon skeleton (although H-shifts often occurred). 1-(1-Methylethyl)-1-cyclobutanol gave the 1,2-dimethylcyclopentyl cation (41), 1-(2-methylpropyl)-1-cyclobutanol gave mainly the cations **3***a*–**4***a*, and 1-(3-methylbutyl)-1-cyclobutanol gave **1***a*–**2***a* cleanly.

*Nuclear magnetic resonance spectra of the cations*

All $^1H$ and $^{13}C$ nmr spectra were obtained on a Bruker WH-90 FT-NMR spectrometer and previously described procedures were used for temperature calibration, lock, etc. (14). $^1H$ nmr spectra were obtained in a few cases but are not very useful for determining *K* values and are not further reported. $^{13}C$ nmr spectra were obtained at approximately 10–15°C intervals and generally involved about 4000 accumulations. Complete $^{13}C$ assignments were made for each cation, except for **11**, **12**, **14**, and **15** which are very complex, from off-resonance spectra and comparisons to the known 1-methyl analogs. Table 9 records the peaks of importance to the actual or attempted *K* determinations. Complete $^{13}C$ nmr assignments are available on request or are in the thesis of N.E.O. Any special observations on the $^{13}C$ spectra, such as dynamic line-broadening, are given in Table 9. Nuclear magnetic resonance procedures used to determine the *K*'s have already been discussed.

# Carbon-13/carbon-12 isotope effects on nitrogen-15 chemical shielding in some diamagnetic cyano complexes

RODERICK E. WASYLISHEN[1]

*Department of Chemistry, University of Winnipeg, Winnipeg, Man., Canada R3B 2E9*

Received February 22, 1982

RODERICK E. WASYLISHEN. Can. J. Chem. **60**, 2194 (1982).

Carbon-13/carbon-12 isotope-induced $^{15}N$ chemical shifts of 0.06 to 0.10 ppm have been observed for the cyanide ion and several transition metal cyanides. In each case, the $^{15}N$ resonance of the $^{13}C$ labelled isotopomers is to high field of that in the corresponding carbon-12 species. The sensitivity of the $^{15}N$ and $^{13}C$ shielding constants in the cyanide ion to small changes in the CN bond length are evaluated using the theoretical formulation of Jameson: $(\partial\sigma(^{15}N)/\partial r)_e = -872 \pm 160$ ppm/Å and $(\partial\sigma(^{13}C)/\partial r)_e = -473 \pm 90$ ppm/Å. Nitrogen-15 chemical shifts in the metal complexes exhibit basically the same behaviour as do the $^{13}C$ chemical shifts in these same complexes.

RODERICK E. WASYLISHEN. Can. J. Chem. **60**, 2194 (1982).

Dans les cas d'ions cyanures et de plusieurs cyanures de métaux de transition, on a observé des déplacements chimiques de 0,06 à 0,10 ppm pour des $N^{15}$ soumis à des inductions provoquées par des carbone-13/carbone 12. Dans chaque cas, la résonance du $^{15}N$ des composés marqués au $^{13}C$ se situe vers les champs forts par rapport à celle des substances correspondantes contenant du $^{12}C$. On a évalué la sensibilité des constantes de blindage du $^{15}N$ et du $^{13}C$ de l'ion cyanure vis à vis des petites variations dans la longueur de la liaison CN, en utilisant la formulation théorique de Jameson: $(\partial\sigma(^{15}N)/\partial r)_e = -872 \pm 160$ ppm/Å et $(\partial\sigma(^{13}C)/\partial r)_e = -473 \pm 90$ ppm/Å. Les déplacements chimiques du $^{15}N$ des complexes métalliques se comportent sensiblement de la même manière que les déplacements chimiques du $^{13}C$ dans ces mêmes complexes.

[Traduit par le journal]

## Introduction

With the availability of high resolution multinuclear nmr systems, particularly those equipped with superconducting magnets ($B_0$ = 5 to 12 T) there appears to be renewed interest in the effects of isotope substitution on chemical shielding constants (1). A part of this interest stems from the utility of isotope-induced shifts in studying reaction mechanisms, most notably $^{18}O$-induced shifts in $^{31}P$, $^{15}N$, and $^{13}C$ nmr (1*c*, 2–4).

Here we report $^{15}N$ chemical shifts and $^{13}C/^{12}C$ isotope effects on $^{15}N$ chemical shifts in the cyanide ion and several diamagnetic cyano complexes. Previously, $^{13}C/^{12}C$ isotope effects have been observed in $^{1}H$, $^{13}C$, $^{19}F$, $^{59}Co$, $^{113}Cd$, and $^{199}Hg$ nmr (5–10). Observed chemical shifts are generally to high field when $^{12}C$ is replaced by $^{13}C$; however, in dimethylcadmium and dimethylmercury downfield shifts are observed (9, 10). Also, several examples of downfield deuterium-induced $^{13}C$ chemical shifts, once considered rare, have recently been reported (11–13).

The magnitude of isotope effects is observed to depend on a number of factors including the chemical shift range of the nucleus under observation, the fractional change in mass upon isotopic substitution, and the remoteness of the nucleus under observation from the point of substitution (11, 14). These general empirical observations are reasonably well accounted for by an approximate theoretical model developed by Jameson (15). For a diatomic molecule, she has shown that the magnitude of the isotopic shift, $\Delta\sigma$, is determined entirely by anharmonic vibrational averaging.

$$[1]\quad \Delta\sigma = \langle\sigma^i\rangle^T - \langle\sigma\rangle^T \simeq -\frac{(\mu^i - \mu)}{2\mu} f_{anh}(T) \left(\frac{\partial\sigma}{\partial r}\right)_e$$

where

$$f_{anh}(T) = \frac{3h\ (1 + \alpha\omega/6B_e^2)}{16\pi^2 c r_e \mu\omega} \coth\left(\frac{hc\omega}{2kT}\right)$$

The $\mu$'s are the reduced masses of the two isotopomers, $B_e$ is the rotational constant, $\omega$ is the vibrational frequency, $\alpha$ is the rotational–vibrational interaction constant, $(\partial\sigma/\partial r)_e$ is a measure of the dependence of the shielding constant, $\sigma$, on internuclear distance in the neighbourhood of the equilibrium bond length, $r_e$, and the other symbols are standard. Observed $^{13}C/^{12}C$ and $^{15}N/^{14}N$ secondary isotope effects on $^{15}N$ and $^{13}C$ chemical shifts in the cyanide ion are discussed in terms of this theory.

## Experimental

Isotopically enriched $KC^{15}N$ (95% $^{15}N$) and $K^{13}C^{15}N$ (90% $^{13}C$ and 90% $^{15}N$) were obtained from Merck, Sharp, and Dohme and Prochem., respectively. Metal complexes, $M(CN)_4^{2-}$ (M =

TABLE 1. $^{15}N$ chemical shifts and $^{13}C/^{12}C$ isotope effects on $^{15}N$ chemical shifts in some diamagnetic cyano complexes

| Species | $\delta(^{15}N)$, ppm[a] | Isotope shift, ppm[b] | $^1J(^{15}N, ^{13}C)$, Hz[c] |
|---|---|---|---|
| $CN^-$ | 274.3 (0.0) | 0.075±0.005 | 6.1±0.1 |
| HCN | 252.4[d] (−21.9) | — | 18.5±0.1[e] |
| $Ni(CN)_4^{2-}$ | 290.2 (15.9) | 0.066±0.010 | 9.8±0.2 |
| $Pd(CN)_4^{2-}$ | 281.1 (6.8) | 0.101±0.025 | 8.3±1.0 |
| $Pt(CN)_4^{2-}$ | 270.8 (−3.5) | 0.077±0.010 | 11.4±0.2 |
| $Zn(CN)_4^{2-}$ | 274.4 (0.1) | 0.069±0.010 | 8.9±0.2 |
| $Cd(CN)_4^{2-}$ | 277.7 (3.4) | 0.081±0.020 | 7.4[5]±0.2 |
| $Hg(CN)_4^{2-}$ | 278.3 (4.0) | 0.067±0.010 | 7.2±0.2 |

[a]All chemical shifts were measured relative to external 0.4 *M* $KC^{15}N$ which is taken to be 106.1 ppm to high field of neat nitromethane (17) or 274.3 ppm to low field of liquid ammonia (18). Values in brackets are relative to $CN^-$, negative values are high field shifts.
[b]Here the isotope shift is defined as $\Delta\sigma = \sigma(^{15}N^{13}C) - \sigma(^{15}N^{12}C)$. Positive values indicate greater shielding in the heavier isotopomer.
[c]The sign of $^1J(^{15}N, ^{13}C)$ is probably negative in all these compounds (19).
[d]Reference 18.
[e]Reference 19.

Ni, Zn, Cd, and Hg) were prepared by treating 0.30 mmol of $M(CN)_2$ with stoichiometric amounts of $KC^{15}N$ (0.30 mmol) and $K^{13}C^{15}N$ (0.30 mmol) (16). $Pd(CN)_4^{2-}$ and $Pt(CN)_4^{2-}$ were prepared by dissolving 0.30 mmol $K_2MCl_4$ in 1.50 mL $D_2O$ and adding stoichiometric quantities of KCN (0.60 mmol), $KC^{15}N$ (0.30 mmol), and $K^{13}C^{15}N$ (0.30 mmol) (16). All $M(CN)_4^{2-}$ solutions were prepared in 1.50 mL $D_2O$, therefore the concentration of all complexes is 0.20 molal.

Nitrogen-15 nmr spectra were obtained at 40.55 MHz using a Bruker WH-400 spectrometer. Computer acquisition times of 8.192 s were used to collect all spectra. The probe temperature was 297 ± 2 K.

## Results and discussion

Nitrogen-15 chemical shifts and $^{13}C/^{12}C$ isotope-induced $^{15}N$ chemical shifts are given in Table 1. The $^{15}N$ nmr spectrum of 0.20 *m* $KC^{15}N$ and 0.20 *m* $K^{13}C^{15}N$ in $D_2O$ is shown in Fig. 1. The $^{15}N$ chemical shift of the $^{13}C^{15}N^-$ ion is approximately 3.04 Hz (0.075 ppm) upfield of that in $^{12}C^{15}N^-$. The low field line of the doublet in $^{13}C^{15}N^-$, for which $^1J(^{15}N, ^{13}C) = 6.08 \pm 0.10$ Hz, is coincident with the singlet observed for $^{12}C^{15}N^-$. The nitrogen-15 spectra of $Zn(CN)_4^{2-}$ and $Pt(CN)_4^{2-}$ are shown in Figs. 2 and 3. The $^{15}N$ nmr spectrum of $Pt(CN)_4^{2-}$ shows additional splittings due to scalar coupling with $^{195}Pt$ ($I = \frac{1}{2}$, natural abundance, 33.8%), giving $^2J(^{195}Pt, ^{15}N) = 61.2 \pm 0.2$ Hz. To our knowledge, this is the first reported $^2J(^{195}Pt, ^{15}N)$ value (20).

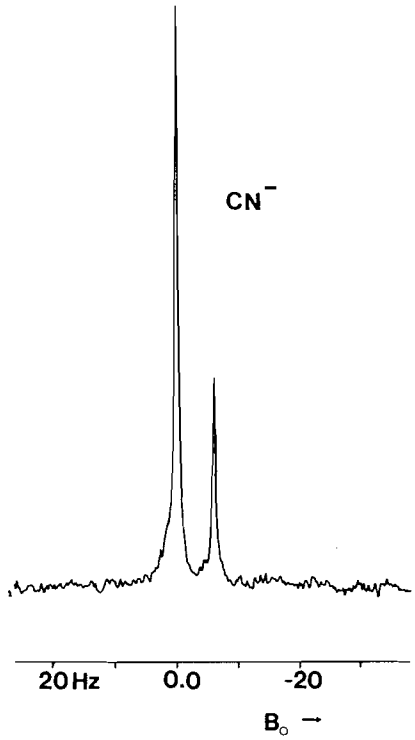

FIG. 1. Nitrogen-15 nmr spectrum of 0.20 *m* $KC^{15}N$ and 0.20 *m* $K^{13}C^{15}N$ in $D_2O$ at 40.55 MHz. All frequencies are relative to the chemical shift of $^{12}C^{15}N^-$.

### *(i) Isotope effects*

The $^{13}C/^{12}C$ isotope effects on $^{15}N$ chemical shifts in the cyanide ion and the complexes studied here range from 0.066 to 0.10 ppm. The magnitudes of the $^{13}C/^{12}C$ isotope effects are intermediate between those observed in $^{13}C$ nmr (0.01–0.03 ppm (6)) and $^{19}F$ nmr (0.067–0.192 ppm (7)). They are more than twice the $^{15}N/^{14}N$ isotope effect on $^{13}C$ chemical shifts (0.02–0.04 ppm) observed in these same complexes (21). $^2H/^1H$ isotope effects on nitrogen shielding in $^{15}NH_2D$ (0.68 ± 0.03 ppm relative to $NH_3$ (22)) are also large compared to the $^2H/^1H$ isotope-induced $^{13}C$ chemical shift in $^{13}CH_3D$ (0.187 ppm relative to $CH_4$ (23)). The greater sensitivity to isotopic substitution of $^{15}N$ compared with $^{13}C$ chemical shifts results mainly from the relative values of the last factor in eq. [1]. For example, in the isoelectronic molecules $N_2$ and

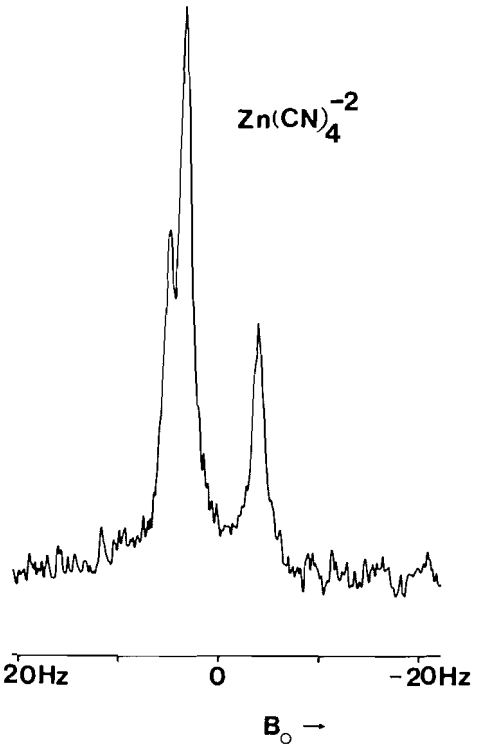

FIG. 2. Nitrogen-15 nmr spectrum of 0.20 *m* $K_2Zn(CN)_4$ in $D_2O$ at 40.55 MHz. The sample contains approximately equal concentrations of $^{15}N$ and $^{13}C^{15}N$ labelled cyanide. All frequencies are relative to the chemical shift of external 0.4 *m* $KC^{15}N$ (aq).

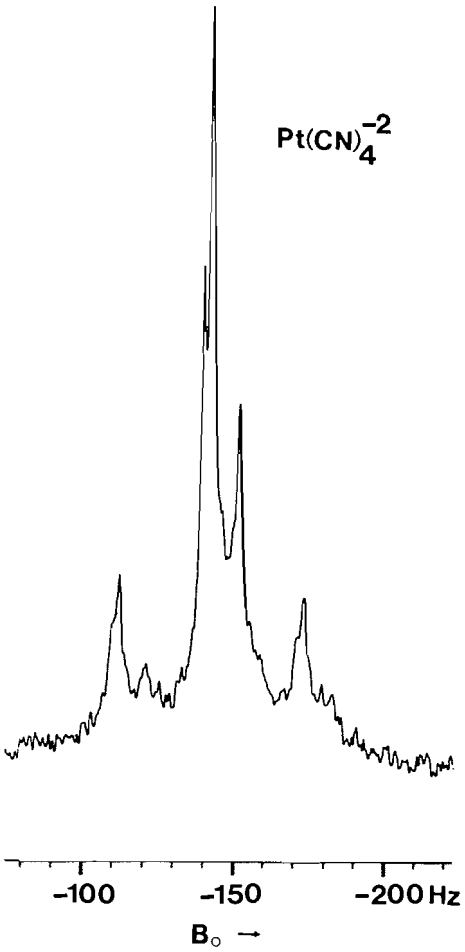

FIG. 3. Nitrogen-15 nmr spectrum of 0.20 *m* $K_2Pt(CN)_4$ in $D_2O$ at 40.55 MHz. The sample contains approximately equal concentrations of $^{15}N$ and $^{13}C^{15}N$ labelled cyanide. All frequencies are relative to the chemical shift of external 0.4 *m* $KC^{15}N$ (aq).

CO, $(\partial\sigma/\partial r)_e$ has been measured to be $-776 \pm 118$ ppm/Å($^{15}N$) and $-226 \pm 44$ ppm/Å($^{13}C$), respectively (24).

Since most of the variables in eq. [1] are available for the cyanide ion, we have calculated $(\partial\sigma(^{15}N)/\partial r)_e$ and $(\partial\sigma(^{13}C)/\partial r)_e$ from the $^{15}N$ (this work) and $^{13}C$ (ref. 21) isotope shifts in the cyanide ion. Taking values of $r_e$, $B_e$, $\omega_e$, and $\alpha_e$ for the cyanide ion from the *ab initio* CI calculations of Ha and Zumofen (25), $(\partial\sigma(^{15}N)/\partial r)_e = -872$ ppm/Å and $(\partial\sigma(^{13}C)/\partial r)_e = -473$ ppm/Å. The error in these derivatives is probably 20% or more.[2] The value of $(\partial\sigma(^{15}N)/\partial r)_e$ calculated here for the cyanide ion is within experimental error of the value recently measured in the isoelectronic molecule $N_2$ (24); however, the values of $(\partial\sigma(^{13}C)/\partial r)_e$ in the cyanide ion and CO differ by a factor of approximately 2. These calculations indicate that the isotope shifts in $CN^-$ (aq) result from mass-substitution effects on the anharmonic vibrational averages over the dependence of the chemical shifts on internuclear separation. The fact that the analogous isotope shifts for the $M(CN)_4^{-2}$ (aq) complexes are within experimental error of the $CN^-$ (aq) values implies that complexation of $CN^-$ does not significantly affect this configurational average.

Both positive and negative $^{15}N/^{14}N$ isotope-induced $^{15}N$ chemical shifts have been reported in $N_2O_3$ and $N_2O_3^{2-}$ respectively (27). These isotope shifts, $-0.24$ to 0.37 ppm, are much larger than those reported here. Also, the $^{18}O/^{16}O$ isotope-induced $^{15}N$ shift for the nitrate ion, 0.138 ppm/$^{18}O$ (3), is somewhat larger than those reported here. Unfortunately, the model of Jameson (1*a*, 15) is difficult to apply to these polyatomic species.

[2]Using spectroscopic data ($r_e$, $B_e$, $\omega_e$, and $\alpha_e$) for the cyanide radical (26) we obtain $(\partial\sigma(^{15}N)/\partial r)_e = -800$ ppm/Å and $(\partial\sigma(^{13}C)/\partial r)_e = -434$ ppm/Å.

*(ii) $^{15}N$ chemical shifts*

Nitrogen-14 chemical shifts for several diamagnetic complexes have been previously reported (27–29), however, very efficient $^{14}N$ quadrupole relaxation in these complexes leads to broad resonances precluding accurate nitrogen chemical shift data.

The cyano complexes studied here show substantial downfield $^{15}N$ chemical shifts relative to those measured in hydrogen cyanide and acetonitrile, $\delta(^{15}N)$ = 244 ppm and 264 ppm (18), respectively. In fact, $\delta(^{15}N)$ for all of the complexes in Table 1 is within 16 ppm of the value observed for the cyano ion in KCN (aq). The $^{13}C$ chemical shifts in the same complexes are all 15 to 42 ppm downfield relative to $\delta(^{13}C)$ in HCN and 13 to 40 ppm upfield of $\delta(^{13}C)$ in $CN^-$ (aqueous) (30, 31).

In the previous $^{13}C$ nmr studies it was noted that, in cyanide metal complexes with partly filled *nd* levels, there is an upfield $^{13}C$ shift as *n* increases, while for complexes in which the *d* shell is filled, small downfield shifts were observed (30, 31). This trend also holds for the $^{15}N$ shifts. On going from $Ni(CN)_4^{2-}$ to $Pd(CN)_4^{2-}$ to $Pt(CN)_4^{2-}$ (all square planar $nd^8$ complexes, $n$ = 3, 4, and 5 respectively) the $^{15}N$ chemical shifts are 290.2, 281.1, and 270.8 ppm. For the tetrahedral cyanides of the zinc family there are small downfield shifts as one proceeds down the group. The origin of these shifts is not clear at this time.

**Acknowledgements**

The nmr spectra reported here were obtained at the Southwestern Ontario NMR Center funded by a Major Installation Grant from the Natural Sciences and Engineering Research Council of Canada. I wish to thank Dr. Robert Lenkinski for making instrument time available for this study, Brian A. Pettitt for his encouragement and comments, and N.S.E.R.C. for financial support.

# Detection limitations of photomultiplier tubes in pulsed-laser emission spectroscopy: time-resolved fluorescence spectra of chlorophyll solutions[1]

A. DE WILTON, L. V. HALEY, AND J. A. KONINGSTEIN

*The Ottawa-Carleton Institute for Research and Graduate Studies in Chemistry, Carleton University, Department of Chemistry, Ottawa, Ont., Canada K1S 5B6*

Received January 12, 1982

A. DE WILTON, L. V. HALEY, and J. A. KONINGSTEIN. Can. J. Chem. **60**, 2198 (1982).

An experimental method is described for determination of the onset of saturation effects on the performance of photomultiplier tubes (PMTs) used in time-resolved pulsed-laser spectroscopy. Changes in the dark level response in time (on the 0–100 ns time scale) of the PMT were observed to indicate saturation of the tube. At low repetition rates conditions were found for which an RCA 8850 PMT and an RCA 7102 PMT can be used to obtain reliable fluorescence decays on the 0–100 ns time scale while operating at high anode currents, without modification of interdynode voltages.

Results for time-resolved fluorescence studies of Chl *a* in solution, in benzene and in pyridine, are discussed. The fluorescence decays at ~680 nm indicate that several Chl *a* species are present in each solution. In pyridine, the main fluorescence process at 677 nm, characterised by a lifetime of ~7 ns, is assigned as arising from ligated monomeric species of Chl *a*. A second longer-lived and weaker component ($\tau \simeq 75$ ns) is assigned to the ligated monomeric species of Chl *a'*. A third, and even weaker process characterised by a lifetime $\tau \simeq 145$ ns is also observed. The time-resolved fluorescence spectral band shape of this component has a unique narrow profile, and is assigned to a dimeric or more highly aggregated species of Chl *a*. The time-resolved measurements also indicate that another emission band occurs at 740 nm, and that this process has a lifetime 75 ns $< \tau <$ 145 ns.

A. DE WILTON, L. V. HALEY et J. A. KONINGSTEIN. Can. J. Chem. **60**, 2198 (1982).

On décrit une méthode expérimentale pour déterminer le début des effets de saturation sur la performance des tubes photomultiplicateurs (TPM) utilisés dans la spectroscopie laser à impulsion, à résolution en fonction du temps. On a observé des variations dans la réponse au niveau sombre dans le temps (dans l'échelle de temps allant de 0 à 100 ns) du TMP indiquant ainsi la saturation du tube. A de faibles vitesses de répétition, on a trouvé les conditions dans lesquelles on peut utiliser des tubes photomultiplicateurs RCA8850 et RCA7102 pour obtenir des valeurs sures pour la désintégration de la fluorescence à des échelles de temps allant de 0 à 100 ns lorsqu'on opère avec de forts courants anodiques sans modification des voltages interdynodes.

On discute des résultats obtenus lors d'études de fluorescence, résolue en fonction du temps, du composé Chl *a* en solution dans le benzène et dans la pyridine. Les désintégrations de la fluorescence à 680 nm indiquent que plusieurs espèces de Chl *a* sont présents dans chaque solution. Dans la pyridine, on attribue le mode principal de fluorescence à 677 nm, caractérisé par un temps de vie d'environ 7 ns, à des espèces monomères de Chl *a* reliées entre elles. On attribue une deuxième composante plus faible et d'une durée de vie plus longue ($\tau = 75$ ns) à des espèces monomères de Chl *a'* reliées entre elles. On a également observé un troisième processus qui est encore plus faible et qui est caractérisé par un temps de vie $\tau \simeq 145$ ns. La forme de la bande spectrale de fluorescence, résolue en fonction du temps, de ce composé a un profil étroit caractéristique et on l'attribue à une espèce dimère ou à une espèce plus fortement agrégée de Chl *a*. Les mesures, résolues en fonction du temps, indiquent également qu'une autre bande d'émission apparaît à 740 nm et que ce processus a une durée de vie de 75 ns $< \tau <$ 145 ns.

[Traduit par le journal]

## I. Introduction

The measurement and interpretation of fluorescence decay curves has been simplified by the introduction of pulsed lasers to induce the fluorescence processes. The emitted radiation, after passing through a monochromator, reaches a photomultiplier tube (PMT), and the signal generated by this "square-law" detector is processed by either a boxcar integrator or by a photon-counting system. The former has the advantage that the fluorescence decay can be studied on the 0–100 ns time scale, with a gate width of $\gtrsim$2 ns. On the other hand, while photon-counting systems are more easily adapted to multichannel analysis, with the advantage of improved S/N of the fluorescence decay curve obtained by increasing the sampling time per channel, the gate width is in general >20 ns.

Of relevance to both systems is the ability of the detector (PMT) to process intense light pulses of short duration. There are two important quantities to consider. The first is the time response of the PMT, and the second is the light level which should be chosen so that saturation of the PMT does not occur. In fact, saturation can result in a change of the response time in addition to non-linear response with regard to the signal generated by the radiation incident on the photocathode (1). These effects can lead to erroneous determination of lifetimes from fluorescence and phosphorescence data (2), particularly when a weak emission with a longer lifetime follows a shorter-lived and more intense emission process.

Gating the PMT high voltage supply can overcome this difficulty in certain cases (3, 4). For some PMT's the maximum average anode current can be increased by modification of the resistors of the dynode chain (5, 6). When employing a conventional dc PMT power supply with the detection system exposed to high intensity pulsed radiation, it is necessary to carry out a series of calibrations to detect the onset of saturation effects at higher light levels, before analysis of the decay of fluorescence (1).

Because our detection system utilizes a boxcar, we are interested in the ways in which saturation effects influence fluorescence decay curves on the 0–100 ns time scale. In this paper we describe a study of such effects for the fluorescence of Chlorophyll *a* (Chl *a*) in pyridine and benzene solutions, which is characterised by processes with lifetimes of $\gtrsim 10$ ns, induced by laser pulses having a FWHM of $\sim 4$ ns at a repetition rate of 25 Hz.

## II. Experimental

A detailed description of the experimental set up has been given in an earlier publication (7). Of relevance to the present work are the PAR boxcar integrator and the PMT which are the fundamental electronic components in the detection system. The PAR boxcar (main frame Model 162) is equipped with gated integrators (Model 165 and 164) which allow one to achieve 2 ns temporal resolution. In experiments for detection of fluorescence radiation in the red ($\sim 680$ nm) from Chl *a* in benzene and in pyridine, one of each of the following PMT's was used: RCA C31034A, RCA 7102, RCA 8850, and ITT FW130. In the case of weak signals a preamplifier was placed between the PMT and the input of the boxcar. This preamplifier consists of one or two cascading fast-pulsed amplifiers (Le Croy 101a) with gains of $\sim 10$ and $\sim 100$ respectively.

Fluorescence decay curves were recorded by setting the wavelength of the monochromator at the position of maximum intensity of a fluorescence band, and the aperture of the boxcar was scanned over the 0–100 ns scale. Since the boxcar does not integrate at the repetition rate (25 Hz) of the $N_2$-pumped tunable-dye laser, scans were recorded over a period of 15 min. In some cases 2 or 3 scans were averaged. The intensity data were corrected for a background level and the fluorescence decay time was obtained from a semi-log plot of intensity versus time. The background is due to noise from (*i*) the electronics of the boxcar (and preamplifier) and (*ii*) the PMT. In the following we shall refer to this background, when the PMT is not exposed to light, as the dark level.

In order to be able to use the 0–100 ns scale of the boxcar, care was taken to avoid the dead time of the instrument. This was achieved by delaying the PMT signal, so that the peak of the laser pulse appeared at $t \simeq 30$ ns on the 0–100 ns time scale of the boxcar. This time is defined as $t_0$.

The fluorescence in the red of chlorophyll *a* (Chl *a*) in solution was excited by pulsed radiation at 447 nm. Chl *a* was obtained from Sigma Chemical Co. and dried by codistillation with dried benzene. Benzene (Fisher ACS Reagent grade) and pyridine (BDH Aristar) were dried over neutral activated alumina (Woelm Activity 1). All solutions were deoxygenated and sample handling took place in a dry-nitrogen-purged glovebag. The water content of the Chl *a* solutions was estimated from a combination absorption band of $H_2O$ in the near infrared at $\sim 1940$ nm.

## III. Time-dependent photomultiplier response at the onset of saturation

Although the effects of saturation of PMT's due to strong light levels are well known in ordinary spectroscopy (1–3, 8, 9) (non-linear response), there is a lack of information on how saturation influences the time response of these light detectors. In order to study such saturation effects, a series of experiments were carried out as described below.

An uncooled RCA 7102 PMT (with S-1 response) was left for several days in the dark at 1500 V and its dark level in real time was recorded as shown in Fig. 1*C*. This figure shows a pattern of peaks and valleys in the dark level which occur at specific

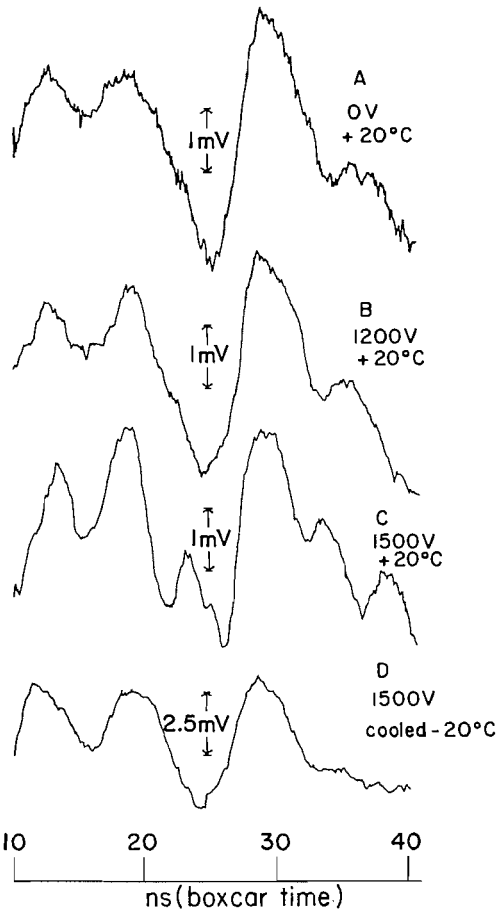

FIG. 1. Part of the dark level of a RCA 7102 PMT recorded on the 0–100 ns scale of the boxcar.

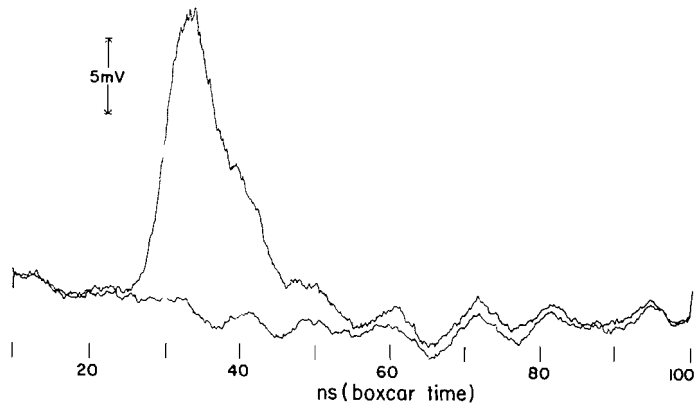

FIG. 2. Dark level and decay of fluorescence signal at 678 nm from $10^{-5}$ *M* Chl *a* in pyridine as recorded using RCA 7102 PMT.

points in time on the 0–100 ns scale of the boxcar. These peaks and valleys are characteristic for the system (PMT + boxcar) because they are reproducible. A change in the high voltage from 1500 V to 1200 V, and finally to 0 V does not result in drastic changes in the dark-level pattern, although one notes that there are more changes between the patterns of Fig. 1*B* and 1*C* than between Fig. 1*B* and 1*A*. The pattern of Fig. 1*D* is that of a cooled (−20°C) 7102 PMT, also at 1500 V. The peaks and valleys occur at approximately the same positions as those of Fig. 1*A*, 1*B*, and 1*C*. The contributions to the dark level from the PMT become clear if one compares Fig. 1*A* with 1*B*, 1*C*, and 1*D*, when one notices the absence in Fig. 1*D* of peaks at $t \approx 14$ ns, $t \approx 23$ ns, and $t \approx 34$ ns. We conclude that the latter are due to the PMT and the rest of the pattern is due to boxcar noise and/or rf pick up. The effect of the rf radiation was minimized by (*i*) shielding of the PMT and input and output joints of the PMT housing and (*ii*) by introducing a common ground for all components of the system. Although only a part of the dark level on the 0–100 ns scale is shown, similar patterns were recorded over the full range examined, from 0 to 1000 ns.

In the next series of experiments we exposed the cooled PMT (at 1500 V) to fluorescence of Chl *a* in pyridine at 678 nm at low light levels. Figure 2 shows traces of dark and signal levels and we find that the fluorescence decay is modulated with the same characteristic pattern as the dark level. Subtraction of the latter from the former results in the decay curve of Fig. 3. Also shown is the position and shape of the laser pulse in real time. This pulse has decayed to zero intensity at $t \approx 40$ ns. The fluorescence decay curve reveals short- and longer-lived fluorescence processes (Fig. 4). The short-lived process was found from Fig. 4 to be characterised by $\tau = 7 \pm 1$ ns, which is typical for Chl *a* in pyridine (10). Immediately after exposure of the PMT to the low-level light signal, the dark level was recorded and found to be identical to that before the tube was exposed to pulsed light. However, if exposed to light levels which were 100 times that of the run shown in Fig. 2, it was found that the modulations in the fluorescence decay curves no longer followed those present in the dark level *before* the PMT was exposed to the pulsed-fluorescence light at 678 nm (Fig. 5). A semilog plot of the fluorescence intensity versus time for the same Chl *a* solution now resulted in a non-linear plot. Such behaviour is to be expected if the PMT is saturated. On continued exposure of the PMT to high light levels, we found that the modulation of the fluorescence decay curves remained while that of the dark level diminished (see Fig. 6). The longer the tube was exposed to high light levels, the flatter the dark-level curve. Figure 6 shows that the oscillations in the signal intensity (versus time) bear no relation to the modulation in the dark level. The proper dark level recorded before the onset of saturation is shown in Fig. 2. It was found that the PMT required at least 24 h in the dark (cooled and at 500 V) to recover from saturation. The modulation in the dark level returned gradually, from the flat baseline (Fig. 6) to the pattern shown in Fig. 2. The recovery time was shorter if the PMT was not fully saturated, i.e., some modulation in the dark level was still visible. The above observations pertain to a RCA 7102 PMT, but we recorded similar behaviour for the following PMT's: RCA C31034A, RCA 8850, and ITT FW130.

The well-known red-sensitive C31034A PMT was found to saturate at lower light levels than the 7102 PMT. In order that the signal be displayed at the 100 mV scale, cascading amplifiers have to be

employed with the RCA C31034A, but they broaden the signal and introduce noise. We conclude that the RCA 7102 PMT is the better tube for pulsed-laser spectroscopy in the red spectral regions. This is because signals can be directly recorded on the 100 mV scale of the boxcar whilst its noise characteristics, as recorded with the boxcar (with a 2 ns gate), are in fact very small (see Fig. 1). The 7102 PMT does not require a preamplifier and consequently any broadening of the laser pulse, due to the detection system, is limited to that caused by the response time of the tube and the gate width of the boxcar.

The ITT FW130 should not be used in pulsed work, because its response time is too slow. If exposed to a laser pulse with a FWHM of 3.2 ns, we record an output signal which has a FWHM of 40 ns!

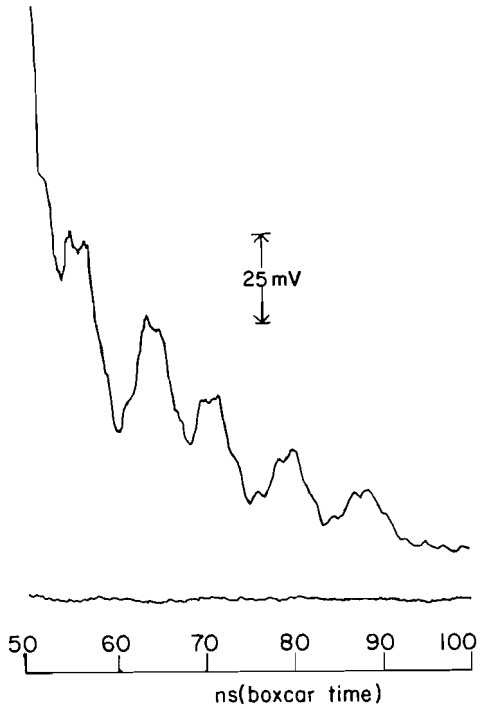

FIG. 6. Part of the dark level and signal level shown in Fig. 5, under higher gain.

The cathode sensitivity of the RCA 8850 PMT is better than that of the 7102 PMT in the blue spectral region. The former has a longer anode pulse decay time (~4 ns), but if it is operated at 2500 V, this PMT does not require a preamplifier to display the signals at the 100 mV scale of the integrator and was found to be very effective for investigation of fluorescence decay curves on the 0–100 ns scale, in the spectral region of 400–550 nm.

Some characteristic parameters of the PMT's used in these investigations are shown in Table 1. Of importance here is the maximum value of the average anode current which is generated by the incident photons. Keeping in mind that the input impedance of the boxcar (and preamplifiers) is 50 Ω, one calculates that for the 7102 PMT, under continuous radiation, the maximum input voltage into the amplifier should be 0.5 mV. In reality, we found that effective saturation in the pulsed mode, without preamplification of the signal, takes place on the 250 mV scale of the Model 165 integrator (PMT cooled and at 1500 V). Thus, it appears that this PMT behaves extremely well in the pulsed mode, without changing the resistors of the dynode chain. However, the laser operates at only 25 Hz. It may be that an increase in the repetition rate could cause saturation at lower input levels.

The low value for the maximum average anode current of 100 nA for the C31034A PMT is responsible for the fact that preamplifiers or an increase in high voltage are required to meet the input requirements of the boxcar. The RCA 8850 PMT would theoretically saturate if the input signal to the boxcar is 10 mV (continuous radiation). If cooled and operated at 2200 V, we find that pulsed signals can be processed safely at the 250 mV scale. This appears to be the same for the ITT FW130 PMT, but, as already indicated, this tube should not be used for time-resolved spectroscopic studies on the 0–100 ns time scale.

To conclude this section, we note that in pulsed spectroscopy with low repetition rates, certain PMT's commonly used in fluorescence and Raman spectroscopy seem to perform rather well in processing strong light signals without modification to their interdynode voltages. In addition, we emphasize the usefulness of recording the dark level in time both before and after running a fluorescence decay or time-resolved spectrum.

## IV. Decay of fluorescence and time-resolved emission spectrum of chlorophyll *a* in solution

Having found the experimental conditions for time-resolved studies with our pulsed-laser system, we discuss in this section some relevant experimental data for Chl *a* in solution and offer possible explanations in terms of simple models.

Due to the complexity of the chemical equilibria, particularly those involving water, the interpretation of time-resolved fluorescence spectra and fluorescence decay curves of Chl *a* in solution is not a straightforward matter.

*Chl* a *in pyridine solution*

In an earlier publication, we reported on the observation of fluorescence at 680 nm of Chl *a* in pyridine (11). The solutions used in the experiments were not free of water; in fact, the number of $H_2O$ molecules exceeded the number of chlorophyll molecules by more than two orders of magnitude. Because chlorophyll *a* in wet pyridine may form penta- and hexa-coordinated complexes with pyridine and water (12, 13), only a small amount (if any) of free monomer chlorophyll *a* molecules may be found in these solutions. Also of importance to this work is the knowledge that an equilibrium exists between Chl *a* and Chl *a'*. Chl *a'* is the C10 epimer of Chl *a*. This alteration results in a strain in the ring, thus the *a'* isomer is less stable and is the minority species in the equilibrium between Chl *a* – Chl *a'* in solution. In pyridine solutions a substantial amount (~20%) of Chl *a'* may be present (14). However, the ratio of concentrations of the penta- to the hexa-coordinated complexes for the two isomers does not necessarily have to be the same, because of steric effects.

We assume that due to the great abundance of pyridine, chlorophyll is present predominantly as the hexacoordinated species (12) Chl *a*.$pyr_2$, with only a small amount of Chl *a*.$pyr_1$ and that transitions from these species dominate the fluorescence spectrum, as discussed below. The ligand-free Chl *a* has both axial positions above and below the plane of the molecule unoccupied. Chl *a*.$pyr_1$ has one pyridine ligand which is bonded through the pyridine nitrogen atom. In Chl *a*.$pyr_2$, the remaining axial position is occupied, thus completing the maximum coordination of six for the central magnesium atom. The interpretation of the spectral information can furthermore be influenced by the presence of emission from chlorophyll dimers or aggregates. Such aggregates can be subdivided into those which do or do not contain $H_2O$ molecules. It is well known that the predicted fluorescence intensity from a theoretical symmetrical dimer is approximately identical to that of the monomer (16, 17, 21, 22), although dynamical processes in the real aggregates may quench this fluorescence.

Analysis of the fluorescence decay curve of a $10^{-5}$ *M* solution of Chl *a* in wet pyridine (~1200 ppm $H_2O$) resulted in the following observations. The main fluorescence at 677 nm is due to a process with a lifetime $\tau = 7 \pm 1$ ns which we assign to the combined fluorescence from the monomer species Chl *a*.$pyr_1$ and Chl *a*.$pyr_2$. We reported previously the presence of a fluorescence process characterised by $\tau = 45 \pm 5$ ns (Fig. 7 of ref. 11). A more careful analysis of the decay, taking into account the contribution to the intensity from a longer-lived species, yields a corrected value of $75 \pm 10$ ns. This is assigned to a combined fluorescence from Chl *a'*.$pyr_1$ and Chl *a'*.$pyr_2$ because (*i*) we anticipate a considerable amount of Chl *a'* to be present and (*ii*) this fluorescence, like that characterised by $\tau = 7 \pm 1$ ns, is observed even under very high intensity laser radiation where the dimeric species are expected to dissociate. Lastly, a process having $\tau = 145 \pm 10$ ns was observed, and this fluorescence was found to disappear if the sample was exposed to high light levels (11). Time-resolved spectra are depicted in Fig. 7. The gradual disappearance of fluorescence due to Chl *a*.$(pyr)_{1,2}$ and the appearance of that due to Chl *a'*.$(pyr)_{1,2}$ is observable if one compares the spectra which are recorded at $t = 3$ ns (the peak of the fluorescence signal) at $t \simeq 200$ ns and at $t \simeq 300$ ns, all times being measured from $t_0$, the peak of the laser excitation pulse. The existence of fluorescence from a process characterised by $\tau = 145 \pm 10$ ns becomes clear if one compares these spectra with those recorded at times $t = 325$ ns and $t = 360$ ns. Finally, the fluorescence spectrum observed at $t = 360$ ns is free from interference from the other spectra. We note that the band has a unique profile. Since this fluorescence can be made to disappear if too much laser radiation enters the solution, one may conclude that the chemical species from which the fluorescence originates is more easily destroyed than the monomeric species. We assign the long-lived fluorescence as originating from chemical species composed of two or more chlorophyll molecules. Such an assignment is supported by the line shape as recorded, because presently available theoretical information (17) predicts that the stronger the interaction between the component molecules of a dimer (or aggregate), the narrower the line width of the fluorescence band in comparison to that of the monomer.

Time-resolved spectra in the time range from 300–500 ns reveal that the intensity of the vibronic side band at 740 nm shows a peculiar behaviour in time when compared to the intensity in the wing of the main band at 665 nm. In this time region, contributions to the intensity from the processes characterised by lifetimes $\tau \simeq 7$ ns have vanishing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

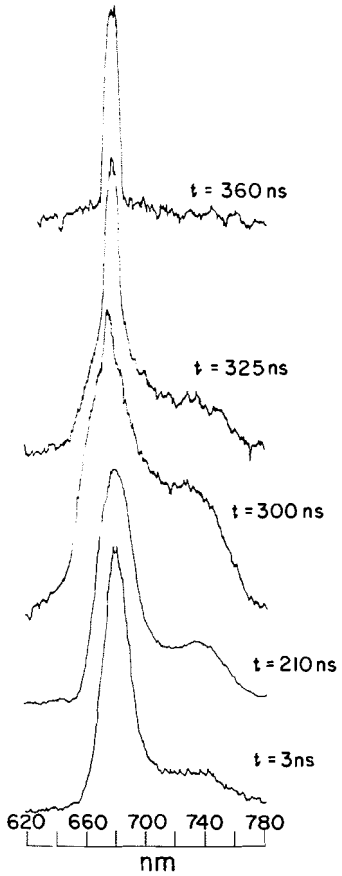

FIG. 7. Time-resolved fluorescence spectra of $10^{-5}$ *M* Chl *a* in wet pyridine. Relative intensities are not to scale, the spectrum recorded at $t = 360$ ns is ~100 times weaker than the spectrum recorded at $t = 3$ ns.

intensity, while the shape of the emission band having a lifetime $\tau \simeq 145$ ns is such that the intensities at 740 nm and at 665 nm are zero.

The fluorescence decay measurements indicate that at 665 nm, in the wing of the main band, the intensity is due to the two processes governed by lifetimes of $\tau \simeq 7$ ns and $\tau \simeq 75$ ns, also present in the intensity at the peak of the main band. The intensity at 740 nm is also related to those two processes, but in addition, examination of the time-resolved spectra shows that a third process, characterised by a lifetime 75 ns $< \tau <$ 145 ns, contributes to the intensity. This component was also found in solutions having a higher concentration of chlorophyll than the original solution, and apparently higher concentrations of the aggregates, because they did not appear to photodissociate at high laser powers. Although the presence of this fluorescence process is even more evident in the more concentrated solutions we failed to obtain a more accurate value for the lifetime. This is because there are three competing processes in the fluorescence decay. This component of the fluorescence at 740 nm is assigned to a dimer or higher aggregate for the following reasons. The species could not be destroyed by photodissociation in the more concentrated solution. Previous experiments on chlorophyll aggregates in solid solutions revealed the appearance of a red-shifted fluorescence band (15), and because this band was assigned to the aggregate, we believe that the same assignment belongs to the process at 740 nm characterised by a lifetime 75 ns $< \tau <$ 145 ns. Furthermore, the position of the two excited states of the aggregate and their lifetimes, as determined by the present study, are in agreement with the predictions made by Fong for an asymmetric dimer (16).

*Chl* a *in benzene solution*

We have also investigated the time-resolved fluorescence spectrum and fluorescence decay of chlorophyll *a* in benzene. The decay curve for the peak of the fluorescence at 14880 $cm^{-1}$ (672 nm) for a $10^{-5}$ *M* solution containing ~100 ppm $H_2O$ is shown in Fig. 8. Again, we found an indication of fluorescence processes which are characterised by short (6–8 ns) and longer (> 30 ns) lifetimes. Because of weak signals, it was not possible to probe the time-resolved spectrum at times greater than $t \simeq 100$ ns. In benzene solutions containing higher concentrations of water (~1200 ppm and ~2000 ppm $H_2O$), a red shift of 20 $cm^{-1}$ was observed in the peak of the fluorescence relative to that in the drier (100 ppm $H_2O$) solution (Fig. 9).

Time-resolved fluorescence spectra recorded for the benzene solution containing ~100 ppm $H_2O$ are displayed in Fig. 10. While the peak of the fluorescence at $t = 5$ ns (the time at which the maximum fluorescence intensity is observed) centres around 14880 ± 10 $cm^{-1}$, the position of the peaks in the fluorescence spectra at $t = 0$ ns and $-2$ ns is at 14860 ± 10 $cm^{-1}$. Time-resolved measurements on the wetter solution (~1200 ppm $H_2O$) yielded only one fluorescence band at 14860 ± 10 $cm^{-1}$, the position of which is equal to the position of the fluorescence at $t = 0$ ns for the drier solution.

It is well known that there exists a time delay between the time at which a laser pulse reaches its maximum intensity and the time at which the fluorescence intensity induced by the laser pulse has maximum intensity, which is related to such properties as the lifetime $\tau$ of the excited state from which the fluorescence transition originates and the

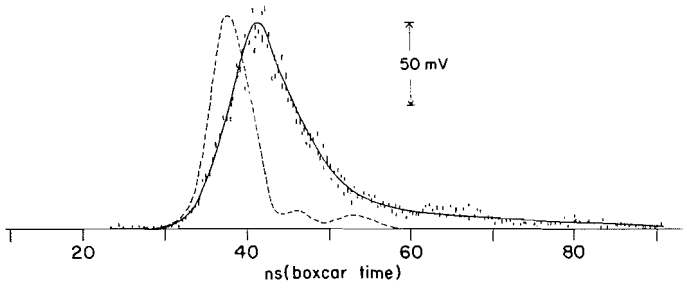

FIG. 8. Fluorescence decay (solid line) at 672 nm for $10^{-5}$ *M* Chl *a* in benzene (containing ~ 100 ppm $H_2O$) corrected for the dark level (with × 10 preamplification). Position and shape (dashed line) of the laser pulse in time as recorded with boxcar and × 10 preamplification (corrected for dark level).

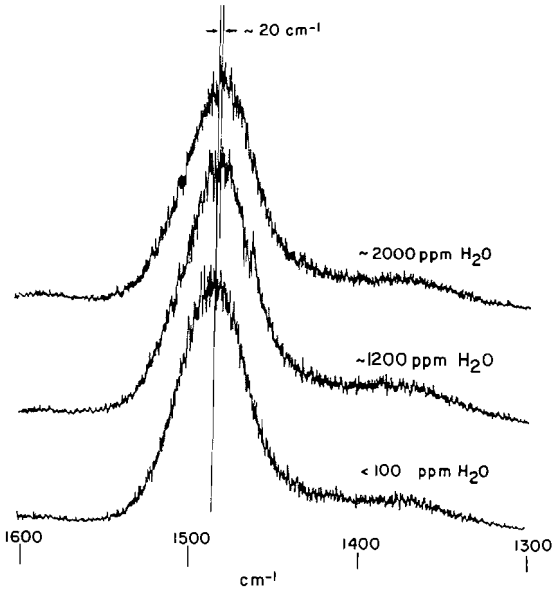

FIG. 9. Fluorescence spectra at 672 nm of $10^{-5}$ Chl *a* in benzene solutions containing different water concentrations, recorded at $t$ = 5 ns, the time at which maximum fluorescence intensity is observed. Wavenumber scale should be multiplied by a factor of 10.

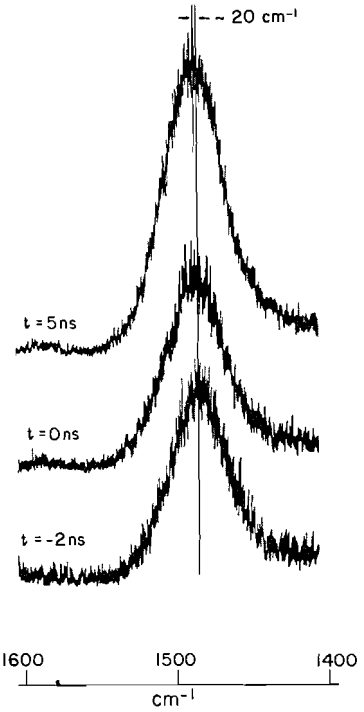

FIG. 10. Time-resolved fluorescence spectra of $10^{-5}$ *M* Chl *a* in benzene containing ~ 100 ppm $H_2O$. Wavenumber scale should be multiplied by a factor of 10.

cross section of the absorption transition from ground to excited state (18, 19). Thus, for equal absorption cross sections, one finds that the build up of fluorescence of a short-lived excited state occurs more rapidly than that of a longer-lived fluorescence process. We took advantage of this knowledge to explain the data displayed in Fig. 10. Apparently, they suggest that apart from a fluorescence transition which originates in an excited state having $\tau$ = 6–8 ns there also exists another excited state which must have a lifetime $\tau < 7 \pm 1$ ns. We conclude that this short-lived species ($\tau < 7$ ns), which is present in the drier solution, is the major component in the wetter solutions, because the position of the fluorescence transitions from these species are both at 14860 ± 10 $cm^{-1}$. It is known that dimers exist in solutions of Chl *a* in dry benzene. However, in our driest solution (100 ppm $H_2O$), the number of water molecules is two orders of magnitude larger than the number of Chl *a* molecules. Consequently, it is believed that the spectral features shown in Figs. 9 and 10 are due to hydrated monomeric species.

We complete this section with a remark on the overall fluorescence intensity of these solutions. The smaller the concentration of $H_2O$, the weaker this overall intensity. This observation suggests that for drier solutions even weaker fluorescence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

signals can be expected (20). Because the concentration of dimers is higher in such solutions, it could well be that the fluorescence of dimers (which do *not* contain water) is weak indeed.

## V. Concluding remarks

In this work an experimental method is described which allows one to determine the onset of saturation effects on the performance of PMT's in time-resolved pulsed laser spectroscopy. At low repetition rates, conditions were found under which certain PMT's can be used to obtain reliable fluorescence decay measurements on the 0–100 ns time scale, without modification of the PMT for use in the pulsed mode.

From the fluorescence decays of Chl *a* in pyridine and in benzene solutions, and time-resolved spectroscopic measurements of this fluorescence, it is concluded that several chemical species are present. Long-lived fluorescence processes at 677 nm and 740 nm from these species in pyridine are assigned to chlorophyll dimers or higher aggregates. The position of one of the fluorescence bands of the aggregate is within experimental error equal to that of the monomeric species and the position of the other is red shifted by 1250 $cm^{-1}$. The intensities of the aggregate bands are approximately two orders of magnitude weaker than that of the monomeric species. It is reasonable to assume that only small amounts of dimers and higher aggregates are present in the $\sim 10^{-5}$ *M* solution of Chl *a* in pyridine. This would lead to the conclusion that the intrinsic fluorescence intensity of the aggregated and monomeric species are not all that different. Simple exciton theory predicts that for a symmetric dimeric chlorophyll species, one fluorescence transition should have non-vanishing intensity and the position of the transition could indeed be close to that of the ligated monomer (donor and acceptor) species (12). On the other hand, if the dimer is asymmetric we expect non-vanishing intensity for both components in the fluorescence spectrum. It appears that the time-resolved studies presented in this work contribute to the knowledge of chlorophyll dimers or higher aggregates in solution. It is equally clear that the present work indicates that any detailed understanding of the time-resolved fluorescence from chlorophyll in solution requires further studies.

# Time-resolved pulsed-laser Raman studies at the nanosecond level of an aqueous solution of $UO_2(NO_3)_2$[1]

M. ASANO AND J. A. KONINGSTEIN

*The Ottawa-Carleton Institute for Research and Graduate Studies in Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6*

Received January 13, 1982

M. ASANO and J. A. KONINGSTEIN. Can. J. Chem. **60**, 2207 (1982).

The pulsed-laser Raman spectrum of aqueous solution of $UO_2(NO_3)_2 \cdot 6H_2O$ is reported. Raman shifts were observed which could be assigned to the $\nu_1$ mode of the $UO_2$ unit in species $(UO_2)_3(OH)_5^+$, $(UO_2)_2(OH)_2^{2+}$, and $UO_2^{2+}$. Vibrational ground and excited level transitions were induced, where part of the laser radiation at 22350 $cm^{-1}$ was used as an optical pump while the remaining part served as Raman probe. The lifetimes of the excited states were 7 μs and 1.5 μs for the trinuclear and dinuclear species, respectively. An analysis of the population characteristics of the ground and electronic excited states of the trinuclear species was performed and compared with the time evolution of the scattered light due to vibrational Raman processes in the ground and electronic excited states

M. ASANO et J. A. KONINGSTEIN. Can. J. Chem. **60**, 2207 (1982).

On rapporte le spectre Raman par laser à impulsion d'une solution aqueuse de $UO_2(NO_3)_2 \cdot 6H_2O$. On a observé des déplacements Raman qui peuvent être attribuées au mode $\nu_1$ de la portion $UO_2$ des espèces $(UO_2)_3(OH)_5^+$, $(UO_2)_2(OH)_2^{2+}$ et $UO_2^{2+}$. On a déduit les niveaux vibrationnels de transition de l'état fondamental et de l'état excité lorsqu'on utilise une partie de la radiation du laser à 22350 $cm^{-1}$ comme une pompe optique tandis que la partie restante sert de sonde Raman. Les temps de vie des états excités sont respectivement de 7 μs et de 1,5 μs pour les espèces trinucléaires et dinucléaires. On a réalisé une analyse des caractéristiques de la population des états électroniques fondamental et excité des espèces trinucléaires et on les a comparé au temps d'émission de la lumière diffuse due aux processus vibrationnels Raman dans les états électroniques fondamental et excité.

[Traduit par le journal]

## I. Introduction

With the availability of pulsed tunable lasers it has become possible to induce Raman transitions from excited states of ions in solids or molecules in solution. These excited states were prepared by absorption of laser radiation at specific wavelength and the light scattering spectra were induced by that part of the laser radiation which is not used in the optical pumping process. Experiments have also been carried out with two lasers and in that case the optical pump and Raman probe (*i*) can be delayed in time, and (*ii*) their wavelengths do not have to be the same.

In this paper emphasis is placed on part of the excited level vibrational Raman spectrum of the trinuclear species $(UO_2)_3(OH)_5^+$ in aqueous solution. Time-resolved measurements of the Raman intensities for this species — using one laser — were performed which are related to the time evolution of the ground and excited state populations, and the results were compared with theoretical calculations. The species mentioned above occurs in aqueous solutions of the uranyl salt $UO_2(NO_3)_2$ with a specific pH. In order to carry out the time-resolved measurements, light scattering spectra of the solutions having different pH values were investigated and Raman bands of the spectra were assigned. These assignments were based on the knowledge of the emission and absorption spectra, not only of the trinuclear species but also of the mononuclear $UO_2^{2+}$ and dinuclear $(UO_2)_2(OH)_2^{2+}$ species. The absorption and emission spectra are discussed in section III and the time-resolved aspects of the light scattering spectra in sections IV and V.

## II. Experimental methods

All solutions used in the present spectroscopic investigations were prepared from a reagent grade $UO_2(NO_3)_2.6H_2O$ (99.8% pure). In a 0.02 *M* solution of the salt, hydrolysis of the uranyl ion occurs and, by adjusting the pH, the species $UO_2^{2+}$, $(UO_2)_2(OH)_2^{2+}$, and $(UO_2)_3(OH)_5^+$ are formed in different concentrations (5, 6). Using values of equilibrium constants pertaining to the chemical equilibrium of some of these species their concentrations may be calculated (5) — see Table 1. The species $UO_2NO_3^+$ too can be present in these 0.02 *M* solutions, but its concentration is negligibly small (7, 8).

Absorption, fluorescence, and Raman spectra were obtained. A pulsed-Raman apparatus was used to record the emission spectra, which were induced by radiation of a $N_2$ laser-pumped tunable-dye laser (pulsed). The duration of the pulse was 3.2 ns (FWHM) with its peak power ~100 kW. The emitted light was dispersed by a Jobin Yvon monochromator and detected by a RCA 8850 photomultiplier. The signals generated by this PMT were fed into a PAR model 162 boxcar equipped with a model 165 gated integrator. The light scattering apparatus (9) allowed us to carry out lifetime measurements of weak fluorescence while time-resolved Raman and fluorescence spectra could be recorded by adjusting the 2 ns gate of the boxcar at different

points in time. Except otherwise stated, the recorded Raman spectra were obtained with the gate fixed at a point in time at which the intensity of the laser pulse had reached a maximum value. Measurements were performed making sure that the PMT was operating in its linear regime and photochemical decomposition of the uranyl species was prevented by moving the 50 × 10 × 10 mm quartz cell — which contained the solutions — up and down with respect to the laser beam. The frequency of the lateral displacement was 1/5 Hz and solutions could be studied for 2 h before the effect of photodecomposition became noticeable.

The excitation spectra of the green phosphorescence of some solutions were recorded with a Perkin-Elmer Fluorescence Spectrophotometer 204-S and absorption spectra were recorded with a Carry model 14 spectrometer.

## III. Results

### *A. Absorption and emission spectra of uranyl nitrate solutions*

It shall be shown in section III*B* that the pulsed-laser Raman spectra of some of the solutions of the uranyl nitrate salt exhibit, besides Raman transitions of the electronic ground state, transitions between vibrational levels of an electronic excited state. In order to assign the spectra it is necessary to consider part of the electronic energy level diagrams of the $UO_2$ unit which is present in some of the species mentioned in section II (Table 1). Some information regarding the energy level diagram can be obtained if one considers the absorption and fluorescence spectra of the aqueous solutions with a pH = 0.9, 4.2, and 4.5. Spectra are shown in Figs. 1 and 2 and a short discussion is given below regarding some relevant features.

The absorption spectrum of the solution with pH = 0.9 is very similar to that of an aqueous solution of the uranyl perchlorate salt (10), which is known to contain a high concentration of the mononuclear uranyl ion $UO_2^{2+}$. The spectrum shown in Fig. 1 of the solution with pH = 0.9 is also assigned to spectroscopic transitions of the $UO_2^{2+}$ ion. An analysis of the vibronic progression present in the absorption and fluorescence spectrum reveals that the frequency of a vibrational mode of $UO_2^{2+}$ in an electronic excited state has a value of 720 $cm^{-1}$ while the frequency of this mode of the electronic ground state is 875 $cm^{-1}$. The mode is assigned to the symmetric stretching vibration ($\nu_1$) and the 0–0 transition between the electronic surfaces occurs at 20550 $cm^{-1}$. The electronic transition is between the $S_0$ ground state and the $T_0$ excited state and the latter is split into spin–orbit components for the $UO_2^{2+}$ ion in the solid state (11, 12).

The solutions with pH = 4.5 and 4.2 contain more than one species and, according to Table 1, the trinuclear species $(UO_2)_3(OH)_5^{+}$ has the highest concentration at pH 4.5. We note that the extinction coefficients of the absorption bands of this solution (Fig. 2) are stronger than those of the solution (pH = 0.9) which contains only the mononuclear species. The vibrational progression in the spectra of the pH = 4.5 solution is less distinct than that shown in Fig. 1 of $UO_2^{2+}$ and is even less distinct for the pH 4.2 solutions (absorption spectrum, not shown here). We assign features of absorption and fluorescence spectra of the pH = 4.5 solution to transitions between electronic states of the $UO_2$ unit present in the trinuclear species. The frequency $\nu_1^{T_0} = 710\ cm^{-1}$ for a mode in the excited state is obtained from the vibrational progression visible in the absorption spectrum and the frequency $\nu_1^{S_0} = 840\ cm^{-1}$ for this mode in the ground state is obtained from the emission spectrum. The mode is assigned to the symmetric stretching vibration of the $UO_2$ unit and the 0–0 transition between the electronic surface $S_0$ and $T_0$ is at 19600 $cm^{-1}$. The structure of this trinuclear species has been discussed in the literature (7, 8). Three $UO_2$ units and three hydroxy ions are arranged in a ring with the $UO_2$ bridged to two hydroxy ions and vice versa. The other two $OH^-$ ions are situated above and below this ring and they are bound to the three uranium atoms. From Table 2 one can see that small differences exist between the frequencies $\nu_1^{T_0}$ and $\nu_1^{S_0}$ for the $UO_2$ unit in the trinuclear species and those of the mononuclear $UO_2^{2+}$ ion. In addition it can be said that for both the mono- and trinuclear species Raman scattering of the $\nu_2$ or $\nu_3$ mode was not observed. As a result we assume that the $UO_2$ unit is also linear in the trinuclear species. The chemical bond between $OH^-$ and the $UO_2$ in the latter has a marked effect on the strength of the absorption bands as was mentioned above.

The energy level diagrams shown in Fig. 3 are for the trinuclear species and the assignment of the electronic states is based on that of the $UO_2^{2+}$ ion, although of course the energy and labelling of each state in terms of the $UO_2^{2+}$ molecular orbital diagram is not valid.

In previous publications from this laboratory we emphasised the importance of the measurement of the transmission value of a sample (at a given wavelength) as a function of the intensity of the laser beam in relation to carrying out excited level

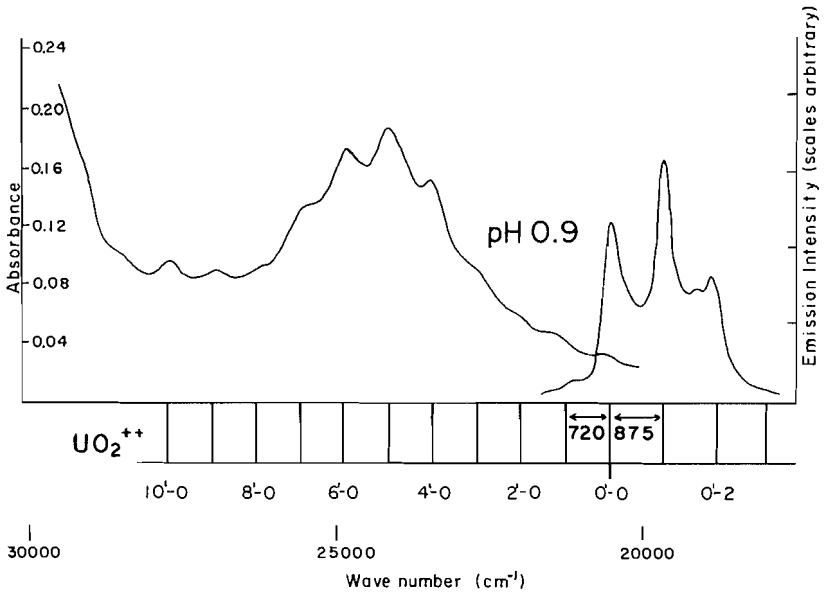

FIG. 1. The absorption (left) and pulsed laser induced emission spectrum (right) of a 0.02 $M$ aqueous solution of $UO_2(NO_3)_2$ at 300 K. The value of pH = 0.9 suggests that the species $UO_2^{2+}$ dominates over that of others containing the $UO_2$ unit — see also Table 1. Band spacings due to a vibrational mode in the $T_0$ excited state and those due to the mode in the $S_0$ ground state are indicated in the bottom part.

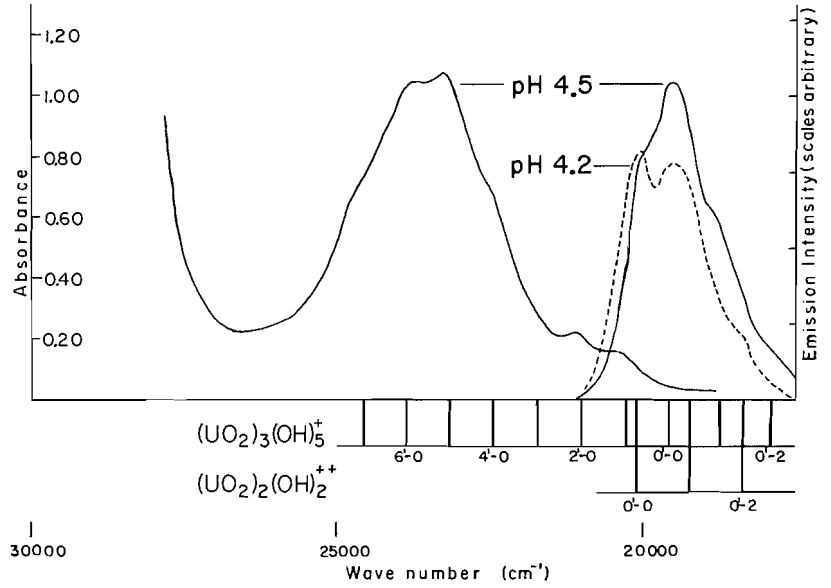

FIG. 2. The absorption (left) and pulsed laser induced emission spectra (right) of the pH = 4.5 (solid line) and pH = 4.2 (dashed line) aqueous solutions of $UO_2(NO_3)_2$. The assignment of the vibrational progressions due to a normal mode of the trinuclear $(UO_2)_3(OH)_5^+$ and dinuclear $(UO_2)_2(OH)_2^{2+}$ species is shown at the bottom.

Raman spectroscopy. Part of the photons of the laser beam are absorbed by the sample and causes the creation of population of an electronic excited state and part of the radiation not involved in optical pumping serves as a Raman probe. For low light levels one finds that excited states are not populated and the value of the transmission $T$ is due to the excited state ← ground state absorption at $\lambda_l$. Upon an increase of $I_l$ — which is achieved by focussing the laser beam in the solution — a situation could occur where the number of photons actually exceeds the number of molecules (in the

*Values of the $\nu_1$ mode of the $UO_2$ unit in the ground ($S_0$) and electronic excited ($T_0$) state of each of the species (in $cm^{-1}$).

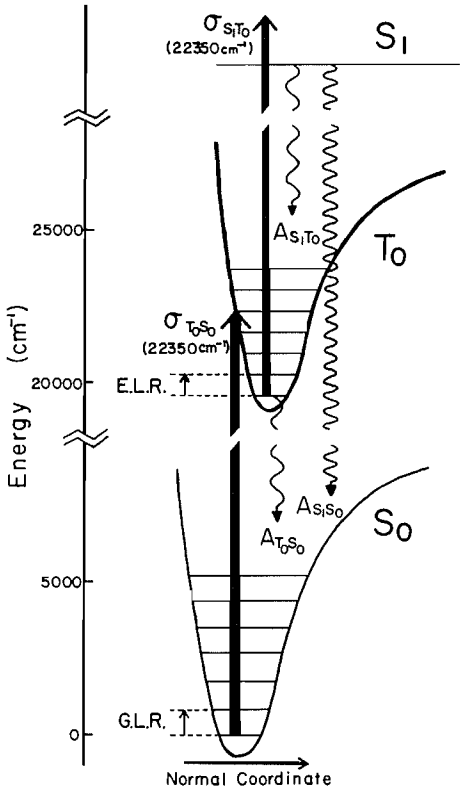

FIG. 3. Part of the energy level diagrams of the trinuclear species $(UO_2)_3(OH)_5^+$ appropriate to the present study. The excited level Raman (ELR) and ground level Raman (GLR) transitions are indicated, together with the energy of the optical pump and that of the Raman probe. The pump and probe induces several emission processes which are designated by their Einstein coefficients (for spontaneous emission).

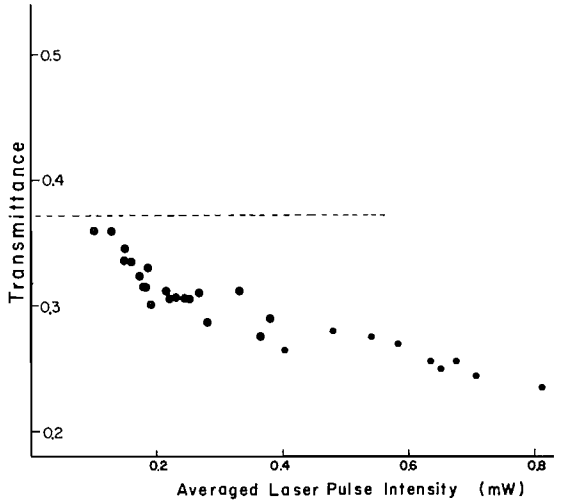

FIG. 4. Transmission studies at 22350 $cm^{-1}$ (see Fig. 3) of the 0.02 $M$ $UO_2(NO_3)_2$ aqueous solution with pH = 4.5. The dashed line represents the value of $T$ for low light levels (encountered in a normal absorption experiment) and is primarily due to $T_0 \leftarrow S_0$ transitions of the trinuclear species. Focusing of the laser beam causes population of $T_0$ and consecutive absorption of laser photon (with an energy of 22350 $cm^{-1}$) due to $S_1 \leftarrow T_0$ transitions reduces the value of $T$. The value of $T$ for high (pulsed) laser power levels does not reach a constant value. This suggests that — during the 3.2 ns duration of the laser pulse — effective saturation of $T_0$ does not occur. The average value of 0.8 mW corresponds to $0.72 \times 10^{14}$ photons per pulse.

irradiated area). Depending on the lifetime of the excited state, population of that state can take place. Consecutive absorption of other laser photons can now result in a change of the value of the transmissions. The results shown in Fig. 4 of the solution with a pH = 4.5 is a case in point. If laser radiation at $\lambda_l$ = 447 nm (22350 $cm^{-1}$) is allowed to enter the solution in the 1 cm long quartz cell, then this radiation is primarily absorbed by the $(UO_2)_3(OH)_5^+$ species. This energy reaches the $v' = 0$ level of the $T_0$ state via vibrational relaxation from $v' = 4$ (see Fig. 3). For unfocused radiation, saturation of this excited state does not take place and the transmission is independent of $I_l$. Focusing the laser beam leads to a different situation. Apparently the $v' = 0$ level of $T_0$ of a large number of the trinuclear species becomes populated and consecutive absorption of other photons with $\lambda_l$ = 447 nm takes place. The cross section $\sigma_{S_1T_0} > \sigma_{T_0S_0}$ and consequently the value of $T$ decreases upon an increase of $I_l$. Relevant to the transmission studies are the results of lifetime measurements of the green emission (induced by the laser radiation at 447 nm) of this solution — see Fig. 5. The upper trace of this figure shows the decay of the emission intensity in time if the sample is exposed to the non-focused laser beam. The lower trace was recorded for emission which emerged from the

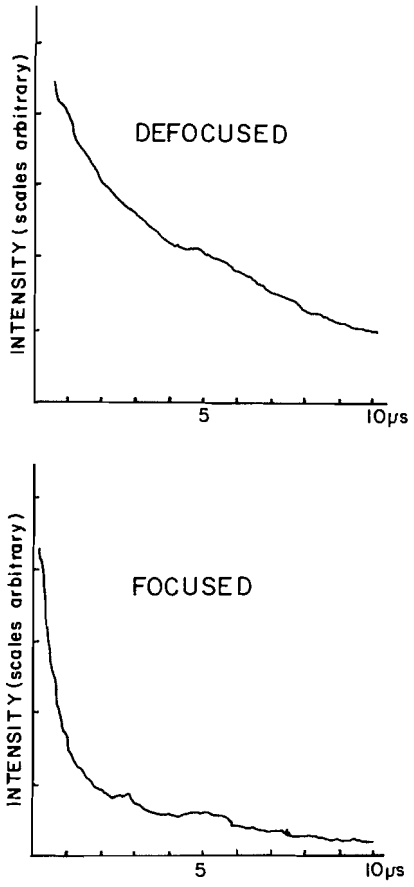

FIG. 5. Top: the decay of phosphorescence induced by a defocused laser beam at $\nu_l = 22350\,cm^{-1}$ propagating through the pH = 4.5 aqueous solution recorded with the 162 Model P.A.R. boxcar averager with 165 Model gated integrator. The curve is a single exponential decay characterised with a lifetime of 7 μs, which is thought to belong to the $T_0$ state of the trinuclear species $(UO_2)_3(OH)_5^+$. Bottom: decay curve for the emission recorded from the focused part of the laser beam in the solution. This curve shows double exponential decays characterised by lifetimes of 7 μs and 1.5 μs. Due to the population of $T_0$ of the trinuclear species a competition occurs between the processes $T_0 \rightarrow S_0$ and $S_1 \leftarrow T_0$. The competition is in favour of the latter, hence the reduction in the intensity of the former process. The emission characterised by a lifetime of 1.5 μs is assigned to the process $T_0 \rightarrow S_0$ of the dinuclear species $(UO_2)_2(OH)_2^{2+}$ which, according to Table 1, is present in the solution.

focused part of the laser beam at 447 nm, which induced the emission spectrum. Both traces reveal the presence of a short- ($\tau \sim 1.5\,\mu s$) and long-lived ($\tau \sim 7\,\mu s$) phosphorescence process although the intensity of the latter appears to be much weaker in the focused case. This reduction in intensity can be understood if one considers the results of the transmission experiments in conjunction with the energy level diagram of Fig. 3. The $T_0$ excited state of the trinuclear species becomes populated with $\lambda_l = 447$ nm (focused beam) for high laser intensity and a competition takes place between the spontaneous emission $T_0 \rightarrow S_0$ and the induced absorption process $S_1 \leftarrow T_0$ at $22350\,cm^{-1}$. This competition favours the $S_1 \leftarrow T_0$ process (stimulated emission $T_0 \rightarrow S_0$ cannot occur (13) because of the behaviour of $T$ at high laser intensity levels) and a decrease in the green phosphorescence intensity takes place, which can be observed with the unaided eye. The short-lived phosphorescence is not due to the trinuclear species and is assigned to the dinuclear species. The mononuclear species which is present in the solution with pH = 4.5 does not interfere with the interpretation of the transmission experiment. Measurements of $T$ versus $I_l$ of the pH = 0.9 solutions for focused and unfocused laser radiation at $\lambda_l = 447$ nm does *not* cause a change in $T$. The transmission measurement yields the following values of the cross section for the trinuclear species at 447 nm: $\sigma_{T_0S_0} = 4.4 \times 10^{-19}\,cm^2$ and $\sigma_{S_1T_0} = 1.5 \times 10^{-18}\,cm^2$ (see also section IV).

### *B, Pulsed-laser Raman spectra of uranyl nitrate solutions*

Parts of the pulsed-laser Raman spectrum of the 0.02 *M* $(UO_2)(NO_3)_2$ solution in water is shown in Fig. 6. The intensity level of the pulsed laser operating at 447.4 nm ($23350\,cm^{-1}$) was so chosen that population of an excited state could take place. The recording of good quality Raman spectra was difficult as a result of the generation of (*i*) green phosphorescence and (*ii*) the Rayleigh background. Spectral shifts were recorded in the region of $550\,cm^{-1} < \Delta\tilde{\nu} < 1100\,cm^{-1}$. The Raman shift of $\Delta\tilde{\nu} = 1046\,cm^{-1}$ is due to the $\nu_1$ mode of the $NO_3^-$ ion and the spectrum of the solution with pH = 0.9 (lower trace, Fig. 6) clearly shows Stokes scattering to the first vibrational level at $873\,cm^{-1}$ of the $\nu_1$ mode of the $UO_2^{2+}$ ion. The polarisation of the incident laser beam was such that polarised and depolarised lines could be recorded but neither scattering to the $\nu_2$ mode nor the $\nu_3$ mode was observed. Vibrational light scattering of the $\nu_1$ mode at $842\,cm^{-1}$ of the $UO_2$ unit of the trinuclear species dominates the spectrum of the solution with pH = 4.5 (upper trace, Fig. 6). This species is not present in the solution with pH = 3.6 (middle trace, Fig. 6), but other bands are observed with a shift of 856 and $871\,cm^{-1}$. This former band has vanishing intensity in the pH = 0.9 solution and is assigned to the shift of the $\nu_1$ mode of the $UO_2$ unit of $(UO_2)_2(OH)_2^{2+}$. Besides these shifts, one observes in the upper and middle spectra shifts at $\sim 704\,cm^{-1}$ and $716\,cm^{-1}$. The frequencies are close

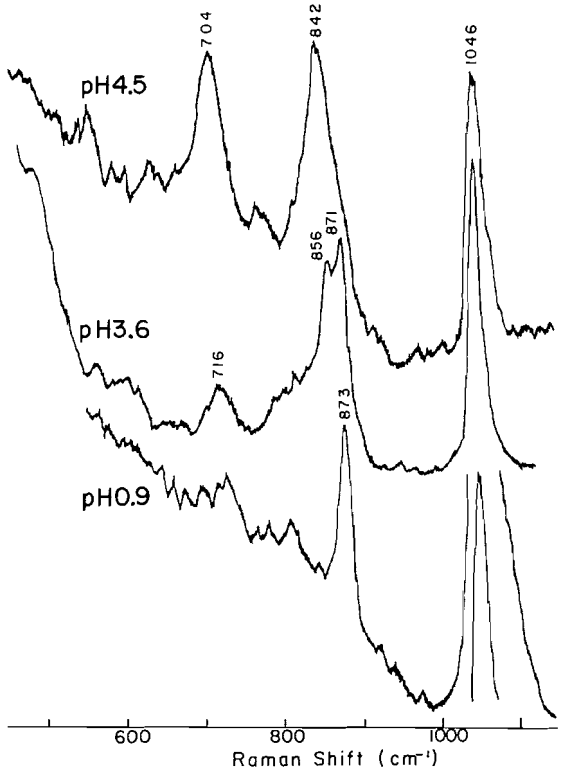

FIG. 6. Part of the pulsed-laser Raman spectra of the solutions with different pH of $UO_2(NO_3)_2$ induced by $\nu_l = 22350\,cm^{-1}$. The assignment of the spectra — see text and Table 2 — is: Lower trace: $\nu_1{}^{S_0} = 873\,cm^{-1}$ of $UO_2^{2+}$ and $\nu_1$ of $NO_3^-$ at $1046\,cm^{-1}$. Middle trace: $\nu_1{}^{S_0} = 871\,cm^{-1}$ of $UO_2^{2+}$ and $\nu_1{}^{S_0} = 856\,cm^{-1}$ of the $UO_2$ unit of $(UO_2)_2(OH)_2^{2+}$. The shift at $716\,cm^{-1}$ is assigned to vibrational scattering of $\nu_1{}^{T_0}$ in the $T_0$ excited state from the dinuclear species. Upper trace: $\nu_1{}^{S_0} = 842\,cm^{-1}$ and $\nu_1{}^{T_0} = 704\,cm^{-1}$ of $(UO_2)_3(OH)_5^+$.

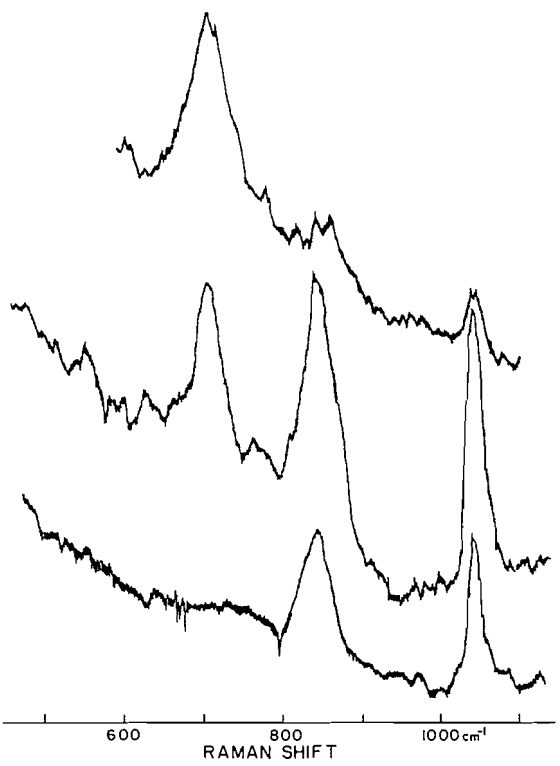

FIG. 7. Part of the Raman spectrum of the pH = 4.5 solution. Lower trace: recorded from the defocused part of the laser beam, hence indicating the ground state Raman scattering only. Middle trace: recorded from the defocused and focused parts of the path of the laser beam; ground and excited level Raman scattering from the trinuclear species are recorded. Upper trace: spatial filtering of the focused part of the laser beam, hence primarily the ELR spectrum.

to those found for the frequency $\nu_1{}^{T_0}$ of the symmetric stretching mode of the $UO_2$ unit in the tri- and dinuclear species (compare Table 1). The assignment of the Raman band to that of scattering of the $\nu_1{}^{T_0}$ mode becomes unambiguous if one considers the spectra shown in Fig. 7. These spectra are taken from the solution with pH = 4.5 under the following experimental conditions. The lower trace was recorded with the laser beam defocused and the middle trace with the beam focused (see also upper trace of Fig. 6). As explained in section III*A*, the green phosphorescence of this solution disappears in the small focused part of the path of laser beam. This part is 0.5 mm long and occurs before and behind the focal point of the $f = 30$ mm microscope objective lens. The focal point was adjusted to occur in the middle of the 10 mm long quartz cell. The density of electronically excited trinuclear species has reached maximum values in that short (0.5 mm) part of the path of the focused laser beam. The spectrum shown in the upper trace of Fig. 7 was recorded from scattered light which emerged from the 0.5 mm path only. The $S_0$ ground state spectrum has nearly completely vanished and scattering from the $\nu_1{}^{T_0}$ mode of the $UO_2$ unit of the trinuclear species in the $T_0$ electronic excited state only remains visible.

Returning to the middle trace of Fig. 6, we find that the solution with pH = 3.6, which revealed the presence of Raman scattering of the dinuclear species, exhibits a shift at $716\,cm^{-1}$ which was not observed in the spectrum obtained with the defocused beam. The value of $716\,cm^{-1}$ is higher than that observed for the $\nu_1$ mode in the $T_0$ excited state of the trinuclear species. It could well be that the Raman band at $716\,cm^{-1}$ (or part of it) is due to scattering from the $T_0$ electronic excited state of the dinuclear species. In that case we conclude from intensity comparisons that the concentration of these excited states is much smaller than those of the trinuclear species.

## IV. Time evolution of the Raman pulse due to scattering in ground and electronic excited state

In this section, a comparison is made of the intensity of the laser pulse at different points in time $I_l(t)$ and that of the pulse due to Raman scattered light at the same points in time. The scattering is induced by the laser pulse of the $\nu_1$ vibrational mode of the $UO_2$ unit of the trinuclear species in ground and electronic excited states. The temporal shape of the laser pulse recorded with the boxcar (gate width 2 ns) is shown in Fig. 8. The true shape of the laser pulse is different from the one recorded with the boxcar because both the response time of the PMT and the 2 ns gate affect the shape of the original pulses (14) (the true FWHM of 3.2 ns of the pulse is broadened to 5.6 ns). However, this difference does not affect the comparison of intensities of time-resolved spectra mentioned above because the instrumental time base for both laser and Raman pulse is identical.

The experimental data of interest here is the integrated area of the Raman band of the $\nu_1$ mode of the trinuclear species in the $S_0$ ground and $T_0$ electronic excited states, which are denoted here by respectively $\nu_1{}^{S_0}$ and $\nu_1{}^{T_0}$. The integrated intensities of Raman scattering to these modes measured at time $t$ are denoted by $I_{\nu_1}{}^{S_0}(t)$ and $I_{\nu_1}{}^{T_0}(t)$ and the following expressions apply:

[1] $$I_{\nu_1}{}^{S_0}(t) = n_{S_0}(t)\phi l Q_{\nu_1}{}^{S_0} I_l(t)$$

and

[2] $$I_{\nu_1}{}^{T_0}(t) = n_{T_0}(t)\phi l Q_{\nu_1}{}^{S_0} I_l(t)$$

where the Raman cross section

$$Q_{\nu_1}{}^{S_0} = \frac{2^7\pi^5}{3^2C^5}(\nu_l - \nu_1{}^{S_0})^4 |\alpha|^2$$

is independent of time in the non-resonance case (a corresponding expression can be written for $\nu_1{}^{T_0}$). Also $n_{S_0}(t)$ and $n_{T_0}(t)$ are the time-dependent concentrations of species in the states $S_0$ and $T_0$ respectively, $\phi$ is the cross sectional area of the focused laser beam, and $l$ is the length of the focused part of the laser beam (0.5 mm) as discussed in the previous section. The area $\phi$ is assumed to be constant over the $l$ = 0.5 mm distance and the number of scattering centers in the electronic ground and excited states are equal to $n_{S_0}(t)\phi l$ and $n_{T_0}(t)\phi l$. The time evolution of the intensity of the laser pulse is represented by $I_l(t)$. One obtains from eqs. [1] and [2] the expressions

[1a] $$n_{S_0}(t) \propto I_{\nu_1}{}^{S_0}(t)/I_l(t)$$

and

[2a] $$n_{T_0}(t) \propto I_{\nu_1}{}^{T_0}(t)/I_l(t)$$

Values of $n_{S_0}(t)$ and $n_{T_0}(t)$ — calculated from eqs. [1*a*] and [1*b*] — at specific points in time (in arbitrary units) are shown in Fig. 8.

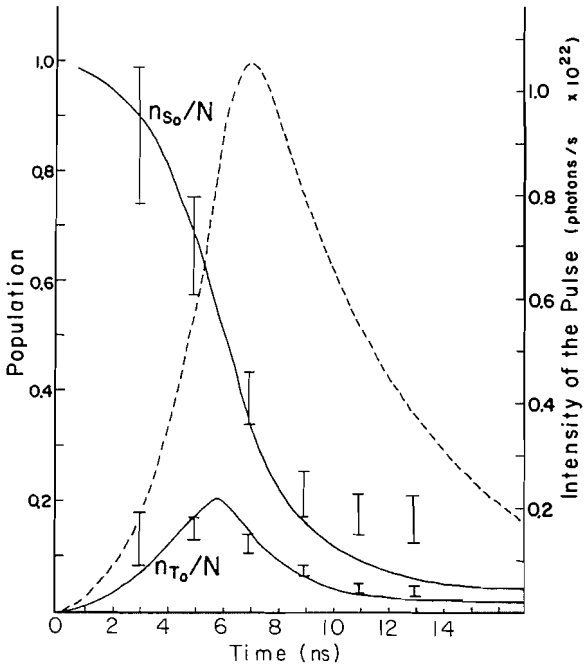

FIG. 8. The dashed curve represents the laser pulse as recorded with the boxcar. The vertical bars are data for $I_{\nu_1}{}^{S_0}/I_l$ (upper) and $I_{\nu_1}{}^{T_0}/I_l$ (lower) at different points in time. The solid lines are calculated for the depopulation of the ground state $S_0$ (upper) and the population of the excited state $T_0$ (lower) of the trinuclear species $(UO_2)_3(OH)_5{}^+$ during the time of the pulse.

The recorded spectra are resonance Raman spectra because the frequency of the exciting radiation is coincident with that of absorption transitions $T_0 \leftarrow S_0$ and $S_1 \leftarrow T_0$. In fact, the laser radiation with $\nu_l$ = 22350 $cm^{-1}$ is in resonance with the fourth vibrational level of $\nu_1{}^{T_0}$. Because we are dealing with a vibrational Raman effect in resonance one predicts that the rise and decay time of the Raman scattered light pulse could be very much different from that of the pulse in the non-resonance case (1–4). The ratios $I_{\nu_1}{}^{S_0}(t)/I_l(t)$ and $I_{\nu_1}{}^{T_0}(t)/I_l(t)$ would in that case not be proportional to the concentrations $n_{S_0}(t)$ and $n_{T_0}(t)$. Instead, these ratios would show a gradual increase upon an increase of $t$. The results shown in Fig. 8 are not in agreement with the above; rather it appears that the ratio $I_{\nu_1}{}^{S_0}(t)/I_l(t)$ decreases upon an increase of $t$. This behaviour is expected if we assume that the concentration of ground states $S_0$ decreases during optical pumping with $I_l(t)$. Consequently we assume that the resonance Raman effects are small

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

and that eq. [1*a*] is valid. The ratio $I_{\nu_1}^{T_0}(t)/I_l(t)$ as function of $t$ is different from $I_{\nu_1}^{S_0}/I_l(t)$. The intensity $I_{\nu_1}^{T_0}(t)$ can also be affected by resonance. But, because the lifetime $\tau_{S_1}$ of the state $S_1$ is thought to be shorter than $\tau_{T_0} = 7\,\mu s$ of $T_0$, we predict that the shape of the Raman scattered light pulse due to $\nu_1^{T_0}$ approaches that of $I_l(t)$. However, the maximum intensity of the scattered light should occur after a point in time at which the laser pulse has reached its maximum value. This again is not observed and we therefore assume that eq. [2*a*] is applicable.

In addition to the above, another complication could arise if we assume that the vibrational relaxation process between levels of the $T_0$ electronic surface is slow. This could result in a situation where the vibrational levels up to $v' = 4$ of $T_0$ are populated, which in turn means that the Boltzman statistics cannot be applied to calculate population numbers for these levels. It has previously been shown that a deviation from Boltzman statistics also can change the Raman scattered light pulse (15). This effect, however, can be neglected because it is known that the vibrational relaxations occur in the picosecond time scale (e.g., see refs. 16, 17, and 18). In order to populate the vibrational levels with such short lifetimes, a larger cross section than the value $\sigma_{T_0S_0} = 4.4 \times 10^{-19}\,cm^2$ is required (15).

As explained in section III*A*, light scattering spectra were recorded from the central part ($l$ = 0.5 mm) of the laser beam trace. The concentrations $n_{S_0}(x, t)$, $n_{T_0}(x, t)$, and $n_{S_1}(x, t)$ are taken to be independent of the coordinate $x$ of the travelling light wave, where $0 < x < 0.5$ mm, because the number of photons at the central focused part of the laser beam, $I_l^0(t)$, and the cross section of the beam there, are assumed to be constant. In that case, we can use a series of expressions which pertain to the calculation of the temporal behaviour of the population members of a three level system ($S_0$, $T_0$, and $T_1$ shown in Fig. 3).

Thus

$$[3]\quad \frac{dn_{S_0}(t)}{dt} = -\frac{1}{\phi}\sigma_{T_0S_0}n_{S_0}(t)I_l^0(t) + A_{T_0S_0}n_{T_0}(t) + A_{S_1S_0}n_{S_1}(t)$$

$$[4]\quad \frac{dn_{T_0}(t)}{dt} = \frac{1}{\phi}(\sigma_{T_0S_0}n_{S_0}(t) - \sigma_{S_1T_0}n_{T_0}(t))I_l^0(t) - A_{T_0S_0}n_{T_0}(t) + A_{S_1T_0}n_{S_1}(t)$$

$$[5]\quad \frac{dn_{S_1}(t)}{dt} = \frac{1}{\phi}\sigma_{S_1T_0}n_{T_0}(t)I_l^0(t) - (A_{S_1S_0} + A_{S_1T_0})n_{S_1}(t)$$

In these expressions $\sigma$ are absorption cross sections, the $A$ coefficients are those for spontaneous emission, and $\phi$ is the area of the laser beam in the focused part of the beam.

The lifetime of the state $T_0$ is 7 μs ($\tau_{T_0} = 1/A_{T_0S_0}$) which is much longer than the 3.2 ns duration of the laser pulse. Consequently the system does *not* achieve a steady state. In addition to the above we have

$$[6]\quad N = n_{S_0}(t) + n_{T_0}(t) + n_{S_1}(t)$$

Equations [3]–[5] can be simplified if the following is taken into account. Because $\tau_{T_0}$ is much longer than 3.2 ns (and thus $A_{T_0S_0}$ is very small), we neglect all terms which contain $A_{T_0S_0}$. Shown in Fig. 9 is the excitation spectrum for the green fluorescence ($T_0 \rightarrow S_0$) at 515 nm. From this spectrum, one concludes that pumping near 42000 $cm^{-1}$ does not result in energy transfer into $T_0$. This energy difference of 42000 $cm^{-1}$ is equal to that of the (pseudo) consecutive two photon absorption process (with pulsed laser radiation at 22350 $cm^{-1}$) via the channel $T_0(v = 5) \leftarrow S_0(v = 0)$ at 22350 $cm^{-1}$; $T_0(v = 5) \rightarrow T_0(v = 0)$ followed by $S_1 \leftarrow T_0(v = 0)$ also at 22350 $cm^{-1}$. Because energy transfer from $S_1 \rightarrow T_0$ does not take place, the coefficient $A_{S_1T_0}$ also can be dropped from eqs. [4] and [5]. Furthermore we assume that the lifetime of $S_1$ is also longer than 3.2 ns and after integration we get:

$$[7]\quad n_{S_0}(t) = N \exp\left\{-\frac{1}{\phi}\sigma_{T_0S_0}F(t)\right\}$$

$$[8]\quad n_{T_0}(t) = \frac{1}{\phi}\sigma_{T_0S_0}\exp\left\{-\frac{1}{\phi}\sigma_{S_1T_0}F(t)\right\}G(t)$$

where

$$F(t) = \int_0^t I_l^0(t')dt'$$

and

$$G(t) = \frac{1}{N}\int_0^t n_{S_0}(t')I_l^0(t')\exp\left\{\frac{1}{\phi}\sigma_{S_1T_0}F(t')\right\}dt'$$

The temporal aspects of $n_{S_0}(t)$ and $n_{T_0}(t)$ are calculated with these expressions. First, numerically integrated values of $F(t)$ at different $t$ were obtained and with the known value of $\sigma_{T_0S_0} = 4.4 \times 10^{-19}\,cm^2$, values of $n_{S_0}(t)/N$ as a function $\phi$ were calculated and compared with the experimental data of Fig. 8. Then, numerically integrated values of $G(t)$ were obtained from a best fit of $n_{S_0}(t)_N$ with experiment in combination with values of $\sigma_{S_1T_0}$. Finally, the best fit was made with the experimental values of $n_{T_0}(t)/N$ by varying the value of $\sigma_{S_1T_0}$. The

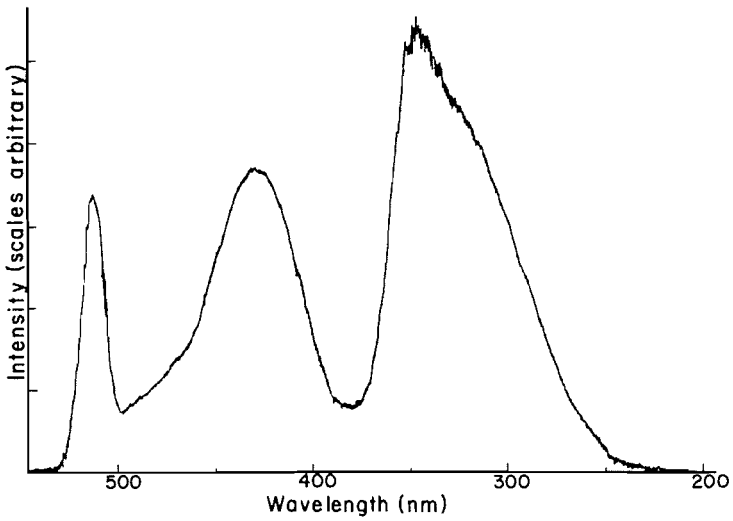

FIG. 9. Excitation spectrum of the phosphorescence of $(UO_2)_3(OH)_5^+$ detected at 515 nm.

best possible fit to the experimental data with $\phi = 8.5 \times 10^{-6}\,cm^2$ and $\sigma_{S_1T_0} = 1.5 \times 10^{-18}\,cm^2$ are shown as solid lines in Fig. 8. The differences between the calculated populations (solid lines) and experimental data are small. Finally using the intensity of the $\nu_1$ mode of $NO_3^-$ as an internal standard we obtain $Q_{\nu_1}{}^{T_0}/Q_{\nu_1}{}^{S_0} \approx 9$.

## V. Concluding remarks

In this paper, an example is given in which the radiation of a pulsed laser can be used to produce excited states of the $UO_2$ unit of the species $(UO_2)_3(OH)_5^+$ and $(UO_2)_2(OH)_2^{2+}$, while part of the radiation not used for optical pumping can serve as a Raman probe to induce light scattering transitions from 7 μs and 1.5 μs lived excited states of these species. By employing standard expressions for the temporal behaviour of population numbers of ground and excited states, an attempt was made to compute these numbers and to compare them with experimental data. Due to the fact that the lifetime of the excited states is longer than the duration of the laser pulse we employed expressions for a *non*-steady-state situation. The comparison is reasonable and can be used for other systems which permit the observation of their excited level Raman spectra.

## VI. Acknowledgement

The authors wish to thank Dr. L. V. Haley for discussions and technical assistance.

Reçu le 19 octobre 1981

MICHEL MANFAIT, ALAIN J. P. ALIX, JACQUELINE DELAUNAY-ZECHES et THÉOPHILE THEOPHANIDES. Can. J. Chem. **60**, 2216 (1982).

Les spectres Raman laser des complexes dimères pontés du nitrate de di-μ-hydroxo-bis(diammine) platine(II): $[(NH_3)_2Pt(OH)_2Pt(NH_3)_2](NO_3)_2$ et des dérivés isotopiques (substitutions H/D, $^{16}O/^{18}O$) ont été obtenus à l'état solide dans le domaine 0–4000 $cm^{-1}$. Les spectres infrarouge de ces complexes ont été obtenus à l'état solide dans KBr (200–4000 $cm^{-1}$). Les attributions des différentes fréquences de vibration de l'ion nitrate, des ligands $NH_3$, des groupes hydroxo et du squelette carré plan sont discutées en détail pour le complexe et ses dérivés isotopiques.

MICHEL MANFAIT, ALAIN J. P. ALIX, JACQUELINE DELAUNAY-ZECHES, and THÉOPHILE THEOPHANIDES. Can. J. Chem. **60**, 2216 (1982).

The laser Raman spectra of the hydroxo-bridged platinum(II) complexes, di-μ-hydroxo-bis(diammine) platinum(II)-nitrate $[(NH_3)_2Pt(OH)_2Pt(NH_3)_2](NO_3)_2$, and isotopic derivatives involving the atoms H/D and $^{16}O/^{18}O$ are recorded in the solid state in the range 0–4000 $cm^{-1}$. The infrared spectra of the complexes are recorded in KBr pellets in the range 200–4000 $cm^{-1}$. Assignments of the different lines for the nitrate ion, the ammonia molecules, the hydroxo groups, and the square planar skeleton vibrations of the complex and its isotopic analogs are given.

## Introduction

Il est maintenant bien reconnu que le complexe de platine *cis*-dichlorodiammine platine(II) (*cis*-DDP, *cis*-platine) est un agent antitumoral très efficace contre plusieurs types de cancers (1). L'étude des réactions d'hydrolyse du *cis*-platine a conduit à la synthèse de nouveaux composés di- et tri-nucléaires hydroxo-pontés (2, 3).

Nous nous sommes intéressés en particulier au complexe dimère du nitrate de di-μ-hydroxo-bis-(diammine platine(II)) de formule $[(NH_3)_2Pt(II)-(OH)_2Pt(II)(NH_3)_2](NO_3)_2$ dont la structure a été résolue récemment par Faggiani *et al.* (2). Ces auteurs ont donné également une première attribution très incomplète des spectres de vibration du dimère, surtout en ce qui concerne les vibrations du squelette $[N_2PtO_2PtN_2]$.

Nous avons entrepris l'étude des vibrations moléculaires (4) du dimère et de ses dérivés isotopiques H/D, $^{16}O/^{18}O$ par spectroscopie Raman et infrarouge ainsi qu'une analyse en coordonnées normales complète du squelette (voir partie 2, réf. 5). Dans ce travail nous donnons les spectres Raman et infrarouge du complexe à l'état solide et de ses divers isotopes (D, $^{18}O$). Les attributions des différentes fréquences sont discutées en détail en termes de vibrations de l'anion (ion nitrate $NO_3^-$) et de vibrations du cation dinucléaire pour lequel une distinction adéquate est faite pour les parties ammines, hydroxydes et squelette. En particulier, nous avons attribué les modes de vibrations mettant en jeu les liaisons platine–oxygène (ν(Pt—O), δ(PtOPt)) dans le cycle biponté carré-plan $Pt_2O_2$ (voir Fig. 1).

Ces résultats, obtenus sur les attributions des vibrations impliquant les liaisons Pt—O, sont d'une grande importance quant à l'interprétation

des mécanismes d'interactions des complexes du platine(II) avec les acides nucléiques intervenant dans les processus cancéreux: voir en particulier l'étude des drogues anticancéreuses, comme le *cis*-platine, en interaction avec l'ADN (6, 7).

## Matériels et méthodes

*Préparation des composés*

Le complexe dimère du nitrate de di-μ-hydroxo-bis(diammine platine(II)) est préparé à partir du *cis*-dichlorodiammine platine(II) (Johnson-Matthey Co.) suivant la méthode décrite par Faggiani *et al*. (2). Le complexe deutérié est obtenu par dissolution du dimère dans $D_2O$ (99.8% Merck) suivie d'une évaporation lente sous vide, dans le noir et à température ambiante. Cette procédure est répétée trois fois. Le complexe substitué $^{18}O$ a été préparé comme le deutérié à partir d'une évaporation sous vide d'une solution dans $H_2{}^{18}O$, à température ambiante. L'examen des différents spectres montre qu'il y a bien eu une substitution isotopique.

*Instrumentation*

Les spectres Raman du complexe et de ses dérivés isotopiques sous forme solide ont été obtenus sur un spectromètre triple monochromateur Coderg modèle T800 avec un laser à argon ionisé Coherent Radiation modèle 52B (488.0 nm, puissance 200 mW). La technique de la cellule tournante a été utilisée afin d'éviter une dégradation thermique des échantillons (caractère explosif de ces composés). Les spectres infrarouge des complexes dans le KBr ont été enregistrés sur un spectromètre Perkin Elmer 521 pour le domaine 200–4000 $cm^{-1}$. Les fréquences des raies sont mesurées avec une précision de ± 2 $cm^{-1}$. L'intensité des raies est mesurée par la hauteur de crête.

## Résultats et discussions

La structure cristalline a été déterminée par diffraction de rayons X par Faggiani *et al*. (2). Le dimère cristallise dans le groupe d'espace triclinic $P\bar{1}$ avec une molécule par maille ($Z = 1$). La symétrie moléculaire du cation $[(NH_3)_2Pt(OH)_2Pt(NH_3)_2]^{2+}$ se rapproche de la symétrie idéale $D_{2h}$ (protons omis). La symétrie de site est $C_i$. Il en résulte, quelque soit la symétrie considérée (molécule libre $D_{2h}$, molécule dans le cristal $C_i$), une non-coincidence des fréquences Raman et infrarouge.

Les spectres Raman à l'état solide des complexes, $[(NH_3)_2Pt(OH)_2Pt(NH_3)_2](NO_3)_2$, $[(NH_3)_2Pt(^{18}OH)_2Pt(NH_3)_2](NO_3)_2$ et $[(ND_3)_2Pt(OD)_2Pt(ND_3)_2](NO_3)_2$ sont représentés respectivement sur les Figs. 2a, 2b, 2c. Les spectres infrarouge de ces mêmes composés sont donnés dans les Figs. 3a, 3b, 3c. Les fréquences Raman et infrarouge des divers complexes sont reportées dans le Tableau 1.

Les différents critères d'attribution des fréquences ont été les suivants.

(*i*) Attribution des fréquences de l'ion nitrate $NO_3^-$; elles sont en général séparées des fréquences du complexe et ne varient pas par substitution isotopique (H/D, $^{16}O/^{18}O$).

(*ii*) Attribution des fréquences du ligand $NH_3$ (respectivement $ND_3$); cette attribution est assez classique (2, 8, 9) et ne pose pas de problème.

(*iii*) Attribution des fréquences du groupe hydroxo; les fréquences d'élongation ν(OH) et de balancement $\rho_w$(OH) ont été attribuées par comparaison avec des résultats équivalents obtenus pour des complexes binucléaires pontés du même type (10–13).

(*iv*) Attribution des fréquences du squelette du complexe; les vibrations normales du cation binucléaire sont considérées dans l'approximation du point (les groupes hydroxo et les ammines sont réduits respectivement aux points O′ ($m_{O'} = m_O + m_H$) et N′ ($m_{N'} = m_N + 3m_H$):

$$\Gamma(D_{2h}) = 4A_g(\mathrm{R}) + B_{1g}(\mathrm{R}) + B_{2g}(\mathrm{R}) + 3B_{3g}(\mathrm{R}) + A_u(—) + 3B_{1u}(\mathrm{ir}) + 3B_{2u}(\mathrm{ir}) + 2B_{3u}(\mathrm{ir})$$

(*v*) Attribution des fréquences des vibrations du couplage squelette–ligands $NH_3$; les couplages Pt—$NH_3$ (rocking) donnent lieu à des mouvements de fréquences bien séparées de celles du squelette et/ou des ligands libres (faibles couplages cinématiques et dynamiques justifiés par l'approximation du point).

*Ion nitrate $NO_3^-$*

Les quatre fréquences de vibration observées, reportées dans le Tableau 1, confirment une structure $D_{3h}$ pour l'ion $NO_3^-$ ($A_1' + A_2'' + 2E'$) (14) qui de ce fait n'apparaît pas être coordonné (la symétrie serait dans ce dernier cas soit $C_{2v}$ soit $C_s$ et on observerait une levée de dégénérescence).

*Ligands $NH_3/ND_3$*

L'attribution des modes de vibration des ligands $NH_3$ et $ND_3$ est directe (voir pour comparaison notre travail sur $[Pt(NH_3)_4]^{2+}$ (8, 9)). Les bandes dans le domaine 3107–3253 $cm^{-1}$ (Raman) et 3100–3245 $cm^{-1}$ (infrarouge) correspondent aux modes d'élongation symétriques et antisymétriques ($\nu_{as}(NH) > \nu_s(NH)$). Ces bandes se déplacent à 2275–2467 $cm^{-1}$ (Raman) et à 2380–2425 $cm^{-1}$ (infrarouge) pour le complexe deutérié. Ces fréquences semblent ne pas se modifier dans le cas du complexe $^{18}O$.

Les modes de déformation $\delta_s(NH_2)$ et $\delta_{as}(NH_2)$ sont observés respectivement dans les domaines 1318–1396 $cm^{-1}$ et 1573–1596 $cm^{-1}$ (Raman), 1312–1322 $cm^{-1}$ et 1551–1608 $cm^{-1}$ (infrarouge) pour $NH_3$. Les modes correspondants $\delta_s(ND_2)$ et $\delta_{as}(ND_2)$ sont déplacés à environ 1023 $cm^{-1}$ (raie masquée par la $\nu_s(NO) = 1046\ cm^{-1}$) et 1105–1168

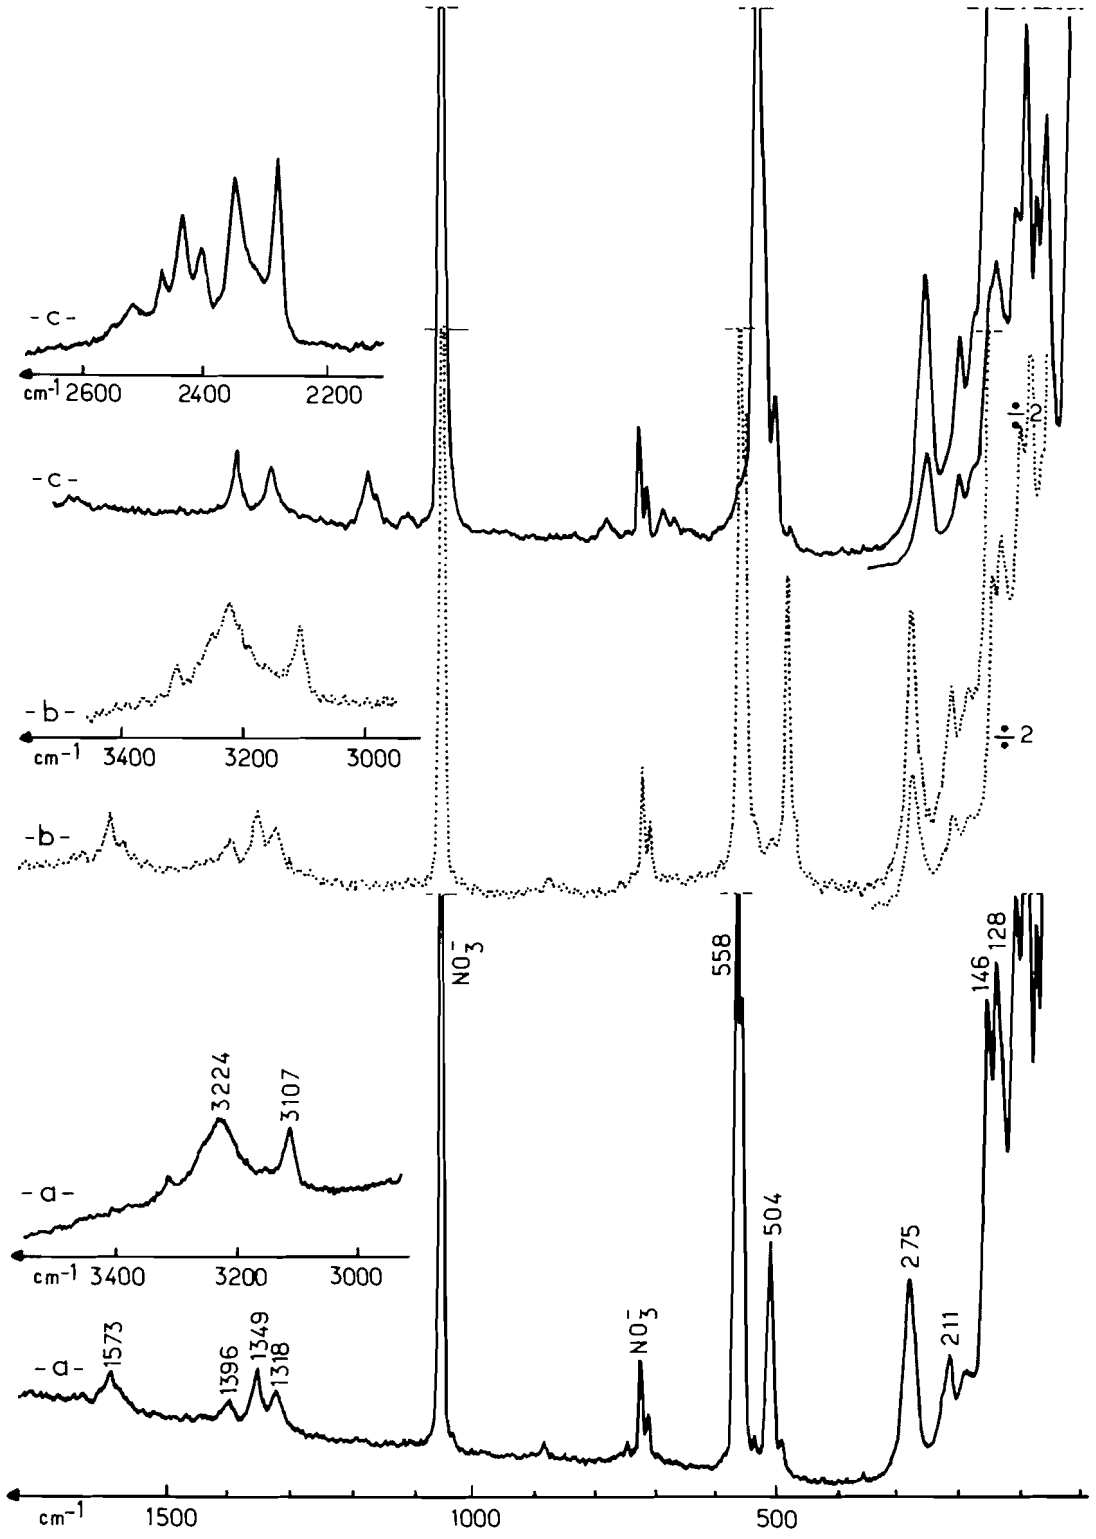

FIG. 2. Spectres Raman à l'état solide: (a) $[(NH_3)_2Pt(II)(OH)_2\ Pt(II)(NH_3)_2](NO_3)_2$, (b) $[(NH_3)_2Pt(II)(^{18}OH)_2Pt(II)(NH_3)_2](NO_3)_2$ et (c) $[(ND_3)_2Pt(II)(OD)_2Pt(II)(ND_3)_2](NO_3)_2$. Excitation laser 488.0 nm. Largeur des fentes 4 $cm^{-1}$.

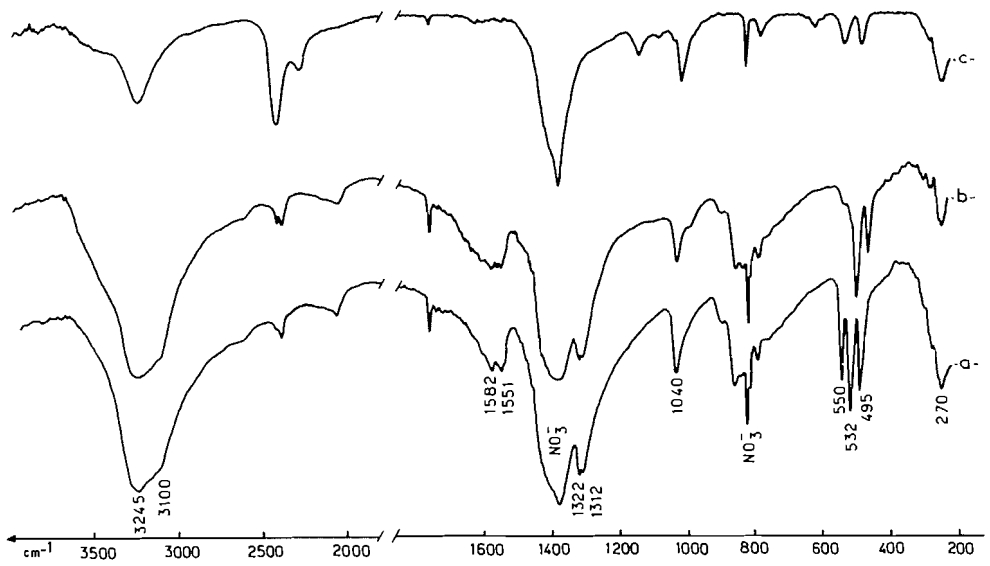

FIG. 3. Spectres infrarouge dans KBr: (a) $[(NH_3)_2Pt(II)(OH)_2Pt(II)(NH_3)_2](NO_3)_2$, (b) $[(NH_3)_2Pt(II)(^{18}OH)_2Pt(II)(NH_3)_2](NO_3)_2$ et (c) $[(ND_3)_2Pt(II)(OD)_2Pt(II)(ND_3)_2](NO_3)_2$.

$cm^{-1}$ (Raman), 1021–1041 $cm^{-1}$ et 1082–1165 $cm^{-1}$ (infrarouge). L'ensemble des déplacements isotopiques des fréquences satisfait au rapport $\nu(H)/\nu(D) = 1{,}3–1{,}4$.

*Groupes hydroxo OH/OD/$^{18}$OH*

Les modes d'élongation $\nu$(OH), $\nu$(OD) sont attribués aux raies 3310 $cm^{-1}$ (R), 3460 $cm^{-1}$ (ir) et 2515 $cm^{-1}$ (R), respectivement. Bien que l'ensemble des modes d'élongation $\nu$(NH) et $\nu$(OH) soient relativement superposés, il nous paraît malgré tout raisonnable de distinguer les différents domaines (c'est-à-dire, $\nu_s$(NH), $\nu_{as}$(NH) et $\nu$(OH)) comme présentés ci-dessus.

Le mode de vibration de déformation $\delta$(Pt—OH) est pointé à 1040 $cm^{-1}$ (ir) et se déplace à 780 $cm^{-1}$ dans le complexe deutérié; rapport $\nu(OH)/\nu(OD) = 1.33$. Ce mode est complètement masqué dans le spectre Raman du complexe par la bande très intense $\nu_1$(NO) = 1046 $cm^{-1}$ du nitrate, mais apparaît clairement à 773 $cm^{-1}$ dans le spectre Raman du deutérié.

*Squelette $[N_2PtO_2PtN_2]$ ($D_{2h}$)*

La localisation des raies correspondant aux mouvements des atomes d'azote dans le squelette (c'est-à-dire relativement aux atomes lourds de platine) est faite compte tenu de nos résultats antérieurs sur l'ion $[Pt(NH_3)_4]^{2+}$ (8, 9) et ceux sur le nitrate de *cis*-diaquo diammine platine(II) (15).

Les mouvements d'élongation des quatre liaisons PtN donnent lieu à quatre fréquences de vibration. Les modes symétriques sont pointés à 558 $cm^{-1}$ (Raman, très intense) et 550 $cm^{-1}$ (infrarouge) pour le complexe et se déplacent respectivement à 525 $cm^{-1}$ (R) et 532 $cm^{-1}$ (ir) pour le deutérié. Les modes antisymétriques sont vus à 552 $cm^{-1}$ (R, peu intense) et 532 $cm^{-1}$ (ir, forte) pour le complexe et à 515 $cm^{-1}$ (R) et 494 $cm^{-1}$ (ir) pour le deutérié. Ces déplacements isotopiques ($\Delta\nu$-(Pt—N)) de l'ordre de 30 $cm^{-1}$ sont assez caractéristiques de la substitution H/D dans les complexes platine–ammines (8). Il nous a été très difficile d'obtenir le spectre Raman du complexe en solution dans l'eau. Cependant, nous avons pu observer la raie $\nu_s$(PtN) de type $A_g$ à 550 $cm^{-1}$ (polarisée) et la raie $\nu_{as}$(PtN) de type $B_{3g}$ à 545 $cm^{-1}$ (dépolarisée).

Les mouvements de déformations angulaires planes des deux groupements $PtN_2$ donnent lieu à quatre fréquences de vibration. Les modes de déformation d'angle de type ciseau symétrique $\delta_s$-($PtN_2$) et antisymétrique $\delta_{as}$($PtN_2$) sont pointés à 275 $cm^{-1}$ (Raman, large et peu intense) et 270 $cm^{-1}$ (ir, moyenne); ils se déplacent à 248 $cm^{-1}$ (R et ir) par deutération. Le mode de déformation de type rotation plane $\rho_{r,s}$($PtN_2$) est attribué à la raie 211 $cm^{-1}$ (R) et à 193 $cm^{-1}$ (R) pour le complexe et son homologue deutérié. Le mode antisymétrique $\rho_{r,as}$-($PtN_2$) (actif en ir, $B_{2u}$) n'a pas été observé.

Le mode de déformation de type torsion angulaire (hors du plan) $\rho_{t,as}$($PtN_2$) est attribué à la raie 128 $cm^{-1}$ (R). Le mode $\rho_{t,s}$ ($PtN_2$) (ir, $A_u$) étant inactif, n'est pas observable. Le mode de déformation de type balancement (hors du plan) $\rho_{w,as}$($PtN_2$) est attribué à la raie 146 $cm^{-1}$ (R). Le mode $\rho_{w,s}$($PtN_2$) (ir, $B_{3u}$) n'est pas observé. Les précédentes attribu-

tions proposées sont confirmées par l'analyse en coordonnées normales du squelette des complexes (voir partie 2 (5)).

L'attribution précise des différentes raies associées aux divers mouvements de vibration d'un cycle biponté est dans le cas présent assez complexe étant donné que les groupes hydroxo et les ligands $NH_3$ ont des masses similaires $m(OH) \simeq m(NH_3)$, que les liaisons PtN et PtO ont des longueurs pratiquement égales ($PtN = 2.03_0$ Å $\simeq PtN = 2.01_5$ Å (2)) et que les mouvements impliquant les liaisons platine–oxygène et platine–azote sont de même symétrie. Le problème a cependant été résolu sans trop de difficultés, en particulier par l'obtention des spectres Raman et infrarouge du complexe $^{18}O$.

En accord avec les analyses en coordonnées normales d'un cycle biponté quadriatomique plan (15, 16), les fréquences de vibration d'élongation sont exprimées en termes de fréquences symétriques et antisymétriques du pont simple. La fréquence de respiration du cycle $\nu_s(PtO)$ est observée à 504 $cm^{-1}$, 495 $cm^{-1}$ et 481 $cm^{-1}$ (Raman) pour les complexes H, D, $^{18}O$. Le mouvement de type antisymétrique $B_{3g}$ est attribué à la raie $\nu_{as}(PtO)$ pointée à 488 $cm^{-1}$, 473 $cm^{-1}$ et 468 $cm^{-1}$ (Raman, H, D, $^{18}O$). Pour l'infrarouge, la bande forte à 495 $cm^{-1}$ (482 $cm^{-1}$: D; 471 $cm^{-1}$: $^{18}O$) est attribuée à la fois à $\nu_s(PtO)$ et $\nu_{as}(PtO)$. Cette coïncidence des deux modes de vibration actifs en infrarouge, de symétrie $B_{1u}$, $B_{2u}$, est observée en particulier dans les cycles *carrés* plans (c'est-à-dire PtOPt = 90°) (voir l'analyse théorique dans les travaux de Baran (17)).

On constate (voir Tableau 1) que la substitution $^{18}O$ conduit à un déplacement des fréquences infrarouge $\nu_s(PtN)$ et $\nu_{as}(PtN)$ de l'ordre d'une dizaine de $cm^{-1}$ alors que les fréquences Raman associées aux $\nu(PtN)$ ne sont pas affectées. Cette anomalie trouve une explication dans le cadre de l'analyse en coordonnées normales (5) qui indique en fait, que les fréquences ir $\nu_s(PtO)$ et $\nu_s(PtN)$ d'une part et $\nu_{as}(PtO)$ et $\nu_{as}(PtN)$ d'autre part sont fortement couplées. Seul le mode $A_g$ de déformation angulaire du cycle $\delta_s(Pt_2O_2)$ est observé à 83 $cm^{-1}$ (R) dans le complexe. Cette fréquence ne bouge pas dans les complexes D ou $^{18}O$.

*Couplages squelette–ligands*

Les bandes des modes "rocking", $\rho_r(NH_3) = \rho_r(PtNH)$, sont vues à 879 $cm^{-1}$ (R), 843, 863, 908 $cm^{-1}$ (ir) pour le dimère et se déplacent à 660, 679 $cm^{-1}$ (R), 600, 622, 650 $cm^{-1}$ (ir) pour le deutérité. Il s'avère qu'il est quasiment impossible d'attribuer les modes de torsion de type $\tau(HNPtO)$ et $\tau(HNPtN')$ (ce dernier est observé aux environs de 200 $cm^{-1}$ dans les complexes carrés plans tétraammines (8)).

ALAIN J. P. ALIX, MICHEL MANFAIT, ODILE KRUG et THÉOPHILE THEOPHANIDES. Can. J. Chem. **60**, 2222 (1982).

Une analyse complète en coordonnées normales a été conduite pour le squelette [$N_2'$ Pt $O_2'$ Pt $N_2'$] du nitrate de di-μ-hydroxo-bis(diammine) platine(II) dans le cadre de l'approximation du point et en assumant une configuration de symétrie $D_{2h}$.

La méthode de construction d'une base de 18 coordonnées de symétrie indépendantes repose sur la théorie des vibrations moléculaires dans le système de coordonnées rectilignes dépendantes. Un champ de forces général de valence est obtenu par raffinement et reproduit d'une façon satisfaisante les fréquences de la molécule mère et de son dérivé deutérié. Le calcul de toutes les distributions énergétiques permet la description des modes normaux et spécialement ceux impliqués dans les vibrations du cycle carré plan ($Pt_2O_2$) qui présentent des coulages importants.

Additionnellement, nous avons calculé indépendamment certains fragments du complexe dimère entier qui peuvent être ainsi comparés avec des molécules de même type.

ALAIN J. P. ALIX, MICHEL MANFAIT, ODILE KRUG, and THÉOPHILE THEOPHANIDES. Can. J. Chem. **60**, 2222 (1982).

A full normal coordinate analysis of the skeleton [$N_2'$ Pt $O_2'$ Pt $N_2'$] of the di-μ-hydroxo-bis(diammine) platinum(II) nitrate has been performed according to the Point Mass Model approximation and assuming a $D_{2h}$ molecular symmetry.

The method of construction of a set of 18 independent symmetry valence coordinates was based on the theory of molecular vibrations in dependent rectilinear coordinates. A refined general valence force field which reproduces satisfactorily the frequencies of the molecule and its deuterated analog has been obtained. Calculations of all distributions of vibrational energy allow us to describe all normal modes of vibration and especially the ones related to the square planar ring modes ($Pt_2O_2$) showing evidence of strong couplings.

In addition we have calculated independently some fragments of the whole dimeric complex, which may be used for comparison with related compounds.

## Introduction

Dans la première partie de ce travail (1), nous avons présenté en détail l'analyse par spectroscopie Raman et infrarouge du complexe dinucléaire ponté: nitrate de di-μ-hydroxo-bis(diammine platine(II)) de formule $[(NH_3)_2$ Pt $(OH)_2$ Pt $(NH_3)_2)]$ $(NO_3)_2$ et de certains de ses dérivés isotopiques (substitution H/D, $^{16}O/^{18}O$).

Dans le présent travail, nous reportons l'analyse complète en coordonnées normales du complexe dans l'approximation du point massique (PMM: "point mass model" (2, 3)); c'est-à-dire que les groupes ($NH_3$) et (OH) sont respectivement réduits aux points N′ et O′ de masse $m(N') = m(NH_3)$ et $m(O') = m(OH)$. Le calcul de l'édifice [$N_2'$ Pt $O_2'$ Pt $N_2'$], de symétrie $D_{2h}$, correspond alors au calcul du squelette du complexe considéré.

L'utilisation du formalisme de la théorie des vibrations moléculaires en coordonnées rectilignes dépendantes (pour détails voir réfs. 4–8), conduit à la définition d'une base de 18 coordonnées internes de valence et/ou de 18 coordonnées symétriques indépendantes n'impliquant pas les relations de redondances. Ce système se révèle ainsi particulièrement adéquat pour décrire les vibrations du complexe entier ou de ses divers fragments pris indépendemment tels que: pont simple Pt O Pt, double pontage $Pt_2O_2'$, monomère $O_2'$ Pt $N_2'$...

Un champ de forces général de valence est obtenu par raffinement et reproduit d'une façon exacte les fréquences observées pour le complexe (H) et assez satisfaisante pour le dérivé deutérié (D). Le calcul de l'ensemble des distributions d'énergie: potentielle (PED), cinétique (KED), totale (TED) et vibrationnelle (PKTED) donne la description des modes normaux de vibration et révèle les couplages (cinématiques et dynamiques) entre les mouvements du cycle carré plan ($Pt_2O_2'$) et des édifices terminaux ($PtN_2'$).

## Expérimentation

*Paramètres structuraux* (voir Fig. 1)

Les distances Pt—N = 2,01$_5$ Å et Pt—O = 2,03 Å sont issues des résultats de diffraction des rayons X de Faggiani *et al.* (9). Le cycle $Pt_2$ $O_2$ est supposé parfaitement plan et carré. Les

angles $\beta = \widehat{NPtN}$ sont fixés à la valeur 90° ce qui implique la définition des angles plats $\delta = \widehat{NPtO}$ (hors du plan).

L'analyse en coordonnées normales du complexe entier sera effectué dans le cadre de l'approximation du modèle des masses ponctuelles (PMM = "Point Mass Model" (2, 3)). Les groupes OH et $NH_3$ sont rassemblés aux points O′ et N′ de masses respectives $m(O') = m(O) + m(H)$ et $m(N') = m(N) + 3m(H)$.

On constate ainsi dans le cas du squelette non deutéré que, non seulement l'ensemble des distances relatives aux liaisons de pont (PtO) et terminales (PtN) sont sensiblement identiques, mais que les masses des atomes réduits sont presque égales ($m(O') \simeq m(N')$). Il est alors prévisible que les mouvements correspondants du cycle $Pt_2O_2'$ et des groupements terminaux $Pt\,N_2'$ seront d'énergie comparable et donc qu'il est à envisager d'importants couplages (au moins du type cinématique) entre les différents mouvements.

*Spectres Raman et infrarouge* (fréquences observées)

Les spectres Raman et infrarouge du complexe $[(NH_3)_2\,Pt(OH)_2\,Pt\,(NH_3)_2](NO_3)_2$ et de ses dérivés isotopiques (substitutions H/D, $^{16}O/^{18}O$) ont été décrits en détail dans la première partie de ce travail (1). L'attribution des fréquences observées a été faite dans réf. 1 conjointement au présent travail, c'est-à-dire que dans tous les cas possibles d'ambiguité (voir par exemple les raies Raman à 83 $cm^{-1}$ ($A_g$), 128 $cm^{-1}$ ($B_{1g}$), 146 $cm^{-1}$ ($B_{2g}$) et 211 $cm^{-1}$ ($B_{3g}$)), l'analyse en coordonnées normales a été conduite pour chaque cas de permutation des fréquences. Les valeurs excessives ou même aberrantes des constantes de force internes de valence obtenues pour l'un ou l'autre de ces calculs nous ont permis de rejeter les permutations correspondantes hormis l'attribution finale qui est reportée dans le Tableau 1.

## Coordonnées internes de valence

La figure 1 représente le squelette $[N_2'\,Pt\,O_2'\,Pt\,N_2']$ du complexe, ainsi que l'ensemble des coordonnées internes de valence qui permettent de décrire les différentes variations des liens et angles valenciels.

Le système complet de coordonnées internes $\mathbf{R}^c$ comprend ainsi 26 coordonnées internes soit 8 coordonnées surabondantes. Un système plus simple peut-être défini en ne prenant pas en compte les angles $\alpha_i$ et $\varepsilon_i$ et conduit au système tronqué $\mathbf{R}^t$ comprenant 22 coordonnées (dont 4 surabondantes). Ce système a l'avantage de ne pas faire intervenir directement les paramètres reliés aux coordonnées $\alpha_i$ et $\varepsilon_i$ tels que par exemple $f_\varepsilon = f(\widehat{Pt\,O'\,Pt}), f_\alpha = f(\widehat{O'PtO'})$... dont on trouve peu de données dans la littérature.

Le système de 18 coordonnées internes de valence indépendantes $\mathbf{R}^{ind}$ est obtenu en prenant des combinaisons symétriques $t$ et $\tau$ des coordonnées du système $\mathbf{R}^t$, soit $\mathbf{R}^{ind} = \{4r_i, 4R_i, 4\gamma_i, 4\delta_i, t, \tau\}$ ou: $t = 2^{-1/2}(\beta_1 + \beta_2)$ et $\tau = 2^{-1}(\tau_1 - \tau_2 + \tau_3 - \tau_4)$.

Les relations de redondances sont alors implicitement exprimées dans la relation:

$$[1] \quad \mathbf{R}^{ind} = \mathbf{T}\mathbf{R}^c$$

faisant intervenir le formalisme de la matrice $\mathbf{T}$ reliant les systèmes dépendant $\mathbf{R}^c$ et indépendant $\mathbf{R}^{ind}$ (pour détails et expressions analytiques de $\mathbf{T}$, voir réfs. 4–8).

correspond alors 18 fréquences fondamentales de représentation:

$$\Gamma = 4A_g(\mathrm{R}) + B_{1g}(\mathrm{R}) + B_{2g}(\mathrm{R}) + 3B_{3g}(\mathrm{R}) + A_u(—) + 3B_{1u}(\mathrm{ir}) + 3B_{2u}(\mathrm{ir}) + 2B_{3u}(\mathrm{ir})$$

On construit un système **S** de 18 coordonnées de symétrie indépendantes à partir du système $\mathbf{R}^{ind}$, par les méthodes classiques de théorie des groupes (10), soit:

[2] $\quad \mathbf{S} = \mathbf{U}\mathbf{R}^{ind}$

où, **U** est une matrice orthogonale. Le Tableau 2 donne les coordonnées de symétrie du squelette ainsi que la description des mouvements correspondants.

## Champ de forces général de valence

*Principes de la méthode*

La méthode standard des matrices **G** et **F** de Wilson *et al.* (10) et le formalisme de la matrice **T** (4–8) permet de définir un champ de forces général de valence symétrique sous la forme:

[3] $\quad \mathbf{F} = \mathbf{U}\mathbf{F}^{ind}\tilde{\mathbf{U}}$

où, $\mathbf{F}^{ind}$ représente la matrice des constantes de force internes de valence définit dans le système indépendant $\mathbf{R}^{ind}$. Les relations entre $\mathbf{R}^c$ et $\mathbf{R}^{ind}$ conduisent à l'expression:

[4] $\quad \mathbf{F}^{ind} = \tilde{\mathbf{T}}\mathbf{F}^c\mathbf{T}$

La matrice **F** est obtenue par raffinement, à partir d'une solution initiale $\mathbf{F}^{(0)}$ de l'équation séculaire

[5] $\quad |\mathbf{G}\mathbf{F}^{(0)} - \lambda\mathbf{E}| = 0$

où $\mathbf{F}^{(0)}$ est définie par le modèle cinématique de la méthode de couplage pas à pas (introduction linéaire des éléments extradiagonaux de **G**: pour détails voir la revue sur les méthodes d'approximations du champ de forces Alix *et al.* (11) et réfs. 12 et 13).

Les constantes de forces internes de valence $\mathbf{F}^{ind}$ sont alors calculées à partir de [3] sous la forme:

[6] $\quad \mathbf{F}^{ind} = \tilde{\mathbf{U}}\mathbf{F}\mathbf{U}$

La connaissance des paramètres du système complet $\mathbf{R}^c$ passe ainsi par la définition des compliances définies selon (4–8):

[7] $\quad \mathbf{n}^{ind} = [\mathbf{F}^{ind}]^{-1}$

[8] $\quad \mathbf{n}^c = \mathbf{T}\mathbf{n}^{ind}\tilde{\mathbf{T}}$

Ainsi que démontré par Alix (7, 8), seules les constantes de force $\mathbf{F}_{ij}{}^c$ associées aux coordonnées internes indépendantes sont déductibles directement des constantes correspondantes $\mathbf{F}_{ij}{}^{ind}$. Toutes les autres constantes $\mathbf{F}_{ij}{}^c$ associées à une ou deux coordonnées de redondances restent indéterminées (i.e., la matrice $\mathbf{F}^c$ reste indéterminable à

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

partir de $\mathbf{F}^{ind}$ car la relation [4] ne peut être inversée, **T** étant rectangulaire). Il en résulte que nous ne donnerons dans ce travail que les valeurs numériques des constantes de forces indépendantes $\mathbf{F}_{ij}^{ind}$.

*Détermination pratique des constantes de force*

La résolution de l'équation séculaire [5] nécessite au préalable la définition complète de la matrice Λ des valeurs $\lambda_k$ reliées aux fréquences observées par la relation:

$$[9] \quad \lambda_k = \frac{4\pi^2 \nu_k^2}{c^2 \mathcal{N}} = \left[\frac{\nu_k(\text{cm}^{-1})}{1303{,}16}\right]^2$$

Les fréquences non observées $\nu_{16}$, $\nu_{17}$ et $\nu_{18}$ (infrarouge) ont été fixées aux valeurs respectives 150, 150 et 40 $cm^{-1}$. Ce choix repose sur la comparaison des résultats obtenus pour des composés soit de même type, soit de même symétrie (14–19).

Les mouvements hors du plan Pt $N_2$ peuvent ainsi être classés de la façon suivante:

torsion angulaire: [100–130 $cm^{-1}$]; $\rho_{t,as} = 128\ cm^{-1}$(R)

balancement: [≃150 $cm^{-1}$]; $\rho_{\omega,as} = 146\ cm^{-1}$(R)

rotation plane: [150–200 $cm^{-1}$]; $\rho_{r,s} = 211\ cm^{-1}$(R)

La torsion du cycle $Pt_2O_2$ est assumée à 40 $cm^{-1}$.

La fréquence $\nu_{10}(A_u)$ étant inactive, a été calculée en imposant la condition $f_{\delta\delta}{}^t = 0$. Il en résulte que le mouvement hors du plan de torsion angulaire symétrique ($\rho_{t,s}$(Pt $N_2$)) a une fréquence calculée à 108 $cm^{-1}$.

Le champ de forces raffiné, symétrique de valence est reporté dans le Tableau 3. Le Tableau 4 présente les constantes de force internes de valence indépendantes ($F_{ij}^{ind}$) les plus significatives. Les constantes n'apparaissant pas dans le Tableau 4 peuvent être considérées comme nulles (i.e., $F_{rr}{}^t$, $F_{RR}{}^t$, $F_{RR}{}^c$, $F_{\beta R}$, $F_{\delta\delta}{}^g$, $F_{\delta\delta}{}^t$, $F_{\delta\tau}$, $F_{r\gamma}$, $F_{R\gamma}$ etc.).

Le Tableau 5 donne les fréquences calculées pour le complexe (H) et son dérivé deutérié (D). Le champ de forces raffiné reproduit ainsi d'une façon parfaite les fréquences de la molécule mère et d'une façon satisfaisante, celles de son isotopomère.

Le Tableau 6 présente les distributions d'énergie vibrationnelle en termes de contribution des diverses coordonnées de symétrie $S_i$ aux modes normaux de vibration $Q_k$ de fréquence $\nu_k$ (pour détails voir réfs. 20–24). Pour des raisons d'économie d'impression,[3] nous ne donnerons pas les

TABLEAU 3. Constantes de forces symétriques de valence[a] (champ de forces raffiné)

$$F(A_g) = \begin{vmatrix} 2{,}502_5 & & & \\ 0{,}048_2 & 2{,}799_3 & & \\ 0{,}098_6 & 0{,}015_2 & 0{,}406_2 & \\ 0{,}168_5 & 0{,}024_8 & 0{,}124_2 & 0{,}255_8 \end{vmatrix}$$

$$F(B_{1g}) = |0{,}0531|$$

$$F(B_{2g}) = |0{,}125_3|$$

$$F(B_{3g}) = \begin{vmatrix} 2{,}158_9 & & \\ -0{,}003_9 & 2{,}753_9 & \\ -0{,}064_1 & 0{,}017_5 & 0{,}280_0 \end{vmatrix}$$

$$F(A_u) = |(0{,}115_1)^b|$$

$$F(B_{1u}) = \begin{vmatrix} 2{,}346_7 & & \\ -0{,}018_2 & 2{,}670_3 & \\ -0{,}360_4 & -0{,}034_7 & 0{,}739_1 \end{vmatrix}$$

$$F(B_{2u}) = \begin{vmatrix} 2{,}339_5 & & \\ -0{,}032_5 & 2{,}506_6 & \\ 0{,}106_2 & 0{,}010_2 & 0{,}215_7 \end{vmatrix}$$

$$F(B_{3u}) = \begin{vmatrix} 0{,}063_3 & \\ 0{,}009_4 & 0{,}023_9 \end{vmatrix}$$

[a] Toutes les constantes $F_U$ sont exprimées en mdyn/Å.
[b] $f_{\delta\delta}{}^t = 0$ implique $F(A_u) = F(B_{1u}) + F(B_{2g}) - F_{11}(B_{3u})$.
[c] Les calculs ont été effectués avec 7 chiffres significatifs; seules les 4 premières décimales sont reportées dans le tableau.

TABLEAU 4. Constantes de force internes de valence indépendantes ($f_{ij}^{ind}$)

| Constantes[a] | Types[b] | Valeurs[c] |
|---|---|---|
| $f_r$ | $f$(Pt O) | $2{,}33_7$ |
| $f_{rr}^g$ | $f$(Pt O, Pt O') | $0{,}08_8$ |
| $f_{rr}^c$ | $f$(Pt O, Pt O) | $0{,}08_4$ |
| $f_R$ | $f$(Pt N) | $2{,}68_3$ |
| $f_{RR}^g$ | $f$(Pt N, Pt N') | $0{,}05_2$ |
| $f_\beta$ | $f$(Pt $N_2$) | $0{,}40_6$ |
| $f_{\beta r}$ | $f$(Pt $N_2$, Pt O) | $0{,}05_0$ |
| $f_{\beta\gamma}$ | $f$(Pt $N_2$, N Pt O) | $0{,}06_2$ |
| $f_\gamma$ | $f$(N Pt O) | $0{,}37_3$ |
| $f_{\gamma\gamma}^g$ | $f$(N Pt O, N'Pt O') | $0{,}12_5$ |
| $f_{\gamma\gamma}^t$ | $f$(N Pt O, N'Pt'O') | $-0{,}10_5$ |

| $f_{r\gamma}^c$ | $f$(Pt O, OPt'N') | $0{,}12_2$ |

[a] Les indices supérieurs c, g, t sont utilisés respectivement pour definir les intéractions *cis*, *gem* et *trans* (voir Fig. 1).
[b] Le symbole prime est utilisé pour distinguer deux atomes de même nature; ex. PtO,PtO' = $r_1, r_2$ et/ou $r_3, r_4$ etc.
[c] Valeurs en mdyn/Å; excepté pour $f_\tau$, les valeurs inférieures à |0,05| ne sont pas reportées.

[3] L'ensemble des calculs tels que matrices **G**, **F**, **L**, **Λ** et les distributions d'énergie DEP, DEC, DET sont à la disposition de tout lecteur qui en ferait la demande.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

distributions d'énergie potentielle, cinétique et totale définies selon:

[10] DEP: $V_{ij}^{(k)} = F_{ij} L_{ik} L_{jk}/\lambda_k$ (PED)

[11] DEC: $T_{ij}^{(k)} = (\mathbf{G}^{-1})_{ij} L_{ik} L_{jk}$ (KED)

[12] DET: $E_{ij}^{(k)} = [V_{ij}^{(k)} + T_{ij}^{(k)}]/2$ (TED)

L'étude détaillée de ces diverses distributions indique que les couplages cinématiques sont très importants (DEC), et ceci essentiellement pour les vibrations associées aux mouvements du cycle carré plan: voir pour détails la correspondance entre les Tableaux 2 et 6.

On retiendra en particulier de la détermination du champ de forces général de valence raffiné pour la molécule et son dérivé deutérié, les valeurs suivantes des constantes de force internes de valence indépendantes (mdyn/Å):

$$F_r(\mathrm{PtO}) = 2{,}33_7 \qquad F_R(\mathrm{Pt\ N}) = 2{,}68_3 \qquad F_r/F_R = 0{,}87$$
$$F_\beta(\widehat{\mathrm{NPtN}}) = 0{,}40_7 \qquad F_\gamma(\widehat{\mathrm{NPtO}}) = 0{,}37_3 \qquad F_\delta(\widehat{\mathrm{NPtO}}) = 0{,}08_9$$

## Calculs additionnels

*Champ de forces des divers fragments du complexe*

Indépendamment de la détermination du champ de forces raffiné pour le complexe [$N_2'$ Pt $O_2'$ Pt $N_2'$], $\mathscr{D}_{2h}$, nous avons calculé les constantes de force associées aux divers fragments du complexe pour lesquels nous avons transféré ou attribué les fréquences de vibration en fonction de la nature et de la symétrie propre (locale) du fragment considéré (voir Tableau 7).

*(i) Pont [Pt O' Pt]:* $\mathscr{C}_{2v}(2a_1 + b_1)$

Le transfert des fréquences $\nu_1 = 504 = \nu_s(\mathrm{PtO})$; $\nu_4 = 83 = \nu_s(\mathrm{O'Pt_2})$ et $\nu_7 = 488\,\mathrm{cm^{-1}} = \nu_{as}(\mathrm{PtO})$, conduit à la valeur $f_r(\mathrm{PtO}) = 2{,}44\,\mathrm{mdyn/Å}$. Les autres constantes de force ont cependant des valeurs inacceptables (i.e., $f_{rr}^c, f_\varepsilon$).

*(ii) Double pont: [cycle $Pt_2O_2'$]:* $\mathscr{D}_{2h}(2a_g + b_{3g} + b_{1u} + b_{2u} + b_{3u})$

L'étude des cycles bipontés de type [$M_2L_2$] (M = métal, L = ligand) a fait l'objet de travaux théoriques précis, en particulier pour le cas du pontage par l'oxygène (25–28). Il a ainsi été mis en évidence par Baran (25, 26), une forte corrélation entre les valeurs des fréquences infrarouges d'élongations symétrique et anti-symétrique $\nu_s(\mathrm{MO})$, $\nu_{as}(\mathrm{MO})$ et celle de l'angle $\widehat{\mathrm{MOM}}$. Pour un cycle carré plan, $\widehat{\mathrm{MOM}} = 90°$, les fréquences tombent en parfaite coïncidence, ce qui est le cas effectivement observé pour le dimère ($\nu_s = \nu_{as} = 495\,\mathrm{cm^{-1}}$).

Les constantes de force significatives ont été

calculées aux valeurs suivantes: $F_r(\mathrm{PtO}) = 2{,}26$, $f_\tau(\mathrm{Pt_2\,O_2}) = 0{,}00_7$.

Les interactions de type $f_{rr}$ ont des valeurs négligeables, ce qui justifie la proximité des fréquences d'élongation du cycle $Pt_2O_2$ (c.-à-d., 504, 488 et 495 $cm^{-1}$).

*(iii) "Monomère" [$O_2'$ Pt $N_2'$]:* $\mathscr{C}_{2v}$ $(4a_1 + a_2 + b_1 + 3b_2)$

L'étude indépendante de la moitié de l'édifice global conduit à des résultats très intéressants dans la mesure ou les constantes de force obtenues ont des valeurs parfaitement acceptables et comparables avec celles du complexe entier (voir Tableau 4):

$F_r(\mathrm{PtO}) = 2{,}36_7$ $\quad F_R(\mathrm{PtN}) = 2{,}67_3$ $\quad F_r/F_R = 0{,}88_6$

$F_\beta(\mathrm{NPtN}) = 0{,}34_4$ $\quad f_\gamma(\mathrm{NPtO}) = 0{,}08_3$ $\quad f_\delta(\overline{\mathrm{NPtO}}) = 0{,}06_9$

$F^g_{RR}(\mathrm{PtN,PtN'}) = 0{,}13_0$ $\quad F^g_{rR} = 0{,}04_8$

On constate que le champ de forces symétrique de valence est sensiblement diagonal. Les seuls termes non diagonaux sont relatifs aux interactions $F_{12}(A_1)$ et $F_{12}(B_2)$.

*Champ de forces symétrique simplifié pour le complexe entier*

A partir des résultats préliminaires issus de l'étude des différents fragments, il a été recherché par raffinement la possibilité de déterminer un champ de forces de valence symétrique simplifié pour le squelette complet. Ce champ diagonal est défini par $F_{ij} = 0\ \forall_i, \forall_j$. Les calculs montrent qu'il n'est pas possible de reproduire correctement les fréquences des espèces $A_g$ et $B_{1u}$ sans introduire de constantes d'interaction ou sans obtenir de valeurs aberrantes pour les constantes de force principales.

Les valeurs $F_{ii}$ obtenues pour le champ de forces simplifié sont les suivantes: $A_g$: 1,90, 2,80, $0{,}22_5$, 0,45; $B_{3g}$: 2,00, 2,75, 0,30; $B_{1u}$: 1,60, 2,40, 1,00; $B_{2u}$: 2,07, 2,43, 0,25.

Les autres constantes correspondant aux espèces de dimension 1 ($B_{1g}$, $B_{2g}$, $A_u$) sont les mêmes que celles obtenues pour le champ de forces général de valence symétrique (voir Tableau 3).

On déduit du champ de forces symétrique de valence diagonal, les valeurs suivantes des constantes de force internes de valence:

$f_r(\mathrm{Pt\ O}) = 1{,}90$ $\quad f_R(\mathrm{PtN}) = 2{,}60$ $\quad F_r/F_R = 0{,}73$

$f_\beta(\mathrm{NPtN}) = 0{,}22_6$ $\quad f_\gamma(\mathrm{NPtO}) = 0{,}50$ $\quad f_\delta(\overline{\mathrm{NPtO}}) = 0{,}09$

## Discussion et conclusion

Dans ce travail nous avons pu déterminer un champ de forces général de valence raffiné pour un complexe du type [$Z_2$ X $Y_2$ X $Z_2$], de symétrie $D_{2h}$, présentant un cycle carré plan $X_2$ $Y_2$. Il existe assez peu d'exemples dans la littérature d'analyses en coordonnées normales complètes de complexes dinucléaires de même types ou de même symétries.

Nous tenons à souligner l'importance pratique de la méthode de travail proposée, c.-à-d., la détermination des constantes de forces dans un système de coordonnées indépendantes ($\mathbf{R}^{ind}$ et/ou **S**), n'impliquant pas les redondances d'une façon explicite. Les calculs des divers fragments du complexe sont parfaitement cohérents avec ceux du squelette complet, et peuvent ainsi servir de base à un raffinement d'un champ de forces général (surtout dans les cas où il existe peu de données dans la littérature, et où il s'avère difficile de transférer des valeurs de constantes de force; c'est le cas des composés comportant des liaisons platine–oxygène).

Les travaux d'Adams *et al.* (29, 30), sur les composés $[M_2X_6]^{2-}$, (M = Pt, Pd, Au, Al; X = Br, Cl, I), conduisent à la détermination de quelques constantes de force internes de valence (champ de forces symétrique diagonal), dont en particulier $f_r$ et $f_R$, satisfaisant le rapport $f_r/f_R$ = 75–100% (X = Cl → Br → I.).

Les résultats présentés dans ce travail sont cohérents avec ceux d'Adams *et al.* Les rapports $f_r/f_R = f(\mathrm{Pt—O})/f(\mathrm{Pt—N}) = f_r(\mathrm{cycle})/f_R(\mathrm{terminal})$ sont respectivement égaux à: 0,87: champ de forces général du squelette entier; 0,89: champ de forces général du "monomère"; et 0,73: champ de forces simplifié (diagonal) du squelette entier.

Les valeurs finales $f_r(\mathrm{Pt—O}) = 2{,}34$ et $f_R(\mathrm{Pt—N}) = 2{,}68$ mettent en évidence le caractère prononcé de la liaison platine–oxygène. Ce résultat fondamental tend à corroborer l'existence d'un méca-

TABLEAU 7. Correspondances entre les espèces des fréquences du complexe entier et de ses divers fragments

Received February 25, 1982

MICHAEL J. ADAM and LAURANCE D. HALL. Can. J. Chem. **60**, 2229 (1982).

Metal-complexing, salicylaldimine ligands **4**, **7**, **8**, and **9** have been synthesized from 2-amino-2-deoxy-D-glucopyranose and some of its derivatives with salicylaldehyde and 3-formyl-2-hydroxybenzoic acid. Copper(II), zinc, and cobalt(II) complexes were formed from ligand **7**, whereas only copper(II) would complex with ligand **8**. The sugar ligand **4** forms a water-soluble complex with copper(II) and ligand **9** forms a binuclear copper(II) complex. These products have been studied by $^1$H nmr, visible absorption, and esr spectroscopy, mass spectrometry, and by their magnetic moment data.

MICHAEL J. ADAM et LAURANCE D. HALL. Can. J. Chem. **60**, 2229 (1982).

Utilisant l'amino-2 désoxy-2 D-glucopyrannose ainsi que quelques-uns de ses dérivés et la salicylaldéhyde ainsi que l'acide formyl-3 hydroxy-2 benzoïque, on a préparé les ligands du type salicylaldimine, **4**, **7**, **8** et **9**, qui sont des complexants métalliques. On a préparé les complexes de cuivre(II), de zinc et de cobalt(II) à partir du ligand **7**, tandis que seul le cuivre(II) peut être complexé par le ligand **8**. Le ligand **7** forme un complexe soluble dans l'eau avec le cuivre(II) et le ligand **9** forme un complexe binucléaire de cuivre(II). On a caractérisé ces produits par la rmn du $^1$H, par les spectres d'absorption dans le visible, par les spectres de rpe et de masse et par leurs données de moment magnétique.

[Traduit par le journal]

## Introduction

In spite of the fact that it has been known for about 100 years (2, 3) that sugars can form complexes with metals, the field of sugar–metal complexes is still largely unexplored. For example, although at least 70 crystalline complexes which contain a sugar and an inorganic salt have been reported (2) since 1973, these complexes are mainly restricted to group IA and IIA metals, and their structures are, for the most part, unknown. Literature on the complexation of sugars with transition metals and metals other than those in groups IA and IIA is in comparison much more recent (4) and less abundant.

The ability of sugars to sequester metals is of current interest for a wide variety of reasons, some of the more important of which include the possible development of novel classes of metal-based affinity chromatography materials (5), chiral homogeneous catalysts (6), metal-chelators for clinical use (7), and of models for biologically important chelates (8). Further interests include nuclear magnetic resonance studies of the interactions of many metals with sugars (9, 10). These and many other studies would be advanced by the development of general methods whereby metals can be readily attached to sugars.

Metal complexes of Schiff's bases have occupied a central role in the development of coordination chemistry (11) and, since 1840, a tremendous variety of stable chemical species have been synthesized containing either transition or nontransition metals. That amino sugars form Schiff's bases readily with salicylaldehyde and other aromatic aldehydes (12) has been known since 1922 (13) when Irvine and Earl first showed that sparingly water-soluble Schiff's bases of 2-amino-2-deoxy-D-glucopyranose (glucosamine) could be formed with salicylaldehyde. Prompted by this knowledge, we have explored the formation of metal complexes from such amino sugar – Schiff's base ligands. We start this by discussing the synthesis of Schiff's base ligands of salicylaldehyde and 3-formyl-2-hydroxybenzoic acid with both alkylamine and glucosamine derivatives, along with their metal complexes. Then visible absorption spectroscopy, esr and nmr spectroscopy, mass spectrometry, and magnetic moments are examined as tools for the structure determination of the compounds synthesized.

## Results and discussion

### *Synthesis*

#### *Schiff's base formation*

The Schiff's base ligands considered here are derived from 2-hydroxybenzaldehyde (salicylaldehyde) **1** and 3-formyl-2-hydroxybenzoic acid (3-aldehydro-salicylic acid) **2**. The reaction between 2-amino-2-deoxy-D-glucopyranose hydrochloride **3** and salicylaldehyde is very easily accomplished, using sodium bicarbonate in aqueous methanol, with the water-insoluble product **4** being obtained

in a high yield (13). As well as the parent sugar, glucosamine derivatives such as methyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranoside hydrobromide **5** (14) and 1,3,4,6-tetra-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranose **6** (15) also condense with salicylaldehyde to form the Schiff's bases **7** and **8** respectively.

Schiff's bases formed from 3-aldehydo-salicylic acid **2**, in comparison to the salicylaldehyde derivatives, previously have received very little attention and, to our knowledge, syntheses of such derivatives from amino sugars have not before been reported. The formation of the Schiff's base between the blocked glucosamine sugar **5** and this aldehyde readily afforded compound **9** in high yield.

The sugar – Schiff's base compounds **4**, **7**, **8**, and **9** are crystalline stable compounds (as are their alkyl counterparts) and are bright yellow in color. These compounds are, however, acid- and base-labile due to their azomethine linkage.[3]

*Schiff's base – metal complexes*

Salicylaldimine–metal complexes are generally readily prepared by reaction, in alcoholic solution, of the salicylaldimine with a metal ion (usually acetate salt) or by the condensation of an amine with the preformed salicylaldehyde–metal complex. The products usually precipitate and can be easily purified by recrystallization.

[3]Sugar Schiff's bases are, fortunately, stable to cold anhydrous acylating reagents. Thus, the amino sugar **6** was prepared by using *p*-methoxybenzaldehyde as an amino blocking group with subsequent acetylation and Schiff's base cleavage.

Although the latter synthetic method has been used by other workers more often than the former, it was found in this study that the first method was more suitable for the formation of sugar complexes. Thus, when a methanol solution of cupric acetate was added to a methanol solution of **7** at room temperature, the copper–sugar complex **10** precipitated immediately as a brown solid in 90% yield.[4]

The ir spectrum showed a shift in the —C=N— absorption to lower frequency compared with the parent ligand (**7**, 1630 $cm^{-1}$; **10**, 1590 $cm^{-1}$), indicating the coordination of the nitrogen atom to the copper ion.

Both zinc and cobaltous acetate also complexed with the ligand **7** in methanol to form the yellow and green bis-complexes, **11** and **12**, respectively; the yields for these complexes were, however, lower than that obtained for the copper analogue, being 41% and 51% respectively. Surprisingly, nickel(II) complexes could not be formed using any of the sugar ligands, even though most simple alkyl salicylaldimine ligands readily complex with nickel(II). When Ni(II) acetate was mixed with a methanol solution of the sugar ligand no colour change could be seen, and both starting materials were recovered upon volume reduction. If the sugar amine was condensed with the preformed salicylaldehyde–nickel complex, the sugar–salicylaldimine was isolated after work-up, indicating that condensation takes place, but that the metal dissociates from the ligand. This lack of complexation may be due to the combined effects of a normally lower stability constant for nickel–salicylaldimine complexes compared to the analogous copper(II) complexes, and the possibility that the sugar–salicylaldimines are poorer ligands. Although stability constants were not determined for these sugar complexes, some evidence of the suggestions that they are more labile than their alkyl counterparts is derived from the observation that the sugar complexes decomposed back to their parent ligands when run on silica gel thin-layer chromatography (tlc), whereas alkyl complexes such as Cu(cyclohexyl-sal)$_2$ are stable on silica gel. Furthermore, the zinc and cobalt complexes **11** and **12** decomposed when dissolved in hot methanol, and had to be recrystallized under cold conditions (see Experimental). Upon heating the green cobalt complex in methanol the solution turned orange, and after cooling and volume reduction the salicylaldehyde–cobalt complex was isolated, indicating that Schiff's base cleavage had occurred. In contrast, the copper complex **10** was stable to this treatment; thus, it seems that the zinc and cobalt complexes are more labile than the copper complex.

The sugar–salicylaldimine ligand **8** also forms a complex **13** with copper, subsequently proven to be Cu(SugII – sal)$_2$; this was obtained as shiny olive-green crystals in 90% yield when a hot, ethanolic solution of cupric acetate and ligand **8** were mixed and allowed to cool. This complex could be recrystallized from hot ethanol and decomposed only partially on silica gel tlc. However, attempted complexation of **8** with zinc and cobaltous acetate failed to yield any product.

One of the more interesting complexes prepared was the copper complex **15** of the free sugar–salicylaldimine ligand **4** which was highly water soluble. Although the structure **15** proposed for this complex was consistent with the evidence obtained from elemental analysis and mass spectrometry, the esr spectrum of this material indicates a mixture of compounds is present. This material also decomposed readily by Schiff's base cleavage and was, therefore, not successfully purified.

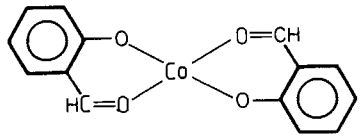
Complexes derived from 3-aldehydo-salicylic acid can be prepared by mixing the ligand and metal salt, usually the metal acetate, in an alcohol solution, and then filtering the precipitated product from the reaction mixture. For example, the reaction of the sugar ligand **9** and cupric acetate in ethanol resulted in a leaf-green product **16** in 80% yield. As will be discussed in more detail later, mass spectrometry and esr spectroscopy lead to the conclusion that this product has the binuclear copper structure as shown. The structure proposed previously by Poddar (16) for such complexes, where the nitrogen substituent R is nonbridging, is shown for **17**. We feel that this type of structure is highly unlikely in light of our own findings and also from simple model building (see below).

### *Proof of structure*

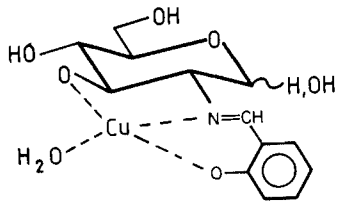
#### *Nuclear magnetic resonance spectroscopy*

In order for metal complexation to occur with the ligands **4**, **7**, **8**, and **9**, the hydroxyl function on the aromatic ring should be in close proximity with the nitrogen atom of the sugar group and probably strongly hydrogen bonded to it. Evidence for such hydrogen bonding comes from the characteristically low field shifts of the hydroxyl protons of **7**, **8**,

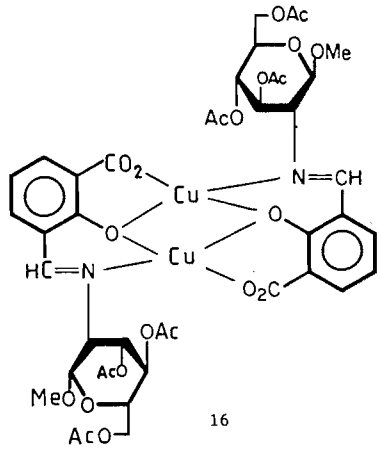
[4]For convenience the sugar unit shown in **10**, **11**, and **12** will be abbreviated as Sug I. In complexes incorporating the sugar units derived from compounds **6** and **3**, the sugar moiety will be abbreviated to Sug II and III respectively. Also, the metal complexes themselves will be abbreviated $M_x$(R-sal)$_y$ or $M_x$(R-salicylic)$_y$ where M is the metal, R is the amine group, $x$ or $y$ can be either one or two, sal = **1** and salicylic = **2**.



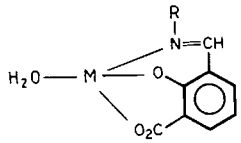
14



15



16



17

and **9**, (12.4 ppm, 12 ppm, and 14 ppm respectively).

Compound **9** has a very interesting proton nmr spectrum which provides additional evidence for the existence of a strong hydrogen bond in this molecule. The resonances of the imine-proton and H-2 are both broader than one would expect, and it can be shown by spin decoupling that this is a result of vicinal spin–spin coupling of these protons to the hydrogen-bonded hydroxyl protons; thus, irradiation of the hydroxyl resonance at 14 ppm results in sharpening of the imine and H-2 resonances. That these resonances show broadening rather than a clearly resolved coupling implies that the hydroxyl-proton is exchanging at an intermediate rate.

*Visible absorption studies*

Visible absorption spectroscopy was used to investigate the coordination geometry of the sugar–copper complexes Cu(SugI – sal)$_2$ **10**, and Cu(SugII – sal)$_2$ **13**, and the cobalt complex Co(SugI – sal)$_2$ **12**.

Although the visible absorption spectra of the Cu(R-sal)$_2$ complexes (where R = *n*-Bu, *i*-Pr, and *t*-Bu) have been reported elsewhere (17, 18), they have been remeasured here for comparison purposes, along with those of the sugar complexes, in order to obtain systematic information about their coordination geometry; all of the observed spectra are shown in Fig. 1.

The crystal structure of the complex Cu(R-sal)$_2$, where R = *n*-Bu, shows that this complex adopts a "normal" planar configuration (19). In contrast, complexes where R = *i*Pr and *t*-Bu are distorted toward tetrahedral configuration, and the inference is that this is due to the presence of bulky R groups because the *t*-Bu complex has more tetrahedral character than does the isopropyl complex.

When the *t*-Bu complex is dissolved, no structural change is observed (18), whereas when R = *i*-Pr or cyclohexyl, these complexes appear to exist in solution as an equilibrium mixture of square planar and pseudotetrahedral complexes as revealed by $^1$H nmr (20) and esr (17) studies.

All the visible spectra (*d–d* transitions) in Fig. 1 appear as shoulders on the long wavelength side of the intense bands in the near-ultraviolet, except for that of the Cu(*t*-Bu-sal)$_2$ derivative which appears as a broad peak. Although these spectra do not lend themselves to detailed discussion, one important observation concerning the three alkyl complexes, where R = *n*-Bu, *i*-Pr, and *t*-Bu, can be made; namely, the tendency for the intensities of the *d–d* spectra to increase and to shift to longer wavelengths, in the order *n*-Bu to *t*-Bu. This trend is consistent with a progressive distortion of the

For personal use only.

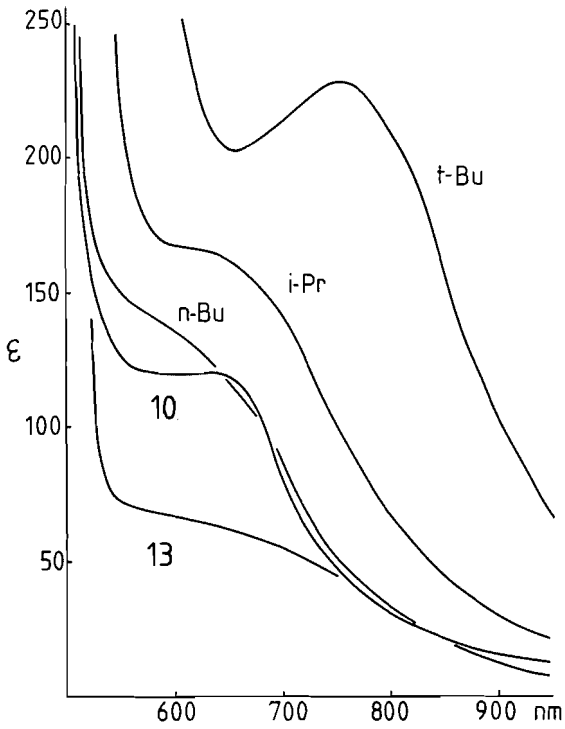

FIG. 1. Visible absorption spectra ($CHCl_3$), comparing the sugar–copper complexes **10** and **13** with the previously known analogous *N*-alkyl complexes where the nitrogen substituent is either *n*-butyl, *i*-propyl, or *tert*-butyl. As the alkyl group is changed from *n*-Bu to *t*-Bu (made more bulky) the intensity of the *d–d* spectra increases along with a shift to longer wavelength. The sugar complexes, however, do not fit into this sequence.

coordination geometry towards a tetrahedron (17, 18) with increase in the bulk of the R-group; the greater the tetrahedral distortion, the greater the spectral change.

That the spectra for the two sugar complexes **10** and **13** are not more similar to the spectrum of the *t*-Bu complex implies that the sugar substituents are effectively less bulky than the *t*-Bu group, possibly due to their lower effective symmetry. Of course, it may simply be that, due to the very different nature of sugar substituents, it is not possible to compare these complexes to those complexes in which R is an alkyl group.

The solid-mull visible spectrum of Cu(Sug I-sal)$_2$ **10** consists of three bands at 9500, 13500, and 20000 $cm^{-1}$ which is characteristic of a pseudotetrahedral Cu(R-sal)$_2$ complex (11, 17, 18). Therefore, the visible absorption spectra in the solid state and solution suggest that, when dissolved, this complex loses a significant amount of its tetrahedral character.

The visible spectrum of the cobalt–sugar complex Co(SugI-sal)$_2$ is straightforward and consists of three bands at 7300, 11250, and 17240 $cm^{-1}$. This suggests that it has the tetrahedral geometry expected for a cobalt(II)–salicylaldimine complex (18).

*Electron spin resonance spectroscopy*

All of the esr spectral parameters acquired in this work for the copper–sugar complexes and for the Cu(R-sal)$_2$ complexes where R = *n*-butyl, isopropyl, and *tert*-butyl are shown in Table 1. Here $g_0$ and $a_0$ are parameters from the room temperature solution spectrum and the $g_{||}$ and $A_{||}$ values are from the frozen 77 K solution or spin dilute powder spectrum. The room temperature solution spectra and the polycrystalline spectra for all of the complexes in Table 1 are shown in Figs. 2 and 3 respectively.

A classification of the Cu(R-sal)$_2$ complexes can be made on the basis of esr results in the same way as previously described for the visible absorption spectra (17). As the geometry becomes more tetrahedral in nature, the $A_{||}$ value becomes smaller, and at the same time $g_{||}$ and $g_0$ begin to increase while $a_0$ decreases, as does $A_{||}$. The Cu(R-sal)$_2$ complexes with R = *n*-butyl, isopropyl, and *tert*-butyl have esr parameters which clearly show the effect of tetrahedral distortion on these spectral parameters. As R changes from *n*-Bu to *t*-Bu, the *A* values decrease and the *g* values increase (Table 1 (c), (d), and (e)). The $g_{||}$ and $A_{||}$ parameters for the isopropyl complex are only approximate because this complex exists as a mixture of geometrical isomers in solution, which broadens the $g_{||}$ components, making them difficult to measure.

As was the case with the visible absorption data, it is not clear just where the sugar complexes Cu(Sug I-sal)$_2$ **10** and Cu(Sug II-sal)$_2$ **13** fall within the series of alkyl complexes. The *A* values suggest that the sugar complexes are square planar, but the *g* values put them about midway between the *n*-alkyl planar and *tert*-butyl pseudotetrahedral complexes.

When the copper complex **10** was cocrystallized in the Zn(sug I-sal)$_2$ matrix it was found to adopt the tetrahedral structure of the zinc complex. The characteristic tetrahedral $Cu^{2+}$ esr spectrum obtained (f) is quite different from that of the pure copper complex, which implies that the latter has little tetrahedral character.

Additional information concerning these complexes could be obtained from direct inspection of their esr spectra. The rate of tumbling of the complexes in solution (designated by the correlation time $\tau_c$) can affect the esr spectra dramatically,

as shown in Fig. 2 (a)–(d). As the molecule tumbles more and more slowly, the low field transitions (lines) broaden to a greater extent than do the high field lines; this is because incomplete averaging of the $g$ and $A$ anisotropies affects the low field lines before the high field line. This information can then be used to compare the effective "size" of copper complexes. From the spectra in Fig. 2, it is clear that the suger complexes are much "larger" than their alkyl counterparts. The esr spectrum of the *t*-Bu complex is very broad and poorly resolved due to its high tetrahedral character (21).

The polycrystalline spectra shown in Fig. 3 also contain additional information; insofar that they all have an axial type of line shape, this implies that in each case the copper centre possesses an axial, or near axial symmetry. Spectrum (d) of the isopropyl complex also reveals that a mixture of geometries is present for this molecule in solution. This deduction is based on the observation of the broad $g_{\|}$ components in this spectrum which have been previously attributed (17) to overlapping lines of a mixture of planar and pseudotetrahedral species. This has an important corollary in that it now seems

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

safe to assume from the spectra in Fig. 3 that the other sugar and alkyl complexes exist as a single structural species in solution. That the binuclear copper complex **16** did not give either a room temperature or a 77 K solution spectrum can be explained on the basis of exchange coupling between the two copper ions to product singlet ($S = 0$) and triplet ($S = 1$) electronic states. Since the singlet state is expected to have zero magnetic moment, only molecules in the triplet state can give rise to an esr signal. Therefore, if the triplet state is not populated, which is most likely the case here, no esr spectrum will be seen.

*Magnetic moments*

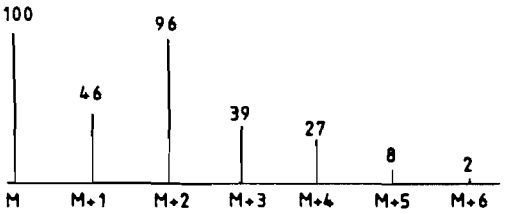
Often associated with red spectral shifts, as seen for the alkyl complexes of Cu(R-Sal)$_2$ with pseudotetrahedral structures, are large magnetic moments; a $\mu_{eff}$ value of $\geq$ 1.89 BM has been considered characteristic of nonplanar geometry (20). This does not, however, appear to be a reliable structural criterion; for example, recent measurements (20) of solid Cu(*i*-Pr-sal)$_2$ and Cu(*t*-Bu-sal)$_2$, which are known to be pseudotetrahedral, have yielded values of 1.84 and 1.83 BM respectively compared to 1.90–1.93 BM obtained earlier (20). The magnetic moments calculated from the esr and Faraday methods for the copper complexes shown previously are given in Table 2. Initially it was thought that the change in $\mu_{eff}$ for the solid complex Cu(Sug I-sal)$_2$ (1.91 BM) upon dissolution of the solid reflected a change in geometry. However, in light of the recent data (20) cited above for Cu(*i*-Pr-sal)$_2$ and Cu(*t*-Bu-sal)$_2$, it does not seem wise to be too dogmatic on this conclusion.

*Mass spectrometry*

Copper has two isotopes ($^{63}$Cu, 69.09% and $^{65}$Cu, 30.91%) which confer defined isotope patterns to the mass spectral fragmentation of copper-containing complexes and thereby make this a useful tool for structure determination. Using the relative ratios of 7:3 for the two copper isotopes, and taking into account the 1.08% isotope effect for each $^{13}$C of a molecule which has 42 carbon atoms, one can calculate the simulated spectrum shown below for the binuclear copper complex **16**.

TABLE 2. Magnetic moments of copper complexes

| Complex | $\mu_{eff}$ from esr (BM) | $\mu_{eff}$ Faraday (BM) |
|---|---|---|
| (a) Cu(Sug I-sal)$_2$ **10** | 1.84 | 1.91 |
| (b) Cu(Sug II-sal)$_2$ **13** | 1.84 | |
| (c) Cu(*n*-Bu-sal)$_2$ | 1.83 | |
| (d) Cu(*i*-Pr-sal)$_2$ | 1.84 | |
| (e) Cu(*t*-Bu-sal)$_2$ | 1.85 | |
| (f) Cu(Sug III-sal)$_2$ **15** | 1.85 | |



This simulation gives exactly the same molecular ion pattern as that obtained experimentally (see Experimental). This evidence, along with the parent mass of 1056 and the lack of an esr spectrum, provides good evidence for the assignment of a binuclear structure for the copper complex **16**. Obviously, such isotope patterns were also very useful for characterizing the mononuclear copper complexes.

Zinc has four isotopes in natural abundance ($^{64}$Zn, 48.89%, $^{66}$Zn, 27.81%; $^{67}$Zn, 4.11%; and $^{68}$Zn, 18.57%) which also confer well defined isotope patterns to the mass spectrum of zinc complexes. The zinc–sugar complex **11** did indeed reveal this well defined isotope pattern.

## Conclusions

It is obvious that this study has done no more than prove the existence of a new area of metal-chelation chemistry based on ligands derived from amino-containing monosaccharides. Given the ease with which the solubility of sugars can be manipulated, it should be relatively easy to tailor the physical properties of the resultant metal-chelates, and by choice of the appropriate amino-sugar it is also feasible to control their geometry. A recent extension of this work describes (22) the formation of metal complexes from amine-containing polysaccharides.

## Experimental

All solutions were concentrated using a Buchi rotary evaporator. All melting points were determined using a Thomas Hoover Unimelt instrument (Model 6404-K) and are corrected. All optical rotations were determined using a Perkin–Elmer Polarimeter (model 241-MC).

Thin-layer chromatography (tlc) was performed on silica gel plates (Baker-flex Silica gel 1B2-F) using 1:1 toluene – ethyl acetate.

Sources for the key chemicals used in the synthesis of compounds in this chapter are as follows: salicylaldehyde was obtained from Fisher and was vacuum distilled before use; salicylic acid (Malinckrodt); hexamethylenetetramine (Matheson, Coleman and Bell); cyclohexylamine, *tert*-butylamine, *n*-butylamine, and *i*-propylamine (Eastman); D-glucosamine hydrochloride (Sigma); benzyl chloroformate (Aldrich); anisaldehyde (Matheson, Coleman and Bell); cupric and cobaltous acetate (Fisher); zinc acetate (Matheson, Coleman and Bell); nickel acetate (Baker).

Electron spin resonance spectra were recorded at X-band using a Varian E-3 instrument in the derivative absorption mode. Spectrometer settings – modulation amplitude, filter time

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

constant, and scan rate – were chosen in each case to avoid distortion of the spectral lines, and power levels were nonsaturating. The ambient temperature was always 25°C ± 1, and the field was always increased from left to right.

The field was calibrated using a proton nmr magnetometer and the X-band microwave frequency was monitored on a Hewlett–Packard 5245-L electronic counter equipped with a 8–18 GHz frequency converter.

Spectra at 77 K were obtained using a Dewar-insert containing liquid nitrogen, at 0.16 mW microwave power, the lowest available. Oxygen was prevented from condensing in the sample tube by sealing the top with a rubber septum cap. All low temperature spectra were recorded in 3 mm id quartz tubes when nonpolar organic solvents were used, and in 1 mm id Pyrex tubes for aqueous solutions. At room temperature, both these types of tubes were used. The 3 mm id tube was preferred for use with the dilute chloroform solutions of the copper complexes since more sample could be placed in the esr cavity, thereby giving a better signal-to-noise ratio. Powder samples of metal complexes were run inside melting point capillary tubes placed inside a 3 mm id quartz tube.

Proton nmr spectra were measured at 270 MHz with a prototype of a home-built spectrometer based on a Bruker WP-60 console, a Nicolet 1180 computer (32K), a Nicolet 293A pulse controller unit, a Diablo Disk model 30, and an Oxford Instruments Superconducting solenoid. The concentration of most samples ranged from 0.01 to 0.10 *M*. All deuterated solvents were obtained from Merck Sharp and Dohme (Montreal, Canada) and tetramethylsilane was used as an internal standard.

Infrared spectra were run on a Perkin–Elmer 137 spectrometer. Samples were prepared as the Nujol mull and polystyrene film was used to calibrate the spectra.

All visible absorption spectra were run on a Cary 14 spectrometer and solutions were made in chloroform at approximately 0.01 *M* concentrations.

The solution magnetic moments were determined from the esr solution spectra and were calculated from $g_0$ by the relationship

$$\mu_{eff} = g_0 \sqrt{S(S+1)}$$

where $S$ is $\frac{1}{2}$ for copper(II). The single, solid magnetic moment determination was performed on a Faraday instrument by Professor R. C. Thompson of this department.

All microanalysis was performed by Mr. P. Borda, of this department. The mass spectra were obtained using an Atlas CH-4B mass spectrometer by Dr. G. Eigendorf.

The compound, 3-formyl-2-hydroxybenzoic acid **2**, was prepared by the method of Duff and Bills (23).

Methyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranoside hydrobromide **5** was prepared by a combination of the methods by Chargraff and Bovarnick (24), Fodar and Otvos (25), and Irvine and Earl (13).

1,3,4,6-Tetra-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranose **6** was prepared by the method of Bergman and Zervas (15), using *p*-methoxybenzaldehyde to protect the amino function.

The sugar salicylaldimines **4**, **7**, and **8** were all prepared readily by the method of Irvine and Earl (14) by mixing vigorously the amino sugar and salicylaldehyde together in water, or in a methanol–water mixture, with one equivalent of sodium bicarbonate added in the preparation of compounds **4** and **7**.

The preparation of the salicylaldimine–metal complexes Cu(cyclohexyl-sal)$_2$, Cu(*n*-Bu-sal)$_2$, Cu(*t*-Bu-sal)$_2$, and Cu(*i*-Pr-sal)$_2$ was readily carried out by the original method of Schiff and repeated from a more recent reference by Holm and Swaminathan (26). Both copper(II) and nickel(II) complexes were prepared in ≥ 60% yield by heating under reflux an ethanolic solution of 0.1 mol of the appropriate nickel or copper salicylaldehyde complex together with a 10% mol excess of the amine. The products were obtained by cooling the reaction mixture and filtration of the precipitate.

*Preparation of methyl-3,4,6-tri-*O*-acetyl-2-deoxy-2-(3-carboxylsalicylaldimino)-β-D-glucopyranoside* **9**

To a solution of amino sugar **5** (0.51 g, 1.27 mmol) in methanol (4 mL) was added a solution of sodium bicarbonate (0.25 g, 3 mmol) in $H_2O$ (4 mL) and a solution of 3-formyl-2-hydroxybenzoic acid (0.22 g, 1.28 mmol) in methanol (4 mL). The mixture was stirred at room temperature for 1 h and then evaporated to dryness and a small amount of ethanol added. The resulting precipitate was filtered, washed with cold ethanol, and dried under vacuum to give the product in 70% yield. The compound was recrystallized from ethanol; mp 251–252°C, $[\alpha]_D^{22}$ +245.0° (*c* 2, $CHCl_3$). *Anal.* calcd. for $C_{21}H_{25}N_1O_{11}$: C 53.94, H 5.39, N 2.99; found: C 53.52, H 5.54, N 2.80.

*Preparation of Schiff's base metal complexes from ligands* **4**, **7**, **8**, *and* **9**

Ligand **4** was dissolved in methanol at room temperature and ligands **7**, **8**, and **9** were dissolved in hot ethanol. To these stirred mixtures was then added an alcoholic solution of the appropriate metal acetate (molar equivalents). The complex precipitated either immediately or upon cooling and was separated by filtration and purified as shown below.

*Bis-{N-(methyl-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl-2-salicylaldimino)} Cu(II)* **10** was obtained in 90% yield and was analytically pure directly from the reaction mixture. Slow crystallization from an acetone solution yielded dark-brown cubic crystals, mp 250–251°C, $[\alpha]_D^{22}$ +777° (*c* 0.74, $CHCl_3$). *Anal.* calcd. for $C_{40}H_{49}CuN_2O_{18}$: C 52.91, H 5.29, N 3.08; found: C 53.08, H 5.21, N 3.02; ms (low resolution) calcd. for $C_{40}H_{48}CuN_2O_{18}$: 907 ($Cu^{63}$), 909 ($Cu^{65}$) amu (M:M+1:M+2:M+3; 100:40:50:20); found: 907 and 909 amu (M:M+1:M+2:M+3; 100:40:50:20).

*Bis-{N-(methyl-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl-2-salicylaldimino)} Zn(II)* **11** was obtained in 41% yield from acetone–chloroform, mp 272–273°C, $[\alpha]_D^{22}$ +240.3° (*c* 0.77, $CHCl_3$). *Anal.* calcd. C for $_{40}H_{48}N_2O_{18}Zn$: C 52.80, H 5.28, N 3.08; found: C 53.00, H 5.40, N 3.07; ms (low resolution) calcd. for $C_{40}H_{48}N_2O_{18}Zn$: 908 ($Zn^{64}$), 910 ($Zn^{66}$), 911 ($Zn^{67}$), 912 ($Zn^{68}$) amu (M:M+1:M+2:M+3:M+4; 100:44:65:33:46); found: 908, 910, 911, 912 amu (M:M+1:M+2:M+3:M+4; 100:50:70:30:45).

*Bis-{N-(methyl-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl-2-salicylaldimino)} Co(II)* **12** was obtained in 58% yield from chloroform, mp 260–261°C, $[\alpha]_D^{22}$ −25.6° (*c* 0.39, $CHCl_3$). *Anal.* calcd. for $C_{40}H_{48}CoN_2O_{18}$: C 53.18, H 5.31, N 3.10; found: C 53.06, H 5.39, N 3.20; ms (low resolution) calcd. for $C_{40}H_{48}CoN_2O_{18}$: 903 amu; found 903 amu.

*Bis-{N-(1,3,4,6-tetra-*O*-acetyl-2-deoxy-β-D-glucopyranose-2-salicylaldimino)} Cu(II)* **13** was obtained in 90% yield from ethanol, mp. 125–126°C, $[\alpha]_D^{22}$ +194° (C 0.5 $CHCl_3$). *Anal.* calcd. for $C_{42}H_{48}CuN_2O_{20}$: C 52.30, H 4.98, N 2.90; found: C 51.9, H 5.03, N 2.84; ms (low resolution) calcd. for $C_{42}H_{48}CuN_2O_{20}$: 963 ($Cu^{63}$), 965 ($Cu^{65}$) amu (M:M+1:M+2:M+3; 100:40:50:20); found: 963, 965 amu (M:M+1:M+2:M+3; 100:40:50:20).

*(N-2-amino-2-deoxy-α,β-D-glucopyranose-salicylaldimino)-Cu(II)* **14** was prepared in 65% yield, mp, 150°C (dec.), $[\alpha]_D^{22}$ +244.7° (*c* 0.76, $H_2O$). *Anal.* calcd. for $C_{13}H_{18}CuNO_7$: C 42.90, H 4.95, N 3.85; found: C 43.50, H 4.82, N 3.68; ms (low resolution) calcd. for $C_{13}H_{18}CuNO_7$: 363 ($Cu^{63}$), 365 ($Cu^{65}$) amu (M:M+2; 10:4); found: 363, 365, 420 amu.

*Bis-{N-(methyl-3,4,6-tri-O-acetyl-2-deoxy-2-[3-carboxyl-salicylaldimino])} $Cu_2$(II)* **16** was obtained in 80%

yield, mp > 270°C, $[\alpha]_D^{22}$ +100.0° (*c* 0.16, $CHCl_3$). *Anal.* calcd. for $C_{42}H_{46}Cu_2N_2O_{22}$: 1056 ($Cu^{63}$ $Cu^{63}$), 1058 ($Cu^{63}$ $Cu^{65}$), 1060 ($Cu^{65}$ $Cu^{65}$) amu (M:M+1:M+2:M+3:M+4:M+5:M+6; 100:46:96:39:27:8:2); found: 1056, 1058, 1060 amu (M:M+1:M+2:M+3:M+4:M+5:M+6; 100:50:95:40:30:10:2).

## Acknowledgements

It is a pleasure to thank the Natural Sciences and Engineering Research Council of Canada for their support of this work via operating grants to L.D.H. (A-1905) and a Postgraduate Scholarship to M.A. (1977–1979). The authors would also like to thank Drs. R. C. Thompson and R. Morrison of this department for many helpful discussions relating to coordination chemistry and to Dr. Jeremy K. M. Sanders, on sabbatical leave from Cambridge University, for his thoughts on several aspects of this work.

# Synthèse de nucléosides pyrimidiques à partir de bromures de désoxy-4-pentopyranosyles non totalement protégés[1]

CHRISTIAN H. GAGNIEU, ANNIE V. GROUILLER ET HENRI PACHECO

*Service de Chimie Biologique, Bât. 406, INSA, 20 av. Albert Einstein, 69621 Villeurbanne, France*

Reçue le 11 décembre 1981

CHRISTIAN H. GAGNIEU, ANNIE V. GROUILLER et HENRI PACHECO. Can. J. Chem. **60**, 2238 (1982).

La synthèse des nucléosides **15–19** a été réalisée avec de très bons rendements selon la méthode de Hilbert–Johnson, par condensation de la diméthoxy-2,4-pyrimidine avec des bromo désoxy-4-pentopyranosides dont l'hydroxyle en C-3 est libre. La présence de ce groupement augmente la réactivité des bromures mais ne semble pas jouer de rôle important dans la stéréochimie de la réaction; celle-ci étant surtout influencée par l'encombrement stérique et la nature du substituant en C-2.

CHRISTIAN H. GAGNIEU, ANNIE V. GROUILLER, and HENRI PACHECO. Can. J. Chem. **60**, 2238 (1982).

The synthesis of nucleosides **15–19** has been completed in high yield following the method of Hilbert–Johnson, by condensation of 2,4-dimethoxypyrimidine with bromo-4-deoxypento pyranosides in which the C-3 hydroxyl group is free. The presence of this group augments the reactivity of the bromides but does not appear to play an important role in the stereochemistry of the reaction, which is above all influenced by steric factors and the nature of the C-2 substituent.

## Introduction

L'obtention de nucléosides pyrimidiques à structure désoxy-4-pentopyranosique, présentant un groupement hydroxyle libre en C-3′, constitue une étape importante dans le développement de nos travaux sur l'application de la réaction de Neber à la synthèse de nucléosides aminés en C-4′(1). En particulier, la préparation de nucléosides porteurs de groupements O-alkylés ou O-acylés, aromatiques et aliphatiques en C-2′, et d'un hydroxyle libre en C-3′ est nécessaire pour l'étude de l'influence des substituants de la partie osidique des nucléosides sur la stéréochimie de cette réaction. Lors des essais de synthèse des nucléosides O-acylés en C-2′ par les méthodes classiques de condensation de bases pyrimidiques avec des sucres totalement protégés (2), nous nous sommes heurtés à d'importants problèmes quant au choix des groupements protecteurs des pentopyranosides de départ. Ainsi, nous avons été amené à envisager la synthèse de ces nucléosides directement à partir de sucres possédant un hydroxyle non protégé en C-3. Ces synthèses ont été réalisées par la méthode de Hilbert–Johnson, dans laquelle des halogénoses sont condensés en l'absence de catalyseur avec des dialkoxy-2,4-pyrimidines (3).

Le type de synthèse que nous rapportons ici est un premier exemple de l'application de cette réaction à la préparation directe de nucléosides pyrimidiques non totalement protégés. Le présent article décrit la synthèse des méthylglycosides de départ hydroxylés en C-3, la préparation de leurs dérivés bromoglycosidiques et les résultats obtenus lors de la condensation de ces derniers avec la diméthoxy-2,4-pyrimidine.

## Résultats et discussion

*Synthèse des méthylglycosides*

Ces synthèses ont été réalisées à partir de deux composés connus: le désoxy-4-*O*-isopropylidène-1,2-β-DL-*thréo*-pentopyranose(4) et les méthyl *O*-benzyl-3-désoxy-4-α et β-DL-*thréo*-pentopyranosides (5).

L'acétylation et la benzoylation du désoxy-4-*O*-isopropylidène-1,2-β-DL-*thréo*-pentopyranose par les chlorures d'acétyle et de benzoyle dans la pyridine conduisent avec des rendements quasi quantitatifs aux acétyl et benzoyl-3-*O*-isopropylidène-1,2-désoxy-4-β-DL-*thréo*-pentopyranoses **1** et **2**. La méthanolyse du groupement isopropylidène du composé **2**, catalysée par de la résine Dowex 50H$^+$ en suspension dans du méthanol bouillant conduit très rapidement aux méthyl *O*-benzoyl-3-désoxy-4-α et β-DL-*thréo*-pentopyranosides **4** avec un rendement de 80%. Cette méthanolyse appliquée au composé **1** doit être réalisée à plus basse température (40°C) afin de minimiser la réaction de désacétylation qui se produit lorsque les conditions sont trop drastiques. Les méthyl *O*-acétyl-3-désoxy-4-α et β-DL-*thréo*-pentopyranosides (**3**) ont été obtenus avec un rendement de 65%. La benzylation en C-2 des composés **3** et **4** par le bromure de benzyle dans le *N*, *N* diméthylformamide en présence d'oxyde d'argent à été obtenue avec des rendements accep-

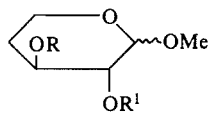
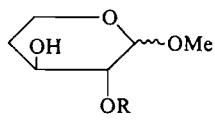
**1** R = Ac
**2** R = Bz



**3** α,β R = Ac, $R^1$ = H
**4** α,β R = Bz, $R^1$ = H
**5** α,β R = Ac, $R^1$ = Bn
**6** α,β R = Bz, $R^1$ = Bn
**7** α,β R = Ac, $R^1$ = Me
**8** α,β R = Bz, $R^1$ = Me
**9** α,β R = Bn, $R^1$ = Ac
**10** α,β R = Bn, $R^1$ = Bz



**11** α,β R = Ac
**12** α,β R = Bz
**13** α,β R = Bn
**14** α,β R = Me

tables (env. 70%) grâce à l'adjonction dans le milieu réactionnel de quantités catalytiques d'iodure de potassium. Les méthyl *O*-acétyl et *O*-benzoyl-3-*O*-benzyl-2-désoxy-4-α et β-DL-*thréo*-pentopyranosides **5** et **6** obtenus ont été désacylés par du méthylate de sodium en solution méthanolique pour donner les méthyl *O*-benzyl-2-désoxy-4-α et β-DL-*thréo*-pentopyranosides (**13**).

La méthylation en C-2 des composés **3** et **4** par l'iodure de méthyle dans le *N,N* diméthylformamide en présence d'oxyde d'argent conduit avec d'excellents rendements aux méthyl *O*-acétyl et *O*-benzoyl-3-*O*-méthyl-2-désoxy-4-α et β-DL-*thréo*-pentopyranosides **7** et **8** qui sont désacylés comme précédemment pour donner les méthyl *O*-méthyl-2-désoxy-4-α et β-DL-*thréo*-pentopyranosides (**14**).

L'acétylation et la benzoylation en C-2 du méthyl *O*-benzyl-3-désoxy-4-α et β-DL-*thréo*-pentopyranosides par la méthode précédemment décrite conduisent avec de très bons rendements aux méthyl *O*-acétyl et *O*-benzoyl-2-*O*-benzyl-3-désoxy-4-α et β-DL-*thréo*-pentopyranosides **9** et **10** qui sont soumis à une hydrogénolyse en présence de palladium sur charbon pour donner les méthyl *O*-acétyl et *O*-benzoyl-2-désoxy-4-α et β-DL-*thréo*-pentopyranosides **11** et **12**.

Tous les composés cités sont nouveaux; leurs structures ont été déterminées en rmn du proton (tableaux 1 et 2) et confirmées par micro-analyse.

*Synthèse des bromoglycosides*

Les bromoglycosides sont synthétisés de façon classique par action d'un excès d'acide bromhydrique gazeux anhydre sur les méthylglycosides **11–14** dissous dans du dichlorométhane fraîchement distillé sur hydrure de sodium. Dans les conditions optimales, la réaction est rapide et quantitative, mais les bromures qui ne sont stables qu'au sein de leur milieu de synthèse ne peuvent être facilement isolés. En effet, leur réactivité inhabituelle, dont la cause reste à déterminer, est à l'origine de la création d'un équilibre réactionnel dépendant de la concentration de la solution en acide bromhydrique (schéma 1). Ainsi, l'élimination de l'acide en excès, qu'il est nécessaire d'effectuer avant la condensation des bromures avec la diméthoxy-2,4-pyrimidine, conduit à une resynthèse partielle mais toujours importante des produits de départ. La grande réactivité des bromures est à mettre en relation avec la présence de

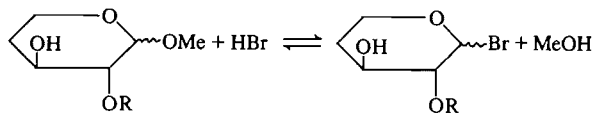


SCHÉMA 1

l'hydroxyle libre en C-3 puisque nous avons pu isoler des bromures relativement stables en présence de traces de méthanol à partir de méthylglycosides de la même série totalement protégés.

L'obtention de solutions neutres de bromoglycosides est conditionnée par l'élimination simultanée de l'acide bromhydrique en excès et du méthanol réactionnel. Cette élimination a été réalisée par dégazage partiel des solutions avec un courant d'azote anhydre suivi d'un traitement par du tamis moléculaire 10 Å en poudre. Ce composé, à l'égal des autres tamis moléculaires, piège très efficacement les acides minéraux (6) tel que l'acide bromhydrique mais il a également la propriété d'adsorber de petites molécules polaires telles que le méthanol.

Les solutions obtenues à l'issue de ces traitements sont utilisées directement comme milieu de synthèse des nucléosides.

*Synthèse des nucléosides*

Les solutions de bromoglycosides sont traitées par un excès de diméthoxy-2,4-pyrimidine et portées à reflux pendant 10 minutes. Après divers traitements du milieu réactionnel, les nucléosides sont obtenus purs avec de bons rendements (77 à

90%) par cristallisation ou chromatographie sur colonne de gel de silice (voir schéma 2).

Il est bien connu que le degré de stéréospécificité des réactions de glycosylation est dépendant pour une grande part de la nature du substituant en C-2 du sucre de départ. Ceci est vrai en particulier pour la réaction de Hilbert–Johnson avec laquelle les nucléosides sont très souvent obtenus sous forme de mélange anomérique (7). La réaction de glycosylation de sucres non protégés en C-3, telle que nous l'avons réalisée ne fait pas exception à ces règles générales.

Lors de la synthèse des nucléosides **17** et **18**, benzylés ou méthylés en C-2′, des mélanges d'anomères ont été obtenus avec prédominance nette des isomères *cis* 1′,2′, ce qui correspond dans notre série osidique à une configuration β majoritaire. Dans le cas des composés benzylés en C-2′, le rapport des anomères α et β est d'environ 1:5, alors que dans le cas des composés méthylés ce rapport est de 1:3. Cette différence de proportion, qui découle d'une augmentation de la quantité relative de l'isomère α dans le mélange des anomères du composé méthylé **18**, nous permet de dire que l'approche de la diméthoxy-2,4-pyrimidine au moment de la condensation avec les bromoglycosides n'est pas influencée par l'encombrement stérique de substituants en C-2 de ces derniers. En effet, si cet encombrement intervenait à ce niveau dans la stéréochimie de la réaction, il serait logique d'obtenir le résultat inverse, c'est-à-dire une proportion plus importante de l'isomère *trans* 1′,2′ pour les composés benzylés puisque le groupement benzyle a un volume moléculaire très supérieur au groupement méthyle. En revanche, cet encombrement stérique peut influer sur l'équilibre d'anomérisation des composés bromés de départ, car l'absence de substituants en C-4 et C-5 crée un déséquilibre stérique au niveau du site anomérique, variable suivant la taille du substituant en C-2 et de nature à renforcer l'effet stérique de ce dernier. De ce fait il est logique de penser que l'équilibre existant entre les paires d'ions **A** et **B**, (schéma 3) qui sont considérées comme des intermédiaires dans les réactions de glycosylation à partir d'halogénosucres (8), est déplacé préférentiellement dans le sens de la formation du composé **A** dont l'ion bromure est en relation *trans* avec le groupement en C-2. L'attaque nucléophile de type $S_N2$ des paires d'ion **A** et **B** par la base aboutit à la formation préférentielle de nucléosides *cis* 1′,2′.

La formation d'un ion carbonium à partir des bromures peut être également envisagée; mais les paramètres stériques que nous venons de citer

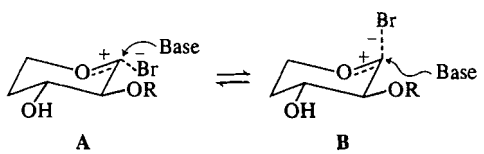
SCHÉMA 2

orienteraient la réaction de condensation vers la formation de nucléosides *trans* 1′,2′. Enfin, il n'est pas exclu que l'hydroxyle libre en C-3 ait une influence sur la stéréochimie de la réaction. Des travaux de recherche sur l'existence et le cas échéant sur la nature de cette influence sont en cours.

Lors de la synthèse des nucléosides **15** et **16**, acétylés et benzoylés en C-2′, seuls les isomères *trans* 1′,2′ ont été obtenus, ce qui est en accord avec l'hypothèse d'une réaction assistée par le groupement acyle via un ion acyloxonium; celui-ci étant connu pour orienter la réaction de glycosylation vers la formation préférentielle et souvent exclusive de nucléosides *trans* (2).

Notons que dans la synthèse du nucléosides dérivant du méthylglycoside **11** acétylé en C-2, le composé majoritaire obtenu ne correspond pas à la structure **15** attendue, mais à la structure **19** dans laquelle le groupement acétyle est en C-3. Ce résultat ne peut être expliqué que par l'existence d'une transestérification intramoléculaire liée à la présence de l'hydroxyle libre en C-3 du sucre de départ et catalysée par les conditions acides de la réaction de bromuration. Ce type de transestérification acide-catalysée est très courant en chimie des sucres (9).

Les configurations anomériques de tous les nucléosides synthétisés ont été déterminées sans ambiguité en rmn du proton sur la base des valeurs des constantes de couplage $^3J_{1',2'}$ et des déplacements chimiques des protons anomériques (tableau 3).



**A** **B**

SCHÉMA 3

## Partie expérimentale

*Méthodes générales*

Le déroulement des réactions a été suivi en ccm sur gel de silice (Kieselgel 60 $F_{254}$, Merck 5535) et la révélation des chromatogrammes a été réalisée par pulvérisation de réactif phosphomolybdique suivie d'un chauffage à 100°C. La purification des composés a été réalisée par chromatographie liquide sous basse pression avec des colonnes Lobar (Merck, Lichroprep Si60) ou sur gel de silice (Kieselgel 60 et 60 $F_{254}$, Merck 7734 et 10757). Les points de fusion, mesurés sur banc Kofler ne sont pas corrigés. Les indices de réfraction ont été mesurés sur un réfractomètre OPL et les spectres ir ont été enregistrés sur le spectrophotomètre Beckman Acculab-4. Les spectres de rmn ont été enregistrés à 80 et 60 MHz sur les spectromètres Brüker WP 80 et Perkin Elmer R 24 B. Les déplacements chimiques sont exprimés en ppm, le tétraméthylsilane étant pris comme référence zéro. Les microanalyses ont été effectuées par le service central de microanalyse du C.N.R.S., division de Lyon. Le dichlorométhane utilisé dans les réactions de bromuration a été distillé sur hydrure de sodium afin d'éliminer l'alcool éthylique utilisé commercialement comme stabilisant de ce solvant. L'acide bromhydrique gazeux a été séché par barbotage dans de l'acide orthophosphorique à 85% puis traité par de la tournure de cuivre afin de piéger d'éventuelles traces de brome. L'azote utilisé pour le dégazage des solutions de bromuration a été Séché sur acide sulfurique à 98% et le tamis moléculaire 10 Å (Merck 5703) a été réduit en poudre puis activé 3 h à 130°C. La diméthoxy-2,4-pyrimidine a été préparée par la méthode de Bhat et Munson (10) et distillée deux fois pour éliminer toute trace de méthanol.

*Méthode générale d'acylation*

A une solution du composé à acyler (10 mmol) dans un mélange de $CH_2Cl_2$ anhydre (20 mL) et de pyridine (5 mL), refroidie à −15°C, est ajouté goutte à goutte et sous forte agitation, du chlorure de benzoyle (25 mmol, 3,5 g, 2,9 mL) ou d'acétyle (25 mmol, 2 g, 1,8 mL) en solution dans $CH_2Cl_2$ (5 mL). Après addition complète, le vase à réaction est sorti du bain réfrigérant et la solution est ramenée progressivement à température ambiante (20°C) en 15 min. On rajoute alors de l'eau (20 mL) et on décante la phase organique. On extrait la phase aqueuse par 20 mL de $CH_2Cl_2$ et on lave les phases organiques réunies par une solution saturée de $NaHCO_3$. Après séchage sur $Na_2SO_4$, l'extrait organique est évaporé sous vide et le résidu huileux obtenu est coévaporé avec du toluène (2 × 30 mL) pour donner les dérivés acylés, soit sous forme d'huiles jaunâtres qui sont purifiées par chromatographie sur gel de silice, soit sous forme de pâtes semi-cristallines qui sont purifiées par recristallisation.

O-*acétyl-3-désoxy-4*-O-*isopropylidène*-1,2-β-DL-*thréo-pentopyranose (1)*

Synthèse à partir du désoxy-4-*O*-isopropylidène-1,2-β-DL-*thréo*-pentopyranose (**4**) (1,5 g, 8.7 mmol); *le composé* **1** est obtenu sous forme cristalline (1,740 g, 97%): pf 58–59°C; $R_f$ 0,65 (AcOEt–hexane, 1:1); $\nu_{max}$ (KBr): 2880 ($CH_3$), 1730 et 1240 (ester), 1370 et 1390 (isopropylidène) $cm^{-1}$. *Anal.* calc. pour $C_{10}H_{16}O_5$: C 55,56, H 7,41; trouvée: C 55,67, H 7,55.

*Méthyl* O-*acétyl-2*-O-*benzyl-3-désoxy-4*-α *et* β-DL-thréo-*pentopyranosides (9α et 9β)*

Synthèse à partir des méthyl *O*-benzyl-3-désoxy-4-α et β-DL-*thréo*-pentopyranosides (**5**) (2 g, 8,4 mmol). La chromatographie des extraits réactionnels dans le solvant AcOEt–hexane 2:1 permet d'isoler les isomères α et β de **9** (2,282 g, rendement global: 97%). *Le composé* **9α** est une huile: $R_f$ 0,41 (AcOEt–hexane, 2:1); $\nu_{max}$ (film): 3040, 3060, 740 et 700 (benzyle), 1735 et 1240 (ester) $cm^{-1}$. *Le composé* **9β** est cristallisé: pf 84–86°C; $R_f$ 0,46 (AcOEt–hexane, 2:1); $\nu_{max}$ (KBr): caractéristiques identiques à **9α**. *Anal.* calc. pour $C_{15}H_{20}O_5$ (**9α** + **9β**): C 64,29, H 7,14; trouvée: C 64,00, H 7,13.

O-*benzoyl-3-désoxy-4*-O-*isopropylidène-1,2*-β-DL-*thréo-pentopyranose (2)*

Synthèse à partir du désoxy-4-*O*-isopropylidène-1,2-β-DL-*thréo*-pentopyranose (**4**) (1,5 g, 8,7 mmol). L'extrait réactionnel cristallise spontanement; des recristallisations successives dans le solvant hexane–$CH_2Cl_2$ fournissent *le composé* **2** sous forme de plaquettes nacrées (1,65 g, 96%): pf 91–93°C; $R_f$ 0,53 (AcOEt–hexane, 1:3); $\nu_{max}$ (KBr): 3070, 3030, 1610 et 710 (phényle), 1730 et 1230 (ester), 1380 et 1370 (isopropylidène) $cm^{-1}$. *Anal.* calc. pour $C_{15}H_{18}O_5$: C 64,75, H 6,47; trouvée: C 64,48, H 6,35.

*Méthyl* O-*benzoyl-2*-O-*benzyl-3-désoxy*-4-α *et* β-DL-thréo-*pentopyranosides (10α et 10β)*

Synthèse à partir des méthyl *O*-benzyl-3-désoxy-4-α et β-DL-*thréo*-pentopyranosides (1,5 g, 6,3 mmol); l'huile obtenue après traitement du milieu réactionnel est purifiée par chromatographie sur gel de silice dans le solvant AcOEt–hexane 1:3 pour donner les composés **10α** et **10β** (2,07 g, 96%); *le composé* **10β** est recristallisé dans le mélange éther–pentane 1:5 pour donner des cristaux blancs: pf 65–70°C; $R_f$ 0,57 (AcOEt–hexane, 1:2); $\nu_{max}$ (KBr): 3060, 3020, 1600, 1580, 725 et 740 (phényles), 1720 et 1285 (ester) $cm^{-1}$. *L'isomère* **10α** est une huile: $R_f$ 0,47 (AcOEt–hexane, 1:2); $\nu_{max}$ (film): caractéristiques identiques à **10β**. *Anal.* calc. pour $C_{20}H_{22}O_5$ (**10α** + **10β**): C 70,18, H 6,43; trouvée: C 70,27, H 6,28.

*Méthanolyse des groupements isopropylidène*

Les composés **1** et **2** (10 mmol) sont dissous dans du méthanol (20 mL) contenant de la résine Dowex 50 $H^+$ (env. 1 g) fraîchement activée par HCl. Les suspensions obtenues sont chauffées à 40°C pour le composé **1** et à 65°C pour le composé **2** pendant 1 h et 0,5 h respectivement. Après filtration de la suspension et lavage de la résine par du méthanol à 40°C, le solvant est évaporé et les résidus huileux obtenus sont chromatographiés sur colonne de gel de silice.

*Méthyl* O-*acétyl-3-désoxy-4*-α *et* β-DL-thréo-*pentopyranosides (3α et 3β)*

Les isomères **3α** et **3β** sont obtenus dans le rapport 1:1; ils sont séparés par chromatographie dans le solvant AcOEt–hexane 1:1; rendement global 65%; *le composé* **3β** est isolé sous forme d'une huile qui cristallise très lentement dans le mélange éther–hexane 1:5: pf 49–50°C; $R_f$ 0,25 (AcOEt–hexane, 1:1); $\nu_{max}$ (KBr): 3280 (OH), 2860 (OMe), 1740 et 1240 (ester) $cm^{-1}$. *Le composé* **3α** est une huile: $R_f$ 0,18 (AcOEt–hexane, 1:1); $\nu_{max}$ (film): caractéristiques identiques à **3β**. *Anal.* calc. pour $C_8H_{14}O_5$ (**3α** + **3β**): C 50,53, H 7,37; trouvée: C 50,67, H 7,30.

Les isomères α et β sont obtenus dans le rapport 55:45, et sont séparés de la même manière que les composés **3**; rendement global 80%; *le composé* **4β** est cristallisé: pf 95–98°C; $R_f$ 0,42 (AcOEt–hexane, 1:1); $\nu_{max}$ (KBr): 3270 (OH), 3060, 3040, 1600, 1585 et 715 (phényle), 2870 (OMe), 1730 et 1285 (ester) $cm^{-1}$. *Le composé* **4α** est une huile: $R_f$ 0,36 (AcOEt–hexane, 1:1); $\nu_{max}$ (film): caractéristiques identiques à **4β**. *Anal.* calc. pour $C_{13}H_{16}O_5$ (**4α** + **4β**): C 61,90, H 6,35; trouvée: C 61,94, H 6,50.

*Méthylation*

Les composés à méthyler (10 mmol) sont dissous dans du DMF (25 mL) contenant de l'oxyde d'argent (20 mmol) et de l'iodure de méthyle (50 mmol, 7,1 g, 3,1 mL). La suspension obtenue est agitée pendant 18 h à température ambiante puis les sels sont filtrés et lavés à l'éther (3 × 25 mL). Le filtrat est alors additionné d'eau (30 mL) et la phase aqueuse est extraite à l'éther (3 × 25 mL). La solution éthérée est lavée à l'eau (25 mL), séchée sur $Na_2SO_4$ et évaporée sous pression réduite pour donner les composés méthylés sous forme d'une huile jaune.

*Méthyl* O-*acétyl-3-désoxy-4-*O-*méthyl-2-α et* β-DL-thréo-*pentopyranosides (7α et7β)*

Synthèse à partir des composés **3α** et **3β**; la purification des produits est réalisée par chromatographie liquide sous basse pression dans le solvant pentane–éther 1:5; rendement: 91%. *Le composé* **7β** cristallise dans le mélange éther–hexane 1:5: pf 32,5°C; $R_f$ 0,65 (pentane–éther, 1:5); $\nu_{max}$ (KBr): 2850 (OMe), 1740 et 1245 (ester) $cm^{-1}$. *Le composé* **7α** est un liquide incolore: $n_D^{20}$ 1,4455; $R_f$ 0,49 (pentane–éther, 1:5); $\nu_{max}$ (film): caractéristiques identiques à **7β**. *Anal.* calc. pour $C_9H_{16}O_5$ (**7α** + **7β**): C 51,94, H 7,84; trouvée: C 52,10, H 7,71.

*Méthyl* O-*benzoyl-3-désoxy-4-*O-*méthyl-2-α et* β-DL-thréo-*pentopyranosides (8α et 8β)*

Synthèse à partir de **4α** et **4β**; la purification des composés est réalisée par chromatographie sur colonne sèche de gel de silice dans le solvant pentane–éther 1:1; rendement: 89%. Les deux composés sont isolés sous forme d'huiles incolores. *Composé* **8α**: $R_f$ 0,48 (pentane–éther, 1:1); $\nu_{max}$ (film): 2850 (OMe), 1720 et 1270 (ester) $cm^{-1}$. *Composé* **8β**: $R_f$ 0,34 (pentane–éther, 1:1); $\nu_{max}$ (film): caractéristiques identiques à **8α**. *Anal.* calc. pour $C_{14}H_{18}O_5$ (**8α** + **8β**): C 63,16, H 6,77; trouvée: C 63,34, H 6,91.

*Benzylation*

Le composé à benzyler (10 mmol) est dissous dans du DMF anhydre (10 mL) et à la solution obtenue sont ajoutés successivement: du bromure de benzyle (25 mmol, 4,3 g, 3 mL) et de l'oxyde d'argent (14 mmol, 3,25 g). La suspension ainsi formée est agitée à température ambiante pendant 5 min puis de l'iodure de potassium (0,4 mmol, 70 mg) est ajouté. Le mélange est agité pendant 6 h puis dilué par AcOEt (40 mL). Le précipité qui se forme instantanément est filtré et rincé par AcOEt (20 mL); le filtrat est évaporé à 50°C sous pression réduite et le résidu huileux obtenu est purifié pour donner les composés benzylés attendus.

*Méthyl* O-*acétyl-3-*O-*benzyl-2-désoxy-4-α et* β-DL-thréo-*pentopyranosides (5α et 5β)*

Synthèse à partir de **3α** et **3β**; les produits sont purifiés par chromatographie sur colonne de gel de silice dans le solvant AcOEt–hexane 1:3; rendement: 72%. Les deux composés sont recristallisés dans le mélange éther–pentane 1:5. *Composé* **5α**: pf 84°C; $R_f$ 0,39 (AcOEt–hexane, 1:3); $\nu_{max}$ (KBr): 3030, 3015, 3000, 740 et 705 (benzyle), 1740 et 1250 (ester) $cm^{-1}$. *Composé* **5β**: pf 68–69°C; $R_f$ 0,31 (AcOEt–hexane, 1:3); $\nu_{max}$ (KBr): caractéristiques identiques à **5α**. *Anal.* calc. pour $C_{15}H_{20}O_5$ (**5α** + **5β**): C 64,29, H 7,14; trouvée: C 64,53, H 6,97.

*Méthyl* O-*benzoyl-3-*O-*benzyl-2-désoxy-4-α et* β-DL-thréo-*pentopyranosides (6α et 6β)*

Synthèse à partir de **4α** et **4β**; les produits sont purifiés par chromatographie sur colonne de gel de silice dans le solvant AcOEt–hexane, 1:3; rendement: 65–75%. *Le composé* **6α** qui est obtenu sous forme d'huile après chromatographie, peut être recristallisé dans le mélange éther–hexane 1:6: pf 67–69°C; $R_f$ 0,43 (AcOEt–hexane, 1:3); $\nu_{max}$ (KBr): 3060, 3030, 1600, 1580, 710 et 690 (phényle), 1720 et 1270 (ester) $cm^{-1}$. *Le composé* **6β** est une huile; $R_f$ 0,33 (AcOEt–hexane, 1:3); $\nu_{max}$ (KBr): caractéristiques identiques à **6α**. *Anal.* calc. pour $C_{20}H_{22}O_5$ (**6α** + **6β**): C 70,18, H 6,43; trouvée: C 70,29, H 6,57.

*Hydrogénolyse des groupements benzyles*

Tous les oses soumis à l'hydrogénolyse ont été purifiés de façon à éliminer toute trace de pyridine pouvant provenir des réactions d'acylation; ce composé ayant entraîné dans quelques cas un ralentissement ou un blocage de la réaction.

Une solution éthanolique dégazée (45 mL) de composés benzylés (10 mmol) contenant de l'acide acétique pur (8 mL) et du palladium à 10% sur charbon (300 mg) est mise en contact à température ambiante avec de l'hydrogène gazeux sous faible pression hydrostatique. La solution est agitée pendant 18 h, filtrée sur Célite, évaporée sous pression réduite à 50°C et coévaporée 3 fois avec du toluène pour éliminer l'acide acétique. Le liquide sirupeux obtenu est purifié pour donner les composés débenzylés attendus.

*Méthyl* O-*acétyl-2-désoxy-4-α et* β-DL-thréo-*pentopyranosides (11α et 11β)*

Synthèse à partir de **9α** et **9β**; les produits sont purifiés sur colonne de gel de silice dans le solvant AcOEt–hexane 1:1; rendement: 96%. Les composés **11α** et **11β** sont recristallisés, après chromatographie, dans l'éther éthylique à −20°C. *Composé* **11α**: pf 61–62°C; $R_f$ 0,22 (AcOEt–hexane, 1:1); $\nu_{max}$ (KBr): 3390 (OH), 2870 (OMe), 1750, 1715 et 1270 (ester) $cm^{-1}$. *Composé* **11β**: pf 69–70°C; $R_f$ 0,27 (AcOEt–hexane, 1:1); $\nu_{max}$ (KBr): 3420 (OH), 2850 (OMe), 1745 et 1260 (ester) $cm^{-1}$. *Anal.* calc. pour $C_8H_{14}O_5$ (**11α** + **11β**): C 50,53, H 7,37; trouvée: C 50,76, H 7,65.

*Méthyl* O-*benzoyl-2-désoxy-4-α et* β-DL-thréo-*pentopyranosides (12α et 11β)*

Synthèse à partir de **10α** et **10β**; les purifications sont effectuées sur colonne de gel de silice dans le solvant AcOEt–hexane 1:1; rendement: 93%. Les composés **12α** et **12β** sont recristallisés dans un mélange AcOEt–hexane. *Composé* **12α**: pf 77°C; $R_f$ 0,26 (AcOEt–hexane, 1:1); $\nu_{max}$ (KBr): 3500 et 3400 (OH), 1730 et 1710, 1285 et 1260 (ester); 1600, 1580, 715 et 690 (phényle) $cm^{-1}$. *Composé* **12β**: pf 85–87°C; $R_f$ 0,35 (AcOEt–hexane, 1:1); $\nu_{max}$ (KBr): 3440 (OH), 3110, 3070, 3040, 1600, 1580 et 725 (phényle), 1730 et 1270 (ester) $cm^{-1}$. *Anal.* calc. pour $C_{13}H_{16}O_5$ (**12α** + **12β**): C 61,90, H 6,35; trouvée: C 61,99, H 6,48.

*Méthanolyse des groupements acyles*

À une solution méthanolique (50 mL) des sucres acétylés ou benzoylés (10 mmol) est ajoutée une solution de MeONa obtenue par dissolution de sodium (5 mmol, 115 mg) dans du méthanol (5 mL). Le mélange obtenu est chauffé à reflux 0,5 h, neutralisé à température ambiante par de la résine Dowex 50 $H^+$ méthanolique et filtré. Le filtrat est évaporé à sec et le résidu pâteux obtenu est purifié par chromatographie sur colonne de gel de silice.

*Méthyl* O-*benzyl-2-désoxy-4-α et* β-DL-thréo-*pentopyranosides (13α et 13β)*

Synthèse à partir de **5α**, **5β** et **6α** et **6β**; les produits sont purifiés par chromatographie dans le solvant AcOEt–hexane 1:1; rendement moyen: 94%. Les composés **13α** et **13β** sont obtenus sous forme d'huiles incolores. *Composé* **13α**: $R_f$ 0,46

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

(AcOEt–hexane, 1:1); $\nu_{max}$ (film): 3470 (OH), 3100, 3070, 3040, 740 et 700 (benzyle), 2840 (OMe) $cm^{-1}$. *Composé* **13β**: $R_f$ 0,36 (AcOEt–hexane, 1:1); $\nu_{max}$ (film): caractéristiques identiques à **13α**. *Anal.* calc. pour $C_{13}H_{18}O_4$ (**13α** + **13β**): C 65,55, H 7,56; trouvée: C 65,50, H 7,82.

*Méthyl désoxy-4-*O*-méthyl-2-α et* β-DL-threo-*pentopyranosides (**14α** et **14β**)*

Synthèse à partir de **7α**, **7β** et **8α**, **8β**; les produits sont purifiés par chromatographie dans le solvant AcOEt pur; rendement moyen: 84%. Les composés **14α** et **14β** sont des liquides incolores. *Composé* **14α**: $n_D^{20}$ 1,4510; $R_f$ 0,40 (AcOEt); $\nu_{max}$ (film): 3470 (OH), 2840 (OMe) $cm^{-1}$. *Composé* **14β**: $n_D^{20}$ 1,4525; $R_f$ 0,32 (AcOEt); $\nu_{max}$ (film): caractéristiques identiques à **14α**. *Anal.* calc. pour $C_7H_{14}O_4$ (**14α** + **14β**): C 51,85, H 8,64; trouvée: C 51,59, H 8,76.

*Méthode générale de bromuration*

Dans les réactions de bromuration, l'acide bromhydrique a été utilisé sous forme de solution à demi saturation dans $CH_2Cl_2$ à 0°C (environ 500 mg/10 mL $CH_2Cl_2$). Cet acide est ajouté à une solution de méthylglycoside (10 mmol) dans $CH_2Cl_2$ (60 mL) à raison de 5 équivalents par équivalent de sucre. La solution obtenue est agités à 0°C jusqu'à disparition complète des produits de départ (10–15 min). Le vase à réaction est alors sorti du bain refrigérant et la solution est dégazée par un fort courant d'azote anhydre. Ce dégazage, suivi en ccm, est stoppé dès l'apparition des premiers indices de resynthèse des produits de départ (5–10 min.); on ajoute alors en une seule fois le tamis moléculaire 10 Å en poudre (10 g) et la suspension orange obtenue est agitée jusqu'à disparition totale des vapeurs d'HBr dans le vase à réaction (environ 2 min).

*Condensation des bromoglycosides avec la diméthoxy-2,4-pyrimidine*

À la solution neutre de bromoglycoside obtenue précédemment est ajoutée en une seule fois de la DMP (2 équivalents par équivalent de bromure) et le mélange obtenu est porté à reflux pendant 10 min. Le solvant est évaporé pour donner un résidu pâteux qui est trituré dans du méthanol chaud (50°C). La suspension obtenue est filtrée, le gâteau de filtration est rincé 2 fois par du méthanol chaud et le filtrat est évaporé à sec. L'huile résiduelle orange obtenue est diluée avec le mélange acétone–méthanol 10:1 (10 mL/g de résidu) et le précipité blanc cristallin d'uracyle qui se forme en faible quantité est filtré puis rincé par de l'acétone pure. Le filtrat est évaporé et le concentré réactionnel huileux obtenu est purifié pour donner les nucléosides attendus.

*(O-acétyl-2 et O-acétyl-3-désoxy-4-α-DL-threo-pentopyranosyl)-1-méthoxy-4-pyrimidinone-2 (**15** et **19**)*

Synthèse à partir de **11**; le concentré réactionnel est dilué par le mélange acétone–hexane 1,5:1 (5 mL/g de concentré); il se forme lentement à température ambiante un précipité blanc de composé **19** (51%). La solution de cristallisation est chromatographiée sur colonne de gel de silice dans le solvant acétone–hexane 1,5:1 pour donner le composé **15** (30%) et un peu de nucléoside **19** (6%); rendement global: 87%. Ces composés peuvent être recristallisés dans le mélange $CH_3OH$–éther 1:10. *Composé* **15**: pf 152–154°C; $R_f$ 0,25 (acétone–hexane, 1,5:1); $\nu_{max}$ (KBr): 3380 (OH), 2900 (OMe), 1740 et 1240 (ester), 1670, 1640, 1550 et 1485 (base) $cm^{-1}$. *Anal.* calc. pour $C_{12}H_{16}N_2O_6$: C 50,70, H 5,63, N 9,36; trouvée: C 50,92, H 5,79, N 9,27. *Composé* **19**: pf 203–204°C; $R_f$ 0,30 (acétone–hexane 1,5:1); $\nu_{max}$ (KBr): 3110 (OH), 2890 (OMe), 1740 et 1260 (ester), 1645, 1550 et 1480 (base) $cm^{-1}$. *Anal.* calc. pour $C_{12}H_{16}N_2O_6$: C 50,70, H 5,63, N 9,36; trouvée: C 50,61, H 5,72, N 9,73.

*(O-benzoyl-2-désoxy-4-α-DL-threo-pentopyranosyl)-1-méthoxy-4-pyrimidinone-2 (**16**)*

Synthèse à partir de **12**; le concentré réactionnel est dilué par de l'acétate d'éthyle pur (6 mL/g de concentré); et le précipité blanc de *composé* **16** qui se forme est filtré puis rincé par AcOEt pur; rendement: 80–85%: pf 195–197°C; $R_f$ 0,40 (AcOEt); $\nu_{max}$ (KBr): 3300 (OH), 1720 et 1260 (ester), 1650, 1635, 1540 et 1480 (base), 710 (phényle) $cm^{-1}$. *Anal.* calc. pour $C_{17}H_{18}N_2O_6$: C 58,96, H 5,20, N 8,09; trouvée: C 59,10, H 5,30, N 7,87.

*(O-benzyl-2-désoxy-4-α et* β-DL-threo-*pentopyranosyl)-1-méthoxy-4-pyrimidinone-2 (**17α** et **17β**)*

Synthèse à partir de **13**; le concentré réactionnel ne cristallise pas par adjonction de solvants, il est chromatographié sur gel de silice dans le solvant acétone–hexane 1,5:1 pour donner le composé **17β** pur (67%) et le composé **17α** (10%) contenant des traces du composé β. Ces nucléosides sont obtenus sous forme de laques qui cristallisent par trituration dans l'éther éthylique anhydre. *Composé* **17α**: pf 155–165°C; $R_f$ 0,23 (acétone–hexane, 1,5:1); $\nu_{max}$ (KBr): 3420 (OH), 2900 (OMe), 1660, 1635, 1550 et 1490 (base), 700 (phényle) $cm^{-1}$. *Anal.* calc. pour $C_{17}H_{20}N_2O_5$: C 61,45, H 6,02, N 8,43; trouvée: C 61,51, H 6,12, N 8,56. *Composé* **17β**: pf 137°C; $R_f$ 0,32 (acétone–hexane, 1,5:1); $\nu_{max}$ (KBr): 3370 (OH), 2890 (OMe), 1640, 1620, 1540 et 1470 (base), 700 (phényle) $cm^{-1}$. *Anal.* calc. pour $C_{17}H_{20}N_2O_5$: C 61,45, H 6,02, N 8,43; trouvée: C 61,25, H 6,05, N 8,38.

*(Désoxy-4-*O*-méthyl-2-α et* β-DL-threo-*pentopyranosyl)-1-méthoxy-4-pyrimidinone-2 (**18α** et **18β**)*

Synthèse à partir de **14**; le concentré réactionnel est chromatographié sur gel de silice dans le solvant acétone–hexane 5:1 pour donner les composés **18β** (55%) et **18α** (23%) sous forme de laques qui cristallisent dans l'éther éthylique; rendement global: 77%. *Composé* **18α**: pf 205–206°C; $R_f$ 0,45 (acétone–hexane, 5:1); $\nu_{max}$ (KBr): 3400 (OH), 2845 (OMe), 1680, 1620, 1540 et 1480 (base) $cm^{-1}$. *Anal.* calc. pour $C_{11}H_{16}N_2O_5$: C 51,56, H 6,25, N 10,94; trouvée: C 51,54, H 6,42, N 10,79. *Composé* **18β**: pf 178–179°C; $R_f$ 0,60 (acétone–hexane, 5:1); $\nu_{max}$ (KBr): 3470 (OH), 1665, 1630, 1540 et 1480 (base) $cm^{-1}$. *Anal.* calc. pour $C_{11}H_{16}N_2O_5$: C 51,56, H 6,25, N 10,94; trouvée: C 51,45, H 6,32, N 11,05.

Received February 25, 1982

PETER C. BURGERS, JOHN L. HOLMES, F. P. LOSSING, ALEXANDER A. MOMMERS, FRANK R. POVEL, and JOHAN K. TERLOUW. Can. J. Chem. **60**, 2246 (1982).

Ionic heats of formation and collisional activation (CA) mass spectra for fifteen isomeric or tautomeric $[C_4H_4O]^{+\cdot}$ ions are described. Twelve of these species can be characterised by means of their CA mass spectra alone. The relative thermodynamic stabilities of keto–enol tautomers and the ease of interconversion of some ions are discussed. It is emphasised that CA spectra *alone* (i.e. in the absence of other information, such as heat of formation, etc.) may not easily be correlated with the appropriate ion structures.

PETER C. BURGERS, JOHN L. HOLMES, F. P. LOSSING, ALEXANDER A. MOMMERS, FRANK R. POVEL et JOHAN K. TERLOUW. Can. J. Chem. **60**, 2246 (1982).

On a déterminé les chaleurs de formation ionique et les spectres de masse d'activation de collision (AC) de quinze ions isomères ou tautomères $[C_4H_4O]^+$. On peut caractériser douze de ces espèces en faisant appel uniquement à leur spectre de masse AC. On discute des stabilités thermodynamiques relatives des tautomères céto–énol et de la facilité d'interconversion de quelques ions. On souligne le fait que les spectres de AC seuls (i.e. en l'absence d'autres informations, tels la chaleur de formation, etc.) ne peuvent être facilement reliés aux structures appropriées de l'ion.

## Introduction

Attempts to understand qualitatively the unimolecular decomposition of organic ions in the gas phase were, in the 1960's, concentrated upon identifying which atoms actively participated in the transition-state — by the classical method of isotopic labelling (1). Interpretation of results then leaned heavily upon analogies drawn from reactions of neutral organic compounds in solution or in the gas phase. The confirmation of proposed mechanisms in the majority of cases still awaits unequivocal methods for the identification of the reacting configurations (RC) of precursor ions (the structure which leads directly to the transition state (2)) and the structures of the product ions and neutral fragments.

In recent years considerable progress has been made towards this end and it is now often possible to obtain a detailed description of a reaction pathway provided that several complementary techniques are used. Such methods include (*i*) the accurate determination of appearance energies (AE) in order to evaluate the energy barrier for the fragmentation and thus to permit a choice between possible daughter ion structures; (*ii*) the study of metastable ion (MI) phenomena which arise from dissociations of ions of low internal energy (2) having lifetimes of the order of μs; (*iii*) collisional activation (CA) and collisional ionisation (charge stripping [CS]) mass spectra of mass-selected ions may be used to characterise product ion structures and also as a probe for the possible isomerisation of the precursor ion prior to fragmentation (3). Each of these methods, in contrast with observations derived from normal mass spectra, focuses attention on restricted ranges of ion internal energy and in *combination* provide a powerful (although still largely empirical) tool for the study of gas phase ion fragmentations.

In general, these advances in technique have established the existence of many isomeric (radical) cations as stable entities in the gas phase. Of these, relatively few have been observed in condensed phases as either neutral or charged species and so analogies cannot readily be drawn from solution chemistry for the behaviour of such ions.

Some years ago we employed these methods to investigate a longstanding problem in gas phase ion chemistry, namely, the identity of the $[C_4H_4O]^{+\cdot}$ daughter ion produced by loss of CO from ionised 2- and 4-pyrone and which generates the base peak in their normal mass spectra. It was shown (4),

contrary to earlier conclusions, that the $[C_4H_4O]^{+\cdot}$ ions from both precursors mainly had the [furan]$^{+\cdot}$ structure and that some ionised vinyl ketene $[CH_2{=}CH{-}CH{=}C{=}O]^{+\cdot}$ was also generated. The properties of the only five readily accessible isomeric $[C_4H_4O]^{+\cdot}$ ions were studied in this early work. Other stable configurations undoubtedly exist and further investigation is warranted to provide the necessary reference ions whose MI and CA mass spectra would permit the ready identification of unknown $[C_4H_4O]^{+\cdot}$ product ions. Of particular interest are isomers containing a hydroxyl group. It has been shown that enol ions have lower $\Delta H_f$ values than their tautomers derived from ionised saturated (5) and unsaturated aldehydes and ketones (6). $[C_4H_4O]^{+\cdot}$ ions considered in the present work include some highly unsaturated keto–enol pairs and also an —OH substituted alkene–yne for which no keto counterpart exists. It should be noted that such species also provide information as to the stabilising effects of substituents in $\pi$-bonded systems and additional basic data for methods for the estimation of ionic heats of formation (7).

We here present evidence for the identification of fifteen isomeric (or tautomeric) $[C_4H_4O]^{+\cdot}$ radical cations.

## Results and discussion

The CA mass spectra and ionic heats of formation of the $[C_4H_4O]^{+\cdot}$ ions are shown in Table 1. The ions will be discussed by group, in the order of their presentation in Table 1, namely the ethers (furan and vinyloxy ethyne, $HC{\equiv}C{-}O{-}CH{=}CH_2$), the three ketenes (vinylketene, $CH_2{=}CH{-}CH{=}C{=}O$; dimethylene ketene

and buta-1,2-dienone, $CH_3{-}CH{=}C{=}C{=}O$), the hydroxy-containing species (1-hydroxybuta-1-en-3-yne, $HOCH{=}CH{-}C{\equiv}CH$; 2-hydroxybuta-1-en-3-yne, $CH_2{=}C(OH){-}C{\equiv}CH$; 4-hydroxybuta-1-en-3-yne, $CH_2{=}CH{-}C{\equiv}C(OH)$; and hydroxybutatriene, $CH_2{=}C{=}C{=}CHOH$), the aldehydes and ketones (buta-2,3-dien-al, $CH_2{=}C{=}CH{-}CHO$; 2-butynal, $CH_3{-}C{\equiv}C{-}CHO$; 3-cyclopropenecarbaldehyde,

methylethynyl ketone, $CH_3{-}CO{-}C{\equiv}CH$; methylcyclopropenone,

and 3-butynal).

The CA mass spectra are tabulated so as clearly to emphasise those peaks whose significant intensity differences permit the characterisation of ion structures. In a number of cases the CA mass spectra were only readily assigned to specific ion structures with the aid of ancillary observations. All structure assignments are given in the detailed discussions which follow.

*Ether ions*

The CA mass spectrum of furan agrees well with our previously reported (partial) CA mass spectrum (4); it is dominated by the peak at *m/z* 39 $[C_3H_3]^+$ (corresponding to CHO loss) and is readily distinguished from the other isomers by the *B* and *D* ion clusters (see Table 1). Vinyloxyethyne has the highest $\Delta H_f$ of any of the $[C_4H_4O]^+$ ions so far investigated, 251 kcal mol$^{-1}$ (IE = 9.40 eV, $\Delta H_f$ [$HC{\equiv}C{-}O{-}CH{=}CH_2$] = 34 kcal mol$^{-1}$ (8)). Its CA mass spectrum is highly characteristic, being dominated by the reactions

$$HC{\equiv}C{-}O{-}CH{=}CH_2^{+\cdot} \longrightarrow \underset{m/z\ 42}{CH_2C\overset{+\cdot}{O}} + C_2H_2$$

$$\longrightarrow \underset{m/z\ 27}{CH_2CH^+} + HC_2O^{\cdot}$$

showing that this molecular ion does not readily rearrange to any of its thermodynamically more stable structures prior to collision-induced fragmentation. Similarly furan, which must ring open before fragmenting, does not communicate with the linear ether.

*Ketene ions*

Thermal decomposition of the en–yne ether, $CH_2{=}CH{-}C{\equiv}C{-}O{-}CH_2CH_3$, was proposed in our earlier study (9) to produce vinylketene plus ethene. This has been confirmed by microwave and infrared spectroscopy (10, 11), which in addition showed that the *trans*-rotamer is generated. Ionised vinylketene remains the $[C_4H_4O]^{+\cdot}$ isomer of lowest $\Delta H_f$ (see Table 1). The CA mass spectrum agrees well with that previously reported (4, 9).

CA mass spectra identical with that of [vinylketene]$^{+\cdot}$ were obtained from the *m/z* 68 ions produced by the dissociative ionisation of 5,6-dihydro-2-pyrone

and 2-cyclohexen-1-one. Loss of $CH_2O$ and $C_2H_4$ respectively, via a $4\pi + 2\pi$ cycloreversion reaction, readily rationalises the production of [vinylketene]$^{+\cdot}$. The heats of formation of the $[C_4H_4O]^{+\cdot}$ daughter ions were found to be 200 $\pm$ 2 kcal mol$^{-1}$ (AE *m/z* 68 = 10.56 eV, $\Delta H_f$[lactone]

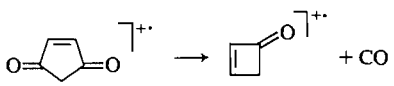
*The sum of the relative abundances of ions in each $m/z$ series (e.g. $m/z$ 54 → 49) have been normalized to 100 units. The relative abundances of each *group* of ions ($A$–$E$) have also been normalized, but relative to group $C$ = 100 units.

= −69 ± 2 kcal mol$^{-1}$,[2] $\Delta H_f$[CH$_2$O] = −25.9 kcal mol$^{-1}$ (12)) and 194 kcal mol$^{-1}$ (9), respectively.

In an earlier study (13), it was concluded that [vinylketene]$^{+\cdot}$ was the predominant $m/z$ 68 ion generated by the loss of H$_2$O from *cis* and *trans* crotonic acids and cyclopropanecarboxylic acid. However, the metastable peaks for these reactions were of composite shape and it was considered that the [C$_4$H$_4$O]$^{+\cdot}$ isomer ionised cyclobutenone might be cogenerated. Accordingly, the behaviour of 4-cyclopenten-1,3-dione was investigated, because the simple dissociative ionisation thereof might well be expected to generate [cyclobutenone]$^{+\cdot}$ ions, i.e.



The $\Delta H_f$[C$_4$H$_4$O]$^{+\cdot}$ from this dione was found to be 224 kcal mol$^{-1}$ (AE $m/z$ 68 = 10.88 eV, $\Delta H_f$[4-cyclopenten-1,3-dione] = −53 kcal mol$^{-1}$ (8), $\Delta H_f$[CO] = −26.4 kcal mol$^{-1}$ (12)). This must represent an *upper limit* for the $\Delta H_f$ because the metastable peak for the above reaction was of dished shape. The approximate minimum kinetic energy release (calculated from the width of the metastable peak across its maxima (2)) $T_{min}$ = 0.19 eV. Our revised estimated value for $\Delta H_f$ [cyclobutenone]$^{+\cdot}$ = 223 ± 3 kcal mol$^{-1}$,[3] reinforced the suggestion that it may be generated from the dione as described above.

However, the CA mass spectrum of the $m/z$ 68 daughter ions was closely similar to that of [vinylketene]$^{+\cdot}$, as indeed were those of the [C$_4$H$_4$O]$^{+\cdot}$ daughter ions from the three isomeric acids referred to above. It is therefore concluded that *if* it is generated, [cyclobutenone]$^{+\cdot}$ has a CA mass spectrum essentially indistinguishable from that of its valence isomer [vinylketene]$^{+\cdot}$, i.e. although the cyclic ion could be generated at threshold, it readily ring-opens with little energy requirement.

The mass spectral properties of the unsaturated ether, CH$_2$=CH—C≡C—OCH$_2$CH$_3$, which readily yields vinylketene at ca. 150°C, were studied under conditions at which thermolysis was negligible. $m/z$ 68 is the base peak in the normal mass spectrum of the compound and there is an intense metastable peak for its generation from the molecular ion, $m/z$ 96. The CA mass spectrum of $m/z$ 68 ions generated in the first field-free region was clearly that of [vinylketene]$^{+\cdot}$ and this dissociative ionisation therefore must parallel the thermal decomposition. Surprisingly, however, the ion-source generated [C$_4$H$_4$O]$^{+\cdot}$ ions cannot have this structure alone, because their CA mass spec-

[2]By additivity (ref. 8) and assuming a ring-strain correction of +3±2 kcal mol$^{-1}$. The values of +26 and −34 kcal mol$^{-1}$ were assumed for C$_t$—(O) and O—(C$_t$)(C), respectively.

[3]Ionisation energy ≃ 9.3 eV (estimated), $\Delta H_f$[cyclobutenone] = +8 kcal mol$^{-1}$ by additivity (ref. 8) and assuming ring strain is the same as for cyclobutene and that CO—(C$_d$)(C) = −33 kcal mol$^{-1}$.

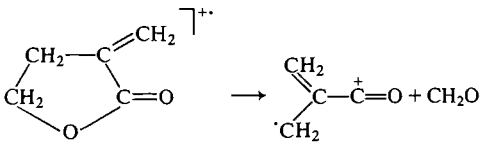
trum is wholly different from that of [vinylketene]$^{+\cdot}$. These observations are further discussed below under hydroxy-containing ions.

Dimethyleneketene can conveniently be generated via the dissociative ionisation of α-methylene-γ-butyrolactone. Loss of $CH_2O$ produces $[C_4H_4O]^{+\cdot}$ ions, base peak in the normal mass spectrum, and can reasonably be expected to produce the desired species:



The AE $m/z$ 68 from this lactone, 10.44 ± 0.05 eV, leads to $\Delta H_f[C_4H_4O]^{+\cdot}$ = 198 ± 2 kcal mol$^{-1}$ ($\Delta H_f$[lactone] = −69 ± 2 kcal mol$^{-1}$ (8); $\Delta H_f$ [$CH_2O$] = −25.9 kcal mol$^{-1}$ (12)). This fragmentation is accompanied by an intense Gaussian-type metastable peak, with a kinetic energy release calculated from the width of the peak at half-height, $T_{0.5}$ = 0.006 eV, and thus there is no evidence to indicate that this reaction involves a significant reverse energy barrier. The CA mass spectrum was independent of electron energy and that derived from the ion source generated $[C_4H_4O]^{+\cdot}$ ions was the same as that for ions produced in the first field-free region, indicating that more than one structure is unlikely to be involved. It is concluded from the above evidence that these $[C_4H_4O]^{+\cdot}$ ions are *not* merely slightly energy-rich [vinylketene]$^{+\cdot}$, but represent a different structure, namely dimethyleneketene. The most pronounced differences from the CA mass spectrum of [vinylketene]$^{+\cdot}$ are: the absence of $m/z$ 42, $[CH_2{=}C{=}O]^{+\cdot}$, the much lower intensity of $m/z$ 27 $[C_2H_3]^+$, and the enhanced intensity of $m/z$ 40, $[C_3H_4]^{+\cdot}$. The latter process is that of lowest energy requirement ($\Delta H_f$(products) = $\Delta H_f(CH_2CCH_2)^{+\cdot}$ + $\Delta H_f$(CO) = 243 kcal mol$^{-1}$ (14)). In the normal mass spectrum this fragmentation generates an intense metastable peak and analysis (15) of the $[C_3H_4]^{+\cdot}$ daughter ions shows them to have, as expected, the [allene]$^{+\cdot}$ structure, i.e. [propyne]$^{+\cdot}$ is not produced at higher internal energies of the fragmenting ions. All of these differences are in keeping with the ion generated from this lactone having the *branched* ketene structure shown above, in contrast with the *linear* [vinylketene]$^{+\cdot}$.

The above results permit further analysis of observations of the elimination of $H_2O$ from ionised methacrylic acid (13) where it had been proposed that metastable molecular ions rearrange to [crotonic acid]$^{+\cdot}$ via a 1,2-methyl shift, yielding [vinylketene]$^{+\cdot}$ (and [cyclobutenone]$^{+\cdot}$) on loss of $H_2O$. The apparent $\Delta H_f$ of the $[C_4H_4O]^{+\cdot}$ daughter ion, 215 kcal mol$^{-1}$ (AE $m/z$ 68 = 10.64 eV; $\Delta H_f$ [$CH_2{=}C(CH_3)COOH$] = −88.2 kcal mol$^{-1}$ (8), $\Delta H_f[H_2O]$ = −57.8 kcal mol$^{-1}$ (14)), is a maximum value (the reaction has a reverse energy barrier (13)) and so in principle permits the cogeneration of
